Proof. If $x_0 = \varepsilon$ and $u_i, v_i \in yx_0^*u_0$ for some string y, then $u_i = yu_0 = v_i$. So let $x_0 = \varepsilon$ and $u_i \ne v_i$ for some $1 \le i \le n-1$. Then there is no y such that $u_i, v_i \in yx_0^*u_0$. Lemma 3.2 entails the claim. $\square$

LEMMA 3.4. *If $|u_i| = |v_i|$ and $u_i \ne v_i$ for some $1 \le i \le n-1$, then $u \to v$ terminates.*

Proof. If $x_0 = \varepsilon$, then the claim follows by Lemma 3.3, so let $x_0 \ne \varepsilon$. If $|u_i| = |v_i|$, $u_i = yx_0^pu_0$, $v_i = yx_0^{p'}u_0$, then $p = p'$ and hence $u_i = v_i$. So let for some $1 \le i \le n-1$ both $|u_i| = |v_i|$ and $u_i \ne v_i$. Then there is no y such that $u_i, v_i \in yx_0^*u_0$. By Lemma 3.2 the claim follows. $\square$

LEMMA 3.5. *Let $x_0 \ne \varepsilon$. Define the equivalence relation $\sim$ on Σ^* by $s \sim t$ if*

$$|s| \equiv |t| \mod |x_0|.$$

If $u_i \not\sim v_i$ for some $1 \le i \le n-1$, then $u \to v$ terminates.

Proof. If $u_i = yx_0^pu_0$, $v_i = yx_0^{p'}u_0$ for some y, then $|u_i| - |v_i| = (p-p')|x_0|$. So if $|u_i| - |v_i|$ is not an integer multiple of $|x_0|$, then $u_i \ne v_i$ and there is no y such that $u_i, v_i \in yx_0^*u_0$. Lemma 3.2 then implies the claim. $\square$

This finishes the conclusions drawn from Lemma 3.2. Let us now cover two further simple cases.

LEMMA 3.6. *Let $\Delta = |x_0ux_n| - |v|$. If $|x_0| \ge |x_n|$ and $\Delta > |x_0|$, then $u \to v$ terminates or $u = v$.*

Proof. By Lemma 3.5 $u \to v$ terminates if for some $1 \le i \le n-1$, $|u_i| - |v_i|$ is not an integer multiple of $|x_0|$. So let $|u_i| - |v_i|$ be an integer multiple of $|x_0|$ for all $1 \le i \le n-1$. Then $\Delta = \sum_{1 \le i \le n-1}(|u_i| - |v_i|)$ must be an integer multiple of $|x_0|$. By premise, then $\Delta \ge 2|x_0|$. So

$$|u| - |v| = \Delta - |x_0| - |x_n| \ge |x_0| - |x_n| \ge 0;$$

hence the rule is terminating unless $u = v$ (see, e.g., [13]). $\square$

LEMMA 3.7. *If $|u_\ell| < |v_\ell|$ for some $1 \le \ell \le n-1$ and $|u_j| = |v_j|$ for all $1 \le j \le \ell - 1$, then $u \to v$ terminates.*

By duality $u \to v$ terminates, too, if $|u_\ell| < |v_\ell|$ for some $1 \le \ell \le n-1$ and $|u_j| = |v_j|$ for all $\ell + 1 \le j \le n-1$.

The two SRSs *bbab* $\to$ *abbaaabaa* and *babaab* $\to$ *abaaabbaa* are not confluent as the self-overlap b of u is not a self-overlap of v. The two SRSs terminate by Lemma 3.7.

Proof. Form the b-tuple representation through

$$f(w) = \begin{cases} 1 & \text{if } |w| \le |u_\ell|, \\ 0 & \text{else.} \end{cases}$$

To prove $T_f(sut) >_{lex} T_f(svt)$ let s' be the longest suffix of s that does not contain b, and let t' denote the longest prefix of t that does not contain b. By definition of f one gets $f(s'u_0) \ge f(s'x_0u_0)$ and $f(u_j) = f(v_j)$ for all $1 \le j \le \ell - 1$; hence

$$\begin{aligned} &T_f(sut) \\ &\quad = (\dots, \quad f(s'u_0), f(u_1), \dots, f(u_{\ell-1}), 1, f(u_{\ell+1}), \dots, f(u_{n-1}), f(u_nt'), \dots) \\ &\quad >_{lex} (\dots, f(s'x_0u_0), f(v_1), \dots, f(v_{\ell-1}), 0, f(v_{\ell+1}), \dots, f(v_{n-1}), f(u_nx_nt'), \dots) \\ &\quad = T_f(svt). \qquad \square \end{aligned}$$

By Lemma 3.4, u not a factor of v and $|u_\ell| = |v_\ell|$ for all $1 \le \ell \le n-1$ implies termination. Together with Lemma 3.7 this yields the following.

LEMMA 3.8. *Let u not be a factor of v. Then $u \to v$ terminates unless there is $1 \le \ell \le n-1$ such that $|u_\ell| > |v_\ell|$ and $|u_j| = |v_j|$ for all $1 \le j \le \ell - 1$.*

4. The hard cases. Throughout this section let (3.1) and (3.2) hold.

Let $\mathsf{maxu} = \max\{|u_i| \mid 1 \le i \le n-1\}$. Call a string w that contains no b and such that $|w| > \mathsf{maxu}$ a *wall*. Intuitively, a wall separates rewrite steps; the factor $bu_1bu_2 \dots bu_{n-1}b$ of u never overlaps with a wall. The only overlaps u can form with a wall are u_0 and u_n. Application of $u \to v$ then can only increase the wall by x_0, x_n, respectively.

Let us call a string $bw_0bw_1 \dots bw_{N-1}bw_Nb, N \ge 2$ a *basin* if w_0 and w_N are walls and $w_1, \dots, w_{N-1}$ are no walls and $w_1bw_2 \dots bw_{N-1} \ne v_1bv_2 \dots bv_{n-1}$. Let u not be a factor of v. Then basins are the only locations where rewrite steps may still take place. Particularly, u is not a factor of any string $bw'bv_1 \dots bv_{v-1}bw''b$, where w', w'' are walls since u is not a factor of v, and so $bu_1bu_2 \dots bu_{n-1}b \ne bv_1bv_2 \dots bv_{n-1}b$. The only way to increase by a rewrite step the number of basins is to turn a nonwall into a wall.

We are going to distinguish the cases $|x_0| > |x_n|$ and $|x_0| = |x_n|$. For these two cases we have only two complicated termination proofs to offer.

LEMMA 4.1. *If $|x_0| > |x_n|$ and u is not a factor of v then $u \to v$ terminates.*

By duality $u \to v$ also terminates if $|x_n| > |x_0|$ and u is not a factor of v. The system *babaab* $\to$ *aababba* is an example where Lemma 4.1 applies. The system *abaab* $\to$ *aabbaa* for which Kurth gave an ad hoc proof [7, p. 127], is an example where the dual of Lemma 4.1 applies. Both systems are not confluent.

Proof. First let us state a few properties that we will use during the proof.

Since Lemma 3.3 handles the case $|x_0| = 0$, we may assume $|x_0| > 0$. Lemma 3.5 leaves the case where

$$u_i \sim v_i \quad \text{for all } 1 \le i \le n-1. \tag{4.1}$$

By premise and the dual of Lemma 3.3 we have $|x_0| > |x_n| > 0$, and hence

$$x_n \not\sim 0. \tag{4.2}$$

By Lemma 3.8 we need to prove termination only in the case where there is some $1 \le \ell \le n-1$ such that

$$|u_\ell| > |v_\ell| \quad \text{and} \quad |u_j| = |v_j| \quad \text{for all } 1 \le j \le \ell - 1. \tag{4.3}$$

Obviously ℓ is unique. Let $\Delta = |x_0 u x_n| - |v|$. By Lemma 3.6, termination is proven if $\Delta > |x_0|$. So assume

$$\Delta \le |x_0|. \tag{4.4}$$

If there is an infinite reduction, $w_1 \to w_2 \to \dots$, and p, p' are arbitrary strings, then $pw_1p' \to pw_2p' \to \cdots$ is an infinite reduction as well. One may choose p and p' such that pw_1p' has prefix bw' and suffix $w''b$, where w', w'' are walls. This property is preserved by reduction steps.

We prove the claim by showing a strict decrease from sut to svt, where $sut \to svt$ is a reduction step and s starts with bw' and t ends with $w''b$ and w', w'' are walls. Let s' and t' denote the longest suffix of s and the longest prefix of t, respectively, that contains no letter b.

We apply five termination functions lexicographically to prove termination. More precisely, we construct $f_1, \dots, f_5$ such that

$$(f_1(sut), \dots, f_5(sut)) >_{lex} (f_1(svt), \dots, f_5(svt)).$$

Termination function f_1. The termination function f_1 yields the number of nonwalls: $f_1(bw_0bw_1 \dots bw_{m-1}bw_mb) = \sum_{0 \le i \le m} g_1(w_i)$, where the w_i contain no letter b and where g_1 is defined by

$$g_1(w) = \begin{cases} 1 & \text{if } |w| \le \mathsf{maxu}, \\ 0 & \text{else.} \end{cases}$$

One gets that $f_1(sut) \ge f_1(svt)$:

$$\begin{aligned} f_1(sut) - f_1(svt) &= f_1(bs'ut'b) - f_1(bs'vt'b) \\ &= \underbrace{g_1(s'u_0) - g_1(s'x_0u_0)}_{\ge 0} + \underbrace{f_1(bu_1bu_2 \dots bu_{n-1}b)}_{=n-1} \\ &\quad - \underbrace{f_1(bv_1bv_2 \dots bv_{n-1}b)}_{\le n-1} + \underbrace{g_1(u_nt') - g_1(u_nx_nt')}_{\ge 0} \ge 0. \end{aligned}$$

If one of the $|v_i|$, $1 \le i \le n-1$, is greater than maxu, then $f_1(bv_1bv_2 \dots bv_{n-1}b) < n-1$ and hence $f_1(sut) > f_1(svt)$. In this case we have already proved termination. This leaves the case where

$$|v_i| \le \mathsf{maxu} \quad \text{for all } 1 \le i \le n-1. \tag{4.5}$$

If a wall is created, i.e., $g_1(s'u_0) > g_1(s'x_0u_0)$ or $g_1(u_nt') > g_1(u_nx_nt')$, then again $f_1(sut) > f_1(svt)$ and termination is already proven. So henceforth one may assume that the number of walls is not changed during a rewrite step:

$$g_1(s'u_0) = g_1(s'x_0u_0), \tag{4.6}$$

$$g_1(u_nt') = g_1(u_nx_nt'). \tag{4.7}$$

We are going to distinguish four cases:

$$|s'u_0| > \mathsf{maxu},\ |s'x_0u_0| > \mathsf{maxu},\ |u_nt'| > \mathsf{maxu},\ |u_nx_nt'| > \mathsf{maxu}, \tag{4.8}$$

$$|s'u_0| > \mathsf{maxu},\ |s'x_0u_0| > \mathsf{maxu},\ |u_nt'| \le \mathsf{maxu},\ |u_nx_nt'| \le \mathsf{maxu}, \tag{4.9}$$

$$|s'u_0| \le \mathsf{maxu},\ |s'x_0u_0| \le \mathsf{maxu},\ |u_nt'| > \mathsf{maxu},\ |u_nx_nt'| > \mathsf{maxu}, \tag{4.10}$$

$$|s'u_0| \le \mathsf{maxu},\ |s'x_0u_0| \le \mathsf{maxu},\ |u_nt'| \le \mathsf{maxu},\ |u_nx_nt'| \le \mathsf{maxu}\,. \tag{4.11}$$

As explained in detail below, the termination functions f_2, f_3, f_4, and f_5 take care of the cases (4.8), (4.9), (4.10), and (4.11), respectively.

Termination function f_2. The termination function f_2 assigns to a string w its number of basins. A basin cannot be created during a rewrite step that preserves f_1. A basin is destroyed in case (4.8): $f_2(sut) - f_2(svt) = 1$ because $bs'ut'b$ is a basin, whereas $bs'vt'b$ is not. Hence termination is proven for case (4.8), and the termination proof of cases (4.9), (4.10), and (4.11) is postponed.

Termination function f_3. Based on premises (4.3) and (4.1) the auxiliary function g_3 is defined as follows:

$$g_3(bw_0bw_1 \dots bw_{n-1}bw_nb) = \begin{cases} 2 & \text{if } |w_\ell| = |u_\ell| \text{ and } w_n \not\sim u_{n-\ell}, \\ 1 & \text{if } |w_\ell| \le |u_\ell|,\ w_\ell \sim u_\ell, \text{ and } w_n \sim u_{n-\ell}, \\ 0 & \text{else.} \end{cases}$$

Next, let the set $W(w)$ of strings be defined by

$$W(w) = \{bw_0bw_1 \dots bw_{n-1}bw_nb \mid w_0, \dots, w_n \in (\Sigma \setminus \{b\})^*, \\ |w_0| > \mathsf{maxu}, |w_1|, \dots, |w_n| \le \mathsf{maxu}\}.$$

Observe that by definition two strings $w', w'' \in W(w), w' \ne w''$ have the only overlap b. Now the termination function f_3 is defined by

$$f_3(w) = \sum_{w' \in W(w)} g_3(w').$$

We are going to prove that $f_3(sut) > f_3(svt)$ in case (4.9) and $f_3(sut) \ge f_3(svt)$ in cases (4.10) and (4.11).

Case (4.9). $|s'u_0| > \mathsf{maxu}$ and $|u_nt'| \le \mathsf{maxu}$ and so

$$f_3(sut) - f_3(svt) = g_3(bs'ut'b) - g_3(bs'vt'b) \\ = \begin{cases} 2 & \text{if } u_nt' \not\sim u_{n-\ell}, \\ 1 & \text{else} \end{cases} \quad - \quad \begin{cases} 1 & \text{if } u_nx_nt' \sim u_{n-\ell}, \\ 0 & \text{else} \end{cases} \\ = \begin{cases} 2-1 & \text{if } u_nx_nt' \sim u_{n-\ell}, \\ 1-0 & \text{if } u_nt' \sim u_{n-\ell} \\ 2-0 & \text{else.} \end{cases} \quad \ge 1,$$

The case $1 - 1$ cannot occur since $u_nx_nt' \not\sim u_nt'$ by (4.2). Thus termination of case (4.9) is proven.

In the remaining cases (4.10) and (4.11), where $|s'u_0| \le \mathsf{maxu}$, we have to prove $f_3(sut) \ge f_3(svt)$. Let $s = bs_1bs_2 \dots bs_{m-1}bs'$, $m \ge 1$, $s_1, \dots, s_{m-1}, s' \in (\Sigma \setminus \{b\})^*$,

and let D be the least positive integer such that $|s_{m-D}| > \mathsf{maxu}$. ($D$ is well defined, for $|s_1| > \mathsf{maxu}$ is presupposed.) Let $w = bw_0bw_1 \dots bw_nb$ denote the unique string that begins and ends with b, contains b exactly $n+2$ times, and such that sut has prefix $bs_1bs_2 \dots bs_{m-D-1}w$. Likewise, let $w' = bw'_0bw'_1 \dots bw'_nb$ denote the unique string that begins and ends with b, contains b exactly $n+2$ times, and such that svt has prefix $bs_1bs_2 \dots bs_{m-D-1}w'$.

There are walls neither in $bs'u_0bu_1 \dots bu_{n-1}b$ nor in $bs'x_0u_0bv_1 \dots bv_{n-1}b$ by premises $|s'u_0| \le \mathsf{maxu}$, (4.5), and (4.6); so one gets

$$f_3(sut) - f_3(svt) = g_3(w) - g_3(w'). \tag{4.12}$$

We are going to prove that $g_3(w) - g_3(w') \ge 0$.

The string w is a prefix of the string

$$\underbrace{bs_{m-D} \dots bs_{m-1}b}_{1}\, s'u_0 \underset{\uparrow}{b}\underbrace{u_1 \dots bu_{n-\ell-1}b}_{3}\, u_{n-\ell}\underset{\uparrow}{b}\underbrace{u_{n-\ell+1} \dots bu_{n-1}b}_{5}\, u_nt'b.$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad 2 \qquad\qquad\qquad\quad 4$$

The string w may end in any of the domains $1, \dots, 5$. By premise, it must not end at $u_nt'b$. Accordingly we perform a case analysis on n.

Case 1. $n < D$. Then $w_\ell = s_{m-D+\ell} = w'_\ell$ and $w_n = s_{m-D+n} = w'_n$ and so $g_3(w) = g_3(w')$.

Case 2. $n = D$. Then $w_\ell = s_{m-D+\ell} = w'_\ell$, $w_n = s'u_0$, and $w'_n = s'x_0u_0$ and so $g_3(w) = g_3(w')$ by $s'u_0 \sim s'x_0u_0$.

Case 3. $D < n < D+n-\ell$ or, equivalently, $\ell < D < n$. Then $w_\ell = s_{m-D+\ell} = w'_\ell$, $w_n = u_{n-D}$, $w'_n = v_{n-D}$; hence $w_n \sim w'_n$ by (4.1) which implies that $g_3(w) = g_3(w')$.

Case 4. $n = D+n-\ell$ or, equivalently, $D = \ell$. Then $w_\ell = s'u_0$, $w'_\ell = s'x_0u_0$, $w_n = u_{n-\ell}$, and $w'_n = v_{n-\ell}$. Note that $g_3(w) \ne 2$ and $g_3(w') \ne 2$ by $w_n \sim u_{n-\ell} \sim w'_n$. Hence $g_3(w) \ge g_3(w')$ by $|w_\ell| \le |w'_\ell|$ and by $w_\ell \sim w'_\ell$.

Case 5. $D+n-\ell < n \le D+n-1$ or, equivalently, $1 \le D < \ell$. Then $w_\ell = u_{\ell-D}$, $w'_\ell = v_{\ell-D}$, $w_n = u_{n-D}$, and $w'_n = v_{n-D}$. From $|w_\ell| = |w'_\ell|$ by (4.3) and $w_n \sim w'_n$ we infer $g_3(w) = g_3(w')$.

Summarizing this case analysis, we have shown $g_3(w) \ge g_3(w')$, and so $f_3(sut) \ge f_3(svt)$ by (4.12), in the remaining cases (4.10) and (4.11). These cases are again postponed.

Termination function f_4. The termination function f_4 is defined by

$$f_4(bw_0bw_1 \dots bw_{m-1}bw_mb) = \sum_{0 \le i \le m} g_4(w_i),$$

where $w_i \in (\Sigma \setminus \{b\})^*$ for all $0 \le i \le m$, and g_4 is defined by

$$g_4(w) = \begin{cases} \mathsf{maxu} - |w| & \text{if } |w| \le \mathsf{maxu}, \\ 0 & \text{else.} \end{cases}$$

Recall that $\Delta = |x_0ux_n| - |v| \le |x_0|$ by premise (4.4).

Case (4.11). Here $|s'x_0u_0| \le \mathsf{maxu}$ and $|u_nx_nt'| \le \mathsf{maxu}$, so $f_4(sut) > f_4(svt)$:

$$\begin{aligned} &f_4(sut) - f_4(svt) \\ &\qquad = \underbrace{g_4(s'u_0) - g_4(s'x_0u_0)}_{=|x_0|} - \underbrace{\Delta}_{\le |x_0|} + \underbrace{g_4(u_nt') - g_4(u_nx_nt')}_{=|x_n|} \ge |x_n| > 0. \end{aligned}$$

Case (4.10). $|s'x_0u_0| \leq \mathsf{maxu}$ and $|u_nt'| > \mathsf{maxu}$ hold and so

$$f_4(sut) - f_4(svt) = \underbrace{g_4(s'u_0) - g_4(s'x_0u_0)}_{=|x_0|} - \underbrace{\Delta}_{\leq |x_0|} + \underbrace{g_4(u_nt') - g_4(u_nx_nt')}_{=0} \geq 0.$$

Because the decrease in case (4.10) need not be strict we need a fifth termination function f_5.

Termination function f_5. $f_5(w)$ counts the factors in w of the form

$$bw_0u_0bu_1 \dots bu_{n-1}bu_nw_nb,$$

where u_nw_n is a wall. We have $f_5(sut) - f_5(svt) = 1$ for the remaining case (4.10) by the fact that $u_i \neq v_i$ for some $1 \leq i \leq n-1$.

We conclude that $(f_1(sut), \dots, f_5(sut)) >_{lex} (f_1(svt), \dots, f_5(svt))$ for every step $sut \to svt$. Hence $u \to v$ terminates. □

At last, there is the case $|x_0| = |x_n|$. Here we show that $u \to v$ terminates unless it admits a loop of lengths 1 or 2. A loop is a reduction sequence where the start string reappears as a factor in the final string. Kurth characterized the existence of loops of lengths 1 and 2 for arbitrary one-rule SRSs.

THEOREM 4.2 (Kurth [7, p. 139]). *A string rewriting rule $u \to v$ admits a loop of length 1 if and only if u is a factor of v.*

THEOREM 4.3 (Kurth [7, p. 142]). *If u is not a factor of v, then the following two propositions are equivalent:*

1. *$u \to v$ has a loop of length 2;*
2. *there are strings g, h, k such that $u = gh$, $v = hk$, and ggh is a factor of hkk.*

The case where a grid rule $u \to v$ admits a loop of length 2 really exists, as witnessed by the SRS $abaab \to aababa$. It has the following loop of length 2:

$$abaabab \to aababaab \to aabaababa.$$

To apply Kurth's characterization, choose $g = ab$, $h = aab$, $k = aba$. Then $ggh = ab\,ab\,aab$, which is a factor of $hkk = aab\,aba\,aba$.

As a surprising fact, neither loops of other lengths nor infinite nonlooping reductions are essential to grid rules: It suffices to exclude loops of lengths 1 and 2 to ensure termination.

LEMMA 4.4. *If $|x_0| = |x_n|$ and $u \to v$ does not terminate, then $u \to v$ has a loop of length 1 or 2.*

Proof. Let us exclude loops of length 1.

Suppose that $u \to v$ is nonterminating; i.e., there is an infinite reduction sequence. First we proceed as in the proof of Lemma 4.1. The termination functions f_1, f_2, and f_4 as defined in the proof of Lemma 4.1 are applied lexicographically so as to show that an infinite reduction exists where the values of f_1, f_2, and f_4 remain constant. (Termination function f_3 yields no progress in the case $|x_0| = |x_n|$ because the crucial property (4.2) fails to hold.) We have to show that $f_4(sut) \geq f_4(svt)$ in case (4.9); this is the dual to case (4.10). We refer to Lemma 4.1 for details. From such an infinite reduction we are going to extract a loop of length 2.

The infinite reduction sequence must finally contain steps of sort case (4.9) or case (4.10) exclusively, as these are the only steps that may keep $f_1, \dots, f_4$ constant. Because f_1 is finally constant, the number of basins is bounded. By the pigeonhole principle, infinitely many steps of the infinite reduction sequence take place in one basin. Steps of sort case (4.9) take place with u_0 overlapping the left wall of the

basin; steps of sort case (4.10) take place with u_n overlapping the right wall of the basin. Each step strictly increases the thickness of its assigned wall. As soon as a wall is as thick as $|u_n| + |u_0|$, rewrite steps at opposite sides of the wall can be done independently because redexes will no longer overlap. So an infinite reduction can be extracted that starts from a single basin. If two steps of the same sort follow each other, then $v_i = u_i$ holds for all $1 \leq i \leq n-1$, a contradiction. Hence the steps of the two kinds must alternate. By the same argument they must also overlap. However, with that we have the required loop of length 2. □

Theorem 1.2 now follows immediately from Lemma 3.1 and its dual and Lemmas 4.1 and 4.4.

5. A glimpse of practice. A few figures may illustrate the distribution of grid rules $u \to v$ for $|v| = 7$. They are obtained using the author's reimplementation of Kurth's sieve. There are 3,151,054 length increasing rule representatives in total. They divide into 3,145,038 grid rules and 6,016 nongrid rules. As much as 3,004 nongrid rules have loops of length 1 and 57 have loops of length 2 but not of length 1. Among the grid rules 2,736,925 rules satisfy $\#_b(u) > \#_b(v)$ for some letter b; 7,118 rules have loops of length 1; 400,007 rules satisfy Lemma 3.1 or 3.3 or their duals; 964 rules satisfy one of Lemmas 3.2, 3.6, 3.7, or 4.1, or their duals; and the following 16 rules are proper, terminating instances of Lemma 4.4 or its dual:

$abaabb \to aababba$	$abbaab \to aabbaba$	$baabb \to aabbbaa$
$baaabb \to abaabba$	$baabab \to abaabba$	$baabab \to abababa$
$baabbb \to ababbba$	$bababb \to ababbba$	$babbab \to ababbba$
$bababb \to abbabba$	$babbbb \to abbbbba$	$bbabbb \to abbbbba$
$bbcabc \to abbcbca$	$bcabbc \to abcbbca$	$babccb \to abbccba$
$bacbb \to acbbbac$		

Finally, the following 8 rules admit loops of length 2:

$abaaab \to aabaaba$	$baaab \to aababaa$	$abaaba \to aababaa$
$baaaab \to abaaaba$	$babbab \to abbabba$	$bbaabb \to abbabba$
$bcaabc \to abcabca$	$bcacb \to acbcbca$	

6. Total division orders. A *division order* [4] is an order $>$ on strings over an alphabet Σ such that

- $s > t$ if s is a factor of t;
- if $s > t$, then $usv > utv$ for all $u, v \in \Sigma^*$.

If $s > t$ or $t > s$ or $s = t$ for all $s, t \in \Sigma^*$, then $>$ is called *total*. Termination of a SRS R is usually shown by constructing a total division order $>$ such that $u > v$ for each rule $u \to v$ of R. We say that in this case R *is ordered by the total division order* $>$.

Total division orders and grid rules are closely related by the following result of Cohen and Scott.

Definition 6.1 (dominates, rational [1]). *A string $u \in \Sigma^*$ is said to* dominate *$v \in \Sigma^*$ if $\#_b(u) > \#_b(v)$ for all $b \in \Sigma$. An order $> \subseteq \Sigma^* \times \Sigma^*$ is called* rational *if $u > v$ holds for all $u, v \in \Sigma$ such that u dominates v.*

Theorem 6.2 (Cohen and Scott [1]). *Every total division order on strings is rational.*

Theorem 6.3. *Every string rewriting rule that can be ordered by a total division order is a grid rule.*

Proof. Assume that $u \to v$ is not a grid rule. Then v dominates u, and so $v > u$ for every total division order $>$ by Theorem 6.2. If $>$ orders $u \to v$, then $v > u > v$, a contradiction to irreflexivity of $>$. □

In effect, this means that total division orders are irrelevant for the termination problem of one-rule SRSs. Note, however, that Theorem 6.3 does not imply decidability whether a rule can be ordered by a total division order.

7. Conclusion. Termination of SRSs is an undecidable property. Whether termination is undecidable even for *one-rule SRSs* stays an exciting open problem. This paper solves this problem partially: Termination is decidable for the class of $u \to v$, where some letter from u occurs in v as often or less often. We call such rules *grid* rules.

All rules that can be ordered by a total division order are grid rules (Theorem 6.3), so a termination sieve can dispose of all total division orders. Even better: the only interesting rules left are the nongrid rules. These can be enumerated directly, and their number grows far slower than the total number of length increasing rules. Thus the sieve becomes faster and finer and gives access to larger and more interesting rules.

Acknowledgments. The idea to pursue this work was triggered by Kurth's "Criterion C" and by McNaughton's Theorem 1.4. Hans Zantema suggested to consider reduction lengths and pointed out an error in a preliminary version of the proof of Lemma 3.1. One referee gave very useful hints which helped improve the presentation.

RANDOMNESS, COMPUTABILITY, AND DENSITY*

ROD G. DOWNEY†, DENIS R. HIRSCHFELDT‡, AND ANDRÉ NIES§

Abstract. We study effectively given positive reals (more specifically, computably enumerable reals) under a measure of relative randomness introduced by Solovay [manuscript, IBM Thomas J. Watson Research Center, Yorktown Heights, NY, 1975] and studied by Calude, Hertling, Khoussainov, and Wang [*Theoret. Comput. Sci.*, 255 (2001), pp. 125–149], Calude [*Theoret. Comput. Sci.*, 271 (2002), pp. 3–14], Kučera and Slaman [*SIAM J. Comput.*, 31 (2002), pp. 199–211], and Downey, Hirschfeldt, and LaForte [*Mathematical Foundations of Computer Science* 2001, Springer-Verlag, Berlin, 2001, pp. 316–327], among others. This measure is called *domination* or *Solovay reducibility* and is defined by saying that α dominates β if there are a constant c and a partial computable function φ such that for all positive rationals $q < \alpha$ we have $\varphi(q)\downarrow < \beta$ and $\beta - \varphi(q) \leqslant c(\alpha - q)$. The intuition is that an approximating sequence for α generates one for β whose rate of convergence is not much slower than that of the original sequence. It is not hard to show that if α dominates β, then the initial segment complexity of α is at least that of β.

In this paper we are concerned with structural properties of the degree structure generated by Solovay reducibility. We answer a natural question in this area of investigation by proving the density of the Solovay degrees. We also provide a new characterization of the random computably enumerable reals in terms of splittings in the Solovay degrees. Specifically, we show that the Solovay degrees of computably enumerable reals are dense, that any incomplete Solovay degree splits over any lesser degree, and that the join of any two incomplete Solovay degrees is incomplete, so that the complete Solovay degree does not split at all. The methodology is of some technical interest, since it includes a priority argument in which the injuries are themselves controlled by randomness considerations.

Key words. randomness, computably enumerable reals, algorithmic information theory, Kolmogorov complexity, Solovay reducibility

1. Introduction.

In this paper we are concerned with effectively generated reals in the interval $(0, 1]$ and their relative randomness. In what follows, *real* and *rational* will mean positive real and positive rational, respectively. It will be convenient to work modulo 1, that is, identifying $n + \alpha$ and α for any $n \in \omega$ and $\alpha \in (0, 1]$, and we do this below without further comment.

Our basic objects are reals that are limits of computable increasing sequences of rationals. We call such reals *computably enumerable* (c.e.), but they have also been called *recursively enumerable*, *left computable* (by Ambos-Spies, Weihrauch, and Zheng [1]), and *left semicomputable*. If, in addition to the existence of a computable increasing sequence $q_0, q_1, \ldots$ of rationals with limit α, there is a total computable function f such that $\alpha - q_{f(n)} < 2^{-n}$ for all $n \in \omega$, then α is called *computable*.

These and related concepts have been widely studied. In addition to the papers and books mentioned elsewhere in this introduction, we may cite, among others, early work of Rice [26], Lachlan [21], Soare [28], and Ceĭtin [8] and more recent papers by Ko [17, 18], Calude, Coles, Hertling, and Khoussainov [5], Ho [16], and Downey and LaForte [14].

A computer M is *self-delimiting* if, for each binary string σ, $M(\sigma)\downarrow$ implies that $M(\sigma')\uparrow$ for all σ' properly extending σ. It is *universal* if for each self-delimiting computer N there is a constant c such that, for each binary string σ, if $N(\sigma)\downarrow$, then $M(\tau)\downarrow = N(\sigma)$ for some τ with $|\tau| \leqslant |\sigma| + c$.

Fix a self-delimiting universal computer M. We can define Chaitin's number $\Omega = \Omega_M$ via

$$\Omega = \sum_{M(\sigma)\downarrow} 2^{-|\sigma|}.$$

The properties of Ω relevant to this paper are independent of the choice of M. A c.e. real is an Ω-*number* if it is Ω_M for some self-delimiting universal computer M.

The c.e. real Ω is random in the canonical Martin-Löf sense. Recall that a *Martin-Löf test* is a uniformly c.e. sequence $\{V_e : e > 0\}$ of c.e. subsets of $\{0,1\}^*$ such that for all $e > 0$,

$$\mu(V_e\{0,1\}^\omega) \leqslant 2^{-e},$$

where μ denotes the usual product measure on $\{0,1\}^\omega$. The string $\sigma \in \{0,1\}^\omega$ and the real $0.\sigma$ are *random* or, more precisely, 1-random if $\sigma \notin \bigcap_{e>0} V_e\{0,1\}^\omega$ for every Martin-Löf test $\{V_e : e > 0\}$.

An alternate characterization of the random reals can be given via the notion of a *Solovay test*. We give a somewhat nonstandard definition of this notion, which will be useful below. A Solovay test is a c.e. multiset $\{I_i : i \in \omega\}$ of intervals with rational endpoints such that $\sum_{i\in\omega} |I_i| < \infty$, where $|I|$ is the length of the interval I. As Solovay [32] showed, a real α is random if and only if $\{i \in \omega : \alpha \in I_i\}$ is finite for every Solovay test $\{I_i : i \in \omega\}$.

Many authors have studied Ω and its properties, notably Chaitin [10, 11, 12] and Martin-Löf [25]. In the very long and widely circulated manuscript [32] (a fragment of which appeared in [33]), Solovay carefully investigated relationships between Martin-Löf-Chaitin prefix-free complexity, Kolmogorov complexity, and properties of random languages and reals. See Chaitin [10] for an account of some of the results in this manuscript.

Solovay discovered that several important properties of Ω (whose definition is model-dependent) are shared by another class of reals he called Ω-like, whose definition is model-independent. To define this class, he introduced the following reducibility relation among c.e. reals, called *domination* or *Solovay reducibility*.

DEFINITION 1.1. *Let α and β be c.e. reals. We say that α* dominates *β, and write $\beta \leqslant_s \alpha$, if there are a constant c and a partial computable function $\varphi : \mathbb{Q} \to \mathbb{Q}$ such that for each rational $q < \alpha$ we have $\varphi(q)\downarrow < \beta$ and*

$$\beta - \varphi(q) \leqslant c(\alpha - q).$$

We write $\beta <_s \alpha$ if $\beta \leqslant_s \alpha$ and $\alpha \not\leqslant_s \beta$, and we write $\alpha \equiv_s \beta$ if $\alpha \leqslant_s \beta$ and $\beta \leqslant_s \alpha$.

The notation $\leqslant_{\mathrm{dom}}$ has sometimes been used instead of $\leqslant_{\mathrm{s}}$.

The prefix-free complexity $H(\tau)$ of a binary string τ is the length of the shortest binary string σ such that $M(\sigma)\downarrow = \tau$, where M is a fixed self-delimiting universal

computer. (The choice of M does not affect the prefix-free complexity, up to a constant additive factor.) Most of the statements about $H(\tau)$ made below also hold for the standard Kolmogorov complexity $K(\tau)$. For more on the definitions and basic properties of $H(\tau)$ and $K(\tau)$, see Chaitin [12], Calude [3], and Li and Vitanyi [24]. Among the many works dealing with these and related topics, and in addition to those mentioned elsewhere in this paper, we may cite Solomonoff [30, 31], Kolmogorov [19], Levin [22, 23], Schnorr [27], and the expository article by Calude and Chaitin [4].

As shown by Schnorr (see Chaitin [9]), a real α is random if and only if there is a constant c such that $H(\alpha \upharpoonright n) > n - c$ for all $n \in \omega$. (We identify a real $\alpha \in (0, 1]$ with the infinite binary string σ such that $\alpha = 0.\sigma$. The fact that certain reals have two different dyadic expansions need not concern us here, since all such reals are rational.) Solovay reducibility is naturally associated with randomness because of the following fact, whose proof we sketch for completeness.

THEOREM 1.2 (Solovay [32]). *Let $\beta \leqslant_s \alpha$ be c.e. reals. There is a constant k such that $H(\beta \upharpoonright n) \leqslant H(\alpha \upharpoonright n) + k$ for all $n \in \omega$.*

Proof sketch. We first sketch the proof of the following lemma, implicit in [32] and noted by Calude, Hertling, Khoussainov, and Wang [6].

LEMMA 1.3. *Let $c \in \omega$. There is a constant k such that for all $n \geqslant 1$ and all binary strings σ, τ of length n with $|0.\sigma - 0.\tau| < c2^{-n}$, we have $|H(\tau) - H(\sigma)| \leqslant k$.*

The proof of the lemma is relatively simple. We can easily write a program P that, for each sufficiently long σ, generates the $2c+1$ binary strings τ' of length n with $|0.\sigma - 0.\tau'| < c2^{-n}$. For any binary strings σ, τ of length n with $|0.\sigma - 0.\tau| < c2^{-n}$, in order to compute τ it suffices to know a program for σ and the position of τ on the list generated by P on input σ.

Turning to the proof of the theorem, let φ and c be as in Definition 1.1. Let $\alpha_n = 0.(\alpha \upharpoonright n)$. Since α_n is rational and $\alpha - \alpha_n < 2^{-(n+1)}$, we have $\beta - \varphi(\alpha_n) < c2^{-(n+1)}$. Thus, by the lemma, there is a constant k such that $H(\beta \upharpoonright n) \leqslant H(\varphi(\alpha_n)) + k$ for all $n \geqslant 1$, which implies that $H(\beta \upharpoonright n) \leqslant H(\alpha \upharpoonright n) + k$. □

Solovay observed that Ω dominates all c.e. reals, and Theorem 1.2 implies that if a c.e. real dominates all c.e. reals then it must be random. This led Solovay to define a c.e. real to be Ω-*like* if it dominates all c.e. reals. The point is that the definition of Ω-like seems quite model-independent (in the sense that it does not require a choice of self-delimiting universal computer), as opposed to the model-dependent definition of Ω. However, Calude, Hertling, Khoussainov, and Wang [6] showed that the two notions coincide.

THEOREM 1.4 (Calude, Hertling, Khoussainov, and Wang [6]). *A c.e. real is Ω-like if and only if it is an Ω-number.*

This circle of ideas was completed recently by Kučera and Slaman [20], who proved the converse to the fact that Ω-like reals are random.

THEOREM 1.5 (Kučera and Slaman [20]). *A c.e. real is random if and only if it is Ω-like.*

It is natural to seek to understand the c.e. reals under Solovay reducibility. A useful characterization of this reducibility is given by the following lemma, which we prove in the next section.

LEMMA 1.6. *Let α and β be c.e. reals. The following are equivalent.*

1. $\beta \leqslant_s \alpha$.
2. *For some computable sequence of rationals $a_0, a_1, \ldots$ such that*

$$\alpha = \sum_{n \in \omega} a_n$$

there are a constant c and a computable sequence of rationals $\varepsilon_0, \varepsilon_1, \ldots < c$ such that

$$\beta = \sum_{n\in\omega} \varepsilon_n a_n.$$

3. *For* every *computable sequence of rationals $a_0, a_1, \ldots$ such that $\alpha = \sum_{n\in\omega} a_n$ there are a constant c and a computable sequence of rationals $\varepsilon_0, \varepsilon_1, \ldots < c$ such that $\beta = \sum_{n\in\omega} \varepsilon_n a_n$.*

Phrased another way, Lemma 1.6 says that the c.e. reals dominated by a given c.e. real α essentially correspond to splittings of α under arithmetic addition.

COROLLARY 1.7. *Let $\beta \leqslant_s \alpha$ be c.e. reals. There are a c.e. real γ and a rational c such that $c\alpha = \beta + \gamma$.*

Proof. Let $a_0, a_1, \ldots$ be a computable sequence of rationals such that $\alpha = \sum_{n\in\omega} a_n$. Let $c \in \mathbb{Q}$ and $\varepsilon_0, \varepsilon_1, \ldots < c$ be as in Lemma 1.6. Define $\gamma = \sum_{n\in\omega}(c - \varepsilon_n)a_n$. Since each ε_n is less than c, the real γ is c.e., and of course $\beta + \gamma = c\alpha$. □

Solovay reducibility has a number of other beautiful interactions with arithmetic, as we now discuss.

The relation $\leqslant_{\mathrm{S}}$ is reflexive and transitive, and hence $\equiv_{\mathrm{S}}$ is an equivalence relation on the c.e. reals. Thus we can define the *Solovay degree* $[\alpha]$ of a c.e. real α as its $\equiv_{\mathrm{S}}$ equivalence class. (When we mention Solovay degrees below, we always mean Solovay degrees of c.e. reals.) The Solovay degrees form an upper semilattice, with the join of $[\alpha]$ and $[\beta]$ being $[\alpha+\beta]$=$[\alpha\beta]$, a fact observed by Solovay and others, such as Calude, Hertling, Khoussainov, and Wang [6]. ($\oplus$ is definitely not a join operation here.) We note the following slight improvement of this result. Recall that an upper semilattice U is *distributive* if for all $a_0, a_1, b \in U$ with $b \leqslant a_0 \vee a_1$ there exist $b_0, b_1 \in U$ such that $b_0 \vee b_1 = b$ and $b_i \leqslant a_i$ for $i = 0, 1$.

LEMMA 1.8. *The Solovay degrees of c.e. reals form a distributive upper semilattice with $[\alpha] \vee [\beta] = [\alpha + \beta] = [\alpha\beta]$.*

Proof. Suppose that $\beta \leqslant_{\mathrm{S}} \alpha_0 + \alpha_1$. Let $a_0^0, a_1^0, \ldots$ and $a_0^1, a_1^1, \ldots$ be computable sequences of rationals such that $\alpha_i = \sum_{n\in\omega} a_n^i$ for $i = 0, 1$. By Lemma 1.6, there are a constant c and a computable sequence of rationals $\varepsilon_0, \varepsilon_1, \ldots < c$ such that $\beta = \sum_{n\in\omega} \varepsilon_n(a_n^0 + a_n^1)$. Let $\beta_i = \sum_{n\in\omega} \varepsilon_n a_n^i$. Then $\beta = \beta_0 + \beta_1$ and, again by Lemma 1.6, $\beta_i \leqslant_{\mathrm{S}} \alpha_i$ for $i = 0, 1$. This establishes distributivity.

To see that the join in the Solovay degrees is given by addition, we again apply Lemma 1.6. Certainly, for any c.e. reals β_0 and β_1 we have $\beta_i \leqslant_{\mathrm{S}} \beta_0 + \beta_1$ for $i = 0, 1$, and hence $[\beta_0 + \beta_1] \geqslant_{\mathrm{S}} [\beta_0], [\beta_1]$. Conversely, suppose that $\beta_0, \beta_1 \leqslant \alpha$. Let $a_0, a_1, \ldots$ be a computable sequence of rationals such that $\alpha = \sum_{n\in\omega} a_n$. For each $i = 0, 1$ there are a constant c_i and a computable sequence of rationals $\varepsilon_0^i, \varepsilon_1^i, \ldots < c_i$ such that $\beta_i = \sum_{n\in\omega} \varepsilon_n^i a_n$. Thus $\beta_0 + \beta_1 = \sum_{n\in\omega}(\varepsilon_n^0 + \varepsilon_n^1)a_n$. Since each $\varepsilon_n^0 + \varepsilon_n^1$ is less than $c_0 + c_1$, a final application of Lemma 1.6 shows that $\beta_0 + \beta_1 \leqslant_{\mathrm{S}} \alpha$.

The proof that the join in the Solovay degrees is also given by multiplication is a similar application of Lemma 1.6. □

There is a least Solovay degree, the degree of the computable reals, as well as a greatest one, the degree of Ω. For proofs of these facts and more on c.e. reals and Solovay reducibility, see, for instance, Chaitin [10, 11, 12], Calude, Hertling, Khoussainov, and Wang [6], Calude and Nies [7], Calude [2], Kučera and Slaman [20], and Downey, Hirschfeldt, and LaForte [15].

Despite the many attractive features of the Solovay degrees, their structure is largely unknown. Downey, Hirschfeldt, and LaForte (to be submitted) have shown that this structure is very complicated by proving that it has an undecidable first-order theory.

One question addressed in the present paper is whether the structure of the Solovay degrees is dense. Indeed, up to now, it was not known even whether there is a *minimal* Solovay degree. That is, intuitively, if a c.e. real α is not computable, must there be a c.e. real that is also not computable, yet is strictly less random than α? In the process of understanding a degree structure, the question of density has always played a key role and has been one of the first to be addressed. For instance, the Sacks Density Theorem (see [29]) was one of the earliest and most important results in the study of the c.e. Turing degrees.

In this paper, we show that the Solovay degrees of c.e. reals are dense. To do this we divide the proof into two parts. We prove that if $\alpha <_{\mathrm{S}} \Omega$, then there is a c.e. real γ with $\alpha <_{\mathrm{S}} \gamma <_{\mathrm{S}} \Omega$, and we also prove that every *incomplete* Solovay degree splits over each lesser degree.

The nonuniform nature of the argument is essential given the techniques we use, since, in the splitting case, we have a priority construction in which the control of the injuries is directly tied to the enumeration of Ω. The fact that if a c.e. real α is Solovay-incomplete, then Ω must grow more slowly than α is what allows us to succeed. (We will discuss this more fully in section 3.) This unusual technique is of some technical interest and clearly cannot be applied to proving upwards density, since in that case the top degree is the degree of Ω itself. To prove upwards density, we use a different technique, taking advantage of the fact that, however we construct a c.e. real, it is automatically dominated by Ω.

In light of these results, and further motivated by the general question of how randomness can be produced, it is natural to ask whether the complete Solovay degree can be split, or in other words, whether there exist nonrandom c.e. reals α and β such that $\alpha + \beta$ is random. We give a negative answer to this question, thus characterizing the random c.e. reals as those c.e. reals that cannot be written as the sum of two c.e. reals of lesser Solovay degrees.

We remark that there are (non-c.e.) nonrandom reals whose sum is random; the following is an example of this phenomenon. Define the real α by letting $\alpha(n) = 0$ if n is even and $\alpha(n) = \Omega(n)$ otherwise. (Here we identify a real with its dyadic expansion as above.) Define the real β by letting $\beta(n) = 0$ if n is odd and $\beta(n) = \Omega(n)$ otherwise. Now α and β are clearly nonrandom, but $\alpha + \beta = \Omega$ is random.

Before turning to the details of the paper, we point out that there are other reducibilities one can study in this context. Downey [13] and Downey, Hirschfeldt, and LaForte [15] introduced two such reducibilities, sw-reducibility and rH-reducibility, and showed, among other things, that the results of this paper also hold for rH-reducibility. The proofs are essentially the same as those in this paper. Ultimately, the basic reducibility we seek to understand is H-reducibility, where $\sigma \leqslant_H \tau$ if $H(\sigma \upharpoonright n) \leqslant H(\tau \upharpoonright n) + O(1)$. Not much is known about this directly, but it is again possible to adapt the methods of this paper to prove the analogous results for H-reducibility.

2. Preliminaries. The following lemma, implicit in [32] and proved in [15], provides an alternate characterization of Solovay reducibility, which is the one that we will use below.

LEMMA 2.1. *Let α and β be c.e. reals, and let $\alpha_0, \alpha_1, \ldots$ and $\beta_0, \beta_1, \ldots$ be computable increasing sequences of rationals converging to α and β, respectively. Then $\beta \leqslant_s \alpha$ if and only if there are a constant d and a total computable function f such that for all $n \in \omega$,*

$$\beta - \beta_{f(n)} < d(\alpha - \alpha_n).$$

Whenever we mention a c.e. real α, we assume that we have chosen a computable increasing sequence $\alpha_0, \alpha_1, \ldots$ converging to α. The previous lemma guarantees that, in determining whether one c.e. real dominates another, the particular choice of such sequences is irrelevant. For convenience of notation, we adopt the convention that, for any c.e. real α mentioned below, the expression $\alpha_s - \alpha_{s-1}$ is equal to α_0 when $s = 0$.

We will also make use of two more lemmas, the first of which has Lemma 1.6 as a corollary.

LEMMA 2.2. *Let $\beta \leqslant_s \alpha$ be c.e. reals and let $\alpha_0, \alpha_1, \ldots$ be a computable increasing sequence of rationals converging to α. There is a computable increasing sequence $\hat{\beta}_0, \hat{\beta}_1, \ldots$ of rationals converging to β such that for some constant c and all $s \in \omega$,*

$$\hat{\beta}_s - \hat{\beta}_{s-1} < c(\alpha_s - \alpha_{s-1}).$$

Proof. Fix a computable increasing sequence $\beta_0, \beta_1, \ldots$ of rationals converging to β, let d and f be as in Lemma 2.1, and let $c > d$ be such that $\beta_{f(0)} < c\alpha_0$. We may assume without loss of generality that f is increasing. Define $\hat{\beta}_0 = \beta_{f(0)}$.

There must be an $s_0 > 0$ for which $\beta_{f(s_0)} - \beta_{f(0)} < d(\alpha_{s_0} - \alpha_0)$, since otherwise we would have

$$\beta - \beta_{f(0)} = \lim_s \beta_{f(s)} - \beta_{f(0)} \geqslant \lim_s d(\alpha_s - \alpha_0) = d(\alpha - \alpha_0),$$

contradicting our choice of d and f. It is now easy to define $\hat{\beta}_1, \ldots, \hat{\beta}_{s_0}$ so that $\hat{\beta}_0 < \cdots < \hat{\beta}_{s_0} = \beta_{f(s_0)}$ and $\hat{\beta}_s - \hat{\beta}_{s-1} \leqslant d(\alpha_s - \alpha_{s-1}) < c(\alpha_s - \alpha_{s-1})$ for all $s \leqslant s_0$. For example, if we let μ be the minimum value of $d(\alpha_s - \alpha_{s-1})$ for $s \leqslant s_0$ and let t be least such that $\hat{\beta}_0 + d(\alpha_t - \alpha_0) < \beta_{f(s_0)} - 2^{-t}\mu$, then we can define

$$\hat{\beta}_{s+1} = \begin{cases} \hat{\beta}_s + d(\alpha_{s+1} - \alpha_s) & \text{if } s+1 < t, \\ \beta_{f(s_0)} - 2^{-(s+1)}\mu & \text{if } t \leqslant s+1 < s_0, \\ \beta_{f(s_0)} & \text{if } s+1 = s_0. \end{cases}$$

We can repeat the procedure in the previous paragraph with s_0 in place of 0 to obtain an $s_1 > s_0$ and $\hat{\beta}_{s_0+1}, \ldots, \hat{\beta}_{s_1}$ such that $\hat{\beta}_{s_0} < \cdots < \hat{\beta}_{s_1} = \beta_{f(s_1)}$ and $\hat{\beta}_s - \hat{\beta}_{s-1} < c(\alpha_s - \alpha_{s-1})$ for all $s_0 < s \leqslant s_1$.

Proceeding by recursion in this way, we define a computable increasing sequence $\hat{\beta}_0, \hat{\beta}_1, \ldots$ of rationals with the desired properties. □

We are now in a position to prove Lemma 1.6.

LEMMA 1.6. *Let α and β be c.e. reals. The following are equivalent.*

1. *$\beta \leqslant_s \alpha$.*
2. *For some computable sequence of rationals $a_0, a_1, \ldots$ such that*

$$\alpha = \sum_{n \in \omega} a_n,$$

there are a constant c and a computable sequence of rationals $\varepsilon_0, \varepsilon_1, \ldots < c$ such that

$$\beta = \sum_{n \in \omega} \varepsilon_n a_n.$$

3. *For* every *computable sequence of rationals $a_0, a_1, \ldots$ such that $\alpha = \sum_{n \in \omega} a_n$ there are a constant c and a computable sequence of rationals $\varepsilon_0, \varepsilon_1, \ldots < c$ such that $\beta = \sum_{n \in \omega} \varepsilon_n a_n$.*

Proof. It is easy to see that $3 \Rightarrow 2 \Rightarrow 1$. We prove that $1 \Rightarrow 3$.

Suppose that $\beta \leqslant_{\mathrm{S}} \alpha$. Given a computable sequence of rationals $a_0, a_1, \ldots$ such that $\alpha = \sum_{n\in\omega} a_n$, let $\alpha_n = \sum_{i\leqslant n} a_i$ and apply Lemma 2.2 to obtain c and $\hat{\beta}_0, \hat{\beta}_1, \ldots$ as in that lemma. Define $\varepsilon_n = (\hat{\beta}_n - \hat{\beta}_{n-1})a_n^{-1}$. Now $\sum_{n\in\omega} \varepsilon_n a_n = \sum_{n\in\omega} \hat{\beta}_n - \hat{\beta}_{n-1} = \beta$, and for all $n \in \omega$,

$$\varepsilon_n = (\hat{\beta}_n - \hat{\beta}_{n-1})a_n^{-1} = (\hat{\beta}_n - \hat{\beta}_{n-1})(\alpha_n - \alpha_{n-1})^{-1} < c. \qquad \square$$

We finish this section with a simple lemma which will be quite useful below.

LEMMA 2.3. *Let $\alpha \not\leqslant_s \beta$ be c.e. reals. The following hold for all total computable functions f and all $k \in \omega$.*

1. *For each $n \in \omega$ there is an $s \in \omega$ such that either*
   (i) $\alpha_t - \alpha_{f(n)} < k(\beta_t - \beta_n)$ *for all $t > s$, or*
   (ii) $\alpha_t - \alpha_{f(n)} > k(\beta_t - \beta_n)$ *for all $t > s$.*
2. *There are infinitely many $n \in \omega$ for which there is an $s \in \omega$ such that $\alpha_t - \alpha_{f(n)} > k(\beta_t - \beta_n)$ for all $t > s$.*

Proof. If there are infinitely many $t \in \omega$ such that $\alpha_t - \alpha_{f(n)} \leqslant k(\beta_t - \beta_n)$ and infinitely many $t \in \omega$ such that $\alpha_t - \alpha_{f(n)} \geqslant k(\beta_t - \beta_n)$, then

$$\alpha - \alpha_{f(n)} = \lim_t \alpha_t - \alpha_{f(n)} = \lim_t k(\beta_t - \beta_n) = k(\beta - \beta_n),$$

which implies that $\alpha \equiv_{\mathrm{S}} \beta$.

If there are infinitely many $t \in \omega$ such that $\alpha_t - \alpha_{f(n)} \leqslant k(\beta_t - \beta_n)$, then

$$\alpha - \alpha_{f(n)} = \lim_t \alpha_t - \alpha_{f(n)} \leqslant \lim_t k(\beta_t - \beta_n) = k(\beta - \beta_n).$$

So if this happens for all but finitely many n, then $\alpha \leqslant_{\mathrm{S}} \beta$. (The finitely many n for which $\alpha - \alpha_{f(n)} > k(\beta - \beta_n)$ can be brought into line by increasing the constant k.) $\square$

3. Main results. We now proceed with the proofs of our main results. We begin by showing that every incomplete Solovay degree can be split over any lesser Solovay degree.

THEOREM 3.1. *Let $\gamma <_s \alpha <_s \Omega$ be c.e. reals. There are c.e. reals β^0 and β^1 such that $\gamma <_s \beta^i <_s \alpha$ for $i = 0, 1$ and $\beta^0 + \beta^1 = \alpha$.*

Proof. We want to build β^0 and β^1 so that $\gamma \leqslant_{\mathrm{S}} \beta^i \leqslant_{\mathrm{S}} \alpha$ for $i = 0, 1$, $\beta^0 + \beta^1 = \alpha$, and the following requirement is satisfied for each $e, k \in \omega$ and $i < 2$:

$$R_{i,e,k} : \Phi_e \text{ total } \Rightarrow \exists n(\alpha - \alpha_{\Phi_e(n)} \geqslant k(\beta^i - \beta^i_n)).$$

By Lemma 2.2 and the fact that $\gamma/c \equiv_{\mathrm{S}} \gamma$ for any rational c, we may assume without loss of generality that $2(\gamma_s - \gamma_{s-1}) \leqslant \alpha_s - \alpha_{s-1}$ for each $s \in \omega$. (Recall our convention that $\mu_0 - \mu_{-1} = \mu_0$ for any c.e. real μ.)

In the absence of requirements of the form $R_{1-i,e,k}$, it is easy to satisfy simultaneously all requirements of the form $R_{i,e,k}$: for each $s \in \omega$, simply let $\beta^i_s = \gamma_s$ and $\beta^{1-i}_s = \alpha_s - \gamma_s$. In the presence of requirements of the form $R_{1-i,e,k}$, however, we cannot afford to be quite so cavalier in our treatment of β^{1-i}; enough of α has to be kept out of β^{1-i} to guarantee that β^{1-i} does not dominate α.

Most of the essential features of our construction are already present in the case of two requirements $R_{i,e,k}$ and $R_{1-i,e',k'}$, which we now discuss. We assume that $R_{i,e,k}$ has priority over $R_{1-i,e',k'}$ and that both Φ_e and $\Phi_{e'}$ are total. We will think of the β^j as being built by adding amounts to them in stages. Thus β^j_s will be the

total amount added to β^j by the end of stage s. At each stage s we begin by adding $\gamma_s - \gamma_{s-1}$ to the current value of each β^j; in the limit, this ensures that $\beta^j \geqslant_{\mathrm{s}} \gamma$.

We will say that $R_{i,e,k}$ is satisfied through n at stage s if $\Phi_e(n)[s]\downarrow$ and $\alpha_s - \alpha_{\Phi_e(n)} > k(\beta^i_s - \beta^i_n)$. The strategy for $R_{i,e,k}$ is to act whenever either it is not currently satisfied or the least number through which it is satisfied changes. Whenever this happens, $R_{i,e,k}$ initializes $R_{1-i,e',k'}$, which means that the amount of $\alpha - 2\gamma$ that $R_{1-i,e',k'}$ is allowed to funnel into β^i is reduced. More specifically, once $R_{1-i,e',k'}$ has been initialized for the mth time, the total amount that it is thenceforth allowed to put into β^i is reduced to 2^{-m}.

The above strategy guarantees that if $R_{1-i,e',k'}$ is initialized infinitely often, then the amount put into β^i by $R_{1-i,e',k'}$ (which in this case is all that is put into β^i except for the coding of γ) adds up to a computable real. In other words, $\beta^i \equiv_{\mathrm{s}} \gamma <_{\mathrm{s}} \alpha$. But it is not hard to argue, with the help of Lemma 2.3, that this means that there is a stage s after which $R_{i,e,k}$ is always satisfied and the least number through which it is satisfied does not change. So we conclude that $R_{1-i,e',k'}$ is initialized only finitely often, and that $R_{i,e,k}$ is eventually permanently satisfied.

This leaves us with the problem of designing a strategy for $R_{1-i,e',k'}$ that respects the strategy for $R_{i,e,k}$. The problem is one of timing. To simplify notation, let $\hat{\alpha} = \alpha - 2\gamma$ and $\hat{\alpha}_s = \alpha_s - 2\gamma_s$. Since $R_{1-i,e',k'}$ is initialized only finitely often, there is a certain amount 2^{-m} that it is allowed to put into β^i after the last time it is initialized. Thus if $R_{1-i,e',k'}$ waits until a stage s such that $\hat{\alpha} - \hat{\alpha}_s < 2^{-m}$, adding nothing to β^i until such a stage is reached, then from that point on it can put all of $\hat{\alpha} - \hat{\alpha}_s$ into β^i, which of course guarantees its success. The problem is that, in the general construction, a strategy working with a quota 2^{-m} cannot effectively find an s such that $\hat{\alpha} - \hat{\alpha}_s < 2^{-m}$. If it uses up its quota too soon, it may find itself unsatisfied and unable to do anything about it.

The key to solving this problem (and the reason for the hypothesis that $\alpha <_{\mathrm{s}} \Omega$) is the observation that, since the sequence $\Omega_0, \Omega_1, \ldots$ converges much more slowly than the sequence $\hat{\alpha}_0, \hat{\alpha}_1, \ldots, \Omega$ can be used to modulate the amount that $R_{1-i,e',k'}$ puts into β^i. More specifically, at a stage s, if $R_{1-i,e',k'}$'s current quota is 2^{-m}, then it puts into β^i as much of $\hat{\alpha}_s - \hat{\alpha}_{s-1}$ as possible, subject to the constraint that the total amount put into β^i by $R_{1-i,e',k'}$ since the last stage before stage s at which $R_{1-i,e',k'}$ was initialized must not exceed $2^{-m}\Omega_s$. As we will see below, the fact that $\Omega >_{\mathrm{s}} \alpha$ implies that there is a stage v after which $R_{1-i,e',k'}$ is allowed to put in all of $\hat{\alpha} - \hat{\alpha}_v$ into β^i.

In general, at a given stage s there will be several requirements, each with a certain amount that it wants (and is allowed) to direct into one of the β^j. We will work backwards, starting with the weakest priority requirement that we are currently considering. This requirement will be allowed to direct as much of $\hat{\alpha}_s - \hat{\alpha}_{s-1}$ as it wants (subject to its current quota, of course). If any of $\hat{\alpha}_s - \hat{\alpha}_{s-1}$ is left then the next weakest priority strategy will be allowed to act, and so on up the line.

We now proceed with the full construction. We say that $R_{i,e,k}$ has stronger priority than $R_{i',e',k'}$ if $2\langle e,k\rangle + i < 2\langle e',k'\rangle + i'$.

We say that $R_{i,e,k}$ is satisfied through n at stage s if

$$\Phi_e(n)[s]\downarrow \wedge\, \alpha_s - \alpha_{\Phi_e(n)} > k(\beta^i_s - \beta^i_n).$$

Let $n^{i,e,k}_s$ be the least n through which $R_{i,e,k}$ is satisfied at stage s, if such an n exists, and let $n^{i,e,k}_s = \infty$ otherwise.

A stage s is e-expansionary if

$$\max\{n \mid \forall m \leqslant n(\Phi_e(m)[s]\downarrow)\} > \max\{n \mid \forall m \leqslant n(\Phi_e(n)[s-1]\downarrow)\}.$$

Let q be the last e-expansionary stage before stage s (or let $q = 0$ if there have been none). We say that $R_{i,e,k}$ requires attention at stage s if s is an e-expansionary stage and there is an $r \in [q, s)$ such that either $n_r^{i,e,k} = \infty$ or $n_r^{i,e,k} \neq n_{r-1}^{i,e,k}$.

If $R_{i,e,k}$ requires attention at stage s, then we say that each requirement of weaker priority than $R_{i,e,k}$ is initialized at stage s.

Each requirement $R_{i,e,k}$ has associated with it a c.e. real $\tau^{i,e,k}$, which records the amount put into β^{1-i} for the sake of $R_{i,e,k}$.

We decide how to distribute $\delta = \alpha_s - \alpha_{s-1}$ between β^0 and β^1 at stage s as follows.

1. Let $j = s$ and $\varepsilon = 2(\gamma_s - \gamma_{s-1})$, and add $\gamma_s - \gamma_{s-1}$ to the current value of each β^i.

2. Let $i < 2$ and $e, k \in \omega$ be such that $2\langle e, k\rangle + i = j$. Let m be the number of times $R_{i,e,k}$ has been initialized and let t be the last stage at which $R_{i,e,k}$ was initialized. Let

$$\zeta = \min(\delta - \varepsilon, 2^{-(j+m)}\Omega_s - (\tau_{s-1}^{i,e,k} - \tau_t^{i,e,k})).$$

(It is not hard to check that ζ is nonnegative.) Add ζ to ε and to the current values of $\tau^{i,e,k}$ and β^{1-i}.

3. If $\varepsilon = \delta$ or $j = 0$, then add $\delta - \varepsilon$ to the current value of β^0 and end the stage. Otherwise, decrease j by one and go to step 2.

This completes the construction. Clearly, $\gamma \leqslant_{\mathrm{S}} \beta^i \leqslant_{\mathrm{S}} \alpha$ for $i = 0, 1$ and $\beta^0 + \beta^1 = \alpha$.

We now show by induction that each requirement initializes requirements of weaker priority only finitely often and is eventually satisfied. Assume by induction that $R_{i,e,k}$ is initialized only finitely often. Let $j = 2\langle e, k\rangle + i$, let m be the number of times $R_{i,e,k}$ is initialized, and let t be the last stage at which $R_{i,e,k}$ is initialized. If Φ_e is not total then $R_{i,e,k}$ is vacuously satisfied and eventually stops initializing requirements of weaker priority, so we may assume that Φ_e is total. It suffices to prove the following statements, which are clearly equivalent and imply that $R_{i,e,k}$ is satisfied:

1. $\lim_s n_s^{i,e,k}$ exists and is finite;
2. $R_{i,e,k}$ eventually stops requiring attention.

Assume for a contradiction that $R_{i,e,k}$ requires attention infinitely often. Since $\Omega \not\leqslant_{\mathrm{S}} \alpha$, part 2 of Lemma 2.3 implies that there are $v > u > t$ such that for all $w > v$ we have $2^{-(j+m)}(\Omega_w - \Omega_u) > \alpha_w - \alpha_u$. Furthermore, by the way the amount ζ added to $\tau^{i,e,k}$ at a given stage is defined in step 2 of the construction, $\tau_u^{i,e,k} - \tau_t^{i,e,k} \leqslant 2^{-(j+m)}\Omega_u$ and $\tau_{w-1}^{i,e,k} - \tau_u^{i,e,k} \leqslant \alpha_{w-1} - \alpha_u$. Thus for all $w > v$,

$$\begin{aligned}
&\alpha_w - \alpha_{w-1} = \alpha_w - \alpha_u - (\alpha_{w-1} - \alpha_u)\\
&< 2^{-(j+m)}(\Omega_w - \Omega_u) - (\alpha_{w-1} - \alpha_u) = 2^{-(j+m)}\Omega_w - (2^{-(j+m)}\Omega_u + \alpha_{w-1} - \alpha_u)\\
&\leqslant 2^{-(j+m)}\Omega_w - (\tau_u^{i,e,k} - \tau_t^{i,e,k} + \tau_{w-1}^{i,e,k} - \tau_u^{i,e,k}) = 2^{-(j+m)}\Omega_w - (\tau_{w-1}^{i,e,k} - \tau_t^{i,e,k}).
\end{aligned}$$

From this we conclude that, after stage v, the reverse recursion performed at each stage never gets past j, and hence everything put into β^i after stage v is put in either to code γ or for the sake of requirements of weaker priority than $R_{i,e,k}$.

Let τ be the sum of all $\tau^{1-i,e',k'}$ such that $R_{1-i,e',k'}$ has weaker priority than $R_{i,e,k}$. Let $s_l > t$ be the lth stage at which $R_{i,e,k}$ requires attention. If $R_{1-i,e',k'}$ is the $(p+1)$st requirement on the priority list and $p > j$, then $\tau^{1-i,e',k'} - \tau^{1-i,e',k'}_{s_l} \leqslant 2^{-(p+l)}\Omega$. Thus

$$\tau - \tau_{s_l} \leqslant \sum_{p\in\omega} 2^{-(p+l)}\Omega = 2^{-l}\Omega \leqslant 2^{-l},$$

and hence τ is computable.

Putting together the results of the previous two paragraphs, we see that $\beta^i \leqslant_{\mathrm{S}} \gamma$. Since $\alpha \not\leqslant_{\mathrm{S}} \gamma$, this means that $\alpha \not\leqslant_{\mathrm{S}} \beta^i$. It now follows from Lemma 2.3 that there is an $n \in \omega$ such that $R_{i,e,k}$ is eventually permanently satisfied through n, and such that $R_{i,e,k}$ is eventually never satisfied through any $n' < n$. Thus $\lim_s n^{i,e,k}_s$ exists and is finite, and hence $R_{i,e,k}$ is satisfied and eventually stops requiring attention. □

We now show that the Solovay degrees are upwards dense, which together with the previous result implies that they are dense.

THEOREM 3.2. *Let $\gamma <_S \Omega$ be a c.e. real. There is a c.e. real β such that $\gamma <_S \beta <_S \Omega$.*

Proof. We want to build $\beta \geqslant_{\mathrm{S}} \gamma$ to satisfy the following requirements for each $e, k \in \omega$:

$$R_{e,k} : \Phi_e \text{ total } \Rightarrow \exists n(\beta - \beta_{\Phi_e(n)} \geqslant k(\gamma - \gamma_n))$$

and

$$S_{e,k} : \Phi_e \text{ total } \Rightarrow \exists n(\Omega - \Omega_{\Phi_e(n)} \geqslant k(\beta - \beta_n)).$$

As in the previous proof, the analysis of an appropriate two-strategy case will be enough to outline the essentials of the full construction. Let us consider the strategies $S_{e,k}$ and $R_{e',k'}$, the former having priority over the latter. We assume that both Φ_e and $\Phi_{e'}$ are total.

The strategy for $S_{e,k}$ is basically to make β look like γ. At each point of the construction, $R_{e',k'}$ has a certain fraction of Ω that it is allowed to put into β. (This is in addition to the coding of γ into β, of course.) We will say that $S_{e,k}$ is satisfied through n at stage s if $\Phi_e(n)[s]\downarrow$ and $\Omega_s - \Omega_{\Phi_e(n)} > k(\beta_s - \beta_n)$. Whenever either it is not currently satisfied or the least number through which it is satisfied changes, $S_{e,k}$ initializes $R_{e',k'}$, which means that the fraction of Ω that $R_{e',k'}$ is allowed to put into β is reduced.

As in the previous proof, if $S_{e,k}$ is not eventually permanently satisfied through some n, then the amount put into β by $R_{e',k'}$ is computable, and hence $\beta \equiv_{\mathrm{S}} \gamma$. But, as before, this implies that there is a stage after which $S_{e,k}$ is permanently satisfied through some n and never again satisfied through any $n' < n$. Once this stage has been reached, $R_{e',k'}$ is free to code a fixed fraction of Ω into β, and hence it too succeeds.

We now proceed with the full construction. We say that a requirement $X_{e,k}$ has stronger priority than a requirement $Y_{e',k'}$ if either $\langle e,k\rangle < \langle e',k'\rangle$ or $\langle e,k\rangle = \langle e',k'\rangle$, $X = R$, and $Y = S$.

We say that $R_{e,k}$ is satisfied through n at stage s if $\Phi_e(n)[s]\downarrow$ and

$$\beta_s - \beta_{\Phi_e(n)} > k(\gamma_s - \gamma_n).$$

We say that $S_{e,k}$ is satisfied through n at stage s if $\Phi_e(n)[s]\downarrow$ and

$$\Omega_s - \Omega_{\Phi_e(n)} > k(\beta_s - \beta_n).$$

For a requirement $X_{e,k}$, let $n_s^{X_{e,k}}$ be the least n through which $X_{e,k}$ is satisfied at stage s, if such an n exists, and let $n_s^{X_{e,k}} = \infty$ otherwise.

As before, a stage s is e-expansionary if

$$\max\{n \mid \forall m \leqslant n(\Phi_e(m)[s]\downarrow)\} > \max\{n \mid \forall m \leqslant n(\Phi_e(n)[s-1]\downarrow)\}.$$

Let $X_{e,k}$ be a requirement and let q be the last e-expansionary stage before stage s (or let $q = 0$ if there have been none). We say that $X_{e,k}$ requires attention at stage s if s is an e-expansionary stage and there is an $r \in [q, s)$ such that either $n_r^{X_{e,k}} = \infty$ or $n_r^{X_{e,k}} \neq n_{r-1}^{X_{e,k}}$.

At stage s, proceed as follows. First add $\gamma_s - \gamma_{s-1}$ to the current value of β. If no requirement requires attention at stage s, then end the stage. Otherwise, let $X_{e,k}$ be the strongest priority requirement requiring attention at stage s. We say that $X_{e,k}$ acts at stage s. If $X = S$, then initialize all weaker priority requirements and end the stage. If $X = R$, then let $j = \langle e, k\rangle$ and let m be the number of times that $R_{e,k}$ has been initialized. If s is the first stage at which $R_{e,k}$ acts after the last time it was initialized, then let t be the last stage at which $R_{e,k}$ was initialized (or let $t = 0$ if $R_{e,k}$ has never been initialized), and otherwise let t be the last stage at which $R_{e,k}$ acted. Add $2^{-(j+m)}(\Omega_s - \Omega_t)$ to the current value of β and end the stage.

This completes the construction. Since β is bounded by $\gamma + \sum_{i\geqslant 0} 2^{-i}\Omega = \gamma + 2\Omega$, it is a well-defined c.e. real. Furthermore, $\gamma \leqslant_{\mathrm{S}} \beta$.

We now show by induction that each requirement initializes requirements of weaker priority only finitely often and is eventually satisfied. Assume by induction that there is a stage u such that no requirement of stronger priority than $X_{e,k}$ requires attention after stage u. If Φ_e is not total, then $X_{e,k}$ is vacuously satisfied and eventually stops requiring attention, so we may assume that Φ_e is total. It suffices to prove the following statements, which are clearly equivalent and imply that $X_{e,k}$ is satisfied:

1. $\lim_s n_s^{X_{e,k}}$ exists and is finite;
2. $X_{e,k}$ eventually stops requiring attention;
3. $X_{e,k}$ acts only finitely often.

First suppose that $X = R$. Let $j = \langle e, k\rangle$ and let m be the number of times that $R_{e,k}$ is initialized. (Since $R_{e,k}$ is not initialized at any stage after stage u, this number is finite.) Suppose that $R_{e,k}$ acts infinitely often. Then the total amount added to β for the sake of $R_{e,k}$ after any stage $v > u$ is greater than or equal to $2^{-(j+m)}(\Omega - \Omega_v)$, and hence $\beta \equiv_{\mathrm{S}} 2^{-(j+m)}\Omega \equiv_{\mathrm{S}} \Omega \not\leqslant_{\mathrm{S}} \gamma$. It now follows from Lemma 2.3 that there is an $n \in \omega$ such that $R_{e,k}$ is eventually permanently satisfied through n, and such that $R_{e,k}$ is eventually never satisfied through $n' < n$. Thus $\lim_s n_s^{R_{e,k}}$ exists and is finite, and hence $R_{e,k}$ is satisfied and eventually stops requiring attention.

Now suppose that $X = S$ and $S_{e,k}$ acts infinitely often. If $v > u$ is the mth stage at which $S_{e,k}$ acts then the total amount added to β after stage v for purposes other than coding γ is bounded by $\sum_{i\geqslant 0} 2^{-(i+m)}\Omega < 2^{-m+1}$. This means that $\beta \equiv_{\mathrm{S}} \gamma \not\geqslant_{\mathrm{S}} \Omega$. It now follows from Lemma 2.3 that there is an $n \in \omega$ such that $S_{e,k}$ is eventually permanently satisfied through n, and such that $S_{e,k}$ is eventually never satisfied through $n' < n$. Thus $\lim_s n_s^{S_{e,k}}$ exists and is finite, and hence $S_{e,k}$ is satisfied and eventually stops requiring attention. □

Combining Theorems 3.1 and 3.2, we have the following result.

THEOREM 3.3. *The Solovay degrees of c.e. reals are dense.*

We finish by showing that the hypothesis that $\alpha <_{\mathrm{S}} \Omega$ in the statement of Theorem 3.1 is necessary. This fact will follow easily from a stronger result which shows

that, despite the upwards density of the Solovay degrees, there is a sense in which the complete Solovay degree is very much above all other Solovay degrees. We begin with a lemma giving a sufficient condition for domination.

LEMMA 3.4. *Let α and β be c.e. reals and let $\alpha_0, \alpha_1, \dots$ and $\beta_0, \beta_1, \dots$ be computable increasing sequences of rationals converging to α and β, respectively. Let f be an increasing total computable function and let $k > 0$ be a natural number. If there are infinitely many $s \in \omega$ such that $k(\alpha - \alpha_s) > \beta - \beta_{f(s)}$, but only finitely many $s \in \omega$ such that $k(\alpha_t - \alpha_s) > \beta_{f(t)} - \beta_{f(s)}$ for all $t > s$, then $\beta \leqslant_s \alpha$.*

Proof. By taking $\beta_{f(0)}, \beta_{f(1)}, \dots$ instead of $\beta_0, \beta_1, \dots$ as an approximating sequence for β, we may assume that f is the identity.

By hypothesis, there is an $r \in \omega$ such that for all $s > r$ there is a $t > s$ with $k(\alpha_t - \alpha_s) \leqslant \beta_t - \beta_s$. Furthermore, there is an $s_0 > r$ such that $k(\alpha - \alpha_{s_0}) > \beta - \beta_{s_0}$. Given s_i, let s_{i+1} be the least number greater than s_i such that $k(\alpha_{s_{i+1}} - \alpha_{s_i}) \leqslant \beta_{s_{i+1}} - \beta_{s_i}$.

Assuming by induction that $k(\alpha - \alpha_{s_i}) > \beta - \beta_{s_i}$, we have

$$k(\alpha - \alpha_{s_{i+1}}) = k(\alpha - \alpha_{s_i}) - k(\alpha_{s_{i+1}} - \alpha_{s_i}) > \beta - \beta_{s_i} - (\beta_{s_{i+1}} - \beta_{s_i}) = \beta - \beta_{s_{i+1}}.$$

Thus $s_0 < s_1 < \cdots$ is a computable sequence such that $k(\alpha - \alpha_{s_i}) > \beta - \beta_{s_i}$ for all $i \in \omega$.

Now define the computable function g by letting $g(n)$ be the least s_i that is greater than or equal to n. Then $\beta - \beta_{g(n)} < k(\alpha - \alpha_{g(n)}) \leqslant k(\alpha - \alpha_n)$ for all $n \in \omega$, and hence $\beta \leqslant_{\mathrm{S}} \alpha$. □

THEOREM 3.5. *Let α and β be c.e. reals and let $\alpha_0, \alpha_1, \dots$ and $\beta_0, \beta_1, \dots$ be computable increasing sequences of rationals converging to α and β, respectively. Let f be an increasing total computable function and let $k > 0$ be a natural number. If β is random and there are infinitely many $s \in \omega$ such that $k(\alpha - \alpha_s) > \beta - \beta_{f(s)}$, then α is random.*

Proof. As in Lemma 3.4, we may assume that f is the identity. If α is rational then we can replace it with a nonrational computable real α' such that $\alpha' - \alpha'_s \geqslant \alpha - \alpha_s$ for all $s \in \omega$, so we may assume that α is not rational.

We assume that α is nonrandom and there are infinitely many $s \in \omega$ such that $k(\alpha - \alpha_s) > \beta - \beta_s$, and we show that β is nonrandom. The idea is to take a Solovay test $A = \{I_i : i \in \omega\}$ such that $\alpha \in I_i$ for infinitely many $i \in \omega$ and use it to build a Solovay test $B = \{J_i : i \in \omega\}$ such that $\beta \in J_i$ for infinitely many $i \in \omega$.

Let

$$U = \{s \in \omega \mid k(\alpha - \alpha_s) > \beta - \beta_s\}.$$

Except in the trivial case in which $\beta \equiv_{\mathrm{S}} \alpha$, Lemma 2.3 guarantees that U is Δ^0_2. Thus a first attempt at building B could be to run the following procedure for all $i \in \omega$ in parallel. Look for the least t such that there is an $s < t$ with $s \in U[t]$ and $\alpha_s \in I_i$. If there is more than one number s with this property then choose the least among such numbers. Begin to add the intervals

$$(*) \qquad [\beta_s, \beta_s + k(\alpha_{s+1} - \alpha_s)], [\beta_s + k(\alpha_{s+1} - \alpha_s), \beta_s + k(\alpha_{s+2} - \alpha_s)], \dots$$

to B, continuing to do so as long as s remains in U and the approximation of α remains in I_i. If the approximation of α leaves I_i, then end the procedure. If s leaves U, say at stage u, then repeat the procedure (only considering $t \geqslant u$, of course).

If $\alpha \in I_i$, then the variable s in the above procedure eventually assumes a value in U. For this value, $k(\alpha - \alpha_s) > \beta - \beta_s$, from which it follows that $k(\alpha_u - \alpha_s) > \beta - \beta_s$

for some $u > s$, and hence that $\beta \in [\beta_s, \beta_s + k(\alpha_u - \alpha_s)]$. So β must be in one of the intervals $(*)$ added to B by the above procedure.

Since α is in infinitely many of the I_i, running the above procedure for all $i \in \omega$ guarantees that β is in infinitely many of the intervals in B. The problem is that we also need the sum of the lengths of the intervals in B to be finite, and the above procedure gives no control over this sum, since it could easily be the case that we start working with some s, see it leave U at some stage t (at which point we have already added to B intervals whose lengths add up to $\alpha_{t-1} - \alpha_s$), and then find that the next s with which we have to work is much smaller than t. Since this could happen many times for each $i \in \omega$, we would have no bound on the sum of the lengths of the intervals in B.

This problem would be solved if we had an infinite computable subset T of U. For each I_i, we could look for an $s \in T$ such that $\alpha_s \in I_i$, and then begin to add the intervals $(*)$ to B, continuing to do so as long as the approximation of α remained in I_i. (Of course, in this easy setting, we could also simply add the single interval $[\beta_s, \beta_s + k\,|I_i|]$ to B.) It is not hard to check that this would guarantee that if $\alpha \in I_i$ then β is in one of the intervals added to B, while also ensuring that the sum of the lengths of these intervals is less than or equal to $k\,|I_i|$. Following this procedure for all $i \in \omega$ would give us the desired Solovay test B. Unless $\beta \leqslant_{\mathrm{S}} \alpha$, however, there is no infinite computable $T \subseteq U$, so we use Lemma 3.4 to obtain the next best thing.

Let

$$S = \{s \in \omega \mid \forall t > s(k(\alpha_t - \alpha_s) > \beta_t - \beta_s)\}.$$

If $\beta \leqslant_{\mathrm{S}} \alpha$ then β is nonrandom, so, by Lemma 3.4, we may assume that S is infinite. Note that $k(\alpha - \alpha_s) \geqslant \beta - \beta_s$ for all $s \in S$. In fact, we may assume that $k(\alpha - \alpha_s) > \beta - \beta_s$ for all $s \in S$, since if $k(\alpha - \alpha_s) = \beta - \beta_s$, then $k\alpha$ and β differ by a rational amount, and hence β is nonrandom.

The set S is co-c.e. by definition, but it has an additional useful property. Let

$$S[t] = \{s \in \omega \mid \forall u \in (s, t](k(\alpha_u - \alpha_s) > \beta_u - \beta_s)\}.$$

If $s \in S[t-1] - S[t]$, then no $u \in (s, t)$ is in S, since for any such u we have

$$k(\alpha_t - \alpha_u) = k(\alpha_t - \alpha_s) - k(\alpha_u - \alpha_s) \leqslant \beta_t - \beta_s - (\beta_u - \beta_s) = \beta_t - \beta_u.$$

In other words, if s leaves S at stage t then so do all numbers in (s, t).

To construct B, we run the following procedure P_i for all $i \in \omega$ in parallel. Note that B is a multiset, so we are allowed to add more than one copy of a given interval to B.

1. Look for an $s \in \omega$ such that $\alpha_s \in I_i$.
2. Let $t = s + 1$. If $\alpha_t \notin I_i$, then terminate the procedure.
3. If $s \notin S[t]$, then let $s = t$ and go to step 2. Otherwise, add the interval

$$[\beta_s + k(\alpha_{t-1} - \alpha_s), \beta_s + k(\alpha_t - \alpha_s)]$$

to B, increase t by one, and repeat step 3.

This concludes the construction of B. We now show that the sum of the lengths of the intervals in B is finite and that β is in infinitely many of the intervals in B.

For each $i \in \omega$, let B_i be the set of intervals added to B by P_i and let l_i be the sum of the lengths of the intervals in B_i. If P_i never leaves step 1, then $B_i = \emptyset$. If

P_i eventually terminates then $l_i \leqslant k(\alpha_t - \alpha_s)$ for some $s, t \in \omega$ such that $\alpha_s, \alpha_t \in I_i$, and hence $l_i \leqslant k\,|I_i|$. If P_i reaches step 3 and never terminates, then $\alpha \in I_i$ and $l_i \leqslant k(\alpha - \alpha_s)$ for some $s \in \omega$ such that $\alpha_s \in I_i$, and hence again $l_i \leqslant k\,|I_i|$. Thus the sum of the lengths of the intervals in B is less than or equal to $k \sum_{i \in \omega} |I_i| < \infty$.

To show that β is in infinitely many of the intervals in B, it is enough to show that, for each $i \in \omega$, if $\alpha \in I_i$ then β is in one of the intervals in B_i.

Fix $i \in \omega$ such that $\alpha \in I_i$. Since α is not rational, $\alpha_u \in I_i$ for all sufficiently large $u \in \omega$, so P_i must eventually reach step 3. By the properties of S discussed above, the variable s in the procedure P_i eventually assumes a value in S. For this value, $k(\alpha - \alpha_s) > \beta - \beta_s$, from which it follows that $k(\alpha_u - \alpha_s) > \beta - \beta_s$ for some $u > s$, and hence that $\beta \in [\beta_s, \beta_s + k(\alpha_u - \alpha_s)]$. So β must be in one of the intervals $(*)$, all of which are in B_i. □

COROLLARY 3.6. *If α^0 and α^1 are c.e. reals such that $\alpha^0 + \alpha^1$ is random then at least one of α^0 and α^1 is random.*

Proof. Let $\beta = \alpha^0 + \alpha^1$. For each $s \in \omega$, either $3(\alpha^0 - \alpha^0_s) > \beta - \beta_s$ or $3(\alpha^1 - \alpha^1_s) > \beta - \beta_s$, so for some $i < 2$ there are infinitely many $s \in \omega$ such that $3(\alpha^i - \alpha^i_s) > \beta - \beta_s$. By Theorem 3.5, α^i is random. □

Combining Theorem 3.1 and Corollary 3.6, we have the following results, the second of which also depends on Theorem 1.5.

THEOREM 3.7. *A c.e. real γ is random if and only if it cannot be written as $\alpha + \beta$ for c.e. reals $\alpha, \beta <_s \gamma$.*

THEOREM 3.8. *Let* **d** *be a Solovay degree of c.e. reals. The following are equivalent:*

1. **d** *is incomplete.*
2. **d** *splits.*
3. **d** *splits over any lesser Solovay degree.*

SPACE COMPLEXITY IN PROPOSITIONAL CALCULUS*

MICHAEL ALEKHNOVICH†, ELI BEN-SASSON‡, ALEXANDER A. RAZBOROV§, AND AVI WIGDERSON‡

Abstract. We study space complexity in the framework of propositional proofs. We consider a natural model analogous to Turing machines with a read-only input tape and such popular propositional proof systems as *resolution*, *polynomial calculus*, and *Frege* systems. We propose two different space measures, corresponding to the maximal number of bits, and clauses/monomials that need to be kept in the memory simultaneously. We prove a number of lower and upper bounds in these models, as well as some structural results concerning the clause space for resolution and Frege systems.

Key words. proof complexity, resolution, Frege, polynomial calculus

1. Introduction.

Complexity of propositional proofs plays as important a role in the theory of feasible proofs as the role played by the complexity of Boolean circuits in the theory of efficient computations. It is also well recognized that there exists a very productive cross-fertilization of techniques between the two fields. Partly because of this similarity, most of the research in the proof-complexity area concentrated on complexity measures related to *size*, which is the most interesting measure in the circuit complexity framework. In other words, the main effort in proof complexity was invested in investigating the amount of *time* (or at least time-like resources) taken by proofs; we recommend the excellent recent survey [BP98] for further reading on this subject.

During the workshop "Complexity Lower Bounds" held at the Fields Institute in Toronto in 1998, A. Haken raised the question of whether something intelligent can be said about the amount of *space* taken by propositional proofs. Quite surprisingly, it turned out that this very natural question had been virtually untouched in the past. Apparently, the only early paper devoted to the space of proofs is [Koz77], but it dealt only with *equational* theories involving no propositional connectives.

Recently, Esteban and Toran [ET99] proposed a convenient definition of space complexity for resolution which measures the number of clauses to be kept simultaneously in the memory to infer the tautology.[1] This model is analogous to a Turing machine computation, with a special read-only input tape from which the axioms can be downloaded to the working memory when needed and erased from the working memory as many times as necessary. They showed some upper and lower bounds for

[1]Throughout this paper, all propositional systems will prove that ϕ is a tautology by actually proving that its negation, $\neg\phi$, is unsatisfiable.

clause space (see section 3) and noticed the connection between the clause complexity for resolution and the pebbling game on the graph of a derivation.

Our goals in this paper are to generalize the natural notion of space complexity to other propositional proof systems and complexity measures and to research its properties. The first question arising is how to measure the memory content at any given moment of time for a specified proof system. Recall (see, e.g., [Kra95]) that the most customary measures for size complexity of propositional proofs are the bit size and the number of lines. Of these two, the bit size is by far more important, and can be defined analogously, and naturally, in the context of space complexity. The only simplification we allowed ourselves is in fact customary for the size complexity as well. Namely, instead of the bit space we consider the *variable* space (Definition 3.3) which is the overall number of occurrences of variables. This changes the complexity only by at most a logarithmic factor but makes things substantially cleaner.

It turns out that the line complexity is less adequate a measure for space complexity than it is a size measure. The reason is quite simple: if the language of the proof system is sufficiently strong and allows unbounded fan-in AND gates, then one gets only trivial results. Specifically, we can prove everything that is provable with just $O(1)$ memory cells, one of them containing a big AND of *all* formulae derived at previous steps.

One notable proof system that is not closed under the AND operation is *resolution*, in which case lines are just clauses. In the current paper we in particular show that the clause complexity, as opposed to the line complexity, makes perfect sense even for rather strong systems and can be considered as its natural replacement in space-complexity studies.

It turns out that all tautologies can be proven within *polynomial* space for any "reasonable" space measure. Specifically, *every* disjunctive normal form tautology in n variables already has a resolution proof with the clause space $(n + 1)$ [ET99], and this upper bound trivially holds for stronger proof systems. This in itself implies a *quadratic* upper bound on the *variable* space, but for the case of Frege systems we are able to improve it to a *linear* upper bound in the number of variables (Theorem 6.3).

These upper bounds determine the range of parameters in which the whole story develops. We ask which tautologies indeed require that much space and which can be proved within, say, (quasi)logarithmic space resources. We propose some lower bound techniques that in many cases allow us to answer this question for specific tautologies, proof systems, and space measures. It is worth noting that all these techniques are purely semantic in nature and thus can be applied to stronger *semantic* versions of the proof systems in question (see definitions in section 3.2). Let us also point out that it is not quite clear to which extent semantic versions of propositional proof systems are actually stronger than ordinary ones in the context of space complexity. On the contrary, we show for our weakest proof system (resolution) and for our strongest one (Frege system) that the space complexity differs from its semantic analogue by at most a constant multiplicative factor (Theorem 3.7, Corollary 6.6).

For many good reasons, bounded fan-in conjunctive normal forms (CNFs) (like Tseitin's tautologies) are always preferred in proving lower bounds or separation results. For tautologies from this class (and in the clause space model) we were able to prove strong lower bounds only for resolution (Theorem 3.18, Corollary 3.27.)[2]

Finally, we prove one lower bound in the variable space model that does not follow from our clause space bounds. Our argument applies in parallel to both

[2]Corollary 3.27 was also independently proved in [Tor99].

resolution and polynomial calculus (abbreviated throughout the paper by PC), and this situation is already familiar from the proof *size* complexity. For example, [CEI96] proved that every resolution proof of size S can be transformed into a PC proof of degree $O(\sqrt{n \log S})$, and [IPS97] used essentially the same argument for showing that every PC proof of size S can be also transformed into another PC proof of degree $O(\sqrt{n \log S})$. For that reason we find it very instructive to introduce a natural minimal common extension of resolution and PC called polynomial calculus augmented with resolution (PCR) that is at least as efficient as resolution in terms of proof size and space. The above-cited results [CEI96, IPS97] can then be considered as specifications of one general theorem about PCR which says that the degree of every size S PCR proof can be reduced to $O(\sqrt{n \log S})$. Our quadratic lower bounds for the variable space are also very naturally formulated and proved in terms of this new system (Theorem 5.1).

1.1. Summary of results. We introduce the clause space and variable space measures for resolution and PC. The *clause space* of a proof is the maximal number of clauses/monomials that need to be kept in the memory during the verification of a proof, and the *variable space* is the maximal number of overall symbols that need to be kept during such a verification.

We prove tight lower bounds for resolution clause space for a variety of formulas that includes the *pigeonhole principle*, *counting principles*, and several other interesting cases. This is done by proving a general lower bound that applies to all these cases. Via a different technique, we present a lower bound for the graph-based *Tseitin tautologies* that is *linear* in the number of variables appearing in this formula, and hence optimal.

For PC we prove nearly optimal (up to a small multiplicative constant) lower bounds for *wide tautologies* that include the pigeonhole principle. For this proof we use more complicated techniques than those used for the case of resolution. We show that these techniques are needed by proving that, for some cases, PC is strictly more efficient than resolution.

Using our clause space lower bounds for resolution and PC, we derive nearly optimal (up to a small multiplicative constant) lower bounds for the variable space of wide tautologies, such as the pigeonhole principle.

Finally, we prove *linear*, and hence optimal, *upper* bounds on the variable space of Frege proofs for *any* tautology.

1.2. Paper organization. Following several general definitions (section 2) we define the resolution clause space measure and prove lower bounds for it in section 3. In section 4 we define PC and its extension to multivalued logic and prove our clause space lower bounds for this system. The variable space lower bounds for resolution and PC appear in section 5. Finally, we present optimal upper bounds for Frege variable space in section 6 and conclude with some interesting open problems (section 7).

2. General definitions. Let x be a Boolean variable, i.e., a variable that ranges over the set $\{0,1\}$. Throughout this paper we shall identify $\mathbf{1}$ with $True$ and $\mathbf{0}$ with $False$. A *literal* of x is either x (denoted sometimes as x^1) or $\bar{x}$ (denoted sometimes as x^0). A *clause* is a disjunction of literals. We write $x^\epsilon \in C$ iff the clause C contains the literal x^ϵ. A *CNF formula* is a set of clauses.

For any Boolean function $f : \{0,1\}^n \to \{0,1\}$, $Vars(f)$ will denote its set of variables. An *assignment to* f is a mapping $\alpha : Vars(f) \to \{0,1\}$. A *restriction* is a mapping $\rho : Vars(f) \to \{0,1,\star\}$. We denote by $|\rho|$ the number of assigned

variables, $|\rho| = |\rho^{-1}(\{0,1\})|$. We say that a restriction ρ' *extends* ρ iff they coincide on $\rho^{-1}(\{0,1\})$.

The restriction of f by ρ, denoted $f|_\rho$, is the Boolean function obtained from f by setting the value of each $x \in \rho^{-1}(\{0,1\})$ to $\rho(x)$ and leaving each $x \in \rho^{-1}(\star)$ as a variable.

We say that an assignment α *satisfies* f if $f(\alpha) = 1$. For Boolean functions $f_1, \ldots, f_k, g$ we say that $f_1, \ldots, f_k$ *semantically imply* g, $f_1, \ldots, f_k \models g$ if every assignment to $V \stackrel{\text{def}}{=} Vars(f_1) \cup \cdots \cup Vars(f_k) \cup Vars(g)$ satisfying $f_1, \ldots, f_k$ satisfies g as well (i.e., for all $\alpha \in \{0,1\}^V (f_1(\alpha) = \cdots = f_k(\alpha) = 1 \Rightarrow g(\alpha) = 1)$). For $\mathcal{F}, \mathcal{G}$, two sets of functions, we say that $\mathcal{F}$ implies $\mathcal{G}$ ($\mathcal{F} \models \mathcal{G}$) if, for all $g \in \mathcal{G}$, $\mathcal{F} \models g$.

Notation. Throughout this paper, a, b will denote Boolean constants, x, y, z will denote Boolean variables; f, g, h will denote functions; φ, ψ will denote formulas; A, B, C, D will denote clauses; α, β will denote assignments; and ρ will denote restrictions. Calligraphic letters $\mathcal{A}, \mathcal{M}, \mathcal{N}, \mathcal{T}$ will denote sets of formulas. For n, a nonnegative integer, let $[n] \stackrel{\text{def}}{=} \{1, 2, \ldots, n\}$. For $\mathcal{M}$, a set, we denote by $|\mathcal{M}|$ its cardinality.

3. Resolution clause space. In this section we prove lower bounds for resolution clause space for a number of principles which include various modifications of the pigeonhole principle, counting principles, and the principle GT_n. (The latter was used in the recent work of [BG99] to produce a tautology with large minimal proof width and polynomially bounded proof size.) These results follow from a general lower bound for *semiwide tautologies*, also introduced in this section (Theorem 3.13). We also show how to transform any semiwide tautology (and, in particular, any of the above mentioned examples) to an equivalent 3-CNF form while preserving clause space hardness (Theorem 3.18).

We will start by giving definitions of the resolution clause space, proceed to show the equivalence of *semantic* and *syntactic* resolution, and then prove the lower bounds.

Notation. Throughout section 3 we do not distinguish between a clause C and the Boolean function computed by it.

3.1. Resolution clause space—definitions. Recall that a CNF formula is a set of clauses. The *resolution rule* is the following derivation rule.

Resolution rule. Derive $A \vee B$ from $\{A \vee x, B \vee \overline{x}\}$, where A, B are any clauses and x is any variable.

Let $\mathcal{T} = \{C_1, C_2, \ldots, C_m\}$ be a CNF formula over n variables. A *resolution proof* (or *derivation*) of a clause E from $\mathcal{T}$ is a sequence of clauses $\pi = \{D_1, D_2 \ldots, D_s\}$ such that the last clause is E and each D_i is either some initial clause $C_j \in \mathcal{T}$ or is derived from previous clauses using the resolution rule. A *resolution refutation of* $\mathcal{T}$ is a resolution derivation of the empty clause, $\mathbf{0}$ from $\mathcal{T}$. Notice that by the definition of the resolution rule, all lines in a resolution proof must be clauses. Notice that every refutation gives rise to a labeled directed acyclic graph, called the *refutation DAG*. Each node in this graph is labeled by a clause of the proof. The sources are labeled by $C \in \mathcal{T}$, the single sink by $\mathbf{0}$, and each node in the middle is connected to the two clauses that were used to derive it.

The definition of the resolution clause space was first given in [ET99]. We recast it here in slightly different terms (so that it will be easier for us to generalize this definition for stronger proof systems in the forthcoming sections).

Suppose we are given a resolution proof from $\mathcal{T}$ and wish to verify it using a minimal amount of memory. The proof π, as well as the CNF $\mathcal{T}$, are written on a

read-only memory tape. We keep in our *working memory* a subset of the clauses in the proof (starting with the empty set), and at each time step we either add a clause $C \in \mathcal{T}$ to our memory, *or* apply a single resolution derivation to two clauses *in the memory*, and add the resulting clause to it, *or* remove an unnecessary clause from the memory. The *clause space* of the proof π is the maximal number of clauses we need to keep at some time during the verification of the proof. Of course, there are many ways to verify a single proof (e.g., we may keep all clauses in the proof, in which case the space will be $|\pi|$), and we naturally define the space to be the minimal one over all possible verifications of π. Finally, the *resolution clause space* of $\mathcal{T}$ is the minimal space of a refutation π of $\mathcal{T}$ (if such a refutation exists, and ∞ otherwise).

We now present a formal definition of the clause space that captures our intuition and will be easy to work with rigorously. We start with a different definition of a resolution proof that exposes the clause space naturally. Comparing this definition with our previous one, we see they are equivalent in size, up to a polynomial factor.

DEFINITION 3.1 (syntactical resolution derivation). *A* configuration *is a set of clauses. A* proof π *from a CNF* $\mathcal{T}$ *is a sequence of configurations* $\mathcal{M}_0, \ldots, \mathcal{M}_s$ *such that* $\mathcal{M}_0 = \emptyset$ *and, for all* $t \in [s]$, $\mathcal{M}_t$ *is obtained from* $\mathcal{M}_{t-1}$ *by one of the following rules:*

AXIOM DOWNLOAD. $\mathcal{M}_t := \mathcal{M}_{t-1} \cup C$ *for some clause* $C \in \mathcal{T}$;
MEMORY ERASING. $\mathcal{M}_t := \mathcal{M}_{t-1} - \mathcal{M}'$ *for some* $\mathcal{M}' \subseteq \mathcal{M}_{t-1}$;
INFERENCE. $\mathcal{M}_t := \mathcal{M}_{t-1} \cup C$, *for some* C *obtained by a single application of the resolution rule to two clauses in* $\mathcal{M}_{t-1}$.

We use the notation $\mathcal{M} \rightsquigarrow \mathcal{M}'$ *to mean that* $\mathcal{M}'$ *is the immediate successor of* $\mathcal{M}$ *in a derivation. If* $\mathcal{M}_s = \{\mathbf{0}\}$ *(the empty clause), then the derivation is called a* refutation of $\mathcal{T}$.

DEFINITION 3.2 (clause space). *The* clause space *of a set of configurations* $\pi = \{\mathcal{M}_0, \ldots, \mathcal{M}_s\}$ *is*

$$CSpace(\pi) \stackrel{\text{def}}{=} \max\{|\mathcal{M}_i| : i \in [s]\}.$$

The resolution clause space *of a CNF* $\mathcal{T}$ *is*

$$CSpace(\mathcal{T}) \stackrel{\text{def}}{=} \min\{CSpace(\pi)\},$$

where the minimum is taken over all refutations of $\mathcal{T}$, *and is defined to be* ∞ *if no such refutation exists (i.e.,* $\mathcal{T}$ *is satisfiable).*

Although we will prove variable space lower bounds only in section 5 (and in this section concentrate on *clause* space lower bounds), we nonetheless present its definition now (for the sake of coherence).

DEFINITION 3.3 (variable space). *The* variable space *of a configuration* $\mathcal{M}$ *is* $\sum_{C \in \mathcal{M}} |C|$, *where* $|C|$ *is the number of literals in* C. *The* variable space of a set of configurations $\pi = \{\mathcal{M}_0, \ldots, \mathcal{M}_s\}$ *is*

$$VSpace_R(\pi) \stackrel{\text{def}}{=} \max\left\{\sum_{C \in \mathcal{M}_i} |C| : i \in [s]\right\}.$$

The resolution variable space *of a CNF* $\mathcal{T}$ *is*

$$VSpace_R(\mathcal{T}) \stackrel{\text{def}}{=} \min\{VSpace_R(\pi)\},$$

where the minimum is taken over all refutations π of $\mathcal{T}$, and is defined to be ∞ if no such refutation exists (i.e., $\mathcal{T}$ is satisfiable).

As we already mentioned, the research of clause space in resolution was started by Esteban and Toran in [ET99]. They in particular defined the following tautologies[3] CT_n and showed hardness of their proof in terms of clause space.

DEFINITION 3.4 (COMPLETE-TREE tautologies). *CT_n is the following set of axioms:*

$$\{ x_1^{\epsilon_1} \vee x_2^{\epsilon_2} \vee \cdots \vee x_n^{\epsilon_n} \mid \vec{\epsilon} \in \{0,1\}^n \}.$$

They also gave an upper bound for *any* tautology $\mathcal{T}$ over n variables. (We state it in our language.)

THEOREM 3.5 (see [ET99]). *If $\mathcal{T}$ is a contradictory set of clauses over n variables, then $CSpace(\mathcal{T}) \leq n+1$.*

This bound is tight for the principle CT_n.

CT_n contains an exponential number of axioms. In this section we define the class of *semiwide* tautologies of polynomial size which are hard to refute for resolution in terms of clause space. This class contains such popular principles as PHP_n^m, $onto - PHP_n^m$, $Count_p$, GT_n. We also show via a slightly different approach the space hardness of Tseitin tautologies for expander graphs.

3.2. Equivalence of syntactic and semantic resolution. All our lower bounds in this paper will work for *semantical* proof systems, which are stronger versions of the regular proof systems. In this subsection we define semantical resolution and then prove that, with respect to clause space, syntactical and semantical derivations are equivalent, up to a constant factor.

We start by pointing out that the *inference* rule of Definition 3.1 is *sound*; i.e., if $\mathcal{M}_t$ was derived from $\mathcal{M}_{t-1}$ by an application of this rule, then $\mathcal{M}_{t-1} \models \mathcal{M}_t$. The *semantical resolution proof system* replaces this rule by the following stronger *semantical inference* rule.

SEMANTICAL INFERENCE. $\mathcal{M}_t := \mathcal{M}_{t-1} \cup C$ for some C such that $\mathcal{M}_{t-1} \models C$.

The definition of proof space in semantical resolution is analogous to that of the syntactical resolution system. Denote by $CSpace^{sem}(\mathcal{T})$ the clause space of refuting $\mathcal{T}$ in semantical resolution.

The semantical inference rule generalizes the inference rule, and hence any syntactical resolution derivation is also a semantical one. Notice that when it comes to *size*, semantical resolution is much stronger than syntactical resolution because once $\mathcal{M}_t$ is unsatisfiable, we can derive $\mathbf{0}$ in a single step. We will now prove that with respect to space, there is no big difference between the two, and they are equivalent up to a constant factor.

A CNF formula is *minimal unsatisfiable* if it is unsatisfiable and removing any clause from it will make it satisfiable. We will need a very useful theorem, due to Tarsi [Tar], which originally appeared in [AL86].

THEOREM 3.6 (Tarsi's theorem). *If $\mathcal{T}$ is a minimal unsatisfiable CNF formula on n variables and m clauses, then $m > n$.*

Proof. Consider the following bipartite graph on $\mathcal{T} \times Vars(\mathcal{T})$: a clause C is connected to a variable x iff x appears in C (either as a positive or negative literal).

[3]Throughout the paper we assume that all tautologies are represented in the negated form of a contradictory CNF $\mathcal{T}$.

Clearly, there is no matching from $\mathcal{T}$ to $Vars(\mathcal{T})$ in this graph because the formula is unsatisfiable. Hence, by Hall's theorem, there must be some set $S \subset \mathcal{T}$ such that $|N(S)| < |S|$. Let S be such a set of maximal size. By the maximality of S, for any $V \subseteq \mathcal{T} - S$ we have $|N(V) - N(S)| \geq |V|$. Thus there is a matching from $\mathcal{T} - S$ into $Vars(\mathcal{T}) - N(S)$. By the minimal unsatisfiability of $\mathcal{T}$, if $S \neq \mathcal{T}$, then S is satisfiable, and $\mathcal{T} - S$ is satisfiable by its matching into $Vars(\mathcal{T}) - N(S)$. Thus we conclude that $S = \mathcal{T}$ and hence $m = |S| = |\mathcal{T}| > |N(S)| = |Vars(\mathcal{T})| = n$. □

The main theorem of this subsection is the following.

THEOREM 3.7. *For any unsatisfiable CNF* $\mathcal{T}$*,*

$$CSpace^{sem}(\mathcal{T}) \leq CSpace(\mathcal{T}) \leq 2 \cdot CSpace^{sem}(\mathcal{T}).$$

Proof. The first inequality is trivial because a syntactical resolution derivation is also a legitimate semantical one. Let π be a semantical refutation of $\mathcal{T}$ with clause space s. We wish to show that $\mathcal{T}$ has a clause space $2s$ syntactical refutation. The only difference between the two systems is in the inference rule, so we focus on this rule. Suppose $\mathcal{M}_{t+1}$ was inferred from $\mathcal{M}_t$ by the semantic inference rule ($\mathcal{M}_{t+1} := \mathcal{M}_t \cup \{C\}$, $\mathcal{M}_t \models C$), where $|\mathcal{M}_t|, |\mathcal{M}_{t+1}| \leq s$.

Let ρ be the unique minimal size restriction on the variables of C such that $C|_\rho = 0$. Now we use the soundness of the step to claim that $\mathcal{M}_t|_\rho$ must be unsatisfiable. $\mathcal{M}_t|_\rho$ contains a minimal unsatisfiable subformula $\mathcal{M}'$, which, by Tarsi's theorem, has at most $s - 1$ variables. By Theorem 3.5, the contradictory set of clauses $\mathcal{M}'$ can be refuted in space s. It is an easy exercise to adjust this proof and derive C from $\mathcal{M}_t$ with the same clause space s.

We need a space of s cells for saving $\mathcal{M}_t$. Additionally, we use s cells to derive $C \in \mathcal{M}_{t+1}$ from $\mathcal{M}_t$. □

3.3. Lower bounds for semiwide tautologies. We are ready to prove our lower bounds for the clause space of semantical resolution proofs. The main idea is the following. Consider a derivation that keeps at most k clauses in the memory. We shall show that for some classes of tautologies (called *semiwide*; see Definition 3.10) we can inductively construct restrictions of maximal size k that satisfy the memory content. Thus, there can be no space k refutation because the empty clause cannot be satisfied.

Although this proof technique is very simple, we will use similar ideas when proving lower bounds for stronger proof systems. Also, these results will be useful for proving lower bounds for the variable space complexity. For this reason we present our proof method in a somewhat fancy style.

The main idea of our lower bounds is to come up with some set of memory-configurations $\mathbb{A}$ ("$\mathbb{A}$" stands for "admissible") such that

- it does not contain contradictory configurations;
- any memory-configuration achievable in small memory is the semantical corollary of some configuration from $\mathbb{A}$.

Notice that we do *not* require $\mathbb{A}$ to contain all the formulas which can be derived using small space. We require only that, for any such formula φ, there exists a memory configuration $\mathcal{M} \in \mathbb{A}$ implying φ.

In all our cases these "dominating" memory-configurations will be CNF's of a very simple nature, namely, sets of *disjoint* clauses:

$$\mathcal{M} \in \mathbb{A} \Rightarrow \mathcal{M} = \left\{ \bigvee_{j \in J_i} x_j^{\epsilon_j} \mid 1 \leq i \leq k \right\},$$

where $J_i \cap J_{i'} = \emptyset$ for different i, i'. Moreover, in this section we will be interested only in the following partial case of this definition naturally corresponding to ordinary restrictions.

DEFINITION 3.8 (proper 1-CNF's). *$\mathcal{M}$ is called a* proper 1-CNF *if it is a set of pairwise distinct literals, i.e.,*

$$\mathcal{M} = \{x_{j_1}^{\epsilon_1}, x_{j_2}^{\epsilon_2}, \ldots, x_{j_k}^{\epsilon_k}\},$$

and $j_{i_1} \neq j_{i_2}$ for different i_1, i_2.

The heart of our lower bounds for clause space for resolution is the following (trivial) locality lemma which informally claims that small 1-CNF's are enough to imply any small space consequence of the axioms. Later on we shall present an analogous locality lemma, Lemma 4.14, for PC, which will be less trivial.

LEMMA 3.9 (locality lemma for resolution). *Let $\mathcal{M}$ be a proper 1-CNF. Suppose that $\mathcal{M}_1$ is the semantical resolution corollary of $\mathcal{M}$ (i.e., $\mathcal{M}_1$ is a set of clauses and $\mathcal{M} \models \mathcal{M}_1$); let $|\mathcal{M}_1| = s$. Then there exists $\mathcal{M}_1^{-1} \subseteq \mathcal{M}$ such that $\mathcal{M}_1^{-1} \models \mathcal{M}_1$ and $|\mathcal{M}_1^{-1}| \leq s$.*

Proof. Suppose $\mathcal{M}_1 = \{C_1, C_2, \ldots, C_s\}$. For any clause C_i which is the semantical corollary of $\mathcal{M}$ there exists some $x_{j_i}^{\epsilon_i} \in \mathcal{M} \cap C_i$. Thus $\mathcal{M}_1$ is the semantical corollary of the configuration $\mathcal{M}_1^{-1} = \{x_{j_1}^{\epsilon_1}, x_{j_2}^{\epsilon_2}, \ldots, x_{j_s}^{\epsilon_s}\}$. □

A contradictory set of clauses is called *n-wide* if all its axioms have width (= the number of literals) $\geq n$. [ET99] proved that every n-wide tautology has clause space $> n$. In section 4.4 we shall prove PC lower bounds for these tautologies. In the case of the weaker resolution system, we can prove lower bounds for a bigger class of *semiwide* tautologies.

DEFINITION 3.10 (semiwide tautologies). *Suppose that $\mathcal{T}$ is a contradictory set of clauses which is divided into two groups: $\mathcal{T} = \mathcal{P} \dot{\cup} \mathcal{R}$, where $\mathcal{P}$ is satisfiable.*

For $\mathcal{M}$, a proper 1-CNF, we say that $\mathcal{M}$ is $\mathcal{P}$-consistent *iff $\mathcal{P} \cup \mathcal{M}$ is consistent. Equivalently, $\mathcal{M}$ is $\mathcal{P}$-consistent iff it can be extended to a proper 1-CNF which implies all axioms of $\mathcal{P}$ ($\exists \mathcal{M}' \supseteq \mathcal{M}$ $(\mathcal{M}' \models \mathcal{P})$).*

Finally, $\mathcal{T}$ is n-semiwide iff there exists a partition $\mathcal{T} = \mathcal{P} \dot{\cup} \mathcal{R}$ such that $\mathcal{P}$ is satisfiable and for every axiom $C \in \mathcal{R}$, for every $\mathcal{P}$-consistent proper 1-CNF $\mathcal{M}$ with $|\mathcal{M}| < n$, it can be extended to a $\mathcal{P}$-consistent proper 1-CNF $\mathcal{M}' \supseteq \mathcal{M}$ such that $\mathcal{M}' \models C$.

Before we show that n-semiwide tautologies demand clause space at least $n + 1$ to be refuted, we give several natural examples.

It is obvious that every n-wide tautology is also n-semiwide: we let $\mathcal{P} = \emptyset$, and if we fix the values of $n - 1$ variables by a proper 1-CNF $\mathcal{M}$, any clause $C = x_1^{\epsilon_1} \vee x_2^{\epsilon_2} \vee \cdots \vee x_N^{\epsilon_N}$ with $N \geq n$ can be satisfied by fixing some unassigned variable (i.e., the variable which is not contained in $\mathcal{M}$) x_j. In particular, the COMPLETE-TREE tautology CT_n is n-semiwide.

Another example is the pigeonhole principle with m pigeons and n holes PHP_n^m which states that there is no 1-1 map from $[m]$ to $[n]$, as long as $m > n$. The propositional formulation of this principle has received much consideration in proof complexity and is one of the major test cases for comparing different proof systems. In particular, our $(n + 1)$ lower bound on the clause space of refuting PHP_n^m was independently proved in [Tor99].

We discuss here only the onto-version of this principle which constrains 1-1 maps to be onto. One can easily extend our arguments to other PHP-like principles and $Count_p$.

DEFINITION 3.11 (onto-pigeonhole principle). *$Onto - PHP_n^m$ is the union of the following four groups of axioms:*

(i) $P_i \stackrel{\text{def}}{=} \bigvee_{1\le j\le n} x_{ij}$ $(i \in [m])$;

(ii) $H_j \stackrel{\text{def}}{=} \bigvee_{1\le i\le n} x_{ij}$ $(j \in [n])$;

(iii) $Q_{i_1,i_2;j} \stackrel{\text{def}}{=} \bar{x}_{i_1 j} \vee \bar{x}_{i_2 j}$ $(i_1, i_2 \in [m],\ i_1 \neq i_2;\ j \in [n])$;

(iv) $Q_{i;j_1,j_2} \stackrel{\text{def}}{=} \bar{x}_{ij_1} \vee \bar{x}_{ij_2}$ $(i \in [m];\ j_1, j_2 \in [n],\ j_1 \neq j_2)$.

One can see that $onto - PHP_n^m$ is n-semiwide by taking the partition $\mathcal{P} \dot\cup \mathcal{R}$ with $\mathcal{P} = \{\, Q_{i_1,i_2;j} \mid i_1, i_2, j \,\} \cup \{\, Q_{i;j_1,j_2} \mid i, j_1, j_2 \,\}$ and $\mathcal{R} = \{\, P_i \mid i \,\} \cup \{\, H_j \mid j \,\}$. The proper 1-CNF $\mathcal{M}$ is $\mathcal{P}$-consistent iff it does not put either two pigeons in the same hole (i.e., contains the literals $x_{i_1 j}, x_{i_2 j}$) or one pigeon in two different holes (i.e., contains the literals x_{ij_1}, x_{ij_2}), in other words iff positive literals in $\mathcal{M}$ form a partial matching. Now if $n-1$ variables are fixed, then when we take the axiom P_i we can put the ith pigeon in some unassigned hole (that is, to add the corresponding positive literal). Dually, if we take the axiom H_j we can put some unassigned pigeon in the jth hole. Thus we can always satisfy an axiom from $\mathcal{R}$ with some extended $\mathcal{P}$-consistent proper 1-CNF.

Another principle, GT_n, states that in every transitive directed graph which does not contain cycles of size two, there must exist a source node with no incoming edges. This principle, formulated in [Kri85], was shown to have a proof of polynomial size [Sta96]. Recently, [BG99] used this principle to produce a tautology of polynomial proof size and large minimal proof width.

Quite surprisingly, this very same principle also shows that large clause space complexity does not imply large proof size.

DEFINITION 3.12. *GT_n is the following contradictory set of axioms over $n(n-1)$ variables x_{ij} $(i, j \in [n], i \neq j)$ consisting of three groups:*

(i) $T_{ijk} \stackrel{\text{def}}{=} (x_{ij} \wedge x_{jk}) \to x_{ik}$ $(i, j, k \in [n], i \neq j \neq k)$;

(ii) $C_{ij} \stackrel{\text{def}}{=} \bar{x}_{ij} \vee \bar{x}_{ji}$ $(i, j \in [n], i \neq j)$;

(iii) $S_j \stackrel{\text{def}}{=} \bigvee_{k\neq j} x_{kj}$ $(j \in [n])$.

The first group of axioms says that the graph is transitive. The second group states that there are no cycles of size two. The axiom S_j says that j is not the source node. Clearly, this set of axioms is contradictory. To see that it is $\frac{n}{2}$-semiwide take the partition $\mathcal{T} = \mathcal{P} \dot\cup \mathcal{R}$, where $\mathcal{P}$ consists of the axioms of the first and second groups. Then the proper 1-CNF $\mathcal{M}$ is $\mathcal{P}$-consistent iff it does not contain a cycle of positive literals (i.e., chains like $x_{i_1 i_2}, x_{i_2 i_3}, \ldots, x_{i_k i_1}$) and it does not contain a chain $x_{i_1 i_2}, x_{i_2 i_3}, \ldots, x_{i_{k-1} i_k}$ together with the literal $\bar{x}_{i_1 i_k}$. Now suppose that $\mathcal{M}$ is $\mathcal{P}$-consistent and assigns not more than $\frac{n}{2} - 1$ variables and we are to extend it to satisfy some axiom $S_j \in \mathcal{R}$. We can choose the index $k \neq j$ such that no variables $x_{ki}, x_{ik}, i \in [n]$ are contained in $\mathcal{M}$ and let $\mathcal{M}' = \mathcal{M} \cup \{x_{kj}\}$. Thus GT_n is $\frac{n}{2}$-semiwide.

In the next theorem, which is the main result of this section, we show that semiwide tautologies are hard for resolution in terms of clause space. The intuition of the proof is simple: we show inductively that a configuration of $k < n$ clauses can be satisfied by a restriction that sets $\le k$ variables.

THEOREM 3.13. *For any n-semiwide tautology $\mathcal{T}$,*

$$CSpace^{sem}(\mathcal{T}) > n.$$

Proof. Fix the partition $\mathcal{T} = \mathcal{P} \dot\cup \mathcal{R}$ in accordance with Definition 3.10.

DEFINITION 3.14 (admissible configurations for $\mathcal{T}$). *We call* $\mathcal{M}$ admissible *iff* $\mathcal{M}$ *is a* $\mathcal{P}$*-consistent proper* 1*-CNF and* $|\mathcal{M}| \le n$.

Consider the set $\mathbb{A}$ of all admissible configurations. We claim that the following holds: for each configuration $\mathcal{M}$, derivable in space $\le n$, there exists a configuration $\mathcal{M}^{-1} \in \mathbb{A}$ such that $\mathcal{M}^{-1} \models \mathcal{M}$ and $|\mathcal{M}^{-1}| \le |\mathcal{M}|$. This is obviously enough to prove the theorem since $\mathbb{A}$ does not contain contradictory configurations.

We prove it by induction. The basis is trivial: in the beginning of the derivation the memory contains an empty set. To check the induction step suppose that $\mathcal{M}_t \rightsquigarrow \mathcal{M}_{t+1}$ and that there exists $\mathcal{M}_t^{-1} \in \mathbb{A}$ such that $\mathcal{M}_t^{-1} \models \mathcal{M}_t,\ |\mathcal{M}_t^{-1}| \le |\mathcal{M}_t|$.

Let us consider the three cases corresponding to the possible derivation steps: axiom download, semantic inference step, and memory erasing.

Axiom download ($\mathcal{M}_{t+1} := \mathcal{M}_t \cup \{C\},\ C \in \mathcal{T}$). In this case $|\mathcal{M}_t| \le n-1$ (since there is free space for the new axiom). Thus $|\mathcal{M}_t^{-1}| \le n-1$; hence it can be extended to $\mathcal{P}$-consistent proper 1-CNF $\mathcal{M}_{t+1}^{-1}$ which satisfies C. (If $C \in \mathcal{R}$ this follows from the definition of semiwide tautology, and if $C \in \mathcal{P}$ it is obvious.) Since C is a clause we can satisfy it by fixing just one variable. Thus we can assume without loss of generality (w.l.o.g.) that $|\mathcal{M}_{t+1}^{-1}| \le |\mathcal{M}_t^{-1}| + 1$.

Clearly, $\mathcal{M}_{t+1}^{-1} \in \mathbb{A}$ and $\mathcal{M}_{t+1}^{-1} \models \mathcal{M}_{t+1}$. Also, $|\mathcal{M}_{t+1}^{-1}| \le |\mathcal{M}_t^{-1}| + 1 \le |\mathcal{M}_t| + 1 = |\mathcal{M}_{t+1}|$.

Semantical inference ($\mathcal{M}_{t+1} := \mathcal{M}_t \cup \{C\},\ \mathcal{M}_t \models C$). In this case $\mathcal{M}_t^{-1} \models \mathcal{M}_{t+1}$. By the locality lemma, Lemma 3.9, there exists $\mathcal{M}_{t+1}^{-1} \subseteq \mathcal{M}_t^{-1}$ such that $\mathcal{M}_{t+1}^{-1} \models \mathcal{M}_{t+1}$ and $|\mathcal{M}_{t+1}^{-1}| \le |\mathcal{M}_{t+1}|$.

Memory erasing ($\mathcal{M}_{t+1} := \mathcal{M}_t - \mathcal{M}' \subseteq \mathcal{M}_t$). This is analogous to the case of inference step.

Theorem 3.13 follows. □

So far we have strongly used the existence of axioms of width n to show that a given tautology is semiwide and thus prove a lower bound of n on the clause space. We now go one step further to show that we can transform any semiwide tautology to the following 3-CNF version which requires essentially the same space as the "standard" version.

DEFINITION 3.15 (strong nondeterministic extensions). *For* $C(\vec{x})$ *a clause, a* strong nondeterministic extension of C *is any Boolean function* $f(\vec{x}, \vec{y})$ *such that*

- *if* $C(\vec{\alpha}) = 0$*, then* $f(\vec{\alpha}, \vec{y}) \equiv 0$*;*
- *if* $x_j^\epsilon \in C$*, then there exists an assignment* $\vec{\beta}$ *to* $\vec{y}$ *such that setting* x_j *to* ϵ *and* $\vec{y}$ *to* $\vec{\beta}$ *fixes* f *to* 1*. Formally,*

$$f\left[\epsilon/x_j,\ \vec{\beta}/\vec{y}\right] \equiv 1.$$

Example 3.16. One standard strong nondeterministic extension of a clause $C = x_1 \vee x_2 \vee \cdots \vee x_n$ is the function represented by the following 3-CNF family over $n+2$ clauses and $2n+1$ variables:

$$\{\bar{y}_0\} \cup \{y_{j-1} \vee x_j \vee \bar{y}_j \mid 1 \le j \le n\} \cup \{y_n\}.$$

DEFINITION 3.17 (extended version of $\mathcal{T}$). *An* extended version of the tautology $\mathcal{T}$*, denoted* $\widetilde{\mathcal{T}}$*, is derived by replacing every axiom* C_i *with some CNF set of clauses* $\mathcal{EC}_i$ *representing a strong nondeterministic extension of* C_i *such that distinct* $\mathcal{EC}_i$ *use distinct extension variables* $\vec{y_i} = \langle y_{i1}, y_{i2}, \ldots, y_{ik_i} \rangle$.

THEOREM 3.18. *If $\mathcal{T}$ is n-semiwide, and $\widetilde{\mathcal{T}}$ is some extended version of it, then*

$$CSpace^{sem}(\widetilde{\mathcal{T}}) > n.$$

Proof. As in the proof of Theorem 3.13, we are going to define the set of admissible configurations $\mathbb{A}$. After that the proof will be very similar to that of Theorem 3.13. Let, as before, the partition $\mathcal{T} = \mathcal{P} \dot\cup \mathcal{R}$ be chosen according to Definition 3.10. For every clause $C_i \in \mathcal{T}$ and every $x_j^\epsilon \in C_i$ we *rigidly fix once and for all* an arbitrary assignment $\vec\beta_{ij}$ to the variables $\vec y_i$ such that the restriction which sends x_j to ϵ and sends $\vec y_i$ to $\vec\beta_{ij}$ forces to 1 all clauses from $\mathcal{EC}_i$.

DEFINITION 3.19 (admissible configurations for $\widetilde{\mathcal{T}}$). *We call a proper 1-CNF $\mathcal{M}$ admissible for $\widetilde{\mathcal{T}}$ iff there exists a $\mathcal{T}$-admissible configuration $\widehat{\mathcal{M}}$ (in ordinary variables $\vec x$) such that*

- *for every original variable $x_j^\epsilon \in \mathcal{M}$, we also have $x_j^\epsilon \in \widehat{\mathcal{M}}$;*
- *if $\mathcal{M}$ contains at least one auxiliary variable from $\vec y_i$, then there exists $x_j^\epsilon \in \widehat{\mathcal{M}}$ such that the values of* all *auxiliary variables in $\vec y_i$ belonging to $\mathcal{M}$ are consistent with $\vec\beta_{ij}$.*

Consider the set $\mathbb{A}$ of all configurations admissible for $\widetilde{\mathcal{T}}$. We claim that the following holds: for each configuration $\mathcal{M}$ derivable in space n, there exists a configuration $\mathcal{M}^{-1} \in \mathbb{A}$ such that $\mathcal{M}^{-1} \models \mathcal{M}$ and $|\mathcal{M}^{-1}| \le |\mathcal{M}|$. This is obviously enough to prove the theorem since $\mathbb{A}$ does not contain contradictory configurations.

We prove it by induction. The basis, inference step, and memory erasing can be handled with the help of the locality lemma, Lemma 3.9, as in Theorem 3.13.

Consider the axiom download. Let $\mathcal{M}_{t+1} \leftarrow \mathcal{M}_t \cup \{C\}$, $C \in \mathcal{EC}_i$. By the induction hypothesis there exist configurations $\mathcal{M}_t^{-1}, \widehat{\mathcal{M}}_t^{-1}$ with properties described in Definition 3.19 and such that $\mathcal{M}_t^{-1} \models \mathcal{M}_t$ and $|\mathcal{M}_t^{-1}| \le |\mathcal{M}_t|$.

Case 1. $\mathcal{M}_t^{-1}$ already contains some auxiliary variable from $\mathcal{EC}_i$.

Then we have already assigned in $\widehat{\mathcal{M}}_t^{-1}$ some variable x_j with $x_j^\epsilon \in C_i$ to ϵ such that the values of all auxiliary variables $\vec y_i$ in $\mathcal{M}_t^{-1}$ are consistent with $\vec\beta_{ij}$. Either $x_j^\epsilon \in C$ or $y_{i\ell}^{\beta_{ij\ell}} \in C$ for some $\ell \le k_i$. In the first case we let $\mathcal{M}_{t+1}^{-1} \stackrel{\text{def}}{=} \mathcal{M}_t^{-1} \cup \{x_j^\epsilon\}$, and in the second case we let $\mathcal{M}_{t+1}^{-1} \stackrel{\text{def}}{=} \mathcal{M}_t^{-1} \cup \{y_{i\ell}^{\beta_{ij\ell}}\}$. Also put $\widehat{\mathcal{M}}_{t+1}^{-1} \stackrel{\text{def}}{=} \widehat{\mathcal{M}}_t^{-1}$.

Case 2. $\mathcal{M}_t^{-1}$ does not contain any auxiliary variables from $\mathcal{EC}_i$.

W.l.o.g. we can assume that $|\widehat{\mathcal{M}}_t^{-1}| \le |\mathcal{M}_t^{-1}|$ (simply leave in $\widehat{\mathcal{M}}_t^{-1}$ only those x_j^ϵ which are really used for fulfilling the two conditions in Definition 3.19). Since $\widehat{\mathcal{M}}_t^{-1}$ is $\mathcal{T}$-admissible and $|\widehat{\mathcal{M}}_t^{-1}| \le |\mathcal{M}_t^{-1}| \le |\mathcal{M}_t| < n$, arguing as in the proof of Theorem 3.13, we can find some $x_j^\epsilon \in C_i$ such that $\widehat{\mathcal{M}}_t^{-1} \cup \{x_j^\epsilon\}$ is still $\mathcal{T}$-admissible. Arguing as in Case 1 above, we can extend $\mathcal{M}_t^{-1}$ with either x_j^ϵ itself or with some $y_{i\ell}^{\beta_{ij\ell}}$ to get $\mathcal{M}_{t+1}^{-1}$ with $\mathcal{M}_{t+1}^{-1} \models C$.

Theorem 3.18 follows. □

3.4. Tseitin tautologies. A Tseitin tautology is an unsatisfiable CNF capturing the basic combinatorial principle that, for every graph, the sum of degrees of all vertices is even. These tautologies were originally used by Tseitin [Tse68] to present the first superpolynomial lower bounds on proof size for a certain restricted form of resolution (regular resolution).

The main theorem in this subsection is Theorem 3.24 that presents a linear lower bound on the clause space of Tseitin formulas. This result was independently obtained in [Tor99].

DEFINITION 3.20 (Tseitin formulas). *Fix G, a finite connected graph, with $|V(G)| = n$. $\sigma : V(G) \to \{0,1\}$ is said to have* odd-weight *if $\Sigma_{v \in V(G)} \sigma(v) \equiv 1 \pmod 2$. Denote by $d_G(v)$ the degree of v in G. Fix σ an odd-weight function. Assign a distinct variable x_e to each edge $e \in E(G)$. For $v \in V(G)$ define $PARITY_{v,\sigma} \stackrel{\text{def}}{=} (\bigoplus_{e \ni v} x_e \equiv \sigma(v) (\mathrm{mod}\ 2))$. The* Tseitin formula *of G and σ is*

$$T(G,\sigma) \stackrel{\text{def}}{=} \bigwedge_{v \in V(G)} PARITY_{v,\sigma}.$$

If the maximal degree of G is constant, then the initial size and width of $T(G,\sigma)$ are small as well.

LEMMA 3.21. *If d is the maximal degree of G, then $T(G,\sigma)$ is a d-CNF with at most $n \cdot 2^{d-1}$ clauses and at most $nd/2$ variables.*

We shall need the following lemma from [Urq95].

LEMMA 3.22 (see [Urq95]). *If G is connected, then $T(G,\sigma)$ is contradictory iff σ is an odd-weight function. Moreover, for any $v \in V(G)$ there is an assignment satisfying all axioms from $\{ PARITY_{u,\sigma} \mid u \neq v \}$.*

The space lower bound on Tseitin formulas will be directly connected to the following notion of expansion.

DEFINITION 3.23 (connectivity expansion). *For G, a connected graph on n vertices, let $c(G)$ be the minimal number of edges that one must remove from G in order to obtain a graph in which all connected components have size $\leq n/2$.*

THEOREM 3.24. *For G a graph of maximal degree d,*

$$CSpace^{sem}(T(G,\sigma)) > c(G) - d.$$

Proof. Our invariant will be a specially tailored sequence of restrictions, defined hereby.

DEFINITION 3.25 (admissible configurations for $T(G,\sigma)$). *Suppose that $\mathcal{M}$ is a proper 1-CNF with $|\mathcal{M}| < c(G)$. Let $E(\mathcal{M}) \subseteq E(G)$ be the subset of edges corresponding to the variables of $\mathcal{M}$. Then $G \setminus E(\mathcal{M})$ (the graph G after removing the edges $E(\mathcal{M})$) has a uniquely defined maximal connected component $V_{max}(\mathcal{M})$ with $|V_{max}(\mathcal{M})| > n/2$.*

We call the proper 1-CNF $\mathcal{M}$ with $|\mathcal{M}| < c(G)$ admissible *for $T(G,\sigma)$ if there exists a proper 1-CNF $\mathcal{M}'$ such that $\mathcal{M}' \supseteq \mathcal{M}$ and $\mathcal{M}' \models PARITY_{v,\sigma}$ for any $v \notin V_{max}(\mathcal{M})$. (In other words, $\mathcal{M}$ is consistent with $\{ PARITY_{v,\sigma} \mid v \notin V_{max}(\mathcal{M}) \}$.)*

Remark. It is important to notice the following *monotonicity property*: if $\mathcal{M}$ is admissible and $\mathcal{M}' \subseteq \mathcal{M}$, then $V_{\max}(\mathcal{M}') \supseteq V_{\max}(\mathcal{M})$ and $\mathcal{M}'$ is admissible, too. That is exactly what we need the condition $|\mathcal{M}| < c(G)$ for.

LEMMA 3.26. *Suppose that $\mathcal{M}$ is admissible for $T(G,\sigma)$. Then for any $v_0 \in V_{max}(\mathcal{M})$ there exists a proper 1-CNF $\mathcal{M}' \supseteq \mathcal{M}$ such that for all $v \neq v_0$ $\mathcal{M}' \models PARITY_{v,\sigma}$. (In other words we can extend the assignment $\mathcal{M}$ to satisfy all axioms except that of v_0.)*

Proof. Let us consider the restriction ρ which corresponds to $\mathcal{M}$ ($\rho(x_e) = \epsilon$ iff $x_e^\epsilon \in \mathcal{M}$). If we apply this restriction to the tautology $T(G,\sigma)$ it will be partitioned to the independent formulas: $T^i = \bigwedge_{v \in V_i} PARITY_{v,\sigma'}$ for different connected components V_i of the graph $(G \setminus E(\mathcal{M}))$, where

$$\sigma'(v) \stackrel{\text{def}}{=} \sigma(v) \oplus \bigoplus_{\substack{e \ni v \\ \rho(x_e) \neq *}} \rho(x_e).$$

$V_{\max}(\mathcal{M})$ is the component with maximal size. By the definition of admissible configurations, all T^i are satisfiable for $V_i \neq V_{\max}(\mathcal{M})$. By Lemma 3.22 there exists an assignment to the edges in $V_{\max}(\mathcal{M})$ which satisfies all axioms except $PARITY_{v_0,\sigma'}$. The lemma follows. □

Now let us finish the proof of Theorem 3.24. Let $\mathbb{A}$ be the set of configurations admissible for $T(G,\sigma)$. As usual we claim that for each configuration $\mathcal{M}$, derivable in space $c(G)-d$, there exists a configuration $\mathcal{M}^{-1} \in \mathbb{A}$ such that $\mathcal{M}^{-1} \models \mathcal{M}$ and $|\mathcal{M}^{-1}| \leq |\mathcal{M}|$. We prove it by induction. The basis, inference step, and memory erasing can be handled with the help of the locality lemma, Lemma 3.9, just as in Theorems 3.13 and 3.18.

Consider the axiom download. Let $\mathcal{M}_{t+1} := \mathcal{M}_t \cup \{C\},\ C \in PARITY_{v,\sigma}$ for some vertex v. The proof splits into two cases.

Case 1. $v \notin V_{\max}(\mathcal{M}_t^{-1})$. Since $\mathcal{M}_t^{-1}$ is admissible, there exists $\mathcal{M}_t' \supseteq \mathcal{M}_t^{-1}$ such that for all $v \notin V_{\max}(\mathcal{M}_t^{-1})$, $\mathcal{M}_t' \models PARITY_{v,\sigma}$ (and in particular $\mathcal{M}_t' \models C$). Let $x_e^\epsilon \in \mathcal{M}_t'$ be a literal which forces C to true (i.e., $x_e^\epsilon \in C$). Let $\mathcal{M}_{t+1}^{-1} = \mathcal{M}_t^{-1} \cup \{x_e^\epsilon\}$. It is clear that $V_{\max}(\mathcal{M}_{t+1}^{-1}) = V_{\max}(\mathcal{M}_t^{-1})$ (since $e \ni v$) and $\mathcal{M}_{t+1}^{-1} \in \mathbb{A}$.

Case 2. $v \in V_{\max}(\mathcal{M}_t^{-1})$. Let us add to $E(\mathcal{M}_t^{-1})$ all the edges adjacent to v: $E' = E(\mathcal{M}_t^{-1}) \cup E(v)$. By the induction hypothesis, $|\mathcal{M}_t^{-1}| \leq c(G)-d-1$ (there is one free memory cell for axiom download); hence $|E'| < c(G)$. Let $V'_{\max}$ be the maximal connected component in $G \setminus E'$. By our remark on the monotonicity, $V'_{\max} \subseteq V_{\max}(\mathcal{M}_t^{-1})$. Fix any $v_0 \in V'_{\max}$ and let $\mathcal{M}'$ be the proper extension of $\mathcal{M}_t^{-1}$ from Lemma 3.26 such that for all $u \neq v_0$ $\mathcal{M}' \models PARITY_{u,\sigma}$. Let $x_e^\epsilon \in \mathcal{M}'$ be a literal which forces C to true (i.e., $x_e^\epsilon \in C$). Let $\mathcal{M}_{t+1}^{-1} = \mathcal{M}_t^{-1} \cup \{x_e^\epsilon\}$. It is clear that $V_{\max}(\mathcal{M}_{t+1}^{-1}) \supseteq V'_{\max} \ni v_0$; hence $\mathcal{M}_{t+1}^{-1} \in \mathbb{A}$.

Theorem 3.24 follows. □

If G is an expander, then the clause space of refuting $T(G,\sigma)$ is linear in the input size, and we get the following.

COROLLARY 3.27. *There exist arbitrarily large unsatisfiable* 3*-CNF formulas* $\mathcal{T}$ *with*

$$CSpace^{sem}(\mathcal{T}) = \Omega(|\mathcal{T}|).$$

Proof. Let G be a 3-regular expander with expansion $\epsilon > 0$ (i.e., for all $(V' \subset V)(|V'| \leq n/2 \Rightarrow |E(G) \cap (V' \times (V \setminus V'))| \geq \epsilon|V'|)$). Let σ be an odd-weight function on $V(G)$. Let $\mathcal{T} = T(G,\sigma)$. By Lemma 3.21, $\mathcal{T}$ is an unsatisfiable 3-CNF formula with $O(|V|)$ clauses and variables. On the other hand, it is easy to verify that $c(G) = \Omega(|V|)$. □

4. Clause space in PC. In this section we give definitions of the clause space in the stronger proof system called *polynomial calculus* (PC). We then show that the proof techniques of the previous section are not good enough for PC by proving an upper bound of $\frac{2}{3}n+O(1)$ on the clause space of CT_n. Finally, we generalize our proof systems to *multivalued logic*, since our lower bounds will be presented more naturally in this setting. The lower bound itself appears in the next section.

4.1. PC. In PC we work within a fixed field $\mathbb{F}$. A line in a PC derivation is a polynomial over $\mathbb{F}$, represented as a sum of monomials.[4] With every polynomial

[4]Since all our results apply to any field $\mathbb{F}$, we do not mention it in our future definitions and statements and simply assume $\mathbb{F}$ is some fixed field.

$P(x_1, \ldots, x_n)$ we associate the Boolean function $||P||$, called the *interpretation* of P, which is the characteristic function of the set of its roots in $\{0,1\}^n$, i.e.,

$$||P||(\alpha) = 1 \text{ iff } P(\alpha) = 0.$$

For $\mathcal{P}$ a set of polynomials, $||\mathcal{P}|| \stackrel{\text{def}}{=} \{||P|| : P \in \mathcal{P}\}$.

Notation. Throughout this section we sometimes identify a polynomial P with its interpretation $||P||$ as a Boolean function, and it will be clear from the context which of the two we mean. In particular, for $\mathcal{P}$ a set of polynomials, and $\mathcal{M}$ a set of Boolean functions, we will use the notation $\mathcal{M} \models \mathcal{P}$, ($\mathcal{P} \models \mathcal{M}$, resp.) to denote $\mathcal{M} \models ||\mathcal{P}||$ ($||\mathcal{P}|| \models \mathcal{M}$, resp.).

The natural representation of the clause $\bigvee_{i=1}^n x_i$ as a polynomial is by $\prod_{i=1}^n (1 - x_i)$. Notice that this polynomial has 2^n monomials, and, since we will define the clause space of a polynomial to be the number of monomials appearing in it, this representation makes PC much weaker than resolution. For this reason we use an augmented version of PC that is strictly stronger than resolution, with respect to space as well as size. We denote this augmented system by PCR (*polynomial calculus augmented with resolution*). In this system, we introduce a distinct *variable* for every *literal* and add some axioms forcing x_i and $\bar{x}_i$ to have distinct values in $\{0,1\}$. Thus, a line in PCR is a polynomial over the variable set $x_1, \bar{x}_1, x_2, \bar{x}_2, \ldots$, and the following inference rules are used:

DEFAULT AXIOMS. $x(1-x)$ for all variables x (forcing $\{0,1\}$ solutions), and $x + \bar{x} = 1$ for all pairs of distinct variables $x, \bar{x}$ (forcing x to be the negation of $\bar{x}$).

SCALAR ADDITION. Derive $\alpha P_1 + \beta P_2$ from P_1, P_2, for α, β scalars in $\mathbb{F}$, and for P_1, P_2 any polynomials over $\mathbb{F}$.

VARIABLE MULTIPLICATION. Derive $x \cdot P$ from P, for x any variable, and for P any polynomial over $\mathbb{F}$.

A PCR derivation of a polynomial Q from a set of polynomials $\mathcal{P} = \{P_1, \ldots, P_m\}$ is a sequence of configurations $\pi = \{\mathcal{M}_0, \mathcal{M}_1, \ldots, \mathcal{M}_s\}$, where $\mathcal{M}_0 = \emptyset$, $\mathcal{M}_s = \{Q\}$, and, for $1 \leq t \leq s$, $\mathcal{M}_t$ must be one of the following:

Axiom download. $\mathcal{M}_t := \mathcal{M}_{t-1} \cup \{P\}$ for some axiom $P \in \mathcal{P}$ or some default axiom P.

Memory erasing. $\mathcal{M}_t := \mathcal{M}_{t-1} - \mathcal{M}'$ for some subset of polynomials $\mathcal{M}' \subseteq \mathcal{M}_{t-1}$.

Inference. $\mathcal{M}_t := \mathcal{M}_{t-1} \cup \{P\}$ for P inferred from some subset $\mathcal{M}' \subseteq \mathcal{M}_{t-1}$ by a single application of scalar addition or variable multiplication rules.

Just like in resolution, our lower bounds will apply to the *semantical* version of PC. In this system, we replace the inference step of the above definition with the following semantical inference step:

Semantical inference. $\mathcal{M}_t := \mathcal{M}_{t-1} \cup \{P\}$ for P such that $||\mathcal{M}_{t-1}|| \models ||P||$.

The clause and variable space of a PCR derivation are the natural analogues of the same measures in resolution. Namely, a *configuration* is a set of polynomials, and its clause space is the number of *distinct* monomials that appear in the polynomials. (Notice that a certain monomial may appear in several polynomials, but we count it only once.) The variable space of a configuration is the sum of degrees of these distinct monomials.

A *refutation of* $\mathcal{P}$ is a derivation of the polynomial 1 from $\mathcal{P}$. The *clause space of a derivation* is the maximal clause space of a configuration in it, and the clause space of $\mathcal{P}$, denoted $MSpace(\mathcal{P})$, is the minimal clause space of a refutation of $\mathcal{P}$, if it exists, and ∞ otherwise. (We use the letter M, for *monomial space*, to distinguish it from resolution clause space.) The variable space of $\mathcal{P}$, denoted $VSpace_{PCR}(\mathcal{P})$, and the semantical clause space of a PCR proof, denoted $MSpace^{sem}(\mathcal{P})$, are analogously defined.

Remark. A polynomial is a linear combination of clauses. It is worth noting that the clause space lower bounds of section 4.4 apply to any sound calculus that uses lines that are *arbitrary* Boolean functions of clauses. (The linearity, however, will be important in section 5 for the *variable* space lower bounds.) The strongest such system is *functional calculus* (FC), which has as lines any Boolean function over clauses and has the single semantical inference rule that allows us to derive any function g from $\mathcal{M}$ whenever $\mathcal{M} \models g$. A definition of this system and its clause space appear in the appendix.

We end this section by noting that PCR is at least as efficient as resolution with respect to variable and clause space. The proof of the following lemma follows from the fact that PCR can efficiently simulate a resolution derivation.

LEMMA 4.1. *For $\mathcal{T}$, a contradictory set of clauses, and $\mathcal{P}$, its natural formulation as a set of polynomials,*

- $MSpace(\mathcal{P}) \leq CSpace(\mathcal{T}) + O(1)$;
- $VSpace_{PCR}(\mathcal{P}) \leq 2 \cdot VSpace_R(\mathcal{T})$.

4.2. PCR upper bounds for CT_n. We now show that $MSpace(CT_n)$ is substantially smaller than $CSpace^{sem}(CT_n)$. This result shows the necessity of using more complicated techniques than those in section 3 to prove PCR lower bounds. (Recall that $CSpace^{sem}(CT_n) = n$.)

THEOREM 4.2. $MSpace(CT_n) \leq 2n/3 + 6$.

Proof.

DEFINITION 4.3. *We say that a PCR proof π has k* temporary memory cells *if whenever the transition $\mathcal{M}_{t-1} \rightsquigarrow \mathcal{M}_t$ is an axiom download, then $MSpace(\mathcal{M}_{t-1}) \leq MSpace(\pi) - k$. (Informally, distinct monomials appearing in the current configuration $\mathcal{M}_t$ are stored in distinct "memory cells." The definition says that whenever we start downloading an axiom, there exist at least k (out of $MSpace(\pi)$) free memory cells.)*

We prove by induction the following claim saying that if we can refute CT_n in small space, we can also refute $CT_{\ell \cdot n}$ in small space.

CLAIM 4.4 (amplification). *If there exists a PCR refutation π of CT_n with*

$$MSpace(\pi) \leq s + k$$

such that π has k temporary cells, then for all integers $\ell \geq 1$

$$MSpace(CT_{\ell \cdot n}) \leq \ell \cdot s + k.$$

Moreover, the corresponding refutation also has k temporary memory cells.

Proof. The proof is by induction on $\ell \geq 1$. For the induction step, suppose π_ℓ is a refutation of $CT_{\ell \cdot n}$ with $MSpace(\pi_\ell) \leq \ell \cdot s + k$ which has k temporary cells. We shall use π_ℓ to refute $CT_{(\ell+1) \cdot n}$. We have only to show how to derive an axiom $A \in CT_{\ell \cdot n}$ from $CT_{(\ell+1) \cdot n}$ using small memory because, if we can derive any axiom of $CT_{\ell \cdot n}$ in small space, we can use π_ℓ directly, replacing each axiom download in π_ℓ with our small space derivation.

Suppose the tth step of π_ℓ is an axiom download of $A \in CT_{\ell \cdot n}$. $A = \bigvee_{j=1}^{\ell n} x_j^{\epsilon_j}$ for some $\vec{\epsilon} = \{\epsilon_1, \ldots, \epsilon_{\ell n}\} \in \{0,1\}^{\ell n}$. By the induction hypothesis, $MSpace(\mathcal{M}_{t-1}) \leq \ell \cdot s$ because $\mathcal{M}_{t-1}$ has k empty memory cells. We use these empty memory cells and additional s memory cells to derive A from all axioms $B \in CT_{(\ell+1)\cdot n}$ that agree with A on all variables of A (i.e., $B = A \vee \bigvee_{j=\ell n+1}^{(\ell+1)n} x_j^{\epsilon_j}$ for some $\epsilon_{\ell n+1}, \ldots, \epsilon_{(\ell+1)n} \in \{0,1\}$). The total memory of the new proof is $MSpace(CT_{\ell \cdot n}) + s$. It also has k temporary memory cells, since it downloads axioms only during the emulation of the proof of CT_n. □

To prove Theorem 4.2 it is sufficient to produce a PCR refutation of CT_3 with clause space six and four temporary memory cells ($s = 2$, $k = 4$). At the beginning of this refutation we infer the configuration $\{x_1, x_2\}$ in the obvious way. After that the proof proceeds as follows (we omit straightforward intermediate transitions):

$$\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \rightsquigarrow \begin{pmatrix} x_1 \\ x_2 \\ \text{Axiom: } \bar{x}_1\bar{x}_2x_3 \end{pmatrix} \rightsquigarrow \begin{pmatrix} x_1 \\ x_2 \\ \bar{x}_2x_3 \end{pmatrix} \rightsquigarrow \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix}$$
$$\rightsquigarrow \begin{pmatrix} 1-\bar{x}_1 \\ 1-\bar{x}_2 \\ 1-\bar{x}_3 \end{pmatrix} \rightsquigarrow \begin{pmatrix} 1-\bar{x}_1 \\ \bar{x}_1-\bar{x}_1\bar{x}_2 \\ \bar{x}_1\bar{x}_2-\bar{x}_1\bar{x}_2\bar{x}_3 \end{pmatrix} \rightsquigarrow \begin{pmatrix} 1-\bar{x}_1\bar{x}_2\bar{x}_3 \end{pmatrix}$$
$$\rightsquigarrow \begin{pmatrix} 1-\bar{x}_1\bar{x}_2\bar{x}_3 \\ \text{Axiom: } \bar{x}_1\bar{x}_2\bar{x}_3 \end{pmatrix} \rightsquigarrow \begin{pmatrix} 1 \end{pmatrix}.$$

All the configurations explicitly displayed here have at most four clauses. Two more temporary clauses are needed to keep intermediate polynomials. □

Remark. For the stronger system FC, we get better upper bounds than those of the previous theorem (namely, CT_n can be refuted in clause space $n/2 + 2$). For a definition of this proof system, and a proof of this and related results, see the appendix.

4.3. PCR over multivalued logic. In this subsection we extend our proof systems to work with multivalued variables. The motivation is the usual one: in many cases, the multivalued logic is a natural vista to view lower bounds for the Boolean case which is our true interest. For example, [RWY97] used R-way (read-once) branching programs to formulate and prove some partial results about the resolution (size) complexity of the weak (i.e., when $m \gg n$) pigeonhole principle PHP_n^m. Crucial to their results are two dual interpretations of PHP_n^m in terms of multivalued logic; here we are interested only in one of them, the *Column Model*. In this model, the pigeonhole principle has the following form: suppose $x_1, \ldots, x_n$ are variables of m-valued logic, where $m > n$ ("$x_j = i$" has the intended meaning "the ith pigeon sits in the jth hole"). Then there exists $i \in [m]$ which is not in the set $\{x_1, \ldots, x_n\}$.

In the proofs of our remaining lower bounds, it will be also very convenient to treat PHP_n^m in this way. In particular, this will allow us to formulate our bounds in terms of a simple, uniform, and concise criterion fulfilled by both CT_n and PHP_n^m (Definition 4.12 below).

We need to generalize some previous definitions.

DEFINITION 4.5. *Let us fix some finite domain D. Instead of Boolean variables, we use* multivalued variables *x_j ranging over the domain D. A* multivalued Boolean function *$f(x_1, \ldots, x_n)$ is a mapping from D^n to $\{0,1\}$, where, as before, we identify* 1 *with True and* 0 *with False. The notions of* a (multivalued) satisfying assignment

$a \in D^n$ and semantical implication *$f_1, \ldots, f_k \models g$ are generalized to the case of multivalued logic straightforwardly.*

Thus, the only remaining thing we still need to define is the set of allowable lines.

DEFINITION 4.6 (multivalued clauses). *Suppose that D is some finite domain. A* multivalued literal *is the formal expression x_j^π, where π is some nonconstant function $\pi : D \to \{0,1\}$.*

A multivalued clause *is a disjunction of multivalued literals corresponding to distinct variables*

$$C = x_{j_1}^{\pi_1} \vee x_{j_2}^{\pi_2} \vee \cdots \vee x_{j_w}^{\pi_w},\ k \neq l \to j_k \neq j_l,$$

with the straightforward interpretation $||C||(\alpha) \stackrel{\text{def}}{=} \pi_1(\alpha_{j_1}) \vee \cdots \vee \pi_w(\alpha_{j_w})$.

The width *of a multivalued clause is the number of multivalued literals in it.*

DEFINITION 4.7. *Denote by x_j^i the multivalued literal $x_j^{\chi_i}$, where χ_i is the characteristic function of i ($\chi_i(i') = 1$ iff $i' = i$).*

We are ready to define multivalued semantical resolution and PCR.

DEFINITION 4.8 (multivalued resolution). Multivalued semantical resolution over domain *D is the system analogous to semantical resolution which works with multivalued clauses instead of usual ones.*

The clause and variable complexity are analogous to that of semantical resolution. Denote by $CSpace_D^{sem}(\mathcal{T})$ the clause space of refuting $\mathcal{T}$ in semantical resolution over domain D.

DEFINITION 4.9 (multivalued PCR). *Suppose that $\mathbb{F}$ is a field.* Multivalued semantical PCR over domain *D is the semantical system which keeps in memory polynomials over $\mathbb{F}$ with literals x_j^π for all possible j, π as their variables. As in the Boolean case, the interpretation is given by the characteristic function of the set of roots:*

$$||P||(\alpha_1, \ldots, \alpha_n) = 1 \quad \textit{iff} \quad P[\pi(\alpha_j)/x_j^\pi] = 0$$

in the field $\mathbb{F}$. The clause and variable complexity are analogous to that of semantical PCR. Denote by $MSpace_D^{sem}(\mathcal{P})$ the clause space of refuting $\mathcal{P}$ in semantical resolution over domain D.

We conclude this subsection with one possible translation from multivalued systems to ordinary ones. This straightforward translation preserves the variable and clause space lower bounds.

DEFINITION 4.10. *Suppose that P is some multivalued proof system over domain D; $\mathcal{T}$ is a contradictory set of axioms. Replace each multivalued variable x_j with the tuple $x_{1j}, x_{2j}, \ldots, x_{mj}$, where $m = |D|$. The intuitive meaning of x_{ij} is "$x_j = i$," i.e., the same as of the multivalued literal x_j^i.*

Let us denote by $PR_D(\mathcal{T})$ the following set of axioms over Boolean variables x_{ij}:

- *$\bar{x}_{i_1 j} \vee \bar{x}_{i_2 j}$ for $i_1 \neq i_2$;*
- *$\phi\left[\bigvee_{i \in \pi^{-1}(1)} x_{ij} / x_j^\pi\right]$ for all $\phi \in \mathcal{T}$.*

It is clear that each refutation of $PR_D(\mathcal{T})$ can be transformed into the refutation of $\mathcal{T}$ without increase in either variables or clauses. Thus we have the following trivial proposition which shows how to use multivalued systems for proving Boolean lower bounds.

PROPOSITION 4.11. *For $\mathcal{T}$, a contradictory set of multivalued clauses over domain D,*

$$CSpace_D^{sem}(\mathcal{T}) \leq CSpace(PR_D(\mathcal{T})).$$

For $\mathcal{P}$, a contradictory set of polynomials over domain D,

$$MSpace_D^{sem}(\mathcal{P}) \leq MSpace(PR_D(\mathcal{P})).$$

4.4. Wide tautologies and lower bounds for PCR. In this section we define a natural class of *wide* tautologies which turn out to be hard for PCR in terms of clause complexity. In section 5 we will also show that wide tautologies are hard for PCR (and hence for resolution as well) in terms of *variable* complexity. The previous upper bound on the clause space of CT_n (Theorem 4.2) shows that selecting *one* variable per clause in the memory, and using this variable to satisfy our clause, will not work for PCR. Surprisingly, we show that selecting *two* variables per clause does the job.

DEFINITION 4.12 (multivalued wide tautology). *A family of multivalued clauses $\mathcal{T}$ over multivalued variables $x_1, \ldots, x_n$ is* wide *iff every clause in it has maximal possible width n.*

One obvious example of a (Boolean) wide family is CT_n. The second example, and our main motivation, is PHP_n^m. Namely, suppose that $|D| = m > n$, and let $\mathcal{T} \stackrel{def}{=} \{ x_1^i \vee x_2^i \vee \cdots \vee x_n^i \mid i \in [m] \}$. Then $PR_D(\mathcal{T}) = PHP_n^m$. By Proposition 4.11, lower bounds for the space complexity of this multivalued version imply lower bounds for the space complexity of the ordinary (Boolean) pigeonhole principle.

Now we show that wide tautologies are hard. The heart of our lower bounds for PCR is the locality lemma, Lemma 4.14.

DEFINITION 4.13 (proper 2-CNF's). *$\mathcal{M}$ is called a* proper 2-CNF *iff*

$$\mathcal{M} = \left\{ x_{j_1^1}^{i_1^1} \vee x_{j_1^2}^{i_1^2},\ x_{j_2^1}^{i_2^1} \vee x_{j_2^2}^{i_2^2}, \ldots, x_{j_k^1}^{i_k^1} \vee x_{j_k^2}^{i_k^2} \right\},$$

where $j_1^1, j_1^2, j_2^1, \ldots, j_k^2$ are pairwise distinct indices and $i_1^1, \ldots, i_k^2 \in [m]$ (not necessarily distinct). (In other words, the proper 2-CNF says that for every $\ell \in [k]$ either $x_{j_\ell^1} = i_\ell^1$ or $x_{j_\ell^2} = i_\ell^2$.)

LEMMA 4.14 (locality lemma for PCR). *Let $\mathcal{M}$ be a proper 2-CNF, and let $\mathcal{M}_1$ be a set of polynomials such that $\mathcal{M} \models \mathcal{M}_1$. Then there exists a proper 2-CNF $\mathcal{M}_1^{-1}$ such that $\mathcal{M}_1^{-1} \models \mathcal{M}_1$ and $|\mathcal{M}_1^{-1}| \leq 2 \cdot MSpace_D^{sem}(\mathcal{M}_1)$.*

Remark. Notice that $\mathcal{M}_1^{-1}$ is not necessarily a proper subformula of $\mathcal{M}$.

Proof. In our proof we will use the following corollary of Hall's matching theorem.

LEMMA 4.15 (Hall's theorem). *For a family of sets $V_1, \ldots, V_k$ (not necessarily distinct), if for all index sets $I \subseteq [k]$*

$$\left| \bigcup_{i \in I} V_i \right| \geq |I|,$$

then the family $V_1, \ldots, V_k$ has a system of distinct representatives. *That is, there exist $v_i \in V_i$ such that $\{v_1, \ldots, v_k\}$ are pairwise distinct.*

COROLLARY 4.16. *For a family of sets $V_1, \ldots, V_k$, if for all index sets $I \subseteq [k]$*

$$\left| \bigcup_{i \in I} V_i \right| \geq 2 \cdot |I|,$$

then we can assign to each V_i two *distinct representatives $v_{i1}, v_{i2} \in V_i$ such that all $2k$ elements $v_{11}, v_{12}, \ldots, v_{k1}, v_{k2}$ are pairwise distinct.*

Proof. Just apply Hall's matching theorem to the system

$$V_1, V_1, V_2, V_2, \ldots, V_k, V_k. \qquad \square$$

Now let us prove Lemma 4.14. Note that $||\mathcal{M}_1|| = g(C_1, \ldots, C_s)$, where $s = MSpace_D^{sem}(\mathcal{M}_1)$, $C_1, \ldots, C_s$ are multivalued clauses, and g is some Boolean function. Let us gradually construct the required proper 2-CNF $\mathcal{M}_1^{-1}$. Suppose w.l.o.g. that $\mathcal{M} = \{x^0_{1,1} \vee x^0_{1,2},\ x^0_{2,1} \vee x^0_{2,2}, \ldots, x^0_{k,1} \vee x^0_{k,2}\}$.

For a clause C denote by $V(C) \subseteq [k]$ the index set of those axioms $x^0_{j,1} \vee x^0_{j,2}$ of $\mathcal{M}$ for which C contains at least one variable $x_{j,1}, x_{j,2}$. (Formally, $V(C) \stackrel{\text{def}}{=} \left\{ j \,\middle|\, \exists \epsilon \in \{1,2\}\ \exists \pi (x^\pi_{j,\epsilon} \in C) \right\}$.) For $\Gamma \subseteq [s]$, let us denote $\bar{\Gamma} = [s] \setminus \Gamma$, $V(\Gamma) = \bigcup_{\gamma \in \Gamma} V(C_\gamma)$. Let Γ be any maximal subset $\Gamma \subseteq [s]$ with the property

$$|V(\Gamma)| \leq 2 \cdot |\Gamma|.$$

Then for any $I \subseteq \bar{\Gamma}$,

$$|V(I) \setminus V(\Gamma)| > 2 \cdot |I|.$$

(Otherwise we could add the set I to Γ, contradicting the maximality of Γ.) Hence, by Corollary 4.16, for any clause C_γ with $\gamma \in \bar{\Gamma}$, we can choose two unique *representative indices* $j_1, j_2 \in V(C_\gamma)$ such that $j_1, j_2 \notin V(\Gamma)$. Let $x_{rep_1(C_\gamma)}, x_{rep_2(C_\gamma)}$ be two corresponding *representative variables* from C_γ which lie in the intersection with axioms numbers j_1, j_2 of $\mathcal{M}$. Denote by $sat_\epsilon(C_\gamma)$ the value of $x_{rep_\epsilon(C_\gamma)}$ which forces C_γ to $True$. Such a value must exist because C_γ is a clause in which $x^\pi_{rep_\epsilon(C_\gamma)}$ appears for some *nonconstant* π (see Definition 4.6).

Let

$$\mathcal{M}_1^{-1} = \left\{ x^0_{j,1} \vee x^0_{j,2} \,|\, j \in V(\Gamma) \right\} \cup \left\{ x^{sat_1(C_\gamma)}_{rep_1(C_\gamma)} \vee x^{sat_2(C_\gamma)}_{rep_2(C_\gamma)} \,\middle|\, \gamma \in \bar{\Gamma} \right\}.$$

Clearly, $\mathcal{M}_1^{-1}$ is a proper 2-CNF. Let us estimate the size of $\mathcal{M}_1^{-1}$:

$$|\mathcal{M}_1^{-1}| = |V(\Gamma)| + |\bar{\Gamma}| \leq 2 \cdot |\Gamma| + |\bar{\Gamma}| \leq 2 \cdot s.$$

Claim 4.17. $\mathcal{M}_1^{-1} \models \mathcal{M}_1$.

Proof. We need to show that every assignment α satisfying $\mathcal{M}_1^{-1}$ satisfies $g(C_1, C_2, \ldots, C_s)$ as well. Suppose that α satisfies all the clauses of $\mathcal{M}_1^{-1}$. Notice that for all $\gamma \in \bar{\Gamma}$ $C_\gamma(\alpha) = 1$. (Since α satisfies $\mathcal{M}_1^{-1}$, it satisfies $x^{sat_1(C_\gamma)}_{rep_1(C_\gamma)} \vee x^{sat_2(C_\gamma)}_{rep_2(C_\gamma)}$, and every one of these representative variables from C_γ forces C_γ to $True$.)

We are going to show that α can be changed in such a way that it will still preserve the value of all clauses $C_1, \ldots, C_s$ (and, hence, of g) but at the same time will satisfy $\mathcal{M}$. For an axiom $x^0_{j,1} \vee x^0_{j,2}$ of $\mathcal{M}$ either $j \in V(\Gamma)$ (in this case the axiom is satisfied since it also appears in $\mathcal{M}_1^{-1}$) or we can choose the variable $x_{j,\epsilon}$ which is *not* a representative variable of any clause C_γ with $\gamma \in \bar{\Gamma}$. (Notice that different clauses cannot have representatives from the same axiom.) In the latter case we just set $x_{j,\epsilon}$ to zero. This does not change the values of clauses $C_1, \ldots, C_s$, but the axioms of $\mathcal{M}$ get satisfied.

Thus we can get the new assignment α' which satisfies $\mathcal{M}$ and such that $C_i(\alpha) = C_i(\alpha')$ for all i. Since $||\mathcal{M}|| \models g(C_1, \ldots, C_s)$, we have

$$g(C_1(\alpha), \ldots, C_s(\alpha)) = g(C_1(\alpha'), \ldots, C_s(\alpha')) = 1.$$

Lemma 4.14 follows. □

We are now ready to prove our main theorem.

THEOREM 4.18. *For any wide tautology $\mathcal{T}$ over n variables with domain D, $MSpace_D^{sem}(\mathcal{T}) \geq \frac{n}{4}$.*

Remark. The same lower bound, with the same proof, applies to the much stronger FC, in which each line is an arbitrary Boolean function and all derivations rule are purely semantical. For a definition of this system and related results see the appendix.

Proof. The proof is quite analogous to the proof of Theorem 3.13. Let us denote by $\mathbb{A}$ the set of all proper 2-CNF's of size $\leq \frac{n}{2}$. As in the previous cases we claim that for any configuration $\mathcal{M}$, achievable in space $\frac{n}{4}$, there exists a configuration $\mathcal{M}^{-1} \in \mathbb{A}$ such that $|\mathcal{M}^{-1}| \leq 2 \cdot MSpace_D^{sem}(\mathcal{M})$ and $\mathcal{M}^{-1} \models \mathcal{M}$. We prove it by induction.

The inference step can be treated with the help of the locality lemma, Lemma 4.14. Namely, if $\mathcal{M}_t \models \mathcal{M}_{t+1}$, first take $\mathcal{M}_t^{-1}$ as $\mathcal{M}_{t+1}^{-1}$, and then shrink it to the required size $2 \cdot MSpace_D^{sem}(\mathcal{M}_{t+1})$ by applying Lemma 4.14.

The axiom download is also straightforward. Suppose that $\mathcal{M}_{t+1} \leftarrow \mathcal{M}_t \cup \{C\}$, $C \in \mathcal{T}$. Take $\mathcal{M}_t^{-1}$ and choose two literals $x_{j_1}^{\pi_1}, x_{j_2}^{\pi_2} \in C$ such that x_{j_1} and x_{j_2} are not contained in $\mathcal{M}_t^{-1}$. Such a pair of literals must exist because C has width n and $|\mathcal{M}_t| < n/4$, and hence $|\mathcal{M}_t^{-1}| \leq n/2$. Then let $\mathcal{M}_{t+1}^{-1} = \mathcal{M}_t^{-1} \cup \{x_{j_1}^{i_1} \vee x_{j_2}^{i_2}\}$ for i_1, i_2 satisfying $\pi_1(i_1) = \pi_2(i_2) = 1$.

Theorem 4.18 follows. □

COROLLARY 4.19. *$MSpace^{sem}(CT_n) \geq MSpace_D^{sem}(CT_n) \geq n/4$.*

As said previously, a lower bound on multivalued logic is also a lower bound on two-valued Boolean logic, and thus we get the following.

COROLLARY 4.20. *For all $m > n$,*

$$MSpace^{sem}(PHP_n^m) \geq MSpace_D^{sem}(PHP_n^m) \geq n/4.$$

5. Variable complexity for PCR. The variable space is a very natural space measure as it is tightly connected to the bit space, which is the actual number of bits needed to write down a memory configuration. If each variable index is written in binary notation, then the bit space is linear in $\log n$ times the variable space. As follows from Theorem 3.5, every (Boolean) proof system which simulates resolution has variable space upper bounded by n^2. In this section we show that any PCR proof (over an arbitrary field) of any wide tautology requires variable space $\Omega(n^2)$. This bound is tight for both CT_n and PHP_n^m.

THEOREM 5.1. *For any wide tautology $\mathcal{T}$ over n variables with domain D and any ground field $\mathbb{F}$, $VSpace_{PCR}^{sem}(\mathcal{T}) = \Omega(n^2)$.*

To understand the intuition of the proof, and to see how heavily it depends on our previous clause space lower bounds, we prove first the following (easy) special case of our theorem.

LEMMA 5.2. *$VSpace_R^{sem}(CT_n) \geq \frac{1}{4}n^2$.*

Proof. By Theorem 3.13, $CSpace^{sem}(CT_n) > n$. Let $\pi = \{\mathcal{M}_0, \ldots, \mathcal{M}_s\}$ be a semantical resolution refutation of CT_n, and let t be the first time there is some clause $C \in \mathcal{M}_t$ of width $\lceil n/2 \rceil$. Such a t must exist because, by the definition of the resolution rule, the width of a clause may decrease by at most 1 in every step, all axioms have width n, and the empty clause has width 0. Let ρ be the minimal size restriction that sets C to 0. $|\rho| = |C| = \lceil n/2 \rceil$, and it is easy to see that $CT_n|_\rho$ is simply $CT_{\lfloor n/2 \rfloor}$, and $\pi|_\rho$ is a legitimate proof of it. Applying Theorem 3.13 once again, $CSpace^{sem}(CT_{\lfloor n/2 \rfloor}) > \lfloor n/2 \rfloor$, meaning there is some $t' < t$ such that $|\mathcal{M}_{t'}| > \lfloor n/2 \rfloor$.

By the definition of t, all clauses of $\mathcal{M}_{t'}$ have width larger than $\lceil n/2 \rceil$, and the lemma is proved. □

Proof of Theorem 5.1. First we need to define some notation. A term $x_{j_1}^{\pi_1} \cdot \ldots \cdot x_{j_d}^{\pi_d}$ is *multilinear* if all $j_1, \ldots, j_d$ are pairwise distinct. A *multilinear monomial* is an expression $a \cdot t$, where $a \in F^*$ and t is a multilinear term. Finally, a *multilinear polynomial* is a sum of multilinear monomials. Since we are interested only in the semantical version of PCR, and because of the identity $x_j^{\pi} \cdot x_j^{\pi'} = x_j^{(\pi\pi')}$, we will assume w.l.o.g. that all our multivalued terms, monomials, and polynomials are multilinear. Also, throughout the proof of Theorem 5.1 all the terms, monomials, and polynomials are multivalued; thus we omit this word, too. For a term t, let $\mathrm{Supp}(t)$ be the set of all j for which x_j^{π} appears in t for some π. For a polynomial P, $\mathrm{Supp}(P) \stackrel{\mathrm{def}}{=} \bigcup_{t \in P} \mathrm{Supp}(t)$.

There is a natural correspondence between subsets of the set of terms of a polynomial P and its subpolynomials; thus we sometimes write $t \in P$ when the term t is contained in P, and $P_1 \subseteq P$ which means that P_1 is a subpolynomial of P. $|P|$ is the number of terms in P.

For $\rho : \{x_1, \ldots, x_n\} \to D \cup \{*\}$ a restriction and P a polynomial, $\rho(P)$ is the polynomial produced after the substitution of the literals x_j^{π}, $j \in \rho^{-1}(D)$ with $\pi(\rho(x_j))$ and cancellation of terms. Notice that there can be many different polynomials corresponding to the same multivalued function $f : D^n \to \{0, 1\}$. We say that such polynomials are *semantically equivalent* and write $P_1 \sim P_2$. For example, $x \sim 1 - \bar{x}$ in case of Boolean PCR.

Our proof will consist of several stages. The heart of it will be the following construction based on Hall's theorem. (We already used a similar idea in proving Theorem 4.18.)

LEMMA 5.3 (matching lemma). *Suppose that P is a polynomial and t is some term (not necessarily from P). Then there exists a subpolynomial $\Gamma \subseteq P$ and a restriction ρ such that ρ does not assign the variables of $\mathrm{Supp}(t) \cup \mathrm{Supp}(\Gamma)$ and ρ maps all terms of $P \setminus \Gamma$ to zero. (Thus, in particular, $\rho(t) = t$ and $\rho(P) = \Gamma$.) Moreover, $|\mathrm{Supp}(t) \cup \mathrm{Supp}(\Gamma)| + |\rho| \le |P| + \deg t$.*

Proof. Let Γ be any maximal subpolynomial of P with the property

$$|\mathrm{Supp}(t) \cup \mathrm{Supp}(\Gamma)| \le |\Gamma| + \deg t.$$

Denote $V = \mathrm{Supp}(t) \cup \mathrm{Supp}(\Gamma)$. Then for any subset of terms $S \subseteq P \setminus \Gamma$, $|\mathrm{Supp}(S) \setminus V| > |S|$. (Otherwise we could add S to Γ and Γ would not be maximal.) Thus by Hall's theorem there exists a matching

$$\mu : [\text{terms of } P \setminus \Gamma] \to \mathrm{Supp}(P) \setminus V$$

which gives each term from $P \setminus \Gamma$ its *unique representative* from $\mathrm{Supp}(P) \setminus V$. Now we define the restriction ρ as follows. It maps these unique representatives to the values which force the corresponding terms to 0. Thus ρ does not touch the variables from V and $|\mathrm{Supp}(t) \cup \mathrm{Supp}(\Gamma)| + |\rho| \le \deg t + |\Gamma| + |P \setminus \Gamma| = \deg t + |P|$. □

Now let us prove Theorem 5.1. Suppose that we have some PCR refutation $\{\mathcal{M}_0, \mathcal{M}_1, \ldots, \mathcal{M}_s\}$ of $\mathcal{T}$. W.l.o.g. we can assume that all polynomials in the memory do not contain nonzero subpolynomials semantically equivalent to zero. (There is no sense in keeping such subpolynomials.) Let us fix the first moment q when some polynomial from $\mathcal{M}_q$ contains a (multilinear!) term with degree less than or equal to $\frac{n}{2}$. Let t be any such term which has the smallest possible degree (in particular, $\deg t \le \frac{n}{2}$), and let $P \in \mathcal{M}_q$ be any polynomial which contains t. Our proof splits into two cases.

Case 1. $\deg t \geq \frac{n}{4}$.

In this case we can assume that $|P| \leq \frac{n}{8}$ since otherwise $VS(P)$ is already greater than $\frac{n^2}{32}$ (recall that t is the smallest degree monomial from $\mathcal{M}_q$), and we are done.

LEMMA 5.4. *Suppose that P is a polynomial with no subpolynomials semantically equivalent to zero and that t is a term of P. Then there exists a restriction ρ which forces P to a nonzero constant c from F^* and assigns at most $|\rho| \leq \deg t + |P|$ variables.*

Proof. We apply our matching lemma, Lemma 5.3, to the polynomial P and the term t. We get the subpolynomial Γ and the restriction ρ which kills all the monomials from $P \setminus \Gamma$.

Notice that $\Gamma \neq \emptyset$ since it must contain t. Thus by our assumption, $\Gamma \not\sim 0$, and we can choose an assignment α to $\mathrm{Supp}(\Gamma)$ which maps it to some constant $c \in F^*$. Let us extend our restriction ρ to the restriction ρ' by α (this is possible because ρ and α assign to disjoint sets of variables). Then $\rho'(P) = c$ and $|\rho'| \leq |\rho| + |\mathrm{Supp}(\Gamma)| \leq |P| + \deg t$. □

The rest of Case 1 is simple. Hitting the first $(q+1)$ lines of the original refutation with the restriction ρ from Lemma 5.4, we get a new valid refutation $\{\rho(\mathcal{M}_0), \rho(\mathcal{M}_1), \ldots, \rho(\mathcal{M}_q)\}$ of the principle $\rho(\mathcal{T})$ (since $c \in \rho(\mathcal{M}_q)$ and $c \neq 0$).

Notice that since $|\rho| \leq \deg t + |P|$ we have $|\rho| \leq \frac{5n}{8}$, so $\rho(\mathcal{T})$ is a wide tautology over $\geq \frac{3n}{8}$ variables. Thus by Theorem 4.18 there exists $j < q$ such that $\rho(\mathcal{M}_j)$ (and, hence, $\mathcal{M}_j$) contains at least $\frac{3n}{32}$ monomials. Each monomial of $\mathcal{M}_j$ had degree $> \frac{n}{2}$ before applying ρ'; therefore $VS(\mathcal{M}_j) \geq \frac{3n^2}{64}$.

Case 2. $\deg t \leq \frac{n}{4}$.

DEFINITION 5.5. *We say that a polynomial P is* d-minimal *iff it does not contain a nonzero subpolynomial semantically equivalent to a polynomial of degree $\leq d$.*

Since $t \in P$, P is not $\frac{n}{4}$-minimal. Let us represent $P = P_0 + P_1$, where P_1 is $\frac{n}{4}$-minimal and $P_0 \sim P_0'$ with $\deg P_0' \leq \frac{n}{4}$. (We can construct such a representation by consecutively moving subpolynomials semantically equivalent to polynomials of degree $\leq \frac{n}{4}$ from P_1 to P_0.)

P does not contain nonzero subpolynomials semantically equivalent to zero; in particular, $P_0 \not\sim 0$. However, there still can be several nonzero polynomials $P_0' \sim P_0$ with $\deg P_0' \leq \frac{n}{4}$. Let P_0' be the polynomial of the smallest degree semantically equivalent to P_0. If there are several such polynomials we choose arbitrarily one with the smallest number of monomials of highest degree. Let s be some maximal-degree term of P_0'.

Now let us apply our matching lemma, Lemma 5.3, to the polynomial P_1 and the term s. It will yield $\Gamma \subseteq P_1$ and the restriction ρ which kills the terms from $P_1 \setminus \Gamma$.

All terms in P_1 are of degree $\geq \frac{n}{4}$; therefore, similarly to Case 1, we can assume that $|P_1| \leq \frac{n}{8}$. Hence, $|\mathrm{Supp}(s) \cup \mathrm{Supp}(\Gamma)| + |\rho| \leq \deg s + |P_1| \leq \frac{3n}{8}$.

Now we use the fact that $\mathcal{M}_q$ is the *first* configuration when a term t of degree $\leq \frac{n}{2}$ appears. It is clear that the step $\mathcal{M}_{q-1} \rightsquigarrow \mathcal{M}_q$ is a semantical inference. (It cannot be an axiom download because all axioms have degree n). Notice that all terms of polynomials from $\mathcal{M}_{q-1}$ have degree greater than $\frac{n}{2}$. Assume also that $CS(\mathcal{M}_{q-1}) \leq \frac{n}{8}$. (Otherwise $VS(\mathcal{M}_{q-1}) \geq \frac{n^2}{16}$.) Now we are going to arrive at a contradiction from all these assumptions.

First we claim that ρ can be extended to a restriction ρ_1 that does not assign the variables in $|\mathrm{Supp}(s) \cup \mathrm{Supp}(\Gamma)|$ and kills (= sets to zero) all the terms of $\mathcal{M}_{q-1}$. To see this notice that ρ has assigned $|\rho|$ variables, and we should keep unassigned $|\mathrm{Supp}(s) \cup \mathrm{Supp}(\Gamma)|$ variables; their sum is $|\rho| + |\mathrm{Supp}(s) \cup \mathrm{Supp}(\Gamma)| \leq |P_1| + \deg s \leq \frac{3n}{8}$,

and we need to kill at most $\frac{n}{8}$ terms in $\mathcal{M}_{q-1}$ of degree $\geq n/2$ each. We consecutively kill terms $t \in \mathcal{M}_{q-1}$ by choosing a free unassigned variable from $\mathrm{Supp}(t) \setminus (\mathrm{Supp}(s) \cup \mathrm{Supp}(\Gamma) \cup \rho^{-1}(D))$.

Since $\mathcal{M}_{q-1} \models P$ we have $\rho_1(P) \sim 0$. Thus $\rho_1(P_0 + P_1) \sim 0$ and $\rho_1(P_0' + P_1) \sim 0$ and $\rho_1(P_0') + \Gamma \sim 0$ (because $\rho(P_1 - \Gamma) = 0$, and ρ_1 does not touch variables from $\mathrm{Supp}(\Gamma)$). Since $\deg(\rho_1(P_0')) \leq \deg(P_0') \leq n/4$ and P_1 is $n/4$-minimal, Γ should in fact be identically zero.

We proved that $\rho_1(P_0') \sim 0$. Let $d = \deg s = \deg(P_0')$. Notice that every term of degree d in $\rho_1(P_0')$ is also contained in P_0' (because a restriction either decreases the degree of a term, or kills it, or does not change it at all). Additionally, $\rho_1(P_0')$ contains s because $\rho_1(s) = s$. Thus we get a polynomial $P_0'' = P_0' - \rho_1(P_0')$ such that $P_0'' \sim P_0$, $\deg(P_0'') \leq d$, and P_0'' contains fewer terms of degree d than P_0'. This contradicts our choice of P_0' as the polynomial of smallest degree with smallest number of monomials of highest degree. Thus this situation cannot take place. Theorem 5.1 follows.

As direct corollaries, we obtain the following tight bounds.

COROLLARY 5.6. $VSpace_R(CT_n) \geq VSpace^{sem}_{PCR}(CT_n) \geq \Omega(n^2)$.

COROLLARY 5.7. $VSpace_R(PHP^m_n) \geq VSpace^{sem}_{PCR}(PHP^m_n) \geq \Omega(n^2)$.

6. Upper bounds for Frege systems. In this section we show that the variable space complexity of CT_n is upper bounded by $O(n)$ for Frege systems. It will imply several nice corollaries and in particular the equivalence of semantical and syntactical versions for Frege proofs. We start by defining Frege proof systems and the variable space measure for them.

DEFINITION 6.1 (Frege proof systems). *A* Frege proof system *works with arbitrary propositional formulas. A* line *in a derivation is an arbitrary formula φ over some complete basis. Every inference rule is specified by a* scheme

$$\frac{A_1, \ldots, A_k}{B},$$

where A_i, B are propositional formulas, and altogether there are only finitely many of them. A formula ψ is derived from formulas $\varphi_1, \ldots, \varphi_k$ using this inference rule if there is a set of substitutions σ of formulas for the variables appearing in the scheme such that $\varphi_i = A_i^\sigma$ for $i = 1, \ldots, k$ and $\psi = B^\sigma$. We use the notation $\varphi_1, \ldots, \varphi_k \vdash \psi$ to denote that ψ was derived from $\varphi_1, \ldots, \varphi_k$ using a single rule.

The notions of a Frege proof (derivation) and refutation are analogous to those of resolution and PC. The notion of a semantical Frege proof is the natural extension of semantical systems to Frege. Finally, we give the definition of variable space of a Frege proof.

DEFINITION 6.2 (Frege variable space). *For $\mathcal{M}$, a configuration, the* variable space of $\mathcal{M}$ *is $VSpace_F(\mathcal{M}) \stackrel{\text{def}}{=} \sum_{\phi \in \mathcal{M}} VSpace_F(\phi)$, where $VSpace_F(\phi)$ is the number of occurrences of variables in ϕ. The* Frege variable space of a set of configurations $\pi = \{\mathcal{M}_0, \ldots, \mathcal{M}_s\}$ *is*

$$VSpace_F(\pi) \stackrel{\text{def}}{=} \max\{VSpace_F(\mathcal{M}_i) : i \in [s]\},$$

and the Frege variable space *of a CNF $\mathcal{T}$ is*

$$VSpace_F(\mathcal{T}) \stackrel{\text{def}}{=} \min\{VSpace_F(\pi)\},$$

where the minimum is taken over all Frege refutations π of $\mathcal{T}$.

To prove our main result we essentially use the compact rule of representing information analogous to Horner's scheme for quick evaluation of the polynomial P at a given point x:

$$P(x) = a_0 + x \cdot (a_1 + x \cdot (a_2 + \cdots)).$$

Let us begin with the case when the language of our Frege system $\mathcal{F}$ consists of the standard connectives $\neg, \wedge, \vee, \rightarrow$ and the constant $\mathbf{0}$. (At the end of the section we will show how to modify our proofs to embrace the case of Frege systems in other languages.) It is easy to see that the standard simulation of one Frege system by another Frege system in the same language [CR79] also preserves variable space up to a constant multiplicative factor. Therefore, in the following theorem (which is our main result about variable space for Frege) we can unambiguously use the notation $VSpace_F(\mathcal{T})$, and we can assume in its proof that $\mathcal{F}$ contains any prescribed finite set of sound inference rules.

THEOREM 6.3. $VSpace_F(CT_n) = O(n)$.

Proof. We describe an algorithm for refuting CT_n. Let us call a proof *k-linear* if every line in the proof is derived from k axioms and at most one line that is not an axiom. A k-linear proof gives rise to a proof DAG that looks like a line, and hence the name. Clearly, if every formula in a k-linear proof has small variable space, then so does the whole proof. We shall present a 2-linear proof of CT_n such that all intermediate lines have $O(n)$ variable space.

To this end we define the sequence of read-once formulas $\varphi_0, \ldots, \varphi_{2^{(n-1)}-1}$ such that $\varphi_0 = (x_1 \vee x_2 \vee \cdots \vee x_n)$ and $\varphi_{2^{(n-1)}-1} = (x_1 \wedge x_2 \wedge \cdots \wedge x_n)$ and show how to infer φ_{t+1} from φ_t within $O(n)$ variable space using only two initial clauses from CT_n. The line φ_t encodes in linear space the following claim: *Any satisfying assignment for CT_n, when viewed as a number in binary representation, must be greater than $2 \cdot t$.*

Fix $0 \leq t < 2^{n-1}$, and let $a_1 a_2 \ldots a_{n-1}$ be its binary representation. We let

$$\varphi_t \stackrel{\text{def}}{=} x_1 *_1 (x_2 *_2 (x_3 *_3 (\ldots (x_{n-1} *_{n-1} x_n)))),$$

where $*_i = \wedge$ if $a_i = 1$ and $*_i = \vee$ if $a_i = 0$. Notice that, indeed, any assignment satisfying φ_t, when viewed as a binary number, must have value greater than $2 \cdot t$. Notice that all assignments in $\{0,1\}^n$ that satisfy φ_t satisfy φ_{t+1} as well, *except* for the two assignments that are the binary representation of the numbers $2t+1$ and $2t+2$. Thus, since φ_t "almost" implies φ_{t+1}, we have room for hope that we can derive the latter from the former in small space. We now show that this is indeed the case.

In order to show how to infer φ_{t+1} from φ_t and the initial axioms we need to define one more intermediate formula ψ_t. Let $0 \leq m < n$ be the largest index such that $a_m = 0$ (thus, $t = a_1 a_2 \ldots a_{m-1} 011 \ldots 1$), and let

$$\psi_t \stackrel{\text{def}}{=} x_1 *_1 (x_2 *_2 (x_3 *_3 (\ldots (x_{m-1} *_{m-1} x_m)))).$$

In other words, ψ_t is obtained from φ_t by cutting off the maximal suffix consisting entirely of $\wedge$s and encodes that "the satisfying assignment for CT_n must be greater than $2t+1$."

Define two clauses corresponding to the binary representations of the numbers $2t+1, 2t+2$, respectively.

$$A_t = x_1^{a_1} \vee x_2^{a_2} \vee \cdots \vee x_{m-1}^{a_{m-1}} \vee x_m \vee \bar{x}_{m+1} \vee \cdots \vee \bar{x}_n$$

and

$$B_t = x_1^{a_1} \vee x_2^{a_2} \vee \cdots \vee x_{m-1}^{a_{m-1}} \vee \bar{x}_m \vee x_{m+1} \vee \cdots \vee x_n.$$

It is obvious from the semantics of φ_t, ψ_t described above that $\{\varphi_t, A_t\} \models \psi_t$ and $\{\psi_t, B_t\} \models \varphi_{t+1}$. The question is how to produce compact syntactic inferences.

As we noticed before, we can assume w.l.o.g. that $\mathcal{F}$ contains any prescribed finite set of inference rules, and in particular we can assume that $\mathcal{F}$ contains modus ponens. Therefore, it is sufficient to produce inferences of the tautological formulas $(\varphi_t \wedge A_t) \to \psi_t$ and $(\psi_t \wedge B_t) \to \varphi_{t+1}$ that use $O(n)$ variable space. We will consider only the first formula; the second proof is analogous.

For $1 \le \ell \le n$, let $\varphi_t^{(\ell)}, A_t^{(\ell)}, \psi_t^{(\ell)}$ be the suffixes of φ_t, A_t, ψ_t, respectively, that are obtained by crossing out the variables $x_1, \ldots, x_{\ell-1}$. (And we let $\psi_t^{(\ell)} \stackrel{\text{def}}{=} \bot$ if $\ell > m$.) We are going to infer (in linear variable space) all the formulas $(\varphi_t^{(\ell)} \wedge A_t^{(\ell)}) \to \psi_t^{(\ell)}$ by induction on $\ell = n, n-1, \ldots, 1$.

In the base case $\ell = n$ we have $\varphi_t^{(n)} = x_n,\ A_t^{(n)} = \bar{x}_n$, and we get a substitutional instance of the axiom $(A \wedge \bar{A} \to B)$.

In order to infer $(\varphi_t^{(\ell)} \wedge A_t^{(\ell)}) \to \psi_t^{(\ell)}$ from $(\varphi_t^{(\ell+1)} \wedge A_t^{(\ell+1)}) \to \psi_t^{(\ell+1)}$, we use the rule

$$\frac{A \wedge B \to C}{(D \vee A) \wedge (D \vee B) \to (D \vee C)}$$

if $a_\ell = 0$ and the rule

$$\frac{A \wedge B \to C}{(D \wedge A) \wedge (\bar{D} \vee B) \to (D \wedge C)}$$

if $a_\ell = 1$.

We showed how to make the transition from φ_t to φ_{t+1}. At the end we get $\varphi_{2^{(n-1)}-1} = x_1 \wedge x_2 \wedge \cdots \wedge x_n$, which together with $\bar{x}_1 \vee \bar{x}_2 \vee \cdots \vee \bar{x}_n$ implies a contradiction. Theorem 6.3 is proved. □

COROLLARY 6.4. *Any tautological formula φ can be inferred from the empty set of axioms $\mathcal{T} = \emptyset$ in variable space $O(VSpace_F(\varphi))$.*

Proof. W.l.o.g. assume that $\{x_1, \ldots, x_n\}$ is the complete list of variables appearing in φ. By induction on the logical complexity of a formula ψ (not necessarily tautological) we produce, for any $\epsilon \in \{0,1\}^n$, an inference of $x_1^{\epsilon_1} \vee x_2^{\epsilon_2} \vee \cdots \vee x_n^{\epsilon_n} \vee \psi^{\psi(\bar{\epsilon}_1, \ldots, \bar{\epsilon}_n)}(x_1, \ldots, x_n)$ (where, naturally, $\psi^1 \stackrel{\text{def}}{=} \psi$ and $\psi^0 \stackrel{\text{def}}{=} \bar{\psi}$) that has variable space $O(VSpace_F(\psi))$. Since φ is a tautology, this in particular gives, for any $\epsilon \in \{0,1\}^n$, an inference of $x_1^{\epsilon_1} \vee x_2^{\epsilon_2} \vee \cdots \vee x_n^{\epsilon_n} \vee \varphi(x_1, \ldots, x_n)$ with variable space $O(VSpace_F(\varphi))$. Now we have only to modify the proof of CT_n from Theorem 6.3 by replacing every formula ψ in it with $(\psi \vee \varphi)$ and modifying inference rules accordingly. □

COROLLARY 6.5. *For any tautology $\mathcal{T}$ over n variables*

$$VSpace_F(\mathcal{T}) = O\left(n + \max_{\varphi \in \mathcal{T}} VSpace_F(\varphi)\right).$$

Proof. The proof is similar to the proof of Corollary 6.4. Namely, for every $\epsilon \in \{0,1\}^n$ we can find $\varphi_\epsilon \in \mathcal{T}$ such that $\varphi_\epsilon \to (x_1^{\epsilon_1} \vee x_2^{\epsilon_2} \vee \cdots \vee x_n^{\epsilon_n})$ is a tautology. When we need the axiom $x_1^{\epsilon_1} \vee x_2^{\epsilon_2} \vee \cdots \vee x_n^{\epsilon_n}$ from CT_n, we download this φ_ϵ, infer $\varphi_\epsilon \to (x_1^{\epsilon_1} \vee x_2^{\epsilon_2} \vee \ldots \vee x_n^{\epsilon_n})$, and apply modus ponens. □

Let $VSpace_F^{sem}(\mathcal{T})$ denote the *semantical* Frege variable space of refuting $\mathcal{T}$.

COROLLARY 6.6. *Semantic and syntactic versions of Frege systems are equivalent in the following variable space model:*

$$VSpace_F^{sem}(\mathcal{T}) \le VSpace_F(\mathcal{T}) \le O(VSpace_F^{sem}(\mathcal{T})).$$

Proof. As in the proof of Theorem 3.7, we show how to emulate the semantic inference π by a syntactic one. The only difference between semantical and syntactical versions is in the inference step. Assume that $\{\varphi_1, \varphi_2, \dots, \varphi_k\} \vdash \psi$. Then we can produce the syntactic proof of the tautology $\varphi_1 \wedge \varphi_2 \wedge \cdots \wedge \varphi_k \to \psi$ according to Corollary 6.4 and repeatedly apply modus ponens. □

At the end we briefly discuss how to generalize these results to the case of Frege systems $\mathcal{F}$ in arbitrary complete language L. The problem with the general translation is that the sizes of the resulting formulas may grow very rapidly. However, at least it is not a problem with the logical constant $\mathbf{0}$: it can be trivially replaced with $x \wedge \bar{x}$.

Quite fortunately, the specific language that consists of the remaining connectives $\{\neg, \wedge, \vee, \to\}$ is known to be the weakest in the sense that it can be modeled in any other complete language with only *linear* blow-up in the variable space. More exactly, the following holds.

LEMMA 6.7 (Reckhow [Rec76]). *If $\mathcal{F}$ is a Frege system over any complete language L, then there are L-formulas $NOT(x,z)$, $AND(x,y,z)$, $OR(x,y,z)$, and $IMP(x,y,z)$ such that*

(1) *$NOT(x,z)$ contains one occurrence of x, and $AND(x,y,z)$, $OR(x,y,z)$, and $IMP(x,y,z)$ contain exactly one occurrence of each of x and y;*

(2) *the four formulas represent the Boolean functions $\neg x$, $(x \wedge y)$, $(x \vee y)$, and $(x \to y)$; in particular, the truth values of the formulas are independent of the truth value of z.*

Thus we can rewrite the proof of Theorem 6.3 and its corollaries almost literally, replacing our standard connectives with $NOT(x,z)$, $AND(x,y,z)$, $OR(x,y,z)$, and $IMP(x,y,z)$.

7. Open questions. We conclude this paper with a short list of interesting open questions:

1. Is there any way to capture the notion of propositional space complexity in the uniform framework of first-order theories of bounded arithmetic?
2. Find an unsatisfiable CNF $\mathcal{T}$ in n variables such that $VSpace_R(\mathcal{T}) \ge \omega(n)$ and $\mathcal{T}$ has only polynomially many clauses. (CT_n has exponentially many clauses, and the bound in Corollary 5.7 is linear only in the overall number of variables mn.) We conjecture that $VSpace_R(T(G,\sigma)) \ge \Omega(n^2)$ if G is a 3-regular expander graph and even that

$$VSpace_{PCR}(T(G,\sigma)) \ge \Omega(n^2)$$

when $char(F) \ne 2$.
3. Are there any other interesting fragments of Frege systems, not contained in PCR, for which the notion of variable space makes sense (perhaps cutting planes, depth 2 Frege, etc.)? Can one prove nontrivial lower bounds for these systems?
4. Can we prove the analogue of Theorem 3.7 for variable space? What can be said about the relation between the syntactical and semantical versions of other proof systems with respect to either clause or variable space?

5. Is it possible to prove superconstant clause space lower bounds for PCR-proofs of any bounded fan-in tautology or of $Count_p$? Once more, we conjecture that Corollary 3.27 can be extended to PCR over any field with $char(F) \neq 2$.
6. (See [ET99].) Is it possible to find some strong connection between the clause complexity of a tautology and its minimal proof width for resolution?

Appendix. The purely semantical system called FC works with *arbitrary* Boolean functions, regardless of their syntactical representation complexity. In fact our space complexity for FC defined below will simply minimize over all such representations. Although this system is not natural, the clause space lower bound for the polynomial calculus applies to it as well, and it is a useful tool for proving lower bounds when an abstraction from particulars of a given syntactical system is desirable and instructive.

The line of an FC derivation is an arbitrary Boolean function. The single inference rule is the semantical one, i.e., derive g from $f_1, f_2, \ldots, f_k$ whenever $f_1, f_2, \ldots, f_k \models g$. The definitions of derivations and refutations are analogous to those of resolution and PC.

When defining the clause space for FC, we must overcome the following problem. A line in FC is an *arbitrary* Boolean function f. Clearly, f can be represented by many circuits over some complete Boolean basis, each with a different amount of clauses. The natural way to solve this problem is to define the clause space to be the minimal number of clauses in any such representation.

DEFINITION 7.1 (clause space for FC). *For $\mathcal{M}$ a set of Boolean functions over $x_1, \ldots, x_n$, the* clause space *of $\mathcal{M}$ in FC, denoted $FCSpace(\mathcal{M})$, is the minimal s such that we can choose s clauses with the property that every $f \in \mathcal{M}$ can be represented as a Boolean function over the chosen clauses. Formally,*

$$\begin{aligned} FCSpace(\mathcal{M}) \stackrel{\text{def}}{=} \min \{\, s \mid \exists (C_1(x_1, \ldots, x_n), C_2(x_1, \ldots, x_n), \ldots, \\ C_s(x_1, \ldots, x_n)) \text{ for all } (f(x_1, \ldots, x_n) \in \mathcal{M}) \exists g(y_1, \ldots, y_s) \\ (f \equiv g(C_1, \ldots, C_s)) \,\}, \end{aligned}$$

where C_i are clauses, and g runs over arbitrary Boolean functions in s variables.

We can also define multivalued FC over the domain D in a natural way.

DEFINITION 7.2 (multivalued FC). FC over the domain D *(FC(D)) is the purely semantical system which keeps in memory arbitrary functions $f(x_1, \ldots, x_n) : D^n \to \{0, 1\}$. The inference rule is the semantical one.*

The clause space measure $FCSpace_D(\mathcal{M})$ of a set of such functions $\mathcal{M}$ is the minimal s such that we can choose s multivalued clauses with the property that every $f \in \mathcal{M}$ can be represented as an (ordinary!) Boolean function over the chosen multivalued clauses.

We now prove our main theorems for FC. The first is a better upper bound on clause space of CT_n, which is proved using the method of Theorem 4.2.

THEOREM 7.3. $FCSpace(CT_n) \leq n/2 + 2$.

Proof. By Claim 4.4 (that applies to FC just as well), we need analyze only the base case and show that $FCSpace(CT_2) \leq 2$ ($s = k = 1$):

$$\begin{pmatrix} \text{Axiom: } x_1 \vee x_2 \\ \text{Axiom: } x_1 \vee \bar{x}_2 \end{pmatrix} \rightsquigarrow \begin{pmatrix} x_1 \end{pmatrix} \rightsquigarrow \begin{pmatrix} x_1 \\ \text{Axiom: } \bar{x}_1 \vee x_2 \end{pmatrix}$$
$$\rightsquigarrow \begin{pmatrix} \neg(\bar{x}_1 \vee \bar{x}_2) \end{pmatrix} \rightsquigarrow \begin{pmatrix} \neg(\bar{x}_1 \vee \bar{x}_2) \\ \text{Axiom: } \bar{x}_1 \vee \bar{x}_2 \end{pmatrix} \rightsquigarrow \begin{pmatrix} \bot \end{pmatrix}. \qquad \square$$

Although FC is much stronger than PCR, it turns out that Theorem 4.18 applies equally well to the FC.

THEOREM 7.4. *For any wide tautology $\mathcal{T}$ over n variables with domain D, $FCSpace(\mathcal{T}) \geq \frac{n}{4}$.*

Proof. The proof is identical to the proof of Theorem 4.18. (Notice that in the proof of Lemma 4.14 we used the fact $s = MSpace_D^{sem}(\mathcal{M}_1)$ *only* to write down the representation $||\mathcal{M}_1|| = g(C_1, \ldots, C_s)$ for an *unspecified* Boolean function g, and this transition works perfectly well in the context of FC). □

AN ENUMERATIVE GEOMETRY FRAMEWORK FOR ALGORITHMIC LINE PROBLEMS IN $\mathbb{R}^3$*

THORSTEN THEOBALD†

Abstract. We investigate the enumerative geometry aspects of algorithmic line problems when the admissible bodies are balls or polytopes. For this purpose, we study the common tangent lines/transversals to k balls of arbitrary radii and $4-k$ lines in $\mathbb{R}^3$. In particular, we compute tight upper bounds for the maximum number of real common tangents/transversals in these cases. Our results extend the results of Macdonald, Pach, and Theobald who investigated common tangents to four unit balls in $\mathbb{R}^3$ [*Discrete Comput. Geom.*, 26 (2001), pp. 1–17].

Key words. tangents, balls, transversals, lines, enumerative geometry, real solutions, computational geometry

1. Introduction.

Algorithmic questions involving lines in $\mathbb{R}^3$ belong to the fundamental problems in computational geometry [36, 26], computer graphics [28], and robotics [33]. As an initial reference example from computational geometry, consider the problem of determining which bodies of a given scene cannot be seen from *any* viewpoint outside of the scene. From the geometric point of view, this leads to the problem of determining the *common tangents to four given bodies* in $\mathbb{R}^3$ (cf. section 2). Other algorithmic tasks leading to the same geometric core problem include computing smallest enclosing cylinders [32], computing geometric permutations/stabbing lines [27, 2], controlling a laser beam in manufacturing [26], or solving placement problems in geometric modeling [10, 17].

If the bodies are polytopes, the common tangents are common transversals of edges [27]; so, in fact, the main geometric task is to compute the common transversals to four given lines in $\mathbb{R}^3$. This geometric problem has been well known for many years (see, e.g., [16]). In particular, if a configuration has only finitely many common transversals, then this number is bounded by 2; and it is well known how to characterize the configurations with infinitely many common transversals.

On the other hand, the following theorem in [21] shows that this situation completely changes if the bodies under investigation are unit balls (see also [35, 23]).

PROPOSITION 1. *Four unit balls in* $\mathbb{R}^3$ *have at most* 12 *common tangent lines unless their centers are located on the same line. Furthermore, there exists a configuration with* 12 *tangents; i.e., the upper bound is tight.*

Essentially, this means that algebraically this tangent problem is of degree 12. Note that due to this high degree, proving the characterization of the configurations with infinitely many common tangents is a highly nontrivial task.

However, concerning the class of tangent problems to four given bodies, Proposition 1 solves only one particular case. In the present paper, we develop techniques to analyze a substantially larger class of variants. In particular, we aim at filling the gaps between the two extreme situations mentioned before by considering common

TABLE 1

Summary of results and references of known results. For the case of four balls of general radii we are able to provide a formulation with Bézout bound 12 *(which improves the results from* [17] *substantially; see section* 4*).*

	Upper bound # solutions		# Real solutions of our construction		Characterization of degenerate instances	
4 lines	2	(well known)	2	(well known)	yes	(well known)
3 lines, 1 ball	4		4		yes	
2 lines, 2 balls	8		8		–	
1 line, 3 balls	12		12		–	
4 unit balls	12	[21]	12	[21]	yes	[21]
4 balls	12	([17])	12	[21]	–	

tangents/transversals to k balls and $4-k$ lines, $k \in \{0,\dots,4\}$. For convenience of notation, we consider a transversal of a line as a tangent to the line. Our investigations do not only clarify the exact growth in algebraic degree from 2 to 12 but also provide effective means to tackle these questions when the symmetry (in the sense of identical bodies) is lost. From the algorithmic point of view, these problems of common tangents immediately arise in the mentioned applications when the class of admissible bodies in the scene consists of both balls and polytopes (see section 2).

As the main contribution of this paper, we compute *tight* upper bounds for the number of common tangents to k balls and $4-k$ lines in the finite case, $k \in \{0,\dots,4\}$. Here, *tightness* refers to the following (quite strong) sense of real algebraic geometry (cf. [34]): On the one hand, for each k we bound the number of solutions by algebraic methods, say, by some number m. Then, on the other hand, we provide a construction which indeed leads to m solutions in *real* space $\mathbb{R}^3$ (which would not be possible if any polynomial formulation contained some complex solutions or solutions at infinity).

The general difficulty of proving tight bounds of this kind may be seen by the following two aspects. For the classical enumerative geometry problem of conics tangent to five given conics (dating back to Steiner in 1847) the existence problem of 3264 *real* solutions had not been solved until a few years ago (see [30] and [14, sect. 7.2]). Furthermore, as pointed out in [34], there are nearly no criteria or general techniques for tackling these type of questions. For these reasons, it is even more remarkable that in *all* (!) of the situations there exists a construction matching the upper bound.

Table 1 summarizes our results and provides references of known results. It shows the upper bounds for the number of solutions and the matching numbers of real solutions in our constructions. The last column shows that only in a few cases are we able to explicitly characterize the configurations with an infinite number of common tangents. Namely, besides the already existing results for four lines and four unit balls, we add the characterization for three lines and one ball. In the entries with a "–" we cannot give such a characterization and will discuss this issue at the end of the paper.

Let us point out that the proofs of these results are of quite different flavors. For $k \in \{1,2\}$, the upper bounds immediately follow from Bézout's theorem. Whereas for $k=1$ it is easy to give a construction matching this bound, the construction for $k=2$ is quite involved. In particular, for $k=2$ we apply tools from algebraic geometry and computer algebra (e.g., standard bases) to prove correctness of the construction. However, proving the tight upper bound for three balls and one line is completely different. Here, the Bézout bound in our formulation will be 16 instead of 12. In order to find a better bound for the number of real solutions, we have to analyze the

underlying algebraic geometry of the problem in detail. Finally, in the proof for four balls of general radii we use elementary geometry to find a formulation with Bézout bound 12. Altogether, we think that this variety of techniques can serve to provide many ideas when tackling related problems.

This paper is structured as follows. In section 2, we establish the connection between the algorithmic problems and the geometric tangent problems. Then, after providing some algebraic background on Plücker coordinates in section 3, we prove the necessary results for Table 1 in section 4. We conclude the paper with a short discussion of the remaining open questions.

2. Motivation and algorithmic background. The problem under investigation represents the algebraic core problem within several algorithmic applications mentioned in the introduction. Exemplarily, we describe two of them.

Partial visibility. Consider the following problem from ray-tracing with moving viewpoints. Here, we want to compute information on the viewpoint positions where the visibility topology of the scene changes. As a special case, this includes tackling the following core problem of partial visibility.

A set $B \subset \mathbb{R}^n$ (say, $n \in \{2,3\}$) is called a *(convex) body* if it is bounded, closed, convex, and contains an inner point. Now we consider a scene consisting of a set $\mathcal{B}$ of (not necessarily disjoint) bodies from a specific class $\mathcal{X}$ in $\mathbb{R}^n$. ($\mathcal{X}$ might be the set of all balls or the set of all polytopes.) A body $B \in \mathcal{B}$ is called *partially visible from a viewpoint* v if there exists a line segment connecting v and B not intersecting with the interior of any other body in $\mathcal{B}$. A body $B \in \mathcal{B}$ is called *partially visible* if B can be seen from some viewpoint "outside" of the scene, i.e., if there exists a ray starting at B not intersecting with the interior of any other body in $\mathcal{B}$. We call such a ray a *visibility ray* for B. Bodies which are not partially visible can be immediately removed from the scene, which reduces the complexity of the visualization process. In case of dense crystals whose atoms are visualized as sufficiently large balls, the reduction in complexity may be quite substantial.

In the two-dimensional case, checking partial visibility of a body B can be reduced to a finite number of geometric problems as follows (cf. the treatment of stabbing lines in [12]). Without loss of generality let $|\mathcal{B}| \geq 2$. If there exists a visibility ray for B, then we can continuously transform (i.e., translate and rotate) the visibility ray until we reach a situation where the underlying line is tangent to at least two of the bodies. (One of them might be B itself.) Hence, it suffices to compute the set of all common tangent lines to a pair of bodies in $\mathcal{B}$ and check whether one of these lines contains a visibility ray. For any pair of bodies, the number of common tangent lines is at most four (which is a very special case of the results in [6, 19] on the number of common supporting hyperplanes in general dimension).

In the three-dimensional case we can essentially proceed analogously. Since a line in $\mathbb{R}^3$ has four degrees of freedom, the core problem is to compute the common tangents to four bodies in $\mathbb{R}^3$ (cf. [27, 2]). However, in the three-dimensional case, there are also some special cases where we can transform a visibility ray only to a situation with two or three bodies, or where a configuration with four bodies has an infinite number of common tangents.

For a polytope P, any tangent to P intersects an edge of P. Hence, if $\mathcal{X}$ contains balls and polytopes, we have to compute common tangents/transversals to k lines and $4-k$ balls, $0 \leq k \leq 4$. An algorithmic treatment of the situations with infinitely many common tangents (depending on the class $\mathcal{X}$ of bodies) requires an *a priori* characterization of the configurations with infinitely many common tangents.

In contrast to some other problems in computational geometry, characterizing these situations cannot be neglected (say, by applying perturbation techniques [11]), since the large algebraic degree involved makes it highly nontrivial to guarantee a correct perturbation.

Envelopes. Let $\mathcal{B}$ be a collection of n convex bodies in $\mathbb{R}^3$. A line l is called a *line transversal* of $\mathcal{B}$ if it intersects every member of $\mathcal{B}$. The set of line transversals of $\mathcal{B}$ can be represented as the region enclosed between an upper and a lower envelope as follows (see [7, 1, 2]). These representations are important in the design of data structures supporting ray shooting queries (i.e., seeking the first body, if any, met by a query ray) [1].

If we exclude lines parallel to the yz-plane, a line l in $\mathbb{R}^3$ can be uniquely represented by its projections on the xy- and xz-planes: $y = \sigma_1 x + \sigma_2$, $z = \sigma_3 x + \sigma_4$. Hence, a line can be represented by the quadruple $(\sigma_1, \sigma_2, \sigma_3, \sigma_4) \in \mathbb{R}^4$.

Let B be a convex body in $\mathbb{R}^3$. For fixed $\sigma_1, \sigma_2, \sigma_3$, the set of lines $(\sigma_1, \sigma_2, \sigma_3, \sigma_4)$ that intersect B is obtained by translating a line in the z-direction between two extreme values, $(\sigma_1, \sigma_2, \sigma_3, \phi_B^-(\sigma_1, \sigma_2, \sigma_3))$ and $(\sigma_1, \sigma_2, \sigma_3, \phi_B^+(\sigma_1, \sigma_2, \sigma_3))$, which represent lines tangent to B from below and from above, respectively. Hence, the set of line transversals to $\mathcal{B}$ can be represented as

$$\{(\sigma_1, \sigma_2, \sigma_3, \sigma_4) \ : \ \max_{B \in \mathcal{B}} \phi_B^-(\sigma_1, \sigma_2, \sigma_3) \leq \sigma_4 \leq \min_{B \in \mathcal{B}} \phi_B^+(\sigma_1, \sigma_2, \sigma_3),$$

which is a region enclosed between a lower envelope and an upper envelope in $\mathbb{R}^4$. If the elements of $\mathcal{B}$ are balls or polytopes, then the set of line transversals defines a semialgebraic set in $\mathbb{R}^4$ (see [2]). Assuming general position, the vertices (= zero-dimensional faces) of the boundary of this region correspond to lines which are tangent to four of the bodies in $\mathcal{B}$. Similar to the first scenario, any implementation of this basic step has to cope with the enumerative questions treated in the present paper.

The role of an algebraic oracle. In both of these algorithmic scenarios, the problem is reduced to the core problem of finding the common tangents/transversals to k lines and $4 - k$ balls. In literature, core problems of this type are considered to be problems of *constant description complexity* (see, e.g., [2]). Often, it is assumed that one has access to an *algebraic oracle* computing the necessary tangents, and the algorithm is formulated in terms of that oracle. From this point of view, our analysis can be seen as the necessary mathematical investigations on how to build this algebraic oracle.

In particular, any implementation of this algebraic oracle or any interface to a black box subroutine establishing that oracle has to cope with the enumerative questions. From the viewpoint of data structures it is always useful and sometimes even necessary to know a good (i.e., tight) upper bound on the number of these tangent lines. From the viewpoint of program verification, knowing a tight upper bound on the number of tangent lines offers the possibility of strong and valuable consistency checks within a program (in particular with regard to the necessary numerical subroutines; cf. section 5). Finally, from the viewpoint of efficiency, understanding the geometry of the basic problem helps to find the right polynomial formulations for the underlying numerical algorithms.

3. Plücker coordinates. In several of the proofs, we use the well-known Plücker coordinates of lines in projective space $\mathbb{P}^3$ (see, e.g., [16, 8]). Let $x = (x_0, x_1, x_2, x_3)^T$, $y = (y_0, y_1, y_2, y_3)^T \in \mathbb{P}^3$ be two different points on a line l. Then l can be represented (of course not uniquely) by the 4×2-matrix L whose two columns are x and y. The

Plücker vector $p = (p_{01}, p_{02}, p_{03}, p_{12}, p_{13}, p_{23})^T \in \mathbb{P}^5$ of the line is defined by the determinants of the 2×2-submatrices of L, i.e., $p_{ij} = x_i y_j - x_j y_i$. It is well known that the set of vectors in $\mathbb{P}^5$ satisfying the Plücker relation

$$p_{01}p_{23} - p_{02}p_{13} + p_{03}p_{12} = 0 \tag{1}$$

is in one-to-one correspondence with the set of lines in $\mathbb{P}^3$. A line l intersects with a line l' in $\mathbb{P}^3$ if and only if their Plücker vectors p and p' satisfy

$$p_{01}p'_{23} - p_{02}p'_{13} + p_{03}p'_{12} + p_{12}p'_{03} - p_{13}p'_{02} + p_{23}p'_{01} = 0. \tag{2}$$

In order to characterize lines tangent to balls we consider tangent lines to arbitrary quadrics in $\mathbb{P}^3$. Throughout the presentation, we will identify a quadric surface in $\mathbb{P}^3$ with its symmetric 4×4-representation matrix. For example, the sphere with radius r and center $(c_1, c_2, c_3)^T \in \mathbb{R}^3$, in $\mathbb{P}^3$ described by $(x_1 - c_1x_0)^2 + (x_2 - c_2x_0)^2 + (x_3 - c_3x_0)^2 = r^2x_0^2$, is identified with the matrix

$$\begin{pmatrix} c_1^2 + c_2^2 + c_3^2 - r^2 & -c_1 & -c_2 & -c_3 \\ -c_1 & 1 & 0 & 0 \\ -c_2 & 0 & 1 & 0 \\ -c_3 & 0 & 0 & 1 \end{pmatrix}.$$

LEMMA 2. *Let L be a 4×2-matrix representing the line $l \subset \mathbb{P}^3$. l is tangent to a quadric Q in $\mathbb{P}^3$ if and only if the 2×2-matrix L^TQL is singular.*

Proof. If we denote the two columns of L by x and y, then the line l consists of all points

$$\left\{ z = (z_0, z_1, z_2, z_3)^T \,:\, z = \lambda x + \mu y,\, (\lambda, \mu)^T \in \mathbb{R}^2 \setminus \{(0,0)^T\} \right\}.$$

By definition, l is tangent to Q if and only if this line intersects the quadric exactly once (namely, with multiplicity 2) or if it is contained in the quadric. The homogeneous quadratic equation

$$(\lambda x + \mu y)^T Q (\lambda x + \mu y) = 0$$

can be made affine by setting $\mu = 1$. Since the discriminant of this affine quadratic equation in λ is

$$(2x^TQy)^2 - 4(x^TQx)(y^TQy) = -4 \det(L^TQL),$$

the statement follows immediately. ∎

In order to transfer this condition to Plücker coordinates, we introduce the operator

$$\wedge^2 : \mathbb{R}^{m,n} \to \mathbb{R}^{\binom{m}{2},\binom{n}{2}}$$

(cf. [35]). The row and column indices of the resulting matrix are subsets of cardinality 2 of $\{1, \ldots, m\}$ and $\{1, \ldots, n\}$, respectively. For $I \subset \{1, \ldots, m\}$ and $J \subset \{1, \ldots, n\}$, with $|I| = |J| = 2$,

$$(\wedge^2 A)_{I,J} := \det A_{[I,J]},$$

where $A_{[I,J]}$ denotes the 2×2-submatrix of the given matrix A with row indices I and column indices J. Let l be a line in $\mathbb{P}^3$ and L be a 4×2-matrix representing l.

By interpreting the 6×1-matrix $\wedge^2 L$ as a vector in $\mathbb{P}^5$, we observe $\wedge^2 L = p_l$, where p_l is the Plücker vector of l.

LEMMA 3. *A line $l \subset \mathbb{P}^3$ is tangent to a quadric Q if and only if the Plücker vector p_l of l satisfies*

$$p_l^T(\wedge^2 Q)p_l = 0. \tag{3}$$

Proof. Let L be a 4×2-matrix whose two columns contain different points of l. The Cauchy–Binet formula from multilinear algebra (see, e.g., [22]) implies

$$\begin{aligned}\det(L^T Q L) &= (\wedge^2 L^T)(\wedge^2 Q)(\wedge^2 L)\\ &= (\wedge^2 L)^T(\wedge^2 Q)(\wedge^2 L).\end{aligned}$$

Now the claim follows from Lemma 2. ∎

For a sphere with radius r and center $(c_1, c_2, c_3)^T \in \mathbb{R}^3$ the quadratic form $p_l^T(\wedge^2 Q)p_l$ results in

$$\begin{pmatrix} p_{01}\\ p_{02}\\ p_{03}\\ p_{12}\\ p_{13}\\ p_{23}\end{pmatrix}^T \begin{pmatrix} c_2^2+c_3^2-r^2 & -c_1c_2 & -c_1c_3 & c_2 & c_3 & 0\\ -c_1c_2 & c_1^2+c_3^2-r^2 & -c_2c_3 & -c_1 & 0 & c_3\\ -c_1c_3 & -c_2c_3 & c_1^2+c_2^2-r^2 & 0 & -c_1 & -c_2\\ c_2 & -c_1 & 0 & 1 & 0 & 0\\ c_3 & 0 & -c_1 & 0 & 1 & 0\\ 0 & c_3 & -c_2 & 0 & 0 & 1\end{pmatrix} \begin{pmatrix} p_{01}\\ p_{02}\\ p_{03}\\ p_{12}\\ p_{13}\\ p_{23}\end{pmatrix}. \tag{4}$$

4. Proofs and constructions. We show the following theorem.

THEOREM 4. *Given $4-k$ lines and k balls in $\mathbb{R}^3$, $0 \le k \le 4$. If there exist only finitely many common tangent lines to these four bodies, then the number of these tangents is bounded by*

$$\begin{cases} 2 & \text{if } k = 0,\\ 4 & \text{if } k = 1,\\ 8 & \text{if } k = 2,\\ 12 & \text{if } k \in \{3, 4\}.\end{cases}$$

These bounds are tight; i.e., for each k there exists a configuration where the number of different real tangent lines matches the stated number. The bounds are tight even if the balls are unit balls.

For brevity, we denote the maximum numbers of tangent lines in the five situations by N_k, $k \in \{0, \dots, 4\}$. Before proving the statements in the following lemmas, let us recall the following version of Bézout's theorem (see, e.g., [8, p. 91]).

THEOREM 5 (Bézout). *Let $f_1, \dots, f_n$ be homogeneous polynomials in $x_0, \dots, x_n$ of degrees $d_1, \dots, d_n > 0$. If $f_1, \dots, f_n$ have a finite number of common zeros in projective n-space $\mathbb{P}^n$, then the number of zeros (counted with multiplicity) is bounded by $d_1 \cdot d_2 \cdots d_n$.*

Note that the upper bounds $N_0 \le 2$, $N_1 \le 4$, $N_2 \le 8$ immediately follow from Bézout's theorem. Namely, since the common tangent lines to three lines and one ball can be formulated by three linear equations of the form (2), one equation of the form (3) as well as the Plücker relation (1) in the six homogeneous variables $p_{01}, \dots, p_{23}$, we obtain $N_1 \le 4$. Analogously, we obtain $N_0 \le 2$, $N_2 \le 8$.

Further, note that the common transversals to four given lines in three-dimensional space are a well-studied problem in enumerative geometry, and it is well known that

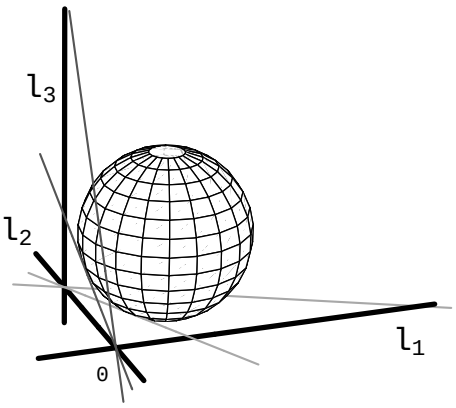

FIG. 1. *The figure shows a configuration with three lines l_1, l_2, l_3, and one ball of radius* 11/10*, leading to four common tangent lines. The two tangent lines in the x_1x_2-plane are drawn in light grey, whereas the two tangent lines in the x_2x_3-plane are drawn in dark grey.*

the upper bound of 2 can actually be achieved in real space $\mathbb{R}^3$ (see, e.g., [16]); hence $N_0 = 2$. The number of common transversals is finite if and only if the Plücker vectors of the four given lines are linearly independent.

In the following, let $B(c, r)$ denote the (closed) ball with center c and radius r.

LEMMA 6. $N_1 = 4$.

Proof. Since $N_1 \leq 4$, it suffices to give a construction with three lines and one ball, leading to four common tangents. Let l_1 be the x_1-axis, l_2 be the x_2-axis, and l_3 be parallel to the x_3-axis and passing through $(0, 2, 0)^T$ (see Figure 1); hence $l_1 \cap l_2 = \{(0, 0, 0)^T\}$ and $l_2 \cap l_3 = \{(0, 2, 0)^T\}$.

Each line intersecting the three lines l_1, l_2, and l_3 is located in the x_1x_2-plane (in which case it passes through $(0, 2, 0)^T$) or is located in the x_2x_3-plane (in which case it passes through the origin). For $1 < r < \sqrt{2}$ the ball $B((1, 1, 1)^T, r)$ intersects both the x_1x_2-plane and the x_2x_3-plane but does not intersect with any of the lines l_1, l_2, l_3. Hence, since there are two tangents to the ball passing through the origin and lying in the x_1x_2-plane, and since there are two tangents to the ball passing through $(0, 2, 0)^T$ and lying in the x_1x_3-plane, there are four common tangents altogether. Figure 1 shows a configuration with $1 < r = 11/10 < \sqrt{2}$. We remark that by appropriate scaling, the ball can be transformed into a unit ball. Furthermore, by slightly perturbing the configuration, the lines can be made pairwise skew. □

To complete the entries for three lines and one ball in Table 1, it remains to characterize the configurations with infinitely many common tangent lines. If the three lines are not pairwise skew, then all common tangent lines lie in the same plane or pass through a point of intersection. Since the resulting characterization can be easily established, we can assume that the three lines are pairwise skew.

It is well known that the common transversals of three pairwise skew lines define a hyperboloid (see, e.g., [31, 3]). By applying a translation and a rotation, the hyperboloid can be transformed into

$$\frac{x_1^2}{a^2} + \frac{x_2^2}{b^2} - \frac{x_3^2}{c^2} = 1 \qquad \text{with } a, b, c > 0. \tag{5}$$

This transformation changes the center of the ball into some new center $(p_1, p_2, p_3)^T \in \mathbb{R}^3$. Now the characterization of infinitely many common tangent lines is given by the following lemma.

LEMMA 7. *Let l_1, l_2, l_3 be three pairwise skew lines whose common transversals generate a hyperboloid of the form (5), and let B_4 be a ball with center $(p_1, p_2, p_3)^T$ and radius $r > 0$. Then there exist infinitely many common tangents to l_1, l_2, l_3, B_4 if and only if $p_1 = p_2 = 0$, $a = b$, and in the x_1x_3-plane the circle $x_1^2 + (x_3 - p_3)^2 = r^2$ is a tangent circle to both branches of the hyperbola $x_1^2/a^2 - x_3^2/c^2 = 1$.*

Proof. The hyperboloid (5) can be parametrized by one of the two sets of generating lines. In particular, this hyperboloid is generated by the set of lines

$$\left\{ (x_1, x_2, 0)^T + \lambda \left(-\frac{a}{bc} x_2, \frac{b}{ac} x_1, 1 \right)^T : \lambda \in \mathbb{R} \right\}, \tag{6}$$

$$\text{where } \frac{x_1^2}{a^2} + \frac{x_2^2}{b^2} = 1 \tag{7}$$

(see, e.g., [18]). In order to characterize those lines which are tangent to the ball, we can apply Lemma 3 to the lines (6) and obtain a polynomial equation in x_1, x_2 of degree at most 4. After bringing the terms of even degree in x_1 to the left side and the terms of odd degree in x_1 to the right side, squaring the equation yields a new equation in which every term is of even degree in x_1. Now we can use (7) to eliminate x_2 and obtain a polynomial equation of degree at most 8 in x_1. Since a univariate polynomial with infinitely many common zeros is the zero polynomial, this polynomial formulation in a single variable implies that if the hyperboloid contains infinitely many tangent lines to the ball, then *all* lines in the parametrization are tangent lines to the ball.

Since the intersection of the hyperboloid with any plane parallel to the x_1x_2-axis is symmetric with respect to the origin, a necessary condition for infinitely many common tangents is $p_1 = p_2 = 0$. In this situation, a configuration with infinitely many common tangents further implies $a = b$. Hence, since $p_1 = p_2 = 0$ and $a = b$, both the hyperboloid and the ball are rotational symmetric with respect to the x_3-axis, and it suffices to consider the section through the x_1x_3-plane. In this section, the circle $x_1^2 + (x_3 - p_3)^2 = r^2$ must be a tangent circle to both branches of the hyperbola $x_1^2/a^2 - x_3^2/c^2 = 1$.

If, conversely, $p_1 = p_2 = 0$, $a = b$, and in the x_1x_3-plane the circle $x_1^2 + (x_3 - p_3)^2 = r^2$ is a tangent circle to the hyperbola $x_1^2/a^2 - x_3^2/c^2 = 1$, then the rotational symmetry implies that every line in the hyperboloid $x_1^2/a^2 + x_2^2/b^2 - x_3^2/c^2 = 1$ is tangent to the ball B_4. Hence, there are infinitely many common tangents. ∎

LEMMA 8. $N_2 = 8$.

Proof. Since $N_2 \leq 8$, it suffices to give a construction with two lines and two balls of the same radius, leading to eight common tangent lines. We start from the following configuration with six different common tangent lines. The two balls are symmetrically located on the x_1-axis: $c_3 = (\gamma, 0, 0)^T$, $c_4 = (-\gamma, 0, 0)^T$; the radius r will be specified below. The lines l_1 and l_2 are chosen in a plane $x_2 = \beta$ for some $\beta > 0$ such that the lines intersect in $(0, \beta, 0)^T$. Hence, every common transversal of the two lines either lies in the plane $x_2 = \beta$ or passes through the point $(0, \beta, 0)^T$. If the two balls intersect with each other, and $\beta < r$, and $(0, \beta, 0)^T$ is not contained in the union of the balls $B(c_3, r)$, $B(c_4, r)$, then there are exactly six different common tangents (see Figure 2): two tangents pass through $(0, \beta, 0)^T$ and lie in the plane $x_1 = 0$; two tangents lie in the plane $x_2 = \beta$ and are parallel to the x_1-axis; and two tangents lie in the plane $x_2 = \beta$ and pass through $(0, \beta, 0)^T$. For the following considerations it is quite useful to have a succinct description of the last two tangents and also to work with integer coefficients for β, γ, and r. In particular, we will force

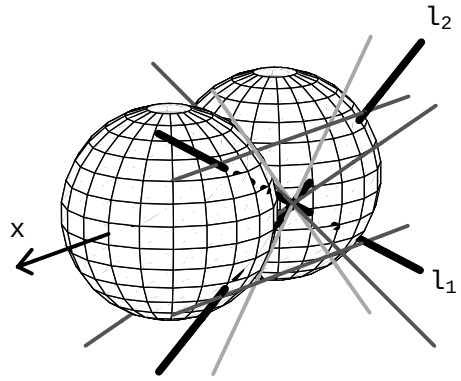

FIG. 2. *The figure shows a construction with two lines and two balls, leading to six different tangent lines. The two tangents lying in the plane $x_2 = \beta$ and passing through $(0, \beta, 0)^T$ are drawn in light grey. The other four tangents are drawn in dark grey.*

the two tangents in the plane $x_2 = \beta$ and passing through $(0, \beta, 0)^T$ to be of the form $(0, \beta, 0)^T + \lambda(1, 0, \pm 1)^T$. In order to obtain these tangents, β, γ, and r have to satisfy $\beta^2 + \gamma^2/2 = r^2$ and $r > \gamma$. An appropriate choice is $\beta = 7$, $\gamma = 8$, and $r = 9$, so that the tangents of the last type are

$$t_1 := \left\{(0,7,0)^T + \lambda(1,0,1)^T \,:\, \lambda \in \mathbb{R}\right\} \text{ and } t_2 := \left\{(0,7,0)^T + \lambda(1,0,-1)^T \,:\, \lambda \in \mathbb{R}\right\}.$$

Now the key observation is that these two tangents have multiplicity 2. In order to prove this we consider the system of Plücker equations stemming from (2) and (4). Independent of the specific choice of lines l_1, l_2 with the above properties, the common transversals of l_1 and l_2 are given by the common zeros of the two linear, homogeneous polynomials

$$\begin{aligned} f_1 &= -7p_{03} + p_{23}, \\ f_2 &= 7p_{01} + p_{12}. \end{aligned}$$

The quadratic equations resulting from the balls $B(c_3, r)$ and $B(c_4, r)$ are

$$\begin{aligned} f_3 &= -81p_{01}^2 - 17p_{02}^2 - 17p_{03}^2 - 16p_{02}p_{12} + p_{12}^2 - 16p_{03}p_{13} + p_{13}^2 + p_{23}^2, \\ f_4 &= -81p_{01}^2 - 17p_{02}^2 - 17p_{03}^2 + 16p_{02}p_{12} + p_{12}^2 + 16p_{03}p_{13} + p_{13}^2 + p_{23}^2. \end{aligned}$$

Furthermore, let $f_5 = p_{01}p_{23} - p_{02}p_{13} + p_{03}p_{12}$ be the polynomial of the Plücker relation (1).

The tangent t_1 has Plücker coordinate $(1, 0, 1, -7, 0, 7)^T$. In order to compute the multiplicity of this tangent, we follow the method and the notation in [9, sect. 4.4]. First we pass to an affine version of the polynomials by adding the polynomial $f_6 = p_{01} - 1$; this forces $p_{01} = 1$ in any common zero of the system. Then we move the point t_1 to the origin by applying the linear variable transformation

$$(p_{01}, p_{02}, p_{03}, p_{12}, p_{13}, p_{23})^T = (q_{01}, q_{02}, q_{03}, q_{12}, q_{13}, q_{23})^T + (1, 0, 1, -7, 0, 7)^T.$$

The local intersection multiplicity μ can be computed as the vector space dimension of the quotient ring

$$\mu = \dim R_l / I_l,$$

where $R_l := \mathbb{C}[q_{01}, \ldots, q_{23}]_{\langle q_{01},\ldots,q_{23}\rangle}$ is the local ring whose elements are the rational functions in $q_{01}, \ldots, q_{23}$ with nonvanishing denominator at 0. I_l is the ideal defined by $f_1, \ldots, f_6$ in the local ring R_l.

In order to compute μ, we use the fact that in case of finite dimension

$$\dim R_l/I_l = \dim R_l/\langle \mathrm{LT}(I_l)\rangle,$$

where $\langle \mathrm{LT}(I_l)\rangle$ denotes the ideal generated by the leading terms of I_l (see, e.g., [9, Chap. 4, Cor. 4.5]). This dimension can be easily extracted from a standard basis of I_l. (For the convenience of the reader, a short review of standard bases can be found in the appendix.) Since by our choice of β, γ, and r all coefficients are integers, we can apply a computer algebra package (e.g., `Singular` [15]) to compute a standard basis $\{h_1, \ldots, h_6\}$ of the ideal I_l with respect to antigraded reverse lexicographical order:

$$\begin{aligned}
h_1 &= q_{01},\\
h_2 &= 112q_{02} + 34q_{03} + 14q_{12} - 16q_{13},\\
h_3 &= 14q_{03} + q_{12},\\
h_4 &= q_{12},\\
h_5 &= 64q_{23},\\
h_6 &= 112q_{13}^2.
\end{aligned}$$

Hence, the leading monomials of $h_1, \ldots, h_6$ with respect to antigraded reverse lexicographical order are q_{01}, q_{02}, q_{03}, q_{12}, q_{23}, q_{13}^2. The desired multiplicity μ is the cardinality of the set of cosets $\{1 + I_l, q_{13} + I_l\}$, which implies $\mu = 2$. By symmetry, the tangent t_2 has multiplicity 2 as well.

Now we choose one particular configuration of the presented class, namely the one with $l_1 := t_1$ and $l_2 := t_2$. By perturbing this configuration, the two double tangent lines will split into four different tangent lines: first, we slightly increase the x_2-coordinate of the line l_2 so that the resulting line l_2' becomes $(0, \beta', 0)^T + \lambda(1, 0, -1)^T$ for some $\beta' > \beta$. In this process, the double tangent t_1 splits into two tangents t_1^a and t_1^b intersecting l_1 and l_2' in different orders; i.e., one of the tangents t_1^a, t_1^b touches l_1, l_2, B_3, and B_4 in the order (B_3, l_1, l_2, B_4) and one of them in the order (B_3, l_2, l_1, B_4). However, the tangent t_2 is still a double zero of the system of polynomials, since the parallel lines t_2 and l_2' intersect in the plane at infinity of $\mathbb{P}^3$.

Similarly, we can make the double tangent t_2 split into two tangents by slightly decreasing the x_2-coordinate of the line l_1; denote the resulting line by l_1'. Figure 3 shows the configuration for l_1' passing through the points $(0, 6.5, 0)^T$, $(2, 6.5, 2)^T$ and l_2' passing through the points $(0, 7.5, 0)^T$, $(2, 7.5, -2)^T$. □

For N_3 the situation is more involved. The Bézout bound gives 16, but, in fact, the number of real common tangents is bounded by 12. Our proof is based on some algebraic-geometric investigations of the common tangents to four unit balls by Macdonald [20]. By appropriately applying these considerations to the situation with three balls and one line, it will turn out that there are always two solutions at infinity with multiplicity at least 2. For the general background on the algebraic and geometric concepts used in the subsequent proofs, easily accessible introductions can be found in [25, 29].

We start with the following observation in [35]. The sphere with center $(c_1, c_2, c_3)^T \in \mathbb{R}^3$ and radius r has the homogeneous equation in $\mathbb{P}^3$

$$(x_1 - c_1x_0)^2 + (x_2 - c_2x_0)^2 + (x_3 - c_3x_0)^2 = r^2x_0^2.$$

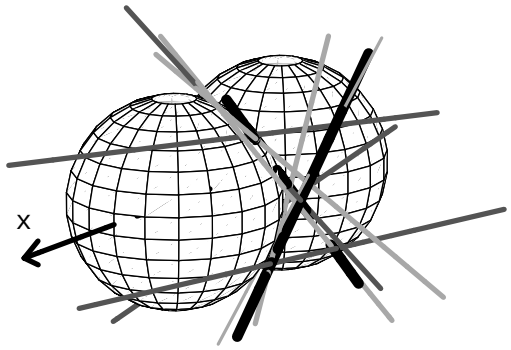

FIG. 3. *Construction with two lines and two balls, leading to eight common tangent lines.*

In the plane at infinity $x_0 = 0$, this gives the equation

$$x_1^2 + x_2^2 + x_3^2 = 0,$$

which is independent of the center and the radius. Let ω denote this conic section in the plane at infinity. Later in the proof, we will work in the space of lines in $\mathbb{P}^3$. In that situation, we will have to consider those tangents through any point $z \in \omega$ in the plane at infinity rather than z itself. For this reason, we provide a characterization of these tangents.

LEMMA 9. *Let $z = (0, \zeta_1, \zeta_2, \zeta_3)^T \in \omega$. The tangent to the conic ω at z which lies in the plane at infinity has Plücker coordinate*

$$(p_{01}, p_{02}, p_{03}, p_{12}, p_{13}, p_{23})^T = (0, 0, 0, \zeta_3, -\zeta_2, \zeta_1)^T.$$

In particular, the tangent contains the points $(0, -\zeta_2, \zeta_1, 0)^T$, $(0, \zeta_3, 0, -\zeta_1)^T$, and $(0, 0, -\zeta_3, \zeta_2)^T$.

Proof. Since $\zeta_0 = 0$ we can compute in projective plane $\mathbb{P}^2$; so let $\overline{z} = (\zeta_1, \zeta_2, \zeta_3)^T$. The conic section

$$x^T A x = 0 \qquad \text{with } A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

is regular in $\overline{z}$ with tangent $\{y = (y_1, y_2, y_3)^T \in \mathbb{P}^2 : \overline{z}^T A y = 0\}$. In particular, $(-\zeta_2, \zeta_1, 0)^T$, $(\zeta_3, 0, -\zeta_1)^T$, $(0, -\zeta_3, \zeta_2)^T$, and $\overline{z}$ itself lie on this tangent. Now any two of these points can be used to compute the Plücker coordinate of the tangent line. □

Consider a configuration with a line l_1 and three spheres Q_2, Q_3, and Q_4 in $\mathbb{R}^3$. The idea for proving the solutions at infinity is to transfer the geometry of ω to the space of lines in $\mathbb{P}^3$. More precisely, let t be a tangent to ω at z in the plane at infinity. Since the quadrics $\wedge^2 Q_2, \wedge^2 Q_3, \wedge^2 Q_4 \in \mathbb{P}^5$ characterize the tangents to Q_2, Q_3, Q_4, the Plücker vector p_t of t is contained in $\wedge^2 Q_2$, $\wedge^2 Q_3$, and $\wedge^2 Q_4$. Let Ω denote the quadric in $\mathbb{P}^5$ defined by the Plücker equation (1). Since t is a line in $\mathbb{P}^3$, t is also contained in Ω. We will show that the tangent hyperplanes to the quadrics $\wedge^2 Q_2$, $\wedge^2 Q_3$, $\wedge^2 Q_4$, Ω at p_t contain a common subspace of dimension 2. In connection with

the linear form defined by the transversals of the line l_1, this will prove the multiplicity of at least 2.

Let us investigate the spheres Q_2, Q_3, Q_4 first. For $i \in \{2,3,4\}$, we are looking for lines whose Plücker vectors lie in the tangent hyperplane of $\wedge^2 Q_i$ at p_t. The geometric concept behind this relation is *polarity*. Recall that the polar plane of a point $a \in \mathbb{P}^n$ with respect to an arbitrary quadric Q is defined by

$$\{y \in \mathbb{P}^n \,:\, a^T Q y = 0\}.$$

If $a \in Q$, then the polar hyperplane is a tangent hyperplane. The polar line of a line $l \in \mathbb{P}^3$ is defined by

$$\{y \in \mathbb{P}^3 \,:\, a^T Q y = 0 \text{ for all } a \in l\}.$$

The following lemma establishes a connection between the tangent hyperplanes to $\wedge^2 Q$ and the concept of polarity for a quadric Q.

LEMMA 10. *Let t be a tangent line to a quadric $Q \subset \mathbb{P}^3$, and let the point $a \in \mathbb{P}^3$ be contained in the polar line of t. Then, for any line l containing a, the Plücker vector p_l of l is contained in the tangent hyperplane to $\wedge^2 Q$ at p_t, i.e., $p_t^T(\wedge^2 Q)p_l = 0$.*

Proof. Let T be a representation of t by a 4×2-matrix as described in section 3. Further, let b be a point on l with $b \neq a$, and let $L = (a, b)$ be a representation of l by a 4×2-matrix. Since a is contained in the polar line of t, we have $T^T Q a = (0,0)^T$. Hence, by reasoning as in Lemma 3, we can conclude

$$p_t^T(\wedge^2 Q)p_l = \det(T^T Q L) = 0. \qquad \square$$

In particular, the following version of a well-known relationship (see, e.g., [25]) shows that the precondition of Lemma 10 is satisfied if $a = t \cap Q$.

LEMMA 11. *If t is tangent to a quadric Q at some point a, then a is contained in the polar line of t.*

Proof. Let $y \neq a$ be a point on t. Since t lies on the polar plane (namely, the tangent plane) of a with respect to Q, we have $a^T Q y = 0$. Since also $a^T Q a = 0$, a lies on the polar line of t with respect to Q. $\square$

Finally, we are ready to prove the upper bound for N_3.

LEMMA 12. $N_3 \leq 12$.

Proof. Let L_1 be the hyperplane (2) in $\mathbb{P}^5$ characterizing the transversals of the line l_1; that is, any point on L_1 which satisfies the Plücker relation is the Plücker coordinate of a transversal to l_1. Let $\wedge^2 Q_2, \wedge^2 Q_3, \wedge^2 Q_4$ be the quadrics (4) characterizing the tangents to the three balls. Further, let $z = (0, \zeta_1, \zeta_2, \zeta_3)^T \in \omega$, and let $\pi \subset \Omega \subset \mathbb{P}^5$ be the set of Plücker vectors whose corresponding lines in $\mathbb{P}^3$ pass through z. π can be written as the image of the projective mapping $h : \mathbb{P}^3 \to \Omega \subset \mathbb{P}^5$,

$$h(y_0, y_1, y_2, y_3) = \wedge^2 \begin{pmatrix} 0 & y_0 \\ \zeta_1 & y_1 \\ \zeta_2 & y_2 \\ \zeta_3 & y_3 \end{pmatrix}.$$

Since h is linear, it follows that π is a two-dimensional plane in $\mathbb{P}^5$ with $\pi \subset \Omega$.

Let t be the tangent to ω at z in the plane at infinity. By Lemmas 11 and 10, π is contained in the tangent hyperplane to $\wedge^2 Q_i$ at p_t, $2 \leq i \leq 4$.

In order to show that π is also contained in the tangent hyperplane to Ω at p_t, let y be a point different from z, and let l be a line through z and y. Then, by Lemma 9, the Plücker vectors p_t and p_l satisfy

$$\begin{aligned} p_t^T \Omega p_l &= (0,0,0,\zeta_3,-\zeta_2,\zeta_1) \cdot \frac{1}{2} \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} -\zeta_1 y_0 \\ -\zeta_2 y_0 \\ -\zeta_3 y_0 \\ \zeta_1 y_2 - \zeta_2 y_1 \\ \zeta_1 y_3 - \zeta_3 y_1 \\ \zeta_2 y_3 - \zeta_3 y_2 \end{pmatrix} \\ &= -\frac{1}{2} y_0 (\zeta_1^2 + \zeta_2^2 + \zeta_3^2) \\ &= 0\,. \end{aligned}$$

Hence, the four tangent hyperplanes of $\wedge^2 Q_2$, $\wedge^2 Q_3$, $\wedge^2 Q_4$, Ω at p_t contain a common subspace of dimension at least 2. By Lemma 9, the tangents to the conic ω lie on a conic $\overline{\omega}$, namely on

$$p_{12}^2 + p_{13}^2 + p_{23}^2 = 0,$$

in the two-dimensional subspace of $\mathbb{P}^5$ given by $p_{01} = p_{02} = p_{03} = 0$. The restriction of the hyperplane L_1 to the subspace $p_{01} = p_{02} = p_{03} = 0$ defines a one-dimensional subspace $\overline{L_1}$. Since $\overline{L_1}$ is one-dimensional, it intersects with $\overline{\omega}$ at two points $b_1, b_2 \in \mathbb{P}^5$ in the plane $p_{01} = p_{02} = p_{03} = 0$. Further, since b_1 and b_2 satisfy the Plücker relation, they are Plücker vectors of some tangents t_1 and t_2 to ω. Altogether, the five tangent hyperplanes of $\wedge^2 Q_2$, $\wedge^2 Q_3$, $\wedge^2 Q_4$, Ω, L_1 at b_1 and b_2 contain a common subspace of dimension at least 1. Hence, the tangent hyperplanes are not independent, which implies that the multiplicity of intersection in b_1 and b_2 is at least 2 (see, e.g., [24, p. 115]). □

In order to show that $N_3 = 12$ it remains to give a construction with one line l_1 and three balls B_2, B_3, B_4 of the same radius r, leading to 12 common tangents. Let l_1 be the x_3-axis, and let the centers c_2, c_3, c_4 of the balls constitute an equilateral triangle with edge length 1 in the x_1x_2-plane, say $c_2 = (\sqrt{3}/3, 0, 0)^T$, $c_3 = (-\sqrt{3}/6, 1/2, 0)^T$, $c_4 = (-\sqrt{3}/6, -1/2, 0)^T$ (see Figure 4). For $1/2 < r < \sqrt{3}/3$, the balls are non-disjoint, and none of them contains the origin.

Let t be a line which intersects l_1, and let H be the plane containing t and l_1. The three cuts $H \cap B_1$, $H \cap B_2$, and $H \cap B_3$ are discs (maybe degenerated to single points or empty sets). Unless H is equidistant to two of the centers, one of these discs is strictly contained in one of the other two. Hence, any common tangent to the line and the three balls lies in one of the three planes which contain the x_3-axis and which are equidistant to two of the centers.

For example, one of these planes is the x_1x_3-plane, which is equidistant to c_2 and c_3. The section through this plane contains two disjoint discs: one representing the (identical) intersections of the plane with B_2 and B_3, and the second one because of B_1. These two discs are separated by the line l_1. Hence, in this plane there are four common tangents. Altogether, since there are three planes of this kind, we have 12 common tangents.

Finally, it remains to analyze the common tangents to four balls (with arbitrary radii) in $\mathbb{R}^3$. Of course, this problem can also be formulated in Plücker coordinates. However, since the solutions of these equations have a common component at infinity

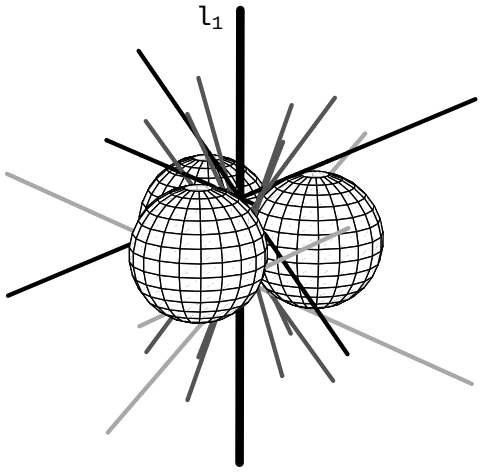

FIG. 4. *Construction with one line and three balls, leading to* 12 *tangents.*

[35], we prefer to compute the number of tangents by an elementary approach. Recently, in [17] the common tangents to four balls have been formulated by polynomial equations with Bézout number 24. We improve this result by giving a polynomial formulation with Bézout number 12; this is optimal by Proposition 1.

The idea for obtaining the system with Bézout bound 12 is to generalize the approach for unit balls in [21]. Note that in the proof we will always refer to the generic case. For this reason—in contrast to Proposition 1—the proof does not provide a precise characterization of the cases with infinitely many common tangent lines.

LEMMA 13. $N_4 \leq 12$.

Proof. Let $c_1, \ldots, c_4$ be affinely independent, and, without loss of generality, let r_4 be the smallest of the radii. We consider functions $\rho_i : [0, r_4] \to \mathbb{R}$ with $\rho_i(0) = 0$, $\rho_i(r_4) = r_i$. Let $\rho_4(t) = t$, while $\rho_i(t)$ for $1 \leq i \leq 3$ will be specified below. First we describe the set of lines which are tangent to the balls $B(c_i, \rho_i(t))$ for $t > 0$.

A line l will be specified by its homogeneous direction vector $s = (s_1, s_2, s_3)^T$ and its closest point p to the origin.

The line l has distance $\rho_i(t)$ from some point c_i if and only if the line $l - p$ (which passes through the origin) has distance $\rho_i(t)$ from $c_i - p$, i.e., if and only if

$$((c_i - p) \times s)^2 = \rho_i^2(t) s^2.$$

Introducing the moment vector $m := p \times s$ and applying Lagrange's identity gives

$$(c_i \times s)^2 - 2\langle c_i, p \rangle s^2 + m^2 - \rho_i^2(t) s^2 = 0. \tag{8}$$

Choosing c_4 to be at the origin and subtracting (8) for index 4 from this equation for index $i \in \{1, 2, 3\}$ yields linear equations in p:

$$\langle c_i, p \rangle = \frac{1}{2s^2}(c_i \times s)^2 - \frac{1}{2}(\rho_i^2(t) - t^2), \qquad 1 \leq i \leq 3. \tag{9}$$

Setting $M := (c_1, c_2, c_3)^T$, we obtain the vector equation

$$p = \frac{1}{2s^2} M^{-1} \begin{pmatrix} (c_1 \times s)^2 \\ (c_2 \times s)^2 \\ (c_3 \times s)^2 \end{pmatrix} - \frac{1}{2} M^{-1} \begin{pmatrix} \rho_1^2(t) - t^2 \\ \rho_2^2(t) - t^2 \\ \rho_3^2(t) - t^2 \end{pmatrix}. \tag{10}$$

Now the key idea is that if we choose parametrizations $\rho_i(t)$ with $\rho_i^2(t) - t^2 = C_i$ for some constants $C_i \in \mathbb{R}$, $1 \le i \le 3$, then the vector p is uniquely determined by the direction vector s. Furthermore, the conditions $\rho_i(r_4) = r_i$ imply $C_i = r_i^2 - r_4^2$; hence, $\rho_i^2(t) = t^2 + (r_i^2 - r_4^2)$. By Cramer's rule,

$$M^{-1} = \frac{1}{6V}(c_2 \times c_3, c_3 \times c_1, c_1 \times c_2),$$

where $V := \det(c_1, c_2, c_3)/6$ denotes the oriented volume of the tetrahedron $c_1c_2c_3c_4$. By introducing the normal vectors

$$n_1 := (c_2 \times c_3)/2, \quad n_2 := (c_3 \times c_1)/2, \quad n_3 := (c_1 \times c_2)/2,$$

and substituting (10) into $\langle p, s\rangle = 0$, we can eliminate p and obtain a homogeneous cubic condition for the direction vector s:

$$\sum_{i=1}^{3} \left((c_i \times s)^2 + s^2(r_i^2 - r_4^2)\right) \langle n_i, s\rangle = 0.$$

Any solution s of this equation is the direction vector of a line with distances $\rho_i(t)$ from the four centers for *some* parameter t. Substituting the radius condition $||p|| = r_4$ into (10) gives an equation of degree 4. Since $\rho_i(r_4) = r_i$, $1 \le i \le 4$, any common solution of the cubic and the quartic equation gives a common tangent to the four balls $B(c_i, r_i)$. By Bézout's theorem, the formulation of the tangent problem by a cubic and a quartic equation implies $N_4 \le 12$. □

5. Conclusion and open questions. We have investigated the enumerative geometry questions for the common tangents to four bodies in $\mathbb{R}^3$ when the bodies are balls or polytopes. These results reflect the algebraic complexity inherent in the mentioned applications. In other words, whenever we want to focus on exact computations for the visibility or envelope problems described in section 2, we have to cope with solving systems of polynomial equations of the stated degrees.

The main open problem is to complete the characterization of the degenerate instances in Table 1. For example, in the case of four balls with arbitrary radii there are some obvious situations with infinitely many common tangent lines: whenever the four centers are collinear and the four balls are inscribed in the same hyperboloid H. We conjecture that there does not exist any configuration with four balls of arbitrary radii, noncollinear centers, and infinitely many common tangent lines. However, we were not able to prove this.

From the practical point of view, actually computing the numerical values of the solutions (which has, e.g., been done in finding the constructions given in this paper) requires either multidimensional numerical methods such as homotopy methods or combinations of symbolic techniques with univariate polynomial solvers. (For an introduction into all these techniques see [9].) Since generally these techniques are still computationally expensive, it is important to apply the most appropriate polynomial formulations of the concrete problems. From this point of view, our results provide optimal formulations. Finally, let us mention that there are many research efforts in improving the efficiency of the two mentioned numerical polynomial solving techniques. In particular, for recent improvements and the state of the art of the first technique see [37], and with regard to the second technique see [4, 5, 13].

Appendix: Standard bases. We review the definitions of a standard basis, starting from Gröbner basis theory (see [9]). The theory of Gröbner bases provides computational methods to find "nice" generators for an ideal I in a polynomial ring $\mathbb{C}[x_1, \ldots, x_n]$. The theory of *standard bases* extends this theory for ideals in local rings. More precisely, let $R_l := \mathbb{C}[x_1, \ldots, x_n]_{\langle x_1, \ldots, x_n \rangle}$ be the set of rational functions f/g in $x_1, \ldots, x_n$ with $g(0, \ldots, 0) \neq 0$. R_l defines a *local* ring; i.e., it contains exactly one maximal ideal. Since the algebraic-geometric definitions of intersection multiplicities are related to the concept of local rings, standard bases provide a powerful tool to effectively compute intersection multiplicities.

From the various possible term orders, we restrict ourselves to considering the *antigraded reverse lexicographical order* (arevlex). For $\alpha, \beta \in \mathbb{N}_0^n$, we have $x^\alpha >_{arevlex} x^\beta$ if and only if

$$\sum_{i=1}^{n} \alpha_i < \sum_{i=1}^{n} \beta_i$$

or

$$\sum_{i=1}^{n} \alpha_i = \sum_{i=1}^{n} \beta_i \quad \text{and} \quad x^\alpha >_{revlex} x^\beta,$$

where $>_{revlex}$ denotes the reverse lexicographical order of Gröbner basis theory. For any polynomial f, the leading term of f, denoted $\mathrm{LT}(f)$, is the maximal term of f with regard to the arevlex-order.

For an ideal I in R_l, the *set of leading terms of* I, abbreviated $\mathrm{LT}(I)$, is the set of leading terms of elements of I.

A *standard basis* of I is a set $\{g_1, \ldots, g_t\} \subset I$ such that $\langle \mathrm{LT}(I) \rangle = \langle \mathrm{LT}(g_1), \ldots, \mathrm{LT}(g_t) \rangle$. Given a set of polynomial generators of I, a standard basis of I can be effectively computed by variants of the Buchberger algorithm.

Acknowledgments. The author would like to thank Abhi Dattasharma for his useful comments and the anonymous referees for their suggestions and for pointing out the issue of envelopes.

QUANTUM CIRCUITS THAT CAN BE SIMULATED CLASSICALLY IN POLYNOMIAL TIME*

LESLIE G. VALIANT†

Abstract. A model of quantum computation based on unitary matrix operations was introduced by Feynman and Deutsch. It has been asked whether the power of this model exceeds that of classical Turing machines. We show here that a significant class of these quantum computations can be simulated classically in polynomial time. In particular we show that two-bit operations characterized by 4×4 matrices in which the sixteen entries obey a set of five polynomial relations can be composed according to certain rules to yield a class of circuits that can be simulated classically in polynomial time. This contrasts with the known universality of two-bit operations and demonstrates that efficient quantum computation of restricted classes is reconcilable with the Polynomial Time Turing Hypothesis. The techniques introduced bring the quantum computational model within the realm of algebraic complexity theory. In a manner consistent with one view of quantum physics, the wave function is simulated deterministically, and randomization arises only in the course of making measurements. The results generalize the quantum model in that they do not require the matrices to be unitary. In a different direction these techniques also yield deterministic polynomial time algorithms for the decision and parity problems for certain classes of read-twice Boolean formulae. All our results are based on the use of gates that are defined in terms of their graph matching properties.

1. Background.

The now classical theory of computational complexity is based on the computational model proposed by Turing [33] augmented in two ways: On the one hand, random operations are often allowed in addition to the originally proposed deterministic ones [24]. On the other hand, the number of computational steps is restricted to be at most polynomial in the input length, which allows such striking phenomena as NP-completeness to be expressed [10]. Taken together, the resulting theory has provided strong circumstantial evidence for the robustness of the resulting model [16]. The following statement is a variant of how this robustness is sometimes expressed and might be called the Polynomial Time Turing Hypothesis:

> *Any physical computing device can be simulated by a randomizing Turing machine that, as the input instances vary, takes a number of steps that grows as at most some fixed polynomial in the quantity $T + S + E$, where T, S, and E are the time, space, and energy used by the computing device.*

While no generally accepted counterexample is known, this hypothesis has, and can be expected to continue to, come under repeated challenge. The fundamental sources of challenge are functions that arise in accepted laws of physics but which are

not known to be polynomial time computable classically. Such a challenge has been recognized since the late 1970s for the matrix permanent (i.e., the determinant with all positive signs). On the one hand, the wave function for indistinguishable bosons can be expressed as a permanent (e.g., [29]). On the other hand, this function is known to be $\#P$-complete [34], or, in other words, as hard as counting the number of solutions of NP-complete problems and therefore at least as hard as the decision question for NP-complete problems. An approach to resolving this particular challenge is proposed by Troyansky and Tishby [32]. The second such source, the one that has received the most attention and is the subject of this paper, is the class of functions that can be computed as compositions of fixed size unitary operations and first discussed in detail by Deutsch [12]. A third source of challenge is the Jones polynomial, as discussed by Freedman [19].

Each of these sources poses a challenge in implying that among the following three statements at least one must be true: (a) the Polynomial Time Turing Hypothesis is false, (b) some physical reason excludes the possibility of a physical device evaluating appropriate instances of the function, or (c) the supposed hard function can be computed classically in polynomial time by a yet undiscovered algorithm. Identifying the statement or statements in such a list that are true would clearly add to our knowledge and offers a valid scientific goal. This paper is concerned with an instance of (c).

The unitary matrix model can be traced to Benioff [2], who observed that classical binary Boolean operations could be formulated as fixed size unitary matrix transformations. Subsequently, Feynman [17] and Deutsch [12] suggested that unitary transformations as realized by quantum devices offer a model of computation that may violate the Polynomial Time Turing Hypothesis and asked whether it did. Bernstein and Vazirani [3] showed how uniformity over all input sizes could be incorporated in the quantum computation model and hence that quantum polynomial time class BQP could be defined. While it is not generally believed that this class contains all of #P or even NP, Shor [30] was able to show that two particular problems, namely integer factorization and discrete logarithms, which are not known to be polynomial time computable, do lie in BQP.

In this model of quantum computation a gate operating on k Boolean bits is represented as a $2^k \times 2^k$ unitary matrix. A unitary matrix U is any matrix with complex number entries such that $UU^{*t} = I$, where I is the identity matrix, U^* is the complex conjugate of U, and U^{*t} is the transpose of U^*. We note, however, that our constructions are all based on general matrix properties in which unitarity plays *no* essential part, and, in that sense, our treatment generalizes the quantum computational model (cf. [18]).

Some basic results on this quantum computational model can be found in [12, 13, 14, 15, 27]. Most notably, it is known that there exist two-bit gates which, in conjunction with arbitrary one-bit gates, can approximate arbitrary unitary matrices. On the other hand, it is easy to see that circuits composed of one-bit gates alone can be simulated deterministically in polynomial time since it is possible to follow the evolution of each bit independently. A more interesting class, where only a discrete set of gates is allowed but following the evolution of a small set of basis operators is sufficient, is attributed to Knill [20].

Our approach can be viewed as a branch of algebraic complexity theory [7, 8, 31, 34] in which computation gates are simulated by graph matching properties. In [34, 35] this approach is developed in the context of the matrix permanent. In the

current paper we use encodings by matrix functions that, in contrast, are known to be polynomial time computable. In particular we use the following three functions: the Pfaffian, the decision problem for matchings, and the parity problem for matchings.

2. Pfaffians. Here we shall describe some standard graph-theoretic notions and their relation to the Pfaffian of a matrix. In the subsequent section we shall introduce a more general notion, that of a Pfaffian Sum. In later sections we shall go on to show that certain quantum circuits can be represented as graphs in such a way that the Pfaffian Sum of the adjacency matrix of the graph corresponds to the basic computational properties of the corresponding circuit. Further, the probability of the circuit evolving from one state to another will be expressible as a Pfaffian Sum.

A weighted undirected graph, or simply a *graph*, G is a triple (V, E, W), where V is a set of *vertices* each represented by a distinct positive integer, E is a set of *edges* or unordered pairs (i, j) of the vertices $i, j \in V$, and W is the set of *weights*, each weight $w(i, j)$ corresponding to the edge $(i, j) \in E$. For example, $V = \{1, 2, 3\}$, $E = \{(1, 2), (2, 3), (1, 3)\}$, $w(1, 2) = w(2, 3) = w(1, 3) = 2$ is the complete graph on three vertices in which every edge has weight 2.

An $n \times n$ matrix C is *skew-symmetric* if for all i, j $(1 \leq i, j \leq n)$ $C(i, j) = -C(j, i)$. The *matrix of the graph* $G = (V, E, W)$ where $V = \{1, 2, \ldots, n\}$ is the $n \times n$ matrix $M(G)$ where the (i, j) entry $M(G)(i, j)$ is defined to equal

(i) $w(i, j)$ if $i < j$,
(ii) $-w(i, j)$ if $i > j$, and
(iii) 0 otherwise.

In the more general case that $V = \{k_1, k_2, \ldots, k_n\}$ where $k_1 < k_2 < \cdots < k_n$, weight $w(k_i, k_j)$ replaces $w(i, j)$ in (i) and (ii) in this definition. For brevity we shall abbreviate $M(G)$ by G whenever it is clear that a matrix is intended.

The Pfaffian of an $n \times n$ skew-symmetric matrix C is defined to be zero if n is odd, one if $n = 0$, and if n is even with $n = 2k$ and $k > 0$ then it is defined as

$$\mathrm{Pf}(C) = \sum_{\pi} \epsilon_\pi w(i_1, i_2) w(i_3, i_4) \ldots w(i_{2k-1}, i_{2k}),$$

where

(i) $\pi = [i_1, i_2, i_3, \ldots, i_{2k}]$ is a permutation on $[1, 2, \ldots, n]$,
(ii) summation is over all such permutations π where further
$i_1 < i_2, i_3 < i_4, \cdots, i_{2k-1} < i_{2k}$, and
$i_1 < i_3 < i_5 < \cdots < i_{2k-1}$, and
(iii) $\epsilon_\pi \in \{-1, 1\}$ is the sign of the permutation; i.e., it is -1 or $+1$ according to whether the number of transpositions or swaps of pairs of distinct elements i_j, i_k needed to reorder π to the identity permutation is odd or even. (An equivalent definition in this context is that it is the sign or parity of the number of overlapping pairs, where a pair of edges (i_{2r-1}, i_{2r}), (i_{2s-1}, i_{2s}) is *overlapping* iff $i_{2r-1} < i_{2s-1} < i_{2r} < i_{2s}$ or $i_{2s-1} < i_{2r-1} < i_{2s} < i_{2r}$. Note that it is implicit here that $i_{2r-1} < i_{2r}$ and $i_{2s-1} < i_{2s}$.)

A *matching* $E^* \subseteq E$ of G is a set of edges such that if (i, j), (r, s) are distinct edges in E^*, then i, j, r, s are all distinct vertices. In a graph with an even number $2k$ of nodes a matching E^* is *perfect* if it contains k edges. (In other words every $i \in V$ is an endpoint of, or is *saturated* by, some edge in E^*.)

We shall use the following graph-theoretic interpretation of the Pfaffian: If C is the matrix of the graph G, then there is a one-on-one correspondence between monomials in the Pfaffian and perfect matchings in G. The monomial $w(i_1, i_2)$

$w(i_3, i_4) \ldots w(i_{2k-1}, i_{2k})$ in $\mathrm{Pf}(G)$ corresponds to the perfect matching $\{(i_1, i_2), (i_3, i_4), \ldots, (i_{2k-1}, i_{2k})\}$ in G. The coefficient ϵ_π of this monomial is the parity of the number of overlapping pairs of edges, in the sense defined above.

The following fact, due to Cayley [9] (see also [5, Theorem 9.5.2]) relates the Pfaffian to the determinant.

THEOREM 1. *For any skew-symmetric matrix C*

$$\mathrm{Det}\,(C) = (\mathrm{Pf}\,(C))^2.$$

It is known that for matrices with elements from any field the complexity of computing the determinant is to within a constant multiplicative factor the same as that of matrix multiplication [31]. Further, for $n \times n$ matrices this cost is known to be upper bounded by $O(n^\alpha)$, where $\alpha < 2.38$ [11]. It follows that the square of the Pfaffian is polynomial time computable, and for complex matrices so is the square of the modulus $|\mathrm{Pf}(C)|^2 = |(\mathrm{Pf}(C))^2|$. Efficient parallel algorithms for these functions also follow from similar results for the determinant [4].

For an $n \times n$ matrix C we call a set $A = \{i_1, i_2, \ldots, i_r\} \subseteq \{1, 2, \ldots, n\}$ an *index set*. Further, we denote by $C[i_1, i_2, \ldots, i_r]$ or $C[A]$ the $(n-r) \times (n-r)$ matrix obtained by deleting the i_jth row and column from C for all the r values of j $(1 \leq j \leq r)$.

The following fact is useful for proving negative results about how the Pfaffians of different submatrices of a matrix constrain each other.

THEOREM 2. *For any skew-symmetric $n \times n$ matrix C and any distinct $i < j < k < l \in \{1, 2, \ldots, n\}$*

$$\begin{aligned}\mathrm{Pf}(C)\mathrm{Pf}(C[i,j,k,l]) &- \mathrm{Pf}(C[i,j])\mathrm{Pf}(C[k,l]) \\ &+ \mathrm{Pf}(C[i,k])\mathrm{Pf}(C[j,l]) - \mathrm{Pf}(C[i,l])\mathrm{Pf}(C[j,k]) = 0\end{aligned}$$

and

$$\begin{aligned}-\mathrm{Pf}(C[j,k,l])\mathrm{Pf}(C[i]) &+ \mathrm{Pf}(C[i,k,l])\mathrm{Pf}(C[j]) \\ &- \mathrm{Pf}(C[i,j,l])\mathrm{Pf}(C[k]) + \mathrm{Pf}(C[i,j,k])\mathrm{Pf}(C[l]) = 0.\end{aligned}$$

Proof. These can be derived from the Grassmann–Plücker identity for Pfaffians [36]. □

3. Pfaffian Sums. We start by defining the notion of a Pfaffian Sum, which expresses the Pfaffian summed over exponentially many minors of a matrix. In graph-theoretic terms the Pfaffian Sum generalizes the Pfaffian in that it has terms not only for the perfect matchings but for matchings of all sizes. This generalization is necessary where we wish to simulate the more general quantum gates. The main result in this section is that the Pfaffian Sum can be expressed in terms of the standard Pfaffian, and its square is therefore also computable in polynomial time.

DEFINITION. *The* Pfaffian Sum *of an $n \times n$ skew-symmetric matrix C is a polynomial over indeterminates $\lambda_1 \ldots \lambda_n$ such that*

$$\mathrm{PfS}(C) = \sum_A \left(\prod_{i \in A} \lambda_i \right) \mathrm{Pf}(C[A]).$$

Summation here is over the various 2^n principal minors obtained from C by deleting some subset A of the indices, including the empty set. In this paper we shall need only the instances in which each λ_i is fixed to be 0 or 1. The i for which $\lambda_i = 0$

can be thought of as the *unomittable* indices and those with $\lambda_i = 1$ as the *omittable* indices. Then for this $(0,1)$-*case* the Pfaffian Sum is simply the sum of the $\mathrm{Pf}(C[A])$ over those A that contain only omittable indices. This is the only case that we shall use.

We note that one can similarly define a *Determinant Sum*

$$\mathrm{DetS}(C) = \sum_A \left(\prod_{i \in A} \lambda_i \right) \mathrm{Det}\,(C[A]).$$

It is easy to verify that for any matrix C

$$\mathrm{DetS}(C) = \mathrm{Det}\,(C + \Delta),$$

where $\Delta(i,j) = 0$ if $i \neq j$, and $\Delta(i,i) = \lambda_i$ for every i. Thus a summed determinant is as easy to compute as a single determinant. We shall now show that the same holds for the Pfaffian. We define the $n \times n$ matrix $\Lambda^{(n)}$ as follows:

$$\Lambda^{(n)}(i,j) = \begin{cases} (-1)^{j-i+1}\lambda_i\lambda_j & \text{if} \quad i < j, \\ (-1)^{i-j}\lambda_i\lambda_j & \text{if} \quad i > j, \\ 0 & \text{if} \quad i = j. \end{cases}$$

Also for an $n \times n$ matrix C we define C^+ to be the $(n+1) \times (n+1)$ matrix of which the first n rows and columns equal C itself, and the $(n+1)$st row and column entries are all zero.

Pfaffian Sum Theorem. *For an $n \times n$ skew-symmetric matrix C*

$$\mathrm{PfS}(C) = \begin{cases} \mathrm{Pf}(C + \Lambda^{(n)}) & \textit{if} \quad n \quad \textit{is even,} \\ \mathrm{Pf}(C^+ + \Lambda^{(n+1)}) & \textit{with } \lambda_{n+1} \textit{ set to } 1, \quad \textit{if } n \quad \textit{is odd.} \end{cases}$$

Lieb [25] gave a proof for the instance of this relationship in which the λ_i are equal for all i, and n is even. One can derive our result from that instance. We shall, however, give a direct proof of this fact that makes the associated combinatorial structures more explicit.

Lemma 1. *If matrix C' is obtained from skew-symmetric matrix C by first interchanging the elements of rows i and j, and then interchanging the elements of columns i and j, then* $\mathrm{Pf}(C) = -\mathrm{Pf}(C')$.

Proof. The specified matrix operation clearly leaves the determinant function unchanged. By Theorem 1 it follows that the operation either leaves the Pfaffian invariant or multiplies it by -1. Assume without loss of generality that $i < j$. Then each monomial in $\mathrm{Pf}(C)$ that contains $C(i,j)$ as a factor will have an identical monomial in $\mathrm{Pf}(C')$ except that the latter will contain $C'(i,j)$, where $C'(i,j) = -C'(j,i) = -C(i,j)$. Therefore at least some terms in $\mathrm{Pf}(C)$ and $\mathrm{Pf}(C')$ have opposite signs, and it follows that they all must have opposite signs. □

Lemma 2. *If skew-symmetric matrices C, C' are identical except that for some $i \in \{1, 2, \ldots, n\}$ for all j $C(i,j) = -C'(i,j)$ and $C(j,i) = -C'(j,i)$, then* $\mathrm{Pf}(C) = -\mathrm{Pf}(C')$.

Proof. The monomials of $\mathrm{Pf}(C)$, $\mathrm{Pf}(C')$ can be paired so that they are identical except that they contain one factor $C(k,i)$ or $C'(k,i)$, respectively, or one factor of $C(i,k)$ or $C'(i,k)$, respectively, for some k. In either case the two factors will have opposite signs by assumption, and hence so will the monomials. □

LEMMA 3. *Let $\Lambda^{(n)}$ be the $n \times n$ skew-symmetric matrix defined above with n even. Then*

$$\mathrm{Pf}(\Lambda^{(n)}) = \lambda_1 \ldots \lambda_n.$$

Proof. We prove this by induction on even values of n. Clearly $\mathrm{Pf}(\Lambda^{(2)}) = \lambda_1\lambda_2$. Now assume that the result holds for some even $n-2$. Consider the monomials in the expansion for $\Lambda^{(n)}$. In all the monomials that contain the element $\Lambda^{(n)}(n-1,n) = \lambda_{n-1}\lambda_n$ the complementary factors clearly sum to $\Lambda^{(n-2)}$, which by induction equals $\lambda_1 \ldots \lambda_{n-2}$. It is therefore sufficient to observe that all the other monomials in $\Lambda^{(n)}$ cancel in pairs: Any such other monomial contains a product $\Lambda^{(n)}\ (i,n-1)\Lambda^{(n)}(j,n)$ and has a companion monomial that is identical except that this product is replaced by $\Lambda^{(n)}(i,n)\Lambda^{(n)}(j,n-1)$, which is equal in value but gives rise to the opposite sign because of the extra transposition $(n-1,n)$. □

Proof of theorem. First we assume that n is even. For some fixed $A \subseteq \{1,\ldots,n\}$ consider the monomial set N of $\mathrm{Pf}(C + \Lambda^{(n)})$ that involve λ elements in all rows and columns indexed by A, and involve C elements in the remaining rows and columns. We claim that the monomials in N sum to

$$\mathrm{Pf}(C[A])\mathrm{Pf}(\Lambda^{(A)}), \tag{1}$$

where $\Lambda^{(A)}$ is the $\Lambda^{|A|}$ matrix in which for each λ_i there has been substituted the indeterminate λ_j, where j is the ith smallest element of A. By applying Lemma 3 to the second term here and summing over all choices of A, the theorem then follows.

To establish this claim we consider a sequence of σ transpositions or swaps on the indices (i.e., row and column numbers) of the original matrix that results in the indices A migrating to $n-|A|+1$, $n-|A|+2,\ldots,n$, and an accompanying process of sign changes to the elements described below. We claim that the following hold for every A:

(a) The sequence of transpositions and sign changes to the elements causes all monomials in N to remain unchanged in sign in the Pfaffian.
(b) The matrix that is the outcome of the process has the C entries in the first $n-|A|$ rows/columns and these contribute a multiplicand of $\mathrm{Pf}(C([A])$ (with positive sign) to the sum of N.
(c) The matrix that is the outcome of the process has the λ entries in the last $|A|$ rows/columns and these contribute a multiplicand of $\mathrm{Pf}(\Lambda^{(A)})$ to the sum of N.

The conjunction of these three claims clearly implies that the quantity (1) above equals the original sum of N as needed.

For (a) we note that by Lemma 1 the number of sign changes to the Pfaffian, and hence the monomials in N, caused by σ transpositions is $(-1)^\sigma$, and we shall observe below that the effect of the sign changes to be specified to the elements is a compensatory $(-1)^\sigma$ factor. Claim (b) is true by the definition of $\mathrm{Pf}(C[A])$. With regard to (c) we first observe that while the elements $\Lambda^{(n)}(i,j)$ and hence $\Lambda^{(A)}(i,j)$ alternate in sign as j varies and i is fixed, this is not necessarily the case for the pattern of the λ entries that contribute to N in the matrix *before* the transpositions. For example, entries in adjacent columns after the transpositions will have the same sign if the indices of the columns before the transpositions differ by an even number. It will be useful to consider the particular sequence of transpositions where the largest indices in A are moved up to fill the positions $n, n-1,\ldots,n-|A|+1$, in this order, and each one is moved by a succession of $(i,i+1)$ transpositions. Clearly the number

of such transpositions has the same parity as the number of indices that need to be moved by an odd number of such neighbor transpositions. However, the indices j that need an odd number of such transpositions to reach their destination are exactly those for which the signs of the entries are different from those of the entries of $\Lambda^{(n)}$ in the destination row/column. What we consider, therefore, is the process in which for just these indices we will change the sign of all the entries in that row and column in the course of moving it. The effect of these sign changes to the elements in a row and column is, by Lemma 2, to change the sign of the Pfaffian. We conclude that this process of transpositions and sign changes would result in the λ_i entries having moved to the $|A|$ highest indices, forming a $\Lambda^{(A)}$ matrix there, as required for claim (c), and that the effect of the sign changes on the monomial set N in the Pfaffian is a compensatory $(-1)^\sigma$ factor as required for claim (a).

Now we consider the case that n is odd. Since $n+1$ is now even it is clear from the previous analysis that $\mathrm{Pf}(C^+ + \Lambda^{(n+1)})$ will again equal the Pfaffian Sum, but now summation can be restricted to those A that contain n since otherwise the $\mathrm{Pf}(C^+[A])$ contribution vanishes. Hence this Pfaffian sum is equal to that of the original C if λ_{n+1} is set to 1. □

4. Matchgates. We shall simulate each quantum or other gate by what we call a matchgate.

A *matchgate* Γ is a quadruple (G, X, Y, T), where G is a graph (V, E, W), $X \subseteq V$ is a set of *input* vertices, $Y \subseteq V$ is a set of *output* vertices, and $T \subseteq V$ is a set of *omittable* vertices such that (i) X, Y, and T are all disjoint, and (ii) for all $i \in T$, if $j \in X$, then $j < i$ and if $j \in Y$, then $j > i$.

The matchings we consider will be those that saturate all the unomittable nodes, i.e., $V - T$, and also some, possibly empty, subset of T. Whenever we refer to the Pfaffian Sum of a matchgate fragment, such as G' below, we shall assume the substitutions $\lambda_i = 1$ if $i \in T$ and $\lambda_i = 0$ otherwise.

We call $X \cup Y$ the *external* nodes. For $Z \subseteq X \cup Y$ we define the *character* $\chi(\Gamma, Z)$ of Γ with respect to Z to be the product

$$\mu(\Gamma, Z)\mathrm{PfS}(G'),$$

where (a) $G' = (V - Z, E', W')$, where further E' is the restriction of E to edges with both endpoints in $V - Z$, and W' is the corresponding restriction of W, and (b) the *modifier* $\mu(\Gamma, Z) \in \{-1, 1\}$ counts the parity of the number of overlaps between matching edges in E' and external edges. The external edges are the edges that link each matchgate to the rest of the circuit. We consider there to exist one external edge from each node in $X \cap Z$ and from each node in $Y \cap Z$. The other endpoint of each of the former is some node of lower index than any in V and of each of the latter is some node of index higher than any in V. Figure 1 gives an illustrative example.

The character $\chi(\Gamma, Z)$, therefore, takes into account overlaps between the internal edges of matchgate Γ and the external edges that link its external nodes to the rest of the circuit. The significance of condition (ii) in the definition of matchgates is that it guarantees that the modifier $\mu(\Gamma, Z)$ is always well defined: for any fixed Z the external edges that arise are uniquely defined, but it has to be guaranteed that the parity of the overlap of any one such external edge with *every* matching of E' that saturates all the unomittable nodes is the same. Condition (ii) achieves this by not allowing an omittable node in the gate to be numbered intermediate between the endpoints of an external edge. (That case might produce different overlap parity for the given external edge and the various internal matchings depending on whether the

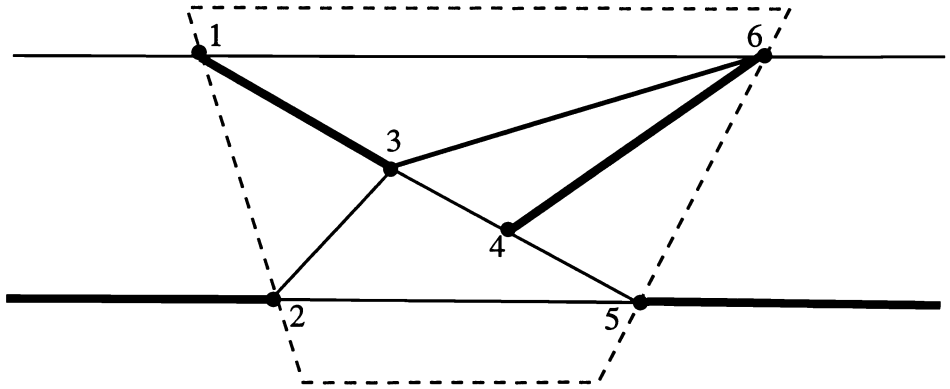

FIG. 1. *Illustration of a matchgate Γ with inputs $X = \{1, 2\}$ and outputs $Y = \{5, 6\}$, with the external nodes $Z = \{2, 5\}$ matched. The character $\chi(\Gamma, Z)$ is the product of the modifier $\mu(\Gamma, Z)$ and of the Pfaffian Sum of the matchgate after nodes Z have been removed. Now $\mu(\Gamma, Z) = 1$ since the externally matched edges (i.e., those from nodes 2 and 5) overlap exactly twice with the internally matched edges, whether the edges $\{1, 3\}$ and $\{4, 6\}$ as shown in this example, or any alternative ones, such as $\{1, 6\}, \{3, 4\}$.*

omittable node was in the matching.) To verify this note that if for $i \in X \cap Z$ there are r nodes $j < i$ where $j \in V - Z$, then the parity of the overlap of the external edge from i with the internal edges is the parity of r.

We define the character matrix $\chi(\Gamma)$ of $\Gamma = (G, X, Y, T)$ as a $2^{|X|} \times 2^{|Y|}$ matrix where the rows represent the subsets of the inputs X, and the columns the subsets of the outputs Y, and the entries the corresponding values of $\chi(\Gamma, Z)$ for the various choices of Z. Matchgates with $|X| = |Y| = k$ can then be regarded as square matrix transformations defined by the character matrix. For example, $k = 1$ corresponds to one-bit 2×2 matrix transformations and $k = 2$ corresponds to two-bit 4×4 transformations. In all cases we need to specify a correspondence between subsets of X and the rows of the matrix and another correspondence between subsets of Y and the columns of the matrix. We insist that there is the following consistency between the row and column orderings. We assume that there is a bijection f that maps the elements of X to elements of Y such that if the ith row corresponds to subset X' of X and the ith column to subset Y' of Y, then Y' is the image of X' under f. The *character matrix* $\chi(\Gamma)$ is therefore defined as a matrix of the elements $\chi(\Gamma, Z)$ with some such consistent row/column ordering.

The character matrix defines a linear transformation from linear combinations of the $2^{|X|}$ components $\underline{x} \in \{0, 1\}^{|X|}$ to linear combinations of the $2^{|Y|}$ components $\underline{y} \in \{0, 1\}^{|Y|}$. The character matrix can also be thought of as determining the nondeterministic steps allowed by a matchgate. If vector $\underline{x} \in \{0, 1\}^{|X|}$ is specified for the bits of X, then for each possible $\underline{y} \in \{0, 1\}^{|Y|}$ the corresponding element in the $2^{|I|} \times 2^{|Y|}$ character matrix gives the *value* to be associated with nondeterministic output $\underline{y}$ for input $\underline{x}$. The overall computations of the circuits composed of these matchgates are like counting Turing machines [34] or quantum computations [3, 13] in that values may be multiplied over the steps of individual nondeterministic computation branches and then added over all possible branches to obtain the numerical value of the computation.

First we shall show that all one-bit or 2×2 matrix transformations can be simulated by matchgates.

PROPOSITION 1. *For any field F and any 2×2 matrix B of elements from F there exists a four node matchgate Γ with weights drawn from F such that $\chi(\Gamma) = B$.*

Proof. Consider the matchgate (G, X, Y, T), where G is the complete graph on nodes $V = \{1, 2, 3, 4\}$, $X = \{1\}$, $Y = \{4\}$, $T = \{2\}$, and W is as variously specified below.

We shall identify row 1 of the matrix with $\emptyset$ and row 2 with $\{1\}$. Similarly we identify column 1 with $\emptyset$ and column 2 with $\{4\}$. Let us abbreviate $B(1,1) = a$, $B(1,2) = b$, $B(2,1) = c$, and $B(2,2) = d$. Now it is immediate from the definitions that the modifier is always 1 since in this case external edges cannot overlap with internal ones. The character is simply the (0,1)-Pfaffian Sum for the gate with the external nodes corresponding to the variables set to 1 removed and with T as the omittable nodes. In particular,

$\chi(\Gamma, \emptyset) = w(2,3)w(1,4) - w(1,3)w(2,4) + w(1,2)w(3,4)$,
$\chi(\Gamma, \{1\}) = w(3,4)$,
$\chi(\Gamma, \{4\}) = w(1,3)$, and
$\chi(\Gamma, \{1,4\}) = w(2,3)$.

Each of these statements can be verified by inspection. For example, in the second of these, since one of the four nodes, namely node 1, is matched externally, and there is one omittable node, namely 2, in the matchgate, the only matching is the one that involves the remaining two nodes, namely $\{3, 4\}$.

First suppose that at least one of b, c, or d is nonzero. Then by fixing $w(1,3) = b$, $w(3,4) = c$, $w(2,3) = d$, and setting the remaining weights so that $-bw(2,4) + cw(1,2) + dw(1,4) = a$, the four components of B can be set to the arbitrary values a, b, c, and d as desired.

In the special case that $b = c = d = 0$ we consider the same matchgate but make $T = \emptyset$. Then setting $w(2,3) = 0$ ensures that $b = c = d = 0$. The expression for $\chi(\Gamma, \emptyset)$ is unchanged and therefore by setting the remaining weights one can set $B(1,1)$ to the arbitrary value of a. □

To model two-bit or 4×4 matrices we consider two-bit matchgates, i.e., where $|X| = 2$, $|Y| = 2$. The characters of these can be viewed as above, with the rows representing subsets of X and the columns subsets of Y.

PROPOSITION 2. *For any field F and any 4×4 matrix B of elements from F where all the off diagonal elements are zero and $B(1,1)B(4,4) = B(2,2)B(3,3)$ there exists a matchgate Γ with weights drawn from F such that $\chi(\Gamma) = B$.*

Proof. Consider $V = \{1, 2, 3, 4, 5, 6\}$, $X = \{1, 2\}$, $Y = \{5, 6\}$, and $T = \emptyset$. The rows of the matrices have ordering $\emptyset$, $\{1\}$, $\{2\}$, $\{1, 2\}$, and the columns have ordering $\emptyset$, $\{6\}$, $\{5\}$, $\{5, 6\}$.

First suppose that $B(4,4) \neq 0$. Then let the only nonzero weights be $w(1,6) = B(3,3)/B(4,4)$, $w(2,5) = B(2,2)/B(4,4)$, and $w(3,4) = B(4,4)$. It can be verified that this matchgate has the required character.

If $B(4,4) = 0$, then we have various special cases: (a) $w(1,6)$, $w(2,3)$, $w(4,5) \neq 0$ solves the case $B(1,1) \neq 0$, $B(2,2) \neq 0$, $B(3,3) = 0$, $B(4,4) = 0$. (b) $w(2,5)$, $w(1,3)$, $w(4,6) \neq 0$ solves the case $B(1,1) \neq 0$, $B(2,2) = 0$, $B(3,3) \neq 0$, $B(4,4) = 0$. (c) $w(2,3)$, $w(4,5) \neq 0$ solves the case $B(1,1) = 0$, $B(2,2) \neq 0$, $B(3,3) = 0$, $B(4,4) = 0$. (d) $w(1,3)$, $w(4,6) \neq 0$ solves the case $B(1,1) = 0$, $B(2,2) = 0$, $B(3,3) \neq 0$, $B(4,4) = 0$. To solve the remaining case of $B(1,1) \neq 0$, $B(2,2) = 0$, $B(3,3) = 0$, $B(4,4) = 0$ we can consider the eight node matchgate with $X = \{1, 2\}$, $Y = \{7, 8\}$,

and nonzero edges $w(1,3)$, $w(2,4)$, $w(5,7)$, and $w(6,8)$. □

We now turn to more general 4×4 matrices.

PROPOSITION 3. *For any field F and any 4×4 matrix B of elements from F satisfying the nine equations $B(1,2) = B(1,3) = B(2,1) = B(2,4) = B(3,1) = B(3,4) = B(4,2) = B(4,3) = 0$, and $B(1,1)B(4,4) - B(2,2)B(3,3) = B(1,4)B(4,1) - B(2,3)B(3,2)$, there exists a matchgate Γ with weights drawn from F such that $\chi(\Gamma) = B$, provided $B(4,4) \neq 0$.*

Proof. Consider $V = \{1,2,3,4,5,6\}$, $X = \{1,2\}$, $Y = \{5,6\}$, $T = \emptyset$, and row/column ordering as in Proposition 2. We let $t = 1/B(4,4)$ and consider the following set of nonzero weights: $w(1,6) = tB(3,3)$, $w(2,5) = tB(2,2)$, $w(1,2) = tB(1,4)$, $w(5,6) = tB(4,1)$, $w(1,5) = -tB(3,2)$, $w(2,6) = -tB(2,3)$, $w(3,4) = B(4,4)$. □

Now consider the following set of what we call the *matchgate identities* for 4×4 character matrices:

$$
\begin{aligned}
&B(1,1)B(4,4) - B(2,2)B(3,3) - B(1,4)B(4,1) + B(2,3)B(3,2) = 0\\
&B(2,1)B(4,4) - B(2,2)B(4,3) - B(4,1)B(2,4) + B(2,3)B(4,2) = 0\\
&B(3,1)B(4,4) + B(3,3)B(4,2) - B(4,1)B(3,4) - B(3,2)B(4,3) = 0\\
&B(1,3)B(4,4) + B(3,3)B(2,4) - B(1,4)B(4,3) - B(2,3)B(3,4) = 0\\
&B(1,2)B(4,4) - B(2,2)B(3,4) - B(1,4)B(4,2) + B(3,2)B(2,4) = 0
\end{aligned}
$$

PROPOSITION 4. *For any field F and any set of values of the 11 entries of the 4×4 matrix B other than $R = \{B(1,1), B(1,2), B(1,3), B(2,1), B(3,1)\}$ such that $B(4,4) \neq 0$, there exists a matchgate Γ with weights drawn from F such that $\chi(\Gamma)$ equals B in the 11 entries other than R, and in each of the R entries $\chi(\Gamma)$ equals various polynomials in terms of these other 11 entries and $1/B(4,4)$. In particular, $B = \chi(\Gamma)$ satisfies the five matchgate identities.*

Proof. Consider the matchgate of Proposition 3 but modify it by making $T = \{4\}$ and adding four more nonzero edge weights: $w(1,3) = -B(3,4)$, $w(2,3) = B(2,4)$, $w(3,5) = B(4,2)$, $w(3,6) = -B(4,3)$. This is illustrated in Figure 2.

By inspection, for any $Z \subseteq X \cup Y$ one can write down $\chi(\Gamma, Z)$: If $\mid Z \mid$ is even, then all the matchings that contribute to $\chi(\Gamma, Z)$ saturate the omittable node 4 and do so necessarily with edge $\{3,4\}$. Hence this case reverts back to Proposition 3 since the newly added edges are all incident to node 3 and can, therefore, play no part. Hence in the corresponding eight positions in B we can regard seven as being arbitrary, and the eighth, namely $B(1,1)$, as being constrained by the first matchgate relation in terms of the other seven exactly, as in Proposition 3, since $B[4,4] \neq 0$.

We now consider the eight entries of $\chi(\Gamma, Z)$, where $|Z|$ is odd. By inspecting Figure 1 and recalling the definition of $\chi(\Gamma, Z)$ we obtain immediately that

$$
\begin{aligned}
&\chi(\Gamma, \{2,5,6\}) = B(3,4),\\
&\chi(\Gamma, \{1,5,6\}) = B(2,4),\\
&\chi(\Gamma, \{1,2,6\}) = B(4,2),\\
&\chi(\Gamma, \{1,2,5\}) = B(4,3),\\
&\chi(\Gamma, \{1\}) = tB(2,2)B(4,3) + tB(4,1)B(2,4) - tB(2,3)B(4,2),\\
&\chi(\Gamma, \{2\}) = -tB(3,3)B(4,2) + tB(4,1)B(3,4) + tB(3,2)B(4,3),\\
&\chi(\Gamma, \{5\}) = -tB(3,3)B(2,4) + tB(1,4)B(4,3) + tB(2,3)B(3,4),\\
&\chi(\Gamma, \{6\}) = tB(2,2)B(3,4) + tB(1,4)B(4,2) - tB(3,2)B(2,4).
\end{aligned}
$$

The first equality states simply that the arbitrary chosen value $B(3,4)$ is in fact the value of the character $\chi(\Gamma, \{2,5,6\})$ for the given matchgate, exactly as desired.

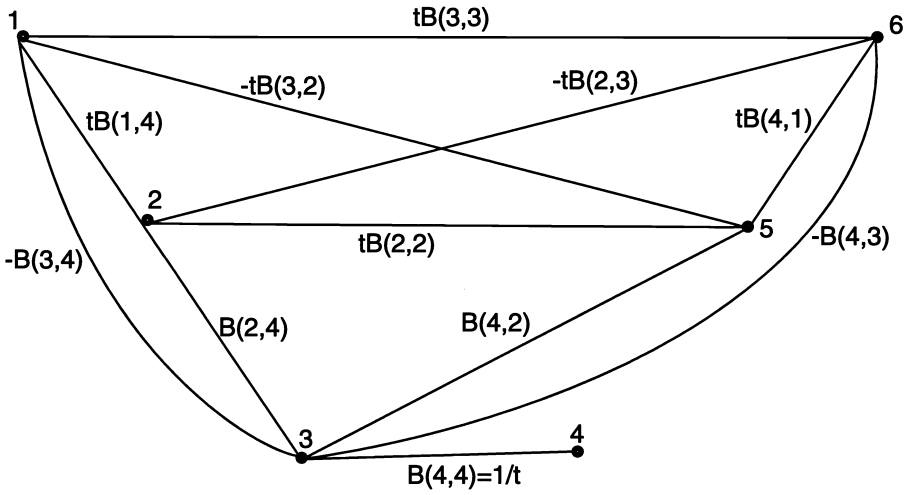

FIG. 2. *A matchgate with inputs* $\{1,2\}$ *and outputs* $\{5,6\}$*, designed to have character that equals the given matrix* B *in* 11 *of the* 16 *entries, as required by Proposition* 4. *The quantity* t *denotes* $1/B(4,4)$.

The same holds for $B(2,4), B(4,2)$, and $B(4,3)$. Hence, in addition to the seven entries in the character that we said could be fixed arbitrarily, here are a further four.

The last four statements describe the remaining four entries of the character in terms of the 11 arbitrarily fixed, and of $B(4,4)$, which, as we saw, is constrained by the first matchgate identity. These four statements assert nothing other than that if $B(2,1), B(3,1), B(1,3)$, and $B(1,2)$ do equal the corresponding character entries of the specified matchgate, then these quantities obey the last four matchgate identities, respectively. □

A related question is to characterize the subclass of the feasible character matrices that are also unitary. For matrices in which the only nonzero entries are those appearing in the first matchgate identity this is easy. We note that in that case restricting the matrix to rows/columns $\{1,4\}$ imposes a unitary constraint on the four remaining elements, as does the restriction to rows/columns $\{2,3\}$. However, unitary 2×2 matrices can be written as [5]

$$e^{i\alpha} \begin{bmatrix} e^{-i\beta/2} & 0 \\ 0 & e^{i\beta/2} \end{bmatrix} \begin{bmatrix} \cos\gamma/2 & -\sin\gamma/2 \\ \sin\gamma/2 & \cos\gamma/2 \end{bmatrix} \begin{bmatrix} e^{-i\delta/2} & 0 \\ 0 & e^{i\delta/2} \end{bmatrix}, \tag{2}$$

where $\alpha, \beta, \gamma, \delta$ are real valued. In other words the 2×2 matrix with elements $B(1,1), B(4,1), B(1,4), B(4,4)$ can be written in this form with appropriate $\alpha_1, \beta_2, \gamma_1, \delta_1$, as can the 2×2 with elements $B(2,2), B(2,3), B(3,2), B(3,3)$ for appropriate $\alpha_2, \beta_2, \gamma_2, \delta_2$. However, the first matchgate identity is equivalent to saying that the difference of the determinants of these two 2×2 matrices is zero. However, the determinant of the expression (2) is $e^{i\alpha}$. It follows that, except for the restriction that $e^{i\alpha_1} - e^{i\alpha_2} = 0$, and $B(4,4) \neq 0$, the space of matchgate character matrices is spanned as the values of $\alpha_1, \beta_1, \gamma_1, \delta_1, \alpha_2, \beta_2, \gamma_2$, and δ_2 range over the reals.

THEOREM 3. *Given any matchgate Γ there exists another matchgate Γ' that has the same character as Γ and has an even number of nodes, exactly one of which is omittable.*

Proof. Suppose $\Gamma = (G, X, Y, T)$, where $G = (V, E)$. We can assume that $\mid V \mid$ is odd, since otherwise we can add an omittable node with no incident edges. Suppose $X = \{i_1, \ldots, i_r\}$ and $Y = \{j_1, \ldots, j_s\}$. Then $\Gamma' = (G', X', Y', T')$, where $G' = (V', E')$ and $\mid V' \mid = \mid V \mid +1$ is obtained as follows via a graph G'':

(i) G'' is isomorphic to G except that it has an extra omittable node with index j_1 with no incident edges. The nodes $1, \ldots, j_1 - 1$ in G'' correspond to the same indices in G, while nodes $j_1 + 1, \ldots, \mid V \mid +1$ correspond to $j_1, \ldots, \mid V \mid$ in G, respectively.

(ii) G' is the graph whose matrix is the sum of the matrix of G'' plus $\Lambda^{(n)}$ as defined in the Pfaffian Sum theorem, where $n = \mid V' \mid = \mid V \mid + 1$. Here $\lambda_i = 1$ iff i is omittable in Γ or if $i = j_1$, and otherwise $\lambda_i = 0$.

(iii) $\Gamma' = (G', X', Y', T')$, where $X' = \{i_1, \ldots, i_r\}$, $Y' = \{j_1 + 1, \ldots, j_s + 1\}$, and $T' = \{j_1\}$.

Now for any $Z \subseteq X \cup Y$ there is a $Z' \subseteq X' \cup Y'$ for the corresponding set of nodes in G'. The theorem asserts for all such corresponding pairs Z, Z' that

$$\mu(\Gamma, Z)\mathrm{PfS}(G - Z) = \mu(\Gamma', Z')\mathrm{PfS}(G' - Z').$$

Now $\mu(\Gamma, Z) = \mu(\Gamma', Z')$ clearly. Also it is immediate that $\mathrm{PfS}(G - Z) = \mathrm{PfS}(G'' - Z')$ since the only difference between $G - Z$ and $G'' - Z'$ is that the latter graph contains an additional omittable node with no incident edges. It, therefore, remains to verify that $\mathrm{PfS}(G'' - Z') = \mathrm{PfS}(G' - Z')$. Now $\mid V' - Z' \mid$ is either even or odd, and we claim that in either case the necessary equality is an instance of the Pfaffian Sum theorem. The important observation is that all the omittable nodes in G'' have indices k in the range $i_r < k \leq j_1$. Hence we can think of $G' - Z'$ as being obtained from $G'' - Z'$ by the addition of a Λ matrix for the indices $i_r + 1, i_r + 2, \ldots, j_1$, the entries being zero where any row or column is outside this range. It follows that independent of the choice of Z' we can appeal directly to the Pfaffian Sum theorem to verify the equality that $\mathrm{PfS}(G'' - Z') = \mathrm{PfS}(G' - Z')$: In the case that $\mid Z' \mid$, and hence $\mid G'' - Z' \mid$ also, is even the claim follows by the first case of the Pfaffian Sum theorem, since then $\mathrm{PfS}(G'' - Z') = \mathrm{Pf}(G' - Z') = \mathrm{PfS}(G' - Z')$. Where $\mid Z' \mid$, and hence $\mid G'' - Z' \mid$ also, is odd we note that the contributions to $\mathrm{PfS}(G'' - Z')$ all have node j_1 omitted (since it has no incident edges). Now since the added Λ matrix has nonzero entries for (k, l) only where $k, l \leq j_1$ the effect of adding Λ to $G'' - Z' - \{j_1\}$ is, again by the first case of the Pfaffian Sum theorem, to make $\mathrm{PfS}(G'' - Z')$ equal $\mathrm{Pf}(G' - Z' - \{j_1\}) = \mathrm{PfS}(G' - Z')$. □

The following is proved in [36] and shows that Proposition 4 is essentially optimal. The only gap is that Proposition 4 assumes that $B[4, 4] \neq 0$.

THEOREM 4. *Suppose that for a matchgate Γ with inputs $X = \{i, j\}$ and outputs $\{k, l\}$ with $i < j < k < l$, B is the character matrix for row ordering $\phi, \{i\}, \{j\}, \{i, j\}$ and column ordering $\phi, \{l\}, \{k\}, \{k, l\}$. Then B obeys the five matchgate identities.*

We conclude this section by observing that there is an alternative approach to designing matchgates with desired characters. In this approach one considers matrices that differ from the identity by a multiple of an infinitesimal quantity ϵ. Such matrices have been used to investigate universal quantum gates [14, 15]. In particular, we define the class $\{J_{\alpha\beta} \mid 1 \leq \alpha, \beta \leq 4\}$ of 4×4 matrices with $\{0, 1\}$ entries as follows:

$$J_{\alpha\beta}(i, j) = \delta_{i\alpha}\delta_{j\beta}, \qquad 1 \leq \alpha, \beta, i, j \leq 4,$$

where $\delta_{rs} = 1$ iff $r = s$, and $\delta_{rs} = 0$ otherwise. Clearly each $J_{\alpha\beta}$ has a unit entry at (α, β) and a zero entry elsewhere.

We now define three vector spaces of 4×4 matrices where the a_i are complex numbers:

X1: $a_1 J_{11} + a_2 J_{22} + a_3 J_{33} + (a_2 + a_3 - a_1) J_{44}$.

X2: $J + a_4 J_{23} + a_5 J_{32} + a_6 J_{14} + a_7 J_{41}$, where $J \in$ X1.

X3: $J + a_8(J_{21} + J_{43}) + a_9(J_{12} + J_{34}) + a_{10}(J_{31} - J_{42}) + a_{11}(J_{13} - J_{24})$, where $J \in$ X2.

PROPOSITION 5. *There is a set of* 11 *matchgates whose characters are* $I + \epsilon B_i$ *for* $i = 1, 2, \ldots, 11$, *where* $B_1, \ldots, B_{11}$ *span* X3.

Proof. We enumerate 11 matrices B_i for $i = 1, 2, \ldots, 11$ that span the space X3. In each case we show how to construct a matchgate with character $I + \epsilon B_i$, where ϵ is an infinitesimal indeterminate. In our listing we first describe the matrix B_i such that the character of the matchgate is $I + \epsilon B_i$, and then list all the nonzero weights in the matchgate.

The first six all have $V = \{1, 2, 3, 4\}$, $X = \{1, 2\}$, $Y = \{3, 4\}$, and $T = \emptyset$. The rows of the matrices have ordering $\emptyset$, $\{1\}$, $\{2\}$, $\{1, 2\}$, and the columns have ordering $\emptyset$, $\{4\}$, $\{3\}$, $\{3, 4\}$.

(i) $J_{11} + J_{22}$: $w(1,4) = 1, \quad w(2,3) = 1 + \epsilon$.

(ii) $J_{11} + J_{33}$: $w(1,4) = 1 + \epsilon, \quad w(2,3) = 1$.

(iii) $J_{11} + J_{22} + J_{32}$: $w(1,4) = 1, \quad w(2,3) = 1 + \epsilon, \quad w(1,3) = -\epsilon$.

(iv) $J_{11} + J_{22} + J_{23}$: $w(1,4) = 1, \quad w(2,3) = 1 + \epsilon, \quad w(2,4) = -\epsilon$.

(v) $J_{11} + J_{22} + J_{14}$: $w(1,4) = 1, \quad w(2,3) = 1 + \epsilon, \; w(1,2) = -\epsilon$.

(vi) $J_{11} + J_{22} + J_{41}$: $w(1,4) = 1, \; w(2,3) = 1 + \epsilon, \; w(3,4) = -\epsilon$.

The seventh matchgate has $V = \{1, 2, 3, 4, 5, 6\}$, $X = \{1, 2\}$, $Y = \{5, 6\}$, and $T = \emptyset$. The rows of the matrices have ordering $\emptyset$, $\{1\}$, $\{2\}$, $\{1, 2\}$, and the columns have ordering $\emptyset$, $\{6\}$, $\{5\}$, $\{5, 6\}$.

(vii) $J_{11} + J_{22} + J_{33} + J_{44}$: $w(1,6) = 1, \quad w(2,5) = 1, \quad w(3,4) = \epsilon$.

The last four matchgates are defined as the seventh except now $T = \{4\}$:

(viii) $J_{21} + J_{43}$: $w(1,6) = w(2,5) = w(3,4) = 1, \quad w(3,6) = -\epsilon$.

(ix) $J_{12} + J_{34}$: $w(1,6) = w(2,5) = w(3,4) = 1, \quad w(1,3) = -\epsilon$.

(x) $J_{31} - J_{42}$: $w(1,6) = w(2,5) = w(3,4) = 1, \quad w(3,5) = -\epsilon$.

(xi) $J_{13} - J_{24}$: $w(1,6) = w(2,5) = w(3,4) = 1, \quad w(2,3) = -\epsilon$.

It is easily verified that in each case the matchgate described has character $I + \epsilon J$, where J is the claimed matrix. Further, it is clear that these 11 matrices span the 11-dimensional space X3. □

5. Matchcircuits. We now discuss how matchgates can be combined in large numbers to form circuits. In the first instance the global properties of circuits that we seek are of the same nature as those of individual gates: we define input and output nodes for a circuit and wish to establish the character matrix of the circuit from the character matrices of the constituents and the particulars of how the gates are connected together. These latter particulars need special attention if the characters of the constituents are to be composed so that no untoward sign effects arise. The only difference between a matchgate and a matchcircuit is that modifiers are assumed to be $+1$ for the latter since we do not consider a circuit to be externally connected.

One important purpose of combining matchgates is to derive matchgates with new characters. A most basic operation is that of putting two two-bit gates in sequence, as illustrated in Figure 3. We shall assume that for G_1 and G_2 the ordering in the character matrix is $\phi, \{1\}, \{2\}, \{1, 2\}$ for the inputs and $\phi, \{6\}, \{5\}, \{5, 6\}$ for

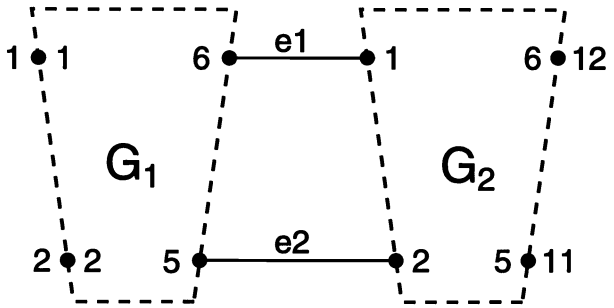

FIG. 3. *A composition of two six node matchgates, G_1 and G_2, that forms a* 12 *node matchgate G. The original labeling $\{1,2,5,6\}$ of the external nodes of G_1, G_2, as well as the new labeling $\{1,2,11,12\}$ of the external nodes of G are shown. In the composition all the* 12 *nodes are renumbered $\{1,\ldots,12\}$ from left to right in the diagram.*

the outputs. For G we assume these orderings to be the same for the inputs and $\phi, \{12\}, \{11\}, \{11,12\}$ for the outputs.

The important point now is that if gate G is formed from constituent gate G_1 appended by gate G_2 as shown, and if the character matrices of G_1 and G_2 are B_1 and B_2, respectively, then the character matrix of G will be $B = B_1B_2$ where matrix multiplication is implied. To see this consider, for example, the entry $B(2,3)$ which corresponds to input $\{1\}$ and output $\{11\}$ of the composite gate G. In the matrix product $B = B_1B_2$ the corresponding value is

$$B_1(2,1)B_2(1,3) + B_1(2,2)B_2(2,3) + B_1(2,3)B_2(3,3) + B_1(2,4)B_2(4,3).$$

It is easy to verify that the four terms correspond, respectively, to sets of matchings in G that (i) contain neither edge $e1$ nor edge $e2$, (ii) have $e1$ but not $e2$, (iii) have $e2$ but not $e1$, and (iv) have both $e1$ and $e2$. In the Pfaffian expression for G these terms all have positive signs since the potential overlap between $e1$ and $e2$ is always even, and their overlap with the internal edges of G_1 and G_2 are already accounted for in the characters of G_1 and G_2 through the modifier.

In this way if, for example, B_1 and B_2 are $I + \epsilon J_1$ and $I + \epsilon J_2$, then their composition will have character $I + (J_1 + J_2)\epsilon + O(\epsilon^2)$. Clearly if we also have a matchgate for $I + \epsilon J_1$, then we can obtain one for $I + a\epsilon J_1$, where a is any complex number by replacing ϵ in the matchgate weights by $a\epsilon$. It follows that if we have matchgates for a set of infinitesimals, such as the 11 in Proposition 5, then we can construct a matchgate for any linear combination of the infinitesimals, up to a $O(\epsilon^2)$ term.

It also follows that if we set $\epsilon = 1/n$, then if we compose n copies of the gate for $I + \epsilon J = e^{\epsilon J} + O(\epsilon^2)$, then we obtain a gate for $e^J + O(1/n)$, as can be seen from the relation

$$(e^{A/n} + O(1/n^2))^n = e^A + O(1/n)$$

which holds for all matrices A that are independent of n. Note that e^A is defined here as the power series $1 + A + A^2/2! + \ldots$. This n-fold composition or *iteration* offers an alternative approach to constructing matchgates with desired characters.

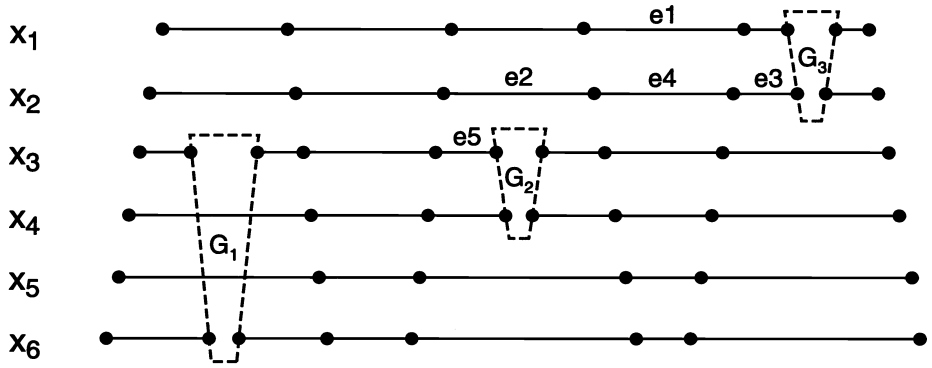

FIG. 4. *An example of a circuit composed of gates G_1, G_2, and G_3 acting on bits $\{x_3, x_6\}$, $\{x_3, x_4\}$ and $\{x_1, x_2\}$, respectively. In this example $e3$ and $e5$ are external edges, $e2$ is a parallel edge, $e1$ and $e4$ are connecting edges, and the internal edges within G_1, G_2, and G_3 are not shown. The nodes in the overall circuit are numbered so as to be increasing from left to right. The input and output node sets X, Y are the leftmost and rightmost six nodes, respectively.*

More generally let $\Gamma_1, \ldots, \Gamma_m$ be a set of matchgates $\Gamma_i = (G_i, X_i, Y_i, T_i)$, where $G_i = (V_i, E_i, W_i)$ and $|X_i| = |Y_i|$. A *matchcircuit* $\Gamma = (G, X, Y, T)$ with $G = (V, E, W)$ is a composition of $\Gamma_1, \ldots, \Gamma_m$ that can be obtained in the following way: (1) The Γ_i are first reordered as necessary. (2) Each external node of Γ_i has one external edge. An output node of Γ_i can be linked to an input node of Γ_j if $i < j$, via a *linking chain* of an odd number of edges all of weight 1, and in that case that output node and that input node are considered as members of a set D. (3) Nodes in X_i or Y_i that are not in D are the endpoints of linking chains of odd length, the other endpoints of which are considered as the members of X or Y, the input and output nodes of the circuit, respectively. An odd length chain between a node in X and a node in Y represents a bit on which the circuit does not act. (4) T is the union of the T_i. (5) The node set is now renumbered as necessary so that for each i all the nodes in V_i are *contiguous* in V (i.e., if j, k are nodes originating from V_i, and $j < l < k$ for some node l in V, then l originates from a node in V_i and is not a node on a linking chain or from a different V_i), the nodes X have smaller indices than any other node, and Y have larger indices.

Figure 4 shows an example of a matchcircuit with $|X| = |Y| = 6$ and with three matchgates. When we construct a matchcircuit from matchgates we have in mind the construction shown. Note that if $n = |X| = |Y|$, then for each gate $2n$ new nodes are introduced with a relative numbering implied by the left to right ordering shown.

MATCHCIRCUIT THEOREM. *If matchcircuit Γ is a composition of matchgates $\Gamma_1, \ldots, \Gamma_m$, then*

$$\mathrm{PfS}(G) = \sum_S \epsilon_S \prod_{1 \le i \le m} \mathrm{PfS}(G_i - S_i),$$

where (1) *S is a mapping that determines for each node in D whether it is to be matched by an edge internal or external to the matchgate from which it originated,* (2) *S_i is the set of external nodes in Γ_i that are assigned by S to be matched by an external edge, and* (3) *$\epsilon_S \in \{-1, 1\}$ (and depends on the choice of S and on the nature*

of the composition Γ).

Proof. The different choices of the assignment S partition the matchings of G. In order to establish the theorem it suffices to show that the matchings of G that respect S contribute to $\mathrm{PfS}(G)$ a term

$$\prod_{1\le i\le m} \mathrm{PfS}(G_i - S_i) \tag{3}$$

up to a multiplicative factor of 1 or -1.

It is clear that for any sets $U_1 \subseteq T_1$, $U_2 \subseteq T_2, \ldots, U_m \subseteq T_m$, and $U = U_1 \cup U_2 \cup \cdots \cup U_m$ each matching in $\mathrm{PfS}(G)$ that omits U corresponds one to one to the union of matchings from $\Gamma_1, \ldots, \Gamma_m$ that omit $U_1, \ldots, U_m$, respectively. Hence the monomials in $\mathrm{PfS}(G)$ that are consistent with S are identical to the monomials in (3) above. It remains therefore only to establish that either all the corresponding pairs of monomials have equal signs (and hence $\epsilon_S = 1$) or they all have unequal signs (and hence $\epsilon_S = -1$).

For all the matchings in G that are consistent with a single S the external edges (and other chain edges) matched are identical. Hence the matchings for the fixed S differ only as far as the edges that are entirely internal to the various Γ_i separately. Within any one such Γ_i the signs of the various terms in $\mathrm{PfS}(G_i - S_i)$ are whatever they are. When they form subterms of $\mathrm{PfS}(G)$ their signs are not affected relative to each other. This is because for any two edges from distinct gates, say edge (u, v) of E_i and (w, x) of E_j, either $u < v < w < x$ or $w < x < u < v$ and therefore there is no overlap in either case. It follows that the contributions from the various $\mathrm{PfS}(G_i - S_i)$ simply multiply together.

It remains to observe that the external and other linking edges generate no overlap. This is because the overlap between the external edges and those within gates is, as previously observed, fixed by virtue of condition (ii) in the definition of matchgates. The overlap among the external edges and linking chain edges is clearly fixed also since there is just one matching being considered for these. It remains to observe that the fixed matching in the linking edges that are not external (i.e., not directly incident to a gate) have no overlap with internal gate edges by virtue of condition (5) in the definition of matchcircuits that imposes an adequate constraint on their numbering. □

We shall think of a matchcircuit as acting on a sequence of bits $x_1, \ldots, x_n$ and of a k-bit matchgate as acting on a subset of these n bits. We say that a matchcircuit is in *standard description* if when the character matrix of a gate is described to be B it is the case that any one diagonal element of B refers to exactly the same subset of $\{x_1, \ldots, x_n\}$ for the inputs as for the outputs. Thus if, for example, $B(2, 2)$ refers to an input subset of $\{1\}$ and an output subset of $\{6\}$, as in Proposition 2, then a standard description would insist that output 6 of this gate be the same x_i bit as input 1 of this gate. Clearly, a circuit not in standard description can be put into standard description at the expense only of reordering the outputs (and renaming the bits operated on inside the circuit.)

The following Main theorem gives some general conditions that are sufficient to guarantee that the above Matchcircuit theorem can be applied with $\epsilon_S = 1$ in all cases. This in turn ensures that when the matchgates are composed into a matchcircuit, the character matrix of the circuit is the matrix product of the character matrices of the individual gates when these are regarded as acting on all n bits. This follows from the argument used earlier in the section to show that the composition of the two

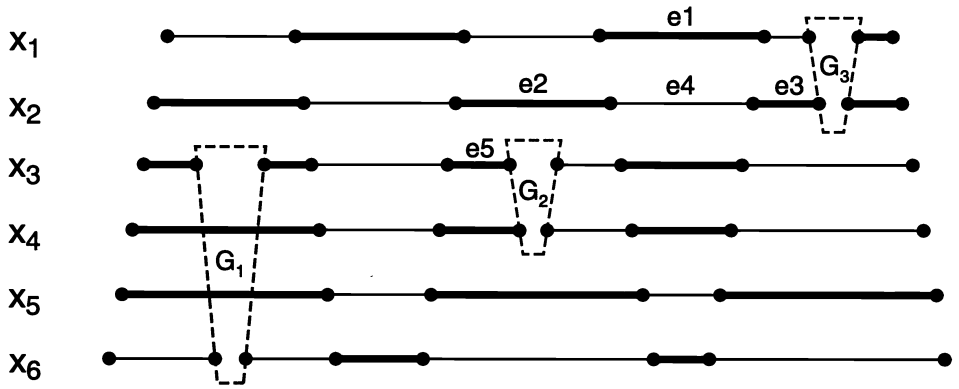

FIG. 5. *The matching for the matchcircuit shown in Figure* 4 *when* G_1, G_2, *and* G_3 *are realizing mappings* J_{22}, J_{41}, *and* J_{34}, *respectively. The matched edges outside of* G_1, G_2, *and* G_3 *are shown in bold. In this instance the circuit realizes the mapping* $(0,1,1,1,1,0) \to (1,1,0,0,1,0)$, *where an entry is* 1 *or* 0 *according to whether the node in* X *or* Y *corresponding to it is saturated by an edge in the matching.*

matchgates shown in Figure 3 corresponds to the multiplication of their character matrices.

MAIN THEOREM. *For any matchcircuit composed of two-bit matchgates any entry in its character matrix can be expressed as a Pfaffian Sum of the circuit with the corresponding external nodes removed if the circuit when described in standard form is composed of* (a) *matchgates with any character* B *such that* $B(i,j) = 0$ *for all* i,j *such that* $i \neq j$, (b) *matchgates operating on any two bits with indices differing by one (e.g.,* x_i, x_{i+1}*) that have character* B *in which the only nonzero entries are among* $B(1,1)$, $B(2,2)$, $B(3,3)$, $B(4,4)$, $B(1,4)$, $B(4,1)$, $B(2,3)$, $B(3,2)$, *and* (c) *any matchgate operating on bits* x_1 *and* x_2.

Proof. Figure 4 shows a circuit with three gates G_1, G_2, and G_3. They illustrate the cases (a), (b), and (c), respectively, since G_2 acts on adjacent gates x_3, x_4, and G_3 acts on the end bits x_1, x_2. Also shown is a systematic way of adding chains of edges to join gate outputs to gate inputs so that in the composition the Pfaffians multiply and add with positive sign.

Figure 5 illustrates the following specific nondeterministic branch of a computation of the above circuit: The input is $(x_1, x_2, x_3, x_4, x_5, x_6) = (0,1,1,1,1,0)$. Before the composition all of the gates G_1, G_2, and G_3 have external node sets $\{1,2,7,8\}$, row ordering $\emptyset$, $\{1\}$, $\{2\}$, $\{1,2\}$, and column ordering $\emptyset$, $\{8\}$, $\{7\}$, $\{7,8\}$. In the illustration gate G_1 is realizing the identity mapping from input $x_3 = 1, x_6 = 0$ to output $x_3 = 1, x_6 = 0$. It is placed in the circuit so that input 1 and output 8 of the gate act on bit x_3, and input 2 and output 7 act on bit x_6. It can be thought of, therefore, as internally realizing the character entry $(2,2)$ or the mapping J_{22}. Similarly gate G_2 realizes mapping J_{41} and is placed in the circuit so that input 1 and output 8 of the gate act on bit x_3, and input 2 and output 7 act on bit x_4. Gate G_3 realizes mapping J_{34} and is placed in the circuit so that input 1 and output 8 of the gate act on bit x_1, and input 2 and output 7 act on bit x_2. By saying here that the various gates realize various mappings we are in fact specifying a particular choice of S in the statement of the Matchcircuit theorem. Equivalently we are specifying particular

subsets of matchings in all the gates.

What we need to show is that for any such choice of S that corresponds to nonzero character entries for all the gates, whether of types (a), (b), or (c) in the statement of the Main theorem, the value of ϵ_S in the Matchcircuit theorem is always $+1$. To see this we classify the edges in the circuit into categories: ones that are *internal* to a gate, ones that are *external* edges (those that connect the external nodes of a gate to the outside, e.g., $e3$, $e5$ in Figure 4), those that are *parallel* to gates (e.g., $e2$), which are defined to be those above or below the gates in Figure 4, and *connecting* edges (e.g., $e1$, $e4$), which are sets of n edges that connect the external/parallel edges of one gate to the external/parallel edges of another. Clearly there are three sources of overlapping edges that might affect ϵ_S: overlap between internal and external edges, overlap between external/parallel edges and connecting edges, and overlap among the external/parallel edges involved in the same gate. The first source is already taken into account in the definition of the character of a matchgate. The second contributes $+1$ since any particular connecting edge (e.g., $e4$) forces the external/parallel edges at its two ends ($e2$, $e3$) to be either both matched or neither matched, and hence the overlaps of these latter edges with any connecting edge (e.g., $e1$) above the connecting edge ($e4$) in question will occur in pairs and hence cancel.

The remaining case is that of overlaps among the external/parallel edges of the same gate, and these can be only between an edge externally connected to a gate (e.g., $e5$) and a parallel edge above it (e.g., $e2$). In case (c) since the gate acts on x_1, x_2, there are no parallel edges above the gate, and hence there is no contribution to ϵ_S. In case (b) since the gate has an even number of external edges that are in the matching and their overlaps are with parallel edges above, these contributions will be in even pairs and will also cancel. Finally, in case (a) matched external edges will occur in pairs with the same x_i (e.g., for gate G_1 in Figure 5; such a pair occurs for x_3 and not for x_6). Overlaps with the parallel edges above will therefore again occur in pairs and cancel.

With regard to the details of the construction for composing matchgates that Figure 3 illustrates, the reader can verify that there is much redundancy. All the nodes other than matchgate nodes or the circuit input and output nodes can be eliminated. □

We note that if we take into account the matchgate identities, then case (a) can be simulated by case (b) and is technically redundant in the above theorem. To see this note that a case (a) matrix is a diagonal matrix with some $(a, b, c, bc/a)$ on the diagonal. This can be simulated by two diagonal one-bit gates, the first with diagonal (a, b) acting on the first bit, and the second with diagonal $(1, c/a)$ acting on the second bit. Each of these one-bit gates can then be viewed as a two-bit gate that ignores the other bit and is feasible for a matchgate. Hence a case (a) two-qubit gate acting on bits i, j can be replaced by two one-bit gates acting on bits $i, i+1$ and $j, j+1$, respectively.

We call Ω the class of matchcircuits defined in the above theorem and limited to the classes of matchgates that can be constructed. In particular the gates that can be used in unrestricted ways include those of Proposition 2. Those that can be applied to neighboring bits include those of Proposition 3. Those that can be applied to the end bits x_1, x_2 include those of Proposition 4.

Now consider a member M of this class Ω. For any input variable x_i or output variable y_j that is to be fixed to have value 0 we delete this input/output node and the edges incident to it. This forces the circuit to have value 0 for this variable since the

corresponding $X \cup Y$ node will not be saturated. If we wish to set the variable to 1 we retain the corresponding nodes and edges. (This $\{0,1\}$ interpretation of the variable values is the complement of that considered for the character, but this is an inessential technicality.) For $\underline{x} \in \{0,1\}^n$, $\underline{y} \in \{0,1\}^n$ we define $M_{\underline{x},\underline{y}}$ to be the matchcircuit M with these modifications. In the case that the matchgates are unitary, we can regard the circuit as a quantum matchcircuit.

COROLLARY 1. *For a quantum matchcircuit $M \in \Omega$ started in state $\underline{x}$ the probability that it terminates in state $\underline{y}$ is $|\mathrm{PfS}(M_{\underline{x},\underline{y}})|^2$.* □

A critical aspect of our theory, which we have not mentioned and which goes beyond the standard quantum computational model, is that it is capable of simulating in polynomial time *nondeterministic summation* over the *inputs* of the simulated circuit evaluations in addition to the nondeterministic branches. Thus if $\underline{x}^*, \underline{y}^*$ assign subsets of the inputs and outputs fixed values, we first excise the external nodes that are so fixed to have value 0 and retain those fixed as 1. We then apply to the resulting matchcircuit M the various transformations described in the following.

THEOREM 5. *For any matchcircuit $M \in \Omega$, if x^*, y^* are partial assignments to the inputs and outputs, then each of the three quantities*

$$\left(\sum_{\underline{x},\underline{y}} \mathrm{PfS}(M_{\underline{x},\underline{y}})\right)^2, \qquad \sum_{\underline{x},\underline{y}} |\ \mathrm{PfS}(M_{\underline{x},\underline{y}})\ |^2, \quad \textit{and} \qquad \sum_{\underline{x},\underline{y}} (\mathrm{PfS}(M_{\underline{x},\underline{y}}))^2,$$

where summation is over all $\underline{x}$ and $\underline{y}$ that agree with $\underline{x}^*$ and $\underline{y}^*$, respectively, can be evaluated in time polynomial in the size of M.

Proof. For the first quantity we define the nondeterministic input and output nodes in M as omittable nodes in the matchcircuit and appeal to the Pfaffian Sum theorem.

For the second quantity we construct for M its complex conjugate matchcircuit M^* which is identical to M except that corresponding weights are complex conjugates of each other, and the node indices are from a disjoint interval of, say, higher numbers, and in reverse order. For each nondeterministic input or output node we join the corresponding nodes of M and M^* by an edge of weight one. We claim that the Pfaffian of the result is the desired quantity. This follows from the observation that each subset of the joining edges that is matched represents a distinct truth assignment to the nondeterministic nodes, and its contribution to the Pfaffian will be the product of some $\mathrm{PfS}(M_{\underline{x},\underline{y}})$ and its complex conjugate. The only technical issue that needs to be verified is that the contribution of the newly added edges to the parity of the sign is $+1$ for all choices of $\underline{x}$ and $\underline{y}$. To see this we note that the edges between the outputs clearly interact with each other with even parity and with the copies of M and M^* totally symmetrically. Similarly the edges between the inputs, which now span the whole circuit, also interact with each other and with the edges between the outputs with even parity. Also, they interact with the edges that touch the input nodes of M and M^* symmetrically and with all other edges of M, M^* with even parity. Figure 6 illustrates this construction.

The third quantity is computed in the same way as the second except that instead of M^* we simply use a second copy of M. □

This result, clearly, has applications broader than the quantum computation model, since it is not restricted to unitary matrices. We note, however, that if we do restrict ourselves to the quantum model, or any other model with a similar probabilistic interpretation, then our computational mechanisms may be compared with

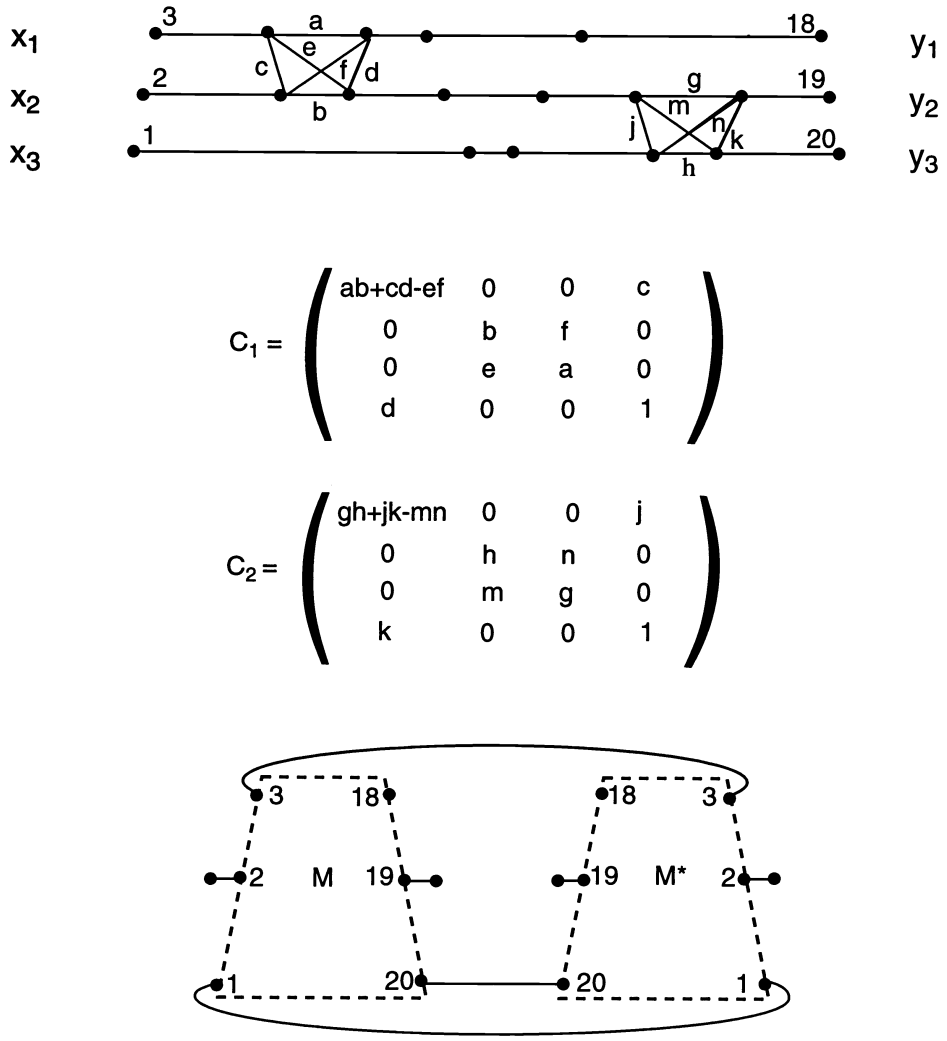

FIG. 6. *At the top we illustrate a* 20*-node matchcircuit* M *on* 3 *qubits that realizes the composition of a transformation* C_1 *on* x_1, x_2*, followed by* C_2 *on* x_2, x_3*. The* 0-1 *interpretation of the character matrix of* M *is the complement of that of the gates but could be made the same if each input and output of* M *were extended by a further edge. At the bottom the diagram illustrates how a copy of* M *is composed with a copy of its complex conjugate with reverse numbering in order to realize the second part of Theorem* 5*. In this example the Pfaffian(Sum) of the adjacency matrix will equal* $\Sigma|\mathrm{PfS}(M_{\underline{x},\underline{y}})|^2$ *with* $\underline{x}$ *summed over all values such that* $x_2 = 0$*, and* y *summed over all values with* $y_1 = 1$ *and* $y_2 = 0$*, and hence in the quantum interpretation will equal the probability that such evolutions occur.*

aspects of quantum physics. In particular, the second part of the above theorem can be seen as a deterministic process that computes the exact probability associated with a particular set of evolutions between quantum states. The result to follow builds on this by showing that in randomized polynomial time one can generate an output state according to the probability distribution that the quantum mechanical

interpretation of a quantum matchcircuit specifies. This is precisely equivalent to the idea of performing a measurement in quantum mechanics.

MEASUREMENT THEOREM. *For any quantum matchcircuit $M \in \Omega$ if $\underline{x}$ is a total assignment to the inputs, and $\underline{y}^*$ a partial assignment to the outputs, then there is a randomized procedure that runs in time polynomial in the size of M and generates an output $\underline{y}$ consistent with $\underline{y}^*$ with probability*

$$|\mathrm{PfS}(M_{\underline{x},\underline{y}})|^2 / \sum |\mathrm{PfS}(M_{\underline{x},\underline{z}})|^2,$$

where summation in the denominator is over all $\underline{z}$ consistent with $\underline{y}^*$.

Proof. We proceed in the manner described in [23] for generating a random combinatorial structure when we can count their number. The procedure has m stages if there are m nondeterministic variables. In each stage we consider one such variable y_i and fix its value as follows: We evaluate for $y_i = 0$, and separately for $y_i = 1$, the quantity

$$\sum |\mathrm{PfS}(M_{\underline{x},\underline{y}})|^2,$$

where the summation is over the $\underline{y}$ variables that have not been fixed yet. Each of the two evaluations is a call of the procedure in the second part of Theorem 5. If we obtain the values p_0 and p_1 for these two calls, then with probability $p_0/(p_0 + p_1)$ we fix $y_i = 0$ and with probability $p_1/(p_0 + p_1)$ we fix $y_i = 1$. It is clear that the procedure has the desired result. □

In conclusion we note that we can generalize the Measurement theorem to sum nondeterministically over unspecified inputs also. There is an obvious restriction, however, on how the various nondeterministic choices can be correlated. If they are all independent, then nothing special needs to be done. Otherwise one option is to relate pairs of them by joining such a pair by an edge or a chain of two edges, and this corresponds to the read-twice circuits discussed below. Controlling the overlaps of the added edges becomes problematic in general, however. The next section takes this route under circumstances when these overlaps do not matter.

6. Matchnets. We shall compose matchgates now in a different way. For quantum computation we needed to be careful in constructing matchcircuits so that the effects of the constituent matchgates simply add, without any uncontrollable sign effects. Thus our simulation of quantum computation was limited by (a) what individual matchgates could achieve and by (b) the constrained composition rules that were adopted to maintain control of the signs. In the two applications in this section we shall be limited by (a) alone. In the first application we shall be detecting the *existence* of solutions and in the second the *parity* of the number of solutions.

For our current purposes we shall consider matchgates with empty output node sets Y. For simulating i-argument Boolean functions we shall use matchgates with i input variables X. In this section the sign of the character of each gate will be immaterial, and hence consideration of the modifier in the definition of a matchgate is redundant.

In this section we define algorithms for *read-twice* Boolean formulae. These are formulae that are conjunctions of expressions such that each variable influences at most two of the expressions. To describe the individual expressions we consider the following classification of Boolean functions:

0-argument functions: $B01 = \{1, 0\}$
1-argument functions: $B11 = \{x\}$
2-argument functions: $B21 = \{xy, x + y, x \oplus y = 1, x \oplus y = 0\}$
3-argument functions: $B31 \cup B32 \cup B33$, where
$B31 = \{xyz, x(y = z), x'yz + xy'z + xyz', x(y + z),$
$x \oplus y \oplus z = 1, xy + yz + zx,$
$x + (y = z), xy + (y = z)\},$
$B32 = \{x + y + z, \neg(xyz + x'y'z')\}$, and
$B33 = \{xyz + x'y'z', xyz + x'y', xy + y'z,$
$x + yz, z = x + y, x'y'z' + xy + yz + zx\}.$

Altogether there are 23 Boolean functions listed here. It is easily verified that any Boolean function of three or fewer variables is identical to one of these 23 functions once x, y, and z have been replaced by appropriate instances of the three variables or of their negation. For example, the OR gate $z = x + y$ in B33 can be interpreted as $z' = x' + y'$ which is equivalent to the AND gate $z = xy$, which is therefore not listed separately. However, $xyz + x'y'z'$ and $\neg(xyz + x'y'z')$, for example, are not equivalent in this sense. We note that only the last 16 functions, those in $B31 \cup B32 \cup B33$, depend on all three of their arguments, and that the first seven, namely those in $B01 \cup B11 \cup B21$, can all be obtained by appropriately fixing some inputs of some member of $B31$. Hence our claims about algorithms for $B31$ apply equally to $B01 \cup B11 \cup B21 \cup B31$.

Let us therefore first consider the eight 3-argument functions in the set $B31$. In each case we shall describe a matchgate whose character, as described by a vector of length 8, specifies the Boolean function at the eight possible input values. A further special property of these gates is that the character entries are always 0 or 1 and (a) whenever it is 0 the gate has no matchings, and (b) whenever it is 1 then it has exactly one matching. In other words in the corresponding Pfaffian there is either zero or one nonvanishing monomial. Also in all nine cases $V = \{1, 2, 3, 4\}$, $X = \{1, 2, 3\}$, $Y = \emptyset$, and, where not otherwise stated, $T = \{4\}$. It remains only to specify the nonzero edge weight set in each case. We shall specify the actual function realized using x, y, z to represent inputs 1, 2, 3, respectively. We use the same numbering convention as before. Thus $Z = \{1, 3\} \subseteq X$ will give the character matrix element corresponding to $x = 1, y = 0, z = 1$. Also, we denote the negation of a variable x by x'.

xyz: All weights zero.
$(x = y)z$: $w(1, 2) = 1$.
$(x + y)z$: $w(1, 4) = 1$, $w(2, 4) = 1$.
$x + (y = z)$: $w(1, 4) = 1$, $w(2, 4) = 1$, $w(3, 4) = 1$, $w(2, 3) = 1$.
$xy + (y = z)$: $w(1, 4) = 1$, $w(3, 4) = 1$, $w(2, 3) = 1$.
$xy + yz + zx$: $w(1, 4) = 1$, $w(2, 4) = 1$, $w(3, 4) = 1$.
$x \oplus y \oplus z = 1$: $w(1, 2) = 1$, $w(2, 3) = 1$, $w(3, 1) = 1$.
$xyz' + xy'z + x'yz$: $w(1, 4) = 1$, $w(2, 4) = 1$, $w(3, 4) = 1$, $T = \emptyset$.

Let us next consider the two 3-argument functions in the set $B32$. The setup is exactly as for the $B31$ gates above with the one exception that whenever the Boolean function takes the value 1 there may now be more than one matching in the matchgate and this number is even (though the corresponding Pfaffian is in fact nonzero—a property which is not exploited.) The two functions here are disjunction and not-all-equals. We note that it is enough to implement functions to within negations of the inputs: One can unnegate an input by adding a single edge to the old input and

declaring the new endpoint the new input. This may change the modifier, but that is not relevant for this section.) In order to retain four node constructions we shall describe gates where x and z are negated in the disjunction and y in the not-all-equals:

$x' + y + z'$: $w(1,2) = 1$, $w(1,3) = 1$, $w(1,4) = 1$, $w(2,3) = 1$, $w(3,4) = 1$.
$\neg(xy'z + x'yz')$: $w(1,2) = 1$, $w(1,4) = 1$, $w(2,3) = 1$, $w(3,4) = 1$.

A matchnet is a set of matchgates with no output nodes where pairs of input nodes from different matchgates may be joined (a) by a single edge of weight 1 if the input nodes are to have the same value or (b) by a chain of two edges both of weight 1 if the input nodes are to have opposite values. We can then define the matchnet of a read-twice Boolean formula as follows: if the formula is a conjunction of a number of 3-argument Boolean expressions, then the matchnet is simply the union of matchgates, one for each such expression, in addition to single edges or chains of length two to constrain pairs of variables in the expressions to have equal or unequal values, as required.

More formally a *matchnet* is a matchcircuit having no input or output nodes, and composed of matchgates with no outputs, where condition (1) in the definition of matchcircuits is redundant, and conditions (2) and (3) are replaced by the above condition, that inputs of different matchgates may be linked by edge chains of length one or two.

The following theorem results using standard algorithms for finding matchings and for computing determinants.

THEOREM 6. *If F is a read-twice formula consisting of gates from $B01 \cup B11 \cup B21 \cup B31 \cup B32$, then the matchnet of F has a matching iff F is satisfiable. If F is a read-twice formula F consisting of gates from $B01 \cup B11 \cup B21 \cup B31$, then the matchnet of F has an odd number of matchings iff F has an odd number of satisfying assignments. The existence of a solution for the formula in the first case and the parity of the number of solutions in the second case can both be computed in deterministic time polynomial in the size of F.* □

A variety of special cases of these results were previously known and some related problems are known to be NP-hard. One strength of the result above is that a broad variety of gates can be treated together. Some trivial special cases include restricting the gates to two argument functions or to parity functions. A more interesting case that was previously known was read-twice formulae consisting only of $x + y + z$ gates (from $B32$), for which it was known that satisfiability is polynomial time solvable [28, p. 207]. For that case it was further known that counting the number of solutions is #P-complete [6], although the parity problem for it is apparently open. The construction in [22] for read-twice formulae (of the form of conjunctions of disjunctions of conjunctions) implies that the existence problem for read-twice formulae constructed from $z = x + y$ functions is NP-complete. Also one can deduce that the corresponding counting problem is #P-complete and, using [37], that the corresponding parity problem is NP-hard via randomized reduction.

THEOREM 7. *None of the six functions in $B33$ has a matchgate where either the parity of the number of matchings or the existence of matchings defines the required function. Neither of the functions in $B32$ has a matchgate where the parity of the number of matchings defines the required function.*

Proof. Assume to the contrary that such matchgates exist and, without loss of generality, that they have an odd number n of nodes. If n is even one can add

an omittable node having no incident edges. Assume that the input node set is $X = \{1, 2, 3\}$ and that $Y = \emptyset$.

Construct the matrix $P = B^+ + \Lambda^{(n+1)}$ exactly as in the second part of the Pfaffian Sum theorem. Let $i = 1, j = 2, k = 3, l = n + 1$ in Theorem 2 and use the abbreviation $P(a, b, c, d)$ to denote the Pfaffian of P with rows/columns $1, 2, 3, n + 1$ removed according to whether a, b, c, d equal 1. Then Theorem 2 implies

$$\begin{aligned} P(0,0,0,0)P(1,1,1,1) - P(1,1,0,0)P(0,0,1,1) \\ = P(1,0,0,1)P(0,1,1,0) - P(1,0,1,0)P(0,1,0,1). \end{aligned}$$

Since in each term $d = a \oplus b \oplus c$, the last argument is indeed redundant, and we can abbreviate $P(a, b, c, d)$ with $P(a, b, c)$ to get

$$\begin{aligned} P(0,0,0)P(1,1,1) - P(1,1,0)P(0,0,1) \\ = P(1,0,0)P(0,1,1) - P(1,0,1)P(0,1,0). \end{aligned} \tag{4}$$

The main observation now is that $P(a, b, c)$ is nothing other than the component of the character (up to a factor of ± 1) of the gate where the inputs set to 1 are removed from the gate. This is because renaming the nodes and then applying the Pfaffian Sum theorem would give exactly the same matrix as P with the corresponding rows/columns removed.

It follows, for example, that the all-equal function $xyz + x'y'z'$ cannot be realized since it would require the first of the four terms in (4) to be nonzero and the rest zero. This holds clearly if the Pfaffian equals the parity. Equally it precludes the possibility that matchings exist for just the desired subsets of inputs because in that case we could place random values on the edges of the matchgate and the Pfaffians would have forbidden zero and nonzero patterns for some such random values. Note that when considering existence rather than parity, instead of appealing to the Pfaffian Sum theorem to eliminate omittable nodes, we simply connect these nodes as a complete subgraph.

This same argument can be applied also to the remaining five functions in $B33$: $x'y'z' + xyz$, $z = x + y$, $x + yz$, $xy + y'z$, and $xyz + x'y'$. A similar argument holds for the $B32$ functions for the case of parity. □

We observe finally that numerous open problems remain regarding read-twice formulae composed of gates from the 23 gates that we enumerated. In particular the complexity of determining the existence, the parity, and the number of the solutions each remains unresolved for several cases.

7. Conclusion. The exact power of matchgate techniques for deriving polynomial time classical algorithms remains to be resolved. Are there indirect methods not yet identified for mapping richer classes computations into matchgates? Can our particular class of polynomially simulatable circuits be extended by allowing in addition arbitrary use of one-bit gates? Do circuits based on k-bit matchgates for $k > 2$ have greater power for encoding computations?

We have defined a class of quantum computations for which the outcome can be predicted by linear algebra computations in polynomial time by classical computers. While the standard quantum mechanical formulation is linear also, it is linear in exponentially more dimensions than is ours. This brings new focus to the question of whether scalable quantum devices are restricted to those that are polynomial time simulatable classically, as nonquantum devices are believed to be.

FINDING DOUBLE EULER TRAILS OF PLANAR GRAPHS IN LINEAR TIME*

ZHI-ZHONG CHEN†, XIN HE‡, AND CHUN-HSI HUANG§

Abstract. This paper answers an open question in the design of complimentary metal-oxide semiconductor VLSI circuits. The question asks whether a *polynomial-time* algorithm can decide if a given planar graph has a plane embedding $\mathcal{E}$ such that $\mathcal{E}$ has an Euler trail $P = e_1 e_2 \dots e_m$ and its dual graph has an Euler trail $P^* = e_1^* e_2^* \dots e_m^*$, where e_i^* is the dual edge of e_i for $i = 1, 2, \dots, m$. This paper answers this question in the affirmative by presenting a *linear-time* algorithm.

Key words. planar graph, dual graph, Euler trail

1. Introduction.

Throughout this paper, a graph may have multiple edges but never has loops. A graph G is *planar* if it can be drawn on the plane so that the edges intersect only at their end vertices. Such a drawing is called an *embedding* of G. A *plane graph* is a planar graph with a fixed embedding. A *two-terminal graph* [1] (TTG) $G = (V, E)$ is a plane graph with a pair (s, t) of specified vertices on the outer face such that adding the edge $\{s, t\}$ to G yields a biconnected plane graph [4, 6]. We call s the *source* of G and t the *sink* of G. We also call s and t the *poles* of G and the other vertices the *nonpoles* of G. As in previous studies, we visualize G in such a way that s is at the South Pole while t is at the North Pole.

The poles of G divide the boundary of the outer face into two paths, which are called the *west side* and the *east side* of G, respectively. In the dual graph $G^* = (V^*, E^*)$ of G, there are two dual vertices s^* and t^* corresponding to the outer face of G. The dual edges incident to s^* (respectively, t^*) in G^* correspond to the edges on the west (respectively, east) side of G. Figure 1.1(2) shows a TTG G and its dual G^*. G^* is a TTG with source s^* and sink t^* [12].

In complimentary metal-oxide semiconductor (CMOS) technology, the basic layout of a circuit C of transistors on a VLSI chip uses two rows of transistors: A row of pMOS transistors is laid out next to a row of nMOS transistors [13]. The circuit C can be represented by a pair of TTGs: The p-transistors are represented by G, where each edge of G represents a p-transistor. The n-transistors are represented by the dual graph G^* of G, where each edge of G^* represents an n-transistor. In Figure 1.1, (1) shows a circuit implementing the Boolean function $z = \bar{e} \wedge (\bar{a} \vee \bar{b}) \wedge (\bar{c} \vee \bar{d})$, and (2) shows the corresponding TTGs G and G^*.

1.1. Double Euler trails and optimal layouts. A *trail* P in G is a sequence $e_1 e_2 \dots e_k$ of distinct and oriented edges of G such that, for each $i \in \{1, \dots, k-1\}$, the ending vertex of e_i and the starting vertex of e_{i+1} are the same. Possibly, P has repeated vertices. An *Euler trail* is a trail that visits each edge of G exactly once. For each edge e of G, let e^* be the dual edge of e in G^*. If the sequence $P^* = e_1^* e_2^* \dots e_k^*$ is also a trail in G^*, we call P a *double trail* [2] in G and call P^* the *dual trail* of P. If P is a double trail and traverses every edge of G exactly once, we call P a *double Euler trail* (DET) in G.

For each edge e in G, the p-transistor represented by e has the same input as the n-transistor represented by e^*; hence, in the layout, the two transistors are required to be laid out vertically aligned (to facilitate input line connection) [13]. Transistors which are physically adjacent and have common diffusion regions may be collapsed. Otherwise, a vertical gap must be inserted between the diffusion region of the two transistors. Two transistors corresponding to two consecutive edges on a double trail can be laid out physically adjacent without vertical gap [13]. Figure 1.1(3) shows a layout of C using this approach. Note that the sequence eab is a double trail of G. So, in the layout, no vertical gaps are needed between the transistors e, a, b. This is also true for transistors c, d because of the double trail cd. However, since the edges b and c are incident in G but not in G^*, there is a vertical gap between the transistors b and c in the layout. In Figure 1.2, (1) shows a logically equivalent circuit and (2) shows the corresponding TTGs G and G^*. Since $abecd$ is a DET of G, the transistors can be laid out in this order with no vertical gap, as seen in Figure 1.2(3).

1.2. Problem definitions. The circuits in Figures 1.1(1) and 1.2(1) are logically equivalent. Thus, the TTGs G in Figures 1.1(2) and 1.2(2) should be viewed as different embeddings of each other. That is, to obtain a different embedding of a TTG, we may not only horizontally flip blocks of the TTG as one does traditionally but also vertically flip blocks of the TTG. We postpone the precise definition of "different embeddings" until the end of section 2. For convenience, we regard G as a different embedding of itself.

[2] Previously called "dual trail." We reserve the term "dual trail" exclusively to refer to a trail in G^*.

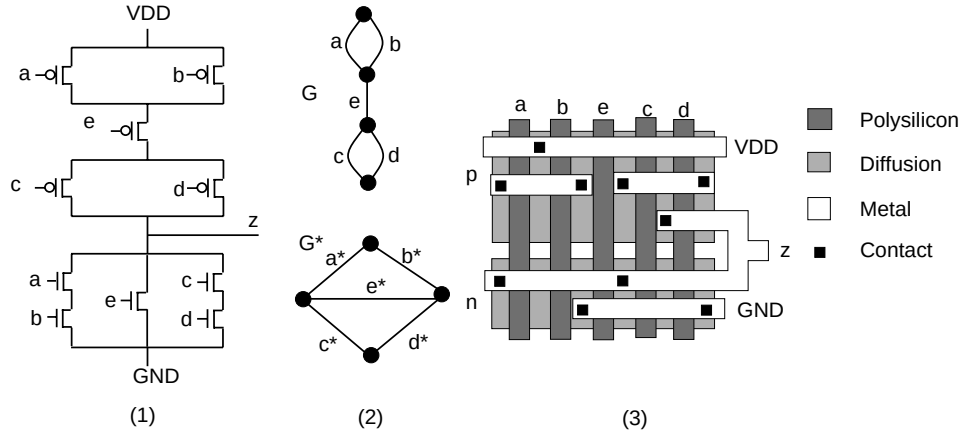

FIG. 1.2. (1) *A circuit C logically equivalent to the circuit in Figure* 1.1(1). (2) *The corresponding TTGs G and G*.* (3) *A layout of C using the DET abecd.*

As seen from Figures 1.1 and 1.2, even if G has no DET, a different embedding of G may have one. A *valid embedding* of G is a different embedding of G that has a DET. A *double-trail cover* (DTC) $\mathcal{Q}$ of G is a set of edge-disjoint double trails in G such that each edge of G appears in a trail in $\mathcal{Q}$. The *size* of $\mathcal{Q}$ is the number of double trails in it. $\mathcal{Q}$ is a *minimum* DTC of G if the size of $\mathcal{Q}$ is minimized over all DTCs of G. A different embedding of G with a minimum DTC leads to a layout with the minimum number of vertical gaps (hence the minimum chip area). We are interested in the following problems:

DET-F problem. Given a TTG G, decide whether G has a DET.

DET-V problem. Given a TTG G, decide whether G has a valid embedding.

DTC-F problem. Given a TTG G, find a minimum DTC of G.

DTC-V problem. Given a TTG G, find a different embedding $\mathcal{G}$ of G and a minimum DTC $\mathcal{Q}$ of $\mathcal{G}$ such that the size of $\mathcal{Q}$ is minimized over all different embeddings of G.

1.3. Previous work and our result. The layout method described above was first introduced by Uehara and VanCleemput [13]. Most previous studies in this area are concerned with *series-parallel* (SP) graphs, a much restricted subclass of TTGs. This is partially because the problems above for general TTGs are more difficult to solve. A heuristic algorithm for solving the DTC-V problem for SP graphs was given in [13]. Lengauer and Müller [7] developed linear-time algorithms for finding a minimum trail cover (not DTC) for SP graphs. Nair, Buss, and Reif [10] presented polynomial-time algorithms for solving the DTC-F problem and the DTC-V problem both for a restricted class of embedded SP graphs. Maziasz and Hayes [8, 9] gave a linear-time algorithm for solving the DTC-F problem for SP graphs and a worst-case exponential-time algorithm for the DTC-V problem for SP graphs. Linear-time algorithms for solving the DET-V problem for SP graphs were given in [5]. These algorithms are based on dynamic programming and are complicated. Whether the DTC-V problem for SP graphs can be solved in polynomial time is still open.

For general TTGs, a linear-time algorithm for solving the DET-F problem was given in [1]. The DTC-F problem is NP-hard [14, 15], which implies that the DTC-V problem for TTGs is also NP-hard. Whether the DET-V problem for general TTGs

can be solved in *polynomial time* is posed as an open question in [1].

Here, we answer this question in the affirmative by presenting a *linear-time* algorithm for the DET-V problem. Our algorithm is based on careful analysis of the structures of DTCs of TTGs. In more details, we first find out the types of those DTCs that are the intersection of a DET of a TTG G and a subgraph of G. We then define two operations for composing such DTCs of edge-disjoint subgraphs into a single such DTC of a larger subgraph. We further prove that the two operations have nice properties based on which a linear-time algorithm can be designed. The main data structure we use is the *SPQR-decomposition tree* of a TTG [3].

1.4. Organization of this paper. Section 2 describes the *SPQR decomposition* of a TTG. Section 3 shows several useful properties of different embeddings of a TTG. Section 4 discusses the special case of the DET-V problem where neither the input TTG nor its dual graph has an odd-degree vertex. Section 5 gives a polynomial-time algorithm for the DET-V problem. Section 6 refines this algorithm to a linear-time algorithm.

2. SPQR decomposition. Throughout this paper, for a TTG G, G^* denotes the dual graph of G, $s(G)$ denotes the source of G, $t(G)$ denotes the sink of G, and $|G|$ denotes the total number of vertices and edges in G. For an unordered list L, we write $L = \langle a_1, \ldots, a_k \rangle$, where a_1 through a_k are the elements of L. For an ordered list L, we write $L = (a_1, \ldots, a_k)$, where $a_1, \ldots, a_k$ are the elements of L and are ordered in this order.

In the rest of this section, fix a TTG G. A *cut vertex* of G is a vertex whose removal disconnects G. G is *biconnected* if it has no cut vertex. A *biconnected component* of G is a maximal subgraph of G with no cut vertex. A *split pair* of G is either a pair of adjacent vertices or a pair of vertices whose removal disconnects G', where G' is the graph obtained from G by adding the edge $\{s(G), t(G)\}$. A *split component* of a split pair $\langle u, v \rangle$ is either an edge $\{u, v\}$ or a maximal subgraph H of G such that H is a TTG with poles u and v and $\langle u, v \rangle$ is not a split pair of H. A split pair $\langle u, v \rangle$ of G is *maximal* if there is no other split pair $\langle w_1, w_2 \rangle$ in G such that $\langle u, v \rangle$ is contained in a split component of $\langle w_1, w_2 \rangle$.

The *decomposition tree* T of G describes a recursive decomposition of G with respect to its split pairs [2, 3]. T is a rooted ordered tree whose nodes are of four types: S, P, Q, and R. Each node μ of T has an associated TTG, called the *skeleton* of μ and denoted by $\mathrm{Sk}(\mu)$. Also, it is associated with an edge in the skeleton of the parent χ of μ, called the *virtual edge* of μ in $\mathrm{Sk}(\chi)$. T is recursively defined as follows.

Trivial case. G consists of a single edge $\{s(G), t(G)\}$. Then, T consists of a single Q-node whose skeleton is G itself.

Series case. G is not biconnected. Let $c_1, \ldots, c_{k-1}$ ($k \geq 2$) be the cut vertices of G. Since G is a TTG, each $c_i \in \{c_1, \ldots, c_{k-1}\}$ is contained in exactly two biconnected components G_i and G_{i+1} of G such that $s(G)$ is in G_1 and $t(G)$ is in G_k. The root of T is an S-node μ. $\mathrm{Sk}(\mu)$ is a path $e_1, \ldots, e_k$, where the edge $e_i = \{c_{i-1}, c_i\}$, $c_0 = s(G)$, and $c_k = t(G)$.

Parallel case. $s(G)$ and $t(G)$ constitute a split pair of G with split components $G_1, \ldots, G_k$ ($k \geq 2$). Then, the root of T is a P-node μ. $\mathrm{Sk}(\mu)$ consists of k parallel edges between $s(G)$ and $t(G)$, denoted by $e_1, \ldots, e_k$.

Rigid case. None of the above cases applies. Let $\langle s_1, t_1 \rangle, \ldots, \langle s_k, t_k \rangle$ ($k \geq 1$) be the maximal split pairs of G. For $i = 1, \ldots, k$, let G_i be the union of all the split components of $\langle s_i, t_i \rangle$. The root of T is an R-node μ. $\mathrm{Sk}(\mu)$ is obtained from G by replacing each subgraph G_i with an edge $e_i = \{s_i, t_i\}$. Note that adding the edge

$\{s(G), t(G)\}$ to $\mathrm{Sk}(\mu)$ yields a triconnected graph. By this, $\mathrm{Sk}(\mu)$ has no different embedding other than itself [11].

In the last three cases, μ has children $\nu_1, \ldots, \nu_k$ (in this order) such that ν_i is the root of the decomposition tree of graph G_i for all $i \in \{1, \ldots, k\}$. The virtual edge of node ν_i is the edge e_i in $\mathrm{Sk}(\mu)$. G_i is called the *pertinent graph* of ν_i and is denoted by $\mathrm{Pt}(\nu_i)$. Note that G is the pertinent graph of the root of T. Figure 2.1 illustrates the decomposition tree of a TTG G. The skeletons of the nodes μ and ν are also shown.

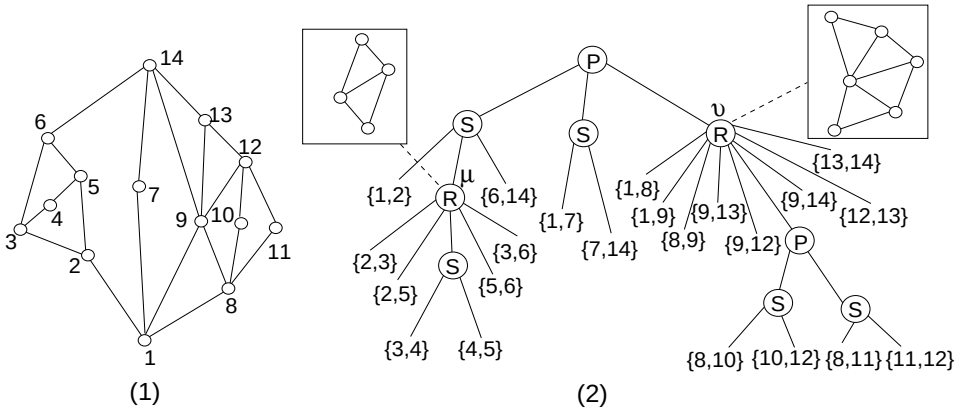

FIG. 2.1. (1) *A TTG G.* (2) *Its decomposition tree T.*

By the definition of T, no child of an S-node is an S-node and no child of a P-node is a P-node.

LEMMA 2.1 (see [3]). *T has $O(|G|)$ nodes. Also, the total number of edges of the skeletons stored at the nodes of T is $O(|G|)$.*

The *dual decomposition tree* of T is the decomposition tree of the dual graph of G.

LEMMA 2.2. *The dual decomposition tree of T can be obtained from T by exchanging the roles of the S-nodes and the P-nodes and further changing the skeleton of each node to the dual graph of the skeleton.*

Proof. The proof is obvious. □

A *different embedding* of G is obtained from G by a sequence of operations from the following set [7, 8, 9, 10, 13]:

- horizontally flipping the skeleton of an R-node around its poles;
- permuting the children of a P-node;
- vertically flipping the skeleton of an R-node, which is equivalent to horizontally flipping the dual skeleton around its poles;
- permuting the children of an S-node, which is equivalent to permuting the children of the dual P-node.

Note that if $\mathcal{G}$ is a different embedding of a TTG G, the circuits represented by $\mathcal{G}$ and G are logically equivalent. Also note that the commonly known definition of "different embeddings" allows only the first two operations [2, 3]. Hence, the meaning of the phrase "different embedding" used here is different from its commonly known meaning.

3. Properties of embeddings and double trails. Throughout this paper, a list is ordered unless stated explicitly otherwise. An unordered list is actually a multiset. So, for two unordered lists $L_1 = \langle a_1, \ldots, a_k \rangle$ and $L_2 = \langle b_1, \ldots, b_\ell \rangle$, we write

$L_1 \cup L_2$ for the unordered list $\langle a_1, \ldots, a_k, b_1, \ldots, b_\ell \rangle$. For an ordered (respectively, unordered) list L and a set S, let $L - S$ denote the ordered (respectively, unordered) list obtained from L by deleting all appearances of each $x \in S$.

The following fact is well known.

FACT 1. *For a connected graph G, the following two statements hold:*

- *G has a closed Euler trail if and only if it has no odd-degree vertex; in this case G is called* Eulerian.
- *G has an open Euler trail if and only if it contains exactly two odd-degree vertices, which are the first and the last vertex of the trail.*

In the rest of this section, fix a TTG G. Let T be the decomposition tree of G. A *block* of G is either the pertinent graph of a node in T or the union of the pertinent graphs of some consecutive children of a P- or S-node in T. A *proper block* of G is a block B such that $G \neq B$. Let $B = \mathrm{Pt}(\mu)$, where μ is a node of T. For every child ν of μ in T, we call $\mathrm{Pt}(\nu)$ a *child block* of B.

The following properties of double trails are clear. They play very important roles in our algorithm.

Noncrossing property. Let Q be a double trail of G. Let e' and e'' be two consecutive edges in Q. Then, e' and e'' appear consecutively around v in G, where v is the ending vertex of e' in Q.

Let B be a block of G. Let e_1 (e_2, respectively) be the edge in B incident to $s(B)$ that is on the west (east, respectively) side of B. (If there is only one edge in B incident to $s(B)$ then $e_1 = e_2$.) Let e_3 (e_4, respectively) be the edge in B incident to $t(B)$ that is on the west (east, respectively) side of B. (If there is only one edge in B incident to $t(B)$, then $e_3 = e_4$.) We call e_1, e_2, e_3, e_4 the *access edges* of B. Each access edge e_i is incident to a pole of B and its dual edge e_i^* is incident to a pole of B^*; only access edges of B satisfy this property.

Access-edge property. Let Q be any double trail of G. Let e', e'' be two consecutive edges in Q such that e' is in B and e'' is not in B. Then, e' must be an access edge of B.

LEMMA 3.1 (see [1]). *Let $e = \{u, v\}$ be an edge in G and $e^* = \{F_1, F_2\}$ its dual edge. Let Q be a maximal double trail in G starting with e. If the direction of e in Q and the direction of e^* in the dual trail Q^* are given, then Q is uniquely determined and can be traced out in $O(|Q|)$ time.*

Proof (sketch). Suppose that Q traverses e from u to v while Q^* traverses e^* from F_1 to F_2. Then, the successor of e in Q must be the edge incident to v and on the face F_2 of G. Repeating this argument, we can uniquely trace out all edges of Q. □

The *degree parity* of a vertex in G is 0 if its degree is even and is 1 otherwise.

FACT 2. *If G is Eulerian, then so is every different embedding of G.*

Proof. Let μ be a node of T, and $B = \mathrm{Pt}(\mu)$. Clearly, no vertex gets a different degree after B is horizontally flipped. Similarly, when μ is a P-node, no vertex gets a different degree after the children of μ are permuted.

Suppose that μ is an R-node. After B is vertically flipped, only the poles $s(B)$ and $t(B)$ may get a different degree in the resulting embedding. Let m_B be the number of edges in B. For each vertex v in B, let $d_B(v)$ be the degree of v in B. Thus, $2m_B = d_B(s(B)) + d_B(t(B)) + \sum_{v \neq s(B), t(B)} d_B(v)$. Since $d_B(v)$ is even for all $v \notin \{s(B), t(B)\}$, $d_B(s(B))$ and $d_B(t(B))$ must have the same parity. Thus, vertically flipping B creates no odd-degree vertex.

Next, suppose μ is an S-node. Let $B_1, \ldots, B_k$ be the child blocks of B. Since no B_i contains an odd-degree nonpole, the two poles $s(B_i)$ and $t(B_i)$ must have the same

degree parity within B_i (as proved in the last paragraph). Suppose that $d_{B_1}(s(B_1))$ is even. Then, $d_{B_1}(t(B_1))$ must be even. Since $t(B_1) = s(B_2)$ and $d_B(t(B_1)) = d_{B_1}(t(B_1)) + d_{B_2}(s(B_2))$ is even, $d_{B_2}(s(B_2))$ must be even. Continuing this argument, we can see that all $s(B_i)$ and $t(B_i)$ must have even degree within B_i. By this, permuting the children of μ creates no odd-degree vertex. Similarly, if $d_{B_1}(s(B_1))$ is odd, then all $s(B_i)$ and $t(B_i)$ must have odd degree within B_i. Thus, permuting the children of μ creates no odd-degree vertex. □

For a trail P in G and a proper block B of G, the *intersection* of P and B, denoted by $P \cap B$, is the list $(Q_1, Q_2, \ldots, Q_k)$, where Q_1 is the first (maximal) subtrail of P in B, Q_2 is the second (maximal) subtrail of P in $B, \ldots,$ and Q_k is the last (maximal) subtrail of P in B. An *ordered* DTC (ODTC) of G is a list $(P_1, \ldots, P_\ell)$ such that $\{P_1, \ldots, P_\ell\}$ is a DTC of G. For an ODTC $\mathcal{P} = (P_1, \ldots, P_\ell)$ of G and a proper block B of G, the *intersection* of $\mathcal{P}$ and B, denoted by $\mathcal{P} \cap B$, is the list $(Q_{1,1}, \ldots, Q_{1,k_1}, \ldots, Q_{\ell,1}, \ldots, Q_{\ell,k_\ell})$, where $(Q_{i,1}, \ldots, Q_{i,k_i})$ is the intersection of P_i and B for all $i \in \{1, \ldots, \ell\}$. Clearly, $\mathcal{P} \cap B$ is an ODTC of B.

Let $\varphi_G : V \to \{1, 2, 3\}$ be the function that maps $s(G)$ to 1, maps $t(G)$ to 2, and maps each nonpole of G to 3. The *starting pair* (respectively, *ending pair*) of a double trail P in G is the pair $(\varphi_G(u), \varphi_{G^*}(x))$, where u is the starting (respectively, ending) vertex of P and x is the starting (respectively, ending) vertex of the dual trail of P. The *extreme quadruple* of a double trail P in G is the quadruple (p_1, p_2, p_3, p_4), where (p_1, p_2) is the starting pair of P and (p_3, p_4) is the ending pair of P. The *σ-extreme list* of an ODTC $(P_1, \ldots, P_k)$ is the list $(q_1, \ldots, q_k)$, where q_i is the extreme quadruple of P_i for all $i \in \{1, \ldots, k\}$. The *π-extreme list* of an ODTC $(P_1, \ldots, P_k)$ is the list $(p_1, q_2, \ldots, q_k)$, where p_1 is the ending pair of P_1 and q_i is the extreme quadruple of P_i for all $i \in \{2, \ldots, k\}$. The *δ-extreme list* of an ODTC $(P_1, \ldots, P_k)$ is the list $(p_1, q_2, \ldots, q_{k-1}, p_k)$, where p_1 is the ending pair of P_1, p_k is the starting pair of P_k, and q_i is the extreme quadruple of P_i for all $i \in \{2, \ldots, k-1\}$.

LEMMA 3.2. *Let B be a block of G. Let $\mathcal{P} = (P_1, \ldots, P_\ell)$ be an ODTC of G. Let D be a TTG, and let $\mathcal{Q} = (Q_1, \ldots, Q_k)$ be an ODTC of D. Let H be the TTG obtained from G by replacing B with D. Then, the following three statements hold:*

1. *Suppose that* (1) *the σ-extreme list of $\mathcal{Q}$ equals that of $\mathcal{P} \cap B$ and* (2) *no trail in $\mathcal{P}$ starts or ends with an edge of B. Then, H has an ODTC $\mathcal{P}'$ whose σ-extreme list equals that of $\mathcal{P}$.*
2. *Suppose that* (1) *the π-extreme list of $\mathcal{Q}$ equals that of $\mathcal{P} \cap B$ and* (2) *P_1 starts with an edge of B while no trail in $\mathcal{P} - \{P_1\}$ starts or ends with an edge of B. Then, H has an ODTC $\mathcal{P}'$ whose π-extreme list equals that of $\mathcal{P}$.*
3. *Suppose that* (1) *the δ-extreme list of $\mathcal{Q}$ equals that of $\mathcal{P} \cap B$ and* (2) *P_1 starts with an edge of B and P_ℓ ends with an edge of B while no trail in $\mathcal{P} - \{P_1, P_\ell\}$ starts or ends with an edge of B. Then, H has an ODTC $\mathcal{P}'$ whose δ-extreme list equals that of $\mathcal{P}$.*

Proof. For each $P_i \in \mathcal{P}$, if $P_i \cap B$ is empty, then let $P'_i = P_i$; otherwise, let P'_i be the trail obtained from P_i by replacing each $S_j \in P_i \cap B$ with Q_j, where S_j is the jth trail in $\mathcal{P} \cap B$. Then, $P' = (P'_1, \ldots, P'_\ell)$ is the required ODTC of H. □

4. The case where G and G^* are Eulerian. Throughout this section, fix an Eulerian TTG G whose dual graph is also Eulerian. Let T be the decomposition tree of G. By Fact 2, each different embedding $\mathcal{G}$ of G and its dual $\mathcal{G}^*$ are still Eulerian. So, each DET P of a valid embedding of G must start and end at the same vertex, and so does the dual trail of P.

4.1. Types of DTCs of proper blocks. Suppose that G has a valid embedding $\mathcal{G}$ and P is a DET of $\mathcal{G}$. Fix a proper block B of $\mathcal{G}$. Since P starts and ends at the same vertex and so does the dual trail of P, we may assume that the starting edge of P is not in B. Then, each double trail in $P \cap B$ must start and end at poles of B. Let $P \cap B = (P_1, \ldots, P_k)$. For each $i \in \{1, \ldots, k\}$, let P_i^* be the dual trail of P_i.

LEMMA 4.1.

1. *If $k \geq 2$, then each $P_i \in \{P_1, \ldots, P_k\}$ uses two distinct access edges of B. Consequently, $k \leq 2$.*
2. *If P_i starts and ends at the same pole of B, then P_i^* must start and end at different poles of B^*.*
3. *If $k = 2$ and P_1 starts and ends at different poles of B, then P_1^* must start and end at the same pole of B^*.*

Proof. Let e_1 and e_2 be the two access edges that are incident to $s(B)$ and on the west side and the east side of B, respectively. Let e_3 and e_4 be the two access edges that are incident to $t(B)$ and on the west side and the east side of B, respectively. We prove the three statements separately as follows.

Statement 1. Suppose $k \geq 2$. Consider an arbitrary $P_i \in \{P_1, \ldots, P_k\}$. Let e (respectively, e') be the starting (respectively, ending) edge of P_i. Since the starting edge of P is not in B, $e \in \{e_1, \ldots, e_4\}$ by the access-edge property. Even if e' is the ending edge of P, since P is an Euler trail, e' must be incident to the starting edge of P which is not in B by our assumption. So, $e' \in \{e_1, \ldots, e_4\}$. Thus, we are done if $e \neq e'$. Towards a contradiction, assume $e = e'$. Then, $e = \{s(B), t(B)\}$ is the unique edge of P_i. In turn, $\{s(B^*), t(B^*)\}$ is the unique edge of P_i^*. It follows that B consists of a single edge, contradicting the assumption that $k \geq 2$. Therefore, $e \neq e'$ and P_i uses two distinct access edges of B. Since B has at most four access edges (namely e_1 through e_4), $k \leq 2$.

Statement 2. Without loss of generality, suppose that P_i starts and ends at $s(B)$. Then, $e_1 \neq e_2$. By the access-edge property, we can assume that P_i starts with e_1 and ends with e_2. Hence, P_i^* starts at the west side and ends at the east side of B. (See Figure 4.1(1).)

Statement 3. Suppose that $k = 2$ and P_1 starts and ends at different poles of B. Then, by statement 1, e_1 through e_4 are distinct edges. Without loss of generality, assume that P_1 starts with e_1. Towards a contradiction, suppose that P_1 ends with e_4. Then, P_2 starts with e_2 and ends with e_3. Since B is a plane graph, P_1 and P_2 must cross each other somewhere inside B. However, this is impossible by the noncrossing property. Hence, P_1 ends with e_3; in turn P_1^* starts and ends at the west side of B. (See Figure 4.1(2).) □

Based on Lemma 4.1, $P \cap B$ can be only of the following five possible types:

- *Type* σ_1. $k = 1$; P_1 starts at one pole and ends at the other pole, and so does P_1^*.
- *Type* σ_2. $k = 1$; P_1 starts at one pole and ends at the same pole while P_1^* starts at one pole and ends at the other pole.
- *Type* σ_3. $k = 1$; P_1 starts at one pole and ends at the other pole while P_1^* starts at one pole and ends at the same pole.
- *Type* σ_4. $k = 2$; P_1 starts at one pole u and ends at u while P_2 starts at the other pole v and ends at v; P_1^* starts at one pole and ends at the other pole, and so does P_2^*.
- *Type* σ_5. $k = 2$; P_1 starts at one pole and ends at the other pole, and so does P_2; P_1^* starts at one pole x and ends at x while P_2^* starts at the other pole y

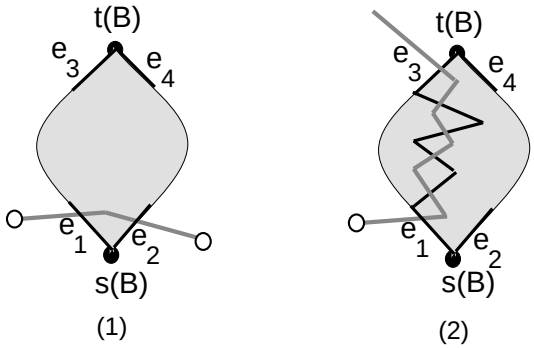

FIG. 4.1. *The proof of Lemma* 4.1.

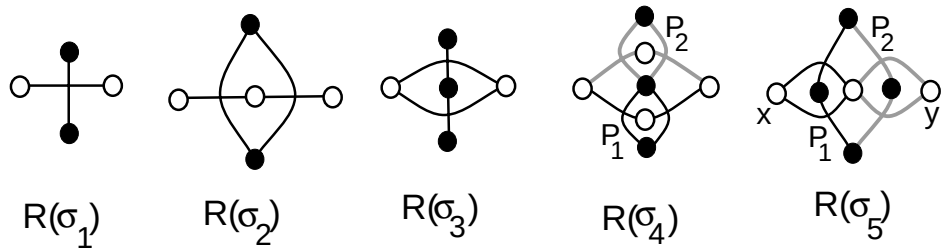

FIG. 4.2. *Representative graphs for* σ*-types.*

and ends at y.

Define $\Sigma = \{\sigma_1, \ldots, \sigma_5\}$. Each σ_i is called a *σ-type*. For a TTG H, let $\mathcal{K}_\sigma(H)$ denote the set of all $\sigma_i \in \Sigma$ such that a different embedding of H has a Type-σ_i ODTC. We call each member of $\mathcal{K}_\sigma(H)$ a *σ-type of H*. For each $\sigma_i \in \Sigma$, a *representative graph* $R(\sigma_i)$ is shown in Figure 4.2 in which the solid lines denote the edges in the trail P_1 and the dual trail P_1^*, while the light lines denote the edges in the trail P_2 and the dual trail P_2^*. Note that σ_i is the unique σ-type of $R(\sigma_i)$ for all $i \in \{1, \ldots, 5\}$.

4.2. Composing DTCs. Let H_1 and H_2 be two vertex-disjoint TTGs. The *series composition* of H_1 and H_2, denoted by $H_1 \star H_2$, is the TTG obtained from H_1 and H_2 by identifying $t(H_1)$ with $s(H_2)$, $s(H_1^*)$ with $s(H_2^*)$, and $t(H_1^*)$ with $t(H_2^*)$. The *parallel composition* of H_1 and H_2, denoted by $H_1 \diamond H_2$, is the TTG obtained from H_1 and H_2 by identifying $s(H_1)$ with $s(H_2)$, $t(H_1)$ with $t(H_2)$, and $t(H_1^*)$ with $s(H_2^*)$. For an integer $k \geq 3$ and k vertex-disjoint TTGs $H_1, \ldots, H_k$, let $H_1 \star H_2 \star \cdots \star H_k = (\cdots((H_1 \star H_2) \star H_3) \star \cdots H_{k-1}) \star H_k$ and $H_1 \diamond H_2 \diamond \cdots \diamond H_k = (\cdots((H_1 \diamond H_2) \diamond H_3) \diamond \cdots H_{k-1}) \diamond H_k$. We call $H_1 \star \cdots \star H_k$ (respectively, $H_1 \diamond \cdots \diamond H_k$) the *series* (respectively, *parallel*) *composition* of H_1 through H_k.

Define two binary operators $\star$ and $\diamond$ over Σ as in Tables 4.1 and 4.2; each empty entry in Table 4.1 (respectively, 4.2) indicates that the $\star$ (respectively, $\diamond$) operator is undefined for that entry.

LEMMA 4.2. *Both $\star$ and $\diamond$ are commutative and associative operators over Σ.*

Proof. One can use Tables 4.1 and 4.2 to verify. □

LEMMA 4.3. *Let H be a TTG. Then, the following two statements hold:*

1. *Suppose $H = H_1 \star H_2$, where $\mathcal{K}_\sigma(H_1) = \{\sigma_i\}$ and $\mathcal{K}_\sigma(H_2) = \{\sigma_j\}$. Then, $\mathcal{K}_\sigma(H) = \{\sigma_i \star \sigma_j\}$ if $\sigma_i \star \sigma_j$ is defined, while $\mathcal{K}_\sigma(H) = \emptyset$ otherwise.*

2. *Suppose* $H = H_1 \diamond H_2$, *where* $\mathcal{K}_\sigma(H_1) = \{\sigma_i\}$ *and* $\mathcal{K}_\sigma(H_2) = \{\sigma_j\}$. *Then,* $\mathcal{K}_\sigma(H) = \{\sigma_i \diamond \sigma_j\}$ *if* $\sigma_i \diamond \sigma_j$ *is defined, while* $\mathcal{K}_\sigma(H) = \emptyset$ *otherwise.*

Proof. By statement 1 in Lemma 3.2, it suffices to verify that for every $\sigma_i, \sigma_j \in \Sigma$, $\mathcal{K}_\sigma(R(\sigma_i) \star R(\sigma_j)) = \{\sigma_i \star \sigma_j\}$ and $\mathcal{K}_\sigma(R(\sigma_i) \diamond R(\sigma_j)) = \{\sigma_i \diamond \sigma_j\}$. For the verification, it is helpful to note that for each $\sigma_i \in \Sigma$, $R(\sigma_i)$ remains unchanged after a horizontal or vertical flipping. We show only one example for each of the $\star$ and the $\diamond$ operators. The other cases can be verified similarly.

Consider the graph $R(\sigma_1)$, with poles u and v, and the graph $R(\sigma_3)$ with poles v and w. Let x and y be the west side and the east side of their series composition $H' = R(\sigma_1) \star R(\sigma_3)$. (See Figure 4.3(1).) The only DTC of H' consists of a single double trail P_1 which starts at u, passing through v and ends at w, while the dual trail P_1^* starts at x, travels to y, to x, and to y again. This is a Type-σ_1 DTC. So $\mathcal{K}_\sigma(R(\sigma_1) \star R(\sigma_3)) = \{\sigma_1\} = \{\sigma_1 \star \sigma_3\}$ as to be shown.

Consider the graph $R(\sigma_4)$ with poles u, v, the west side x and the east side y; and the graph $R(\sigma_5)$ with poles u, v, the west side y and the east side z. (See Figure 4.3(2).) Let $H'' = R(\sigma_4) \diamond R(\sigma_5)$. The only DTC of H'' consists of two double trails P_1 and P_2 as shown in Figure 4.3(2). This is a Type-σ_5 DTC. So $\mathcal{K}_\sigma(R(\sigma_4) \diamond R(\sigma_5)) = \{\sigma_5\} = \{\sigma_4 \diamond \sigma_5\}$. □

Let μ be a node in T and $B = \mathrm{Pt}(\mu)$. For convenience, we also use $\mathcal{K}_\sigma(\mu)$ to denote $\mathcal{K}_\sigma(B)$.

LEMMA 4.4. *Let* μ *be a nonroot node of* T *and* $B = \mathrm{Pt}(\mu)$. *Then,* $|\mathcal{K}_\sigma(B)| \leq 1$. *Moreover,* $\mathcal{K}_\sigma(\mathrm{Pt}(\nu))$ *for all descendants* ν *(including* μ *itself) of* μ *in* T *can be computed in* $O(|B|)$ *time.*

Proof. The proof is by induction. In case μ is a leaf node of T, the lemma trivially holds because $\mathcal{K}_\sigma(B) = \{\sigma_1\}$. Suppose that μ is a nonleaf node of T. Let $\nu_1, \ldots, \nu_k$ be the children of μ in T. Let $B_i = \mathrm{Pt}(\nu_i)$ for all $i \in \{1, \ldots, k\}$. By the inductive hypothesis, $|\mathcal{K}_\sigma(B_i)| \leq 1$. If $\mathcal{K}_\sigma(B_i) = \emptyset$ for some $i \in \{1, \ldots, k\}$, then clearly $\mathcal{K}_\sigma(B) = \emptyset$. So, suppose that each $\mathcal{K}_\sigma(B_i)$ consists of a unique $\sigma_{j_i} \in \Sigma$. Consider the following three cases:

Case 1. μ is an R-node. Then, $\mathrm{Sk}(\mu)$ has no different embedding other than itself. Let H be the TTG obtained from $\mathrm{Sk}(\mu)$ by replacing the virtual edge of ν_i in $\mathrm{Sk}(\mu)$

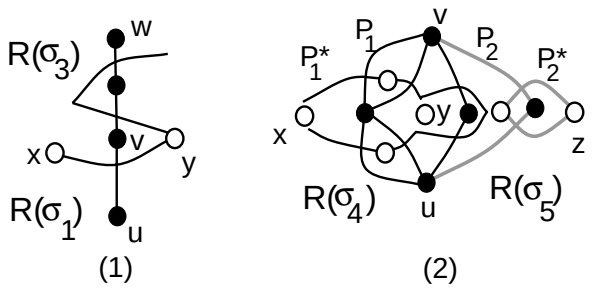

FIG. 4.3. *The proof of Lemma* 4.3.

with $R(\sigma_{j_i})$ for all $i \in \{1, \ldots, k\}$. Since $\mathcal{K}_\sigma(B_i) = \mathcal{K}_\sigma(R(\sigma_{j_i}))$ for all $i \in \{1, \ldots, k\}$, by repeatedly applying statement 1 in Lemma 3.2, we have $\mathcal{K}_\sigma(\mu) = \mathcal{K}_\sigma(H)$. $\mathcal{K}_\sigma(H)$ can be computed as follows.

Let P_1 be the maximal double trail in H which starts at $s(H)$ and whose dual trail P_1^* starts at $s(H^*)$. Let M be the set of all edges of H not traversed by P_1. In case $M = \emptyset$, we check if $\{P_1\}$ is a DTC of H of a σ-type; if it is, then $\mathcal{K}_\sigma(\mu)$ consists of this σ-type, while $\mathcal{K}_\sigma(\mu) = \emptyset$ otherwise. Suppose $M \neq \emptyset$. If M contains no access edge of H, then $\mathcal{K}_\sigma(\mu) = \emptyset$. Otherwise, let $e \in M$ be an access edge of H. We find the maximal double trail P_2 in H such that e and e^* are, respectively, the starting edge of P_2 and its dual trail P_2^*. If $\{P_1, P_2\}$ is a DTC of H of a σ-type, then $\mathcal{K}_\sigma(\mu)$ consists of this σ-type, while $\mathcal{K}_\sigma(\mu) = \emptyset$ otherwise.

Case 2. μ is an S-node. Then, each different embedding $\mathcal{B}$ of B can be written as $\mathcal{B}_{1'} \star \cdots \star \mathcal{B}_{k'}$, where $(1', 2', \ldots, k')$ is a permutation of $(1, 2, \ldots, k)$ and $\mathcal{B}_{i'}$ is a different embedding of $B_{i'}$ for all $i \in \{1, \ldots, k\}$. By Lemma 4.3, if $(\cdots((\sigma_{j_{1'}} \star \sigma_{j_{2'}}) \star \sigma_{j_{3'}}) \star \cdots) \star \sigma_{j_{k'}}$ is undefined, then $\mathcal{K}_\sigma(\mathcal{B}) = \emptyset$; otherwise, by Lemma 4.2, $\mathcal{K}_\sigma(\mathcal{B}) = \{(\cdots((\sigma_{j_1} \star \sigma_{j_2}) \star \sigma_{j_3}) \star \cdots) \star \sigma_{j_k}\}$. Thus, $|\mathcal{K}_\sigma(B)| \leq 1$.

Case 3. μ is a P-node. It is similar to Case 2. □

4.3. The algorithm. We process the nodes of T in post-order. When processing a nonroot node μ of T, we compute $\mathcal{K}_\sigma(\mu)$ as in the proof of Lemma 4.4. Let μ be the root of T. Let $\nu_1, \ldots, \nu_k$ be the children of μ in T. For each $i \in \{1, \ldots, k\}$, let $B_i = \mathrm{Pt}(\nu_i)$. If $\mathcal{K}_\sigma(B_i) = \emptyset$ for some $i \in \{1, \ldots, k\}$, then G has no valid embedding and we stop immediately. So, suppose that $\mathcal{K}_\sigma(B_1) = \{\sigma_{j_1}\}, \ldots, \mathcal{K}_\sigma(B_k) = \{\sigma_{j_k}\}$. We distinguish three cases as follows.

- *Case* 1. μ is an R-node. Then, $\mathrm{Sk}(\mu)$ has no different embedding other than itself. As in Case 1 in the proof of Lemma 4.4, we construct a TTG H from $\mathrm{Sk}(\mu)$. By the same argument as in Case 1 in the proof of Lemma 4.4, G has a DET if and only if H has a DET.

  To test if H has a DET, we pick an arbitrary edge e in H and fix a direction as the starting point. The dual edge e^* can be directed in two ways. Once the direction of e^* is fixed, we can uniquely trace the dual trail by Lemma 3.1.

  More specifically, let e be the edge incident to $s(B)$ whose dual edge e^* is incident to $s(H^*)$. Let x be the endpoint of e^* other than $s(H^*)$. Let P (respectively, Q) be the maximal double trail in H which starts at $s(H)$ and whose dual trail starts at $s(H^*)$ (respectively, x). By Lemma 3.1, P and Q can be found in $O(|\mathrm{Sk}(\mu)|)$ time. By statement 1 in Lemma 3.2, if either P or Q is a DET in H, then G has a DET. If neither P nor Q is a DET in H,

then H has no DET, and hence G has no DET either.

- *Case* 2. μ is an S-node. First we prove the following claim.
  Claim. For a TTG $H = H_1 \star H_2$ with $|\mathcal{K}_\sigma(H_1)| \leq 1$ and $|\mathcal{K}_\sigma(H_2)| \leq 1$, H has a valid embedding if and only if $\mathcal{K}_\sigma(H_1) = \mathcal{K}_\sigma(H_2) = \{\sigma_2\}$.
  To see the "if" part of the claim, it suffices to observe that a series composition of two copies of $R(\sigma_2)$ has a valid embedding. To see the "only if" part, suppose that H has a DET P. Then, P is obtained by concatenating the double trail(s) in the DTC of H_1 and the double trail(s) in the DTC of H_2. This can be done only in the following two possible ways.
  (a) The DTC of H_1 consists of a single double trail P_1 starting and ending at the same pole of H_1, and the DTC of H_2 consists of a single double trail P_2 starting and ending at the same pole of H_2. That is, $\mathcal{K}_\sigma(H_1) = \mathcal{K}_\sigma(H_2) = \{\sigma_2\}$. In this case, if H is obtained by identifying the common pole where both P_1 and P_2 start and end, we indeed get a DET of H.
  (b) The DTC of H_1 consists of a single double trail P_1 starting and ending at the same pole of H_1, and the DTC of H_2 consists of two double trails P_2 and P_3, each starting and ending at the different poles of H_2. (In this case, by concatenating P_2, P_1, P_3 in this order, we get a closed Euler trail P of H.) That is, $\mathcal{K}_\sigma(H_1) = \{\sigma_2\}$ and $\mathcal{K}_\sigma(H_2) = \{\sigma_5\}$. In this case, however, the dual trail P^* of P starts at one pole of the dual graph H^* and ends at the other pole of H^*. (This can be verified by using the representative graphs in Figure 4.2.) Hence, P^* is not a closed Euler trail of H^*. So, this case is impossible. This completes the proof of the claim.
  Observe that for each nonempty proper subset $\{1', \ldots, h'\}$ of $\{1, \ldots, k\}$, $B_{1'} \star \cdots \star B_{h'}$ has at most one σ-type. This follows from Lemmas 4.2 and 4.3. By the claim and this observation, G has a valid embedding if and only if $\{1, \ldots, k\}$ can be partitioned into two sets $\{1', \ldots, h'\}$, $\{1'', \ldots, g''\}$ such that σ_2 is the σ-type of both $B_{1'} \star \cdots \star B_{h'}$ and $B_{1''} \star \cdots \star B_{g''}$. By Table 4.1, such a partition is possible if and only if (1) σ_2 is the σ-type of exactly two of $B_1, \ldots, B_k$ and (2) σ_5 is the σ-type of all the rest.
- *Case* 3. μ is a P-node. It suffices to modify the argument in Case 2 by replacing each symbol "$\star$" with "$\diamond$," "σ_2" with "σ_3," and "σ_5" with "σ_4."

By Lemmas 2.1 and 4.4, the time needed to process the entire tree T is $O(|G|)$. Thus, we have the following.

THEOREM 4.5. *Given an Eulerian TTG G whose dual graph is also Eulerian, it takes $O(|G|)$ time to decide if G has a valid embedding.*

5. An $O(|G|^3)$-time algorithm. Throughout the rest of this paper, let G be a TTG, and let T be its decomposition tree. The *reverse* of a trail $e_1 e_2 \ldots e_k$ in G is the trail $e_k e_{k-1} \ldots e_1$. Section 5.1 investigates how a DET of G can intersect a block of G. Section 5.2 (respectively, 5.3) shows how a DET P can intersect the series (respectively, parallel) composition of two or more blocks of G, given the way that P intersects the blocks. Section 5.4 describes the algorithm for deciding the existence of a DET.

5.1. Types of DTCs of proper blocks. Suppose that G has a valid embedding $\mathcal{G}$ and P is a DET of $\mathcal{G}$. Let e_s and e_t be the starting and the ending edge of P, respectively. Fix a proper block B of $\mathcal{G}$. Let $P \cap B = (P_1, \ldots, P_k)$. For each $i \in \{1, \ldots, k\}$, let P_i^* be the dual trail of P_i.

Case 1. Neither e_s nor e_t is in B. Then, as discussed in section 4.1, $P \cap B$ can only be of a σ-type.

Case 2. Exactly one of e_s and e_t is in B. If e_s is in B, let $Q_i = P_i$ for all $i \in \{1, \ldots, k\}$; otherwise, let Q_i be the reverse of P_{k-i+1} for all $i \in \{1, \ldots, k\}$. Let Q_i^* be the dual trail of Q_i for each $i \in \{1, \ldots, k\}$.

Without loss of generality, suppose that Q_1 starts with e_s and ends with an access edge of B that is incident to a pole u of B. Similarly to the proof of statement 1 in Lemma 4.1, we can show that each $Q_i \in \{Q_2, \ldots, Q_k\}$ must use exactly two access edges of B. Since B has at most four access edges, k must be either 1 or 2. If $k = 2$, the trail Q_2 or its reverse either starts with an access edge incident to u and ends with an access edge incident to the other pole v of B, or it starts and ends with the two access edges incident to v. Based on these observations, the ODTC $(Q_1, \ldots, Q_k)$ can only be of the following possible types:

- *Type* π_1. $k = 1$; Q_1 ends at a pole; Q_1^* ends at a pole.
- *Type* π_2. $k = 2$; Q_1 ends at a pole, and Q_2 starts at a pole and ends at the other pole; Q_1^* ends at a pole, and Q_2^* starts at a pole and ends at the other pole.
- *Type* π_3. $k = 2$; Q_1 ends at a pole, and Q_2 starts at a pole and ends at the other pole; Q_1^* ends at a pole x, and Q_2^* starts at the other pole y and ends at y.
- *Type* π_4. $k = 2$; Q_1 ends at a pole u, and Q_2 starts at the other pole v and ends at v; Q_1^* ends at a pole, and Q_2^* starts at a pole and ends at the other pole.

Note that, for each type π_i, the trail Q_1 is required to end at a pole and starts with the edge e_s. However, the edge e_s might be either incident to a pole or not incident to a pole.

Define $\Pi = \{\pi_1, \ldots, \pi_4\}$. We call the elements of Π *π-types*. For a TTG H, let $\mathcal{K}_\pi(H)$ denote the set of all $\pi_i \in \Pi$ such that a different embedding of H has a Type-π_i DTC. We call each member of $\mathcal{K}_\pi(H)$ a *π-type of H*. For each $\pi_i \in \Pi$, a *representative graph* $R(\pi_i)$ is shown in Figure 5.1. Note that for all $i \in \{1, \ldots, 4\}$, π_i is the unique π-type of $R(\pi_i)$.

Case 3. Both e_s and e_t are in B. Then, $k > 1$ or else B could not have been a proper block of G. Without loss of generality, suppose that P_1 starts with e_s and P_k ends with e_t. Each of P_1 and P_k uses at least one access edge of B. Similarly to the proof of statement 1 in Lemma 4.1, we can show that each $P_i \in \{P_2, \ldots, P_{k-1}\}$ must use exactly two access edges of B. Thus, k must be either 2 or 3. By considering which access edges are used by which P_i, it can be seen that $P \cap B$ can be only one of the following possible types:

- *Type* δ_1. $k = 2$; P_1 ends at a pole, and P_2 starts at the same pole; P_1^* ends at a pole, and P_2^* starts at the other pole.
- *Type* δ_2. $k = 2$; P_1 ends at a pole, and P_2 starts at the other pole; P_1^* ends at a pole, and P_2^* starts at the same pole.
- *Type* δ_3. $k = 2$; P_1 ends at a pole, and P_2 starts at the other pole; P_1^* ends at a pole, and P_2^* starts at the other pole.
- *Type* δ_4. $k = 3$; P_1 ends at a pole u, P_2 starts at the other pole v and ends at v, and P_3 starts at u; P_1^* ends at a pole x, P_2^* starts at x and ends at the other pole y, and P_3^* starts at y.
- *Type* δ_5. $k = 3$; P_1 ends at a pole u, P_2 starts at u and ends at the other pole v, and P_3 starts at v; P_1^* ends at a pole x, P_2^* starts at the other pole y and ends at y, and P_3^* starts at x.
- *Type* δ_6. $k = 3$; P_1 ends at a pole u, P_2 starts at a pole and ends at the other

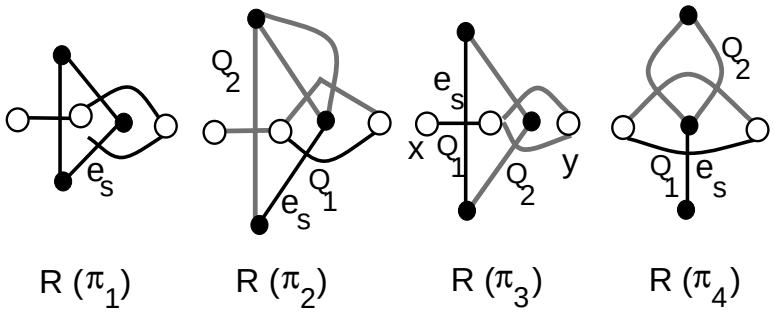

FIG. 5.1. *Representative graphs for π-types.*

pole, and P_3 starts at the pole $v \neq u$; P_1^* ends at a pole x, P_2^* starts at a pole and ends at the other pole, and P_3^* starts at the pole $y \neq x$.

Note that for each type δ_i, the trail P_1 is required to end at a pole and starts with the edge e_s. However, e_s might be either incident to a pole or not incident to a pole. The trail P_2 in the types $\delta_1, \delta_2, \delta_3$ (the trail P_3 in the types $\delta_4, \delta_5, \delta_6$, respectively) is required to start at a pole and ends with the edge e_t. However, e_t might be either incident to a pole or not incident to a pole.

Define $\Delta = \{\delta_1, \ldots, \delta_6\}$. We note that when $B = G$, $P \cap B$ must be of the following type:

- *Type* δ_0. $k = 1$.

We call the elements of $\Delta \cup \{\delta_0\}$ *δ-types*. For a TTG H, let $\mathcal{K}_\delta(H)$ denote the set of all $\delta_i \in \Delta \cup \{\delta_0\}$ such that a different embedding of H has a Type-δ_i DTC. We call each member of $\mathcal{K}_\delta(H)$ a *δ-type of H*. For each $\delta_i \in \Delta$, a *representative graph* $R(\delta_i)$ is shown in Figure 5.2. Note that for all $i \in \{1, \ldots, 6\}$, δ_i is the unique δ-type of $R(\delta_i)$.

Define $\Gamma = \Sigma \cup \Pi \cup \Delta$. Let H be a representative graph in Figures 5.1 and 5.2. If $\mathcal{Q}_1$ and $\mathcal{Q}_2$ are two DTCs of H such that $\mathcal{Q}_2$ can be obtained from $\mathcal{Q}_1$ by reversing the direction of exactly one double trail on which neither e_s nor e_t appears, then we view $\mathcal{Q}_1$ and $\mathcal{Q}_2$ as the same DTC. A DTC $\mathcal{Q}$ of H is *valid* if $\mathcal{Q}$ is of a σ-, π-, or δ-type. From the figures, we can see that H has a unique valid DTC. Thus, if H is a graph in Figure 5.1, then we think that e_s and its dual edge have been oriented by the valid DTC of H. Similarly, if H is a graph in Figure 5.2, then we think that e_s and e_t and their dual edges have been oriented by the valid DTC of H.

5.2. Series composition of DTCs. This subsection shows how to compute the π- or δ-types of a series composition of two or more TTGs $H_1, \ldots, H_k$, when the σ-, π-, or δ-types of H_1 through H_k are given. This is needed by our algorithm to process the S-nodes of T. Let $\Gamma_1 = \Sigma_1 \cup \Pi_1 \cup \Delta_1$ and $\Gamma_2 = \Sigma_2 \cup \Pi_2 \cup \Delta_2$ be two subsets of Γ, where for $i = 1, 2$, $\Sigma_i \subseteq \Sigma$, $\Pi_i \subseteq \Pi$, and $\Delta_i \subseteq \Delta$. Define

$$\begin{aligned}\Gamma_1 \star \Gamma_2 = {} & (\cup_{\sigma_i \in \Sigma_1, \sigma_j \in \Sigma_2} \mathcal{K}_\sigma(R(\sigma_i) \star R(\sigma_j))) \cup (\cup_{\sigma_i \in \Sigma_1, \pi_j \in \Pi_2} \mathcal{K}_\pi(R(\sigma_i) \star R(\pi_j))) \\ & \cup (\cup_{\pi_i \in \Pi_1, \sigma_j \in \Sigma_2} \mathcal{K}_\pi(R(\pi_i) \star R(\sigma_j))) \cup (\cup_{\sigma_i \in \Sigma_1, \delta_j \in \Delta_2} \mathcal{K}_\delta(R(\sigma_i) \star R(\delta_j))) \\ & \cup (\cup_{\delta_i \in \Delta_1, \sigma_j \in \Sigma_2} \mathcal{K}_\delta(R(\delta_i) \star R(\sigma_j))) \cup (\cup_{\pi_i \in \Pi_1, \pi_j \in \Pi_2} \mathcal{K}_\delta(R(\pi_i) \star R(\pi_j))).\end{aligned}$$

If $\Gamma_1 = \emptyset$ or $\Gamma_2 = \emptyset$, then $\Gamma_1 \star \Gamma_2 = \emptyset$.

Recall that, by the definition, $\mathcal{K}_\sigma(H)$ is the set of $\sigma_i \in \Sigma$ such that a different embedding of H has a type-σ_i ODTC. In the case $H = H_1 \star H_2$, if we switch H_1 and

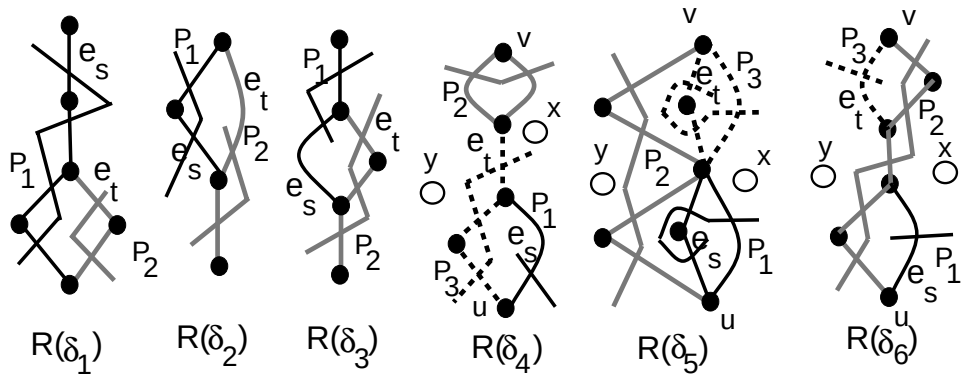

FIG. 5.2. *Representative graphs for δ-types.*

H_2, the graph $H_2 \star H_1$ is a different embedding of H, and hence the σ-types of $H_1 \star H_2$ and $H_2 \star H_1$ both belong to $\mathcal{K}_\sigma(H)$. This remark is also true for $\mathcal{K}_\pi(H)$ and $\mathcal{K}_\delta(H)$. Thus, the operator $\star$ defined on Γ_1 and Γ_2 is trivially commutative by its definition. For later reference, we state this in the following lemma.

LEMMA 5.1. *If* Γ_1 *and* Γ_2 *are two subsets of* Γ*, then* $\Gamma_1 \star \Gamma_2 = \Gamma_2 \star \Gamma_1$.

For each $\sigma_i \in \Sigma$ and each $\delta_j \in \Delta$, the (i,j)-entry of Table 5.1 contains all $\delta_k \in \{\sigma_i\} \star \{\delta_j\}$. For each $\pi_i \in \Pi$ and each $\sigma_j \in \Sigma$, the (i,j)-entry of Table 5.2 contains all $\pi_k \in \{\pi_i\} \star \{\sigma_j\}$. For each $\pi_i \in \Pi$ and each $\pi_j \in \Pi$, the (i,j)-entry of Table 5.3 contains all $\delta_k \in \{\pi_i\} \star \{\pi_j\}$. These tables can be verified by inspecting the representative graphs in Figures 4.2, 5.1, and 5.2. As examples, we verify one entry from each of Tables 5.1, 5.2, and 5.3. They are shown in Figure 5.3. In each case, two representative graphs are composed in series by identifying the common pole v. The type of the resulting graph is shown in the figure.

Suppose that $H = H_1 \star H_2 \star \cdots \star H_k$ and that $\mathcal{K}_\sigma(H_i)$, $\mathcal{K}_\pi(H_i)$, and $\mathcal{K}_\delta(H_i)$ have already been computed for all $i \in \{1, \ldots, k\}$. Our goal is to calculate $\mathcal{K}_\sigma(H)$, $\mathcal{K}_\pi(H)$, and $\mathcal{K}_\delta(H)$ for the series composition H. $\mathcal{K}_\sigma(H)$ can be computed as in section 4.2. By definition, $\mathcal{K}_\pi(H)$ contains all the π-types of all different embeddings of H. Essentially, this means that the computation of $\mathcal{K}_\pi(H)$ requires the evaluation of all expressions consisting of one operand from some $\mathcal{K}_\pi(H_i)$ and one operand from each of $\mathcal{K}_\sigma(H_1), \ldots, \mathcal{K}_\sigma(H_{i-1}), \mathcal{K}_\sigma(H_{i+1}), \ldots, \mathcal{K}_\sigma(H_k)$ connected by the operator $\star$. Although the operator $\star$ is commutative, it is not associative. This makes the calculation of $\mathcal{K}_\pi(H)$ very complex. The calculation of $\mathcal{K}_\delta(H)$ is even more complex. The rest of this subsection discusses how to perform these calculations.

A $\star$-*expression* E, its *value*, and its *operand multiset* $\mathrm{Op}(E)$ are defined inductively as follows. Each $\gamma \in \Gamma$ is a $\star$-expression, its value is $\{\gamma\}$, and its operand multiset is $\langle\gamma\rangle$. Each (possibly empty) $\Gamma_1 \subseteq \Gamma$ is a $\star$-expression, its value is Γ_1, and its operand multiset is $\langle\Gamma_1\rangle$. If E_1 and E_2 are $\star$-expressions, then $(E_1 \star E_2)$ is a $\star$-expression, its operand multiset is $\mathrm{Op}(E_1) \cup \mathrm{Op}(E_2)$, and its value is $(\Gamma_1 \star \Gamma_2)$, where Γ_1 and Γ_2 are the value of E_1 and E_2, respectively.

We identify a $\star$-expression with its value. For a list $(X_1, \ldots, X_k)$ of elements or subsets of Γ, let $X_1 \star X_2 \star \cdots \star X_k$ denote the $\star$-expression $(\cdots((X_1 \star X_2) \star X_3) \star \cdots X_k)$. For a subset Γ_1 of Γ and a list $L = (\sigma_{i_1}, \ldots, \sigma_{i_k})$ of σ-types, let $\Gamma_1 \star [L]_\star$ denote the $\star$-expression $\Gamma_1 \star \sigma_{i_1} \star \cdots \star \sigma_{i_k}$ if $k \geq 1$; and denote Γ_1 otherwise. For a $\sigma_i \in \Sigma$ and a nonnegative integer k, let σ_i^k denote the list of k σ_i's.

The *parse tree* T_E of a $\star$-expression E is defined inductively as follows. If $|\mathrm{Op}(E)| = 1$, then T_E consists of a single node labeled with the unique element of $\mathrm{Op}(E)$. If $E = (E_1 \star E_2)$, then T_E is obtained from the parse tree T_{E_1} of E_1 and the parse tree T_{E_2} of E_2 by introducing a new node r and letting the roots of T_{E_1} and T_{E_2} be the children of r.

For convenience, each node v in a parse tree T_E is viewed as an ancestor of v itself in T_E.

LEMMA 5.2. *Suppose $\Delta_1 \subseteq \Delta$. Let $L = (\sigma_{i_1}, \ldots, \sigma_{i_q})$ be a list of σ-types. Then, the following two statements hold:*

1. *For every $\star$-expression E with $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Delta_1 \rangle$, if σ_2 is not in L, then $E \subseteq \Delta_1 \star [L]_\star$; otherwise, $E \subseteq \Delta_1 \star [L - \{\sigma_5\}]_\star$.*
2. *Let U be the union of the values of all $\star$-expressions E with $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Delta_1 \rangle$. If σ_2 is not in L, then $U = \Delta_1 \star [L]_\star$; otherwise, $U = \Delta_1 \star [L - \{\sigma_5\}]_\star$.*

Proof. We prove the two statements separately as follows.

Statement 1. First, we claim that if σ_i and σ_j are (possibly the same) elements of Σ with $\{\sigma_i, \sigma_j\} \neq \{\sigma_2, \sigma_5\}$, then $\Delta_1 \star (\sigma_i \star \sigma_j) \subseteq \Delta_1 \star \sigma_i \star \sigma_j = \Delta_1 \star \sigma_j \star \sigma_i$. One may verify this claim using Tables 4.1 and 5.1, under the assumption that $|\Delta_1| = 1$. This claim then holds for every $\Delta_1 \subseteq \Delta$.

Second, we claim that $(\Delta_1 \star \sigma_5 \star \sigma_2) \cup (\Delta_1 \star \sigma_2 \star \sigma_5) \subseteq \Delta_1 \star (\sigma_5 \star \sigma_2) = \Delta_1 \star \sigma_2$. One may verify this claim using Tables 4.1 and 5.1, under the assumption that $|\Delta_1| = 1$. This claim then holds for every $\Delta_1 \subseteq \Delta$.

Third, we claim that for every nonempty list L of σ-types and every permutation L' of L, if σ_2 is not in L, then $\Delta_1 \star [L']_\star \subseteq \Delta_1 \star [L]_\star$; otherwise, $\Delta_1 \star [L']_\star \subseteq \Delta_1 \star [L - \{\sigma_5\}]_\star$. This is shown by induction on the number q of elements of L as follows. The claim trivially holds when $q = 1$. Let $q \geq 2$ and $L = (\sigma_{i_1}, \ldots, \sigma_{i_q})$

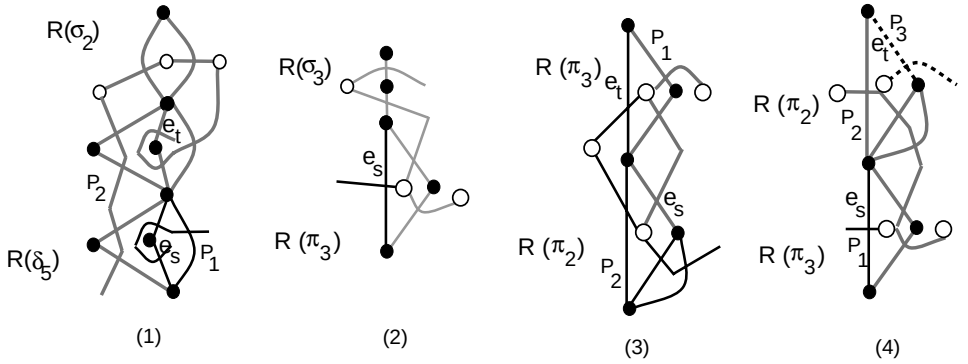

FIG. 5.3. (1) $\sigma_2 \star \delta_5 = \delta_1$; (2) $\pi_3 \star \sigma_3 = \pi_3$; (3) $\pi_2 \star \pi_3 = \delta_2$; (4) $\pi_2 \star \pi_3 = \delta_6$.

be a list of σ-types. Let $L' = (\sigma_{j_1}, \ldots, \sigma_{j_q})$ be a permutation of L. If σ_5 or σ_2 does not occur in L, then, by the first claim, $\Delta_1 \star [L']_\star \subseteq \Delta_1 \star [L]_\star$. So, suppose that both σ_5 and σ_2 occur in L. Consider a sublist $(\sigma_{j_k}, \sigma_{j_{k+1}}, \ldots, \sigma_{j_\ell})$ of L' such that $\{\sigma_{j_k}, \sigma_{j_\ell}\} = \{\sigma_5, \sigma_2\}$ and $\{\sigma_5, \sigma_2\} \cap \{\sigma_{j_{k+1}}, \ldots, \sigma_{j_{\ell-1}}\} = \emptyset$. By the first claim, $\Delta_1 \star [L']_\star = \Delta_1 \star \sigma_{j_1} \star \cdots \star \sigma_{j_k} \star \sigma_{j_\ell} \star \sigma_{j_{k+1}} \star \cdots \star \sigma_{j_{\ell-1}} \star \sigma_{j_{\ell+1}} \star \cdots \star \sigma_{j_q}$. This together with the second claim implies that $\Delta_1 \star [L']_\star \subseteq \Delta_1 \star \sigma_{j_1} \star \cdots \star \sigma_{j_{k-1}} \star \sigma_2 \star \sigma_{j_{k+1}} \star \cdots \star \sigma_{j_{\ell-1}} \star \sigma_{j_{\ell+1}} \star \cdots \star \sigma_{j_q}$. Now, the third claim follows from the inductive hypothesis.

Let L and E be as described in the lemma. Let T_E be the parse tree of E, and let v be the leaf node labeled with Δ_1. Let $v, u_1, \ldots, u_m$ be the path from v to the root of T_E. For each $i \in \{1, \ldots, m\}$, let E_i be the $\star$-expression whose parse tree is the subtree of T_E rooted at the child of u_i that is not an ancestor of v. Then, $E = \Delta_1 \star E_1 \star \cdots \star E_m$. Define $E'_1 = \sigma_{j_1} \star \cdots \star \sigma_{j_a}$, where $\langle \sigma_{j_1}, \ldots, \sigma_{j_a} \rangle$ equals $\mathrm{Op}(E_1)$ if σ_2 is not in $\mathrm{Op}(E_1)$, while it equals $\mathrm{Op}(E_1) - \{\sigma_5\}$ otherwise. Define $E'_2 = \sigma_{k_1} \star \cdots \star \sigma_{k_b}$, $\ldots$, $E'_m = \sigma_{\ell_1} \star \cdots \star \sigma_{\ell_c}$ similarly. Since operator $\star$ is commutative and associative over Σ (by Lemma 4.2) and $\sigma_5 \star \sigma_2 = \sigma_2$, we have $E_i = E'_i$ for all $i \in \{1, \ldots, m\}$. Thus, $E = \Delta_1 \star E'_1 \star \cdots \star E'_m$. By Table 4.1, if two elements σ_g and σ_h of Σ satisfy $\sigma_g \star \sigma_h = \sigma_2$, then $\sigma_2 \in \{\sigma_g, \sigma_h\}$; similarly, if two elements σ_g and σ_h of Σ satisfy $\sigma_g \star \sigma_h = \sigma_5$, then $\sigma_g = \sigma_h = \sigma_5$. By this fact, for every $i \in \{1, \ldots, m\}$, if σ_2 (respectively, σ_5) is not in $\mathrm{Op}(E'_i)$, then σ_2 (respectively, σ_5) does not result when we evaluate E'_i from left to right. Thus, by the first claim, $E \subseteq \Delta_1 \star \sigma_{j_1} \star \cdots \star \sigma_{j_a} \star \sigma_{k_1} \star \cdots \star \sigma_{k_b} \star \cdots \star \sigma_{\ell_1} \star \cdots \star \sigma_{\ell_c}$. Now, by the third claim, statement 1 holds.

Statement 2. First suppose that σ_2 is not in L. Then, by statement 1, $U \subseteq \Delta_1 \star [L]_\star$. On the other hand, $\Delta_1 \star [L]_\star \subseteq U$ because $\Delta_1 \star [L]_\star$ is a $\star$-expression whose operand multiset is $\langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Delta_1 \rangle$. So, $U = \Delta_1 \star [L]_\star$.

Next, suppose that σ_2 is in L. Then, by statement 1, $U \subseteq \Delta_1 \star [L - \{\sigma_5\}]_\star$. On the other hand, we can modify the $\star$-expression $\Delta_1 \star [L - \{\sigma_5\}]_\star$ by replacing one appearance of σ_2 with $(\sigma_2 \star \sigma_5 \star \cdots \star \sigma_5)$ in which σ_5 appears as many times as in L. The resulting $\star$-expression has the same value as $\Delta_1 \star [L - \{\sigma_5\}]_\star$, since $\sigma_2 \star \sigma_5 = \sigma_2$, and is a $\star$-expression whose operand multiset is $\langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Delta_1 \rangle$. So, $\Delta_1 \star [L - \{\sigma_5\}]_\star \subseteq U$. This completes the proof of statement 2. □

Lemma 5.2 still holds after replacing each appearance of "Δ" in it with "Π," as stated in the following.

LEMMA 5.3. *Suppose* $\Pi_1 \subseteq \Pi$. *Let* $L = (\sigma_{i_1}, \ldots, \sigma_{i_q})$ *be a list of* σ*-types. Then, the following two statements hold:*

1. *For every* $\star$*-expression* E *with* $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Pi_1 \rangle$, *if* σ_2 *is not in* L,

then $E \subseteq \Pi_1 \star [L]_\star$*; otherwise,* $E \subseteq \Pi_1 \star [L - \{\sigma_5\}]_\star$.

2. *Let* U *be the union of the values of all* $\star$*-expressions* E *with* $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Pi_1 \rangle$*. If* σ_2 *is not in* L*, then* $U = \Pi_1 \star [L]_\star$*; otherwise,* $U = \Pi_1 \star [L - \{\sigma_5\}]_\star$.

Proof. It suffices to modify the proof of Lemma 5.2 by replacing each appearance of "Δ" with "Π" and "Table 5.1" with "Table 5.2." □

LEMMA 5.4. *Suppose that* $\Pi_1 \subseteq \Pi$ *and* $\Pi_2 \subseteq \Pi$*. Then, for every* $\sigma \in \{\sigma_1, \sigma_3, \sigma_4\}$, $\Pi_1 \star \Pi_2 \star \sigma = \Pi_2 \star \Pi_1 \star \sigma \subseteq \Pi_1 \star \sigma \star \Pi_2 = \Pi_1 \star (\sigma \star \Pi_2) = \Pi_1 \star (\Pi_2 \star \sigma)$.

Proof. One may verify the lemma using Tables 5.1, 5.2, and 5.3, under the assumption that $|\Pi_1| = |\Pi_2| = 1$. This then implies the lemma for every $\Pi_1 \subseteq \Pi$ and every $\Pi_2 \subseteq \Pi$. □

LEMMA 5.5. *Suppose that* $\Pi_1 \subseteq \Pi$ *and* $\Pi_2 \subseteq \Pi$*. Let* $L = (\sigma_{i_1}, \ldots, \sigma_{i_q})$ *be a list of* σ*-types. Let* q_2 *and* q_5 *be the number of appearances of* σ_2 *and* σ_5 *in* L*, respectively. Let* $L' = L - \{\sigma_2, \sigma_5\}$*. Then, the following two statements hold:*

1. *For every* $\star$*-expression* E *with* $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Pi_1, \Pi_2 \rangle$*, if* $q_2 \geq 7$*, then* $E = \emptyset$*; otherwise,* $E \subseteq \cup_{(a,b,c,d,h,k)} (\Pi_1 \star [L']_\star \star [\sigma_2^a]_\star \star [\sigma_5^b]_\star) \star (\Pi_2 \star [\sigma_2^c]_\star \star [\sigma_5^d]_\star) \star [\sigma_2^h]_\star \star [\sigma_5^k]_\star$*, where* (a, b, c, d, h, k) *ranges over all sextuples of nonnegative integers such that* (1) $a + c + h = q_2$*;* (2) $b \leq 1$*,* $d \leq 1$*,* $k \leq 1$*, and* $b + d + k \leq q_5$*;* (3) *if* $a \geq 1$*, then* $b = 0$*;* (4) *if* $c \geq 1$*, then* $d = 0$*;* (5) *if* $h \geq 1$*, then* $k = 0$*; and* (6) *if* $q_2 = 0$*, then* $b + d + k \geq \min\{1, q_5\}$.
2. *Let* U *be the union of the values of all* $\star$*-expressions* E *with* $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Pi_1, \Pi_2 \rangle$*. If* $q_2 \geq 7$*, then* $U = \emptyset$*; otherwise,* $U = \cup_{(a,b,c,d,h,k)} (\Pi_1 \star [L']_\star \star [\sigma_2^a]_\star \star [\sigma_5^b]_\star) \star (\Pi_2 \star [\sigma_2^c]_\star \star [\sigma_5^d]_\star) \star [\sigma_2^h]_\star \star [\sigma_5^k]_\star$*, where* (a, b, c, d, h, k) *ranges over all sextuples of nonnegative integers that satisfy the conditions* (1) *through* (6) *in statement* 1.

Proof. We prove the two statements separately as follows.

Statement 1. Let T_E be the parse tree of E, v_1 be the leaf node of T_E labeled with Π_1, v_2 be the leaf node of T_E labeled with Π_2, and w be the lowest common ancestor of v_1 and v_2 in T_E. Let $v_1, u_1, \ldots, u_\ell, w$ be the path from v_1 to w in T_E. Similarly, let $v_2, u_{\ell+1}, \ldots, u_p, w$ be the path from v_2 to w in T_E. Let $w, u_{p+1}, \ldots, u_r$ be the path from w to the root of T_E. For each $i \in \{1, \ldots, r\}$, let E_i be the $\star$-expression whose parse tree is the subtree of T_E rooted at the child of u_i that is neither an ancestor of v_1 nor an ancestor of v_2. Then, $E = (\Pi_1 \star E_1 \star \cdots \star E_\ell) \star (\Pi_2 \star E_{\ell+1} \star \cdots \star E_p) \star E_{p+1} \star \cdots \star E_r$. Suppose that $\cup_{1 \leq x \leq \ell} \mathrm{Op}(E_x) = \langle \sigma_{j_1}, \ldots, \sigma_{j_f} \rangle$, $\cup_{\ell+1 \leq x \leq p} \mathrm{Op}(E_x) = \langle \sigma_{j_{f+1}}, \ldots, \sigma_{j_g} \rangle$, and $\cup_{p+1 \leq x \leq r} \mathrm{Op}(E_x) = \langle \sigma_{j_{g+1}}, \ldots, \sigma_{j_q} \rangle$. Let L_1 be the list $(\sigma_{j_1}, \ldots, \sigma_{j_f})$, L_2 be the list $(\sigma_{j_{f+1}}, \ldots, \sigma_{j_g})$, and L_3 be the list $(\sigma_{j_{g+1}}, \ldots, \sigma_{j_q})$. If σ_2 is not in L_1, then let $L_1' = L_1$; otherwise, let $L_1' = L_1 - \{\sigma_5\}$. Similarly, L_2' and L_3' are defined from L_2 and L_3, respectively. Then, by statement 1 in Lemma 5.2 and statement 1 in Lemma 5.3, $E \subseteq (\Pi_1 \star [L_1']_\star) \star (\Pi_2 \star [L_2']_\star) \star [L_3']_\star = (\Pi_1 \star [L_1']_\star) \star (\Pi_2 \star [L_2']_\star) \star [L_3' - \{\sigma_2, \sigma_5\}]_\star \star [L_3' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star$. In turn, by Lemma 5.4, $E \subseteq (\Pi_1 \star [L_1']_\star \star [L_3' - \{\sigma_2, \sigma_5\}]_\star) \star (\Pi_2 \star [L_2']_\star) \star [L_3' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star$. So, by statement 1 in Lemma 5.3, $E \subseteq (\Pi_1 \star [L_1']_\star \star [L_3' - \{\sigma_2, \sigma_5\}]_\star) \star (\Pi_2 \star [L_2' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star \star [L_2' - \{\sigma_2, \sigma_5\}]_\star) \star [L_3' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star$. In turn, by Lemma 5.4, $E \subseteq (\Pi_1 \star [L_1']_\star \star [L_3' - \{\sigma_2, \sigma_5\}]_\star \star [L_2' - \{\sigma_2, \sigma_5\}]_\star) \star (\Pi_2 \star [L_2' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star) \star [L_3' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star$. Moreover, by statement 1 in Lemma 5.3, $E \subseteq (\Pi_1 \star [L_1' - \{\sigma_2, \sigma_5\}]_\star \star [L_3' - \{\sigma_2, \sigma_5\}]_\star \star [L_2' - \{\sigma_2, \sigma_5\}]_\star \star [L_1' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star) \star (\Pi_2 \star [L_2' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star) \star [L_3' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star$. Note that $\mathrm{Op}([L']_\star) = \mathrm{Op}([L_1' - \{\sigma_2, \sigma_5\}]_\star) \cup \mathrm{Op}([L_3' - \{\sigma_2, \sigma_5\}]_\star) \cup \mathrm{Op}([L_2' - \{\sigma_2, \sigma_5\}]_\star)$. Thus, by statement 1 in Lemma 5.3, $E \subseteq (\Pi_1 \star [L']_\star \star [L_1' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star) \star (\Pi_2 \star [L_2' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star) \star [L_3' - \{\sigma_1, \sigma_3, \sigma_4\}]_\star$.

Let a (respectively, c and h) be the number of appearances of σ_2 in L_1' (respectively, in L_2' and L_3'). Let b (respectively, d and k) be the smaller of 1 and the number

of appearances of σ_5 in L'_1 (respectively, L'_2 and L'_3). By the definition of L'_1, L'_2, L'_3, the sextuple (a, b, c, d, h, k) satisfies the conditions (1) through (6) in the lemma.

Note that for every $\pi \in \Pi$ and every $\delta \in \Delta$, $\pi \star \sigma_2 \star \sigma_2 \star \sigma_2 = \emptyset$, $\delta \star \sigma_2 \star \sigma_2 \star \sigma_2 = \emptyset$. If $q_2 \geq 7$, then at least one of a, c, h is ≥ 3 and hence $E = \emptyset$. Otherwise, since $\pi \star \sigma_5 \star \sigma_5 = \pi \star \sigma_5$ and $\delta \star \sigma_5 \star \sigma_5 = \delta \star \sigma_5$ for every $\pi \in \Pi$ and every $\delta \in \Delta$, $E \subseteq (\Pi_1 \star [L']_\star \star [\sigma_2^a]_\star \star [\sigma_5^b]_\star) \star (\Pi_2 \star [\sigma_2^c]_\star \star [\sigma_5^d]_\star) \star [\sigma_2^h]_\star \star [\sigma_5^k]_\star$. This completes the proof of statement 1.

Statement 2. If $q_2 \geq 7$, then $U = \emptyset$ by statement 1. Next, suppose that $q_2 \leq 6$. Then, by statement 1, $U \subseteq \cup_{(a,b,c,d,h,k)}(\Pi_1 \star [L']_\star \star [\sigma_2^a]_\star \star [\sigma_5^b]_\star) \star (\Pi_2 \star [\sigma_2^c]_\star \star [\sigma_5^d]_\star) \star [\sigma_2^h]_\star \star [\sigma_5^k]_\star$, where (a, b, c, d, h, k) ranges over all sextuples of nonnegative integers that satisfy the conditions (1) through (6) in statement 1. On the other hand, if $q_2 = q_5 = 0$, then for each sextuple (a, b, c, d, h, k) satisfying the conditions (1) through (6) in statement 1, $(\Pi_1 \star [L']_\star \star [\sigma_2^a]_\star \star [\sigma_5^b]_\star) \star (\Pi_2 \star [\sigma_2^c]_\star \star [\sigma_5^d]_\star) \star [\sigma_2^h]_\star \star [\sigma_5^k]_\star$ is a $\star$-expression whose operand multiset is $\langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Pi_1, \Pi_2 \rangle$; and so $(\Pi_1 \star [L']_\star \star [\sigma_2^a]_\star \star [\sigma_5^b]_\star) \star (\Pi_2 \star [\sigma_2^c]_\star \star [\sigma_5^d]_\star) \star [\sigma_2^h]_\star \star [\sigma_5^k]_\star \subseteq U$. If $q_2 \geq 1$ or $q_5 \geq 1$, then for each sextuple (a, b, c, d, h, k) satisfying the conditions (1) through (6) in statement 1, we can modify the $\star$-expression $(\Pi_1 \star [L']_\star \star [\sigma_2^a]_\star \star [\sigma_5^b]_\star) \star (\Pi_2 \star [\sigma_2^c]_\star \star [\sigma_5^d]_\star) \star [\sigma_2^h]_\star \star [\sigma_5^k]_\star$ either (i) by replacing one appearance of σ_2 with $(\sigma_2 \star \sigma_5 \star \cdots \star \sigma_5)$ in which σ_5 appears $q_5 - (b + d + k)$ times or (ii) by replacing one appearance of σ_5 with $(\sigma_5 \star \cdots \star \sigma_5)$ in which σ_5 appears $q_5 - (b + d + k) + 1$ times. The resulting $\star$-expression has the same value as $(\Pi_1 \star [L']_\star \star [\sigma_2^a]_\star \star [\sigma_5^b]_\star) \star (\Pi_2 \star [\sigma_2^c]_\star \star [\sigma_5^d]_\star) \star [\sigma_2^h]_\star \star [\sigma_5^k]_\star$, since $\sigma_2 \star \sigma_5 = \sigma_2$ and $\sigma_5 \star \sigma_5 = \sigma_5$, and is a $\star$-expression whose operand multiset is $\langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Pi_1, \Pi_2 \rangle$. So, $(\Pi_1 \star [L']_\star \star [\sigma_2^a]_\star \star [\sigma_5^b]_\star) \star (\Pi_2 \star [\sigma_2^c]_\star \star [\sigma_5^d]_\star) \star [\sigma_2^h]_\star \star [\sigma_5^k]_\star \subseteq U$. Consequently, $\cup_{(a,b,c,d,h,k)}(\Pi_1 \star [L']_\star \star [\sigma_2^a]_\star \star [\sigma_5^b]_\star) \star (\Pi_2 \star [\sigma_2^c]_\star \star [\sigma_5^d]_\star) \star [\sigma_2^h]_\star \star [\sigma_5^k]_\star \subseteq U$, where (a, b, c, d, h, k) ranges over all sextuples of nonnegative integers that satisfy the conditions (1) through (6) in statement 1. This completes the proof of statement 2. □

5.3. Parallel composition of DTCs. Let $\Gamma_1 = \Sigma_1 \cup \Pi_1 \cup \Delta_1$ and $\Gamma_2 = \Sigma_2 \cup \Pi_2 \cup \Delta_2$ be two subsets of Γ, where for $i = 1, 2$, $\Sigma_i \subseteq \Sigma$, $\Pi_i \subseteq \Pi$, and $\Delta_i \subseteq \Delta$. Define

$$\begin{aligned}\Gamma_1 \diamond \Gamma_2 = {} & (\cup_{\sigma_i \in \Sigma_1, \sigma_j \in \Sigma_2} \mathcal{K}_\sigma(R(\sigma_i) \diamond R(\sigma_j))) \cup (\cup_{\sigma_i \in \Sigma_1, \pi_j \in \Pi_2} \mathcal{K}_\pi(R(\sigma_i) \diamond R(\pi_j))) \\ & \cup (\cup_{\pi_i \in \Pi_1, \sigma_j \in \Sigma_2} \mathcal{K}_\pi(R(\pi_i) \diamond R(\sigma_j))) \cup (\cup_{\sigma_i \in \Sigma_1, \delta_j \in \Delta_2} \mathcal{K}_\delta(R(\sigma_i) \diamond R(\delta_j))) \\ & \cup (\cup_{\delta_i \in \Delta_1, \sigma_j \in \Sigma_2} \mathcal{K}_\delta(R(\delta_i) \diamond R(\sigma_j))) \cup (\cup_{\pi_i \in \Pi_1, \pi_j \in \Pi_2} \mathcal{K}_\delta(R(\pi_i) \diamond R(\pi_j))).\end{aligned}$$

If $\Gamma_1 = \emptyset$ or $\Gamma_2 = \emptyset$, then $\Gamma_1 \diamond \Gamma_2 = \emptyset$.

As in the paragraph right before Lemma 5.1, we can argue that the operator $\diamond$ is commutative by its definition. For later reference, we state this in the following lemma.

LEMMA 5.6. If Γ_1 and Γ_2 are two subsets of Γ, then $\Gamma_1 \diamond \Gamma_2 = \Gamma_2 \diamond \Gamma_1$.

For each $\sigma_i \in \Sigma$ and each $\delta_j \in \Delta$, the (i, j)-entry of Table 5.4 contains all $\delta_k \in \{\sigma_i\} \diamond \{\delta_j\}$. For each $\pi_i \in \Pi$ and each $\sigma_j \in \Sigma$, the (i, j)-entry of Table 5.5 contains all $\pi_k \in \{\pi_i\} \diamond \{\sigma_j\}$. For each $\pi_i \in \Pi$ and each $\pi_j \in \Pi$, the (i, j)-entry of Table 5.6 contains all $\delta_k \in \{\pi_i\} \diamond \{\pi_j\}$. These tables can be verified by inspecting the graphs in Figures 4.2, 5.1, and 5.2. As examples, we verify one entry from each of the Tables 5.4, 5.5 and 5.6. They are shown in Figure 5.4. In each case, two representative graphs are composed in parallel by identifying their common poles. The type of the resulting graph is shown in the figure.

By modifying the four paragraphs right before Lemma 5.2 by replacing each letter "$\star$" with "$\diamond$," we can define a $\diamond$-*expression* E, its *value*, etc. Moreover, we can prove

TABLE 5.4
$\{\sigma_i\} \diamond \{\delta_j\}$.

the following four lemmas, just via modifying the proofs of Lemmas 5.2 through 5.5 by replacing each appearance of "σ_2," "σ_3," "σ_4," "σ_5," "$\star$," "q_2," "q_5," "Table 5.1," "Table 5.2," and "Table 5.3" in them with "σ_3," "σ_2," "σ_5," "σ_4," "$\diamond$," "q_3," "q_4," "Table 5.4," "Table 5.5," and "Table 5.6," respectively. We state these corresponding lemmas as follows.

LEMMA 5.7. *Suppose $\Delta_1 \subseteq \Delta$. Let $L = (\sigma_{i_1}, \ldots, \sigma_{i_q})$ be a list of σ-types. Then, the following two statements hold:*

1. *For every $\diamond$-expression E with $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Delta_1 \rangle$, if σ_3 is not in L, then $E \subseteq \Delta_1 \diamond [L]_\diamond$; otherwise, $E \subseteq \Delta_1 \diamond [L - \{\sigma_4\}]_\diamond$.*
2. *Let U be the union of the values of all $\diamond$-expressions E with $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Delta_1 \rangle$. If σ_3 is not in L, then $U = \Delta_1 \diamond [L]_\diamond$; otherwise, $U = \Delta_1 \diamond [L - \{\sigma_4\}]_\diamond$.*

LEMMA 5.8. *Suppose $\Pi_1 \subseteq \Pi$. Let $L = (\sigma_{i_1}, \ldots, \sigma_{i_q})$ be a list of σ-types. Then, the following two statements hold:*

1. *For every $\diamond$-expression E with $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Pi_1 \rangle$, if σ_3 is not in L, then $E \subseteq \Pi_1 \diamond [L]_\diamond$; otherwise, $E \subseteq \Pi_1 \diamond [L - \{\sigma_4\}]_\diamond$.*
2. *Let U be the union of the values of all $\diamond$-expressions E with $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Pi_1 \rangle$. If σ_3 is not in L, then $U = \Pi_1 \diamond [L]_\diamond$; otherwise, $U = \Pi_1 \diamond [L - \{\sigma_4\}]_\diamond$.*

LEMMA 5.9. *Suppose that $\Pi_1 \subseteq \Pi$ and $\Pi_2 \subseteq \Pi$. Then, for every $\sigma \in \{\sigma_1, \sigma_2, \sigma_5\}$, $\Pi_1 \diamond \Pi_2 \diamond \sigma = \Pi_2 \diamond \Pi_1 \diamond \sigma \subseteq \Pi_1 \diamond \sigma \diamond \Pi_2 = \Pi_1 \diamond (\sigma \diamond \Pi_2) = \Pi_1 \diamond (\Pi_2 \diamond \sigma)$.*

LEMMA 5.10. *Suppose that $\Pi_1 \subseteq \Pi$ and $\Pi_2 \subseteq \Pi$. Let $L = (\sigma_{i_1}, \ldots, \sigma_{i_q})$ be a list of σ-types. Let q_3 and q_4 be the number of appearances of σ_3 and σ_4 in L, respectively. Let $L' = L - \{\sigma_3, \sigma_4\}$. Then, the following two statements hold:*

1. *For every $\diamond$-expression E with $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Pi_1, \Pi_2 \rangle$, if $q_3 \geq 7$, then $E = \emptyset$; otherwise, $E \subseteq \cup_{(a,b,c,d,h,k)} (\Pi_1 \diamond [L']_\diamond \diamond [\sigma_3^a]_\diamond \diamond [\sigma_4^b]_\diamond) \diamond (\Pi_2 \diamond [\sigma_3^c]_\diamond \diamond [\sigma_4^d]_\diamond) \diamond [\sigma_3^h]_\diamond \diamond [\sigma_4^k]_\diamond$, where (a, b, c, d, h, k) ranges over all sextuples of*

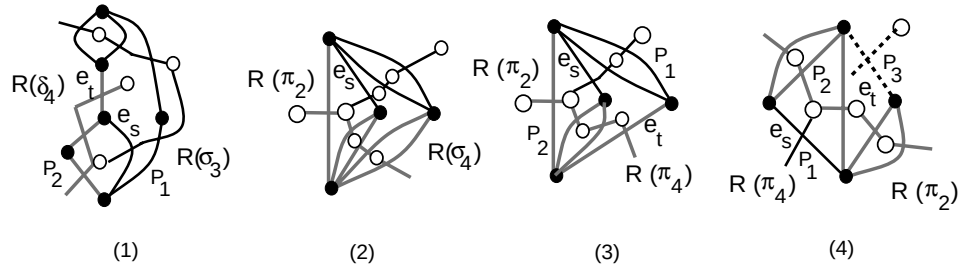

FIG. 5.4. (1) $\sigma_3 \diamond \delta_4 = \delta_2$; (2) $\pi_2 \diamond \sigma_4 = \pi_2$; (3) $\pi_2 \diamond \pi_4 = \delta_1$; (4) $\pi_2 \diamond \pi_4 = \delta_6$.

nonnegative integers such that (1) $a + c + h = q_3$; (2) $b \leq 1$, $d \leq 1$, $k \leq 1$, *and* $b + d + k \leq q_4$; (3) *if* $a \geq 1$, *then* $b = 0$; (4) *if* $c \geq 1$, *then* $d = 0$; (5) *if* $h \geq 1$, *then* $k = 0$; *and* (6) *if* $q_3 = 0$, *then* $b + d + k \geq \min\{1, q_4\}$.

2. *Let* U *be the union of the values of all* $\diamond$*-expressions* E *with* $\mathrm{Op}(E) = \langle \sigma_{i_1}, \ldots, \sigma_{i_q}, \Pi_1, \Pi_2 \rangle$. *If* $q_3 \geq 7$, *then* $U = \emptyset$; *otherwise,* $U = \cup_{(a,b,c,d,h,k)}(\Pi_1 \diamond [L']_\diamond \diamond [\sigma_3^a]_\diamond \diamond [\sigma_4^b]_\diamond) \diamond (\Pi_2 \diamond [\sigma_3^c]_\diamond \diamond [\sigma_4^d]_\diamond) \diamond [\sigma_3^h]_\diamond \diamond [\sigma_4^k]_\diamond$, *where* (a, b, c, d, h, k) *ranges over all sextuples of nonnegative integers that satisfy the conditions* (1) *through* (6) *in statement* 1.

5.4. An $O(|G|^3)$-time algorithm. Let e_s and e_t be a pair of distinct edges of G. We want to decide whether G has a valid embedding that has a DET starting with e_s and ending with e_t. To do this, we process the nodes of T in post-order. For each node μ of T such that neither e_s nor e_t is in $\mathrm{Pt}(\mu)$, we compute $\mathcal{K}_\sigma(\mathrm{Pt}(\mu))$ as in section 4.3; we may assume that $|\mathcal{K}_\sigma(\mathrm{Pt}(\mu))| = 1$ since otherwise no valid embedding of G has a DET starting with e_s and ending with e_t. For each Q-node μ such that $\mathrm{Pt}(\mu)$ consists of e_s only or e_t only, we set $\mathcal{K}_\pi(\mathrm{Pt}(\mu)) = \{\pi_1\}$.

Consider the processing of a non-Q-node μ such that e_s or e_t is in $\mathrm{Pt}(\mu)$. Let $\nu_1, \ldots, \nu_r$ be the children of μ in T. Let $B = \mathrm{Pt}(\mu)$. For each $i \in \{1, \ldots, r\}$, let $B_i = \mathrm{Pt}(\nu_i)$, and e_i be the virtual edge of ν_i in $\mathrm{Sk}(\mu)$.

- *Case* 1. B contains both e_s and e_t but no child of B does. Without loss of generality, we may assume that B_1 contains e_s and B_2 contains e_t. Then, none of $B_3, \ldots, B_r$ contains e_s or e_t. Let $\Pi_1 = \mathcal{K}_\pi(B_1)$ and $\Pi_2 = \mathcal{K}_\pi(B_2)$. For each $j \in \{3, \ldots, r\}$, let $\mathcal{K}_\sigma(B_j) = \{\sigma_{\ell_j}\}$. Let L be the list $(\sigma_{\ell_3}, \ldots, \sigma_{\ell_r})$.
  - *Case* 1.1. μ is an R-node. Then, $\mathrm{Sk}(\mu)$ has no different embedding other than itself. Based on statements 1 and 2 in Lemma 3.2, we compute $\mathcal{K}_\delta(B)$ as follows. We initialize $\mathcal{K}_\delta(B) = \emptyset$. After this, for each quadruple $D = (\pi_{i_1}, \pi_{i_2}, G_1, G_2)$ such that $\pi_{i_1} \in \mathcal{K}_\pi(B_1)$, $\pi_{i_2} \in \mathcal{K}_\pi(B_2)$, and G_1 (respectively, G_2) is obtained from $R(\pi_{i_1})$ (respectively, $R(\pi_{i_2})$) by horizontally and/or vertically flipping it, we first construct a TTG H_D from $\mathrm{Sk}(\mu)$ by replacing e_1 with G_1, e_2 with G_2, and e_j with $R(\sigma_{\ell_j})$ for all $j \in \{3, \ldots, r\}$. We then obtain the maximal double trail P_1 in H_D such that (1) e_s and its dual edge e_s^* are, respectively, the starting edge of P_1 and its dual trail P_1^* and (2) the direction of e_s in P_1 and that of e_s^* in P_1^* are the same as oriented by the unique valid DTC of G_1. Similarly, we obtain the maximal double trail P_2 in H_D such that (1) e_t and its dual edge e_t^* are, respectively, the starting edge of P_2 and its dual trail P_2^* and (2) the direction of e_t in P_2 and that of e_t^* in P_2^* are the same as oriented by the unique valid DTC of G_2. Let P_2' be the

reverse of P_2. Let M be the set of all edges of H_D traversed by neither P_1 nor P_2. Suppose $M = \emptyset$. If P_1 and P_2' are distinct, we check if P_1 and P_2' form a DTC of H_D of a δ-type. If P_1 and P_2' are the same, we check if P_1 forms a DTC of H_D of a δ-type. In both cases, if the condition is true, we add this δ-type to $\mathcal{K}_\delta(B)$.

Suppose that $M \neq \emptyset$ and P_1 and P_2 are edge-disjoint. We try to find an access edge $e \in M$ such that e is incident to a pole u of H_D and the dual edge e^* of e is incident to a pole x of H_D^*. If such e exists, then we obtain the maximal double trail P_3 in H_D such that (1) e and e^* are, respectively, the starting edge of P_3 and its dual trail P_3^* and (2) u and x are, respectively, the starting vertex of P_3 and P_3^*. Note that the other endpoint of e (respectively, e^*) is not a pole of H_D (respectively, H_D^*). If $\{P_1, P_2', P_3\}$ is a DTC of H_D of a δ-type, we add this δ-type to $\mathcal{K}_\delta(B)$. Similarly, if $\{P_1, P_2', P_3'\}$ is a DTC of H_D of a δ-type, we add this δ-type to $\mathcal{K}_\delta(B)$, where P_3' is the reverse of P_3.

- *Case* 1.2. μ is an S-node. Let q_2 and q_5 be the number of appearances of σ_2 and σ_5 in L, respectively. Let $L' = L - \{\sigma_2, \sigma_5\}$. By statement 2 in Lemma 5.5 and statements 1 and 2 in Lemma 3.2, if $q_2 \geq 7$, then $\mathcal{K}_\delta(B) = \emptyset$; otherwise, $\mathcal{K}_\delta(B) = \cup_{(a,b,c,d,h,k)}(\Pi_1 \star [L']_\star \star [\sigma_2^a]_\star \star [\sigma_5^b]_\star) \star (\Pi_2 \star [\sigma_2^c]_\star \star [\sigma_5^d]_\star) \star [\sigma_2^h]_\star \star [\sigma_5^k]_\star$, where (a, b, c, d, h, k) ranges over all sextuples of nonnegative integers that satisfy the conditions (1) through (6) in statement 1 in Lemma 5.5.
- *Case* 1.3. μ is a P-node. Let q_3 and q_4 be the number of appearances of σ_3 and σ_4 in L, respectively. Let $L' = L - \{\sigma_3, \sigma_4\}$. By statement 2 in Lemma 5.10 and statements 1 and 2 in Lemma 3.2, if $q_3 \geq 7$, then $\mathcal{K}_\delta(B) = \emptyset$; otherwise, $\mathcal{K}_\delta(B) = \cup_{(a,b,c,d,h,k)}(\Pi_1 \diamond [L']_\diamond \diamond [\sigma_3^a]_\diamond \diamond [\sigma_4^b]_\diamond) \diamond (\Pi_2 \diamond [\sigma_3^c]_\diamond \diamond [\sigma_4^d]_\diamond) \diamond [\sigma_3^h]_\diamond \diamond [\sigma_4^k]_\diamond$, where (a, b, c, d, h, k) ranges over all sextuples of nonnegative integers that satisfy the conditions (1) through (6) in statement 1 in Lemma 5.10.

• *Case* 2. B contains both e_s and e_t and so does one child block of B. Without loss of generality, we can assume that B_1 contains both e_s and e_t. Then, none of $B_2, \ldots, B_r$ contains e_s or e_t. Let $\Delta_1 = \mathcal{K}_\delta(B_1) - \{\delta_0\}$. For each $j \in \{2, \ldots, r\}$, let $\mathcal{K}_\sigma(B_j) = \{\sigma_{\ell_j}\}$. Let L be the list $(\sigma_{\ell_2}, \ldots, \sigma_{\ell_r})$.

- *Case* 2.1. μ is an R-node. Then, based on statements 1 and 3 in Lemma 3.2, we compute $\mathcal{K}_\delta(B)$ as follows. We initialize $\mathcal{K}_\delta(B) = \emptyset$. After this, for each pair $D = (\delta_i, G_1)$ such that $\delta_i \in \Delta_1$ and G_1 is obtained from $R(\delta_i)$ by horizontally and/or vertically flipping it, we first construct a TTG H_D from $\mathrm{Sk}(\mu)$ by replacing e_1 with G_1 and e_j with $R(\sigma_{\ell_j})$ for all $j \in \{2, \ldots, r\}$. Similarly to Case 1.1, we then check if H_D has a δ-type DTC; if it has, we add the δ-type of the DTC into $\mathcal{K}_\delta(B)$.
- *Case* 2.2. μ is an S-node. Then, by statement 2 in Lemma 5.2 and statements 1 and 3 in Lemma 3.2, if σ_2 is not in L, then $\mathcal{K}_\delta(B) = \Delta_1 \star [L]_\star$; otherwise, $\mathcal{K}_\delta(B) = \Delta_1 \star [L - \{\sigma_5\}]_\star$.
- *Case* 2.3. μ is a P-node. Then, by statement 2 in Lemma 5.7 and statements 1 and 3 in Lemma 3.2, if σ_3 is not in L, then $\mathcal{K}_\delta(B) = \Delta_1 \diamond [L]_\diamond$; otherwise, $\mathcal{K}_\delta(B) = \Delta_1 \diamond [L - \{\sigma_4\}]_\diamond$.

• *Case* 3. B contains one of e_s and e_t. We assume that B contains e_s; the other case is similar. Without loss of generality, we can assume that B_1 contains e_s. Then, none of $B_2, \ldots, B_r$ contains e_s or e_t. Let $\Pi_1 = \mathcal{K}_\pi(B_1)$. For each

$j \in \{2, \ldots, r\}$, let $\mathcal{K}_\sigma(B_j) = \{\sigma_{\ell_j}\}$. Let L be the list $(\sigma_{\ell_2}, \ldots, \sigma_{\ell_r})$.

- *Case* 3.1. μ is an R-node. Then, based on statements 1 and 2 in Lemma 3.2, we compute $\mathcal{K}_\pi(B)$ as follows. We initialize $\mathcal{K}_\pi(B) = \emptyset$. After this, for each pair $D = (\pi_i, G_1)$ such that $\pi_i \in \Pi_1$ and G_1 is obtained from $R(\pi_i)$ by horizontally and/or vertically flipping it, we first construct a TTG H_D from $\mathrm{Sk}(\mu)$ by replacing e_1 with G_1 and e_j with $R(\sigma_{\ell_j})$ for all $j \in \{2, \ldots, r\}$. Similarly to Case 1.1, we then check if H_D has a π-type DTC; if it has, we add the π-type of the DTC into $\mathcal{K}_\pi(B)$.
- *Case* 3.2. μ is an S-node. Then, by statement 2 in Lemma 5.3 and statements 1 and 2 in Lemma 3.2, if σ_2 is not in L, then $\mathcal{K}_\pi(B) = \Pi_1 \star [L]_\star$; otherwise, $\mathcal{K}_\pi(B) = \Pi_1 \star [L - \{\sigma_5\}]_\star$.
- *Case* 3.3. μ is a P-node. Then, by statement 2 in Lemma 5.8 and statements 1 and 2 in Lemma 3.2, if σ_3 is not in L, then $\mathcal{K}_\pi(B) = \Pi_1 \diamond [L]_\diamond$; otherwise, $\mathcal{K}_\pi(B) = \Pi_1 \diamond [L - \{\sigma_4\}]_\diamond$.

By the above discussions, it takes $O(|\mathrm{Sk}(\mu)|)$ time to process μ. Thus, by Lemma 2.1, the time needed to compute $\mathcal{K}_\delta(G)$ is $O(|G|)$. Note that G has a DET starting with e_s and ending with e_t if and only if $\delta_0 \in \mathcal{K}_\delta(G)$. Thus, by trying all pairs (e_s, e_t) of edges of G, we can decide in $O(|G|^3)$ time whether G has a DET.

THEOREM 5.11. *Given a TTG G, it takes $O(|G|^3)$ time to decide if G has a valid embedding.*

6. An $O(|G|)$-time algorithm. This section refines the algorithm in section 5.4. The basic idea is that we do not specify the starting and the ending edges in advance. Rather, we try to discover them when processing T in post-order. Throughout this section, we assume that G^* is not Eulerian; the case where G is not Eulerian is similar. Let T^* be the dual decomposition tree of T.

First, we need some definitions and lemmas. Recall that the degree parity of a vertex in G is 0 if its degree is even and is 1 otherwise. The *pole-parity multiset* M_G of G consists of the degree parities of the poles of G. The *pole-status* of G is the pair (M_G, M_{G^*}), where M_G and M_{G^*} are the pole-parity multiset of G and G^*, respectively.

G is *E-good* if it is Eulerian. G is *O-good* if its odd-degree vertices are just its poles. G is *good* if it is either E- or O-good. G is *bad* if it has at least one odd-degree nonpole.

A node μ of T is *E-good* (respectively, *O-good*, *good*, or *bad*) if all different embeddings of $\mathrm{Pt}(\mu)$ are E-good (respectively, O-good, good, or bad).

LEMMA 6.1. *Let μ be a node of T. Let $B = \mathrm{Pt}(\mu)$. Then, exactly one of the following* (1) *through* (3) *holds:* (1) *μ is E-good;* (2) *μ is O-good;* (3) *μ is bad. Moreover, for all descendants ν (including μ itself) of μ in T, it takes $O(|B|)$ total time to* (a) *decide whether ν is E-good, O-good, or bad, and* (b) *compute the pole-parity multiset of $\mathrm{Pt}(\nu)$ when ν is good.*

Proof. The proof is by induction. In case μ is a leaf node of T, B is a single edge; hence, μ is O-good.

Next, suppose that μ is a nonleaf node. Let $\nu_1, \ldots, \nu_q$ be the children of μ in T. For each $i \in \{1, \ldots, q\}$, let $B_i = \mathrm{Pt}(\nu_i)$ and e_i be the virtual edge of ν_i in $\mathrm{Sk}(\mu)$. If some child of μ is bad, then μ must be bad. So, assume that no child of μ is bad. By the inductive hypothesis, each child of μ is either E- or O-good. Let $\mathcal{B}$ be an (arbitrary) different embedding of B. For each $i \in \{1, \ldots, q\}$, let $\mathcal{B}_i$ be the child block of $\mathcal{B}$ that is a different embedding of B_i. For the purpose of deciding whether $\mathcal{B}$ is E-good, O-good, or bad, we may assume that $\mathcal{B}_i = B_i$ for all $i \in \{1, \ldots, q\}$ because

$\mathcal{B}_i$ is E-good (respectively, O-good) if and only if B_i is too.

Case 1. μ is a P-node. Then, $\mathcal{B}$ can be obtained from B by permuting the children of μ. Permuting the children of μ does not change the degree parity of any vertex in B. Thus, if an odd (respectively, even) number of children of μ is O-good, μ is O-good (respectively, E-good).

Case 2. μ is an S-node. Then, $\mathcal{B}$ can be obtained from B by permuting the children of μ. When every child of μ is E-good, permuting the children of μ does not change the degree parity of any vertex in B, and hence $\mathcal{B}$ is E-good and so is μ. Similarly, when every child of μ is O-good, μ is O-good. So, suppose that μ has both E-good children and O-good children. Then, some E-good $\mathcal{B}_i$ must be next to an O-good $\mathcal{B}_j$ in $\mathcal{B}$. The common pole of $\mathcal{B}_i$ and $\mathcal{B}_j$ in $\mathcal{B}$ has odd degree. Thus, $\mathcal{B}$ is bad and so is μ.

Case 3. μ is an R-node. Then, $\mathrm{Sk}(\mu)$ has no different embedding other than itself. $\mathcal{B}$ is obtained from $\mathrm{Sk}(\mu)$ by replacing e_i with $\mathcal{B}_i$ for all $i \in \{1, \ldots, q\}$. Note that the edges of $\mathrm{Sk}(\mu)$ are just $e_1, \ldots, e_q$. For all $i \in \{1, \ldots, q\}$, we mark e_i if ν_i is O-good. If some nonpole in $\mathrm{Sk}(\mu)$ is incident to an odd number of marked edges, then μ is bad. Otherwise, if a pole of $\mathrm{Sk}(\mu)$ is incident to an odd number of marked edges, then μ is O-good; otherwise, μ is E-good.

Next we describe the implementation of this procedure. Let T_μ be the subtree of T rooted at the node μ. We perform a post-order computation on T_μ. Each leaf node ν is an O-good node, and both poles of $\mathrm{Pt}(\nu)$ have odd parity. For each internal node ν in T_μ, whether ν is E-good, O-good, or bad, the pole-parity multiset of $\mathrm{Pt}(\nu)$ can be determined as in the three cases above, in at most $O(|\mathrm{Sk}(\nu))|$ time. Thus, the total time needed is $O(|B|)$ by Lemma 2.1. □

By Lemma 2.2, each node of T is also a node of the dual decomposition tree T^* of T. A node μ of T^* is *E-good* (respectively, *O-good*, *good*, or *bad*) if all different embeddings of the dual graph of $\mathrm{Pt}(\mu)$ are E-good (respectively, O-good, good, or bad). Lemma 6.1 still holds after changing T to T^*, $\mathrm{Pt}(\mu)$ to its dual graph, and $\mathrm{Pt}(\nu)$ to its dual graph.

Let μ be a node of T and $B = \mathrm{Pt}(\mu)$. μ is *doubly good* if for every different embedding $\mathcal{B}$ of B, neither $\mathcal{B}$ nor $\mathcal{B}^*$ has an odd-degree nonpole. μ is *doubly bad* if for every different embedding $\mathcal{B}$ of B, $\mathcal{B}$ or $\mathcal{B}^*$ has at least one odd-degree nonpole. By Lemma 6.1, μ is either doubly good or doubly bad. μ is *critical* if (1) all children of μ are doubly good and (2) μ is doubly bad or is the root of T.

LEMMA 6.2. *If G has a valid embedding, then either one or two nodes of T are critical.*

Proof. Note that each leaf node of T is doubly good. Thus, at least one node of T is critical. If the root of T is critical, then all nodes of T except the root must be doubly good and the root is the unique critical node. Otherwise, let $\mu_1, \ldots, \mu_k$ be the critical nodes in T and $B_i = \mathrm{Pt}(\mu_i)$. By the definition of critical nodes, none of $\mu_1, \ldots, \mu_k$ can be an ancestor of another. Thus, no two of $B_1, \ldots, B_k$ share an edge. On the other hand, for each $i \in \{1, \ldots, k\}$, either B_i or B_i^* has an odd-degree nonpole; any DET of G must start or end with an edge in B_i. Therefore, if $k \geq 3$, G cannot have a DET. □

LEMMA 6.3. *Let μ be a doubly bad node of T, and let $B = \mathrm{Pt}(\mu)$. Then, all different embeddings $\mathcal{B}$ of B such that $\mathcal{B}$ has a π-type DTC have the same pole-status p, which can be computed as follows:*

1. *If μ is an E-good node of T, then $p = (\langle 0, 0\rangle, \langle 0, 1\rangle)$.*
2. *If μ is an O-good node of T, then $p = (\langle 1, 1\rangle, \langle 0, 1\rangle)$.*

3. *If μ is an E-good node of T^*, then $p = (\langle 0,1\rangle, \langle 0,0\rangle)$.*
4. *If μ is an O-good node of T^*, then $p = (\langle 0,1\rangle, \langle 1,1\rangle)$.*
5. *If μ is a bad node of both T and T^*, then $p = (\langle 0,1\rangle, \langle 0,1\rangle)$.*

Proof. Suppose that a different embedding $\mathcal{B}$ of B has a π-type DTC. Then, both $\mathcal{B}$ and $\mathcal{B}^*$ have at most one odd-degree nonpole (see Figure 5.1). Indeed, at least one of $\mathcal{B}$ and $\mathcal{B}^*$ has exactly one odd-degree nonpole because μ is doubly bad. If μ is a bad node of T, then the pole-parity multiset of $\mathcal{B}$ is $\langle 0,1\rangle$. On the other hand, by Lemma 6.1, if μ is an E-good (respectively, O-good) node of T, then the pole-parity multiset of $\mathcal{B}$ is $\langle 0,0\rangle$ (respectively, $\langle 1,1\rangle$). Similarly, by checking whether μ is a good node of T^*, we can decide the pole-parity multiset of $\mathcal{B}^*$. □

Let $B = \mathrm{Pt}(\mu)$, where μ is a nonroot node of T. A π- or δ-type γ of B is *useful* if some valid embedding $\mathcal{G}$ of G has a DET P such that $P \cap \mathcal{B}$ is of Type γ, where $\mathcal{B}$ is the block of $\mathcal{G}$ that is a different embedding of B.

Even for a doubly good node μ, the block $B = \mathrm{Pt}(\mu)$ might contain the starting edge e_s and/or the ending edge e_t of a DET of a valid embedding of G (when e_s and/or e_t is incident to a pole of B). Thus, a σ-type of B might actually be a π- or δ-type. In the following, we investigate which σ-type can be mapped to which π- or δ-type. The mapping from σ-types to π-types is specified by the following function: $f : \{1,\ldots,5\} \to \{1,\ldots,4\}$, where $f(1) = f(2) = f(3) = 1$, $f(4) = 4$, and $f(5) = 3$.

LEMMA 6.4. *Let μ be a doubly good nonroot node of T. Let $B = \mathrm{Pt}(\mu)$. Suppose that π_j is a useful π-type of B. Then, $\mathcal{K}_\sigma(B) = \{\sigma_i\}$ for some $\sigma_i \in \Sigma$, and $\pi_j = \pi_{f(i)}$.*

Proof. Suppose that a DET P of a valid embedding $\mathcal{G}$ of G starts with an edge e_s of $\mathcal{B}$ but ends with an edge not in $\mathcal{B}$, where $\mathcal{B}$ is the block of $\mathcal{G}$ that is a different embedding of B. Let P^* be the dual trail of P. Since μ is doubly good, neither $\mathcal{B}$ nor $\mathcal{B}^*$ has an odd-degree nonpole. Moreover, since G^* is not Eulerian, P^* must start at an odd-degree vertex of $\mathcal{B}^*$ by Facts 1 and 2. Thus, P^* starts at a pole of $\mathcal{B}^*$. On the other hand, P starts at a pole of $\mathcal{B}$. This is because of the following: (1) If G is Eulerian, P starts and ends at the same vertex of $\mathcal{B}$. Since e_s is in $\mathcal{B}$ and the ending edge e_t is not in $\mathcal{B}$, their common end vertex must be a pole of $\mathcal{B}$. (2) If G is not Eulerian, P starts at an odd-degree vertex of $\mathcal{B}$ by Facts 1 and 2. By these facts, $P \cap \mathcal{B}$ is of a σ-type; this type is unique by Lemma 4.4. Let σ_i be this type.

To determine the π-type of $P \cap \mathcal{B}$, we first note that if $P \cap \mathcal{B}$ is of Type σ_1, σ_2, or σ_3, then $P \cap \mathcal{B}$ consists of a single trail and hence can be only of Type π_1. Thus, $\pi_1 = \pi_{f(i)}$ for $i = 1,2,3$. Now, suppose that $P \cap \mathcal{B}$ is of Type σ_4. Then, $P \cap \mathcal{B}$ consists of two double trails P_1 and P_2, where P_1 starts with e_s. Moreover, P_1 starts and ends at the same pole of $\mathcal{B}$, and so does P_2; the dual trail P_1^* of P_1 starts and ends at different poles of $\mathcal{B}^*$, and so does the dual trail P_2^* of P_2. Thus, $P \cap \mathcal{B}$ is of Type π_4. On the other hand, $P \cap \mathcal{B}$ is not of Type π_1 because $P \cap \mathcal{B}$ consists of two double trails; $P \cap \mathcal{B}$ is not of Type π_2 or π_3 either because P_2 starts and ends at the same pole of $\mathcal{B}$. Therefore, $\pi_4 = \pi_{f(4)}$. Similarly, we can verify that $\pi_3 = \pi_{f(5)}$. □

The mapping from σ-types to δ-types is specified by the following function: $g : \{1,2,3,5\} \to \{1,\ldots,4\}$, where $g(1) = 2$, $g(2) = 4$, $g(3) = 3$, and $g(5) = 1$.

LEMMA 6.5. *Suppose that G is Eulerian. Let μ be a doubly good nonroot node of T. Let $B = \mathrm{Pt}(\mu)$. Suppose that δ_j is a useful δ-type of B. Then, the following two statements hold:*

1. *If μ is not an S-node, then $\mathcal{K}_\sigma(B) = \{\sigma_5\}$ and $\delta_j = \delta_{g(5)}$.*

2. *If μ is an S-node, then $\mathcal{K}_\sigma(B) = \{\sigma_i\}$ for some $\sigma_i \in \{\sigma_1, \sigma_2, \sigma_3\}$ and $\delta_j = \delta_{g(i)}$.*

Proof. Suppose that a DET P of a valid embedding $\mathcal{G}$ of G starts with an edge e_s of $\mathcal{B}$ and ends with an edge e_t of $\mathcal{B}$, where $\mathcal{B}$ is the block of $\mathcal{G}$ that is a different embedding of B. Let P^* be the dual trail of P. Since G is Eulerian but G^* is not, P starts and ends at the same vertex of $\mathcal{B}$ (say, v) while P^* starts and ends at different vertices of $\mathcal{B}^*$, by Facts 1 and 2. Both e_s and e_t are incident to v.

Case 1. v is a pole of $\mathcal{B}$. Then, since μ is doubly good, P^* starts at one pole of $\mathcal{B}^*$ and ends at the other pole. Thus, $P \cap \mathcal{B}$ is of a σ-type. Moreover, since $\mathcal{B} \neq \mathcal{G}$, $P \cap \mathcal{B}$ contains more than one trail (otherwise, the single trail in $P \cap \mathcal{B}$ would be the entire DET P). Hence, $P \cap \mathcal{B}$ is of Type σ_4 or σ_5. Indeed, it is not of Type σ_4 because P starts and ends at the same vertex. Thus, $P \cap \mathcal{B}$ is of Type σ_5 and hence consists of two double trails P_1 and P_2, where P_1 starts with e_s and P_2 ends with e_t. To determine the δ-type of $P \cap \mathcal{B}$, we note that P_1 starts at v and ends at the other pole u of $\mathcal{B}$ while P_2 starts at u and ends at v. Moreover, since $P \cap \mathcal{B} = (P_1, P_2)$ is of Type σ_5, the dual trail P_1^* of P_1 starts and ends at the same pole x of $\mathcal{B}^*$ while the dual trail P_2^* of P_2 starts and ends at the other pole y of $\mathcal{B}^*$. Thus, $P \cap \mathcal{B}$ is of Type δ_1. On the other hand, $P \cap \mathcal{B}$ is not of Type δ_4, δ_5 or δ_6 because $P \cap \mathcal{B}$ consists of only two double trails. Moreover, $P \cap \mathcal{B}$ is not of Type δ_2 because the ending pole of P_1^* is different from the starting pole of P_2^*. Similarly, $P \cap \mathcal{B}$ is not of Type δ_3 because the ending pole of P_1 is the same as the starting pole of P_2. Therefore, $\delta_1 = \delta_{g(5)}$.

Case 2. v is not a pole of $\mathcal{B}$. Then, since P^* starts at one pole of $\mathcal{B}^*$ and ends at the other pole, one of e_s and e_t is on the west side of $\mathcal{B}$ and the other is on the east side. Thus, v is a cut vertex of $\mathcal{B}$ and μ is an S-node. Let $\mathcal{B}_1$ (respectively, $\mathcal{B}_2$) be the block of $\mathcal{B}$ whose source (respectively, sink) is that of $\mathcal{B}$ and whose sink (respectively, source) is v. Then, $\mathcal{B} = \mathcal{B}_1 \star \mathcal{B}_2$. Since $\mathcal{B}^*$ is good, neither $\mathcal{B}_1^*$ nor $\mathcal{B}_2^*$ has an odd-degree nonpole. We assume that e_s is on the west side of $\mathcal{B}_1$; the other cases are similar.

Case 2.1. $\mathcal{B}_1$ contains e_t. Then, e_t is on the east side of $\mathcal{B}_1$. Moreover, P^* starts at the source of $\mathcal{B}_1^*$ and ends at the sink of $\mathcal{B}_1^*$, by Facts 1 and 2. As in Case 1, we can prove that $P \cap \mathcal{B}_1$ is of Type σ_5 and hence consists of two double trails P_1 and P_3, where P_1 starts with e_s and P_3 ends with e_t. On the other hand, $P \cap \mathcal{B}_2$ must start at the sink of $\mathcal{B}_2$ and can leave $\mathcal{B}_2$ only at its sink; so, $P \cap \mathcal{B}_2$ consists of a single trail P_2 and is of Type σ_2. Consequently, $P \cap \mathcal{B}$ is of Type $\sigma_5 \star \sigma_2 = \sigma_2$ by Table 4.1. To determine the δ-type of $P \cap \mathcal{B}$, we note that P_1 starts at v and ends at the other pole u of $\mathcal{B}_1$ while P_3 starts at u and ends at v. Moreover, P_2 starts at the pole $w \neq v$ of $\mathcal{B}_2$ and ends at w. Since u, v, w are three distinct vertices of $\mathcal{B}$, no two of the trails P_1 through P_3 can be concatenated into a single trail in $P \cap \mathcal{B}$. So, $P \cap \mathcal{B} = (P_1, P_2, P_3)$ because P_1 starts with e_s and P_3 ends with e_t. In turn, $P \cap \mathcal{B}$ is of Type δ_4. On the other hand, $P \cap \mathcal{B}$ is not of Type δ_1, δ_2, or δ_3 because $P \cap \mathcal{B}$ consists of three trails; $P \cap \mathcal{B}$ is not of Type δ_5 or δ_6 because P_2 starts and ends at the same vertex of $\mathcal{B}$. Therefore, $\delta_4 = \delta_{g(2)}$.

Case 2.2. $\mathcal{B}_1$ does not contain e_t. Then, e_t is on the east side of $\mathcal{B}_2$. Moreover, by Facts 1 and 2, P^* starts at the source of $\mathcal{B}_1^*$ and ends at the sink of $\mathcal{B}_2^*$. By this and the fact that P starts and ends at the common pole v of $\mathcal{B}_1$ and $\mathcal{B}_2$, $P \cap \mathcal{B}_1$ must start at v and cannot reenter $\mathcal{B}_1$ after leaving it, while $P \cap \mathcal{B}_2$ must start at the sink of $\mathcal{B}_2$ and cannot leave $\mathcal{B}_2$ after entering it. Consequently, $P \cap \mathcal{B}_1$ consists of a single double trail P_1, and $P \cap \mathcal{B}_2$ consists of a single double trail P_2 too. So, both $P \cap \mathcal{B}_1$ and $P \cap \mathcal{B}_2$ are of Type π_1. In turn, $P \cap \mathcal{B} = (P_1, P_2)$ is of Type δ_2 or δ_3 by

Table 5.3; $P \cap \mathcal{B}$ cannot be of Type δ_0 or else $\mathcal{B}$ could not have been a proper block of G. Moreover, each of P_1 and P_2 starts and ends at different vertices; so each of $P \cap \mathcal{B}_1$ and $P \cap \mathcal{B}_2$ is of Type σ_1 or σ_3.

Suppose that one of $P \cap \mathcal{B}_1$ and $P \cap \mathcal{B}_2$ is of Type σ_1 and the other is of Type σ_3. We assume that $P \cap \mathcal{B}_1$ is of Type σ_1 and $P \cap \mathcal{B}_2$ is of Type σ_3; the other case is similar. Then, the unique σ-type of $\mathcal{B}$ is $\sigma_1 \star \sigma_3 = \sigma_1$ by Table 4.1. Note that the starting vertex of P^* (which is also the starting vertex of the dual trail P_1^* of P_1) and the ending vertex of P^* (which is also the ending vertex of the dual trail P_2^* of P_2) are different vertices in G^*. Since $P \cap \mathcal{B}_1 = (P_1)$ is of Type σ_1, the starting and the ending vertices of P_1^* must be different. On the other hand, since $P \cap \mathcal{B}_2 = (P_2)$ is of Type σ_3, the starting and the ending vertices of P_2^* must be the same. These requirements together imply that the ending vertex of P_1^* and the starting vertex of P_2^* must be the same pole of $\mathcal{B}^*$. Therefore, the ODTC $P \cap \mathcal{B} = (P_1, P_2)$ is not of Type δ_3 but is of Type δ_2. So, $\delta_2 = \delta_{g(1)}$.

Suppose that both of $P \cap \mathcal{B}_1$ and $P \cap \mathcal{B}_2$ are of Type σ_1 or both of them are of Type σ_3. Then, the unique σ-type of $\mathcal{B}$ is σ_3 by Table 4.1. Similarly to the above case where $P \cap \mathcal{B}_1$ and $P \cap \mathcal{B}_2$ are of different σ-types, we can prove that the ending vertex of the dual trail P_1^* of P_1 and the starting vertex of the dual trail P_2^* of P_2 must be different poles of $\mathcal{B}^*$. Hence, the ODTC $P \cap \mathcal{B} = (P_1, P_2)$ is not of Type δ_2 but is of Type δ_3. So, $\delta_3 = \delta_{g(3)}$. □

LEMMA 6.6. *Suppose that G is not Eulerian. Let μ be a doubly good nonroot node of T. Let $B = \mathrm{Pt}(\mu)$. Suppose that δ_j is a useful δ-type of B. Then, $\mathcal{K}_\sigma(B)$ equals $\{\sigma_4\}$ or $\{\sigma_5\}$ and $\delta_j = \delta_3$.*

Proof. Suppose that a DET P of a valid embedding $\mathcal{G}$ of G starts with an edge e_s of $\mathcal{B}$ and ends with an edge e_t of $\mathcal{B}$, where $\mathcal{B}$ is the block of $\mathcal{G}$ that is a different embedding of B. Let P^* be the dual trail of P. Since $\mathcal{B}$ is a proper block of $\mathcal{G}$, $P \cap \mathcal{B}$ consists of at least two trails P_1 and P_2, where P_1 starts with e_s and P_2 ends with e_t. Since μ is doubly good, neither $\mathcal{B}$ nor $\mathcal{B}^*$ has an odd-degree nonpole. By Facts 1 and 2, P starts at a pole of $\mathcal{B}$ and ends at the other pole of $\mathcal{B}$, and P^* starts at a pole of $\mathcal{B}^*$ and ends at the other pole of $\mathcal{B}^*$. So, both e_s and e_t are access edges of $\mathcal{B}$. In turn, each of P_1 and P_2 uses exactly two access edges of $\mathcal{B}$. Since $\mathcal{B}$ has at most four access edges, P_1 and P_2 are the only two trails in $P \cap \mathcal{B}$. Therefore, $P \cap \mathcal{B} = (P_1, P_2)$ is of Type σ_4 or σ_5. Let P_1^* and P_2^* be the dual trail of P_1 and P_2, respectively.

Case 1. $P \cap \mathcal{B}$ is of Type σ_4. Then, P_1 starts at a pole u of $\mathcal{B}$ and ends at u while P_1^* starts at a pole x of $\mathcal{B}^*$ and ends at the other pole y of $\mathcal{B}^*$. Because neither $\mathcal{G}$ nor $\mathcal{G}^*$ is Eulerian, P_2 starts at the other pole v of $\mathcal{B}$ and ends at v while P_2^* starts at x and ends at y. Thus, $P \cap \mathcal{B}$ is of Type δ_3.

Case 2. $P \cap \mathcal{B}$ is of Type σ_5. Then, P_1 starts at a pole u of $\mathcal{B}$ and ends at the other pole v of $\mathcal{B}$ while P_1^* starts at a pole x of $\mathcal{B}^*$ and ends at x. Because neither $\mathcal{G}$ nor $\mathcal{G}^*$ is Eulerian, P_2 starts at u and ends at v while P_2^* starts at the other pole y of $\mathcal{B}^*$ and ends at y. Thus, $P \cap \mathcal{B}$ is of Type δ_3. □

Let μ be a node of T, and let ν be a child of μ in T. A σ-, π-, or δ-type γ_1 of $\mathrm{Pt}(\mu)$ is *consistent* with a σ-, π-, or δ-type γ_2 of $\mathrm{Pt}(\nu)$ if a different embedding H of $\mathrm{Pt}(\mu)$ has a Type-γ_1 DTC $\mathcal{Q}$ such that $\mathcal{Q} \cap B$ is a Type-γ_2 DTC of B, where B is the block of H that is a different embedding of $\mathrm{Pt}(\nu)$.

To describe the improved algorithm concisely, we abuse the notation to use $\mathcal{K}_\pi(B)$ (respectively, $\mathcal{K}_\delta(B)$) to mean its arbitrary subset that contains all useful π-types (respectively, δ-types) of a block B of G.

The algorithm works as follows. First, for all nodes μ of T, we determine if μ is a

good node of T and compute the pole-parity multiset of $\mathrm{Pt}(\mu)$ if so; we also determine if μ is a good node of T^* and compute the pole-parity multiset of the dual graph of $\mathrm{Pt}(\mu)$ if so. By Lemma 6.1, this takes $O(|G|)$ time in total. Then, we find the critical nodes of T based on Lemma 6.1. If T has more than two critical nodes, then we stop immediately since G has no valid embedding by Lemma 6.2. So, suppose that T has one or two critical nodes. For all doubly good nonroot nodes μ of T, we compute $\mathcal{K}_\sigma(\mu)$ as in section 4.3. After this, we distinguish two cases as follows.

- *Case* 1. T has two critical nodes, say μ and μ'. Let $B = \mathrm{Pt}(\mu)$ and $B' = \mathrm{Pt}(\mu')$. Then, μ is not an ancestor of μ' and vice versa. Thus, both μ and μ' are doubly bad, and every DET of a valid embedding of G starts with an edge of one of B and B' and ends with an edge of the other. We need to compute $\mathcal{K}_\pi(B)$ and $\mathcal{K}_\pi(B')$. After knowing $\mathcal{K}_\pi(B)$ and $\mathcal{K}_\pi(B')$, we are done by calling the algorithm in section 5.4 to compute $\mathcal{K}_\delta(G)$. We describe the computation of $\mathcal{K}_\pi(B)$ below. $\mathcal{K}_\pi(B')$ is computed similarly. Let $\nu_1, \ldots, \nu_q$ be the children of μ in T. For each $i \in \{1, \ldots, q\}$, let e_i be the virtual edge of ν_i in $\mathrm{Sk}(\mu)$. If $|\mathcal{K}_\sigma(\nu_i)| = 0$ for some $i \in \{1, \ldots, q\}$, then $\mathcal{K}_\pi(B) = \emptyset$ by Lemma 6.4. So, suppose $\mathcal{K}_\sigma(\nu_i)$ consists of a unique $\sigma_{k_i} \in \Sigma$ for all $i \in \{1, \ldots, q\}$.
  - *Case* 1.1. μ is an R-node. Let $H = \mathrm{Sk}(\mu)$. By an *extreme vertex* of H, we mean a pole of H or a nonpole v of H such that for an odd number of edges e_i incident to v in H, ν_i is an O-good node of T. Similarly, by an *extreme face* of H, we mean the west or east side of H or an inner face F of H such that for an odd number of edges e_i on the boundary of F, ν_i is an O-good node of T^*. If H has more than three extreme vertices, then it has at least two odd-degree nonpoles, x and y. In every DET P of G, each of x and y must be either the starting vertex or the ending vertex. However, we allow only one of the starting and the ending vertices of P to be in H. Hence, G has no DET in this case. Similarly, if H has more than three extreme faces, then G has no valid embedding. Let W be the set of all children ν_i of μ such that e_i is incident to an extreme vertex of H and is also on an extreme face of H. Since μ is an R-node, for each (extreme) vertex v of H and each (extreme) face F of H, at most two edges incident to v are on F; so, a very rough estimate shows $|W| \leq 18$. Moreover, every DET of a valid embedding of G either starts or ends with an edge of $\mathrm{Pt}(\nu_i)$ for some $\nu_i \in W$. Thus, for each $\nu_i \in W$, we set $\mathcal{K}_\pi(\mathrm{Pt}(\nu_i)) = \{\pi_{f(k_i)}\}$ and then compute the set Π_i of all π-types of B consistent with Type $\pi_{f(k_i)}$ of $\mathrm{Pt}(\nu_i)$ as in Case 3.1 in section 5.4. By Lemma 6.4 and statements 1 and 2 in Lemma 3.2, $\cup_{\nu_i \in W} \Pi_i$ is $\mathcal{K}_\pi(B)$.
  - *Case* 1.2. μ is an S-node (respectively, P-node). For each $j \in \{1, \ldots, 5\}$, let $I_j = \{i \in \{1, \ldots, q\} \mid \sigma_{k_i} = \sigma_j\}$. For each $j \in \{1, \ldots, 5\}$ such that $I_j \neq \emptyset$, we select an arbitrary $i \in I_j$, set $\mathcal{K}_\pi(\mathrm{Pt}(\nu_i)) = \{\pi_{f(k_i)}\}$, and compute the set Π_j of all π-types of B consistent with Type $\pi_{f(k_i)}$ of $\mathrm{Pt}(\nu_i)$ as in Case 3.2 (respectively, 3.3) in section 5.4. By Lemma 6.4 and statements 1 and 2 in Lemma 3.2, $\cup_{1 \leq j \leq 5, I_j \neq \emptyset} \Pi_j$ is $\mathcal{K}_\pi(B)$.
- *Case* 2. T has exactly one critical node, say μ. Let $B = \mathrm{Pt}(\mu)$. If μ is the root of T, we need to compute $\mathcal{K}_\delta(B)$; otherwise, we need to compute $\mathcal{K}_\pi(B)$ and $\mathcal{K}_\delta(B)$. The former case is easier, and here we consider only the latter case. So, we assume that μ is not the root. Then, μ is doubly bad. Let $\nu_1, \ldots, \nu_q$ be the children of μ in T. For each $i \in \{1, \ldots, q\}$, let e_i be the virtual edge of ν_i in $\mathrm{Sk}(\mu)$. If $\mathcal{K}_\sigma(\nu_i) = \emptyset$ for some $i \in \{1, \ldots, q\}$, then $\mathcal{K}_\pi(B) = \mathcal{K}_\delta(B) = \emptyset$ by

Lemmas 6.4, 6.5, and 6.6. So, suppose $\mathcal{K}_\sigma(\nu_i) = \{\sigma_{k_i}\}$ for all $i \in \{1, \ldots, q\}$. For each $j \in \{1, \ldots, 5\}$, let $I_j = \{i \in \{1, \ldots, q\} \mid \sigma_{k_i} = \sigma_j\}$. For each $j \in \{1, 2, 3\}$, let $I'_j = \{i \in I_j \mid \nu_i \text{ is an S-node}\}$. Let $I'_5 = \{i \in I_5 \mid \nu_i \text{ is not an S-node}\}$.

- *Case* 2.1. μ is an R-node. $\mathcal{K}_\pi(B)$ can be computed as in Case 1.1. We next explain the computation of $\mathcal{K}_\delta(B)$. Let $H = \mathrm{Sk}(\mu)$. As in Case 1.1, we define *extreme vertices* and *extreme faces* of H. If H has more than four extreme vertices, then it has at least three odd-degree nonpoles and each of them must be the starting or the ending vertex of any DET of G. Hence, G has no DET in this case. Similarly, if H has more than four extreme faces, then G has no valid embedding. If G is not Eulerian, we define a set W of children of μ as in Case 1.1; otherwise, let W be the set of all children ν_i of μ such that (1) e_i is on an extreme face of H and (2) at least one endpoint of e_i is on two extreme faces of H. Since μ is an R-node, for each pair of (extreme) faces of H, at most two vertices can appear on both of them; so, a very rough estimate shows $|W| \leq 96$. Moreover, every DET of a valid embedding of G that starts and ends both with edges of B must start with an edge of $\mathrm{Pt}(\nu_i)$ and end with an edge of $\mathrm{Pt}(\nu_j)$ for some $\nu_i, \nu_j \in W$ (possibly $\nu_i = \nu_j$). Thus, for each $\nu_i \in W$ and each $\nu_j \in W$ with $\nu_i \neq \nu_j$, we set $\mathcal{K}_\pi(\mathrm{Pt}(\nu_i)) = \{\pi_{f(k_i)}\}$ and $\mathcal{K}_\pi(\mathrm{Pt}(\nu_j)) = \{\pi_{f(k_j)}\}$, and further compute the set $\Delta_{i,j}$ of all δ-types of B consistent with both Type $\pi_{f(k_i)}$ of $\mathrm{Pt}(\nu_i)$ and Type $\pi_{f(k_j)}$ of $\mathrm{Pt}(\nu_j)$, as in Case 1.1 in section 5.4. Moreover, for each $\nu_i \in W$, we compute a set Δ_i as follows. In case G is not Eulerian, if $\sigma_{k_i} \in \{\sigma_4, \sigma_5\}$, then we set $\mathcal{K}_\delta(\mathrm{Pt}(\nu_i)) = \{\delta_3\}$, and set Δ_i to be the set of all δ-types of B consistent with Type δ_3 of $\mathrm{Pt}(\nu_i)$, as in Case 2.1 in section 5.4; otherwise, we set $\Delta_i = \emptyset$. In case G is Eulerian, if either (1) ν_i is not an S-node and $\sigma_{k_i} = \sigma_5$ or (2) ν_i is an S-node and $\sigma_{k_i} \in \{\sigma_1, \sigma_2, \sigma_3\}$, then we set $\mathcal{K}_\delta(\mathrm{Pt}(\nu_i)) = \{\delta_{g(k_i)}\}$, and set Δ_i to be the set of all δ-types of B consistent with Type $\delta_{g(k_i)}$ of $\mathrm{Pt}(\nu_i)$, as in Case 2.1 in section 5.4; otherwise, we set $\Delta_i = \emptyset$. By Lemmas 3.2, 6.4, 6.5, and 6.6, the union of the computed sets $\Delta_{i,j}$ and Δ_i is $\mathcal{K}_\delta(B)$.
- *Case* 2.2. μ is an S-node (respectively, P-node). $\mathcal{K}_\pi(B)$ can be computed as in Case 1.2. We next explain the computation of $\mathcal{K}_\delta(B)$. For each $j \in \{1, \ldots, 5\}$ with $|I_j| \geq 2$, we arbitrarily select two distinct $i, i' \in I_j$, set $\mathcal{K}_\pi(\mathrm{Pt}(\nu_i)) = \{\pi_{f(k_i)}\}$ and $\mathcal{K}_\pi(\mathrm{Pt}(\nu_{i'})) = \{\pi_{f(k_{i'})}\}$, and compute the set Δ_j of all δ-types of B consistent with both Type $\pi_{f(k_i)}$ of $\mathrm{Pt}(\nu_i)$ and Type $\pi_{f(k_{i'})}$ of $\mathrm{Pt}(\nu_{i'})$, as in Case 1.2 (respectively, 1.3) in section 5.4. Also, for each pair of distinct $j, j' \in \{1, \ldots, 5\}$ with $I_j \neq \emptyset$ and $I_{j'} \neq \emptyset$, we arbitrarily select one $i \in I_j$ and one $i' \in I_{j'}$, set $\mathcal{K}_\pi(\mathrm{Pt}(\nu_i)) = \{\pi_{f(k_i)}\}$ and $\mathcal{K}_\pi(\mathrm{Pt}(\nu_{i'})) = \{\pi_{f(k_{i'})}\}$, and compute the set $\Delta_{j,j'}$ of all δ-types of B consistent with both Type $\pi_{f(k_i)}$ of $\mathrm{Pt}(\nu_i)$ and Type $\pi_{f(k_{i'})}$ of $\mathrm{Pt}(\nu_{i'})$, as in Case 1.2 (respectively, 1.3) in section 5.4. Furthermore, in case G is Eulerian, for each $j \in \{1, 2, 3, 5\}$ with $I'_j \neq \emptyset$, we arbitrarily select one $i \in I'_j$, set $\mathcal{K}_\delta(\mathrm{Pt}(\nu_i)) = \{\delta_{g(k_i)}\}$, and compute the set Δ'_j of all δ-types of B consistent with Type $\delta_{g(k_i)}$ of $\mathrm{Pt}(\nu_i)$, as in Case 2.2 (respectively, 2.3) in section 5.4. On the other hand, in case G is not Eulerian, for each $j \in \{4, 5\}$ with $I_j \neq \emptyset$, we arbitrarily select one $i \in I_j$, set $\mathcal{K}_\delta(\mathrm{Pt}(\nu_i)) = \{\delta_3\}$, and compute the set Δ'_j of all δ-types of

B consistent with Type δ_3 of $\mathrm{Pt}(\nu_i)$, as in Case 2.2 (respectively, 2.3) in section 5.4. By Lemmas 3.2, 6.4, and 6.5, the union of the computed sets Δ_j, $\Delta_{j,j'}$, and Δ'_j is $\mathcal{K}_\delta(B)$.

After processing the unique critical node μ, we know $\mathcal{K}_\pi(B)$ and $\mathcal{K}_\delta(B)$. Note that μ is doubly bad and $\mathcal{K}_\sigma(B) = \emptyset$. We then proceed to processing the parent χ of μ. Let $B_\chi = \mathrm{Pt}(\chi)$. Let $\mu_1, \ldots, \mu_p$ be the children of χ, where $\mu_1 = \mu$. For each $i \in \{1, \ldots, p\}$, let e'_i be the virtual edge of μ_i in $\mathrm{Sk}(\chi)$. Since B or B^* has an odd-degree nonpole, each DET of a valid embedding of G must start and/or end with an edge of B. So, for each $i \in \{2, \ldots, p\}$, if $\mathcal{K}_\sigma(\mathrm{Pt}(\mu_i)) = \emptyset$, then $\mathcal{K}_\pi(\mathrm{Pt}(\mu_i)) = \emptyset$ too, and hence G has no valid embedding. Thus, we may assume each $\mathcal{K}_\sigma(\mathrm{Pt}(\mu_i))$ consists of a unique $\sigma_{\ell_i} \in \Sigma$. $\mathcal{K}_\pi(B_\chi)$ can be computed from $\mathcal{K}_\pi(B), \mathcal{K}_\sigma(\mathrm{Pt}(\mu_2)), \ldots, \mathcal{K}_\sigma(\mathrm{Pt}(\mu_p))$, as in Case 3 in section 5.4. To compute $\mathcal{K}_\delta(B_\chi)$, we first compute the set Δ_0 of all δ-types of B_χ consistent with a δ-type in $\mathcal{K}_\delta(B)$, as in Case 2 in section 5.4. After this, for each $\pi_h \in \mathcal{K}_\pi(B)$, we compute a set Δ_h as follows.

- *Case* 2.3. χ is an R-node. We use Lemma 6.3 to compute the unique pole-status S of the different embeddings of B that have a π-type DTC. Let $H = \mathrm{Sk}(\chi)$. Let v_1 and v_2 be the endpoints of e'_1. Let F_1 and F_2 be the endpoints of the dual edge of e'_1. For each list $L = (a_1, a_2, b_1, b_2)$ such that $S = (\langle a_1, a_2\rangle, \langle b_1, b_2\rangle)$, we compute a set Δ_L as follows. For each vertex $v \notin \{v_1, v_2\}$ of H, we define v to be an *extreme vertex* of H as in Case 1.1. Similarly, for each vertex $F \notin \{F_1, F_2\}$ of H^*, we define F to be an *extreme face* of H as in Case 1.1. For each $j \in \{1, 2\}$, we say that v_j is an *extreme vertex* of H if (1) v_j is a pole of H, or (2) $a_j = 0$ and an odd number of edges $e'_i \neq e'_1$ incident to v_j satisfy that μ_i is an O-good node of T, or (3) $a_j = 1$ and an even number of edges $e'_i \neq e'_1$ incident to v_j satisfy that μ_i is an O-good node of T. Similarly, for each $j \in \{1, 2\}$, we say that F_j is an *extreme face* of H if (1) F_j is a pole of H^*, or (2) $b_j = 0$ and an odd number of edges $e'_i \neq e'_1$ on F_j satisfy that μ_i is an O-good node of T^*, or (3) $b_j = 1$ and an even number of edges $e'_i \neq e'_1$ on F_j satisfy that μ_i is an O-good node of T^*. As in Case 2.1, H has at most four extreme vertices and at most four extreme faces, unless G has no valid embedding. As in Case 2.1, we define a set W of children μ_i of χ. Let $W' = W - \{\mu\}$. For each $\mu_i \in W'$, we set $\mathcal{K}_\pi(\mathrm{Pt}(\mu_i)) = \{\pi_{f(\ell_i)}\}$, and then compute the set Δ'_i of all δ-types of B_χ consistent with both Type π_h of $\mathrm{Pt}(\mu)$ and Type $\pi_{f(\ell_i)}$ of $\mathrm{Pt}(\mu_i)$, as in Case 1.1 in section 5.4. Let $\Delta_L = \cup_{\mu_i \in W'} \Delta'_i$. Let Δ_h be the union of the computed sets Δ_L.
- *Case* 2.4. χ is an S-node (respectively, P-node). For each $j \in \{1, \ldots, 5\}$, let $I''_j = \{i \in \{2, \ldots, p\} \mid \sigma_{\ell_i} = \sigma_j\}$. For each $j \in \{1, \ldots, 5\}$ with $|I''_j| \geq 1$, we arbitrarily select one $i \in I''_j$, set $\mathcal{K}_\pi(\mathrm{Pt}(\mu_i)) = \{\pi_{f(\ell_i)}\}$, and compute the set Δ'_j of all δ-types of B_χ consistent with both Type π_h of $\mathrm{Pt}(\mu)$ and Type $\pi_{f(\ell_i)}$ of $\mathrm{Pt}(\mu_i)$, as in Case 1.2 (respectively, 1.3) in section 5.4. Let Δ_h be the union of the computed sets Δ'_j.

By Lemmas 3.2, 6.4, 6.5, 6.6, and 6.3, $\mathcal{K}_\delta(B_\chi) = \Delta_0 \cup (\cup_{\pi_h \in \mathcal{K}_\pi(B)} \Delta_h)$. This completes the processing of χ; each ancestor of χ is processed in the same way. Once we finish processing the root of T, we have $\mathcal{K}_\delta(G)$; G has a valid embedding if and only if $\delta_0 \in \mathcal{K}_\delta(G)$.

Obviously, processing each node μ of T takes $O(|\mathrm{Sk}(\mu)|)$ time. Thus, we have the following.

THEOREM 6.7. *Given a TTG G whose dual graph is not Eulerian, it takes $O(|G|)$ time to decide if G has a valid embedding.*

Acknowledgment. The authors would like to thank the referee for suggestions that considerably improved the readability of this paper.

THE COMBINATORIAL STRUCTURE OF WAIT-FREE SOLVABLE TASKS*

HAGIT ATTIYA† AND SERGIO RAJSBAUM‡

Abstract. This paper presents a self-contained study of wait-free solvable tasks. A new necessary condition for wait-free solvability, based on a restricted set of executions, is proved. This set of executions induces a very simple-to-understand structure, which is used to prove tight bounds for k-set consensus and renaming. The framework is based on topology, but uses only elementary combinatorics, and, in contrast to previous works, does not rely on algebraic or geometric arguments.

Key words. distributed systems, shared memory systems, atomic read/write registers, combinatorial topology, wait-free solvable tasks, consensus, set consensus, renaming

1. Introduction.

This paper studies the tasks that can be solved by a wait-free protocol in a shared-memory asynchronous system, consisting of $n+1$ processes that communicate by reading and writing atomic shared registers. We assume that processes are completely asynchronous and run at completely arbitrary speeds. Processes start with *inputs* and, after performing some protocol, have to decide on some *outputs*. A *task* specifies the sets of outputs that are allowable for each assignment of inputs to processes. A protocol is *wait-free* if a process decides on an output after a finite number of its own events, regardless of the behavior of other processes. A task is *wait-free solvable* if there is a wait-free protocol solving it.

The study of wait-free solvable tasks is central to the theory of distributed computing. Early research studied specific tasks and showed them to be solvable (e.g., approximate agreement [13], $2n$-renaming [2], k-set consensus with at most $k-1$ failures [11]) or unsolvable (e.g., consensus [15], $n+1$-renaming [2]). In 1988, a necessary and sufficient condition for the solvability of a task in the presence of a single process failure was presented [6]. In 1993, a significant advancement was made in the understanding of wait-free solvability [7, 22, 25], yielding new impossibility results for k-set consensus ([7, 22, 25], and later [10, 19, 20]) and renaming [20, 22], as well as a necessary and sufficient condition for wait-free solvability [22, 23] (which is undecidable [16, 21]).

Of particular interest is the use of topological notions to investigate the problem, suggested in [22, 25] and implicit in [7]. Yet, much of this development remained inaccessible to many researchers, since it relied on algebraic and geometric tools of topology. Furthermore, different topology techniques were used in each of these works,

for example, a direct, combinatorial application of Sperner's lemma in [7], a more involved form of Brouwer fixed point theorem in [25], and a combination of continuous and algebraic tools of simplicial approximation and Mayer–Vietoris sequences in [22].

In this paper, we study wait-free solvable tasks, starting from first principles. We introduce a new necessary condition for wait-free solvability and use it to prove the impossibility of solving k-set consensus and renaming. Our approach borrows critical ideas from previous works in this area, especially [7, 8, 20, 22, 23, 25], and integrates them into a unified framework. Our goal was to deepen the understanding of the wait-free solvability problem, in particular to learn which tools of topology are needed to investigate this problem.

1.1. Our contributions. We develop a formal model that captures wait-free solvability in terms of combinatorial mathematics, inspired by topology. To explain our model, here is a rough description of key notions from combinatorial topology. (Precise definitions appear in section 4.1.)

A *colored simplex* is a set in which every element, called a *vertex*, is colored with a different process id. A *colored complex* is a collection of colored simplexes which is closed under containment. A mapping from the vertices of one colored complex to the vertices of another is *simplicial* if it maps a simplex to a simplex; it is *color preserving* if each vertex is mapped to a vertex with the same process id. Finally, a complex whose largest simplex contains m vertices is a *pseudomanifold* if every simplex with $m-1$ vertices is contained in either one or two simplexes with m vertices.

Although these definitions do not require algebraic or geometric interpretations, it is sometimes useful to have a topological intuition in mind. In topology a complex is viewed as a discretization of a continuous space. For example, in three dimensions, a pseudomanifold is obtained by "chopping" a surface into triangular pieces, where each one corresponds to a simplex. If we chop it into smaller and smaller pieces, we obtain closer approximations to the surface, and it is said that finer *subdivisions* are obtained. A simplicial map is analogous to a continuous map, and in topology is often interpreted as instructions of how to bend and fold one complex into another, possibly stretching it but without tearing it apart.

The novel combinatorial concept we use is of a pseudomanifold being a *divided image* of a simplex, having the same boundary as the simplex. A divided image of a complex is obtained by taking a divided image of each one of its simplexes and pasting them together. (An example appears in Figure 2.) A subdivision of a complex preserves all the topological structure of the complex, while a divided image preserves only some of its topological structure. (The divided image shown in Figure 2 is actually a subdivision.) Our results show that the topological structure that is preserved suffices to prove the set consensus impossibility, and if in addition the divided image is orientable we can also prove the renaming impossibility. This new necessary condition for wait-free solvability is our main result, Theorem 5.14.

Given a task, and a wait-free protocol solving it, we show that a subset of the protocol's executions, called *immediate snapshot executions* [7, 25], induces a divided image of the input complex. The decisions made by the protocol induce a simplicial map from this divided image to the output complex which must agree with the task specification. A solution for the participating set task [8] is used to show that the above property is also sufficient: If there is a simplicial map from the divided image induced by immediate snapshots executions to the output complex, which agrees with the task, then the task is wait-free solvable.

The divided image induced by immediate snapshot executions is shown to be

orientable and *connected*. We show that an orientable chromatic divided image induces an *algebraic span* [20].

Using the standard Sperner's lemma, we show that k-set consensus is wait-free solvable only if $k > n$. Using results of [20], we prove a combinatorial theorem about the number of monochromatic simplexes in any binary coloring of an orientable and connected divided image. This theorem is used to prove that M-renaming is wait-free solvable only if $M \geq 2n$. (Both bounds are tight; see [11] and [2], respectively.)

The main contribution of this paper, in our opinion, is in providing an alternative, combinatorial framework in which further research related to distributed solvability can be pursued. We believe our work is the first to provide an elementary, yet rigorous, treatment of this topic. From ideas that were developed in great generality in algebraic topology, our framework distills the properties that are required for the study of wait-free solvability, in particular properties that are sufficient to prove specific impossibility results. It does not require any previous topology background from the reader.

1.2. Relation to other work. The combinatorial topology framework we develop for wait-free solvability is related to the 1-failure model of Biran, Moran, and Zaks [6]; while they use graphs and edges (sets of two vertices), we use complexes and simplexes (sets of one or more vertices). Herlihy and Shavit also use simplexes [22, 23] but often given a geometric interpretation and considered as subsets of Euclidean space; in our work, we always consider combinatorial structures.

Divided images play a role similar to *spans* (both the geometric version used in [19, 22, 23] and the algebraic version introduced in [20]). As discussed after Definition 4.1, divided images have weaker mathematical properties than geometric spans; in particular, a divided image of a simplex may have "holes." We prove that an orientable divided image corresponds naturally to an algebraic span. It was shown that geometric spans exist [22], but the proof requires a combination of algebraic (homology theory) and geometric (subdivided simplexes) arguments.

The notion of immediate snapshot executions was introduced by Borowsky and Gafni [7] and by Saks and Zaharoglou [25]. These works contain many of the ideas needed to show that immediate snapshot executions induce a divided image. However, they centered on properties of immediate snapshot executions needed to prove the impossibility result for set consensus. For this result, it is not necessary to show that they are connected and orientable or that they induce an algebraic span or our simpler combinatorial notion of a divided image. No general conditions for wait-free solvability were derived from them, and no general model, like the one developed here, has appeared before.

The main difference between our necessary condition for wait-free solvability and the one proved by Herlihy and Shavit [22] is that we construct a *specific* well-structured divided image (induced by immediate snapshot executions), while they show that an *arbitrary* span exists.

1.3. Organization. The rest of this paper is organized as follows. In section 2, we describe the distributed computing model. In section 3, we define immediate snapshot executions and study their properties. Section 4 starts with the topology concepts used in the rest of the paper (section 4.1), and then we show how to model a task and a distributed computing system (as described in section 2) with the combinatorial topology concepts (sections 4.2 and 4.3). The condition for wait-free solvability is developed in section 5. Additional mathematics is developed in section 6, and is

later used in section 7, to prove impossibility of wait-free solutions for set consensus and renaming. We conclude with a discussion in section 8.

2. Model of computation. Our model is standard and was used in many papers; we follow [1].

A *system* consists of $n+1$ processes $p_0, \ldots, p_n$. A *process* is a deterministic state machine; each process has a (possibly infinite) set of *local states*, including a subset called the *initial states* and a subset called the *output states*. Processes communicate by means of a finite number of *single-writer multireader atomic registers*. No assumption is made regarding the size of the registers, and therefore we may assume that process p_i has a single register, R_i, to which it can write its entire state. Process p_i has two atomic operations available to it:

- $write_i$: p_i writes a value v to R_i.
- $read_i(R_j)$: p_i reads the register R_j and returns its value v.

A system configuration consists of the states of the processes and registers. Formally, a *configuration* C is a vector $\langle s_0, \ldots, s_n, v_0, \ldots, v_n \rangle$ where s_i is the local state of process p_i and v_j is the value of the register R_j. Denote $\text{state}_i(C) = s_i$. Each register may attain values from some *domain* which includes a special "undefined" value, $\perp$. An *initial configuration* is a configuration in which every local state is an initial state and all registers are set to $\perp$.

We consider an interleaving model of concurrency, where executions are modeled as sequences of events. An event is performed by a single process p_i, which applies either a $write_i$ operation or a $read_i(R_j)$ operation, but not both, performs some local computation, and changes to its next local state. The next configuration is the result of these modifications.

The state machine of each process p_i models a *local protocol*, $\mathcal{P}_i$, that determines p_i's next event—$\mathcal{P}_i$ determines whether p_i is to write or read, and (in case of a read) which register R_j to read—as a function of p_i's local state. If p_i reads R_j, then $\mathcal{P}_i$ determines p_i's next state as a function of p_i's current state and the value v read from R_j. If p_i writes to R_i, then $\mathcal{P}_i$ determines p_i's next state as a function of p_i's current state. We assume that all local protocols are identical; i.e., processes have the same state machine, which do not depend on the process id. If the local protocol has to depend on the id, then the id has to be encoded in the input (see the discussion below in this section and in section 4.3).

A *protocol* is a collection $\mathcal{P}$ of local protocols $\mathcal{P}_0, \ldots, \mathcal{P}_n$.

An *event of* p_i is denoted below simply by p_i's index, i. An *execution* of a system is a finite or infinite alternating sequence of configurations and events $C_0, j_1, C_1, \ldots, C_{k-1}, j_k, \ldots$, where C_0 is an initial configuration and C_k is the result of applying the event j_k to C_{k-1}, for all $k \geq 1$. The *schedule* of this execution is $j_1, \ldots, j_k, \ldots$.

Given an execution $\alpha = C_0, j_1, C_1, \ldots$, and a process p_i, the *view of* p_i *in* α, denoted $\alpha|i$, is the sequence $\text{state}_i(C_0), \text{state}_i(C_1), \ldots$.

To model decision tasks, we identify two special components of each process's state: an *input* and an *output*. It is assumed that initial states differ only in the value of the input component; moreover, the input component never changes. If we want to have a local protocol which depends on the process id, then the id has to be provided explicitly as part of the input. The protocol cannot overwrite the output: The output is initially $\perp$; once a non-$\perp$ value is written to the output component of the state, it never changes; when this happens, we say that the process *decides*. The output states are the states with non-$\perp$ output value.

A view of process p_i in a finite execution α is *final* if there is a configuration in α

in which p_i decides; since the output cannot be overwritten, it follows that p_i's output is not $\perp$ in some suffix of α. A final view is *minimal* if none of its prefixes is final. A minimal final view is the prefix of p_i's view in α up to (and including) the first configuration in which p_i decides.

A *task* Δ has a domain $\mathcal{I}$ of input values and a domain $\mathcal{O}$ of output values; Δ specifies for each assignment of inputs to the processes on which outputs processes can decide.

A protocol *solves* Δ if any finite execution α can be extended to an execution α' in which all processes decide on values which are allowable for the inputs in α. Because the outputs cannot be overwritten, if a process decides on a value in α, it must have the same output in α'. This means that outputs already written by the processes can be completed to outputs for all processes that are allowable for the inputs in α.

A protocol is *wait-free* if in any execution of the protocol a process either has a finite number of events or it decides. This implies that if a process has an infinite number of events, it must decide after a finite number of events.

We do not require processes to halt—they solve the decision task and decide by writing to the output component; processes can continue to participate. We typically consider the behavior of a process until it decides, and, therefore, the above distinction does not matter.

For the rest of the paper, we consider *full-information* protocols, in which a process remembers everything and writes everything it knows. Formally, we add a *history* component to the input and output components described above. The history component of p_i consists of the sequence of operations executed so far by p_i and their results. Initially, the sequence is empty; after p_i executes a $write_i$ operation, *write* is appended to the sequence; after it executes a $read_i(R_j)$, returning the value v, $read[j, v]$ is appended. Clearly, a task is solvable if and only if it can be solved by a full-information protocol; hence, there is no loss of generality in considering only full-information protocols if efficiency issues are ignored.

Since we consider only deterministic protocols, the state of a process is uniquely determined by its history component. In fact, the behavior of all full-information protocols is very similar; protocols differ only in what value a process decides on and when the process makes the decision. Thus, the decision value is a function of the input component and the history component, and various protocols differ only in this function.

We also assume, without loss of generality, that the local protocol of each process p_i is in *standard form*: p_i proceeds in a sequence of *steps*; in each step p_i writes its entire state to R_i and then reads $R_0, \ldots, R_n$ (in some fixed order); after reading, p_i determines whether to decide and on which value.

Below, we rely on the notion of executions that cannot be distinguished by a process; this happens when the process has the same view in both executions. Formally, two executions, α_1 and α_2, are *indistinguishable to process* p_i, denoted $\alpha_1 \overset{p_i}{\sim} \alpha_2$, if $\alpha_1|p_i = \alpha_2|p_i$. This notion of indistinguishability can be extended to sets of processes in the natural manner: if P is a set of processes, then $\alpha_1 \overset{P}{\sim} \alpha_2$ if and only if $\alpha_1 \overset{p_i}{\sim} \alpha_2$ for every process $p_i \in P$. Typically, we shall be interested in pairs of executions which are indistinguishable to all processes, except one. If $\alpha_1 \overset{P}{\sim} \alpha_2$, for $P = \{p_0, \ldots, p_{i-1}, p_{i+1}, \ldots, p_n\}$, and $\alpha_1|p_i \neq \alpha_2|p_i$, then we denote $\alpha_1 \overset{\neg p_i}{\sim} \alpha_2$.

3. Immediate snapshot executions. We start by introducing immediate snapshot executions. In section 3.1, we prove their basic properties, and in section 3.2 these

properties are extended to prove that immediate snapshot executions are connected in a certain sense.

Consider a full-information protocol in standard form; we now restrict our attention to a subset of the executions of this protocol. An *immediate snapshot* (in short, IS) execution consists of a sequence of *rounds*. The kth round is specified by a nonempty *concurrency class* of process ids, s_k; s_k specifies the *active* processes that take a step in round k. First every process in s_k performs a write operation (in increasing order of ids), and then every process in s_k reads all the registers, i.e., performs $n+1$ read operations (in some fixed order, say increasing order of ids). Intuitively, each round contains a concurrent write by every active process, followed by a concurrent atomic snapshot by every active process.

We assume that the protocol is wait-free. Since a process decides within a finite number of its own steps, we can restrict our attention to IS executions in which all views are minimal final; that is, a process takes steps only until it decides. Specifically, all IS executions are finite, and a process decides in its last active round.

Given a protocol and initial states for the processes (inputs), an IS execution, α, is determined by the sequence of concurrency classes; thus, we abuse notation and write $\alpha = s_1, s_2, \ldots, s_l$. Sometimes, we view an IS execution as a *concatenation* of two sequences of concurrency classes, and we write $\alpha = \alpha_1\alpha_2$ if $\alpha_1 = s_1, s_2, \ldots, s_r$ and $\alpha_2 = s_{r+1}, s_{r+2}, \ldots, s_l$.

The *number of steps* of p_i in α is the number of rounds in which it is active. The *total number of steps* in α, denoted $|\alpha|$, is the sum of the number of steps of all processors.

IS executions capture the computational power of the model. If a full-information protocol $\mathcal{P}$ solves a task Δ, it solves Δ in the subset of IS executions. Conversely, a protocol for the participating set task [8] can be used to simulate IS executions in a full-information manner, implying the next lemma.

LEMMA 3.1. *Let Δ be a task. There is a wait-free protocol which solves this task if and only if there is a wait-free protocol which solves this task only in IS executions.*

3.1. Basic properties of IS executions. Here, we consider the IS executions of a given full-information protocol in standard form, with some fixed inputs. The first property of the IS executions follows from the fact that the protocol is deterministic, and the views are minimal final.

LEMMA 3.2. *If α and α' are two distinct IS executions, then α is not a prefix of α'.*

Although they are very well-structured, IS executions still contain uncertainty, since a process does not know exactly which processes are active in the last round. That is, if p_i is active in round k and observes some other process p_j to be active (i.e., perform a write), p_i does not know whether p_j is active in round $k-1$ or in round k. Consider, for example, the executions in Figure 1. Only p_0 distinguishes between executions α_1 and α_2; p_1 and p_2 have the same views in both executions and cannot distinguish between them. (Note that p_0 distinguishes between α_1 and α_2, since in α_2, p_0 reads the initial value in p_2's register, while in α_1, p_0 reads the first write of p_2.) In Lemma 3.4, we prove that this is the only uncertainty processes have in IS executions of full-information protocols.

A process p_j is *unseen* in an execution α, if there is a round k, such that $p_j \notin s_r$ for every round $r < k$ and $s_r = \{p_j\}$ for every nonempty round $r \geq k$. Intuitively, no other process ever sees a step by p_j, since p_j's steps (if any) are taken after all processes no longer take steps.

Round number	1	2	3
p_0	w	r	
p_1		w	r
p_2	w	r

p_2		w	r

Execution α_2.

FIG. 1. *Executions α_1 and α_2 are indistinguishable to p_1 and p_2.*

LEMMA 3.3. *If a process p_j is unseen in an IS execution α, then there is no IS execution $\alpha' \neq \alpha$ such that $\alpha \overset{\neg p_j}{\sim} \alpha'$.*

Proof. Assume process p_j is unseen in $\alpha = s_1, \ldots, s_r$, but there exists an IS execution $\alpha' = s'_1, \ldots, s'_l \neq \alpha$ such that $\alpha \overset{\neg p_j}{\sim} \alpha'$. Let k be the round such that $s_i = \{p_j\}$ for every $i \geq k$ and $p_j \notin s_i$ for every round $y < k$.

Let k_0 be the first round in which α and α' differ, that is, $s_{k_0} \neq s'_{k_0}$. If $k_0 > \min\{r, l\}$, then one execution is a prefix of the other, which is impossible by Lemma 3.2; thus, $k_0 \leq \min\{r, l\}$.

If $k_0 \geq k$, then $s_{k_0} = \{p_j\}$ in α, while in α', s'_{k_0} must include some other process, p_i; however, p_i also distinguishes between α and α', which is a contradiction. If $k_0 < k$, then $p_j \notin s_{k_0}$. Since no process in s_{k_0} distinguishes between α and α', then the same processes must be in s'_{k_0}, which contradicts the assumption that $s_{k_0} \neq s'_{k_0}$. □

If p_j is not unseen in α, then it is *seen*; p_j is *seen* in round k, if $p_j \in s_k$, and for some $r \geq k$, there is some process $p_i \neq p_j$ that is in s_r. The *last seen round* of p_j is the largest k such that p_j is seen in round s_k; since IS executions are finite, the last seen round is well-defined.

Let $\{p_j\}^*$ be a finite (possibly empty) sequence of singleton concurrency classes, each one being $\{p_j\}$. Assume that p_j is seen in an IS execution $\alpha = s_1, \ldots, s_l$. The *tail position* of p_j in α is the smallest value of r for which α can be written as $s_1, \ldots, s_r, \{p_j\}^*$; $\{p_j\}^*$ is the *tail*, which may be empty. In this case, $s_r \neq \{p_j\}$ and $s_{r'} = \{p_j\}$ for every r', $r < r' \leq l$.

Below, the notation $\{p_j\}^*$ is used to denote the sequence of singleton concurrency classes needed to have a minimal final view for p_j; the views of other processes do not change. That is, we schedule p_j again and again in a concurrency class by itself until it decides.

LEMMA 3.4. *Let $\alpha = \alpha_1 s_k, s_{k+1}, \ldots, s_l$ be an IS execution in which a process p_j is seen. If s_k is the last seen round of p_j in α with tail position t, then consider an IS execution α' of the following form:*

(1) *If $s_k = \{p_j\}$, then $\alpha' = \alpha_1, s_k \cup s_{k+1}, s_{k+2}, s_{k+3}, \ldots, s_t, \{p_j\}^*$.*

(2) *If $s_k \neq \{p_j\}$, then $\alpha' = \alpha_1, \{p_j\}, s_k - \{p_j\}, s_{k+1}, s_{k+2}, \ldots, s_t, \{p_j\}^*$.*

In both cases, $\alpha' \overset{\neg p_j}{\sim} \alpha$, and α' is the only IS execution such that $\alpha' \overset{\neg p_j}{\sim} \alpha$.

Proof. Clearly, $\alpha' \overset{\neg p_j}{\sim} \alpha$, in both cases: p_j distinguishes between both executions and may take a different number of steps in the execution, but no other process does, since p_j cannot communicate with other processes. (Its steps afterwards are not seen.) We now show that α' is the only IS execution with this property.

First, notice that an IS execution α'' which is different from α and α' cannot be a prefix or an extension of either one, by Lemma 3.2.

If $s_k \neq \{p_j\}$ (case (2)), then clearly there is another process $p_i \in s_k$. If $s_k = \{p_j\}$ (case (1)), then there is another process $p_i \in s_{k+1}$: s_{k+1} is not empty and does not include p_j. Moreover, if some s_r, $r > k$, includes p_j, then $s_{r'} = \{p_j\}$ for every

nonempty round, with $r' \geq r$. (Otherwise, k is not the last seen round of p_j.) In both cases, for any IS execution α'', which is neither α nor α', $\alpha \overset{p_j}{\not\sim} \alpha''$, which proves the uniqueness of α'. ∎

In the similar execution, α', we either add p_j to the next concurrency class or take p_j into an earlier singleton concurrency class (by itself). Executions α_1 and α_2 in Figure 1 provide a simple example, where p_0's first step is either in a singleton class (the first concurrency class in α_2) or it is merged with the next class, with p_2 (the first concurrency class in α_2).

The views of processes other than p_j are the same in both executions, and they take the same number of steps. Process p_j distinguishes between the executions and may take a different number of steps until it decides. However, p_j distinguishes between the executions only after its last seen round and may take a different number of steps only in the tail.

3.2. Connectivity of IS executions. Recall that we are considering the IS executions of a given full-information protocol in standard form, with some fixed inputs.

The main theorem of this section is that any pair of IS executions with a common prefix γ are "transitively indistinguishable." Specifically, two IS executions α and α' are γ-*similar*, denoted $\alpha \approx_\gamma \alpha'$, if there exist IS executions $\gamma\beta_0, \ldots, \gamma\beta_r$, and processes, $p_{i_1}, \ldots, p_{i_r}$, such that $\alpha = \gamma\beta_0 \overset{\neg p_{i_1}}{\sim} \gamma\beta_1 \ldots \overset{\neg p_{i_r}}{\sim} \gamma\beta_r = \alpha'$. Note that γ-similarity is an equivalence relation. Clearly it is reflexive and symmetric, and it is a transitive property; that is, if $\alpha_1 \approx_\gamma \alpha_2$ and $\alpha_2 \approx_\gamma \alpha_3$, then $\alpha_1 \approx_\gamma \alpha_3$. A restricted case is when γ is empty, in which case the chain of indistinguishability need not have a common prefix.

The main lemma used to prove this theorem extends Lemma 3.4 to any round, not only the last seen round. We write $\alpha = \alpha_1 \cdot s_k \cdot \alpha_2$ when s_k is the kth concurrency class of α, where α_1 contains $k-1$ concurrency classes and α_2 is an arbitrary sequence of concurrency classes.

LEMMA 3.5. *Consider an IS execution $\alpha = \alpha_1 \cdot s_k \cdot \alpha_2$, in which a process $p_i \in s_k$. There is an IS execution α' of the following form:*

(1) *If $s_k = \{p_i\}$ and s_{k+1} is not empty with $p_i \notin s_{k+1}$, then $\alpha' = \alpha_1 \cdot s'_k \cdot \alpha'_2$, where $s'_k = s_{k+1} \cup \{p_i\}$.*

(2) *If $p_i \in s_k$ and $s_k - \{p_i\} \neq \emptyset$, then $\alpha' = \alpha_1 \cdot \{p_i\} \cdot s''_{k+1} \cdot \alpha''_2$, where $s''_{k+1} = s_k - \{p_i\}$.*

In both cases, $\alpha \approx_{\alpha_1} \alpha'$.

Before proving the lemma, we state two corollaries of it. The first corollary says that we can *flatten* a concurrency class, replacing it with a sequence of singleton sets with its processes. The result follows by repeatedly applying part (2) of Lemma 3.5 to all processes in s_k.

LEMMA 3.6. *Consider an IS execution $\alpha = \alpha_1 \cdot s_k \cdot \alpha_2$, where $s_k = \{p_{i_1}, \ldots, p_{i_r}\}$. Then $\alpha \approx_{\alpha_1} \alpha'$, where α' is an IS execution of the form $\alpha_1 \cdot \{p_{i_1}\} \cdots \{p_{i_r}\} \cdot \alpha'_2$.*

Since a concurrency class does not specify the order in which processes appear, the result allows us to reorder singleton concurrency classes. That is, we can take a pair of singleton concurrency classes, $\{p_i\}, \{p_j\}$ $(i \neq j)$, join it by Lemma 3.5(1) to get $\{p_j, p_i\}$, and then use Lemma 3.5(2) to flatten it in reverse order to get $\{p_j\}, \{p_i\}$. This implies the next lemma

LEMMA 3.7. *Consider an IS execution $\alpha = \alpha_1 \cdot \{p_i\} \cdot \{p_j\} \cdot \alpha_2$. Then $\alpha \approx_{\alpha_1} \alpha'$, where α' is an IS execution of the form $\alpha_1 \cdot \{p_j\} \cdot \{p_i\} \cdot \alpha'_2$.*

Now, applying Lemmas 3.6 and 3.7 to all concurrency classes of α_2, we can obtain an IS execution with only singleton sets, in any desired order.

LEMMA 3.8. *Consider an IS execution $\alpha = \alpha_1\alpha_2$. For any permutation $i_0, \ldots, i_n$ of $0, \ldots, n$, there is a unique IS execution α' of the form $\alpha_1 \cdot \{p_{i_0}\}^* \cdots \{p_{i_n}\}^*$ such that $\alpha \approx_{\alpha_1} \alpha'$.*

The uniqueness of α' follows from Lemma 3.2.

Proof of Lemma 3.5. Let L be the maximal number of steps taken in any IS execution with the same input as α.[1] We prove the lemma by reverse induction on $|\alpha_1 \cdot s_k|$. The base case is when $|\alpha_1 \cdot s_k| = L$. In this case, α_2 is empty and s_k is the last concurrency class; Lemma 3.4 can be applied to derive the lemma. (In fact, part (1) is trivial.)

For the induction step, assume the lemma holds when $|\alpha_1 \cdot s_k| \geq \ell+1$. We prove the lemma for $|\alpha_1 \cdot s_k| = \ell$. Write α_2 as a sequence of concurrency classes, $s_{k+1}, \ldots, s_{k+m}$. By the induction hypothesis, Lemma 3.8 can be applied to $\alpha_1 \cdot s_k, \ldots, s_{k+j}$, for every j, $1 \leq j \leq m$, since it has $\ell + 1$ or more steps.

To prove part (1), apply Lemma 3.8 with prefix $\alpha_1 \cdot s_k, s_{k+1}$ and move all singleton concurrency classes with p_i to the end; we get an IS execution $\alpha' = \alpha_1 \cdot s_k, s_{k+1} \cdot \{p_{i_1}\}^* \cdots \{p_{i_n}\}^* \cdot \{p_i\}^*$ such that $\alpha \approx_{\alpha_1 \cdot s_k, s_{k+1}} \alpha'$. Since p_i is last seen in s_k, Lemma 3.4(1) can be applied to obtain the desired execution.

To prove part (2), apply Lemma 3.8 with prefix $\alpha_1 \cdot s_k$ and move all singleton concurrency classes with p_i to the end; we get an IS execution $\alpha' = \alpha_1 \cdot s_k \cdot \{p_{i_1}\}^* \cdots \{p_{i_n}\}^* \cdot \{p_i\}^*$ such that $\alpha \approx_{\alpha_1 \cdot s_k} \alpha'$. Since p_i is last seen in s_k, Lemma 3.4 (2) can be applied to obtain the desired execution. □

We can now state and prove the main result of this section.

THEOREM 3.9. *If α and α' are IS executions of the same protocol with a common prefix γ and the same inputs, then $\alpha \approx_\gamma \alpha'$.*

Proof. Denote $\alpha = \gamma\alpha_2$ and $\alpha' = \gamma\alpha_2'$. Apply Lemma 3.8 to α_2 to obtain an IS execution with only singleton sets in which the processes appear in increasing order of indices $\{p_0\}^* \cdot \{p_1\}^*, \ldots, \{p_n\}^*$. Similarly, apply Lemma 3.8 to α_2' to obtain an IS execution with singleton sets in which the processes appear in the same order of indices. That is,

$$\gamma\alpha_2 \approx_\gamma \gamma\{p_0\}^* \cdot \{p_1\}^*, \ldots, \{p_n\}^* \quad \text{and} \quad \gamma\alpha_2' \approx_\gamma \gamma\{p_0\}^* \cdot \{p_1\}^*, \ldots, \{p_n\}^*.$$

By the uniqueness condition of Lemma 3.8, these IS executions are equal, and hence $\alpha \approx_\gamma \alpha'$. □

The theorem is proved completely within the domain of distributed computing. We believe that the proof technique is interesting in itself; it resembles lower bounds on the number of rounds necessary for solving consensus [14] or k-set consensus [12] in the synchronous model. This theorem directly implies that there is no wait-free protocol solving consensus.

4. Modeling tasks and protocols using topological structures. In this section we model distributed tasks using combinatorial topology; this is an adaptation of [22, 23] to our framework.

[1] The existence of L for a wait-free protocol follows from Konig's lemma. Consider the tree of executions of the protocol: the root is the initial configuration, and the children of a configuration are the configurations obtained after executing a concurrency class; the leaves are configurations with only minimal final views. Every node in the tree has finite degree, and there is no infinite path. Therefore the tree is finite.

4.1. Combinatorial topology preliminaries. We start with the basic topological concepts used in this paper. Previous papers in this area, e.g., [12, 19, 22, 23, 25], used geometric or algebraic interpretations of topological structures; in contrast, our approach is purely combinatorial, abstracting ideas from [17, 24, 26].

4.1.1. Basic notions. The basis of our definitions is the notion of a complex. A *complex* K is a collection of finite nonempty sets closed under containment; that is, if σ is an element of K, then every nonempty subset of σ is an element of K. A nonempty subset of σ is a *face* of σ. A face of σ is *proper* if it is not equal to σ. An element of a complex is called a *simplex*. A complex K' is a *subcomplex* of a complex K if $K' \subseteq K$.

The *dimension* of a simplex σ, $dim(\sigma)$, is the number of its elements minus one. A simplex of dimension m (with $m+1$ elements) is called an m-simplex. The *dimension* of a complex K is the maximum dimension of its simplexes; we consider only complexes of finite dimension. A complex of dimension m is called an m-complex. A superscript notation is often used to denote the dimension of simplexes and complexes: σ^m is an m-simplex and K^m is an m-complex.

The *vertex set* of K is the union of its 0-simplexes; the 0-simplex $\{v\}$ is identified with v.

Consider two complexes K and L. A function f from the vertices of K to the vertices of L is *simplicial* if, for every simplex $\{v_0, \ldots, v_k\}$ of K, $\{f(v_0), \ldots, f(v_k)\}$ is a simplex of L; $\{f(v_0), \ldots, f(v_k)\}$ is treated as a set, since f need not be one-to-one and may have repetitions. A simplicial map f can be extended to all simplexes of K: f maps every simplex σ of K to a simplex $f(\sigma)$ of L (perhaps of smaller dimension). We extend f to a set S of simplexes of K, by defining $f(S)$ to be the set of simplexes $f(\sigma)$ in L, where σ ranges over all simplexes of S. Clearly, if S is a subcomplex of K, then $f(S)$ is a subcomplex of L.

4.1.2. Divided images. An m-complex K^m is *full to dimension* i, $i \leq m$, if every j-simplex, $j \leq i$, of K^m is contained in some i-simplex of K^m.

Assume K^m is full to dimension m. An $(m-1)$-simplex of K^m is *external* if it is contained in exactly one m-simplex; otherwise, it is *internal*. The *boundary complex* of K^m, *bound*(K^m), is the subcomplex with all the faces of the external simplexes of K^m; clearly, *bound*(K^m) is full to dimension $m-1$. Abusing notation, *bound*(σ^m) denotes the $(m-1)$-faces of a simplex σ^m.

A complex K^m is an *m-pseudomanifold* if it is full to dimension m and every $(m-1)$-simplex is contained in either one or two m-simplexes.[2] An *m-manifold* is an m-pseudomanifold in which every $(m-1)$-simplex is contained in two m-simplexes; i.e., it has no external simplexes. For example, if K^3 is the complex containing a single 3-simplex σ^3 and all its faces, then *bound*(K^3) is a 2-manifold which looks like a hollow tetrahedron.

Let τ^{m-1} be an internal $(m-1)$-simplex of an m-pseudomanifold, which is contained in two m-simplexes, τ_1^m and τ_2^m. The *link* vertices of τ^{m-1} are v_1, the vertex of τ_1^m not in τ^{m-1}, and v_2, the vertex of τ_2^m not in τ^{m-2}.

The following combinatorial definition is used later (section 5.1) to cast the structure of a protocol in the topological framework. Very roughly, L^m will represent the possible input configurations, K^m the possible executions of a protocol, and $\psi(\sigma) \subseteq K^m$ will be the executions starting with input configuration σ.

[2] In topology, pseudomanifolds are assumed to have additional properties, which we do not require for our applications.

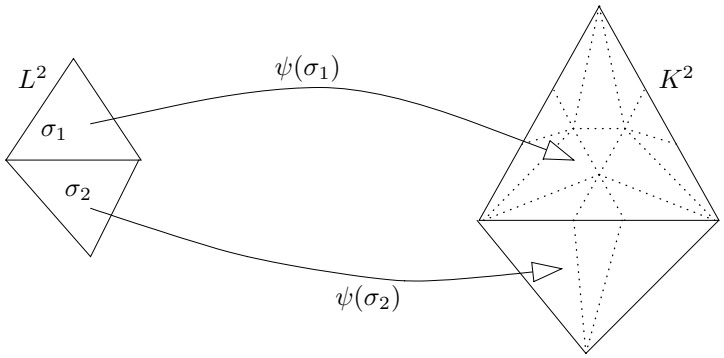

FIG. 2. *K^2 is a divided image of L^2 under ψ.*

DEFINITION 4.1. *Let L^m, K^m be complexes and ψ a function that assigns to each simplex of L^m a finite subcomplex of K^m. The complex K^m is a* divided image of L^m under ψ *if*

1. $\psi(\emptyset) = \emptyset$,
2. *for every $\tau \in K^m$ there is a simplex $\sigma \in L^m$ such that $\tau \in \psi(\sigma)$,*
3. *for every $\sigma^0 \in L^m$, $\psi(\sigma^0)$ is a single vertex,*
4. *for every $\sigma, \sigma' \in L^m$, $\psi(\sigma \cap \sigma') = \psi(\sigma) \cap \psi(\sigma')$, and*
5. *for every $\sigma \in L^m$, $\psi(\sigma)$ is a $dim(\sigma)$-pseudomanifold with $\psi(bound(\sigma)) = bound(\psi(\sigma))$.*

K^m is a divided image of L^m *if for some ψ, K^m is a divided image of L^m under ψ.*

Notice that in condition 5, $bound(\sigma)$ is a set of simplexes, while $\psi(bound(\sigma))$ is the complex which is the union of $\psi(\tau)$, over the simplexes $\tau \in bound(\sigma)$.

Intuitively, a divided image is obtained from L^m by replacing every simplex of L^m with a pseudomanifold, making sure that they "fit together" (in the sense of condition 4). In addition, condition 2 guarantees that ψ maps L^m "onto" K^m; condition 3 guarantees that ψ maps vertices of L^m to vertices of K^m; finally, condition 5 guarantees that ψ preserves the dimension and the boundary of simplexes in L^m.

Figure 2 shows a divided image of a complex containing two simplexes. In the figure, solid lines show the boundaries of σ_1 and of σ_2, and their image in K^2 under ψ.

Remark. The concept of a divided image is reminiscent of the notion of *acyclic carrier*[3] used by Munkres to study *subdivisions*, a fundamental concept of algebraic topology (cf. [24, 26]), as both associate subcomplexes of one complex to simplexes of another. However, divided images, even if they are connected, are different from subdivisions: For example, a 2-dimensional torus with a triangle removed from its surface is a divided image of a 2-simplex, since its boundary is a 1-dimensional triangle; yet, it is neither an acyclic carrier nor a subdivided simplex since it has "holes" (nontrivial homology groups).

Let $M(\sigma^m)$ be the complex consisting of a set σ^m with $m+1$ elements and all its proper subsets; $M(\sigma^m)$ is an m-pseudomanifold consisting of a single m-simplex and all its faces.

The next lemma states some simple properties of divided images.

LEMMA 4.2. *Let K^m be a divided image of L^m under ψ.*

(1) *For every σ, $\sigma' \in L^m$, if $\sigma' \subseteq \sigma$, then $\psi(\sigma') \subseteq \psi(\sigma)$.*

[3]Not to be confused with the notion of *carrier* defined later.

(2) *For every pair of j-simplexes $\sigma_1^j, \sigma_2^j \in L^m$, if $\sigma_1^j \neq \sigma_2^j$, and $\sigma_1^j \cap \sigma_2^j \neq \emptyset$, then $\psi(\sigma_1^j) \cap \psi(\sigma_2^j)$ is a pseudomanifold of dimension strictly smaller than j, i.e., dimension $|\sigma_1^j \cap \sigma_2^j| - 1$.*

(3) *For every i-simplex $\sigma^i \in L^m$, $\psi(\sigma^i)$ is a divided image of $M(\sigma^i)$ under $\psi|M(\sigma^i)$.*

(4) *A simplex $\tau^{m-1} \in K^m$ is external if and only if for some external simplex $\sigma^{m-1} \in L^m$, $\tau^{m-1} \in \psi(\sigma^{m-1})$.*

Proof. (1) By Definition 4.1(4) if $\sigma' \subseteq \sigma$, then $\psi(\sigma') = \psi(\sigma \cap \sigma') = \psi(\sigma) \cap \psi(\sigma') \subseteq \psi(\sigma)$.

(2) Let $\sigma^i = \sigma_1^j \cap \sigma_2^j$. Since $\sigma_1^j \neq \sigma_2^j$, and $\sigma_1^j \cap \sigma_2^j \neq \emptyset$, then $0 \leq i < j$. By Definition 4.1(4), $\psi(\sigma^i) = \psi(\sigma_1^j) \cap \psi(\sigma_2^j)$. By Definition 4.1(5), $\psi(\sigma^i)$ is an i-pseudomanifold.

(3) It follows from (1) that $\psi(\sigma^i) = K^i$ is a divided image of an i-simplex.

(4) A simplex $\tau^{m-1} \in K^m$ is external if and only if there is a unique τ^m containing τ^{m-1}. By Definition 4.1(2), for some σ^j, $\tau^m \in \psi(\sigma^j)$. By Definition 4.1(5) $j \geq m$. Since L^m is an m-complex, and $\sigma^j \in L^m$, $j = m$. So $\tau^{m-1} \in \mathit{bound}(\psi(\sigma^m))$. By Definition 4.1(5), this happens if and only if $\tau^{m-1} \in \psi(\mathit{bound}(\sigma^m))$, i.e., $\tau^{m-1} \in \psi(\sigma^{m-1})$, for some σ^{m-1}.

To prove that σ^{m-1} is external, assume, by way of contradiction, that there is another m-simplex, $\sigma_1^m \neq \sigma^m$, such that $\sigma^{m-1} \subseteq \sigma_1^m$. It follows from (1) that $\tau^{m-1} \in \psi(\sigma^m) \cap \psi(\sigma_1^m)$. Since $\tau^m \in \psi(\sigma^m)$, it cannot be that $\tau^m \in \psi(\sigma_1^m)$ because otherwise $\tau^m \in \psi(\sigma^m \cap \sigma_1^m)$, contradicting (2). However, since τ^{m-1} is contained in some m-simplex of $\psi(\sigma_1^m)$, it must be that such a simplex τ_1^m is different from τ^m, a contradiction to the fact that τ^{m-1} is external.

To prove the other direction, assume for some external simplex $\sigma^{m-1} \in L^m$, $\tau^{m-1} \in \psi(\sigma^{m-1})$. Thus, $\tau^{m-1} \in \psi(\mathit{bound}(\sigma_1^m))$ for some σ_1^m containing σ^{m-1}. By Definition 4.1(5) $\tau^{m-1} \in \mathit{bound}(\psi(\sigma_1^m))$, so τ^{m-1} is contained in a unique τ_1^m of $\psi(\sigma_1^m)$. If $\tau^{m-1} \in K^m$ is not external there is another simplex τ_2^m containing τ^{m-1}. As argued above, there is another simplex, σ_2^m, with $\tau_2^m \in \psi(\sigma_2^m)$. Since $\tau^{m-1} \in \tau_1^m \cap \tau_2^m$, $\tau^{m-1} \in \psi(\sigma_1^m) \cap \psi(\sigma_2^m)$, and by Definition 4.1(4) we have that $\tau^{m-1} \in \psi(\sigma_1^m \cap \sigma_2^m)$. Definition 4.1(5) implies that $\sigma_1^m \cap \sigma_2^m$ is an $(m-1)$-simplex, which is equal to σ^{m-1}, by Definition 4.1(4), a contradiction to the fact that σ^{m-1} is external. □

Of particular importance for us is the case where K^m is a divided image of $M(\sigma^m)$ under ψ. In this case, for any $\sigma \in M(\sigma^m)$, $\sigma \subseteq \sigma^m$, and by Lemma 4.2(1), $\psi(\sigma) \subseteq \psi(\sigma^m)$. Thus, $\cup_{\sigma \in M(\sigma^m)} \psi(\sigma) = \psi(\sigma^m)$. On the other hand, by condition (2), $\cup_{\sigma \in M(\sigma^m)} \psi(\sigma) = K^m$, which proves the next lemma.

LEMMA 4.3. $\psi(\sigma^m) = K^m$.

The *carrier* of a simplex $\tau \in K^m$, denoted $\mathit{carr}(\tau)$, is the simplex $\sigma \in L^m$ of smallest dimension such that $\tau \in \psi(\sigma)$, that is, the "smallest" simplex in L^m which is mapped to τ. By Definition 4.1(2), every simplex $\tau \in K^m$ is in $\psi(\sigma)$, for some $\sigma \in L^m$, and by Lemma 4.2(2) it is unique. For example, in Figure 2, the carrier of τ_1 is σ_1, while the carrier of τ_2 is σ_2.

4.1.3. Connectivity. For any j, $1 \leq j \leq m$, the *j-graph of K^m* consists of one vertex for every j-simplex of K^m, and there is an edge between two vertices if the intersection of the two corresponding simplexes is a $(j-1)$-simplex of K^m. K^m is *j-connected* if its j-graph is connected. A *j-path* in K^m is a sequence of j-simplexes such that every two consecutive simplexes share a $(j-1)$-face. Thus a j-path corresponds to a path in the j-graph.

Divided images need not be connected. For example, consider K^2 from Figure 2, take some disjoint 3-simplex σ^3, and let $K'^2 = K^2 \cup \mathit{bound}(\sigma^3)$. Then K'^2 is a divided image of L^2 under ψ', where $\psi'(\sigma_1) = \psi(\sigma_1)$, $\psi'(\sigma_2) = \psi(\sigma_2) \cup \mathit{bound}(\sigma^3)$. In Appendix A, we prove that any divided image contains a connected divided image; moreover, we later show that the specific divided images constructed in this paper are connected.

4.1.4. Colorings. A complex K is *colored* by associating a value from some set, called *colors*, with each of its vertices. A coloring is *proper* if different vertices in the same simplex have different colors. A simplicial map $f : K \to L$ is *color preserving* if, for every vertex v of K, $f(v)$ has the same color as v. If a coloring is proper and f is color preserving, then for any simplex $\{v_0, \ldots, v_k\}$ the vertices $f(v_0), \ldots, f(v_k)$ are different; i.e., $f(\sigma)$ has the same dimension as σ.

Let K^m be a divided image of L^m. A simplicial map $\chi : K^m \to L^m$ is a *Sperner coloring* if, for every $v \in K^m$, $\chi(v) \in \mathit{carr}(v)$. Intuitively, the "colors" are the vertices of L^m, and χ "folds" K^m into L^m with the requirement that each vertex of K^m goes to a vertex of its carrier. This notion generalizes the usual Sperner coloring, where L^m is an m-simplex with all its faces, and the vertices are the colors $\{0, 1, \ldots, m\}$. That is, the vertices at the "corners" of K^m are colored $0, 1, \ldots, m$, and a vertex in a boundary is colored with one of the colors of the "corners" of that boundary. The main combinatorial definition we use is the following.

Definition 4.4. *A complex K^m is a* chromatic divided image *of L^m if it is a divided image of L^m with a proper Sperner coloring χ.*

4.2. Modeling tasks. Here we cast the notion of task (introduced in section 2) in terms of combinatorial topology. Denote $\mathit{ids} = \{0, \ldots, n\}$. For some domain of values V, let $P(V)$ be the set of all pairs consisting of an id from ids and a value from V.

For a domain of inputs $\mathcal{I}$, an *input complex*, $\mathcal{I}^n$, is a complex that includes n-simplexes (i.e., subsets of $n+1$ elements) of $P(\mathcal{I})$ and all their faces such that the vertices in an n-simplex have different id fields. For a domain of outputs $\mathcal{O}$, an *output complex*, $\mathcal{O}^n$, is defined similarly over $\mathcal{O}$. That is, if (i, val) is a vertex of $\mathcal{I}^n$, then val denotes an input for process p_i, while if (i, val) is a vertex of $\mathcal{O}^n$, then val is an output for process p_i. $\mathcal{I}^n$ and $\mathcal{O}^n$ are properly colored by the id fields and are full to dimension n; each complex is also colored (not necessarily properly) by the corresponding domain of values.

Using the combinatorial topology notions, a *task* is a triple $\langle \mathcal{I}^n, \mathcal{O}^n, \Delta \rangle$; $\mathcal{I}^n$ is an input complex, $\mathcal{O}^n$ is an output complex, and Δ maps each n-simplex of $\mathcal{I}^n$ to a nonempty set of n-simplexes in $\mathcal{O}^n$. We sometimes mention only Δ when $\mathcal{I}^n$ and $\mathcal{O}^n$ are clear from the context. The simplexes in $\Delta(\sigma^n)$ are the *admissible* output simplexes for σ^n: If σ^n is an input simplex and $\tau^n \in \Delta(\sigma^n)$, then τ^n can be output when the system starts with input σ^n.

Δ can be extended to input simplexes of dimension smaller than n, since the outputs of some processes in an execution can be completed to outputs for all processes that are admissible for the inputs of the execution. Therefore, Δ maps an input simplex σ of dimension smaller than n to the faces of n-simplexes in $\Delta(\sigma^n)$ with the same dimension and ids for all input simplexes σ^n that contain σ. Extended in this manner, $\Delta(M(\sigma^n))$ is a subcomplex of $\mathcal{O}^n$.

Remark. There is another variant of wait-free solvability, where Δ is explicitly defined for input simplexes of dimension smaller than n. This can be captured in our

model by adding as part of the input a bit that tells the process whether to participate or not; nonparticipating processes output some default value.

4.3. Protocol complexes. For an execution α, the set $\{(0, \alpha|0), \ldots, (n, \alpha|n)\}$ is denoted by $views(\alpha)$. The *protocol complex* $\mathcal{P}^n$ of a protocol $\mathcal{P}$ is the complex whose n-simplexes are the sets of minimal final $views(\alpha)$, for every execution α of $\mathcal{P}$, and all their faces. $\mathcal{P}^n$ is colored with four colors—an id, an input, a view, and an output value; the ids coloring is proper. $\mathcal{P}^n$ depends on the possible interleavings of events (schedules) and on the transitions of processes and their local states.

Given an input n-simplex σ, the *protocol complex for* σ, $\mathcal{P}^n(\sigma)$, is the subcomplex of $\mathcal{P}^n$ containing all n-simplexes corresponding to executions of $\mathcal{P}$, where processes start with inputs σ, and all their faces. Intuitively, $\tau \in \mathcal{P}^n(\sigma)$ if and only if there is an execution α with inputs σ such that the views of processes in τ are the same as in α. It is possible that two executions, α and α', satisfy the above condition for a simplex of dimension n, but, in this case, α and α' are indistinguishable to all processes. If τ is a face of two n-simplexes, σ_1 and σ_2, corresponding to executions α_1 and α_2, and τ contains a vertex with id p_i, then $\alpha_1 \overset{p_i}{\sim} \alpha_2$.

Since $\mathcal{P}$ is deterministic and wait-free, every process writes an output after a finite number of steps, implying that $\mathcal{P}^n(\sigma)$ is finite.

$\mathcal{P}$ implies a *decision map* $\delta_{\mathcal{P}} : \mathcal{P}^n \to \mathcal{O}^n$ specifying the output for each final view of a process. If $\mathcal{P}$ solves Δ, then $\delta_{\mathcal{P}}$ is simplicial, since $\delta_{\mathcal{P}}(\tau)$ is an output simplex, for every $\tau \in \mathcal{P}^n$. Clearly, $\delta_{\mathcal{P}}$ preserves the ids coloring and, for every input n-simplex σ, $\delta_{\mathcal{P}}(\mathcal{P}^n(\sigma))$ is a complex.

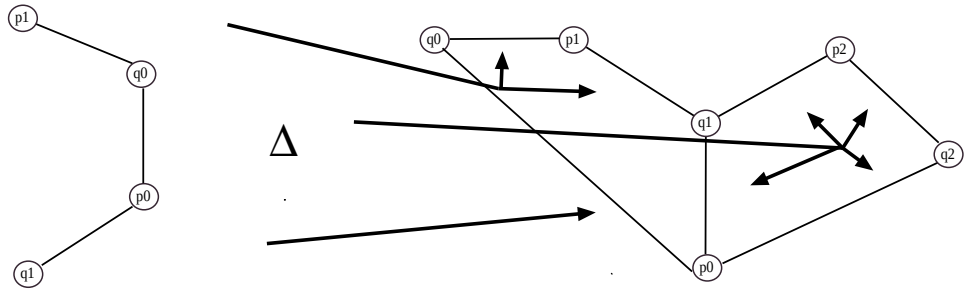
Figure 3 presents an example of a task for two processes, p and q. A vertex of the input (output) complex contains an id and an input (output) value. A task is defined by stating Δ: for input $\{(p,1),(q,0)\}$ the output can be $\{(p,1),(q,0)\}$ or $\{(p,1),(q,1)\}$; for input $\{(p,0),(q,1)\}$ the output can be $\{(p,0),(q,0)\}$; for input $\{(p,0),(q,0)\}$ the output can be $\{(p,0),(q,1)\}$, $\{(p,2),(q,1)\}$, $\{(p,2),(q,2)\}$, $\{(p,0),(q,2)\}$, or $\{(p,0),(q,1)\}$. The figure also includes a protocol complex (with all executions, not only IS executions) that solves the task. Here a vertex is labeled with an id, then an input, and then the output. For input $\{(p,1),(q,0)\}$, each process executes one read (of all the registers) and one write operation. For input $\{(p,0),(q,0)\}$, p executes one write, then one read, and then one write, while q executes one write and one read. For input $\{(p,0),(q,1)\}$, p executes one write, then one read, and then one write, while q does not execute any operation. There are various ways of assigning outputs to the processes so that the protocol solves the task.

The above definitions imply the following topological interpretation of the operational definition of a protocol solving a task (presented at the end of section 2).

PROPOSITION 4.5. *$\mathcal{P}$ solves $\langle \mathcal{I}^n, \mathcal{O}^n, \Delta \rangle$ if and only if $\delta_{\mathcal{P}}(\mathcal{P}^n(\sigma)) \subseteq \Delta(M(\sigma))$ for every n-simplex $\sigma \in \mathcal{I}^n$. In this case, we say that $\delta_{\mathcal{P}}$* agrees *with Δ.*

Since the protocol depends only on the inputs (see section 2), if two input n-simplexes σ and σ' have the same inputs, i.e., differ only by a permutation of the ids, then $\mathcal{P}^n(\sigma)$ can be obtained from $\mathcal{P}^n(\sigma')$ by applying the same permutation to the ids. Therefore, the decision map must be *anonymous*; i.e., $\delta_{\mathcal{P}}(\mathcal{P}^n(\sigma))$ determines $\delta_{\mathcal{P}}(\mathcal{P}^n(\sigma'))$.

5. A condition for wait-free solvability. We prove that the subcomplex induced by IS executions is a chromatic divided image of the input complex; moreover, this subcomplex is shown to be connected and orientable. This implies our main result, a necessary condition for tasks which are solvable by a wait-free protocol (The-



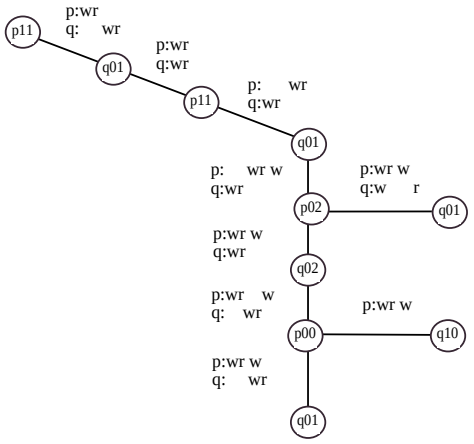


FIG. 3. *A protocol complex and a task for two processes, p and q.*

orem 5.14). In section 7, we present two impossibility results which are implied by this condition; the set consensus impossibility result follows from the divided image property only, while the renaming impossibility also relies on orientability.

5.1. The ISE complex and divided images. The *IS executions* (ISE) complex, $\mathcal{E}^n$, is the subcomplex of the protocol complex containing all IS executions; $\mathcal{E}^n(\sigma^n)$ is the subcomplex of all IS executions starting with an input simplex $\sigma^n \in \mathcal{I}^n$.

Figure 4 contains an example of an ISE complex for a single input simplex (the one on the left); each 2-simplex corresponds to an execution where each process is active in exactly one round. There are simplexes that correspond to executions α_1 and α_2 from Figure 1; indeed, the vertices that correspond to p_1 and p_2 are the same in these simplexes; i.e., p_1 and p_2 have the same views. The 1-simplexes on the boundary correspond to executions in which two processes take one step each and do not see the

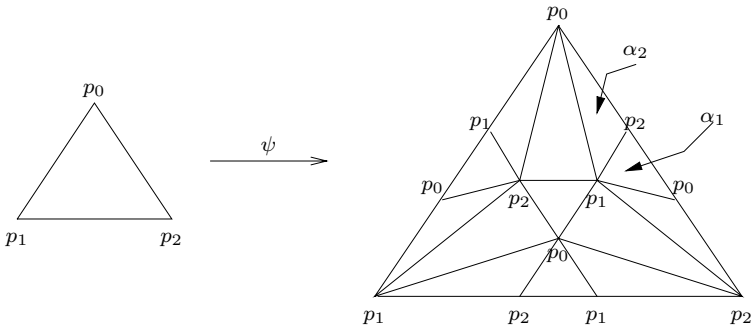

FIG. 4. *The ISE complex, when each process takes at most one step.*

third process; corner vertices correspond to "solo" executions where a process does not see other processes. The 2-simplex in the center corresponds to the IS execution consisting of one round, in which all three processes are active.

The protocol complex shown in Figure 3, including all executions, is not a divided image of the input complex, since the subcomplex for the input simplex $\{(p,0),(q,0)\}$ is not a pseudomanifold. We now show that the ISE complex of a wait-free protocol, using only read/write operations, is a chromatic divided image of the input complex; we start with some definitions.

For a simplex σ of $\mathcal{I}^n$, $\mathcal{O}^n$, or $\mathcal{E}^n$, $ids(\sigma)$ is the set of ids appearing as the first component of vertices in σ. For a simplex σ of $\mathcal{I}^n$, $inputs(\sigma)$ is σ. For a simplex σ of $\mathcal{E}^n$, $inputs(\sigma)$ is the set of pairs of ids with inputs appearing in vertices of σ (taking the input component from the state). For a simplex σ of $\mathcal{E}^n$, $views(\sigma)$ is the set of views appearing in vertices of σ and $observed(\sigma)$ is the set of ids of processes whose operations appear in $views(\sigma)$. If p_i is not in $observed(\sigma)$, then the views in σ are the same as in an execution in which p_i does not take a step; since a process always "observes itself," $ids(\sigma) \subseteq observed(\sigma)$.

We define a function ψ that assigns a subcomplex of $\mathcal{E}^n$ to each input simplex $\sigma \in \mathcal{I}^n$; intuitively, $\psi(\sigma)$ contains all the executions with input σ, in which only processes in $ids(\sigma)$ are observed taking steps.

DEFINITION 5.1. *For $\sigma \in \mathcal{I}^n$, let $\psi(\sigma)$ be the complex containing all simplexes $\tau \in \mathcal{E}^n$, such that $inputs(\tau) = inputs(\sigma)$ and $observed(\tau) = ids(\sigma)$, and all their faces.*

Clearly, $\psi(\sigma)$ is full to dimension $dim(\sigma)$. The next lemma is useful below.

LEMMA 5.2. *For any $\tau \in \mathcal{E}^n$ and $\sigma \in \mathcal{I}^n$, $\tau \in \psi(\sigma)$ if and only if $inputs(\tau) \subseteq inputs(\sigma)$ and $observed(\tau) \subseteq ids(\sigma)$.*

Proof. Assume τ is in $\psi(\sigma)$. If τ is of the same dimension as σ, then the claim is immediate from the definition. So assume τ is a face of τ' which is of the same dimension as σ. Thus, $inputs(\tau) \subseteq inputs(\tau')$ and $observed(\tau) \subseteq observed(\tau')$; the definition of ψ implies that $inputs(\tau) \subseteq inputs(\sigma)$ and $observed(\tau) \subseteq ids(\sigma)$.

To prove the converse direction, assume $inputs(\tau) \subseteq inputs(\sigma)$ and $observed(\tau) \subseteq ids(\sigma)$. Since the protocol is wait-free, the processes in $ids(\sigma) - ids(\tau)$ (if there are any) should be able to run on their own, after all processes in $ids(\tau)$ have obtained the views in τ, and decide. This implies that there is an execution in which all processes in $ids(\sigma) - ids(\tau)$ (if any) observe only processes in $ids(\sigma)$, and processes in $ids(\tau)$ have the same views as in τ. Let π be the simplex in $\mathcal{E}^n$ that corresponds to this execution. Note that $inputs(\pi) = inputs(\sigma)$ and $observed(\pi) = ids(\sigma)$. Therefore, $\pi \in \psi(\sigma)$. Since τ is a face of π, the claim follows. ∎

We proceed to prove that Definition 4.4 holds, and hence that the conditions of Definition 4.1 hold. Clearly, process ids are a proper Sperner coloring of $\mathcal{E}^n$. Condition 1 is trivial.

LEMMA 5.3. *Condition* 2 *of Definition* 4.1 *holds.*

Proof. Consider a simplex $\tau \in \mathcal{E}^n$. Let $\tau^n \in \mathcal{E}^n$ be such that $\tau \subseteq \tau^n$. Then there is a simplex $\sigma^n \in \mathcal{I}^n$ with $inputs(\tau^n) = inputs(\sigma^n)$. Since $ids(\tau^n) \subseteq observed(\tau^n)$, then $observed(\tau^n) = ids(\sigma^n)$ and $\tau^n \in \psi(\sigma^n)$. Since τ is a face of τ^n, $\tau \in \psi(\sigma^n)$. ∎

Since the protocol is deterministic, we have the next lemma.

LEMMA 5.4. *Condition* 3 *of Definition* 4.1 *holds.*

By Lemma 5.2, $\tau \in \psi(\sigma \cap \sigma')$ if and only if $inputs(\tau) \subseteq inputs(\sigma \cap \sigma') = inputs(\sigma) \cap inputs(\sigma')$ and $observed(\tau) \subseteq ids(\sigma \cap \sigma') = ids(\sigma) \cap ids(\sigma')$. This happens if and only if $\tau \in \psi(\sigma) \cap \psi(\sigma')$, implying the next lemma.

LEMMA 5.5. *Condition* 4 *of Definition* 4.1 *holds.*

By Lemma 3.3, if a process p_j is unseen in an execution, then there is no other execution that differs only in p_j's view. By Lemma 3.4, if p_i is seen in an execution, then there is another execution that differs only in p_j's view. This implies the next lemma.

LEMMA 5.6. *Let τ_1^i be an i-simplex of $\psi(\sigma^i)$ corresponding to an IS execution α, and $j \in ids(\tau_1^i)$. Process p_j is unseen in α by processes with $ids(\sigma^i)$, if and only if there is no other i-simplex $\tau_2^i \in \psi(\sigma^i)$, that differs only in the vertex colored with p_j.*

Since the boundary corresponds to executions in which some processes are unseen, the above lemma can be used to prove that ψ preserves the boundary.

LEMMA 5.7. *For every simplex $\sigma^i \in \mathcal{I}^n$, $\psi(bound(\sigma^i)) = bound(\psi(\sigma^i))$.*

Proof. To prove that $\psi(bound(\sigma^i)) \subseteq bound(\psi(\sigma^i))$, consider $\tau \in \psi(bound(\sigma^i))$. Then $\tau \in \psi(\sigma^{i-1})$ for some face σ^{i-1} of σ^i. Since $\psi(\sigma^{i-1})$ is full to dimension $i-1$, there is some $\tau^{i-1} \in \psi(\sigma^{i-1})$ such that $\tau \subseteq \tau^{i-1}$. By the definition of ψ, $\tau^{i-1} \in \psi(\sigma^i)$. Since $\psi(\sigma^i)$ is full to dimension i, there is some $\tau^i \in \psi(\sigma^i)$ such that $\tau^{i-1} \subset \tau^i$. Since $\tau^{i-1} \in \psi(\sigma^{i-1})$, it follows that $observed(\tau^{i-1}) = ids(\sigma^{i-1})$. Let p_j be the process id in $ids(\sigma^i) - ids(\sigma^{i-1})$. Note that $j \notin observed(\tau^{i-1})$; that is, no process sees a step by p_j in τ^{i-1}. Furthermore, in τ^i, p_j sees only steps by processes in $ids(\sigma^i)$. Since the protocol is deterministic, there is only one possible view for p_j. Namely, τ^{i-1} is contained in a single i-simplex τ^i, and hence $\tau^{i-1} \in bound(\psi(\sigma^i))$. Since τ is a face of τ^{i-1} and ψ is closed under inclusion, $\tau \in bound(\psi(\sigma^i))$.

To prove that $\psi(bound(\sigma^i)) \supseteq bound(\psi(\sigma^i))$, consider some $\tau \in bound(\psi(\sigma^i))$. Since $bound(\psi(\sigma^i))$ is full to dimension $i-1$, τ is a face of some $\tau^{i-1} \in bound(\psi(\sigma^i))$. Since τ^{i-1} is external in $\psi(\sigma^i)$, it is a face of a single $\tau^i \in \psi(\sigma^i)$. Assume that $ids(\tau^i) - ids(\tau^{i-1}) = \{p_j\}$; then, by Lemma 5.6, p_j is unseen in the execution corresponding to τ^i, and $p_j \notin observed(\tau^{i-1})$. Let σ^{i-1} be the face of σ^i that does not include the vertex whose id is p_j; clearly, $observed(\tau^{i-1}) = ids(\sigma^{i-1})$. By the definition of ψ, $\tau^{i-1} \in \psi(\sigma^{i-1})$; thus, $\tau^{i-1} \in \psi(bound(\sigma^i))$, implying that $\tau \in \psi(bound(\sigma^i))$. ∎

We have shown in Lemma 3.4 that the uncertainty about another process is restricted to its last seen round, if it is seen. Thus, once we fix the views of all processes but one, the remaining process may have only one of two views, which translates into the next lemma.

LEMMA 5.8. *Let τ_1^i be an i-simplex of $\psi(\sigma)$, corresponding to an IS execution α, such that $ids(\sigma) = ids(\tau_1^i)$ and $j \in ids(\tau_1^i)$. If p_j is seen in α, then there is exactly one other i-simplex $\tau_2^i \in \psi(\sigma)$ that differs only in p_j's view.*

Lemma 5.7 implies that if p_j is seen in an IS execution α, then α corresponds to an internal simplex. We now prove that an internal $(i-1)$-simplex is contained in

exactly two i-simplexes, showing that the ISE complex is a pseudomanifold.

LEMMA 5.9. *For every simplex $\sigma^i \in \mathcal{I}^n$, $\psi(\sigma^i)$ is an i-pseudomanifold.*

Proof. As noted before, $\psi(\sigma^i)$ is full to dimension i. We show that any simplex $\tau^{i-1} \in \psi(\sigma^i)$ is contained in at most two i-simplexes. Let $\tau^i \in \psi(\sigma^i)$ be such that τ^{i-1} is a face of τ^i. Since τ^{i-1} and τ^i are properly colored by the ids, $ids(\tau^i) - ids(\tau^{i-1}) = \{j\}$ for some process p_j. Furthermore, any i-simplex of $\psi(\sigma^i)$ containing τ^{i-1} has a vertex colored with p_j. Let α be the prefix of an execution with steps by processes in $ids(\sigma^i)$ corresponding to τ^i; this prefix exists since $observed(\tau^i) = ids(\sigma^i)$. There are two cases.

Case 1. p_j is unseen in α. Let σ^{i-1} be the face of σ^i that does not include the vertex whose id is p_j; then $observed(\tau^{i-1}) = ids(\sigma^{i-1})$. Since p_j does not see an id not in $ids(\sigma^i)$, its view is determined. Hence, τ^i is unique.

Case 2. p_j is seen in α. Let k be the last seen round of p_j in α. Lemma 5.8 implies that there are only two possible views for p_j which are compatible with the views in τ^{i-1}. □

Lemmas 5.7 and 5.9 imply condition 5 of Definition 4.1. Therefore, $\mathcal{E}^n$ is a chromatic divided image of $\mathcal{I}^n$ under ψ. If a protocol $\mathcal{P}$ solves a task Δ, then it solves Δ in IS executions. Clearly, $\delta_{\mathcal{P}}$ is a color-preserving (on process ids), anonymous simplicial map from $\mathcal{E}^n$ to $\mathcal{O}^n$ that agrees with Δ. This implies the next theorem.

THEOREM 5.10. *Let $\langle \mathcal{I}^n, \mathcal{O}^n, \Delta \rangle$ be a task. If there is a wait-free protocol which solves this task, then there is a chromatic divided image of $\mathcal{I}^n$, K^n, and there is a color-preserving (on ids), anonymous simplicial map δ from K^n to $\mathcal{O}^n$ that agrees with Δ.*

5.2. Connectivity of the ISE complex. Since the ISE complex is a divided image of the input simplex, it contains a connected divided image of the input simplex (see Appendix A). Translating Theorem 3.9 to combinatorial topology implies the following, stronger property of the ISE complex—it is connected itself.

A divided image of a simplex σ^n under ψ is *well connected* if for every $\sigma^i \in M(\sigma^n)$, if $i \geq 1$, then $\psi(\sigma^i)$ is i-connected, and if $i \geq 2$, then $bound(\psi(\sigma^i))$ is $(i-1)$-connected.

THEOREM 5.11. *Let $\mathcal{E}^n$ be an ISE chromatic divided image of $M(\sigma^n)$ under ψ starting with input σ^n. Then $\mathcal{E}^n$ is well connected.*

The theorem can be extended to show that if $\mathcal{I}^n$ is i-connected, then so is $\psi(\mathcal{I}^n)$. The proof follows from the fact that if σ_1^i and σ_2^i are two simplexes of $\mathcal{I}^n$ with $\sigma^{i-1} = \sigma_1^i \cap \sigma_2^i$, then $\psi(\sigma_1^i) \cap \psi(\sigma_2^i)$ contains an $(i-1)$-simplex, τ^{i-1}, by Lemma 4.2(2). Thus, there is an i-path from any i-simplex in $\psi(\sigma_1^i)$ to any simplex in $\psi(\sigma_2^i)$ going through τ^{i-1}. Transitivity implies the claim for i-simplexes of $\mathcal{I}^n$ connected by an i-path.

5.3. Orientability of the ISE complex. Let K^m be an m-pseudomanifold. An *orientation* of a simplex is an equivalence class of orderings of its vertices, consisting of one particular ordering and all even permutations of it. If the vertices are colored with process ids, then the *positive* orientation is the one in which the vertices are ordered with the ids from small to large, and the *negative* orientation is the one where the two vertices with smallest ids are exchanged (each one with all its even permutations). Let $\sigma^{(i)}$ be the face of σ^m in which the vertex with id i is removed; e.g., $\sigma^{(1)}$ is the face with ids $\{0, 2, \ldots, m\}$. An orientation of an m-simplex σ induces an orientation on each of its faces, $\sigma^{(i)}$, according to the sign of $(-1)^i$. Consider an m-simplex σ and its $(m-1)$-face, $\sigma^{(i)}$. If σ is oriented positive, with its ids in order, $\langle 0, 1, 2, \ldots, m \rangle$, σ induces the orientation $(-1)^i$ to the face $\sigma^{(i)}$. On the other hand, if σ is oriented negative, $\langle 1, 0, 2, \ldots, m \rangle = -\langle 0, 1, 2, \ldots, m \rangle$, and σ induces the

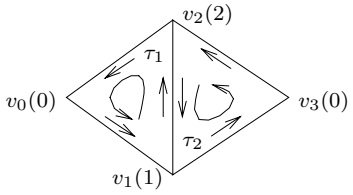

FIG. 5. *An oriented 2-pseudomanifold, with a coloring (in brackets).*

orientation $(-1)(-1)^i$ to the face $\sigma^{(i)}$. For example, in Figure 5, τ_1 is positively oriented $\langle v_0, v_1, v_2\rangle$, and the induced orientations are $\langle v_0, v_1\rangle$, $\langle v_1, v_2\rangle$, and $\langle v_2, v_0\rangle$; τ_2 is negatively oriented $\langle v_2, v_1, v_3\rangle$, and the induced orientations are $\langle v_1, v_3\rangle$, $\langle v_3, v_2\rangle$, and $\langle v_2, v_1\rangle$.

K^m is *orientable* if there is an orientation for each of its m-simplexes such that an $(m-1)$-simplex contained in two m-simplexes gets opposite induced orientations from each of the m-simplexes. K^m together with such an orientation is an *oriented* pseudomanifold. For example, the complex in Figure 5 is an oriented 2-pseudomanifold.

An m-pseudomanifold is *chromatic* if it is properly colored with $m+1$ colors. The next simple lemma (e.g., [5]) shows that, for chromatic pseudomanifolds, the previous (common) definition of orientability is equivalent to a simpler combinatorial definition.

LEMMA 5.12. *A chromatic pseudomanifold K^m is orientable if and only if its m-simplexes can be partitioned into two disjoint classes such that if two m-simplexes share an $(m-1)$-face, then they belong to different classes.*

Proof. Assume K^m is orientable and partition its simplexes into two classes, one containing the simplexes with positive orientations and the other containing the simplexes with negative orientations. Since K^m is orientable, if two m-simplexes τ_1 and τ_2 share an $(m-1)$-face, then the shared face gets opposite induced orientations. Since K^m is chromatic, this implies that τ_1 and τ_2 have opposite orientations, and they are in different classes.

To prove the converse direction, consider the partition of the simplexes of a chromatic pseudomanifold K^m into two disjoint classes; orient the simplexes of the first class in the positive direction and the simplexes of the second class in the negative direction. Consider two m-simplexes σ_1 and σ_2 that share an $(m-1)$-face, $\sigma^{(i)}$. By assumption, σ_1 and σ_2 are in different classes; without loss of generality, σ_1 is oriented positive and σ_2 is oriented negative, Since K^m is chromatic, σ_1 is oriented $\langle 0, 1, 2, \ldots, m\rangle$ and σ_2 is oriented $\langle 1, 0, 2, \ldots, m\rangle = -\langle 0, 1, 2, \ldots, m\rangle$. Hence, σ_1 induces the orientation $(-1)^i$ to the shared face $\sigma^{(i)}$, while σ_2 induces the orientation $(-1)(-1)^i$; that is, they induce opposite orientations. □

A chromatic divided image of $M(\sigma^m)$ under ψ is *orientable* if $\psi(\sigma)$ is orientable for every $\sigma \in M(\sigma^m)$.

THEOREM 5.13. *Let $\mathcal{E}^n$ be an ISE chromatic divided image of $M(\sigma^n)$ under ψ starting with input σ^n. Then $\mathcal{E}^n$ is orientable.*

Proof. Let σ^i be a face of σ^m; we explicitly partition the i-simplexes of $\psi(\sigma^i)$ to two disjoint classes. Consider an i-simplex $\tau \in \psi(\sigma^i)$ and the IS execution α corresponding to τ. For any process p_j that is seen in α, we can write $\alpha = s_1, \ldots, s_r, \{p_j\}^*$, where r is the tail position of p_j in α. The tail $\{p_j\}^*$ is nonempty for at most one seen process p_j. If the tail is not empty for some seen process p_j, then $\hat{r}(\sigma^i)$ is p_j's tail position. Otherwise, then the tail position r is the same for all seen processes

and is equal to the number of concurrency classes in α; in this case, $\hat{r}(\sigma^i) = r$. The simplex τ is in positive if $\hat{r}(\tau)$ is even; otherwise, it is in negative.

Consider two i-simplexes, τ_1^i and τ_2^i, sharing an $(i-1)$-face, τ^{i-1}; the link vertices of τ^{i-1} are colored with the same id, say p_j. By Lemma 5.9 and its proof, without loss of generality, p_j is in the kth concurrency class of τ_1^i and the kth concurrency class of τ_2^i is $\{p_j\}$, where k is the last seen round of p_j in τ_1^i. The views of all processes but p_j are the same in τ_1^i and in τ_2^i; p_j may have a tail with a different number of steps in τ_1^i and τ_2^i, but these are not counted in $\hat{r}(\tau_1^i)$ and $\hat{r}(\tau_2^i)$. Therefore, the number of concurrency classes in τ_1^i without its tail has the opposite parity of the number of concurrency classes in τ_2^i without its tail, and the simplexes are in different classes. □

Putting together Theorems 5.10, 5.11, and 5.13, we have our main result.

THEOREM 5.14 (main characterization). *Let $\langle \mathcal{I}^n, \mathcal{O}^n, \Delta \rangle$ be a task. If there is a wait-free protocol which solves this task, then there is a well connected, orientable, chromatic divided image of $\mathcal{I}^n$, and there is a color-preserving (on ids), anonymous simplicial map δ from it to $\mathcal{O}^n$ that agrees with Δ.*

Herlihy and Rajsbaum [20] introduced algebraic spans as a tool for proving impossibilities of renaming and set consensus using algebraic techniques. In Appendix B, we show that an orientable chromatic divided image induces an algebraic span.

6. Counting simplexes. In this section we present two theorems about the number of certain simplexes in a chromatic divided image. The first is the well-known Sperner's lemma, which will be applied in section 7.1 for the set consensus impossibility. The second is a theorem about the number of monochromatic simplexes in a binary coloring of a connected, orientable chromatic divided image; this theorem is used in section 7.2 to show a lower bound on renaming.

Recall the definition of a Sperner's coloring from section 4.1.4. The following is a restatement of Sperner's lemma in our notation; it holds for both oriented and nonorientable divided images. It will be used to prove the set consensus impossibility in section 7.1, and hence this result does not depend on orientability. It is a well-known result, and the proof is a simple parity counting argument (e.g., [4]).

THEOREM 6.1 (Sperner's lemma). *Consider a divided image K^m of $M(\sigma^m)$ under ψ and a Sperner coloring $\chi : K^m \to M(\sigma^m)$. There is an odd number of simplexes $\tau \in K^m$ with $\chi(\tau) = \sigma^m$; in particular, at least one simplex goes to σ^m.*

We proceed to the second result, which will be applied to prove the renaming impossibility.

Let K^m be an orientable, chromatic divided image of σ^m under ψ, with proper coloring *id*. Assume in addition that K^m has a binary coloring b, with colors $\{0, 1\}$. Fix an orientation of K^m and an induced orientation on its boundary.

Let $\#\text{mono}(K^m)$ be the number of monochromatic m-simplexes of K^m, counted by orientation; i.e., an m-simplex with all its vertices colored by b with the same color is counted as $+1$ if it is positively oriented; otherwise, it is counted as -1. For example, consider a complex K^m with two m-simplexes, as in Figure 5, with all vertices colored 1. In this case, both simplexes are monochromatic; the count is 0, since the simplexes have opposite orientations, and hence one is counted $+1$ and the other is counted -1.

The theorem applies to divided images with structural symmetry; i.e., any pair of divided images of faces (of the same dimension) are isomorphic under a bijection that maps the process ids consistently. Formally, a mapping $f : L^m \to K^m$ is *id consistent* if, for any two vertices $v_1, v_2 \in L^m$, $id(v_1) = id(v_2)$ implies $id(f(v_1)) = id(f(v_2))$. A

divided image of σ under ψ has *structural symmetry* if, for any two i-faces, σ_1^i and σ_2^i, of σ, there is an id consistent simplicial bijection (one-to-one mapping), ζ, between the vertices of $\psi(\sigma_1^i)$ and the vertices of $\psi(\sigma_2^i)$.

A binary coloring, b, of K^m with structural symmetry ζ is *symmetric* if isomorphic vertices have the same color; that is, $b(\zeta(v)) = b(v)$ for every vertex $v \in bound(K^m)$. Implicitly, if K^m has a symmetric binary coloring, then it has structural symmetry. Notice that ζ need not be unique, and a binary coloring is symmetric relative to a particular choice of ζ. It is not trivial to prove that a coloring is symmetric; this is done when the theorem is applied (section 7.2).

The main property used to prove the renaming impossibility has a flavor similar to Sperner's lemma, but it assumes that the divided image is orientable and symmetric. This result was proved implicitly in [20], based on the existence of algebraic spans. Here we state the result in our notation and show that divided images are sufficient to obtain the required algebraic spans. Thus, the proof uses a result of [20] that is stated in algebraic terms.[4] The basic algebraic formalisms needed appear in Appendix B.

THEOREM 6.2. *Assume K^m is a chromatic divided image of σ^m under ψ, with a symmetric binary coloring b. If K^m is connected and oriented, then $\#mono(K^m) \neq 0$.*

Proof. The proof is similar to the proof of Theorem 6.2 in [20]. The coloring of K^m defined by $c(v) = (b(v) + id(v)) \bmod (m+1)$, for every v, induces a symmetric map from K^m to $M(\sigma^m)$, and hence a corresponding symmetric chain map. Theorem B.2 implies that there is a chain map from $M(\sigma^m)$ to K^m. The composition of these chain maps is the required chain map from $M(\sigma^m)$ to $M(\sigma^m)$, and hence the result follows from Lemma 6.1 in [20]. □

7. Applications. In this section, we apply the condition for wait-free solvability presented earlier (Theorem 5.10) to derive lower bounds for k-set consensus and renaming. The renaming lower bound relies on Theorem 6.2 and, therefore, on the fact that the ISE complex is orientable.

7.1. *k*-set consensus. In the *k-set consensus* task [11], processes start with inputs from some domain and have to decide on at most k different outputs; each output has to be the input of some process.

Captured in our combinatorial topology language, the k-set consensus task is the triple $\langle \mathcal{D}^n, \mathcal{D}^n, \Delta \rangle$. $\mathcal{D}^n$ is $P(\mathcal{D})$, for some domain $\mathcal{D}$, and Δ maps each $\sigma^n \in \mathcal{D}^n$ to the subset of n-simplexes in $\mathcal{D}^n$ that contain at most k different values from the values in σ^n. Theorem 5.10 and Sperner's lemma are used to prove the next lower bound, which is tight: If $k > n$, then there is a simple wait-free protocol for k-set consensus [11].

THEOREM 7.1. *If $k \leq n$, then there does not exists a wait-free protocol that solves the k-set consensus task.*

Proof. Assume, by way of contradiction, that $\mathcal{P}$ is a wait-free protocol for the k-set consensus task, $k \leq n$. We show that $\mathcal{P}$ must have at least one execution in which $k+1$ different values are output, which implies that $\mathcal{P}$ does not solve the k-set consensus task correctly. This is done by applying Theorem 6.1 to the ISE complex, which is a chromatic divided image of the input complex, by Theorem 5.10. Let $\delta_{\mathcal{P}}$ be the decision map implied by $\mathcal{P}$. Note that $\delta_{\mathcal{P}}$ can also be seen as a simplicial map into $\mathcal{I}^n$.

[4] The combinatorial proof in [3] had a mistake.

Consider the input simplex σ of dimension $k+1$, where processes $p_0, \ldots, p_k$ have different inputs $v_0, \ldots, v_k$, respectively. By Theorem 5.10, $\mathcal{E}^n(\sigma)$ is a divided image of σ. Let v be the value $\delta_{\mathcal{P}}$ assigns to some vertex in $\mathcal{E}(\sigma)$, and let σ' be its carrier in $M(\sigma)$. The nontriviality condition implies that v is the input of some process in σ', and therefore we get the following.

CLAIM 7.2. *$\delta_{\mathcal{P}}$ is a Sperner coloring of $\mathcal{E}^n(\sigma)$.*

By Theorem 6.1, there is a simplex $\tau \in \mathcal{E}^n(\sigma)$ with $\delta_{\mathcal{P}}(\tau) = \sigma$. Thus, at least $k+1$ values are output in some IS execution with input σ, which is a contradiction. □

7.2. Renaming. In the *renaming* task [2], processes start with inputs (*original name*) from a large domain and are required to decide on distinct outputs (*new names*) from a domain which is as small as possible. Clearly, the task is trivial if processes can access their id; in this case, process p_i decides on i, which yields the smallest possible domain. To avoid trivial solutions, it is required that the processes and the protocol are *anonymous* [2]. That is, process p_i with original name x executes the same protocol as process p_j with original name x.

Captured in our combinatorial topology language, the M-renaming task is the triple $\langle \mathcal{D}^n, M^n, \Delta \rangle$. $\mathcal{D}^n$ contains all subsets of some domain $\mathcal{D}$ (of original names) with different values, M^n contains all subsets of $[0, M]$ (of new names) with different values, and Δ maps each $\sigma^n \in \mathcal{D}^n$ to all n-simplexes of M^n. We use Theorems 5.10 and 6.2 to prove that there is no wait-free anonymous protocol for the M-renaming task if $M \leq 2n-1$. The bound is tight, since there is an anonymous wait-free protocol for $2n$-renaming [2].

THEOREM 7.3. *If $M < 2n$, then there is no anonymous wait-free protocol that solves the M-renaming task.*

Proof. Assume, by way of contradiction, that $\mathcal{P}$ is a wait-free protocol for the M-renaming task, $M \leq 2n-1$. Assume that $\mathcal{D} = [0, 2n]$; i.e., assume that the original names are only between 0 and $2n$. Since we consider a bounded set of inputs, we can assume, without loss of generality, that every process takes the same number of steps. Moreover, by an observation of Eli Gafni (see Herlihy [18]), we may assume, without loss of generality, that $\mathcal{P}$ is comparison-based. That is, the protocol produces the same outputs on inputs which are order-equivalent.

By Theorem 5.10, the ISE complex, $\mathcal{S}$, is a chromatic divided image of the input complex $\mathcal{D}^n$. By Theorem 5.13, $\mathcal{S}$ is orientable, and by Theorem 5.11 $\mathcal{S}$ is connected. Let ζ be the *order preserving* mapping between any two subsets of process ids, of the same size, i.e., the mapping that maps the smallest id in one set to the smallest id in the second set, etc. It is obvious that $\mathcal{S}$ has structural symmetry under ζ, since we consider only executions in which all processes take the same number of steps.

Let $\delta_{\mathcal{P}}$ be the decision map implied by $\mathcal{P}$ and define δ' to be the binary coloring which colors each vertex in $\mathcal{S}$ with the parity of the value assigned to it by $\delta_{\mathcal{P}}$. Fix an input simplex σ^n. Since the protocol is comparison-based and anonymous, δ' is a symmetric coloring of $\mathcal{S}(\sigma^n)$ (with respect to ζ). Therefore, the assumptions of Theorem 6.2 are satisfied, and, therefore, at least one m-simplex of $\mathcal{S}(\sigma^n)$ is monochromatic under δ'.

On the other hand, note that the domain $[0, 2n-1]$ does not include $n+1$ different odd names; similarly, the domain $[0, 2n-1]$ does not include $n+1$ different even names. This implies that δ' cannot color any simplex of $\mathcal{S}$ with all zeroes or with all ones; i.e., no simplex of $\mathcal{S}$ is monochromatic, which is a contradiction. □

8. Discussion. This paper presents a study of wait-free solvability based on combinatorial topology. Informally, we have defined the notion of a chromatic divided

image and proved that a necessary condition for wait-free solvability is the existence of a simplicial chromatic mapping from a divided image of the inputs to the outputs that agrees with the task specification. In fact, we show the existence of a specific, well-structured chromatic divided image, the ISE complex; the ISE complex is proved to be orientable and connected, which allowed us to prove theorems about its combinatorial properties. These properties were then used to derive tight lower bounds for k-set consensus and renaming. Our results do not use homology groups, whose computation may be complicated.

Borowsky and Gafni [9] introduce another model of computation, based on an iterated version of ISs, and prove that it is equivalent to the wait-free model, when only decision tasks are concerned. In this model, there is a sequence of IS objects, each used at most once by each process: in its i-step, a process writes its entire state to the ith object. It is easy to check that the iterated ISE complex is a divided image of the input complex; the proof is completely analogous to the proof that the ISE complex is a divided image of the input complex. Therefore, the characterization and impossibility results of this paper hold for this model as well. This exemplifies how our combinatorial framework can be useful for other models of computation.

Several questions remain open. First, it is of interest to find other applications to the necessary condition presented here. Second, there are several directions to extend our framework, e.g., to allow fewer than n failures (as was done for one failure in [6]), to handle other primitive objects besides read/write registers (cf. [19, 10]), and to incorporate ongoing tasks.

Appendix A. Connectivity of divided images. It is useful to note the following lemma.

LEMMA A.1. *If K^m is full to dimension j and j-connected, then it is i-connected for every i, $0 < i < j$.*

Proof. Fix some i, $0 < i < j$, and consider two i-simplexes, σ_1^i and σ_2^i in K^m. Since K^m is full to dimension j, and $i < j$, it follows that there are two j-simplexes σ_1^j and σ_2^j in K^m such that $\sigma_1^i \subset \sigma_1^j$ and $\sigma_2^i \subset \sigma_2^j$. Since K^m is j-connected, it follows that there is a j-path in K^m from σ_1^j to σ_2^j. This path can be used to obtain an i-path in K^m from σ_1^i to σ_2^i. □

We now prove the following theorem.

THEOREM A.2. *Let K^m be a divided image of L^m under ψ. There exists a complex H^m, $H^m \subseteq K^m$, and $\tilde{\psi}$, a restriction of ψ to H^m, such that H^m is a divided image of L^m under $\tilde{\psi}$, and $\tilde{\psi}(\sigma^i)$ is i-connected. Moreover, bound$(\tilde{\psi}(\sigma^i))$ is $(i-1)$-connected for every $\sigma^i \in L^m$, $i > 1$.*

Proof. We construct H^m by defining $\tilde{\psi}(\sigma^i)$ for every $\sigma^i \in L^m$, by induction on i. We show that the properties of Definition 4.1 hold and that $\tilde{\psi}(\sigma^i)$ is i-connected.

For $i = 0$, for every $\sigma^0 \in L^m$, let $\tilde{\psi}(\sigma^0) = \psi(\sigma^0)$.

Assume $\tilde{\psi}(\sigma^j)$ has been defined for $j < i$, satisfying the required properties. Let $\tilde{\psi}(\sigma^i)$ be the complex containing every face of every $\tau^i \in \psi(\sigma^i)$ such that there exists an i-path from τ^i to some simplex with an $(i-1)$-face in $\tilde{\psi}(bound(\sigma^i))$.

First notice that $\tilde{\psi}(\sigma^i)$ is an i-pseudomanifold, since $\tilde{\psi}(\sigma^i) \subseteq \psi(\sigma^i)$, and it is full to dimension i. It is also simple to see it has properties 1, 2, and 3 of Definition 4.1. Next, we prove condition 4 of Definition 4.1.

CLAIM A.3. $\tilde{\psi}(\sigma \cap \sigma') = \tilde{\psi}(\sigma) \cap \tilde{\psi}(\sigma')$.

Proof. By definition of $\tilde{\psi}$ if $\sigma^{i-1} \subseteq \sigma^i$, then $\tilde{\psi}(\sigma^{i-1}) \subseteq \tilde{\psi}(\sigma^i)$. Hence, for every face σ^j of σ^i, $\tilde{\psi}(\sigma^j) \subseteq \tilde{\psi}(\sigma^i)$. This implies that $\tilde{\psi}(\sigma \cap \sigma') \subseteq \tilde{\psi}(\sigma) \cap \tilde{\psi}(\sigma')$. Assume $\tau^i \in \tilde{\psi}(\sigma) \cap \tilde{\psi}(\sigma')$. Thus $\tau^i \in \psi(\sigma) \cap \psi(\sigma')$ and $\tau^i \in \psi(\sigma \cap \sigma')$. This implies that there exists an i-path from τ^i to a simplex containing some $\tau^{i-1} \in \tilde{\psi}(\mathit{bound}(\sigma \cap \sigma'))$. ∎

Next, we prove condition 5 of Definition 4.1.

CLAIM A.4. $\tilde{\psi}(\mathit{bound}(\sigma^i)) = \mathit{bound}(\tilde{\psi}(\sigma^i))$.

Proof. Assume $\tau^{i-1} \in \tilde{\psi}(\mathit{bound}(\sigma^i))$. Then $\tau^{i-1} \in \tilde{\psi}(\sigma^{i-1})$ for some face σ^{i-1} of σ^i. Thus, $\tau^{i-1} \in \psi(\sigma^{i-1})$ and $\tau^{i-1} \in \psi(\mathit{bound}(\sigma^i)) = \mathit{bound}(\psi(\sigma^i))$. It follows that there exists a unique $\tau^i \in \psi(\sigma^i)$ containing τ^{i-1}. This implies that $\tau^{i-1} \in \mathit{bound}(\tilde{\psi}(\sigma^i))$.

Before proving the other direction of the claim, notice that $\mathit{bound}(\tilde{\psi}(\sigma^i)) \subseteq \mathit{bound}(\psi(\sigma^i))$. Otherwise, if $\tau^{i-1} \in \mathit{bound}(\tilde{\psi}(\sigma^i))$, then there exists a unique $\tau^i \in \tilde{\psi}(\sigma^i)$ containing τ^{i-1}. If there is another i-simplex $\tau \in \psi(\sigma^i)$ containing τ^{i-1}, τ would also be in $\tilde{\psi}(\sigma^i)$, by definition of $\tilde{\psi}$, since τ and τ^i are connected by a (one step) i-path.

Assume that $\tau^{i-1} \in \mathit{bound}(\tilde{\psi}(\sigma^i))$, and let τ^i be the unique i-simplex in $\tilde{\psi}(\sigma^i)$ containing τ^{i-1}. Then $\tau^{i-1} \in \mathit{bound}(\psi(\sigma^i))$, since we have just proved that $\mathit{bound}(\tilde{\psi}(\sigma^i)) \subseteq \mathit{bound}(\psi(\sigma^i))$. Hence $\tau^{i-1} \in \psi(\mathit{bound}(\sigma^i))$, and thus $\tau^{i-1} \in \psi(\sigma^{i-1})$, for some face σ^{i-1} of σ^i. Since $\tau^i \in \tilde{\psi}(\sigma^i)$, there exists an i-path from τ^i to an i-simplex containing some $\tau_1^{i-1} \in \tilde{\psi}(\mathit{bound}(\sigma^i))$. Assume $\tau_1^{i-1} \in \tilde{\psi}(\sigma_1^{i-1})$. Thus there exists an $(i-1)$-path from τ^{i-1} to τ_1^{i-1}, by using this i-path. By the induction hypothesis, there exists an $(i-1)$-path from τ_1^{i-1} to an $(i-1)$-simplex containing some $\tau^{i-2} \in \tilde{\psi}(\mathit{bound}(\sigma_1^{i-1}))$. Therefore there exists an $(i-1)$-path from τ^{i-1} to the $(i-1)$-simplex containing τ^{i-2}. The definition of $\tilde{\psi}$ implies that $\tau^{i-1} \in \tilde{\psi}(\sigma_1^{i-1})$, and thus $\tau^{i-1} \in \tilde{\psi}(\mathit{bound}(\sigma^i))$. ∎

To complete the proof of the lemma, we show, by induction on i, that $\tilde{\psi}(\sigma^i)$ is i-connected, and that, for $i > 1$, $\tilde{\psi}(\mathit{bound}(\sigma^i))$ is $(i-1)$-connected.

To show that $\tilde{\psi}(\mathit{bound}(\sigma^2))$ is 1-connected, observe that $\tilde{\psi}(\sigma^1)$ is 1-connected because, since it is finite, it is a graph which consists of a simple path. The lemma follows since Definition 4.1(4) holds.

For the induction step, we first show that $\tilde{\psi}(\sigma^i)$ is i-connected. By the induction hypothesis, the boundary of $\tilde{\psi}(\sigma^i)$ is $(i-1)$-connected. Thus, it suffices to consider two adjacent $(i-1)$-simplexes τ^{i-1}, τ'^{i-1} of $\mathit{bound}(\tilde{\psi}(\sigma^i))$, that is, such that $\tau^{i-1} \cap \tau'^{i-1}$ is an $(i-2)$-simplex, τ^{i-2}. In this case, we need to show that τ^i is i-connected to τ'^i, where these are the single i-simplexes of $\tilde{\psi}(\sigma^i)$ with $\tau^{i-1} \subset \tau^i$ and $\tau'^{i-1} \subset \tau'^i$.

To prove that τ^i is i-connected to τ'^i, we construct an i-path $(\tau^i =)\tau_0^i, \tau_1^i, \ldots, \tau_\ell^i (= \tau'^i)$, all of whose simplexes contain τ^{i-2}. Denote the pairwise intersections $\tau_1^{i-1}, \tau_2^{i-2}, \ldots, \tau_\ell^{i-1}$, and $\tau_0^{i-1} = \tau^{i-1}$.

Notice that there is a unique $(i-1)$-face of τ_0^i, τ_1^{i-1} that (a) contains τ^{i-2} and (b) is different from τ_0^{i-1}. Now, τ_1^{i-1} is not in $\mathit{bound}(\tilde{\psi}(\sigma^i))$ because $\mathit{bound}(\tilde{\psi}(\sigma^i))$ is a pseudomanifold, and hence τ^{i-2} is contained in only two $(i-1)$-simplexes, τ^{i-1} and τ'^{i-1}. It follows that τ_1^{i-1} is contained in two i-simplexes, $\tau^i (= \tau_0^i)$, and τ_1^i.

Repeating this argument, we obtain an i-path $(\tau^i =)\tau_0^i, \tau_1^i, \ldots, \tau_\ell^i$. This path either ends in τ'^i or it repeats a simplex and the construction is stopped at that point. We now show that it can end only in τ'^i, and hence $\tau'^i = \tau_\ell^i$. Consider $\tau_{\ell+1}^{i-1}$, the unique $(i-1)$-face of τ_ℓ^i, that satisfies conditions (a) and (b) above, i.e., that contains τ^{i-2}, and is different from τ_ℓ^{i-1}. We have seen that this face cannot be external (unless it is equal to τ'^{i-1}, $\tau_\ell^i = \tau'^i$, and then we are done) because $\mathit{bound}(\tilde{\psi}(\sigma^i))$ is a pseudomanifold, and hence τ^{i-2} is contained in only two $(i-1)$-simplexes, τ^{i-1}, τ'^{i-1}.

Thus the path must have a loop. That is, the face $\tau_{\ell+1}^{i-1}$ is contained in τ_ℓ^i, and in some other previous simplex in the i-path, and the next simplex after τ_ℓ^i in the i-path is a previous simplex. However, this is impossible, since each previous $(i-1)$-simplex satisfying conditions (a) and (b) in the i-path already is contained in two i-simplexes, or else is τ^{i-1} which is an external simplex.

The proof that $\tilde{\psi}(\mathit{bound}(\sigma^{i+1}))$ is i-connected follows from the fact that $\tilde{\psi}(\sigma^i)$ is i-connected: it suffices to prove that for any $\sigma_1, \sigma_2 \in \mathit{bound}(\sigma^{i+1})$, $\tilde{\psi}(\sigma_1) \cap \tilde{\psi}(\sigma 2)$ contains an $(i-1)$-simplex. This follows from Definition 4.1(4) because $\tilde{\psi}(\sigma_1) \cap \tilde{\psi}(\sigma 2) = \tilde{\psi}(\sigma_1 \cap \sigma_2)$, and from Definition 4.1(5) because $\tilde{\psi}(\sigma_1 \cap \sigma_2)$ is an $(i-1)$-pseudomanifold. □

Appendix B. Algebraic spans. We start by describing very briefly some algebraic preliminaries; for more details and examples see [24, section 1.13] and [20].

Let K be an n-dimensional simplicial complex and $\sigma = (v_0, \ldots, v_q)$ a q-simplex of K. An *orientation* for σ is an equivalence class of orderings on $v_0, \ldots, v_q$, consisting of one particular ordering and all even permutations of it. For example, an orientation of a 1-simplex (v_0, v_1) is just a direction, either from v_0 to v_1 or vice-versa. An orientation of a 2-simplex (v_0, v_1, v_2) can be either "clockwise," as in (v_0, v_1, v_2), or "counterclockwise," as in (v_0, v_2, v_1).

Recall that, by Lemma 5.12, a chromatic pseudomanifold K^m is orientable if and only if its m-simplexes can be partitioned into two disjoint classes such that if two m-simplexes share an $(m-1)$-face, then they belong to different classes.

A *q-chain* of K is a formal sum of oriented q-simplexes: $\sum_{i=0}^{\ell} \lambda_i \cdot \sigma_i^q$, where λ_i is an integer. When writing chains, we typically omit q-simplexes with zero coefficients, unless they are all zero, when we simply write 0. We write $1 \cdot \sigma^q$ as σ^q and $-1 \cdot \sigma^q$ as $-\sigma^q$. We identify $-\sigma^q$ with σ^q having the opposite orientation. The q-chains of K (with component-wise addition) form a free Abelian group $C_q(K)$, called the qth *chain group* of K. For dimension -1, we adjoin the infinite cyclic group Z in dimension -1, $C_{-1}(K) = Z$.

A *boundary* operator $\partial_q : C_q(K) \to C_{q-1}(K)$ is a homomorphism such that, for a q-chain α,

$$\partial_{q-1}\partial_q \alpha = 0,$$

and the *augmentation* $\partial_0 : C_0(K) \to C_{-1}(K)$ is an epimorphism (i.e., a surjective homomorphism).

For an oriented simplex $\sigma^q = (v_0, \ldots, v_q)$, let $\mathrm{face}_i(\sigma^q)$, the ith *face* of σ^q, be the $(q-1)$-simplex $(v_0, \ldots, \hat{v}_i, \ldots, v_q)$, where circumflex denotes omission. The usual boundary operator $\partial_q : C_q(K) \to C_{q-1}(K)$, $q > 0$, is defined on simplexes:

$$\partial \sigma^q = \sum_{i=0}^{q} (-1)^i \cdot \mathrm{face}_i(\sigma^q),$$

and is extended additively to chains: $\partial(\alpha_0 + \alpha_1) = \partial\alpha_0 + \partial\alpha_1$. For $q = 0$, $\partial_0(v) = 1$, and extend linearly.[5] (We sometimes omit subscripts from boundary operators.)

The *chain complex* $C(K)$ is the sequence of groups and homomorphisms $\{C_q(K), \partial_q\}$.

[5] Munkres [24] uses ϵ for ∂_0.

Let $C(K) = \{C_q(K), \partial_q\}$ and $C(L) = \{C_q(L), \partial'_q\}$ be chain complexes for simplicial complexes K and L. An *augmentation-preserving chain map* (or chain map) ϕ is a family of homomorphisms.

$$\phi_q : C_q(K) \to C_q(L)$$

such that $\partial'_q \circ \phi_q = \phi_{q-1} \circ \partial_q$.

Let $S^n = M(\sigma^n)$, for a simplex σ^n, and let $\mathcal{P}^n$ be a divided image of S^n under ψ. An *algebraic span* is a chain map $\phi : C(S^n) \to C(\mathcal{P}^n)$ that is carried by ψ. The chain map ϕ is *carried* by ψ if each simplex appearing with a nonzero coefficient in $\phi(\sigma^i)$ is in the subcomplex $\psi(\sigma^i)$.

A properly colored m-pseudomanifold K^m is *orientable* if its m-simplexes can be oriented so that two m-simplexes sharing an $(m-1)$-face give opposite orientations to the face. That is, the chain $\partial(\sigma_1 + \sigma_2)$ has zero coefficient on the face that σ_1 and σ_2 share. Such an orientation is called *coherent,* and partitions the m-simplexes in two classes, so that simplexes sharing an $(m-1)$-face are in different classes. The orientation of simplexes of dimension other than m can be arbitrary. Also, if K^m is orientable, then it has exactly two coherent orientations.

The next proposition follows directly from the definition of pseudomanifold and of orientability. Indeed, in an m-pseudomanifold every $(m-1)$-simplex is contained in either one or two m-simplexes. For any $(m-1)$-simplex σ contained in two m-simplexes σ_1, σ_2, the chain $\partial(\sigma_1 + \sigma_2)$ has zero coefficient on σ.

PROPOSITION B.1. *Let K^m be an m-pseudomanifold with a coherent orientation and c the chain which is the sum of all its m-simplexes. Then $\partial(c)$ is a chain of $(m-1)$-simplexes, which as a set is equal to bound(K^m).*

In the renaming applications we assume a divided image with structural symmetry, in order to use Theorem 6.2. In such cases we assume that the corresponding algebraic span preserves the symmetry, that is, that symmetric simplexes have associated symmetric simplexes under the chain map. Let $\mathcal{E}^n$ be the ISE complex on input σ^n, a divided image of σ^n under ψ, where each process executes a fixed number of steps.

THEOREM B.2. *There is an algebraic span from $M(\sigma^n)$ to $\mathcal{E}^n$. Moreover, if $\mathcal{E}^n$ has structural symmetry, then the algebraic span preserves it.*

Proof. Give an arbitrary orientation to the simplexes of $M(\sigma^n)$ to obtain a chain complex $C(M(\sigma^n))$.

By Theorem 5.10 we know that $\mathcal{E}^n$ is a chromatic divided image of $M(\sigma^n)$ under ψ. By Theorem 5.13 we can give to every pseudomanifold $\psi(\sigma)$ a coherent orientation and obtain the chain complex $C(\mathcal{E}^n)$.

Let $\dot{\psi}$ be the chain map that associates to $\sigma^i \in M(\sigma^n)$, the chain which is the sum of the i-simplexes that appear in $\psi(\sigma^i)$, with sign defined as follows: $\dot{\psi}(\sigma^n)$ is the sum of the n-simplexes in $\psi(\sigma^n)$. If $\dot{\psi}(\sigma^i)$ has been defined, then $\dot{\psi}(\text{face}_j(\sigma^i))$ is the sum of the $(i-1)$-simplexes in $\psi(\text{face}_j(\sigma^i))$ with sign $(-1)^j$.

We proceed to prove that $\dot{\psi}$ is a chain map. First, $\dot{\psi}_q$ is a well-defined homomorphism, since it is defined on simplexes (the generators of the group $C_q(M(\sigma^n))$) and extended linearly. Now, $\dot{\psi}_q(\sigma^q) = c$ satisfies the hypothesis of Proposition B.1, and hence $\partial'_q(c)$ is equal to *bound*$(\psi(\sigma^q))$, as a set. Since $\partial_q(\sigma^q)$ is equal to $\sum_{i=0}^{q}(-1)^i \cdot \text{face}_i(\sigma^q)$, and equal to *bound*$(\sigma^q)$ as a set, and by the last requirement of the definition of a divided image, we have that $\partial'_q \circ \phi_q = \phi_{q-1} \circ \partial_q$, since the orientations correspond. Notice that with $q = 0$ we use condition 3 of Definition 4.1. ∎

Acknowledgments. We thank Javier Bracho, Eli Gafni, John Havlicek, Maurice Herlihy, Guy Rey, Nir Shavit, Ronit Teplixke, and Mark Tuttle for comments on the paper and very useful discussions. We especially thank an anonymous referee for many comments that allowed us to correct errors and improve the overall presentation.

RECOGNIZING DART-FREE PERFECT GRAPHS*

V. CHVÁTAL†, J. FONLUPT‡, L. SUN§, AND A. ZEMIRLINE¶

Abstract. A graph G is called a *Berge graph* if neither G nor its complement contains a chordless cycle whose length is odd and at least five; what we call a *dart* is the graph with vertices u, v, w, x, y and edges uv, vw, uy, vy, wy, xy; a graph is called *dart-free* if it has no induced subgraph isomorphic to the dart. We present a polynomial-time algorithm to recognize dart-free Berge graphs; this algorithm uses as a subroutine the polynomial-time algorithm for recognizing claw-free Berge graphs designed previously by Chvátal and Sbihi [*J. Combin. Theory Ser. B*, 44 (1988), pp. 154–176].

Key words. perfect graphs

1. Introduction.

Claude Berge proposed the notion of a *perfect graph*, which is a graph G such that, for each induced subgraph F of G, the chromatic number of F equals the largest number of pairwise adjacent vertices in F; he made the following conjecture.

CONJECTURE 1.1 (The Strong Perfect Graph Conjecture). *A graph is perfect if and only if it contains, as an induced subgraph, no odd hole chordless cycle whose number of vertices is odd and at least five and no complement of such a cycle.*

Berge publicized the Strong Perfect Graph Conjecture as early as April 1960—at the Second International Meeting on Graph Theory, organized by Horst Sachs at the University of Halle-Wittenberg—but published it only three years later [1]; the first widely available reference to it is [2]. For an account of the early history of the conjecture, see [3, 4].

A *hole* is a chordless cycle with at least four vertices; an *antihole* is the complement of a hole; holes and antiholes are called *even* or *odd* according to the parity of their number of vertices. Following Chvátal and Sbihi [6], we shall call a graph a *Berge graph* if it contains no odd hole and no odd antihole: in these terms, the Strong Perfect Graph Conjecture asserts that a graph is perfect if and only if it is a Berge graph. Its "only if" part is trivial and its "if" part remains open.

Progress towards proving the Strong Perfect Graph Conjecture is often made by proving that all graphs in some restricted class of Berge graphs are perfect. A popular way of creating restricted classes of Berge graphs for this purpose is to forbid a single induced subgraph F: the resulting class consists of all Berge graphs that are *F-free* in the sense of containing no induced subgraph isomorphic to F. In particular, with a *claw* defined as the first graph in Figure 1.1, Parathasarathy and Ravindra [10]

proved that all claw-free Berge graphs are perfect; with a *diamond* defined as the second graph in Figure 1.1, Tucker [12] proved that all diamond-free Berge graphs are perfect; Sun [11] strengthened both of these results by proving that, with a *dart* defined as the third graph in Figure 1.1, all dart-free Berge graphs are perfect.

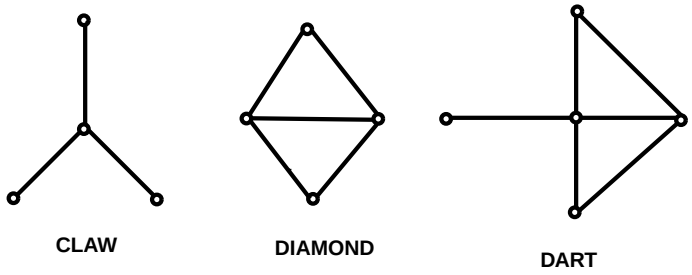

FIG. 1.1. *The claw, the diamond, and the dart.*

Another fundamental conjecture concerning perfect graphs is the following.

CONJECTURE 1.2. *There is a polynomial-time algorithm to recognize perfect graphs.*

Again, progress towards proving this conjecture is often made by designing a polynomial-time algorithm to recognize members of some restricted class of perfect graphs. In particular, Chvátal and Sbihi [6] designed a polynomial-time algorithm to recognize claw-free perfect graphs; Fonlupt and Zemirline [8, 9] designed a polynomial-time algorithm to recognize diamond-free perfect graphs; the subject of the present paper is a polynomial-time algorithm to recognize dart-free Berge graphs.

For a recent survey of results on perfect graphs and related subjects, see [5].

2. Theorems. Many theorems elucidate the structure of objects in some class $\mathcal{C}$ in terms of some proper subclass $\mathcal{C}_0$ of $\mathcal{C}$: they assert that, unless an object in $\mathcal{C}$ is primitive in the sense of belonging to $\mathcal{C}_0$, it must have a structural fault of a prescribed type. We follow this paradigm in three iterations.

First, let us call a graph *friendly* if, for each of its vertices x such that x is the center of a claw, the subgraph of G induced by the neighbors of x consists of vertex-disjoint cliques. Trivially, every friendly graph is dart-free; however, the converse is false (see either of the two graphs in Figure 2.1).

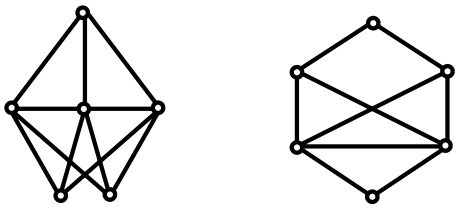

FIG. 2.1. *Two unfriendly dart-free graphs.*

Our first theorem specifies structural faults appearing in every dart-free graph that is not friendly. One of these faults is the presence of *adjacent twins*, meaning two adjacent vertices such that no vertex distinct from both is adjacent to precisely one of them.

THEOREM 2.1. *Unless a dart-free graph is friendly, it has at least one of the following properties:*

(i) *it is disconnected;*
(ii) *its complement is disconnected;*
(iii) *it contains adjacent twins.*

Next, let us call a graph a *bat* if it consists of a chordless path $a_1a_2 \dots a_m$ and an additional vertex z that is adjacent to a_1, a_i, a_{i+1}, a_m for some i with $3 \leq i \leq m-3$ and adjacent to no other a_j. Occasionally, we shall refer to z as the *head* of the bat and to a_1, a_m as its *wing-tips*; see Figure 2.2.

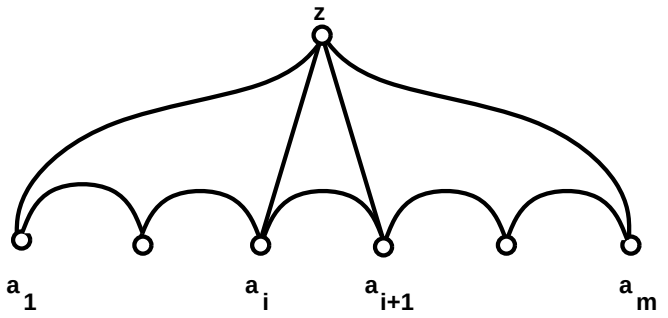

FIG. 2.2. *A bat.*

There are infinitely many bats; we call a graph *bat-free* if it contains none of them (as an induced subgraph). Our second theorem specifies structural faults appearing in every friendly Berge graph that is not bat-free. One of these faults is a clique-cutset; to describe the other fault, we need a few definitions. By a *z-edge*, we mean any edge whose endpoints are both adjacent to a vertex z; for any graph G and any vertex z of G, we let $G*z$ denote the graph obtained from $G - z$ by removing all the z-edges; we say that G has a *rosette* centered at z if $G*z$ is disconnected and the subgraph of G induced by all the neighbors of z consists of vertex-disjoint cliques.

THEOREM 2.2. *Every friendly graph containing no odd hole has at least one of the following properties:*

(i) *it is bat-free;*
(ii) *it has a clique-cutset that is a maximal clique;*
(iii) *it has a rosette.*

Any of the three graphs in Figure 2.4 shows that property (i) in this theorem cannot be dropped; the two graphs in Figure 2.3 show that neither (ii) nor (iii) can be dropped.

The two notions of a clique-cutset and a rosette may appear unrelated in terms of G; in terms of a certain graph which we call the *clique graph of* G, they are nearly dual to each other. The clique graph of G is bipartite; its white vertices are the vertices of G and its red vertices are the maximal cliques in G (here, as usual, "maximal" is meant with respect to set-inclusion rather than size); a white vertex z is adjacent to a red vertex C if and only if $z \in C$. Trivially, the removal of a red vertex C and all its neighbors disconnects the clique graph of G if and only if $G - C$ is disconnected; trivially, the removal of a white vertex z and all its neighbors disconnects the clique graph of G if and only if $G*z$ is disconnected.

Theorem 2.2 is closely related to the following theorem of Conforti and Rao [7]: *If a bipartite graph H containing no cycle of length four and no chordless cycle of*

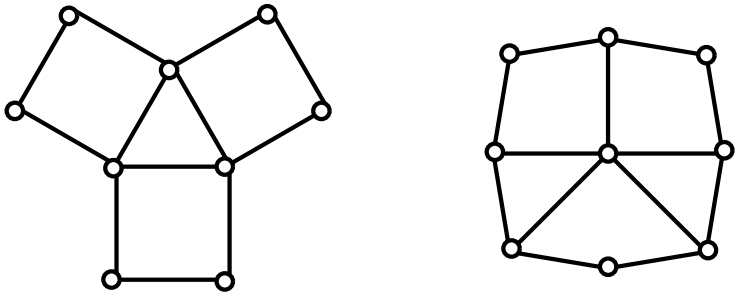

FIG. 2.3. *Neither* (ii) *nor* (iii) *in Theorem* 2.2 *can be dropped.*

length congruent to 2 *modulo* 4 *contains a cycle of length congruent to* 2 *modulo* 4*, then* H *has a vertex* v *such that the removal of* v *and all its neighbors disconnects* H*.* We are going to sketch a derivation of the Conforti–Rao theorem from a weaker form of Theorem 2.2, where "friendly" is replaced by "diamond-free."

Given a bipartite graph H that satisfies the hypothesis of the Conforti–Rao theorem, color the vertices in one part of H red, color the vertices in the other part of H white, and consider the graph G defined as follows: the vertices of G are the white vertices of H and two vertices of G are adjacent if and only if they have a common neighbor in H. Since H contains no chordless cycle of length six, H is the clique graph of G; since H contains no cycle of length four, G is diamond-free; since H contains no chordless cycle of length congruent to 2 modulo 4, G contains no odd hole. The shortest cycle of length congruent to 2 modulo 4 in H has precisely one chord (cf. Lemma 3.1 of Conforti and Rao [7]) and induces a bat in G. Now Theorem 2.2 (with "friendly" replaced by "diamond-free") guarantees that H has a vertex v such that the removal of v and all its neighbors disconnects H.

Our third theorem specifies a structural fault appearing in every friendly Berge graph that is neither bipartite nor claw-free: by a *separator* in a graph G, we mean any cutset consisting of at most two vertices except cutsets S such that S consists of two nonadjacent vertices, $G - S$ has precisely two components, and one of these components consists of a single vertex.

THEOREM 2.3. *Every bat-free friendly graph containing no odd hole has at least one of the following properties:*

(i) *it is bipartite;*
(ii) *it is claw-free;*
(iii) *it has a separator.*

Again, none of the three properties in this theorem can be dropped: see the three graphs in Figure 2.4.

Our polynomial-time algorithm to recognize friendly Berge graphs evolves from Theorems 2.1, 2.2, and 2.3; in analyzing it, we shall use a strengthening of Theorem 2.2. There, a bat in a friendly graph G is called *fragile* if, with C standing for the unique maximal clique of G that contains the triangle of the bat, the two wing-tips of the bat belong to distinct components of $G - C$.

THEOREM 2.4. *Let* G *be a friendly graph containing no odd hole. If* G *contains a bat with head* z *such that the two wing-tips of the bat belong to the same component of* $G * z$*, then* G *and* z *have at least one of the following properties:*

(i) G *contains a fragile bat with head* z*;*
(ii) G *contains a clique-cutset* C *such that* $z \in C$ *and some component of* $G - C$

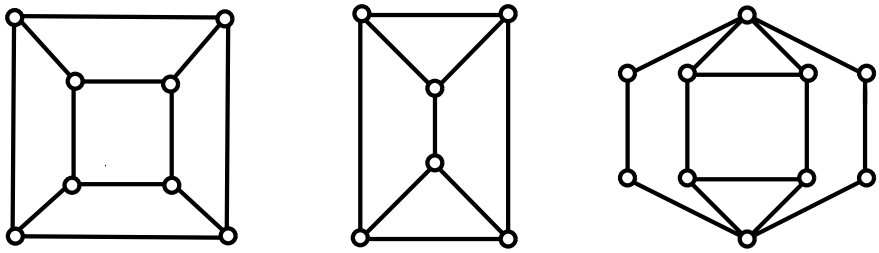

FIG. 2.4. *None of the three properties in Theorem* 2.3 *can be dropped.*

includes no neighbor of z.

Neither of the two properties in this theorem can be dropped: see the two graphs in Figure 2.5.

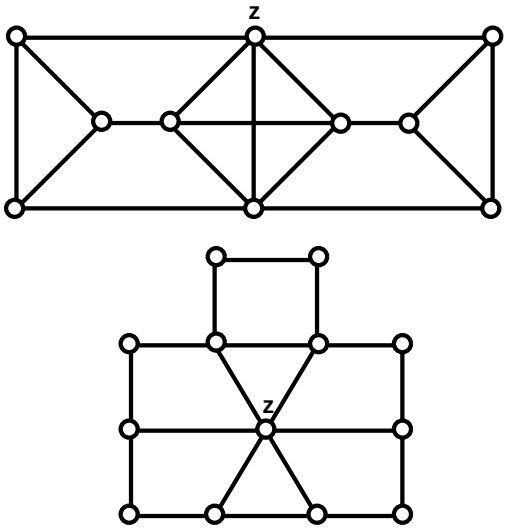

FIG. 2.5. *Neither of the two properties in Theorem* 2.3 *can be dropped.*

To derive Theorem 2.2 from Theorem 2.4, consider an arbitrary friendly graph G containing no odd hole. We may assume that G contains a bat (else it has property (i) of Theorem 2.2) and that, with z standing for the head of the bat, the two wing-tips of the bat belong to the same component of $G*z$ (else G has property (iii) of Theorem 2.2). Now G has property (i) of Theorem 2.4 or else it has property (ii) of Theorem 2.4. In the former case, the unique maximal clique of G that contains the triangle of the bat is a cutset of G; in the latter case, the unique maximal clique of G that contains C is a cutset of G.

Theorems 2.1, 2.3, and 2.4 will be proved in section 3; the algorithm and its analysis are the subject of section 4.

3. Proofs. All our subgraphs are induced. When A is a path with vertices $a_1, a_2, \ldots, a_m$ and edges $a_1a_2, a_2a_3, \ldots, a_{m-1}a_m$, we write $A = a_1a_2 \ldots a_m$ and borrow

the notation used for intervals: $A[a_i, a_j] = a_i a_{i+1} \dots a_j$, $A[a_i, a_j) = a_i a_{i+1} \dots a_{j-1}$, etc. Any path of the form $a_1 a_2 \dots a_k$ will be called a *prefix* of A and any path of the form $a_k a_{k+1} \dots a_m$ will be called a *suffix* of A.

3.1. Proof of Theorem 2.1. Consider an arbitrary graph G such that G is not friendly, G is connected, its complement $\overline{G}$ is connected, and G contains no adjacent twins. We shall find a dart in G.

It is a routine matter to verify that a graph is not friendly if and only if it contains (as an induced subgraph) either a dart or else the graph with vertices u_1, u_2, u_3, v_1, v_2 and the seven edges v_1v_2, u_iv_j $(i = 1, 2, 3; j = 1, 2)$. In particular, we may assume that our G contains an induced subgraph of the second kind. Now consider the subgraph of G induced by all the common neighbors of u_1, u_2, and u_3; let Q denote the component of this subgraph that contains v_1 and v_2.

CASE 1. *There are vertices x, w_1, w_2 such that $x \notin Q, w_1 \in Q, w_2 \in Q$, and $xw_1 \in E, xw_2 \notin E$.*

Since Q is connected, we may assume that $w_1w_2 \in E$; since $x \notin Q$, we have $xu_i \notin E$ for at least one i. Now the subgraph of G induced by $u_1, u_2, u_3, w_1, w_2, x$ contains an induced dart.

CASE 2. *The set of vertices of $G - Q$ partitions into sets A and B such that $xw \in E$ whenever $x \in A, w \in Q$ and such that $xw \notin E$ whenever $x \in B, w \in Q$.*

Since $\overline{G}$ is connected, we have $B \neq \emptyset$; in turn, since G is connected, there is an edge ab with $a \in A, b \in B$. Since v_1 and v_2 are not adjacent twins, some vertex v is adjacent to precisely one of them; note that $v \in Q$. Now a, b, v, v_1, v_2 induce a dart in G. □

3.2. Two simple lemmas.

LEMMA 3.1. *Let G be a graph with at least four vertices and with a unique triangle $v_1v_2v_3$. If all three graphs $G - \{v_1, v_2\}$, $G - \{v_1, v_3\}$, $G - \{v_2, v_3\}$ are connected, then G contains an odd hole.*

Proof. Let Q be any component of $G - \{v_1, v_2, v_3\}$. We may assume that Q is bipartite (else Q contains an odd hole and we are done); thus the set of vertices of Q splits into stable sets S_1 and S_2. Since each $G - \{v_i, v_j\}$ is connected, each of the three vertices v_k must have a neighbor in $S_1 \cup S_2$. Hence two of the three vertices, say v_1 and v_2, must have a neighbor in the same S_i. Since Q is connected, it follows that the subgraph of G induced by $Q \cup \{v_1, v_2\}$ is not bipartite, and so it contains an odd hole. □

LEMMA 3.2. *Let an edge e of a graph G extend into no triangle. If G is friendly, then $G-e$ is friendly; if G contains no odd hole, then $G-e$ contains no odd hole.* □

3.3. Proof of Theorem 2.3. By a *pseudobat*, we shall mean any graph with vertices $a_1, a_2, \dots, a_m$ and z such that

(i) $a_1a_2 \dots a_m$ is a (not necessarily chordless) path;

(ii) z is adjacent to a_1, a_i, a_{i+1} and a_m for some i with $3 \leq i \leq m - 3$ (and possibly to other vertices a_j);

(iii) $za_1a_ia_m$ is a claw.

(In a friendly graph, condition (iii) is equivalent to saying that both $za_1a_ia_m$ and $za_1a_{i+1}a_m$ are claws.)

LEMMA 3.3. *Let G be a friendly graph containing no odd hole; let z be a vertex of G that belongs to no triangle; let $u_1u_2 \dots u_r$, $v_1v_2 \dots v_s$, and $w_1w_2 \dots w_t$ be vertex-disjoint paths in $G - z$ such that u_1, v_1, and w_1 are neighbors of z and $u_rv_sw_t$ is a triangle. Then G contains an induced pseudobat.*

Proof. The proof is by induction on the number of vertices of G. The induction hypothesis allows us to assume that the three paths are chordless and that together they cover all the vertices of $G - z$. Lemma 3.1 guarantees that G contains a triangle T other than $u_r v_s w_t$. Trivially, T meets at least two of the three chordless paths; the induction hypothesis allows us to assume that T meets at most two of the paths. Hence symmetry allows us to assume that T is $v_j w_k w_{k+1}$ for some j and k; in turn, the induction hypothesis allows us to assume that $j = s$ (consider $G - v_s$).

CASE 1. $v_s w_{t-1} \in E$.

Since G is friendly, at least two of the three vertices u_r, v_{s-1}, w_{t-1} must be adjacent (consider the neighborhood of v_s), and so we are done by the induction hypothesis applied to $G - w_t$.

CASE 2. $v_s w_{t-1} \notin E$.

Write $v_0 = z$. The induction hypothesis allows us to assume that v_{s-1} is adjacent neither to w_k nor to w_t (consider $G - w_{t-1}$). Thus the path $v_{s-1} \dots v_2 v_1 v_0 w_1 w_2 \dots w_t$ along with the additional vertex v_s induces a pseudobat in G. □

LEMMA 3.4. *Let G be a friendly graph containing no odd hole. If G contains an induced pseudobat, then it contains an induced bat.*

Proof. The proof is by induction on the number of edges of G. Let $a_1, a_2, \dots, a_m$ and z be as in our definition of a pseudobat. Note that $a_1 a_{i+1} \notin E$ and $a_{i+1} a_m \notin E$ since G is friendly (consider the neighborhood of z). The induction hypothesis allows us to assume that G is the pseudobat and that the two paths $a_1 a_2 \dots a_i$ and $a_{i+1} a_{i+2} \dots a_m$ are chordless.

CASE 1. *z is adjacent to some a_j other than a_1, a_i, a_{i+1}, a_m.*

Symmetry allows us to assume that $2 \le j \le i - 1$. If $j = i - 1$, then $a_{i-1} a_{i+1} \in E, a_1 a_{i-1} \notin E, a_{i-1} a_m \notin E$ (consider the neighborhood of z), and we are done by the induction hypothesis applied to $G - a_i$. Thus we may assume that $j \le i - 2$; in particular, $a_j a_i \notin E$ (since the path $a_1 a_2 \dots a_i$ is chordless). If $a_j a_m \notin E$, then we are done by the induction hypothesis applied to the pseudobat induced in G by $a_j a_{j+1} \dots a_m$ and z; if $a_j a_m \in E$, then $a_1 a_j \notin E$, $a_j a_{i+1} \notin E$, $a_1 a_{i+1} \notin E$ (consider the neighborhood of z), and we are done by the induction hypothesis applied to the pseudobat induced in G by $a_1 a_2 \dots a_j a_m a_{m-1} \dots a_{i+1}$ and z.

CASE 2. *z is adjacent to no a_j other than a_1, a_i, a_{i+1}, a_m.*

We may assume that the path $a_1 a_2 \dots a_m$ has at least one chord (else G is a bat and we are done). If no chord of this path extends into a triangle, then G has an odd hole since conditions of Lemma 3.1 are satisfied for G or for the subgraph induced in G by $a_1 a_2 \dots a_i a_{i+1}$ and z or for the subgraph induced in G by $a_i a_{i+1} \dots a_m$ and z. Thus we may assume that a chord e extends into a triangle, T; since $z \notin T$, symmetry allows us to assume that T is $a_j a_k a_{k+1}$ for some j and k with $1 \le j \le i$ and $i + 1 \le k \le m - 1$. Among all such triangles, choose one with j as small as possible. If $j \le i - 1$, then Lemma 3.3 guarantees that $G - a_i$ contains an induced pseudobat (in which case we are done by the induction hypothesis). Thus we may assume that $j = i$.

SUBCASE 2.1. $a_i a_{i+2} \notin E$.

Now $k \ge i+3$ and (since $z a_1 a_i a_m$ is a claw) $k \le m-2$, and so $z a_k \notin E, z a_{k+1} \notin E$; minimality of j implies that $a_{i-1} a_k \notin E$ or $a_{i-1} a_{k+1} \notin E$ (or both); hence $a_i a_{i-1} z a_k$ or $a_i a_{i-1} z a_{k+1}$ is a claw. It follows that $a_i a_{i-1} z a_k$ is a claw (consider the neighborhood of a_i), and so we are done by the induction hypothesis applied to the pseudobat induced in G by $a_{i-1} \dots a_2 a_1 z a_{i+1} a_{i+2} \dots a_k$ and a_i.

SUBCASE 2.2. $a_i a_{i+2} \in E$.

Now $a_{i-1}a_{i+2} \in E$ (consider the neighborhood of a_i), and so minimality of j implies $a_{i-1}a_{i+1} \notin E$, $a_{i-1}a_{i+3} \notin E$; since the path $a_{i+1}a_{i+2}\dots a_m$ is chordless, $a_{i+1}a_{i+3} \notin E$. Thus G is not friendly (consider the neighborhood of a_{i+2}), a contradiction. □

Proof of Theorem 2.3. Consider an arbitrary bat-free friendly graph G that contains no odd hole, is not bipartite, and is not claw-free. We shall find a separator in G.

For each vertex x of G, write $x \in A$ if x is in a triangle; write $x \in B$ if x is the center of a claw. By assumption, $A \neq \emptyset$ and $B \neq \emptyset$.

CASE 1. $A \cap B \neq \emptyset$.

Let z be a vertex in $A \cap B$. Since G is friendly, z has neighbors c_1, c_2, d_1, d_2 such that $c_1c_2 \notin E, d_1d_2$ and $c_id_j \notin E$ for all choices of i and j. Lemma 3.4 guarantees that $G - z$ contains no two vertex-disjoint paths from $\{c_1, c_2\}$ to $\{d_1, d_2\}$; now, by Menger's theorem, $G - z$ contains a vertex w such that $G - \{z, w\}$ contains no path from $\{c_1, c_2\}$ to $\{d_1, d_2\}$. Observe that $\{z, w\}$ is a separator in G.

CASE 2. $A \cap B = \emptyset$.

Let T be a triangle in G, let z be a vertex in B and let N denote the neighborhood of z. Lemmas 3.3 and 3.4 guarantee that G contains no three vertex-disjoint paths from N to T; now, by Menger's theorem, G contains a set S of at most two vertices such that $G - S$ contains no path from N to T. Observe that S is a separator in G. □

3.4. Proof of Theorem 2.4. The following simple fact will be used quite a few times.

LEMMA 3.5. *Let G be a graph with a chordless path $x_1x_2\dots x_n$ such that $n \geq 5$; let z be a vertex of G such that*

- *$zx_j \in E$ if and only if j is one of $1, 2, n-1, n$*

and such that

- *$x_2x_3\dots x_{n-1}$ is a connected component of $G - \{z, x_1, x_n\}$.*

If G is friendly, then $G - \{zx_1, zx_2, zx_{n-1}, zx_n\}$ is friendly; if G contains no odd hole, then $G - \{zx_1, zx_2, zx_{n-1}, zx_n\}$ contains no odd hole.

Proof. First of all, note that

(i) zx_1x_2 is the only triangle containing zx_1

(any other triangle zx_1y would form a dart with x_2 and x_{n-1}); similarly,

(ii) zx_nx_{n-1} is the only triangle containing zx_n.

Now write $F = G - \{zx_2, zx_{n-1}\}$. It is a routine matter to verify, using (i) and (ii), that F is friendly. The only hole in F that has a chord in G is $zx_1x_2\dots x_n$; if this hole is odd, then $zx_2x_3\dots x_{n-1}$ is an odd hole in G. The rest follows from (i) and (ii) by two applications of Lemma 3.2. □

Unless indicated otherwise, we shall use $a_1, \dots, a_i, a_{i+1}, \dots, a_m$ and z to denote the vertices of a generic bat just as we did in its definition: the bat consists of a chordless path $a_1a_2\dots a_m$ and an additional vertex z that is adjacent to a_1, a_i, a_{i+1}, a_m for some i with $3 \leq i \leq m-3$ and to no other a_j. Trivially, if a friendly graph contains a bat, then the triangle za_ia_{i+1} in the bat extends into a unique maximal clique; we shall often rely tacitly on a lemma that guarantees a stronger conclusion under the additional assumption that the friendly graph contains no odd hole.

LEMMA 3.6. *If a friendly graph G containing no odd hole contains a bat, then each edge of the triangle in the bat extends into a* unique *maximal clique of G.*

Proof. Since za_ia_{i+1} extends into a unique maximal clique, our task reduces to proving that no vertex of G other than z, a_i, a_{i+1} is adjacent to precisely two of

z, a_i, a_{i+1}. Assume the contrary. Symmetry allows us to distinguish between two cases.

CASE 1. *G includes a vertex x such that $xz \in E$, $xa_i \in E$, $xa_{i+1} \notin E$, and $x \neq a_{i+1}$.*

We must first have $xa_{i-1} \in E$ (else $a_{i-1}a_ia_{i+1}zx$ is a dart) and $xa_1 \in E$ (else $a_1a_ia_{i+1}zx$ is a dart) and $xa_m \in E$ (else $a_mzxa_ia_{i+1}$ is a dart), and then $i = 3$ (else $a_1a_{i-1}a_mzx$ is a dart). However, then $a_1a_2a_3a_mx$ is a dart, a contradiction.

CASE 2. *G includes a vertex x such that $xa_i \in E$, $xa_{i+1} \in E$, $xz \notin E$, and $x \neq z$.*

We must first have $xa_{i-1} \in E$ (else $a_{i-1}a_ia_{i+1}xz$ is a dart) and $xa_{i+2} \in E$ (else $a_{i+2}a_{i+1}a_ixz$ is a dart), and then $xa_j \notin E$ whenever $1 \leq j \leq i-2$ (else $a_jxa_{i+1}a_ia_{i+2}$ is a dart). However, then one of the holes $za_1a_2 \ldots a_iz$ and $za_1a_2 \ldots a_{i-1}xa_{i+1}z$ is odd, a contradiction. □

A path in G will be called *x-sparse* if it is chordless and contains no x-edge.

LEMMA 3.7. *Let a friendly graph containing no odd hole contain a bat. Then every z-sparse path joining the two wing-tips of the bat passes through the maximal clique that contains the triangle of the bat.*

Proof. Consider a counterexample G with the smallest number of edges. Some portion $b_1b_2 \ldots b_n$ of the z-sparse path is vertex-disjoint from the bat, with b_1 having at least one neighbor in $A[a_1, a_{i-1}]$ and with b_n having at least one neighbor in $A[a_{i+2}, a_m]$. Write $B = b_1b_2 \ldots b_n$. Since B is a portion of a z-sparse path from a_1 to a_m, neither a_1b_1 nor b_na_m is a z-edge. Minimality of G guarantees that

- every vertex of G belongs either to the bat or to B;
- no edges of G go from $A[a_1, a_{i-1}]$ to $B - b_1$;
- no edges of G go from $A[a_{i+2}, a_m]$ to $B - b_n$.

Furthermore, Lemma 3.2 and minimality of G guarantee that

- every edge of G that belongs neither to the bat nor to B has at least one of the four vertices a_i, a_{i+1}, b_1, b_n for an endpoint:

all other edges would have the form zb_j with $1 < j < n$, and so they could be removed.

CASE 1. *There are subscripts s, t such that $s < t$, $a_ib_t \in E$, $a_{i+1}b_s \in E$.*

Let t be as small as possible subject to the assumption of this case; once t has been fixed, let s be as large as possible subject to the assumption of this case. By Lemma 3.2 and minimality of G, each of the two edges $a_ib_t, a_{i+1}b_s$ extends into a triangle; since $a_ib_s \notin E$ and $a_{i+1}b_t \notin E$, it follows that $a_{i+1}b_{s-1}, a_ib_{t+1} \in E$.

SUBCASE 1.1. *$a_{i+1}b_r \in E$ for some r with $r < s - 1$.*

Let r be as large as possible subject to the assumption of this case. Since G is friendly, we have $r \leq s - 3$ (consider the neighborhood of a_{i+1}); maximality of r guarantees that $a_{i+1}b_j \notin E$ whenever $r < j < s - 1$; minimality of t guarantees that $a_ib_j \notin E$ whenever $r < j < s-1$. By Lemma 3.2 and minimality of G, the edge $a_{i+1}b_r$ extends into a triangle; since $a_ib_r \notin E$, it follows that $a_{i+1}b_{r-1} \in E$. However, then $G, B[b_{r-1}, b_s]$, and a_{i+1} satisfy the hypothesis of Lemma 3.5, and so the minimality of G is contradicted.

SUBCASE 1.2. *$a_{i+1}b_r \in E$ for no r with $r < s - 1$.*

Let F denote the subgraph of G induced by $A[a_1, a_i]$ and $B[b_1, b_{s-1}]$. By assumption of this case, no vertex of F other than a_i and b_{s-1} is adjacent to a_{i+1}; trivially, F contains a chordless path P from a_i to b_{s-1}. By Lemma 3.1, the subgraph of G induced by the union of P, a_{i+1}, and $B[b_s, b_t]$ contains an odd hole.

CASE 2. *There are no subscripts s, t such that $s < t$, $a_ib_t \in E$, $a_{i+1}b_s \in E$.*

By assumption of this case, there is a subscript j such that a_i is adjacent to none of $b_j, b_{j+1}, \ldots, b_n$ and such that a_{i+1} is adjacent to none of $b_1, b_2, \ldots, b_{j-1}$. Trivially,

$G - \{z, a_i\}$ contains a chordless path C from a_1 to a_{i+1} and $G - \{z, a_{i+1}\}$ contains a chordless path D from a_i to a_m. Since a_1 and a_{i+1} belong to distinct components of $G - \{z, a_i, b_j\}$, path C must pass through b_j; since a_i and a_m belong to distinct components of $G - \{z, a_{i+1}, b_j\}$, path D must also pass through b_j. Write

$$C_1 = C[a_1, b_j], \quad C_2 = C[b_j, a_{i+1}], \quad D_1 = D[a_i, b_j], \quad D_2 = D[b_j, a_m];$$

let c_k and d_k denote the number of edges in C_k and D_k, respectively. Since at least one of the four numbers $c_1 + c_2 + 2$, $d_1 + d_2 + 2$, $c_1 + d_2 + 2$, $d_1 + c_2 + 1$ is odd, at least one of the four cycles Cz, Dz, C_1D_2z, D_1C_2 is odd. Since none of the four subgraphs of G induced by these four cycles contains a triangle (in particular, neither za_ib_1 nor $za_{i+1}b_n$ is a triangle as the neighborhood of z consists of vertex-disjoint cliques), it follows that G contains an odd hole. □

By a *z-splitter*, we mean a bat (with head z) along with a z-sparse path between the two wing-tips of the bat that passes through one of a_i, a_{i+1}.

LEMMA 3.8. *Let G be a friendly graph containing no odd hole and let z be a vertex of G such that G contains a z-splitter. Then G contains a fragile bat with head z.*

Proof. Among all counterexamples (G, z), choose one with G having as few edges as possible. In this G and for this z, consider a z-splitter with as few vertices as possible.

Symmetry allows us to assume that the z-sparse path between the two wing-tips of the bat in the z-splitter passes through a_{i+1}; now minimality of the z-splitter implies that this path has the form $XBA[a_{i+1}, a_m]$ with X a prefix of $A[a_1, a_i)$. Write $B = b_1b_2 \dots b_n$. Minimality of the z-splitter guarantees that

- B is chordless and vertex-disjoint from A;
- no vertex in $A[a_1, a_i)$ has a neighbor in $B(b_1, b_n]$;
- a_{i+1} is adjacent to no vertex in $B[b_1, b_n)$.

We claim that

(α) some vertex in $A(a_1, a_i)$ is adjacent to b_1.

To justify this claim, assume the contrary: no vertex in $A(a_1, a_i)$ has a neighbor in B. With F standing for the graph induced in G by $\{z\} \cup A[a_1, a_{i+1}] \cup B$, Lemma 3.1 guarantees that za_ia_{i+1} is not the only triangle in F; as $XBA[a_{i+1}, a_m]$ is a z-sparse path, all other triangles in F must have the form $a_ib_kb_{k+1}$ with $1 \le k < n$. Let k be the smallest subscript such that $a_ib_k \in E$, write $b_0 = a_1$, and let j be the largest subscript such that $zb_j \in E$ and $0 \le j < k$. Now the path $b_j \dots b_ka_i \dots a_m$ and z induce in G a bat with head z, whose wing-tips b_j and a_m are joined by the z-sparse path $b_j \dots b_na_{i+1} \dots a_m$. Hence minimality of our z-splitter is contradicted: a proper subset of its vertex-set (a_2 is missing) induces another z-splitter. This contradiction completes the justification of (α).

Furthermore, we claim that

(β) z has no neighbor in B.

To justify this claim, assume the contrary and let k be the smallest subscript such that $zb_k \in E$; note that (since $XBA[a_{i+1}, a_m]$ is z-sparse) $k < n$. If $a_ib_s \in E$ for some s such that $1 \le s \le k$, then let s be the largest subscript with this property, note that (since $a_{i+1}b_k \notin E$) $s < k$, and set $r = i$; else let r be the largest subscript such that $a_rb_1 \in E$ and set $s = 1$. In either case, the path $b_k \dots b_sa_r \dots a_m$ and z induce in G a bat with head z, whose wing-tips b_k and a_m are joined by the z-sparse path $b_k \dots b_na_{i+1} \dots a_m$. Hence minimality of our z-splitter is contradicted: a proper

subset of its vertex-set (a_1 is missing) induces another z-splitter. This contradiction completes the justification of (β).

Lemma 3.7 guarantees that

- no edge of G goes from $A[a_1, a_i) \cup B$ to $A(a_{i+1}, a_m]$.

Let K denote the maximal clique in G that contains the triangle za_ia_{i+1}. Since (G, z) is a counterexample, a_1 and a_m belong to the same component of $G - K$. Hence there is a path $c_1c_2 \dots c_p$ in $G - K$ such that c_1 has a neighbor in $A[a_1, a_i) \cup B$ and c_p has a neighbor in $A(a_{i+1}, a_m]$; among all such paths, choose one with p as small as possible and write $C = c_1c_2 \dots c_p$. Minimality of p guarantees that

- C is chordless and vertex-disjoint from $A[a_1, a_i) \cup B \cup A(a_{i+1}, a_m]$;
- no vertex of $C(c_1, c_p]$ has a neighbor in $A[a_1, a_i) \cup B$;
- no vertex of $C[c_1, c_p)$ has a neighbor in $A(a_{i+1}, a_m]$.

With G_0 standing for the subgraph of G induced by the union of the splitter and C, observe that G_0 has no clique-cutset K' such that $z \in K'$. Hence (G_0, z) is also a counterexample; now mimimality of G guarantees that

- G has no vertices outside the splitter and C.

Lemma 3.2 and minimality of G guarantee that

- every edge a_ic_j extends into a triangle;
- every edge $a_{i+1}c_j$ extends into a triangle;

note that

- if a_ic_jx is a triangle and $j > 1$, then $x = c_{j-1}$ or $x = c_{j+1}$;
- if $a_{i+1}c_jx$ is a triangle and $1 < j < p$, then $x = c_{j-1}$ or $x = c_{j+1}$.

There is a chordless path from a_1 to a_m of the form YCZ such that Y is a prefix of XB and Z is a suffix of $A(a_{i+1}, a_m]$; Lemma 3.7 guarantees that this path is not z-sparse; since neither Y nor Z contains a z-edge, it follows that C includes at least one neighbor of z. Let v denote the first neighbor of z on C.

We claim that

(γ) no edge of G goes from $A[a_1, a_{i+1}) \cup B \cup C[c_1, v)$ to $A(a_{i+1}, a_m] \cup C(v, c_p]$.

To justify this claim, assume the contrary. This assumption implies that some edge of G joins a_i to a vertex in $C(v, c_p]$; it follows that $C[v, c_p]$ contains an a_i-edge. There is a suffix Y of $A(a_{i+1}, a_m]$ such that $C[v, c_p]Y$ is a chordless path; write $D = C[v, c_p]Y$ and note that (as D is vertex-disjoint from K) each vertex of D is adjacent to at most one of z, a_i, and a_{i+1}. Consider a minimal portion $D[x, y]$ of D such that x, y are neighbors of z and such that $D[x, y]$ contains an a_i-edge; note that no vertex of $D(x, y)$ is adjacent to z. If $D[x, y]$ contains precisely one a_i-edge, then the subgraph of G induced by $D[x, y] \cup \{z, a_i\}$ satisfies the hypothesis of Lemma 3.1, and so G contains an odd hole. Hence $D[x, y]$ contains at least two a_i-edges. These two a_i-edges lie on $C[v, c_p]$; consider a minimal portion $C[c_r, c_s]$ of $C[v, c_p] \cap D(x, y)$ that contains two a_k-edges with $k = i$ or $k = i + 1$. Lemma 3.5 and minimality of G guarantee that $C(c_r, c_s)$ is not a connected component of $G - \{a_k, c_r, c_s\}$; it follows that some vertex of $C(c_r, c_s)$ is adjacent to a_t with $\{t, k\} = \{i, i + 1\}$; now $C(c_r, c_s)$ contains precisely one a_t-edge and no a_k-edge. However, then Lemma 3.1 guarantees that the subgraph of G induced by $C(c_r, c_s) \cup \{a_i, a_{i+1}\}$ contains an odd hole; this contradiction completes the justification of (γ).

The subgraph of G induced by $A[a_{i+1}, a_m] \cup C[v, c_p]$ contains a chordless path from a_{i+1} to v; let P denote this path. We propose to find, in the subgraph of G induced by $A[a_1, a_{i+1}] \cup B \cup C[c_1, v]$, chordless paths P_0, P_1 from v to a_{i+1} such that P_0 has an even number of edges and P_1 has an odd number of edges. This will complete

the proof of Lemma 3.8: one of the cycles P_0P and P_1P is odd and, by virtue of (γ), chordless.

In finding P_0 and P_1, we shall rely tacitly on the fact that

- the subgraph of G induced by $A(a_1, a_i) \cup B$ is connected and includes no neighbor of z,

which is guaranteed by (α) and (β).

CASE 1. *At least one of a_i and a_{i+1} has a neighbor in $C[c_1, v)$.*

Since the subgraph of G induced by $A[a_1, a_i) \cup B \cup C[c_1, v] \cup \{a_{i+1}\}$ is connected, it contains a chordless path P_0 from v to a_{i+1}; by assumption of this case, $c_1 \neq v$, and so $a_1v \notin E$; it follows that P_0 is z-sparse. Since the subgraph of G induced by P_0 and z contains no triangle, it must be bipartite; in particular, the cycle P_0z must be even; hence P_0 has an even number of edges.

Let u be the last vertex on $C[c_1, v)$ adjacent to one of a_i, a_{i+1}. If $ua_{i+1} \in E$ and u has a neighbor in $A[a_1, a_i)$, then $u = c_1$; in this case, let w denote the last neighbor of u on $A[a_1, a_i]$; Lemma 3.1 guarantees that the subgraph of G induced by z, $A[w, a_{i+1}]$, and $C[u, v]$ contains an odd hole. If $ua_{i+1} \in E$ and u has no neighbor in $A[a_1, a_i)$, then $A[a_1, a_{i+1}]C[u, v]$ and z induce a bat whose wing-tips are joined by a z-sparse path in the subgraph of G induced by $A[a_1, a_i) \cup B \cup C[c_1, v]$, contradicting Lemma 3.7. Hence $ua_i \in E$. With Q standing for $C[u, v]$ reversed, write $P_1 = Qa_ia_{i+1}$; since $P_1[v, a_i]z$ is a hole, P_1 has an odd number of edges.

CASE 2. *Neither a_i nor a_{i+1} has a neighbor in $C[c_1, v)$.*

SUBCASE 2.1. *c_1 has a neighbor in $A(a_1, a_i) \cup B[b_1, b_n)$.*

By assumption of this subcase, the subgraph of G induced by $A(a_1, a_i) \cup B \cup \{a_{i+1}\} \cup C[c_1, v]$ contains a chordless path P_0 from v to a_{i+1} and the subgraph of G induced by $A(a_1, a_i] \cup B[b_1, b_n) \cup C[c_1, v]$ contains a chordless path Q from v to a_i. Observe that each of P_0z, Qz is a hole, and so each of P_0, Q has an even number of edges. Set $P_1 = Qa_{i+1}$ and observe that P_1 is a chordless path.

SUBCASE 2.2. *c_1 has no neighbor in $A(a_1, a_i) \cup B[b_1, b_n)$.*

The subgraph of G induced by $A(a_1, a_i] \cup B$ contains a chordless path Q from b_n to a_i. Since G contains no odd hole, its subgraph induced by $Q \cup C[c_1, v] \cup \{z, a_{i+1}\}$ must not satisfy the hypothesis of Lemma 3.1; under the assumption of this subcase, this means $c_1b_n \notin E$. Hence a_1 is the unique neighbor of c_1 in $A[a_1, a_i) \cup B$.

The subgraph of G induced by $A[a_1, a_i) \cup B \cup \{a_{i+1}\}$ contains a chordless path S from a_1 to a_{i+1}. Observe that each of $A[a_1, a_i]z$, Sz is a hole, and so each of $A[a_1, a_i]$, S has an even number of edges. With R standing for $C[c_1, v]$ reversed, each of $RA[a_1, a_{i+1}]$ and RS is a chordless path; one of these paths has an even number of edges and the other has an odd number of edges. □

A path $w_1w_2 \dots w_m$ in G will be called *z-special* if

- $w_1w_2 \dots w_m$ is a chordless path in $G * z$,
- w_1 and w_m are neighbors of z,
- z has at least two neighbors in $w_2w_3 \dots w_{m-1}$, the set N of these neighbors forms a clique, and $w_1w \notin E, w_mw \notin E$ whenever $w \in N$.

(Note that w_1 and w_m may or may not be adjacent.)

LEMMA 3.9. *Let G be a friendly graph containing no odd hole and let z be a vertex of G such that z is the center of a claw. If G contains a z-special path, then G and z have at least one of the following properties:*

(i) *G contains a fragile bat with head z;*

(ii) *G contains a clique-cutset K such that $z \in K$ and some component of $G - K$ includes no neighbor of z.*

Proof. Note that the neighborhood of z consists of vertex-disjoint cliques. We shall proceed by induction on the number of neighbors of z on the z-special path. Let A denote the z-special path; write $A = a_1 a_2 \dots a_m$; let a_i be the first neighbor of z on $A(a_1, a_m)$ and let a_j be the last neighbor of z on $A(a_1, a_m)$; let K denote the maximal clique in G that contains z and all its neighbors on $A(a_1, a_m)$. Write

$$A_O = A[a_1, a_i) \cup A(a_j, a_m] \text{ and } A_I = A(a_i, a_j) - K.$$

(The subscripts O and I are mnemonic for "outside" and "inside".) If A_O and A_I belong to the same connected component of $G - K$, then $G - K$ contains a path $b_1 b_2 \dots b_n$ such that b_1 has a neighbor in A_O and b_n has a neighbor in A_I. If A_O and A_I belong to distinct connected components of $G - K$, then consider a component Q of $G - K$ that includes a vertex of A_I: unless (ii) holds (in which case we are done), Q includes a neighbor of z, and so Q contains a path $b_1 b_2 \dots b_n$ such that b_1 is a neighbor of z and b_n has a neighbor in A_I. Hence we may assume in any case that $G - K$ contains a path $b_1 b_2 \dots b_n$ such that

- b_1 has a neighbor in $A_O \cup \{z\}$;
- b_n has a neighbor in A_I;

taking n as small as possible, we may assume further that

- $b_1 b_2 \dots b_n$ is chordless and vertex-disjoint from A;
- no b_k with $k > 1$ has a neighbor in $A_O \cup \{z\}$;
- no b_k with $k < n$ has a neighbor in A_I.

Write $B = b_1 b_2 \dots b_n$ and note that

- every neighbor of z in $A \cup B$ belongs to $K \cup \{a_1, a_m, b_1\}$.

Let F denote the subgraph of $G * z$ induced by $A \cup B$.

Case 1. *b_1 has no neighbor in A_O.*

F contains a chordless path C from b_1 to a_1 that avoids $A[a_j, a_m]$; by assumption of this case, C must pass through a_i; if some other interior vertex of C also belongs to K, then C is z-special and we are done by the induction hypothesis; hence we may assume that b_1, a_i, a_1 are the only neighbors of z on C; in particular, C is z-sparse. Similarly, F contains a z-sparse path D from b_1 to a_m such that D avoids $A[a_1, a_i]$ and such that b_1, a_j, a_m are the only neighbors of z on D.

If a_j has no neighbor on $C[b_1, a_i)$, then $C[b_1, a_i]$, $A[a_j, a_m]$, and z induce in G a bat with head z, whose wing-tips are joined by the z-sparse path D, and so (i) follows by Lemma 3.8. If a_j has a neighbor on $C[b_1, a_i)$, then let x be the first neighbor of a_j on $C[b_1, a_i)$; note that x is not the last vertex on $C[b_1, a_i)$ (else $x a_i z a_j a_{j+1}$ would be a dart); now $C[b_1, x] a_j$, $A[a_1, a_i]$, and z induce in G a bat with head z, whose wing-tips are joined by the z-sparse path C, and so (i) follows again by Lemma 3.8.

Case 2. *At least one of $z b_1 a_1$ and $z b_1 a_m$ is a triangle.*

Symmetry allows us to assume that $z b_1 a_1$ is a triangle.

Subcase 2.1. *b_1 has no neighbor in $A(a_1, a_i)$.*

F contains a chordless path C from b_1 to a_1 that avoids $A[a_j, a_m]$; by assumption of this subcase, C must pass through a_i. Lemma 3.1 applied to the subgraph of G induced by $C \cup \{z\}$ guarantees that a_i is not the only interior vertex of C that belongs to K. Hence C is z-special and we are done by the induction hypothesis.

Subcase 2.2. *b_1 has a neighbor in $A(a_1, a_i)$ and it has a neighbor in $A(a_j, a_m]$.*

Let u be the last neighbor of b_1 on $A(a_1, a_i)$ and let v be the first neighbor of b_1 on $A(a_j, a_m]$; Lemma 3.1 guarantees that $z a_i a_j$ is not the only triangle in the subgraph

of G induced by $A[u, a_i] \cup A[a_j, v] \cup \{b_1, z\}$. Hence $v = a_m$, which brings us back to a mirror image of Subcase 2.1.

SUBCASE 2.3. *b_1 has a neighbor in $A(a_1, a_i)$ and it has no neighbor in $A(a_j, a_m]$.*

F contains a chordless path C from b_1 to a_m that avoids $A[a_1, a_i]$; by assumption of this subcase, C must pass through a_j. If C is z-special, then we are done by the induction hypothesis; hence we may assume that a_j is the only interior vertex of C that belongs to K. With x standing for the last neighbor of b_1 on $A(a_1, a_i)$, observe that $b_1A[x, a_i]A[a_j, a_m]$ and z induce a bat in G, whose wing-tips are joined by the z-sparse path C; hence (i) follows by Lemma 3.8.

CASE 3. *b_1 has a neighbor in A_O; neither zb_1a_1 nor zb_1a_m is a triangle.*

By assumption of this case, F contains a chordless path C from a_1 to a_m that avoids at least one of a_i and a_j and has the following property: *If b_1 appears on C at all, then it appears either before all the vertices of $C \cap K$ or after all the vertices of $C \cap K$.* If C includes at least two vertices of K, then C is z-special or else one of $C[a_1, b_1]$, $C[b_1, a_m]$ is z-special and we are done by the induction hypothesis; hence we may assume that

- C includes at most one vertex of K.

Note that

- if C includes a vertex of K, then this vertex is a_i or a_j.

The assumption of this case guarantees that

- C has no chords in G except possibly a_1a_m.

If $a_1a_m \notin E$, then $A[a_1, a_i]$, $A[a_j, a_m]$, and z induce a bat with head z, whose wing-tips are joined by the z-sparse path C; Lemma 3.7 guarantees that C includes a vertex of K; hence the bat and C constitute a splitter and (i) follows by Lemma 3.8. We propose to complete the proof by deriving a contradiction from the assumption that

- $a_1a_m \in E$.

Since C includes no z-edge, Lemma 3.1 applied to the subgraph of G induced by $C \cup \{z\}$ guarantees that

- no interior vertex of C is adjacent to z.

Now all the vertices of C come from $(A \cup B) - K$, which is $A_O \cup A_I \cup B$. With F_0 standing for the subgraph of $G * z$ induced by $A_O \cup A_I \cup B$, observe that $A[a_1, a_i)$ is a connected component of $F_0 - b_1$ and that $A(a_j, a_m]$ is another; it follows that

- $C = A[a_1, x]b_1A[y, a_m]$

for some x on $A[a_1, a_i)$ and some y on $A(a_j, a_m]$.

SUBCASE 3.1. *$x = a_{i-1}$ and $y = a_{j+1}$.*

Let H_1 denote the subgraph of G induced by $A[a_1, a_i] \cup A[a_j, a_m]$ and let H_2 denote the subgraph of G induced by C. By definition, H_1 is a hole of length at least six; by assumption of this subcase, H_2 is a hole whose length is one less than the length of H_1. Hence one of H_1, H_2 is odd, a contradiction.

SUBCASE 3.2. *$x \neq a_{i-1}$ or $y \neq a_{j+1}$.*

Symmetry allows us to assume that $x \neq a_{i-1}$. Observe that B extends into a chordless path D in F such that D leads from b_1 to some vertex in $A \cap K$ other than a_j and such that no interior vertex of D has a neighbor in $A_O \cup \{z\}$. Lemma 3.1 is contradicted by the subgraph of G induced by C, z, and D. □

LEMMA 3.10. *Let G be a friendly graph containing no odd hole and let xyz be a triangle in G such that z is the center of a claw; let K be the maximal clique in G that contains the triangle xyz. If $G * z$ contains a chordless path P from x to y such that some neighbor of z on P does not belong to K, then G and z have at least one of the following properties:*

(i) *G contains a fragile bat with head z;*

(ii) *G contains a clique-cutset K' such that $z \in K'$ and some component of $G - K'$ includes no neighbor of z.*

Proof. The neighborhood of z consists of vertex-disjoint cliques $K_1, K_2, \ldots, K_m$ such that $K = K_1$. By assumption, $G * z$ contains a chordless path P from x to y such that some neighbor of z on P does not belong to K_1. Let $P[a, f]$ be a minimal segment of P such that a, f belong to the same K_r and some vertex of $P(a, f)$ belongs to a K_s with $s \neq r$; write $Q = P[a, f]$. By minimality of Q, no interior vertex of Q belongs to K_r; Lemma 3.1 guarantees that the subgraph of G induced by Q and z contains a triangle other than zaf; hence some two interior vertices of Q belong to the same K_t. Let c and d be the first and the last vertex in Q that belong to K_t; note that (by minimality of Q) all the neighbors of z in $Q[c, d]$ belong to K_t. Let b be the last neighbor of z in $Q[a, c)$ and let e be the first neighbor of z in $Q(d, f]$. Then $Q[b, e]$ is a z-special path and the desired conclusion follows by Lemma 3.9. ∎

Proof of Theorem 2.4. Note that the assumption

"a_1 and a_m belong to the same component of $G * z$"

is equivalent to the assumption

"a_i and a_{i+1} belong to the same component of $G * z$."

Write $A = a_1 a_2 \ldots a_m$ and let K denote the maximal clique in G that contains the triangle za_ia_{i+1}. We may assume that the bat is not fragile: $G - K$ contains a path from a_1 to a_m. Hence $G - a_ia_{i+1}$ contains a path P from a_i to a_{i+1} with all interior vertices outside K; write $P = p_1 p_2 \ldots p_t$.

Case 1. *P contains no z-edge.*

Now P is a path in $G * z$; we may assume that P is a chordless path in $G * z$ (but not necessarily a chordless path in $G - a_ia_{i+1}$); then Lemma 3.10 allows us to assume that no interior vertex of P is adjacent to z. Since $G * z$ contains the path $A[a_1, a_i]PA[a_{i+1}, a_m]$, it contains a chordless path Q from a_1 to a_m such that all neighbors of z on Q come from $\{a_1, a_i, a_{i+1}, a_m\}$; Lemma 3.7 guarantees that Q contains at least one of a_i, a_{i+1}. If Q contains precisely one of a_i, a_{i+1}, then the desired conclusion follows from Lemma 3.8; else the desired conclusion follows from Lemma 3.9.

Case 2. *P contains precisely one z-edge.*

Let p_jp_{j+1} be the unique z-edge on P and let K' denote the maximal clique in G that contains the triangle zp_jp_{j+1}. Since $G * z$ contains $P[p_1, p_j]$, $P[p_{j+1}, p_t]$, and a path from p_1 to p_t, it contains a chordless path Q from p_j to p_{j+1}. Lemma 3.10 allows us to assume that all the neighbors of z on Q come from K'. However, then the walk $P[p_1, p_{j-1}]QP[p_{j+2}, p_t]$ in $G * z$ contains no vertices of K other than a_i and a_{i+1}, which brings us back to Case 1.

Case 3. *P contains at least two z-edges.*

We may assume that P is a chordless path in $G - a_ia_{i+1}$. By assumption of this case, z has at least four neighbors on $P(p_1, p_t)$; with p_r standing for the first neighbor of z on $P(p_1, p_t)$ and with p_s standing for the last neighbor of z on $P(p_1, p_t)$, let us write

$$B = b_1 b_2 \ldots b_n = p_r p_{r-1} \ldots p_1 p_t p_{t-1} \ldots p_s \quad \text{and} \quad b_j = p_1, b_{j+1} = p_t.$$

Now B and z induce in G a bat; note that $b_j = a_i$, $b_{j+1} = a_{i+1}$, and so K is the maximal clique in G that contains the triangle zb_jb_{j+1} in this new bat.

By assumption, $G * z$ contains a chordless path Q from b_j to b_{j+1}; Lemma 3.10 allows us to assume that all the neighbors of z on Q come from K. Since $G * z$ contains

the path $B[b_1, b_j]QB[b_{j+1}, b_n]$, it contains a chordless path C from b_1 to b_n such that all vertices of C come from $B \cup Q$; write $C = c_1c_2 \dots c_p$. Lemma 3.7 allows us to assume that C contains at least one vertex of K; Lemma 3.9 allows us to assume that C contains at most one vertex of K; let x be the unique vertex in $C \cap K$.

Lemma 3.7 allows us to assume that

- ∘ no vertex in $C[c_1, x)$ has a neighbor in $B(b_{j+1}, b_n]$;
- ∘ no vertex in $C(x, c_p]$ has a neighbor in $B[b_1, b_j)$;

in turn, Lemma 3.8 allows us to assume that

- • x is distinct from b_j and b_{j+1};
- ∘ no vertex in $C[c_1, x)$ is adjacent to b_{j+1};
- ∘ no vertex in $C(x, c_p]$ is adjacent to b_j.

Now if x has no neighbor in $B(b_1, b_j)$, then $B[b_1, b_j]C[x, c_p]$ and z induce a bat; since this bat and C constitute a z-splitter, Lemma 3.8 allows us to assume that

- ∘ x has a neighbor in $B(b_1, b_j)$;
- ∘ x has a neighbor in $B(b_{j+1}, b_n)$.

Letting u denote the first neighbor of x in $B(b_1, b_j)$ and letting v denote the last neighbor of x in $B(b_{j+1}, b_n)$, we may just as well assume that

- • $C = B[b_1, u]xB[v, b_n]$.

Since $C \cup \{z\}$ induces a cycle in G and since zx is the unique chord of this cycle, C has an even number of edges; $B \cup \{z\}$ induces a bat in G, and so B has an odd number of edges; let us note for future reference that

- • the lengths of B and C differ in parity.

Recall that the vertex-set of P induces in G a hole H such that

- • B is a segment of H.

We propose to complete the proof by contradicting the assumption that the subgraph of G induced by $H \cup \{z, x\}$ is friendly and contains no odd hole.

For this purpose, first note that (since the neighborhood of z consists of vertex-disjoint cliques and since b_j, b_{j+1} are the only vertices of K on H),

- • z and x have no common neighbor on H other than b_j and b_{j+1}.

H is a concatenation of two paths: path B from b_1 to b_n and its counterpart $\overline{B}$ $(= H - B(b_1, b_n))$ from b_n to b_1. Starting with the subgraph F of G induced by $H \cup \{z, x\}$, keep reducing F as long as possible by the following two operations:

(α) If $\overline{B}$ contains a vertex w such that
w is adjacent to x and the edge xw extends into no triangle,
then remove the edge xw from F.

(β) If $\overline{B}$ contains a segment $w_1w_2 \dots w_d$ such that
w_1, w_2, w_{d-1}, w_d are adjacent to x,
none of $w_3, \dots, w_{d-2}$ are adjacent to x,
and none of $w_1, w_2, \dots, w_d$ are adjacent to z,
then remove the four edges $xw_1, xw_2, xw_{d-1}, xw_d$ from F.

Lemma 3.2 guarantees that the invariant

- • F is a friendly graph containing no odd hole

is maintained after each application of (α); Lemma 3.5 guarantees that this invariant is maintained after each application of (β). Now let us distinguish between two subcases.

SUBCASE 3.1. *x has a neighbor on $\overline{B}$.*

Since transformation (α) is not (any more) applicable to F, the assumption of this subcase guarantees that $\overline{B}$ contains an x-edge, e. Let $\overline{B}_0$ be a minimal segment of $\overline{B}$ that contains e, begins at a neighbor of z, and ends at a neighbor of z. Since

transformation (β) is not (any more) applicable to F, edge e is the only x-edge in $\overline{B}_0$. However, then the subgraph of F induced by $\overline{B}_0 \cup \{z, x\}$ contradicts Lemma 3.1.

SUBCASE 3.2. *x has no neighbor on $\overline{B}$.*

The concatenation of B and $\overline{B}$ is H; by assumption of this subcase, the concatenation of C and $\overline{B}$ is another hole; since the lengths of B and C differ in parity, one of these two holes is odd, a contradiction. □

4. The algorithm. Theorem 2.3 suggests a recursive algorithm that, given any friendly bat-free graph G, finds out whether or not G is a Berge graph. This algorithm, TEST(G), uses a procedure DECOMP1(G; S) that, given any friendly graph G and a separator S in G, either finds an odd hole in G at once or else constructs friendly graphs G_1 and G_2 such that

- if G is a bat-free Berge graph,
  then both of G_1 and G_2 are bat-free Berge graphs;
- if G is not a Berge graph,
  then at least one of G_1 and G_2 is not a Berge graph.

DECOMP1(G; S) goes as follows.

By definition, the set of vertices of $G - S$ splits into disjoint nonempty sets V_1 and V_2 such that no edge of G joins a vertex in V_1 to a vertex in V_2; if S consists of two nonadjacent vertices, then each V_i includes at least two vertices. Let F_i denote the subgraph of G induced by $V_i \cup S$. If S is a clique, then DECOMP1(G; S) simply returns F_1 and F_2. If S consists of nonadjacent vertices u and v, then we may assume that both $G - u$ and $G - v$ are connected (else a one-point separator could be used in place of S) and find a chordless path P_i from u to v in each F_i; now if both P_i have an odd number of edges, then DECOMP1(G; S) returns graphs G_1 and G_2 such that each G_i is F_i with one additional edge, uv; if both P_i have an even number of edges, then DECOMP1(G; S) returns graphs G_1 and G_2 such that each G_i is F_i with one additional vertex, w, and two additional edges, uw and vw; if one P_i has an odd number of edges and the other P_i has an even number of edges, then DECOMP1(G; S) returns the odd hole $P_1 \cup P_2$.

```
TEST(G):
(Step 1) if G is bipartite then return true end
(Step 2) if      G is claw-free
         then if G is a Berge graph then return true else return false end
         end
(Step 3) if G has no separator then return false end
(Step 4) S = separator in G;
         if      DECOMP1(G; S) returns graphs G1 and G2
         then return TEST(G1)∧TEST(G2);
         else    return false;
         end
```

LEMMA 4.1. *Let G be a friendly graph. If* TEST(G) *returns* true*, then G is a Berge graph; if* TEST(G) *returns* false*, then G is not a Berge graph or else G contains a bat.*

Proof. We use induction on the number of vertices of G. If TEST(G) returns *false* in Step 3, then Theorem 2.3 guarantees that G contains an odd hole or a bat. If DECOMP1(G; S) returns graphs G_1 and G_2 in Step 4, then G_1 and G_2 are both friendly; if both of them are Berge graphs, then G is a Berge graph; if at least one of them is not a Berge graph, then G is not a Berge graph; if at least one of them

contains a bat, then G contains a bat. (When S consists of vertices u and v that are nonadjacent in G and adjacent in G_i, it may help to keep in mind that u and v have no common neighbor.) □

LEMMA 4.2. TEST(G) *runs in polynomial time.*

Proof. Each step of the algorithm, except for the recursive calls to evaluate TEST(G_1) and TEST(G_2) in Step 4, can be executed in polynomial time; in particular, Step 2 can be executed in polynomial time by the algorithm of Chvátal and Sbihi [6]. Thus our task reduces to showing that the number $t(G)$ of nodes in the recursion tree of TEST(G) does not exceed some polynomial in n, the number of vertices of the input graph G.

For this purpose, first note that

$$t(G) = 1 \text{ whenever } n \leq 4$$

(since every graph with at most four vertices is bipartite or claw-free). Now induction on n shows that

$$t(G) \leq 4n - 17 \text{ whenever } n \geq 5 :$$

if G_1, G_2 are the graphs returned by DECOMP1(G;S) in Step 4, then

$$t(G) = 1 + t(G_1) + t(G_2)$$

and, with n_i standing for the number of vertices of G_i,

$$n_1 \leq n - 1,\ n_2 \leq n - 1,\ \text{and } n_1 + n_2 \leq n + 4. \qquad \square$$

Our main algorithm, given any friendly graph G, returns *true* if and only if G is a Berge graph. This algorithm, BERGE(G), is also recursive; it evolves from Theorem 2.2 much as Algorithm TEST(G) evolves from Theorem 2.3.

If G, the input of BERGE(G), contains a clique-cutset C, then we call a procedure DECOMP2(G; C) which goes as follows: Let $F_1, F_2, \ldots, F_k$ be the components of $G-C$; let G_i denote the subgraph of G induced by $F_i \cup C$; return $G_1, G_2, \ldots, G_k$.

If G contains a rosette centered at z (but G contains no clique-cutset), then we call a more complicated procedure DECOMP3(G; z) which goes as follows: Let $F_1, F_2, \ldots, F_k$ be the components of $G * z$; let G_i denote the subgraph of G induced by $F_i \cup \{z\}$. Let N denote the subgraph of G induced by all the neighbors of z; let H be the graph obtained from N by adding pairwise nonadjacent vertices $w_1, w_2, \ldots, w_k$ along with all the edges xw_i such that $x \in N \cap F_i$. Return $G_1, G_2, \ldots, G_k$ and H.

DECOMP3 is illustrated in Figure 4.1. There, G is not a Berge graph but G_1, G_2, G_3 are; the unique odd hole in G is contained in none of G_1, G_2, G_3, but it reappears in H.

In general, H may be seen as a device for detecting those odd holes in G that are contained in none of $G_1, G_2, \ldots, G_k$: at first, one might be tempted to conjecture that G is a Berge graph if and only if $G_1, G_2, \ldots, G_k$ and H are all Berge graphs. Unfortunately, this is not the case: two counterexamples are shown in Figure 4.2. Fortunately, these two counterexamples are harmless: each of them has a clique-cutset, and so it can be subjected to DECOMP2 instead of DECOMP3.

We make it our policy to subject G to DECOMP3 only if it has no clique-cutset. Under this assumption (as we shall prove later), G is a Berge graph if and only if $G_1, G_2, \ldots, G_k$ and H are all Berge graphs *and* none of $G_1, G_2, \ldots, G_k$ contains a fragile bat with head z. The proviso involving fragile bats cannot be dropped: see Figure 4.3.

A straightforward algorithm NoFB$(F; z)$, given any graph F along with a vertex z of F such that the neighborhood of z in F consists of vertex-disjoint cliques, returns *true* if and only if F contains no fragile bat with head z. There, as usual, $N(v)$ denotes the neighborhood of v.

NoFB$(F; z)$:
for all z-edges xy
do $C =$ the maximal clique of F that contains xyz;
  for all choices of distinct components A, B of $F - C$
  do if $A - N(y)$ contains a path from $N(z)$ to $N(x)$ and
    $B - N(x)$ contains a path from $N(z)$ to $N(y)$
    then return *false*;
    end
  end
end
return *true*;

Berge(G):
(Step 1) **if** G has a clique-cutset, C
  then $G_1, G_2, \ldots, G_k =$ the output of Decomp2$(G; C)$;
    return Berge$(G_1) \wedge$ Berge$(G_2) \wedge \cdots \wedge$ Berge(G_k);
  end
(Step 2) **if** G has a rosette, centered at some vertex z
  then $G_1, G_2, \ldots, G_k, H =$ the output of Decomp3$(G; z)$;
    return Berge$(G_1) \wedge$ Berge$(G_2) \wedge \cdots \wedge$ Berge(G_k)
      $\wedge$Test(H)
      $\wedge$NoFB$(G_1; z) \wedge$ NoFB$(G_2; z) \wedge \ldots$ NoFB$(G_k; z)$;
  end
(Step 3) return Test(G);

Theorem 4.3. *Given any friendly graph G, algorithm* Berge(G) *returns* true *if and only if G is a Berge graph.*

Proof. We use induction on the number of vertices of G.

Case 1. Berge(G) *returns in Step* 1.

This case is trivial.

Case 2. Berge(G) *returns in Step* 2.

It is easy to see that H is friendly and bat-free; hence Lemma 4.1 guarantees that H is a Berge graph if and only if Test$(H) =$ *true*. Thus our task reduces to proving the following statements:

(i) If G contains an odd hole, then one of $G_1, \ldots, G_k, H$ contains an odd hole or else one of $G_1, \ldots, G_k$ contains a bat with head z.

(ii) If some G_i contains a bat with head z, then it contains an odd hole or a fragile bat with head z.

(iii) Every antihole of length at least seven in G is contained in one of $G_1, \ldots, G_k$.

(iv) If H contains an odd hole, then G contains an odd hole.

(v) H contains no antihole of length at least seven.

(vi) If some G_i contains a bat with head z, then G contains an odd hole.

Proof of (i). Let G contain an odd hole. If this hole contains at most one z-edge, then it is contained in one of $G_1, \ldots, G_k$. Thus we may assume that the hole has the form $e_1P_1e_2P_2 \ldots e_tP_t$ where $e_1, e_2, \ldots, e_t$ are z-edges, $t \geq 2$, and each P_i is a chordless path in G that contains no z-edge; since P_i does not pass through z, all its edges come from some $F_{j(i)}$, and so P_i is a chordless path in $G_{j(i)} - z$. If some P_i has

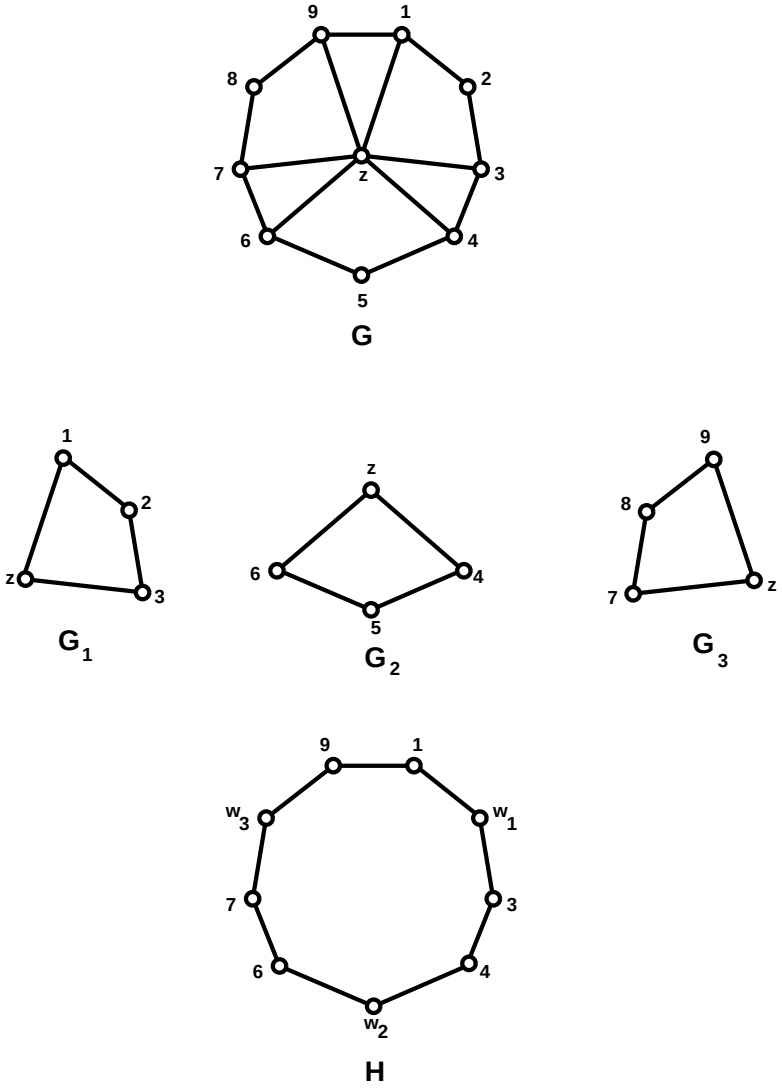

FIG. 4.1. DECOMP3 *illustrated.*

an odd number of edges, then the subgraph of G induced by $P_i \cup \{z\}$ is not bipartite; since it contains no triangle, it contains an odd hole and we are done. Thus we may assume that each P_i has an even number of edges. Now t is odd, and so the closed walk $e_1 w_{j(1)} e_2 w_{j(2)} \dots e_t w_{j(t)}$ in H has an odd length, $3t$; hence the subgraph H_0 of H induced by all the vertices of this walk is not bipartite. If H_0 contains no triangle, then it contains an odd hole and we are done. Thus we may assume that H_0 contains a triangle. It is easy to see that the triangle consists of some e_i and some w_j. However, then both endpoints of e_i belong to F_j, and so both P_{i-1} (with $P_0 = P_t$) and P_i are fully contained in F_j; the subgraph of G_j induced by $P_{i-1} \cup P_i \cup \{z\}$ contains a bat.

Proof of (ii). If some G_i contains a bat with head z, then—since $G_i * z$ is connected—Theorem 2.4 guarantees that G_i contains an odd hole (in which case we are done), or G_i contains a fragile bat with head z (in which case we are done

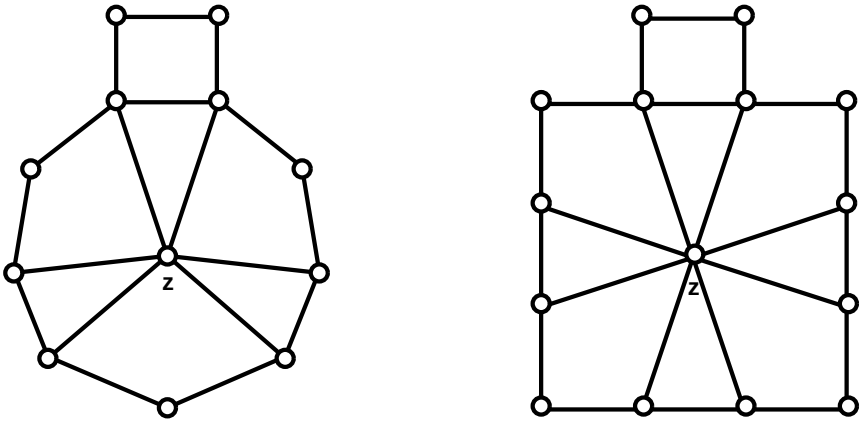

FIG. 4.2. *Clique-cutsets create counterexamples.*

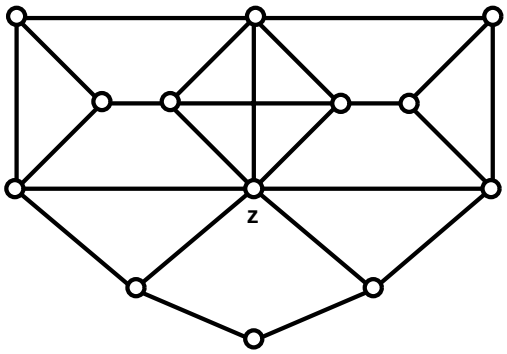

FIG. 4.3. *The significance of fragile bats.*

again), or G_i contains a clique-cutset C such that $z \in C$ and some component of G_i includes no neighbor of z (in which case C is a clique-cutset in G, contradicting our assumption that BERGE(G) does not return in Step 1).

Proof of (iii). Let A be an antihole of length at least seven in G. Observe that $z \notin A$ (since the neighborhood of z consists of vertex-disjoint cliques). If A is contained in one of $G_1, \ldots, G_k$, then we are done; else symmetry allows us to assume that A includes at least one vertex of G_1 and at least one vertex of G_2. Since A is connected, it follows that A contains an edge x_1x_2 with $x_1 \in G_1, x_2 \in G_2$. Note that x_1x_2 is a z-edge. In every antihole of length at least six, each edge is contained in a hole of length four; in particular, x_1x_2 is contained in a hole $x_1x_2y_2y_1$. Since the neighborhood of z consists of vertex-disjoint cliques and x_1, x_2 are adjacent to z, neither y_1 nor y_2 is adjacent to z. Hence $x_1y_1y_2x_2$ is a path in $G * z$ and yet its endpoints belong to distinct components of $G * z$, a contradiction.

Proof of (iv). Let H contain an odd hole. Since $w_1, w_2, \ldots, w_k$ have pairwise disjoint neighborhoods, this hole has the form

$$u_1v_1w_{j(1)}u_2v_2w_{j(2)} \ldots u_tv_tw_{j(t)}$$

such that u_1v_1, u_2v_2, $\ldots$, u_tv_t are z-edges in G and t is odd. Replacing each path $v_iw_{j(i)}u_{i+1}$ (here, $u_{t+1} = u_1$) by a chordless path P_i from v_i to u_{i+1} in $F_{j(i)}$, we obtain

a cycle C in $G - z$.

Note that each P_i, although chordless in $G * z$, may have chords in G. However, choosing C with as few edges as possible, we claim that each P_i is chordless in G or else G contains an odd hole (in which case we are done). To justify this claim, consider a chord xy of P_i in G. The assumption that C has as few edges as possible guarantees that neither x nor y equals v_i or u_{i+1} (if $x = v_i$, then we may replace v_i and P_i by y and $P[y, u_{i+1}]$); first choosing x as close to v_i as possible and then y as close to u_{i+1} as possible, we conclude that G_i contains a bat with head z. Since BERGE(G) did not return in Step 1, G has no clique-cutset; hence Theorem 2.4 guarantees that G contains an odd hole.

Now we may assume that each P_i is chordless in G. Let F denote the subgraph of G induced by the vertices of C; note that the edge-set of F partitions into edge-sets of $P_1, P_2, \ldots, P_t$ and edge-sets of pairwise vertex-disjoint cliques formed by z-edges.

If some P_i has an odd number of edges, then the subgraph of G induced by $P_i \cup \{z\}$ is not bipartite; since it contains no triangle, it contains an odd hole and we are done. Thus we may assume that each P_i has an even number of edges. Now C has an odd number of edges, and so F is not bipartite. If F contains no triangle, then it contains an odd hole and we are done. Thus we may assume that F contains a triangle.

Observe that at least one vertex of this triangle is an interior vertex of some P_i. Let u denote this vertex and let v, w denote the remaining two vertices of the triangle so that, proceeding from u along C in some cyclic order, we encounter first v and then w; let a denote the immediate predecessor of u in this order and let b denote the immediate successor of u.

Observe that uv, uw, vw are z-edges and au, ub are not; it follows that the five vertices u, v, w, a, b are distinct and (since the path P_i is chordless) the subgraph of G induced by them has no edges other than uv, uw, vw, au, ub. Hence Lemma 3.4 (with F in place of G) guarantees that F contains an odd hole (in which case we are done) or a bat. Thus we may assume that F contains a bat. The bat consists of a head x and a chordless path $a_1 a_2 \ldots a_m$ such that x is adjacent to a_1, a_i, a_{i+1}, a_m for some i with $3 \leq i \leq m - 3$ (and to no other a_j). Again, all three edges of the triangle $x a_i a_{i+1}$ must be z-edges. Since all the paths $P_1, P_2, \ldots, P_t$ are chordless in G, x and a_i cannot belong to the same P_j; hence the path $x a_1 a_2 \ldots a_i$ must involve at least one z-edge; similarly, the path $a_{i+1} a_{i+2} \ldots a_m x$ must involve at least one z-edge. Thus a_1 and a_m belong to the same component of $G * x$; since BERGE(G) did not return in Step 1, G has no clique-cutset; hence Theorem 2.4 guarantees that G contains an odd hole.

Proof of (v). Each vertex in an antihole of length at least seven has the property that its neighborhood contains a chordless path with three edges; no vertex of H has this property.

Proof of (vi). Let G_i contain a bat with head z. The two wing-tips of this bat belong to the same component of $G * z$ (this component is F_i). Now Theorem 2.4 guarantees that G contains an odd hole (in which case we are done) or G has a clique-cutset (contradicting our assumption that BERGE(G) does not return in Step 1).

CASE 3. BERGE(G) *returns in Step* 3.

Now G has neither a clique-cutset nor a rosette; hence Theorem 2.2 guarantees that G is bat-free or else G contains an odd hole; in turn, Lemma 4.1 guarantees that TEST(G) = *true* if and only if G is a Berge graph. □

THEOREM 4.4. BERGE(G) *runs in polynomial time.*

Proof. A clique-cutset in G can be found (or its absence established) in polynomial time by an algorithm designed by Whitesides [13]; evidently, a rosette in G can be found (or its absence established) in polynomial time; DECOMP2$(G; C)$, DECOMP3 $(G; z)$ and NOFB$(G_i; z)$ can be executed in polynomial time; by Lemma 4.2, TEST(H) in Step 2 and TEST(G) in Step 3 can be evaluated in polynomial time. Thus our task reduces to showing that the number $t(G)$ of nodes in the recursion tree of BERGE(G) does not exceed some polynomial in n, the number of vertices of the input graph G.

We are going to show that $t(G) \leq n^2$. More precisely, with $\overline{e}(G)$ standing for the number of edges in the complement of G, we claim that $t(G) \leq 2\overline{e}(G) + 1$. Justifying this claim by induction on $\overline{e}(G)$ amounts to proving that

$$2(\overline{e}(G_1) + \overline{e}(G_2) + \cdots + \overline{e}(G_k)) + k \leq 2\overline{e}(G)$$

whenever $G_1, \ldots, G_k$ are returned by DECOMP2$(G; C)$ or $G_1, \ldots, G_k, H$ are returned by DECOMP3$(G; z)$. A stronger inequality,

$$\overline{e}(G_1) + \overline{e}(G_2) + \cdots + \overline{e}(G_k) + \binom{k}{2} \leq \overline{e}(G),$$

follows from observing that (i) there is a clique C such that $G_i \cap G_j = C$ whenever $i \neq j$ and that (ii) for every choice of distinct i and j, there are nonadjacent vertices x_i and x_j with $x_i \in G_i - C$, $x_j \in G_j - C$. The first observation is trivial. (We have $C = \{z\}$ in case of DECOMP3.) To make the second observation in case of DECOMP2, choose any x_j in $G_j - C$. To make the second observation in case of DECOMP3, first recall that the subgraph N of G induced by the neighborhood of z consists of vertex-disjoint cliques and then note that (since G has no clique-cutset) each G_i meets at least two of these cliques; hence x_i and x_j can be chosen from two distinct cliques of N. □

Finally, Theorem 2.1 reduces the task of recognizing dart-free Berge graphs in polynomial time to the task of recognizing friendly Berge graphs in polynomial time: given any dart-free graph H, we can find in polynomial time a family $\mathbf{F}$ of pairwise vertex-disjoint friendly induced subgraphs of H such that H is a Berge graph if and only if all the members of $\mathbf{F}$ are Berge graphs. The procedure is obvious. To initialize, we set $\mathbf{F} = \{H\}$. While some member G of $\mathbf{F}$ has one of the properties (i), (ii), (iii) of Theorem 2.1, we replace it in $\mathbf{F}$ by its connected components (in case G is disconnected) or by graphs $G_1, G_2, \ldots, G_k$ such that $\overline{G}_1, \overline{G}_2, \ldots, \overline{G}_k$ are connected components of $\overline{G}$ (in case $\overline{G}$ is disconnected) or by $G - w$ such that w and some other vertex of G are adjacent twins. Upon termination, Theorem 2.1 guarantees that all the members of $\mathbf{F}$ are friendly.

Acknowledgment. We thank an anonymous referee for thoughtful comments that helped to improve the presentation of this paper.

ALGORITHMS FOR A MINIMUM VOLUME ENCLOSING SIMPLEX IN THREE DIMENSIONS*

YUNHONG ZHOU† AND SUBHASH SURI‡

Abstract. We develop a combinatorial algorithm for determining a *minimum volume simplex* enclosing a set of points in $\mathcal{R}^3$. If the *convex hull* of the points has n vertices, then our algorithm takes $\Theta(n^4)$ time. Combining our exact but slow algorithm with a simple but crude approximation technique, we also develop an ε-approximation algorithm. The algorithm computes in $O(n + 1/\varepsilon^6)$ time a simplex whose volume is within $(1 + \varepsilon)$ factor of the optimal for any $\varepsilon > 0$.

Key words. shape approximation, bounding volumes, centroid

1. Introduction.

Approximating a geometric body by a combinatorially simpler shape is a problem with many applications. In computer graphics and robotics, for instance, checking for collision between complex geometric models is frequently a computational bottleneck. Therefore, collision detection packages commonly use simple bounding objects, such as axis-aligned bounding boxes [3, 14, 16], discrete oriented polytopes [9, 13], or spheres [10] to quickly eliminate pairs whose bounding objects are collision-free. Since intersecting simple bounding objects is computationally more efficient than checking objects themselves, this heuristic performs well in practice. (Suri, Hubbard, and Hughes [21] and Zhou and Suri [23] give theoretical proofs of these heuristics.) While in computer graphics and robotics rectangular boxes and spheres tend to be the approximating shapes of choice, in many applications, such as hyperspectral imaging and remote sensing, the natural object is a bounding *simplex.*

A key information processing task in hyperspectral imaging is to determine the parameters of a linear model for a set of multidimensional data vectors. These vectors could represent a set of spectral radiances or reflectances sampled finely in wavelength. A common model is to write these data vectors as a *convex* combination of certain extreme vectors, called *endmembers.* The *full unmixing* problem, as it is often called, is to determine both the endmembers and the associated proportions. The endmembers are defined as the corners of the *smallest volume simplex* enclosing the data vectors, and thus the problem of algorithmically fitting a simplex around a set of points has been considered by various researchers in Earth sciences [4, 5, 6, 20]. The method of Erlich and Full [5] works from "inside out"—it takes a set of extreme data points as initial guesses for the endmembers, then pushes the faces of the simplex out until all the data points are in the interior. Craig's method [4] works from outside in. Fuhrmann's method [6] uses a gradient descent approach. All of these methods are heuristics and do not always compute the smallest enclosing simplex. These heuris-

tics also lack any provable bound on the relative volume of the simplex found or the worst-case analysis of the running time.

Computing circumscribing or inscribed shapes of a given class, such as simplex, is also a fundamental problem in computational convexity. The paper by Gritzmann and Klee [8] gives a broad survey of results on the basic problems of computing, approximating, or measuring the smallest volume convex sets of a class containing a given convex body. In particular, Klee [11] proved the following useful *centroid property:* if T is a minimum volume simplex enclosing a convex body P, then the centroid of each facet of T touches P. Klee and Laskowski [12] used this centroid property to develop an efficient algorithm for computing the *smallest area triangle* containing a convex polygon in the plane. Their result was shortly improved to a linear time algorithm by O'Rourke et al. [17].

1.1. Related work. O'Rourke [18] has published a technical report claiming an $O(n^4)$ time algorithm for a minimum volume simplex in $\mathcal{R}^3$. Shortly after distributing the report in 1984, however, O'Rourke discovered a fatal flaw in a crucial lemma and has since retracted the claim [*personal communication, June* 1999]. The three-dimensional smallest simplex problem has since remained open.

Unlike the minimum volume simplex, efficient algorithms are known for other enclosing shapes such as bounding boxes, spheres, or ellipsoids in three, and sometimes in any fixed, dimensions. The axis-aligned bounding box is trivially computed in $O(n)$ time for any fixed dimension by computing the span of the enclosed polytope in each dimension and taking the cross product of these intervals. When the box can be arbitrarily oriented, O'Rourke [19] describes an $O(n^3)$ algorithm in three dimensions, where n is the number of vertices of the convex polytope.

The problem of computing the smallest ball enclosing a set of points is a classical one, dating back to Sylvester in 1857. In any fixed dimension, the smallest enclosing ball can be computed in optimal linear time using the fixed-dimensional linear programming algorithm of Megiddo [15]. Using an abstraction called "LP-type problems," the smallest enclosing ellipsoid can also be computed in (randomized) linear time [7]. Unlike spheres or ellipsoids, which have constant "combinatorial dimensions," simplices do not seem amenable to the abstract framework of "LP-type problems"—specifically, the simplex problem lacks the "locality" property exploited by the LP-type scheme.

A polynomial-time algorithm for the minimum volume simplex can be obtained by formulating the problem as an instance of *cubic programming* with linear constraints in 12 variables. The simplex is defined by four vertices and thus 12 variables. The objective function is the volume of the simplex, which is a cubic function of these variables. The condition that all points of the input lie inside the simplex can be written as linear constraints. If we adopt the model that a constant number of fixed-degree multinomials can be simultaneously solved in constant time, then this optimization problem can be solved in $O(n^6)$ time, since the feasible region defined by the constraints is a convex polytope in $\mathcal{R}^{12}$.

1.2. Our contribution. We develop an $O(n^4)$ time combinatorial algorithm for computing the smallest simplex enclosing a set of points in $\mathcal{R}^3$. The *algebraic complexity* of our algorithm is a significant improvement over the previous results. In all but one case, we need only to solve a *quadratic function in one variable,* which is trivially done. In the last case, we do require solving a degree ten polynomial; however, it is a single-variable polynomial, whose roots can be found efficiently by numerical methods. Building on the earlier work by Klee [11] and Vegter and Yap [22],

we further characterize the geometric properties of an optimal simplex and develop geometric procedures for computing the local optima of each combinatorial type. Let P be a convex polytope of n vertices in $\mathcal{R}^3$. (Given a set of points S, the minimum volume enclosing simplex for S is the same as the one enclosing the convex hull of S. Thus, we may assume from now on that the underlying body to be enclosed is a convex polytope.)

If T is the smallest simplex enclosing P, then each facet of T must touch P. The centroid property of Klee [11] says that each centroid p_i lies on P.[1] This alone is insufficient for determining the simplex, since the facets of T may have rotational degrees of freedom. In particular, each facet of T may contact P in a vertex, edge, or face of P. Let us denote these contact types as V (vertex), E (edge), or F (face). We may classify enclosing simplices according to the contact types of their facets. Since each facet of T has three possible contact types, altogether there are 15 such classes, which we call *combinatorial types.* Some example combinatorial types are $FFFF$, $FFEV$, and $VVEE$. Of these, only the type $FFFF$ is trivial, in the sense that given the contacts (actual faces of P), one can easily compute the unique simplex, if there is one. The other cases require nontrivial geometric reasoning to determine the smallest simplex.

We use a theorem of Vegter and Yap [22], which says that a locally minimal simplex does not have more than four degrees of freedom, to eliminate some of these combinatorial types. (A simplex's degree of freedom is the sum of its facets' degrees of freedom. A facet's degree of freedom is 0, 1, or 2, respectively, when its contact type is F, E, or V.) We add a new technical lemma to further reduce the possible combinatorial types to six plus the trivial type $FFFF$. For each of these six types, we develop geometric procedures to determine the unique simplex with the centroid property. In all but one case, our geometric procedures are highly efficient, requiring nothing more than solving a quadratic equation in one unknown. The combinatorial type $EEEE$ (all facets touching P at an edge),[2] however, proves to be quite difficult and requires computing the roots of a tenth degree polynomial. While this computation is necessarily expensive and requires numerical methods, in the standard RAM model of computation, its cost is $O(1)$.

Once we can compute the local optima for each combinatorial type in constant time, our simplex algorithm is enumerative. We test each quadruple of P (vertices, edges, and faces) as a possible contact type, check if it supports a simplex with the centroid property, and keep track of the smallest volume simplex found. The worst-case running time of this algorithm is $\Theta(n^4)$.

Next, we combine our slow but exact algorithm with a simple, fast, but crude approximation scheme to develop an ε-approximation algorithm. The algorithm computes in $O(n+\frac{1}{\varepsilon^6})$ time a simplex whose volume is within $(1+\varepsilon)$ factor of the optimal for any $\varepsilon > 0$.

2. Properties of centroids and locally optimal simplices. We assume throughout that P is a convex polytope of n vertices, and we want to compute a minimum volume simplex enclosing P. Let T denote a simplex, with vertices q_i, and facets t_i, for $1 \le i \le 4$. The facet t_i is *opposite* q_i, and let point p_i denote the *centroid* of t_i. Figure 1 illustrates these basic definitions. We recall from elementary geometry that if $\triangle abc$ is a triangle in $\mathcal{R}^3$ and d is the centroid of $\triangle abc$, then $d = (a+b+c)/3$.

[1] Recall that the centroid of a triangle (a, b, c) is the point $\frac{1}{3}(a+b+c)$.

[2] Vegter and Yap [22] give an example for which the type $EEEE$ simplex has local minimum.

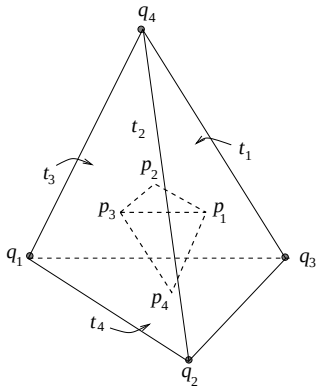

FIG. 1. *A simplex T with its vertices, faces, and centroids.*

Geometrically, d is the intersection of three median lines of $\triangle abc$. The distance from any vertex of the triangle to its opposite side is three times the distance from d to the side. For instance, the distance from a to bc is three times the distance from d to bc. The following lemma establishes two simple but useful facts relating the distances in a simplex.

LEMMA 2.1. *Let T be a simplex with vertices q_i, facets t_i, and centroids p_i, as above.*

1. *Given any pair i, j, where $1 \leq i < j \leq 4$, edges q_iq_j and p_ip_j are parallel; $q_iq_j = 3p_ip_j$; and vectors $\overrightarrow{q_iq_j}$ and $\overrightarrow{p_ip_j}$ are oppositely directed.*
2. *The triangle defined by three centroids is parallel to the fourth facet of T—for instance, $\triangle p_1p_2p_3$ is parallel to t_4. The distance between $\triangle p_1p_2p_3$ and t_4 is one third the distance between q_4 and t_4. The triangle $\triangle p_1p_2p_3$ is homothet to t_4, with area ratio $1/9$. By symmetry, the same holds for the other three facets.*

Proof.

1. Without loss of generality, consider $i = 1$ and $j = 2$. By the definition of centroid, we have $p_1 = (q_2 + q_3 + q_4)/3$ and $p_2 = (q_1 + q_3 + q_4)/3$. Therefore, $p_1 - p_2 = (q_2 - q_1)/3$. In vector notation, it is equivalent to $\overrightarrow{q_1q_2} = -3\overrightarrow{p_1p_2}$, which proves the claim.
2. In the triangle $\triangle q_2q_3q_4$, the distance from the centroid p_1 to edge q_2q_3 is $1/3$ the distance from q_4 and q_2q_3. Taking the vertical projection of these distances into the plane containing t_4, the distance from p_1 to t_4 is $1/3$ the distance from q_4 to t_4. A similar argument holds for p_2 and p_3. Thus, p_1, p_2, p_3 are equidistant from t_4, and therefore $\triangle p_1p_2p_3$ is parallel to t_4. Next, since $p_1p_2 \parallel q_1q_2$, $p_2p_3 \parallel q_2q_3$, and $p_3p_1 \parallel q_3q_1$, we conclude that triangles $\triangle p_1p_2p_3$ and $\triangle q_1q_2q_3$ are homothets. Furthermore, because their length ratio is $1/3$, the area ratio is $1/9$. ∎

If T is the smallest simplex enclosing P, then each facet of T must touch P. We will call T a *centroidal simplex* if all facet centroids of T lie on P. That is, T is centroidal if $p_i \in P$ for $i = 1, 2, 3, 4$. We will use the following theorem of Klee [11], which shows that a locally minimal enclosing simplex is always centroidal. (Klee proves this theorem for any dimension [11]. For the sake of completeness, we include

a proof of the centroid property in three dimensions in Appendix A.1.)

LEMMA 2.2 (centroid lemma [11]). *If T is an enclosing simplex of polytope P with locally minimal volume, then T is centroidal.*

Consider a locally minimal simplex T enclosing P. Each facet of T touches P, and this contact can be of one of three types: V (vertex), E (edge), or F (face). (That is, $T \cap P$ is a vertex, edge, or face of P.) We classify enclosing simplices according to the contact types of their facets. Since each facet of T has three possible contact types, altogether there are 15 such classes, which we call *combinatorial types.* These types are $FFFF$, $FFFE$, $FFFV$, $FFEE$, $FFEV$, $FFVV$, $FEEE$, $FEEV$, $FEVV$, $FVVV$, $EEEE$, $EEEV$, $EEVV$, $EVVV$, $VVVV$. For instance, type $FFEE$ means that simplex touches P in two faces and two edges.

A facet t of T has 0, 1, or 2 (rotational) *degrees of freedom* if the contact type of t is F, E, or V, respectively. A simplex's degree of freedom is the sum of its facets' degrees of freedom. Thus, a simplex of type $FFFF$ has zero degrees of freedom, while type $FEEV$ has four degrees of freedom. We will use the following result of Vegter and Yap [22], which says that a locally minimal simplex does not have more than four degrees of freedom.

LEMMA 2.3 (degrees of freedom [22]). *If T is an enclosing simplex of P with locally minimal volume, then T has at most four degrees of freedom.*

The "degrees of freedom" lemma allows us to exclude six of the 15 combinatorial types. We further eliminate two more types ($FFEV$ and $FFVV$) using a local perturbation argument, which leaves us seven classes of simplices to search.

LEMMA 2.4 (classification lemma). *Given a convex polytope P in $\mathcal{R}^3$, there always exists a minimum volume simplex enclosing P whose combinatorial type is one of the following seven: $FFFF$, $FFFE$, $FFFV$, $FFEE$, $FEEE$, $FEEV$, $EEEE$.*

Proof. Of the original 15 classes, we can eliminate the following six because they each have five or more degrees of freedom: $FEVV$, $FVVV$, $EEEV$, $EEVV$, $EVVV$, $VVVV$. Of the remaining nine, we show that classes $FFEV$ and $FFVV$ are nonessential, meaning that one can always find a minimum volume simplex in the remaining seven classes. Next, we show by a perturbation argument that the combinatorial types $FFEV$ and $FFVV$ are nonessential.

We perturb the vertices of P slightly to get a polytope $\hat{P}$; we use the notation $\hat{x}$ to denote the face x after the perturbation. The perturbed polytope satisfies the following condition: consider two facets $\hat{f}_1, \hat{f}_2$ and let ℓ be the line of intersection of the planes supporting these facets; then the line ℓ is *not parallel* to any plane determined by an edge $\hat{e}_3$ and a vertex $\hat{v}_4$ of $\hat{P}$, where $\hat{e}_3$ and $\hat{v}_4$ are disjoint from $\hat{f}_1, \hat{f}_2$.

We now observe that cases $FFEV$ and $FFVV$ cannot arise in this perturbed polytope. Indeed, if T is a simplex of type $FFVV$, whose facets t_1, t_2 are coplanar with facets $\hat{f}_1, \hat{f}_2$, and whose centroids p_3, p_4 are coincident with vertices $\hat{v}_3, \hat{v}_4$, then the line $\ell = t_1 \cap t_2$ is parallel to the line p_3p_4, which is parallel to $\hat{v}_3, \hat{v}_4$, and thus to the plane defined by $\hat{v}_4$ and any edge containing $\hat{v}_3$, a contradiction. Similarly, if T is a simplex of type $FFEV$, whose facets t_1, t_2 are coplanar with facets $\hat{f}_1, \hat{f}_2$, facet t_3 contains the edge $\hat{e}_3$, and the centroid p_4 is coincident with vertex $\hat{v}_4$, then the line $\ell = t_1 \cap t_2$ is parallel to the line p_3p_4. Because p_3 lies on $\hat{e}_3$, it follows that ℓ is parallel to the plane determined by edge $\hat{e}_3$ and vertex $\hat{v}_4$, again a contradiction.

If $T, \hat{T}$, respectively, are the minimum volume simplices enclosing P and $\hat{P}$, then $|\mathrm{Vol}(\hat{T}) - \mathrm{Vol}(T)| \to 0$, because $\hat{P}$ is an arbitrarily small perturbation of P. As we argued above, the minimum volume simplex for $\hat{P}$ cannot have combinatorial type $FFEV$ or $FFVV$. Let $\hat{T}'$ be the simplex enclosing P that is homothet to $\hat{T}$. Because

$\hat{P}$ is a small perturbation of P and $\hat{T}'$ is a homothetic copy of $\hat{T}$, $|\mathrm{Vol}(\hat{T}) - \mathrm{Vol}(\hat{T}')| \to 0$. Therefore, we have $|\mathrm{Vol}(\hat{T}') - \mathrm{Vol}(T)| \to 0$. In the limit of the perturbation, $\hat{T}'$ converges to a simplex T' enclosing P, with $\mathrm{Vol}(T') = \mathrm{Vol}(T)$. Furthermore, since the perturbation removes only degeneracies, the degrees of freedom can decrease only in going from $\hat{T}'$ to T'. Because T' is also the limit of $\hat{T}$ and $\hat{T}$ is centroidal, T' is centroidal with the same combinatorial type as $\hat{T}$. Thus, T' is a centroidal simplex enclosing P with the same volume as T, and its combinatorial type is neither $FFEV$ nor $FFVV$. □

3. Computing centroidal simplices. We now turn to the main contribution of our paper, which is to develop geometric procedures for computing a centroidal simplex of each combinatorial type. Specifically, given a set of four contact elements (vertices, edges, or faces of P), such that their contact types define a valid combinatorial type (Lemma 2.4), we show below how to find a centroidal simplex determined by these contacts. Observe that not every centroidal simplex necessarily encloses P, but checking for enclosure is relatively straightforward, and we discuss that in the next section. If the simplex T is defined by four vertices q_i, for $i = 1, 2, 3, 4$, where q_i has coordinates (x_i, y_i, z_i), then we have

$$A(T) = \begin{bmatrix} x_1 & y_1 & z_1 & 1 \\ x_2 & y_2 & z_2 & 1 \\ x_3 & y_3 & z_3 & 1 \\ x_4 & y_4 & z_4 & 1 \end{bmatrix} \qquad \text{and} \qquad \mathrm{Vol}(T) = \frac{1}{6}|\det(A)|.$$

The first type, $FFFF$, is quite trivial. Given four faces of P, we can easily compute the simplex defined by their supporting planes. (Intersecting three planes at a time gives the four vertices of the simplex.) We check in constant time if P lies in this simplex and, if so, compute its volume. The remaining six cases of Lemma 2.4 are less trivial.

3.1. Combinatorial type *FFFV*. Let f_1, f_2, f_3 be three faces of P and v a vertex of P. We want to compute the unique centroidal simplex determined by (f_1, f_2, f_3, v). (See Figure 1.) Let q_4 denote the intersection point of the three planes determined by f_1, f_2, f_3. Let $p_4 = v$, the centroid of facet t_4. The centroid p_1 of facet t_1 lies on the face f_1. Next, because p_1, p_4, respectively, are centroids of facets t_1, t_4, we have

$$p_1 - p_4 = \frac{(q_2 + q_3 + q_4)}{3} - \frac{(q_1 + q_2 + q_3)}{3} = \frac{(q_4 - q_1)}{3}.$$

Thus, $p_1p_4 \parallel q_1q_4$. We can now determine p_1 because it is the intersection of the plane determined by f_1 and the line passing through p_4 parallel to faces f_2 and f_3. Similarly, we can determine the centroids p_2 and p_3. Once we have all four centroids, we can compute the remaining three vertices of T from the following formula:

$$\begin{aligned} q_1 &= p_2 + p_3 + p_4 - 2p_1, \\ q_2 &= p_1 + p_3 + p_4 - 2p_2, \\ q_3 &= p_1 + p_2 + p_4 - 2p_3. \end{aligned}$$

With all four vertices of T known, we can compute its volume.

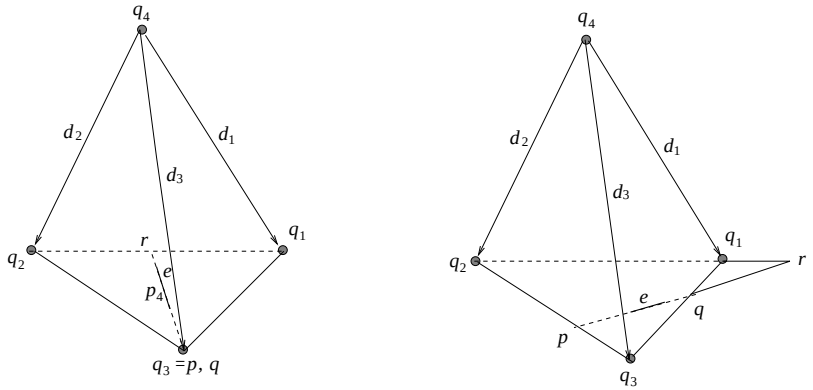

FIG. 2. *Type FFFE.* (a) *Case* 1. (b) *Case* 2.

3.2. Combinatorial type *FFFE*. Let f_1, f_2, f_3 be three faces of P and e an edge of P. We want to compute the unique centroidal simplex determined by (f_1, f_2, f_3, e). Let q_4 denote the intersection point of the three planes determined by f_1, f_2, f_3. Let p, q, r, respectively, denote the intersection points of line e with planes determined by faces f_1, f_2, f_3. (See Figure 2.) Let $\overrightarrow{d_1}, \overrightarrow{d_2}, \overrightarrow{d_3}$, respectively, be three unit vectors such that $\overrightarrow{d_i}$ is the direction of q_4q_i for $i = 1, 2, 3$. (The direction of q_4q_i can be obtained by calculating the intersection of its two adjacent faces, and the sign of $\overrightarrow{d_i}$ is chosen to ensure that P lies in the cone spanned by $\overrightarrow{d_1}, \overrightarrow{d_2}, \overrightarrow{d_3}$.)

We use a linear transform L to map q_4 to origin and $(\overrightarrow{d_1}, \overrightarrow{d_2}, \overrightarrow{d_3})$ into (x, y, z) basis. In the new coordinate system, $q_4 = (0, 0, 0)$, $p = (0, p_y, p_z)$, $q = (q_x, 0, q_z)$, $r = (r_x, r_y, 0)$. The edge e lies inside the cone spanned by $(\overrightarrow{d_1}, \overrightarrow{d_2}, \overrightarrow{d_3})$. We need to consider two cases.

1. **At least one of $p_y, p_z, q_x, q_z, r_x, r_y$ is zero.** Without loss of generality, assume that $p_y = 0$. Thus, p is collinear with q_4, q_3, and we have $p = q_3 = q$. Because the line containing e passes through q_3 and the centroid of $\triangle q_1q_2q_3$, this line is the median of $\triangle q_1q_2q_3$, and r is the middle point of q_1q_2. We can now determine $\triangle q_1q_2q_4$ because we know the vertex q_4, the directions $\overrightarrow{q_4q_1}, \overrightarrow{q_4q_2}$, and the middle point of q_1q_2. Thus, in this case, we know all the vertices of the simplex, and T is determined.
2. **None of $p_y, p_z, q_x, q_z, r_x, r_y$ is zero.** Of the three points p, q, r, two should lie on the boundary of the cone spanned by $(\overrightarrow{d_1}, \overrightarrow{d_2}, \overrightarrow{d_3})$, and one is outside. A point is outside the cone if it has one negative coordinate. Without loss of generality, we assume that p and q are on the boundary of the cone. Thus, $p_y, p_z, q_x, q_z > 0$ because they are nonzero. Suppose $q_1 = (l_x, 0, 0)$, $q_2 = (0, l_y, 0)$, and $q_3 = (0, 0, l_z)$. We get the following implications (the first because q_2, p, q_3 are collinear, and the second because q_3, q, q_1 are collinear):

$$\frac{p_y}{l_y} + \frac{p_z}{l_z} = 1 \implies l_y = \frac{p_y}{1 - \frac{p_z}{l_z}},$$
$$\frac{q_x}{l_x} + \frac{q_z}{l_z} = 1 \implies l_x = \frac{q_x}{1 - \frac{q_z}{l_z}}.$$

Thus,

$$l_x l_y l_z \;=\; \frac{p_y q_x l_z}{(1-\frac{p_z}{l_z})(1-\frac{q_z}{l_z})} \;=\; \frac{p_y q_x}{\lambda(1-p_z\lambda)(1-q_x\lambda)}, \text{ where } \lambda \;=\; \frac{1}{l_z}.$$

Because T has minimum volume, and the volume is proportional to $l_x l_y l_z$, the term $l_x l_y l_z$ should be locally minimal. We need to maximize the function $f(\lambda) = \lambda(1-p_z\lambda)(1-q_z\lambda)$. The derivative $f'(\lambda) = 3p_z q_z \lambda^2 - 2(p_z+q_z)\lambda + 1$ has the following two roots:

$$\lambda_1 = \frac{p_z + q_z - \sqrt{p_z^2 + q_z^2 - p_z q_z}}{3p_z q_z}, \quad \lambda_2 = \frac{p_z + q_z + \sqrt{p_z^2 + q_z^2 - p_z q_z}}{3p_z q_z}.$$

We claim that $0 < \lambda_1 < \min\{1/p_z, 1/q_z\} \le \lambda_2$. (This follows from straightforward algebra.) Thus, λ_2 is too big, and $\lambda = \lambda_1$ is the only choice. This yields

$$l_z \;=\; \frac{1}{\lambda} \;=\; p_z + q_z + \sqrt{p_z^2 + q_z^2 - p_z q_z}.$$

Once l_z is known, we can compute l_x and l_y, and the original coordinates of q_1, q_2, q_3 from the inverse transform L^{-1}.

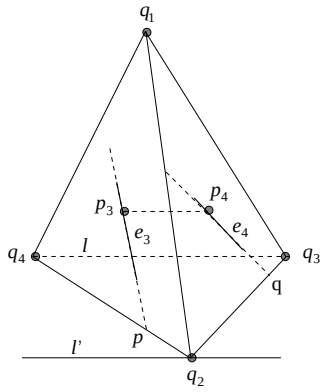

FIG. 3. *Combinatorial type FFEE.*

3.3. Combinatorial type *FFEE*. See Figure 3. Let f_1, f_2 be two faces of P and e_3, e_4 be two edges of P. We want to compute the unique centroidal simplex determined by (f_1, f_2, e_3, e_4). Assume that facets t_1, t_2 of T are determined by f_1, f_2, and facets t_3, t_4 are constrained by edges e_3, e_4. Let p_i be the centroid of facet t_i, and let line ℓ be the intersection of the planes determined by faces f_1 and f_2. Then, by Lemma 2.1, we first observe that $\ell \parallel p_3p_4$ and that $q_4q_3 = 3p_3p_4$. Let us use $c = q_4q_3$ to denote this quantity.

Let p, q, respectively, denote the intersection of plane through f_1 with lines through e_3 and e_4. Let $\overrightarrow{e_3}$, $\overrightarrow{e_4}$, and $\overrightarrow{\ell}$, respectively, denote the direction vectors of e_3, e_4, and ℓ. There exist scalars $\lambda_1, \lambda_2, \lambda_3$ such that $p_3 = p + \lambda_1 \overrightarrow{e_3}$, $p_4 = q + \lambda_2 \overrightarrow{e_4}$, and $p_3p_4 = p_4 - p_3 = \lambda_3 \overrightarrow{\ell}$. Thus,

$$p - q \;=\; -\lambda_1 \overrightarrow{e_3} + \lambda_2 \overrightarrow{e_4} - \lambda_3 \overrightarrow{\ell}. \tag{1}$$

The three equations in (1) have a unique solution for $(\lambda_1, \lambda_2, \lambda_3)$ if and only if $\det(\overrightarrow{e_3}, \overrightarrow{e_4}, \overrightarrow{\ell}) \neq 0$. The determinant $\det(\overrightarrow{e_3}, \overrightarrow{e_4}, \overrightarrow{\ell})$ is zero exactly when vectors $\overrightarrow{e_3}, \overrightarrow{e_4}, \overrightarrow{\ell}$ are dependent, which occurs exactly when e_3, e_4 are coplanar. We claim that the case when e_3, e_4 are coplanar is not needed—in Appendix A.2, we show that in this case there is an infinite family of centroidal simplices, whose limiting case is either $FFFF$ or $FFFE$. Thus, in the following, we assume that e_3, e_4 are not coplanar.

Since $\det(\overrightarrow{e_3}, \overrightarrow{e_4}, \overrightarrow{\ell}) \neq 0$, there is unique solution $(\lambda_1, \lambda_2, \lambda_3)$. With this solution, we know $p_3 = p + \lambda_1 \overrightarrow{e_3}$ and $p_4 = q + \lambda_2 \overrightarrow{e_4}$. By the centroid property, the distance from q_2 to plane t_2 is three times the distance from p_3 to t_2. We draw a line $\ell' \parallel \ell$ in the plane of t_1 whose distance to t_2 is three times the distance between p_3 and t_2. Now q_2 lies on ℓ' and $\ell' \parallel \ell$. We compute the distance between ℓ and ℓ', and let it be h. We want to fix the point q_2 on line ℓ' such that q_2p intersects with ℓ at point q_4, q_2q intersects with ℓ at point q_3, and $q_4q_3 = c$.

This can be done as follows. We choose ℓ' as the x-axis, and the line perpendicular to ℓ' as the y-axis such that line ℓ has y-coordinate h. Because q_4, p, q_2 are collinear, and q_2, q, q_3 are collinear, we have

$$(q_4q_2)_x = \frac{h * (pq_2)_x}{p_y} \qquad \text{and} \qquad (q_2q_3)_x = \frac{h * (q_2q)_x}{q_y}.$$

We plug these two equations into $q_4q_3 = c$, thus,

$$c = q_4q_3 = (q_4q_2)_x + (q_2q_3)_x = \frac{h * (pq_2)_x}{p_y} + \frac{h * (q_2q)_x}{q_y} = \frac{h * (q_{2x} - p_x)}{p_y} + \frac{h * (q_x - q_{2x})}{q_y},$$

and solve for q_{2x}:

$$q_{2x} = \frac{cp_yq_y/h + p_xq_y - q_xp_y}{q_y - p_y}.$$

Observe that we must have $p_y \neq q_y$, because otherwise $pq \parallel p_3p_4$, which would imply that e_3, e_4 are coplanar, a contradiction. From q_{2x}, we calculate q_2, and then get q_4, q_3, and finally $q_1 = 3p_3 - q_2 - q_4$. This completes the discussion of combinatorial type $FFEE$.

3.4. Combinatorial type *FEEV*. See Figure 4. Given a face f, two edges e_1, e_2, and a vertex v of P, we want to compute the unique centroidal simplex determined by (f, e_1, e_2, v). Let us suppose that $v = p_3$ is the centroid of facet t_3, while facet t_4 is coplanar with the face f. The remaining two facets of T are constrained by e_1 and e_2, with the centroid theorem ensuring that $p_1 \in e_1$ and $p_2 \in e_2$. Because the plane $p_1p_2p_3$ is parallel to t_4, if we draw a plane through p_3 and parallel to f, it will intersect e_1 at p_1 and e_2 at p_2.[3] Once p_1, p_2, p_3 are known, we can determine t_1, t_2, t_3 easily, as follows.

Since t_1 contains e_1 and $t_1 \parallel p_2p_3$, the plane containing t_1 is uniquely determined. Similarly, the plane containing t_2 is uniquely determined since t_2 contains e_2 and is parallel to p_3p_1. Once we know t_1, t_2, and t_4, this case reduces to combinatorial type $FFFV$, which has already been discussed.

[3]Observe that this construction fails if edges e_1 or e_2 are parallel to the plane $p_1p_2p_3$. This is a case of input degeneracy, since edge e_1 must be parallel to the plane determined by edge e_2 and vertex v_3. The symbolic perturbation argument of Lemma 2.4 can be used to show that this degenerate case need not be considered.

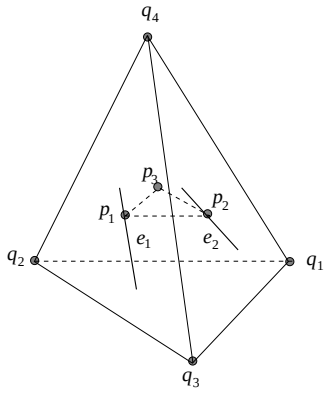

FIG. 4. *Combinatorial type FEEV.*

3.5. Combinatorial type *FEEE*. Given a face f, and three edges e_1, e_2, e_3 of P, we want to compute the unique centroidal simplex determined by (f, e_1, e_2, e_3). Let us suppose that f is coplanar with the facet t_4 of T. We first calculate the intersection points p, q, r, respectively, where the lines containing the edges e_1, e_2, e_3 intersect the plane containing f. (See Figure 5.) Next, choose any linear transform L that maps the plane containing f into the xy plane. Under this transform, the points p, q, r have new coordinates, and denote them as $p = (p_x, p_y, 0), q = (q_x, q_y, 0), r = (r_x, r_y, 0)$. Let $\overrightarrow{u}$ denote the direction of e_1 and scale it so that $\overrightarrow{u} = (u_x, u_y, 1)$. Similarly, let $\overrightarrow{v} = (v_x, v_y, 1)$ and $\overrightarrow{w} = (w_x, w_y, 1)$ denote the scaled direction of e_2 and e_3.

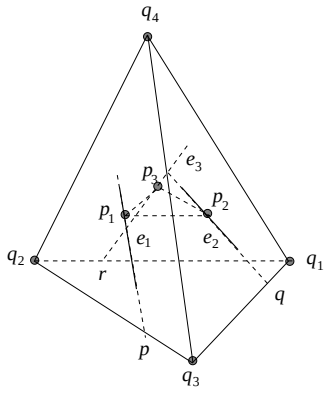

FIG. 5. *Combinatorial type FEEE.*

Since the centroid triangle $\triangle p_1, p_2, p_3$ is parallel to t_4, let h denote the common height of the three centroids p_1, p_2, p_3. The centroid p_i is also contained in edge e_i for $i = 1, 2, 3$. If h is fixed, the coordinates of the three centroids can be written as $p + hu, q + hv, r + hw$, respectively, and we know that the triangle formed by these centroids is a homothet of the base triangle t_4, with the area ratio $1/9$. Furthermore,

the height of the simplex is $3h$. Thus, the volume of the simplex can be expressed as

$$\mathrm{Vol}(T) = \frac{1}{3} * (3h) * 9 * \frac{1}{2} \begin{vmatrix} p_x + hu_x & p_y + hu_y & 1 \\ q_x + hv_x & q_y + hv_y & 1 \\ r_x + hw_x & r_y + hw_y & 1 \end{vmatrix} = \frac{9}{2} * (ah^3 + bh^2 + ch), \text{ where}$$

$$a = \begin{vmatrix} u_x & u_y & 1 \\ v_x & v_y & 1 \\ w_x & w_y & 1 \end{vmatrix}, \qquad b = \begin{vmatrix} p_x & u_y & 1 \\ q_x & v_y & 1 \\ r_x & w_y & 1 \end{vmatrix} + \begin{vmatrix} u_x & p_y & 1 \\ v_x & q_y & 1 \\ w_x & r_y & 1 \end{vmatrix}, \qquad c = \begin{vmatrix} p_x & p_y & 1 \\ q_x & q_y & 1 \\ r_x & r_y & 1 \end{vmatrix}.$$

For the volume to be minimized, we need $3ah^2 + 2bh + c = 0$, which solves to

$$h_{1,2} = \frac{-b \pm \sqrt{b^2 - 3ac}}{3a}.$$

(If $a = 0$, then the minimization occurs for $h = -c/2b$.) For each of the two roots of this equation, we calculate the corresponding simplex and its volume. Once we know h, we get $p_1 = (p_x + hu_x,\ p_y + hu_y,\ h)$, $p_2 = (q_x + hv_x,\ q_y + hv_y,\ h)$, $p_3 = (r_x + hw_x,\ r_y + hw_y,\ h)$.

Because $q_2q_3 \parallel p_2p_3$ and q_2, p, q_3 are collinear, we can draw the line ℓ_1 passing through p and parallel to q_2q_3; similarly, we draw a line ℓ_2 passing through q and parallel to p_3p_1 and line ℓ_3 passing through r and parallel to p_1p_2. Now, $q_1 = \ell_2 \cap \ell_3$, $q_2 = \ell_3 \cap \ell_1$, $q_3 = \ell_1 \cap \ell_2$. The final vertex is determined as $q_4 = p_1 + p_2 + p_3 - 2/3(q_1 + q_2 + q_3)$. Finally, the transform L^{-1} maps the coordinates of q_1, q_2, q_3, q_4 back to the original space.

3.6. Combinatorial type *EEEE*. See Figure 6. Our final case is also the most complicated. Given four edges e_1, e_2, e_3, e_4 of P, we want to compute the unique centroidal simplex determined by them. We first use a linear transform L that maps the line containing e_4 to the x-axis. In the new coordinate system, e_i can be written as $o_i + \lambda v_i$ for $i = 1, 2, 3$. Suppose that t_4 makes an angle of θ with the xy-coordinate plane. Then, there is a rotation $R(\theta)$ around the x-axis that maps the plane containing t_4 into the xy plane. The orthogonal transform $R(\theta)$ can be written in matrix notation as

$$R(\theta) = \begin{vmatrix} 1 & 0 & 0 \\ 0 & \cos\theta & \sin\theta \\ 0 & -\sin\theta & \cos\theta \end{vmatrix}.$$

Each edge e_i, for $i = 1, 2, 3$, has new coordinates $R(\theta)(o_i + \lambda v_i) = o_i(\theta) + \lambda v_i(\theta)$. The centroid p_i lies on e_i, and the three centroids p_1, p_2, p_3 have the same height (z-coordinate). Letting this height be h, we have

$$(o_i(\theta) + \lambda_i v_i(\theta))_z = o_{iz}(\theta) + \lambda_i v_{iz}(\theta) = h \Rightarrow \lambda_i = \frac{h - o_{iz}(\theta)}{v_{iz}(\theta)} \text{ for } i = 1, 2, 3.$$

The volume of the simplex T can be written as

$$\mathrm{Vol}(T) = \frac{1}{3} * (3h) * 9 * \frac{1}{2} \begin{vmatrix} o_{1x}(\theta) + \lambda_1 v_{1x}(\theta) & o_{1y}(\theta) + \lambda_1 v_{1y}(\theta) & 1 \\ o_{2x}(\theta) + \lambda_2 v_{2x}(\theta) & o_{2y}(\theta) + \lambda_2 v_{2y}(\theta) & 1 \\ o_{3x}(\theta) + \lambda_3 v_{3x}(\theta) & o_{3y}(\theta) + \lambda_3 v_{3y}(\theta) & 1 \end{vmatrix}$$

$$
\begin{aligned}
&= \frac{9}{2} * h * \begin{vmatrix} o_{1x}(\theta) + \frac{h-o_{1z}(\theta)}{v_{1z}(\theta)} v_{1x}(\theta) & o_{1y}(\theta) + \frac{h-o_{1z}(\theta)}{v_{1z}(\theta)} v_{1y}(\theta) & 1 \\ o_{2x}(\theta) + \frac{h-o_{2z}(\theta)}{v_{2z}(\theta)} v_{2x}(\theta) & o_{2y}(\theta) + \frac{h-o_{2z}(\theta)}{v_{2z}(\theta)} v_{2y}(\theta) & 1 \\ o_{3x}(\theta) + \frac{h-o_{3z}(\theta)}{v_{3z}(\theta)} v_{3x}(\theta) & o_{3y}(\theta) + \frac{h-o_{3z}(\theta)}{v_{3z}(\theta)} v_{3y}(\theta) & 1 \end{vmatrix} \\
&= \frac{9}{2} \frac{h}{v_{1z}(\theta) v_{2z}(\theta) v_{3z}(\theta)} \\
&\quad \times \begin{vmatrix} o_{1x}(\theta)v_{1z}(\theta) + (h - o_{1z}(\theta))v_{1x}(\theta) & o_{1y}(\theta)v_{1z}(\theta) + (h - o_{1z}(\theta))v_{1y}(\theta) & v_{1z}(\theta) \\ o_{2x}(\theta)v_{2z}(\theta) + (h - o_{2z}(\theta))v_{2x}(\theta) & o_{2y}(\theta)v_{2z}(\theta) + (h - o_{2z}(\theta))v_{2y}(\theta) & v_{2z}(\theta) \\ o_{3x}(\theta)v_{3z}(\theta) + (h - o_{3z}(\theta))v_{3x}(\theta) & o_{3y}(\theta)v_{3z}(\theta) + (h - o_{3z}(\theta))v_{3y}(\theta) & v_{3z}(\theta) \end{vmatrix} \\
&= \frac{9}{2} \frac{h}{v_{1z}(\theta) v_{2z}(\theta) v_{3z}(\theta)} [a(\theta)h^2 + b(\theta)h + c(\theta)],
\end{aligned}
$$

where

$$
\begin{aligned}
a(\theta) &= \begin{vmatrix} v_{1x}(\theta) & v_{1y}(\theta) & v_{1z}(\theta) \\ v_{2x}(\theta) & v_{2y}(\theta) & v_{2z}(\theta) \\ v_{3x}(\theta) & v_{3y}(\theta) & v_{3z}(\theta) \end{vmatrix} = \begin{vmatrix} v_{1x} & v_{1y} & v_{1z} \\ v_{2x} & v_{2y} & v_{2z} \\ v_{3x} & v_{3y} & v_{3z} \end{vmatrix} \\
b(\theta) &= \begin{vmatrix} v_{1x}(\theta) & o_{1y}(\theta)v_{1z}(\theta) - o_{1z}(\theta)v_{1y}(\theta) & v_{1z}(\theta) \\ v_{2x}(\theta) & o_{2y}(\theta)v_{2z}(\theta) - o_{2z}(\theta)v_{2y}(\theta) & v_{2z}(\theta) \\ v_{3x}(\theta) & o_{3y}(\theta)v_{3z}(\theta) - o_{3z}(\theta)v_{3y}(\theta) & v_{3z}(\theta) \end{vmatrix} \\
&\quad + \begin{vmatrix} o_{1x}(\theta)v_{1z}(\theta) - o_{1z}(\theta)v_{1x}(\theta) & v_{1y}(\theta) & v_{1z}(\theta) \\ o_{2x}(\theta)v_{2z}(\theta) - o_{2z}(\theta)v_{2x}(\theta) & v_{2y}(\theta) & v_{2z}(\theta) \\ o_{3x}(\theta)v_{3z}(\theta) - o_{3z}(\theta)v_{3x}(\theta) & v_{3y}(\theta) & v_{3z}(\theta) \end{vmatrix} \\
&= \begin{vmatrix} v_{1x} & o_{1y}v_{1z} - o_{1z}v_{1y} & v_{1z}(\theta) \\ v_{2x} & o_{2y}v_{2z} - o_{2z}v_{2y} & v_{2z}(\theta) \\ v_{3x} & o_{3y}v_{3z} - o_{3z}v_{3y} & v_{3z}(\theta) \end{vmatrix} + \begin{vmatrix} o_{1x}v_{1z}(\theta) - o_{1z}(\theta)v_{1x} & v_{1y} & v_{1z} \\ o_{2x}v_{2z}(\theta) - o_{2z}(\theta)v_{2x} & v_{2y} & v_{2z} \\ o_{3x}v_{3z}(\theta) - o_{3z}(\theta)v_{3x} & v_{3y} & v_{3z} \end{vmatrix} \\
c(\theta) &= \begin{vmatrix} o_{1x}(\theta)v_{1z}(\theta) - o_{1z}(\theta)v_{1x}(\theta) & o_{1y}(\theta)v_{1z}(\theta) - o_{1z}(\theta)v_{1y}(\theta) & v_{1z}(\theta) \\ o_{2x}(\theta)v_{2z}(\theta) - o_{2z}(\theta)v_{2x}(\theta) & o_{2y}(\theta)v_{2z}(\theta) - o_{2z}(\theta)v_{2y}(\theta) & v_{2z}(\theta) \\ o_{3x}(\theta)v_{3z}(\theta) - o_{3z}(\theta)v_{3x}(\theta) & o_{3y}(\theta)v_{3z}(\theta) - o_{3z}(\theta)v_{3y}(\theta) & v_{3z}(\theta) \end{vmatrix} \\
&= \begin{vmatrix} o_{1x}v_{1z}(\theta) - o_{1z}(\theta)v_{1x} & o_{1y}v_{1z} - o_{1z}v_{1y} & v_{1z}(\theta) \\ o_{2x}v_{2z}(\theta) - o_{2z}(\theta)v_{2x} & o_{2y}v_{2z} - o_{2z}v_{2y} & v_{2z}(\theta) \\ o_{3x}v_{3z}(\theta) - o_{3z}(\theta)v_{3x} & o_{3y}v_{3z} - o_{3z}v_{3y} & v_{3z}(\theta) \end{vmatrix}.
\end{aligned}
$$

The preceding calculations have used two key properties of the rotation $R(\theta)$. One is the x-coordinate of any point is invariant under $R(\theta)$ and the other that $R(\theta)$ restricted to the yz-plane is orthogonal. We can write the volume function as

$$
\mathrm{Vol}(T) = \frac{9}{2} \left[A(\theta)h^3 + B(\theta)h^2 + C(\theta)h \right], \text{ where}
$$

$$
A(\theta) = \frac{a(\theta)}{s(\theta)}, \quad B(\theta) = \frac{b(\theta)}{s(\theta)}, \quad C(\theta) = \frac{c(\theta)}{s(\theta)}, \quad s(\theta) = v_{1z}(\theta)v_{2z}(\theta)v_{3z}(\theta).
$$

The volume function $\mathrm{Vol}(T) = V(\theta, h)$ has two parameters, θ and h. For the volume to be locally minimal, we need that

$$
\frac{\partial V(\theta, h)}{\partial \theta} = 0, \qquad \frac{\partial V(\theta, h)}{\partial h} = 0.
$$

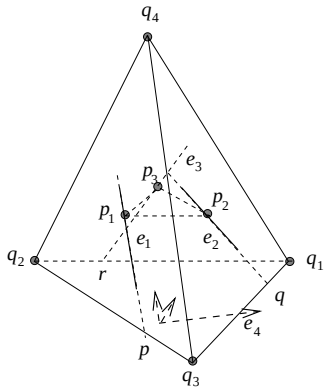

FIG. 6. *Type EEEE.*

The above equations solve to

$$3A(\theta)h^2 + 2B(\theta)h + C(\theta) = 0 \qquad \text{and} \qquad A'(\theta)h^2 + B'(\theta)h + C'(\theta) = 0.$$

We plug $a(\theta), b(\theta), c(\theta), s(\theta)$ into $A(\theta), B(\theta), C(\theta)$ and use the fact that $a(\theta) = a$ is a constant. Then

$$a_1h^2 + b_1h + c_1 = 0, \qquad a_2h^2 + b_2h + c_2 = 0,$$

where $a_1 = 3a, b_1 = 2b(\theta), c_1 = c(\theta), a_2 = as'(\theta), b_2 = [b(\theta)s'(\theta) - b'(\theta)s(\theta)], c_2 = [c(\theta)s'(\theta) - c'(\theta)s(\theta)]$.

We now need to discuss two cases depending on whether or not $a_1b_2 - a_2b_1 = 0$.

1. **Case 1. $a_1b_2 - a_2b_1 \neq 0$.** In this case, h is uniquely determined by the two equations above. We get $h = -(a_1c_2 - a_2c_1)/(a_1b_2 - a_2b_1)$. If we plug the expression of h into the first equation, and simplify a little, we get the following:

$$(a_1c_2 - a_2c_1)^2 + a_1c_1b_2^2 + a_2c_2b_1^2 = b_1b_2(a_1c_2 + a_2c_1).$$

Replacing $a_i, b_i, c_i, i = 1, 2$ by original $a, b(\theta), c(\theta), s(\theta)$ gives

$$\begin{aligned} a\left[3c'(\theta)s(\theta) - 2c(\theta)s'(\theta)\right]^2 &+ 3c(\theta)\left[b(\theta)s'(\theta) - b'(\theta)s(\theta)\right]^2 \\ &+ 4b(\theta)^2s'(\theta)\left[c(\theta)s'(\theta) - c'(\theta)s(\theta)\right] \\ = 2b(\theta)\left[b(\theta)s'(\theta) - b'(\theta)s(\theta)\right]&\left[4c(\theta)s'(\theta) - 3c'(\theta)s(\theta)\right]. \end{aligned}$$

In this expression, $b(\theta), c(\theta), s(\theta)$ are homogeneous polynomials of variables $\cos\theta$ and $\sin\theta$. The function $b(\theta)$ has degree 1, $c(\theta)$ has degree 2, and $s(\theta)$ has degree 3. Because these functions are trigonometric, their derivatives have the same degree as the functions themselves. Thus, the preceding equation is a homogeneous polynomial of degree 10 with variables $\cos\theta$ and $\sin\theta$, which can be converted into a tenth degree polynomial with single variable $\tan\theta$. While there is no analytic formula for the roots of a degree 10 polynomial, we can use numerical methods to solve for its roots. All the real roots need

to be checked separately. Once we have a root θ, we can compute

$$h = -\frac{2c(\theta)s'(\theta) - 3c'(\theta)s(\theta)}{b(\theta)s'(\theta) - 3b'(\theta)s(\theta)}.$$

Once we have h and θ, we calculate $\lambda_i = (h - o_{iz}(\theta))/v_{iz}(\theta)$, and t_i's centroid $p_i = o_i + \lambda_i v_i$, for $i = 1, 2, 3$. Now, the facet t_1 is determined by the plane that contains e_1 and is parallel to p_2p_3, t_2's plane contains e_2 and is parallel to p_3p_1, t_3's plane contains e_3 and is parallel to p_1p_2, and t_4's plane contains e_4 and is parallel to the plane containing the triangle $\triangle p_1p_2p_3$. The simplex T is now determined.

2. **Case 2. $a_1b_2 - a_2b_1 = 0$.** By plugging in the expressions for a_i, b_i, we get the equivalent equation

$$3b'(\theta)s(\theta) - b(\theta)s'(\theta) = 0.$$

This is actually a degree 4 polynomial in $\tan\theta$. We may compute the roots of this polynomial analytically or using numerical methods. Given a root θ, we can calculate h by solving

$$3ah^2 + 2b(\theta)h + c(\theta) = 0.$$

Once we have h and θ, we calculate the simplex T as in Case 1. This completes the discussion of type $EEEE$.

4. An exact algorithm. We can now describe our algorithm for computing the minimum volume simplex T enclosing P. Let L be a list containing all the vertices, edges, and faces of P. We consider all 4-tuples of L. If the combinatorial type of a tuple is not among the seven types listed in Lemma 2.4, we ignore the tuple and move on to the next tuple. Otherwise, we use the appropriate geometric procedure described in the preceding section to compute the centroidal simplex determined by this tuple. Once the centroidal simplex T is found, we also need to check if $P \subset T$.

The enclosure check is easily done in $O(1)$ time for all cases except $FFFV$ and $FEEV$. Observe that, in the remaining cases, all the contacts are of type F or E. Given a contact type F or E, we can locally decide if the facet of T determined by that contact has P on the correct side. For each face of P, store the outward normal—the one pointing away from P. If a face $f \in P$ supports the facet t of T, then it suffices to check that the outward normals of f and t point in the same direction. Given an edge contact e supporting a facet t, it suffices to check that the normal to t is a convex combination of the normals to the two faces incident to e.

On the other hand, a vertex v of P can have arbitrarily high degree (number of faces incident to it). Thus, checking if a facet $t \in T$ touching v lies entirely to one side of P can be expensive. However, since the only combinatorial types involving vertex contacts are $FFFV$ and $FEEV$, we can afford to spend even linear time per vertex contact. Given a vertex v, there are $O(n^3)$ triples of face or edge contacts to consider in conjunction with v. For each such combinatorial type, we spend $O(deg(v))$ time checking simplex enclosure, where $deg(v)$ is the number of faces or edges incident to v. The sum over all vertices v is

$$O(n^3) \sum_{v \in P} deg(v) \;=\; O(n^4),$$

since, by Euler's theorem, the sum of vertex degrees is $O(n)$. Thus, we can summarize our main result in the following theorem.

THEOREM 4.1. *Given a convex polytope P of n vertices in $\mathcal{R}^3$, we can determine the minimum volume simplex enclosing P in $\Theta(n^4)$ worst-case time.*

Next, we develop a faster approximation algorithm for the minimum enclosing simplex.

5. An approximation algorithm. One can easily compute in $O(n)$ time a simplex whose volume is within a constant factor of the optimal, using the following result of Barequet and Har-Peled [2]. Given a geometric object Q, and a positive number c, we use cQ to denote the uniform scaling of Q by factor c.

LEMMA 5.1 (see [2]). *Given a three-dimensional convex polytope P of n vertices, one can compute in $O(n)$ time an arbitrarily oriented rectangular box B_{apr} enclosing P such that $\text{Vol}(B_{\text{apr}}) \leq c_1 \text{Vol}(P)$ for $c_1 \geq 6\sqrt{6}$. Furthermore, P contains a translated copy of the box $\frac{1}{c_2}B_{\text{apr}}$, where $c_2 \geq 107$ is a positive number.*

A minimum volume simplex containing B_{apr} is a constant factor approximation of the optimal simplex containing P. While this is a simple approximation algorithm, the approximation factor is quite poor. We now turn this scheme into an ε-approximation scheme, following the approach of [2]. The main idea is to replace the polytope P with a *low-complexity* convex polytope P' enclosing P, and to compute an exact minimum volume simplex of P', using the algorithm of section 4. The closeness of P' to P will ensure that the optimal simplex enclosing P' is within ε factor of the optimal simplex of P. We begin with some definitions.

We denote a rectangular box B in $\mathcal{R}^3$ as a triple of orthogonal vectors (b_1, b_2, b_3), where b_1, b_2, b_3 are vectors having the directions and sizes of the edges of B. The *grid* generated by B is the set of points $\text{Grid}(B) = \{i_1b_1 + i_2b_2 + i_3b_3 | i_1, i_2, i_3 \in Z\}$. Given a grid G, the (i_1, i_2, i_3)th cell of G is $B^G_{(i_1,i_2,i_3)} = \{x_1b_1 + x_2b_2 + x_3b_3 | i_j \leq x_j < i_j + 1, j = 1, 2, 3\}$. We will approximate the polytope P by a set of grid points. Let P_G be the corners of all those cells in G that contain a vertex of P, and let P' be the convex hull of P_G. We can describe our ε-approximation algorithm now.

Algorithm ε-APPROXIMATION ENCLOSING TETRAHEDRON (P).
1. Compute a box B_{apr} enclosing P as in Lemma 5.1.
2. Compute the convex polytope $P' = CH(P_G)$, where $G = \text{Grid}(\frac{1}{2}B_\varepsilon)$, and B_ε is a translated copy of $\frac{\varepsilon}{428}B_{apr}$ centered at the origin.
3. Compute $T'_{\text{apr}} = T_{\text{opt}}(P')$ by our exact algorithm given in section 4.
4. Compute T_{apr} homothet to T'_{apr} such that every face of T_{apr} touches P.

end Algorithm

Let us first analyze the time complexity of this algorithm. Since $P' \subseteq P \oplus B_\varepsilon \subseteq B_{\text{apr}} \oplus B_\varepsilon$, and since the latter box contains at most $k = 856/\varepsilon + 3$ grid points in each orthogonal direction of the box, P' contains at most k^3 grid points. By a result of Andrews [1], the convex polytope P' has $O(k^{3/2}) = O(1/\varepsilon^{\frac{3}{2}})$ vertices. The dominant step of the algorithm is step 3, which takes $O((1/\varepsilon^{\frac{3}{2}})^4) = O(1/\varepsilon^6)$ time. The total time is therefore $O(n + 1/\varepsilon^6)$.

Finally, we show that the $\text{Vol}(T_{\text{apr}})$ is at most $(1 + \varepsilon)$ times the volume of the optimal simplex enclosing P. By Lemma 5.1, the approximate box B_{apr} is such that a translated copy of $\frac{1}{107}B_{\text{apr}}$ is contained in P. Thus, a uniform scaling by factor $\varepsilon/4$ gives that a translated copy of $\frac{\varepsilon}{428}B_{\text{apr}} = B_\varepsilon$ lies inside $\frac{\varepsilon}{4}P$. Since $P' \subseteq P \oplus B_\varepsilon$, it follows that $P' \subseteq P \oplus \frac{\varepsilon}{4}P$—that is, P' lies inside the Minkowski sum of P and

some translation of $\frac{\varepsilon}{4}P$. Thus, if $T_{\text{opt}}(P)$ is an optimal enclosing simplex of P, then $(1+\frac{\varepsilon}{4})T_{\text{opt}}(P)$ is an enclosing tetrahedron of P'. Because $T'_{\text{apr}} = T_{\text{opt}}(P')$ is an enclosing simplex of P' with minimal volume, we get

$$\text{Vol}(T_{\text{apr}}) \le \text{Vol}(T'_{\text{apr}}) = \text{Vol}(T_{\text{opt}}(P')) \le \left(1+\frac{\varepsilon}{4}\right)^3 \text{Vol}(T_{\text{opt}}) \le (1+\varepsilon)\text{Vol}(T_{\text{opt}}).$$

This completes the analysis of our approximation algorithm, and we summarize the main result in the following theorem.

THEOREM 5.2. *Given a convex polytope of v vertices in $\mathcal{R}^3$, and a real parameter $0 < \varepsilon < 1$, we can compute in $O(n + 1/\varepsilon^6)$ time a simplex enclosing P with volume at most $(1+\varepsilon)$ times the volume of an optimal enclosing simplex.*

6. Concluding remarks. We have described an exact algorithm for determining a *minimum volume simplex* enclosing a set of points in $\mathcal{R}^3$. If the *convex hull* of the points has n vertices, then our algorithm takes $\Theta(n^4)$ time. Combining our exact but slow algorithm with a simple but crude approximation technique, we also develop an ε-approximation algorithm. The algorithm computes in $O(n + 1/\varepsilon^6)$ time a simplex whose volume is within $(1+\varepsilon)$ factor of the optimal for any $\varepsilon > 0$. We are currently implementing the exact algorithm. While its overall complexity, both the running time as well as implementation effort, may be too large for any practical use, we hope to use it as a benchmark for developing fast and simple approximation algorithms.

A. The appendix. In this appendix, we include the proofs of various technical lemmas. We first begin with a proof of the centroid property. This property was established by Klee [11] for any dimension; we include a proof in three dimensions for completeness.

A.1. Proof of centroid property. Without loss of generality, assume that facet t_4 of T violates the centroid property. Let $Q = t_4 \cap P$ be the intersection of t_4 with P, where Q is a point, segment, or a convex polygon. Clearly, $p_4 \notin Q$. Since Q is convex, there exists a line ℓ in the plane of t_4 that separates p_4 and Q. Consider the point $p_4(\lambda) = \frac{1}{1+\lambda}(p_4 + \lambda q_4)$ on the segment p_4q_4 for $\lambda \in (0,1)$. Let $t_4(\lambda)$ denote the plane containing the point $p_4(\lambda)$ and the line ℓ. The line through q_4 and q_i intersects the plane $t_4(\lambda)$ at the point $q_i(\lambda)$ for $i = 1, 2, 3$.

Because volumetric ratios are invariant under nonsingular affine transformations, we may assume without loss of generality that ℓ is X-axis, $p_4 = (0,1,0)$, and $q_4 = (0,0,1)$. Then $p_4(\lambda) = (0, \frac{1}{1+\lambda}, \frac{\lambda}{1+\lambda})$ and plane $t_4(\lambda)$ is given by the equation $z = \lambda y$. Suppose that $q_i(\lambda) = (1-\tau_i)q_4 + \tau_i q_i = (\tau_i q_{ix}, \tau_i q_{iy}, 1-\tau_i)$; then $1 - \tau_i = \lambda\tau_i q_{iy}$, or $\tau_i = (1+\lambda q_{iy})^{-1}$, for $i = 1, 2, 3$. When λ is small enough, each τ_i is positive. The volume of tetrahedron $T(\lambda)$ is $1/6$ times the absolute value of the determinant

$$D(\lambda) = \begin{vmatrix} \tau_1 q_{1x} & \tau_1 q_{1y} & 1-\tau_1 & 1 \\ \tau_2 q_{2x} & \tau_2 q_{2y} & 1-\tau_2 & 1 \\ \tau_3 q_{3x} & \tau_3 q_{3y} & 1-\tau_3 & 1 \\ 0 & 0 & 1 & 1 \end{vmatrix} = \begin{vmatrix} \tau_1 q_{1x} & \tau_1 q_{1y} & -\tau_1 & 0 \\ \tau_2 q_{2x} & \tau_2 q_{2y} & -\tau_2 & 0 \\ \tau_3 q_{3x} & \tau_3 q_{3y} & -\tau_3 & 0 \\ 0 & 0 & 1 & 1 \end{vmatrix}$$

$$= (\tau_1\tau_2\tau_3) \begin{vmatrix} q_{1x} & q_{1y} & -1 \\ q_{2x} & q_{2y} & -1 \\ q_{3x} & q_{3y} & -1 \end{vmatrix}.$$

Since τ_i's are all 1 when $\lambda = 0$, the third determinant is equal to $D(0)$. Thus,

$$\frac{\text{Vol}(T(\lambda))}{\text{Vol}(T)} = \tau_1\tau_2\tau_3 = \prod_{i=1}^{3}(1+\lambda q_{iy})^{-1} = \left[\prod_{i=1}^{3}(1+\lambda q_{iy})\right]^{-1}$$
$$= \left[1 + \left(\sum_{i=1}^{3} q_{iy}\right)\lambda + o(\lambda)\right]^{-1} = 1 - \left(\sum_{i=1}^{3} q_{iy}\right)\lambda + o(\lambda).$$

Since p_4 is the centroid of $\triangle q_1q_2q_3$, we have $\sum_{i=1}^{3} q_{iy} = 3p_{4y} = 3$. Thus,

$$\frac{\text{Vol}(T(\lambda))}{\text{Vol}(T)} = 1 - 3\lambda + o(\lambda).$$

For small enough λ, $T(\lambda)$ is also an enclosing simplex of P, but the volume of $T(\lambda)$ is strictly less than the volume of T, which conflicts the assumed minimality of T. Thus, the simplex T must be centroidal.

Next, we give a proof for the case of coplanar e_3, e_4 in combinatorial type $FFEE$, which we claimed in section 3.3 that we did not need.

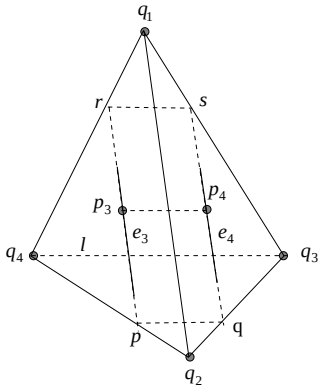

FIG. 7. *Combinatorial type $FFEE$ with coplanar e_3, e_4.*

A.2. Type $FFEE$ when e_3, e_4 are coplanar. Let π be the plane spanned by (coplanar) edges e_3, e_4. (See Figure 7.) Then, $q_4q_3 \parallel p_3p_4$ implies that $q_4q_3 \parallel \pi$, which in turn implies that $q_4q_3 \parallel pq$. Similarly, if r, s denote the intersections of plane through f_2 with lines through e_3 and e_4, then $q_4q_3 \parallel rs$ (Figure 3).

Let $x = pq/q_4q_3$, and $y = rs/q_4q_3$. Then, $\text{dist}(q_2, \ell) = \frac{1}{1-x}\text{dist}(p, \ell)$, and $\text{dist}(q_1, \ell)\frac{1}{1-y}\text{dist}(r, \ell)$, where $\text{dist}(x, \ell)$ denotes the distance from point x to line ℓ. Since the volume of a simplex is 1/3 the base area times height, we have

$$\text{Vol}(T) = \frac{1}{3} * \left[\frac{1}{2}q_4q_3 * \text{dist}(q_2, \ell)\right] * [\text{dist}(q_1, \ell) * \cos\theta]$$
$$= \frac{c}{6} * \cos\theta * \text{dist}(q_1, \ell) * \text{dist}(q_2, \ell)$$
$$= \left[\frac{c}{6} * \cos\theta * \text{dist}(p, \ell) * \text{dist}(r, \ell)\right] * \frac{1}{1-x} * \frac{1}{1-y},$$

where θ is the angle between planes defined by faces f_1 and f_2, and recall that $c = q_4q_3$.

In order for T to be centroidal, p, p_3, r should be collinear, as should the triple q, p_4, s. In the plane of t_3, if we choose $\{\overrightarrow{q_4q_2}, \overrightarrow{q_4q_1}\}$ as the basis, then $p = (1-x, 0)$, $r = (0, 1-y)$, and $p_3 = (1/3, 1/3)$. It is easy to verify that p, p_3, r are collinear if and only if $\frac{1}{1-x} + \frac{1}{1-y} = 3$, and q, p_4, s are collinear if and only if $\frac{1}{1-x} + \frac{1}{1-y} = 3$. Thus, if e_3, e_4 are coplanar and T is centroidal, then necessarily $\frac{1}{1-x} + \frac{1}{1-y} = 3$. However, if this condition is satisfied, then the position of T is not fixed! We need only q_4, q_3 to satisfy that $q_4q_3 = c$, and both of them belong to the line ℓ. Then the intersection of q_4p and q_3q is q_2, the intersection of q_4r and q_3s is q_1, and it guarantees that e_3, e_4 contain the centroids of t_3, t_4, respectively.

In summary, if there exists one centroidal simplex in this instance, then there exists a continuous family of them. We can take the limit of this continuous family in one direction, and the limiting simplex will have fewer degrees of freedom and the same volume as any of these intermediate centroidal simplices. Thus, the volume of a centroidal simplex of type $FFEE$ in this case is no smaller than the best simplex in class $FFFF$ or $FFFE$. Thus, we need not consider this case.

Acknowledgments. We thank Ken Clarkson, Joseph O'Rourke, and Chee Yap for several helpful discussions.

PERCEPTRON, WINNOW, AND PAC LEARNING*

ROCCO A. SERVEDIO†

Abstract. We analyze the performance of the widely studied Perceptron and Winnow algorithms for learning linear threshold functions under Valiant's probably approximately correct (PAC) model of concept learning. We show that under the uniform distribution on boolean examples, the Perceptron algorithm can efficiently PAC learn nested functions (a class of linear threshold functions known to be hard for Perceptron under arbitrary distributions) but cannot efficiently PAC learn arbitrary linear threshold functions. We also prove that Littlestone's Winnow algorithm is not an efficient PAC learning algorithm for the class of positive linear threshold functions, thus answering an open question posed by Schmitt [*Neural Comput.*, 10 (1998), pp. 235–250]. Based on our results we conjecture that no "local" algorithm can learn linear threshold functions efficiently.

Key words. linear threshold function, PAC learning, Perceptron, Winnow

1. Introduction.

The classical Perceptron algorithm and Littlestone's Winnow algorithm are two algorithms for learning linear threshold functions which have been studied extensively in the online mistake bound model [4, 8, 13, 16, 17, 19, 28]. In this model the learning algorithm sequentially makes predictions on examples as they are received, using a hypothesis which it can update after each example, and the performance of an algorithm is measured by the worst-case number of prediction mistakes it makes on any example sequence. The well-known Perceptron convergence theorem [6, 20, 24] establishes conditions under which the Perceptron algorithm will make a bounded number of mistakes on a (possibly infinite) sequence of examples, and Littlestone [14, 15, 16] has obtained similar results for the Winnow algorithm.

Despite widespread interest in the Perceptron and Winnow algorithms, relatively little is known about their performance in Valiant's commonly used probably approximately correct (PAC) model of concept learning [26]. In this paper we establish some positive and negative results which help to clarify the learning abilities of Perceptron and Winnow in the PAC model.

In the PAC learning model there is a fixed distribution $\mathcal{D}$ from which labelled examples are drawn; the goal of the learner is to find a hypothesis which closely approximates the target function under distribution $\mathcal{D}$. It has long been known that if the space of possible examples is the n-dimensional unit sphere S^n, then the Perceptron algorithm is not an efficient PAC learning algorithm for the class of linear threshold functions because of "hard" distributions which concentrate their weight on examples close to the separating hyperplane. Baum [5] has shown that if $\mathcal{D}$ is restricted to be the uniform distribution on S^n, though, then Perceptron is an efficient PAC learning algorithm for the class of linear threshold functions. Schmitt [25] has shown that Perceptron is not an efficient PAC learning algorithm for the class of linear threshold functions over the example space $\{0,1\}^n$; his proof works by exhibiting a

nested boolean function (a special type of linear threshold function) and a distribution which is concentrated on "hard" examples for that function. No results analogous to these have appeared for the Winnow algorithm; as Schmitt noted, it was not known "whether Littlestone's rules can PAC identify in polynomial time" [25].

This paper makes the following contributions: In section 3 we show that under the uniform distribution on $\{0,1\}^n$ the Perceptron algorithm is an efficient PAC learning algorithm for the class of nested boolean functions. This demonstrates that Schmitt's negative result for nested functions depends on choosing a "hard" distribution. However, in section 4 we give a simple proof that the Perceptron algorithm is not an efficient PAC learning algorithm for the class of linear threshold functions under the uniform distribution on $\{0,1\}^n$. This provides an interesting contrast to Baum's result and answers an open question in Schmitt [25]. Finally, we prove in section 5 that the Winnow algorithm is not an efficient PAC learning algorithm for the class of positive linear threshold functions over $\{0,1\}^n$. To the best of our knowledge this is the first negative result for Winnow in the PAC model. We conclude in section 6 with suggestions for future research.

2. Preliminaries. A concept class C on an example space X is a collection of boolean functions on X. The sets C and X are striated; i.e., $C = \cup_{n\geq 1} C_n$ and $X = \cup_{n\geq 1} X_n$, where each $c \in C_n$ has domain X_n. Throughout this paper X_n will be the boolean cube $\{0,1\}^n$. We will mainly deal with the class H_n of n-dimensional linear threshold functions. A boolean function $f : \{0,1\}^n \to \{-1,1\}$ is a linear threshold function if there is a weight vector $w \in \mathbb{R}^n$ and a threshold $\theta \in \mathbb{R}$ such that $f(x) = 1$ iff $w \cdot x \geq \theta$. Such a pair (w, θ) is said to represent f. See [7, 21] for extensive treatments of linear threshold functions on $\{0,1\}^n$.

2.1. Perceptron. Throughout its execution the Perceptron algorithm maintains a weight vector w and a threshold θ as its current hypothesis. The algorithm proceeds in a series of steps; in each step it receives an example x, uses its hypothesis to make a prediction on x, and adjusts its hypothesis if the prediction is incorrect. Initially, the algorithm starts with weight vector $w = (0, \ldots, 0)$ and threshold $\theta = 0$. Upon receiving an example x, the algorithm predicts according to the threshold function $w \cdot x \geq \theta$. If the prediction is incorrect, the hypothesis is updated according to the following rule:

- On a false positive prediction, set $w \leftarrow w - x$ and set $\theta \leftarrow \theta + 1$.
- On a false negative prediction, set $w \leftarrow w + x$ and set $\theta \leftarrow \theta - 1$.

No change is made if the hypothesis was correct on x. If each example x belongs to $\{0,1\}^n$, then each w_i and θ will always be integers; this fact will prove useful later.

The well-known Perceptron convergence theorem bounds the number of mistakes which the Perceptron algorithm can make.

THEOREM 2.1 (see [6, 20, 24]). *Let $\langle x^1, y_1\rangle, \ldots, \langle x^m, y_m\rangle$ be a sequence of labeled examples with $\|x^i\| \leq R$ and $y_i \in \{-1,1\}$ for all i. Let u be a vector and θ, ξ be such that $y_i(u \cdot x^i - \theta) \geq \xi$ for all i, where $\xi > 0$. Then the total number of mistakes made by the Perceptron algorithm on this example sequence is at most*

$$\frac{(R^2+1)(\|u\|^2+\theta^2)}{\xi^2}.$$

2.2. Winnow. The Winnow algorithm takes as input an initial vector $w^I \in \mathbb{R}^n$, a promotion factor $\alpha \in \mathbb{R}$, and a threshold $\theta \in \mathbb{R}$. The algorithm requires that w^I is positive (i.e., each coordinate of w^I is positive), that $\alpha > 1$, and that $\theta > 0$. Like

the Perceptron algorithm, Winnow proceeds in a series of trials and predicts in each trial according to the threshold function $w \cdot x \geq \theta$. If the prediction is correct, then no update is performed; otherwise the weights are updated as follows:

- On a false positive prediction for all i set $w_i \leftarrow \alpha^{-x_i} w_i$;
- On a false negative prediction for all i set $w_i \leftarrow \alpha^{x_i} w_i$.

It should be noted that, in this form, Winnow is capable only of expressing positive threshold functions as its hypotheses. This limitation can be easily overcome, however, by using various simple transformations on the input (see [14, 15]). Littlestone has proved the following result, analogous to the Perceptron convergence theorem, bounding the number of mistakes which Winnow makes.

THEOREM 2.2 (see [16]). *Let $\langle x^1, y_1 \rangle, \ldots, \langle x^m, y_m \rangle$ be a sequence of labeled examples with $x^i \in [0,1]^n$ and $y_i \in \{-1, 1\}$ for all i. Let u be a positive vector and $\delta > 0$ be such that whenever $y_i = 1$ we have $u \cdot x \geq 1$ and whenever $y_i = -1$ we have $u \cdot x \leq 1 - \delta$. If Winnow is run on this example sequence with initial parameters w^I, α, θ where $w^I = (1, \ldots, 1)$, $\alpha = 1 + \frac{\delta}{2}$ and $\theta > 0$, then the total number of mistakes made by Winnow on this example sequence is at most*

$$\frac{8n}{\delta^2 \theta} + \max\left\{0, \frac{14}{\delta^2} \sum_{i=1}^{n} u_i \ln(u_i \theta)\right\}.$$

2.3. PAC learning with online learning algorithms. In Valiant's PAC learning model [12, 26] the learning algorithm has access to an *example oracle* $EX(c, \mathcal{D})$ which, in one time step, provides a labelled example $\langle x, c(x) \rangle$, where x is drawn from the distribution $\mathcal{D}$ on the example space X. The function $c \in C$ is called the *target concept*; the goal of the learning algorithm is to construct a hypothesis h which, with high probability, has low error with respect to c. We thus have the following.

DEFINITION 2.3. *We say that an online learning algorithm A (such as Perceptron or Winnow) is an efficient PAC learning algorithm for concept class C over X if there is a polynomial $p(\cdot, \cdot, \cdot)$ such that the following conditions hold for any $n \geq 1$, any distribution $\mathcal{D}$ over X_n, any $c \in C_n$, and any $0 < \epsilon, \delta < 1$:*

- *Given any example $x \in X_n$ algorithm A always evaluates its hypothesis on x and (once provided with $c(x)$) updates its hypothesis in poly(n) time.*
- *If algorithm A is run on a sequence of examples generated by successive calls to $EX(c, \mathcal{D})$, then with probability at least $1 - \delta$ algorithm A will generate a hypothesis h such that $\Pr_{x \in \mathcal{D}}[h(x) \neq c(x)] < \epsilon$ after at most $p(n, \frac{1}{\epsilon}, \frac{1}{\delta})$ calls to $EX(c, \mathcal{D})$.*

An algorithm A is said to be an efficient PAC learning algorithm under a fixed distribution $\mathcal{D}$ if it satisfies the above definition for the fixed distribution $\mathcal{D}$. The most natural distribution over a finite set is of course the uniform distribution; we write $\mathcal{U}_n$ to denote the uniform distribution over $\{0,1\}^n$.

2.4. PAC learning versus online mistake bound learning. Several generic techniques are known [1, 11, 14] for converting any online mistake bound learning algorithm to a PAC algorithm. These conversion procedures yield PAC learning algorithms whose running time is polynomially related to the running time of the original online algorithm. Using these conversion procedures Theorems 2.1 and 2.2 imply that Perceptron and Winnow are efficient PAC learning algorithms for certain restricted linear threshold learning problems. For example, one straightforwardly obtains the following.

COROLLARY 2.4. *Let C_W be the class of linear threshold functions $w \cdot x \geq \theta$ over $\{0,1\}^n$ such that each w_i is an integer and $\sum_{i=1}^n |w_i| < W$. Then both Perceptron and Winnow yield PAC learning algorithms for C_W which run in time poly$(n, W, \frac{1}{\epsilon}, \frac{1}{\delta})$.*

It is well known, though, that there are linear threshold functions over $\{0,1\}^n$ which require integer coefficients of magnitude $2^{\Omega(n)}$. (See, e.g., [10]; we will see an example of such a linear threshold function in section 5.1.) For functions such as these the time bound of Corollary 2.4 is exponentially large in n and hence does not shed light on whether or not Perceptron and Winnow are efficient PAC learning algorithms.

3. Perceptron can learn nested functions under $\mathcal{U}_n$. In this section we establish a sufficient condition for a family of threshold functions to be efficiently learnable by Perceptron under $\mathcal{U}_n$. We prove that nested functions satisfy this condition and thereby immediately obtain the main result of this section. This complements Schmitt's result [25] that the Perceptron algorithm cannot efficiently PAC learn nested functions under arbitrary distributions.

The class of nested functions, denoted NF_n, was introduced by Anthony, Brightwell, and Shawe-Taylor in [3].

DEFINITION 3.1. *The class of nested functions over $x_1, \ldots, x_n$ is defined as follows:*

1. *For $n = 1$, the functions x_1 and $\overline{x}_1$ are nested.*
2. *For $n > 1$, $f(x_1, \ldots, x_n)$ is nested if $f = g * l_n$, where g is a nested function on $x_1, \ldots, x_{n-1}$, $*$ is either $\vee$ or $\wedge$, and l_n is either x_n or $\overline{x}_n$.*

It is easy to verify that the class of nested functions is equivalent to the class of 1-decision lists of length n in which the variables appear in the reverse order $x_n, \ldots, x_1$. The following lemma establishes a canonical representation of nested functions as threshold functions.

LEMMA 3.2. *Any $f \in NF_n$ can be represented by a linear threshold function*

$$w_1 x_1 + \cdots + w_n x_n \geq \theta_n$$

with $\theta_n = k + \frac{1}{2}$ for some integer k, $w_i = \pm 2^{i-1}$, and $\sum_{w_i<0} w_i < \theta_n < \sum_{w_i>0} w_i$.

Proof. The proof is by induction on n. For $n = 1$ the appropriate threshold function is $x_1 \geq \frac{1}{2}$ or $-x_1 \geq -\frac{1}{2}$. For $n > 1$, f must be of the form $g * l_n$, where g is a nested function on $x_1, \ldots, x_{n-1}$. By the induction hypothesis, g can be expressed as a threshold function $w_1 x_1 + \cdots + w_{n-1} x_{n-1} \geq \theta_{n-1}$, with $w_1, \ldots, w_{n-1}, \theta_{n-1}$ satisfying the conditions of the lemma. There are four possibilities:

1. $f = g \wedge x_n$: then f is $w_1 x_1 + \cdots + w_{n-1} x_{n-1} + 2^{n-1} x_n \geq \theta_n = \theta_{n-1} + 2^{n-1}$.
2. $f = g \wedge \overline{x}_n$: then f is $w_1 x_1 + \cdots + w_{n-1} x_{n-1} - 2^{n-1} x_n \geq \theta_n = \theta_{n-1}$.
3. $f = g \vee x_n$: then f is $w_1 x_1 + \cdots + w_{n-1} x_{n-1} + 2^{n-1} x_n \geq \theta_n = \theta_{n-1}$.
4. $f = g \vee \overline{x}_n$: then f is $w_1 x_1 + \cdots + w_{n-1} x_{n-1} - 2^{n-1} x_n \geq \theta_n = \theta_{n-1} - 2^{n-1}$.

In each case it can be verified that the stated threshold function is equivalent to f and that $w_1, \ldots, w_n, \theta_n$ satisfy the conditions of the lemma. ∎

DEFINITION 3.3. *Let G_n be a collection of hyperplanes in $\mathbb{R}^n$. A family $G = \cup_{n \geq 1} G_n$ of hyperplanes is said to be* gradual *if there is some constant $c > 0$ such that the following condition holds: for every $\tau \geq 0$, every $n \geq 1$, and every hyperplane in G_n, at most $c\tau 2^n$ boolean examples $x \in \{0,1\}^n$ lie within Euclidean distance τ of the hyperplane. A class of linear threshold functions F is said to be gradual if there is a mapping $\varphi : F \to G$, where G is a gradual family of hyperplanes, such that for all $f \in F$, if $\varphi(f)$ is the hyperplane $w \cdot x = \theta$, then (w, θ) represents the linear threshold function f.*

LEMMA 3.4. *The class of nested functions is gradual.*

Proof. We use the representation established in Lemma 3.2; so let $f \in NF_n$ and let $w \cdot x \geq \theta$ be a linear threshold function which represents f with $w_i = \pm 2^{i-1}$ and $\theta = k + \frac{1}{2}$ for some integer k. For $x \in \{0,1\}^n$, if $w \cdot x = t$, then t must be an integer, but since every integer has a unique binary representation, at most one $x \in \{0,1\}^n$ can satisfy $w \cdot x = t$ for any given value of t. Consequently, no example $x \in \{0,1\}^n$ can have $|w \cdot x - \theta| < \frac{1}{2}$, and

$$|\{x \in \{0,1\}^n : |w \cdot x - \theta| \leq m\}| \leq 2m + 1$$

for $m \geq \frac{1}{2}$. The lemma follows by noting that $\|w\| = (\frac{4^n - 1}{3})^{1/2} = \Theta(2^n)$ and that the distance from a point x' to the hyperplane $w \cdot x = \theta$ is $\|w\|^{-1} \cdot |w \cdot x' - \theta|$. □

This lemma ensures that relatively few points can lie close to the separating hyperplane for a nested function; consequently, as we run Perceptron most of the updates will cause the algorithm to make significant progress, and it will achieve ϵ-accuracy in polynomial time. The following theorem formalizes this intuition.

THEOREM 3.5. *If C is a gradual class of linear threshold functions, then Perceptron is an efficient PAC learning algorithm for C under $\mathcal{U}_n$.*

Proof. The proof is similar to the proof of Theorem 1 in [5]. Let $w \cdot x \geq \theta$ be a gradual linear threshold function which represents c. We assume without loss of generality that w, θ have been normalized; i.e., $\|w\| = 1$, so $|w \cdot x - \theta|$ is the distance from x to the hyperplane. By Definition 3.3, there is some constant $k > 0$ such that for all $\tau > 0$ the probability that a random example drawn from $EX(c, \mathcal{U}_n)$ is within distance τ of the hyperplane $w \cdot x = \theta$ is at most $\tau/2k$. Letting $\tau = k\epsilon$, we have that with probability at most $\epsilon/2$, a random example drawn from $EX(c, \mathcal{U}_n)$ is within distance $k\epsilon$ of the hyperplane. Let $B \subseteq \{0,1\}^n$ be the set of examples x which lie within distance $k\epsilon$ of the hyperplane; so $\Pr_{x \in \mathcal{U}_n}[x \in B] \leq \epsilon/2$.

Let (w_t, θ_t) represent the Perceptron algorithm's hypothesis after t updates have been made. If (w_t, θ_t) is not yet ϵ-accurate, then with probability at most $1/2$ the next example which causes an update will be in B. Consider the following potential function:

$$N_t(\alpha) = \|\alpha w - w_t\|^2 + (\alpha\theta - \theta_t)^2.$$

Recalling our Perceptron update rules, we see that $N_{t+1}(\alpha) - N_t(\alpha)$ is

$$\begin{aligned}
\Delta N(\alpha) &= \|\alpha w - w_{t+1}\|^2 + (\alpha\theta - \theta_{t+1})^2 - \|\alpha w - w_t\|^2 - (\alpha\theta - \theta_t)^2 \\
&= \mp 2\alpha w \cdot x \pm 2\alpha\theta \pm 2w_t \cdot x \mp 2\theta_t + \|x\|^2 + 1 \\
&\leq 2\alpha A \pm 2(w_t \cdot x - \theta_t) + n + 1
\end{aligned}$$

with $A = \mp(w \cdot x - \theta)$. Since x was misclassified, we know that $\pm(w_t \cdot x - \theta_t) \leq 0$, and hence $\Delta N(\alpha) \leq 2\alpha A + n + 1$. If $x \in B$, then $A \leq 0$; if $x \notin B$, then $A \leq -k\epsilon\alpha$. As a result, $\Delta N(\alpha) < n + 1$ for $x \in B$, and $\Delta N(\alpha) < n + 1 - 2k\epsilon\alpha$ for $x \notin B$.

Suppose that during the course of its execution the Perceptron algorithm has made r updates on examples in B and s updates on examples outside B. Since (w, θ) have been normalized we have that $|\theta| \leq \sqrt{n}$, and hence $N_0(\alpha) \leq \alpha^2(n+1)$. Since $N_t(\alpha)$ must always be nonnegative, it follows that

$$0 \leq r(n+1) + s(n + 1 - 2k\epsilon\alpha) + \alpha^2(n+1).$$

If we set $\alpha = \frac{12(n+1)}{5k\epsilon}$, then simplifying the above inequality we obtain

$$0 \leq r - \frac{19}{5}s + \frac{144(n+1)^2}{25(k\epsilon)^2},$$

from which it follows that if $m_1 = \frac{144(n+1)^2}{25(k\epsilon)^2}$ updates have been made, at least 7/12 of the updates must have been on examples in B.

Let $m = \max\{144 \ln \frac{\delta}{2}, m_1\}$ and consider running the Perceptron algorithm for $2m/\epsilon$ examples. Let $h_1, h_2, \ldots$ denote the hypotheses which are generated by the Perceptron algorithm during the course of its execution on these $2m/\epsilon$ examples. We have that

$$\begin{aligned}
\Pr[\text{each } h_i \text{ has error } > \epsilon] &= \Pr[(\text{each } h_i \text{ has error } > \epsilon)\ \& \\
&\qquad (\text{fewer than } m \text{ updates take place})] \\
&\quad + \Pr[(\text{each } h_i \text{ has error } > \epsilon)\ \& \\
&\qquad (\text{at least } m \text{ updates take place})] \\
&\le \Pr[(\text{fewer than } m \text{ updates take place}) \mid \\
&\qquad (\text{each } h_i \text{ has error} > \epsilon)] \\
&\quad + \Pr[(\text{at least } m \text{ updates take place}) \mid \\
&\qquad (\text{each } h_i \text{ has error} > \epsilon)].
\end{aligned}$$

To bound the first of these conditional probabilities, we note that conditioned on the event that each h_i has error at least ϵ, the expected number of updates is at least $2m$. A straightforward Chernoff bound [2] shows that this first conditional probability is at most $\delta/2$.

To bound the second conditional probability, we recall that if at least m updates take place, then at least 7/12 of the updates must be on examples in B. However, as noted earlier, if each h_i has error at least ϵ, then for each update the probability that the update is in B is at most 1/2. Another application of Chernoff bounds shows that the second conditional probability is at most $\delta/2$, and the theorem is proved. □

As an immediate corollary of Theorem 2.1 we have that the Perceptron is a PAC learning algorithm for the class of nested functions under the uniform distribution on $\{0,1\}^n$.

4. Perceptron cannot learn H_n under U_n. A very simple argument suffices to establish this result. We require the following definition.

DEFINITION 4.1 (see [25]). *The* weight complexity *of a linear threshold function f is the smallest positive integer t such that f can be represented as $w \cdot x \ge \theta$, with each w_i and θ an integer and $\max\{|w_1|, \ldots, |w_n|, |\theta|\} \le t$.*

THEOREM 4.2. *The Perceptron algorithm is not an efficient PAC learning algorithm for the class of linear threshold functions under the uniform distribution on $\{0,1\}^n$.*

Proof. We take $\epsilon = \frac{1}{2^n+1}$; so any ϵ-accurate hypothesis must agree exactly with the target concept, since misclassification of a single example would imply an error rate under the uniform distribution of at least $\frac{1}{2^n} > \epsilon$. Håstad [9] has constructed a linear threshold function which has weight complexity $2^{\Omega(n \log n)}$. If we take this as our target concept, then it follows that at least $2^{\Omega(n \log n)}$ update steps must be performed by the Perceptron algorithm in order to achieve exact identification (since Perceptron hypothesis weights are always integral and each weight is increased by at most 1 during each Perceptron update step). However, the amount of computation time which a PAC learning algorithm is allowed is only $\text{poly}(n, \frac{1}{\epsilon}) = \text{poly}(n, 2^n) = 2^{O(n)}$. □

5. Winnow cannot learn H_n. Although the Winnow algorithm has been extensively studied in the online mistake bound learning model, little is known about its performance in other learning models. In this section we show that Winnow is not an efficient PAC learning algorithm for the class of positive linear threshold functions. More precisely, we prove the following theorem.

THEOREM 5.1. *Given any positive start vector w^I, any promotion factor $\alpha > 1$ and any threshold $\theta > 0$, there is a positive threshold function c, a distribution $\mathcal{D}$ on $\{0,1\}^n$, and a value $\epsilon > 0$ for which Winnow(w^I, α, θ) will not generate a hypothesis h such that $\Pr_{x \in \mathcal{D}}[h(x) \neq c(x)] \leq \epsilon$ in poly$(n, \frac{1}{\epsilon})$ steps.*

As a consequence of the proof of this theorem, we will obtain an explicit family of "hard" threshold functions and corresponding example sequences which cause Winnow to make exponentially many mistakes. Maass and Turan [18] have used a counting argument to show that, given any (w^I, α, θ), there exists a target threshold function and example sequence which together cause Winnow(w^I, α, θ) to make exponentially many mistakes, but no explicit construction was known.

5.1. A threshold function with large coefficients and a small specifying set. The proof of Theorem 3.5 makes use of several lemmas. In the first lemma we show that a nested boolean function with alternating connectives requires exponentially large coefficients. (Similar results can be found in [21, 22].)

LEMMA 5.2. *Let n be odd and let $u \cdot x \geq \theta$ be a positive threshold function which represents the nested function*

$$f_n = (\dots(x_1 \vee x_2) \wedge x_3) \vee x_4) \dots) \vee x_{n-1}) \wedge x_n.$$

For all $i \geq 3$ we have that $u_i \geq F_{i-3} u_3$, where F_i is the ith Fibonacci number: $F_0 = 1, F_1 = 1, F_2 = 1, F_3 = 2, F_4 = 3, \dots$.

Proof. The proof is by induction on k, where $n = 2k + 1$. For clarity we use two base cases. The case $k = 1$ is trivial. If $k = 2$, then since $f_5(0,0,0,1,1) = 1$ and $f_5(0,0,1,0,1) = 0$, we find that $u_4 \geq u_3$. Similarly, since $f_5(0,0,1,1,0) = 0$, we find that $u_5 \geq u_3$.

We now suppose that the lemma is true for $k = 1, 2, \dots, j-1$ and let $n = 2j+1$. By assumption, $(u_1, \dots, u_n)$ and θ are such that $u \cdot x \geq \theta$ represents f_n. If we fix $x_n = 1$ and $x_{n-1} = 0$, then it follows that $u_1 x_1 + \cdots + u_{n-2} x_{n-2} \geq \theta - u_n$ is a threshold function which represents f_{n-2}; so by the induction hypothesis the lemma holds for $u_3, \dots, u_{n-2}$, and we need only show that it holds for u_{n-1} and u_n.

Since $f_n(1,1,\dots,1,0,0,1) = 0$, we have that $u_1 + u_2 + \cdots + u_{n-3} + u_n < \theta$. On the other hand, since $f_n(0,0,\dots,0,1,1) = 1$, we have that $u_{n-1} + u_n \geq \theta$. From these two inequalities it follows that

$$u_{n-1} \geq u_1 + u_2 + \cdots + u_{n-3}.$$

Since u is positive, this inequality implies that

$$u_{n-1} > u_3 + u_4 + \cdots + u_{n-3}.$$

Using the induction hypothesis we obtain the inequality

$$u_{n-1} \geq (1 + F_1 + \cdots + F_{n-6}) u_3 = F_{n-4} u_3.$$

Similarly, since $f_n(1,1,\dots,1,0) = 0$, we have that $u_1 + u_2 + \cdots + u_{n-1} < \theta$; so

$$u_n \geq u_1 + u_2 + \cdots + u_{n-2} > u_3 + u_4 + \cdots + u_{n-2}.$$

By the induction hypothesis, we find that

$$u_n \geq (1 + F_1 + \cdots + F_{n-5})u_3 = F_{n-3}u_3,$$

and the lemma is proved. □

Since $F_n = \Omega(\phi^n)$, where $\phi = \frac{1+\sqrt{5}}{2}$, we have shown that f_n must have coefficients whose ratio is exponentially large.

We require a definition from [3] before stating the next lemma.

DEFINITION 5.3. *Let $c \in H_n$. We say that c is* consistent *with a set $S = \{\langle x^1, b_1\rangle, \langle x^2, b_2\rangle, \ldots, \langle x^m, b_m\rangle\}$ of labelled examples if $c(x^i) = b_i$ for all i. The set S is said to* specify *c in H_n if c is the only function in H_n which is consistent with S; we say that such a set is a* specifying set *for c in H_n. The* specification number *of c, denoted $\sigma_n(c)$, is the smallest size of any specifying set for c in H_n.*

The following results are proved in [3].

LEMMA 5.4.

1. *Every $c \in H_n$ has a unique specifying set of size $\sigma_n(c)$.*
2. *If $c \in NF_n$, then $\sigma_n(c) = n + 1$.*
3. *Given any $c \in H_n$, let $c\uparrow(x_1, \ldots, x_{n-1}) = c(x_1, \ldots, x_{n-1}, 1)$ and let $c\downarrow(x_1, \ldots, x_{n-1}) = c(x_1, \ldots, x_{n-1}, 0)$. Then $\sigma_n(c) \leq \sigma_{n-1}(c\uparrow) + \sigma_{n-1}(c\downarrow)$.*
4. *If $c \in H_n$ and c depends on only coordinates $1, 2, \ldots, k$, then the specification number of c in H_n is $\sigma_n(c) = 2^{n-k}\sigma_k(c)$.*

We use the results of Lemma 5.4 to show that the function g_n defined below has a small specifying set.

LEMMA 5.5. *Let n be even and let g_n be the linear threshold function represented by*

$$x_1 + 2x_2 + 4x_3 + \cdots + 2^{n-2}x_{n-1} + (2^{n-2} + 1)x_n \geq 4 + 16 + \cdots + 2^{n-4} + 2^{n-2} + \frac{1}{2}.$$

Then $\sigma_n(g_n) \leq 5n - 8$.

Proof. The function $g_n\downarrow$ is represented by

$$x_1 + 2x_2 + 4x_3 + \cdots + 2^{n-2}x_{n-1} \geq 4 + 16 + \cdots + 2^{n-2} + \frac{1}{2}.$$

It is straightforward to verify that this is precisely the nested function

$$(\ldots(x_1 \vee x_2) \wedge x_3) \vee x_4)\ldots) \wedge x_{n-1}$$

on $n - 1$ variables. By part 2 of Lemma 5.4, we have $\sigma_{n-1}(g_n\downarrow) = n$.

The function $g_n\uparrow$ is represented by

$$x_1 + 2x_2 + 4x_3 + \cdots + 2^{n-2}x_{n-1} \geq 4 + 16 + \cdots + 2^{n-4} - \frac{1}{2}.$$

Again, one can easily verify that this is precisely the nested function

$$(\ldots(x_3 \vee x_4) \wedge x_5) \vee x_6)\ldots) \wedge x_{n-3}) \vee x_{n-2}) \vee x_{n-1}$$

on the $n - 3$ variables $x_3, \ldots, x_{n-1}$; in this nested function the boolean connectives alternate between $\vee$ and $\wedge$ until the very end, where two consecutive $\vee$'s occur. Since $g_n\uparrow$ does not depend on the two variables x_1, x_2, parts 4 and 2 of Lemma 5.4 imply that $\sigma_{n-1}(g_n\uparrow) = 4\sigma_{n-3}(g_n\uparrow) = 4(n - 2)$. It follows from part 3 of Lemma 5.4 that $\sigma_n(g_n) \leq 5n - 8$. □

5.2. Proof of Theorem 3.5. One more lemma is required. We prove that the coefficients of x_{n-1} and x_n in any representation of g_n must be almost, but not exactly, equal.

LEMMA 5.6. *Let n be even and let g_n be as defined in Lemma* 5.5. *Let $v \cdot x \geq \theta$ represent g_n. Then $v_{n-1} < v_n < v_{n-1} + v_3$.*

Proof. Let e_j denote the boolean vector whose jth coordinate is 1 and all of whose other coordinates are 0. Let $a = e_3 + e_5 + e_7 + \cdots + e_{n-1}$. Since $g_n(a) = 0$, it follows that $v_3 + v_5 + \cdots + v_{n-1} < \theta$. On the other hand, let $b = e_3 + e_5 + \cdots + e_{n-3} + e_n$. Since $g_n(b) = 1$, it follows that $v_3 + v_5 + \cdots + v_{n-3} + v_n \geq \theta$. Combining these two inequalities, we find that $v_n > v_{n-1}$.

To see that v_n cannot be much greater than v_{n-1}, let $c = e_1 + e_5 + e_7 + e_9 + \cdots + e_{n-3} + e_n$. Since $g_n(c) = 0$, we have $v_1 + v_5 + \cdots + v_{n-3} + v_n < \theta$. On the other hand, let $d = e_1 + e_3 + \cdots + e_{n-1}$. Since $g_n(d) = 1$, we have that $v_1 + v_3 + \cdots + v_{n-1} \geq \theta$. Combining these two inequalities, we find that $v_n < v_{n-1} + v_3$, and the lemma is proved. □

Proof of Theorem 3.5. We first prove the theorem for the restricted case in which we assume that $w^I = (1, \ldots, 1)$. After we have done this we will show how this assumption can be eliminated.

Fix $\alpha > 1$ and $\theta > 0$. Let S denote the specifying set for the threshold function g_n; we know from Lemma 5.5 that $|S| \leq 5n - 8$. Let $\mathcal{D}$ be the distribution on $\{0,1\}^n$ which is uniform on S and gives zero weight to vectors outside of S. We will show that with g_n as the target concept, $\mathcal{D}$ as the distribution over examples, and $\epsilon = \frac{1}{5n-7}$ as the error parameter, Winnow$((1, \ldots, 1), \alpha, \theta)$ cannot achieve a hypothesis $h(x)$ which satisfies $\Pr_{\mathcal{D}}[h(x) \neq c(x)] \leq \epsilon$ in $\text{poly}(n, \frac{1}{\epsilon}) = \text{poly}(n)$ steps. To see this, first note that by our choice of ϵ and $\mathcal{D}$, any threshold function $w \cdot x \geq \theta$ which is ϵ-accurate with respect to g_n must be consistent with S. (This technique was first used by Pitt and Valiant in [23].) Since S is a specifying set for g_n, though, if $w \cdot x \geq \theta$ is consistent with S, then it must in fact agree exactly with g_n. We will show that there is no value of α which could enable Winnow to generate a vector w such that $w \cdot x \geq \theta$ represents $g_n(x)$ in $\text{poly}(n)$ steps.

Let (w, θ) be such that Winnow generates w and $w \cdot x \geq \theta$ represents $g_n(x)$. Since $g_n\downarrow$ is precisely the nested function f_{n-1} of Lemma 5.2 and w is positive, by Lemma 5.2 we have that $w_{n-1} \geq F_{n-4} w_3$. Combining this with Lemma 5.6, we obtain

$$1 < \frac{w_n}{w_{n-1}} < 1 + \frac{1}{F_{n-4}} = 1 + \frac{1}{\Omega(\phi^n)}.$$

Since we assumed that $w^I = (1, \ldots, 1)$, and every example for Winnow lies in $\{0,1\}^n$, it follows that $\frac{w_n}{w_{n-1}} = \alpha^j$ for some positive integer j, and hence that $\alpha = 1 + \frac{1}{\Omega(\phi^n)}$. However, then at least $\Omega(n\phi^n)$ update steps are required to achieve $w_{n-1} \geq F_{n-4} w_3$; consequently, no hypothesis consistent with g_n can be achieved in $\text{poly}(n)$ steps.

Now we consider the case of an arbitrary positive start vector w^I; so fix some positive w^I, $\alpha > 1$, and $\theta > 0$. We assume without loss of generality that $w_1^I \leq w_2^I \leq \cdots \leq w_n^I$, since if this is not already the case renaming variables will make it so. Since all examples for Winnow are in $\{0,1\}^n$, at every point in the execution of Winnow the ratio of weights w_i and w_j must be $\frac{w_i^I}{w_j^I} \cdot \alpha^c$ for some integer c. If there is no integer i_1 such that

$$1 < \frac{w_n^I}{w_{n-1}^I} \cdot \alpha^{i_1} < 1 + \frac{1}{F_{n-4}},$$

then Winnow can never achieve a hypothesis which represents the threshold function $g_n(x)$, and can hence never achieve ϵ-accuracy; so we assume that such an i_1 exists. Similarly, if there is no integer i_2 such that

$$1 < \frac{w^I_{n-1}}{w^I_n} \cdot \alpha^{i_2} < 1 + \frac{1}{F_{n-4}},$$

then there is a threshold function which Winnow can never achieve (the function g_n with a permutation on the variables is such a function); so such an i_2 must exist as well. Taking the product of these inequalities, we find that

$$1 < \alpha^{i_1+i_2} < \left(1 + \frac{1}{F_{n-4}}\right)^2.$$

Since $i_1 + i_2$ must be a positive integer, this implies that $\alpha < (1 + \frac{1}{F_{n-4}})^2$. Now consider a threshold function which requires that $w_1 \geq F_{n-4}w_n$. (Again, g_n with a permutation on the variables is such a function.) Since $w^I_1 \leq w^I_n$ and $\alpha < (1+\frac{1}{F_{n-4}})^2$, it follows that $\Omega(n\phi^n)$ update steps will be required. Hence no hypothesis consistent with g_n can be achieved in polynomial time, and the theorem is proved. □

As an immediate consequence of this proof, we note that the example sequence which simply cycles through S will force Winnow to make exponentially many mistakes on g_n.

6. Conclusion. Many questions remain to be answered about the PAC learning ability of simple online algorithms such as Perceptron and Winnow. Perceptron is now known to be a PAC learning algorithm for linear threshold functions under the uniform distribution on the n-dimensional unit sphere and is known not to be a PAC learning algorithm for linear threshold functions under the uniform distribution on $\{0,1\}^n$. Analogous results have yet to be obtained for Winnow under uniform distributions. More generally, it would be interesting to identify the class of threshold functions which Perceptron (Winnow) can PAC learn under the uniform distribution and under arbitrary distributions.

The linear threshold function g_n used in our Winnow proof is very similar to a nested function; in particular, both $g_n\uparrow$ and $g_n\downarrow$ are nested functions. In light of this fact, and of Schmitt's proof that Perceptron is not a PAC learning algorithm for the class of nested functions, it would be interesting to determine whether Winnow is capable of PAC learning the class of nested functions (or, equivalently, the class of decision lists).

Both the Perceptron and Winnow algorithms are *local* in the sense of [27]: each update to a weight w_i depends only on the value of $w \cdot x$, the value of w_i, the value of x_i, and the correct classification of the example. Such algorithms are of particular interest because they require very limited communication between the processors that perform the updates for each weight and are hence well suited for implementation on a distributed system such as a neural network. Known algorithms for learning threshold functions efficiently, such as the algorithm of [18] which is based on linear programming, are nonlocal. We conjecture that local learning algorithms cannot efficiently learn the unrestricted class of threshold functions.

A final issue is attribute efficiency. A learning algorithm is said to be *attribute efficient* if, when the target concept has k relevant variables out of n, the number of calls which the algorithm makes to the example oracle is polynomial in k and poly-

logarithmic in n. Littlestone's results for Winnow show that it is an attribute efficient algorithm for certain simple subclasses of threshold functions such as disjunctions and r-out-of-k threshold functions. Our results imply that Winnow is not an attribute efficient PAC learning algorithm for the unrestricted class of linear threshold functions. It would be interesting to gain a better understanding of the abilities and limitations of Winnow as an attribute efficient learning algorithm.

Acknowledgment. We thank Les Valiant for helpful comments and suggestions.

MINIMIZING THE FLOW TIME WITHOUT MIGRATION*

BARUCH AWERBUCH†, YOSSI AZAR‡, STEFANO LEONARDI§, AND ODED REGEV‡

Abstract. We consider the classical problem of scheduling jobs in a multiprocessor setting in order to minimize the flow time (total time in the system). The performance of the algorithm, both in offline and online settings, can be significantly improved if we allow preemption, i.e., interrupt a job and later continue its execution, perhaps migrating it to a different machine. Preemption is inherent to make a scheduling algorithm efficient. While in the case of a single processor most operating systems can easily handle preemptions, migrating a job to a different machine results in a huge overhead. Thus, it is not commonly used in most multiprocessor operating systems. The natural question is whether migration is an inherent component for an efficient scheduling algorithm in either the online or offline setting.

Leonardi and Raz [*Proceedings of the Twenty-Ninth Annual ACM Symposium on Theory of Computing*, El Paso, TX, 1997, pp. 110–119] showed that the well-known algorithm, *shortest remaining processing time* (SRPT), performs within a logarithmic factor of the optimal offline algorithm. Note that SRPT must use *both* preemption and migration to schedule the jobs. It is not known if better approximation factors can be reached and thus SRPT, although it is an online algorithm, becomes the best known algorithm in the offline setting. In fact, in the online setting, Leonardi and Raz showed that no algorithm can achieve a better bound.

Without migration, no (offline or online) approximations are known. This paper introduces a new algorithm that does not use migration, works online, and is just as effective (in terms of approximation ratio) as the best known offline algorithm that uses migration.

1. Introduction.

Objectives. One of the most basic performance measures in multiprocessor scheduling problems is the overall time the jobs are spending in the system. This includes the delay of waiting for service as well as the actual service time. This measure captures the overall quality of service of the system. Multiprocessor scheduling problems arise, for example, in the context of server farms accommodating requests for retrieving Web contents over the Internet.

We consider the classical problem of minimizing the flow time in a multiprocessor setting with jobs which are released over time. The performance of the algorithm, both

in offline and online settings, can be significantly improved if we allow preemption, i.e., interrupt a job and later continue its execution, perhaps migrating it to a different machine. As shown below, preemption is inherent to make a scheduling algorithm efficient.

While in the case of a single processor, most operating systems can easily handle preemptions, migrating a job to a different machine results in a huge overhead. Thus, it is not commonly used in most multiprocessor operating systems. The natural question is whether migration is an inherent component for an efficient scheduling algorithm in either the online or offline setting.

Existing work. Surveys on approximation algorithms for scheduling can be found in [4, 7]. In the nonpreemptive case it is impossible to achieve a "reasonable" approximation. Specifically, even for one machine one cannot achieve an approximation factor of $O(n^{\frac{1}{2}-\epsilon})$ unless $NP = P$, where n is the number of jobs [6]. For $m > 1$ it is impossible to achieve an $O(n^{\frac{1}{3}-\epsilon})$ approximation factor unless $NP = P$ [8]. Thus, preemptions really seem to be essential.

Existing work: Single processor. Minimizing the flow time on one machine with preemption can be done optimally in polynomial time using the natural algorithm shortest remaining processing time (SRPT) [1].

Existing work: Multiple processors with migration. For more than one machine the preemptive problem becomes NP-hard [2]. Only very recently, Leonardi and Raz [8] showed that SRPT achieves logarithmic approximation for the multiprocessor case, showing a tight bound of $O(\log(\min\{n/m, P\}))$ on $m > 1$ machines with n jobs, where P denotes the ratio between the processing time of the longest and the shortest jobs.

Note that SRPT must use both preemption and migration to schedule the jobs. In the offline setting, it is not known if better approximation factors can be reached. In fact, in the online setting SRPT is optimal; i.e., no algorithm can achieve a better bound up to a constant factor [8]. For the easier problem of minimizing the total completion time a constant approximation can be achieved [3].

Existing work: Multiple processors without migration. In a recent paper by Kalyanasundaram and Pruhs [5] an algorithm is shown that converts any multiprocessor preemptive schedule to a nonmigratory one. However, it is assumed that the number of processors available is a constant factor more than in the original schedule. An important property of their algorithm is that the jobs are scheduled to begin later than their original start time and are completed before their original completion time. Thus, the total flow time is not increased by their transformation. By combining their methods with a migratory algorithm such as SRPT, one can achieve a logarithmic factor approximation with the assumption that a constant factor more machines are available.

Our result: Multiple processors without migration. Without migration, no (offline or online) approximations are known (without increasing the number of processors). We present in section 2 a new algorithm for minimizing flow time that uses local preemption but does not migrate jobs between machines. We show in section 3 that our algorithm performs as well as the best known offline algorithm (SRPT) for the preemptive problem that uses migration. More specifically, our algorithm guarantees, on all input instances, a small performance gap in comparison to the optimal offline schedule that allows both preemption and migration. Denote by P the ratio between the processing time of the longest and the shortest jobs. Then our algorithm performs by at most an $O(\min\{\log P, \log n\})$ factor of the optimal flow time of any (possibly

migratory) schedule. The algorithm can be easily implemented in polynomial time in the size of the input instance.

Our algorithm is also online. We note that in the proof of the $\Omega(\log P)$, $\Omega(\log(n/m))$ lower bounds of [8] for online algorithms, the optimal algorithm does not use migration. Hence, the (randomized) lower bound holds also for a nonmigratory algorithm. This implies that our algorithm is optimal with respect to the parameter P; i.e., no online algorithm can achieve a better bound both when the offline algorithm is or is not allowed to migrate jobs (the first claim is obviously stronger), while there is still a small gap between the $O(\log n)$ upper bound and the $\Omega(\log(n/m))$ lower bound for large m. An $\Omega(\log n)$ competitive lower bound for our algorithm is also proved in section 4 for any m.

Our algorithm and its analysis draw on some ideas from the SRPT algorithm [8]. Moreover, we eliminated several difficulties in the analysis by basing the analysis on classes of jobs. Basically, our algorithm prefers short jobs over long jobs. However, unlike SRPT, our algorithm may continue to run a job on a machine even when a shorter job is waiting to be processed. This seems essential in the nonmigratory setting since being too eager to run a shorter job may result in an unbalanced commitment to machines. A nonmigratory algorithm has to trade off between the commitment of a job to a machine and the decrease in the flow time yielded by running a shorter job. Our algorithm runs the job with the SRPT among all the jobs that were already assigned to that machine, and a new job is assigned to a machine if its processing time is considerably shorter than the job that is currently running.

The model. We are given a set J of n jobs and a set of m identical machines. Each job j is assigned a pair (r_j, p_j), where r_j is the release time of the job and p_j is its processing time. In the preemptive model a job that is running can be preempted and continued later on any machine. Our model allows preemption but does not allow migration; i.e., a job that is running can be preempted but must later continue its execution on the same machine on which its execution began. The scheduling algorithm decides which of the jobs should be executed at each time. Clearly, a machine can process at most one job in any given time and a job cannot be processed before its release time. For a given schedule define c_j to be the completion time of job j in this schedule. The flow time of job j for this schedule is $F_j = c_j - r_j$. The total flow time is $\sum_{j \in J} F_j$. The goal of the scheduling algorithm is to minimize the total flow time for each given instance of the problem. In the offline version of the problem all the jobs are known in advance. In the online version of the problem each job is introduced at its release time, and the algorithm bases its decision only upon the jobs that were already released.

2. The algorithm. A job is called alive at time t for a given schedule if it has already been released but has not been completed yet. Our algorithm classifies the jobs that are alive into classes according to their remaining processing times. A job j whose remaining processing time is in $[2^k, 2^{k+1})$ is in class k for $-\infty < k < \infty$. Notice that a given job changes its class during its execution. The algorithm holds a pool of jobs that are alive and have not been processed at all. In addition, the algorithm holds a stack of jobs for each of the machines. The stack of machine i holds jobs that are alive and have already been processed by machine i. The algorithm works as follows:

- Each machine processes the job at the top of its stack.

- When a new job arrives the algorithm looks for a machine that is idle or currently processing a job of a higher class than the new job. In case it finds one, the new job is pushed into the machine's stack and its processing begins. Otherwise, the job is inserted into the pool.
- When a job is completed on some machine it is popped from its stack. The algorithm compares the class of the job at the top of the stack with the minimum class of a job in the pool. If the minimum is in the pool, then a job that achieves the minimum is pushed into the stack (and removed from the pool).

Clearly, when a job is assigned to a machine it will be processed only on that machine and thus the algorithm does not use migration. In fact, the algorithm bases its decisions only on the jobs that were released up to the current time and hence is an online algorithm. Note that it may seem that the algorithm has to keep track of all the infinite number of classes through which a job evolves. However, the algorithm recalculates the classes of jobs only at arrival or completion of a job.

3. Analysis. We denote by A our scheduling algorithm and by OPT the optimal offline algorithm that minimizes the flow time for any given instance. For our analysis we can even assume that OPT may migrate jobs between machines. Whenever we talk about time t we mean the moment after the events of time t happened. For a given scheduling algorithm S we define $V^S(t)$ to be the volume of a schedule at a certain time t. This volume is the sum of all the remaining processing times of jobs that are alive. In addition, we define $\delta^S(t)$ to be the number of jobs that are alive. $\Delta V(t)$ is defined to be the volume difference between our algorithm and the optimal algorithm, i.e., $V^A(t) - V^{OPT}(t)$. We also define by $\Delta\delta(t) = \delta^A(t) - \delta^{OPT}(t)$ the alive jobs difference at time t between A and OPT. For a generic function f (V, ΔV, δ or $\Delta\delta$) we use $f_{\geq h,\leq k}(t)$ to denote the value of f at time t when restricted to jobs of classes between h and k. Similarly, the notation $f_{=k}(t)$ will represent the value of function f at time t when restricted to jobs of class precisely k.

Let $\gamma^S(t)$ be the number of nonidle machines at time t. Notice that because our algorithm does not migrate jobs, there are situations in which $\gamma^A(t) < m$ and $\delta^A(t) \geq m$. We denote by $\mathcal{T}$ the set of times in which $\gamma^A(t) = m$, that is, the set of times in which none of the machines is idle. Denote by $P_{\min}$ the processing time of the shortest job and by $P_{\max}$ the processing time of the longest job. Note that $P = P_{\max}/P_{\min}$. Denote by $k_{\min} = \lfloor \log P_{\min} \rfloor$ and $k_{\max} = \lfloor \log P_{\max} \rfloor$ the classes of the shortest and longest jobs upon their arrival.

We start by observing the simple fact that the flow time is the integral over time of the number of jobs that are alive. (For example, see [8].)

FACT 3.1. *For any scheduler S,*

$$F^S = \int_t \delta^S(t)dt.$$

First we note that the algorithm preserves the following property of the stacks.

LEMMA 3.2. *In each stack the jobs are ordered in a strictly increasing class order and there is at most one job whose class is at most $k_{\min}$.*

Proof. At time $t = 0$ the lemma is true since all the stacks are empty. The lemma is proved by induction on time. The classes of jobs in the stacks change in one of three cases. The first is when the class of the currently processed job decreases. Since the currently processed job is the job with the lowest class, the lemma remains true.

The second case is when a new job arrives. In case it enters the pool there is no change in any stack. Otherwise, it is pushed into a stack whose top is of a higher class which preserves the first part of the lemma. Since the class of the new job is at least $k_{\min}$, the second part of the lemma remains true as well. The third case is when a job is completed on some machine. If no job is pushed into the stack of that machine the lemma remains easily true. If a new job is pushed to the stack, then the lemma remains true in much the same way as in the case of the arrival of a new job. □

COROLLARY 3.3. *There are at most* $2 + \log P$ *jobs in each stack.*

Proof. The number of classes of jobs in each stack is at most $k_{\max} - k_{\min} + 1 \leq 2 + \log P$. □

We look at the state of the schedule at a certain time t. First let us look at $t \notin \mathcal{T}$.

LEMMA 3.4. *For* $t \notin \mathcal{T}$, $\delta^A(t) \leq \gamma^A(t)(2 + \log P)$.

Proof. By definition of $\mathcal{T}$, at time t at least one machine is idle. This implies that the pool is empty. Moreover, all the stacks of the idle machines are obviously empty. So, all the jobs that are alive are in the stacks of the nonidle machines. The number of nonidle machines is $\gamma^A(t)$, and the number of jobs in each stack is at most $2 + \log P$ according to Corollary 3.3. □

Now, assume that $t \in \mathcal{T}$ and let $\hat{t} < t$ be the earliest time for which $[\hat{t}, t) \subset \mathcal{T}$. We denote the last time in which a job of class more than k was processed by t_k. In case such jobs were not processed at all in the time interval $[\hat{t}, t)$ we set $t_k = \hat{t}$. So, $\hat{t} \leq t_{k_{\max}} \leq t_{k_{\max}-1} \leq \cdots \leq t_{k_{\min}} \leq t$.

LEMMA 3.5. *For* $t \in \mathcal{T}$, $\Delta V_{\leq k}(t) \leq \Delta V_{\leq k}(t_k)$.

Proof. Notice that in the time interval $[t_k, t)$, algorithm A is constantly processing on all the machines jobs whose class is at most k. The offline algorithm may process jobs of higher classes. Moreover, that can cause jobs of class more than k to actually lower their classes to k and below therefore adding even more to $V^{OPT}_{\leq k}(t)$. Finally, the release of jobs of class $\leq k$ in the interval $[t_k, t)$ is not affecting $\tilde{\Delta} V_{\leq k}(t)$. Therefore, the difference in volume between the two algorithms cannot increase. □

LEMMA 3.6. *For* $t \in \mathcal{T}$, $\Delta V_{\leq k}(t_k) \leq m2^{k+2}$.

Proof. First we claim that at any moment $t_k - \epsilon$, for any $\epsilon > 0$ small enough, the pool does not contain jobs whose class is at most k. In case $t_k = \hat{t}$, at any moment just before t_k there is at least one idle machine which means the pool is empty. Otherwise, $t_k > \hat{t}$ and by definition we know that a job of class more than k is processed just before t_k. Therefore, the pool does not contain any job whose class is at most k.

At time t_k jobs of class at most k might arrive and fill the pool. However, these jobs increase both $V^{OPT}_{\leq k}(t_k)$ and $V^{A}_{\leq k}(t_k)$ by the same amount, so jobs that arrive exactly at t_k do not change $\Delta V_{\leq k}(t_k)$ and can be ignored.

Since the jobs in the pool at time t_k can be ignored, we are left with the jobs in the stacks. Using Lemma 3.2, $\Delta V_{\leq k}(t_k) \leq m(2^{k+1} + 2^k + 2^{k-1} + \cdots) \leq m2^{k+2}$. □

LEMMA 3.7. *For* $t \in \mathcal{T}$, $\Delta V_{\leq k}(t) \leq m2^{k+2}$.

Proof. Combining Lemma 3.5 and 3.6, we obtain $\Delta V_{\leq k}(t) \leq \Delta V_{\leq k}(t_k) \leq m2^{k+2}$. □

The claim of the following lemma states a property that will be used in the proof of both the $O(\log P)$ and the $O(\log n)$ approximation results.

LEMMA 3.8. *For* $t \in \mathcal{T}$, *for* $k_{min} \leq k_1 \leq k_2 \leq k_{max}$, $\delta^A_{\geq k_1, \leq k_2}(t) \leq 2m(k_2 - k_1 + 2) + 2\delta^{OPT}_{\leq k_2}(t)$.

Proof. We note that $\delta^A_{\geq k_1,\leq k_2}(t)$ can be expressed as

$$\begin{aligned}
\sum_{i=k_1}^{k_2} \delta^A_{=i}(t) &\leq \sum_{i=k_1}^{k_2} \frac{\Delta V_{=i}(t) + V^{OPT}_{=i}(t)}{2^i} \\
&\leq \sum_{i=k_1}^{k_2} \frac{\Delta V_{\leq i}(t) - \Delta V_{\leq i-1}(t)}{2^i} + 2\delta^{OPT}_{\geq k_1,\leq k_2}(t) \\
&\leq \frac{\Delta V_{\leq k_2}(t)}{2^{k_2}} + \sum_{i=k_1}^{k_2-1} \frac{\Delta V_{\leq i}(t)}{2^{i+1}} - \frac{\Delta V_{\leq k_1-1}(t)}{2^{k_1}} + 2\delta^{OPT}_{\geq k_1,\leq k_2}(t) \\
&\leq 4m + \sum_{i=k_1}^{k_2-1} 2m + \delta^{OPT}_{\leq k_1-1}(t) + 2\delta^{OPT}_{\geq k_1,\leq k_2}(t) \\
&\leq 2m(k_2 - k_1 + 2) + 2\delta^{OPT}_{\leq k_2}(t).
\end{aligned}$$

The first inequality follows since 2^i is the minimum processing time of a job of class i. The second inequality follows since the processing time of a job of class i is less than 2^{i+1}. The fourth inequality is derived by applying Lemma 3.7, observing that $\Delta V_{\leq k_1-1}(t) \geq -V^{OPT}_{\leq k_1-1}(t)$ and that 2^{k_1} is the maximum processing time of a job of class at most $k_1 - 1$. The claim of the lemma then follows. ∎

The following corollary of Lemma 3.8 is used in the proof of the $O(\log P)$ approximation ratio of Theorem 3.10.

COROLLARY 3.9. *For $t \in \mathcal{T}$, $\delta^A(t) \leq 2m(4 + \log P) + 2\delta^{OPT}(t)$.*

Proof. We express

$$\begin{aligned}
\delta^A(t) &= \delta^A_{\leq k_{\max},\geq k_{\min}}(t) + \delta^A_{<k_{\min}}(t) \\
&\leq 2m(k_{\max} - k_{\min} + 2) + 2\delta^{OPT}(t) + m \\
&\leq 2m(4 + \log P) + 2\delta^{OPT}(t).
\end{aligned}$$

The second inequality follows from the claim of Lemma 3.8, when $k_2 = k_{\max}$ and $k_1 = k_{\min}$, and from the claim of Lemma 3.2 stating that the stack of each machine contains at most one job of class less than $k_{\min}$. The third inequality is obtained since $k_{\max} - k_{\min} + 5/2 \leq \log P + 4$. ∎

THEOREM 3.10. *$F^A \leq 2(5 + \log P) \cdot F^{OPT}$; that is, algorithm A has a $2(5 + \log P)$ approximation factor even compared to the flow time of the (possibly migratory) schedule of the optimal offline algorithm.*

Proof.

$$\begin{aligned}
F^A &= \int_t \delta^A(t)dt \\
&= \int_{t\notin\mathcal{T}} \delta^A(t)dt + \int_{t\in\mathcal{T}} \delta^A(t)dt \\
&\leq \int_{t\notin\mathcal{T}} \gamma^A(t)(2 + \log P)dt + \int_{t\in\mathcal{T}} (2m(4 + \log P) + 2\delta^{OPT}(t))dt \\
&\leq (2 + \log P) \int_{t\notin\mathcal{T}} \gamma^A(t)dt + 2(4 + \log P) \int_{t\in\mathcal{T}} m dt + 2\int_{t\in\mathcal{T}} \delta^{OPT}(t)dt \\
&\leq (8 + 2\log P) \int_t \gamma^A(t)dt + 2\int_t \delta^{OPT}(t)dt \\
&\leq 2(5 + \log P) \cdot F^{OPT}.
\end{aligned}$$

The first equality is from the definition of F^A. The second is obtained by looking at the time in which none of the machines is idle and the time in which at least one machine is idle separately. The third inequality uses Lemma 3.4 and Corollary 3.9. The fifth inequality is true since $\gamma^A(t) = m$ when $t \in \mathcal{T}$. Finally, $\int_t \gamma^A(t)dt$ is the total time spent processing jobs by the machines which is exactly $\sum_{j \in J} p_j$. That sum is upper bounded by the flow time of OPT since each job's flow time must be at least its processing time. □

We now turn to prove the $O(\log n)$ approximation ratio of the algorithm. A different argument is required to prove this second bound. The main idea behind the proof of the $O(\log P)$ approximation ratio was to bound for any time $t \in \mathcal{T}$ the alive jobs difference between A and OPT by $O(m \log P)$. A similar approach does not allow us to prove the $O(\log n)$ approximation ratio: It is possible to construct instances where the alive jobs difference is $\Omega(n)$. The proof that follows uses ideas drawn from the proof given by Leonardi and Raz [8] of the $O(\log(n/m))$ approximation ratio for SRPT when migration is allowed. The idea behind the proof is that the worst case ratio between the algorithm's flow time and the optimal flow time can be raised only if a "big" alive jobs difference is kept for a "long" time period.

We need to introduce more notation. Recall that $\mathcal{T}$ is defined to be the set of times in which $\gamma^A(t) = m$. We denote by $T = \int_{t \in \mathcal{T}} dt$ the size of set $\mathcal{T}$. For any $t \in \mathcal{T}$, define by $\delta^{A,P}(t)$ the number of jobs in the pool of algorithm A, i.e., not assigned to a machine, at time t, and by $\Delta\delta^P(t) = \delta^{A,P}(t) - 2\delta^{OPT}(t)$ the difference between the number of jobs in the pool of algorithm A and twice the number of jobs not finished by the optimal algorithm. For any machine l, time t, define by $\delta^{A,l}(t)$ the number of jobs assigned to machine l at time t in the schedule of algorithm A. Moreover, define by $\mathcal{T}^l = \{t | \delta^{A,l}(t) > 0\}$ the set of times when machine l is assigned with at least one job and by $T^l = \int_{t \in \mathcal{T}^l} dt$ the size of set $\mathcal{T}^l$.

LEMMA 3.11. *For any time $t \in \mathcal{T}$, if $\Delta\delta^P(t) \geq 2mi$, for $i \geq 3$, then the pool of algorithm A contains at least $2m$ jobs of remaining processing time at most $\frac{V^A(t)}{m2^{i-3}}$.*

Proof. Let k_{high} be the maximum integer such that $\delta^{A,P}_{\geq k_{high}}(t) \geq 2m$ and let k_{low} be the maximum integer such that $\delta^{A,P}_{< k_{low}}(t) < 2m$. Note that both numbers are well defined and $k_{low} \leq k_{high}$ since there are at least $6m > 2m$ jobs in the pool. Then,

$$2m \leq \delta^{A,P}_{\geq k_{high}}(t) \leq \delta^{A}_{\geq k_{high}}(t) \leq \frac{V^A(t)}{2^{k_{high}}},$$

thus yielding $2^{k_{high}} \leq \frac{V^A(t)}{2m}$. In particular, the last inequality follows since $2^{k_{high}}$ is the minimum processing time of a job of class k_{high}.

By the definition of k_{high}, we have

$$\begin{aligned}
\Delta\delta^P_{\leq k_{high}}(t) &= \delta^{A,P}_{\leq k_{high}}(t) - 2\delta^{OPT}_{\leq k_{high}}(t) \\
&= \delta^{A,P}(t) - \delta^{A,P}_{> k_{high}}(t) - 2(\delta^{OPT}(t) - \delta^{OPT}_{> k_{high}}(t)) \\
&= \Delta\delta^P(t) - \delta^{A,P}_{> k_{high}}(t) + 2\delta^{OPT}_{> k_{high}}(t) \\
&\geq 2m(i-1),
\end{aligned}$$

where the last inequality follows since $\delta^{A,P}_{> k_{high}}(t) < 2m$.

From Lemma 3.8, we get

$$\begin{aligned}\Delta\delta^P_{\le k_{high}}(t) &= \delta^{A,P}_{\le k_{high},\ge k_{low}}(t) + \delta^{A,P}_{<k_{low}}(t) - 2\delta^{OPT}_{\le k_{high}}(t)\\ &\le \delta^{A}_{\le k_{high},\ge k_{low}}(t) + \delta^{A,P}_{<k_{low}}(t) - 2\delta^{OPT}_{\le k_{high}}(t)\\ &\le \delta^{A,P}_{<k_{low}}(t) + 2m(k_{high} - k_{low} + 2),\end{aligned}$$

thus yielding $\delta^{A,P}_{<k_{low}}(t) \ge 2m(i + k_{low} - k_{high} - 3)$. Therefore, we get that $2m > 2m\ (i + k_{low} - k_{high} - 3)$ and thus $k_{low} \le k_{high} - i + 3$. It follows that there exist at least $2m$ jobs of class at most $k_{low} \le k_{high} - i + 3$ in the pool of the algorithm. The remaining processing time of these $2m$ jobs is bounded by $2^{k_{high}-i+4} \le \frac{V^A(t)}{m2^{i-3}}$, thus proving the claim. ∎

LEMMA 3.12. *For any machine l, time $t \in \mathcal{T}^l$, if $\delta^{A,l}(t) \ge i$ for $i \ge 1$, then there exists a job with remaining processing time at most $\frac{T^l}{2^{i-2}}$ assigned to machine l at time t.*

Proof. For any time $t \in \mathcal{T}^l$, there is at most one job assigned to machine l for every specific class. Assume k to be the highest class of a job assigned to machine l, obviously satisfying $T^l \ge 2^k$. If $\delta^{A,l}(t) \ge i$, then there is a job of class at most $k - i + 1$ assigned to machine l, with processing time at most $2^{k-i+2} \le \frac{T^l}{2^{i-2}}$. ∎

At this stage of the exposition we give a brief overview of the proof. Roughly speaking, Lemmas 3.11 and 3.12 show that if the alive jobs difference between the algorithm and the optimum is order of mi, then the remaining processing time of the jobs on execution is proportional to $1/2^i$. This implies, as we will show in Lemmas 3.14 and 3.15, that one new job is released for every nonidle machine in every interval of size proportional to $1/2^i$. This fact is exploited in Theorem 3.17 to argue that the integral of the alive jobs difference between A and OPT (e.g., order of mi) is logarithmic in the number of jobs that are released (i.e., order of 2^i).

We partition the set of time instants $\mathcal{T}$ when no machine is idle into a collection of disjoint intervals $I_k = [t_k, r_k)$, $k = 1, \ldots, s$, and associate an integer i_k with each interval such that for any time $t \in I_k$, $2m(i_k - 1) < \Delta\delta^P(t) < 2m(i_k + 2)$.

Each maximal time interval $[t_b, t_e)$ contained in $\mathcal{T}$ is dealt with separately. Assume we already dealt with all times in $\mathcal{T}$ which are smaller than t_b, and we have created $k - 1$ intervals. We then define $t_k = t_b$. Given t_k we choose $i_k = \lfloor \frac{\Delta\delta^P(t_k)}{2m} \rfloor$. Given an interval's t_k and i_k, we define

$$r_k = \min\{t_e, t | t > t_k, \Delta\delta^P(t) \ge 2m(i_k + 2) \text{ or } \Delta\delta^P(t) \le 2m(i_k - 1)\};$$

that is, r_k is the first time $\Delta\delta^P(t)$ reaches the value $2m(i_k+2)$ or the value $2m(i_k-1)$. As long as $r_k < t_e$, we continue with the next interval beginning at $t_{k+1} = r_k$.

OBSERVATION 3.13. *When an interval k begins, $2mi_k \le \Delta\delta^P(t_k) < 2m(i_k + 1)$. When it ends, either $\Delta\delta^P(r_k) \le 2m(i_k - 1)$, $\Delta\delta^P(r_k) \ge 2m(i_k + 2)$, or $\Delta\delta^P(r_k) \le 0$.*

Proof. The first part is clear by the way we choose i_k. The second part is clear when r_k is not equal to some t_e, that is, $t_k \in \mathcal{T}$. Otherwise, $r_k \notin \mathcal{T}$ and therefore $\delta^{A,P}(r_k) = 0$ and $\Delta\delta^P(r_k) \le 0$. ∎

Denote by $x_k = r_k - t_k$ the size of interval I_k and define $\mathcal{T}_i = \{\cup I_k | i_k = i\}$, $i \ge 1$, as the union of the intervals I_k with $i_k = i$. We indicate by $T_i = \int_{t\in\mathcal{T}_i} dt$ the size of set $\mathcal{T}_i$. We also denote by $D = \max\{T, \max_{t\in\mathcal{T}}\{V^A(t)/m\}\}$. The following lemma relates the number of jobs, n, and the values of T_i.

LEMMA 3.14. *The following lower bound holds for the number of jobs:*

$$n \geq \frac{m}{8D} \sum_{i \geq 4} T_i \; 2^{i-5}.$$

Proof. We prove the lemma by associating with every interval a set of jobs that have been, during the interval itself, either released, or completed by OPT, or moved to execution or completed by algorithm A. Consider an interval I_k, with a corresponding $i_k \geq 4$. According to Observation 3.13, when the interval starts $\Delta\delta^P(t_k)$ is between $2mi_k$ and $2m(i_k+1)$. This interval ends when $\Delta\delta^P(r_k)$ goes above $2m(i_k+2)$ or below $2m(i_k-1)$. (It might also reach 0 but $0 < 2m(i_k-1)$.) In the first case we have the evidence of at least m jobs finished by OPT. (Recall that $\Delta\delta^P(t) = \delta^{A,P}(t) - 2\delta^{OPT}(t)$.) In the second case we have the evidence of at least $2m$ jobs that either leave the pool to be assigned to a machine by algorithm A or arrive to both A and OPT. In both cases we charge $n_k \geq m$ jobs to interval I_k. We can then conclude with a first lower bound $n_k \geq m$ on the number of jobs charged to any interval $I_k \in \mathcal{T}_i$, $i_k \geq 4$.

Next, we give a second lower bound, based on Lemma 3.11, stating that during an interval $I_k = [t_k, r_k)$ there exist in the pool $2m$ jobs with remaining processing time at most $\frac{D}{2^{i_k-4}}$, since $\Delta\delta^P(t) > 2m(i_k - 1)$ for any $t \in [t_k, r_k)$. This implies that all the m machines are processing jobs with remaining processing time at most $\frac{D}{2^{i_k-5}}$. We look at any subinterval of I_k of length $\frac{D}{2^{i_k-5}}$. For each machine, during this subinterval, a job is either finished by the algorithm or is preempted by a job of lower class. Therefore, we can charge at least m jobs that are either released or finished with any subinterval of size $\frac{D}{2^{i_k-5}}$ of I_k. A second lower bound on the number of jobs charged to any interval is then given by $n_k \geq m\lfloor \frac{x_k 2^{i_k-5}}{D} \rfloor$.

Now observe that each job is charged at most four times: when it is released, when it is assigned to a machine by A, when it is finished by A, and when it is finished by OPT. Then,

$$\frac{m}{2D} \sum_{i \geq 4} T_i \; 2^{i-5} \leq \sum_{k | i_k \geq 4} m \; \max\left\{1, \left\lfloor \frac{x_k 2^{i_k-5}}{D} \right\rfloor \right\} \leq 4n,$$

where the first inequality is obtained by summing over I_k's instead of over T_i's and the simple fact that $\alpha \leq \max\{1, \lfloor 2\alpha \rfloor\}$ and the second inequality follows from the lower bounds we have shown on the charged jobs. The lemma easily follows. ∎

We next bound the number of jobs that are assigned to a machine l during the time instants of $\mathcal{T}^l$. We partition the set of time instants $\mathcal{T}^l$ into a set of disjoint intervals $I_k^l = [t_k^l, r_k^l)$, $k = 1, \ldots, s^l$, and associate an integer i_k^l with each interval such that for any time $t \in I_k^l$, $\delta^{A,l}(t) = i_k^l$. Consider a maximal interval of times $[t_b^l, t_e^l)$ contained in $\mathcal{T}^l$. Assume $t_k^l = t_b^l$. Given t_k^l and i_k^l, define $r_k^l = \min\{t_e^l, t | t > t_k^l, \delta^{A,l}(t) \neq i_k^l\}$. In case $r_k^l < t_e^l$, we set $t_{k+1}^l = r_k^l$. Denote by $x_k^l = r_k^l - t_k^l$ the size of interval I_k^l. Define by $\mathcal{T}_i^l = \{\cup I_k^l | i_k^l = i\}$, $i \geq 1$, the union of the intervals I_k^l when the number of jobs assigned to machine l is exactly i and by $T_i^l = \int_{t \in \mathcal{T}_i^l} dt$ the size of set $\mathcal{T}_i^l$.

LEMMA 3.15. *The following lower bound holds for the number of jobs assigned to machine l:*

$$n^l \geq \frac{1}{4T^l} \sum_{i \geq 1} T_i^l \; 2^{i-2}.$$

Proof. For each interval I_k^l we charge at least one job. Every job will be charged at most twice: when it is assigned to a machine by A and when it is finished by A.

Consider the generic interval I_k^l, with the corresponding i_k^l. The interval starts when $\delta^{A,l}(t_k)$ reaches i_k^l, from above or from below. The interval ends when $\delta^{A,l}(r_k)$ reaches $i_k^l + 1$ or $i_k^l - 1$. In the first case we have the evidence of one job that is assigned by A to machine l and in the second case of one job that is finished by A. In both cases we charge one job to interval I_k^l.

Next we give a second lower bound, based on Lemma 3.12. Lemma 3.12 states that during an interval $I_k^l = [t_k^l, r_k^l)$, machine l is constantly assigned with a job of remaining processing time at most $T^l/2^{i_k^l-2}$. We look at any subinterval of I_k^l of length $T^l/2^{i_k^l-2}$. During this subinterval, a job is either finished by the algorithm or is preempted by a job of a lower class. In any case, a job that is assigned or finished during any subinterval of size $T^l/2^{i_k^l-2}$ is charged. A second lower bound on the number of jobs charged to any interval is then given by $n_k \geq \lfloor x_k^l 2^{i_k^l-2}/T^l \rfloor$.

Now observe that each job is considered at most twice: when it is assigned to machine l and when it is finished by A. Then, from the inequalities

$$\frac{1}{2T^l} \sum_{i \geq 1} T_i^l \; 2^{i-2} \leq \sum_{k | i_k^l \geq 1} \max \left\{ 1, \left\lfloor \frac{x_k^l 2^{i_k^l-2}}{T^l} \right\rfloor \right\} \leq 2n^l,$$

the claim follows. □

Before completing the proof, we still need a simple mathematical lemma.

LEMMA 3.16. *Given a sequence $a_1, a_2, \ldots$ of nonnegative numbers such that $\sum_{i \geq 1} a_i \leq A$ and $\sum_{i \geq 1} 2^i a_i \leq B$, then $\sum_{i \geq 1} i a_i \leq \log(4B/A)A$.*

Proof. Define a second sequence, $b_i = \sum_{j \geq i} a_j$ for $i \geq 1$. Then it is known that $A \geq b_1 \geq b_2 \geq \cdots$. Also, it is known that $\sum_{i \geq 1} 2^i a_i = \sum_{i \geq 1} 2^i (b_i - b_{i+1}) = \frac{1}{2} \sum_{i \geq 1} 2^i b_i + b_1$. This implies that $\sum_{i \geq 1} 2^i b_i \leq 2B$.

The sum we are trying to upper bound is $\sum_{i \geq 1} b_i$. This can be viewed as an optimization problem where we try to maximize $\sum_{i \geq 1} b_i$ subject to $\sum_{i \geq 1} 2^i b_i \leq 2B$ and $b_i \leq A$ for $i \geq 1$. This corresponds to the maximization of a continuous function in a compact domain and any feasible point where $b_i < A, b_{i+1} > 0$ is dominated by the point we get by replacing b_i, b_{i+1} with $b_i + 2\epsilon, b_{i+1} - \epsilon$. Therefore, it is upper bounded by assigning $b_i = A$ for $1 \leq i \leq k$ and $b_i = 0$ for $i > k$, where k is large enough such that $\sum_{i \geq 1} 2^i b_i \geq 2B$. A choice of $k = \lceil \log(2B/A) \rceil$ is adequate, and the sum is upper bounded by kA from which the result follows. □

THEOREM 3.17. *$F^A = O(\log n) F^{OPT}$; that is, algorithm A has an $O(\log n)$ approximation ratio even compared with the flow time of the (possibly migratory) schedule of the optimal offline algorithm.*

Proof.

$$\begin{aligned}
F^A &= \int_t \delta^A(t) dt \\
&= \sum_{l=1}^m \int_t \delta^{A,l}(t) dt + \int_{t \in \mathcal{T}} \delta^{A,P}(t) dt \\
&= \sum_{l=1}^m \int_{t \in \mathcal{T}^l} \delta^{A,l}(t) dt + \int_{t \in \mathcal{T}} (2\delta^{OPT}(t) + \Delta\delta^P(t)) dt \\
&\leq \sum_{l=1}^m \int_{t \in \mathcal{T}^l} \delta^{A,l}(t) dt + 2F^{OPT} + \sum_i \int_{t \in \mathcal{T}_i} 2m(i+2) dt
\end{aligned}$$

$$\leq \sum_{l=1}^{m} \sum_{i\geq 1} i\ T_i^l + 2F^{OPT} + 2m \sum_i (i+2)\ T_i$$
$$= \sum_{l=1}^{m} \sum_{i\geq 1} i\ T_i^l + 2F^{OPT} + 2m \sum_i (i-3)\ T_i + 2m \sum_i 5\ T_i$$
$$\leq \sum_{l=1}^{m} \sum_{i\geq 1} i\ T_i^l + 2F^{OPT} + 2m \sum_{i\geq 4} (i-3)\ T_i + 10F^{OPT}$$
$$\leq \sum_{l=1}^{m} \sum_{i\geq 1} i\ T_i^l + 12F^{OPT} + 2m \sum_{i\geq 1} i\ T_{i+3}.$$

The second equality is obtained by separately considering the contribution of every machine l and the contribution of the jobs in the pool. The fourth inequality is obtained by partitioning $\mathcal{T}$ into the $\mathcal{T}_i$'s such that at any time $t \in \mathcal{T}_i$, $\Delta\delta^P(t) < 2m(i+2)$. The seventh inequality is obtained by observing that $m\sum_i T_i \leq \sum_j p_j \leq F^{OPT}$, since all machines are busy processing jobs at any time $t \in \mathcal{T}$.

We upper bound $\sum_{i\geq 1} i\ T_{i+3}$ under the constraint $\sum_{i\geq 1} T_{i+3} \leq T \leq D$ and the constraint on n given by Lemma 3.14. By choosing $a_i = T_{i+3}$ we see that $\sum_{i\geq 1} a_i \leq D$ and $\sum_{i\geq 1} 2^i a_i \leq 32\frac{n}{m}D$. These two bounds together with Lemma 3.16 result in the upper bound $\sum_{i\geq 1} i a_i \leq (7 + \log\frac{n}{m})D$. A similar argument is used for the other sum. We choose $a_i = T_i^l$ instead. First note that $\sum_{i\geq 1} a_i \leq T^l$. Then, according to Lemma 3.15, $\sum_{i\geq 1} 2^i a_i \leq 16n^l T^l$. The upper bound by Lemma 3.16 is $\sum_{i\geq 1} i a_i \leq (6 + \log n^l)T^l$.

We finally express the total flow time of algorithm A as

$$\begin{aligned} F^A &\leq \sum_{l=1}^{m} \sum_{i\geq 1} iT_i^l + 12F^{OPT} + 2m \sum_{i\geq 1} i\ T_{i+3} \\ &\leq \sum_{l=1}^{m} O(T^l \log n^l) + 12F^{OPT} + O\left(mD \log \frac{n}{m}\right) \\ &= O(\log n) \sum_{l=1}^{m} T^l + 12F^{OPT} + O\left(\log \frac{n}{m}\right) F^{OPT} \\ &= O(\log n) F^{OPT}. \end{aligned}$$

The third equality follows since $mD \leq \max\{mT, \max_{t\in\mathcal{T}}\{V^A(t)\}\} \leq \sum_{j\in J} p_j \leq F^{OPT}$. The fourth equality follows since $\sum_{l=1}^{m} T^l = \sum_j p_j \leq F^{OPT}$. □

4. Tightness of the analysis. In this section we present an $\Omega(\log n)$ lower bound on the competitive ratio of the algorithm analyzed in the previous section. The number of machines is an arbitrary $m \geq 2$ but note that the lower bound uses only the first two machines. While presenting the lower bound we assume an order between jobs with the same release time. The algorithm deals with jobs released at the same time following the specified order.[1] Moreover, we assume that the algorithm arbitrarily decides whether to schedule a job on an idle machine or on a machine

[1] This can be forced by releasing some jobs slightly after previous ones in the specified order and decreasing their processing times appropriately.

processing a job of higher class. The latter assumption is crucial in proving the lower bound, and it agrees with the definition of the algorithm.

We choose P, the ratio between the maximum and the minimum processing time to be a power of 2. The maximum processing time is $P/2$ and the minimum is $1/2$. At each time $r_i = P(1 - \sum_{j=i}^{\frac{1}{2}\log P-1} \frac{1}{2^{2j+1}})$, for $i = 0, \ldots, \frac{1}{2}\log P - 1$, three jobs are released; one job of processing time $\frac{P}{2^{2i+1}}$ followed by two jobs of processing time $\frac{P}{2^{2i+2}}$. Finally, two jobs of size $\frac{1}{2}$ are released every $1/2$ time unit between time $r_{\frac{1}{2}\log P} = P$ and $2P - 1/2$.

Let us consider the behavior of the algorithm and of the optimal solution in this instance. At time r_0 the released job of processing time $P/2$ is assigned to machine 1, and a job of processing time $P/4$ is assigned to machine 2 while the second job of processing time $P/4$ preempts the job on execution on machine 1. The two jobs of processing time $P/4$ are finished at time $r_0 + P/4$, where the job of size $P/2$ is taken again on execution on machine 1. In general, at time r_i, $i = 1, \ldots, \frac{1}{2}\log P$, i jobs are in the queue of machine 1, the smallest of remaining processing time $\frac{P}{2^{2i}}$, while no job is on execution on machine 2. The job on execution on machine 1 is preempted by the job of size $\frac{P}{2^{2i+1}}$ that is released at time r_i. Immediately afterwards it is preempted by a job of size $\frac{P}{2^{2i+2}}$ that is released at time r_i while the other job of size $\frac{P}{2^{2i+2}}$ released at time r_i is scheduled on machine 2.

At time P, $\frac{1}{2}\log P$ jobs are in the queue of machine 1, the smallest of size 1, while no job is in the pool or assigned to the other machines. The two jobs of size $1/2$ released every $1/2$ time unit between time P and $2P - 1/2$ are scheduled on machines 1 and 2. Observe that $\frac{1}{2}\log P$ jobs are waiting on queue 1 between time P and $2P$, thus leading to a flow time of $\Omega(P \log P)$ for the algorithm on this instance of $n = \frac{3}{2}\log P + 4P$ jobs.

On the other hand, an optimal solution schedules the job of size $\frac{P}{2^{2i+1}}$ released at time r_i for $i = 0, \ldots, \frac{1}{2}\log P - 1$ on machine 1 and the two jobs of size $\frac{P}{2^{2i+2}}$ released at time r_i on machine 2. Observe that in this schedule machines 1 and 2 are idle at time r_i. Thus, the jobs of size $\frac{1}{2}$ are scheduled at their release times on machines 1 and 2 and are completed before the next two jobs of size $\frac{1}{2}$ are released. The flow time of the optimal solution is then $O(P)$.

It follows that the ratio between the flow time of the algorithm and the flow time of the optimal solution is $\Omega(\log P)$ that is also $\Omega(\log n)$.

5. Conclusions. In this paper we considered the problem of finding a preemptive schedule that optimizes the total flow time of a set of jobs released over time when job migration is not allowed. We presented a new online algorithm that is almost as effective as the best known algorithm that uses migration [8].

In our algorithm jobs are kept in a pool since the release time until they are assigned to a machine. An interesting open problem is to devise an efficient algorithm that assigns jobs to machines at the time of release. A challenging open problem is also to devise a constant offline approximation algorithm for optimizing total flow time even if both preemption and migration are allowed.

PSEUDORANDOM FUNCTIONS AND FACTORING*

MONI NAOR†, OMER REINGOLD‡, AND ALON ROSEN†

Abstract. The computational hardness of factoring integers is the most established assumption on which cryptographic primitives are based. This work presents an efficient construction of *pseudorandom functions* whose security is based on the intractability of factoring. In particular, we are able to construct efficient length-preserving pseudorandom functions, where each evaluation requires only a (small) *constant* number of modular multiplications per output bit. This is substantially more efficient than any previous construction of pseudorandom functions based on factoring and matches (up to a constant factor) the efficiency of the best-known factoring-based *pseudorandom bit generators*.

1. Introduction.

Almost any interesting cryptographic task must be based on the computational hardness of some problem. Proving such hardness assumptions exceeds by far the state of the art of complexity theory. It is therefore desirable to base the security of a cryptographic construction on as reasonable an assumption as possible. A natural approach is to rely on a well-studied problem where many algorithms have been tried and their complexity is well understood. The most established candidate in these respects, and certainly the one with the best pedigree, is the problem of factoring integers (see [22] for the state of the art of factoring).

The focus of this paper is an efficient construction of *pseudorandom functions* (see definition below) whose security is based on the intractability of factoring. In particular, we are able to construct efficient length-preserving pseudorandom functions whose evaluation requires only a constant number of modular multiplications per output bit. This is substantially more efficient than any previous construction of pseudorandom functions based on factoring and matches (up to a constant factor) the efficiency of the best-known factoring-based *pseudorandom bit generators*.

Pseudorandom functions,[1] originally defined by Goldreich, Goldwasser, and Micali (GGM) [13] are an important cryptographic primitive. A distribution of functions is pseudorandom if it satisfies the following requirements:

- *Easy to sample.* It is easy to sample a function according to the distribution.
- *Easy to compute.* Given such a function, it is easy to evaluate it at any given point.

[1]Note the difference between a pseudorandom function and a bit generator—the latter expands a random seed to some fixed length sequence that should be indistinguishable from a random sequence of similar length; there is no "probing" in the attack.

- *Pseudorandom.* It is hard to tell apart a function sampled according to the pseudorandom distribution from a uniformly distributed function when the distinguisher is given access to the function as a black-box.

Pseudorandom functions have a wide range of applications, most notably in cryptography, but also in computational complexity and computational learning theory. Coming up with efficient constructions for such functions is a challenge of great practical and theoretical interest.

The new construction improves the one by Naor and Reingold (NR) [20], who showed how to construct pseudorandom functions based on factoring, where the cost of evaluation is comparable to two modular exponentiations. The drawback of those functions is that the output is only a single bit. In order to apply them for achieving a length-preserving pseudorandom function, one would need to repeat the process n times, rendering it inefficient. The improvement we propose lies in a method to expand the one-bit output of the NR functions to polynomially many bits while paying only a small overhead in the complexity of the evaluation (i.e., one modular multiplication for each additional output bit). This improvement will be achieved through a surprising combination of the NR functions and the Blum–Blum–Shub (BBS) pseudorandom generator [5]. As will be demonstrated in what follows, in general, such a composition does *not* necessarily yield a pseudorandom function. This, in particular, implies a nonstraightforward proof of security.

The method we suggest enables us to construct efficient length-preserving pseudorandom functions which are at least as secure as factoring Blum-integers and can be evaluated at the cost of fewer than three modular exponentiations. This is comparable to another attractive construction by NR [20] of pseudorandom functions which are at least as secure as the *decisional Diffie–Hellman (DDH)* problem. While the DDH problem has received much attention recently (see [4]), it is not nearly as well established as factoring.

Organization. The next section contains the background material and our construction. The main result of our work, the efficient construction of a pseudorandom function which is at least as secure as factoring Blum-integers, is presented in section 4. The proof of security is given in section 5.

2. Old and new constructions.

2.1. Background. When GGM originally defined pseudorandom functions [13], they were at least partly motivated by the construction of the BBS pseudorandom *generator* [5] and, in particular, by an open question suggested there—the *easy-access* problem.[2] Nevertheless, the actual GGM construction of pseudorandom functions did not appear to have any direct connection to the BBS generator (apart from the fact that the BBS generator can be used as a building block for the GGM construction). The current work suggests a construction which is directly related to the BBS generator. We now turn to survey previous constructions of pseudorandom functions (as well as the BBS generator).

[2]The *easy-access* problem arises when one notices that it is easy to access exponentially far away bits in the BBS pseudorandom pad. The question is whether the BBS pad remains pseudorandom even when the distinguisher has access to these exponentially far away bits.

2.1.1. The BBS generator.

The Blum–Micali paradigm (cf. [7, 27]). Let $f : \{0,1\}^n \to \{0,1\}^n$ be a one-way permutation (i.e., one where it is easy to compute $f(x)$ but intractable to find $x = f^{-1}(y)$), and let $\mathcal{B}(\cdot)$ be a hard-core predicate for $f(\cdot)$ (i.e., given y, it is difficult to guess $\mathcal{B}(f^{-1}(y))$). Let $\ell : \mathbb{N} \to \mathbb{N}$ be a function so that $\ell(n) > n$ for all n. Blum and Micali proposed the following scheme to construct a generator stretching an n-bit seed, x, to an ℓ-bit pseudorandom string:

$$\mathcal{B}(x), \mathcal{B}(f(x)), \ldots, \mathcal{B}(f^{(k)}(x)), \ldots, \mathcal{B}(f^{(\ell(n)-1)}(x)). \tag{1}$$

As a candidate one-way permutation (based on factoring), BBS [5] considered the squaring function modulo an integer $N = P \cdot Q$ (i.e., the mapping $x \mapsto x^2 \bmod N$).[3] Following [5], the values of N are restricted to integers of the form $N = P \cdot Q$, where P and Q are two distinct primes both congruent to 3 mod 4. (Such integers are known as Blum-integers.)

Blum-integers. Restricting N to a Blum-integer enabled BBS to prove that the squaring function is indeed a permutation (when its domain is limited to the subgroup of *quadratic-residues* in $\mathbb{Z}_N^*$). Let $N = P \cdot Q$ be an integer; an element in $\mathbb{Z}_N^*$ is called a quadratic-residue if it has a square-root; namely, there is a $y \in \mathbb{Z}_N^*$ such that $y^2 = x \bmod N$. It is easy to verify that the set of quadratic-residues in $\mathbb{Z}_N^*$ forms a subgroup (which we denote by QR_N). We note that every $x^2 \in QR_N$ has exactly four distinct square-roots, $\pm x, \pm y \in \mathbb{Z}_N^*$, and, in the special case that N is a Blum-integer, it is possible to prove [5] that exactly one of these square-roots resides in QR_N (which implies that squaring is indeed a permutation over QR_N).

Constructing the BBS generator. The BBS pseudorandom generator is obtained by applying the Blum–Micali paradigm to the squaring permutation together with the $\mathcal{LSB}(\cdot)$ (least significant bit) hard-core predicate. This generator has been originally proven secure assuming intractability of the quadratic residuosity problem in [5], and subsequently under the assumption that factoring Blum-integers is hard (Assumption 4.1) in [26] (by adapting the techniques in [1]). Note also that it is the basis for the Blum–Goldwasser public-key encryption scheme [6]. For simplicity of exposition, we choose to replace the $\mathcal{LSB}(\cdot)$ hard-core predicate with the Goldreich–Levin $\mathcal{B}_r(\cdot)$ predicate [14] (where $\mathcal{B}_r(m)$ denotes the inner product, $\langle m, r \rangle \bmod 2$). We obtain a generator which stretches an n-bit seed, $x \in QR_N$, to an ℓ-bit pseudorandom string (and is completely analogous to the BBS generator):[4]

$$\mathcal{B}_r(x), \mathcal{B}_r(x^2), \ldots, \mathcal{B}_r(x^{2^k}), \ldots, \mathcal{B}_r(x^{2^{\ell(n)-1}}). \tag{2}$$

The BBS generator is considered efficient (relative to other generators based on factoring); each bit in its output can be obtained at the cost of one modular multiplication. In particular, by performing $2n$ modular multiplications, it is possible to stretch an n-bit seed to a $2n$-bit pseudorandom string.

[3] It was shown by Rabin [23] that the problem of factoring an integer $N = P \cdot Q$ can be reduced to the problem of extracting square-roots in $\mathbb{Z}_N^*$. Thus, if factoring $N = P \cdot Q$ is hard, then squaring is indeed one-way.

[4] We denote by n the size (in bits) of N and by x^{2^j} the value of $x^{2^j} \bmod N$.

The easy-access problem. In the BBS generator, a seed (x, N) defines an infinite (ultimately periodic) bit-sequence $b_0, b_1, \ldots$ (even though a pseudorandom string generated with an n-bit long seed consists of only polynomially many (in n) bits). An interesting feature of the BBS generator is that knowledge of the factorization of N allows *easy access* to each of the first 2^n bits; that is, if $\log i < n$, the ith bit, b_i, can be computed in poly(n) time (by first computing $\beta_i = 2^{i-1} \bmod \varphi(N)$ and then setting $b_i = \mathcal{B}_r(x^{\beta_i})$). However, as GGM noted [13], this easily accessible exponentially long bit-string *may not* appear "random." What BBS have proved is that any single polynomially long interval of *consecutive* bits in the string is pseudorandom (provided that factoring Blum-integers is hard). Indeed, it might be the case that, say, given $b_1, \ldots, b_n$ and $b_{2\sqrt{n}+1}, \ldots, b_{2\sqrt{n}+n}$, it is easy to compute any other bit in the string.

The *easy-access* problem is whether direct access to exponentially far away bits in the BBS bit-sequence is an operation which preserves pseudorandomness. This problem was discussed in [2, 8, 5, 13] and is still unresolved.

2.1.2. The GGM construction. Motivated in part by the easy-access problem, GGM [13] introduced the notion of pseudorandom functions and provided a generic construction based on any length-doubling pseudorandom generator. Note that a pseudorandom function may be viewed as an exponentially long bit-string which remains pseudorandom even after its bits are accessed in a direct manner. Thus, in some sense, GGM have bypassed the easy-access problem.[5]

When applied to an efficient pseudorandom generator based on factoring (e.g., the BBS generator), the GGM construction yields a length-preserving pseudorandom function which is as secure as factoring but requires as much as $O(n^2)$ modular multiplications per evaluation. On the other hand, a positive answer to the easy-access problem implies that the function

$$f^{BBS}_{N,g,r}(i) = G^{BBS}_{N,r,n}(g^{2^{i \cdot n}}) \tag{3}$$

is a length-preserving pseudorandom function which is at least as secure as factoring and requires only $O(n)$ modular multiplications per evaluation. Thus, in some sense, the question of whether it is possible to construct such efficient pseudorandom functions (which require as much modular multiplications as $f^{BBS}_{N,g,r}$) based on factoring remained open.

2.1.3. The NR constructions. About a decade after the GGM paper appeared, NR [19] suggested a parallel construction of pseudorandom functions. The NR construction was obtained by introducing a new cryptographic primitive, the *pseudorandom synthesizer*. By applying their method to specific constructions of pseudorandom synthesizers, they were later able to present efficient pseudorandom functions based on standard number-theoretic assumptions [20]. These constructions are considerably more efficient than the constructions which would have been obtained by applying the generic GGM construction to specific pseudorandom generators that are based on the same assumptions.

The DDH construction. The DDH construction is a construction of length-preserving pseudorandom functions as secure as the DDH problem requiring roughly

[5] What GGM have actually demonstrated is how to construct exponentially long, easily accessible, pseudorandom strings based on *any* one-way function (following [16]). However, this does not imply that the *specific* BBS bit-sequence remains pseudorandom given direct access to exponentially many of its bits.

$2n$ modular multiplications per evaluation [20]. This already matches the efficiency offered by $f^{BBS}_{N,g,r}$ and, to the best of our knowledge, is the most efficient construction of pseudorandom functions to date (based on standard intractability assumptions).

The factoring construction. The factoring construction is a construction of pseudorandom functions at least as secure as factoring requiring roughly $2n$ modular multiplications per evaluation [20]. (Their proof of security utilizes Biham, Boneh, and Reingold's [3] result that breaking the generalized Diffie–Hellman assumption over composites implies an efficient algorithm for factoring.)

For every $n \in \mathbb{N}$, a key of a function in the NR pseudorandom function ensemble, F_n, is a tuple $(N, \vec{a}, g, r)$, where N is an n-bit Blum-integer, r is an n-bit string, g is a quadratic-residue in $\mathbb{Z}^*_N$, and $\vec{a} = (a_{1,0}, a_{1,1}, a_{2,0}, a_{2,1}, \ldots, a_{n,0}, a_{n,1})$ is a sequence of $2n$ elements in $\{1, \ldots, N\}$. For any n-bit input $x = x_1 x_2 \ldots x_n$, the NR function (with a single bit of output) is defined as

$$f_{N,\vec{a},g,r}(x) = \mathcal{B}_r(g^{\Pi_{i=1}^n a_{i,x_i}}). \tag{4}$$

The NR construction gives a pseudorandom function which *seems* to be as efficient as $f^{BBS}_{N,g,r}$. Note however, that the NR function has only one bit of output, whereas $f^{BBS}_{N,g,r}$ has linear output length. While this may be sufficient for some applications, in most scenarios it is not. The goal of our work is to match the result one would have obtained by proving that $f^{BBS}_{N,g,r}$ are indeed pseudorandom functions. That is, we provide a new construction of pseudorandom functions that (1) are at least as secure as factoring Blum-integers, (2) have linear output length, and (3) require only $O(n)$ modular multiplications per evaluation.

2.2. Our construction. The NR pseudorandom function, $f_{N,\vec{a},g,r}$, is obtained by extracting the $\mathcal{B}_r(\cdot)$ predicate from the value of the function

$$h_{N,\vec{a},g}(x) = g^{\Pi_{i=1}^n a_{i,x_i}}. \tag{5}$$

It turns out that, even though it is not pseudorandom in itself, the function $h_{N,\vec{a},g}$ is unpredictable in some weak sense. Assuming the intractability of factoring Blum-integers, NR have shown [20, 21] that $h_{N,\vec{a},g}$ is unpredictable against an *adaptive* sample and a *random* challenge. That is, for a random $x \in \{0,1\}^n$, no polynomial-time adversary is able to predict the value of $h(x)$ after adaptively querying the value of $h(y)$ for polynomially many $y \neq x$ of his choice.

The main idea behind our construction is using the value of $h_{N,\vec{a},g}$ as a seed to the BBS pseudorandom generator. At first glance, it is not clear why this method should work *at all*. Indeed, applying a pseudorandom generator to an "unpredictable" value does *not* necessarily yield a pseudorandom function (see section 5.1 for a more detailed discussion on the subject). The reason for which our construction *does* work lies in the *specific* number theoretic features which the function $h_{N,\vec{a},g}$ and the BBS generator have in common.

This enables us to expand the output length of the NR function to polynomially many bits while paying a "reasonable" overhead in the complexity of the evaluation (i.e., one modular multiplication for each additional output bit). Specifically, let $N, \vec{a}, g$, and r be defined as in the NR function; the function we propose is defined as

$$f_{N,\vec{a},g,r}(x) = G^{BBS}_{N,r,\ell}(g^{\Pi_{i=1}^n a_{i,x_i}}). \tag{6}$$

Even though this does not solve the particular easy-access problem, it *does* match the efficiency one would have obtained by proving that $f^{BBS}_{N,g,r}$ are indeed pseudorandom functions (as well as the efficiency of the DDH-based pseudorandom functions by

NR [20]). By taking $\ell(n) = n$, we obtain a length-preserving pseudorandom function which is at least as secure as factoring, has linear output length, and requires only $3n$ modular multiplications per evaluation. This already matches (up to a constant factor) the efficiency of the best-known factoring-based pseudorandom *generators* (which also require $O(n)$ multiplications per evaluation) and certainly improves the efficiency of the GGM pseudorandom functions which use BBS as a building block.

3. Preliminaries. For the sake of completeness, we present the formal definition of pseudorandom functions. Our exposition follows the ones appearing in [11, 12, 19].

3.1. Pseudorandom functions—definition. Pseudorandom functions were defined by GGM [13]. Loosely speaking, these are efficient distributions of functions that cannot be efficiently distinguished from the uniform distribution. That is, an efficient algorithm that gets a function as a black-box cannot tell (with nonnegligible advantage) from which of the distributions it was sampled.[6] To formalize the notion of pseudorandom functions, we will need to consider ensembles of functions.

DEFINITION 3.1. *Let ℓ_d and ℓ_r be any two integer functions. An $I^{\ell_d} \to I^{\ell_r}$* function ensemble *is a sequence $F = \{F_n\}_{n\in\mathbb{N}}$ of random variables such that the random variable F_n assumes values in the set of $I^{\ell_d(n)} \to I^{\ell_r(n)}$ functions. The* uniform $I^{\ell_d} \to I^{\ell_r}$ function ensemble*, $R = \{R_n\}_{n\in\mathbb{N}}$, has R_n uniformly distributed over the set of $I^{\ell_d(n)} \to I^{\ell_r(n)}$ functions.*

An explicit description of a function $f : I^{\ell_d} \to I^{\ell_r}$ requires as many as $2^{\ell_r 2^{\ell_d}}$ bits. This suggests an alternative view of pseudorandom functions: These are distributions of exponentially long bit-sequences that cannot be distinguished from random by an efficient algorithm which has direct access to the sequence. To be of practical value, however, we require that pseudorandom functions can be efficiently sampled and computed. This property is not satisfied by every function ensemble (e.g., the uniform function ensemble: it contains $2^{\ell_r 2^{\ell_d}}$ functions whose mere representation requires as many as $\ell_r 2^{\ell_d}$ bits); we therefore restrict ourselves to efficiently computable function ensembles.

DEFINITION 3.2. *A function ensemble, $F = \{F_n\}_{n\in\mathbb{N}}$, is* efficiently computable *if there exist probabilistic polynomial-time algorithms, $\mathcal{I}$ and $\mathcal{V}$, and a mapping from strings to functions, ϕ such that $\phi(\mathcal{I}(1^n))$ and F_n are identically distributed and $\mathcal{V}(i, x) = (\phi(i))(x)$.*

We denote by f_i the function assigned to i (i.e., $f_i \stackrel{\text{def}}{=} \phi(i)$). We refer to i as the key of f_i and to $\mathcal{I}$ as the key-generating algorithm of F.

In particular, functions in efficiently computable function ensembles have relatively succinct representation (i.e., of polynomial rather than exponential length). As a consequence, these ensembles may have only exponentially many functions (out of double-exponentially many possible functions).

The distinguisher, in our setting, is defined to be an oracle machine that can make queries to a function (which is either sampled from the pseudorandom function ensemble[7] or from the uniform function ensemble[8]). We assume that on input 1^n

[6] For a detailed exposition on pseudorandom functions and their applications, we refer the reader to [24].

[7] We stress that, in the case that the function is sampled from the pseudorandom function ensemble, the distinguisher is *not* given the representation of the function f_i (i.e., the key i).

[8] As we have mentioned, it is not clear even how to efficiently represent a uniformly distributed function (as the representation it is too large to store). Still, one may simulate such a function by answering given queries with independently and uniformly chosen answers (while memorizing previous answers for the sake of consistency).

the oracle machine makes only n-bit queries. For any probabilistic oracle machine, $\mathcal{M}$, and any $I^n \to I^{\ell(n)}$ function, O, we denote by $\mathcal{M}^O(1^n)$ the distribution of $\mathcal{M}$'s output on input 1^n and with access to O.

DEFINITION 3.3. *An efficiently computable $I^n \to I^{\ell(n)}$ function ensemble, $F = \{F_n\}_{n\in\mathbb{N}}$, is* pseudorandom *if, for every probabilistic polynomial-time oracle machine $\mathcal{M}$, every polynomial $p(\cdot)$, and all sufficiently large n's,*

$$\left|\Pr\left[\mathcal{M}^{F_n}(1^n) = 1\right] - \Pr\left[\mathcal{M}^{R_{n,\ell}}(1^n) = 1\right]\right| < \frac{1}{p(n)},$$

where $R = \{R_{n,\ell}\}_{n\in\mathbb{N}}$ is the uniform $I^n \to I^{\ell(n)}$ function ensemble.

The term "pseudorandom functions" is hereafter used as an abbreviation for "efficiently computable pseudorandom function ensemble."

3.2. Notation.

- $\mathbb{N}$ denotes the set of all natural numbers.
- For any integer $k \in \mathbb{N}$, denote by $[k]$ the set of integers $\{0, 1, \ldots, k-1\}$.
- For any integer $N \in \mathbb{N}$, the multiplicative group modulo N is denoted by $\mathbb{Z}_N^*$.
- The order of $\mathbb{Z}_N^*$ (i.e., the number of $x \in [N]$ such that $\gcd(x, N) = 1$) is denoted by $\varphi(N)$.
- I^n denotes the set of all n-bit strings, $\{0,1\}^n$.
- U_n denotes the random variable uniformly distributed over I^n.
- Let x and y be any two-bit strings; then x, y denote the string x concatenated with y.

4. The main result. We are now ready to present the main result of our work, an efficient construction of pseudorandom functions whose security is based on the intractability of factoring. Specifically, we are able to show how any procedure which is able to distinguish our functions from randomly chosen ones can be turned into an algorithm which factors a nonnegligible fraction of Blum-integers. We begin by formalizing the assumption that factoring Blum-integers is hard.

4.1. The factoring assumption. In order to keep our result general, we let N be generated by *some* polynomial-time algorithm FIG (where FIG stands for factoring-instance-generator).

DEFINITION 4.1. *A factoring-instance-generator, FIG, is a probabilistic polynomial-time algorithm such that, on input 1^n, its output, $N = P \cdot Q$, is distributed over n-bit integers, where P and Q are two primes that satisfy $P = Q = 3 \bmod 4$. (Such N is known as a Blum-integer.)*

A natural example for a factoring-instance-generator would be to let $FIG(1^n)$ be uniformly distributed over *n-bit* Blum-integers.[9] However, other choices were previously considered (e.g., letting P and Q obey some "safety" conditions).[10] We now formalize the assumption that factoring Blum-integers is hard.

DEFINITION 4.2 (ϵ-factoring). *Let $\mathcal{A}$ be a probabilistic Turing machine, and let $\epsilon = \epsilon(n)$ be a real-valued function. $\mathcal{A}$ ϵ-factors if, for infinitely many n's,*

$$\Pr[\mathcal{A}(P \cdot Q) \in \{P, Q\}] > \epsilon(n),$$

[9] We note that *n-bit* Blum-integers are a nonnegligible fraction of all *n-bit* integers and that it is easy to sample a uniformly distributed *n-bit* Blum-integer.

[10] For example, it is often required that P and Q be of equal size and that P, Q be of the form $P = 2P' + 1$ and $Q = 2Q' + 1$ for some primes P', Q'.

where the distribution of $N = P \cdot Q$ is $FIG(1^n)$.

In spite of the extensive research directed toward the construction of efficient integer factoring algorithms, the best algorithms currently known for factoring an integer N have (heuristic) running-time $L(N) \stackrel{\text{def}}{=} e^{1.92(\log N)^{1/3}(\log\log N)^{2/3}}$ (cf. [22]). This (together with the fact that Blum-integers are a nonnegligible fraction of all n-bit integers) leads us to the following assumption.

ASSUMPTION 4.1 (factoring integers generated by *FIG*). *Let $\mathcal{A}$ be any probabilistic polynomial-time machine. There is no positive constant α such that $\mathcal{A}$ $\frac{1}{n^\alpha}$-factors.*

All exponentiations in the rest of this section are in $\mathbb{Z}_N^*$. To simplify the notation, we omit the expression "mod N" from now on.

4.2. The construction.

CONSTRUCTION 4.1. *We define a function in the ensemble $F = \{F_n\}_{n\in\mathbb{N}}$. For every $n \in \mathbb{N}$, a key of a function in F_n is a tuple $(N, \vec{a}, g, r)$, where N is an n-bit Blum-integer, g is a quadratic-residue in $\mathbb{Z}_N^*$, $\vec{a} = (a_{1,0}, a_{1,1}, a_{2,0}, a_{2,1}, \ldots, a_{n,0}, a_{n,1})$ is a sequence of $2n$ elements in $[N]$, and r is an n-bit string. For any n-bit input $x = x_1 x_2 \ldots x_n$ and for every integer-valued function $\ell = \ell(n)$, the function $f_{N,\vec{a},g,r} : I^n \to I^{\ell(n)}$ is defined by*

$$f_{N,\vec{a},g,r}(x) \stackrel{\text{def}}{=} \mathcal{B}_r(g^{\Pi_{i=1}^n a_{i,x_i}}), \mathcal{B}_r(g^{2\Pi_{i=1}^n a_{i,x_i}}), \ldots, \mathcal{B}_r(g^{2^k \Pi_{i=1}^n a_{i,x_i}}), \ldots, \mathcal{B}_r(g^{2^{\ell-1}\Pi_{i=1}^n a_{i,x_i}}),$$

where $\mathcal{B}_r(m)$ denotes the inner product, $\langle m, r\rangle \bmod 2$. The distribution of functions in F_n is induced by the following distribution on their keys: $\vec{a}$, g, and r are uniform in their range, and the distribution of N is $FIG(1^n)$.

REMARK 4.1. *Construction* 4.1 *employs a Blum-integer, N. In this we follow* [5] *and many other works. As discussed in section* 2.1.1*, this restriction implies that squaring is a permutation on the subgroup of quadratic-residues in $\mathbb{Z}_N^*$. Nevertheless, as was pointed out to us by Shai Halevi and an anonymous referee, it is rather easy to extend our construction (as well as many previous results) in order to allow an arbitrary moduli $N = P \cdot Q$ (that is assumed to be hard to factor) instead of a Blum-integer. The main observation that is needed is that, for any such N, squaring is a permutation on the subgroup of 2^n-powers in $\mathbb{Z}_N^*$. See* [15, 25] *for additional details on avoiding the restriction to a Blum-integer in related contexts.*

An additional variant of the construction is discussed in section 6*. There, we discuss how to replace the Goldreich–Levin hard-core bit with the $\mathcal{LSB}$ predicate.*

4.3. Efficiency of the construction. Consider a function $f_{N,\vec{a},g,r} \in F_n$ as in Construction 4.1. Computing the value of this function at any given point, x, involves one multiple product $y = \prod_{i=1}^n a_{i,x_i}$ (which can be performed modulo $\varphi(N)$), one modular exponentiation, $z = g^y \bmod N$, and $\ell(n) - 2$ successive modular squarings $z^2, \ldots, z^{2^k}, \ldots, z^{2^{\ell-1}}$ (which require less than one modular multiplication each). The value of the function is finally obtained by computing $\mathcal{B}_r(z), \mathcal{B}_r(z^2), \ldots, \mathcal{B}_r(z^{2^{\ell-1}})$ (which is a cheap operation compared to modular multiplication). As discussed in [20], it is possible to use preprocessing in order to get improved efficiency.[11] This gives us a pseudorandom function which can be evaluated roughly at the cost of $2n+\ell(n)$ modular multiplications. (A modular exponentiation is counted as n modular multiplications.)

[11] The most obvious preprocessing would be to compute the values g^{2^i} (for every positive integer i up to the length of $(P-1)\cdot(Q-1)$). See [20] for additional preprocessing techniques which further improve the efficiency.

An attractive feature of our construction is that, for each input, we can have a *variable* length output; i.e., if for some x's one needs more bits in the output of $f(x)$, then the natural way of simply taking more bits of the form $\mathcal{B}_r(z^{2^j})$ works. While it is possible to get this feature generically by combining a pseudorandom function and a generator, here we get it "for free."

5. Proof of security. The following theorem establishes the security of Construction 4.1.

THEOREM 5.1. *If the factoring assumption holds (Assumption* 4.1*), then* $F = \{F_n\}_{n\in\mathbb{N}}$ *(as in Construction* 4.1*) is an efficiently computable pseudorandom function ensemble.*

REMARK 5.1. *The proof of Theorem* 5.1 *yields a more quantitative version as well: Assume that there exists a probabilistic polynomial-time oracle machine with running-time* $t(n)$ *that distinguishes* $f_{N,\vec{a},g,r}$ *from* $\rho_{n,\ell}$ *with advantage* $\epsilon(n)$ *(where* $\rho_{n,\ell}$ *is uniformly distributed in the set of functions with domain* $\{0,1\}^n$ *and range* $\{0,1\}^{\ell(n)}$*). Let* $q = q(n)$ *be a bound on the number of queries made this machine. Then there exists a probabilistic polynomial-time algorithm with running-time* $poly(\frac{1}{\epsilon(n)}, t(n), \ell(n))$ *that* ϵ''*-factors for* $\epsilon''(n)$ *which equals* $\Omega(\frac{\epsilon(n)^2}{q(n)^2\cdot\ell(n)^2})$.

5.1. On the methodology.

5.1.1. A simple approach does not work. In order to prove Theorem 5.1, one might be tempted to use the following approach: Recall the definition of the function $h_{N,\vec{a},g}(x) = g^{\Pi_{i=1}^n a_{i,x_i}}$ in (5). As mentioned above, it was shown in [20, 21] that $h_{N,\vec{a},g}$ is unpredictable against an *adaptive* sample and a *random* challenge. In light of this, Construction 4.1 can be viewed as based on the following methodology:

1. Take an "unpredictable" function $h_s : \{0,1\}^n \to \{0,1\}^n$.
2. Take a pseudorandom generator $G : \{0,1\}^n \to \{0,1\}^\ell$.
3. Obtain a pseudorandom function $f : \{0,1\}^n \to \{0,1\}^\ell$ by setting $f_s(x) = G(h_s(x))$.

Unfortunately, this method does not work in general. As will be demonstrated next, there exist an "unpredictable" function and a pseudorandom generator such that their composition is *not* a pseudorandom function.

5.1.2. The counterexample. Consider the following (unnatural) counterexample:

1. (a) Let $h'_s : \{0,1\}^n \to \{0,1\}^{\frac{n}{2}}$ be an unpredictable function.
   (b) For $y \in \{0,1\}^{\frac{n}{2}}$, define $h_{s,y} : \{0,1\}^n \to \{0,1\}^n$ as $h_{s,y}(x) = (h'_s(x), y)$.
   (c) Clearly $h_{s,y}$ is unpredictable.
2. (a) Let $G' : \{0,1\}^{\frac{n}{2}} \to \{0,1\}^\ell$ be a pseudorandom generator.
   (b) For $z, y \in \{0,1\}^{\frac{n}{2}}$, define $G : \{0,1\}^n \to \{0,1\}^\ell$ as $G(z,y) = G'(y)$.
   (c) Clearly G is pseudorandom.
3. However, the function $f : \{0,1\}^n \to \{0,1\}^\ell$ obtained by setting $f_{s,y}(x) = G(h_{s,y}(x))$ is always equal to $G'(y)$ (regardless of the value of x). Obviously, $f_{s,y}$ cannot be pseudorandom.

It seems that the reason our construction *does* work lies in the *specific* number theoretic features which the function $g^{\Pi_{i=1}^n a_{i,x_i}}$ and the BBS generator have in common. Since we do not know what precisely are the features of a function h_s and of a pseudorandom generator G that are needed in order to obtain a pseudorandom function (using the above methodology), we are forced to provide a direct proof for our construction. As most proofs of pseudorandomness do, we will use a *hybrid argument*,

i.e., mixing a truly random and pseudorandom distribution. The type of hybrid we apply is the *reverse hybrid*, where first the random part is used and only then the pseudorandom one. This is an instance of the *principle of deferred decision* (see [18]): Do not commit to any value in the pseudorandom part of the distribution until you have to.

5.2. Proof of Theorem 5.1.

Proof. Let $F = \{F_n\}_{n\in\mathbb{N}}$ be as in Construction 4.1. It is clear that F is efficiently computable. Assume that F is not pseudorandom; then there exist a probabilistic polynomial-time oracle machine $\mathcal{M}$ and a nonnegligible real-valued function $\epsilon = \epsilon(n)$ such that, for infinitely many n's,

$$\left|\Pr\left[\mathcal{M}^{f_{N,\vec{a},g,r}}(1^n) = 1\right] - \Pr\left[\mathcal{M}^{\rho_{n,\ell}}(1^n) = 1\right]\right| > \epsilon(n), \tag{7}$$

where, in the first probability, $f_{N,\vec{a},g,r}$ is distributed according to F_n and, in the second probability, $\rho_{n,\ell}$ is distributed according to $R_{n,\ell}$ (the uniform ensemble of functions with domain $\{0,1\}^n$ and range $\{0,1\}^{\ell(n)}$).

A hybrid black-box. Inequality (7) tells us that there is a nonnegligible difference between the output behavior of $\mathcal{M}$ in the case it is given access to a black-box which answers according to $f_{N,\vec{a},g,r}$ and in the case it is given access to a black-box which answers according to $\rho_{n,\ell}$. However, $\mathcal{M}$'s response is still a well defined random variable even when its queries are answered according to some other distribution. This means that we are allowed to invoke $\mathcal{M}$ and answer its queries in whatever way we find suitable for our purposes. The way we choose to do it is by defining a *hybrid black-box*.[12] Informally, this is a black-box which starts by answering $\mathcal{M}$'s queries according to $\rho_{n,\ell}$ and then switches mode to continue and answer according to $f_{N,\vec{a},g,r}$.

Let $t = t(n)$ be a polynomial that bounds the running-time of $\mathcal{M}$; assume without loss of generality that $\mathcal{M}$ always makes exactly t queries. Since each single answer given to these queries is ℓ-bit long, we have that the total number of bits which $\mathcal{M}$ gets as answers during its execution is precisely $t \cdot \ell$. Each one of these bits corresponds to a location for which one of the hybrid black-box distributions will switch from answering according to $\rho_{n,\ell}$ to answering according to $f_{N,\vec{a},g,r}$. (Note that this may also happen in the middle of an answer.)

Definition 5.1 (hybrid black-box). *Let J be an element in $[t \cdot \ell + 1]$ written as $J = I \cdot \ell + k$ (where $0 \le I \le t$ and $0 \le k < \ell$). The Jth hybrid black-box, $H^J_{N,\vec{a},g,r}$, is defined by the answers it gives to $\mathcal{M}$'s queries. The first I queries are answered according to $\rho_{n,\ell}$ (i.e., at random), and the answer to the $(I+1)$st query up to the kth bit-location is according to $\rho_{n,\ell}$, and from then on, according to $f_{N,\vec{a},g,r}$. All remaining queries are answered according to $f_{N,\vec{a},g,r}$.*

Notice that $H^0_{N,\vec{a},g,r}$ is a black-box which always answers according to $f_{N,\vec{a},g,r}$, whereas $H^{t\cdot\ell}_{N,\vec{a},g,r}$ always answers according to $\rho_{n,\ell}$. By inequality (7), we have that $\mathcal{M}$ distinguishes between $f_{N,\vec{a},g,r}$ and $\rho_{n,\ell}$ with advantage $\epsilon(n)$. Therefore, if we pick J at random, the expected advantage that $\mathcal{M}$ has in distinguishing between $H^J_{N,\vec{a},g,r}$ and $H^{J+1}_{N,\vec{a},g,r}$ is at least $\epsilon'(n) = \frac{\epsilon(n)}{t(n)\cdot\ell(n)}$. An example of a hybrid black-box is depicted in Figure 1.

[12] This is just a methodological modification of the standard hybrid technique (see [11] for details on the hybrid technique).

	1	2	$\cdots$	I	$I+1$	$I+2$	$\ldots$	t
1	r	r	$\cdots$	r	r

FIG. 1. *Illustrates the Jth hybrid black-box, $H^J_{N,\vec{a},g,r}$ (where $J = I \cdot \ell + k$). Columns correspond to queries given to the black-box, and rows correspond to individual bits in the relevant answers.*

5.2.1. Simplified proof. We start by giving a simplified version of the proof under the assumption that $\mathcal{M}$ decides membership in F_n with advantage $\epsilon(n)$ for *any* sequence $\vec{a}$ of $2n$ elements in $[N]$. (Recall that $\vec{a}$ equals $(a_{1,0}, a_{1,1}, a_{2,0}, a_{2,1}, \ldots, a_{n,0}, a_{n,1})$.) We then proceed and show how to modify the proof so it will work for a randomly chosen $\vec{a}$.

Roughly speaking, we show how, given a distinguisher for our pseudorandom functions, we can construct an algorithm that on input $(v^2 \bmod N, N, r)$ predicts the value of $\mathcal{B}_r(u)$, where u is the unique quadratic-residue in $\mathbb{Z}^*_N$ which satisfies $u^2 = v^2 \bmod N$. Using the Goldreich–Levin reconstruction algorithm, we are then able to retrieve u (see [11] for details). This means that we can extract square-roots in $\mathbb{Z}^*_N$ and consequently factor Blum-integers (as described in [23]).

THEOREM 5.2 (Goldreich–Levin [14]). *Let $z, r \in \{0,1\}^n$. Given an oracle that, on input r, predicts the value of $\mathcal{B}_r(z)$ with advantage $\epsilon(n)$ (over the choice of r) in time $t(n)$, there exists a probabilistic polynomial-time algorithm with running-time $O(\frac{n^2 \cdot t(n)}{\epsilon(n)^2})$ that retrieves z with probability at least $\Omega(\epsilon(n))$.*

The following lemma can be viewed as the heart of the simplified part of the proof. It describes how, given a distinguisher for our pseudorandom functions, it is possible to construct an algorithm, $\mathcal{D}$, which can be used by the reconstruction algorithm as an oracle for the value of $\mathcal{B}_r(u)$.

LEMMA 5.3. *Assume there exists a probabilistic polynomial-time machine $\mathcal{M}$ satisfying inequality* (7) *for* any *choice of $\vec{a}$. Then there exists a probabilistic polynomial-time algorithm $\mathcal{D}$ such that, for infinitely many n's,*

$$\left|\Pr\left[\mathcal{D}(v^2, N, r, \mathcal{B}_r(u)) = 1\right] - \Pr\left[\mathcal{D}(v^2, N, r, b) = 1\right]\right| > \epsilon'(n),$$

where the distribution of $N = P \cdot Q$ is $FIG(1^n)$, v is uniformly distributed in $\mathbb{Z}^*_N$, r is a random n-bit string, $b \in_R \{0,1\}$, and u is the unique quadratic-residue in $\mathbb{Z}^*_N$ which satisfies $u^2 = v^2 \bmod N$.

Using an averaging argument, it can be shown that, on at least an $\frac{\epsilon'(n)}{2}$ fraction of the choices of N and v^2, algorithm $\mathcal{D}$ distinguishes the value of $\mathcal{B}_r(u)$ from random with advantage $\frac{\epsilon'(n)}{2}$ (over the choice of r). In particular, $\mathcal{D}$ can be used in order to predict $\mathcal{B}_r(u)$ with probability $\frac{1}{2} + \frac{\epsilon'(n)}{4}$. By Theorem 5.2, we know that we can use $\mathcal{D}$ in order to construct a probabilistic polynomial-time algorithm that retrieves $u \bmod N$ with probability $\Omega(\epsilon'(n))$. We now have that $u^2 = v^2 \bmod N$ and $\Pr[u \neq \pm v] = 1/2$. This implies (cf. [23]) that $\Pr[gcd(u - v, N) \in \{P, Q\}] = 1/2$, which enables us to construct an algorithm that $\Omega\left(\epsilon'(n)^2\right)$-factors, in contradiction to Assumption 4.1.

Description of $\mathcal{D}$. Let the input of $\mathcal{D}$ be (v^2, N, r, α), where the distribution of N, v, and r is as in Lemma 5.3. Let u be the unique quadratic-residue in $\mathbb{Z}_N^*$ which satisfies $u^2 = v^2 \bmod N$. On this input, $\mathcal{D}$ first picks $J = I \cdot \ell + k$ at random in $[t \cdot \ell]$. Then $\mathcal{D}$ invokes $\mathcal{M}$ and answers its queries in a way that simulates $H^J_{N,\vec{a},g,r}$ (for some value of $\vec{a}$ and g) if α equals $\mathcal{B}_r(u)$ and simulates $H^{J+1}_{N,\vec{a},g,r}$ if α is a random bit. $\mathcal{D}$ will now be able to utilize the expected advantage that $\mathcal{M}$ has in distinguishing between $H^J_{N,\vec{a},g,r}$ and $H^{J+1}_{N,\vec{a},g,r}$ in order to guess the actual distribution of α. Specifically, $\mathcal{D}$ will answer $\mathcal{M}$'s queries in the following way:

1. Answer the first I queries according to $\rho_{n,\ell}$.
2. Answer the $(I+1)$st query with $b_0, b_1, \ldots, b_{k-1}, \alpha, \mathcal{B}_r(u^2), \ldots, \mathcal{B}_r(u^{2^{\ell-k-1}})$ (where $b_0 b_1 \ldots b_{k-1}$ denotes a random k-bit string).
3. Answer the remaining queries consistently according to $f_{N,\vec{a},g,r}$.

The challenge in constructing $\mathcal{D}$ is to assign values to $\vec{a}$ and g such that the above answers will be distributed according to the correct hybrid black-box distribution and will be efficiently computable by $\mathcal{D}$.

Defining $\vec{a}$ and g. The way we define the value of g depends on the choice of J, whereas the values assigned to $\vec{a}$ will depend on the $(I+1)$st query made by $\mathcal{M}$. We require that, if x is the $(I+1)$st query, then the value of the $(k+1)$st bit of $f_{N,\vec{a},g,r}(x)$ (which is answered with α by $\mathcal{D}$) will be equal to $\mathcal{B}_r(u)$. In addition, we require that $\mathcal{D}$ will be able to efficiently compute the answers to all the subsequent queries made by $\mathcal{M}$ (starting from the $(k+2)$nd bit-location in the answer to the $(I+1)$st query).

The definition of g. $\mathcal{D}$ computes $s = \ell \cdot n - k$ and sets $g = v^{2^s} \bmod N$.

CLAIM 5.1. *Let γ be the order of g in $\mathbb{Z}_N^*$; then γ is odd.*

Proof. It will be sufficient to show that the size of QR_N is odd. This implies that all quadratic-residues in $\mathbb{Z}_N^*$ (and, in particular, g) have odd order. Since N is a Blum-integer, for every quadratic-residue in $\mathbb{Z}_N^*$, exactly one of its four square-roots resides in QR_N. This means that $|QR_N| = \frac{|\mathbb{Z}_N^*|}{4} = \frac{(P-1)\cdot(Q-1)}{4}$. Since $P = Q = 3 \bmod 4$, we have that $\frac{P-1}{2}$ and $\frac{Q-1}{2}$ are odd, which implies that $\frac{(P-1)\cdot(Q-1)}{4}$ is also odd, and the claim follows. □

CLAIM 5.2. *For every $0 < i < s$, $g^{2^{-i} \bmod \gamma} = v^{2^{s-i}} \bmod N$.*[13]

Proof. By Claim 5.1, we have that γ is odd. This implies that $2 \in \mathbb{Z}_\gamma^*$ and, therefore, $2^{-1} \bmod \gamma$ exists (and is simply $\frac{\gamma+1}{2}$). For simplicity of exposition, let us denote by $g^{2^{-1}}$ the value $g^{2^{-1} \bmod \gamma} \bmod N$. We now have that, whenever 2^{-1} appears in the exponent, it denotes the value $2^{-1} \bmod \gamma = \frac{\gamma+1}{2}$. Similarly, 2^{-i} in the exponent denotes the value $2^{-i} \bmod \gamma = (\frac{\gamma+1}{2})^i \bmod \gamma$. Therefore, for every i, the value $g^{2^{-i}} \bmod N$ is a quadratic-residue (since g is a quadratic-residue). Take $i = 1$; we now have that both $g^{2^{-1}}$ and $v^{2^{s-1}}$ are square-roots of g and they are both quadratic-residues. Since squaring is a permutation over the set of quadratic-residues in $\mathbb{Z}_N^*$ (for any Blum-integer N), we must have that $g^{2^{-1}}$ and $v^{2^{s-1}}$ are equal. By induction on $0 < i < s$, we get that $g^{2^{-i}} = v^{2^{s-i}} \bmod N$. □

COROLLARY 5.1. *Let $u = g^{2^{-s}} \bmod N$; then $u^2 = v^2 \bmod N$.*

The definition of $\vec{a}$. Since the first I queries of $\mathcal{M}$ are answered randomly, we can defer the assignment to the values of $\vec{a}$ until $\mathcal{D}$ is given the $(I+1)$st query, $x = x_1 x_2 \ldots x_n$. It is then possible to define $\vec{a}$ so that the value of the $(k+1)$st

[13] Note that γ is not known to $\mathcal{D}$. However, as long as $s - i > 0$, it is possible for $\mathcal{D}$ to compute $v^{2^{s-i}} \bmod N$.

bit of $f_{N,\vec{a},g,r}(x)$ (namely, $\mathcal{B}_r(g^{2^k\Pi_{i=1}^n a_{i,x_i}})$) will be equal to $\mathcal{B}_r(u)$.[14] Let $\vec{a}$ be the vector $(a_{1,0}, a_{1,1}, a_{2,0}, a_{2,1}, \ldots, a_{n,0}, a_{n,1})$, where, for all i, $a_{i,x_i} = 2^{-\ell} \bmod \gamma$ and $a_{i,\overline{x_i}}$ is uniformly distributed in $[N]$.

CLAIM 5.3. *Let $\vec{a}, g$, and u be defined as above; then*

$$\mathcal{B}_r(g^{2^k\Pi_{i=1}^n a_{i,x_i}}) = \mathcal{B}_r(u).$$

Proof. By the above notation,

$$g^{2^k\Pi_{i=1}^n a_{i,x_i}} = g^{2^{k-\ell n}} = g^{2^{-s}} = u \bmod N,$$

and the claim follows. □

The running-time of $\mathcal{D}$. We now show that $\mathcal{D}$ is indeed able to complete steps (2) and (3) (i.e., answer all the remaining queries of $\mathcal{M}$ starting from the $(k+2)$nd bit-location in the answer to the $(I+1)$st query in a way which is consistent with the definition of $\vec{a}$ and g). The key point is that $\mathcal{D}$ can achieve this task even though it does not actually know the values of a_{i,x_i}.

CLAIM 5.4. *Algorithm $\mathcal{D}$ is able to efficiently complete the answer to the $(I+1)$st query (step 2).*

Proof. Since $v^2 = u^2 \bmod N$ and since v^2 and r are given to $\mathcal{D}$ in the input, $\mathcal{D}$ is able to complete the answer to the $(I+1)$st query and answer $\mathcal{M}$ with

$$b_0, b_1, \ldots, b_{k-1}, \alpha, \mathcal{B}_r(v^2), \ldots, \mathcal{B}_r(v^{2^{\ell-k-1}})$$

as required. □

CLAIM 5.5. *For* any *query $y \neq x$, $\mathcal{D}$ is able to efficiently compute the value of $f_{N,\vec{a},g,r}(y)$ (step 3).*

Proof. It will be sufficient to show that, for any query $y = y_1 y_2 \ldots y_n \neq x$, $\mathcal{D}$ is able to compute the value $g^{\Pi_{i=1}^n a_{i,y_i}}$, and thus it is always able to answer the query with the value of $f_{N,\vec{a},g,r}(y)$. Now

$$\begin{aligned} g^{\Pi_{i=1}^n a_{i,y_i}} &= g^{(\Pi_{\{y_i=x_i\}} a_{i,y_i})(\Pi_{\{y_i\neq x_i\}} a_{i,y_i})} \\ &= g^{(2^{-\ell j})(\Pi_{\{y_i\neq x_i\}} a_{i,y_i})} \\ &= v^{(2^{s-\ell j})(\Pi_{\{y_i\neq x_i\}} a_{i,y_i})} \bmod N, \end{aligned}$$

where j is the number of locations for which y_i equals x_i. Since $j < n$ (remember that $y \neq x$) and since $k < \ell$, we always have that $s - \ell j = (n-j)\ell - k$ is at least 1 over the integers. As we have already stated, $\mathcal{D}$ knows the value of v^2; therefore, by performing the appropriate exponentiations, it is always able to compute $g^{\Pi_{i=1}^n a_{i,y_i}} = v^{(2^{s-\ell j})(\Pi_{\{y_i\neq x_i\}} a_{i,y_i})}$ as required. (Remember that $\mathcal{D}$ knows the value of a_{i,y_i} for all $y_i \neq x_i$.) □

We are finally ready to establish Lemma 5.3. Recall that, given some J, the value of α determines which of the possible hybrid black-boxes is simulated by $\mathcal{D}$. If α equals $\mathcal{B}_r(u)$, then $\mathcal{D}$ simulates $H^J_{N,\vec{a},g,r}$, whereas if α is a random bit, $\mathcal{D}$ simulates $H^{J+1}_{N,\vec{a},g,r}$. Since the expected advantage $\mathcal{M}$ has in distinguishing the above neighboring hybrid black-boxes is $\epsilon'(n)$ and since $\mathcal{D}$ picks J at random, we expect that $\mathcal{D}$ will be able to decide with advantage $\epsilon'(n)$ whether α is indeed the value of $\mathcal{B}_r(u)$.

[14] It is worth noticing that this would not have been possible in the case that $\mathcal{D}$ would have answered $\mathcal{M}$'s queries in a reverse order (i.e., by first answering according to $f_{N,\vec{a},g,r}$ and then switching mode to $\rho_{n,\ell}$).

5.2.2. Completing the proof. To complete the proof, we follow the same lines, along with an additional "randomization" of the values in $\vec{a}$, achieved by taking $a_{i,x_i} = \xi_i + 2^{-\ell} \bmod \gamma$. This causes the value of the $(k+1)$st bit in the answer to the $(I+1)$st query to change into $\mathcal{B}_r(g^{2^k \Pi_{i=1}^n a_{i,x_i}}) = \mathcal{B}_r(g^{2^k \Pi_{i=1}^n (\xi_i + 2^{-\ell})}) = \mathcal{B}_r(u \cdot w)$, where w is an element in $\mathbb{Z}_N^*$ which is completely determined by the ξ_i's and by the value of v^2 (and is efficiently computable given the above values). Note that now algorithm $\mathcal{D}$ becomes an oracle for the value of $\mathcal{B}_r(u \cdot w)$ and will therefore be used in order to retrieve $u \cdot w$ (rather than u).

Jumping ahead, we note that letting $\mathcal{D}$ pick the random ξ_i's by itself would have caused the value of w (and therefore $u \cdot w$) to change each time $\mathcal{D}$ is invoked. This would not allow the reconstruction algorithm to retrieve $u \cdot w$ for any specific value of w. The solution to this problem will be to fix the values which determine w in advance and then use $\mathcal{D}$ (which now takes only r as input) as an oracle for $\mathcal{B}_r(u \cdot w)$.[15] For the time being, we ignore the above issue and let $\mathcal{D}$ pick the random ξ_i's by itself. We now give the (full) analogue of Lemma 5.3.

LEMMA 5.4. *Assume there exists a probabilistic polynomial-time machine $\mathcal{M}$ satisfying inequality* (7). *Then there exists a probabilistic polynomial-time algorithm $\mathcal{D}$ such that, for infinitely many n's,*

$$\left|\Pr\left[\mathcal{D}(v^2, N, r, \mathcal{B}_r(u \cdot w)) = 1\right] - \Pr\left[\mathcal{D}(v^2, N, r, b) = 1\right]\right| > \epsilon'(n) - n \cdot 2^{-O(n)},$$

where the distribution of $N = P \cdot Q$ is $FIG(1^n)$, v is uniformly distributed in $\mathbb{Z}_N^*$, r is a random n-bit string, $b \in_R \{0,1\}$, $u \cdot w$ is the unique quadratic-residue in $\mathbb{Z}_N^*$ which satisfies $(u \cdot w)^2 = v^2 \cdot w^2 \bmod N$, and w is a randomly chosen quadratic-residue in $\mathbb{Z}_N^*$ (which is completely determined by the value of v^2 and $\mathcal{D}$'s internal coin tosses and is efficiently computable by $\mathcal{D}$).

Proof. On input (v^2, N, r, α), $\mathcal{D}$ is defined as follows:

1. (a) Sample $J = I \cdot \ell + k$ uniformly at random in $[t \cdot \ell]$.
   (b) Sample J random bits (needed in order to simulate the hybrid black-box).
   (c) Sample $\vec{\xi} = (\xi_1, \xi_2, \ldots, \xi_n, \xi_1', \xi_2', \ldots, \xi_n')$ by uniformly picking $2n$ elements in $[N]$.
2. Compute $s = \ell \cdot n - k$, and set $g = v^{2^s} \bmod N$.
3. Invoke $\mathcal{M}$ on input 1^n:
   (a) Answer each of its first I queries with a random string in $\{0,1\}^\ell$.
   (b) Let $x_1 x_2 \ldots x_n$ be $\mathcal{M}$'s $(I+1)$st query.
   For $1 \le i \le n$, denote by a_{i,x_i} the value $\xi_i + 2^{-\ell} \bmod \gamma$ and by $a_{i,\overline{x_i}}$ the value ξ_i'. Denote by $\vec{a}$ the sequence $(a_{1,0}, a_{1,1}, a_{2,0}, a_{2,1}, \ldots, a_{n,0}, a_{n,1})$. ($a_{i,x_i}$ is not actually known to $\mathcal{D}$.)
   Let $b_0 b_1 \ldots b_{k-1}$ be a random k-bit string; answer the $(I+1)$st query with the ℓ-bit string

$$b_0, b_1, \ldots, b_{k-1}, \alpha, \mathcal{B}_r(g^{2^{k+1} \Pi_{i=1}^n a_{i,x_i}}), \ldots, \mathcal{B}_r(g^{2^{\ell-1} \Pi_{i=1}^n a_{i,x_i}}).$$

   (c) Answer each remaining query of $\mathcal{M}$, y with the value $f_{N,\vec{a},g,r}(y)$.

[15] Here we use a special property of the $\mathcal{B}_r$ predicate, which enables the reconstruction of $u \cdot w$ by asking only queries which refer to $u \cdot w$ (i.e., $u \cdot w$ is *fixed* throughout the process, and only r changes from one query to another). As discussed in section 6, a similar property is satisfied by the $\mathcal{LSB}$-based reconstruction techniques by Alexi et al. [1, 10]. See section 6 for an analogous construction that uses the $\mathcal{LSB}$ predicate.

4. If $\mathcal{M}$ outputs 1, then output 1.
   If $\mathcal{M}$ outputs 0, then output 0.

Why does $\mathcal{D}$ predict the value of $\mathcal{B}_r(u \cdot w)$? To define u, we set $u = g^{2^{-s}} \bmod N$. As before (see Corollary 5.1), we have that $u^2 = v^2 \bmod N$. To define w, we set $w = v^{(\Sigma_{i=0}^{n-1}\beta_i 2^{\ell(n-i)})} \bmod N$, where β_i are the coefficients (over $\mathbb{Z}$) of the polynomial $p(x) = \prod_{i=1}^{n}(\xi_i + x) = x^n + \sum_{i=0}^{n-1}\beta_i x^i$. Note that the β_i's can be efficiently computed given the ξ_i's (either recursively or by interpolation). Given the values of the β_i's and of v^2, we are able to compute w. (Note that the exponent of v in the definition of w is always even.) Therefore, w is an efficiently computable quadratic-residue in $\mathbb{Z}_N^*$ which is completely determined by the value of v^2 and $\mathcal{D}$'s internal coin tosses (i.e., the ξ_i's sampled in step 1c).

CLAIM 5.6. *Let $\vec{a}$, g, u, and w be defined as above; then $\mathcal{B}_r(g^{2^k \Pi_{i=1}^n a_{i,x_i}}) = \mathcal{B}_r(u \cdot w)$.*

Proof. Using the above notation (and Claim 5.2), we have

$$\begin{aligned} g^{2^k \Pi_{i=1}^n a_{i,x_i}} &= g^{2^k \Pi_{i=1}^n (\xi_i + 2^{-\ell})} \\ &= g^{2^k p(2^{-\ell})} \\ &= g^{2^{k-\ell n} + \Sigma_{i=1}^{n-1}\beta_i 2^{-(\ell i - k)}} \\ &= g^{2^{-s}} \cdot v^{(\Sigma_{i=1}^{n-1}\beta_i 2^{s-(\ell i-k)})} \\ &= u \cdot v^{(\Sigma_{i=1}^{n-1}\beta_i 2^{\ell(n-i)})} \\ &= u \cdot w \bmod N, \end{aligned}$$

and the claim follows. □

This implies that the $(k+1)$st bit in the answer that the $f_{N,\vec{a},g,r}$ black-box is supposed to give to the $(I+1)$st query (and is answered with α instead) is equal to $\mathcal{B}_r(u \cdot w)$. As we have already seen, this fact can be used by $\mathcal{D}$ in order to decide whether α equals $\mathcal{B}_r(u \cdot w)$.

The running-time of $\mathcal{D}$. It is clear that steps 1, 2, and 3a can be carried out in time $poly(n, \ell(n))$. In order to prove that steps 3b and 3c can be carried out in time $poly(n, \ell(n)) \cdot t(n)$, we observe that, if, for some j in $[\ell]$, $\mathcal{D}$ is able to compute $\lambda = g^{2^j \Pi_{i=1}^n a_{i,x_i}} \bmod N$, then, by squaring and taking the inner product of the results with r, it is also able to compute any bit-sequence of the form $\mathcal{B}_r(\lambda), \mathcal{B}_r(\lambda^2), \ldots, \mathcal{B}_r(\lambda^{2^{\ell-j-1}})$.

CLAIM 5.7. *Algorithm $\mathcal{D}$ is able to efficiently complete the answer to the $(I+1)$st query (step* 3b*).*

Proof. By the above observation, it will be sufficient to show that $\mathcal{D}$ is able to efficiently compute the value of $g^{2^{k+1}\Pi_{i=1}^n a_{i,x_i}}$. To see that, notice that $g^{2^k \Pi_{i=1}^n a_{i,x_i}}$ equals $u \cdot w$ (see Claim 5.6). This implies that $g^{2^{k+1}\Pi_{i=1}^n a_{i,x_i}} = u^2 \cdot w^2 = v^2 \cdot w^2 \bmod N$. Since both the values of v^2 and w^2 are known to $\mathcal{D}$, it is possible for it to efficiently answer the $(I+1)$st query (as described in step 3b). □

CLAIM 5.8. *For* any *query $y \neq x$, $\mathcal{D}$ is able to efficiently compute the value of $f_{N,\vec{a},g,r}(y)$ (step* 3c*).*

Proof. By the above observation, it will be sufficient to show that $\mathcal{D}$ is able to compute the value $g^{\Pi_{i=1}^n a_{i,y_i}}$ (and, consequently, it will be able to compute the value of $f_{N,\vec{a},g,r}(y)$). Given a query $y = y_1 y_2 \ldots y_n \neq x$, $\mathcal{D}$ starts by computing (in time $poly(n)$) the coefficients, $\delta_i \in \mathbb{Z}$, of the polynomial $q(x) = \prod_{\{y_i = x_i\}}(\xi_i + x) =$

$\sum_{i=0}^{j} \delta_i x^i$ (where j is the number of locations for which y_i equals x_i). Under this notation, $\prod_{\{y_i=x_i\}} a_{i,y_i}$ equals $q(2^{-\ell})$, we then have

$$\begin{aligned} g^{\Pi_{i=1}^{n} a_{i,y_i}} &= g^{(\Pi_{\{y_i=x_i\}} a_{i,y_i})(\Pi_{\{y_i\neq x_i\}} a_{i,y_i})} \\ &= g^{(\Sigma_{i=0}^{j} \delta_i 2^{-\ell i})(\Pi_{\{y_i\neq x_i\}} a_{i,y_i})} \\ &= \prod_{i=0}^{j} g^{(\delta_i 2^{-\ell i})(\Pi_{\{y_i\neq x_i\}} a_{i,y_i})} \\ &= \prod_{i=0}^{j} v^{2^{s-\ell i}(\delta_i \Pi_{\{y_i\neq x_i\}} a_{i,y_i})} \bmod N; \end{aligned}$$

since $i \leq j < n$ (remember that $y \neq x$) and since $k < \ell$, we always have that the value of $s - \ell i = (n-i)\ell - k$ is at least 1 over the integers. Therefore, $\mathcal{D}$ is always able to compute all the values $v^{2^{s-\ell i}(\delta_i \Pi_{\{y_i\neq x_i\}} a_{i,y_i})} \bmod N$ by performing the appropriate exponentiations of v^2. (Remember that $\mathcal{D}$ knows the value of all δ_i's and the value of a_{i,y_i} for all $y_i \neq x_i$.) Finally, by taking the product of the above values (reduced mod N), $\mathcal{D}$ is able to compute the value of $g^{\Pi_{i=1}^{n} a_{i,y_i}}$ as required. □

The success-probability of $\mathcal{D}$. To find the success-probability of $\mathcal{D}$, we notice that the distribution of the function $f_{N,\vec{a},g,r}$ (which is induced by the way $\mathcal{D}$ chooses $\vec{a}$ and g) is statistically close to the distribution of functions in F_n. To see this, we will need the following claims regarding the distributions of $\vec{a}$ and g.

CLAIM 5.9. *g is a uniformly distributed quadratic-residue in $\mathbb{Z}_N^*$.*

Proof. Since v^2 is a uniformly distributed quadratic-residue in $\mathbb{Z}_N^*$ and squaring is a permutation over the set of quadratic-residues in $\mathbb{Z}_N^*$, it immediately follows that $g = v^{2^s}$ is a uniformly distributed quadratic-residue in $\mathbb{Z}_N^*$. □

CLAIM 5.10. *Let ξ_i and a'_{i,x_i} be uniformly distributed elements in $[N]$, and denote by a_{i,x_i} the value $\xi_i + 2^{-\ell} \bmod \gamma$. Then the statistical distance of a_{i,x_i} and $a'_{i,x_i} \bmod \gamma$ is $2^{-O(n)}$.*

Proof. Note that γ divides $(P-1)(Q-1)$. Therefore, the distribution of a_{i,x_i} conditioned on the event that $\xi_i \in [(P-1)(Q-1)]$ is the same as the distribution of $a'_{i,x_i} \bmod \gamma$ conditioned on the event that $a'_{i,x_i} \in [(P-1)(Q-1)]$ (and in both cases it is simply the uniform distribution over $[\gamma]$). It remains to notice that

$$\begin{aligned} \Pr\left[\xi_i \in [(P-1)(Q-1)]\right] &= \Pr\left[a'_{i,x_i} \in [(P-1)(Q-1)]\right] \\ &= \frac{(P-1)(Q-1)}{N} \\ &= 1 - \tfrac{P+Q}{N} + \tfrac{1}{N} \\ &= 1 - 2^{-O(n)}, \end{aligned}$$

which completes the proof. □

CLAIM 5.11. *Let $f_{N,\vec{a}',g,r}$ be distributed according to F_n, and let $f_{N,\vec{a},g,r}$ be distributed as in the construction of $\mathcal{D}$. Then the statistical distance of $f_{N,\vec{a}',g,r}$ and $f_{N,\vec{a},g,r}$ is $n \cdot 2^{-O(n)}$.*

Proof. Let each element in $\vec{a}' = (a'_{1,0}, a'_{1,1}, a'_{2,0}, a'_{2,1}, \ldots, a'_{n,0}, a'_{n,1})$ be uniformly distributed in $[N]$. By Claim 5.10, we have that, for every $1 \leq i \leq n$, a_{i,x_i} and $a'_{i,x_i} \bmod \gamma$ are of statistical distance $2^{-O(n)}$. It follows (by the triangle inequality) that $\vec{a}$ and $\vec{a}' \bmod \gamma$ are of statistical distance $n \cdot 2^{-O(n)}$. It is then immediate that $f_{N,\vec{a},g,r}$ and $f_{N,\vec{a}',g,r}$ are of statistical distance $n \cdot 2^{-O(n)}$. □

Since applying any function (even a randomized one) does not increase the statistical distance, then, by Claim 5.11, we have that, for infinitely many n's,

$$\left|\Pr\left[\mathcal{M}^{f_{N,\vec{a}',g,r}}(1^n)=1\right]-\Pr\left[\mathcal{M}^{f_{N,\vec{a},g,r}}(1^n)=1\right]\right|<n\cdot 2^{-O(n)}.$$

To complete the proof, we recall Definition 5.1 of the hybrid distribution, $H^J_{N,\vec{a},g,r}$. By Claim 5.6, we have that $g^{2^k\Pi_{i=1}^n a_{i,x_i}}=u\cdot w \bmod N$. Therefore, the value of the $(k+1)$st bit in the answer that $\mathcal{D}$ is supposed to give to the $(I+1)$st query is precisely equal to $\mathcal{B}_r(u\cdot w)$. Given that $J=j$ and that $\alpha=\mathcal{B}_r(u\cdot w)$ (where $u\cdot w$ is a quadratic-residue in $\mathbb{Z}_N^*$), the distribution that $\mathcal{M}$ sees is $H^j_{N,\vec{a},g,r}$. On the other hand, if α is random, then the distribution that $\mathcal{M}$ sees is $H^{j+1}_{N,\vec{a},g,r}$. We now have that, for infinitely many n's,

$$\begin{aligned}
&\left|\Pr\left[\mathcal{D}(v^2 \bmod N,N,r,\mathcal{B}_r(u\cdot w))=1\right]-\Pr\left[\mathcal{D}(v^2 \bmod N,N,r,b)=1\right]\right|\\
&=\frac{1}{t(n)\cdot\ell(n)}\cdot\left|\sum_{j=0}^{t\cdot\ell-1}\left(\Pr\left[\mathcal{D}(v^2,N,r,\mathcal{B}_r(u\cdot w))=1\mid J=j\right]-\Pr\left[\mathcal{D}(v^2,N,r,b)=1\mid J=j\right]\right)\right|\\
&=\frac{1}{t(n)\cdot\ell(n)}\cdot\left|\sum_{j=0}^{t\cdot\ell-1}\left(\Pr\left[\mathcal{M}^{H^j_{N,\vec{a},g,r}}(1^n)=1\right]-\Pr\left[\mathcal{M}^{H^{j+1}_{N,\vec{a},g,r}}(1^n)=1\right]\right)\right|\\
&=\frac{1}{t(n)\cdot\ell(n)}\cdot\left|\Pr\left[\mathcal{M}^{f_{N,\vec{a},g,r}}(1^n)=1\right]-\Pr\left[\mathcal{M}^{\rho_{n,\ell}}(1^n)=1\right]\right|\\
&\le\frac{\epsilon(n)}{t(n)\cdot\ell(n)}+n\cdot 2^{-O(n)},
\end{aligned}$$

where the distribution of $N=P\cdot Q$ is $FIG(1^n)$, v is uniformly distributed in $\mathbb{Z}_N^*$, r is a random n-bit string, $b\in_R\{0,1\}$, $u\cdot w$ is the unique quadratic-residue in $\mathbb{Z}_N^*$ which satisfies $(u\cdot w)^2=v^2\cdot w^2 \bmod N$, and w is a randomly chosen quadratic-residue in $\mathbb{Z}_N^*$. The proof of Lemma 5.4 is complete. □

REMARK 5.2. *From the proof of Lemma* 5.4*, we get that* $\mathcal{D}$ *works even if the distinguisher* $\mathcal{M}$ *has access to* $N, g,$ *and* r.

Reconstructing $u\cdot w$ mod N. Technically, $\mathcal{D}$ is not suitable to be used as an oracle for the Goldreich–Levin reconstruction algorithm, first because it is not a predictor for the value $\mathcal{B}_r(u\cdot w)$ but rather a distinguisher. Furthermore, the value of w potentially changes each time $\mathcal{D}$ is invoked (since it depends on v^2 and $\vec{\xi}$), which does not allow the reconstruction algorithm to retrieve $u\cdot w$ for any specific value of w. The transformation to a suitable predictor, however, is not difficult. By fixing the values of v^2 and $\vec{\xi}$ in advance, we are able to construct an algorithm, $\mathcal{D}_{N,\vec{\xi},v^2}$, which invokes $\mathcal{D}$ as a subroutine and with nonnegligible probability succeeds in predicting $\mathcal{B}_r(u\cdot w)$. On input r, $\mathcal{D}_{N,\vec{\xi},v^2}$ is defined as follows:

1. Sample two independent random bits α, β in $\{0,1\}$.
2. Invoke $\mathcal{D}$ on input (v^2,N,r,α); feed it with $\vec{\xi}$ on its random tape.
3. (a) If $\mathcal{D}$ outputs 1, then output α.
   (b) If $\mathcal{D}$ outputs 0, then output β.

Note that, now, the value of w does not change each time $\mathcal{D}_{N,\vec{\xi},v^2}$ is invoked. This means that it is possible to use $\mathcal{D}_{N,\vec{\xi},v^2}$ as an oracle in order to reconstruct $u\cdot w$.

LEMMA 5.5. *Assume there exists a probabilistic polynomial-time machine* $\mathcal{M}$ *satisfying inequality* (7)*, and let* $\mathcal{D}_{N,\vec{\xi},v^2}$ *be as above. Then, with probability* $\frac{\epsilon'(n)}{2}$

(over the choices of N, v^2, and $\vec{\xi}$), it holds that, for infinitely many n's,

$$\Pr\left[\mathcal{D}_{N,\vec{\xi},v^2}(r) = \mathcal{B}_r(u \cdot w)\right] > \frac{1}{2} + \frac{\epsilon'(n)}{4},$$

where the distribution of $N = P \cdot Q$ is $FIG(1^n)$, v is uniformly drawn from $\mathbb{Z}_N^*$, r is a random n-bit string, $\vec{\xi}$ is a random vector of $2n$ elements in $[N]$, $w = w(\vec{\xi}, v^2)$ is a quadratic-residue in $\mathbb{Z}_N^*$, and $u \cdot w$ is the unique quadratic-residue in $\mathbb{Z}_N^*$ which satisfies $(u \cdot w)^2 = v^2 \cdot w^2 \bmod N$.

Proof. By Lemma 5.4, $\mathcal{D}$ has an $(\epsilon'(n) - n \cdot 2^{-O(n)})$ advantage in distinguishing $\mathcal{B}_r(u \cdot w)$ from a randomly chosen bit. Using an averaging argument, it is easy to see that on at least an $\frac{\epsilon'(n)}{2}$ fraction of the choices of N, v^2, and $\vec{\xi}$, algorithm $\mathcal{D}$ has an $\frac{\epsilon'(n)}{2}$ advantage in distinguishing $\mathcal{B}_r(u \cdot w)$ from a randomly chosen bit. It is then straightforward that $\mathcal{D}_{N,\vec{\xi},v^2}$ can predict the value of $\mathcal{B}_r(u \cdot w)$ with advantage $\frac{\epsilon'(n)}{4}$ as required. ∎

The factoring algorithm. For the sake of completeness, we now turn to describe an algorithm, $\mathcal{A}$, which uses $\mathcal{D}_{N,\vec{\xi},v^2}$ as oracle and succeeds to $\epsilon''(n)$-factor (where $\epsilon''(n) = \Omega(\epsilon'(n)^2)$); this is in contradiction to Assumption 4.1 and will complete the proof.

LEMMA 5.6. *Assume there exists a probabilistic polynomial-time machine $\mathcal{M}$ satisfying inequality* (7)*. Then there exists a probabilistic polynomial-time algorithm, $\mathcal{A}$, that $\epsilon''(n)$-factors.*

Proof. On input N, $\mathcal{A}$ is defined as follows:

1. (a) Sample v uniformly at random in $\mathbb{Z}_N^*$, and compute $v^2 \bmod N$.
   (b) Sample $\vec{\xi} = (\xi_1, \xi_2, \ldots, \xi_n, \xi'_1, \xi'_2, \ldots, \xi'_n)$ by uniformly picking $2n$ elements in $[N]$.
2. Compute the value of $w = v^{(\Sigma_{i=0}^{n-1} \beta_i 2^{\ell(n-i)})} \bmod N$, where β_i are the coefficients (over $\mathbb{Z}$) of the polynomial $p(x) \stackrel{\text{def}}{=} \prod_{i=1}^{n}(\xi_i + x) = x^n + \sum_{i=0}^{n-1} \beta_i x^i$ (and are easily found given the ξ_i's).
3. Invoke the Goldreich–Levin reconstruction algorithm, $\mathcal{R}(1^n)$.
   (a) Whenever asked for $\mathcal{B}_{r_i}(z)$, invoke $\mathcal{D}_{N,\vec{\xi},v^2}$ on input r_i, and give its output as an answer. (Recall that $\mathcal{D}_{N,\vec{\xi},v^2}$ invokes $\mathcal{M}$ and answers its queries.)
   (b) Denote by z the output of $\mathcal{R}$.
4. Compute $u = z \cdot w^{-1} \bmod N$. Given that $\mathcal{R}$ outputs the correct value (i.e., $z = u \cdot w$), we have that $u^2 = v^2 \bmod N$. If $u \neq \pm v \bmod N$, output $gcd(u - v, N)$ which is indeed in $\{P, Q\}$. Otherwise, output "failed."

The running-time of $\mathcal{A}$. It is clear that steps 1, 2, and 4 can be carried out efficiently by $\mathcal{A}$ (and, in addition, are independent of $\mathcal{D}_{N,\vec{\xi},v^2}$). As for step 3, assuming that $\mathcal{D}_{N,\vec{\xi},v^2}$ has nonnegligible advantage in predicting $\mathcal{B}_r(u \cdot w)$ (which by Lemma 5.5 happens with nonnegligible probability), we are guaranteed (by Theorem 5.2) that $\mathcal{R}$ will terminate in polynomial time.

The success-probability of $\mathcal{A}$. Since, with probability $\frac{\epsilon'(n)}{2}$, $\mathcal{D}_{N,\vec{\xi},v^2}$ predicts the value of $\mathcal{B}_r(u \cdot w)$ with advantage $\frac{\epsilon'(n)}{4}$, then, by Theorem 5.2, we have that $\mathcal{R}$ retrieves the value of $u \cdot w$ with probability at least $\Omega(\epsilon'(n)^2)$ (over the choices of N, v^2, and $\vec{\xi}$). Note that $u \cdot w$ and w are both quadratic-residues in $\mathbb{Z}_N^*$; therefore, u

must also be a quadratic-residue in $\mathbb{Z}_N^*$. Given that, the probability that u does not equal $\pm v \bmod N$ is exactly 1/2. We are finally able to conclude that $\mathcal{A}$ $\epsilon''(n)$-factors as required. □

This completes the proof of Theorem 5.1. □

6. Using other hard-core bits. In Construction 4.1, we use the Goldreich–Levin hard-core bit, $\mathcal{B}_r$. The other, more natural, hard-core bit *in this context* is the $\mathcal{LSB}$ predicate, shown to be secure by Alexi et al. [1]. (The $\mathcal{LSB}$ predicate was the one originally used in the BBS construction.) The key property which we require from the $\mathcal{B}_r$ predicate is that its reconstruction algorithm *fixes* the unknown value and changes r throughout the process (see footnote 15). As pointed out to us by Roger Fischlin [9], a similar property is satisfied by the $\mathcal{LSB}$-based reconstruction techniques [1, 10] (see Theorem 6.1, where r is explicitly considered).

The above observation suggests that using the $\mathcal{LSB}$ predicate in Construction 4.1 (rather than using the $\mathcal{B}_r$ predicate) may yield a secure pseudorandom function. However, we were not able to prove it. What we are able to do is to slightly modify Construction 4.1 in order to obtain a secure pseudorandom function that is secure when using the $\mathcal{LSB}$ predicate.

Interestingly, the modified construction does not exactly follow the paradigm of applying the BBS generator to the unpredictable function $h(x) = g^{\Pi_{i=1}^n a_{i,x_i}}$ (but rather multiplies each of the elements in the sequence with r before applying the $\mathcal{LSB}$ predicate).

CONSTRUCTION 6.1 ($\mathcal{LSB}$ version of pseudorandom functions). *We define a function in the ensemble $F = \{F_n\}_{n\in\mathbb{N}}$. For every $n \in \mathbb{N}$, a key of a function in F_n is a tuple $(N, \vec{a}, g, r)$, where N is an n-bit Blum-integer, g is a quadratic-residue in $\mathbb{Z}_N^*$, r is an element in $\mathbb{Z}_N^*$, and $\vec{a} = (a_{1,0}, a_{1,1}, a_{2,0}, a_{2,1}, \ldots, a_{n,0}, a_{n,1})$ is a sequence of $2n$ elements in $[N]$. For any n-bit input $x = x_1 x_2 \ldots x_n$ and for every integer function $\ell = \ell(n)$, the function $f_{N,\vec{a},g} : I^n \to I^{\ell(n)}$ is defined by*

$$f_{N,\vec{a},g,r}(x) \stackrel{\text{def}}{=} \mathcal{LSB}(r \cdot g^{\Pi_{i=1}^n a_{i,x_i}}), \mathcal{LSB}(r \cdot g^{2\Pi_{i=1}^n a_{i,x_i}}), \ldots, \mathcal{LSB}(r \cdot g^{2^{\ell-1}\Pi_{i=1}^n a_{i,x_i}}).$$

The distribution of functions in F_n is induced by the following distribution on their keys: $\vec{a}$ and g are uniform in their range, and the distribution of N is $FIG(1^n)$.

Sketch of proof of security. The proof of security of Construction 6.1 is similar to the case of the $\mathcal{B}_r$ hard-core predicate. Specifically it is shown how, given a distinguisher for the above pseudorandom functions, we can construct an algorithm $\mathcal{D}$ that on input $(v^2 \bmod N, N, r)$ predicts the value of $\mathcal{LSB}(r \cdot u \cdot w)$, where $u \cdot w$ is the unique quadratic-residue in $\mathbb{Z}_N^*$ which satisfies $(u \cdot w)^2 = v^2 \cdot w^2 \bmod N$, and w is a randomly chosen quadratic-residue in $\mathbb{Z}_N^*$ (which is completely determined by the value of v^2 and $\mathcal{D}$'s internal coin tosses and is efficiently computable by $\mathcal{D}$). Using the reconstruction algorithm of Alexi et al. [1] (see [10] for tighter results), we are then able to retrieve $u \cdot w$ (and so u). As before, this means that we can extract square-roots in $\mathbb{Z}_N^*$ and consequently factor Blum-integers.

THEOREM 6.1 (see [1, 10]). *Let $z, r \in \mathbb{Z}_N^*$. Given an oracle that, on input r, predicts the value of $\mathcal{LSB}(r \cdot z)$ with advantage $\epsilon(n)$ (over the choice of r) in time $t(n)$, there exists a probabilistic polynomial-time algorithm with running-time $O(\frac{n^2 \cdot t(n)}{\epsilon(n)^2})$ that retrieves z with probability at least $\Omega(\epsilon(n))$.*

As in the proof of Theorem 5.1, the security of Construction 6.1 is proved using the following main lemma (which is the analogue of Lemma 5.4).

LEMMA 6.2. *Assume there exists a probabilistic polynomial-time machine $\mathcal{M}$ satisfying inequality (7). Then there exists a probabilistic polynomial-time algorithm $\mathcal{D}$ such that, for infinitely many n's,*

$$\left|\Pr\left[\mathcal{D}(v^2, N, r, \mathcal{LSB}(r \cdot u \cdot w)) = 1\right] - \Pr\left[\mathcal{D}(v^2, N, r, b) = 1\right]\right| > \epsilon'(n) - n \cdot 2^{-O(n)},$$

where the distribution of $N = P \cdot Q$ is $FIG(1^n)$, v is uniformly distributed in $\mathbb{Z}_N^*$, r is a random n-bit string, $b \in_R \{0,1\}$, $u \cdot w$ is the unique quadratic-residue in $\mathbb{Z}_N^*$ which satisfies $(u \cdot w)^2 = v^2 \cdot w^2 \bmod N$, and w is a randomly chosen quadratic-residue in $\mathbb{Z}_N^*$ (which is completely determined by the value of v^2 and $\mathcal{D}$'s internal coin tosses and is efficiently computable by $\mathcal{D}$).

Proof sketch. The proof of Lemma 6.2 is essentially identical to the proof of Lemma 5.4. Given v^2, N, r, and $J = I \cdot \ell + k$, the values of $g, \vec{a}, u$, and w are defined exactly as before. The following claim establishes the correctness of $\mathcal{D}$ (and is proved exactly in the same way as Claim 5.6).

CLAIM 6.1. *Let $\vec{a}, g, u$, and w be defined as above; then $\mathcal{LSB}(r \cdot g^{2^k \Pi_{i=1}^n a_{i,x_i}}) = \mathcal{LSB}(r \cdot u \cdot w)$.*

As before, this implies that the $(k+1)$st bit in the answer that the $f_{N,\vec{a},g,r}$ black-box is supposed to give to the $(I+1)$st query (and is answered with α instead) is equal to $\mathcal{LSB}(r \cdot u \cdot w)$. As we have already seen, this fact can be used by $\mathcal{D}$ in order to decide whether or not α equals $\mathcal{LSB}(r \cdot u \cdot w)$.

As for $\mathcal{D}$'s running-time, since the values of $g, \vec{a}, u$, and w are identical to the case of Lemma 5.4, it follows that $\mathcal{D}$ is able to efficiently compute both $r \cdot g^{2^{k+1} \Pi_{i=1}^n a_{i,x_i}}$ and $r \cdot g^{\Pi_{i=1}^n a_{i,y_i}}$ for all $y \neq x$. In particular, $\mathcal{D}$ can be implemented in time $poly(n, \ell(n)) \cdot t(n)$.

Finally, since the distribution of the key $(N, \vec{a}, g, r)$ chosen by $\mathcal{D}$ is identical to the distribution of the key chosen by the distinguisher in the proof of Lemma 5.4, the success-probability of $\mathcal{D}$ is identical to the success-probability of the distinguisher in the proof of Lemma 5.4. □

7. Further research. The proof of Theorem 5.1 is tailored to the specific cryptographic primitives which are used in Construction 4.1 (i.e., the "unpredictable" function $g^{\Pi_{i=1}^n a_{i,x_i}}$ and the BBS generator). An interesting open problem would be to provide an alternative proof for Theorem 5.1. Such a proof might make use of more general notions and different techniques and will hopefully shed more light on the reasons for which our construction yields a pseudorandom function. In particular, it may provide new constructions of pseudorandom functions based on more general (or more efficient) cryptographic primitives.

As we have demonstrated, in section 5.1, there exists an "unpredictable" function and a pseudorandom generator such that their composition is *not* a pseudorandom function. It should be interesting to recognize what precisely are the features of a function h_s (from an ensemble $H = \{h_s\}$) and of a pseudorandom sequence generator G that are needed in order to prove that our construction indeed yields pseudorandom functions.

Comparing to the DDH pseudorandom functions. As we have already mentioned, the efficiency of Construction 4.1 is comparable to the efficiency of the DDH functions by NR [20]. Apart from being slightly more efficient than our functions, the DDH functions have some additional properties:

- The simple algebraic structure of the DDH functions implies several attractive features (e.g., zero-knowledge proof for the value of the function, function sharing, and oblivious evaluation of the value of the function). In spite of the

similarity between the two constructions, we do not know how to prove that similar protocols are secure in our case.

- As opposed to the proof of Theorem 5.1, the security of the DDH functions does not decrease proportionally to the number of queries which are made by the adversary.[16] (This is due to the random self-reducibility of the DDH assumption [20].)

It is natural to consider the features of the DDH functions as guidelines for further research regarding our functions.

Acknowledgments. We would like to thank Roger Fischlin for pointing out the applicability of the $\mathcal{LSB}$ reconstruction techniques of [1, 10] to our construction (as described in section 6 and discussed in footnote 15). We would like to thank Shai Halevi for the observations discussed in Remark 4.1. Finally, we would like to thank the anonymous referees for many helpful comments.

GENERATORS OF $H_1(\Gamma_h, \mathbb{Z})$ FOR TRIANGULATED SURFACES: CONSTRUCTION AND CLASSIFICATION*

R. HIPTMAIR† AND J. OSTROWSKI‡

Abstract. We consider a bounded Lipschitz-polyhedron $\Omega \subset \mathbb{R}^3$ of general topology equipped with a tetrahedral triangulation that induces a mesh Γ_h of the surface $\partial\Omega$. We seek a maximal set of surface edge cycles that are independent in $H_1(\Gamma_h, \mathbb{Z})$ and bounding with respect to the exterior of Ω.

We present an algorithm for constructing suitable 1-cycles in Γ_h: First, representatives of a basis of the homology group $H_1(\Gamma_h, \mathbb{Z})$ are constructed, merely using the combinatorial description of the surface mesh Γ_h. Then, a duality pairing based on linking numbers is used to determine those combinations that are bounding with respect to $\mathbb{R}^3 \setminus \Omega$. This is the key to circumventing a triangulation of the exterior region $\mathbb{R}^3 \setminus \Omega$ in the computations. For shape-regular, quasi-uniform families of meshes, the asymptotic complexity of the algorithm is shown to be $O(N^2)$, where N is the number of edges of Γ_h.

The scheme provides an essential preprocessing step for all boundary element methods for eddy current simulation, which rely on discrete divergence-free vectorfields and their description through stream functions.

1. Background.

This paper straddles the fields of algebraic topology, graph theory, and numerical approximation. More precisely, starting out from boundary element method computations of electromagnetic fields, we encounter a problem of discrete cellular homology and solve it via continuous fields and numerical approximations.

Throughout the paper we have in mind the following task faced in computational electromagnetism (for details see [13]): A Lipschitz-polyhedron Ω in three-dimensional Euclidean space, the conductor, is equipped with a tetrahedral triangulation Ω_h. The goal is to compute the eddy currents in Ω that are triggered by an exciting loop current. This involves the solution of partial differential equations on the entire space. A boundary element method is used to take into account the unbounded exterior $\Omega' := \mathbb{R}^3 \setminus \Omega$. It relies on a divergence-free surface current $\boldsymbol{\lambda}$ as auxiliary unknown, which is discretized by means of twisted discrete 1-forms on the surface mesh $\Gamma_h := \Omega_h \cap \partial\Omega$. These 1-forms are special representatives of Whitney-forms [24]. Their degrees of freedom are associated with the edges of the surface mesh. Thus, they can be regarded as complex-valued 1-cochains of the simplicial cellular complex provided by Γ_h.

The discrete surface current has to be a closed form. In the context of a boundary element method the most efficient way to realize this constraint is through discrete

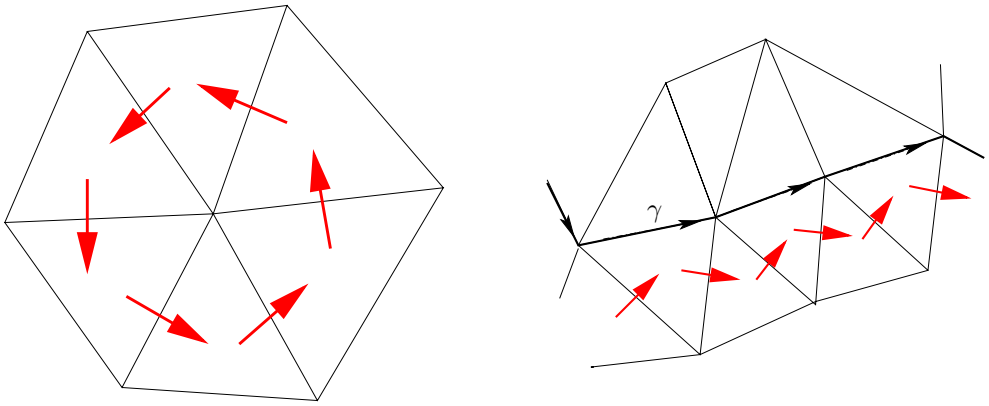

FIG. 1. *Left: Current generated by local stream function. Right: Current sheet along a* 1*-cycle* γ.

potentials (stream functions; see Figure 1); i.e., the 1-cochains are represented as exterior derivatives of 0-cochains. However, if the first Betti number $\beta_1(\Gamma)$, $\Gamma := \partial\Omega$, does not vanish, potentials do not supply all of the desired space. What is missing is the space spanned by representatives of a basis of the cohomology group $H^1(\Gamma_h, \mathbb{C})$. Its dimension is known to be equal to $\beta_1(\Gamma)$.

As $\partial\Gamma = \emptyset$ and Γ is orientable, we can exploit the (Poincaré-)duality between cohomology and homology $H^1(\Gamma_h, \mathbb{C}) \cong H_1(\Gamma_h, \mathbb{C})$. Moreover, as these groups are torsion free [15, section II], we need only consider integral coefficients, i.e., $H_1(\Gamma_h, \mathbb{Z})$. Representatives of the latter group are given by nonbounding edge cycles in Γ_h. If we know them, we can recover surface currents in $H^1(\Gamma_h, \mathbb{C})$ as sheets of current traveling along the 1-cycles as sketched in Figure 1 (left). Yet, not all of $H_1(\Gamma_h, \mathbb{Z})$ is really desired, because $\boldsymbol{\lambda}_h$ can be regarded as an approximation of the trace $\mathbf{H} \times \mathbf{n}$ ($\mathbf{n}$ exterior unit normal) of the magnetic field $\mathbf{H}$. Ampere's law tells us that

$$\int_{\partial S} \mathbf{H} \cdot d\vec{s} = \int_S \mathbf{j} \cdot d\vec{S}, \tag{1.1}$$

where S is any orientable 2-surface and $\mathbf{j}$ stands for a current. If S has its boundary on Γ, we expect

$$\int_{\partial S} \mathbf{n} \times \boldsymbol{\lambda}_h \cdot d\vec{s} = \int_S \mathbf{j} \cdot d\vec{S}. \tag{1.2}$$

Outside Ω currents cannot exist. This means that the integral of $\mathbf{n} \times \boldsymbol{\lambda}_h$ along any 1-cycle in Γ_h will vanish if that cycle is bounding relative to $\Omega' := \mathbb{R}^3 \setminus \Omega$. Current sheets skirting nonbounding surface edge cycles that are not bounding with respect to Ω' fail to meet this constraint. Thus *relevant* surface edge cycles in $H_1(\Gamma_h, \mathbb{Z})$ are marked by the property that they are bounding relative to Ω'. Zeroing in on relevant cycles, we will end up with a subgroup of $H_1(\Gamma_h, \mathbb{Z})$ of dimension $\frac{1}{2}\beta_1(\Gamma)$. To get an idea of what relevant cycles look like, imagine a ring-shaped hollow Ω, for instance the closed circular pipe of Figure 2. Only the circles γ_1 on the outer surface surrounding the central hole and γ_2 linking the inner cavity qualify as relevant independent representatives of $H_1(\Gamma, \mathbb{Z})$.

It is not only a matter of economy to discard the redundant generators of $H^1(\Gamma_h, \mathbb{C})$. On the contrary, it is essential for the applicability of the boundary element method,

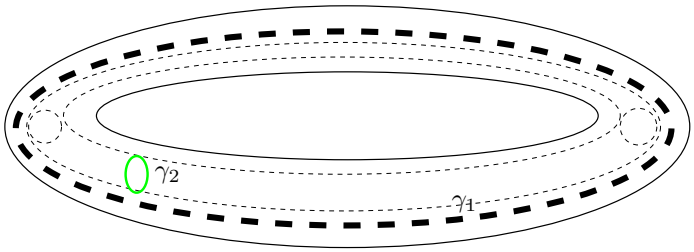

FIG. 2. *The two relevant surface* 1*-cycles* γ_1 *and* γ_2 (*modulo homology*) *for a toroidal pipe.*

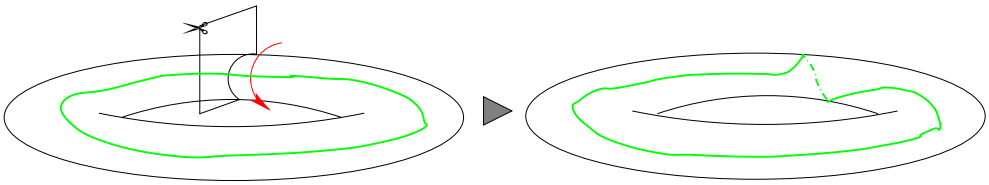

FIG. 3. *Destroying a* 1*-cycle bounding relative to* Ω'.

because in the model excitations are taken into account by prescribing the total current in a loop-shaped part of Ω, the so-called inductor. In computational practice, this is done by fixing the contribution of the relevant representative of $H^1(\Gamma_h, \mathbb{C})$ to the boundary element space. Choosing one that does not bound with respect to Ω' is physically meaningless. In Figure 2 only γ_1 is suitable to impose a loop current.

In principle, relevant 1-cycles can be constructed based on a triangulation of $\mathcal{O}\backslash\Omega$, where $\mathcal{O}$ is a sufficiently large cube containing $\bar{\Omega}$. Then there are algorithms for the construction of so-called cutting surfaces in Ω', whose boundaries are the desired 1-cycles. Pioneering work in this field was done by Brown [4]. His algorithm finds generators of $H_1(\bar{\Omega}, \mathbb{Z})$ by successive retractions applied to elements of Ω_h. However, it is not clear whether the method can cope with arbitrary meshes, and the resulting cycles are not located on Γ. On top of that, the computational costs might behave like $O(N^3)$, where N is the number of edges of Ω_h. Profound theoretical and algorithmic investigations on the construction of cutting surfaces were conducted by Kotiuga [17, 16, 15]. In [12, Chap. 3], an actual computation of cutting surfaces is presented. It involves the solution of a finite element problem on the triangulated complement Ω'. Yet, this option is not available to us. First, a rationale for using boundary element methods is to avoid meshing parts of the exterior of Ω. Second, the computations turn out to be extremely expensive. Their complexity is at least $O(N^3)$, where N now stands for the number of elements in the exterior mesh. Very effective algorithms for construction of generators of $H_1(\Gamma_h, \mathbb{Z})$ have been developed in computational topology [23, 18]. They can guarantee quite a few particular properties of the cycles but short of picking relevant cycles.

At first glance it seems that we could successfully tackle the problem in an entirely discrete setting, relying on the connectivity of Ω_h alone. Yet, consider a plain triangulated torus. Cut it at its small circle, twist by 2π, and reconnect as in Figure 3. If we had found a surface 1-cycle bounding with respect to the exterior, this operation will render it nonrelevant. However, the combinatorial description of the mesh remains the same. It is evident that it is impossible to find the desired 1-cycles merely using combinatorial information about Ω_h. Unless we want to use an exterior

mesh, we also have to rely on information about the geometry of Ω.

The main objective of this paper is to convey how blending combinatorial and geometric techniques can yield a fast algorithm for the construction and classification of generators of $H_1(\Gamma_h,\mathbb{Z})$. In section 2 we fix the framework and basic concepts of cellular homology. Then, to make the presentation self-contained, in section 3 we follow [19] and introduce the construction of generators of $H_1(\Gamma_h,\mathbb{Z})$ based on graph algorithms. Those are reminiscent of so-called cotree gauging methods, widely employed in computational electromagnetism (see [2, section 5.3], [8], and [14]). In section 4 we appeal to the venerable topological notion of linking numbers to come up with an algebraic characterization of 1-cycles bounding with respect to the exterior. We point out that a different classification problem has been treated in [7] using rather similar ideas. The numerical computation of linking numbers is detailed in section 5.

2. Setting and notations. Denote by $\mathcal{S}_0 := \mathcal{V}_h, \mathcal{S}_1 := \mathcal{E}_h$, and $\mathcal{S}_2 := \mathcal{F}_h$ the sets of vertices, edges, and faces of the surface mesh Γ_h covering Γ. From an abstract point of view, Γ_h can be regarded as a nondegenerate simplicial cellular complex [9]. We say that an l-simplex $\mathbf{x} \in \mathcal{S}_l$ is contained in another k-simplex $\mathbf{y} \in \mathcal{S}_k$, $\mathbf{x} \prec \mathbf{y}$, if all vertices of $\mathbf{x}$ are vertices of $\mathbf{y}$, too. For $\mathbf{x} \in \mathcal{S}_l$ we introduce the k-simplicial neighborhood

$$\mathcal{S}_k(\mathbf{x}) := \{\mathbf{y} \in \mathcal{S}_k,\ \mathbf{x} \prec \mathbf{y} \text{ or } \mathbf{y} \prec \mathbf{x}\}.$$

Each simplex is endowed with an interior orientation prescribed by an ordering of its vertices. From a combinatorial point of view, the oriented triangulation Γ_h can be completely described by the *incidence relations* $\iota_{l-1}^{l} : \mathcal{S}_{l-1} \times \mathcal{S}_l \mapsto \{-1,0,1\}$, where $\iota(\mathbf{x},\mathbf{y}) = 0$, if $\mathbf{x}$ is not contained in $\mathbf{y}$, and, otherwise, $\iota(\mathbf{x},\mathbf{y}) = \pm 1$, if the induced orientation of $\mathbf{x}$ with respect to $\mathbf{y}$ is the same as/opposite to the interior orientation of $\mathbf{x}$ (cf. [11, section 2.2] and [2, section 5.2]).

Mappings $\mathcal{S}_l \mapsto \mathbb{Z}$ are called surface l-chains. They form a free Abelian group $C_l(\Gamma_h,\mathbb{Z})$. We adopt the convenient sum notation $\gamma := \sum_{\mathbf{x}\in\mathcal{S}_l} \alpha_{\mathbf{x}}\mathbf{x}$, $\alpha_{\mathbf{x}} \in \mathbb{Z}$ for a surface l-chain γ with $\gamma(\mathbf{x}) = \alpha_{\mathbf{x}}$. The coefficients $\alpha_{\mathbf{x}}$ will be referred to as weights. We define the set of l-simplices contained in an l-chain as

$$\mathcal{S}_l(\gamma) := \{\mathbf{x} \in \mathcal{S}_l,\ \gamma(\mathbf{x}) \neq 0\}, \qquad \gamma \in C_l(\Gamma_h,\mathbb{Z}).$$

For $l > 0$ we define the *boundary* $\partial_l\mathbf{x}$ of $\mathbf{x} \in \mathcal{S}_l$ as

$$\partial_l\mathbf{x} := \sum_{\mathbf{y}\in\mathcal{S}_{l-1}(\mathbf{x})} \iota(\mathbf{y},\mathbf{x})\cdot\mathbf{y} \quad \Rightarrow \quad \partial_l\mathbf{x} \in C_{l-1}(\Gamma_h,\mathbb{Z})$$

and get the *boundary homomorphism* $\partial_l : C_l(\Gamma_h,\mathbb{Z}) \mapsto C_{l-1}(\Gamma_h,\mathbb{Z})$ by extension:

$$\partial_l\left(\sum_{\mathbf{x}\in\mathcal{S}_l}\alpha_{\mathbf{x}}\mathbf{x}\right) := \sum_{\mathbf{x}\in\mathcal{S}_l}\alpha_{\mathbf{x}}\partial_l\mathbf{x}.$$

We will need cycles and 1-boundaries, i.e., subgroups of $C_1(\Gamma_h,\mathbb{Z})$ defined by

$$Z_1(\Gamma_h,\mathbb{Z}) := \mathrm{Ker}(\partial_1), \qquad B_1(\Gamma_h,\mathbb{Z}) := \mathrm{Im}(\partial_2),$$

respectively (cf. [22, section IV,V] for a lucid exposition). A 1-cycle γ is said to be bounding in Γ_h if $\gamma \in B_1(\Gamma_h,\mathbb{Z})$. Two 1-cycles are called *homologous* if their difference is a boundary, that is,

$$\omega,\eta \in C_1(\Gamma_h,\mathbb{Z}): \quad \omega \sim \eta \quad :\Leftrightarrow \quad \omega - \eta \in B_1(\Gamma_h,\mathbb{Z}).$$

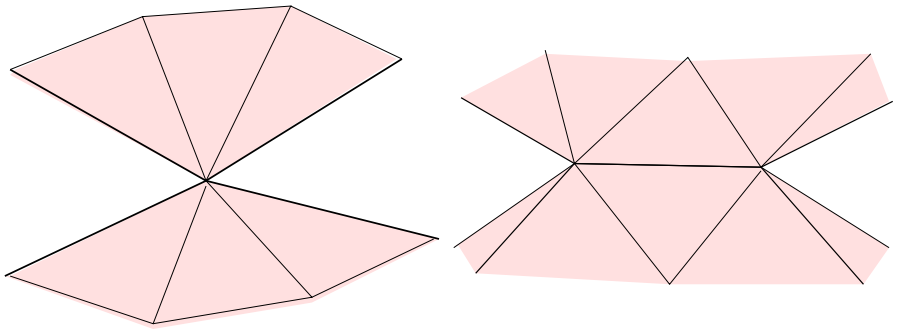

FIG. 4. *Surface configurations not possible in the case of a Lipschitz-polyhedron.*

A fundamental property of the incidence relations guarantees that $B_1(\Gamma_h, \mathbb{Z}) \subset Z_1(\Gamma_h, \mathbb{Z})$. The quotient group is called the first homology group $H_1(\Gamma_h, \mathbb{Z}) := Z_1(\Gamma_h, \mathbb{Z})/B_1(\Gamma_h, \mathbb{Z})$. It has finite rank $\beta_1(\Gamma_h)$, which is called the first Betti number of Γ_h [20, section 5.2].

As the current task reaches beyond mere combinatorics, some assumptions on the geometry of Ω have to be made. We demand that Ω has a Lipschitz-continuous boundary; that is, Γ has to have a local representation as the graph of a Lipschitz-continuous function [10, Sect 1.2.1]. Topologically speaking, this forces $\bar{\Omega}$ to be homeomorphic to a compact domain with a smooth boundary. First, this implies $\partial\Gamma = \emptyset$ and that each $\mathbf{t} \in \mathcal{F}_h$ is a face of a tetrahedron of Ω_h. A second consequence is that Γ is orientable. Thus, we can fix an orientation of $\partial\Omega$ and endow all triangles $\mathbf{t} \in \mathcal{F}_h$ with the induced orientation. Third, the surface is "locally flat" in the sense that exactly two faces in $\mathcal{F}_h$ are incident with each edge in $\mathcal{E}_h$. Situations like the "double cone" and "double ridge" depicted in Figure 4 are ruled out.

As the meshes are used for finite element computations, it also makes sense to reign in distortions of tetrahedra. We attribute the mesh Ω_h a shape-regularity measure ρ, $\rho > 0$, if

$$\max_{T\in\Omega_h} \frac{\operatorname{diam}(T)}{\sup\{r > 0 : \exists \mathbf{c} \in T, |\mathbf{x} - \mathbf{c}| < r \Rightarrow \mathbf{x} \in T\}} \leq \rho, \tag{2.1}$$

with $\operatorname{diam}(T) := \sup_{\mathbf{x},\mathbf{y}\in T} |\mathbf{x} - \mathbf{y}|$ [5, Chap. 3, section 3.1]. We infer that

$$\tfrac{4}{3}\pi \left(\operatorname{diam}(T)/\rho\right)^3 \leq \operatorname{Vol}(T) \leq \tfrac{1}{6} \operatorname{diam}(T)^3, \quad T \in \Omega_h. \tag{2.2}$$

Another common concept is q-quasi-uniformity [5], $0 < q \leq 1$, of a mesh that claims

$$q^{-1} \min_{T\in\Omega_h} \operatorname{diam}(T) \geq \max_{T\in\Omega_h} \operatorname{diam}(T). \tag{2.3}$$

The expression on the right-hand side is commonly called the meshwidth of Ω_h. Obviously, (2.1) and (2.3) hold for Γ_h instead of Ω_h with the same constants.

3. Construction of representatives of basis of $H_1(\Gamma_h, \mathbb{Z})$. This part of the algorithm is purely combinatorial and relies on interpreting Γ_h as a graph. We are using the standard definition of a graph as an ordered triple (VG, EG, Ψ) of sets VG ("vertices"), EG ("edges")[1] and an incidence function $\Psi : EG \mapsto \{VG \times VG\}$ [1, Chap. 1].

[1] Be aware of the ambiguity of the terms "vertex" and "edge," which may refer either to a graph or simplices of a mesh.

We interpret Γ_h as a graph in two different ways: The incidence function $\Psi_{\mathfrak{D}} : \mathcal{E}_h \mapsto \mathcal{F}_h$ of the graph $\mathfrak{D} := (\mathcal{F}_h, \mathcal{E}_h, \Psi_{\mathfrak{D}})$ is given by $\Psi_{\mathfrak{D}}(\mathbf{e}) := \mathcal{S}_2(\mathbf{e})$. Due to $\sharp\mathcal{S}_2(\mathbf{e}) = 2$ for all $\mathbf{e} \in \mathcal{E}_h$ it is well defined.[2] This graph $\mathfrak{D}$ is commonly known as the dual graph of the mesh Γ_h. The other graph is the actual edge graph $\mathfrak{G} := (\mathcal{V}_h, \mathcal{E}_h, \Psi_{\mathfrak{G}})$ with incidence function $\Psi_{\mathfrak{G}} : \mathcal{E}_h \mapsto \mathcal{V}_h$, $\Psi_{\mathfrak{G}}(\mathbf{e}) := \mathcal{S}_0(\mathbf{e})$.

The components $\mathfrak{D}^i$, $i = 1, \ldots, p$, $p \in \mathbb{N}$, of $\mathfrak{D}$ correspond to the different connected components of the surface Γ. In a straightforward manner they give rise to components $\Gamma_h^1, \ldots, \Gamma_h^p$ of Γ_h. If a 1-cycle is bounding in Γ_h all its restrictions to connected components have to be bounding, too. Otherwise, two triangles of different components would have to be adjacent, which is impossible. Therefore,

$$H_1(\Gamma_h, \mathbb{Z}) = \bigoplus_{i=1}^{p} H_1(\Gamma_h^i, \mathbb{Z}). \tag{3.1}$$

Hence, without loss of generality, we can focus on a single component Γ_h^i. Its sets of simplices will be tagged by a superscript i. Note that the geometric constraints enforce $\mathcal{V}_h^i \cap \mathcal{V}_h^j = \emptyset$ for $i \neq j$. Thus, a natural partitioning of the vertex-graph $\mathfrak{G}$ into components $\mathfrak{G}^1, \ldots, \mathfrak{G}^p$ is also implied.

Let $T_{\mathfrak{D}}^i$ be a spanning tree of $\mathfrak{D}^i$, i.e., a spanning subgraph of $\mathfrak{D}^i$ that is a tree (cf. Figure 8). It induces a natural partitioning of $\mathcal{E}_h^i$ into edges contained in $T_{\mathfrak{D}}^i$ and the complement set $\mathcal{E}_\flat^i$.

LEMMA 3.1. *No nontrivial* 1*-cycle only comprising edges in* $\mathcal{E}_\flat^i$ *can be bounding in* Γ_h^i.

Proof. Assume that there is a nontrivial bounding 1-cycle ω in $\mathcal{E}_\flat^i$; i.e., there is $\varphi \in C_2(\Gamma_h^i, \mathbb{Z})$, $\varphi \neq 0$ such that $\partial_2 \varphi = \omega$. If two triangles $\mathbf{t}, \mathbf{t}' \in \varphi$ share an edge $\mathbf{e}$ then $\iota(\mathbf{e}, \mathbf{t})\iota(\mathbf{e}, \mathbf{t}') = -1$ as $\mathbf{t}$ and $\mathbf{t}'$ carry the orientation induced by Γ. If $\mathbf{e}$ is not contained in $\mathcal{S}_1(\omega)$, this means that $\mathbf{t}$ and $\mathbf{t}'$ must have the same weight in φ. Eventually,

$$\mathbf{t}, \mathbf{t}' \in \mathcal{F}_h : \quad (\mathcal{S}_1(\mathbf{t}) \cap \mathcal{S}_1(\mathbf{t}')) \subset \mathcal{E}_h^i \quad \Rightarrow \quad \varphi(\mathbf{t}) = \varphi(\mathbf{t}').$$

Hence, two triangles connected by a path in $T_{\mathfrak{D}}^i$ have the same weights in φ. This will be true for all $\mathbf{t} \in \mathcal{F}_h$, since $T_{\mathfrak{D}}^i$ is a spanning tree: $\varphi = \kappa \cdot \sum_{\mathbf{t} \in \mathcal{F}_h^i} \mathbf{t}$ for some $\kappa \in \mathbb{Z} \setminus \{0\}$. However, the boundary of Γ_h^i, which is considered as a 2-chain, is empty. This refutes the assumption. ∎

LEMMA 3.2. *Each* $\gamma \in Z_1(\Gamma_h^i, \mathbb{Z})$ *is homologous to a* 1*-cycle comprising only edges in* $\mathcal{E}_\flat^i$.

Proof. Fix an arbitrary $\mathbf{t}_r \in \mathcal{F}_h$ as "root" of $T_{\mathfrak{D}}^i$. This makes it possible to assign to each triangle $\mathbf{t}$ of $T_{\mathfrak{D}}^i$ a unique number $d(\mathbf{t}) \in \mathbb{N}$, its distance to the root, i.e., the length of the unique path in $T_{\mathfrak{D}}^i$ connecting $\mathbf{t}$ and $\mathbf{t}_r$. Then set

$$d(\mathbf{e}) := \min\{d(\mathbf{t}),\, \mathbf{e} \prec \mathbf{t}\}, \qquad \mathbf{e} \in \mathcal{E}_h.$$

Please observe that (identifying $T_{\mathfrak{D}}^i$ with its edge set)

$$\mathbf{t} \in \mathcal{F}_h,\ d(\mathbf{t}) > 0 \quad \Rightarrow \quad \begin{cases} \exists_1 \mathbf{e} \in \mathcal{S}_1(\mathbf{t}) :\ d(\mathbf{e}) = d(\mathbf{t}) - 1, \\ d(\mathbf{e}') = d(\mathbf{t})\ \forall \mathbf{e}' \in (\mathcal{S}_1(\mathbf{t}) \cap T_{\mathfrak{D}}^i) \setminus \{\mathbf{e}\} \end{cases} \tag{3.2}$$

by elementary properties of the tree.

[2] $\sharp$ extracts the cardinality of a finite set.

We sort the edges of $T^i_{\mathfrak{D}}$ with respect to this "distance function," get a sequence $(\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_M)$, and write $\mathcal{TE}_k := \{\mathbf{e}_1, \dots, \mathbf{e}_k\}$, $k = 1, \dots, M$. Let j be the smallest index of an edge in $T^i_{\mathfrak{D}}$ contained in a cycle γ, i.e., $\mathcal{S}_1(\gamma) \cap \mathcal{TE}_{j-1} = \emptyset$. Select

$$\mathbf{t} \in \mathcal{S}_2(\mathbf{e}_j) \text{ such that } d(\mathbf{t}) = \max\{d(\mathbf{t}'),\, \mathbf{t}' \in \mathcal{S}_2(\mathbf{e}_j)\} = d(\mathbf{e}_j) + 1.$$

Transform γ into a homologous 1-cycle γ' according to

$$\gamma' := \gamma - \gamma(\mathbf{e}_j) \cdot \iota(\mathbf{e}_j, \mathbf{t}) \cdot \partial_2 \mathbf{t}.$$

By definition of the boundary operator $\gamma'(\mathbf{e}_j) = 0$, but γ' will probably contain the other edges of $\mathbf{t}$, which might belong to $T^i_{\mathfrak{D}}$. Fortunately, as we see from (3.2), their distance to the root will be greater than that of $\mathbf{e}_j$ in case they belong to $T^i_{\mathfrak{D}}$. This establishes $\mathcal{E}(\gamma') \cap \mathcal{TE}_j = \emptyset$. Repeating this construction, we arrive at a path $\tilde{\gamma}$ with $\tilde{\gamma} \sim \gamma$ and $\mathcal{E}(\tilde{\gamma}) \cap \mathcal{TE}_M = \emptyset$, sloppily speaking, a homologous cycle in $\mathcal{E}^i_\flat$. □

LEMMA 3.3. *The subgraph* $\mathfrak{G}^i_\flat := (\mathcal{V}^i_h, \mathcal{E}^i_\flat, \Psi_{\mathfrak{G}\,|\mathcal{E}^i_\flat})$ *is connected.*

Proof. Assume that there are two components in $\mathfrak{G}^i_\flat$, spawning a partition $\mathcal{V}^i_h = \mathcal{V}_1 \cup \mathcal{V}_2$. Define

$$\mathcal{E}_B := \{\mathbf{e} \in \mathcal{E}^i_h,\, \mathcal{S}_0(\mathbf{e}) \cap \mathcal{V}_1 \neq \emptyset \text{ and } \mathcal{S}_0(\mathbf{e}) \cap \mathcal{V}_2 \neq \emptyset\}$$

and note that $\mathcal{E}_B \neq \emptyset$ as $\mathfrak{G}^i$ is connected. Next, set

$$\mathcal{F}_B := \{\mathbf{t} \in \mathcal{F}^i_h,\, \mathcal{S}_1(\mathbf{t}) \cap \mathcal{E}_B \neq \emptyset\}.$$

By the definition of components of a graph we know $\mathcal{E}_B \cap \mathcal{E}^i_\flat = \emptyset$, hence $\mathcal{E}_B \subset T^i_{\mathfrak{D}}$, where, for convenience, the tree is identified with the set of edges it contains. For all $\mathbf{t} \in \mathcal{F}_B$ both $\mathcal{S}_0(\mathbf{t}) \cap \mathcal{V}_1 \neq \emptyset$ and $\mathcal{S}_0(\mathbf{t}) \cap \mathcal{V}_2 \neq \emptyset$, which establishes

$$\sharp(\mathcal{S}_1(\mathbf{t}) \cap \mathcal{E}_B) = 2.$$

We conclude that in the subgraph $(\mathcal{F}_B, \mathcal{E}_B, \Psi_{\mathfrak{D}\,|\mathcal{E}_B})$ of $T^i_{\mathfrak{D}}$, which is a valid graph as $\sharp(\mathcal{S}_2(\mathbf{e}) \cap \mathcal{F}_B) = 2$ holds for all $\mathbf{e} \in \mathcal{E}_B$, every vertex has degree 2 such that it must contain a circuit. This contradicts its being contained in the tree $T^i_{\mathfrak{D}}$. □

According to the previous lemma we can find a single spanning tree $T^i_{\mathfrak{G}}$ of $\mathfrak{G}^i_\flat$ (see Figure 9). It also defines a subset of $\mathcal{E}^i_\flat$ in a natural fashion. Viewing $T^i_{\mathfrak{G}}$ as a set of edges, we write $\mathcal{E}^i_* := \mathcal{E}^i_\flat \setminus T^i_{\mathfrak{G}}$ for the remainder. Since $T^i_{\mathfrak{G}}$ is a spanning tree in $\mathfrak{G}^i_\flat$, for each $\mathbf{e} \in \mathcal{E}^i_*$ we can find a unique fundamental circuit $\mathbf{s}_\mathbf{e}$ in $\mathfrak{G}^i_\flat$ that, except for $\mathbf{e}$, only contains edges in $T^i_{\mathfrak{G}}$ [1, section 1.8] (see Figure 10).

LEMMA 3.4. *Every vertex in* $\mathbf{s}_\mathbf{e}$ *belongs to exactly two edges of* $\mathbf{s}_\mathbf{e}$, $\mathbf{e} \in \mathcal{E}^i_*$.

Proof. The proof is a straightforward consequence of [1, Thm. 1.2]. □

From the above lemma we infer that the $\mathbf{s}_\mathbf{e}$, $\mathbf{e} \in \mathcal{E}^i_*$, do not intersect themselves. Thus, it confirms that $\mathbf{s}_\mathbf{e}$ can be easily converted into a 1-cycle $\gamma_\mathbf{e}$ by fixing $\gamma_\mathbf{e}(\mathbf{e}) = 1$ and assigning weights ± 1 to its edges. The assignment of weights can proceed sequentially along $\mathbf{s}_\mathbf{e}$.

THEOREM 3.5. $\{\gamma_\mathbf{e},\, \mathbf{e} \in \mathcal{E}^i_*\}$ *represents a basis of* $H_1(\Gamma^i_h, \mathbb{Z})$.

Proof. Lemma 3.1 tells us that $\gamma_\mathbf{e} \notin B_1(\Gamma^i_h, \mathbb{Z})$. Moreover, as $\gamma_\mathbf{e}(\mathbf{e}') = \delta_{\mathbf{e},\mathbf{e}'}$, $\mathbf{e}, \mathbf{e}' \in \mathcal{E}^i_*$, the different 1-cycles are independent in $H_1(\Gamma^i_h, \mathbb{Z})$.

Let $\eta \in Z_1(\Gamma^i_h, \mathbb{Z})$. Due to Lemma 3.2 we can find a homologous 1-cycle η' covering only edges in $\mathcal{E}^i_\flat$. Set

$$\pi := \eta' - \sum_{\mathbf{e} \in \mathcal{E}^i_*} \eta'(\mathbf{e}) \cdot \gamma_\mathbf{e}.$$

      $\{\mathbf{v}'\} := \mathcal{S}_0(\mathbf{e}') \setminus \{\mathbf{v}\}$;
      if $(\mathbf{v}' \in \mathcal{L}_h)$ { $\mathcal{L}_h := \mathcal{L}_h \setminus \{\mathbf{v}'\}$; Q.push_back($\mathbf{v}'$); $\mathbf{v}'$.depth = $\mathbf{v}$.depth+1; }
      else { $\mathcal{E}_*^i := \mathcal{E}_*^i \cup \{\mathbf{e}'\}$; }
    }}}

FIG. 6. *Algorithm: Construction of trees* $T_{\mathfrak{G}}^i$ *and sets* $\mathcal{E}_*^i$.

Assume that π is not trivial. Then π is a 1-cycle and $\mathcal{S}_1(\pi)$ is completely contained in the tree $T_{\mathfrak{G}}^i$. In the subgraph $\mathfrak{G}_{|\mathcal{S}_1(\pi)}$ every vertex must have degree ≥ 2, which is implied by $\pi \in Z_1(\Gamma_h, \mathbb{Z})$. Hence, there is a circuit in $\mathfrak{G}_{|\mathcal{S}_1(\pi)}$. At the same time it is supposed to be contained in a tree, which, by contradiction, forces $\pi = 0$.

In sum, every cycle is homologous to a combination of the $\gamma_{\mathbf{e}}$. □

Be aware that we have found generators of $H_1(\Gamma_h, \mathbb{Z})$ that, by construction, have a geometric meaning as closed curves in Γ, too.

An outline of the combinatorial algorithms for the construction of the circuits $\mathbf{s}_{\mathbf{e}}$, $\mathbf{e} \in \mathcal{E}_*^i$, is given in Figures 5–7. The sets $\mathcal{D}_h$, $\mathcal{E}_h^D$, and $\mathcal{L}_h$, and the related queries can be efficiently realized through marking simplices of Γ_h. The individual steps of the algorithm in the case of a triangulated torus are illustrated in Figures 8–10.

If access to local incidence information is possible in constant time, the total computational effort will be proportional to $\sharp\mathcal{F}_h + (1 + \beta_1(\Gamma)) \cdot \sharp\mathcal{V}_h$. The algorithm produces ordered sequences $\mathbf{s}_{\mathbf{e}}$ of edges, $\mathbf{e} \in \mathcal{E}_*^i$, that represent circuits. Notice that the algorithm from Figure 5 permits us to identify the connected components of Γ_h without additional effort.

Remark. By a cheap algorithm we can always replace each $\gamma_{\mathbf{e}}$, $\mathbf{e} \in \mathcal{E}_*^i$, by a homologous edge cycle that does not contain two edges of the same surface triangle. For these "straightened" cycles, still denoted by $\Gamma_{\mathbf{e}}$, will hold

$$\sharp\mathcal{E}_h(\gamma_{\mathbf{e}}) \leq \sharp\mathcal{F}_h(\gamma_{\mathbf{e}}).$$

Often, this estimate is extremely pessimistic, as in most cases the cycles $\gamma_{\mathbf{e}}$, $\mathbf{e} \in \mathcal{E}_*^i$, will cover only a fraction of the edges in $\mathcal{E}_h$. The example of Figure 11 is typical. However, this cannot be guaranteed, in particular for very coarse surface meshes that

```
foreach (e ∈ E*^i) {
  list<Edge> s_e; s_e := ∅; {x, y} := S_0(e); s_e.push_back(e);
  do {
    while (x.depth > y.depth) {
      foreach (e' ∈ S_1(x) \ E_h^D) {
        {z} := S_0(e') \ {x};
        if (z.depth < x.depth)   { s_e.push_back(e'); x ← z; break; }}}
    while (x.depth ≤ y.depth and x ≠ y) {
      foreach (e' ∈ S_1(y) \ E_h^D) {
        {z} := S_0(e') \ {y};
        if (z.depth ≤ y.depth)   { s_e.push_front(e'); y ← z; break; }}}
  }
  while (x ≠ y); }
```

FIG. 7. *Algorithm: Construction of circuits* $\mathbf{s_e}$, $\mathbf{e} \in \mathcal{E}^i_*$. *They are assembled in STL-list-containers* [21, *section* 17.2.2].

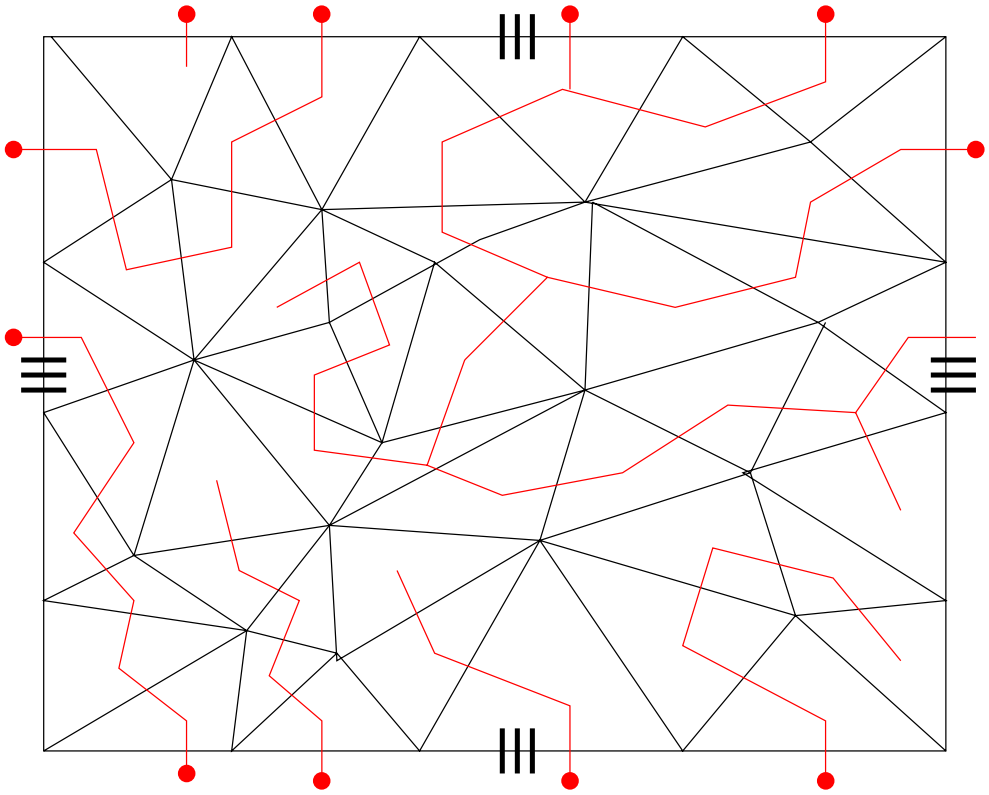

FIG. 8. *Tree* $T_{\mathfrak{D}}$ *in the case of a triangulated torus, which is represented by identifying opposite sides of a rectangle. Output of the algorithm from Figure* 5.

barely resolve the topology of Γ.

4. Identification of relevant cycles. As pointed out in the first section, finding generators of $H_1(\Gamma_h, \mathbb{Z})$ that bound relative to Ω' involves geometric considerations. This forces us to resort to concepts of homology theory on subsets of the

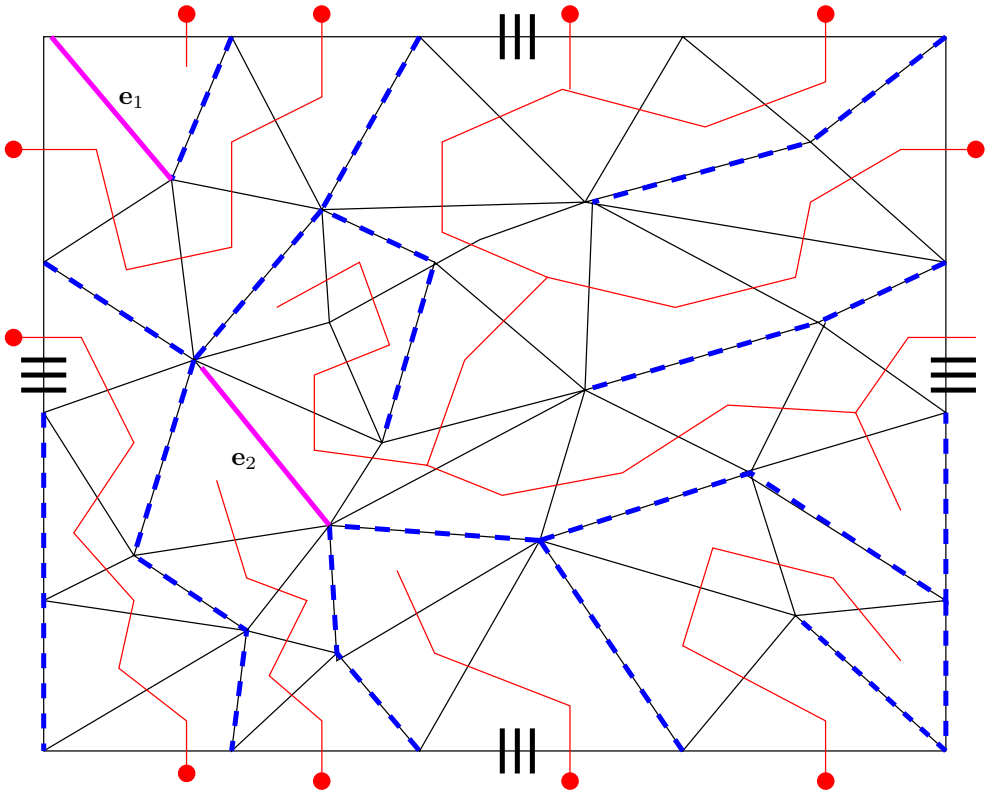

FIG. 9. *Construction of* $T_{\mathfrak{G}}$ (*dashed lines*) *on the torus according to the algorithm from Figure* 6, *yielding* $\mathcal{E}^i_* := \{\mathbf{e}_1, \mathbf{e}_2\}$.

Euclidean space $\mathbb{R}^3$. For a domain $D \subset \mathbb{R}^3$ we adopt the notation $Z_1(D,\mathbb{Z})$ for the group of 1-cycles, i.e., oriented closed curves in D. An element of $Z_1(\Gamma_h,\mathbb{Z})$ is said to bound relative to Ω (or Ω') if it can be represented by an oriented closed edge curve on Γ and if it is the boundary of an orientable 2-surface in Ω (or Ω').

The linking number (cf. [20, section 5.2], [4, Appendix I]) will be a crucial device.

DEFINITION 4.1. *Given two piecewise differentiable disjoint* 1*-cycles* $\gamma, \gamma' \in Z_1(\mathbb{R}^3,\mathbb{Z})$ *we define their* relative linking number *by*

$$L(\gamma,\gamma') := -\int_\gamma \int_{\gamma'} \operatorname{grad}_{\mathbf{y}} G(\mathbf{x},\mathbf{y}) \cdot (d\vec{s}(\mathbf{x}) \times d\vec{s}(\mathbf{y})), \quad G(\mathbf{x},\mathbf{y}) := \frac{1}{4\pi|\mathbf{x}-\mathbf{y}|}.$$

Obviously $L(\gamma,\gamma') = L(\gamma',\gamma)$. Moreover, $L(\gamma,\gamma') \in \mathbb{Z}$. The linking number can also be expressed as $L(\gamma,\gamma') = \int_\gamma \mathbf{H}_{\gamma'}$ where $\mathbf{H}_{\gamma'}$ is a 1-form defined on $\mathbb{R}^3 \setminus \gamma'$ by

$$\langle \mathbf{H}_{\gamma'}(\mathbf{x}), \mathbf{v} \rangle := -\int_{\gamma'} \operatorname{grad}_{\mathbf{y}} G(\mathbf{x},\mathbf{y}) \cdot (\mathbf{v} \times d\vec{s}(\mathbf{y})), \qquad \mathbf{v} \in \mathbb{R}^3.$$

Straightforward computations show that $\mathbf{H}_{\gamma'}$ is closed, as the **curl** of its vector proxy vanishes on $\mathbb{R}^3 \setminus \gamma'$. If two 1-cycles $\gamma_1, \gamma_2 \in Z_1(\mathbb{R}^3 \setminus \gamma', \mathbb{Z})$ are homologous, i.e., the boundary of an oriented surface S, then, by Stokes' theorem,

$$L(\gamma_1,\gamma') - L(\gamma_2,\gamma') = \int_{\gamma_1-\gamma_2} \mathbf{H}_{\gamma'} = \int_{\partial S} \mathbf{H}_{\gamma'} = \int_S d\mathbf{H}_{\gamma'} = 0. \tag{4.1}$$

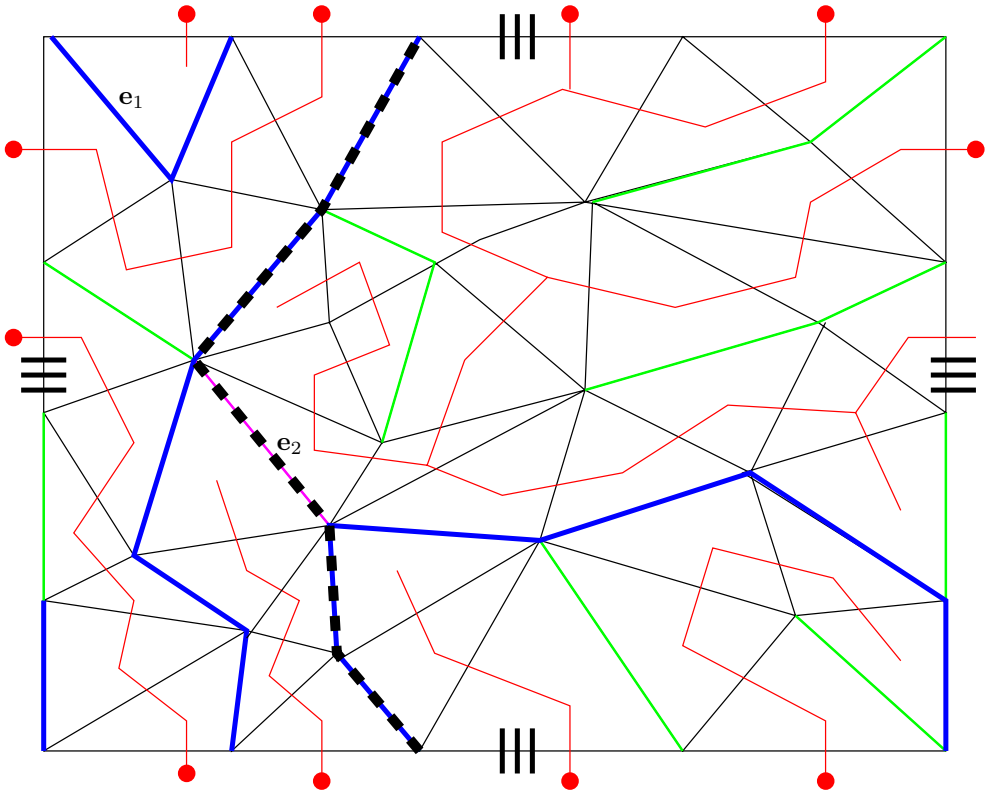

FIG. 10. *Two circuits* $\mathbf{s}_{\mathbf{e}_1}$ (*solid*) *and* $\mathbf{s}_{\mathbf{e}_2}$ (*dashed*) *on the triangulated torus as produced by the algorithm from Figure* 7.

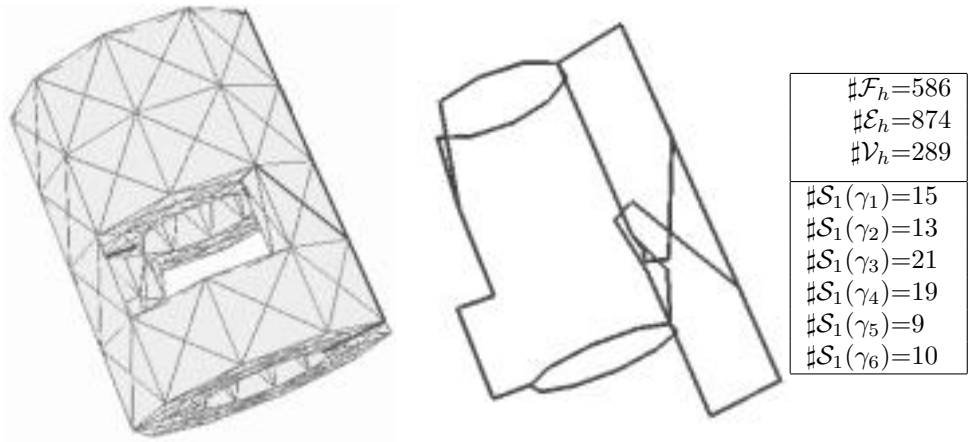

FIG. 11. *Surface mesh* (*left*) *and cycles* $\gamma_1, \ldots, \gamma_6$ (*right*) *in the case of a cyclinder with two intersecting holes drilled through it.*

Thus, the linking number defines a (bilinear) pairing

$$L : H_1(\Omega, \mathbb{Z}) \times H_1(\Omega', \mathbb{Z}) \mapsto \mathbb{Z} \tag{4.2}$$

between homology classes of 1-cycles in the interior and exterior of Ω. Recall that for a connected Γ an argument based on the Mayer–Vietoris exact sequence [3, section 2] shows

$$H_1(\Gamma,\mathbb{Z}) \cong H_1(\Omega',\mathbb{Z}) \oplus H_1(\Omega,\mathbb{Z}). \tag{4.3}$$

In addition, we know [20, section 6.6] that the first Betti numbers of Ω and its complement agree, i.e., $\beta_1(\Omega) = \beta_1(\Omega')$, and set $L := \beta_1(\Omega)$. Thanks to (4.3), this means that a basis of $H_1(\Gamma,\mathbb{Z})$ can be represented by L 1-cycles $\pi'_1,\dots,\pi'_L \in H_1(\Omega',\mathbb{Z})$ bounding relative to Ω and L 1-cycles $\pi_1,\dots,\pi_L \in H_1(\Omega,\mathbb{Z})$ bounding relative to Ω'. As exposed in [20, section 6.8], the pairing defined in (4.2) is nondegenerate in the sense that

$$L(\gamma,\gamma') = 0 \quad \forall \gamma' \in H_1(\Omega',\mathbb{Z}) \quad \Rightarrow \quad \gamma = 0 \quad \text{in } H_1(\Omega,\mathbb{Z}),$$

and vice versa. Thus, we can always choose the above 1-cycles such that

$$L(\pi_i,\pi'_j) = \delta_{ij}, \qquad 1 \le i,j \le L. \tag{4.4}$$

Retraction will give us 1-cycles $\in Z_1(\Gamma,\mathbb{Z})$ located on the boundary that are homologous to $\pi_1,\dots,\pi_L,\pi'_1,\dots,\pi'_L$ in $\bar\Omega$ and $\bar\Omega'$, respectively. We are calling them fundamental 1-cycles $\phi_1,\dots,\phi_L,\phi'_1,\dots,\phi'_l$, and note that still

$$L(\pi_i,\phi'_j) = \delta_{ij}, \qquad 1 \le i,j \le L.$$

Besides, the fundamental cycles provide a basis for $H_1(\Gamma,\mathbb{Z})$. By simple retraction to the 1-skeleton of Γ_h we also get a basis of $H_1(\Gamma_h,\mathbb{Z})$ for which we keep the notation $\{\phi_1,\dots,\phi_L,\phi'_1,\dots,\phi'_L\}$.

Linking numbers are well defined for disjoint 1-cycles only. Otherwise, the formula from Definition 4.1 will produce noninteger values. Therefore, we need a tool to disentangle surface 1-cycles.

DEFINITION 4.2. *For $\gamma \in Z_1(\Gamma_h,\mathbb{Z})$ we define the* submerged 1-cycle $\gamma\downarrow$ *as the homology class of γ in $H_1(\bar\Omega,\mathbb{Z})$.*

In the current setting, in which $\bar\Omega$ is homeomorphic to a compact set with smooth boundary, $H_1(\bar\Omega,\mathbb{Z}) = H_1(\Omega,\mathbb{Z})$ and $\gamma\downarrow$ can as well be regarded as an element of $H_1(\Omega,\mathbb{Z})$. We note the following consequences:

$$\phi_i\downarrow = \pi_i \text{ in } H_1(\Omega,\mathbb{Z}), \qquad \phi'_i\downarrow = 0, \qquad i = 1,\dots,L. \tag{4.5}$$

This is due to the fact that the exterior cycles π'_i are bounding relative to $\mathbb{R}^3$ and, consequently, ϕ'_i is bounding relative to $\bar\Omega$. Submersion is crucial for introducing the following "bilinear" pairing:

$$\langle\cdot,\cdot\rangle : \begin{cases} Z_1(\Gamma_h,\mathbb{Z}) \times Z_1(\Gamma_h,\mathbb{Z}) & \mapsto \quad \mathbb{Z} \\ (\eta_1,\eta_2) & \mapsto \quad L(\eta_2\downarrow,\eta_1). \end{cases} \tag{4.6}$$

Due to (4.1) it is well defined as $L(\beta,\eta) = 0$ for any 1-cycle $\beta \in Z_1(\Omega,\mathbb{Z})$ bounding relative to Ω and $\eta \in Z_1(\Gamma_h,\mathbb{Z})$. From (4.5) we conclude that $\langle\eta,\phi'_i\rangle = 0$ for all $i = 1,\dots,L$.

The point about this pairing is that it offers a criterion for telling the type of 1-cycles.

LEMMA 4.3. *$\gamma \in Z_1(\Gamma_h,\mathbb{Z})$ is bounding relative to Ω' if and only if $\langle\gamma,\phi_i\rangle = 0$ for all $i = 1,\dots,L$.*

Proof. The 1-cycle γ has a unique (modulo homology) representation with respect to the fundamental cycles

$$\gamma \sim \sum_{l=1}^{L} (\alpha_l \phi_l + \beta_l \phi'_l), \qquad \alpha_l, \beta_l \in \mathbb{Z}.$$

Recall that the 1-cycles $\phi_1, \ldots, \phi_L$, which have been "projected" onto the boundary of Ω from the interior, are bounding with respect to the exterior, whereas this is not true for $\phi'_1, \ldots, \phi'_L$. Thus, γ is bounding relative to Ω', if and only if it does not contain any contributions from $\phi'_1, \ldots, \phi'_L$, since the latter cannot be bounding relative to Ω' by definition. In short, γ is bounding relative to Ω' if and only if $\beta_l = 0$ for all $l = 1, \ldots, L$.

$$\begin{aligned}\langle \gamma, \phi_i \rangle = L(\phi_i \downarrow, \gamma) &= L\left(\phi_i \downarrow, \sum_{l=1}^{L} \alpha_l \phi_l + \beta_l \phi'_l\right) \\ &= \sum_{l=1}^{L} \alpha_l L(\phi_i \downarrow, \phi_l) + \sum_{l=1}^{L} \beta_l L(\phi_i \downarrow, \phi'_l) = \sum_{l=1}^{L} \beta_l \delta_{il} = \beta_i,\end{aligned}$$

as $L(\phi_i \downarrow, \phi_l) = 0$, because ϕ_l is bounding relative to $\bar{\Omega}'$, and $L(\phi_i \downarrow, \phi'_l) = L(\pi_i, \pi'_l) = \delta_{il}$ according to (4.4). □

The lemma seems to be of limited value, since we do not know the fundamental cycles explicitly. However, as $\langle \eta, \phi'_i \rangle = 0$ throughout, we need only a basis of $H_1(\Gamma_h, \mathbb{Z})$.

COROLLARY 4.4. *$\gamma \in Z_1(\Gamma_h, \mathbb{Z})$ is bounding relative to Ω' if and only if $\langle \gamma, \tau_i \rangle = 0$ for any basis $\{\tau_1, \ldots, \tau_{2L}\}$ of $H_1(\Gamma_h, \mathbb{Z})$.*

Proof. The basis property ensures that each ϕ_i, $i = 1, \ldots, L$, can be represented as a combination of τ_j (modulo homology). □

We have already got a basis at our disposal, namely the generators $\gamma_1, \ldots, \gamma_{2L}$ created by the graph algorithm of section 3. It goes without saying that any desired cycle can be obtained as an integral combination of these generators. So

$$\delta = \sum_{j=1}^{2L} \kappa_j \gamma_j \text{ bounding with respect to } \Omega' \quad \Leftrightarrow \quad \sum_{j=1}^{2L} \kappa_j \langle \gamma_j, \gamma_i \rangle = 0, \quad i = 1, \ldots, 2L.$$

In other words, $\delta \in Z_1(\Gamma_h, \mathbb{Z})$ is bounding with respect to $\bar{\Omega}'$ if and only if $\vec{\kappa} = (\kappa_1, \ldots, \kappa_{2L})^T \in \mathbb{Z}^{2L}$ satisfies

$$\vec{\kappa} \in \mathrm{Ker}(G^T), \qquad G := (\langle \gamma_j, \gamma_i \rangle)_{i,j=1}^{2L} \in \mathbb{Z}^{2L,2L}.$$

This suggests the following approach to the construction of the relevant surface 1-cycles:

1. Determine $\gamma_1, \ldots, \gamma_{2L}$ through spanning tree techniques (see section 3).
2. Compute the matrix G by evaluation of the pairing $\langle \cdot, \cdot \rangle$ (see section 5).
3. Use Gaussian elimination with full pivoting in $\mathbb{Z}$ to obtain an integral basis for $\mathrm{Ker}(G^T)$. Every basis vector will define a combination of $\gamma_1, \ldots, \gamma_{2L}$ that provides a relevant cycle.

The independence of the cycles thus obtained is clear from the linear independence of the basis vectors of $\mathrm{Ker}(G^T)$. However, do we get all L possible nonbounding surface

1-cycles (up to homology) that are bounding with respect to Ω'? The next result gives an affirmative answer.

THEOREM 4.5.

$$\dim \operatorname{Ker}(G^T) = L.$$

Proof. Start with a representation by means of fundamental cycles

$$\gamma_i \sim \sum_{l=1}^{L} (\alpha_{il}\phi_l + \beta_{il}\phi'_l), \qquad \alpha_{il}, \beta_{il} \in \mathbb{Z}, \quad i = 1 \ldots, 2L. \tag{4.7}$$

Observe that for $i, j = 1, \ldots, 2L$

$$\begin{aligned}\langle \gamma_i, \gamma_j \rangle &= \sum_{l,k=1}^{L} (\alpha_{il}\alpha_{jk} \langle \phi_l, \phi_k \rangle + \alpha_{il}\beta_{jk} \langle \phi_l, \phi'_k \rangle + \beta_{il}\alpha_{jk} \langle \phi'_l, \phi_k \rangle + \beta_{il}\beta_{jk} \langle \phi'_l, \phi'_k \rangle) \\ &= \sum_{l=1}^{L}\sum_{k=1}^{L} \beta_{il}\alpha_{jk} \langle \phi'_l, \phi_k \rangle = \sum_{l=1}^{L} \beta_{il}\alpha_{jl},\end{aligned}$$

as $\langle \phi_l, \phi_k \rangle = \langle \phi_l, \phi'_k \rangle = \langle \phi'_l, \phi'_k \rangle = 0$ and $\langle \phi'_l, \phi_k \rangle = \delta_{lk}$. In short, we may write

$$G = B \cdot A^T, \quad A = (\alpha_{il}) \in \mathbb{Z}^{2L,L}, \quad B = (\beta_{il}) \in \mathbb{Z}^{2L,L}.$$

As both $\phi_1, \ldots, \phi_l, \phi'_1, \ldots, \phi'_L$ and $\gamma_1, \ldots, \gamma_{2L}$ are bases of $H_1(\Gamma_h, \mathbb{Z})$, the matrix $(A|B) \in \mathbb{Z}^{2L,2L}$ has full rank. This also holds for A and B: $\operatorname{rank}(A) = \operatorname{rank}(B) = L$. From this we infer $\operatorname{rank}(G) = L$, which means $\dim \operatorname{Ker}(G) = L$. ∎

5. Evaluation of pairing. In order to obtain the matrix G, we have to provide an algorithm for computing representatives of the submerged cycles $\gamma_i\downarrow$, $i = 1, \ldots, 2L$. It turns out to be most efficient to split the task into two parts:

1. The computation of shifted surface 1-cycles $\hat{\gamma}_i$, $i = 1, \ldots, 2L$, that clear all vertices of Γ_h and satisfy $\hat{\gamma}_i = \gamma_i$ in $H_1(\Gamma, \mathbb{Z})$. This resembles the barycentric perturbation proposed in [7, section 4.1].
2. Replacing every γ_i by a 1-cycle $\check{\gamma}_i$ such that $\check{\gamma}_i = \gamma_i$ in $H_1(\bar{\Omega}, \mathbb{Z})$, $i = 1, \ldots, 2L$, and $\check{\gamma}_i \cap \hat{\gamma}_j = \emptyset$ for all i, j.

As the linking numbers are well defined on homology classes, by construction

$$\langle \gamma_i, \gamma_j \rangle = L(\check{\gamma}_j, \hat{\gamma}_i). \tag{5.1}$$

For the discussion of the algorithmic details pick some $i \in \{1, \ldots, 2L\}$ and set $\gamma := \gamma_i$. Recall that γ is a 1-chain $\in Z_1(\Gamma_h, \mathbb{Z})$ with weights $\in \{-1, 0, 1\}$ and that it is naturally associated with a closed non-self-intersecting edge curve in Γ_h. Denote by $\mathcal{V}_h(\gamma)$ and $\mathcal{E}_h(\gamma)$ the set of vertices and edges "contained" in γ. As γ has an orientation we can number the edges in $\mathcal{E}_h(\gamma) := \{\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_N\}$, $N \in \mathbb{N}$. Then, to each vertex $\mathbf{v} \in \mathcal{V}_h(\gamma)$ assign the number of that edge $\mathbf{e} \in \mathcal{E}_h(\gamma)$ for which $\iota(\mathbf{v}, \mathbf{e}) \cdot \gamma(\mathbf{e}) = -1$. By the construction of γ this is well defined (cf. Lemma 3.4) and furnishes a numbering of the vertices of γ: $\mathcal{V}_h(\gamma) = \{\mathbf{v}_1, \ldots, \mathbf{v}_N\}$. By setting

$$\mathbf{t}_i := \text{triangle } \mathbf{t} \in \mathcal{F}_h : \ \iota(\mathbf{e}_i, \mathbf{t}) \cdot \gamma(\mathbf{e}_i) = 1, \qquad i = 1, \ldots, N,$$

we fix a sequence $(\mathbf{t}_1, \ldots, \mathbf{t}_N)$ of triangles. Be aware that one triangle might occur twice in this sequence. The triangles are located on one side of γ, because all triangles in $\mathcal{F}_h$ have the same orientation inherited from Γ (see Figure 12).

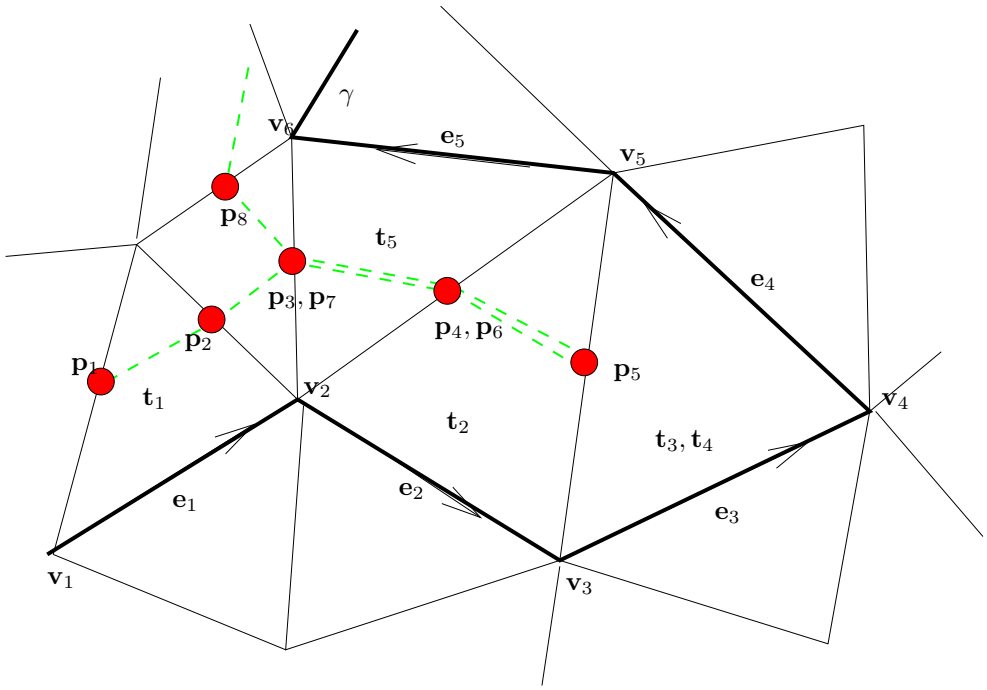

FIG. 12. *Numbering of edges, vertices, and triangles in connection with a path* γ. *Shifted path as polygon* $(\mathbf{p}_1, \mathbf{p}_2, \dots)$.

```
list<Point> U:= ∅;
for (i = 1; i ≤ N; i++) {
  U.push_back(v_i);
  T := tetrahedron adjacent to v_i and v_{i+1} ;
  U.push_back(center of gravity of T);}
```

FIG. 13. *Submerging of a cycle* $(\mathbf{v}_1, \dots, \mathbf{v}_N)$. *Output is polygon* U.

The 1-cycles $\check{\gamma}$ and $\hat{\gamma}$ will be computed as closed oriented polygons $U := (\mathbf{u}_1, \dots, \mathbf{u}_{2N})$ and $P := (\mathbf{p}_1, \dots, \mathbf{p}_M)$, $M \in \mathbb{N}$, given by sequences of points $\mathbf{p}_i, \mathbf{u}_i \in \mathbb{R}^3$ (which are supposed to be connected by straight lines). This is sufficient, since we need only U and P for the evaluation of path integrals. Note that, throughout, all sequences (of simplices and points) will be assumed to be cyclic.

We get the polygon U by starting with the sequence of vertices $(\mathbf{v}_1, \dots, \mathbf{v}_N)$. Then we insert the center of gravity of a tetrahedron adjacent to two consecutive vertices $\mathbf{v}_i$, $\mathbf{v}_{i+1}$ after $\mathbf{v}_i$, $i = 1, \dots, N$. The simple algorithm is shown in Figure 13. Only at this stage do we make use of the volume mesh Ω_h!

The polygon P defining the shifted cycle $\hat{\gamma}$ runs through midpoints of certain edges in $\bigcup_{\mathbf{v} \in \mathcal{V}_h(\gamma)} \mathcal{S}_1(\mathbf{v}) \setminus \mathcal{E}_h(\gamma)$. It is constructed by the algorithm sketched in Figure 14. Obviously, P provides a 1-cycle $\sim \gamma$ in $H_1(\Gamma, \mathbb{Z})$. Formally, this can be proved by considering a refined surface mesh $\tilde{\Gamma}_h$ generated by subdividing each triangle of Γ_h into four congruent smaller triangles. Viewing γ as an element of $Z_1(\tilde{\Gamma}_h, \mathbb{Z})$ the shifted cycle $\hat{\gamma}$ is seen to emerge by successively adding the boundaries of triangles of $\tilde{\Gamma}_h$ to γ. We skip the tedious details. We remark that the "dead end" conspicuous in Figure 12

```
list<Point> P := ∅;
for (i = 1, i ≤ N, i++) {
  P.push_back(midpoint of that edge of t_i adjacent to v_i);
  {e} := S_1(t_i) \ S_1(v_i); t := t_i;
  while (e ∉ S_1(t_{i+1})) {
    P.push_back(midpoint of e); {t} ← S_2(e)\{t}; {e} ← (S_1(t)∩S_1(v_{i+1}))\{e}; }}
```

FIG. 14. *Construction of an oriented polygon P representing a shifted cycle. Note that we identify $\mathbf{t}_{N+1} := \mathbf{t}_1$. See also Figure* 12.

cannot occur with straightened 1-cycles (cf. the remark at the end of section 3).

It is straightforward that the computational effort it takes to get U and P is proportional to $N + \sharp\mathcal{F}_h$. Moreover, a bounded shape-regularity measure ρ from (2.2) implies that only a small number of edges can be incident on a vertex. Assuming a certain shape regularity we end up with a complexity $O(N)$ for the construction of P and U.

Next, we have to compute the relative linking number of a submerged 1-cycle $\check{\gamma}$ and a shifted 1-cycle $\hat{\gamma}$. They are supplied as closed polygons $U = (\mathbf{u}_1, \ldots, \mathbf{u}_{2N})$, $N \in \mathbb{N}$, and $P = (\mathbf{p}_1, \ldots, \mathbf{p}_M)$, $M \in \mathbb{N}$. Recalling Definition 4.1 and (5.1), we have to compute the linking numbers

$$\begin{aligned} L(\check{\gamma}, \hat{\gamma}) &= -\sum_{i=1}^{2N} \sum_{j=1}^{M} \int_{[\mathbf{u}_i, \mathbf{u}_{i+1}]} \int_{[\mathbf{p}_i, \mathbf{p}_{i+1}]} \operatorname{grad}_{\mathbf{y}} G(\mathbf{x}, \mathbf{y}) \cdot (d\vec{s}(\mathbf{x}) \times d\vec{s}(\mathbf{y})) \\ &= -\sum_{i=1}^{2N} \sum_{j=1}^{M} \int_0^1 \int_0^1 \operatorname{grad}_{\mathbf{y}} G(\mathbf{x}_j(\sigma), \mathbf{y}_i(\tau)) \cdot \mathbf{z}_{ij} \, d\sigma d\tau, \end{aligned}$$

where $\mathbf{y}_i(\tau) := \mathbf{u}_i + \tau(\mathbf{u}_{i+1} - \mathbf{u}_i)$, $\mathbf{x}_j(\sigma) := \mathbf{p}_j + \sigma(\mathbf{p}_{j+1} - \mathbf{p}_j)$, $\mathbf{z}_{i,j} := (\mathbf{p}_{j+1} - \mathbf{p}_j) \times (\mathbf{u}_{i+1} - \mathbf{u}_i)$. Analytic expressions are available for the inner integrals

$$f_{ij}(\tau) := \int_0^1 \operatorname{grad}_{\mathbf{y}} G(\mathbf{x}_j(\sigma), \mathbf{y}_i(\tau)) \cdot \mathbf{z}_{ij} \, d\sigma.$$

For the outer integrals we have to resort to numerical quadrature. Here, it is important to take into account the singular behavior of the kernel $G(\mathbf{x}, \mathbf{y})$ for $\mathbf{x} \to \mathbf{y}$. It entails an *adaptive* approach to quadrature: We use a Gauß–Legendre quadrature formula of order $2n$ (i.e., with n nodes), $n \in \mathbb{N}$, on each interval of an equidistant subdivision of $[0;1]$ into k_{ij}, $k_{ij} \in \mathbb{N}$, parts. Adaptivity will be achieved by adjusting k_{ij} depending on the relative position of the line segments $[\mathbf{u}_i, \mathbf{u}_{i+1}]$ and $[\mathbf{p}_i, \mathbf{p}_{i+1}]$.

The Gauß–Legendre formulas give us an approximation $\tilde{I}_{ij}$ for $\int_0^1 f_{ij}(\tau)\, d\tau$. Standard estimates of the quadrature error [6, Thm. 9.5] yield

$$\epsilon_{ij} := \left| \int_0^1 f_{ij}(\tau)\, d\tau - \tilde{I}_{ij} \right| \le \frac{1}{2n-1} \left(\frac{1}{2k_{ij}} \right)^{2n} \sup_{\xi \in [0;1]} \left| \frac{d^{2n} f_{ij}}{d\tau^{2n}}(\xi) \right|. \tag{5.2}$$

Using

$$\frac{d^m f_{ij}}{d\tau^m}(\tau_0) = \int_0^1 D_{\mathbf{y}}^{m+1} G(\mathbf{x}_j(\sigma), \mathbf{y}_i(\tau_0)) (\underbrace{\mathbf{u}_{i+1} - \mathbf{u}_i, \ldots, \mathbf{u}_{i+1} - \mathbf{u}_i}_{m \text{ times}}, \mathbf{z}_{ij})\, d\sigma$$

and, for $\mathbf{x} \neq \mathbf{y}$, $\mathbf{w}_l \in \mathbb{R}^3$,

$$D_{\mathbf{y}}^{m+1} G(\mathbf{x}, \mathbf{y})(\mathbf{w}_1, \dots, \mathbf{w}_{m+1}) = (-1)^{m+1}(m+1)! \, \frac{1}{|\mathbf{x}-\mathbf{y}|^{m+2}} \, w_1^r \cdot \dots \cdot w_{m+1}^r,$$

where $w_l^r := |\mathbf{x}-\mathbf{y}|^{-1}(\mathbf{x}-\mathbf{y}) \cdot \mathbf{w}_l$, we can estimate

$$\epsilon_{ij} \leq |\mathbf{u}_{i+1} - \mathbf{u}_i|^{m+1} |\mathbf{p}_{j+1} - \mathbf{p}_j| (m+1)! \, \frac{1}{d_{ij}^{m+2}},$$

with the distance

$$d_{ij} := \inf\{|\mathbf{x}-\mathbf{y}|, \, \mathbf{x} \in [\mathbf{u}_i, \mathbf{u}_{i+1}], \, \mathbf{y} \in [\mathbf{p}_j, \mathbf{p}_{j+1}]\}.$$

Finally,

$$\epsilon_{ij} \leq \frac{(2n+1)!}{2n-1} \left(\frac{1}{2k_{ij}} \right)^{2n} |\mathbf{u}_{i+1} - \mathbf{u}_i|^{2n+1} |\mathbf{p}_{j+1} - \mathbf{p}_j| \, \frac{1}{d_{ij}^{2n+2}}.$$

The exact linking numbers are integers. We must be able to recover them despite the impact of quadrature errors. This is guaranteed if $2NM\epsilon_{ij} \leq \theta$ for some tolerance $\theta < \frac{1}{2}$. We get the following a priori criterion for choosing k_{ij}:

$$k_{ij} \geq \frac{1}{2} \left(\frac{(2n+1)!}{2n-1} \, \frac{|\mathbf{u}_{i+1} - \mathbf{u}_i|^{2n+1} |\mathbf{p}_{j+1} - \mathbf{p}_j|}{d_{ij}^{2n+2}} \, \theta^{-1} 2NM \right)^{\frac{1}{2n}}.$$

We will gauge the costs of evaluating $L(\check{\gamma}, \hat{\gamma})$ for a q-quasi-uniform, $0 < q \leq 1$, mesh Ω_h of meshwidth $h > 0$, and shape-regularity measure $\rho > 0$. Then $|\mathbf{u}_{i+1} - \mathbf{u}_i| \leq h$ and $|\mathbf{p}_{j+1} - \mathbf{p}_j| \leq h$. We find that $k_{ij} = 1$ is sufficient if

$$d_{ij} \geq h S_n, \quad S_n := \left(\frac{(2n+1)!}{2n-1} \, \frac{2NM}{\theta} \right)^{\frac{1}{2(n+1)}} \leq (2n+1) \left(\frac{2NM}{\theta} \right)^{\frac{1}{2(n+1)}}.$$

The geometric restrictions on Ω_h also force two edges of U and P to be farther apart than $C_2 h$ with a geometric constant $C_2 = C_2(\rho)$, $1 > C_2 > 0$. Fix j and take into account that due to shape regularity there are fewer than

$$\frac{\pi(\frac{4}{3}d^3 + |\mathbf{p}_j - \mathbf{p}_{j+1}| d^2)}{\min_{T \in \Omega_h} \mathrm{Vol}(T)} \leq \left(\frac{\rho}{qh} \right)^3 d^2 (\tfrac{4}{3}d + h) \leq \left(\frac{\rho}{qh} \right)^3 d^3 (\tfrac{4}{3} + C_2^{-1}) = C(\rho, q) \left(\frac{d}{h} \right)^3$$

tetrahedra in a d-neighborhood, $d > C_2 h$, of $[\mathbf{p}_j, \mathbf{p}_{j+1}]$. This is also an upper bound for (half) the number of edges of U contained in that neighborhood. Hence, the total number of subintervals required for a sufficiently accurate quadrature on the "near edges" (edges $[\mathbf{u}_i, \mathbf{u}_{i+1}]$ with $d_{ij} < h S_n$) is as follows:

$$\begin{aligned} K_j &\leq 2C(\rho, q) \int_{C_2 h}^{S_n h} \frac{d^3}{h^3} \left(\left(\frac{(2n+1)!}{2n-1} \, \frac{h^{2n+2}}{d^{2n+2}} \, \theta^{-1} 2NM \right)^{\frac{1}{2n}} + 1 \right) dd \\ &\leq 2C(\rho, q) \int_{C_2}^{S_n} s^{2-\frac{1}{n}}(\dots) + s^3 \, ds \leq 4C(\rho, q) \left(S_n^4 - C_2^4 \right). \end{aligned}$$

Taking into account that also $N, M \le C(\rho, q)h^{-2}$, we end up with

$$S_n \le C(\rho, q, \theta)(2n+1)h^{-2/n} \quad \Rightarrow \quad K_j \le C(\rho, q, \theta)n^4 h^{-8/n}.$$

This translates into an asymptotic total effort (measured in terms of quadrature nodes) of $O(n^4 h^{-(2+8/n)})$ for the treatment of all "near edges." The "far edges" take at most $2NM$ evaluations. This teaches us that we should choose $n \ge 4$ in order to balance the effort required to treat "near" and "far" pairs of line segments. The bottom line is that assuming a certain shape regularity and quasi-uniformity of Ω_h, at worst we encounter total computational costs of the order $O((\sharp\mathcal{F}_h)^2) \cdot \beta_1(\Gamma_h)^2$. As pointed out before, in most practical computations the costs will be much lower.

Remark. In [7, section 4.1] the linking numbers are computed by projecting the edge cycles onto a plane and counting oriented intersections of the projected curves. This obviously allows us to compute the relative linking number of U and P with an effort proportional to $N \cdot M$, because all pairs of projected edges have to be examined. Yet, carrying out the projection in a stable fashion might be challenging in finite precision arithmetic.

A THEOREM ON SENSITIVITY AND APPLICATIONS IN PRIVATE COMPUTATION*

ANNA GÁL† AND ADI ROSÉN‡

Abstract. In this paper we prove a theorem that gives an (almost) tight upper bound on the sensitivity of a multiple-output Boolean function in terms of the sensitivity of its coordinates and the size of the range of the function. We apply this theorem to get improved lower bounds on the time (number of rounds) to compute Boolean functions by private protocols. These bounds are given in terms of the sensitivity of the function being computed and the amount of randomness used by the private protocol. These lower bounds are tight (up to constant factors) for the case of the `xor` function and together with the results in [E. Kushilevitz and A. Rosén, *SIAM J. Discrete Math.*, 11 (1998), pp. 61–80.] establish a tight (up to constant factors) tradeoff between randomness and time in private computation.

Key words. sensitivity, private computation, randomness, lower bounds

1. Introduction.

An important characteristic of a Boolean function is its sensitivity. Informally, the sensitivity of a function is the maximum number of input variables such that changing the value of just one variable at a time changes the value of the function as well. The sensitivity of Boolean functions and its relation to other complexity measures have been studied extensively. A number of important results have been achieved via arguments about sensitivity. For example, lower bounds on the time required for CREW PRAM computation [33, 10, 28] and lower bounds on the size of reliable circuits from unreliable gates [11, 30, 31, 14, 15] were given in terms of the sensitivity of the function being computed. A generalization of sensitivity, block sensitivity, was defined by Nisan [28]. Studying block sensitivity revealed that sensitivity provides lower bounds for several other measures, including Boolean decision tree complexity [28] and the degree of real polynomials representing Boolean functions [29]. The relation between sensitivity and block sensitivity has been studied in a number of papers [28, 17, 32, 20]. In several settings, average sensitivity is an important measure. It has been shown that the average sensitivity of a function is related to its Fourier coefficients [19] and that the average sensitivity of functions computable by constant depth circuits must be low [26]. Bounds on the sensitivity of various classes of functions were given in [34, 35].

In this paper we prove a theorem on the sensitivity of multiple-output Boolean functions. We give an almost tight upper bound on the sensitivity of such functions, in terms of the sensitivity of each coordinate, and the size of the range of the function.

More formally, we prove the following theorem:

Let $F : \{0,1\}^n \to \{0,1\}^m$ be an m-output Boolean function with coordinate functions $f_j : \{0,1\}^n \to \{0,1\}$ such that $s(f_j) \leq k$ for each $1 \leq j \leq m$, where $s(f)$ is the sensitivity of f. If the range of F contains D different values, then the sensitivity of F is at most $k \cdot 4(\log_2 D + 2)$.

Note that the restriction on the size of the range of F can be interpreted as a condition on the "correlation" between the coordinate functions f_j. Without this restriction, the number of possible values of an m-output Boolean function is 2^m. It is easy to see that $s(F) \leq km$ must always hold. Similarly, if we restrict the range of F to be a q-dimensional subcube of $\{0,1\}^m$, that is, we require that $m - q$ of the m coordinate functions are constants (and the other q coordinate functions can be arbitrary functions), then $s(F) \leq kq$ must hold. Our results show that even if the range of F is an *arbitrary subset* of size 2^q of $\{0,1\}^m$, the sensitivity of F cannot be much larger. Our bound is almost tight, as for q independent coordinates the sensitivity kq is achieved.

We use the above theorem to prove lower bounds in information-theoretic private computation. We believe, however, that the theorem is of independent interest and may find additional applications. Using the above theorem and the machinery of [25] we prove improved lower bounds on the number of rounds required to privately compute a Boolean function. The lower bound is given in terms of the sensitivity of the function being computed and the amount of randomness used by the protocol overall. For the case of the function `xor` (exclusive or) these lower bounds are tight, up to a small constant factor. A private protocol to compute a Boolean function f allows a number of players, each possessing a single input bit, to compute the value of the function f on their combined input in a way that no single player learns any "unnecessary" information (in particular, the inputs of the other players).[1] Private computation in this setting was first considered by Yao [36] and has been the subject of a considerable amount of research [1, 2, 4, 5, 7, 8, 9, 12, 13, 16, 22, 21, 23].

Using randomness any function can be computed privately if the number of players is at least three. On the other hand, for most functions (except very simple ones), randomness is necessary in order to compute the function privately. Randomness as a resource has been the subject of extensive research in the past decade. In the context of private computation, the main questions addressed about randomness as a resource have been the minimum number of random bits required for private computation of different functions and tradeoffs between the amount of randomness and the amount of time (i.e., number of rounds) required for the computation [5, 22, 25, 24, 6]. It is worthwhile to note that one can also characterize the class of functions computable by linear size circuits in terms of the amount of randomness required for their private computation [24]. The question of whether private computations in general can be carried out in constant number of rounds was addressed in [1, 3, 18].

A lower bound on the number of rounds required for the private computation of Boolean functions was given by Kushilevitz and Rosén [25]. They proved that it takes at least $\Omega(\log s(f)/d)$ rounds to privately compute a function f of sensitivity $s(f)$ using d random bits overall. They also gave protocols to compute the function `xor` that use a small number of random bits and at the same time are efficient in terms of rounds: for any $d \geq 2$, they provided a protocol to privately compute the

[1] In the literature, a more general notion of t-privacy is used, requiring that no coalition of t players learns extra information. Here we discuss the case of $t = 1$. See section 3 for a formal definition of private protocols.

xor of n bits, using $O(\log n/\log d) = O(\log s(\texttt{xor})/\log d)$ rounds and d random bits. However, the exact tradeoff between randomness and rounds was left as an open question. Using our theorem on sensitivity we prove that it takes $\Omega(\log s(f)/\log d)$ rounds to privately compute a Boolean function f using d random bits overall.

2. A theorem on sensitivity. In this section we prove a theorem that gives an upper bound on the sensitivity of a Boolean function $F : \{0,1\}^n \to \{0,1\}^m$, in terms of the sensitivity of the coordinate functions $f_j : \{0,1\}^n \to \{0,1\}$, and the size of the range of F.

DEFINITION 2.1 (sensitivity).

- *For a binary vector y, denote by $y^{(i)}$ the binary vector obtained from y by flipping the ith entry.*
- *A function f is* sensitive *to its ith variable on input y if $f(y) \neq f(y^{(i)})$.*
- *$s_y(f)$ is the number of variables to which the function f is sensitive on input y.*
- *The* sensitivity *of a function f is $s(f) = \max_y s_y(f)$.*
- *The* average sensitivity *of a function f is $as(f) = \frac{1}{2^n}\sum_{y\in\{0,1\}^n} s_y(f)$.*

Note that for a multiple-output Boolean function $F : \{0,1\}^n \to \{0,1\}^m$ the value of F on each input $x \in \{0,1\}^n$ is a binary vector of length m, and $F(x) \neq F(y)$ if and only if $f_j(x) \neq f_j(y)$ for at least one of the coordinate functions f_j, $1 \leq j \leq m$.

FACT 1. *Let $F : \{0,1\}^n \to \{0,1\}^m$ be an m-output Boolean function with coordinate functions $f_j : \{0,1\}^n \to \{0,1\}$ such that $s(f_j) \leq k$ for each $1 \leq j \leq m$. Then $s(F) \leq km$.*

Proof. The statement follows from the simple fact that $s(F) \leq \sum_{j=1}^m s(f_j)$. □

Note that this bound is tight: taking $f_j(x) = x_j$, we have $s(f_j) = 1 = k$ and $s(F) = m = km$.

The proof of Fact 1 shows that if we restrict the range of F to be a q-dimensional subcube of $\{0,1\}^m$, then $s(F) \leq kq$ must hold. In the following theorem we prove that the sensitivity of F cannot be much larger, even if the range of F is an *arbitrary subset* of size 2^q of $\{0,1\}^m$.

THEOREM 2.2. *Let $F : \{0,1\}^n \to \{0,1\}^m$ be an m-output Boolean function with coordinate functions $f_j : \{0,1\}^n \to \{0,1\}$ such that $s(f_j) \leq k$ for each $1 \leq j \leq m$. If the range of F contains D different values, then the sensitivity of F is at most $k \cdot 4(\log_2 D + 2)$.*

We observe that this bound is almost tight. Consider again the functions $f_j(x) = x_j$, each of sensitivity $k = 1$. In this case the sensitivity of F is $k \cdot \log_2 D$, as $D = 2^n = 2^m$. Note that our bound holds for every k and D, independent of the values of n and m.

In the following the function F and the functions f_j are as defined in the above theorem. In particular, we always assume that $s(f_j) \leq k$.

For our argument it is convenient to use the following definition.

DEFINITION 2.3 (sensitivity restricted to a set). *For $F(x) = (f_1(x), \ldots, f_m(x))$ and $x \in \{0,1\}^n$, let $S(x)$ denote the set of vectors $y \in \{0,1\}^n$ that are at Hamming distance 1 from x and for which $F(y) \neq F(x)$. Let $U \subseteq \{0,1\}^n$. We use the notation $S(x,U) = S(x) \cap U$ and say that $|S(x,U)|$ is the sensitivity of F on x restricted to the set U.*

Notation. Let $V \subseteq \{0,1\}^n$ be a subset of input vectors. We partition the set V into levels with respect to a fixed vector $v_0 \in V$. The set V_i is the set of vectors in V that are at Hamming distance i from v_0 and is called the ith level of V with respect to v_0. Note that $V_0 = \{v_0\}$. The notation used for the levels V_i does not

indicate their dependence on the choice of v_0. This should nevertheless be clear from the context. For $x \in V_i$ we use the notation $\sigma_{V,v_0}(x) = |S(x, V_{i+1})|$ and $\sigma_{V,v_0}(V_i) = min_{x \in V_i} \sigma_{V,v_0}(x)$. Note that σ_{V,v_0} depends on the choice of both V and $v_0 \in V$, since the levels V_i are defined with respect to v_0, and if $x \in V_i$, then $\sigma_{V,v_0}(x)$ is the sensitivity of F on x restricted to the set V_{i+1}. We omit from our notation the dependence of the set $S(x)$ and $\sigma_{V,v_0}(x)$ on F.

2.1. The proof. Our argument proceeds in two stages. First we choose a subset $V \subseteq \{0,1\}^n$ of inputs with certain properties that we define below. Informally these properties say that if F has sensitivity s on some input v_0, then we can start with v_0 and build a set of inputs V such that for "many" levels V_i of V (partitioning V into levels with respect to v_0) the following holds: on each input from V_i the sensitivity of F restricted to V_{i+1} is "high" (in terms of s). That is, not only the sensitivity of F is high on each selected input, but it remains high even when restricted to the next level of the set V.

In the second stage we use the set V to demonstrate a large number (in terms of s) of different values for F. This will give us the relation between the sensitivity s and the number of possible values D.

We start with a lemma stating that if the sensitivity of F on an input x is s, then the sensitivity must be "almost" s on many inputs from the set $S(x)$. Moreover, this holds even if we consider the sensitivity with respect to a partition of the inputs into levels.

LEMMA 2.4. *Let $F : \{0,1\}^n \to \{0,1\}^m$ be an m-output Boolean function with coordinate functions $f_j : \{0,1\}^n \to \{0,1\}$ such that $s(f_j) \leq k$ for $1 \leq j \leq m$. Let $S(x,U)$ be defined with respect to F as above. Let $B = \{0,1\}^n$, and let $v_0 \in B$. Let B_i denote the ith level of B with respect to v_0, that is, the set of vectors in B that are at Hamming distance i from v_0. Let $x \in B_i$, and let $S \subseteq S(x, B_{i+1})$ such that $|S| = \sigma$. Then there are at least $\sigma/2$ nodes $v \in S$ such that $|S(v, B_{i+2})| \geq \sigma - 4k$.*

Proof. We think of B as the n-dimensional hypercube, with an edge connecting two nodes if and only if their Hamming distance is exactly 1. We number the nodes in S from 1 to σ and name them v_ℓ, $1 \leq \ell \leq \sigma$. (Recall that $S \subseteq B_{i+1}$.) Let $v_{(\ell,j)}$ for $1 \leq \ell, j \leq \sigma$, $\ell \neq j$, be the node in B_{i+2} whose Hamming distance to both v_ℓ and v_j is 1. (Note that by our notation $v_{(\ell,j)}$ and $v_{(j,\ell)}$ denote the same node.) Let $e_{\ell,j}$ be the edge that connects v_ℓ to $v_{(\ell,j)}$.

Call an edge *sensitive* if it connects nodes x and y such that $F(x) \neq F(y)$. First we show that among the $\sigma(\sigma-1)$ edges $e_{\ell,j}$ at most $\sigma 2(k-1)$ are not sensitive edges. To this end we partition the $\sigma(\sigma-1)$ edges into σ sets. The set E_ℓ contains the edges $e_{j,\ell}$ for $j \neq \ell$, $1 \leq j \leq \sigma$; that is, the set E_ℓ contains for each node v_j, $j \neq \ell$, the edge that connects v_j to the node $v_{(j,\ell)}$.

Now we claim that in each set E_ℓ there are at most $2(k-1)$ edges which are not sensitive. Since $v_\ell \in S$, there is some coordinate t such that $f_t(v_\ell) \neq f_t(x)$. Without loss of generality assume that $f_t(x) = 0$ and $f_t(v_\ell) = 1$. For an edge $e_{j,\ell}$ which is not sensitive, we have that $F(v_j) = F(v_{(\ell,j)})$, and, in particular, $f_t(v_j) = f_t(v_{(\ell,j)})$. There can be at most $k-1$ such edges with $f_t(v_j) = 1$, since the sensitivity of f_t is at most k, and together with v_ℓ there are at most k nodes adjacent to x on which f_t is 1. Similarly, together with x there are at most k nodes adjacent to v_ℓ on which f_t is 0. It follows that in E_ℓ there are at most $2(k-1)$ edges which are not sensitive. Thus, among the $\sigma(\sigma-1)$ edges $e_{\ell,j}$ at most $\sigma 2(k-1)$ are not sensitive. By a simple averaging argument there are at most $\sigma/2$ nodes in S which are adjacent to at least $4(k-1)$ nonsensitive edges in $\cup_{\ell=1}^{\sigma} E_\ell$.

It follows that there are at least $\sigma/2$ nodes in S which are adjacent to more than $\sigma - 1 - 4(k-1) \geq \sigma - 4k$ sensitive edges in $\cup_{\ell=1}^{\sigma} E_\ell$. That is, there are at least $\sigma/2$ nodes in S such that the sensitivity of F restricted to B_{i+2} is at least $\sigma - 4k$ on each of them. □

Now we are ready to prove the existence of a set V of input vectors with the desired properties.

LEMMA 2.5. *If the sensitivity of F on v_0 is s, then there is a set $V \subseteq B = \{0,1\}^n$ such that $\sigma_{V,v_0}(V_i) \geq s/4$ for $i = 0, \ldots, \lceil s/(8k) \rceil - 1$.*

Proof. We construct the set V by building its levels V_i inductively. (Recall that V_i denotes the ith level of V with respect to v_0; that is, V_i is the set of vectors from V that are at Hamming distance i from v_0.) We have $V_0 = \{v_0\}$. We also partition the set B into levels with respect to v_0.

We prove by induction on i that we can build sets $V_0, \ldots, V_i$ such that

- for $0 \leq j < i$ and any $x \in V_j$, we have $\sigma_{V,v_0}(x) \geq (1/2)s - j2k$;
- for any $x \in V_i$, we have $\sigma_{B,v_0}(x) \geq s - i4k$.

If the sensitivity of F on v_0 is s, then by Lemma 2.4 there is a set $V_1 \subseteq S(v_0, B_1)$ of at least $s/2$ nodes such that for any $x \in V_1$ we have $|S(x, B_2)| = \sigma_{B,v_0}(x) \geq s - 4k$. This proves the statement for $i = 1$.

Now assume we have built the set V by levels up to level i. We now build level $i+1$. Consider a node $x \in V_i$. By the induction hypothesis $\sigma_{B,v_0}(x) \geq s - i4k$ for $x \in V_i$, that is, $|S(x, B_{i+1})| \geq s - i4k$. By Lemma 2.4 there is a set G_x of at least $(1/2)(s - i4k)$ nodes $v \in S(x, B_{i+1})$ such that $|S(v, B_{i+2})| \geq (s - i4k) - 4k = s - (i+1)4k$.

To build the set V_{i+1} we let

$$V_{i+1} = \cup_{x \in V_i} G_x \ .$$

It follows that each node $x \in V_i$ has at least $(1/2)s - i2k$ neighbors y in V_{i+1} for which $F(x) \neq F(y)$; that is, for any $x \in V_i$ it holds that

$$\sigma_{V,v_0}(x) \geq (1/2)s - i2k \ .$$

Moreover, for all the nodes $y \in V_{i+1}$, it holds that $\sigma_{B,v_0}(y) \geq s - (i+1)4k$. Thus our induction step is complete. Now, as long as $i \leq s/(8k)$ we have that $\sigma_{V,v_0}(x)$, for any $x \in V_i$, is at least $(1/2)s - (s/(8k))2k = (1/4)s$. □

This completes the first stage of our proof. Next we will show, using the set V guaranteed by the above lemma, that F must take many different values. We start by a claim that selects a number of different values among the neighbors of a single input vector.

CLAIM 1. *Let $x \in \{0,1\}^n$ and $S \subseteq S(x)$. If $|S| \geq \xi$, then for some ℓ, such that $\xi/k \leq \ell \leq m$, we can find ℓ vectors $y_1, \ldots, y_\ell$ among the vectors in the set S, and ℓ coordinates $j_1, \ldots, j_\ell$ among the m coordinates of F, such that $f_{j_a}(y_a) \neq f_{j_a}(x)$ for $a = 1, \ldots, \ell$ and $f_{j_a}(y_b) = f_{j_a}(x)$ for $1 \leq a < b \leq \ell$.*

The above claim says, for example, that if $F(x)$ is 0 in all coordinates, then we can find ℓ vectors $y_1, \ldots, y_\ell$ in S, for $\xi/k \leq \ell \leq m$, and a set of ℓ coordinates such that if we appropriately reorder the coordinates of F, then the values of F on these vectors have the following form: $F(y_1) = (1.....)$, $F(y_2) = (01....)$, $F(y_3) = (001...)$, $F(y_4) = (0001..)$, and so on.

Proof of Claim 1. We can take any vector from S as y_1, and let j_1 be the first coordinate where $F(y_1)$ and $F(x)$ differ, that is, $f_{j_1}(y_1) \neq f_{j_1}(x)$. Since the sensitivity of each f_j is at most k, there are at most $k-1$ other vectors in S on which the value of F differs from $F(x)$ in the same coordinate j_1. Pick any of the remaining vectors from

S as y_2, and let j_2 be the first coordinate where $F(y_2)$ and $F(x)$ differ. Thus we can continue this process for at least $\ell \geq \xi/k$ steps and find the vectors and coordinates required by the claim. Note that $\ell \leq m$, since there are only m coordinates. □

Selecting different values. We now define a procedure to select input vectors from the set V guaranteed by Lemma 2.5 in a way that F has a different value on each selected vector.

DEFINITION 2.6.

- *A* signature *of a node x is a subset $T \subseteq [1...m]$ of coordinates, and a set of cardinality $|T|$ of binary values $\epsilon_j \in \{0,1\}$, such that $f_j(x) = \epsilon_j$ for $j \in T$. The signature of x serves as a witness of the value of F on x. We say that the length of the signature is $|T|$.*
- *We say that the signatures of the nodes x and y are* inconsistent *if there is a coordinate j that participates in both signatures but $f_j(x) \neq f_j(y)$.*
- *We say that a node z* preserves *the signature of the node x if for each coordinate j participating in the signature of x it holds that $f_j(z) = f_j(x)$.*
- *For $x \in V_i$, let $S_x \subseteq S(x, V_{i+1})$ be the subset of $S(x, V_{i+1})$ consisting of the nodes that preserve the signature of x.*

The following observation follows directly from the definitions above.

OBSERVATION 1. *For any two nodes x and y, if the signatures of x and y are inconsistent, then $S_x \cap S_y = \emptyset$.*

The next observation requires a simple proof.

OBSERVATION 2. *If the length of the signature of a node $x \in V_i$ is ν, then $|S_x| \geq |S(x, V_{i+1})| - \nu k$.*

Proof. Since the sensitivity of each f_j is at most k, there are at most νk vectors in $S(x, V_{i+1})$ on which F takes a value that differs from $F(x)$ in at least one of the ν coordinates that belong to the signature of x. □

We now describe the procedure for selecting input vectors with different values. In this process we will assign to each selected vector a *signature* (defined above) and an *address*, which is a sequence of integers, representing the way the vector was selected, as defined in what follows. The procedure selects from each level V_i a subset of the nodes that we denote by Z_i. The procedure starts with selecting the node v_0 to which we assign a signature of size 0 and address of size 0 (i.e., an empty signature and an empty address). We thus have $Z_0 = \{v_0\}$. For any i, the procedure selects the set Z_{i+1} after the set Z_i has been determined. To determine the set Z_{i+1} we start with the sets $S_x \subseteq S(x, V_{i+1})$ for $x \in Z_i$. (Recall that the nodes in S_x preserve the signature of x by definition.) If S_x is not empty, we apply Claim 1 to x and S_x to get nodes to be included in Z_{i+1}. We get a set Y_x of at least $\ell \geq |S_x|/k$ vectors, $Y_x = \{y_1, \ldots, y_\ell\}$. Note that Claim 1 selects ℓ coordinates, such that for every $1 \leq a \leq \ell$ the value of $F(y_a)$ differs from the value of $F(x)$ on the ath selected coordinate, and the value of a coordinates are fixed. On the other hand, since for each vector $y \in S_x$ the value $F(y)$ must be consistent with the signature of x, none of the ℓ coordinates chosen by Claim 1 participates in the signature of x. We thus set the *signature* of y_a by adding the additional a coordinates and their values fixed by Claim 1 to the signature of x (which is consistent with $F(y_a)$). Thus, if the length of the signature of x is ν, then the length of the signature of y_a is $\nu + a$. We obtain the *address* of y_a by appending the integer a to the address of x. The set Z_{i+1} is defined to be the union of the vectors selected for each node $x \in Z_i$, that is, $Z_{i+1} = \cup_{x \in Z_i} Y_x$. We continue this procedure as long as the last set Z_i is not empty.

Next we analyze the properties of our procedure. First note that the address

of a node $x \in Z_i$ consists of exactly i integers. We also have the following simple observation.

OBSERVATION 3. *For $x \in Z_i$, the length of the signature of x is exactly $\sum_{u=1}^{i} t_u$ if the address of x is $(t_1, t_2, \ldots, t_i)$.*

The following two claims show that the values of F on all inputs in $Z = \cup_{i \geq 0} Z_i$ are all different.

CLAIM 2. *For any two vectors y and z from the same level Z_i $(i \geq 1)$, the signatures of y and z are inconsistent.*

Proof. We prove the claim by induction on i. The statement holds for $i = 1$, since the vectors in Z_1 and their signatures were selected by applying Claim 1 to v_0. Now assume that we have proved the statement for i; that is, for any $x_1, x_2 \in Z_i$ the signatures of x_1 and x_2 are inconsistent. Then by Observation 1 we have $S_{x_1} \cap S_{x_2} = \emptyset$. Recall that every $y \in Z_{i+1}$ must belong to a set S_x for some $x \in Z_i$. Thus for every $y \in Z_{i+1}$ we have a unique $x \in Z_i$ such that $y \in S_x$. Let $y, z \in Z_{i+1}$. If $y, z \in S_x$ for $x \in Z_i$, then the signatures of y and z must be inconsistent in the part that was appended to the signature of x after applying Claim 1 to x and S_x. If $y \in S_{x_1}$ and $z \in S_{x_2}$, for $x_1 \neq x_2$, then the signatures of y and z must be inconsistent in the part that was "inherited" from x_1 and x_2, respectively. ∎

COROLLARY 1. *For any two vectors y and z from the same level Z_i $(i \geq 1)$, we have $F(y) \neq F(z)$.*

We will think of the set $Z = \cup_{i \geq 0} Z_i$ as a tree rooted at v_0. For a node $z \in Z_{i+1}$, we define its *parent* to be the node $x \in Z_i$ such that $z \in S_x$. Note that there is exactly one such node since for any $x, y \in Z_i$ we have $S_x \cap S_y = \emptyset$ by Observation 1 and Claim 2. Thus Z indeed forms a rooted tree. We say that y is an *ancestor* of z if there is a path from z to y in Z such that each step along the path leads from a node to its parent.

CLAIM 3. *For any two vectors from different levels $y \in Z_{i_1}$ and $z \in Z_{i_2}$, $i_1 \neq i_2$, we have $F(y) \neq F(z)$.*

Proof. Assume that there are vectors $y \in Z_i$ and $z \in Z_j$ for $i < j$ such that $F(y) = F(z)$. This is only possible if y is an ancestor of z, since each vector we select must preserve the signature of its parent and by Claim 2 the signatures are all inconsistent within each level. For the case that y is an ancestor of z, note that z must preserve the signature of each of its ancestors on the path in Z from z to y, in particular the signature of y' for some $y' \in S_y \subseteq S(y, V_{i+1})$. However, this is not possible if $F(y) = F(z)$ because y' and its signature were selected by applying Claim 1 to y; thus the signature of y' contains a coordinate $\ell \in [1...m]$ such that $f_\ell(y') \neq f_\ell(y)$. ∎

Counting the number of selected values. Since no two selected input vectors are mapped to the same value by F, it remains to show that we select a "large" number of vectors. We will prove the following theorem.

THEOREM 2.7. *If for a set $V \subseteq \{0,1\}^n$ and vector $v_0 \in V$ the sensitivity of F restricted to the levels of V satisfies $\sigma_{V,v_0}(V_i) \geq \xi = \Delta k$ for $i = 0, \ldots, i^* - 1$, then F takes at least $\sum_{i=0}^{i^*} \binom{\Delta}{i}$ different values.*

Proof. Let V be a set that satisfies the conditions set forth in the theorem. We will show that by applying the procedure described above to the set V, we select at least $\sum_{i=0}^{i^*} \binom{\Delta}{i}$ input vectors. Let $Z = \cup_{i \geq 0} Z_i$ be the set obtained by applying our procedure to the set V.

We say that the *degree* of a node $z \in Z$ is the number of vectors selected by our procedure from the set S_z (by applying Claim 1 to z and S_z), that is, the number of

z's children in the tree.

OBSERVATION 4. *If for some $0 \le i \le i^* - 1$ and $x \in Z_i$ the length of the signature of x is ν, then the degree of x is at least $\Delta - \nu$.*

Proof. Since $\sigma_{V,v_0}(V_i) \ge \xi = \Delta k$ for $i = 0, \ldots, i^*-1$, we have that $|S(x, V_{i+1})| \ge \xi$. Thus, $|S_x| \ge \xi - \nu k = k(\Delta - \nu)$ must hold by Observation 2. It follows from Claim 1 that the degree of x is at least $\Delta - \nu$. □

As described in the above selection procedure, we number the children of a given node by the number of additional coordinates we fix when applying Claim 1 to this node. Thus the address $(t_1, t_2, \ldots, t_i)$ of a node in Z_i specifies the path to follow on the tree from v_0 to reach this node. The path contains one node from each level Z_ℓ for $0 \le \ell \le i$ such that the node from Z_j on the path is the t_jth child of the node from Z_{j-1}.

The following lemma is helpful in counting the number of vertices in Z_i.

LEMMA 2.8. *If $t_u \ge 1$ is an integer for $1 \le u \le i \le i^*$ and $(t_1, t_2, \ldots, t_i)$ satisfies*

$$\sum_{u=1}^{i} t_u \le \Delta \,, \tag{2.1}$$

then $(t_1, t_2, \ldots, t_i)$ is a valid address in the tree Z.

Proof. We prove by induction on i that if $(t_1, t_2, \ldots, t_i)$ is a solution of (2.1) such that $t_u \ge 1$ is an integer for $1 \le u \le i \le i^*$, then $(t_1, t_2, \ldots, t_i)$ is a valid address in the tree.

To prove the statement for $i = 1$, we need to observe that v_0 has at least Δ children; thus if $t_1 \le \Delta$, then (t_1) is a valid address.

Assume the statement is true for $i \le i^* - 1$, and let $(t_1, t_2, \ldots, t_i, t_{i+1})$ be a solution to $\sum_{u=1}^{i+1} t_u \le \Delta$. It follows that

$$\sum_{h=1}^{i} t_h \le \Delta - t_{i+1} < \Delta \,;$$

thus by our induction hypothesis $(t_1, t_2, \ldots, t_i)$ is a valid address that leads to a node v. By Observation 3, the length of the signature of v is $\sum_{h=1}^{i} t_h$, and by Observation 4 its degree in the tree is at least $\Delta - \sum_{h=1}^{i} t_h$. If $(t_1, t_2, \ldots, t_i, t_{i+1})$ is a solution to $\sum_{u=1}^{i+1} t_u \le \Delta$, then $1 \le t_{i+1} \le \Delta - \sum_{h=1}^{i} t_h$, thus v has indeed at least t_{i+1} children and $(t_1, t_2, \ldots, t_{i+1})$ is a valid address. □

We now prove the following lemma.

LEMMA 2.9. *The number of nodes selected in level $i \le i^*$, $|Z_i|$, satisfies*

$$|Z_i| \ge \binom{\Delta}{i} \,.$$

Proof. The number of nodes $|Z_i|$ at level i is the number of different sequences of length i $(t_1, t_2, \ldots, t_i)$, where $t_u \ge 1$ is an integer for $1 \le u \le i$, and such that $(t_1, t_2, \ldots, t_i)$ corresponds to a valid address in the tree.

There are exactly $\binom{\Delta}{i}$ different solutions for (2.1) where $t_u \ge 1$ is integer for $1 \le u \le i$ (cf. [27]). To see this, note that we can specify a solution for (2.1) by choosing i distinct integers between 1 and Δ, and this gives a bijection between solutions of (2.1) with the required properties and sets of i distinct integers between 1 and Δ. Suppose that the i distinct integers are $1 \le n_1 < \cdots < n_i \le \Delta$. Then

by taking $t_1 = n_1$ and $t_u = n_u - n_{u-1}$ we get a solution for (2.1) with the required properties. Thus by Lemma 2.8 we have that the number of nodes selected at level $i \le i^*$ is $|Z_i| \ge \binom{\Delta}{i}$. □

Since we have shown that F takes different values on each input in Z, Theorem 2.7 follows from the above lemma. □

We can now conclude this section with the following proof.

Proof of Theorem 2.2. Let the sensitivity of F be s. Then there is at least one node v_0 that has sensitivity s. Using Lemma 2.5 we construct a set $V \subseteq \{0,1\}^n$ such that $\sigma_{V,v_0}(V_i) \ge s/4$ for any $0 \le i \le \lceil s/(8k) \rceil - 1$.

We apply Theorem 2.7 to the set V with parameters $i^* = \lceil s/(8k) \rceil$ and $\Delta = \lfloor s/(4k) \rfloor$.

We get that the number of values that F takes is at least

$$\sum_{i=0}^{\lceil s/(8k) \rceil} \binom{\lfloor s/(4k) \rfloor}{i} \ge 2^{\lfloor s/(4k) \rfloor - 1} .$$

Since by the hypothesis of the theorem the number of values that F takes is D, we get

$$2^{\lfloor s/(4k) \rfloor - 1} \le D$$

and

$$s \le k \cdot 4(\log_2 D + 2) . \quad \square$$

3. Applications to private computation. In this section we apply the theorem on sensitivity of the previous section to give improved lower bounds on the number of rounds required for the private computation of Boolean functions, given a certain amount of randomness. Comparing our results with known protocols [25] shows that our lower bounds are tight (up to a small constant factor) in terms of the sensitivity of the functions and the amount of randomness. We first briefly define private protocols and the complexity measures that we are interested in.

Let $f : \{0,1\}^n \to \{0,1\}$ be any Boolean function. A set of n players P_i ($1 \le i \le n$), each possessing a single input bit x_i (known *only* to P_i), collaborate in a protocol to compute the value of $f(x)$. The protocol operates in rounds. In each round each player may toss some coins and then sends messages to the other players. (Messages are sent over private channels so that other than the intended receiver no other player can listen to them.) After sending its messages, each player receives the messages sent to it by the other players in the current round. In addition, each player chooses to locally output the value of the function at a certain round. We say that the protocol computes the function $f : \{0,1\}^n \to \{0,1\}$ if for every input $x \in \{0,1\}^n$ the output produced by each player is $f(x)$. Sometimes it is more convenient to model the coin tossing done by each player, as a set of binary random tapes R_i, each R_i being provided to player P_i. The number of random coins tossed by player P_i is the number of random bits it reads from its random tape.

Notation. We denote by R_i a specific random tape provided to player P_i and by $\vec{R} = (R_1, \ldots, R_n)$ the vector of the random tapes of all the players. By $\vec{r} = (r_1, \ldots, r_n)$ we denote the random variable for these tapes and vector of tapes. Note that if we fix $\vec{R}$, we obtain a deterministic protocol. By C_i we denote a specific sequence of messages received by P_i, and c_i denotes the random variable (depending on $\vec{r}$) for the sequence of messages received by P_i.

Informally, *privacy* with respect to player P_i means that player P_i cannot learn anything (in particular, the inputs of the other players) from the messages it receives, except what is implied by its input bit, and the value of the function computed. Formally,

DEFINITION 3.1 (privacy). *A protocol $\mathcal{A}$ for computing a function f is* private *with respect to player P_i if for any two input vectors x and y, such that $f(x) = f(y)$ and $x_i = y_i$, for any sequence of messages C_i, and for any random tape R_i provided to P_i,*

$$Pr[c_i = C_i | R_i, x] = Pr[c_i = C_i | R_i, y],$$

where the probability is over the random tapes of all other players.

A protocol is said to be private if it is private with respect to all players.

DEFINITION 3.2 (randomness complexity). *A d-random protocol is a protocol such that for any input assignment the total number of coins tossed by all players in any execution is at most d.*

Let $View_i^t$ be the view of player i at round t, that is, the input bit to this player and all the messages it has seen until round t. Note that $View_i^t$, for any i and t, is a function of the input assignment x and the random tapes of all the players. We can thus write it as $View_i^t(x, \vec{r})$. We denote by $T_i(x, \vec{r})$ the round number in which player P_i outputs its result as a function of the input to all players and of the random tapes given to all players.

DEFINITION 3.3 (rounds complexity). *A ρ-round protocol is a protocol such that for all i, x, $\vec{R}$ we have $T_i(x, \vec{R}) \leq \rho$.*

We will also make use of the following definition.

DEFINITION 3.4 (expected rounds complexity).[2] *An expected ρ-round protocol is a protocol such that there exists a player P_i such that, for all x, $E_{\vec{r}}[T_i(x, \vec{r})] \leq \rho$.*

We are interested in tradeoffs between the rounds complexity (and expected rounds complexity) and the randomness complexity of private protocols.

Our proof follows the line of proof of [25]. We get (almost) tight lower bounds by using our result of the previous section on the sensitivity of multiple-output Boolean functions. For completeness we give below the full proof. We will prove the following theorem.

THEOREM 3.5. *Let $\mathcal{A}$ be a ρ-round d-random ($d \geq 2$) private protocol to compute a Boolean function f. Then, $\rho \geq \Omega(\frac{\log s(f)}{\log d})$, where $s(f)$ is the sensitivity of f.*

To prove the above theorem we use the following lemma from [25].

LEMMA 3.6 ([25, Lemma 4.11]). *Consider a private d-random protocol to compute a Boolean function f. Fix random tapes $\vec{R} = (R_1, \ldots, R_n)$. Then, for any P_i, $View_i^t(x, \vec{R})$ can assume at most 2^{d+2} different values (over the values of x).*

Using the above lemma we can prove our next lemma, following the proof in [25], but using our tight bound on the sensitivity of multiple-output Boolean functions.

LEMMA 3.7. *Consider a private d-random protocol to compute a Boolean function f, and consider a specific vector of random tapes $\vec{R}$ and the deterministic protocol derived by it. Then for every player P_i, the function $View_i^t(x, \vec{R})$ (as a function of x only) has sensitivity at most $Q(t) \stackrel{\triangle}{=} (4(d+4))^{t-1}$.*

Proof. First note that since we fix the random tapes the views of the players are functions of the input assignment x only. (We regard each bit of the view as a

[2] We adopt this weak definition, rather than requiring the property to hold for *all* players, as we are interested here in lower bounds.

Boolean function of x.) We prove the lemma by induction on t. For $t = 1$ the view of any player depends only on its single input bit. Thus, the claim is obvious. For $t > 1$ assume the claim holds for any $\ell < t$ and for any player. For $t > 1$ the view of any P_i is composed of the input bit of P_i, and bits that were received as messages, each one in some round $\ell < t$. Each such message bit is a function of the view of the player that sent it at the round in which it was sent. That is, each such message bit is a function of a view with sensitivity at most $Q(t-1)$, and hence the sensitivity of each such message bit (regarded as a Boolean function of x) is at most $Q(t-1)$. Clearly the input bit of P_i has sensitivity 1 which is at most $Q(t-1)$. Thus, the view under consideration is composed of coordinates each having sensitivity at most $Q(t-1)$. Moreover, by Lemma 3.6 the view can assume at most 2^{d+2} values. It follows from Theorem 2.2 that the sensitivity of the view under consideration is at most $Q(t-1) \cdot 4(d+4) = Q(t)$. □

We can now give the proof of the main theorem of this section.

Proof of Theorem 3.5. Consider the deterministic protocol obtained from a d-random private protocol ($d \geq 2$) by fixing the vector of random tapes to be a given vector $\vec{R}$.

We prove that for any player P_i there is at least one input assignment x such that

$$T_i(x, \vec{R}) \geq \log s(f)/(2 + \log(d+4)) + 1 \ .$$

This proves our theorem, since for every player it shows a run of the protocol where the player outputs its value only after $\log s(f)/(2 + \log(d+4)) + 1$ rounds.

Let y be an input assignment on which the sensitivity $s(f)$ is obtained. That is, y has $s(f)$ neighbors (in the inputs hypercube) where the value of f is different from $f(y)$. Denote this set of neighbors by $S(y)$. Denote by t the value of $T_i(y, \vec{R})$, i.e., the time step at which P_i outputs the value of f when the input to all players is y.

Now consider the view of P_i at round t, denoted $View^t(x, \vec{R})$, and the sensitivity of this view. Assume towards a contradiction that the sensitivity of $View^t(x, \vec{R})$ is less than $s(f)$. Then, in particular, the sensitivity of this view on y is less than $s(f)$. It follows that for at least one input assignment $z \in S(y)$, $View^t(y, \vec{R}) = View^t(z, \vec{R})$, and P_i would output the same value for f on inputs y and z, contradicting the fact that it is a correct protocol.

Thus the sensitivity of $View^t(x, \vec{R})$ on input y is at least $s(f)$, and t is such that $s(View_i^t(x, \vec{R})) \geq s(f)$. By Lemma 3.7, we get $(4(d+4))^{t-1} \geq s(f)$, i.e., $t \geq \frac{\log s(f)}{2+\log(d+4)} + 1$. It follows that $T_i(y, \vec{R}) \geq \frac{\log s(f)}{2+\log(d+4)} + 1$. □

Using similar techniques, that also follow the proofs from [25], we can obtain the following improved bound on the expected number of rounds of private protocols.

THEOREM 3.8. *Let $\mathcal{A}$ be an expected ρ-round, d-random ($d \geq 2$) private protocol to compute a Boolean function f. Then, $\rho \geq \Omega(\frac{as(f)}{n} \cdot \frac{\log as(f)}{\log d})$.*

Proof. To prove the theorem we consider a protocol $\mathcal{A}$ and fix any player P_i. We say that the protocol is *late* on input x and vector of random tapes $\vec{R}$ if $T_i(x, \vec{R}) \geq \frac{\log as(f)}{4+2\log(d+4)} + 1$. We define a $0-1$ random variable $L(x, \vec{r})$ to be 1 if and only if the protocol is late on x and $\vec{r}$. For the purpose of this proof we also define a uniform distribution on the 2^n input assignments. (This is not to say that the input assignments are actually drawn according to such distribution.)

We first show that for any deterministic protocol to compute f, derived from a private protocol by fixing $\vec{R}$, not only is there at least one input on which the protocol is late but that this happens for a large fraction of the inputs.

LEMMA 3.9. *Consider a player P_i and any fixed vector of random tapes $\vec{R} = (R_1, \ldots, R_n)$. Then*

$$E_x[L(x, \vec{R})] \geq \frac{as(f) - \sqrt{as(f)}}{2n} .$$

Proof. Consider the views of P_i, $View_i^t$, given the vector of random tapes $\vec{R}$. For any round t such that $t < \frac{\log as(f)}{4+2\log(d+4)} + 1$, by Lemma 3.7, we get that $s(View_i^t) < (4(d+4))^{\frac{\log as(f)}{4+2\log(d+4)}} = \sqrt{as(f)}$. Any function g computed from such a view can have at most the same sensitivity and thus clearly an average sensitivity of at most $\sqrt{as(f)}$. Such function g can have the same values as f on at most $2^n(1 - \frac{as(f)-\sqrt{as(f)}}{2n})$ input assignments. It follows that at least $2^n \frac{as(f)-\sqrt{as(f)}}{2n}$ input assignments are late. ∎

The lower bound on the expected number of rounds now follows. Since at least $2^n \frac{as(f)-\sqrt{as(f)}}{2n}$ input assignments are late for any set of random tapes, $E_{\vec{r},x}[L(x, \vec{r})] \geq \frac{as(f)-\sqrt{as(f)}}{2n}$. Hence, there is at least one input assignment x for which $E_{\vec{r}}[L(x, \vec{r})] \geq \frac{as(f)-\sqrt{as(f)}}{2n}$. For such x we get

$$E_{\vec{r}}[T_i(x, \vec{r})] \geq \left(\frac{as(f) - \sqrt{as(f)}}{2n}\right) \cdot \left(\frac{\log as(f)}{4 + 2\log(d+4)} + 1\right),$$

as needed. ∎

4. Conclusions. In this paper we prove an almost tight upper bound on the sensitivity of multiple-output Boolean functions, in terms of the sensitivity of each output coordinate, and the size of the range of the function. Using this bound, we establish improved lower bounds on the number of rounds of private protocols, in terms of the sensitivity of the function that they compute, and the amount of randomness that they use. These lower bounds are tight (up to a small constant factor) for the function `xor`.

We believe that the theorem on the sensitivity is of independent interest, and it would be interesting to see if it can find additional applications. Also, it would be interesting to close the remaining (small constant factor) gap in our bound on sensitivity. In fact, we conjecture that the right bound is $k\lceil \log_2 D \rceil$, which can be achieved for $D = 2^q$ by a construction of q independent coordinate functions.

Acknowledgments. We thank Eyal Kushilevitz for many useful discussions on privacy and randomness and on the theorem on sensitivity presented here. We also thank Dimitri Achlioptas for useful discussions.

A LINEAR ALGORITHM FOR FINDING THE INVARIANT EDGES OF AN EDGE-WEIGHTED GRAPH*

F. M. MALVESTUTO† AND M. MEZZINI‡

Abstract. Given an edge-weighted graph where all weights are nonnegative reals, an edge reweighting is an assignment of nonnegative reals to edges such that, for each vertex, the sums of given and new weights assigned to the edges incident on the vertex do coincide. An edge is then said to be *invariant* if its weight is the same for any edge reweighting. We show that the set of invariant edges of an arbitrary edge-weighted graph can be determined in time linear in the size of the underlying graph. Moreover, an application to the security of statistical data is discussed.

1. Introduction.

Let $G = (V, E)$ be a graph without isolated vertices (where self-loops and parallel edges may exist), and let $\boldsymbol{w} = (w(e))_{e\in E}$ be a vector of nonnegative reals. The pair $\Gamma = (G, \boldsymbol{w})$ is referred to as an *edge-weighted graph* EWG. Let $\mathbf{A}$ be the incidence matrix of G and let $\boldsymbol{b} = (b(v))_{v\in V}$ be the vector of nonnegative reals such that, for each vertex v of G, $b(v)$ equals the sum of the weights of the edges incident to v. Consider the following system of linear equations:

$$\mathbf{A}\boldsymbol{x} = \boldsymbol{b}. \tag{1}$$

For every edge of G, let $L[x(e)]$ and $U[x(e)]$ denote, respectively, the minimum and the maximum of the variable $x(e)$ over the nonnegative solutions of equation system (1). An edge e of G is an *invariant edge* of Γ if $L[x(e)] = U[x(e)]$. Thus, an edge e of G is an invariant edge of Γ if and only if $x(e) = w(e)$ for every nonnegative solution of equation system (1). The following two examples show two EWGs which have all and no invariant edges, respectively.

EXAMPLE 1. *Consider the EWG $\Gamma = (G, \boldsymbol{w})$ shown in Figure 1, where α, β, and γ are any positive reals. By making use of standard algebraic methods, one finds there is no nonnegative solution of equation system (1) other than $\boldsymbol{w}$. Therefore, each edge of G is an invariant edge of Γ.* □

EXAMPLE 2. *Consider the EWG $\Gamma = (G, \boldsymbol{w})$ shown in Figure 2. The general expression of a nonnegative solution of equation system (1) is*

$$x(1,1) = 1 - 2\lambda, \qquad x(1,2) = x(1,3) = \lambda, \qquad x(2,3) = 1 - \lambda,$$

where the parameter λ ranges from 0 to 1/2. Therefore, one has

$$\begin{aligned} &L[x(1,1)] = 0, && U[x(1,1)] = 1,\\ &L[x(1,2)] = L[x(1,3)] = 0, && U[x(1,2)] = U[x(1,3)] = 1/2,\\ &L[x(2,3)] = 1/2, && U[x(2,3)] = 1, \end{aligned}$$

and hence, no edge of G is an invariant edge of Γ. □

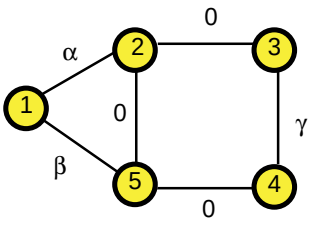

FIG. 1.

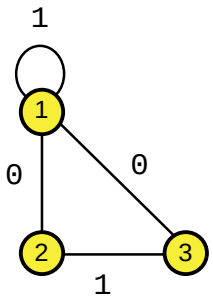

FIG. 2.

The problem addressed in this paper lies in finding the set of invariant edges of an arbitrary EWG. The following obvious fact allows us to limit our considerations to EWGs with underlying simple graphs (i.e., graphs without parallel edges).

Fact 1. Let $\Gamma = (G, \boldsymbol{w})$ be an EWG, where $G = (V, E)$ is a nonsimple graph. Let S be a set of two or more parallel edges and let e_0 be an arbitrarily chosen element of S. Let $G' = (V, E)$ be the graph with edge set $E' = (E - S) \cup \{e_0\}$. Consider the EWG $\Gamma' = (G', \boldsymbol{w}')$, where $\boldsymbol{w}'$ is defined as follows:

$$w'(e) = \begin{cases} w(e), & e \notin S, \\ \displaystyle\sum_{e' \in S} w(e'), & e = e_0. \end{cases}$$

Then, an edge not in S is an invariant edge of Γ if and only if it is an invariant edge of Γ', and an edge in S is an invariant edge of Γ if and only if $w'(e_0) = 0$ and e_0 is an invariant edge of Γ'.

The problem of finding the set of invariant edges of an EWG arises in the security analysis of statistical data, which will be discussed in section 6, and Gusfield [7] proved that if G is bipartite, then the set of invariant edges of Γ can be determined in time linear in the size of G. Here we present a linear time algorithm which finds the set of invariant edges of an arbitrary EWG.

2. Background. Let $G = (V, E)$ be a simple graph with vertex-edge incidence matrix $\mathbf{A}$. For any vector $\boldsymbol{x} = (x(e))_{e \in E}$, the *support* of $\boldsymbol{x}$ is the set $S = \{e \in E \colon x(e) \neq 0\}$, and the *signed support* of $\boldsymbol{x}$ is the ordered set pair (S^+, S^-), where $S^+ = \{e \in E \colon x(e) > 0\}$ and $S^- = \{e \in E \colon x(e) < 0\}$; moreover, the set $E - S$ is called the *zero set* of $\boldsymbol{x}$. The nonzero solutions of the homogeneous equation system $\mathbf{A}\boldsymbol{y} = \mathbf{0}$ are referred to as *circulations* in G and the linear space of the solutions of the homogeneous equation system $\mathbf{A}\boldsymbol{y} = \mathbf{0}$ is referred to as the *circulation space*.

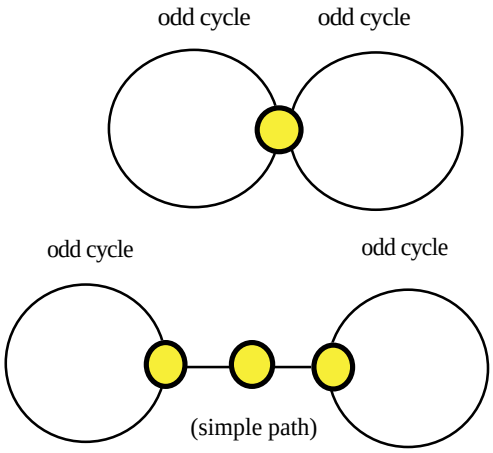

FIG. 3.

Thus, a nonempty subset S of E corresponds to a set of columns of $\mathbf{A}$ that are linearly dependent (over the field of reals) if and only if S contains the support of a circulation in G. A *minimal circulation* in G is a circulation in G with inclusion-minimal support. The following is a well-known result of linear algebra.

PROPOSITION 1 (e.g., see page 107 in [3]). *Let S and (S^+, S^-) be the support and the signed support of a circulation in G, respectively. For each edge e in S, there is a minimal circulation in G with support C and signed support (C^+, C^-) such that e is in C, $C^+ \subseteq S^+$ and $C^- \subseteq S^-$.*

The set of supports of minimal circulations in G can be viewed as the family of *circuits* of a matroid [20], which we denote by $\boldsymbol{\mathcal{M}}(G)$, whose rank (i.e., the rank of $\mathbf{A}$) is given by $|V| - q$, where q is the number of connected components of G that are bipartite (in that they contain no odd cycles); see Theorem 1, page 421 in [6], or [19]. Explicitly, a subset of E is a circuit of $\boldsymbol{\mathcal{M}}(G)$ if and only if it is the edge set of either an even simple cycle or a pair of two edge-disjoint odd simple cycles that either have exactly one vertex in common or are vertex-disjoint and are connected by a simple path (see Figure 3) [5].

Let Z be a (proper or improper) subset of E. We say that a circuit of $\boldsymbol{\mathcal{M}}(G)$ is *Z-traversable* if it is the support of a (minimal) circulation whose signed support (C^+, C^-) is such that $Z \cap C^- = \emptyset$.

Consider now the vectors that are linear combinations of rows of $\mathbf{A}$. The inclusion-minimal supports of these vectors are the *cocircuits* of $\boldsymbol{\mathcal{M}}(G)$; that is, they are minimal edge sets whose removal decreases the rank of $\boldsymbol{\mathcal{M}}(G)$ [20]. Moreover, an edge e of G is a *coloop* of $\boldsymbol{\mathcal{M}}(G)$ if the singleton $\{e\}$ is a cocircuit of $\boldsymbol{\mathcal{M}}(G)$. In other words, an edge e of G is a coloop of $\boldsymbol{\mathcal{M}}(G)$ if and only if the incidence vector of $\{e\}$ is a linear combination of rows of $\mathbf{A}$ or, equivalently, if and only if e is not in any circuit of $\boldsymbol{\mathcal{M}}(G)$ [20].

3. Invariant edges. In this section, we state a few characteristic properties of invariant edges of an arbitrary EWG which will be used later on. We need some preliminary definitions and results.

Let $\Gamma = (G, \boldsymbol{w})$ be an EWG with $G = (V, E)$ and let Z be the zero set of $\boldsymbol{w}$. A circulation in G with signed support (S^+, S^-) is said to be *legal* in Γ if $Z \cap S^- = \emptyset$. Accordingly, a circuit of $\boldsymbol{\mathcal{M}}(G)$ is Z-traversable if and only if it is the support of a

(minimal) circulation in G which is legal in Γ. It should be noted that if the weights of the edges of G are all positive, then Z is empty so that each circulation in G is legal in Γ.

THEOREM 1. *Let $\Gamma = (G, \boldsymbol{w})$ be an EWG. An edge of G is not an invariant edge of Γ if and only if it belongs to the support of a circulation in G which is legal in Γ.*

Proof. ("only if") Let e be an edge of G that is not an invariant edge of Γ. Then, there exists a nonnegative solution $\boldsymbol{x}$ of (1) with $x(e) \neq w(e)$. The vector $\boldsymbol{y} = \boldsymbol{x} - \boldsymbol{w}$ is then a circulation in G. Let S and (S^+, S^-) be the support and the signed support of $\boldsymbol{y}$, respectively, and let Z be the zero set of $\boldsymbol{w}$. Then e is in S and, since $y(e') = x(e') \geq 0$ for each e' in Z, one has $Z \cap S^- = \emptyset$; that is, e belongs to the support of a circulation which is legal in Γ.

("if") Let $\boldsymbol{y}$ be a legal circulation with support S and signed support (S^+, S^-), and let e be in S. Consider the solution $\boldsymbol{x} = \boldsymbol{w} + \boldsymbol{y}$ of equation system (1). If $\boldsymbol{x}$ is nonnegative everywhere, then the statement follows from the fact that e is in S, which implies $x(e) \neq w(e)$. Otherwise, let

$$S' = \{e' \colon x(e') < 0\} \qquad \text{and} \qquad \lambda = \min\{-w(e')/y(e') \colon e' \in S'\}.$$

Since S' is a subset of S^- and $\boldsymbol{y}$ is a legal circulation, λ is positive. Then the vector $\boldsymbol{y}' = \lambda \boldsymbol{y}$ is a circulation in G having the same support and the same signed support as $\boldsymbol{y}$. Consider the solution $\boldsymbol{x}' = \boldsymbol{w} + \boldsymbol{y}'$ of equation system (1). It is easily seen that $\boldsymbol{x}'$ is nonnegative everywhere since, for each e' not in S, one has trivially $x'(e') \geq 0$ and, for each e' in S', one has

$$x'(e') = w(e') + \lambda y(e') = -y(e')(-w(e')/y(e') - \lambda) \geq 0.$$

Finally, since e is in the support S of $\boldsymbol{y}$, one has

$$x'(e) = w(e) + \lambda\, y(e) \neq w(e),$$

which proves the statement. □

THEOREM 2. *Let $\Gamma = (G, \boldsymbol{w})$ be an EWG and let Z be the zero set of $\boldsymbol{w}$. An edge of G is not an invariant edge of Γ if and only if it belongs to some Z-traversable circuit of $\boldsymbol{\mathcal{M}}(G)$.*

Proof. ("if") It follows from the "if" part of Theorem 1.

("only if") If e is not an invariant edge of Γ, then by the "only-if" part of Theorem 1 there is a circulation in G with support S and signed support (S^+, S^-) such that e is in S and $Z \cap S^- = \emptyset$. But, by Proposition 1, there is a minimal circulation in G such that its support contains e and its signed support (C^+, C^-) is such that $C^- \subseteq S^-$. Therefore, one has $Z \cap C^- \subseteq Z \cap S^- = \emptyset$, which proves the statement. □

EXAMPLE 1 (continued). *The zero set of $\boldsymbol{w}$ is $Z = \{(2,3), (2,5), (4,5)\}$. The minimal circulations in G are summarized in Figure 4 by taking λ to be any nonzero real. So, $\boldsymbol{\mathcal{M}}(G)$ contains one circuit which is not Z-traversable. By Theorem 2, each edge of G is an invariant edge of Γ.* □

EXAMPLE 2 (continued). *The zero set of $\boldsymbol{w}$ is $Z = \{(1,2), (1,3)\}$. The minimal circulations in G are summarized in Figure 5 by taking λ to be any nonzero real. So, $\boldsymbol{\mathcal{M}}(G)$ contains one circuit which is Z-traversable. By Theorem 2, no edge of G is an invariant edge of Γ.* □

Note that if the zero set Z of $\boldsymbol{w}$ is empty, then, by Theorem 2, an edge of G is an invariant edge of Γ if and only if it is not in any circuit of $\boldsymbol{\mathcal{M}}(G)$; that is, if and

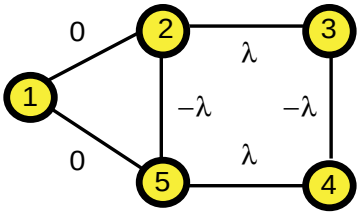

FIG. 4.

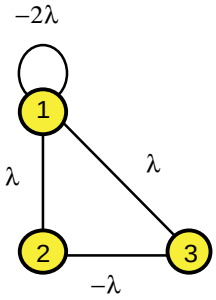

FIG. 5.

only if it is a coloop of $\boldsymbol{\mathcal{M}}(G)$. We now prove that the same holds in a more general case. In what follows, by the *kernel* of Γ [15] we mean the intersection of Z with the set of invariant edges of Γ □

LEMMA 1. *Let $\Gamma = (G, \boldsymbol{w})$ be an EWG whose kernel is empty. An edge of G is an invariant edge of Γ if and only if it is a coloop of $\boldsymbol{\mathcal{M}}(G)$.*

Proof. ("if") If an edge of G is a coloop of $\boldsymbol{\mathcal{M}}(G)$, then it is an invariant edge of Γ by the "only-if" part of Theorem 2.

("only if") Let e be an invariant edge of Γ. Suppose by contradiction that e is in some circuit of $\boldsymbol{\mathcal{M}}(G)$. Then, as is shown below, e should belong to the support of a legal circulation in Γ, which contradicts Theorem 1. To show that, suppose that e is in the circuit C_0 of $\boldsymbol{\mathcal{M}}(G)$. By the "only-if" part of Theorem 2, C_0 cannot be Z-traversable, where Z is the zero set of $\boldsymbol{w}$. Thus, if $\boldsymbol{c}_0$ is any minimal circulation in G with support C_0 and signed support (C_0^+, C_0^-), one has $Z \cap C_0^- \neq \emptyset$. Let $Z \cap C_0^- = \{e_1, \ldots, e_p\}$. Since the kernel of Γ is empty, no edge in Z is an invariant edge of Γ. Then, by the "only-if" part of Theorem 1, for each e_i, $1 \leq i \leq p$, there is a legal circulation $\boldsymbol{y}_i$ of Γ such that, if S_i is the support of $\boldsymbol{y}_i$, e_i is in S_i; moreover, if (S_i^+, S_i^-) is the signed support of $\boldsymbol{y}_i$, then $y_i(e_i) > 0$, since $Z \cap S_i^- = \emptyset$. Now consider the circulation

$$\boldsymbol{c}_i = [-c_0(e_i)/y_i(e_i)]\boldsymbol{y}_i.$$

Since $c_0(e_i) < 0$ (recall that $e_i \in C_0^-$) and $y_i(e_i) > 0$, $\boldsymbol{c}_i$ has the same support and signed support as $\boldsymbol{y}_i$, and hence is legal in Γ. Let

$$\boldsymbol{y} = \boldsymbol{c}_0 + \sum_{i=1,\ldots,p} \boldsymbol{c}_i.$$

Since the circulation space of $\mathbf{A}$ is a linear space, $\boldsymbol{y}$ is still a circulation in G. Let S and (S^+, S^-) be the support and signed support of $\boldsymbol{y}$, respectively. Finally, we now prove that (i) e is in S, and (ii) the circulation $\boldsymbol{y}$ is legal in Γ.

Proof of (i). Since e is an invariant edge of Γ, by the "if" part of Theorem 2, e is in the support of none of the legal circulations $\boldsymbol{c}_i$ so that $c_i(e) = 0$ for each i, $1 \leq i \leq p$. Therefore, $y(e) = c_0(e)$ and, since e is in C_0, one has that e is also in S.

Proof of (ii). In order to prove that the intersection of Z with S^- is empty, we separately examine the edges $e_1, \ldots, e_p$ in $Z \cap C_0^-$ and the edges in $Z - C_0^-$. For each i and j, $1 \leq i, j \leq p$, $c_j(e_i) \geq 0$, since $Z \cap S_j^- = \emptyset$. Moreover, for each i, $1 \leq i \leq p$, one has

$$c_i(e_i) = -c_0(e_i)$$

and, hence,

$$y(e_i) = c_0(e_i) + c_i(e_i) + \sum_{j \neq i} c_j(e_i) = \sum_{j \neq i} c_j(e_i) \geq 0.$$

Therefore, each e_i is not in S^-.

We now consider the edges in $Z - C_0^-$. If e' is such an edge, then $c_0(e') \geq 0$. Moreover, since $Z \cap S_i^- = \emptyset$, $1 \leq i \leq p$, one has $c_i(e') \geq 0$. Therefore

$$y(e') = c_0(e') + \sum_{i=1,\ldots,p} c_i(e') \geq 0,$$

and, hence, e' is not in S^-.

After proving (i) and (ii), by the "if" part of Theorem 1, one has that e is not an invariant edge of Γ (a contradiction). □

As a consequence of Lemma 1, we obtain the following characterization of invariant edges of an EWG.

THEOREM 3. *Let $\Gamma = (G, \boldsymbol{w})$ be an EWG with kernel K. The set of invariant edges of Γ is the union of K with the set of coloops of $\boldsymbol{\mathcal{M}}(G - K)$.*

Proof. Let $\Gamma' = (G', \boldsymbol{w}')$, where $G' = G - K$, and let $\boldsymbol{w}'$ be the restriction of $\boldsymbol{w}$ to the edge set of G'. It is clear that an edge of G is an invariant edge of Γ if and only if either it is in K or it is an invariant edge of Γ'. On the other hand, the kernel of Γ' is empty so that, by Lemma 1, the invariant edges of Γ' are exactly the coloops of $\boldsymbol{\mathcal{M}}(G')$. □

By Theorem 3, the set of invariant edges of $\Gamma = (G, \boldsymbol{w})$ can be found by determining first the kernel K of Γ and, then, the set of coloops of $\boldsymbol{\mathcal{M}}(G - K)$. We shall solve the problem of the kernel of an EWG in section 5 and, in the next section, we shall give a linear algorithm for finding the set of coloops of the matroid on a graph.

4. Finding the coloop set. Let $G = (V, E)$ be a simple graph. Bearing in mind that a subset of E is a cocircuit of $\boldsymbol{\mathcal{M}}(G)$ if and only if it is a minimal edge set whose removal decreases the rank of $\boldsymbol{\mathcal{M}}(G)$, one easily obtains the following proposition.

PROPOSITION 2 (see [5]). *An edge of G is a coloop of $\boldsymbol{\mathcal{M}}(G)$ if and only if its removal creates one more bipartite connected component.*

Let e be a coloop of $\boldsymbol{\mathcal{M}}(G)$. The graph $G - e$ has or has not one more connected component than G. By Proposition 2, in the former case e must be a bridge, which we call an *algebraic bridge* of G, and in the latter case, as is shown below, e is an *odd edge*, by which we mean that e is common to all odd cycles of the connected component G containing e.

LEMMA 2. *An edge of a simple graph G is a coloop of $\boldsymbol{\mathcal{M}}(G)$ if and only if it is either an algebraic bridge or an odd edge.*

Proof. The statement is trivial if the graph is bipartite since, by Proposition 2, each coloop of $\boldsymbol{\mathcal{M}}(G)$ is a bridge and vice versa. Consider now a graph G which is not bipartite. Without loss of generality, we assume G is connected. It is sufficient to prove that a coloop e of $\boldsymbol{\mathcal{M}}(G)$ is not a bridge if and only if it is an odd edge. If e is not a bridge, then, by Proposition 2, $G - e$ is bipartite and connected and, hence, every odd cycle of G must contain e; that is, e is an odd edge of G. On the other hand, if e is an odd edge of G, then $G - e$ is connected and contains no odd cycles so that, by Proposition 2, e is a coloop of $\boldsymbol{\mathcal{M}}(G)$. □

EXAMPLE 1 (continued). *The coloops of $\boldsymbol{\mathcal{M}}(G)$ are the two edges missing from the even simple cycle supporting the minimal circulations shown in Figure* 4. *Both of them are odd edges.* □

EXAMPLE 2 (continued). *$\boldsymbol{\mathcal{M}}(G)$ has no coloops (see Figure* 5*).* □

Let $G = (V, E)$ be a simple graph which without loss of generality we assume to be connected. We first show that the problem of finding the set of coloops of $\boldsymbol{\mathcal{M}}(G)$ is polynomial; next, we shall give a linear algorithm based on Lemma 2.

In [14, 16, 17] an $O(|E|)$ algorithm is given to decide whether the incidence vector of a given subset of E is orthogonal to the space of circulations in G. By applying that algorithm to each singleton, one can determine the set of coloops of $\boldsymbol{\mathcal{M}}(G)$ in $O(|E|^2)$ time. In the next two subsections, we give two linear algorithms for finding the algebraic bridges and the odd edges of G; so, by Lemma 2, determining the whole set of coloops of $\boldsymbol{\mathcal{M}}(G)$ requires $O(|E|)$ time.

4.1. Algebraic bridges. Let $G = (V, E)$ be a connected simple graph, and let B be the set of bridges of G. Consider the tree $T = (N, A)$ whose nodes represent the connected components of $G - B$ and whose arcs represent the bridges of G. A node n of T is marked if the corresponding connected component of $G - B$ is not bipartite. If no node of T is marked, then G is bipartite and the bridges of G are all and the only algebraic bridges. Otherwise, there is at least one marked node of T; then, arbitrarily choose a marked node r of T and let T_r be the directed tree obtained by rooting T at r. For each node n of T_r, $n \neq r$, let $par(n)$ be the parent of n in T_r. Of course, a bridge of G is algebraic if and only if the (directed) arc $\langle par(n), n\rangle$ of T_r is such that the subtree of T_r rooted at n contains no marked nodes. Thus, in order to get the algebraic bridges of G, it is sufficient to perform a postorder traversal of T_r[1]: when node n is examined, $n \neq r$; if n is marked, then the edge of G corresponding to the arc $\langle par(n), n\rangle$ is removed from B and the vertex $par(n)$ is marked if it was unmarked. So, the ultimate value of B is exactly the set of algebraic edges of G. Now, since the construction of T and B and the postorder traversal of T_r require $O(|E|)$ time, we have the following theorem.

THEOREM 4. *The set of algebraic bridges of a connected simple graph can be found in time linear in the number of its edges.*

4.2. Odd edges. Let $G = (V, E)$ be a connected simple graph. Trivially, if G is bipartite, then G contains no odd edges. In the case where G is not bipartite, we shall show that the set of odd edges of G can be found in $O(|E|)$. To achieve this, we need the following technical lemmas, the first two of which refer to general properties of the symmetric difference ($\oplus$) of cycles.

LEMMA 3 (see, e.g., [1]). *The symmetric difference of two distinct nondisjoint cycles is a set of edge-disjoint cycles.*

LEMMA 4. *If the symmetric difference of two or more cycles contains an odd number of edges, then the number of such cycles having odd lengths is odd.*

Proof. It easily follows from the fact that, for every two sets C and C', $|C \oplus C'|$ is odd if and only if $|C|$ and $|C'|$ have different parities. □

Let T be the edge set of a spanning tree of G. For each back-edge e (i.e., e not in T), the set $T \cup [e]$ contains exactly one simple cycle; such simple cycles, one for each back-edge, are called the *fundamental cycles* of G with respect to T [18].

LEMMA 5 (see, e.g., page 251 in [1]). *Let T be the edge set of a spanning tree of a simple graph G. Every cycle of G can be expressed as a symmetric difference of fundamental cycles of G with respect to T.*

LEMMA 6. *Let G be a nonbipartite connected simple graph and let T be a spanning tree of G. An edge of G is an odd edge of G if and only if it is in all odd fundamental cycles with respect to T and in no even fundamental cycle with respect to T.*

Proof. ("if") Let e be an edge of G that is in all odd fundamental cycles with respect to T and in no even fundamental cycle with respect to T. Let C be any odd cycle. By Lemma 5, C can be expressed as symmetric difference of fundamental cycles with respect to T, and, by Lemma 4, the number of odd fundamental cycles in its expression is odd so that, since e is in all of them and in no even fundamental cycle with respect to T, e belongs to C.

("only if") Let e be an odd edge of G. Of course e is in all odd fundamental cycles with respect to T. Suppose by contradiction that there is an even fundamental cycle C' with respect to T that contains e. Let C be an odd cycle containing e. By Lemma 3, $C \oplus C'$ contains an odd cycle, say C'', because the lengths of C and C' have different parities. So, since e is in both C and C', e is not in C'', which contradicts the hypothesis that e is in all odd cycles of G. □

From a computational point of view, the fundamental cycles of G with respect to a given spanning tree can be constructed using an $O(|V|^3)$ algorithm (see, e.g., Algorithm 8.10 in [18]). So, by Lemma 6 one can resort to that algorithm to find the set of odd edges of G in $O(|V|^3)$ time. However, we shall use Lemma 6 to work out an algorithm which runs in $O(|E|)$ time. It consists of two phases.

Phase I. Arbitrarily choose a vertex r of G and perform a traversal of G with the depth-first search (DFS) technique to produce

- the edge set T of a directed spanning tree of G,
- the set B of back-edges that create odd fundamental cycles of G with respect to T, and
- a vertex table which, for each vertex v, reports the following information items:
  - the DFS number of v, denoted by $n(v)$;
  - a label, denoted by $col(v)$, which is set to "white" or "black" depending on whether the length of the path from r to v in the spanning tree is even or odd;
  - if $v \neq r$, the parent of v, denoted by $par(v)$;
  - if $v \neq r$, the tree-edge $\langle par(v), v \rangle$, denoted by $arc(v)$.

Phase II. First of all, join a back-edge to *Odd* if it is the unique element of B. Next, in order to decide if a tree-edge e can be joined to *Odd*, compute

- the number of the even fundamental cycles that contain e, denoted by NEC[e], and
- the number of the odd fundamental cycles that contain e, denoted by NOC[e],

as follows. For each vertex u, let $N(u)$ be the set of neighbors of u in G and let $C(u)$ be the set of children of u in T. Then, set (see Figure 6)

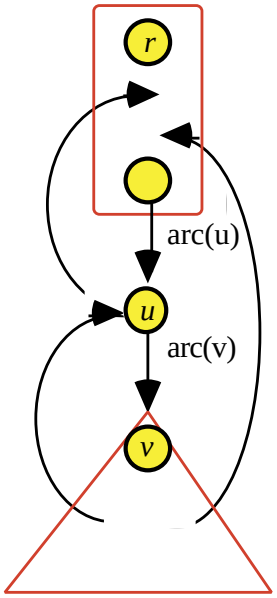

FIG. 6.

$$\text{NEC}[arc(u)] = |P_{even}(u)| + \sum_{v \in C(u)} \text{NEC}[arc(v)] - |S_{even}(u)|, \tag{2}$$

where

$$P_{even}(u) = \{v \in N(u) \colon par(u) \neq v \text{ and } col(v) \neq col(u) \text{ and } n(v) < n(u)\},$$
$$S_{even}(u) = \{v \in N(u) \colon par(v) \neq u \text{ and } col(v) \neq col(u) \text{ and } n(v) > n(u)\},$$

and

$$\text{NOC}[arc(u)] := |P_{odd}(u)| + \sum_{v \in C(u)} \text{NOC}[arc(v)] - |S_{odd}(u)|, \tag{3}$$

where

$$P_{odd}(u) = \{v \in N(u) \colon par(u) \neq v \text{ and } col(v) = col(u) \text{ and } n(v) < n(u)\},$$
$$S_{odd}(u) = \{v \in N(u) \colon par(v) \neq u \text{ and } col(v) = col(u) \text{ and } n(v) > n(u)\}.$$

After calculating the quantities NEC[e] and NOC[e] for each edge e in T, determine the set of odd edges, denoted by *Odd*, as follows (see Lemma 6): for each edge e in T, join e to *Odd* if NEC[e] = 0 and NOC[e] = $|B|$.

The following algorithm details the steps of Phase II.

ALGORITHM 1.

Input: A nonbipartite, connected simple graph $G = (V, E)$, a vertex r of G, T, B and the vertex table of G.

Output: The set *Odd* of odd edges of G.

(1) Set $Odd := \emptyset$. Set $k := |B|$. If $k = 1$, then $Odd := Odd \cup B$.
For each edge e in T, set NEC[e] := NOC[e] := 0.

(2) For each child u of r in T, TRAVERSE (G, u).

(3) For each edge e in T, if $\mathrm{NEC}[e] = 0$ and $\mathrm{NOC}[e] = k$, then add e fo *Odd*.

PROCEDURE TRAVERSE (G, u).

For each neighbor v of u, do:

begin

If v is a child of u, then do:

begin

TRAVERSE (G, v);

$\mathrm{NEC}[arc(u)] := \mathrm{NEC}[arc(u)] + \mathrm{NEC}[arc(v)]$;

$\mathrm{NOC}[arc(u)] := \mathrm{NOC}[arc(u)] + \mathrm{NOC}[arc(v)]$

end;

otherwise, if v is not the parent of u, then do:

Case 1. if $n(v) > n(u)$ and $col(v) \neq col(u)$, then set

$$\mathrm{NEC}[arc(u)] := \mathrm{NEC}[arc(u)] - 1;$$

Case 2. if $n(v) > n(u)$ and $col(v) = col(u)$, then set

$$\mathrm{NOC}[arc(u)] := \mathrm{NOC}[arc(u)] - 1;$$

Case 3. if $n(v) < n(u)$ and $col(v) \neq col(u)$, then set

$$\mathrm{NEC}[arc(u)] := \mathrm{NEC}[arc(u)] + 1;$$

Case 4. if $n(v) < n(u)$ and $col(v) = col(u)$, then set

$$\mathrm{NOC}[arc(u)] := \mathrm{NOC}[arc(u)] + 1$$

end.

THEOREM 5. *Let G be a nonbipartite, connected simple graph. The value of Odd computed by Algorithm 1 with input G and vertex r is exactly the set of odd edges of G.*

Proof. It is sufficient to prove that the quantities $\mathrm{NEC}[e]$ and $\mathrm{NOC}[e]$, for each tree-edge e, equal the number of even fundamental cycles containing e and the number of odd fundamental cycles containing e, respectively. The statement is proven by structural induction.

Basis. Assume that u is a leaf of T. Then, u has no children so that if v is a neighbor of u, then v must be an ancestor of u. If $v = u$, then the self-loop (u, u) contributes to neither $\mathrm{NEC}[arc(u)]$ nor $\mathrm{NOC}[arc(u)]$. If v is a proper ancestor of the parent of u, then $n(v) < n(u)$ and the back-edge (u, v) correctly adds 1 to either $\mathrm{NEC}[arc(u)]$ or $\mathrm{NOC}[arc(u)]$.

Inductive step. Let u be not a leaf of T and assume the statement holds for each one of the children of u. Thus, if v is a child of u, then values of both $\mathrm{NEC}[arc(v)]$ and $\mathrm{NOC}[arc(v)]$ are right. It is then easily seen that, by formulae (2) and (3), the statement also holds for u. □

From the complexity-theoretic point of view, it is easily seen that the time of Algorithm 1 is dominated by the time required by the DFS traversal and, hence, is $O(|E|)$. So, by Theorem 5 one has the following corollary.

COROLLARY 1. *Let $G = (V, E)$ be a nonbipartite, connected simple graph. The set of odd edges of G can be found in $O(|E|)$ time.*

5. Finding the kernel. Let $\Gamma = (G, \boldsymbol{w})$ be an EWG with $G = (V, E)$ and kernel K. If the zero set Z of $\boldsymbol{w}$ is empty, then K is empty too and we are done. Assume that

Z is not empty. If G is bipartite, Gusfield [7] proved that K equals the set of directed edges joining strongly connected components of the *mixed graph* $G(Z)$ obtained from G by directing all the edges in Z from one side of the bipartition to the other one so that it can be computed in time linear in the size of G. In this section we show that, even in the case where G is not bipartite, the kernel of Γ can be computed in time linear in the size of G.

With Γ we associate a bipartite EWG $\Gamma' = (G', \boldsymbol{w}')$, which we call a *bipartite EWG associated* with Γ. The graph $G' = (V', E')$ is constructed as follows. Let B be a maximal bipartite partial graph of G and let $\{V_1, V_2\}$ be a bipartition of V such that each edge of B has one end in V_1 and the other end in V_2. Let $\overline{V}$ be a "copy" of V, that is, $\overline{V} \cap V = \emptyset$ and $|\overline{V}| = |V|$. If v is a vertex of G, then by $\bar{v}$ we denote the copy of v. The vertex set of G' is taken to be $V' = V \cup \overline{V}$, and the edge set of G' is taken to be

$$E' = \bigcup_{e \in E} f(e),$$

where f is function defined on E as follows:

— if e is a self-loop, say (v, v), then $f(e) = \{(v, \bar{v})\}$;
— if $e = (u, v)$ is an edge of B, then $f(e) = \{(u, v), (\bar{u}, \bar{v})\}$;
— if $e = (u, v)$ is neither a self-loop nor an edge of B, then $f(e) = \{(u, \bar{v}), (\bar{u}, v)\}$.

The set $f(e)$ will be referred to as the *image* of e in G'. Let $V_1' = V_1 \cup \overline{V}_2$ and $V_2' = \overline{V}_1 \cup V_2$, where $\overline{V}_1 = \{\bar{v} : v \in V_i\}$, $i = 1, 2$. The graph G' is bipartite and the partition $\{V_1', V_2'\}$ of V' is such that each edge of G' has one end in V_1' and the other end in V_2'. Furthermore, G' is connected if and only if G is not bipartite. Finally, to each edge e' of G' we assign the weight $w'(e') = w(e)$, where e is the edge of G for which $e' \in f(e)$. Let $\mathbf{A}'$ be the incidence matrix of G' and let $\boldsymbol{b}' = (b'(v'))_{v' \in V'}$, where $b'(v')$ equals the sum of the weights $w'(e')$ of the edges of G' incident to v'. Consider the equation system

$$\mathbf{A}'\boldsymbol{x}' = \boldsymbol{b}'. \tag{4}$$

For every edge e' of G', let $L[x'(e')]$ and $U[x'(e')]$ denote the minimum and the maximum of the variable $x'(e')$ over the nonnegative solutions of equation system (4), respectively. Moreover, for every edge e of G, let $L[f(e)]$ and $U[f(e)]$ denote the minimum and the maximum of the expression $\sum_{e' \in f(e)} x'(e')$ over the nonnegative solutions of equation system (4), respectively. First, observe that if $\boldsymbol{x}'$ is a (nonnegative) solution of equation system (4), then a (nonnegative) solution $\boldsymbol{x}''$ of equation system (4) can be obtained by setting for each edge e' of G'

$$x''(e') = x'(e') \text{ if } \{e'\} \text{ is the image of a self-loop of } G$$

and

$$x''(e') = x'(e'') \text{ if } \{e', e''\} \text{ is the image of an edge of } G \text{ that is not a self-loop.}$$

It follows that, if $\{e', e''\}$ is the image of an edge of G that is not a self-loop, then

$$L[x'(e')] = L[x'(e'')] \quad \text{and} \quad U[x'(e')] = U[x'(e'')]. \tag{5}$$

Second, if $\boldsymbol{x}$ is a (nonnegative) solution of equation system (1), then a (nonnegative) solution $\boldsymbol{x}'$ of equation system (4) can be obtained by setting for each edge e' of G'

$$x'(e') = x(e), \text{ where } e \text{ is the edge of } G \text{ whose image } f(e) \text{ contains } e'.$$

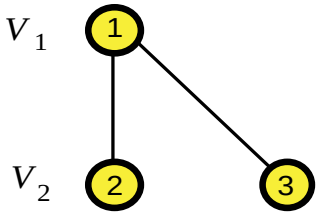

FIG. 7.

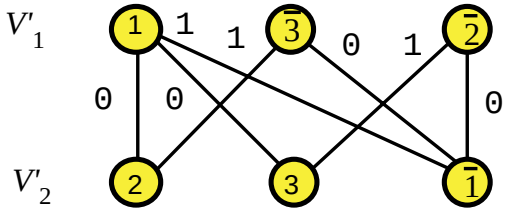

FIG. 8.

On the other hand, if $\boldsymbol{x}'$ is a (nonnegative) solution of equation system (4), then a (nonnegative) solution $\boldsymbol{x}$ of equation system (1) can be obtained by setting for each edge e of G

$$x(e) = \left[\sum_{e' \in f(e)} x'(e')\right] \Big/ |f(e)|.$$

Therefore, one has

$$L[x(e)] = (1/|f(e)|)L[f(e)] \quad \text{and} \quad U[x(e)] = (1/|f(e)|)U[f(e)]. \tag{6}$$

EXAMPLE 2 (continued). *By choosing as the maximal bipartite partial graph of G the graph shown in Figure* 7*, we associate with Γ the bipartite EWG $\Gamma' = (G', \boldsymbol{w}')$ shown in Figure* 8.

The general expression of a nonnegative solution of equation system (4) *is*

$$\begin{aligned} x'(1,2) &= x'(\bar{1},\bar{3}) = \mu, \\ x'(1,3) &= x'(\bar{1},\bar{2}) = \nu, \\ x'(1,\bar{1}) &= 1 - \mu - \nu, \\ x'(2,\bar{3}) &= 1 - \mu, \\ x'(\bar{2},3) &= 1 - \nu, \end{aligned}$$

where μ and ν are bounded as shown in Figure 9*. At this point, it is easy to check formulae* (5) *and* (6). □

We now state some technical results to relate the kernels of Γ and Γ'.

LEMMA 7. *Let $\Gamma = (G, \boldsymbol{w})$ be an EWG and let $\Gamma' = (G', \boldsymbol{w}')$ be a bipartite EWG associated with Γ. An edge e of G is an invariant edge of Γ if and only if $L[f(e)] = U[f(e)]$, where $f(e)$ is the image of e in G'.*

Proof. The proof follows from formula (6). □

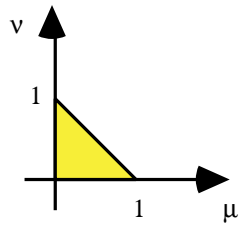

FIG. 9.

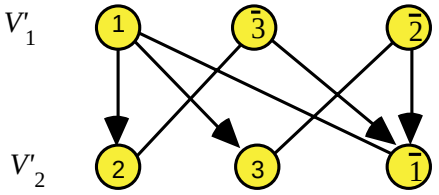

FIG. 10.

LEMMA 8. *Let $\Gamma = (G, \boldsymbol{w})$ be an EWG and let $\Gamma' = (G', \boldsymbol{w}')$ be a bipartite EWG associated with Γ. An edge e of G belongs to the kernel of Γ if and only if its image in G' is contained in the kernel of Γ'.*

Proof. If e is a self-loop of G, then the statement immediately follows from formula (6) and Lemma 7. We now prove the statement in the case where e is not a self-loop and $f(e) = \{e', e''\}$.

("if") If both e' and e'' belong to the kernel of Γ', then $x'(e') = x'(e'') = 0$ for every solution $\boldsymbol{x}'$ of equation system (4). Therefore, $L[x'(e') + x'(e'')] = U[x'(e') + x'(e'')] = 0$ and the statement follows from formula (6).

("only if") If e belongs to the kernel of Γ, then, by formula (6), one has

$$x'(e') + x'(e'') = 0$$

for every nonnegative solution $\boldsymbol{x}'$ of equation system (4). By the nonnegativity of $\boldsymbol{x}'$, $x'(e') = x'(e'') = 0$, which proves that both e' and e'' belong to the kernel of Γ'. □

COROLLARY 2. *Let $\Gamma = (G, \boldsymbol{w})$ be an EWG and let $\Gamma' = (G', \boldsymbol{w}')$ be a bipartite EWG associated with Γ'. An edge of G belongs to the kernel of Γ if and only if an element of its image in G' belongs to the kernel of Γ'.*

Proof. The proof follows from Lemma 8 and formula (5). □

EXAMPLE 2 (continued). *The zero set of $\boldsymbol{w}'$ is $Z' = \{(1,2), (1,3), (\bar{1}, \bar{2}), (\bar{1}, \bar{3})\}$. The mixed graph $G'(Z')$ is strongly connected (see Figure 10). So, the kernel of Γ' is empty. By Corollary 2, the kernel of Γ is empty.* □

THEOREM 6. *The kernel of an EWG can be found in time linear in the size of G.*

Proof. Let $\Gamma = (G, \boldsymbol{w})$ be an EWG and let $\Gamma' = (G', \boldsymbol{w}')$ be a bipartite EWG associated with Γ. If G is bipartite, then the statement was proven by Gusfield [7]. Otherwise, since G' is bipartite, the kernel K' of Γ' can be found in time linear in the size of G' and, hence, of G. So, it is sufficient to prove that both constructing G' and determining K from K' take a linear time. In order to construct G', we perform a DFS traversal of G, which allows us to find both a maximal bipartite partial graph B of G and the nontree edges that create odd cycles when added to B. When an edge

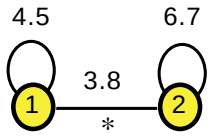

FIG. 11.

e' of G' is created, we get e' to point to the edge e of G for which $e' \in f(e)$. Finally, by Corollary 2, the set K can be obtained as follows. Initially, each edge e of G is unmarked. For each element e' of K', if the edge e of G that e' points to is unmarked, then e is marked and added to K. □

6. Security of statistical data. In the security analysis of statistical data [4, 7, 8, 9, 10, 11, 12, 13, 15, 16, 17], EWGs and, more in general, weighted hypergraphs can be used to control the amount of information that is implicitly released when statistical data are made public, in order to avoid disclosure of confidential data. We now illustrate this application by discussing a typical case. Suppose that we are given a data set $\{b_i : i \in I\}$, where b_i is the value of a confidential variable b of nonnegative real type (e.g., salary) for individual i in the population I. The sum of values of b over a subset I' of I is called *sensitive* if I' contains exactly one individual. Now, given a statistical summary $\sigma = \{b(v) : v \in V\}$ where $b(v)$ is the sum of b over a subset $I(v)$ of I containing at least two people, for each v in V, the problem that naturally arises consists of checking that no sensitive sum is implicitly released. We now present a graph-theoretic approach to this problem. Let $I_\sigma = \cup_{v \in V} I(v)$, which we call the set of individuals *covered* by σ. The *basic partition* of I_σ is the coarsest partition of I_σ such that each $I(v)$ can be obtained as the union of one or more classes of the partition. A class J of the basic partition of I_σ will be indexed by the set $e = \{v \in V : J \subseteq I(v)\}$. If E is the index set of the classes of the basic partition of I_σ, the pair $G = (V, E)$ defines a hypergraph where hyperedge e is incident to vertex v if and only if v belongs to e. Consider the weighted hypergraph $\Gamma = (G, \boldsymbol{w})$, where, for each hyperedge e of G, $w(e)$ is given by the sum of the values of the variable b over the class $J(e)$ of the basic partition of I_σ indexed by e; that is,

$$w(e) = \sum_{i \in J(e)} b_i.$$

Finally, a hyperedge e of G is *marked* if $|J(e)| = 1$. Then, no sensitive sum is implicitly released given σ if and only if no invariant hyperedge of Γ is marked. If this is the case, the statistical summary σ is said to be *safe*. Since the invariant edges of an EWG can be found in linear time, one has that, if G is a graph, then one can decide whether σ is or is not safe in linear time, too.

EXAMPLE 3. *Consider five individuals with salaries* $b_1 = 2.0$, $b_2 = 2.5$, $b_3 = 3.8$, $b_4 = 3.7$, *and* $b_5 = 3.0$. *Suppose that the two sums* $b_1 + b_2 + b_3$ *and* $b_3 + b_4 + b_5$ *are made public. Let* $\sigma_1 = \{b_1 + b_2 + b_3, b_3 + b_4 + b_5\}$. *The set of individuals covered by* σ_1 *is* $\{1, \ldots, 5\}$ *and its basic partition consists of the three classes* $\{1, 2\}$, $\{3\}$, *and* $\{4, 5\}$. *Thus, the weighted hypergraph* Γ_1 *associated with* σ_1 *is the EWG shown in Figure* 11, *where the edge* $(1, 2)$ *is marked. Since the set of invariant edges of* Γ_1 *turns out to be empty,* σ_1 *is safe. Next, suppose that the sum* $b_1 + b_2 + b_4 + b_5$ *is also made public.*

Let $\sigma_2 = \{b_1 + b_2 + b_3, b_3 + b_4 + b_5, b_1 + b_2 + b_4 + b_5\}$. *Again, the set of individuals covered by* σ_2 *is* $\{1, \ldots, 5\}$ *and its basic partition consists of the three classes* $\{1, 2\}$,

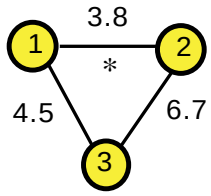

FIG. 12.

$\{3\}$, *and* $\{4,5\}$. *The weighted hypergraph* Γ_2 *associated with* σ_2 *is the EWG shown in Figure* 12, *where the edge* $(1,2)$ *is marked. Since each edge is an invariant edge of* Γ_2, σ_2 *is not safe (and the salary* b_3 *is unprotected).* □

Let $\sigma = \{b(v)\colon v \in V\}$ be a statistical summary of the data set $\{b_i\colon i \in I\}$ and let $\Gamma = (G, \boldsymbol{w})$ be the associated weighted hypergraph. It is worth noting that if v is a "leaf" of G, that is, if v belongs to exactly one hyperedge e of G, then the class of the basic partition of I_σ indexed by e coincides with $I(v)$ so that $w(e) = b(v)$; furthermore, the hyperedge e is definitely an invariant hyperedge of Γ, and, since $|I(v)| > 1$, it is not marked. As we are interested in checking the existence of marked invariant hyperedges of Γ (if any), we can reduce Γ by deleting all leaves of G and their incident hyperedges. Let $\Gamma' = (G', \boldsymbol{w}')$ be the resulting weighted hypergraph. Of course, σ is safe if and only if no invariant hyperedge of Γ' is sensitive. We now show that if σ is a two-dimensional table with suppressions, then G' is always a graph so that one can decide whether σ is or is not safe in linear time. Let σ be obtained from a complete two-dimensional table T by suppressing all sensitive cells ("primary suppressions") as well as additional (internal or marginal) cells to exclude the possibility of arriving at the contents of sensitive cells by indirect methods ("complementary suppressions"). Denote by

— $T(r,c)$ the value of internal cell (r,c), $1 \le r \le m$, and $1 \le c \le n$,
— $T(r,+)$ the rth row total, $1 \le r \le m$, and
— $T(+,c)$ the cth column total, $1 \le c \le n$.

Assume that each $T(r,c)$ is the sum of the values of a confidential variable of nonnegative real type over the set $I(r,c)$ of individuals. So, a cell (r,c) of T is sensitive if $|I(r,c)| = 1$. We first detail the structure of the weighted hypergraph $\Gamma = (G, \boldsymbol{w})$ associated with σ and then show that the reduction of Γ results in an EWG. Let U, R, and C be the set of unsuppressed internal cells, the set of marginal cells corresponding to unsuppressed row totals, and the set of marginal cells corresponding to unsuppressed column totals, respectively. Then the vertex set of G is

$$V = U \cup R \cup C.$$

Let $S = \{(r,c) \notin U\colon r \notin R \text{ and } c \notin C\}$. Moreover, for each $r \in R$, let $C_r = \{c \notin C\colon (r,c) \notin U\}$; analogously, for each $c \in C$, let $R_c = \{r \notin R\colon (r,c) \notin U\}$. Then, the set of individuals covered by σ is $I_\sigma = \cup_{(r,c)\notin S} I(r,c)$ and the basic partition of I_σ contains

— one class $I(r,c)$ for each (r,c) in U and for each (r,c) not in U with $r \in R$ and $c \in C$,
— one class $\cup_{c\in C_r} I(r,c)$ for each $r \in R$ with $C_r \neq \emptyset$, and
— one class $\cup_{r\in R_c} I(r,c)$ for each $c \in C$ with $R_c \neq \emptyset$.

Recall that the hyperedges of G are the indices of these classes. The hyperedge e

indexing a class such as $I(r,c)$ is

$$\begin{aligned}
&e=\{(r,c),(r,+),(+,c)\} && \text{if } (r,c)\in U, r\in R, c\in C,\\
&e=\{(r,c),(r,+)\} && \text{if } (r,c)\in U, r\in R, c\notin C,\\
&e=\{(r,c),(+,c)\} && \text{if } (r,c)\in U, r\notin R, c\in C,\\
&e=\{(r,c)\} && \text{if } (r,c)\in U, r\notin R, c\notin C,\\
&e=\{(r,+),(+,c)\} && \text{if } (r,c)\notin U, r\in R, c\in C,
\end{aligned}$$

and $w(e)$ is always set to $T(r,c)$. For the hyperedge e indexing a class such as $\cup_{c\in C_r} I(r,c)$, one has $e=\{(r,+)\}$ and

$$w(e)=\sum_{c\in C_r} T(r,c),$$

and for the hyperedge e indexing a class such as $\cup_{r\in R_c} I(r,c)$, one has $e=\{(+,c)\}$ and

$$w(e)=\sum_{r\in R_c} T(r,c).$$

At this point, it should be clear that the leaves of G are all and the only vertices of the type (r,c), of the type $(r,+)$ with $r\in R$ and $C_r=\{1,\dots,n\}$, and of the type $(+,c)$ with $c\in C$ and $R_c=\{1,\dots,m\}$. Let L be the set of leaves of G and let $R'=R-L$ and $C'=C-L$. After deleting all the leaves of the hypergraph G, we remain with the hypergraph $G'=(V',E')$ whose hyperedges are incident to at most two vertices. More precisely, one has that $V'=R'\cup C'$ and E' consists of the edges

$$\begin{aligned}
&\{(r,+),(+,c)\} && \text{if } (r,c)\notin U, r\in R, c\in C,\\
&\{(r,+)\} && \text{with } r\in R',\\
&\{(+,c)\} && \text{with } c\in C'.
\end{aligned}$$

To sum up, the reduction of the weighted hypergraph associated with σ is an EWG and, therefore, the safety of σ can be tested in linear time.

EXAMPLE 4. *Consider the table of Figure* 13 *whose entries are assumed to be nonnegative reals. Suppose that the following cells*

$$(1,1),(1,2),(2,1),(2,2),(2,3),(4,4)$$

are all sensitive. The table of Figure 14 *is obtained from the table of Figure* 13 *by suppressing all the six sensitive cells and the additional cells* $(3,3)$, $(3,+)$, $(4,+)$, *and* $(+,4)$.

The reduced weighted hypergraph $\Gamma'=(G',\boldsymbol{w}')$ *associated with the table of Figure* 14 *is the EWG shown in Figure* 15. *The invariant edges of* Γ' *are the edge joining the vertices* $(2,+)$ *and* $(+,3)$ *and the self-loop at vertex* $(+,3)$. *One of these two edges is marked and, therefore, the table of Figure* 14 *is not safe.* ∎

7. Closing remarks. We solved the problem of finding the set of invariant edges of an EWG under the assumption that edge weights are nonnegative reals. The case where edge weights are nonnegative integers is an open problem. However, if the underlying graph of the EWG is bipartite, then Gusfield's algorithm still holds owing to the total unimodularity of the incidence matrix.

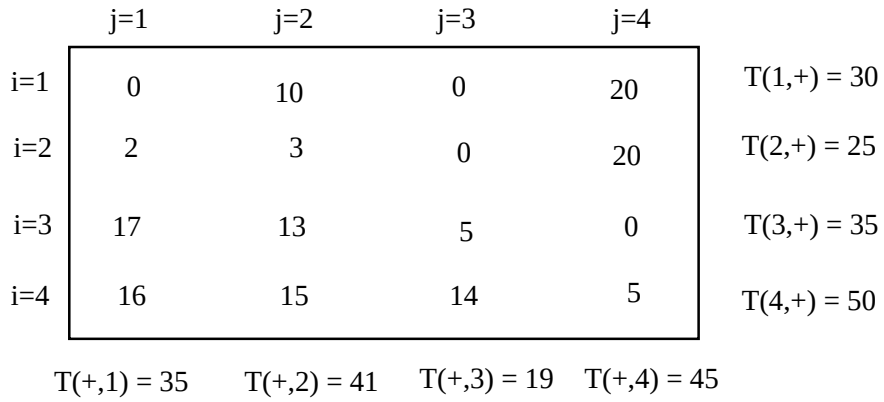

FIG. 13.

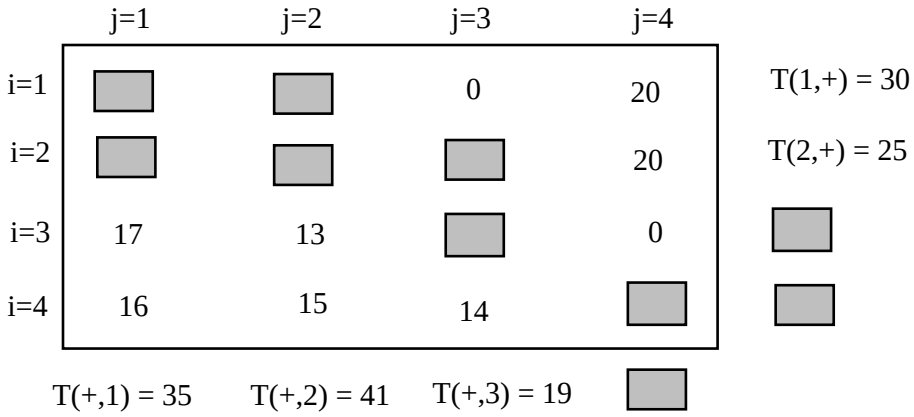

FIG. 14.

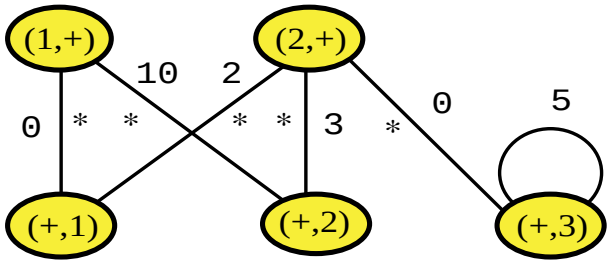

FIG. 15.

A natural generalization of the problem dealt with in this paper is the search of invariant edges of an edge-weighted hypergraph. It should be noted that mutatis mutandis Theorem 3 (see section 3) applies to edge-weighted hypergraphs, too. So, in order to find the invariant edges of an edge-weighted hypergraph $(G, \boldsymbol{w})$, we have to devise a procedure for computing its kernel, say K, and the coloops of the matroid $\boldsymbol{\mathcal{M}}(G-K)$. It should be clear that, in order to find to coloops of $\boldsymbol{\mathcal{M}}(G-K)$, we need a formula for the rank of the incidence matrix of G. At present, such a formula is

known only for special classes of hypergraphs, e.g., for the class of connected uniform hypergraphs [2].

Acknowledgments. The authors wish to thank M. Moscarini for her valuable suggestions and the two referees for their comments.

CHARACTERIZATIONS OF 1-WAY QUANTUM FINITE AUTOMATA*

ALEX BRODSKY† AND NICHOLAS PIPPENGER†

Abstract. The 2-way quantum finite automaton introduced by Kondacs and Watrous [*Proceedings of the* 38*th Annual Symposium on Foundations of Computer Science*, 1997, IEEE Computer Society, pp. 66–75] can accept nonregular languages with bounded error in polynomial time. If we restrict the head of the automaton to moving classically and to moving only in one direction, the acceptance power of this 1-way quantum finite automaton is reduced to a proper subset of the regular languages.

In this paper we study two different models of 1-way quantum finite automata. The first model, termed measure-once quantum finite automata, was introduced by Moore and Crutchfield [*Theoret. Comput. Sci.*, 237 (2000), pp. 275–306], and the second model, termed measure-many quantum finite automata, was introduced by Kondacs and Watrous [*Proceedings of the* 38*th Annual Symposium on Foundations of Computer Science*, 1997, IEEE Computer Society, pp. 66–75].

We characterize the measure-once model when it is restricted to accepting with bounded error and show that, without that restriction, it can solve the word problem over the free group. We also show that it can be simulated by a probabilistic finite automaton and describe an algorithm that determines if two measure-once automata are equivalent.

We prove several closure properties of the classes of languages accepted by measure-many automata, including inverse homomorphisms, and provide a new necessary condition for a language to be accepted by the measure-many model with bounded error. Finally, we show that piecewise testable sets can be accepted with bounded error by a measure-many quantum finite automaton, introducing new construction techniques for quantum automata in the process.

1. Introduction.

In 1997 Kondacs and Watrous [9] showed that a 2-way quantum finite automaton (2QFA) could accept the language $L = a^n b^n$ in linear time with bounded error. The ability of the reading head to be in a superposition of locations rather than in a single location at any time during the computation gives the 2QFA its power. Even if we restrict the head of a 2QFA from moving left, we can still construct a 2QFA that can accept the language $L' = \{x \in \{a,b\}^* \mid |x|_a = |x|_b\}$ in linear time with bounded error. However, if we restrict the head of a 2QFA to moving right on each transition, we get the 1-way quantum finite automaton (1QFA) of Kondacs and Watrous [9], which, when accepting with bounded error, can accept only a proper subset of the regular languages.

If the reading head is classical, then quantum mechanical evolution hinders language acceptance, restricting the set of languages accepted by 1QFAs with bounded error to a proper subset of the regular languages [9].

During its computation, a 1QFA performs measurements on its configuration. Since the acceptance capability of a 1QFA depends on the measurements that the QFA may perform during the computation, we investigate two models of 1QFAs that differ only in the type of measurement that they perform during the computation.

†Department of Computer Science, University of British Columbia, Canada (abrodsky@cs.ubc.ca, nicholas@cs.ubc.ca).

The first model, termed measure-once quantum finite automata (MO-QFAs), is similar to the one introduced by Moore and Crutchfield [12]. The second model, termed measure-many quantum finite automata (MM-QFAs), is similar to the one introduced by Kondacs and Watrous [9] and is more complex than the MO-QFA. The main difference between the two models is that a MO-QFA performs one measurement at the end of its computation, while a MM-QFA performs a measurement after every transition. This makes the measure-many model more powerful than the measure-once model, where the power of a model refers to the acceptance capability of the corresponding automata.

First, we present results dealing with MO-QFAs. We show that the class of languages accepted by MO-QFAs with bounded error is exactly the class of group languages. Consequently, this class of languages accepted by MO-QFAs is closed under inverse homomorphisms, word quotients, and Boolean operations. We show that MO-QFAs that do not accept with bounded error can accept nonregular languages and, in particular, can solve the word problem over the free group. We also describe an algorithm that determines if two MO-QFAs are equivalent and prove that probabilistic finite automata (PFAs) can simulate MO-QFAs.

Second, we shift our focus to MM-QFAs. We show that the classes of languages accepted by these automata are closed under complement, inverse homomorphisms, and word quotients. We prove by example that the class of languages accepted by MM-QFAs with bounded error is not closed under homomorphisms and prove a necessary condition for membership within this class. We also relate the sufficiency of this condition to the question of whether the class is closed under Boolean operations. Finally, we show, by construction, that MM-QFAs can accept piecewise testable sets with bounded error and introduce novel concepts for constructing MM-QFAs.

The rest of the paper is organized in the following way: section 2 contains the definitions of the quantum automata and background information, section 3 discusses measure-once quantum finite automata, section 4 discusses measure-many quantum finite automata, and section 5 summarizes.

2. Definitions and background.

2.1. Definition of an MO-QFA.

An MO-QFA is defined by a 5-tuple:

$$M = (Q, \Sigma, \delta, q_0, F),$$

where Q is a finite set of states; Σ is a finite input alphabet with an end-marker symbol \$; δ is the transition function

$$\delta : Q \times \Sigma \times Q \to \mathbb{C}$$

that represents the probability density amplitude that flows from state q to state q' upon reading symbol σ; the state q_0 is the initial configuration of the system; and F is the set of accepting states. For all states $q_1, q_2 \in Q$ and symbols $\sigma \in \Sigma$ the function δ must be unitary, thus satisfying the condition

$$\sum_{q' \in Q} \overline{\delta(q_1, \sigma, q')}\delta(q_2, \sigma, q') = \begin{cases} 1, & q_1 = q_2, \\ 0, & q_1 \neq q_2. \end{cases} \tag{2.1}$$

We assume that all input is terminated by the end-marker \$; this is the last symbol read before the computation terminates. At the end of a computation, M measures

its configuration; if it is in an accepting state, then it accepts, otherwise it rejects. This definition is equivalent to that of the QFA defined by Moore and Crutchfield [12].

The configuration of M is a linear superposition of states and is represented by an n-dimensional complex unit vector, where $n = |Q|$. This vector is denoted by

$$|\Psi\rangle = \sum_{i=1}^{n} \alpha_i |q_i\rangle,$$

where $\{|q_i\rangle\}$ is the set of orthonormal basis vectors corresponding to the states of M. The coefficient α_i is the probability density amplitude of M being in state q_i. Since $|\Psi\rangle$ is a unit vector, it follows that $\sum_{i=1}^{n} |\alpha_i|^2 = 1$.

The transition function δ is represented by a set of unitary matrices $\{U_\sigma\}_{\sigma\in\Sigma}$ where U_σ represents the unitary transitions of M upon reading symbol σ. If M is in configuration $|\Psi\rangle$ and reads symbol σ, then the new configuration of M is denoted by

$$|\Psi'\rangle = U_\sigma |\Psi\rangle = \sum_{q_i,q_j\in Q} \alpha_i \delta(q_i, \sigma, q_j) |q_j\rangle.$$

Measurement is represented by a diagonal zero-one projection matrix P where $P_{ii} = [q_i \in F]$. The probability of M accepting string x is defined by

$$p_M(x) = \langle \Psi_x | P | \Psi_x \rangle = \| P|\Psi_x\rangle \|^2,$$

where $|\Psi_x\rangle = U(x)|q_0\rangle = U_{x_n} U_{x_{n-1}} \dots U_{x_1} |q_0\rangle$.

2.2. Definition of an MM-QFA. An MM-QFA is defined by a 6-tuple:

$$M = (Q, \Sigma, \delta, q_0, Q_{acc}, Q_{rej}),$$

where Q is a finite set of states, Σ is a finite input alphabet with an end-marker symbol \$, δ is a unitary transition function of the same form as for an MO-QFA, and the state q_0 is the initial configuration of M. The set Q is partitioned into three subsets: Q_{acc} is the set of halting accepting states, Q_{rej} is the set of halting rejecting states, and Q_{non} is the set of nonhalting states.

The operation of an MM-QFA is similar to that of an MO-QFA except that after every transition, M measures its configuration with respect to the three subspaces that correspond to the three subsets Q_{non}, Q_{acc}, and Q_{rej}: $E_{non} = \mathit{Span}(\{|q\rangle \mid q \in Q_{non}\})$, $E_{acc} = \mathit{Span}(\{|q\rangle \mid q \in Q_{acc}\})$, and $E_{rej} = \mathit{Span}(\{|q\rangle \mid q \in Q_{rej}\})$. If the configuration of M is in E_{non}, then the computation continues; if the configuration is in E_{acc}, then M accepts, otherwise it rejects. After every measurement the superposition collapses into the measured subspace and is renormalized.

Just like MO-QFAs, the configuration of an MM-QFA is represented by a complex n-dimensional vector, the transition function is represented by unitary matrices, and measurement is represented by diagonal zero-one projection matrices that project the vector onto the respective subspaces.

The definition of an MM-QFA is almost identical to the definition by Kondacs and Watrous in [9]. The only difference is that we require only one end-marker at the end of the tape, rather than two end-markers at the start and end of the tape; this does not affect the acceptance power of the automaton; see Appendix A for further details.

Since M can have a nonzero probability of halting partway through the computation, it is useful to keep track of the cumulative accepting and rejecting probabilities.

Therefore, in some cases we use the representation of Kondacs and Watrous [9] that represents the state of M as a triple $(|\Psi\rangle, p_{acc}, p_{rej})$, where p_{acc} and p_{rej} are the cumulative probabilities of accepting and rejecting. The evolution of M on reading symbol σ is denoted by

$$(P_{non}|\Psi'\rangle,\ p_{acc} + \|P_{acc}|\Psi'\rangle\|^2,\ p_{rej} + \|P_{rej}|\Psi'\rangle\|^2),$$

where $|\Psi'\rangle = U_\sigma|\Psi\rangle$, and P_{acc}, P_{rej}, and P_{non} are the diagonal zero-one projection matrices that project the configuration onto the nonhalting, accepting, and rejecting subspaces.

2.3. Language acceptance. A QFA M is said to accept a language L with cut-point λ if for all $x \in L$, the probability of M accepting x is greater than λ, and if for all $x \notin L$, the probability of M accepting x is at most λ. A QFA M accepts L with bounded error if there exists an $\epsilon > 0$ such that for all $x \in L$ the probability of M accepting x is greater than $\lambda + \epsilon$ and for all $x \notin L$ the probability of M accepting x is less than $\lambda - \epsilon$. We call ϵ the margin.

We partition the languages accepted by QFAs into several natural classes. Let the class $\mathbf{RMO}_\epsilon$ be the set of languages accepted by an MO-QFA with a margin of at least ϵ. Let the restricted class of languages, $\mathbf{RMO} = \cup_{\epsilon>0}\mathbf{RMO}_\epsilon$, be the set of languages accepted by an MO-QFA with bounded error, and let the unrestricted class of languages, $\mathbf{UMO} = \mathbf{RMO}_0$, be the set of languages accepted by an MO-QFA with unbounded error. We define the languages classes $\mathbf{RMM}_\epsilon$, $\mathbf{RMM}$, and $\mathbf{UMM}$ accepted by an MM-QFA in a similar fashion.

Since the cut-point of a QFA can be arbitrarily raised or lowered, we could without loss of generality fix the cut-point to be $\frac{1}{2}$. However, for the purposes of presentation we use the general cut-point definition stated above.

2.4. Reversible finite automata. Unitary operations are reversible, thus QFAs bear a strong resemblance to various variants of reversible finite automata. A group finite automaton (GFA) is a deterministic finite automaton (DFA) $M = (Q, \Sigma, \delta, q_0, F)$ with the restriction that for every state $q \in Q$ and every input symbol $\sigma \in \Sigma$ there exists exactly one state $q' \in Q$ such that $\delta(q', \sigma) = q$, i.e., δ is a complete one-to-one function and the automaton derived from M by reversing all transitions is deterministic.

A reversible finite automata (RFA) is a DFA $M = (Q, \Sigma, \delta, q_0, F)$ such that for every state $q \in Q$ and for every symbol $\sigma \in \Sigma$ there is at most one state $q' \in Q$ such that $\delta(q', \sigma) = q$, or, if there exist distinct states $q_1, q_2 \in Q$ and symbol $\sigma \in \Sigma$ such that $\delta(q_1, \sigma) = q = \delta(q_2, \sigma)$, then $\delta(q, \Sigma) = \{q\}$. The latter type of state is called a spin state because once an RFA enters it, it will never leave it. This definition is equivalent to the one used by Ambainis and Freivalds [3] and is an extension of Pin's [17] definition.

2.5. Previous work. Moore and Crutchfield [12] introduced a variant of the MO-QFA model and investigated the model in terms of quantum regular languages (QRLs). They showed several closure properties including closure under inverse homomorphisms and derived a method for bilinearizing the representation of an MO-QFA that transforms it into a generalized stochastic system.

Kondacs and Watrous [9] introduced a variant of the MM-QFA that was derived from their 2QFA model. Using a technique similar to Rabin's [18], Kondacs and Watrous proved that 1QFAs that accept with bounded error are restricted to accepting a proper subset of the regular languages and that the language $L = \{a, b\}^*b$ is not a member of that subset.

Ambainis and Freivalds [3] showed that MM-QFAs could accept languages with probability higher than $\frac{7}{9}$ if and only if the language could be accepted by an RFA, which is equivalent to being accepted with certainty by an MM-QFA. In [2] Ambainis, Bonner, Freivalds, and Kikusts construct a hierarchy of languages such that the ith language in the hierarchy can be accepted by an MM-QFA with at most probability p_i, where the series (p_i) converges to $\frac{1}{2}$ and is strictly decreasing.

Ambainis, Nayak, Ta-Shma, and Vazirani [5], and Nayak [13], investigated how efficiently MM-QFAs can be constructed compared to DFAs. They showed that for some languages the accepting MM-QFA is exponentially larger than the corresponding DFA.

In [1] Amano and Iwama studied a restricted version of the 2QFA model where the head was not allowed to move right. They showed that the emptiness problem for this model is not decidable. This is another instance where quantum mechanics provides computational power that is not achievable in the classical case.

3. MO-QFAs.

3.1. Bounded error acceptance. Restricting MO-QFAs to accept with bounded error greatly reduces their accepting power; this is not surprising since PFAs suffer a similar fate [18]. Since MM-QFAs can accept only a proper subset of the regular languages if they are required to accept with bounded error and since every MO-QFA can be simulated exactly by an MM-QFA, the class **RMO** is a proper subset of the regular languages. The class **RMO** is exactly the class of languages accepted by GFAs, otherwise known as group languages, and whose syntactic semigroups are groups; see Eilenberg [7]. This result is implied by Theorem 7 in [12] but is not stated in the paper. To prove this result we first need Lemma 3.1.

LEMMA 3.1. *Let U be a unitary matrix. For any $\epsilon > 0$ there exists an integer $n > 0$ such that for all vectors x, where $\|x\|^2 \leq 1$, it is true that $\|(I - U^n)x\|^2 < \epsilon$.*

Proof. Let $m = \dim(U)$. Since U is a normal matrix, U^n can be written as

$$U^n = PD^nP^{-1},$$

where P is a unitary matrix and D is the diagonal matrix of eigenvalues with the jth eigenvalue having the form $e^{i\pi r_j}$ [14]. If all eigenvalues in D are rotations through rational fractions of π, i.e., r_j is rational, then let $n = 2\prod_{j=1}^{m} q_j$, where q_j is the denominator of r_j. Thus $D^n = I$ and we are done.

Otherwise, at least one eigenvalue is a rotation of unity through an irrational fraction of π. Let $l \leq m$ be the number of these eigenvalues. For the other $m - l$ eigenvalues compute n, just as above, and let $D' = D^n$. The value of the jth element on the diagonal of D' is either 1 or $e^{i\pi n r_j}$, where r_j is some irrational real number. Consider taking D' to some power $k \in \mathbb{Z}^+$. The values that are 1 do not change, but the other l values that are of the form $e^{i\theta_j k}$, where $\theta_j = \pi n r_j$, form a vector that varies through a dense subset in an l-dimensional torus. Hence, there exists k such that the l-dimensional vector is arbitrarily close to $\vec{1} = (1, 1, \ldots, 1)$. Thus, for any $\epsilon' > 0$ there exists a $k > 0$ such that $\|(I - D'^k)\vec{1}\|^2 < \epsilon'$. Hence

$$\begin{aligned}
\|(I - U^{nk})x\|^2 &= \|(I - PD^{nk}P^{-1})x\|^2 \\
&= \|P(I - D'^k)P^{-1}x\|^2 \\
&\leq \|(I - D'^k)m\vec{1}\|^2 \\
&= m^2\|(I - D'^k)\vec{1}\|^2 \\
&\leq m^2\epsilon'.
\end{aligned}$$

Select ϵ' such that $\epsilon' < \frac{\epsilon}{m^2}$ to complete the proof. □

Lemma 3.2, due to Bernstein and Vazirani [6], states that if two configurations are close, then the differences in probability distributions of the configurations are small. This lemma relates the closeness of configurations to the variation distance between their probability distributions and allows us to partition the set of reachable configurations into equivalence classes. The variation distance between two probability distributions is the maximum difference in the probabilities of the same event occurring with respect to both distributions.

LEMMA 3.2 (Bernstein and Vazirani [6]). *Let $|\psi\rangle$ and $|\varphi\rangle$ be two complex vectors such that $\| |\psi\rangle\|^2 = \| |\varphi\rangle\|^2 = 1$ and $\| |\psi\rangle - |\varphi\rangle\|^2 < \epsilon$. The total variation distance between the probability distributions resulting from the measurement of $|\psi\rangle$ and $|\varphi\rangle$ is at most 4ϵ.*

Theorem 3.3 follows from these two lemmas.

THEOREM 3.3. *A language L can be accepted by an MO-QFA with bounded error if and only if it can be accepted by a GFA.*

Proof. The "if" direction follows from the fact that the transition function for a GFA is also a valid transition function for an MO-QFA that can accept the same language with certainty.

For the "only if" direction, by contradiction, assume that there exists a language L that can be accepted by an MO-QFA with bounded error but cannot be accepted by a GFA. Since the class **RMO** is a subset of the regular languages, L must be regular. Let $M = (Q, \Sigma, \delta, q_0, F)$ be an MO-QFA that accepts L with bounded error. If two strings x and y take M into the same reachable configuration, then for any string z the probability of M accepting xz is equal to the probability of M accepting yz, which means that $xz \in L$ if and only if $yz \in L$. Therefore, the space of reachable configurations of M's computation can be partitioned into a finite number of equivalence classes defined by the corresponding minimal DFA for L.

Let $|\psi\rangle$ and $|\varphi\rangle$ denote reachable configurations of M and let $\sim_L$ be the right invariant equivalence relation induced by L. Since L cannot be accepted by a GFA, there must exist two distinct equivalence classes $[y]$ and $[y']$, an equivalence class $[x]$, and a symbol $\sigma \in \Sigma$ such that $[y\sigma] \sim_L [y'\sigma] \sim_L [x]$. If U_σ is the transition matrix for symbol σ, $|\psi\rangle \in [y]$ and $|\varphi\rangle \in [y']$, then $U_\sigma|\psi\rangle \in [x]$ and $U_\sigma|\varphi\rangle \in [x]$.

Since M accepts L with bounded error, let ϵ be the margin. By Lemma 3.1 there exists an integer $k > 0$ such that $\|(I - U_\sigma^k)|\psi\rangle\|^2 < \frac{\epsilon}{4}$ and $\|(I - U_\sigma^k)|\varphi\rangle\|^2 < \frac{\epsilon}{4}$. Hence, $U_\sigma^k|\psi\rangle \in [y]$ because if

$$\begin{aligned}\|(I - U_\sigma^k)|\psi\rangle\|^2 &= \| |\psi\rangle - U_\sigma^k|\psi\rangle\|^2 \\ &= \|V(|\psi\rangle - U_\sigma^k|\psi\rangle)\|^2 \\ &< \frac{\epsilon}{4},\end{aligned}$$

where V is an arbitrary unitary matrix, then by Lemma 3.2 the probability of $VU_\sigma^k|\psi\rangle$ being measured in a particular state is within ϵ of $V|\psi\rangle$ being measured in the same state; this probability is less than the margin. Similarly $U_\sigma^k|\varphi\rangle \in [y']$. Hence $[y] \sim_L [y\sigma^k]$ and $[y'] \sim_L [y'\sigma^k]$.

We assumed that $[x] \sim_L [y\sigma] \sim_L [y'\sigma]$ and showed that $[y] \sim_L [y\sigma^k]$ and $[y'] \sim_L [y'\sigma^k]$; therefore, $[y] \sim_L [x\sigma^{k-1}] \sim_L [y']$. Let z be the string that distinguishes $[y]$ and $[y']$. Then the string $\sigma^{k-1}z$ partitions $[x]$ into at least two distinct equivalence classes, but this is a contradiction. Therefore, there cannot exist a language L that can be accepted by an MO-QFA with bounded error but not by a GFA. □

Theorem 3.3 implies that $\mathbf{RMO}_\epsilon = \mathbf{RMO}_{\epsilon'}$ for all $\epsilon, \epsilon' > 0$; hence there are most two distinct classes of languages accepted by MO-QFAs: the restricted class **RMO**, which is equivalent to the class of languages accepted by a GFA, and the unrestricted class **UMO**.

It follows immediately from Theorem 3.3 that the class **RMO** is closed under Boolean operations, inverse homomorphisms, and word quotients and is not closed under homomorphisms.

3.2. Nonregular languages. Unlike the class **RMO**, the class **UMO** contains languages that are nonregular. This is not surprising given that Rabin [18] proved a similar result for PFAs. In fact our proof closely mimics Rabin's [18] technique.

LEMMA 3.4. *Let $L = \{x \in \{a,b\}^* \mid |x|_a \neq |x|_b\}$; there exists a 2-state MO-QFA M that accepts L with cut-point 0.*

Proof. Let $M = (Q, \Sigma, \delta, q_0, F)$, where $Q = \{q_0, q_1\}$, $\Sigma = \{a, b\}$, $F = \{q_1\}$, and δ is defined by the transition matrices

$$U_a = U_b^{-1} = \begin{bmatrix} \cos\alpha & \sin\alpha \\ -\sin\alpha & \cos\alpha \end{bmatrix},$$

where α is an irrational fraction of π. Since U_a is a rotation matrix and α is an irrational fraction of π, the orbit formed by applying U_a to $|q_0\rangle$ is dense in the circle, and there exists only one k, such that $U_a^k|q_0\rangle = |q_0\rangle$, namely $k = 0$. This also holds for $U_b = U_a^{-1}$. Thus, $U(x)|q_0\rangle = |q_0\rangle$ if and only if the number of U_a rotations applied to $|q_0\rangle$ is equal to the number of U_b rotations, which is true if and only if the $|x|_a = |x|_b$. Otherwise, M has a nonzero probability of halting in state q_1. ∎

Lemma 3.4 implies that the class **RMO** is properly contained within the class **UMO**, and therefore the two classes are distinct.

The MO-QFA in Lemma 3.4 solves the word problem for the infinite cyclic group: is the input word equal to the identity element in the group, where the group has only one generator element, say a, and its inverse $b = a^{-1}$? We can generalize this result to the general word problem for the free group. The word problem for a free group is to decide whether or not a product of a sequence of elements of the free group reduces to the identity [10].

LEMMA 3.5. *The word problem for the free group language can be accepted by an MO-QFA.*

Proof. Construct a free group of rotation matrices drawn from the group SO_3 as discussed by Wagon [20]. Let $M = (Q, \Sigma, \delta, q_0, F)$ be a 3-state MO-QFA where $\Sigma = \{a, a^{-1}, b, b^{-1}, \dots\}$ such that $|\Sigma|$ is equal to the sum of the number of rotation matrices and their inverses, δ is defined by the rotation matrices and their inverses, and $F = \{q_0\}$. The MO-QFA will accept identity words with certainty and reject non-identity words with a strictly nonzero probability, hence solving the word problem for the free group. ∎

3.3. Equivalence of MO-QFAs. In classical automata theory there is an algorithm to determine if two automata are equivalent. We say that QFAs M and M' are equivalent if their probability distributions over Σ^* are the same: for every word $x \in \Sigma$, the probability of M accepting x is equal to the probability of M' accepting x. In order to determine if two MO-QFAs are equivalent we first bilinearize them using the method detailed by Moore and Crutchfield [12]; this yields two generalized stochastic systems. We then apply Paz's [15, p. 21, p. 140] method for testing stochastic system equivalence to the generalized stochastic systems to determine if they have the same distribution.

3.4. Simulation of MO-QFAs by PFAs. Most classical computation is either deterministic or probabilistic; hence it is useful to ask how probabilistic automata compare to their quantum analogues. In the case of MO-QFAs, any language accepted by an MO-QFA can also be accepted by a PFA. If L can be accepted by an MO-QFA with bounded error, then it can also be accepted by a PFA with bounded error.

THEOREM 3.6. *Let M be an MO-QFA that accepts L with cut-point λ; then*

1. *there exists a PFA that accepts L with some cut-point λ',*
2. *if M accepts L with bounded error, then there exists a PFA that accepts L with bounded error.*

Proof. The second result follows from Theorem 3.3 because every GFA is also a PFA.

Since we can bilinearize M, L is a generalized cut-point event (GCE) [15, p. 153]. Since the class of GCEs is equal to the class of probabilistic cut-point events (PCEs) [15, p. 153], which are accepted by PFAs, there exists a PFA that can accept L with some cut-point λ'. □

Combining Theorem 3.6 with Lemma 3.5 yields a new insight into the languages accepted by PFAs.

COROLLARY 3.7. *The word problem for the free group language can be solved by a PFA.*

4. MM-QFAs. MM-QFAs are more powerful than MO-QFAs because a measurement is performed after every transition. This allows the machine to terminate before reading the entire string and simulate the spin states of RFAs.

As mentioned before, an MM-QFA uses one end-marker while the Kondacs and Watrous [9] 1QFA uses two end-markers. The second marker does not add any more power to the model (see Appendix A) but makes constructing an MM-QFA easier because the MM-QFA can start in an arbitrary configuration. Hence, for the sake of conciseness and clarity we shall assume that some of the MM-QFAs constructed in the following proofs have two end-markers.

4.1. Closure properties. Unlike the closure properties of the classes **RMO** and **UMO**, which can be derived easily, the closure properties of the classes **RMM** and **UMM** are not as evident and in one important case are unknown. We show that the classes **RMM** and **UMM** are closed under complement, inverse homomorphism, and word quotient. Similar to the class **RMO**, the class **RMM** is not closed under homomorphisms. It remains an open problem to determine whether the classes **RMM** and **UMM** are closed under Boolean operations.

Theorem 4.1 proves that both classes are closed under complement and inverse homomorphisms by showing that each class $\mathbf{RMM}_\epsilon$ is closed under complement and inverse homomorphisms; closure under word quotient follows directly from the latter, given the presence of end-markers.

THEOREM 4.1. *The class $\mathbf{RMM}_\epsilon$ is closed under complement, inverse homomorphisms, and word quotient.*

Proof. Closure under complement follows from the fact that we can exchange the accept and reject states of the MM-QFA. This exchanges the probabilities of acceptance and rejection but does not affect the margin.

Given an MM-QFA M and a homomorphism h we construct an MM-QFA M' that accepts $h^{-1}(L)$. Let $M = (Q, \Sigma, \delta, Q_{acc}, Q_{rej})$ and $M' = (Q', \Sigma, \delta', Q'_{acc}, Q'_{rej})$. Assume that δ and δ' are defined in terms of matrices $\{U_\sigma\}_{\sigma\in\Sigma}$ and $\{U'_\sigma\}_{\sigma\in\Sigma}$. Unlike the proof for MO-QFAs in [12], the direct construction of

$$U'_\sigma = U(h(\sigma))$$

will not work because a measurement occurs between transitions, and combining transitions without taking this into account could produce incorrect configurations. After every transition some amount of probability amplitude is placed in the halting states and should not be allowed to interact with the nonhalting states in the following transitions. This is achieved by storing the amplitude in additional states; this technique is also used in [5]. Assume without loss of generality that

$$Q_{non} = \{q_i \in Q \mid 0 \le i < n_{non}\},$$
$$Q_{halt} = \{q_i \in Q \mid n_{non} \le i < n\},$$

where $n = |Q|$ and $n_{non} = |Q_{non}|$. Let $m = \max_{\sigma\in\Sigma}\{|h(\sigma)|\}$ and let

$$Q' = Q \cup Q'_{halt},$$

where

$$Q'_{halt} = \{q_i\}_{i=n+1}^{n+m(n-n_{non})},$$
$$Q'_{acc} = Q_{acc} \cup \{q_{n+j(i-n_{non})} \in Q'_{halt} \mid q_i \in Q_{acc}, 1 \le j \le m\},$$
$$Q'_{rej} = Q_{rej} \cup \{q_{n+j(i-n_{non})} \in Q'_{halt} \mid q_i \in Q_{rej}, 1 \le j \le m\}.$$

Intuitively, we replicate the halting states m times; each replication is termed a halting state set.

We construct δ' from the matrices of δ. Let V_σ be a unitary block matrix

$$V_\sigma = U_{shift} \begin{bmatrix} U_\sigma & \\ & I_{m(n-n_{non})} \end{bmatrix},$$

where

$$U_{shift} = \begin{bmatrix} I_{n_{non}} & & \\ & & I_{n-n_{non}} \\ & I_{m(n-n_{non})} & \end{bmatrix}.$$

The matrix U_{shift} is a unitary matrix that shifts the amplitudes in the halting set i to the halting set $i+1$ and the amplitude in halting set m to halting set 0. Analogous to the MO-QFA case where $U'_\sigma = U(h(\sigma))$, for MM-QFAs let

$$U'_\sigma = V(h(\sigma)) = V_{x_k} V_{x_{k-1}} \dots V_{x_1},$$

where $h(\sigma) = x = x_1 x_2 \dots x_k$ and $k \le m$.

After every x_i subtransition the halting amplitude is shifted and stored in the $m+1$ halting sets of states. When the subtransition is done, the amplitude in halt state set 0 is zero, which is what is required to prevent unwanted interactions. A minimum of m subtransitions must occur before halting set m contains nonzero amplitude, but no more than m subtransitions will ever occur; therefore halting set 0 will never receive nonzero amplitude from halting set m. Since M' has the same distribution as M, the margin will not decrease.

Closure under word quotient follows from closure under inverse homomorphism and the presence of both end-markers. □

Just like the class **RMO**, the class **RMM** is not closed under homomorphisms.

THEOREM 4.2. *The class* **RMM** *is not closed under homomorphisms.*

Proof. Let $L = \{a, b\}^* c$ and define a homomorphism h to be $h(a) = a$, $h(b) = b$, and $h(c) = b$. Since L can be accepted by an RFA, $L \in \mathbf{RMM}$ [3], but $h(L) = \{a, b\}^* b \notin \mathbf{RMM}$, the result follows. □

A more interesting question is whether the classes **RMM** and **UMM** are closed under Boolean operations. Unlike MO-QFAs that have two types of states, accept and reject, MM-QFAs have three types of states: accept, reject, and nonhalt. Consequently, the standard procedure of taking the tensor product of two automata to obtain their intersection or union does not work. A general method of intersecting two MM-QFAs is not known. Thus, it is not known whether **RMM** and **UMM** are closed under Boolean operations.

4.2. Bounded error acceptance. The restriction of bounded error acceptance reduces the class of languages that an MM-QFA can accept to a proper subclass of the regular languages [9]. To study the languages in class **RMM**, we look at their corresponding minimal automata. Ambainis and Freivalds [3] showed that if the minimal DFA $M(L) = (Q, \Sigma, \delta, q_0, F)$ contains an irreversible construction, defined by two distinct states $q_1, q_2 \in Q$ and strings $x, y, z \in \Sigma^*$ such that $\delta(q_1, x) = \delta(q_2, x) = q_2$, $\delta(q_2, y) \in F$, and $\delta(q_2, z) \notin F$, then an RFA cannot accept L and an MM-QFA cannot accept it with a probability greater than $\frac{7}{9}$; this condition is both sufficient and necessary.

We derive a similar necessary condition for a language L to be a member of the class **RMM**. This condition, called the partial order condition, is a relaxed version of a condition defined by Meyer and Thompson [11]. A language L is said to satisfy the partial order condition if the minimal DFA for L satisfies the partial order condition. A DFA satisfies the partial order condition if it does not contain two distinguishable states $q_1, q_2 \in Q$ such that there exists strings $x, y \in \Sigma^+$, where $\delta(q_1, x) = \delta(q_2, x) = q_2$, and $\delta(q_2, y) = q_1$. States q_1 and q_2 are said to be distinguishable if there exists a string $z \in \Sigma^*$ such that $\delta(q_1, z) \in F$ and $\delta(q_2, z) \notin F$ or vice versa [8]. Using a result in [9], Theorem 4.3 proves that the partial order condition is necessary for an MM-QFA to accept L with bounded error.

THEOREM 4.3. *If $M = (Q, \Sigma, \delta, q_0, F)$ is a minimal DFA for language L that does not satisfy the partial order condition, then $L \notin \mathbf{RMM}$.*

Proof. By contradiction, assume that $L \in \mathbf{RMM}$. Let $L_b = \{a, b\}^* b$. Since the minimal DFA for L does not satisfy the partial order condition, there exist states $q_1, q_2 \in Q$ and strings $x, y \in \Sigma^+$ as defined above and a distinguishing string $z \in \Sigma^*$ such that $\delta(q_1, z) \notin F$ if and only if $\delta(q_2, z) \in F$. Without loss of generality assume that $\delta(q_1, z) \notin F$ and $\delta(q_2, z) \in F$.

Let s be the shortest string such that $\delta(q_0, s) = q_1$. Let $L' = s^{-1} L z^{-1}$. By Theorem 4.1, $L' \in \mathbf{RMM}$. Define the homomorphism h as

$$\begin{aligned} h(a) &= xy, \\ h(b) &= x, \\ h(\Sigma - \{a, b\}) &= xy, \end{aligned}$$

where the last definition is for completeness. Let $L'' = h^{-1}(L')$. By Theorem 4.1 $L'' \in \mathbf{RMM}$. But $L'' = L_b \notin \mathbf{RMM}$, a contradiction. □

The partial order condition is so named because once the state q_2 is visited, there is no path back to state q_1. Thus, there exists a partial order on the states of the DFA. We do not know whether this condition is also sufficient for MM-QFA acceptance with bounded error. While we do not know whether the class **RMM** is

closed under Boolean operations, Theorem 4.6 relates closure under intersection to the partial order condition.

LEMMA 4.4. *Let M be a DFA that satisfies the partial order condition. The minimal DFA M' that accepts $L(M)$ satisfies the partial order condition.*

Proof. Let $M = (Q, \Sigma, \delta, q_0, F)$ be a DFA and $M' = (Q', \Sigma, \delta', q_0', F')$ be the corresponding minimal DFA. Assume by contradiction that M' does not satisfy the partial order condition. Hence, M' has two states that correspond to the equivalence classes $[q_1']$ and $[q_2']$ such that $[q_1']x \sim_L [q_2']x \sim_L [q_2']$ and $[q_2']y \sim_L [q_1']$. By the Myhill–Nerode theorem [8], the equivalence classes partition the set of reachable states in Q. Hence, for each equivalence class $[q_i']$ there is a corresponding subset of Q. Let Q_1 and Q_2 denote the subsets of Q corresponding to the equivalence classes $[q_1']$ and $[q_2']$ and assign an arbitrary order on each subset. Select the first state, say $p_1 \in Q_1$, and define the set $R = \{q \in Q_2 \mid \exists n, m \in \mathbb{Z}^+,\ \delta(p_1, x^m) = \delta(q, x^n) = q\}$. If there exists a state $r \in R$ and string $y \in \Sigma^+$ such that $\delta(r, y) = p_1$, then M does not satisfy the partial order condition, and this is a contradiction. Otherwise, there does not exist a $y \in \Sigma^+$ such that $\delta(r, y) = p_1$ for all $r \in R$. In this case there is a partial order on p_1 and on $Q_1 \backslash \{p_1\}$ because p_1 will never be visited again if M reads a sufficient number of x's. Remove p_1 from Q_1 and repeat the procedure on $p_2 \in Q_1$. After a finite number of iterations either we will find a p_i that satisfies our requirements, which means that M does not satisfy the partial order condition and is a contradiction, or none of the states in Q_1 will have the required characteristics, in which case M' satisfies the partial order condition. Therefore, if M satisfies the partial order condition, so will its minimal equivalent M'. □

LEMMA 4.5. *Let L' and L'' be languages that satisfy the partial order condition. Then $L = L' \cap L''$ also satisfies the partial order condition.*

Proof. Let $M' = (Q', \Sigma, \delta', q_0', F')$ be the minimal DFA accepting the language L' and let $M'' = (Q'', \Sigma, \delta'', q_0'', F'')$ be the minimal DFA accepting the language L''. We first construct an automaton M that accepts $L' \cap L''$ by combining M' and M'' using a direct product. Define $M = (Q, \Sigma, \delta, q_{00}, F)$, where $Q = Q' \times Q''$, $q_{00} = (q_0', q_0'')$, $F = \{(q', q'') \in Q \mid q' \in F' \ \wedge \ q'' \in F''\}$, and $\delta((q', q''), \sigma) = (\delta'(q', \sigma), \delta''(q'', \sigma))$.

We argue that if M' and M'' satisfy the partial order condition, then so will M. Assume, by contradiction, that M does not satisfy the partial order condition. Then there exist two states $q_{ij} = (q_i', q_j'')$ and $q_{kl} = (q_k', q_l'')$ and strings $x, y, z \in \Sigma^+$ such that $\delta(q_{ij}, x) = \delta(q_{kl}, x) = q_{kl}$, $\delta(q_{kl}, y) = q_{ij}$, and $\delta(q_{ij}, z) \in F$ if and only if $\delta(q_{kl}, z) \notin F$. In the first case assume that either $i \neq k$ or $j \neq l$, and without loss of generality, assume the former. Then there exists state $q_i' \in Q'$ and state $q_k' \in Q'$ such that $\delta'(q_i', x) = \delta'(q_k', x) = q_k'$, $\delta_1(q_k', y) = q_i'$. But this means that M' does not satisfy the partial order condition, a contradiction. In the second case assume that $i = k$ and $j = l$. This implies that $q_{ij} = q_{kl}$ and hence there cannot exist a string z that distinguishes the two states, also a contradiction. Therefore M must satisfy the condition.

Since M satisfies the partial order condition and accepts L, by Lemma 4.4 the minimal automaton that accepts L satisfies the partial order condition, and hence L itself satisfies the partial order condition. □

THEOREM 4.6. *If the partial order condition is sufficient for acceptance with bounded error by MM-QFAs, then the class* **RMM** *is closed under intersection.*

Proof. By Lemma 4.5 the intersection of two languages that satisfy the partial order condition is a language that satisfies the partial order condition. □

One method for proving that the class **RMM** is not closed under intersection

involves intersecting two languages in **RMM** and showing that the resulting language is not in **RMM**. By Theorem 4.6 this method will not work unless the partial order condition is insufficient. To study whether the partial order condition is sufficient, as well as necessary, we show that a well-known class of languages can be accepted by an MM-QFA with bounded error.

4.3. Piecewise testable sets. A piecewise testable set is a Boolean combination of sets of the form

$$L_z = \Sigma^* z_1 \Sigma^* z_2 \Sigma^* \dots \Sigma^* z_n \Sigma^*,$$

where $z_i \in \Sigma$ [16]. Intuitively, L_z is the language of strings that contains the successive symbols of z as a subsequence; we call such a language a partial piecewise testable set.

Piecewise testable sets, introduced by Simon in [19], form a natural family of star-free languages. Such sets define a class of computations that wait for a partially ordered sequence of trigger events (input symbols); if a trigger event (symbol) is read that is not next in the sequence, it is simply ignored. Another natural interpretation of piecewise testable sets is subsequence searching. Consider a language where a word is said to be in the language if it contains a finite Boolean combination of subsequences. Such a language is a piecewise testable set and word acceptance corresponds to searching the words for the required subsequences. Finally, such languages belong to a class of languages whose MM-QFAs have an arbitrarily large, but finite, set of ordered states.

We show, by construction, that MM-QFAs can accept partial piecewise testable sets with bounded error. The MM-QFAs we construct accept with one-sided error and are what we call "end-decisive." We say that an MM-QFA accepts with positive one-sided error if it accepts strings in the language with nonzero probability and rejects strings not in the language with certainty. We say that an MM-QFA accepts with negative one-sided error if it accepts strings in the language with certainty and rejects strings not in the language with nonzero probability.

We say that an MM-QFA is end-decisive if it will not be observed in an accept state until the end-marker \$ is read. An MM-QFA is co-end-decisive if it will not be observed in a reject state until the end-marker is read.

Classes of languages that are accepted by end-decisive MM-QFAs with the same one-sided error, i.e., all positive or all negative, are closed under intersection and union. Furthermore, if language L can be accepted by an end-decisive MM-QFA with bounded error, and language L' can be accepted by an end-decisive MM-QFA with bounded one-sided error, then the union or intersection of L and L' can be accepted by an end-decisive MM-QFA with bounded error. To construct these MM-QFAs we introduce two useful concepts: junk states and trigger chains.

A junk state is a halting state of an end-decisive or co-end-decisive MM-QFA. If the MM-QFA is end-decisive, then all its junk states are reject states. If the MM-QFA is co-end-decisive, then all its junk states are accept states. An end-decisive or co-end-decisive MM-QFA may be observed in a junk state at any point of the computation. While junk states are either accept or reject states, we treat the junk state as a separate halting state. Any accept or reject state that is not a junk state is called a decisive state. Intuitively, a junk state signals a failed computation.

Each end-decisive or co-end-decisive automata that accepts with bounded error has probability, bounded by some constant $\tau < 1$, of ending up in a junk state and a probability $1 - \tau$ of ending up in a decisive state. If $\tau \not< 1$, then the amount

of probability amplitude ending up in a decisive state can become arbitrarily small, dropping below any fixed margin. Thus, τ must be strictly less than one for the MM-QFA to accept with bounded error; τ is independent of the input string x.

A trigger chain is a construction of junk states and transition matrices that causes a reduction in amplitude of a particular state only if the amplitude of another state is decreased, presumably by some previous transition. Trigger chains correspond directly to partial piecewise testable sets. Consider the matrix

$$X = \begin{bmatrix} \frac{1}{2} & \frac{1}{\sqrt{2}} & \frac{1}{2} \\ \frac{1}{\sqrt{2}} & 0 & -\frac{1}{\sqrt{2}} \\ \frac{1}{2} & -\frac{1}{\sqrt{2}} & \frac{1}{2} \end{bmatrix}.$$

This matrix is a special case of a transition matrix introduced by Ambainis and Freivalds [3]. This matrix operates on three states and is a triggering mechanism of the chain. Consider the vectors

$$|\psi\rangle = (\alpha, 0, \beta)^T$$

and

$$X|\psi\rangle = \left(\frac{\alpha}{2} + \frac{\beta}{2}, \frac{\alpha}{\sqrt{2}} - \frac{\beta}{\sqrt{2}}, \frac{\alpha}{2} + \frac{\beta}{2}\right)^T.$$

The vectors $|\psi\rangle$ and $X|\psi\rangle$ are equal if and only if $\alpha = \beta$. If $\alpha \neq \beta$, then the amplitudes of the first and third state are averaged, with the remainder of the amplitude going into the second state. We define a generalized version of X by embedding it into a larger identity block matrix. Define X_i to be

$$X_i = \begin{bmatrix} I_i & & \\ & X & \\ & & I_{s-i-3} \end{bmatrix},$$

where I_m is an $m \times m$ identity matrix, X is defined as above, and s is the number of states, i.e., the size of X_i. The matrix X_i operates on a triple of states, q_i through to q_{i+2}. We assume that state q_{i+1}, the second state, is a junk state unless otherwise noted.

THEOREM 4.7. *Let L_z be a partial piecewise testable set. There exists an end-decisive MM-QFA that accepts L_z with bounded positive one-sided error.*

Proof. We construct an MM-QFA M with $m+1$ states that accepts L_z where $z = z_0 z_1 \dots z_n$ and $m = 2n + 4$.

For each link in the trigger chain we require a junk state and a nonhalting state. We order the states to correspond with the description of the X_i matrices. Specifically, the first $2n+1$ states are the nonhalting states, interleaved with junk states. Each triple of states $(q_{2i}, q_{2i+1}, q_{2i+2})$ corresponds to a link of the trigger chain, of which there are $n+1$. State q_{2n+1} is the decisive accept state and state q_{2n+3} is the decisive reject state. The junk states are rejecting states.

Let $m = 2n + 4$ and $M = (Q, \Sigma, \delta, q_0, Q_{acc}, Q_{rej})$, where

$$\begin{aligned} Q &= \{q_0, \dots, q_m\}, \\ Q_{junk} &= \{q_i \in Q \mid 0 < i < 2n \ \wedge \ i \equiv 1 \bmod 2\} \cup \{q_{2n+4}\}, \\ Q_{acc} &= \{q_{2n+1}\}, \\ Q_{rej} &= \{q_{2n+3}\}. \end{aligned}$$

Define δ by the transition matrices $\{U_\sigma\}_{\sigma\in\Sigma}$. Each transition matrix U_σ consists of a product of matrices:

$$U_\sigma = U_{\sigma,0}U_{\sigma,1}\dots U_{\sigma,n},$$

where the matrices $U_{\sigma,i}$ implement the triggers.

Define $U_{\sigma,i}$ to be

$$U_{\sigma,i} = \begin{cases} S, & i = 0 \ \wedge \ z_0 = \sigma, \\ X_{2i-2}, & 1 \le i \le n \ \wedge \ z_i = \sigma, \\ I_{m+1}, & \text{otherwise}, \end{cases}$$

where

$$S = \begin{bmatrix} 0 & 1 & & \\ 1 & 0 & & \\ & & I_{m-1} & \end{bmatrix}.$$

The matrix S shifts the amplitude of q_0 to the junk state q_1. This is the first trigger that is activated when z_0 is read.

Finally, let the transition matrix for the end-marker \$ be

$$U_\$ = FX_{2n},$$

where

$$F = \begin{bmatrix} R & & & & & & & \\ & \ddots & & & & & & \\ & & R & & & & & \\ & & & 0 & 0 & 0 & 0 & 1 \\ & & & 0 & 1 & 0 & 0 & 0 \\ & & & 0 & 0 & 0 & 1 & 0 \\ & & & 0 & 0 & 1 & 0 & 0 \\ & & & 1 & 0 & 0 & 0 & 0 \end{bmatrix}$$

and the matrix

$$R = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}.$$

The matrix F sends all amplitude into the junk states. The matrix X_{2n} sends some minimum amount of amplitude into an accept state if the amplitudes of states q_{2n} and q_{2n+2} differ.

The initial configuration of the machine is $|\psi_{init}\rangle = (\alpha_0, \alpha_1, \dots, \alpha_m)^T$, where

$$\alpha_i = \begin{cases} \frac{1}{\sqrt{n+2}}, & 0 \le i \le 2n+2 \ \wedge \ i \equiv 0 \pmod 2, \\ 0, & \text{otherwise}, \end{cases}$$

i.e., the amplitude is evenly distributed among all nonhalting states.

The only decisive accepting state in the machine is q_{2n+1}, and amplitude flows into it only when the end-marker is read. In order for it to get a nonzero amplitude, the amplitudes of states q_{2n} and q_{2n+2} must differ. Since all nonhalting states start

with the same amplitude, and since the amplitude of state q_{2n+2} will not change during the execution of the machine until the end-marker is read, the amplitude of state q_{2n-2} must change in order for the amplitude of state q_{2n} to change. Following the same argument, state q_{2i} will not change in amplitude until state q_{2i-2} changes in amplitude. Furthermore, the change in amplitude of state q_{2i} is governed by the matrix components X_{2i-2} and X_{2i}. Hence, the initial change of amplitude of state q_{2i} depends exclusively on a change in amplitude of state q_{2i-2} and is governed by component X_{2i-2} that is located in the transition matrix U_{z_i}. If any other transition matrix is applied, then the amplitude of state q_{2i} will not change. Hence, M can read $(\Sigma - \{z_i\})^*$ without changing the amplitude of state q_{2i}, but, as soon as z_i is read, component X_{2i-2} will be applied and q_{2i} will have a decreased amplitude, provided state q_{2i-2} already had a decrease of its amplitude. Finally, the amplitude of any state q_{2i} will never increase beyond its initial value, and once the amplitude of state q_{2i} decreases, it will never increase beyond $\frac{1}{\sqrt{n+2}}(1 - (\frac{1}{2})^{n+1})$. For the case of symbol z_0, the amplitude of state q_0 is changed by matrix S to 0 and is the starting trigger. When the end-marker is read, a minimum of $\frac{1}{\sqrt{2(n+2)}}(\frac{1}{2})^{n+1}$ of amplitude is placed into the accepting state only if the amplitude of state q_{2n} has decreased. The amplitude from q_{2n+2} is channeled into a decisive reject state. The rest of the amplitude from the remaining $n+1$ nonhalting states is channeled into junk states. If the amplitudes of q_{2n} and q_{2n+2} do not differ, then all amplitude is channeled into junk and decisive reject states.

The probability of M accepting a string not in the language is 0, while the probability of M accepting a string in the language is at least $\frac{1}{n+2}(\frac{1}{2})^{2n+3}$. We select the cut-point to be strictly between the two values. □

Any Boolean combination of partial piecewise testable sets may be expressed as a union of intersections of partial piecewise testable sets and complements of partial piecewise testable sets, i.e.,

$$\bigcup_{i=0}^{s}\left(\bigcap_{j=0}^{t}\tilde{L}_{ij}\right), \tag{4.1}$$

where $\tilde{L}_{ij}$ is a partial piecewise testable set or the complement thereof.

We first show how to construct the implicants of the above expression, i.e., $\cap_{j=0}^{t}\tilde{L}_{ij}$, and then how to take the union of the implicants. An implicant can be written in the form

$$\bigcap_{j=0}^{t}\tilde{L}_{ij} = \left(\bigcap_{j=0}^{r}L_{ij}\right)\bigcap\left(\bigcap_{j=r}^{t}\overline{L}_{ij}\right),$$

where the L_{ij}'s are partial piecewise testable sets. By De Morgan's rule, the latter part of this expression can be rewritten as $\overline{\cup_{j=r}^{t}L_{ij}}$. Let $L^{\cap}{}_i = \cap_{j=0}^{r}L_{ij}$, let $L^{\cup}{}_i = \cup_{j=r}^{t}L_{ij}$, and let $L_i = L^{\cap}{}_i \cap \overline{L^{\cup}{}_i}$.

First, we show that $L^{\cap}{}_i$ can be accepted by an end-decisive MM-QFA with bounded positive one-sided error. Second, we show that $\overline{L^{\cup}{}_i}$ can be accepted by an end-decisive MM-QFA with bounded error. Third, we show that L_i can be accepted by an end-decisive MM-QFA with bounded error. Finally, we show that $\cup_{i=0}^{s}L_i$ can be accepted by an end-decisive MM-QFA with bounded error. We first need two composition lemmas.

We say that an MM-QFA M accepts L with cut-point λ and maximum margin η if for all $x \in \Sigma^*$,

$$\lambda - \eta < \Pr[M(x) = \text{accept}] < \lambda + \eta.$$

Usually, the maximum margin will be exponentially greater than the margin ϵ; this creates problems when we compose automata.

LEMMA 4.8. *Let M and M' be end-decisive MM-QFAs that accept L and L', respectively, with cut-points λ and λ', margins ϵ and ϵ', and maximum margins η and η'. There exists an end-decisive MM-QFA M'' such that the inequalities*

$$(4.2)\quad (\lambda+\epsilon)\cdot(\lambda'+\epsilon') \le \Pr[M''(x)=\text{accept}] \le (\lambda+\eta)\cdot(\lambda'+\eta') \quad \forall x \in L \cap L',$$
$$(4.3)\quad (\lambda-\eta)\cdot(\lambda'+\epsilon') \le \Pr[M''(x)=\text{accept}] \le (\lambda-\epsilon)\cdot(\lambda'+\eta') \quad \forall x \in \overline{L} \cap L',$$
$$(4.4)\quad (\lambda+\epsilon)\cdot(\lambda'-\eta') \le \Pr[M''(x)=\text{accept}] \le (\lambda+\eta)\cdot(\lambda'-\epsilon') \quad \forall x \in L \cap \overline{L'},$$
$$(4.5)\quad (\lambda-\eta)\cdot(\lambda'-\eta') \le \Pr[M''(x)=\text{accept}] \le (\lambda-\epsilon)\cdot(\lambda'-\epsilon') \quad \forall x \in \overline{L} \cap \overline{L'}$$

are satisfied.

Proof. Let $M = (Q, \Sigma, \delta, q_0, Q_{acc}, Q_{rej})$ and $M' = (Q', \Sigma, \delta', q_0', Q'_{acc}, Q'_{rej})$ be end-decisive MM-QFAs that accept L and L'. Using these two MM-QFAs we construct an MM-QFA $M'' = (Q'', \Sigma, \delta'', q_0'', Q''_{acc}, Q''_{rej})$ that satisfies the above inequalities.

Let $Q'' = Q \times Q'$ and $q_0'' = (q_0, q_0')$. The sets of halting states are defined as

$$Q''_{acc} = \{(q_i, q_j') \in Q'' \mid q_i \in Q_{acc} \ \wedge \ q_j' \in Q'_{acc}\},$$
$$Q''_{rej} = \{(q_i, q_j') \in Q'' \mid (q_i \in Q_{rej} \ \vee \ q_j' \in Q'_{rej})\},$$

and the transition function δ'' is defined as

$$\delta''((q,q'),\sigma,(r,r')) = \delta(q,\sigma,r)\cdot\delta'(q',\sigma,r'),$$

which is a tensor product of the transition functions δ and δ'.

Since M and M' are end-decisive, i.e., the accepting states will have only nonzero amplitude when the end-marker is read, thus the MM-QFA M'' will be end-decisive.

By the tensor product construction, the probability of M'' accepting x is

$$\Pr[M''(x) = \text{accept}] = \Pr[M(x) = \text{accept}] \cdot \Pr[M'(x) = \text{accept}].$$

Since

$$\begin{aligned}
\lambda + \epsilon \le \Pr[M(x) = \text{accept}] \le \lambda + \eta \quad & \forall x \in L,\\
\lambda - \eta \le \Pr[M(x) = \text{accept}] \le \lambda - \epsilon \quad & \forall x \notin L,\\
\lambda' + \epsilon' \le \Pr[M'(x) = \text{accept}] \le \lambda' + \eta' \quad & \forall x \in L',\\
\lambda' - \eta' \le \Pr[M'(x) = \text{accept}] \le \lambda' - \epsilon' \quad & \forall x \notin L',
\end{aligned}$$

multiplying out the probabilities yields the inequalities (4.2), (4.3), (4.4), and (4.5). ∎

COROLLARY 4.9. *Let M and M' be end-decisive MM-QFAs that accept L and L', respectively, with bounded positive one-sided error. There exists an end-decisive MM-QFA that accepts $L \cap L'$ with bounded positive one-sided error.*

Proof. Let λ, λ', ϵ, and ϵ' be the respective cut-points and margins of MM-QFAs M and M'. Since $\lambda - \epsilon = \lambda' - \epsilon' = 0$, $\lambda + \epsilon > 0$, and $\lambda' + \epsilon' > 0$, the result follows from Lemma 4.8. ∎

We mentioned before that the maximum margin of an MM-QFA that accepts language L could be exponentially greater than the margin. This prevents us from directly constructing intersections or unions of languages that are accepted by end-decisive MM-QFAs with bounded error. To get around this problem we use a tensor power technique to magnify the ratio of the probability of a true positive to the probability of a false positive.

LEMMA 4.10. *Let M be an end-decisive MM-QFA that accepts words in L with probability at least $\lambda + \epsilon$ and accepts words not in L with probability at most $\lambda - \epsilon$. For any positive integer n there exists an MM-QFA M' that accepts words in L with probability at least $(\lambda + \epsilon)^n$ and accepts words not in L with probability at most $(\lambda - \epsilon)^n$.*

Proof. Using Lemma 4.8 to compose n copies of M yields the result. □

We first use Lemma 4.10 to construct finite unions of languages that are accepted by end-decisive MM-QFAs with bounded error.

LEMMA 4.11. *Let M be an end-decisive MM-QFA that accepts L with bounded error and let M' be an end-decisive MM-QFA that accept L' with bounded error. There exists an end-decisive MM-QFA M'' that accepts $L'' = L \cup L'$ with bounded error.*

Proof. Assume that M accepts words in L with probability at least $\lambda + \epsilon$ and accepts words not in L with probability at most $\lambda - \epsilon$. Similarly, assume that M' accepts words in L' with probability at least $\lambda' + \epsilon'$ and accepts words not in L' with probability at most $\lambda' - \epsilon'$.

Using Lemma 4.10, let M_s be the sth tensor power of M and let M'_t be the tth tensor power of M'.

Let $M_s = (Q, \Sigma, \delta, q_0, Q_{acc}, Q_{rej})$ and $M'_t = (Q', \Sigma, \delta', q'_0, Q'_{acc}, Q'_{rej})$, where $Q = \{q_0, \ldots, q_{n-1}\}$ and $Q' = \{q'_0, \ldots, q'_{m-1}\}$. Let δ and δ' be represented by the unitary matrices U_σ and U'_σ, respectively.

Let $M'' = (Q'', \Sigma, \delta'', Q''_{acc}, Q''_{rej})$ where $Q'' = \{q''_0, \ldots, q''_{n+m-1}\}$; δ'' is represented by the matrices

$$U''_\sigma = \begin{bmatrix} U_\sigma & 0 \\ 0 & U'_\sigma \end{bmatrix},$$

$Q''_{acc} = \{q''_i \in Q'' \mid q_i \in Q_{acc} \vee q'_{i-n} \in Q'_{acc}\}$, and $Q''_{rej} = \{q''_i \in Q'' \mid q_i \in Q_{rej} \vee q'_{i-n} \in Q'_{rej}\}$. The automata are initialized with the amplitude evenly divided between the states q''_0 and q''_n, i.e., each state contains $\frac{1}{\sqrt{2}}$ amplitude. Intuitively, M and M' run in parallel, not interacting unless one of the two crashes. In that case the computation is over.

If $x \in L \cap L'$, then

$$\Pr[M''(x) = \text{accept}] \geq \frac{(\lambda + \epsilon)^s + (\lambda' + \epsilon')^t}{2};$$

if $x \in L \cap \overline{L'}$, then

$$\Pr[M''(x) = \text{accept}] \geq \frac{(\lambda + \epsilon)^s}{2};$$

if $x \in \overline{L} \cap L'$, then

$$\Pr[M''(x) = \text{accept}] \geq \frac{(\lambda' + \epsilon')^t}{2};$$

and if $x \in \overline{L} \cap \overline{L'}$, then

$$\Pr[M''(x) = \text{accept}] \leq \frac{(\lambda - \epsilon)^s + (\lambda' - \epsilon')^t}{2}.$$

The last case corresponds to $x \notin L''$. By setting s and t appropriately, we can ensure that

$$(\lambda - \epsilon)^s + (\lambda' - \epsilon')^t \ll \min\{(\lambda + \epsilon)^s, (\lambda' + \epsilon')^t\}.$$

Hence, the MM-QFA M'' accepts $L \cup L'$ with bounded error. Furthermore, M'' is end-decisive because both M_s and M_t are end-decisive. □

COROLLARY 4.12. *Let M and M' be end-decisive MM-QFAs that accept L and L', respectively, with bounded positive one-sided error. There exists an end-decisive MM-QFA that accepts $L \cup L'$ with bounded positive one-sided error.*

Proof. Since $\lambda - \epsilon = \lambda' - \epsilon' = 0$, the same argument as in Corollary 4.9 applies. □

One useful property of languages that are accepted by end-decisive MM-QFAs with bounded positive one-sided error is that we can usually construct end-decisive MM-QFAs that can accept the complement of such languages with bounded error. We say that an end-decisive MM-QFA accepts with positive amplitude if the amplitude in its accept states is always nonnegative.

LEMMA 4.13. *Let L be a language that is accepted by an end-decisive MM-QFA with bounded positive one-sided error and positive amplitude. There exists an end-decisive MM-QFA that accepts $\overline{L}$ with bounded error.*

Proof. Let $M = (Q, \Sigma, \delta, q_0, Q_{acc}, Q_{rej})$ be an end-decisive MM-QFA that accepts L with bounded positive one-sided error. Since M rejects all strings not in L with certainty, for every computation of M on $x \notin L$ zero amplitude is placed into the accepting states of M. Let $n = |Q|$, let $a = |Q_{acc}|$, and assume that $Q_{acc} = \{q_{n-1}, q_{n-2}, \ldots, q_{n-a}\}$.

We use M to construct an end-decisive MM-QFA M' to accept $\overline{L}$ with bounded error. Let $M' = (Q', \Sigma, \delta', q_0, Q'_{acc}, Q'_{rej})$, where

$$\begin{aligned} Q' &= Q \cup \{q_n, q_{n+1}, \ldots, q_{n+3a}\}, \\ Q'_{rej} &= Q_{rej} \cup Q_{acc} \cup \{q_{n+i} \in Q' \mid i \equiv 2 \bmod 3\}, \\ Q'_{acc} &= \{q_{n+i} \in Q' \mid i \equiv 0 \bmod 3\}, \end{aligned}$$

and the transition function δ' is extended in the following manner. For all symbols except the end-marker, the transition function for M' is defined by the matrices

$$U'_\sigma = \begin{bmatrix} U_\sigma & \\ & I_{3a} \end{bmatrix}.$$

The end-marker transition is defined by the matrix

$$U'_\$ = \begin{bmatrix} U_\$ & \\ & I_{3a} \end{bmatrix} X,$$

where matrix X performs an averaging and cleanup operation. We define X in terms of 4×4 submatrices. Every accept state $q_{n-a+i} \in Q_{acc}$ in M becomes a reject state in M'. Additionally, for each such state, three additional states were added to M', q_{n+3i}, q_{n+3i+1}, and q_{n+3i+2}, which are an accepting, a nonhalting,

and a rejecting state, respectively. The matrix X operates on the 4-tuples of states $(q_{n-a+i}, q_{n+3i}, q_{n+3i+1}, q_{n+3i+2})$. Each operation is localized to the 4-tuple of states and hence can be described by a 4×4 matrix X_i. Assume that the order of rows and columns of the matrix correspond to the order in the 4-tuple. Let

$$X_i = \overbrace{\begin{bmatrix} 1 & & & \\ & 1 & & \\ & & 0 & 1 \\ & & 1 & 0 \end{bmatrix}}^{\text{cleanup}} \overbrace{\begin{bmatrix} \frac{1}{2} & \frac{1}{\sqrt{2}} & \frac{1}{2} & \\ -\frac{1}{\sqrt{2}} & 0 & \frac{1}{\sqrt{2}} & \\ \frac{1}{2} & -\frac{1}{\sqrt{2}} & \frac{1}{2} & \\ & & & 1 \end{bmatrix}}^{\text{averaging}}.$$

Since M accepts with positive amplitude, the amplitude in state q_{n-a+i} will be nonnegative. If the nonhalting state q_{n+3i+1} contains a fixed amount of amplitude α, and the old accept state q_{n-a+i} contains β amplitude. Then, the averaging operation places $\frac{\alpha-\beta}{\sqrt{2}}$ amplitude in the accept state q_{n+3i}. Then, the cleanup operation places any amplitude remaining in the nonhalting state q_{n+3i+1} into the reject state q_{n+3i+2}.

We initialize M' in the same way as M except that a fraction of the amplitude is placed in the new nonhalting states. These states behave as reservoirs until the end-marker is read. The amount of amplitude placed in the states is greater than the maximum amount of amplitude that any accepting state may ever contain, i.e., $\alpha > \beta \geq 0$.

If $x \in L$, then at least one of the accept states of M will contain a minimum amount of positive amplitude. Hence, the amount of amplitude in at least one of the accept states of M' will be strictly less than $\frac{\alpha}{\sqrt{2}}$ by some fixed amount. If $x \notin L$, then all accept states of M' will have exactly $\frac{\alpha}{\sqrt{2}}$ amplitude in them.

Hence, if $x \in L$, the probability of M' accepting x will be strictly less than that if $x \notin L$. Hence, M' accepts $\overline{L}$ with bounded error. Since the accept states are only observed after the end-marker is read, M' is end-decisive. □

If L is a language that can be accepted by an end-decisive MM-QFA with bounded error and L' is a language that can be accepted by an end-decisive MM-QFA with bounded positive one-sided error, then we use Lemma 4.10 to construct an MM-QFA that accepts the intersection of the two languages.

LEMMA 4.14. *Let M be an end-decisive MM-QFA that accepts L with bounded error and let M' be an end-decisive MM-QFA that accept L' with bounded positive one-sided error. There exists an MM-QFA M'' that accepts $L'' = L \cap L'$ with bounded error.*

Proof. Let MM-QFA M accept L with cut-point λ, margin ϵ, and maximum margin η, and let MM-QFA M' accept M' with cut-point λ', margin ϵ', and maximum margin η'.

First, consider the inequalities in Lemma 4.8 that occur when we compose the MM-QFAs M and M' using the tensor technique. Since MM-QFA M' accepts with bounded positive one-sided error, the inequalities are

$$\begin{aligned}
(\lambda+\epsilon)\cdot(\lambda'+\epsilon') \leq \Pr[N(x) = \text{accept}] \leq (\lambda+\eta)\cdot(\lambda'+\eta') \quad & \forall x \in L \cap L', \\
(\lambda-\eta)\cdot(\lambda'+\epsilon') \leq \Pr[N(x) = \text{accept}] \leq (\lambda-\epsilon)\cdot(\lambda'+\eta') \quad & \forall x \in \overline{L} \cap L', \\
(\lambda+\epsilon)\cdot 0 \leq \Pr[N(x) = \text{accept}] \leq (\lambda+\eta)\cdot 0 \quad & \forall x \in L \cap \overline{L'}, \\
(\lambda-\eta)\cdot 0 \leq \Pr[N(x) = \text{accept}] \leq (\lambda-\epsilon)\cdot 0 \quad & \forall x \in \overline{L} \cap \overline{L'}.
\end{aligned}$$

These reduce to three cases:

$$\Pr[M''(x) = \text{accept}] \geq (\lambda + \epsilon) \cdot (\lambda' + \epsilon') \quad \forall x \in L \cap L', \tag{4.6}$$

$$\Pr[M''(x) = \text{accept}] \leq (\lambda - \epsilon) \cdot (\lambda' + \eta') \quad \forall x \in \overline{L} \cap L', \tag{4.7}$$

$$\Pr[M''(x) = \text{accept}] = 0 \quad \forall x \in \overline{L'}. \tag{4.8}$$

If we can guarantee that

$$(\lambda - \epsilon) \cdot (\lambda' + \eta') < (\lambda + \epsilon) \cdot (\lambda' + \epsilon'),$$

then the tensor technique is sufficient to construct the intersection. Let M_n be the nth tensor composition of M. By Lemma 4.10 M_n accepts words in L with probability at least $(\lambda+\epsilon)^n$ and accepts words not in L with probability at most $(\lambda-\epsilon)^n$. Construct MM-QFA M'' by composing M_n with M' using the tensor technique; for sufficiently large constant n the inequality

$$(\lambda - \epsilon)^n \cdot (\lambda' + \eta') < (\lambda + \epsilon)^n \cdot (\lambda' + \epsilon')$$

will be satisfied. Thus, MM-QFA M'' accepts L'' end-decisively with bounded error. □

We now assemble our array of tools to construct an arbitrary Boolean combination of partial piecewise testable sets.

THEOREM 4.15. *Piecewise testable sets can be accepted by end-decisive MM-QFAs with bounded error.*

Proof. Let L be a piecewise testable set. We first rewrite it in canonical form:

$$\begin{aligned}
L &= \bigcup_{i=0}^{s} \bigcap_{j=0}^{t} \tilde{L}_{ij} \\
&= \bigcup_{i=0}^{s} \left(\cap_{j=0}^{r} L_{ij} \bigcap \cap_{j=r}^{t} \overline{L}_{ij} \right) \\
&= \bigcup_{i=0}^{s} \left(\cap_{j=0}^{r} L_{ij} \bigcap \overline{\cup_{j=r}^{t} L_{ij}} \right) \\
&= \bigcup_{i=0}^{s} \left(L^{\cap}{}_{i} \bigcap \overline{L^{\cup}{}_{i}} \right) \\
&= \bigcup_{i=0}^{s} L_i.
\end{aligned}$$

By Theorem 4.7 we can construct end-decisive MM-QFAs that accept partial piecewise testable sets, L_{ij}, with bounded positive one-sided error. Using these constructions and Corollaries 4.9 and 4.12, we can construct end-decisive MM-QFAs that accept languages $L^{\cap}{}_{i}$ and $L^{\cup}{}_{i}$ with bounded positive one-sided error.

The constructions in Theorem 4.7 channel only nonnegative amplitude into their accept states; furthermore, the constructions in Lemmas 4.8 and 4.11 do not negate amplitude. Consequently, the constructions for languages $L^{\cap}{}_{i}$ and $L^{\cup}{}_{i}$ channel only positive amplitude into their accept states. Hence, said constructions accept with positive amplitude. Since $L^{\cup}{}_{i}$ is also accepted with bounded positive one-sided error, by Lemma 4.13, we can construct an end-decisive MM-QFA that can accept $\overline{L^{\cup}{}_{i}}$ with bounded error.

Since $L^{\cap}{}_{i}$ is accepted by an end-decisive MM-QFA with bounded positive one-sided error and $\overline{L^{\cup}{}_{i}}$ is accepted by an end-decisive MM-QFA with bounded error, by Lemma 4.14, we can construct an end-decisive MM-QFA that accepts $L_i = L^{\cap}{}_{i} \cap \overline{L^{\cup}{}_{i}}$

with bounded error.

Since the languages L_i can be accepted by end-decisive MM-QFAs with bounded error, by Lemma 4.11, we can construct an end-decisive MM-QFA that accepts $L = \cup_i L_i$ with bounded error. □

5. Conclusions. We defined two models of 1QFA: the measure-once model that performs one measurement at the end of the computation, and the measure-many model that performs a measurement after every transition. The measure-many model is strictly more powerful than the measure-once but is more difficult to characterize.

When restricted to accepting with bounded error, measure-once automata can accept only group languages, while unrestricted measure-once automata can accept irregular sets and, in particular, can solve the word problem on the free group. Any language accepted by an MO-QFA can also be accepted by a PFA; therefore PFAs can also solve the word problem on the free group. We also sketched an algorithm for determining equivalence of two MO-QFAs.

The measure-many automaton is difficult to characterize. We have shown that the two classes of languages, those accepted with and without bounded error, are closed under complement and inverse homomorphisms; it is still an open question if these classes are closed under Boolean operations. We defined the partial order condition for languages and proved that it is a necessary condition for a language to be accepted by an MM-QFA with bounded error. We also showed that piecewise testable sets can be accepted with bounded error by MM-QFAs, and in the process detailed several novel construction techniques.

We do not know if the partial order condition is also a sufficient condition for bounded acceptance. If it is, then the two classes of languages accepted by an MM-QFA are closed under intersection.[1]

Appendix A. End-marker theorems.

THEOREM A.1. *Let M be an MO-QFA that has both left and right end-markers. There exists an MO-QFA M' that uses only one end-marker and is equivalent to M.*

Proof. Let $M = (Q, \Sigma, \delta, q_0, F)$ be an MO-QFA with left and right end-markers, effectively allowing M to start in any possible configuration. Let the symbol $\not\in$ denote the left end-marker. Define $M' = (Q, \Sigma, \delta', q_0, F)$ from M. Let δ be defined in terms of the transition matrices $\{U_\sigma\}_{\sigma\in\Sigma}$. We define δ' from δ in the following way: for every $\sigma \in \Sigma$ let

$$U'_\sigma = U_{\not\in}^{-1} U_\sigma U_{\not\in},$$

and let

$$U'_\$ = U_\$ U_{\not\in}.$$

Now consider what happens when M and M' read a string $x = x_1 \dots x_n$. Since

$$\begin{aligned} U'(x\$) &= U'_\$ U'_{x_n} \dots U'_{x_1} \\ &= U_\$ U_{\not\in} U_{\not\in}^{-1} U_{x_n} U_{\not\in} \dots U_{\not\in}^{-1} U_{x_1} U_{\not\in} \\ &= U_\$ U_{x_n} \dots U_{x_1} U_{\not\in} \\ &= U(\not\in x\$), \end{aligned}$$

[1] After this paper was submitted, Ambainis, Kikusts, and Valdats [4] showed that this condition is not sufficient and that the class **RMM** is not closed under intersection.

the probability of M accepting x is equal to the probability of M' accepting x. Thus one end-marker on the right suffices, and by symmetry one left end-marker would also suffice. Therefore, an MO-QFA starting in configuration $|q_0\rangle$ can simulate an MO-QFA starting in any arbitrary configuration. □

THEOREM A.2. *Let M be an MM-QFA that has both left and right end-markers. There exists an MM-QFA M' that uses only a right end-marker and is equivalent to M.*

Proof. Let $M = (Q, \Sigma, \delta, Q_{acc}, Q_{rej})$ be an MM-QFA that uses two end-markers and accepts L. Assume without loss of generality that

$$\begin{aligned} Q_{non} &= \{q_i \in Q \mid 0 \le i < n_{non}\}, \\ Q_{acc} &= \{q_i \in Q \mid n_{non} \le i < n_{acc}\}, \\ Q_{rej} &= \{q_i \in Q \mid n_{acc} \le i < n_{rej} = n = |Q|\}, \end{aligned}$$

which facilitates a simpler description of M'. We construct $M' = (Q', \Sigma, \delta', Q'_{acc}, Q'_{rej})$ that accepts L with only the right end-marker. Let $Q' = Q \cup \{q_n, q_{n+1}, \ldots, q_{2n-n_{non}}\}$, $Q'_{acc} = \{q_{n+i-n_{non}} \in Q' \mid q_i \in Q_{acc}\}$, and $Q'_{rej} = \{q_{n+i-n_{non}} \in Q' \mid q_i \in Q_{rej}\}$. Assume that δ is defined in terms of transition matrices $\{U_\sigma\}_{\sigma\in\Sigma}$. The construction of $\{U'_\sigma\}_{\sigma\in\Sigma}$ is similar to that in the proof of Theorem A.1. Let I_l represent an identity matrix of size l and $m = n - n_{non}$. We define δ' in terms of its unitary block matrices. For all $\sigma \in \Sigma$ let

$$U'_\sigma = \begin{bmatrix} U_{\not\sigma}^{-1} & \\ & I_m \end{bmatrix} S \begin{bmatrix} U_\sigma & \\ & I_m \end{bmatrix} \begin{bmatrix} U_{\not\sigma} & \\ & I_m \end{bmatrix},$$

$$U'_\$ = S \begin{bmatrix} U_\$ & \\ & I_m \end{bmatrix} \begin{bmatrix} U_{\not\$} & \\ & I_m \end{bmatrix},$$

where

$$S = \begin{bmatrix} I_{n_{non}} & & \\ & & I_m \\ & I_m & \end{bmatrix}$$

transfers (sweeps) all probability amplitude from states in the old halting states to the new halting states. The old halting states, those in Q_{acc} and Q_{rej}, are no longer halting states in M'. The operation of M' is similar to the operation of the QFA constructed in Theorem A.1. The "sweeping" operation saves the amplitude that was in the old states, while it performs the $U_{\not\sigma}^{-1}$ operation in the new halting states (since otherwise the $U_{\not\sigma}^{-1}$ would corrupt the amplitude stored in the original halting states). □

FAST GREEDY ALGORITHMS FOR CONSTRUCTING SPARSE GEOMETRIC SPANNERS*

JOACHIM GUDMUNDSSON†, CHRISTOS LEVCOPOULOS‡, AND GIRI NARASIMHAN§

Abstract. Given a set V of n points in $\mathbb{R}^d$ and a real constant $t > 1$, we present the first $O(n \log n)$-time algorithm to compute a geometric t-spanner on V. A geometric t-spanner on V is a connected graph $G = (V, E)$ with edge weights equal to the Euclidean distances between the endpoints, and with the property that, for all $u, v \in V$, the distance between u and v in G is at most t times the Euclidean distance between u and v. The spanner output by the algorithm has $O(n)$ edges and weight $O(1) \cdot wt(MST)$, and its degree is bounded by a constant.

1. Introduction.

Complete graphs represent ideal communication networks, but they are expensive to build; sparse spanners represent low-cost alternatives. The weight of the spanner network is a measure of its sparseness; other sparseness measures include the number of edges, the maximum degree, and the number of Steiner points. Spanners for complete Euclidean graphs as well as for arbitrary weighted graphs find applications in robotics, network topology design, distributed systems, design of parallel machines, and many other areas and have been a subject of considerable research [1, 2, 4, 8, 11].

Consider a set V of n points in $\mathbb{R}^d$, where the dimension d is a constant. A network on V can be modeled as an undirected graph G with vertex set V and with edges $e = (u, v)$ of weight $wt(e)$. A Euclidean network is a geometric network where the weight of the edge $e = (u, v)$ is equal to the Euclidean distance $d(u, v)$ between its two endpoints u and v. Let $t > 1$ be a real number. We say that G' is a *t-spanner* for V if, for each pair of points $u, v \in V$, there exists a path in G' of weight at most t times the Euclidean distance between u and v. A *sparse t-spanner* is defined to be a t-spanner of size (number of edges) $O(n)$ and weight (sum of edge weights) $O(1) \cdot wt(MST)$, where $wt(MST)$ is the total weight of a minimal spanning tree. Given a geometric network $G = (V, E)$, a (generic) weight function wt defined on its edges, and two vertices $u, v \in V$, we let $D_{\{G,wt\}}(u, v)$ denote the weight of the shortest path from u to v in G for the weight function wt.

The problem of constructing spanners has been investigated by many researchers. Levcopoulos and Lingas [10] presented an $O(n \log n)$-time algorithm that produced a sparse t-spanner for the two-dimensional case. It works by taking any t-spanner which has the form of a (possibly partial) triangulation and achieving almost the same t as that triangulation. However, the problem gets much more difficult in higher

dimensions. There are several algorithms that run in time $O(n \log n)$ [3, 9, 15, 17]. However, they only guarantee a linear number of spanner edges, and they do not guarantee low weight. Das and Narasimhan [8] gave an $O(n \log^2 n)$-time algorithm that constructs, for any set V of n points in $\mathbb{R}^d$ and any constant $t > 1$, a sparse t-spanner for V in which the degree of every point is bounded by a constant. Chen, Das, and Smid [5] showed that the lower bound for computing any t-spanner for a given set of points V in R^d is $\Omega(n \log n)$ in the algebraic computation tree model.

Mount [12] showed that a significant result claimed in Arya et al. [2] of an $O(n \log n)$-time algorithm to compute a low-weight Euclidean spanner is incorrect. Thus the problem of devising an $O(n \log n)$-time algorithm to produce low-weight spanners remained unsolved.

Before a correct $O(n \log n)$-time algorithm was presented, sparse spanners were used in designing efficient approximation schemes for geometric problems. Rao and Smith [14] made a breakthrough by showing an optimal $O(n \log n)$-time approximation scheme for the well-known Euclidean *traveling salesperson problem*, assuming that it is possible to compute sparse spanners in time $O(n \log n)$. Also, Czumaj and Lingas [6] showed approximation schemes for minimum-cost multiconnectivity problems in geometric graphs that also depended on the assumption that sparse spanners could be computed in $O(n \log n)$ time. Thus the existence of an $O(n \log n)$-time algorithm to construct sparse spanners became a critical open problem. Note that the most efficient algorithm to construct sparse spanners is due to Das and Narasimhan [8] and runs in $O(n \log^2 n)$ time. In this paper we show the following theorem.

THEOREM 1. *Given a set V of n points in d-dimensional space and any real constant $t > 1$, in the algebraic decision tree model of computation, a sparse t-spanner of the complete Euclidean graph can be constructed in $O(\frac{n \log^2 n}{\log \log n})$ time. If the model is extended with indirect addressing, a sparse t-spanner of the complete Euclidean graph can be constructed in $O(n \log n)$ time. The constants implicit in the O-notation depend on t and d.*

It was shown in [8] that the greedy algorithm produces spanners with $O(n)$ edges and weight $O(wt(MST))$. However, a naive implementation of the greedy algorithm (shown in Figure 1) takes $O(n^3 \log n)$ time, mainly due to the fact that a quadratic number of shortest path queries are needed to be answered in a "dynamic" graph with $O(n)$ edges. Each of the queries takes $O(n \log n)$ time.

Our algorithm is inspired by the algorithm due to Das and Narasimhan [8]. They showed how to use clustering in order to speed up shortest path queries; i.e., they showed that approximate shortest path queries sufficed to produce sparse spanners. However, their algorithm was not efficient enough because they were unable to main-

tain the clusters efficiently, and the algorithm had to frequently rebuild the clusters. For convenience, we will refer to the $O(n \log^2 n)$-time algorithm from [8] as the *DN-clustering* spanner algorithm. We retain the general framework of that algorithm. Our main contribution is in developing techniques to efficiently perform clustering. We believe that the techniques that we have developed are likely to be useful in designing other greedy-style "dynamic algorithms," i.e., in situations where only insertions take place and particularly in increasing order of length. What we prove in this paper is that, after some preprocessing, given a linear-sized edge-weighted graph with integral edge weights in the range $[0, N]$, and given a set of cluster centers, one can perform clustering very efficiently in only $O(n + N)$ time.

The terms length and weight are used interchangeably throughout the paper.

2. An improved spanner algorithm. We first describe the previous cluster-based spanner algorithm due to Das and Narasimhan [8]. Then, in section 2.2, we present a simple modification to the DN-clustering algorithm to construct sparse t-spanners.

2.1. The DN-clustering spanner algorithm. The algorithm by Das and Narasimhan [8] can roughly be described as follows.

The algorithm starts with an empty spanner G'. A preprocessing step helps to eliminate all but a linear number of edges from further consideration. For a given value of t, this step is performed by a call to an $O(n \log n)$-time algorithm presented by Salowe [15] or Arya et al. [2] to compute a spanner with stretch factor $\sqrt{t/t'}$ (for some $t > t' > 1$). Among the edges not eliminated, very short edges (i.e., those of length at most D/n, where D is the distance between the farthest pair of points) are simply added to G' since their contribution to the overall weight of the spanner cannot be more than the weight of a minimum spanning tree, $wt(MST)$. For the remaining edges, the greedy algorithm is simulated by sorting the edges (by increasing weight) and then processing them in $\log n$ phases. Greedy processing of an edge $e = (u, v)$ entails a shortest path query, i.e., checking whether $D_{\{G', wt\}}(u, v) \leq \sqrt{tt'} \cdot wt(e)$. If the answer to the query is no, then edge e is added to the spanner G', or else it is discarded. Whenever shortest path queries are required to be answered, these are not solved on the spanner G' being constructed. Instead, they are solved on a cluster graph H, which is simultaneously maintained. A set of points $C \subseteq V$ is a cluster of radius r with cluster center $v \in C$ if, for every point $u \in C$, there is a path in G' between v and u of length at most r. A set of clusters $C_1, \ldots, C_k$ is a cluster cover of G' if every point in V belongs to at least one cluster. A cluster graph H can be constructed from a cluster cover by adding two types of edges: intracluster edges (edges connecting the cluster center of a cluster C to all other vertices in C) and intercluster edges (edges connecting two cluster centers). The cluster graph H from [8] has the following properties:

1. distances in H "approximate" distances in the current spanner graph G',
2. every vertex in H has bounded degree, and
3. "specialized" shortest path queries in H can be answered in $O(1)$ time.

Item 1 was demonstrated by showing that corresponding distances in H and G' differ by only a small constant factor. The shortest path query when processing edge $e = (u, v)$ is "specialized" in the sense that, at the instant that this query is processed, the cluster graph H has only edges between clusters (the so-called intercluster edges) whose lengths are within a constant factor of $wt(e)$.

In order to understand how shortest path queries can be answered efficiently, we note that, in an unweighted graph with bounded degree, checking whether the

distance between two vertices u and v is at most a constant $\sqrt{tt'}$ can be achieved in $O(1)$ time (since there are only $O(1)$ vertices at the distance t from u). Thus, for all practical purposes, the cluster graph H behaves like an unweighted graph of bounded degree for which a bounded radius subgraph around vertex u needs to be searched for the presence of vertex v. It is thus easily shown that specialized shortest path queries can be answered in $O(1)$ time.

Since the edges considered have weights in the range $(D/n, D]$ and they are processed in $\log n$ phases, the edges can be sorted into $\log n$ bins, where the ith bin has edges of weight in the range $(2^{i-1} \cdot D/n, 2^i \cdot D/n]$. In order for shortest path queries to be answered quickly, the cluster graph has to be carefully maintained. At the end of each phase, the cluster graph is recomputed from scratch using the graph G'. This was deemed necessary since, in order to answer specialized shortest path queries about edge $e{=}(u, v)$ in constant time, all intercluster edges in H need to be of length within a constant factor of $d(u, v)$.

The time complexity analysis is straightforward. Preprocessing steps ran in $O(n \log n)$ time. The $O(n)$ shortest path queries were processed in $O(n)$ time, since each query took only $O(1)$ time. The cluster graph computation at the start of each phase took $O(n \log n)$ time (since it involved running Dijkstra's shortest path algorithm on linear-sized graphs starting from sequentially selected cluster centers). Since there were $\log n$ phases, the cluster graph computations took a total of $O(n \log^2 n)$ time. The crucial observation made in [8] was that shortest path queries need not be answered precisely. Instead, approximate shortest path queries suffice to produce low-weight spanners. The second observation was that shortest path queries are expensive if the shortest path involves a number of short edges and that clustering can help to eliminate all short edges. This, of course, meant that the greedy algorithm, too, was only approximately simulated by the algorithm.

2.2. A faster spanner algorithm. In this section, we present a simple modification to the DN-clustering algorithm to construct sparse t-spanners. This algorithm improves on the time complexity of the DN-clustering algorithm and runs in time $O(\frac{n \log^2 n}{\log \log n})$ in the algebraic decision tree model of computation.

First we observe that there is wide disparity in the overall time spent by the DN-clustering algorithm on shortest path queries ($O(n)$) and the time spent on the cluster graph computations ($O(n \log^2 n)$). In order to balance the two costs, it is necessary to do fewer than $O(\log n)$ cluster graph computations. This in turn would make the shortest path queries more expensive because it increases the ratio between the lengths of the longest and shortest edges in the cluster graph, which implies that the number of edges along the shortest path between two cluster centers will also increase, and therefore the query time will also increase. Instead of processing the edges in $\log n$ phases, we process them in $\frac{4 \cdot d \cdot \log n}{\log \log n}$ batches. We use the term batches to distinguish from the word phases used by the earlier DN-clustering algorithm.

If the clustering is recomputed after processing every batch of edges, the total time for cluster graph computations will be $O(\frac{n \log^2 n}{\log \log n})$, since each call to the clustering algorithm takes $O(n \log n)$ time. We carefully analyze the cost of the $O(n)$ shortest path queries and show that it can now be answered in a total of $O(n \log n)$ time. In phase i of the DN-clustering algorithm, edges from the ith bin were processed. These edges had weights in the range $(W, 2W]$, where $W = 2^{i-1}(D/n)$. During phase i, the cluster graph H could have intercluster edges whose weights were in the range $(\delta W, 2W(1+2\delta)]$, where $\delta < \frac{1}{2}$ is a positive constant. This meant that, for edge (u, v) of weight $l \in (W, 2W]$, checking whether there is a path from u to v of length at most

$t \cdot l$ could be done in $O(1)$ time. More precisely, it was observed in [8] that, if there exists a path from u to v of length at most $t \cdot l$, then the number of edges on this path can be at most $\frac{2t}{\delta}$. It was further observed that, since the vertices of H had a constant degree bound (say, c), and since there are at most $O(c^{\frac{2t}{\delta}})$ vertices that lie $\frac{2t}{\delta}$ edges away from vertex u, this shortest path query could be done in $O(c^{\frac{2t}{\delta}} \log c^{\frac{2t}{\delta}})$ time. A tighter analysis was unnecessary in the DN-clustering algorithm of [8] since c, t, and δ were all constants; below we show an improved analysis of this cost.

Recall that our algorithm works in $\frac{4 \cdot d \cdot \log n}{\log \log n}$ batches. Batch i of our algorithm can be described as follows. For $W = 2^{\frac{(i-1) \cdot \log \log n}{4 \cdot d}}(D/n)$, the edges processed in batch i have weights in the range $(W, W2^{\frac{\log \log n}{4 \cdot d}}]$; i.e., they are in the range $(W, W(\log n)^{\frac{1}{4 \cdot d}}]$. Thus, for edge (u, v) of weight $l \in (W, W(\log n)^{\frac{1}{4 \cdot d}}]$, we need to check whether there is a path from u to v of length at most $\sqrt{tt'} \cdot l$. During batch i, the cluster graph H can have intercluster edges with weights in the range $(\delta W, (1 + 2\delta)W(\log n)^{\frac{1}{4 \cdot d}}]$. Thus, if there does exist such a path from u to v, then the number of edges on this path can be at most $\frac{\sqrt{tt'}(\log n)^{\frac{1}{4 \cdot d}}}{\delta}$. The crucial observation we make is that the vertices of the cluster graph correspond to clusters of radius δW. These clusters may overlap, but their centers can lie in only one cluster. In other words, if these clusters are shrunk in half, they do not intersect. Thus the vertices correspond to disjoint clusters of radius $\delta \cdot W/2$. Now it is possible to bound the number of vertices within distance at most $\sqrt{tt'} \cdot l = \sqrt{tt'}W(\log n)^{\frac{1}{4 \cdot d}}$. Packing arguments [8] show that, in $\mathbb{R}^d$, the number of balls of radius r that can be packed in a ball of radius R is bounded by $O((R/r)^d)$. Thus the number of balls of radius $r = \frac{\delta W}{2}$ that can be packed in a ball of radius $R = \sqrt{tt'}W(\log n)^{\frac{1}{4 \cdot d}}$ is at most $O((\frac{t \cdot (\log n)^{\frac{1}{4 \cdot d}}}{\delta})^d)$. Due to the constant degree, the maximum number of vertices and edges that can be reached when performing Dijkstra's algorithm starting from vertex u is $O((\frac{t \cdot (\log n)^{\frac{1}{4 \cdot d}}}{\delta})^d) = O((\log n)^{\frac{1}{4}})$ (since t, d, and δ are constants). We conclude that Dijkstra's algorithm for a shortest path query has a time complexity of $O((\log n)^{\frac{1}{4}} \cdot (\log((\log n)^{1/4}))) = O(\log n)$. Thus all $O(n)$ shortest path queries can be answered in $O(n \log n)$ time. Note that, even though the clustering and shortest path costs are not precisely balanced, it is possible to prove (using lengthy but straightforward algebraic calculations) that (asymptotically) it cannot be improved. The obtained spanner satisfies the leapfrog property [8] (also defined in section 5), which implies that the weight of the spanner is $O(wt(MST)$.

THEOREM 2. *In the algebraic decision tree model of computation, given a set V of n points in d-dimensional space and any real constant $t > 1$, a sparse t-spanner of the complete Euclidean graph can be constructed in $O(\frac{n \log^2 n}{\log \log n})$ time. The constants implicit in the O-notation depend on t and d.*

3. A fast spanner algorithm that uses indirect addressing. In the rest of the paper, we describe an efficient algorithm to construct sparse spanners with a running time of $O(n \log n)$. This algorithm is also inspired by the DN-clustering algorithm in [8]. As explained in section 2.1, the reason their algorithm runs in time $O(n \log^2 n)$ is that the clustering step takes $O(n \log n)$ time per phase. The running time for our algorithm is achieved by designing a linear time algorithm for an "approximate" version of the clustering step, thus executing all the clustering steps in $O(n \log n)$ total time.

One crucial idea that we employ to speed up the clustering is to replace the real-valued edge weights by integral values. As observed in [8], the shortest path

queries required by the algorithm need not be answered precisely; approximately correct answers suffice. A convenient way to achieve the *integralization* is to use the *floor/ceiling* function. However, this assumes a more powerful model of computation. In order to get around this problem, we reduce the dependence of the algorithm on the floor/ceiling function and compute the floor/ceiling function by using operations allowed under the algebraic computation tree model extended with indirect addressing. The second crucial component of our algorithm is an implementation of the clustering algorithm in $O(n)$ time assuming small integral edge weights for the edges. We also prove that the integralization introduces only a bounded amount of error and that this error bound helps to prove the correctness of the other required operations. The third and final crucial component in our algorithm is that we show how it is possible to select the cluster centers for each stage of the algorithm in linear time.

The improved spanner algorithm can be roughly described as follows; see Figure 2. It is important to note that the skeleton of the algorithm is similar to the DN-clustering algorithm from [8]. In particular, this improved algorithm also runs in $O(\log n)$ phases. If a fewer number of phases are used, then the error due to integralization could be too large. Even if a fewer number of phases can be used, the running time of the overall algorithm will remain as $O(n \log n)$, since it is dominated by other steps in the algorithm. In particular, the integralization itself has an initial cost of $O(n \log n)$.

The algorithm starts with an empty spanner G' and employs the same first (preprocessing) step to eliminate all but a linear number of edges. For a given value of t, this step is performed by a call to an $O(n \log n)$-time algorithm presented by Arya et al. [2] to compute a spanner with stretch factor $\sqrt{t/t'}$ (for some $t > t' > 1$) and with bounded degree. As in [8], in the next step, short edges of length at most D/n are simply added to G'; their contribution to the overall weight of the spanner is bounded by $O(wt(MST))$. The greedy algorithm is then simulated on the remaining edges of the initial spanner.

The edges of the graph have real-valued weights that are equal to the Euclidean distance between their endpoints. The edges are sorted by increasing weight and then processed in $\log n$ phases. Each of the edges in the spanner graph also have corresponding integer-valued weights that are sufficiently close approximations of the real-valued weights; these integer-valued weights change through the course of the algorithm, becoming coarser and coarser approximations as the algorithm progresses. In order to distinguish between the real- and integer-valued weights, we assume that there are two different weight functions defined on the edges of G'. For edge $e = (u, v)$, the real-valued weight function $wt(e)$, as mentioned before, is defined as the Euclidean distance $d(u, v)$ between u and v. The integer-valued weight function, denoted by $Iwt_i(e)$, is a function of $wt(e)$ and the phase number i. It is maintained during the execution of the algorithm, as will be described later. Whenever the phase number is clear from the context, we use the simpler notation $Iwt(e)$ instead of $Iwt_i(e)$. Also, unless specified otherwise, we assume that, when we refer to the weight of an edge, we are referring to the real-valued weight of the edge.

At the start of each phase, the integer-valued weight function $Iwt(e)$ is recomputed for this phase. Then a set of vertices of G' are selected as cluster centers, and a cluster graph H is constructed from the current spanner graph G', using the weight function Iwt. This cluster graph H is a simpler graph than the graph G', and distances between vertices in H are reasonably close to distances between the same pair of vertices in G'. Clustering is made more precise in section 3.2. The difference

between this and the one in [8] lies in the fact that the cluster centers have to be selected before the clustering is done, and the clustering is done with the weight function Iwt. As mentioned before, we improve on the time complexity of this clustering step and show how it can be implemented to run in $O(n)$ time. Once the cluster graph H is constructed, the algorithm processes the set of edges for that phase. Greedy processing of an edge $e = (u, v)$ entails, as before, a shortest path query, i.e., checking whether $D_{\{G',wt\}}(u, v) \leq t \cdot wt(e)$. We answer an approximate version of this query, i.e., performing a shortest path query on the simpler graph H and not on the partial spanner graph G'. If the answer to the approximate query is "no," edge e is added to the graph G'; otherwise, it is discarded. Each of the steps is described in more detail in the rest of the paper.

In section 3.1, we describe the integralization process and analyze the error due to it. The clustering algorithm is described in section 3.2, and, finally, in section 3.3, we describe how to compute the shortest paths in the cluster graph and prove that the total running time of the algorithm is $O(n \log n)$.

The detailed algorithm is given in Figure 2. The inputs are V, which is a set of n points in d-dimensional space, and two constants t and t' such that $1 < t' \leq t$. As one can see, it is similar to the DN-clustering algorithm except for the integralization steps (steps 10, 11, 14, and 22) and the computation of the cluster centers (steps 12 and 21). In sections 4 and 5, we will show that the output G' indeed is a t-spanner and that a suitable selection of the input parameter t' will guarantee that G' has small weight. Recall that the truly time-critical step of this algorithm is the clustering step (step 15) and selecting the new cluster centers for the next phase (step 21). Both of these steps will be closely described in section 3.2. Note that the two values bounding δ are decided in Lemmas 14 and 17.

3.1. Integralization. As mentioned before, in order to speed up the cluster graph computation, we replace the real-valued edge weights by integral values. The integralization changes in every phase. It is done in such a way that the edge weights and distances encountered in that phase are always in the range $[0, N]$, where $N = c \cdot n$ for some constant integer c. The choice of c will dictate the errors introduced in the distance computations; this will be discussed later.

A closer inspection of a phase leads to the following simple observations. At the start of phase i, the spanner graph constructed so far has edges of weight at most W_i. During phase i, the edges considered for inclusion by the greedy algorithm are in the range $(W_i, 2W_i]$. The shortest path query for an edge of length l involves checking whether the distance between a given pair of vertices is at most $t \cdot l$. Hence the longest paths that need to be dealt with during phase i are of weight $t \cdot 2W_i$. The idea is to make the largest distance we consider in phase i correspond to the integer $c \cdot n$. To be on the safe side, since there are small errors in the distance computations, we set $2(t \cdot 2W_i)$ to correspond to $c \cdot n$. Thus, in phase i, the unit integer length will correspond to the real length of $U_i = \frac{4 \cdot t \cdot W_i}{c \cdot n}$.

Although a constant-time floor/ceiling function is not used in the algorithm, a convenient way to describe the integralization is as follows:

$$Iwt_i(e) := \left\lceil \frac{wt(e)}{U_i} \right\rceil.$$

We will describe below how the integralization step is performed.

3.1.1. Error bounds. As defined above, we observe that the integralization function Iwt always involves a rounding up ($Iwt_i(e) \cdot U_i \geq wt(e)$). Thus, in phase i, the

error in the length of any single edge is at most U_i. In other words, $Iwt_i(e) \cdot U_i - wt(e) \leq U_i$. Note that this error is an additive or an absolute error. Since any simple path can use at most $n-1$ edges, the error in the length of any simple path of the spanner graph is less than nU_i. Another consequence is that, given two simple paths P_1 and P_2, if $Iwt(P_1) = Iwt(P_2)$, then $|wt(P_1) - wt(P_2)| < nU_i$. It follows that nU_i is also a bound on the error that can be introduced when running Dijkstra's single-source shortest path algorithm using the integral weights instead of the real weights. The following lemma formalizes this statement.

LEMMA 3. *In phase i, if $D_{\{G', wt\}}(u, v) > W_i$ for some $u, v \in G'$, then*

$$D_{\{G', wt\}}(u, v) \leq D_{\{G', Iwt\}}(u, v) \cdot U_i < \left(1 + \frac{4t}{c}\right) \cdot D_{\{G', wt\}}(u, v).$$

Proof. Since $wt(e) \leq Iwt_i \cdot U_i = \lceil \frac{wt(e)}{U_i} \rceil \cdot U_i < wt(e) + U_i$, we have

$$\begin{aligned} D_{\{G', wt\}}(u, v) &\leq D_{\{G', Iwt\}}(u, v) \cdot U_i \\ &< D_{\{G', Iwt\}}(u, v) + nU_i \\ &= D_{\{G', wt\}}(u, v) + \frac{4tW_i}{c} \\ &< \left(1 + \frac{4t}{c}\right) D_{\{G', wt\}}(u, v). \qquad \square \end{aligned}$$

As a direct consequence, we obtain the following important corollary.

COROLLARY 4. *For a path P in G' with $wt(P) \geq \delta W_i$, the absolute error in computing its weight is at most nU_i, and the relative error is at most $\frac{nU_i}{\delta W_i} = \frac{4t}{c\delta}$.*

3.1.2. Computing the integralization. Here we show how to compute the integer values of the weights of the edges over all phases in $O(n \log n)$ total time without using the floor/ceiling function.

We first observe that the spanner graph has at most $O(n)$ edges at the start of any phase. Consider a specific phase i. In this phase, for a specific edge e, since its integer value is in the range $[0, N]$ (where $N = c \cdot n$), $Iwt(e)$ can be computed in $O(\log n)$ time without the use of the floor/ceiling function by performing a binary search on the set of real values $j \cdot U_i$, for $j = 0, \ldots, N$. We assume that the function INTEGRALIZE(E_i, i) performs this operation for each edge in the set E_i in $O(\log n)$ time per edge.

If the above observations are used in a naive fashion for all edges, then the cost of integralization is $O(n \log n)$ just for one phase. Since the number of phases is not constant, the integralization would turn out to be too expensive. We have to show that the algorithm spends $O(\log n)$ time for computing the integralization of an edge weight over all the phases. The idea is to compute the integral value in $O(\log n)$ time when the edge is encountered for the first time. Integralizations of an edge for subsequent phases is done by calling REINTEGRALIZE, and are computed in constant time from the integer weights of the edge computed in the previous phase. If the integral weight of an edge is I in phase i, then the integral weight of the edge in phase $i+1$ will be $I/2$ if I is even and $(I+1)/2$ if it is odd. This is correct since $U_{i+1} = 2U_i$; i.e., the integralization in phase $i+1$ is twice as coarse as that in phase i. Checking if an integer is odd or even cannot be done in constant time in our model but can be easily accomplished by using $O(n)$ preprocessing. One way to accomplish this would be to build a balanced leaf-oriented binary tree including $c \cdot n$ leaves with the values $1, \ldots, cn$. Every element in the tree, with value val, also contains a pointer to the element in the tree containing the value $\lceil \frac{val}{2} \rceil$. Assume for simplicity that $c \cdot n = 2^{c'}$. The tree can be built top-down in linear time. The root will have value 1. Consider a node v with value ℓ. The left child of v will have the value $2\ell - 1$, and the right child will have value 2ℓ. This step is repeated until all of the leaves are at level c'. Hence, by using $O(n)$-time preprocessing, the integral weight of an edge for the next phase can be computed in constant time. Another way to handle this problem would be to extend the model of computation with trigonometric functions, i.e., the sine function.

Note also that the relative error for an edge with newly computed weight is less than U_{i+1}; hence Lemma 3 still holds. It is clear that REINTEGRALIZE(E') performs its operation for each edge in the edge set E' in $O(1)$ time per edge.

The above explanation proves that the integralization is computed in $O(n \log n)$ time for all edges over all phases. The integer weights are then used directly in the clustering algorithms described below.

3.2. Clustering the graph. Now we turn our attention to the main contribution of this paper, namely, how to construct a cluster graph in linear time. First we have some definitions. Here we assume that $G = (V, E)$ is a metric graph with a weight function w defined on its edges E. The following definition of a cluster is modified from the one in [8] to allow for arbitrary weight functions. The definition of a cluster cover is also modified and is defined for a given set of cluster centers. Figure 3 illustrates a cluster and a cluster cover.

DEFINITION 5 (cluster, cluster center, and radius). *Given a vertex $v \in V$ and a nonnegative real value r,* CLUSTER(G, v, r, w) *is defined as the set of all vertices $U \subseteq V$ such that $D_{\{G,w\}}(v, u) \leq r$ for all $u \in U$. The vertex v is called the* cluster center *of this cluster, and r is called the* radius *of the cluster.*

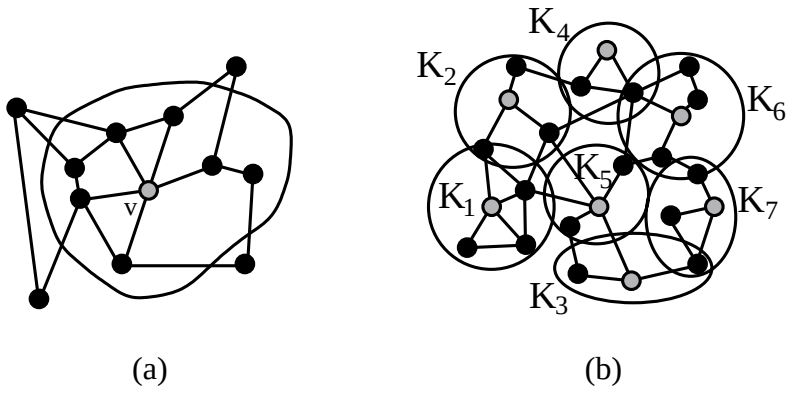

FIG. 3. (a) *A cluster with center at v and radius r.* (b) *The clusters $K_1, \ldots, K_7$ form a cluster cover.*

DEFINITION 6 (cluster-cover). *Given a set of cluster centers $C = \{v_1, \ldots, v_m\} \subseteq V$ and a radius r, the* CLUSTER-COVER(G, C, r, w) *(if it exists) is a set of clusters $K = \{K_1, \ldots, K_m\}$ such that K_i, for $1 \leq i \leq m$, is a cluster with radius r and cluster center v_i and such that $K_1 \cup K_2 \cup \cdots \cup K_m = V$.*

The set C and the radius r will be chosen in such a way that the cluster cover always exists. In general, clusters in a cluster cover may overlap. In our algorithm, the cluster centers will be reasonably far apart so that the amount of overlap is limited. We also modify the definition from [8] of a cluster graph so that it is a bit more general and is defined for a given set of clusters and for an arbitrary weight function.

DEFINITION 7 (cluster graph). *Assume that $C = \{v_1, v_2, \ldots, v_m\} \subseteq V$ is a given set of cluster centers. For a given radius r, we assume that $K = \{K_1, K_2, \ldots, K_m\}$ is equal to* CLUSTER-COVER(G, C, r, w). *Given a second radius $R > r$,* CLUSTER-GRAPH(G, w, C, r, R) *is defined as a graph $H = (V, E_H)$ with a weight function w defined on its edges E_H. The weight of an edge $[u, v]$ in E_H is defined to be equal to $D_{\{G,w\}}(u, v)$. (We use square brackets to distinguish cluster graph edges from the edges of G.) The edges of H are defined as follows.*

Intracluster edges. *For all K_i and for all $u \in K_i$, $[u, v_i] \in E_H$.*

Intercluster edges. *For all $v_i, v_j \in C$, $[v_i, v_j]$ is an intercluster edge if either*

1. *$v_i \notin K_j$ and $v_j \notin K_i$ and $D_{\{G,w\}}(v_i, v_j) \leq R$ (type 1), or*
2. *there exists $e = (u_i, u_j) \in E$ such that $u_i \in K_i$ and $u_j \in K_j$ (type 2).*

3.2.1. Computing the cluster cover. Here we describe how the cluster cover is computed efficiently under some assumptions. Once a cluster cover is computed, we show later that it is straightforward to construct the cluster graph.

Note that the input to the cluster cover computation is a weighted graph $G = (V, E)$ with a weight function w defined on its edges, a set $C \subseteq V$ of cluster centers, and a radius R. We will assume that $|V| = n$, $|E| = O(n)$, the weight function w is an integral, and the radius R is an integer. Since we do not have to deal with distances greater than R, we can safely assume that the weight of any edge is an integer value in the range $[0, R]$. We will further assume that the cluster centers are chosen in such a way that a cluster cover exists, which will be shown in section 3.3. The obvious way to implement this algorithm is as it was done in [8], i.e., to run Dijkstra's

single-source shortest path algorithm from all the cluster centers and to compute the clusters in the cluster cover. However, this has a running time of $O(n \log n)$. In order to speed it up, we run Dijkstra's algorithm in *parallel* from all the cluster centers and use a simple and fast priority queue, which we denote by PQ. The priority queue we use is an array of size R, indexed from 1 to R, as shown in Figure 4. This is sufficient for our purposes because of the following reasons. First, the weight function is integral, and the array contains all possible distance values from the cluster centers to vertices in the clusters. Second, it is well known that, in Dijkstra's algorithm, once a vertex has been extracted from the priority queue, its distance from the source will never be updated again, and the distance from the source at the time of the extraction is the correct distance from the source. In other words, the minimum value of the items in the priority queue is monotonic. Since the priority queue is an array, EXTRACT-MIN can be implemented as a scan through the array for the "next" largest item.

One problem is that clusters can overlap and that vertices may have entries in the priority queue with distances from several cluster centers. Let σ denote the maximal number of clusters that a vertex may belong to. The problem can be taken care of by augmenting the priority queue entries to be a pointer to a linked list where every entry in the list also stores information about the vertex as well as the corresponding cluster center. Since a vertex belongs to at most σ clusters, the space complexity of the priority queue will be $O(n \cdot \sigma + R)$. Also, every vertex contains a list of the clusters it belongs to.

It should be noted that this version of Dijkstra's algorithm, as shown in Figure 5, needs to perform a number of RELAX steps and that in each such step the priority queue may need to be updated. The process of RELAXing an edge (u, v) consists of testing whether we can improve the shortest path to v found so far by going through u and, if so, updating the value for v, i.e., adding a new entry and removing an old entry. Since every vertex contains information about which clusters it belongs to and the distance to each cluster center, each update is performed in time $O(\sigma)$. It should be pointed out that this is the only place where we are unable to eliminate the use of indirect addressing since it is critical that this update be performed efficiently, i.e.,

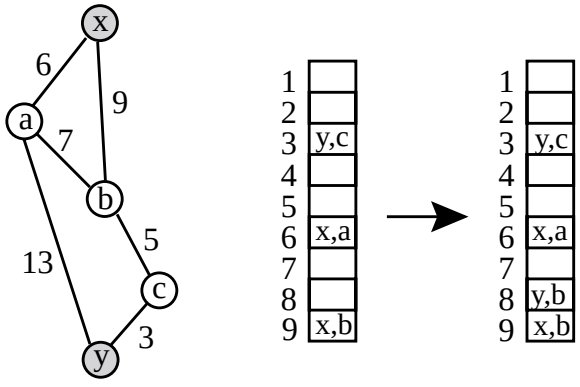

FIG. 4. *An example of how the cluster cover is computed with x and y as cluster centers and radius $R = 9$. The array to the left is the initial priority queue after all edges leading out of x and y have been processed. The array to the right shows the final priority queue. Note that, after vertex c was processed, the edge (c, b) was relaxed, and (y, b) was inserted into the priority queue with length 8.*

Algorithm ParallelDijkstra

```
1.  Q := Initialize(G', ClusterCenters)                    O(n)
2.  while Q ≠ ∅ do                                         O(n · σ)
3.      u := ExtractMin(Q)
4.      for each vertex v adjacent to u do                 O(1)
5.          Relax(u, v, Iwt)                               O(σ)
```

Fig. 5. *The parallel Dijkstra algorithm.*

in constant time. Also note that an edge (u, v) may be Relaxed several times ($O(\sigma)$ times), each time with respect to a different cluster center.

Thus the time and space complexity of the algorithm is affected by the amount of overlap of the clusters in the cluster cover. The space complexity of the data structure is $O(n \cdot \sigma + R)$. Furthermore, the Relax operation has a running time of $O(\sigma)$, and the total number ($O(n \cdot \sigma)$) of ExtractMin operations can be performed in total time $O(n \cdot \sigma + R)$. A careful implementation of cluster cover can be made to run in time $O(n \cdot \sigma^2 + R)$. The value of R in our applications will be $O(n)$; hence the time complexity will be $O(n \cdot \sigma^2)$.

3.2.2. Computing the cluster graph. Now we are ready to describe how to compute the cluster graph. The input is a weighted graph G with a weight function w, a set of cluster centers $C = \{v_1, \ldots, v_m\}$, and two different radii r and R, where $R > r$. In order to compute the cluster graph, the algorithm computes a cluster cover from the same set of cluster centers but with the two radii r and R. Let the cluster covers with radii, r and R be denoted by K_r and K_R, respectively. We augment the cluster cover procedure to also produce a data structure that supports the following queries for both the cluster covers.

- FindCenters(v, K): *Given $v \in V$, it returns all cluster centers v_i such that v is in a cluster from K centered at v_i; i.e., $D_{\{G,w\}}(v, v_i)$ is at most the radius of the clusters in K. It also returns $D_{\{G,w\}}(v, v_i)$ for these cluster centers.*
- ComputeDistance(v_i, v): *Given $v \in V$ and a cluster center v_i, it returns the quantity $D_{\{G,w\}}(v, v_i)$ if $D_{\{G,w\}}(v, v_i) \leq R$; otherwise, it returns the value ∞.*

Now the cluster graph $H = (V, E_H)$ is computed easily as follows. The intracluster edges of H are computed by performing FindCenters queries for each vertex $v \in V$ in the cluster cover K_r and adding the corresponding edges. Recall that FindCenters returns a set T of 2-tuples, where each tuple t consists of a vertex $t.u$ and its distance $t.d$ to v. The algorithm is described in pseudocode in Figure 6 and has a running time of $O(n \cdot \sigma)$.

From Definition 7, we have that each intercluster edge can be one of two types—either type 1 or type 2. The type 2 edges are only added after the initial construction

Algorithm IntraEdges

```
1. for every vertex v ∈ V do
2.     T := FindCenters(v, K_r)
3.     for every element t ∈ T do
4.         AddEdge(H, v, t.u, t.d); Comment: add edge (v, t.u) of weight t.d to H
```

Fig. 6. *Algorithm to add intracluster edges.*

```
Algorithm InterEdgesType1
1.  for every cluster center v in K_r do
2.      T := FindCenters(v, K_R)
3.      for every element t ∈ T do
4.          if (ComputeDistance(v, t.u) ≥ r) then
5.              AddEdge(H, v, t.u, t.d)
```

FIG. 7. *Algorithm to add intercluster edges of type* 1.

to maintain the cluster graph and will be considered in the next paragraph. An edge $[v_i, v_j]$ of type 1 is added if $v_i \notin K_j$, $v_j \notin K_i$, and $D_{\{G,w\}}(v_i, v_j) \leq R$, where $K_i, K_j \in K_r$ are clusters with centers at v_i and v_j. For every cluster center v_i, we use the FindCenters query to list all the clusters from K_R that it is contained in. The centers v_j of these clusters satisfy the condition that $D_{\{G,w\}}(v_i, v_j) \leq R$. Now we use the ComputeDistance queries to make sure that $v_i \notin K_j$ and $v_j \notin K_i$. Adding the intercluster edges of type 1 is done in time $O(n \cdot \sigma^2)$, as shown in the algorithm in Figure 7.

The time complexity of computing the cluster graph is $O(n \cdot \sigma^2)$. Having the cluster centers selected before performing the clustering enables clusters to be grown in "parallel," and thus the above algorithm is able to use one common priority queue to grow all the clusters and is consequently able to perform the clustering efficiently.

3.2.3. Maintaining the cluster graph during a phase. An edge $[v_i, v_j]$ of type 2 is added if there exists an edge $e = (u_i, u_j) \in E$ such that $u_i \in K_i$ and $u_j \in K_j$. During the computation of the cluster graph H at the start of a phase, only intracluster edges and intercluster edges of type 1 are added. Additional edges may be added during a phase of the greedy algorithm. Every time the greedy algorithm decides to add an edge $e = (u, v)$ to the partial spanner graph, several intercluster edges of type 2 may be added to H. This is achieved as follows: for every edge $e = (u_i, u_j)$ that is to be added to G', perform FindCenters queries for u_i and u_j from K_r, and join the corresponding cluster centers by intercluster edges in H. The weight of such edges is computed by performing two ComputeDistance queries for u_i and u_j with the corresponding cluster centers and adding it to the weight of (u_i, u_j). Note that this gives a safe upper bound on the true distance between u_i and u_j. The ratio of R to r determines the maximum error represented by the bound. It is clear that the function shown in Figure 8 runs in $O(\sigma^2)$ time, and it is performed $O(n)$ times.

3.2.4. Selecting the cluster centers for a phase. In order for the ClusterGraph function to be implemented efficiently, it needs to have the set of cluster

```
Algorithm InterEdgesType2(u_i, u_j)
1.  T_1 := FindCenters(u_i, K_r)
2.  T_2 := FindCenters(u_j, K_r)
3.  for every t_1 ∈ T_1 do
4.      for every t_2 ∈ T_2 do
5.          AddEdge(H, t_1.u, t_2.u, t_1.d + w(u_i, u_j) + t_2.d)
```

FIG. 8. *Algorithm to add intercluster edges of type* 2.

centers as input. For the first phase, the cluster centers C_1 are identified in a greedy fashion using the weighted graph $G' = (V, E')$ with real-valued edge weights, and using a radius of $r = \delta W_1$. That is, select any point $v \in V$ not belonging to any clusters already computed, as a cluster center, and compute the cluster with center at v. Continue this procedure until all points in V belong to a cluster. This is referred to as NAIVE-CENTERS in the algorithm given in Figure 2. NAIVE-CENTERS runs in $O(\sigma n \log n)$ time, since this can be implemented using the standard Dijkstra's algorithm.

For subsequent phases, cluster centers are identified (using UPDATECENTERS) in a different way. As a first approximation, the set of cluster centers is always chosen as a subset of the cluster centers used in the previous phase. It may turn out that this choice of cluster centers does not give us a cluster cover. Later we describe how to augment the set of cluster centers to ensure that a cluster cover is obtained.

At the end of each phase, the algorithm selects a set of cluster centers for the next phase. These centers are guaranteed to be sufficiently far apart from each other. More specifically, the cluster centers C_i used in phase i are guaranteed to be at a distance of at least $r/2$.

At the end of phase i, the set of cluster centers for phase $i + 1$ is computed. Initially we set $C_{i+1} := C_i \backslash M_i$; i.e., a subset M_i of the cluster centers is deleted from the list of cluster centers. Later C_{i+1} is augmented appropriately. We now describe how the set M_i is chosen. M_1 is the empty set, implying that C_2 is identical to C_1. For $i > 1$, the algorithm iteratively picks a cluster center from C_i and marks all cluster centers that are within distance r from it. The cluster centers that are marked are inserted into M_i and hence deleted in the next phase. We will refer to this process as a "thinning" of centers in C_i. This is easily implemented by calling the FINDCENTERS after the cluster cover for phase i has been computed. The next cluster center is then picked, and the process continues until all centers have been processed. Now set $C_{i+1} := C_i \backslash M_i$. Clearly this process runs in time $O(m \cdot \sigma)$. It is important to note that, since the integralization changes in every iteration, vertices that are at distance r' in one iteration are at distance at least $r'/2$ in the next iteration. Since the integers are rounded up, it is possible that clustering from centers C_{i+1} with radius r in phase $i + 1$ may not give us a cluster cover.

Steps 1 through 3 (described below) are repeated until a clustering from cluster centers C_{i+1} with radius r gives us a cluster cover in phase $i + 1$.

- *Step* 1. Run PARALLELDIJKSTRA from all vertices of C_{i+1} using the integralization of phase $i+1$. Let K_i be the set of vertices not covered by the clusters centered at C_{i+1}.
- *Step* 2. Greedily pick a subset $K' \subseteq K_i$ such that no two vertices in K' belong to the same cluster from the cluster cover of phase i.
- *Step* 3. If K_i is empty, then **Stop**. Else let K be the result of "thinning" out of the centers in K', and set $C_{i+1} := C_{i+1} \cup K$.

It is easy to see that, after the above process, the new centers are guaranteed to remain at a distance of at least $r/2$. Second, because the process continues until all vertices are covered, it produces a set of cluster centers that will produce a cluster cover in the next phase. Finally, we argue that the number of times steps 1 through 3 are executed is $O(1)$ per phase. Let $\mathcal{C}$ be a cluster from the cluster cover of phase i. Let $\mathcal{P}$ be the region composed of the circular discs of radius r centered at vertices of $\mathcal{C}$. In each iteration of steps 1 through 3, at least one vertex of $\mathcal{C}$ is picked for K_i. This vertex is either chosen for K, or else a large constant fraction of its area

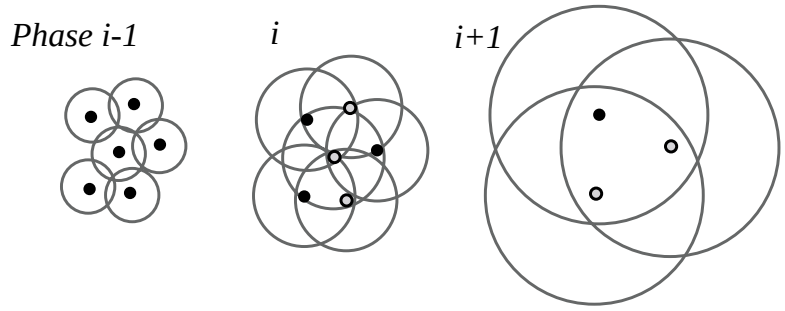

FIG. 9. *If a cluster contains another cluster center, then this cluster center is marked for deletion in the next phase. The figure shows an example of a set of cluster centers, where the cluster centers that are marked for deletion for the next phase are marked in grey.*

is covered by some circular discs of radius r centered at vertices of K. Clearly the region $\mathcal{P}$ will be covered by at most a constant number (exponentially proportional to the dimension of the space d) of circular discs of radius r. Thus steps 1 through 3 will only be executed a constant number of times, each of which takes $O(n)$ time.

We now show that, in phase i, the cluster centers are guaranteed to be at a distance of at least $r/2$ from each other. In phase 1, since cluster centers are identified by using a radius of r, all cluster centers are at a distance of at least r from each other. In phase $i-1$, if two cluster centers are at a distance of r or less, then one of them will get marked and will subsequently be deleted from the list C_i for phase i, as shown in Figure 9. Lemma 8 specifies conditions under which vertices belong to at most a constant number of clusters.

It follows from this lemma that no vertex of H is in more than a constant number of clusters of radius r or of radius R (since $\frac{R}{r} = \frac{1}{\delta}$).

LEMMA 8. *Let $C = \{v_1, \ldots, v_m\} \subseteq V$ be a set of vertices such that, for any pair of vertices $v_i, v_j \in C$, $D_{\{G,w\}}(v_i, v_j) > r'$. If $K = \{K_1, \ldots, K_m\}$ is returned by* CLUSTER-COVER$(G, C, c' \cdot r')$*, where c' is a constant, then each vertex $v \in V$ is contained in at most a constant (which depends on the dimension d and c') number of clusters from K.*

The conditions of the lemma are true for the cluster graph as constructed above with $r' = r/2$ and $c' = 2$ or $c' = 4t/\delta$. Hence any vertex in H is part of at most a constant number of clusters in K_r or K_R. The proof follows from standard packing arguments; see also section 2.2. Similar arguments also show that the number of intercluster edges incident to a cluster center is also a constant (although it might have a large number of intracluster edges). It follows that the degree of any vertex in H that is not a cluster center must be a constant, and the size of H is $O(n)$. Thus σ is also bounded by a constant. Note that IMPROVED-GREEDY uses integralized weights so the resulting clusters are approximate clusters; they are a little bit larger (since integers are always rounded up) than the exact clusters. It is clear that this does not affect the correctness of Lemma 8.

3.3. Answering shortest path queries. When the algorithm IMPROVED-GREEDY considers an edge $e = (u, v)$ for inclusion in the spanner graph, it needs to answer a shortest path query. It needs to check if $D_{\{G',wt\}}(u, v) \leq t \cdot d(u, v)$, where G' is the spanner graph constructed so far. As noted in [8], it is sufficient for this query to be answered approximately. So it is sufficient to devise a procedure to

efficiently check if $D_{\{G',wt\}}(u,v) \leq t(1+\epsilon') \cdot d(u,v)$ for some small $\epsilon' > 0$. In other words, it is sufficient to check if $D_{\{G',Iwt\}}(u,v) \leq t(1+\epsilon'') \cdot d(u,v)/U_i$ for some small $\epsilon'' > 0$. In fact, the algorithm will check if $D_{\{H,Iwt\}}(u,v) \leq \sqrt{tt'} \cdot d(u,v)/U_i$. The time complexity of this test is constant if $D_{\{H,Iwt\}}(u,v) < c' \cdot r$ for some constant c'. Hence we conclude this section with the following theorem, which follows from the above arguments.

THEOREM 9. IMPROVED-GREEDY *runs in time* $O(n \log n)$.

Proof. Following the steps of the IMPROVED-GREEDY algorithm shown in Figure 2, we have that step 1 in the initialization and steps 8 and 11 take time $O(n \log n)$; step 2 takes constant time; step 6 runs in $O(\log n)$ time, while steps 3 and 10 take linear time. The integralization of the weight of the edges in steps 11, 14, and 22 takes a total of $O(\log n)$ time per edge. Since each edge is considered exactly once, the total time spent on integralizing and reintegralizing the weight of the edges is $O(n \log n)$ according to section 3.1. Step 15 requires linear time since σ is bounded by a constant. On line 16, every edge in the input spanner is considered once. For each edge, the algorithm performs one shortest path query in the cluster graph. As mentioned above, each query takes constant time. Hence the total time complexity for computing a linear number of shortest path queries is $O(n)$. Finally, updating the centers is easily done in linear time. From this it follows that IMPROVED-GREEDY runs in time $O(n \log n)$. ∎

In 1999, Thorup [16] showed that single-source shortest path queries could be answered in linear time for undirected graphs with integer edge weights. However, this algorithm was not used in this paper since it does not visit the vertices in order of increasing distance, which is crucial for our algorithm. Also, it uses bit-shift for computing the floor function in constant time, which is not allowed in the computational model used in our algorithm.

4. The graph produced by IMPROVED-GREEDY is a *t*-spanner. In order to show that the produced spanner graph G' is a t-spanner, we need two main results. First, we need to show that the cluster graph H approximates the spanner graph G'; i.e., $D_{\{G',wt\}}(v,u) \leq D_{\{H,Iwt\}}(v,u) \cdot U_i \leq \alpha D_{\{G',wt\}}(v,u)$ for some constant α close to 1. This is done in Lemmas 12 and 13. Second, we need to show, in Lemma 14, that H is always a valid cluster graph of G'. From these results, we easily obtain Theorem 15, which says that the produced spanner G' is a t-spanner of the complete Euclidean graph.

Since the clusters are computed using the function $Iwt(\cdot)$ instead of $wt(\cdot)$, clusters are not as precise as they were in [8]. In this section, we will assume that the smaller radii r_i is δW_i and the larger radii R_i is W_i, where δ is a positive constant decided in Lemmas 14 and 17. Finally, we set $\epsilon = \frac{nU_i}{\delta W_i}$. Some of the results in this section and the next are modified versions of analogous results in [8].

LEMMA 10. *Let* K *be equal to* CLUSTER$(G', v, \delta W_i, Iwt_i)$*, i.e., a cluster with cluster center* v *and radius* δW_i *computed in iteration* i *of the algorithm. If* u *is a vertex in* K*, then* $D_{\{G',wt\}}(v,u) \leq (1+\epsilon)\delta W_i U_i$*. Otherwise, if* $u \notin K$*, then* $D_{\{G',wt\}}(v,u) > \delta W_i U_i$*.*

Proof. The lemma follows from Corollary 4 and the fact that a cluster from K with center at v consists of all vertices within integer distance $\delta W_i/U_i$ from v. ∎

Consider the cluster graph H that results from the clustering performed on G' at the start of phase i. The following results apply to edges and paths in H.

LEMMA 11. *If u is a cluster center and $[u, v]$ is an intracluster edge in H, then*

$$D_{\{G',wt\}}(u, v) \leq (1 + \epsilon)\delta W_i U_i. \tag{1}$$

If $[v_j, v_k]$ is an intercluster edge in H, then

$$\delta W_i U_i < D_{\{G',wt\}}(u, v) \leq (1 + \epsilon) \cdot (W_i + 2\delta W_i)U_i. \tag{2}$$

Proof. The first statement is a direct consequence of Lemma 10; the same holds for the left inequality in (2). The right inequality in the second statement follows from Definition 7 since an intercluster edge of type 2 may be constructed to connect two cluster centers v_j and v_k since there exists an edge $(x, y) \in G'$ such that $x \in K_j$, $y \in K_k$, and $Iwt(x, y) < W_i/U_i$. □

For simplicity, in the rest of this section, we will leave out the unit length U_i. The following lemma is straightforward since H is an approximation of G'.

LEMMA 12. *If there exists a path P_H in H between vertices u and v such that $Iwt(P_H) = L$, then there exists a path $P_{G'}$ in G' between vertices u and v such that $Iwt(P_{G'}) \leq L$.*

We first introduce some definitions. A vertex u is defined to be *sufficiently far* from a vertex v if (1) no single cluster contains both u and v and (2) $D_{\{G',wt\}} \geq W_i$. Define a *cluster path* in H to be a path where the first and last edges may be intracluster edges but all intermediate edges are intercluster edges.

The next lemma is the approximate converse of Lemma 12.

LEMMA 13. *Let u be sufficiently far from v. Let $P_{G'}$ be a path between u and v in G' such that $wt(P_{G'}) = L_1$. Then there exists a cluster path P_H between u and v in H such that*

$$Iwt(P_H) = L_2 < L_1 \cdot \frac{(1 + \epsilon)(1 + 6\delta)}{1 - 2\delta(1 + \epsilon)}.$$

Proof. The proof is similar to the proof of Lemma 4 in [8]. Let the path from u to v having weight L_1 in G' be P. We shall use the notation $P(y, x)$ to denote the vertices of P between vertices y and x, not including y. We construct a cluster path Q from u to v in H with weight L_2 as follows. Let C_0 be any cluster, with center v_0, containing u. The first edge of Q is the intracluster edge $[u, v_0]$. Next, among all clusters with centers adjacent to v_0 in H, let C_1, with center v_1, intersect the furthest vertex along $P(u, v)$, say, w_1. Add the intercluster edge $[v_0, v_1]$ to Q. Next, among all clusters with centers adjacent to v_1 in H, let C_2, with center v_2, intersect the furthest vertex along $P(w_1, v)$, say, w_2. Add the intercluster edge $[v_1, v_2]$ to Q. This process continues until we reach a cluster center, v_m, whose cluster contains v. At this stage, complete Q by adding the intracluster edge $[v_m, v]$, as shown in Figure 10. Three cases arise, and the lemma is proved in each of these cases.

Case 1 ($m = 1$). In this case, there is only one intercluster edge along Q. Since u is sufficiently far from v, we know that $L_1 > W_i - 2(1+\epsilon)\delta W_i$. Now $L_2 = Iwt([u, v_0]) + Iwt([v_0, v_1]) + Iwt([v_1, v])$. However, $Iwt([u, v_0]) \leq (1 + \epsilon)\delta W_i$ and $Iwt([v, v_1]) \leq (1+\epsilon)\delta W_i$, while $Iwt([v_0, v_1]) \leq 2(1+\epsilon)\delta W_i + D_{\{G',Iwt\}}(v, u) \leq 2(1+\epsilon)\delta W_i + (1+\epsilon)L_1$. This result follows from the procedure ADDINTEREDGESTYPE2, since $wt([v_0, v_1])$ is at most $2(1 + \epsilon)\delta W_i$ plus the length of the shortest edge connecting vertices of the two clusters to which u and v belong. So $L_2 \leq (1 + \epsilon)L_1 + 4(1 + \epsilon)\delta W_i$, and we have that $W_i < \frac{(1+\epsilon)L_1}{1-2(1+\epsilon)\delta}$. Combining these inequalities, we get

$$L_2 \leq (1 + \epsilon)L_1 + \frac{4(1 + \epsilon)\delta}{1 - 2(1 + \epsilon)\delta} \cdot L_1 < \frac{(1 + \epsilon)(1 + 2\delta)}{1 - 2\delta(1 + \epsilon)} \cdot L_1.$$

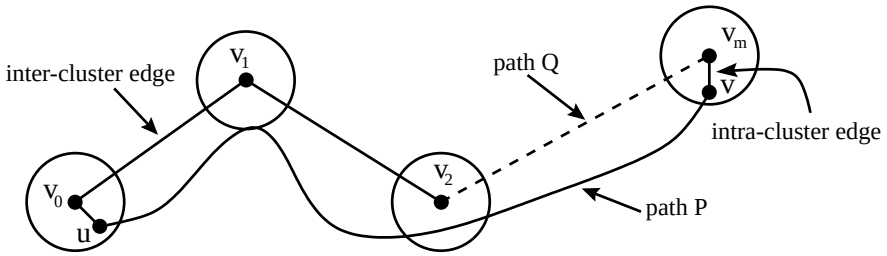

FIG. 10. *Paths in H approximate paths in G'.*

Case 2 ($m \geq 2$ and m even). Suppose $[v_i, v_{i+1}]$ and $[v_{i+1}, v_{i+2}]$ are any two consecutive intercluster edges on Q. Observe that the sum of their weights is greater than W_i. If this were not so, then the edge $[v_i, v_{i+2}]$ would instead have been added to Q while Q was being constructed. Divide Q into portions $Q_0, Q_1, \ldots$, where Q_{2i} is the portion between v_{2i} and v_{2i+2}. Similarly, divide P into portions $P_0, P_1, \ldots$, where P_{2i} is the portion between the last vertex intersecting C_{2i} and the first vertex intersecting C_{2i+2}. We shall first prove that, for any even i, the weight of Q_{2i} is no more than a constant times the weight of P_{2i}.

Let the weight of P_{2i} be p_{2i} and that of Q_{2i} be q_{2i}. Since there cannot be an intercluster edge between v_{2i} and v_{2i+2}, we have that $p_{2i} > W_i - 2\delta(1+\epsilon)W_i$. Thus $W_i < \frac{p_{2i}}{1-2(1+\epsilon)\delta}$. Select r to be any vertex of P_{2i} within the intermediate cluster C_{2i+1}. The vertex r splits P_{2i} into two portions. Let p'_{2i} (respectively, p''_{2i}) be the initial (respectively, final) portions; thus $p_{2i} = p'_{2i} + p''_{2i}$. From the procedure InterEdgesType2, we have $Iwt([v_{2i}, v_{2i+1}]) \leq (1+\epsilon)p'_{2i} + 2\delta(1+\epsilon)W_i$, and, similarly, $Iwt([v_{2i+1}, v_{2i+2}]) \leq (1+\epsilon)p''_{2i} + 2\delta(1+\epsilon)W_i$. Adding the two, we get $q_{2i} \leq (1+\epsilon)p_{2i} + 4\delta(1+\epsilon)W_i$. We now have two inequalities relating p_{2i}, q_{2i} and W_i. Thus

$$q_{2i} < (1+\epsilon)p_{2i} + 4\delta(1+\epsilon) \cdot \frac{p_{2i}}{1-2\delta(1+\epsilon)} < p_{2i} \cdot \frac{(1+\epsilon)(1+2\delta)}{1-2\delta(1+\epsilon)}.$$

Summing over all even values of i and taking into account the two intracluster edges at either end of Q, we get

$$L_2 < L_1 \cdot \frac{(1+\epsilon)(1+2\delta)}{1-2\delta(1+\epsilon)} + 2\delta(1+\epsilon)W_i.$$

Since u is sufficiently far from v, we know that $L_1 > W_i - 2\delta(1+\epsilon)W_i$. That is, $\frac{L_1}{1-2\delta(1+\epsilon)} > W_i$. Substituting this in the above inequality, we obtain

$$L_2 < L_1 \cdot \frac{(1+\epsilon)(1+4\delta)}{1-2\delta(1+\epsilon)}.$$

Case 3 ($m \geq 3$ and m odd). The analysis will be exactly the same as in the previous case, except that we have to account for the last intercluster edge along Q and, correspondingly, the portion of P between the last two clusters. Let q_{m-1} be the integer weight of $[v_{m-1}, v_m]$, and let p_{m-1} be the weight of the portion of P between the last vertex intersecting C_{m-1} and the first vertex intersecting C_m. Clearly $q_{m-1} \leq (1+\epsilon)p_{m-1} + 2\delta(1+\epsilon)W_i$. This inequality can be rewritten as $q_{m-1} < (\frac{(1+\epsilon)(1+2\delta)}{1-2\delta(1+\epsilon)})p_{m-1} + 2\delta(1+\epsilon)W_i$. We then sum up as above to get

$$L_2 < L_1 \cdot \frac{(1+\epsilon)(1+2\delta)}{1-2\delta(1+\epsilon)} + 4\delta(1+\epsilon)W_i.$$

Since $L_1 > W_i - 2\delta(1+\epsilon)W_i$, we have that $L_1 \cdot \frac{4\delta(1+\epsilon)}{1-2\delta(1+\epsilon)} > 4\delta(1+\epsilon)W_i$. Substituting this in the above inequality, we obtain

$$L_2 < L_1 . \frac{(1+\epsilon)(1+6\delta)}{1-2\delta(1+\epsilon)}.$$

That completes the proof of the lemma. □

Before processing group E_i (which contains edges with weights in the range $(W_i, 2W_i]$), the algorithm constructs a fresh cluster graph H using a radius of δW_i.

LEMMA 14. *During the processing of any group E_i, the graph H always represents a valid cluster graph of G'.*

Proof. Let the edges in E_i be ordered by increasing weight as $e_{i1}, \ldots, e_{il}$. The proof is by induction. In the base case, when none of the edges have been processed, the lemma is obviously true. Now assume that the lemma is true just before the algorithm decides to examine edge e_{ij}=(u, v). If this edge is not added to G', then the lemma still holds. Now suppose this edge is added to G'. Since $wt(u, v) > W_i$ and $\delta < 1/2$, the distance between any two previous cluster centers in the new G' will remain greater than δW_i, and thus the previous cluster cover will remain valid. Also, the previous intracluster edges and the intercluster edges of type 1 (see the definition of intercluster edges) will remain the same. We have only to make sure that we add new intercluster edges of type 2, and it is easily seen that this is done by the algorithm. It remains to decide what weights are to be assigned to these new intercluster edges in H. Consider one such edge $[x, y]$, where x (respectively, y) is the center of the cluster to which u (respectively, v) belongs. The weight of this edge should be assigned $D_{\{G', Iwt\}}(x, y)$ (the shortest path in the new graph G' between x and y). However, it will be too time consuming to compute this directly. Instead the algorithm assigns the weight as $Iwt([x, u]) + Iwt(u, v) + Iwt([y, v])$ (see section 3.2.3). We now show that our choice of δ makes this acceptable.

Assume the contrary, i.e., that a shorter alternate path P exists between x and y. Let $Iwt(P)$ denote its integral weight in this phase. Since P cannot involve the edge (u, v), it contains only edges of the previous G'. However, we know that (u, v) was selected to be added to G'; thus no cluster path existed between u and v of weight within $\sqrt{tt'} \cdot Iwt(u, v)$ in H. Furthermore, since u is sufficiently far from v, we may use Lemma 13 to get

$$Iwt(P) + 2\delta W_i(1+\epsilon) > \frac{1-2\delta(1+\epsilon)}{(1+\epsilon)(1+6\delta)} \cdot \sqrt{tt'} \cdot Iwt(u, v).$$

We have that $Iwt(P) < Iwt([x, u]) + Iwt(u, v) + Iwt([v, y])$, which is at most $Iwt(u, v) + 2\delta W_i(1+\epsilon)$. Putting these two results together, we obtain

$$4\delta(1+\epsilon)W_i + Iwt(u, v) > \frac{1-2\delta(1+\epsilon)}{(1+\epsilon)(1+6\delta)} \cdot \sqrt{tt'} \cdot Iwt(u, v).$$

Using the fact that $Iwt(u, v) > W_i$, we get

$$4\delta(1+\epsilon) > \frac{1-2\delta(1+\epsilon)}{(1+\epsilon)(1+6\delta)} \cdot \sqrt{tt'} - 1.$$

If we solve this inequality for δ, we see that the only positive solutions are

$$\delta > \frac{\sqrt{tt'} - (1+\epsilon)}{2(\sqrt{tt'}(1+\epsilon) + 5 + 7\epsilon + 2\epsilon^2)}.$$

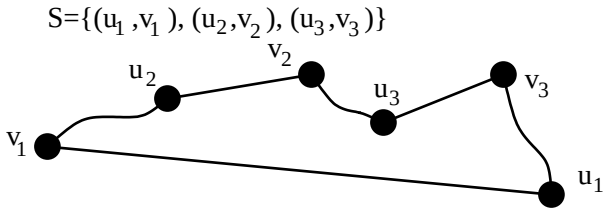

FIG. 11. *Illustration of the definition of the leapfrog property.*

According to our choice of δ in the algorithm IMPROVE-GREEDY, the above inequality will never be satisfied (see Figure 2). Hence we have a contradiction. □

The following theorem now concludes this section.

THEOREM 15. *The graph produced by* IMPROVED-GREEDY *is a t-spanner of the complete Euclidean graph.*

Proof. The proof follows from the fact that G' is a $\sqrt{tt'}$ spanner of G and that G is a $\sqrt{t/t'}$ spanner of the complete graph. □

5. The weight of G' is $O(wt(MST))$. In [4], it was shown that the greedy algorithm produces a spanner that has $O(n)$ edges and a total weight of $O(\log n) \cdot wt(MST(V))$, where $MST(V)$ is the minimum spanning tree of V. The analysis of the greedy algorithm was then improved in [7]. The proof relies on a property known as the *leapfrog property*. This property restricts how a set of line segments may be positioned in space. Here we provide a definition which is technical and nonintuitive.

Let $t \geq t' > 1$. A set of line segments, denoted E', in d-dimensional space satisfy the (t', t)-*leapfrog* property if the following is true for every possible $S = \{(u_1, v_1), \ldots, (u_m, v_m)\}$, which is a subset of E':

$$t' \cdot wt(u_1, v_1) < \sum_{i=2}^{m} wt(u_i, v_i) + t \cdot \left(\sum_{i=1}^{m-1} wt(v_i, u_{i+1}) + wt(v_m, u_1) \right).$$

Informally, this definition says that, if there exists an edge between u_1 and v_1, then any path, not including (u_1, v_1), must have length greater than $t' \cdot wt(u_1, v_1)$, as shown in Figure 11. The following fact was shown by Das and Narasimhan [8].

FACT 16 (Theorem 3 in [8]). *There exists a constant $0 < \phi < 1$ such that the following holds: if a set of line segments E' in d-dimensional space satisfies the (t', t)-leapfrog property, where $t \geq t' \geq \phi t + 1 - \phi > 1$, then $wt(E') = O(wt(MST))$, where MST is a minimum spanning tree connecting the endpoints of E'. The constant implicit in the O-notation depends on t and d.*

Now suppose that we construct a t-spanner such that, for every spanner edge (u, v), the second shortest path is not necessarily longer than $t \cdot wt(u, v)$ but longer than $t' \cdot wt(u, v)$ for some t' such that $t \geq t' > 1$. In this case, the t-spanner satisfies the (t, t')-leapfrog property, as can be proved by using arguments similar to those used in Lemma 2.4 in [7]. Hence the produced spanner will then have total weight $O(wt(MST(V)))$.

So it remains to prove that the weight of the second shortest path between u and v is greater than $t' \cdot wt(u, v)$. First, note that the edges in E_0 do not contribute much because their total length is at most equal to the length of the longest edge ($< n \cdot D/n$), which is less than the weight of the minimum spanning tree. We estimate $wt(E' \backslash E_0)$, where E' is the set of edges produced by the algorithm.

LEMMA 17. *Let $e=(u,v) \in E' \backslash E_0$. The weight of the second shortest path between u and v is greater than $t' \cdot wt(u,v)$.*

Proof. Let C be the shortest simple cycle in G' containing e. We have to estimate $wt(C) - wt(u,v)$. Let $e_1 = (u_1, v_1)$ be the longest edge on the cycle. Then $e_1 \in E' \backslash E_0$, and, among the cycle edges, it is examined last by the algorithm. What happens while the algorithm is examining e_1?

Assume that e_1 is examined in phase i. There is an alternate path in G' from u_1 to v_1 of weight $wt(C) - wt(u_1, v_1)$. However, since the algorithm eventually decides to add e_1 to the spanner, at that moment, the weight of each cluster path from u_1 to v_1 is larger than $\sqrt{tt'} \cdot Iwt(u_1, v_1) \cdot U_i$. Notice that $Iwt(u_1, v_1) \cdot U_i$ and $wt(u_1, v_1)$ are larger than W_i. This implies that u_1 and v_1 are not contained in the same cluster. Thus u_1 is sufficiently far from v_1. Lemma 13 implies that the weight of each path in G' between u_1 and v_1 is large; i.e.,

$$wt(C) - wt(u_1, v_1) > \sqrt{tt'} \cdot Iwt(u_1, v_1) \cdot U_i > \sqrt{tt'} \cdot wt(u_1, v_1) \cdot \frac{1 - 2\delta(1+\epsilon)}{(1+\epsilon)(1+6\delta)}.$$

However, we know, according to the algorithm, that $\delta \leq \frac{\sqrt{tt'} - (1+\epsilon)t'}{2(1+\epsilon)(\sqrt{tt'}+3t')}$. Substituting, we obtain $wt(C) - wt(u_1, v_1) > t' \cdot wt(u_1, v_1)$. ∎

Finally, since Lemma 17 holds, we can use the following observation which, together with Fact 16, concludes the proof of Theorem 1.

OBSERVATION 18. *$E' \backslash E_0$ satisfies the (t', t)-leapfrog property.*

Proof. Consider any subset of the edges $S = \{(u_1, v_1), \ldots, (u_m, v_m)\}$ of E'. By Lemma 17, we know that $t' \cdot d(u_1, v_1)$ is smaller than the weight of the second shortest path between u_1 and v_1 in G'. Consider a path P from v_1 to u_1, composed of the shortest path from v_1 to u_2 (of weight $\leq t \cdot d(v_1, u_2)$), the edge (u_2, v_2), the shortest path from v_2 to u_3 (of weight $\leq t \cdot d(v_2, u_3)$), and so on, until the final portion is the shortest path from v_m to u_1. Clearly $wt(P)$ is at least as large as the weight of the second shortest path between u_1 and v_1. However, $wt(P)$ is also equal to the right-hand side of the definition of the leapfrog property. The observation follows. ∎

This concludes the proof of Theorem 1.

6. Conclusions and open problems. This paper represents an important advancement in the study of spanners; we present the first correct $O(n \log n)$-time algorithm to construct low-weight spanners (weight $O(1) \cdot wt(MST)$) and a small number of edges (only $O(n)$ edges). The implementation of clustering techniques is of independent interest in the design of efficient algorithms.

The main theoretical open problem that remains unsolved is to design an algorithm to construct a sparse t-spanner in time $O(n \log n)$ in the algebraic decision tree model of computation.

Acknowledgments. We are grateful to Michiel Smid for numerous helpful discussions. We are also very grateful to a diligent referee for many good comments and for helping us fix a subtle error in section 3.2.4.

GRAPH NONISOMORPHISM HAS SUBEXPONENTIAL SIZE PROOFS UNLESS THE POLYNOMIAL-TIME HIERARCHY COLLAPSES*

ADAM R. KLIVANS† AND DIETER VAN MELKEBEEK‡

Abstract. Traditional hardness versus randomness results focus on time-efficient randomized decision procedures. We generalize these trade-offs to a much wider class of randomized processes. We work out various applications, most notably to derandomizing Arthur-Merlin games. We show that every language with a bounded round Arthur-Merlin game has subexponential size membership proofs for infinitely many input lengths unless exponential time coincides with the third level of the polynomial-time hierarchy (and hence the polynomial-time hierarchy collapses). Since the graph nonisomorphism problem has a bounded round Arthur-Merlin game, this provides the first strong evidence that graph nonisomorphism has subexponential size proofs.

We also establish hardness versus randomness trade-offs for space bounded computation.

Key words. derandomization, pseudorandomness, graph isomorphism, interactive proofs, Arthur-Merlin games, hardness versus randomness, universal traversal sequences, unique satisfiability, learning theory, rigid matrices

1. Introduction.

Randomness has proven to be a valuable tool in computer science. It is an indispensable resource in areas like cryptography and distributed computing. The situation is less clear for algorithms. Several computational problems turn out to have simple randomized solutions that require less time or space than the known deterministic algorithms. It is conceivable, however, that efficient deterministic algorithms exist for all of these problems.

In fact, many complexity theorists believe that randomness *cannot* significantly reduce the time or space complexity of a problem. To this end, they try to construct efficient pseudorandom generators—deterministic procedures that stretch seeds containing a few random bits into much longer bit sequences that look random to the randomized process in question. This allows us to reduce the amount of randomness needed and, in some cases, eliminate the need for random bits completely without increasing the need for other resources by much.

Considerable progress has been made in the construction of pseudorandom generators that fool arbitrary time-bounded decision procedures. We now know how to construct them out of certain types of "hard" computational problems. The existence of such hard problems is still open. These constructions are often referred to as *hardness versus randomness trade-offs*; they rule out the possibility that both hard problems exist and randomness speeds up some time-bounded decision problem.

1.1. Traditional hardness versus randomness trade-offs.

Blum and Micali [BM84] and Yao [Yao82] were the first to realize this connection. Nisan and Wigderson

[NW94] established a whole range of hardness versus randomness trade-offs using an average-case hardness notion. They showed how to use any language in exponential time that requires large circuits to be computed exactly on slightly more than half of the inputs, to construct a pseudorandom generator that fools circuits of polynomial size. They obtained nontrivial derandomizations of polynomial-time randomized decision algorithms under average-case hardness assumptions and even deterministic polynomial-time simulations under the strongest of their hypotheses. Babai, Fortnow, Nisan, and Wigderson [BFNW93] and Impagliazzo and Wigderson [IW97] relaxed the hardness condition from an average-case condition to a worst-case one. For their constructions, they had only to start from a language in exponential time that requires large circuits to be computed exactly on *every* input. As a corollary, they showed how to simulate every polynomial-time randomized decision algorithm deterministically in subexponential time for infinitely many input lengths unless exponential time collapses to the second level of the polynomial-time hierarchy (and, in fact, to the class MA) [BFNW93].

The authors of these papers [NW94, BFNW93, IW97] used their techniques to derandomize traditional models of randomized computation, most notably BPP. We show how to apply the techniques used to derandomize BPP to more general models of randomized computation. The key observation we make is that the reductions used in the proofs are "black-box"; i.e., they relativize. More specifically, the above papers start from a Boolean function f and construct a proposed pseudorandom generator based on it. They then argue that any small circuit that distinguishes the output of the proposed pseudorandom generator from the uniform distribution can be transformed into a small circuit that computes f. We observe that these reductions work for *any* nonuniform model of computation that satisfies certain closure properties. In particular, they work for oracle circuits given any fixed oracle B, i.e., for circuits consisting of AND, OR, and NOT gates and gates that evaluate the oracle B. Thus, in order to build a pseudorandom generator that looks random to any small B-oracle circuit, we need only assume the existence of a function f that cannot be computed by small B-oracle circuits. The same holds for more recent constructions by Sudan, Trevisan, and Vadhan [STV01] that provide alternate proofs for some of the earlier results [NW94, BFNW93, IW97].

1.2. Derandomizing Arthur-Merlin games. The above observations allow us to apply the classical hardness versus randomness results to various settings, in particular to the nondeterministic setting of Arthur-Merlin games [Bab85].

Arthur-Merlin games are verification procedures in which a prover (Merlin) tries to convince a randomized polynomial-time verifier (Arthur) of some fact, say, that a given input belongs to some language. Arthur-Merlin games define an extension of the classical proof paradigm in two ways: the use of randomness by the verifier and the interaction between the prover and the verifier. Of particular interest is the class AM of languages for which there exists an Arthur-Merlin game with a bounded number of rounds of interaction between the verifier and the prover. The class AM forms a randomized extension of NP. The most notable problem in AM not known to be in NP is graph nonisomorphism [GMW91, GS89, BM88].

Derandomizing Arthur-Merlin games requires security against the nondeterministic adversary Merlin. Rudich [Rud97] pointed out that pseudorandom generators in the traditional cryptographic setting, where an adversary has more resources than the generator, cannot hope to have this property. This is because a nondeterministic adversary can guess the seed the verifier will use and run the generator on this seed

TABLE 1
Hardness versus randomness trade-offs for AM.

Hardness assumption	Derandomization consequence
$\exists f \in \mathsf{NEXP} \cap \mathsf{coNEXP} : C_f^{\mathrm{SAT}}(n) = n^{\omega(1)}$	$\mathsf{AM} \subseteq \cap_{\epsilon>0}\mathsf{NTIME}[2^{n^\epsilon}]$
$\exists f \in \mathsf{NEXP} \cap \mathsf{coNEXP} : C_f^{\mathrm{SAT}}(n) = 2^{n^{\Omega(1)}}$	$\mathsf{AM} \subseteq \cup_{c>0}\mathsf{NTIME}[2^{(\log n)^c}]$
$\exists f \in \mathsf{NE} \cap \mathsf{coNE} : C_f^{\mathrm{SAT}}(n) = 2^{\Omega(n)}$	$\mathsf{AM} = \mathsf{NP}$

to obtain the pseudorandom sequence the verifier will use. From a derandomization perspective, however, we can limit the resources the adversary can use. Nisan and Wigderson exploited this fact in the BPP setting. We use it in the context of Arthur-Merlin games. The drawback of cryptographic pseudorandom generators does not apply because the adversaries do not have the resources to run the generator—even if they correctly guess the seed.

We give evidence that AM coincides with NP. More specifically, we show that the existence of an exponential-time decidable language with high worst-case SAT-oracle complexity implies nontrivial derandomizations of AM. Examples of the trade-offs we obtain are presented in Table 1, where we use C^B to denote circuit complexity given access to oracle B. We provide the precise definitions in section 2 and the general trade-off statement in section 3.

For example, the first line of Table 1 states that, if there exists a function computable in NEXP∩coNEXP which requires SAT-oracle circuits of superpolynomial size for almost all input lengths, then AM is contained in nondeterministic subexponential time, i.e., has subexponential size proofs. The third line of Table 1 states that, if we go further and assume that there exists a function in NE ∩ coNE which requires SAT-oracle circuits of size $2^{\epsilon n}$ for some $\epsilon > 0$ and almost all input lengths, then every language in AM has polynomial size proofs.

If the hardness condition on the left-hand side of Table 1 holds for infinitely many input lengths, then the corresponding derandomization on the right-hand side works for infinitely many input lengths. We refer to the *weak* version of Table 1 when we assume the above hardness conditions hold only for infinitely many input lengths. As in the above papers [NW94, BFNW93, IW97], we typically state our theorems assuming the hardness conditions are true for every input length. Both interpretations hold for all of our results.

We can view the assumptions in Table 1 as statements concerning the relationships among computation, nonuniformity, and nondeterminism. For example, the third entry in the table states that, if nonuniformity and nondeterminism cannot significantly speed up computation, then we can derandomize AM. We point out that, if the hardness assumption in the first row of the weak version of Table 1 fails, then exponential time collapses to the third level of the polynomial-time hierarchy.

Arvind and Köbler [AK97] obtained similar results to those in Table 1 using *nondeterministic* circuits but needed average-case hardness assumptions instead of worst-case ones. Nondeterministic circuits consist of AND, OR, and NOT gates and have some additional input bits y. An input x is accepted if there is a setting of the additional input bits y that makes the circuit accept x. Nondeterministic circuits can be efficiently simulated by SAT-oracle circuits but presumably not the other way around. Nondeterministic circuits do not seem to have the closure properties that

allow us to relax the hardness hypothesis from average-case to worst-case, whereas SAT-oracle circuits do. Bridging the gap between average-case and worst-case assumptions is crucial. It allows us to conclude that every language in AM, and graph nonisomorphism, in particular, has subexponential size proofs for infinitely many input lengths unless the polynomial-time hierarchy collapses. See the weak version of the first line in Table 1. Without any unproven hypothesis, the smallest proofs known for the nonisomorphism of two graphs on n vertices are of size $2^{O(\sqrt{n \log n})}$, namely, the transcripts of the deterministic graph isomorphism algorithm by Babai, Kantor, and Luks [BL83, BKL83].

Recently, Miltersen and Vinodchandran [MV99] managed to relax the hardness assumption in the last line of Table 1. They showed that AM collapses to NP if there exists a Boolean function in $\mathsf{NE} \cap \mathsf{coNE}$ with exponential nondeterministic circuit complexity (instead of SAT-oracle circuit complexity). Their technique works only under strong hardness assumptions. In particular, it does not apply to the rest of Table 1. See section 6 for a more detailed discussion.

1.3. Generalizing hardness versus randomness trade-offs. Our simulations of AM are a special case of a general derandomization tool which applies to any randomized process for which we can efficiently check whether a particular choice of random bits results in a successful computation. For example, for a fixed BPP algorithm and input, at least 2/3 of the random strings result in a "successful" computation. Any randomized function computation with this property, regardless of whether it involves a decision problem or not, falls within our framework. We formally define the notion of a success predicate in section 4. If we can decide the success predicate of a randomized process with polynomial size B-oracle circuits, then assuming the existence of a function with high B-oracle circuit complexity implies the existence of a pseudorandom generator suitable for derandomizing the process. Table 2 gives a summary of these trade-offs. The symbol $\mathcal{A}$ in Table 2 represents an arbitrary class of oracles and determines the complexity of computing the generator G.

TABLE 2
Overview of pseudorandom generator constructions.

Hardness assumption	Complexity of G	Seed length
$\exists f \in \mathsf{EXP}^{\mathcal{A}} : C_f^B(n) = n^{\omega(1)}$	$\mathsf{EXP}^{\mathcal{A}}$	$O(n^\epsilon)$ for arbitrary $\epsilon > 0$
$\exists f \in \mathsf{EXP}^{\mathcal{A}} : C_f^B(n) = 2^{n^{\Omega(1)}}$	$\mathsf{EXP}^{\mathcal{A}}$	$(\log n)^{O(1)}$
$\exists f \in \mathsf{E}^{\mathcal{A}} : C_f^B(n) = 2^{\Omega(n)}$	$\mathsf{E}^{\mathcal{A}}$	$O(\log n)$

In this paper, we illustrate the power of our generalization by applying it to the following randomized processes from different areas of theoretical computer science:

(i) the Valiant–Vazirani random hashing procedure which prunes the number of satisfying assignments of a propositional formula to one [VV86],
(ii) exact learning of circuits using equivalence queries and access to an NP oracle [BCG+96],
(iii) the construction of matrices with high rigidity [Val77],
(iv) the construction of polynomial size universal traversal sequences [AKL+79].

Consider the first item above. Valiant and Vazirani [VV86] give a randomized algorithm that takes as input a propositional formula ϕ and outputs with high probability a list of formulas with the following property: If ϕ is satisfiable, then some

formula in the output list has exactly one satisfying assignment; if ϕ is unsatisfiable, then no formula in the list is satisfiable. Strictly speaking, the Valiant–Vazirani procedure is not a "BPP algorithm," and it is not clear how one could use a pseudorandom generator for BPP to derandomize it. One reason for this is that checking if the Valiant–Vazirani procedure was "successful," (i.e., it outputs a list of formulas with the above property) does not seem to be computable in polynomial time. Checking if the Valiant–Vazirani procedure succeeds for a particular input and choice of random bits *is* polynomial-time computable, however, if we are given access to an oracle for SAT. From this observation, we can prove that the existence of a Boolean function in exponential time with high SAT-oracle circuit complexity implies the existence of a pseudorandom generator which can be used to derandomize the Valiant–Vazirani procedure.

More specifically, we show that, given a propositional formula ϕ, we can construct in subexponential time a collection of polynomial size formulas satisfying the above Valiant–Vazirani property unless the polynomial-time hierarchy collapses. If there exists a language in E with SAT-oracle circuit complexity $2^{\epsilon n}$ for some $\epsilon > 0$, then we achieve a polynomial-time deterministic procedure. It follows that, under the same hypothesis, we can find in polynomial time a satisfying assignment for a propositional formula using *nonadaptive* access to an oracle for SAT. The latter contrasts with the standard adaptive method of binary search. We obtain derandomization results of a similar kind for the other items in the above list. We refer to section 5 for the precise statements.

1.4. Relationship to extractors. Our generalized hardness versus randomness trade-offs have also played a crucial role in the recent breakthrough extractor constructions by Trevisan [Tre99]. An extractor is a combinatorial object used to "extract" randomness from a corrupt or weakly random source. More specifically, applying an extractor to a probability distribution with some crude randomness results in a distribution which is almost uniform over strings of length related to the amount of crude randomness in the original distribution. We refer to the survey paper by Nisan and Ta-Shma [NT99] for background, precise definitions, and constructions.

In retrospect, from the observation that the construction due to Impagliazzo and Wigderson [IW97] is a black-box transformation of a hard function, one can directly prove the existence of the type of extractors found in the aforementioned work of Trevisan [Tre99]. See section 6 for a discussion.

1.5. Universal traversal sequences and randomized logspace. We also obtain some results related to the construction of universal traversal sequences and the derandomization of randomized logspace. Universal traversal sequences are instructions for walks on arbitrary undirected graphs of a given size that have the property that any vertex of the graphs is visited at least once by the walk. The instructions depend only on the number of vertices of the graph and not on its structure. A major open problem is to give a deterministic polynomial-time (or logspace) construction of such sequences. A logspace construction of universal traversal sequences, for example, would show that undirected connectivity is computable in logspace.

We give polynomial-time constructions of universal traversal sequences under the assumption that there exists a language in E with circuit complexity $2^{\epsilon n}$ for some ϵ. We also show that, if there is a language in linear space that requires circuits of size $2^{\Omega(n)}$, then BPL = L, where BPL denotes the languages recognizable in randomized logspace with bounded two-sided error. In fact, we need only the weaker hypothesis that there exists a language in linear space that requires branching programs of size

$2^{\epsilon n}$. This answers a question raised by Clementi, Rolim, and Trevisan [CRT98]. As a corollary, under the same hypothesis, we can generate universal traversal sequences in logspace.

1.6. Organization. Section 2 introduces our notation. In section 3, we generalize the techniques used to derandomize BPP and show how to use them in the Arthur-Merlin setting. Section 4 defines a broad class of randomized processes and shows how our approach allows us to reduce the randomness of any process that fits within this class. In section 5, we apply this framework to the four examples mentioned above. We discuss directions for further research and some recent progress in section 6.

2. Notation. Most of our complexity theoretic notation is standard. We refer the reader to the textbooks by Balcázar, Díaz, and Gabarró [BDG95] and by Papadimitriou [Pap94].

An *oracle circuit* D is a circuit with AND, OR, and NOT gates as well as oracle gates, which compute membership of the string formed by their input bits to some unspecified oracle B. The function D^B the circuit computes depends on the oracle B. For fixed B, we will use the term *B-oracle circuit* to denote an oracle circuit with access to B as an oracle. In this paper, we measure the *size* of a circuit by its number of connections.

Given a Boolean function $f : \{0,1\}^* \to \{0,1\}$ and an oracle B, the *circuit complexity* $C_f^B(n)$ of f at length n relative to B is the smallest integer t such that there is a B-oracle circuit of size t that computes f on inputs of length n. The *hardness* $H_f^B(n)$ of f at length n relative to B is the largest integer t such that, for any oracle circuit D of size at most t with n inputs,

$$\left| \Pr_x[D^B(x) = f(x)] - \frac{1}{2} \right| < \frac{1}{t},$$

where x is uniformly distributed over $\{0,1\}^n$.

A *pseudorandom generator* G is a sequence of functions $(G_n)_{n\in\mathbb{N}}$ such that G_n maps $\{0,1\}^{s(n)}$ to $\{0,1\}^n$ for some function $s : \mathbb{N} \to \mathbb{N}$ with $s(n) < n$. The function s is called the *seed length* of G. We say that G is *computable in* $\mathcal{C}$ if the problem of deciding the ith bit of $G_n(\sigma)$ given $\langle n, \sigma, i\rangle$ belongs to $\mathcal{C}$. Given an oracle B, G_n is said to be *secure against* B if, for any oracle circuit D of size at most n,

$$|\Pr_\rho[D^B(\rho) = 1] - \Pr_\sigma[D^B(G_n(\sigma)) = 1]| < \frac{1}{n}, \tag{1}$$

where ρ is uniformly distributed over $\{0,1\}^n$ and σ is uniformly distributed over $\{0,1\}^{s(n)}$. G is said to be secure against B if G_n is secure against B for almost all n.

For any function $t : \mathbb{N} \to \mathbb{N}$, AM-TIME$[t(n)]$ represents the class of languages L for which there exists a deterministic Turing machine M that runs in time $O(t(n))$ on inputs of the form $\langle x, y, z\rangle$, where $x \in \{0,1\}^n$ and $y, z \in \{0,1\}^{t(n)}$, such that, for any input x,

$$x \in L \Rightarrow \Pr_{|y|=t(n)}[\exists z \in \{0,1\}^{t(n)} : M(\langle x, y, z\rangle) = 1] \geqslant \frac{2}{3}, \tag{2}$$

$$x \notin L \Rightarrow \Pr_{|y|=t(n)}[\exists z \in \{0,1\}^{t(n)} : M(\langle x, y, z\rangle) = 1] \leqslant \frac{1}{3}, \tag{3}$$

where $n = |x|$ and the probabilities are with respect to the uniform distribution. AM denotes $\cup_{c>0}\mathsf{AM\text{-}TIME}[n^c]$. The above definition of Arthur-Merlin games allows two-sided error. Requiring a one-sided error leads to the same class modulo polynomial factors. More precisely, an Arthur-Merlin game running in time $O(t(n))$ can be transformed into an equivalent Arthur-Merlin game running in time $(t(n))^{O(1)}$ satisfying (2) with the 2/3 on the right-hand side replaced by 1 [FGM+89]. In particular, one can assume without loss of generality that every language in AM has a polynomial-time one-sided error Arthur-Merlin game. We will not exploit that fact in this paper, but later work [MV99] crucially relies on it.

$\mathsf{EXP} = \cup_{c>0}\mathsf{DTIME}[2^{n^c}]$, and $\mathsf{E} = \cup_{c>0}\mathsf{DTIME}[2^{cn}]$. Similarly, $\mathsf{NEXP} = \cup_{c>0}\mathsf{NTIME}[2^{n^c}]$, and $\mathsf{NE} = \cup_{c>0}\mathsf{NTIME}[2^{cn}]$.

For any complexity class $\mathcal{C}$, the class infinitely-often-$\mathcal{C}$ (i.o.-$\mathcal{C}$) consists of all languages L for which there is a language $L' \in \mathcal{C}$ such that $L \cap \{0,1\}^n = L' \cap \{0,1\}^n$ for infinitely many lengths n.

For any function $s : \mathbb{N} \to \mathbb{N}$, $\Omega(s)$ denotes the class of all functions $t : \mathbb{N} \to \mathbb{N}$ for which there exists a constant $\epsilon > 0$ such that $t(n) \geqslant \epsilon \cdot s(n)$ for almost all n. $\omega(s)$ is the class of t such that, for any $c > 0$ and almost all n, $t(n) \geqslant c \cdot s(n)$.

3. Derandomizing Arthur-Merlin games. In this section, we develop methods for derandomizing Arthur-Merlin games and give evidence that the class AM of languages with bounded round Arthur-Merlin games is not much larger than NP and may even coincide with it. For clarity of exposition and to provide an initial outline for our arguments, we first state all of our theorems without proofs. We then fill in details starting in section 3.1.

As is customary in the area of derandomization, our approach will be to construct pseudorandom generators with appropriate security properties. The following lemma states that, to derandomize $\mathsf{AM} = \cup_{c>0}\mathsf{AM\text{-}TIME}[n^c]$, the pseudorandom generator need only be secure against SAT. See section 3.1 for a proof.

LEMMA 3.1. *Let $s, t, \tau : \mathbb{N} \to \mathbb{N}$ be constructible functions. If there is a pseudorandom generator G computable in $\mathsf{NTIME}[\tau(n)] \cap \mathsf{coNTIME}[\tau(n)]$ and with seed length s that is secure against* SAT*, then*

$$\mathsf{AM\text{-}TIME}[t(n)] \subseteq \mathsf{NTIME}[2^{s(t'(n))} \cdot \tau(s(t'(n))) \cdot t(n)], \tag{4}$$

where $t'(n) = O(t(n) \log^2 t(n))$.

In order to build such a pseudorandom generator, we will extend previous work [NW94, BFNW93, IW97, STV01] to the nondeterministic setting of Arthur-Merlin games. The main construction in these papers is a reduction from a circuit that distinguishes the output of a pseudorandom generator based on f from the uniform distribution to a circuit capable of computing f. We argue that this construction works for any nonuniform model of computation satisfying certain closure properties and, in particular, for B-oracle circuits for any fixed oracle B. In this way, we obtain pseudorandom generators secure against B from functions which small B-oracle circuits cannot compute.

We begin with a generalized version of the main result of Nisan and Wigderson [NW94]. Their construction works for any nonuniform model which is closed under precomputation and complementation. In particular, it carries through for oracle circuits. See section 3.2 for a more detailed argument.

THEOREM 3.2. *Let B be any oracle, let g be a Boolean function, and let $\ell : \mathbb{N} \to \mathbb{N}$ be a constructible function. If*

$$H_g^B(\ell(n)) \geqslant n^2,$$

then there exists a pseudorandom generator G which is secure against B and has a constructible seed length $s(n) = O(\ell^2(n)/\log n)$. Computing any bit of $G(\sigma)$ for $\sigma \in \{0,1\}^{s(n)}$ takes time $2^{O(s(n))}$ plus one evaluation of g on an input of length $\ell(n)$.

Theorem 3.2 states that the existence of functions with high average-case oracle circuit complexity, say, SAT oracles, implies the existence of pseudorandom generators secure against the corresponding oracle, in this case SAT. We would like to relax this assumption from average-case to worst-case, however, so we will need to examine worst-case to average-case reductions, also known as *hardness amplifications*.

The worst-case to average-case hardness transformation of Babai et al. [BFNW93] requires only closure of the model of computation under majority, complementation, and certain arithmetic field operations. Since oracle circuits have these closure properties, the transformation also works for this model. This observation enables us to establish the first two lines of derandomization results for Arthur-Merlin games in Table 1 but falls short in establishing the last line. For the last line, sometimes referred to as a "high-end" derandomization, we appeal to the reduction in Impagliazzo and Wigderson [IW97], which also carries through for oracle circuits and is powerful enough to establish all of Table 1. An alternate to the Impagliazzo–Wigderson construction is described by Sudan, Trevisan, and Vadhan [STV01] and is more amenable to generalization. In section 3.3, we provide the details of this generalization and obtain the following hardness amplification result.

THEOREM 3.3. *There exist positive constants γ and δ such that, for any oracle B, Boolean function f, and constructible function $h : \mathbb{N} \to \mathbb{N}$ satisfying*

$$h(n) \leqslant (C_f^B(\gamma n))^\delta / n,$$

the following holds: There exists a Boolean function g such that $H_g^B(n) \geqslant h(n)$. Computing g on an input of length n takes time $2^{O(n)}$ plus evaluating f on all inputs of length γn.

Combining Theorems 3.2 and 3.3 yields our main derandomization tool. Some instantiations are given in Table 2.

THEOREM 3.4. *There exists a positive constant c such that the following holds for any class $\mathcal{A}$ of oracles, oracle B, a Boolean function $f \in \mathsf{E}^{\mathcal{A}}$, and a constructible function $\ell : \mathbb{N} \to \mathbb{N}$: If*

$$C_f^B(\ell(n)) \geqslant n^c,$$

then there exists a pseudorandom generator G computable in $\mathsf{E}^{\mathcal{A}}$ which is secure against B and has a constructible seed length $s(n) = O(\ell^2(n)/\log n)$. The same holds if E is replaced by EXP.

In this section, we will apply Theorem 3.4 with $\mathcal{A} = \mathsf{NP} \cap \mathsf{coNP}$ and $B = \mathrm{SAT}$. Note that $\mathsf{EXP}^{\mathsf{NP} \cap \mathsf{coNP}} = \mathsf{NEXP} \cap \mathsf{coNEXP}$. Together with Lemma 3.1, Theorem 3.4 yields the following result.

THEOREM 3.5. *If there is a Boolean function $f \in \mathsf{NEXP} \cap \mathsf{coNEXP}$ such that $C_f^{\mathrm{SAT}}(n) = n^{\omega(1)}$, then*

$$\mathsf{AM} \subseteq \cap_{\epsilon > 0} \mathsf{NTIME}[2^{n^\epsilon}].$$

We can rephrase the weak version of Theorem 3.5 as follows.

THEOREM 3.6. *If $\mathsf{NEXP} \cap \mathsf{coNEXP} \not\subseteq \mathsf{P}^{\mathsf{NP}}/\mathsf{poly}$, then $\mathsf{AM} \subseteq \cap_{\epsilon > 0} \text{i.o.-}\mathsf{NTIME}[2^{n^\epsilon}]$.*

So, if the conclusion of Theorem 3.6 fails to hold, then $\mathsf{NEXP} \cap \mathsf{coNEXP} \subseteq$

$\mathsf{P}^{\mathsf{NP}}/\mathsf{poly}$, which implies that $\mathsf{EXP} = \Sigma_3^{\mathsf{p}} \cap \Pi_3^{\mathsf{p}}$ [KL82]. Therefore, we obtain the following theorem.

THEOREM 3.7. *If exponential time does not collapse to the third level of the polynomial-time hierarchy, then every language in* AM*, and graph nonisomorphism, in particular, has subexponential size proofs for infinitely many lengths.*

More generally, Theorem 3.4 yields the following derandomization result for Arthur-Merlin games. Note that $\mathsf{E}^{\mathsf{NP}\cap\mathsf{coNP}} = \mathsf{NE} \cap \mathsf{coNE}$.

THEOREM 3.8. *If there is a Boolean function $f \in \mathsf{NE} \cap \mathsf{coNE}$ and a constructible function $\ell : \mathbb{N} \to \mathbb{N}$ such that*

$$C_f^{\mathrm{SAT}}(\ell(n)) = \Omega(n),$$

then

$$\mathsf{AM} \subseteq \cup_{c>0}\mathsf{NTIME}[2^{\ell^2(n^c)/\log n}].$$

Theorem 3.8 yields a range of hardness versus randomness trade-offs for the various choices of the parameter ℓ. Since $C_f^B(n)$ is always at most $O(2^n/n)$, the hypothesis of Theorem 3.8 cannot be met for ℓ sublogarithmic. On the other hand, the conclusion becomes trivial in the case where ℓ is polynomial. Therefore, the interesting range for ℓ lies between logarithmic and subpolynomial. For example, for ℓ polylogarithmic, Theorem 3.8 (combined with some padding) yields the second line in Table 1 and the following. Recall that quasi-polynomial means $2^{\log^{O(1)} n}$.

THEOREM 3.9. *If there is a Boolean function $f \in \mathsf{NEXP} \cap \mathsf{coNEXP}$ such that $C_f^{\mathrm{SAT}}(n) = \Omega(2^{n^\epsilon})$ for some $\epsilon > 0$, then every language in* AM *has quasi-polynomial size proofs.*

Theorem 3.8 achieves complete derandomizations of Arthur-Merlin games in case of logarithmic ℓ.

THEOREM 3.10. *If there is a Boolean function $f \in \mathsf{NE}\cap\mathsf{coNE}$ such that $C_f^{\mathrm{SAT}}(n) \in 2^{\Omega(n)}$, then $\mathsf{AM} = \mathsf{NP}$. In particular, the same hypothesis implies that graph nonisomorphism has polynomial size proofs.*

We wish to point out that, under the hypothesis of Theorem 3.10, the proof of Lemma 3.1 describes an explicit certificate for graph nonisomorphism or any other AM-language.

We also note that, for derandomizing AM, it is actually sufficient to construct efficient pseudorandom generators that are secure against SAT-oracle circuits with *parallel* access to the oracle. All theorems in this section also hold for oracle circuits with such restricted access.

Finally, we note that our derandomizations also apply to Arthur-Merlin games where the number of rounds of interaction is not necessarily bounded by a constant. Via standard transformations (see [BM88]), one can show that any language possessing an Arthur-Merlin game with ℓ rounds and verifier complexity $t(n)$ is contained in $\mathsf{AM}\text{-}\mathsf{TIME}[t'(n)]$, where $t'(n) = t(n)^{O(\ell)}$), so we can apply the theorems from this section directly.

3.1. Proof of Lemma 3.1. Let L be a language satisfying (2) and (3), and consider

$$L' = \{\langle x, y\rangle \mid y \in \{0,1\}^{t(|x|)} \text{ and } \exists\, z \in \{0,1\}^{t(|x|)} : M(\langle x, y, z\rangle) = 1\}.$$

By Cook's theorem [Coo71, Coo88], since L' is in nondeterministic linear time, there exists a circuit of size $t'(n) = O(t(n)\log^2 t(n))$ that many-one reduces L' to SAT on

```
counter ← 0
for every σ ∈ {0,1}^{s(t'(n))}
    for  i ← 1,...,t(n)
         guess ρ_i ∈ {0,1}
         guess a computation path p for N(⟨n,σ,i,ρ_i⟩)
         if N(⟨n,σ,i,ρ_i⟩) rejects along p
            then reject and abort
    guess z ∈ {0,1}^{t(n)}
    counter ← counter + M(⟨x,ρ,z⟩)
if counter > 2^{t'(n)-1} then accept
```

FIG. 1. *Nondeterministic algorithm for deciding L.*

inputs $\langle x, y\rangle$ with $x \in \{0,1\}^n$ and $y \in \{0,1\}^{t(n)}$. For any fixed value of $x \in \{0,1\}^n$, let C_x denote the corresponding oracle circuit obtained by hardwiring x. Note that C_x makes a single oracle query and outputs the answer to that query. Since G is a pseudorandom generator secure against SAT, conditions (2) and (3) imply that

$$\Pr_{\sigma}[C_x^{\mathrm{SAT}}(G_{t'(n)}(\sigma)) = 1] \begin{cases} > \frac{1}{2} & \text{if } x \in L, \\ < \frac{1}{2} & \text{if } x \notin L, \end{cases} \tag{5}$$

where the probability is with respect to the uniform distribution of σ over $\{0,1\}^{s(t'(n))}$.

Since G is computable in $\mathsf{NTIME}[\tau(n)] \cap \mathsf{coNTIME}[\tau(n)]$, there exists a nondeterministic Turing machine N running in time τ that accepts $\{\langle n, \sigma, i, b\rangle \mid i\text{th bit of } G_n(\sigma) \text{ equals } b\}$. Now consider the nondeterministic algorithm in Figure 1.

Figure 1 describes a nondeterministic Turing machine that runs in time $2^{s(t'(n))} \cdot \tau(s(t'(n))) \cdot t(n)$. The largest possible value of counter at the end of the outer loop over all possible nondeterministic choices in the algorithm of Figure 1 equals $2^{s(t'(n))} \cdot \Pr_\sigma[C_x^{\mathrm{SAT}}(G_{t'(n)}(\sigma)) = 1]$. It follows from (5) that the machine accepts L. This finishes the proof of Lemma 3.1.

3.2. Proof of Theorem 3.2. This and the next section establish our generalization of known hardness versus randomness trade-offs. The key observation is that, using the appropriate notion of relativization, the known hardness versus randomness trade-offs *relativize*.

Relativization is the idea of giving all computing devices access to one or more oracles for arbitrary but fixed computational problems. Most theorems in computational complexity relativize; i.e., they hold under relativization. This is often just stated as a remark, as it is straightforward to verify that the proof of the theorem carries through when oracles are introduced. The few known nonrelativizing results are almost all in the area of interactive proofs and probabilistically checkable proofs. One of their distinguishing features is that they rely on considerable combinatorics and algebra. The latter are also crucial ingredients in the known hardness versus randomness trade-offs, which might lead one to believe that these trade-offs also do not relativize. However, a careful examination in this and the next section will reveal that the hardness versus randomness trade-offs do relativize. In fact, they relativize in the very strong way stated in Theorem 3.4.

We start with the construction of a pseudorandom generator out of a Boolean function that is hard on average. Nisan and Wigderson use the following notion of a combinatorial design in their construction of a pseudorandom generator.

DEFINITION 3.11 (see [NW94]). *An (m, ℓ) design of size k over a universe Ω is a collection $\mathcal{S} = (S_1, S_2, \ldots, S_k)$ of subsets of Ω, each of size ℓ, such that, for any $1 \leqslant i < j \leqslant k$, the intersection $S_i \cap S_j$ has size at most m.*

In particular, in order to construct G_n, Nisan and Wigderson need a $(\log n, \ell)$ design of size n for a given value of $\ell \geqslant \log n$. The size of the design universe will be the seed length $s(n)$ of G_n and therefore should be small. Nisan and Wigderson [NW94] show that the greedy approach works and that it yields a $(\log n, \ell)$ design of size n over a universe of size $O(\ell^2/\log n)$. See [Tre99, Lemma 7] for a detailed analysis.

LEMMA 3.12 (see [NW94]). *A $(\log n, \ell)$ design of size n can be constructed over a universe of size $s \in O(\ell^2/\log n)$ in time $2^s \cdot n^{O(1)}$.*

Given a function $g : \{0,1\}^\ell \to \{0,1\}$ and a $(\log n, \ell)$ design $\mathcal{S} = (S_1, S_2, \ldots, S_n)$ over $\{1, 2, \ldots, s\}$, Nisan and Wigderson define their pseudorandom generator G_n as follows:

$$G_n : \{0,1\}^s \to \{0,1\}^n : \sigma \to g(\sigma|_{S_1})\, g(\sigma|_{S_2}) \ldots g(\sigma|_{S_n}), \tag{6}$$

where $\sigma|_{S_i}$ denotes the substring of σ consisting of the bits indexed by the elements from S_i.

The following theorem, combined with Lemma 3.12, finishes the proof of Theorem 3.2.

THEOREM 3.13. *Let B be any oracle, let $g : \{0,1\}^\ell \to \{0,1\}$, and let $\mathcal{S} = (S_1, S_2, \ldots, S_n)$ a $(\log n, \ell)$ design over $\{1, 2, \ldots, s\}$. If $H_g^B \geqslant n^2$, then G_n as defined by (6) is secure against B.*

The proof follows along the lines of the one by Nisan and Wigderson [NW94]. It is an application of Yao's observation that distinguishability from the uniform distribution implies predictability [Yao82] and uses the so-called hybrid argument [GM84].

Proof. We proceed by contradiction. Assume that G_n is not secure against B. This means that there exists an oracle circuit D of size at most n such that either

$$\Pr_\sigma[D^B(G_n(\sigma)) = 1] - \Pr_\rho[D^B(\rho) = 1] > \frac{1}{n} \tag{7}$$

or else $\Pr_\rho[D^B(\rho) = 1] - \Pr_\sigma[D^B(G_n(\sigma)) = 1] > \frac{1}{n}$, where ρ is uniformly distributed over $\{0,1\}^n$ and σ over $\{0,1\}^s$. We will assume that (7) holds. The other case is similar.

Consider the following sequence of "hybrid" distributions $\mathcal{D}_0, \ldots, \mathcal{D}_n$:

$$\begin{array}{lcccccccccc}
\mathcal{D}_0 & = & g(\sigma|_{S_1}) & g(\sigma|_{S_2}) & & & \ldots & & & g(\sigma|_{S_{n-1}}) & g(\sigma|_{S_n}) \\
\mathcal{D}_1 & = & \rho_1 & g(\sigma|_{S_2}) & & & \ldots & & & g(\sigma|_{S_{n-1}}) & g(\sigma|_{S_n}) \\
\vdots & & & & & & \vdots & & & & \\
\mathcal{D}_i & = & \rho_1 & \rho_2 & \ldots & \rho_{i-1} & \rho_i & g(\sigma|_{S_{i+1}}) & \ldots & g(\sigma|_{S_{n-1}}) & g(\sigma|_{S_n}) \\
\vdots & & & & & & \vdots & & & & \\
\mathcal{D}_{n-1} & = & \rho_1 & \rho_2 & & & \ldots & & & \rho_{n-1} & g(\sigma|_{S_n}) \\
\mathcal{D}_n & = & \rho_1 & \rho_2 & & & \ldots & & & \rho_{n-1} & \rho_n
\end{array}$$

As before, ρ is uniformly distributed over $\{0,1\}^n$ and σ over $\{0,1\}^s$.

Since the left-hand side of (7) can be written as

$$\Pr_{y\in\mathcal{D}_0}[D^B(y)=1]-\Pr_{z\in\mathcal{D}_n}[D^B(z)=1]=\sum_{i=1}^{n}\Pr_{y\in\mathcal{D}_{i-1}}[D^B(y)=1]-\Pr_{z\in\mathcal{D}_i}[D^B(z)=1],$$

there must exist an index i, $1\leqslant i\leqslant n$, such that

$$\Pr_{y\in\mathcal{D}_{i-1}}[D^B(y)=1]-\Pr_{z\in\mathcal{D}_i}[D^B(z)=1]\geqslant\frac{1}{n^2}. \tag{8}$$

The only difference between $\mathcal{D}_{i-1}$ and $\mathcal{D}_i$ is the way the ith bit is generated: In $\mathcal{D}_{i-1}$, it is set to $g(\sigma|_{S_i})$, whereas in $\mathcal{D}_i$, it is a random bit. Equation (8) says that, in the former case, the B-oracle circuit D^B is more likely to accept than in the latter case. This suggests the following randomized predictor $P(x)$ for $g(x)$:

(i) Pick $\rho_1,\rho_2,\ldots,\rho_i\in\{0,1\}$ uniformly at random.
(ii) Set $\sigma|_{S_i}$ equal to x, and pick the other bits of σ uniformly at random.
(iii) If $D^B(\rho_1,\rho_2,\ldots,\rho_i,g(\sigma|_{S_{i+1}}),\ldots,g(\sigma|_{S_n}))$ accepts, then output ρ_i; otherwise, output $\overline{\rho_i}$ (the complement of ρ_i).

Claim 3.14.

$$\Pr_{\rho,\sigma}[P(x)=g(x)]-\frac{1}{2}=\Pr_{y\in\mathcal{D}_{i-1}}[D^B(y)=1]-\Pr_{z\in\mathcal{D}_i}[D^B(z)=1], \tag{9}$$

where x denotes $\sigma|_{S_i}$.

We argue the claim by conditioning on all of ρ and σ except ρ_i. Let $\tilde{y}$ denote y with the ith bit flipped.

(i) Case $D^B(y)=D^B(\tilde{y})$. Since the value of the ith component does not affect D^B, the right-hand side of (9) vanishes. $P(x)$ is a random bit in this case, so the left-hand side also vanishes.

(ii) Case $D^B(y)\neq D^B(\tilde{y})$. Then $D^B(z)$ accepts with probability $\frac{1}{2}$, and $P(x)$ equals $g(x)$ precisely when $D^B(y)=1$.

This finishes the proof of the claim.

Note that $x\doteq\sigma|_{S_i}$ is uniformly distributed over $\{0,1\}^m$. By an averaging argument, (8) and (9) imply that we can fix ρ and all of σ outside of S_i such that

$$\Pr_x[P(x)=g(x)]\geqslant\frac{1}{2}+\frac{1}{n^2}. \tag{10}$$

Note that

$$P(x)=D^B(\rho_1,\rho_2,\ldots,\rho_i,g(\sigma|_{S_{i+1}}),\ldots,g(\sigma|_{S_n}))\oplus\overline{\rho_i}. \tag{11}$$

Since $|S_j\cap S_i|\leqslant\log n$ for $j\neq i$, each of the components $g(\sigma|_{S_j})$, $i<j\leqslant n$, depend only on $\log n$ bits of x and therefore can be computed by circuits of size at most n with input x. There are at most $n-1$ such components. As ρ is fixed and the size of D is at most n, it follows that the right-hand side of (11) can be evaluated by a B-oracle circuit C^B of size at most $(n-1)n+n=n^2$. In combination with (10), this leads to the contradiction that $H_g^B<n^2$. □

3.3. Proof of Theorem 3.3. Sudan, Trevisan, and Vadhan showed the following list decoding result which is used to give a strong worst-case to average-case hardness amplification [STV01, Definition 22 and Lemma 28].

Theorem 3.15 (see [STV01]). *There exists a family of maps $(\mathcal{C}_{N,\epsilon})_{N\in\mathbb{N},\epsilon>0}$, where $\mathcal{C}_{N,\epsilon}:\{0,1\}^N\to\{0,1\}^{N'(N,\epsilon)}$ such that the following hold.*

(i) *$\mathcal{C}_{N,\epsilon}$ is computable in time polynomial in N and $1/\epsilon$. In particular, $N' \doteq N'(N,\epsilon)$ is polynomial in N and $1/\epsilon$.*

(ii) *There exists a randomized algorithm that, on input N and ϵ and given oracle access to a string $y \in \{0,1\}^{N'}$, runs in time polynomial in $\log N$ and $1/\epsilon$ and outputs with high probability a list of randomized oracle machines M_j with the following properties:*

- *For every $x \in \{0,1\}^N$ such that $(\mathcal{C}_{N,\epsilon}(x))_i = y_i$ for at least $(\frac{1}{2}+\epsilon)N'$ of the positions i, $1 \leqslant i \leqslant N'$, there exists an index j such that, for any position i, $1 \leqslant i \leqslant N$, $M_j^y(i)$ outputs x_i with high probability.*
- *Each machine M_j runs in time polynomial in $\log N$ and $1/\epsilon$.*

By Adleman's argument [Adl78], we can transform the randomized procedures in (ii) of Theorem 3.15 into circuits. This yields the following corollary.

COROLLARY 3.16. *There exists a constant c such that, for any $N \in \mathbb{N}$, $x \in \{0,1\}^N$, and $y \in \{0,1\}^{N'}$ satisfying $(\mathcal{C}_{N,\epsilon}(x))_i = y_i$ for at least $(\frac{1}{2}+\epsilon)N'$ of the positions i, $1 \leqslant i \leqslant N'$, there exists an oracle circuit D of size $(\frac{1}{\epsilon}\log N)^c$ such that $D^y(i) = x_i$ for every $1 \leqslant i \leqslant N$.*

We define g such that its truth-table at length $n' \doteq \log N'$ equals the encoding $\mathcal{C}_{N,\epsilon}$ of the truth-table of f at length $n \doteq \log N$. We set $\epsilon = 1/h(n')$, where $h(n')$ is the hardness level we want to achieve. Since $h(n') \in O(2^{n'}/n')$, (i) in Theorem 3.15 implies that N and N' are polynomially related, so we can set $n = \gamma \cdot n'$ for some positive constant γ.

Now suppose that there exists a B-oracle circuit of size at most $h(n')$ that computes g correctly on at least $(\frac{1}{2}+\frac{1}{h(n')})N'$ of the inputs of length n'. By plugging this circuit in as the oracle y in Corollary 3.16, we obtain a B-oracle circuit that computes f at length $n = \gamma \cdot n'$ correctly and has size at most $(\frac{1}{\epsilon}\log N)^c \cdot h(n') = (\gamma n')^c \cdot (h(n'))^{c+1}$. In other words,

$$C_f^B(\gamma n') \leqslant (\gamma n')^c \cdot (h(n'))^{c+1}. \tag{12}$$

For $\delta < 1/(c+1)$, (12) contradicts the upper bound on $h(n')$ in the hypothesis of Theorem 3.3. Therefore, $H_g^B(n') \geqslant h(n')$. □

4. A general framework for derandomization. In the previous section, we showed that an Arthur-Merlin protocol can be viewed as an SAT-oracle distinguisher for a pseudorandom generator, and, if a Boolean function f exists with sufficient hardness against SAT-oracle circuits, we can construct a pseudorandom generator based on f that will look random to our Arthur-Merlin protocol. Still, we have only applied our results to randomized *decision* algorithms. In this section, we show how to relax this condition and obtain hardness versus randomness trade-offs for a broader class of randomized processes. Under a sufficient hardness condition depending upon the particular randomized algorithm, we are able to reduce the algorithm's randomness to a logarithmic factor and, in some cases, provide a complete derandomization. Weaker hardness conditions yield partial derandomizations.

We first define the notion of a *randomized process* to which our approach applies.

DEFINITION 4.1. *A randomized process that uses $r(n)$ random bits on inputs of length n is a pair (F,π), where the following hold:*

(i) *F is a function that takes a string x and a string ρ of length $r(|x|)$, and outputs the outcome of the process on input x using ρ as the random bit sequence.*

(ii) *π is a predicate with the same domain as F. Intuitively π indicates whether the process succeeds on input x using ρ, i.e., whether ρ is a "good" choice*

of random bits for the given input x. We call π the success predicate of the randomized process.

In the case of Arthur-Merlin games, F is Boolean. More specifically, for the game defined by (2) and (3) in section 2, $F(x,\rho)$ coincides with the predicate $\exists z \in \{0,1\}^{t(n)} : M(\langle x,\rho,z\rangle) = 1$; the success predicate $\pi(x,\rho)$ equals $F(x,\rho)$ if $x \in L$ and the complement of $F(x,\rho)$ otherwise. In the specific randomized processes we will consider in section 5, F will be non-Boolean.

What matters for our derandomization results are the complexity of the success predicate π and, more precisely, the property stated in the following straightforward lemma.

LEMMA 4.2. *Let B be any oracle, and let (F,π) be a randomized process using $r(n)$ random bits such that, for any fixed input x of length n, the predicate $\pi_x : \{0,1\}^{r(n)} \to \{0,1\}$, where $\pi_x(\rho) \doteq \pi(x,\rho)$, can be decided by a B-oracle circuit of size $t(n) \geqslant r(n)$. If G is a pseudorandom generator with seed length $s(n)$ which is secure against B, then, for any input x of length n,*

$$|\Pr_{\rho}[\pi(x,\rho)=1] - \Pr_{\sigma}[\pi(x,G_{t(n)}(\sigma)[1..r(n)])=1]| = O(1/t(n)),$$

where ρ is uniformly distributed over $\{0,1\}^{r(n)}$ and σ is uniformly distributed over $\{0,1\}^{s(t(n))}$.

In our applications, we will be concerned with randomized processes that use a polynomial number of random bits. We will choose the oracle B in Lemma 4.2 powerful enough so that it can check the process efficiently in the following sense.

DEFINITION 4.3. *Let B be an oracle, and let (F,π) be a randomized process using a polynomial number $r(n)$ of random bits. We say that B can* efficiently check *(F,π) if there is a polynomial p such that, for any fixed input x of length n, the predicate $\pi_x : \{0,1\}^{r(n)} \to \{0,1\}$, where $\pi_x(\rho) \doteq \pi(x,\rho)$, can be decided by a B-oracle circuit of size $p(n)$.*

Using the success predicate as a distinguisher as in Lemma 4.2, Theorem 3.4 yields our general derandomization result.

THEOREM 4.4. *Let $\mathcal{A}$ be a class of oracles, B an oracle, d a positive constant, and $\ell : \mathbb{N} \to \mathbb{N}$ a constructible function. Let (F,π) be a randomized process using a polynomial number of random bits such that B can efficiently check (F,π). If there exists a Boolean function $f \in \mathsf{E}^{\mathcal{A}}$ such that $C_f^B(\ell(n)) = \Omega(n)$, then there exist a function G computable in $\mathsf{E}^{\mathcal{A}}$ and a constructible function $s(n) = O(\ell^2(n^{O(1)})/\log n)$ such that, for any input x of length n,*

$$|\Pr_{\rho}[\pi(x,\rho)=1] - \Pr_{\sigma}[\pi(x,G(\sigma))=1]| = O(1/n^d),$$

where ρ is uniformly distributed over $\{0,1\}^{r(n)}$ and σ is uniformly distributed over $\{0,1\}^{s(n)}$. The same holds if E is replaced by EXP.

See Table 2 for some interesting instantiations of Theorem 4.4.

In order to reduce the randomness of a randomized process, we will first analyze the complexity of an oracle B capable of efficiently checking the associated success predicate and then construct a pseudorandom generator secure against B based on a function with presumed hardness against B. We will see several examples of this in the next section.

5. More applications. We will now apply the general framework of section 4 to various other constructions in computational complexity. As is customary, we

state only our results in terms of the strongest of the assumptions in Table 2, yielding polynomial-time deterministic simulations. It should be noted, however, that weaker assumptions can be taken (e.g., that the polynomial-time hierarchy does not collapse) in order to achieve weaker, but still subexponential, deterministic simulations.

5.1. Valiant–Vazirani. Our first example is the randomized Boolean hashing protocol developed by Valiant and Vazirani [VV86]. They give a method for pruning the satisfying assignments of a propositional formula to one.

THEOREM 5.1 (see [VV86]). *There exists a randomized polynomial-time algorithm that, on input a propositional formula ϕ, outputs a list of propositional formulas such that*

(i) *every satisfying assignment to any of the formulas on the list also satisfies ϕ;*
(ii) *if ϕ is satisfiable, then, with high probability, at least one of the formulas on the list has exactly one satisfying assignment.*

Let $F(x, \rho)$ denote the list of formulas the Valiant–Vazirani algorithm produces on input x using coin flips specified by ρ. We define the success predicate $\pi(x, \rho)$ to hold unless x is a satisfiable formula and none of the formulas in $F(x, \rho)$ has a unique satisfying assignment. It is clear that (F, π) corresponds to a formalization of the Valiant–Vazirani process and fits within our framework.

THEOREM 5.2. *If there is a Boolean function $f \in \mathsf{E}$ such that $C_f^{\mathrm{SAT}}(n) = 2^{\Omega(n)}$, then, given a propositional formula ϕ, we can generate in polynomial time a list of propositional formulas such that*

(i) *every satisfying assignment to any of the formulas on the list also satisfies ϕ;*
(ii) *if ϕ is satisfiable, then at least one of the formulas on the list has exactly one satisfying assignment.*

Proof. Let (F, π) be the formalization as described above. Notice that checking whether a given propositional formula has at least two satisfying assignments is an NP question. Hence we can check, in polynomial time, whether a propositional formula has a unique satisfying assignment using two queries to SAT. It follows that SAT can efficiently check (F, π). Applying Theorem 4.4 to (F, π) yields a pseudorandom generator G computable in E that looks random to the Valiant–Vazirani process. Enumerating over all seeds and collecting all formulas produce the desired list of formulas in polynomial time. □

We now have the following corollary about computing satisfying assignments nonadaptively.

COROLLARY 5.3. *If there is a Boolean function $f \in \mathsf{E}$ such that $C_f^{\mathrm{SAT}}(n) = 2^{\Omega(n)}$, then, given a satisfiable propositional formula ϕ, we can find a satisfying assignment for ϕ in polynomial time given nonadaptive oracle access to* SAT.

Proof. A satisfying assignment to a uniquely satisfiable propositional formula ψ can be found in polynomial time using nonadaptive oracle queries to SAT: We set a variable v of ψ iff the formula obtained from ψ by substituting TRUE for v is satisfiable.

We run the latter procedure on each formula ψ of the list produced by Theorem 5.2 on input ϕ and output the first satisfying assignment we obtain. □

We also obtain interesting structural observations. Recall that the class $\#\mathsf{P}$ contains all functions $f : \Sigma^* \to \mathbb{N}$ for which there exists a nondeterministic polynomial-time Turing machine M such that $f(x)$ equals the number of accepting computations of M on input x. A language L belongs to $\oplus\mathsf{P}$ if there exists a $\#\mathsf{P}$ function f such that an input x belongs to L iff $f(x)$ is odd. A GapP function is the difference of two $\#\mathsf{P}$ functions, and SPP denotes the class of all languages whose characteristic

function is a GapP function. The class PP contains all languages L for which there exists an $f \in \mathsf{GapP}$ such that $x \in L$ iff $f(x) > 0$. SPP is contained in both $\oplus\mathsf{P}$ and PP. We refer the reader to the survey by Fortnow [For97] for background on these counting classes. Theorem 5.2 implies the following corollary.

COROLLARY 5.4. *If there is a Boolean function $f \in \mathsf{E}$ such that $C_f^{\mathrm{SAT}}(n) = 2^{\Omega(n)}$, then NP is contained in SPP.*

Proof. Let $h(\phi, i)$ denote the #P function that gives the number of satisfying assignments to the ith formula of the list produced by Theorem 5.2 on input ϕ. Then

$$1 - \prod_i (1 - h(\phi, i)) \tag{13}$$

equals the characteristic function of SAT. By the closure properties of GapP [FFK94], (13) belongs to GapP. □

Similarly, we can conditionally derandomize the result by Toda and Ogiwara [TO92] that the polynomial-time hierarchy does not add power to GapP in a randomized setting. Applying our techniques to their main lemma yields the following theorem.

LEMMA 5.5. *Let B be any oracle. If there is a Boolean function $f \in \mathsf{E}$ such that $C_f^{\mathrm{SAT}^B}(n) = 2^{\Omega(n)}$, then $\mathsf{GapP}^{\mathsf{NP}^B}$ is contained in GapP^B.*

This allows us to show the following theorem.

THEOREM 5.6. *For any integer $k \geqslant 1$, the following holds: If there is a Boolean function $f \in \mathsf{E}$ such that $C_f^{\mathrm{TQBF}_k}(n) = 2^{\Omega(n)}$, then Σ_k^{p} is contained in SPP.*

Here TQBF_k denotes the language of all true fully quantified propositional formulas with at most $k-1$ quantifier alternations.

Proof. Corollary 5.4 relativizes and, under the given assumption, implies that the characteristic function of any language in Σ_k^{p} is contained in $\mathsf{GapP}^{\mathrm{TQBF}_{k-1}}$. The successive application of Lemma 5.5 with $B = \mathrm{TQBF}_{k-2}$, $B = \mathrm{TQBF}_{k-3}$, ..., $B = \mathrm{TQBF}_1$, and $B = \varnothing$ yields, under the given assumption, that $\mathsf{GapP}^{\mathrm{TQBF}_k}$ is contained in GapP. □

COROLLARY 5.7. *Let B be any oracle hard for the polynomial-time hierarchy under polynomial-time Turing reductions. If there is a Boolean function $f \in \mathsf{E}$ such that $C_f^B(n) = 2^{\Omega(n)}$, then the polynomial-time hierarchy is contained in SPP.*

Corollary 5.7 is strongly related to Toda's theorem [Tod91] that the polynomial-time hierarchy lies in $\mathsf{BP} \cdot \oplus\mathsf{P}$. Applying our derandomization technique directly to Toda's theorem, along with the observation that $\oplus\mathsf{P}$ is closed under majority [PZ83] (in fact $\oplus\mathsf{P}^{\oplus\mathsf{P}} = \oplus\mathsf{P}$), yields the following theorem.

THEOREM 5.8. *If there is a Boolean function $f \in \mathsf{E}$ such that $C_f^{\oplus\mathrm{SAT}}(n) = 2^{\Omega(n)}$, then the polynomial-time hierarchy is contained in $\oplus\mathsf{P}$.*

5.2. Learning circuits. Learning theory represents another area where we can apply our techniques. We will focus on exact concept learning with equivalence queries [Ang88, Lit88], in which the learner presents hypotheses to a teacher, who then tells the learner whether the hypothesis agrees with the concept in question. If it does, the learner has succeeded; otherwise, the teacher provides a counterexample, and the learner continues.

A fundamental question is whether we can efficiently learn Boolean circuits in this model. If $\mathsf{P} = \mathsf{NP}$, we can; if one-way functions exist, we cannot [PW90]. Without any complexity theoretic assumption, Bshouty et al. [BCG+96] showed that access to an NP oracle and to a source of randomness suffice to efficiently learn Boolean circuits. We give evidence that we may be able to dispense with the source of randomness.

THEOREM 5.9. *If there is a Boolean function $f \in \mathsf{NE} \cap \mathsf{coNE}$ such that $C_f^{\mathrm{TQBF}_2}(n) = 2^{\Omega(n)}$, then we can perform the following task in deterministic polynomial time given access to an* NP *oracle: exactly learn Boolean circuits of size t using equivalence queries with hypotheses that are circuits of size $O(tn + n \log n)$.*

As before, TQBF_2 denotes the language of all true, fully quantified propositional formulas with at most one quantifier alternation.

Proof. We apply Theorem 4.4 to a randomized process (F, π) underlying the algorithm of Bshouty et al. [BCG+96]. We define F in the obvious way, namely, as the candidate-equivalent circuit the learner outputs. The specification of the success predicate π is somewhat more involved than in the examples we have seen so far. We want only to consider a random seed as "good" if the learner, when using this seed, finds an equivalent circuit no matter how the teacher picks the counterexamples. Therefore, we define $\pi(x, \rho)$ to indicate whether, for every choice of candidate counterexamples, either one of them fails to be a valid counterexample on input x and random seed ρ or the learner ends up with an equivalent circuit to x. It follows from the construction of Bshouty et al. that π is a Π_2^{p} predicate, and their analysis shows that, for any input x, $\pi(x, \rho)$ holds with high probability.

Using the derandomization provided by Theorem 4.4, we end up with a polynomial number of candidate circuits, at least one of which is equivalent to x. So we just present each of these to the teacher and will succeed. □

Bshouty et al. used their learning theory result to improve the known collapse of the polynomial-time hierarchy in case NP would have polynomial size circuits: They showed that the latter implies that the polynomial-time hierarchy is contained in $\mathsf{ZPP}^{\mathsf{NP}}$. Along similar lines, we obtain the following derandomization.

COROLLARY 5.10. *If* NP *has polynomial size circuits and there is a Boolean function $f \in \mathsf{E}^{\mathsf{NP}}$ such that $C_f(n) = 2^{\Omega(n)}$, then the polynomial-time hierarchy is contained in P^{NP}.*

Proof. If NP has polynomial size circuits and there is a Boolean function $f \in \mathsf{E}^{\mathsf{NP}}$ such that $C_f(n) = 2^{\Omega(n)}$, then the same function f also satisfies $C_f^{\mathrm{SAT}}(n) = 2^{\Omega(n)}$. Therefore, by applying Theorem 3.4 with $\mathcal{A} = \mathsf{NP}$ and $B = \mathrm{SAT}$, we obtain a pseudorandom generator G computable in E^{NP} which is secure against SAT and has logarithmic seed length. If follows that $\mathsf{ZPP}^{\mathsf{NP}} = \mathsf{P}^{\mathsf{NP}}$. To finish the proof, it suffices to combine this with the Bshouty et al. [BCG+96] result that the polynomial-time hierarchy collapses to $\mathsf{ZPP}^{\mathsf{NP}}$ if NP has polynomial size circuits. □

5.3. Rigid matrices. Several researchers have studied the problem of finding explicit constructions of combinatorial objects that have been proven to exist nonconstructively (by using the probabilistic method, for example). In many cases, an explicit construction of some combinatorial object yields an interesting complexity theoretic result. One of the notable examples of this is the problem of matrix rigidity. The rigidity of a matrix M over a ring S, denoted $R_M^S(r)$, is the minimum number of entries of M that must be changed to reduce its rank to r or below. (An entry can be changed to any element of S.) Valiant [Val77] proved that an explicit construction of an infinite family of highly rigid matrices yields a circuit lower bound.

THEOREM 5.11 (see [Val77]). *Let $\epsilon, \delta > 0$ be constants. For any positive integer n, let M_n be an $n \times n$ matrix over a ring S_n. If $R_{M_n}^{S_n}(\epsilon n) \geqslant n^{1+\delta}$ for infinitely many values of n, then the linear transformations defined by the family M_n cannot be computed by linear size log-depth circuits consisting of gates computing binary linear operators on S_n.*

Valiant also proved that almost all matrices over an infinite field have rigidity

$(n-r)^2$, and almost all matrices over a fixed finite field have rigidity $\Omega((n-r)^2/\log n)$. The best known explicit constructions achieve rigidity $\Omega(n^2/r)$ over infinite fields [PV91, Raz] and $\Omega(\frac{n^2}{r}\log(\frac{n}{r}))$ [Fri90] over finite fields. These are not sufficient to obtain circuit lower bounds using Theorem 5.11. Under a hardness assumption, our derandomization technique will give an explicit construction to which Theorem 5.11 applies—a family of matrices M_n over $S_n = \mathbb{Z}_{p(n)}[x]$ such that $R^{S_n}_{M_n}(r) \in \Omega((n-r)^2/\log n)$, where $p(n)$ is polynomially bounded.

We will use the following lemma, which follows directly from Valiant's paper [Val77].

LEMMA 5.12 (see [Val77]). *Let S be a ring with at least two elements, and let n be a positive integer. All but at most a $\frac{1}{n}$ fraction of the $n \times n$ matrices M over S satisfies*

$$R^S_M(r) \geqslant \frac{(n-r)^2 - 2n - 2\log n}{1 + 2\log n}. \tag{14}$$

We can use our technique to achieve the nonconstructive rigidity bounds by noticing that there exist polynomial size SAT-oracle circuits which can check if a matrix is rigid.

THEOREM 5.13. *If there exists a Boolean function $f \in \mathsf{E}$ such that $C^{\mathrm{SAT}}_f(n) = 2^{\Omega(n)}$, then, given integers $n \geqslant 1$ and $p \geqslant 2$, we can construct in time polynomial in $n + \log p$ a list of $n \times n$ matrices M over $S = \mathbb{Z}_p$, most of which satisfy* (14).

Proof. Let ρ be a string of length $n^2 \cdot \lceil \log p \rceil$. We will view ρ as the concatenation of n^2 blocks of $\lceil \log p \rceil$ bits each. Let $F(\langle 1^n, p\rangle, \rho)$ denote the matrix whose ijth entry is the $(n(i-1)+j)$th block of ρ interpreted as a number in binary and taken modulo p. We define the predicate $\pi(\langle 1^n, p\rangle, \rho)$ to be true if $M = F(\langle 1^n, p\rangle, \rho)$ satisfies (14). Note that the latter is a coNP predicate: If (14) is violated for some r, we can guess modified values for fewer than the right-hand side of (14) many entries of M and verify that the rank of the modified matrix over S is at most r. So we can decide π by one query to an oracle for SAT. Moreover, Lemma 5.12 states that, for most sequences ρ, the predicate holds. By applying Theorem 4.4 to (F, π), we obtain a pseudorandom generator which, on most seeds, outputs a matrix with the required rigidity property. Enumerating over all seeds gives us the desired list of matrices in polynomial time. □

Now we need to combine this list of matrices into a single matrix with similarly high rigidity. We can do so by switching to the ring of univariate polynomials over $\mathbb{Z}_p$.

LEMMA 5.14. *Given $n \times n$ matrices $M_0, M_1, \ldots, M_k$ over $\mathbb{Z}_p$, where p is a prime larger than k, we can construct in time polynomial in $n + k + \log p$ an $n \times n$ matrix N over $\mathbb{Z}_p[x]$ such that*

$$R^{\mathbb{Z}_p[x]}_N(r) \geqslant \max_{0 \leqslant i \leqslant k} R^{\mathbb{Z}_p}_{M_i}(r), \tag{15}$$

where the entries of N are polynomials of degree at most k.

Proof. Let $q_{ij}(x)$ be the polynomial of degree at most k such that $q_{ij}(\ell)$ equals the ijth entry of M_ℓ, $0 \leqslant \ell \leqslant k$; i.e., q_{ij} interpolates the ijth entries of all $k+1$ matrices. Note that the q_{ij}'s exist and that each coefficient can be computed in time polynomial in $k + \log p$. Let N be the matrix whose ijth entry is q_{ij}. We now argue that (15) holds.

Let $m = R^{\mathbb{Z}_p[x]}_N(r)$, and let N' be a matrix obtained by changing m entries of N such that the rank of N' is at most r. Then every $(r+t) \times (r+t)$ minor of N' has

determinant 0 for $0 < t \leqslant n - r$. Thus the determinant of any $(r + t) \times (r + t)$ minor of N' can be viewed as an identically 0 polynomial in its entries. Let $\phi_a(N')$ be the matrix obtained by substituting $a \in \mathbb{Z}_p$ for x in every entry of N'. (Recall that N' has entries from $\mathbb{Z}_p[x]$.) Every $(r+t) \times (r+t)$ minor of $\phi_a(N')$ has determinant 0 for $0 < t \leqslant n - r$. We conclude by noticing that changing m or fewer entries of $\phi_a(N)$ has reduced its rank to a value less than or equal to r. However, $\phi_a(N)$ equals M_a for $a \in \{0, 1, \ldots, k\}$. Therefore, $R^{\mathbb{Z}_p}_{M_i}(r) \leqslant m$ for any $0 \leqslant i \leqslant k$; i.e., (15) holds. □

Given this construction of rigid matrices, we can conclude the following relationship among circuit lower bounds.

THEOREM 5.15. *If there exists a function $f \in \mathsf{E}$ such that $C^{\mathrm{SAT}}_f(n) = 2^{\Omega(n)}$, then there exists a polynomially bounded function $p(n)$ and a polynomial-time computable family of matrices M_n, where M_n is an $n \times n$ matrix over $\mathbb{Z}_{p(n)}[x]$ such that the linear transformations defined by the family M_n cannot be computed by log-depth linear size circuits which have special gates that can compute binary linear operators over $\mathbb{Z}_{p(n)}[x]$.*

Proof. For any polynomial time computable function $p(n)$, Theorem 5.13 allows us to efficiently compute a list of $(n + \log p(n))^c$ matrices M over $\mathbb{Z}_{p(n)}$ for some constant c, most of which are rigid. Provided $p(n)$ is a prime satisfying

$$p(n) \geqslant (n + \log p(n))^c, \tag{16}$$

Lemma 5.14 efficiently combines them into a single matrix N over $\mathbb{Z}_{p(n)}[x]$ which satisfies a rigidity condition sufficient for Theorem 5.11. The smallest prime value for $p(n)$ that satisfies (16) is polynomially bounded in n, and we can compute it in time polynomial in n. □

We point out that the weaker assumption that there exists a function $f \in \mathsf{E}$ such that $C_{f(n)} = 2^{\Omega(n)}$ immediately implies (by padding) the existence of a function in P with superpolynomial circuit complexity, regardless of the depth restrictions. Viewed that way, Theorem 5.15 uses a stronger hypothesis to produce a weaker conclusion, namely, the existence of a function in P that requires superpolynomial size but only for circuits of restricted depth. However, Theorem 5.15 adds credibility to Valiant's program of exhibiting an explicit function that cannot be computed by linear size log-depth circuits using matrix rigidity. Theorem 5.15 shows that, under a reasonable assumption, Valiant's program will work.

5.4. Universal traversal sequences. Universal traversal sequences, introduced by Cook, form another example where explicit constructions have important complexity theoretic implications. A universal traversal sequence for size n is a sequence σ of labels from $\{1, 2, \ldots, n-1\}$ such that, for any undirected connected graph G with n vertices in which the incident edges at every vertex have been assigned distinct labels from $\{1, 2, \ldots, n-1\}$, the following process always visits every vertex of G: Pick an arbitrary start vertex, and, in subsequent steps, go along the edge with the label matching the next symbol of σ; in case of no match, stay put during that step and continue with the next symbol of σ.

If we can construct universal traversal sequences in logspace, then we can solve undirected graph connectivity in logspace, and symmetric logspace equals logspace [LP82]. However, we do not know how to generate universal traversal sequences in logspace or even in polynomial time. Aleliunas et al. [AKL+79] showed that most sequences of length $O(n^3)$ over $\{1, 2, \ldots, n-1\}$ are universal traversal sequences for size n, but, as of now, the best explicit construction, due to Nisan [Nis92], yields universal traversal sequences of length $n^{O(\log n)}$. We give evidence supporting the

belief that explicit universal traversal sequences of polynomial size can be generated efficiently.

A straightforward application of our technique would yield a polynomial-time construction under the assumption that E requires exponential size SAT-oracle circuits. Since being a universal traversal sequence is a coNP predicate, Theorem 4.4 applied to the Aleliunas et al. process and oracle $B = \text{SAT}$ would efficiently generate under that hypothesis a collection of sequences, most of which are universal traversal sequences. Concatenating all of them would yield the desired universal traversal sequence of polynomial size. However, we can do better and dispense with the oracle B.

THEOREM 5.16. *If there is a Boolean function $f \in E$ such that $C_f(n) = 2^{\Omega(n)}$, then we can construct universal traversal sequences in polynomial time.*

Proof. Let G encode a graph with n vertices with edge labels as above. For any sequence σ over $\{1, 2, \ldots, n-1\}$, let $\tau(G, \sigma)$ indicate whether, for every vertex v of G, the walk in G starting from v and dictated by σ visits every vertex of G. Let $F(G, \rho)$ denote the sequence of length $c \cdot n^3$ over $\{1, 2, \ldots, n-1\}$ (where c is some sufficiently large constant) as specified by the successive bits of ρ. Let $\pi(G, \rho)$ equal $\tau(G, F(G, \rho))$. Note that π is a P predicate, so $B = \varnothing$ can efficiently check the randomized process (F, π). Since every universal traversal sequence σ satisfies $\tau(G, \sigma)$, the result of Aleliunas et al. [AKL+79] shows that for any graph G, $\pi(G, \rho)$ holds for most ρ. Therefore, Theorem 4.4 allows us to generate in polynomial time a collection of sequences σ, most of which satisfy $\tau(G, \sigma)$. Their concatenation forms a single sequence σ' satisfying $\tau(G, \sigma')$. Since the σ's are independent of G, so is their concatenation σ'. Hence we have constructed a sequence σ' which satisfies $\tau(G, \sigma')$ for every edge labeled graph G with n vertices; i.e., we have found a universal traversal sequence σ'. □

Under the assumption that *linear space* requires exponential size circuits, we can actually construct universal traversal sequences in *logspace*. In fact, that assumption allows us to build logspace computable pseudorandom generators for logspace and hence to derandomize BPL, the class of languages accepted by logspace randomized Turing machines with bounded two-sided error.

THEOREM 5.17. *If there is a Boolean function $f \in \text{DSPACE}[n]$ such that $C_f(n) = 2^{\Omega(n)}$, then $\text{BPL} = \text{L}$.*

Along the lines of Babai, Nisan, and Szegedy [BNS92], the pseudorandom generators behind Theorem 5.17 let us conclude the following corollary.

COROLLARY 5.18. *If there is a Boolean function $f \in \text{DSPACE}[n]$ such that $C_f(n) = 2^{\Omega(n)}$, then we can construct universal traversal sequences in logspace.*

Remark. We can actually relax the hypothesis in both Theorem 5.17 and Corollary 5.18 to the existence of a Boolean function in linear space that requires *branching programs* of size $2^{\Omega(n)}$: *If there is a Boolean function $f \in \text{DSPACE}[n]$ that requires branching programs of size $2^{\Omega(n)}$, then $\text{BPL} = \text{L}$, and we can construct universal traversal sequences in logspace.*

This stronger statement forms a more natural space-bounded analogue of the Impagliazzo–Wigderson [IW97] result than Theorem 5.17. The proof of the statement goes along the lines of the proof of Theorem 3.4. However, it needs a more space-efficient transformation of worst-case hardness into average-case hardness than the one by Sudan, Trevisan, and Vadhan [STV01] which we used in the proof of Theorem 3.4. The original construction by Impagliazzo and Wigderson [IW97], building on previous work by Babai et al. [BFNW93] and by Impagliazzo [Imp95], would do. Instead of going through the details of the latter constructions, we provide the details

for the weaker statement given in Theorem 5.17, for which the Sudan, Trevisan, and Vadhan construction used in our proof of Theorem 3.4 works fine.

5.5. Proof of Theorem 5.17. In order to establish Theorem 5.17, it suffices to show the following: If the function f in Theorem 3.4 is in linear space and $\ell(n) = \Theta(\log n)$, then we can make the pseudorandom generator G provided by Theorem 3.4 computable in linear space. This is because the seed length $s(n)$ of G in Theorem 3.4 is logarithmic for logarithmic $\ell(n)$.

The proof of Theorem 3.4 consists of two steps:

(i) Converting the worst-case hard function f into an average-case hard function g using Theorem 3.3.

(ii) Applying Theorem 3.2 to the average-case hard function g to obtain the pseudorandom generator G.

First, we argue that, if the function f in Theorem 3.3 is in linear space, then so is the function g. This is because the code $\mathcal{C}_{N,\epsilon}$ in Theorem 3.15 is actually computable in space $O(\log N + \log 1/\epsilon)$, as follows from a straightforward analysis of the paper by Sudan, Trevisan, and Vadhan [STV01].

We next apply Theorem 3.2 to the function g in order to obtain the pseudorandom generator G. Computing the ith bit of $G(\sigma)$ for $\sigma \in \{0,1\}^{s(n)}$ amounts to computing the set S_i of a $(\log n, \ell)$ design $\mathcal{S} = (S_1, S_2, \ldots, S_n)$ over $\{1, 2, \ldots, s(n)\}$ and evaluating g on input $\sigma|_{S_i}$. The latter can be done in space $O(s(n))$ since g is in linear space.

The greedy design construction of Lemma 3.12 requires too much space, namely, $\Theta(n)$. However, the next lemma describes a different approach, which needs only $O(s(n)) = O(\log n)$ space. The construction goes along the lines of Impagliazzo and Wigderson [IW97]. Allender informed us that Wigderson showed him the same construction [ARZ99]. For any $\ell(n) = \Theta(\log n)$, it yields a $(\log n, \ell(n))$ design of size n^δ over $\{1, 2, \ldots, s(n)\}$ for some positive δ and $s(n) = O(\log n)$. Note that this design is smaller than the one obtained through the greedy construction, which yields $\delta = 1$. However, designs of the former type are good enough for Theorem 3.13 (with appropriately modified parameters) and Theorem 3.2 to carry through. So, the next lemma finishes the proof of Theorem 5.17.

LEMMA 5.19. *For any positive constant c, there are positive constants α and γ such that we can generate an $(\alpha s, c\alpha s)$ design of size $2^{\gamma s}$ over $\{1, 2, \ldots, s\}$ in space $O(s)$.*

Proof. We will show that the following process has a positive probability of generating an (m, ℓ) design of size $k \doteq 2^{\gamma s}$ over $\Omega = \{1, 2, \ldots, s\}$ for sufficiently small positive constants α and γ, where $m \doteq \alpha s$ and $\ell \doteq \beta s$ with $\beta \doteq c\alpha$: Pick k subsets of Ω of size ℓ in a pairwise independent way such that each of the $\binom{s}{\ell}$ subsets has about the same probability of being selected.

More precisely, we will do the following. We choose an integer $a \geqslant 0$ such that $2^a \leqslant k^3 \cdot \binom{s}{\ell} < 2^{a+1}$, pick k numbers $r_i \in \{0, 1, \ldots, 2^a - 1\}$ at random in a pairwise independent way, and set S_i to be the $[(r_i \bmod \binom{s}{\ell}) + 1]$st subset of Ω of size ℓ (say, using the lexicographical order). Known constructions of such sample spaces [CG89] need only $O(a)$ random bits and can generate the samples from the random bits in space $O(a)$. Moreover, checking whether a given sample $S_1, \ldots, S_k$ forms an (m, ℓ) design can be done within the same space bounds. Therefore, we can cycle through all possible random bit sequences, check the corresponding candidate design, and output the first valid one. This process runs in space $O(a) = O(s)$ and succeeds provided the probability of picking a valid design this way is positive. The remainder of the proof will argue the latter.

CLAIM 5.20. *Let S, S' be subsets of Ω of size ℓ chosen independently and uniformly at random. Then, for some constants d_β and $d' > 0$,*

$$\Pr\left[\,|S \cap S'| \geqslant 2\beta^2 s\,\right] \leqslant d_\beta \cdot s \cdot \exp(-d'\beta^2 s).$$

Proof of Claim 5.20. First, consider a subset S of Ω obtained by doing the following independently for every $i \in \Omega$: Put i in S with probability β. Similarly, and independently, construct S'. Then, by Chernoff's bounds [MR97, Theorem 4.1],

$$\Pr\left[\,|S \cap S'| \geqslant 2\beta^2 s\,\right] \leqslant \exp(-d'\beta^2 s)$$

for some constant $d' > 0$. Stirling's formula yields that

$$\begin{aligned}\Pr\left[\,|S| = \beta s\,\right] &= \binom{s}{\beta s} \cdot \beta^{\beta s}(1-\beta)^{s-\beta s} \\ &\sim \frac{1}{\sqrt{2\pi\beta(1-\beta)}} \cdot \frac{1}{\sqrt{s}}.\end{aligned}$$

So

$$\begin{aligned}\Pr\left[\,|S \cap S'| \geqslant 2\beta^2 s \;\middle|\; |S| = |S'| = \beta s\right] &\leqslant \Pr\left[\,|S \cap S'| \geqslant 2\beta^2 s\,\right] \cdot \Pr\left[\,|S| = |S'| = \beta s\,\right] \\ &\leqslant d_\beta \cdot s \cdot \exp(-d'\beta^2 s)\end{aligned}$$

for some constant d_β depending on β. Since the above distribution of S and S' conditioned on $|S| = |S'| = \beta s$ coincides with the uniform distribution of the statement of the claim, this finishes the proof of the claim. □

There is a constant $d < 2k^3$ such that, for any $1 \leqslant i \leqslant k$ and any $T \subseteq \Omega$ with $|T| = \ell$,

$$\frac{d}{2^a} \leqslant \Pr[S_i = T] \leqslant \frac{d+1}{2^a}.$$

Because of the pairwise independence, it follows that, for any $1 \leqslant i < j \leqslant k$, the distribution of (S_i, S_j) differs from uniform by at most

$$\begin{aligned}\binom{s}{\ell}^2 \cdot \left[\left(\frac{d+1}{2^a}\right)^2 - \left(\frac{d}{2^a}\right)^2\right] &= (2d+1)\left(\frac{\binom{s}{\ell}}{2^a}\right)^2 \\ &< (2c+1)\left(\frac{2}{k^3}\right)^2 \\ &< \frac{4(4k^3+1)}{k^6} \\ &< \frac{17}{k^3}\end{aligned}$$

in L_1-norm. Therefore, by Claim 5.20,

$$\Pr\left[\,|S_i \cap S_j| \geqslant 2\beta^2 s\,\right] \leqslant \frac{17}{k^3} + d_\beta \cdot s \cdot \exp(-d'\beta^2 s).$$

Recall that $m \doteq \alpha s$, $\ell \doteq \beta s$, and $\beta \doteq c\alpha$. Hence, for $\alpha \leqslant 1/(2c^2)$,

$$\Pr[S_1, S_2, \ldots, S_k \text{ is not an } (m,\ell) \text{ design}] \leqslant \binom{k}{2} \cdot \left(\frac{17}{k^3} + d_\beta \cdot s \cdot \exp(-d'\beta^2 s)\right). \tag{17}$$

The right-hand side of (17) approaches 0 for $k = 2^{\gamma s}$ provided $0 < \gamma < \frac{d'\beta^2}{\ln 4} = \frac{d'c^2\alpha^2}{\ln 4}$. This finishes the proof of the lemma. □

6. Recent progress and further research. In this paper, we have demonstrated the power of relativization in the area of derandomization. We gave several striking examples, most notably Arthur-Merlin games. New applications have been discovered recently, and we are convinced that even more will follow.

Critical to our argument is the idea that the analyses of the Nisan–Wigderson and other generators work for a large class of predicates and statistical tests—whenever the generator fails a statistical test, the computation of the predicate on which the generator is based reduces to the computation of the test. This idea lies at the heart of the breakthrough extractor constructions of Trevisan [Tre99]. In fact, following Trevisan [Tre99], Miltersen [Mil98] explicitly describes the role of relativization there. He argues that every relativizable construction of a pseudorandom generator out of a hard Boolean function yields an extractor. We showed that the Impagliazzo–Wigderson construction relativizes. Applying Miltersen's argument to the latter yields Trevisan's extractors.

Another application of relativization along the lines of our work is the following: Nisan and Wigderson [NW94] observed that, if E has circuits of size $2^{o(n)}$, then, for every function $t(n) = 2^{\Omega(n)}$ and every positive constant ϵ,

$$\mathsf{DTIME}[t] \subseteq \mathsf{DSPACE}[t^{\epsilon}]. \tag{18}$$

They concluded from their main results that every language in BPP can be decided in deterministic polynomial time for infinitely many input lengths unless (18) holds. Lu [Lu00] noticed that the inclusion (18) even follows if E has B-oracle circuits of size $2^{o(n)}$ for some oracle B that is decidable in linear space. Therefore, by setting $B = \mathrm{SAT}$, the weak version of Theorem 3.10 implies that every language in AM has polynomial size proofs for infinitely many input lengths unless (18) holds [Lu00].

A different line of further research consists of relaxing the hardness condition for derandomizing Arthur-Merlin games. In particular, we would like to replace the SAT-oracle circuit model by the weaker nondeterministic circuit model in Theorem 3.8. Miltersen and Vinodchandran recently managed to do this for the special case of Theorem 3.10. They showed that, if $\mathsf{NE} \cap \mathsf{coNE}$ requires nondeterministic circuits of size $2^{\Omega(n)}$, then AM collapses to NP. They use a different technique, suited for one-sided error classes, and exploit the fact that all languages in AM possess a one-sided error-bounded round Arthur-Merlin game. More specifically, they prove that, if there exists a Boolean function $f \in \mathsf{E}^{\mathcal{A}}$ that requires nondeterministic B-oracle circuits of size $2^{\Omega(n)}$, then there exists a hitting set generator computable in $\mathsf{E}^{\mathcal{A}}$ with logarithmic seed length that works for conondeterministic B-oracle circuits. Instantiating this statement with $\mathcal{A} = \mathsf{NP} \cap \mathsf{coNP}$ and $B = \varnothing$ yields their main result. In a similar way, the SAT-oracle circuits in section 5.3 on rigid matrices can be replaced by nondeterministic circuits [MV99], and the TQBF_2-oracle circuits in section 5.2 on exact learning can be replaced by nondeterministic SAT-oracle circuits.

Due to its one-sided character, the technique of Miltersen and Vinodchandran does not apply to our results in section 5.1 on derandomizing the Valiant–Vazirani hashing procedure. It also only works at the "high-end" of the derandomization spectrum, i.e., under strong hardness assumptions, as in the last lines of Tables 1 and 2. The weakest hardness assumption Miltersen and Vinodchandran can handle is the existence of a Boolean function in $\mathsf{NEXP} \cap \mathsf{coNEXP}$ that requires nondeterministic circuits of size $2^{n^{\alpha}}$ for some constant $\alpha > \frac{1}{2}$. (Then they obtain quasi-polynomial size proofs for any language in AM, as in Theorem 3.9.) In particular, it remains open whether the existence of a Boolean function $f \in \mathsf{NEXP} \cap \mathsf{coNEXP}$ that requires

superpolynomial size nondeterministic circuits implies that graph nonisomorphism has subexponential size proofs. We present this as an open problem for further research.

Acknowledgments. We want to express our sincere gratitude to Oded Goldreich, Madhu Sudan, Luca Trevisan, and Salil Vadhan for their encouragement and collaboration. We would also like to thank Rudi Seitz for his contribution to section 5.4; Theorem 5.16 was proved jointly with him.

The first author wishes to thank Dan Spielman and Salil Vadhan for their support on all aspects of this paper. The first author also wishes to thank Henry Cohn, Steven Rudich, and Avi Wigderson for important conversations.

The second author wishes to thank his adviser Lance Fortnow for the guidance, suggestions, and support he received, and for the statement of Corollary 5.10, in particular. He also wants to thank the following people for stimulating and helpful discussions about issues related to this paper: Eric Allender, Laci Babai, Behfar Bastani, Harry Buhrman, Valentine Kabanets, Peter Bro Miltersen, Mike Saks, Madhu Sudan, Avi Wigderson, and Shiyu Zhou. The second author is grateful to Eric Allender, Peter Bro Miltersen, Valentine Kabanets, and Salil Vadhan for the comments he received on an earlier version of the paper [vM98].

The authors would also like to thank the journal referees for their helpful suggestions and comments.

ON COUNTING INDEPENDENT SETS IN SPARSE GRAPHS*

MARTIN DYER†, ALAN FRIEZE‡, AND MARK JERRUM§

Abstract. We prove two results concerning approximate counting of independent sets in graphs with constant maximum degree Δ. The first implies that the Markov chain Monte Carlo technique is likely to fail if $\Delta \geq 6$. The second shows that no fully polynomial randomized approximation scheme can exist for $\Delta \geq 25$, unless RP = NP.

1. Introduction.

Counting independent sets in graphs is one of several combinatorial counting problems which have received recent attention. The problem is known to be #P-complete, even for low-degree graphs [5]. On the other hand, it has been shown that, for graphs of maximum degree $\Delta = 4$, randomized approximate counting is possible [9, 5]. This success has been achieved using the *Markov chain Monte Carlo* method [8] to construct a *fully polynomial randomized approximation scheme (fpras)*. This has led to a natural question of how far this success might extend.

Here we consider in more detail this question of counting independent sets in graphs with constant maximum degree. We prove two results. The first, in section 2, shows that the Monte Carlo Markov chain method is likely to fail for graphs with $\Delta = 6$. This leaves open only the case $\Delta = 5$.

Our second result gives an explicit value of Δ above which approximate counting, using any kind of polynomial-time algorithm, is impossible unless RP = NP. The bound we obtain is $\Delta = 25$, though we suspect that the true value is in single figures, probably 6.

We note that Berman and Karpinski [2] have recently given new explicit bounds for the approximation ratio for the maximum independent set and other problems in low-degree graphs. These directly imply an inapproximability result for counting. (See Luby and Vigoda [9], specifically the proof of their Theorem 4.) However, the bound on Δ obtained this way is larger than ours by at least two orders of magnitude.

The questions we address in this article could also be studied in a more general setting in which vertices included in an independent set have weights or "fugacities" other than 1. In this setting, the weight of an independent set of size k is deemed to be λ^k for some constant k, and the goal is to compute the sum of the weights of all independent sets. One could then ask, for each Δ, at what exact λ an fpras ceases to

exist (assuming such a λ exists). This question is a more precise version of the one we ask: for $\lambda = 1$, what is the largest Δ for which an fpras exists?

A reasonable guess is that the critical λ just identified is greater than 1 when $\Delta \leq 5$, and less than 1 when $\Delta \geq 6$. One might even rashly conjecture (though we shall not do so) that this critical λ is the same as that marking the boundary between unique and multiple Gibbs measures in the independent set (hard core gas) model in the regular infinite tree of degree Δ (the so-called Bethe lattice). Brightwell and Winkler have computed the fugacity λ at which multiple Gibbs measures appear in the Bethe lattice [3]. The only observation we offer here is that our results are consistent with the critical λ's being the same in both situations.

2. Markov chain Monte Carlo. For a graph G, let $\mathcal{I}(G)$ denote the collection of independent sets of G. Let $\mathcal{M}(G)$ be any Markov chain, asymptotically uniform on $\mathcal{I}(G)$, with transition matrix P_G. In this section, G will be a bipartite graph with a vertex bipartition into classes of equal size n. Let $b(n) \leq n$ be any function of n, and suppose we have $P_G(\sigma_1, \sigma_2) = 0$ whenever $|\sigma_1 \oplus \sigma_2| > b(n)$, where $\oplus$ denotes symmetric difference. We will say that $\mathcal{M}(G)$ is $b(n)$-*cautious*. Thus a $b(n)$-cautious chain is not permitted to change the status of more than $b(n)$ vertices in G at any step. Ideally, for ease of implementation, we would wish to have $b(n)$ a constant (as in [9, 5]). However, we will show that no $b(n)$-cautious chain on $\mathcal{I}(G)$ can mix rapidly unless $b(n) = \Omega(n)$. Thus any chain which does mix rapidly on $\mathcal{M}(G)$ must change the status of a sizable proportion of the vertices at each step.

Before stating our result, we need to formalize what we mean by mixing, rapid or otherwise. Let $\mathcal{M}$ be an ergodic Markov chain with state space Ω, distribution p_t at time t, and asymptotic distribution $p_\infty = \pi$. Let $x_0 \in \Omega$ be the initial state of $\mathcal{M}$, so that p_0 assigns unit mass to state x_0. Define the *mixing time* $\tau(x_0)$ *of* $\mathcal{M}$*, with initial state* $x_0 \in \Omega$, as the first t for which $\mathrm{d_{TV}}(p_t, \pi) \stackrel{\text{def}}{=} \frac{1}{2}||p_t - \pi||_1 \leq e^{-1}$; then define the *mixing time* τ as the maximum of $\tau(x_0)$ over choices of initial state x_0. We are able to show the following.

THEOREM 2.1. *Suppose* $\Delta \geq 6$ *and* $b(n) \leq 0.35n$*. Then there exists a constant* $\gamma > 0$ *and a bipartite graph* G_0*, regular of degree* Δ*, on* $n+n$ *vertices (more precisely a sequence of such graphs parameterized by* n*) with the following property: any* $b(n)$*-cautious Markov chain on* $\mathcal{I}(G_0)$ *has mixing time* $\tau = \Omega(e^{\gamma n})$*.*

Since, of course, there does exist a $2n$-cautious chain which mixes rapidly, our result cannot be strengthened much further. Although we do not identify a specific initial state x_0 satisfying $\tau(x_0) = \Omega(e^{\gamma n})$, our proof does provide a definite (and natural) initial distribution p_0 from which $\tau = \Omega(e^{\gamma n})$ steps are required to achieve $\mathrm{d_{TV}}(p_\tau, \pi) \leq e^{-1}$. The remainder of this section is devoted to the proof of Theorem 2.1.

The counterexample graph G_0 is just a random regular graph of degree Δ. Specifically, let $K_{n,n}$ denote the complete bipartite graph with vertex bipartition V_1, V_2, where $|V_1| = |V_2| = n$, and let G be the union of Δ perfect matchings selected independently and uniformly at random in $K_{n,n}$. (Since the perfect matchings are independent, they may well share some edges.) Denote by $\mathcal{G}(n, n, \Delta)$ the probability space of bipartite graphs G so defined. Where no confusion can arise, we simply write $\mathcal{G}$ for this class below. Note that $\mathcal{G}$ is a class of graphs with degree bound Δ. It is well known (see [1]) that, provided Δ is taken as constant, Δ-regular graphs occur in $\mathcal{G}(n, n, \Delta)$ with probability bounded away from 0. Since we prove that almost every graph $G \in \mathcal{G}(n, n, \Delta)$, for $\Delta \geq 6$, has the property we seek, it will follow that almost every Δ-regular graph (in the induced probability space) has the property too.

Let $0 < \alpha, \beta < 1$ be chosen values. For $G \in \mathcal{G}$, we consider the collection $\mathcal{I}_G(\alpha, \beta)$ of $\sigma \in \mathcal{I}(G)$ such that $|\sigma \cap V_1| = \alpha n$ and $|\sigma \cap V_2| = \beta n$. We will call $\sigma \in \mathcal{I}_G(\alpha, \beta)$ an (α, β)-*set*. Using linearity of expectation, we may easily compute the expected number $\mathcal{E}(\alpha, \beta) = \mathbf{E}(|\mathcal{I}_G(\alpha, \beta)|)$ of (α, β)-sets in G: it is just the number of ways of choosing an αn-subset from V_1 and a βn-subset from V_2, multiplied by the probability that all Δ perfect matchings avoid connecting the αn-subset to the βn-subset. Thus, using Stirling's formula,

$$\begin{aligned}\mathcal{E}(\alpha, \beta) &= \binom{n}{\alpha n}\binom{n}{\beta n}\left[\binom{(1-\beta)n}{\alpha n}\Big/\binom{n}{\alpha n}\right]^{\Delta} \\ &= \left(\frac{(1-\beta)^{(\Delta-1)(1-\beta)}(1-\alpha)^{(\Delta-1)(1-\alpha)}}{\alpha^{\alpha}\beta^{\beta}(1-\alpha-\beta)^{\Delta(1-\alpha-\beta)}}\right)^{n(1+o(1))} \\ &= e^{\varphi(\alpha,\beta)n(1+o(1))}, \qquad (1)\end{aligned}$$

where

$$\begin{aligned}\varphi(\alpha, \beta) = \varphi_{\Delta}(\alpha, \beta) &= -\alpha \ln \alpha - \beta \ln \beta - \Delta(1-\alpha-\beta)\ln(1-\alpha-\beta) \\ &\quad + (\Delta-1)\big((1-\alpha)\ln(1-\alpha) + (1-\beta)\ln(1-\beta)\big). \qquad (2)\end{aligned}$$

Mostly, Δ will be treated as a constant, and we shall suppress the subscript of φ except when we want to emphasize the dependence on Δ.

We shall treat φ as a function of real arguments α and β, even though a combinatorial interpretation is possible only when αn and βn are integers. Then φ is defined on the triangle

$$\mathcal{T} = \{(\alpha, \beta) : \alpha, \beta \geq 0 \text{ and } \alpha + \beta \leq 1\}$$

and is clearly symmetrical in α, β. (The function φ is defined by (2) on the interior of $\mathcal{T}$ and can be extended to the boundary by taking limits.) Moreover, the following facts are established in the appendix about the stationary points of φ on $\mathcal{T}$.

CLAIM 2.2.

(i) *The function φ has no local minima in the interior of $\mathcal{T}$, and no local maxima on the boundary of $\mathcal{T}$.*

(ii) *All local maxima of φ satisfy $\alpha + \beta + \Delta(\Delta-2)\alpha\beta \leq 1$.*

(iii) *If $\Delta \leq 5$, φ has only a single local maximum, which is on the line $\alpha = \beta$.*

(iv) *If $\Delta \geq 6$, φ has exactly two local maxima, symmetrical in α, β, and a single saddle-point on $\alpha = \beta$. The maximum with $\alpha < \beta$ occurs at $(\alpha, \beta) \approx (0.03546955, 0.40831988)$ when $\Delta = 6$ and at $(\alpha, \beta) \approx (0.01231507, 0.45973533)$ when $\Delta = 7$.*

Suppose, for the sake of discussion, we had the additional information that the number $|\mathcal{I}_G(\alpha, \beta)|$ of (α, β)-sets is reasonably well concentrated about its expectation $\mathcal{E}(\alpha, \beta)$. Then it would follow from (iii) and (iv) that a "typical" independent set in a random graph $G \in \mathcal{G}(n, n, \Delta)$ undergoes a dramatic change in passing from $\Delta = 5$ to $\Delta = 6$. For $\Delta \leq 5$, a typical independent set σ would be balanced, i.e., the sets $|\sigma \cap V_1|$ and $|\sigma \cap V_2|$ would be of nearly equal size, whereas for $\Delta \geq 6$ it would be unbalanced.

Unfortunately, we have not been able to prove a concentration result, and it is unclear whether such a result should be expected. Therefore, in examining the first (apparently) unbalanced case, $\Delta = 6$, we must make a slight detour. First, observe

that a knowledge of φ does at least provide an *upper* bound on $|\mathcal{I}_G(\alpha,\beta)|$ via Markov's inequality. In this way we can bound from above the number of (α,β)-sets that lie in the strip $|\alpha-\beta|\le\eta$ for some $\eta>0$. Then, we use a quite crude lower bound to show that the number of (α^*,β^*)-sets—for some chosen α^*,β^* with $\beta^*-\alpha^*>\eta$—is much greater that this.

We shall first deal with the boundary case $\Delta=6$. Once this has been done, it will be easy to dispense with the remaining cases, i.e., $\Delta\ge 7$, which are less finely balanced. So suppose for the time being that $\Delta=6$. Consider the function φ restricted to the region $\mathcal{D}=\mathcal{T}\cap\{(\alpha,\beta):|\alpha-\beta|\le\eta\}$, where $\eta=0.18$. Since the two local maxima of φ on $\mathcal{T}$ lie outside $\mathcal{D}$ (see Claim 2.2(iv)), it must be the case that the maxima of φ on $\mathcal{D}$ all lie on one or the other (and hence, by symmetry, both) of the lines $|\alpha-\beta|=\eta$. Numerically, the (unique) maximum with $\beta-\alpha=\eta$, achieved at $(\alpha,\beta)\approx(0.10021227,0.28021227)$, is a little less than $c=0.70824602$. (The uniqueness of the maximum may be verified by calculus; then the location of the maximum may be found to arbitrary precision by repeated evaluation of the derivative of $\varphi(\alpha,\alpha+0.18)$ with respect to α. Only simple function evaluations are required.)

Now define

$$\theta(\alpha)=-\alpha\ln\alpha-(1-\alpha)\ln(1-\alpha)+(\ln 2)(1-\Delta\alpha)$$

for $\Delta\alpha<1$. Then, for *any* graph $G\in\mathcal{G}$, the total number of independent sets σ with $|\sigma\cap V_1|=\alpha n$ is (crudely) at least

$$|\mathcal{I}_G(\alpha,*)|\ge e^{\theta(\alpha)n(1-o(1))}.$$

(Choose αn vertices from V_1; then choose any subset of vertices from the at least $(1-\Delta\alpha)n$ unblocked vertices in V_2.) Set $\alpha^*=0.015$. Then, by numerical computation, $\theta(\alpha^*)$ is a little greater than $0.70864644>c$. Thus, with high probability, the number of (α,β)-sets in $G\in\mathcal{G}$ lying in either connected component of $\mathcal{T}\setminus\mathcal{D}$ is greater than the number lying within $\mathcal{D}$ by an exponential factor, specifically $e^{\gamma n}$, where $\gamma=0.0004$. The graph G_0 of Theorem 2.1 is any graph $G_0\in\mathcal{G}$ that exhibits the exponential gap just described. (A randomly chosen graph will do with high probability.) The remainder of our argument concerns G_0.

Now consider a $0.35n$-cautious chain $\mathcal{M}(G_0)=\mathcal{M}_0$ on $\mathcal{I}(G_0)$. Let A comprise all (α,β)-sets with $\alpha\ge\beta$, i.e.,

$$A=\big\{\sigma\in\mathcal{I}(G_0):|\sigma\cap V_1|\ge|\sigma\cap V_2|\big\},$$

and assume without loss of generality that A is no larger than its complement $\overline{A}=\mathcal{I}\setminus A$. Denote by M the set of (α,β)-sets with $(\alpha,\beta)\in\mathcal{D}$. Since $\mathcal{M}_0$ is $0.35n$-cautious, it cannot make a transition from A to $\overline{A}$ except by using a state in M. Now, we have already seen that

$$|A|\ge e^{\gamma n}\,|M|. \tag{3}$$

Intuitively, since M is very small in relation to A, the mixing time of $\mathcal{M}_0$ must be very large. This intuition is captured in the following claim, which is implicit in a line of argument used by Jerrum [7].

Claim 2.3. *Let $\mathcal{M}$ be a Markov chain with state space Ω, transition matrix P, and stationary distribution π. Let $A\subset\Omega$ be a set of states such that $\pi(A)\le\frac{1}{2}$, and*

$M \subset \Omega$ be a set of states that form a "barrier" in the sense that $P_{ij} = 0$ whenever $i \in A \setminus M$ and $j \in \overline{A} \setminus M$. Then the mixing time of $\mathcal{M}$ is at least $\pi(A)/8\pi(M)$.

For completeness, a proof using "conductance" is provided in the appendix. Theorem 2.1, in the boundary case $\Delta = 6$, follows from Claim 2.3 and inequality (3) because the sets A and M that we defined earlier satisfy the conditions of the claim. Note that the proof of Claim 2.3 actually provides an explicit initial distribution p_0 from which the mixing time is large, namely, the uniform distribution on A.

Finally, suppose $\Delta \geq 7$. We shall see presently that

$$\varphi_\Delta(\alpha, \beta) < 0.6763 < \ln 2 \quad \text{for all } \Delta \geq 7 \text{ and } (\alpha, \beta) \in \mathcal{D}. \tag{4}$$

On the other hand, there are at least 2^n (α, β)-sets in either connected component of $\mathcal{T} \setminus \mathcal{D}$: this comes simply from considering independent sets with $\alpha = 0$ or $\beta = 0$. Once again, with high probability, the number of (α, β)-sets in $G \in \mathcal{G}$ lying in either connected component of $\mathcal{T} \setminus \mathcal{D}$ is greater than the number lying within $\mathcal{D}$ by an exponential factor, specifically $e^{\gamma n}$, where $\gamma = 0.015$. Theorem 2.1, in the general case $\Delta \geq 7$, follows as before.

It remains only to verify (4). By calculus, $\varphi_\Delta(\alpha, \beta)$ as a function of Δ is monotonically decreasing over the whole region $\mathcal{T}$; thus we need check only the case $\Delta = 7$. (The partial derivative $\partial \varphi_\Delta(\alpha, \beta)/\partial \Delta$ is a function of α and β only; it is zero on $\alpha = 0$ and monotonically decreasing as a function of β.) We now argue, as before, that the maxima of φ on $\mathcal{D}$ all lie on the lines $|\alpha - \beta| = 0.18$. (Here we again use Claim 2.2(iv).) Once again, by calculus, φ has a unique maximum on each of these lines, and direct calculation yields (4).

3. Hardness of approximate counting. The result of the previous section implies that the usual approach to approximating the number of independent sets in a low-degree graph must fail when $\Delta \geq 6$, at least in the worst case. Here we show that, if the degree bound is somewhat larger, then *any* approach to approximating the number of independent sets is doomed to failure, under a reasonable complexity assumption. Precisely, the remainder of this section is devoted to proving the following theorem.

THEOREM 3.1. *Unless* RP = NP*, there is no polynomial-time algorithm that estimates the* logarithm *of the number of independent sets in a Δ-regular graph ($\Delta \geq 25$) within relative error at most $\varepsilon = 10^{-4}$.*

We give a randomized reduction from the following problem E2LIN2, analyzed by Håstad. The input is a system $\mathcal{A}$ of m equations over $\mathbb{Z}_2$ in n variables $x_1, x_2, \ldots, x_n$, such that each equation has exactly two variables. (Thus each equation is of the form $x_i + x_j = 0$ or $x_i + x_j = 1$.) The objective is to find a maximum cardinality consistent subset of equations in $\mathcal{A}$, i.e., to assign values to the variables so as to maximize the number m_C of satisfied equations. Håstad [10] showed, using the powerful theory of probabilistically checkable proofs (PCPs), that it is NP-hard to estimate m_C within any constant factor smaller than $12/11$.[1] Therefore consider an instance $\mathcal{A}$ of E2LIN2, as above. We will construct (by a randomized algorithm) a graph $G = (V, E)$, regular of degree Δ. We then show that, if we can approximate the logarithm of the number of independent sets in G to within the required relative error, we can (with high probability) approximate the size of m_C in $\mathcal{A}$ to within a factor $12/11 - \varepsilon$. Theorem 3.1 will then follow.

[1] In other words, determining a number in the range $[(11/12+\varepsilon)m_C, m_C]$ is as hard as determining m_C exactly. Following convention, Håstad normalizes approximation ratios to be greater than 1, taking the reciprocal in the case of a maximization problem.

Let us write $[n] = \{1, 2, \ldots, n\}$. We construct the graph $G = G(\mathcal{A})$ as follows. We assume $m \geq n$; otherwise, $\mathcal{A}$ is decomposable or consistent. Let $M = m^6$ and, for each $i \in [n]$, let A_i be the multiset of equations containing x_i, with (multiset) cardinality d_i. We represent x_i by a regular bipartite graph H_i of degree $\delta = \Delta - 1$, with vertex partition (L_i, R_i) and edge set F_i. Here $L_i = \bigcup_{a \in A_i} L_{i,a}$, $R_i = \bigcup_{a \in A_i} R_{i,a}$, where the sets $L_{i,a}$, $R_{i,a}$ partition L_i and R_i, respectively, and for all i, a, $|L_{i,a}| = |R_{i,a}| = M$. Thus H_i is bipartite with both its vertex sets of size Md_i. Later, we will associate L_i with the assignment $x_i = 0$, and R_i with $x_i = 1$.

The graph $H_i = (L_i, R_i, F_i)$ will be sampled from $\mathcal{G}(Md_i, Md_i, \delta)$, where $\mathcal{G}$ is the class of random graphs defined in section 2. Just as in that section, and for the same reason, we are at liberty to reject graphs which are not δ-regular. Clearly, the property of being δ-regular can be checked in polynomial time.

The equations a of $\mathcal{A}$ determine the edges connecting the H_i in G, as follows. If a is the equation $x_i + x_j = 1$ ($x_i + x_j = 0$, resp.), we add an arbitrary perfect matching between $L_{i,a}$ and $L_{j,a}$ ($R_{j,a}$, resp.) and another between $R_{i,a}$ and $R_{j,a}$ ($L_{j,a}$, resp.). Thus G is a regular graph of degree Δ. We will show that approximating the logarithm of the number of independent sets in G to within a factor $(1 + 10^{-4})$ will allow us to approximate the E2LIN2 instance within the Håstad bound.

Before returning to the issue of approximation, we will need to establish some crucial properties of the "typical" independent set in G. For this purpose, let I be sampled uniformly from $\mathcal{I}(G)$, the set of all independent sets in G. First we show that I "occupies about half the available space" in each $L_{i,a}$ or $R_{i,a}$.

Let $\mathcal{L}_{i,a}$ be the set of vertices in $L_{i,a}$ with no neighbor in I, and let $\mathcal{L}_i = \bigcup_{a \in A_i} \mathcal{L}_{i,a}$.

LEMMA 3.2. *Suppose that I is sampled uniformly at random (u.a.r.) from $\mathcal{I}(G)$. Then, except for probability $e^{-\Omega(m^2)}$, either $|\mathcal{L}_{i,a}| < m^4$ or $|\mathcal{L}_{i,a}| = (2 \pm O(1/m)) \times |I \cap L_{i,a}|$.*

Proof. If we condition on $I \cap (V \setminus L_{i,a})$, then $I \cap L_{i,a}$ is a random subset of $\mathcal{L}_{i,a}$. If $|\mathcal{L}_{i,a}| \geq m^4$, then Chernoff's bound implies that

$$\mathbf{Pr}\left[|I \cap L_{i,a}| \notin \frac{1}{2}\Big(1 \pm \frac{1}{m}\Big)\,|\mathcal{L}_{i,a}|\right] \leq 2\exp\Big(-\frac{1}{3}m^2\Big),$$

from which the lemma follows. ∎

Clearly, we may define $\mathcal{R}_{i,a}$ and $\mathcal{R}_i$ symmetrically and prove an analogous result. It is also clear that we may claim Lemma 3.2 for all i, a simultaneously, since there are fewer than m^2 such pairs. Now imagine that we choose an independent set $I \in \mathcal{I}(G)$ u.a.r. in two steps: first the part of I that lies outside H_i, followed by the restriction of I to H_i. We now deduce from Lemma 3.2 that, with high probability, at least around half of L_i is "available" to I in the second step.

Let $\mathcal{L}'_i$ be the set of vertices in L_i with no neighbor in I outside of H_i.

LEMMA 3.3. *Suppose that I is sampled u.a.r. from $\mathcal{I}(G)$. Except for probability $e^{-\Omega(m^2)}$,*

$$|\mathcal{L}'_i| \geq \left(\frac{1}{2} - O\left(\frac{1}{m}\right)\right)|L_i|. \tag{5}$$

Proof. If $L_{i,a}$ is joined by a matching to $V_{j,a}$ ($V \in \{L, R\}$), then, from Lemma 3.2, $M \geq (2 - O(1/m))|I \cap V_{j,a}|$. Hence

$$\big|\{v \in L_{i,a} : \{v, w\} \in E \setminus F_i \text{ implies } w \notin I\}\big| \geq \left(\frac{1}{2} - O\left(\frac{1}{m}\right)\right)|L_{i,a}|.$$

Summing this over all $a \in A_i$ gives the lemma. ∎

Again, we may define $\mathcal{R}_i'$ and prove a corresponding result. We now show that for each i either $|\mathcal{L}_i|$ or $|\mathcal{R}_i|$ is "small." We will temporarily drop the suffix i and write H rather than H_i, etc. Let $N = |L| = dM \le m^7$, $a = |\mathcal{L}'|/N$, $b = |\mathcal{R}'|/N$. Write $\sigma = I \cap H$, where I is a uniformly chosen independent set in G. We will say that σ is an (α, β)-set if $|\sigma \cap L| = \alpha a N$, $|\sigma \cap R| = \beta b N$.

LEMMA 3.4. *Let $\delta \ge 24$. If I is a uniformly chosen independent set in G, then, except for probability $e^{-\Omega(m^2)}$,*

$$\min(|\mathcal{L}_i|, |\mathcal{R}_i|) \le \lambda N, \tag{6}$$

where $\lambda = 0.009$.

Proof. We focus attention on a particular H in G (corresponding to a particular variable in the E2LIN2 instance). Suppose that the whole of G aside from the edges within H has been fixed (i.e., the random choices have already been made), except that we have not chosen the edges of H itself. Ultimately, we want to argue about a random independent set I. However, for the time being, suppose that we simply fix the portion of I that lies outside of H; doing this fixes the sets $\mathcal{L}'$ and $\mathcal{R}'$ of vertices in H that have no neighbor in I. About I, we assume only that it satisfies inequality (5) of Lemma 3.3 so that $a \ge b \ge \frac{1}{2} - O(\frac{1}{m})$, where, without loss of generality, we have taken $a \ge b$.

We now reveal H and examine the number of extensions of I to H as a function of α and β. It is easy to see that there are at least 2^{aN} independent sets in H in total. We will show that, for α, β not satisfying the condition of the lemma, the number of (α, β)-sets is so much smaller than this that they appear with probability $e^{-\Omega(m^2)}$. It will be sufficient to show that the expected number of (α, β)-sets in such a case is $2^{aN - \Omega(m^2)}$, because Markov's inequality will then imply the required inequality for the actual number. Now the expected number of (α, β)-sets in H is

$$\begin{aligned}
\mathcal{E}(\alpha,\beta) &= \binom{aN}{\alpha a N}\binom{bN}{\beta b N}\left[\binom{(1-b\beta)N}{\alpha a N}\Big/\binom{N}{\alpha a N}\right]^{\delta} \\
&\le \binom{aN}{\alpha a N}\binom{bN}{\beta b N}\left[\frac{[(1-b\beta)N]^{\underline{\alpha a N}}}{(\alpha a N)!} \times \frac{(\alpha a N)!}{N^{\underline{\alpha a N}}}\right]^{\delta} \\
&\le \binom{aN}{\alpha a N}\binom{bN}{\beta b N}(1-b\beta)^{\alpha a \delta N} \\
&\le \left[\left(\alpha^{\alpha}(1-\alpha)^{(1-\alpha)}\right)^{-a}\left(\beta^{\beta}(1-\beta)^{(1-\beta)}\right)^{-b} e^{-\alpha\beta a b \delta}\right]^{N(1+o(1))} \\
&= e^{\psi(\alpha,\beta)N(1+o(1))}, \qquad (7)
\end{aligned}$$

where an underlined superscript denotes "falling factorial power," and

$$\begin{aligned}
\psi(\alpha,\beta) = &-a(\alpha\ln\alpha + (1-\alpha)\ln(1-\alpha)) \\
&- b(\beta\ln\beta + (1-\beta)\ln(1-\beta)) - \alpha\beta a b\delta. \qquad (8)
\end{aligned}$$

Note that ψ is defined in the unit square $\mathcal{U} = \{(\alpha, \beta) : 0 \le \alpha, \beta \le 1\}$. As before, we shall treat α and β (and indeed a and b) as real variables, even though a combinatorial interpretation requires aN, bN, $\alpha a N$, and $\beta b N$ to be integers. The key property of ψ is captured in the following claim, whose proof can be found in the appendix.

CLAIM 3.5. *Let $\delta = 24$, $\eta > 0$ be sufficiently small, and suppose $\frac{1}{2} - \eta \le b \le a \le 1$. For any $(\alpha, \beta) \in \mathcal{U}$, the inequality $\psi(\alpha, \beta) \ge a \ln 2 - \eta$ entails $\min\{\alpha a, \beta b\} \le 0.004$.*

Recall the crude lower bound 2^{aN} on the total number of independent sets σ extending I to H. The claim tells us that only very unbalanced independent sets—those with either $|\sigma \cap L| \le 0.004$ or $|\sigma \cap R| \le 0.004$—make a significant contribution to that total. All of the above argument was for an independent set I that is fixed outside H, so we have not yet proved Lemma 3.4. Nevertheless, all the key calculations are out of the way, and we can complete the proof with a little algebra.

Let $\mathcal{I}$ be the set of all independent sets on $V(G) \setminus V(H)$. Let $\mathcal{I}_{\text{good}} \subseteq \mathcal{I}$ be the independent sets I that satisfy inequality (5) of Lemma 3.3, and $\mathcal{I}_{\text{bad}} = \mathcal{I} \setminus \mathcal{I}_{\text{good}}$. Let $N(I, H)$ be the number of independent sets in H consistent with I, and let $N^*(I, H)$ be the number of such that do not satisfy inequality (6) of Lemma 3.4. Denote by $\mathcal{H}$ the (multi)set of all possible choices for the graph H viewed as a disjoint union of δ perfect matchings. (Thus each possible graph H will occur with multiplicity μ, where μ is the number of 1-factorizations of H—i.e., decompositions into disjoint perfect matchings—of H. Note that our reduction requires us to select *uniformly* from $\mathcal{H}$.) For convenience, set $\varepsilon = e^{-\Omega(m^2)}$. We have shown in Lemma 3.3 that

$$\sum_{I \in \mathcal{I}_{\text{bad}}} N(I, H) \le \varepsilon \sum_{I \in \mathcal{I}} N(I, H) \qquad \text{for all } H \in \mathcal{H}. \tag{9}$$

(Note that the sum on the right-hand side is the total number of independent sets in G, while that on the left-hand side is the number violating inequality (5).) We will show below that a random H satisfies

$$\sum_{I \in \mathcal{I}_{\text{good}}} N^*(I, H) \le \varepsilon \sum_{I \in \mathcal{I}_{\text{good}}} N(I, H) \tag{10}$$

with high probability, specifically, with probability at least $1 - \varepsilon$. Putting (9) and (10) together, a random H satisfies

$$\begin{aligned} \frac{\sum_{I \in \mathcal{I}} N^*(I, H)}{\sum_{I \in \mathcal{I}} N(I, H)} &\le \frac{\varepsilon \sum_{I \in \mathcal{I}_{\text{good}}} N(I, H) + \sum_{I \in \mathcal{I}_{\text{bad}}} N(I, H)}{\sum_{I \in \mathcal{I}} N(I, H)} \\ &\le \varepsilon + \varepsilon = 2\varepsilon \end{aligned}$$

with high probability, which is what we require.

We now prove (10). Claim 3.5 taken in conjunction with Lemma 3.2 shows that

$$\frac{\sum_{H \in \mathcal{H}} N^*(I, H)}{|\mathcal{H}|} \le \varepsilon^2 \widehat{N}(I) \qquad (I \in \mathcal{I}_{\text{good}})$$

for some $\widehat{N}(I)$ satisfying $\widehat{N}(I) \le N(I, H)$ for all $H \in \mathcal{H}$. (Specifically, $\widehat{N} = 2^{aN}$ will do here.) Summing this over $I \in \mathcal{I}_{\text{good}}$ gives

$$\frac{1}{|\mathcal{H}|} \sum_{H \in \mathcal{H}} \sum_{I \in \mathcal{I}_{\text{good}}} N^*(I, H) \le \varepsilon^2 \sum_{I \in \mathcal{I}_{\text{good}}} \widehat{N}(I),$$

giving

$$\frac{1}{|\mathcal{H}|} \sum_{H \in \mathcal{H}} \frac{\sum_{I \in \mathcal{I}_{\text{good}}} N^*(I, H)}{\sum_{I \in \mathcal{I}_{\text{good}}} \widehat{N}(I)} \le \varepsilon^2,$$

which implies that

$$\frac{1}{|\mathcal{H}|}\sum_{H\in\mathcal{H}}\frac{\sum_{I\in\mathcal{I}_{\text{good}}}N^*(I,H)}{\sum_{I\in\mathcal{I}_{\text{good}}}N(I,H)}\le\varepsilon^2. \tag{11}$$

Let

$$\mathcal{H}^*=\left\{H\in\mathcal{H}:\sum_{I\in\mathcal{I}_{\text{good}}}N^*(I,H)\ge\varepsilon\sum_{I\in\mathcal{I}_{\text{good}}}N(I,H)\right\}.$$

Then, from (11),

$$\frac{1}{|\mathcal{H}|}\,\varepsilon\,|\mathcal{H}^*|\le\varepsilon^2,$$

so

$$\frac{|\mathcal{H}^*|}{|\mathcal{H}|}\le\varepsilon,$$

as is required to establish (10) and complete the proof. □

We now establish the relationship between the number of independent sets in G and the maximum size of a consistent subset of $\mathcal{A}$. Let $\mathcal{I}=\mathcal{I}(G)$. For $\sigma\in\mathcal{I}$ let $S_\sigma\subseteq[n]$ be defined by

$$S_\sigma=\{i:\ |L_i\cap\sigma|>|R_i\cap\sigma|,\ i\in[n]\}.$$

For $S\subseteq[n]$ let $\mathcal{I}_S=\{\sigma\in\mathcal{I}:\ S_\sigma=S\}$ and let $\mu_S=|\mathcal{I}_S|$. Recall that m is the number of equations in $\mathcal{A}$.

LEMMA 3.6. *For $S\subseteq[n]$ let $\theta(S)$ be the number of equations in $\mathcal{A}$ satisfied by the assignment $x_i=1$ $(i\in S)$, $x_i=0$ $(i\notin S)$. Then*

$$4^{M\theta(S)}3^{M(m-\theta(S))}\le\mu_S\le4^{M\theta(S)}3^{M(m-\theta(S))}2^{2\lambda mM}(1+o(1)), \tag{12}$$

where λ is as in Lemma 3.4.

Proof. Fix $S\subseteq[n]$, and for $\sigma\in\mathcal{I}_S$ let $J_\sigma=\sigma\cap\left(\bigcup_{i\in S}L_i\cup\bigcup_{i\notin S}R_i\right)$. Informally, J_σ restricts σ to the left or right of each subgraph H_i, according to which side contains the larger part of σ. Let

$$\hat{\mu}_S=|\{J_\sigma:\ \sigma\in\mathcal{I}_S\}|\le\mu_S.$$

We show that

$$\hat{\mu}_S=4^{M\theta(S)}3^{M(m-\theta(S))}. \tag{13}$$

This immediately proves the lower bound in (12). Furthermore, Lemma 3.4 implies that for a fixed value J of J_σ there are (up to a factor $(1+e^{-\Omega(m^2)})$) at most

$$\prod_{i\in[n]}2^{\lambda d_iM}=2^{\lambda M\sum_i d_i}=2^{2\lambda mM}$$

sets $\sigma\in\mathcal{I}_S$ with $J_\sigma=J$. The upper bound then follows.

To prove (13) we consider the number of possible choices for $J \cap L_{i,a}$, $J \cap R_{i,a}$, $J \cap L_{j,a}$, and $J \cap R_{j,a}$ for every equation $a : x_i + x_j = z_a$ ($z_a \in \{0,1\}$). For given S, let us define

$$X_{i,a} = \begin{cases} L_{i,a} & \text{if } i \in S; \\ R_{i,a} & \text{if } i \notin S. \end{cases}$$

Then there are two cases, determined by the status of a.

(1) Equation a is satisfied by the assignment derived from S. Then there are 2^M choices for each of $J \cap X_{i,a}$, $J \cap X_{j,a}$, giving 4^M in all.
(2) Equation a is not satisfied by the assignment derived from S. Then the subgraph of G induced by $X_{i,a} \cup X_{j,a}$ is a matching of size M and hence contains 3^M independent sets.

Multiplying the estimates from the two cases over all $a \in \mathcal{A}$ proves (13) and the lemma. □

We now proceed to the proof of Theorem 3.1. Let $Z_I = Z_I(G)$ denote the logarithm of the number of independent sets of $G(\mathcal{A})$. Let $Z_C = Z_C(\mathcal{A})$ denote the maximum number of consistent equations in $\mathcal{A}$.

Let Y_I be some estimate of Z_I satisfying $|Y_I/Z_I - 1| \le \varepsilon = 10^{-4}$. Using Y_I, we define

$$Y_C = \left(\frac{Y_I}{M} - m \ln 3\right) \frac{1.001}{\ln(4/3)}.$$

A simple calculation will then show that $1 \le Y_C/Z_C \le 12/11 - \varepsilon$, so that Y_C determines Z_C with sufficient accuracy to beat the approximability bound for E2LIN2.

From Lemma 3.6 we see that

$$Y_I \ge (1-\varepsilon)M(Z_C \ln(4/3) + m \ln 3).$$

Hence, since $Z_C \ge m/2$,

$$\frac{Y_C}{1.001} \ge (1-\varepsilon)Z_C - \frac{\varepsilon m \ln 3}{\ln(4/3)} \ge Z_C\left(1 - \frac{\varepsilon \ln 12}{\ln(4/3)}\right) \ge 0.9991 Z_C,$$

which implies that $Y_C \ge Z_C$. On the other hand, Lemma 3.6 also implies that

$$Y_I \le (1+\varepsilon)\big[M\big(Z_C \ln(4/3) + m \ln 3 + 2m\lambda \ln 2\big) + n \ln 2\big],$$

where $\lambda \le 0.009$. Hence

$$\begin{aligned} \frac{Y_C}{1.001} &\le (1+\varepsilon)Z_C + \frac{\varepsilon m \ln 3}{\ln(4/3)} + \frac{(1+\varepsilon)2m\lambda \ln 2}{\ln(4/3)} + \frac{(1+\varepsilon)\ln 2}{n \ln(4/3)} \\ &\le Z_C\left(1 + \varepsilon + \frac{2\varepsilon \ln 3}{\ln(4/3)} + \frac{4(\ln 2)(1+\varepsilon)\lambda}{\ln(4/3)} + O\left(\frac{1}{n^2}\right)\right) \\ &\le Z_C\left(1.0877 + O\left(\frac{1}{n^2}\right)\right), \end{aligned}$$

which implies that Y_C/Z_C is bounded away from $12/11$ for n large enough. Summarizing, the existence of a polynomial-time algorithm, meeting the specification in Theorem 3.1, for estimating the number of independent sets in a 25-regular graph

would entail the existence of a randomized (two-sided error) algorithm for approximating the solution to an E2LIN2 instance with relative error better than 12/11. (The algorithm is randomized because the reduction is too.) Because the latter problem is NP-hard, we could deduce that NP $\subseteq$ BPP. But this inclusion in turn implies that RP = NP (see Papadimitriou [11, Problem 11.5.18]). Thus we have established Theorem 3.1.

Appendix.

Proof of Claim 2.2. We start by computing partial derivatives of φ up to order two:

$$\frac{\partial\varphi}{\partial\alpha} = -\ln\alpha - (\Delta-1)\ln(1-\alpha) + \Delta\ln(1-\alpha-\beta), \tag{14}$$

$$\frac{\partial\varphi}{\partial\beta} = -\ln\beta - (\Delta-1)\ln(1-\beta) + \Delta\ln(1-\alpha-\beta), \tag{15}$$

$$\frac{\partial^2\varphi}{\partial\alpha^2} = -\frac{1}{\alpha} + \frac{\Delta-1}{1-\alpha} - \frac{\Delta}{1-\alpha-\beta}, \tag{16}$$

$$\frac{\partial^2\varphi}{\partial\beta^2} = -\frac{1}{\beta} + \frac{\Delta-1}{1-\beta} - \frac{\Delta}{1-\alpha-\beta}, \tag{17}$$

$$\frac{\partial^2\varphi}{\partial\alpha\,\partial\beta} = -\frac{\Delta}{1-\alpha-\beta}. \tag{18}$$

Parts (i)–(iv) of Claim 2.2 may then be verified as follows:

(i) From (16), it can easily be checked that $\partial^2\varphi/\partial\alpha^2 < 0$ on the interior of $\mathcal{T}$, and hence φ can have no interior local minima. On $\alpha = 0$, φ has a maximum at $\beta = \frac{1}{2}$ using (15), but then from (14) we find $\partial\varphi/\partial\alpha = +\infty$ at $\alpha = 0$, $\beta = \frac{1}{2}$. Similarly $\beta = 0$. On $\alpha + \beta = 1$, both $\partial\varphi/\partial\alpha, \partial\varphi/\partial\beta = -\infty$, so φ can have no maximum.

(ii) Since both $\partial^2\varphi/\partial\alpha^2, \partial^2\varphi/\partial\beta^2 < 0$, φ has a maximum if and only if the Hessian of φ has a positive determinant. The condition for this is $\alpha + \beta + \Delta(\Delta-2)\alpha\beta \le 1$, as may be checked from (16)–(18).

(iii) From (14) and (15), the conditions for a stationary point of φ may be written

$$\beta = f(\alpha), \quad \alpha = f(\beta),$$

where

$$f(x) = 1 - x - x^{1/\Delta}(1-x)^{1-1/\Delta} = (1-x)\left[1 - \left(\frac{x}{1-x}\right)^{1/\Delta}\right] \quad (0 \le x \le 1).$$

Thus, at any stationary point,

$$\alpha = f(f(\alpha)). \tag{19}$$

Clearly $f(x) \le 0$ for $x \ge \frac{1}{2}$, so $\alpha < \frac{1}{2}$ at any stationary point. Similarly $\beta < \frac{1}{2}$. To study the roots of (19), the change of variable $y = (\alpha/(1-\alpha))^{1/\Delta}$ proves to be convenient. With a little calculation we may express α, $f(\alpha)$, and $f(f(\alpha))$ in terms of y:

$$\alpha = \frac{y^\Delta}{1+y^\Delta}, \tag{20}$$

$$f(\alpha) = (1-\alpha)(1-y) = \frac{1-y}{1+y^\Delta},$$

and

$$\begin{aligned} f(f(\alpha)) &= (1 - f(\alpha)) - \big(f(\alpha)(1 - f(\alpha))^{\Delta-1}\big)^{1/\Delta} \\ &= \left(\alpha + \frac{y}{1+y^\Delta}\right) - \frac{\big((1-y)(y+y^\Delta)^{\Delta-1}\big)^{1/\Delta}}{1+y^\Delta} \\ &= \alpha + \frac{y}{1+y^\Delta}\left[1 - \left(\frac{(1-y)(1+y^{\Delta-1})^{\Delta-1}}{y}\right)^{1/\Delta}\right], \end{aligned}$$

and hence (19) is equivalent to

$$(1 + y^{\Delta-1})^{\Delta-1} = \frac{y}{1-y} \qquad (0 \le y < 1). \tag{21}$$

Note that the implicit mapping from α to y is a bijection, so we may legitimately study the solution set of (19) through that of (21). Note also that (21) has a root y' satisfying $y + y^\Delta = 1$, and this exists for any $\Delta > 0$. The reader may check that $y + y^\Delta = 1$ is equivalent to $\alpha = f(\alpha)$, and thus y' satisfies $\alpha = \beta$. To analyze (21) in general, let

$$g(y) = (\Delta - 1)\ln(1 + y^{\Delta-1}) + \ln(1 - y) - \ln y,$$

so $g(y) = 0$ has the same roots as (21). Then one may check that $g'(y) = 0$ if and only if

$$h(y) \stackrel{\text{def}}{=} \Delta(\Delta - 2)y^{\Delta-1} - (\Delta - 1)^2 y^\Delta - 1 = 0.$$

But $h(0) = -1$, $h(1) = -2$, and h has a single maximum on $[0, 1]$ at $y'' = (\Delta - 2)/(\Delta - 1)$. Now $h(y'') = (\Delta - 2)^\Delta/(\Delta - 1)^{\Delta-1} - 1 > 0$ if and only if $\Delta \ge 6$, and $h(y'') < 0$ otherwise. Therefore h has two roots in $[0, 1]$ if $\Delta \ge 6$; otherwise, it has no roots. Thus g has a single root in $[0, 1]$ if $\Delta \le 5$; otherwise, it has at most three roots. In the latter case, however, $g(0) = +\infty$, $g(1) = -\infty$, $g(y') = 0$, and a simple calculation shows

$$g'(y') = \frac{(\Delta - 1)^2(1 - y')^2 - 1}{y'(1 - y')} > 0$$

if and only if $\Delta \ge 6$, and $g'(y') < 0$ otherwise. These facts imply that g has exactly three roots if $\Delta \ge 6$.

Now the reader may check that the point (α', α') corresponding to y' (i.e., given by solving $y' = (\alpha'/(1 - \alpha'))^{1/\Delta}$) satisfies

$$\alpha + \beta + \Delta(\Delta - 2)\alpha\beta \le 1,$$

i.e.,

$$\left(\frac{1-\alpha}{\alpha}\right)\left(\frac{1-\beta}{\beta}\right) \ge (\Delta - 1)^2$$

if and only if $y' \ge y''$. This holds if and only if $\Delta \le 5$. Thus this point is a maximum for $\Delta \le 5$; otherwise, it is a saddle-point.

Thus φ has one stationary point in $\mathcal{T}$ (on $\alpha = \beta$) if $\Delta \le 5$, and this is a maximum.

(iv) By the above, if $\Delta \geq 6$, φ has no boundary maximum on $\mathcal{T}' = \{(\alpha, \beta) \in \mathcal{T} : \alpha \leq \beta\}$ and therefore by continuity has a maximum in the interior of $\mathcal{T}'$. By symmetry there is also a maximum in $\mathcal{T} \setminus \mathcal{T}'$. Thus, when $\Delta \geq 6$, φ has two symmetrical maxima and a single saddle-point on the line $\alpha = \beta$. Numerical values for the two maximum points can be obtained by solving (21) for y. Since we are assured that (21) has exactly three roots, we may locate these roots to arbitrary precision by repeated function evaluations. Once y is known to adequate precision, α can be recovered from (20). □

Proof of Claim 2.3. Let $\Omega = \{1, \ldots, N\}$ be an enumeration of the state space. When x is an N-vector and P an $N \times N$ matrix, we will use x_A to mean the vector $(x_i : i \in A)$ and P_{AB} to mean the matrix $(P_{ij} : i \in A, j \in B)$. First note that

$$\begin{aligned} \mathrm{d_{TV}}(p_{t+1}, p_t) = \mathrm{d_{TV}}(p_t P, p_{t-1} P) &= \tfrac{1}{2} \max_{||z||_\infty \leq 1} (p_t - p_{t-1}) P z \\ &\leq \tfrac{1}{2} \max_{||w||_\infty \leq 1} (p_t - p_{t-1}) w = \mathrm{d_{TV}}(p_t, p_{t-1}), \end{aligned}$$

since $||Pz||_\infty \leq ||z||_\infty$. Hence, by induction, $\mathrm{d_{TV}}(p_{t+1}, p_t) \leq \mathrm{d_{TV}}(p_1, p_0)$ and hence, using the triangle inequality, $\mathrm{d_{TV}}(p_t, p_0) \leq t\, \mathrm{d_{TV}}(p_1, p_0)$. Now, for $\emptyset \subset S \subset \Omega$, define

$$\Phi(S) = \sum_{i \in S} \sum_{j \in \overline{S}} \pi_i P_{ij} / \pi(S).$$

Thus $\Phi = \min\{\Phi(S) : S \subset \Omega \text{ and } 0 < \pi(S) \leq \frac{1}{2}\}$ is the "conductance" of $\mathcal{M}$. (Conductance is normally considered in the context of time-reversible Markov chains. However, both the definition and the line of argument employed here apply to non–time-reversible chains.) Now

$$\sum_{\substack{i \in A \\ j \in \overline{A}}} \pi_i P_{ij} \leq \sum_{\substack{i \in A \\ j \in \overline{A} \cap M}} \pi_i P_{ij} + \sum_{\substack{i \in A \cap M \\ j \in \overline{A}}} \pi_i P_{ij} \leq \pi(\overline{A} \cap M) + \pi(A \cap M) = \pi(M).$$

So by setting $(p_0)_A = \pi_A / \pi(A)$, $(p_0)_{\overline{A}} = 0$, we have that

$$\mathrm{d_{TV}}(p_1, p_0) = \tfrac{1}{2} ||\pi_A - \pi_A P||_1 / ||\pi_A||_1 = ||\pi_A P_{A\overline{A}}||_1 / ||\pi_A||_1 = \Phi(A) \leq \pi(M)/\pi(A).$$

But $\mathrm{d_{TV}}(\pi, p_0) \geq \frac{1}{2}$, because $\pi(A) \leq \frac{1}{2}$, and hence

$$\mathrm{d_{TV}}(\pi, p_t) \geq \mathrm{d_{TV}}(\pi, p_0) - \mathrm{d_{TV}}(p_t, p_0) \geq \tfrac{1}{2} - t\Phi(A).$$

Thus we cannot achieve $\mathrm{d_{TV}}(\pi, p_t) \leq e^{-1}$ until

$$t \geq (\tfrac{1}{2} - e^{-1})/\Phi \geq \pi(A)/8\pi(M).$$

By an averaging argument there must exist some initial state $x_0 \in A$ for which $\tau(x_0) \geq \pi(A)/8\pi(M)$. □

Proof of Claim 3.5. Differentiating (8), we have

$$\begin{aligned} \frac{\partial \psi}{\partial \alpha} &= a(-\ln \alpha + \ln(1-\alpha) - \beta b \delta), \\ \frac{\partial \psi}{\partial \beta} &= b(-\ln \beta + \ln(1-\beta) - \alpha a \delta), \end{aligned} \tag{22}$$

and

$$\frac{\partial^2\psi}{\partial\alpha^2} = \frac{-a}{\alpha(1-\alpha)}, \qquad \frac{\partial^2\psi}{\partial\beta^2} = \frac{-b}{\beta(1-\beta)}, \qquad \frac{\partial^2\psi}{\partial\alpha\,\partial\beta} = -ab\delta. \tag{23}$$

The following three facts about ψ are easily verified:

$$\psi(\alpha,\beta) \geq \psi(1-\alpha,\beta) \qquad \text{if } \alpha \leq \tfrac{1}{2}, \tag{24}$$

$$\psi(\alpha,\beta) \geq \psi(\alpha,1-\beta) \qquad \text{if } \beta \leq \tfrac{1}{2}, \tag{25}$$

$$\psi(\alpha,\beta) \geq \psi(\beta,\alpha) \qquad \text{if } \beta \leq \alpha \leq 1-\beta. \tag{26}$$

We wish to determine the regions where $\psi \geq a\ln 2$. These are connected neighborhoods of the local maxima of ψ. From (22) we see that ψ has no boundary maxima for α,β in the unit square $\mathcal{U}$. Thus, from (23), ψ has only local maxima or saddle-points in $\mathcal{U}$, and a stationary point is a local maximum if and only if

$$\alpha(1-\alpha)\beta(1-\beta) \leq 1/(ab\delta^2). \tag{27}$$

Thus, at any local maximum, either $\beta(1-\beta) \leq 1/(b\delta)$ or $\alpha(1-\alpha) \leq 1/(a\delta)$. If the former holds, this and $b\delta \geq 11.5$ (which holds for η sufficiently small) imply that $\beta < 0.1$, and hence $\beta < 1.2/b\delta$. An identical argument holds for α. Let us denote the rectangle $[\ell_\alpha, u_\alpha] \times [\ell_\beta, u_\beta]$ by $[\ell_\alpha, u_\alpha \,|\, \ell_\beta, u_\beta]$. Thus any local maximum of ψ must lie in the region $[0,1\,|\,0,1.2/b\delta] \cup [0,1.2/a\delta\,|\,0,1]$ and hence in the enclosing region $[0,1\,|\,0,1.2/b\delta] \cup [0,1.2/b\delta\,|\,0,1]$. (Recall that $a \geq b$.) In the square $[0,1.2/b\delta\,|\,0,1.2/b\delta]$, we have $\alpha,\beta \leq 1.2/b\delta < 0.11$ and hence

$$\psi(\alpha,\beta) < 2a(-0.11\ln(0.11) - 0.89\ln(0.89)) < a\ln 2.$$

Then, from (24) and (25), we also have $\psi(\alpha,\beta) < a\ln 2$ in $[1-1.2/b\delta, 1\,|\,0,1.2/b\delta]$ and $[0,1.2/b\delta\,|\,1-1.2/b\delta,1]$. Now, if $\beta \leq 1.2/b\delta$, let $\rho = 1-2\alpha$ and consider the upper bound

$$\psi(\alpha,\beta) \leq \Psi(\rho,\beta) \stackrel{\text{def}}{=} a(\ln 2 - \tfrac{1}{2}\rho^2) + b\beta(1-\ln\beta) - \tfrac{1}{2}(1-\rho)\beta ab\delta. \tag{28}$$

For fixed β, it is easily shown that Ψ is maximized if $\rho = \frac{1}{2}b\delta\beta \leq 0.6$. If $b\delta\beta = 1.2$, then $\rho = 0.6$ and

$$\max_\rho \Psi(\rho,\beta) \leq a(\ln 2 - 0.18) + 0.11a(1-\ln(0.11)) - 0.24a < a\ln 2.$$

Thus $\psi < a\ln 2$ everywhere on the boundary of $[1.2/b\delta, 1-1.2/b\delta\,|\,0,1.2/b\delta]$ (but not including the shared boundary with $\mathcal{U}$). Hence, by (26), $\psi < a\ln 2$ everywhere on the boundary of $[0,1.2/b\delta\,|\,1.2/b\delta, 1-1.2/b\delta]$. Moreover, $\psi(\alpha,\beta) \geq \psi(\beta,\alpha)$ for all points (α,β) in $[1.2/b\delta, 1-1.2/b\delta\,|\,0,1.2/b\delta]$. It follows that it is sufficient to determine β^* such that $\psi(\alpha,\beta) < a\ln 2$ everywhere in $[1.2/b\delta, 1-1.2/b\delta\,|\,\beta^*, 1.2/b\delta]$. To this end, again consider

$$\Psi_0(\beta) = \max_\rho \Psi(\rho,\beta) = a\ln 2 + b\beta(1-\ln\beta) - \tfrac{1}{2}ab\beta\delta + \tfrac{1}{8}ab^2\beta^2\delta^2.$$

Now $\Psi_0 < a\ln 2$ if

$$b\beta\delta^2 - 4\delta + 8(1-\ln\beta)/a < 0.$$

This inequality is satisfied, provided

$$2\left(1-\sqrt{1-2b\beta(1-\ln\beta)/a}\right) < \ b\beta\delta < \ 2\left(1+\sqrt{1-2b\beta(1-\ln\beta)/a}\right).$$

The right-hand inequality is clearly irrelevant since we are assuming that $\beta \le 1.2/b\delta$. Thus we need consider only the left-hand inequality; i.e., for fixed $\gamma = b\beta < 1.2/\delta$, we require that

$$\gamma\delta > 2\max_{a,b}\left(1-\sqrt{1-2\gamma(1-\ln\gamma+\ln b)/a}\right),$$

where the maximum is over $\frac{1}{2}-\eta \le b \le a \le 1$. Considering b first, the maximum occurs when $b=a$. So we have

$$\gamma\delta > \max_{\frac{1}{2}-\eta\le a\le 1} 2\left(1-\sqrt{1-2\gamma(1-\ln\gamma+\ln a)/a}\right). \tag{29}$$

But, because $a \ge \gamma$, the maximum now occurs when $a = \frac{1}{2}-\eta$. Thus it is enough to require that

$$\gamma\delta > 2\left(1-\sqrt{1-4\gamma(1-\ln\gamma-\ln 2)}\right),$$

because this will imply (29), provided that η is sufficiently small. To achieve $\gamma = 0.004$, it is sufficient that $\delta \ge 23.9$. □

SAFE WEAK MINIMIZATION REVISITED*

DIETER SPREEN†

Abstract. Minimization operators of different strengths have been studied in the framework of "predicative (safe) recursion." In this paper, a modification of these operators is presented. By adding the new operator to those used by Bellantoni–Cook and Leivant to characterize the polynomial-time computable functions, one obtains a characterization of the nondeterministic polynomial-time computable multifunctions. Thus the generation of the nondeterministic polytime multifunctions from the deterministic polytime functions parallels the generation of the computable functions from the primitive recursive ones.

Key words. implicit computational complexity, safe (predicative) recursion, recursion on notation, minimization, nondeterministic polynomial time, multifunction, normal form theorem

1. Introduction.

As is well known, unbounded minimization allows the generation of the computable functions from the primitive recursive ones. If one restricts to bounded minimization, then the latter class is closed under this operation. By relaxing the minimization condition in such a way that the smallest zero of a given function is no longer asked for but the smallest argument that is mapped onto an even result is asked for, Bellantoni [1, 2] could derive a machine-independent characterization of the class $\Box^p$ of functions computable in deterministic polynomial time by querying oracles in the polynomial-time hierarchy. The result is in the style of Cobham's classical characterization of the polytime functions [5]. Bellantoni showed that the class $\Box^p$ is the smallest class of functions containing certain basic functions and being closed under substitution, limited recursion on notation, and his weakened minimization operator.

Surprisingly, as is also demonstrated by Bellantoni, the characterization remains true in a tiered, resource-bound–free framework, where, in addition to safe composition and safe (predicative) recursion on notation, an unbounded version of relaxed minimization is used that allows us only to minimize safe arguments.

The ramified (predicative) approach to resource-bounded computations, now referred to as *implicit computational complexity*, has independently been introduced by Simmons [11], Leivant [7, 8], and Bellantoni and Cook [3]. One underlying idea is that data objects are used computationally in different guises. One has two types of values: values which are known in their entirety and which therefore can be examined completely, e.g., being recursed upon; and those values which are still emerging and which therefore can only be accessed in a more restricted way, e.g., by examining a few low-order bits. In the first case, the values are called normal; in the other they are called safe.

Bellantoni's result shows that, even in its relaxed form, minimization (bounded or unbounded) is still a powerful operation. In a recent paper, Danner and Pollett [6]

weakened Bellantoni's safe minimization operation again by first limiting the verification that a computed function argument c is minimal to only those numbers d that are less than the length of c and then prescribing which bits of c a further computation may at most have access to. This operation, called limited safe weak minimization, is necessarily multivalued. They showed that the smallest class of multifunctions generated from certain initial functions by safe composition, safe recursion on notation, and this new operation is exactly the class **NPMV** of partial multifunctions computable in nondeterministic polynomial time.

As already stated by Danner and Pollet, the definition of limited safe weak minimization is reminiscent of limited minimization and thus not in the spirit of implicit computational complexity. In this paper, we propose a modified version of safe weak minimization which remedies this problem. Moreover, we show that the abovementioned characterization of **NPMV** holds true when the new version of safe weak minimization is used.

The paper is organized as follows. Section 2 contains basic definitions. Here the various minimization operators considered in the literature are introduced. Our modification of these operators as well as the main result are presented in section 3. The proof of this theorem follows from two propositions, one of which is a normal form result for multifunctions in **NPMV**. It entails that every function in this class can be generated from certain basic functions by safe composition, safe recursion on notation, and safe minimization on notation, the new minimization operator introduced in this paper. The proof is given in section 4. Final remarks appear in section 5.

The normal form result is based on an appropriate encoding of Turing machine computations. In the appendix, a coding of finite sequences is presented, and functions are defined by using only safe composition and safe recursion on notation that allow us to check whether a number is the code of a finite sequence and, if this is the case, the computation of the elements of the sequence as well as its length from the code.

2. Basic definitions and facts. A *partial multifunction* is a map $f\colon \mathbb{N}^k \rightharpoonup \mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ for some k, where $\mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ is the collection of all finite subsets of the natural numbers. Alternatively, f can be viewed as a relation on $\mathbb{N}^{k+1}$ satisfying the constraint that, for all $\bar{x}$, $\{\, y \mid (\bar{x}, y) \in f \,\}$ is finite. We write $f(\bar{x}) \mapsto y$ when y is a (possible) outcome of f and read $f(\bar{x})$ as the set of all y with $f(\bar{x}) \mapsto y$. Therefore, we also write $y \in f(\bar{x})$ instead of $f(\bar{x}) \mapsto y$. If f is single-valued, i.e., $f(\bar{x}) = \{y\}$, we identify y with $\{y\}$ and write $f(\bar{x}) = y$. For two partial multifunctions f and g, $f(\bar{x}) \leq g(\bar{x})$ means that, for every $y \in f(\bar{x})$, there is some $z \in g(\bar{x})$ such that $y \leq z$.

The *length* $|x|$ of a number x is defined as $\lceil \log_2(x+1) \rceil$. If $\bar{x}$ is a vector of n numbers, we write $|\bar{x}|$ for the vector $|x_1|, \ldots, |x_n|$. Similarly, we write $\bar{f}(\bar{x})$ for $f_1(\bar{x}), \ldots, f_m(\bar{x})$ so that, e.g., $\bar{y} \in \bar{f}(\bar{x})$ means that $y_1 \in f_1(\bar{x}), \ldots, y_m \in f_m(\bar{x})$.

Inputs to functions are categorized as *normal* or *safe*; the normal ones are written to the left of a semicolon, and the safe ones are written to the right. The variables x, y, z are usually used in normal position, and a, b, c are usually used in safe position. For a function class B, the subclass consisting of the functions with only normal arguments is denoted by $\mathrm{Norm}(B)$.

In [1, 3], Bellantoni and Cook characterized the class **FP** of polytime functions inductively by using a set B_0 of initial functions and safe composition as well as safe recursion on notation as closure operations.

DEFINITION 2.1. *The set B_0 consists of the functions* (1)–(5) *below.*

(i) (Constant) 0 *(a zero-ary function).*

(ii) (Projections) $\pi_j^{n,m}(x_1, \ldots, x_n; x_{n+1}, \ldots, x_{n+m}) = x_j$ *for* $1 \leq j \leq n+m$.

(iii) (Successors) $s_0(;a) = 2a$, *and* $s_1(;a) = 2a+1$. *Write "*ai*" for* $s_i(;a)$, *where* $i \in \{0,1\}$.

(iv) (Predecessor) p *such that* $p(;0) = 0$ *and* $p(;a0) = p(;a1) = a$.

(v) (Conditional)

$$\operatorname{cond}(;a,b,c) = \begin{cases} b & \text{if } a \bmod 2 = 0, \\ c & \text{otherwise,} \end{cases}$$

where $x \bmod 2$ *is the value of the low-order bit of* x.

Observe that the predecessor is a string predecessor just as the two successor operations are string successors.

The operations of safe composition and safe recursion on notation are defined as follows. Note that we directly consider multifunctions.

DEFINITION 2.2 (safe composition). *A multifunction* f *is defined by* safe composition *from given multifunctions* h, $\bar{r}$, *and* $\bar{t}$ *(in symbols,* $f = \mathrm{SC}(h,\bar{r},\bar{t})$*) when*

$$f(\bar{x};\bar{a}) = \bigcup \{\, h(\bar{y};\bar{b}) \mid \bar{y} \in \bar{r}(\bar{x};) \wedge \bar{b} \in \bar{t}(\bar{x};\bar{a}) \,\}.$$

As usual, we write $f(\bar{x};\bar{a}) = h(\bar{r}(\bar{x};);\bar{t}(\bar{x};\bar{a}))$.

DEFINITION 2.3 (safe recursion on notation). *A multifunction* f *is defined by* safe recursion on notation *from given multifunctions* g *and* h_0, h_1 *(in symbols,* $f = \mathrm{SRN}(g,h_1,h_2)$*) when, for* $i \in \{0,1\}$,

$$\begin{aligned} f(0,\bar{x};\bar{a}) &= g(\bar{x};\bar{a}), \\ f(yi,\bar{x};\bar{a}) &= h_i(y,\bar{x};\bar{a},f(y,\bar{x};\bar{a})) \quad \text{for } yi \neq 0. \end{aligned}$$

Let $[B_0;\mathrm{SC},\mathrm{SRN}]$ denote the smallest class of functions containing B_0 and closed under safe composition as well as safe recursion on notation.

THEOREM 2.4 (Bellantoni and Cook). $\mathbf{FP} = \mathrm{Norm}([B_0;\mathrm{SC},\mathrm{SRN}])$.

This theorem gives strong reasons to consider the polytime functions as the complexity-theoretic analogue of the primitive recursive functions. So the following question comes up: What is the complexity-theoretic analogue of the partial recursive functions, and can the functions in this class be generated from the polytime functions by applying a suitable minimization operator? This question was the starting point for recent investigations of Danner and Pollett [6].

In his dissertation [1, 2], Bellantoni introduced a safe minimization operator.

DEFINITION 2.5 (safe minimization). *A function* f *is defined by* safe minimization *from a given function* h *(in symbols,* $f = \mathrm{SM}(h)$*) when*

$$f(\bar{x};\bar{a}) = \begin{cases} s_1(;\mu b.\, h(\bar{x};\bar{a},b) \bmod 2 = 0) & \text{if there is some such } b, \\ 0 & \text{otherwise.} \end{cases}$$

Moreover, he showed that the functions in $\Box^p$, i.e., the functions computable on a polynomial-time bounded oracle Turing machine with an oracle in the polynomial-time hierarchy, are exactly the functions that can be generated from functions in B_0 by safe composition, safe recursion on notation, and safe minimization and have only normal arguments.

THEOREM 2.6 (Bellantoni). $\Box^p = \mathrm{Norm}([B_0;\mathrm{SC},\mathrm{SRN},\mathrm{SM}])$.

This class is far beyond what could be considered as a complexity-theoretic analogue of the partial recursive functions. In their paper [6], Danner and Pollett intro-

duced two weakenings of safe minimization, safe weak minimization and limited safe weak minimization, and, by using the latter operator instead of safe minimization, they showed that the collection of functions in the resulting class that have only normal arguments is exactly the class **NPMV** of all partial multifunctions computable in nondeterministic polynomial time, thus answering the above-posed question.

DEFINITION 2.7 (safe weak minimization). *A multifunction f is defined by* safe weak minimization *from a given a multifunction g when*

$$f(\bar{x};\bar{a}) \mapsto b \Leftrightarrow g(\bar{x};\bar{a},b) \bmod 2 \mapsto 0 \wedge (\forall c < |b|) g(\bar{x};\bar{a},c) \bmod 2 \mapsto 1.$$

If f is defined by safe weak minimization from g, we write

$$f(\bar{x};\bar{a}) = \mu^{w} b.\, g(\bar{x};\bar{a},b) \bmod 2 = 0.$$

As is shown in the next example, if f is defined from g by safe weak minimization, then, for any inputs $\bar{x}$ and $\bar{a}$, $f(\bar{x};\bar{a})$ may have superexponentially many outputs even if g is single-valued.

Example 2.8. Set $g(x;a) = \mathrm{cond}(;P(x;b),1,0)$, where the function P is defined by, for $i \in \{0,1\}$,

$$P(0;b) = b, \qquad P(xi;b) = p(;P(x;b)).$$

$P(x;b)$ takes $|x|$ predecessors of b.

It follows that $g(x;b)$ has value 0 if the $(|x|+1)$st low-order bit of b is 1; otherwise, its value is 1. Now let

$$f(x;) = \mu^{w} b.\, g(x;b) \bmod 2 = 0.$$

Then $f(x;) \mapsto b$ for all numbers b such that $|b| \le 2^{|x|}$ and the $(|x|+1)$st low-order bit of b is 1.

By definition, if the $(|x|+1)$st low-order bit of b is 0, then $g(x;b) = 1$, and hence $f(x;) \not\mapsto b$. Now suppose that $|b| > 2^{|x|}$ and $g(x;b) \bmod 2 = 0$. As $g(x;2^{|x|}) \bmod 2 = 0$, it follows that $f(x;) \not\mapsto b$. On the other hand, if $|b| \le 2^{|x|}$ so that the $(|x|+1)$st low-order bit of b is 1, then $f(x;) \mapsto b$, since for d with $d < |b|$ one has that $|d| \le |x|$ and hence that the $(|x|+1)$st low-order bit of d is 0, which means that $g(x;d) = 1$.

Thus the cardinality of $f(x;)$ is equal to the cardinality of the set of binary sequences of length $2^{|x|}-1$; i.e.,

$$\|f(x;)\| = 2^{2^{|x|}-1}.$$

Since, for any function $h \in \mathbf{NPMV}$, one has that $\|h(\bar{x})\| \le 2^{p(|\bar{x}|)}$ for some polynomial p, it follows that the class **NPMV** is not closed under safe weak minimization, which means that this operation is still too strong.

Define the function $a \underline{\bmod} v = a \bmod 2^{|v|}$. Then $a \underline{\bmod} v$ is the number given by the $|v|$ low-order bits of a. For a sequence $\bar{a} = a_1, \ldots, a_k$, write $\bar{a} \underline{\bmod} v$ for $a_1 \underline{\bmod} v$, $\ldots$, $a_k \underline{\bmod} v$.

DEFINITION 2.9 (limited safe weak minimization). *A multifunction f is defined by* limited safe weak minimization *from given multifunctions g and h (in symbols, $f = \mathrm{LSWM}(g,h)$) when*

$$f(\bar{x};\bar{a}) = (\mu^{w} b.\, g(\bar{x};\bar{a},b) \bmod 2 = 0) \underline{\bmod} h(\bar{x};).$$

THEOREM 2.10 (Danner and Pollett).

$$\mathbf{NPMV} = \mathrm{Norm}([B_0; \mathrm{SC}, \mathrm{SRN}, \mathrm{LSWM}]).$$

If f is defined by limited safe weak minimization from g and h, then the application of $\underline{\mathrm{mod}}$ cuts the possibly superexponentially many outputs b of $\mu^w b.\, g(\bar{x}; \bar{a}, b) \bmod 2 = 0$ down to those with $|b| \leq |z|$ for some z with $h(\bar{x};) \mapsto z$, thus to exponentially many. Limited safe weak minimization is reminiscent of limited minimization. As Danner and Pollett remark, by using this operation, one enters the "gray area" of implicit computational complexity.

3. Safe minimization on notation. In this section, we present a modification of safe weak minimization which follows the ideas of implicit computational complexity and show that an analogue of Theorem 2.10 holds.[1] The idea is to minimize with respect to the prefix order on binary representations.

For numbers a and b, respectively, let $a_n \dots a_0$ and $b_m \dots b_0$ be their binary representations. Define $a \sqsubseteq b$ if $n \leq m$ and $a_i = b_i$ for all $i \leq n$. Write $a \sqsubset b$ if $a \sqsubseteq b$ and $a \neq b$.

DEFINITION 3.1. *Let $g(\bar{x}; \bar{a})$ be a multifunction. A multifunction $h(\bar{x}; \bar{a})$ is a* companion *of g if*

$$h(\bar{x}; \bar{a}) \bmod 2 \mapsto 1 \Rightarrow g(\bar{x}; \bar{a}) \bmod 2 \not\mapsto 0.$$

DEFINITION 3.2 (safe minimization on notation). *A multifunction f is defined by* safe minimization on notation *from a given multifunction g and its companion h (in symbols, $f = \mathrm{SMN}(g, h)$) when*

$$f(\bar{x}; \bar{a}) \mapsto b \Leftrightarrow g(\bar{x}; \bar{a}, b) \bmod 2 \mapsto 0 \wedge (\forall c \sqsubset b) h(\bar{x}; \bar{a}, c) \bmod 2 \mapsto 1.$$

Call a multifunction $g(\bar{x}; \bar{a})$ *consistent* if not both $g(\bar{x}; \bar{a}) \bmod 2 \mapsto 0$ and $g(\bar{x}; \bar{a}) \bmod 2 \mapsto 1$. Then a multifunction is consistent exactly if it is its own companion. If a multifunction f is defined by safe minimization on notation from a given consistent multifunction g (and its companion g), we say that f is defined by *consistent safe minimization on notation* (in symbols: $f = \mathrm{CSMN}(g)$). We also write $f(\bar{x}; \bar{a}) = \mu^c b.\, g(\bar{x}; \bar{a}, b) \bmod 2 = 0$ in this case.

In order to see the effect of the modified quantification in the second condition in Definition 3.2, let us consider the functions defined in Example 2.8 again.

Example 3.3. As has been shown for the multifunction f,

$$f(x;) = \{\, b \mid |x| + 1 \leq |b| \leq 2^{|x|} \,\} = \{\, b \mid 2^{|x|} \leq b < 2^{2^{|x|}} \,\}.$$

Since the function g is single-valued, it is consistent. Define

$$f'(x;) = \mu^c b.\, g(x; b) \bmod 2 = 0.$$

Then $f'(x;)$ is the set of all numbers of minimal length such that the $(|x|+1)$st bit is 1, which means that it is the set of all numbers of exactly length $|x| + 1$. Hence

$$f'(x;) = \{\, b \mid 2^{|x|} \leq b < 2^{|x|+1} \,\}.$$

[1] This research has been motivated by an earlier version of Danner and Pollett's paper in which only safe weak minimization was studied. It should be noted that the definitions and results in this section have been obtained independently of what the authors presented in their revised version.

For numbers a and b, let $a \preceq b$ if $|a| \leq |b|$. Then $\preceq$ is a preorder. Write $a \prec b$ if $a \preceq b$ and not $b \preceq a$.

Obviously, $a \sqsubset b$ exactly if $a \prec b$ and $a = b \operatorname{mod} a$. Therefore, we have the following lemma, which is useful in the derivation of our main result below.

LEMMA 3.4. *Let f, g, and h be multifunctions, and let h be a companion of g. Then f is obtained by safe minimization on notation from g and h if and only if, for any $\bar{x}$, $\bar{a}$, and b,*

$$f(\bar{x}; \bar{a}) \mapsto b \Leftrightarrow g(\bar{x}; \bar{a}, b) \bmod 2 \mapsto 0 \wedge (\forall c \prec b) h(\bar{x}; \bar{a}, b \operatorname{mod} c) \bmod 2 \mapsto 1.$$

THEOREM 3.5.

$$\mathbf{NPMV} = \mathrm{Norm}([B_0; \mathrm{SC}, \mathrm{SRN}, \mathrm{CSMN}]) = \mathrm{Norm}([B_0; \mathrm{SC}, \mathrm{SRN}, \mathrm{SMN}]).$$

The theorem follows from the following propositions, the first of which will be proved in the next section. Obviously $[B_0; \mathrm{SC}, \mathrm{SRN}, \mathrm{CSMN}] \subseteq [B_0; \mathrm{SC}, \mathrm{SRN}, \mathrm{SMN}]$.

PROPOSITION 3.6. *Let $f \in \mathbf{NPMV}$. Then there are functions $T(z; \bar{a}, c)$, $\mathrm{res}(z; a)$, and $\mathrm{bnd}(\bar{x};)$ in $[B_0; \mathrm{SC}, \mathrm{SRN}]$ such that, for all inputs $\bar{x}$,*

$$f(\bar{x}) = \mathrm{res}(\mathrm{bnd}(\bar{x};); \mu^c b. T(\mathrm{bnd}(\bar{x};); \bar{x}, b) \bmod 2 = 0).$$

COROLLARY 3.7. *Let $f(\bar{x}) \in \mathbf{NPMV}$. Then $f(\bar{x};) \in [B_0; \mathrm{SC}, \mathrm{SRN}, \mathrm{CSMN}]$.*

The proof of the converse implication uses a technique of Bellantoni.

DEFINITION 3.8. *Let f be a multifunction (note that we do not separate the arguments into normal and safe here), and let q be a polynomial.*

(i) *Function $f(\bar{x}, \bar{a})$ is a* polynomial checking function on $\bar{x}$ with threshold q *if, for all $\bar{x}$, $\bar{a}$, w, and v satisfying $|v| \geq q(|\bar{x}|) + |w|$,*

$$f(\bar{x}, \bar{a}) \operatorname{mod} w = f(\bar{x}, \bar{a} \operatorname{mod} v) \operatorname{mod} w.$$

(ii) *Function $f(\bar{x}, \bar{a})$ is* polymax bounded by q on $\bar{x}$ *if, for all $\bar{x}$, $\bar{a}$, $|f(\bar{x}, \bar{a})| \leq q(|\bar{x}|) + \max_i |a_i|$.*

Note that the equation in Definition 3.8 (i) has to be understood as an equation between sets.

PROPOSITION 3.9. *If $f(\bar{x}; \bar{a})$ is in $[B_0; \mathrm{SC}, \mathrm{SRN}, \mathrm{SMN}]$, then f is a polymax-bounded polynomial checking function on $\bar{x}$.*

Proof. The proof proceeds by induction on the length of the derivation of f as a function in $[B_0; \mathrm{SC}, \mathrm{SRN}, \mathrm{SMN}]$. Without restriction we can assume that the polynomial of the size bound and the polynomial of the checking threshold are identical by summing the two together.

For the initial functions zero, projection, predecessor, conditional, and successors, the polynomial is at most 1, and the statement of the proposition is easily verified.

The proof that the statement holds in the induction cases is the same as in [1] and/or [3, 2], except in the case of safe minimization on notation discussed below.

Let h be a companion of g, and assume that $f = \mathrm{SMN}(g, h)$. By the induction hypothesis, there are polynomials q_g and q_h, respectively, witnessing that g and h are polychecking and polymax-bounded on $\bar{x}$. Let q be the sum of q_g and q_h.

In order to verify that f is polymax-bounded on $\bar{x}$, we show that, for all $c \in f(\bar{x}; \bar{a})$,

$$|c| \leq q(|\bar{x}|) + 2.$$

Assume, to the contrary, that $|c| > q(|\bar{x}|) + 2$, and set $v = 2^{q(|\bar{x}|)+1}$ as well as $b = c \operatorname{\underline{mod}} v$. Then $|v| = q(|\bar{x}|)+2$. Since g is polychecking on $\bar{x}$ with polynomial threshold q, it follows that

$$\begin{aligned} g(\bar{x};\bar{a},c) \bmod 2 &= g(\bar{x};\bar{a} \operatorname{\underline{mod}} v, c \operatorname{\underline{mod}} v) \bmod 2 \\ &= g(\bar{x};\bar{a} \operatorname{\underline{mod}} v, b \operatorname{\underline{mod}} v) \bmod 2 \\ &= g(\bar{x};\bar{a},b) \bmod 2. \end{aligned}$$

As $c \in f(\bar{x};\bar{a})$, we have that $g(\bar{x};\bar{a},c) \bmod 2 \mapsto 0$. Thus $g(\bar{x};\bar{a},b) \bmod 2 \mapsto 0$ as well. From our assumption on $|c|$, we obtain that $v \prec c$. Hence $h(\bar{x};\bar{a},b) \bmod 2 \mapsto 1$, by Lemma 3.4, in contradiction to the fact that h is a companion of g. Define $p(|\bar{x}|) = q(|\bar{x}|) + 2$. Then p witnesses that f is polymax-bounded on $\bar{x}$.

For the proof that f is also polychecking on $\bar{x}$ with threshold p, let $\bar{x}$, $\bar{a}$, w, and v be such that $|v| \geq p(|\bar{x}|) + |w|$. Then $|v| \geq q(|\bar{x}|) + 2$. By the induction hypothesis, it thus follows for c with $|c| \leq q(|\bar{x}|) + 2$ that

$$g(\bar{x};\bar{a},c) \bmod 2 = g(\bar{x};\bar{a} \operatorname{\underline{mod}} v, c \operatorname{\underline{mod}} v) \bmod 2 = g(\bar{x};\bar{a} \operatorname{\underline{mod}} v, c) \bmod 2$$

and correspondingly for h. As we have seen above, it follows for $c \in f(\bar{x};\bar{a})$ as well as for $c \in f(\bar{x};\bar{a} \operatorname{\underline{mod}} v)$ that $|c| \leq q(|\bar{x}|) + 2$. Hence $f(\bar{x};\bar{a}) = f(\bar{x};\bar{a} \operatorname{\underline{mod}} v)$, which entails that

$$f(\bar{x};\bar{a}) \operatorname{\underline{mod}} w = f(\bar{x};\bar{a} \operatorname{\underline{mod}} v) \operatorname{\underline{mod}} w. \qquad \square$$

COROLLARY 3.10. *Let $f(\bar{x};\bar{a})$ be a multifunction in $[B_0; \mathrm{SC}, \mathrm{SRN}, \mathrm{SMN}]$. Then $f(\bar{x},\bar{a})$ is computable in nondeterministic polynomial time.*

Proof. The proof is by induction on the definition of f. The initial functions are clearly computable in polynomial time and hence in **NPMV**. When g is given inductively, we assume that it is computed by a nondeterministic Turing machine M_g in time p_g.

For safe composition, note that **NPMV** is closed with respect to composition. Now suppose that $f(y,\bar{x};\bar{a})$ is defined by safe recursion on notation from g and h_0, h_1. Then, for any y, we have that $f(y,\bar{x};\bar{a}) \mapsto z$ exactly if there is a sequence $t_0, \ldots, t_{|y|}$ such that $g(\bar{x};\bar{a}) \mapsto t_{|y|}$, $h_{y(i)}(\lfloor y/2^{i+1} \rfloor, \bar{x};\bar{a},t_{i+1}) \mapsto t_i$ for all $i < |y|$, and $t_0 = z$. Here, $y(i)$ denotes the ith bit of y. Furthermore, for any such sequence and all i, we have that $f(\lfloor y/2^i \rfloor, \bar{x};\bar{a}) \mapsto t_i$, so $|t_i| \leq q(|y|,|\bar{x}|,|\bar{a}|)$, where q is the polynomial length-bound existing by the preceding lemma. Thus, to compute $f(y,\bar{x},\bar{a})$, guess a sequence $t_0, \ldots, t_{|y|}$ so that, for every t_i, $|t_i| \leq q(|y|,|\bar{x}|,|\bar{a}|)$, and verify that the above condition holds for each element of the sequence by running M_g, M_{h_0}, or M_{h_1}, respectively, and comparing the output to the previous element of the sequence. If none of the verifications fails and $t_0 = z$, then accept and output z. Guessing the sequence takes $|y|q(|y|,|\bar{x}|,|\bar{a}|)$ steps, and the verification takes time $|y|p(|y|,|\bar{x}|,|\bar{a}|,q(|y|,|\bar{x}|,|\bar{a}|))$, where p is the sum of the polynomials p_g, p_{h_0}, and p_{h_1}.

Finally, assume that $f = \mathrm{SMN}(g,h)$, and let q be the polynomial length-bound existing by the preceding lemma so that $|f(\bar{x};\bar{a})| \leq q(|\bar{x}|,|\bar{a}|)$. We compute $f(\bar{x},\bar{a})$ as follows. Guess b with $|b| \leq q(|\bar{x}|,|\bar{a}|)$. Next verify that $g(\bar{x},\bar{a},b) \bmod 2 \mapsto 0$, and reject if not. If the verification is successful, run M_h on input $\bar{x},\bar{a},c$ for every $c \sqsubset b$. If M_h accepts with output 1 in each case, then accept with output b; otherwise, reject. Guessing b takes $q(|\bar{x}|,|\bar{a}|)$ steps, and the verifications take at most time $(1 + q(|\bar{x}|,|\bar{a}|))p(|\bar{x}|,|\bar{a}|,q(|\bar{x}|,|\bar{a}|))$, where p is the sum of the polynomials p_g and p_h. $\square$

In the proof of Proposition 3.9, we took advantage of the proviso made in the definition of safe minimization on notation, namely, that the second argument of this operator has to be a companion of the first argument. As can be seen from the following example, without this condition, the class **NPMV** would not be closed under safe minimization on notation, which means that Theorem 3.5 and hence Proposition 3.9 would be false. The same holds for the operation of consistent safe minimization on notation and the requirement that the argument of this operator be consistent.

Example 3.11. Let $g_1(x,b) \mapsto 0,1$ and $g_2(x,b) \mapsto 1$ for all $x,b \in \mathbb{N}$. Then $g_1, g_2 \in \mathbf{NPMV}$, but neither is g_1 consistent nor is g_2 a companion of g_1. Now, for $i = 1,2$, define f_i by

$$f_i(x) \mapsto b \Leftrightarrow g_1(x,b) \bmod 2 \mapsto 0 \wedge (\forall c \sqsubset b) g_i(x,c) \bmod 2 \mapsto 1.$$

Then it is readily verified that $f_i(x) \mapsto z$ for all $z \in \mathbb{N}$. Thus $f_i \notin \mathbf{NPMV}$, since otherwise there exists some polynomial p_i such that $\|f_i(x)\| \leq 2^{p_i(|x|)}$.

If, however, we consider the function $h \in \mathbf{NPMV}$ with $h(x,b) \mapsto 0$ for all $x,b \in \mathbb{N}$, then h is a companion of g_1, and $\mathrm{SMN}(g_1,h)$ is the nowhere defined function.

4. Proof of the normal form result. The proof of Proposition 3.6 proceeds in the usual way by an appropriate encoding of Turing machine computations. In the appendix, a coding of finite sequences of numbers is presented such that there are functions $\mathrm{first}, \mathrm{last}, \mathrm{lth}, \mathrm{dc}, \mathrm{seq} \in [B_0; \mathrm{SC}, \mathrm{SRN}]$, with the following properties: if w is the Gödel number of a sequence $a_1, \ldots, a_k$, then $\mathrm{first}(y;a) = a_1$ for all y with $|y| \geq |a_1|$, $\mathrm{last}(y;w) = a_k$ for all y with $|y| \geq |w|$, $\mathrm{lth}(y;w) = k$, and $\mathrm{dc}(y,z;w) = a_{|z|+1}$ for all y with $|y| \geq k, |a_j|$ $(1 \leq j \leq k)$ and z with $|z| < \mathrm{lth}(y;w)$.

Moreover, for z,w with $|z| \geq |w|$, $\mathrm{seq}(z;w) = 1$ if w is the Gödel number of a finite sequence, and $\mathrm{seq}(z;w) = 0$ otherwise.

In addition, functions $\leq, <, \mathrm{ebit}, \mathrm{obit} \in [B_0; \mathrm{SC}, \mathrm{SRN}]$ are defined such that, for z,a,b with $|z| \geq |a|, |b|$, $\leq(z;a,b) = 1$ if $a \leq b$, and $\leq(z;a,b) = 0$ otherwise, and correspondingly for $<(z;a,b)$. Moreover, $\mathrm{ebit}(x;a)$ and $\mathrm{obit}(x;a)$, respectively, are the coefficients of $2^{2|x|}$ and $2^{2|x|+1}$ in the binary expansion of a.

The Turing machines we work with have n read-only input tapes, m read/write work tapes, and one write-only output tape. The alphabet consists of the symbols 0, 1, and $*$ ($*$ for blank), and the state set is $Q = \{q_0, q_1, q_2, \ldots, q_r\}$. We always presume that q_0 is the starting and q_1 the accepting state.

Our machines work nondeterministically and in polynomial time. Moreover, we assume the following, again without loss of generality.

(i) The accepting state q_1 can only be entered within the given time limit.

(ii) The head on the output tape prints only 0's and 1's. If the machine is in state q_1, the finite content of the output tape right to its head is the binary representation of the output of the machine.

(iii) In the start situation, the machine is in state q_0, and on each input tape the input is written in such a way that it starts one cell right of the cell scanned by the head.

A *configuration* is a $(3n+3m+2)$-tuple

$$(q, u_1, a_1, v_1, \ldots, u_{n+m}, a_{n+m}, v_{n+m}, v_{n+m+1}),$$

where

(i) q is the present state of the machine,

(ii) v_{n+m+1} is the finite content of the output tape right to its head, written in reverse order, and, for $1 \leq j \leq n+m$,

(iii) u_j, is the finite content of tape j left to its head,
(iv) a_j is the content of the cell scanned by the head on tape j, and
(v) v_j is the finite content of tape j right to its head, written in reverse order.

We always assume that the words u_j and v_j are of the form $b_1 \dots b_k$ such that b_1 is not $*$.

In order to encode configurations, we code every state q_i by i. The words u_j, a_j, and v_j are coded as follows. Replace each 0 by "10," each 1 by "11," and each $*$ by "00." The resulting strings of zeros and ones are then the binary representations of the codes of these words. In this way, we obtain a $(3n + 3m + 2)$-tuple $(i, \bar{u}_1, \bar{a}_1, \bar{v}_1, \dots, \bar{u}_{n+m}, \bar{a}_{n+m}, \bar{v}_{n+m}, \bar{v}_{n+m+1})$ of numbers, which is encoded as explained in the beginning of this section.

As is easily verified, a number w is the code of an entry of some configuration just if, for every odd i such that the coefficient of 2^{i-1} in the binary expansion of w is not 0, the coefficient of 2^i is 1. This is tested by the function $\mathrm{seq1} \in [B_0; \mathrm{SC}, \mathrm{SRN}]$ defined in the appendix. Moreover, w is the code of the binary representation of some number, written in reverse order, exactly if, in addition, the binary representation of w contains no substring of the form 100.

Let the function P be as in Example 2.8, set $\hat{s}_1(z;) = s_1(;z)$, and define

$$\begin{aligned}
&\mathrm{seq4}(0; w) = 1,\\
&\mathrm{seq4}(zi; w) = \mathrm{cond}(;\mathrm{seq4}(z; w), 0, \mathrm{cond}(; P(z; w),\\
&\qquad\qquad \mathrm{cond}(; P(\hat{s}_1(z;); w), \mathrm{cond}(; P(\hat{s}_1^2(z;); w), 1, 0), 1), 1))
\end{aligned}$$

for $zi \neq 0$. Then $\mathrm{seq4} \in [B_0; \mathrm{SC}, \mathrm{SRN}]$, and, for z, w with $|z| \geq |w|$, we have that $\mathrm{seq4}(z; w) = 1$ if the binary representation of w contains no substring of the form 100 and $\mathrm{seq4}(z; w) = 0$ otherwise.

If w is the code of the binary representation of some number, written in reverse order, we need to compute that number. Let

$$\begin{aligned}
&\mathrm{nb}(0; w) = 0,\\
&\mathrm{nb}(yi; w) = \mathrm{cond}(; \mathrm{obit}(y; w), \mathrm{nb}(y; w),\\
&\qquad\qquad \mathrm{cond}(; \mathrm{ebit}(y; w), s_0(; \mathrm{nb}(y; w)), s_1(; \mathrm{nb}(y; w))))
\end{aligned}$$

for $yi \neq 0$. Then $\mathrm{nb} \in [B_0; \mathrm{SC}, \mathrm{SRN}]$, and, in case w is such a code, we have for $|y| \geq |w|$ that $\mathrm{nb}(y; w)$ is the corresponding number.

Now let M be a Turing machine in the way described above. We need to construct a Turing predicate $T_M(y; \bar{x}, c) \in [B_0; \mathrm{SC}, \mathrm{SRN}]$ such that, for $y, \bar{x}, c$ with $|y| \geq r, |c|, |x_i|$, for $1 \leq i \leq n$, $T_M(y; \bar{x}, c) = 1$ exactly if c is the Gödel number of an accepting computation of machine M with respect to input $\bar{x}$.

1. Set

$$\begin{aligned}
\mathrm{cf}_M(y; c) = \mathrm{seq}(y; c) \wedge \mathrm{lth}(y; c) = 3n + 3m + 2 \wedge {\leq}(y; \mathrm{first}(y; c), r)\\
\wedge \bigwedge_{i=1}^{3n+3m+1} \mathrm{seq1}(y; \mathrm{dc}(y, 2^i - 1; c)).
\end{aligned}$$

Since $3n+3m+2$ is a fixed number, the term $\mathrm{lth}(y; c) = 3n+3m+2$ can be expressed in such a way that it is in $[B_0; \mathrm{SC}, \mathrm{SRN}]$. Hence $\mathrm{cf}_M \in [B_0; \mathrm{SC}, \mathrm{SRN}]$. If $|y| \geq r, |c|$, $\mathrm{cf}_M(y; c) = 1$ just if c is the Gödel number of a configuration of M.

2. By using the transition table of machine M, one can further construct a function $\mathrm{trans}_M \in [B_0; \mathrm{SC}, \mathrm{SRN}]$ such that, for y, c, d with $|y| \geq r, |c|, |d|$, $\mathrm{trans}_M(y; c, d) = 1$ if c and d, respectively, are Gödel numbers of configurations c' and d' of M and there is a transition from c' to d' and $\mathrm{trans}_M(y; c, d) = 0$ otherwise.

3. Let $a \vee b = \mathrm{cond}(; a, \mathrm{cond}(; b, 0, 1), 1)$, define

$$\begin{aligned} f_6(0, y; c) &= \mathrm{seq}(y; c), \\ f_6(zi, y; c) &= [f_6(z, y; c) \wedge \mathrm{trans}_M(y; \mathrm{dc}(y, z; c), \mathrm{dc}(y, \hat{s}_1(z;); c)) \\ &\qquad \wedge <(y; s_1(; z), \mathrm{lth}(y; c))] \vee [\leq(y; \mathrm{lth}(y; c), s_1(; z)) \wedge f_6(z, y; c)] \end{aligned}$$

for $zi \neq 0$, and set

$$\mathrm{comp}_M(y; c) = f_6(y, y; c).$$

Then $\mathrm{comp}_M \in [B_0; \mathrm{SC}, \mathrm{SRN}]$, and, for y, c with $|y| \geq r, |c|$, we have that $\mathrm{comp}_M(y; c) = 1$ exactly if c is the Gödel number of a sequence of codings of configurations $c_0, \ldots, c_k$ of M such that there is a transition from c_j to c_{j+1} for all $j < k$.

4. Let $=(y; a, b) = \leq(y; a, b) \wedge \leq(y; b, a)$ and $\mathrm{cr}(y; w) = \mathrm{seq1}(y; w) \wedge \mathrm{seq4}(y; w)$. Moreover, let I be the set of all i with $1 \leq i \leq 3n + 3m + 1$ such that i is not divisible by 3 if $1 \leq i \leq n$. Define

$$\begin{aligned} \mathrm{init}_M(y; \bar{x}, c) = \mathrm{cf}_M(y; c) \wedge \leq(y; \mathrm{first}(y; c), 0) \wedge \bigwedge_{i \in I} \leq(y; \mathrm{dc}(y, 2^i - 1; c), 0) \\ \wedge \bigwedge_{i=1}^{n} [\mathrm{cr}(y; \mathrm{dc}(y, 2^{3i} - 1; c)) \wedge =(y; \mathrm{nb}(y; \mathrm{dc}(y, 2^{3i} - 1; c)), x_i)]. \end{aligned}$$

Again, $\mathrm{init}_M \in [B_0; \mathrm{SC}, \mathrm{SRN}]$, and, for $y, \bar{x}, c$ with $|y| \geq r, |c|, |x_i|$, for $1 \leq i \leq n$, we have that $\mathrm{init}_M(y; \bar{x}, c) = 1$ just if c is the coding of the start configuration of machine M with respect to input $\bar{x}$.

5. Let

$$\mathrm{acc}_M(y; c) = \mathrm{cf}_M(y; c) \wedge =(y; \mathrm{first}(y; c), 1).$$

Then $\mathrm{acc}_M \in [B_0; \mathrm{SC}, \mathrm{SRN}]$, and, for y, c with $|y| \geq r, |c|$, $\mathrm{acc}_M(y; c) = 1$ exactly if c is the code of an accepting configuration.

6. Finally, we can define the Turing predicate. Set

$$T_M(y; \bar{x}, c) = \mathrm{comp}_M(y; c) \wedge \mathrm{init}_M(y; \bar{x}, \mathrm{first}(y; c)) \wedge \mathrm{acc}_M(y; \mathrm{last}(y; c)).$$

Now we can prove Proposition 3.6. Let $f \in \mathbf{NPMV}$. Then there is some nondeterministic Turing machine M that computes f in time p. Set

$$T(z; \bar{x}, c) = \mathrm{cond}(; T_M(z; \bar{x}, c), 1, 0)$$

and

$$\mathrm{res}(z; b) = \mathrm{nb}(z; \mathrm{dc}(z, 2^{3n+3m}; \mathrm{last}(z; b))).$$

If $f(\bar{x}) \mapsto y$, there exists an accepting computation of M of length at most $p(|\bar{x}|)$ with output y. Let c be its Gödel number, and assume there were numbers z, d with $|z| \geq |c|$ and $d \sqsubset c$ such that $T(z; \bar{x}, d) \bmod 2 = 0$. Then d is the Gödel number of an

accepting computation of M on input $\bar{x}$, which means that the sequences coded by c and d have the same first element. This is impossible since the choice of our sequence encoding $d \sqsubset c$ implies that the sequence coded by d is a proper final segment of the sequence coded by c. Thus $c = \mu^c b.\, T(z; \bar{x}, b) \bmod 2 = 0$ for all z with $|z| \geq |c|$.

During the computation, each head can visit at most $p(|\bar{x}|)$ cells. Thus the length of the code of every configuration in this computation is bounded by $2[2(n + m + 1)p(|\bar{x}|) + 2|r| + 3n + 3m + 1]$. Note that there are $3n + 3m + 1$ commas in each configuration. Moreover, the coding of both the words on the tapes as well as the configuration requires multiplication by 2. Set

$$q(|\bar{x}|) = 4(n + m + 1)p(|\bar{x}|)^2 + (4|r| + 6n + 6m + 3)p(|\bar{x}|).$$

Then $|c| \leq q(|\bar{x}|)$. As has been shown in [1, 3], one can easily construct a function $\mathrm{bnd} \in [B_0; \mathrm{SC}, \mathrm{SRN}]$ such that $q(|\bar{x}|) \leq |\mathrm{bnd}(\bar{x};)|$. It follows that $\mathrm{last}(\mathrm{bnd}(\bar{x};); c)$ is the coding of the last configuration in the computation coded by c, and hence $\mathrm{res}(\mathrm{bnd}(\bar{x};); c)$ is its result.

This shows that

$$f(\bar{x}) \subseteq \mathrm{res}(\mathrm{bnd}(\bar{x}); \mu^c b.\, T(\mathrm{bnd}(\bar{x}); \bar{x}, b) \bmod 2 = 0).$$

The converse inclusion is obvious by our general assumption of M and the construction of the functions T and res.

5. Conclusion. Bellantoni showed in his dissertation [1, 2] that when unbounded minimization is allowed over safe positions in the presence of safe recursion on notation, the resulting functions lie in the polynomial hierarchy. Verifying the minimality of a certain number a requires us to test whether all smaller numbers satisfy the given property. There are exponentially many such numbers with respect to the length of a. Therefore, it is quite obvious that the polytime functions are not closed under this operation.

In the present paper, we modified Bellantoni's minimization operator by requiring a weaker kind of minimality: only the numbers with a binary representation that is a proper prefix of the binary representation of a have to be tested. There are only polynomially many such numbers with respect to the length of a, which implies that the minimality test can be performed in polynomial time. However, now there may be several such minimal numbers a: the resulting function is multivalued.

The characterization derived in the paper is partly based on a normal form theorem which is similar to Kleene's normal form theorem for the computable functions [9]. Here it was shown that the nondeterministic polytime multifunctions can be generated from the deterministic polytime functions by an application of a weakened unbounded minimization operator. Kleene's theorem says that the computable functions can be generated by an application of full unbounded minimization from the primitive recursive ones.

So there is a certain similarity between the computable functions and the nondeterministic polytime functions as well as the primitive recursive functions and the deterministic polytime functions. Danner and Pollett [6] give more examples for this correspondence.

The minimization operator introduced in this paper is a partial operator: it can only be applied to multifunctions that are given together with a companion. To check the property of being a companion seems not to be an easy task, in general. It remains an open question whether the nondeterministic polytime multifunctions can also be generated by using only *total*, fully "implicit" operators.

In order to derive Proposition 3.9, it would be sufficient to require that the condition given in the definition of a companion holds only for those arguments which are used in the verification process. However, then the modified requirement would be part of the minimality condition and hence would have to be tested in polynomial time. It is not clear how this could be done in the case of nondeterministic polytime multifunctions. The situation is similar to the one in classical computability theory, where one has to require that the function minimized over is defined on all arguments used in the minimality verification. Dropping this condition leads to a minimization operator under which the class of computable functions is no longer closed [10].

Appendix. As is well known, there are codings of finite sequences such that the corresponding decodings are in **FP**. By Bellantoni and Cook's theorem, this means that they can be defined from initial functions in B_0 with the help of safe composition and safe recursion on notation. However, in this case, all of their parameters appear in the normal position, whereas here we need them in the safe position. As we will see, this can only be achieved in such a way that, for any input, the entire output of the function does not have the properties we are interested in, but certain of its low-order bits do. Moreover, there will be an additional normal parameter, the length of which is an upper bound on the low-order bits that may be used.

In what follows, we use a coding of finite sequences of numbers, which is essentially due to Buss [4]. The code or *Gödel number* of a sequence $a_1, \dots, a_k$ is constructed as follows. First replace each a_i by $a_i 1$, and write the resulting numbers in binary notation so that we have a string of 0's, 1's, and commas. Then write the string in reverse order, and replace each 0 by "10," each 1 by "11," and each comma by "00." The resulting string of zeros and ones is the binary representation of the Gödel number $\langle a_1, \dots, a_k \rangle$. For example, the Gödel number of 0,1,2 is $(1110110011110011)_2$ or 60,659. The empty sequence has the Gödel number $\langle\rangle = 0$.

Let us show now that the functions testing whether a number is the Gödel number of a finite sequence and, if this is the case, computing the length of the sequence as well as its ith element for given i, are in $[B_0; \mathrm{SC}, \mathrm{SRN}]$. To this end, we need several helper functions.

1. Let the function P be as in Example 2.8, and define

$$\begin{aligned} &\mathrm{rev}(0; a) = 0, \\ &\mathrm{rev}(xi; a) = \mathrm{cond}(; P(x; a), s_0(; \mathrm{rev}(x; a)), s_1(; \mathrm{rev}(x; a))) \qquad \text{for } xi \neq 0. \end{aligned}$$

Then the binary representation of $\mathrm{rev}(y; x)$ corresponds to the $|y|$ low-order bits of x written in reverse order.

2. Let

$$\begin{aligned} f_0(0; a, b) &= 1, \\ f_0(zi; a, b) &= \mathrm{cond}(; f_0(z; a, b), 0, \mathrm{cond}(; p(; f_0(z; a, b)), \\ &\qquad \mathrm{cond}(; P(z; a), \mathrm{cond}(; P(z; b), 1, 3), \mathrm{cond}(; P(z; b), 0, 1)), 3)) \end{aligned}$$

for $zi \neq 0$, and set

$$\leq(z; a, b) = \mathrm{cond}(; f_0(z; \mathrm{rev}(z; a), \mathrm{rev}(z; b)), 0, 1).$$

In case that $|z| \geq |a|, |b|$, we have that $\leq(z; a, b) = 1$ if $a \leq b$ and $\leq(z; a, b) = 0$ otherwise.

3. Set $\hat{s}_1(z;) = s_1(;z)$, let

$$\begin{aligned} f_1(0;w) &= w, \\ f_1(yi;w) &= \mathrm{cond}(;f_1(y;w), \mathrm{cond}(;p(;f_1(y;w)), f_1(y;w), p^2(;f_1(y;w))), \\ &\qquad p^2(;f_1(y;w))) \end{aligned}$$

for $yi \neq 0$, and define

$$\mathrm{truncate}(y;w) = p^2(;f_1(\hat{s}_1(y;);w)).$$

If w is the Gödel number of a sequence $a_1, \dots, a_k$ and $|a_1| \leq |y|$, then $\mathrm{truncate}(y;w) = \langle a_2, \dots, a_k \rangle$.

4. Let $\mathrm{sg}(z;) = {\leq}(z;z,0)$, and set

$$\begin{aligned} \mathrm{tr}(0,y;w) &= w, \\ \mathrm{tr}(zi,y;w) &= \mathrm{cond}(;\mathrm{sg}(z;), \mathrm{truncate}(y;\mathrm{tr}(z,y;w)), w) \qquad \text{for } zi \neq 0. \end{aligned}$$

For z with $|z| > 0$, we have that $\mathrm{tr}(z,y;w) = \mathrm{truncate}^{|z|-1}(y;w)$.

5. Set

$$\begin{aligned} \mathrm{ebit}(x;a) &= \mathrm{cond}(;P(x;P(x;a)),0,1), \\ \mathrm{obit}(x;a) &= \mathrm{cond}(;p(;P(x;P(x;a))),0,1). \end{aligned}$$

Then $\mathrm{ebit}(x;a)$ and $\mathrm{obit}(x;a)$, respectively, are the coefficients of $2^{2|x|}$ and $2^{2|x|+1}$ in the binary expansion of a. Moreover, let $P'(x,y;) = P(x;y)$, and define

$$\begin{aligned} f_2(0,z;w) &= 0, \\ f_2(yi,z;w) &= \mathrm{cond}(;f_2(y,z;w), \mathrm{cond}(;\mathrm{ebit}(y;w), \\ &\qquad \mathrm{cond}(;\mathrm{obit}(y;w), \mathrm{cond}(;\mathrm{sg}(P'(y,z;);),1,0),0),0),1) \end{aligned}$$

for $yi \neq 0$. If w is as above and $|y| > 1 + |a_1|$, then $f_2(y,z;w) = 1$ if $1 + |a_1| < |z|$ and $f_2(y,z;w) = 0$ otherwise.

6. Define

$$\begin{aligned} f_3(0,y;w) &= 0, \\ f_3(zi,y;w) &= \mathrm{cond}(;f_2(y,\hat{s}_1(z;);w), \\ &\qquad \mathrm{cond}(;\mathrm{ebit}(z;w), s_0(;f_3(z,y;w)), s_1(;f_3(z,y;w))), f_3(z,y;w)) \end{aligned}$$

for $zi \neq 0$, and set

$$\mathrm{first}(y;w) = p(;f_3(\hat{s}_1^2(y;),\hat{s}_1^2(y;);w)).$$

If w is as above again and $|y| \geq |a_1|$, then $\mathrm{first}(y;w) = a_1$.

7. Finally, let

$$\begin{aligned} f_4(0,y;w) &= 0, \\ f_4(zi,y;w) &= \mathrm{cond}(;\mathrm{tr}(z,y;w), f_4(z,y;w), \mathrm{cond}(;\mathrm{tr}(\hat{s}_1(z;),y;w),z,1)) \end{aligned}$$

for $zi \neq 0$. Set

$$\mathrm{lth}(y;w) = f_4(\hat{s}_1(y;),\hat{s}_1(y;);w)$$

and

$$\mathrm{dc}(y,z;w) = \mathrm{first}(y;\mathrm{tr}(\hat{s}_1(z;),y;w));$$

then $\mathrm{lth}, \mathrm{dc} \in [B_0; \mathrm{SC}, \mathrm{SRN}]$. Moreover, for w as above and y such that $|y| \geq k, |a_j|$ for $1 \leq j \leq k$, we have that $\mathrm{lth}(y;w) = k$ and $\mathrm{dc}(y,z;w) = a_{|z|+1}$ as long as $|z| < \mathrm{lth}(y;w)$.

If we want to compute the last element of the sequence coded by w, we cannot do this by composing the functions dc and lth because of the restriction in the definition of safe composition. Let, therefore,

$$<(z;a,b) = \mathrm{cond}(;\leq(z;a,b),0,\mathrm{cond}(;\leq(z;b,a),1,0)),$$

and set

$$f_5(0,z;w) = w,$$
$$f_5(yi,z;w) = \mathrm{cond}(;<(z;|s_1(;y)|,\mathrm{lth}(z;w)),f_5(y,z;w),\mathrm{truncate}(z;f_5(y,z;w)))$$

for $yi \neq 0$. Now define

$$\mathrm{last}(z;w) = \mathrm{first}(z;f_5(z,z;w)).$$

Note that

$$|0| = 0, \qquad |xi| = s(|x|;) \qquad \text{for } xi \neq 0,$$

where

$$s(0;) = 1, \qquad s(x0;) = s_1(;x) \quad \text{for } x \neq 0, \qquad s(x1;) = s_0(;s(x;)).$$

Thus $\mathrm{last} \in [B_0; \mathrm{SC}, \mathrm{SRN}]$. Moreover, if w is the Gödel number of a finite sequence and $|z| \geq |w|$, then $\mathrm{last}(z;w)$ is the last element of the sequence coded by w.

Observe that w is the Gödel number of a finite sequence exactly if the binary expansion of w satisfies the following four conditions.

(i) Either $w = 0$ or w is odd.

(ii) For every even j such that the coefficient of 2^{j-1} is not 0, the coefficient of 2^j is 1.

(iii) There is no substring of the form 1000.

(iv) There is no substring of the form 0010.

Set

$$\mathrm{seq1}(0;w) = 1,$$
$$\mathrm{seq1}(zi;w) = \mathrm{cond}(;\mathrm{seq1}(z;w),0,\mathrm{cond}(;\mathrm{ebit}(z;w),1,\mathrm{cond}(;\mathrm{obit}(z;w),0,1)))$$

for $zi \neq 0$,

$$\mathrm{seq2}(0;w) = 1,$$
$$\mathrm{seq2}(zi;w) = \mathrm{cond}(;\mathrm{seq2}(z;w),0,\mathrm{cond}(;P(z;w),\mathrm{cond}(;P(\hat{s}_1(z;);w),$$
$$\mathrm{cond}(;P(\hat{s}_1^2(z;);w),\mathrm{cond}(;P(\hat{s}_1^3(z;);w),1,0),1),1),1))$$

for $zi \neq 0$, and

$$\mathrm{seq3}(0;w) = 1,$$
$$\mathrm{seq3}(zi;w) = \mathrm{cond}(;\mathrm{seq3}(z;w),0,\mathrm{cond}(;P(z;w),\mathrm{cond}(;P(\hat{s}_1(z;);w),1,$$
$$\mathrm{cond}(;P(\hat{s}_1^2(z;);w),\mathrm{cond}(;P(\hat{s}_1^3(z;);w),0,1),1)),1))$$

for $zi \neq 0$. Moreover, let $a \wedge b = \mathrm{cond}(;a,0,\mathrm{cond}(;b,0,1))$, and define

$$\mathrm{seq}(z;w) = \mathrm{cond}(;w,{\leq}(z;w,0),1) \wedge \mathrm{seq1}(z;w) \wedge \mathrm{seq2}(z;w) \wedge \mathrm{seq3}(z;w).$$

Then $\mathrm{seq} \in [B_0;\mathrm{SC},\mathrm{SRN}]$, and for z,w with $|z| \geq |w|$, we have that $\mathrm{seq}(z;w) = 1$ if w is the Gödel number of a finite sequence and $\mathrm{seq}(z;w) = 0$ otherwise.

Acknowledgment. The author is grateful to the referees for a careful reading and the improvement suggestions.

TESTING MEMBERSHIP IN LANGUAGES THAT HAVE SMALL WIDTH BRANCHING PROGRAMS*

ILAN NEWMAN†

Abstract. Combinatorial property testing, initiated formally by Goldreich, Goldwasser, and Ron in [*J. ACM*, 45 (1998), pp. 653–750] and inspired by Rubinfeld and Sudan [*SIAM J. Comput.*, 25 (1996), pp. 252–271], deals with the following relaxation of decision problems: Given a fixed property and an input x, one wants to decide whether x has the property or is "far" from having the property.

The main result here is that, if $\mathcal{G} = \{g_n : \{0,1\}^n \to \{0,1\}\}$ is a family of Boolean functions which have oblivious read-once branching programs of width w, then, for every n and $\epsilon > 0$, there is a randomized algorithm that always accepts every $x \in \{0,1\}^n$ if $g_n(x) = 1$ and rejects it with high probability if at least ϵn bits of x should be modified in order for it to be in $g_n^{-1}(1)$. The algorithm makes $(\frac{2^w}{\epsilon})^{O(w)}$ queries. In particular, for constant ϵ and w, the query complexity is $O(1)$.

This generalizes the results of Alon et al. [*Proceedings of the 40th IEEE Symposium on Foundations of Computer Science*, IEEE Computer Society, 1999, pp. 645–655] asserting that regular languages are ϵ-testable for every $\epsilon > 0$.

1. Introduction.

Combinatorial property testing, initiated formally by Goldreich, Goldwasser, and Ron in [11] and inspired by Rubinfeld and Sudan [16], deals with the following relaxation of decision problems: Given a fixed property and an input x, one wants to decide whether x has the property or is "far" from having the property. A property here is a set of binary strings (those inputs that have the "property") and is identified with its characteristic function (that is, "1" on all inputs that have the property and "0" elsewhere). Being "far" is measured by the number of bits that need to be changed for an input x in order for it to have the property (i.e., the Hamming distance). A property is said to be (ϵ, q)-testable if there is a randomized algorithm that, for every input, $x \in \{0,1\}^n$ queries at most q bits of x and with probability $2/3$ distinguishes between the case when x has the property and the case when x is ϵn-far from having the property. Varying ϵ and n may result in different algorithms with different query complexity $q = q(\epsilon, n)$ that may depend on both ϵ and n. If, for a fixed $\epsilon > 0$ and every large enough n, a property P is (ϵ, q)-testable with a number of queries q that is independent of the length of the input, n, then we say that P is ϵ-testable. If, for every $\epsilon > 0$, P is ϵ-testable, then P is said to be *testable*.

Apart from being a natural relaxation of the standard decision problem, combinatorial property testing emerges naturally in the context of probably approximately correct (PAC) learning, program checking [10, 6, 16], probabilistically checkable proofs [3], and approximation algorithms [11].

In [11], the authors mainly consider graph properties and show (among other

things) the quite surprising fact that the graph property of being bipartite is testable. They also raise the question of obtaining general results identifying classes of properties that are testable. Some interesting examples are given in [11], and several additional ones can be obtained by applying the regularity lemma [1]. Alon et. al. [2] proved that membership in any regular language is testable, hence obtaining a general result identifying a nontrivial class of properties, each being testable. Here we further pursue this direction: We prove that if a language has a (nonuniform) oblivious read-once branching program (BP) of width w, then it is $(\epsilon, (\frac{2^w}{\epsilon})^{O(w)})$-testable. In particular, this shows that every family of functions that can be defined by a nonuniform collection of constant width oblivious read-once BPs is testable. This also generalizes and gives an alternative proof and algorithm for the result of [2], as regular languages can be represented by constant width oblivious read-once BPs. We note, however, that the dependence of the query complexity here is worse than in [2].

A BP of width w is a deterministic *leveled* BP in which every level contains at most w vertices. In what follows, we will be interested in BPs of width w that have the further restriction of being *oblivious read-once*. Namely, every level is associated with a variable (all nodes in a level query the same variable), and each variable appears in at most one level. BPs have been extensively studied as a model of computation for Boolean functions. ([7] contains a survey text; see also [4, 5, 13] for a partial list of different aspects involving BPs and read-once BPs.)

The size of a BP (and a read-once BP) is tightly related to the space complexity of the function it computes: If a language is in $SPACE(s)$, then it has a BP of total size at most $n \cdot 2^{O(s)}$ [8] and also a read-once BP of width $2^{O(2^s)}$ [12]. However, the inverse of the last assertion is not true even for computable languages. The result of [2] and the result here, in its uniform manifestation, may be viewed as asserting that "very small" space functions are "efficiently" testable: All regular languages are in $SPACE(O(1))$ and hence have a read-once BP of $O(1)$ size. What happens for $SPACE(\omega(1))$ functions? It is known that $SPACE(O(1)) = SPACE(o(\log\log n))$ = Regular [12]. Hence the above question is interesting for $SPACE(s)$ with $s = \Omega(\log\log n)$. The result here says nothing directly for $s = \Omega(\log\log n)$. However, we get rid of the strong "uniformity" of the deterministic finite automata (DFAs) used in [2]. In regular languages, the same finite automaton is used to test all the words, even of different lengths. On the other hand, when represented by a family of BPs, each BP computes the characteristic function of the property for a given input length. There are languages of arbitrary complexity that can be represented by $O(1)$-width oblivious BPs. Our results apply to such cases as well. This includes the family of $O(1)$-terms disjunctive normal form (DNF), $O(1)$-clauses conjunctive normal form (CNF), and some other interesting examples (see section 4).

Finally, we note that $SPACE(O(\log n))$ functions are not testable in general; [2, 11, 15] contain lower bounds showing that some functions in $SPACE(O(\log n))$ are not ϵ-testable and sometimes not even (ϵ, n^δ)-testable for some fixed $\epsilon, \delta < 1$. However, the question of whether properties in $SPACE(s)$ for $\log\log n \le s << \log n$ are "efficiently" testable is open. In particular, we do not have any candidate for a $SPACE(O(\log\log n))$ function whose ϵ-testing requires $n^{\Omega(1)}$ queries for some fixed $\epsilon > 0$.

2. Definitions and notation. We identify properties with the collection of their characteristic Boolean functions, namely: A property $\mathcal{P} \subseteq \{0,1\}^*$ is identified with $\{f : \{0,1\}^n \longrightarrow \{0,1\}\}$ so that $f(x) = 1$ if and only if $x \in \mathcal{P}$.

An oblivious leveled BP is a directed graph B in which the nodes are partitioned into levels $L_0, \ldots, L_m$. There are two special nodes: a "start" node belonging to L_0 and an "accept" node belonging to L_m. Edges are going only from a level to nodes in the consecutive level. Each node has at most two out-going edges, one of which is labeled by "0" and the other by "1." In addition, all edges in between two consecutive levels are associated with a member of $\{1, \ldots, n\}$ (a Boolean variable). An input $x \in \{0,1\}^n$ naturally defines a path starting at the *start*-node: At each step, if the edges are associated with i, then the edge with the label identical to the value of x_i is chosen. A leveled BP defines a Boolean function $g : \{0,1\}^n \longrightarrow \{0,1\}$ in the following way: $g(x) = 1$ if the path that x defines reaches *accept*. This definition of BPs is essentially equivalent to what is sometimes called "deterministic" BPs (as each input defines at most one path from each node). However, note that this definition is slightly different from the standard definition of deterministic BPs, in which every vertex has exactly two outgoing edges; one is labeled by "1" and the other by "0." Here, instead, an input x can be "stuck" at an internal node v due to the fact that v has just one outgoing edge that is associated with i and is labeled by a value that is opposite to that of x_i. (This cannot happen in the standard definition.) A leveled BP is of width w (w-width) if its largest level contains w nodes.

An *oblivious read-once* BP computing $g : \{0,1\}^n \longrightarrow \{0,1\}$ is a leveled BP with the additional property that edges ending in distinct levels are labeled with distinct variables. This implies also that there are exactly $n+1$ levels (for a function that depends on all its n variables). We number the levels of the BP from 0 (containing the start s) and on and associate to the edges in between levels the formal Boolean variables $X_1, \ldots, X_n$ consecutively (by possibly renaming the variables). We may assume that the last level is numbered by n.

In what follows, we consider only oblivious read-once BPs. For a given BP, B, and two nodes u, v, we define $B[u : v]$ the (sub) BP for which its start node is u and its accept node is v. If $u \in L_i$ and $v \in L_j$, then $B[u : v]$ computes a Boolean function on the variables $X_i, \ldots, X_j$. The length of $B[u : v]$ in this case is $\nu = j - i$. Such $B[u : v]$, as a subprogram of a read-once oblivious BP, is also read-once oblivious BP. When discussing such a BP $B[u : v]$, we renumber its levels so that its first level, which is level L_i in B, is denoted $L_0(B[u : v])$, and its last level is denoted by $L_\nu(B[u : v])$. When it is clear from the context which is the BP that is considered, we just refer to its first and last levels as L_0, L_ν, respectively (where ν is the length of the corresponding BP).

We will be interested in BPs for which the start and accept nodes are not always defined. Namely, the BP B might have multiple nodes in its first and last levels. For such a BP of length n, any choice of start and accept nodes $(s, t) \in L_0 \times L_n$ defines a different function on n variables. If no path from a node $v \in B$ reaches the last level, then deleting v from B will not change the function that B computes for any choice of start and accept nodes in the first and last levels. Similarly, we may delete every vertex that can be reached from no vertex of the first level. Also, when we talk about $B[u : v]$, for some specific nodes u, v, we may delete any node from $B[u : v]$ that either is not reachable from u or cannot reach v. In particular, this means that u is the only node in $L_0(B[u : v])$, and v is the only node in the last level of $B[u : v]$. Such nodes that can be deleted from the BP are called "unnecessary nodes." In what follows, we always assume that all BPs under discussion contain no "unnecessary nodes."

For integers $a < b$, we denote by $B_{a:b}$ the subprogram of B containing all nodes in levels $L_a, L_{a+1}, \ldots, L_b$. $B_{a:b}$ has undefined source and sink. Note that, if B is an

oblivious read-once BP of width w, then, for any two nodes u, v and any two numbers a and b, $B[u:v]$ and $B_{a:b}$ are oblivious read-once BPs of width at most w. (The width can become smaller as nodes might become "unnecessary.")

Let $x, y \in \{0,1\}^n$; we define $dist(x,y) = hamming(x,y) = |\{i|\ x_i \neq y_i\}|$. Let $g : \{0,1\}^n \longrightarrow \{0,1\}$ such that $g^{-1}(1) \neq \phi$; we define $dist(x,g) = \min\{dist(x,y)|\ y \in g^{-1}(1)\}$. For a BP B and two nodes u and v in levels L_i, L_j, respectively, let $dist(x, B[u:v]) = dist(x[i,j], g')$, where g' is the function computed by $B[u:v]$ on the formal variables $X_i, X_{i+1}, \ldots, X_j$.

Let B be an oblivious read-once BP with fixed start and accept nodes that computes a Boolean function $g : \{0,1\}^n \longrightarrow \{0,1\}$. A randomized algorithm $\mathcal{A}$ is a 1-sided error ϵ-test for B (g) of query complexity $c(\mathcal{A})$ if, for every input $x \in \{0,1\}^n$, it queries at most $c(\mathcal{A})$ queries and

1. for every input $x \in g^{-1}$, the algorithm accepts;
2. for every input $x \in \{0,1\}^n$ for which $dist(x,g) \geq \epsilon n$, the algorithm rejects with probability at least 2/3.

Let $\mathcal{B}_w^n$ be the set of all oblivious read-once BPs of width w and length n. For $B \in \mathcal{B}_w^n$, we denote $\tilde{c}(\epsilon, B) = \min\{c(\mathcal{A}) :\ \mathcal{A}$ is a 1-sided error ϵ-test for $B\}$. Namely, $\tilde{c}(\epsilon, B)$ is the query complexity of the best 1-sided error ϵ-test for B. Let $\tilde{q}(\epsilon, w) = \max\{\tilde{c}(\epsilon, B) :\ B \in \mathcal{B}_w^n\}$. Namely, $\tilde{q}(\epsilon, w)$ is the worst query complexity needed to ϵ-test a w-width BP. Formally, $\tilde{q}(\epsilon, w)$ is a function of n too; however, as we shall see, asymptotically this is not the case.

Finally, in what follows, for ease of notation, we neglect taking $\lceil\ \rceil$ and $\lfloor\ \rfloor$ for numbers, even when they need to be integers, whenever this is clear from the context and has no bearing on the essence of proofs.

3. Results. Our main result is the following.

THEOREM 1. *Let $g : \{0,1\}^n \longrightarrow \{0,1\}$ be computed by an oblivious read-once BP of width w. Then there is an ϵ-test for g that makes $(\frac{2^w}{\epsilon})^{O(w)}$ queries.*

COROLLARY 3.1. *If $g : \{0,1\}^n \longrightarrow \{0,1\}$ has a read-once BP of width $w = O(1)$, then g is testable.*

The proof of Theorem 1 uses several reduction steps in order to reduce testing of a w-width BP to testing of $(w-1)$-width BPs. This approach has prospects since 1-width BPs are testable, as asserted by the following proposition.

PROPOSITION 1. *If $g : \{0,1\}^n \longrightarrow \{0,1\}$ is computable by an oblivious read-once BP of width $w = 1$, then g is $(\epsilon, O(\frac{1}{\epsilon}))$-testable by a 1-sided error algorithm.*

Proof. We assume that g is not identically "0" and not identically "1," as otherwise the test is trivial (with no queries at all). Let B be a BP of width $w = 1$ computing the nonzero function g. It is clear from the definition that g is a one-term DNF. That is, written in formal variables, $X_1, \ldots, X_n$, $g = \Pi_{i=1}^n t_i$, where t_i is either X_i or $\bar{X}_i$. g does not necessarily depend on all of its variables; in this case, we just look at the variables it does depend on. Let x be an input such that $dist(g,x) \geq \epsilon n$ (assuming that there is such x). It is easy to see that, for at least $\epsilon \cdot n$ of the places $\{1, \ldots, n\}$, x_i is not consistent with t_i. Hence sampling $O(\frac{1}{\epsilon})$ bits of an input x and rejecting if x_i is inconsistent with t_i are guaranteed to succeed with probability 2/3 for ϵn-far inputs, and with probability 1 for any input x for which $g(x) = 1$. ∎

For the proof of the case $w \geq 2$, we will need some machinery developed hereafter.

3.1. Main definitions and some intuition. The algorithm for ϵ-testing w-width BPs will be recursive on the width. Namely, our aim is to reduce ϵ-testing of a w-width BP to testing of $(w-1)$-width BPs with possibly a smaller ϵ. Key notions are that of *r-full* levels and decomposable BPs. They are defined below.

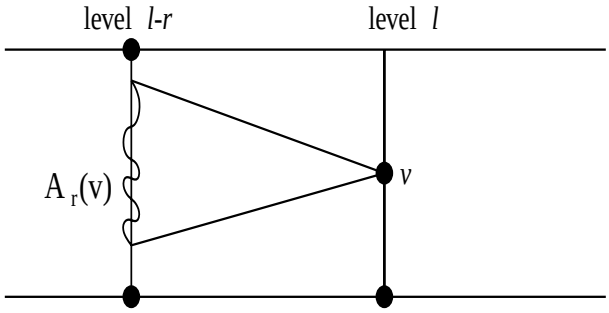

FIG. 1. *$A_r(v)$ is the set of nodes in level L_{l-r} that can reach v. Here v is* not *r-full as not all nodes in level L_{l-r} can reach v.*

For an integer r and a node v in a BP, we denote

$$A_r(v) = \{u | \text{ there is a path of length } r \text{ from } u \text{ to } v\}.$$

See Figure 1.

DEFINITION 3.2. *Let v be a vertex in level L_l of a BP with start and accept nodes that are not necessarily defined. We say that v is* r-full *if $A_r(v)$ contains all nodes of level L_{l-r}. If every vertex in level L_l is r-full, then L_l is said to be r-full.*

Namely, a vertex v is r-full if v is reachable from every vertex of level L_{l-r}; see Figure 1. Note that, for every two nodes u and v of a BP B, v is always 1-full with respect to $B[u : v]$. This is due to the fact that $B[u : v]$ contains no "unnecessary nodes."

FACT 1. *Assume that $v \in L_l$ is r-full for a certain r and l; then*

- *v is r'-full for every $r' > r$;*
- *if $u \in L_{l+1}$ is a neighbor of v, then u is $(r+1)$-full.*

Proof. For the first part, assume that $r' > r$ and $v' \in L_{l-r'}$. Then, as we assume that there are no "unnecessary vertices," v' can reach some vertex $v'' \in L_{l-r}$. In turn, v'' can reach v by the assumption that v is r-full. Hence v' can reach v.

For the second part, if v is r-full, it can be reached from any $w \in L_{l-r}$. Since u is a neighbor of v, it can also be reached by every $w \in L_{l-r}$. □

The following is a crucial ingredient for the rest of what follows.

DEFINITION 3.3. *Let $\delta < 1$. A BP of length ν, with start and accept nodes that are not necessarily defined, is said to be* δ-decomposable *if, for some $\frac{\delta\nu}{20} \le \ell \le \nu - 1$ and $r \le \lfloor \frac{\delta\ell}{10} \rfloor$, L_ℓ is r-full.*

For a given BP, B, the role of the non δ-decomposable subprogram of B is the following: We first show in section 3.2 that, if B' is not δ-decomposable for $\delta < \epsilon$, then ϵ-testing B' can indeed be reduced to testing "narrower" BPs. Then, in section 3.3, we show how a general BP can be decomposed into disjoint nondecomposable subprograms such that testing the BP can be reduced to testing not too many of the nondecomposable parts of it.

3.2. Testing nondecomposable BPs. The following lemma, which is the main technical part of the proof of Theorem 1, relates testing w-width nondecomposable BPs to the test of general $(w-1)$-width BPs.

LEMMA 3.4. *Let $\delta \le \epsilon$, and let B be a non δ-decomposable BP of width w and length n. Then ϵ-testing $B[s : t]$, for any start and accept nodes s and t, requires at most $O(\frac{w^4}{\delta^3}(\log \frac{w^2}{\delta})^2) \cdot \tilde{q}(0.8\epsilon, w-1)$ queries.*

Proof. The idea of the proof is as follows: We fix $O(\frac{1}{\delta^2})$ levels that are equally spaced in B, leaving out enough space in the beginning of B. The assumption that B is not δ-decomposable will imply that, for each of two nodes u, v in the levels we choose, the test of $B[u : v]$ can be reduced to tests of $(w-1)$-width BPs. We then show how to combine the results of the tests on $B[u : v]$ for all such u, v into an ϵ-test for B.

Formally, let $m = \lceil \frac{\delta^2 n}{400} \rceil$. Let $\{l_0, \ldots, l_p\}$ be the set of numbers that are m apart, starting from $\lceil \frac{20m}{\delta} \rceil$ and ending at or before n. Namely, $l_i = \lceil \frac{20m}{\delta} \rceil + i \cdot m$, $i = 0, 1, \ldots, p = \lfloor \frac{n-l_0}{m} \rfloor = O(\frac{1}{\delta^2})$. Let $\mathcal{S} = L_{l_0} \times \cdots \times L_{l_p}$. Our first aim is to show that, for every pair $(u, v) \in L_{l_i} \times L_{l_{i+1}}$, the ϵ_1-test of $B[u : v]$ can be reduced to a small number of general tests of $(w-1)$-width BPs.

We first need the following claims.

CLAIM 3.5. *For every $l \geq l_0$, level L_l is not $(2m)$-full.*

Proof. The proof is immediate from the choice of parameters and the fact that B is not δ-decomposable. ∎

For each l such that $l_i < l \leq l_{i+1}$, let $F(l)$ be the set of all $(l - l_i)$-full vertices in level L_l. In other words, $v \in F(l)$ if it is in the lth level and it is reachable from every vertex of the l_ith level. By our assumption on B, $F(l) \neq L_l$, as otherwise L_l would be $(l - l_{i-1})$-full in contradiction with Claim 3.5.

Hence the above implies the following claim.

CLAIM 3.6. *Let u, v be vertices in levels $L_{l_i}, L_{l_{i+1}}$, respectively, and let l be such that $l_i \leq l \leq l_{i+1}$.*

- *Let u' be in level L_l, and assume that $u' \notin F(l)$; then $B[u : u']$ is of width $w' \leq w - 1$.*
- *Let v' be in level L_l, and assume that $v' \in F(l)$; then $B[v' : v]$ is of width $w' \leq w - 1$.*

Proof. Let $u' \notin F(l)$ be in level L_l. As $u' \notin F(l)$, u' is not $(l - l_i)$-full; then, by Fact 1, it is also not $(l - l')$-full for every $l' > l_i$. Namely, for every intermediate level $L_{l'}$, $l_i < l' < l$, there is a vertex that cannot reach u' and hence can be deleted from $B[u : u']$.

For the second part, assume first that v' is in level L_l for $l > l_i$ and $v' \in F(l)$. Let t be any node at level $L_{l'}$, $l < l' \leq l_{i+1}$, that is reachable from v'. Since $v' \in F(l)$, it follows that t is $(l' - l_i)$-full. Hence not all vertices in level $L_{l'}$ are reachable from v', as otherwise level $L_{l'}$ will be $(l' - l_i)$-full, in contradiction to Claim 3.5. As this is true for every $l < l' \leq l_{i+1}$, it follows that $B[v' : v]$ is of width $w' \leq w - 1$. If v' is in level L_{l_i}, then the same argument for t will work except that t will be $(l' - l_{i-1})$-full. Again, this implies that level $L_{l'}$, $l_i < l' \leq l_{i+1}$, cannot have all of its nodes reachable from v'. Otherwise, it would be $(l' - l_{i-1})$-full, in contradiction to Claim 3.5. ∎

Claim 3.6 asserts that $B[v_i : v_{i+1}]$ is indeed of width of at most $(w-1)$ unless $v_i \notin F(l_i)$ and $v_{i+1} \in F(l_{i+1})$. We still need to deal with the case for which $v_i \notin F(l_i)$ and $v_{i+1} \in F(l_{i+1})$, where the subprogram $B[v_i : v_{i+1}]$ might be of width w. The key observation here is that any path from v_i to v_{i+1} must start at $L_{l_i} - F(l_i)$ (as v_i is such) and end in $F(l_{i+1})$. Hence this path must intersect $F(l)$ for some intermediate level L_l, $l_i < l \leq l_{i+1}$. In addition, by Fact 1, once it intersects $F(l)$, it intersects $F(l')$ for every $l' > l$ (see Figure 2). This suggests the following.

Let $k = \frac{10}{\delta}$; we choose $k+1$ numbers, $p_0, \ldots, p_k$, that are $\frac{m}{k}$ apart in the range $\{l_i, \ldots, l_{i+1}\}$: $p_j = l_i + j \cdot \frac{m}{k}$, $j = 0, \ldots, k$.

CLAIM 3.7. *For every $u \in L_{l_i} - F(l_i)$ and $v \in F(l_{i+1})$, the following hold:*

- *If $y \in \{0,1\}^n$ is such that $dist(y, B[u : v]) = 0$, then, for some $j \in \{1, \ldots, k\}$,*

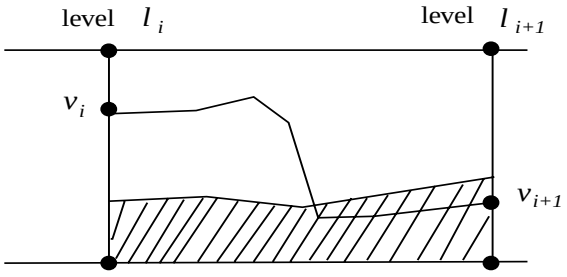

FIG. 2. *Vertices in shadowed area are in $F()$. If a path from v_i to v_{i+1} intersects $F(l)$ at some intermediate level L_l, then it intersects $F()$ for every following level.*

there are some $u' \in L_{p_{j-1}} - F(p_{j-1})$, $v' \in F(p_j)$ so that $dist(y, B[u : u']) = dist(y, B[v' : v]) = 0$.

- *If $y \in \{0,1\}^n$ is such that $dist(y, B[u : v]) \geq (1-\alpha)\epsilon m$ for some $\alpha < 1$, then, for every $j \in \{1, \ldots, k\}$ and for every $u' \in L_{p_{j-1}} - F(p_{j-1})$ and $v' \in F(p_j)$ such that u can reach u', u' can reach v', and v' can reach v,*

$$dist(y, B[u : u']) + dist(y, B[v' : v]) \geq (1-\alpha)\epsilon m - \frac{m}{k} \geq (0.9-\alpha)\epsilon m.$$

Proof. If $dist(y, B[u : v]) = 0$, then, by the discussion above, there is some level $l_i < l \leq l_{i+1}$ so that the path, $Path(y)$, that y defines from u to v intersects $F(l')$ for each $l \leq l' \leq l_{i+1}$ and does not intersect $F(l'')$ for each $l_i \leq l'' < l$. Let j be the smallest such that $p_j \geq l$. Let u' be the vertex that $Path(y)$ intersects in $L_{p_{j-1}}$, and let v' be the vertex that $Path(y)$ intersects in L_{p_j}. Clearly, for these j, u', v', the first part of the claim holds.

For the second part, assume that, for $y \in \{0,1\}^n$, there are $j \in \{1, \ldots, k\}$, $u' \in L_{p_{j-1}} - F(p_{j-1})$, and $v' \in F(p_j)$ such that u can reach u', u' can reach v', and v' can reach v, and such that $dist(y, B[u : v]) < (0.9-\alpha)\epsilon m$. Then, certainly, $dist(y, B[u : v]) < (1-\alpha)\epsilon m$: First, by changing at most $(0.9-\alpha)\epsilon m$ bits of y in the range $\{l_i + 1, \ldots, p_{j-1}\}$ and $\{p_j + 1, \ldots, l_{i+1}\}$, we can get a y' such that its corresponding parts (to the places above) traverse B from u to u' and from v' to v. Then, by changing possibly additional $m/k \leq 0.1\epsilon m$ bits, namely, all bits in the range $\{p_{j-1} + 1, \ldots, p_j\}$, we get a y'' that traverses B from u to v through u' and v'. ∎

We now can present the algorithm that $(1-\alpha)\epsilon$-tests $B[u : v]$ for each $(u, v) \in L_{l_i} \times L_{i+1}$, given that we have a general 1-sided error test for $(w-1)$-width BPs. Note that the length of $B[u : v]$ for any such u and v is m.

Algorithm $A_1((1-\alpha)\epsilon, w, B[u : v])$.
The first parameter is relative distance, the 2nd is width, and $(u, v) \in L_{l_i} \times L_{l_{i+1}}$.

1. If $u \in F(l_i)$ or $v \notin F(l_{i+1})$, then, by Claim 3.6, $B[u : v]$ is already of width $w' \leq w - 1$. This test is done by calling the general $(1-\alpha)\epsilon$-testing procedure for $(w-1)$-width BPs.
2. Otherwise, if $u \notin F(l_i)$ and $v \in F(l_{i+1})$, let $k = \frac{10}{\delta}$ and $\rho = 1 + \frac{\log(kw^2)}{\log 3}$. We choose in the range $\{l_i, \ldots, l_{i+1}\}$ $k+1$ numbers, $p_0, \ldots, p_k$, that are $\frac{m}{k}$ apart: $p_j = l_i + j \cdot \frac{m}{k}$, $j = 0, \ldots, k$.

   For every triplet $(j, u'v')$ such that $j \in \{1, \ldots, k\}$, $u' \in L_{p_{j-1}} - F(p_{j-1})$, $v' \in F(p_j)$, and such that u can reach u', u' can reach v' and v' can reach v, a $(0.9-\alpha)\epsilon$-test is performed ρ independent times on $B[u : u']$ and $B[v' : v]$. This is done by calling the general procedure for testing $(w-1)$-width BPs.
   If there is a triplet $(j, u'v')$ for which all ρ tests pass, then the outcome of A_1 is "Yes." Otherwise, if, for every triplet (j, u', v'), one or more of the ρ tests on either $B[u : u']$ or $B[v' : v]$ answer "No," then the outcome of A_1 is "No."

CLAIM 3.8. *Let B be a w-width BP that is not δ-decomposable, and let m, k be as above. Let $x \in \{0,1\}^n$ be any input; then Algorithm A_1 makes $O(\frac{w^2}{\delta} \cdot \log \frac{w^2}{\delta})$ calls for a general $(1-\alpha)\epsilon$-test of $(w-1)$-width programs on x and*

- *if $dist(x, B[u:v]) = 0$, then A_1 answers "Yes" on x with probability 1;*
- *if $dist(x, B[u:v]) \geq (1-\alpha)\epsilon m$, then the outcome of A_1 on x is "No" with probability at least 2/3.*

Proof. For each triplet (j, u', v') that is relevant to the second case of Algorithm A_1, Claim 3.6 asserts that $B[u:u']$ and $B[v':v]$ are of width at most $(w-1)$. Hence all calls of A_1 are to tests of $(w-1)$-width BPs. There are at most $O(k \cdot w^2) = O(\frac{w^2}{\delta})$ such triplets; hence the claim on the number of calls to $(w-1)$-width tests is obvious.

We assume that the general $(w-1)$-test is a 1-sided error. Let $x \in \{0,1\}^n$ be an input with $dist(x, B[u:v]) = 0$. A "No" result will be obtained if $B[u:v]$ is of width at most $w-1$ and the general $(w-1)$-width test answers "No" (1st case of A_1) or if, for every triplet (j, u', v') as above, one of the tests, to either $B[u:u']$ or $B[v':v]$, answers "No." Both cases occur with probability 0 by Claim 3.7.

Now let $x \in \{0,1\}^n$ be an input for which $dist(x, B[u:v]) \geq (1-\alpha)\epsilon m$. If $B[u:v]$ is of width $(w-1)$, then A_1 answers "Yes" only if the general $(w-1)$-width test errs. This occurs with probability at most 1/3. If $B[u:v]$ is of width w, then, by Claim 3.7, for every triplet (j, u', v') as above, $dist(y, B[u:u']) + dist(y, B[v':v]) \geq (0.9-\alpha)\epsilon m$. However, for each such triplet, either $dist(y, B[u:u']) \geq (0.9-\alpha)\epsilon \cdot \frac{j-1}{k} \cdot m$ or $dist(y, B[v':v]) \geq (0.9-\alpha)\epsilon \cdot (1-\frac{k-j}{k})m$. In any of these cases, a general $(0.9-\alpha)\epsilon$-test to the corresponding $(w-1)$-width BP would erroneously say "Yes" with probability at most 1/3. Since there are ρ such independent tests, all of these tests would err with probability at most $(\frac{1}{3})^\rho \leq \frac{1}{3kw^2}$. This would cause A_1 to erroneously say "Yes" due to this triplet. As there are at most kw^2 possible triplets, A_1 errs with probability at most 1/3. ∎

We now formally end the proof of Lemma 3.4 by presenting the following proposition and the testing algorithm it implies.

PROPOSITION 2. *Let B be a non δ-decomposable BP of width w and length n. Let $m, \{l_0, \ldots, l_p\}$, and $\mathcal{S}$ be as defined above (right after the statement of Lemma 3.4). Let $y \in \{0,1\}^n$; then, for any start and accept nodes $(s,t) \in L_0 \times L_n$, the following hold.*

1. *If $dist(y, B[s:t]) = 0$, then there exists a tuple $(v_0, \ldots, v_p) \in \mathcal{S}$ such that s can reach v_0, v_p can reach t, and $dist(y, B[v_i : v_{i+1}]) = 0$ for $i = 0, \ldots, p-1$.*
2. *Let $dist(y, B[s:t]) \geq \epsilon n$; then, for each $(v_0, \ldots, v_p) \in \mathcal{S}$ such that s can reach v_0 and v_p can reach t, $\Sigma_{i=0}^{i=p-1} dist(x, B[v_i : v_{i+1}]) \geq \epsilon n - l_0 - (n - l_p) \geq 0.9\epsilon n$.*

Proof. If $dist(y, B[s:t]) = 0$, then the path that y takes in B defines the tuple $(v_0, \ldots, v_p) \in \mathcal{S}$ which contains the nodes in which this path intersects L_{l_i}, $i = 0, \ldots, p$, along the way from s to t. This tuple asserts the first item of the proposition.

If $dist(y, B[s:t]) \geq \epsilon n$, then, for any $(v_0, \ldots, v_p) \in \mathcal{S}$ such that s can reach v_0 and v_p can reach t, $dist(y, B[v_0 : v_p]) \geq \epsilon n - l_0 - (n - l_p) \geq 0.9\epsilon n$. However, $dist(y, B[v_0 : v_p]) = \Sigma_{i=0}^{i=p-1} dist(x, B[v_i : v_{i+1}])$. ∎

Proposition 2 defines a way to combine answers to tests on BPs of the form $B[v_i : v_{i+1}]$ into an ϵ-test of B. Intuitively, on an input $x \in \{0,1\}^n$, we just need to check for all tuples $(v_0, \ldots, v_p) \in \mathcal{S}$, and check whether there exists one for which $dist(x, B[v_i : v_{i+1}]) = 0$ for $i = 0, \ldots, p-1$.

Formally, let $x \in \{0,1\}^n$ be the input. The following is an ϵ-test of B for any

start and accept nodes:

Algorithm $A_2(\epsilon, w)$. (B is a non δ-decomposable BP of width w.)

Let m and $\mathcal{S}$ be as above, and let $\nu = 1 + \frac{\log(pw^2)}{\log 3} = O(\log \frac{w}{\delta})$.

1. For each $(u,v) \in L_{l_i} \times L_{l_{i+1}}, i = 0, \ldots, p-1$, call $A_1(0.9 \cdot \epsilon, w, B[u:v])$ (namely, with $\alpha = 0.1$) independently, for ν times. If for (u,v), all of these tests answer "Yes," then define $T(u,v) = 1$. Otherwise, if there is a test out of the ν tests that answers "No" for (u,v), then set $T(u,v) = 0$.
2. Define the following directed graph $G = (V,E)$: $V = L_0 \cup L_n \cup (\cup_{i=0}^{p} L_{l_i})$, and

$$E = \{(s,u) \in L_0 \times L_{l_0} | s \text{ can reach } u \text{ in } B\}$$

$$\cup \{(v,t) \in L_{l_p} \times L_n | v \text{ can reach } t \text{ in } B\}$$

$$\cup \{(u,v) \in L_{l_i} \times L_{l_{i+1}}, i = 0, \ldots, p-1 | \text{ such that } T(u,v) = 1\}.$$

3. Answer "Yes" for $(s,t) \in L_0 \times L_n$ if and only if s can reach t in G.

CLAIM 3.9. *For any $(s,t) \in L_0 \times L_n$ and for every input x, the following hold.*

1. *If $dist(x, B[s:t]) = 0$, then Algorithm A_2 answers "Yes" on (s,t) with probability* 1.
2. *If $dist(x, B[s:t]) > \epsilon n$, then Algorithm A_2 answers "No" on (s,t) with probability at least* 2/3.

Proof. Assume that $dist(x, B[s:t]) = 0$ for an input $x \in \{0,1\}^n$ and $(s,t) \in L_0 \times L_n$. Then, by Proposition 2, there exists a tuple $(v_0, \ldots, v_p) \in \mathcal{S}$ such that s can reach v_0, v_p can reach t, and $dist(y, B[v_i : v_{i+1}]) = 0$ for $i = 0, \ldots, p-1$. By Claim 3.8, Algorithm A_1 answers "Yes" on each of the calls $A_1(0.9 \cdot \epsilon, w, B[v_i : v_{i+1}])$ with probability 1. Hence the path $(s, v_0, \ldots, v_p, t)$ is a valid path in G with probability 1, causing A_2 to answer "Yes" with the same probability.

For the second part, assume that $dist(x, B[s:t]) > \epsilon n$. Then, by Proposition 2, for each $(v_0, \ldots, v_p) \in \mathcal{S}$ such that s can reach v_0 and v_p can reach t, $\Sigma_{i=0}^{i=p-1} dist(x, B[v_i : v_{i+1}]) \geq 0.9\epsilon n$. However, then, for each such $(v_0, \ldots, v_p) \in \mathcal{S}$, for some $i \leq p-1$, $dist(x, B[v_i : v_{i+1}]) \geq 0.9\epsilon \frac{n}{p} > 0.9\epsilon m$. Let E' be the set that contains for each $(v_0, \ldots, v_p) \in \mathcal{S}$ a corresponding (v_i, v_{i+1}) for which $dist(x, B[v_i : v_{i+1}]) \geq 0.9\epsilon m$. Note that E' contains an (s,t)-cut in G. Namely, s cannot reach t in $G - E'$.

For each member $(v_i, v_{i+1}) \in E'$, Claim 3.8 asserts that Algorithm A_1 answers "No" on the call $A_1(0.9 \cdot \epsilon, w, B[v_i : v_{i+1}])$ with probability 2/3. Hence it answers erroneously "Yes" on all ν calls for a pair $(u,v) \in E'$ with probability at most $(\frac{1}{3})^\nu \leq \frac{1}{3pw^2}$. Namely, $T(u,v)$ is set erroneously to "1" in step 1 of the algorithm with probability at most $\frac{1}{3pw^2}$. However, there are at most pw^2 possible pairs in E'. This implies that with probability at most 1/3 there exists a pair $(u,v) \in E'$ for which $T(u,v) = 1$. In particular, it follows that s cannot reach t in G with probability at least 2/3. □

CLAIM 3.10. *For any $(s,t) \in L_0 \times L_n$ and for every input x, Algorithm A_2 makes $O(\frac{w^2}{\delta^2} \log \frac{w}{\delta})$ calls to A_1 with distance parameter 0.9ϵ.*

Proof. There are $O(pw^2) = O(\frac{w^2}{\delta^2})$ possible pairs $(u,v) \in L_{l_i} \times L_{l_{i+1}}, i = 0, \ldots, p-1$. For each pair (u,v), there are $\nu = O(\log \frac{w}{\delta})$ calls for A_1. □

COROLLARY 3.11. *Algorithm A_2 provides a 1-sided error ϵ-test for $B[s:t]$ for every start and accept nodes $(s,t) \in L_0(B) \times L_n(B)$, making at most $O(\frac{w^4}{\delta^3}(\log \frac{w^2}{\delta})^2) \cdot \tilde{q}(0.8\epsilon, w-1)$ queries.*

Proof. Claim 3.9 asserts the correction of A_2 as a 1-sided error ϵ-test for $B[s:t]$ for each $(s,t) \in L_0(B) \times L_n(B)$. Observe that the calls for A_1 do not depend on the

choice of s and t. Hence, with the same number of queries as described above for a given choice of s,t, A_2 provides an ϵ-test for every choice of s and t; for each s and t, the outcome has at least probability $2/3$ of being correct.

According to Claim 3.8, each call for A_1 results in possibly $O(\frac{w^2}{\delta}\cdot\log\frac{w^2}{\delta})$ calls to a general 0.8ϵ-test of $(w-1)$-width BPs. Claim 3.10 asserts that there are $O(\frac{w^2}{\delta^2}\log\frac{w}{\delta})$ calls to A_1; hence the claim follows. □

This ends the proof of Lemma 3.4. □

3.3. The general case. In order to test general w-width BPs, it remains to be shown how to reduce testing of decomposable BPs to that of nondecomposable ones. We need the following proposition.

PROPOSITION 3. *For a BP, B, and $t > r$, let t_1, t_2 be r-full vertices in L_t, and let $u \in L_l$ with $l \le t - r$. Then, for every $y \in \{0,1\}^n$,*

$$|dist(y, B[u : t_2]) - dist(y, B[u : t_1])| \le r.$$

Proof. The closest y' to y that traverses B from u to t_1 must intersect $A_r(t_2)$. Hence, by changing only the r last bits of y', we get a y'' that traverses B from u to t_2. □

DEFINITION 3.12. *Let $y \in \{0,1\}^n$ and $0 \le a < b \le n$; we define*

$$dist(y, B_{a:b}) = \min\{dist(y, B[u : v])| \ \ u \in L_a, v \in L_b\}.$$

CLAIM 3.13. *Let $B[s : t]$ be a BP of length ν with start vertex s (the only vertex at level L_0) and accept vertex t (the only vertex at level L_ν). Assume that there are a sequence of numbers $l_0 = 1, \ldots, l_h = \nu$ and a sequence of numbers $r_1, \ldots, r_h$, such that level L_{l_i} is r_i-full for each $i = 1, \ldots, h$. Then, for every $y \in \{0,1\}^\nu$, $\Sigma_i dist(y, B_{l_i:l_{i+1}}) \ge dist(y, B[s : t]) - \Sigma_i r_i$.*

Proof. Let y be such that $\Sigma_1^h dist(y, B_{l_{i-1}:l_i}) = d$. We will show that $dist(y, B[s : t]) \le d + \Sigma_i r_i$, which implies the claim.

Indeed, let $w_i = y[l_{i-1} + 1, : l_i]$, $i = 1, \ldots, h$, be the substring of y that corresponds to the variables of $B_{l_{i-1}:l_i}$. Let y'_i, $i = 1, \ldots, h$, be such that $dist(w_i, y'_i) = d_i$, $dist(y'_i, B_{l_{i-1}:l_i}) = 0$, and so that $\Sigma_1^h d_i = d$. Then for each y'_i, $i = 1, \ldots, h$, let $(u_i, v_i) \in L_{l_{i-1}} \times L_{l_i}$ be such that $dist(y'_i, B_{l_{i-1}:l_i}) = dist(y'_i, B[u_i : v_i]) = 0$. Namely, u_i, v_i are the start and end nodes through which y'_i travels through $B_{l_{i-1}:l_i}$. Then, by Proposition 3, for every $i = 1, \ldots, h$, there is a string z_i such that $dist(y'_i, z_i) \le r_i$ and $dist(z_i, B[u_i : u_{i+1}]) = 0$. However, then, the string $z = z_1 \cdot \ldots \cdot z_h$, which is the concatenation of $z_i, i = 1, \ldots, h$, "travels" in B through all the $u_i, i = 0, \ldots, h$. In particular, $dist(z, B[s : t]) = 0$ (as s and t are the only nodes in levels L_0, L_ν, respectively).

On the other hand, $dist(y, B[s : t]) \le dist(y, z) \le \Sigma_i dist(w_i, z_i) \le \Sigma_i (dist(w_i, y'_i) + dist(y'_i, z')) \le \Sigma_i (d_i + r_i) = d + \Sigma_i r_i$. □

We are ready now to prove Theorem 1.

Proof. Let B be a BP of width w and length n with start and accept nodes $s \in L_0$ and $t \in L_n$, respectively. Let $a_0 = 0$, and let $a_1 = l_1$ be the smallest integer such that level L_{a_1} is r_1-full for $r_1 \le \frac{\epsilon l_1}{20}$. Let l_2 be the smallest integer for which level L_{a_2}, $a_2 = a_1 + l_2$ is r_2-full for $r_2 \le \frac{\epsilon l_2}{20}$, etc. This defines a sequence of numbers $\mathcal{L} = (a_0, a_1, \ldots)$ of which the last may or may not be n. If the last number in $\mathcal{L}$ is not n, then we add n as the last member resulting in a sequence $\mathcal{L}'$; otherwise, we set $\mathcal{L}' = \mathcal{L}$. Assume that $\mathcal{L}' = (a_0 = 0, a_1, \ldots, a_h = n)$. This defines a sequence

of h BPs (with start and accept nodes that are not necessarily defined), $B_1, \ldots, B_h$, $B_i = B_{a_{i-1}:a_i}$ of length $l_i = a_i - a_{i-1}$.

Note that, by our choice, for every $i = 1, \ldots, h$, either $l_i = O(1)$ or B_i is not ϵ_1-decomposable for $\epsilon_1 = 0.5\epsilon$. Moreover, for every $i = 1, \ldots, h-1$, the last level of B_i is r_i-full, and for B_h (with L_n as last level) L_n is either r_i-full if $n \in \mathcal{L}$ or is 1-full if n was added to result in $\mathcal{L}'$ (as t is always 1-full in $B[s:t]$).

An ϵ-test of B is done as follows: For $4/\epsilon$ times, independently an $i \in \{1, \ldots, h\}$ is chosen at random with probability proportional to the length l_i. Let I be the multiset that contains the $4/\epsilon$ chosen i's, possibly with multiplicity. Let T_i be a Boolean flag associated with each $i \in I$. For each $i \in I$, an ϵ_1-test is performed on $B_{a_{i-1}:a_i}$ for every choice of start and accept nodes $(u, v) \in L_{a_{i-1}} \times L_{a_i}$. If for some pair $(u, v) \in L_{a_{i-1}} \times L_{a_i}$, the answer to (u, v) in this test is "Yes" then we mark T_i as "1." Otherwise, if, for all such pairs (u, v), the answer is "No," we mark it as "0."

Finally, if there exists a chosen $i \in I$ for which $T_i = 0$, then the answer to the ϵ-test for B is "No." Otherwise, if for all chosen i's $T_i = 1$, then the answer to the ϵ-test on B is "Yes."

Let us first analyze the query complexity of the above test: As was remarked before, each B_i is either of $O(1)$ length or non ϵ_1-decomposable. Hence, for each chosen i, an ϵ_1-test for each start and accept node $(u, v) \in L_{a_{i-1}} \times L_{a_i}$ can either be done in $O(1)$ queries (in the former case) or it can be done by calling Algorithm A_2 for nondecomposable BPs. Note that, in the latter case, Corollary 3.11 asserts that one call to A_2 provides a test for each start and accept node.

Since there are at most $4/\epsilon$ calls for A_2 (with $\delta = \epsilon_1$), the total complexity is

$$\tilde{q}(\epsilon, w) \leq \frac{4}{\epsilon} \cdot O\left(\frac{w^4}{\epsilon_1^3}\left(\log \frac{w^2}{\epsilon_1}\right)^2\right) \cdot \tilde{q}(0.8\epsilon_1, w-1) = O\left(\frac{w^4}{\epsilon^4}\left(\log \frac{w^2}{\epsilon}\right)^2\right) \cdot \tilde{q}(0.4\epsilon, w-1),$$

which implies that $\tilde{q}(\epsilon, w) = (\frac{2^w}{\epsilon})^{O(w)}$.

Let us check the error probability of this algorithm. If, for an input $x \in \{0,1\}^n$, $dist(x, B[s:t]) = 0$, then, for every $i \in I$ that is chosen in the algorithm above, $dist(x, B[u:v]) = 0$ for some $(u, v) \in L_{a_{i-1}} \times L_{a_i}$. Hence the answer will be "Yes" with probability 1.

For an input x such that $dist(x, B[s:t]) \geq \epsilon n$, by Claim 3.13, $\Sigma_i dist(x, B_{a_i:a_{i+1}}) \geq \epsilon n - \Sigma_i r_i$. However, as $r_i \leq \frac{\epsilon \cdot l_i}{20}, i = 1, \ldots, h-1$, and $r_h \leq \max\{1, \frac{\epsilon \cdot l_h}{20}\}$, we conclude that $\Sigma r_i \leq \frac{\epsilon n}{20} + 1$, and hence $\Sigma dist(x, B_{a_i:a_{i+1}}) \geq \frac{94}{100}\epsilon n$ for large enough n. Thus, by sampling one $i \in \{1, \ldots, h\}$ as above, we get that $dist(x, B_{a_i:a_{i+1}}) \geq \frac{1}{2}\epsilon l_i = \epsilon_1 l_i$ with probability at least 0.44ϵ. To see this, let $D = \{i |\ dist(x, B_{a_{i-1}:a_i}) \geq \frac{1}{2}\epsilon l_i\}$, and let $d_i = dist(x, B_{a_{i-1}:a_i})$; then

$$\frac{94}{100}\epsilon n \ \leq\ \Sigma_{i \in D} d_i + \Sigma_{i \notin D} d_i \ \leq \Sigma_{i \in D} l_i + \frac{1}{2}\epsilon \Sigma_{i \notin D} l_i \ \leq \text{Prob}(i \in D) \cdot n + \frac{1}{2}\epsilon n,$$

which implies that $\text{Prob}(i \in D) \geq 0.44\epsilon$.

Assuming that $i \in D$, for every $u \in L_{a_{i-1}}, v \in L_{a_i}$, $dist(x, B[u:v]) \geq \epsilon_1 l_i$. Thus the success probability for a chosen i is at least $0.44\epsilon \cdot \frac{2}{3}$. Namely, $i \in D$, and the ϵ_1-test on B_i answers "No" as it should for at least one pair of start and accept nodes of B_i. Making $4/\epsilon$ independent, such tests will again reduce the error probability to below $\frac{1}{3}$. □

3.4. Time complexity. We end this section with a note on the total running time of the algorithm. Every fixed BP, B, defines a property $\mathcal{P}_B \subseteq \{0,1\}^n$. We have

presented in the section above an "algorithm scheme." Namely, it produces an ϵ-test for any given ϵ and w-width oblivious read-once BP, B. For the algorithm scheme, the input is ϵ and B, while, for the property tester, the input is $x \in \{0,1\}^n$. These two notions should not be confused. Thus, in analyzing the running time of the ϵ-test of $\mathcal{P}_B$ for a given BP, B, we may assume that we have at hand the decomposition of B into nondecomposable parts for all possible recursion levels. We also assume that we have $F(l)$ for every level l and for every possible subprogram that is considered in any of the recursion levels. We do not discuss how this data is represented or computed, which is out of the scope of this paper. We note, however, that, by computing all-pairs-connectivity, the data above can easily be obtained. Hence the above can be done in polynomial time (in the length of B and $1/\epsilon$).

For an input $x \in \{0,1\}^n$, the operations in a given recursion level involve sampling a decomposable subprogram, calling A_1 and A_2, and processing the return answers of Algorithms A_1 and A_2. Sampling one decomposable program takes $O(\log n)$ steps since there might be $O(n)$ nondecomposable B_i's in the top level. Once all calls to A_1 are done, computing the outcome of Algorithm A_2, for a w-width BP in the top recursion level, is done by forming the graph G and then checking whether s can reach t in G. Given the answers of the calls to A_1, preparing the graph G takes $O(pw^2) = O(\frac{w^2}{\epsilon^2})$ steps. Then, solving the connectivity problem on G takes $O(\frac{w^2}{\epsilon^2})$ steps. Putting this together yields the following recursion for the time $t(\epsilon, w, n)$, where ϵ is the distance parameter, w is the width, and n is the length of the BP:

$$t(\epsilon,w,n) = \frac{4}{\epsilon} \cdot \left[O(\log n) + O\left(\frac{w^2}{\epsilon^2}\right) + O\left(\frac{w^2}{\epsilon^2} \log \frac{w}{\epsilon}\right) \right.$$
$$\left. \cdot O\left(\frac{w^2}{\epsilon} \cdot \log \frac{w^2}{\epsilon}\right) \cdot t(0.4\epsilon, w-1, n) \right].$$

The $\frac{4}{\epsilon}$ term comes from the number of i's chosen in the top level general test. The $\log n$ comes from sampling one i. The $O(\frac{w^2}{\epsilon^2})$ term comes from deciding the connectivity in A_2, and the rest come from A_1 multiplied by the number of calls to it from A_2.

Solving the above yields $t(\epsilon, w, n) = (\frac{2^w}{\epsilon})^{O(w)} \cdot \log n$.

4. Examples of interesting functions and open problems. We present here some examples of functions that have narrow width, read-once BPs and are "efficiently" testable. (Sometimes a direct efficient testing algorithm is obvious.) The first nontrivial such family is of all regular languages with a direct testing algorithm by [2]. We remark here that, for this case, our algorithm is conceptually different than that of [2]. The dependence of the query complexity on w in this case is similar to what would result from [2]. The dependence on ϵ is worse.

Other very simple families are k-term-DNF and k-clauses-CNF, each having 2^k-width oblivious read-once BP. A function $g : \{0,1\}^n \longrightarrow \{0,1\}$ is k-term-DNF if it has a DNF representation (a disjunction of terms where each is a conjunction of literals) with at most k terms. Analogously, a k-clause CNF is defined. Two remarks are due here: For both k-term-DNF and k-clause-CNF, ϵ-tests are known (folklore): k-term DNF is $(\epsilon, O(\frac{k \log k}{\epsilon}))$-testable by testing for each term separately. k-term CNF can be tested by 0 queries for any $\epsilon > \frac{k}{n}$ as such function is either constant or every input has distance at most k to a satisfiable one.

It is also interesting to note that 1-term-DNF includes examples of functions that are, say, in uniform $SPACE(\log\log n)$ but not regular and hence do not belong to $SPACE(o(\log\log n))$. One such interesting example is the following example of Papadimitriou [14]: Let b be a binary string without leading 0's. We denote by $n(b)$ the natural number whose binary representation is b. Let $L = \{b_1\$b_2\$\ldots\$b_k|\ n(b_i) = i\}$. Clearly $L \in SPACE(\log\log n)$. It is also not hard to see that L is not regular. However, as L contains at most one word of each length, it obviously has a BP of width $w = 1$. Note that, although we have here an alphabet of size 3, we may actually encode everything in binary by encoding each symbol with two bits.

In view of Theorem 1, one may ask what is the true dependence of ϵ-testing w-width read-once BPs on w and ϵ. This remains open at this point. Another more puzzling question is whether $SPACE(\log\log n)$ can be "efficiently" testable. (By this we mean with complexity, say, less than n^δ for any $\delta > 0$.) Currently we do not have any candidate for a counterexample to this.

Another issue is how far the current result may be generalized. One restriction that may be considered is being "read-once"—can this be replaced by, say, polynomial total size? To this, the answer is false: Barrington [4] has proved that every NC^1 function has a polynomial length oblivious leveled BP of width 5. However, in [2], examples of such functions that require $\theta(\sqrt{n})$ queries are presented. Hence, instead, one may ask whether constant width linear size BPs are testable. A negative answer is given in [9]: They show that there is a Boolean function $g : \{0,1\}^n \longrightarrow \{0,1\}$ that is computed by a read-twice constant width oblivious BP and that is not ϵ-testable for some fixed $\epsilon > 0$ (a read-k-times BP is a BP where each variable appears in at most k levels).

SELF-STABILIZING SYMMETRY BREAKING IN CONSTANT SPACE*

ALAIN MAYER†, RAFAIL OSTROVSKY‡, YORAM OFEK§, AND MOTI YUNG¶

Abstract. We investigate the problem of self-stabilizing round-robin token management on a bidirectional ring of identical processors. Each processor is an asynchronous probabilistic finite state (i.e., constant space) machine which sends and receives constant-size messages and whose state transition is triggered by the receipt of a message. We also show that this problem is equivalent to symmetry breaking (i.e., leader election).

We justify and suggest a two-layer (hardware and software) solution to the token management problem: The subproblem of reducing an arbitrary but nonzero number of tokens (in an otherwise arbitrary initial system state) to exactly one token (and a legal system state) is solved in hardware and takes only small polynomial time. The detection of a complete lack of tokens (communication deadlock) is done by a software clock. In high-speed networks the hardware layer can be implemented using fast universal switches (i.e., finite state machines) *independent* of the size of the network. We note that randomization is essential, since Dijkstra showed that for arbitrary rings the subproblem does not have a deterministic solution (regardless of the computational power of the identical processors). The use of the software layer (deadlock detection) in our solution is minimized.

Key words. self-stabilization, self-stabilizing protocols, distributed algorithms, token ring protocols, media access protocols

1. Introduction.

We consider a network whose topology is an arbitrary-size ring of uniform (identical) processors whose size is independent of the ring size. We use asynchronous message-passing. Each processor can change its state and send messages only upon receiving a message from one of its two adjacent neighbors. This is usually called a message-driven model (discussed further in section 2.2).

Our first goal is the design of a *fault-tolerant token management protocol*. A token management (TMA) scheme guarantees that the ring network always contains a predefined number of tokens which circulate in a round-robin fashion (e.g., a token in a token ring, slots in a slotted ring). In addition, any node waiting to see a token should be only minimally delayed. An important concern is to make the TMA scheme fault-tolerant. We aim at making the system able to recover from an arbitrary transient fault which puts the system in any (even maliciously chosen) state. In fact, Dijkstra considered such a fault-tolerant token management scheme in the shared memory model in his seminal paper, which introduced the notion of *self-stabilization*

[Dij74]. Informally, the goal of self-stabilization is for the system to reach "normal" operation, starting from an arbitrary initial state (see section 2.1 for more details). Of course, while making the scheme fault-tolerant, we should *not* sacrifice efficiency in both the speed and space requirements. That is, most of the solution should be realized in hardware and should rely as little as possible on a software clock or any other software mechanisms. (See Figure 1 and sections 1.1 and 2.2 for more details.)

Dijkstra's original solution assumed the presence of a leader. However, choosing a leader among identical processors is one of the most basic problems in distributed computing; a leader can coordinate any distributed task. How difficult is it to elect a leader in a self-stabilizing fashion in our model? Our second contribution is a pair of reductions (see section 2.4 for a definition) from leader election to self-stabilizing bidirectional round-robin TMA and vice versa. We show that token management and leader election are equally hard.

1.1. Design of hardware-based protocols. One motivation for considering the above model comes from existing architectures of high-speed communication networks. The bottleneck in these architectures is typically the speed of the processors with which they can process incoming messages. Hence, it is important that essential protocols, such as media access control, can be implemented in simple hardware. This enables a (constant-size) control message to go through many high-speed hardware switches (finite-state machines) and through many communication links during a single software clock-tick.

In many systems (e.g., token rings [BCK+83], MetaNet [OY90]; see section 8), fair access to the network is achieved by passing a single *token* (i.e., a constant-size control signal) in a round-robin fashion on a physical or logical ring. When a network node needs permission for a certain action, it waits for a token, holds it for a single unit of time, and then passes it on to other processors to ensure fairness.

The above approach is efficient only when being designed in hardware. Furthermore, the switching hardware should decide even before the token arrives if there is a need to hold it. This depends only on the local state and the requirements of the network node. For example, let us consider the case when only a single processor on a ring competes for a resource. The fact that the processor must give up a token to ensure fairness (i.e., to check if there is some other processor waiting) *does not* incur a slowdown proportional to the size of the ring. When the processor gives up a token it does not wait for the number of software clock-ticks proportional to the size of the ring: the constant-bit control message makes a full round without substantial delay by going through high-speed switches at each node and does not wait for software clock-ticks at any of them. Moreover, the constant-bit control signal essentially does not decrease the bandwidth of the communication links, making the above scheme useful in practice. The interplay between hardware and software is thus as follows: in normal operation the high-speed switch can work while the software monitors it. This implies the two-layer solution depicted in Figure 1. An efficient solution lets the software intervene only in rare "catastrophic" events (e.g., by employing long time intervals for time-outs).

1.2. Related work. Dijkstra [Dij73] showed that round-robin TMA, even when starting with two or more tokens, is impossible on a ring of unknown size of uniform and deterministic processors. He gave a solution in the presence of a leader. However, the problem of "whether a system of *probabilistic* automata can have a round-robin TMA scheme" remained open.

Israeli and Jalfon showed that if each token executes a symmetric random walk,

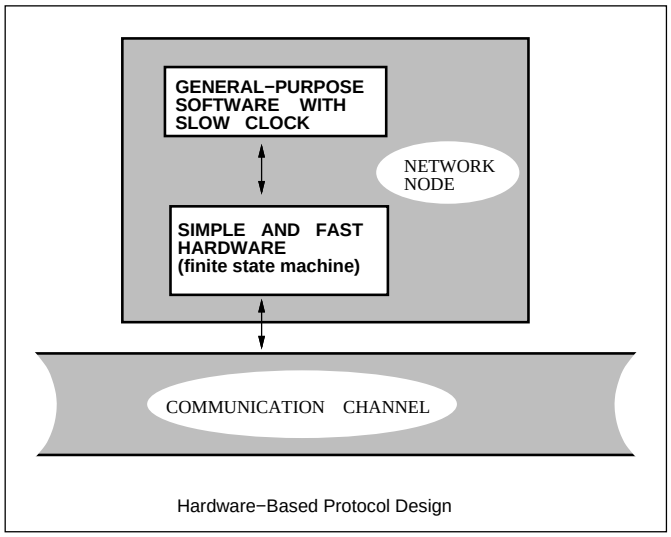

FIG. 1. *Node model.*

such that when two tokens meet one gets eliminated, then eventually only one token will remain [IJ90a]. Notice, however, that their solution gives up the round-robin property. This relaxation implies that its use is mainly for mutual exclusion (to solve contention). It cannot be used for regulation and fair coordination of the network communication medium, which is the usual task of token systems. Indeed, Lamport and Lynch [LL90] mention that "there is one important property that is harder to achieve in coordination problems than in contention—namely self-stabilization." It seems possible to extend the random walk solution to achieve a basic round-robin property: all tokens are sent only in one direction and at each step, each token flips a coin and either stays for a single clock-tick or advances; when two tokens meet, one gets eliminated. However, this solution increases the round-trip delay of a token and thus drastically decreases the throughput of the network, given that the token is used for access control.

Other solutions to self-stabilizing TMA either assume that there is a distinguished node (leader) or make further assumptions about the network size (such as the number of nodes being prime or odd). Leader election is a difficult problem (see section 6) and hence the assumption of having a distinguished node available at all times is very strong. In practice, the size of a token ring being constrained to be prime or odd is rather awkward. Brown, Gouda, and Wu [BGW89] and Afek and Brown [AB89] proposed solutions using a leader. Note that the first solution actually works for more general topologies than rings, while the latter is the only previous solution designed for the message-passing model. Burns and Pachl [BP88] and Herman [Her90] present solutions for special size rings. It is worthwhile mentioning that the first presents a deterministic and uniform solution and the latter is probabilistic and uniform.

There are many papers concerning self-stabilizing leader election (mostly on general topology networks), e.g., [AKY90, APV91, DIM91, KP90, IL94, AO94, ILS95]. All of them either are not message-driven and use the paradigm of local checking (introduced in [AKY90] and [APV91]), perform repeated snapshots [KP90], or use additional restrictions on the size of the ring [ILS95]. In section 2.2 we explain why these paradigms are not suitable for our purpose. Furthermore, most of the previ-

ous work uses logarithmic size memory (to use identification-based techniques). Following the preliminary version of this paper with its two-layer (hardware-software) and small memory approach, subsequent work paid attention to small space restrictions [IL94, AO94, PY94, ILS95]. In this context the work of [MOY96] further restricts this model to *unidirectional* networks in order to cover such architectures as FDDI (see section 8).

Organization of the rest of the paper. In section 2 we present our model and definitions and an overview of our results. In section 3 we present a straightforward modification of a known simple algorithm for the attrition problem on rings to make it "solve" TMA. We show that its fault-tolerance does not satisfy self-stabilization. In section 4 we present our TMA algorithm, and in section 5 we demonstrate correctness and give the time analysis. In sections 6 and 7 we present the reductions between the TMA problem and the leader election problem. In section 8 we present applications.

2. Model and results.

2.1. Self-stabilization. A system S consists of processors and their interconnection-links. The global state of S is the cross-product of the local states of its components. Let P denote a desired predicate over the global state, e.g., there exists a single token in the system.

An algorithm A in system S is self-stabilizing with respect to a predicate P if it satisfies the following two properties (following Schneider's survey [Schn93]):

- Closure: P is closed under the execution of A on S. That is, once P is established in S, A does not falsify it.
- Convergence: Starting from an arbitrary global state, A guarantees to reach a global state in S which st satisfies P.

The above definition covers at least the following: arbitrary inconsistencies when initializing the system S, transmission errors, process failure and its recovery, and memory loss and contamination. Note that this allows us from now on to concentrate on correct executions starting in an arbitrary initial state, rather than trying to cover the above problems case by case.

Arora and Gouda [AG92] introduced the notion of *stabilization* with respect to predicates P and Q as an algorithm which satisfies closure and convergence with respect to P, given that the initial state satisfies Q.

Some of our solutions are randomized. Correctness in this case generalizes the above definition of convergence to occur with probability 1.

2.2. Model of a high-speed ring network. In the following we describe our system S. We restrict ourselves to networks whose topology is a ring. We let n denote the number of nodes in the ring. Each processor (node) in the ring is a probabilistic, finite state machine (PFSM). The PFSM communicates with its two neighbors via asynchronous message-passing. That is, every message sent on a link is eventually received by the respective neighbor. The PFSM has a constant-size buffer for each of its two neighbors. Hence, the PFSM can receive only constant-size (control) messages. The PFSM performs a state transition and sends its own control messages only upon the receipt of such a message. Thus, the processing at a node is done in a message-driven, asynchronous fashion. This is in contrast to other self-stabilizing models, such as local checking, where each node is continuously requesting information from its immediate neighbors. Message-driven computing is better suited for our hardware-based model: There is no need for a notion of time and hence for a clock, which adds to the complexity of the required hardware. It also seems

problematic to find the right trade-off for the time-out value: A small value adds an unacceptable message overhead on each link of the network; a large value delays the stabilization-time. We can assume that the ring is oriented by using a self-stabilizing automata-based orientation protocol as suggested in [IJ90b]. A link between two nodes is modeled as two independent FIFO-channels. We allow neighboring nodes to detect *message collision* as a primitive event. That is, two control messages traveling in opposite directions are said to *collide* if they physically cross each other on the link.[1]

2.3. Self-stabilizing TMA and maintenance. Let predicate P be defined as follows: The set of global states in which there is exactly one token (in a buffer or on a link) in each direction and the state of each PFSM correctly reflects the last token passed through that node. We call a self-stabilizing algorithm for predicate P and system S a TMA scheme.

Let Q be the predicate over the global states in which there is at least one token. Node and token states are still arbitrary. We define *token maintenance* (TM) as the stabilization with respect to P and Q. As mentioned in section 1.2, it is exactly for the problem of TM that Dijkstra has shown that there is no general deterministic solution, namely either lack of stabilization or a deadlock must occur.

We define a TM algorithm to be *fair* if every node always sends a received token to the opposite neighbor within one time unit. This property is important for implementing fair media access control.

We say a TM is *nondeadlocking* if it never reaches a state with no tokens. In our context this is a requirement that prevents systems from relying on the slower (software) layer when not necessary.

2.4. Reduction. Let A be a self-stabilizing algorithm with respect to a predicate P. Let σ be the space requirement of A on each node and let τ be A's stabilization time.

DEFINITION 2.1. *We define Algorithm A' to be a* polynomial time space-preserving self-stabilizing reduction *to A with respect to a predicate P' and a system S if A' is executed concurrently with A in S, it stabilizes to P', its space requirement in addition to A's space on each node is $O(\sigma)$, its messages are of length $O(\sigma)$, and its stabilization time is $O(\tau + p(n))$, where p denotes an arbitrary polynomial.*

Note that the above definition allows Algorithm A' to introduce additional randomness.

2.5. Our results. Given the definition of system S and predicates P and Q in section 2.3, our first contribution is a fair, nondeadlocking stabilizing protocol for S with respect to P and Q (TM) with stabilization time $O(n \log n)$. An attractive feature of such a TM algorithm is that we can choose an *arbitrary* number of PFSMs, plug them together in a ring, and consequently obtain a correct token maintenance scheme. In a second step, our TM algorithm can be augmented to token management via the following two-layer approach: A node times out after it does not see a token for "long enough" and inserts a new token into the system S in an uncoordinated fashion, i.e., without consulting any other node. This time-out has to be dependent

[1] Our links are unit-capacity and so a handshake protocol for the control messages to detect a collision can be implemented. This is similar to [APV91] which showed this to be a necessary condition to avoid an initial state with infinitely flooded channels. Alternatively, if we assume an upper bound on the communication-delay for control messages over a single link, we can detect collision by using a local time-out as is done in practice.

on the ring size. Hence, the corresponding clock needs to be implemented in software. This software time-out needs only be triggered when all tokens in the system are lost within one round-trip delay and hence its use is minimized. Furthermore, if a nondeadlocking TM is used, each node times out at most once during the stabilization period and never times out once S has stabilized. This is in contrast to the type of time-out needed for implementing local checking.

Our second contribution is a pair of polynomial time space-preserving self-stabilizing reductions from TMA to leader election and vice versa. Given the fundamental significance of leader election in distributed computing, this result demonstrates that token management is a basic problem. Furthermore, given the result of Angluin [Ang80] about the impossibility to elect a leader deterministically among identical processors, this result provides an alternative proof that randomization is required for TM in our model.

3. A simple (and failed) approach for TM. Here we demonstrate the difference between self-stabilizing and non-self-stabilizing solutions. [AAGHK89] and [AAHK91] present algorithms for the attrition problem on rings. A procedure solves the attrition problem if, when initiated by every candidate, it eventually takes all but exactly one of these candidates into a permanent state of noncontention. In order to appreciate the inherent difficulty of the self-stabilizing TM problem, we modify an attrition algorithm in order to make it "solve" the TM problem and show that such an approach is not powerful enough.

Consider the code below. Assume that tokens are generated by some time-out mechanism, as advocated in section 2.5. When a node times out, it becomes active and executes the loop below. Inactive nodes simply forward tokens unchanged. The state space of a node consists of the following two local variables: $active \in \{true, false\}$ and $flip \in \{heads, tails\}$. The state space of a token is the variable $value \in \{heads, tails\}$. The complete state space of a node or a link includes the tokens which currently are located at that device.

```
while active do
        flip := random independent uniform coin toss
        value(token) := flip
        send(token)
        receive(next-token)
        if flip = heads and value(next-token) = tails, then active := false
end while
```

Arbitrary initial states in this state space include the following:

1. All nodes are inactive and there is more than one token.
2. There is one token (say, with value = heads) and one active node (say, with flip = tails).
3. There are more tokens than active nodes.
4. There are more active nodes than tokens.

For initial states 1 and 3 the above protocol remains indefinitely in states in which there is more than one token; the protocol does not guarantee convergence. For initial states 2 and 4 it is possible that a state is reached in which there are no tokens, hence the protocol is deadlocking. In general, it is not hard to see that the number of active nodes equals the number of tokens is a necessary condition for nondeadlocking convergence to states in which there is exactly one token circulating. The above algorithm cannot deal with inconsistent initialization, which is an important aspect of self-stabilization (see section 2.1).

4. The TM algorithm *A*. In this section we present first high level ideas and then an exact formulation of the fair and nondeadlocking TM algorithm A on a bidirectional ring. The algorithm stabilizes to a state in which exactly one token circulates in each direction of the ring. Any client program is free to choose one of these tokens as its unique token with respect to the network-function associated with it (e.g., access control). We call tokens circulating in one direction *positive* tokens and the token circulating in the opposite direction *negative* tokens.

4.1. Basic ingredients. The following type of control messages are used:

- Tokens: A token t is a constant-size message which carries a value $V(t) \in \{-3, -2, -1, 1, 2, 3\}$. Tokens which go clockwise always have a positive value, and tokens which go counter-clockwise always have a negative value. When a token passes through a node, it leaves a "footprint" of its value on this node, overwriting any previous "footprint."
- Probes: A probe p is also a constant-size message, but it does not leave any "footprints." Probes also carry a value $V(p) \in \{-3, -2, -1, 1, 2, 3\}$.

Nodes store "footprints" of passing tokens. When we say that node i has a certain "value" $V(i)$, we mean the value of its current "footprint."

Having introduced the basic elements, we now present an overview of the algorithm: We note that line numbers used in this overview refer to lines in the code-like description of the algorithm, which can be found in section 4.3. The most basic operation of a node i is to receive a token t, copy the value (or footprint) of t into its own register ($V(i) := V(t)$), and forward the token (lines B10 and B11). In order to make the system self-stabilizing we need to add at least the following two mechanisms: *token generation* and *token elimination*. It should be noted at this point that both operations use local information only. As we will see later, this implies that these decisions are not always optimal with respect to the global state. In particular, it is possible that they cause the number of tokens in the system to increase temporarily. But overall, the system gets "more organized" with each step and thus convergence to a legal state is assured. In order to implement elimination, we introduce the notion of a *token collision*. Every time a positive and a negative token (t_1 and t_2) meet on the ring, they execute a collision operation. A collision between t_1 and t_2 consists of executing the following operations: if t_1 and t_2 have identical absolute values ($|V(t_1)| = |V(t_2)|$), then the tokens flip a fair coin to agree on a new, distinct value (lines A4, A5) while maintaining their sign (see Figure 2). In other words, they agree on new, up to the sign identical, footprints. In the other case, where their absolute values are different (e.g., $|V(t_1)| < |V(t_2)|$), the token with the smaller absolute value (e.g., t_1) is eliminated (line A2). The intuition behind the collision operation is the following: if two tokens have distinct values and these values originate from a previous collision, then there must be more than one pair of tokens in the system. If the (absolute) values are equal, we still cannot be sure that there is really just one pair, so we must continue to check, i.e., choose a new random value. Note that the above is the only condition on which a token is eliminated and thus the nondeadlocking property of the algorithm follows easily. As mentioned in section 2.2, a collision can be detected by the corresponding endpoints, which in reality are the entities executing the above operations.

Now let us focus on the generation operation: when a token t arrives at node i and sees a footprint identical to its own ($V(t) = V(i)$), it assumes that the footprint at node i was left behind by itself. If this assumption is correct, it implies that neither token t nor node i has seen another token since t left i at its last visit. In that case t

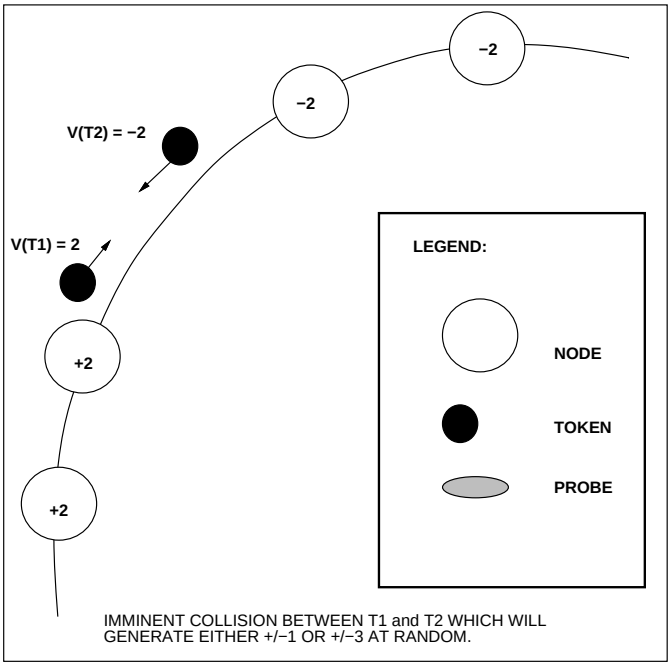

FIG. 2. *Token collision.*

can conclude that it is the only token left in the system and generates a new token of opposite sign (see Figure 3). The idea of token generation based on marking has been used by [Mis83] for unidirectional rings, though his method is different and actually uses $O(\log n)$ space.

So far we have described the collision (and thus the elimination) and the generation operation. Unfortunately, this is not enough to ensure convergence. To see why, consider a state in which all tokens travel in the same direction (we call such a state *skewed*). In such a state there are only positive (or only negative) tokens left; if each pair of neighboring tokens leaves distinct footprints behind, neither a collision nor a generation will ever take place.

To overcome this difficulty we introduce "exploration" by a second kind of message, called a *probe*. As we will show now, probes are used to explore the current state and, if appropriate, turn around a token from positive to negative (or vice versa). Probes are always generated by tokens ("fathers") in pairs ("siblings"). Siblings travel in opposite directions to each other. A probe traveling in the same direction as its father token is called a *forward probe*; analogously, a probe traveling in the opposite direction is called a *backward probe*. Now, every time a token suspects that the system is in a skewed state, it sends a forward and backward probe to "explore" the global situation. The condition to send probes is enabled when a token sees footprints (values) of a token of the same kind (direction) which are larger (in absolute values) than its own. So, for example, a positive token t will send out probes if, upon arriving at some node i, the condition $V(t) < V(i)$ holds (line B6). A probe p is basically carrying the value of its father ($V(p) = V(t)$) and an enabled/disabled bit (initially enabled).

After a probe p has been generated (and p is enabled), one of the following two events will occur: (i) p meets or collides with a token t which has a value of opposite

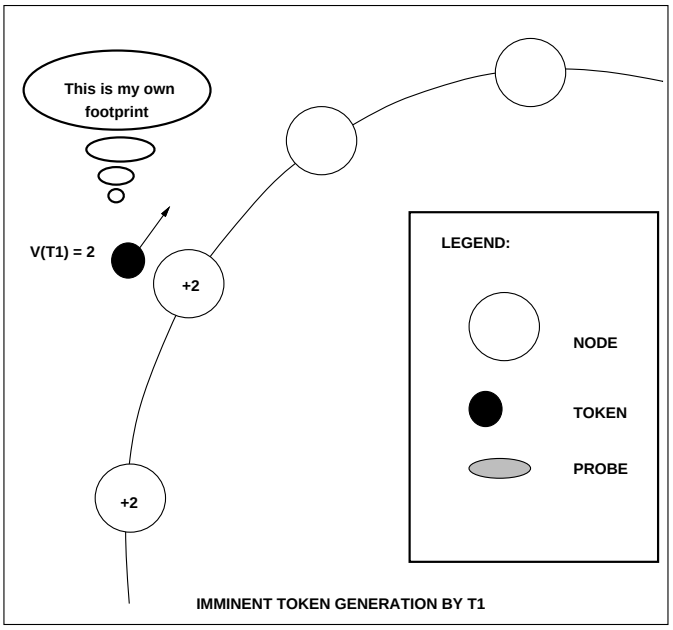

FIG. 3. *Token generation.*

sign ($V(p)V(t) < 0$) or (ii) p collides with a probe p' which has the same value as p and p thus assumes that p' is its sibling. In the first case, p has obtained evidence (i.e., the token t) that the current state is not skewed and thus p will be disabled (lines D1–D2, E1–E2). In the second case, p has not obtained any evidence that the current state is not skewed, so it will rely on the experience of p', since if p' is indeed p's sibling, these two probes have together covered the whole ring. If both are still enabled, then the probes conclude that the current state is indeed skewed, and thus the backward probe, whose next collision is with its father-token, will change the sign (and direction) of its father (line E9). Otherwise, they conclude (correctly) that the current state still contains tokens of opposite sign, and thus they eliminate each other (line F7).

4.2. How to piece the basic operations together. It is easy to reconstruct how a lone token will generate a token of opposite sign. So we provide now an intuition on how the operations described above work together to reduce the number of tokens, if there are more tokens in the system than just one positive and one negative. Consider the following simple observation: Let $r, v \in \{1, 2, 3\}$. Let r be a random value and v be either an arbitrary ("initial") value or another independently obtained random value. Thus $\Pr(r \neq v) > 0$ and in an infinite sequence of comparisons of two such values we get a mismatch with probability 1.

Now, if in a collision at least one of the tokens carries a value obtained in a previous collision (and is thus random), then exactly the comparison operation described above will be executed and a token will be eliminated if there is a mismatch. Thus our strategy should be to ensure that this kind of collision is repeatedly going to take place as long as the system has not stabilized to one pair of tokens. In order to show this, we have to make sure that probes which originate from an "initial" state or have been produced erroneously are not an obstacle by causing tokens to repeatedly

turn and thus preventing these useful collisions. This will be done by again using our simple observation with respect to comparing values when (erroneous) backward probes and tokens collide. Thus we will be able to conclude that despite the presence of arbitrary probes, the system stabilizes to exactly one pair of tokens.

All we have to add to make the algorithm complete are conditions on which a disabled probe who does not have a sibling probe (anymore) can be eliminated from the system. Note that this task is facilitated by the fact that erroneous decisions are not affecting the convergence of the tokens.

It should be mentioned that the condition for a token to send out probes will be true in a skewed state every time it visits a node. This condition can also hold in a nonskewed state and even in a stabilized state. But on the other hand, only one forward and one backward probe of each value is needed and there are only 3 values. Hence, constant buffer size at each node is sufficient (a node receiving a second probe before sending out the first can simply delete the second probe). Given the constant size of probes, the communication-overhead in a stabilized state is minimal.

4.3. Formal description of the algorithm. In the following, we present the different types of messages used in the algorithm:

- *positive tokens*: circulating clockwise on the ring;
- *negative tokens*: circulating counter-clockwise on the ring;
- *probes*: tokens can send out probes to avoid getting stuck in an skewed state. A token will send out probes in both directions. A probe circulating in the same direction as its father token is called a *forward probe*, otherwise it is called a *backward probe*.

Next we present the data-structures used by the algorithm:

- $V(i)$: value of node i ($1 \leq |V(i)| \leq 3$).
- $V(t)$: value of token t ($1 \leq |V(t)| \leq 3$).
- $S(t)$: bit indicating that token t is currently sending out probes. This bit holds from the time a pair of probes is generated until t's next collision or turn. $S(t)$ is used as a guard for the turn operation.
- $L(t)$: value of node that t visited last.
- $V(p)$: value of probe p. $V(p)$ indicates the value of probe p's father-token. The test $V(t) = V(p)$ is used as a guard to turn a token t. The test $V(p_1) = V(p_2)$ is used to detect sibling probes upon a collision of two probes.
- $E(p)$: bit indicating whether the probe p is enabled.
- $T(p)$: if p is a backward probe and has decided to turn its father-token, then this bit is set.

Next we describe the algorithm by stating what is done on each message-driven event.

Positive token t_1 and negative token t_2 collide:
A1: IF $|V(t_1)| \neq |V(t_2)|$, THEN
A2: eliminate token with smaller absolute value
A3: ELSE
A4: $V(t_1) :=$ RANDOM($\{1, 2, 3\} - \{V(t_1)\}$);
A5: $V(t_2) := -V(t_1)$
A6: END;
A7: $S(t_1) :=$ FALSE; $S(t_2) :=$ FALSE;

Node i receives positive token t:
B1: IF $V(i) = V(t)$, THEN
B2: generate token t' (* negative *);
B3: $V(t) :=$ RANDOM($\{1, 2, 3\} - \{V(t)\}$);
B4: $V(t') := -V(t)$; $L(t') := V(i)$;
B5: $S(t) :=$ FALSE; $S(t') :=$ FALSE
B6: ELSIF $V(t) < V(i)$, THEN (* t follows a larger-valued, positive token *)
B7: generate forward probe p_1 and backward probe p_2;
B8: $V(p_{1,2}) := V(t)$; $E(p_{1,2}) :=$ TRUE;
B9: $T(p_{1,2}) :=$ FALSE;
B8: $S(t) :=$ TRUE
B9: END;
B10: $L(t) := V(i)$; $V(i) := V(t)$;
B11: send positive token t (and negative token if one newly generated)

Node i receives negative token t:
symmetric to the receipt of a positive token

Node i receives forward probe p:
C1: send probe p

Node i receives backward probe p:
D1: IF $(V(i)V(p) < 0)$ AND $E(p)$, THEN
D2: $E(p) :=$ FALSE
D3: END;
D4: send probe p

Token t and probe p collide:
E1: IF $V(t)V(p) < 0$, THEN (* p is a forward probe *)
E2: IF $E(p)$, THEN $E(p) :=$ FALSE
E3: ELSE eliminate p
E4: END
E5 ELSE (* p is a backward probe *)
E6: IF $\neg E(p)$, THEN eliminate p
E7: ELSIF $E(p)$ AND $T(p)$, THEN
E8: IF $(V(p) = V(t))$ AND $S(t)$, THEN
E9: turn t;
E10: $V(t) := -L(t)$;
E11: $S(t) :=$ FALSE
E12: END;
E13: eliminate p
E14: END
E15: END

Forward probe p_1 and backward probe p_2 collide:
F1: IF $V(p_1) = V(p_2)$, THEN
F2: IF $E(p_1)$ AND $E(p_2)$, THEN
F3: $T(p_2) :=$ TRUE;
F4: eliminate p_1
F5: ELSE eliminate p_1 and p_2
F6: END
F7: END

Note that we make use of a function RANDOM(S) which returns a random value drawn from the set S. We only use it for sets of size 2 and thus it can be thought to be a fair coin.

5. Analysis. In this section we give a correctness proof of the TM algorithm introduced in the previous sections, and we analyze its stabilization time.

Let $t(n)$ be the expected stabilization time. The stabilization time is the time interval starting at the end of the last transient fault and ending when the system has

reached a legal state. Our main theorem is as follows.

THEOREM. *Algorithm A is a fair and nondeadlocking self-stabilizing TM algorithm for system S with* $t(n) = O(n \log n)$.

Since the proof is quite involved, we will precede its presentation with a subsection introducing all necessary definitions and a subsection giving an overview.

5.1. Definitions. We start with defining a global state of the system and the transitions among those global states. A global state is basically the value of each node, the value of each token, and the positions of the tokens on the ring. A transition from a state to its successor state consists of either a collision among two tokens, or a turn of a token, or a generation of a token. Further we define a local state of a ring segment with respect to the probes present on it. Note that probes are "invisible" in the global state. One can think of a local state as putting a magnifying glass on a segment of the ring.

DEFINITION 5.1 (local and global state, state transition, segment).

1. *The* global state *of the system is defined by*
   - *for each token t, its value* $V(t)$,
   - *the positions of the tokens on the ring,*
   - *for each node i, its value* $V(i)$.
2. *The* (global) state transition *from state s to state* s' *is defined by a* successor *function* $S : s' = S(s)$, *where* s' *results from s by applying one of the following transitions:* {*collision, turn, generation*}. *A node copying a new value from a passing token is strictly speaking also a state transition. But for our purposes this is not an "interesting" operation by itself. Let* $S^j(s)$ *be the* j*th successor of s.*
3. $|s|$ *denotes the number of tokens in state s.*
4. *A sequence of nodes starting at some node i and ending at some node j, such that* $V(i) = V(i+1) = \cdots = V(j)$ *is called a* segment σ *of value* $V(\sigma) = V(i)$. *We will say that a token or a probe is* on *segment* σ *if it is on a node k,* $i \le k \le j$, *or if it is on a link* $(l, l+1)$, $i \le l < j$. *We will use the symbol t alternatively for the token itself or for the segment the token t creates by leaving its footprints behind.*
5. *The* local state *of a segment* σ *in a global state s is defined by*
   - *its value* $V(\sigma)$,
   - *for each probes p on* σ, *its value* $V(p)$ *and its position. Let* $f^\sigma(s)$ $(b^\sigma(s))$ *denote the set of enabled forward probes (backward probes) on* σ.

In terms of the above definition we can now define the correctness condition for TM.

DEFINITION 5.2 (correctness). *For an* arbitrary *state s with* $|s| \ge 1$ *there are infinitely many successor-states and, in particular, there is a state* $S^l(s)$ *such that* $|S^l(s)| = 2$ *and every state* $S^{l'}(s)$ $(l' > l)$ *results from a collision of two tokens with identical absolute value.*

Since "initially" we have no control over the values stored in the nodes or on the tokens, we will define now a predicate over states, which will indicate that, although the system may not have stabilized yet (and indeed might have more tokens than "initially"), we have reached a certain level of order in the system. Intuitively, this means that every node has at least seen one token, and thus the neighborhood of a token is no longer influenced by the "initial" state.

DEFINITION 5.3 (cover). *We say that a state s has the predicate* cover, *i.e., cover(s), if*

FIG. 4. *Sequence of pairs.*

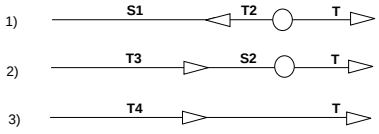

FIG. 5. *"Outgoing" covers.*

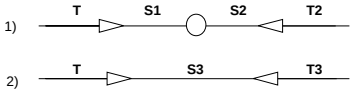

FIG. 6. *"Ingoing" covers.*

- $|s| \geq 2$;
- *the ring is a concatenation of segments, such that a segment boundary is either at the current position of a token or at a previous collision-point. Following the scenario in Figure* 4*, we enumerate all allowable neighborhoods first to the left of a (positive) token* t *and then to the right of* t*. ("$\triangleleft$", "$\triangleright$" denote tokens (and their direction), "$\bigcirc$" denote previous collision-points,* s*'s denote segments, and* t*'s denote tokens and the segment they are creating.) Tokens traveling from left to right are positive tokens and thus their value is always positive. Tokens traveling from right to left are negative tokens and carry a negative value.*
  The values in the scenarios of Figure 5 *are constrained as follows:* $|V(t2)| = |V(t)|$, $|V(s1)| \neq |V(t2)|$; $V(s2) = -V(t)$, $|V(t3)| \neq |V(s2)|$; $V(t4) \neq V(t)$.
  The values in the scenarios of Figure 6 *are constrained as follows:* $|V(s1)| \neq |V(t)|$, $V(s2) = -V(s1) : |V(t2)| \neq |V(s2)|$, $|V(s3)| \neq |V(t)| : |V(s3)| \neq |V(t3)|$.

We conclude this section with the following sequence of simple definitions.

DEFINITION 5.4 (fragment). *A* fragment *is a largest concatenation of segments, such that the structural requirement of a cover is still fulfilled and at least one token is present on this part of the ring.*

DEFINITION 5.5 (block). *We say that a segment* σ *has the predicate* block *in state* s*, i.e., block(*σ*,* s*), if all probes in* $b^{\sigma}(s)$ *have identical values.*

DEFINITION 5.6 (state as a sequence of pairs). *If for state* s *cover(*s*) holds, then we can view* s *alternatively as a sequence of pair of numbers. Every pair represents one token and the segment it is traveling on (through its* token *component and* segment

component).

For example, the cover in Figure 4 corresponds to the sequence $s = (t1, s1)(t2, s1)(t3, s2)(t4, s2)$.

5.2. Overview of the proof. The proof will be structured as follows: For every state s with $s \geq 1$ we define a *subgoal* and show that this subgoal will indeed be reached. For every possible sequence of these subgoals, the last one is always to reach stability. Thus, if the algorithm reaches for each state the desired subgoal, correctness is assured. The following is now a list of different states and their subgoals:

1. For a state s with $|s| \geq 1$ and $\neg cover(s)$ the subgoal is to show that there is a successor state $S^{l_1}(s)$ for which $cover(S^{l_1}(s))$ holds. Note that it is very well possible that $|S^{l_1}(s)| > |s|$ and thus, at first glance, the successor state seems to be farther away from our ultimate goal. However, the predicate cover implies that we have reached a higher level of order in the system, since as soon as cover holds, no generation transition can take place anymore and cover is a stable predicate. Thus, it guarantees that the system does not move away anymore from its goal state (by generating additional tokens). Another important fact is that any state with a cover has a successor state. If the state is skewed, this property holds thanks to our probes scheme.
2. For a state s with $cover(s)$, $|s| > 2$, and $|s|$ being odd, the subgoal is to show that there is a successor state $S^{l_2}(s)$ such that either $|S^{l_2}(s)| < |s|$ or $\Pr(|S^{l_2}| < |s|) > 0$. If the first disjunctive part of our goal holds, then we have made direct progress towards the goal state; otherwise, we must have at least reached a state in which we could have made progress, i.e., there was a nonzero probability to reduce the number of tokens in the transition to this state. This probability follows from the fact that in a state with an odd number of tokens, there will be always at least one token which collides consecutively with at least two other tokens. Since in the first collision it picked up a random value independent of the rest of the system, the subgoal follows.
3. For a state s with $cover(s)$, $|s| > 2$, and $|s|$ being even, the subgoal is to show that either $|S^{l_3}(s)| < |s|$ or $\Pr(|S^{l_3}(s)| < |s|) > 0$ or there is a pair of tokens (t_1, t_2) of the following form $(t_1, \sigma_1)(t_2, \sigma_2)$ such that $\Pr(block(\sigma_2, S^{l_3}(s))) > 0$. Thus, in the case in which there is an even number of tokens, we restrict ourselves to an even more modest goal. This is necessary since tokens can (at least temporarily) form pairs such that every token collides only with its partner and then turns and repeats this cycle. However note that in order to turn, a token needs to be supplied with probes. Now if a *block* of probes is on the adjacent segment of a token, then the token, which carries a random value independent of the rest of the system, has a nonzero probability to mismatch these probes and will break out of its local cycle.
4. For a state s with $|s| = 2$, $cover(s)$, the subgoal is to show that the leftover probes will eventually be removed from the system. This task is considerably simplified by the fact that as long as the system is in a state with more than two tokens, we are allowed to make "mistakes" with respect to this task, since we have shown convergence to a state with two tokens for arbitrary configurations of probes.
5. For a state s with $s = (t_1, \sigma_1)(t_2, \sigma_2)$, we show that if there are no leftover probes, we have reached stability.

The rest of the proof basically ties all the above subgoals together and shows that in an infinite sequence of states, the desired stable state is reached with probability 1.

5.3. Correctness proof. In order to prove our main theorem, we will introduce a series of lemmas. The first lemma addresses the nondeadlocking property of the algorithm.

LEMMA 5.7. *For every state s for which $|s| \geq 1$, $\forall l > 0$, $|S^l(s)| \geq 1$.*

Proof. The only condition on which a token is eliminated is the collision of two tokens (line A1 in the algorithm). Thus, every time a token is eliminated another token survives. □

The following lemma proves that we reach our first subgoal, a state s for which $cover(s)$ holds.

LEMMA 5.8. *For every state s, for which $|s| \geq 1$, there exists a finite $l > 0$ such that $cover(S^l(s))$ holds.*

Proof. First we need to show that every state s, for which $\neg cover(s)$ holds, has a successor state: (i) s is skewed, $|s| \geq 2$: Assume that no transition takes places. Then eventually $s = (t_1, \sigma_1)(t_2, \sigma_2) \dots (t_{|s|}, \sigma_{|s|})$, where all $V(t_i)$ are either positive or negative and $\sigma_i = t_{i+1}$. Thus, as can be easily seen, $cover(s)$ holds. (ii) s is not skewed, $|s| \geq 2$: There are always two opposite tokens facing each other with no other token in between. Thus, either a turn or a collision transition is imminent. (iii) $|s| = 1$: If the token does not turn, then a generation transition will take place after at most one round.

Consider a link $(i, i+1)$ as a pair of values of its end-nodes $(V(i), V(i+1))$ together with the values of tokens which might be in transit on this link. Based on this information, we can decide for every link whether it could be a part of a fragment, i.e., the link is *consistent*.

First note that if a token has crossed a link and updated the value of the destination-node, the link will become consistent. Thus, a token can enlarge a fragment by crossing the first inconsistent link outside of its fragment. In that case, we say that the token is at the *border* of its fragment. Further, every generation, collision, and turn transition preserves the fragment in which (or at whose border) it occurs (see lines A1–A6, B2–B4, E9–E10). Hence the consistency of a link is a stable property.

Consequently, it remains to show that eventually every link will be crossed by a token and that at least two tokens will be present: By Lemma 5.7, all successor states have at least one token and thus at least one fragment. Assume that there is a fragment which does not grow and assume that the token t at the border of this fragment is moving away from the border (if not it will either turn and thus move away or enlarge the fragment). At some point it will either turn or collide with another token t' (otherwise t would enlarge the fragment on the other border). Assume without loss of generality that in the latter case t' survives the collision and thus is now moving towards the border of the fragment. t left footprints of opposite sign and thus t' cannot turn until it reaches a node which t never visited. Thus, we have shown a contradiction.

If a state is reached with a single fragment spanning the whole ring and just one token is alive, then after at most one round a second token will be generated (condition on line B1), and thus a cover will have been reached. □

The next few lemmas show that the cover predicate is stable and well defined with respect to the successor function. We also show that no generation can take place in a state in which the cover predicate holds.

LEMMA 5.9. *Every state s, for which $cover(s)$ holds, has a successor state.*

Proof.

- s is skewed: If no transition takes place then eventually $s = (t_1, \sigma_1)(t_2, \sigma_2) \dots$

$(t_{|s|}, \sigma_{|s|})$, where $V(t_i)$ are either all positive or all negative and $\sigma_i = t_{i+1}$. Thus, for at least one token t_i the condition to send out probes (line B7 or the symmetric case) will be true every time t_i visits a node. t_i sends forward probes on σ_i and backward probes on t_i. Given the structure of s, these probes cannot be disabled (i.e., conditions on lines D1, C1, and E1 cannot become true). Thus, two enabled siblings (or probes from two tokens with the same value) will meet and thus the T-bit on the backward probe is set and a token (which still has the S-bit set) is turned.

- s is not skewed and consequently there is a fragment $(t_1, \sigma_1)(t_2, \sigma_2)$, where $V(t_1) > 0$, $V(t_2) < 0$. Thus, a turn transition or a collision transition is imminent. □

LEMMA 5.10. *For every state s for which cover(s) holds, $|S(s)| \leq |s|$.*

Proof. By definition of a cover, the only condition on which the algorithm generates a new token (line B1 in the algorithm) cannot be enabled in s. □

LEMMA 5.11. *For every state s for which cover(s) holds, cover($S(s)$) holds.*

Proof. By Lemma 5.10, there is no generation transition leading out of s. Given that $|s| > 2$, every possible collision transition preserves the cover (see lines A1–A6). In every turn transition, the new absolute value of the turned token is the same as the value of the token it was following, and thus the result is identical to a collision (see lines E10 and B10). Also, if $|s| = 2$ and cover(s) holds, then, by definition of a cover, all collisions will take place between tokens of equal absolute value and so $|s|$ will always remain two. □

LEMMA 5.12. *For every state s, for which cover(s) holds, there exists a finite $l > 0$ such that $S^l(s)$ results from a collision transition.*

Proof. By Lemma 5.9, we have always a "next" transition, and by Lemma 5.10, there is no generation transition. If all successor states of s were results of turn transitions, then the sum of the absolute values of all tokens would steadily increase. Remember that the new value of a token t after its turn is set to $-L(t)$, where $L(t) = V(i)$ for i being the last node visited. And $S(t)$ is set only if $V(i) > V(t)$. Also, since cover(s) holds and t does not collide, it remains on the same segment from the time $S(t)$ is set until it turns. See lines (B10, B6, B7, E10). Since this sum is bounded, this is not possible. □

LEMMA 5.13. *Starting in any state s for which cover(s) holds, no token will be in two or more consecutive turn transitions.*

Proof. After a token t has been in a turn transition, its absolute value ($|V(t)|$) has been increased. Furthermore, it is traveling on a segment whose absolute value is t's old value (see the definition of *cover*), and thus $S(t)$ is false. Hence, as long as it is on this segment, t will not turn again. t can leave this segment only through a collision-transition. The lemma follows. □

LEMMA 5.14. *For every state s for which cover(s) holds, and for every token t in s, there exists a finite $l_t > 0$ such that $S^{l_t}(s)$ results from a collision transition involving token t.*

Proof. By induction on $|s|$, we have the following:

Basis: $|s| = 2$: follows immediately from Lemma 5.12.

Hypothesis: $|s| = n$.

Step: $|s| = n + 1$. Assume that token t will never be involved in a collision transition. Then by Lemma 5.13, t can be involved in only one turn transition. Thus, token t will be neither in a turn transition nor in a collision transition for infinitely many successor states. By definition of a cover, token t will eventually be in the

following fragment: $(t, \sigma_1)(t', \sigma_2)$, where $V(t)$ and σ_1 are either both positive or both negative and $t' = \sigma_1$. Now, if t' turns, then t is in a collision. If t' is in a collision where one token is eliminated, then we can apply the hypothesis. If no token is eliminated, then t is in a collision. Thus t' cannot be in a turn transition nor in a collision transition. It will eventually be in a analogous fragment as t. Then we can look at t''s right neighbor, etc. Finally, we will get a contradiction with Lemma 5.9 and thus our assumption that t will never be involved in a collision transition was wrong. ∎

The next lemma shows that any token which is involved in at least two consecutive collisions creates a nonzero probability that a token will be eliminated.

LEMMA 5.15. *The following two statements concern probabilistic elimination of tokens and hold in any state s with cover(s):*

(1) *If, starting in state s, there is at least one token which consecutively collides with at least two opposite tokens (let $S^k(s)$ be the state resulting from the second collision), then* $\Pr(|S^k(s)| < |s|) > 0$.
(2) *If* $\Pr(|S^k(s)| < |s|) = 0$, *then every token has collided with at most one opposite token during all transitions leading from s to $S^k(s)$.*

Proof. (1) The value the token carries after a first collision is random and independent of any other value in the system. Thus, there is a nonzero probability that in a second consecutive collision the tokens carry distinct absolute values, and consequently there is a nonzero probability that one of the tokens involved in the collision will be eliminated (see lines A1–A2). In addition, no new tokens are generated (by Lemma 5.10). (2) follows from the contraposition of (1) and Lemma 5.13. Note that a token needs to turn at least once between any two collisions to ensure that $\Pr(.) = 0$, and by Lemma 5.13 a token can turn at most once. ∎

The next lemma shows that our second subgoal will be reached.

LEMMA 5.16. *For every state s with odd$(|s|)$ and cover(s), there exists a finite $l > 0$, such that* $(|S^l(s)| < |s|) \vee (\Pr(|S^l(s)| < |s|) > 0)$.

Proof. By Lemma 5.14, every token t present in s will be eventually involved in a collision transition with another token t'. If one of these tokens is eliminated, then we are done. Otherwise the fragment of these two tokens right after the collision looks as follows: $(t, \sigma_1)(t', \sigma_2)$, where $V(t), V(\sigma_2) < 0$ and $V(t'), V(\sigma_1) > 0$. Since the number of tokens in s is odd, there will be a token t which, after its first collision with t', will be involved in a collision with a different token t'' ($t'' \neq t'$). By Lemma 5.13, there cannot be two or more consecutive turns by a token. Thus t must have been involved in two consecutive collisions. Now we can use Lemma 5.15 and we are done. ∎

DEFINITION 5.17 (partner, pair, local cycle, neighbor).

- *Starting in some state s for which cover(s) and even$(|s|)$ hold, $|s| > 2$, we call two tokens involved in their first collision* partners *with respect to state s, and the function partner$_s(t)$ yields the partner of token t with respect to state s. By Lemma* 5.14*, this function is well defined. Both partners together form a* pair.
- *A* local cycle *of a pair is a sequence of the three transitions which brings both tokens back to the same relative position: Each token is involved in a turn transition and in a collision transition with its partner. Note that if both tokens started out with the same value, this is exactly the scenario for which the probability of decreasing the number of tokens is zero (Lemma* 5.15*).*
- *The two tokens on the left and on the right (which might coincide) of a pair are called* neighbors *of that pair.*

The next few lemmas provide useful facts about pairs of tokens and the local state of adjacent segments.

LEMMA 5.18. *Let s be a state, such that cover(s) holds, $|s| > 2$, and even($|s|$) holds. If in s the neighbors of a pair are not a pair, or if a pair does not correspond to one of the following fragments, then there exists a finite $l > 0$, such that $(|S^l(s)| < |s|) \vee (\Pr(|S^l(s)| < |s|) > 0)$. For any pair the fragment is in one of the following scenarios. $(t, \sigma_1)(partner_s(t), \sigma_2)$ with the following restrictions:*

1. *Pair is about to collide: $V(t) > 0$, $V(partner_s(t)) < 0$, $|V(t)| = |V(partner_s(t))|$, $\sigma_1 = \sigma_2$.*
2. *Pair right after collision: $V(t) < 0$, $V(partner_s(t)) > 0$, $|V(t)| = |V(partner_s(t))|$.*
3. *Both tokens in positive direction: $V(t) > 0$, $V(partner_s(t)) > 0$, $|V(t)| > |V(partner_s(t))|$, $|V(\sigma_2)| = |V(t)|$.*
4. *Both tokens in negative direction: $V(t) < 0$, $V(partner_s(t)) < 0$, $|V(t)| < |V(partner_s(t))|$, $|V(\sigma_1)| = |V(partner_s(t))|$.*

Proof. If the neighbors are not a pair, an argument similar to the proof of Lemma 5.16 shows that a token must be involved in two consecutive collisions. If a pair is not in one of the scenarios above, a collision transition with an elimination is imminent. □

LEMMA 5.19. *If in state s (cover(s), $|s| > 2$, even($|s|$) both hold) a pair is in scenario 2, then for every probe $p \in b^{\sigma_1}(s)$ (where $V(\sigma_1) < 0$) the value $V(p)$ is mutually independent from $V(t)$ (and symmetrically for $p \in b^{\sigma_2}(s)$).*

Proof. For every probe $p \in b^{\sigma_1}(s)$ we can conclude that token t cannot have produced p since its last collision because its partner creates a segment of opposite sign (cf. scenario 2). The lemma follows now since the value $V(t)$ is random and mutually independent from every other value in the system. □

LEMMA 5.20. *If in state s (cover(s), $|s| > 2$, even($|s|$) both hold) a pair is in scenario 2, and for at least one of t or $partner_s(t)$ the next transition is not a turn, then there exists a finite $l > 0$, such that $(|S^l(s)| < |s|) \vee (\Pr(|S^l(s)| < |s|) > 0)$.*

Proof. Assume without loss of generality that t's next transition is not a turn. By Lemma 5.14, every token will be involved in a collision leading into a successor state (and thus every token is involved in a future transition). From this it follows that t will be involved in a future transition and the only transition which is possible is a collision. If the other token involved in this particular transition is not $partner_s(t)$, then we can apply Lemma 5.15; if this token is indeed $partner_s(t)$, then, since $|s| > 2$, $partner_s(t)$ must have been in at least two consecutive collisions, and thus we can also apply Lemma 5.15 with respect to $partner_s(t)$. □

The next lemma shows that our third subgoal is reached.

LEMMA 5.21. *If the system is in state s, cover(s) holds, $|s| > 2$, even($|s|$) holds, and a pair is in scenario 2, where $V(\sigma_2) > 0$, then there exists a finite $l > 0$, such that either $(|S^l(s)| < |s|) \vee (\Pr(|S^l(s)| < |s|) > 0)$ or $\Pr(block(\sigma_2, s^l)) > 0$.*

Proof. If either t's or $partner_s(t)$'s next transition is not a turn, then we can apply Lemma 5.20. Otherwise the transitions of t and $partner_s(t)$ form a local cycle. In order to maintain this cycle, both tokens must continuously turn and thus use probes in $|b^{\sigma_1}(s)|$ and $|b^{\sigma_2}(s)|$.

So let us consider how $|b^{\sigma_2}(S^k(s))|$ can change for $k > 0$: First note that the neighbors also will form a local cycle (otherwise we can again invoke Lemma 5.20). This implies that there will always be new "incarnations" of σ_2 with initially $|b^{\sigma_2}(S^k(s))| = 0$. Note that all probes entering σ_2 are either generated by the neighbors or passed

through the neighbors, and thus their fragment is in scenario 3 (otherwise the probes would get disabled). In order to pass through this fragment, the incoming backwards probes must mismatch all probes in $f^{\sigma_4}(s)$, all of which originated at token $partner_s(t')$. If incoming backwards probes originated with $partner_s(t')$, then they obviously match, otherwise they match with nonzero probability, since the forward probe carries a random value independent of the value of the backward probe (by Lemma 5.19). Now if the first incoming probe matches, only probes generated by $partner_s(t')$ will be on $partner_s(t')$ and consequently on σ_2. Thus for some finite $l > 0$, $\Pr(block(\sigma_2, s^l)) > 0$, or, in other words, the neighboring pair acts as a *probabilistic filter* with respect to incoming backwards probes.

Note that if there are any disabled probes on σ_2 which match any of the enabled probes, then they will merely eliminate the enabled probes and thus not interfere with the block predicate. □

LEMMA 5.22. *For every state s ($cover(s)$, $|s| > 2$, $even(s)$ both hold), there exists a finite $l > 0$, such that either* $(|S^l(s)| < |s|) \vee (\Pr(|S^l(s)| < |s|) > 0)$.

Proof. By Lemma 5.14, there is a successor state in which a pair is guaranteed to be in scenario 2, where $V(\sigma_1) < 0$, $V(\sigma_2) > 0$. By Lemma 5.21, if $\neg((|S^l(s)| < |s|) \vee (Pr(|S^l(s)| < |s|) > 0))$, then there is a nonzero probability that there is a block on at least one of σ_1 or σ_2. By Lemma 5.19, the value of the block is independent of the token's value. Thus, there is a nonzero probability that the block has a different value than the token, and thus the next transition of the token is not a turn. Using Lemma 5.20 and noting that the probability for a block on σ_2 and the probability that there will be an elimination in the subsequent collision (second in a row) are independent, we are done. □

The last few lemmas concern the last two subgoals, i.e., states with two tokens.

LEMMA 5.23. *For every state s with $cover(s)$, $|s| = 2$, there is a finite $l > 0$, such that $S^l(s) = (t_1, \sigma_1)(t_2, \sigma_2)$, where $V(t_1), V(\sigma_2) > 0$, $V(t_2), V(\sigma_1) < 0$, and $V(t_1) < V(\sigma_2)$.*

Proof. Lemma 5.12 guarantees that there will always be a state s' as described above except maybe for the condition $V(t_1) < V(\sigma_2)$. If this condition does not hold, then by simply following the algorithm, we can conclude that the full condition holds in either $S(s')$ or $S^2(s')$. □

LEMMA 5.24. *If there are no enabled probes at the time of a transition into a state s of the form of Lemma* 5.23*, then the system has reached stability.*

Proof. Remember that $s = (t_1, \sigma_1)(t_2, \sigma_2)$, where $V(t_1), V(\sigma_2) > 0$, $V(t_2), V(\sigma_1) < 0$, and $V(t_1) < V(\sigma_2)$. Assume without loss of generality that just before the next transition, $s = (t_1, \sigma_2)(t_2, \sigma_2)$. Thus t_1 is sending out probes ($S(t_1) = \text{TRUE}$). All of its forward probes are in $f^{\sigma_2}(s)$ and all of its backward probes are in $b^{t_1}(s)$. Following the algorithm, we get $S(s) = (t_2, \sigma_3)(t_1, \sigma_4)$, where $V(\sigma_3) > 0$, $V(\sigma_4) < 0$. For all probes which were in $f^{\sigma_2}(s)$, the conditions on lines E1 and E2 became true before the transition and thus have been disabled. All these forward probes are now on σ_4. All enabled backward probes are now in $b^{\sigma_3}(S(s))$. Thus before the next transition, all backward probes will have been in a collision with a disabled forward probe, and thus both are eliminated (line F7). □

LEMMA 5.25. *For every state s as in the form of Lemma* 5.23*, with initial enabled probes, there is* (i) *a probability of at least* 1/2 *that those enabled probes cause one token to turn, in which case the system will be stabilized by $S^3(s)$, or else* (ii) *all enabled initial probes will be disabled.*

Proof. Trivially, $|b^{t_1}(s)| = |f^{t_1}(s)| = |b^{t_2}(s)| = |f^{t_2}(s)| = 0$. Without loss

of generality let us assume that just before the next transition $s = (t_1, \sigma_2)(t_2, \sigma_2)$. Thus we concentrate on $b^{\sigma_2}(s)$. If before t_1 reached σ_2, $|b^{\sigma_2}(s)| \neq 0$, then there is a probability of 1/2 for each of these probes that it will match t_1's forward probes (since $V(t_1)$ is random and independent). If indeed there is a matching probe, then $S(s) = (t_1, t_2)(t_2, t_1)$, and all probes which were in $b^{\sigma_2}(s)$ are disabled. By Lemma 5.9 $S^2(s)$ is reached by a turn of t_2. It is easy to see then that $S^3(s)$ is reached through a collision between t_1 and t_2 and there are no initial enabled probes.

Furthermore, it is easy to see that all initial probes (which we just showed are disabled by S^2) are removed from the system by $S^3(s)$. □

We now get to our first main theorem which ties all the previous lemmas together and shows the correctness of Algorithm A.

THEOREM 5.26. *Algorithm A is a correct self-stabilizing solution for* fair nondeadlocking round-robin TM *on system S. Furthermore, the lifetime of any control-signal, except for one pair of a positive and a negative token, is finite.*

Proof. The following chain of arguments proves that starting the system in an arbitrary state s, $|s| > 0$, will lead with probability 1 to a stable state $S^l(s)$ with $|S^l(s)| = 2$ $(l \geq 0)$.

By Lemma 5.8, $cover(S^{l_1}(s))$ holds for a finite l_1. If $|S^{l_1}(s)| > 2$, then by Lemma 5.16 and Lemma 5.22 there exists a finite l_2, such that $(|S^{l_2}(s)| < |S^{l_1}(s)|) \vee (\Pr(|S^{l_2}(s)| < |S^{l_1}(s)|) > 0)$. Also, by Lemma 5.10 and by Lemma 5.11, $|S^k(s)| \leq |S^{l_1}(s)|$ $\forall k > l_1$. Suppose now we have an infinite sequence of states such that $|S^m(s)| = |S^{l_1}(s)|$ $(\forall m \geq 0)$. The number of different states in the system is finite. So some state s' for which $|\Pr(|S(s')| < |s|) > 0$ is visited infinitely often. Therefore, the probability of the computation we have supposed is zero. This argument can be repeated until for some l_3 we have $|S^{l_3}(s)| = 2$. By Lemma 5.24, Lemma 5.23, and an argument similar to the above, there is now an l_4 for which $S^{l_4}(s)$ is stable. Using Lemma 5.25 together with the argument above, we can conclude that the lifetime of every signal except for one positive and one negative token is indeed finite. □

5.4. Stabilization-time. The following sequence of lemmas will show that the following theorem holds.

THEOREM 5.27. *Algorithm A has* $t(n) = O(n \log n)$.

LEMMA 5.28. *For every s a state* $S^l(s)$ *with* $cover(S^l(s))$ *is reached for the expected* $l = O(n)$.

Proof. From the proof of Lemma 5.8, it follows that the maximum time to enlarge a fragment is the time it takes for a token to traverse it. Also note that an initial probe either causes a token to turn within n time units or gets disabled. This holds since a probe which fails to turn a token will reach the opposite end of a fragment. If there is no change in sign of the nodes outside the fragment, the tokens on that fragment will not turn before a cover is reached. Also, if there is a change in sign, the probe gets disabled. □

LEMMA 5.29. *For every state s with* $cover(s)$*, there is an l whose expected worst case bound is* $O(n \log n)$*, such that* $|S^l(s)| = 2$.

Proof. Let $k = |s|$. If s is skewed, then after at most $O(n/k)$ time units a turn operation will take place. This holds by Lemma 5.9 and the fact that the maximum distance between two equal-valued tokens is $O(n/k)$ (important for nonconstant k). Now for every state which is not skewed a useful collision takes place within $O(n/k)$ expected time units (by Lemmas 5.16 and 5.22 and the fact that in a nonskewed state there are tokens going in opposite directions at distance at most $O(n/k)$). Thus, the expected time to reach a state with two tokens can be expressed as $\sum_{k=1}^{n} n/k =$

$O(n \log n)$. ∎

LEMMA 5.30. *For a state s, such that cover(s) holds and $|s| = 2$, the system stabilizes in $O(n)$ expected time.*

Proof. If there are initial probes, then after an expected constant number of rounds there will be a turn and then Lemma 5.25 applies, or all initial probes are disabled before such a turn can take place. ∎

6. Reduction from leader election (L) to TMA. Leader election (symmetry breaking) is an important procedure in many parallel and distributed computing scenarios (see, e.g., [AAGHK89, AAHK86, AB89, AM89, Ang80, Dij74, It90, IR81, FL84, PKR82, RL81, SS89]). This is especially true in our model, where the nodes in the ring are identical finite state machines. In this section we present an algorithm which, given a correct TMA-algorithm, achieves self-stabilizing leader election. We start with the appropriate definition.

DEFINITION 6.1. *A self-stabilizing leader election algorithm (L) is a self-stabilizing algorithm with respect to predicate P = "there exists a single leader" and, furthermore, after stabilization, the leader node remains unchanged.*

The control messages used by the L-algorithm are the tokens of the TMA-algorithm. These tokens are augmented essentially by a new data-field which indicates whether the token has seen (i) zero, (ii) one, or (iii) more than one leader since its last collision. If the system has stabilized, then, upon a collision, it will always be the case that one token will be in state (i) and one token will be in state (ii) (since together they have covered the ring exactly once since their last collision). If the system has not yet stabilized, it is possible that (a) both tokens are in state (i), in which case there is no leader, or (b) that both tokens are either in state (ii) or state (iii), which indicates that there are multiple leaders. For the L-algorithm we assume that a collision is always associated with a node. (The precise definition depends on the implementation of a collision.) Thus in case (a) a new leader is created on the node associated with the collision and in case (b) we also create a new leader and then put both tokens in a "delete mode" until their next collision. If a token passes through a node in delete mode, it will remove the leader-predicate from that node.

We use the tokens of our TMA-algorithm as control messages. We augment the messages and nodes with the following data-structures:

- $L(i)$: the bit indicating that node i is a leader.
- $L(t)$: the leader-value of token t $(0 \le L(t) \le 2)$.
- $D(t)$: the bit indicating that token t is in delete mode.

Tokens t_1 and t_2 collide on node i:

```
L1:   IF (L(t1) + L(t2) = 1) OR D(t1) OR D(t2), THEN
L2:     L(t1) = L(t2) := 0; D(t1) = D(t2) := FALSE
L3:   ELSIF L(t1) + L(t2) = 0, THEN
L4:     L(i) := TRUE;
L5:     L(t1) := 1; L(t2) := 0
L6:   ELSIF (L(t1) + L(t2) > 1), THEN
L7:     L(i) := TRUE;
L8:     D(t1) = D(t2) := TRUE;
L9:     L(t1) := 1; L(t2) := 0
      END IF
```

Token t arrives at node i:

```
D1:   IF D(t) AND L(i), THEN
D2:     L(i) := FALSE
D3:   END IF
```

THEOREM 6.2. *Algorithm L is a correct polynomial time space-preserving self-stabilizing reduction from TMA to leader election. Furthermore,* $p(n) = O(n)$.

Proof. We show that at the third collision there is exactly one node i for which $L(i)$ holds and no node j will change its value $L(j)$ from that point on: Note first that at the second collision either none or both of the tokens are in the delete mode, since the tokens agreed on the mode in their first collision (lines L2, L8). If they are in the delete mode, then they created a new leader at their first collision (line L7) and removed every other leader on the ring (line D2). Now assume that none is in the delete mode. Then, their L-values correctly reflect the number of leaders in the ring. Thus, if there is no leader, then one will be created (line L4), and if there is more than one leader, then one new leader is created (line L7) and all others will be removed by the time of the third collision. □

7. Reduction from TMA to L. In this section we present an algorithm which, given a correct L-algorithm, achieves self-stabilizing TMA.

The algorithm is simple. We maintain one bit at the leader and one bit on each token. If a token arrives at the leader and its bit mismatches the leader bit, the token is removed; otherwise the leader chooses a new bit at random and the token copies it. Every time a token is removed the leader generates a counter-token in the opposite direction. This token is used to find out whether the leader just removed the last token from the system. (This can happen as initially the bits on the token and leader are arbitrary.) If a counter-token collides with a token, it is removed, and if a counter-token arrives at the leader, the leader will generate a new token (and remove the counter-token).

We use tokens (circulating in one direction) and counter-tokens (circulating in the opposite direction) as control messages and we use the leader of our L-algorithm. We augment the messages and the leader node with the following data-structures:

- $B(l)$: the bit at leader (l) indicating the current value of the token.
- $B(t)$: the value of token t.

Token t arrives at leader l:
T1: IF $B(l) \neq B(t)$, THEN
T2: eliminate t;
T3: generate counter-token;
T4: ELSE
T5: $B(l) :=$ random$(0, 1)$; /* fair coin */
T6: $B(t) := B(l)$

Counter-token t arrives at leader l:
T7: generate token t;
T8: $B(t) := B(l)$

Token t and counter-token t' collide:
T9: delete t'.

The above algorithms establishes the following theorem.

THEOREM 7.1. *Algorithm TMA is a correct polynomial time space-preserving self-stabilizing reduction from leader election to TMA. Furthermore,* $p(n) = O(n \log n)$.

Proof. First note that after n time units all present counter-tokens have actually been generated by the leader, and thus a token is generated if and only if there are no tokens in the system (since a counter-token is eliminated upon a collision with a token (line T9) and if a counter-token arrives at the leader, a token is generated (line T7)).

Let k be the number of tokens in the system at this point. From the randomization used by the leader (line T4), it is easy to see that n time units later, the expected number of tokens in the system is $k/2$. Finally, note that the last token will not be removed as its bit always matches the bit of the leader (line T1). □

8. Applications. Our work is derived from the needs of actual systems. The main goals are the development of self-stabilizing mechanisms for high-speed local area ring networks (LANs) and embedded rings on general topology networks. Note that many existing and suggested LAN architectures, such as FDDI [R86], MetaRing [CO90], Cambridge LAN [HN88], Magnet [LTG90], and ATM-ring [OMS89], have ring-based topologies. Also, a recent suggestion for control on a general topology network is to embed a virtual ring to support on-line high-speed control mechanisms [OY90]. Having self-stabilizing mechanisms can prevent potentially costly centralized and duplicated monitoring and recovery protocols. (For the high cost of such mechanisms, see, e.g., [BCK+83].) As explained in section 1.1, for such architectures, e.g., [R86, CO90, OY90], we need hardware-oriented algorithms to support fast on-line processing at a low-level protocol.

In particular, *TMA* is an important regulation control task in well established (e.g., token ring) and more recently suggested (e.g., MetaRing [CO90]) LANs. MetaRing employs a variant of a token, called the *SAT-token*. The SAT-token distributes transmission permits or quotas to the active nodes, and as a result, multiple nodes can access the network at the same time. In this new scheme a node will hold the SAT-token only if it is not satisfied. (It could not send the quota given to it by the SAT-token during its previous visit.) It has been shown that in high-speed implementations, the efficiency and effectiveness of this new fairness scheme increase as the transfer delay of the SAT-token decreases. Since the Meta-Ring (unlike token ring) allows concurrent transmission, it has been further shown that when the SAT-token is used, the fairness and correct operation are preserved even during stabilization time, when there are several SAT-tokens in the system, as long as the TMA scheme is round-robin and fair.

Acknowledgments. We are happy to thank Yehuda Afek, Baruch Awerbuch, Amotz Bar-Noy, Shay Kutten, Sergio Rajsbaum, and Baruch Schieber for helpful discussions. We are also grateful to the anonymous referees for their help in greatly improving the exposition of this paper.

APPROXIMATING THE LONGEST CYCLE PROBLEM IN SPARSE GRAPHS*

TOMÁS FEDER†, RAJEEV MOTWANI‡, AND CARLOS SUBI§

Abstract. We consider the problem of finding long paths and cycles in Hamiltonian graphs. The focus of our work is on sparse graphs, e.g., cubic graphs, that satisfy some property known to hold for Hamiltonian graphs, e.g., k-cyclability.

We first consider the problem of finding long cycles in 3-connected cubic graphs whose edges have weights $w_i \geq 0$. We find cycles of weight at least $(\sum w_i^a)^{\frac{1}{a}}$ for $a = \log_2 3$. Based on this result, we develop an algorithm for finding a cycle of length at least $m^{(\log_3 2)/2} \approx m^{0.315}$ in 3-cyclable graphs with vertices of degree at most 3 and with m edges. As a corollary of this result, for arbitrary graphs with vertices of degree at most 3 that have a cycle of length l (or, more generally, a 3-cyclable minor with degrees at most 3 and with l edges), we find a cycle of length at least $l^{(\log_3 2)/2}$.

We consider the graph property of 1-*toughness* that is common to Hamiltonian graphs and 3-connected cubic graphs, and we try to determine if 1-toughness implies the existence of long cycles. We show that 2-connectivity and 1-toughness, for constant degree graphs, may give cycles that are only of logarithmic length. However, we exhibit a class of 3-connected 1-tough graphs with degrees up to 6, where we can find cycles of length at least $m^{\log_3 2}/2$.

1. Introduction.

Over the last decade, there has been tremendous progress in the area of approximation algorithms. For most canonical NP-hard problems, either dramatically improved approximation algorithms have been devised, or strong negative results have been established, leading to a substantially improved understanding of the approximability of these problems. However, there is one problem which has resisted all attempts at devising either positive or negative results—longest paths and cycles in undirected graphs. Essentially, there is no known algorithm which guarantees an approximation ratio better than $n/\text{polylog}(n)$, and there are no hardness of approximation results that explain this situation. This is true even for the problem of finding long paths and cycles in bounded-degree Hamiltonian graphs, and indeed it has been conjectured that this special case is already very hard to approximate.

We examine the following question: If a graph has a Hamiltonian cycle, what is the longest cycle that can be found in polynomial time? Our approach is to select properties of Hamiltonian graphs and use them to construct long cycles. For instance, Hamiltonian graphs are k-cyclable for all k; i.e., any k vertices lie on a common cycle. For 3-cyclable graphs with vertices of degree at most 3, we find a cycle of length at least $m^{(\log_3 2)/2}$. Before describing these and other results in greater detail, we briefly review the previous work in this area.

Previous work. The first approximation algorithm was due to Monien [11], who gave a polynomial-time algorithm for finding paths of length $\Omega(\log n/\log\log n)$ in Hamiltonian graphs. Fürer and Raghavachari [7, 8] and Karger, Motwani, and Ramkumar [10] improved this to find paths of length $\Omega(\log n)$ in Hamiltonian graphs. Karger, Motwani, and Ramkumar also pointed out that the Hamiltonian cycle problem appears difficult even in *cubic* graphs and devised an algorithm for finding paths of length $\Omega(\sqrt{n}\log n)$ in *random* cubic Hamiltonian graphs. Alon, Yuster, and Zwick [1] presented an algorithm for finding paths of length $c\log n$ for any constant c as long as the graph had such a path (no assumption of Hamiltonicity). A recent result of Vishwanathan [14] gives an algorithm for finding paths of length $\Omega((\log n/\log\log n)^2)$ in Hamiltonian graphs.

The situation from the point of view of hardness results is equally dismal. Karger, Motwani, and Ramkumar [10] showed that, unless P = NP, it is impossible to find paths of length $n - n^\epsilon$ in Hamiltonian graphs for any ϵ. They also established that there is no constant-factor approximation algorithm for the longest path problem (unless P = NP) and that, if there is a polynomial-time algorithm with ratio $2^{O(\log^{1-\epsilon} n)}$, then NP $\subseteq$ DTIME$(2^{O(\log^{1/\epsilon} n)})$. They extend the latter result to bounded-degree graphs and conjecture that the problem is as hard even in bounded-degree Hamiltonian graphs. More recent work, of Bazgan, Santha, and Tuza [3], establishes that the longest path problem cannot be approximated within constant factors in *cubic* Hamiltonian graphs. They also showed that, for any $\epsilon > 0$, this problem is not approximable within ratio $2^{O(\log^{1-\epsilon} n)}$ unless NP $\subseteq$ DTIME$(2^{O(\log^{1/\epsilon} n)})$.

Overview of results. The focus of our work is on sparse graphs, e.g., cubic graphs, that satisfy some property known to hold for Hamiltonian graphs, e.g., k-cyclability. It was conjectured by Bondy and Simonovits [4] that every 3-connected cubic graph has a cycle of length at least n^c for some constant $c > 0$. This was verified by Jackson [9], who showed that 3-connected cubic graphs have cycles of length at least n^c for $c = \log_2(1+\sqrt{5}) - 1 \approx 0.69$. A key tool in our work is a constructive and generalized version of this result. In section 2, we consider the problem of finding long cycles in 3-connected cubic graphs whose edges have weights $w_i \geq 0$. We find cycles of weight at least $(\sum w_i^a)^{\frac{1}{a}}$ for $a = \log_2 3$; the exponent $\frac{1}{a} \approx 0.63$ is smaller than that of Jackson, but the proof is much simpler and constructive and also gives the first result for the weighted case. (We note that the best upper bound known [4] for 3-connected cubic graphs has exponent $\log 8/\log 9 \approx 0.96$.)

Based on our algorithm for weighted cycles in 3-connected cubic graphs, together with an algorithm given in section 3 for finding a cycle through three given edges in 3-connected cubic graphs when such a cycle exists, we describe in section 4 an algorithm for finding cycles of length at least $m^{(\log_3 2)/2}$ in 3-cyclable graphs with vertices of degree at most 3. As a corollary, we find a cycle of length at least $l^{(\log_3 2)/2}$ in any graph with vertices of degree at most 3 that has a 3-cyclable minor with degrees at most 3 and with l edges. (Note that a cycle of length l is such a minor.) A similar approximation for the longest path problem in graphs with vertices of degree at most 3 follows from this result.

In section 5, we consider the graph property of 1-*toughness* that is common to Hamiltonian graphs and 3-connected cubic graphs, and we try to determine if 1-toughness implies the existence of long cycles. We show that 2-connectivity and 1-toughness, for constant degree graphs, may give cycles that are only of logarithmic length and only slightly longer paths. However, we exhibit a class of 3-connected 1-tough graphs with degrees up to 6 where we can find cycles of length at least $m^{\log_3 2}/2$.

2. Weighted 3-connected cubic graphs. In this section, we establish the following result.

THEOREM 2.1. *Let $G(V, E)$ be an n-vertex, 3-connected, cubic graph. Suppose that each edge $e_i \in E$ has associated with it a weight $w_i \geq 0$. Then G has a cycle of total weight at least*

$$L_a(w) = \left(\sum {w_i}^a\right)^{\frac{1}{a}}$$

for $a = \log_2 3 \approx 1.58$, and such a cycle can be found in polynomial time. In the unit weight case, this gives a cycle of length at least $(\frac{3}{2}n)^d$ for $d = \log_3 2 \approx 0.63$.

The rest of this section is devoted to the proof of this theorem. We first prove some relevant lemmas. The bound will follow from combining and dropping weights as follows.

LEMMA 2.2. *Consider a collection of weights $w_i \geq 0$. Suppose we repeatedly perform one of the following operations: either select two weights and replace them with their sum or select three weights, drop the smallest one, and replace the other two with their sum. In the end, when only one weight remains, it will be at least $L_a(w) = (\sum {w_i}^a)^{\frac{1}{a}}$ for $a = \log_2 3$.*

Proof. We show that the quantity $\sum {w_i}^a$ is not reduced by either operation. That is, if $0 \leq x \leq y \leq z$, then $x^a + y^a + z^a \leq (y + z)^a$. We can assume $x = y$. If $z = y$, then $3y^a = (2y)^a$. As z increases, $\frac{d}{dz} 2y^a + z^a = az^{a-1} \leq \frac{d}{dz}(y + z)^a = a(y + z)^{a-1}$. ∎

We shall simplify the graph by removing and combining edges so that the weights are treated as in Lemma 2.2. We define an operation on *cubic graphs* which selects an edge h, removes it from the graph, and then collapses the two resulting paths of length 2 into single edges. We will refer to this as *the H-transform applied at edge h*; the transformation is illustrated in Figure 2.1. Note that, when we apply the H-transform to a cubic graph G with n vertices and $3n/2$ edges, we will obtain a cubic graph G' with $n - 2$ vertices and $(3n/2) - 3$ edges.

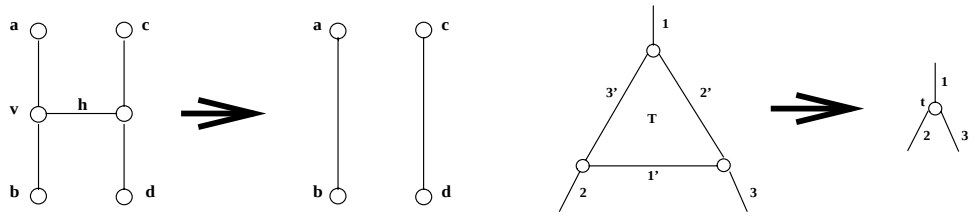

FIG. 2.1. *An illustration of the H-transform and the T-transform.*

LEMMA 2.3. *Let G be a 3-connected cubic graph with no triangles. Then there exists a vertex v such that applying the H-transform at any of the three edges incident on v will result in a new graph G', which is also a 3-connected cubic graph.*

Proof. We claim that applying the H-transform at an edge h of a 3-connected cubic graph G with no triangles results in a new graph G' which is also 3-connected and cubic if and only if the graph G does not have two other edges e, f, such that e, f, h are not all three incident to the same vertex, and removing e, f, h disconnects G.

The "only if" part is immediate since, if G has two such edges e, f, then, in G', the two edges e, f, or possibly edges obtained from them after collapsing paths of length 2 into single edges, will disconnect G', contrary to 3-connectivity.

For the "if" part, suppose that G' is not 3-connected. Then G' has two edges l, m that disconnect it. If l is a contracted path of length 2 from G, then the middle vertex of this path, on which h is incident, together with m disconnect G, contrary to the 3-connectivity of G. So h, l, m are edges in G that separate it, not all three incident to the same vertex, so these are the required edges e, f, h, completing the proof of the "if" part.

We can assume that G has three edges e, f, g whose removal disconnects it into two components K and K' having at least two vertices each. (Otherwise, any v will have the desired property, by the preceding claim.) Choose such a configuration with K minimal. Since K is not a triangle, it has some vertex v on which none of e, f, g is incident. Let h be an edge incident on v, drop h, and combine each of the two resulting paths of length 2 into single edges to obtain G'. Suppose G' is not 3-connected. Then, by the claim, G has two edges l, m such that h, l, m are edges in G that separate it, not all three incident to the same vertex. If either K or K', say, K', has exactly one of h, l, m in it, say, l, then l would have to separate one of e, f, g from the other two, say, e, but then e, l would separate G, contradicting 3-connectivity. So we can assume that none of h, l, m is in K'. However, this contradicts the minimality of K. □

While Lemma 2.3 assumed the absence of triangles, we must be able to handle triangles. To this end, we define an operation for removing a triangle $T = \{u, v, w\}$ which involves replacing the three vertices in T by a "supervertex" t whose three incident edges are the three edges incident on u, v, and w that were *not* a part of the triangle T (see Figure 2.1). It is obvious that applying this transformation to a cubic graph G will result in a cubic graph G'. Moreover, since any two edges separating G' would also separate G, this transformation also preserves 3-connectivity.

LEMMA 2.4. *Let $G \neq K_4$ be a 3-connected cubic graph having at least one triangle T. If T is replaced by a supervertex, then the resulting graph G' is also 3-connected and cubic.*

We now provide the proof of Theorem 2.1. Let G be a 3-connected cubic graph. If G has no triangle, then we select v as in Lemma 2.3, and, if the three edges incident on v are 1, 2, and 3 of weights $w_1 \leq w_2 \leq w_3$, we remove edge 1 and combine edges 2 and 3. (The two edges at the other end of 1 also get combined.) Notice that the combination of weights is as in Lemma 2.2.

If $G \neq K_4$ has triangles, we can replace a triangle with a supervertex as in Lemma 2.4. We must decide what to do with the weights inside the triangle. For a triangle T with incident edges 1, 2, and 3, we can label the edges of T with $1'$, $2'$, and $3'$, where, if 1 was incident on a vertex of T, then label $1'$ goes to the edge joining the other two vertices of T, and similarly for 2 and 3 (see Figure 2.1). The weights of $1'$, $2'$, and $3'$ are then added to 1, 2, and 3, respectively. Notice that, if 1 is later removed by an application of Lemma 2.3, then also removing $1'$ gives a path 2, $3'$, $2'$, and 3, thus justifying the way the weights are handled. This works recursively for supervertices consisting of triangles whose vertices are themselves supervertices consisting of triangles, and so on.

Finally, if $G = K_4$, then label disjoint pairs of edges $1, 1'$, $2, 2'$, and $3, 3'$. Then removing $1, 1'$ gives a cycle $2, 3', 2', 3$, so we can remove the pair of disjoint edges of least weight and apply Lemma 2.2. This completes the proof.

3. Cycle through three edges. In this section, we establish the following result.

PROPOSITION 3.1. *Let G be a 3-connected cubic graph, and let e, f, g be three edges in it. Then G has a cycle through e, f, g if and only if removing e, f, g does not*

disconnect G. Such a cycle can be found in polynomial time.

If removing e, f, g disconnects G into two components K and K', then the cycle would have to go between K and K' an even number of times and so could not include all three edges. This proves the "only if" part.

The proof of the "if" part is based on reducing the graph to a K_4 by repeatedly applying the H-transform and the T-transform. If e, f, g are three edges in K_4 that do not disconnect it, then they are not all three incident to the same vertex, so they either form a triangle or a path of length 3 that can be completed to a cycle of length 4. This produces the desired cycle.

We observe that we can find a cycle through two given edges l, m in G by selecting an endpoint u of l and an endpoint v of m, finding three disjoint paths from u to v, and observing that some two of these three paths form the desired cycle.

We denote by G^* the graph obtained from G by removing e, f, g. By assumption, G^* is connected.

Suppose first that G has no triangles. Then we can find a vertex v such that applying the H-transform at any of the three edges h_1, h_2, h_3 incident on v will result in a new graph G' which is also a 3-connected cubic graph. There are then three cases.

Case 1. None of e, f, g is incident on v. If removing h_1 from G^* does not disconnect G^*, then applying the H-transform at h_1 will result in a graph G' such that the three edges e, f, g, or edges obtained from them by contracting paths of length 2, do not disconnect it. Otherwise, removing h_1 from G^* disconnects it, creating, in particular, a component C_1 not containing v. Similarly, removing h_2 or h_3 from G^* creates components C_2, C_3 not containing v, respectively. Since G is 3-connected, the three edges e, f, g must go from C_1 to C_2, from C_1 to C_3, and from C_2 to C_3, respectively. However, then h_1, e, f separate G, and we could not have applied the H-transform at h_1 unless C_1 consists of a single vertex. In this last case, e, f get collapsed to a single edge l so that we just need to find a cycle through l, g in G', and this can be done as observed above.

Case 2. Precisely one of e, f, g is incident on v. Say $g = h_3$. As before, if removing h_1 from G^* does not disconnect G^*, then we can apply the H-transform at h_1. Otherwise, removing h_1 or h_2 from G^* creates components C_1, C_2 not containing v, respectively. The edge $g = h_3$ goes from v to either C_1 or C_2, say, C_2. The edges e, f must go from C_1 to C_2 since G is 3-connected. However, then h_1, e, f separate G, and, as before, we would not have applied the H-transform at h_1 unless C_1 consists of a single vertex, in which case e, f get collapsed to a single edge l, and we can find a cycle through l, g in G'.

Case 3. Precisely two of e, f, g are incident on v. Say $f = h_2$ and $g = h_3$. Then the H-transform at h_1 collapses f, g to a single edge l, and we can find a cycle through l, e in G'.

It is not possible that all three of e, f, g are incident on v since they would disconnect G. This completes the study of the H-transform. We consider next the T-transform, with four cases.

Case 1. None of e, f, g are inside the triangle T. Then after replacing T with a supervertex t to obtain G', the three edges e, f, g will still not disconnect G'.

Case 2. Precisely one of e, f, g is inside the triangle T. Say e is in T. Then, after replacing T with a supervertex t, it is sufficient to find a cycle in G' through f, g, and t; we can always ensure that e gets visited inside T. If either f or g is incident on t, then we just need to find a cycle through f, g, and this is done as observed before.

Otherwise, to ensure that t is visited, we can let e' be one of the three edges $1, 2, 3$ incident on T and find a cycle through e', f, g in G', provided that these three edges do not disconnect G'. If they do, then each of the edges $1, 2, 3$ disconnects G^* (even if e is included in G^*), creating components C_1, C_2, C_3 not containing T, respectively. Then adding two edges f, g to G^* to obtain G will not make it 3-connected, which is a contradiction.

Case 3. Precisely two of e, f, g are inside the triangle T. Say e, f are the edges $1', 2'$ in T. Let e', f' be the two corresponding edges $1, 2$ incident to T. Clearly, e', f', g disconnect G if and only if e, f, g disconnect G, so we can assume they do not. A cycle entering and leaving T at e', f' can be made to go through e, f inside T; we can thus carry out the T-transform.

Case 4. The three edges e, f, g constitute the triangle T. Then T is the desired cycle.

This completes the proof.

4. 3-cyclable graphs. A graph G is said to be *k-cyclable* if, for any choice of k vertices, there is a cycle in G containing all k of them. Clearly, if a graph has a Hamiltonian cycle, it is k-cyclable for all k. If k is a constant, then, given k vertices, one can find in polynomial time a cycle containing all k of them if one exists. This requires finding k disjoint paths connecting the vertices. A polynomial-time algorithm for the disjoint paths problem with a constant number of paths was given by Robertson and Seymour [12, 13] in their work on graph minors. For 3-cyclable graphs with vertices of degree at most 3, however, finding a cycle through three vertices will require only the result in section 3. Note that, in particular, 3-connected cubic graphs are 3-cyclable.

In the rest of this section, we will establish the following result (and its corollary).

THEOREM 4.1. *Let G be a 3-cyclable graph with vertices of degree at most 3 and with m edges. Then we can find, in polynomial time, a cycle in G of length at least $m^{\frac{1}{2a}}$, where $a = \log_2 3$.*

Proof. We will need three properties of the 3-cyclable graph G.

1. G is 2-connected since it is 2-cyclable.
2. If there is an edge $f = uv$ such that the subgraph $G - \{u, v\}$ on the vertices other than u, v has two or more connected components, then we can remove the edge f from G and still have a 3-cyclable graph. For, if a cycle uses f, it could use instead a path from u to v in the connected component of $G - \{u, v\}$ not visited by the original cycle. (The justification for counting edges so removed will be given in the following corollary.)
3. For any two vertices u, v, the graph $G - \{u, v\}$ on the remaining vertices has at most two connected components. For, if it has at least three components, then three vertices in the three components cannot be on a cycle, contradicting 3-cyclability.

Suppose there are two edges e_1, e_2 that separate G into two components K and K'. If K has no edge separating the two vertices incident on e_1, e_2, then we say that K is a 2-*component*. The *graph* of a 2-component K is obtained from K by connecting the two vertices incident on e_1, e_2 by an edge e and replacing all maximal 2-components contained in it by single supervertices. The graph of a 2-component is a 3-connected graph with edges replaced by paths. This follows from the fact that, if we replace all maximal paths whose vertices other than the starting and ending vertices have degree 2 by single edges and add the edge e, then there will be no parallel edges, by properties (1), (2), and (3). The resulting graph must be 3-connected since, otherwise, we could

identify a new 2-component contained in it, contrary to maximality. At the top level of G, if G is 3-connected, apply Theorem 2.1. Otherwise, select a 2-component K, adjacent via two edges e_1, e_2 to its complement K', which has some $r \geq 0$ edges, each separating the two vertices incident on e_1, e_2, thus decomposing K' into $(r+1)$ 2-components; so G is a cycle of $(r+2)$ 2-components.

So suppose G is not 3-connected, and perform the above decomposition into 2-components. The 2-components so selected have a tree structure: at the top level, we have a cycle of 2-components, which are viewed as the children of the root; for a 2-component in this tree, its children are the maximal 2-components contained in it.

We assign a weight w_i to each 2-component in the tree so that, if the 2-component has m_i edges, then $w_i \geq {m_i}^d$, where $d = \frac{1}{a} = \log_3 2$. We do this inductively, starting at the leaves. So suppose, for a given 2-component, we have assigned weights to the maximal 2-components contained in it. The graph of the 2-component is a 3-connected graph with edges replaced by paths. To every such path, assign a weight equal to the sum of the weights of the supervertices in it plus the number of edges connecting these supervertices. The special edge e is given weight 0. Apply then Theorem 2.1 to the 3-connected graph, obtaining a cycle of weight $w \geq (\sum w_i^a)^{\frac{1}{a}} \geq (\sum m_i)^{\frac{1}{a}} = m^d$. Assign weight w to the 2-component, completing the induction. At the top level, we have a cycle of 2-components, so we add their weights plus the number of edges in the cycle.

Unfortunately, the cycles that we selected for each 2-component to define the weights of the 2-component do not necessarily connect since the cycle for a 2-component may not go through the special edge e that links it to its parent in the tree. We shall define cycles that do go through e so that, if a 2-component has weight w, then the cycle through e visits at least $w^{\frac{1}{2}} \geq m^{\frac{1}{2a}}$ edges other than e, and this will complete the proof.

Consider a 2-component whose weight w was defined by finding a cycle C of weights w_i, and suppose, for each i, we have found a path inside the corresponding maximal 2-component of length at least ${w_i}^{\frac{1}{2}}$. We write $w_i = \epsilon_i w$, with $\sum \epsilon_i = 1$. Clearly, if C goes through e, we can just select C and have a cycle through e of length at least $\sum {w_i}^{\frac{1}{2}} \geq w^{\frac{1}{2}}$ since $\sum {\epsilon_i}^{\frac{1}{2}} \geq 1$, where the sums are over the weights in C.

Suppose C does not go through e. By 3-connectivity, we can join an endpoint of e to C with three disjoint paths and, in particular, obtain two disjoint paths joining the two endpoints of e to C, respectively. The two disjoint paths enter C at two distinct vertices, thus decomposing the weights of C into two subsets S and T delimited by these two vertices. If $\sum {\epsilon_i}^{\frac{1}{2}} \geq 1$ when the sum is taken over the weights in either S or T, then we are done. If this is not the case, then we will show that the largest weight $w_1 = \epsilon_1 w$ in S and the largest weight $w_2 = \epsilon_2 w$ in T satisfy ${\epsilon_1}^{\frac{1}{2}} + {\epsilon_2}^{\frac{1}{2}} > 1$. If $w_2 = 1$, then the cycle through e and S goes through the edge of weight w_1 and at least one other edge (of weight at least $w_2 = 1$). So we can assume $w_1, w_2 > 1$. It will then be sufficient to make the cycle through e go through the edges corresponding to the two weights w_1, w_2. Each of these two edges is a path with a maximal 2-component in it; then we can select two representative vertices from the two maximal 2-components, plus a vertex from the complement of the 2-component to represent edge e; a cycle through these three vertices must exist by 3-cyclability; this implies that there is a cycle through the three selected edges in the graph of the 2-component, and since this graph is a 3-connected cubic graph, such a cycle can be found in polynomial time by Proposition 3.1.

It remains to prove the claim about the sum of the $\epsilon_i^{\frac{1}{2}}$. Notice that, if $w_i \geq w_{i'}$

and $0 \le \delta \le w_{i'}$, then ${w_i}^{\frac{1}{2}} + {w_{i'}}^{\frac{1}{2}} \ge (w_i + \delta)^{\frac{1}{2}} + (w_{i'} - \delta)^{\frac{1}{2}}$. For the argument, we modify the weights by choosing the appropriate values δ as follows. We can ensure that S will have at most one nonzero weight smaller than w_1 and, similarly, that T will have at most one nonzero weight smaller than w_2. Thus S has $s \ge 1$ weights equal to w_1 and one weight $0 \le w_1' < w_1$; similarly, T has $t \ge 1$ weights equal to w_2 and one weight $0 \le w_2' < w_2$.

We thus have $s\epsilon_1 + \epsilon_1' + t\epsilon_2 + \epsilon_2' = 1$, with $s\epsilon_1^{\frac{1}{2}} + {\epsilon_1'}^{\frac{1}{2}} < 1$ and $t\epsilon_2^{\frac{1}{2}} + {\epsilon_2'}^{\frac{1}{2}} < 1$. We write $\epsilon_1' = \lambda\epsilon_1$ with $0 \le \lambda < 1$ and let $s' = s + \lambda$. Similarly, we write $\epsilon_2' = \mu\epsilon_2$ with $0 \le \mu < 1$ and let $t' = t + \mu$. Then $s'\epsilon_1 + t'\epsilon_2 = 1$. Also, $s'\epsilon_1^{\frac{1}{2}} \le (s + \lambda^{\frac{1}{2}})\epsilon_1^{\frac{1}{2}} < 1$, and similarly $t'\epsilon_2^{\frac{1}{2}} < 1$. However, then $s'\epsilon_1 < \epsilon_1^{\frac{1}{2}}$ and $t'\epsilon_2 < \epsilon_2^{\frac{1}{2}}$, so $\epsilon_1^{\frac{1}{2}} + \epsilon_2^{\frac{1}{2}} > 1$. This completes the proof. □

COROLLARY 4.2. *Let G be a graph with vertices of degree at most 3. Let l be the maximum number of edges in a 3-cyclable minor of G with degrees at most 3. (So l is at least the length of the longest cycle in G.) Then we can find, in polynomial time, a cycle of length at least $l^{(\log_3 2)/2}$.*

Proof. Note that a 3-cyclable minor K with degrees at most 3 is obtained from a subgraph H of G by skipping some vertices of degree 2 in H so that an edge in K corresponds to a path with internal vertices of degree 2 in H.

We can assume G is 2-connected. Otherwise, some edge f separates G into two components, and the 3-cyclable minor must be contained in one of these two components. We may thus remove f; the problem decomposes into 2-connected subproblems.

The structure of the graph as a tree of 2-components is still the same as before, even if the graph is not 3-cyclable. The only difference is that we cannot avoid parallel edges in the graph of a 2-component. Parallel edges occur only in one new kind of 2-component: Let P_3 be the graph consisting of three parallel edges joining two vertices; the graph of a 2-component may now also be P_3, with one of the three parallel edges being the special edge e linking to the parent in the tree, and one or both of the other two parallel edges f_1, f_2 being a path of vertices corresponding to 2-components that are children of this 2-component in the tree.

We proceed to simplify the graph as follows, from the leaves of the tree up to the root. For the special P_3 2-component, we remove one of the two parallel edges f_1, f_2—the one corresponding to a subgraph of smaller size. Thus we have no parallel edges anymore, as before.

As we go up the tree, we must also make sure that we will be able to obtain, from a cycle in a 2-component, a new cycle containing the special edge e. This is not possible if the two edges f_1 and f_2 with weights w_1 and w_2, together with e, separate the 3-connected graph of the 2-component. All such possible pairs (f_1, f_2) which together with e separate the 3-connected graph must be disjoint. We replace one of f_1, f_2, the one corresponding to a subgraph of smaller size, with a single edge (of weight 1).

If the 3-cyclable minor of size l reaches the root of the tree of 2-components, then the simplified graph will have $m \ge l$ edges, by induction from the leaves up to the root of the tree of 2-components. The reason is that, when f_1 or f_2 is removed or reduced to a single edge, the 3-cyclable minor of size l necessarily does have vertices in one of the two subgraphs corresponding to f_1 and f_2. We then get a cycle of length at least $m^{(\log_3 2)/2}$ with the previous algorithm.

It may seem that one should not count the edges removed to satisfy property 2 above. However, when a single edge f_1 is removed from P_3, at least one edge

corresponding to e is later added, and one can count both edges since $x^{\frac{1}{2a}} + 1 \geq (x+2)^{\frac{1}{2a}}$ for $a, x \geq 1$.

If the 3-cyclable minor of size l does not reach the root of the tree of 2-components, consider the 2-component closest to the root that it reaches. The 3-cyclable minor does not have vertices corresponding to the special edge e connecting this 2-component to its parent. On this 2-component, we do not simplify the graph for pairs of edges f_1, f_2 which together with e disconnect the graph of the 2-component (neither in the case of P_3 nor in the case of a 3-connected graph); we assign to e weight 1. As before, we have $m \geq l$ edges by induction from the leaves of the tree up to this 2-component and get a cycle of length at least $m^{(\log_3 2)/2}$ with the previous algorithm. □

An algorithm that approximates the longest cycle problem can be used to approximate the longest path problem by guessing and adding the edge that would complete the long path into a cycle and then removing this edge after a long cycle is found and getting back a path. In our case, since adding an edge could create two vertices of degree four, we can instead add the edge between two new vertices inserted in the middle of two existing edges.

5. Long cycles and toughness. A graph G is said to be 1-*tough* if it has the following property: *For every set S of vertices, the graph $G - S$ on the remaining vertices has at most $|S|$ components.* There has been interest in devising algorithms for long paths/cycles in graphs that are 1-tough [5, 10, 14] because Hamiltonian and weakly Hamiltonian graphs are 1-tough. There has been some work that shows that, for graphs with large degree sums, 1-toughness implies the existence of long cycles [2]. In the above results, 3-connected cubic graphs are 1-tough since every component is delimited by at least three separating vertices, while each separating vertex delimits at most three components. The graphs in Theorem 4.1 are not necessarily 1-tough. However, all 2-connected graphs with vertices of degree at most 3 can be made 1-tough without significantly altering the structure of the graph, namely, by replacing each vertex of degree 3 with a triangle; then each vertex of S delimits at most two components of $G - S$, and each component of $G - S$ is delimited by at least two vertices of S, giving 1-toughness.

We show that there are 1-tough cubic graphs that are only 2-connected, and where the length of the longest cycle is only logarithmic in the number of vertices, thus giving an exponential gap with respect to the 3-connected case for cubic graphs.

THEOREM 5.1. *There are arbitrarily large 1-tough, 2-connected, n-vertex k-regular graphs for $k \geq 3$ whose longest cycle has length $O(k \log_k n)$ and whose longest path has length $O(k \log_k^2 n)$. The graphs for $k = 3$ are planar.*

Proof. We give an inductive construction, and, for the induction to go through, we will need a condition that is slightly stronger than 1-toughness. We say that a graph with some chosen special edges is *extra 1-tough* if, when counting the number of components of $G - S$, we also count as components any special edges both of whose endpoints are in S; the total is still at most $|S|$. Notice that K_{k+1}, with all edges incident to one chosen vertex v as special, is extra 1-tough.

Suppose we have constructed a 2-connected k-regular graph G with some special edges, starting with K_{k+1} as just described, and this graph is extra 1-tough. We select a special edge e and replace it with $H = K_{k+1}$ as follows. Break one of the special edges (v, w) in H, and replace e with H by connecting v and w to the vertices to which e is incident. The resulting graph is still 2-connected, k-regular, and extra 1-tough. To see this last property, notice that the t vertices in S not in H still give at most t components, while the $|S| - t$ vertices in H subdivide the component corresponding

to e as follows. The vertices v and w may each create at most one extra component, while the remaining vertices in H create no component except for the special edge (v, u) for each u chosen if v is also chosen. This proves extra 1-toughness.

We apply this construction inductively. Starting with K_{k+1}, we replace the k special edges with H, where each copy of H brings in $k-1$ special edges. We then replace the $k(k-1)$ special edges with a copy of H again, so we now have $k(k-1)^2$ special edges, and we continue in this fashion. The resulting graph will have the structure of two balanced trees of degree k connected at the leaves, where one tree corresponds to the subdivision into special edges at v, while the other tree brings the special edges back together into the remaining vertices of $H-v$. The trees have height $O(\log_k n)$, and the longest cycle will go from one root to the other and back, visiting the k vertices in $H-v$ for each vertex in the second tree. The cycle will thus have length at most $O(k \log_k n)$. The longest path has a middle section that goes from one root v_1 to the other root v_2, then back to a child of v_1, then back to a child of a child of v_2, and so on. This gives the $O(k \log_k^2 n)$ bound for paths. □

It remains open whether 3-connected graphs always have cycles or paths of length n^c for some $c < 1$ by also assuming the graph to be planar or of bounded degree. It was shown by Karger, Motwani, and Ramkumar [10] that there are 3-connected graphs that are 1-tough, have a 2-factor, and are 3-cyclable, with longest path of length $O(\log n)$; the examples, however, have two vertices adjacent to all vertices.

THEOREM 5.2. *Let G be a 3-connected graph with maximum degree at most 6 such that every vertex of degree 4 belongs to at least one triangle, every vertex of degree 5 belongs to at least two edge-disjoint triangles, and every vertex of degree 6 belongs to at least three edge-disjoint triangles. Then G is 1-tough. Let T be a minimal set of triangles satisfying the conditions on vertices of degree 4, 5, and 6. If no two vertices of degree 5 or 6 are adjacent, then no triangle in T shares two different edges with two other triangles of T. If this condition on the triangles of T holds, then we can find in polynomial time a cycle of length $r^{\log_3 2}$, where r is the number of edges of G minus 2/3 the number of edges belonging to triangles of T.*

Proof. The triangles that are assumed to exist for vertices of degree 4, 5, and 6 imply that the neighborhood of every vertex contains at most three independent vertices. As a consequence, if we select a set S of vertices, each vertex of S will be adjacent to at most three components of $G-S$. On the other hand, each component of $G-S$ is delimited by at least three vertices of S by 3-connectivity. It follows that $G-S$ has at most $|S|$ components; that is, G is 1-tough.

Suppose now that the vertices of degree 5 or 6 are independent; thus their neighbors are of degree 3 or 4. Since degree 4 vertices require only one triangle, it follows that a vertex of degree 6 will not have any triangle in T other than the three edge-disjoint triangles required to be in T. If a triangle t_1 in T shares two distinct edges with two triangles t_2 and t_3 in T, then some vertex v of t_1 must be of degree 5; say, it is a vertex v common to t_1 and t_2. If the vertex of t_2 not on t_1 and the vertex of t_3 not on t_1 are the same, then we can drop t_1 or t_2 from T. Otherwise, either v also belongs to t_3, in which case t_2 and t_3 can be used as the two edge-disjoint triangles for v and we can drop t_1, or v does not belong to t_3. In this last case, either the triangle t_4 which is edge-disjoint from t_1 is also edge-disjoint from t_2, in which case we can drop t_1, or it shares an edge with t_2, in which case we can drop t_2.

So we assume that every triangle of T shares at most one edge with other triangles of T. We first consider the case where all triangles of T are edge-disjoint. It is known that the operation of replacing a vertex u of degree at least 4 with two adjacent vertices

v and w each having at least two neighbors, the neighborhoods of v and w being disjoint and giving the neighborhood of u when combined, preserves 3-connectivity. We give weight $1/2$ to the edges of T and weight 1 to the remaining edges. We replace each vertex of degree 4 with two vertices as just explained, with one of the two vertices incident to a triangle in T, and give weight 0 to the edge joining the two new vertices. For degree 5 vertices, we replace them with a path of length 2 of weight 0 edges, and distribute the adjacencies to make the new vertices have degree 3, in such a way that the first and last vertex of the weight 0 path are incident to two edge-disjoint triangles in T. For degree 6 vertices, we replace them with a star of degree 3 consisting of three weight 0 edges, so that the three leaves are incident to three edge-disjoint triangles in T. By Theorem 2.1, we can find a cycle of weight at least $r^{\log_3 2}$ in the resulting cubic graph. This cycle, however, might visit some vertex of the original graph more than once. However, then it must visit two edges of the same selected triangle in T, and these two edges of weight $1/2$ can be replaced with a single direct edge, so we avoid such conflicts and obtain a cycle of length at least $r^{\log_3 2}$ in the original graph.

Notice that a vertex of degree 6 belongs only to three edge-disjoint triangles in T, while a vertex of degree 5 can have at most two triangles sharing an edge in T. So only two or three triangles can share an edge e. When this happens, we cannot preserve all two or three triangles when introducing weight 0 edges, but we can preserve one of them, say, t, and introduce single weight 0 edges at the endpoints of e separating t from the other one or two triangles that used to share e. Notice that, if there are two separated triangles, they cannot both give a conflict at their vertices not on e, so we can restrict our attention to the case of only one separated triangle. We thus have a gadget with five edges of weight $1/2$, at most two edges of weight 0, and at most four incoming edges. This gadget is traversed by at most one or two paths. We can verify that these paths can be modified within the gadget so as to avoid conflicts and in such a way that the resulting path lengths are at least the sum of the original path weights. This completes the proof. □

A graph is said to be α-tough if, for every set S of vertices that leaves a graph $G - S$ on the remaining vertices with $k \geq 2$ connected components, we have $|S| \geq \alpha k$. It has been conjectured that there is a constant α such that all α-tough graphs have a Hamiltonian cycle. It is known that it is not enough to take $\alpha = 1.5$: Consider a 3-connected cubic graph that does not have a Hamiltonian cycle, and replace every vertex with a triangle; since every vertex of the resulting graph has at most two independent neighbors, it follows that every vertex of S is adjacent to at most two components of $G - S$, while every component of $G - S$ is delimited by at least three vertices of S by 3-connectivity, giving 1.5-toughness. In this direction, we would like to know if $(1 + \epsilon)$-tough graphs with $\epsilon > 0$, which are, in particular, 3-connected, always have cycles of length at least n^c for some $c = c(\epsilon) < 1$.

Acknowledgment. We are grateful to Sudipto Guha for several helpful discussions.

IMPROVED APPROXIMATION ALGORITHMS FOR THE VERTEX COVER PROBLEM IN GRAPHS AND HYPERGRAPHS*

ERAN HALPERIN†

Abstract. We obtain improved algorithms for finding small vertex covers in bounded degree graphs and hypergraphs. We use semidefinite programming to relax the problems and introduce *new* rounding techniques for these relaxations. On graphs with maximum degree at most Δ, the algorithm achieves a performance ratio of $2-(1-o(1))\frac{2\ln\ln\Delta}{\ln\Delta}$ for large Δ, which improves the previously known ratio of $2-\frac{\log\Delta+O(1)}{\Delta}$ obtained by Halldórsson and Radhakrishnan. Using similar techniques, we also present improved approximations for the vertex cover problem in hypergraphs. For k-uniform hypergraphs with n vertices, we achieve a ratio of $k-(1-o(1))\frac{k\ln\ln n}{\ln n}$ for large n, and for k-uniform hypergraphs with maximum degree at most Δ the algorithm achieves a ratio of $k-(1-o(1))\frac{k(k-1)\ln\ln\Delta}{\ln\Delta}$ for large Δ. These results considerably improve the previous best ratio of $k(1-c/\Delta^{\frac{1}{k-1}})$ for bounded degree k-uniform hypergraphs, and $k(1-c/n^{\frac{k-1}{k}})$ for general k-uniform hypergraphs, both obtained by Krivelevich. Using similar techniques, we also obtain an approximation algorithm for the weighted *independent set* problem, matching a recent result of Halldórsson.

1. Introduction.

Given a hypergraph $H=(V,E)$, a *vertex cover* of H is a set $C\subset V$ such that, for every $e\in E$, there exists $v\in e\cap C$. The *vertex cover* problem is the problem of finding a vertex cover of minimum size. The weighted version of the problem is obtained when every $v\in V$ has a nonnegative weight $w(v)$ and the goal is to find a vertex cover of H of minimum total weight.

The *vertex cover* problem in hypergraphs is equivalent to the *set cover* problem. An instance of the *set cover* problem is a set S and a collection C of subsets of S. A cover of S is a subset $X\subseteq C$ such that every $s\in S$ is contained in one of the sets of X. The goal is to find a cover of minimal size. It is clear that this is another formulation for the *vertex cover* problem in a hypergraph, by identifying every edge with an element of S, and every vertex with the subset that contains all the edges containing it.

The greedy algorithm gives a $(\ln n+1)$-approximation ratio for the *set cover* problem [5], where $|V|=n$. Moreover, the *set cover* problem cannot be approximated within a factor of less than $\ln n$ unless $NP\subseteq DTIME[n^{\log\log n}]$ [6].

As the approximation ratio for the *vertex cover* problem in general hypergraphs cannot be improved, we consider some of its subproblems. We first consider the *vertex cover* problem in bounded degree graphs. The *vertex cover* problem in graphs is known to be APX-complete [22], and furthermore, it cannot be approximated within a factor of $\frac{7}{6}\approx 1.1666$ [15]. A 2-approximation algorithm for the *vertex cover* problem

in a graph is trivial, one has to find a *maximal* matching in the graph and take all its vertices as a cover. The best algorithms known for the problem were found by Bar-Yehuda and Even [2] and by Monien and Speckenmeyer [21]. These algorithms achieve a ratio of $(2 - \frac{\ln\ln n}{2\ln n})$, where n is the number of vertices in the graph.

In graphs with maximal degree Δ, Hochbaum [17] shows how to approximate the *vertex cover* problem within a factor of $(2 - \frac{2}{\Delta})$. Halldórsson and Radhakrishnan [13] improve this and give a $(2 - \frac{\log\Delta + O(1)}{\Delta})$-approximation algorithm for the problem. We improve this result and give a $(2 - (1 - o(1))\frac{2\ln\ln\Delta}{\ln\Delta})$-approximation algorithm using semidefinite programming relaxations and new rounding techniques for the relaxed solution. Notice that $\frac{\ln\ln\Delta}{\ln\Delta} \gg \frac{\ln\Delta}{\Delta}$, and thus our algorithm substantially improves the known algorithms.

We next consider the vertex cover problem in hypergraphs with edges of size at most k for a given k. It is equivalent to the set cover problem restricted to instances in which every element is found in at most k sets. For simplicity we consider k-uniform hypergraphs, which are hypergraphs in which all edges are of size k. All our results can be easily extended to the case where each edge is of size at most k. A k-approximation algorithm is straightforward using a maximal matching. For any fixed k, the best algorithm known [20] achieves a ratio of $k(1 - c/n^{\frac{k-1}{k}})$. For bounded degree k-uniform hypergraphs, the best algorithm known [20] achieves a ratio of $k(1 - c/\Delta^{\frac{1}{k-1}})$. In this paper we present an algorithm which, for a fixed k, achieves a ratio of $(k - (1 - o(1))k(k-1)\frac{\ln\ln\Delta}{\ln\Delta})$ for k-uniform hypergraphs, where Δ is the maximal degree in the hypergraph. This result can be extended to the case where k is allowed to grow slowly with Δ. For general k-uniform hypergraphs with n vertices, our algorithm achieves a ratio of $(k - (1 - o(1))\frac{k\ln\ln n}{\ln n})$. These results apply to the set cover problems in which every element is contained in at most k sets. The methods used in [2, 21] for graphs cannot be extended easily to hypergraphs, and thus our techniques establish a uniform approach for the vertex cover problem in graphs and in hypergraphs.

Finally, we show that our techniques can be easily used in other problems, and we consider as an example the *independent set* problem in bounded degree graphs. Given a graph $G = (V, E)$, an independent set $I \subseteq V$ is a set of vertices satisfying that no two vertices in I are adjacent. The *independent set* problem is the problem of finding a maximum size independent set in G. If the vertices of G are weighted, then the weighted version of the problem is finding a maximum weight independent set in G. This problem was studied extensively by many researchers [17, 13, 4, 3, 11, 12, 25, 10], and it is known to be hard to approximate within a factor of $n^{1-\epsilon}$ for any $\epsilon > 0$, unless NP-hard problems have randomized polynomial time algorithms [14]. For bounded degree graphs, Halldórsson and Radhakrishnan [12] found the first nontrivial approximation algorithm which achieves a ratio of $O(\Delta/\ln\ln\Delta)$, where Δ is the maximal degree in the graph. Vishwanathan [25] found a polynomial $O(\Delta\ln\ln\Delta/\ln\Delta)$-approximation algorithm for the unweighted case. This algorithm uses an algorithm of Alon and Kahale [1] as a black box, which by itself uses an algorithm of Karger, Motwani, and Sudan [18] as a black box. We present an algorithm which uses a more direct approach. Furthermore, our result extends to the weighted case. Recently, a similar result for the weighted case was obtained independently by Halldórsson [10].

To sum up, the following are the main improvements achieved in this paper:

- A polynomial time randomized algorithm for the weighted *vertex cover* problem in graphs which achieves a ratio of $2-(1-o(1))\frac{2\ln\ln\Delta}{\ln\Delta}$ for large Δ, where

Δ is the maximal degree in the graph (see Theorem 2.1). This substantially improves the previous ratio of $2 - \frac{\log \Delta}{\Delta}$ [13]. In particular, for large n, this gives a ratio of $2-(1-o(1))\frac{2\ln\ln n}{\ln n}$ for general graphs, where n is the number of vertices in the graph, which slightly improves the known $2 - \frac{\ln\ln n}{2\ln n}$ ratio [2, 21].

- For every fixed k, a polynomial time randomized algorithm for the weighted *vertex cover* problem in k-uniform hypergraphs which achieves a ratio of $k - (1 - o(1))\frac{k(k-1)\ln\ln\Delta}{\ln\Delta}$, for large Δ, where Δ is the maximal degree in the hypergraph (see Theorem 4.1). In general k-uniform hypergraphs, the algorithm achieves a ratio of $k - (1 - o(1))\frac{k\ln\ln n}{\ln n}$, where n is the number of vertices in the hypergraph and n is large. (Note that the maximum degree in this case is at most n^{k-1}.) These results substantially improve the former ratios of $k(1 - c/\Delta^{\frac{1}{k-1}})$ and $k(1 - c/n^{\frac{k-1}{k}})$ [20].
- In section 5 we introduce a randomized $\Omega(\frac{\log\Delta}{\Delta\log\log\Delta})$-approximation algorithm for the independent set problem in weighted graphs, matching a recent bound of Halldórsson [10].

The rest of the paper is organized as follows. In section 2 we describe an approximation algorithm for the weighted *vertex cover* problem in bounded degree graphs, p-claw free graphs, and sparse graphs. In section 4 we describe an approximation algorithm for the weighted *vertex cover* problem in bounded degree hypergraphs, and in section 5 we describe an approximation algorithm for the weighted *independent set* problem in bounded degree graphs.

2. Vertex cover in graphs. We first need some notations and definitions. Let $G = (V, E)$ be a weighted graph with n vertices and m edges. Assume $V = \{1, \ldots, n\}$ and that for every $i \in V$ we have a positive weight w_i. For a set $S \subseteq V$, let $e(S)$ be the set of edges in the subgraph induced by S. Let $w(S)$ be the total weight of S, i.e., $w(S) = \sum_{i\in S} w_i$. Let Δ denote the maximal degree in G. A p-claw in G is an induced subgraph of G isomorphic to $K_{1,p}$. G is a p-claw free graph if G does not contain a p-claw. Let $vc(G)$ denote the size of the minimal vertex cover in G.

2.1. Relaxations of the vertex cover problem. The minimum vertex cover can be formulated using the following integer linear program:

$$\begin{array}{lll} \text{Minimize} & \sum w_i \cdot x_i, & \\ & x_i + x_j \geq 1 \quad , & (i,j) \in E, \\ & x_i \in \{0,1\} \quad , & i \in V. \end{array} \tag{1}$$

As solving integer programs is known to be NP-hard, this formulation of the problem cannot help us directly in finding a good approximation algorithm. On the other hand, a 2-approximation algorithm is obtained by using the following relaxation to the integer program (1):

$$\begin{array}{lll} \text{Minimize} & \sum w_i \cdot x_i, & \\ & x_i + x_j \geq 1 \quad , & (i,j) \in E, \\ & 0 \leq x_i \leq 1 \quad , & i \in V. \end{array} \tag{2}$$

Let us denote the optimum of relaxation (2) by $lp(G)$. It is clear that $lp(G) \leq vc(G)$, and it is easy to see that the set $S = \{i : x_i \geq \frac{1}{2}\}$ is a cover for G and that its size is no more than $2 \cdot lp(G)$. Solving relaxation (2) can be done in polynomial time

using the ellipsoid method [8, 23], and therefore solving relaxation (2) and taking S as a cover is a polynomial 2-approximation algorithm for the problem [16].

For the complete graph of n vertices with all weights equal to 1, the integrality ratio of relaxation (2) is $(2-\frac{2}{n})$, i.e., the ratio $vc(K_n)/lp(K_n)$ is at least $(2-\frac{2}{n})$, and this ratio is attained when all variables are equal to $\frac{1}{2}$. In order to eliminate this case, we define the following semidefinite relaxation:

$$\text{(3)} \qquad \begin{aligned} \text{Minimize} \quad & \sum_{i=1}^{n} w_i \cdot \frac{1+v_0 \cdot v_i}{2}, \\ & v_i \in \mathbb{R}^n, \|v_i\| = 1 \quad , \quad i \in V, \\ & (v_j - v_0) \cdot (v_i - v_0) = 0 \quad , \quad (i,j) \in E. \end{aligned}$$

Let us denote the optimum of relaxation (3) by $sd(G)$. In [19] it is proved that this is indeed a relaxation to the vertex cover problem. Moreover, they show that the integrality gap of relaxation (3) is at least $2-\epsilon$ for every constant $\epsilon > 0$; i.e., for every $\epsilon > 0$ there is a graph G_ϵ such that $vc(G_\epsilon)/sd(G_\epsilon)$ is at least $2-\epsilon$. They also show that $sd(G) \leq lp(G)$ for every G, and therefore relaxation (3) is tighter.

By assigning every dot product $v_i \cdot v_j$ a variable y_{ij}, relaxation (3) can be formulated as minimizing a linear function of the variables y_{ij}, subject to linear constraints on the variables and the constraint that the matrix $Y = \{y_{ij}\}_{1 \leq i,j \leq n}$ is positive semidefinite; i.e., for every $v \in \mathbb{R}^n$, $v^t Y v \geq 0$. For every $\epsilon > 0$, this program can be solved within an additive error of ϵ in polynomial time in $\log \frac{1}{\epsilon}$ and n using the ellipsoid method [8, 23]. Using Choleski decomposition, one can find the vectors v_i from the matrix Y in polynomial time.

Using relaxation (3), one can easily attain a 2-approximation algorithm for the *vertex cover* problem by solving the relaxation and considering the set $S = \{i \in V | v_0 \cdot v_i \geq 0\}$ as the cover. It can be easily verified that this is indeed a 2-approximation algorithm, and that its worst case occurs when all vectors are orthogonal to v_0.

The intuition for our algorithm is that whenever two vectors corresponding to adjacent vertices are very close to being orthogonal to v_0, they are close to being opposite to each other and therefore a large independent set can be found among those vertices. Thus, subtracting the independent set from the set of those vertices gives a relatively small vertex cover.

2.2. The approximation algorithm. We are now ready to describe an approximation algorithm for the minimum vertex cover. The input of the algorithm is a graph $G = (V, E)$ with $|V| = n$, and $|E| = m$, and a weight function w. Let x be a small positive number to be determined later. In Figure 1, we give the flow of the algorithm. The algorithm first solves the semidefinite program (3), then partitions the vertices of the graph into three parts, finds a large independent set in one of them, and outputs a result using this partition.

We now give an intuition as to why the algorithm finds a large independent set inside S_2. I' is the set of vertices whose vectors are relatively close to r. In section 2.3 we show how to choose c such that the expectation of the sum $\sum_{(i,j) \in e(I')} (w_i + w_j)$ is less than a constant factor of the expected total weight of I'. We thus do not have many vertices in I' which are not isolated in the subgraph induced by I', and therefore, if we remove the nonisolated vertices from I', we are left with an independent set I of total weight which is a constant factor of $w(I')$. We choose c such that $w(I')$ is maximal and thus get a large independent set.

It is easy to see that the algorithm finds a vertex cover. To show this, we have to show that, for every $(i,j) \in E$, i or j are in the cover. If $i \in S_1$ or $j \in S_1$, we are

Algorithm. VC-G

Input: A weighted graph $G = (V, E)$.
Output: A vertex cover of G.

1. Solve relaxation (3).
2. Let $S_1 = \{i \mid v_0 \cdot v_i \geq x\}$, $S_2 = \{i \mid -x \leq v_0 \cdot v_i < x\}$.
3. Find a large independent set I in S_2, using the following procedure (see [18]). Let c be a positive number to be determined later.
   (a) Choose an n-dimensional random vector r, and let $I' = \{i \in S_2 \mid v_i \cdot r \geq c\}$.
   (b) Remove vertices from I' which are nonisolated in the subgraph induced by I'. The remaining vertices form an independent set I.
4. Output $S_1 \cup (S_2 \setminus I)$.

FIG. 1. *Algorithm* VC-G *for finding a small vertex cover in a graph.*

done. If $i \in V \setminus (S_1 \cup S_2)$, then $v_0 \cdot v_i < -x$ and therefore

$$v_j \cdot v_0 = 1 + v_i \cdot v_j - v_0 \cdot v_i \geq x.$$

Thus, $j \in S_1$ and is therefore in the cover. We are left with the case that $i, j \in S_2$. However, as I is independent, at least one of i and j is not in I and is therefore in the cover.

2.3. Analysis of the algorithm. The main result we prove in this section is the following theorem.

THEOREM 2.1. *Let $G = (V, E)$ be a weighted graph with maximal degree at most Δ. The randomized algorithm* VC-G *achieves a performance ratio of*

$$2 - \frac{2 \ln \ln \Delta}{\ln \Delta} + o\left(\frac{\ln \ln \Delta}{\ln \Delta}\right).$$

In order to prove Theorem 2.1, we need some known results about n-dimensional probability space. Recall that $\phi(x) = \frac{1}{\sqrt{2\pi}} e^{\frac{-x^2}{2}}$ is the density function of a standard normal random variable. Let $N(x)$ be the tail of the standard normal distribution, i.e., $N(x) = \int_x^\infty \phi(x)dx$. We will use the following bounds on $N(x)$ (see Lemma VII.2 of Feller [7]).

LEMMA 2.2. *For every $c \geq 1$, $\phi(c)(\frac{1}{c} - \frac{1}{c^3}) < N(c) < \frac{\phi(c)}{c}$.*

A random vector $r = (r_1, \ldots, r_n)$ is said to have the *n-dimensional standard normal distribution* if the components r_i are independent random variables, each one having the standard normal distribution. In this paper a random n-dimensional vector will always denote a vector chosen from the n-dimensional standard distribution. We will use the following (see Theorem IV.16.3 in [24]).

LEMMA 2.3. *Let u be any unit vector in $\mathbb{R}^n$. Let r be a random n-dimensional vector. The projection of r on u, given by the product $r \cdot u$, is distributed according to the standard normal distribution.*

We now prove a lemma which bounds the size of the independent set I found in algorithm VC-G. This lemma is derived from Lemma 7.1 of [18].

LEMMA 2.4. *Let $G = (V, E)$ be a weighted graph with maximal degree Δ and weight function w. Let x be a number such that $x = \Theta(\frac{\ln\ln\Delta}{\ln\Delta})$. Assume $V = \{1, \ldots, n\}$ and that for every $i \in V$ there corresponds an n-dimensional unit vector v_i such that for every $(i, j) \in E$, $v_i \cdot v_j \leq -1 + 2x$. Then there is a constant C such that, for Δ sufficiently large, an independent set of total weight at least $C \cdot \frac{w(V)}{\Delta^x \cdot \sqrt{x \cdot \ln\Delta}}$ can be found by a randomized algorithm in polynomial time.*

Proof. As explained in section 2.2, we let c be a positive number to be determined later, and we let r be a random n-dimensional vector. Let $I' = \{i \in V \mid v_i \cdot r \geq c\}$. By the linearity of the expectation,

$$E(w(I')) = \sum_{i \in V} w_i \cdot N(c) = w(V) \cdot N(c).$$

Let $X = \sum_{(i,j) \in e(I')} (w_i + w_j)$. We upper bound the expectation of X as follows. By the linearity of the expectation, the expectation of X is

$$\sum_{(i,j) \in E} (w_i + w_j) \cdot Pr(i, j \in I').$$

Thus, in order to upper bound the expectation of X, it is sufficient to bound the probability that a given edge will be in the subgraph induced by I'.

By the terms of the lemma, for every $(i, j) \in E$, $v_i \cdot v_j \leq -1 + 2x$, and hence $\|v_i + v_j\| \leq 2\sqrt{x}$. We now bound the probability that i and j are both in I'.

$$\begin{aligned} &Pr(v_i \cdot r \geq c \wedge v_j \cdot r \geq c) \\ &\leq Pr((v_i + v_j) \cdot r \geq 2c) \\ &= Pr\left(\frac{v_i + v_j}{\|v_i + v_j\|} \cdot r \geq \frac{2c}{\|v_i + v_j\|}\right) \\ &= N\left(\frac{2c}{\|v_i + v_j\|}\right) \leq N\left(\frac{c}{\sqrt{x}}\right). \end{aligned}$$

We therefore get that the expectation of X is at most

$$N\left(\frac{c}{\sqrt{x}}\right) \cdot \sum_{(i,j) \in E} (w_i + w_j) \leq N\left(\frac{c}{\sqrt{x}}\right) \cdot w(V) \cdot \Delta.$$

We are now ready to determine c. We need the following claim.

CLAIM 2.5. *Let $c = \sqrt{\frac{2x}{1-x} \cdot \ln\Delta}$. If $x = \omega(\frac{1}{\ln\Delta})$, then, for sufficiently large Δ, the expectation of X is at most $(1 + o(1))\sqrt{x}$ fraction of the expected total weight of I'.*

Proof. As $x = \omega(\frac{1}{\ln\Delta})$, we have that $c = \omega(1)$, and therefore by Lemma 2.2 we get

$$\begin{aligned} \frac{N\left(\frac{c}{\sqrt{x}}\right)}{N(c)} &\leq \frac{\phi\left(\frac{c}{\sqrt{x}}\right)\sqrt{x}}{\phi(c)(1 - \frac{1}{c^2})} \\ &\leq \frac{(1 + o(1))\sqrt{x}\phi\left(\frac{c}{\sqrt{x}}\right)}{\phi(c)} = \frac{(1 + o(1))\sqrt{x}}{\Delta}. \end{aligned}$$

Thus, we get that

$$N\left(\frac{c}{\sqrt{x}}\right) \leq \frac{(1 + o(1))\sqrt{x}N(c)}{\Delta}.$$

As the expectation of X is at most $w(V) \cdot \Delta \cdot N(\frac{c}{\sqrt{x}})$, and the expected total weight of I' is $w(V) \cdot N(c)$, the claim follows. □

Let $\alpha w(V)$ be the expectation of $w(I') - X$. By Claim 2.5, $\alpha \geq N(c)(1 - 2\sqrt{x})$. Furthermore, $w(I') - X \leq w(V)$. Consider the variable $w(V) - w(I') + X$. It is nonnegative with expectation $(1 - \alpha)w(V)$, and therefore, by applying the Markov inequality to $w(V) - w(I') + X$, we get

$$Pr(w(I') - X \geq \frac{\alpha w(V)}{2}) \geq \frac{\alpha}{2 - \alpha}.$$

For each $i \in I'$ let $d_{I'}(i)$ be the degree of i in the subgraph induced by I'. In the induced subgraph by I' we get that

$$\sum_{d_{I'}(i)>0} w_i \leq \sum_{(i,j)\in e(I')} (w_i + w_j) = X.$$

Therefore, if we take $I = I' \setminus \{i : d_{I'}(i) > 0\}$ we are left with an independent set of weight at least $w(I') - X$, which is at least $\frac{\alpha w(V)}{2}$ with probability at least $\frac{\alpha}{2-\alpha}$. By Lemma 2.2 we have

$$\alpha \geq \frac{N(c)}{2} \geq \frac{C'}{\Delta^{\frac{x}{1-x}} \cdot \sqrt{x \cdot \ln \Delta}} \geq \frac{C}{\Delta^x \cdot \sqrt{x \cdot \ln \Delta}}, \tag{4}$$

where C and C' are some constants. The last inequality holds since $x = \Theta(\frac{\ln \ln \Delta}{\ln \Delta})$. It is easy to see that $\frac{2-\alpha}{\alpha}$ is only polylogarithmic in Δ, and therefore, if we repeat this process a polylogarithmic number of times, with very high probability, one of those times, we will get an independent set of size at least $\frac{\alpha w(V)}{2}$, and by (4) the lemma is proved. □

We are now ready to prove Theorem 2.1. Let

$$x = \frac{\ln \ln \Delta - \frac{3}{2} \ln \ln \ln \Delta + \ln(C/2)}{\ln \Delta}.$$

Clearly, $x = \frac{\ln \ln \Delta}{\ln \Delta}(1 - o(1))$. For $i = 1, 2$, let $value(S_i) = \sum_{i \in S_i} w_i \frac{1 + v_0 \cdot v_i}{2}$; that is, $value(S_i)$ is the contribution of the vertices in S_i to the semidefinite program. Clearly, it is sufficient to show that

$$\frac{w(S_1) + w(S_2) - w(I)}{value(S_1) + value(S_2)} \leq 2 - \frac{2 \ln \ln \Delta}{\ln \Delta} + o\left(\frac{\ln \ln \Delta}{\ln \Delta}\right).$$

As $value(S_1) \geq w(S_1)(1 + x)/2$, then

$$\frac{w(S_1)}{value(S_1)} \leq \frac{2}{1 + x} = 2 - 2x + o(x). \tag{5}$$

Moreover, as $x = \Theta(\frac{\ln \ln \Delta}{\ln \Delta})$, then by Lemma 2.4 we have that

$$\begin{aligned} w(S_2) - w(I) &\leq w(S_2)\left(1 - \frac{C}{\Delta^x \sqrt{x \ln \Delta}}\right) \\ &= w(S_2)\left(1 - \frac{2 \ln \ln \Delta}{\ln \Delta}\right) = w(S_2)(1 - 2x + o(x)), \end{aligned}$$

and, as $value(S_2) \geq w(S_2)(1-x)/2$, we get that

$$\frac{w(S_2) - w(I)}{value(S_2)} \leq \frac{2 - 4x + o(x)}{1-x} = 2 - 2x + o(x). \tag{6}$$

By (5) and (6), we get that the performance ratio of the algorithm is at most $2 - 2x + o(x)$, which proves Theorem 2.1. □

3. Vertex cover in *p*-claw free graphs. In this section we show that the same algorithm gives a better performance for p-claw free graphs.

We first note that in the proof of Theorem 2.1, Δ can be replaced by the maximal degree in S_2, since we needed only an upper bound on the degrees of S_2 to obtain the bound on X. We thus have the following claim.

CLAIM 3.1. *Let $G = (V, E)$ be a weighted graph. Let $\Delta(S_2)$ be the maximal degree of the subgraph induced by S_2 in algorithm* VC-G *running on G. Algorithm* VC-G *achieves a ratio of*

$$2 - \frac{2 \ln \ln \Delta(S_2)}{\ln \Delta(S_2)} + o\left(\frac{\ln \ln \Delta(S_2)}{\ln \Delta(S_2)}\right).$$

We now prove that our algorithm gives a better ratio for p-claw free graphs.

THEOREM 3.2. *Let $G = (V, E)$ be a weighted $(p+1)$-claw free graph. Algorithm* VC-G *achieves a performance ratio of*

$$2 - \frac{2 \ln \ln p}{\ln p} + o\left(\frac{\ln \ln p}{\ln p}\right).$$

Proof. We first show that S_2 contains no triangles. Assume the opposite. Let $i, j, k \in S_2$ be a triangle in S_2. By definition of S_2, we have

$$0 \leq (v_i + v_j + v_k)^2 \leq -3 + 12x < 0.$$

Therefore, the set of neighbors of every vertex in S_2 is an independent set. As G is a $(p+1)$-claw free graph, we have that the largest degree in S_2 cannot exceed p. Thus, by Claim 3.1 we get the desired ratio. □

4. Vertex cover in hypergraphs. For a given k, let $H = (V, E)$ be a hypergraph, with m edges and with n vertices, in which every edge is of size at most k. Assume $V = \{1, \ldots, n\}$ and that for every vertex i there is a positive weight w_i. We consider the minimum *vertex cover* problem in H. Again, let $vc(H)$ denote the weight of the minimum vertex cover in H. Let Δ be the maximal degree in H. For a set $S \subseteq V$, let $e(S)$ denote the set of edges in the subhypergraph induced by S, and let $w(S)$ denote the total weight of S. We assume for simplicity that the hypergraph is k-uniform. Our results can be easily extended to the nonuniform case.

4.1. Relaxations for the vertex cover problem in hypergraphs. Consider the next semidefinite relaxation to the problem:

$$\begin{aligned}
\text{Minimize} \quad & \sum_{i=1}^{n} w_i \cdot \frac{1 + v_0 \cdot v_i}{2}, \\
& \sum_{i,j \in e, i<j} v_i \cdot v_j \leq \sum_{i \in e} v_0 \cdot v_i + \frac{(k-4)(k-1)}{2} + k - 2 \quad , \quad e \in E, \\
& \sum_{i \in e} v_0 \cdot v_i \geq -k + 2 \quad , \quad e \in E, \\
& v_i \cdot v_i = 1 \quad , \quad i \in V.
\end{aligned} \tag{7}$$

Algorithm. VC-H

Input: A weighted graph $G = (V, E)$.
Output: A vertex cover of G.

1. Solve the semidefinite program (7).
2. Let $S_1 = \{i \mid v_0 \cdot v_i \geq b\}$ and $S_2 = \{i \mid a \leq v_0 \cdot v_i < b\}$.
3. Project all the vectors in S_2 to the space orthogonal to v_0 and normalize the vectors. For every $i \in S_2$, let v_i' be the projected vector.
4. Choose a random n-dimensional vector r, and let $I' = \{i \in S_2 \mid v_i' \cdot r \geq c\}$.
5. Remove vertices with positive degree from I' until there is no edge in I'. Let I be the remaining independent set.
6. Output $S_1 \cup (S_2 \setminus I)$.

FIG. 2. *Algorithm* VC-H *for finding a small vertex cover in a hypergraph.*

We first claim that this is indeed a relaxation; i.e., for every vertex cover C of H, there are vectors satisfying the constraints of relaxation (7) which also satisfy $\sum_{i=1}^{n} w_i \cdot \frac{1+v_0 \cdot v_i}{2} = w(C)$. Let $C \subseteq V$ be a vertex cover of H. Let v_0 be an arbitrary unit vector. Assign v_i to be v_0 if $i \in C$ and $-v_0$ otherwise. It is clear that $\sum_{i=1}^{n} w_i \cdot \frac{1+v_0 \cdot v_i}{2} = w(C)$. We still have to show that the constraints of the relaxation are satisfied. Consider an edge $e \in E$. By the definition of the vectors, not all $i \in e$ equal $-v_0$, and therefore the second constraint holds trivially; i.e., we have that $\sum_{i \in e} v_0 \cdot v_i \geq -k + 2$. It is easy to see that if not all vectors in e equal v_0, we have

$$\sum_{i,j \in e, i<j} v_i \cdot v_j \leq \frac{(k-4)(k-1)}{2},$$

and therefore

$$\sum_{i,j \in e, i<j} v_i \cdot v_j \leq \sum_{i \in e} v_0 \cdot v_i + \frac{(k-4)(k-1)}{2} + k - 2.$$

If all vectors in e equal v_0, the above trivially holds. Therefore all constraints are satisfied and this is indeed a relaxation.

4.2. The approximation algorithm. We are now ready to describe our algorithm. The algorithm is an extension of algorithm VC-G given in Figure 1. The input of the algorithm is $H = (V, E)$, and the weight function is w. Let x be a small positive number to be determined later. Let c be a positive number to be determined later. Moreover, let $a = --1 + \frac{2}{k} - (k-1)x$ and $b = -1 + \frac{2}{k} + x$. The algorithm is given in Figure 2.

It is easy to see that $S_1 \cup (S_2 \setminus I)$ is a cover for the following reason: Assume the opposite. Let $e \in E$ be an edge which is not covered by $S_1 \cup (S_2 \setminus I)$, i.e., $e \subseteq I \cup (V \setminus (S_1 \cup S_2))$. If there exists $i \in (V \setminus (S_1 \cup S_2)) \cap e$, then there is $j \in S_1 \cap e$; otherwise, we have

$$\sum_{j \in e} v_0 \cdot v_i < a + (k-1) \cdot b = -k + 2,$$

which is a contradiction. We can therefore assume that all $i \in e$ are in I, but I is independent, which is a contradiction. Therefore, algorithm VC-H finds a cover to the hypergraph.

4.3. Analysis of the algorithm. In this section we prove the following theorem:

THEOREM 4.1. *Let k be an integer such that $k^3 = o(\frac{\ln\ln\Delta}{\ln\ln\ln\Delta})$. Let $H = (V, E)$ be a weighted k-uniform hypergraph with maximal degree Δ. There is a proper choice of x and c such that the randomized algorithm* VC-H *achieves a performance ratio of*

$$k - k(k-1)\frac{\ln\ln\Delta}{\ln\Delta} + o\left(\frac{\ln\ln\Delta}{\ln\Delta}\right).$$

In order to prove Theorem 4.1, we first have to bound the weight of I. We need the following lemma, which bounds the probability that a given edge in the subhypergraph induced by S_2 will be in I'.

LEMMA 4.2. *Let $e \in E$ be an edge in the subhypergraph induced by S_2. If $x = \Theta(\frac{\ln\ln\Delta}{\ln\Delta})$, then, for sufficiently large Δ, the probability that e will be an edge in the subhypergraph induced by I' is at most $N(\frac{c}{\sqrt{d_k \cdot x}})$, where $d_k = \frac{k}{2(k-1)}$.*

Proof. For a given $i \in e$, let u_i be the projection of v_i to the space orthogonal to v_0. Let $a_i = v_0 \cdot v_i$. We therefore have that $v_i = a_i \cdot v_0 + u_i$. As $i \in S_2$, we know that $a \le a_i < b$, and thus $a^2 \ge a_i^2 > b^2$. Let $v_i' = \frac{u_i}{\|u_i\|}$ be the normalized projection of v_i. By the definition of a_i, u_i,

$$u_i \cdot u_j = v_i \cdot v_j - a_i \cdot a_j$$

and

$$\|u_i\| = \sqrt{1 - a_i^2} \ge \sqrt{1 - a^2}.$$

Now, by the constraints of relaxation (7) we have

$$\sum_{i,j \in e, i<j} v_i \cdot v_j \le \frac{(k-4)(k-1)}{2} + kx.$$

Considering all the above we get

$$\begin{aligned}
\sum_{i,j\in e,i<j} v_i' \cdot v_j' &= \sum_{i,j\in e,i<j} \frac{u_i \cdot u_j}{\|u_i\| \cdot \|u_j\|} \\
&= \sum_{i,j\in e,i<j} \frac{v_i \cdot v_j - a_i \cdot a_j}{\sqrt{(1-a_i^2)(1-a_j^2)}} \\
&\le \frac{\sum_{i,j\in e,i<j}(v_i \cdot v_j - a_i \cdot a_j)}{1-a^2} \\
&\le \frac{(k-4)(k-1)/2 + kx - \binom{k}{2}b^2}{1-a^2} \\
&= -\frac{k}{2} + \frac{k^2 \cdot d_k}{2} \cdot x - \frac{k^4 x^2}{4(k-1)(2+kx)} \le -\frac{k}{2} + \frac{k^2 \cdot d_k}{2} \cdot x.
\end{aligned}$$

The last equality follows by assigning $a = -1 + \frac{2}{k} - (k-1)x$, $b = -1 + \frac{2}{k} + x$, and using some simple, though cumbersome, calculations. We can therefore bound the

norm of the sum of the projected vectors v'_i for $i \in e$:

$$\left\| \sum_{i \in e} v'_i \right\|^2 \leq \frac{k^3 \cdot x}{2(k-1)} = k^2 \cdot d_k \cdot x.$$

The probability that all $i \in e$ will be in I' is bounded by

$$Pr\left(\left(\sum_{i \in e} v'_i \right) \cdot r \geq k \cdot c \right) = N\left(\frac{k \cdot c}{\| \sum_{i \in e} v'_i \|} \right) \leq N\left(\frac{c}{\sqrt{d_k \cdot x}} \right),$$

and the lemma follows. □

For every vertex, the probability that this vertex will be in I' is $N(c)$. Therefore, the expected total weight of I' is $w(S_2) \cdot N(c)$. Let $X = \sum_{e \in e(I')} \sum_{i \in e} w_i$. We want to find c such that X will be smaller than $w(I')$ by at least a constant factor.

LEMMA 4.3. *Let* $c = \sqrt{\frac{2d_k \cdot x}{1 - d_k \cdot x} \cdot \ln \Delta}$. *If* $x = \Theta(\frac{\ln \ln \Delta}{\ln \Delta})$, *then, for sufficiently large* Δ, *the expectation of* X *is at most* $\sqrt{2x}$ *fraction of the expected weight of the vertices in* I'.

Proof. As $x = \omega(\frac{1}{\ln \Delta})$, we have that $c = \omega(1)$, and therefore by Lemma 2.2 we have that

$$\begin{aligned} N\left(\frac{c}{\sqrt{d_k \cdot x}} \right) &\leq \phi\left(\frac{c}{\sqrt{d_k \cdot x}} \right) \cdot \frac{\sqrt{d_k \cdot x}}{c} \\ &= \phi(c) \cdot \frac{\sqrt{d_k \cdot x}}{\Delta \cdot c} \\ &\leq \frac{N(c)}{\Delta} \cdot \frac{\sqrt{d_k \cdot x}}{1 - 1/c^2} \leq \frac{\sqrt{2x} N(c)}{\Delta}. \end{aligned} \tag{8}$$

Now, the expected total weight of I' is $w(S_2) \cdot N(c)$. By the linearity of the expectation and by Lemma 4.2, the expectation of X can be bounded as follows:

$$\begin{aligned} E(X) &= \sum_{e \in E(S_2)} \sum_{i \in e} w_i \cdot Pr(e \in e(I')) \\ &\leq N\left(\frac{c}{\sqrt{d_k \cdot x}} \right) \cdot \sum_{e \in E} \sum_{i \in e} w_i \\ &\leq N\left(\frac{c}{\sqrt{d_k \cdot x}} \right) \cdot \sum_{i \in V} \Delta \cdot w_i \\ &= N\left(\frac{c}{\sqrt{d_k \cdot x}} \right) \cdot \Delta \cdot w(S_2). \end{aligned}$$

Thus, by (8), the lemma follows. □

Let $\alpha_k w(S_2)$ be the expectation of $w(I') - X$. $w(I') - X \leq w(S_2)$, and therefore, by the Markov inequality applied to $w(S_2) - w(I') + X$, the probability that $w(I') - X$ is at least $\frac{\alpha_k w(S_2)}{2}$ is lower bounded by $\frac{\alpha_k}{2 - \alpha_k}$. By the definition of α_k, for some constant C,

$$\alpha_k \geq (1 - \sqrt{2x}) N(c) \geq \frac{2C}{\Delta^{d_k \cdot x} \sqrt{d_k x \ln \Delta}}. \tag{9}$$

We are now ready to prove Theorem 4.1. Once again, for $i = 1, 2$, let $value(S_i) = \sum_{i \in S_i} \frac{1+v_0 \cdot v_i}{2}$. We first determine x. Set

$$x = \frac{\ln \ln \Delta - \frac{3}{2} \ln \ln \ln \Delta + \ln(Cd_k) - \ln(k^2)}{d_k \ln \Delta}.$$

Notice that, by the terms of the lemma, k is very small, and

$$x \leq \frac{\ln \ln \Delta}{d_k \ln \Delta}, \tag{10}$$

$$k^3 x = o(1). \tag{11}$$

By the definition of x,

$$\Delta^{d_k x} = \frac{d_k \ln \Delta}{k^2 \sqrt{\pi} (\ln \ln \Delta)^{3/2}},$$

and thus by (9) and (10)

$$\frac{\alpha_k}{2} = \frac{k^2 x}{2} \left(\frac{\ln \ln \Delta}{x d_k \ln \Delta} \right)^{3/2} \geq \frac{k^2 x}{2}.$$

Therefore, as $\frac{2-\alpha_k}{\alpha_k}$ is only logarithmic in Δ, if we repeat the process a polylogarithmic number of times, then with high probability, in at least one of these times, we will get an independent set I of total weight at least $\frac{k^2 x w(S_2)}{2}$. Therefore, in this case

$$w(S_2) - w(I) \leq w(S_2) \left(1 - \frac{k^2 x}{2} \right).$$

On the other hand, $value(S_2) \geq w(S_2)(\frac{1}{k} - \frac{(k-1)x}{2})$. Combining these facts with (11), we get

$$\frac{w(S_2) - w(I)}{value(S_2)} \leq \frac{1 - \frac{k^2 x}{2}}{\frac{1}{k} - \frac{(k-1)x}{2}} = k - \frac{k^2 x}{2} + \frac{k^3 x^2}{2} = k - \frac{k^2 x}{2} + o(x). \tag{12}$$

From (10) and (11), and as $value(S_1) \geq w(S_1)(\frac{1}{k} + \frac{x}{2})$, we get that

$$\frac{w(S_1)}{value(S_1)} \leq \frac{2k}{2 + kx} = k - \frac{k^2 x}{2} + o(x). \tag{13}$$

By (12) and (13) we get that the performance ratio of the algorithm is at most

$$k - \frac{k^2 x}{2} + o(x) = k - k(k-1) \frac{\ln \ln \Delta}{\ln \Delta} + o\left(\frac{\ln \ln \Delta}{\ln \Delta} \right),$$

and thus Theorem 4.1 is proved.

It is straightforward that our algorithm can be extended to hypergraphs with maximal edge size k. This can be obtained in the following way: Given a hypergraph H with maximal edge size k, take every edge e of size l, where $l < k$, add new $k - l$ vertices to H, and replace e by a new edge containing the new $k - l$ vertices and the vertices of e. It is obvious that the new hypergraph is a k-uniform hypergraph and that Δ remains the same; thus Theorem 4.1 can be used.

It is easy to see that for k which satisfy $k^3 = o(\frac{\ln \ln n}{\ln \ln \ln n})$, for hypergraphs with maximal edge size k, algorithm VC-H achieves a ratio of $k - (1 - o(1))k \frac{\ln \ln n}{\ln n}$, as the maximal degree Δ cannot exceed n^{k-1}.

Algorithm. IS

Input: A weighted graph $G = (V, E)$.
Output: An independent set of G.

1. Solve relaxation (14).
2. Let $S_0 = \{i \in V \mid \frac{v_0 \cdot v_i + 1}{2} < \frac{1}{p}\}$, $S_1 = \{i \in V \mid \frac{1}{p} \leq \frac{v_0 \cdot v_i + 1}{2} < \frac{1}{2}\}$, and $I_2 = S_2 = \{i \in V \mid \frac{1}{2} \leq \frac{v_0 \cdot v_i + 1}{2}\}$.
3. Use the greedy algorithm on the set S_0 to find an independent set $I_0 \subseteq S_0$.
4. Project all vectors v_i corresponding to vertices in S_1 to the space orthogonal to v_0 and normalize them. The projected vectors will be denoted by v_i'.
5. Choose a random n-dimensional vector r, and let $I' = \{i \in S_1 \mid v_i' \cdot r \geq c\}$.
6. Remove all nonisolated vertices in the subgraph induced by I'. The remaining set is I_1.
7. Return the set with the largest total weight between I_0, I_1, I_2.

FIG. 3. *Algorithm* IS *for finding a large independent set on a graph.*

5. Independent set approximation. In this section we consider a simple application of our methods to the *independent set* problem. Recently, the same result was derived independently by Halldórsson [10], using a different approach.

Let $G = (V, E)$ be a weighted graph. Assume $V = \{1, \ldots, n\}$ and that for every $1 \leq i \leq n$ there is a positive weight w_i. Let Δ be the maximal degree in G. Consider the following semidefinite relaxation for the *independent set* problem:

$$\begin{aligned} \text{Maximize} \quad & \sum_{i=1}^{n} w_i \cdot \frac{1 + v_0 \cdot v_i}{2}, \\ & (v_i + v_0) \cdot (v_j + v_0) = 0 \quad , \quad (i,j) \in E, \\ & \|v_i\| = 1 \quad , \quad i \in V. \end{aligned} \tag{14}$$

It is easy to see that this is indeed a relaxation to the *independent set* problem. It can be derived from relaxation (3) by replacing v_0 by $-v_0$.

Let $p \geq 3$ and c be parameters to be chosen later. Consider the algorithm presented in Figure 3. We show that this algorithm achieves the desired ratio. In the next lemma, we show that partitioning the problem into three parts reduces the performance of the algorithm by a factor of three.

LEMMA 5.1. *Assume $Z = Z_0 + Z_1 + Z_2$, where Z_k, for $k = 0, 1, 2$, is the value of the relaxation restricted to the set S_k. For $k = 0, 1, 2$, let $I_k \subseteq S_k$ be an independent set which satisfies $w(I_k) \geq \beta \cdot Z_k$. Let m be such that $w(I_m)$ is maximized. Then $w(I_m) \geq \beta \cdot \alpha(G)/3$, where $\alpha(G)$ is the maximum weight of an independent set in G.*

Proof. It is clear that $Z \geq \alpha(G)$. Therefore, we have the following inequalities:

$$w(I_m) \geq \frac{w(I_0) + w(I_1) + w(I_2)}{3} \geq \frac{\beta(Z_0 + Z_1 + Z_2)}{3} = \frac{\beta}{3} \cdot Z \geq \frac{\beta}{3} \cdot \alpha(G).$$

Therefore, the lemma follows. ∎

We now show that algorithm IS finds an independent set of total weight at least $\Theta(\frac{\log \Delta}{\Delta \cdot \log\log \Delta} \cdot \alpha(G))$. We use Lemma 5.1 with $\beta = \frac{\log \Delta}{\Delta \log\log \Delta}$.

For S_0, we know that $Z_0 \leq \frac{w(S_0)}{p}$ and that the greedy algorithm produces an independent set I_0 of total weight at least $w(S_0)/(\Delta+1)$. Therefore, we get that $w(I_0)$ is of total weight at least $\frac{p}{\Delta+1} \cdot Z_0$.

For S_2, by the constraints of relaxation (14), we have that S_2 is an independent set, and therefore I_2 is an independent set, and thus $w(I_2) = w(S_2) = Z_2$.

We now analyze the case of S_1. For this we need the following lemma.

LEMMA 5.2. *The randomized algorithm* IS *produces with a nonnegligible probability a set I_1 of total weight at least $\Omega(\frac{\Delta^{2/p} \cdot Z_1}{\Delta\sqrt{\ln \Delta}})$.*

Proof. As in section 4.3, for every $i \in S_1$, let $a_i = v_0 \cdot v_i$ and assume $v_i = a_i v_0 + u_i$, where $u_i \cdot v_0 = 0$. For $i \in S_1$, we have that $-1 + \frac{2}{p} \leq a_i < 0$. Now,

$$\|u_i\| = \sqrt{1 - a_i^2},\ u_i \cdot u_j = v_i \cdot v_j - a_i a_j.$$

For $i \in S_1$, let $v_i' = \frac{u_i}{\|u_i\|}$ be the normalized projection of v_i. We thus have the following for $(i,j) \in E$:

$$\begin{aligned}
\frac{u_i \cdot u_j}{\|u_i\|\|u_j\|} &= \frac{v_i \cdot v_j - a_i a_j}{\sqrt{(1-a_i^2)(1-a_j^2)}} \\
&= \frac{-1 - a_i - a_j - a_i a_j}{\sqrt{(1-a_i^2)(1-a_j^2)}} \\
&= -\sqrt{\frac{(1+a_i)(1+a_j)}{(1-a_i)(1-a_j)}} \\
&\leq -\frac{1}{p-1}.
\end{aligned}$$

Let $x = \frac{p-2}{2p-2}$. As $p \geq 3$, $x \geq \frac{1}{4}$. We thus have that for every $(i,j) \in e(S_2)$, $v_i' \cdot v_j' \leq -1 + 2x$. Let

$$X = \sum_{(i,j) \in e(I')} (w_i + w_j).$$

As $x \geq \frac{1}{4}$, we have that $x = \omega(\frac{1}{\ln \Delta})$, and thus, by choosing $c = \sqrt{\frac{2x}{1-x} \ln \Delta}$, the terms of Claim 2.5 are fulfilled, and, for sufficiently large Δ, the expectation of X is at most $(1 + o(1))\sqrt{x}$ fraction of the expected total weight of I'. As $x \leq \frac{1}{2}$, we get that the expectation of X is at most $(1 + o(1))\frac{1}{\sqrt{2}}$ fraction of the expectation of I'. Therefore, the expectation of $w(I') - X$ is $\Omega(w(S_1)N(c))$. By applying the Markov inequality to nonnegative random variable $w(S_1) - w(I') + X$, we get that the probability that $w(I') - X$ is less than half its expectation is lower bounded by $\Omega(N(c)) = \Omega(\frac{\Delta^{2/p}}{\Delta\sqrt{\ln \Delta}})$. Clearly, by repeating this process a polynomial number of times, with high probability, in at least one of the iterations $w(I') - X$ is at least half its expectation. By the fact that $\sum_{d_{I'}(i)>0} w_i \leq X$, by taking off vertices with positive degree from the subgraph induced by I', we are left with an independent set of total weight at least

$$w(I') - X = \Omega(w(S_1) \cdot N(c)) = \Omega\left(\frac{\Delta^{2/p} w(S_1)}{\Delta\sqrt{\ln \Delta}}\right).$$

Now, $Z_1 \leq \frac{w(S_1)}{2}$, and so

$$w(I_1) \geq \Omega\left(\frac{\Delta^{2/p} \cdot Z_1}{\Delta\sqrt{\ln \Delta}}\right). \qquad \square$$

Altogether, we have the following:

$$\begin{aligned} w(I_0) &\geq \tfrac{p}{\Delta+1} Z_0, \\ w(I_1) &\geq \Omega\big(\tfrac{\Delta^{2/p}}{\Delta\sqrt{\ln \Delta}} \cdot Z_1\big), \\ w(I_2) &= Z_2. \end{aligned}$$

By Lemma 5.1, setting $p = \frac{4 \ln \Delta}{3 \ln \ln \Delta}$ gives a ratio of $\Omega(\frac{\ln \Delta}{\Delta \ln \ln \Delta})$, as desired.

6. Concluding remarks. We obtained improved algorithms for finding small vertex covers in bounded degree graphs and hypergraphs. On graphs with maximum degree at most Δ, we presented an algorithm which achieves a performance ratio of $2-(1-o(1))\frac{2 \ln \ln \Delta}{\ln \Delta}$. For general graphs, we get a ratio of $2-(1-o(1))\frac{2 \ln \ln n}{\ln n}$. It will be interesting if an approximation algorithm with a ratio of $2-f(\Delta)$ will be introduced for the *vertex cover* problem in bounded degree graphs, where $f(n) = \omega(\frac{\ln \ln n}{\ln n})$. It is also interesting if, for such a function f, an approximation algorithm with a ratio of $2-f(n)$ exists for general graphs. It will also be interesting if a $(k - f(n))$-approximation algorithm will be found for k-uniform hypergraphs, with such a function f.

DUAL-BOUNDED GENERATING PROBLEMS: ALL MINIMAL INTEGER SOLUTIONS FOR A MONOTONE SYSTEM OF LINEAR INEQUALITIES*

E. BOROS†, K. ELBASSIONI‡, V. GURVICH†, L. KHACHIYAN‡, AND K. MAKINO§

Abstract. We consider the problem of enumerating all minimal integer solutions of a monotone system of linear inequalities. We first show that, for any monotone system of r linear inequalities in n variables, the number of maximal infeasible integer vectors is at most rn times the number of minimal integer solutions to the system. This bound is accurate up to a *polylog*(r) factor and leads to a polynomial-time reduction of the enumeration problem to a natural generalization of the well-known dualization problem for hypergraphs, in which dual pairs of hypergraphs are replaced by dual collections of integer vectors in a box. We provide a quasi-polynomial algorithm for the latter dualization problem. These results imply, in particular, that the problem of incrementally generating all minimal integer solutions to a monotone system of linear inequalities can be done in quasi-polynomial time.

1. Introduction.

Consider a system of r linear inequalities in n integer variables

$$Ax \geq b, \quad x \in \mathcal{C} = \{x \in \mathbb{Z}^n \mid 0 \leq x \leq c\}, \tag{1.1}$$

where $A \in \mathbb{R}^{r \times n}$ is a given $r \times n$-matrix, $b \in \mathbb{R}^r$ is an r-vector, $c \in \mathbb{R}^n_+$ is a nonnegative n-vector, some or all of whose components may be infinite, and $\mathbb{Z}$, $\mathbb{R}$, and $\mathbb{R}_+$ denote, respectively, the set of integers, the set of reals, and the set of nonnegative reals. A vector $x \in \mathcal{C}$ is called a *feasible solution* of (1.1) if $Ax \geq b$. We shall assume that (1.1) is a *monotone system*; i.e., if $x \in \mathcal{C}$ is feasible, then all vectors $y \in \mathcal{C}$ with $y \geq x$ are also feasible. For instance, (1.1) is monotone if the matrix A is nonnegative, though the nonnegativity of A is not necessary; e.g., if $r = 1$, $n = 2$, and $c = (1, 2)$, then the system $5x_1 - x_2 \geq 3$ is monotone.

Let us denote by $\mathcal{F}_{A,b,c}$ the set of all minimal feasible solutions for the monotone system (1.1):

$$\mathcal{F}_{A,b,c} = \left\{ y \;\middle|\; \begin{array}{c} y \in \mathcal{C}, \quad Ay \geq b, \quad \text{and} \\ \nexists \text{ feasible solution } x \text{ of (1.1)} \\ \text{such that } x \leq y \text{ and } x \neq y \end{array} \right\}.$$

In this paper, we are concerned with the problem of generating all vectors of $\mathcal{F}_{A,b,c}$ for a monotone system (1.1). Since the number of minimal feasible solutions of a monotone system may be exponential in the size of the input, the efficiency of such generation is measured customarily in terms of the sizes of both the input and the output (see, e.g., [19]). More precisely, we focus on the problem of generating a "next" element of $\mathcal{F}_{A,b,c}$ sequentially.

GEN$(A, b, c, \mathcal{X})$. *Given a monotone system* (1.1) *defined by* (A, b, c) *and a subset* $\mathcal{X} \subseteq \mathcal{F}_{A,b,c}$ *of its minimal feasible vectors, either find a new minimal integral vector* $x \in \mathcal{F}_{A,b,c} \setminus \mathcal{X}$ *or show that no such vector exists; i.e.,* $\mathcal{X} = \mathcal{F}_{A,b,c}$.

Clearly, the entire set $\mathcal{F}_{A,b,c}$ can be generated by initializing $\mathcal{X} = \emptyset$ and iteratively solving the above problem $|\mathcal{F}_{A,b,c}| + 1$ times. Accordingly, we say that the family $\mathcal{F}_{A,b,c}$ can be generated in *incremental q-time* if the problem GEN$(A, b, c, \mathcal{X})$ can be solved in $q(n, r, |\mathcal{X}|)$ operations for every subset $\mathcal{X} \subseteq \mathcal{F}_{A,b,c}$. In particular, we say that $\mathcal{F}_{A,b,c}$ can be generated in *incremental polynomial* or *quasi-polynomial* time if q is a polynomial or quasi-polynomial expression, respectively. These complexity notions are stated here for the unit-cost model of computation, in which the $q(n, r, |\mathcal{X}|)$ bound applies to the number of comparisons $(\leq, \geq)$ and the arithmetic and rounding operations $(+, -, \times, /, \lfloor\ \rfloor)$ required to solve problem GEN$(A, b, c, \mathcal{X})$ for *real* input (A, b, c). All of our results in this paper will also be valid, with the same bound for the number of operations, for *rational* input (A, b, c) in the bit model of computation, where the number of bits used in the operations depends linearly on the binary size of the input data.

Let us note here that the above definition for the complexity of sequential generation, based on GEN$(A, b, c, \mathcal{X})$, does indeed grasp the essence of sequential generation correctly. Namely, if there is any algorithm $\mathbf{A}$ generating all the elements of $\mathcal{F}_{A,b,c}$ sequentially, say, in the order $\mathcal{F}_{A,b,c} = \{x^1, x^2, \ldots, x^K\}$ and $x^{K+1} =$ "STOP" such that $\{x^1, \ldots, x^k\}$ is generated by $q(n, r, k-1)$ operations for every $k = 1, \ldots, K+1$, then, using the same algorithm $\mathbf{A}$, problem GEN$(A, b, c, \mathcal{X})$ can also be solved in $O(q(n, r, |\mathcal{X}|))$ operations *for every subset* $\mathcal{X} \subseteq \mathcal{F}_{A,b,c}$.

The problem of generating the family $\mathcal{F}_{A,b,c}$ of all minimal feasible solutions to a monotone system (1.1) includes, as special cases, several well-known problems from the literature.

First, if A is integral and $c = +\infty$, the generation of $\mathcal{F}_{A,b,c}$ can be regarded as the computation of the Hilbert basis for the polynomial ideal which has $\{x \in \mathbb{Z}^n \mid Ax \geq b, x \geq 0\}$ as its Newton polyhedron.

If A is a binary matrix, $b = \mathbf{e}_r$, and $c = \mathbf{e}_n$, where $\mathbf{e}_d$ denotes the vector of all ones of dimension d, then $\mathcal{F}_{A,b,c}$ is the set of (characteristic vectors of) all minimal transversals to the hypergraph defined by the rows of A. In this case, problem GEN$(A, b, c, \mathcal{X})$ turns into the well-known *hypergraph dualization problem*, that is, the incremental enumeration of all minimal transversals (or, equivalently, all maximal independent sets) of a given hypergraph (see, e.g., [12]). For several special classes of hypergraphs, GEN$(A, \mathbf{e}_r, \mathbf{e}_n, \mathcal{X})$ can be solved efficiently, including 2-monotonic, threshold, matroid, read-bounded, and acyclic hypergraphs (see [4, 8, 9, 11, 13, 16, 21, 23, 24, 26, 27]), and, most notably, when the hyperedges are all of size 2, that is, when the hypergraph is the edge set of a graph (see [19, 20, 29]). The latter result has been extended to an incremental polynomial solution for all hypergraphs with bounded edge sizes (see, e.g., [6, 12, 13]), in which case even an efficient parallel solution exists (see [5]). There is no incremental polynomial-time algorithm known for the dualization of an arbitrary hypergraph. The best known result is an incremental

quasi-polynomial-time algorithm, proposed by Fredman and Khachiyan [14], which solves $\mathrm{GEN}(A, \mathbf{e}_r, \mathbf{e}_n, \mathcal{X})$ in $O(nt) + t^{o(\log t)}$ time, where $t = \max\{r, |\mathcal{X}|\}$. Recent improvements on this procedure can be found in [15, 28].

If A is binary, $c = \mathbf{e}_n$, and $b = Ac - \mathbf{e}_r$, then the vectors in $\mathcal{F}_{A,b,c}$ correspond (in a one-to-one way) to the maximal matchings of the hypergraph, formed by the columns of A. It was shown in [20] that $\mathrm{GEN}(A, b, c, \mathcal{X})$ can be solved in this case in polynomial time, thus providing an efficient generation of all maximal matchings. More generally, if A is binary, $c = \mathbf{e}_n$, and b is arbitrary, then the vectors in $\mathcal{F}_{A,b,c}$ are the characteristic vectors of the so-called *multiple transversals* of the hypergraph formed by the rows of A, and an incremental quasi-polynomial generation is provided in [7] for this case.

If $c = \mathbf{e}_n$ and $r = 1$, then (1.1) is also known as a *binary knapsack problem*, for which $\mathcal{F}_{A,b,c}$ can be generated in incremental polynomial time with an amortized complexity of $O(n^2)$ time per element as shown by Lawler, Lenstra, and Rinnooy Kan [20]. Improving on this result, Uno [30] showed recently that, in this special case, $\mathcal{F}_{A,b,c}$ can be generated in $O(n)$ time per element in the worst case.

More generally, Lawler, Lenstra, and Rinnooy Kan considered the case of a nonnegative matrix A with b arbitrary and $c = \mathbf{e}_n$ and conjectured that no efficient generation of $\mathcal{F}_{A,b,\mathbf{e}_n}$ is possible in this case unless P = NP.

As our main result, we shall show that problem $\mathrm{GEN}(A, b, c, \mathcal{X})$ can in fact be solved in quasi-polynomial time for any monotone system (1.1); that is, all minimal integer solutions of (1.1) can be generated in incremental quasi-polynomial time, both in the unit-cost and the bit models of computation.

THEOREM 1.1. *Problem GEN$(A, b, c, \mathcal{X})$ can be solved in $t^{o(\log t)}$ time, where* $t = \max\{n, r, |\mathcal{X}|\}$.

This result implies that $\mathrm{GEN}(A, b, c, \mathcal{X})$ cannot be NP-hard unless all NP-complete problems can be solved in quasi-polynomial time. We mention in passing that, if c is bounded and the number of nonzero coefficients per inequality in (1.1) is fixed, the results of [5] also imply that problem $\mathrm{GEN}(A, b, c, \mathcal{X})$ can be efficiently solved in parallel.

2. Uniformly dual-bounded monotone systems. Let us note first that, without any loss of generality, the finiteness of $\mathcal{C}$ can always be assumed. Namely, defining $J^* = \{j \mid c_j = \infty\}$, $J_* = \{1, \dots, n\} \setminus J^*$, and

$$\bar{c}_j = \begin{cases} \max_{i:a_{ij}>0} \left\lceil \frac{b_i - \sum_{k\in J_*} \min\{0, a_{ik}\} c_k}{a_{ij}} \right\rceil & \text{for } j \in J^* \text{ and} \\ c_j & \text{for } j \in J_*, \end{cases} \tag{2.1}$$

we have $\mathcal{F}_{A,b,c} = \mathcal{F}_{A,b,\bar{c}}$. To see this equality, let us consider an arbitrary vector $x = (x_1, \dots, x_n) \in \mathcal{F}_{A,b,c}$ such that $x_j > 0$ for some $j \in J^*$. We claim that $x_j \le \bar{c}_j$. For this, let us observe first that the restriction of A on J^* must be nonnegative: $a_{ij} \ge 0$ for all $i \in \{1, \dots, r\}$ and $j \in J^*$; otherwise, the monotonicity of (1.1) could be violated by sufficiently increasing x_j, the jth component of x. Thus we have

$$\begin{aligned} a_{ij}x_j + \sum_{k\in J_*} \min\{0, a_{ik}\} c_k &\le a_{ij}x_j + \sum_{k\in J_*} \min\{0, a_{ik}\} x_k \\ &\le a_{ij}x_j + \sum_{k\in J_*} a_{ik}x_k \\ &\le \sum_{k\in J^*} a_{ik}x_k + \sum_{k\in J_*} a_{ik}x_k = a^i x \end{aligned}$$

since the restriction of A on J^* is nonnegative, where a^i denotes the ith row of A. Let us consider now the vector x' obtained from x by decreasing its jth component by 1. Then $x' \in \mathcal{C}$, and, by the minimality of x, x' is infeasible for (1.1). Hence $b_i - a_{ij} \leq a^i x - a_{ij} = a^i x' < b_i$ for some $i \in \{1, \ldots, r\}$, implying $a^i x < b_i + a_{ij}$. Thus we can conclude that

$$a_{ij} x_j + \sum_{k \in J_*} \min\{0, a_{ik}\} c_k < b_i + a_{ij},$$

from which our claim follows.

Since the bounds in (2.1) are easy to compute and since appending these bounds to (1.1) does not change the set $\mathcal{F}_{A,b,c}$ by the above observation, we shall assume in what follows that all components of the nonnegative vector c are finite, even though this may not be the case for the original system. This assumption does not entail any loss of generality and allows us to consider $\mathcal{F}_{A,b,c}$ as a system of integral vectors in a finite box.

Let us also note that the input monotone system (1.1) can be assumed to be feasible and nontrivial; that is, $\mathcal{F}_{A,b,c} \neq \emptyset$ and $\mathcal{F}_{A,b,c} \neq \{0\}$. For a finite and nonnegative c, this is equivalent to $Ac \geq b$ and $0 \not\geq b$.

Generalizing systems of monotone inequalities, we shall consider arbitrary monotone subsets of the finite integral box $\mathcal{C}$. For a collection of integral vectors $\mathcal{A} \subseteq \mathcal{C}$, let us denote, respectively, by $\mathcal{A}^+ = \{x \in \mathcal{C} \mid x \geq a \text{ for some } a \in \mathcal{A}\}$ and $\mathcal{A}^- = \{x \in \mathcal{C} \mid x \leq a \text{ for some } a \in \mathcal{A}\}$ the *ideal* and *filter* generated by $\mathcal{A}$. Generalizing standard terminology of the theory of hypergraphs, elements in $\mathcal{C} \setminus \mathcal{A}^+$ will be called *independent* of $\mathcal{A}$, and let us denote by $\mathcal{I}(\mathcal{A})$ the set of all *maximal independent* elements of $\mathcal{A}$. Then, for a finite box $\mathcal{C}$, we have

$$\mathcal{A}^+ \cap \mathcal{I}(\mathcal{A})^- = \emptyset \quad \text{and} \quad \mathcal{A}^+ \cup \mathcal{I}(\mathcal{A})^- = \mathcal{C}. \tag{2.2}$$

In particular, if $\mathcal{A} = \mathcal{F}_{A,b,c}$ is the set of all minimal feasible integral vectors for (1.1) and $\mathcal{C}$ is finite, then the ideal $\mathcal{F}^+_{A,b,c}$ is the set of all feasible solutions of (1.1), while the filter $\mathcal{C} \setminus \mathcal{F}^+_{A,b,c}$ is the collection of all *infeasible* vectors. This filter is generated by the set $\mathcal{I}(\mathcal{F}_{A,b,c})$ consisting of all *maximal infeasible* integral vectors for (1.1):

$$\mathcal{C} \setminus \mathcal{F}^+_{A,b,c} \;=\; \mathcal{I}(\mathcal{F}_{A,b,c})^- \;=\; \{x \in \mathcal{C} \mid Ax \not\geq b\} \;=\; \bigcup_{y \in \mathcal{I}(\mathcal{F}_{A,b,c})} \{y\}^-.$$

Let us return finally to the generation of minimal feasible solutions of a monotone system (1.1). Our approach for the solution of this problem will be based on the *joint generation* of the union $\mathcal{F}_{A,b,c} \cup \mathcal{I}(\mathcal{F}_{A,b,c})$. The following statement, ensuring the efficiency of such an approach, is instrumental in our proofs and may also be of independent interest.

THEOREM 2.1. *If the monotone system* (1.1) *is feasible, then, for any nonempty subset* $\mathcal{X} \subseteq \mathcal{F}_{A,b,c}$, *we have*

$$|\mathcal{I}(\mathcal{X}) \cap \mathcal{I}(\mathcal{F}_{A,b,c})| \leq rn|\mathcal{X}|. \tag{2.3}$$

In particular, for $\mathcal{X} = \mathcal{F}_{A,b,c}$, *this implies the inequality*

$$|\mathcal{I}(\mathcal{F}_{A,b,c})| \leq rn|\mathcal{F}_{A,b,c}|.$$

Using the terminology introduced in [7], the above statement claims that $\mathcal{F}_{A,b,c}$ for a monotone system (1.1) is *uniformly dual-bounded*. This property, more precisely inequality (2.3), guarantees that, if we manage to generate the elements of the union $\mathcal{F}_{A,b,c} \cup \mathcal{I}(\mathcal{F}_{A,b,c})$ one-by-one in some efficient way, then, at any given moment during this generation, the number of produced maximal infeasible vectors is polynomially limited by the number of obtained minimal feasible vectors. Thus, by simply disregarding the maximal infeasible vectors in this process, we get an efficient algorithm for the generation of minimal feasible vectors.

Let us remark here that such an approach would certainly be too wasteful for the generation of maximal infeasible solutions, as the following example shows. Let us consider the monotone system (A, b, c) consisting of the r inequalities $x_1 + x_2 \geq 1$, $x_3 + x_4 \geq 1, \ldots, x_{2r-1} + x_{2r} \geq 1$ in $n = 2r$ variables, with $c = \mathbf{e}_{2r}$. This system has 2^r minimal feasible binary vectors and only r maximal infeasible ones, i.e.,

$$|\mathcal{F}_{A,b,c}| \geq 2^{|\mathcal{I}(\mathcal{F}_{A,b,c})|}.$$

Thus $|\mathcal{F}_{A,b,c}|$ cannot be bounded by a polynomial in r, n, and $|\mathcal{I}(\mathcal{F}_{A,b,c})|$ in general. Therefore, in the joint generation process, we may get unlucky in the worst case and get first exponentially many minimal feasible vectors before obtaining the first maximal infeasible one.

In fact, not only is such a joint generation approach inefficient for the generation of maximal infeasible vectors, but, more generally, a result analogous to that of Theorem 1.1 is highly unlikely to hold.

PROPOSITION 2.2. *Let us consider a monotone system* (1.1)*, where A is an $r \times n$ binary matrix, $c = \mathbf{e}_n$, and all of the r components of b but one are equal to* 1*. Further, let $\mathcal{X} \subseteq \mathcal{I}(\mathcal{F}_{A,b,c})$. Then it is NP-complete to decide if $\mathcal{I}(\mathcal{F}_{A,b,c}) \setminus \mathcal{X} \neq \emptyset$.*

Proof. We can use arguments analogous to those of [22]. Consider the well-known NP-hard problem of determining whether a given graph $G = (V, E)$ contains an independent set of size t, where $t \geq 2$ is a given threshold. Let us introduce $|V|$ binary variables $x_v, v \in V$, and write $|E|$ inequalities $x_v + x_{v'} \geq 1$, one for every edge $e = (v, v') \in E$, followed by the inequality $\sum_{v \in V} x_v \geq |V| - t$. It is easily seen that, if x is the characteristic vector of an edge $e \in E$, then $\mathbf{e} - x$ is a maximal infeasible binary vector for the above system of inequalities. Deciding whether there are other such vectors is equivalent to determining whether the given graph G has an independent set of size at least t. □

According to our earlier remark, Proposition 2.2 implies that no incrementally efficient generation of maximal infeasible vectors is possible, regardless of the order of their generation, unless all NP-hard problems can be solved with the same efficiency. On the other hand, it is easy to see that, if the right-hand side vector b is bounded by a constant and the matrix A is integral and nonnegative, then listing all maximal infeasible binary vectors of (1.1) can be done in polynomial time.

Note also that the enumeration of all maximal infeasible binary vectors to a system of nonnegative linear inequalities $a^1 x \geq b_1, \ldots, a^r x \geq b_r$, with integer coefficients, is equivalent to the enumeration of all maximal solutions satisfying at least one of r knapsack inequalities $a^1 x \leq b_1 - 1, \ldots, a^r x \leq b_r - 1$. An exponential algorithm for the latter problem and its relation to the facet enumeration for some $0, 1$-polytopes [1] are discussed in [20].

Let us remark finally that the bounds in Theorem 2.1 are sharp for $r = 1$: for instance, the single inequality $x_1 + \cdots + x_n \geq n$ in binary variables has only one maximal infeasible vector and exactly n minimal feasible ones. For larger values of

r, these bounds are accurate up to a factor polylogarithmic in r. To see this, let us consider the input (A, b, c) consisting of $r = 2^k$ inequalities of the form

$$x_{i_1} + x_{i_2} + \cdots + x_{i_k} \geq 1, \quad i_1 \in \{1, 2\},\ i_2 \in \{3, 4\}, \ldots, i_k \in \{2k-1, 2k\},$$

in $n = 2k$ variables, where $x = (x_1, \ldots, x_n) \in \mathcal{C} = \{x \in \mathbb{Z}^n \mid 0 \leq x \leq c\}$. For any positive integer vector c, we have 2^k maximal infeasible integer vectors and only k minimal feasible integer vectors in this system; that is,

$$|\mathcal{I}(\mathcal{F}_{A,b,c})| = \frac{rn}{2(\log r)^2} |\mathcal{F}_{A,b,c}|.$$

3. Joint generation and dualization. As we have indicated, maximal infeasible vectors play a crucial role in our analysis. More precisely, for $\mathcal{X} \subseteq \mathcal{F}_{A,b,c}$, we shall use the equivalence

$$\mathcal{X} = \mathcal{F}_{A,b,c} \Longleftrightarrow \mathcal{X}^+ \cup \mathcal{I}(\mathcal{F}_{A,b,c})^- = \mathcal{C}$$

to verify the "completeness" of $\mathcal{X}$. In other words, our generation of minimal feasible solutions will in fact involve all maximal infeasible solutions as well. For this reason, we shall consider the *joint generation* of minimal feasible and maximal infeasible vectors by repeatedly solving the following problem.

GEN$(A, b, c, \mathcal{X}, \mathcal{Y})$. *Given a monotone system* (1.1) *defined by* (A, b, c) *and subsets* $\mathcal{X} \subseteq \mathcal{F}_{A,b,c}$ *and* $\mathcal{Y} \subseteq \mathcal{I}(\mathcal{F}_{A,b,c})$*, either find a new integral vector* $x \in (\mathcal{F}_{A,b,c} \cup \mathcal{I}(\mathcal{F}_{A,b,c})) \setminus (\mathcal{X} \cup \mathcal{Y})$ *or show that no such vector exists; i.e.,* $\mathcal{X} = \mathcal{F}_{A,b,c}$ *and* $\mathcal{Y} = \mathcal{I}(\mathcal{F}_{A,b,c})$.

Extending the results of [3] and [17] from the Boolean case $\mathcal{C} = \{0, 1\}^n$ to arbitrary integer boxes, we show that, for a monotone system, GEN$(A, b, c, \mathcal{X}, \mathcal{Y})$ is polynomially equivalent to the following *dualization* problem.

DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$. *Given a family of vectors* $\mathcal{A} \subseteq \mathcal{C}$ *and a subset* $\mathcal{B} \subseteq \mathcal{I}(\mathcal{A})$ *of its maximal independent vectors, either find a new maximal independent vector* $x \in \mathcal{I}(\mathcal{A}) \setminus \mathcal{B}$ *or prove that no such vector exists; i.e.,* $\mathcal{B} = \mathcal{I}(\mathcal{A})$.

More specifically, we present a simple algorithm which, given a proper subset $\mathcal{Z}$ of the (disjoint) union $\mathcal{F}_{A,b,c} \cup \mathcal{I}(\mathcal{F}_{A,b,c})$, finds a new vector in the union by performing $poly(n, r)$ comparisons and operations $+, -, \times, /, \lfloor\ \rfloor$ and by solving, if necessary, problem DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$ for $\mathcal{A} = \mathcal{Z} \cap \mathcal{F}_{A,b,c}$ and $\mathcal{B} = \mathcal{Z} \cap \mathcal{I}(\mathcal{F}_{A,b,c})$.

Next, by invoking Theorem 2.1, which we shall prove separately in section 5, we can argue that, since the number of maximal infeasible integer vectors for (1.1) is relatively small, we can efficiently generate all elements of $\mathcal{F}_{A,b,c}$ by generating all vectors in the union $\mathcal{F}_{A,b,c} \cup \mathcal{I}(\mathcal{F}_{A,b,c})$ and discarding the elements belonging to $\mathcal{I}(\mathcal{F}_{A,b,c})$. This leads to the following result.

THEOREM 3.1. *Problem GEN$(A, b, c, \mathcal{X})$ can be reduced in strongly polynomial time to DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$.*

To complete the proof of Theorem 1.1, we need to show that DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$, the *dualization problem over integer boxes*, can indeed be solved efficiently. As mentioned earlier, for $\mathcal{C} = \{0, 1\}^n$, problem DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$ turns into the well-known hypergraph dualization problem. In section 7, we extend the hypergraph dualization algorithms of [14] to problem DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$ and show that the latter problem can be solved in quasi-polynomial time.

THEOREM 3.2. *Given two sets* $\mathcal{A}$ *and* $\mathcal{B} \subseteq \mathcal{I}(\mathcal{A})$ *in an* n*-dimensional box* $\mathcal{C} = \{x \in \mathbb{Z}^n \mid 0 \leq x \leq c\}$*, problem DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$ can be solved in* $poly(n) + m^{o(\log m)}$ *time, where* $m = |\mathcal{A}| + |\mathcal{B}|$.

As before, Theorem 3.2 is stated in the unit-cost model of computation: the bound of the theorem applies to the number of comparisons between components of $\mathcal{A}$ and $\mathcal{B}$ required to solve the dualization problem. Other applications of the dualization problem on boxes can be found in [2, 10, 25].

Clearly, Theorem 1.1 follows from Theorems 3.1 and 3.2. The special cases of Theorems 2.1 and 3.1 for Boolean systems can be found in [7].

4. Bounded number of inequalities. Even though generating all maximal infeasible vectors for (1.1) is NP-hard by Proposition 2.2, this problem can be solved efficiently if the number of inequalities in (1.1) is a fixed constant. Specifically, for $r = \text{const}$, $|\mathcal{F}_{A,b,c}|$ can be bounded by a polynomial in n and $|\mathcal{I}(\mathcal{F}_{A,b,c})|$, and, consequently, all elements of $\mathcal{I}(\mathcal{F}_{A,b,c})$ can be generated in quasi-polynomial time. In fact, for $r = \text{const}$, the problem of generating $\mathcal{I}(\mathcal{F}_{A,b,c})$ as well as the problem of generating $\mathcal{F}_{A,b,c}$ can be solved separately in incremental polynomial time.

For a subset $\mathcal{Y} \subseteq \mathcal{C}$, let $\mathcal{I}^{-1}(\mathcal{Y})$ denote the set of all minimal integral vectors of the ideal $\mathcal{C} \setminus \mathcal{Y}^-$.

THEOREM 4.1. *Suppose that the monotone system* (1.1) *is nontrivial; i.e.,* $0 \notin \mathcal{F}_{A,b,c}$. *Then, for any nonempty subset* $\mathcal{Y} \subseteq \mathcal{I}(\mathcal{F}_{A,b,c})$, *we have*

$$\left|\mathcal{I}^{-1}(\mathcal{Y}) \cap \mathcal{F}_{A,b,c}\right| \leq \left(n|\mathcal{Y}|\right)^r. \tag{4.1}$$

In particular, for $\mathcal{Y} = \mathcal{I}(\mathcal{F}_{A,b,c})$, *we get*

$$|\mathcal{F}_{A,b,c}| \leq \left(n|\mathcal{I}(\mathcal{F}_{A,b,c})|\right)^r.$$

Generalizing the results of [20, 30] for knapsack problems, we can show that both minimal feasible and maximal infeasible solutions can be generated efficiently if the number of inequalities in the input monotone system is fixed.

THEOREM 4.2. *If the number of inequalities in* (1.1) *is bounded, then both* $\mathcal{F}_{A,b,c}$ *and* $\mathcal{I}(\mathcal{F}_{A,b,c})$ *can be generated in incremental polynomial time.*

The remainder of the paper consists of the proofs of Theorems 2.1, 3.1, 3.2, 4.1, and 4.2 in sections 5, 6, 7, 8, and 9, respectively.

5. Proof of Theorem 2.1. We first need some notation and definitions.

Let $\mathcal{C} = \{x \in \mathbb{Z}^n \mid 0 \leq x \leq c\}$ be a box, and let $f : \mathcal{C} \to \{0,1\}$ be a discrete binary function. The function f is called *monotone* if $f(x) \geq f(y)$ whenever $x \geq y$ and $x, y \in \mathcal{C}$. We denote by $T(f)$ and $F(f)$ the sets of all true and all false vectors of f; i.e.,

$$T(f) = \{x \in \mathcal{C} | f(x) = 1\} = (\text{MIN}[f])^+, \qquad F(f) = \{x \in \mathcal{C} | f(x) = 0\} = (\text{MAX}[f])^-,$$

where MIN$[f]$ and MAX$[f]$ are the sets of all minimal true and all maximal false vectors of f, respectively.

Let $\sigma \in \mathbb{S}_n$ be a permutation of the coordinates, and let x, y be two n-vectors. We say that y is a *left-shift* of x and write $y \succeq_\sigma x$ if the inequalities

$$\sum_{j=1}^{k} y_{\sigma_j} \geq \sum_{j=1}^{k} x_{\sigma_j}$$

hold for all $k = 1, \ldots, n$. A discrete binary function $f : \mathcal{C} \to \{0,1\}$ is called 2-*monotonic with respect to* σ if $f(y) \geq f(x)$ whenever $y \succeq_\sigma x$ and $x, y \in \mathcal{C}$. Clearly, $y \geq x$ implies $y \succeq_\sigma x$ for any $\sigma \in \mathbb{S}_n$ so that any 2-monotonic function is monotone.

The function f will be called *regular* if it is 2-monotonic with respect to the identity permutation $\sigma = (1, 2, \dots, n)$. Any 2-monotonic function can be transformed into a regular one by appropriately reindexing its variables. To simplify notation, we shall state Lemma 5.1 below for regular functions; i.e., we fix $\sigma = (1, 2, \dots, n)$ in this lemma.

For a given subset $\mathcal{A} \subseteq \mathcal{C}$, let us denote by $\mathcal{A}^*$ all of the vectors which are left-shifts of some vectors of $\mathcal{A}$; i.e., $\mathcal{A}^* = \{y \in \mathcal{C} \mid y \succeq x \text{ for some } x \in \mathcal{A}\}$. Clearly, $T(f) = (\mathrm{MIN}[f])^*$ for a regular function f. (In fact, the subfamily of *right-most* vectors of $\mathrm{MIN}[f]$ would be enough to use here.)

Given monotone discrete functions f and g, we call g a *regular majorant* of f if $g(x) \geq f(x)$ for all $x \in \mathcal{C}$ and g is regular. Clearly, $T(g) \supseteq (\mathrm{MIN}[f])^*$ must hold in this case, and the discrete function h defined by $T(h) = (\mathrm{MIN}[f])^*$ is the unique minimal regular majorant of f.

For a vector $x \in \mathcal{C}$ and for an index $1 \leq k \leq n$, let the vectors $x(k]$ and $x[k)$ be defined by

$$x_j(k] = \begin{cases} x_j & \text{for } j \leq k, \\ 0 & \text{otherwise} \end{cases}$$

and

$$x_j[k) = \begin{cases} x_j & \text{for } j \geq k, \\ 0 & \text{otherwise.} \end{cases}$$

Let us denote by $\mathbf{e}^j$ the jth unit vector in $\mathbb{R}^n$ for $j = 1, \dots, n$, and let $p(x)$ denote the number of positive components of the vector $x \in \mathcal{C}$.

LEMMA 5.1. *Given a monotone discrete binary function $f : \mathcal{C} \to \{0, 1\}$ such that $f \not\equiv 0$ and a regular majorant $g \geq f$, we have the inequality*

$$|F(g) \cap \mathrm{MAX}[f]| \leq \sum_{x \in \mathrm{MIN}[f]} p(x). \tag{5.1}$$

Proof. Let us denote by h the unique minimal regular majorant of f. Then we have $F(g) \cap \mathrm{MAX}[f] \subseteq F(h) \cap \mathrm{MAX}[f]$, and hence it is enough to show the statement for $g = h$, i.e., when $T(g) = (\mathrm{MIN}[f])^*$.

For a vector $y \in \mathcal{C} \setminus \{c\}$, let us denote by $l = l_y$ the index of the last component which is less than c_l; i.e., $l = \max\{j \mid y_j < c_j\} \in \{1, \dots, n\}$. We claim that, for every $y \in F(h) \cap \mathrm{MAX}[f]$, there exists an $x \in \mathrm{MIN}[f]$ such that

$$y = x(l-1] + (x_l - 1)\mathbf{e}^l + c[l+1), \tag{5.2}$$

where $l = l_y$. To see this claim, first observe that $y \neq c$ because $y \in F(f)$ and $f \not\equiv 0$. Second, for any j with $y_j < c_j$, we have $y + \mathbf{e}^j \in T(f)$ by the definition of a maximal false point. Hence there exists a minimal true vector $x \in \mathrm{MIN}[f]$ such that $x \leq y + \mathbf{e}^l$ for $l = l_y$. We must have $x(l-1] = y(l-1]$ since, if $x_i < y_i$ for some $i < l$, then $y \geq x + \mathbf{e}^i - \mathbf{e}^l \succeq x$ would hold, i.e., $y \succeq x$ would follow, implying $y \in (\mathrm{MIN}[f])^*$ and yielding a contradiction with $y \in F(h) = \mathcal{C} \setminus (\mathrm{MIN}[f])^*$. Finally, the definition of $l = l_y$ implies that $y[l+1) = c[l+1)$. Hence our claim and the equality (5.2) follow.

The above claim implies that

$$F(h) \cap \mathrm{MAX}[f] \subseteq \{x(l-1] + (x_l - 1)\mathbf{e}^l + c[l+1) \mid x \in \mathrm{MIN}[f],\ x_l > 0\},$$

and hence (5.1) and thus the lemma follow. □

LEMMA 5.2. *Let $f : \mathcal{C} \to \{0,1\}$ be a monotone discrete binary function such that $f \not\equiv 0$ and*

$$x \in T(f) \quad \Rightarrow \quad \alpha x \stackrel{\text{def}}{=} \alpha_1 x_1 + \cdots \alpha_n x_n \geq \beta, \tag{5.3}$$

where $\alpha = (\alpha_1, \ldots, \alpha_n)$ is a given real vector and β is a real threshold. Then

$$|\{x \in \mathcal{C} \mid \alpha x < \beta\} \cap \mathrm{MAX}[f]| \leq \sum_{x \in \mathrm{MIN}[f]} p(x).$$

Proof. Suppose that some of the weights $\alpha_1, \ldots, \alpha_n$ are negative, say, $\alpha_1 < 0, \ldots, \alpha_k < 0$, and $\alpha[k+1) \geq 0$. Since $\alpha x \geq \beta$ for any $x \in T(f)$ and since f is monotone, we have $x \in T(f) \ \Rightarrow \alpha[k+1)x \geq \beta - \alpha(k]c(k]$. By the negativity of the weights $\alpha_1, \ldots, \alpha_k$, we also have $\{x \in \mathcal{C} \mid \alpha x < \beta\} \subseteq \{x \in \mathcal{C} \mid \alpha[k+1)x < \beta - \alpha(k]c(k]\}$. Hence it suffices to prove the lemma for the nonnegative weight vector $\alpha[k+1)$ and the threshold $\beta - \alpha(k]c(k]$. In other words, we can assume without loss of generality that the original weight vector α is nonnegative.

Let $\sigma \in \mathbb{S}_n$ be a permutation such that $\alpha_{\sigma_1} \geq \alpha_{\sigma_2} \geq \cdots \geq \alpha_{\sigma_n} \geq 0$. Then the threshold function

$$g(x) = \begin{cases} 1 & \text{if } \alpha x \geq \beta, \\ 0 & \text{otherwise} \end{cases}$$

is 2-monotonic with respect to σ. By (5.3), we have $g \geq f$ for all $x \in \mathcal{C}$; i.e., g is a majorant of f. In addition, $F(g) = \{x \in \mathcal{C} \mid \alpha x < \beta\}$, and hence Lemma 5.2 follows from Lemma 5.1. □

Proof of Theorem 2.1. We are now ready to show inequality (2.3) and finish the proof of Theorem 2.1. For this, we shall prove, in fact, the following stronger inequality:

$$|\mathcal{I}(\mathcal{X}) \cap \mathcal{I}(\mathcal{F}_{A,b,c})| \leq r \sum_{x \in \mathcal{X}} p(x). \tag{5.4}$$

Given a nonempty set $\mathcal{X} \subseteq \mathcal{F}_{A,b,c}$, consider the monotone discrete function $f : \mathcal{C} \to \{0,1\}$ defined by the condition $\mathrm{MIN}[f] = \mathcal{X}$. Since (1.1) is monotone, any true vector of f also satisfies (1.1):

$$x \in T(f) \quad \Rightarrow a_{k1}x_1 + \cdots + a_{kn}x_n \geq b_k$$

for all $k = 1, \ldots, r$. In addition, $f \not\equiv 0$ because $\mathcal{X} \neq \emptyset$. Thus, by Lemma 5.2, we have the inequalities

$$|\{x \mid a_{k1}x_1 + \cdots + a_{kn}x_n < b_k\} \cap \mathrm{MAX}[f]| \leq \sum_{x \in \mathcal{X}} p(x) \tag{5.5}$$

for each $k = 1, \ldots, r$. Now, from $\mathrm{MAX}[f] = \mathcal{I}(\mathcal{X})$, we deduce that

$$\mathcal{I}(\mathcal{F}_{A,b,c}) \cap \mathcal{I}(\mathcal{X}) \subseteq \bigcup_{k=1}^{r} \{x \mid a_{k1}x_1 + \cdots + a_{kn}x_n < b_k\} \cap \mathrm{MAX}[f],$$

and hence (5.4) follows by (5.5), thus implying (2.3) and completing the proof of the theorem. □

6. Generating minimal feasible solutions. As mentioned in the introduction, the proof of Theorem 3.1 has two ingredients. First, we show that, given a monotone system (1.1), the sets $\mathcal{I}(\mathcal{F}_{A,b,c})$ and $\mathcal{F}_{A,b,c}$ can be jointly enumerated by iteratively solving the dualization problem DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$. Second, we argue that, due to Theorem 2.1, the number of maximal infeasible vectors for (1.1) is relatively small, and hence the generation of $\mathcal{F}_{A,b,c}$ polynomially reduces to the joint generation of $\mathcal{I}(\mathcal{F}_{A,b,c})$ and $\mathcal{F}_{A,b,c}$.

6.1. Joint generation of dual subsets in an integral box. As was observed in [3, 17], for $c = \mathbf{e}_n$, problem GEN$(A, b, c, \mathcal{A}, \mathcal{B})$ can be reduced in polynomial time to the dualization problem DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$. Extending this observation, we prove it here for any integral vector c.

PROPOSITION 6.1. *Problem GEN$(A, b, c, \mathcal{A}, \mathcal{B})$ can be solved in poly$(n, |\mathcal{A}|, |\mathcal{B}|) + T^*$ time, where T^* denotes the time required to solve problem DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$.*

Proof. In fact, we can prove a more general statement. Let us consider an arbitrary *antichain* $\mathcal{F} \subseteq \mathcal{C}$ (i.e., a family $\mathcal{F}$ of vectors such that $x \not\leq y$ for any two distinct elements $x, y \in \mathcal{F}$), assume that there is a polynomial-time membership oracle $\mathfrak{O}(\mathcal{F}^+)$ for the monotone set $\mathcal{F}^+$, and consider the following problem.

GEN$(\mathfrak{O}(\mathcal{F}^+), \mathcal{A}, \mathcal{B})$. *Given subsets $\mathcal{A} \subseteq \mathcal{F}$ and $\mathcal{B} \subseteq \mathcal{I}(\mathcal{F})$, either find a new element $x \in (\mathcal{F} \cup \mathcal{I}(\mathcal{F})) \setminus (\mathcal{A} \cup \mathcal{B})$ or show that no such vector exists, i.e., $\mathcal{A} = \mathcal{F}$ and $\mathcal{B} = \mathcal{I}(\mathcal{F})$.*

We can show that this more general problem also reduces in polynomial time to DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$.

Our proof uses two subroutines, the first of which takes as input a vector $x \in \mathcal{F}^+$ and returns a minimal vector x^* in $\mathcal{F}^+ \cap \{x\}^-$. Such a vector $x^* = \min_{\mathcal{F}}(x)$ can, for instance, be computed by coordinate descent:

$$\begin{array}{rcl} x_1^* & \leftarrow & \min\{y_1 \mid (y_1, y_2, \dots, y_{n-1}, y_n) \in \mathcal{F}^+ \cap \{x\}^-\}, \\ x_2^* & \leftarrow & \min\{y_2 \mid (x_1^*, y_2, \dots, y_{n-1}, y_n) \in \mathcal{F}^+ \cap \{x\}^-\}, \\ & \dots & \\ x_n^* & \leftarrow & \min\{y_n \mid (x_1^*, x_2^*, \dots, x_{n-1}^*, y_n) \in \mathcal{F}^+ \cap \ \{x\}^-\}. \end{array}$$

The second subroutine is to compute, for a given vector $x \in \mathcal{I}(\mathcal{F})^-$, a maximal vector $x^* \in \mathcal{I}(\mathcal{F})^- \cap x^+$. Similarly, this problem can be done by coordinate descent. Note that each of the n coordinate steps in the above procedures can be reduced via binary search to at most $\log(\|c\|_\infty + 1)$ membership queries for the monotone family $\mathcal{F}^+$. Though this bound depends on the size of the box $\mathcal{C}$, in general, in our case, when $\mathcal{F} = \mathcal{F}_{A,b,c}$ is the set of minimal integer solutions for an explicitly given monotone system (1.1), both of the above coordinate descents can be clearly performed in $O(nr)$ comparisons $(\leq, \geq)$ and arithmetic operations $(+, -, \times, /, \lfloor\ \rfloor)$, regardless of the box size.

Using these subroutines, our proof of Proposition 6.1 can now be completed by the following algorithm.

Algorithm $\mathcal{J}$.

Input: An oracle $\mathfrak{O}(\mathcal{F}^+)$ and subsets $\mathcal{A} \subseteq \mathcal{F}$ and $\mathcal{B} \subseteq \mathcal{I}(\mathcal{F})$.

Step 1. Check whether $\mathcal{B} \subseteq \mathcal{I}(\mathcal{A})$. Since $\mathcal{B} \subseteq \mathcal{I}(\mathcal{F})$ and $\mathcal{A} \subseteq \mathcal{F}$, each vector $x \in \mathcal{B}$ is independent of $\mathcal{A}$, and we have only to check the maximality of x for $\mathcal{I}(\mathcal{A})$. In other words, we have to check whether or not $x + \mathbf{e}^j \geq y$ for some unit vector $\mathbf{e}^j$, $j \in \{1, \dots, n\}$, and some vector $y \in \mathcal{A}$. Since both $\mathcal{A}$ and $\mathcal{B}$ are explicitly given, this can be done in *poly*$(n, |\mathcal{A}|, |\mathcal{B}|)$ comparisons. If there is an $x \in \mathcal{B} \setminus \mathcal{I}(\mathcal{A})$, then $x \notin \mathcal{F}^+$ because $x \in \mathcal{B} \subseteq \mathcal{I}(\mathcal{F})$. This and the inclusion $\mathcal{A} \subseteq \mathcal{F}$ imply that $x \notin \mathcal{A}^+$. Since

$x \notin \mathcal{I}(\mathcal{A})$, we can find a coordinate $j \in \{1, \ldots, n\}$ for which $y = x + \mathbf{e}^j \notin \mathcal{A}^+$. By the maximality of x in $\mathcal{C} \setminus \mathcal{F}^+$, y belongs to $\mathcal{F}^+$. Now, using the first subroutine and letting $y^* = \min_{\mathcal{F}}(y)$, we can conclude that $y^* \in \mathcal{F} \setminus \mathcal{A}$; i.e., y^* is a new minimal integral vector in $\mathcal{F}$. Otherwise, if $\mathcal{B} \subseteq \mathcal{I}(\mathcal{A})$, we continue with the next step.

Step 2. Similar to the previous step, we check whether $\mathcal{A} \subseteq \mathcal{I}^{-1}(\mathcal{B})$, where $\mathcal{I}^{-1}(\mathcal{B})$ denotes the set of integral vectors which are minimal in $\mathcal{C} \setminus \mathcal{B}^-$. If $\mathcal{A}$ contains an element that is not minimal in $\mathcal{C} \setminus \mathcal{B}^-$, we can find a new vector in $\mathcal{I}(\mathcal{F}) \setminus \mathcal{B}$ and stop. Otherwise, we continue with the next step.

Step 3. In this case, we have $\mathcal{B} \subseteq \mathcal{I}(\mathcal{A})$ and $\mathcal{A} \subseteq \mathcal{I}^{-1}(\mathcal{B})$, and thus the following equivalence holds:

$$(\mathcal{A}, \mathcal{B}) = (\mathcal{F}, \mathcal{I}(\mathcal{F})) \quad \Leftrightarrow \quad \mathcal{B} = \mathcal{I}(\mathcal{A}).$$

To see this, assume that $\mathcal{B} = \mathcal{I}(\mathcal{A})$, and suppose, on the contrary, that there is an $x \in \mathcal{F} \setminus \mathcal{A}$. Since $x \notin \mathcal{A} = \mathcal{I}^{-1}(\mathcal{B})$ and $x \notin \mathcal{B}^- \subseteq \mathcal{I}(\mathcal{F})^-$, there must exist a $y \in \mathcal{I}^{-1}(\mathcal{B}) = \mathcal{A} \subseteq \mathcal{F}$ such that $y \leq x$. Hence we get two distinct elements $x, y \in \mathcal{F}$ such that $y \leq x$, which contradicts the definition of $\mathcal{F}$. The existence of an $x \in \mathcal{I}(\mathcal{F}) \setminus \mathcal{B}$ leads to a similar contradiction.

To check the stopping criterion $\mathcal{B} = \mathcal{I}(\mathcal{A})$, we solve problem DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$. If $\mathcal{B} \neq \mathcal{I}(\mathcal{A})$, we obtain a new point $x \in \mathcal{I}(\mathcal{A}) \setminus \mathcal{B}$. By (2.2), either $x \in \mathcal{F}^+$ or $x \in \mathcal{I}(\mathcal{F})^-$, and we can decide which of these two cases holds by asking the oracle $\mathfrak{O}(\mathcal{F}^+)$ or, in our special case, by checking the feasibility of x for (1.1). In the first case, we conclude that $x^* = \min_{\mathcal{F}}(x)$ is a new vector in $\mathcal{F} \setminus \mathcal{A}$. In the second case, we can extend $\mathcal{I}(\mathcal{F}) \setminus \mathcal{B}$ by using the second subroutine to compute a maximal vector in $x^+ \cap \mathcal{I}(\mathcal{F})^-$. □

As we noted, the above procedure can be used for any antichain $\mathcal{F} \subseteq \mathcal{C}$ defined by a polynomial-time membership oracle for $\mathcal{F}^+$ since the coordinate descend subroutines used by the algorithm can always be implemented in $n \log(\|c\|_\infty + 1)$ membership tests. Accordingly, Proposition 6.1 also holds for an arbitrary antichain defined by a polynomial-time membership oracle, provided that the polynomial term in the proposition includes a multiplicative factor of $\log(\|c\|_\infty + 1)$.

6.2. Uniformly dual-bounded antichains. Let $\mathcal{F} \subseteq \mathcal{C}$ be an antichain defined by a polynomial-time membership oracle $\mathfrak{O}(\mathcal{F}^+)$ for $\mathcal{F}^+$. Given an input description $\mathcal{D}$ of $\mathcal{F}$ and a vector $x \in \mathcal{C}$, such an oracle checks the membership of x in $\mathcal{F}^+$ in time bounded by a polynomial in the size of x and the length $|\mathcal{D}|$ of the input description of $\mathcal{F}$. For instance, the antichain $\mathcal{F}_{A,b,c}$ of minimal feasible integer vectors for (1.1) is defined by the triple $\mathcal{D} = (A, b, c)$, and the membership test for a given $x \in \mathcal{C}$ simply checks if $Ax \geq b$. The generation problem can thus be considered more generally for arbitrary antichains.

GEN$(\mathfrak{O}(\mathcal{F}^+), \mathcal{X})$. *Given an antichain $\mathcal{F} \subseteq \mathcal{C}$ defined by a polynomial-time membership oracle $\mathfrak{O}(\mathcal{F}^+)$ and a subset $\mathcal{X} \subseteq \mathcal{F}$, either find a new vector $x \in \mathcal{F} \setminus \mathcal{X}$ or show that no such vector exists; i.e., $\mathcal{X} = \mathcal{F}$.*

Extending the notion of dual-bounded hypergraphs defined in [7], we say that an antichain $\mathcal{F} \subseteq \mathcal{C}$ with an input description $\mathcal{D}$ is *uniformly dual-bounded* if there exists a polynomial $q(x, y)$ such that

$$|\mathcal{I}(\mathcal{F}) \cap \mathcal{I}(\mathcal{X})| \leq q(|\mathcal{D}|, |\mathcal{X}|)$$

for any nonempty subset $\mathcal{X} \subseteq \mathcal{F}$ (see [7] for further details and examples). As we show below, the uniform dual-boundedness of an antichain is a sufficient condition to be able to reduce polynomially generation to dualization.

PROPOSITION 6.2. *Suppose $\mathcal{F}$ is uniformly dual-bounded and defined by a polynomial-time membership oracle $\mathfrak{O}(\mathcal{F}^+)$ for $\mathcal{F}^+$. Then problem GEN$(\mathfrak{O}(\mathcal{F}^+), \mathcal{X})$ is polynomial-time reducible to at most $q(|\mathcal{D}|, |\mathcal{X}|) + 1$ instances of problem DUAL $(\mathcal{C}, \mathcal{A}, \mathcal{B})$.*

Proof. Given a set $\mathcal{X} \subseteq \mathcal{F}$, we repeatedly run Algorithm $\mathcal{J}$, starting with $\mathcal{A} = \mathcal{X}$ and $\mathcal{B} = \emptyset$, until it either produces a new element in $\mathcal{F} \setminus \mathcal{X}$ or proves that $\mathcal{X} = \mathcal{F}$ by generating the entire family $\mathcal{I}(\mathcal{F})$. By Step 1, either $\mathcal{B} \subseteq \mathcal{I}(\mathcal{X})$ is maintained during the execution of the algorithm or a new element $x \in \mathcal{F}$ can be found. Thus, as long as Algorithm $\mathcal{J}$ outputs elements of $\mathcal{I}(\mathcal{F})$, these elements also belong to $\mathcal{I}(\mathcal{X})$, and hence the total number of such elements does not exceed $q(|\mathcal{D}|, |\mathcal{X}|)$. □

Proof of Theorem 3.1. By Theorem 2.1, the antichain $\mathcal{F} = \mathcal{F}_{A,b,c}$ of minimal integer solutions to the monotone system (1.1), for which we have $\mathcal{D} = (A, b, c)$, is uniformly dual-bounded with $q(|\mathcal{D}|, |\mathcal{X}|) = rn|\mathcal{X}|$. Furthermore, the reduction of Proposition 6.2 is strongly polynomial. For this reason, Theorem 3.1 follows from Theorem 2.1 and Proposition 6.2. □

7. Dualization in products of chains. In this section, we prove Theorem 3.2. Let $\mathcal{C} \stackrel{\text{def}}{=} \mathcal{C}_1 \times \cdots \times \mathcal{C}_n$ be an integer box defined by the product of n chains $\mathcal{C}_i = [l_i : u_i]$, where $l_i, u_i \in \mathbb{Z}$ are, respectively, the lower and upper bounds of chain $\mathcal{C}_i$. For given antichains $\mathcal{A} \subseteq \mathcal{C}$ and $\mathcal{B} \subseteq \mathcal{I}(\mathcal{A})$, we say that $\mathcal{B}$ is *dual to* $\mathcal{A}$ if $\mathcal{B} = \mathcal{I}(\mathcal{A})$; i.e., $\mathcal{B}$ contains all the maximal elements of $\mathcal{C} \setminus \mathcal{A}^+$. If $\mathcal{C}$ is the unit cube, we obtain the familiar notion of dual hypergraphs, where $\mathcal{I}(\mathcal{A})$ corresponds to the family of complementary sets of the minimal transversals of $\mathcal{A}$. In the following two subsections, we will show how to extend the hypergraph dualization algorithms of [14] to arbitrary antichains $\mathcal{A}$ of integral vectors in a box $\mathcal{C}$. Note that, by (2.2), our problem can be stated as of checking whether $\mathcal{C} = \mathcal{A}^+ \cup \mathcal{B}^-$, and, if not, find an element $x \in \mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$.

As in [14], we shall analyze the running time of the algorithms in terms of the *volume* $v = v(\mathcal{A}, \mathcal{B}) \stackrel{\text{def}}{=} |\mathcal{A}||\mathcal{B}|$ of the input problem. In general, a given problem will be decomposed into a number of subproblems of smaller volume, which we will solve recursively. Since we have assumed that $\mathcal{B} \subseteq \mathcal{I}(\mathcal{A})$, (2.2) implies that the following condition holds for the original problem and all subsequent subproblems:

$$a \not\leq b \quad \text{for all} \quad a \in \mathcal{A}, b \in \mathcal{B}. \tag{7.1}$$

Let $C(v) = C(v(\mathcal{A}, \mathcal{B}))$ denote the number of subproblems that have to be solved in order to solve the original problem (the maximum number of recursive calls on a problem of volume $\leq v$), and let $m \stackrel{\text{def}}{=} |\mathcal{A}| + |\mathcal{B}|$ and $[n] \stackrel{\text{def}}{=} \{1, \ldots, n\}$. We start with the following proposition that provides the base case for recursion.

PROPOSITION 7.1. *Suppose* $\min\{|\mathcal{A}|, |\mathcal{B}|\} \leq \text{const}$*; then problem DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$ is solvable in time poly(n, m).*

Proof. Let us assume without loss of generality that $\mathcal{B} = \{b^1, \ldots, b^k\}$ for some constant k. Then $\mathcal{C} = \mathcal{A}^+ \cup \mathcal{B}^-$ *if and only if*, for every $t = (t_1, \ldots, t_k) \in [n]^k$ for which

$$b^j_{t_j} \neq u_{t_j} \quad \text{for all} \quad j \in [k], \tag{7.2}$$

there exists an $a \in \mathcal{A}$ such that

$$a_i \leq \max(\{b^j_i + 1 \mid j \in [k], t_j = i\} \cup \{l_i\}) \quad \text{for all } i \in [n]. \tag{7.3}$$

To see this, assume first that $\mathcal{C} = \mathcal{A}^+ \cup \mathcal{B}^-$, and consider any $t \in [n]^k$ such that (7.2) holds. Let $x \in \mathcal{C}$ be defined by taking $x_i = \max(\{b_i^j + 1 \mid j \in [k],\ t_j = i\} \cup \{l_i\})$ for $i = 1, \ldots, n$. Then $x \in \mathcal{C} \setminus \mathcal{B}^-$, and hence $x \in \mathcal{A}^+$, implying that there is an $a \in \mathcal{A}$ satisfying (7.3). On the other hand, let us assume that, for every $t \in [n]^k$ satisfying (7.2), there is an $a \in \mathcal{A}$ for which (7.3) holds. Consider an arbitrary $x \in \mathcal{C} \setminus \mathcal{B}^-$. Then there must exist an index $t_j \in [n]$ for every $j \in [k]$ such that $x_{t_j} \geq b_{t_j}^j + 1$. The vector $t = (t_1, \ldots, t_k) \in [n]^k$ constructed in this way then satisfies (7.2), and, therefore, there is an $a \in \mathcal{A}$ such that $a_i \leq \max(\{b_i^j + 1 \mid j \in [k],\ t_j = i\} \cup \{l_i\}) \leq x_i$ for all $i = 1, \ldots, n$, thus implying $x \in \mathcal{A}^+$.

The condition given in (7.2) and (7.3) can clearly be checked in $poly(n, m)$ time for any constant k. If the condition does not hold for some $t \in [n]^k$, then the element x, defined by $x_i = \max(\{b_i^j + 1 \mid j \in [k],\ t_j = i\} \cup \{l_i\})$ for $i = 1, \ldots, n$, belongs to $\mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$. □

Note that, to complete the solution of the dualization problem, we need to find an element *maximal* in $\mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$. This can easily be done in polynomial time and even independently of the chain sizes, as shown in the next proposition. Therefore, in the following subsections, we shall only show how to obtain an element $x \in \mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$, when such an element exists.

PROPOSITION 7.2. *Given an $x \in \mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$, it can be extended to a maximal element with the same property in $O(nm)$ time.*

Proof. Note that, for $i = 1, \ldots, n$, the ith component of any maximal element in $\mathcal{C} \setminus \mathcal{A}^+$ must belong to the set $\{a_i - 1 \mid a \in \mathcal{A}\} \cup \{u_i\}$. Thus a new element $x' \geq x$ maximal in $\mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$ can be found as follows. For $i = 1, \ldots, n$, we find iteratively the set $\mathcal{A}_i \stackrel{\text{def}}{=} \{a \in \mathcal{A} \mid a_1 \leq x'_1, \ldots, a_{i-1} \leq x'_{i-1}, a_i > x_i, a_{i+1} \leq x_{i+1}, \ldots, a_n \leq x_n\}$ and then set $x'_i \leftarrow \min(\{a_i - 1 \mid a \in \mathcal{A}_i\} \cup \{u_i\})$. □

7.1. Algorithm A. Assume that $\mathcal{A}, \mathcal{B}$ satisfy (7.1), and let $\mathcal{C} = \mathcal{C}_1 \times \cdots \times \mathcal{C}_n$, where $\mathcal{C}_i = [l_i : u_i]$. We say that a coordinate $i \in [n]$ is *essential* for a point $a \in \mathcal{A}$ ($b \in \mathcal{B}$) if $a_i > l_i$ (respectively, $b_i < u_i$). Let us denote by $E(x)$ the set of essential coordinates of a point $x \in \mathcal{A} \cup \mathcal{B}$. The following lemma generalizes a well-known fact for dual Boolean functions (cf. [14]).

LEMMA 7.3. *Let $\mathcal{A}, \mathcal{B} \subseteq \mathcal{C}$ be given subsets. Then either* (i) *there exists an element $y \in \mathcal{A} \cup \mathcal{B}$ with few essential coordinates $|E(y)| \leq \log m$, where $m = |\mathcal{A}| + |\mathcal{B}|$, or* (ii) *if no such element y exists, then $\mathcal{B} \neq \mathcal{I}(\mathcal{A})$, and an element $x \in \mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$ can be found in $poly(n, m)$ time.*

Proof. Let $z \in \mathcal{C}$ be the vector obtained by picking each coordinate z_i randomly from $\{l_i, u_i\}$, $i = 1, \ldots, n$, and consider the random variable $N(z) \stackrel{\text{def}}{=} |\{a \in \mathcal{A} \mid z \geq a\}| + |\{b \in \mathcal{B} \mid z \leq b\}|$. Then the expected value of $N(z)$ is given by

$$\begin{aligned} \mathbb{E}[N(z)] &= \sum_{a \in \mathcal{A}} \Pr\{z \geq a\} + \sum_{b \in \mathcal{B}} \Pr\{z \leq b\} \\ &= \sum_{a \in \mathcal{A}} \prod_{i \in E(a)} \Pr\{z_i = u_i\} + \sum_{b \in \mathcal{B}} \prod_{i \in E(b)} \Pr\{z_i = l_i\} \\ &= \sum_{a \in \mathcal{A}} \left(\frac{1}{2}\right)^{|E(a)|} + \sum_{b \in \mathcal{B}} \left(\frac{1}{2}\right)^{|E(b)|}. \end{aligned} \tag{7.4}$$

If we have $\mathbb{E}[N(z)] \geq 1$, then, by letting $r = \min\{|E(z)| \ :\ z \in \mathcal{A} \cup \mathcal{B}\}$, we get by (7.4) that

$$1 \leq \mathbb{E}[N(z)] \leq (|\mathcal{A}| + |\mathcal{B}|) \left(\frac{1}{2}\right)^r = m \left(\frac{1}{2}\right)^r,$$

from which part (i) of the lemma follows.

On the other hand, if $\mathbb{E}[N(z)] < 1$, then we can find an element $x \in \mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$ (in fact a corner of the finite box $\mathcal{C}$) in polynomial time, proving part (ii) of the lemma. To see this, let us consider, for each $i = 1, \ldots, n$, the variables $z_j \in \{l_j, u_j\}$ random for $j > i$, as above, compute the expectations of $N(x_1, \ldots, x_{i-1}, l_i, z_{i+1}, \ldots, z_n)$ and $N(x_1, \ldots, x_{i-1}, u_i, z_{i+1}, \ldots, z_n)$ analogously to (7.4), and select the value for $x_i \in \{l_i, u_i\}$ so as to minimize the corresponding expectation. Clearly, $N(x) < 1$ will hold in this case; thus $N(x) = 0$, implying that $x \notin \mathcal{A}^+ \cup \mathcal{B}^-$. □

Next we show that, for any dual pair $(\mathcal{A}, \mathcal{B})$, an essential coordinate with high frequency exists for either $\mathcal{A}$ or $\mathcal{B}$.

LEMMA 7.4. *Let $\mathcal{A}, \mathcal{B} \subseteq \mathcal{C}$ be a pair of dual subsets, $\mathcal{B} = \mathcal{I}(\mathcal{A})$, for which $|\mathcal{A}||\mathcal{B}| \geq 1$. Then there exists a coordinate $i \in [n]$, which is essential in $\mathcal{A}$ or in $\mathcal{B}$ with frequency at least $1/\log m$, where $m = |\mathcal{A}| + |\mathcal{B}|$.*

Proof. By Lemma 7.3, the set $\mathcal{A} \cup \mathcal{B}$ must contain an element y with a logarithmically small number of essential coordinates. Suppose, without loss of generality, that $y \in \mathcal{A}$. From our assumptions and condition (7.1), we know that, for every $b \in \mathcal{B}$, there is an $i \in E(b) \cap E(y)$ such that $b_i < y_i$. Letting $\mathcal{B}_i^y \stackrel{\text{def}}{=} \{b \in \mathcal{B} \mid b_i < y_i\}$ for $i \in E(y)$, we conclude that

$$|\mathcal{B}| = \left| \bigcup_{i \in E(y)} \mathcal{B}_i^y \right| \leq \sum_{i \in E(y)} |\mathcal{B}_i^y|,$$

and therefore there is an $i \in [n]$ which is essential for at least $|\mathcal{B}|/|E(y)| \geq |\mathcal{B}|/\log m$ many elements of $\mathcal{B}$. □

We are now ready to state the first dualization algorithm. Given an integral box $\mathcal{C}$ and subsets $\mathcal{A}, \mathcal{B} \subseteq \mathcal{C}$ that satisfy (7.1), in time $poly(n, m) + m^{O(\log^2 m)}$ the algorithm will either prove that $\mathcal{C} = \mathcal{A}^+ \cup \mathcal{B}^-$ or find an $x \in \mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$.

Step 1. If $|\mathcal{A}||\mathcal{B}| \leq 1$, then the dualization problem can be solved in $O(n)$ time.

Step 2. For each $k \in [n]$, if $a_k < l_k$ for some $a \in \mathcal{A}$ ($b_k > u_k$ for some $b \in \mathcal{B}$), set $a_k \leftarrow l_k$ (respectively, set $b_k \leftarrow u_k$). (Note that $\mathcal{A}, \mathcal{B} \subseteq \mathcal{C}$ holds initially but might not hold after decomposing $\mathcal{C}$; see Step 4 below.) Note that condition (7.1) continues to hold after such replacements. Thus, in $O(nm)$ time, we can ensure that $\mathcal{A}, \mathcal{B} \subseteq \mathcal{C}$ hold.

Step 3. Check if there is a $y \in \mathcal{A} \cup \mathcal{B}$ with at most $\log m$ essential coordinates. If no such y can be found, a new point in $\mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$ can be obtained as described in the proof of Lemma 7.3 (ii). Otherwise, assume, without loss of generality, that $y = a^o \in \mathcal{A}$, and find an $i \in E(a^o)$ for which $|\{b \in \mathcal{B} \mid b_i < a_i^o\}| \geq |\mathcal{B}|/\log m$. Let us suppose, again without any loss of generality, that $i = 1$ and set $\mathcal{C}_1' \leftarrow [a_1^o : u_1]$, $\mathcal{C}_1'' \leftarrow [l_1 : a_1^o - 1]$. Let, further,

$$\mathcal{A}'' = \{a \in \mathcal{A} \mid a_1 < a_1^o\}, \qquad \mathcal{B}' = \{b \in \mathcal{B} \mid b_1 \geq a_1^o\}.$$

Observe that $|\mathcal{A}''| \leq |\mathcal{A}| - 1$ since $a^o \notin \mathcal{A}''$ and that $|\mathcal{B}'| \leq (1 - 1/\log m)|\mathcal{B}|$ by our choice of a^o and i.

Step 4. Denoting by $\mathcal{C}' = \mathcal{C}_1' \times \mathcal{C}_2 \times \cdots \times \mathcal{C}_n$ and $\mathcal{C}'' = \mathcal{C}_1'' \times \mathcal{C}_2 \times \cdots \times \mathcal{C}_n$ the two subboxes of $\mathcal{C}$ induced by the above partitioning, it is then easy to see that $\mathcal{A}$ and $\mathcal{B}$ are dual in $\mathcal{C}$ *if and only if*

$$\mathcal{A}, \mathcal{B}' \text{ are dual in } \mathcal{C}' \tag{7.5}$$

and

$$\mathcal{A}'', \mathcal{B} \text{ are dual in } \mathcal{C}''. \tag{7.6}$$

Thus, by applying the algorithm recursively to these two subproblems, we reduce the computation on a problem of size $v = |\mathcal{A}||\mathcal{B}|$ to computing the solution for two subproblems (7.5)–(7.6) of volumes

$$\begin{aligned} v(\mathcal{A}, \mathcal{B}') &= |\mathcal{A}||\mathcal{B}'| \leq |\mathcal{A}|(1-\epsilon)|\mathcal{B}| = (1-\epsilon)v \quad \text{and} \\ v(\mathcal{A}'', \mathcal{B}) &= |\mathcal{A}''||\mathcal{B}| = (|\mathcal{A}|-1)|\mathcal{B}| \leq v-1, \end{aligned}$$

where $\epsilon = 1/\log m$. This leads to the recurrence

$$C(v) \leq 1 + C((1-\epsilon)v) + C(v-1),$$

which was shown in [14] to evaluate to $C(v) \leq (3+2v\epsilon)^{\log v/\epsilon}$, implying that the running time of the algorithm is $poly(n) + m^{O(\log^2 m)}$.

In the next subsection, we shall give an algorithm that solves the problem in $poly(n,m) + m^{o(\log m)}$ time.

7.2. Algorithm B. Algorithm A of the previous subsection decomposes problem DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$ into two subproblems, (7.5) and (7.6). As we shall see below, subproblems (7.5) and (7.6) are not independent, and we can utilize their dependence to get a more efficient dualization algorithm. Given an integral box $\mathcal{C} = \mathcal{C}_1 \times \cdots \times \mathcal{C}_n$, where $\mathcal{C}_i = [l_i : u_i]$, and subsets of integral vectors $\mathcal{A}, \mathcal{B}$ that satisfy the necessary condition (7.1), we proceed as follows.

Step 1. If $\min\{|\mathcal{A}|, |\mathcal{B}|\} \leq 2$, the duality of $\mathcal{A}$ and $\mathcal{B}$ can be tested in $O(n^3 m)$ using Proposition 7.1.

Step 2. For each $k \in [n]$,

2.1. if $a_k > u_k$ for some $a \in \mathcal{A}$ ($b_k < l_k$ for some $b \in \mathcal{B}$), then a (respectively, b) can clearly be discarded from further consideration;

2.2. if $a_k < l_k$ for some $a \in \mathcal{A}$ ($b_k > u_k$ for some $b \in \mathcal{B}$), we set $a_k \leftarrow l_k$ (respectively, $b_k \leftarrow u_k$).

Thus we may assume for the next steps that $\mathcal{A}, \mathcal{B} \subseteq \mathcal{C}$.

Step 3. Let $a^o \in \mathcal{A}$, $b^o \in \mathcal{B}$. By (7.1), there exists an $i \in [n]$ such that $a^o_i > b^o_i$. Let us assume, without any loss of generality, that $i = 1$ and set $\mathcal{C}'_1 \leftarrow [a^o_1 : u_1]$, $\mathcal{C}''_1 \leftarrow [l_1 : a^o_1 - 1]$. (Alternatively, we may set $\mathcal{C}''_1 \leftarrow [l_1 : b^o_1]$ and $\mathcal{C}'_1 \leftarrow [b^o_1 + 1 : u_1]$.) Let $\mathcal{C}'$ and $\mathcal{C}''$ be the two resulting subboxes as defined in Step 4 of the previous subsection. Define, further,

$$\begin{aligned} \mathcal{A}'' &= \{a \in \mathcal{A} \mid a_1 < a^o_1\}, \qquad \mathcal{A}' = \mathcal{A} \setminus \mathcal{A}'', \qquad \epsilon_1^{\mathcal{A}} = \frac{|\mathcal{A}'|}{|\mathcal{A}|}, \\ \mathcal{B}' &= \{b \in \mathcal{B} \mid b_1 \geq a^o_1\}, \qquad \mathcal{B}'' = \mathcal{B} \setminus \mathcal{B}', \qquad \epsilon_1^{\mathcal{B}} = \frac{|\mathcal{B}''|}{|\mathcal{B}|}. \end{aligned}$$

Observe that $\epsilon_1^{\mathcal{A}} > 0$ and $\epsilon_1^{\mathcal{B}} > 0$ since $a^o \in \mathcal{A}'$ and $b^o \in \mathcal{B}''$.

Step 4. Define

$$\epsilon(v) = 1/\chi(v), \qquad \text{where } \chi(v)^{\chi(v)} = v = v(\mathcal{A}, \mathcal{B}).$$

If $\min\{\epsilon_1^{\mathcal{A}}, \epsilon_1^{\mathcal{B}}\} > \epsilon(v)$, we use the decomposition rule given above, which amounts to solving recursively two subproblems, (7.5), (7.6), of respective volumes:

$$\begin{aligned} v(\mathcal{A}, \mathcal{B}') &= |\mathcal{A}||\mathcal{B}'| = |\mathcal{A}|(1-\epsilon_1^{\mathcal{B}})|\mathcal{B}| = (1-\epsilon_1^{\mathcal{B}})v(\mathcal{A}, \mathcal{B}), \\ v(\mathcal{A}'', \mathcal{B}) &= |\mathcal{A}''||\mathcal{B}| = (1-\epsilon_1^{\mathcal{A}})|\mathcal{A}||\mathcal{B}| = (1-\epsilon_1^{\mathcal{A}})v(\mathcal{A}, \mathcal{B}). \end{aligned}$$

This gives rise to the recurrence

$$C(v) \le 1 + C((1-\epsilon_1^{\mathcal{B}})v) + C((1-\epsilon_1^{\mathcal{A}})v) \le 1 + 2C((1-\epsilon(v))v). \tag{7.7}$$

Step 5. Let us now suppose that $\epsilon_1^{\mathcal{B}} \le \epsilon(v)$. In this case, we begin by solving subproblem (7.5). If $\mathcal{A}, \mathcal{B}'$ are not dual in $\mathcal{C}'$, we get a point x maximal in $\mathcal{C}' \setminus [\mathcal{A}^+ \cup (\mathcal{B}')^-]$, and we are done. Otherwise, we claim that

$$\mathcal{A}'', \mathcal{B} \text{ are dual in } \mathcal{C}'' \iff \text{for all } a \in \widetilde{\mathcal{A}} : \mathcal{A}'', \mathcal{B}'' \text{ are dual in } \mathcal{C}''(a), \tag{7.8}$$

where $\widetilde{\mathcal{A}} = \{a \in \mathcal{A} \mid a_1 \le a_1^o\}$ and $\mathcal{C}''(a) = \mathcal{C}_1'' \times [a_2 : u_2] \times \cdots \times [a_n : u_n]$.

Proof of (7.8). The forward direction does not use (7.5). Suppose that there is an $a \in \widetilde{\mathcal{A}}$ such that $\mathcal{A}''$ and $\mathcal{B}''$ are not dual in $\mathcal{C}''(a)$; i.e., there is an $x \in \mathcal{C}''(a) \setminus [(\mathcal{A}'')^+ \cup (\mathcal{B}'')^-]$. Then $x_i \ge a_i$ for $i = 2, \ldots, n$. If $x \in (\mathcal{B}')^-$, i.e., $x \le b$, for some $b \in \mathcal{B}'$, then, by the definition of $\mathcal{B}'$, $b_1 \ge a_1^o$. On the other hand, $a \in \widetilde{\mathcal{A}}$ implies that $a_1 \le a_1^o$. However, then,

$$(a_1, a_2, \ldots, a_n) \le (a_1^o, x_2, \ldots, x_n) \le (b_1, b_2, \ldots, b_n),$$

which contradicts the assumed condition (7.1). This shows that $x \in \mathcal{C}'' \setminus [(\mathcal{A}'')^+ \cup (\mathcal{B}' \cup \mathcal{B}'')^-]$, and hence $\mathcal{A}''$ and $\mathcal{B}$ are not dual in $\mathcal{C}$.

For the other direction, let $x \in \mathcal{C}'' \setminus [(\mathcal{A}'')^+ \cup \mathcal{B}^-]$. Since $x \notin (\mathcal{B}')^-$ and $x = (x_1, x_2, \ldots, x_n) < y \stackrel{\text{def}}{=} (a_1^o, x_2, \ldots, x_n)$, the vector y also satisfies $y \in \mathcal{C}' \setminus (\mathcal{B}')^-$. We conclude, therefore, assuming (7.5), that $y \in \mathcal{A}^+$; i.e., there is an $a \in \mathcal{A}$ such that $a \le y$. However, this implies that $a \in \widetilde{\mathcal{A}}$ and hence that $x \in \mathcal{C}''(a) \setminus [(\mathcal{A}'')^+ \cup (\mathcal{B}'')^-]$ for some $a \in \widetilde{\mathcal{A}}$.

It follows by (7.8) that, once we discover that (7.5) holds, we can reduce the solution of subproblem (7.6) to solving $|\widetilde{\mathcal{A}}|$ subproblems, each of which has a volume of $v(|\mathcal{A}''|, |\mathcal{B}''|) \le \epsilon_1^{\mathcal{B}} v(\mathcal{A}, \mathcal{B})$. Thus we obtain the recurrence

$$C(v) \le 1 + C((1-\epsilon_1^{\mathcal{B}})v) + |\mathcal{A}|C(\epsilon_1^{\mathcal{B}} v). \tag{7.9}$$

Step 6. Finally, if $\epsilon_1^{\mathcal{A}} \le \epsilon(v) < \epsilon_1^{\mathcal{B}}$, we solve subproblem (7.6), and, if we discover that $\mathcal{A}'', \mathcal{B}$ are dual in $\mathcal{C}''$, we obtain the following decomposition rule, symmetric to (7.8):

$$\mathcal{A}, \mathcal{B}' \text{ are dual in } \mathcal{C}' \iff \text{for all } b \in \widetilde{\mathcal{B}} : \mathcal{A}', \mathcal{B}' \text{ are dual in } \mathcal{C}'(b),$$

where $\widetilde{\mathcal{B}} = \{b \in \mathcal{B} \mid b_1 \ge a_1^o - 1\}$ and $\mathcal{C}'(b) = \mathcal{C}_1' \times [l_2 : b_2] \times \cdots \times [l_n : b_n]$. This reduces our original problem into one subproblem of volume $\le (1-\epsilon_1^{\mathcal{A}})v$, plus $|\widetilde{\mathcal{B}}|$ subproblems, each of volume at most $\epsilon_1^{\mathcal{A}} v$, thus giving the recurrence

$$C(v) \le 1 + C((1-\epsilon_1^{\mathcal{A}})v) + |\mathcal{B}|C(\epsilon_1^{\mathcal{A}} v), \tag{7.10}$$

which is the symmetric version of (7.9).

Using induction on $v \geq 9$, it can be shown that recurrences (7.7), (7.9), and (7.10) imply $C(v) \leq v^{\chi(v)}$ (see [14]). As $\chi(m^2) < 2\chi(m)$ and $v(\mathcal{A}, \mathcal{B}) < m^2$, we get $\chi(v) < \chi(m^2) < 2\chi(m) \sim 2 \log m / \log \log m$. Let us also note that every step above can be implemented in $O(n^3 m)$ time, independently of the sizes of the chains $|\mathcal{C}_i|$. This establishes the bound stated in Theorem 3.2.

8. Bounding the size of $\mathcal{F}_{A,b,c}$. To prove inequality (4.1) of Theorem 4.1, let us consider an arbitrary nonempty antichain $\mathcal{Y} \subseteq \mathcal{I}(\mathcal{F}_{A,b,c})$. For any $y \in \mathcal{I}(\mathcal{F}_{A,b,c})$, we can find an index $i = \rho(y) \in [r] \stackrel{\text{def}}{=} \{1, \ldots, r\}$ such that y violates the ith inequality of the system; i.e., $a^i y < b_i$, where a^i and b_i denote the ith row and component of A and b, respectively.

Consider a vector $x \in \mathcal{I}^{-1}(\mathcal{Y}) \cap \mathcal{F}_{A,b,c}$, and let x_l be a positive component of x. Then there exists a vector $y^l \in \mathcal{Y}$ such that $y^l \geq x - \mathbf{e}^l$. Let $i = \rho(y^l)$, and assume, without loss of generality, that

$$a^i_1 \geq a^i_2 \geq \cdots \geq a^i_n. \tag{8.1}$$

We claim that $x(l] = z^l(l]$, where

$$z^l = y^l(l] + \mathbf{e}^l. \tag{8.2}$$

It follows from $y^l \geq x - \mathbf{e}^l$ that $z^l(l] \geq x(l]$. If $z^l_l > x_l$, then $y^l_l \geq x_l$, which implies $y^l \geq x$, which is a contradiction. Thus $z^l_l = x_l$ holds. Moreover, if $z^l_j > x_j$ for some $j < l$, then we have $y^l_j \geq x_j + 1$. By (8.1), $a^i(y^l - \mathbf{e}^j + \mathbf{e}^l) < b_i$; i.e., $y^l - \mathbf{e}^j + \mathbf{e}^l$ is infeasible for (1.1). However, $y^l - \mathbf{e}^j + \mathbf{e}^l \geq x$ by $y^l \geq x - \mathbf{e}^l$, and hence $y^l - \mathbf{e}^j + \mathbf{e}^l$ must be feasible. This shows that $x(l] = z^l(l]$ and consequently leads to the representation

$$x = \bigvee_{l \in [n]:\, x_l > 0} z^l, \tag{8.3}$$

where, for vectors $v, u \in \mathcal{C}$, we let $v \vee u$ denote the componentwise maximum of v and u.

Not all of the vectors z^l are necessary for this representation. Suppose that $\rho(y^l) = \rho(y^{l'}) = i$ for some positive components x_l and $x_{l'}$ of x and for $l' < l$. Then (8.3) remains valid if we drop $z^{l'}$, the vector with the smaller index l'. In other words, by sorting the ith row of A and then selecting from among the vectors $y^l \in \rho^{-1}(i)$ the one with the highest $l = l_i$, we obtain at most r vectors z^{l_i} such that

$$x = \bigvee_{i \in [r]} z^{l_i}. \tag{8.4}$$

The latter representation readily implies (4.1).

9. Polynomial generation of $\mathcal{F}_{A,b,c}$ and $\mathcal{I}(\mathcal{F}_{A,b,c})$. Theorem 4.1 implies that, for $r \leq$ const, the antichain $\mathcal{I}(\mathcal{F}_{A,b,c})$ is uniformly dual-bounded, and, consequently, $\mathcal{I}(\mathcal{F}_{A,b,c})$ can be generated in incremental quasi-polynomial time via Algorithm $\mathcal{J}$ presented in section 6. In this section, we show that, for bounded r, the antichains $\mathcal{I}(\mathcal{F}_{A,b,c})$ and $\mathcal{F}_{A,b,c}$ can, in fact, be generated in incremental polynomial time. Since the sizes $|\mathcal{F}_{A,b,c}|$ and $|\mathcal{I}(\mathcal{F}_{A,b,c})|$ are (uniformly) polynomially related by Theorems 2.1 and 4.1, the required result will follow from Proposition 6.1, provided that Step 3 of Algorithm $\mathcal{J}$, the dualization step, can be done in polynomial time. Thus it is enough to show that problem DUAL$(\mathcal{C}, \mathcal{A}, \mathcal{B})$ can be solved in polynomial

time if $\mathcal{A} \subseteq \mathcal{F}_{A,b,c}$ is a subset of the minimal solutions of a monotone system (1.1) with bounded r.

For $i \in [r] = \{1, \dots, r\}$, let $\sigma_{(i)} = (\sigma_{(i)1}, \dots, \sigma_{(i)n}) \in \mathbb{S}_n$ be a permutation of the coordinates such that

$$a^i_{\sigma_{(i)1}} \geq a^i_{\sigma_{(i)2}} \geq \cdots \geq a^i_{\sigma_{(i)n}}. \tag{9.1}$$

Given $\mathcal{A} \subseteq \mathcal{F}_{A,b,c}$ and $\mathcal{B} \subseteq \mathcal{I}(\mathcal{F}_{A,b,c})$, we may assume that $0 \notin \mathcal{A}$ (otherwise, $\mathcal{F}_{A,b,c} = \{0\}$ and $\mathcal{I}(\mathcal{F}_{A,b,c}) = \emptyset$) and $\mathcal{B} \neq \emptyset$ (otherwise, Proposition 7.1 can be used to generate a point $x \in \mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$). Now we proceed in two basic steps.

Step 1. For every $y \in \mathcal{B}$ and for each pair of indices $\sigma_{(i)j}$ and $\sigma_{(i)l}$ with $y_{\sigma_{(i)j}} > 0$, $y_{\sigma_{(i)l}} < c_{\sigma_{(i)l}}$, and $j < l$, check if there exists a $y' \in \mathcal{B}$ such that

$$y' \geq y - \mathbf{e}^{\sigma_{(i)j}} + \mathbf{e}^{\sigma_{(i)l}}, \tag{9.2}$$

where $i = \rho(y)$ is the index of an infeasible inequality for y, as defined in the previous section. Note that $y - \mathbf{e}^{\sigma_{(i)j}} + \mathbf{e}^{\sigma_{(i)l}}$ is infeasible and hence is an independent element of $\mathcal{A}$. If no such y' can be found, we generate a new maximal independent vector $y' \in \mathcal{I}(\mathcal{A}) \setminus \mathcal{B}$, satisfying (9.2), and halt.

Step 2. For every collection $(y^i \in \rho^{-1}_{\mathcal{B}}(i) \mid i \in [r])$, where $\rho^{-1}_{\mathcal{B}}(i) \stackrel{\text{def}}{=} \{y \in \mathcal{B} \mid \rho(y) = i\}$, and for every $(l_i \mid i \in [r], y^i_{l_i} < c_{l_i}) \in [n]^r$, construct the vector $x = \bigvee_{i \in [r]} z^{l_i}$, where z^{l_i} is given by (8.2) (according to the permutation $\sigma_{(i)}$ and using $y^l = y^{l_i}$). If $x \notin \mathcal{A}^+ \cup \mathcal{B}^-$, then a new maximal independent vector can be generated.

Clearly, the above two steps run in $poly(n, m) + O((n|\mathcal{B}|)^r)$ time, which is polynomially bounded for constant r. It is also clear that, if the algorithm outputs a point $x \in \mathcal{C}$, then $x \notin \mathcal{A}^+ \cup \mathcal{B}^-$, so it remains to verify that the algorithm indeed outputs such a point if $\mathcal{A}^+ \cup \mathcal{B}^- \neq \mathcal{C}$. To see this, let x be a minimal vector in $\mathcal{C} \setminus (\mathcal{A}^+ \cup \mathcal{B}^-)$. From our assumptions, it follows that $x \neq 0$, and thus there exists an index l with $x_l > 0$. By the minimality of x, there exists a vector $y^l \in \mathcal{B}$ such that $y^l \geq x - \mathbf{e}^l$. Let $i = \rho(y^l)$, assume without any loss of generality that (8.1) holds, and consider an index $j < l$. If $y^l_j > x_j$, we get $y^l - \mathbf{e}^j + \mathbf{e}^l \geq x$, and therefore a new maximal independent point $x' \geq x$ must have been output in Step 1 of the algorithm (cf. (9.2)). On the other hand, if, for every $l \in [n]$ such that $x_l > 0$ and for every $y^l \in \mathcal{B}$ such that $y^l \geq x - \mathbf{e}^l$, we have $x(l] = z^l(l]$ (in the ordering implied by $\sigma(i)$, where $i = \rho(y^l)$), then we can conclude that x satisfies (8.4), and, consequently, it must have been created in Step 2.

10. Concluding remarks. We mention in closing that, in section 5, we actually proved Theorem 2.1 for arbitrary systems of 2-monotonic inequalities in integer variables. Consequently, the set of minimal feasible integer vectors for any system of 2-monotonic inequalities is uniformly dual-bounded. By Proposition 6.2, this implies that all minimal integer solutions to a system of 2-monotonic inequalities can be generated in incremental quasi-polynomial time, provided that the system has a polynomial-time feasibility oracle. Theorems 4.1 and 4.2 also hold for arbitrary systems of 2-monotonic inequalities. These generalize results known for a single Boolean 2-monotonic inequality discussed in [4, 8, 9, 18, 24, 26, 27].

LOWER BOUNDS FOR LEADER ELECTION AND COLLECTIVE COIN-FLIPPING IN THE PERFECT INFORMATION MODEL*

ALEXANDER RUSSELL†, MICHAEL SAKS‡, AND DAVID ZUCKERMAN§

Abstract. Collective coin-flipping is the problem of producing common random bits in a distributed computing environment with adversarial faults. We consider the *perfect information* model: all communication is by broadcast and corrupt players are computationally unbounded. Protocols in this model may involve many asynchronous rounds. We assume that honest players communicate only uniformly random bits. We demonstrate that any n-player coin-flipping protocol that is resilient against corrupt coalitions of linear size must use either at least $[1/2 - o(1)] \log^* n$ communication rounds or at least $[\log^{(2k-1)} n]^{1-o(1)}$ communication bits in the kth round, where $\log^{(j)}$ denotes the logarithm iterated j times. In particular, protocols using one bit per round require $[1/2 - o(1)] \log^* n$ rounds. These bounds also apply to the leader election problem. The primary component of this result is a new bound on the influence of random sets of variables on Boolean functions. Finally, in the one-round case, using other methods we prove a new bound on the influence of sets of variables of size βn for $\beta > 1/3$.

Key words. perfect information model, collective coin-flipping, leader election

1. Introduction.

Collective coin-flipping is the problem of producing a common random bit in a distributed computing environment with adversarial faults. We consider the *perfect information* model introduced by Ben-Or and Linial [5], which can be informally described as follows. A protocol in this model consists of a sequence of rounds. In each round, each player privately generates a uniformly random string of bits of some specified length (possibly 0) and broadcasts the string. Each broadcast is received by all players and the identity of the sender is known with certainty. The round ends after all broadcasts are received. After the completion of all rounds, the outcome of the protocol is computed separately by each player as a prespecified function of all the values broadcast during the protocol; for the coin-flipping problem the outcome is a single bit. A protocol Π is said to be an (n, r, ℓ)-protocol if n is the number of players, r is the number of rounds, and each player broadcasts at most ℓ bits in each round.

Faults are modeled by the presence of an unknown set of b corrupt players who collude in order to bias the outcome. Players are assumed to be computationally unbounded. In addition, the system is not able to enforce perfect synchrony within a

round; thus in each round, the corrupt players may wait to see the broadcasts of the other players before selecting their strings.

While not necessary for previous upper bounds, we strengthen our lower bounds by assuming that corrupt players may cheat only in ways that are undetectable to the other players. This means that when the protocol specifies that such a player broadcast a bit string of a given length, he must do so; however, he may cheat by broadcasting a string that he chooses rather than a random string.

The simplest protocol is one that designates a single player to flip a coin, the value of which is the outcome of the protocol; of course, this is unsatisfactory if that player happens to be faulty. More generally, an $(n, 1, 1)$-protocol is defined by a Boolean function $f : \{0,1\}^n \to \{0,1\}$; each player i broadcasts a bit r_i and the outcome is $f(r_1, \ldots, r_n)$. Throughout the paper we use the terms Boolean function and $(n, 1, 1)$-protocol interchangeably.

The primary goal in designing a protocol is to ensure that it can tolerate as many cheaters as possible.

DEFINITION 1.

1 *Let* Π *be a coin-flipping protocol for* n *players, and let* $\gamma \in (0, 1/2]$.

(a) *For* $B \subseteq [n]$, Π *is* (B, γ)-resilient *if for any strategy of the players in* B,

$$\gamma \leq \Pr[\Pi \text{ has outcome } 1] \leq 1 - \gamma,$$

where the probability is taken with respect to the random bits generated by the players outside of B.

(b) Π *is* (b, γ)*-resilient for an integer* $b \leq n$ *if it is* (B, γ)*-resilient for all* B *with* $|B| \leq b$.

2. *Let* $\Pi = (\Pi_n : n \geq 1)$ *be a sequence where* Π_n *is an* n*-player protocol, and let* $b(n)$ *be a function mapping* n *to an integer* $b(n) \leq n$. *We say that* Π *is* $b(n)$-resilient *if there exists* $\gamma > 0$ *(independent of* n*) such that for all* n, Π_n *is* $(b(n), \gamma)$*-resilient.*

For example, in the case of $(n, 1, 1)$-protocols, the PARITY function, $\sum_{i=1}^{n} r_i \bmod 2$, is not even 1-resilient, while the MAJORITY function is $c\sqrt{n}$-resilient for any positive c. Ajtai and Linial [1] constructed a Boolean function that is $\Omega(n/\log^2 n)$-resilient. Kahn, Kalai, and Linial, in a 1988 tour de force, proved an upper bound on the resilience of Boolean functions.

THEOREM 2 (see [13]). *If* $b(n) = \omega(\frac{n}{\log n})$, *then no sequence* $(f_n : n \geq 1)$ *is* $b(n)$*-resilient.*

We emphasize that this bound applies only to $(n, 1, 1)$-protocols. Indeed, Alon and Naor [2] showed that there are protocols using n rounds that are $\Omega(n)$-resilient, and this was followed by a sequence of papers giving more efficient protocols with linear resilience. In what follows $\log^{(k)}(n)$ denotes the maximum of 1 and the kth iterated base 2 logarithm, and $\log^* n$ is the least integer k such that $\log^{(k)}(n) = 1$. The most efficient known protocol is that of [16], requiring $\log^* n + O(1)$ rounds; players send messages of length $O(\log^{(k)} n)$ during the kth round. The protocol achieves βn-resilience for any $\beta < 1/2$. (As noted in [17] no protocol can be $n/2$-resilient.) This protocol can be modified to yield a one bit per round protocol with $\big[1 + o(1)\big] \log n$ rounds. Subsequently, Feige [9] gave a simpler protocol with similar properties.

Despite rapid progress in our understanding of *protocols* for the problem, very little beyond Theorem 2 was known on the negative side. The major contribution of this article is an extension of Theorem 2 to protocols with many rounds. We will prove the following theorem.

THEOREM 3. *Let $\Pi = (\Pi_n : n \geq 1)$ be a sequence of protocols, where Π_n is an $(n, r(n), 1)$-protocol for $r(n) \leq \frac{1}{2}\log^* n - \log^* \log^* n$. Then*

1. *Π_n is not $\Omega(n)$-resilient and*
2. *if*

$$b(n) = \omega\left(\frac{(r(n))^2}{\log^{(2r(n)-1)} n} \cdot n\right),$$

then Π is not $b(n)$-resilient.

For instance, when $r(n) = 1$ this reduces to Theorem 2, and when $r(n) = 2$ it implies that no $(n, 2, 1)$-protocol can be $\omega(n/\log\log\log n)$-resilient.

We extend the notation above to describe protocols with variable communication complexity: a protocol Π is said to be an $(n, r, \vec{\ell})$-protocol if n is the number of players, r is the number of rounds, and no more than ℓ_k bits are broadcast by any player in the kth round, where $\vec{\ell} = (\ell_1, \ldots, \ell_r)$. We will prove that the conclusion of Theorem 3 holds even if we relax the requirement that each player sends only one bit per round.

THEOREM 4. *There is a function $\eta : \mathbb{N} \to [0, 1]$ with $\eta(n) = o(1)$ so that for any sequence $\Pi = (\Pi_n : n \geq 1)$ of protocols, where Π_n is an $(n, r(n), \vec{\ell})$-protocol with*

$$r(n) \leq \frac{1}{2}\log^* n - \log^* \log^* n \qquad \text{and} \qquad \ell_k(n) \leq (\log^{(2k-1)} n)^{1-\eta(n)},$$

Π_n is not $\Omega(n)$-resilient.

Recall that current upper bounds provide $(n, \log^* n + O(1), \vec{\ell})$-protocols which are linearly resilient, where $\ell_k = O(\log^{(k)} n)$.

The *leader election* problem is that of selecting a "leader" among n players so that the probability that any coalition (of appropriate size) can elect one of its own members is at most $1 - \epsilon$ for a constant $\epsilon > 0$ independent of n. Adopting the above model, the notion of resilience may be extended to this scenario. Collective coin-flipping may be reduced to leader election at the cost of an extra round: the leader may flip a fair coin. Our bounds shall then naturally apply to this problem as well. For a more detailed discussion of coin-flipping, leader election, and the perfect information model, see [7, 14].

Section 2 gives definitions, notation, and preliminary facts. The two main theorems are proved in section 3 and section 4. In section 5 an observation is made about the behavior of large linear sized coalitions. We conclude with some open questions.

2. Preliminaries.

2.1. General notation. Throughout, $\ln x$ denotes the natural logarithm and $\log x$ the logarithm base 2. To avoid logarithms of negative numbers, iterated logarithms are defined inductively as follows: for $x \geq 1$, $\log^{(0)}(x) = x$, and for $k \geq 1$,

$$\log^{(k)} x = \begin{cases} 1 & \text{if } \log^{(k-1)} x < 2, \\ \log\left(\log^{(k-1)} x\right) & \text{otherwise.} \end{cases}$$

For $x \geq 1$, define $\log^*(x)$ to be the smallest natural number k for which $\log^{(k)} x = 1$.

For a positive real number y and integer k the *tower* function $\mathrm{T}(k; y)$ is defined by

$$\mathrm{T}(0; y) = y, \text{ and}$$
$$\mathrm{T}(k; y) = 2^{\mathrm{T}(k-1;y)} \text{ for } k > 0.$$

Observe that for any $y \geq 1$, $k \leq \ell$, $\log^{(k)}(\mathrm{T}(\ell; y)) = \mathrm{T}(\ell - k; y)$.

For an integer n, we denote the set $\{1, \ldots, n\}$ by $[n]$. For $J \subseteq [n]$, a finite set X, and $\alpha \in X^J$, $C(\alpha)$ denotes the set of all points $x \in X^n$ such that $x_j = \alpha_j$ for all $j \in J$. If $\alpha \in X^J$ and $\beta \in X^{[n]\setminus J}$, then $[\alpha : \beta]$ denotes the unique point of $\{0,1\}^n$ belonging to $C(\alpha) \cap C(\beta)$.

If S is a set, the notation $x \in_U S$ indicates that x is selected uniformly at random from S.

2.2. Coin-flipping protocols and influence. We want to formalize the definition of protocol given in the introduction. We below define $(n, r, \vec{\ell})$-protocols and a number of related notions; (n, r, ℓ)-protocols, where communication is constant across rounds, are covered as a special case. For an $(n, r, 1)$-protocol Π we suppress the third index and simply say that Π is an (n, r)-protocol.

Formally, an $(n, r, \vec{\ell})$-*protocol* is a function

$$\Pi : (\{0,1\}^{\ell_1})^n \times \cdots \times (\{0,1\}^{\ell_r})^n \to \{0,1\}.$$

Such a protocol is executed in r rounds. In the presence of a set $B \subset [n]$ of bad players, the protocol operates as follows. In round i, the players in $[n] \setminus B$ select $\alpha^i \in (\{0,1\}^{\ell_i})^{[n]\setminus B}$ uniformly at random. Then, depending on $\alpha^1, \ldots, \alpha^i$, the players in B choose their values. Formally, an $(n, r, \vec{\ell})$-*strategy* for B is a sequence $S = (S_1, S_2, \ldots, S_r)$ of functions where

$$S_i : \left(\{0,1\}^{\ell_1}\right)^{[n]\setminus B} \times \cdots \times \left(\{0,1\}^{\ell_i}\right)^{[n]\setminus B} \to \left(\{0,1\}^{\ell_i}\right)^{B}.$$

The function S_i specifies the choices of the bad players in round i as a function of the choices of the good players in the first i rounds. The outcome of protocol Π, with bad player set B playing strategy S, is a function of the sequence

$$\vec{\alpha} = (\alpha^1, \ldots, \alpha^r) \in \left(\{0,1\}^{\ell_1}\right)^{[n]\setminus B} \times \cdots \times \left(\{0,1\}^{\ell_r}\right)^{[n]\setminus B}$$

of the random coins of the good players, which is denoted $\Pi(\vec{\alpha}; S)$ and is defined to be

$$\Pi\big([\alpha^1 : S_1(\alpha^1)], \ldots, [\alpha^r : S_r(\alpha^1, \ldots, \alpha^r)]\big).$$

Definition 5. *For a protocol Π, $B \subseteq [n]$, and strategy S,*

- *$p^1_\Pi(B; S)$ denotes the probability that $\Pi(\vec{\alpha}; S) = 1$ if*

$$\vec{\alpha} \in_U \left(\{0,1\}^{\ell_1}\right)^{[n]\setminus B} \times \cdots \times \left(\{0,1\}^{\ell_r}\right)^{[n]\setminus B};$$

- *$p^1_\Pi(B)$ is the maximum of $p^1_\Pi(B; S)$ over all strategies S;*
- *$p^1_\Pi = p^1_\Pi(\emptyset)$, the* natural probability of Π*, is the probability that the outcome is 1 if there are no bad players;*
- *$I^1_\Pi(B)$, the* influence of B towards 1*, is defined to be $p^1_\Pi(B) - p^1_\Pi$;*
- *$p^0_\Pi(B; S)$, $p^0_\Pi(B)$, p^0_Π, and $I^0_\Pi(B)$ are defined analogously;*
- *$I_\Pi(B)$, the* influence of B on Π*, is defined to be*

$$I^1_\Pi(B) + I^0_\Pi(B).$$

An $(n,1)$-protocol corresponds to a Boolean function $f : \{0,1\}^n \to \{0,1\}$, and we typically use the letter f (instead of Π) for such a protocol. It is not hard to see that $p_f^1(B)$ is the probability, with respect to $\alpha \in_U \{0,1\}^{[n]\setminus B}$, that $1 \in f(C(\alpha))$ and that $I_f(B)$ is the probability that f is not constant on $C(\alpha)$. Furthermore, if $|B| = 1$, then $I_f^1(B) = I_f^0(B)$.

The following result, observed in [6] (cf. Proposition 2.2 of [13]), implies that the most resilient one-round protocols are given by Boolean functions that are monotone.

PROPOSITION 6. *For any Boolean function f, there exists a monotone Boolean function g on the same set of variables for which*

1. $p_f^1 = p_g^1$ *and*
2. *for all $B \subset [n]$, $I_f^1(B) \geq I_g^1(B)$ and $I_f^0(B) \geq I_g^0(B)$.*

Finally, we need a variant of a fact first noted in [10] and based on a result in [13], which asserts that if no variable in a Boolean function has large influence, then the average influence of a variable cannot be too small. For completeness, we include a proof.

LEMMA 7. *Let $\gamma \in (0, \frac{1}{2})$ and $\theta \in (0, \frac{1}{8})$. Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function with $p_f^1 \in (\gamma, 1-\gamma)$. If $I_f(\{i\}) \leq \theta$ for each $i \in [n]$, then*

$$\sum_{i\in[n]} I_f(\{i\}) \geq \frac{\gamma \log(\frac{1}{\theta})}{20}.$$

Proof. Let $\bar{v} \in \mathbb{R}^n$ denote the vector with $v_i = I_f(\{i\})$. For $p > 0$, the l_p norm of $\bar{v}$, denoted $\|\bar{v}\|_p$, is defined to be $(S_p)^{1/p}$, where $S_p = \sum |v_i|^p$.

By complementing if necessary, we may assume that $p_f^1 \leq 1/2$. Since the function f is Boolean and $p_f^1 \geq \gamma$, [13, eq. (3.4.1)] asserts that for any $\delta \in (0,1)$ and $t \geq 1$,

$$\delta^{-t} S_{\frac{2}{1+\delta}} + t^{-1} S_1 \geq \frac{\gamma}{2}. \tag{2.1}$$

Inequality (2.10.1) of Hardy, Littlewood, and Pólya [11] asserts that

$$S_r \leq (S_q)^{\frac{s-r}{s-q}} (S_s)^{\frac{r-q}{s-q}}$$

for $0 < q < r < s$, which is equivalent to

$$(S_r)^{\frac{s-q}{s}} \leq (S_q)^{\frac{s-r}{s}} (\|v\|_s)^{r-q}.$$

Setting $q = 1$ and $r = \frac{2}{1+\delta}$ and letting s tend to ∞, we obtain

$$S_{\frac{2}{1+\delta}} \leq S_1 \theta^{\frac{1-\delta}{1+\delta}}.$$

Substituting this into the inequality (2.1) and setting $\delta = 1/2$ we get

$$\left(2^t \theta^{\frac{1}{3}} + \frac{1}{t}\right) S_1 \geq \frac{\gamma}{2}.$$

Choose t such that $\theta = 2^{-3t}/t^3$ (noting that $t > 1$ since $\theta < 1/8$). Then the previous inequality implies $S_1 \geq t\gamma/4$. Since $2^{-3t}/t^3 \geq 2^{-5t}$ for $t \geq 1$, we have

$$t \geq \frac{1}{5} \log\left(\frac{1}{\theta}\right),$$

and therefore

$$S_1 \geq \frac{\gamma \log \frac{1}{\theta}}{20}. \qquad \square$$

2.3. A tail bound for submartingales. Our main theorems are proved by considering a certain stochastic process which, for a Boolean function, selects a set of variables likely to have large influence. Our analysis of this stochastic process involves a tail bound for submartingales, which we record below.

DEFINITION 8. *A* submartingale *is a sequence of real valued random variables* $Z_0, Z_1, \ldots$ *for which* $\mathbb{E}[Z_i \mid Z_{i-1}] \geq Z_{i-1}$.

We were unable to find the exact form of the following tail bound in the literature, so we have included a proof. The basic method is developed in [8, 4, 12]. Our treatment follows [3, 15].

LEMMA 9. *Let* $(Z_i : i \in \{0, \ldots, n\})$ *form a submartingale with* $Z_0 = 0$. *Define* $X_i = Z_i - Z_{i-1}$ *for* $i \in \{1, \ldots, n\}$ *and assume that* $X_i \in [0,1]$ *and* $\mathbb{E}[X_i \mid Z_{i-1}] \geq \mu_i$. *Setting* $\mu = \sum_i \mu_i$ *and* $Z = Z_n$,

$$\Pr[Z < (1-\delta)\mu] < e^{-\frac{\delta^2 \mu}{2}}$$

for all $\delta > 0$.

Proof. Observe that for any $\alpha > 0$,

$$\Pr[Z < (1-\delta)\mu] = \Pr\left[e^{-\alpha Z} > e^{-\alpha(1-\delta)\mu}\right] < \frac{\mathbb{E}\left[e^{-\alpha Z}\right]}{e^{-\alpha(1-\delta)\mu}}.$$

Letting $\ell(x) = 1 + x(e^{-\alpha} - 1)$, we have $e^{-\alpha x} \leq \ell(x)$ for all $x \in [0,1]$ because the exponential function is convex. For any $[0,1]$ valued random variable Y,

$$\mathbb{E}\left[e^{-\alpha Y}\right] \leq \mathbb{E}\left[\ell(Y)\right] = 1 + \mathbb{E}[Y](e^{-\alpha} - 1).$$

By induction, we compute

$$\begin{aligned}
\mathbb{E}\left[e^{-\alpha Z_k}\right] &= \mathbb{E}\left[e^{-\alpha Z_{k-1}} \cdot e^{-\alpha X_k}\right] \\
&= \mathbb{E}\left[\left(e^{-\alpha Z_{k-1}}\right) \mathbb{E}\left[e^{-\alpha X_k} \,\middle|\, Z_{k-1}\right]\right] \\
&\leq \mathbb{E}\left[\left(e^{-\alpha Z_{k-1}}\right) \left(1 + \mathbb{E}\left[X_k \,\middle|\, Z_{k-1}\right](e^{-\alpha} - 1)\right)\right] \\
&\leq \prod_i (1 + \mu_i(e^{-\alpha} - 1)) < e^{\sum_i^k \mu_i (e^{-\alpha} - 1)}.
\end{aligned}$$

Hence

$$\Pr\left[Z < (1-\delta)\mu\right] < \frac{e^{\mu(e^{-\alpha}-1)}}{e^{-\alpha(1-\delta)\mu}}.$$

Setting $\alpha = \ln(\frac{1}{1-\delta})$, we have

$$\Pr\left[Z < (1-\delta)\mu\right] < \left(\frac{e^{-\delta}}{(1-\delta)^{(1-\delta)}}\right)^{\mu} \leq e^{-\frac{\delta^2 \mu}{2}},$$

since $(1-\delta)^{(1-\delta)} > e^{-\delta + \frac{\delta^2}{2}}$. ∎

3. Proof of Theorem 3. We begin by considering (n, r)-protocols; each round consists of a single bit broadcast by each player. Fix the integer r. We say that a protocol Π is α-*nontrivial* if the natural probability of Π is at least α, i.e., $p^1_\Pi \geq \alpha$, terminology that we apply also in the multibit case. By complementing the output

if necessary, we may assume that the protocol is 1/2-nontrivial. We want to show that if Π is an (n,r)-protocol, then for n sufficiently large there is a set B of $b \ll n$ players so that B can almost always force the outcome to 1. For $r = 1$ this follows from Theorem 2.

We illustrate the ideas for $r > 1$ by looking at the two round case. By separating the inputs associated with each round, a two round protocol may be viewed as a function to functions:

$$\Pi : \{0,1\}^n \to \{g : \{0,1\}^n \to \{0,1\}\}.$$

As Π is 1/2-nontrivial, many g's will be 1/4-nontrivial (any constant less than 1/2 would do) and by Theorem 2, for each such g there is a sublinear set of players B_2 that can force this g to be 1 with high probability. Also by Theorem 2, there is a sublinear set of players B_1 that can likewise force the output of Π to be one of these g's. A natural strategy is to choose $B = B_1 \cup B_2$.

The problem with this plan is that B_2 depends on g; we really need one B_2 that works for many g's. We show this by proving that a random B_2 will work with significant probability for any 1/4-nontrivial g. It follows that a random B_2 will work for many g's. For general r, we will proceed by induction, with our inductive assumption being that a random sublinear set of players can control the protocol with significant probability.

To make these ideas rigorous, we begin with some definitions. For $\beta \in [0,1]$, we say that a subset B is *β-powerful in* Π if $p^1_\Pi(B) \geq 1 - \beta$.

DEFINITION 10. *Let $C_n(r;\alpha,\beta)$ (written $C_n(r;\gamma)$ when $\alpha = \beta = \gamma$) denote the collection of pairs $\langle \delta, b\rangle$ so that for any (n,r)-protocol Π that is α-nontrivial, at least a δ fraction of sets $B \subset [n]$ of size b are β-powerful in Π.*

In this notation, we are aiming to show that for some $\delta > 0$ and $b \ll n$, $(\delta, b) \in C_n(r; 1/2, o(1))$ for sufficiently large n. We prove the somewhat stronger statement that $(\delta, b) \in C_n(r; o(1))$.

The basis case of the induction on r is provided by the following result for one-round protocols.

LEMMA 11. *Let $n \in \mathbb{N}$ and $\gamma \in (0, \frac{1}{2})$ and $b \leq n$, and assume $\gamma b \geq 400n/\log n$. Then $\langle \delta(n,b,\gamma), b\rangle \in C_n(1;\gamma)$, where*

$$\delta(n,b,\gamma) = \frac{1}{2}\left(\frac{b}{4n}\right)^{2^{\frac{80n}{b\gamma}}}.$$

The induction step is provided by the following lemma.

LEMMA 12. *Fix n. If $\langle \delta_1, b_1\rangle \in C_n(r_1;\gamma_1)$ and $\langle \delta_2, b_2\rangle \in C_n(r_2;\gamma_2)$, then*

$$\left\langle \frac{\delta_1\delta_2}{2}, b_1 + b_2 \right\rangle \in C_n\left(r_1 + r_2; \frac{2\gamma_1}{\delta_2} + \gamma_2\right).$$

These two lemmas are combined to prove the following lemma.

LEMMA 13. *Let $b \leq n \in \mathbb{N}$ and $\gamma \in (0, \frac{1}{2})$. Define $\lambda_0 = \frac{1}{2}$ and for $r \geq 1$ define*

$$\lambda_r = 4\lambda_{r-1}\left(\frac{4n}{b}\right)^{2^{\frac{160n}{b\gamma}\lambda_{r-1}}}.$$

Then for all $r \geq 1$ such that $\gamma b \geq 800\lambda_{r-1}n/\log n$,

$$\left\langle \frac{1}{\lambda_r}, rb \right\rangle \in C_n(r; r\gamma).$$

An immediate consequence of this lemma is the following corollary.

COROLLARY 14. *Let n, b, γ, and λ_i be as in Lemma 13 and suppose that r is an integer such that*

$$\frac{\gamma b \log n}{800n} \geq \lambda_{r-1}.$$

Then if Π is an (n,r)-protocol that is $r\gamma$-nontrivial, there exists at least one subset B of size rb that is $r\gamma$-powerful.

We first deduce the main theorem from this corollary.

Proof of Theorem 3. We prove the second part of the theorem first.

Let $r(n)$ be an integer valued function with $r(n) \leq (1/2 - \epsilon)\log^* n$ and let $\Pi = (\Pi_n : n \geq 1)$ be a sequence where Π_n is an $(n, r(n))$-protocol. Let

$$b(n) = \frac{(r(n))^2 n}{\log^{(2r(n)-1)} n} a(n),$$

where $a(n)$ is any function tending to infinity. Let n be sufficiently large, and suppose for contradiction that for some $\gamma > 0$, Π is $(b(n), \gamma)$-resilient. Without loss of generality we may assume that $p^1_{\Pi_n} \geq 1/2$. Let $b'(n) = b(n)/r(n)$ and

$$\gamma' = \gamma'(n) = \frac{\gamma}{2r(n)}.$$

By the previous corollary applied to b' and γ', if

$$\frac{\gamma a(n) \log n}{1600 \log^{(2r-1)} n} \geq \lambda_{r-1}, \tag{3.1}$$

then there is at least one subset of size $r(n)b'(n) = b(n)$ that is $(r(n)\gamma'(n) = \gamma/2)$-powerful, which would contradict our assumption. So it suffices to show that inequality (3.1) hold When $r = 1$ inequality (3.1) holds, for large enough n, by inspection. Otherwise, taking $\log^{(2r-2)}$ of both sides, the left-hand side is at least $\frac{1}{2}\log^{(2r-1)} n$ for large enough n and so it suffices to show that this is an upper bound on $\log^{(2r-2)} \lambda_{r-1}$. In the following proposition, T denotes the tower function, as defined in section 2.1.

PROPOSITION 15. *Let $b \leq n$ and $\gamma \in (0,1)$. For all integers $r \geq 0$, $\lambda_r \leq \kappa_r$ where*

$$\kappa_r = \frac{b\gamma}{320n} \mathrm{T}\left(2r; \frac{640n}{b\gamma}\right).$$

Proof. κ_r satisfies the recurrence

$$\kappa_0 = 2,$$
$$\kappa_r = \left(\frac{b\gamma}{320n}\right) 2^{2^{\frac{320n}{b\gamma}\kappa_{r-1}}},$$

so it suffices to show that

$$\lambda_r \leq \left(\frac{b\gamma}{320n}\right) 2^{2^{\frac{320n}{b\gamma}\lambda_{r-1}}},$$

which follows from

$$\begin{aligned}
\lambda_r &= 4\lambda_{r-1}\left(\frac{4n}{b}\right)^{2^{\frac{160n}{b\gamma}\lambda_{r-1}}} \\
&= \left(\frac{b\gamma}{320n}\right)\left(\frac{1280n\lambda_{r-1}}{b\gamma}\right)\left(\frac{4n}{b}\right)^{2^{\frac{160n}{b\gamma}\lambda_{r-1}}} \\
&\le \left(\frac{b\gamma}{320n}\right)\left(\frac{5120n^2\lambda_{r-1}}{b^2\gamma}\right)^{2^{\frac{160n}{b\gamma}\lambda_{r-1}}} \\
&= \left(\frac{b\gamma}{320n}\right)2^{\log\left(\frac{5120n^2\lambda_{r-1}}{b^2\gamma}\right)2^{\frac{160n}{b\gamma}\lambda_{r-1}}} \\
&\le \left(\frac{b\gamma}{320n}\right)2^{2^{\frac{320n}{b\gamma}\lambda_{r-1}}}. \qquad \square
\end{aligned}$$

Using the proposition, and the assumption about b, for n sufficiently large we have

$$\log^{(2r-2)}\lambda_{r-1} \le \frac{640n}{b\gamma} \le \frac{640}{a(n)\gamma}\log^{(2r(n)-1)} n < \frac{1}{2}\log^{(2r(n)-1)} n,$$

as required to complete the proof of the second part of the theorem.

For the first part of the theorem, it suffices to note that if $r(n) \le \frac{1}{2}\log^* n - \Delta$ for $\Delta = \log^*\log^* n$, then $r(n)^2 = o(\log^{(2r(n)-1)} n)$. This follows by taking $\log^{(\Delta)}$ of both sides: $\log^{(\Delta)}(r(n)^2) \le 2$ while $\log^{(\Delta)}(\log^{(2r(n)-1)} n) \ge \mathrm{T}(\Delta; 2)$. Hence we can choose $b(n) = o(n)$ so that it satisfies the hypothesis and, hence, the conclusion of the second part of the theorem. $\square$

So it remains to prove Lemmas 11, 12, and 13.

3.1. Proof of Lemma 11. Let f be a γ-nontrivial function on n variables. We want to show that for b in the given range, a "large" fraction of the sets of size b are γ-powerful. In light of Proposition 6, we may assume that f is monotone.

Fix $\gamma \in (0, 1/2)$. We first describe a stochastic process for selecting a sequence of variables $v_1, v_2, \ldots, v_d$ for an integer d to be specified, and show that with probability at least $1/2$, the process produces a set of variables that is γ-powerful. The process depends on a parameter s, which we will also specify later. Having selected the first k of these variables $v_1, \ldots, v_k$, let f_k denote the (monotone) Boolean function on $n-k$ variables obtained by setting each v_i to 1. We then select v_{k+1} as follows:

1. If there is a variable v whose influence in f_k is at least 2^{-s}, let v_{k+1} be such a variable of lowest index.
2. Otherwise, choose v_{k+1} uniformly at random from among the remaining $n-k$ variables.

We will establish the following claim.

CLAIM A. *Let n be sufficiently large and let $d \in [n]$ and $\gamma \in (0, 1/2)$, and suppose that $\gamma d \ge \frac{160n}{\log n}$. Let s, the parameter of the process, be $\frac{80n}{\gamma d}$. Then*

$$\Pr\Big[\{v_1, \ldots, v_d\} \textit{ is } \gamma\textit{-powerful in } f\Big] \ge 1/2.$$

Define random variables X_k and Z_k, for $i = 0, \ldots, d$, by

$$X_k = \begin{cases} 1 & \text{if } p^1_{f_{k-1}} \geq 1 - \gamma, \\ I^1_{f_{k-1}}(v_k) & \text{otherwise,} \end{cases}$$

$$Z_k = \sum_{i=1}^{k} X_i.$$

Claim A is easily deduced from the following two claims. In both claims, n, d, γ, and s are as in Claim A.

CLAIM B. *If $Z_d \geq 1 - 2\gamma$, then $\{v_1, \ldots, v_d\}$ is γ-powerful in f.*

CLAIM C. *Suppose $3 \leq s \leq \log(20n) - \log\log(20n)$. For each $k = 1, \ldots, d$,*

$$\mathbb{E}\Big[X_k \,\Big|\, X_0, \ldots, X_{k-1}\Big] \geq \frac{s\gamma}{20n}.$$

Assume Claims B and C. Let $s = 80n/\gamma d$. Since $\gamma d \geq 160n/\log n$, and $d \leq n$, s satisfies the hypothesis of Claim C and therefore

$$\mathbb{E}[Z_d] \geq \frac{ds\gamma}{20n} \geq 4.$$

Applying Lemma 9 with $\mu = 4$ and $\delta = 3/4$ gives

$$\Pr[Z_d < 1] \leq e^{-9/8};$$

now applying Claim B yields the conclusion of Claim A.

To prove Claim B, assume that $Z_d \geq 1 - 2\gamma$. It suffices to show that $p^1_{f_d} \geq 1 - \gamma$, since this is equivalent to $\{v_1, \ldots, v_d\}$ being γ-powerful. Since $p^1_{f_k}$ is nondecreasing in k, we may assume that $p^1_{f_k} < 1 - \gamma$ for $k < d$. Then, recalling the definition of Z_d,

$$Z_d = \sum_{k=1}^{d} I_{f_{k-1}(v_k)}.$$

Now for each $k \geq 1$, $p^1_{f_k} = p^1_{f_{k-1}} + I^1_{f_{k-1}}(v_k)$, and hence $p^1_{f_d} = p^1_f + Z_d$. Since $p^1_f \geq \gamma$ by hypothesis, $p^1_{f_d} \geq 1 - \gamma$, as required for Claim B.

Since v_1, v_2, …, v_{k-1} determine X_0, …, X_{k-1}, Claim C follows if we show

$$\mathbb{E}[X_k | v_1, \ldots, v_{k-1}] \geq \frac{s\gamma}{20n}.$$

If $p_{f_{k-1}} \geq 1-\gamma$, then X_k is identically 1. Otherwise, $X_k = I_{f_{k-1}}(v_k)$. If v_k was selected by rule 1, then $X_k \geq 2^{-s}$, which is at least $s\gamma/(20n)$ for $s \leq \log(20n) - \log\log(20n)$. If rule 2 was used to select v_k, Lemma 7 gives the desired conclusion. This establishes Claim C and thus Claim A.

We now complete the proof of Lemma 11. The idea is that there are few variables chosen by rule 1, so with nonnegligible probability a random set of variables will contain them all.

More specifically, the hypothesis of the lemma implies that if we set $d = \lfloor b/2 \rfloor$, then d and γ satisfy the hypothesis of Claim A. We will use Claim A to show that a random subset of size b is γ-powerful with the required probability. Choose $s = 80n/(\gamma d)$ in accordance with Claim A, and observe that $s \leq \frac{1}{2}\log n$.

First, we reformulate the selection process for $v_1, v_2, \ldots, v_d$ in such a way that all random selections are made at the beginning of the process. We select a pair (S, σ), where S is a set of d variables chosen uniformly at random and σ is a bijection from $[d]$ to S chosen uniformly at random from the $d!$ such maps. Then $\vec{v}(S, \sigma) = (v_1, \ldots, v_d)$ is selected as above, except that rule 2 is replaced by "let i be the least integer such that $\sigma(i)$ is not a member of $\{v_1, \ldots, v_{k-1}\}$ and set $v_k = \sigma(i)$." It is easy to see that this process generates the same distribution over sequences $v_1, \ldots, v_d$ as the original process. Let $R_1(S, \sigma)$ be the set of v_i's chosen according to rule 1, and let $R_2(S, \sigma)$ be the set of those v_i's chosen according to rule 2. Obviously, $R_2(S, \sigma) \subseteq S$. Also, $|R_1(S, \sigma)| \leq 2^s$, since $I_{f_{k-1}}(v_k) \geq 2^{-s}$ if $v_k \in R_1(S, \sigma)$ and $\sum_{k=1}^{d} I_{f_{k-1}}(v_k) \leq p^1_{f_d} \leq 1$.

Now, consider a randomly chosen set B of size b. We view the probability space for B as consisting of triples (S, σ, T), where S and σ are as above and T is a random subset of size $b - d$ of $[n] \setminus S$. The set B is $S \cup T$. For B to be γ-powerful, it suffices that (i) $\vec{v}(S, \sigma)$ is γ-powerful and (ii) $R_1(S, \sigma) - S \subseteq T$, since then B contains the γ-powerful set $R_1(S, \sigma) \cup R_2(S, \sigma)$. By Claim A, event (i) occurs with probability at least $1/2$. Now, for any $S_0 \subset [n]$ of size b, we may estimate the probability of event (ii) conditioned on $S = S_0$: since $R_1(S, \sigma) - S$ has size at most $2^s = 2^{80n/\gamma d} \leq b/4$, and T is a random subset of $[n] \setminus S$ of size $b - d \geq b/2$, the probability that T contains $R_1(S, \sigma) - S$ is at least

$$\left(\frac{b-d}{n-d}\right)\left(\frac{b-d-1}{n-d-1}\right)\cdots\left(\frac{b-d-\lfloor 2^s\rfloor+1}{n-d-\lfloor 2^s\rfloor+1}\right) \geq \left(\frac{b}{4n}\right)^{2^s} \geq \left(\frac{b}{4n}\right)^{2^{80n/\gamma d}}.$$

Then $\Pr[\text{event (ii)} \mid \text{event (i)}] \geq \left(\frac{b}{4n}\right)^{2^{80n/\gamma d}}$, from which follows the statement of the lemma.

This completes the proof of Lemma 11.

3.2. Proof of Lemma 12. We first give a modified (and slightly more general) formulation of the lemma which will make the exposition a bit clearer.

LEMMA 16. *Fix n. If $\langle \delta_1, b_1 \rangle \in C_n(r_1; \frac{\alpha_1 \delta_2}{2}, \beta_1)$ and $\langle \delta_2, b_2 \rangle \in C_n(r_2; \alpha_2, \beta_2)$, then*

$$\left\langle \frac{\delta_1 \delta_2}{2}, b_1 + b_2 \right\rangle \in C_n(r_1 + r_2; \alpha_1 + \alpha_2, \beta_1 + \beta_2).$$

To deduce Lemma 12 from this, suppose that δ_1, b_1, r_1, γ_1, δ_2, b_2, r_2, and γ_2 are given satisfying the hypotheses of Lemma 12. Apply the above lemma with the same δ_i, b_i, and r_i, and with $\alpha_1 = 2\gamma_1/\delta_2$, $\beta_1 = \gamma_1$, and $\alpha_2 = \beta_2 = \gamma_2$.

So we prove Lemma 16.

Proof. Let $\Pi : (\{0,1\}^n)^{r_1 + r_2} \to \{0,1\}$ be an $(n, r_1 + r_2)$-protocol with $p^1_\Pi \geq \alpha_1 + \alpha_2$. We want to lower bound the probability that a (uniformly) random subset B of $[n]$ of size $b_1 + b_2$ is $\beta_1 + \beta_2$-powerful in Π.

A random subset B of size $b_1 + b_2$ can be selected by selecting subsets B_1, B_2, C, where B_1 is a uniformly random subset of size b_1, B_2 is a uniformly random subset of size b_2, and C is a uniformly random subset of $n - (B_1 \cup B_2)$ of size $b_1 + b_2 - |B_1 \cup B_2|$. Clearly, the probability that $B = B_1 \cup B_2 \cup C$ is $\beta_1 + \beta_2$-powerful is at least the probability that $B_1 \cup B_2$ is $\beta_1 + \beta_2$-powerful, so we lower bound this latter probability.

To do this, we define an event V that implies that $B_1 \cup B_2$ is $\beta_1 + \beta_2$-powerful and such that $\Pr_{B_1, B_2}[V]$ can be analyzed.

The input to Π is a vector in $(\{0,1\}^n)^{r_1 + r_2}$. Fixing the outcome of the first r_1 rounds to $\vec{\sigma} \in (\{0,1\}^n)^{r_1}$ gives rise to an (n, r_2)-protocol $\Pi[\vec{\sigma}] : (\{0,1\}^n)^{r_2} \to \{0,1\}$

by assigning

$$\Pi[\vec{\sigma}](\vec{\tau}) = \Pi(\sigma^1, \ldots, \sigma^{r_1}, \tau^1, \ldots, \tau^{r_2}).$$

Then $p^1_{\Pi[\vec{\sigma}]}$ can be viewed as a function of $\vec{\sigma}$. Let $\mathcal{E}$ be the set of those $\vec{\sigma}$ for which $p^1_{\Pi[\vec{\sigma}]} \geq \alpha_2$.

For $B_2 \subset [n]$, let $\mathcal{E}_{B_2}$ be the set of all $\vec{\sigma} \in \mathcal{E}$ such that B_2 is β_2-powerful with respect to the protocol $\Pi[\vec{\sigma}]$, i.e.,

$$\mathcal{E}_{B_2} = \left\{ \vec{\sigma} \in \mathcal{E} \ : \ p^1_{\Pi[\vec{\sigma}]}(B_2) \geq 1 - \beta_2 \right\}.$$

For each $B_2 \subseteq [n]$ of size b_2, let $\hat{\Pi}_{B_2}$ be the (n, r_1)-protocol $\hat{\Pi} = \hat{\Pi}_{B_2}$ given by

$$\hat{\Pi}_{B_2}(\vec{\sigma}) = \begin{cases} 1 & \text{if } \vec{\sigma} \in \mathcal{E}_{B_2}, \\ 0 & \text{otherwise.} \end{cases}$$

We now define V to be the event (depending on B_1 and B_2) that B_1 is β_1-powerful in $\hat{\Pi}_{B_2}$.

First we show that V implies that $B_1 \cup B_2$ is $\beta_1 + \beta_2$-powerful in Π. Consider the following two-step strategy for $B_1 \cup B_2$: (i) For the first r_1 rounds, B_1 plays so as to maximize the probability that $\vec{\sigma} \in \mathcal{E}_{B_2}$. Assuming this is successful then (ii) during the next r_2 rounds, B_2 tries to force the outcome of Π to be 1. The probability that this strategy fails is at most the sum of the probability that (i) fails and that (ii) fails given that (i) succeeds. The probability that (i) fails is at most β_1 by the definition of V. Assuming that (i) succeeds, the probability that (ii) fails is at most β_2 by the definition of the relation $\mathcal{E}_{B_2}$. Thus, given V, $B_1 \cup B_2$ is $\beta_1 + \beta_2$-powerful.

It remains to show that $\Pr[V] \geq \delta_1\delta_2/2$. To do this we consider, for $\eta > 0$, the event U_η (depending on B_2 alone) that $\Pr_{\vec{\sigma}}[\vec{\sigma} \in \mathcal{E}_{B_2}] \geq \eta$. We will show that when $\eta = \frac{\alpha_1\delta_2}{2}$, $\Pr[U_\eta] \geq \delta_2/2$ and $\Pr[V|U_\eta] \geq \delta_1$, which immediately gives the desired lower bound on $\Pr[V]$.

First we lower bound $\Pr[U_\eta]$. For fixed B_2 we have

$$\Pr_{\vec{\sigma}}[\vec{\sigma} \in \mathcal{E}_{B_2}] = \Pr_{\vec{\sigma}}[\vec{\sigma} \in \mathcal{E}] \times \frac{|\mathcal{E}_{B_2}|}{|\mathcal{E}|}. \tag{3.2}$$

By the definition of $\mathcal{E}$,

$$\mathop{\mathbb{E}}_{\vec{\sigma}}[p^1_{\Pi[\vec{\sigma}]}] \leq \Pr_{\vec{\sigma}}[\vec{\sigma} \in \mathcal{E}] + (1 - \Pr_{\vec{\sigma}}[\vec{\sigma} \in \mathcal{E}])\alpha_2 \leq \Pr_{\vec{\sigma}}[\vec{\sigma} \in \mathcal{E}] + \alpha_2.$$

We also have $\mathbb{E}_{\vec{\sigma}}[p^1_{\Pi[\vec{\sigma}]}] = p^1_\Pi \geq \alpha_1 + \alpha_2$, and thus

$$\Pr_{\vec{\sigma}}[\vec{\sigma} \in \mathcal{E}] \geq \alpha_1. \tag{3.3}$$

Letting $W = W(B_2)$ denote the random variable $|\mathcal{E}_{B_2}|/|\mathcal{E}|$ and combining (3.3) and (3.2), we have

$$\Pr_{B_2}[U_\eta] \geq \Pr_{B_2}[W \geq \eta/\alpha_1].$$

So we lower bound this latter probability. For $\sigma \in \mathcal{E}$, the protocol $\Pi[\vec{\sigma}]$ is an (n, r_2) protocol that is α_2-nontrivial. Thus, by the hypothesis of the lemma, for any $\vec{\sigma} \in \mathcal{E}$,

$$\Pr_{\substack{B_2 \subset [n] \\ |B_2| = b_2}} \left[\vec{\sigma} \in \mathcal{E}_{B_2} \right] \geq \delta_2.$$

Summing over $\sigma \in \mathcal{E}$ and dividing by $|\mathcal{E}|$ we obtain $\mathbb{E}_{B_2}[W] \geq \delta_2$. Since $W \in [0,1]$, we also have $\mathbb{E}_{B_2}[W] \leq \Pr_{B_2}[W \geq \eta/\alpha_1] + \eta/\alpha_1$, which implies $\Pr_{B_2}[W \geq \eta/\alpha_1] \geq \delta_2 - \eta/\alpha_1$. Setting $\eta = \alpha_1\delta_2/2$ we have $\Pr_{B_2}[U_{\alpha_1\delta_2/2}] \geq \Pr_{B_2}[W \geq \delta_2/2] \geq \delta_2/2$ as required.

Finally, we lower bound $\Pr[V|U_\eta]$. V is the event that B_1 is β_1-powerful in $\hat{\Pi}_{B_2}$. The event U_η implies that the protocol $\hat{\Pi}_{B_2}$ is η-nontrivial, and for $\eta = \alpha_1\delta_2/2$, the hypothesis of the lemma implies that the probability that V occurs is at least δ_1. ∎

3.3. Proof of Lemma 13. Fix b, n, and γ as hypothesized. Let $H(r)$ denote the hypothesis $\gamma b \geq 800 n \lambda_{r-1}/\log n$, and let $C(r)$ denote the conclusion

$$\left\langle \frac{1}{\lambda_r}, rb \right\rangle \in C_n(r; r\gamma).$$

We want to show that $H(r)$ implies $C(r)$ for all $r \geq 1$. We proceed by induction on r.

The basis case is immediate from Lemma 11. For the induction step, let $r \geq 1$, and suppose that $H(r)$ implies $C(r)$. Assume $H(r+1)$ is true; we want to show $C(r+1)$ holds. Now $H(r+1)$ implies $H(r)$ since $\lambda_r \geq \lambda_{r-1}$, and hence $C(r)$ holds. If $\gamma' \in (0, 1/2)$ is such that $\gamma' b \geq 400 n/\log n$, then Lemma 11 implies

$$\langle \delta(n, b, \gamma'), b \rangle \in C_n(1; \gamma').$$

Combining this and $C(r)$ using Lemma 12, and setting $\gamma' = \frac{\gamma}{2\lambda_r}$, gives

$$\left\langle \frac{\delta(n, b, \gamma')}{2\lambda_r}, (r+1)b \right\rangle \in C_n(r+1, (r+1)\gamma),$$

which is equivalent to $C(r+1)$.

This completes the proof of Lemma 13 and the proof of the main theorem.

4. Extensions to protocols with longer messages. We now indicate how to generalize the bounds proven above to protocols which permit players to send longer messages. Recall that for $n, r \in \mathbb{N}$ and $\vec{\ell} = (\ell_1, \ldots, \ell_r) \in \mathbb{N}^r$, we say that Π is a $(n, r, \vec{\ell})$-protocol if n is the number of players, r is the number of rounds, and no more than ℓ_k bits are broadcast by each player in the kth round.

We extend Definition 10 to account for variable message lengths.

DEFINITION 17. *Let $C_n^{\vec{\ell}}(r; \alpha, \beta)$ (written $C_n^{\vec{\ell}}(r; \gamma)$ when $\alpha = \beta = \gamma$) denote the collection of pairs $\langle \delta, b \rangle$ so that for any $(n, r, \vec{\ell})$-protocol Π that is α-nontrivial, at least a δ fraction of sets $B \subset [n]$ of size b are β-powerful in Π.*

We begin by considering a single-round protocol $f : (\{0,1\}^\ell)^n \to \{0,1\}$ in which each player broadcasts ℓ bits. Simply treating f as a function on $n\ell$ Boolean variables and examining the stochastic process of Section 3.1 yields the following version of Claim A.

CLAIM D (cf. Claim A). *Let $n\ell$ be sufficiently large and let $d \in [n]$ and $\gamma \in (0, 1/2)$, and suppose that $\gamma d \geq \frac{160n\ell}{\log(n\ell)}$. Let s, the parameter of the process, be $\frac{80n\ell}{\gamma d}$. Then*

$$\Pr\Big[\{v_1, \ldots, v_d\} \text{ is } \gamma\text{-powerful in } f\Big] \geq 1/2.$$

If the Boolean variables $\{v_1, \ldots, v_d\}$ are γ-powerful in $f : \{0,1\}^{n\ell} \to \{0,1\}$, then the $\{0,1\}^\ell$-valued variables $\{x \mid \exists i, v_i \text{ is a component of } x\}$ are γ-powerful in f, again viewed as a function on $(\{0,1\}^\ell)^n$. Observe that applying Claim A in this way does not exploit the fact that each player controls many bits of the function f. The proof of Lemma 11 now yields the following lemma.

LEMMA 18 (cf. Lemma 11). *Let $n, \ell \in \mathbb{N}$ and $\gamma \in (0, \frac{1}{2})$ and $b \leq n$, and assume $\gamma b \geq 400n\ell/\log(n\ell)$. Then $\langle \delta, b\rangle \in C_n^{(\ell)}(1;\gamma)$, where*

$$\delta = \delta(n, b, \ell, \gamma) = \frac{1}{2}\left(\frac{b}{4n}\right)^{2^{\frac{80n\ell}{\gamma b}}}.$$

The number of bits broadcast per round is immaterial to the proof of Lemma 12; restating that lemma for multibit protocols yields the following lemma.

LEMMA 19 (cf. Lemma 12). *Fix n. If $\langle \delta_1, b_1\rangle \in C_n^{\vec{\ell}}(r_1;\gamma_1)$ and $\langle \delta_2, b_2\rangle \in C_n^{\vec{m}}(r_2;\gamma_2)$, then*

$$\left\langle \frac{\delta_1\delta_2}{2}, b_1 + b_2 \right\rangle \in C_n^{(\vec{\ell},\vec{m})}\left(r_1 + r_2; \frac{2\gamma_1}{\delta_2} + \gamma_2\right),$$

where $(\vec{\ell}, \vec{m})$ denotes the vector $(\ell_1, \ldots, \ell_{r_1}, m_1, \ldots, m_{r_2})$.

We combine these to prove the following lemma.

LEMMA 20 (cf. Lemma 13). *Let $b \leq n$, $\gamma \in (0, 1/2)$, and $l_i \in \{1, 2, \ldots\}$ for each $i \geq 0$. Define $\lambda_0 = \frac{1}{2}$, and for $r \geq 1$ define*

$$\lambda_r = 4\lambda_{r-1}\left(\frac{4n}{b}\right)^{2^{\frac{160nl_{r-1}}{\gamma b}\lambda_{r-1}}}.$$

Assume that for each $r \geq 1$, $\lambda_r l_r \geq \lambda_{r-1} l_{r-1}$. Then, if $\gamma b \geq 800nl_{r-1}\lambda_{r-1}/\log n$,

$$\left\langle \frac{1}{\lambda_r}, rb \right\rangle \in C_n^{\vec{\ell}}(r; r\gamma),$$

where $\ell_i = l_{r-i}$, so $\vec{\ell} = (\ell_1, \ldots, \ell_r) = (l_{r-1}, \ldots, l_0)$.

Proof. Fix b, n, γ, and l_i as hypothesized. Let $H(r)$ denote the hypothesis $\gamma b \geq 800nl_{r-1}\lambda_{r-1}/\log n$, and let $C(r)$ denote the conclusion

$$\left\langle \frac{1}{\lambda_r}, rb \right\rangle \in C_n^{\vec{\ell}}(r; r\gamma),$$

where $\vec{\ell} = (l_{r-1}, \ldots, l_0)$. We want to show that $H(r)$ implies $C(r)$ for all $r \geq 1$. We proceed by induction on r.

The basis case is immediate from Lemma 18. For the induction step, let $r \geq 1$, and suppose that $H(r)$ implies $C(r)$. Assume $H(r+1)$ is true; we want to show that

$C(r+1)$ holds. Now $H(r+1)$ implies $H(r)$ since, by assumption, $\lambda_r l_r \geq \lambda_{r-1} l_{r-1}$, and hence $C(r)$ holds. If $\gamma' \in (0, 1/2)$ is such that $\gamma' b \geq 400 n l_r / \log n$, then Lemma 18 implies that

$$\langle \delta(n, b, l_r, \gamma')), b \rangle \in C_n^{(l_r)}(1; \gamma').$$

Combining this and $C(r)$ using Lemma 19, and setting $\gamma' = \frac{\gamma}{2\lambda_r}$, gives

$$\left\langle \frac{\delta(n, b, l_r, \gamma')}{2\lambda_r}, (r+1)b \right\rangle \in C_n^{\vec{\ell}}(r+1, (r+1)\gamma),$$

where $\vec{\ell} = (l_r, \ldots, l_0)$, which is equivalent to $C(r+1)$. □

This may be applied to prove Theorem 4.

Proof of Theorem 4. Fix n. Set $\alpha = \frac{1}{\log^* n}$ and define $\gamma = \alpha^2$, $b = \lceil \alpha^2 n \rceil$, and, for $i \in \{0, \ldots, r-1\}$,

$$l_i = \max\left(1, \left\lfloor \frac{\alpha\gamma b (\log^{(2(r-i)-1)} n)^{1-\alpha}}{800n} \right\rfloor\right). \tag{4.1}$$

Note that

$$\begin{aligned} l_o &\geq \frac{\alpha^5 (\log^{(2r-1)} n)^{1-\alpha}}{800} = \frac{(\log^{(\log^* n - 2\log^* \log^* n - 1)} n)^{1-\alpha}}{800(\log^* n)^5} \\ &= \frac{(T(2\log^* \log^* n - 1; 1))^{1-o(1)}}{800(\log^* n)^5} = (\log^* n)^{\omega(1)} \end{aligned}$$

so that, when n is sufficiently large, $\gamma < \frac{1}{2}$ and $l_{r-1} \geq \cdots \geq l_0 > 1$. In this case, with λ_i defined as in Lemma 20,

$$\begin{aligned} \lambda_i = 4\lambda_{i-1}\left(\frac{4n}{b}\right)^{2^{\frac{160 n l_{i-1}\lambda_{i-1}}{b\gamma}}} &= 2^{\log 4 + \log \lambda_{i-1} + 2^{\left(\frac{160 n l_{i-1}\lambda_{i-1}}{b\gamma} + \log\log \frac{4n}{b}\right)}} \\ &\leq 2^{2^{\frac{160 n l_{i-1}\lambda_{i-1}}{b\gamma} + \log\log 4 + \log\log \lambda_{i-1} + \log\log \frac{4n}{b}}} \end{aligned}$$

and, as $\max(\log\log 4, \log\log \lambda_{i-1}, \log\log(4n/b)) < 160 n l_{i-1}\lambda_{i-1}/\gamma b$,

$$\lambda_i \leq 2^{2^{\frac{640 n l_{i-1}\lambda_{i-1}}{b\gamma}}} \leq 2^{2^{\alpha(\log^{(2(r-i)+1)} n)^{1-\alpha}\lambda_{i-1}}}.$$

As noted above, these l_i are monotonically increasing (in i) and therefore satisfy the hypothesis of Lemma 20. We show that for sufficiently large n, $\lambda_i \leq (\log^{(2(r-i)-1)} n)^\alpha$. Since this is clearly true for λ_0, by induction

$$\lambda_i \leq 2^{2^{\alpha(\log^{(2(r-i)+1)} n)^{1-\alpha}\lambda_{i-1}}} \leq 2^{2^{\alpha(\log^{(2(r-i)+1)} n)}} \leq (\log^{(2(r-i)-1)} n)^\alpha, \tag{4.2}$$

where we have applied the inequality $x^\epsilon \leq \epsilon x$, valid when, for example, $x \geq 4$ and $\epsilon \in [1/\sqrt{x}, 1]$. (We apply the inequality with $\epsilon = \alpha$ and $x = \log^{(2(r-i))} n$; both these requirements are met for sufficiently large n.)

Finally, from (4.1) and (4.2) above,

$$\frac{800 n l_{r-1}\lambda_{r-1}}{\log n} \leq \alpha\gamma b \leq \gamma b,$$

so that Lemma 20 applies. This asserts the existence of an $r\gamma = o(1)$-powerful set of $rb = o(n)$ players for any protocol Π under the following assumptions:

- Π is $r\gamma = o(1)$-nontrivial,
- Π lasts for r rounds, with $r \leq \frac{1}{2}\log^* n - \log^* \log^* n$, and
- Π calls for no more than

$$l_{r-k} = \Omega\left(\frac{(\log^{(2k-1)} n)^{(1-\alpha)}}{\text{poly}(\log^* n)}\right) = (\log^{(2k-1)} n)^{(1-O(\alpha))}$$

communication bits in the kth round. □

5. The influence of large coalitions. Applying the results of [13], one can show that, for a Boolean function f with $p_f^1 = 1/2$ and $b(n) = \Theta(n)$, there is always a coalition L of size $b(n)$ for which $p_f^0(L) \geq 1 - 1/n^c$ for some appropriate constant c (depending on b). When $b(n) \geq n/2$, however, the following observation from [17] may be applied.

PROPOSITION 21. *Let X be a finite probability space and $f : X^n \to \{0,1\}$. Let $A_1, A_2 \subset [n]$ be a partition of the variables on which f is defined (so that $A_1 \cup A_2 = [n]$ and $A_1 \cap A_2 = \emptyset$). Then for at least one of these two sets, A_i,*

$$p_f^1(A_i) = 1 \qquad \text{or} \qquad p_f^0(A_i) = 0.$$

Below we observe that near this $\frac{n}{2}$ threshold (specifically, for $b(n) > (1/3 + \epsilon)n$), the above bound of [13] may be improved to $1 - 1/\exp(\Omega(n))$.

In preparation for the lemma, we record a Chernoff bound (see, e.g., [3]).

LEMMA 22. *Let $X_i, i = 1, \ldots, n$, be independent random variables, each uniformly distributed in $\{0,1\}$. Then*

$$\Pr\left[\sum_i X_i - \frac{n}{2} > a\right] < \exp\left(-\frac{a^2}{2n}\right).$$

THEOREM 23. *Let $\gamma > \frac{1}{3}$. Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function and let $\mathfrak{B} = \{B \subset [n] : |B| = \lceil \gamma n \rceil\}$. If $p_f^1(B) < 1$ for all $B \in \mathfrak{B}$, then for all $B \in \mathfrak{B}$, $p_f^0(B) \geq 1 - \epsilon$, where*

$$\epsilon = \exp\left(-\frac{(1-3\gamma)^2}{8(1-\gamma)}n\right).$$

Proof. Assume that f is monotone. Recall that a min-term of a monotone function f is a minimal subset of variables which, if set to 1, ensures that $f = 1$. If f has a min-term of cardinality at most γn, then clearly there is $B \in \mathfrak{B}$ for which $p_f^1(B) = 1$. Otherwise all min-terms have cardinality larger than γn. Fix $B \in \mathfrak{B}$ and consider an input $\vec{x} = x_1 \ldots x_n$, where each x_i, for $i \notin B$, is chosen independently at random in $\{0,1\}$, and $x_i = 0$ for $i \in B$. Then $\mathbb{E}[\sum_i x_i] \leq \frac{1-\gamma}{2}n$, so that by applying the above Chernoff bound,

$$\Pr\left[\sum_i x_i > \gamma n\right] < \exp\left(-\frac{(3\gamma-1)^2}{8(1-\gamma)}n\right).$$

Then $p_f^0(B) > 1 - \exp\left(-\frac{(3\gamma-1)^2}{8(1-\gamma)}n\right)$, as desired. □

6. Open problems. We summarize the known results concerning protocols that are resilient against a linear number of corrupt players:

1. By [16] there is an $(n, \big[1+o(1)\big]\log n, 1)$-protocol which is $\Omega(n)$-resilient. By Theorem 3, there is no $(n, (1/2-\epsilon)\log^* n, 1)$-protocol that is $\Theta(n)$-resilient.
2. By [16], there is an $(n, \log^* n + O(1), \vec{\ell})$-protocol, where $\ell_k = O(\log^{(k)} n)$, that is $\Omega(n)$-resilient. By Theorem 4, there is no $(n, (1/2-o(1))\log^* n, \vec{\ell})$-protocol that is $\Theta(n)$-resilient for some $\ell_k = (\log^{(2k-1)} n)^{1-o(1)}$.
3. It is not difficult to show that Theorem 2 actually implies that there can be no $(n, 1, o(\log n))$-protocol that is $\Theta(n)$-resilient.

These suggest several avenues of investigation:

1. In the case where each player sends a single bit per round (item 1 above), $\big[1+o(1)\big]\log n$ rounds are sufficient to guarantee $\Omega(n)$-resilience, $\big[1/2 - o(1)\big]\log^* n$ rounds are necessary—what is the right answer?
2. In the general case (item 2 above), can Theorem 4 be strengthened to show any $\Omega(n)$-resilient protocol has some round k during which $\Omega(\log^{(k)} n)$ communication occurs?
3. From (3) above, no one-round protocol using $o(\log n)$ bits per player can be $\Omega(n)$-resilient. Even abandoning all constraints on the number of bits sent per round, is there a one (or even constant) round $\Omega(n)$-resilient protocol?
4. We have focused on protocols where honest players flip a fair coin; what can be said when the honest players' coin flips are biased?

Acknowledgments. We thank Nati Linial for pointing out the failure of iterative methods in the multibit case and several illuminating discussions. We also thank Uri Feige for suggesting our last open question and for useful discussions.

HARDNESS OF APPROXIMATE HYPERGRAPH COLORING*

VENKATESAN GURUSWAMI†, JOHAN HÅSTAD‡, AND MADHU SUDAN§

Abstract. We introduce the notion of covering complexity of a verifier for probabilistically checkable proofs (PCPs). Such a verifier is given an input, a claimed theorem, and an oracle, representing a purported proof of the theorem. The verifier is also given a random string and decides whether to accept the proof or not, based on the given random string. We define the covering complexity of such a verifier, on a given input, to be the minimum number of proofs needed to "satisfy" the verifier on every random string; i.e., on every random string, at least one of the given proofs must be accepted by the verifier. The covering complexity of PCP verifiers offers a promising route to getting stronger inapproximability results for some minimization problems and, in particular, (hyper)graph coloring problems. We present a PCP verifier for NP statements that queries only four bits and yet has a covering complexity of one for true statements and a superconstant covering complexity for statements not in the language. Moreover, the acceptance predicate of this verifier is a simple not-all-equal check on the four bits it reads. This enables us to prove that, for *any* constant c, it is NP-hard to color a 2-colorable 4-uniform hypergraph using just c colors and also yields a superconstant inapproximability result under a stronger hardness assumption.

Key words. graph coloring, hypergraph coloring, hardness of approximations, PCP, covering PCP, set splitting

1. Introduction.

The study of probabilistically checkable proof (PCP) systems has led to major breakthroughs in theoretical computer science in the past decade. In particular, this study has led to a surprisingly clear understanding of the complexity of finding approximate solutions to optimization problems. A recurring theme in this study is the association of new complexity measures to verifiers of PCP systems and construction of efficient verifiers under the new measure. The new measures are then related to some special subclass of optimization problems to gain new insight about the approximability of problems in this subclass of optimization problems. This paper presents yet another such complexity measure, the *covering complexity* of a verifier, and relates it to a subclass of optimization problems, namely, *hypergraph coloring* problems. Below we elaborate on some of the notions above such as PCPs, approximability, and hypergraph coloring, and we introduce our new complexity measure.

PCPs. The centerpiece of a PCP system is the probabilistic verifier. This verifier is a randomized polynomial time algorithm whose input is a "theorem" and who is

also given oracle access to a "proof." Using the traditional equivalence associated with randomized algorithms, it is convenient to think of the verifier as having two inputs: the "theorem" and a "random string." Based on these two inputs, the verifier settles on a strategy to verify the proof; namely, it decides on a sequence of queries to ask the oracle and prepares a predicate P. It then queries the oracle, and, if it receives as response bits $a_1, \ldots, a_q$, it applies the predicate $P(a_1, \ldots, a_q)$ and accepts iff the predicate is satisfied.[1] The quality of the PCP system is roughly related to its ability to distinguish valid proofs (true "theorems" with correct "proofs") from invalid theorems (incorrect "theorems" from any purported "proof"). Hopefully the verifier accepts valid proofs with much higher probability than it does invalid theorems.

To study the power of PCP systems in a complexity-theoretic setting, we quantify some of the significant resources of the verifier above and then study the resources needed to verify proofs of membership for some hard language. Fix such a language L, and consider a verifier V whose goal is to verify proofs of membership in L. The above paragraph already hints at four measures we may associate with such a verifier, and we define them in two steps. For functions $r, q : \mathbb{Z}^+ \to \mathbb{Z}^+$, we say that a V is (r, q)-restricted if, on input x (implying the theorem $x \in L$) of length n, V requires a random string of length $r(n)$ and makes $q(n)$ queries to the proof oracle. We say that V verifies L with completeness c and soundness s if (1) for every $x \in L$, there exists an oracle Π such that V, on input x and oracle access to Π, outputs accept with probability at least c, and (2) for every $x \notin L$ and every oracle Π, V outputs accept with probability at most s. The class of all languages L that have an (r, q)-restricted verifier verifying it with completeness c and soundness s is denoted $\mathrm{PCP}_{c,s}[r, q]$.

Covering complexity. In the variant of PCPs that we consider here, we stick with (r, q)-restricted verifiers but alter the notion of completeness and soundness. Instead of focusing on the one proof that maximizes the probability with which the verifier accepts a given input, here we allow multiple proofs to be provided to the verifier. We say that a set of proofs $\{\Pi_1, \ldots, \Pi_k\}$ *covers* a verifier V on input x if, for every random string, there exists one proof Π_i such that V accepts Π_i on this random string. We are interested in the smallest set of proofs that satisfy this property, and the cardinality of this set is said to be the *covering complexity* of the verifier on this input. Analogous to the class PCP, we may define the class $\mathrm{cPCP}_{c,s}[r, q]$ (for covering PCP) to be the class of all languages for which there exist (r, q)-restricted verifiers that satisfy the following conditions: (Completeness) If $x \in L$, the covering complexity of V on x is at most $1/c$. (Soundness) If $x \notin L$, then the covering complexity of V on x is at least $1/s$.

Notions somewhat related to covering complexity have been considered in the literature implicitly and explicitly in the past. Typically these notions have been motivated by the approximability of minimization problems, such as graph coloring, set cover, and the closest vector problem. Our specific notion is motivated by graph and hypergraph coloring problems. We describe our motivation next. We defer the comparison with related notions to later in this section.

Hypergraph coloring, approximability, and inapproximability. An l-uniform hypergraph H is given by a set of vertices V and a set of edges E, where an edge $e \in E$ is itself a subset of V of cardinality l. A k-coloring of H is a map

[1] This description of a verifier is somewhat restrictive. More general definitions allow the verifier to be adaptive, deciding on later queries based on responses to previous ones. For this paper, the restricted version suffices.

from V to the set $\{1, \ldots, k\}$ such that no edge is *monochromatic*. The hypergraph coloring problem is that of finding, given H, the smallest k for which a k-coloring of H exists. When $l = 2$, then the hypergraph is just a graph, and the hypergraph coloring problem is the usual graph coloring problem.

Graph and hypergraph coloring problems have been studied extensively in the literature from both the combinatorial and algorithmic perspectives. The task of determining if an l-uniform graph is k-colorable is trivial if $l = 1$ or $k = 1$, and almost so if $l = k = 2$. Every other case turns out to be NP-hard. The case of $l = 2$, $k \geq 3$ is a classical NP-hard problem, while the case of $k = 2$, $l \geq 3$ was shown to be NP-hard by Lovász [23]. Thus even the property of a hypergraph being 2-colorable is nontrivial. This property, also called *Property B*, has been studied in the extremal combinatorics literature for a long time. Much work has been done on determining sufficient conditions under which a hypergraph family is 2-colorable and on solving the corresponding algorithmic questions [11, 6, 7, 25, 26, 29, 27].

The hardness of the coloring problem motivates the study of the *approximability* of the graph and hypergraph coloring problems. In the context of these problems, an (l, k, k')-approximation algorithm is one that produces (in polynomial time) a k'-coloring of every k-colorable l-uniform hypergraph for some $k' > k$, with the "approximation" being better as k' gets closer to k. Even this problem turns out to be nontrivial, with the best known algorithms for coloring even 3-colorable graphs requiring $n^{\Omega(1)}$ colors [9, 19], where n is the number of vertices. Similarly, inspired in part by the approximate graph coloring algorithms, several works [1, 10, 22] have provided approximation algorithms for coloring 2-colorable hypergraphs. The best known result for 2-colorable 4-uniform hypergraphs is a polynomial time coloring algorithm that uses $\tilde{O}(n^{3/4})$ colors [1, 10].

To justify the intractability of the approximation versions of the hypergraph coloring problem, one looks for *inapproximability* results. Inapproximability results show that it is NP-hard to achieve the goals of an (l, k, k')-approximation algorithm by producing a polynomial time computable reduction from, say, satisfiability (SAT) to a "gap" problem related to hypergraph coloring. Here we assume a conservative definition of such a reduction, namely, the many-one reduction. The many-one version of such a reduction would reduce a formula φ to an l-uniform hypergraph H such that H is k-colorable if φ is satisfiable and H is not k'-colorable if φ is not satisfiable. Since the existence of an (l, k, k')-approximation algorithm now gives the power to decide if φ is satisfiable or not, this shows that the approximation problem is NP-hard. In what follows, when we say that an (l, k, k')-approximation problem is NP-hard, we always implicitly mean that the "gap version" of the problem is NP-hard.

This methodology combined with the PCP technique has been employed heavily to get hardness results of graph coloring problems. This approach started with the results of [24] and culminates with the essentially tight results of [12], which show that the $(2, n^{\varepsilon}, n^{1-\varepsilon})$-approximation problem is NP-hard under randomized reductions. However, for graphs whose chromatic number is a small constant, the known hardness results are much weaker. For example, for 3-colorable graphs, the best known hardness result rules out only coloring using four colors [20, 16]. This paper is motivated by the quest for strong (superconstant) inapproximability for coloring graphs whose chromatic number is a small constant. We do not get such results for graph coloring but do get such inapproximability results for hypergraph coloring and, in particular, for coloring 4-uniform hypergraphs.

Graph coloring and covering PCPs. In examining the reasons why the current techniques have been unable to show strong hardness results for inapproximability of coloring 3-colorable graphs, a natural question arises: Are PCPs really necessary to show such hardness results, or would something weaker suffice? To date there are no reasons showing that PCPs are necessary. And while the first result showing the intractability of coloring 3-colorable graphs with four colors [20] did use the PCP technique, [16] shows that PCPs are not needed in this result. The starting point of our work is the observation that *covering* PCPs are indeed necessary for showing strong hardness results for graph coloring. Specifically, in Proposition 2.1, we show that, if the $(2, c, \omega(1))$-approximation problem for coloring is NP-hard for $c < \infty$, then NP $\subseteq$ cPCP$_{\gamma,o(1)}[\log, 2]$ for some $\gamma > 0$. (Similar results can also be derived from hardness results for coloring hypergraphs, though we don't do so here.)

Previous approaches have realized this need implicitly but have relied on deriving the required results via PCPs. In particular, they use the trivial containment PCP$_{1,s}[r, q] \subseteq$ cPCP$_{1,s}[r, q]$ and build upon the latter result to derive hardness for coloring. (Notice that we do not have such a simple containment when the completeness parameter is not equal to 1. This special case of $c = 1$ is important in general and is referred to as *perfect completeness*.) For our purposes, however, this trivial containment is too weak. In particular, it is known that PCP$_{c,s}[\log, q] \subseteq$ P for every c, s, q such that $c > s2^q$ (cf. [8, Lemma 10.6]). Thus it is not possible to show NP $\subseteq$ cPCP$_{\gamma,o(1)}[\log, O(1)]$ for any constant $\gamma > 0$, using the trivial containment mentioned above (and such a covering PCP is essential for superconstant hardness results for coloring hypergraphs). Thus it becomes evident that a direct construction of covering PCPs may be more fruitful, and we undertake such constructions in this paper.

Related notions. Typically, every approach that applies PCP to minimization problems has resulted, at least implicitly, in some new complexity measures. Two of those that are close to, and likely to be confused with, the notion of covering complexity are the notions of "multiple assignments" [2] and the "covering parameter" of [12]. Here we clarify the distinctions.

In the former case, the multiple assignments of [2], the proof oracle is expected to respond to each query with an element of a large alphabet (rather than just a bit). When quantifying the "quality" of a proof, however, the oracle is allowed to respond with a subset of the alphabet, rather than just a single element, and the goal of the prover is to pick response sets of small sizes so that, on every random string, the verifier can pick one element from each response set to the different queries so that it leads to acceptance. Once again, we have a notion of covering all random strings with valid proofs, but this time the order of quantifiers is different. The notion of multiple assignments is interesting only when the alphabet of the oracles responses are large, while our notion remains interesting even when the oracle responds with an element of a binary alphabet.

The second related notion is the covering parameter of Feige and Kilian [12]. Since the names are confusingly similar (we apologize for not detecting this at an early stage), we refer to their notion as the FK-covering parameter. In a rather simplified sense, their parameter also allows multiple proofs to be presented to the verifier. However, their notion of coverage requires that, on every random string and every possible accepting pattern of query responses for the verifier, there should exist a proof which gives this accepting pattern (and is hence accepted). For any fixed verifier and input, the FK-covering number is always larger than ours since

we do not need every accepting pattern to be seen among the proofs. Though the notions appear close, the motivation, the application, and the technical challenges posed by the FK-covering parameter and ours are completely different. Both notions arise from an attempt to study graph coloring, but their focus is on general graphs (with high chromatic number), while ours is on graphs of small chromatic number. In their case, separation of the FK-covering parameter is sufficient but not necessary to give inapproximability of coloring. For our parameter, separation is necessary but not sufficient to get the same. Finally, in their constructions, the challenge is to take a traditional PCP and enhance it to have small FK-covering completeness, and they use the PCP directly to argue that the soundness is not large. In our case, the completeness is immediate, and the soundness needs further analysis.

Gadgets and covering complexity. Returning to our notion of covering complexity, while it seems essential to study this to get good hardness results on coloring, the reader should also be warned that this notion is somewhat less robust than usual notions that one deals with in PCPs. Specifically, prior notions were not very sensitive to the predicate applied by the verifier in deciding its final output. They could quantify the power of the verifier by simple parameters such as number of bits read or number of accepting configurations. Here we are forced to pay attention to the verifier's computations and restrict these to get interesting results. It is reasonable to ask why this happens, and we attempt to give some justification below.

In standard PCPs, it is often possible to use "gadgets" (whenever they are available) to convert the acceptance predicate of the verifier from one form to another for only a small loss in the performance. For example, suppose one has a PCP verifier V_1 that reads three bits of a proof and accepts if they are not all equal (NAE). Such a verifier would directly prove the hardness of the "Max NAE-3SAT" problem. However, by application of a gadget, the same verifier can be transformed into one that proves the hardness of the "Max 3SAT" problem. The gadget notices that the function $\mathrm{NAE}(a, b, c)$ for three Boolean variables a, b, c is simply $(a \vee b \vee c) \wedge (\neg a \vee \neg b \vee \neg c)$, which is a conjunction of two 3SAT clauses. Thus a transformed verifier V_2 which picks three bits of the proof as V_1 does and then picks one of the two clauses implied by the check performed by V_1 and verifies just this one clause is now a verifier whose acceptance predicate is a 3SAT condition. Furthermore, if the acceptance probability of V_1 on the same proof is $1 - \alpha$, then the acceptance probability of V_2 on some given proof is exactly $1 - \alpha/2$. Thus, if V_1 proves inapproximability of Max NAE-3SAT, then V_2 proves inapproximability of Max 3SAT.

Unfortunately, a similar transformation does not apply in the case of covering complexity. Notice that two proofs, the oracle that always responds with 0 and the one that responds with 1, always suffice to cover any verifier whose acceptance predicate is 3SAT. Yet there exist NAE 3-SAT verifiers that cannot be covered by any constant number of proofs. (For example, the verifier that picks three of the n bits of the proof uniformly and independently at random and applies the NAE 3-SAT predicate to them needs $\Omega(\log n)$ proofs to be covered.) Thus, even though a gadget transforming NAE 3SAT to 3SAT does exist, it is of no use in preserving covering complexity of verifiers. This nonrobust behavior of covering PCP (cPCP) verifiers forces us to be careful in designing our verifiers, and our two results differ mainly in the predicate applied by the verifier.

Our results. Our first result is a containment of NP in the class $\mathrm{cPCP}_{1,\varepsilon}[O(\log n), 4]$ for every $\varepsilon > 0$. If the randomness is allowed to be slightly superlogarithmic, then the soundness can be reduced to some explicit $o(1)$ function. Technically, this result

is of interest in that it overcomes the qualitative limitation described above of passing through standard PCPs. Furthermore, the proof of this result is also of interest in that it shows how to apply the (by now) standard Fourier-analysis-based techniques to the studying of covering complexity as well. Thus it lays out the hope for applying such analysis to other cPCPs as well.

Unfortunately, the resulting cPCP fails to improve inapproximability of graph coloring or even hypergraph coloring. As noted earlier, covering PCPs are only necessary but not sufficient to get hardness results for hypergraph coloring. In order to get hardness results for hypergraph coloring from covering PCPs, one needs verifiers whose acceptance condition is an NAE SAT predicate (though, in this case, it is also reasonable to allow the responses of the queries to be elements of a nonbinary alphabet, and a result over a q-ary alphabet will give a result for q-colorable hypergraphs).

Keeping this objective in mind, we design a second verifier (whose query complexity is also 4 bits) whose acceptance predicate simply checks if the four queried bits are not all equal. The verifier has perfect completeness, and its covering soundness can be made an arbitrarily large constant (Theorem 4.2). This result immediately yields a superconstant lower bound on coloring 2-colorable 4-uniform hypergraphs: we prove that c-coloring such hypergraphs is NP-hard for any constant c (Theorem 4.4), and, moreover, there exists a constant $c_0 > 0$ such that, unless NP $\subseteq$ DTIME($n^{O(\log\log n)}$), there is no polynomial time algorithm to color a 2-colorable 4-uniform hypergraph using $c_0 \frac{\log\log n}{\log\log\log n}$ colors (Theorem 4.6). A similar hardness result also holds for coloring 2-colorable k-uniform hypergraphs for any $k \geq 5$ by reduction from the case of 4-uniform hypergraphs (Theorem 4.7). Prior to our work, no nontrivial inapproximability results seem to be known for coloring 2-colorable hypergraphs, and, in fact, it was not known if 3-coloring a 2-colorable 4-uniform hypergraph is NP-hard.

We note that we do not have analogous results for the hardness of coloring 2-colorable 3-uniform hypergraphs. The difficulty in capturing the problem stems from the difficulty of analyzing the underlying maximization problem. The natural maximization version of hypergraph 2-coloring is the following: color the vertices with two colors so that a maximum number of hyperedges are nonmonochromatic. For l-uniform hypergraphs, this problem is known as Max l-Set Splitting. For $l = 4$ (the case we study here), a tight hardness result of $7/8 + \varepsilon$ is known [17], and this fact works its way into our analysis. For $k = 3$, a tight hardness result is not known for the maximization version (see [14]), and, in fact, nontrivial approximation algorithms exist [13], and our inability to show hardness results for 3-uniform hypergraphs seems to stem from this fact.

Organization. In section 2, we go over some of the definitions more formally and relate covering complexity to approximability of hypergraph coloring. In section 3, we analyze a simple cPCP verifier that makes four queries and has perfect completeness and $o(1)$ soundness. In section 4, we analyze a more complicated cPCP verifier with similar parameters whose acceptance condition is NAE SAT. This yields the hardness result for coloring 2-colorable, 4-uniform hypergraphs.

This is the complete version of the conference paper [15].

2. Preliminaries.

In this section, we introduce covering PCPs formally and establish a connection (in the wrong direction) between covering PCPs and inapproximability of hypergraph coloring.

2.1. PCPs.

We first give a formal definition of a PCP. Below verifiers are probabilistic oracle Turing machines whose output, on input x and random string r

with oracle O, is denoted $V^O(x,r)$. The output is a bit with 1 denoting acceptance and 0 denoting rejection.

DEFINITION 1. *Let c and s be real numbers such that $1 \geq c > s \geq 0$. A probabilistic polynomial time oracle Turing machine V is a PCP verifier with soundness s and completeness c for a language L iff*

- *for $x \in L$ there exists oracle Π such that $\mathrm{Prob}_r[V^\Pi(x,r)=1] \geq c$,*
- *for $x \notin L$, for all Π, $\mathrm{Prob}_r[V^\Pi(x,r)=1] \leq s$.*

Two parameters of interest in a PCP are the number of random bits used by the verifier and the number of queries it makes to the proof oracle. Most of the time, the symbols of Π are bits, and whenever this is not the case, this is stated explicitly.

DEFINITION 2. *For functions $r, q : \mathbb{Z}^+ \to \mathbb{Z}^+$, a verifier V is (r,q)-restricted if, on any input of length n, it uses at most $r(n)$ random bits and makes at most $q(n)$ queries to Π.*

We can now define classes of languages based on PCPs.

DEFINITION 3 (PCP). *A language L belongs to the class $\mathrm{PCP}_{c,s}[r,q]$ if there is an (r,q)-restricted verifier V for L with completeness c and soundness s.*

Next we have the definition of covering PCP.

DEFINITION 4 (covering PCP). *A language L belongs to the class $\mathrm{cPCP}_{c,s}[r,q]$ if there is an (r,q)-restricted verifier V such that, on input x,*

(i) *if $x \in L$, then there is a set of proofs $\{\Pi_1, \ldots, \Pi_k\}$ for $k \leq 1/c$ such that, for every random string r, there exists a proof Π_i such $V^{\Pi_i}(x,r)=1$; and*

(ii) *if $x \notin L$, then for every set of k proofs $\{\Pi_1, \Pi_2, \ldots, \Pi_k\}$ with $k < 1/s$, there is a random string r for which V rejects* every *Π_i, $1 \leq i \leq k$.*

One usually requires "perfect completeness" ($c = 1$) when seeking PCP characterizations. It is clear from the above definitions that $\mathrm{PCP}_{1,s}[r,q] \subseteq \mathrm{cPCP}_{1,s}[r,q]$, and thus obtaining a PCP characterization for a language class is at least as hard as obtaining a covering PCP characterization with similar parameters.

2.2. Covering PCPs and graph coloring. We now verify our intuition that "good" covering PCPs (i.e., those which have a large gap in covering complexity between the completeness and soundness cases) are necessary for strong lower bounds on approximating the chromatic number. As usual, for a graph G, we denote by $\chi(G)$ its chromatic number, i.e., the minimum number of colors required in a proper coloring of G.

Below, we use the phrase "it is NP-hard to distinguish $f(n)$-colorable graphs from $g(n)$-colorable graphs" to mean that "the $(2, f, g)$-approximation problem is NP-hard." As mentioned in section 1, note that we are using a conservative definition of NP-hardness, and hence this statement implies that there is a many-one reduction from SAT that maps satisfiable instances of SAT to $f(n)$ colorable graphs and maps unsatisfiable instances to graphs that are not $g(n)$-colorable. Under this assumption, we show how to get nice covering PCPs. Below and throughout this paper, the function log denotes logarithms to base two.

PROPOSITION 2.1. *Suppose, for functions $f, g : \mathbb{Z}^+ \to \mathbb{Z}^+$, given a graph G on n vertices, it is NP-hard to distinguish between the cases $\chi(G) \leq f(n)$ and $\chi(G) \geq g(n)$. Then*

$$\mathrm{NP} \subseteq \mathrm{cPCP}_{\lceil \log f(n) \rceil^{-1}, \lceil \log g(n) \rceil^{-1}} \left[O(\log n), 2 \right] .$$

Proof. Let the vertex set of G be $V = \{v_1, v_2, \ldots, v_n\}$. The covering PCP consists of proofs $\Pi_1, \Pi_2, \ldots, \Pi_k$ that correspond to "cuts" $\Gamma_1, \ldots, \Gamma_k$ of G; i.e., each Π_i is n-bits long, with the jth bit being 1 or 0 depending on which side of the cut Γ_i contains

v_j. The verifier simply picks two vertices v_{j_1} and v_{j_2} at random such that they are adjacent in G and then checks if the j_1th and j_2th bits differ in *any* of the k proofs. The minimum number k of proofs required to satisfy the verifier for all its random choices is clearly the *cut cover number* $\kappa(G)$ of G, i.e., the minimum number of cuts that cover all edges of G. It is easy to see that $\kappa(G) = \lceil \log \chi(G) \rceil$, and therefore the claimed result follows. □

One can get a similar result for any base q by letting the proofs be q-ary strings and letting the verifier read two q-ary symbols from the proof. In light of this, we get the following.

COROLLARY 2.2. *Suppose that there exists an $\varepsilon > 0$ such that it is NP-hard, given an input graph G, to distinguish between the cases when G is 3-colorable and when $\chi(G) \geq n^{\varepsilon}$. Then* $\mathrm{NP} \subseteq \mathrm{cPCP}_{1,(\varepsilon \log_3 n)^{-1}}\big[O(\log n), 2\big]$, *where the covering PCP is over a ternary alphabet, and the verifier's action is to simply read two ternary symbols from the proof and check that they are not equal.*

In light of the above corollary, very powerful covering PCP characterizations of NP are necessary in order to get strong hardness results for coloring graphs with small chromatic number. A result similar to Proposition 2.1, with an identical proof, also holds for hypergraph coloring and thus motivates us to look for good covering PCP characterizations of NP in order to prove hardness results for coloring 2-colorable hypergraphs.

PROPOSITION 2.3. *Suppose that there exists a function $f : \mathbb{Z}^+ \to \mathbb{Z}^+$ such that, given an input r-uniform hypergraph on n vertices, it is NP-hard to distinguish between the cases when it is 2-colorable and when it is not $f(n)$-colorable. Then* $\mathrm{NP} \subseteq \mathrm{cPCP}_{1,\frac{1}{\log f(n)}}\big[O(\log n), r\big]$. *In particular, if c-coloring 2-colorable r-uniform hypergraphs is NP-hard for every constant c, then* $\mathrm{NP} \subseteq \mathrm{cPCP}_{1,\frac{1}{k}}\big[O(\log n), r\big]$ *for every constant $k \geq 1$.*

3. PCP construction I. We now move on to the constructions of our proof systems. For a reader familiar with PCPs, we first give a preview of our constructions. Both our PCPs (of this section and the next) go through the standard path. We start with strong 2-prover 1-round proof systems of Raz [28], apply the composition paradigm [5], and then use the long code of [8] at the bottom level. One warning: in the literature, it is common to use a variant of the long code—called the "folded long code"—we do not use the folded version. (Readers unfamiliar with the terms above will find elaborations in section 3.1.)

As usual, the interesting aspects of the constructions are the choice of the inner verifiers and the analyses of their soundness. The inner verifiers that we use are essentially from [17]: The inner verifier in section 4 is exactly the same as the one used by [17, section 7] to show hardness of Max 4-Set Splitting, while the one in this section is a small variant. The goals of the analyses are different since we are interested in the number of proofs required to cover all random strings. Despite the difference, we borrow large parts of our analysis from that of [17]. In the current section, our analysis essentially shows that if our verifier, on some fixed input, rejects every proof oracle with probability at least γ, then on any set of k proofs nearly γ^k fraction of random strings end up rejecting all of the proofs. Thus the standard soundness of the verifier we construct *is* of interest, and we analyze this using lemmas from [17]. The analysis of the verifier in section 4 does involve some new components, and we will comment upon these in the next section.

3.1. Preliminaries: Label Cover, long codes, proof composition. Our PCP constructions (also) follow the paradigm of *proof composition* by composing an "outer verifier" with an "inner verifier." In its most modern and easy to apply form, one starts with an *outer proof system* which is a 2-*Prover* 1-*Round proof system* (2P1R) construction for NP. We abstract the 2P1R by a graph-theoretic optimization problem called Label Cover. The specific version of Label Cover we refer to is the maximization version $\text{LabelCover}_{\max}$ discussed in [3] (see [3] for related versions and the history of this problem).

Label Cover. A $\text{LabelCover}_{\max}$ instance $\mathcal{LC}$ consists of a bipartite graph $H = (U, W, F)$ with vertex set $U \cup W$ and edge set F, "label sets" L_U, L_W which represent the possible *labels* that can be given to vertices in U, W, respectively, and *projection functions* $\pi_{u,w} : L_W \to L_U$ for each $u \in U$ and $w \in W$ such that $(u, w) \in F$. The optimization problem we consider is to assign a label $\ell(u) \in L_U$ (resp., $\ell(w) \in L_W$) to each $u \in U$ (resp., $w \in W$) such that the fraction of edges $e = (u', w')$ with $\ell(u') = \pi_{u',w'}(\ell(w'))$ (call such an edge "satisfied") is maximized. The optimum value of a $\text{LabelCover}_{\max}$ instance $\mathcal{LC}$, denoted $\mathsf{OPT}(\mathcal{LC})$, is the maximum fraction of "satisfied" edges in any label assignment. In the language of $\text{LabelCover}_{\max}$, the PCP theorem [5, 4], together with the parallel repetition theorem of Raz [28], yields parts (i)–(iii) of the theorem below. Here we need an additional property that is also used in [17, sections 6, 7]. First we need a definition: For $u \in U, w \in W$, a set $\beta \subseteq L_W$ and $0 < \varepsilon \leq 1$ define

$$\mu_\varepsilon(\beta, u, w) = \sum_{x \in L_U} \min\left\{1, \varepsilon \cdot \left|\pi_{u,w}^{-1}(x) \cap \beta\right|\right\}. \tag{1}$$

The definition above is quite technical (and borrowed directly from [17]), but the intuition is that β projects mostly onto different elements of L_U iff the "measure" μ is large.

THEOREM 3.1 (see [3, 17]). *There exist $d_0, e_0 < \infty$, and $c > 0$ and a transformation that, given a parameter $\delta > 0$, maps instances φ of* SAT *to instances $\mathcal{LC} = (U, W, F, L_U, L_W, \{\pi_{u,w} | (u, w) \in F\})$ of* $\text{LabelCover}_{\max}$*, in time $n^{O(\log \delta^{-1})}$, such that the following hold.*

(i) $|U|, |W| \leq n^{d_0 \log \delta^{-1}}$*, where n is the size of the* SAT *instance φ.*

(ii) $|L_U|, |L_W| \leq \delta^{-e_0}$.

(iii) *If φ is satisfiable, then $\mathsf{OPT}(\mathcal{LC}) = 1$, while, if φ is not satisfiable, then $\mathsf{OPT}(\mathcal{LC}) \leq \delta$.*

(iv) *For every $0 < \varepsilon \leq 1$, $w \in W$, and every $\beta \subseteq L_W$, $|\beta| \geq \varepsilon^{-1}$,*

$$\mathop{\mathbf{E}}_{u \in_R N(w)}\left[\frac{1}{\mu_\varepsilon(\beta, u, w)}\right] \leq (\varepsilon|\beta|)^{-c}, \tag{2}$$

where $N(w) = \{u \in U | (u, w) \in F\}$.

Remark. As mentioned earlier, conditions (i)–(iii) are standard for $\text{LabelCover}_{\max}$. The need for condition (iv) is inherited from some lemmas of [17] that we use (specifically, Lemmas 3.3 and 3.4). This condition is shown in Lemma 6.9 of [17].

To use the hardness of Label Cover, we use the standard paradigm of proof composition. The use of this paradigm requires an error-correcting code, which in our case is again the long code. We define this next.

The long code. We first remark on some conventions and notation we use through the rest of this paper: We represent Boolean values by the set $\{1, -1\}$ with

1 standing for FALSE and -1 for TRUE. This representation has the nice feature that XOR just becomes multiplication. For any domain D, denote by $\mathcal{F}_D$ the space of all Boolean functions $f : D \to \{1, -1\}$. For any set D, $|D|$ denotes its cardinality.

We now describe a very redundant error-correcting code called the *long code*. The long code was first used in [8] and has been very useful in most PCP constructions since.

The long code of an element x in a domain D, denoted $\mathsf{LONG}(x)$, is simply the evaluations of all the $2^{|D|}$ Boolean functions in $\mathcal{F}_D$ at x. If A is the long code of a, then we denote by $A(f)$ the coordinate of A corresponding to function f so that $A(f) = f(a)$.

We note that most of the proofs used in the literature use the "folded long code," which is a code of half the length of the long code, involving evaluations of the elements x at exactly one of the functions f or $-f$ (but not both). For reasons that will become clearer later, we *cannot* use the folded long code here and work with the actual long code.

Constructing a "composed" PCP. Note that Theorem 3.1 implies a PCP where the proof is simply the labels of all vertices in U, W of the $\text{LabelCover}_{\max}$ instance, and the verifier picks an edge $e = (u, w) \in F$ at random and checks if the labels of u and w are "consistent"; i.e., $\pi_{u,w}(\ell(w)) = \ell(u)$. An alternative is to choose a random neighbor w' of u and instead check that $\pi_{u,w}(\ell(w)) = \pi_{u,w'}(\ell(w'))$. By defining $\ell(u)$ to be the most common value of $\pi_{u,w'}(\ell(w'))$, it is easy to see that the probability of acceptance in the latter PCP (that uses w, w' for the check) is at most the probability of acceptance in the former PCP (that uses u, w for the check).

By the properties guaranteed in Theorem 3.1, either PCP uses $O(\log n \log \delta^{-1})$ randomness and has perfect completeness and soundness of at most δ. While the soundness is excellent, the number of bits it reads from the proof in total (from the two "locations" it queries) is large (namely, $O(\log \delta^{-1})$). In order to improve the query complexity, one "composes" this "outer" verification with an "inner" verification procedure. The inner verifier is given as input a projection function $\pi : L_W \to L_U$ and has oracle access to purported encodings, via the encoding function Enc of some error-correcting code, of two labels $a \in L_U$ and $b \in L_W$, and its aim is to check that $\pi(b) = a$ (with "good" accuracy) by making very few queries to $\mathsf{Enc}(a)$ and $\mathsf{Enc}(b)$. The inner verifiers we use have a slightly different character: they are given input two projections π_1 and π_2 (specifically $\pi_{u,w}$ and $\pi_{u,w'}$) and have oracle access to purported encodings $\mathsf{Enc}(b)$ and $\mathsf{Enc}(c)$ of two labels $b, c \in L_W$, and the aim is to test whether $\pi_1(b) = \pi_2(c)$. This interesting feature was part of and necessary for Håstad's construction for set splitting [17], and our PCPs also inherit this feature.

In our final PCP system, the proof is expected to be the encodings of the labels $\ell(w)$ of all vertices $w \in W$ using the encoding Enc. For efficient constructions, the code used is the *long code* of [8], i.e., $\mathsf{Enc} \stackrel{\text{def}}{=} \mathsf{LONG}$. We denote the portion of the (overall) proof that corresponds to w by $\mathsf{LP}(w)$, and, in a "correct" proof, $\mathsf{LP}(w)$ would just be $\mathsf{LONG}(\ell(w))$. (The notation LP stands for "long proof.")

The construction of a PCP now reduces to the construction of a good *inner verifier* that, given a pair of strings B, C which are purportedly long codes and projection functions π_1 and π_2, checks if these strings are the long codes of two "consistent" strings b and c whose respective projections agree (i.e., satisfy $\pi_1(b) = \pi_2(c)$). Given such an inner verifier IV, one can get a "composed verifier" V_{comp} using standard techniques as follows (given formula φ the verifier first computes the $\text{LabelCover}_{\max}$ instance $\mathcal{LC}$ in polynomial time and then proceeds with the verification):

1. Pick $u \in U$ at random and $w, w' \in N(u)$, at random.
2. Run the inner verifier with input $\pi_{u,w}$ and $\pi_{u,w'}$ and oracle access to $\mathsf{LP}(w)$ and $\mathsf{LP}(w')$.
3. Accept iff the inner verifier IV accepts.

We denote by $V_{\text{comp}}(\mathsf{IV})$ the composed verifier obtained using the inner verifier IV. The (usual) soundness analysis of the composed PCP proceeds by saying that, if there is a proof that causes the verifier V_{comp} to accept with large, say, $(s+\varepsilon)$, probability, where s is the soundness we are aiming for, then this proof can be "decoded" into labels for $U \cup W$ that "satisfy" more than a fraction δ of the edges in the $\text{LabelCover}_{\max}$ instance, and by Theorem 3.1, therefore, the original formula φ was satisfiable. In our case, we would like to make a similar argument and say that, if at most k proofs together satisfy all tests of V_{comp}, then these proofs can be "decoded" into labels for $U \cup W$ that satisfy more than δ fraction of edges of $\mathcal{LC}$.

3.2. The inner verifier. We now delve into the specification of our first "inner verifier," which we call Basic-IV4. This inner verifier is essentially the same as the one for 4-set splitting in [17] but has a different acceptance predicate. Recall that the inner verifier is given input two projection functions $\pi_1, \pi_2 : L_W \to L_U$, has oracle access to two tables $B, C : \mathcal{F}_{L_W} \to \{1, -1\}$, and aims to check that B (resp., C) is the long code of b (resp., c) which satisfies $\pi_1(b) = \pi_2(c)$.

`Inner Verifier` Basic-IV4$_p^{B,C}$ (π_1, π_2)
Choose uniformly at random $f \in \mathcal{F}_{L_U}$, $g_1, h_1 \in \mathcal{F}_{L_W}$
Choose at random $g', h' \in \mathcal{F}_{L_W}$ such that $\forall b \in L_W$,
$\mathbf{Pr}[g'(b) = 1] = p$ and $\mathbf{Pr}[h'(b) = 1] = p$
Set $g_2 = -g_1(f \circ \pi_1 \wedge g')$; $h_2 = -h_1(-f \circ \pi_2 \wedge h')$.
Accept iff $(B(g_1) \neq B(g_2)) \vee (C(h_1) \neq C(h_2))$

For a technical reason, as in [17], the final inner verifier needs to run the above inner verifier for the bias parameter p chosen at random from an appropriate set of values. The specific distribution we use is the one used by Håstad [17]. (The constant c used in its specification is the constant from (2) in the statement of Theorem 3.1.)

`Inner Verifier` IV4$_\gamma^{B,C}$ (π_1, π_2)
Set $t = \lceil 1/\gamma \rceil$, $\varepsilon_1 = \gamma$, and $\varepsilon_i = \gamma^{1+2/c}\varepsilon_{i-1}$ for $1 < i \leq t$.
Choose $p \in \{\varepsilon_1, \ldots, \varepsilon_t\}$ uniformly at random.
Run Basic-IV4$_p^{B,C}(\pi_1, \pi_2)$.

Note that the inner verifier above has perfect completeness. Indeed, when B, C are long codes of b, c, where $\pi_1(b) = \pi_2(c) = a$ (say), then, for each $f \in \mathcal{F}_{L_U}$, if $f(a) = 1$, then $B(g_1) = g_1(b)$, while $B(g_2) = B(-g_1(f \circ \pi_1 \wedge g')) = -g_1(b)$, and so these are not equal, and similarly for the case when $f(a) = -1$.

3.3. Covering soundness analysis. Let $X(\gamma)$ be the indicator random variable for the rejection of a particular proof $\Pi = \{\mathsf{LP}(w) : w \in W\}$ by the composed verifier $V_{\text{comp}}(\text{IV4}_\gamma)$ (henceforth $V_1(\gamma)$). The probability that $V_1(\gamma)$ rejects Π taken over its random choices is clearly the expectation

$$\mathop{\mathbf{E}}_{u,w,w',p,f,g_1,h_1,g_2,h_2}\big[X(\gamma)\big] = \mathbf{E}\left[\left(\frac{1 + B(g_1)B(g_2)}{2}\right)\left(\frac{1 + C(h_1)C(h_2)}{2}\right)\right]. \tag{3}$$

Here B, C are shorthand for $\mathsf{LP}(w)$ and $\mathsf{LP}(w')$, respectively, and equal $\mathsf{LONG}(\ell(w))$ and $\mathsf{LONG}(\ell(w'))$, respectively, in a "correct" proof. We wish to say that no k proofs can together satisfy all of the tests which $V_1(\gamma)$ performs. Now, if $X_k(\gamma)$ is the indicator random variable for the rejection of a set of k proofs $\{\mathsf{LP}_i(w) : w \in W\}$, $1 \le i \le k$, by the verifier $V_1(\gamma)$, then the overall probability that $V_1(\gamma)$ rejects all of these k proofs, taken over its random choices, is exactly

$$\mathop{\mathbf{E}}_{u,w,w',p,f,g_1,h_1,g_2}[X_k(\gamma)] = \frac{1}{4^k}\left(\mathbf{E}\left[\prod_{i=1}^{k}\big(1 + B_i(g_1)B_i(g_2)\big)\big(1 + C_i(h_1)C_i(h_2)\big)\right]\right), \tag{4}$$

where we use the shorthand B_i, C_i for $\mathsf{LP}_i(w), \mathsf{LP}_i(w')$, respectively.

We now argue (see Lemma 3.2 below) that, if this rejection probability is much smaller than 4^{-k}, then there is a way to obtain labels $\ell(u)$ for $u \in V \cup W$ by "decoding" Π_1 such that more than δ fraction of the edges (u, w) are satisfied by this labeling; i.e., $\ell(u) = \pi_{u,w}(\ell(w))$. Together with Theorem 3.1, this implies that the rejection probability (from (4)), for any set of k proofs for a false claim of satisfiability (of φ), can be made arbitrarily close to $\frac{1}{4^k}$ and, in particular, is nonzero, and thus the covering soundness of the composed verifier is at most $1/k$.

LEMMA 3.2. *There exists $a' < \infty$ such that, for every integer $k \ge 1$, every ε, $0 < \varepsilon < 4^{-k}$, and all $\gamma \le \varepsilon/8$, if $\mathbf{E}[X_k(\gamma)] < \frac{1}{4^k} - \varepsilon$, then $\mathsf{OPT}(\mathcal{LC}) > \gamma^{-a'\gamma^{-1}}$.*

Before presenting the formal proof of Lemma 3.2, we first highlight the basic approach. The power of arithmetizing the rejection probability for a set of k proofs as in (4) is that one can expand the product and analyze the expectation of

$$\frac{1}{4^k}\sum_{S,T\subseteq[k]} B_S(g_1)B_S(g_2)C_T(h_1)C_T(h_2), \tag{5}$$

where $B_S = \prod_{i\in S} B_i$ and $C_T = \prod_{i\in T} C_i$, where empty products are defined to be 1. A special term is $S = T = \emptyset$, which is the constant 1. We analyze the rest of the terms individually. We can now imagine two new proofs $\tilde{B} = B_S$ and $\tilde{C} = C_T$ which are exclusive-ors of subsets of the k given proofs. Now one can apply existing techniques from [17] to analyze terms involving the tables $\tilde{B}$ and $\tilde{C}$ and show that $\tilde{B}(g_1)\tilde{B}(g_2)$ and $\tilde{C}(h_1)\tilde{C}(h_2)$ cannot be too negative, and similarly if the expectation of $\tilde{B}(g_1)\tilde{B}(g_2)\tilde{C}(h_1)\tilde{C}(h_2)$ is too much below zero; then, in fact, $\mathsf{OPT}(\mathcal{LC})$ is quite large. In short, at a high level, we are saying that, if there exist k proofs such that the verifier accepts at least one of them with good probability, then some exclusive-or of these proofs is also accepted by the verifier with good probability, and we know that this cannot happen by the soundness analysis of [17] for the case of a single proof. This intuition is formalized via the next two lemmas from [17].

Before stating the lemmas, we make a slight digression to point out the relevance of not employing folding here. Folded long codes are typically used as follows: Given a table $A = \mathsf{LP}(w)$ supposedly giving the long code of the encoding of the label assigned to w, conceptually we assume that we have a long proof $A' = \mathsf{FoldedLP}(w)$ which respects the constraints $A'(f) = -A'(-f)$. We generate such an A' for ourselves from A' by setting $A'(f) = A(f)$ if $f(x_0) = 1$ and $A'(-f) = -A(f)$ if $f(x_0) = -1$, where x_0 is some fixed element of the concerned domain (i.e., L_U or L_W as the case might be). Such a table A', which satisfies $A'(-f) = -A'(f)$ for every function f, is said to be *folded*. We then pretend that the verifier works with the long code but carry out the soundness analysis only for folded tables. In our case, we could also do the same to analyze the acceptance of a single proof. However, when faced with

multiple proofs, the intermediate tables we consider, such as B_S above, need not be folded even if the original proofs we were given were folded; in particular, this will be the case when S has even cardinality. Thus our analysis needs to work with nonfolded tables as well. This is why we work with the long code directly.

Now we go back to the technical lemmas.

LEMMA 3.3 (see [17]). *For every $\gamma > 0$ and for all $B : \mathcal{F}_{L_W} \to \{1, -1\}$ and all $w \in W$,*

$$\mathop{\mathbf{E}}_{p,v \in N(w), f, g, g'} \big[B(g_1)B(g_2)\big] \geq -4\gamma,$$

where the distribution of p, f, g_1, g_2 is the same as the one in $\mathrm{IV4}_\gamma$.

This lemma is Lemma 7.9 in [17] combined with the calculation in the first half of Lemma 7.14 in the same paper. Similarly, the next lemma follows from Lemma 7.12 of the same paper and a similar calculation.

LEMMA 3.4 (see [17]). *There exists $a < \infty$ such that, for every $\gamma > 0$ and all proof tables $\{B_w\}$ and $\{C_w\}$, indexed by $w \in W$ with $B_w, C_w : \mathcal{F}_{L_W} \to \{1, -1\}$, we have that $\mathbf{E}\big[B_w(g_1)B_w(g_2)C_{w'}(h_1)C_{w'}(h_2)\big]$ is at least*

$$-7\gamma - \mathsf{OPT}(\mathcal{LC})\gamma^{-a\gamma^{-1}},$$

where the expectation is taken over $p, u, w, w', g_1, h_1, g_2, h_2$, and where the distribution of p, g_1, g_2, h_1, h_2 is the same as the one in $\mathrm{IV4}_\gamma$.

We are now ready to prove Lemma 3.2.

Proof of Lemma 3.2. The proof is actually simple given Lemmas 3.3 and 3.4. We pick a $\gamma > 0$ that satisfies $\gamma < \frac{\varepsilon}{8}$. By (4), if $\mathbf{E}[X_k(\gamma)] < 4^{-k} - \varepsilon$, then there exist subsets S_1, S_2 of $\{1, 2, \ldots, k\}$, $S_1 \cup S_2 \neq \emptyset$, such that

$$\mathbf{E}\big[B_{S_1}(g_1)B_{S_1}(g_2)C_{S_2}(h_1)C_{S_2}(h_2)\big] < -\varepsilon, \tag{6}$$

where B_{S_1} (resp., C_{S_2}) denotes $\Pi_{j \in S_1} B_j$ (resp., $\Pi_{j \in S_2} C_j$).

Suppose one of S_1, S_2 is empty (say, $S_2 = \emptyset$). Lemma 3.3 applied to B_{S_1} (which is a function mapping $\mathcal{F}_{L_W} \to \{1, -1\}$) gives $\mathbf{E}[B_{S_1}(g_1)B_{S_1}(g_2)] \geq -4\gamma$, which, together with (6) above, yields $\gamma > \frac{\varepsilon}{4}$, which is a contradiction since $\gamma \leq \varepsilon/8$.

Now suppose that both S_1 and S_2 are nonempty. Now we apply Lemma 3.4 to B_{S_1} and C_{S_2} to get that the expectation in (6) is at least $-7\gamma - \mathsf{OPT}(\mathcal{LC})\gamma^{-a\gamma^{-1}}$. Together with (6), this yields (using $\varepsilon \geq 8\gamma$)

$$\mathsf{OPT}(\mathcal{LC}) > \gamma\gamma^{a\gamma^{-1}} > \gamma^{a'\gamma^{-1}}$$

for some *absolute* constant a'. □

We are now ready to state and prove the main theorem of this section.

THEOREM 3.5. *For every constant k,* $\mathrm{NP} \subseteq \mathrm{cPCP}_{1, \frac{1}{k}}[\log, 4]$.

Proof. The theorem follows from Lemma 3.2 and Theorem 3.1. Let $\varepsilon = \frac{1}{2} \cdot 4^{-k}$ and $\gamma = \varepsilon/8$, and pick $\delta > 0$ small enough so that $\gamma^{-a'\gamma^{-1}} > \delta$. By Lemma 3.2, we have that $\mathbf{E}[X_k(\gamma)] < \frac{1}{4^k} - \varepsilon = \frac{1}{2 \cdot 4^k}$ implies $\mathsf{OPT}(\mathcal{LC}) > \delta$. Consider the PCP with verifier $V_{\mathrm{comp}}(\mathrm{IV4}_\gamma)$. Using Theorem 3.1, we get that, if the input formula φ is not satisfiable, then the verifier $V_{\mathrm{comp}}(\mathrm{IV4}_\gamma)$ rejects any k proofs with probability at least $\frac{1}{2 \cdot 4^k}$. Since it clearly has perfect completeness and makes only four queries, the claimed result follows. □

Remark on tightness of the analysis. In fact, Lemma 3.2 can be used to show that, for any $\varepsilon > 0$, there exists a (covering) PCP verifier that makes four queries, has

perfect completeness, and rejects any set of k proofs with probability at least $\frac{1}{4^k} - \varepsilon$. Note that this analysis is in fact *tight* for the verifier V_{comp}(IV4) since a random set of k proofs is accepted with probability $1 - 4^{-k}$. It would have been sufficient to prove that, for any k proofs, the set of verifier coins causing the verifier to reject all k proofs is nonempty. We do not know a simpler proof of this weaker statement.

4. PCP construction II and hardness of hypergraph coloring. In the previous section, we gave a PCP construction which made only four queries into the proof and had covering soundness smaller than any desired constant. This is already interesting in that it highlights the power of taking the covering soundness approach (since, as remarked in the introduction, one cannot achieve arbitrarily low soundness using classical PCPs with perfect completeness that make some fixed constant number of queries). We next turn to applying this to get a strong inapproximability result for hypergraph coloring.

The predicate tested by the inner verifier IV4$_\gamma$ is $F(x, y, z, w) = (x \neq y) \vee (z \neq w)$, and, to get a hardness result for hypergraph coloring, we require the predicate to be NAE(x, y, z, w), which is true unless all of x, y, z, w are equal. Note that NAE(x, y, z, w) is true whenever $F(x, y, z, w)$ is true, so one natural approach is to simply replace the predicate F tested by IV4$_\gamma$ by NAE without losing perfect completeness. The challenge, of course, is to prove that the covering soundness does not suffer in this process, and this is exactly what we accomplish. For completeness, we describe the inner verifier below.

`Inner Verifier` IV-NAE4$_\gamma^{B,C}$ (π_1, π_2)
  Pick p as in IV4$_\gamma$.
  Pick $f, g_1, h_1, g', h', g_2, h_2$ as in Basic-IV4$_p$.
  Accept iff not all of $B(g_1), B(g_2), C(h_1), C(h_2)$ are equal.

To analyze the soundness of the resulting composed verifier, we need to understand the not-all-equal predicate NAE. Note that NAE(x, y, z, w) rejects iff

$$\frac{1}{8}(1 + xy + xz + xw + yz + yw + zw + xyzw) = 1,$$

and this sum equals zero otherwise. With similar notation as in the previous section, this implies that, for a given choice of g_1, g_2, h_1, h_2, the verifier rejects all k proofs iff

$$8^{-k} \sum_{S_1,S_2,S_3,S_4,S_1\oplus S_2\oplus S_3\oplus S_4=\emptyset} B_{S_1}(g_1)B_{S_2}(g_2)C_{S_3}(h_1)C_{S_4}(h_2) = 1, \tag{7}$$

where $\oplus$ denotes the exclusive-or of characteristic vectors or, worded differently, the symmetric difference of sets. If the verifier accepts one of the proofs, then the right-hand side of (7) must equal zero. Hence we study the expected value of this quantity.

Before proceeding with the analysis, we shed some insight into the analysis and explain what is new this time. Let $T = S_1 \oplus S_2 = S_3 \oplus S_4$. The terms corresponding to T, being the empty set, are exactly the terms that appeared in the analysis of the verifier of section 3. Let us turn our attention to terms where $T \neq \emptyset$. Typically, when a sum such as the above appears, we would just analyze the individual terms. Unfortunately, it turns out that we are unable to do this in our case. To see why, consider a typical summand above, namely, $B_{S_1}(g_1)B_{S_1\oplus T}(g_2)C_{S_3}(h_1)C_{S_3\oplus T}(h_2)$. These are more general than the terms analyzed in section 3, which were of the form

$B_S(g_1)B_S(g_2)C_{S'}(h_1)C_{S'}(h_2)$. The first two elements of such a product come from an identical distribution, and similarly for the last two elements of the product. This in turn enabled a certain "pairing" up of terms from which a good solution to the Label Cover instance could be extracted (see the analysis in Lemma 7.12 of [17] for more details). But now, since $T \neq \emptyset$, the first two tables, B_{S_1} and $B_{S_1 \oplus T}$, are different, and so are the last two. Therefore, we now have to deal with individual terms which are the product of four elements, each of which comes from a different distribution. It does not seem possible to analyze such a term by itself and extract meaningful solutions to the Label Cover instance.

To cope with this problem, we now bunch together terms $B_{S_1}(g_1)B_{S_1 \oplus T}(g_2)C_{S_3}(h_1)$ $C_{S_3 \oplus T}(h_2)$ that involve the same T but different S_1 and S_3. (Alternatively, one could think of this as fixing T and then picking S_1 and S_3 as random subsets of $[k]$ and considering the expectation of the terms over S_1, S_3 as well.) This makes the distribution of the first pair as a whole identical to that of the second pair and allows us to analyze the terms above. More formally, for each nonempty $T \subseteq [k]$, we define

$$B^T(g_1, g_2) = \sum_S B_S(g_1)B_{S \oplus T}(g_2), \tag{8}$$

and similarly for C. Using this notation, the sum in (7) equals

$$\begin{aligned} 8^{-k} \Bigg(& 1 + \sum_S B_S(g_1)B_S(g_2) + \sum_S C_S(h_1)C_S(h_2) \\ & + \sum_S B_S(g_1)B_S(g_2)C_S(h_1)C_S(h_2) + \sum_{T \neq \emptyset} B^T(g_1, g_2)C^T(h_1, h_2) \Bigg), \end{aligned} \tag{9}$$

where the first four terms correspond to the case where $T = \emptyset$. Lemma 3.3 can be used to lower bound the expectation of the first two sums over g_1, g_2, h_1, h_2, and Lemma 3.4 can be used to lower bound the expectation of the third sum as a function of the optimum of the Label Cover instance. Thus we need only to study the last sum.

We show that, if the last term is too negative, then one can extract an assignment of labels to the provers. The intuition behind the proof is as follows. B^T and C^T are two functions chosen independently from the same distribution. Further, the queried pairs (g_1, g_2) and (h_1, h_2) are also chosen from the same distribution but are not independent of each other (and are related via f). If we ignore this dependence for a moment, then we get

$$\begin{aligned} \mathbf{E}[B^T(g_1, g_2)C^T(h_1, h_2)] &= \mathbf{E}[B^T(g_1, g_2)]\,\mathbf{E}[C^T(h_1, h_2)] \\ &= \mathbf{E}[B^T(g_1, g_2)]\,\mathbf{E}[B^T(g_1, g_2)] \geq 0, \end{aligned}$$

and this would be good enough for us. Unfortunately, (g_1, g_2) and (h_1, h_2) are not independent. The intuition behind the proof of the next inequality is that, if this correlation affects the expectation of $\mathbf{E}[B^T(g_1, g_2)C^T(h_1, h_2)]$, then there is some correlation between the tables for B^T and C^T, and so a reasonable strategy for assigning labels to w and w' can be extracted. Specifically, we get the following lemma.

LEMMA 4.1. *There exists $a' < \infty$ such that the following holds: Let $T \neq \emptyset$, $0 < \varepsilon < 2^{-k}$, and $\gamma \leq \varepsilon/8$ be such that*

$$\mathbf{E}\left[B^T(g_1, g_2)C^T(h_1, h_2)\right] \leq -\varepsilon,$$

where the expectation is taken over the distribution of $u, w, w', p, g_1, h_1, f, g', h', g_2, h_2$ *as in IV-NAE*4_γ. *Then* $\mathsf{OPT}(\mathcal{LC}) \geq \gamma^{a'\gamma^{-1}}$.

As usual, we postpone the proof of the lemma and instead prove the resulting theorem.

THEOREM 4.2. *For every constant* k, $\mathrm{NP} \subseteq \mathrm{cPCP}_{1,\frac{1}{k}}[\log, 4]$, *where, moreover, the predicate verified by the PCP upon reading bits* x, y, z, w *is* $\mathrm{NAE}(x, y, z, w)$.

Proof. We have only to analyze the soundness of the verifier. Let a be the constant from Lemma 3.4 and a' be the constant from Lemma 4.1. Let $b = \max\{a, a'\}$. Let $\gamma = 2^{-(k+5)}$, and let $\delta < \gamma^{b\gamma^{-1}}$. To create a verifier for an instance of SAT, reduce the instance of SAT to an instance of Label Cover using Theorem 3.1 with parameter δ, and then use the verifier based on using IV-NAE4_γ as the inner verifier. To show soundness, we need to show that, if this verifier is covered by k proofs, then the instance of Label Cover has an optimum greater than δ.

Suppose we have k proofs such that the verifier always accepts one of the proofs. This implies that the expectation, over $u, w, w', p, f, g_1, g_2, h_1, h_2$, of (9) is 0. This implies that at least one of summands in (9) is less than or equal to $-2^{-(k+2)}$ in expectation (since there are at most $4 \cdot 2^k$ summands in the expression). If it is a summand in one of the first two sums, then this contradicts Lemma 3.3. If it is a summand in the third sums, then, by Lemma 3.4, we get that $\mathsf{OPT}(\mathcal{LC}) \geq \gamma^{a\gamma^{-1}} > \delta$. If it is a summand in the last sum, then, by Lemma 4.1, we get that $\mathsf{OPT}(\mathcal{LC}) \geq \gamma^{a'\gamma^{-1}} > \delta$. Thus, in the last two cases, we get that the optimum is more than δ as desired. ∎

Before going on to the proof of Lemma 4.1, we discuss the consequences of Theorem 4.2 to hypergraph coloring. Before doing so, we just note that, in fact, one can prove a stronger claim in Theorem 4.2 that, given any k proofs, the probability that the verifier rejects all of them is at least $\frac{1}{8^k} - \varepsilon$ for $\varepsilon > 0$ as small as we seek. The proof is really the same as that of Theorem 4.2 since we have argued that all terms in the expansion (9) are arbitrarily small in the case when the optimum value of the Label Cover instance is very small. Once again, this soundness analysis is tight since a random set of k proofs will, in expectation, satisfy a fraction $1 - \frac{1}{8^k}$ of the verifier's checks.

4.1. Hardness results for hypergraph coloring. Since the predicate used by the PCP of Theorem 4.2 is that of 4-set splitting, we get the following corollary.

COROLLARY 4.3. *For every constant* $k \geq 2$, *given an instance of* 4*-set splitting, it is NP-hard to distinguish between the case when there is a partition of the universe that splits all of the* 4*-sets and when, for every set of* k *partitions, there is at least one* 4*-set which is not split by any of the* k *partitions.*

The above hardness can be naturally translated into a hardness result for coloring 4-uniform hypergraphs, and this gives us our main result.

THEOREM 4.4 (main theorem). *For any constant* $c \geq 2$, *it is NP-hard to color a* 2*-colorable* 4*-uniform hypergraph using* c *colors.*

Proof. The proof follows from the above corollary since a 4-set splitting instance can be naturally identified with a 4-uniform hypergraph whose hyperedges are the 4-sets, and it is easy to see that the minimum number of partitions k needed to split all 4-sets equals $\lceil \log c \rceil$, where c is the minimum number of colors to color the hypergraph such that no hyperedge is monochromatic. ∎

In light of the discussion after the proof of Theorem 4.2, we in fact have the following stronger result.

THEOREM 4.5. *For any constant $c \geq 2$ and every $\varepsilon > 0$, it is NP-hard to color a 2-colorable 4-uniform hypergraph using c colors such that at least a fraction $\left(1 - \frac{1}{8^{\lfloor \log c \rfloor}} + \varepsilon\right)$ of the hyperedges are properly colored (i.e., are not monochromatic).*

THEOREM 4.6. *Assume* NP $\not\subseteq$ DTIME$(n^{O(\log \log n)})$. *Then there exists an absolute constant $c_0 > 0$ such that there is no polynomial time algorithm that can color a 2-colorable 4-uniform hypergraph using $c_0 \frac{\log \log n}{\log \log \log n}$ colors, where n is the number of vertices in the hypergraph.*

Proof. This follows since the covering soundness of the PCP in Theorem 4.2 can be made an explicit $o(1)$ function. Indeed, nothing prevents having a k that is a function of n. We need to have $\gamma = 2^{-(k+5)}$ and to reach a contradiction $\delta < \gamma^{O(\gamma^{-1})}$. The proof size we need is $n^{O(\log \delta^{-1})} 2^{\delta^{-O(1)}}$. We can thus have $n^{O(\log \log n)}$ size proofs by letting $\delta^{-1} = (\log n)^b$ for some small enough constant b. The value of k can then satisfy $2^k = \Omega(\gamma^{-1}) = \Omega(\frac{\log \log n}{\log \log \log n})$. Similarly to Theorem 4.4, this implies that 2^k-coloring a 2-colorable 4-uniform hypergraph is hard unless NP $\subseteq$ DTIME$(n^{O(\log \log n)})$. ∎

We now show that a hardness result similar to Theorem 4.4 also holds for 2-colorable k-uniform hypergraphs for any $k \geq 5$.

THEOREM 4.7. *Let $k \geq 5$ be an integer. For any constant $\ell \geq 2$, it is NP-hard to color a 2-colorable k-uniform hypergraph using ℓ colors.*

Proof. The proof works by reducing from the case of 4-uniform hypergraphs, and the claimed hardness then follows using Theorem 4.4.

Let $\mathcal{H}$ be a 4-uniform hypergraph with vertex set V. Suppose that $k = 4s + t$, where $1 \leq t \leq 4$. Construct a k-uniform hypergraph $\mathcal{H}'$ as follows. The vertex set of $\mathcal{H}'$ is $V^{(1)} \cup V^{(2)} \cup \cdots \cup V^{(s\ell+1)}$, where the sets $V^{(j)}$ are independent copies of V. On each $V^{(j)}$, take a collection $\mathcal{F}^{(j)}$ of 4-element subsets of $V^{(j)}$ that correspond to the hyperedges in $\mathcal{H}$. A hyperedge of $\mathcal{H}'$ (which is a $(4s + t)$-element subset of $\bigcup_j V^{(j)}$) is now given by the union of s 4-sets belonging to s different $\mathcal{F}^{(j)}$'s, together with t vertices picked from a 4-set belonging to yet another $\mathcal{F}^{(j)}$. More formally, for every set of $(s+1)$ distinct indices $j_1, j_2, \ldots, j_{s+1}$, every choice of elements $e_{j_i} \in \mathcal{F}^{(j_i)}$ for $i = 1, \ldots, s + 1$, and every t-element subset $f_{j_{s+1}}$ of $e_{j_{s+1}}$, there is a hyperedge $(e_{j_1} \cup \cdots \cup e_{j_s} \cup f_{j_{s+1}})$ in $\mathcal{H}'$.

If $\mathcal{H}$ is 2-colorable, then clearly any 2-coloring of it induces a 2-coloring of $\mathcal{H}'$, and hence $\mathcal{H}'$ is 2-colorable as well.

Suppose $\mathcal{H}$ is not ℓ-colorable and that we are given an ℓ-coloring of $\mathcal{H}'$. Since $\mathcal{H}$ is not ℓ-colorable, each $\mathcal{F}^{(j)}$, for $1 \leq j \leq s\ell + 1$, must contain a monochromatic set g_j. By the pigeonhole principle, there must be a color c such that $(s + 1)$ different g_j's have color c. The hyperedge of $\mathcal{H}'$ constructed from those $(s + 1)$ sets is then clearly monochromatic (all its vertices have color c), and we conclude that $\mathcal{H}'$ is not ℓ-colorable.

Since the reduction runs in polynomial time when k and ℓ are constants, the proof is complete. ∎

4.2. Discrete Fourier transforms. Before going on to the proof of Lemma 4.1, we now introduce a tool that has been crucial in the analysis on inner verifiers. This was hidden so far from the reader but already used in the proofs of Lemmas 3.3 and 3.4 in [17]. Now we need to introduce them explicitly.

In general, we consider functions mapping D to $\{1, -1\}$. For $\alpha \subseteq D$ and $f \in \mathcal{F}_D$, let $\chi_\alpha(f) = \prod_{x \in \alpha} f(x)$. Notice that $\chi_{\{x\}}$ is the long code of x. For any function A

mapping $\mathcal{F}_D$ to the reals, we have the corresponding Fourier coefficients

$$\hat{A}_\alpha = 2^{-2^{|D|}} \sum_f A(f)\chi_\alpha(f),$$

where $\alpha \subseteq D$. We have the Fourier inversion formula given by

$$A(f) = \sum_\alpha \hat{A}_\alpha \chi_\alpha(f)$$

and Plancherel's equality that states that

$$\sum_\alpha \hat{A}_\alpha^2 = 2^{-2^{|D|}} \sum_f A(f)^2.$$

In the case when A is a Boolean function, the latter sum is clearly 1.

We think of an arbitrary table A as being somewhat close to (or coherent with) the long code of x if there exists a small set α containing x such that $\hat{A}_\alpha$ is nonnegligibly large. Thus, when viewing the long proofs of w and w', our goal is to show that the $\mathsf{LP}(w)$ and $\mathsf{LP}(w')$ have coherence with the long codes of strings x and y such that $\pi_{u,w}(x)$ and $\pi_{u,w'}(y)$ are equal.

4.3. Proof of Lemma 4.1. Fix $T \subseteq [k]$. Throughout this section, the quantities that we define depend on T, but we do not include it as a parameter explicitly.

Recall that we need to show that, if the expectation, over $u, w, w', p, g_1, g_2, h_1, h_2$ of $B^T(g_1, g_2)C^T(h_1, h_2)$, is too negative (less than $-\varepsilon$), then we can assign labels to the Label Cover problem with acceptance probability more than δ. Recall that $g_2 = g_1(f \circ \pi_1 \wedge g')$ is defined in terms of other random variables f and g' and similarly h_2 in terms of f and h'. For brevity, we let X denote the quantity $B^T(g_1, g_2)C^T(h_1, h_2)$. Notice that X is a random variable depending on all of the variables above. We first analyze the expectation of X over g_1 and h_1 (for fixed choice of u, w, w', p, f, g', and h'). Next we calculate the expectation over f, g', and h'. In both stages, we get exact expressions. Finally, we make some approximations for the expectation over u, w, w'. (The careful reader may observe that we do not take expectations over p—in fact, the lemma holds for every choice of p of the inner verifier IV-NAE4$_\gamma$.)

The crux of this proof is the functions $B^*, C^* : \mathcal{F}_{L_W} \to \{1, -1\}$, defined as follows: We let

$$B^*(g) = \mathop{\mathbf{E}}_h \left[\sum_S B_S(h) B_{S \oplus T}(gh) \right]$$

and

$$C^*(g) = \mathop{\mathbf{E}}_h \left[\sum_S C_S(h) C_{S \oplus T}(gh) \right].$$

Note that, for a fixed choice of f and g', we have $\mathbf{E}_{g_1}[B^T(g_1, g_2)] = B^*(-((f \circ \pi_1) \wedge g'))$. We get a similar expression for C^T, and thus we get

$$\mathop{\mathbf{E}}_{g_1, h_1}[X] = B^*(-((f \circ \pi_1) \wedge g'))C^*(-((-f \circ \pi_2) \wedge h')).$$

Let us call the above quantity Y.

In what follows, we rely crucially on the properties of the Fourier coefficients of B^* and C^*. Let $\hat{F}_\beta$ and $\hat{G}_\beta$ denote the Fourier coefficients of B^* and C^*, respectively. From the definitions and some standard manipulation, we get

$$\hat{F}_\beta = \sum_S \hat{B}_{\beta,S}\hat{B}_{\beta,S\oplus T} \quad \text{and} \quad \hat{G}_\beta = \sum_S \hat{C}_{\beta,S}\hat{C}_{\beta,S\oplus T}.$$

Using simple Fourier expansion, we can rewrite the quantity we are analyzing as

$$\begin{aligned} Y &= B^*(-((f\circ\pi_1)\wedge g'))C^*(-((-f\circ\pi_2)\wedge h')) \\ &= \sum_{\beta,\beta'} \hat{F}_\beta\hat{G}_{\beta'}\chi_\beta(-((f\circ\pi_1)\wedge g'))\chi_{\beta'}(-((-f\circ\pi_2)\wedge h')) \\ &= \sum_{\beta,\beta'} \hat{F}_\beta\hat{G}_{\beta'}\prod_{y\in\beta}(-(f(\pi_1(y))\wedge g'(y)))\prod_{z\in\beta'}(-(-f(\pi_2(z))\wedge h'(z))). \end{aligned}$$

The main property about the Fourier coefficients of B^* and C^* is that their L_1 norm is bounded. Specifically, we have

$$\sum_\beta |\hat{F}_\beta| \le \sum_{\beta,S} |\hat{B}_{\beta,S}\hat{B}_{\beta,S\oplus T}| \le \sum_S \left(\sum_\beta \hat{B}^2_{\beta,S}\right)^{1/2}\left(\sum_\beta \hat{B}^2_{\beta,S\oplus T}\right)^{1/2} \le 2^k. \tag{10}$$

We start by defining the strategy we use to assign labels and prove that, if the expectation (of Y) is large, then the labels give an assignment to the Label Cover instance with objective of at least $\delta = \gamma^{a'\gamma^{-1}}$.

Strategy. Given $w \in W$ and tables $B_1,\dots,B_k$ corresponding to $\mathsf{LP}(w)$ in k different proofs, compute B_S for every $S \subseteq [k]$, B^* and its Fourier coefficients. Pick a nonempty set $\beta \subseteq L_W$ with probability $2^{-k}|\hat{F}_\beta|$, and assign as label to w, an element $x \in \beta$ chosen uniformly at random. With remaining probability, since $\sum_{\beta\neq\emptyset}|\hat{F}_\beta|$ may be less than 2^k, assign no label to w.

Preliminary analysis. We now give a preliminary expression for the success probability of the strategy. Consider picking u, w, and w' (and the associated π_1 and π_2) at random and checking for the event $\pi_1(\ell(w)) = \pi_2(\ell(w'))$. The probability of this event is lower bounded by the probability that $\pi_1(\beta)$ and $\pi_2(\beta')$ intersect, and we assign the elements corresponding to this intersection to w and w'. The probability of these events is at least

$$\mathop{\mathbf{E}}_{u,w,w'}\left[\sum_{\beta,\beta':\pi_1(\beta)\cap\pi_2(\beta')\neq\emptyset}\frac{2^{-2k}}{|\beta|\cdot|\beta'|}|\hat{F}_\beta||\hat{G}_{\beta'}|\right]. \tag{11}$$

Below we show that this quantity is large if the expectation of Y is too small. We now return to the expectation of Y.

An exact expression for the expectation of Y. We start with some notation. Fix u, w, w', p, and π_1 and π_2. For $x \in L_U$ and $\beta, \beta' \subseteq L_W$, let $s_x(\beta) = |\beta \cap \pi_1^{-1}(x)|$, and let $t_x(\beta') = |\beta' \cap \pi_2^{-1}(x)|$. Since the argument of s_x is always β and the argument of t_x is always β', we use the shorthand s_x for $s_x(\beta)$ and t_x for $t_x(\beta')$. Further, for real p and nonnegative integers s, t, let $\alpha(p,s,t) = \frac{1}{2}\left((-1)^s(1-2p)^t + (1-2p)^s(-1)^t\right)$, and let $\eta(p,s) = \frac{1}{2}\left((-1)^s + (1-2p)^s\right)$. Next we show that

$$\mathop{\mathbf{E}}_{f,g',h'}[Y] = \sum_{\beta,\beta'}\hat{F}_\beta\hat{G}_{\beta'}\prod_{x\in L_U}\alpha(p,s_x,t_x). \tag{12}$$

To prove the above, it suffices to show that

$$\mathop{\mathbf{E}}_{f,g',h'}\left[\prod_{y\in\beta}\left[-(f(\pi_1(y))\wedge g'(y))\right]\prod_{z\in\beta'}\left[-(-f(\pi_2(z))\wedge h'(z))\right]\right]=\prod_{x\in L_U}\alpha(p,s_x,t_x).$$

Factors corresponding to y and z with different projections on L_U are independent, and thus the expectation can be broken down into a product of expectations, one for each $x\in L_U$. Fix $x\in L_U$, and consider the term

$$\mathop{\mathbf{E}}_{f,g',h'}\left[\prod_{y\in\beta\cap\pi_1^{-1}(x)}(-(f(\pi_1(y))\wedge g'(y)))\prod_{z\in\beta'\cap\pi_2^{-1}(x)}(-(-f(\pi_2(z))\wedge h'(z)))\right]$$
$$=\mathop{\mathbf{E}}_{f,g',h'}\left[\prod_{y\in\beta\cap\pi_1^{-1}(x)}(-(f(x)\wedge g'(y)))\prod_{z\in\beta'\cap\pi_2^{-1}(x)}(-(-f(x)\wedge h'(z)))\right].$$

If $f(x)=1$ (or "false"), the first product equals $(-1)^{s_x}$, and the second equals $(1-2p)^{t_x}$. Similarly, if $f(x)=-1$, the first product equals $(1-2p)^{s_x}$, and the second equals $(-1)^{t_x}$. The events happen with probability $1/2$ each and thus give that the expectation above (for fixed x) equals

$$\frac{1}{2}\left((-1)^{s_x}(1-2p)^{t_x}+(1-2p)^{s_x}(-1)^{t_x}\right)=\alpha(p,s_x,t_x).$$

Taking the product over all x's gives (12).

Inequalities on E[*Y*]. For every u, we now show how to lower bound the expectation of Y over w,w',f,g',h' in terms of a sum involving only β's and β' that *intersect* in their projections. This brings us much closer to the expression derived in our preliminary analysis of the success probability of our strategy for assigning labels, and we lower bound a closely related quantity. Specifically, we now use the inequality $\mathbf{E}_{w,w',f,g',h'}[Y]\le-\varepsilon$ (as guaranteed by the lemma statement) to show

$$\mathop{\mathbf{E}}_{u,w,w'}\left[\sum_{\beta,\beta'|\pi_1(\beta)\cap\pi_2(\beta')\neq\emptyset}2|\hat{F}_\beta\hat{G}_{\beta'}|e^{-\mu_p(\beta)/2}\right]\ge\varepsilon, \tag{13}$$

where $\mu_p(\beta)=\mu_p(\beta,u,w)=\sum_x\min\{1,ps_x\}$ is the quantity defined in (1). (A similar inequality with $\mu_p(\beta')$ in the exponent follows by symmetry.)

To prove the above, consider the following expression, which is closely related to the expectation of Y as given by (12):

$$Y_1=\left(\sum_\beta\hat{F}_\beta\prod_x\eta(p,s_x)\right)\left(\sum_{\beta'}\hat{G}_{\beta'}\prod_x\eta(p,t_x)\right).$$

First we note that $\mathbf{E}_{w,w'}[Y_1]=(\mathbf{E}_w[(\sum_\beta\hat{F}_\beta\prod_x\eta(p,s_x))])^2\ge0$. (Here we are using the fact that the tables B^T and C^T are chosen from the same distribution.) Next we note that the difference between Y and Y_1 arises only from terms involving β,β' such that $\pi_1(\beta)\cap\pi_2(\beta')\neq\emptyset$. To verify this, note that, if $s=0$ or $t=0$, then $\alpha(p,s,t)=$

$\eta(p,s)\cdot\eta(p,t)$. Since either s_x or t_x equals 0 for every x, if $\pi_1(\beta)\cap\pi_2(\beta')=\emptyset$, we get that terms corresponding to such pairs of β,β' vanish in $Y-Y_1$. We conclude that

$$\mathop{\mathbf{E}}_{w,w',f,g',h'}[Y]=\mathop{\mathbf{E}}_{w,w'}[Y_1]$$

$$+\sum_{\beta,\beta':\pi_1(\beta)\cap\pi_2(\beta')\neq\emptyset}\hat{F}_\beta\hat{G}_{\beta'}\left(\prod_x\alpha(p,s_x,t_x)-\prod_x(\eta(p,s_x)\cdot\eta(p,t_x))\right).$$

Using $\mathbf{E}_{w,w',f,g',h'}[Y]\le-\varepsilon$, $\mathbf{E}[Y_1]\ge0$ and taking absolute values, we get

$$\begin{aligned}\varepsilon&\le\left|\sum_{\beta,\beta':\pi_1(\beta)\cap\pi_2(\beta')\neq\emptyset}\hat{F}_\beta\hat{G}_{\beta'}\left(\prod_x\alpha(p,s_x,t_x)-\prod_x(\eta(p,s_x)\cdot\eta(p,t_x))\right)\right|\\&\le\sum_{\beta,\beta':\pi_1(\beta)\cap\pi_2(\beta')\neq\emptyset}|\hat{F}_\beta\hat{G}_{\beta'}|\left(\prod_x|\alpha(p,s_x,t_x)|+\prod_x|\eta(p,s_x)|\right),\end{aligned}\tag{14}$$

where the last inequality uses $|\eta(p,t)|\le1$ for every $t\ge0$.

Next we simplify the terms of the left-hand side above. First we show that, for every $t\ge0$,

$$|\alpha(p,s,t)|,|\eta(p,s)|\le e^{-\min\{1,ps\}/2}.\tag{15}$$

First we note that both $|\alpha(p,s,t)|$ and $|\eta(p,s)|$ are upper bounded by $\frac12(1+(1-2p)^s)\le\frac12(1+e^{-2ps})$. If $p\ge s^{-1}$, then we have $\frac12(1+e^{-2ps})\le\frac12(1+e^{-2})\le e^{-1/2}$ as required. If $p\le\frac1s$, let us set $\lambda(z)=2e^{-z/2}-(1+e^{-2z})$. To show (15), we need to prove that $\lambda(z)\ge0$ for $z\in[0,1]$. We have $\lambda''(z)=\frac12e^{-z/2}-4e^{-2z}$, and hence $\lambda''(z)\le0$ in the interval in question, and we have only to check the inequality at the end points. We have $\lambda(0)=0$ and $\lambda(1)=2e^{-1/2}-(1+e^{-2})>0$.

Using (15), we conclude that

$$\prod_x|\alpha(p,s_x,t_x)|+\prod_x|\eta(p,s_x)|\le2\prod_xe^{-\min\{1,ps_x\}}=2e^{-\mu_p(s_x)}.$$

Substituting the above into (14) gives (13).

Based on (13), we want to prove that the strategy for assigning labels is a good one. First we prove that large sets β do not contribute much to the left-hand side of the sum in (13). Define

$$K=p^{-1}(\varepsilon^{-1}2^{2k+4}(4k+8+2\log\varepsilon^{-1}))^{1/c}.$$

We have the following lemma.

LEMMA 4.8. *We have*

$$\mathbf{E}\left[\sum_{\pi(\beta)\cap\pi(\beta')\neq\emptyset,|\beta|\ge K}2|\hat{F}_\beta\hat{G}_{\beta'}|e^{-\mu_p(\beta)/2}\right]\le\varepsilon/4.$$

Proof. By property (iv) of Theorem 3.1, we have that the probability that $\mu_p(\beta)\le(4k+8+2\log\varepsilon^{-1})$ is at most $\varepsilon2^{-(2k+4)}$. A similar chain of inequalities to (10) shows

that $\sum |\hat{G}_{\beta'}| \le 2^k$. The sum in the lemma can hence be estimated as

$$\begin{aligned} 2^{k+1} \sum_{|\beta|\ge K} |\hat{F}_\beta| \mathop{\mathbf{E}}_u[e^{-\mu_p(\beta)/2}] &\le 2^{k+1} \sum_{|\beta|\ge K} |\hat{F}_\beta| \big(2^{-(2k+4)}\varepsilon + e^{-(2k+4+\log \varepsilon^{-1})}\big) \\ &\le 2^{2k+1}(2^{-(2k+4)}\varepsilon + 2^{-(2k+4)}\varepsilon) \\ &\le \varepsilon/4, \end{aligned}$$

and the lemma follows. □

By the same argument applied to β' of size at least K, together with (13), we get

$$\mathbf{E}\left[\sum_{\pi(\beta)\cap\pi(\beta')\neq\emptyset, |\beta|,|\beta'|\le K} 2|\hat{F}_\beta \hat{G}_{\beta'}|\right] \ge \varepsilon/2. \tag{16}$$

We now relate to the probability of success of our strategy for assigning labels. From (11) we know this quantity is at least

$$\begin{aligned} &\mathop{\mathbf{E}}_{u,w,w'}\left[\sum_{\beta,\beta':\pi_1(\beta)\cap\pi_2(\beta')\neq\emptyset} \frac{2^{-2k}}{|\beta|\cdot|\beta'|}|\hat{F}_\beta||\hat{G}_{\beta'}|\right] \\ &\quad\ge \mathop{\mathbf{E}}_{u,w,w'}\left[\sum_{\pi_1(\beta)\cap\pi_2(\beta')\neq\emptyset, |\beta|,|\beta'|\le K} \frac{2^{-2k}}{K^2}|\hat{F}_\beta||\hat{G}_{\beta'}|\right] \\ &\quad\ge \frac{\varepsilon 2^{-(2k+2)}}{K^2}, \end{aligned}$$

where the last inequality uses (16). (It is easy to convert this randomized strategy for assigning labels to a deterministic one that does equally well.) The dominating factor in the expression is the term $p^{-O(1)}$ (from the definition of K), which can be calculated to be $\gamma^{O(\gamma^{-1})}$, and the proof of Lemma 4.1 is complete. □

4.3.1. Comparison to previous proof of Theorem 4.4. We point out that the conference version of this paper [15] contained a different proof of Theorem 4.4. The current proof is significantly simpler, and, furthermore, it is only a minor adjustment of similar proofs in [17]. The key observation to make the current proof possible is the insight that we should treat the terms of (7) in the collections given by $B^T(g_1, g_2)C^T(h_1, h_2)$, as it does not seem possible to handle them one by one in an efficient manner. The previous proof did not make this observation explicitly and ended up being significantly more complicated. This "simplicity" in turn has already enabled some further progress on the hypergraph coloring problem; in particular, using this style of analysis, Khot [21] shows a better superconstant hardness for a-colorable 4-uniform hypergraphs for $a \ge 7$.

4.3.2. Subsequent related work. In a very recent work, Holmerin [18] showed that the vertex cover problem considered on 4-uniform hypergraphs is NP-hard to approximate within a factor of $(2-\varepsilon)$ for arbitrary $\varepsilon > 0$. (A subset S of vertices of a hypergraph H is said to be a vertex cover if every hyperedge of H intersects S.) He proves this by modifying the soundness analysis of Håstad's 4-set splitting verifier (which is also the verifier we use in section 4) to show that any proof which sets only a fraction ε of bits to -1 will cause some 4-tuple tested by the verifier to consist of only 1's. This in turn shows that, for every constant $\varepsilon > 0$, given a 2-colorable

4-uniform hypergraph, it is NP-hard to find an independent set that consists of a fraction ε of vertices. Note that this result is stronger, as a small independent set implies a large chromatic number, and it thus immediately implies the hardness of coloring such a 2-colorable 4-uniform hypergraph with $1/\varepsilon$ colors, and hence our main result (Theorem 4.4). We stress that the verifier in Holmerin's paper is the same as the one in this paper; however, the analysis in [18] obtains our result without directly referring to covering complexity.

Acknowledgments. We would like to thank the anonymous referees and Oded Goldreich for useful comments on the presentation of the paper.

PHASE CHANGE OF LIMIT LAWS IN THE QUICKSORT RECURRENCE UNDER VARYING TOLL FUNCTIONS*

HSIEN-KUEI HWANG† AND RALPH NEININGER‡

Abstract. We characterize all limit laws of the quicksort-type random variables defined recursively by $\mathcal{L}(X_n) = \mathcal{L}(X_{I_n} + X^*_{n-1-I_n} + T_n)$ when the "toll function" T_n varies and satisfies general conditions, where $(X_n), (X^*_n), (I_n, T_n)$ are independent, I_n is uniformly distributed over $\{0, \dots, n-1\}$, and $\mathcal{L}(X_n) = \mathcal{L}(X^*_n)$. When the "toll function" T_n (cost needed to partition the original problem into smaller subproblems) is small (roughly $\limsup_{n\to\infty} \log E(T_n)/\log n \le 1/2$), X_n is asymptotically normally distributed; nonnormal limit laws emerge when T_n becomes larger. We give many new examples ranging from the number of exchanges in quicksort to sorting on a broadcast communication model, from an in-situ permutation algorithm to tree traversal algorithms, etc.

Key words. quicksort, binary search trees, analysis of algorithms, limit distribution, method of moments, contraction method

1. Quicksort recurrence.

Quicksort, invented by Hoare [37], is one of the most widely used general-purpose sorting algorithms and was selected to be among the top ten most influential algorithms in science and engineering in the 20th century; see JaJa [41]. For more information on the practical implementation and recent development of quicksort, see, for example, [5, 49, 75]. Assume that the input comes from a sequence of independent and identically distributed random variables with a common continuous distribution, the cost measures, say, X_n, on quicksort can generally be described by $X_0 = 0$, and, for $n \ge 1$,

$$X_n \stackrel{d}{=} X_{I_n} + X^*_{n-1-I_n} + T_n, \tag{1}$$

where $(X_n), (X^*_n), (T_n, I_n)$ are independent, $X_n \stackrel{d}{=} X^*_n$, and I_n is uniformly distributed over $\{0, \dots, n-1\}$. Here the symbol $\stackrel{d}{=}$ denotes equivalence in distribution, and T_n is either a deterministic function of n or a random variable depending on I_n or not. Throughout this paper, we call T_n the *toll function*. Note that this description implicitly assumes that the randomness is preserved for each subfile after partitioning, a property enjoyed by many partitioning schemes but easily violated if carelessly implemented; see Sedgewick [71] for a detailed discussion. Our aim in this paper is to develop a distribution theory for X_n based on the stochastic behavior of T_n.

The motivation of such a study is multifold. First, the model is simple yet prototypical of many sophisticated divide-and-conquer schemes. Viewing this recurrence

from an equally important binary search tree perspective, we can study a large number of extensions and variants (see Devroye [19] and Gonnet and Baeza-Yates [31]). Second, the inherent phase change of the limit laws from normal to nonnormal is a new, interesting phenomenon, which should also occur in many other structures. Third, how sensitive is the limit law of the cost with respect to the toll function? For such a simple structure, a certain "robustness" is expected. Also, the extent to which the normal law persists is helpful in giving a deeper understanding of the associated algorithms; roughly, the variance is increasing as the toll function grows, and the algorithms become less useful in practice if the variance is too large. Fourth, a complete characterization of the limit law under varying toll functions is still lacking in the literature. Fifth, the diverse examples we collected were the catalysts that stimulated our study.

The most studied special case is $T_n = n + O(1)$, which corresponds to the number of comparisons used by quicksort to sort a random input or, equivalently, to the total path length of a random binary search tree. It is known that

$$\frac{X_n - E(X_n)}{n} \xrightarrow{d} Y,$$

where "$\xrightarrow{d}$" denotes convergence in distribution. Here Y satisfies

$$Y \stackrel{d}{=} UY + (1-U)Y^* + 2U\log U + 2(1-U)\log(1-U) + 1, \tag{2}$$

where $Y \stackrel{d}{=} Y^*$, U is a uniform random variable over the unit interval, and Y, Y^*, and U are independent; see Rösler [66], Régnier [64], and Fill and Janson [26].

Other known cases leading to a normal limit law are

- the number of leaves in a random binary search tree for which $T_n = \delta_{n1}$, the Kronecker symbol (see Devroye [18, 20] and Flajolet, Gourdon, and Martínez [28]);
- the log-product of subtree sizes for which $T_n = \log n$ (see Fill [25]);
- the number of occurrences of any fixed pattern with T_n equal to the probability of the pattern when n is equal to the size of the pattern (see Flajolet, Gourdon, and Martínez [28]);
- the number of occurrence of subtrees of a given fixed size (see Aldous [1] and Devroye [18, 20]);
- the number of nodes whose subtree sizes are larger than a given page size $b \geq 1$ (see Flajolet, Gourdon, and Martínez [28]).

The case when $T_n = n^\alpha$, where $\alpha > 1$, was studied by Neininger [54]; this case leads again to nonnormal limit laws.

The rough picture reflected by these sporadic examples is that, if the toll function is small such as $\log n$ or $O(1)$, then the limit law of the total cost is normal, and that for the large toll function such as n it is nonnormal. However, when does the limit law of the total cost fail to be normal? We show, under general conditions, that $\sqrt{n}$ is roughly the separating line between normal and nonnormal limit laws; this is intuitively in accordance with the classical law of errors. For, from a structural point of view, if the toll function is small, then the contribution from each subproblem is not dominating so that the normal limit law is quite expected. (In vivid terms, the situation resembles the democratic system.) On the other hand, if the toll function is large, then the main contribution comes from a few subproblems of large size, rendering large variance and thus nonnormal law in the limit (totalitarian system?).

An even more intuitive guess is that, if $\mathrm{Var}(T_n) = o(\mathrm{Var}(X_n))$, then X_n would be asymptotically normally distributed; otherwise, the limit law would be nonnormal. This guess, although false in general, is true for the conditions we consider.

These examples will turn out to be special cases of our general results. We will discuss more new examples in section 6.

We give two different approaches, based, respectively, on the contraction method (see Rösler and Rüschendorf [69]) and the method of moments, to prove the different limit laws for several reasons. First, we propose the two approaches in a consistent and synthetic way so that they are likely to be applied to other algorithmic problems. Indeed, almost all asymptotic properties of the moments are encapsulated into an "asymptotic transfer" lemma, which relates the asymptotic behavior of the toll function T_n to that of the total cost X_n. Such a transfer also clarifies the sensitivity of the total cost with respect to the toll function (see also Devroye [20]). Second, each approach has its own advantages and inconveniences; we give them for more methodological interests. Third, both approaches can more or less be classified as "computational," in contrast to the "probabilistic" approach used by Devroye in the companion paper [20].

The contraction method, first introduced by Rösler [66] for the analysis in distribution of the quicksort algorithm (namely, (1) with $T_n = n - 1$), starts from a recursive equation satisfied by the random variable in question. Then one computes the first or the second moments, scales properly, proves that the scaled recurrence stabilizes in the limit, and chooses a suitable probability metric so that the stabilized equation defines a map of measures that is a contraction in this metric and has a unique fixed-point in some space of probability measures. The weak convergence of the scaled random variables to this fixed-point then follows from the contraction properties; see Rösler [67], Rachev and Rüschendorf [62], and Rösler [68] for more information and Rösler and Rüschendorf [69] for a survey. This approach is especially simple if the limiting map has contraction properties in the minimal L_2 metric. In this case, only knowledge of the first moment is required for the application of the method. This property will become clear in the case of "large" toll functions (very roughly, $E(T_n) \gg \sqrt{n}$). For "small" toll functions, the limiting equation necessitates the use of a probability metric that is ideal of order larger than two as well as information on the variance. In either case, a feature of the contraction method is that the dependence between T_n and I_n can be succinctly handled. For other applications of the contraction method, see [17, 50, 52, 56].

The method of moments, one of the most classical ways of deriving limit distributions, has been widely applied to problems in diverse fields (see, for example, Billingsley [8, section 30] and Diaconis [21]). It consists in first computing the mean and variance, properly scaling the random variable, computing by induction the higher moments of the scaled random variable, applying Carleman's criterion to justify the unicity of the limit law, and then concluding the convergence in distribution and of all moments (or convergence in L_p for all $p > 0$) by the Fréchet–Shohat moment convergence theorem (see Loève [44]). While the method of moments is usually used as the "last weapon" for proving limit laws, it does have some advantages: first, it provides more information than weak convergence; second, it is more transparent and self-contained and requires less advanced theory. We systematize the use of this method so that all major tasks boil down to the asymptotic transfer from the toll function to the total cost. Previously, this method was applied by Hennequin in his Ph.D. thesis [36, section IV.4] to characterize the limit laws of his generalized quick-

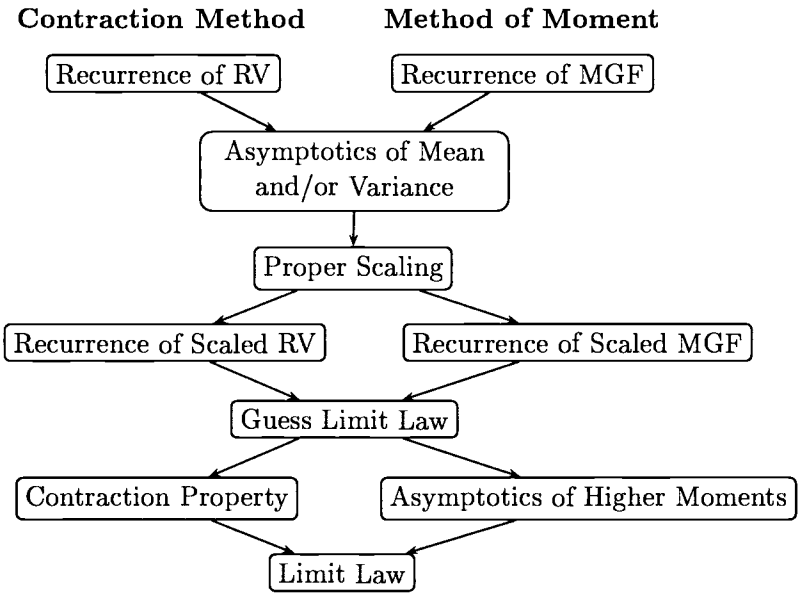

FIG. 1. *Main steps used by the contraction method and the method of moments. Here RV denotes "random variable," and MGF denotes "moment generating function."*

sort (covering, in particular, the quicksort with median-of-$(2k+1)$). His proof is, however, incomplete in that his Abelian lemma [36, p. 79] gives only an estimate inside the unit circle for the generating function in question so that his application of the singularity analysis (see Flajolet and Odlyzko [29]) is not fully justified. We use a different approach, more elementary in nature, to link the asymptotics of the toll function and that of the total cost. For recent applications of the method of moments to similar problems, see Fill [25], Flajolet, Poblete, and Viola [30], Dobrow and Fill [22], and Schachinger [70].

A schematic diagram illustrating the two approaches is given in Figure 1.

Typically, the method of moments requires more assumptions on the moments of the toll function than the contraction method, and the results obtained are stronger. On the other hand, it is also possible to obtain the convergence of all moments by the contraction method based on moment generating functions; see Rösler [66] for details. For another approach to recursive random variables, which we might term the "inductive approximation approach," see Pittel [58] and the references therein. See also [14, 56] for an interesting example for which the method of moments applies but the contraction method fails (the space requirement of random m-ary search trees when $m > 26$).

Viewing our results as bridging the transition from normal to "the quicksort law" (2), we can investigate other kinds of transitions by looking at different recurrences (or algorithms). A closely related recurrence to (1) is the one-sided quicksort recurrence

$$X_n \stackrel{d}{=} X_{I_n} + T_n, \tag{3}$$

for which we can vary the toll function to bridge the normal law and the Dickman

distribution; see [40]. Roughly, our results say that, if the toll function is of logarithmic order, then the limit law is normal; the limit law is nonnormal for larger toll functions; see section 7 for more precise results and examples.

For the class of problems we study in this paper and many others, an important feature distinguishing normal and nonnormal limit laws is the effect of cancellation caused by centering the random variable. Roughly, *the more cancellations of higher moments, the more likely the limit law is normal*. Since our settings cover almost all practical variations of the toll functions, the cancellation effect will be more "visible" in different cases, especially in the method of moments.

We give the main asymptotic transfer results in the next section. Then we prove the phase change of the limit laws in sections 3 and 4. We first give a more straightforward proof by the method of moments under stronger assumptions; then we apply the contraction method under more general settings. Continuities of the variation of the limit laws are discussed in section 5. We discuss many examples in section 6. In particular, the number of exchanges used by quicksort gives an intriguing example of T_n depending on I_n. Section 7 addresses a similar distribution theory for the recurrence (3); this is included because it is closely related.

Notation. Throughout this paper, X_n and T_n are related by (1). We use consistently the following notation: $x_n := E(X_n)$, $t_n := E(T_n)$, $P_n(y) := E(e^{X_n y})$, $Q_n(y) := E(e^{T_n y})$, $H_n := \sum_{1\le k\le n} 1/k$. The symbols U and $N(0,1)$ always represent a uniform $[0,1]$ and a standard normal random variable, respectively. The symbol n_0 denotes a suitable nonnegative integer whose value may vary from one occurrence to another. All unspecified limits (including O, o, $\sim$) are taken to be $n \to \infty$.

Slowly varying functions. A nonnegative function $L(n)$ defined for $n \ge n_0 \ge 0$ and not identically zero is called *slowly varying* if, for all real $\lambda > 0$,

$$L(n) \sim L(\lfloor \lambda n \rfloor) \qquad (n \to \infty).$$

If $n_0 > 0$, we define $L(n) = 0$ for $0 \le n < n_0$. Typical slowly varying functions include any powers of $\log n$ and $\log\log n$, $e^{(\log n)^\alpha (\log\log n)^\beta}$, where $0 \le \alpha, \beta < 1$, and $e^{\log n/\log\log n}$.

2. Mean and asymptotic transfers. We develop the main elementary tools in this section that will be used later. While the same results can be obtained via differential equations and suitable analytic tools, we content ourselves with the elementary approach due to the simplicity of the recurrence. See [15] for more general recurrences of quicksort type.

The mean $x_n := E(X_n)$ satisfies, by (1), $x_0 = 0$ and

$$x_n = \frac{2}{n} \sum_{0\le k<n} x_k + t_n \qquad (n \ge 1), \tag{4}$$

where $t_n := E(T_n)$.

LEMMA 1. *Let $\{b_n\}_{n\ge1}$ be a given sequence, and define a_n by $a_0 := 0$, and*

$$a_n = \frac{2}{n} \sum_{0\le k<n} a_k + b_n \qquad (n \ge 1). \tag{5}$$

Then, for $n \ge 1$,

$$a_n = b_n + 2(n+1) \sum_{1\le k<n} \frac{b_k}{(k+1)(k+2)}. \tag{6}$$

Proof. Take the difference $(n+1)a_n - na_n$, and then iterate the resulting recurrence. □

From this lemma, we obtain the exact solution for $E(X_n)$,

$$E(X_n) = t_n + 2(n+1)\sum_{1\le k<n}\frac{t_k}{(k+1)(k+2)}, \tag{7}$$

for $n \ge 1$; see Devroye [20] for a concrete interpretation of each term on the right-hand side of (7).

The main tool we need is the following lemma linking the asymptotic behavior of the toll function to that of the total cost.

LEMMA 2 (asymptotic transfers). *Assume that a_n satisfies* (5). (i) *The conditions $b_n = o(n)$ and $\sum_k b_k/k^2 < \infty$ are both necessary and sufficient for*

$$a_n \sim \Upsilon[b]n, \qquad \Upsilon[b] := 2\sum_{k\ge1}\frac{b_k}{(k+1)(k+2)};$$

(ii) *if $b_n \sim nL(n)$, then*

$$a_n \sim \begin{cases} \Upsilon[b]n & if\ \ \sum_{k\ge1} L(k)/k < \infty, \\ 2n\sum_{k\le n}\dfrac{L(k)}{k} & if\ \ \sum_{k\le n} L(k)/k \to \infty; \end{cases}$$

(iii) *if $b_n \sim n^\alpha L(n)$, where $\alpha > 1$, then*

$$a_n \sim \frac{\alpha+1}{\alpha-1}\, n^\alpha L(n).$$

Proof. The sufficiency part of (i) follows directly from the exact solution (6). For the necessary part, assume that $a_n \sim cn$ for some constant c. Then, by (4),

$$b_n = a_n - \frac{2}{n}\sum_{0\le k<n} a_k = o(n).$$

From this and (6), we deduce that $c = \Upsilon[b] < \infty$.

Part (ii) also results from (6) and the estimate (see Bingham, Goldie, and Teugels [9, Proposition 1.5.9a])

$$L(n) = o\left(\sum_{k\le n}\frac{L(k)}{k}\right). \tag{8}$$

For part (iii), we have

$$a_n \sim n^\alpha L(n) + 2n\sum_{1\le k\le n} k^{\alpha-2}L(k).$$

However,

$$\sum_{1\le k\le n} k^{\alpha-2}L(k) \sim L(n)\sum_{1\le k\le n} k^{\alpha-2} \sim \frac{n^{\alpha-1}}{\alpha-1}\, L(n);$$

see Proposition 1.5.8 of Bingham, Goldie, and Teugels [9, p. 26]. □

Remarks. 1. If $b_n = o(\sqrt{n})$, then $a_n = \Upsilon[b]n + o(\sqrt{n})$.

2. If $b_n \sim n^\alpha L(n)$, where $\alpha \geq 1/2$, $\alpha \neq 1$, then

$$a_n = \Upsilon[b]n + \frac{\alpha+1}{\alpha-1} n^\alpha L(n)(1+o(1)). \tag{9}$$

3. If we replace the two $\sim$'s for b_n in the lemma by $O(.)$ (or $o(.)$) in cases (ii) and (iii), then the same results hold by replacing $\sim$ for a_n by $O(.)$ (or $o(.)$).

3. Limit laws. I. Method of moments. We study the limit laws of X_n. Briefly, we derive weak convergence and convergence of all moments of X_n (properly normalized) to some Y when estimates for moments of T_n are available. We consider mainly the case when T_n is independent of I_n. The case when T_n depends on I_n requires a straightforward extension of the method; we will discuss briefly the dependence extension for small toll functions; the large toll functions will be discussed via examples in section 6.

Let $P_n(y) := E(e^{X_n y})$. Then from (1) and independence

$$P_n(y) = \frac{Q_n(y)}{n} \sum_{0\leq k<n} P_k(y) P_{n-1-k}(y) \qquad (n \geq 1),$$

with $P_0(y) := 1$, where $Q_n(y) := E(e^{T_n y})$.

Before going further, we need to discard the special case when $T_n = c$ for $n \geq 1$, which yields $X_n = cn$ for $n \geq 1$.

LEMMA 3. *Assume that I_n and T_n are independent for $n \geq 1$. The variance of X_n is zero for $n \geq 1$ iff $T_n = c$ for $n \geq 1$ and for some constant c.*

Proof. Let $\phi_n(y) := e^{-x_n y} P_n(y)$. Then $\phi_n'(0) = 0$, and

$$\phi_n''(0) = \mathrm{Var}(X_n) = \frac{2}{n} \sum_{0\leq k<n} \phi_k''(0) + \psi_n \qquad (n \geq 2),$$

where, defining $\Delta_{n,k} = x_k + x_{n-1-k} - x_n$,

$$\begin{aligned} \psi_n &= Q_n''(0) + \frac{2}{n} t_n \sum_{0\leq k<n} \Delta_{nk} + \frac{1}{n} \sum_{0\leq k<n} \Delta_{nk}^2 \\ &= E(T_n^2) - (E(T_n))^2 + \frac{1}{n} \sum_{0\leq k<n} \Delta_{nk}^2 - \left(\frac{1}{n} \sum_{0\leq k<n} \Delta_{nk} \right)^2. \end{aligned} \tag{10}$$

The assertion of the lemma follows from the Cauchy–Schwarz inequality and induction. □

Define $Y_\alpha = Y_\alpha(T)$ by

$$Y_\alpha \stackrel{d}{=} \begin{cases} U^\alpha Y_\alpha + (1-U)^\alpha Y_\alpha^* + T & \text{if } \alpha > 1/2,\ \alpha \neq 1, \\ UY + (1-U)Y^* + h(T,U) & \text{if } \alpha = 1, \end{cases} \tag{11}$$

where $Y \stackrel{d}{=} Y^*$ and Y, Y^*, T, U are independent and $h(T,U) = 2U\log U + 2(1-U)\log(1-U) + T$. Here T is essentially the limit distribution of T_n/t_n. It will turn out that Y_α is the limit law of X_n after properly normalized. From this defining

equation, it follows that the mth moment of Y_α, denoted by η_m, satisfies, if it exists, the recurrence $\eta_0 = 1$ and, for $m \geq 1$,

$$\eta_m = \begin{cases} \displaystyle\sum_{a+b+c=m} \binom{m}{a,b,c} \tau_a \eta_b \eta_c B(b\alpha+1, c\alpha+1) & \text{if } \alpha > 1/2,\ \alpha \neq 1, \\ \displaystyle\sum_{a+b+c+d=m} \binom{m}{a,b,c,d} \tau_a \eta_b \eta_c \int_0^1 x^{b\alpha}(1-x)^{c\alpha} \Lambda(x)^d \,\mathrm{d}x & \text{if } \alpha = 1, \end{cases} \tag{12}$$

where $\tau_m = E(T^m)$, $\Lambda(x) := 2x\log x + 2(1-x)\log(1-x)$, and $B(u,v)$ denotes the beta integral

$$B(u,v) := \int_0^1 x^{u-1}(1-x)^{v-1}\,\mathrm{d}x = \frac{\Gamma(u)\Gamma(v)}{\Gamma(u+v)} \qquad (u,v>0),$$

Γ being the Gamma function. Also, the moment generating function $\eta(z) := E(e^{Y_\alpha z})$ satisfies

$$\eta(z) = \begin{cases} \tau(z) \int_0^1 \eta(x^\alpha z)\eta((1-x)^\alpha z)\,\mathrm{d}x & \text{if } \alpha > 1/2,\ \alpha \neq 1, \\ \tau(z) \int_0^1 \eta(x^\alpha z)\eta((1-x)^\alpha z) e^{\Lambda(x)z}\,\mathrm{d}x & \text{if } \alpha = 1, \end{cases}$$

provided that both $\eta(z)$ and $\tau(z) := E(e^{Tz})$ exist.

LEMMA 4. *Assume that $\alpha > 0$. If the moment generating function of T exists, then $\{\eta_m\}_m$ characterizes uniquely the distribution $\mathcal{L}(Y_\alpha)$.*

Proof. Assume that the series $\sum_m \tau_m z^m/m!$ converges for $|z| \leq \delta$ for some $\delta > 0$. We show that $|\eta_m| \leq m! K^m$ for a sufficiently large K. By induction, using (12), we have

$$\begin{aligned} \frac{|\eta_m|}{m!} &\leq \frac{m\alpha+1}{m\alpha-1} \sum_{0\leq b<m} \int_0^1 x^{b\alpha} \sum_{0\leq a\leq m-b} \frac{|\tau_a|}{a!} K^{m-a}(1-x)^{(m-a-b)\alpha}\,\mathrm{d}x \\ &\leq K^m \left(\sum_{a\geq 0} \frac{|\tau_a|}{a!}K^{-a}\right) \frac{m\alpha+1}{m\alpha-1} \sum_{0\leq b<m} \int_0^1 x^{b\alpha}(1-x)^{(m-b)\alpha}\,\mathrm{d}x \\ &\leq K^m \left(\sum_{a\geq 0} \frac{|\tau_a|}{a!}K^{-a}\right) \frac{m\alpha+1}{m\alpha-1} \left(\frac{1}{m\alpha+1} + (m-1)\int_0^1 x^\alpha(1-x)^{(m-1)\alpha}\,\mathrm{d}x\right) \\ &= K^m \left(\sum_{a\geq 0} \frac{|\tau_a|}{a!}K^{-a}\right) \left[\frac{1}{m\alpha-1} + \frac{(m\alpha+1)(m-1)\Gamma(\alpha+1)\Gamma(m\alpha+1-\alpha)}{(m\alpha-1)(m\alpha+1)\Gamma(m\alpha+1)}\right]. \end{aligned}$$

Take first K so large that the series $\sum_a |\tau_a| K^{-a}/a!$ converges. Then, since the terms in brackets tend to zero as $m \to \infty$, there exists an $m_0 > 0$ such that

$$\left(\sum_{a\geq 0} \frac{|\tau_a|}{a!}K^{-a}\right) \left[\frac{1}{m\alpha-1} + \frac{(m\alpha+1)(m-1)\Gamma(\alpha+1)\Gamma(m\alpha+1-\alpha)}{(m\alpha-1)(m\alpha+1)\Gamma(m\alpha+1)}\right] < 1$$

for $m > m_0$. On the other hand, $|\eta_m| \leq m! K^m$ for $m \leq m_0$ if K was chosen sufficiently large. We conclude that $|\eta_m| \leq m! K^m$, and the required assertion then follows from Carleman's criterion stating that *the moment sequence $\{\eta_m\}_m$ uniquely characterizes a distribution if* $\sum_m \eta_{2m}^{-1/(2m)} = \infty$. ∎

The condition we impose (that $\tau(z)$ exists) is certainly far from optimal but is sufficient for practical applications.

Define

$$\Upsilon[t] := 2\sum_{k\geq 1}\frac{t_k}{(k+1)(k+2)}.$$

THEOREM 1 (large toll functions). *Let (X_n) be given by (1), where T_n is independent of I_n. If*

$$E(T_n)\sim n^\alpha L(n) \quad\text{and}\quad E\left(\frac{T_n}{t_n}\right)^m \to \tau_m \qquad (m=2,3,\dots), \tag{13}$$

where $\alpha > 1/2$, and $\tau(z) := \sum_m \tau_m z^m/m!$ exists, then

$$\frac{X_n-\xi_n}{n^\alpha L(n)} \xrightarrow{d} Y_\alpha,$$

with convergence of all moments, where $Y_\alpha = Y_\alpha(T)$ is defined as above and

$$\xi_n = \begin{cases} \Upsilon[t]n & \text{if } 1/2<\alpha<1,\\ E(X_n) & \text{if } \alpha=1,\\ 0 & \text{if } \alpha>1. \end{cases}$$

For small toll functions, we distinguish two overlapping cases: (i)

$$t_n = O(\sqrt{n}/(\log n)^{1/2+\varepsilon}) \quad\text{and}\quad E(T_n^m)=O(t_n^m) \tag{14}$$

for $m=2,3,\dots$; and (ii)

$$t_n\sim\sqrt{n}L(n),\quad E(T_n^2)\sim\tau_2 t_n^2,\quad\text{and}\quad E(T_n^m)=O(t_n^m) \tag{15}$$

for $m=3,4,\dots$. More general conditions can be studied, but we content ourselves with these two for simplicity of presentation.

In the first case, define

$$s^2(n) := \sigma^2 n, \qquad \sigma^2 := \Upsilon[\psi] = 2\sum_{k\geq 1}\frac{\psi_k}{(k+1)(k+2)}, \tag{16}$$

where ψ_k is given in (10). In the second case, define $s(n)$ as in (16) if $\sum_{k\geq 1} L^2(k)/k < \infty$ and

$$s^2(n) := \left(\frac{9}{2}\pi - 16 + 2\tau_2\right) n\sum_{k\leq n}\frac{L^2(k)}{k} \tag{17}$$

if $\sum_{k\leq n} L^2(k)/k\to\infty$. Note that $\sigma>0$ by (10) and (16), and the leading constant $\frac{9}{2}\pi - 16 + 2\tau_2$ is positive since $\frac{9}{2}\pi > 14$ and $\tau_2\geq 1$ by $E(T_n^2)\geq t_n^2$.

THEOREM 2 (small toll functions). *Let (X_n) be given by (1), where T_n is independent of I_n. If T_n satisfies either (14) or (15), then*

$$\frac{X_n-\Upsilon[t]n}{s(n)} \xrightarrow{d} N(0,1),$$

with mean and variance satisfying $E(X_n)\sim\Upsilon[t]n$ and $\operatorname{Var}(X_n)\sim s^2(n)$. The limit holds with convergence of all moments.

The proof uses the method of moments and the asymptotic transfer lemma.

3.1. Large toll functions. For simplicity of presentation, we split the proof of Theorem 1 into three cases, $1/2 < \alpha < 1$, $\alpha = 1$, and $\alpha > 1$, although we can easily encapsulate them into one.

Case L1. $1/2 < \alpha < 1$. In this case, $\xi_n = \Upsilon[t]n$, and, by (7),

$$E(X_n) \sim \Upsilon[t]n + \frac{\alpha+1}{\alpha-1} n^\alpha L(n).$$

Shift the mean by $\Upsilon[t]n$ by defining $\Pi_n(y) := P_n(y)e^{-\Upsilon[t]ny}$. Then $\Pi_0(y) = 1$, and

$$\Pi_n(y) = \frac{Q_n(y)e^{-\Upsilon[t]y}}{n} \sum_{0\le k<n} \Pi_k(y)\Pi_{n-1-k}(y) \qquad (n \ge 1). \tag{18}$$

Taking m times derivatives with respect to y on both sides and then substituting $y = 0$, we have, by defining $\Pi_{n,m} := \Pi_n^{(m)}(0) = E((X_n - \Upsilon[t]n)^m)$,

$$\Pi_{n,m} = \frac{2}{n} \sum_{0\le k<n} \Pi_{k,m} + R_{n,m} \qquad (n \ge 1), \tag{19}$$

with $\Pi_{0,m} = 0$, where

$$R_{n,m} := \sum_{\substack{a+b+c+d=m\\ b,c<m}} \binom{m}{a,b,c,d} Q_n^{(a)}(0) \frac{(-\Upsilon[t])^d}{n} \sum_{0\le k<n} \Pi_{k,b}\Pi_{n-1-k,c}.$$

By assumption (13),

$$Q_n^{(m)}(0) = E(T_n^m) \sim \tau_m n^{m\alpha} L^m(n) \qquad (m \ge 1).$$

For convenience, define $\tau_0 = \tau_1 = 1$. We proceed by induction. Assume

$$\Pi_{n,m} \sim g_m n^{m\alpha} L^m(n). \tag{20}$$

This holds true for $m = 1$ by (9) with $g_1 = (\alpha+1)/(\alpha-1)$. By induction and slow variation of $L(n)$, we deduce that, for $m \ge 2$,

$$\begin{aligned}
&R_{n,m}\\
&\sim \sum_{\substack{a+b+c=m\\ b,c<m}} \binom{m}{a,b,c} \tau_a g_b g_c n^{a\alpha-1} L^a(n) \sum_{0\le k<n} k^{b\alpha} L^b(k)(n-1-k)^{c\alpha} L^c(n-1-k)\\
&\sim L^m(n) \sum_{\substack{a+b+c=m\\ b,c<m}} \binom{m}{a,b,c} \tau_a g_b g_c n^{a\alpha-1} \sum_{0\le k<n} k^{b\alpha}(n-1-k)^{c\alpha}\\
&\sim n^{m\alpha} L^m(n) \sum_{\substack{a+b+c=m\\ b,c<m}} \binom{m}{a,b,c} \tau_a g_b g_c B(b\alpha+1, c\alpha+1).
\end{aligned}$$

It follows, by the asymptotic transfer lemma, that

$$\Pi_{n,m} \sim \frac{m\alpha+1}{m\alpha-1} n^{m\alpha} L^m(n) \sum_{\substack{a+b+c=m\\ b,c<m}} \binom{m}{a,b,c} \tau_a g_b g_c B(b\alpha+1, c\alpha+1) \qquad (m \ge 2).$$

Thus, if we define g_m recursively by

$$g_m = \frac{m\alpha+1}{m\alpha-1} \sum_{\substack{a+b+c=m\\ b,c<m}} \binom{m}{a,b,c} \tau_a g_b g_c B(b\alpha+1, c\alpha+1) \qquad (m \ge 2),$$

then (20) holds for all $m \ge 1$. Note that $g_m = \eta_m$ for $m \ge 1$; see (12). We conclude, by the Fréchet–Shohat moment convergence theorem (see [44]) and Lemma 4, that $\{\eta_m\}$ is the sequence of moments of some distribution function and that $(X_n - \Upsilon[t]n)/(n^\alpha L(n))$ converges in distribution to Y_α.

Case L2. $\alpha = 1$. Define this time $\Pi_n(y) := P_n(y)e^{-x_n y}$, where $x_n = E(X_n)$. Then $\Pi_0(y) = 1$, and

$$\Pi_n(y) = \frac{Q_n(y)}{n} \sum_{0\le k<n} \Pi_k(y)\Pi_{n-1-k}(y) e^{\Delta_{n,k}y} \qquad (n \ge 1),$$

where $\Delta_{n,k} = x_k + x_{n-1-k} - x_n$. Observe first, by (7), that

$$\begin{aligned}\Delta_{n,k} = t_k + t_{n-1-k} - t_n &- 2(k+1) \sum_{k\le j<n} \frac{t_j}{(j+1)(j+2)} \\ &- 2(n-k) \sum_{n-k<j<n} \frac{t_j}{(j+1)(j+2)};\end{aligned}$$

from this and $t_n \sim nL(n)$, we deduce that, for $k = \lfloor xn \rfloor$,

$$\Delta_{n,k} \sim \Lambda(x) nL(n), \qquad \Lambda(x) := 2x\log x + 2(1-x)\log(1-x), \tag{21}$$

uniformly for $0 \le x \le 1$.

Write as above $\Pi_{n,m} = \Pi_{n,m}(0)$. Then $\Pi_{n,m}$ satisfies (19) with

$$R_{n,m} := \sum_{\substack{a+b+c+d=m\\ b,c<m}} \binom{m}{a,b,c,d} \frac{Q_n^{(a)}(0)}{n} \sum_{0\le k<n} \Pi_{k,b}\Pi_{n-1-k,c}\Delta_{n,k}^d.$$

Note that $\Pi_{n,1} = 0$. We prove by induction that

$$\Pi_{n,m} \sim g_m n^m L^m(n). \tag{22}$$

The case $m = 1$ is true with $g_1 = 0$. For $m \ge 2$, we have, similarly as above,

$$\begin{aligned} R_{n,m} &\sim \sum_{\substack{a+b+c+d=m\\ b,c<m}} \binom{m}{a,b,c,d} \tau_a g_b g_c n^{a-1} L^a(n) \\ &\qquad \times \sum_{0\le k<n} k^b L^b(k)(n-1-k)^c L^c(n-1-k)\Delta_{n,k}^d \\ &\sim n^m L^m(n) \sum_{\substack{a+b+c+d=m\\ b,c<m}} \binom{m}{a,b,c,d} \tau_a g_b g_c \int_0^1 x^b(1-x)^c \Lambda^d(x)\,\mathrm{d}x. \end{aligned}$$

It follows, by Lemma 2, that (22) holds with

$$g_m = \frac{m+1}{m-1} \sum_{\substack{a+b+c+d=m \\ b,c<m}} \binom{m}{a,b,c,d} \tau_a g_b g_c \int_0^1 x^b (1-x)^c \Lambda^d(x)\,\mathrm{d}x \qquad (m \ge 2).$$

Thus convergence in distribution follows as in Case L1.

Note that $\mathrm{Var}(X_n) \sim g_2 n^2 L^2(n)$, where

$$g_2 = 7 - \frac{2}{3}\pi^2 + 3\mathrm{Var}(T). \tag{23}$$

Case L3. $\alpha > 1$. In this case, no centering is needed since $\xi_n = 0$. We apply mutatis mutandis the same argument in Case L1 for $P_n(y)$. The proof is similar and is omitted here.

3.2. Small toll functions. When t_n is small, namely, $t_n = O(\sqrt{n}L(n))$, $E(X_n)$ is linear, so we center X_n as in Case L1 above by defining $\Pi_n(y) := P_n(y)e^{-\Upsilon[t]ny}$. Write again $\Pi_{n,m} := \Pi_n^{(m)}(0)$. Then $\Pi_n(y)$ satisfies (18) and

$$\Pi_{n,1} = \Pi_n'(0) = t_n - 2n\sum_{j\ge n} t_j j^{-2} + O(1).$$

Variance. By (18), the sequence $\Pi_{n,2}$ satisfies (19) with

$$R_{n,2} = Q_n''(0) - t_n^2 + (t_n - \Upsilon[t])(2\Pi_{n,1} - t_n + \Upsilon[t]) + \frac{2}{n}\sum_{0\le k<n} \Pi_{k,1}\Pi_{n-1-k,1}$$

(the recurrence of $\Pi_{n,1}$ being used to simplify).

Thus, by the asymptotic transfer lemma, if $\sum_k R_{k,2}/k^2 < \infty$, then

$$\mathrm{Var}(X_n) \sim \sigma^2 n, \qquad \sigma^2 := 2\sum_{k\ge 1} \frac{R_{k,2}}{(k+1)(k+2)}. \tag{24}$$

However, the condition $\sum_k R_{k,2}/k^2 < \infty$ is not so transparent. We thus consider two simple overlapping cases.

Case S1. $t_n = O(\sqrt{n}(\log n)^{-1/2-\varepsilon})$. In this case, we have

$$\Pi_{n,1} = O(\sqrt{n}(\log n)^{-1/2-\varepsilon})$$

and, by (14),

$$R_{n,2} = O(n(\log n)^{-1-2\varepsilon});$$

thus

$$\mathrm{Var}(X_n) \sim \sigma^2 n.$$

Case S2. $t_n \sim \sqrt{n}L(n)$. By (9),

$$\Pi_{n,1} \sim -3\sqrt{n}L(n),$$

from which we deduce, using (15), that

$$R_{n,2} \sim \left(\frac{9}{4}\pi - 8 + \tau_2\right) nL^2(n).$$

Applying Lemma 2 yields

$$\mathrm{Var}(X_n) \sim \begin{cases} \sigma^2 n & \text{if } \sum_k L^2(k)/k < \infty, \\ \left(\dfrac{9}{2}\pi - 16 + 2\tau_2\right) n \displaystyle\sum_{k\le n} \frac{L^2(k)}{k} & \text{if } \sum_k L^2(k)/k = \infty. \end{cases}$$

Note that the definition of σ^2 in (24) can be shown to be identical to (16).

Asymptotic normality. For higher moments, we again use (19) but split $R_{n,m}$ into two parts: $R_{n,m} = R^{(1)}_{n,m} + R^{(2)}_{n,m}$, where

$$R^{(1)}_{n,m} := \sum_{1\le b<m} \binom{m}{b} \frac{1}{n} \sum_{0\le k<n} \Pi_{k,b}\Pi_{n-1-k,m-b},$$

$$R^{(2)}_{n,m} := \sum_{\substack{a+b+c+d=m \\ a+d\ge 1 \\ b,c<m}} \binom{m}{a,b,c,d} Q^{(a)}_n \frac{(-\Upsilon[t])^d}{n} \sum_{0\le k<n} \Pi_{k,b}\Pi_{n-1-k,c}.$$

Case S1. $t_n = O(\sqrt{n}(\log n)^{-1/2-\varepsilon})$. Assume that, for $m \ge 1$,

$$\begin{cases} \Pi_{n,2m} \sim g_m n^m, \\ \Pi_{n,2m-1} = o(n^{m-1/2}). \end{cases}$$

This is true for $m = 1$ with $g_1 = \sigma^2$. By induction, we have

$$R^{(2)}_{n,m} = O(n^{m/2}(\log n)^{-1/2-\varepsilon}).$$

The main contribution for even moments comes from $R^{(1)}_{n,m}$.

$$\begin{aligned} R^{(1)}_{n,2m} &\sim \sum_{1\le j<m} \binom{2m}{2j} \frac{1}{n} \sum_{0\le k<n} \Pi_{k,2j}\Pi_{n-1-k,2m-2j} \\ &\sim \sum_{1\le j<m} \binom{2m}{2j} g_j g_{m-j} \frac{1}{n} \sum_{0\le k<n} k^j (n-1-k)^{m-j} \\ &\sim \frac{n^m}{m+1} \sum_{1\le j<m} \frac{\binom{2m}{2j}}{\binom{m}{j}} g_j g_{m-j}. \end{aligned}$$

By Lemma 2,

$$\Pi_{n,2m} \sim \frac{n^m}{m-1} \sum_{1\le j<m} \frac{\binom{2m}{2j}}{\binom{m}{j}} g_j g_{m-j} \qquad (m \ge 2).$$

Thus we take g_m so that $g_1 = \sigma^2$ and

$$g_m = \frac{1}{m-1} \sum_{1\le j<m} \frac{\binom{2m}{2j}}{\binom{m}{j}} g_j g_{m-j} \qquad (m \ge 2).$$

The solution is given by

$$g_m = \frac{(2m)!}{2^m m!}\, \sigma^{2m} \qquad (m \ge 1),$$

which denotes the $2m$th moment of the normal distribution with mean zero and variance σ^2.

Similarly, for $m \geq 2$,

$$R^{(1)}_{n,2m-1} = o(m^{m-1/2}),$$

and thus, by the o-version of Lemma 2,

$$\Pi_{n,2m-1} = o(n^{m-1/2}).$$

The asymptotic normality follows.

Case S2. $t_n \sim \sqrt{n}L(n)$. In this case, noting that $L^2(n)$ is also slowly varying, we have (see (8))

$$Q_n''(0) \sim \tau_2 t_n^2 \sim \tau_2 n L^2(n) = o\left(n \sum_{k \leq n} \frac{L^2(k)}{k}\right).$$

In particular, if $\sum_k L^2(k)/k < \infty$, then $t_n = o(\sqrt{n}\,)$. The proof then follows the same line of argument as in Case S1.

3.3. T_n depends on I_n. In this case, we have $P_0(y) = 1$ and

$$P_n(y) = \frac{1}{n} \sum_{0 \leq k < n} P_k(y) P_{n-1-k}(y) Q_{n,k}(y) \qquad (n \geq 1),$$

where $Q_{n,k}(y)$ is the moment generating function of T_n conditioned on $I_n = k$.

First, Lemma 3 still holds since ψ_n satisfies

$$\psi_n = \frac{1}{n} \sum_{0 \leq k < n} \left(Q''_{n,k}(0) - Q'_{n,k}(0)^2\right) + \frac{1}{n} \sum_{0 \leq k < n} \left(Q'_{n,k}(0) + \Delta_{n,k}\right)^2, \tag{25}$$

and the same argument applies.

A full extension of the limit laws of X_n to this case requires more assumptions on the asymptotic behavior of $Q_{n,k}(y)$. There is, however, a special case for which the extension is trivial: Case S1, namely, when T_n satisfies (14). The asymptotic normality holds without any additional assumptions. Intuitively, this is the case when each toll summand has only limited contribution to the total cost; thus whether T_n depends on I_n or not does not change the "democratic" nature of the problem, rendering the same law of errors to take effect. Case S2 needs one more condition (26), and the extension is also straightforward.

Define $s(n)$ as in (16) with ψ_k replaced by (25) when T_n satisfies (14). In the case when $t_n \sim \sqrt{n}L(n)$, we need, in addition to (15), the following estimate:

$$E(T_n \sqrt{I_n} L(I_n)) + E(T_n \sqrt{n-1-I_n} L(n-1-I_n)) \sim \tau_2' n L^2(n). \tag{26}$$

Define $s(n)$ by

$$s^2(n) := \left(2\tau_2 - 6\tau_2' + \frac{9}{2}\pi\right) n \sum_{k \leq n} \frac{L^2(k)}{k}$$

if $\sum_k L^2(k)/k$ diverges and $s^2(n) := \sigma^2 n$ otherwise.

THEOREM 2′ (small toll functions—T_n dependent on I_n). *Let* (X_n) *be given by* (1). *If* T_n *satisfies either* (14) *or the two estimates* (15) *and* (26), *then*

$$\frac{X_n - \Upsilon[t]n}{s(n)} \xrightarrow{d} N(0,1),$$

with mean and variance satisfying $E(X_n) \sim \Upsilon[t]n$ *and* $\mathrm{Var}(X_n) \sim s^2(n)$. *In either case, convergence of all moments holds.*

The proof of Theorem 2 requires only minor modifications, and the $R_{n,2}$ there should be replaced by

$$\begin{aligned} R_{n,2} = \frac{1}{n}\sum_{0\le k<n} Q''_{n,k}(0) - 2\Upsilon[t]\Pi_{n,1} - \Upsilon[t]^2 \\ + \frac{2}{n}\sum_{0\le k<n} Q'_{n,k}(0)\left(\Pi_{k,1} + \Pi_{n-1-k,1}\right) \\ + \frac{2}{n}\sum_{0\le k<n} \Pi_{k,1}\Pi_{n-1-k,1}. \end{aligned}$$

We leave aside the discussions of large toll functions since (i) such cases can be succinctly incorporated in the settings by the contraction method, (ii) Theorem 2′ covers most practical applications, and (iii) we will describe one such example in section 6.

4. Limit laws. II. Contraction method. We consider the limit laws of X_n using the contraction method in this section. An advantage of this approach is that dependence of T_n on I_n can be easily handled.

4.1. Outline of the method. According to our discussions in the previous section, we first introduce the standardized versions (Y_n) of (X_n) by $Y_0 := 0$ and

$$Y_n := \frac{X_n - x_n}{s(n)} \qquad (n \ge 1),$$

where $s(n) > 0$ is an appropriate scaling to be defined later.

We first sketch the method of proof. The first step is to transform the original recurrence (1) into a modified recurrence for the scaled quantities (Y_n),

$$Y_n \overset{d}{=} A_1^{(n)} Y_{I_n} + A_2^{(n)} Y^*_{n-1-I_n} + b_n \qquad (n \ge 1), \tag{27}$$

where, for $n \ge 1$, $A_1^{(n)} = s(I_n)/s(n)$, $A_2^{(n)} = s(n-1-I_n)/s(n)$, and

$$b_n = \frac{1}{s(n)}\left(x_{I_n} + x_{n-1-I_n} - x_n + T_n\right) =: h_n(T_n, I_n). \tag{28}$$

According to (1), (Y_n), (Y^*_n), and $(A_1^{(n)}, A_2^{(n)}, b_n)$ are independent, and $Y_n \overset{d}{=} Y^*_n$ for all $n \ge 0$. Note that the value $s(0)$ can be chosen arbitrarily since $Y_0 = 0$.

If the coefficients $A_1^{(n)}$, $A_2^{(n)}$, and the additive term b_n converge as $n \to \infty$, say, to A_1, A_2, and b, respectively, and we expect that (Y_n) converges in distribution, then the weak limit Y of (Y_n) should satisfy the limiting equation corresponding to (27):

$$Y \overset{d}{=} A_1 Y + A_2 Y^* + b, \tag{29}$$

where Y, Y^*, and (A_1, A_2, b) are independent and $Y \stackrel{d}{=} Y^*$.

The contraction method then proceeds by showing that a fixed-point equation like (29) has exactly one solution in a certain space of probability measures and that the scaled random variables under consideration converge in distribution to this fixed-point.

Usually, the existence and uniqueness of a fixed-point of the limiting equation in a subspace of probability distributions is shown by endowing the subspace with a metric and by proving that the limiting equation defines a contraction map on this space. Then the existence of a unique fixed-point is implied by Banach's fixed-point theorem in the case of a complete metric or an appropriate substitute in the incomplete case.

In particular, the minimal L_2-metric ℓ_2 is often used, where ℓ_r-metrics are defined on the spaces $\mathcal{M}_r$ of probability measures on the Borel σ-algebra of $\mathbb{R}$ with finite absolute rth moment by

$$\ell_r(\nu, \varrho) := \inf\{\|X - Y\|_r \,:\, X \stackrel{d}{=} \nu, Y \stackrel{d}{=} \varrho\} \qquad (\nu, \varrho \in \mathcal{M}_r)$$

for $r \geq 1$. We denote by $\mathcal{M}_r(0) \subset \mathcal{M}_r$ the subspace of the centered probability measures in $\mathcal{M}_r$. The metric spaces $(\mathcal{M}_r, \ell_r)$ and $(\mathcal{M}_r(0), \ell_r)$ are complete, and convergence in the ℓ_r-metric is equivalent to weak convergence and convergence of the rth absolute moment. For simplicity, we write $\ell_r(X, Y) := \ell_r(\mathcal{L}(X), \mathcal{L}(Y))$. The infimum in the definition of ℓ_r is attained for all $\nu, \varrho \in \mathcal{M}_r$, and (X, Y) are called optimal couplings of ν, ϱ if $\ell_r(\nu, \varrho) = \|X - Y\|_r$; see Bickel and Freedman [7], Rachev [60], and Rachev and Rüschendorf [63] for more properties of the minimal L_r-metric.

The existence of a unique fixed-point $\mathcal{L}(Y)$ in $\mathcal{M}_2(0)$ for (29) and the convergence in ℓ_2 of (Y_n) given by (27) to Y holds particularly if the following properties are satisfied (see Rösler [68]):

(a) $E(b_n) = E(b) = 0, \quad E(b^2) < \infty$.
(b) $\|(A_1^{(n)}, A_2^{(n)}, b_n) - (A_1, A_2, b)\|_2 \to 0$.
(c) $E(A_1^2) + E(A_2^2) < 1$.
(d) For all $n_1 \in \mathbb{N}$, $E[\mathbf{1}_{\{I_n \leq n_1\}}(A_1^{(n)})^2] + E[\mathbf{1}_{\{n-1-I_n \leq n_1\}}(A_2^{(n)})^2] \to 0$.

This is the line we will follow for large toll functions T_n. In the case of small toll functions, we will end up with a well-known limiting equation that is not a contraction on $(\mathcal{M}_2(0), \ell_2)$ and has the normal distributions as solutions. In this case, asymptotic normality will be derived by a change of the metric as used in Rachev and Rüschendorf [62]. The metric used later is ideal of order larger than two, which implies the contraction properties of the limiting equation with respect to this metric on the appropriate space.

4.2. Large toll functions. Assume that

$$E(T_n) \sim n^\alpha L(n) \quad \text{and} \quad \left(\frac{T_n}{E(T_n)}, \frac{I_n}{n}\right) \xrightarrow{L_2} (T, U),$$

where $\alpha > 1/2$, $L(n)$ is slowly varying, and T is square-integrable. In particular, T_n may depend on I_n, and T may depend on U. For our applications to quicksort and binary search trees, this U comes up (essentially) as the first partitioning element of quicksort (or the root of the associated binary search tree). Therefore, I_n has, conditioned on $U = u$, the binomial $B(n-1, u)$ distribution, and $I_n/n \to U$ holds in L_p for all $p > 0$.

For the scaling factor, we assume at the moment that the variance of X_n admits an expansion of the form

$$\operatorname{Var}(X_n) \sim \sigma^2 n^{2\alpha} L^2(n),$$

where $\sigma = \sigma(\alpha, (T, U))$ is a positive constant given later in Corollary 1. This will later turn out to be true (up to degenerate cases). Therefore, we use the scaling $s(n) := n^\alpha L(n)$ and define $Y_0 := 0$ and

$$Y_n := \frac{X_n - x_n}{n^\alpha L(n)} \qquad (n \geq 1).$$

Note that the initial values of L have to be chosen such that $L(n) > 0$ for all $n \geq 1$. We have, for $n \geq 1$,

$$\begin{aligned} Y_n \stackrel{d}{=} \left(\frac{I_n}{n}\right)^\alpha \frac{L(I_n)}{L(n)} Y_{I_n} + \left(\frac{n-1-I_n}{n}\right)^\alpha \frac{L(n-1-I_n)}{L(n)} Y^*_{n-1-I_n} \\ + h_n(\alpha, (T_n, I_n)), \end{aligned} \tag{30}$$

where $h_n(\alpha, (T_n, I_n)) := (x_{I_n} + x_{n-1-I_n} - x_n + T_n)/(n^\alpha L(n))$.

Observe that our formal L_2-convergence assumption on I_n/n is equivalent to $I_n/n \to U$ in L_p for all $p \geq 0$. Using this and the estimate

$$\frac{L(I_n)}{L(n)} \xrightarrow{L_2} 1,$$

we obtain

$$\begin{aligned} \left\| \left(\frac{I_n}{n}\right)^\alpha \frac{L(I_n)}{L(n)} - U^\alpha \right\|_2 &\leq \left\| \left(\frac{I_n}{n}\right)^\alpha - U^\alpha \right\|_2 + \left\| \left(\frac{I_n}{n}\right)^\alpha \left(\frac{L(I_n)}{L(n)} - 1\right) \right\|_2 \\ &= o(1) + \left\| \frac{L(I_n)}{L(n)} - 1 \right\|_2 \to 0. \end{aligned} \tag{31}$$

Analogously,

$$\left\| \left(\frac{n-1-I_n}{n}\right)^\alpha \frac{L(n-1-I_n)}{L(n)} - (1-U)^\alpha \right\|_2 \to 0.$$

Finally, $h_n(\alpha, (T_n, I_n))$ also converges:

$$h_n(\alpha, (T_n, I_n)) \stackrel{L_2}{\to} h(\alpha, (T, U)), \tag{32}$$

where, for $\alpha > 1/2$,

$$h(\alpha, (T, U)) := \begin{cases} \dfrac{\alpha+1}{\alpha-1}(U^\alpha + (1-U)^\alpha - 1) + T & \text{if} \quad \alpha \neq 1, \\ 2U \log U + 2(1-U)\log(1-U) + T & \text{if} \quad \alpha = 1. \end{cases} \tag{33}$$

For $\alpha = 1$, (32) is proved by the relation (see (21))

$$\frac{x_{I_n} + x_{n-1-I_n} - x_n}{nL(n)} \xrightarrow{L_2} 2U \log U + 2(1-U)\log(1-U)$$

and our assumption $T_n/t_n \to T$ in L_2. The case $\alpha \neq 1$ is established by using the asymptotic expansions (9) for $1/2 < \alpha < 1$ and Lemma 2 for $\alpha > 1$, respectively:

$$\begin{aligned}
&\frac{1}{n^\alpha L(n)}(x_{I_n} + x_{n-1-I_n} - x_n + T_n)\\
&= \frac{1}{n^\alpha L(n)}\frac{\alpha+1}{\alpha-1}(I_n^\alpha L(I_n) + (n-1-I_n)^\alpha L(n-1-I_n) - n^\alpha L(n) + T_n) + o(1)\\
&\to \frac{\alpha+1}{\alpha-1}(U^\alpha + (1-U)^\alpha - 1) + T \quad \text{in } L_2,
\end{aligned}$$

where $o(1)$ depends on the randomness but the convergence is uniform. This establishes the stabilization of the modified recursion (30) to the limiting equation

$$Y \stackrel{d}{=} U^\alpha Y + (1-U)^\alpha Y^* + h(\alpha,(T,U)). \tag{34}$$

Note that this equation coincides for independent T, U with (11) in the case $\alpha = 1$; for $\alpha > 1/2$, $\alpha \neq 1$, (34) is a translated version of (11) in the sense that Y is a fixed-point of (34) iff $Y + (\alpha+1)/(\alpha-1)$ is a fixed point of (11). This is because, in Theorem 1, the random variable is not centered for $\alpha \neq 1$ by the exact mean so that the mean of Y_α there equals $(\alpha+1)/(\alpha-1)$, while our Y has mean zero.

The limiting equation (34) defines a map $S_{\alpha,(T,U)}$ on $\mathcal{M}_2$:

$$S_{\alpha,(T,U)} : \mathcal{M}_2 \to \mathcal{M}_2, \quad \nu \mapsto \mathcal{L}(U^\alpha Z + (1-U)^\alpha Z^* + h(\alpha,(T,U))), \tag{35}$$

where $Z, Z^*, (T,U)$ are independent, $Z \stackrel{d}{=} Z^* \stackrel{d}{=} \nu$, and $h(\alpha,(T,U))$ is given by (33).

THEOREM 3. *Let (X_n) be given by (1). Assume that*

$$E(T_n) \sim n^\alpha L(n) \quad \textit{and} \quad \left(\frac{T_n}{E(T_n)}, \frac{I_n}{n}\right) \xrightarrow{L_2} (T,U),$$

where $\alpha > 1/2$, and that T is square-integrable. Then

$$\ell_2\left(\frac{X_n - E(X_n)}{n^\alpha L(n)}, Y_{\alpha,(T,U)}\right) \to 0,$$

where $\mathcal{L}(Y_{\alpha,(T,U)})$ is the unique fixed-point in $\mathcal{M}_2(0)$ of the map $S_{\alpha,(T,U)}$ defined in (35).

Proof. First, we show that the restriction of $S_{\alpha,(T,U)}$ to $\mathcal{M}_2(0)$ is a map into $\mathcal{M}_2(0)$. Let $\nu \in \mathcal{M}_2(0)$. Then $S_{\alpha,(T,U)}(\nu)$ has a finite second moment because of independence and the same property of the coefficients. The assumption $T_n/E(T_n) \to T$ in L_2 implies that $E(T) = 1$, and, therefore, $E(h(\alpha,(T,U))) = 0$ for all $\alpha > 1/2$. This implies $E(S_{\alpha,(T,U)}(\nu)) = 0$, and thus $S_{\alpha,(T,U)}(\nu) \in \mathcal{M}_2(0)$.

By Theorem 3 in Rösler [67] or Lemma 1 in Rösler and Rüschendorf [69], $S_{\alpha,(T,U)}$ is Lipschitz continuous on $(\mathcal{M}_2(0), \ell_2)$, where the Lipschitz constant $\operatorname{lip}(S_{\alpha,(T,U)})$ satisfies

$$\operatorname{lip}(S_{\alpha,(T,U)}) \le (E(U^{2\alpha}) + E((1-U)^{2\alpha}))^{1/2}.$$

Since $\alpha > 1/2$, we have $\operatorname{lip}(S_{\alpha,(T,U)}) \le \sqrt{2/(2\alpha+1)} < 1$; thus $S_{\alpha,(T,U)}$ is a contraction on $\mathcal{M}_2(0)$. By Banach's fixed-point theorem, $S_{\alpha,(T,U)}$ has a unique fixed-point $\mathcal{L}(Y_{\alpha,(T,U)})$ in $\mathcal{M}_2(0)$.

By (30) and (34), the standardized variables $Y_n = (X_n - E(X_n))/n^\alpha L(n)$ and $Y_{\alpha,(T,U)}$ satisfy, respectively,

$$Y_n \stackrel{d}{=} A_1^{(n)} Y_{I_n} + A_2^{(n)} Y^*_{n-1-I_n} + b_n$$

and

$$Y_{\alpha,(T,U)} \stackrel{d}{=} A_1 Y_{\alpha,(T,U)} + A_2 Y^*_{\alpha,(T,U)} + b.$$

It remains to check the conditions (a)–(d).

First, by taking expectations in (30) and (34), respectively, we obtain $E(b_n) = E(b) = 0$; also, $E(b^2) < \infty$ since T is square-integrable. Thus (a) is satisfied. Condition (b) is established in (31) and (32), and condition (c) is the contraction property of $S_{\alpha,(T,U)}$. Finally, condition (d) follows from $|s(I_n)/s(n)|, |s(n-1-I_n)/s(n)| < 1$ since

$$\begin{aligned} &E(\mathbf{1}_{\{I_n \le n_1\}}(A_1^{(n)})^2) + E(\mathbf{1}_{\{n-1-I_n \le n_1\}}(A_2^{(n)})^2) \\ &\le P(I_n \le n_1) + P(n-1-I_n \le n_1) \\ &= \frac{2n_1}{n} \to 0 \end{aligned}$$

for all $n_1 \in \mathbb{N}$. We complete the proof by applying Rösler's theorem [68]. □

Note that, if $h(\alpha,(T,U)) = 0$, then the limit distribution $\mathcal{L}(Y_{\alpha,(T,U)})$ is degenerate, namely, $Y_{\alpha,(T,U)} = 0$ almost surely. In this case, more knowledge on the asymptotics of T_n is necessary, and a scaling other than $n^\alpha L(n)$ should be used. (Our limit law yields merely $\mathrm{Var}(X_n) = o(n^\alpha L(n))$.)

COROLLARY 1. *If $h(\alpha,(T,U)) \neq 0$ (see (33)), then the sequence (X_n) of Theorem 3 satisfies*

$$\mathrm{Var}(X_n) \sim \sigma^2 n^{2\alpha} L^2(n),$$

where $\sigma^2 = \sigma^2(\alpha,(T,U))$ is defined by

$$\sigma^2 = \begin{cases} \dfrac{\alpha(\alpha+1)^2 B(\alpha,\alpha) + 2(\alpha^2 - 2\alpha - 1)}{(2\alpha-1)(\alpha-1)^2} + C & \text{if } \alpha \neq 1, \\ 7 - \dfrac{2\pi^2}{3} + C & \text{if } \alpha = 1, \end{cases}$$

with $C = C(\alpha,(T,U))$ given by

$$C = \begin{cases} \dfrac{2\alpha+1}{2\alpha-1}\left(\mathrm{Var}(T) + 2\dfrac{\alpha+1}{\alpha-1} E\left[T(U^\alpha + (1-U)^\alpha)\right] - \dfrac{4}{\alpha-1}\right) & \text{if } \alpha \neq 1, \\ 3(\mathrm{Var}(T) + 4E[T(U\log U + (1-U)\log(1-U))] + 2) & \text{if } \alpha = 1. \end{cases}$$

Proof. By Theorem 3, $\mathrm{Var}(X_n) = \mathrm{Var}(n^\alpha L(n) Y_n) \sim E(Y^2_{\alpha,(T,U)}) n^{2\alpha} L^2(n)$; thus $\sigma^2 = E(Y^2_{\alpha,(T,U)})$. Since $Y_{\alpha,(T,U)}$ solves (34), we deduce, by taking squares and expectations, that

$$E(Y^2_{\alpha,(T,U)}) = \frac{2\alpha+1}{2\alpha-1} E(h^2(\alpha,(T,U))),$$

which leads to the expressions in the corollary. □

If T is independent of U, then $C = (2\alpha+1)\mathrm{Var}(T)/(2\alpha-1)$, which coincides with (23) for $\alpha = 1$. Moreover, $C = 0$ if $T = 1$, which holds particularly if the toll functions (T_n) are all deterministic.

4.3. Small toll functions. In this section, we consider small toll functions by the contraction method, assuming again that T_n and I_n may be dependent. We choose the scaling $s(n) := \sqrt{\mathrm{Var}(X_n)}$. As in the analysis by the method of moments, we consider two cases:

$$t_n = O(\sqrt{n}/(\log n)^{1/2+\epsilon}), \quad E(T_n^2) = O(t_n^2), \quad \text{and} \quad E\left(\frac{T_n}{s(n)}\right)^{2+\delta} \to 0, \tag{36}$$

where $0 < \delta \le 1$; and

$$\begin{cases} t_n \sim \sqrt{n}L(n), \quad E(T_n^2) \sim \tau_2 n L^2(n), \quad E\left(\dfrac{T_n}{s(n)}\right)^{2+\delta} \to 0, \quad \text{and} \\ E(T_n\sqrt{I_n}L(I_n)) + E(T_n\sqrt{n-1-I_n}L(n-1-I_n)) \sim \tau_2' n L^2(n). \end{cases} \tag{37}$$

In particular, if we assume (14) or (15), then (36) or (37) hold, respectively.

We first look for convergence in (27) in order to derive a limiting equation. In the case (36), we have (see (16)) $s(n)^2 \sim \sigma^2 n$; thus

$$A_1^{(n)} = \frac{s(I_n)}{s(n)} \to U^{1/2} \quad \text{in } L_{2+\delta}. \tag{38}$$

Similarly,

$$A_2^{(n)} = \frac{s(n-1-I_n)}{s(n)} \to (1-U)^{1/2} \quad \text{in } L_{2+\delta}. \tag{39}$$

For the additive term in (27), we obtain $(x_{I_n} + x_{n-1-I_n} - x_n)/s(n) \to 0$ in $L_{2+\delta}$ by the expansion $E(X_n) = \Upsilon[t]n + o(\sqrt{n}\,)$. This, together with $T_n/s(n) \to 0$, gives

$$\frac{x_{I_n} + x_{n-1-I_n} - x_n + T_n}{s(n)} \to 0 \quad \text{in } L_{2+\delta}. \tag{40}$$

The recursion (27) for $Y_n = (X_n - E(X_n))/s(n)$ and $Y_n = 0$ if $s(n) = 0$ now leads to the limiting equation

$$Y \stackrel{d}{=} U^{1/2}Y + (1-U)^{1/2}Y^*. \tag{41}$$

The conditions (38)–(40) are also satisfied in the case of (37) using the corresponding expansions for $s(n)$. Briefly, the conditions (38) and (39) are proved by $(\sum_{k\le I_n} L^2(k)/k)/(\sum_{k\le n} L^2(k)/k) \to 1$. For (40), if $\sum_k L^2(k)/k < \infty$, then $L(k) \to 0$, implying that $(x_{I_n} + x_{n-1-I_n} - x_n)/s(n) \to 0$ in $L_{2+\delta}$. If $\sum_k L^2(k)/k = \infty$, the same $L_{2+\delta}$ convergence follows from $L^2(n) = o(\sum_{k\le n} L^2(k)/k)$; see (8).

In all cases, we obtain the limiting equation (41). Therefore, we cannot follow the line as for large toll functions since (41) has no contraction properties on $(\mathcal{M}_2(0), \ell_2)$ and is not a contraction for any ℓ_r-metric. This is well known and is discussed in Rachev and Rüschendorf [62] and Rösler and Rüschendorf [69]. Thus we have to choose a metric that is $(r,+)$-ideal, where $r > 2$, and to refine the work space $\mathcal{M}_2(0)$ in order to obtain contraction properties for (41).

The situation here is similar to the size of random tries discussed in Rachev and Rüschendorf [62]. We obtain weak convergence of (Y_n) to a normal distribution by applying similar arguments; see also Rösler and Rüschendorf [69].

We define, for $r = m + 1/p$ with $m \in \mathbb{N}$ and $p \in [1, \infty)$,

$$\mathcal{F}_r := \{f \in C^{m+1} : \|f^{(m+1)}\|_q \le 1\},$$

where $1/p + 1/q = 1$ and $f^{(m+1)}$ denotes the $(m+1)$st derivative of the function $f : \mathbb{R} \to \mathbb{R}$. Then we will use the metric

$$\mu_r(X, Y) := \sup_{f \in \mathcal{F}_r} |E[f(X) - f(Y)]|,$$

which was introduced and studied in Maejima and Rachev [46]; see also Rachev and Rüschendorf [61].

We briefly state the properties of μ_r, which are used subsequently. The metric μ_r is $(r, +)$-ideal; i.e., $\mu_r(cX, cY) = |c|^r \mu_r(X, Y)$ for $c \neq 0$ and $\mu_r(X + Z, Y + Z) \le \mu_r(X, Y)$ if Z is independent of X, Y. An upper estimate for μ_r in Zolotarev's metric ζ_r and corresponding properties for the metric ζ_r (see Zolotarev [76]) imply that $\mu_r(X, Y) < \infty$ if $E(X^j) = E(Y^j)$ for all $j = 1, \dots, m$ and $E(|X|^r), E(|Y|^r) < \infty$. Convergence in μ_r implies convergence in distribution since a lower estimate in Levy's metric L is valid: $(L(X, Y))^{r+1} \le C(r)\mu_r(X, Y)$ for some constant $C(r) < \infty$. We will also use the fact that convergence in ℓ_r implies convergence in μ_r. This follows from the upper estimate $\mu_r(X, Y) \le C'(r)\kappa_r(X, Y)$ with some constant $C'(r) < \infty$ and the difference pseudomoment κ_r and the fact that κ_r and ℓ_r are topologically equivalent (see Rachev [60, p. 301]).

The following proof of asymptotic normality is based on the approach used in Rachev and Rüschendorf [62] mentioned above. The differences here are that we derive convergence in $\mu_{2+\delta}$ rather than only weak convergence and that the estimate of the additive term $h_n(T_n, I_n)$ is simplified. These improvements are due to the fact that more information on the moments is known in our case.

THEOREM 4. *Let (X_n) be given by* (1). *If T_n satisfies either* (36) *or* (37), *then, for $0 < \delta \le 1$,*

$$\mu_{2+\delta}\left(\frac{X_n - E(X_n)}{\sqrt{\mathrm{Var}(X_n)}}, N(0, 1)\right) \to 0.$$

Proof. Let $r := 2 + \delta$, and denote $Y_n := (X_n - x_n)/s(n)$ if $s(n) = \sqrt{\mathrm{Var}(X_n)} > 0$ and $Y_n := 0$ otherwise. The key idea of the proof is to introduce a mixed quantity that combines the structure of the modified recursion with the normal distribution; see [62] and [69, section 6]. We denote by N, N^* two independent standard normal random variables that are also independent of all other quantities.

Then we define the distributions of our mixtures M_n by $M_n := 0$ if $s(n) = 0$ and, for $s(n) > 0$, by

$$\begin{aligned} M_n &\stackrel{d}{:=} \frac{s(I_n)}{s(n)} N + \frac{s(n-1-I_n)}{s(n)} N^* + h_n(T_n, I_n) \\ &\stackrel{d}{=} \left[\left(\frac{s(I_n)}{s(n)}\right)^2 + \left(\frac{s(n-1-I_n)}{s(n)}\right)^2\right]^{1/2} N + h_n(T_n, I_n), \end{aligned} \tag{42}$$

with $h_n(T_n, I_n)$ given in (28). A comparison with (27) shows that $E(M_n) = 0$, $E(M_n^2) = 1$, and $E|M_n|^r < \infty$ if $s(n) > 0$; thus μ_r-distances between Y_n, M_n,

and $N(0,1)$ are finite. We have $s(n) > 0$ for all n sufficiently large, say, for all $n \geq n_0$. For these n, we estimate

$$\mu_r(Y_n, N(0,1)) \leq \mu_r(Y_n, M_n) + \mu_r(M_n, N(0,1)).$$

By (38) and (39), the factor between the brackets in (42) converges to 1 in L_r; this, together with the L_r-convergence of $h_n(T_n, I_n)$ to 0, yields $\ell_r(M_n, N(0,1)) \to 0$ and, therefore, $\mu_r(M_n, N(0,1)) \to 0$. Here we used the estimates (38)–(40).

For the estimate of the term $\mu_r(Y_n, M_n)$, we have, for $n \geq n_0$,

$$Y_n \stackrel{d}{=} \frac{s(I_n)}{s(n)} Y_{I_n} + \frac{s(n-1-I_n)}{s(n)} Y^*_{I_n} + h_n(T_n, I_n).$$

We denote by λ_n the joint distribution of (T_n, I_n). By the $(r,+)$-ideality of μ_r, we have, for $n \geq n_0$,

$$\begin{aligned}
\mu_r(Y_n, M_n) &= \sup_{f \in \mathcal{F}_r} |E(f(Y_n) - f(M_n))| \\
&= \sup_{f \in \mathcal{F}_r} \left| \int E\left[f\left(\frac{s(k)}{s(n)} Y_k + \frac{s(n-1-k)}{s(n)} Y^*_{n-1-k} + h_n(t,k) \right) \right.\right. \\
&\qquad \left.\left. - f\left(\frac{s(k)}{s(n)} N + \frac{s(n-1-k)}{s(n)} N^* + h_n(t,k) \right) \right] \mathrm{d}\lambda_n(t,k) \right| \\
&\leq \int \mu_r\left(\frac{s(k)}{s(n)} Y_k + \frac{s(n-1-k)}{s(n)} Y^*_{n-1-k} + h_n(t,k), \right. \\
&\qquad \left. \frac{s(k)}{s(n)} N + \frac{s(n-1-k)}{s(n)} N^* + h_n(t,k) \right) \mathrm{d}\lambda_n(t,k) \\
&\leq \frac{1}{n} \sum_{k=0}^{n-1} \left(\mu_r\left(\frac{s(k)}{s(n)} Y_k, \frac{s(k)}{s(n)} N \right) \right. \\
&\qquad \left. + \mu_r\left(\frac{s(n-1-k)}{s(n)} Y^*_{n-1-k}, \frac{s(n-1-k)}{s(n)} N^* \right) \right) \\
&\leq \frac{2}{n} \sum_{k=0}^{n-1} \left(\frac{s(k)}{s(n)} \right)^r \mu_r(Y_k, N).
\end{aligned} \tag{43}$$

Thus we obtain the reduction inequality

$$\mu_r(Y_n, N(0,1)) \leq \frac{2}{n} \sum_{k=0}^{n-1} \left(\frac{s(k)}{s(n)} \right)^r \mu_r(Y_k, N(0,1)) + o(1).$$

By (38) and (39),

$$\frac{2}{n} \sum_{k=0}^{n-1} \left(\frac{s(k)}{s(n)} \right)^r = 2E\left(\frac{s(I_n)}{s(n)} \right)^r \to 2E(U^{r/2}) = \frac{2}{r/2+1} < 1.$$

From this and the reduction inequality, we deduce by a bootstrapping argument (see Rösler [66, p. 94] or Rachev and Rüschendorf [62, p. 786]) that $\mu_r(Y_n, N(0,1)) \to 0$. (First prove that $\mu_r(Y_n, N(0,1))$ remains bounded; then refine the approximation.) □

5. Continuous change of limits. The limit distributions $\mathcal{L}(Y_{\alpha,(T,U)})$ in Theorem 3 are continuous in the parameters $(\alpha,(T,U))$ as $\alpha > 1/2$. This continuity still holds as $\alpha \downarrow 1/2$ in the case of deterministic toll functions and in the random case under appropriate assumptions.

THEOREM 5. *Let $\alpha \to \beta > 1/2$ and $T = T(\alpha) \to V$ in L_2 for a square-integrable V. Then*

$$\ell_2(Y_{\alpha,(T,U)}, Y_{\beta,(V,U)}) \to 0.$$

Let $\alpha \downarrow 1/2$ and $T = T(\alpha)$ satisfy $\|T\|_{2+\delta} = o(\sigma(\alpha,(T,U)))$ as $\alpha \downarrow 1/2$ with $0 < \delta \le 1$. If T is independent of U, then

$$\mu_{2+\delta}\left(\frac{Y_{\alpha,(T,U)}}{\sigma(\alpha,(T,U))}, N(0,1)\right) \to 0.$$

The property still holds if T, U are dependent, provided that (i) *$h(\alpha,(T,U)) \neq 0$ for h given in* (33) *and* (ii) *$\sigma(\alpha,(T,U))$ in Corollary* 1 *is properly divergent.*

Proof (sketch). Consider the special case $\beta = 1$. For $\alpha > 1/2$, we have, by definition,

$$Y_{\alpha,(T,U)} \stackrel{d}{=} U^\alpha Y_{\alpha,(T,U)} + (1-U)^\alpha Y^*_{\alpha,(T,U)} + \frac{\alpha+1}{\alpha-1}(U^\alpha + (1-U)^\alpha - 1) + T,$$
$$Y_{1,(V,U)} \stackrel{d}{=} U Y_{1,(V,U)} + (1-U) Y^*_{1,(V,U)} + 2U\log U + 2(1-U)\log(1-U) + V,$$

where $(Y_{\alpha,(T,U)}, Y_{1,(V,U)})$, $(Y^*_{\alpha,(T,U)}, Y^*_{1,(V,U)})$, (T,U,V) are independent, and the variates $(Y_{\alpha,(T,U)}, Y_{1,(V,U)})$, $(Y^*_{\alpha,(T,U)}, Y^*_{1,(V,U)})$ are optimal couplings of $\mathcal{L}(Y_{\alpha,(T,U)})$ and $\mathcal{L}(Y_{1,(V,U)})$. To match these two fixed-point equations, we use the Taylor expansion

$$x^\alpha = x + (\alpha-1)x\log x + \int_1^\alpha (\alpha - y)(x^{y-1} + x^y(\log x)^2)\,\mathrm{d}y, \tag{44}$$

where $x \in (0,1)$ and $\alpha > 0$. Using the representations of $Y_{\alpha,(T,U)}, Y_{1,(V,U)}$ given in the coupled fixed-point equations in the estimate $\ell_2(Y_{\alpha,(T,U)}, Y_{1,(V,U)}) \le \|Y_{\alpha,(T,U)} - Y_{1,(V,U)}\|_2$, we obtain, after tedious calculations, that

$$\ell_2(Y_{\alpha,(T,U)}, Y_{1,(V,U)}) \ll \max\{|\alpha-1|, \sqrt{|\alpha-1|\|T-V\|_2}, \|T-V\|_2\} \tag{45}$$

as $\alpha \to 1$ and $T \to V$ in L_2. In particular, we used the expansion

$$B(\alpha,\alpha) = 1 - 2(\alpha-1) + (4-\pi^2/6)(\alpha-1)^2 + O((\alpha-1)^3) \tag{46}$$

to derive $\sigma(\alpha,(T,U)) \to \sigma(1,(V,U))$ as $\alpha \to 1$ and $T \to V$ in L_2. This implies the assertion for $\beta = 1$. The general case $\beta > 1/2$ can be treated by the same approach and is indeed simpler since the expansions (44) and (46) are not needed.

For the second part, we denote $r := 2 + \delta$ and $Z_{\alpha,(T,U)} := Y_{\alpha,(T,U)}/\sigma(\alpha,(T,U))$. These rescaled quantities satisfy the fixed-point equation

$$Z_{\alpha,(T,U)} \stackrel{d}{=} U^\alpha Z_{\alpha,(T,U)} + (1-U)^\alpha Z^*_{\alpha,(T,U)} + \frac{1}{\sigma(\alpha,(T,U))}\left[\frac{\alpha+1}{\alpha-1}(U^\alpha + (1-U)^\alpha - 1) + T\right],$$

where $Z_{\alpha,(T,U)}$, $Z^*_{\alpha,(T,U)}$, (U,T) are independent and $Z_{\alpha,(T,U)} \stackrel{d}{=} Z^*_{\alpha,(T,U)}$. We denote by N, N^* two independent standard normal distributed random variables independent of the other quantities. Then

$$N(0,1) \stackrel{d}{=} U^{1/2}N + (1-U)^{1/2}N^*.$$

Moreover, we define, similarly to (42), the mixtures

$$M_{\alpha,(T,U)} \stackrel{d}{=} U^\alpha N + (1-U)^\alpha N^* + \frac{1}{\sigma(\alpha,(T,U))}\left[\frac{\alpha+1}{\alpha-1}(U^\alpha + (1-U)^\alpha - 1) + T\right].$$

Then $E(M_{\alpha,(T,U)}) = 0$, $E(M^2_{\alpha,(T,U)}) = 1$, and $E|M_{\alpha,(T,U)}|^r < \infty$; thus the μ_r distances between $Z_{\alpha,(T,U)}$, $N(0,1)$, and $M_{\alpha,(T,U)}$ are finite. It follows that

$$\mu_r(Z_{\alpha,(T,U)}, N(0,1)) \le \mu_r(Z_{\alpha,(T,U)}, M_{\alpha,(T,U)}) + \mu_r(M_{\alpha,(T,U)}, N(0,1)).$$

A calculation similar to (43) implies, for $\alpha > 1/2$, that

$$\begin{aligned}\mu_r(Z_{\alpha,(T,U)}, M_{\alpha,(T,U)}) &\le 2E(U^{r\alpha})\mu_r(Z_{\alpha,(T,U)}, N(0,1)) \\ &\le \frac{2}{1+r/2}\mu_r(Z_{\alpha,(T,U)}, N(0,1)).\end{aligned}$$

Note that the assumptions (i) and (ii) for the dependent case are also satisfied in the case when T and U are independent (see Corollary 1). The asymptotic normality for dependent and independent cases can be derived under conditions (i) and (ii) by proving $\mu_r(M_{\alpha,(T,U)}, N(0,1)) = o(1)$ as $\alpha \downarrow 1/2$. This follows from the convergence in ℓ_r, which is obtained using the fixed-point equations for $N(0,1)$, $M_{\alpha,(T,U)}$, $\|T\|_r = o(\sigma(\alpha,(T,U)))$ and that $\sigma(\alpha,(T,U))$ is properly divergent, giving

$$\begin{aligned}&\ell_r(M_{\alpha,(T,U)}, N(0,1)) \\ &\le 2\,\|U^{1/2} - U^\alpha\|_r \|N\|_r \\ &\quad + \frac{1}{\sigma(\alpha,(T,U))}\left[\left\|\frac{\alpha+1}{\alpha-1}(U^\alpha + (1-U)^\alpha - 1)\right\|_r + \|T\|_r\right],\end{aligned}$$

which tends to zero as $\alpha \downarrow 1/2$ under our assumptions. It follows that

$$\mu_r(Z_{\alpha,(T,U)}, N(0,1)) \le \frac{2}{1+r/2}\mu_r(Z_{\alpha,(T,U)}, N(0,1)) + o(1);$$

thus $2/(1+r/2) < 1$ implies $\mu_r(Z_{\alpha,(T,U)}, N(0,1)) \to 0$. □

Note that, in the case $\alpha \downarrow 1/2$ and $T = 1$, which holds especially for deterministic toll functions, all conditions of the theorem are satisfied.

We may endow $(1/2,\infty) \times L_2$ with the metric $d((\alpha,T),(\beta,V)) := |\alpha - \beta| + \|T - V\|_2$. Then, for fixed U, the map $Y : (1/2,\infty) \times L_2 \to \mathcal{M}_2(0)$, $(\alpha,T) \mapsto \mathcal{L}(Y_{\alpha,(T,U)})$ is locally Lipschitz continuous with respect to d and ℓ_2. This follows by making all the constants explicit in the estimate (45) and in the corresponding one for general $\beta > 1/2$.

6. Examples. In this section, we discuss many examples, most of which are new.

The number of exchanges of quicksort. The number of exchanges used by quicksort satisfies (1) with T_n dependent on I_n. While Theorem 1 does not apply, its proof does. The starting point is the recurrence $P_0(y) = 1$ and, for $n \geq 1$,

$$P_n(y) = \frac{1}{n} \sum_{0 \leq k < n} P_k(y) P_{n-1-k}(y) \sum_{0 \leq j \leq \min\{k, n-1-k\}} \pi_{n,k,j} e^{jy},$$

where $\pi_{n,k,j}$ denotes the probability that there are exactly j exchanges when the rank of the pivot element is $k+1$ so that (see Sedgewick [71, p. 55])

$$\pi_{n,k,j} = \frac{\binom{k}{j}\binom{n-1-k}{j}}{\binom{n-1}{k}}. \tag{47}$$

Note that the exact number of exchanges used depends on implementation details, and we count only the essential random part.

Using the identity

$$\sum_{j \geq 1} \pi_{n,k,j} j(j-1)\cdots(j-v+1) = \frac{(n-v-1)!k!(n-1-k)!}{(n-1)!(k-v)!(n-k-1-v)!}, \tag{48}$$

valid for $v = 0, 1, 2, \ldots$ and (7), we easily obtain

$$E(X_n) = \frac{n+1}{3} H_n - \frac{7}{9} n + \frac{1}{18} \qquad (n \geq 2).$$

For higher moments, we proceed as in section 3 ($\alpha = 1$) by defining $\Pi_n(y) := P_n(y) e^{-x_n y}$ and $\Pi_{n,m} := \Pi_n^{(m)}(0)$. Then, by the same approach, we deduce that

$$\Pi_{n,m} \sim g_m n^m \qquad (n \geq 2),$$

where $g_0 = 1$, $g_1 = 0$, and, for $n \geq 2$,

$$g_m = \sum_{a+b+c=m} \binom{m}{a, b, c} g_a g_b \times \int_0^1 x^a (1-x)^b \left(\frac{x}{3} \log x + \frac{1-x}{3} \log(1-x) + x(1-x) \right)^c \, \mathrm{d}x.$$

Thus

$$\frac{X_n - x_n}{n} \xrightarrow{d} Y$$

as well as convergence of all moments, where

$$Y \stackrel{d}{=} UY + (1-U)Y^* + \frac{U}{3} \log U + \frac{1-U}{3} \log(1-U) + U(1-U),$$

with $Y \stackrel{d}{=} Y^*$ and Y, Y^*, U independent.

On the other hand, Theorem 3 applies by establishing

$$\frac{T_n}{n/6} \xrightarrow{L_2} 6U(1-U).$$

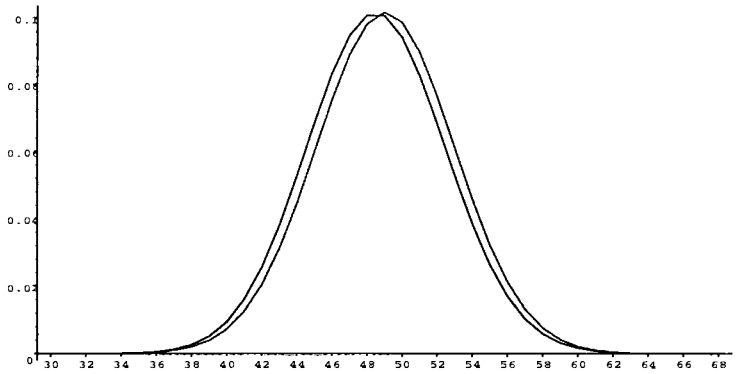

FIG. 2. *The histogram of* $P(X_{60} = k)$ *for* k *from* 30 *to* 68 *and the corresponding normal curve* $e^{-(k-E(X_{60})-1/2)^2/(2\mathrm{Var}(X_{60}))}/\sqrt{2\pi \mathrm{Var}(X_{60})}$. *We shifted the normal density by* 1/2*; otherwise, the two curves will be almost indistinguishable.*

This follows from (48).

In particular, by the recurrence of g_m or by Corollary 1, we obtain $\mathrm{Var}(X_n) \sim (\frac{11}{60} - \frac{\pi^2}{54})n^2$.

Note that, by (48),

$$\begin{aligned} E(T_n^k) &\sim E(T_n(T_n-1)\cdots(T_n-k+1)) \\ &= \frac{k!k!(n-k-1)!}{(2k+1)!(n-2k-1)!} \\ &\sim \frac{k!k!}{(2k+1)!}\, n^k \end{aligned}$$

for $k \geq 1$. Thus T_n/n has in the limit a beta distribution:

$$P\left(\frac{T_n}{n} < x\right) \to 1 - \sqrt{1-4x} \qquad (0 < x < 1/4).$$

Unlike the number of comparisons, which has quadratic worst-case behavior, the number of exchanges is at most of order $n \log n$. Also, it is interesting to note that the histograms of $P(X_n = i)$ are very close to normal curves for n small; see Figure 2. An explanation of this phenomenon is that the leading constant of the variance (as well as g_3) is very small: $\frac{11}{60} - \frac{\pi^2}{54} \approx 0.00056288$. The "nonnormality character" of Y will emerge for large enough n.

The limit law (49) is different from that of the number of comparisons (2); however, the limit distributions are related by their defining fixed-point equations. Indeed, the correlation of the number of comparisons and the number of exchanges is asymptotic to

$$\frac{\sqrt{5}(39-4\pi^2)}{2\sqrt{(21-2\pi^2)(99-10\pi^2)}} \approx -0.864042\ldots.$$

This can be proved by the bivariate limit law of both variates that can be derived by a multivariate extension of the contraction method (see Neininger [53] for details).

Thus *the number of comparisons and the number of exchanges are highly negatively correlated*. Intuitively, when the shape of the corresponding binary search tree is very skewed, few key exchanges are needed; on the other hand, the number of exchanges reaches its maximum when the pivot element is around $n/2$ (see (47)). Roughly, the more "balanced" the permutation, the more exchanges are needed. The situation here is more or less the same when one uses the median-of-$(2t+1)$ quicksort: while the number of comparisons decreases with t, the number of exchanges increases. We might say that we trade off the number of exchanges for the number of comparisons.

Note that the same limit law (2) for $T_n = n + O(1)$ persists for $T_n = n + \omega(n)$, where $\omega(n) = o(n)$ and $\sum_n \omega(n)/n^2 < \infty$; this reflects the "robustness" of the limit laws.

Paged trees. Fix a page (or bucket) size $b \geq 1$. Cut all nodes with subtree sizes $\leq b$. The resulting tree is called the b-index of the tree; see Flajolet, Gourdon, and Martínez [28] and Mahmoud [48]. What is the size of a random b-index? And what is the total path length? Obviously, both random variables satisfy (1) (with different initial conditions). The asymptotic normality of the size was established for fixed b by Flajolet, Gourdon, and Martínez [28] with mean equal to $2(n+1)/(b+2)-1$. The variance is equal to (the expression given in [28] being wrong)

$$2\left(4H_{2b+2} - 4H_{b+1} - \frac{(b+1)(5b+2)}{(2b+3)(b+2)}\right)\frac{n+1}{b+2} \qquad (n \geq 2b+2).$$

Indeed, we can prove that the asymptotic normality holds for $2 \leq b = o(n)$. This does not follow directly from our results but is easily amended by truncating the first b terms in our exact and asymptotic expressions (6) and by applying the same arguments.

If we vary b such that $2 \leq b = o(n)$, then the path length of the b-index gives an interesting example with mean of order n/b, which varies from linear to any function tending to infinity. Thus the limit laws change from nonnormal to normal when b increases.

This variation of path length suggests in turn a variation of quicksort: stop subfiles of size less than or equal to b, where b can vary with n. We can show that the limit law of the total number of comparisons used in the quicksort partitioning stages does not change as long as $b = o(n)$. This images another "robustness" of the limit laws.

Leaves and patterns in binary search trees. Our Theorem 2 can be applied to the number of times a given pattern appears in a random binary search tree; see Devroye [18] and Flajolet, Gourdon, and Martínez [28]. The number of times a subtree of size k appears is also asymptotically normally distributed; see Aldous [1] and Devroye [20]. By the correspondence between increasing trees (or binary recursive trees) and permutations, some patterns on trees like the number of leaves also lead to well-known distributions in random permutations; see Bergeron, Flajolet, and Salvy [6] and Flajolet, Gourdon, and Martínez [28].

Analysis of tree traversal algorithms. Binary search trees can be implemented in several different ways: two-pointers, threaded with or without flag, triply linked (with a pointer to parent), etc.; and the nodes can be traversed in different orders: inorder, preorder, postorder, breadth-first, depth-first, etc.; see [2, 10, 11, 12, 13, 23, 24, 32, 51, 65] and [31]. The analysis of the cost of these algorithms then reduces to the calculation of certain parameters on trees such as the number of nodes with null (or nonnull) left (or right) branches, the number of nodes with both nonnull left and right branches, and the number of nodes that are a left child and whose right branch

is not empty. All these quantities can be systematically analyzed by applying our results; see Brinck and Foo [11] and Brinck [10] for analysis of the mean of some cost measures.

For example, the major cost (number of pointer operations) needed to traverse a threaded binary search tree in preorder and in inorder is essentially given by (neglecting minor parameters)

$$X_n \stackrel{d}{=} X_{I_n} + X^*_{n-1-I_n} + T_{I_n},$$

where

$$Q_n(y) := E(e^{T_n y}) = \prod_{1\le k\le n} \frac{k-1+e^y}{k} \qquad (n \ge 1), \tag{49}$$

essentially the Stirling numbers of the first kind (enumerating the number of records in independent and identically distributed sequences, the number of cycles in random permutations, etc.). The distribution of X_n is asymptotically normal. Likewise, the moment generating function $P_n(y)$ of the cost for postorder traversal satisfies

$$P_n(y) = \frac{e^y}{n} \sum_{0\le k\le n-2} P_k(y) P_{n-1-k}(y) Q_k^2(y) V_k(y) + \frac{e^y}{n} P_{n-1} Q_{n-1}^2(y),$$

where $Q_n(y)$ is defined as in (49) and $V_n(y)$ denotes the moment generating function for the depth of the first node in postorder; see (53). The mean was derived by Brinck [10]. Indeed, the exact forms of these generating functions are immaterial because our results are strong enough to prove the asymptotic normality of the cost within a large range of variation for the toll function; see also section 7 for the asymptotic normality of the depth of the first node in postorder.

Secondary parameters of quicksort. If we always sort smaller files first, then the number of stack pushes and pops used to sort a random input satisfies $P_n(y) = 1$ for $n \le 4$ and

$$P_n(y) = \frac{e^y}{n} \sum_{0\le k<n} P_k(y) P_{n-1-k}(y) + \frac{2}{n}(1-e^y)\left(P_{n-1}(y) + P_{n-2}(y)\right) \qquad (n \ge 5).$$

Our results apply, and the number of stack pushes is asymptotically normally distributed. If we stop sorting subfiles of sizes less than a certain given value and then use a final insertionsort to complete the sorting, then the number of comparisons and exchanges used by the insertionsort is again normal in the limit. For more information on analysis of quicksort, see Sedgewick [71], Hennequin [35], and Chern and Hwang [14].

Sorting on a broadcast communication model. The model consists of n processors sharing a common channel for communications, allowing one processor to broadcast at each time epoch. To each processor a certain number is attached. (The numbers are distinct.) The sorting problem is to order these numbers in increasing order. The algorithm proposed in Shiau and Yang [72] is as follows. Select first a loser (a preferable term being "a leader") by the coin-flipping procedure in Prodinger [59]. Split the processors into two subsets containing, respectively, smaller and larger numbers; then sort recursively by the same approach; see Shiau and Yang [72] for details. The number of rounds of coin-tossings (in order to resolve the conflict for using the channel)

satisfies (1) with T_n given by ($Q_n(y) := E(e^{T_n y})$)

$$Q_n(y) = \frac{e^y}{2^n} \sum_{1 \le k \le n} \binom{n}{k} Q_k(y) + \frac{e^y}{2^n} Q_n(y) \qquad (n \ge 2),$$

with $Q_1(y) = 1$. The mean of X_n is studied by Grabner and Prodinger [33]. By the results of Fill, Mahmoud, and Szpankowski [27], our results apply, and X_n is asymptotically normal.

In-situ permutation algorithm. The problem in question is as follows: Given a sequence of numbers $\{a_1, \dots, a_n\}$ and a permutation $\{\pi_1, \dots \pi_n\}$, output $\{a_{\pi_1}, \dots, a_{\pi_n}\}$ using at most $O(1)$ space. An algorithm was given by MacLeod [45] and analyzed by Knuth [43]. Kirschenhofer, Prodinger, and Tichy [42] showed that the major cost X_n of the algorithm satisfies the quicksort recurrence (1) with $T_n = I_n$. They extended Knuth's analysis of the first two moments by computing the asymptotics of all moments (noncentered).

Theorem 3 applies, and we obtain

$$\frac{X_n - E(X_n)}{n} \xrightarrow{d} Y, \tag{50}$$

where $Y \stackrel{d}{=} UY + (1-U)Y^* + U \log U + (1-U)\log(1-U) + U$. Note that

$$E(X_n) \sim n \log n, \qquad \operatorname{Var}(X_n) \sim \sigma^2(1, (2U, U))\, n^2 = \left(2 - \frac{\pi^2}{6}\right) n^2.$$

We can indeed prove convergence of all moments using the same approach in section 3 starting from $P_0(y) = 1$ and

$$P_n(y) = \frac{1}{n} \sum_{0 \le k < n} e^{ky} P_k(y) P_{n-1-k}(y) \qquad (n \ge 1). \tag{51}$$

Note that X_n can also be viewed as the *left path length* of random binary search trees (by counting only left branches). In general, one may consider *weighted path length* by assigning weight α to each left branch and β to each right branch in a random binary search tree; our tools apply.

Recursive trees. Interestingly, the limit distribution (50) also appears as the limit distribution of the total path length of random recursive trees; see Dobrow and Fill [22] and Mahmoud [47]. This can be explained in two ways. First, by a well-known transformation from multiway trees to binary trees (see Cormen, Leiserson, and Rivest [16]), we can actually prove a bijection between the total path length of a recursive tree of n nodes and the left path length of a random binary search tree of $n-1$ nodes, the latter having the same distribution as the major cost of the in-situ permutation algorithm.

Second, the underlying recurrence for total path length of recursive trees is almost identical to (51)

$$X_n \stackrel{d}{=} X_{J_n} + X_{n-J_n} + J_n,$$

where J_n is uniformly distributed over $\{1, 2, \dots, n-1\}$.

This connection makes it possible to derive the limit laws of other parameters on recursive trees by our approaches (up to minor modifications) like the number of

leaves, the number of nodes with a specified degree, etc.; see Smythe and Mahmoud [73] for a survey of recursive trees. Note that the number of leaves satisfies $P_0(y) = 1$, $P_1(y) = e^y$, and

$$P_n(y) = \frac{1}{n-1} \sum_{1\le k\le n-2} P_k(y)P_{n-1-k}(y) + \frac{P_{n-1}(y)}{n-1} \qquad (n \ge 2),$$

the underlying distribution being essentially the Eulerian numbers; see Bergeron, Flajolet, and Salvy [6].

Superlinear toll functions. The Wiener index of a graph is defined as the sum of the distances between all pairs of nodes. This index plays an important role in connection with physico-chemical properties (like boiling point, heat of information, crystal defects) of chemical structures; see Gutman, Klavzar, and Mohar [34] and Trinajstić [74]. The Wiener index of a random binary search tree satisfies, neglecting the independence assumptions, (1) with

$$T_n = 2I_n(n-1-I_n) + Z_n + I_n Z^*_{n-1-I_n} + (n-1-I_n)Z'_{I_n},$$

where Z_n denotes the total path length, which satisfies (1) with $T_n = n-1$. The mean is easily seen to be

$$E(X_n) = 2n^2H_n - 6n^2 + 8nH_n - 10n + 6H_n \qquad (n \ge 1).$$

However, our results fail since Z_n and X_n are not independent. The variance satisfies $\mathrm{Var}(X_n) \sim (\frac{20}{3} - \frac{2}{3}\pi^2)n^4$, and the characterization of the limit law of X_n necessitates a multivariate extension of our approach; see Neininger [55] for details.

Other examples. For other examples of the quicksort type leading to an asymptotically normal distribution, see Fill [25], Hofri and Shachnai [38], Panholzer and Prodinger [57], and Chern, Hwang, and Tsai [15].

7. One-sided quicksort recurrence. In this section, we briefly discuss the recurrence (3). Assume that T_n is independent of I_n. Then the moment generating function of X_n satisfies $P_0(y) = 1$ and, for $n \ge 1$,

$$P_n(y) = \frac{Q_n(y)}{n} \sum_{0\le k<n} P_k(y),$$

which, by considering the difference $nP_n(y) - (n-1)P_{n-1}(y)Q_n(y)/Q_{n-1}(y)$, can be easily solved, giving

$$P_n(y) = Q_n(y) \prod_{1\le k<n} \frac{k + Q_k(y)}{k+1} \qquad (n \ge 1).$$

Thus $X_n - T_n$ is the sum of independent mixed random variables. The asymptotic transfer from the toll function to the total cost in this case is much simpler.

LEMMA 5. *Define* $a_0 = 0$ *and, for* $n \ge 1$,

$$a_n = b_n + \frac{1}{n} \sum_{0\le k<n} a_k. \tag{52}$$

Then

$$a_n = b_n + \sum_{1\le k<n} \frac{b_k}{k+1} \qquad (n \ge 1).$$

Proof. The proof is omitted. □

LEMMA 6 (asymptotic transfer). *Assume a_n satisfies* (52). *If $b_n \sim n^\alpha L(n)$, where $L(n)$ is slowly varying, then*

$$a_n \sim \begin{cases} \displaystyle\sum_{1\le k<n} \frac{L(k)}{k+1} & \text{if } \alpha = 0, \\ \displaystyle\frac{\alpha+1}{\alpha}\, n^\alpha L(n) & \text{if } \alpha > 0. \end{cases}$$

Proof. The proof is omitted. □

For the limit laws, we have roughly

$$\begin{aligned} \frac{P_n(y)}{Q_n(y)} &= \prod_{1\le k<n} \left(1 + \frac{Q_k(y)-1}{k+1}\right) \\ &\approx \exp\left(\sum_{1\le k<n} \frac{Q_k(y)-1}{k+1}\right) \\ &\approx \exp\left(y \sum_{1\le k<n} \frac{Q_k'(0)}{k+1} + \frac{y^2}{2} \sum_{1\le k<n} \frac{Q_k''(0)}{k+1} + O\left(|y|^3 \sum_{1\le k<n} \frac{|Q_k'''(0)|}{k+1}\right)\right). \end{aligned}$$

Thus, for small toll functions, if

$$\sum_{1\le k<n} \frac{Q_k''(0)}{k+1} \to \infty$$

and

$$\left(\sum_{1\le k<n} \frac{Q_k''(0)}{k+1}\right)^{-3/2} \sum_{1\le k<n} \frac{|Q_k'''(0)|}{k+1} \to 0,$$

then X_n is asymptotically normally distributed.

On the other hand, for larger toll functions, if $T_n/t_n \xrightarrow{d} T$, then roughly

$$\begin{aligned} \frac{P_n(y)}{Q_n(y)} &\approx \exp\left(\sum_{1\le k\le n} \frac{Q_k(y)-1}{k+1}\right) \\ &\approx \exp\left(\int_0^x \frac{Q(v)-1}{v}\, \mathrm{d}v\right), \end{aligned}$$

where $Q(y)$ denotes the moment generating function of T.

Instead of making these heuristics rigorous, we state a simpler result, describing mainly the phase change from normal to nonnormal laws.

THEOREM 6. *Let X_n satisfy* (3), *where T_n is independent of I_n. Assume that*

$$E(T_n) \sim n^\alpha L(n) \quad \text{and} \quad E\left(\frac{T_n}{t_n}\right)^m \to \tau_m \qquad (m \ge 1),$$

where $\alpha > 0$, and that $Q(z) := \sum_{m\ge 0} \tau_m z^m/m!$ has a nonzero radius of convergence. Then

$$\frac{X_n}{n^\alpha L(n)} \xrightarrow{d} X,$$

with convergence of all moments, where $G(z) := E(e^{zX})$ *satisfies*

$$G(z) = \int_0^1 \exp\left(\frac{1}{\alpha}\int_0^{w^\alpha z} \frac{Q(v)-1}{v}\,\mathrm{d}v\right)\mathrm{d}w$$

for sufficiently small z*. On the other hand, if*

$$t_n \sim L(n) \quad \textit{and} \quad E(|T_n|^m) = O(t_n^m) \qquad (m = 2, 3)$$

and

$$s^2(n) := \sum_{1\le k<n} \frac{Q_k''(0)}{k+1} \to \infty,$$

then

$$\frac{X_n - \sum_{1\le k<n} Q_k'(0)/(k+1)}{s(n)} \xrightarrow{d} N(0,1).$$

Proof (sketch). The proof of the asymptotic normality follows from the above argument using moment generating functions and Curtiss's continuity theorem. For large toll functions, we use the method of moments as above by proving

$$P_n^{(m)}(0) \sim g_m n^{m\alpha} L^m(n),$$

where $g_0 = 1$ and, for $m \ge 1$,

$$g_m = \sum_{0\le j\le m} \binom{m}{j} \frac{g_j}{j\alpha+1}\,\tau_{m-j}.$$

The required result follows from the same arguments we used for (1). □

When $\alpha > 0$, the contraction method gives another access to the limit law, where T_n may depend on I_n.

THEOREM 7. *Let* (X_n) *be given by* (3)*. Assume that*

$$E(T_n) \sim n^\alpha L(n) \quad \textit{and} \quad \left(\frac{T_n}{E(T_n)}, \frac{I_n}{n}\right) \xrightarrow{L_2} (T, U),$$

where $\alpha > 0$ *and* T *is square-integrable. Then*

$$\ell_2\left(\frac{X_n}{n^\alpha L(n)}, X_{\alpha,(T,U)}\right) \to 0,$$

where $\mathcal{L}(X_{\alpha,(T,U)})$ *is the unique fixed-point of the map*

$$S_{\alpha,(T,U)} : \mathcal{M}_2 \to \mathcal{M}_2, \quad \nu \mapsto \mathcal{L}(U^\alpha Z + T),$$

with $Z, (T, U)$ *independent and* $\mathcal{L}(Z) = \nu$*.*

Proof. The proof is omitted. □

If $T \ne (\alpha+1)(1-U^\alpha)/\alpha$, then

$$\mathrm{Var}(X_n) \sim \sigma^2 n^{2\alpha} L^2(n),$$

where $\sigma = \sigma(\alpha, (T, U))$ is defined by

$$\sigma^2 = \frac{1}{2\alpha} + \frac{2\alpha+1}{2\alpha}\left(\mathrm{Var}(T) + \frac{2(\alpha+1)}{\alpha}E(TU^\alpha) - \frac{2}{\alpha}\right).$$

When $T = (\alpha+1)(1-U^\alpha)/\alpha$, $\mathrm{Var}(X_n) = o(n^{2\alpha}L^2(n))$.

Tree traversals. The simplest example is when $T_n = 1$ for $n \geq 1$. The distribution is essentially the Stirling numbers of the first kind; see (49). This classical example also appears in a large number of problems; see Bai, Hwang, and Liang [3] for some examples. This distribution also has another concrete interpretation: the depth of the first node in inorder traversal.

Interestingly, the depth of the first node in postorder traversal of a random binary search tree satisfies a slightly different recurrence: $P_0(y) = P_1(y) = 1$, and, for $n \geq 2$,

$$P_n(y) = \frac{e^y}{n}\sum_{1\leq k<n} P_k(y) + \frac{e^y}{n}P_{n-1}(y), \tag{53}$$

which can be asymptotically solved as

$$P_n(y) = \frac{n^{e^y-1}}{\Gamma(y)}\varpi(e^y)\left(1+O(n^{-1})\right) + O(n^{-1}),$$

uniformly for $|y| \leq \delta$, where

$$\varpi(y) = e^y + \int_0^1 w^y e^{yw}\left(1-y-yw^{-1}\right)\mathrm{d}w.$$

This is derived by applying singularity analysis (see [29]) to the generating function $P(z, e^y) = \sum_n P_n(y)z^n$, which satisfies

$$P(z,y) = (1-z)^{-y}e^z + (1-z)^{-y}e^{-y(1-z)}\int_{1-z}^1 w^y e^{yw}\left(1-y-yw^{-1}\right)\mathrm{d}w.$$

Therefore, the distribution of X_n is asymptotically Poisson with parameter $\log n$ and thus asymptotically normal; see [39]. The mean was discussed by Brinck [10].

Quickselect. The number of comparisons and exchanges used by quickselect to find the smallest (or the largest) elements satisfies (3) with toll functions of linear mean. Our theorems apply and, in particular, the limit law of the number of comparisons is Dickman. The same limit law actually persists for selecting the mth smallest (or largest) element when $m = o(n)$; see Hwang and Tsai [40] for more details.

The Stirling distribution also naturally appears as the number of partitioning stages used by quickselect to find the smallest or the largest element. This gives yet another addition to the large list of concrete interpretations of the Stirling numbers of the first kind.

Logarithmic product of cycle sizes in random permutation. Permutations can be decomposed into a set of cycles. Given a random permutation of n elements, let $\sigma_1 \leq \cdots \leq \sigma_k$ denote the cycle sizes. Define $X_n := \sum_{1\leq j\leq k}\log\sigma_j$, which appeared as a good approximation to the logarithmic order of a random permutation. Then X_n satisfies (1) with $T_n = \log n$ and

$$E(e^{X_n y}) = \prod_{1\leq k\leq n}\left(1+\frac{y^k-1}{k}\right).$$

Our result gives the well-known asymptotic normality of X_n with mean $\frac{1}{2}\log^2 n$ and variance $\frac{1}{3}\log^3 n$; see Barbour and Tavaré [4] for further information.

Acknowledgment. We thank Uwe Rösler for helpful suggestions.

ARE BITVECTORS OPTIMAL?*

H. BUHRMAN†, P. B. MILTERSEN‡, J. RADHAKRISHNAN§, AND S. VENKATESH¶

Abstract. We study the *static membership problem*: Given a set S of at most n keys drawn from a universe U of size m, store it so that queries of the form "Is u in S?" can be answered by making few accesses to the memory. We study schemes for this problem that use space close to the information theoretic lower bound of $\Omega(n \log(\frac{m}{n}))$ bits and yet answer queries by reading a small number of bits of the memory.

We show that, for $\epsilon > 0$, there is a scheme that stores $O(\frac{n}{\epsilon^2} \log m)$ bits and answers membership queries using a randomized algorithm that reads just one bit of memory and errs with probability at most ϵ. We consider schemes that make no error for queries in S but are allowed to err with probability at most ϵ for queries not in S. We show that there exist such schemes that store $O((\frac{n}{\epsilon})^2 \log m)$ bits and answer queries using just one bitprobe. If multiple probes are allowed, then the number of bits stored can be reduced to $O(n^{1+\delta} \log m)$ for any $\delta > 0$. The schemes mentioned above are based on probabilistic constructions of set systems with small intersections.

We show lower bounds that come close to our upper bounds (for a large range of n and ϵ): Schemes that answer queries with just one bitprobe and error probability ϵ must use $\Omega(\frac{n}{\epsilon \log(1/\epsilon)} \log m)$ bits of storage; if the error is restricted to queries not in S, then the scheme must use $\Omega(\frac{n^2}{\epsilon^2 \log(n/\epsilon)} \log m)$ bits of storage.

We also consider deterministic schemes for the static membership problem and show tradeoffs between space and the number of probes.

Key words. data structures, set membership problem, bit probe model, set systems

1. Introduction.

In this paper, we study the *static membership* problem: Given a subset S of at most n keys from a universe $U = \{1, 2, \ldots, m\}$, store it so that queries of the form "Is u in S?" can be answered by making few accesses to the memory. This is a fundamental data structure problem with a long history. Yao [37] showed that, if the data structure consists of a table with n cells, where the keys are stored explicitly and the universe from which the set S is chosen is large enough, then the sorted table with binary search is optimal. In order to study data structures where elements of the set S are not stored explicitly, Yao (in the same paper) proposed the *cell probe model*. In this model, the set S is stored as a table of cells, each capable of holding one element of the universe; that is, if the universe has size m, where m is a power of two, then each cell holds $\log m$ bits. Queries are to be answered by probing the table adaptively; that is, each probe can depend on the results of earlier probes and the query element u. The goal is to process membership queries with as few probes as possible and, at the same time, keep the size of the table small.

Fredman, Komlós, and Szemerédi [16] gave a solution for the static membership problem in the cell probe model that used a constant number of probes and a table of size $O(n)$. We shall refer to this scheme as the FKS scheme. Note that, if one is required to store sets of size at most n, then there is an information theoretic lower bound of $\lceil \log \sum_{i \le n} \binom{m}{i} \rceil$ on the number of bits used. For $n \le m^{1-\Omega(1)}$, this implies that the data structure must store $\Omega(n \log m)$ bits (and must, therefore, use $\Omega(n)$ cells). Thus, up to constant factors, the FKS scheme uses optimal space and number of cell probes. In fact, Fiat et al. [12], Brodnik and Munro [5, 6], and Pagh [25] obtain schemes that use space (in bits) that is within a small additive term of $\lceil \log \sum_{i \le n} \binom{m}{i} \rceil$ and yet answer queries by reading at most a constant number of cells.

An important variation of the cell probe model is the *bitprobe* model, where each cell holds just a single bit rather than an element of the universe. Thus, in this model, the query algorithm is given bitwise access to the data structure. Arguably, the bitprobe complexity of a data structure problem is a fundamental measure; this, in particular, applies to decision problems such as the membership problem, where the final answer to a query *is* a single bit. The bitprobe model is older than the cell probe model. The membership problem was studied in the bitprobe model already by Minsky and Papert in their 1969 book *Perceptrons* [24]. They were interested in *average*-case upper bounds for this problem and did not study worst-case bounds. Although the bitprobe complexity of several other static and dynamic data structure problems has been studied since then [9, 13, 14, 15, 22, 36], the bitprobe complexity of the static membership problem has received very little attention since the work of Minsky and Papert.[1] In this paper, we study *worst*-case bounds for the membership problem. Thus our goal is to *answer queries using the minimum number of bitprobes* and, at the same time, *keep the number of bits stored in the table small*.

1.1. Randomized schemes. We investigate the complexity of the static membership problem when the query processing algorithm tosses coins to decide which bits of the memory to read and is allowed to answer incorrectly with a certain small probability. Though using Las Vegas–style randomization to *construct* data structures is a well-known and established technique (used, for instance, in many hashing-based data structures, such as the FKS scheme), Monte Carlo–style randomization in the *query algorithm* has been used in the field of data structures only very recently [23, 19]. We consider two kinds of randomized schemes: (a) those that make one-sided errors, where the errors are restricted to negative instances alone (that is, these schemes never say "No" when the query element u is in the set S); (b) schemes that are allowed to make two-sided errors (that is, errors are allowed for positive as well as negative instances). It is also possible to consider schemes that make errors on positive instances alone; but for the important case of one-probe schemes, we show that such schemes cannot do better than deterministic schemes.

1.1.1. Randomized schemes with two-sided error. Our main result says that there are randomized schemes that use *just one bitprobe* and yet use space close to the information theoretic lower bound of $\Omega(n \log m)$ bits.

THEOREM 1. *For any $0 < \epsilon \le \frac{1}{4}$, there is a scheme for storing subsets S of size at most n of a universe of size m using $O(\frac{n}{\epsilon^2} \log m)$ bits so that any membership*

[1] The only exception that we are aware of is a remark by Yao and Yao [36] stating without proof that, if one ignores constant factors, the FKS scheme is optimal in the bitprobe model as well: that is, every scheme that uses $O(n \log m)$ bits of storage must use $\Omega(\log m)$ bitprobes (assuming $n \ll m$). For justification and generalization of this remark, see Theorem 6 of this paper.

query "Is $u \in S$?" can be answered with error probability at most ϵ by a randomized algorithm which probes the memory at just one location determined by its coin tosses and the query element u.

In contrast, deterministic schemes that answer queries using a single bitprobe need m bits of storage (see Theorem 11). By allowing randomization, we can reduce this bound (for constant ϵ) to $O(n \log m)$ bits. This is within a *constant factor* of the space used by a sorted table or a hash table; for $n \leq m^{1-\Omega(1)}$, it is within a constant factor of the *information theoretic* minimum number of bits needed to store the data. *Yet membership queries can be answered with small error probability by looking at a single bit of the data structure.* Note that we allow randomization only in the query algorithm; it is still the case that, for each set S, there is exactly one associated data structure $\phi(S)$. Also, the probability of error is at most ϵ for *all* sets and *all* queries.

Many of the previous results for the membership problem have been based on hashing [16, 37, 36]. We depart from this tradition. The proof of Theorem 1 is based on two-colorings of set systems. The set systems we use are related to those considered by Erdős, Frankl, and Füredi [10] in their study of r-cover-free families of sets. Similar set systems have been used to great advantage in the construction of pseudorandom generators and extractors, starting with the papers of Nisan [26] and Nisan and Wigderson [27] (for recent applications, see [35, 31, 30, 2]); we refer to them as NW-designs.

The properties of NW-designs are, unfortunately, not strong enough for our proof. So we construct an appropriate set system ourselves. In section 3, we describe this set system in more detail and relate it to the existence of a certain kind of strong *expander graphs*. Although we believe that such schemes can have practical uses, our proof relies on an existential argument, which we have not been able to make constructive. Subsequently, Ta-Shma [32], using recent developments in pseudorandomess [33, 34], has obtained an explicit one-probe randomized scheme with two-sided error ϵ for a certain range of n and ϵ. This scheme uses less space than the scheme in Theorem 9.

Is the result of Theorem 1 the best possible? As remarked above, $\Omega(n \log m)$ bits of space are necessary if $n \leq m^{1-\Omega(1)}$. So let us concentrate on the dependence of the size on the error probability ϵ. Unfortunately, our construction does not permit us to have subconstant error probability and still use optimal space. We show that this limitation is unavoidable: if ϵ is made subconstant, then we must use more than $n \log m$ space.

THEOREM 2. *Suppose $\frac{n}{m^{1/3}} \leq \epsilon \leq \frac{1}{4}$. Then any two-sided ϵ-error randomized scheme which answers queries using one bitprobe must use space $\Omega(\frac{n}{\epsilon \log(1/\epsilon)} \log m)$.*

Interestingly, the proof uses upper bounds as well as lower bounds for r-cover-free families [10].

1.1.2. Randomized schemes with one-sided error. As stated above, we do not use NW-designs in our proof of Theorem 1 but instead use a related set system. If we use NW-designs, then we do not get the same savings in space. However, we can now ensure that the error made while processing the query is one-sided.

THEOREM 3. *For any $0 < \epsilon \leq \frac{1}{4}$, there is a scheme for storing subsets S of size at most n of a universe of size m using $O((\frac{n}{\epsilon})^2 \log m)$ bits so that any membership query "Is $u \in S$?" can be answered with error probability at most ϵ by a randomized algorithm which makes a single bitprobe to the data structure. Furthermore, if $u \in S$, the probability of error is 0.*

Note that the dependence on n is now quadratic, unlike in the two-sided scheme, where it was linear. Though this scheme does not operate with optimal space, it still

uses significantly less space than a bitvector. We also show that the scheme we have is essentially optimal: there is necessarily a quadratic dependence on $\frac{n}{\epsilon}$ for any scheme with one-sided error.

THEOREM 4. *Suppose* $\frac{n}{m^{1/3}} \leq \epsilon \leq \frac{1}{4}$. *Consider the static membership problem for sets* S *of size at most* n *from a universe of size* m. *Then any scheme with one-sided error* ϵ *that answers queries using at most one bitprobe must use* $\Omega(\frac{n^2}{\epsilon^2 \log(n/\epsilon)} \log m)$ *bits of storage.*

To prove this theorem, we again use the lower bounds for r-cover-free families.

Remarks.

1. The proof of Theorem 3 is nonconstructive. We also show that there is an explicit one-sided error randomized scheme that uses $O((\frac{n \log m}{\epsilon})^2)$ bits of storage and answers queries using one bitprobe. This result uses the explicit NW-designs (see Theorem 9).
2. One might also consider one-probe one-sided error schemes where no error is made for query elements *not* in the set S. In this case, we show (Theorem 11) that randomness does not help at all: such a scheme must use m bits of storage.

Thus there is no one-sided error, one-probe scheme that uses optimal space. However, the space requirement can be reduced if we allow more probes.

THEOREM 5. *Suppose* $0 < \delta < 1$. *There is a randomized scheme with one-sided error* $n^{-\delta}$ *that solves the static membership problem using* $O(n^{1+\delta} \log m)$ *bits of storage and* $O(\frac{1}{\delta})$ *bitprobes.*

To prove this, we combine a two-sided scheme obtained from Theorem 1 with ideas for one-sided schemes from Theorem 3.

Connection with communication complexity. Theorems 1–4 can also be viewed in the communication complexity setting: Alice gets $u \in \{1, \ldots, m\}$, Bob gets $S \subseteq \{1, \ldots, m\}$ of size at most n, and Alice sends a single message to Bob after which Bob announces whether $u \in S$. Indeed, as was pointed out in [23], this communication game characterizes the data structure problem in the following way: If s is the optimal number of bits in the data structure that can be queried with one bitprobe and a particular bound on the error on positive and negative instances, then $\log s \pm o(\log s)$ is the number of bits sent from Alice to Bob in an optimal protocol for the communication problem with the same error bounds. Thus Theorems 1–4 give bounds for the communication problem which are optimal within a low order term.

Connection with coding theory. The membership problem in the bitprobe model has an interesting coding theoretic interpretation: We are trying to give an encoding $\phi(u)$ of any m-bit string u with at most n 1's so that the length of the encoding is close to the *first order entropy* of u and so that any bit of u can be retrieved by looking at a few bits of $\phi(u)$. Thus we are trying to construct a *locally decodable source code* analogous to the locally decodable *channel* codes of [4, 21].

1.2. Deterministic schemes. As noted previously, the FKS hashing scheme is a data structure for storing sets of size at most n from a universe of size m using $O(n \log m)$ bits so that membership queries can be answered using $O(\log m)$ bitprobes. We show that the FKS scheme makes an optimal number of bitprobes, within a constant factor, for this amount of space. This fact follows from the following general time-space tradeoff.

THEOREM 6. *Suppose a deterministic scheme stores subsets of size* n *from a universe of size* m *using* s *bits of storage and answers membership queries with* t *bitprobes to memory. Then* $\binom{m}{n} \leq \max_{i \leq nt} \binom{2s}{i}$.

COROLLARY 1.1. *Let $\epsilon > 0$, $c \geq 1$ be any constants. There is a constant $\delta > 0$ so that the following holds. Let $n \leq m^{1-\epsilon}$, and let a scheme for storing sets of size at most n of a universe of size m as data structures of at most $cn \log m$ bits be given. Then any deterministic algorithm answering membership queries using this structure must make at least $\delta \log m$ bitprobes in the worst case.*

While the FKS scheme makes an optimal number of probes, the probes made are *adaptive*. In fact, adaptiveness seems to be quite inherent in hashing-based schemes. Somewhat surprisingly, as a corollary to the proof of Theorem 1, we can prove that there is a scheme that uses $O(n \log m)$ bits and answers membership queries with $O(\log m)$ *nonadaptive* bitprobes. Thus adaptive probes do not help much when we consider deterministic schemes that use $O(n \log m)$ space.

More generally, from Theorem 6, it follows that any deterministic scheme that answers queries using t bitprobes must use space at least $ntm^{\Omega(1/t)}$ in the worst case. We show the existence of schemes which almost match the lower bound.

THEOREM 7.

1. *There is a nonadaptive scheme that stores sets of size at most n from a universe of size m using $O(ntm^{\frac{2}{t+1}})$ bits and answers queries using $2t+1$ bitprobes. This scheme is nonexplicit.*
2. *There is an explicit adaptive scheme that stores sets of size at most n from a universe of size m using $O(m^{1/t} n \log m)$ bits and answers queries using $O(\log n + \log\log m) + t$ bitprobes.*

Thus, somewhat surprisingly, if we care only about space up to a polynomial, adaptive schemes are not more powerful than nonadaptive ones.

Finally, we turn our attention to deterministic *two-probe* schemes and ask if they can do better than one-probe schemes, where bitvectors are optimal. We have not been able to answer this question in general. We can show that this is the case if the two bitprobes made are nonadaptive. Thus the second bitprobe is useless for nonadaptive schemes. However, we show that there is a scheme with two adaptive bitprobes that does better than any scheme with two nonadaptive bitprobes for $n = 2$. We do not know whether a second adaptive probe helps for values of n greater than 2.

THEOREM 8.

1. *Any scheme for storing subsets S of size at most n ($n \geq 2$) of a universe of size m such that membership queries can be answered by two nonadaptive bitprobes uses space $s \geq m$ bits.*
2. *Let $m \geq 2$, and let $n = 2$. Then there is a scheme with two adaptive bitprobes and space $s = O(m^{3/4})$.*

1.3. Organization of the paper. We start with the formal definitions in the next section. In section 3, randomized schemes with one-sided error and two-sided error are presented. In section 4, we prove lower bound results for randomized schemes. We end with results on deterministic schemes in section 5.

2. Notation and definitions.

Notation. Unless mentioned explicitly, all logarithms in this paper are to the base 2. We use $[m]$ to denote the set $\{1, 2, \ldots, m\}$. For a set A, $\binom{A}{n}$ denotes the set of all subsets of A of size n, and $\binom{A}{\leq n}$ denotes the set of all its subsets of size at most n.

DEFINITION 2.1 (storing schemes). *An (n, m, s)-*storing scheme *is a method for representing any subset of size at most n of a universe of size m as an s-bit string. Formally, an (n, m, s)-storing scheme is a map ϕ from $\binom{[m]}{\leq n}$ to $\{0,1\}^s$.*

DEFINITION 2.2 (deterministic query schemes). *A deterministic* (m, s, t)-query scheme *is a family* $\{T_u\}_{u\in[m]}$ *of* m *Boolean decision trees of depth at most* t. *Each internal node in a decision tree is marked with an index between* 1 *and* s, *indicating the address of a bit in an* s*-bit data structure. For each internal node, there is one outgoing edge labeled "*0*" and one labeled "*1*." The leaf nodes of every tree are marked "Yes" or "No." Such a tree* T_u *induces a map from* $\{0,1\}^s$ *to* $\{$*Yes, No*$\}$; *this map will also be referred to as* T_u.

DEFINITION 2.3 (deterministic schemes). *An* (n, m, s)*-storing scheme* ϕ *and an* (m, s, t)*-query scheme* $\{T_u\}_{u\in[m]}$ *together form an* (n, m, s, t)-scheme *if, for all* $S \in \binom{[m]}{\leq n}$, *for all* $u \in [m] : T_u(\phi(S)) =$ *Yes if and only if* $u \in S$.

In a nonadaptive scheme, the next probe to be made depends only on the input query q. It does not depend on the results of the previous probes.

DEFINITION 2.4 (nonadaptive query schemes). *A nonadaptive query scheme is a deterministic scheme where, in each decision tree, all nodes on a particular level are marked with the same index between* 1 *and* s *(but nodes on the same level in different trees may be marked differently).*

In a randomized scheme, the storing scheme is deterministic as before. However, the query algorithm is allowed to make random coin tosses to decide the next location to be probed.

DEFINITION 2.5 (randomized schemes). *A randomized* (m, s, t)*-query scheme is a family* $\{\pi_u\}_{u\in[m]}$ *of probability distributions on the set of all Boolean decision trees of depth at most* t. *We answer the query "Is* u *in* S*?" by picking a decision tree according to the distribution* π_u *and return the answer it gives. An* (n, m, s)*-storing scheme and a randomized* (m, s, t)*-query scheme together form an* (n, m, s, t)*-randomized scheme. We say that a randomized scheme has* positive one-sided error ϵ *if, for* $u \notin S$, *the error probability on queries "Is* u *in* S*?" is* 0, *i.e., the answer "No" is always returned, while, if* $u \in S$, *the error probability on the query "Is* u *in* S*?" is at most* ϵ. *Similarly, a randomized scheme has* negative one-sided error ϵ *if, for* $u \in S$, *the error probability on queries "Is* u *in* S*?" is* 0, *i.e., the answer "Yes" is always returned, while, if* $u \notin S$, *the error probability on the query "Is* u *in* S*?" is at most* ϵ. *We say that a randomized scheme has* two-sided error ϵ *if, on query "Is* u *in* S*?," the scheme returns the wrong answer with probability at most* ϵ.

We will be interested in one-probe randomized schemes where, in particular, π_u will be a probability distribution on Boolean decision trees that make at most one probe.

We say that a scheme is *explicit* if there are efficient algorithms that can simulate the storing scheme and the query scheme.

DEFINITION 2.6 (explicit storing schemes). *A family of storing schemes, indexed by* (n, m, s), *is* explicit *if there is a Turing machine, running in time* $s^{O(1)}$, *which, given* $S \subseteq \{0,1\}^m$ *of size* n, *outputs the representation* $\phi(S)$.

DEFINITION 2.7 (explicit query schemes). *A family of (randomized) query schemes, indexed by* (m, s, t), *is* explicit *if there is a (probabilistic) Turing machine, running in time* $(t + \log m)^{O(1)}$, *which, on input* u *and with oracle access to* $\phi(S)$, *executes the correct sequence of probes according to the query scheme and accepts or rejects accordingly.*

DEFINITION 2.8 (explicit schemes). *A family of schemes is explicit if the associated storing and query schemes are explicit.*

3. Upper bounds for randomized schemes. In this section, we show that there exist randomized one-probe schemes that use small space. We first describe the

randomized scheme with one-sided error; the scheme with two-sided error can then be seen as a generalization. Randomized multiprobe schemes with one-sided error will be obtained by combining one-probe schemes with one-sided error and one-probe schemes with two-sided error.

All of our schemes will be based on set systems with small intersections. In particular, we will use a set system of the form $\{\Gamma_u\}_{u\in[m]}$, where $\Gamma_u \subseteq [s]$. The query algorithm, on receiving the query "Is u in S?," will probe a location in Γ_u uniformly and answer "Yes" if and only if it finds a 1 there.

We will describe our schemes using a bipartite graph with vertex sets U and V: U is the universe from which the set S to be stored is drawn, and V is the set of locations in the memory. We connect $u \in U$ to $v \in V$ if, on query "Is u in S?," the cell v in the memory is probed by the algorithm (for some outcome of coin tosses). Thus, when the query element is u, the algorithm probes the memory locations in the neighborhood $\Gamma(u)$ of u with uniform distribution.

3.1. Randomized scheme with one-sided error.

Proof of Theorem 3. Our randomized scheme is based on a bipartite graph with vertex sets U and V, where $U = [m]$ and $|V| = O((\frac{n}{\epsilon})^2 \log m)$. Any instance of the data structure corresponds to a coloring of V using colors from the set $\{0, 1\}$. Hence, if the set $S \subseteq U$ is to be stored correctly, then all locations in $\bigcup_{u\in S} \Gamma(u)$ must be colored 1. This is because the algorithm is not allowed to say "No" when the query element u is in S. Furthermore, since the error probability is at most ϵ, for all $u' \notin S$, at most $\epsilon|\Gamma(u')|$ locations in $\Gamma(u')$ can be colored 1. Thus we get the following condition on the bipartite graph:

$$\forall S \in \binom{U}{\leq n}, \forall u' \in U - S, \left|\Gamma(u') - \bigcup_{u\in S} \Gamma(u)\right| \geq (1-\epsilon)|\Gamma(u')|. \tag{1}$$

We are thus required to pick neighborhoods for vertices $u \in U$ so that the resulting bipartite graph satisfies (1). An NW-design allows us to do this.

Definition 3.1. *A family of sets F is an (m, ℓ, a)-design if F has m sets each of size ℓ and two different sets in F have at most a elements in common.*

Lemma 3.2 (Erdős, Frankl, and Füredi [10, Theorem 2.1]). *If $m \leq \binom{s}{a}/\binom{\ell}{a}^2$, then there is an $(m, \ell, a-1)$-design all of whose elements are subsets of $[s]$.*

We will use an (m, ℓ, a)-design with $a = \lceil \log m \rceil$ and $\ell = \lceil na/\epsilon \rceil$. If $s = \lceil 2e^2\ell^2/a \rceil$ (which is $O((\frac{n}{\epsilon})^2 \log m)$), then

$$\frac{\binom{s}{a}}{\binom{\ell}{a}^2} \;\geq\; \frac{(\frac{s}{a})^a}{(\frac{e\ell}{a})^{2a}} \;\geq\; \frac{(\frac{2e^2\ell^2}{a^2})^a}{(\frac{e\ell}{a})^{2a}} \;\geq\; 2^a \;\geq\; m,$$

and, by the above lemma, there is an (m, ℓ, a)-design (in fact, an $(m, \ell, a-1)$-design), all of whose elements are subsets of $[s]$. Let $\{\Gamma_1, \Gamma_2, \ldots, \Gamma_m\}$ be such a design.

Storing scheme. Suppose the set to be stored is $\{u_1, \ldots, u_k\}$, $k \leq n$. Store a bitstring T of size s with 1's in all locations in $M = \Gamma_{u_1} \cup \Gamma_{u_2} \cup \cdots \cup \Gamma_{u_k}$ and 0 elsewhere.

Query scheme. On query "Is u in S?," do the following:

Step 1. Pick a random location i uniformly from Γ_u.

Step 2. If $T(i)$ is 1, say "Yes," otherwise say "No."

Correctness. If $u \in S$, then every location in Γ_u has a 1, and hence we say "Yes." On the other hand, if $u \notin S$, then $|M \cap \Gamma_u| \leq na$. Hence the probability that

the algorithm says "Yes" when we choose a random location in Γ_u is at most $\frac{na}{|\Gamma_u|} = \frac{na}{\ell} \leq \epsilon$. □

The following theorem gives a slightly weaker bound than the one stated in Theorem 3, but it has the advantage that the scheme is explicit. It is based on the explicit version of Lemma 3.2 (see [10, Example 3.2] or [27]).

THEOREM 9. *For any $\epsilon > 0$ and any n, m, there is an (n, m, s)-storing scheme with $s = O((\frac{n \log m}{\epsilon})^2)$ and an associated randomized one-probe query scheme with a negative one-sided error at most ϵ. This scheme is explicit.*

Proof. Let $\mathbf{F}$ be a finite field of size q, where q is the smallest power of two which is at least $(n \log m)/\epsilon$. If $d = \lceil \log m \rceil - 1$, then the number of univariate polynomials of degree at most d is $q^{d+1} \geq m$. We will associate with the element $u \in [m]$ a unique polynomial

$$p_u(X) \stackrel{\text{def}}{=} \sum_{i=1}^{\lceil \log m \rceil} u_i X^{i-1},$$

where u_i is the ith bit in the binary representation of u. Now we store S as a $q \times q$ bitmap, indexed by $\mathbf{F} \times \mathbf{F}$, with bit (x, y) on if and only if $p_u(x) = y$ for some $u \in S$. The size of the data structure is as claimed. To answer the query "Is u in S?," we pick $x \in \mathbf{F}$ at random and say "Yes" if and only if bit $(x, p_u(x))$ of the bitmap is 1. Clearly, if $u \in S$, we always say "Yes." If $u \notin S$, then, for all $u' \in S$, the graphs of p_u and $p_{u'}$ have at most d points in common. Thus at most nd locations of the form $(x, p_u(x))$ of the bitmap will contain a 1. Note that $nd/q \leq \epsilon$. □

Remark. By choosing parameters more carefully in the above proof, we can reduce the space requirement in the above theorem to $O(\frac{n \log m}{\epsilon \log((n \log m)/\epsilon)})^2$.

3.2. Randomized scheme with two-sided error. We now present a scheme that uses space $O(\frac{n}{\epsilon^2} \log m)$ and answers queries using a single-bit probe, making an error with probability at most ϵ. The space needed depends linearly on n, and, when ϵ is a constant, it is within a constant factor of a sorted table or a hash table.

Proof of Theorem 1. We may assume that m is large, say, $m \geq 100$. We first describe the main ideas of our randomized scheme using the bipartite graph $G = (U, V, E)$, where $U = [m]$ and $V = [s]$. On query "Is u in S?," the query algorithm probes a random location in $\Gamma(u)$ and says "Yes" if and only if the location probed contains 1. Now suppose that we need to store the set $S \subseteq U$ ($|S| \leq n$). Then we need a coloring $\chi_S : V \to \{0, 1\}$, such that, for all $u \in S$, at least $(1 - \epsilon)|\Gamma(u)|$ elements of $\Gamma(u)$ are colored 1, and, for all $u' \notin S$, at least $(1 - \epsilon)|\Gamma(u')|$ elements of $\Gamma(u')$ are colored 0. Thus we need to find neighborhoods for the vertices so that the system of sets $\{\Gamma(u)\}_{u \in U}$ admits such a coloring χ_S for all $S \in \binom{U}{\leq n}$. This motivates the following definition.

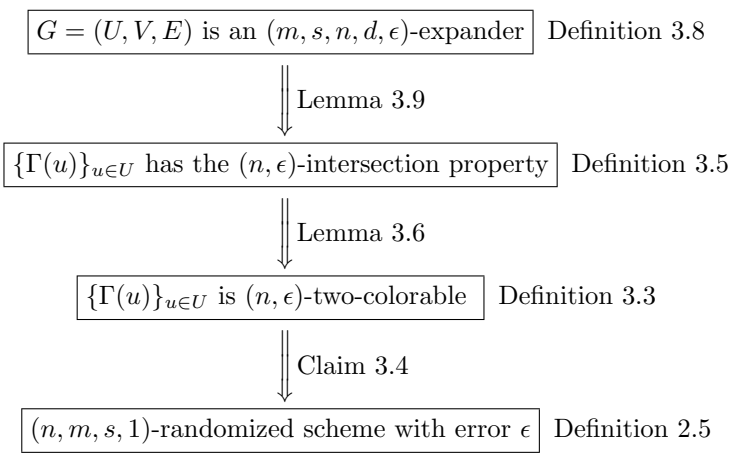
DEFINITION 3.3. *Let $\mathcal{C}_1, \mathcal{C}_0 \subseteq 2^V$. We say that $(\mathcal{C}_1, \mathcal{C}_0)$ is ϵ-two-colorable if there exists $\chi : V \to \{0, 1\}$, such that*

1. *for all $T \in \mathcal{C}_1$, $|\chi^{-1}(0) \cap T| \leq \epsilon |T|$, and*
2. *for all $T \in \mathcal{C}_0$, $|\chi^{-1}(1) \cap T| \leq \epsilon |T|$.*

We say that $\mathcal{C} \subseteq 2^V$ is (n, ϵ)-two-colorable if $(\mathcal{C}_1, \mathcal{C}_0 = \mathcal{C} - \mathcal{C}_1)$ is ϵ-two-colorable for all $\mathcal{C}_1 \in \binom{\mathcal{C}}{\leq n}$.

In this terminology, our goal can be stated as follows: find a bipartite graph $G = (U, V, E)$, with $U = [m]$ and $V = [s]$, such that $\{\Gamma(u)\}_{u \in U}$ is an (n, ϵ)-two-colorable collection of m distinct nonempty sets. We will show that such a graph exists with $|V| = O(\frac{n}{\epsilon^2} \log m)$. For this, we first identify a sufficient condition, which

we call *the* (n,ϵ)*-intersection property*, for a collection to be (n,ϵ)-two-colorable. We then observe that, if G has a certain *expansion property*, then $\{\Gamma(u)\}_{u\in U}$ has the (n,ϵ)-intersection property. Finally, using a probabilistic argument, we show that graphs with the required expansion property exist. To outline the main steps of our proof, we show the following implications and the existence of an (m,s,n,d,ϵ)-expander with $s = O(\frac{n}{\epsilon^2}\log m)$.



Colorable families and randomized schemes.

LEMMA 3.4. *Suppose the bipartite graph $G = (U,V,E)$, with $U = [m]$ and $V = [s]$, is such that $\{\Gamma(u)\}_{u\in U}$ is an (n,ϵ)-two-colorable collection of m nonempty sets. Then there is a randomized scheme for the membership problem that uses s bits to store sets $S \in \binom{U}{\le n}$ and answers membership queries using one bitprobe, and with error probability at most ϵ.*

Proof.

The storing scheme. To store the set $S \in \binom{U}{\le n}$, consider the collections $\mathcal{C}_1 = \{\Gamma(u)\}_{u\in S}$ and $\mathcal{C}_0 = \{\Gamma(u)\}_{u\notin S}$. Since $\{\Gamma(u)\}_{u\in U}$ is an (n,ϵ)-two-colorable collection, $(\mathcal{C}_1,\mathcal{C}_0)$ is ϵ-two-colorable. Let $\chi : V \to \{0,1\}$ be a coloring satisfying the two conditions of Definition 3.3. We store χ as a table of $s = |V|$ bits.

The query scheme. Given a query "Is u in S?," pick i uniformly at random from $\Gamma(u)$, and return "Yes" if $\chi(i) = 1$, and return "No" if $\chi(i) = 0$.

Correctness. If $u \in S$, then $\Gamma(u) \in \mathcal{C}_1$, and $|\chi^{-1}(0) \cap \Gamma(u)| \le \epsilon|\Gamma(u)|$. Thus $\Pr[\chi(i) = 0] \le \epsilon$. Similarly, if $u \notin S$, $\Gamma(u) \in \mathcal{C}_0$ and $\Pr[\chi(i) = 1] \le \epsilon$. □

Intersection property and coloring. Suppose that we wish to ϵ-two-color $(\mathcal{C}_1,\mathcal{C}_0)$. The first thing to try would be to color all of the elements in $\bigcup_{S\in\mathcal{C}_1} S$ with 1 and the rest with 0. Unfortunately, some sets in $\mathcal{C}_0$ might get more than an ϵ fraction of their elements colored 1, and our coloring might not be proper. So we need to first identify those sets in $\mathcal{C}_0$ that might be badly colored in this method: these are precisely the sets that have large intersection with the union of the sets in $\mathcal{C}_1$. Let $\mathcal{C}_0'$ be the collection of these sets. We will now modify our coloring method to pay special attention to sets in $\mathcal{C}_0'$. For now, ignore the sets in $\mathcal{C}_0 - \mathcal{C}_0'$, for they are at no risk of being badly colored while ensuring that the sets in $\mathcal{C}_1$ are properly colored. So we are left with the problem of ϵ-two-coloring $(\mathcal{C}_1,\mathcal{C}_0')$. If $|\mathcal{C}_0'| < |\mathcal{C}_1|$, this is a smaller problem, and we can use induction for this. This motivates the following definition of the ϵ-intersection property. That this definition is sufficient for ϵ-two-colorability

is the main observation of this section, which we state formally in Lemma 3.6 below.

DEFINITION 3.5. *Suppose $\mathcal{C}_1$ and $\mathcal{C}_0$ are collections of sets. We say that $(\mathcal{C}_1, \mathcal{C}_0)$ has the ϵ-intersection property if*

$$\forall\, \mathcal{C}_1' \subseteq \binom{\mathcal{C}_1}{\leq n} (\mathcal{C}_1' \neq \emptyset),\ \left|\left\{S \in \mathcal{C}_0 : \left|T \cap \left(\bigcup_{T' \in \mathcal{C}_1'} T'\right)\right| > \epsilon|T|\right\}\right| < |\mathcal{C}_1'| \text{ and} \tag{2}$$

$$\forall\, \mathcal{C}_0' \subseteq \binom{\mathcal{C}_0}{\leq n} (\mathcal{C}_0' \neq \emptyset),\ \left|\left\{T \in \mathcal{C}_1 : \left|T \cap \left(\bigcup_{T' \in \mathcal{C}_0'} T'\right)\right| > \epsilon|T|\right\}\right| < |\mathcal{C}_0'|. \tag{3}$$

We say that a collection of sets $\mathcal{C}$ has the (n, ϵ)-intersection property if $(\mathcal{C}_1, \mathcal{C}_0 = \mathcal{C} - \mathcal{C}_1)$ has the ϵ-intersection property for all $\mathcal{C}_1 \in \binom{\mathcal{C}}{\leq n}$.

LEMMA 3.6. *Suppose $\mathcal{C}_1, \mathcal{C}_0 \subseteq 2^V$. If $|\mathcal{C}_1| \leq n$ and $(\mathcal{C}_1, \mathcal{C}_0)$ has the (n, ϵ)-intersection property, then $(\mathcal{C}_1, \mathcal{C}_0)$ is ϵ-two-colorable.*

COROLLARY 3.7. *If $\mathcal{C}$ has the (n, ϵ)-intersection property, then $\mathcal{C}$ is (n, ϵ)-two-colorable.*

Proof of Lemma 3.6. We use induction on $|\mathcal{C}_1| + |\mathcal{C}_0|$. The base case, when either $\mathcal{C}_1$ or $\mathcal{C}_0$ is empty, is obvious. For the induction step, consider a pair $(\mathcal{C}_1, \mathcal{C}_0)$ of nonempty collections, with $|\mathcal{C}_1| \leq n$, that has the (n, ϵ)-intersection property. We may assume that $|\mathcal{C}_1| \leq |\mathcal{C}_0|$; otherwise, interchange the roles of 0 and 1. Let

$$\mathcal{C}_0' \stackrel{\text{def}}{=} \left\{T \in \mathcal{C}_0 : \left|T \cap \left(\bigcup_{T' \in \mathcal{C}_1} T'\right)\right| > \epsilon|T|\right\}.$$

Since $(\mathcal{C}_1, \mathcal{C}_0)$ has the (n, ϵ)-intersection property and $1 \leq |\mathcal{C}_1| \leq n$, $|\mathcal{C}_0'| < |\mathcal{C}_1| \leq |\mathcal{C}_0|$. By induction, there exists a two-coloring $\chi : V \to \{0, 1\}$ such that

$$\forall\, T \in \mathcal{C}_1,\ |\chi^{-1}(0) \cap T| \leq \epsilon|T| \text{ and} \tag{4}$$

$$\forall\, T \in \mathcal{C}_0',\ |\chi^{-1}(1) \cap T| \leq \epsilon|T|. \tag{5}$$

We may assume that, if $\chi(v) = 1$, then $v \in \bigcup_{T \in \mathcal{C}_1} T$ (otherwise, change $\chi(v)$ to 0—this cannot hurt (4) and can only help (5)), that is,

$$\chi^{-1}(1) \subseteq \bigcup_{T \in \mathcal{C}_1} T. \tag{6}$$

We claim that χ is also an ϵ-two-coloring of $(\mathcal{C}_1, \mathcal{C}_0)$. For, if $T \in \mathcal{C}_1$, this follows from (4), if $T \in \mathcal{C}_0'$, then it follows from (5), and, if $T \in \mathcal{C}_0 - \mathcal{C}_0'$, then

$$|\chi^{-1}(1) \cap T| \leq \left|T \cap \bigcup_{T' \in \mathcal{C}_1} T'\right| \leq \epsilon|T|,$$

where the first inequality follows from (6) and the second follows from the definition of $\mathcal{C}_0'$. ∎

Expanders and the intersection property. We now relate the (n, ϵ)-intersection property of $\{\Gamma(u)\}_{u \in U}$ to a certain expansion property of $G = (U, V, E)$.

DEFINITION 3.8. *We say that $G = (U, V, E)$ is an (m, s, n, d, ϵ)-expander if $U = [m]$, $V = [s]$, each vertex in U has degree d, and the following condition holds:*

$$\forall S \in \tbinom{U}{\leq 2n},\ |\Gamma(S)| \geq \left(1 - \frac{\epsilon}{2}\right)|S|d. \tag{7}$$

LEMMA 3.9. *Suppose $\epsilon < 1$ and $G = (U, V, E)$ is an (m, s, n, d, ϵ)-expander with $d \geq 1$. Then $\{\Gamma(u)\}_{u \in U}$ is a collection of m nonempty sets and has the (n, ϵ)-intersection property.*

Proof. Since $\epsilon < 1$, we have from (7) that $|\Gamma(\{u, u'\})| > d$ for distinct $u, u' \in U$. Thus $\Gamma(u) \neq \Gamma(u')$, and there are m nonempty sets in $\{\Gamma(u)\}_{u \in U}$. Suppose $\{\Gamma(u)\}_{u \in U}$ does not have the (n, ϵ)-intersection property; then there exists a set $S = \{u_1, \ldots, u_k, v_1, \ldots, v_k\} \subseteq U$ of $2k$ (for some $k \in [n]$) distinct elements such that, for $j = 1, \ldots, k$,

$$\left| \Gamma(v_j) \cap \bigcup_{i=1}^{k} \Gamma(u_i) \right| > \epsilon d.$$

However, then $|\Gamma(S)| < 2kd - k\epsilon d \leq (1 - \frac{\epsilon}{2}) \cdot 2kd = (1 - \frac{\epsilon}{2})|S|d$, violating (7). ∎

Existence of expanders. Finally, we show that the required expander graph exists.

LEMMA 3.10. *For $\epsilon > 0$, $m \geq 8$, and $n \leq m/2$, there is an $(m, \lceil \frac{200n \log m}{\epsilon^2} \rceil, n, \lfloor \frac{\log m}{\epsilon} \rfloor, \epsilon)$-expander.*

Proof. We show the existence of the expander graph $G = (U, V, E)$, where $U = [m]$ and $V = [s]$, using a standard probabilistic argument.[2] For each vertex u in U, we independently choose its set of neighbors in V, $\Gamma(u)$ by picking without replacement $d = \lfloor \frac{\log m}{\epsilon} \rfloor$ elements from V at random. We wish to show that, with nonzero probability, the resulting graph is an expander (satisfying (7)). For $T \in \binom{U}{\leq 2n}$, let

$$\mathcal{E}(T) \stackrel{\text{def}}{=} |\Gamma(T)| < \left(1 - \frac{\epsilon}{2}\right) |T| d.$$

We wish to show that, with nonzero probability, we can (simultaneously) avoid $\mathcal{E}(T)$ for all $T \in \binom{U}{\leq 2n}$.

CLAIM 3.11. $\Pr[\mathcal{E}(T)] \leq \left(\frac{2}{m}\right)^{2|T|}$.

Proof. Let $t \stackrel{\text{def}}{=} |T|$. We prove the claim under the assumption that the neighbors of $u \in U$ are chosen by sampling with replacement. This will imply the claim even for sampling without replacement: to pick a random set of size d, first pick d elements with replacement, resulting in d' distinct elements (say), and then add $d - d'$ new elements randomly. Suppose $T = \{u_1, u_2, \ldots, u_t\}$. Let $N \stackrel{\text{def}}{=} td$. With the choice of elements for $\Gamma(u_1), \ldots, \Gamma(u_t)$, where $\Gamma(u_j) = \{e_{(j-1)d+1}, \ldots, e_{jd}\}$, we associate N random variables $X_1, \ldots, X_N$, such that

$$X_i \stackrel{\text{def}}{=} \begin{cases} 1 & \text{if } e_i \in \{e_1, \ldots, e_{i-1}\}, \\ 0 & \text{otherwise.} \end{cases}$$

[2] The argument we use is different from what is usually used for showing the existence of expander graphs. Consider the random graph G obtained by choosing d random neighbors from V (with replacement) for each vertex in U. We wish to avoid the event $\exists S \subseteq U\, (|S| \leq 2n) : |\Gamma(S)| \leq (1 - \frac{\epsilon}{2})d|S|$. One usually [3, p. 331] bounds the probability of this event by

$$\sum_{i=1}^{2n} \binom{m}{i} \binom{|V|}{(1-\frac{\epsilon}{2})di} \left(\frac{(1-\frac{\epsilon}{2})di}{|V|}\right)^{di}.$$

For our choice of parameters, $d = \lfloor \frac{\log m}{\epsilon} \rfloor$ and $|V| = \lceil \frac{200n \log m}{\epsilon^2} \rceil$, this quantity is not less than 1 (for example, consider the term with $i = n$), although, in Lemma 3.10, we show that G has the required expansion property with high probability.

Thus

$$\mathcal{E}(T) \equiv \sum_{i=1}^{N} X_i > \frac{\epsilon}{2}N. \tag{8}$$

Now, for all $i \in [N]$ and $\sigma \in \{0,1\}^{i-1}$,

$$\Pr[X_i = 1 \mid X_1 X_2 \cdots X_{i-1} = \sigma] \leq \frac{(i-1)}{s} \leq \frac{2nd-1}{s} \leq \frac{\epsilon}{100}.$$

Let $p \stackrel{\text{def}}{=} \frac{\epsilon}{100}$, and define N independent random variables $Y_1, \ldots, Y_N$ such that

$$Y_i = \begin{cases} 1 & \text{with probability } \frac{\epsilon}{100}, \\ 0 & \text{otherwise.} \end{cases}$$

Then, for all k,

$$\Pr\left[\sum_{i=1}^{N} X_i \geq k\right] \leq \Pr\left[\sum_{i=1}^{N} Y_i \geq k\right]. \tag{9}$$

We will use the following form of Chernoff's bound (see, for example, Alon and Spencer [1, Theorem A.12]):

$$\Pr\left[\sum_{i=1}^{N} Y_i \geq (p+\delta)N\right] \leq \left(\frac{ep}{p+\delta}\right)^{(p+\delta)N}. \tag{10}$$

Thus

$$\begin{aligned} \Pr\left[\sum_{i=1}^{N} Y_i \geq \frac{\epsilon}{2}N\right] &\leq \left(\frac{e\epsilon/100}{\epsilon/2}\right)^{\epsilon N/2} \\ &\leq \left(\frac{1}{4}\right)^{\epsilon t d} \\ &\leq \left(\frac{1}{4}\right)^{\epsilon t(\frac{\log m}{\epsilon}-1)} \\ &\leq \left(\frac{2}{m}\right)^{2t}. \end{aligned}$$

Claim 3.11 now follows from (8) and (9). □

Since $\Pr[\mathcal{E}(\emptyset)] = 0$, Claim 3.11 implies that

$$\Pr\left[\bigvee_{T \in \binom{U}{\leq 2n}} \mathcal{E}(T)\right] \leq \sum_{t=1}^{2n} \binom{m}{t} \left(\frac{2}{m}\right)^{2t} \leq \sum_{t=1}^{2n} \left(\frac{4}{m}\right)^{t} < 1,$$

where we use our assumption, $m \geq 8$, to justify the last inequality. Thus, with nonzero probability, G is an expander. □

3.3. Multiprobe randomized scheme with one-sided error. We now show that the space requirement for schemes with one-sided error can be reduced if more bitprobes are allowed.

Proof of Theorem 5. Our scheme will have two tables. The first table, T_1, will come directly from Theorem 1 (with an appropriate choice of ϵ); the second table will be based on ideas used in Theorem 3. Our multiprobe query algorithm will, correspondingly, have two phases. In the first phase, it will probe T_1 several times (to reduce the error). In the second phase, it will probe T_2 just once. The scheme is nonadaptive: the locations to be probed are completely determined by the query element and the random string but do not depend on the actual values read.

We will view the first half of our scheme as a randomized multiprobe scheme with small two-sided error.

LEMMA 3.12. *There is a randomized* $(n, m, O(\frac{n}{\epsilon^2}\log m), t)$*-scheme that makes an error of at most* $(2e\epsilon)^{t/2}$.

Proof. We use the randomized $(n, m, s, 1)$-scheme of Theorem 1 but run the query algorithm t times (with independent coin tosses) and say "Yes" if and only if at least $t/2$ of the t runs give the answer "Yes." Using Chernoff's bound (see (10) above), we conclude that

$$\Pr[\mathsf{Error}] \;\le\; (2e\epsilon)^{t/2}. \qquad \square$$

We will use the above lemma with $\epsilon = n^{-\delta/2}/(2e)$ and $t = \lceil 4/\delta \rceil$. This will give us an $(n, m, O(n^{1+\delta}\log m), \lceil 4/\delta \rceil)$-scheme Π with error probability at most n^{-2}. We use Π to construct our multiprobe scheme $\hat{\Pi}$. The first table, T_1, of our scheme is exactly what Π uses; it has $s = O(n^{1+\delta}\log m)$ bits. The second table, T_2, has $s' = \lceil 2n^{1+\delta}\log m \rceil$ bits. To see how the contents of T_2 are decided, let us first describe how the query algorithm uses T_2.

The query algorithm. Suppose the query algorithm of Π uses random strings of length ℓ. In our query algorithm, for each $u \in [m]$, we have a sequence $\sigma_u = \langle r_1, r_2, \ldots, r_{s'} \rangle$ of strings $r_i \in \{0,1\}^\ell$. On receiving the query "Is u in S?," the algorithm first chooses i uniformly at random from $[s']$ and then uses the query algorithm of scheme Π with the ith element of σ_u (that is, r_i above) as the random string and T_1 as its table. If the answer returned by Π is "Yes," we say "Yes." If the answer is "No," we move on to table T_2, probe the location i there, and say "Yes" if and only if we read a 1. Thus, to completely specify the query algorithm, we must fix sequences σ_u for each $u \in [m]$. We will show later how suitable sequences σ_u can be found. First, let us determine the contents of table T_2.

The table T_2. Once the query algorithm is specified, there is a natural choice for the contents of T_2. Let $\mathsf{Error}_\Pi(S, u, r)$ denote the event "after storing the set S in its table, the protocol Π gives a wrong answer for the query 'Is u in S?' when it uses the random string r." For $S \in \binom{[m]}{\le n}$, let

$$R(S,u) \stackrel{\text{def}}{=} \{i : \mathsf{Error}_\Pi(S, u, \sigma_u(i))\} \text{ and}$$
$$R(S) \stackrel{\text{def}}{=} \bigcup_{u \in S} R(S,u).$$

Since we allow no error for query elements $u \in S$, $T_2(i)$ must be 1 for all $i \in R(S)$ when we store the set S in our tables. Let the remaining bits of T_2 be 0. This clearly ensures that $\Pr_i[\mathsf{Error}_{\hat{\Pi}}(S, u, i)] = 0$ for all $S \in \binom{[m]}{\le n}$ and $u \in S$. It remains only to

ensure that $\Pr_i[\mathsf{Error}_{\hat{\Pi}}(S,u,i)] \le n^{-\delta}$ when $u \notin S$. For this, we need to choose σ_u carefully.

Choosing σ_u. For $u \notin S$, we have $\mathsf{Error}_{\hat{\Pi}}(S,u,i) \equiv \mathsf{Error}_{\Pi}(S,u,\sigma_u(i)) \vee i \in R(S)$. Thus

$$\Pr_i[\mathsf{Error}_{\hat{\Pi}}(S,u,i)] \le \Pr_i[\mathsf{Error}_{\Pi}(S,u,\sigma_u(i))] + \Pr_i[i \in R(S)]. \tag{11}$$

To bound the first term on the right, we show

$$\forall u, S,\ |R(S,u)| \ \le\ n \log m; \tag{12}$$

to bound the second, we show

$$\forall S,\ |R(S)| \ \le\ n \log m. \tag{13}$$

Since $n \log m \le \frac{s'}{2n^\delta}$, using these bounds in (11), we obtain $\Pr_i[\mathsf{Error}_{\hat{\Pi}}(S,u,i)] \le n^{-\delta}$.

Thus we need to choose σ_u such that (12) and (13) hold. Let each σ_u be a sequence of s' randomly (uniformly and independently) chosen strings from $\{0,1\}^\ell$. Now

$$\Pr_{r \in \{0,1\}^\ell}[\mathsf{Error}_{\Pi}(S,u,r)] \ \le\ \frac{1}{n^2}.$$

Since σ_u is obtained by picking $s' = \lceil 2n^{1+\delta} \log m \rceil$ strings from $\{0,1\}^\ell$ independently, we get, using Chernoff's bound (see (10) above), that

$$\Pr_{\{\sigma_u\}}[|R(S,u)| > n \log m] \ \le\ \left(\frac{e/n^2}{1/(4n^\delta)}\right)^{n \log m} \ \le\ \left(\frac{4e}{n}\right)^{n \log m}.$$

(Note that $(n \log m)/s' \ge 1/(4n^\delta)$.) Thus

$$\Pr_{\{\sigma_u\}}\left[\exists u \in [m], S \in \binom{[m]}{\le n} |R(S,u)| > n \log m\right] \le m^{n+1} \left(\frac{4e}{n}\right)^{n \log m} < \frac{1}{2}.$$

Thus (12) holds with probability more than $\frac{1}{2}$.

To ensure (13), we first observe that, for each $i \in [s']$,

$$\Pr[i \in R(S)] \ \le\ \sum_{u \in S} \Pr[i \in R(S,u)] \ \le\ n \times \frac{1}{n^2} = \frac{1}{n}.$$

Furthermore, the events "$i \in R(S)$" are independent for different $i \in [s']$. Thus, using Chernoff's bound (see (10) above), we obtain

$$\Pr_{\{\sigma_u\}}[|R(S)| > n \log m] \ \le\ \left(\frac{e/n}{1/(4n^\delta)}\right)^{n \log m} \ \le\ \left(\frac{4e}{n^{1-\delta}}\right)^{n \log m},$$

and

$$\Pr_{\{\sigma_u\}}\left[\exists S \in \binom{[m]}{\le n} |R(S)| > n \log m\right] \ \le\ m^n \left(\frac{4e}{n}\right)^{n \log m} < \frac{1}{2}.$$

Thus (13) holds with probability more than $\frac{1}{2}$.

Since (12) and (13) both hold with probability more than $\frac{1}{2}$, they hold simultaneously for some choice $\{\sigma_u\}_{u \in [m]}$. We fix one such choice in our query algorithm. ∎

4. Lower bounds for randomized schemes. Consider a scheme that uses space s and just one bitprobe. In general, on receiving a query, the algorithm does one of three things based on the outcome of its coin tosses and the query element.

1. It decides to answer "Yes," regardless of what is stored in the table (which it may or may not read).
2. It decides to answer "No," regardless of what is stored in the table.
3. It computes, based on the coin tosses and the query element, an index $i \in [s]$ and
   (a) answers "Yes" if and only if the ith bit of the table is 1 or
   (b) answers "Yes" if and only if the ith bit of the table is 0.

It will be convenient if our query algorithm has the following *standard form*: it always reads some bit of the table and answers "Yes" if and only if it reads a 1. A scheme with a general query algorithm can be modified easily so that the new query algorithm is in standard form. This modification will roughly double the space required but will keep the error probability the same. Suppose the original algorithm used the table $T : [s] \to \{0,1\}$. The new algorithm will use a table $T' : [s+1] \times \{0,1\} \to \{0,1\}$, whose contents are defined by

$$T'(i,b) \stackrel{\text{def}}{=} \begin{cases} T(i) & \text{if } i \in [s] \text{ and } b = 1, \\ \neg T(i) & \text{if } i \in [s] \text{ and } b = 0, \\ b & \text{if } i = s+1. \end{cases}$$

The query algorithm is then modified as follows: in case 1 above, when the old algorithm always said "Yes," the new algorithm reads the bit $T'(s+1,1)$; in case 2, the new algorithm reads $T'(s+1,0)$; in case 3(a), it reads $T'(i,1)$; and, in case 3(b), it reads $T'(i,0)$. In all cases, the answer is "Yes" if and only if the bit read is 1.

Our lower bounds for randomized one-probe schemes are based on bounds for r-cover-free families.

DEFINITION 4.1. *A family of sets $\mathcal{F}$ is r-cover-free if, for $T_0, T_1, \ldots, T_r \in \mathcal{F}$ such that $T_0 \notin \{T_1, T_2, \ldots, T_r\}$, $T_0 \not\subseteq T_1 \cup \cdots \cup T_r$.*

THEOREM 10 (Füredi [17]). *If $\mathcal{F}$ is an r-cover-free family of sets and $r \le |\mathcal{F}|^{1/3}$, then*

$$\left| \bigcup_{T \in \mathcal{F}} T \right| \ge \frac{r^2}{4 \log r + O(1)} \log |\mathcal{F}|.$$

(Similar bounds have been shown in [8, 29, 7]*.)*

4.1. Randomized schemes with one-sided error.

Proof of Theorem 4. Suppose there is a randomized $(n, m, s, 1)$-scheme with negative one-sided error ϵ. As discussed earlier, this implies that there is a randomized $(n, m, 2s+2, 1)$-scheme with negative one-sided error ϵ, whose query algorithm is in standard form. Consider the bipartite graph $G = (U, V, E)$, where $U = [m]$, $V = [2s+2]$, and $(u, v) \in E$ if and only if location v is probed (with nonzero probability) on query "Is u in S?" In particular, on query "Is u in S?," the algorithm picks an element $v \in \Gamma(u)$ at random, according to some distribution D_u, and answers "Yes" if and only if there is a 1 in location v of the table.

Let $r \stackrel{\text{def}}{=} \lceil \frac{n}{\epsilon} \rceil - 1$; note that $r < \frac{n}{\epsilon}$.

CLAIM 4.2. *$\{\Gamma(u)\}_{u \in U}$ is an r-cover-free family.*

Proof. Suppose the claim is false. Then there exist distinct $u, u_1, u_2, \ldots, u_r \in U$ such that $\Gamma(u) \subseteq \bigcup_{i=1}^{r} \Gamma(u_i)$. Let S be a random subset of $\{u_1, u_2, \ldots, u_r\}$ of size n.

Then, for each $i \in \Gamma(u)$, $\Pr[i \in \Gamma(S)] \geq \frac{n}{r}$. For $T \subseteq V$, let $D_u(T) \stackrel{\text{def}}{=} \sum_{i \in T} D_u(i)$. By linearity of expectation,

$$\mathrm{E}[D_u(\Gamma(S))] \;=\; \sum_{i \in \Gamma(u)} D_u(i) \Pr[i \in \Gamma(S)] \;\geq \frac{n}{r} \sum_{i \in \Gamma(u)} D_u(i) \;=\; \frac{n}{r} \;>\; \epsilon.$$

Fix a choice for S with $D_u(\Gamma(S)) > \epsilon$. When S is stored, all locations in $\Gamma(S)$ must contain a 1 (because the error is negative one-sided). Then, on query "Is u in S?," the query algorithm answers "Yes" with probability more than ϵ, but the error allowed is at most ϵ. □

Claim 4.2 and Theorem 10 imply that, if $r \leq m^{1/3}$, then

$$|V| \;\geq\; \frac{r^2}{4 \log r + O(1)} \log m.$$

Thus $s = \Omega(\frac{n^2}{\epsilon^2 \log(n/\epsilon)} \log m)$. □

We next consider positive one-sided error and observe that bitvectors are optimal in this case.

THEOREM 11. *Let $\epsilon < 1$ and $m \geq 1$. Any randomized $(1, m, s, 1)$-scheme with positive one-sided error ϵ must have $s \geq m$.*

Proof. Since $\epsilon < 1$, for each $u \in [m]$, there must be a coin toss sequence r_u for which the query algorithm says "Yes" when the set $\{u\}$ is stored and the query "Is u in S?" is posed. In this case, the algorithm must probe some location of the table, for otherwise it would say "Yes" with nonzero probability even when the empty set is stored. Let $\ell_u \in [s]$ be the location probed, and let $b_u \in \{0, 1\}$ be the bit read. We claim that $\ell_u \neq \ell_{u'}$ for $u \neq u'$. For, suppose $u \neq u'$ and $\ell_u = \ell_{u'}$. We have two cases.

$b_u = b_{u'}$. Store $S = \{u\}$. On query "Is u' in S?" and coin toss sequence $r_{u'}$, the algorithm will answer "Yes," which is not allowed.

$b_i \neq b_j$. Store the empty set. Either on query "Is u in S?" with coin toss sequence r_u or on query "Is u' in S?" with coin toss sequence $r_{u'}$, the answer will be "Yes." However, when the empty set is stored, the answer should be "No" with probability 1 for all queries.

Thus $\ell_u \neq \ell_{u'}$ when $u \neq u'$, implying $s \geq m$. □

4.2. Randomized schemes with two-sided error. To prove the lower bound for randomized schemes with two-sided error, we need to use *upper bounds* on r-cover-free families together with the lower bound.

Proof of Theorem 2. Fix a randomized $(n, m, s, 1)$-scheme that answers queries with probability of error at most ϵ. We assume that the query algorithm is in standard form, and, as before, we model it using the bipartite graph (U, V, E), where $U = [m]$ and $V = [s]$: on query "Is u in S?," the algorithm probes a random location in $[s]$ according to a distribution D_u ($D_u(i) \neq 0$ if and only if $i \in \Gamma(u)$) and answers "Yes" if and only if the location contains a 1.

For our lower bound, we will need an r-cover-free family $\mathcal{F} \subseteq \binom{[m]}{\leq n}$, where $r = \lfloor \frac{1}{\epsilon} \rfloor$. We first present the argument assuming such a family; later we will obtain our lower bound by choosing a suitably large $\mathcal{F}$. For $S \in \mathcal{F}$, let $T_S \subseteq [s]$ be the set of locations of the table that contain a 1 when S is stored. Let $\ell = \lfloor \frac{1}{2\epsilon} \rfloor$. Since $\epsilon \leq \frac{1}{4}$, we have $\ell \geq 1$.

CLAIM 4.3. *$\{T_S : S \in \mathcal{F}\}$ is ℓ-cover-free.*

Proof. Suppose $T_{S_0} \subseteq T_{S_1} \cup T_{S_2} \cup \cdots \cup T_{S_\ell}$ for some $S_0, S_1, \ldots, S_\ell \in \mathcal{F}$, such that $S_0 \notin \{S_1, S_2, \ldots, S_\ell\}$. We will derive a contradiction.

Since $\mathcal{F}$ is r-cover-free and $r \geq \ell$, we have $S_0 \not\subseteq \bigcup_{i=1}^{\ell} S_i$; let $u \in S_0 - \sum_{i=1}^{\ell} S_i$. Since $u \in S_0$, $D_u(T_{S_0}) \geq 1 - \epsilon$. Thus $D_u(\bigcup_{i=1}^{\ell} T_{S_i}) \geq 1 - \epsilon$ and $D_u(T_{S_i}) \geq \frac{1-\epsilon}{\ell}$ for some $i \in [n]$. Fix one such i. Now, when the scheme stores the set S_i and receives the query "Is u in S_i?," it says "Yes" with probability at least $\frac{1-\epsilon}{\ell} \geq 2\epsilon(1-\epsilon) > \epsilon$. However, this is not possible. □

Using the above claim and Theorem 10, we obtain that, if $\ell \leq |\mathcal{F}|^{1/3}$, then

$$s \geq \frac{\ell^2}{4\log \ell + O(1)} \log |\mathcal{F}|. \tag{14}$$

To prove our lower bound, we need to find an r-cover-free family of large size. If $\epsilon \geq \frac{1}{n}$, we use Lemma 3.2 to obtain $\mathcal{F} \subseteq \binom{[m]}{n}$ of size at least

$$\frac{\binom{m}{\lceil \epsilon n \rceil}}{\binom{n}{\lceil \epsilon n \rceil}^2} \geq \left(\frac{m\epsilon}{e^2 n}\right)^{\epsilon n},$$

where the pairwise intersection of sets is of size at most $\lceil \epsilon n \rceil - 1$. Such a family is $\lfloor \frac{1}{\epsilon} \rfloor$-cover-free, for otherwise some pair of sets would intersect on at least $\lceil \frac{n}{\lfloor 1/\epsilon \rfloor} \rceil \geq \lceil \epsilon n \rceil$ elements. Then (14) gives us (using our assumption $n \leq m^{1/3}$)

$$s \geq \frac{(1/\epsilon)^2}{4\log(1/\epsilon) + O(1)} \log \left(\frac{m\epsilon}{e^2 n}\right)^{\epsilon n} = \Omega\left(\frac{n}{\epsilon \log(1/\epsilon)} \log m\right).$$

If $\epsilon < \frac{1}{n}$, we use the r-cover-free family $\binom{[m]}{1}$ and use (14) to obtain

$$s \geq \frac{(1/\epsilon)^2}{4\log(1/\epsilon) + O(1)} \log m = \Omega\left(\frac{n}{\epsilon \log(1/\epsilon)} \log m\right). \qquad \square$$

5. Deterministic schemes. We now show a time-space tradeoff result for deterministic schemes.

Proof of Theorem 6. Recall that the bitstring used to store the set $S \in \binom{[m]}{n}$ is called $\phi(S)$. Let

$$T_S \stackrel{\text{def}}{=} \{\langle \ell, \phi(S)(\ell) \rangle : \text{location } \ell \text{ of } \phi(S) \text{ is probed on query "Is } u \text{ in } S\text{?" for some } u \in S\}.$$

We now observe that the sets T_S have to be incomparable for different S. For, if $T_{S_1} \supseteq T_{S_2}$ for $S_1 \neq S_2$, store the set S_1, and ask the query "Is u in S_1?" for an element $u \in S_2 - S_1$. The scheme will err on this query, which is a contradiction. Now each T_S is a subset of size at most nt of the set $[s] \times \{0,1\}$. It follows, from the Lubell, Yamamoto, and Meshalkin (LYM) inequality (see, for example, Alon and Spencer [1, p. 183]), that $\binom{m}{n} \leq \max_{i \leq nt} \binom{2s}{i}$. □

We now study deterministic schemes when the number of probes allowed is small.

Proof of Theorem 7*, part* 1. We will obtain our deterministic scheme from a randomized $(m, n, O(tnm^{2/(t+1)}), 1)$-scheme with error probability *less* than $\frac{1}{2}$. The randomized scheme we use will be in the standard form: on query "Is u in S?," the query algorithm will pick a location randomly from a set $\Gamma(u)$ and say "Yes" if and only if a 1 is stored there. The size of $\Gamma(u)$ will be exactly $2t+1$. To obtain the deterministic scheme, we read all locations in $\Gamma(u)$ and say "Yes" if a majority (at least $t+1$) of them contains 1.

To construct the randomized scheme, we use the method of Theorem 1. Using calculations similar to those in the proof of Lemma 3.10, one can show that there is a graph $G = (U, V, E)$, where $U = [m]$ and $V = [s]$, such that $s = O(tnm^{2/(t+1)})$ and $|\Gamma_u| = 2t + 1$ for $u \in U$, such that $\{\Gamma(u)\}_{u \in U}$ has the $(n, \frac{t}{2t+1})$-intersection property. By Lemmas 3.6 and 3.4, it follows that there is an $(m, n, O(tnm^{2/(t+1)}), 1)$-scheme with error probability less than $\frac{1}{2}$. □

Proof of Theorem 7*, part* 2. Our adaptive scheme uses a combination of the FKS scheme and the bitvector scheme.

Storing scheme. Given a set T, do the following.

Step 1. Find a prime $p < n^2 \log m$ such that, if $x \neq y$, $x, y \in T$, then $x \bmod p \neq y \bmod p$. The fact that such a prime exists has been shown by Fredman, Komlós, and Szemerédi [16]. Store p using $O(\log n + \log\log m)$ bits.

Step 2. Now the set $T \bmod p$ consists of n elements, each less than $n^2 \log m$. Store this set using the FKS data structure. This requires space $O(n(\log n + \log\log m))$.

Step 3. For every $x \in T$, do the following: divide the string x into t blocks $B_1, \ldots, B_t$, each of size $\log m/t$. For each such block B_i, construct a look-up table of size $2^{\log m/t}$ with a 1 in the index given by B_i. Space required is $nt2^{\log m/t}$ bits.

Space used by the storing scheme is $O(n(\log n + \log\log m) + nt2^{\log m/t})$.

Query scheme. Given a query u, do the following.

Step 1. Read the prime p. This requires $O(\log n + \log\log m)$ bitprobes.

Step 2. Find $u \bmod p$. Now check if there is an element y in T such that $u \bmod p = y \bmod p$ using the FKS structure. This requires $O(\log n + \log\log m)$ bitprobes.

Step 3. If there is no such y, say "No."

Step 4. If there is such a y, retrieve a pointer to it using $O(\log n)$ bitprobes. Then divide u into t blocks, and check if $x = y$ block by block. This requires t bitprobes.

The time used by the query scheme is $O(\log n + \log\log m) + t$. □

Finally, we consider deterministic schemes that use two bitprobes. We show that two nonadaptive probes do not help even for $n = 2$. We also show that adaptiveness helps for $n = 2$.

Proof of Theorem 8*, part* 1. There are 16 different functions mapping $\{0,1\}^2$ to $\{0,1\}$. We will divide them into 3 classes.

1. Degenerate functions. These are the functions depending on at most one variable. There are 6 such functions, namely, 0, 1, u, y, $\bar{x}$, $\bar{y}$.
2. Inflexible functions. These are the functions f, so that there is a value of $f(x, y)$ which determines the value of u as well as the value of y. For instance, $x \wedge y = 1 \Rightarrow x = y = 1$. There are 8 such functions, namely, $x \wedge y$, $\bar{x} \wedge y$, $x \wedge \bar{y}$, $\bar{x} \wedge \bar{y}$, $x \vee y$, $\bar{x} \vee y$, $x \vee \bar{y}$, $\bar{x} \vee \bar{y}$.
3. Flexible functions. These are functions which are neither degenerate nor inflexible. There are 2 such functions, namely, $x \oplus y$ and $\bar{x} \oplus y$.

Suppose the theorem fails. Fix m at the smallest value for which this happens. Note that the theorem is trivially true for $m = 1$. Let U be a universe of size m. The corresponding scheme associates with each $z \in U$ two locations u_z and v_z in $\{1, \ldots, s\}$ and a Boolean function $f_z : \{0,1\}^2 \to \{0,1\}$. Clearly, if, for some z, f_z is constant, the scheme is incorrect. Now assume that, for some z, f_z is degenerate. Assume that

it depends on its first variable. We can get a scheme for a universe of size $m-1$ by fixing the value of u_z, yielding a structure of size $s-1$. This is a contradiction. Thus we can assume that all functions f_z are inflexible or flexible. Now assume, to the contrary, that $s < m$. Let the multigraph $G = (V, E)$ be given by $V = \{1, \ldots, s\}$ and $E = \{e_z = (u_z, v_z) : z \in U\}$. Let an edge e_z be denoted flexible if the corresponding function f_z is flexible, and let it be denoted inflexible otherwise. As $|E| = m$, $|V| = s$, and $s < m$, G contains a cycle C. (As G is a multigraph, it may be the case that C consists of exactly two identical edges.)

Now there are two cases.

1. *The cycle C contains only flexible edges.* Let Z be the elements corresponding to the edges in C. Fix any setting τ of the bits in the data structure. Each edge e_z on the cycle corresponds to an element $z \in Z$, and we can see if $z \in S$ by adding, modulo 2, the setting $\tau(u_z)$ of the bit u_z and the setting $\tau(v_z)$ of the bit v_z or the setting $\overline{\tau(u_z)}$ of the bit $\overline{u}_z$ and the setting $\tau(v_z)$ of the bit v_z. This quantity summed over all z in Z uniquely determines the parity of the number of elements of $S \cap Z$. But this sum is zero or one depending on the number of z of the second type. As the sum determines the parity of $|Z \cap S|$, either $\emptyset$ or $\{z\}$, where z is any element of Z, has no valid representation.
2. *The cycle C contains an inflexible edge.* Let this edge be e_z. There is a choice of $z \in S$ or $z \notin S$ which makes only one configuration of the values of the bits u_z, v_z possible. Fix this choice. Let us assume that it is $z \in S$. (The case $z \notin S$ is similar.) Now let z_1 be the other edge on C, adjacent to v_z. Having already fixed $v_z = u_{z_1}$, there are two possibilities: having thus fixed u_{z_1} either determines whether $z_1 \in S$ or it does not. If it does, either $\{z\}$ or $\{z, z_1\}$ has no valid representation, and we are done. If it does not, we fix the setting of v_{z_1} in the unique way so that $z_1 \notin S$. Now let z_2 be the other edge on C, adjacent to v_{z_1}. Having already fixed $v_{z_1} = u_{z_2}$, there are two possibilities: fixing u_{z_2} in this manner either determines whether or not $z_2 \in S$ or it does not. If it does, either $\{z\}$ or $\{z, z_1\}$ has no valid representation, and we are done. If it does not, we fix the setting of v_{z_2} in the unique way so that $z_2 \notin S$. Now let z_3 be the other edge on C, adjacent to v_{z_2}, etc. Thus, working our way around the cycle, we finally come to an edge e_{z_l}, adjacent to u_z. Thus we have fixed u_{z_l} as well as $v_{z_l} = u_z$, and we conclude that either $\{z\}$ or $\{z, z_l\}$ has no valid representation.

Thus we have arrived at a contradiction, and we conclude $s \geq m$. □

It is easy to get a three probe nonadaptive scheme for sets of size at most 2 using space $O(m^{1/2})$. Such a scheme can be obtained, for instance, from the explicit one-sided error scheme by setting the parameters appropriately.

Proof of Theorem 8*, part* 2. The structure of the proof is as follows. We will first define a certain combinatorial object. We then show that the existence of this object implies the two-probe scheme claimed in the theorem. Then we show, using the probabilistic method (in particular, the *alteration* technique), that the desired object exists.

Thus let $U = \{1, 2, \ldots, m\}$. Let an *augmented s-partition* of U be a system consisting of

1. a partition of U into classes $U_1, U_2, \ldots, U_s$,
2. a set system $M_1, M_2, \ldots, M_s$ on $\{1, 2, \ldots, s\}$,
3. a set system $N_1, N_2, \ldots, N_s$ on $\{1, 2, \ldots, s\}$,
4. a family of one-to-one maps $f_i : U_i \to M_i$,

5. a family of one-to-one maps $g_i : U_i \to N_i$,

with the following property.

For all $U_i \neq U_j$, $x \in U_i$, and $y \in U_j$, we have *either* $f_i(x) \notin M_j$ and $f_j(y) \notin M_i$ *or* $g_i(x) \notin N_j$ and $g_j(y) \notin N_i$.

CLAIM 5.1. *If an augmented s-partition exists, there is an adaptive two-probe scheme using $3s$ bits solving the membership problem.*

Proof.

Storing scheme. The scheme will make use of three tables T, T_0, and T_1, each of size s. Given a set $S = \{x, y\}$, there are three cases.

1. *u and y are in the same class, U_i.* We let $T[i] = 0$ and $T[j] = 1$ for all $j \neq i$. We let $T_0[f_i(x)] = T_0[f_i(y)] = 1$ and $T_0[j] = 0$ for all $j \notin \{f_i(x), f_i(y)\}$. We let $T_1[j] = 0$ for all j.
2. *u and y are in different classes, $x \in U_i$ and $y \in U_j$. Furthermore, $f_i(x) \notin M_j$ and $f_j(y) \notin M_i$.* We let $T[i] = T[j] = 0$ and $T[k] = 1$ for all $k \notin \{i, j\}$. We let $T_0[f_i(x)] = T_0[f_j(y)] = 1$ and $T_0[j] = 0$ for all $j \notin \{f_i(x), f_j(y)\}$. We let $T_1[j] = 0$ for all j.
3. *x and y are in different classes, $x \in U_i$ and $y \in U_j$. Furthermore, $g_i(x) \notin N_j$ and $g_j(y) \notin N_i$.* We let $T[i] = T[j] = 1$ and $T[k] = 0$ for all $k \notin \{i, j\}$. We let $T_1[g_i(x)] = T_1[g_j(y)] = 1$ and $T_0[j] = 0$ for all $j \notin \{g_i(x), g_j(y)\}$. We let $T_0[j] = 0$ for all j.

Query scheme. Given a query q in class U_i, do the following:

1. Read $T[i]$.
2. If it is 0, read $T_0[f_i(q)]$. If 1 is seen, say "Yes." Otherwise, say "No."
3. If it is 1, read $T_1[g_i(q)]$. If 1 is seen, say "Yes." Otherwise, say "No."

It is easily seen that the augmented partition property ensures that the scheme is correct. □

The theorem now follows from the following claim. □

CLAIM 5.2. *For any m, an augmented $O(m^{3/4})$-partition exists.*

Proof. Let $U' = \{1, 2, \ldots, 2m\}$. We shall construct a "blemished" augmented partition of U' and then alter it so that it has the right property.

We assume, without loss of generality, that $s = 2(2m)^{3/4}$ is an integer and divides $2m$. Thus we can partition U' evenly into $U_1, U_2, \ldots, U_s$, each of size $\frac{1}{2}(2m)^{1/4}$. Now we choose M_i and N_i independently at random from among all subsets of size $\frac{1}{2}(2m)^{1/4}$ of $\{1, 2, \ldots, s\}$. We choose f_i and g_i independently at random from all one-to-one functions.

Now consider fixed $x \in U_i$, $y \in U_j$ for $i \neq j$. We will bound the probability that the property fails for this particular pair. Clearly,

$$\Pr[f_i(x) \in M_j] = \frac{|M_j|}{s} = \frac{\frac{1}{2}(2m)^{1/4}}{2(2m)^{3/4}} = \frac{1}{4(2m)^{1/2}}.$$

By the union bound,

$$\Pr[f_i(x) \in M_j \vee f_j(y) \in M_i] \leq \frac{1}{2(2m)^{1/2}},$$

and, similarly,

$$\Pr[g_i(x) \in N_j \vee g_j(y) \in N_i] \leq \frac{1}{2(2m)^{1/2}}.$$

As the two events are independent, we get

$$\Pr[(f_i(x) \in M_j \vee f_j(y) \in M_i) \wedge (g_i(x) \in N_j \vee g_j(y) \in N_i)] \leq \frac{1}{8m}.$$

Therefore, the expected number of pairs (x, y) for which the desired property does not hold is less than $\binom{2m}{2}\frac{1}{8m} < m$. Hence there is a choice of M_i, N_i, f_i, g_i, such that the number of bad pairs (x, y) is at most m. Now, from each such bad pair, remove one of the elements. We remove at most m elements, yielding a universe of size at least m, as desired. For the remaining elements, the property holds, and we are done. □

The bound of $O(m^{3/4})$ in the above claim has been improved to $O(m^{2/3})$ by Radhakrishnan, Raman, and Rao (see [28]).

Acknowledgments. We are grateful to Venkatesh Raman, S. Srinivasa Rao, and Amnon Ta-Shma for their comments on this work, and to the referees for their help in improving the paper.

ON THE BOUNDARY COMPLEXITY OF THE UNION OF FAT TRIANGLES*

JÁNOS PACH† AND GÁBOR TARDOS‡

Abstract. A triangle is said to be δ-*fat* if its smallest angle is at least $\delta > 0$. A connected component of the complement of the union of a family of triangles is called a *hole*. It is shown that any family of n δ-fat triangles in the plane determines at most $O\left(\frac{n}{\delta}\log\frac{2}{\delta}\right)$ holes. This improves on some earlier bounds of Efrat, Rote, Sharir, and Matoušek, et al. Solving a problem of Agarwal and Bern, we also give a general upper bound for the number of holes determined by n triangles in the plane with given angles. As a corollary, we obtain improved upper bounds for the boundary complexity of the union of fat polygons in the plane, which, in turn, leads to better upper bounds for the running times of some known algorithms for motion planning, for finding a separator line for a set of segments, etc.

Key words. holes, boundary complexity, fat objects

1. Introduction and main results.

Many basic problems in computational geometry related to motion planning [SS83, SS83b, SS89, SS90], range searching [K97, GJ97], computer graphics [AK94], and geographic information systems (GIS) [BK97] lead to questions about the complexity of the boundary of the union of certain geometric objects. When the boundary is simple, these problems can usually be solved more efficiently [GS93]. This was the motivation behind a lot of research during the past fifteen years, establishing upper bounds for the complexity (or, equivalently, for the description size) of the union of various objects.

Perhaps the first results of this kind were the following. Given n simply connected regions in the plane, any two of which share at most two (resp., at most three) boundary points, the boundary of their union consists of at most $6n-12$ (resp., at most $n\alpha(n)$) *simple arcs*, i.e., connected pieces whose interior belongs to the boundary of a single region [KL86] (resp., [EG89]; here $\alpha(n)$ denotes the extremely slowly growing inverse of Ackermann's function). In some sense, this result is the best possible: if two regions are allowed to cross at four boundary points, then the boundary of their union may consist of $\Omega(n^2)$ simple arcs. Indeed, consider n very "skinny" pairwise crossing triangles, no three of which have a point in common.

However, it was discovered by Matoušek et al. [MP94] that, if we restrict how skinny our triangles can be, we can still establish a nearly linear upper bound on the complexity of their union. For any $\delta > 0$, a triangle is said to be δ-*fat* if each of its angles is at least δ. (The reciprocal of the smallest angle of a triangle is often called

its *aspect ratio*.) It turned out that, for any fixed $\delta > 0$, the boundary of the union of n δ-fat triangles in the plane consists of at most $n \log\log n/\delta^3$ simple arcs.

The *boundary complexity* of the union of a family $\mathcal{T}$ of triangles (or simply connected regions) is defined as the number of simple arcs along $\mathrm{Bd}(\cup\mathcal{T})$, the boundary of the union of $\mathcal{T}$. A connected component of the complement of $\cup\mathcal{T}$ is called a *hole*. The heart of the argument in [MP94] was the following statement.

THEOREM 0 (Matoušek et al.). *Any family of n δ-fat triangles in the plane determines $O\left(n/\delta^3\right)$ holes.*

The concept of δ-fatness, as well as the above theorem, has been extended to arbitrary polygons by van Kreveld [K98]. For other extensions and generalizations, see [SH93], [S94], [ES97], [EK98], and [E99].

For *wedges* (i.e., cones) in place of triangles, a somewhat better upper bound was found by Efrat, Rote, and Sharir [ER93]. They proved that the number of holes determined by n wedges in the plane (and the boundary complexity of their union) is $O\left(\frac{n}{\delta^2}\log\frac{2}{\delta}\right)$.

Our first theorem generalizes and strengthens this result.

THEOREM 1. *Any family of n δ-fat triangles in the plane determines $O\left(\frac{n}{\delta}\log\frac{2}{\delta}\right)$ holes. This bound is tight up to the logarithmic factor.*

Theorem 1 can be used to establish a more general upper bound for the number of holes determined by a family of triangles with given angles.

THEOREM 2. *Let $\mathcal{T} = \{T_1, \ldots, T_n\}$ be a family of $n > 1$ triangles in the plane, and let α_i denote the smallest angle of T_i $(1 \le i \le n)$. Suppose $0 < \alpha_1 \le \alpha_2 \le \cdots \le \alpha_n$, and let $k \le n$ be the largest integer satisfying $\sum_{i=1}^{k} \alpha_i < \pi$.*

Then $\mathcal{T}$ determines $O(nk\log k)$ holes. Furthermore, there exists a family $\mathcal{T}' = \{T_1', \ldots, T_n'\}$, where T_i' and T_i are congruent for all i, and $\mathcal{T}'$ determines $\Omega(nk)$ holes.

Of course, the same result applies to wedges, provided that their angles are separated from π. Moreover, in this case, an almost identical upper bound holds for the *boundary complexity* of the union.

THEOREM 3. *Let $\mathcal{T}$ be a family of n wedges in the plane with angles $0 < \alpha_1 \le \cdots \le \alpha_n < \pi$. Let $k \le n$ be the largest integer satisfying $\sum_{i=1}^{k} \alpha_i < \pi$.*

If $k \ge 2$, then the boundary complexity of $\cup\mathcal{T}$ is $O(nk\log k)$. Furthermore, there exists a family of n wedges with angles $\alpha_1, \ldots, \alpha_n$ which determines $\Omega\left((\pi - \alpha_n)nk\right)$ holes.

Notice that Theorem 3 bounds the boundary complexity instead of the number of holes. The bound in Theorem 2 for the number of holes in families of triangles cannot be extended to boundary complexity as there are families of equilateral triangles (for which $k = 2$) with superlinear boundary complexities (at least $\Omega(n\alpha(n))$; cf. [WS88]).

In some applications, e.g., the overlay of triangulated environments in GIS, we cannot assume that *all* of the participating triangles are fat (have bounded aspect ratios). However, very often *most* of them satisfy this condition [ZS99]. To deal with these situations, Agarwal and Bern [AB99] asked whether Theorem 0 can be generalized as follows. Let $\mathcal{T}$ be a family of n triangles in the plane, whose *average* aspect ratio is bounded by a constant. That is, $\sum_{i=1}^{n} \frac{1}{\alpha_i} = O(n)$, where α_i denotes the smallest angle of the ith triangle. Is it then true that $\mathcal{T}$ determines only $O(n)$ (or nearly a linear number of) holes? Theorems 2 and 3 answer this question in the negative. Indeed, let

$$\alpha_i = \begin{cases} \frac{1}{\sqrt{n}} & \text{if } 1 \le i \le \sqrt{n}, \\ 1 & \text{if } \sqrt{n} < i \le n. \end{cases}$$

Then we have $\sum_{i=1}^{n} \frac{1}{\alpha_i} < 2n$, but, according to the second statement of Theorem 2, the number of holes can be as large as $\Omega(n^{3/2})$. This is true even for wedges (see Theorem 3). The first statement of Theorem 2 shows that this bound is tight, apart from the logarithmic factor.

In the case when some of the wedges have angles very close to π, Theorem 3 is not sufficiently tight. A more careful analysis can account more precisely for the contribution of the convex wedges with angles close to π.

THEOREM 4. *Let $\mathcal{T}$ be a family of n wedges in the plane with angles $0 < \alpha_1 \leq \cdots \leq \alpha_n < 2\pi$. Let $l \in [0, n]$ be the largest integer satisfying $\alpha_l < 3\pi/4$, and let $m \in [l, n]$ be the largest integer satisfying $\alpha_m < \pi$. (We set $l = 0$ if $\alpha_1 \geq 3\pi/4$, and we set $l = m = 0$ if $\alpha_1 \geq \pi$.) Let k be the largest integer with $\sum_{j=1}^{k} \alpha_j < \pi$, and, for any $1 \leq i \leq m$, let $k_i \in [0, i)$ be the largest integer such that $\sum_{j=1}^{k_i} \alpha_j < \pi - \alpha_i$.*

Then the boundary complexity of $\cup\mathcal{T}$ is $O(n + \sum_{i=1}^{l} k_i \log k_i + \sum_{i=l+1}^{m} k_i) = O(n + lk \log k + \sum_{i=l+1}^{m} k_i)$, where the sum is taken over all i with $k_i \neq 0$. Furthermore, there is a family of n wedges with angles $\alpha_1, \ldots, \alpha_n$ which determines $\sum_{i=1}^{m'} k_i + m' + 1$ holes, where $m' = \min\{m, n-1\}$.

The rest of the paper is organized as follows. The proofs of Theorems 1, 2–3, and 4 are presented in sections 2–3, 4, and 5, respectively. The last section contains some combinatorial and algorithmic consequences of the main results.

2. Reduction to rhombs and assignment of holes. By a *polygon* we mean a simply connected (bounded or unbounded) region in the plane, whose boundary consists of a finite number of straight-line segments and possibly two half-lines. A family of polygons is said to be in *general position* if no three lines supporting different sides of the polygons pass through the same point. We say that a *point* is *incident* to a hole H if it lies on the boundary of H.

Given a family $\mathcal{P}$ of polygons in the plane, let $h(\mathcal{P})$ and $H(\mathcal{P})$ denote the number of holes determined by $\mathcal{P}$ and the minimum number of nonoverlapping convex polygons the union of these holes can be partitioned into, respectively. Furthermore, let $c(\mathcal{P})$ stand for the number of concave angles of $\Re^2 \setminus \cup\mathcal{P}$, the union of the holes.

LEMMA 2.1. *For any family $\mathcal{P}$ of polygons in the plane, we have*

$$h(\mathcal{P}) \leq H(\mathcal{P}) \leq h(\mathcal{P}) + c(\mathcal{P}).$$

Proof. The lower bound on $H(\mathcal{P})$ follows from the fact that, to cover each hole, we need at least one convex set. To establish the upper bound, we show that every hole with k concave vertices can be partitioned into $k+1$ convex sets. In the case when $k = 0$, the hole itself is convex. For $k > 0$, it is enough to observe that the total number of concave vertices decreases by cutting the hole into two along the angular bisector at a concave vertex. ∎

LEMMA 2.2. *Let $\mathcal{P}$ and $\mathcal{P}'$ be two families of polygons in the plane such that $\cup\mathcal{P}' \subseteq \cup\mathcal{P}$ and any segment connecting two points of $\Re^2 \setminus \cup\mathcal{P}$ which intersects $\cup\mathcal{P}$ also intersects $\cup\mathcal{P}'$.*

Then $H(\mathcal{P}) \leq H(\mathcal{P}')$.

Proof. For any partition of $\Re^2 \setminus \cup\mathcal{P}'$ into a family $\mathcal{C}$ of convex sets, $\{C \setminus \cup\mathcal{P} \mid C \in \mathcal{C}\}$ forms a partition of $\Re^2 \setminus \cup\mathcal{P}$ into convex sets. Note that we needed the condition in the lemma to guarantee that each member of the latter family is convex. ∎

For the rest of this section, we fix an angle $\delta \leq \pi/3$ and set $k := \lceil 2\pi/\delta \rceil$. Clearly, we have $k \geq 6$. Fix any straight line ℓ_0 in the plane. We say that a *segment* (line,

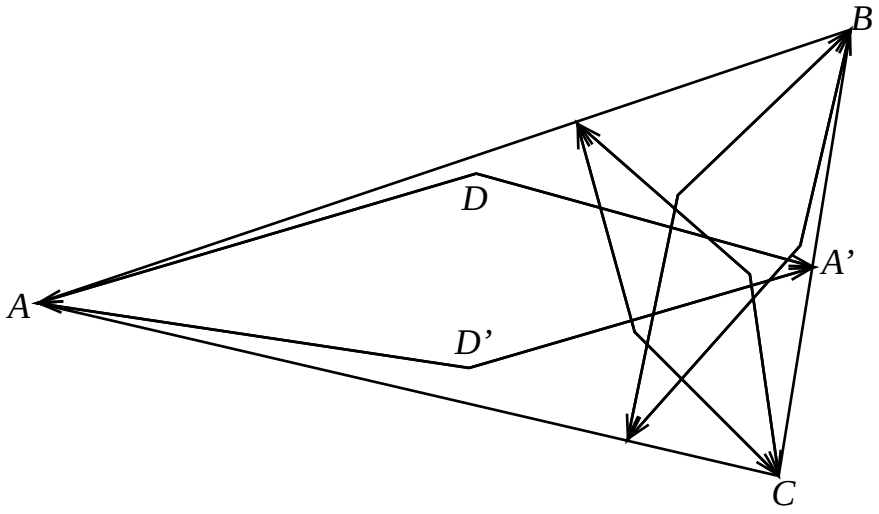

FIG. 1. *Substituting three canonical rhombs for a triangle.*

half-line) is *canonical* if the angle between its supporting line and ℓ_0 is an integer multiple of π/k. A *rhomb* is called *canonical* if (i) all of its sides are canonical, and (ii) two of its angles are equal to π/k.

Next we show that Theorem 1 can be reduced to the following theorem.

THEOREM 2.3. *Any family $\mathcal{R}$ of n canonical rhombs in the plane determines $O(nk\log k)$ holes.*

Proof of Theorem 1 (using Theorem 2.3). Let $\mathcal{T}$ be a family of n δ-fat triangles in the plane. Consider a vertex A of a triangle $ABC \in \mathcal{T}$. By the choice of k, there are at least two canonical half-lines emanating from A, whose initial segments belong to ABC. Therefore, we can pick a point A' on the segment BC and two other points, D and D', in ABC such that $R_A = ADA'D'$ is a canonical rhomb whose angles at A and A' are equal to π/k. Let R_A denote such a rhomb. Similarly, we can define two other canonical rhombs, R_B and R_C, within the triangle ABC. (See Figure 1.)

Let $\mathcal{T}'$ denote the family obtained from $\mathcal{T}$ by replacing every triangle $ABC \in \mathcal{T}$ by the three corresponding canonical rhombs, R_A, R_B, and R_C. By Theorem 2.3, $\mathcal{T}'$ determines $O(nk\log k)$ holes, i.e., $h(\mathcal{T}') = O(nk\log k)$. Now Lemmas 2.1 and 2.2 imply that

$$h(\mathcal{T}) \le H(\mathcal{T}) \le H(\mathcal{T}') \le h(\mathcal{T}') + c(\mathcal{T}').$$

In other words, the number of holes determined by $\mathcal{T}$ may be larger than the number of holes determined by $\mathcal{T}'$, but the difference cannot exceed the total number of concave corners (vertices) in all holes determined by $\mathcal{T}'$. However, every such corner corresponds to a vertex of one of the $3n$ rhombs defined above, so the difference is at most $12n$. □

In the rest of this section and the next section, we establish Theorem 2.3. We may and will assume without loss of generality that the rhombs in $\mathcal{R}$ are in general position. We use the term *edge* only for the sides of the rhombs in $\mathcal{R}$. We call two edges *homothetic* if they are corresponding sides of two homothetic rhombs. We orient every edge e of a rhomb toward its vertex of angle π/k. This vertex is called the *apex* of e. The subsegments of e inherit the orientation of e.

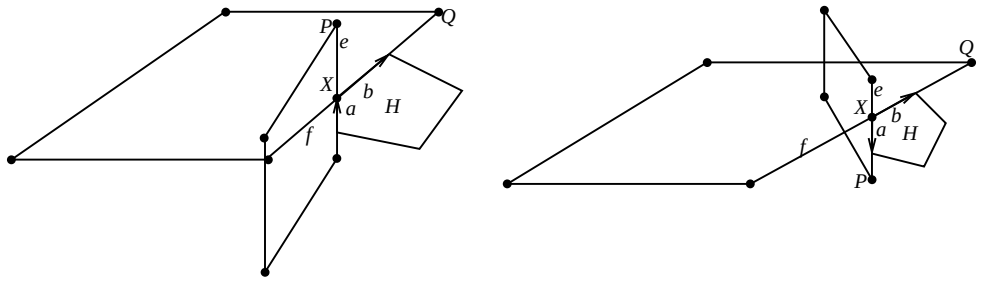

FIG. 2.

Let e be an edge, and let S be a homothecy class of edges not containing e. There may be several holes whose boundaries contain a piece of e next to a piece of some element of S. The first and last such holes along e are said to be *extreme*. Since there are $4n$ edges in at most $4k$ homothecy classes, the number of extreme holes is at most $32kn$. We call the nonextreme holes *intermediate*. Clearly, it is sufficient to bound the number of intermediate holes. As every hole incident to a vertex of a rhomb is extreme, the intermediate holes are convex.

Let H be an intermediate hole. Consider two consecutive segments, a and b, on the boundary of H, belonging to the edges e and f, respectively, and denote their common endpoint by X. Let P and Q denote the apices of e and f, respectively. Suppose that b is oriented away from X. We say that H is a *hole assigned to* e if we have $|X-P| \le |X-Q|$. The distance $|X-P|$ is called the *depth of* H *along* e or, if it leads to no confusion, simply the *depth of* H. We say that H is an *in-hole* or an *out-hole* assigned to e, depending on whether a is oriented toward X or away from X. See Figure 2.

LEMMA 2.4. *Every intermediate hole is assigned to at least one edge.*

Proof. Let H be an intermediate hole. If the segments bounding H are not cyclically oriented, we find two consecutive segments, both oriented away from their common endpoint. In this case, H is an out-hole assigned to one of the edges containing these two segments.

Suppose that the segments forming the boundary of H are cyclically oriented. Let $X_1, X_2, \dots, X_k = X_0$ denote the vertices of H in this cyclic order, and let P_i denote the apex of the edge containing $X_{i-1}X_i$ $(1 \le i \le k)$. Set $P_{k+1} := P_1$ and $X_{k+1} := X_1$. For every $1 \le i \le k$, if H is not an in-hole assigned to the edge containing $X_{i-1}X_i$, then we have

$$|X_i - P_i| > |X_i - P_{i+1}| = |X_i - X_{i+1}| + |X_{i+1} - P_{i+1}|.$$

Summing up these inequalities, we obtain

$$\sum_{i=1}^{k} |X_i - P_i| > \sum_{i=1}^{k} |X_i - P_i| + \mathrm{Per}(H),$$

where $\mathrm{Per}(H)$ stands for the perimeter of H. This contradiction proves that H is an in-hole assigned to an edge supporting one of its sides. □

Next we show that the depths of the in-holes along an edge are $\Omega(1/k)$ apart in a logarithmic scale, and the same is true for the depths of the out-holes. (The depth of

an in-hole can be arbitrarily close to the depth of an out-hole though.) More precisely, we have the following lemma.

LEMMA 2.5. *Let H be an in-hole (out-hole) assigned to an edge e, whose depth is d. Then the depth of no other hole assigned to e is between d and $\left(1-\frac{1}{k}\right)d$ (resp., between d and $\left(1+\frac{1}{k}\right)d$).*

Proof. Let a and b be two consecutive segments of the boundary of H causing H to be assigned to e. Let X be their common endpoint, let f be the edge containing b, and let P and Q be the apices of e and f, respectively. Clearly, a is on e oriented toward X, and b is oriented away from X. The depth of H is $d = |X-P|$. Since H is not an extremal hole, e must cut through the rhomb belonging to the edge f. The length of the piece of XP covered by this rhomb is at least

$$|X-Q|\sin\frac{\pi}{k} \geq |X-P|\sin\frac{\pi}{k} > \frac{d}{k}.$$

Thus the depth of no hole along e can belong to the interval $((1-1/k)d, d)$. The corresponding statement for out-holes can be proved similarly. □

3. Base points. Theorem 2.3 would immediately follow from Lemma 2.5 if we could show that the ratio of the largest and smallest depths of an in-hole (and out-hole) along the same edge is bounded by a polynomial of k. It is not hard to see that this holds for wedges rather than rhombs (and this can be used to give a direct proof of Theorem 3), but the general statement is false. We prove instead that the depths of the intermediate holes (in-holes and out-holes) assigned to a given edge fall into a small number of short intervals.

To formulate our result precisely, we need some preparation. We assign at most *three* so-called *base points* to each edge, according to the following definition.

DEFINITION 3.1 (base points). *Let $e = NP$ be an edge of a rhomb $\Delta = NPSU \in \mathcal{R}$, and let e be oriented toward P. Let Y denote the point of e closest to N that does not belong to the interior of any member of $\mathcal{R}$. Let both P and Y be assigned to e as* base points*. Further, let h denote the oriented half-line (ray) starting at N and passing through U. Consider all edges homothetic to e that either intersect h beyond U or intersect both h and the edge SP. If there is no such edge, then no other base point is assigned to e. Otherwise, let e' denote the edge with this property that intersects h closest to N. If e' intersects h beyond U, then we say that e' is* far from *e and set $Y' := e' \cap h$. If e' intersects the segment PS, then we say that e' is* close to *e and set $Y' := e' \cap PS$. In both cases, Y' is the third base point assigned to e which will be referred to as the* base point forced by *e. Note that this third point is* not *on e. (See Figure 3.)*

The depth of a base point *Y sitting on an edge e is defined as the distance between Y and the apex of e.*

Using the above notation, no point of the open interval YN can be incident to a hole. Thus the depth of a hole assigned to e cannot exceed the depth of the base point Y on e. Consequently, the depth of each hole assigned to e is between the depths of some pair of consecutive base points on e. Although there may be many base points along the same edge, the total number of base points is at most $12n$.

LEMMA 3.2. *If there are two consecutive base points on an edge e with depths d_1 and $d_2 > k^2 d_1$, then there is at most one intermediate hole assigned to e with depth belonging to the interval $(d_1, d_2/k^2)$.*

Proof. Let $e = NP$ be an edge oriented toward P. Choose two consecutive base points on e with depths $d_1 < d_2$, respectively. Let H be an (intermediate) hole

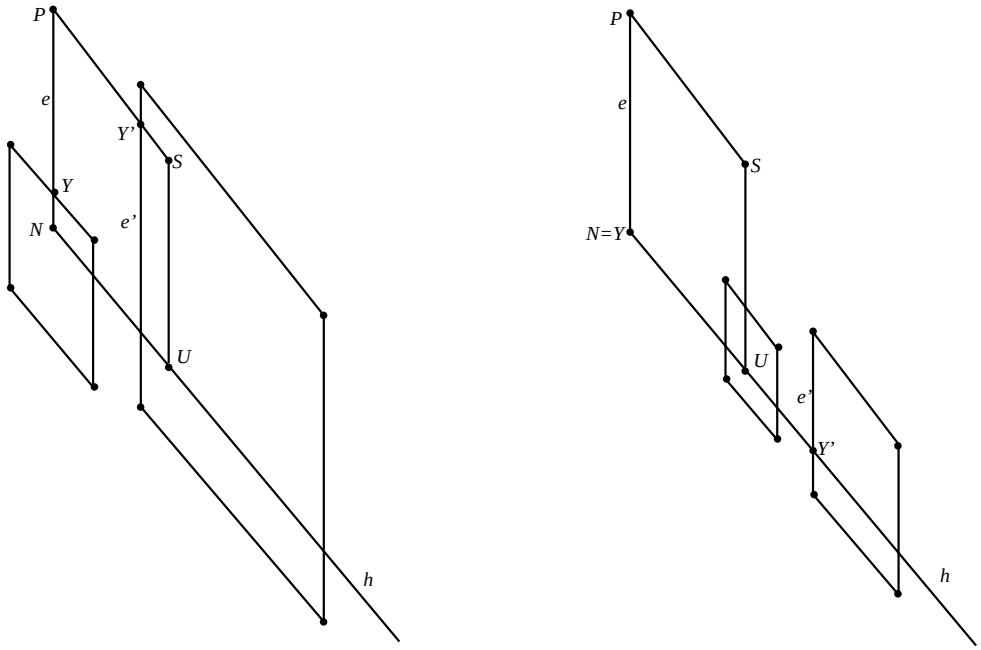

FIG. 3.

assigned to e with depth d satisfying $d > d_1$. We prove that, for every other hole assigned to e, whose depth d' is larger than d, $d' \geq d_2/k^2$ holds.

As before, let a and b be the two consecutive segments on the boundary of H causing H to be assigned to e. Let the segment b belong to the edge f with apex Q. Let X be the common endpoint of a and b. Clearly, a is on e, and b is oriented away from X.

The proof is based on the following claim.

CLAIM. *There is a base point Y on e of depth at least the depth of H such that the angle PYQ is at least $\frac{\pi}{2k}$.*

Proof. We assume without loss of generality that e is vertical and that its upper endpoint is P. As b is oriented away from X, and H is not an extreme hole, we find another edge e_0, homothetic to e, which intersects XQ. Consider the sequence of edges $e_0, e_1, e_2, \ldots, e_t$, where e_i is the edge homothetic to e, containing the base point forced by e_{i-1} $(1 \leq i \leq t)$. The last edge of this sequence, e_t, forces no base point. (See Figure 4.) Let e_i be the edge of the rhomb $\Delta_i = N_i P_i S_i U_i \in \mathcal{R}$ with $e_i = N_i P_i$ oriented toward P_i, and let h_i be the half-line starting at N_i and passing through U_i $(0 \leq i \leq t)$. Notice that h_i intersects e_{i+1} for $i < t$, and denote this point of intersection by X_{i+1}. The intersection of f and e_0 is denoted by X_0. Let Π be the directed polygonal path $QX_0N_0X_1N_1 \ldots X_tN_t$ followed by the half-line h_t. Since all segments of Π (except maybe QX_0) are pointing downward and are at least as steep as f, X must lie above Π.

We distinguish two cases.

Case I. $e = e_{i_0}$ for some $1 \leq i_0 \leq t$. The point $X_{i_0} \in \Pi$ lies below X on the same

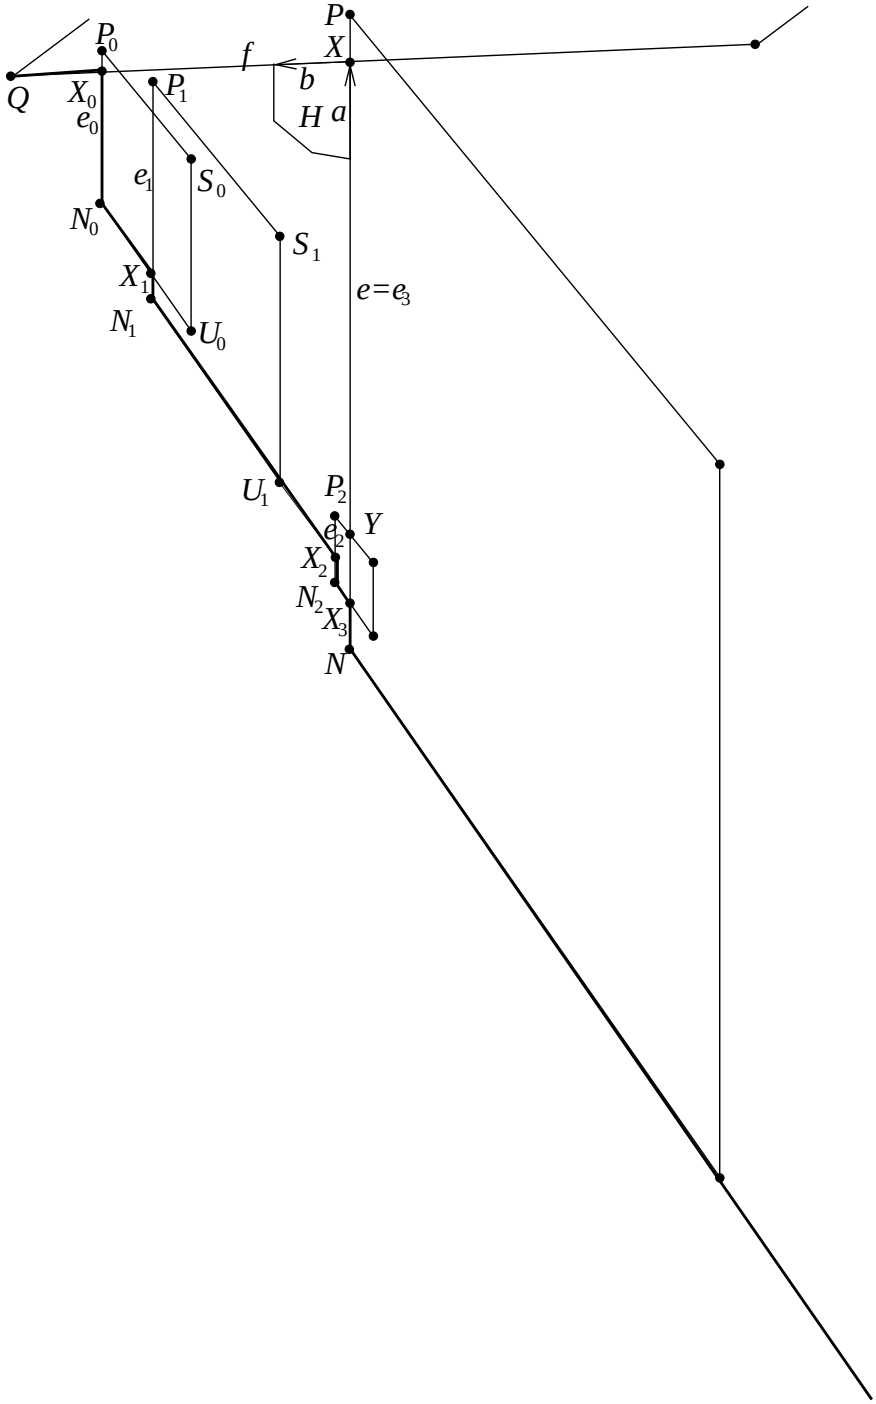

FIG. 4. *The construction of the path* Π *(the bold path).*

vertical edge e. Let Y denote the base point on e forced by e_{i_0-1}. If e is far from e_{i_0-1}, the point Y coincides with X_{i_0}, so it is below X. If e is close to e_{i_0-1}, the open interval $X_{i_0}Y$ belongs to the interior of Δ_{i_0-1}, and the point X incident to H cannot lie on this interval. Therefore, in this case, Y cannot be above X either.

For $0 \le i \le t$, denote by σ_i the strip between the parallel lines containing P_iS_i and N_iU_i. Notice that, if e_i is close to e_{i-1} $(1 \le i \le t)$, then σ_i contains σ_{i-1}.

Let $1 \le j_1 < j_2 < \cdots < j_s$ be the sequence of indices $1 \le j \le i_0$ for which e_j is far from e_{j-1}, and let $j_0 = 0$. For $1 \le i \le s$, the portion of Π between $X_{j_{i-1}}$ and X_{j_i} is contained in σ_{j_i-1}. Thus $X_{j_{i-1}}$ is below the line $P_{j_i-1}U_{j_i-1}$, while X_{j_i} is above the same line. This implies that the angle $X_{j_{i-1}}X_{j_i}P_{j_i}$ is larger than $\pi/(2k)$. If $j_s = i_0$, we have $X_{j_s} = X_{i_0} = Y$. Otherwise, $X_{j_s} \in \sigma_{i_0-1}$, while Y is on the upper boundary of this strip, so the angle $X_{j_s}YP$ is at least π/k. Since we have bounded the slope of each portion of Π, combining these bounds, it follows that the angle PYQ is at least $\pi/(2k)$. This completes the proof of the claim in case I.

Case II. $e \notin \{e_i : 1 \le i \le t\}$. The path Π now cannot cross e. Otherwise, let X' be this point of intersection, and suppose X' lies on the half-line h_i $(i \le t)$. When determining the base point forced by e_i, we must consider the edge e, since the interval $X'P$ contains the point X incident to the hole H and thus cannot be entirely covered by Δ_i. So we have that either $e = e_{i+1}$ or X_{i+1} lies between N_i and X'. Both are contradictory to our assumptions—the latter since X' is not on Π in this case.

So e must lie entirely above Π. Let l denote the line containing e, and let Z be the intersection point $l \cap \Pi$. Suppose that Z belongs to the nonvertical segment of Π starting at the point N_{i_0} for some $i_0 \le t$.

Let j be the largest index between (and including) 1 and i_0 for which e_j is far from e_{j-1}. If there is no such index, set $j = 0$. It follows in exactly the same way as in the previous case that the angle QX_jP_j is at least $\pi/(2k)$. Let Y denote the point of e closest to N that does not belong to the interior of any rhomb in $\mathcal{R}$. Recall that, according to Definition 3.1, Y is a base point, and notice that it does not lie above X.

If l intersects Δ_{i_0}, the point X_j is below the line $P_{i_0}S_{i_0}$, while Y' is on this line or above it. Therefore, in this case, the angle X_jYP is at least π/k. If l does not intersect Δ_{i_0}, consider the portion of Π between X_j to Z, and notice that it lies in the strip between the lines $P_{i_0}S_{i_0}$ and $N_{i_0}U_{i_0}$. Thus X_j is below the line $P_{i_0}U_{i_0}$, but Z (and thus Y) is above the same line. This implies that, in this case, the angle X_jYP is also at least $\pi/(2k)$. Combining this with the same lower bound for the angle QX_jP_j, we obtain that the angle PYQ is at least $\pi/(2k)$. This completes the proof of the claim. □

Now we finish the proof of Lemma 3.2:

The depth of the base point Y is larger than d_1; thus we have $|P-Y| \ge d_2$. Using the law of sines for the triangle QYX, we obtain $|Y - X| \le |Q - X|/\sin\frac{\pi}{2k}$. Since H was assigned to e, we have that $|P - X| \le |Q - X|$. Therefore,

$$\begin{aligned} d_2 &\le |P - Y| = |P - X| + |X - Y| \\ &\le \left(1 + \frac{1}{\sin\frac{\pi}{2k}}\right)|Q - X| \le k|Q - X|. \end{aligned}$$

Note that the rhomb in $\mathcal{R}$ belonging to the edge f covers an interval of e, whose length is at least $|Q - X|\sin(\pi/k) \ge d_2/k^2$. As X is an endpoint of this interval, any hole assigned to e, whose depth d' is larger than the depth $d = |P - X|$ of H, must satisfy the inequality $d' > d_2/k^2$; hence the lemma is true. □

Proof of Theorem 2.3. According to Lemma 2.5, the depths of the intermediate holes assigned to an edge are separated from each other by $\Omega(1/k)$ in a logarithmic scale. By Lemma 3.2, if an edge has $c+1$ base points, then the depths of all holes assigned to this edge, except for at most c of them, fit in c intervals, each of length $2\log k$ in logarithmic scale. Thus this edge has $O(ck\log k)$ holes assigned to it. Thus, by Lemma 2.4, the total number of intermediate holes is $O(nk\log k)$. Since the number of extreme holes is $O(nk)$, Theorem 2.3 follows. □

4. Generalizations—proofs of Theorems 2 and 3.

Proof of Theorem 2. Obviously, the triangles $T_{k+1},\dots,T_n$ are $\pi/(k+1)$-fat. By Theorem 1, they determine $O(nk\log k)$ holes. By adding the first k triangles, we increase the number of intersection points and, therefore, the number of holes by $O(nk)$.

As for the construction, let $l=\lfloor k/2\rfloor$, and arrange $T_1',\dots,T_l'$ so that any two intersect in a single point v, and all of them are contained in a right angle wedge W with apex v. This is possible because we have $\sum_{i=1}^{l}\alpha_i<\pi/2$. Let ε be the distance of v from the nearest other vertex of $T_1',\dots,T_l'$. We place T_i' for $i>l$ so that

- T_i' meets both rays bounding W but does not contain v;
- $T_i'\cap W$ is contained in the ball of radius ε around v;
- the sets $T_i'\cap W$ are pairwise disjoint for $i>l$.

All of these conditions can be satisfied by placing the triangles one by one so that we put a vertex of the next triangle, corresponding to an acute angle, sufficiently close to v. The obtained configuration has $(l-1)(n-l+1)$ holes inside W. This quantity is $\Omega(nk)$, as required, unless $l=1$. In the latter case, we arrange the triangles T_i' $(i>1)$ so that all of them have a point in common outside T_1', and their intersections with T_1' are distinct single points. These triangles determine at least $n-1$ holes. □

We continue with Theorem 3. (Notice that it is a simple special case of Theorem 4.)

Proof of Theorem 3. First we prove the $O(nk\log k)$ bound for the *number of holes* determined by the convex wedges in $\mathcal{T}$. As we have indicated before, the direct proof of this bound along the lines described in section 2 is simpler than the proof of Theorem 1. However, at this point, it is more convenient to deduce it from Theorem 2. Let h be the number of holes determined by the wedges. First, we split each wedge with an obtuse angle into two congruent wedges. Then we replace each wedge by a triangle, intersecting it with a half-plane that contains all intersection points between the boundaries of the original wedges. We make sure that all new angles introduced exceed $\pi/4$. Following this procedure, we obtain a family of at most $2n$ triangles that determine at least $h-n+1$ holes. The value k for this new family (as defined in Theorem 2) is at most 3 larger than the corresponding value for the original family of wedges. Applying Theorem 2 to the triangles, we obtain the desired bound for wedges.

To prove the same upper bound for the *boundary complexity*, notice that $\alpha_i\ge\pi/(k+1)$ for $i>k$. As in the proof of Theorem 2, we can disregard the first k wedges because their contribution to the boundary complexity is at most $4kn$. We proceed as in [MP94]. We partition the remaining wedges into $2k+2$ classes so that all wedges belonging to the ith class contain in their interior a half-line having a $2\pi i/(2k+2)$ positive angle from a reference direction. Now every vertex of the union of all wedges in a given class is either the apex of a wedge or is the last vertex along one of the open half-lines bounding the wedges. Thus the boundary complexity of this union is linear in the number of wedges in the class. Using the combination

lemma of [EG90] (see also Lemma 2.1 in [MP94]) to merge the classes in a binary tree-like fashion, it follows that the boundary complexity of the union of all wedges in all classes is $O(nk\log^2 k)$. To get rid of the extra $\log k$ factor, we consider the family of wedges $\mathcal{T}'$ we obtain at an intermediate step through the combination process. It is the union of some j of the original $2k+2$ families. We can make sure that these are j consecutive families. Applying an affine transformation, if necessary, we can achieve that the angle of every wedge belonging to these families is $\Omega(1/j)$. Since such a transformation does not change the number of holes, we obtain the better bound $O(mj\log j)$ for the number of holes determined by $\mathcal{T}'$, where m is the number of wedges in $\mathcal{T}'$. Using the combination lemma with this better bound, we conclude that the boundary complexity of $\mathcal{T}$ is $O(nk\log k)$.

To verify the last statement of Theorem 3, we use almost the same construction as in the proof of Theorem 2. The only difference is that now we have to start with a wedge W whose angle is smaller than $\pi-\alpha_n$; otherwise, no wedge of angle α_n could intersect it in the required manner. Let $l\in[0,n/2]$ be the largest integer satisfying $\sum_{i=1}^{l}\alpha_i<\pi-\alpha_n$. Clearly, we have $l\geq\min\{\lfloor(1-\alpha_n/\pi)k\rfloor,n/2\}$. Select l wedges in W with angles $\alpha_1,\dots,\alpha_l$ such that the intersection of any two is the apex v of W. Then choose $n-l$ wedges of angles $\alpha_{l+1},\dots,\alpha_n$ such that

- each of them intersects both boundary half-lines of W;
- none of them contains v;
- their intersections with W are pairwise disjoint bounded sets.

The resulting family determines $(l-1)(n-l+1)$ holes in W. This is $\Omega((\pi-\alpha_n)nk)$ unless $l\leq 1$. In the latter case, we use a trivial construction similar to the one described at the end of the proof of Theorem 2: we pick $n-1$ wedges that intersect the remaining wedge in distinct single points. This family determines at least $n-1$ holes. □

5. Wedges of angles close to π—Theorem 4. This section is devoted to the proof of Theorem 4.

First we establish the upper bound $O(B)$ for the *number of holes* in $\mathcal{T}$, where $B=m+lk\log k+\sum_{i=l+1}^{m}k_i$. The same bound on the *boundary complexity* then follows directly from the combination lemma of [EG90]: by Theorem 3, and the boundary complexity of the subfamily consisting of the l smallest wedges in $\mathcal{T}$ is $O(lk\log k)$, and the boundary complexity of the subfamily consisting of the next $m-l$ wedges of $\mathcal{T}$ is $O(m)$, while the boundary complexity of the family of the $n-m$ largest wedges of $\mathcal{T}$ (whose angles are at least π) is clearly $O(m)$, as it determines a single convex hole.

We proceed as in the proof of Theorem 1, but now we have to deal with different angles.

Fix a reference direction, and say that a wedge is *small* if its angle is $\pi/2^s$ for some integer $s\geq 2$ and if the angles between its boundary rays and the reference direction are integer multiples of $\pi/2^s$. A wedge is *large* if its angle is $\pi-2\pi/2^s$ for some integer $s\geq 2$ and if the angles between its boundary rays and the reference direction are integer multiples of $\pi/2^s$.

Let W_i be the wedge in $\mathcal{T}$ of angle α_i, and let P_i be its apex. For $i\leq l$, define W_i' to be the maximal small wedge with apex P_i that is contained in W_i. For $l<i\leq m$, let W_i' be the maximal large wedge with apex P_i that is contained in W_i. Let $\mathcal{T}'=\{W_i'|1\leq i\leq m\}$. By Lemmas 2.1 and 2.2, we have

$$h(\mathcal{T})\leq H(\mathcal{T})\leq H(\mathcal{T}')\leq h(\mathcal{T}')+m.$$

Thus, when passing from $\mathcal{T}$ to $\mathcal{T}'$, the number of holes cannot decrease by more than m.

Let α_i' denote the angle of the wedge W_i' ($i \le m$), and let k' and k_i' be defined for $\mathcal{T}'$ in exactly the same way as k and k_i were defined for $\mathcal{T}$ ($1 \le i \le m$). Notice that $\alpha_i/4 < \alpha_i' \le \alpha_i$, so $k' \le 4k+3$. Furthermore, we have $\pi - \alpha_i' < 4(\pi - \alpha_i)$, which implies that $k_i' \le 16k_i + 15$. Thus it is sufficient to prove the desired upper bound on the number of holes determined by the modified family $\mathcal{T}'$. For notational convenience, from now on, we assume that $\mathcal{T}' = \mathcal{T}$, i.e., that $\mathcal{T}$ consists of l small and $m-l$ large wedges.

We use the terms *wedge*, *apex*, *ray*, and *hole* only for the wedges in $\mathcal{T}$, their apices, their rays, and the holes determined by them. Assume without loss of generality that no three rays have a point in common. We say that two rays are *homothetic* if they are corresponding sides of two wedges that are translates of each other.

A triplet (X, r_1, r_2) is called a *vertex* if X is the intersection point of two distinct rays, r_1 and r_2, and it lies on the boundary of a hole. Our plan is to define several special types of vertices, to bound the number of vertices of each type separately, and finally to bound the number of holes by showing that each hole has a point on its boundary that appears in a vertex of some special type. A vertex (X, r_1, r_2) is said to be *small* (*large*) if both of the wedges supporting r_1 and r_2 are small (resp., large) wedges. The number of small and large vertices can be bounded by the boundary complexity of the family consisting of all small or all large wedges in $\mathcal{T}$, and, by Theorem 3, we have the following claim.

CLAIM 5.1. *There are $O(lk \log k)$ small and $O(m)$ large vertices.*

In what follows, when we consider a vertex (X, r_1, r_2), the wedges supporting r_1 and r_2 will be denoted by W_1 and W_2, respectively. The apices of W_1 and W_2 will be denoted by P_1 and P_2, respectively. If a vertex is neither small nor large, then it is said to be *hybrid*. For a hybrid vertex (X, r_1, r_2), one of W_1 and W_2 is small, and the other is large. In this case, let i and j denote the indices of the corresponding small and large elements of $\mathcal{T}$, respectively, with angles $\alpha_i = \pi/2^s$ and $\alpha_j = \pi - 2\pi/2^t$, respectively, where $1 \le i \le l$, $l+1 \le j \le m$, $s \ge 2$, and $t \ge 2$.

A vertex (X, r_1, r_2) is called *strongly extremal* if it is the first or last vertex along r_1 or r_2. Obviously, we have the following claim.

CLAIM 5.2. *There are at most $4m$ strongly extremal vertices.*

A hybrid vertex (X, r_1, r_2) is said to be *blunt* if $s < t$. Considering the canonical properties of the wedges in $\mathcal{T}$, we see that, if a blunt vertex (X, r_1, r_2) is not strongly extremal, then the boundaries of the wedges meet in three vertices, and X is the middle one (along either boundary). Furthermore, if W_1 is large, we find that r_2 is perpendicular to the angular bisector of W_1 (see Figure 5).

We claim that, along a ray bounding a large vertex, there is at most one blunt vertex that is not strongly extremal. Suppose, for contradiction, that (X, r_1, r_2) and (X, r_1, r_2') are both blunt and not strongly extremal and W_1 is a large wedge with apex P_1. We may also assume that X belongs to the interval $X'P_1$. Here the ray r_2' is parallel to r_2, so the wedges W_1 and W_2 together cover the part of r_2' on one side of X' (see Figure 5). Therefore, (X', r_1, r_2') must be strongly extremal, which is a contradiction. Therefore, the number of blunt vertices that are not strongly extremal is at most $2m$, which implies the following claim.

CLAIM 5.3. *The total number of blunt vertices is $O(m)$.*

A hybrid vertex (X, r_1, r_2) is said to be *sharp* if $s > t + \log k$.

CLAIM 5.4. *The number of sharp vertices is $O(\sum_{j=l+1}^{m} k_j)$.*

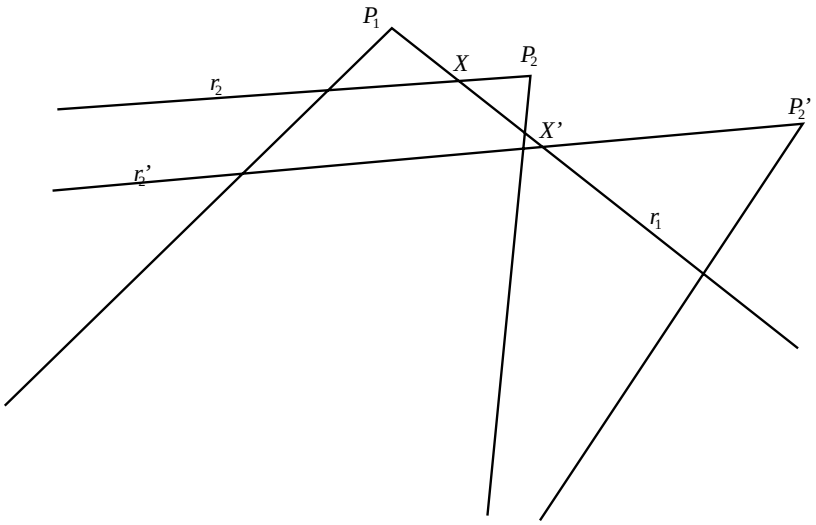

FIG. 5. *Blunt vertices.*

Proof. Let (X, r_1, r_2) be sharp. We have $i \le k_j$, for otherwise none of the angles of the first $k_j + 1$ wedges in $\mathcal{T}$ would exceed $\pi/2^s < \pi/2^{t+\log k}$, and their sum would be less than $\pi - \alpha_j = 2\pi/2^t$, contradicting the definition of k_j. Thus there are at most $O(k_j)$ sharp vertices involving the jth wedge in $\mathcal{T}$ $(j > l)$, and Claim 5.4 follows. ∎

A vertex (X, r_1, r_2) is called *extremal* if it is the first or the last vertex along r_1 among all vertices of the form (X', r_1, r_2') with r_2' being homothetic to r_2.

CLAIM 5.5. *The number of extremal vertices is* $O(B)$.

Proof. It is sufficient to establish this bound for those hybrid extremal vertices which are neither strongly extremal nor blunt nor sharp. Fix such a vertex (X, r_1, r_2). We distinguish two cases.

Case i. W_1 is small, and W_2 is large. For a given small wedge W_1 (which determines s), there are at most $\log k + 1$ possible values for t, without the vertex being sharp or blunt. For a given t, there are at most four homothecy classes possible for W_2 without the vertex being strongly extremal. Thus each ray of a small wedge is involved in at most $8 \log k + 8$ extremal vertices satisfying the condition of case i. Therefore, the total number of extremal vertices of this type is $O(l \log k)$.

Case ii. W_1 is large, and W_2 is small. Fix W_1 to be the jth wedge in $\mathcal{T}$. This determines the value of t. For a given value $s > t$, there are less than 2^{s-t+2} possible homothecy classes for W_2 without the vertex being strongly extremal. Notice that, if z among these classes for all $s > t$ are nonempty, then the sum of $\lceil z/2 \rceil$ of the smallest angles is less than $\pi - \alpha_j = 2\pi/2^t$. This implies that $z = O(k_j)$. The total number of extremal vertices involving r_1 that satisfy the condition in case ii is $O(k_j)$, and the total number of all extremal vertices of this type is $O(\sum_{i=l+1}^{m} k_i)$. ∎

A vertex (X, r_1, r_2) is called *covered* if the interval XP_1 is at least as long as the interval XP_2 and P_1 and W_2 lie on different sides of r_2.

CLAIM 5.6. *The number of covered vertices is* $O(B)$.

Proof. It is enough to consider those hybrid covered vertices that are neither extremal nor sharp nor blunt. Let (X, r_1, r_2) be such a covered vertex. As (X, r_1, r_2) is not extremal, there exists another vertex (X', r_1, r_2') for which X' belongs to the interval XP_1 and the ray r_2' is homothetic to r_2. Here the wedge W_2', whose boundary

ray is r_2', covers all of r_2 except an interval P_2Q. Our goal is to show that W_1 covers a sufficiently large subinterval XY of P_2Q. Considering these intervals XY for different covered vertices involving r_2, we find that they cover any point at most twice. Therefore, any lower bound on the lengths of these intervals yields an upper bound on their number. As in the proof of the previous claim, we distinguish two cases.

Case i. W_1 is small, and W_2 is large. By the relative position of the wedges W_1, W_2, and W_2', we have $|P_2Q| = O(|XY|/2^{s-t})$. This implies that r_2 appears in $O(k_j+1)$ covered vertices that satisfy the condition of case i. Therefore, the total number of covered vertices of this type is $O(m + \sum_{j=l+1}^{m} k_j)$.

Case ii. W_2 is small, and W_1 is large. Here we have to use that (X, r_1, r_2) is not sharp so that $s \le t + \log k$. As in case i, one can show that $|P_2Q| = O(k|XY|)$. Hence r_2 appears in $O(k)$ covered vertices satisfying the condition of case ii, and the total number of covered vertices of this type is $O(lk)$. □

The proof of the upper bound in Theorem 4 can now be completed by showing that each hole determined by $\mathcal{T}$ has a point on its boundary that appears as the leading term of a strongly extremal or a covered vertex. Indeed, if no such strongly extremal vertex exists, then the hole must be a (bounded) convex polygon. Consider the orientation of the edges inherited from the rays oriented toward their apices. If it is not *cyclic*, we find a vertex X with two outgoing edges. Obviously, either (X, r_1, r_2) or (X, r_2, r_1) is covered, where r_1 and r_2 are the two rays containing X. We deal with the cyclically oriented case in exactly the same way as in the proof of Theorem 1: assuming that no vertex around the hole is covered, we obtain several inequalities, whose sum gives a contradiction. This concludes the proof of the upper bound in Theorem 4 on the number of holes as well as on the boundary complexity of $\mathcal{T}$.

It remains to describe a construction for the lower bound. Choose an $\epsilon > 0$ such that $\epsilon < (\pi - \alpha_i - \sum_{j=1}^{k_i} \alpha_j)/n$ for all i, and let ℓ_0 be a fixed horizontal line. By the *direction* of a half-line h from a point P on ℓ_0, we mean the angle between the half-lines h and the part of ℓ_0 to the right of P. We place the wedges W_i with angles α_i $(i = 1, \dots, m')$ one by one, according to the following rules.

1. The apex of W_i is on ℓ_0 sufficiently to the right so that all intersection points of boundaries of wedges already placed are outside W_i and to the left of it.
2. W_i is above ℓ_0.
3. The direction of the right ray of W_i is ϵ larger than the direction of the left ray of W_{k_i}, or it is simply ϵ if $k_i = 0$.

By the choice of k_i and ϵ, all of the above requirements can be satisfied. The value $H = H(\{W_1, \dots, W_{m'}\})$ of the resulting family (see the beginning of section 2 for the definition) is the bound in Theorem 4 for the number of holes. For $i > m'$, we place a wedge of angle α_i such that it does not contain any intersection point between boundaries of W_j for $j \le m'$, but one of its boundary rays is on ℓ_0 and contains the apices of all W_j $(j \le m')$.

6. Concluding remarks and applications. As in [MP94], Theorems 1 and 2 yield the following upper bounds for the boundary complexity of a family of triangles.

COROLLARY 6.1. *The boundary complexity of any family of n δ-fat triangles in the plane is $O(\frac{n}{\delta}(\log\log n \log\frac{2}{\delta} + \log^2\frac{2}{\delta}))$. Moreover, the boundary of the union can be computed in time $O(\frac{n\log n}{\delta}(\log\log n \log\frac{2}{\delta} + \log^2\frac{2}{\delta}))$.*

COROLLARY 6.2. *Let $\mathcal{T} = \{T_1, \dots, T_n\}$ be a family of $n > 1$ triangles in the plane, and let α_i denote the smallest angle of T_i $(1 \le i \le n)$. Suppose $0 < \alpha_1 \le \alpha_2 \le \cdots \le \alpha_n$, and let $k \le n$ be the largest integer such that $\sum_{i=1}^{k} \alpha_i < \pi$.*

Then the boundary complexity of $\mathcal{T}$ cannot exceed $O(nk(\log\log n \log k + \log^2 k))$.

Plugging Theorem 3 into the analysis of the running time of the algorithm described in [ER93], we obtain the following two results.

COROLLARY 6.3. *The union of a family of n δ-fat wedges in the plane can be computed in time $O\left(\frac{n}{\delta}\log^2\frac{2}{\delta} + n\log n\right)$.*

A line ℓ is called a *separator* for a family $\mathcal{S}$ of pairwise disjoint segments in the plane if ℓ avoids all members of $\mathcal{S}$ and there is at least one member of $\mathcal{S}$ on both of its sides.

COROLLARY 6.4. *Given a family $\mathcal{S}$ of n line segments in the plane such that the ratio between the length of the shortest segment in $\mathcal{S}$ and the diameter of $\cup\mathcal{S}$ is at least $\delta > 0$, there is an algorithm which determines whether $\mathcal{S}$ admits a separator, and finds one if it exists, in $O\left(\frac{n}{\delta}\log\frac{n}{\delta}\log^2\frac{1}{\delta}\right)$ time and $O\left(\frac{n}{\delta}\log^2\frac{1}{\delta}\right)$ space.*

Van Kreveld [K98] extended the definition of fatness to a (not necessarily convex) simple polygon. He proved that every δ-fat simple polygon of k vertices can be covered by $O(k)$ δ-fat triangles, and such a covering can be constructed in $O(k\log k)$ time. Therefore, Theorem 1 generalizes to δ-fat simple polygons whose total number of sides is n.

Efrat [E99] introduced another generalization of the notion of fatness to compact connected regions of "constant description complexity" depending on two real parameters. He established an upper bound on the boundary complexity of a system of "fat" objects according to this definition. The dependence of his bounds on the parameters can be improved by using Theorem 1 instead of the results in [MP94].

APPROXIMATE STRING MATCHING: A SIMPLER FASTER ALGORITHM*

RICHARD COLE† AND RAMESH HARIHARAN‡

Abstract. We give two algorithms for finding all approximate matches of a pattern in a text, where the edit distance between the pattern and the matching text substring is at most k. The first algorithm, which is quite simple, runs in time $O(\frac{nk^3}{m}+n+m)$ on all patterns except *k-break periodic* strings (defined later). The second algorithm runs in time $O(\frac{nk^4}{m}+n+m)$ on k-break periodic patterns. The two classes of patterns are easily distinguished in $O(m)$ time.

Key words. algorithms, string matching, edit distance

1. Introduction.

The *approximate string matching* problem is to find all of those positions in a given text which are the left endpoints of substrings whose *edit distance* to a given pattern is at most a given number k. Here, the edit distance between two strings is the minimum number of insertions, deletions, and substitutions needed to convert one string to the other. It is convenient to say that such a substring *matches* the pattern.

This problem is of significant importance, especially in the context of identifying sequences similar to a query sequence in a protein or nucleic acid database. In this case, however, the insertions, deletions, and substitutions need to be appropriately weighted. This variant of the problem is touched on only briefly in this paper for there are other issues to resolve.

Let n be the length of the text and m the length of the pattern. Then an $O(nm)$ algorithm is easy to obtain. This algorithm is a dynamic programming algorithm that finds the edit distance between every prefix of the pattern and every prefix of the text, not counting any cost for characters in the text which are to the left of the pattern. (We will refer to this as the *local edit distance*.) The number of text-pattern prefix pairs is $O(nm)$, and each pair can be processed in constant time, provided the pairs are processed in a certain natural order. The way to think about this order is to consider an array with columns associated with text prefixes of increasing length ordered toward the right and rows associated with pattern prefixes of increasing length ordered downward. Each entry in this array represents the local edit distance of a text-pattern prefix pair. These entries are computed in an order such that all entries in rows $1 \ldots i$ are computed before row $i+1$ is computed, and the entries within a row are processed in order from left to right.

Landau and Vishkin [LV89] obtained an $O(nk)$ algorithm for this problem. This algorithm was based on the above dynamic programming paradigm as well. However,

their order of computing the array entries was a clever one. They observed that, in each 45-degree top-left to bottom-right diagonal, the entries are nondecreasing downward and that one need compute only k entries in each diagonal, namely, those entries whose value is different from the value of the preceding entry in the same diagonal. They show how these entries can be computed in constant time per entry, using a suffix tree of the pattern and the text.

Some other early work on this problem is described in [LV85, LV86, LV88, GG88, GP90].

The question that then arose was whether an $O(n + m)$ time algorithm was possible, at least for the case when k is small, e.g., $O(m^\epsilon)$, for some ϵ between 0 and 1. The intuition which suggests that this would be possible is that most of the pattern must match exactly when k is small.

An algorithm with an average case performance of $O(\frac{nk \log m}{m})$ time on random strings when $k < \frac{m}{\log m + O(1)}$ was given by Chang and Lawler [CL90]. While linear (sublinear, actually) on the average, the worst case performance of this algorithm was still $\Theta(nk)$. The assumption of the text being random is a strong one as random strings do not match with very high probability, but this algorithm may work well even on somewhat less random strings.

Baeza-Yates and Navarro [BN96] gave an algorithm with a running time of $O(n)$ for the case when $mk = O(\log n)$. In addition, they obtained another algorithm whose performance in the average case is $O(n)$ for medium k/m ratios. They also report finding this algorithm to be faster than previous algorithms experimentally, especially in the case when the pattern has moderate size, the error ratio k/m is not too high, and the alphabet size is not too small.

Recently, the above question was answered positively by Sahinalp and Vishkin [SV97], who obtained an algorithm with the following performance. Their algorithm takes $O(nk^{3+\frac{1}{\log 3}}(\frac{\log^* n}{m})^{\frac{1}{\log 3}} + n + m)$ time when there is *no periodicity* anywhere in the text or the pattern. Here, "no periodicity" means that even very local periodicity, e.g., two repeated characters, is not allowed. When there exists any periodicity in the text, the time taken by their algorithm is $O(nk^{8+\frac{1}{\log 3}}(\frac{\log^* n}{m})^{\frac{1}{\log 3}} + n + m)$. Their algorithm uses the technique of deterministic coin tossing in order to sparsify the set of diagonals which need to be processed in the above array and then processes only these diagonals using the Landau–Vishkin algorithm. This technique and the associated proofs of complexity and correctness, especially when there is periodicity present, are fairly involved.

Our contribution in the paper is twofold.

1. We give a very simple way of sparsifying the set of diagonals which need to be processed in the above matrix. This method is completely different from the Sahinalp–Vishkin algorithm and does not use deterministic coin tossing. All it requires is finding all occurrences of a number of aperiodic pattern substrings[1] of suitable length in the text. This immediately gives us an $O(\frac{nk^3}{m} + n + m)$ time algorithm, except when the pattern and the text are *k-break periodic*. By k-break periodic, we mean that there are $O(k)$ substrings of size k^2, each such that the portions of the text and the pattern between these substrings (or *breaks*, as we call them) are all periodic. We believe that k-break periodic is a rather strict property and k-break periodic strings would be quite rare in practice.

[1] "Aperiodic," here and throughout, refers to the usual notion of periodicity; i.e., the largest proper suffix of the substring which is also a prefix has a length of less than half that of the substring. This notion of aperiodicity is much weaker than that required by the Sahinalp–Vishkin algorithm.

2. We show how to process k-break periodic texts and patterns in $O(\frac{nk^4}{m}+n+m)$ time. While processing such strings in $O(\frac{nk^6}{m}+n+m)$ and even $O(\frac{nk^5}{m}+n+m)$ is quite easy, the $O(\frac{nk^4}{m}+n+m)$ time algorithm is nontrivial. The technical difficulties we face in obtaining this algorithm include the fact that the various periodic stretches between breaks need not have the same period and that periodic stretches in the pattern and the text need not align in a match of the pattern. Of course, there cannot be too many misalignments since only k mismatches are allowed.

Thus this paper gives an algorithm for approximate string matching which is not only faster and simpler than the Sahinalp–Vishkin algorithm but also helps us understand what kinds of text and patterns are hard to handle for this problem and why. We conjecture that the right bound is $O(\frac{nk^3}{m}+n+m)$ even for the k-break periodic case but have been unable to obtain an algorithm with this performance. We also believe that obtaining an algorithm which takes $o(\frac{nk^3}{m}+n+m)$ time will be hard.

The rest of this paper is organized as follows. Section 2 gives some necessary definitions. Section 3 gives an overview of our algorithm, and section 4 describes our sparsification algorithm and how it gives an $O(\frac{nk^3}{m}+n+m)$ time algorithm for the case when either the text or the pattern is not k-break periodic. One of the tools used in this algorithm is a simple modification of the Landau–Vishkin algorithm [LV89] and is described in section 5. (This modification is also used in [SV97].) Section 6 describes how to process the text when the pattern is k-break periodic but the text is not. Section 7 describes the first attempt at handling k-break periodic patterns and texts and obtains an $O(\frac{nk^6}{m}+n+m)$ time algorithm. Section 8 gives our more sophisticated scheme to handle such patterns and texts in $O(\frac{nk^4}{m}+n+m)$ time. Section 9 gives some intuition regarding the difficulties to be overcome in obtaining an $O(\frac{nk^3}{m}+n+m)$ time algorithm. Section 10 briefly discusses the weighted version of the problem.

2. Definitions and preliminaries. We assume that suffix trees for the pattern and the text can be constructed in linear time [CR94, F98].

We will assume that m, the pattern length, is at least $5k^3$. The Landau–Vishkin $O(nk+m)=O(\frac{nk^4}{m}+n+m)$ time algorithm is used for shorter patterns.

We will also assume that the text has length $2m-2k$ and the pattern has length m. If the text is longer, then it is partitioned into pieces of length $2m-2k$, with adjacent pieces overlapping in $m+k-1$ characters. The reason this suffices is that any substring of the text which matches the pattern has length in the range $[m-k, m+k]$. Thus all matches of the pattern are completely contained within some piece.

Periodicity. The *period length* of a string is defined to be the smallest i such that two instances of the string, one shifted i to the right of the other, match wherever they overlap. A string is said to be *aperiodic* if its period length is more than half the string length and *periodic* otherwise. A string is *cyclic* if it can be written as u^i, $i \geq 2$. A periodic string can be written as $u^i v$, where u is acyclic, $i \geq 2$, and v is a prefix of u. The following properties of periodic strings are well known (see [CR94]) and will be used implicitly throughout this paper.

1. The period length of a string can be determined in linear time, and so can its lexicographically least cyclic shift.
2. An acyclic string is not identical to any of its cyclic shifts. Therefore, a string s cannot be written as $u^i v$ and as $u'^i v'$, where $u \neq u'$, u, u' are acyclic, v is a prefix of u, v' is a prefix of u', and $|u|+|u'| \leq |s|$.
3. If u is acyclic, then every cyclic shift of u is acyclic as well.

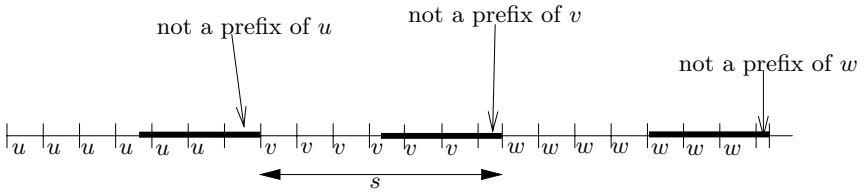

FIG. 1. *A k-break periodic string. Thick regions correspond to aperiodic substrings of length k^2. u, v, w are all at most $k^2/2$ in length.*

4. If string s has period length u but string sa (a is a single character) does not have period length u, then any suffix of sa of length at least $2u$ is aperiodic.

***k*-break periodic strings.** The pattern is said to be *k-break periodic* if it contains at most $2k-1$ disjoint aperiodic substrings of length k^2. The text is said to be *k-break periodic* if it contains at most $10k-2$ disjoint aperiodic substrings of length k^2.

LEMMA 2.1. *It can be determined in $O(m)$ time if the text and the pattern are k-break periodic. Further, if the pattern is not k-break periodic, then $2k$ disjoint aperiodic substrings of the pattern of length k^2 each can be found in $O(m)$ time. Similarly, if the text is not k-break periodic, then $10k-1$ disjoint aperiodic substrings of the text of length k^2 each can be found in $O(m)$ time.*

Proof. We consider only the pattern here. The text is processed similarly.

We process the pattern from left to right, performing various rounds. In each round, a new aperiodic length k^2 substring disjoint from all previously found substrings is determined. The stretches between any two consecutive substrings determined above will have period length at most $k^2/2$. Finally, if the collection of aperiodic strings constructed above has size less than $2k$, then the pattern is k-break periodic. The time taken by all rounds together will be $O(m)$.

A round is performed as follows. The portion of the pattern to the right of the last aperiodic length k^2 substring determined earlier is considered in this round. (If this is the first round, then the pattern is considered starting from its leftmost character.) The shortest prefix s of this portion (see Figure 1) of the pattern with the following properties is determined: $|s| \geq k^2$, and the length k^2 suffix of s is aperiodic. This computation will take $O(|s|)$ time and is described in the next paragraph. The length k^2 suffix of s is added to the collection of disjoint aperiodic strings being constructed. The total time taken over all rounds is clearly $O(m)$.

It remains to show how s is determined in $O(|s|)$ time. Let s' denote the length k^2 prefix of the above portion of the pattern. First, the period length δ of s' is determined in $O(k^2)$ time (see property 1 above). If $\delta > k^2/2$, then $s = s'$. Otherwise, the leftmost pattern character $p[i]$ to the right of s' with the property that $p[i] \neq p[i-\delta]$ is determined; s is the extension of s' up to and including $p[i]$. The time taken above is clearly $O(|s|)$. By property 4, the length k^2 suffix of s is aperiodic, as required. ∎

Canonical periods. Consider a periodic string $u^i v$, where v is a prefix of u, $i \geq 2$, and u is not cyclic. Note that all cyclic shifts of u are distinct since u is not cyclic. The *canonical period* of $u^i v$ is the string y which is the lexicographically smallest circular shift of u. Note that $u^i v$ can be written in a unique way as $xy^j z$, where x is a suffix of y and z is a prefix of y. Also note that, given u, y can be determined in $O(n)$ time (see property 1 above) and that y is acyclic as well (see property 3 above).

The following lemma about edit distance between periodic strings will be instrumental in the design of our algorithm.

LEMMA 2.2. *Consider two strings u^i and xw^jy of the same length, where x is a suffix of w, y is a prefix of w, and u, w are canonical periods of their respective strings. If $|u^i| = |xw^jy| \geq k^3 + k^2$ and $|u|, |w| \leq \frac{k^2}{2}$, then the edit distance between these two strings is at least $k+1$ unless $u = w$.*

Proof. Suppose $u \neq w$. Note that $i \geq 2(k+1)$. There are two cases.

First, suppose $|u| = |w|$; u and w cannot be cyclic shifts of each other as they are both canonical periods. It follows that each occurrence of u must incur at least one mismatch. The lemma follows in this case.

Second, suppose $|u| \neq |w|$. Partition u^i into disjoint substrings of length $|u|+|w|$. There must be at least $k+1$ such substrings. In addition, there must be at least one insertion/deletion/substitution in each such substring by property 2 above. The lemma follows. □

3. Overview. The algorithm first determines if the pattern is k-break periodic. More specifically, it determines whether there is a collection of $2k$ disjoint aperiodic length k^2 substrings in the pattern. Two cases are considered next, depending upon whether or not such a collection of substrings exists.

The sparse case. If such a collection exists, then section 4 describes a *sparsification* procedure that determines $O(\frac{m}{k^2})$ windows in the text, each of size k, which are the only locations where pattern matches can possibly begin. The matches starting in these windows are then found in $O(m)$ time by a simple modification of the Landau–Vishkin algorithm described in section 5.

The k-break periodic case. On the other hand, if no such collection exists, then the pattern is k-break periodic. In this case, in section 6, we show that all matches of the pattern in the text must occur in a portion of the text which is k-break periodic. We also show how this portion can be found in $O(m)$ time. In section 7, we show how to find all occurrences of k-break periodic patterns in k-break periodic texts in $O(k^6)$ time. This is improved to $O(k^4)$ time in section 8. This leads to an overall complexity of $O(\frac{nk^4}{m} + n + m)$ for this case.

4. Sparsification. In this section, we assume that the pattern has $2k$ disjoint aperiodic length k^2 substrings and that these substrings have been found. We call these substrings *breaks*. We show how to determine $O(\frac{m}{k^2})$ text windows, each of size k, in which potential matches of the pattern can begin. This will take $O(m)$ time.

First, we find all exact occurrences of each of these $2k$ breaks in the text. Note that these breaks have equal length. The time taken for this procedure is $O(m)$, using a standard multiple pattern matching algorithm [AC75].

Next, we partition the text into disjoint pieces of size k^2. Consider a particular piece $t[i \ldots j]$. We partition it into disjoint windows of size k each. We will show how to determine at most 12 windows such that any pattern match beginning in this piece must begin in one of these windows.

Note that at least k of the breaks must match exactly in any match of the pattern. Consider one particular break x. As x is aperiodic, any two occurrences of x in the text are at least a distance of $\frac{k^2+1}{2}$ apart. It is not hard to show that any pattern match beginning in $t[i \ldots j]$ with x matching exactly must begin in one of six size k windows in $t[i \ldots j]$ (see Figure 2). We can represent this fact by putting a mark for x on each of these windows. For a match to begin in a particular window, it must

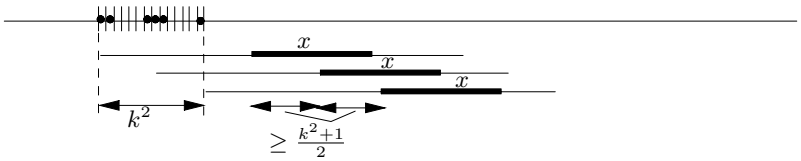

FIG. 2. *Windows which are marked for x. Filled circles indicate marks. Each instance of the pattern shown has x matching exactly.*

receive a mark from each of at least k breaks. Since each break marks at most six windows, there are at most $12k$ marks in all and therefore at most 12 windows in which matches can begin.

The verification of matches beginning in these windows is described next. It shows how all pattern matches beginning in a particular text window of length l can be found in time $O(k(k+l))$. Thus all matches beginning in a particular text window of length k can be found in $O(k^2)$ time. Then the time taken over all $O(\frac{m}{k^2})$ windows will be $O(m)$.

5. The Landau–Vishkin algorithm and sparse match verification. First, we give an overview of the Landau–Vishkin algorithm. Subsequently, we show how to find all pattern matches beginning in a particular text window of length l in time $O(k(k+l))$. We assume that the suffix tree of the pattern and the text combined has been constructed and processed for least common ancestor queries [SV88] so that the longest common prefix of any two suffixes in the text/pattern can be determined in $O(1)$ time.

5.1. The Landau–Vishkin algorithm. We review the Landau–Vishkin algorithm in this section. The classical approach to solving approximate string matching is to model it as a shortest paths problem on a graph defined on the entries of the following matrix.

Consider a matrix $A[0 \ldots m, 0 \ldots 2m-2k]$. $A[i,j]$ will be the value of the best match of $p[1 \ldots i]$ with any suffix of $t[1 \ldots j]$ for $1 \leq i \leq m, 1 \leq j \leq 2m-2k$. The 0th row and column are dummies put in for technical reasons which will become clear shortly.

The dependency graph. To determine the entries of A, we define a *dependency graph* G with weighted edges as follows. For each $i \geq 1$ and $j \geq 1$, there is a directed edge from $A[i,j]$ to each of $A[i,j-1], A[i-1,j], A[i-1,j-1]$, with weights $1, 1, y$, respectively, where y is 0 if $t[j] = p[i]$ and 1 otherwise. In addition, there is an edge from $A[i,0]$ to $A[i-1,0]$ with weight 1 and another from $A[0,j]$ to $A[0,j-1]$ with weight 0 for each $i \geq 1$ and each $j \geq 1$.

It is easy to see that the value of $A[i,j]$ is the weight of the shortest path from $A[i,j]$ to $A[0,0]$.

The algorithm. This algorithm takes $O(k)$ time for each diagonal in A. Consider a diagonal $A[0+*, j+*]$ (here , $*$ takes values from 1 to m). For each $l = 1 \ldots k$, it computes the bottommost vertex on this diagonal whose shortest path has weight l. This is done for each l in sequence, each point taking constant time to compute.

Suppose the above has been done for a particular value of l for all diagonals. Consider $l+1$ now and the diagonal $A[0+*, j+*]$. The bottommost vertex with shortest path $l+1$ on this diagonal is computed in constant time as follows. Let $A[0+a, j-1+a], A[0+b, j+b], A[0+c, j+1+c]$ be the bottommost vertices on their respective diagonals whose shortest paths have weight l (see Figure 3).

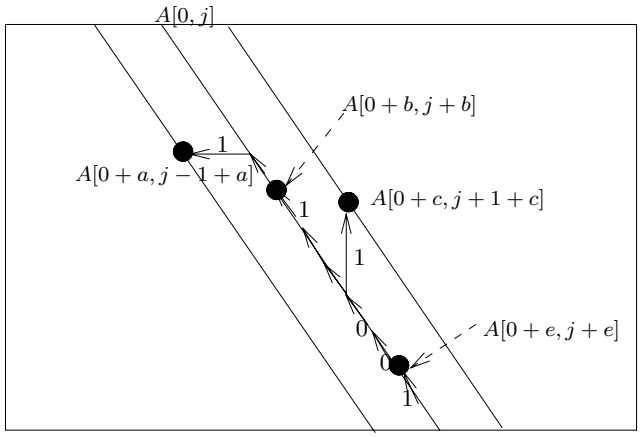

FIG. 3. *Finding the bottommost point on* $A[0+*, j+*]$ *with shortest path value* $l+1$.

Consider the three points $A[0+a, j+a], A[0+b+1, j+b+1], A[0+c+1, j+c+1]$, and take the bottommost of these three points; call this bottommost point $A[0+d, j+d]$. Next, find the bottommost point $A[0+e, j+e]$ such that all the edges on the path from $A[0+e, j+e]$ to $A[0+d, j+d]$ have weight 0. $A[0+e, j+e]$ is the required point. The longest 0 weight path along a diagonal starting at any particular point on the diagonal can be found in constant time using a longest common prefix computation.

5.2. Sparse match verification. We show how to find all pattern matches beginning in a particular text window $t[i \ldots i+l-1]$ of length l in time $O(k(k+l))$. In fact, our description will show how to find pattern matches ending in a particular text window $t[i \ldots i+l-1]$ of length l in time $O(k(k+l))$. Pattern matches beginning in the above window can be found using an analogous procedure. (Imagine reversing the pattern and the text.)

Note that in order to determine pattern matches ending in the above text window, it suffices to determine the bottommost points whose shortest paths have weight k on each of the diagonals $A[0+*, i-m+*] \ldots A[0+*, i-m+l-1+*]$. Let B denote the band formed by these diagonals. Let B' denote the band formed by the diagonals $A[1+*, i-m-k+*] \ldots A[1+*, i-m+l-1+k+*]$. The algorithm is based on the following simple observation.

Observation. If the shortest path of a point in B has weight at most k, then this shortest path stays entirely within B'. This is true because horizontal and vertical edges have weight 1 in G. The shortest path of a point in $B'-B$ might leave B'. However, to compute shortest paths for points in B, it is not necessary to compute shortest paths of points in $B'-B$ correctly; rather, it suffices to compute shortest paths using only edges in B'.

There are $O(k+l)$ diagonals in B'. Running the Landau–Vishkin procedure takes $O(k)$ time per diagonal, giving $O(k(k+l))$ time overall.

Remark. Suppose we are given two strings s_1, s_2, which are substrings of the pattern/text. Then note that the above procedure can easily be generalized to find the edit distances of s_2 with each of the $\Theta(k)$ longest suffixes of s_1 in time $O(k^2)$. Each such distance is determined correctly only if it is at most k. If it exceeds k, then the fact that it exceeds k is determined as well.

Further, note that the above procedure can also be generalized to find, for each of the $\Theta(k)$ longest suffixes of s_2, the edit distances with each of the $\Theta(k)$ longest suffixes of s_1 in time $O(k^2)$. As in the previous paragraph, each such distance is determined correctly if it is at most k; otherwise, the fact that it exceeds k is determined.

6. Text processing for k-break periodic patterns. We assume that the pattern has at most $2k-1$ breaks, i.e., disjoint substrings of length k^2, such that the stretches in between these breaks are periodic with period at most $k^2/2$. We show how to obtain a substring z of the text such that z is k-break periodic (i.e., has at most $10k-2$ breaks) and all potential matches of the pattern lie completely within z. This is done in $O(m)$ time.

Let x be the shortest text substring with its right end coinciding with the middle of the text and having $2(2k-1)+k+1 = 5k-1$ disjoint aperiodic substrings of length k^2. If no such x exists, then x is just the first half of the text. Let y be the shortest substring beginning in the middle of the text and having $5k-1$ disjoint aperiodic substrings of length k^2. If no such y exists, then y is just the second half of the text. We claim that all pattern matches must lie within $z = xy$.

Suppose a match of the pattern has its left end to the left of x. Recall that the text has length $2m-2k$. Then this pattern occurrence must touch or overlap the boundary of x and y, and, therefore, it must overlap the whole of x. (Otherwise, more than k insertions/deletions would be required.) However, x has $5k-1$ disjoint aperiodic substrings of length k^2, and at most $2(2k-1)$ of them can overlap breaks in the pattern; the remaining $k+1$ (or more) aperiodic text substrings of length k^2 must incur at least one mismatch each (because an aperiodic substring of length k^2 when aligned with a periodic stretch with period length at most $k^2/2$ must incur at least one mismatch; see also Figure 1). Therefore, the pattern cannot match in the above configuration, which is a contradiction. Similarly, it can be shown that the pattern cannot match with its right end to the right of y.

Determining x, y. This is done in $O(m)$ time using an algorithm similar to the algorithm in Lemma 2.1.

7. Finding matches of k-break periodic patterns. In this section, we assume that both the text and the pattern are k-break periodic. Recall that there are at most $2k-1$ ($10k-2$, respectively) disjoint aperiodic length k^2 substrings in the pattern (text, respectively) such that the stretches between them are periodic with period length at most $\frac{k^2}{2}$. Recall that these substrings are called breaks.

7.1. The $O(k^6)$ algorithm. First, we classify all potential matches into two categories. The first category contains potential matches in which some break in the pattern or some endpoint in the pattern is within distance $2(k^3+k^2)+k^2$ from the beginning or end of some break or endpoint in the text. The remaining potential matches are in the second category.

7.1.1. The first category. Note that matches in the first category must begin in one of $O(k^2)$ windows, each of size $O(k^3)$. All matches in these windows can be found using the algorithm in section 5 in $O(k^6)$ time. It remains to find matches in the second category.

7.1.2. The second category. Note that all potential matches in the second category also begin in one of $O(k^2)$ windows. Within each window, the order in which the various text and pattern intervals appear from left to right remains the same. The problem is that these windows could be long. Consider one such window.

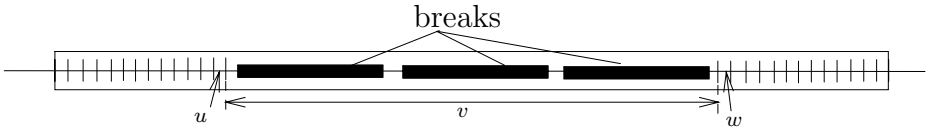

FIG. 4. *An interval.*

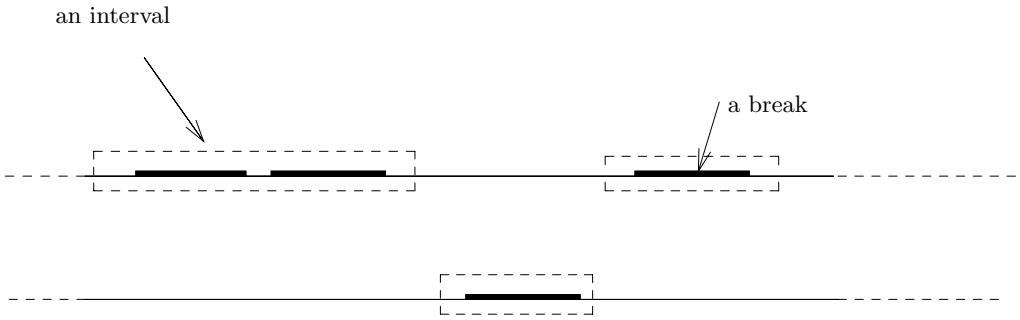

FIG. 5. *Placement of a portion of the pattern in the second category.*

Definitions. We need to form *intervals* in the text and the pattern before proceeding. First, we form groups of breaks in the pattern and the text. A group is a maximal sequence of breaks such that the periodic stretch between neighboring breaks has length less than $2(k^3 + k^2) + k^2$. An *interval* is a substring which includes all breaks in a group and extends on either side by a further distance described below. Let u denote the canonical period of the stretch to the left, and let w denote the canonical period of the stretch to the right. On the left side, the interval extends to the least distance between $k^3 + k^2$ and $k^3 + k^2 + \frac{k^2}{2}$ so as to have an integral number of occurrences of u (see Figure 4). On the right side, the interval extends to the least distance between $k^3 + k^2$ and $k^3 + k^2 + \frac{k^2}{2}$ so as to have an integral number of occurrences of w. Note that there are at least $2(k + 1)$ occurrences of the canonical period on either side. Thus each interval can be written in canonical form as $u^i v w^j$, where $|u^i|, |w^j| \geq k^3 + k^2$, $i, j \geq 2(k + 1)$, and u, w are not cyclic. We call u the *left canonical period* (*lcp*) of this interval and w the *right canonical period* (*rcp*).

Note that there are potentially two exceptions to the rules above, namely, the first and the last intervals in the pattern/text. The leftmost interval may be terminated by the left end of the pattern/text and therefore may not satisfy $|u^i| \geq k^3 + k^2$. Similarly, the rightmost interval may be terminated by the right end of the pattern/text and therefore may not satisfy $|w^j| \geq k^3 + k^2$. Prematurely terminated intervals are called *incomplete*; others are called *complete*.

The case when the pattern has only one interval which is incomplete on both the left and the right needs to be treated as a special case. We will address this case later. Until then, assume that each interval in the pattern is complete either on the right or on the left.

Properties of second category matches. Note that in all matches in this category, an interval or endpoint in the pattern (text, respectively) cannot overlap or touch an interval in the text (pattern, respectively). (See Figure 5.) This is because the period length of any periodic stretch is at most $\frac{k^2}{2}$, and, if such an overlap occurs,

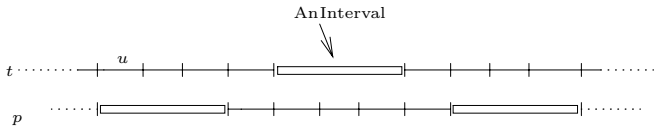

FIG. 6. *Locked intervals.*

then some break or endpoint in the text would be distance at most $2(k^3+k^2)+k^2$ from some break or endpoint in the pattern. Further, in all matches in this category, the endpoints of an interval will be *locked*, i.e., in alignment with the canonical periods in the overlapping periodic stretch (see Figure 6), as is proved in the following lemmas. This property enables us to process this category efficiently.

LEMMA 7.1. *The pattern has a second category match only if the lcps and rcps of all pattern intervals (except possibly the lcp of the first interval, in case it is incomplete on the left, and the rcp of the last interval, in case it is incomplete on the right) and of all text intervals overlapping the pattern are identical (denoted by, say, u). In addition, in any second category match of the pattern, all periodic stretches in the text (pattern, respectively) overlapping intervals in the pattern (text, respectively) must have canonical period u.*

Proof. First, consider the first part of the lemma. Order the intervals involved in this match (i.e., all pattern intervals and all text intervals overlapping the pattern) from left to right in order of occurrence. We show that the rcp of one interval s_1 in this sequence is identical to the lcp of the next interval s_2 in this sequence. Further, if interval s in this sequence is either complete or in the text, we show that the lcp and rcp of s are identical. The first part of the lemma follows.

Let u denote the rcp of s_1 and w denote the lcp of s_2. Note that $|u|, |w| \leq \frac{k^2}{2}$. Further, the suffix of s_1 which is cyclic in u has length at least $k^3 + k^2$ and likewise for the prefix of s_2 which is cyclic in w.

There are two cases for showing that the rcp of s_1 is identical to the lcp of s_2. First, suppose both intervals are in the pattern. Then they are both overlapped by a periodic stretch in the text with canonical period, say, x. However, by Lemma 2.2, $x = u$ and $x = w$. Therefore, $u = w$, as required. Second, suppose that s_1 is in the text and s_2 is in the pattern. (The case when s_1 is in the pattern and s_2 is in the text is symmetric.) Then s_1 is overlapped in the pattern by a stretch with canonical period w. By Lemma 2.2, $u = w$, as required.

Next, suppose s is in the text or is complete. We show that its lcp and rcp are identical. First, note that s will be complete in either case (i.e., if the pattern overlaps the first/last text interval and this interval is incomplete, then this match is in the first category). Assume that s is a complete interval in the text. (The case when s is a complete interval in the pattern is similar.) Let u be the lcp of s and v the rcp. Since s is complete, the prefix of s which is cyclic in u has length at least $k^3 + k^2$ as does the suffix of s which is cyclic in v. Note that $|u|, |v| \leq \frac{k^2}{2}$. The portion of the pattern overlapping s is periodic with canonical period, say, x. Then, by Lemma 2.2, $x = v = u$, as required.

Now consider the second part of the lemma. Consider a periodic stretch in the text having canonical period, say, w, which overlaps an interval s in the pattern. Assume that s is complete on the right. (A similar proof holds for the case when s is complete on the left; any interval must be complete either on the right or on the left, by our assumption above.) Note that $|u|, |w| \leq \frac{k^2}{2}$. Further, the suffix of s which

is cyclic in u has length at least $k^3 + k^2$. It follows from Lemma 2.2 that $u = w$. A similar proof holds for the case of a periodic stretch with canonical period w in the pattern overlapping an interval s in the text. (As stated earlier in this proof, s is necessarily complete in this case.) □

LEMMA 7.2. *Consider a match of the pattern in the second category. Consider any interval s involved in this match (i.e., all pattern intervals and all text intervals overlapping the pattern). If s is complete on the left and has lcp u, then the portions of the text and pattern between s and the next interval (text or pattern; if there is no such interval, then consider the endpoint) to the left have suffix u and incur no cost for edits. If s is complete on the right and has rcp u, then the portions of the text and pattern between s and the next interval (text or pattern; if there is no such interval, then consider the endpoint) to the right have prefix u and incur no cost for edits.*

Proof. We show that, if s is complete on the left and has lcp u, then the portions of the text and pattern between s and the next interval (text or pattern; if there is no such interval, then consider the endpoint) to the left have suffix u and incur no cost for edits. The other case is symmetric. We assume that s occurs in the pattern. The case when it occurs in the text is similar.

Recall from the definition of intervals that there are at least $2(k+1)$ occurrences of u at the beginning of s. Some instance of u in s amongst the rightmost $k+1$ instances must match the text exactly. There are two cases now.

First, suppose there are no intervals to the left of s involved in the above second category match. Then the portion of the pattern to the left of (and including) the above exact match of u has the form vu^i, where v is a suffix of u. Therefore, the portion of the text which overlaps the above portion of the pattern is also periodic with canonical period u (for an exact match of u occurs within s, and the portion of the text overlapping s is part of a periodic stretch with canonical period u by Lemma 7.1). The lemma follows from the fact that u is a prefix of s.

Next, suppose there is an interval to the left of s involved in the above second category match. Let s' be the rightmost such interval. By Lemma 7.1, the rcp of s' must also be u. As before, some instance of u in s amongst the rightmost $k+1$ instances must match the pattern exactly. Similarly, some instance of u in s' amongst the leftmost $k+1$ instances must match the pattern exactly. The portions of the pattern and the text between the above two exact matches of u are both cyclic in u. The number of edit operations in these portions is at least the difference in their lengths and is at most k. This number only reduces if all of these edits are transferred so that they occur at the right end of these portions. Since there are at most k such edits, all of them will now appear either within s or within the portion of the text overlapping s. It follows that the portion of the text starting from the above matching instance of u in s' and extending up to (but not including) the location aligned with the starting character of s matches the pattern exactly and is cyclic in u, as required. □

Definition. For each interval of length l, define its *locked edit distance* to be the minimum over all g, $h' \leq g \leq h$, of the edit distance between this interval and u^g. Here h is the number such that $|u|(h-1) < l + k \leq |u|h$, and h' is the number such that $|u|(h'-1) < l - k \leq |u|h'$. We compute the locked edit distance for each interval in the text and the pattern. Here, note that this distance is needed only if it is at most k. So we will only compute this distance if it is at most k. This computation takes $O(k^3)$ time as there are $O(k)$ intervals, and, for each interval, the algorithm given in section 5 will take $O(k^2)$ time. (Essentially, the shortest paths from certain

points lying on some of at most $2k+1$ diagonals need to be determined if these paths have cost at most k.)

We need special handling for incomplete intervals. Note that incomplete intervals in the text do not play a role in second category matches (i.e., if the pattern overlaps the first/last text interval and this interval is incomplete, then this match is in the first category). For the up to two incomplete intervals in the pattern, we need to redefine *locked edit distance* as follows.

If the rightmost interval in the pattern is incomplete on the right, its locked edit distance is the minimum edit distance between this interval and some prefix of u^h, where h is the number such that $|u|(h-1) < l + k \leq |u|h$. If the leftmost interval in the pattern is incomplete on the left, its locked edit distance is the minimum edit distance between this interval and some suffix of u^h, where h is the number such that $|u|(h-1) < l + k \leq |u|h$. As before, these locked edit distances need to be computed only if they do not exceed k. This can be done in $O(k^2)$ time using the algorithm in section 5 (see the remarks at the end of that section).

COROLLARY 7.3. *The edit distance between the pattern and the text for a second category match is just the sum of the locked edit distances over all pattern intervals and all text intervals overlapped by the pattern.*

Proof. Consider any second category match. By Lemma 7.1, each interval in the pattern is aligned with a periodic stretch in the text which is cyclic in u. Similarly, each interval in the text overlapped by the pattern is aligned with a periodic stretch in the pattern which is cyclic in u. From Lemma 7.2, it follows that each complete interval in the pattern (text, respectively) is aligned with a string in the text (pattern, respectively) which is cyclic in u. Further, an incomplete interval in the pattern which is complete on the right (left, respectively) is aligned with a string in the text which is periodic with period u and has suffix (prefix, respectively) u. (Note that if the endpoint of the text were closer, preventing a suffix of u, this would be a first category match.) The corollary follows from the definition of locked edit distance. □

Remark. Our aim is to determine all locations in the text where matches of the pattern begin. Consider any second category match. Recall from the last paragraph of the proof of Lemma 7.2 that edits in this match can be transferred to within pattern and text intervals (or to within portions in the text and pattern, respectively, overlapping these intervals) without increasing the edit distance. This transfer will not change the starting point of the match in the text except when the edits transferred are to the left of the leftmost interval (pattern or text, whichever is first). Therefore, edits to the left of the leftmost interval will have to be treated differently while determining the starting points of the various matches. Next, we show how these starting points can be determined in time $O(k^4)$ plus the number of matches.

Algorithm for second category matches. All locked edit distances are computed in $O(k^3)$ time as above. Recall from the beginning of this section that all second category matches begin in one of $O(k^2)$ windows. Consider one such window. The pattern occurs in this window if and only if the sum of the locked edit distances of the relevant intervals is at most k. The precise necessary and sufficient conditions for the pattern to occur starting at a particular text location i in this window are described next.

Note that fixing the window under consideration also fixes the left to right sequence of text and pattern intervals involved in matches in this window. Consider the leftmost interval (pattern or text, whichever is first). There are two cases, depending upon whether this interval is in the pattern or in the text. We consider each case in

turn. In each case, we show that the total time taken to output all matches in this window is $O(k^2)$ plus the number of matches.

Case 1. First, consider the case when this interval is in the pattern. Let x be the prefix of the pattern up to and including the right end of this interval. Recall from Lemma 7.2 that x must be aligned with a text substring with period u and having suffix u, in any match in this window. Let u' be a proper suffix of u such that the substring of the text beginning at location i has the form u' followed by several occurrences of u. Let $leftval$ be defined as the minimum edit distance between x and some string y with the following property: y begins with u', ends with u, and has canonical period u, and $|x| - k \leq |y| \leq |x| + k$. The pattern occurs starting at text location i if and only if $leftval$ plus the locked edit distance of all other pattern and text intervals involved in matches in this window sum to at most k.

It remains to describe how $leftval$ is determined in this case. We compute the edit distances of x and each of the $2k + 1$ longest suffixes of the unique string having canonical period u, suffix u, and length $|x| + k$. This takes $O(k^2)$ time using the algorithm in section 5 (see the remarks at the end of that section). For any relevant location i, $leftval$ is easily determined in constant time from this information.

Case 2. Second, consider the case when the leftmost interval is a text interval. Let x be the substring of the text starting from location i and extending up to and including the right end of this interval. Recall from Lemma 7.2 that x must be aligned with a pattern substring with period u and having suffix u, in any match in this window. Let u' be a proper suffix of u such that the pattern begins with u' followed by several occurrences of u. Let $leftval$ be defined as the minimum edit distance between x and some string y with the following properties: y begins with u', ends with u, and has canonical period u, and $|x| - k \leq |y| \leq |x| + k$. The pattern occurs starting at text location i if and only if $leftval$ plus the locked edit distance of all other pattern and text intervals involved in matches in this window sum to at most k.

$leftval$ is determined as follows for this case. Note that x depends on the value of i and that there are too many values of i which need to be considered. The key to fast computation of $leftval$ in this case is that the i's can be partitioned into $O(k)$ equivalence classes based on their offsets with respect to the canonical period u. Specifically, if the left end of the pattern is shifted by distance k, then the edit distance, if no more than k, is unchanged (so long as the left end of the pattern remains in the window in question). For the left end of I has at least $2(k + 1)$ disjoint occurrences of u; one of them is aligned with a copy of u in the pattern. A shift of the pattern left end by k units to the right can be thought of as removing this copy of u from the text, thereby leaving the edit distance unchanged.

We perform the following computation. Let z denote the suffix of u of length $|u'| + k$ if $|u| \geq |u'| + k$ and the string u otherwise. Let x' be formed by concatenating z with the leftmost interval (which is a text interval in this case). Let y' denote the string with canonical period u, suffix u, and length $|x'| + k$. For each of the k longest suffixes of x', we find the edit distances with each of the $3k$ longest suffixes of y'. This takes $O(k^2)$ time using the algorithm in section 5. (In fact, we are really only interested in suffixes of y' with prefix u'.) For any relevant text location i, $leftval$ is easily determined in constant time from this information.

Let u'' be that proper suffix of u such that the text substring starting at location i has prefix u'' followed by several occurrences of u. From Lemma 7.2, we note that, if $|u| \geq |u'| + k$ and $leftval$ is at most k, then $|u''| \leq |u'| + k$. Consider that suffix x''

of x' having the form u'' followed by the leftmost interval. We claim that, if $leftval$ is at most k, then it equals the minimum edit distance of x'' with a suffix y'' of y' whose size is within k of x'' and which begins with u'. To see this, the following three observations suffice. First, x can be obtained from x'' and y from y'' by inserting strings cyclic in u. Second, the leftmost interval is a suffix of both x, x'' and has at least $2(k+1)$ disjoint occurrences of u at its left end. Third, in any approximate match of x and y of value at most k, all but k of the various disjoint occurrences of u must match exactly; the same is true of any approximate match of x'', y'' of value at most k.

The special case. We consider the case when there is only one interval in the pattern, and it is incomplete in both directions. Thus the whole pattern is a single interval. In a second category match, the entire pattern is overlapped by a single periodic stretch in the text with canonical period, say, w, of length at most $\frac{k^2}{2}$. Clearly, in this situation, it suffices to find matches beginning in any window of length $|w|$; all second category matches in which the pattern is completely aligned with the periodic stretch with canonical period w can be interpreted from this information as in the previous paragraph. All matches beginning in a window of length $|w| \leq \frac{k^2}{2}$ can be found in $O(k^3)$ time using the algorithm in section 5.

8. The $O(k^4)$ algorithm. Recall that the pattern is k-break periodic. However, the periods of the periodic stretches between various pairs of consecutive breaks could be different. Suppose the pattern has at most $2k-1$ and the text has at most $10k-2$ *bad segments* of length at most $4|u|$ each such that the stretches between two adjacent bad segments are cyclic with canonical period u for some string u. Such texts and patterns are called *even more periodic*. First, we will show how to handle patterns and texts which are not even more periodic in $O(k^4)$ time. The even more periodic case is the hardest and is handled in section 8.1.

The following steps are performed to determine whether or not the pattern is even more periodic and to process it in case it is not.

Step 1. Recall that the periodic stretches in the pattern could have distinct periods. We choose a multiset U of disjoint substrings $u_1^2, \ldots, u_{2k+1}^2$ of the pattern as follows. The periodic stretches in the pattern are considered in nonincreasing order of period length. For a particular stretch with canonical period, say, v, all (or as many as necessary to achieve the desired cardinality of $2k+1$) disjoint occurrences of v^2 in it are added to U. This procedure continues until U has exactly $2k+1$ substrings in it. Since the pattern is assumed to have length at least $5k^3$ (see beginning of section 2), $2k+1$ such substrings always exist. (Recall that all periods have length at most $k^2/2$, and the total length of breaks is at most $2k^3$.) Let w denote u_{2k+1}.

There are two cases now. If $|w| \leq k$, then nothing is done in this step. Suppose $|w| > k$. Then we show how to obtain $O(\frac{m}{|w|})$ windows, each of size k, in which pattern matches can begin. In fact, we show something stronger, namely, in any window of size $|w|$ in the text, there are only a constant number of the above windows of size k in which pattern matches can begin.

All occurrences of the u_i^2's in the text are found in linear time using a standard multiple pattern matching algorithm [AC75]. Next, the text is partitioned into disjoint windows of size k each. Note that two occurrences of u_i^2 in the text occur at least a distance $|u_i|$ apart (since u_i is a canonical period and therefore not cyclic; see property 2 in section 2 as well). Pattern matches in which u_i^2 matches exactly must therefore begin in $O(\frac{m}{|u_i|}) = O(\frac{m}{|w|})$ windows; this is represented by putting a mark

for u_i^2 on each such window. Over all strings in U, the total number of marks put is at most $(2k+1) * \frac{2m-2k}{|w|}$ (the size of the text is $2m-2k$), and only windows with at least $k+1$ marks can have pattern matches beginning in them. It follows that pattern matches can begin in only $O(\frac{m}{|w|})$ windows of size k each. In addition, any two windows which are more than a distance k apart and which receive $k+1$ marks each must both receive a mark for some u_i^2. Since any two occurrences of u_i^2 occur at least a distance $|u_i| \geq |w|$ apart, any two windows which are more than a distance k apart and which receive $k+1$ marks each must actually be a distance at least $w-2k$ apart. It follows that, in any window of size $|w|$ in the text, there is only a constant number of the above windows of size k in which pattern matches can begin. The total time taken is $O(m)$.

We now include all occurrences of all u_i's which are not identical to w as breaks in the pattern. The number of breaks in the pattern is still $O(k)$, each break being $O(k^2)$ in length. In addition, all periodic stretches have period lengths of at most $|w|$. In the text, all periodic stretches with period lengths of more than $|w|$ are partitioned into disjoint substrings of length k^2; these substrings are also included as breaks. Note that one substring in each stretch could have a length less than k^2; this substring is just merged with the next break to the right. So the text has several breaks now, each of length between k^2 and $2k^2$. Now, as in section 6, the text is trimmed so that it has only $O(k)$ breaks. The key property used in this trimming is that any break, when aligned with a periodic stretch in the pattern (which now has period length of at most $|w|$), must incur at least one mismatch. Thus both the pattern and the text now have $O(k)$ breaks of length $O(k^2)$ each, with all intervening periodic stretches having period length at most $|w|$.

Step 2. We partition p into disjoint pieces of length $2|w|$. A piece-substring is a substring beginning and ending at piece boundaries. A piece-substring is *homogeneous* if at least three-fourths of the pieces in it have the same canonical period; it is *heterogeneous* otherwise.

Step 2: Case 1. If there exists a heterogeneous piece-substring of length $2|w| * (4k+1)$ in the pattern, then this piece-substring must overlap a break in the text in any match of the pattern. This is because any alignment of this piece-substring with a periodic stretch (which now has period length of at most $|w|$) is guaranteed to give at least $k+1$ mismatches. (At least $k+1$ pieces will have a canonical period different from the canonical period of the periodic stretch.)

A heterogeneous piece-substring, if one exists, can be found in $O(m)$ time. In addition, if such a piece-substring exists, then all matches of the pattern must begin in $O(k)$ windows, each of size $O(k^2+k|w|)$. If $|w| \leq k$, then the total size of these windows is $O(k^3)$, and all matches beginning in these windows can be found in $O(k^4)$ time using the algorithm in section 5. If $|w| > k$, then these windows can be further refined by taking intersections with the windows obtained in Step 1 (recall that pattern matches begin in only $O(1)$ length k windows in any length $|w|$ window) to give $O(k^2)$ windows each of size $O(k)$. Thus the total time taken to find all matches using the algorithm in section 5 is $O(k * k^2 * k) = O(k^4)$ in this case as well.

Step 2: Case 2. Suppose there is no heterogeneous piece-substring of length $2|w|*(4k+1)$ in the pattern. Then three-fourths of the pieces in every piece-substring of length $2|w| * (4k+1)$ have the same canonical period, u, say, $|u| \leq |w|$. Any periodic stretch which has a canonical period different from u has a length less than $2|w|(k+1) + 4|w| = 2|w|(k+3)$; otherwise, there would be at least $k+1$ complete pieces occurring contiguously within this periodic stretch, each having a canonical

period different from u; any piece-substring of length $2|w| * (4k+1)$ containing these pieces would then be heterogeneous.

We now make each periodic stretch in the pattern which has a canonical period different from u and a length at least $2|w|$ a break. (This is in addition to the existing breaks.) Periodic stretches in the pattern with canonical periods different from u and length less than $2|w|$ are appended to the next breaks to the right. Thus the pattern now has $O(k)$ breaks, each of length $O(|w|k+k^2)$, and all intervening periodic stretches have period u.

In the text, we redefine the breaks as follows. All existing breaks continue to be breaks. Recall that each of these has length between k^2 and $2k^2$. Call these breaks class 1 breaks. All periodic stretches with canonical period different from u also become breaks now; call these breaks class 2 breaks. Next, both classes of breaks are together reorganized into a new set of breaks so that each resulting break has length at least $4|w|k + 2k^2$ and at most $2(4|w|k + 2k^2)$; this reorganization involves clubbing together existing breaks to form new breaks by including intervening strings and extending at the ends, or alternatively, partitioning a break into smaller breaks, if necessary. The length restrictions on the resulting breaks imply that the above reorganization allows for each class 1 break to be contained completely inside some resulting break; further, if a class 2 break is broken down and distributed over several resulting breaks, then each substring into which it is broken down has length at least $2|w|$. Then each resulting break contains one of the following (below, the first two cases relate to those resulting breaks which include a class 1 break, and the third relates to those resulting breaks which are derived from class 2 breaks):

1. A length k^2 aperiodic substring (these were the original breaks).
2. A substring with period length more than $|w|$ and having at least two consecutive occurrences of the canonical period (see the new breaks defined just before Step 2; also recall that $|w| \leq \frac{k^2}{2}$). Clearly, this canonical period will be different from u.
3. A substring of length $2|w|$ with period length at most $|w|$ and canonical period different from u, $|u| \leq |w|$.

Now, as in section 6, the text is trimmed so that the total number of breaks in each half of the text is $O(k)$. The key property used in this trimming is that any text break, when aligned with a periodic stretch with canonical period u in the pattern, must incur at least one mismatch. This holds because of the properties listed above. Thus both the pattern and the text now have $O(k)$ breaks of length $O(k^2 + |w|k)$ each, with all intervening periodic stretches having canonical period u.

Now consider those substrings of the pattern of length $2|u|$ which do not have canonical period u. There are two subcases now.

First, suppose there are at least $2k$ such disjoint substrings. Then at least k of these substrings must match exactly in any match of the pattern. For such a substring to match exactly, it must be aligned with a text substring which is not a periodic stretch of u's. Recall that the text has $O(k)$ breaks and that all intervening periodic stretches have canonical period u. It follows that there are $O(k)$ windows in which possible matches of the pattern can begin, each window having length $O(|w|k + k^2)$. If $|w| \leq k$, then all these matches can be found in $O(k * k^2 * k) = O(k^4)$ time using the algorithm in section 5. And, if $|w| > k$, then each of the above windows of size $O(|w|k + k^2)$ can be further refined by taking intersections with the windows obtained in Step 1 to get $O(k^2)$ windows of size $O(k)$ each; the $O(k^4)$ time bound follows in this case as well.

The second subcase arises when there are fewer than $2k$ disjoint substrings of length $2|u|$ with canonical period different from u in the pattern. As in section 6, the text can now be trimmed so that it has at most $10k - 2$ of these. Clearly, all stretches in the text and in the pattern between the above substrings are periodic with canonical period u. (This follows from the fact that if two substrings, both having length $2|u|$ and canonical period u, overlap in $|u|$ locations, then their union also has canonical period u by definition.) Next, by extending each substring of length $2|u|$ with canonical period different from u on either side, the intervening stretches can be made cyclic in u (earlier they were just periodic with canonical period u but not necessarily cyclic); the length of each such substring can go up to $4|u|$ in the process. Our text and pattern are now both even more periodic (defined at the beginning of this section).

8.1. The $O(k^4)$ algorithm for the even more periodic case. To get a faster algorithm, we have to define intervals which have stronger properties than those defined in section 7. We define an *interval* in the pattern (text, respectively) to be a set of disjoint substrings of the pattern (text, respectively). Roughly speaking, intervals are formed by extending *bad segments* (substrings of length between $2|u|$ and $4|u|$ which do not have canonical period u) at either end while skipping over other intervals. Intervals will always have the property that they end in at least one, possibly more, occurrences of the period u at each end. The *span* of an interval is the substring between and including the leftmost and the rightmost characters in the interval. In contrast to the intervals defined in section 7, spans of intervals defined here could be nested one inside the other.

Recall the definition of locking from Figure 6. We say that an interval in the pattern (text, respectively) *locks* in a particular alignment if the portion of the text (pattern, respectively), if any, with which this interval is aligned is a cyclic repetition of u.

Our strategy will be to identify intervals in the pattern and the text with total length $O(k|u|)$, with each interval having length at least $2|u|$. These intervals will have the following property: in any match of the pattern, either some pattern interval overlaps some text interval, or all of the pattern and text intervals are locked.

All matches in the first category clearly occur in at most $O(k^2)$ windows, each of length $\max\{k, |u|\}$. If $|u| \leq k$, then the total length of all of these windows is $O(k^3)$, and all matches in these windows can be found in $O(k^4)$ time using the algorithm in section 5. If $|u| > k$, then recall that $|u| \leq |w|$, that potential matches of the pattern have been determined in Step 1, and that there is only a constant number of windows of length k within any length $|w|$ window in which these matches can begin. It follows that all matches must again begin in $O(k^2)$ windows, each of length $O(k)$; these matches can again be found in $O(k^4)$ time.

Matches in the second category will also occur in $O(k^2)$ windows but of larger size. Whether or not the pattern matches in one such window will depend upon the *locked edit distance* of some of the intervals defined. These matches will be easy to find. In particular, if the pattern matches at a particular position in this window, then it will match at all positions which are shifts of multiples of $|u|$ from this position in this window.

8.2. Defining intervals. We show how the pattern is processed. The text is processed similarly.

We define intervals to contain all sufficiently small strings that are not repetitions of string u. More specifically, an interval I will be a string with a 2^i-fold repetition of

string u at either end for a suitable i. The best match of I with a string u^k, $|u^k| \geq |I|$, for suitable k will be in locked alignment. Intervals are chosen to minimize i in a sense made precise below. Further, the intervals are chosen so that, in any match in which the intervals in the text and pattern do not overlap, the intervals are all in locked alignment.

We define intervals as follows in $O(\log k)$ rounds. In each round, a set of partially formed intervals inherited from the previous round is processed. These intervals will be disjoint from each other. Some of the intervals being processed in the current round will be fully formed at the end of this round; these will not be processed in subsequent rounds. The remaining intervals will be processed further in the subsequent rounds.

The first round begins with a minimal collection of disjoint intervals, called *initial* intervals, where each initial interval is just a bad segment (defined at the beginning of section 8.1). Recall that the portions of the string between the initial intervals are cyclic in u. The following procedure is performed in each round i, $i \geq 1$.

2^i-extending interval I. For each partially formed interval I being processed in the current round i, a 2^i-*extension* is determined as below. Starting from the left end of I, walk to the left, skipping over any substrings in fully formed intervals, until either another partially formed interval is reached or 2^i instances of u have been encountered. The same procedure is repeated at the right end. The substrings walked over in this process (ignore the substrings skipped over) along with the substrings in I together constitute the 2^i-extension of I.

An interval I processed in round i is said to be *successful* in this round if, after extension, it does not overlap or touch another extended interval on both the left and on the right.

Finally, we form new intervals by taking a *union* of the various extended intervals. Each new interval comprises maximal collections of extended intervals above such that consecutive extended intervals in each collection overlap or touch each other. Thus, if two extended intervals overlap or touch, then they become part of the same interval now. Each new interval comprises exactly those pattern positions which belong to one of the extended intervals in the corresponding maximal collection of extended intervals. Of these new intervals, some will be fully formed, as described in the next paragraph. Those which are not fully formed will be carried over to the next round.

Condition for full-formedness. Each interval will have an i-*nested cost* to be defined below. Those intervals I whose span has locked edit distance (with respect to u) at most 2^i plus the i-nested cost of I will be fully formed at the end of this round; the remaining intervals will be processed again in the next round.

Definitions. The i-*current cost* of an interval I which is processed in round i is the locked edit distance of the span of I with respect to u if it is fully formed by the end of round i and 2^i plus its i-nested cost if it is not yet fully formed at the end of round i. The *final cost* of an interval is its current cost at the end of the last round or its locked edit distance (with respect to u) if it is fully formed. The i-nested cost of I is the sum of the final costs of the fully formed intervals which were skipped over while forming I and the $(i-1)$-current costs of those partially formed intervals which are nested within I and were unsuccessful in round i. As the base case, we define the 0-current cost of an initial interval to be 1. Lemma 8.1 describes the motivation for the above definitions.

LEMMA 8.1. *For all $i \geq 0$, the i-current cost of an interval I processed in round i is a lower bound on the cost of aligning the span s of I with a periodic stretch of u's.*

Proof. Consider a least cost match of s in a periodic stretch of u's. If $i = 0$, then

the lemma follows from the fact that initial intervals have canonical periods different from u and therefore incur at least one mismatch. So assume that $i > 0$.

Note that s has 2^i occurrences of u at either end, possibly interspersed with intervals fully formed before round i. Some or all of these occurrences of u in s could be out of alignment with u's in text. If all of these occurrences of u at the left end or at the right end are out of alignment, then the cost of aligning s is at least 2^i plus, inductively, the i-nested cost. On the other hand, if at least one occurrence of u on either side aligns, then we claim that all occurrences of u further from the extremes of s from these two occurrences align as well. This is because the portions of s outside these two occurrences of u consist only of u's and other fully formed intervals, and fully formed intervals, by induction, cost at least (and, of course, at most) their locked edit distance. Therefore, the cost of the best match of s is the same as its locked edit distance with respect to u. The claim now follows from the fact that the i-current cost of I is the smaller of this distance and 2^i plus the i-nested cost. □

Termination conditions for the rounds. The ith round is the last round if the sum of the i-current costs of those intervals which are obtained in round i and are not nested inside other intervals and the sum of the final costs of those intervals that are fully formed earlier and not nested inside other intervals (we call both of these kinds of intervals together *final* intervals) exceeds k, or if all intervals are fully formed. When the sum of the above costs is more than k, all matches of the pattern must have some interval in the text overlapping or touching some interval in the pattern. Clearly, the number of rounds is $O(\log k)$. The cost of processing a round, i.e., extending and computing the costs, is $O(k^3)$. (Each of up to $O(k)$ intervals requires a locked edit distance calculation, and each calculation is performed in $O(k^2)$ time using the algorithm described in section 5.) This can be reduced to $O(k^2)$ time by performing the edit distance calculations more carefully, keeping in mind that the collective error that can be tolerated over all edit distance calculations is k. However, the bound of $O(k^3)$ per round suffices to achieve our final bound of $O(k^4)$.

Remark on the text. A similar formation of intervals is done in the text, except that interval formation continues until either each interval is fully formed or $\log k + 1$ rounds are done, whichever is sooner.

Special cases. The above interval formation algorithm needs to be suitably modified to account for the endpoints of the text and the pattern. We will very briefly sketch the special handling of intervals which encounter premature termination at either the left or the right end. Consider an interval which is prematurely terminated on the left. Intervals prematurely terminated on the right are handled similarly. In future rounds, this interval will be extended only to the right until it is fully formed. Recall that full-formedness is related to the locked edit distance of the span of the interval (with respect to u). The locked edit distance for such intervals is defined as in section 7 (i.e., the span of this interval need not be aligned with a cyclic string of u's but with a string whose canonical period is u and which has suffix u).

Interval lengths. We need the following lemma before describing the remainder of the algorithm.

LEMMA 8.2. *The length of the span s of an interval I obtained in round i is at most $8|u|*i$-current cost of I.*

Proof. Consider the various initial intervals J in s. For each such initial interval J, consider the interval $\text{int}_j(J)$ which is the unique interval processed in round j whose span contains J. There may not be such an interval, of course. J is said to be *alive* in round j if it is the leftmost (rightmost, respectively) initial interval in $\text{int}_j(J)$ at the

beginning of round j and $\text{int}_j(J)$ hasn't yet reached the left endpoint (right endpoint, respectively). Let the last round in which J is alive be denoted by $last(J)$. The *contribution* of J to s is defined to be the sum of the lengths of all of the strings involved in extending the intervals $\text{int}_1(J), \ldots, \text{int}_{last(J)}(J)$ plus the length of J itself. Clearly, the length of s is at most the sum of the lengths of the contributions of the various initial intervals in s.

The contribution of J is at most $2 * (\sum_{l=1}^{last(J)} 2^l) * |u| + |J| \leq 2(2^{last(J)+1} - 2)|u| + 4|u| \leq 2 * 2^{last(J)+1} * |u|$ if $last(J) \neq 0$ and $|J| \leq 4|u|$ otherwise. The $(last(J) - 1)$-current cost of $\text{int}_{last(J)-1}(J)$ is at least $2^{last(J)-1}$ plus its $(last(J) - 1)$-nested cost if $last(J) \geq 1$. We call the quantity $2^{last(J)-1}$ the *capacity* of J (unless $last(J) = 0$, in which case the capacity is defined to be 1). It is easy to see that the capacities of the various initial intervals in s sum to at most the i-current cost of I. The lemma follows. □

The algorithm. First, intervals are formed as above. Next, two minimal sets of final text intervals, one on either side of the middle of the text, each with total final cost exceeding k, are chosen. (If either of these two sets does not have final cost exceeding k, then all of the text intervals in the corresponding half are taken.) By Lemma 8.2, the total lengths of the spans of these final text intervals and the final pattern intervals will be $O(k|u|)$. Ignore the remaining text intervals for the moment. Each match in the span of one of these text intervals that overlaps or touches the span of one of the final pattern intervals is found. In addition, matches in which one of the endpoints of the pattern is aligned with one of these text intervals is found. These matches occur in $O(k^2)$ windows, each of size $O(\max\{k, |u|\})$. If $|u| > k$, then each of the above windows can be further refined by taking intersections with the windows obtained in Step 1 to get $O(k^2)$ windows of size $O(k)$ each. All such matches can then be found in $O(k^4)$ time using the algorithm in section 5.

Next, we consider the remaining matches of the pattern. Note that the spans of the final intervals in the pattern cannot overlap with the spans of the above final intervals chosen in the text. In addition, the text can be trimmed so as to contain only the above final intervals, by an argument similar to the one used in section 6. The reason for this is that, by Lemma 8.1, the above final intervals in the left half of the text will incur more than k mismatches if all of them are overlapped by the pattern (note that they must all be aligned with periodic stretches having canonical period u in the matches being considered) and likewise for the above final intervals in the right half. It follows that the spans of the final intervals in the pattern cannot overlap with the spans of any of the final intervals in the text in any of the remaining matches.

The remaining matches occur in $O(k^2)$ windows as well. Consider one such window. Consider the final costs of the final intervals in the pattern and the final costs of those final intervals in the text which overlap the pattern. If any one of these text intervals is partially formed, then the pattern cannot match the text because the final cost of this text interval is more than k, and Lemma 8.1 implies that the span of this interval must incur more than k edit operations when aligned with a periodic stretch of u's. Similarly, if any of the pattern intervals is partially formed, then, again, the sum of the final costs of these pattern intervals exceeds k, and the pattern cannot match. So suppose that all of these text and pattern intervals are fully formed. Then the final cost of each such interval is its locked edit distance. If the sum of these final costs is at most k, then the pattern matches at intervals of $|u|$ in this window with all of these final intervals locked, and otherwise it does not match anywhere in this window. The precise locations where matches occur can be determined as in the

algorithm for second category matches described toward the end of section 7.1.2.

9. Is $O(\frac{nk^3}{m}+n+m)$ running time possible? The following text and pattern appear to form a hard case for our problem. They are defined in terms of an acyclic string u. Apart from $\Theta(k)$ substrings, each of length equal to $|u| = \Theta(k)$, the text and the pattern are periodic with period u. Suppose these *bad* substrings appear at intervals of $\Theta(k^2)$ in the text and at intervals of $\Theta(k)$ in a length $\Theta(k^2)$ prefix of the pattern. There are $\Theta(k^2)$ windows, each of size k, in which one of these pattern substrings overlaps some text substring. Exactly one bad pattern substring overlaps a bad text substring in any of the pattern placements in these windows. Our current $O(k^4)$ algorithm will take $\Theta(k^2)$ time to determine matches, if any, in each window, giving an $\Theta(k^4)$ time algorithm for this case. However, it is conceivable that an algorithm which takes $O(k)$ amortized time per window can be obtained by observing that the average edit distance between pairs of text-pattern substrings must be $O(1)$; otherwise, there can be few matches. The difficulty we face is that the occurrences of u among the bad substrings of the pattern need not align with occurrences of u in the text.

10. The weighted case. In the weighted case, deletions of different characters and the various substitutions may have differing costs, but, by way of normalization, all will be required to have cost at least 1.

The approximate matches with cost $\leq k$ can be found using essentially the same algorithm; the only change needed is to the Landau–Vishkin algorithm to take into account the differing costs. The details are left to the reader.

A important application in the weighted case is to match a pattern against a database of strings. We would like to apply the above algorithm. For efficiency, one approach would be to have a precomputed suffix tree for the database of strings. This suffix tree would then need to be incremented to incorporate the pattern string so as to enable the above algorithm to be used. Following the match calculation, the modification to the suffix tree would need to be undone. It would also be useful to support both insertions and deletions to the database. We leave this topic as an open problem.

A MATTER OF DEGREE: IMPROVED APPROXIMATION ALGORITHMS FOR DEGREE-BOUNDED MINIMUM SPANNING TREES*

J. KÖNEMANN† AND R. RAVI†

Abstract. In this paper, we present a new bicriteria approximation algorithm for the *degree-bounded minimum spanning tree* problem. In this problem, we are given an undirected graph, a nonnegative cost function on the edges, and a positive integer B^*, and the goal is to find a minimum-cost spanning tree T with maximum degree at most B^*. In an n-node graph, our algorithm finds a spanning tree with maximum degree $O(B^* + \log n)$ and cost $O(\mathtt{opt}_{B^*})$, where $\mathtt{opt}_{B^*}$ is the minimum cost of any spanning tree whose maximum degree is at most B^*. Our algorithm uses ideas from Lagrangean duality. We show how a set of optimum Lagrangean multipliers yields bounds on both the degree and the cost of the computed solution.

1. Introduction.

1.1. Motivation and formulation.

In the design of computer networks a fundamental problem is that of transmitting a single information packet from a given source-host to a set of recipient-hosts. This problem is widely known as the *broadcast* or *multicast* problem, depending on whether we want to transmit the packet to all other hosts or to a specific subset of recipients. Both problems have been widely studied [3, 6, 15]. In particular, it is believed that the multicast problem will play an increasingly important role in data networks.

A naive solution to the multicast problem would be to implement it as a series of unicasts. In other words, the source sends a single packet to every recipient host. The routing is done independently for each of the unicasts. However, the cost of this approach in terms of bandwidth consumption becomes unacceptable if the number of hosts in the multicast group grows.

Graph theoretic ideas have turned out to be essential in the design of efficient network routing protocols. A physical network can be modeled as a complete graph where each host is associated with a node, and an edge represents the *virtual link* between the corresponding hosts. Usually, edges of that graph are annotated by the *transmission delay* of the corresponding virtual link. A standard solution to broadcasting and multicasting problems then is to send packets along the edges of a minimum spanning tree (MST) rooted at the source node [15]. Every internal node duplicates the incoming message and sends it to its children.

However, a spanning tree might have a high *fan-out* at certain internal nodes. Switches in point-to-point networks may vary in their ability to support multicasting. That is, some routers may not support multicasting at all and others may support only a limited number of copies they can make of an incoming packet [17]. Bauer

and Varma [1] show that it is natural to model switch capabilities by node degrees in graphs.

The preceding discussion suggests that a solution to the multicasting problem should minimize the total transmission delay *and* the maximum degree of a vertex in the computed solution. Traditional approaches for this kind of *bicriteria* problem often compute the minimum-cost solution under a linear combination of the two cost measures [12, 14]. However, in the case of very disparate objectives, these techniques usually do not produce useful solutions.

In this paper, we address a natural budgeted version of the *degree-bounded minimum spanning tree* (BMST) *problem*. Here, we are given an undirected graph $G = (V, E)$, a cost function $c : E \to \mathbb{R}^+$, and a positive integer $B \geq 2$. We would like to find a spanning tree T of maximum vertex degree at most B and minimum cost. This formulation was first introduced in [14] and can be modeled by the following integer linear program:

$$\text{(IP)} \qquad \texttt{opt}_B = \min \quad \sum_{e \in E} c_e x_e$$

$$\text{(1.1)} \qquad \text{s.t.} \quad x(\delta(v)) \leq B \quad \forall v \in V,$$

$$x \in \text{SP}_G\,,$$

$$x \text{ integer}.$$

Here, $\delta(v)$ denotes the set of all edges of E that are incident to v and SP_G is the spanning tree polyhedron, that is, the convex hull of edge-incidence vectors of spanning trees of G. We note that complete descriptions of SP_G are known in the literature [2, 4].

1.2. Previous work and our result. Ravi et al. [14] showed how to compute a spanning tree T of maximum degree $O(B \log(\frac{n}{B}))$ and total cost at most $O(\log n)\,\texttt{opt}_B$. They generalize their ideas to Steiner trees, generalized Steiner forests, and the node-weighted case.

Another result that is related to our work is given in a paper by Khuller, Raghavachari, and Young [9]. The authors show how to compute a spanning tree of n points in the plane that has degree at most 3 (4) and cost at most 1.5 (1.25)—that of a minimum-cost spanning tree (without any degree constraints).

While the approximation factor of $O(\log n)$ on the cost of the solution cannot be improved substantially (via reductions from the set covering problem [10]) in the node-weighted case, improvements for the edge-weighted case were left open in [14]. Our main result is such an improvement and is stated in the following theorem. We denote the degree of a node v in tree T by $\delta_T(v)$. Let the maximum node degree in a tree T be denoted by $\Delta(T)$.

THEOREM 1.1. *There is a polynomial-time approximation algorithm that, given a graph $G = (V, E)$, a nonnegative cost function $c : E \to \mathbb{R}^+$, a constant $B^* \geq 2$, and a parameter $\omega > 0$, computes a spanning tree T s.t.*

1. $\Delta(T) \leq (1 + \omega)bB^* + \log_b n$ *for any arbitrary constant* $b > 1$, *and*
2. $c(T) < (1 + 1/\omega)\,\texttt{opt}_{B^*}$.

For instance, choosing $\omega = 1/2$ and $b = 2$ would yield a tree with degree at most $3B^* + \log_2 n$ and cost at most $3\,\texttt{opt}_{B^*}$.

1.3. Technique: Lagrangean duality. Our algorithm builds on the Lagrangean dual of (IP) resulting from *dualizing* the degree constraints. We denote its value

by $\texttt{opt}_{LD(B)}$.

$$\text{(LD(B))} \qquad \texttt{opt}_{LD(B)} = \max_{\lambda \geq 0} \min_{T \in \mathrm{SP}_G} \left\{ c(T) + \sum_{v \in V} \lambda_v (\delta_T(v) - B) \right\}.$$

For any fixed $\lambda \geq 0$, an optimum integral solution to (IP) is a feasible candidate for attaining the inner minimum above. Since the maximum degree of such a solution is at most B and $\lambda \geq 0$, it follows that $\texttt{opt}_{LD(B)}$ is a lower bound on $\texttt{opt}_B$.

PROPOSITION 1.2 (see [13]). $\texttt{opt}_{LD(B)} \leq \texttt{opt}_B$.

The interesting fact is that $\texttt{opt}_{LD(B)}$ can be computed in polynomial time [13]. The result is a vector λ^B of optimum Lagrangean multipliers on the nodes and a set of optimum trees $\mathcal{O}^{\mathcal{B}}$, all of which achieve the inner minimum for this set of multipliers. In other words, every tree $T^B \in \mathcal{O}^B$ minimizes the following objective:

$$c(T^B) + \sum_{v \in V} \lambda_v^B (\delta_{T^B}(v) - B).$$

Given λ^B, the task of finding a tree T that minimizes the above objective function is called the Lagrangean subproblem of (LD(B)).

Using $c^{\lambda^B}(uv) = c(uv) + \lambda_u^B + \lambda_v^B$, the last expression can be restated as

$$c^{\lambda^B}(T^B) - B \sum_{v \in V} \lambda_v^B. \tag{1.2}$$

Notice that for a given λ^B and B, the second term is a constant. Hence, any MST of G under cost c^{λ^B}, denoted by $\texttt{MST}(G, c^{\lambda^B})$, is a solution for T.

An important feature of our algorithm is to relax the degree constraints slightly from B to $(1+\omega)B$ for some fixed $\omega > 0$ and show that there is a tree $T \in \mathcal{O}^{(1+\omega)B}$ that satisfies the conditions of Theorem 1.1.

This paper is organized as follows: in section 2 we review results on the related *minimum degree spanning tree problem*. In particular, we present the fundamental ideas from [5, 7]. In section 3, we state our algorithm. Finally, we give the analysis of our procedure in section 4.

2. Minimum degree spanning trees. Related to the BMST problem is the problem of minimizing the maximum degree of a spanning tree (MDST) in some graph G. This problem is $\mathcal{NP}$-hard since the *Hamiltonian path* problem is a special case. In fact, it is $\mathcal{NP}$-complete to decide for any $k \geq 2$ whether G contains a spanning tree of maximum degree k [8].

Fürer and Raghavachari presented an approximation algorithm with an additive performance guarantee of one [7]: i.e., they describe a polynomial-time algorithm that finds a spanning tree T of G s.t. $\Delta(T) \leq \Delta^* + 1$, where Δ^* denotes the minimum possible maximum degree over all spanning trees. In the same paper the authors also give a local search algorithm for the MDST problem. This approach yields a tree with maximum degree at most $b\Delta^* + \log_b n$ for any constant $b > 1$. Later, Fischer noted that this procedure can be adapted to find a minimum-cost spanning tree of approximately minimum maximum degree in an edge-weighted graph [5].

The local search algorithms from [5, 7] play an important role in this paper. In this section we show a minor strengthening of these results that is crucial to the analysis of our algorithm.

2.1. A local improvement algorithm. In this section, we explain the basic ideas from the local search algorithm for the MDST problem. We state the algorithm since we use it later. The procedure starts with a spanning tree T and tries to improve it by *swapping* nontree edges against tree edges.

DEFINITION 2.1. *Given a tree T and a nontree edge uv, let $\mathcal{C}(uv)$ be the unique cycle in $T \cup \{uv\}$ and let $wz \in \mathcal{C}(e)$. We call the swap $\langle uv, wz\rangle$ an* improvement for *w if*

$$\max\{\delta_T(u), \delta_T(v)\} + 1 < \delta_T(w).$$

If an edge swap $\langle uv, wz\rangle$ is an improvement step for either w or z, then the maximum degree of the nodes u, v, w, and z decreases as a result of the swap; we call such a swap simply an improvement.

The algorithm in [7] performs improvement steps as long as possible. In fact, it is not hard to see that, starting with an arbitrary tree, the number of possible improvements is finite. We end up with a *locally optimal tree*.

DEFINITION 2.2. *A tree T is called a* locally optimal tree *(LOT) if no vertex degree can be decreased by applying an improvement swap.*

Computing a LOT might be too ambitious a goal, however. In fact, it is not known how to do this in polynomial time. However, the analysis in [7] shows that it is enough to compute a *pseudo-optimal* tree.

DEFINITION 2.3. *A tree T of maximum degree $\Delta(T)$ is called a* pseudo-optimal tree *(POT) if for all vertices v with $\Delta(T) - \lceil \log_b n \rceil \leq \delta_T(v) \leq \Delta(T)$, no improvement step for v is applicable. Here b is an arbitrary constant bigger than one.*

Fischer's adaptation [5] of the algorithm from [7] computes a minimum-cost spanning tree of approximately minimum maximum degree. To obtain his algorithm we have to make two small changes to the procedure from [7]. First, instead of starting with an arbitrary spanning tree, we start with a minimum-cost spanning tree. Second, an improvement step must be *cost neutral*. That is, for an improvement step $\langle uv, wz\rangle$ to be applicable, we must have $c_{uv} = c_{wz}$. Algorithm 1 states the procedure.

ALGORITHM 1. The algorithm `PLocal` computes a POT.

```
1: Given graph G = (V, E) and cost function c : E → R+
2: T ← MST(G, c)
3: while T is not pseudo optimal do
4:    Identify cost neutral improvement ⟨uv, wz⟩
5:    T ← T − wz + uv
6: end while
```

2.2. Analysis and running time. In what follows, we highlight and strengthen the major ideas of the analysis from [5, 7]. The strengthening is due to Éva Tardos [16] and leads to a shorter and simpler proof of Lemma 4.5 than the one that appeared in the extended abstract [11].

The fundamental underlying proof idea for the unweighted problem is based on an averaging argument that we present here. Let a set $W \subseteq V$ be s.t. for a given graph $G = (V, E)$, the graph $G[V - W]$ has t connected components. A spanning tree of G has to connect these t components *and* the nodes from W. We need exactly $t + |W| - 1$ edges going between the nodes of W and the t connected components to accomplish this. Each of these edges must be incident to a node from W. Hence averaging yields a lower bound of $(t + |W| - 1)/|W|$ on the maximum degree Δ^* of T.

PROPOSITION 2.4 (see [7]). *Let W be a set of size w whose removal splits G into t components. Then $\Delta^* \geq \left\lceil \frac{w+t-1}{w} \right\rceil$.*

We now turn to the weighted case, i.e., the *minimum degree minimum-cost spanning tree* problem. The above-mentioned strengthening of the results from [5] is based on the following definitions.

DEFINITION 2.5. *Given an undirected graph $G = (V, E)$ and a nonnegative cost function c on the edges, let $\mathcal{O}^c$ be defined as*

$$\mathcal{O}^c = \{T : T \text{ is an MST under cost } c\}.$$

In the following we will be talking about convex combinations of spanning trees. Hence we introduce some further simplifying notation.

DEFINITION 2.6. *Let $T_c^\alpha = \sum_{T \in \mathcal{O}^c} \alpha_T T$ be a convex combination of minimum-cost spanning trees of G with respect to cost function c, i.e., $\alpha_T \geq 0$ for all T and $\sum_{T \in \mathcal{O}^c} \alpha_T = 1$. We denote the* fractional degree *of vertex v in T_c^α by*

$$\delta_c^\alpha(v) = \sum_{T \in \mathcal{O}^c} \alpha_T \delta_T(v).$$

Finally we define the minimum maximum degree of convex combinations of spanning trees.

DEFINITION 2.7. *Given $G = (V, E)$ and a nonnegative cost function c on the edges, let Δ_c^* denote the minimum maximum degree of any convex combination of minimum-cost spanning trees, i.e.,*

$$\Delta_c^* = \min_{\text{convex comb. } \alpha} \max_{v \in V} \delta_c^\alpha(v).$$

The following easy proposition will be used in the later analysis.

PROPOSITION 2.8 (see [7]). *For any constant $b > 1$ and a tree T, let S_d be the set of nodes that have degree at least d in T. Then, there is a*

$$d \in \{\Delta_T - \lceil \log_b n \rceil + 1, \ldots, \Delta_T\}$$

s.t. $|S_{d-1}| \leq b|S_d|$.

The main theorem is the following.

THEOREM 2.9 (see [5, 7]). *If T is a pseudo-optimal MST, then $\Delta_T < b\Delta_c^* + \lceil \log_b n \rceil$ for any constant $b > 1$. Moreover, a pseudo-optimal MST can be computed in polynomial time.*

Proof. Given a constant $b > 1$, choose d as in Proposition 2.8. That is, we have $|S_{d-1}| \leq b|S_d|$. Recall that S_d contains the nodes of degree at least d in the tree T.

Removing S_d from T leaves us with a forest F. Let $\widehat{G}$ be obtained from G by contracting each connected component of F. It is now easy to see that every minimum-cost spanning tree of G contains a minimum-cost spanning tree of $\widehat{G}$ (e.g., every edge added by Kruskal's algorithm for finding a minimum-cost spanning tree for G is feasible for a minimum-cost spanning tree of $\widehat{G}$ if it were not contracted in the formation of $\widehat{G}$).

Let $(u, v) \in E - T$ be an edge that connects two components of F s.t. $u, v \notin S_{d-1}$, i.e., both u and v have degree at most $d - 2$. We claim that such an edge cannot be included in any MST of $\widehat{G}$. To see that, let $P_{u,v}^T$ be the edges of the unique u, v-path in T and let $\widehat{P_{u,v}^T}$ be the subset of the edges of $P_{u,v}^T$ that are in $\widehat{G}$.

It follows from the pseudo optimality of T that the cost of edge (u, v) must be higher than the cost of each edge from $\widehat{P_{u,v}^T}$. Otherwise, (u, v) can be swapped in place

of another edge of the same or higher cost in $\widehat{P^T_{u,v}}$, and all such edges are incident to at least one node in S_{d-1}, leading to an improvement. This means (u, v) cannot be a part of any MST of $\widehat{G}$. Equivalently, a minimum-cost spanning tree of G must use edges incident to S_{d-1} to connect the components of F and the nodes of S_d.

By the definition of S_d, we know that F has at least

$$|S_d|d - 2(|S_d| - 1) = |S_d|(d-2) + 2$$

trees. This follows from an easy counting argument after observing that every node in S_d has degree at least d in T and there are at most $|S_d| - 1$ edges going between nodes of S_d.

This means that we need at least

$$|S_d|(d-2) + 2 + |S_d| - 1 = |S_d|(d-1) + 1$$

edges to connect up the components of F and the nodes of S_d in *any spanning tree*. By the preceding argument, each of these edges has to be incident to at least one node of degree at least $d-1$ in an MST. Hence the average degree of a node of S_{d-1} in any MST is

$$\frac{|S_d|(d-1)+1}{|S_{d-1}|}.$$

Moreover, the average degree of a node in S_{d-1} in any *convex combination* of MSTs is also at least the above ratio. Since Δ^*_c denotes the minimum possible maximum degree of any fractional MST, it follows, using our choice of index d from Proposition 2.8, that

$$\Delta^*_c > \frac{d-1}{b}.$$

Using the range of d, we obtain $\Delta(T) < b\Delta^*_c + \lceil \log_b n \rceil$. The results in [5, 7] show a lower bound on the degree of any MST. The extension to fractional MSTs is the mentioned strengthening [16] of the previous ideas.

For the running time we follow [7]. Note that each improvement step can be implemented in polynomial time. We need to bound the number of iterations. The proof uses a potential function argument. Define the potential of a vertex v as

$$\Phi(v) = 3^{\delta_T(v)},$$

where T is the current tree. The total potential is the sum over all vertex potentials, that is,

$$\Phi(T) = \sum_{v \in V} \Phi(v).$$

Now, an improvement step in Algorithm 1 improves the degree of a vertex $v \in S_d$ with $\delta_T(v) = d$ and $d \geq \Delta(T) - \lceil \log_b n \rceil + 1$. Hence, the reduction in the potential is going to be at least

$$(3^d + 2 \cdot 3^{d-2}) - 3 \cdot 3^{d-1} = 2 \cdot 3^{d-2}.$$

Using the range of d, we can lower bound the right-hand side of the last equality by

$$3^{\Delta(T) - \log_b n - 1} = \Omega\left(\frac{3^{\Delta(T)}}{n}\right).$$

The potential $\Phi(T)$ of the tree T is at most $n3^{\Delta(T)}$. This implies that the overall decrease of the potential due to the improvement step is

$$\Omega\left(\frac{\Phi(T)}{n^2}\right).$$

In other words, we reduce the potential by at least a polynomial factor in each iteration. In $O(n^2)$ iterations the reduction is by a constant factor. Hence, the algorithm needs $O(n^3)$ improvement steps in total. ∎

3. The BMST algorithm. In this section, we describe our algorithm for the BMST problem. It uses the Lagrangean formulation (LD(B)) from the introduction and Algorithm 1.

The input to our algorithm consists of a graph G, a nonnegative cost function c, a degree bound B^*, and a positive constant ω. Let $B = (1+\omega)B^*$.

ALGORITHM 2. Our algorithm for the BMST problem.

1: Given graph $G = (V, E)$, a cost function $c : E \to \mathbb{R}^+$, a degree bound $B^* \geq 2$, and a parameter $\omega > 0$
2: $B \leftarrow (1+\omega)B^*$
3: $\lambda^B \leftarrow \texttt{Solve}(LD(B))$
4: $\overline{T} \leftarrow \texttt{PLocal}(G, c^{\lambda^B})$

Since the optimum Lagrange multipliers and pseudo-optimal MSTs can be computed in polynomial time [7, 13], Algorithm 2 runs in polynomial time.

Recall that c^{λ^B} denotes the original cost function c *augmented* by the Lagrangean multipliers λ^B, i.e., $c^{\lambda^B}_{uv} = c_{uv} + \lambda_u + \lambda_v$. We use $\mathcal{O}^B$ to denote the set of all minimum-cost spanning trees of G for cost function c^{λ^B}.

4. Analysis. In this section we prove Theorem 1.1. First, we show that the cost $c(\overline{T})$ of the tree output by Algorithm 2, $\overline{T}$, is small. Then, we prove that $\overline{T}$ has low maximum degree. Our proofs rely on techniques from Lagrangean duality.

4.1. The cost of $\overline{T}$. Recall that $\texttt{opt}_{LD(B)} \leq \texttt{opt}_B$ from Proposition 1.2. Unfortunately, $\texttt{opt}_{LD(B)} = \texttt{opt}_B$ is not true in general. There might be a *duality gap*. However, it can be shown that $\texttt{opt}_{LD(B)}$ equals the optimum objective function value of the relaxation of (IP). The proof is insightful, and hence we present it here.

THEOREM 4.1 (see [13]). $\texttt{opt}_{LD(B)} = \min\{c(T) : T \in SP_G \ \forall v \in V : \delta_T(v) \leq B\}$.

Proof. We can restate (LD(B)) as the following linear program in variables η and λ. Recall that we denote its maximum objective function value by $\texttt{opt}_{LD(B)}$.

$$\begin{aligned} (4.1) \qquad \max \quad & \eta \\ \text{s.t.} \quad & \eta \leq c(T) - \sum_{v \in V} \lambda_v (B - \delta_T(v)) \quad \forall T \in \mathrm{SP}_G\,, \\ & \lambda \geq 0. \end{aligned}$$

The first block of constraints states that η is at most the cost of any spanning tree T of G with respect to the Lagrangean function (1.2). The maximization objective of (4.1) forces η to attain the best possible cost. Writing down the dual of the last

program yields

$$
\begin{aligned}
(4.2) \qquad \min \quad & c\left(\sum_{T\in \mathrm{SP}_G} \alpha_T T\right) \\
\text{s.t.} \quad & \sum_{T\in \mathrm{SP}_G} \alpha_T = 1, \\
& \sum_{T\in \mathrm{SP}_G} \alpha_T \delta_T(v) \le B, \qquad \sum_{T\in \mathrm{SP}_G} \alpha_T = B \quad \forall v \in V, \\
& \alpha \ge 0.
\end{aligned}
$$

Note that $T^\alpha = \sum_{T\in \mathrm{SP}_G} \alpha_T T$ is a convex combination of trees in SP_G. Also, observe that $\sum_{T\in \mathrm{SP}_G} \alpha_T \delta_T(v)$ is precisely the degree $\delta^\alpha(v)$ of this fractional tree at node v. These observations yield the theorem. ∎

The theorem has two nice corollaries that we use. In the following, let λ^B denote the vector of optimum Lagrangean multipliers for (LD(B)). Recall that $\mathcal{O}^B$ is the set of minimum-cost spanning trees under c^{λ^B}.

COROLLARY 4.2. *There exists a convex combination $T^\alpha = \sum_{T\in\mathcal{O}^B} \alpha_T T$ s.t.*

1. $\forall v \in V,\ \delta^\alpha_{c^{\lambda^B}}(v) \le B$ *and*
2. $\lambda^B_v > 0$ *only if* $\delta^\alpha_{c^{\lambda^B}}(v) = B$.

Proof. This follows from complementary slackness applied to the optimum solutions of the dual linear programs (4.1) and (4.2). ∎

The second corollary gives a bound on $\Delta^*_{c^{\lambda^B}}$.

COROLLARY 4.3. $\Delta^*_{c^{\lambda^B}} \le B$.

Proof. By Corollary 4.2, we know that there is a convex combination T^α of trees from $\mathcal{O}^B$ s.t. $\delta^\alpha_{c^{\lambda^B}}(v) \le B$ for all v. Hence

$$\Delta^*_{c^{\lambda^B}} = \min_\alpha \max_{v\in V} \delta^\alpha_{c^{\lambda^B}}(v) \le B. \qquad \blacksquare$$

We now prove that $c(\overline{T})$ is small.

LEMMA 4.4. *For all trees $T \in \mathcal{O}^B$ we have $c(T) < (1 + 1/\omega)\,\mathtt{opt}_{B^*}$.*

Proof. Recall that we defined $B = (1+\omega)B^*$.

The following inequality holds for every $T \in \mathcal{O}^B$:

$$
\begin{aligned}
(4.3) \qquad \sum_{v\in V} \lambda^B_v(\delta_T(v) - B^*) &\le c(T) + \sum_{v\in V} \lambda^B_v(\delta_T(v) - B^*) \\
&\le \mathtt{opt}_{LD(B^*)}.
\end{aligned}
$$

In the first inequality we just added $c(T)$. Note that the right-hand side of the first line is just the Lagrangean objective function (1.2) for B^*. Recall that T is an MST with respect to c^{λ^B}. Moreover, λ^B is a feasible set of multipliers for (LD(B^*)). Hence, the second inequality follows.

We also have

$$
\begin{aligned}
c(T) &= c(T) + \sum_{v\in V} \lambda^B_v(\delta_T(v) - B^*) + \sum_{v\in V} \lambda^B_v(B^* - \delta_T(v)) \\
&\le \mathtt{opt}_{LD(B^*)} + \sum_{v\in V} \lambda^B_v(B^* - \delta_T(v)),
\end{aligned}
$$

where the inequality follows from (4.3). Applying Proposition 1.2 and the fact that $\delta_T(v) \geq 1$ for all $v \in V$ leads to

$$c(T) < \texttt{opt}_{B^*} + B^* \sum_{v \in V} \lambda_v^B.$$

In the remainder of this proof we will derive the inequality $B^* \sum_{v \in V} \lambda_v^B \leq \texttt{opt}_{B^*}/\omega$. This yields the lemma. From Corollary 4.2, we know that there is a convex combination

$$T^\alpha = \sum_{T \in \mathcal{O}^B} \alpha_T T$$

s.t. $\lambda_v^B > 0$ only if $\delta^\alpha_{c^{\lambda^B}}(v) = B$.

We derive a new inequality by summing over all $T \in \mathcal{O}^B$, α_T times the inequality (4.3) for each T. We obtain

$$\sum_{T \in \mathcal{O}^B} \alpha_T \left(\sum_{v \in V} \lambda_v^B (\delta_T(v) - B^*) \right) \leq \texttt{opt}_{LD(B^*)} \sum_{T \in \mathcal{O}^B} \alpha_T. \tag{4.4}$$

The right-hand side is equivalent to $\texttt{opt}_{LD(B^*)}$ because $\sum_{T \in \mathcal{O}^B} \alpha_T = 1$. Reordering the left-hand side yields

$$\sum_{v \in V} \lambda_v^B \left(\left(\sum_{T \in \mathcal{O}^B} \alpha_T \delta_T(v) \right) - B^* \right).$$

Instead of summing over all $v \in V$, it suffices to sum over v, where $\lambda_v^B > 0$. For such v, we have that

$$\delta^\alpha_{c^{\lambda^B}} = \sum_{T \in \mathcal{O}^B} \alpha_T \delta_T(v) = B$$

by Corollary 4.2. Using $B = (1+\omega)B^*$, it follows that the left-hand side of (4.4) is equivalent to

$$\omega B^* \sum_{v \in V} \lambda_v^B,$$

and this finishes the proof of the lemma. □

4.2. The maximum degree of $\overline{T}$.

LEMMA 4.5. $\Delta_{\overline{T}} \leq (1+\omega) b B^* + \lceil \log_b n \rceil$ *for constants* $b > 1$ *and* ω.

Proof. $\overline{T}$ is a pseudo-optimal minimum-cost spanning tree with respect to cost function c^{λ^B}. From Theorem 2.9 we know that

$$\Delta_{\overline{T}} \leq b \Delta^*_{c^{\lambda^B}} + \lceil \log_b n \rceil.$$

An application of Corollary 4.3, noting that $B = (1+\omega)B^*$, yields the lemma. □

5. Conclusions.

5.1. Summary and remarks. In this paper we developed an improved approximation algorithm for the degree-bounded minimum spanning tree problem. For a positive constant B^* and an n-node graph, our method computes a spanning tree whose cost is at most a constant factor worse than the cost of the optimum degree-B^*-bounded minimum spanning tree. Additionally, we proved that the maximum degree of the resulting tree is $O(B^* + \log n)$. Our procedure solves a Lagrangean relaxation of the BMST integer program for slightly relaxed degree constraints ($(1+\omega)B^*$ instead of B^*). We showed how this slack helps to prove low cost of the resulting tree. Our algorithm also makes use of a local search technique from [5, 7]. We showed how a slight strengthening of the results in [5, 7] can be used to prove low maximum degree of the resulting tree.

5.2. Extensions and open questions. An interesting open question is whether our results extend to the case of Steiner trees and general Steiner networks. The central difficulty of such an extension stems from the fact that, in the Steiner case, the subproblem that arises from dualizing the degree constraints (the minimum-cost Steiner tree problem) itself is $\mathcal{NP}$-hard.

Another avenue for extending our work is to examine if our approach is capable of handling individual node degrees. In the current version, node degrees are assumed to be uniform. Lemma 4.5 relies on the pseudo optimality of tree $\overline{T}$ from Algorithm 2 and on results from [5, 7]. These results do not apply to nonuniform degrees. Is there an extension of the known MDST algorithms to handle individual degree bounds?

We believe that the techniques used in this paper can be generalized to apply to a broader class of multicriteria problems. A central point in the development of a more general framework is the identification of key properties of suitable optimization problems; in the BMST problem, the dualization of the degree constraints yields a tractable subproblem. Furthermore, the compact form of the objective function of this subproblem proved to be a key for the analysis.

Acknowledgment. We thank Éva Tardos for permitting us to include her simpler proof of Lemma 4.5 in the paper.

MAINTAINING STREAM STATISTICS OVER SLIDING WINDOWS*

MAYUR DATAR†, ARISTIDES GIONIS†, PIOTR INDYK‡, AND RAJEEV MOTWANI†

Abstract. We consider the problem of maintaining aggregates and statistics over data streams, with respect to the last N data elements seen so far. We refer to this model as the *sliding window* model. We consider the following basic problem: Given a stream of bits, maintain a count of the number of 1's in the last N elements seen from the stream. We show that, using $O(\frac{1}{\epsilon}\log^2 N)$ bits of memory, we can estimate the number of 1's to within a factor of $1+\epsilon$. We also give a matching lower bound of $\Omega(\frac{1}{\epsilon}\log^2 N)$ memory bits for any deterministic or randomized algorithms. We extend our scheme to maintain the sum of the last N positive integers and provide matching upper and lower bounds for this more general problem as well. We also show how to efficiently compute the L_p norms ($p \in [1,2]$) of vectors in the sliding window model using our techniques. Using our algorithm, one can adapt many other techniques to work for the sliding window model with a multiplicative overhead of $O(\frac{1}{\epsilon}\log N)$ in memory and a $1+\epsilon$ factor loss in accuracy. These include maintaining approximate histograms, hash tables, and statistics or aggregates such as sum and averages.

1. Introduction.

Traditional database management systems (DBMSs) expect all data to be managed within some form of persistent *data sets*. For many recent applications, the concept of a *data stream*, possibly infinite, is more appropriate than a data set. By nature, a stored data set is appropriate when significant portions of the data are queried again and again, and updates are small and/or relatively infrequent. In contrast, a data stream is appropriate when the data is changing constantly (often exclusively through insertions of new elements), and it is either unnecessary or impractical to operate on large portions of the data multiple times.

One of the challenging aspects of processing over data streams is that, while the length of a data stream may be unbounded, making it impractical or undesirable to store the entire contents of the stream, for many applications, it is still important to retain some ability to execute queries that reference past data. For example, in order to detect fraudulent credit card transactions, it is useful to be able to detect when the pattern of recent transactions for a particular account differs significantly from the earlier transactional history of that account. In order to support queries of this sort using a bounded amount of storage (either in memory or in a traditional DBMS), it is necessary to devise techniques for storing summary or synoptic information about previously seen portions of data streams. Generally there is a tradeoff between the

size of the summaries and the ability to provide precise answers to queries involving past data.

We consider the problem of maintaining statistics over streams with regard to the last N data elements seen so far. We refer to this model as the *sliding window* model. We identify a simple counting problem whose solution is a prerequisite for efficient maintenance of a variety of more complex statistical aggregates: Given a stream of bits, maintain a count of the number of 1's in the last N elements seen from the stream. We show that, using $O(\frac{1}{\epsilon}\log^2 N)$ bits of memory, we can estimate the number of 1's to within a factor of $1+\epsilon$. We also give a matching lower bound of $\Omega(\frac{1}{\epsilon}\log^2 N)$ memory bits for any deterministic or randomized algorithm. We extend our scheme to maintain the sum of the last N positive integers and provide matching upper and lower bounds for this more general problem as well.

We also show how to efficiently compute the L_p norms ($p \in [1,2]$) of vectors in the sliding window model using our techniques. Using our algorithm, one can adapt many other techniques to work for the sliding window model with a multiplicative overhead of $O(\frac{1}{\epsilon}\log N)$ in memory and a $1+\epsilon$ factor loss in accuracy. These include maintaining approximate histograms, maintaining hash tables, and maintaining statistics and aggregates such as sum and average. Our techniques are simple and easy to implement. We expect that it will be an attractive choice of implementation for streaming applications.

1.1. Motivation, model, and related work. Several applications naturally generate data streams as opposed to data sets. In telecommunications, for example, *call records* are generated continuously. Typically, most processing is done by examining a call record once or operating on a "window" of recent call records (e.g., to update customer billing information), after which records are archived and not examined again. For example, Cortes et al. [2] report working with AT&T long distance call records, consisting of 300 million records per day for 100 million customers. A second application is *network traffic engineering*, in which information about current network performance—latency, bandwidth, etc.—is generated online and is used to monitor and adjust network performance dynamically [7, 16]. In this application, it is generally both impractical and unnecessary to process anything but the most recent data.

There are other traditional and emerging applications in which data streams play an important and natural role, e.g., web tracking and personalization (where the data streams are web log entries or click-streams), medical monitoring (vital signs, treatments, and other measurements), sensor databases, and financial monitoring, to name but a few. There are also applications in which traditional (nonstreaming) data is treated as a stream due to performance constraints. In data mining applications, for example, the volume of data stored on disk is so large that it is only possible to make one pass (or perhaps a very small number of passes) over the data [12, 11]. The objective is to perform the required computations using the stream generated by a single scan of the data, using only a bounded amount of memory and without recourse to indexes, hash tables, or other precomputed summaries of the data. Another example along these lines occurs when data streams are generated as intermediate results of pipelined operators during evaluation of a query plan in an SQL database; without materializing some or all of the temporary results, only one pass on the data is possible [3].

In most of these applications, the goal is to make decisions based on the statistics or models gathered over the "recently observed" data elements. For example, one

might be interested in gathering statistics about packets processed by a set of routers over the last day. Moreover, we would like to maintain these statistics in a continuous fashion. This gives rise to the *sliding window model*: Data elements arrive at every instant; each data element expires after exactly N time steps; and the portion of data that is relevant to gathering statistics or answering queries is the set of the last N elements to arrive. The sliding window refers to the window of active data elements at a given time instant.

Previous work [1, 5, 13] on stream computations addresses the problems of approximating frequency moments and computing the L_p differences of streams. There has also been work on maintaining histograms [14, 10]. While Jagadish et al. [14] address the off-line version of computing optimal histograms, Guha and Koudas [10] provide a technique for maintaining near optimal time-based histograms in an on-line fashion over streaming data. The queries that are supported by histograms constructed in the latter work are range or point queries over the time attribute. In the earlier work, the underlying model is that all of the data elements seen so far are relevant. Recent work by Gilbert et al. [8] considers, among other things, the problem of maintaining *aged aggregates* over data streams. For a data stream $\ldots, a^{(-2)}, a^{(-1)}, a^{(0)}$, where $a^{(0)}$ is the most recently seen data element, the λ-*aging* aggregate is defined as $\lambda a^{(0)} + \lambda(1-\lambda)a^{(-1)} + \lambda(1-\lambda)^2 a^{(-2)} + \cdots$. Aged aggregate queries tend to get asked in the context of telecommunications data. While aging is one technique to discount for the staleness of certain data elements, we believe that the sliding window model is also important since, for most applications, one is not interested in gathering statistics over outdated data. For instance, in network management, depending upon the specific application, we may not want data that is a month old or a year old to affect our decisions. Maintaining statistics like sum/average, histograms, hash tables, frequency moments, and L_p differences over sliding windows is critical to most applications. To our knowledge, there has been no previous work that addresses these problems for the sliding window model.

1.2. Summary of results. We focus completely on the sliding window model for data streams. We formulate a basic counting problem whose solution can be used as a building block for solving most of the problems mentioned earlier.

PROBLEM 1 (BASICCOUNTING). *Given a stream of data elements, consisting of* 0*'s and* 1*'s, maintain at every time instant the count of the number of* 1*'s in the last* N *elements.*

It is easy to verify that an exact solution requires $\Theta(N)$ bits of memory. (Note that we measure space complexity in terms of the number of bits rather than the number of memory words.) For most applications, it is prohibitive to use $\Omega(N)$ memory. For instance, consider the network management application, where a large number of data packets pass through a router every second. However, in most applications, it suffices to produce an approximate answer. Thus our goal is to provide a good approximation using $o(N)$ memory.

It is interesting to observe why naïve schemes do not suffice for producing approximate answers with low memory requirement. For instance, consider the scheme in which we maintain a simple counter which is incremented upon the arrival of a data element, which is 1. The problem is that an old data element expires at every time instant, but we have no way of knowing whether that was a 0 or 1 and whether we should decrement the counter. It is also natural to consider random sampling. Just maintaining a sample of the window elements will fail in the case where the 1's are relatively sparse.

Another approach is to maintain histograms. While this is the approach that we follow, we argue that the known histogram techniques will not work. A histogram technique is characterized by the policy used to maintain the bucket boundaries. We would like to build time-based histograms in which every bucket represents a contiguous time interval and maintains the number of 1's that arrived in that interval. As with all histogram techniques, when a query is presented, we may have to interpolate in some bucket to estimate the answer because a proper subset of the buckets' elements may have expired. Let us consider some schemes of bucketizing and see why they will not work. The first scheme that we consider is that of dividing into k equiwidth buckets. The problem is that the distribution of 1's in the buckets may be nonuniform. We will incur large error when the interpolation takes place in buckets with a majority of the 1's. This suggests another scheme, in which we use buckets of nonuniform width, so as to ensure that each bucket has a near-uniform number of 1's. The problem is that the total number of 1's in the sliding window could change dramatically with time, and the current buckets may turn out to have more or less than their fair share of 1's as the window slides forward. Our solution is a form of a histogram which avoids these problems by using a set of well-structured and nonuniform bucket sizes.

In section 2, we provide a solution for BasicCounting which uses $O(\frac{1}{\epsilon}\log^2 N)$ bits of memory (equivalently, $O(\frac{1}{\epsilon}\log N)$ buckets of size $O(\log N)$) and provides an estimate of the answer at every instant that is within a $1+\epsilon$ factor of the actual answer. Moreover, our algorithm does not require an a priori knowledge of N and caters to the possibility that the window size can be changed dynamically. Our algorithm is guaranteed to work with $O(\log^2 N)$ memory as long as the window size is bounded by N. The algorithm takes $O(\log N)$ worst-case time to process each new data element's arrival but only $O(1)$ amortized time per element. Count queries can be processed in $O(1)$ time. The algorithm itself is relatively simple and easy to implement.

Section 3 presents a matching lower bound. We show that any approximation algorithm (deterministic or randomized) for BasicCounting with relative error $1+\epsilon$ must use $\Omega(\frac{1}{\epsilon}\log^2 N)$ bits of memory. This proves that our algorithm is optimal in terms of memory usage.

In section 4, we extend the technique to handle data elements with positive integer values, instead of just binary values; this is referred to as the Sum problem. We provide matching upper and lower bounds on the memory usage for this general problem as well.

In section 5, we show how our schemes extend to a model which is more suited for real-life applications and also explore some ideas for reducing the memory requirements.

In section 6, we show that we can use our techniques along with the sketching techniques of [13] to efficiently maintain the L_p ($p \in [1,2]$) norms of vectors in the sliding window model.

Finally, section 7 provides a brief discussion of the application of the BasicCounting and Sum algorithms to adapting several other problems in the sliding window model, such as maintaining histograms, hash tables, and statistics or aggregates such as averages/sums. The reduction of these problems to BasicCounting entails a multiplicative overhead of $O(\frac{1}{\epsilon}\log N)$ in memory and a $1+\epsilon$ factor loss in accuracy. This serves to illustrate the usefulness of focusing on the BasicCounting problem. We also discuss upper and lower bounds for other problems such as main-

taining min/max, distinct values estimation, and maintaining sum in the presence of positive and negative values.

2. Algorithm for BasicCounting. Our approach toward solving the Basic-Counting problem is to maintain a histogram that records the timestamp of selected 1's that are *active* in that they belong to the last N elements. We call this histogram the exponential histogram (EH) for reasons that will be clear later. Before getting into the details of our algorithms, we need to introduce some notation.

We follow the conventions illustrated in Figure 1. In particular, we assume that new data elements are coming from the right and the elements at the left are ones already seen. Note that each data element has an *arrival time*, which increments by one at each arrival, with the leftmost element considered to have arrived at time 1. But, in addition, we employ the notion of a *timestamp*, which corresponds to the position of an *active* data element in the current window. We timestamp the active data elements from right to left, with the most recent element being at position 1. Clearly, the timestamps change with every new arrival, and we do not wish to make explicit updates. A simple solution is to record the arrival times in a wraparound counter of $\log N$ bits, and then the timestamp can be extracted by comparison with the counter value of the current arrival. As mentioned earlier, we concentrate on the 1's in the data stream. When we refer to the kth 1, we mean the kth most recent 1 encountered in the data stream.

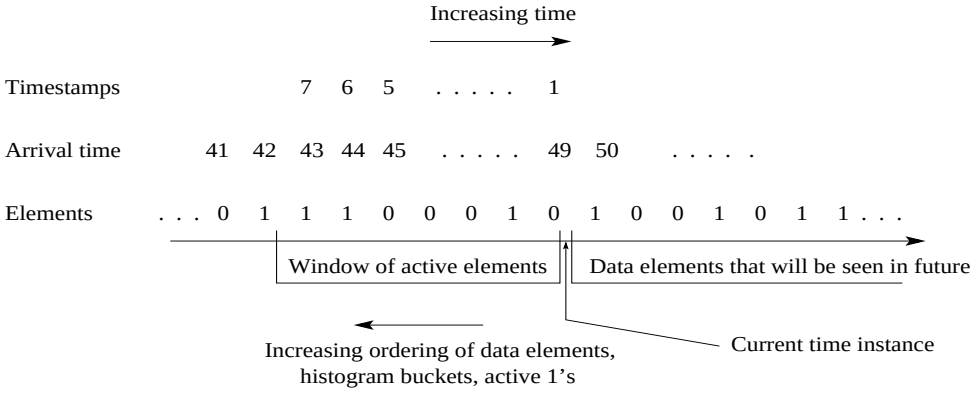

Fig. 1. *An illustration for the notation and conventions followed.*

For an illustration of this notation, consider the situation presented in Figure 1. The current time instant is 49, and the most recent arrival is a zero. The element with arrival time 48 is the most recent 1 and has timestamp 2 since it is the second most recent arrival in the current window. The element with arrival time 44 is the second most recent 1 and has timestamp 6.

We will maintain histograms for the active 1's in the data stream. For every bucket in the histogram, we keep the timestamp of the most recent 1 (called *timestamp*), and the number of 1's (called *bucket size*). For example, in our figure, a bucket with timestamp 2 and size 2 represents a bucket that contains the two most recent 1's with timestamps 2 and 6. Note that the timestamp of a bucket increases as new elements arrive. When the timestamp of a bucket expires (reaches $N + 1$), we are no longer interested in data elements contained in it, so we drop that bucket and reclaim its memory. If a bucket is still active, we are guaranteed that it contains at least a single

1 that has not expired. Thus, at any instant, there is at most one bucket (the last bucket) containing 1's which may have expired. At any time instant, we may produce an estimate of the number of active 1's as follows. For all but the last bucket, we add the number of 1's that are in them. For the last bucket, let C be the count of the number of 1's in that bucket. The actual number of active 1's in this bucket could be anywhere between 1 and C, and so we estimate it to be $C/2$. We obtain the following fact.

FACT 1. *The absolute error in our estimate is at most $C/2$, where C is the size of the last bucket.*

Note that, for this approach, the window size does not have to be fixed a priori at N. Given a window size S, we do the same thing as before except that the last bucket is the bucket with the largest timestamp less than S.

2.1. The approximation scheme. We now define the EHs and present a technique to maintain them so as to guarantee count estimates with relative error at most ϵ for any $\epsilon > 0$. Define $k = \lceil \frac{1}{\epsilon} \rceil$, and assume that $\frac{k}{2}$ is an integer; if $\frac{k}{2}$ is not an integer, we can replace $\frac{k}{2}$ by $\lceil \frac{k}{2} \rceil$ without affecting the basic results.

As per Fact 1, the absolute error in the estimate is $C/2$, where C is the size of the last bucket. Let the buckets be numbered from right to left with the most recent bucket being numbered 1. If C_i is the size of the ith bucket, we know that the true count is at least $1 + \sum_{i=1}^{m-1} C_i$ since the last bucket contains at least one 1, and the remaining buckets contribute exactly their size to the total count. Note that m is the index of the last bucket. Thus the relative estimation error is at most $(C_m/2)/(1 + \sum_{i=1}^{m-1} C_i)$. We will ensure that the relative error is at most $1/k$ by maintaining the following invariant.

INVARIANT 1. *At all times, the bucket sizes $C_1, \ldots, C_m$ are such that, for all $j \leq m$, we have $C_j/2(1 + \sum_{i=1}^{j-1} C_i) \leq \frac{1}{k}$.*

Let $N' \leq N$ be the number of 1's that are active at any instant. Then the bucket sizes must satisfy $\sum_{i=1}^{m} C_i \geq N'$. In order to satisfy this and Invariant 1 with as few buckets as possible, we maintain buckets with exponentially increasing sizes so as to satisfy the following second invariant.

INVARIANT 2. *At all times, the bucket sizes are nondecreasing, i.e., $C_1 \leq C_2 \leq \cdots \leq C_{m-1} \leq C_m$. Further, the bucket sizes are constrained to the following: $\{1, 2, 4, \ldots, 2^{m'}\}$ for some $m' \leq m$ and $m' \leq \log \frac{2N}{k} + 1$. For every bucket size other than the size of the last bucket, there are at most $\frac{k}{2} + 1$ and at least $\frac{k}{2}$ buckets of that size.*

Let $C_j = 2^r$ be the size of the jth bucket. If Invariant 2 is satisfied, then we are guaranteed that there are at least $\frac{k}{2}$ buckets, each of sizes $1, 2, 4, \ldots, 2^{r-1}$, which have indexes less than j. Consequently, $C_j \leq \frac{2}{k}(1 + \sum_{i=1}^{j-1} C_i)$. It follows that, if Invariant 2 is satisfied, then Invariant 1 is automatically satisfied. If we maintain Invariant 2, it is easy to see that, to cover all the active 1's, we would require no more than $m \leq (\frac{k}{2} + 1)(\log(\frac{2N}{k} + 1) + 1)$ buckets. Associated with the bucket is its size and a timestamp. The bucket size takes at most $\log N$ values, and hence we can maintain them using $\log \log N$ bits. Since a timestamp requires $\log N$ bits, the total memory requirement of each bucket is $\log N + \log \log N$ bits. Therefore, the total memory requirement (in bits) for an EH is $O(\frac{1}{\epsilon} \log^2 N)$. It is implied that, by maintaining Invariant 2, we are guaranteed the desired relative error and memory bounds.

The query time for the EH is $O(1)$. We achieve this by maintaining two counters: one for the size of the last bucket (LAST) and one for the sum of the sizes of all buckets (TOTAL). The estimate itself is TOTAL minus half of LAST. Both counters can be

updated in $O(1)$ time for every data element. The following is a detailed description of the update algorithm.

ALGORITHM INSERT.

1. When a new data element arrives, calculate the new expiry time. If the timestamp of the last bucket indicates expiry, delete that bucket, and update the counter LAST containing the size of the last bucket and the counter TOTAL containing the total size of the buckets.
2. If the new data element is 0, ignore it; otherwise, create a new bucket with size 1 and the current timestamp, and increment the counter TOTAL.
3. Traverse the list of buckets in order of increasing sizes. If there are $\frac{k}{2}+2$ buckets of the same size, merge the oldest two of these buckets into a single bucket of double the size. (A merger of buckets of size 2^r may cause the number of buckets of size 2^{r+1} to exceed $\frac{k}{2}+1$, leading to a cascade of such mergers.) Update the counter LAST if the last bucket is the result of a new merger.

Example 1. We illustrate the execution of the algorithm for 10 steps, where, at each step, the new data element is 1. The numbers indicate the bucket sizes from left to right, and we assume that $\frac{k}{2}=1$.

32, 32, 16, 8, 8, 4, 2, 1
32, 32, 16, 8, 8, 4, 4, 2, 1, 1 (new 1 arrived)
32, 32, 16, 8, 8, 4, 4, 2, 1, 1, 1 (new 1 arrived)
32, 32, 16, 8, 8, 4, 4, 2, 2, 1 (merged the older 1's)
32, 32, 16, 8, 8, 4, 4, 2, 2, 1, 1 (new 1 arrived)
32, 32, 16, 8, 8, 4, 4, 2, 2, 1, 1, 1 (new 1 arrived)
32, 32, 16, 8, 8, 4, 4, 2, 2, 2, 1 (merged the older 1's)
32, 32, 16, 8, 8, 4, 4, 4, 2, 1 (merged the older 2's)
32, 32, 16, 8, 8, 8, 4, 2, 1 (merged the older 4's)
32, 32, 16, 16, 8, 4, 2, 1 (merged the older 8's)

Merging two buckets corresponds to creating a new bucket whose size is equal to the sum of the sizes of the two buckets and whose timestamp is the timestamp of the more recent of the two buckets, i.e., the timestamp of the bucket that is to the right. A merger requires $O(1)$ time. Moreover, while cascading may require $\Theta(\log \frac{2N}{k})$ mergers upon the arrival of a single new element, standard arguments allow us to argue that the amortized cost of mergers is $O(1)$ per new data element. It is easy to see that the above algorithm maintains Invariant 2. We obtain the following theorem.

THEOREM 1. *The EH algorithm maintains a data structure which can give an estimate for the* BASICCOUNTING *problem with relative error at most ϵ using at most $(\frac{k}{2}+1)(\log(\frac{2N}{k}+1)+1)$ buckets, where $k=\lceil\frac{1}{\epsilon}\rceil$. The memory requirement is $\log N+\log\log N$ bits per bucket. The arrival of each new element can be processed in $O(1)$ amortized time and $O(\log N)$ worst-case time. At each time instant, the data structure provides a count estimate in $O(1)$ time.*

If, instead of maintaining a timestamp for every bucket, we maintain a timestamp for the most recent bucket and maintain the difference between the timestamps for the successive buckets, then we can reduce the total memory requirement to $O(k\log^2\frac{N}{k})$.

3. Lower bounds. We provide a lower bound which verifies that the EH algorithm is optimal in its memory requirement. We start with a deterministic lower bound of $\Omega(k\log^2\frac{N}{k})$.

THEOREM 2. *Any deterministic algorithm that provides an estimate for the* BASICCOUNTING *problem at every time instant with relative error less than $\frac{1}{k}$ for*

some integer $k \leq 4\sqrt{N}$ *requires at least* $\frac{k}{16}\log^2\frac{N}{k}$ *bits of memory.*

The proof argument will go as follows: We will show that there are a large number of arrangements of 0's and 1's such that any deterministic algorithm which provides estimates with small relative error has to differentiate between every pair of these arrangements. The number of memory bits required by such an algorithm must therefore exceed the logarithm of the number of arrangements. The above argument is formalized by the following lemma.

LEMMA 1. *For* $k/4 \leq B \leq N$, *there exist* $L = \binom{B}{k/4}^{\lfloor \log \frac{N}{B} \rfloor}$ *arrangements of* 0*'s and* 1*'s of length* N *such that any deterministic algorithm for* BASICCOUNTING *with relative error less than* $\frac{1}{k}$ *must differentiate between any two of the arrangements.*

Proof. We partition a window of size N into blocks of size $B, 2B, 4B, \ldots, 2^jB$, from right to left, for $j = \lfloor \log \frac{N}{B} \rfloor - 1$. Consider the ith block of size 2^iB, and subdivide it into B contiguous subblocks of size 2^i. For each block, we choose $\frac{k}{4}$ subblocks and populate them with 1's, placing 0's in the remaining positions. In every block, there are $\binom{B}{k/4}$ possible ways to place the 1's, and therefore the total number of distinct arrangements is $L = \binom{B}{k/4}^{\lfloor \log N/B \rfloor}$.

We now argue that any deterministic algorithm for BASICCOUNTING with relative error less than $\frac{1}{k}$ must differentiate between any pair of these arrangements. In other words, if there exists a pair of arrangements A_x, A_y such that a deterministic algorithm does not differentiate between them, then, after some time interval, the two arrangements will have different answers to the BASICCOUNTING problem, and the algorithm will give a relative error of at least $\frac{1}{k}$ for one of them. To this end, we will assume that the algorithm is presented with one of these L arrangements of length N, followed by a sequence of all 0's of length N.

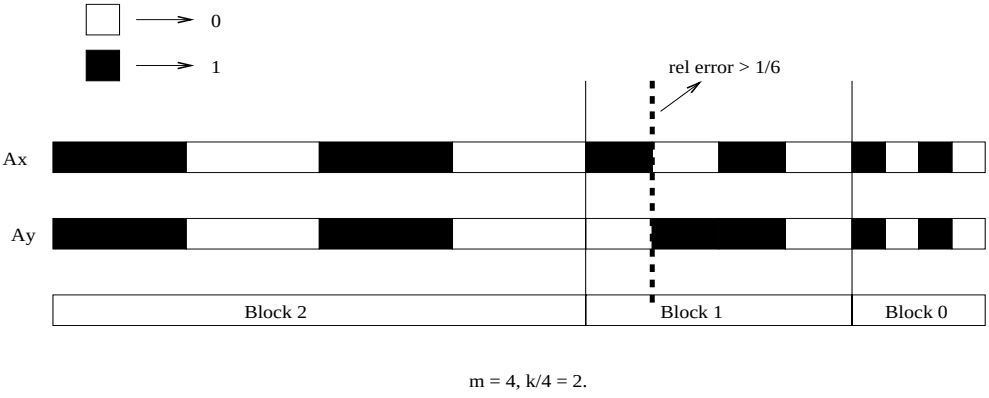

FIG. 2. *A pair of arrangements that should be differentiated by any deterministic algorithm with relative error less than* 1/8.

Refer to Figure 2 for an illustration of a pair of arrangements that should be differentiated by any deterministic algorithm with relative error less than $\frac{1}{8}$.

Consider an algorithm that does not differentiate between two of the above arrangements A_x and A_y. We will use the numerical sequences $x_0, x_1, \ldots, x_j$ and $y_0, y_1, \ldots, y_j$ for $j = \lfloor \log \frac{N}{B} \rfloor - 1$ to encode the two arrangements. The ith number in the sequence specifies the choice of the $k/4$ subblocks from the ith block which are populated with 1's. The two sequences must be distinct since the two arrangements

being encoded are distinct. Let d be an index of a point where the two sequences differ, i.e., $x_d \neq y_d$. Then the two arrangements have a different choice of $k/4$ subblocks in the dth block. Number the subblocks within block d from right to left, and let h be the highest numbered subblock that is chosen for one of the arrangements (say, A_x) but not for the other (A_y). Consider the time instant when this subblock h expires. At that instant, the number of active subblocks in block d for arrangement A_x is c, where $c+1 \leq k/4$, while the number of active subblocks in block d for A_y is $c+1$. Since the arrangements are followed by a sequence of 0's, at this time, the correct answer for A_x is $c2^d + \frac{k}{4}(2^d - 1)$, while, for A_y, the correct answer is $(c+1)2^d + \frac{k}{4}(2^d - 1)$. Thus the algorithm will give an absolute error of at least 2^{d-1} for one of the arrangements, which translates to a relative error of $\frac{1}{k}$ at that point in time. □

To prove Theorem 2, observe that, if we choose $B = \sqrt{Nk}$, then $\log L \geq \frac{k}{16} \log^2 \frac{N}{k}$. We also extend the lower bound on the space complexity to randomized algorithms.

As a reminder, a *Las Vegas algorithm* is a randomized algorithm that always produces the correct answer, although the running time of the algorithm may vary with the different random choices that the algorithm makes. On the other hand, a *Monte Carlo algorithm* is a randomized algorithm that sometimes produces an incorrect solution. We obtain the following lower bounds for these two classes of algorithms.

THEOREM 3. *Any randomized Las Vegas algorithm for* BASICCOUNTING *with relative error less than* $\frac{1}{k}$ *for some integer* $k \leq 4\sqrt{N}$ *requires at least* $\frac{k}{16} \log^2 \frac{N}{k}$ *bits of memory.*

Proof. Define an algorithm A to be ϵ-correct for an input instance I if the value returned by A on input I has relative error less than ϵ. The Yao minimax principle [15] implies that the expected space complexity of the optimal ϵ-correct deterministic algorithm for an arbitrarily chosen input distribution $\mathbf{p}$ is a lower bound on the expected space complexity of the optimal ϵ-correct Las Vegas randomized algorithm. Consider the uniform distribution over the input arrangements in Lemma 1. Then any deterministic algorithm that is ϵ-correct for all of these instances must differentiate between any two distinct arrangements. As a result, the expected space complexity of an optimal deterministic algorithm on this distribution is at least equal to the optimal coding length for the probability distribution. Since the coding length is at least equal to the entropy of the distribution, we get the same lower bound (logarithm of the number of instances) as in the case of a deterministic algorithm. This proves the generalization of Theorem 2 to Las Vegas randomized algorithms. □

THEOREM 4. *Any randomized Monte Carlo algorithm for* BASICCOUNTING *with relative error less than* $\frac{1}{k}$ *for some integer* $k \leq 4\sqrt{N}$ *with probability at least* $1 - \delta$ *(for* $\delta < \frac{1}{2}$*) requires at least* $\frac{k}{64} \log^2 \frac{N}{k} - \log(1 - \delta)$ *bits of memory.*

Proof. We use the analogous version of Yao's minimax principle for Monte Carlo randomized algorithms [15] to establish the lower bound for Monte Carlo algorithms. Consider a deterministic algorithm that is ϵ-correct with probability at least $1 - \delta$ for some $\delta < \frac{1}{2}$. As before, the input distribution $\mathbf{p}$ that we consider is the uniform distribution over all of the arrangements defined in Lemma 1. Since the deterministic algorithm is ϵ-correct with probability at least $1 - \delta$, it is ϵ-correct for at least a $1 - \delta$ fraction of the inputs. Thus, by arguments similar to those in the previous theorem, we get the same lower bound except for an additive loss of $\log(1 - \delta)$ and a multiplicative loss of $\frac{1}{4}$. Asymptotically, the lower bound does not change. □

4. Beyond 0's and 1's. Consider now the extension of BASICCOUNTING to the case where the elements are positive integers.

PROBLEM 2 (SUM). *Given a stream of data elements that are positive integers in the range* $[0 \ldots R]$*, maintain at every time instant the sum of the last* N *elements.*

One obvious way to solve the above problem would be to separately maintain a sliding window sum for each of the $\log R$ bit positions using an EH from section 2. As before, let $k = \lceil \frac{1}{\epsilon} \rceil$. The memory requirement for this approach would be $O(k \log^2 N \log R)$ bits. Next, we present a technique that has a smaller space requirement.

We assume that $\log R = o(N)$. This is a realistic assumption which simplifies our calculations. We generalize the EH to this setting as follows. View the arrival of a data element of value v as the arrival of v data elements with value 1 all at the same time, and employ the same insertion procedure as before. Note that the algorithm in section 2 does not require distinct timestamps; they are required only to be nondecreasing. While earlier there could be at most N active 1's, now there could be as many as NR. The results in section 2 imply that the EH will require at most $(\frac{k}{2} + 1)(\log(\frac{2NR}{k} + 1) + 1)$ buckets. Now each bucket will require $\log N + \log(\log N + \log R)$ bits of memory to store the timestamp and the size of the bucket. Note that there are N distinct timestamps at any point (as before) but that the bucket sizes could take on $\log N + \log R$ distinct values. Thus the number of memory bits required is

$$\left(\frac{k}{2} + 1\right)\left(\log\left(\frac{2NR}{k} + 1\right) + 1\right)(\log N + \log(\log N + \log R)) = O\left(\frac{1}{\epsilon}(\log N + \log R)(\log N)\right).$$

The only catch appears to be that we need $\Omega(R)$ time per insertion. The rest of the section is devoted to devising a scheme that requires only $O(\frac{\log R}{\log N})$ amortized time and $O(\log N + \log R)$ worst-case time per insertion. Note that, if $R = O(poly(N))$, then the amortized insertion time becomes $O(1)$, and the worst-case time becomes $O(\log N)$.

Let S be the total size of the buckets at some time instant. For $j \leq \log(\frac{2NR}{k} + 1)$, let $k_0, k_1, \ldots, k_j$ be a sequence in which k_i denotes the number of buckets of size 2^i. Then $S = \sum_{i=0}^{j} k_i 2^i$. By Invariant 2, we have $l \leq k_i \leq l+1$ for $i < j$ and $1 \leq k_j \leq l+1$, where $l = \frac{k}{2} = \frac{\lceil \frac{1}{\epsilon} \rceil}{2} \geq 1$. Given $l \geq 1$ and S, a sequence $k_0, k_1, \ldots, k_j$ satisfying the above conditions is called an l-canonical representation of S. The algorithm represents every valid sum in its l-canonical form. We claim that the l-canonical representation of any sum S is unique and can be computed in time $O(\log S)$.

LEMMA 2. *The* l*-canonical representation of any positive number* S *is unique.*

Proof. We give a proof by contradiction. Assume that $\mathbf{k} = (k_0, k_1, \ldots, k_j)$ and $\mathbf{k}' = (k'_0, k'_1, \ldots, k'_{j'})$ are two distinct l-canonical representations of S. Without loss of generality, assume that $j \leq j'$. Let d be the smallest index where the sequences differ. We have $d \leq j$ since it cannot happen that they agree on all of the indices less than or equal to j and the second sequence has nonzero components for indices greater than j, given that they have the same sum.

Case 1 ($d < j$). Since $l \leq k_d, k'_d \leq l + 1$, we have $|\sum_{i=0}^{d} k_i 2^i - \sum_{i=0}^{d} k'_i 2^i| = 2^d$. However, $|\sum_{i=d+1}^{j} k_i 2^i - \sum_{i=d+1}^{j'} k'_i 2^i| = c2^{d+1}$ for some integer $c \geq 0$, which is a contradiction since $|\sum_{i=0}^{j} k_i 2^i - \sum_{i=0}^{j'} k'_i 2^i| = 0$.

Case 2 ($d = j$). The sequence $\mathbf{k}'$ must have nonzero indices greater than j; otherwise, the two representations cannot give the same sum. Moreover, it cannot

happen that $k_j \leq k'_j$ since otherwise $\mathbf{k}'$ will have a strictly greater sum. Thus $k_j > k'_j$, and $k_j \leq l+1$. Since k'_j is not the last index, we have $k'_j \geq l$. Therefore, $|k'_j - k_j| \leq 1$, which implies $|\sum_{i=0}^{j} k_i 2^i - \sum_{i=0}^{j} k'_i 2^i| \leq 2^j$. However, $\sum_{i \geq j+1} 2^i \geq k'_i 2^{j+1}$, which gives a contradiction. □

The following procedure computes the l-canonical representation of S in time $O(\log S)$.

PROCEDURE l-CANONICAL. Given S, find the largest j such that $2^j \leq \frac{S}{l} + 1$, and let $S' = S - (2^j - 1)l$. If $S' \geq 2^j$, find m such that $m2^j \leq S' < (m+1)2^j$, and set $k_j = m$; we are guaranteed that $m < l$. Let $\widehat{S} = S' - m2^j < 2^j$. Let $b_0, \ldots, b_{j-1}$ be the binary representation of $\widehat{S}$. Set $k_i = l + b_i$ for $i < j$.

Given S and l, the l-canonical representation of S tells us the exact positions of all of the 1's where the buckets will start. Note that, since multiple 1's "belong" to the same data element, we may have multiple buckets starting at a single data element, implying that multiple buckets could have the same timestamp. The following observation is critical to the incremental maintenance of the buckets. The algorithm in section 2 guarantees that, if a certain data element (which in that case was some active 1) is not "indexed" at a certain time interval, then it will never be "indexed" in the future. By "indexed" we mean that it is the first element of some bucket, and hence its timestamp is maintained as the timestamp of that bucket. As time progresses, buckets may get merged, and some data elements may not be indexed any more. However, it never happens that an element that was not indexed at some time gets indexed later.

The preceding observation allows us to devise the following scheme to incrementally maintain the buckets with small amortized update time. Let us assume that we know the buckets at a certain time instant. We think of each data element as a series of 1's. We buffer B new elements separately and maintain the sum for these elements; that is, the EH is not updated for B steps. During this period, any query can be answered using a combination of the EH and the buffer sum. When the buffer gets full, we first delete any expired buckets in the EH. After the expired buckets are deleted, let S_1 be the sum of the sizes of the active buckets. Let S_2 be the sum of the elements in the buffer. We calculate the l-canonical ($l = \frac{k}{2}$) representation of $S_1 + S_2$ to determine the positions of the new buckets. This requires $O(\log(S_1 + S_2)) = O(\log N + \log R)$ time since $S_1 + S_2 = O(NR)$. We then create the new buckets using the timestamps and values of the elements in the buffer and the timestamps and sizes of the old buckets. The total time required to process the B elements in buffer is $O(B + \log N + \log R)$ since $O(B)$ time suffices to maintain the buffer sum and the number of buckets in the new histogram is $O(\log N + \log R)$. Since the time required to construct the new histogram is $O(\log N + \log R + B)$, the amortized update time per element is $O(1 + \frac{\log N + \log R}{B})$. Choosing $B = \Theta(\log N)$ makes the amortized update time $O(\frac{\log R}{\log N})$ and the worst-case time $O(\log N + \log R)$. The buffer needs $O(\log N(\log N + \log R))$ memory bits, which is the same as the memory requirement of the EH. Note that, if R is *poly*(N), then the amortized update time is $O(1)$ and the worst-case time is $O(\log N)$. We have obtained a memory upper bound of $O(\frac{1}{\epsilon}(\log N + \log R)(\log N))$ bits, as summarized in the following theorem.

THEOREM 5. *The generalized EH for the* SUM *problem maintains a data structure which provides estimates with relative error at most* ϵ *using at most* $(\frac{k}{2}+1)(\log(\frac{2NR}{k}+1)+1)$ *buckets, where* $k = \lceil \frac{1}{\epsilon} \rceil$. *The memory requirement is* $\log N + \log(\log N + \log R)$ *bits per bucket. The arrival of each new element can be processed in* $O(\frac{\log R}{\log N})$ *amortized*

time and $O(\log N + \log R)$ *worst-case time. At each time instant, the data structure provides a sum estimate in* $O(1)$ *time.*

We now prove a lower bound of $\Omega(\frac{1}{\epsilon}(\log N + \log R)(\log N))$ bits. If $\log N = \Omega(\log R)$, then the lower bound from section 3 applies. Thus we need only to consider the case when $R > N$. We will assume that $\log R \leq \frac{N}{k}$; in fact, we assume $\log R = o(N)$. Consider the following arrangements. We break the window of size N into $\log R$ blocks, each of size $\lfloor \frac{N}{\log R} \rfloor$. Consider the ith block for $0 \leq i < \log R$. We choose $k/4$ of the $\lfloor \frac{N}{\log R} \rfloor$ positions and place an element with value 2^i there, setting all other elements to 0. By an argument similar to the one in section 3, any deterministic algorithm with relative error less than $\frac{1}{k}$ must differentiate between any two of these arrangements. The total number of these arrangements is $\binom{N/\log R}{k/4}^{\log R} \geq (\frac{4N}{k \log R})^{\frac{k}{4} \log R}$. The number of memory bits required is at least $\frac{k}{4} \log R \log(\frac{4N}{k \log R}) = \Omega(\frac{1}{\epsilon}(\log N + \log R)(\log N))$. We assume that $R > N$ and that $\log R = O(N^\delta)$ for some $\delta < 1$. Note that the lower bounds also apply for randomized algorithms that provide an approximate answer.

5. Timestamps. In our model (given in section 2), we have assumed that data items arrive at regular time intervals and arrival time increases by one with every new data item that we have seen. However, in most real-life applications, this is not the case, and arrival rates of data items may be bursty. Moreover, we would like to define the sliding window based on real time. In other words, we may want to compute statistics based on the data items that arrived over the last hour, day, etc. It is easy to see that our algorithm can be easily adapted to do this by defining the arrival time based on *real time*; i.e., the arrival time increases by one with every clock-tick.[1] We define N (size of the sliding window) as the number of clock-ticks in the interval over which we want our sliding window to work. For example, N is 3600 if we want statistics based on the last hour, and clock-ticks occur every second. Note that the algorithm does no work except when it sees a data item, and hence it need not do anything during the clock-ticks for which no data items arrive. The invariants are automatically maintained during this period, and the algorithm never uses any extra space during this time. Hence it need not bother to delete the expired buckets until a new data item arrives since its memory requirement does not change. The memory requirement of the algorithm is $O(\frac{1}{\epsilon}(\log N)(\log N + \log R))$, where the second term $(\log N + \log R)$ is the logarithm of the maximum sum (NR) that can occur over N clock-ticks. Thus, if we are guaranteed that much less than N data items arrive over any sliding window, then the memory requirement would be less. This may happen for bursty arrival rates. In other words, our algorithm adapts its memory requirements with the amount of data that we observe.

5.1. Approximate timestamps. The EHs developed in section 2 and section 4 have a memory requirement of $O(\log N)$ for every bucket of the histogram. The timestamp that we maintain with each bucket requires $\log N$ bits and dominates the memory requirement of every bucket. We now explore the idea of maintaining a coarser timestamp with every bucket which requires only $\log \log N$ bits of memory and reduces the memory requirement for the EH from $O(\frac{1}{\epsilon}(\log^2 N))$ to $O(\frac{1}{\epsilon}(\log N)(\log \log N))$. In the case of generalized EH, the memory requirement drops to $O(\frac{1}{\epsilon}(\log N + \log R)(\log(\log N + \log R)))$. The effect of maintaining a coarser

[1] Equal length intervals, into which we partition time, that are assumed small enough so that no two data items are observed within a single interval.

timestamp is that, instead of answering the query over the last N data elements (sliding window size), we may answer the query over the last N/c elements, where $1 \leq c \leq 2$. In other words, we are approximating the window size to within a factor of 2. Note that this does not contradict the lower bound presented before. We no longer guarantee that the answer that we provide has relative error at most ϵ as compared to the correct answer over the last N elements. Instead, we guarantee that the answer will have error at most ϵ as compared to the correct answer over the last N/c data elements, where $1 \leq c \leq 2$. The factor 2 can be further improved to $1+\tau$ for $0 < \tau \leq 1$, and the memory requirement for the timestamp is $\log\log N + \log(\frac{1}{\tau})$. The generalization is obvious, and we explain the idea below for a factor 2 approximation.

We will explain the idea in terms of timestamps. However, as mentioned in section 2, we do not explicitly maintain the timestamp for every bucket and instead maintain the arrival time of the most recent (rightmost) element and calculate the timestamp using the arrival time of the current element. The idea translates to maintaining coarser arrival times. In sections 2 and 4, we maintained the exact timestamp with every bucket. Instead, here we maintain the timestamp to the closest power of 2. Thus, if the timestamp is t, where $2^{l-1} < t \leq 2^l$ $(1 \leq l \leq \lceil \log N \rceil)$, we maintain the timestamp as 2^l. In other words, we approximate the timestamp to the closest power of 2 greater than the timestamp. Since the timestamps now take $\log N$ distinct values, they can be stored using $\log\log N$ bits. The effect of this approximation is as follows: At any time instance, a bucket is active iff its timestamp is less than N. Any bucket whose exact timestamp is less than $N/2$ will still be considered active since the timestamp will be approximated to a value less than $N/2$. On the other hand, buckets whose timestamps are greater than $N/2$ may be wrongly considered inactive and hence deleted as their timestamp will be approximated to a value no less than N. Thus, in the worst case, we are answering the query over the last $N/2$ elements instead of N. If, instead, we approximate the timestamp to the closest power of 2 *less* than the exact timestamp, we get that we will be answering the query over the last cN elements, where $1 \leq c \leq 2$.

6. Computing L_p norms for vectors. We now extend the EH technique and combine it with the sketching technique from Indyk [13] to compute the L_p norms of vectors in the sliding window model. Assume that the window is broken into smaller contiguous buckets. These are numbered right to left and are denoted by $B_1, B_2, \ldots, B_m$. Consider a function f, defined over the intervals, with the following properties:

- P1. $f(B_i) \geq 0$.
- P2. $f(B_i) \leq poly(|B_i|)$.
- P3. $f(B_1 + B_2) \geq f(B_1) + f(B_2)$, where $B_1 + B_2$ denotes the concatenation of adjacent buckets B_1 and B_2.
- P4. $f(B_1 + B_2) \leq C_f(f(B_1) + f(B_2))$, where $C_f \geq 1$ is a constant.
- P5. The function $f(B)$ admits a "sketch" which requires $g_f(|B|)$ space and is composable; i.e., the sketch for $f(B_1 + B_2)$ can be composed efficiently from the sketches for $f(B_1)$ and $f(B_2)$.

If the function f admits these properties, then we can efficiently estimate it for sliding windows using the EH technique. We maintain buckets with the following two invariants; we also associate with every bucket a timestamp and the sketch. For now, we assume that the sketches provide the exact value of the function f. We will shortly relax this requirement and show that our technique works even if the sketches provide only an approximation to the actual function value.

INVARIANT 3. $f(B_{n+1}) \leq \frac{C_f}{k} \sum_{i=1}^{n} f(B_i)$.

INVARIANT 4. $f(B_{n+2}) + f(B_{n+1}) > \frac{1}{k} \sum_{i=1}^{n} f(B_i)$.

Observation 1. We estimate the function f for the current window by composing the sketches of all but the earliest (leftmost) bucket. The leftmost bucket may have certain expired data elements along with a suffix of data elements which are active. Let B_x be the part (suffix) of the leftmost bucket that is active and was ignored (i.e., did not contribute to the estimate). Let B_y be the concatenation of all of the other buckets whose sketch we compose using the sketches of the individual buckets. Then $B_x + B_y$ is the current window, and the exact answer is $f(B_x + B_y)$. However, we estimate the answer as $f(B_y)$; thus we always underestimate. The relative error $\boldsymbol{E_r}$ is $\frac{f(B_x+B_y)-f(B_y)}{f(B_x+B_y)} > 0$ by P1 and P3. Also, we have

$$\begin{aligned}
\boldsymbol{E_r} &\leq \frac{f(B_x + B_y) - f(B_y)}{f(B_y)} && \text{(P1, P3)} \\
&\leq \frac{C_f(f(B_x) + f(B_y)) - f(B_y)}{f(B_y)} && \text{(P4)} \\
&= \frac{C_f f(B_x)}{f(B_y)} + C_f - 1 \\
&\leq \frac{C_f f(B_{n+1})}{\sum_{i=1}^{n} f(B_i)} + C_f - 1 && \text{(P1, P3)} \\
&\leq \frac{C_f^2}{k} + C_f - 1 && \text{(Invariant 3).}
\end{aligned}$$

Observation 2. Invariant 4 and property P2 imply that the number of buckets will be $O(k \log N)$, where N is the size of the window. Thus the memory required to maintain the timestamp and the sketches for all of the buckets will be $O(k \log N(\log N + g_f(N)))$.

Hence, if we maintain the invariants along with the timestamp and the sketches, we can estimate the function f with relative error $0 \leq \boldsymbol{E_r} \leq \frac{C_f^2}{k} + C_f - 1$ using $O(k \log N(\log N + g_f(N)))$ memory bits. We can maintain the invariants along with the timestamp and the sketches as new data elements are added. The algorithm to do this is very similar to that for the EH.

1. When a new data element arrives, calculate the new expiry time. If the timestamp of the last bucket indicates expiry, delete that bucket.
2. Create a new bucket with just the new data element.
3. Traverse the list of buckets from right to left. If Invariant 4 is violated for a pair of buckets (B_{n+1}, B_{n+2}), merge them into a new bucket B'_{n+1}. The sketch for this bucket is composed from the sketches for B_{n+1} and B_{n+2}. We may need to do more than one merge.

We argue that the algorithm maintains Invariants 3 and 4. Adding a new bucket does not violate Invariant 3, as we increase only the size of the suffix. Whenever Invariant 4 is violated, the two buckets involved satisfy $f(B_{n+2}) + f(B_{n+1}) \leq \frac{1}{k} \sum_{i=1}^{n} f(B_i)$. When we merge them, property P4 guarantees that $f(B'_{n+1}) \leq C_f(f(B_{n+2}) + f(B_{n+1})) \leq \frac{C_f}{k} \sum_{i=1}^{n} f(B_i)$, and hence Invariant 3 is valid for the new bucket B'_{n+1}. The algorithm may need to do a lot of merges—as many as the number of buckets (i.e., $O(k \log N)$). However, the amortized time is $O(1)$. We omit details dealing with the fact that the function f for a window of size 1 may be greater than 1 although bounded by some constant R.

THEOREM 6. *A function f with properties* P1–P5 *can be estimated over sliding windows with relative error* $0 \leq \boldsymbol{E_r} \leq \frac{C_f^2}{k} + C_f - 1$ *using* $O(k \log N(\log N + g_f(N)))$ *bits of memory.*

So far we have assumed that the sketches compute the function value f exactly. Instead, in most sketching techniques, the sketches provide a $1+\hat{\epsilon}$ approximation $s(B)$ of the actual function value $f(B)$, i.e., $(1-\hat{\epsilon})f(B) \leq s(B) \leq (1+\hat{\epsilon})f(B)$. In that case, we maintain buckets with Invariants 3 and 4, replacing f with s. Invariant 4, property P2, and the fact that $s(B) \leq (1+\hat{\epsilon})f(B)$ guarantee that the number of buckets will be $O(k \log N)$ as before. We will now analyze the effect of approximation due to sketches on the error.

Maintaining the invariant $s(B_{n+1}) \leq \frac{C_f}{k} \sum_{i=1}^{n} s(B_i)$ guarantees that $f(B_{n+1}) \leq (1+\hat{\epsilon})^2 \frac{C_f}{k} \sum_{i=1}^{n} f(B_i)$. We will use the same technique (please refer to Observation 1) to estimate the function f using sketch estimates s instead of f. Thus, instead of providing the exact answer $f(B_x + B_y)$, we provide the estimate as $s(B_y)$. The relative error $\boldsymbol{E_r}$ is $\frac{f(B_x+B_y)-s(B_y)}{f(B_x+B_y)}$. We have

$$\begin{aligned}
\boldsymbol{E_r} &= \frac{f(B_x + B_y) - s(B_y)}{f(B_x + B_y)} \\
&\leq \frac{f(B_x + B_y) - f(B_y) + f(B_y) - s(B_y)}{f(B_y)} && \text{(P1, P3)} \\
&\leq \frac{f(B_x + B_y) - f(B_y)}{f(B_y)} + \frac{f(B_y) - s(B_y)}{f(B_y)} \\
&\leq \frac{C_f f(B_{n+1})}{\sum_{i=1}^{n} f(B_i)} + C_f - 1 + \hat{\epsilon} && \text{(proved earlier)} \\
&\leq (1+\hat{\epsilon})^2 \frac{C_f^2}{k} + C_f - 1 + \hat{\epsilon}.
\end{aligned}$$

This gives the following theorem.

THEOREM 7. *A function f with properties* P1–P5 *can be estimated over sliding windows with relative error* $0 \leq \boldsymbol{E_r} \leq (1+\hat{\epsilon})^2 \frac{C_f^2}{k} + C_f - 1 + \hat{\epsilon}$ *using* $O(k \log N(\log N + g_f(N)))$ *bits of memory, where $\hat{\epsilon}$ is the bound on relative error of the sketches.*

If $\hat{\epsilon}$ can be made arbitrarily close to 0, keeping the space requirement for the sketches (i.e., $g_f(|B|)$) small, we can get the same error as in the previous theorem by increasing k by a small constant factor.

6.1. L_p norms. We now argue that L_p norms (for $p \in [1,2]$) of vectors under a restricted model admit the properties P1–P5 and hence can be efficiently computed for sliding windows. Consider the restricted model [13] in which the jth data element is a pair (i_j, a_j), where $i_j \in [d] = \{0 \ldots d-1\}$ and $a_j \in \{0 \ldots M\}$ represents an increment to the i_jth dimension of an underlying vector. Every window B represents a vector, and its $L_p(B)$ norm is given by $L_p(B) = (\sum_{i \in [d]} |s_i|^p)^{1/p}$, where $s_i = \sum_{i_j = i, j \in B} a_j$ is the sum of unexpired increments to the ith dimension.

Note that the case in which $p = 1$ is the same as the SUM problem. If the dimension d of the underlying vector is small, one obvious way to maintain the L_p norm is to maintain the approximate sum for each dimension using the techniques in section 4. It would require $O(\frac{1}{\epsilon}(\log N + \log M)(\log N)d)$ bits of memory and give a relative error of ϵ. However, for high dimensional vectors, we propose the use of sketches. We denote $(L_p(B))^p$ by f_p and estimate f_p for $p \in [1,2]$. The function f_p clearly admits properties P1–P4, assuming $M \leq N^{O(1)}$. For P5, $f_p(B)$ admits a sketching technique

which requires $O(\log M \log(1/\delta)/\hat{\epsilon}^2)$ memory bits per sketch and is composable. The technique also requires $O(\log M \log(d/\delta) \log(1/\delta)/\hat{\epsilon}^2)$ random bits, which are common to all sketches. (See Theorem 2 in [13].) The sketches for computing the function are not exact; instead, they provide an approximation with relative error less than $\hat{\epsilon}$ with probability $1 - \delta$.

From Theorem 7, we have that, under the restricted model, we can compute f_p (i.e., $(L_p(B))^p$) with relative error at most $(1+\hat{\epsilon})^2 \frac{4}{k} + 1 + \hat{\epsilon}$ using $O(k \log N(\log N + \log M \log(1/\delta)/\epsilon^2))$ bits of memory. As mentioned before, an additional $O(\log M \log(d/\delta)$ $\log(1/\delta)/\hat{\epsilon}^2)$ bits of memory, which are common to all the sketches, are required. The estimate is approximately correct with high probability. Note that computing $(L_p(B))^p$ with a small relative error translates to computing $L_p(B)$ with a small relative error.

6.2. Lower bounds. The BasicCounting and Sum problems are the special cases of computing L_p norms, where the underlying vector has a single dimension. Thus the lower bounds for these problems apply to the problem of computing the L_p norm. Note that the upper bounds obtained in this section match the lower bounds asymptotically. The L_p norm for $p = 0$ is defined as the distinct value problem, and we deal with this problem in section 7.

7. Applications. We briefly discuss how the EH algorithm for BasicCounting can be used as a building block to adapt several techniques to the sliding window model with a multiplicative overhead of $O(\frac{1}{\epsilon} \log N)$ in memory and a $1+\epsilon$ factor loss in accuracy. The basic idea is that, to adapt to the sliding window setting a scheme relying on exact counters for positive integers, we will use an EH to play the role of a counter. A counter would have required $\Omega(\log N)$ bits of memory, while an EH requires $O(\frac{1}{\epsilon} \log^2 N)$ bits of memory and maintains the count with $1+\epsilon$ error.

7.1. Hash tables. This is the simplest case. Every data element gets hashed to a bucket, and the goal is to maintain the count of elements in each hash bucket. Instead of maintaining a counter for each bucket, we use the EH to maintain approximate counts of the number of data elements hashed into the bucket from the last N data elements in the stream.

7.2. Sums and averages. In section 4, we showed how to maintain the sum of positive integer data elements using the generalized version of the EHs. This requires $O(\frac{1}{\epsilon} \log N(\log R + \log N))$ bits of memory. Since maintaining the sum would require $\log N + \log R$ bits, the multiplicative overhead is $O(\frac{1}{\epsilon} \log N)$. Maintaining averages is similar. The average of the most recent N data elements is just the sum divided by N. If the items are inserted irregularly in real time and we want the average value to represent the sum divided by the number of insertions in the last N clock-ticks, an easy solution would be to use a second instance of the EH that maintains the count (number of insertions) approximately. Since both the sum and count have small relative error, so will their quotient.

7.3. Histograms. Given the bucket boundaries in a histogram, we can maintain the sum, average, and other statistics corresponding to each bucket using generalized EH. Finding the optimal bucket boundaries to optimize the memory requirement is an orthogonal problem. Also, equiwidth histograms are a natural choice of histograms for which the bucket boundaries are fixed. Note that, unlike the histograms discussed in [10], these are not time-based histograms but instead could be based on any attribute of the data.

7.4. Min and max. We prove a lower bound for the memory requirement of an algorithm that maintains min or max over a sliding window. While we argue the lower bound for the case of min, the argument for max is similar. The lower bound is based on a counting argument like the one used to prove the lower bound for BASICCOUNTING in Lemma 1. Let the data elements be drawn from a set of R distinct numbers. Consider all *nondecreasing* arrangements of N numbers. The number of such arrangements is $\binom{N+R-1}{N}$. Consider an algorithm that has seen one of these arrangements. We claim that any deterministic algorithm that gives the correct answer at every time instance henceforth must differentiate between any two such arrangements. To this end, we assume that we will present the algorithm with a sequence consisting of the highest number in the set, similarly to how we present the algorithm with a sequence of 0's in Lemma 1. Since the numbers presented to the algorithm were nondecreasing, at any time instance, the correct answer is the value of the oldest or least recent element which will expire in the next step. As a result, for every pair of arrangements, there will be a time when their oldest elements differ, and hence they have different correct answers. This proves our claim and establishes a lower bound on the number of memory bits required, which is $\log \binom{N+R-1}{N} \geq N \log(R/N)$. This lower bound is also valid for any randomized algorithm by arguments similar to the one in section 3. If $R = poly(N)$, then the lower bound says that we have to store all of the last N elements. The easiest way to maintain the exact minimum over sliding windows is to do the following: Keep the subsequence of data elements in which the leftmost item is the current minimum and the right neighbor or any element (in the subsequence) is the minimum of the elements to the right of the element in the stream. Such a subsequence can be maintained as a list of pairs (value, timestamp), where the list satisfies the property that both the value and the timestamp are strictly increasing. This scheme has a worst-case space requirement of $O(N \log R)$ bits. If the data elements arrive in a random order, then the list that we would maintain is analogous to the right spine of a "treap" where the timestamps are fully ordered and the values of the data elements are heap-ordered. In that case, the expected length of the list is $O(\log N)$, and the space complexity is given by $O(\log N \log R)$.

7.5. Distinct values. It is easy to adapt the technique of Flajolet and Martin [6] to estimate the number of distinct elements in the last N data elements. Their *probabilistic counting technique*[2] maintains a bitmap of size $O(\log R)$, where R is an upper bound on the number of distinct values in the data set. In the case of sliding windows, $R \leq N$, and a bitmap of size $O(\log N)$ suffices. We also maintain with each bit a timestamp of size $O(\log N)$. Whenever a bit is (re)set by a data element, we update the timestamp to that of the data element. This enables us to keep track of the bits that were set by the last N elements. Consequently, we can estimate the number of distinct elements with an expected relative accuracy of $O(\frac{1}{\sqrt{m}})$ using $O(m \log^2 N)$ bits of memory. Note that the lower bound for the BASICCOUNTING problem applies to the distinct value problem. Given an instance of the BASICCOUNTING problem, we can create an input where a 0 is mapped to 0 while every 1 is mapped to some distinct value (the *arrival time* of the element, for instance). Then the number of distinct values is one more than the number of 1's. This reduction shows that the lower bounds for the BASICCOUNTING problem apply to the distinct value problem.

Consider the problem of estimating the number of distinct values over sliding

[2]The technique assumes perfect hash functions. However, it suffices to use hash functions which do not have complete independence.

windows in the presence of deletions. We prove a space lower bound of $\Omega(N)$ bits, where N is the window size. Every data element consists of a value and a bit that indicates if the value is being "inserted" or "deleted." Consider the last N elements that form the current window. These define a collection of values and multiplicities. The multiplicity of a value is the number of times it is inserted in the current window minus the number of times it is deleted from the current window. It is possible for a value to have negative multiplicity since it may have been deleted more times than it was inserted. The number of distinct values is the number of values that have multiplicity greater than zero. Our lower bound holds even if we define the number of distinct values as those with nonzero multiplicity. Given this model we claim the following.

CLAIM 1. *An algorithm that estimates the number of distinct values within a factor* 2 *of the correct answer, over sliding windows and in the presence of deletions, requires* $\Omega(N)$ *bits of space, where* N *is the size of the sliding window.*

Proof. Consider an algorithm A that estimates the number of distinct values to within a factor of 2, over sliding windows and in the presence of deletions. Given any arbitrary bit vector $\boldsymbol{X} = \{x_1, x_2, \ldots, x_N\}$, we present the algorithm with the following input. Every bit x_i is mapped to a value y_i as follows: If x_i is 1, then y_i is set to i. Otherwise, y_i is set to 0. These values are input to the algorithm in the order y_1 to y_N along with the additional bit that represents that these values are being inserted. After the N values have been inserted, let S be the state of the algorithm. We claim that we can recover the last $N/2$ bits of the vector $\boldsymbol{X}$ (i.e., $\{x_{N/2+1}, x_{N/2+2}, \ldots, x_N\}$) using the state S of the algorithm. This proves that the information content of the state S is at least $N/2$ bits, and hence it would require $\Omega(N)$ bits of space. Given the state S, we recover the last bit (x_N) as follows: We insert $N-1$ elements with value 0. The current window now contains $N-1$ inserts of value 0 and an insert of value y_N, which, depending upon the value of x_N, is either 0 or N. The correct answer (i.e., number of distinct values) in that case is either 1 or 2, depending upon whether x_N is 0 or 1. Since the algorithm A estimates to within a factor of 2, it will distinguish between the two cases, and we can infer the last bit x_N. If the algorithm estimates the number of distinct values to be less than 2, then $x_N = 0$; otherwise, $x_N = 1$. Having inferred the last bit x_N, we can infer the previous bit x_{N-1} as follows: We "rewind" to the state S (state after inserting y_1 to y_N). In other words, we run the algorithm from state S again, by storing the state S. We input an element with value equal to y_N and bit set to delete, followed by $N-3$ elements with value equal to 0 and bit set to insert. In other words, we are deleting the value y_N that was inserted last. The current window now consists of $N-3$ inserts of value 0 and an insert of value y_{N-1}, which, depending on x_{N-1}, is either 0 or $N-1$. Note that the current window also contains a pair of elements that insert and delete the value y_N. By similar arguments as before, we can now infer the bit x_{N-1} since the algorithm A gives a factor 2 approximation. We can proceed this way to infer the last $N/2$ bits in the order $x_N, x_{N-1}, \ldots, x_{N/2+1}$. To infer the x_{N-i}th bit (having inferred $x_{N-i+1}, \ldots, x_N$), start with the state S again. Input elements with values $y_{N-i+1}, y_{N-i+2}, \ldots, y_N$ and bit set to delete, followed by $N-2i-1$ inserts of value 0. The current window will then contain $N-2i-1$ inserts of value 0, an insert of value y_{N-i}, and i pairs of inserts and deletions of values $y_{N-i+1}, y_{N-i+2}, \ldots, y_N$. Again, we can infer the bit x_{N-i}. We can do this for $i < N/2$.

The argument above proves that the state S essentially encodes the last $N/2$ bits and probably more, proving the lower bound for the space requirement of S. ∎

7.6. General sum. Consider the problem of maintaining the sum of the last N integers when the integers could be positive or negative. We prove that, even if we restrict the set of integers to $\{1, 0, -1\}$, to approximate the sum within a constant factor requires $\Omega(N)$ bits of memory. Moreover, it is easy to maintain the sum by storing the last N integers, which requires $O(N)$ bits of memory. We assume that the storage required for every integer is a constant independent of the window size N. This proves that the complexity of the problem in the general case (i.e., allowing positive and negative integers) is $\Theta(N)$. We now argue the lower bound of $\Omega(N)$. Consider an algorithm A that provides a constant factor approximation to the problem of maintaining the general sum. Given a bit vector of size $N/2$, we present the algorithm A with the pair $(-1, 1)$ for every 1 in the bit vector and the pair $(1, -1)$ for every 0. Consider the state (i.e., time instant) after we have presented all of the $N/2$ pairs to the algorithm. We claim that we can completely recover the original bit vector by presenting a sequence of 0's henceforth and querying the algorithm on every odd time instant. If the current time instant is T (after having presented the $N/2$ pairs), then it is easy to see that the correct answer at time instant $T + 2i - 1$ $(1 \leq i \leq N/2)$ is 1 iff the ith bit was 1 and -1 iff the ith bit was 0. Since the algorithm A gives a constant factor approximation, its estimate would be positive if the correct answer is 1 and negative if the correct answer was -1. Since the state of the algorithm after feeding the $N/2$ pairs enables us to recover the bit vector exactly for any arbitrary bit vector, it must be using at least $N/2$ bits of memory. This proves the lower bound. We can state the following theorem.

THEOREM 8. *The space complexity of any algorithm that gives a constant factor approximation, at every instant, to the problem of maintaining the sum of last N integers, which appear as a stream of data elements and could be positive or negative, is equal to $\Theta(N)$.*

8. Conclusion. In conclusion, this paper takes the first step toward computing over data streams in the sliding window model. We consider the problem of maintaining statistics over sliding windows and provide upper and lower space bounds for various problems. It remains to consider problems like maintaining other statistics (for instance, variance), clustering (maintaining k-medians), etc. in the sliding window model.

Acknowledgments. The authors would like to thank Yossi Matias for suggesting the idea of maintaining coarser timestamps presented in section 5. They would also like to thank the anonymous referees for their suggestions in improving the presentation.

CURVATURE-CONSTRAINED SHORTEST PATHS IN A CONVEX POLYGON*

PANKAJ K. AGARWAL†, THERESE BIEDL‡, SYLVAIN LAZARD§, STEVE ROBBINS¶, SUBHASH SURI‖, AND SUE WHITESIDES¶

Abstract. Let B be a point robot moving in the plane, whose path is constrained to have curvature at most 1, and let $\mathcal{P}$ be a convex polygon with n vertices. We study the collision-free, optimal path-planning problem for B moving between two *configurations* inside $\mathcal{P}$. (A configuration specifies both a location and a direction of travel.) We present an $O(n^2 \log n)$ time algorithm for determining whether a collision-free path exists for B between two given configurations. If such a path exists, the algorithm returns a shortest one. We provide a detailed classification of curvature-constrained shortest paths inside a convex polygon and prove several properties of them, which are interesting in their own right. For example, we prove that any such shortest path is comprised of at most eight segments, each of which is a circular arc of unit radius or a straight-line segment. Some of the properties are quite general and shed some light on curvature-constrained shortest paths amid obstacles.

Key words. nonholonomic motion planning, shortest paths, mobile robot, curvature constraint, bounded radius of curvature, Dubins path, computational geometry

1. Introduction.

The *path-planning* problem, a central problem in robotics, involves planning a collision-free path for a robot moving amid obstacles and has been widely studied (see, e.g., the book by Latombe [21] and the survey papers by Schwartz and Sharir [31] and Halperin, Kavraki, and Latombe [17]). In the simplest form, given a moving point robot B, a set of obstacles, and a pair of configurations I and F specifying locations for B, we wish to find a continuous, collision-free path for B from I to F. This formulation, however, does not take into account the so-called *nonholonomic constraints* (for instance, bounds on acceleration or curvature) imposed on a robot by its physical limitations (see [21] for a more detailed discussion). Although there has been considerable recent work reported in the robotics and nonlinear-control literature on nonholonomic motion-planning problems (see [3, 5, 19, 20, 22, 24, 32, 42, 43] and

references therein), relatively little theoretical work has been done in this important area from an algorithmic perspective.

In this paper, we study the path-planning problem for a point robot whose configurations are specified by giving both a location and a direction of travel. This means that any solution to the path-planning problem for given initial and final configurations I and F must respect the directions of travel specified by I and F as well as the locations they specify. Furthermore, we require the path of the robot to have curvature at most 1. This curvature constraint arises naturally when the point robot models a real-world robot with a minimum turning radius; see, for example, [21]. Recently, Reif and Wang [29] confirmed that the problem of deciding whether there exists a collision-free curvature-constrained path for B between two given configurations amid polygonal obstacles is NP-hard. As a first step toward understanding which environments admit an efficient solution to this NP-hard problem, we study curvature-constrained path planning inside convex polygons.

We establish several new properties of shortest paths inside convex polygons and use them to characterize shortest paths in such environments. Using these properties and some geometric data structures [10], we present an efficient algorithm that, given initial and desired final configurations I and F in a convex polygon $\mathcal{P}$, determines whether there exists a curvature-constrained path from I to F that lies inside $\mathcal{P}$ and if so, computes a shortest one.

1.1. Previous results. Dubins [15] was perhaps the first to study curvature-constrained shortest paths. He proved that, in the absence of obstacles, a curvature-constrained shortest path from any start configuration to any final configuration consists of at most three segments, each of which is either a straight-line segment or an arc of a circle of unit radius, assuming that the curvature of the path is upper bounded by 1. Using ideas from control theory, Boissonnat, Cérézo, and Leblond [5] and, at the same time, Sussmann and Tang [38] gave an alternative proof. Further characterizations of shortest paths in an obstacle-free environment have been made by Boissonnat and Bui in [4] and Bui, Souères, Boissonnat, and Laumond in [8].

In the presence of polygonal obstacles, Jacobs and Canny [18] proved that, if there exists a curvature-constrained path between two configurations, there exists in the closed free space a curvature-constrained shortest path between these two configurations. Fortune and Wilfong [16] gave a $2^{poly(n,m)}$ time algorithm that decides whether a path exists, without finding one, where n is the total number of vertices in the polygons defining the obstacles and m is the number of bits of precision with which all points are specified. Jacobs and Canny [18], Wang and Agarwal [41], and Sellen [33, 34] gave approximation algorithms for computing an *ε-robust* path. (Informally, a path is ε-robust if it may be deformed by ε in a certain way while remaining feasible.) For the restricted case of pairwise disjoint *moderate obstacles*, i.e., convex obstacles whose boundaries have curvature upper bounded by 1, Agarwal, Raghavan, and Tamaki [1] gave efficient approximation algorithms. Boissonnat and Lazard [6] gave an $O(n^2 \log n)$ time algorithm for computing an exact shortest path for the case when the edges of the pairwise disjoint moderate obstacles consist of n segments that are circular arcs of unit radius or line segments. Their algorithm can be used to compute an optimal curvature-constrained path inside a convex polygon in time $O(n^7)$. Recently, Ahn, Cheong, Matoušek, and Vigneron [2] characterized the region of all points that can be reached from a given configuration in a convex polygon. Wilfong [42, 43] studied a restricted problem in which the robot must stay on one of m line segments (thought of as "lanes") except to turn between lanes. For a scene with

n obstacle vertices, his algorithm preprocesses the scene in time $O(m^2(n^2 + \log m))$, following which queries are answered in time $O(m^2)$.

There has also been work on characterizing shortest curvature-constrained paths when B is allowed to make reversals, that is, to back up. Reeds and Shepp [28] were the first to compute the characterization of such shortest paths in an obstacle-free environment. Boissonnat, Cérézo, and Leblond [5] and Sussmann and Tang [38] presented an alternative proof using ideas from control theory. Souères and Laumond refined the characterization of shortest paths [36]. In the presence of obstacles, Desaulniers proved that a *shortest* path does not necessarily exist even when paths exist [13]. Finally, much work has been done on computing curvature-constrained paths in the presence of obstacles when reversals are allowed; see, e.g., [3, 19, 20, 21, 22, 23, 24, 25, 32, 39, 40].

Other more general dynamic constraints have been considered in [3, 11, 12, 14, 26]. In particular, Sussmann [37] extended the characterization of curvature-constrained shortest paths to the 3-dimensional case.

1.2. Our model and results. Let B be a point robot and $\mathcal{P}$ a closed convex polygon with n vertices. For simplicity, we assume that the edges of $\mathcal{P}$ are in the general position: no two edges are parallel and no unit-radius circle (in $\mathbb{R}^2$) is tangent to three edges of $\mathcal{P}$. We believe that our techniques can be extended to carry through without this general-position assumption, although the technical details would be daunting. A *configuration* X for B is a pair $(\textsc{loc}(X), \psi(X))$, where $\textsc{loc}(X)$ is a point in the plane representing the location of the robot and $\psi(X)$ is an angle between 0 and 2π representing its orientation. When the meaning is clear, we generally write X instead of $\textsc{loc}(X)$.

The image of a differentiable function $\Pi : [0, l] \to \mathbb{R}^2$ is called a *path*. We denote by Π both the function and the path it defines. We regard a path Π as oriented from $\Pi(0)$ to $\Pi(l)$. We assume a path Π is parameterized by its arc length, and we let $\|\Pi\|$ denote its length. We say that Π is a path from a configuration X to another configuration Y if $\Pi(0) = \textsc{loc}(X)$, $\Pi(l) = \textsc{loc}(Y)$, and the oriented angles (with respect to the positive x-axis) of $\Pi'(0)$ and $\Pi'(l)$ are $\psi(X)$ and $\psi(Y)$, respectively. A path is called *moderate* if its average curvature is at most 1 in every positive-length interval.[1] This implies that the curvature is defined almost everywhere and that it is at most 1 wherever it is defined. Indeed, the derivative of a moderate path Π satisfies a Lipschitz condition, and therefore the derivative is differentiable almost everywhere [30, Theorem 8.19].

Any curve that lies entirely within the closed polygon $\mathcal{P}$ is called *free*. A path is *feasible* if it is moderate and free. A path Π from a configuration X to another configuration Y is *optimal* if it is feasible and its length is minimum among all feasible paths from X to Y. (If a feasible path from X to Y exists, then an optimal such path also exists [18].)

Throughout the paper, we say that we *compute* an object as a short way of saying that we compute such an object if one exists and return a flag of nonexistence otherwise.

Main results. Let $\mathcal{P}$ be an n-vertex convex polygon in the plane, and let I and F be two configurations inside $\mathcal{P}$.

(i) We give a classification of optimal paths from I to F.

(ii) We prove that an optimal path from I to F consists of at most eight maximal segments, each of which is either a line segment or a circular arc of unit radius.

[1] The *average curvature* of a path Π in the interval $[s_1, s_2]$ is defined by $\|\Pi'(s_1) - \Pi'(s_2)\|/|s_1 - s_2|$.

(iii) We give an $O(n^2 \log n)$ time algorithm to determine whether a feasible path from I to F exists. If such a path exists, then the algorithm returns an optimal path from I to F. If there are only k edges of $\mathcal{P}$ at a distance of at most 6 from both I and F, then the running time of our algorithm becomes $O((n + k^2) \log n)$.

Note that result (ii) above is actually quite surprising. Indeed, it means that the complexity of optimal paths inside a convex polygon is constant and does not depend on the number of edges of the polygon.

Note also that our algorithm for computing optimal paths is significantly faster than the algorithm implicit in the work of Boissonnat and Lazard [6] on computing an optimal path amid overlapping moderate obstacles, whose running time would be $O(n^7)$.

Some of the properties of moderate paths we prove are interesting in their own right. For example, one of these properties identifies a type of narrow region, called a "pocket," from which a moderate path cannot escape once it enters from outside. The conclusion will highlight this and another of these properties, which require technical definitions from later sections to describe in detail.

Our paper is organized as follows. In section 2, we present basic definitions, notation, and useful known results. In section 3, we give a classification of the optimal paths. In sections 4 and 5, we describe our algorithm. We conclude in section 6 with a discussion and some open problems.

2. Geometric preliminaries. Given a configuration X, let L_X denote the oriented line passing through $\text{LOC}(X)$ with orientation $\psi(X)$. A configuration X *belongs* to an oriented path (or curve) Π if $\text{LOC}(X) \in \Pi$ and L_X is the oriented tangent line to Π at $\text{LOC}(X)$. Note that a configuration X belongs to two oriented unit-radius circles. We will use $\mathcal{C}_X^+$ and $\mathcal{C}_X^-$ to denote the two circles of unit radius, oriented counterclockwise and clockwise, respectively, to which the configuration X belongs.

If X and Y are two points on a simple closed curve γ, then $\gamma^+[X, Y]$ (respectively, $\gamma^-[X, Y]$) denotes the portion of γ from X to Y in the counterclockwise (respectively, clockwise) direction, including X and Y; we will use $\gamma^+(X, Y), \gamma^-(X, Y)$ to denote portions excluding X, Y. Similarly, for a path Π and two configurations $X, Y \in \Pi$, we will use $\Pi[X, Y]$ to denote the portion of Π from X to Y.

Segments and Dubins paths. Let Π be a feasible path. We call a nonempty subpath of Π a *C-segment* (respectively, *S-segment*) if it is a circular arc of unit radius (respectively, line segment) and maximal; i.e., it is not strictly contained in a longer circular arc (respectively, line segment) of the path. A *segment* is either a C-segment or an S-segment. A C-segment on a path Π is called a C^+-segment (respectively, C^--segment) if Π induces a counterclockwise (respectively, clockwise) orientation on it. Suppose Π consists of a C-segment, an S-segment, and a C-segment; then we will say that Π is of type CSC or C_1SC_2 or $C_1S_2C_3$ if, for ease of reference, we want to number segments in order of their appearance in the sequence; superscripts $+$ and $-$ will be used to specify the orientations of C-segments of Π. Abusing the notation slightly, we often use the same symbol to denote both the type of a segment and the segment itself. Thus we may denote the first C-segment occurring in some path of type C_1SC_2 by C_1. The above notation can be generalized to an arbitrarily long sequence. Recall that, throughout the paper, C-segments and S-segments have positive length. Dubins [15] proved the following result.

LEMMA 2.1 (Dubins [15]). *In an obstacle-free environment, an optimal path between any two configurations is of type CCC or CSC or is a substring thereof.*

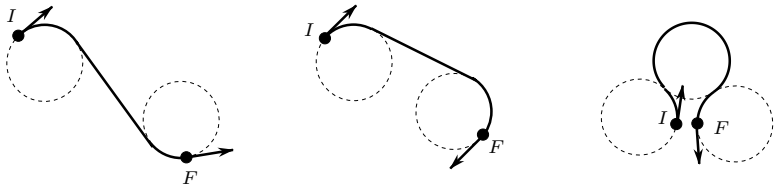

FIG. 2.1. *Different types of Dubins paths.*

We will refer to paths of type CCC or CSC or substrings thereof as *Dubins paths* (see Figure 2.1). In the presence of obstacles, Jacobs and Canny [18] observed that any subpath of an optimal path that does not touch any obstacle except at the endpoints is a Dubins path. In particular, they proved the following.

LEMMA 2.2 (Jacobs and Canny [18]). *Let Ω be a closed polygonal environment, I an initial configuration, and F a final configuration. Then an optimal path from I to F in Ω consists of a sequence $\Pi_1 \cdots \Pi_k$ of feasible paths, where each Π_i is a Dubins path from a configuration X_{i-1} to a configuration X_i, such that $X_0 = I$, $X_k = F$, and, for $0 < i < k$, $\text{LOC}(X_i) \in \partial\Omega$.*

The above lemma implies that an optimal path in a closed polygonal environment consists of C- and S-segments. In the following, we will consider only those paths that are formed by C- and S-segments. We will refer to circles and circular arcs of unit radius simply as circles and circular arcs. Notationally, we distinguish between a C-segment and its supporting circle, that is, the circle on which the circular arc lies, by using the calligraphy font $\mathcal{C}$ for the latter. While the symbols C and $\mathcal{C}$ are similar in appearance, it will be clear from the context whether we are referring to a supporting circle (denoted $\mathcal{C}$) or to a circular arc (denoted C).

Terminal and nonterminal segments. A segment of a feasible path Π is called *terminal* if it is the first or the last segment of Π; otherwise, it is called *nonterminal*. We apply the adjectives terminal and nonterminal to subpaths as well. If the first or last segment in Π is a C-segment, we will refer to it as a C_I-segment or a C_F-segment, respectively. Circles $\mathcal{C}_I^+$, $\mathcal{C}_I^-$, $\mathcal{C}_F^+$, and $\mathcal{C}_F^-$ are called *terminal circles* (see Figure 2.3).

The following lemma states some basic known properties of optimal paths; see [1, 15, 18].

LEMMA 2.3. *In an optimal path inside a convex polygon $\mathcal{P}$,*

(i) *any nonterminal C-segment has length greater than π,*
(ii) *any nonterminal C-segment is tangent to $\partial\mathcal{P}$ or to a terminal circle in at least one point, and*
(iii) *no nonterminal subpath has type CCC.*

Next we prove a property of a CS-subpath in an optimal path, which will be useful for our analysis.

LEMMA 2.4. *Let Π be an optimal path that contains a subpath of type CS, where the C-segment is not terminal. Then the C-segment is tangent to $\partial\mathcal{P}$, and the length of C between its first point and its last point of tangency with $\partial\mathcal{P}$ is greater than π.*

Proof. Let Π be an optimal path containing a subpath Π' of type $C_1C_2S_3$ or $S_1C_2S_3$. See Figure 2.2. Let X be the common endpoint of the first and second segments of Π', let Y be the last point of tangency of C_2 with $\partial\mathcal{P}$ along Π, and let X' be the point antipodal to X on C_2. ($X' \in C_2$ because the length of C_2 is greater than π by Lemma 2.3(i).)

Dubins [15] proved that the perturbations shown in Figure 2.2 (transforming paths $C_1C_2S_3$ and $S_1C_2S_3$ into paths of type $CCCS$ and $SCCS$ by reducing the length of

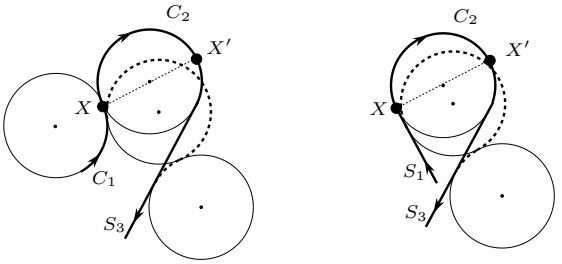

FIG. 2.2. *Length-reducing perturbations.*

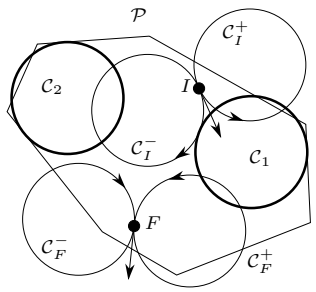

FIG. 2.3. *$\mathcal{PC}$-anchored ($\mathcal{C}_1$) and $\mathcal{PP}$-anchored ($\mathcal{C}_2$) circles.*

the first segment by any arbitrarily small value) shorten the paths in an obstacle-free environment. These shortenings can be done unless an obstacle obstructs the shortcut, i.e., unless $\partial\mathcal{P}$ is tangent to C_2 after X' (along Π). Thus, if $\|\Pi[X,Y]\| \leqslant \pi$, then Π can be shortened in $\mathcal{P}$, which contradicts the optimality of Π. □

Anchored segments. We define here the notion of anchored segments in a way that is similar to the notion introduced in [1]. A C-segment or circle is called *anchored* if it has at least two points of tangency with $\partial\mathcal{P}$ and the terminal circles. The terminal circles are not considered anchored. An anchored C-segment is denoted by $\bar{\bar{C}}$. By our general-position assumption on $\mathcal{P}$, there are a finite number of anchored circles. A C-segment with at least one point of tangency with $\partial\mathcal{P}$ is denoted by $\bar{C}$.

An anchored C-segment or circle is *$\mathcal{PP}$-anchored* if it is tangent to $\partial\mathcal{P}$ at two points and *$\mathcal{PC}$-anchored* if it is tangent to $\partial\mathcal{P}$ at one point and tangent to a terminal circle at another point; see Figure 2.3.

A circular arc is called *long* if its length is greater than π; otherwise, it is called *short*. A $\mathcal{PP}$-anchored C-segment is called *strongly $\mathcal{PP}$-anchored* if it contains the long arc defined by the points of tangency of its supporting circle with $\partial\mathcal{P}$ (see Figure 2.4b). Similarly, a $\mathcal{PC}$-anchored C-segment is called *strongly $\mathcal{PC}$-anchored* if it contains the long arc between a point of tangency of its supporting circle $\mathcal{C}$ with $\partial\mathcal{P}$ and a point of tangency of $\mathcal{C}$ with a terminal circle (see Figure 3.1a).

Closed moderate paths. We state here the following results about closed moderate paths.

PROPOSITION 2.5. *The region bounded by a simple moderate path Π whose initial and final locations coincide (the initial and final orientations may differ) contains at least one disk of unit radius. Moreover, if the initial and final orientations also coincide and if Π is not a circle of unit radius, then the region bounded by Π contains at least two distinct (but possibly overlapping) disks of unit radius.*

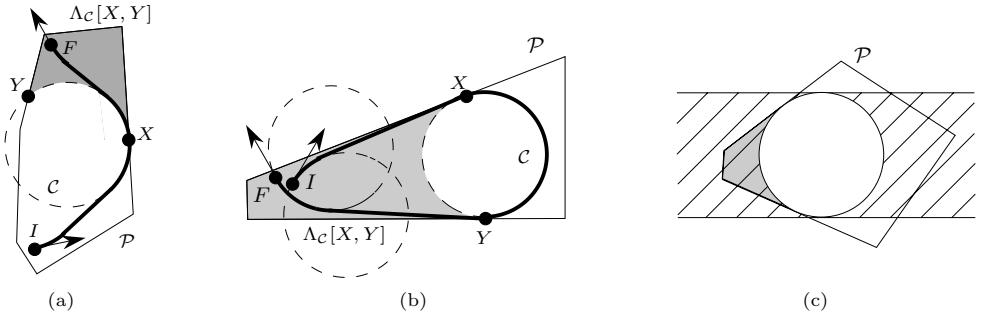

FIG. 2.4. *Pockets.*

The second statement in the proposition above was proved by Pestov and Ionin [27] for the restricted class of closed C^2 continuous curves (i.e., twice differentiable curves with continuous second derivative) whose curvatures are bounded everywhere. At the time we submitted this paper, Ahn et al. [2] presented a simple generalization of Pestov and Ionin's result, which yields the first statement of Proposition 2.5; furthermore, it appears straightforward to generalize their proof to obtain the second statement. Rather than carrying out that generalization here, we include in the appendix the proof we gave in the original version of this paper.

Pockets. We introduce here the notion of pockets. Let $\mathcal{C}$ be a circle intersecting $\partial\mathcal{P}$ at two or more points, and let X, Y be two consecutive[2] intersection points of $\partial\mathcal{P}$ with $\mathcal{C}$ so that the short arc of $\mathcal{C}$ joining X and Y lies inside $\mathcal{P}$. If $\mathcal{C}^+[X,Y]$ is the short arc and the turning angle[3] of $\partial\mathcal{P}^+(X,Y)$ is less than π, then the closed region bounded by $\partial\mathcal{P}^+[X,Y]$ and $\mathcal{C}^+[X,Y]$ is called a *pocket* (see Figure 2.4) and is denoted by $\Lambda_{\mathcal{C}}[X,Y]$. Similarly, we define the pocket $\Lambda_{\mathcal{C}}[X,Y]$ for the case in which $\mathcal{C}^-[X,Y]$ is the shorter arc. We will mostly be interested in pockets for which $\mathcal{C}$ is tangent to $\partial\mathcal{P}$ at X.

We first prove the following simple property of pockets.

LEMMA 2.6. *A pocket cannot contain a unit circle.*

Proof. Any pocket is contained in an open strip of width 2 (see Figure 2.4c) which does not contain any circle of unit radius. Thus there is no room for a unit circle in a pocket. □

We prove the following lemma, which will be crucial for characterizing the optimal paths containing a strongly anchored C-segment.

LEMMA 2.7. *If a feasible path enters the interior of a pocket, then it cannot escape the pocket.*

Proof. For a contradiction, let Π be a feasible path that enters the interior of a pocket $\Lambda_{\mathcal{C}}$ at X and escapes it at Y. See Figure 2.5. Let $\mathcal{C}$ denote the circle defining the pocket $\Lambda_{\mathcal{C}}$, and let $\mathcal{D}$ be the closed disk whose boundary is $\mathcal{C}$. If $\mathcal{C}$ intersects $\mathcal{C}_X^+$ at exactly two points, let them be denoted by X and X^+. If $\mathcal{C} = \mathcal{C}_X^+$, let X^+ denote the point on $\mathcal{C}$ antipodal to X. If the intersection of the two circles consists of exactly one point, denote this point by $X = X^+$. We define X^-, Y^+, and Y^- similarly. Let O_X^+, O_X^-, and O be the centers of the circles $\mathcal{C}_X^+, \mathcal{C}_X^-$, and $\mathcal{C}$, respectively.

We first prove that the segments X^+X^- and Y^+Y^- are diameters of $\mathcal{C}$. See

[2]Since $\mathcal{C}$ and $\partial\mathcal{P}$ are both convex, two consecutive intersection points of $\partial\mathcal{P}$ and $\mathcal{C}$ are consecutive on both $\partial\mathcal{P}$ and $\mathcal{C}$.

[3]The *turning angle* of a convex polygonal chain is $\sum_i(\pi - \theta_i)$, where θ_i is the interior angle at vertex i.

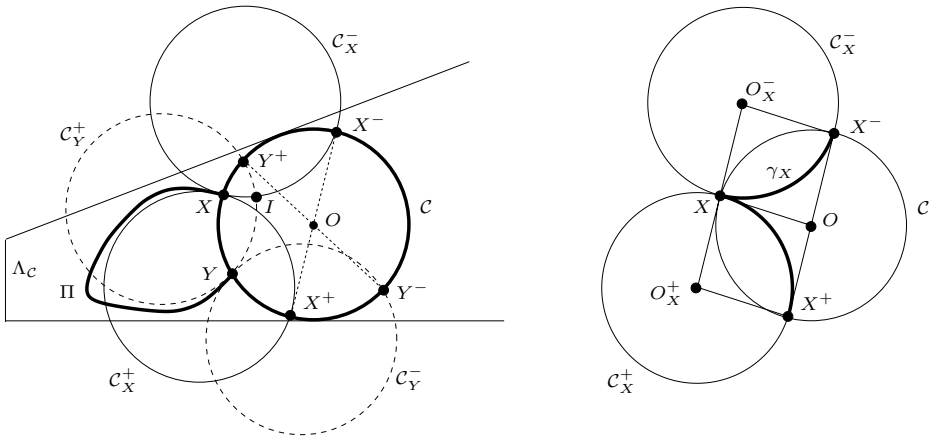

FIG. 2.5. *Illustration of the proof of Lemma* 2.7.

Figure 2.5. The quadrilaterals $O_X^+XOX^+$ and $O_X^-XOX^-$ are parallelograms. (These parallelograms flatten to line segments when $\mathcal{C}$ is equal to $\mathcal{C}_X^+$ or $\mathcal{C}_X^-$, but then X^+X^- is a diameter of $\mathcal{C}$ by definition.) Since the two parallelograms share the edge XO and the edges O_X^+X and XO_X^- are collinear, the two parallelograms are congruent. Therefore, O is the middle point of the segment X^+X^-. Similarly, Y^+Y^- is also a diameter of $\mathcal{C}$.

Let γ_X be the union of the arcs of $\mathcal{C}_X^+$ and $\mathcal{C}_X^-$ in $\mathcal{D}$, i.e., $\gamma_X = (\mathcal{C}_X^+ \cup \mathcal{C}_X^-) \cap \mathcal{D}$, and let γ_Y be defined similarly. The set γ_X either is equal to $\mathcal{C}$ or consists of two unit-radius circular arcs XX^- and XX^+; the same is true for γ_Y. The set γ_X belongs to $\mathcal{D}$, and segments X^+X^- and Y^+Y^- are diameters of $\mathcal{C}$; thus γ_X separates (not necessarily strictly) Y^+ and Y^- in $\mathcal{D}$. Since γ_Y also belongs to $\mathcal{D}$, γ_X and γ_Y intersect by the Jordan curve theorem.

First, note that the region $\Lambda_\mathcal{C} \cup \mathcal{D}$ cannot contain any unit-radius disk except $\mathcal{D}$; this is because O is the only point in $\Lambda_\mathcal{C} \cup D$ that is a distance of at least 1 from the boundary of $\Lambda_\mathcal{C} \cup D$.

Second, note that Π must be simple. Otherwise, Π would contain a simple, moderate subpath Π', lying in $\Lambda_\mathcal{C}$, with equal initial and final locations. This contradicts Proposition 2.5 since, by Lemma 2.6, a pocket cannot contain a unit disk.

Third, locations X and Y cannot be equal. Otherwise, Π would be simple, moderate, and lying in $\Lambda_\mathcal{C}$, with equal initial and final locations. As before, this contradicts Proposition 2.5.

Now we describe how to obtain a path Π' that leads to a contradiction. Consider first the case in which γ_X and γ_Y each consist of two unit-radius circular arcs XX^+, XX^- and YY^+, YY^-, respectively. Let I be the intersection point between γ_X and γ_Y that is the closest to X on γ_X (see Figure 2.5). This ensures that the circular arcs $IX \subset \gamma_X$ and $YI \subset \gamma_Y$ intersect only at I. Let Π' be the concatenation of the circular arc $IX \subset \gamma_X$, the path Π, and the circular arc $YI \subset \gamma_Y$. Path Π' is simple because Π is simple and the arcs IX and IY intersect only at I. Thus Π' is simple, moderate, and contained in the region $\Lambda_\mathcal{C} \cup \mathcal{D}$, which does not contain any unit-radius disk except $\mathcal{D}$. Thus, by Proposition 2.5, Π' encloses $\mathcal{D}$. It follows that the circular arcs IX and IY defining Π' cannot intersect the interior of $\mathcal{D}$. Thus the arcs IX and IY are reduced to a point $I = X = Y$, which is a contradiction.

Consider now the case in which exactly one of γ_X, γ_Y is equal to $\mathcal{C}$. Assume without loss of generality that $\gamma_X = \mathcal{C}$ and γ_Y consists of two unit-radius circular

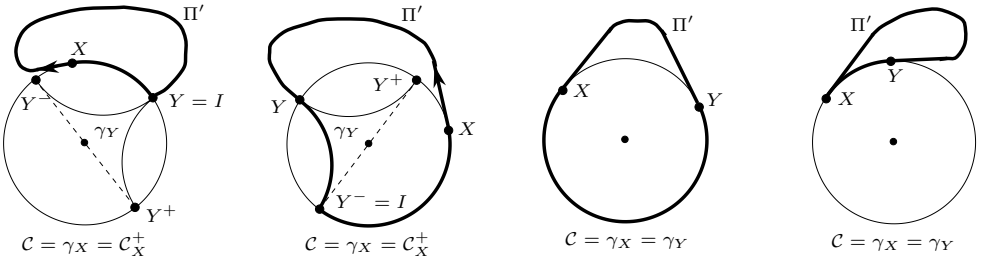

FIG. 2.6. *Illustration of the proof of Lemma* 2.7.

arcs YY^+ and YY^-. See, for example, Figure 2.6a and b. Since $\gamma_X = \mathcal{C}$, circle $\mathcal{C}$ is equal to $\mathcal{C}_X^+$ or $\mathcal{C}_X^-$; assume without loss of generality that $\mathcal{C} = \mathcal{C}_X^+$. Let I be the point in $\gamma_X \cap \gamma_Y = \{Y^-, Y, Y^+\}$ such that $\mathcal{C}^+[I, X]$ has minimum length. It follows that the arc $\mathcal{C}^+[I, X]$ intersects the arc $YI \subset \gamma_Y$ only at I. As before, we define Π' as the concatenation of $\mathcal{C}^+[I, X]$, Π, and YI, and, again, Π' is simple and moderate and must enclose $\mathcal{D}$. It follows that the circular arc YI defining Π' cannot intersect the interior of $\mathcal{D}$, and thus $I = Y$. Thus path Π' is the concatenation of $\mathcal{C}^+[I, X]$ and Π. Path Π lies in $\Lambda_{\mathcal{C}}$, and $\Lambda_{\mathcal{C}} \cap \mathcal{D}$ is an arc of $\mathcal{C}$ of length smaller than π. Thus, since Π' must enclose $\mathcal{D}$, the arc $\mathcal{C}^+[I, X]$ is the long arc of $\mathcal{C}$ joining I and X. Since Y^+Y^- is a diameter of $\mathcal{C}$, the arc $\mathcal{C}^+[I, X]$ strictly contains Y^+ or Y^-, contradicting the definition of I.

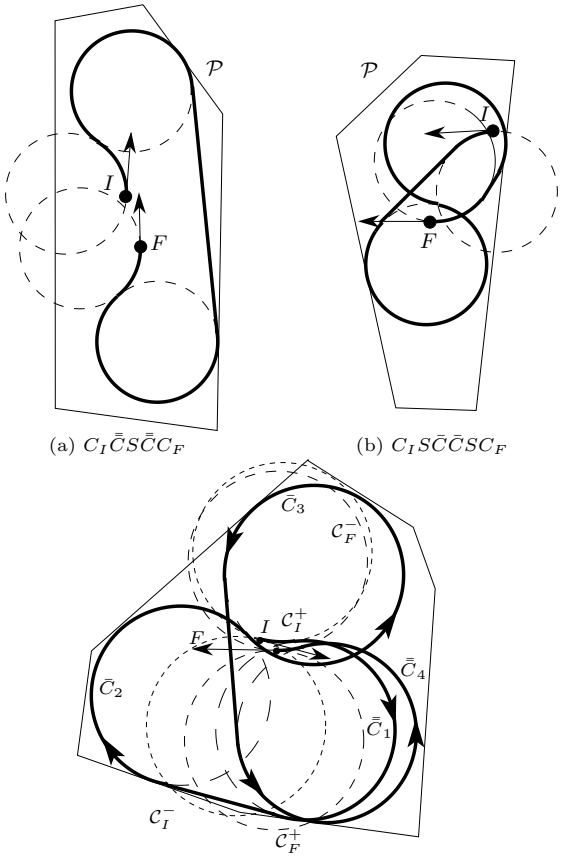
The remaining case is when both γ_X and γ_Y are equal to $\mathcal{C}$. Let Π' be the concatenation of Π and the arc XY of $\mathcal{C}$ joining X to Y such that, if possible, Π' is moderate everywhere (see, for example, Figure 2.6c), or if not possible, XY is the short arc (see Figure 2.6d). In the first case, Π' encloses at least two unit-radius disks by Proposition 2.5, contradicting the fact that $\Lambda_{\mathcal{C}} \cup \mathcal{D}$ contains Π' and only one unit-radius disk $\mathcal{D}$. In the second case, Π' encloses one unit-radius disk by Proposition 2.5 and lies in $\Lambda_{\mathcal{C}}$ because the short arc of $\mathcal{C}$ joining X and Y lies in $\Lambda_{\mathcal{C}}$. Thus $\Lambda_{\mathcal{C}}$ contains a unit disk, contradicting Lemma 2.6. □

3. Classification of optimal paths. The goal of this section is to prove the first of our main results, namely, a detailed characterization of optimal paths in convex polygons. We show that any optimal path is of type $C_I CSCCSCC_F$ or a subsequence of this form. However, not every subsequence of the above sequence can form an optimal path. The following theorem gives a more refined description of optimal path types. Recall that a segment has nonzero length by definition. In the following, we use $\cdot$ to denote a subpath of zero length.

THEOREM 3.1. *An optimal path* Π *inside* $\mathcal{P}$ *either is a Dubins path or is one of the types listed below. Except in case* (B.i), *all of the* C*-segments labeled* $\bar{\bar{C}}$ *are strongly anchored.*

(A) *If* Π *has no nonterminal* CC *subpath, then* Π *is one of the following types:*
  (A.i) $\Pi_I S \bar{\bar{C}} S \Pi_F$, *where* $\Pi_I \in \{C_I, \cdot\}$ *and* $\Pi_F \in \{C_F, \cdot\}$ *(see Figure* 2.4b*),*
  (A.ii) $\Pi_I S \Pi_F$, *where* $\Pi_I \in \{C_I \bar{\bar{C}}, C_I, \cdot\}$ *and* $\Pi_F \in \{\bar{\bar{C}} C_F, C_F, \cdot\}$ *(see Figure* 3.1a*).*

(B) *If* Π *has a nonterminal* CC *subpath, then* Π *is one of the following types:*
  (B.i) $C_I C \bar{\bar{C}} C_F$ *or* $C_I \bar{\bar{C}} C C_F$,
  (B.ii) $\Pi_I S \bar{\bar{C}} C C_F$ *or* $C_I C \bar{\bar{C}} S \Pi_F$, *where* $\Pi_I \in \{C_I, \cdot\}$ *and* $\Pi_F \in \{C_F, \cdot\}$,
  (B.iii) $\Pi_I \bar{C} \bar{C} \Pi_F$, *where* $\Pi_I \in \{C_I \bar{\bar{C}} S, C_I S, C_I, S\}$ *and* $\Pi_F \in \{S \bar{\bar{C}} C_F, S C_F, C_F, S\}$ *(see Figures* 3.1b, c*).*



(a) $C_I\bar{C}S\bar{C}C_F$ (b) $C_IS\bar{C}\bar{C}SC_F$

(c) $C_I\bar{C}_1S\bar{C}_2\bar{C}_3S\bar{C}_4C_F$

FIG. 3.1. *Examples of shortest paths.*

Remark 3.2. We informally checked by a case analysis on figures that, for the polygon and configurations I and F shown in Figure 3.1c, no path of type (A) or (B) is feasible except paths of type $C_ICS\bar{C}\bar{C}SCC_F$. This leads us to believe that the type $C_ICS\bar{C}\bar{C}SCC_F$, having eight segments, does occur as an optimal path type.

The proof of Theorem 3.1 is based on the following lemmas.

LEMMA 3.3 (Agarwal, Raghavan, and Tamaki [1]). *An optimal path has at most one nonterminal CC subpath. Moreover, any nonterminal C-segment that precedes (respectively, follows) a C_1C_2 subpath is oriented the same way as C_1 (respectively, C_2).*

Next we state a lemma whose proof we postpone until section 3.1.

LEMMA 3.4. (i) *If an optimal path has a subpath of type SCS, then the C-segment in that subpath is strongly $\mathcal{PP}$-anchored.*

(ii) *If an optimal path has a subpath of type $C_1C_2C_3S$ (or $SC_3C_2C_1$) so that the C-segment C_2 does not touch $\partial\mathcal{P}$, then C_3 is strongly $\mathcal{PP}$-anchored (see Figure* 3.5*).*

We next characterize some optimal paths that contain a strongly anchored C-segment.

LEMMA 3.5. (i) *If an optimal path Π contains a strongly $\mathcal{PP}$-anchored C-segment $\bar{\bar{C}}$, then $\Pi = \Pi_I\bar{\bar{C}}\Pi_F$, where Π_I and Π_F lie in some pockets defined by $\bar{\bar{C}}$.*

(ii) *If an optimal path Π contains a strongly $\mathcal{PC}$-anchored C-segment $\bar{\bar{C}}$ whose supporting circle is not free, then Π is of type $C_I\bar{\bar{C}}\Pi_F$ or $\Pi_I\bar{\bar{C}}C_F$, where Π_I and Π_F lie in some pockets defined by $\bar{\bar{C}}$.*

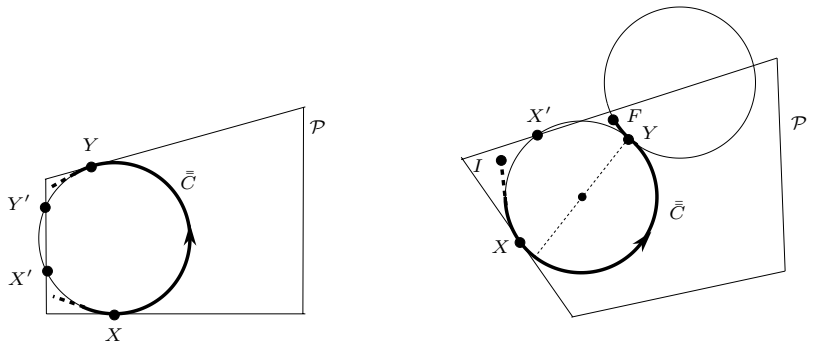


FIG. 3.2. *Illustration of the proof of Lemma* 3.5. *In* (a), *an optimal path containing a strongly $\mathcal{PP}$-anchored C-segment must start and end in a pocket.*

Proof. In case (i), the segment $\bar{\bar{C}}$ is strongly $\mathcal{PP}$-anchored, so it is tangent to $\partial\mathcal{P}$ at two points. Let X be the first point of tangency encountered along $\bar{\bar{C}}$, and let Y be the second point of tangency. See Figure 3.2a. By the general-position assumption, $\bar{\bar{C}}$ does not touch $\partial\mathcal{P}$ at any point other than X and Y. Without loss of generality, let $\bar{\bar{C}}$ be oriented counterclockwise. Let $\bar{\bar{\mathcal{C}}}$ be its supporting circle, and define X' as the first point of intersection between $\bar{\bar{\mathcal{C}}}$ and $\partial\mathcal{P}$ encountered moving clockwise along $\bar{\bar{\mathcal{C}}}$ from X. Notice that X' belongs to $\bar{\bar{\mathcal{C}}}^-(X,Y]$ since the intersection between $\bar{\bar{\mathcal{C}}}$ and $\partial\mathcal{P}$ contains Y.

Segment $\bar{\bar{C}}$ is strongly anchored, so $\|\Pi[X,Y]\| = \|\bar{\bar{\mathcal{C}}}^+[X,Y]\| > \pi$. Point X' is on the short arc $\bar{\bar{\mathcal{C}}}^+[Y,X]$, so $\|\bar{\bar{\mathcal{C}}}^+[X',X]\| < \pi$. The turning angle of $\partial\mathcal{P}^+[X,Y]$ is equal to $\psi(Y)-\psi(X) \pmod{2\pi}$, which, in turn, is equal to $\|\Pi[X,Y]\| > \pi$. The total turning angle around $\partial\mathcal{P}$ is 2π, so the turning angle of $\partial\mathcal{P}^+[X',X] < \pi$. Finally, $\bar{\bar{\mathcal{C}}}$ is tangent to $\partial\mathcal{P}$ at X, so $\bar{\bar{\mathcal{C}}}^+[X',X]$ lies inside the polygon. Thus arc $\bar{\bar{\mathcal{C}}}^+[X',X]$ forms the pocket $\Lambda_{\bar{\bar{\mathcal{C}}}}[X',X]$.

The pocket $\Lambda_{\bar{\bar{\mathcal{C}}}}[X',X]$ contains $\Pi[I,X]$ and thus Π_I, by Lemma 2.7. Indeed, otherwise, the path Π_I contains $\bar{\bar{\mathcal{C}}}^+[X',X]$, and $\partial\mathcal{P}$ is tangent to $\bar{\bar{\mathcal{C}}}$ at X'. This contradicts either the optimality of Π (if $X' = Y$) or the fact that X is the first point of tangency between $\bar{\bar{\mathcal{C}}}$ and $\partial\mathcal{P}$ encountered along Π (if $X' \neq Y$).

Similarly, Π_F is contained in a pocket $\Lambda_{\bar{\bar{\mathcal{C}}}}[Y,Y']$, where Y' is the first point of intersection between $\bar{\bar{\mathcal{C}}}$ and $\partial\mathcal{P}$ encountered moving counterclockwise along $\bar{\bar{\mathcal{C}}}$ from Y.

For case (ii), we assume that $\Pi = \Pi_I\bar{\bar{C}}C_F$; the case in which $\Pi = C_I\bar{\bar{C}}\Pi_F$ is symmetrical. Let X be the first point along $\bar{\bar{C}}$ that is tangent to $\partial\mathcal{P}$, and let Y be the last point of $\bar{\bar{C}}$. See Figure 3.2b. Then the proof is exactly the same as in (i), once noting that X' always exists on $\bar{\bar{\mathcal{C}}}^-(X,Y]$ because $\bar{\bar{\mathcal{C}}}$ is not free by assumption. ∎

LEMMA 3.6. *Let Π be an optimal path that contains a subpath of type $C_1S\bar{\bar{C}}$ or $\bar{\bar{C}}SC_1$, where $\bar{\bar{C}}$ is either a strongly $\mathcal{PP}$-anchored C-segment or a strongly $\mathcal{PC}$-anchored C-segment whose supporting circle is not free. Then C_1 is terminal.*

Proof. We consider the case in which Π contains a subpath of type $C_1S\bar{\bar{C}}$; the case of a subpath of type $\bar{\bar{C}}SC_1$ is symmetrical. Suppose that C_1 is not terminal. If $\bar{\bar{C}}$ is strongly $\mathcal{PP}$-anchored or is a strongly $\mathcal{PC}$-anchored C-segment whose supporting circle is not free, then $\bar{\bar{\mathcal{C}}}$ defines one or more pockets. By Lemma 3.5, C_1 belongs to one of the pockets defined by $\bar{\bar{\mathcal{C}}}$, say, $\Lambda_{\bar{\bar{\mathcal{C}}}}$.

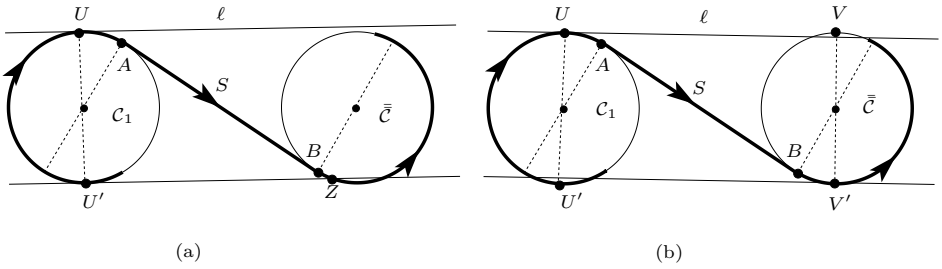

FIG. 3.3. *Illustration of the proof of Lemma* 3.6.

We claim that the circle $\mathcal{C}_1$ supporting the C-segment C_1 is not free. Indeed, otherwise, there would exist a feasible path that enters $\Lambda_{\bar{\bar{\mathcal{C}}}}$ on $\mathcal{C}_1$ (since no circle of unit radius is entirely contained in a pocket by Lemma 2.6) and escapes the pocket on $\bar{\bar{C}}$, contradicting Lemma 2.7.

Since C_1 is not terminal, its length is greater than π by Lemma 2.3(i). The length of $\bar{\bar{C}}$ is also greater than π because anchored circles are not terminal by definition.

Suppose first that the C-segments C_1 and $\bar{\bar{C}}$ have the same orientation along Π. Since the lengths of C_1 and $\bar{\bar{C}}$ are greater than π, the convex hull of C_1 and $\bar{\bar{C}}$ contains $\mathcal{C}_1$. By convexity of $\mathcal{P}$, the convex hull of C_1 and $\bar{\bar{C}}$ and thus $\mathcal{C}_1$ lies inside $\mathcal{P}$, which contradicts the above claim that $\mathcal{C}_1$ is not free.

Suppose now that the C-segments C_1 and $\bar{\bar{C}}$ have opposite orientation along Π (see Figure 3.3). Let A and B be the first and last points of the S-segment, respectively, in the subpath $C_1S\bar{\bar{C}}$. Let U be the last point of tangency along Π between C_1 and $\partial\mathcal{P}$, and let U' be the point antipodal to U on $\mathcal{C}_1$. By Lemma 2.4, U' belongs to C_1. Note that the arc on C_1 joining U' and A is longer than π. Let ℓ be the line tangent to $\mathcal{C}_1$ at U; ℓ contains an edge of $\mathcal{P}$.

If ℓ does not intersect $\bar{\bar{\mathcal{C}}}$, then the line tangent to C_1 at U' (which is parallel to ℓ) intersects the subpath $S\bar{\bar{C}}$ at a point Z (see Figure 3.3a). It follows that the convex hull of $\Pi[U', Z]$ contains $\mathcal{C}_1$. Thus $\mathcal{C}_1$ is free, again contradicting the claim that $\mathcal{C}_1$ is not free. On the other hand, if ℓ intersects $\bar{\bar{\mathcal{C}}}$, then let $V, V' \in \bar{\bar{\mathcal{C}}}$ such that $\overrightarrow{VV'} = \overrightarrow{UU'}$ (see Figure 3.3b). Points B and V lie on opposite sides of ℓ, and $\mathcal{P}$ lies in one of the half-planes bounded by ℓ. Since $B \in \Pi \subset \mathcal{P}$, we conclude that $V \notin \mathcal{P}$. Recall that $\|\bar{\bar{C}}\| \geqslant \pi$; therefore, $V' \in \bar{\bar{C}}$. The point on $\bar{\bar{C}}$ that is antipodal to the last point of $\bar{\bar{C}}$ lies on $\Pi[B, V']$. Thus, by Lemma 2.4 applied on the reversed path of Π, $\bar{\bar{C}}$ is tangent to $\partial\mathcal{P}$ at a point on $\Pi[B, V']$. Since the line tangent to $\bar{\bar{C}}$ at V' separates U' and A, any line tangent to $\Pi[B, V']$ separates U' and A. Thus $U' \notin \mathcal{P}$, which in turn implies that $U' \notin C_1$, thereby contradicting the claim that $U' \in C_1$. □

We now prove Theorem 3.1.

Proof of Theorem 3.1. The proof proceeds by considering how a nonterminal C-segment may appear in Π. If there is no nonterminal C-segment in Π, then Π is of type C_ISC_F or a substring thereof; i.e., Π is a Dubins path.

Assume now that there is a nonterminal C-segment in Π. Then such a segment belongs to a subpath of Π of type either SCS or CC. Suppose Π contains a subpath of type SCS. By Lemma 3.4, the C-segment in SCS must be strongly $\mathcal{PP}$-anchored. Thus, by Lemma 3.6, Π is of type $C_IS\bar{\bar{C}}SC_F$ or substrings (containing $S\bar{\bar{C}}S$) thereof. In other words, Π is of type (A.i).

If Π contains a nonterminal C-segment but not a subpath of type SCS, we know it must contain a subpath of type CC. There are two cases to consider, depending on whether the CC subpath is terminal.

Case 1. Π does not contain any nonterminal subpath of type CC. Thus one of the C-segments in any CC subpath must be a terminal segment. Either Π is of type $C_I C_F$ or $C_I C C_F$, or any nonterminal C-segment of Π is also adjacent to an S-segment. Π must then be of type $C_I C S C C_F$ or any substring thereof containing S and a terminal CC. By Lemma 2.4, the nonterminal C-segments are strongly $\mathcal{PC}$-anchored. All of these types of paths are thus either Dubins paths or paths of type (A.ii).

Case 2. Π contains a nonterminal subpath of type CC. By Lemma 3.3, it is the unique nonterminal CC-subpath in Π. Thus Π has the form $\Pi_I CC \Pi_F$, where Π_I, Π_F do not contain a nonterminal subpath of type CC. Thus any nonterminal C-segment in Π_I must be followed by an S-segment; otherwise, $\Pi_I CC$ will contain a nonterminal CCC-subpath, which contradicts the optimality of Π (Lemma 2.3(iii)). Furthermore, since we have no SCS subpath in Π, a nonterminal C-segment must be preceded by a terminal C-segment. This means that $\Pi_I = C_I CS$ or a subsequence of it. The subsequence cannot be empty, for otherwise the middle CC-subpath of Π would in fact be terminal; nor can it be simply CC, as noted above. Thus $\Pi_I \in \{C_I CS, C_I S, C_I, S\}$. Similarly, $\Pi_F \in \{SCC_F, SC_F, C_F, S\}$.

If $\Pi_I = C_I CS$ or $\Pi_F = SCC_F$, then the nonterminal C-segment in Π_I or Π_F is strongly anchored by Lemma 2.4.

If both Π_I and Π_F contain an S-segment, then the nonterminal CC-subpath in Π is preceded and followed by an S-segment. Thus both C-segments of the nonterminal CC-subpath in Π touch $\partial\mathcal{P}$. Indeed, otherwise Π contains a subpath of type SCC or CCS that does not touch $\partial\mathcal{P}$, which contradicts Lemma 2.2. Hence, if both Π_I and Π_F contain an S, then Π is of type (B.iii).

If neither Π_I nor Π_F contains an S-segment, then the path is of type $C_I CCC_F$. By Lemma 2.2, one of the nonterminal C-segments must touch $\partial\mathcal{P}$. This C-segment is also tangent to a terminal circle and is therefore $\mathcal{PC}$-anchored. Thus the path is of type (B.i). Note that, if both nonterminal C-segments touch $\partial\mathcal{P}$, then the path is of type $C_I \bar{\bar{C}} \bar{\bar{C}} C_F$, which can be considered as type (B.i) or (B.iii).

The last case to consider is when exactly one of Π_I or Π_F contains an S-segment. Say $\Pi_I = C_I$ and $\Pi_F \neq C_F$. The path has the form $C_I C_1 C_2 \Pi_F$, where Π_F starts with an S-segment. We know that C_2 must touch $\partial\mathcal{P}$ by Lemma 2.3(ii). If C_1 also touches $\partial\mathcal{P}$, then the path Π is of type (B.iii). Otherwise, if C_1 does not touch $\partial\mathcal{P}$, then, by Lemma 3.4(ii), C_2 must be strongly $\mathcal{PP}$-anchored. Lemma 3.6 then restricts the path Π to be of type (B.ii). Similarly, if $\Pi_I \neq C_I$ and $\Pi_F = C_F$, the path Π is of type (B.ii) or (B.iii). □

3.1. Proof of Lemma 3.4.

3.1.1. Proof of Lemma 3.4(i). Here we prove Lemma 3.4(i), which states

If an optimal path has a subpath of type SCS, then the C-segment in that subpath is strongly $\mathcal{PP}$-anchored.

Consider an optimal path $\Pi = S_1 C_3 S_5$ from configuration I to configuration F. We show that the path Π can be shortened unless the C-segment C_3 is strongly $\mathcal{PP}$-anchored. Assume without loss of generality that the C_3 is oriented counterclockwise, and refer to Figure 3.4.

First perturbation. We first apply the perturbation shown in Figure 3.4a which transforms the path $\Pi = S_1 C_3 S_5$ into a path $\Pi'(\varepsilon_1) = S_1' C_2' C_3' S_5'$ by reducing the

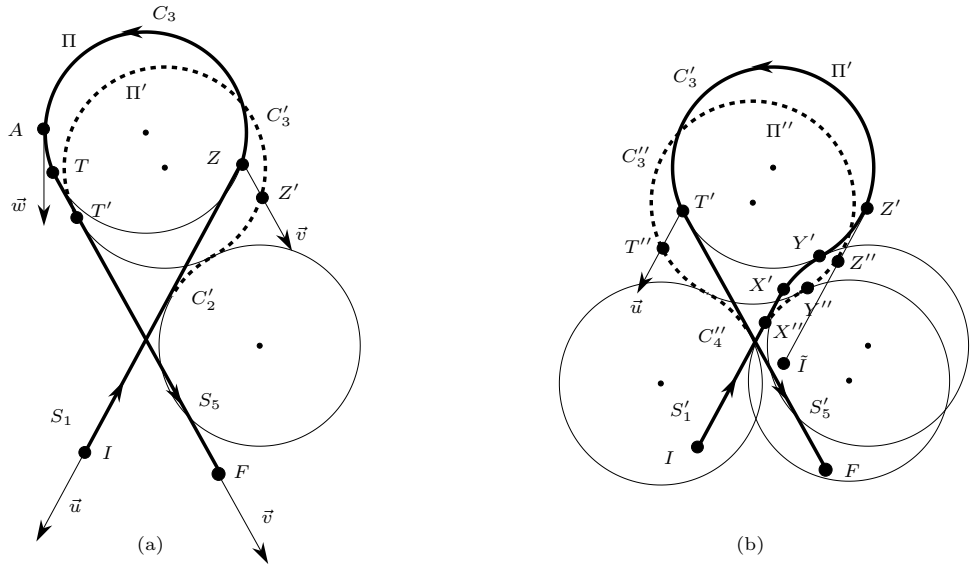

FIG. 3.4. *For the proof of Lemma* 3.4(i).

length of S_5 by a small value ε_1 (i.e., $\|S_5'\| = \|S_5\| - \varepsilon_1$), such that the new segment C_2' is oriented clockwise and is smaller than π. (Segment C_3' is naturally oriented counterclockwise.) For simplicity, in what follows, we denote $\Pi'(\varepsilon_1)$ by Π'.

CLAIM 3.7 (Dubins [15]). *In an obstacle-free environment, path* Π' *is shorter than* Π *for any* $\varepsilon_1 > 0$ *small enough.*

This directly yields that, if the optimal path $S_1C_3S_5$ is tangent to $\partial\mathcal{P}$ at the junction between C_3 and S_5, then the perturbed path Π' has shortened in $\mathcal{P}$ unless C_3 is strongly $\mathcal{PP}$-anchored. By symmetry, we get the same result if the path Π is tangent to $\partial\mathcal{P}$ at the junction between S_1 and C_3. Therefore, we can assume in the following that neither S_1 nor S_5 is touching $\partial\mathcal{P}$.

Second perturbation. We now transform (see Figure 3.4b) the path $\Pi' = S_1'C_2'C_3'S_5'$ into a path $\Pi''(\varepsilon_1, \varepsilon_2) = S_1''C_2''C_3''C_4''S_5''$ by reducing the length of S_1' by a small value ε_2 (i.e., $\|S_1''\| = \|S_1'\| - \varepsilon_2$), such that the length of C_2' does not change (i.e., $\|C_2''\| = \|C_2'\|$) and the new segment C_4'' is oriented clockwise and is smaller than π. (Segments C_2'' and C_3'' are naturally oriented clockwise and counterclockwise, respectively.) For simplicity, we denote $\Pi''(\varepsilon_1, \varepsilon_2)$ by Π''.

CLAIM 3.8. *In an obstacle-free environment, path* Π'' *is shorter than* Π' *for any* $\varepsilon_2 > 0$ *small enough.*

Proof. Refer to Figure 3.4b. Let Y' be the first point of C_3', and let Z' be the first point on C_3' such that the tangent to C_3 at Z' is parallel to the line segment S_1. Point Z' exists on C_3' because, by construction, $\|C_2'\| < \pi$ and $\|C_3'\| > \pi$. Furthermore, $\|C_2'\| = \|C_3'[Y', Z']\|$. We define similarly points Y'' and Z'' on C_3''. Then it follows from $\|C_2'\| = \|C_2''\|$ that $\|C_3'[Y', Z']\| = \|C_3''[Y'', Z'']\|$. Thus, if X' and X'' denote the first point of the segments C_2' and C_2'', respectively, we get $\|\Pi'[X', Z']\| = \|\Pi''[X'', Z'']\|$.

Now let $\tilde{I}$ be the point defined by $\overrightarrow{\tilde{I}Z'} = \overrightarrow{IX'}$ (or $\overrightarrow{I\tilde{I}} = \overrightarrow{X'Z'} = \overrightarrow{X''Z''}$). Let $\tilde{\Pi}'$ be the path from $\tilde{I}$ to F that is the concatenation of the line segment $\tilde{I}Z'$ and $\Pi'[Z', F]$. Similarly, let $\tilde{\Pi}''$ be the path from $\tilde{I}$ to F that is the concatenation of the line segment

$\tilde{I}Z''$ and $\Pi''[Z'', F]$. We get, by construction, that $\|\tilde{\Pi}'\| = \|\Pi'\| - \|\Pi'[X', Z']\|$ and $\|\tilde{\Pi}''\| = \|\Pi''\| - \|\Pi''[X'', Z'']\|$. Since $\|\Pi'[X', Z']\| = \|\Pi''[X'', Z'']\|$, $\|\tilde{\Pi}'\| - \|\tilde{\Pi}''\| = \|\Pi'\| - \|\Pi''\|$. However, we know that $\tilde{\Pi}''$ is shorter than $\tilde{\Pi}'$ because $\tilde{\Pi}''$ is obtained by the Dubins' length-reducing perturbation, shown in Figure 3.4a, applied on the reversed path of $\tilde{\Pi}'$, which is of type SCS. Thus Π'' is shorter than Π' in an obstacle-free environment for any $\varepsilon_2 > 0$ small enough. □

CLAIM 3.9. *If the C-segment C_3 in the optimal path $\Pi = S_1C_3S_5$ is not strongly $\mathcal{PP}$-anchored, then we can choose ε_1 and ε_2 arbitrarily small such that Π'' is free in $\mathcal{P}$.*

Proof. Let $\vec{u}$ be the unit vector whose direction is opposite the direction of S_1, and let $\vec{v}$ be the unit vector whose direction is the same as the direction of S_5. See Figure 3.4a.

In the two perturbations described above, the lengths of C_3 and C_3' increase. More precisely, the translated copy of C_3 by vector $\varepsilon_1\vec{v}$ is part of C_3', and the translated copy of C_3' by vector $\varepsilon_2\vec{u}$ is part of C_3''. Thus, if Z'' and T'' are the translated copies of the endpoints of C_3 by vector $\varepsilon_1\vec{v}+\varepsilon_2\vec{u}$, Π'' is the concatenation of $\Pi''[I, Z'']$, $\Pi''[Z'', T'']$, and $\Pi''[T'', F]$, where $\Pi''[Z'', T'']$ is the translated copy of C_3 by vector $\varepsilon_1\vec{v} + \varepsilon_2\vec{u}$. On the other hand, any arbitrarily small neighborhood around S_1 (respectively, S_5) contains $\Pi''[I, Z'']$ (respectively, $\Pi''[T'', F]$) for any ε_1 and ε_2 small enough. Thus, since we assumed that neither S_1 nor S_5 touches $\partial\mathcal{P}$, neither $\Pi''[I, Z'']$ nor $\Pi''[T'', F]$ touches $\partial\mathcal{P}$ for any ε_1 and ε_2 small enough. Thus it is sufficient to show that, if C_3 is not strongly $\mathcal{PP}$-anchored, then we can choose ε_1 and ε_2 arbitrarily small such that the translated copy of C_3 by vector $\varepsilon_1\vec{v} + \varepsilon_2\vec{u}$ is free.

Let A be the last point of tangency on C_3 with $\partial\mathcal{P}$. Let $\vec{w}$ be the unit vector tangent to C_3 at A (with direction corresponding to the orientation of C_3). If C_3 is not strongly $\mathcal{PP}$-anchored, then, for any $\mu > 0$ small enough, the translated copy of C_3 by $\mu\vec{w}$ is free. On the other hand, for λ_1 and λ_2 such that $\vec{w} = \lambda_1\vec{v} + \lambda_2\vec{u}$, the λ_1 and λ_2 are nonnegative because, by Lemma 2.4, the distance on C_3 between the first point of C_3 and A is greater than π. Therefore, if C_3 is not strongly $\mathcal{PP}$-anchored, then, for any $\mu > 0$ small enough, the path Π'' defined with $\varepsilon_1 = \mu\lambda_1$ and $\varepsilon_2 = \mu\lambda_2$ is free in $\mathcal{P}$. □

By Claims 3.7, 3.8, and 3.9, if the C-segment C_3 in the optimal path $\Pi = S_1C_3S_5$ is not strongly $\mathcal{PP}$-anchored, then we can choose ε_1 and ε_2 arbitrarily small so that Π'' is free and shorter than Π. This concludes the proof of Lemma 3.4(i).

3.1.2. Proof of Lemma 3.4(ii). We prove Lemma 3.4(ii), which states

> *If an optimal path has a subpath of type $C_1C_2C_3S$ (or $SC_3C_2C_1$) so that the C-segment C_2 does not touch $\partial\mathcal{P}$, then C_3 is strongly $\mathcal{PP}$-anchored.*

Consider an optimal path $\Pi = C_1C_2C_3S$ from configuration I to configuration F so that the C-segment C_2 does not touch $\partial\mathcal{P}$. We prove that the C-segment C_3 is strongly $\mathcal{PP}$-anchored. Assume without loss of generality that C_1 is oriented counterclockwise. We assume, for a contradiction, that C_3 is not strongly $\mathcal{PP}$-anchored and show that the path Π can be shortened in $\mathcal{P}$.

Notation. Let O_i, $i = 1, 2, 3$, denote the center of the circle supporting the C-segment C_i of Π. See Figure 3.5a. Let X denote the point of tangency between the C-segments C_2 and C_3, and let Y denote the antipodal point of X on C_3 ($\|C_3\| > \pi$ by Lemma 2.3). Let Z be the point of tangency between the C-segment C_3 and the S-segment. Let T be the last point of tangency with $\partial\mathcal{P}$ on the (oriented) circular arc $\Pi[Y, Z]$; such a point exists by Lemma 2.4. Let T' be the antipodal point of T on C_3.

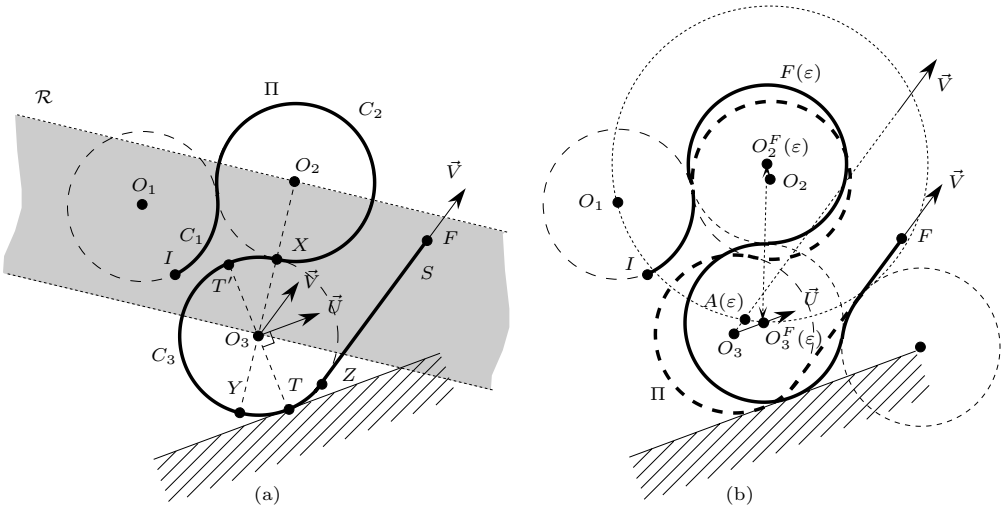

FIG. 3.5. (a) *Path* Π. (b) *A shorter path* $F(\varepsilon)$.

By definition, the circular arc $\Pi(T, Z]$ does not touch $\partial\mathcal{P}$. Furthermore, the circular arc $\Pi[X, T')$ does not touch $\partial\mathcal{P}$ because otherwise C_3 would be strongly $\mathcal{PP}$-anchored. Let $\vec{U}$ be a unit vector tangent to Π at T, and let $\vec{V}$ be a unit vector tangent to Π at any point on the S-segment of Π. Finally, let $ray(O_3, \vec{U})$ and $ray(O_3, \vec{V})$ denote the rays starting at O_3 in the directions $\vec{U}$ and $\vec{V}$, respectively.

First perturbation. Consider the perturbation shown as a thick solid path in Figure 3.5b, where Π has been perturbed into a path $F(\varepsilon)$ of type $CCCCS$. We define this perturbed path $F(\varepsilon)$ by specifying the position of the center $O_3^F(\varepsilon)$ of the supporting circle of its third circular arc, namely, $O_3^F(\varepsilon) = O_3 + \varepsilon\vec{U}$. The path $F(\varepsilon)$ is well defined for any ε small enough because the unit circle centered at $O_3^F(\varepsilon)$ intersects the S-segment of Π (by definition of $\vec{U}$); thus the fourth circular arc of $F(\varepsilon)$ is defined. Also, since the second C-segment of Π and the arcs $\Pi[X, T')$ and $\Pi(T, Z]$ do not touch $\partial\mathcal{P}$, $F(\varepsilon)$ is free for any sufficiently small values of $\varepsilon > 0$.

Second perturbation. To prove that the length of $F(\varepsilon)$ is a decreasing function of ε, we define a path $K_h(k)$ with two perturbation steps. The first step perturbs Π to a path $H(h)$, and the second step then perturbs $H(h)$ to a path $K_h(k)$. As we will show later, ε, h, and k can be chosen so that $F(\varepsilon) = K_h(k)$. Furthermore, we will show that $K_h(k)$ is shorter than Π.

Below, let $O_i^H(h)$, $O_i^K(k)$, $i = 1, 2, 3, 4$, denote the center of the circle supporting the ith C-segment of paths $H(h)$ and $K_h(k)$, respectively.

First step. The path $H(h)$ (see Figure 3.6a) is of type $CCCS$ joining I to F such that $O_1^H(h)$ is identically equal to O_1, $O_3^H(h) = O_3 + h\vec{V}$, and the length of the second circular arc is greater than π. For any h small enough, $H(h)$ is well defined.

Second step. The path $K_h(k)$ (see Figure 3.7) is defined as follows. For a given $H(h)$ and for a sufficiently small $k > 0$, path $K_h(k)$ is of type $CCCCS$ from I to F such that $O_1^K(k)$ and $O_2^K(k)$ are identically equal to O_1 and $O_2^H(h)$, respectively, $O_3^K(k)$ is at distance k counterclockwise from $O_3^H(h)$ along the circular arc of radius 2 centered at $O_2^K(k)$, and the fourth circular arc has length less than π.

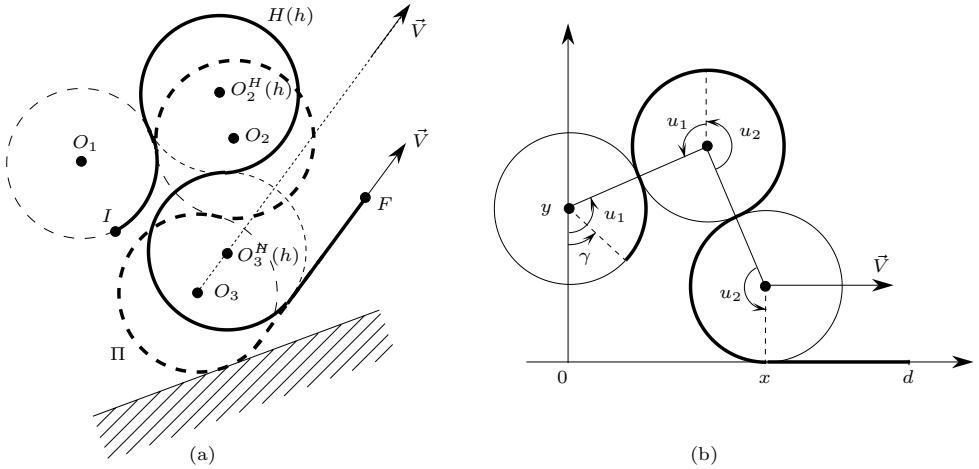

FIG. 3.6. *Length reducing perturbation: The path $H(h)$ is shorter than* Π.

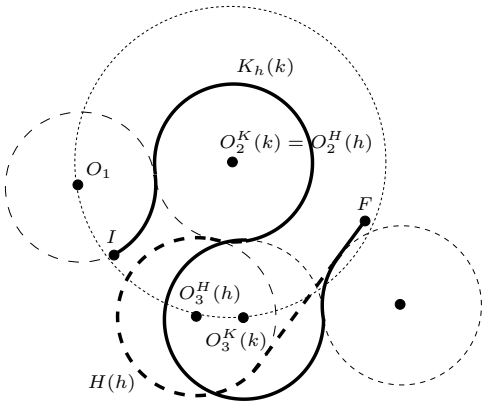

FIG. 3.7. *Dubins' length reducing perturbation: The path $K_h(k)$ is shorter than $H(h)$.*

CLAIM 3.10. *For a given sufficiently small $\varepsilon > 0$, h and k can be chosen such that $F(\varepsilon) = K_h(k)$.*

Proof. Let $\mathcal{R}$ be the open strip bounded by two lines perpendicular to the line O_2O_3 and passing through O_2 and O_3, respectively (see Figure 3.5a). Since the lengths of the circular arcs $\Pi[X,T]$ and $\Pi[X,Z]$ are greater than π by Lemmas 2.4 and 2.3(i), respectively, $ray(O_3,\vec{U})$ and $ray(O_3,\vec{V})$ are directed into $\mathcal{R}$. Thus, for any sufficiently small ε, $O_3^F(\varepsilon)$ belongs to $\mathcal{R}$, and the distance between $O_3^F(\varepsilon)$ and O_2 is less than 2. Consequently, it can be shown that $O_2^F(\varepsilon)$ must lie outside $\mathcal{R}$ on the circle of radius 2 centered at O_1. It follows that, for any open neighborhood $\mathcal{N}$ of O_3, any choice of ε sufficiently small ensures that the circle of radius 2 centered at $O_2^F(\varepsilon)$ intersects $ray(O_3,\vec{U})$ and $ray(O_3,\vec{V})$ in $\mathcal{N}$ (see Figure 3.5b). Let $A(\varepsilon)$ denote the intersection of that circle with $ray(O_3,\vec{V})$ in $\mathcal{N}$; recall that the intersection, in $\mathcal{N}$, of that circle with $ray(O_3,\vec{U})$ is $O_3^F(\varepsilon)$. The polar angle of $ray(O_3,\vec{V})$ is bigger than the polar angle of $ray(O_3,\vec{U})$ by an amount smaller than π. Thus, for ε small enough, the counterclockwise oriented arc, denoted $arc(A(\varepsilon),O_3^F(\varepsilon))$, of the circle of radius 2 centered at $O_2^F(\varepsilon)$ starting at $A(\varepsilon)$ and ending at $O_3^F(\varepsilon)$ is also contained in

the neighborhood $\mathcal{N}$; indeed, since $A(\varepsilon)$ and $O_3^F(\varepsilon)$ converge to O_3 when ε tends to 0, $arc(A(\varepsilon), O_3^F(\varepsilon))$ also tends to O_3 when ε tends to 0. Therefore, we can choose ε such that the line segment $[O_3, A(\varepsilon)]$ and the circular arc $arc(A(\varepsilon), O_3^F(\varepsilon))$ are arbitrarily small.

Choose h equal to the length of the line segment $[O_3, A(\varepsilon)]$, and choose k equal to the length of the circular arc $arc(A(\varepsilon), O_3^F(\varepsilon))$. Then $O_3^H(h) = A(\varepsilon)$ and $O_3^K(k) = O_3(\varepsilon)$, and therefore $K(k) = F(\varepsilon)$. Moreover, we have shown that we can choose ε small enough such that h and k are arbitrarily small. □

CLAIM 3.11. *The length of $K_h(k)$ is strictly smaller than the length of Π for any h and k sufficiently small.*

Proof. The length of $K_h(k)$ has been shown by Dubins [15] to be strictly shorter than the length of $K_h(0) = H(h)$ for any fixed h and for any small enough $k > 0$. Furthermore, the length of $K_h(0) = H(h)$ has been shown in [7] to be strictly shorter than the length of Π. For completeness, we give the proof here. Consider a path of type $CCCS$ such that the length of the second circular arc is greater than π. With the notation of Figure 3.6b, the length of the path is equal to $L = 2(u_1 + u_2) - \gamma + d - x$, where γ and d are some constants. Furthermore, we have

$$\begin{cases} \sin(u_1) + \sin(u_2) = x/2, \\ \cos(u_1) - \cos(u_2) = (y-1)/2. \end{cases}$$

By computing the derivative of each equation with respect to x and solving the system, we obtain the following solution (which is defined, since $(u_1 + u_2) \in (\pi, 2\pi)$, by hypothesis):

$$\begin{cases} \dfrac{\partial u_1}{\partial x} = \dfrac{\sin(u_2)}{2\sin(u_1+u_2)}, \\ \dfrac{\partial u_2}{\partial x} = \dfrac{\sin(u_1)}{2\sin(u_1+u_2)}. \end{cases}$$

Therefore,

$$\frac{\partial L}{\partial x} = \frac{\sin(u_1) + \sin(u_2)}{\sin(u_1+u_2)} - 1 = \frac{\cos\left(\frac{u_1-u_2}{2}\right) - \cos\left(\frac{u_1+u_2}{2}\right)}{\cos\left(\frac{u_1+u_2}{2}\right)}.$$

Since u_1 and u_2 are positive and $(u_1 + u_2) \in (\pi, 2\pi)$, $0 \leqslant \frac{|u_1-u_2|}{2} < \frac{|u_1+u_2|}{2} < \pi$, and thus $\cos\left(\frac{u_1-u_2}{2}\right) > \cos\left(\frac{u_1+u_2}{2}\right)$. Furthermore, $\cos\left(\frac{u_1+u_2}{2}\right) < 0$ since $\frac{u_1+u_2}{2} \in (\frac{\pi}{2}, \pi)$. Therefore, $\partial L/\partial x$ is negative, which means that, as long as $H(h)$ is of type $CCCS$ with the second circular arc greater than π, the length of $H(h)$ is a decreasing function of h. Hence we have shown that the length of $K_h(k)$ is smaller than the length of Π for any h and k sufficiently small. □

To complete the proof of Lemma 3.4(ii), recall that $F(\varepsilon)$ is free in $\mathcal{P}$ for any ε small enough. By Claims 3.10 and 3.11, there exist arbitrarily small values of ε, h, k such that $F(\varepsilon) = K_h(k)$, where the length of $K_h(k)$ is strictly less than the length of Π. This contradicts the optimality of Π and completes the proof.

4. A simple algorithm. Theorem 3.1 can be used to obtain the following simple algorithm for computing an optimal path inside $\mathcal{P}$. We enumerate candidate paths of types described in Theorem 3.1. Our candidate set is guaranteed to contain an optimal path, if any exist. For each such path, we check whether it is feasible and, if so, compute its length. Finally, we either return the shortest feasible path or report that no feasible path exists.

In order to determine whether a path is feasible, we rely on the circle-shooting data structure by Cheng et al. [10] that preprocesses $\mathcal{P}$ in $O(n \log n)$ time into a data structure of linear size that makes it possible to determine in $O(\log n)$ time whether a given circular arc of unit radius intersects $\partial\mathcal{P}$. This immediately implies the following lemma.

LEMMA 4.1. *$\mathcal{P}$ can be preprocessed in $O(n \log n)$ time into a data structure of linear size that enables us to determine in $O(m \log n)$ time whether a given path consisting of m C- and S-segments is feasible.*

To bound the running time of this simple algorithm, we must count the number of candidate paths to check. We note that, once a path type is given and the supporting circles for C-segments are known, there are $O(1)$ candidate paths. These are determined by the choices of the orientations for the C-segments. Hence we are interested in the number of possible supporting circles for each path type. Note that there may be $\Omega(n^2)$ $\mathcal{PP}$-anchored circles (see Lemma 5.3) and $\Omega(n)$ $\mathcal{PC}$-anchored circles.

There are $O(1)$ Dubins path candidates. For paths of types (A.i) and (B.ii), once the $\mathcal{PP}$-anchored circle is chosen, there are $O(1)$ choices for other supporting circles and hence $O(1)$ candidate paths. Since there are $O(n^2)$ $\mathcal{PP}$-anchored circles, there are $O(n^2)$ candidate paths for these two path types.

A path of type (A.ii) may have up to two $\mathcal{PC}$-anchored segments. Once their supporting circles are chosen, there are $O(1)$ path candidates. There are $O(n)$ potential $\mathcal{PC}$-anchored circles. If both anchored segments are present, we have $O(n^2)$ paths to check; otherwise, we have only $O(n)$. Paths of type (B.i) are also determined by a $\mathcal{PC}$-anchored circle; hence there are $O(n)$ of them.

Paths of type (B.iii), i.e., of type $C_I\bar{\bar{C}}_1S\bar{C}_2\bar{C}_3S\bar{\bar{C}}_4C_F$, present a special problem. If we know the supporting circles of the $\bar{C}\bar{C}$ subpath, the rest of the path is determined by a pair of $\mathcal{PC}$-anchored circles $\mathcal{C}_1, \mathcal{C}_4$, for which there are $O(n^2)$ possibilities. Unfortunately, there is an infinite family of supporting circles for the $\bar{C}\bar{C}$ subpath. The following result by Boissonnat and Lazard [6] allows us to consider only a finite set of $\bar{C}\bar{C}$ subpaths.

LEMMA 4.2 (Boissonnat and Lazard [6]). *Given two configurations X and Y and two edges e, e' of $\mathcal{P}$, we can compute[4] in $O(1)$ time a finite set of paths from X to Y of type $C_1S\bar{C}_2\bar{C}_3SC_4$, where $\bar{C}_2$ and $\bar{C}_3$ are tangent to edges e and e', respectively. This set contains all optimal paths from X to Y of type $C_1S\bar{C}_2\bar{C}_3SC_4$.*

Given a pair of edges e, e' and a pair of $\mathcal{PC}$-anchored circles $\mathcal{C}_1, \mathcal{C}_4$, tangent to C_I and C_F, respectively, we choose X to be the configuration determined by the intersection of C_I and $\mathcal{C}_1$ and Y to be the configuration determined by C_F and $\mathcal{C}_4$. By the above lemma, we can compute in $O(1)$ time a constant number of candidate paths for this pair of edges and anchored circles. Doing this for all possible pairs of edges (e, e') and pairs of supporting circles $(\mathcal{C}_1, \mathcal{C}_4)$, we determine $O(n^4)$ path candidates of type (B.iii) in $O(n^4)$ time.

In summary, the simple algorithm examines $O(n^4)$ candidate paths and, for each, spends $O(\log n)$ time checking feasibility, by Lemma 4.1 with $m \leqslant 8$. Therefore, the overall running time is $O(n^4 \log n)$.

PROPOSITION 4.3. *Given a convex polygon $\mathcal{P}$, an initial configuration I, and a final configuration F, an optimal path from I to F inside $\mathcal{P}$ can be computed in time $O(n^4 \log n)$.*

[4]The computation is performed by solving four algebraic systems of three equations in three indeterminates.

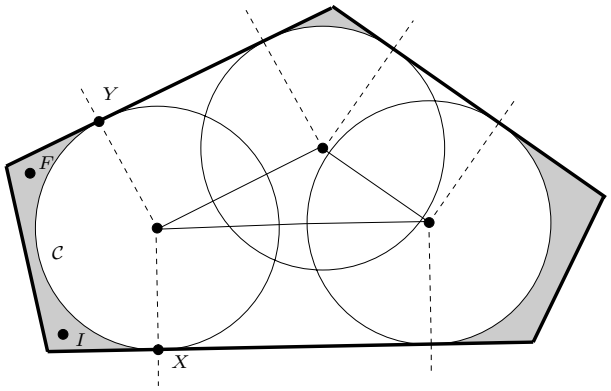

FIG. 5.1. *The free circle $\mathcal{C}$ is centered on the retracted polygon of $\mathcal{P}$.*

5. An efficient algorithm. In this section, we prove additional properties of optimal paths that significantly reduce the number of candidates to examine. We have already shown that we need to consider only $O(1)$ Dubins paths and $O(n)$ candidates for paths of type (B.i). We will show that it suffices to consider only $O(1)$ candidate paths of types (A.i) and (B.ii), $O(n)$ candidate paths of type (A.ii), and $O(n^2)$ candidate paths of type (B.iii).

5.1. Computing paths of types (A.i) and (B.ii). The paths of types (A.i) and (B.ii) contain a strongly $\mathcal{PP}$-anchored C-segment $\bar{\bar{C}}$. The circle $\bar{\bar{\mathcal{C}}}$ supporting $\bar{\bar{C}}$ defines one or two pockets that contain a point of tangency of $\bar{\bar{\mathcal{C}}}$ with $\partial\mathcal{P}$ (see Figures 2.4b and 3.2). By Lemma 2.7, we know that I and F must belong to these pockets. The following lemma states that there exist at most two circles with these properties and that they can be computed efficiently.

LEMMA 5.1. *For a fixed pair of locations I, F, there exist at most two circles that can support a strongly $\mathcal{PP}$-anchored C-segment appearing in an optimal path from I to F, and they can be computed in $O(n)$ time.*

Proof. Consider a strongly $\mathcal{PP}$-anchored segment that lies in an optimal path. Let X and Y denote its points of tangency with $\partial\mathcal{P}$, and let $\mathcal{C}$ denote its supporting circle. Assume without loss of generality that the short arc on $\mathcal{C}$ joining X and Y is $\mathcal{C}^-[X, Y]$ (see Figure 5.1). The proof of the lemma is divided into two cases, which depend on whether or not $\mathcal{C}$ is free.

Case 1. *$\mathcal{C}$ is free.* The center of $\mathcal{C}$ lies at a vertex of the retracted polygon of $\mathcal{P}$ (i.e., the set of points p such that the unit circle centered at p lies inside $\mathcal{P}$). By computing the retracted polygon of $\mathcal{P}$ in linear time, we get (in linear time) the set of the $O(n)$ free $\mathcal{PP}$-anchored circles which contains $\mathcal{C}$. Each of these circles defines one pocket, and all of these pockets are pairwise disjoint (see Figure 5.1). Thus only one of these pockets contains I and F; hence, by Lemma 2.7, $\mathcal{C}$ must be the circle defining this pocket. For each of the $O(n)$ free $\mathcal{PP}$-anchored circles, we can easily check, in $O(1)$ time, whether I and F belong to the corresponding pocket. Indeed (see Figure 5.1), $I, F \in \mathcal{P}$ belong to the pocket if and only if I and F are outside the circle and are in the small wedge defined by the rays emanating from the center of the circle and passing through the points of tangency of the circle with $\partial\mathcal{P}$.

Case 2. *$\mathcal{C}$ is not free.* $\mathcal{C}$ defines two pockets $\Lambda_{\mathcal{C}}[X, X']$ and $\Lambda_{\mathcal{C}}[Y, Y']$ (see Figure 5.2). By Lemma 2.7, one of these pockets contains I, and the other contains F. Thus $I \neq F$, and the line L_{IF} through I and F is defined. Let A and B denote the intersection points of L_{IF} with $\partial\mathcal{P}$.

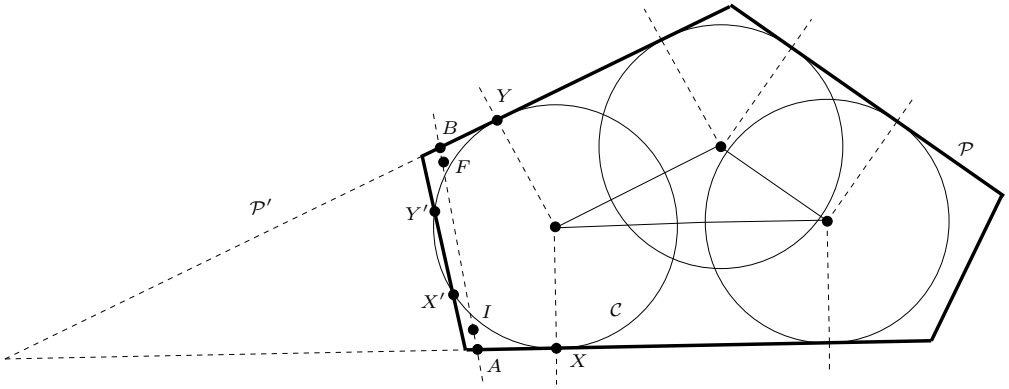

FIG. 5.2. *The nonfree circle $\mathcal{C}$ is centered on the retracted chain of $\partial\mathcal{P}^+[A,B]$.*

With no loss of generality, suppose $I \in \Lambda_{\mathcal{C}}[X,X']$ and $F \in \Lambda_{\mathcal{C}}[Y,Y']$. The segment $[I,F]$ must pass through $\mathcal{C}$ twice since I and F are in distinct pockets. Thus the ray emanating from I in the direction $\overrightarrow{FI}$ cannot intersect $\mathcal{C}$ and therefore leaves $\Lambda_{\mathcal{C}}[X,X']$ through $\partial\mathcal{P}^-[X,X']$. Thus $A \in \partial\mathcal{P}^-[X,X']$. A similar argument shows that $B \in \partial\mathcal{P}^+[Y,Y']$. Hence $X', Y' \notin \partial\mathcal{P}^+[A,B]$, and $X, Y \in \partial\mathcal{P}^+[A,B]$.

The chain $\partial\mathcal{P}^+[A,B]$ does not properly intersect $\mathcal{C}$. Indeed (see Figure 5.2), it properly intersects neither the long arc $\mathcal{C}^+[X,Y]$, by assumption, nor the small arc $\mathcal{C}^-[X,Y]$ because the first intersection between $\mathcal{C}^-[X,Y]$ (respectively, $\mathcal{C}^+[Y,X]$) and $\partial\mathcal{P}$ is X' (respectively, Y'), which does not belong to $\partial\mathcal{P}^+[A,B]$. It then follows from $X, Y \in \partial\mathcal{P}^+[A,B]$ that the circle $\mathcal{C}$ is a free anchored circle in the polygon $\mathcal{P}'$ obtained by extending the two edges of $\partial\mathcal{P}^+[A,B]$ that end at A, B (see Figure 5.2). Moreover, the pocket defined by $\mathcal{C}$ in $\mathcal{P}'$ contains the two pockets $\Lambda_{\mathcal{C}}[X,X']$ and $\Lambda_{\mathcal{C}}[Y,Y']$ and thus contains I and F. As before, at most one free anchored circle in $\mathcal{P}'$ defines a pocket containing I and F, and, given $\mathcal{P}'$, it can be computed in $O(n)$ time.

Note finally that polygon $\mathcal{P}'$ can be determined in $O(n)$ time. This is because I and F determine the points A and B, and the turning angle of $\partial\mathcal{P}^+[A,B]$ is bigger than π. Thus, independent of any assumption about the orientation of the short arc on $\mathcal{C}$ joining X and Y, whether $\mathcal{P}'$ is the polygon obtained by extending the two edges (ending at A, B) of $\partial\mathcal{P}^+[A,B]$ or of $\partial\mathcal{P}^-[A,B]$ can be determined simply by checking which of the turning angles of $\partial\mathcal{P}^+[A,B]$ and $\partial\mathcal{P}^-[A,B]$ is bigger than π.

Hence we have proved that, for a fixed pair of locations I and F, there exist at most two $\mathcal{PP}$-anchored circles (one free and the other nonfree) that can appear in an optimal path from I to F, and they can be computed in $O(n)$ time. □

By the above lemma, we can compute, in $O(n)$ time, a set of $O(1)$ candidate paths of types (A.i) and (B.ii). The candidate paths may be checked for feasibility in $O(\log n)$ time. Therefore, we have the following lemma.

LEMMA 5.2. *An optimal path of type* (A.i) *or* (B.ii) *can be computed in $O(n)$ time.*

The following proposition shows that Lemma 5.1 is essential for establishing the linear running time given in Lemma 5.2; indeed, an algorithm that checked all candidate strongly $\mathcal{PP}$-anchored circles to produce candidate paths would have running time $\Omega(n^2)$.

PROPOSITION 5.3. *There exist convex n-polygons that have $\Omega(n^2)$ strongly $\mathcal{PP}$-anchored circles.*

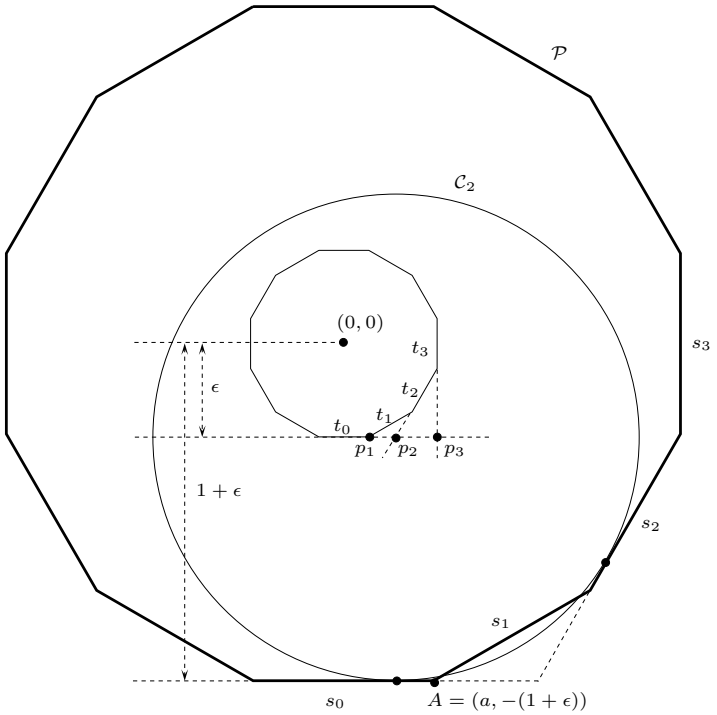

FIG. 5.3. *The circles $\mathcal{C}_i$ centered at p_i, $i = 1,\ 2,\ 3 = \frac{n}{4}$, are strongly $\mathcal{PP}$-anchored: They are tangent to s_0 and s_i, and their long arcs are free.*

Proof. Let $n \geqslant 8$ be a multiple of 4, and let $0 < \epsilon < \tan(\pi/n)$ be a real parameter. Let $\mathcal{P}$ be an n-regular polygon centered at the origin with in-radius $(1+\epsilon)$; i.e., the distance from the origin to each side of $\mathcal{P}$ is $(1+\epsilon)$. We assume that one of the edges, say, s_0, of $\mathcal{P}$ is parallel to the x-axis and lies below the x-axis; see Figure 5.3. The coordinates of the right endpoint of s_0 are $(a, 0)$, where $a = (1+\epsilon)\tan(\pi/n)$. Let the edges of $\mathcal{P}$ in the counterclockwise sense be $s_0, s_1, s_2, \ldots, s_{n-1}$.

The retracted polygon of $\mathcal{P}$ (i.e., the set of points p such that the unit circle centered at p lies inside $\mathcal{P}$) is an n-regular polygon with radius ϵ. Denote its sides by $t_0, t_1, \ldots, t_{n-1}$, where t_i is the retraction of s_i for $0 \leqslant i < n$. For $i = 1, \ldots, n/4$, denote by $p_i = (x_i, -\epsilon)$ the intersection point of the lines supporting t_i and t_0 and by $\mathcal{C}_i$ the unit circle centered at p_i. It is easily seen that $0 < x_1 < \cdots < x_{n/4} \leqslant \epsilon$.

Since the x-coordinate of the point at which $\mathcal{C}_i$ touches the line supporting s_0 is x_i and $x_i < \epsilon < \tan(\pi/n) < a$, $\mathcal{C}_i$ is tangent to s_0 for any $1 \leqslant i \leqslant n/4$. A symmetric argument shows that $\mathcal{C}_i$ is tangent to s_i.

Therefore, we can assign $n/4$ $\mathcal{PP}$-anchored circles to every side of $\mathcal{P}$, and the number of $\mathcal{PP}$-anchored circles of $\mathcal{P}$ is $\Omega(n^2)$. It remains to show that these $\mathcal{PP}$-anchored circles are strongly $\mathcal{PP}$-anchored.

As can be seen from Figure 5.3, the point p_i is a vertex of the polygon defined by the two lines through t_0 and t_i and the edges $t_{i+1}, \ldots, t_{n-1}$. Thus p_i is in the retracted polygon of the polygon formed by the two lines through s_0 and s_i and the edges $s_{i+1}, \ldots, s_{n-1}$. Therefore, $\mathcal{C}_i$ does not properly intersect any of $s_{i+1}, \ldots, s_{n-1}$, and its long arc is free, so $\mathcal{C}_i$ is indeed a strongly $\mathcal{PP}$-anchored circle. ∎

5.2. A monotonicity property of CCSC paths. Subpaths of type $CCSC$ occur in both (A.ii) and (B.iii) path types. In this subsection, we ignore the polygon $\mathcal{P}$ and study paths from X to Y of type $C_1C_2SC_3$, with specified orientations on C_1 and C_3; the orientation of C_1 fixes the orientation of C_2; namely, if C_1 is oriented clockwise (respectively, counterclockwise), then C_2 is oriented counterclockwise (respectively, clockwise).

The positions of circles $\mathcal{C}_1$ and $\mathcal{C}_3$, supporting C_1 and C_3, respectively, are considered fixed, while the position of circle $\mathcal{C}_2$ is determined by M, its point of tangency with $\mathcal{C}_1$. The orientations of these three circles are fixed by the orientations of the corresponding C-segments. The S-segment is determined by the appropriate tangent line, given the orientations on C_2 and C_3. This tangent, if it exists, is unique.

For each $M \in \mathcal{C}_1$, there is at most one path, denoted $\Pi(M)$, from X to Y of type $C_1C_2SC_3$ with the specified orientations on the C_1- and C_3-segments. We are interested in how the path length $\|\Pi(M)\|$ changes as M moves along $\mathcal{C}_1$ in the same direction as the segment C_1.

For certain positions of M, one or more of the segments of $\Pi(M)$ may vanish. For example, when $M = X$, the length of the first segment C_1 changes discontinuously from 2π to 0. At such points, the path length may change discontinuously, so these positions of M are called *singular points* of $\Pi(M)$.

LEMMA 5.4. *Given two configurations X and Y, the paths $\Pi(M)$ of type $C_1C_2SC_3$ from X to Y with specified orientations on the C_1- and C_3-segments admit at most six singular points, and their locations can be computed in $O(1)$ time.*

Proof. We enumerate the possibilities for a segment to vanish in the paths $\Pi(M)$. Figure 5.4 illustrates the six singular points in a path of type $C_1^+C_2^-SC_3^+$.

Segment C_1 vanishes if and only if $M = X$, so X is the only singular point such that C_1 vanishes.

Segment C_2 vanishes if and only if the path type degenerates to C_1SC_3. Then the point M on $\mathcal{C}_1$ is also on the S-segment. Since there is at most one S-segment tangent to $\mathcal{C}_1$ and $\mathcal{C}_3$ that respects their specified orientations, there is at most one singular point $M_1 \in \mathcal{C}_1$ such that C_2 vanishes.

Segment S vanishes if and only if the path type degenerates to either $C_1C_2C_3$ if C_2 and C_3 have opposite orientations or C_1C_2 otherwise. Thus there are at most two singular points $M_2, M_3 \in \mathcal{C}_1$ (common point of C_1 and C_2) such that S vanishes.

Segment C_3 vanishes if and only if the path type degenerates to C_1C_2S. This means that L_Y, the line passing through the configuration Y, is tangent to $\mathcal{C}_2$. There are at most two circles $\mathcal{C}_2$ tangent to $\mathcal{C}_1$ and L_Y that respect the orientations of $\mathcal{C}_1$ and L_Y. Thus there are at most two singular points M_4, M_5 such that C_3 vanishes.

In total, there are no more than six singular points, and they can clearly be computed in $O(1)$ time. □

We next state the monotonicity property of the paths $\Pi(M)$.

LEMMA 5.5. *$\|\Pi(M)\|$ strictly increases as M moves along the oriented circle $\mathcal{C}_1$ between singular points, except when $\mathcal{C}_1$ and $\mathcal{C}_3$ are identical with the same orientation, in which case $\|\Pi(M)\|$ is constant as M moves between singular points.*

Proof. There are four possible orientation assignments for the circles: $C_1^+C_2^-SC_3^+$, $C_1^+C_2^-SC_3^-$, $C_1^-C_2^+SC_3^-$, and $C_1^-C_2^+SC_3^+$. We prove the claim for the first two cases; the other two cases can be proved using a symmetric argument.

Consider a path $\Pi(M)$. Let $\alpha_1 = \|\mathcal{C}_1^+[X, M]\|$ be the length of the first C-segment. Since there is a one-to-one mapping between α_1 and M, we can parameterize Π by α_1. Let $\alpha_2 = \alpha_2(\alpha_1)$, $\alpha_3 = \alpha_3(\alpha_1)$ be the length of the second and third C-segments

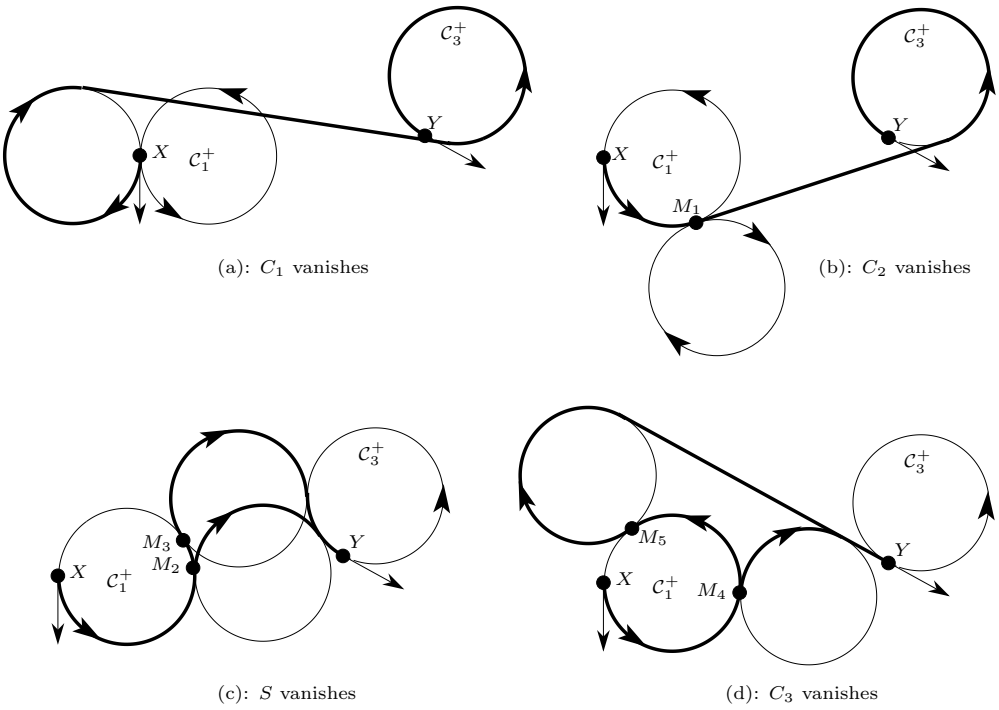

FIG. 5.4. *Paths of type $C_1^+C_2^-SC_3^+$ from X to Y and the six singular points X, M_1, M_2, M_3, M_4, and M_5 on $\mathcal{C}_X^+$.*

of $\Pi(\alpha_1)$, and let $2s = 2s(\alpha_1)$ be the length of the S-segment of $\Pi(\alpha_1)$. Let O_i be the center of the circle $\mathcal{C}_i$ supporting C_i, $i = 1, 2, 3$. Although O_1 and O_3 are fixed, O_2 depends on α_1. By definition,

$$L(\alpha_1) = \|\Pi(\alpha_1)\| = \alpha_1 + \alpha_2 + 2s + \alpha_3. \tag{5.1}$$

As M moves continuously on $\mathcal{C}_1$, the length of every segment in path $\Pi(M)$ changes continuously, except at singular points and at points for which $\Pi(M)$ is not defined (i.e., when $\mathcal{C}_2$ and $\mathcal{C}_3$ have opposite orientation and properly intersect). It follows that the segment lengths are piecewise differentiable functions of α_1 and that L is a piecewise differentiable function of α_1 on the intervals of $[0, 2\pi)$ where the path $\Pi(\alpha_1)$ is defined. For a function $f(\alpha_1)$, we will use $f'(\alpha_1)$ to denote $\partial f/\partial\alpha_1$. Then

$$L'(\alpha_1) = 1 + \alpha_2' + 2s' + \alpha_3'. \tag{5.2}$$

We call a value of α_1 singular if the corresponding point M on $\mathcal{C}_1$ is singular. The lemma can now be restated as follows: In the open intervals between singular points, $L' > 0$ almost everywhere (i.e., at all but a finite number of points) except when $O_1 = O_3$ and $\Pi(M)$ is of type $C_1^+C_2^-SC_3^+$, in which case $L' = 0$ everywhere. The proof is divided into two cases depending on whether O_1 and O_3 are equal.

Case 1. *O_1 is distinct from O_3.* Consider the triangle $\triangle O_1O_2O_3$. See Figure 5.5. We have $\|O_1O_2\| = 2$; let $d = \|O_1O_3\|$, and let $2t = \|O_2O_3\|$. We also define two (counterclockwise) oriented angles $\alpha = \angle O_3O_1O_2$ and $\beta = \angle O_1O_2O_3$. Both angles depend on α_1. Since C_1 is oriented counterclockwise, $\alpha_1 - \alpha$ is a constant, and therefore $\alpha' = 1$.

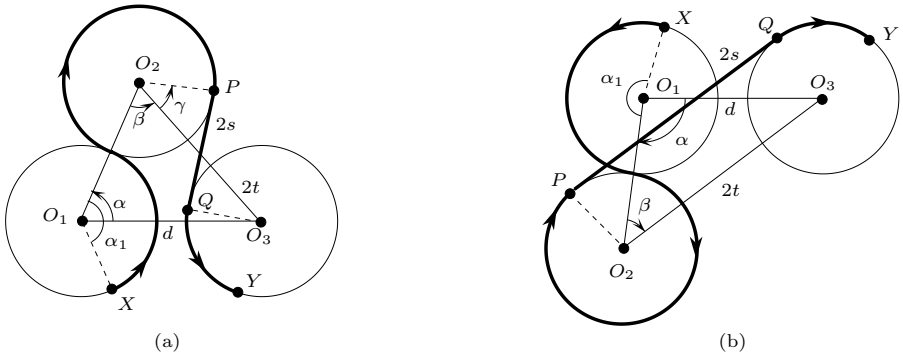

FIG. 5.5. *Paths* $\Pi(M)$ *of types* (a) $C_1^+C_2^-SC_3^+$ *and* (b) $C_1^+C_2^-SC_3^-$.

In view of the above discussion, it is sufficient to prove that $L'(\alpha_1) > 0$ for any nonsingular value of α_1 such that the path $\Pi(\alpha_1)$ is defined and $\alpha \not\equiv 0 \pmod{\pi}$; indeed, there are only a finite number of values α_1 such that $\alpha \equiv 0 \pmod{\pi}$. Since α_1 is not singular, we can assume in the following that $t \neq 0$.

By applying the cosine law to $\triangle O_1O_2O_3$, we obtain

$$4t^2 = 4 + d^2 - 4d\cos\alpha.$$

By differentiating the above equality and noting that $\alpha' = 1$, we get $2tt' = d\sin\alpha$. Applying the sine law to $\triangle O_1O_2O_3$ gives $2t\sin\beta = d\sin\alpha$, because α and β have the same sign, by definition (see Figure 5.5). It follows that

$$t' = \sin\beta. \tag{5.3}$$

We first consider the case when $\Pi(M)$ is of type $C_1^+C_2^-SC_3^-$. Recall that $\psi(X)$ is the polar angle of the tangent vector for configuration X. This angle is constant for all configurations along an S-segment. On the other hand, the angle increases by δ after traversing a C^+-segment of length δ and decreases by the same amount upon traversing a C^--segment of the same length. We therefore have the following:

$$\psi(Y) \equiv \psi(X) + \alpha_1 - \alpha_2 - \alpha_3 \pmod{2\pi}. \tag{5.4}$$

Since X and Y are fixed, we have $1 - \alpha_2' - \alpha_3' = 0$ or $\alpha_2' + \alpha_3' = 1$. Substituting this into (5.2) gives

$$L' = 2 + 2s'.$$

The S-segment is a translation of the segment O_2O_3 (see Figure 5.5b). Thus $s = t$, and hence $s' = t' = \sin\beta$ by (5.3). Thus $L' = 2 + 2\sin\beta$. Since $\Pi(M)$ is of type $C^+C^-SC^-$,

$$\beta + \pi/2 + \alpha_2 \equiv 0 \pmod{2\pi}$$

(see Figure 5.5b); indeed, $\beta = \angle O_1O_2O_3$, $\pi/2 = \angle O_3O_2P$, and $\alpha_2 = \angle PO_2O_1$. Thus $\beta \equiv 3\pi/2 \pmod{2\pi}$ if and only if $\alpha_2 \equiv 0 \pmod{2\pi}$, which occurs only at a singular point (by definition of singular points). Therefore, $L'(\alpha_1) > 0$ for any nonsingular value of α_1 for which the path $\Pi(\alpha_1)$ is defined.

We now turn to the case in which $\Pi(M)$ is of type $C_1^+C_2^-SC_3^+$. Then (5.4) is replaced by

$$\psi(Y) \equiv \psi(X) + \alpha_1 - \alpha_2 + \alpha_3 \pmod{2\pi},$$

so $\alpha_3' = \alpha_2' - 1$. Substituting this into (5.2) gives

$$L' = 2(s' + \alpha_2').$$

In order to find an expression for α_2', it is convenient to define the oriented angle $\gamma = \angle O_3O_2P$, where P is the common point between the segments C_2 and S (see Figure 5.5a). Recall that $\alpha_2 = \angle PO_2O_1$ and $\beta = \angle O_1O_2O_3$. Thus $\gamma + \alpha_2 + \beta \equiv 0 \pmod{2\pi}$, which implies that $\gamma' + \alpha_2' + \beta' = 0$ and

$$L' = 2(s' - \gamma' - \beta'). \tag{5.5}$$

We now find expressions for $s' - \gamma'$ and β'.

With P and Q denoting, respectively, the first and last points of the S-segment, it is easy to see that the segments O_2O_3, PQ, O_2P, and O_3Q form two congruent right triangles (see Figure 5.5a). Thus we have $s^2 + 1 = t^2$, whence $ss' = tt' = t\sin\beta$, using (5.3). Further, $\tan\gamma = s$, so $\gamma' = s'\cos^2\gamma$. Combining the two results,

$$s' - \gamma' = s'\sin^2\gamma = s'\left(\frac{s}{t}\right)^2 = \frac{s}{t}\sin\beta. \tag{5.6}$$

The final derivative needed is β', which again follows from the cosine law applied to triangle $\triangle O_1O_2O_3$ (see Figure 5.5a):

$$d^2 = 4 + 4t^2 - 8t\cos\beta.$$

After a differentiation and rearrangement, this yields $t\beta'\sin\beta = t'(\cos\beta - t)$. Substituting for t' using (5.3) and noting that $\alpha \not\equiv 0 \pmod{\pi}$ implies $\sin\beta \neq 0$, we obtain

$$\beta' = \frac{1}{t}(\cos\beta - t). \tag{5.7}$$

Combining (5.5), (5.6), and (5.7) yields

$$L' = \frac{2}{t}(s\sin\beta + t - \cos\beta).$$

$\Pi(\alpha_1)$ is defined only when $\mathcal{C}_2$ and $\mathcal{C}_3$ do not properly intersect. Thus $t \geqslant 1$ wherever L is defined, thereby implying that $(t - \cos\beta) \geqslant 0$ and that

$$\begin{aligned} L' \leqslant 0 &\Leftrightarrow t - \cos\beta \leqslant -s\sin\beta \\ &\Rightarrow t^2 - 2t\cos\beta + \cos^2\beta \leqslant s^2\sin^2\beta = (t^2 - 1)\sin^2\beta \\ &\Rightarrow t^2\cos^2\beta - 2t\cos\beta + 1 \leqslant 0 \\ &\Rightarrow (t\cos\beta - 1)^2 \leqslant 0 \\ &\Rightarrow \cos\beta = \frac{2}{2t}. \end{aligned}$$

Hence $L' \leqslant 0$ only if $\angle O_3O_1O_2 = \alpha \equiv \pi/2 \pmod{\pi}$ (see Figure 5.5a). Therefore, $L' > 0$ almost everywhere it is defined.

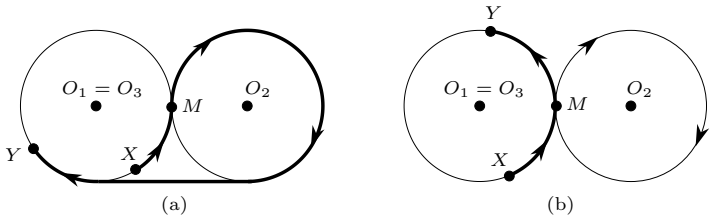

FIG. 5.6. *When $O_1 = O_3$: (a) $\Pi(M)$ is of type $C_1^+C_2^-SC_3^-$; (b) $\Pi(M)$ of type $C_1^+C_2^-SC_3^+$ degenerates to a single C-segment for any $M \in \mathcal{C}_1$.*

Case 2. *O_1 and O_3 are equal.* When $\Pi(M)$ is of type $C_1^+C_2^-SC_3^-$ (see Figure 5.6a), $\alpha_2 = 3\pi/2$ and $s = 2$; thus $L' = 1 + \alpha_3'$. Equation (5.4) still holds, and thus $\alpha_3' = 1$. Therefore, $L' = 2 > 0$ everywhere it is defined.

When $\Pi(M)$ is of type $C_1^+C_2^-SC_3^+$ (see Figure 5.6b), the circles $\mathcal{C}_1$ and $\mathcal{C}_3$ coincide and have the same orientation. Thus both segments C_2 and S vanish, $\Pi(M)$ degenerates to a C-segment, and, consequently, $L' = 0$ everywhere except when $M = X$ or Y, where L is not differentiable. ∎

5.3. Computing type (A.ii) paths. As mentioned in section 4, we can compute in $O(n \log n)$ time the feasible candidates of type (A.ii) paths with at most one $\mathcal{PC}$-anchored segment. If the path is of type $C_I\bar{\bar{C}}S\bar{\bar{C}}C_F$, a naive analysis gives $O(n^2)$ candidates to check. Using Lemma 5.5, we reduce the number of candidates to $O(n)$ and compute them in $O(n \log n)$ time, as follows.

Fix the orientations of the terminal C-segments, and let $\mathcal{C}_I$ and $\mathcal{C}_F$ denote the circles supporting C_I and C_F, respectively. Let us assume that $\mathcal{C}_I$ is oriented counterclockwise. Let $\mathcal{K}_I$ be the sequence of $\mathcal{PC}$-anchored circles that touch $\mathcal{C}_I$ and that are free, sorted by their points of tangency with $\mathcal{C}_I$. The set $\mathcal{K}_F$ is defined analogously for $\mathcal{PC}$-anchored circles tangent to $\mathcal{C}_F$. The sets $\mathcal{K}_I$ and $\mathcal{K}_F$ can be computed in $O(n \log n)$ time, and they have $O(n)$ elements.

By Lemma 3.6, the circles $\bar{\bar{\mathcal{C}}}_1$ and $\bar{\bar{\mathcal{C}}}_2$ supporting the $\bar{\bar{C}}$-segments in an optimal path Π of type $C_I\bar{\bar{C}}_1S\bar{\bar{C}}_2C_F$ are free. (Otherwise, $\bar{\bar{C}}_1$ or $\bar{\bar{C}}_2$ would be a terminal C-segment.) Therefore, the $\bar{\bar{C}}_1$-segment of Π lies on a circle of $\mathcal{K}_I$, and the $\bar{\bar{C}}_2$-segment lies on a circle of $\mathcal{K}_F$. Suppose $\mathcal{C}_2 \in \mathcal{K}_F$ supports the $\bar{\bar{C}}_2$-segment of Π. This fixes the terminal configuration of the subpath $C_I\bar{\bar{C}}_1S\bar{\bar{C}}_2$. By Lemma 5.4, there are at most six singular points, say, $\Sigma_0 = I, \ldots, \Sigma_5$, on $\mathcal{C}_I$ with respect to $\mathcal{C}_2$, sorted in the counterclockwise sense.

For $0 \leqslant i \leqslant 5$, let $\mathcal{K}_I(i) \subseteq \mathcal{K}_I$ be the contiguous subsequence of circles that touch $\mathcal{C}_I$ at a point in the arc $\mathcal{C}_I[\Sigma_i, \Sigma_{i+1}]$. By Lemma 5.5, only the first circle of $\mathcal{K}_I(i)$ is a candidate for $\mathcal{C}_1$. Hence at most six circles in $\mathcal{K}_I$ are candidates for $\mathcal{C}_1$. For each $0 \leqslant i \leqslant 5$, by performing a binary search on $\mathcal{K}_I$, we can find, in $O(\log n)$ time, the first circle of $\mathcal{K}_I$ whose point of tangency with $\mathcal{C}_I$ lies after Σ_i in the counterclockwise sense. Obviously, this is the first circle of $\mathcal{K}_I(i)$. We can therefore compute in $O(\log n)$ time at most six candidate paths for a fixed $\mathcal{C}_2 \in \mathcal{K}_F$. By examining each $\mathcal{C}_2 \in \mathcal{K}_F$ in turn, we compute $O(n)$ candidate paths in $O(n \log n)$ time. We repeat a similar procedure for all possible orientations of C_I and C_F. We can therefore conclude the following.

LEMMA 5.6. *An optimal path of type* (A.ii) *can be computed in $O(n \log n)$ time.*

5.4. Computing type (B.iii) paths. Let Π be an optimal path of the form $\Pi_I\bar{C}_2\bar{C}_3\Pi_F$, i.e., of type (B.iii). Suppose we know the edges e, e' that are tangent to $\bar{C}_2$ and $\bar{C}_3$, respectively.

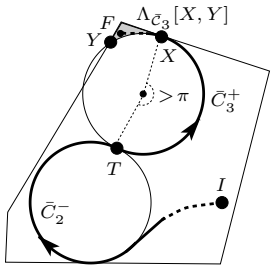

FIG. 5.7. *Illustration of the proof of Lemma* 5.7.

If Π does not contain any $\bar{\bar{C}}$-segment in Π_I or Π_F, then Π is of type $C_I S \bar{C}_2 \bar{C}_3 S C_F$. We can compute Π in $O(\log n)$ time using Lemmas 4.1 and 4.2.

Next consider the case in which Π_I and Π_F each contain a $\bar{\bar{C}}$-segment, i.e., Π is of type $C_I \bar{\bar{C}} S \bar{C}_2 \bar{C}_3 S \bar{\bar{C}} C_F$. We show that, given e and e', we can compute, in $O(\log n)$ time, a set of $O(1)$ candidate circles that contains the $\bar{\bar{C}}$-segments of Π. Given this set, we can compute in $O(\log n)$ time the shortest feasible path of the above type, using Lemmas 4.1 and 4.2. Thus, by considering all $\Theta(n^2)$ pairs of edges of $\mathcal{P}$, we can compute in $O(n^2 \log n)$ time a set of $O(n^2)$ candidate paths for this case. However, we will see later (in Lemma 5.15) that it suffices to consider fewer pairs of edges of $\mathcal{P}$ in some cases.

5.4.1. Properties of paths. We first establish some simple properties of an optimal path Π of type $C_I \bar{\bar{C}}_1 S \bar{C}_2 \bar{C}_3 S \bar{\bar{C}}_4 C_F$. Assume without loss of generality that $\bar{C}_2$ and $\bar{C}_3$ are oriented clockwise and counterclockwise, respectively. By Lemma 3.3, the $\bar{\bar{C}}_1$-segment is oriented clockwise, and the $\bar{\bar{C}}_4$-segment is oriented counterclockwise; i.e., Π is of type $C_I^+ \bar{\bar{C}}_1^- S \bar{C}_2^- \bar{C}_3^+ S \bar{\bar{C}}_4^+ C_F^-$. Let $\bar{\bar{\mathcal{C}}}_1$, $\bar{\mathcal{C}}_2$, $\bar{\mathcal{C}}_3$, and $\bar{\bar{\mathcal{C}}}_4$ denote the circles supporting the C-segments $\bar{\bar{C}}_1$, $\bar{C}_2$, $\bar{C}_3$, and $\bar{\bar{C}}_4$, respectively.

LEMMA 5.7. *If an optimal path is of type $C_I \bar{\bar{C}}_1 S \bar{C}_2 \bar{C}_3 S \bar{\bar{C}}_4 C_F$, then the circles $\bar{\bar{\mathcal{C}}}_1$, $\bar{\mathcal{C}}_2$, $\bar{\mathcal{C}}_3$, and $\bar{\bar{\mathcal{C}}}_4$ are free.*

Proof. Lemma 3.6 directly yields that $\bar{\bar{\mathcal{C}}}_1$ and $\bar{\bar{\mathcal{C}}}_4$ are free. Suppose now, for a contradiction, that $\bar{\mathcal{C}}_3$ is not free. As before, we assume that the orientations are such that $\Pi = C_I^+ \bar{\bar{C}}_1^- S \bar{C}_2^- \bar{C}_3^+ S \bar{\bar{C}}_4^+ C_F^-$. Let T be the point of tangency between $\bar{C}_2$ and $\bar{C}_3$. Moving along $\bar{C}_3^+$, let X be the last point of tangency between $\bar{C}_3$ and $\partial\mathcal{P}$ (see Figure 5.7). Starting at X and moving along $\bar{\mathcal{C}}_3^+$, let Y be the first proper intersection point between $\bar{\mathcal{C}}_3$ and $\partial\mathcal{P}$.

By Lemma 2.4, the length of $\bar{C}_3$ between T and X is greater than π; i.e., $\|\bar{C}_3^+[T,X]\| > \pi$. It follows that $\bar{\mathcal{C}}_3$, X, and Y define a pocket $\Lambda_{\bar{\mathcal{C}}_3}[X,Y]$ (see Figure 5.7). By Lemma 2.7, this pocket contains $\Pi[X,F]$ and therefore contains the C-segment $\bar{\bar{C}}_4$. However, the pocket does not contain the circle $\bar{\bar{\mathcal{C}}}_4$, by Lemma 2.6. The path $\bar{C}_3 S \bar{\bar{C}}_4$ enters the pocket at X, and, since $\bar{\bar{\mathcal{C}}}_4$ is free, it is possible to escape the pocket by extending segment $\bar{\bar{C}}_4$. This contradicts Lemma 2.7, establishing that $\bar{\mathcal{C}}_3$ is free. A symmetric argument shows that circle $\bar{\mathcal{C}}_2$ is free. □

We now introduce the following simple definitions. Given a circle $\mathcal{C}$, a point $M \in \mathcal{C}$ is called *free on* $\mathcal{C}$ if and only if the circle tangent to $\mathcal{C}$ at M is free. Given a circle $\mathcal{C}$ and a point $X \in \mathcal{C}$, a point $M \in \mathcal{C}$ is called the *first free point after* X *along* $\mathcal{C}^+$ if and only if M is free on $\mathcal{C}$ and no point on the arc $\mathcal{C}^+[X,M)$ is free. In Figure 5.8, M^* is the first free point after M_L along $\mathcal{C}_I^+$. Note that M and X might coincide. The circle tangent to $\mathcal{C}$ at the first free point after X is called the *first free circle after* X *along* $\mathcal{C}^+$.

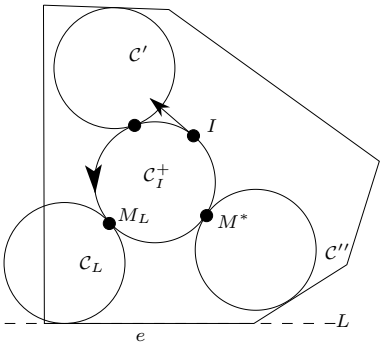

FIG. 5.8. *Definition of $\mathcal{C}'$ and $\mathcal{C}''$.*

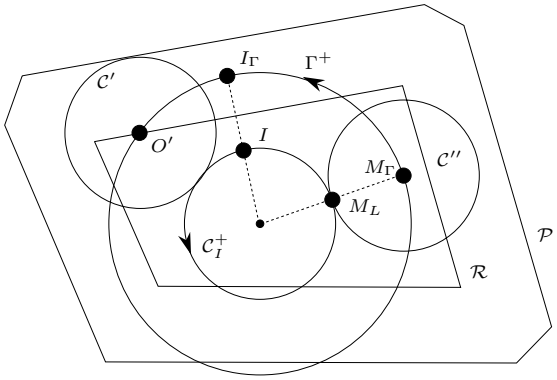

FIG. 5.9. *Illustration of the proof of Lemma* 5.8.

We now show that, given I, F, e, and e', we can compute in $O(\log n)$ time a set of $O(1)$ candidate circles that contain the $\bar{\bar{C}}$-segments of any optimal path from I to F of type $C_I^+\bar{\bar{C}}_1^-S\bar{C}_2^-\bar{C}_3^+S\bar{\bar{C}}_4^+C_F^-$ such that $\bar{C}_2^-$ and $\bar{C}_3^+$ are tangent to e and e', respectively. We show how to compute candidate circles for $\bar{\bar{\mathcal{C}}}_1$; computing candidate circles for $\bar{\bar{\mathcal{C}}}_4$ is similar.

5.4.2. Computing $\bar{\bar{\mathcal{C}}}_1$. We identify two circles $\mathcal{C}'$ and $\mathcal{C}''$ that are the candidate circles for $\bar{\bar{\mathcal{C}}}_1$. See Figure 5.8. $\mathcal{C}'$ is the first free circle after I along $\mathcal{C}_I^+$. Such a circle $\mathcal{C}'$ exists, by Lemma 5.7, if the optimal path from I to F is of type $C_I^+\bar{\bar{C}}_1^-S\bar{C}_2^-\bar{C}_3^+S\bar{\bar{C}}_4^+C_F^-$. For simplicity, we define $\mathcal{C}''$ in the local frame where the line L through e is horizontal and below $\mathcal{P}$. If the distance between L and $\mathcal{C}_I^+$ is greater than 2, then $\mathcal{C}''$ is not defined. Otherwise, there exist two circles that are above L and tangent to both $\mathcal{C}_I^+$ and L. Let $\mathcal{C}_L$ be the leftmost of these two circles, and let M_L be its point of tangency with $\mathcal{C}_I^+$. Let $\mathcal{C}''$ be the first free circle after M_L along $\mathcal{C}_I^+$. Note that $\mathcal{C}'$ depends only on I and $\mathcal{P}$ and that $\mathcal{C}''$ depends only on I, e, and $\mathcal{P}$.

LEMMA 5.8. *After preprocessing $\mathcal{P}$ in $O(n\log n)$ time, for a given edge e, $\mathcal{C}'$ and $\mathcal{C}''$ can be computed in $O(\log n)$ time.*

Proof. Let Γ be the circle of radius 2 concentric with $\mathcal{C}_I^+$ (see Figure 5.9). Let $\mathcal{R}$ be the *retracted polygon* of $\mathcal{P}$ with respect to a unit circle, i.e., $\mathcal{R}$ is the set of points p such that the unit circle centered at p lies inside $\mathcal{P}$; $\mathcal{R}$ is a convex polygonal region with at most n edges, and it can be computed in linear time. We preprocess $\mathcal{R}$ in $O(n\log n)$ time using the algorithm by Cheng et al. [10] so that, given a unit-radius

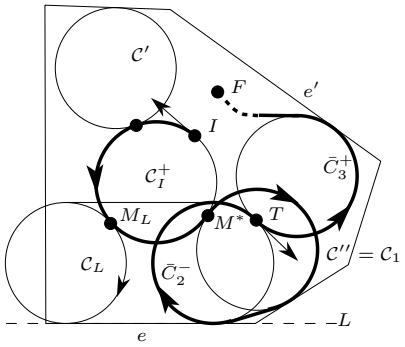

FIG. 5.10. *Circles $\mathcal{C}'$ and $\mathcal{C}''$ with a (supposedly) optimal path* Π.

circle $\mathcal{C}$ and a point $M \in \mathcal{C}$, we can compute in $O(\log n)$ time the first intersection point of $\mathcal{C}$ and $\mathcal{R}$ as we walk along $\mathcal{C}$ in the clockwise (or counterclockwise) direction.

Let I_Γ (respectively, M_Γ) be the intersection point between Γ and the ray emanating from the center of $\mathcal{C}_I^+$ and going through I (respectively, M_L), and let O' be the first intersection point between Γ and $\mathcal{R}$ starting at I_Γ and moving along Γ^+. Note that $O' = I_\Gamma$ if I_Γ lies inside $\mathcal{R}$. The center of $\mathcal{C}'$ is O'. Indeed, by definition of $\mathcal{R}$, the circle centered at O' is free, and any circle (of unit radius) centered at a point on $\Gamma^+[I_\Gamma, O')$ is not free. Since $\mathcal{C}'$ does not depend on the edge e, we can compute it in $O(n)$ time in the preprocessing stage once and for all. The center of $\mathcal{C}''$ is the first intersection point between Γ and $\mathcal{R}$ starting at M_Γ and moving along Γ^+, and it can be computed in $O(\log n)$ time. □

We now state a key lemma, which we prove in the following section.

LEMMA 5.9. *If Π is an optimal path of type $C_I^+ \bar{C}_1^- S \bar{C}_2^- \bar{C}_3^+ S \bar{C}_4^+ C_F^-$, then $\bar{C}_1$ is supported by $\mathcal{C}'$ or $\mathcal{C}''$.*

5.4.3. Proof of Lemma 5.9. Let T be the configuration on Π at the common point between $\bar{C}_2$ and $\bar{C}_3$. See Figure 5.10. As before (in section 5.2), any choice of a point $M \in \mathcal{C}_I^+$ defines one path $\Pi(M)$ of the form $C_I^+ C_1^- S C_2^-$, which begins at I and ends at T, and where $\mathcal{C}_I^+$ and $\mathcal{C}_1^-$ are tangent at M. Since the C-segments C_1^- and C_2^- have the same orientation, the path $\Pi(M)$ always exists, though it might not be free. Let $M^* \in \mathcal{C}_I^+$ be the point such that $\Pi(M^*)$ is a subpath of the optimal path Π. It follows that $\Pi(M^*)$ is an optimal path from I to T. We will show that M^* is the first free point after I or M_L.

We consider different cases based on which of the singular points exist on $\mathcal{C}_I^+$. See Figure 5.11. We first introduce some notation in order to distinguish different singular points. Let $M_1 \in \mathcal{C}_I$ be the point such that the C-segment C_1^- in $\Pi(M)$ vanishes (i.e., $\Pi(M)$ is of type $C_I^+ S C_2^-$); M_1 is only defined when $\mathcal{C}_I$ and $\mathcal{C}_2$ do not properly intersect. Assume, for simplicity, that T is the lowest point of $\mathcal{C}_2^-$, and let L_0 be the horizontal half-line lying to the right of T. Let $\tilde{\mathcal{C}}_1$ and $\tilde{\mathcal{C}}_1'$ be the two circles (if they exist) tangent to $\mathcal{C}_I$ with center on the horizontal line through the center of $\mathcal{C}_2^-$, and let M_2 and M_2' be their respective common points with $\mathcal{C}_I$; assume without loss of generality that M_2 is left of M_2'. The point M_2 (respectively, M_2') is a singular point of $\Pi(M)$ (at which C_2^- vanishes) if and only if $\tilde{\mathcal{C}}_1$ (respectively, $\tilde{\mathcal{C}}_1'$) touches L_0. Otherwise, the C_2-segment of $\Pi(M_2)$ (respectively, $\Pi(M_2')$) has length π (see Figure 5.11b).

Since C_1- and C_2-segments of $\Pi(M)$ have the same orientation, the S-segment vanishes if and only if the path type $C_I^+ C_1^- S C_2^-$ degenerates to $C_I^+ C^-$. Thus, if the

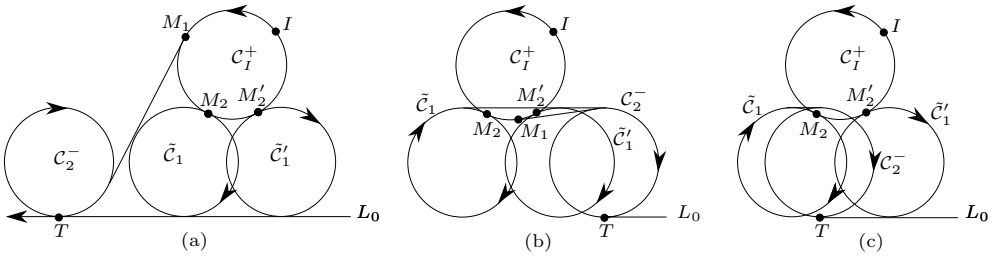

FIG. 5.11. *Singular points of* $\Pi(M)$. *In* (a), $\{I, M_1, M_2, M_2'\}$. *In* (b), $\{I, M_1\}$. *In* (c), $\{I, M_2'\}$.

S-segment vanishes, the C_1- or C_2-segment also vanishes. Therefore, in view of the discussion in section 5.2, only the following points can be singular points:

- I (C_I^+ vanishes),
- M_1, if $\mathcal{C}_I$ and $\mathcal{C}_2$ do not properly intersect (C_1^- vanishes),
- M_2, if $\tilde{\mathcal{C}}_1$ exists and touches L_0 (C_2^- vanishes), and
- M_2', if $\tilde{\mathcal{C}}_1'$ exists and touches L_0 (C_2^- vanishes).

There are three cases to consider, depending on the relative positions of $\mathcal{C}_1$ and $\mathcal{C}_2$.

(i) The distance between $\mathcal{C}_I$ and the line supporting L_0 is at most 2, and $\mathcal{C}_2$ lies to the left of $\tilde{\mathcal{C}}_1$; i.e., both $\tilde{\mathcal{C}}_1$ and $\tilde{\mathcal{C}}_1'$ touch L_0; see Figure 5.11a. In this case, $\mathcal{C}_2$ does not intersect $\mathcal{C}_I$, and therefore M_1 also exists. The singular points are thus $\{I, M_1, M_2, M_2'\}$.

(ii) Either the distance between $\mathcal{C}_I$ and the line supporting L_0 is greater than 2, or neither $\tilde{\mathcal{C}}_1$ nor $\tilde{\mathcal{C}}_1'$ touches L_0; see Figure 5.11b. In both cases, $\mathcal{C}_I$ and $\mathcal{C}_2$ do not intersect, so M_1 exists. The singular points are therefore $\{I, M_1\}$.

(iii) The distance between $\mathcal{C}_I$ and the line supporting L_0 is at most 2, and $\mathcal{C}_2$ lies between $\tilde{\mathcal{C}}_1$ and $\tilde{\mathcal{C}}_1'$. In this case, $\tilde{\mathcal{C}}_1$ does not touch L_0, and $\mathcal{C}_I$ intersects $\mathcal{C}_2$, so the singular points are $\{I, M_2'\}$; see Figure 5.11c.

Before proving for each case that M^* is the first free point along $\mathcal{C}_I^+$ after I or M_L, we state a few claims, which we will need for the proof.

CLAIM 5.10. *M^* is not a singular point of* $\Pi(M)$.

Proof. If M^* is a singular point, the type of $\Pi(M^*)$ degenerates, contradicting that Π is of type $C_I^+ \bar{\bar{C}}_1^- S \bar{C}_2^- \bar{C}_3^+ S \bar{\bar{C}}_4^+ C_F^-$. □

CLAIM 5.11. *M^* is the first free point along $\mathcal{C}_I^+$ after a singular point of* $\Pi(M)$.

Proof. By Lemma 5.7, M^* is free on $\mathcal{C}_I^+$. If there exists $M' \neq M^*$ free on $\mathcal{C}_I^+$ such that $\mathcal{C}_I^+(M', M^*]$ does not contain any singular point, then the path $\Pi(M')$ exists because C_1^- and C_2^- have the same orientation. $\Pi(M')$ is free because the first C_I^+-segment of $\Pi(M')$ is part of the feasible path $\Pi(M^*)$, the circle $\mathcal{C}_1^-$ is free by definition of M', and the circle $\mathcal{C}_2^-$ is free (by Lemma 5.7). Finally, $\|\Pi(M')\| < \|\Pi(M^*)\|$ by the monotonicity property (Lemma 5.5), which contradicts the optimality of $\Pi(M^*)$. □

CLAIM 5.12. *If M_2 and M_2' exist, then* (i) *the length function $\|\Pi(M)\|$ increases at $M = M_2$, and* (ii) *$M^* \in \mathcal{C}_I^+(M_2, M_2')$.*

Proof. If M_2 is not a singular point, then, by Lemma 5.5, $\|\Pi(M)\|$ increases at M_2. If M_2 is a singular point, then $\|\Pi(M)\|$ jumps by 2π at M_2 (see Figure 5.11a). As for (ii), the length of the last C-segment C_2 of $\Pi(M)$ is greater than π if and only if the center of $\mathcal{C}_1$ lies below the center of $\mathcal{C}_2$ (see Figure 5.11); that is, $M \in \mathcal{C}_I^+(M_2, M_2')$. Since C_2 is a nonterminal C-segment of the optimal path Π, $\|C_2\| > \pi$, and therefore $M^* \in \mathcal{C}_I^+(M_2, M_2')$. □

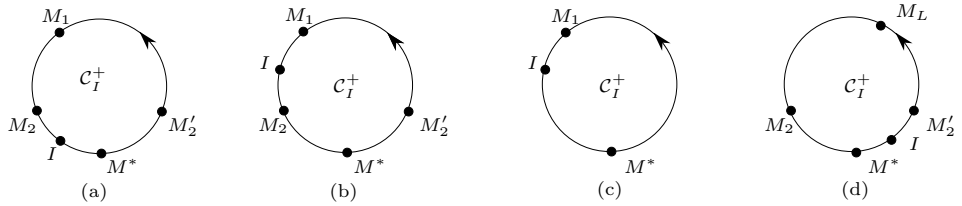

FIG. 5.12. *Some positions of the singular points* $\{I, M_1, M_2, M_2'\}$ *in* (a) *and* (b), $\{I, M_1\}$ *in* (c), *and* $\{I, M_2'\}$ *in* (d).

CLAIM 5.13. *If* M_1 *exists, then the circular arc* $\mathcal{C}_I^+[M_1, M^*]$ *contains* I *or* M_2'. *If* $I \notin \mathcal{C}_I^+[M_1, M^*]$, *then* M_2' *is a singular point.*

Proof. If $I \notin \mathcal{C}_I^+[M_1, M^*]$, then $\Pi(M_1)$ is free because the first C-segment $\mathcal{C}_I^+[I, M_1]$ of $\Pi(M_1)$ is part of $\Pi(M^*)$, and $\mathcal{C}_2^-$ is free by Lemma 5.7. Thus $\Pi(M_1, M^*]$ contains a singular point, because otherwise $\|\Pi(M_1)\| < \|\Pi(M^*)\|$ by the monotonicity property (Lemma 5.5) and Claim 5.10, and thus $\Pi(M^*)$ is not optimal, which is a contradiction. If M_2' also does not lie in $\mathcal{C}_I^+[M_1, M^*]$, then M_2 is a singular point and lies on this arc. By Claim 5.12, $\|\Pi(M_1)\| < \|\Pi(M_2)\| < \|\Pi(M^*)\|$, which is a contradiction. Hence either I or M_2' lies on $\mathcal{C}_I^+[M_1, M^*]$, and M_2' is a singular point if I does not lie in this arc. ∎

We now prove for each of the three cases stated above that M^* is the first free point after I or M_L.

Case (i). The singular points are $\{I, M_1, M_2, M_2'\}$. Since $\mathcal{C}_2$ lies to the left of $\tilde{\mathcal{C}}_1$, one can easily show that $M_1 \in \mathcal{C}_I^+[M_2', M_2]$ (see Figure 5.11a). Refer now to Figures 5.12a and b. By Claim 5.12, $M^* \in \mathcal{C}_I^+(M_2, M_2')$. It follows that $\mathcal{C}_I^+[M_1, M^*]$ does not contain M_2' and thus contains I (by Claim 5.13). Thus $\mathcal{C}_I^+(I, M^*]$ does not contain any singular point except possibly M_2. If $M_2 \notin \mathcal{C}_I^+(I, M^*]$ (Figure 5.12a), then M^* is the first free point after I because, by Claim 5.11, M^* is the first free point after a singular point. Even if $M_2 \in \mathcal{C}_I^+(I, M^*]$ (Figure 5.12b), M^* is the first free point after I. Indeed, if the first free point after I along $\mathcal{C}_I^+$ is $M' \in \mathcal{C}_I^+[I, M_2)$, then $\Pi(M')$ is free because the first arc $\mathcal{C}_I^+[I, M']$ of $\Pi(M')$ is part of Π, and the second and third C-segments of $\Pi(M')$ are free by definition of M' and by Lemma 5.7, respectively. Moreover, by Lemma 5.5 and Claim 5.12, $\|\Pi(M')\| < \|\Pi(M_2)\| < \|\Pi(M^*)\|$, which is a contradiction.

Case (ii). The singular points are $\{I, M_1\}$. See Figure 5.12c. Since M_2' is not a singular point, by Claim 5.13, $I \in \mathcal{C}_I^+[M_1, M^*]$. Consequently, $\mathcal{C}_I^+(I, M^*]$ does not contain any singular point. Therefore, by Claim 5.11, M^* is the first free point after I.

Case (iii). The singular points are $\{I, M_2'\}$. As before, if $\mathcal{C}_I^+(I, M^*]$ does not contain any singular point, M^* is the first free point after I. We thus consider the case in which $M_2' \in \mathcal{C}_I^+(I, M^*]$ (see Figure 5.12d). Since M_2 and M_2' exist, by Claim 5.12, $M^* \in \mathcal{C}_I^+(M_2, M_2')$. It thus follows that M^* is the first free point after M_2' (by Claims 5.11 and 5.12). Thus, in order to show that M^* is the first free point after M_L, it is sufficient to prove that $M_L \in \mathcal{C}_I^+[M_2', M_2]$, which is equivalent to proving that the length of the last C-segment C_2 of $\Pi(M_L)$ is at most π. This can be shown as follows.

We assume, for simplicity, that the edge e (tangent to the C-segment C_2^-) is horizontal and below $\mathcal{P}$ (see Figure 5.10); to be consistent, we no longer assume that T is the lowest point of $\mathcal{C}_2^-$. By Lemma 2.4, the arc length of $\bar{C}_2$ in Π from its point of tangency with the edge e to T must be at least π. In other words, T must be in the right half of $\bar{\mathcal{C}}_2$. On the other hand, by definition of M_L, $\mathcal{C}_L$ is the leftmost circle

of all of the unit circles tangent to L from above that intersect $\mathcal{C}_I$. Since $\mathcal{C}_2$ is tangent to L from above and properly intersects $\mathcal{C}_I$ (because M_1 is not defined in this case), the top point of $\mathcal{C}_L$ is left of the top point of $\mathcal{C}_2$. Thus, since T is on the right half of $\bar{\mathcal{C}}_2$, the arc length of C_2 in $\Pi(M_L)$ is less than π (see Figure 5.10).

5.4.4. Computing the overall path. By Lemmas 5.8 and 5.9, we can compute, in $O(\log n)$ time, two candidates for the circle supporting segment $\bar{\bar{C}}_1$. We can similarly compute two candidates for the circle supporting segment $\bar{\bar{C}}_4$. By Lemma 4.2, this gives us $O(1)$ candidate paths, for which we may check the feasibility in $O(\log n)$ time. Hence, given two edges e and e' of $\mathcal{P}$, we can compute in $O(\log n)$ time an optimal path of type $C_I\bar{\bar{C}}_1S\bar{C}_2\bar{C}_3S\bar{\bar{C}}_4C_F$, where $\bar{C}_2$ and $\bar{C}_3$ are tangent to e and e', respectively.

If the optimal path is of type (B.iii) with only one $\bar{\bar{C}}$-segment in Π_I or Π_F, we get similar results. For example, if an optimal path is of type $C_I\bar{\bar{C}}_1S\bar{C}_2\bar{C}_3SC_F$, then $\bar{\mathcal{C}}_1$ and $\bar{\mathcal{C}}_2$ are free, and $\bar{\bar{C}}_1$ is supported by $\mathcal{C}'$ or $\mathcal{C}''$ as defined above. Thus we obtain the following lemma.

LEMMA 5.14. *Let e, e' be edges of $\mathcal{P}$. In $O(\log n)$ time, we can compute an optimal path of type $\Pi_I\bar{C}_2\bar{C}_3\Pi_F$, where $\Pi_I \in \{C_I\bar{\bar{C}}S, C_IS, C_I, S\}$, $\Pi_F \in \{S\bar{\bar{C}}C_F, SC_F, C_F, S\}$, and $\bar{C}_2$ and $\bar{C}_3$ are tangent to e and e', respectively.*

5.4.5. Finding candidate pairs of edges. Now we describe how to find a suitable set of pairs of edges $\mathcal{E}$ such that, if an optimal path from I to F is of type (B.iii) (i.e., $\Pi_I\bar{C}_2\bar{C}_3\Pi_F$), then the pair of edges (e, e') tangent to $\bar{C}_2$ and $\bar{C}_3$ is in the set $\mathcal{E}$.

Agarwal, Raghavan, and Tamaki [1] showed that, if an optimal path from I to F is of type $\Pi_I\bar{C}_2\bar{C}_3\Pi_F$ such that $\bar{C}_2$ and $\bar{C}_3$ are nonterminal, then $\mathcal{C}_I$ intersects $\bar{\mathcal{C}}_3$ (the circle supporting $\bar{C}_3$), and $\mathcal{C}_F$ intersects $\bar{\mathcal{C}}_2$ (the circle supporting $\bar{C}_2$). Thus the center of $\bar{\mathcal{C}}_3$, which is at most distance 1 from the boundary of the polygon, is at most at distance 3 from I. Since the centers of $\bar{\mathcal{C}}_2$ and $\bar{\mathcal{C}}_3$ are distance 2 apart, they are each at distance less than 5 from I. Thus edges e and e' are at distance less than 6 from I. By symmetry, they are also at distance less than 6 from F. Therefore, we can consider $\mathcal{E}$ to be the set of pairs of edges of $\mathcal{P}$ that are at distance less than 6 from both I and F. Let k denote the number of edges of $\mathcal{P}$ at distance less than 6 from both I and F. Then $|\mathcal{E}| = k^2$, and $\mathcal{E}$ can be computed in $O(k^2)$ time. Lemma 5.14 then gives the following.

LEMMA 5.15. *An optimal path of type* (B.iii) *can be computed in $O(k^2 \log n)$ time.*

Putting everything together, we obtain the following.

THEOREM 5.16. *Given a convex polygon $\mathcal{P}$, an initial configuration I, and a final configuration F, an optimal path from I to F inside $\mathcal{P}$ can be computed in time $O((n + k^2)\log n)$, where k is the number of edges of $\mathcal{P}$ at distance less than* 6 *from both I and F.*

Proof. We have shown in section 4 and in Lemmas 5.2, 5.6, and 5.15 that the Dubins paths and the optimal paths of types (A.i), (A.ii), (B.i), and (B.ii) can be computed in $O(n \log n)$ time, while paths of type (B.iii) can be computed in $O(k^2 \log n)$ time. Choosing the shortest among all of those paths yields an optimal path. ∎

6. Conclusion. For an obstacle-free environment, Dubins' classification of optimal path types yields a constant time algorithm for computing optimal paths [15]. On the other hand, in the presence of general polygonal obstacles, the optimal path-planning problem is NP-hard [29]. In this paper, we have studied a very simple

environment, the inside of a convex polygon. We have given a classification of optimal path types and an $O(n^2 \log n)$ algorithm for optimal path planning. We have found that, surprisingly, the number of straight or circular segments composing optimal paths is bounded by a constant, independent of the number n of sides of the convex polygon.

The running time of the algorithm and the constant bound on the number of segments in an optimal path lead us to speculate that other simple environments may also be amenable to polynomial time algorithmic solution. However, we caution that, although the environment we have considered is simple, our algorithm results from considerable technical analysis.

Our techniques and results may provide useful tools for further study of these problems. In particular, we call attention to two properties of moderate paths that we believe are interesting and possibly useful in their own right:

(i) A feasible path entering the interior of a pocket can never escape the pocket (Lemma 2.7).

(ii) The length of a path of type $CCSC$ from X to Y is a piecewise strictly increasing function of the length of the first C-segment (Lemma 5.5).

Note that property (ii) holds regardless of the environment.

The theory of curvature-constrained path planning is relatively unexplored, so many problems remain. We mention some specific open problems arising from our work and then conclude with a more general one.

First, we ask whether our classification of optimal path types inside a convex polygon is tight; that is, does each possible type of optimal path given in our classification actually arise for some $\mathcal{P}$, I, and F? We believe that the answer is yes, although we have no formal proof of this (see Remark 3.2 for details). Also, we ask whether there is a polygon $\mathcal{P}$ in which all types arise.

Next, in our optimal path-planning algorithm, the most time-consuming part lies in the computation of the optimal paths of type (B.iii) (see Theorem 3.1). Indeed, if we eliminate type (B.iii) from consideration, the complexity of our algorithm drops to $O(n \log n)$. Furthermore, paths of type (B.iii) are rather complex and thus may be difficult to track by a mobile robot. This situation suggests two lines of investigation. First, the paths of type (B.iii) should be studied thoroughly in order to understand when they can be optimal inside a convex polygon (or amid moderate obstacles [1, 6]). We believe that optimal paths can be of type (B.iii) only if the polygon is "small." In other words, it is possible that optimal paths of type (B.iii) arise only as artifacts of tightly constricted environments (see Figure 3.1c). For example, we know (see Theorem 5.16) that, if the terminal configurations are at a distance greater than 6 from the boundary of the polygon, then an optimal path cannot be of type (B.iii). A second approach to handling paths of type (B.iii) is to simply drop them from consideration. In that case, we ask whether we can preprocess the scene such that, for any query of terminal configurations, we can compute a shortest path among the remaining types in sublinear time.

To conclude with a general problem for future research, we ask for the specification of a realistic notion of feasibility that rejects hard-to-follow paths, such as paths of type (B.iii), while admitting fast computation of optimal feasible paths.

Appendix. Closed moderate paths. The purpose of this section is to prove Proposition 2.5, which states

> *A simple moderate path* Π *such that the initial and final locations coincide (the initial and final configurations may differ) bounds a*

region that contains at least one disk of unit radius. Moreover, if the initial and final configurations coincide and if Π *is not a circle of unit radius, then the region bounded by* Π *contains at least two distinct disks of unit radius.*

Proof. We prove these results using some properties of the skeletons. Note that this is an original approach in the field of nonholonomic motion planning. We first recall a definition of skeletons for which several variants are considered in the literature; different terms in use include *medial-axis, central set*, and *cut-locus*. We use here the formulation using maximal disks [35].

Skeletons. Let $\mathcal{R}$ be an open set of $\mathbb{R}^2$ bounded by a simple closed curve. A *maximal disk* is an open disk (of positive radius) included in $\mathcal{R}$ but not included in any other disk contained in $\mathcal{R}$. The *skeleton* of $\mathcal{R}$, denoted $\mathcal{S}(\mathcal{R})$, is the locus of the centers of all the maximal disks. For any $x \in \mathcal{R}$, let $\rho(x)$ denote the intersection between the closure of the maximal disk centered at x and the boundary of $\mathcal{R}$:

$$\rho(x) = \{y \in \partial\mathcal{R} \mid \|xy\| = \min_{z \in \partial\mathcal{R}} \|xz\|\}.$$

Now let $I = F$ denote the initial and final location on the path Π, and let $\mathcal{R}$ be the open region bounded by Π. Assume that $\mathcal{R}$ is not a disk of radius at least 1, as otherwise the result is obvious.

The underlying idea of the proof is the following. The closure of skeleton $\mathcal{S}(\mathcal{R})$ has at least two distinct endpoints (i.e., nodes of degree 1 of the graph) x and x'; indeed, $\mathcal{S}(\mathcal{R})$ does not contain any cycle since Π is simple. One of these endpoints, say, x, is necessarily distinct from the terminal location I of Π. The point x cannot lie on Π because Π is C^1 continuous everywhere except (possibly) at $I \neq x$; therefore, $x \in \mathcal{R}$. Since x is an endpoint of the skeleton, $\rho(x)$ is connected (i.e., $\rho(x)$ is a point or a circular arc). It follows that the maximal disk at x is osculating[5] Π at a point $P \neq I$, and its radius is at least 1. If the initial and final orientations of Π are also equal, x and x' are both centers of maximal disks osculating Π, and thus their radii are greater than or equal to 1.

Formally, we directly show, using a result by Calabi and Riley [9], the following result.

Claim A.1. *There exists a maximal disk in* $\mathcal{R}$ *such that the contact points between its boundary and* Π *are connected.*

Proof. Let D be any maximal disk in $\mathcal{R}$, and let x be its center, and suppose, for a contradiction, that $\rho(x)$ is not connected. See Figure A.1. Then there exist four points $y_1 \neq y_2, y_1' \neq y_2'$ in $\partial D \cap \Pi$ such that the circular arcs $\partial D^+[y_1, y_2]$ and $\partial D^+[y_1', y_2']$ do not strictly contain any point of $\rho(x)$.

One of the two arcs $\Pi^+[y_1, y_2]$ and $\Pi^+[y_1', y_2']$ is C^1 continuous because these two arcs do not overlap, and Π is C^1 continuous everywhere except possibly at $I = F$. Say, without loss of generality, that $\Pi^+[y_1, y_2]$ is C^1 continuous, and denote by $\mathcal{R}'$ the open region bounded by $\Pi^+[y_1, y_2] \cup [x, y_1] \cup [x, y_2]$ (e.g., the shaded region in Figure A.1). By a result of Calabi and Riley [9, Proposition 10], either $\mathcal{R}'$ contains a skeleton point $x_0 \in \mathcal{SR}$ for which $\rho(x_0)$ is connected, or $\Pi^+(y_1, y_2)$ (without its endpoints) contains a point which is the limit of skeleton points contained in $\mathcal{R}'$.

[5]Two curves are osculating at a point P if and only if they are tangent at P and have the same signed curvature at P. Here Π is C^1 continuous, and piecewise C^2 continuous, everywhere except possibly at I. If Π is C^1 but not C^2 at P, we say that a disk is osculating Π at P if and only if they are tangent at P, the signed curvature of the disk is equal to the signed curvature (at P) of one of the two portions (C^2) of Π ending at P, and the other portion does not properly intersect the disk in a neighborhood of P.

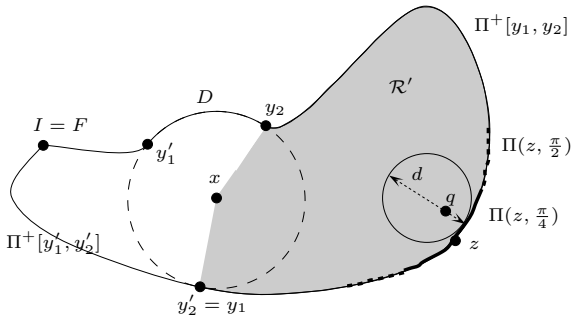

FIG. A.1. *For the proof of Proposition* 2.5.

Suppose, on the contrary, that $\Pi^+(y_1, y_2)$ contains a point z that is the limit of skeleton points $(z_i)_{i\in\mathbb{N}}$ contained in $\mathcal{R}$. Since $\Pi^+(y_1, y_2)$ is C^1, Π is C^1 at z. We get a contradiction because, as we prove below, a point z of $\partial\mathcal{R}$ is a limit of points of the skeleton only if $\partial\mathcal{R}$ is not differentiable at z. Indeed, let $\Pi(z, \frac{\pi}{2})$ be the arc of Π of length $\frac{\pi}{2}$ centered at z (if the length of Π is smaller than $\frac{\pi}{2}$, we choose a smaller value for the length of $\Pi(z, \frac{\pi}{2})$), and let $\Pi(z, \frac{\pi}{4})$ be the arc of Π, centered at z, of length half the length of $\Pi(z, \frac{\pi}{2})$, and, finally, let d be the distance between $\Pi(z, \frac{\pi}{4})$ and $\Pi \setminus \Pi(z, \frac{\pi}{2})$ (note that $d \leqslant \frac{\pi}{4} < 1$). By a result of Dubins [15, Proposition 6], $\Pi(z, \frac{\pi}{2})$ does not intersect any open disk of unit radius tangent to $\Pi(z, \frac{\pi}{4})$. It follows that Π does not intersect any open disk of radius $d/2$ tangent to $\Pi(z, \frac{\pi}{4})$. Now any point $q \in \mathcal{R}$ close enough to z belongs to a normal to $\Pi(z, \frac{\pi}{4})$ at distance $\mu < d/2$ from $\Pi(z, \frac{\pi}{4})$. Thus the disk of radius μ centered at q is not maximal because it is included in a disk of radius $d/2$ tangent to $\Pi(z, \frac{\pi}{4})$, which is included in $\mathcal{R}$. Therefore, any point $q \in \mathcal{R}$ in a small enough neighborhood of z does not belong to the skeleton. □

By Claim A.1, $\mathcal{R}$ contains a point x_0 of its skeleton such that $\rho(x_0)$ is connected. Thus $\rho(x_0)$ is a circular arc or is reduced to a point. If $\rho(x_0)$ is a circular arc, then the constraint on the average curvature of Π implies that this circular arc of Π has a radius greater than or equal to 1, and thus the radius of the maximal disk at x_0 is greater than or equal to 1. Otherwise, if $\rho(x_0)$ is reduced to a point, say, y_0, the maximal disk at x_0 osculates Π at y_0, and thus its radius is greater than or equal to 1. (Indeed, recall that the constraint on the average curvature implies that Π is piecewise C^2 continuous, and its curvature is less than or equal to 1 almost everywhere.) This concludes the proof when the initial and final orientations of Π differ.

If the initial and final configurations are equal, the path Π is C^1 continuous everywhere, and the previous arguments hold for both regions $\mathcal{R}'$ and $\mathcal{R}''$ bounded, respectively, by $\Pi^+[y_1, y_2] \cup [x, y_1] \cup [x, y_2]$ and $\Pi^+[y_1', y_2'] \cup [x, y_1'] \cup [x, y_2']$. (Note, however, that, when $\rho(x)$ is connected, $\mathcal{R}''$ is empty, but then the maximal disk centered at x is of radius at least 1.) □

Acknowledgments. This paper arose from research begun at the International Workshop on Bounded Radius of Curvature, organized by Sue Whitesides and held at the Bellairs Research Institute of McGill University on March 9–16, 1997. We would like to thank Hazel Everett, Micha Godau, Sylvain Petitjean, Kaleem Siddiqi, and Steve Wismath for many useful discussions.

PARALLEL INTEGER SORTING IS MORE EFFICIENT THAN PARALLEL COMPARISON SORTING ON EXCLUSIVE WRITE PRAMS*

YIJIE HAN† AND XIAOJUN SHEN†

Abstract. We present a significant improvement for parallel integer sorting. On the EREW (exclusive read exclusive write) PRAM our algorithm sorts n integers in the range $\{0, 1, \ldots, m-1\}$ in time $O(\log n)$ with $O(n \sqrt{\frac{\log n}{k}})$ operations using word length $k \log(m+n)$, where $1 \le k \le \log n$. In this paper we present the following four variants of our algorithm.
(1) The first variant sorts integers in $\{0, 1, \ldots, m-1\}$ in time $O(\log n)$ and in linear space with $O(n)$ operations using word length $\log m \log n$.
(2) The second variant sorts integers in $\{0, 1, \ldots, n-1\}$ in time $O(\log n)$ and in linear space with $O(n\sqrt{\log n})$ operations using word length $\log n$.
(3) The third variant sorts integers in $\{0, 1, \ldots, m-1\}$ in time $O(\log^{3/2} n)$ and in linear space with $O(n\sqrt{\log n})$ operations using word length $\log(m+n)$.
(4) The fourth variant sorts integers in $\{0, 1, \ldots, m-1\}$ in time $O(\log n)$ and space $O(nm^{\epsilon})$ with $O(n\sqrt{\log n})$ operations using word length $\log(m+n)$.
Our algorithms can then be generalized to the situation where the word length is $k \log(m+n)$, $1 \le k \le \log n$.

1. Introduction.

Sorting is a classical problem which has been studied by many researchers. For elements in an ordered set comparison sorting can be used to sort the elements. It is well known that comparison sorting has time complexity $\theta(n \log n)$. In the case where a set contains only integers both comparison sorting and integer sorting can be used to sort the elements. Since elements of a set are usually represented by binary numbers in a digital computer, integer sorting can, in many cases, replace comparison sorting. The only known time lower bound for integer sorting is the trivial linear bound of $\Omega(n)$. Radix sorting does demonstrate an $O(n)$ upper bound for sorting n integers in the range $\{0, 1, \ldots, n^t - 1\}$, where t is a constant. Researchers worked hard trying to show that, for integers in any range, integer sorting can outperform comparison sorting [4, 13, 19, 21]. Fredman and Willard [13] first showed that n integers in any range can be sorted in $O(n\sqrt{\log n})$ time, thereby demonstrating that in the sequential case, integer sorting is more efficient than comparison sorting. However, prior to this paper no deterministic parallel integer sorting algorithm outperformed the lower bound for parallel comparison sorting on any parallel computation models. (A detailed explanation is given below.) We show, for the first time, that parallel in-

teger sorting is more efficient than parallel comparison sorting on the exclusive write PRAMs.

The parallel computation model we use is the PRAM model [20] which is used widely by parallel algorithm designers. Usually three PRAM models are used, the EREW (exclusive read exclusive write) PRAM, the CREW (concurrent read exclusive write) PRAM, and the CRCW (concurrent read concurrent write) PRAM [20]. In a PRAM model a processor can access any memory cell. On the EREW PRAM simultaneous access to a memory cell by more than one processor is prohibited. On the CREW PRAM, processors can read a memory cell simultaneously, but simultaneous writing to the same memory cell by several processors is prohibited. On the CRCW PRAM, processors can simultaneously read or write to a memory cell. The CREW PRAM is a more powerful model than the EREW PRAM. The CRCW PRAM is the most powerful model among the three variants.

Parallel algorithms can be measured either by their time complexity and processor complexity or by their time complexity and operation complexity, which is the time processor product. A parallel algorithm with small time complexity is regarded as fast while a parallel algorithm with small operation complexity is regarded as efficient.

In order to outperform parallel comparison sorting on the exclusive write PRAM models (i.e., CREW PRAM and EREW PRAM), one has to exhibit a parallel algorithm which matches the time lower bound for parallel comparison sorting algorithms and outperforms the operation lower bound for parallel comparison sorting algorithms. Note that we cannot outperform the time lower bound (only to match it) because on the CREW and EREW PRAMs the time lower bounds for parallel comparison sorting and for parallel integer sorting are the same, namely $\Omega(\log n)$ [11]. The operation lower bound for parallel comparison sorting is $\Omega(n \log n)$ due to the time lower bound for sequential comparison sorting. We explain below that known parallel integer sorting algorithms failed to outperform the lower bound for parallel comparison sorting.

1. Parallel algorithms are known [2, 4, 12, 19, 25] to have operation complexity of $o(n \log n)$ when they are running slower than the $\theta(\log n)$ time lower bound for parallel comparison sorting. But they failed to have $o(n \log n)$ operations when achieving the time lower bound. For example, the CREW algorithm given in [2] (the best prior to this paper) has operation complexity $O(n\sqrt{\log n})$ when running at time $O(\log n \log\log n)$. But the time lower bound for comparison sorting on the CREW PRAM is $\Omega(\log n)$ [11]. It is not clear how to make the algorithm in [2] run in $O(\log n)$ time. Also the CRCW algorithm in [4, 19] has operation complexity $O(n \log\log n)$ when running at time $O(\log n)$. However, the time lower bound for comparison sorting on the CRCW PRAM using a polynomial number of processors is $\Omega(\log n/\log\log n)$ [6].

2. Parallel algorithms are known [2, 9, 29] to have operation complexity $o(n \log n)$ running at the time lower bound for parallel comparison sorting when sorting on small integers. They fail to outperform parallel comparison sorting when sorting on large integers. For example, the previous best results in [2, 12] showed that n integers in the range $\{0, 1, \ldots, 2^{O(\sqrt{\log n})}\}$ can be sorted on the EREW PRAM in $O(\log n)$ time and linear operations. However, no previous deterministic algorithms showed that n integers larger than $2^{O(\sqrt{\log n})}$ can be sorted in $O(\log n)$ time with $o(n \log n)$ operations on exclusive write PRAMs.

3. Parallel algorithms are known [4, 16] to outperform parallel comparison sorting by using a nonstandard word length (word length is the number of bits in each word).

However, they fail to outperform on a standard PRAM where word length is bounded by $O(\log(m+n))$. For example, in [4] it is shown that sorting n integers in the range $\{0, 1, \ldots, m-1\}$ can be done in $O(\log n)$ time with $O(n)$ operations on the EREW PRAM with a word length of $O((\log n)^{2+\epsilon} \log m)$. The use of extra bits in word length in parallel integer sorting is generally regarded as excess. Note that even in this case (use nonstandard word length) our results are better than all previous results.

In this paper we show for the first time that on the exclusive write PRAMs parallel integer sorting is more efficient than parallel comparison sorting. For sorting n integers in the range $\{0, 1, \ldots, m-1\}$ our algorithm runs in $O(\log n)$ time with an operation complexity of $O(n\sqrt{\frac{\log n}{k}})$ when using word length $k \log(m+n)$, where $1 \leq k \leq \log n$. When $k = 1$ our algorithm uses standard word length $\log(m+n)$ and runs in $O(\log n)$ time (which is also the lower bound for integer sorting on the CREW and EREW PRAM and which matches the time lower bound for parallel comparison sorting on the CREW and EREW PRAM) with $O(n\sqrt{\log n})$ operations (while parallel comparison sorting has a lower bound $\Omega(n \log n)$ for the operation complexity due to the sequential time complexity lower bound). This algorithm outperforms parallel comparison sorting on the CREW and EREW PRAMs.

There are many previous results on parallel integer sorting [2, 4, 9, 12, 15, 16, 19, 22, 24, 25, 26, 28, 29]. We give a brief comparison of our results with the previous results.

An important parameter in integer sorting is the word length w, which is the number of bits in a word. Much effort has been spent toward finding good integer sorting algorithms which are conservative in the sense that they do not use extra bits. According to Kirkpatrick and Reisch [21] an integer sorting algorithm sorting n integers in the range $\{0, 1, \ldots, m-1\}$ is said to be conservative if the word length is bounded by $O(\log(m+n))$. Significant progress has been made recently in this regard. Andersson et al. [4] and Han and Shen [19] showed conservative integer sorting algorithms that sort n integers in the range $\{0, 1, 2, \ldots, m-1\}$ in $O(\log n)$ time with $O(n \log\log n)$ operations on the CRCW PRAM. This also implies a conservative sequential algorithm with $O(n \log\log n)$ time. Although much progress has been made on parallel integer sorting on the CRCW PRAM [4, 9, 15, 19], which allows simultaneous read and write to shared memory cells, significant difficulties exist when parallel integer sorting algorithms are to be designed on PRAMs which do not allow simultaneous write.

Consider the problem of sorting n integers in the range $\{0, 1, \ldots, n-1\}$, which is the most important and standard case. Previous best conservative parallel algorithms running in $O(\log n)$ time on CREW and EREW PRAMs use $O(n \log n)$ operations. Rajasekaran and Sen [25], Albers and Hagerup [2], and Dessmark and Lingas [12] were able to reduce the number of operations to $o(n \log n)$ on the CREW PRAM and EREW PRAM but the running time must be over $O(\log n)$. Currently the best result due to Albers and Hagerup [2] sorts in $O(\log n \log\log n)$ time with $O(n\sqrt{\log n})$ operations on the CREW PRAM. On the EREW PRAM the algorithms in [2, 25] have $O(\log n \log\log n)$ time complexity with $O(n \log n / \log\log n)$ operations. Very recently Dessmark and Lingas presented an improved EREW algorithm [12] which needs $O(\log^{3/2} n)$ time with $O(n\sqrt{\log n})$ operations. Thus in regard to the best previous results one cannot sort better than the comparison sorting algorithm [1, 10] (which uses $O(n \log n)$ operations) if one is to sort as fast as the comparison sorting algorithm (using $O(\log n)$ time) on the CREW and EREW PRAMs.

In this paper we significantly improve on this situation (i.e., sorting n integers

in the range $\{0, 1, \ldots, n-1\}$). Our EREW PRAM algorithm sorts in $O(\log n)$ time with $O(n\sqrt{\log n})$ operations. Thus our algorithm uses the same number of operations ($O(n\sqrt{\log n})$) as the algorithm by Albers and Hagerup [2] and by Dessmark and Lingas [12] while our algorithm runs faster (in $O(\log n)$ time) than their algorithm (in $O(\log n \log\log n)$ time on the CREW PRAM and in $O(\log^{3/2} n)$ time on the EREW PRAM). Thus our EREW algorithm is faster by a factor of $\log\log n$ than the previous best CREW algorithm and is faster by a factor of $\log^{1/2} n$ than the previous best EREW algorithm.

Now consider the problem of sorting n integers in the range $\{0, 1, 2, \ldots, m-1\}$. All previous EREW and CREW conservative algorithms [2, 12, 22, 25, 29] require $O(n \log n)$ operations when m is large, even when the time complexity is allowed to be polylogarithmic of n. Actually the number of operations of best previous results is larger than $O(n \log n)$, however, we could assume that these algorithms switch to comparison sorting when m is at a certain threshold value. Our result is the first which sorts arbitrarily large integers with $o(n \log n)$ operations. Our EREW integer sorting algorithm sorts in $O(\log n)$ time with $O(n\sqrt{\log n})$ operations. This is for arbitrarily large values of m.

We also present an algorithm (Theorem 4.1) which sorts integers in $\{0, 1, \ldots, m-1\}$ with $O(\log^{3/2} n)$ time and $O(n\sqrt{\log n})$ operations and it runs in linear space. Previously, Dessmark and Lingas [12] achieved this performance only for sorting integers in the range $\{0, 1, \ldots, n^k\}$ for a constant k. This can also be compared with the sequential algorithm in [3].

We now turn to nonconservative integer sorting. Consider the problem of sorting n integers in the range $\{0, 1, 2, \ldots, m-1\}$ on a computer with word length w. Hagerup and Shen [16] showed that if $w = \Omega(n \log n \log m)$, the sorting can be done in linear space and in $O(n)$ sequential time or in $O(\log n)$ time on a EREW PRAM with $O(n)$ operations. Later, Albers and Hagerup [2] and Andersson et al. [4] improved on the word length. Albers and Hagerup [2] showed that with $w = O(\log n \log\log n \log m)$ the sorting can be done in linear space and in $O(\log^2 n)$ time with $O(n)$ operations on the EREW PRAM. The result of Andersson et al. [4] show that the sorting can be done in linear space and in $O(\log n)$ time with $O(n)$ operations on the EREW PRAM with a word length of $O((\log n)^{2+\epsilon} \log m)$. Dessmark and Lingas [12] showed that the sorting can be done on the EREW PRAM in linear space and in $O(\log n \log\log n)$ time and $O(n)$ operations with a word length of $O(\log m \log n)$. In this paper we improve on all these previous results. We show that the sorting can be done in $O(nm^{\epsilon})$ space and in $O(\log n)$ time with $O(n\sqrt{\frac{\log n}{k}})$ operations on the EREW PRAM with a word length of $O(k \log m)$, where k is a parameter satisfying $1 \le k \le \log n$. When $k = \log n$ our algorithm shows that the sorting can be done in linear space and in $O(\log n)$ time with $O(n)$ operations. It is this version of the algorithm that outperforms all previous algorithms. We note that the main focus of this paper is to present conservative EREW algorithms for integer sorting. The nonconservative algorithm we designed is to be used as a subroutine in our conservative algorithms, although our nonconservative algorithm improves on our best previous results.

Algorithms presented in this paper are deterministic algorithms. These algorithms are stable in the sense that input integers of the same value retain their original relative order in the output.

2. Nonconservative sorting. We present an EREW algorithm using word length $O(\log n \log m)$ to sort n integers in the range $\{0, 1, \ldots, m-1\}$ in $O(\log n)$

time with $O(n)$ operations. The input numbers are assumed in an array. This EREW algorithm is based on the Ajtia, Komlós, and Szemerédi (AKS) sorting network [1], Leighton's column sort [23], Albers and Hagerup's test bit technique [2], and the Benes permutation network [7, 8].

The AKS sorting network [1] has $O(\log n)$ stages. Each stage has no more than $n/2$ comparators. Each comparator has two inputs and two outputs. Each comparator can compare two input numbers and route the smaller number to the left output and the larger number to the right output. When the n input numbers are entered into the AKS sorting network and pass through $O(\log n)$ stages of the sorting network they are sorted at the output of the AKS sorting network.

We will use the principle of Leighton's column sort [23]. This principle states that if we put a set S of n numbers into $\log n$ columns with each column containing $n/\log n$ numbers, then the numbers in S will be sorted by a constant number of the following passes: Sort every column and then perform a fixed permutation among the numbers in all columns. Therefore the principle of Leighton's column sort converts the sorting on n numbers to the sorting on $n/\log n$ numbers (there are $\log n$ columns of them and each of them has to be sorted) and fixed permutations among the n numbers. A fixed permutation is a permutation known before program execution. It does not depend on the value of the input numbers. In Leighton's column sort these permutations are shuffle, unshuffle, and shift. Also note that if the principle of column sort is recursively applied we can enlarge the number of columns to n^ϵ, where $0 < \epsilon < 1$ is a constant, and the number of passes of sorting on columns and permutations is still a constant.

Albers and Hagerup's test bit technique [2] can be used for packed numbers. When there are k numbers packed into a word, we can use this technique to do pairwise comparison of the numbers in two words and extract the larger numbers into one word and smaller numbers into another word. An example will make this clear. A test bit of 0 or 1 is added between the numbers packed into a word. Suppose we pack three numbers a_1, a_2, a_3 (each containing t bits) into a word as $w_1 = 1a_1 1a_2 1a_3$ and pack another three numbers b_1, b_2, b_3 (each containing t bits) into a word as $w_2 = 0b_1 0b_2 0b_3$. That is, we add a test bit of 0 or 1 between the numbers. By setting $w_3 = w_1 - w_2$ and then applying a mask we can extract out the test bits of w_3. These test bits tell us which number is larger. By using these test bits we can subsequently extract out the larger numbers from w_1 and w_2 and put them into one word. Similarly we can also extract out the smaller numbers from w_1 and w_2 and put them into one word. Note that this operation takes constant time no matter how many numbers are packed into one word.

The Benes permutation network [7, 8] is a network with $O(\log n)$ stages. Each stage has $n/2$ switches. Each switch has two inputs and two outputs. When the switch is unset the left input goes to the left output and the right input goes to the right output. When the switch is set the left input goes to the right output and the right input goes to the left output. By setting up the switches in the Benes permutation network any permutation of the input can be realized. We will use butterfly networks (explained below) which also have $O(\log n)$ stages and each stage has $n/2$ switches. Butterfly networks can emulate the Benes network and realize any permutation.

LEMMA 2.1. *If the word length is $O(\log n \log m)$, we can pack n integers in $\{0, 1, \ldots, m-1\}$ into $n/\log n$ words in $O(\log \log n)$ time and $O(n)$ operations on the EREW PRAM.*

Proof. We first pack two integers into one word and we have $n/2$ words left. We

then pack the integers in every two words into one word. We repeat this for $\log\log n$ times until we have $\log n$ integers packed into one word. The time is $O(\log\log n)$. The operation is $n + n/2 + n/4 + n/8 + \ldots = O(n)$. □

With $\log n$ integers packed into one word we can view the n integers in $n/\log n$ words as forming $\log n$ columns. The ith column contains the ith integers in all $n/\log n$ words.

LEMMA 2.2. *The $n/\log n$ integers in each of the $\log n$ columns can be sorted in $O(\log n)$ time and $O(n)$ operations on the EREW PRAM.*

Proof. We build an AKS sorting network on these $n/\log n$ words. On the AKS sorting network we compare two words at each internal node of the network using the test bit technique. Thus each node of the AKS sorting network can be used to compare the $\log n$ integers in the word in parallel. At the output of the AKS sorting network we have sorted $\log n$ columns with the ith column containing ith integers in all $n/\log n$ words. The time is $O(\log n)$ since there are $O(\log n)$ stages in the AKS sorting network. The operation is $(n/\log n) \cdot O(\log n) = O(n)$ because we have only $n/\log n$ words and each of them goes through $O(\log n)$ stages. □

LEMMA 2.3. *A fixed permutation among n integers packed into $n/\log n$ words can be done in $O(\log\log n)$ time and $O(n)$ operations on the EREW PRAM.*

Proof. Simply disassemble the integers in the words so that each word contains one integer. Then apply the permutation. Then reassemble the integers into words. □

"$\log n$" in the paper actually stands for the smallest power of 2 no less than $\log n$. This is achieved without increasing the space to superlinear as follows. Take k to be the smallest integer which is a power of 2 and which is no less than $\log n$. Pack k integers into one word. We obtain $l = \lceil n/k \rceil$ words. We take a number l' which is a power of 2 and which is the smallest number no less than l. We assume that we have l' words. Note that here we do not require that $k = \log(l'k)$. The total number of integers is $l'k \leq 3n$.

For our purpose (because we need to sort integers in a linked list) we also need the following scheme to accomplish the permutation mentioned above. The permutation also can be done by routing the integers through a network N, which is the butterfly network in conjunction with a reverse butterfly network (see Figure 2.1). For permutations, N can be used to emulate the Benes permutation network [7, 8]. Each stage of the butterfly network emulates the processor connection along a dimension on the hypercube. (That is, at dimension j numbers at position a and $a\#j$ are the input into one switch and the output to positions a and $a\#j$ where $a\#j$ is obtained by complementing jth bit of a.) When a and $a\#j$ are in different words we switch integers between the words. (In this case every pair going into a switch is coming from a different word.) When a and $a\#j$ are in the same word (because we pack integers into words) we switch integers within words. (In this case every pair going into a switch is coming from the same word. Here we need k to be a power of 2.) Therefore each stage of the butterfly network can be done in constant time. Because the butterfly network has $O(\log n)$ stages, the permutation can be done in $O(\log n)$ time. Note that since the permutations we performed here are fixed permutations, the setting of the switches in the butterfly network can be precomputed.

THEOREM 2.4. *n integers in the range $\{0, 1, \ldots, m-1\}$ can be sorted on the EREW PRAM with word length $O(\log n \log m)$ in $O(\log n)$ time using $O(n)$ operations and $O(n)$ space.*

Proof. By Leighton's column sort we need only apply Lemmas 2.1, 2.2, and 2.3 a

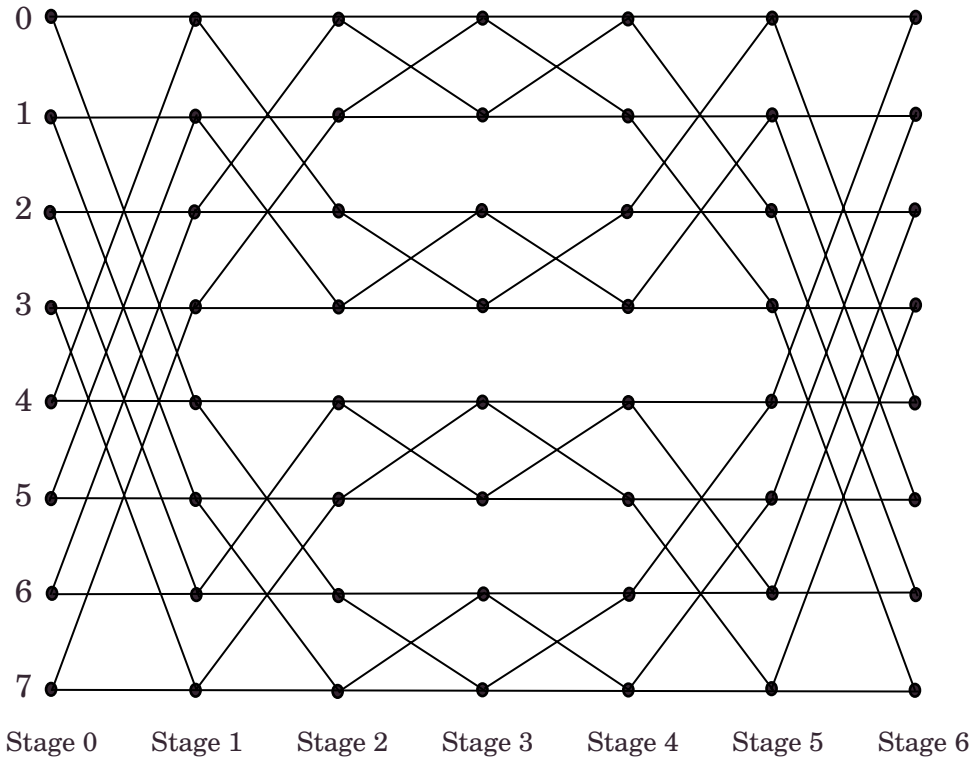

FIG. 2.1. *A permutation network.*

constant number of times. □

The principle of Theorem 2.4 can be applied to the case in which we can pack more than $\log n$ integers into one word. However, in order to apply a recursive version of Leighton's column sort [23] the number of columns cannot be greater than n^ϵ for a constant $0 \leq \epsilon < 1$. Therefore we cannot pack more than n^ϵ integers into one word and then apply the principle of Theorem 2.4. Also note that we may use more columns than the number of integers packed in one word. For example, we may use $\log^2 n$ columns in the column sort even when the number of integers packed in a word is only $\log n$. We will use this fact in the appendix.

The following corollary can now be easily shown.

COROLLARY 2.5. *n integers in the range $\{0, 1, \ldots, m-1\}$ can be sorted on the EREW PRAM with word length $O(k \log m)$, $1 \leq k \leq \log n$, in $O(\log n)$ time using $O(\frac{n \log n}{k})$ operations and $O(n)$ space.*

This corollary is easily obtained by packing k integers into one word and then by applying Lemmas 2.1, 2.2, and 2.3 and Theorem 2.4.

Also note that the sorting can be made stable by appending address bits to each integer. If $m \leq n$, we use an observation which says that n input integers $a_0, a_1, a_2, \ldots, a_{n-1}$ can be divided into n/m sets with ith set containing $a_{im}, a_{im+1}, \ldots, a_{(i+1)m-1}$ and we need only to sort each set. The results of the sorting on each set can be combined to yield the sorted sequence of input integers. This combining takes $O(\log n)$ time and linear operations. This observation is made by Rajasekaran and Sen [25]. Algorithms presented in [2] also make use of this observation. Thus the

address bits used are always being $\min\{\log n, \log m\}$. To add the address bits we can sort in two passes with each pass sorting on $\log m/2$ bits. Therefore the address bits can be added because the number of address bits now is $\min\{\log n, \log m/2\}$.

3. Sorting integers in $\{0, 1, \ldots, n-1\}$. We consider the problem of sorting n integers in the range $\{0, 1, \ldots, n-1\}$ on the EREW PRAM with word length $O(\log n)$. For our purpose we assume that $\sqrt{\log n}$ is a power of 2. The way this is done is to take the smallest integer which is a power of 2 and which is no less than $\sqrt{\log n}$. There is no danger of using superlinear space because this quantity does not determine the space usage.

If input integers with the same value are linked in a linked list in the order they appear in the input, then additional $O(\log n)$ time and $O(n)$ operations suffice for the sorting. This is because we can use linked list contraction [5] to group integers of the same value together. Because we are sorting integers from $\{0, 1, 2, \ldots, n-1\}$ we can use bucket sorting. The first integer in each linked list drops itself into a bucket. Because there are only n buckets, integers dropped into the buckets can be collected in $O(\log n)$ time and $O(n)$ operations. Here the computation is as follows:

1. The first integer (representative integer) in each linked list drops itself into a bucket. This is done for all representative integers in parallel in one step. Because different representative integers have different values the dropping operation has no conflicts among integers.

2. Do a parallel prefix computation to pack integers in the buckets into consecutive locations. This will have all integers dropped into buckets sorted.

Our goal, therefore, is to link integers of the same value into a linked list. Initially, we put all input integers into one linked list. As the computation proceeds, each linked list is split into several linked lists. When the computation ends, all integers with the same value will be linked into a linked list and integers with different values are in different linked lists.

The basic idea of the sorting algorithm is linked list splitting. Let $a_0, a_1, \ldots, a_{n-1}$ be the input integers. The algorithm has $\sqrt{\log n}$ stages. In each stage we examine $\sqrt{\log n}$ bits (we say that we reveal $\sqrt{\log n}$ bits). Initially no bits are revealed. In the first stage we reveal the most significant $\sqrt{\log n}$ bits. In the second stage we reveal the next $\sqrt{\log n}$ bits, and so on. We maintain the property that all integers are linked in a linked list if their revealed bits are the same (of the same value). If the revealed bits for two integers are different, then the two integers are in different linked lists. Initially, all integers are linked into one linked list with a_{i+1} following a_i in the linked list. After the first stage, the input linked list is split into at most $2^{\sqrt{\log n}}$ linked lists because $\sqrt{\log n}$ bits are revealed. After the second stage each linked list further splits itself into at most $2^{\sqrt{\log n}}$ linked lists, and so on.

Now we discuss how each linked list is split in each stage. A linked list is short if it contains fewer than $2^{4\sqrt{\log n}}$ elements and is long if it contains at least $2^{4\sqrt{\log n}}$ elements. We first group every consecutive S elements (integers) in the linked list into one group. For a short linked list, S is the number of total elements in the linked list. For a long linked list, S varies from group to group but is at least $2^{4\sqrt{\log n}}$ and no more than $2^{5\sqrt{\log n}}$. We can consider a grouping as contracting the S elements into one node and/or as ranking the S elements along the linked list within the group. This grouping can be done by linked list contraction algorithms [5, 17, 18]. We then sort integers in each group in parallel. Because revealed bits for the previous stages for integers in the linked list are identical and because we reveal additional $\sqrt{\log n}$ bits in this stage, we are, in fact, sorting no more than $2^{5\sqrt{\log n}}$ $\sqrt{\log n}$-bit integers in each

group. By our nonconservative sorting algorithm presented in the previous section, the sorting can be done in $O(\sqrt{\log n})$ time and $O(S)$ operations for the group (or $O(n)$ operations for all linked lists). Note that if a short linked list contains too few integers (say t integers), we cannot pack $\sqrt{\log n}$ integers into one word and then apply column sort (see the paragraph immediately below Theorem 2.4). In this situation we pack a smaller number of integers ($\log t$ integers) into a word to facilitate column sorting. For example, if a short linked list contains only $\sqrt{\log n}$ integers, then we pack $\log(\sqrt{\log n})$ integers into a word and then apply column sort.

If the linked list is short, there is only one group in the linked list. The sorting will then enable us to split the linked list into $t \le 2^{\sqrt{\log n}}$ linked lists such that each split linked list contains all integers whose revealed bits are the same, where t is the number of bit patterns for the revealed bits. Here we note that for a short linked list, t could be less than $2^{\sqrt{\log n}}$. (For example if the revealed bits for all integers are the same, t will be equal to 1.)

If the linked list is long, we will always split the linked list into exactly $2^{\sqrt{\log n}}$ linked lists no matter how many different bit patterns are revealed by the revealed bits. After sorting in each group, integers in each group are split into $2^{\sqrt{\log n}}$ linked lists. If a bit pattern among the $2^{\sqrt{\log n}}$ bit patterns does not exist in the revealed bits, we create a linked list containing only one dummy element representing this pattern. Note that no more than $2^{\sqrt{\log n}}$ dummy elements will be created for each group. For consecutive (neighboring) groups on a long linked list we then join the split linked lists in the groups such that linked lists with the same revealed bits are joined together. With the help of those dummy elements we now have split a long linked list into exactly $2^{\sqrt{\log n}}$ linked lists.

With the existence of dummy elements in the linked list, the splitting process should be modified a little bit. For a short linked list, after the grouping all dummy elements will be eliminated. For a long linked list, the dummy elements will also be eliminated after grouping, but new dummy elements could be created because we need to split each long linked list to $2^{\sqrt{\log n}}$ linked lists.

Since each group on a long linked list has at least $2^{4\sqrt{\log n}}$ elements and since each such a group creates at most $2^{\sqrt{\log n}}$ dummy elements, the total number of dummy elements created in a stage is at most $n/2^{3\sqrt{\log n}}$. Dummy elements generated in a stage are eliminated in the next stage and new dummy elements are generated for the next stage. For a total of $\sqrt{\log n}$ stages the total number of dummy elements generated is no more than $cn\sqrt{\log n}/2^{3\sqrt{\log n}}$ for a constant c. Here, constant c may be greater than 1 because as dummy elements are generated we have $n' > n$ elements now. In this situation the number of dummy elements generated in the next stage will be $n'/2^{3\sqrt{\log n'}}$.

Let us estimate the complexity. Since each stage takes $O(\sqrt{\log n})$ time and $O(n)$ operations, for a total of $\sqrt{\log n}$ stages the time complexity of the algorithm is $O(\log n)$ with $O(n\sqrt{\log n})$ operations.

Although we have left out several implementation details we hope our presentation in this section can convince most readers that our algorithm works. We therefore give the following theorem. The implementation details are very much ad hoc and several known techniques are adapted to make our implementation fit. The implementation details are described in Appendix A.

THEOREM 3.1. *n integers in the range $\{0, 1, 2, \ldots, n-1\}$ can be sorted in $O(\log n)$ time and $O(n)$ space with $O(n\sqrt{\log n})$ operations on the EREW PRAM with word length $O(\log n)$.*

4. Sorting integers in $\{0, 1, \ldots, m-1\}$. Consider the problem of sorting integers in the range $\{0, 1, \ldots, m-1\}$. All known conservative CREW and EREW parallel algorithms [2, 12, 25], even allowing for polylogarithmic running time, will eventually use $O(n \log n)$ operations when m is sufficiently large. In this section we present two conservative EREW algorithms which use only $O(n\sqrt{\log n})$ operations no matter how large m is. Our first algorithm runs in $O(\log^{3/2} n)$ time and $O(n)$ space with $O(n\sqrt{\log n})$ operations. This algorithm also serves the purpose of introducing ideas to be used in our second algorithm. The basic ideas used in both algorithms are the same. However, the second algorithm is more complicated than the first algorithm. Our second algorithm is the only algorithm in this paper which uses more than linear space. This algorithm sorts in $O(\log n)$ time and $O(nm^{\epsilon})$, $0 < \epsilon < 1$, space with $O(n\sqrt{\log n})$ operations. We note that the linked list splitting idea presented in the previous section does not apply here and therefore new ideas are needed.

First let us outline our approach. We use *bit* $[i]$ to denote bits $i \log m/\sqrt{\log n}$ through $(i+1)\log m/\sqrt{\log n} - 1$. (Bits are counted from the least significant bit starting at 0.) $[i : j]$ is used to denote bits $[i], [i+1], \ldots, [j]$ (or empty if $j < i$). We use $a^{[i]}$ to denote bits $i \log m/\sqrt{\log n}$ through $(i+1)\log m/\sqrt{\log n} - 1$ of a. $a^{[i:j]}$ is used to denote bits $a^{[i]}, a^{[i+1]}, \ldots, a^{[j]}$ (or empty if $j < i$). To sort n integers with each integer containing $\log m$ bits we could use $\sqrt{\log n}$ passes. The ith pass, $0 \le i < \sqrt{\log n}$, sorts bit $[\sqrt{\log n} - i - 1]$. Note that we are sorting from high order bits to low order bits. At the beginning of ith pass the input integers are divided into a collection C of sets such that integers in one set have the same value in bits $[\sqrt{\log n} - i : \sqrt{\log n} - 1]$. In the ith pass we can sort integers in each $s \in C$ independently and in parallel. We call the sorting problem formed by integers in an $s \in C$ an independent (sorting) problem (or an I-problem for short). The sorting in the ith pass further subdivides each $s \in C$ into several sets with each set forming an I-problem for the next pass. Note that if a set s_1 resulting from the subdivision (sorting in the ith pass) of $s \in C$ is a singleton, then the integer $a \in s_1$ needs not to be passed to the next pass because a has been distinguished from other integers and the final rank of a can be determined. When we say an I-problem p we refer to the integers passed from the previous pass to the current pass which form p. When integers in p are sorted in the current pass some of them will be passed to the next pass and these integers are no longer in p. After the current pass finishes, p refers to those integers in the singletons which remained and did not pass to the next pass. Because in a pass we sort $\log m/\sqrt{\log n}$ bits only while each word has $\log m$ bits, each pass can be computed with $O(n\sqrt{\log n})$ operations (by the corollary to Theorem 2.4). This will give us a total of $O(n \log n)$ operations for the algorithm. To reduce the number of operations, we pipeline all passes. Integers will be passed from the ith pass to the $(i+1)$st pass as soon as enough numbers of integers with the same bits $[\sqrt{\log n} - i - 1 : \sqrt{\log n} - 1]$ are accumulated instead of at the end of the ith pass. The details will be explained in the following subsection.

4.1. Sort in $O(\log^{3/2} n)$ time and $O(n\sqrt{\log n})$ operations. We give an outline which explains the essence of our ideas. Suppose we are sorting n integers. If we pass these n integers through the AKS sorting network [1], we will get $O(\log n)$ time and $O(n \log n)$ operations. This is $O(\log n)$ operations per integer. The reason each integer incurs $O(\log n)$ operations is that it must be compared across n integers. If we sort n^t, $0 < t < 1$, integers, then each integer compares across n^t integers, and therefore each integer incurs only $O(t \log n)$ operations. If we take the most significant $\log m/\sqrt{\log n}$ bits out of $\log m$ bits from each integer to form a small integer, we can pack $\sqrt{\log n}$ small integers into one word and therefore we have only $n/\sqrt{\log n}$

words to handle. Sorting these words through the AKS sorting network takes only $O(n\sqrt{\log n})$ operations. However, this sorting may not accomplish the sorting for the input integers. The problems occur when two integers have the same $[\sqrt{\log n}-1]$ bits, i.e., small integers obtained from them are equal. We treat this problem in this way. We use several levels for sorting. We do not sort all small integers at once. At the level 0 we divide them into groups with each group containing $2^{\sqrt{\log n}}$ integers. In the first stage we sort integers in each group. This entails constant operations for each small integer because each small integer has only $\sqrt{\log n}$ bits. In each next stage we merge $2^{\sqrt{\log n}}$ groups into one group. If the sorting/merging reveals that several small integers are equal, then we remove all these small integers and replace them with a dummy. This dummy has the same value as the small integers removed. Removed integers will participate in sorting at level 1 where their $[\sqrt{\log n}-2]$ bits are sorted. Since removed small integers no longer participate in sorting in level 0, each of them incurred a few operations. The operations incurred by each integer at levels greater than 0 depend on when it is passed from level 0. If it is passed down at early stages, it incurs few operations at level 0, but it will incur more operations at higher numbered levels. If it is passed down at later stages, it incurs more operations at level 0, but it will incur less operations at higher numbered levels. This is because if the integer is passed down at later stages, there are only a few integers with the same bit value at bits $[\sqrt{\log n}-1]$ as itself, and therefore the I-problem formed at higher numbered levels is of smaller size, and therefore it incurs fewer operations at higher numbered levels.

In our algorithm the computation is organized into $\sqrt{\log n}$ levels. Each level represents a pass explained in the paragraph before this subsection. There are $\sqrt{\log n}$ stages in each level and stage i_1 at level l_1 is executed concurrently with stage i_2 at level $l_2 > l_1$, where $i_1 - i_2 = l_2 - l_1$. Each stage takes $O(\log n)$ time and $O(n)$ operations. Because there are a total of $2\sqrt{\log n}-1$ stages our algorithm takes $O(\log^{3/2} n)$ time and $O(n\sqrt{\log n})$ operations. The computation at level i, $0 \le i < \sqrt{\log n}$, is to work on bits $[\sqrt{\log n}-i-1]$. We use array $I[0:n-1]$ to represent the n input integer and use $I[i:j]$ to denote $I[i], I[i+1], \ldots, I[j]$. Although the computation at each level is similar, describing the computation at an arbitrary level would be too complicated. Instead we first give pseudo codes outlining the overall structure of the algorithm and then describe the computation at levels 0 and 1 and then generalize it to arbitrary levels.

```
Sort1(A)
{
a.    for i = 0 to n − 1 do in parallel
b.        { A[0][i] = A[i]; /* Put integers at level 0 */

c.    for k = 0 to 2√(log n) − 2 do /*stage k */
d.    {
e.        if k < √(log n), then for l = 0 to k do in parallel B(A, k, l); /* level l */
f.        else for l = k − √(log n) + 1 to √(log n) − 1 do in parallel B(A, k, l);
g.    }
}

B(A, k, l)
{
    1.    for j = 0 to n/2^((k−l+1)√(log n)) and i = i(j) = j2^((k−l+1)√(log n)) to
          (j + 1)2^((k−l+1)√(log n)) − 1 do in parallel

    2.        /* section j, here i(j) indicates that this i is coming from section j. */
```

```
3.      {
4.          if Meet[j][(A[l][i(j)])^[√log n − l, √log n − 1]][(A[l][i(j)])^[√log n − l − 1]], then
5.              /* Integers in the same I-problem (indicated by [(A[l][i(j)])^[√log n − l, √log n − 1]]
                at level l in section j meet if they have the same (A[l][i(j)])^[√log n − l − 1] value. Meet is true
                if at lease two integers meet.*/
6.          {
7.              if l < √log n − 1 then
8.              {
9.                  move A[l][i(j)] to A[l + 1][i(j)]; /* move to next level*/
10.             make one integer among the meet become a dummy with value A[l][i(j)],
                then delete A[l][i(j)];
11.             }
12.         }
13.     }
}
```

The above procedure outlines the overall process of sorting. The Meet operation in procedure B is actually done by sorting and merging. The above procedures give the precise relationship among stage(k), sections(j), levels(l), I-problem (bits $[\sqrt{\log n} - l, \sqrt{\log n} - 1]$), and the value being sorted on (bits $[\sqrt{\log n} - l - 1]$).

The computation at different levels is illustrated in Figure 4.1 and the Meet operation at different levels is illustrated in Figure 4.2.

The computation at level 0 is to sort the n input integers by their most significant $\log m/\sqrt{\log n}$ bits. Each stage at level 0 is to merge $2^{\sqrt{\log n}}$ sorted sequences. (This is indicated by the Meet operation in line 4 of procedure B.) That is, the sorting at level 0 is guided by a complete $2^{\sqrt{\log n}}$-ary tree. Each level of the tree represents the $2^{\sqrt{\log n}}$-way merge in a stage. After stage s and before stage $s + 1$ there are $n/2^{(s+1)\sqrt{\log n}}$ sorted sequences (which are the sections in the procedure B). Suppose integer $a^{[\sqrt{\log n}-1]}$ is in the sorted sequence S. a will remain in level 0 of the algorithm as long as there are fewer than $2^{\sqrt{\log n}}$ integers $b^{[\sqrt{\log n}-1]}$ in S such that $a^{[\sqrt{\log n}-1]} =$

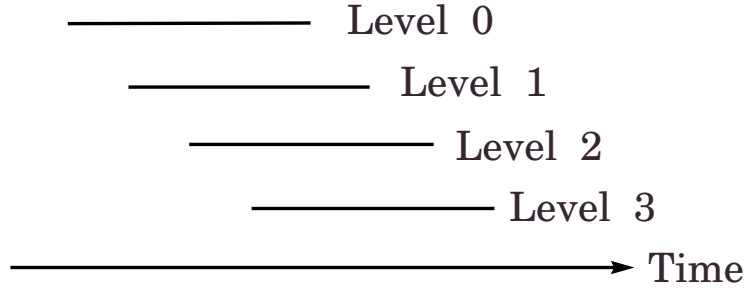

FIG. 4.1. *Computation at different levels is pipelined.*

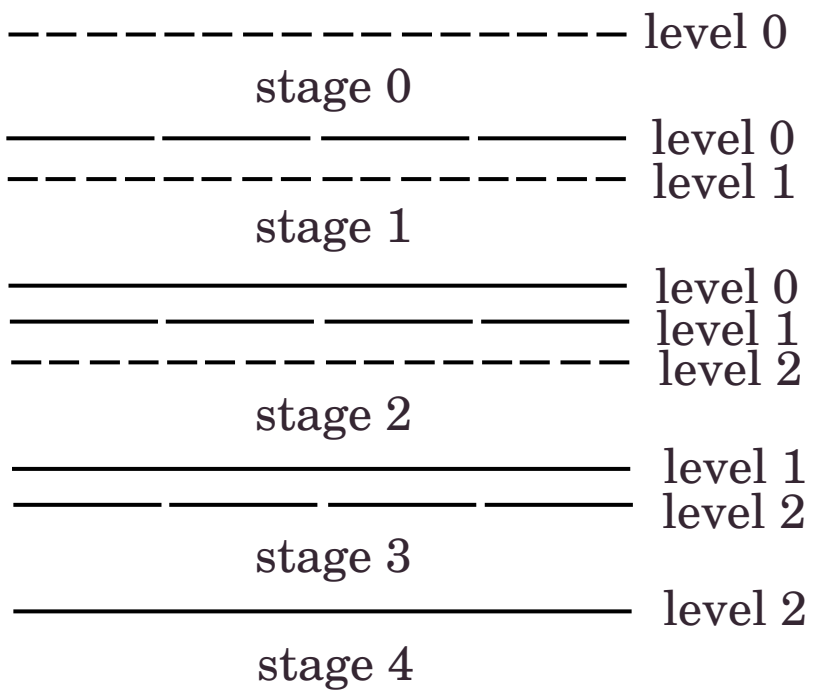

FIG. 4.2. *The merging (Meet) process at different stages.*

$b^{[\sqrt{\log n}-1]}$ (which is what we mean by Meet in procedure B). (Note that all these integers are now consecutive in memory.) Once this condition is not satisfied a will be moved to level 1. Thus one function of level 0 is to group integers $a^{[\sqrt{\log n}-1]}$ and once there are enough integers of the same value grouped together they are sent to level 1. When enough integers of the same value $a^{[\sqrt{\log n}-1]}$ are grouped together in a sorted sequence S and are sent to level 1, we create a dummy with value $a^{[\sqrt{\log n}-1]}$ and place this dummy in S in level 0 to replace the integers sent to level 1. If in a subsequent merge some integers of the same value $a^{[\sqrt{\log n}-1]}$ are grouped together with the dummy (again Meet in procedure B), all these integers (no matter how many) are sent to level 1 and we need only one dummy to represent these integers at level 0. Of course when dummies with the same value $a^{[\sqrt{\log n}-1]}$ are grouped together by the merge only one dummy needs to remain while others can be discarded. After the sorting (i.e., all $\sqrt{\log n}$ stages) in level 0 finishes, integers remain in level 0 are those that do not have $2^{\sqrt{\log n}}$ or more input integers with the same $a^{[\sqrt{\log n}-1]}$ value. For integers with the same $a^{[\sqrt{\log n}-1]}$ value in level 0 (there are less than $2^{\sqrt{\log n}}$ of them) we sort them by their whole integer value (not just the most $\log m/\sqrt{\log n}$ bits) by comparison sorting [1, 10]. Because each such comparison sorting is on no more than $2^{\sqrt{\log n}}$ elements, the number of operations will be bounded by $O(n\sqrt{\log n})$. After this comparison sorting all integers and dummies at level 0 are sorted. Level 0 has divided integers passed to level 1 into I-problems. Integers a with the same $a^{[\sqrt{\log n}-1]}$ value which are passed to level 1 are in one such I-problem. Now we need to sort integers in each I-problem independently and in parallel.

Now consider the computation at level 1. We consider only one I-problem. The

problem is to sort all integer a's by $a^{[\sqrt{\log n}-2]}$ value, where the value $a^{[\sqrt{\log n}-1]}$ for all a's are identical. The sorting at level 1 also has $\sqrt{\log n}$ stages and is also guided by a conceptual $2^{\sqrt{\log n}}$-ary tree. However, many of the leaves may be empty because no integer is passed from level 0. Stage s at level 0 and stage $s-1$ at level 1 (and stage $s-i$ at level i) are executed concurrently. Immediately after stage 0 at level 0 all integers a with the same $a^{[\sqrt{\log n}-1]}$ values in $I[i2^{\sqrt{\log n}} : (i+1)2^{\sqrt{\log n}}-1]$ are grouped together, where $0 \le i < n/2^{\sqrt{\log n}}$. If there are integers a in $I[i2^{\sqrt{\log n}} : (i+1)2^{\sqrt{\log n}}-1]$ which have the same $a^{[\sqrt{\log n}-1]}$ value and are passed down to level 1 in stage 0 of level 0, these integers are merged (sorted) by the $2^{\sqrt{\log n}}$-way merge on the $a^{[\sqrt{\log n}-2]}$ value in stage 0 at level 1. In stage 1 at level 0 all integers a with the same $a^{[\sqrt{\log n}-1]}$ values in $I[i2^{2\sqrt{\log n}} : (i+1)2^{2\sqrt{\log n}}-1]$ are grouped together, where $0 \le i < n/2^{2\sqrt{\log n}}$. Consider integers a with the same $a^{[\sqrt{\log n}-1]}$ value in $I[i2^{2\sqrt{\log n}} : (i+1)2^{2\sqrt{\log n}}-1]$. These integers are grouped into a collection C of at most $2^{\sqrt{\log n}}$ groups (which are sections in procedure B) in stage 0 of level 0 (group j coming from $I[j2^{\sqrt{\log n}} : (j+1)2^{\sqrt{\log n}}-1]$, $i2^{\sqrt{\log n}} \le j \le (i+1)2^{\sqrt{\log n}}-1$). These $2^{\sqrt{\log n}}$ groups are further grouped into one group G in stage 1 of level 0. If some groups in C are passed down to level 1 at stage 0 of level 0, these passed down groups are sorted in stage 0 at level 1 (which execute in parallel with stage 1 of level 0). Note the relation between sections and levels in procedure B. If there is at least one group passed down to level 1, there will be a dummy at level 0 and therefore all integers in G will be passed down at stage 1 of level 0. By using the dummies at level 0 we will be able to build a linked list to link integers passed down at stage 0 with integers passed down at stage 1. And by executing linked list ranking [5] we can then move all integers in G into consecutive memory locations. Here list ranking takes $O(|G|)$ operations and $O(\log n)$ time. Note that linked list linking and ranking here also maintain the stable property for sorting. Our intention is to do a $2^{\sqrt{\log n}}$-way merge (one way for integers in a group in C) at stage 1 of level 1. However, integers in G which are passed down at stage 1 of level 0 (denote this set by G') are not sorted by $a^{[\sqrt{\log n}-2]}$ and therefore they cannot participate in the $2^{\sqrt{\log n}}$-way merge directly. What we do is to first sort integers in G' by bit $[\sqrt{\log n}-2]$ and then perform the merge. Because G' contains less than $2^{2\sqrt{\log n}}$ integers and because sorting is performed on integers each having $\log m/\sqrt{\log n}$ bits, the sorting can be done in $O(\sqrt{\log n})$ time and linear operations by Theorem 2.4.

Thus at level 1 we are forming sorted sequences (sections in procedure B and sorted by bits $[\sqrt{\log n}-2 : \sqrt{\log n}-1]$) and repeatedly merge the sorted sequences (to form larger sections). Suppose integer $a^{[\sqrt{\log n}-2:\sqrt{\log n}-1]}$ is in the sorted sequence S. a will remain in level 1 as long as there are less than $2^{\sqrt{\log n}}$ integers $b^{[\sqrt{\log n}-2:\sqrt{\log n}-1]}$ in S such that $a^{[\sqrt{\log n}-2:\sqrt{\log n}-1]} = b^{[\sqrt{\log n}-2:\sqrt{\log n}-1]}$. (Note that all these integers are now consecutive in memory.) Once this condition is not satisfied a will be moved to level 2 and we will create a dummy with value $a^{[\sqrt{\log n}-2:\sqrt{\log n}-1]}$ at level 1 to replace the integers moved to level 2. As we did in level 0, for integers a stayed in level 1 and never passed to level 2, there are less than $2^{\sqrt{\log n}}$ integers with the same $a^{[\sqrt{\log n}-2:\sqrt{\log n}-1]}$ values and therefore we can sort them by their whole integer value using parallel comparison sorting after the $(\sqrt{\log n}-1)$st stage at level 1.

The relation of level 2 to level 1 is the same as that of level 1 to level 0. In general, integers passed to level i are divided to belong to I-problems with each problem containing integer a's with the same $a^{[\sqrt{\log n}-i:\sqrt{\log n}-1]}$ value. In each such problem at level i, integers are either sorted at level i (by a repeated $2^{\sqrt{\log n}}$-way

merge) or passed down to level $i+1$. Integers passed to level $i+1$ are divided at level i into I-problems such that all integer a's with the same $a^{[\sqrt{\log n}-i-1:\sqrt{\log n}-1]}$ value are in one I-problem.

There are a total of $2\sqrt{\log n}-1$ stages executed in our algorithm. After these stages and after we use parallel comparison sorting to sort integer a's with the same $a^{[\sqrt{\log n}-i-1:\sqrt{\log n}-1]}$ value at level i, integers at all levels are sorted. We can then build a linked list. For integers and dummies in each I-problem we simply let each element point to the next element. We then "insert" integers sorted in each I-problem p at level i into the position of the corresponding dummy at level $i-1$ by using a pointer from the dummy to point to the first integer in p and using another pointer from the last integer in p to point to the successor of the dummy. We therefore build a linked list for all the integers and these integers are in their sorted order in the linked list. After a linked list ranking [5] we have all the integers sorted.

At the end of each stage of our algorithm we use linked list ranking [5] and standard parallel prefix computation [20] to move integers and dummies belonging to each I-problem in consecutive memory locations so that the next stage can proceed. For example, integers in an I-problem p at level i need to be packed to consecutive memory locations because some integers in p are passed to level $i+1$. When some integers and dummies in p are grouped into one group by the merging at level i because they have the same $a^{[\sqrt{\log n}-i-1:\sqrt{\log n}-1]}$ value, we build a linked list to link the integers at level i with the integers already at level $i+1$. (They are represented by the dummies at level i.) We use linked list ranking and prefix computation to move these integers in one group into consecutive memory locations. Because linked list ranking and prefix computation can be done in $O(\log n)$ time and $O(n)$ operations they are within the time and the number of operations allocated to each stage. Note here that we generate one dummy for at least $2^{\sqrt{\log n}}$ integers in each stage. Thus for all stages the total number of dummies generated is bounded by $2n\sqrt{\log n}/2^{\sqrt{\log n}}$.

Now we discuss the $x \le 2^{\sqrt{\log n}}$-way merge performed on a collection C of x sorted sequences in each stage at each level. The integers to be merged are in consecutive memory locations and processors can be easily allocated to them. The integers we are considering here have only $\log m/\sqrt{\log n}$ bits while each word has $\log m$ bits. We have to accomplish the merge in $O(\log n)$ time and a linear number of operations. If the total number of integers to be merged together is $N < 2^{2\sqrt{\log n}}$ we simply sort them by using Theorem 2.4. Otherwise, $N \ge 2^{2\sqrt{\log n}}$ and we sample every $2^{\sqrt{\log n}}$-th integer from each of the $x \le 2^{\sqrt{\log n}}$ sorted sequences (to be merged). If a sequence has no more than $2^{\sqrt{\log n}}$ integers, we sample its first and last integers. The total number of sampled integers is no more than $2N/2^{\sqrt{\log n}}$. We sort all sampled integers into one sequence S using parallel comparison sorting [1, 10]. We make x copies of S. We then merge one copy of S with one sequence in C. Suppose s_1, s_2, $s_1 \le s_2$, are two consecutive integers in S. Then there are no more than $2^{\sqrt{\log n}}$ integers in each sequence in C which are $\le s_2$ and $\ge s_1$. (For equal integers their order is determined first by the sequence they are in and then by the position they are in the sequence.) These integers form a merging subproblem. Because S is merged with each sequence in C, the original merging problem is now transformed into $|S|+1$ ($|S|$ is the number of integers in S) merging subproblems; each of them is to merge x subsequences with each subsequence containing at most $2^{\sqrt{\log n}}$ integers (they come from a sequence in C). For each merging subproblem we use Theorem 2.4 to sort all integers in the subproblem.

It can now be checked that the $2^{\sqrt{\log n}}$-way merge in each stage at each level

takes $O(\log n)$ time and linear operations. At the end of each stage we use linked list ranking and parallel prefix computation to move integers belonging to each I-problem into consecutive memory locations. This computation takes $O(\log n)$ time and $O(n)$ operations. Therefore each stage takes $O(\log n)$ time and $O(n)$ operations.

THEOREM 4.1. *n integers in the range $\{0, 1, \ldots, m-1\}$ can be sorted in $O(\log^{3/2} n)$ time and $O(n)$ space with $O(n\sqrt{\log n})$ operations and $O(\log(m+n))$ word length on the EREW PRAM.*

4.2. Sort in $O(\log n)$ time and $O(n\sqrt{\log n})$ operations. Our second algorithm will run in $O(\log n)$ time with $O(n\sqrt{\log n})$ operations. This algorithm is more complicated. To achieve $O(\log n)$ time we have to allocate only $O(\sqrt{\log n})$ time to each stage. An immediate problem is the following. Consider an I-problem p at level 1. Integers are passed to p at different stages. Suppose several stages have passed and each sorted sequence in p is pretty long. Now in the current stage a set S of integers are passed down from level 0 to p. Although the number of integers in S are few, to merge integers in S with the sorted sequences in p takes a long time because a sorted sequence in p contains too many integers. The problem here is that not all integers in p are passed down in one stage—some are passed down earlier while others are passed down later. If, for example, all integers in p are passed from level 0 at stage 0 (of level 0), then we can merge the integers in p. To avoid the problem that integers are passed down at different stages, we modify our first algorithm (given in Theorem 4.1) as follows.

We append $\log n$ bits to each input integer to indicate the position of each integer in the input. Note that we can assume $\log m > 2 \log n$. To put $\log n$ bits into a integer we could sort in two passes with each pass sorting $\log m/2$ bits. Then in each pass we can put $\log n$ bits into each integer. The process of our sorting is not stable. Adding the $\log n$ address bits stabilizes the sorting. At each level our algorithm sorts $\log m/\sqrt{\log n}$ bits. In the process of our algorithm execution, an integer a in a sorted sequence at level i will stay in level i as long as the number of integers b in the sorted sequence with $b^{[\sqrt{\log n}-i-1:\sqrt{\log n}-1]} = a^{[\sqrt{\log n}-i-1:\sqrt{\log n}-1]}$ is less than $2^{4\sqrt{\log n}}$. Once this condition is not satisfied, a will be passed to level $i+1$. We keep a dummy at level i to replace the integers passed down to level $i+1$. If there are integers c with $c^{[\sqrt{\log n}-i-1:\sqrt{\log n}-1]} = a^{[\sqrt{\log n}-i-1:\sqrt{\log n}-1]}$ left at level i, they keep grouping as integers at level i are merged. If dummies and integers of the same $[\sqrt{\log n} - i - 1 : \sqrt{\log n} - 1]$ bit values are grouped together, we view dummies as smaller than integers and therefore we group dummies with dummies and integers with integers if they have the same value in bits $[\sqrt{\log n}-i-1 : \sqrt{\log n}-1]$. Note that here we do not pass integers to level $i+1$ when integers are grouped with dummies. Instead we keep grouping more integers together. Once the new group contains $2^{4\sqrt{\log n}}$ or more integers with the same $c^{[\sqrt{\log n}-i-1:\sqrt{\log n}-1]}$ value, all integers in the group will be passed to level $i+1$. Integers which remain at a level to the end of the last stage will have less than $2^{4\sqrt{\log n}}$ integers with the same revealed bit values. We can then sort them by their whole integer value by using comparison sorting.

We define a grouped subproblem of sorting (G-problem for short). The n input integers are initially in a G-problem p. As computation proceeds, some integers in p will be passed to level 1 and will no longer be in p. Some dummies will be created and added to p. *All integers at level $i+1$ which are passed from a G-problem at level i at stage t of level i form a G-problem.*

Consider a G-problem at level i. Integers in different G-problems are sorted independently even if they have the same value in bits $[\sqrt{\log n} - i - 1 : \sqrt{\log n} - 1]$.

Integers in a G-problem may have different values in bits $[\sqrt{\log n}-i-1:\sqrt{\log n}-1]$. Thus a G-problem is further divided into I-problems such that each I-problem contains all the integers in the G-problem which have the same bits $[\sqrt{\log n}-i-1:\sqrt{\log n}-1]$. Note that here the definition of an I-problem is slightly different than that which we defined before because now we require integers in an I-problem to be those within the same G-problem. All I-problems in a G-problem can be solved independently.

For the G-problem p at level 0 we execute $(1/2)\log\log n-1$ stages. In the ith stage we sort all $2^{2^{i+2}\sqrt{\log n}}$ integers by their bit $[\sqrt{\log n}-1]$. That is, in the ith stage every array $I[j2^{2^{i+2}\sqrt{\log n}},(j+1)2^{2^{i+2}\sqrt{\log n}}-1]$, $0\le j<n/2^{2^{i+2}\sqrt{\log n}}$, is sorted. Integers may be passed to level 1 at different stages and form different G-problems at level 1. Because there are $(1/2)\log\log n-1$ stages at level 0, only $(1/2)\log\log n-1$ G-problems are created at level 1. Consider integers passed to level 1 at the ith stage which form a G-problem q at level 1. Integers in q with different bit $[\sqrt{\log n}-1]$ are in different I-problems. Consider an I-problem r in q. Because integers are passed at the ith stage there are at most $S=n/2^{(2^{(i+1)}-4)\sqrt{\log n}}$ integers in r for $i\ge 1$ and there are at most $S=n$ integers in r for $i=0$. We can store the integers in r in an array A of size S as follows. For stage 0, integers in r which are passed from $I[j2^{4\sqrt{\log n}},(j+1)2^{4\sqrt{\log n}}-1]$, $0\le j<n/2^{4\sqrt{\log n}}$, at level 0 are stored in $A[j2^{4\sqrt{\log n}},(j+1)2^{4\sqrt{\log n}}-1]$, $0\le j<n/2^{4\sqrt{\log n}}$. For stage $i>0$, integers in r which are passed from $I[j2^{2^{i+2}\sqrt{\log n}},(j+1)2^{2^{i+2}\sqrt{\log n}}-1]$, $0\le j<n/2^{2^{i+2}\sqrt{\log n}}$, at level 0 are stored in

$$A\left[j\frac{2^{2^{i+2}\sqrt{\log n}}}{2^{(2^{(i+1)}-4)\sqrt{\log n}}},(j+1)\frac{2^{2^{i+2}\sqrt{\log n}}}{2^{(2^{(i+1)}-4)\sqrt{\log n}}}-1\right],\qquad 0\le j<n/2^{2^{i+2}\sqrt{\log n}}.$$

Note that although all integers in p can be stored in A there may be many blank cells in A with no integers stored in them. Also integers passed from $I[j2^{2^{i+2}\sqrt{\log n}},(j+1)2^{2^{i+2}\sqrt{\log n}}-1]$ are now in consecutive positions in A and there are at least $2^{4\sqrt{\log n}}$ of them. Integers in each I-problem in q can be stored in an array of size S. We say that the G-problem q has size S.

For each I-problem r in a G-problem of size R we store integers in r in an array A of size R and execute s stages, where s is the minimum integer satisfying $2^{2^{s+1}\sqrt{\log n}}\ge R$. In the ith stage, $0\le i<s$, we sort integers in $A[j2^{2^{i+2}\sqrt{\log n}},(j+1)2^{2^{i+2}\sqrt{\log n}}-1]$, $0\le j<R/2^{2^{i+2}\sqrt{\log n}}$. As we said before, integers are grouped by the sorting and if the number of integers of the same revealed bits is at least $2^{4\sqrt{\log n}}$, they are sent to the next level. (They form an I-problem in a new G-problem in the next level.) We shall use the algorithm of Theorem 2.4 to do the sorting (the details are to be explained below) and therefore the time expended in the ith stage is $c2^i\sqrt{\log n}$ for a constant c.

Our sorting algorithm can be summarized in the following coding:

$Sort2(A,l,g)$ /*Sort on a set of integers at level l in the g-th G-problem*/
{
  for ($i=1$; $i\le s$; $i++$) /* $s=\min\{t|2^{2^{t+2}\sqrt{\log n}}\ge|A|\}$*/
  {
    Divide integers in A to $|A|/2^{2^{i+2}\sqrt{\log n}}$ groups and sort every group in parallel on $[\sqrt{\log n}-l-1,\sqrt{\log n}-1]$ bits;
    if sets S of integers with the same value on bits $[\sqrt{\log n}-l-1,\sqrt{\log n}-1]$ are detected, do in parallel
    {

if $|S| \geq 2^{4\sqrt{\log n}}$, { remove S from A, replace it with a dummy and call $Sort2(S, l+1, g \cdot \log\log n + i - 1)$; }
}
}
}

Note that in $Sort2$ when several sets S's with the same value in bits $[\sqrt{\log n} - l - 1, \sqrt{\log n} - 1]$ are detected in different groups of A and all these sets have size no less than $2^{4\sqrt{\log n}}$, these sets will be moved into one I-problem of a G-problem. The fact that they are moved into the same I-problem is affected by placing them in the same array.

We say that a G-problem (I-problem) p is solved if integers in each I problem at all levels generated from p are sorted. The time complexity for solving a G-problem p can now be expressed as follows. Assume that the size of p is S, p is at level l, and the time complexity of solving p is $f(S, l)$, and let $t = \min\{i | 2^{2^{i+2}\sqrt{\log n}} \geq S\}$. We have

$$f(S,l) = \max\{\max_{i=1}^{t} c2^i\sqrt{\log n} + f(S/2^{(2^{(i+1)}-4)\sqrt{\log n}}, l+1), \\ c\sqrt{\log n} + f(S, l+1)\},$$
$$f(S, \sqrt{\log n}) = 0.$$

Thus the time complexity for solving the G-problem at level 0 is $f(n, 0) = O(\log n)$.

Now let us consider the operation complexity for solving a G-problem. Suppose the integers in an I-problem p is stored in array A. Suppose at the current stage (stage i) p has S integers and dummies. (Note that many integers may have already passed to the next level at earlier stages.) S may be much smaller than the size of A. However, integers are not scattered around in A. Instead, they are stored as segments with each segment containing at least $2^{4\sqrt{\log n}}$ integers stored in consecutive memory locations if the segment does not contain a dummy. Thus in the current stage (stage i) we can pack the integers in $A[j2^{2^{i+2}\sqrt{\log n}}, (j+1)2^{2^{i+2}\sqrt{\log n}} - 1]$, $j = 0, 1, 2, \ldots$, into consecutive memory locations using $O(2^i\sqrt{\log n})$ time and $O(S + d2^i\sqrt{\log n})$ operations, where d is the number of dummies. Since the number of dummies is a fraction of the total number of integers, the total number of operations is linear. After we packed integers we use the corollary to Theorem 2.4 to sort them. The sorting takes $O(2^i\sqrt{\log n})$ time and $O(S2^i)$ operations. This is to say that if an integer a stayed in p until stage i it incurs $O(2^i)$ operations. However, since a is passed to the I-problem q at the next level at stage i, the size of q is the size of p divided by $2^{(2^{(i+1)}-4)\sqrt{\log n}}$ if $i > 0$ and is at most the same as that of p if $i = 0$. Assume that the size of p is S, p is at level l, and the number of operations incurred by an integer a in p is $g(S, l)$. Then

$$g(S,l) = \max\{\max_{i=1}^{t} c2^i + g(S/2^{(2^{(i+1)}-4)\sqrt{\log n}}, l+1), \\ c + g(S, l+1)\},$$
$$g(S, \sqrt{\log n}) = 0.$$

Thus the number of operations incurred by each integer in the G-problem at level 0 is $g(n, 0) = O(\sqrt{\log n})$. Thus the operation complexity for solving the G-problem at level 0 is $O(n\sqrt{\log n})$.

Below we will discuss how to have all the input integers sorted after we solve the G-problem at level 0.

How many G-problems will be created in the execution of our algorithm? Consider a G-problem p at level l with size S. p executes $\log \frac{\log S}{\sqrt{\log n}} - 1$ stages which generates $\log \frac{\log S}{\sqrt{\log n}} - 1$ G-problems at the next level. The ith G-problem, $i > 0$, generated has size $S/2^{(2^{i+1}-4)\sqrt{\log n}}$. Let the number of G-problems at all levels which are generated from p be $h(S, l)$. We have

$$h(S,l) = h(S,l+1) + 1 + \sum_{i=1}^{\log((\log S)/(\sqrt{\log n}))-2} (h(S/2^{(2^{i+1}-4)\sqrt{\log n}}, l+1) + 1),$$

$$h(S, \sqrt{\log n} - 1) = 1.$$

$h(n, 0)$ is the total number of G-problems generated in our algorithm. It is not difficult to see that $h(n, 0) > 2^{\sqrt{\log n}}$. To evaluate the above formula we enlarge it and obtain the following formula:

$$h(S,l) \le 4 \sum_{i=0}^{(\log S)/(\sqrt{\log n})} h(S/2^{i\sqrt{\log n}}, l+1),$$

$$h(S, \sqrt{\log n} - 1) = 1,$$

which can be rewritten as

$$C(j,l) \le 4 \sum_{k=0}^{j} C(k, l+1),$$

$$C(j, \sqrt{\log n} - 1) = 1,$$

where $C(j, l) = h(2^{j\sqrt{\log n}}, l)$.

The total number of groups generated by our algorithm is $h(n, 0)$, which is

$$\begin{aligned} h(n,0) &= C(\sqrt{\log n}, 0) \\ &= 4 \sum_{k_1=0}^{\sqrt{\log n}} C(k_1, 1) \\ &= 4^{\sqrt{\log n}} \sum_{k_1=0}^{\sqrt{\log n}} \sum_{k_2=0}^{k_1} \sum_{k_3=0}^{k_2} \cdots \sum_{k_{\sqrt{\log n}}=0}^{k_{\sqrt{\log n}-1}} 1 \\ &\le 2^{\delta\sqrt{\log n}}, \quad \text{where } \delta < 3.5. \end{aligned}$$

Therefore, there are no more than $2^{\delta\sqrt{\log n}}$ G-problems generated.

We attach a tag to each integer and dummy to indicate which G-problem it is in. Although the tag can be implemented by an $O(\sqrt{\log n})$-bit integer because there are only $2^{\delta\sqrt{\log n}}$ G-problems, to facilitate the computation of the tag when an integer is passed from a G-problem at level i to another G-problem at level $i + 1$, we use an $O(\sqrt{\log n} \log\log\log n)$-bit integer for a tag. If an integer a is in the G-problem p at level i and its tag is t, and it is passed at stage s of level i to another G-problem p_1 at level $i + 1$, we form the new tag for a by appending $O(\log\log\log n)$ bits indicating s

to t. Dummies created to represent integers passed to the next level inherit the new tag of the integers after they are passed. Thus all integers in a G-problem have the same tag. Dummies in a G-problem may have different tags because they represent integers passed to next level at different stages.

Now consider an I-problem p in a G-problem at level i. As the sorting in p proceeds, integers of the same value in bits $[\sqrt{\log n}-i-1 : \sqrt{\log n}-1]$ are grouped in each sorted sequence in p. If the number of integers of the same value $a^{[\sqrt{\log n}-i-1:\sqrt{\log n}-1]}$ is no less than $2^{4\sqrt{\log n}}$, these integers will be passed down to a G-problem at the next level. A dummy will be created in p to represent these integers. The dummy has the tag which is the same as the new tag those integers obtained after they passed to the next level. Integers with value $a^{[\sqrt{\log n}-i-1:\sqrt{\log n}-1]}$ left in p will keep grouping as the sorting proceeds. When a new group contains at least $2^{4\sqrt{\log n}}$ integers they will be passed to another G-problem and another dummy will be created for them. All integers in the G-problem which are passed down at a stage form a new G-problem. When integers and dummies of the same value in bits $[\sqrt{\log n}-i-1 : \sqrt{\log n}-1]$ are grouped together in p, we assume that dummies are smaller than integers and this allows integers to be grouped with integers to form new groups with more than $2^{4\sqrt{\log n}}$ integers. When dummies with the same bit values and the same tag are grouped together (they represent integers passed to the same I-problem in a G-problem), all of them but one can be removed. But dummies with different bit values or different tags cannot cancel each other.

Now suppose that integers and dummies in each I-problems are sorted and occupy consecutive memory locations. We need to put all integers in a G-problem together to form a sorted sequence. If we accomplish this, we will have only $2^{\delta\sqrt{\log n}}$ sorted sequences left because there are only $2^{\delta\sqrt{\log n}}$ G-problems. We first reduce the number of bits used for a tag to $O(\sqrt{\log n})$ (remember we were using $O(\sqrt{\log n}\log\log\log n)$ bits). This is accomplished easily by sorting all input integers in the input array by their tags. Here we are sorting on $O(\sqrt{\log n}\log\log\log n)$ bits and it can be done by Theorem 3.1. Thereafter we reduce the value for a tag to be within $\{0, 1, \ldots, 2^{\delta\sqrt{\log n}}-1\}$ by eliminating unused values. Thus the number of bits used for a tag becomes $\delta\sqrt{\log n}$. Then we sort integer and dummies in an I-problem p at level i by their tag value. Note that integers in p have the same tag value while dummies may have different tags. Note also that integers and dummies in p were sorted by bits $[\sqrt{\log n}-i-1 : \sqrt{\log n}-1]$. By sorting on their tags we arrange dummies with the same tag value into consecutive memory locations while dummies with the same tag value are still in sorted order by their value of bits $[\sqrt{\log n}-i-1 : \sqrt{\log n}-1]$. We then add a pointer for the first and last integers and each dummy in p to point to the dummy at level $i-1$, which represents the integers in p when they are passed from level $i-1$ to level i. We now view that all integers and dummies being stored in a big array A (of course many cells A are blanks). We allocate $2^{\delta\sqrt{\log n}}$ arrays $A_0, A_1, \ldots, A_{2^{\delta\sqrt{\log n}}-1}$; each of them has the same size as A. Array A_i is used to store integers in ith G-problem (integers tagged with i). For each integer a in A, if a is in $A[k]$ and tagged with i, we now move a to $A_i[k]$ in constant time. If a is the first or last integer in an I-problem (therefore, a has a pointer pointing to $A[j]$, which is a dummy at the lower numbered level), a moves this pointer to A_i and points to $A_i[j]$. For each dummy d in $A[k]$ we make $2^{\delta\sqrt{\log n}}$ copies of it and put one copy in the kth cell of each A_i, $0 \le i < 2^{\delta\sqrt{\log n}}$. If the pointer of d (which points to a dummy at the previous level) points to $A[j]$, we copy the pointer to each A_i and make it point to $A_i[j]$, $0 \le i < 2^{4\sqrt{\log n}}$. Note that because each dummy is created at a level for

at least $2^{4\sqrt{\log n}}$ integers, we can allocate $2^{\delta\sqrt{\log n}}$ processors for each dummy. Up to now we have separated integers in different G-problems into different arrays. The integers and dummies in each array A_i together with their pointers form a tree. By using pointer jumping along the Euler tour of the tree [27] we obtain a sorted list of integers in each G-problem. Consider the pointers allocated to each I-problem. If an I-problem does not contain a dummy (i.e., no integers in the I-problem are passed to the next level), then the I-problem has at least $2^{4\sqrt{\log n}}$ integers. We need to use two pointers, one at the beginning of the integers and one at the end of the integers, for linking this I-problem with other I-problems in the same G-problem. If the I-problem has a dummy, we can always allocate three pointers per dummy. Then one pointer is used for the dummy and the other two pointers can be used for the integers in the I-problem. Suppose there are D dummies then the number of pointers used for all I-problems is $O(D + n/2^{4\sqrt{\log n}})$ and the time used is $O(\log n)$.

Now we have a collection C of $\leq 2^{\delta\sqrt{\log n}}$ sorted sequences of integers. We need to merge all sequences in C into one sorted sequence. We first sample every $2^{\delta\sqrt{\log n}}$th integer from each sequence $s \in C$. If a sequence has no more than $2^{\delta\sqrt{\log n}}$ integers, we sample its first and last integer. We obtain a collection C' of $|C|$ sampled sequences. There are no more than $2n/2^{\delta\sqrt{\log n}}$ sampled integers. We merge every pair of sampled sequences by first making $2^{\delta\sqrt{\log n}}$ copies of each sampled sequence and merge the corresponding pair. If integer a is in a sampled sequence s which is merged with every other sampled sequence, then a knows its rank in every sampled sequence. By summing these ranks a knows its rank in all sampled integers. Therefore we have sorted sampled integers into one sequence q. We then make $2^{\delta\sqrt{\log n}}$ copies of q and merge q with each sequence in C. This merge divides the original merge problem (of merging sequence in C) into $|q| + 1$ submerge problems with each submerge problem merging $|C|$ subsequences of no more than $2^{\delta\sqrt{\log n}}$ integers (one subsequence coming from one sequence in C). Since the total number of integers in each submerge problem is no more than $|C|2^{\delta\sqrt{\log n}} \leq 2^{7\sqrt{\log n}}$ we can use comparison sorting [1, 10] to sort integers in each submerge problem.

Let us estimate the space complexity. Each I-problem formed at stage 0 or 1 at each level requires $O(n)$ space. The space needed for I-problems formed in later stages is geometrically decreasing. Thus $O(mn\sqrt{\log n})$ space is used for solving all G-problems. We then allocate $2^{\delta\sqrt{\log n}}$ arrays of A_i's. Thus the total space used is $O(mn\sqrt{\log n}2^{\delta\sqrt{\log n}})$. However, space can be reduced to $O(nm^{\epsilon})$ by using radix sorting.

THEOREM 4.2. *n integers in the range $\{0, 1, \ldots, m-1\}$ ($m \geq n$) can be sorted in $O(\log n)$ time and $O(nm^{\epsilon})$ space with $O(n\sqrt{\log n})$ operations and $O(\log(m+n))$ word length on the EREW PRAM.*

To sort n integers in the range $\{0, 1, 2, \ldots, m-1\}$ with word length $k \log m$ bits, we modify our algorithm to sort $O(\log m/\sqrt{\log n/k})$ bits in each level, and in the ith stage we sort every $2^{2^{i+2}\sqrt{k\log n}}$ integers. This will give $O(\log n)$ time and $O(n\sqrt{\log n/k})$ operations.

THEOREM 4.3. *n integers in the range $\{0, 1, \ldots, m-1\}$ can be sorted in $O(\log n)$ time with $O(n\sqrt{\log n/k})$ operations and $O(k\log(m+n))$ word length on the EREW PRAM.*

5. Conclusions. We presented EREW integer sorting algorithms which outperform parallel comparison sorting. There are several open questions. An immediate one is to further improve operation complexity. Another open problem is to reduce

the space complexity of the algorithm in Theorem 4.2 to linear. Applications of our algorithm to other problems will also be interesting where the advantage of parallel integer sorting over parallel comparison sorting can be made use of.

Appendix A. Implementation of the algorithm in section 3. The subtlety of our algorithm is in how to do grouping, where to place dummy elements, and how to maintain the space complexity within $O(n)$. Grouping should be done with linked list contraction. However, we cannot apply any existing linked list contraction algorithms directly to obtain $O(\sqrt{\log n})$ time and $O(n)$ operations for a stage because we need an algorithm to do partial linked list contraction. The dummy elements generated need to be placed within $O(n)$ space so that processors can be allocated to them. For the space complexity consideration, after grouping we need sort integers within each group and this may seem to require that we place the integers in a group in consecutive memory locations. If we allocate $O(n)$ memory for placing all integers such that all integers in a group occupy consecutive memory locations, then we would need $O(\log n)$ time while we can expend only $O(\sqrt{\log n})$ time in each stage. What we could do instead is to allocate a two dimensional array with $2^{5\sqrt{\log n}}$ rows and n columns. We place the linked lists in the first row. For each group, we could put the integers in the group in the jth column of the array if the first integer in the group is in column j. This scheme facilitates sorting. The only shortcoming of the scheme is that it uses more than $O(n)$ space. We give schemes from which all the problems mentioned above can be resolved.

For implementation purposes we reveal $\sqrt{\log n}$ bits in each stage except the last stage which reveals $10\sqrt{\log n}$ bits. A linked list is very short if it contains no more than $2^{2\sqrt{\log n}}$ integers, is short if it contains less than $2^{6\sqrt{\log n}}$ integers, and is long if it contains at least $2^{6\sqrt{\log n}}$ integers. A group on a short linked list contains all integers in the list. A group on a long linked list contains at least $2^{6\sqrt{\log n}}$ but fewer than $2^{7\sqrt{\log n}}$ integers.

A.1. Blocked linked list. We modify our linked list construction. Instead of linking elements (integers) from memory location to memory location, we require that every $2^{2\sqrt{\log n}}$ elements in a linked list occupy consecutive memory locations and that the first element among these $2^{2\sqrt{\log n}}$ elements is at a memory cell j where $j \bmod 2^{2\sqrt{\log n}} = 0$. We call such $2^{2\sqrt{\log n}}$ elements a block. Thus if we walk down the linked list, we visit $2^{2\sqrt{\log n}}$ consecutive memory locations, then follow the pointer to another memory location, then visit another $2^{2\sqrt{\log n}}$ consecutive memory locations, and so on. We call such a linked list a blocked linked list. For all the linked lists split we maintain this property (except for the linked lists split at the end of the last stage). This property facilitates linked list contraction. The condition on memory cell $j \bmod 2^{2\sqrt{\log n}} = 0$ ensures that processors can be allocated to the elements in the linked lists. Because we use $n/\sqrt{\log n}$ processors, one processor is allocated for $\sqrt{\log n}$ elements or integers.

A.2. Linked list contraction. Now consider grouping. Because linked lists are blocked, the linked list contraction for the bottom $2^{2\sqrt{\log n}}$ elements are automatically done. That is, for a linked list l_1 of length S, we can view it as being already contracted to a linked list l_2 of length $S/2^{2\sqrt{\log n}}$. For the further contraction of l_2, we can allocate one processor for each node in l_2.

Therefore we are now facing the following linked list contraction problem: Contract a linked list in $O(\sqrt{\log n})$ time and $O(n\sqrt{\log n})$ operations (note that here we can assign one processor to each node in the linked list) such that every S element on

the linked list is contracted to a single node, where $2^{c\sqrt{\log n}} \leq S \leq 2^{(c+1)\sqrt{\log n}}$ and c is a constant.

This is a very special linked list contraction problem and no known linked list contraction algorithm can solve it directly. We use the following scheme to solve this problem.

We will apply pointer jumping [30] to contract the linked list. For a linked list of n nodes pointer jumping takes $O(\log n)$ time and $O(n \log n)$ operations to contract the whole list. Since we are going to contract every S element on the linked list we should break the linked list into pieces such that each piece has S nodes of the linked list and then we apply pointer jumping on each piece. Then the pointer jumping will take $O(\log S) = O(\sqrt{\log n})$ time and $O(n \log S) = O(n\sqrt{\log n})$ operations. This scheme is a perfect one except that we do not have a scheme to break the linked list into pieces of S nodes each.

The current best parallel algorithm [17, 18, 14] for breaking the linked list into pieces (symmetry breaking algorithm) can break the linked list into pieces in $O(\log d)$ time and uses linear operations such that each piece has at least two nodes and at most $\log^{(d)} n$ nodes, where d is a constant. Here we are guaranteed that the linked list will be broken up into pieces. But we are not guaranteed that each piece contains between $2^{c\sqrt{\log n}}$ and $2^{(c+1)\sqrt{\log n}}$ nodes.

Should each broken piece contain about the same number of nodes, say T nodes, then we could apply pointer jumping on each piece for $O(\log T)$ time to contract each piece into a single node. The original linked list L_1 of n nodes is thus being contracted into a linked list L_2 of n/T nodes. Now we could apply symmetry breaking on L_2 and then pointer jumping on the pieces of the linked list after symmetry breaking. We could repeat this symmetry breaking and pointer jumping process for $\log S / \log T$ times and would have finished linked list contraction in $O(\log S)$ time and $O(n \log S)$ operations.

The problem now is that each broken piece of the linked list can contain as few as two nodes and as many as $\log^{(c)} n$ nodes. Thus, the shortest piece takes constant time to contract and the longest piece takes $O(\log^{(c+1)} n)$ time to contract when pointer jumping is applied. If we let processors working on the shortest piece wait until after they finish pointer jumping for the processors working on the longest piece, then the progress of the algorithm will not be fast enough for us to get the $O(\sqrt{\log n})$ time for linked list contraction.

Thus the strategy we use is that when the processors working on a short piece P finish pointer jumping they check whether the neighboring pieces (the previous piece and the next piece) have finished contraction (pointer jumping). If both of its neighboring pieces have not finished contraction, P will wait. If one of P's neighbors N has already finished contraction, then the node P contracts into and the node N contracts into are linked on a linked list and then symmetry breaking and pointer jumping can applied to this linked list.

Since no two consecutive nodes can be in a wait state at the same time, every three nodes are contracted into at most two nodes in a step. Thus the whole contraction process takes $O(\sqrt{\log n})$ time and $O(n\sqrt{\log n})$ operations.

A.3. Coping with dummy elements. We first show how we handle short linked lists. The number of bits we revealed for each integer is $\leq \log n - 10\sqrt{\log n}$ before the last stage. Thus we can have at most $n/2^{10\sqrt{\log n}}$ short linked lists before the last stage. Each short linked list can be indexed by an integer range from 0 to $n/2^{10\sqrt{\log n}}$. We can allocate an array A of size n to store only short linked lists.

$A[i2^{7\sqrt{\log n}} \dots (i-1)2^{7\sqrt{\log n}} - 1]$ is reserved for the short linked list indexed i. Once we have a short linked list we sort it with parallel comparison sorting on the whole integer (not just the revealed bits). This entails $O(\sqrt{\log n})$ time for each short list and $O(\sqrt{\log n})$ operations for each integer, and therefore it will not destroy the complexity analysis for the whole algorithm. Thereafter we consider only long linked lists.

Initially we put all n input integers into a linked list, and therefore we start with a long linked list. To facilitate the later processing we add n dummy elements to the initial linked list. We put input integers and dummies alternately in the initial linked list as $a_0, d, a_1, d, a_2, d, \dots, d, a_{n-2}, d, a_{n-1}$, where d is a dummy. Therefore for every t consecutive integers on the linked list we have t dummies. These dummies will later be used for keeping the blocking property of the linked list and for representing missing patterns in a group.

Initially we have one dummy for every two consecutive elements on the linked list. We use $1/2$ to represent this ratio. After several stages this ratio will become smaller. We assume that at the current stage the ratio is $1/b$, i.e., there is a dummy in every b elements on the linked list.

After sorting integers in a group, integers with the same revealed bits (bit pattern) are consecutive on the linked list. However, the number of integers with the same revealed bits may not be a multiple of $2^{2\sqrt{\log n}}$. To maintain the blocking property of the linked list, we make use of dummy elements so that the number of integers and dummies within each group with the same revealed bit pattern become a multiple of $2^{2\sqrt{\log n}}$. For a group G of S integers in a long linked list, we split it into $2^{\sqrt{\log n}}$ linked lists. Let a linked list L split from G have T integers. We put $\lceil T/(2b) \rceil + 2 \cdot 2^{2\sqrt{\log n}} - (T + \lceil T/(2b) \rceil) \% 2^{2\sqrt{\log n}}$ dummies into L, where % is the modulo operation. Thus the total number of integers and dummies in L is a multiple of $2^{2\sqrt{\log n}}$. Summing over all split linked lists, the total dummies we used is $< S/(2b) + 3 \cdot 2^{3\sqrt{\log n}}$. Thus if $S/b \geq S/(2b) + 3 \cdot 2^{3\sqrt{\log n}}$, i.e., $S/(2b) \geq 3 \cdot 2^{3\sqrt{\log n}}$, then we have enough dummies. The ratio of the dummies to the elements in the split linked list is now $1/(2b)$. Thus through one stage the ratio is reduced by at most half. Since there are $\sqrt{\log n}$ stages the smallest ratio we have is $1/2^{\sqrt{\log n}}$. Because $S \geq 2^{6\sqrt{\log n}}$ we can hold $S/(2b) \geq 3 \cdot 2^{3\sqrt{\log n}}$.

A.4. Sorting each group in linear space. We now show how to sort each group in linear space. For a short linked list we reveal all remaining bits of the integers on the list and then sort these integers using comparison sorting [1, 10]. Since there are at most $n/2^{10\sqrt{\log n}}$ very short linked lists (at the beginning of the last stage), the total number of operations involved in sorting short linked lists is $O((n/2^{10\sqrt{\log n}}) \cdot 2^{7\sqrt{\log n}} \cdot \sqrt{\log n}) \leq O(n\sqrt{\log n}/2^{3\sqrt{\log n}})$.

The sorting of integers in a group on a long linked list is done directly on integers on the linked list. For the purpose of sorting we may assume that the number of integers in a group is a power of 2. Otherwise we simply add some dummy elements to make it a power of 2 and store these dummy elements along elements of the linked list so that each memory location on the linked list stores at most two elements. (This can be realized by an array of two rows.) Note that we use a sorting network to accomplish the sorting. In order to sort integers on a linked list, an integer on the linked list has to know the address of the integers that it will compare itself with at each level of the sorting network. Because the AKS sorting network has $O(\sqrt{\log n})$ levels (because we are sorting at most $2^{7\sqrt{\log n}}$ integers in the group), and because in our sorting algorithm we pack $O(\sqrt{\log n})$ integers into one word, each word on the

linked list has to know $O(\sqrt{\log n})$ addresses (one address for each level). Let a_i be the word at memory address $d(a_i)$ (memory address is an $O(\log n)$ bit integer). If a_i needs to be compared with a_j at the first level of the sorting network, we need route address $d(a_i)$ to $d(a_j)$ and address $d(a_j)$ to $d(a_i)$. What we need here is a permutation of the memory addresses, and the permutation is a fixed one (known in advance). Thus we can route the memory address through the permutation network given in section 2. Note that a butterfly network has such a "regular" structure that each node (word) on the linked list can find the address of the nodes it needs to switch with at all levels of the network through pointer jumping [30]. The regularity we are talking about here is that each node needs to know the nodes which are 2^i, $i = 0, 1, 2, \ldots$, positions away from it and this can be done by pointer jumping. The AKS sorting network, on the other hand, does not have this property. Pointer jumping allows nodes on a linked list to meet with nodes which are 2^i positions (distance) away along the linked list, $i = 0, 1, 2, \ldots$. Let S be the number of integers in the group. Then there are $S/\sqrt{\log n}$ words. Each word has an address to be permuted and the permutation takes $O(\sqrt{\log n})$ time. Thus one permutation uses $O(S)$ operations for the group ($O(n)$ operations for all linked lists). However, we need to do $O(\sqrt{\log n})$ permutations for $O(\sqrt{\log n})$ addresses because the AKS sorting network has that many levels. And we have to do all these permutations in $O(S)$ operations for the group ($O(n)$ operations for all linked lists). In order to solve this problem we use a modified version of our nonconservative sorting algorithm. In each node of the sorting network we compare $\sqrt{\log n}$ words with another $\sqrt{\log n}$ words in parallel instead of comparing just two words. That is, we use $\sqrt{\log n} \cdot \sqrt{\log n} = \log n$ columns in the column sort. By the blocking property of the linked list these $\sqrt{\log n}$ words occupy consecutive memory addresses. Thus for each $\sqrt{\log n}$ words we need permute only the address of the first word. When the permutation is done, the addresses of the other words can be figured out. Therefore the number of operations for each permutation is reduced to $O(S/\sqrt{\log n})$ ($O(n/\sqrt{\log n})$ for all linked lists). For all $O(\sqrt{\log n})$ permutations the total number of operations is $O(S)$ ($O(n)$ for all linked lists). In order to keep $O(\sqrt{\log n})$ time for all these $O(\sqrt{\log n})$ permutations, we do them in parallel. For the $\sqrt{\log n}$ words, we let the ith word participate in the ith permutation.

The permutations performed among integers after each sort on columns can be done by routing the integers through the permutation networks given in section 2. Again, since the butterfly network has such a regular connection structure, a word can find the word it will switch with through pointer jumping. We therefore showed that sorting can be done for integers on the linked list.

After sorting we need to move integers to the sorted position. The problem here is that when we are sorting we are moving $\sqrt{\log n}$ bits for each integer through the AKS sorting network. In order for each integer to know the address after sorting the address which is a $\log n$ bit integer should be known to the integer. Note that such an address has $\log n$ bits and we cannot move it through the sorting network (otherwise it will incur $O(n\sqrt{\log n})$ operations *in one stage*). We cannot move integers through the sorting network either because each integer has about $\log n$ bits (it has fewer bits in later stages, though) instead of the $\sqrt{\log n}$ revealed bits.

Since each block has $2^{2\sqrt{\log n}}$ integers we modify the sorting within each group first to sort integers in each block and then to sort the whole group. Sorting integers in each block can be done by Theorem 2.4 and the relative address of the sorted position of an integer a has only $2\sqrt{\log n}$ bits. Therefore the *relative address* can be transferred back to a through the AKS sorting network (as we did in the above

paragraph). Then a can use this address to index into the sorted position. After each block is sorted the integers with the same revealed bits in a block are in consecutive memory locations. Because each block has $2^{2\sqrt{\log n}}$ integers and there are only $2^{\sqrt{\log n}}$ revealed bit patterns, for each bit pattern p we could use a representative integer a_p and let a_p find sorted locations (after the sort for the group) for all integers in the block with bit pattern p. Since the total number of representatives is a fraction of the total number of integers, the representatives can find the sorted positions by routing them through the sorting network.

Before the beginning of the last stage (which reveals $10\sqrt{\log n}$ bits) we use linked list ranking [5] to move all integers in a linked list into consecutive memory locations. Therefore in the last stage the integers to be sorted are based on arrays instead of a linked list.

A RANDOMIZED TIME-WORK OPTIMAL PARALLEL ALGORITHM FOR FINDING A MINIMUM SPANNING FOREST*

SETH PETTIE† AND VIJAYA RAMACHANDRAN†

Abstract. We present a randomized algorithm to find a minimum spanning forest (MSF) in an undirected graph. With high probability, the algorithm runs in logarithmic time and linear work on an exclusive read exclusive write (EREW) PRAM. This result is optimal w.r.t. both work and parallel time, and is the first provably optimal parallel algorithm for this problem under both measures. We also give a simple, general processor allocation scheme for tree-like computations.

1. Introduction. We present a randomized parallel algorithm to find a minimum spanning forest (MSF) in an edge-weighted, undirected graph. On an exclusive read exclusive write (EREW) PRAM [KR90] our algorithm runs in expected logarithmic time and linear work in the size of the input; these bounds also hold with high probability in the size of the input. This result is optimal w.r.t. both work and parallel time and is the first provably optimal parallel algorithm for this problem under both measures.

Here is a brief summary of related results. Following the linear-time sequential MSF algorithm of Karger, Klein, and Tarjan [KKT95] (and building on it) came linear-work parallel MSF algorithms for the concurrent read concurrent write (CRCW) PRAM [CKT94, CKT96] and the EREW PRAM [PR97]. The best CRCW PRAM algorithm known to date [CKT96] runs in logarithmic time and linear work, but the time bound is not known to be optimal. The best EREW PRAM algorithm known prior to our work is the result of Poon and Ramachandran which runs in $O(\log n \log\log n 2^{\log^* n})$ time and linear work. All of these algorithms are randomized. Recently Chong, Han, and Lam [CHL01] presented a deterministic EREW PRAM algorithm for MSF, which runs in logarithmic time with a linear number of processors, and hence with work $O((m+n)\log n)$, where n and m are the number of vertices and edges in the input graph. It was observed by Poon and Ramachandran [PR98] that the algorithm in [PR97] could be sped up to run in $O(\log n \cdot 2^{\log^* n})$ time and linear work by using the algorithm in [CHL01] as a subroutine (and by modifying the "contract" subroutine in [PR97]).

In this paper we improve on the running time of the algorithm in [PR97, PR98] to $O(\log n)$, which is the best possible, and we improve on the algorithm in [CKT96] by achieving the logarithmic time bound on the less powerful EREW PRAM.

Our algorithm has a simple 2-phase structure. It makes subroutine calls to the Chong–Han–Lam (CHL) algorithm [CHL01], which is fairly complex. But outside of these subroutine calls (which are made to the simplest version of the algorithm in [CHL01]), the steps in our algorithm are quite straightforward.

In addition to being the first time-work optimal parallel algorithm for MSF, our algorithm can be used as a simpler alternative to several other parallel algorithms:

1. For the CRCW PRAM we can replace the calls to the CHL algorithm by the (work inefficient) scheme used in [CKT96]. The resulting algorithm runs in logarithmic time and linear work but is considerably simpler than the MSF algorithm in [CKT96] and also is about twice as fast.
2. As modified for the CRCW PRAM, our algorithm is simpler than the linear-work logarithmic-time CRCW algorithm for connected components given in [Gaz91].
3. Our algorithm improves on the EREW connectivity and spanning tree algorithms in [HZ96, HZ01] since we compute a *minimum* spanning tree within the same time and work bounds. Our algorithm also is simpler than the algorithms in [HZ96, HZ01].

In the following we use the notation $S + T$ to denote the union of sets S and T, and we use $S + e$ to denote the set formed by adding the element e to the set S. We say that a result holds *with high probability (or w.h.p.) in* n if the probability that it fails to hold is less than $1/n^c$ for any constant $c > 0$.

The rest of this paper is organized as follows. In section 2 we give a high-level description of our algorithm, which works in two phases. In section 3 we provide the details of phase 1, whose main purpose is to reduce the number of vertices in the graph by at least a $(\log \log n)^2$ factor. Phase 2, given in section 4, finds the MSF of the reduced-vertex graph using a recursion-free version of the [PR97] algorithm. In sections 5 and 6 we prove the algorithm runs in logarithmic time and linear work with high probability. Section 7 gives a simple processor allocation scheme for "tree-structured" computations (a class containing our MSF algorithm) which is space-optimal. In section 8 we discuss the adaptability of our algorithm to realistic parallel models like the bulk-synchronous parallel (BSP) [Val90] and queuing shared memory models (QSM) [GMR99]. Our conclusions are given in section 9.

2. The high-level algorithm. Our algorithm is divided into two phases along the lines of the CRCW PRAM algorithm of [CKT96]. In phase 1, the algorithm reduces the number of vertices in the graph from n to n/k_0 vertices, where n is the number of vertices in the input graph, and[1] $k_0 = (\log^{(2)} n)^2$. To perform this reduction the algorithm uses the familiar recursion tree of depth $\log^* n$ [CKT94, CKT96, PR97], which gives rise to $O(2^{\log^* n})$ recursive calls; however, the time needed per invocation in our algorithm is well below $O(\log n / 2^{\log^* n})$. Thus the total time for phase 1 is $O(\log n)$. We accomplish this by requiring phase 1 to find only a subset of the MSF. By contracting this subset of the MSF we obtain a graph with $O(n/k_0)$ vertices. Phase 2 then uses an algorithm similar to the one in [PR97], but needs no recursion due to the reduced number of vertices in the graph. Thus phase 2 is able to find the MSF of the contracted graph in $O(\log n)$ time and linear work.

We assume that edge weights are distinct. As always, distinctness can be forced by ordering the vertices, then ordering identically weighted edges by their end points.

[1] We use $\log^{(r)} n$ to denote the log function iterated r times and $\log^* n$ to denote the minimum r s.t. $\log^{(r)} n \leq 1$.

The high-level algorithm is given in Figure 2.1.

High-Level(G)

(Phase 1)
$G_t :=$ For all $v \in G$, retain the lightest k_0 edges in edge-list(v)
$M :=$ Find-k-Min$(G_t, \log^* n)$
$G' :=$ Contract all edges in G appearing in M

(Phase 2)
$G_s :=$ Sample edges of G' with prob. $1/\sqrt{k_0} = 1/\log^{(2)} n$
$F_s :=$ Find-MSF(G_s)
$G_f :=$ Filter(G', F_s)
$F :=$ Find-MSF(G_f)
Return$(M + F)$

FIG. 2.1. *The high-level algorithm.*

THEOREM 2.1. *With high probability, High-Level*(G) *returns the MSF of* G *in* $O(\log n)$ *time using* $(m+n)/\log n$ *processors.*

In the following sections we describe and analyze the algorithms for phase 1 and phase 2 and then present the proof of the main theorem for the expected running time. We then obtain a high probability bound for the running time and work. When analyzing the performance of the algorithms in phase 1 and phase 2, we use a time-work framework, assuming perfect processor allocation. This can be achieved with high probability (to within a constant factor), using the load balancing scheme in [HZ96], which requires *superlinear* space. A linear-space load balancing scheme is claimed in [HZ01], though it is difficult to extricate the load balancing computation from the connectivity computation from [HZ01]. In section 7 we give a simple load balancing scheme based on [HZ96], which uses linear space. Its description is abstract and fully self-contained.

3. Phase 1. In phase 1, our goal is to contract the input graph G into a graph with $O(n/k_0)$ vertices. We do this by identifying certain edges in the MSF of G and contracting the connected components formed by these edges. The challenge here is to identify these edges in logarithmic time and linear work.

Phase 1 achieves the desired reduction in the number of vertices by constructing a *k-Min forest* (for $k = k_0$), defined below. This is similar to the algorithm in [CKT96]. However, our algorithm is considerably simpler. We show that a k-Min forest satisfies certain properties, and we exploit these properties to design a procedure *Borůvka-A*, which keeps the sizes of the trees contracted in the various stages of phase 1 very small so that the total time needed for contracting and processing edges in these trees is $o(\log n/2^{\log^* n})$. Phase 1 also needs a *Filter* subroutine, which removes "k-Min heavy" edges. For this, we show that we can use an MSF verification algorithm on the small trees we construct to perform this step. The overall algorithm for phase 1, called Find-k-Min, uses these two subroutines to achieve the stated reduction in the number of vertices within the desired time and work bounds.

3.1. The *k*-Min forest. Phase 1 uses the familiar "sample, contract, and discard edges" framework of earlier randomized algorithms for the MSF problem [KKT95, CKT94, CKT96, PR97]. However, instead of computing an MSF, we will construct the k_0-*Min tree* [CKT96] of each vertex (recall that $k_0 = (\log^{(2)} n)^2$). Contracting the edges in these k_0-Min trees will produce a graph with $O(n/k_0)$ vertices.

To understand what a k-Min tree is, consider the Dijkstra–Jarnik–Prim minimum spanning tree algorithm, given in Figure 3.1. This simple algorithm was discovered

independently by Dijkstra [Dij59], Jarnik [Jar30], and Prim [Prim57], though it is commonly known as Prim's algorithm. The edge set k-Min(v) consists of the first k edges chosen by this algorithm, when started at vertex v. A forest F is a *k-Min forest* of G if $F \subseteq \text{MSF}(G)$ and for all $v \in G$, k-Min$(v) \subseteq F$.

Dijkstra–Jarnik–Prim(G)
    $S := \{v\}$ *(choose an arbitrary starting vertex v)*
    $T := \emptyset$
    Repeat until T contains the MSF of G
        Choose minimum weight edge (a, b) s.t. $a \in S$, $b \notin S$
        $T := T + (a, b)$
        $S := S + b$

FIG. 3.1. *The Dijkstra–Jarnik–Prim algorithm.*

We define $P_T(x, y)$ to be the set of edges on the path from x to y in tree T, and $maxweight\{A\}$ be the maximum weight in a set of edges A.

For any forest F in G, define an edge (a, b) in G to be *F-heavy* if $weight(a, b) > maxweight\{P_F(a, b)\}$, and to be *$F$-light* otherwise. If a and b are not in the same tree in F, then (a, b) is F-light.

This notion of being F-heavy or F-light can be generalized as follows. Suppose F is a k-Min forest for some graph. We will say an edge (a, b) (not necessarily in the graph) is *k-Min-light* if F is not a k-Min forest for the graph $F+(a, b)$, and *k-Min-heavy* otherwise. An equivalent definition for k-Min-lightness and heaviness (which is more suited to proofs) is this: Let M be the k-Min tree of v. We define $weight_v^k(w)$ to be $maxweight\{P_M(v, w)\}$ if w appears in M, otherwise $weight_v^k(w) = maxweight\{M\}$. An edge (a, b) is then k-Min-light iff $weight(a, b) \leq \max\{weight_a^k(b), weight_b^k(a)\}$. Notice that $weight_v^k(w)$ implicitly depends on the underlying graph, which if not clear from the context will be stated explicitly.

FACT 3.1. *The two definitions given for "k-Min-light" (and "k-Min-heavy") are equivalent.*

We claimed earlier that k-Min-lightness is a generalization of F-lightness. To see this, set $k = n - 1$ and observe that an edge is k-Min-light iff it is F-light.

CLAIM 3.1. *If an edge (u, v) is k_1-Min-heavy w.r.t. G_1, it also is k_2-Min-heavy w.r.t. G_2, where $k_2 \leq k_1$, $V(G_1) = V(G_2)$, and $E(G_1) \subseteq E(G_2)$.*

Proof. This follows from two observations: $weight_v^k(w)$ is nondecreasing in k, and $weight_v^k(w)$ is nonincreasing as new edges are added to the underlyinggraph. □

In other words, whenever an edge is found to be k-Min-heavy for $k \geq k_0$ and w.r.t. some subset of the original graph, this is a certificate that the edge is k_0-Min-heavy in the original graph.

CLAIM 3.2. *For any k, $weight_v^k(w) \leq maxweight\{P_{MSF}(v, w)\}$.*

Proof. There are two cases: when w falls inside the k-Min tree of v and when it falls outside. If w lies inside k-Min(v), then $weight_v^k(w)$ must be the same as $maxweight\{P_{MSF}(v, w)\}$ since k-Min$(v) \subseteq MSF$. Now suppose that w falls outside k-Min(v) and $weight_v^k(w) > maxweight\{P_{MSF}(v, w)\}$. There must be a path from v to w in the MSF consisting of edges lighter than $maxweight\{k\text{-Min}(v)\}$. However, at each step in the Dijkstra–Jarnik–Prim algorithm, at least one edge in $P_{MSF}(v, w)$ is eligible to be chosen in that step. Since $w \notin k$-Min(v), the edge with weight $maxweight\{k\text{-Min}(v)\}$ is never chosen, a contradiction. □

LEMMA 3.1. *Let H be a graph formed by sampling each edge in graph G with probability p. The expected number of edges in G that are k-Min-light w.r.t. H for any k is less than n/p.*

Proof. We show that any edge that is k-Min-light in G also is F-light where F is the MSF of H. The lemma then follows from the sampling lemma of [KKT95] which states that the expected number of F-light edges in G is less than n/p. Let us look at any k-Min-light edge (v, w). By Claim 3.2, $weight_v^k(w) \leq maxweight\{P_{MSF}(v, w)\}$, the measure used to determine F-lightness. Thus the criterion for k-Min-lightness, $\max\{weight_v^k(w), weight_w^k(v)\}$, must also be no more than $maxweight\{P_{MSF}(v, w)\}$. Restating this, if (v, w) is k-Min-light, it must be F-light as well. □

We will use the above property of a k-Min forest to develop a procedure Find-k-Min(G, l). It takes as input the graph G and a suitable positive integer l, and returns a k_0-Min forest of G. For $l = \log^* n$, it runs in logarithmic time and linear work. In the next few sections we describe some basic steps and procedures used in Find-k-Min, and then present and analyze this main procedure of phase 1.

Since phase 1 is concerned only with the k_0-Min tree of each vertex, it suffices to retain only the lightest k_0 edges incident on each vertex. Hence, as stated in the first step of phase 1 in algorithm High-Level from section 2, we will discard all but the lightest k_0 edges incident on each vertex since we will not need them until phase 2. This step can be performed in logarithmic time and linear work by a simple randomized algorithm that selects a sample of size $\sqrt{|L|}$ from each adjacency list L, sorts this sample, and then uses this sorted list to narrow the search for the k_0th smallest element to a list of size $O(|L|^{3/4})$.

3.2. Borůvka-A steps. In a basic Borůvka step [Bor26], each vertex chooses its minimum weight incident edge, inducing a number of disjoint trees. All such trees are then contracted into single vertices, and the useless edges are discarded. We will call edges connecting two vertices in the same tree *internal* and all others *external*. All internal edges are useless, and if multiple external edges join the same two trees, all but the lightest are useless.

Our algorithm for phase 1 uses a *modified Borůvka step* in order to reduce the time bound to $o(\log n)$ per step. All vertices are classified as being either *live* or *dead*; only live vertices participate in modified Borůvka steps. After such a step, vertex v's *parent pointer* is $p(v) = w$, where (v, w) is the edge of minimum weight incident on v. In addition, each vertex has a *threshold* which keeps the weight of the lightest discarded edge adjacent to v. The algorithm discards edges known not to be in the k_0-Min tree of any vertex. The threshold variable guards against vertices choosing edges which may not be in the MSF. A dead vertex v has the useful property (shown below) that for any edge e in k_0-Min(v), weight$(e) \leq$ weight$(v, p(v))$, thus dead vertices *need not participate* in any more Borůvka steps.

It is well known that a Borůvka step generates a forest of *pseudo-trees*, where each pseudo-tree is a tree together with one extra edge that forms a cycle of length 2. In our algorithm we will assume that a Borůvka step also removes one of the edges in the cycle so that it generates a collection of rooted trees.

The following three claims refer to any tree resulting from a (modified) Borůvka step. Their proofs are straightforward and are omitted.

CLAIM 3.3. *The sequence of edge weights encountered on a path from v to root(v) is monotonically decreasing.*

CLAIM 3.4. *If depth$(v) = d$, then d-Min(v) consists of the edges in the path from v to root(v). Furthermore, the weight of $(v, p(v))$ is greater than any other edge in*

d-Min(v).

CLAIM 3.5. *If the minimum-weight incident edge of u is (u,v), k-Min$(u) \subseteq (k$-Min$(v) + (u,v))$.*

Claim 3.6 may not be as obvious. A similar claim was proved in [CHL01].

CLAIM 3.6. *Let T be a tree induced by a Borůvka step, and let T' be a subtree of T. If e is the minimum weight incident edge on T, then the minimum weight incident edge on T' is either e or an edge of T.*

Proof. Suppose, on the contrary, that the minimum weight incident edge on T' is $e' \notin T$, and let v and v' be the end points of e and e', which are inside T. Consider the paths P (P') from v (v') to the root of T. By Claim 3.3, the edge weights encountered on P and P' are monotonically decreasing. There are two cases. If T' contains some, but not all of P', then e' must lie along P', a contradiction. If T' contains all of P', but only some of P, then some edge $e'' \in P$ is adjacent to T'. Then $w(e') < w(e'') < w(e)$, also a contradiction. □

The procedure Borůvka-A(H, l, F), given in Figure 3.2, returns a contracted version of H with the number of live vertices reduced by a factor of l. Edges designated as parent pointers, which are guaranteed to be in the MSF of H, are returned in F. Initially $F = \emptyset$.

Borůvka-A(H, l, F)
Repeat $\log l$ times: *($\log l$ modified Borůvka steps)*
$F' := \emptyset$
For each live vertex v
Choose min. weight edge (v, w)
(1) If weight$(v, w) >$ threshold(v), v becomes dead, stop else
p$(v) := w$
$F' := F' + (v,$ p$(v))$
Each tree T induced by edges of F' is one of two types:
If root of T is dead, then
(2) Every vertex in T becomes dead *(Claim 3.5)*
If T contains only live vertices,
(3) If depth$(v) \geq k_0$, v becomes dead *(Claim 3.4)*
Contract the subtree of T made up of live vertices.
The resulting vertex is live, has no parent pointer, and
keeps the smallest threshold of its constituent vertices.
$F := F + F'$

FIG. 3.2. *The Borůvka-A procedure.*

LEMMA 3.2. *If Borůvka-A designates a vertex as dead, its k_0-Min tree has already been found.*

Proof. Vertices make the transition from live to dead only at the lines indicated by a number. By our assumption that we discard only edges that cannot be in the k_0-Min tree of any vertex, if the lightest edge adjacent to any vertex has been discarded, we know its k_0-Min tree has already been found. This covers line (1). The correctness of line (2) follows from Claim 3.5. Since $(v, p(v))$ is the lightest incident edge on v, k_0-Min$(v) \subseteq k_0$-Min$(p(v)) + (v, p(v))$. If $p(v)$ is dead, then v can also be called dead. Since the root of a tree is dead, vertices at depth one are dead, implying vertices at depth two are dead, and so on. The validity of line (3) follows directly from Claim

3.4. If a vertex finds itself at depth $\geq k_0$, its k_0-Min tree lies along the path from the vertex to its root. □

LEMMA 3.3. *After a call to Borůvka-A(H, k_0+1, F), the k_0-Min tree of each vertex is a subset of F.*

Proof. By Lemma 3.2, dead vertices already satisfy the lemma. After a single modified Borůvka step, the set of parent pointers associated with live vertices induce a number of trees. Let $T(v)$ be the tree containing v. We assume inductively that after $\lceil \log i \rceil$ modified Borůvka steps, the $(i-1)$-Min tree of each vertex in the original graph has been found (this is clearly true for $i = 1$). For any live vertex v let (x, y) be the minimum weight edge s.t. $x \in T(v)$, $y \notin T(v)$. By the inductive hypothesis, the $(i-1)$-Min trees of v and y are subsets of $T(v)$ and $T(y)$, respectively. By Claim 3.6, (x, y) is the first external edge of $T(v)$ chosen by the Dijkstra–Jarnik–Prim algorithm, starting at v. As every edge in $(i-1)$-Min(y) is lighter than (x, y), $(2(i-1)+1)$-Min(v) is a subset of $T(v) \cup \{(x, y)\} \cup T(y)$. Since edge (x, y) is chosen in the $(\lceil \log i \rceil + 1)$st modified Borůvka step, $(2i-1)$-Min(v) is a subset of $T(v)$ after $\lceil \log i \rceil + 1 = \lceil \log 2i \rceil$ modified Borůvka steps. Thus after $\log(k_0+1)$ steps, the k_0-Min tree of each vertex has been found. □

LEMMA 3.4. *After b modified Borůvka steps, the length of any edge list is bounded by ${k_0}^{{k_0}^b}$.*

Proof. This is true for $b = 0$. Assuming the lemma holds for $b-1$ modified Borůvka steps, the length of any edge list after that many steps is $\leq {k_0}^{{k_0}^{b-1}}$. Since we contract only trees of height $< k_0$, the length of any edge list after b steps is $< ({k_0}^{{k_0}^{b-1}})^{k_0} = {k_0}^{{k_0}^b}$. □

It is shown in the next section that our algorithm deals only with graphs that are the result of $O(\log k_0)$ modified Borůvka steps. Hence the maximum length edge list is ${k_0}^{{k_0}^{O(\log k_0)}}$.

The costliest step in Borůvka-A is calculating the depth of each vertex. After the minimum weight edge selection process, the root of each induced tree will broadcast its depth to all depth 1 vertices, which in turn broadcast to depth 2 vertices, etc. Once a vertex knows it is at depth $k_0 - 1$, it may stop, letting all its descendents infer that they are at depth $\geq k_0$. Interleaved with each round of broadcasting is a processor allocation step. We account for this cost separately in section 7.

LEMMA 3.5. *Let G_1 have m_1 edges. Then a call to Borůvka-A(G_1, l, F) can be executed in time $O({k_0}^{O(\log k_0)} + \log l \cdot \log n \cdot (m_1/m))$ with $(m+n)/\log n$ processors.*

Proof. Let G_1 be the result of b modified Borůvka steps. By Lemma 3.4, the maximum degree of any vertex after the ith modified Borůvka step in the current call to Borůvka-A is ${k_0}^{{k_0}^{b+i}}$. Let us now look at the required time of the ith modified Borůvka step. Selecting the minimum cost incident edge takes time $O(\log {k_0}^{{k_0}^{b+i}})$, while the time to determine the depth of each vertex is $O(k_0 \cdot \log {k_0}^{{k_0}^{b+i}})$. Summing over the $\log l$ modified Borůvka steps, the total time is bounded by $\sum_i^{\log l} {k_0}^{O(b+i)} = {k_0}^{O(b+\log l)}$. As noted above, the algorithm performs $O(\log k_0)$ modified Borůvka steps on any graph, hence the time is ${k_0}^{O(\log k_0)}$.

The work performed in each modified Borůvka step is linear in the number of edges. Summing over $\log l$ such steps and dividing by the number of processors, we arrive at the second term in the stated running time. □

3.3. Filtering edges via the Filter forest. We will maintain, concurrent with the operation of Borůvka-A, a structure called the *Filter forest*. This collec-

tion of rooted trees records which vertices merged together and the edge weights involved. (This structure appeared first in [K97].) If v is a vertex of the original graph or a new vertex resulting from contracting a set of edges, there is a corresponding vertex $\phi(v)$ in the Filter forest. During a Borůvka step, if a vertex v becomes dead, a new vertex x is added to the Filter forest, as well as a directed edge $(\phi(v), x)$ having the same weight as $(v, p(v))$. If live vertices $v_1, v_2, \ldots, v_j$ are contracted into a live vertex v, a vertex $\phi(v)$ is added to the Filter forest in addition to edges $(\phi(v_1), \phi(v)), (\phi(v_2), \phi(v)), \ldots, (\phi(v_j), \phi(v))$, having the weights of edges $(v_1, \mathrm{p}(v_1))$, $(v_2, \mathrm{p}(v_2)), \ldots,$ $(v_j, \mathrm{p}(v_j))$, respectively. We make the simple observation that the edge weights on the path from $\phi(u)$ to $root(\phi(u))$ are exactly the edge weights of the edges chosen by u (or its representative) in previous Borůvka steps.

It is shown in [K97] that the heaviest weight in the path from u to v in the MSF is the same as the heaviest weight in the path from $\phi(u)$ to $\phi(v)$ in the Filter forest (if there is such a path). We extend this scheme to handle k-Min-lightness.

Let $P_f(y, z)$ be the path from y to z in the Filter forest. If $\phi(u)$ and $\phi(v)$ are in the same Filter tree, then let

$$w_u(v) = w_v(u) = maxweight\{P_f(\phi(u), \phi(v))\}.$$

If $\phi(u)$ and $\phi(v)$ are not in the same Filter tree, then let

$$w_u(v) = maxweight\{P_f(\phi(u), \mathrm{root}(\phi(u)))\},$$
$$w_v(u) = maxweight\{P_f(\phi(v), \mathrm{root}(\phi(v)))\}.$$

In a call to Filter(H, F) (from the procedure Find-k-Min, section 3.4), we examine each edge $e = (u, v)$ in $H - F$ and remove or *filter* e from H if $weight(e) > \max\{w_u(v),\ w_v(u)\}$. Notice that if $w_u(v) = weight_u^{k_0}(v)$ for all v, then we will filter out edges precisely when they are k_0-Min-heavy. We show below that using $w_u(v)$ in lieu of $weight_u^{k_0}(v)$ causes no problems: we retain all k_0-Min-light edges without retaining too many edges in total.

To implement the Filter procedure we use a slight modification to the $O(\log n)$-time, $O(m)$-work MSF verification algorithm of [KPRS97]. If $e = (u, v)$ is the edge being tested and $\phi(u), \phi(v)$ are not in the same Filter tree, we test the pairs $(\phi(u), root(\phi(u)))$ and $(\phi(v), root(\phi(v)))$ instead and delete e if both of these pairs are identified to be deleted. This computation actually takes time $O(\log r)$ where r is the size of the largest tree formed.

Lemmas 3.6 and 3.7, proved below, establish the correctness of the filtering procedure.

LEMMA 3.6. *Suppose b modified Borůvka steps were applied to a graph; then for any vertex u and some $k \geq \min\{k_0, 2^b - 1\}$,*

$$maxweight\{P_f(\phi(u), root(\phi(u)))\} = maxweight\{k\text{-}Min(v)\}.$$

Before proving this we first prove a necessary technical lemma.

LEMMA 3.7. *Let T be a tree of MSF edges after an arbitrary number of Borůvka steps and let $T' = T \cup \{(v, w)\}$, where (v, w), $v \in T$, $w \notin T$ is the edge chosen by T in the next Borůvka step. For any $u \in T$, the maximum weight edge in $P_{T'}(u, w)$ was chosen by the tree containing u in some Borůvka step.*

Proof. Let T be formed after b Borůvka steps. Suppose, without loss of generality, that the lemma is falsified for the first time after the bth Borůvka step. That is, the

heaviest edge in $P_{T'}(u,w)$, say f, was chosen in the bth step. Let $g \neq f$ be the edge chosen by u or u's representative tree in this step. If f lies between g and the root of T, then by Claim 3.3 it is lighter than g, and similarly, if it lies between vertex v and the root of T, then it is lighter than (v,w). Both cases are contradictions. □

We are now ready to prove Lemma 3.6.

Proof. Let $e(u,b)$ be the maximum weight edge chosen by u's tree in the first b Borůvka steps. Assume inductively that $weight(e(u,b-1)) = maxweight\{k(u,b-1)\text{-Min}(u)\}$, where $k(u,b-1) \geq 2^{b-1}-1$ if u is live, $k(u,\cdot) \geq k_0$ if u is dead, and $k(u,b-1)$-Min(u) is contained in a tree of MSF edges after $b-1$ Borůvka steps. If u is dead, it already satisfies the inductive claim for b Borůvka steps, so assume u is alive. Let (z_1,z_2) be the edge chosen by the tree containing u in the bth Borůvka step and let P be the MSF path connecting $k(u,b-1)$-Min(u) to z_1—see Figure 3.3 for a schematic diagram. We have that $weight(z_1,z_2) > weight(e(z_2,b-1))$, because (z_1,z_2) was not already chosen by z_2 in the first $b-1$ steps, and $maxweight\{e(u,b-1)+P+(z_1,z_2)\} = weight(e(u,b))$. This is true because $weight(e(u,b)) = maxweight\{e(u,b-1),(z_1,z_2)\} > maxweight\{P\}$, where the equality is by definition and the inequality is by Lemma 3.7. Let D be the subgraph

$$D = k(u,b-1)\text{-Min}(u) + P + (z_1,z_2) + k(z_2,b-1)\text{-Min}(z_2)$$

and $k(u,b)$ be the smallest number such that $k(u,b)$-Min$(u) \supseteq D$. It follows that $e(u,b)$ is the heaviest edge in $k(u,b)$-Min(u) because when the Dijkstra–Jarnik–Prim algorithm is started from u, until all edges from D are chosen, there is *some* eligible edge from D weighing no more than the edge $e(u,b)$.

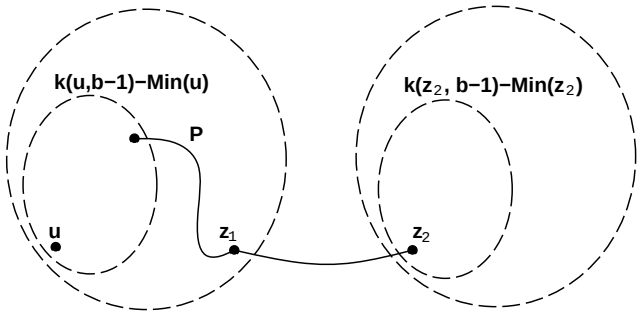

FIG. 3.3. *The larger ovals represent the trees of MSF edges after $b-1$ Borůvka steps containing u and z_2, respectively. The smaller ovals are the $k(u,b-1)$-Min(u) tree and the $k(z_2,b-1)$-Min(z_2) tree.*

If u and z_2 remain live, then $k(u,b) \geq 2\cdot(2^{b-1}-1)+1 \geq 2^b-1$. On the other hand, if u becomes dead after the bth Borůvka step, then (z_1,z_2) is the heaviest edge at the end of a chain C of length at least k_0 and $k(u,b) \geq 2^{b-1}-1+|C| \geq k_0$. In either case our inductive claim is proved for b Borůvka steps. □

LEMMA 3.8. *Suppose the Filter procedure is called only on graphs after performing at least* $\log(k_0+1)$ *Borůvka steps. Then no k_0-Min-light edges are filtered, and all unfiltered edges are k-Min-light for some $k \geq k_0$.*

Proof. Consider an edge (u,v) examined by the Filter procedure. Note that if $\phi(u)$ is in the same Filter tree as $\phi(v)$, by King's observation [K97], $w_u(v) = w_v(u) = maxweight\{P_{MSF}(u,v)\}$. If $weight(u,v)$ is greater than $w_u(v)$, then by Claim 3.1 (u,v) is k_0-Min-heavy and may be safely filtered. On the other hand, if $weight(u,v)$

is less than $w_u(v)$, then (u, v) is k-Min-light for $k = n$. We therefore focus on the case when $\phi(u)$ and $\phi(v)$ are in different Filter trees.

By Lemma 3.6, for some k_1, k_2 we have that $w_u(v) = maxweight\{k_1\text{-Min}(u)\}$ and $w_v(u) = maxweight\{k_2\text{-Min}(v)\}$. Since $maxweight\{k\text{-Min}(u)\}$ is a nondecreasing function of k, if (u, v) is not filtered out, then by Claim 3.1 it must be k_3-Min-light where $k_3 = \max\{k_1, k_2\}$. On the other hand, if (u, v) is filtered out, then it must be k_4-Min-heavy where $k_4 = \min\{k_1, k_2\}$. Because the Filter procedure is applied only after performing at least $\log(k_0 + 1)$ Borůvka steps, by Lemma 3.6 $k_3, k_4 \geq k_0$. □

Remark. Filter is responsible for updating the threshold variables—see section 3.2. When an edge (u, v) is discarded, threshold(u) is updated to reflect the weight of the lightest discarded edge incident to u; threshold(v) is updated similarly.

3.4. Finding a *k*-Min forest. We are now ready to present the main procedure of phase 1, Find-k-Min, which is given in Figure 3.4. (Recall that the initial call, given in section 2, is Find-k-Min$(G_t, \log^* n)$, where G_t is the graph obtained from G by removing all but the k_0 lightest edges on each adjacency list.)

Find-k-Min(H, i)
- $H_c :=$ Borůvka-A$(H, (\log^{(i-1)} n)^4, F)$
- if $i = 3$, return(F)
- $H_s :=$ sample edges of H_c with prob. $1/(\log^{(i-1)} n)^2$
- $F_s :=$ Find-k-Min$(H_s, i - 1)$
- $H_f :=$ Filter(H_c, F_s)
- $F' :=$ Find-k-Min$(H_f, i - 1)$
- Return$(F + F')$

FIG. 3.4. *The Find-k-Min procedure.*

H is a graph with some vertices possibly marked as dead; i is a parameter that indicates the level of recursion (which determines the number of Borůvka steps to be performed and the sampling probability). Lemmas 3.9 and 3.10 establish the correctness of this procedure. The performance of Find-k-Min is analyzed in section 3.5.

LEMMA 3.9. *Let H' be a graph formed by sampling each edge in H with probability p, and let F be a k_0-Min forest of H' (derived by at least $\log(k_0 + 1)$ Borůvka steps). The call to Filter(H, F) returns a graph containing a k_0-Min forest of H, whose expected number of edges is no more than n/p.*

Proof. By Claim 3.1, any edge in the k_0-Min forest of H is k_0-Min-light w.r.t. H'. By Lemma 3.8, no edges k_0-Min-light w.r.t. H' are filtered; this establishes the first part of the lemma. By the second part of Lemma 3.8, all edges not filtered are k-Min-light w.r.t. H' for some k. According to Lemma 3.1, the number of edges in H that are k-Min-light w.r.t. H' for any k is no more than n/p. This establishes the rest of the lemma. □

LEMMA 3.10. *The call Find-k-Min$(G_t, \log^* n)$ returns a set of edges that includes the k_0-Min tree of each vertex in G_t.*

Proof. The proof is by induction on i. For $i = 3$ (the base case) Find-k-Min$(H, 3)$ returns F, which by Lemma 3.3 contains the k_0-Min tree of each vertex. Now assume inductively that Find-k-Min$(H, i - 1)$ returns the k_0-Min tree of H. Consider the call Find-k-Min(H, i). By the induction assumption the call to Find-k-Min$(H_s, i - 1)$ returns the k_0-Min tree of each vertex in H_s. By Lemma 3.9, the call to Filter(H_c, F_s) returns in H_f a set of edges that contains the k_0-Min trees of all vertices in H_c.

Finally, by the inductive assumption, the set of edges returned by the call to Find-k-Min$(H_f, i-1)$ contains the k_0-Min trees of all vertices in H_f. Since F' contains the $(\log^{(i-1)} n)$-Min tree of each vertex in H, and Find-k-Min(H, i) returns $F + F'$, it returns the edges in the k_0-Min tree of each vertex in H. □

3.5. Performance of find-k-Min. In this section we bound the time and work required by the Find-k-Min procedure.

CLAIM 3.7. *The following invariants are maintained at each call to Find-k-Min. The number of live vertices in* $H \le n/(\log^{(i)} n)^4$*, and the expected number of edges in* $H \le m/(\log^{(i)} n)^2$*, where* m *and* n *are the number of edges and vertices in the original graph.*

Proof. These hold for the initial call, when $i = \log^* n$. By Lemma 3.3, the contracted graph H_c has $\le n/(\log^{(i-1)} n)^4$ live vertices. Since H_s is derived by sampling edges with probability $1/(\log^{(i-1)} n)^2$, the expected number of edges in H_s is $\le m/(\log^{(i-1)} n)^2$, maintaining the invariants for the first recursive call.

By Lemma 3.1, the expected number of edges in $H_f \le \frac{n(\log^{(i-1)} n)^2}{(\log^{(i-1)} n)^4} = \frac{n}{(\log^{(i-1)} n)^2}$. Since H_f has the same number of vertices as H_c, both invariants are maintained for the second recursive call. □

LEMMA 3.11. *Find-k-Min*$(G_t, \log^* n)$ *runs in expected* $O(\log n)$ *time and* $O(m)$ *work.*

Proof. Since recursive calls to Find-k-Min proceed in a sequential fashion, the total running time is the sum of the local computation performed in each invocation. Aside from randomly sampling the graph, the local computation consists of calls to Filter and Borůvka-A.

In a given invocation of Find-k-Min, the number of Borůvka steps performed on graph H is the sum of all Borůvka steps performed in all ancestral invocations of Find-k-Min, i.e., $\sum_{i=3}^{\log^* n} O(\log^{(i)} n)$, which is $O(\log^{(3)} n)$. From our bound on the maximum length of edge lists (Lemma 3.4), we can infer that the size of any tree in the Filter forest is ${k_0}^{k_0^{O(\log^{(3)} n)}}$, thus the time needed for each modified Borůvka step and each Filter step is ${k_0}^{O(\log^{(3)} n)}$. Summing over all such steps, the total time required is $o(\log n)$.

The work required by the Filter procedure and *each* Borůvka step is linear in the number of edges. By Claim 3.7, the expected number of edges in an invocation at level i is $O(m/(\log^{(i)} n)^2)$. Since there are $O(\log^{(i)} n)$ Borůvka steps performed in this invocation, the work required is $O(m/\log^{(i)} n)$. There are $2^{\log^* n - i}$ invocations with depth parameter i; therefore the total work is given by $\sum_{i=3}^{\log^* n} 2^{\log^* n - i} O(m/\log^{(i)} n)$, which is $O(m)$. □

4. Phase 2. Recall the phase 2 portion of our overall algorithm High-Level:

(the number of vertices in G_s is $\le n/k_0$)
$G_s :=$ Sample edges of G' with prob. $1/\sqrt{k_0} = 1/\log^{(2)} n$
$F_s :=$ Find-MSF(G_s)
$G_f :=$ Filter(G', F_s)
$F :=$ Find-MSF(G_f)

The procedure Filter(G, F) [KPRS97] returns the F-light edges of G. The procedure Find-MSF(G_1), described below, finds the MSF of G_1 in $O(\frac{m_1}{m} \log n \log^{(2)} n)$ time, where m_1 is the number of edges in G_1.

The graphs G_s and G_f each have expected $m/\sqrt{k_0} = m/\log^{(2)} n$ edges since G_s is derived by sampling each edge with probability $1/\sqrt{k_0}$, and, by the sampling lemma of [KKT95], the expected number of edges in G_f is $(m/k_0)/(1/\sqrt{k_0}) = m/\sqrt{k_0}$. Because we call Find-MSF on graphs having expected size $O(m/\log^{(2)} n)$, each call takes $O(\log n)$ time.

4.1. The Find-MSF procedure. The procedure Find-MSF(H), given in Figure 4.1, is similar to previous randomized parallel algorithms except it uses no recursion. Instead, a separate *BaseCase* algorithm is used in place of recursive calls. We also use slightly different Borůvka steps in order to reduce the work. These modifications are inspired by [PR97] and [PR98].

As its BaseCase, we use the simplest version of the algorithm of Chong, Han, and Lam [CHL01], which takes time $O(\log n)$ using $(m+n)\log n$ processors. By guaranteeing that it is called only on graphs of expected size $O(m/\log^2 n)$, the running time remains $O(\log n)$ with $(m+n)/\log n$ processors. An adaptation of our algorithm to the CRCW PRAM leads to one roughly twice as fast as [CKT96]. Because of a more efficient phase 1 we can afford to make only four BaseCase calls in phase 2, rather than eight calls as in [CKT96].

Find-MSF(H)
  $H_c :=$ Borůvka-B($H, \log^4 n, F$)
  $H_s :=$ Sample edges of H_c with prob. $p = 1/\log^2 n$
  $F_s :=$ BaseCase(H_s)
  $H_f :=$ Filter(H_c, F_s)
  $F' :=$ BaseCase(H_f)
  Return($F + F'$)

FIG. 4.1. *The Find-MSF procedure.*

After the call to Borůvka-B, the graph H_c has $< m/\log^4 n$ vertices. Since H_s is derived by sampling the edges of H_c with probability $1/\log^2 n$, the expected number of edges to the first BaseCase call is $O(m/\log^2 n)$. By the sampling lemma of [KKT95], the expected number of edges to the second BaseCase call is $< (m/\log^4 n)/(1/\log^2 n)$, thus the total time spent in these subcalls is $O(\log n)$. Assuming the size of H conforms to its expectation of $O(m/\log^{(2)} n)$, the calls to Filter and Borůvka-B also take $O(\log n)$ time, as described below.

The Borůvka-B(H, l, F) procedure, shown in Figure 4.2, returns a contracted version of H with $O(m/l)$ vertices. It uses a simple growth control schedule, designating vertices as *inactive* if their degree exceeds l. We can determine if a vertex is inactive by performing list ranking on its edge list for $\log l$ time steps. If the computation has not stopped after this much time, then its edge list has length $> l$.

The last step takes $O(\log n)$ time; all other steps take $O(\log l)$ time, as they deal with edge lists of length $O(l)$. Consequently, the total running time is $O(\log n + \log^2 l)$. For each iteration of the main loop, the work is linear in the number of edges. Assuming the graph conforms to its expected size of $O(m/\log^{(2)} n)$, the total work is linear. The edge-plugging technique as well as the idea of a growth control schedule were introduced by Johnson and Metaxas [JM92].

Borůvka-B(G, l, F)
Repeat $\log l$ times
For each vertex, let it be *inactive* if its edge list
has more than l edges, and *active* otherwise.
For each *active* vertex v
choose min. weight incident edge e
$F := F + e$
Using the edge-plugging technique, build a
single edge list for each induced tree ($O(1)$ time)
Contract all trees of inactive vertices

FIG. 4.2. *The Borůvka-B procedure.*

5. Proof of Theorem 2.1. The set of edges M returned by Find-k-Min is a subset of the MSF of G. By contracting the edges of M to produce G', the MSF of G is given by the edges of M together with the MSF of G'. The call to Filter produces graph G_f by removing from G' edges known not to be in the MSF. Thus the MSF of G_f is the same as the MSF of G'. Assuming the correctness of Find-MSF, the set of edges F constitutes the MSF of G_f, and thus $M + F$ is the MSF of G.

Earlier we have shown that each step of High-Level requires $O(\log n)$ time and work linear in the number of edges. In the next two sections we show that w.h.p, the number of edges encountered in all graphs during the algorithm is linear in the size of the original graph.

6. High probability bounds. Consider a single invocation of Find-k-Min(H, i), where H has m' edges and n' vertices. We want to place likely bounds on the number of edges in each recursive call to Find-k-Min, in terms of m' and i.

For the first recursive call, the edges of H are sampled independently with probability $1/(\log^{(i-1)} n)^2$. Call the sampled graph H_1. By applying a Chernoff bound [AS00], the probability that the size of H_1 is less than twice its expectation is $1 - \exp(-\Omega(m'/(\log^{(i-1)} n)^2))$.

Before analyzing the second recursive call, we recall the sampling lemma of [KKT95] which states that the number of F-light edges is dominated by the negative binomial distribution with parameters n' and p, where p is the sampling probability, and F is the MSF of H_1. As we saw in the proof of Lemma 3.1, every k-Min-light edge must also be F-light. Using this observation, we will analyze the size of the second recursive call in terms of F-light edges and conclude that any bounds we attain apply equally to k-Min-light edges.

We now bound the likelihood that more than twice the expected number of edges are F-light. This is the probability that in a sequence of more than $2n'/p$ flips of a coin, with probability p of heads, the coin comes up heads less than n' times (since each edge selected by a coin toss of heads goes into the MSF of the sampled graph). By applying a Chernoff bound, this is $\exp(-\Omega(n'))$. In this particular instance of Find-k-Min, $n' \leq m/(\log^{(i-1)} n)^4$ and $p = 1/(\log^{(i-1)} n)^2$, so the probability that fewer than $2m/(\log^{(i-1)} n)^2$ edges are F-light is $1 - \exp(-\Omega(m/(\log^{(i-1)} n)^4))$.

Given a single invocation of Find-k-Min(H, i), we can bound the probability that H has more than $2^{\log^* n - i}\, m/(\log^{(i)} n)^2$ edges by $\exp(-\Omega(m/(\log^{(i)} n)^4))$. This follows from applying the argument used above to each invocation of Find-k-Min from the initial call to the current call at depth $\log^* n - i$. Summing over all recursive calls

to Find-k-Min, the total number of edges (and thus the total work) is bounded by $\sum_{i=3}^{\log^* n} 2^{2\log^* n - 2i}\, m/(\log^{(i)} n)^2 = O(m)$ with probability $1-\exp(-\Omega(m/(\log^{(3)} n)^4))$.

The probability that phase 2 uses $O(m)$ work is $1-\exp(-\Omega(m/\log^2 n))$. We omit the analysis as it is similar to the analysis for phase 1.

The probability that our bounds on the time and total work performed by the algorithm fail to hold is exponentially small in the input size. However, this assumes perfect processor allocation. In the next section we show that the probability that work fails to be distributed evenly among the processors is less than $1/m^{\omega(1)}$. Thus the overall probability of failure is very small, and the algorithm runs in logarithmic time and linear work w.h.p.

7. Processor allocation. As stated in section 2, the processor allocation needed for our algorithm can be performed by a fairly simple scheme given in [HZ96] that takes logarithmic time and linear work overall but uses *superlinear* space. An algorithm claimed in [HZ01] uses linear space; however, it is not given a clear description in [HZ01] and, more seriously, it makes heavy use of a nontrivial linked-list based sorting algorithm of Goodrich and Kosaraju [GK96]. In this section we give a self-contained description of a processor allocation scheme for "tree structured" computations which does not use any sorting subroutine.

Let M be a set of m processes which perform some computation. So long as the computation is *tree structured*, in the sense given below, its exact nature is unimportant. At any point in the computation there is a set $D \subseteq M$ of *dead processes* and a stack $\mathcal{S} = (S_0, S_1, \ldots, S_d)$, where $S_0 = M$ and $S_{j+1} \subseteq S_j$. In the ith round of computation, the stack is potentially changed and some set $R_i \subseteq M$ of the processes compute for t_i time steps. Round i follows these steps:

1. Either (a) $\mathcal{S}$ is unchanged, $R_i := S_d - D$, or
   (b) $\mathcal{S} := (S_0, \ldots, S_d, S_{d+1})$, $S_{d+1} \subseteq S_d$, $R_i := S_{d+1} - D$, or
   (c) $\mathcal{S} := (S_0, \ldots, S_{d-1})$, $R_i := S_{d-1} - D$.
2. The R_i do something for $t_i \geq 1$ steps.
3. $D := D + \{\text{some subset of } R_i\}$.

This is a rather technical characterization of a class of algorithms. Informally, any recursive algorithm fits into this scheme if the active processes in one recursive call are a subset of the active processes from its parent call.

Let $p \leq m$ be the number of EREW processors available. Ideally, we would like to simulate round i in $O(\lceil R_i/p \rceil)$ time (i.e., with zero overhead). Like [HZ96] our overhead is nonconstant but usually negligible.

THEOREM 7.1. *For some tree computation, let r be the total number of rounds, $T = \sum_i t_i$ be the total time for all rounds, $W = \sum_i t_i \cdot |R_i|$ be the total work for all rounds, d_{max} be the maximum depth of the stack, and $q = \Omega(\log(mr))$ be a parameter. Then with probability $1 - e^{-\Omega(q)}$ the computation of m processes can be simulated with p EREW processors in $O(T + W/p + r\log q + \log p)$ time. The space required is $O(m + p \cdot d_{max})$. It is assumed there is some (easily computable) bound r_i such that $r_i \geq |R_i|$ and $r_i = O(|R_i|)$.*

In our MSF algorithm the number of rounds $r = O(2^{\log^* n} k_0 \log k_0) = O(\log^3 \log n)$, the time $T = O(\log n)$, work $W = O(m)$, and $d_{max} = O(\log^3 \log n)$. Plugging these values into Theorem 7.1, our MSF algorithm can be simulated in $O(m/p + \log n + \log q \log^3 \log n)$ time with probability at least $1 - e^{-\Omega(q)}$, using space $O(m + p \log^3 \log n)$. Since $p < m/\log n$, the space is linear in m. We could set $q =$

$\Theta(\log(mr)) = \Theta(\log n)$ and achieve a polynomially small error probability or set q as high as $2^{\log n/\log^3 \log n}$ for a much smaller error probability. Also, the "dead processes" correspond to those edges known to be k_0-Min-heavy (in phase 1) or not in the MSF at all (in phase 2).

As in [HZ96] we organize the processes into *blocks* of size $b = qm/p$ (q processors per block) as follows. We imagine placing the processes deterministically into an $m/b \times b$ array, then performing a random rotation on each column. The processes that end up in the same row are in the same block. Computing this initial allocation is easily done in $O(m/p + \log p)$ time. Since processors from different blocks do not communicate we will isolate our discussion to a single arbitrary block. Let B denote the set of processes in this block; initially $|B| = b$.

We maintain the invariant that the block is represented as a linked list $L = L_d, L_{d-1}, \ldots, L_0$, where $L_d = S_d - D$, and, in general, $L_j = S_j - S_{j+1} - D$. That is, $L = B - D$: no dead processes appear in this list, and L_j lists those processes that do not appear higher up in the stack. We also maintain that for all j, L_j has been fairly allocated. What this means is that the ℓth processor ($0 \le \ell < q$) assigned to this block "owns" a sublist $L_{\ell,j}$ of L_j extending from element $\ell\lceil \frac{|L_j|}{q} \rceil$ to element $(\ell+1)\lceil \frac{|L_j|}{q} \rceil - 1$ (if they exist). We assume processor ℓ has a pointer to $L_{\ell,j}$. (These pointers contribute the pd_{max} term to the space in Theorem 7.1. The other space requirements are linear in m.)

Suppose in round i, step 1 is of type (a)—the stack is not altered. Then $R_i \cap L = L_d$ and we already have a fair allocation of L_d. Provided $|L_d|$ is about the same in this block as in any other, step 2 can be simulated optimally in $O(t_i \cdot \lceil |L_d|/q \rceil)$ time. This will be discussed later. To restore our invariants after step 3 we simply need to splice out newly dead processes from L_d and compute a fair allocation for the new list. Let L_d and L'_d be the list before and after step 3. Processor ℓ will find all $L'_{w,d}$ which lie in $L_{\ell,d}$, sending a pointer of $L'_{w,d}$ to processor w. For this task processor ℓ must know $|L'_d|$ and the number of elements from L'_d which lie before $L_{\ell,d}$, both of which can be computed in $O(|L_d|/q + \log q)$ time with a prefix-sums computation. Finally we compute L'_d by splicing out all dead elements, also in $O(|L_d|/q + \log q)$ time.[2] The other two cases for step 1, (b) and (c), involve either splitting L_d into two lists or combining L_d and L_{d-1} into one list, followed by a step to compute a fair allocation for the new list(s). We omit a discussion of these two cases; the techniques used are the same as in step 3.

In implementing step 2 we use the assumption that there is a known upper bound $r_i \ge |R_i|$ on the number of processes taking part in the ith round. (In our MSF algorithm, for instance, this upper bound would hold w.h.p.) We argue that with a certain probability (that depends on q) for every round i, every processor is given no more than $(1+\epsilon)(1+r_i/p)$ active processes. Each of the t_i time steps in step 2 is then easily simulated in $(1+\epsilon)(1+r_i/p)$ time. Consider the $m/b \times b$ array used in the initial allocation, and an arbitrary block and round. Let X_k be 1 if the process initially placed in the kth column is active in the round, and 0 otherwise. Because the rotations on different columns were *independent*, so too are the X_k's. Let $X = \sum_{k=1}^{q} X_k$ be the number of active processes appearing in the block; clearly $E(X) = |R_i|b/m \le r_i b/m$. Since each processor can be thought to have a "dummy" process associated with it which is active in every round, assume, without loss of generality, that $E(X) \ge q$. Noting that X is the sum of independent Bernoulli trials,

[2] The prefix-sums and splicing can, of course, be performed in one pass.

we can bound the probability that X deviates too far from its expectation using a Chernoff bound [AS00]. For $0 < \epsilon < 1$, $\Pr[X > (1+\epsilon)E(X)] < e^{-\Omega(\epsilon^2 E(X))}$, and for constant ϵ, the probability that *any* block in any round gets more than $1+\epsilon$ times its expectation is $< \frac{mr}{b} e^{-\Omega(q)} = e^{-\Omega(q)}$ since $q = \Omega(\log(mr))$. The analysis of our scheme is very similar to that of [HZ96] but considerably more efficient in terms of time. In [HZ96] ϵ is increased in order to reduce the probability of failure. In our scheme we would set ϵ to be a small constant and increase q (number of processors per block) as necessary. It is crucial to keep ϵ small because in either scheme nearly all processors spend an $\epsilon/(1+\epsilon)$ fraction of their time doing nothing! On the other hand, the q parameter can usually be increased dramatically with negligible effects on the overall running time. Hence our scheme achieves a low failure probability without excessive processor idling.

We remark that the space claimed in Theorem 7.1 can be reduced to $O(m)$ at the expense of a slightly more complicated scheme. The idea is to compute fair allocations only when necessary. Very frequently, a previously computed fair allocation is "fair enough." For instance, in step 1(b) L_d is split into two lists, L'_d and L'_{d+1}. If L'_{d+1} contains most of the elements from L_d, we might as well use the fair allocation of L_d instead of computing new ones for L'_{d+1} and L'_d.

8. Adaptations to other practical parallel models. Our results imply good MSF algorithms for the QSM [GMR99] and BSP [Val90] models, which are more realistic models of parallel computation than the PRAM models. Theorem 8.1 given below follows directly from results mapping EREWcomputations on to QSM given in [GMR99]. Theorem 8.2 follows from the QSM to BSP emulation given in [GMR99] in conjunction with the observation that the slowdown in that emulation due to hashing does not occur for our algorithm since the assignment of vertices and edges to processors made by our processor allocation scheme achieves the same effect.

THEOREM 8.1. *An MSF of an edge-weighted graph on n nodes and m edges can be found in $O(g \log n)$ time and $O(g(m+n))$ work w.h.p. using $O(m+n)$ space on the QSM with a simple processor allocation scheme, where g is the gap parameter of the QSM.*

THEOREM 8.2. *An MSF of an edge-weighted graph on n nodes and m edges can be found on the BSP in $O((L+g)\log n)$ time w.h.p. using $(m+n)/\log n$ processors and $O(m+n)$ space with a simple processor allocation scheme, where g and L are the gap and periodicity parameters of the BSP.*

9. Conclusion. We have presented a randomized algorithm for MSF on the EREW PRAM which is provably optimal both in time and work. Our algorithm works within the stated bounds with high probability in the input size and has good performance in other popular parallel models.

One drawback to our algorithm is that it uses a linear number of random bits. A recent MSF algorithm [PR02a] for the EREW PRAM performs linear work but uses only a polylogarithmic number of random bits; however, the time required is suboptimal ($O(\log^2 n \log^* n)$). Unlike the algorithm presented here, the [PR02a] algorithm is not a parallelization of [KKT95] and does not use the sampling lemma from [KKT95].

An open question is how to obtain a *deterministic* time-work optimal MSF algorithm. Pettie and Ramachandran [PR02b] have given a provably optimal *sequential* MSF algorithm; however, its exact complexity (and therefore the complexity of MSF) is still unknown. Parallelizing this optimal sequential algorithm seems very difficult.

LOWER BOUNDS FOR LUCAS CHAINS*

MARTIN KUTZ†

Abstract. Lucas chains are a special type of addition chains satisfying an extra condition: for the representation $a_k = a_j + a_i$ of each element a_k in the chain, the difference $a_j - a_i$ must also be contained in the chain. In analogy to the relation between addition chains and exponentiation, Lucas chains yield computation sequences for Lucas functions, a special kind of linear recurrences.

We show that the great majority of natural numbers n does not have Lucas chains shorter than $(1-\epsilon)\log_\phi n$ for any $\epsilon > 0$, where ϕ is the golden ratio.

Peter L. Montgomery was the first to consider Lucas chains, in the early eighties. He discovered a decomposition theorem for Lucas chains and a lower bound on their length in terms of Fibonacci numbers. His work was not published. Therefore several of Montgomery's original ideas are represented in this paper.

Key words. Lucas chain, addition chain, Lucas function, lower bound, Fibonacci number, golden ratio, smooth number

1. Introduction.

An increasing sequence $1 = a_0 < a_1 < \cdots < a_r = n$ of integers is called an *addition chain* for n if for each index $k \geq 1$ there exist $i \leq j < k$ so that

$$a_k = a_i + a_j. \tag{1}$$

This notion is motivated by the problem of computing x^n from x with few multiplications, so one is primarily interested in chains of small length r for given n. Since their first appearance in [12], addition chains have been intensively studied. See, for example, Schönhage's lower bound in [13] or Bergeron, Berstel, and Brlek's paper [1] on advanced methods for the construction of short addition chains. We refer to Section 4.6.3 of Knuth's classic [5] for a broader survey.

In this paper, we investigate *Lucas chains*, a variant of addition chains introduced by Peter L. Montgomery [9]. Those are chains for which the indices i, j in (1) can be chosen such that either $i = j$ or the difference $a_j - a_i$ is also part of the chain. The term "Lucas chain" is due to the observation that such chains yield computation sequences for Lucas functions, a special kind of linear recurrences.

Montgomery's paper [9], written in 1983, has never been published; for several years no further research was done on Lucas chains. This changed in 1993 when Smith and Lennon introduced the public-key crypto system *LUC* [14], which is based on Lucas functions. Yen and Laih [16] proposed Lucas chains as a means of evaluating the one-way functions of that crypto system; they used the term "Luc chains," though. Then in 1996 in his Ph.D. thesis on crypto systems [2], Bleichenbacher used results from [9] to actually compute short Lucas chains.

*Received by the editors October 9, 2000; accepted for publication (in revised form) June 30, 2002; published electronically October 31, 2002. This work was completed while the author was member of the European graduate school "Combinatorics, Geometry, and Computation" supported by the Deutsche Forschungsgemeinschaft, grant GRK 588/1. Most of this work is part of the author's diploma thesis [6].

†Mathematisches Institut II, Freie Universität Berlin, Arnimallee 3, 14195 Berlin, Germany (kutz@math.fu-berlin.de).

Besides some elaborate techniques for the construction of short Lucas chains, Montgomery [9] proved lower bounds on the length of Lucas chains for given integers. We will show similar results, reusing several of his ideas. From those bounds we will derive the more general statement that the majority of natural numbers n does not have Lucas chains shorter than $(1-\epsilon)\log_\phi n$ for any $\epsilon > 0$, where ϕ is the golden ratio. Two important prerequisites for this bound are a decomposition theorem stating that any Lucas chain can be uniquely factored into a product of so-called *simple* chains, and a lower bound on the length of these chains in terms of Fibonacci numbers.

The results of this paper are from the author's diploma thesis [6], written in ignorance of Montgomery's work. The author is grateful for Montgomery's kind permission to represent several ideas from his original work.

2. From Lucas functions to Lucas chains. Let P and Q be elements from a commutative ring with identity. The *Lucas functions* $V_n(P,Q)$ are defined recursively by [7]:

$$V_0(P,Q) = 2, \quad V_1(P,Q) = P, \quad V_{n+2}(P,Q) = P \cdot V_{n+1}(P,Q) - Q \cdot V_n(P,Q).$$

If α and β are the roots of the polynomial $X^2 - PX + Q$, then

$$P = \alpha + \beta, \quad Q = \alpha\beta, \quad \text{and} \quad V_n(P,Q) = \alpha^n + \beta^n. \tag{2}$$

In the following we will omit the arguments P, Q and simply write V_n.

We ask for a method to compute V_n for some $n \geq 0$ from a given pair P, Q. Looking at the identities

$$\begin{aligned} V_{m+n} &= (\alpha^m + \beta^m)(\alpha^n + \beta^n) - \alpha^n\beta^m - \alpha^m\beta^n \\ &= (\alpha^m + \beta^m)(\alpha^n + \beta^n) - \alpha^m\beta^m(\alpha^{n-m} + \beta^{n-m}) \\ &= V_m \cdot V_n - Q^m \cdot V_{n-m} \end{aligned} \tag{3}$$

for $0 \leq m \leq n$, we see that we can compute V_{m+n} from V_m, V_n, V_{n-m}, and a certain power of Q. This gives rise to the following definition.

DEFINITION 1. *A* Lucas chain *for an integer $n \geq 1$ is an increasing sequence*

$$1 = a_0 < a_1 < a_2 < \cdots < a_r = n$$

of integers such that for every $k \in \{1, \ldots, r\}$,

(L)	*there exist indices i, j with $0 \leq i \leq j < k$ such that $a_k = a_j + a_i$ and $a_j - a_i \in \{0, a_0, a_1, \ldots, a_{k-1}\}$.*

We call r the length *of the chain.*

Example 1. The sequence $(1,2,3,5)$ is a Lucas chain for 5 whereas $(1,2,4,5)$ is not—both are addition chains, though. In the latter sequence, 5 can only be represented as $4+1$ but $4-1=3$ is not part of the sequence.

Example 2. $(1,2,4,8,\ldots,2^l)$ is a Lucas chain of length l for 2^l. For every k, (L) is satisfied with $i = j = k-1$.

Example 3. Let the *Fibonacci numbers* F_n be recursively defined by

$$F_0 = 0, \quad F_1 = 1, \qquad \text{and} \qquad F_n = F_{n-1} + F_{n-2}, \quad n \geq 2.$$

For any $l \geq 0$ the sequence $\mathcal{F}_l = (F_2, F_3, F_4, F_5, \ldots, F_{l+2})$ is a Lucas chain of length l for F_{l+2}. To show (L), let $j = k-1$ and $i = k-2$; then $F_j - F_i = F_{k-3}$. We call $\mathcal{F}_l$ the *lth Fibonacci chain.*

A Lucas chain for n directly yields a computation of V_n. First, we successively compute Q^{a_k} for $k = 1, \ldots, r-1$ with $r-1$ multiplications. Second, we repeatedly use (3) to obtain V_{a_k} for $k = 1, \ldots, r$, which takes two multiplications in each step. Thus we can compute V_n from P and Q with $3r-1$ multiplications altogether.

3. Applications. As stated in the introduction, Lucas chains turned out to be useful in public-key cryptography. Instead of using powers $X^n \bmod N$ with some large integer N for the one-way function as in the RSA scheme [11], the LUC crypto system [14] uses the Lucas function $V_n \bmod N$ for encryption and decryption. In this application, the parameter Q is always chosen to be 1 so that powers of Q need not be computed and (3) simplifies to $V_{m+n} = V_m \cdot V_n - V_{n-m}$ (see also [16]). Hence in this special case, a Lucas chain of length r for n yields a computation of V_n with exactly r multiplications in $\mathbb{Z}/N\mathbb{Z}$.

The LUC crypto system stimulated research on Lucas chains [2, 16], but the use of Lucas functions for public-key cryptography had been considered before: Müller and Nöbauer [10] proposed the *Dickson polynomials* $g_n(x, a)$, given by

$$g_n(x,a) = \sum_{0 \le j \le n/2} \frac{n}{n-j} \binom{n-j}{j} (-a)^j x^{n-2j} \qquad \text{for} \quad n \ge 1$$

and $g_0(x, a) = 2$ with some a from a commutative ring with identity, as one-way functions. Waring's formula tells us that [8, p. 355]

$$g_n(P,Q) = \alpha^n + \beta^n = V_n(P,Q)$$

with α, β as in (2). Hence, from this point of view, the LUC system uses the Dickson polynomials $g_n(x, 1)$ for encryption. Müller and Nöbauer argued that it might be difficult to efficiently compute Dickson polynomials for large n, but von zur Gathen [15] used the equation $g_{n+2} = xg_{n+1} - ag_n$ and a matrix representation of this recurrence relation to show that g_n can be computed in $\mathcal{O}(\log n)$ ring operations. Lucas chains can thus be seen as a tool to reduce the multiplicative constant in this asymptotic expression.

Montgomery [9] already pointed out another application of Lucas chains: For every $n \in \mathbb{N}$, the *nth Chebyshev polynomial* T_n is defined as the unique polynomial satisfying

$$T_n(\cos z) = \cos(nz).$$

If we let $\alpha = e^{iz}$ and $\beta = e^{-iz}$, we get $\cos z = (\alpha^n + \beta^n)/2$ and $P = 2\cos z$, $Q = 1$ by (2). Writing $x = \cos z$ then yields [8, p. 355]

$$2T_n(x) = 2\cos(nz) = g_n(2x, 1) = V_n(2x, 1).$$

In other words, these polynomials are just a special case of the Dickson polynomials over the complex numbers. Again we see that we can compute $T_n(x)$ from x with r multiplications if we have a Lucas chain of length r for n.

4. Basic structural properties. For technical reasons we extend the usual notion of Lucas chains to what we call "prechains." They do not alter the capabilities of the original chains but simplify our arguments and proofs in this section.

DEFINITION 2. *A strictly monotonically increasing sequence $\chi = (a_0, a_1, \ldots, a_r)$ of positive integers is called a* Lucas prechain *if property* (L) *holds for every $k \in$*

$\{1,\dots,r\}$. *We define* $\operatorname{len}(\chi) := r$ *to be the* length *and* $\operatorname{val}(\chi) := a_r/a_0$ *to be the* value *of the prechain. A prechain of length zero is called* trivial.

Obviously, every Lucas chain for some n is a Lucas prechain with value n. Conversely, it is also easy to see that a prechain is nothing but a scaled Lucas chain. Let $\alpha\chi$ denote the sequence $(\alpha a_0,\dots,\alpha a_r)$, $\alpha \in \mathbb{Q}_+$. Property (L) is obviously invariant under such scalar multiplications; i.e., a sequence χ of integers is a Lucas prechain iff $c\chi$ is, $c \in \mathbb{N}_+$. Also note that the first element of a prechain divides all others. This follows by induction since (L) implies that a_0 divides a_k if it divides a_i and a_j. Thus we see that values of Lucas prechains are always integers, and scalar multiplication with $1/a_0$ makes any prechain into a chain without changing length or value.

Example 4. The sequence $(6, 12, 18, 30, 48)$ is a Lucas prechain of length 4 for 8. Multiplication with 1/6 yields the chain $(1, 2, 3, 5, 8)$.

4.1. Multiplying chains. It is a well-known fact that two addition chains for a and b can be combined to yield an addition chain for ab [5, Sect. 4.6.3]. As shown in the proof of Theorem 2 of [9], the same method applies to Lucas chains. We restate it here in terms of prechains.

DEFINITION 3. *Let* $\chi_1 = (a_0,\dots,a_r)$ *and* $\chi_2 = (b_0,\dots,b_s)$ *be Lucas prechains with* $a_r = b_0$. *Then their* composition $\chi_1 \circ \chi_2$ *is defined as the sequence* $(a_0,\dots,a_{r-1}, b_0,\dots,b_s)$.

We see that the composition of two Lucas prechains is also a Lucas prechain because no element is removed from the original sequences. This concept is easily adapted to chains. We simply have to scale the second chain appropriately.

DEFINITION 4. *Let* χ_1 *and* χ_2 *be Lucas chains. Then their* product $\chi_1 * \chi_2$ *is the Lucas chain* $\chi_1 \circ \operatorname{val}(\chi_1)\chi_2$.

Both operations, $\circ$ and $*$, clearly are associative. The following equations are immediate from the definitions:

$$\operatorname{len}(\chi_1 * \chi_2) = \operatorname{len}(\chi_1) + \operatorname{len}(\chi_2), \tag{4}$$

$$\operatorname{val}(\chi_1 * \chi_2) = \operatorname{val}(\chi_1) \cdot \operatorname{val}(\chi_2). \tag{5}$$

In order to obtain a chain for a composite number $n = ab$, we can thus multiply chains χ_1 and χ_2 for a and b, respectively. As with addition chains, we call this technique the *factor method* [5, p. 463].

Example 5. The product chain $(1, 2, 3) * (1, 2, 3, 5, 7) * (1, 2, 4) = (1, 2, 3, 6, 9, 15, 21, 42, 84)$ is a Lucas chain of length $2 + 4 + 2 = 8$ for $3 \cdot 7 \cdot 4 = 84$.

4.2. Decomposing chains. We shall now identify those chains that can be written as products of smaller chains. The following proposition is essentially equivalent to Theorem 5 and Corollary 6 of [9]. But because of its fundamental importance for the understanding of the structure of Lucas chains, we shall prove it here again, in terms of prechains. It states that for Lucas chains, decomposability is a completely local concept.

PROPOSITION 1. *Let* $\chi = (a_0,\dots,a_r)$ *be a Lucas prechain and let* $0 \le m < r$. *Then the following two statements are equivalent:*

(i) $a_{m+1} = 2a_m$,

(ii) $\chi^{(m)} := (a_m, a_{m+1},\dots,a_r)$ *is a Lucas prechain.*

Proof. Assume that (i) holds. We show by induction on $k = m+1,\dots,r$ that a_m divides a_k and that any pair of indices i, j satisfying (L) fulfills

$$m \le i \le j \qquad \text{and} \qquad a_j - a_i \in \{0, a_m,\dots,a_{k-1}\}.$$

For $k = m+1$, property (L) is satisfied with $i = j = m$ only. So let $k > m+1$ and assume that $a_m | a_l$ for $m \le l < k$. Let i, j as in (L). We have the implications

$$\begin{aligned} k > m+1 \;&\Rightarrow\; a_k > a_{m+1} = 2a_m \;\Rightarrow\; a_j > a_m \\ &\Rightarrow\; a_j \ge a_{m+1} = 2a_m \;\Rightarrow\; j \ge m+1, \end{aligned}$$

hence $a_m | a_j$ by induction. Let us now consider the two cases $a_i \ge a_j/2$ and $a_i < a_j/2$. In the first case we get

$$a_i \ge a_j/2 \;\Rightarrow\; a_i \ge a_m \;\Rightarrow\; i \ge m \;\Rightarrow\; a_m | a_i.$$

Otherwise

$$a_i < a_j/2 \;\Rightarrow\; a_j - a_i > a_j/2 \ge a_m \;\Rightarrow\; a_m | (a_j - a_i);$$

combined with $a_m | a_j$ this yields $a_m | a_i$ and thus $i \ge m$. In both cases a_m divides $(a_j + a_i) = a_k$ as was to be shown.

The implication (ii) $\Rightarrow$ (i) is immediate from (L). □

Such a pair (a_m, a_{m+1}) of consecutive elements with $a_{m+1} = 2a_m$ is called a *doubling step* [5, p. 467] of the prechain χ. Note that the positions of doubling steps in a prechain are obviously invariant under scaling, i.e., (a, b) is a doubling step of χ iff (ca, cb) is a doubling step of $c\chi$. It is now very easy to identify those chains that are not representable as products.

DEFINITION 5. *We call a Lucas prechain* simple *if it contains exactly one doubling step—its first two elements.*

The Fibonacci chains $\mathcal{F}_l$ from Example 3 are simple for every $l \ge 1$. Note that by definition, trivial prechains are not simple.

The term *simple* is due to Bleichenbacher [2, Chap. 5]. He observed that Lucas chains that cannot be written as nontrivial products are simple. For our lower bounds in section 6, we need to make this notion a little more precise.

PROPOSITION 2. *Let $\chi = (a_0, \ldots, a_r)$ be a nontrivial Lucas prechain and let $(a_{r_\mu}, a_{r_\mu+1})$, $1 \le \mu \le d$, be all its doubling steps in increasing order, i.e., $1 = a_{r_1} < a_{r_2} < \cdots < a_{r_d}$. Additionally let $r_{d+1} := r$. Then*

$$\chi_\mu := (a_{r_\mu}, a_{r_\mu+1}, \ldots, a_{r_{\mu+1}})$$

is a simple Lucas prechain for every $\mu \in \{1, \ldots, d\}$. We have $\chi = \chi_1 \circ \ldots \circ \chi_d$ and this decomposition into simple prechains is unique.

Proof. By Proposition 1, every χ_μ is a Lucas prechain because they all start with a doubling step. They are also simple because none of them contains more doubling steps. The equation $\chi = \chi_1 \circ \cdots \circ \chi_d$ is immediate from the definition of the χ_μ. For uniqueness, just observe that by Proposition 1 every prechain χ'_μ of a decomposition into simple prechains has to start with a doubling step of χ. To be simple it must not contain any other of χ's doubling steps. And it is also of strictly positive length since trivial prechains are not simple. □

We can directly restate this result for chains. Defining the empty product to be the trivial chain, we get the following theorem, which very much resembles the proof of Theorem 7 in [9].

THEOREM 1. *Every Lucas chain χ has a unique decomposition $\chi = \chi_1 * \cdots * \chi_d$ into simple chains. This induces a factorization*

$$\operatorname{val}(\chi) = \prod_{\mu=1}^{d} \operatorname{val}(\chi_\mu)$$

of its value.

Proof. The statement about the simple chain decomposition is just a reformulation of Proposition 2. The product formula for the values directly follows from equation (5). □

Consequently, the structure of a Lucas chain for some $n \in \mathbb{N}_+$ is intimately related to the prime number factorization of n. Theorem 1 will be very important for our lower bounds in section 6.

5. Trivial bounds. Since Lucas chains resemble computation sequences, we are interested in shortest chains for a given value.

DEFINITION 6. *For every number $n \in \mathbb{N}_+$ we let*

$$t(n) := \min\{\mathrm{len}(\chi) \mid \chi \text{ is a Lucas chain for } n\},$$
$$t'(n) := \min\{\mathrm{len}(\chi) \mid \chi \text{ is a simple Lucas chain for } n\}.$$

A Lucas chain χ is called optimal *if* $\mathrm{len}(\chi) = t(\mathrm{val}(\chi))$.

Note that $t'(1) = \infty$ because any simple chain has value ≥ 2; this will be inconsequential since we shall consider $t'(n)$ for $n \geq 2$ only.

We can already state some basic facts about the function t. Application of the factor method directly yields [9, Thm. 2]

$$t(a \cdot b) \leq t(a) + t(b). \tag{6}$$

Just choose optimal chains χ_1 and χ_2 for a and b, respectively, and compare (4) and (5). Denoting $\log_2$ by lg as usual, we also have the trivial lower bound

$$t(n) \geq \lceil \lg n \rceil \tag{7}$$

because by property (L), no element of a Lucas chain can be more than twice as big as any of its predecessors. Therefore the chains in Example 2 are obviously optimal.

5.1. A known upper bound. Montgomery developed the following *binary method* [9] for the construction of a Lucas chain for any given odd $n \geq 3$.

Let $d_0, d_1, \ldots, d_k$ be the digits in the binary representation of n, starting from the high end. We let $a_0 := d_0 = 1$ and inductively define

$$a_i = 2a_{i-1} + d_i \qquad \text{for} \quad i = 1, \ldots, k.$$

In other words, a_i has the binary representation $d_0 d_1 \ldots d_i$. Then

$$(a_0, a_0 + 1, a_1, a_1 + 1, \ldots, a_{k-1}, a_{k-1} + 1, a_k)$$

is a Lucas chain for n because the elements a_{i+1} and $a_{i+1} + 1$ can always be written as $2a_i$, $a_i + (a_i + 1)$, or $2(a_i + 1)$ so that the respective differences are either 0 or 1. This chain has no more than $2k + 1$ elements. Thus we get the upper bound

$$t(n) \leq 2\lfloor \lg n \rfloor. \tag{8}$$

By application of the factor method to $a = n/2$ and $b = 2$, this bound also carries over to even n.

Example 6. For $n = 37 = 100101_2$, the binary method yields the Lucas chain $(1, 2, 3, 4, 5, 9, 10, 18, 19, 37)$.

6. Lower bounds. It turns out that the trivial bound (7) can be substantially improved upon. Montgomery showed the following [9, Thm. 7].

THEOREM 2 (Montgomery). *Let n be a positive integer with s prime divisors (including multiplicities). Then the number of doubling steps in a Lucas chain for n cannot exceed s, and $n \leq 2^{s-1} F_{t(n)-s+3}$.*

This gives us a lower bound on $t(n)$ for any $n \in \mathbb{N}_+$. The aim of this section is to derive a similar bound that depends on the exact prime number factorization of n and not only on the number of prime factors. That result will then enable us to prove the desired lower bound of $t(n) \geq (1-\epsilon)\log_\phi n$ for the vast majority of integers.

6.1. A lower bound for simple chains. By definition, a simple Lucas chain contains exactly one doubling step. Since these are the most efficient steps available, we expect simple chains to grow notably slower than arbitrary Lucas chains can. The following simple but important lemma, which in different form already appeared in [9], captures this intuition.

LEMMA 1. *Let χ be a simple Lucas chain. Then its value is bounded by*

$$\operatorname{val}(\chi) \leq F_{\operatorname{len}(\chi)+2}.$$

Proof. Since every Lucas chain is also an addition chain, we may apply Theorem A from [5, p. 467]. Letting $d = 1$ there immediately yields the stated inequality. ∎

In order to rephrase Lemma 1 in terms of the function t', we reinterpret it in the following way: *The average growth of a simple Lucas chain of length k is no more than a factor of $\sqrt[k]{F_{k+2}}$ per step.*

DEFINITION 7. *For any integer $n \geq 2$, let $k := \min\{l \mid n \leq F_{l+2}\}$ and define*

$$\Phi(n) := \sqrt[k]{F_{k+2}}.$$

Indeed, this is a useful notion. We obtain the following bound.

PROPOSITION 3. *For every $n \geq 2$, we have*

$$t'(n) \geq \frac{\lg n}{\lg \Phi(n)}.$$

Proof. Let k be the unique integer that satisfies $F_{k+1} < n \leq F_{k+2}$. Then by Lemma 1, any simple chain for n has length at least k. Thus

$$t'(n) \geq k \geq \frac{\lg n}{\lg F_{k+2}}\, k = \frac{\lg n}{\lg \sqrt[k]{F_{k+2}}} = \frac{\lg n}{\lg \Phi(n)}. \qquad \blacksquare$$

6.2. From simple chains to arbitrary chains. Theorem 1 now tells us how to obtain a bound for $t(n)$ from Proposition 3. Any chain for n can be factored into simple chains, and the values of these factors are restricted by the possible (partial) factorizations of the integer n. Hence, we can apply Proposition 3 to all those factorizations and get

$$t(n) \geq \min\left\{ \sum_{i=1}^{d} \frac{\lg f_i}{\lg \Phi(f_i)} \;\middle|\; \prod_{i=1}^{d} f_i = n \right\}. \tag{9}$$

We can already use this formula to achieve nontrivial bounds on $t(n)$ for certain values of n.

Example 7. The prime factors of $n = 85$ are 5 and 17. Proposition 3 yields $t'(5) \geq 3$, $t'(17) > 5.5$, and $t'(85) > 8.9$. Since $(1,2,3,5) * (1,2,3,5,7,10,17)$ is a chain of length 9 for 85, we obtain $t(85) = 9$.

So this technique yields useful results, but it may become impractical due to the combinatorial explosion in cases where n has many factors. In the following we shall see how this drawback can be overcome. The key observation is that short simple chains are potentially more efficient than long ones because the shorter the chain the greater the effect of the initial doubling step on the average growth of the chain. In fact, Proposition 3 already captures this behavior in a very satisfying way. We shall see that it is sufficient to apply it only to the prime number factorization of n. In order to prove this formally, we need some basic facts about the function Φ.

6.3. Properties of the function Φ. The Fibonacci numbers are closely related to the golden ratio

$$\phi = \frac{1+\sqrt{5}}{2},$$

and we have the well-known formula [4, p. 83]

$$F_k = \frac{1}{\sqrt{5}}\left(\phi^k - \hat{\phi}^k\right),$$

where $\hat{\phi} = 1 - \phi = \frac{1}{2}(1-\sqrt{5})$. Since $\hat{\phi} = -\phi^{-1}$, we can restate this as

$$F_k = \frac{1}{\sqrt{5}}\left(\phi^k - (-\phi)^{-k}\right), \tag{10}$$

which will better suit our needs.

LEMMA 2. *For all $k \geq 1$ we have*

$$\sqrt[k+1]{F_{k+3}} < \sqrt[k]{F_{k+2}}.$$

Proof. We first raise both sides of the inequality to the $k(k+1)$st power and apply (10); thus we get

$$\begin{aligned}
&\left[\tfrac{1}{\sqrt{5}}\left(\phi^{k+3} - (-\phi)^{-k-3}\right)\right]^k < \left[\tfrac{1}{\sqrt{5}}\left(\phi^{k+2} - (-\phi)^{-k-2}\right)\right]^{k+1} \\
&\Leftrightarrow \sqrt{5}\,\left[\left(1 + (-1)^k\phi^{-2k-6}\right)\,\phi^{k+3}\right]^k < \left[\left(1 + (-1)^{k+1}\phi^{-2k-4}\right)\,\phi^{k+2}\right]^{k+1} \\
&\Leftrightarrow \sqrt{5}\,\phi^{-2} < \left(1 + (-1)^{k+1}\phi^{-2k-4}\right)^{k+1}\left(1 + (-1)^k\phi^{-2k-6}\right)^{-k}. \qquad (11)
\end{aligned}$$

Numerical computation of the left-hand side of (11) yields $\sqrt{5}\,\phi^{-2} < 0.86$. If k is odd, the right-hand side is greater than one and hence (11) follows. If k is even, the right-hand side of (11) equals

$$\begin{aligned}
&\left(1 - \phi^{-2k-4}\right)^{k+1}\left(1 + \phi^{-2k-6}\right)^{-k} \\
&\quad > \left(1 - \phi^{-2k-4}\right)^{k+1}\left(1 - \phi^{-2k-6}\right)^{k} \\
&\quad > \left(1 - \phi^{-2k-4}\right)^{2k+1} \\
&\quad > 1 - (2k+1)\,\phi^{-2k-4},
\end{aligned}$$

where the last step is by application of the Bernoulli inequality. Now

$$h(x) := 1 - (2x+1)\,\phi^{-2x-4} > \sqrt{5}\,\phi^{-2} \qquad \text{for} \quad x \geq 2$$

since numerical computation for $x = 2$ yields $1 - 5\,\phi^{-8} > 0.89 > \sqrt{5}\,\phi^{-2}$ and

$$h'(x) = \big((2x+1)\ln\phi^2 - 2\big)\phi^{-2x-4} > 0 \qquad \text{for} \quad x \geq 2. \qquad \square$$

LEMMA 3. *The sequence $(\Phi(n))_{n\geq 2}$ is monotonically decreasing. It converges towards the golden ratio:*

$$\lim_{n\to\infty} \Phi(n) = \phi.$$

Proof. The first statement is a direct consequence of Lemma 2. Equation (10) yields

$$\sqrt[k]{F_{k+2}} = \sqrt[k]{\tfrac{1}{\sqrt{5}}\big(\phi^{k+2} - (-\phi)^{-k-2}\big)} = \phi \cdot \sqrt[k]{\tfrac{\phi^2}{\sqrt{5}}\big(1 \pm \phi^{-2k-4}\big)},$$

and so the second statement follows. $\square$

6.4. The lower bound in closed form. We are now able to prove a lower bound for $t(n)$ that does not suffer from the combinatorial explosion of the rule (9).

THEOREM 3. *Let n be any positive integer, and let $n = \prod_1^e p_i$ be its factorization into prime numbers. Then we have*

$$t(n) \geq \sum_1^e \frac{\lg p_i}{\lg \Phi(p_i)}.$$

Proof. Let χ be an optimal chain for n and let $\chi_1 * \cdots * \chi_d$ be its decomposition into simple chains. We let $n_\mu := \mathrm{val}(\chi_\mu)$ be their corresponding values. Since $n = n_1 \cdots n_d$, there exists a partition $I_1, \ldots, I_d$ of the index set $\{1, \ldots, e\}$ so that

$$n_\mu = \prod_{i\in I_\mu} p_i$$

for every $\mu \in \{1, \ldots, d\}$. Since χ is optimal, every χ_μ must also be optimal. Thus, by (4) and Proposition 3 we have

$$\begin{aligned} t(n) &= \sum_{\mu=1}^d t(n_\mu) = \sum_{\mu=1}^d t'(n_\mu) \\ &\geq \sum_{\mu=1}^d \frac{\lg n_\mu}{\lg \Phi(n_\mu)} = \sum_{\mu=1}^d \sum_{i\in I_\mu} \frac{\lg p_i}{\lg \Phi(n_\mu)} \\ &\geq \sum_{\mu=1}^d \sum_{i\in I_\mu} \frac{\lg p_i}{\lg \Phi(p_i)} = \sum_{i=1}^e \frac{\lg p_i}{\lg \Phi(p_i)}, \end{aligned}$$

where the penultimate step makes use of Lemma 3. $\square$

Theorem 3 is a powerful and also practical tool for proving Lucas chains optimal. Let us again consider the chain from Example 5. The prime number factorization is

$84 = 2^2 \cdot 3 \cdot 7$. We have

$$\begin{aligned} t(84) &\geq 2\,\frac{\lg 2}{\lg \Phi(2)} + \frac{\lg 3}{\lg \Phi(3)} + \frac{\lg 7}{\lg \Phi(7)} \\ &= 2\,\frac{\lg 2}{\lg 2} + \frac{\lg 3}{\lg \sqrt{3}} + \frac{\lg 7}{\lg \sqrt[4]{8}} > 7.7, \end{aligned}$$

and thus $t(84) = 8$.

6.5. Comparison of the bounds. Since we used methods similar to those of Montgomery, the bounds from Theorem 3 are close to those from Theorem 2. For example, the latter also yields $t(84) \geq 8$, as we have computed from the former. But there are also cases in which the former is slightly better than the latter. As an example consider $n = 177$, where we get the lower bounds 11, which is the precise value of $t(177)$, and 10, respectively. The main advantage of Theorem 3, however, is its dependence on the prime factors of n and its implicit relation to the golden ratio through the function Φ. This will enable us to derive the general lower bound in the subsequent section.

7. A general lower bound. By now we have considered only concrete lower bounds for individual values. In this section we are going to show that the great majority of numbers n does not have Lucas chains shorter than $(1-\epsilon)\log_\phi n$ for any given $\epsilon > 0$.

For this, observe that our bound from Theorem 3 is closer to $\log_\phi n$ if n contains many large prime factors. The next definition captures this notion.

DEFINITION 8. *Let n be any positive integer with prime number factorization $n = \prod_1^e p_i$. Let $B \in \mathbb{N}_+$ and $\delta \in (0, 1]$. We call n a (B, δ)-*fat *number if*

$$\prod_{p_i \leq B} p_i < n^\delta,$$

*that is, it contains less than a δ-portion (logarithmically) of factors smaller than B. We call n (B, δ)-*smooth *if it is not (B, δ)-fat.*

The term "smooth number" is generally used for integers that contain no prime factors larger than a certain bound B. Note that this is just the special case $\delta = 1$ in the above definition.

As expected, it turns out that fat numbers cannot have short Lucas chains.

LEMMA 4. *Let n be a (B, δ)-fat integer, $B \geq 2$. Then we have*

$$t(n) \geq \frac{1-\delta}{\lg \Phi(B)} \lg n.$$

Proof. Let $\prod_1^e p_i$ be the factorization of n into prime numbers, and let

$$\begin{aligned} S &:= \{i \mid p_i \leq B\}, \\ L &:= \{i \mid p_i > B\} \end{aligned}$$

denote the collection of small and large factors indices, respectively. By Theorem 3 we have

$$\begin{aligned} t(n) &\geq \sum_{i \in S \cup L} \frac{\lg p_i}{\lg \Phi(p_i)} \geq \sum_{i \in L} \frac{\lg p_i}{\lg \Phi(p_i)} \\ &\geq \sum_{i \in L} \frac{\lg p_i}{\lg \Phi(B)} = \frac{1}{\lg \Phi(B)} \lg \prod_{i \in L} p_i \\ &> \frac{\lg n^{1-\delta}}{\lg \Phi(B)} = \frac{1-\delta}{\lg \Phi(B)} \lg n, \end{aligned}$$

where the last line follows from the (B, δ)-fatness of n. Note that we had to exclude $B = 1$ since $\Phi(1)$ is not defined. □

We want to know how many numbers are not of this kind; that is, how frequent are (B, δ)-smooth numbers for given B and δ? While much is known about the frequency of the "ordinary" smooth numbers with $\delta = 1$ (see, for example, [3]), our relaxed notion of smoothness has not yet been investigated. The following lemma gives us satisfactory estimates on the density of (B, δ)-smooth numbers. We let $[N, M] := \{n \in \mathbb{Z} \mid N \leq n \leq M\}$ denote the set of integers between N and M, and let $\pi(x)$ as usual count the numbers of primes less than or equal to x.

LEMMA 5. *For every bound $B \in \mathbb{N}_+$, every $\delta \in (0, 1)$, and every $N \in \mathbb{N}_+$, the interval $[N, 2N - 1]$ contains fewer than*

$$\left(N^{1-\delta} + 1\right) \binom{\delta \lg N + \lg B + \pi(B)}{\pi(B)}$$

(B, δ)-smooth numbers.

Proof. Let n be any (B, δ)-smooth number from the interval $[N, 2N - 1]$, and let $\prod_1^e p_i$ be its factorization into prime numbers. Let $S := \{i \mid p_i \leq B\}$ be the collection of its small factors indices. Then we have

$$\prod_{i \in S} p_i \geq n^\delta \geq N^\delta$$

since n is (B, δ)-smooth. We can successively remove indices from S to obtain a subset $S' \subseteq S$ that satisfies

$$N^\delta \leq f := \prod_{i \in S'} p_i < BN^\delta.$$

Hence, every (B, δ)-smooth number in the interval $[N, 2N - 1]$ has such a divisor f. Any such f is of the form

$$f = 2^{\sigma_2} 3^{\sigma_3} 5^{\sigma_5} \dots p^{\sigma_p},$$

where p is the greatest prime less than or equal to B. Since $f < BN^\delta$, all of the σ's are less than $\lg(BN^\delta)$. Thus, there are fewer than

$$\binom{\lg(BN^\delta) + \pi(B) - 1}{\pi(B) - 1} < \binom{\delta \lg N + \lg B + \pi(B)}{\pi(B)}$$

such f's. Every single $f \geq N^\delta$ divides no more than $N/N^\delta + 1$ numbers in the range $[N, 2N - 1]$, and hence the statement of the lemma follows. □

Now we are prepared to prove the announced asymptotic lower bound for Lucas chains.

THEOREM 4. *For any $\epsilon > \rho > 0$ and increasing $N \in \mathbb{N}_+$, there are only $\mathcal{O}(N^{1-\rho})$ numbers $n \in [N, 2N-1]$ satisfying*

$$t(n) \le (1-\epsilon)\log_\phi n,$$

where the constants hidden in the $\mathcal{O}$ depend on ϵ and ρ.

Proof. Let $\delta := (\epsilon+\rho)/2$ and choose an integer B so that

$$\lg \Phi(B) \le \frac{\lg \phi}{1-\frac{\epsilon-\rho}{2}};$$

by Lemma 3 such a B exists. Now Lemma 4 yields

$$t(n) > \frac{1-\delta}{\lg \Phi(B)} \lg n \ge (1-\delta)\Big(1-\frac{\epsilon-\rho}{2}\Big)\log_\phi n > (1-\epsilon)\log_\phi n$$

for any (B,δ)-fat integer n. Thus, only (B,δ)-smooth numbers can have shorter chains, but by Lemma 5 there are no more than

$$\big(N^{1-\delta}+1\big)\binom{\delta \lg N + \lg B + \pi(B)}{\pi(B)} \in \mathcal{O}\big(N^{1-\rho}\big)$$

of these in any interval $[N, 2N-1]$. □

8. Final remarks. Since $\log_\phi n \approx 1.44 \lg n$, Theorem 4 is a significant improvement on the trivial bound (7). But we may ask how close this comes to the optimum. Examples 5 and 7 show that there are cases in which our bounds are extremely sharp. Yet, the majority of numbers could still need chains much longer than Theorem 4 indicates.

We strongly believe that this is not the case. Comparison of the concrete bounds from Theorem 3 with heuristic computations of short chains for the first million natural numbers suggests that our bound is very sharp. It turned out that for all $n \le 10^6$ we have

$$t(n) \le \left\lceil \sum_1^e \frac{\lg p_i}{\lg \Phi(p_i)} \right\rceil + 2,$$

where $n = \prod_1^e p_i$ is the prime number factorization of n.

It seems that Theorem 4 already captures the behavior of the function t in a most fundamental way.

CONJECTURE 1. *The length function t satisfies*

$$\limsup \frac{t(n)}{\lg n} = \frac{1}{\lg \phi}.$$

In fact, Montgomery already asked in Problem 2 of [9] whether this upper bound holds. And in a private communication Donald E. Knuth conjectured the slightly stronger bound of $t(n) \le \log_\phi n + \mathcal{O}(1)$. Nevertheless, I do not expect Conjecture 1 to be shown in the near future. Though the heuristics have produced good results, it seems to be very hard to actually prove any significantly better upper bound than (8). By now we are not even able to show $t(n) \le \alpha \lg n$ for any $\alpha < 2$.

Acknowledgments. I thank my editor Joachim von zur Gathen for pointing me to Montgomery's paper and for many constructive hints. And I am very grateful for Peter L. Montgomery's permission to represent his results. I also want to thank Donald E. Knuth, who supplied me with a list of precise values of $t(n)$, for his encouragement. Above all, I am indebted to my teacher Arnold Schönhage for his friendly support and valuable advice.

SIMPLE LEARNING ALGORITHMS FOR DECISION TREES AND MULTIVARIATE POLYNOMIALS*

NADER H. BSHOUTY† AND YISHAY MANSOUR‡

Abstract. In this paper we develop a new approach for learning decision trees and multivariate polynomials via interpolation of multivariate polynomials. This new approach yields simple learning algorithms for multivariate polynomials and decision trees over finite fields under *any* constant bounded product distribution. The output hypothesis is a (single) multivariate polynomial that is an ϵ-approximation of the target under *any* constant bounded product distribution.

The new approach demonstrates the learnability of many classes under any constant bounded product distribution and using membership queries, such as j-disjoint disjunctive normal forms (DNFs) and multivariate polynomials with bounded degree over any field.

The technique shows how to interpolate multivariate polynomials with bounded term size from membership queries only. This, in particular, gives a learning algorithm for an $O(\log n)$-depth decision tree from membership queries only and a new learning algorithm of *any* multivariate polynomial over sufficiently large fields from membership queries only. We show that our results for learning from membership queries only are the best possible.

Key words. learning interpolation, multivariate polynomial, decision tree learning

1. Introduction.

From the start of computational learning theory, great emphasis has been put on developing algorithmic techniques for various problems. It seems that great progress has been made in learning using membership queries, especially such functions as decision trees and multivariate polynomials. Generally speaking, three different techniques were developed for those tasks: the Fourier transform technique, the lattice-based techniques, and the multiplicity automata technique. All of the techniques use membership queries (which are also called substitution queries for nonbinary fields).

The Fourier transform technique is based on representing functions using a basis, where a basis function is essentially a parity of a subset of the input. Any function can be represented as a linear combination of the basis functions. Kushilevitz and Mansour [KM93] gave a general technique to recover the significant coefficients. They showed that this is sufficient for learning decision trees under the uniform distribution. Jackson [J94] extended the result to learning disjunctive normal form (DNF) under the uniform distribution. The output hypothesis is a majority of parities. (Also, Jackson [J95] generalizes his DNF learning algorithm from uniform distribution to any fixed constant bounded product distribution.)

The lattice-based techniques are, at a very high level, performing a traversal of the binary cube, moving from one node to its neighbor in order to reach some goal node. Angluin [A88] gave the first lattice-based algorithm for learning monotone DNF. Bshouty [Bs93] developed the monotone theory, which gives a technique for

learning decision trees under any distribution. (The output hypothesis in that case is depth 3 formulas.) Schapire and Sellie [SS93] gave a lattice-based algorithm for learning multivariate polynomials over a finite field under any distribution. (Their algorithm depends polynomially on the size of the monotone polynomial that describes the function.)

Multiplicity automata theory is a well-studied field in automata theory. Recently, some very interesting connections were given, connecting learning such automata and learning decision trees and multivariate polynomials. Ohnishi, Seki, and Kasami [OSK94] and Bergadano and Varricchio [BV96] gave algorithms for learning multiplicity automata. Based on this work, Bergadano, Catlano, and Varricchio [BCV96] showed that this algorithm learns disjoint DNF. Then Beimel et al. [BBB+96] gave an algorithm that is based on Hankel matrices theory for learning multiplicity automata and showed that multivariate polynomials over any field are learnable in polynomial time. (In all the above algorithms the output hypothesis is a multiplicity automaton.)

All three techniques—the Fourier spectrum, the lattice-based, and the multiplicity automata algorithms—also give learnability of many other classes such as learning decision trees over parities (nodes contains parities) under constant bounded product distributions, learning CDNF (poly size DNF that has poly size CNF) under any distribution, and learning j-disjoint DNF (DNF where the intersection of any j terms is 0).

In this paper we develop a new approach for learning decision trees and multivariate polynomials via interpolation of multivariate polynomials over $GF(2)$. This new approach leads to simple learning algorithms for decision trees over the uniform and constant bounded product distributions, where the output hypotheses are a multivariate polynomial (parity of monotone terms).

The algorithm we develop gives a single hypothesis that approximates the target function with respect to *any* constant bounded product distribution. In fact the hypothesis is a good hypothesis under any distribution that *supports small terms*. That is, for any distribution D, where for a term T of size $\omega(\log n)$, we have $\Pr_D[T = 1] = 1/\omega(poly(n))$. Previous algorithms do not achieve this property.

It is also known that any DNF is learnable with membership queries under constant bounded product distribution [J95], where the output hypothesis is a majority of parities. Our contribution for j-disjoint DNF is to use an output hypothesis that is a parity of terms and to show that the output hypothesis is an ϵ-approximation of the target against any constant bounded distribution.

We also study the learnability of multivariate polynomials from membership queries only. We give a learning algorithm for multivariate polynomials over n variables with maximal degree $d < c|\mathcal{F}|$ for each variable, where $c < 1$ is constant, and with terms of size

$$k = O\left(\frac{|\mathcal{F}|}{d}(\log n + \log d)\right)$$

using only membership queries. This result implies learning in polynomial time decision trees of depth $O(\log n)$ with leaves from a field $\mathcal{F}$ from membership queries only.

This result is a generalization of the results in [B95b] and [RB89], where the learning algorithm uses membership and equivalence queries in the former and only membership queries in the latter.

The second result is a generalization of the result in [KM93] for learning Boolean decision trees from membership queries. The above result also gives an algorithm for

learning *any* multivariate polynomial over fields of size $q = n/(d(\log n + \log d))$ from membership queries only.

This result is a generalization of the results in [BT88, CDG+91, Z90] for learning multivariate polynomials under any field. Previous algorithms for learning multivariate polynomials over finite fields $\mathcal{F}$ required asking membership queries with assignments in some extension of the field $\mathcal{F}$ [CDG+91]. In [CDG+91] it is shown that an extension n of the field is sufficient to interpolate any multivariate polynomial (when membership queries with assignments from an extension field are allowed). Following this work, [HR96] gave an algorithm that interpolates polynomials over "large" finite fields, without using extension fields; for smaller fields they use an extension field.

The organization of the paper is as follows. In section 2 we define the learning model and the concept classes. In section 3 we give the algorithm for learning multivariate polynomial for the Boolean domain. In section 4 we give some background for multivariate interpolation. In section 5 we show how to reduce learning multivariate polynomials to zero testing and to other problems. Then in section 6 we give the algorithm for zero testing and also give a lower bound for zero testing multivariate polynomials.

2. The learning model and concept classes.

2.1. Learning models. The learning criterion we consider is *exact learning* [A88] and *PAC-learning* (probably approximately correct) [Val84].

In the exact learning model there is a function f called the *target function* $f : \mathcal{F}^n \to \mathcal{F}$ which is a member of a class functions C defined over the variable set $V_n = \{x_1, \ldots, x_n\}$ for some field $\mathcal{F}$. The goal of the learning algorithm is to output a formula h that is equivalent to f.

The learning algorithm performs a *membership query* (also called a *substitution query* for the nonbinary fields) by supplying an assignment a to the variables in $V_n = \{x_1, \ldots, x_n\}$ as input to a *membership oracle* and receives in return the value of $f(a)$. For our algorithms we will regard this oracle as a procedure $MQ_f()$. The procedure input is an assignment a and its output is $MQ_f(a) = f(a)$.

The learning algorithm performs an *equivalence query* by supplying any function h as input to an *equivalence oracle* with the oracle returning either "yes," signifying that h is equivalent to f, or a *counterexample*, which is an assignment b such that $h(b) \neq f(b)$. For our algorithms we will regard this oracle as a procedure $EQ_f(h)$. We say the *hypothesis* class of the learning algorithm is H if the algorithm supplies the equivalence oracle functions from H.

We say that a class of Boolean function C is *exactly learnable* in polynomial time if for any $f \in C$ over V_n there is an algorithm that runs in polynomial time, asks a polynomial number of queries (polynomial in n and in the size of the target function), and outputs a hypothesis h that is equivalent to f.

The PAC-learning model is as follows. There is a function f called the *target function* which is a member of a class of functions C defined over the variable set $V_n = \{x_1, \ldots, x_n\}$. There is a distribution D defined over the domain $\mathcal{F}^n$. The goal of the learning algorithm is to output a formula h that is ϵ-close to f with respect to some distribution D, that is,

$$\Pr_D[f(x) = h(x)] \geq 1 - \epsilon.$$

Such a function h is called an ϵ-approximation of f with respect to the distribution D.

In the PAC or *example query* model, the learning algorithm asks for an example from the *example oracle*, and receives an example $(a, f(a))$, where a is chosen from $\{0,1\}^n$ according to the distribution D.

We say that a class of Boolean functions C is *PAC-learnable* under the distribution D in polynomial time if for any $f \in C$ over V_n, there is an algorithm that runs in polynomial time, asks a polynomial number of queries (polynomial in n, $1/\epsilon$, $1/\delta$, and the size of the target function), and with probability at least $1-\delta$ outputs a hypothesis h that is an ϵ-approximation of f with respect to the distribution D.

It is known from [A88] that if a class is exactly learnable in polynomial time from equivalence queries and membership queries, then it is PAC-learnable with membership queries in polynomial time under any distribution D.

Let $\mathcal{D}$ be a set of distributions. We says that C is PAC-learnable under $\mathcal{D}$ if there is a PAC-learning algorithm for C such that for any distribution $D \in \mathcal{D}$ unknown to the learner and for any $f \in C$ the learning algorithm runs in polynomial time and outputs a hypothesis h that is an ϵ-approximation of f under any distribution $D' \in \mathcal{D}$.

2.2. The concept classes and distributions. A function over a field $\mathcal{F}$ is a function $f : X \to \mathcal{F}$ for some set X. All classes considered in this paper are classes of functions where $X = \mathcal{F}^n$. The elements of $\mathcal{F}^n$ are called *assignments*. We will consider the set of variables $V_n = \{x_1, \ldots, x_n\}$ where x_i will describe the value of the i-projection of the assignment in the domain $\mathcal{F}^n$ of f. For an assignment a, the ith entry of a will be denoted by a_i. A restriction α is a partial assignment, namely, it assigns values to some subset U_α of the variables V_n. A function f restricted by α, denoted by f_α, has as inputs the variables in $V_n - U_\alpha$. Given an assignment β for $V_n - U_\alpha$ the value of $f_\alpha(\beta)$ is $f(\alpha \cup \beta)$.

A *literal* is a nonconstant polynomial $p(x_i)$. A *monotone literal* is x_i^r for some nonnegative integer r. A *term* (*monotone term*) is a product of literals (monotone literals). A *multivariate polynomial* is a linear combination of monotone terms. A *multivariate polynomial with nonmonotone terms* is a linear combination of terms. The *degree* of a literal $p(x_i)$ is the degree of the polynomial p. The *size* of a term $p_{i_1}(x_{i_1}) \cdots p_k(x_{i_k})$ is k.

Let $MUL_{\mathcal{F}}(n,k,t,d)$ be the set of all multivariate polynomials over the field $\mathcal{F}$ over n variables with at most t monotone terms, where each term is of size at most k and each monotone literal is of degree at most d. For the binary field $\mathcal{B}$ the degree is at most $d = 1$ so we will use $MUL(n,k,t)$. $MUL^\star_{\mathcal{F}}(n,k,t,d)$ will be the set of all multivariate polynomials with nonmonotone terms with the above properties. We use $MUL^\star(n,k,t)$ when the field is the binary field. Throughout the paper we will assume that $t \geq n$. Since every term in $MUL^\star_{\mathcal{F}}(n,k,t,d)$ can be written as a multivariate polynomial in $MUL_{\mathcal{F}}(n,k,(d+1)^k,d)$ we have the following proposition.

PROPOSITION 2.1.

$$MUL^\star_{\mathcal{F}}(n,k,t,d) \subseteq MUL_{\mathcal{F}}(n,k,t(d+1)^k,d).$$

For the Boolean field $\mathcal{B} = \{0,1\}$ a DNF is a disjunction of terms. A j-disjoint DNF is a DNF where the conjunction of any j terms is 0. A k-DNF is a DNF with terms of size at most k literals.

A *decision tree* (with leaves from some field $\mathcal{F}$) over V_n is a binary tree whose nodes are labeled with variables from V_n and whose leaves are labeled with constants from $\mathcal{F}$. Each decision tree T represents a function $f_T : \{0,1\}^n \to \mathcal{F}$. To compute $f_T(a)$ we start from the root of the tree T: if the root is labeled with x_i, then $f_T(a) = f_{T_R}(a)$ if $a_i = 1$, where T_R is the right subtree of the root (i.e., the subtree

of the right child of the root with all its descendents). Otherwise (when $a_i = 0$), $f_T(a) = f_{T_L}(a)$, where T_L is the left subtree of the root. If T is a leaf, then $f_T(a)$ is the label of this leaf.

It is not hard to see that a Boolean decision tree of depth k can be represented in $MUL^\star(n, k, 2^k)$ (each leaf in the decision tree defines a term and the function is the sum of all terms), and that a j-disjoint k-DNF of size t can be represented in $MUL^\star(n, k(j-1), t^{j-1})$. (See, for example, [K94].) So for constant k and $d = O(\log n)$ the number of terms is polynomial.

For a DNF and a multivariate polynomial, f, we define $size(f)$ to be the number of terms in f. For a decision tree the size will be the number of leaves in the tree.

A *product distribution* is a distribution D that satisfies $D(a_1, \ldots, a_n) = \prod_i D_i(a_i)$ for some distributions D_i on $\mathcal{F}$. A product distribution is *fixed constant bounded* if there is a constant $0 < c < 1/2$, that is, independent of the number of variables n, such that for any variable x_i, $c \leq \text{Prob}[x_i = 1] \leq 1 - c$. A distribution D *supports small terms* if for every term of size $\omega(\log n)$, we have $\Pr_D[T = 1] = 1/\omega(poly(n))$, where n is the number of variables.

3. Simple algorithm for the Boolean domain. In this section we give an algorithm that PAC-learns with membership queries $MUL^\star(n, n, t)$ under any distribution that supports small terms in polynomial time in n and t. We remind the reader that we assume $t \geq n$. However, all the algorithms in the paper run in polynomial time also when $t < n$.

3.1. Zero test $MUL(n, k, t)$. We first show how to zero test elements in $MUL(n, k, t)$ in polynomial time in n and 2^k assuming k is known to the learner. The algorithm will run in polynomial time for $k = O(\log n)$. Let $f \in MUL(n, k, t)$. Choose a term $T = x_{i_1} \cdots x_{i_j}$, $j \leq k$, of maximal size in f. Choose any values from $\{0, 1\}$ for the variables not in T. The projection will not be the zero function because the term T will stay alive in the projection. Since the projection is a nonzero function with $j \leq k$ variables there is at least one assignment for $x_{i_1}, \ldots, x_{i_j}$ that gives value 1 for the function. This shows that for a random and uniform assignment a, $f(a) = 1$ with probability at least $1/2^j \geq 1/2^k$. So to zero test a function $f \in MUL(n, k, t)$, randomly and uniformly choose polynomial the number of assignments a_i. If $f(a_i)$ is zero for all the assignments, then with high probability we have $f \equiv 0$. Now from the above we have the following claim.

CLAIM 3.1. *For any $f \in MUL(n, k, t)$, $f \not\equiv 0$, the probability that $m = 2^k \log(1/\delta)$ randomly chosen elements $a_1, \ldots, a_m$ in $\{0, 1\}^n$ satisfies $f(a_1) = \ldots = f(a_m) = 0$ is at most δ.*

This implies the following claim.

CLAIM 3.2. *For $f \in MUL(n, O(\log t), t)$, there is a polynomial time probabilistic zero testing algorithm that succeeds with high probability.*

In Figure 1 we have the code for `zero_test`(h, α) that tests if the polynomial h is identical to the target function f on all the inputs that obey a given restriction α. For that case we have the following lemma.

LEMMA 3.3. *For any $f \in MUL(n, k, t)$, and any h, if $(h \oplus f)_\alpha \equiv 0$, then* `zero_test`$(h, \alpha)$ *returns TRUE, and if $(h \oplus f)_\alpha \not\equiv 0$, then* `zero_test`$(h, \alpha)$ *returns FALSE with probability at least $1 - \delta$.*

3.2. Learning $MUL(n, k, t)$. We now show how to reduce zero test to learning monotone polynomials.

```
FUNCTION MQ-hf(h: function, r: assignment);                    /* queries f ⊕ h at r */
RETURN h(r) ⊕ MQ_f(r);

FUNCTION zero_test(h: function, α: restriction);               /* testing if h ⊕ f is zero */
m ← 2^k log(1/δ)                                               /* number of queries */
FOR i = 1 to 2^k log(1/δ) DO
    α_i ← α;
    FOR j = 1 to n DO                                          /* extending α randomly */
        IF {x_j ← b_j} ∉ α_i, THEN
            α_i ← α_i ∪ {x_j ← random_bit()};
    END-FOR;
    IF MQ-hf(h, α_i) = 1, THEN                                 /* Evaluating h ⊕ f at α_i */
        RETURN FALSE;                                          /* Found an assignment for which h ⊕ f is not zero */
END-FOR;
RETURN TRUE;
```

FIG. 1. *The zero test function for polynomials. The function* `zero_test` *checks if the input polynomial h is identical to the target function f on the inputs that obey the restriction α. If they are identical, it outputs TRUE, and if they are not identical, it outputs (with high probability) FALSE. (The function* `random_bit()` *returns* 0 *with probability half and* 1 *with probability half.)*

Let $f \in MUL(n,k,t)$. We first show how to find one term in f. If $f(0) = 1$, then we know that $T = 1$ is a term in f. If $f(0) = 0$, then let $f_0 = f$. Since we can zero test we can find the minimal i_1 such that $f_0|_{x_1 \leftarrow 0,\ldots,\ldots,x_{i_1} \leftarrow 0} \equiv 0$. This implies that $f_{x_1 \leftarrow 0,\ldots,\ldots,x_{i_1-1} \leftarrow 0} = x_{i_1} f_1(x_{i_1+1},\ldots,x_n)$ for some multivariate polynomial f_1. If $f_1(0) = 1$, then we know that $T = x_{i_1}$ is a term in f. We continue recursively with $f_1 = f_{x_1 \leftarrow 0,\ldots,\ldots,x_{i_1-1} \leftarrow 0, x_{i_1} \leftarrow 1}$ until $f_j(0) \equiv 1$, in this case $T = x_{i_1} \cdots x_{i_j}$ is a term in f. Note that we invoke the function `zero_test` at most n times to recover a single term. A formal definition of `Find_Term`, the function that finds a single term, is found in Figure 2.

After we find a term T we define $\hat{f} = f + T$. This removes the term T from f, and thus $\hat{f} \in MUL(n,k,t-1)$. We continue recursively with $\hat{f}$ until we recover all the terms of f. Membership queries for $\hat{f}$ can be simulated by membership for f because $MQ_{\hat{f}}(a) = MQ_f(a) + T(a)$. The formal definition of `Monotone_Polynomial`, the function that interpolates a monotone polynomial, is found in Figure 2.

The function `Monotone_Polynomial` invokes the function `Find_Term` once for each of the terms. Each invocation of `Find_Term` may invoke `zero_test` at most n times. This gives the following claim.

CLAIM 3.4. *For $f \in MUL(n,k,t)$, the function* `Monotone_Polynomial` *returns a polynomial h, such that $h \equiv f$ with probability at least $1 - nt\delta$, uses $nt2^k \log \frac{1}{\delta}$ membership queries, and runs in time $O(nt2^k \log \frac{1}{\delta})$.*

In particular this gives the following claim.

CLAIM 3.5. *For $f \in MUL(n, O(\log t), t)$, there is a polynomial time probabilistic interpolation algorithm that succeeds with high probability to learn f from membership queries.*

3.3. Learning $MUL^\star(n,n,t)$. We now give a PAC-learning algorithm that learns $MUL^\star(n,n,t)$ under any distribution that support small terms. We first give the idea of the algorithm.

Let $f \in MUL^\star(n,n,t)$. To PAC-learn f we randomly choose an assignment a and define $f'(x) = f(x \oplus a)$. A term in f of size k will have on average $k/2$ monotone

```
FUNCTION Find_Term(h:function, a:offset, α: restriction);   /* Finds a term in f ⊕ h */
β ← α; T ← ∅;
FOR i = 1 to n DO
    IF{x_i ← b} ∉ α, THEN                                   /* check if variable is alive */
      tmp_β ← β ∪ {x_i ← a_i};                               /* try to restrict x_i */
      IF zero_test(h, tmp_β)=TRUE, THEN                     /* does x_i appear in all remaining terms? */
        T ← T ∪ {x_i};                                      /* add x_i to the term T */
        β ← β ∪ {x_i ← (1 − a_i)};                          /* restrict x_i */
        γ ← {x_j ← a_j | j ≥ i + 1, {x_j ← b} ∉ α};         /* complete the restriction β */
        IF MQ-hf(h, β ∪ γ) = 1, THEN
          RETURN T;                                         /* x_i was the only variable left. we are done! */
      ELSE β ← tmp_β;                                       /* there are terms without x_i, search for such a term*/
END-FOR;
```

```
FUNCTION Monotone_Polynomial(a: offset, α: restriction);
                                                            /* learn the monotone representation */
h = 0;                                                      /* initial hypothesis */
WHILE zero_test(h, a) =FALSE DO                             /* test if we are done? */
    h ← h ⊕ Find_Term(h, a, α);                             /* add another monotone term */
END-WHILE;
RETURN h;
```

FIG. 2. *The code of the learning algorithm for a polynomial using the representation of the monotone terms. The offset and the restriction are introduced to extend the algorithm to handle learning a polynomial with a small number of nonmonotone terms. If the target function, f, is a sparse monotone polynomial, we can set the offset, a, to the zero vector and the restriction, α, to be an empty set.*

literals in f', and terms with $k = \Omega(\log t)$ variable will have with high probability $\Omega(k)$ monotone literals.

We perform a zero restriction, i.e., for each i, with probability $1/2$ we substitute $x_i \leftarrow 0$ in f'. Since a term of size k in f has on average $k/2$ monotone literals after the shift $f(x \oplus a)$, in the zero restriction this term will be zero with probability (about) $1 - 2^{-k/2}$. This probability is greater than $1 - 1/poly(t)$ for $k = \Omega(\log t)$. Therefore with high probability all the terms of size more than $\Omega(\log t)$ will be removed by the zero restriction. This ensures that with high probability the projection f'' is in $MUL^{\star}(n, O(\log t), t)$, and therefore by Proposition 2.1 $f'' \in MUL(n, O(\log t), poly(t))$. Now we can use the algorithm in subsection 3.2, `Monotone_Polynomial`, to learn f''. Notice that for multivariate polynomial h (with monotone terms) when we performed a zero restriction, we deleted some of the monotone terms from h; therefore, the monotone terms of f'' are monotone terms of f'.

We continue to take zero restrictions and collect terms of f' until the sum of terms that appear in at least one restriction defines a multivariate polynomial which is a good approximation of f'. We get a good approximation of f' with respect to any distribution that supports small terms since we collect all the small size terms (i.e., terms of size $O(\log t)$).

THEOREM 3.6. *There is a polynomial time probabilistic PAC-learning algorithm with membership queries that learns $MUL^{\star}(n, n, t)$ under any distribution that supports small terms.*

We now prove that the function `Non_Monotone_Polynomial` (given in Figure 3) PAC-learns with membership queries any multivariate polynomial with at most t nonmonotone terms under distributions that support small terms. For the analysis of the correctness of the algorithm we first need to formalize the notion of distributions that

```
FUNCTION Non_Monotone_Polynomial();  /* learns a polynomial with t non-monotone terms */
a ← random_assignment();             /* we will learn f(x ⊕ a) */
r = (t/ε)^c (ln (t/4 (t/ε)^{4c}));
FOR j = 1 to r DO
    α_j ← ∅;                                   /* build a random restriction */
    FOR i = 1 to n DO
        IF random_bit()= TRUE,                 /* restrict x_i with probability half */
            THEN α_j ← α_j ∪ {x_i ← a_i}
    END-FOR;
    h_j ← Monotone_Polynomial(a, α_j);         /* find terms of f(a ⊕ x) restricted by α_j */
END-FOR;
T ← {T | T is a term of h_j and |T| ≤ 4c log(t/ε)}   /* collect all short term found */
h(x ⊕ a) = ⊕_{T∈T} T;
RETURN h(x ⊕ a);
```

```
FUNCTION random_assignment();
FOR i = 1 to n DO
    a_i ← random_bit();
END-FOR;
RETURN (a_1, ..., a_n);
```

FIG. 3. *The algorithm to learn a polynomial with t nonmonotone terms. First we fix a random offset a. Then we choose many zero restrictions, α_j, randomly. For each zero restriction we reconstruct the polynomial by finding its monotone terms. Finally, our hypothesis includes all the short terms.*

support small terms. The following is one way to define this notion.

DEFINITION 3.7. *Let $\mathcal{D}_{c,t,\epsilon}$ include any distribution D such that for any DNF f with t terms, each of size greater than $c\log(t/\epsilon)$, we have $\Pr_D[f=1] \le \epsilon$.*

Notice that all the constant bounded product distributions D, where $1-d \le \Pr_D[x_i=1] \le d$ for all i, are in $\mathcal{D}_{1/\log(1/d),t,\epsilon}$. In what follows we will assume that $c \ge 2$ and $\epsilon < 1/8$. We will use the Chernoff bound (see [ASE]).

LEMMA 3.8. *Let $X_1, \ldots, X_m \in \{0,1\}$ be independent random variables where $\Pr[X_i = 1] = 1/2$. Then for any γ we have*

$$\Pr\left[\sum_{i=1}^{m} X_i \le \frac{m}{2} - \gamma\right] \le 2^{-\frac{2\gamma^2}{m}}.$$

Let $f = T_1 \oplus \cdots \oplus T_t$ be a multivariate polynomial where $T_1, \ldots, T_t$ are terms and $|T_1| \le |T_2| \le \cdots \le |T_t|$. Our algorithm starts by choosing a random assignment a and defines $f'(x) = f(x \oplus a)$. All terms that are of size s (in f') will contain on average $s/2$ monotone literals. Therefore by the Chernoff bound we have the following lemma.

LEMMA 3.9. *With probability at least $1-\epsilon$, all the terms in f' of size more than $\alpha c\log(t/\epsilon)$ contain at least $(\alpha/4)c\log(t/\epsilon)$ monotone literals, where $\alpha \ge 4$ and $c \ge 2$.*

Proof. Let T be any term of size at least $\alpha c\log(t/\epsilon)$. Let $P(T)$ be the number of monotone literals in T. We have

$$\Pr\left[P(T) < \frac{\alpha}{4} c \log\frac{t}{\epsilon}\right] \le 2^{-\frac{\alpha c}{8}\log\frac{t}{\epsilon}} = \left(\frac{\epsilon}{t}\right)^{\frac{\alpha c}{8}} \le \frac{\epsilon}{t}.$$

Since the number of terms of f' is t the lemma follows. □

With probability at least $1-\epsilon$, all the terms of size more than $4c\log(t/\epsilon)$ will contain at least $c\log(t/\epsilon)$ monotone literals and all terms of size $8c\log(t/\epsilon)$ will contain

at least $2c\log(t/\epsilon)$ monotone literals. For the analysis, we now split the function f' into 3 functions f'_1, f'_2, and f'_3. The function $f'_1 = T_1 \oplus \cdots \oplus T_{t_1}$ will contain all terms that are of size at most $4c\log(t/\epsilon)$. The function $f'_2 = T_{t_1+1} \oplus \cdots \oplus T_{t_2}$ will contain all terms of size between $4c\log(t/\epsilon)$ and $8c\log(t/\epsilon)$, and the function $f'_3 = T_{t_2+1} \oplus \cdots \oplus T_t$ will contain all terms of size more than $8c\log(t/\epsilon)$.

Since $f'_1 \in MUL^\star(n, 4c\log(t/\epsilon), t)$, we have $f'_1 \in MUL(n, 4c\log(t/\epsilon), t(t/\epsilon)^{4c})$ by Proposition 2.1. Similarly, $f'_2 \in MUL(n, 8c\log(t/\epsilon), t(t/\epsilon)^{8c})$.

Our algorithm will find all the terms in f'_1, some of the terms in f'_2, and none of the terms in f'_3. The following lemma shows that this is sufficient in order to learn f.

LEMMA 3.10. *Let $f \in MUL^\star(n, n, t)$, $a \in \{0,1\}^n$ be any assignment, and $f'(x) = f(x \oplus a)$. Let $g = f'_1 \oplus h$, where h is a multivariate polynomial that contains some of the monotone terms in f'_2. Then for any $D \in \mathcal{D}_{c,t,\epsilon}$ we have*

$$\Pr_D[g \neq f'] \leq \epsilon,$$

assuming that all the terms in f' of size more than $\alpha c\log(t/\epsilon)$ contain at least $(\alpha/4)c\log(t/\epsilon)$ monotone literals, where $\alpha \geq 4$ and $c \geq 2$.

Proof. The error is

$$\Pr_D[g \neq f'] = \Pr_D[(f'_1 \oplus h) \oplus f' = 1] = \Pr_D[h \oplus f'_2 \oplus f'_3 = 1].$$

Let

$$f'_2 = \hat{T}_{t_1+1}\tilde{T}_{t_1+1} \oplus \cdots \oplus \hat{T}_{t_2}\tilde{T}_{t_2} \in MUL^\star(n, 8c\log(t/\epsilon), t),$$

where $T_i = \hat{T}_{t_i}\tilde{T}_{t_i}$, $\hat{T}_{t_i}$ is the part of the term that contains monotone literals and $\tilde{T}_{t_i}$ is the part that contains the nonmonotone literals. If $\hat{T}_{t_1+1} = x_{i_1} \cdots x_{i_k}$ and $\tilde{T}_{t_1+1} = \bar{x}_{j_1} \cdots \bar{x}_{j_l}$, then notice that when we change $\hat{T}_{t_1+1}\tilde{T}_{t_1+1}$ to the sum of monotone terms, we get

$$\sum_{S \subseteq \{j_1,\ldots,j_l\}} \hat{T}_{t_1+1} \prod_{q \in S} x_{j_q}.$$

So every monotone term in f'_2 will contain one of the terms $\hat{T}_i$, $t_1 + 1 \leq i \leq t_2$. Therefore we can write $f'_2 = \hat{T}_{t_1+1}f'_{2,1} \oplus \cdots \oplus \hat{T}_{t_2}f'_{2,t_2-t_1}$, where $f'_{2,i}$ are multivariate polynomials with monotone terms. Since h is a multivariate polynomial that contains some of the terms in f'_2, we have $f'_2 \oplus h = \hat{T}_{t_1+1}h_{2,1} \oplus \cdots \oplus \hat{T}_{t_2}h_{2,t_2-t_1}$. By our assumption, $|\hat{T}_i| \geq c\log(t/\epsilon)$, for $t_1 + 1 \leq i \leq t_2$, and $|T_i| \geq 2c\log(t/\epsilon)$, for $i \geq t_2 + 1$. Since D is a distribution that supports small terms, i.e., $D \in \mathcal{D}_{c,t,\epsilon}$, we have

$$\Pr_D[(h \oplus f_2) \oplus f_3 = 1] \leq \Pr_D[\hat{T}_{t_1+1} \vee \cdots \vee \hat{T}_{t_2} \vee T_{t_2+1} \vee \cdots \vee T_t] \leq \epsilon,$$

and the lemma follows. ∎

The algorithm will proceed as follows. We choose

$$r = \left(\frac{t}{\epsilon}\right)^c \left(\ln\left(\frac{t}{4}\left(\frac{t}{\epsilon}\right)^{4c}\right)\right)$$

zero restrictions $\alpha_1, \ldots, \alpha_r$ for f'. Recall that a zero restriction α of f' is a function f'_α where, with probability $1/2$, $x_i \leftarrow 0$ and, with probability $1/2$, the variable x_i remains alive. We will show that with some constant probability we have the following:

(A) For every monotone term in f_1' there is a restriction α_i such that $(f_1')_{\alpha_i}$ contains this term.

(B) For every $i = 1, \ldots, r$ we have $(f_3')_{\alpha_i} \equiv 0$.

We define $T(\alpha_i) = 0$ if the restriction α_i and the term T share a variable, and $T(\alpha_i) = *$ if they do not share a variable. The next lemma proves (A), namely, that all the small terms would be recovered (as monotone terms).

LEMMA 3.11. *Let $f \in MUL^\star(n, n, t)$, $a \in \{0,1\}^n$ be any assignment, and $f'(x) = f(x \oplus a)$. The probability that for each monotone term T of f_1', whose size is at most $4c\log(t/\epsilon)$, there exists a random restriction α_i, such that $T(\alpha_i) \neq 0$ is at least $3/4$.*

Proof. Let $\mathcal{T}_1$ be the set of monotone terms in f_1'. By the definition of f_1', we have that $|\mathcal{T}_1| \leq t(t/\epsilon)^{4c}$ and every term in $\mathcal{T}_1$ is of size at most $4c\log(t/\epsilon)$. Let A be the event that for each term $T \in \mathcal{T}_1$ there is a restriction α_i such that $T(\alpha_i) \neq 0$. We have

$$\begin{aligned}
\Pr[\text{not } A] &= \Pr[(\exists T \in \mathcal{T}_1)(\forall \alpha_i)\ T(\alpha_i) = 0] \\
&\leq t\left(\frac{t}{\epsilon}\right)^{4c} \Pr[(\forall \alpha_i)\ T(\alpha_i) = 0] \\
&\leq t\left(\frac{t}{\epsilon}\right)^{4c} \left(1 - \frac{1}{2^{c\log(t/\epsilon)}}\right)^r = \frac{1}{4},
\end{aligned}$$

which completes the proof of the lemma. ∎

The next lemma proves (B), namely, that with high probability none of the large terms survives any of the zero restrictions.

LEMMA 3.12. *Let $f \in MUL^\star(n, n, t)$ and let $a \in \{0,1\}^n$ be a random assignment. The probability that for some term T of $f'(x) = f(x \oplus a)$, whose size is at least $8c\log(t/\epsilon)$, there exists a random restriction α_i, such that T is a term of f'_{α_i}, $1 \leq i \leq r$, is at most 2ϵ, where the probability is taken over the choice of a and α_i.*

Proof. Let $\mathcal{T}_3$ be the set of terms of f' of size at least $8c\log(t/\epsilon)$. Clearly the number of terms in $\mathcal{T}_3$ is at most t. Let B be the event that for every $T \in \mathcal{T}_3$ and each restriction α_i, $T(\alpha_i) = 0$, and therefore f'_{α_i} does not contain T. Let B' be the event that we select an a such that every term T of f', whose size is at least $8c\log(t/\epsilon)$, has at least $2c\log(t/\epsilon)$ monotone literals.

By Lemma 3.9, with probability at least $1 - \epsilon$, event B' holds. Assume that B' holds. We compute the probability that B does not hold, given that B' holds.

$$\begin{aligned}
\Pr[\text{not } B \mid B'] &= \Pr[(\exists i)(\exists T \in \mathcal{T}_3)\ T(\alpha_i) \neq 0] \\
&\leq rt\left(\frac{1}{2}\right)^{2c\log(t/\epsilon)} \\
&\leq \epsilon.
\end{aligned}$$

Clearly,

$$\Pr[\text{not } B] \leq \Pr[\text{not } B'] + \Pr[\text{not } B \mid B'] \leq 2\epsilon,$$

which completes the proof of the lemma. ∎

From Lemmas 3.11 and 3.12 we have that with probability at least $3/4 - 2\epsilon$ all the projections f'_{α_i} contain terms of size at most $8c\log(t/\epsilon)$ and for each monotone term of f_1' there is a projection f'_{α_i} that contains the term. Therefore, the algorithm proceeds by learning each projection $f'_{\alpha_i} \in MUL(n, 8c\log(t/\epsilon), t(t/\epsilon)^{8c})$ using the monotone

polynomial algorithm and collecting all the terms of size at most $4c\log(t/\epsilon)$. This ensures that with probability $3/4-2\epsilon$ we recover all the terms of f_1'. By Lemma 3.10 this implies that the error is at most ϵ. (The details of the algorithm are found in Figure 3.)

The running time of the function `Non_Monotone_Polynomial`, and the number of membership queries, are bounded by

$$O\left(r\cdot\left(t\left(\frac{t}{\epsilon}\right)^{8c}\right)\cdot n\cdot 2^{8c\log(t/\epsilon)}\log 1/\delta\right)=O\left(\left(\frac{t}{\epsilon}\right)^{16c}t^2 n\log(1/\delta)\ln(t/\epsilon)\right).$$

Recall that the constant c depends on the distribution. For example, for the uniform distribution, $c=1$.

The above analysis algorithm can also be used to learn functions $f:\{0,1\}^n\to\mathcal{F}$ of the form $f=\lambda_1T_1+\cdots+\lambda_tT_t$, where $\lambda_i\in\mathcal{F}$, T_i are terms and $+$ is the addition of a field $\mathcal{F}$. These functions can be computed as follows. For an assignment a, $f(a)=\sum_{T_i(a)=1}\lambda_i$. This gives the learnability of decision trees with leaves that contain elements from the field $\mathcal{F}$.

4. Multivariate interpolation. In this section we show how to generalize the above algorithm for any multivariate polynomial over any field. Let

$$f=\sum_{\alpha\in\mathcal{I}}a_\alpha x_1^{\alpha_1}\cdots x_n^{\alpha_n}$$

be a multivariate polynomial over the field $\mathcal{F}$, where $a_\alpha\in\mathcal{F}$ and $\alpha_1,\ldots,\alpha_n$ are integers. We will denote the class of all multivariate polynomials over the field $\mathcal{F}$ and over the variables $x_1,\ldots,x_n$ by $\mathcal{F}[x_1,\ldots,x_n]$. The number of terms of f is denoted by $|f|$. We have $|f|=|\mathcal{I}|$ when all a_α are not zero. When $f=0$ then $|f|=0$ and when $f=c\in\mathcal{F}\backslash\{0\}$ then $|f|=1$. Let d be the maximal degree of variables in f, i.e., $\mathcal{I}\subseteq[d]^n$ where $[d]=\{0,1,\ldots,d\}$. Suppose $\mathcal{F}'=\{\gamma_0,\ldots,\gamma_d\}\subseteq\mathcal{F}$ are $d+1$ distinct field constants, where $\gamma_0=0$ is the zero of the field. A univariate polynomial $f(x_1)\in\mathcal{F}[x_1]$ over the field $\mathcal{F}$ of degree at most d can be interpolated from membership queries as follows. Suppose that

$$f(x_1)=\Delta^{(d)}(f)x_1^d+\cdots+\Delta^{(1)}(f)x_1+\Delta^{(0)}(f),$$

where $\Delta^{(i)}(f)$ is the coefficient of x^i in f in its polynomial representation. Then

$$\begin{cases} f(\gamma_0) &=& \Delta^{(d)}(f)\gamma_0^d+\cdots+\Delta^{(1)}(f)\gamma_0+\Delta^{(0)}(f),\\ f(\gamma_1) &=& \Delta^{(d)}(f)\gamma_1^d+\cdots+\Delta^{(1)}(f)\gamma_1+\Delta^{(0)}(f),\\ \vdots & \vdots & \vdots\\ f(\gamma_d) &=& \Delta^{(d)}(f)\gamma_d^d+\cdots+\Delta^{(1)}(f)\gamma_d+\Delta^{(0)}(f). \end{cases}$$

This is a linear system of equations and can be solved for $\Delta^{(i)}(f)$ as follows:

$$\frac{\det\begin{vmatrix} \gamma_0^d & \cdots & \gamma_0^{i+1} & f(\gamma_0) & \gamma_0^{i-1} & \cdots & \gamma_0 & 1\\ \gamma_1^d & \cdots & \gamma_1^{i+1} & f(\gamma_1) & \gamma_1^{i-1} & \cdots & \gamma_1 & 1\\ \vdots & & \vdots & \vdots & \vdots & & \vdots & \vdots\\ \gamma_d^d & \cdots & \gamma_d^{i+1} & f(\gamma_d) & \gamma_d^{i-1} & \cdots & \gamma_d & 1 \end{vmatrix}}{\det|V(\gamma_0,\ldots,\gamma_d)|}, \tag{1}$$

where $V(\gamma_0, \ldots, \gamma_d)$ is the Vandermonde matrix.

If f is a multivariate polynomial, then f can be written as

$$f(x_1, \ldots, x_n) = \Delta^{(d)}(f)x_1^d + \cdots + \Delta^{(1)}(f)x_1 + \Delta^{(0)}(f),$$

where $\Delta^{(i)}(f)$ is a multivariate polynomial over the variables $x_2, \ldots, x_n$. We can still use (1) to find $\Delta^{(i)}(f)$ by replacing each $f(\gamma_i)$ with $f(\gamma_i, x_2, \ldots, x_n)$. Notice that from the first equation in the system, since $\gamma_0 = 0$, we have

$$\Delta^{(0)}(f) = f(0, x_2, \ldots, x_n). \tag{2}$$

From (1) a membership query for $\Delta^{(i)}$ can be simulated using $d+1$ membership queries to f. From (2), a membership query to $\Delta^{(0)}$ can be simulated using one membership query to f.

We now extend the Δ operators as follows: for $\mathbf{i} = (i_1, \ldots, i_k) \in [d]^k$,

$$\Delta^{\mathbf{i}} = \Delta^{i_k}\Delta^{i_{k-1}} \cdots \Delta^{i_1}.$$

Here Δ always operates on the variable with the smallest index. So Δ^{i_1} operates on x_1 in f to give a function f' that depends on $x_2, \ldots, x_n$. Then Δ^{i_2} operates on x_2 in f' and so on. We will also write $x^{\mathbf{i}}$ for the term $x_1^{i_1}x_2^{i_2} \cdots x_k^{i_k}$. The weight of $\mathbf{i}$, denoted by $wt(\mathbf{i})$, is the number of nonzero entries in $\mathbf{i}$.

The operator $\Delta^i(f)$ gives the coefficient of x_1^i in f when represented in $\mathcal{F}[x_2, \ldots, x_n][x_1]$; the operator $\Delta^{\mathbf{i}}(f)$ gives the coefficient of $x^{\mathbf{i}}$ when f is represented in

$$\mathcal{F}[x_{k+1}, \ldots, x_n][x_1, \ldots, x_k].$$

Suppose $\mathcal{I} \subseteq [d]^k$ is such that $\Delta^{\mathbf{i}}f \neq 0$ for all $\mathbf{i} \in \mathcal{I}$ and $\Delta^{\mathbf{i}}f = 0$ for all $\mathbf{i} \notin \mathcal{I}$, that is, $x^{\mathbf{i}}$ for $\mathbf{i} \in \mathcal{I}$ are the k-suffixes of all terms of f. Here the k-suffix of a term $x_1^{i_1} \cdots x_n^{i_n}$ is $x_1^{i_1} \cdots x_k^{i_k}$. Since $\mathbf{i} \in \mathcal{I}$ if and only if $x^{\mathbf{i}}$ is a k-suffix of some term in f, it is clear that $|\mathcal{I}| \leq |f|$ and we must have

$$f = \sum_{\mathbf{i} \in \mathcal{I}} (\Delta^{\mathbf{i}}f)x^{\mathbf{i}}.$$

Now we will show how to simulate membership queries for $(\Delta^{\mathbf{i}}f)(x_{k+1}, \ldots, x_n)$, $\mathbf{i} \in \mathcal{I}$, using a polynomial number (in n and $|f|$) of membership queries to f. Suppose we want to find $(\Delta^{\mathbf{i}}f)(c)$ for some $c \in \mathcal{F}^{n-k}$ using membership queries to f. We take r assignments $\hat{\gamma}_1, \ldots, \hat{\gamma}_r \in \mathcal{F}^k$ and ask membership queries for $(\hat{\gamma}_i, c)$ for all $i = 1, \ldots, r$. If $f(\hat{\gamma}_i, c) = \omega_i$, then

$$\begin{cases} \sum_{\mathbf{i} \in \mathcal{I}} (\Delta^{\mathbf{i}}f)(c)\hat{\gamma}_1^{\mathbf{i}} = \omega_1, \\ \quad \vdots \qquad\qquad \vdots \quad \vdots \\ \sum_{\mathbf{i} \in \mathcal{I}} (\Delta^{\mathbf{i}}f)(c)\hat{\gamma}_r^{\mathbf{i}} = \omega_r. \end{cases}$$

Now if $\mathcal{I} = \{\mathbf{i}_1, \ldots, \mathbf{i}_r\}$ and $\det|\mathbf{M}[\hat{\gamma}_j; \mathbf{i}_j]| \neq 0$ for

$$\mathbf{M}[\hat{\gamma}_j; \mathbf{i}_j] = \begin{bmatrix} \hat{\gamma}_1^{\mathbf{i}_1} & \cdots & \hat{\gamma}_1^{\mathbf{i}_r} \\ \vdots & \vdots & \vdots \\ \hat{\gamma}_r^{\mathbf{i}_1} & \cdots & \hat{\gamma}_r^{\mathbf{i}_r} \end{bmatrix},$$

then the above linear system of equations can be solved in time $poly(r) = poly(|\mathcal{I}|) \leq poly(|f|)$. The solution gives $(\Delta^{\mathbf{i}}f)(c)$. The existence of $\hat{\gamma}_i$ where the above determinant is not zero will be proven in the next section.

5. Reducing learning to zero testing (for any field). In this section we show how to use the results from the previous section to learn multivariate polynomials.

Let $MUL_{\mathcal{F}}(n,k,t,d)$ be the set of all multivariate polynomials over the field $\mathcal{F}$ over n variables with t terms, where each term is of size k and the maximal degree of each variable is at most d. We would like to answer the following questions. Let $f \in MUL_{\mathcal{F}}(n,k,t,d)$.

1. Is there a polynomial time algorithm that uses membership queries to f and decides whether $f \equiv 0$?
2. Given $i \leq n$, is there a polynomial time algorithm that uses membership queries to f and decides whether f depends on x_i?
3. Given $\{\mathbf{i}_1, \ldots, \mathbf{i}_r\} \subseteq [d]^n$, where $wt(\mathbf{i}_j) \leq k$ for all j and $r \leq t$, is there an algorithm that runs in polynomial time and finds $\gamma_1, \ldots, \gamma_r \in \mathcal{F}^k$ such that

$$\begin{vmatrix} \gamma_1^{\mathbf{i}_1} & \cdots & \gamma_1^{\mathbf{i}_r} \\ \vdots & \vdots & \vdots \\ \gamma_r^{\mathbf{i}_1} & \cdots & \gamma_r^{\mathbf{i}_r} \end{vmatrix} \neq 0?$$

4. Is there a polynomial time algorithm that uses membership queries to f and identifies f?

When we say polynomial time we usually mean polynomial time in n, k, t, and d, but all the results of this section hold for any time complexity T if we allow a blow up of $poly(n,t)$ in the complexity.

We show that 1, 2, and 4 are equivalent and $1 \Rightarrow 3$. Obviously $2 \Rightarrow 1$, $4 \Rightarrow 1$, and $4 \Rightarrow 2$. We will show $1 \Rightarrow 2$, $1 \Rightarrow 3$, and $1 + 2 + 3 \Rightarrow 4$.

To prove $1 \Rightarrow 2$ notice that $f \in MUL_{\mathcal{F}}(n,k,t,d)$ is independent of x_i if and only if $g = f|_{x_i \leftarrow 1} - f|_{x_i \leftarrow 0} \equiv 0$. Since g is the coefficient of x_i in f, we have $g \in MUL_{\mathcal{F}}(n-1,k,t,d)$. Therefore we can zero test g in polynomial time.

To prove $1 \Rightarrow 3$, let $\gamma_1, \ldots, \gamma_s$ be a zero test for functions in $MUL_{\mathcal{F}}(n,k,t,d)$, that is, run the algorithm that zero test for the input 0 and take all the membership queries in the algorithm $\gamma_1, \ldots, \gamma_s$. We now have $f \in MUL_{\mathcal{F}}(n,k,t,d)$ is 0 if and only if $f(\gamma_i) = 0$ for all $i = 1, \ldots, s$. Consider the $s \times r$ matrix with rows $[\gamma_j^{\mathbf{i}_1}, \ldots, \gamma_j^{\mathbf{i}_r}]$. If this matrix has rank r, then we choose r linearly independent rows. If the rank is less than r, then its columns are dependent, and therefore there are constants c_i, $i = 1, \ldots, r$, such that

$$\sum_{i=1}^{r} c_i \gamma_j^{\mathbf{i}_i} = 0 \quad \text{for} \quad j = 1, \ldots, s.$$

This shows that the multivariate polynomial $\sum_{i=1}^{r} c_i x^{\mathbf{i}_i}$ is 0 for all $\gamma_1, \ldots, \gamma_s$. Since $\sum_{i=1}^{r} c_i x^{\mathbf{i}_i}$ is in $MUL_{\mathcal{F}}(n,k,t,d)$ we get a contradiction.

Now we show that $1 + 2 + 3 \Rightarrow 4$. This will use results from the previous section. The algorithm first checks whether f depends on x_1, and if yes it generates a tree with a root labeled with x_1 that has d children. The ith child is the tree for $\Delta^i(f)$. If the function is independent of x_1, it builds a tree with one child for the root. The child is $\Delta^0(f)$. We then recursively build the tree for the children. The previous section shows how to simulate membership queries at each level in polynomial time. This algorithm obviously works and its correctness follows immediately from the previous section and 1–3 above.

The complexity of the algorithm is the size of the tree times the membership query simulation. The size of the tree at each level is bounded by the number terms in f, and the depth of the tree is bounded by n; therefore, the tree has at most $O(nt)$ nonzero nodes. The total number of nodes is at most a factor of d from the nonzero nodes. Thus the algorithm has complexity the same as zero testing with a blow up of $poly(n,t,d)$ queries and time.

Now that we have reduced the problem to zero testing, we will investigate in the next section the complexity of zero testing of $MUL_{\mathcal{F}}(n,k,t,d)$.

6. Zero test of $MUL_{\mathcal{F}}(n,k,t,d)$. In this section we will study the zero testing of $MUL_{\mathcal{F}}(n,k,\star,d)$ when the number of terms is unknown and might be exponentially large. The time complexity for the zero testing should be polynomial in n and d. (We have $k<n$ so it is also polynomial in k.) We will show the following theorem.

THEOREM 6.1. *The class $MUL_{\mathcal{F}}(n,k,\star,d)$, where $d \le c|\mathcal{F}|$, is zero testable in randomized polynomial time in n, d, and t (here t is not the number of terms in the target, but only a free parameter) for some constant $c<1$ if and only if*

$$k = O\left(\frac{|\mathcal{F}|}{d}(\log n + \log d + \log t)\right).$$

The algorithm for the zero testing is simply to randomly and uniformly choose $poly(n,d)$ points a_i from $\mathcal{F}^n$ and query f at a_i and receive $f(a_i)$. If for all the points a_i, f is zero, then with high probability $f \equiv 0$.

This theorem implies the following one.

THEOREM 6.2. *The class $MUL_{\mathcal{F}}(n,k,t,d)$, where $d < c|\mathcal{F}|$ for some constant c, is learnable in randomized polynomial time (in n, d, and t) from membership queries if*

$$k = O\left(\frac{|\mathcal{F}|}{d}(\log n + \log d + \log t)\right).$$

Proof of Theorem 6.1 *(upper bound).* Let $\phi(n,k,d)$ be the maximal possible number of roots of a multivariate polynomial in $MUL_{\mathcal{F}}(n,k,\star,d)$. We will show the following facts:

1. $\phi(n,k,d) \le |\mathcal{F}|^{n-k}\phi(k,k,d)$,
2. $\phi(k,k,d) \le |\mathcal{F}|^k - (|\mathcal{F}|-d)^k$, and
3. $\phi(1,1,d) = d$.

This implies that if $f \not\equiv 0$, when we randomly uniformly choose an assignment $a \in \mathcal{F}^n$, we have

$$\begin{aligned}
\Pr_a[f(a)\neq 0] &\ge 1 - \frac{\phi(n,k,d)}{|\mathcal{F}|^n} \\
&\ge 1 - \frac{\phi(k,k,d)}{|\mathcal{F}|^k} \\
&\ge 1 - \frac{|\mathcal{F}|^k - (|\mathcal{F}|-d)^k}{|\mathcal{F}|^k} \\
&\ge \left(1 - \frac{d}{|\mathcal{F}|}\right)^k \\
&\ge e^{-O\left(\frac{dk}{|\mathcal{F}|}\right)}.
\end{aligned}$$

For $d \leq c|\mathcal{F}|$ we have that this probability is bounded by $\frac{1}{poly(n,d,t)}$. Therefore the expected running time to detect that f is not 0 is $poly(n,d,t)$.

It remains to prove conditions (1) and (2). To prove (1) let $f \in MUL_{\mathcal{F}}(n,k,\star,d)$ with a maximal number of roots. Let m be a term in f with a maximal number of variables. Suppose, without loss of generality, that $m = x_1^{i_1} \cdots x_k^{i_k}$. For any substitution $a_{k+1}, \ldots, a_n$ of the variables $x_{k+1}, \ldots, x_n$, the term m will stay alive in the projection $g = f|_{x_i \leftarrow a_i, i=k+1,\ldots,n}$ because it is maximal in f. Since g has at most $\phi(k,k,d)$ roots, the result (1) follows.

The proof of (2) is similar to the proof of Schwartz [Sch80] and Zippel [Zip79]. Let $f \in MUL_{\mathcal{F}}(k,k,\star,d)$. Write f as polynomial in $\mathcal{F}[x_2,\ldots,x_d][x_1]$,

$$f = f_d x_1^d + f_{d-1} x_1^{d-1} + \cdots + f_0.$$

Let t be the number of roots of f_d. Since $f_d \in MUL_{\mathcal{F}}(k-1,k-1,\star,d)$, we have

$$t \leq \phi(k-1,k-1,d).$$

For $|\mathcal{F}|^{k-1} - t$ assignments a for $x_2,\ldots,x_d$, we have $f_d(a) \neq 0$. For those assignments we get a polynomial in x_1 of degree d that has at most d roots for x_1. For t assignments a for $x_2,\ldots,x_k$, we have that f_d is zero and then the possible values of x_1 (to get a root for f) are bounded by $|\mathcal{F}|$. This implies that

$$\begin{aligned}\phi(k,k,d) &\leq d(|\mathcal{F}|^{k-1} - t) + t|\mathcal{F}| \\ &= d|\mathcal{F}|^{k-1} + (|\mathcal{F}| - d)t \\ &\leq d|\mathcal{F}|^{k-1} + (|\mathcal{F}| - d)\phi(k-1,k-1,d).\end{aligned}$$

The theorem follows by induction on k. □

Proof of Theorem 6.1 *(lower bound).* Let $\mathcal{A}$ be a randomized algorithm that zero tests $f \in MUL_{\mathcal{F}}(n,k,\star,d)$. Algorithm $\mathcal{A}$ asks membership queries to f and if $f \not\equiv 0$, it returns with probability at least 2/3 the answer "no." If all the membership queries in the algorithm return 0, the algorithm returns the answer "yes" indicating that $f \equiv 0$.

We run the algorithm for $f \equiv 0$. Let $D_1,\ldots,D_l$, $l = (dnt)^\lambda$, be the distributions that the membership assignments $a_1,\ldots,a_l$ are chosen to zero test f. Notice that if all membership queries answers are 0 while running the algorithm for $f \equiv 0$, it would again choose membership queries according to the distributions $D_1,\ldots,D_l$. Now randomly and uniformly choose $\gamma_{i,j} \in \mathcal{F}$, $i = 1,\ldots,p$, $j = 1,\ldots,d$, and define

$$f^\star = \prod_{i=1}^{p} \prod_{j=1}^{d} (x_i - \gamma_{i,j}),$$

where $p = 2\lambda \frac{|\mathcal{F}|}{d}(\ln n + \ln d + \ln t)$. Note that the degree of $f^\star$ is d and the size of each term is at most p. Let $I[f^*(a_i)] = 1$ if $f^\star(a_i) \neq 0$ and 0 otherwise. For every input a we have

$$E_{f^\star}\left[I[f^\star(a)]\right] = \left(1 - \frac{1}{|\mathcal{F}|}\right)^{pd}.$$

Therefore,

$$E_{f^\star} E_{(\forall i) a_i \in D_i \{0,1\}^n} \left[\bigvee_i I[f^\star(a_i)]\right] \leq E_{f^\star} E_{(\forall i) a_i \in D_i \{0,1\}^n} \left[\sum_i I[f^\star(a_i)]\right]$$

$$\leq E_{(\forall i)a_i \in D_i}\{0,1\}^n \left[\sum_i E_{f^\star} I[f^\star(a_{i_0})]\right]$$
$$= l\left[\left(1 - \frac{1}{|\mathcal{F}|}\right)^{pd}\right]$$
$$\leq \frac{2}{3}.$$

This shows that there exists $f^\star \not\equiv 0$ such that running algorithm $\mathcal{A}$ for $f^\star$ will give the wrong answer, i.e., "yes," with probability more than 2/3. This is a contradiction. □

A DETERMINISTIC POLYNOMIAL-TIME ALGORITHM FOR HEILBRONN'S PROBLEM IN THREE DIMENSIONS*

HANNO LEFMANN† AND NIELS SCHMITT‡

Abstract. Heilbronn conjectured that among arbitrary n points in the two-dimensional unit square $[0,1]^2$, there must be three points which form a triangle of area $O(1/n^2)$. This conjecture was disproved by a nonconstructive argument of Komlós, Pintz, and Szemerédi [*J. London Math. Soc.*, 25 (1982), pp. 13–24], who showed that for every n there exists a configuration of n points in the unit square $[0,1]^2$ where all triangles have area $\Omega(\log n/n^2)$. Here we will consider a three-dimensional analogue of this problem and show how to find deterministically in polynomial time n points in the unit cube $[0,1]^3$ such that the volume of every tetrahedron among these n points is $\Omega(\log n/n^3)$.

1. Introduction.

An old conjecture of Heilbronn states that for every distribution of n points in the two-dimensional unit square $[0,1]^2$ (or unit disc) there exist three distinct points which form a triangle of area $O(1/n^2)$. Erdős observed that this conjecture, if true, would be best possible, as for n a prime the points $(i, i^2 \bmod n)_{i=0,\ldots,n-1}$ on the moment-curve in the $n \times n$ grid would show after rescaling; see [2]. However, Komlós, Pintz, and Szemerédi [15] disproved Heilbronn's conjecture by proving that for every n there exists a configuration of n points in the unit square $[0,1]^2$ with every three points forming a triangle of area $\Omega(\log n/n^2)$. Using techniques from derandomization, this existence argument was made constructive in [6], where a polynomial time algorithm was given, which finds n points in $[0,1]^2$ achieving this lower bound $\Omega(\log n/n^2)$ on the minimum triangle area. Upper bounds on Heilbronn's triangle problem were given by Roth [17], [18], [19], [20], [21] and Schmidt [23] in a series of papers (see Rothschild and Straus [22] for related results), and the current best upper bound $O(1/n^{8/7-\varepsilon})$ for arbitrarily small $\varepsilon > 0$ is due to Komlós, Pintz, and Szemerédi [14].

Using arguments from Kolmogorov complexity, Jiang, Li, and Vitány [12] recently proved that if n points are dropped uniformly at random and independently of each other in the unit square $[0,1]^2$, then the expected value of the smallest area of a triangle among these n points is $\Theta(1/n^3)$.

Also, Barequet [3] recently considered a k-dimensional version of Heilbronn's problem. For a subset $S = \{p_0, \ldots, p_k\} \subset \mathbb{R}^k$ of $(k+1)$ points, the set $S^* = \{p_0 + \sum_{i=1}^k \lambda_i \cdot (p_i - p_0) \mid \sum_{i=1}^k \lambda_i \leq 1; \lambda_1, \ldots, \lambda_k \in [0,1]\}$ is called a *simplex*. If $k = 3$, then S^* is called a *tetrahedron*. The *volume* of the simplex $S^* \subset \mathbb{R}^k$ is defined

by $\mathrm{vol}(S^*) := 1/k \cdot h \cdot \mathrm{vol}(S')$, where h is the distance of p_k to the affine space generated by $p_0, \ldots, p_{k-1}$ and S' is in this space the simplex generated by $p_0, \ldots, p_{k-1}$.

For given dimension $k \geq 3$, Barequet showed that for every n there exist n points in the k-dimensional unit cube $[0,1]^k$ such that the minimum volume of every simplex spanned by any $(k+1)$ of these n points is $\Omega(1/n^k)$. Barequet gave three different approaches for proving his lower bound. The first one, for dimension $k = 3$, uses a Greedy-type argument (also see [23] for the case $k = 2$), and Barequet obtained a configuration of n points in the three-dimensional unit cube $[0,1]^3$ such that the minimum volume of every tetrahedron is $\Omega(1/n^4)$. Indeed, this Greedy-type argument yields an on-line algorithm for the problem. The second approach yields a better lower bound, was worked out for arbitrary but fixed dimension $k \geq 3$, and uses a random argument: $2n$ points are dropped uniformly at random and independently of each other in the k-dimensional unit cube $[0,1]^k$. For some suitable constant $c_k > 0$, the expected number of $(k+1)$-point simplices with volume at most $\beta := c_k/n^k$ is at most n. Deleting one point from every such small simplex with volume at most β yields the existence of n points in $[0,1]^k$ with every $(k+1)$-point simplex having minimum volume $\Omega(1/n^k)$. The third approach, however, is similar to Erdős' construction (and according to Bollobás [5] was known to him), namely, taking the points $P_l = ((l^j \bmod n)/n)_{j=1,\ldots,k}$ for $l = 0, 1, \ldots, n-1$ on the moment-curve. The volume of any $(k+1)$-point simplex is given by a Vandermonde determinant, which cannot vanish for n a prime, rescaled by a factor $\Theta(1/n^k)$ and this gives a minimum value for the volume of any $(k+1)$ points of these n points on the moment-curve of $\Omega(1/n^k)$.

The corresponding problem for dimension $k = 1$ is trivial as there are always n points in the unit interval $[0,1]$ with minimum distance between two distinct points $\Omega(1/n)$, and this bound cannot be improved.

In [16] Barequet's lower bound was improved by a factor $\Theta(\log n)$ for dimensions $k \geq 3$ using a probabilistic existence argument based on a variant of Theorem 2.2. For the proof the continuous structure of the unit cube $[0,1]^k$ was crucial.

THEOREM 1.1 (see [16]). *For every fixed integer $k \geq 2$ and for every n, there exists a configuration of n points in the k-dimensional unit cube $[0,1]^k$ such that the volume of any simplex spanned by any $(k+1)$ points is $\Omega(\log n/n^k)$.*

Here we will give for dimension $k = 3$ a deterministic polynomial-time algorithm for the result in Theorem 1.1.

THEOREM 1.2. *For every positive integer n, one can find deterministically in polynomial time a configuration of n points in the unit cube $[0,1]^3$ such that the volume of any tetrahedron spanned by any four of these points is $\Omega(\log n/n^3)$.*

The proof of Theorem 1.2 is based on techniques from combinatorics and number theory. Some of our arguments are given for the case of arbitrary dimension $k \geq 3$, where appropriate. However, so far we are able only to provide a deterministic polynomial-time algorithm for the case $k = 3$.

2. Hypergraphs. In our arguments we will use hypergraphs. It will turn out that the notions *independence number of a hypergraph* and *2-cycles* are important in our considerations.

DEFINITION 2.1. *Let $\mathcal{G} = (V, \mathcal{E})$ be a hypergraph; i.e., each edge $E \in \mathcal{E}$ is a nonempty subset of V of arbitrary cardinality. The hypergraph $\mathcal{G}$ is* k-uniform *if every edge $E \in \mathcal{E}$ contains exactly k vertices.*

A subset $I \subseteq V$ is called independent *if I contains no edge $E \in \mathcal{E}$. The largest size of an independent set in $\mathcal{G}$ is called the* independence number $\alpha(\mathcal{G})$.

In a k-uniform hypergraph $\mathcal{G} = (V, \mathcal{E})$, $k \geq 3$, a 2-cycle *is a pair $\{E_1, E_2\}$ of distinct edges $E_1, E_2 \in \mathcal{E}$ with $|E_1 \cap E_2| \geq 2$. A 2-cycle $\{E_1, E_2\}$ in $\mathcal{G}$ is called* $(2, j)$-cycle *if $|E_1 \cap E_2| = j$, where $j = 2, \ldots, k-1$.*

Let $B_k(\rho) = \{x \in \mathbb{R}^k \mid \|x\| \leq \rho\} \subset \mathbb{R}^k$ be the k-dimensional ball around the origin with radius ρ. We will reformulate our combinatorial, geometrical problem as a problem of finding a large independent set in a suitably defined hypergraph. To do so, we will discretize the three-dimensional search space $[0,1]^3$; namely, we will consider only points from the set $B_3(\rho) \cap \mathbb{Z}^3$, where ρ will be of suitable size, i.e., polynomial in n. With this discretization, we also have to take care of tetrahedra of volume 0—these are degenerate tetrahedra.

For some parameter $\beta > 0$ and for the given set of grid-points in $B_3(\rho) \cap \mathbb{Z}^3$, we form a hypergraph $\mathcal{G}(\beta) = (V, \mathcal{E}_3 \cup \mathcal{E}_4)$ with the vertex set V being this set $B_3(\rho) \cap \mathbb{Z}^3$ of $\Theta(\rho^3)$ grid-points. The edges contain three or four vertices. The 4-element edges $E \in \mathcal{E}_4$ are determined by all subsets of four points from the set $B_3(\rho) \cap \mathbb{Z}^3$, no three on a line, which form a tetrahedron of volume at most β, where later we will set $\beta := \rho^3 \cdot \log n / n^3$. For technical reasons we will also use 3-element edges $E' \in \mathcal{E}_3$, determined by triples of points from $B_3(\rho) \cap \mathbb{Z}^3$ which lie on a line. Then an independent set in this hypergraph $\mathcal{G}(\beta)$ corresponds to a subset of points in the set $B_3(\rho) \cap \mathbb{Z}^3$, where no tetrahedron has "small" volume, i.e., all tetrahedra have a volume bigger than β, which after rescaling yields the desired result. In order to show the existence of a large independent set, we will use the following result due to Ajtai, Komlós, Pintz, Spencer, and Szemerédi [1] (see [10]), stated here in an algorithmic variant proven in [4] (see [11]).

THEOREM 2.2 (see [1], [4], [10], [11], [7]). *Let $k \geq 3$ be a fixed integer. Let $\mathcal{G} = (V, \mathcal{E})$ be a k-uniform hypergraph with average degree $t^{k-1} = k \cdot |\mathcal{E}|/|V|$. If for some constant $\gamma > 0$ the hypergraph $\mathcal{G}$ contains at most*

$$|V| \cdot t^{2k-j-1-\gamma}$$

$(2, j)$-cycles for $j = 2, \ldots, k-1$, then one can find in $\mathcal{G}$ in polynomial time an independent set of size

$$\Omega\left(\frac{|V|}{t} \cdot (\log t)^{1/(k-1)}\right). \tag{1}$$

If, in addition to the k-element edges, the hypergraph $\mathcal{G} = (V, \mathcal{E})$ contains also at most $|V| \cdot t^{i-1-\delta}$ many i-element edges for some $\delta > 0$ and $i = 2, \ldots, k-1$, then (1) *holds, too.*

If the parameter t^{k-1} is an upper bound on the average degree of the hypergraph $\mathcal{G}$ with respect to the k-element edges, then (1) *holds, too.*

In recent years, several applications of Theorem 2.2 have been found; see [4]. Here we will give another application of this deep result.

A main part of the proof of Theorem 1.2 consists of counting the degenerate (respectively, nondegenerate) tetrahedra in $B_3(\rho) \cap \mathbb{Z}^3$. The road map for its proof is as follows. We want to apply Theorem 2.2 for $k = 4$ to the hypergraph $\mathcal{G}(\beta)$. To do so, in sections 4 and 5 we will bound from above the number of 3- and 4-element edges in $\mathcal{G}(\beta)$, which are the number of collinear triples of points and the number of tetrahedra of volume at most β in $B_3(\rho) \cap \mathbb{Z}^3$, respectively. Then, in section 6 we will estimate the numbers of $(2, j)$-cycles, $j = 2, 3$, among the 4-element edges in $\mathcal{G}(\beta)$, that is, the number of pairs of tetrahedra in $B_3(\rho) \cap \mathbb{Z}^3$ with volume at most β, which

have j vertices in common. With these estimates we will see that the assumptions of Theorem 2.2 are fulfilled, and the desired result will follow.

In section 3, we will first recall and explain some tools, which we will use in our arguments.

3. Grids in $\mathbb{Z}^k$. We will use some results from linear algebra and number theory, which will be stated in the following.

3.1. Grids.

DEFINITION 3.1. *A* grid L *of* $\mathbb{Z}^k$ *is a subset of* $\mathbb{Z}^k$*, which is generated by all linear combinations of some linearly independent vectors* $q_1, \dots, q_m \in \mathbb{Z}^k$*, where all coefficients are integers; i.e.,* $L = \mathbb{Z}q_1^\top + \cdots + \mathbb{Z}q_m^\top$.

The parameter $m = \operatorname{rank}(L)$ *is called the* rank *of the grid* L*, and the set* $Q = \{q_1, \dots, q_m\}$ *is called the* basis *of* L.

DEFINITION 3.2. *Let* $Q = \{q_1, \dots, q_m\} \subset \mathbb{Z}^k$ *be a set of linearly independent vectors.*

(i) *The* $k \times m$ generator matrix *of* Q *(up to the ordering of the vectors) is defined by*

$$G(Q) := (q_1, \dots, q_m)_{k \times m}.$$

(ii) *The* fundamental parallelepiped F_Q *of* Q *is the following set:*

$$F_Q := \left\{ \sum_{i=1}^{m} \alpha_i \cdot q_i \mid 0 \le \alpha_i \le 1,\ i = 1, \dots, m \right\} \subseteq \mathbb{R}^k .$$

The vertices *of the fundamental parallelepiped* F_Q *are all the points* $\sum_{i=1}^{m} \alpha_i \cdot q_i$ *with* $\alpha_1, \dots, \alpha_m \in \{0, 1\}$.

(iii) *The* volume *of the fundamental parallelepiped* $F_Q \subseteq \mathbb{R}^k$ *of* Q *is given by*

$$\operatorname{vol}(F_Q) := \left(\det(G(Q)^\top \cdot G(Q))\right)^{1/2},$$

where $G(q)^\top$ *is the transpose of the generator matrix* $G(Q)$.

The following result can be found in [8].

LEMMA 3.3 (see [8]). *Let* Q *and* Q' *be two bases of a grid* L *in* $\mathbb{Z}^k$*. Then the volumes of the corresponding fundamental parallelepipeds are equal; i.e.,* $\operatorname{vol}(F_Q) = \operatorname{vol}(F_{Q'})$*. The parameter* $d(L) := \operatorname{vol}(F_Q)$ *is called the* determinant *of the grid* L.

For integers $a_1, \dots, a_n \in \mathbb{Z}$, which are not all equal to 0, let $\gcd(a_1, \dots, a_n)$ denote the *greatest common divisor* of $a_1, \dots, a_n$. From elementary number theory we recall the well-known lemma of Bézout.

LEMMA 3.4. *Let* $a_1, \dots, a_k \in \mathbb{Z}$ *be integers, which are not all equal to* 0*. Then there exist integers* $y_1, \dots, y_k \in \mathbb{Z}$ *such that*

$$a_1 \cdot y_1 + \cdots + a_k \cdot y_k = \gcd(a_1, \dots, a_k) .$$

LEMMA 3.5 (see [9]). *Let* $a = (a_1, \dots, a_k) \in (\mathbb{Z} \setminus \{0\})^k$ *be a sequence of nonzero integers with* $\gcd(a_1, \dots, a_k) = 1$*. Then the set* L *of all solutions in* $\mathbb{Z}^k$ *of the equation*

$$a_1 \cdot X_1 + \cdots + a_k \cdot X_k = 0$$

is a grid in $\mathbb{Z}^k$ *with* $\operatorname{rank}(L) = k - 1$.

An algorithm for determining a basis of a grid $L \subseteq \mathbb{Z}^k$ can be found in [9].

We use the standard scalar product $\langle a, b\rangle := \sum_{i=1}^{k} a_i \cdot b_i$ for vectors $a = (a_1, \ldots, a_k)^\top \in \mathbb{R}^k$ and $b = (b_1, \ldots, b_k)^\top \in \mathbb{R}^k$. The Euclidean distance $\operatorname{dist}(a, b)$ of the corresponding points is defined by $\operatorname{dist}(a, b) := (\sum_{i=1}^{k}(a_i - b_i)^2)^{1/2}$. The length of a vector $a \in \mathbb{R}^k$ is defined by $\|a\| := \sqrt{\langle a, a\rangle}$. For a point $p \in \mathbb{R}^k$ and a real affine subspace $V \subseteq R^k$, let $\operatorname{dist}(p, V) := \min\{\operatorname{dist}(p, v) \mid v \in V\}$. For vectors $q_1, \ldots, q_m \in \mathbb{R}^k$ let $\operatorname{span}(q_1, \ldots, q_m)$ be the linear space over the reals, generated by $q_1, \ldots, q_m$. Where appropriate in this paper, we will not distinguish between points $p \in \mathbb{Z}^k$ and the corresponding vectors $p^\top \in \mathbb{Z}^k$.

The following results can be found in [13].

LEMMA 3.6 (see [13]). *Let V be a $(k-1)$-dimensional linear subspace of $\mathbb{R}^k$, and let $a \in \mathbb{R}^k \setminus \{0^k\}$ be any nonzero vector which is orthogonal to V. The distance $\operatorname{dist}(p, V)$ of every point $p \in \mathbb{R}^k$ to the subspace V is given by*

$$\operatorname{dist}(p, V) = \frac{|\langle p^\top, a\rangle|}{\|a\|} .$$

LEMMA 3.7 (see [13]). *Let $q_1, \ldots, q_m \in \mathbb{R}^k$ be linearly independent vectors. Then, with $U := \operatorname{span}(q_1, \ldots, q_{m-1})$, the volume of the fundamental parallelepiped $F_{\{q_1,\ldots,q_m\}}$ satisfies*

$$\operatorname{vol}(F_{\{q_1,\ldots,q_m\}}) = \operatorname{dist}(q_m, U) \cdot \operatorname{vol}(F_{\{q_1,\ldots,q_{m-1}\}}) .$$

LEMMA 3.8 (see [8]). *Let U and L be grids in $\mathbb{Z}^k$ with $U \subseteq L$ and $\operatorname{rank}(L) = \operatorname{rank}(U) = m$. Then the following holds:*

(i) *There exists a positive integer $\lambda \in \mathbb{N}\setminus\{0\}$ such that $\lambda \cdot L = \{\lambda \cdot x \mid x \in L\} \subseteq U$.*

(ii) *For every basis $b_1, \ldots, b_m$ of L there is a basis $a_1, \ldots, a_m$ of U of the following form:*

$$\begin{aligned} a_1 &= v_{1,1} \cdot b_1, \\ a_2 &= v_{2,1} \cdot b_1 + v_{2,2} \cdot b_2, \\ &\vdots \\ a_m &= v_{m,1} \cdot b_1 + \cdots + v_{m,m} \cdot b_m, \end{aligned} \tag{2}$$

with $v_{i,j} \in \mathbb{Z}$ and $v_{i,i} \neq 0$ for $1 \leq j \leq i \leq m$.

(iii) *For each basis $a_1, \ldots, a_m$ of U, there is a basis $b_1, \ldots, b_m$ of L such that (2) is fulfilled.*

Lemma 3.8 can be made constructive in polynomial time, for example, by using for (ii) a variant of the LLL-algorithm (Lenstra, Lenstra, Lovàsz); see [9].

In our arguments we will use only part (iii) of Lemma 3.8. However, for the proof of part (iii), parts (i) and (ii) are used. A proof of Lemma 3.8 can be found in [8, Theorem I, p. 11–13].

Crucial to our arguments is the following result.

LEMMA 3.9. *Let $k \in \mathbb{N}$ be fixed. Let L be a grid in $\mathbb{Z}^k$ with $\operatorname{rank}(L) = m$, and let $a_1, \ldots, a_m \in L$ be linearly independent. Then there exists a basis $b_1, \ldots, b_m$ of L with $\|b_i\| = O(\max_{j=1,\ldots,m} \|a_j\|)$ for $i = 1, \ldots, m$.*

Proof. The arguments are similar to those in [8, Lemma 8, p. 135–136]. For completeness we include the proof.

By Lemma 3.8(iii) we can find a basis $c_1, \dots, c_m \in \mathbb{Z}^k$ of L such that

$$\begin{aligned} a_1 &= v_{1,1} \cdot c_1, \\ a_2 &= v_{2,1} \cdot c_1 + v_{2,2} \cdot c_2, \\ &\vdots \\ a_m &= v_{m,1} \cdot c_1 + \cdots + v_{m,m} \cdot c_m, \end{aligned} \tag{3}$$

with $v_{i,j} \in \mathbb{Z}$ and $v_{i,i} \neq 0$ for $1 \leq j \leq i \leq m$. With this we will construct the desired basis $b_1, \dots, b_m \in \mathbb{Z}^k$ of L with $\|b_i\| = O(\max_{l=1,\dots,m} \|a_l\|)$ for $i = 1, \dots, m$.

For $i = 1, \dots, m$ we proceed as follows. If $v_{i,i} \in \{+1, -1\}$, then we set $b_i := v_{i,i} \cdot a_i$; hence $\|b_i\| = \|a_i\|$. Otherwise, for $|v_{i,i}| \geq 2$, we solve the system of equations (3) successively for $c_1, \dots, c_m$, and we obtain

$$c_i = \frac{1}{v_{i,i}} \cdot a_i + l_{i,i-1} \cdot a_{i-1} + \cdots + l_{i,1} \cdot a_1$$

for $i = 1, \dots, m$ with rational numbers $l_{i,i-1}, \dots, l_{i,1} \in \mathbb{Q}$. For each $j < i$ we choose integers $t_{i,j} \in \mathbb{Z}$ such that

$$|t_{i,j} + l_{i,j}| \leq \frac{1}{2} .$$

Then, we set $k_{i,j} := t_{i,j} + l_{i,j}$ for $j < i$ and $k_{i,i} := 1/v_{i,i}$ and fix b_i by

$$\begin{aligned} b_i &:= k_{i,i} \cdot a_i + k_{i,i-1} \cdot a_{i-1} + \cdots + k_{i,1} \cdot a_1 \\ &= c_i + t_{i,i-1} \cdot a_{i-1} + \cdots + t_{i,1} \cdot a_1; \end{aligned}$$

hence $b_i \in L$, and $b_1, \dots, b_m$ is a basis of L. By construction we have $|k_{i,j}| \leq 1/2$ for $j \leq i$; hence

$$\|b_i\| \leq \|k_{i,i} \cdot a_i\| + \|k_{i,i-1} \cdot a_{i-1}\| + \cdots + \|k_{i,1} \cdot a_1\| \leq \frac{i}{2} \cdot \max_{j=1,\dots,i} \|a_j\| . \qquad \square$$

3.2. Maximal grids in $\mathbb{Z}^k$. In our arguments we will use the notion of *maximal* grids.

DEFINITION 3.10. *A grid L in $\mathbb{Z}^k$ is called* m-maximal *if* $\operatorname{rank}(L) = m$ *and there exists no other grid L' in $\mathbb{Z}^k$ with $rank(L') = m$, which contains L as a proper subset.*

A vector $a = (a_1, \dots, a_k)^\top \in \mathbb{Z}^k \setminus \{0^k\}$ is called *primitive*, if $\gcd(a_1, \dots, a_k) = 1$ and $a_j > 0$ for $j = \min\{i \mid a_i \neq 0\}$.

For a subset $A = \{x_1, \dots, x_m\} \subseteq \mathbb{R}^k$ of vectors, let $A^\perp = \{a \in \mathbb{R}^k \mid \langle a, x_1 \rangle = \cdots = \langle a, x_m \rangle = 0\}$ be the *orthogonal of A*.

Mainly we will deal here with $(k-1)$-maximal grids in $\mathbb{Z}^k$.

LEMMA 3.11. *Let $a = (a_1, \dots, a_k)^\top \in \mathbb{Z}^k \setminus \{0^k\}$ be an integer-valued vector, where not all entries are equal to 0. Then the set $L_a = (\mathbb{R} \cdot a)^\perp \cap \mathbb{Z}^k$ of all solutions of the equation $a_1 \cdot X_1 + \cdots + a_k \cdot X_k = 0$ over $\mathbb{Z}^k$ is a $(k-1)$-maximal grid in $\mathbb{Z}^k$.*

Proof. By linearity and symmetry we can assume that $\gcd(a_1, \dots, a_k) = 1$, that $a_i \neq 0$ for $i = 1, \dots, r$, and that $a_i = 0$ for $i > r$. By Lemma 3.5 the set of all solutions of the equation $a_1 \cdot X_1 + \cdots + a_r \cdot X_r = 0$ over $\mathbb{Z}^r$ is a grid L^* in $\mathbb{Z}^r$ with $\operatorname{rank}(L^*) = r-1$. Then the set of all solutions of the equation $a_1 \cdot X_1 + \cdots + a_k \cdot X_k = 0$ over $\mathbb{Z}^k$ is the grid $L = L^* \times \mathbb{Z}^{k-r}$ in $\mathbb{Z}^k$ with $\operatorname{rank}(L) = k-1$.

To see the maximality of the grid L, let L' be a grid in $\mathbb{Z}^k$ with $\operatorname{rank}(L') = k-1$, and $L \subseteq L'$. The set $V \subseteq \mathbb{R}^k$ of all solutions of the equation $a_1 \cdot X_1 + \cdots + a_k \cdot X_k = 0$ over $\mathbb{R}^k$ is a $(k-1)$-dimensional linear subspace of $\mathbb{R}^k$. Then we have $L' \subseteq \operatorname{span}(L') = \operatorname{span}(L) = V$; hence each vector in L' is a solution of the equation $a_1 \cdot X_1 + \cdots + a_k \cdot X_k = 0$, and thus $L' \subseteq L$. Therefore, L is a $(k-1)$-maximal grid in $\mathbb{Z}^k$. □

LEMMA 3.12. *For every grid L in $\mathbb{Z}^k$ with $\operatorname{rank}(L) = k-1 \geq 1$ there is exactly one primitive vector $a_L = (a_1, \ldots, a_k)^\top \in \mathbb{Z}^k \setminus \{0^k\}$ with $a_L \perp L$; i.e., $\langle a_L, x^\top \rangle = 0$ for each $x \in L$.*

Proof. Let $Q \subseteq \mathbb{Z}^k$ be a basis of L, and let $G(Q)$ be its generator matrix. The system of linear equations

$$G(Q)^\top \cdot (X_1, \ldots, X_k)^\top = 0 \tag{4}$$

has a nontrivial solution $(a_1, \ldots, a_k) \in \mathbb{Z}^k \setminus \{0^k\}$, and every solution X satisfies $X \perp L$. Dividing each entry of $(a_1, \ldots, a_k)$ by $\gcd(a_1, \ldots, a_k)$ and possibly multiplying the resulting vector by -1, we obtain a primitive vector $a_L = (a'_1, \ldots, a'_k)^\top \in \mathbb{Z}^k \setminus \{0^k\}$, which is a solution of (4). Since the rank of the matrix $G(Q)$ is equal to $k-1$, the solutions of the system (4) in $\mathbb{R}^k$ form a one-dimensional subspace, and therefore the vector a_L is unique. □

COROLLARY 3.13.

(i) *For every grid L' in $\mathbb{Z}^k$ with $\operatorname{rank}(L') = k-1$ there is exactly one $(k-1)$-maximal grid L in $\mathbb{Z}^k$ with $L' \subseteq L$.*

(ii) *There is a bijective mapping between the set of all $(k-1)$-maximal grids L in $\mathbb{Z}^k$ and the set of all primitive vectors a_L in $\mathbb{Z}^k$; i.e., $a_L \in \mathbb{Z}^k$ is the unique primitive normal vector of the grid L.*

DEFINITION 3.14. *Let L be a $(k-1)$-maximal grid in $\mathbb{Z}^k$. A* residue class *of L is a set L' of the form $L' = x + L$ with $x \in \mathbb{Z}^k$.*

LEMMA 3.15. *Let L be a $(k-1)$-maximal grid in $\mathbb{Z}^k$ with primitive normal vector $a_L \in \mathbb{Z}^k$. Then there exists a point $v \in \mathbb{Z}^k \setminus L$ such that $\mathbb{Z}^k$ can be partitioned into the* residue classes *$s \cdot v + L$, $s \in \mathbb{Z}$, i.e.,*

$$\mathbb{Z}^k = \biguplus_{s \in \mathbb{Z}} (s \cdot v + L) \,,$$

where $\uplus$ symbolizes the union of pairwise disjoint sets.

Moreover, for each point $x \in L$ it is

$$\operatorname{dist}(s \cdot v + x, \operatorname{span}(L)) = \frac{|s|}{\|a_L\|} \,.$$

Proof. For every point $x \in L$ we have $\langle x^\top, a_L \rangle = 0$ and for each point $v \in \mathbb{Z}^k \setminus L$ it is $\langle v^\top, a_L \rangle \in \mathbb{Z} \setminus \{0\}$. As a_L is primitive, the greatest common divisor of its entries is equal to 1, and by Lemma 3.4 there exists a point $v \in \mathbb{Z}^k \setminus L$ such that $\langle v^\top, a_L \rangle = 1$.

Using $a_L \perp L$ and Lemma 3.6 we infer the following for each integer $s \in \mathbb{Z}$ and each point $x \in L$:

$$\begin{aligned} \operatorname{dist}(s \cdot v + x, \operatorname{span}(L)) &= \frac{|\langle s \cdot v^\top + x^\top, a_L \rangle|}{\|a_L\|} \\ = \frac{|\langle s \cdot v^\top, a_L \rangle + \langle x^\top, a_L \rangle|}{\|a_L\|} &= \frac{|s|}{\|a_L\|} \,; \end{aligned}$$

hence distinct residue classes of L have a distance which is a multiple of $1/\|a_L\|$.

Now let $p \in \mathbb{Z}^k$ be an arbitrary point. We will show that p is contained in some residue class of L. With $s := \langle p^\top, a_L\rangle \in \mathbb{Z}$ we have

$$\langle p^\top - s \cdot v^\top, a_L\rangle = \langle p^\top, a_L\rangle - s \cdot \langle v^\top, a_L\rangle = s - s = 0\,;$$

thus $p - s \cdot v \in L$; hence $p \in s \cdot v + L$.

To see that $(s \cdot v + L) \cap (t \cdot v + L) = \emptyset$ for $s \neq t$, we assume to the contrary that $s \cdot v + x = t \cdot v + y$ for some $x, y \in L$. Then we have $(s-t) \cdot v = y - x$, and since $v \notin L$ but $y - x \in L$, we conclude that $s = t$, which is a contradiction. □

LEMMA 3.16. *Let L be a $(k-1)$-maximal grid in $\mathbb{Z}^k$ with primitive normal vector $a_L = (a_1, \ldots, a_k)^\top \in \mathbb{Z}^k$ and with basis Q. Then the determinant $d(L)$ of L, i.e., the volume of the fundamental parallelepiped determined by Q, satisfies*

$$d(L) = \mathrm{vol}(F_Q) = \|a_L\|.$$

Proof. Let $Q = \{q_1, \ldots, q_{k-1}\}$ be a basis of L. As stated in Lemma 3.15 there exists a vector $q_k \in \mathbb{Z}^k$ such that $\mathbb{Z}^k = \uplus_{s\in\mathbb{Z}}(s \cdot q_k + L)$; i.e., $\{q_1, \ldots, q_k\}$ is a basis of $\mathbb{Z}^k$. Since $\mathrm{dist}(q_k, \mathrm{span}(L)) = 1/\|a_L\|$, we infer by Lemma 3.7, where $U := \mathrm{span}(q_1, \ldots, q_{k-1})$, that

$$1 = d(\mathbb{Z}^k) = \mathrm{vol}(F_{\{q_1,\ldots,q_k\}}) = \frac{1}{\|a_L\|} \cdot d(L). \qquad \square$$

3.3. Simplices and maximal grids in $\mathbb{Z}^k$.

DEFINITION 3.17. *For a subset $S = \{p_0, \ldots, p_k\} \subset \mathbb{R}^k$ of $(k+1)$ points, the set*

$$S^* = \left\{ p_0 + \sum_{i=1}^{k} \lambda_i \cdot (p_i - p_0) \mid \sum_{i=1}^{k} \lambda_i \leq 1; \lambda_1, \ldots, \lambda_k \in [0,1] \right\}$$

is called a simplex. *For short, we identify S and S^* and call each of them* simplex *and specify by calling the points $p \in \{p_0, \ldots, p_k\}$, which satisfy $(\{p_0, \ldots, p_k\}\backslash\{p\})^* \neq S^*$,* vertices *of the simplex.*

(i) *The* rank *of the simplex S is defined by*

$$\mathrm{rank}(S) = \dim(\mathrm{span}(\{p_1 - p_0, \ldots, p_k - p_0\}))\,.$$

(ii) *The simplex S is* nondegenerate, *if* $\mathrm{rank}(S) = k$. *If* $\mathrm{rank}(S) < k$, *we call S a* degenerate simplex. *A simplex $S = \{p_0, \ldots, p_k\} \subset \mathbb{R}^k$ is called a* triangle *for $k = 2$, and for $k = 3$ it is called a* tetrahedron.

(iii) *The* volume *of a simplex $S = \{p_0, \ldots, p_k\} \subset \mathbb{R}^k$ is defined by*

$$\mathrm{vol}(S) = \frac{1}{k} \cdot h \cdot \mathrm{vol}(S')\,,$$

where h is the distance of p_k to the affine space generated by $p_0, \ldots, p_{k-1}$, and $S' = \{p_0, \ldots, p_{k-1}\}$.

Recall that $B_k(\rho) = \{x \in \mathbb{R}^k \mid \|x\| \leq \rho\} \subset \mathbb{R}^k$ is the k-dimensional ball around the origin with radius $\rho \in \mathbb{R}_0^+$. The following result will be used frequently in our arguments.

LEMMA 3.18. *Let $S \subseteq B_k(\rho) \cap \mathbb{Z}^k$ be a set of points with* $\mathrm{rank}(S) \leq k - 1$. *Then there exists a $(k-1)$-maximal grid L of $\mathbb{Z}^k$ such that S is contained in some*

residue class $v + L$ of L for some $v \in \mathbb{Z}^k$, and L has a basis $q_1, \dots, q_{k-1} \subset \mathbb{Z}^k$ with $\max_{i=1,\dots,k-1} \|q_i\| = O(\rho)$.

Proof. Let $S = \{p_0, \dots, p_m\} \subseteq B_k(\rho) \cap \mathbb{Z}^k$ with $r = \operatorname{rank}(S)$. The vectors $p_1 - p_0, \dots, p_m - p_0$ span a grid L' in $\mathbb{Z}^k$ with $\operatorname{rank}(L') = r$, and have length $\|p_i - p_0\| \le 2 \cdot \rho$ for $i = 1, \dots, m$. We take $(k - 1 - r)$ unit vectors from $\mathbb{Z}^k \setminus L'$, add them to L', and we obtain a grid L'' of $\mathbb{Z}^k$ with $\operatorname{rank}(L'') = k - 1$ and $L' \subseteq L''$. By Corollary 3.13 there is exactly one $(k-1)$-maximal grid L of $\mathbb{Z}^k$ with $L' \subseteq L'' \subseteq L$. By Lemma 3.9 we can find a basis $q_1, \dots, q_{k-1}$ of L with $\|q_i\| = O(\rho)$ for $i = 1, \dots, k-1$. Then we have $S \subseteq p_0 + L$. ∎

THEOREM 3.19. *Let $k \in \mathbb{N}$ be fixed. Let L be a $(k-1)$-maximal grid of $\mathbb{Z}^k$ with primitive normal vector $a_L \in \mathbb{Z}^k$, and let $Q = \{q_1, \dots, q_{k-1}\}$ be a basis of L with* $\max_i \|q_i\| = O(\rho)$. *Then the following holds:*

(i) *The primitive normal vector a_L satisfies $\|a_L\| = O(\rho^{k-1})$.*

(ii) *There are $O(\rho \cdot \|a_L\|)$ different residue classes L' of L with $L' \cap B_k(\rho) \neq \emptyset$.*

(iii) *For every residue class L' of L it is $|L' \cap B_k(\rho)| = O\big(\rho^{k-1}/\|a_L\|\big)$.*

Proof. (i) By Lemma 3.16 we have $\|a_L\| = d(L) = \operatorname{vol}(F_Q)$, and by using the assumption $\max_i \|q_i\| = O(\rho)$ we know that $F_Q \subseteq B_k(c \cdot \rho)$ for some constant $c > 0$. Since $\dim(F_Q) = k - 1$, the volume $\operatorname{vol}(F_Q)$ of the parallelepiped F_Q is $O(\rho^{k-1})$.

(ii) By Lemma 3.15 the distances of different residue classes of L are multiples of $1/\|a_L\|$. The Euclidean distance between any two points in the ball $B_k(\rho)$ is at most $2 \cdot \rho$; hence $O(\rho \cdot \|a_L\|)$ distinct residue classes of L have a nonempty intersection with $B_k(\rho)$.

(iii) The volume of a $(k-1)$-dimensional space S intersected with $B_k(\rho)$ is $O(\rho^{k-1})$. Since $F_Q \subseteq B_k(c \cdot \rho)$ and $\operatorname{vol}(F_Q) = \|a_L\|$, we can cover the set $S \cap B_k(\rho)$ by $O\big(\rho^{k-1}/\|a_L\|\big)$ distinct translates of the parallelepiped F_Q. As L is maximal, the interior of F_Q (only the vertices are excluded) contains no points from L, which finishes the proof. ∎

3.4. Representations by sums of squares. We will use some results from elementary number theory. For integers $k, d \in \mathbb{N}$ let $r_k(d)$ be the number of vectors $(x_1, \dots, x_k)^\top \in \mathbb{Z}^k$ with $x_1^2 + \dots + x_k^2 = d$.

LEMMA 3.20. *For fixed integers $k \in \mathbb{N}$ and all integers $n \in \mathbb{N}$ it is*

$$\sum_{d=1}^{n} r_k(d) = \Theta(n^{k/2}) \,. \tag{5}$$

Proof. The sum $\sum_{d=1}^{n} r_k(d)$ counts the number of grid-points in $\mathbb{Z}^k$ in the k-dimensional ball $B_k(\sqrt{n})$. If we put around each of these grid-points k-dimensional unit cubes $[0,1]^k$, with centers being the grid-points, then all the points of these unit cubes are contained in a k-dimensional ball around the origin with radius $\sqrt{n} + \sqrt{k}/2$, since the diagonal of every k-dimensional unit cube $[0,1]^k$ has length $\sqrt{k}$. Moreover, the unit cubes cover the k-dimensional ball around the origin with radius $\sqrt{n} - \sqrt{k}/2$. Since the number of unit cubes is equal to $\sum_{d=1}^{n} r_k(d)$, we infer

$$\frac{\pi^{k/2}}{\Gamma(k/2+1)} \cdot \left(\sqrt{n} - \frac{\sqrt{k}}{2}\right)^k \le \sum_{d=1}^{n} r_k(d) \le \frac{\pi^{k/2}}{\Gamma(k/2+1)} \cdot \left(\sqrt{n} + \frac{\sqrt{k}}{2}\right)^k \;;$$

thus $\sum_{d=1}^{n} r_k(d) = \Theta(n^{k/2})$. (Recall that $R^k \cdot \pi^{k/2}/\Gamma(k/2+1)$ is the volume of the k-dimensional ball around the origin with radius $R \in \mathbb{R}^+$.) ∎

COROLLARY 3.21. *For fixed integers $k, r \in \mathbb{N}$ and for all integers $n \in \mathbb{N}$, it is*

$$\sum_{d=1}^{n} \frac{r_k(d)}{d^r} = \begin{cases} O\left(n^{k/2-r}\right) & \text{if } k/2-r>0, \\ O\left(\log n\right) & \text{if } k/2-r=0, \\ O(1) & \text{if } k/2-r<0. \end{cases}$$

Proof. We assume without loss of generality that n is a power of 2, i.e., $n = 2^l$. Set $n_i = 2^i$ for $i = 0, \ldots, l$. With (5) we infer for some constant $c_k > 0$ that

$$\sum_{d=1}^{n} \frac{r_k(d)}{d^r} \le \sum_{i=0}^{l} \sum_{d=n_i}^{n_{i+1}} \frac{r_k(d)}{d^r} \le \sum_{i=0}^{l} \sum_{d=n_i}^{n_{i+1}} \frac{r_k(d)}{n_i^r} = \sum_{i=0}^{l} 2^{-i\cdot r} \cdot \sum_{d=n_i}^{n_{i+1}} r_k(d)$$
$$\le \sum_{i=0}^{l} 2^{-i\cdot r} \cdot \sum_{d=1}^{n_{i+1}} r_k(d) \le \sum_{i=0}^{l} 2^{-i\cdot r} \cdot c_k \cdot (n_{i+1})^{k/2} = c_k \cdot 2^{k/2} \cdot \sum_{i=0}^{l} 2^{i\cdot(k/2-r)} .$$

The sum $\sum_{i=0}^{l} 2^{i\cdot(k/2-r)}$ is bounded from above as follows: (i) for $k/2-r>0$ by $O\left(2^{l\cdot(k/2-r)}\right) = O\left(n^{k/2-r}\right)$, (ii) for $k/2-r=0$ by $O(l) = O(\log n)$, and (iii) for $k/2-r<0$ by $O(1)$. ∎

For a $(k-1)$-maximal grid L in $\mathbb{Z}^k$ with primitive normal vector $a_L \in \mathbb{Z}^k$ and a positive integer d, we denote by $r_k(d; a_L)$ the number of grid-points P in L such that the square of the Euclidean distance between P and the origin O is equal to d, i.e., $(\mathrm{dist}(O,P))^2 = d$.

In our arguments we will use the following variants of Lemma 3.20 and Corollary 3.21.

LEMMA 3.22. *Let $k \in \mathbb{N}$ be a fixed integer. Let L be a $(k-1)$-maximal grid in $\mathbb{Z}^k$ with primitive normal vector $a_L \in \mathbb{Z}^k$. For all integers $n \in \mathbb{N}$, it is*

$$\sum_{d=1}^{n} r_k(d; a_L) = O\left(\frac{n^{(k-1)/2}}{\|a_L\|}\right) . \tag{6}$$

Proof. The sum $\sum_{d=1}^{n} r_k(d; a_L)$ is equal to the number of grid-points in L in the k-dimensional ball $B_k(\sqrt{n})$. By Theorem 3.19(iii) this sum $\sum_{d=1}^{n} r_k(d; a_L)$ is $O((\sqrt{n})^{k-1}/\|a_L\|)$, from which inequality (6) follows. ∎

With (6) the following is straightforward with the same arguments used in the proof of Corollary 3.21.

COROLLARY 3.23. *Let $k, r \in \mathbb{N}$ be fixed integers and let L be a $(k-1)$-maximal grid in $\mathbb{Z}^k$ with primitive normal vector $a_L \in \mathbb{Z}^k$. For all positive integers $n \in \mathbb{N}$, it is*

$$\sum_{d=1}^{n} \frac{r_k(d; a_L)}{d^r} = \begin{cases} O\left(\frac{1}{\|a_L\|} \cdot n^{(k-1)/2-r}\right) & \text{if } (k-1)/2-r>0, \\ O\left(\frac{1}{\|a_L\|} \cdot \log n\right) & \text{if } (k-1)/2-r=0, \\ O\left(\frac{1}{\|a_L\|}\right) & \text{if } (k-1)/2-r<0. \end{cases}$$

4. Degenerate simplices in $B_k(\rho) \cap \mathbb{Z}^k$.

THEOREM 4.1. *Let $k \in \mathbb{N}$ be a fixed integer. The number $D_k(\rho)$ of degenerate simplices in $B_k(\rho) \cap \mathbb{Z}^k$ satisfies $D_k(\rho) = O\left(\rho^{k^2} \cdot \log \rho\right)$.*

The set of all these degenerate simplices in $B_k(\rho) \cap \mathbb{Z}^k$ can be constructed in time polynomial in ρ.

Proof. For fixed $k \in \mathbb{N}$, by inspecting every $(k+1)$-element subset $S \subset B_k(\rho) \cap \mathbb{Z}^k$ of points, we can determine all degenerate simplices in $B_k(\rho) \cap \mathbb{Z}^k$ in time $O(\rho^{k(k+1)})$,

since there are $O\big(\binom{\rho^k}{k+1}\big)$ $(k+1)$-element subsets at all. To check whether or not $\mathrm{vol}(S) = 0$, one simply computes in time $O(1)$ the determinant of the matrix with columns $p_1 - p_0, \ldots, p_k - p_0$.

By Lemma 3.18 each degenerate $(k+1)$-element subset of points in $B_k(\rho) \cap \mathbb{Z}^k$ is contained in a residue class L' of some $(k-1)$-maximal grid L in $\mathbb{Z}^k$, where L has a basis $q_1, \ldots, q_{k-1} \in \mathbb{Z}^k$ with $\|q_i\| = O(\rho)$ for $i = 1, \ldots, k-1$. By Theorem 3.19(i) it suffices to consider all primitive normal vectors $a_L \in \mathbb{Z}^k$ of length $\|a_L\| = O(\rho^{k-1})$ and the corresponding residue classes L' of L with $L' \cap B_3(\beta) \neq \emptyset$.

Having fixed a $(k-1)$-maximal grid L in $\mathbb{Z}^k$, determined by its primitive normal vector $a_L \in \mathbb{Z}^k$, by Theorem 3.19(ii) there are $O(\rho \cdot \|a_L\|)$ residue classes L' of the grid L, which intersect the ball $B_k(\rho)$ in a nonempty set.

By Theorem 3.19(iii) each set $L' \cap B_k(\rho)$ contains $O(\rho^{k-1}/\|a_L\|)$ points. From each set $L' \cap B_k(\rho)$ we can select $(k+1)$ points in $O\big(\binom{\rho^{k-1}/\|a_L\|}{k+1}\big)$ ways to obtain a degenerate simplex. This implies the following upper bound on the number $D_k(\rho)$ of degenerate simplices in $B_k(\rho) \cap \mathbb{Z}^k$:

$$D_k(\rho) = O\left(\sum_{a \in \mathbb{Z}^k,\, \|a\| = O(\rho^{k-1})} \rho \cdot \|a\| \cdot \binom{\rho^{k-1}/\|a\|}{k+1}\right)$$

$$= O\left(\rho^{k^2} \cdot \sum_{a \in \mathbb{Z}^k,\, \|a\| = O(\rho^{k-1})} \frac{1}{\|a\|^k}\right) = O\left(\rho^{k^2} \cdot \sum_{d=1}^{O(\rho^{2k-2})} \frac{r_k(d)}{d^{k/2}}\right) = O(\rho^{k^2} \cdot \log \rho)\,,$$

since by Corollary 3.21 we have $\sum_{d=1}^{n} r_k(d)/d^{k/2} = O(\log n)$. ∎

5. Nondegenerate tetrahedra in $B_3(\rho) \cap \mathbb{Z}^3$. From now on we consider only the case of dimension $k = 3$. We will determine for positive reals β the number $N_3(\rho; \beta)$ of nondegenerate tetrahedra $S = \{p_0, \ldots, p_3\}$ in $B_3(\rho) \cap \mathbb{Z}^3$ with volume $\mathrm{vol}(S) \leq \beta$. Recall that the *volume* of a (possibly degenerate) tetrahedron S is defined by

$$\mathrm{vol}(S) = \frac{1}{3} \cdot h \cdot G\,,$$

where h is the distance between p_3 and the affine space defined by p_0, p_1, p_2, and G is the area of the triangle p_0, p_1, p_2.

We will show in this section the following result.

THEOREM 5.1. *The number $N_3(\rho; \beta)$ of nondegenerate tetrahedra $S \subseteq B_3(\rho) \cap \mathbb{Z}^3$ with $\mathrm{vol}(S) \leq \beta$ satisfies $N_3(\rho; \beta) = O(\beta \cdot \rho^9)$.*

The set of all these nondegenerate tetrahedra in $B_3(\rho) \cap \mathbb{Z}^3$ can be constructed in time polynomial in ρ.

Proof. By inspecting every 4-element subset $S = \{p_0, \ldots, p_3\} \subset B_3(\rho) \cap \mathbb{Z}^3$, we can determine all tetrahedra in $B_3(\rho) \cap \mathbb{Z}^3$ with volume at most β in time $O(\rho^{12})$, since checking whether or not $\mathrm{vol}(S) \leq \beta$ can be done in time $O(1)$.

First we consider the number of nondegenerate triangles S in $B_3(\rho) \cap L$ for a 2-maximal grid L in $\mathbb{Z}^3$, where we distinguish whether $\mathrm{area}(S) \geq v$ or $\mathrm{area}(S) \leq v$ for some real number $v > 0$.

LEMMA 5.2. *Let L be a 2-maximal grid in $\mathbb{Z}^3$ with primitive normal vector $a_L \in \mathbb{Z}^3$. Let $v, \beta > 0$ be real numbers. For every residue class L' of L the number of nondegenerate tetrahedra $S = \{p_0, p_1, p_2, p_3\}$ in $B_3(\rho) \cap \mathbb{Z}^3$ with $S \setminus \{p_3\} \subseteq L'$ and*

$\operatorname{area}(S \setminus \{p_3\}) \geq v$ *and* $\operatorname{vol}(S) \leq \beta$ *is at most*

$$O\left(\frac{\beta \cdot \rho^8}{v \cdot \|a_L\|^3}\right).$$

Proof. Let L' be a residue class of a 2-maximal grid L in $\mathbb{Z}^3$ with primitive normal vector $a_L \in \mathbb{Z}^3$. By Lemma 3.18 we can assume that L has a basis $q_1, q_2 \in \mathbb{Z}^3$, with $\|q_1\|, \|q_2\| = O(\rho)$. By Theorem 3.19(iii) the set $L' \cap B_3(\rho)$ contains $O(\rho^2/\|a_L\|)$ points; hence we can choose $O(\binom{\rho^2/\|a_L\|}{3})$ different sets of three points from this set. In particular, for every real $v > 0$, we can choose from the set $L' \cap B_3(\rho)$ three vertices of a nondegenerate triangle S' with $\operatorname{area}(S') \geq v$ in $O(\binom{\rho^2/\|a_L\|}{3})$ ways. Since the desired tetrahedra should have volume at most β, the corresponding fourth point has distance $O(\beta/v)$ from the real affine space generated by L'. By Lemma 3.15 the distance between distinct residue classes of L is a multiple of $1/\|a_L\|$, and since for every residue class L'' of L the set $L'' \cap B_3(\rho)$ contains $O(\rho^2/\|a_L\|)$ points, the fourth point can be chosen in

$$O\left(\frac{\beta}{v} \cdot \|a_L\| \cdot \frac{\rho^2}{\|a_L\|}\right) = O\left(\frac{\beta \cdot \rho^2}{v}\right)$$

ways. Altogether we obtain for the number of desired simplices

$$O\left(\binom{\rho^2/\|a_L\|}{3} \cdot \frac{\beta \cdot \rho^2}{v}\right) = O\left(\frac{\beta \cdot \rho^8}{v \cdot \|a_L\|^3}\right). \qquad \square$$

Next we will consider the nondegenerate triangles in $B_3(\rho) \cap \mathbb{Z}^3$ with area at most v. For this case we will use the following lemma.

LEMMA 5.3. *Let L be a 2-maximal grid in $\mathbb{Z}^3$ with primitive normal vector $a_L \in \mathbb{Z}^3$. For every residue class L' of L, and every two fixed distinct points P and Q on L', the number of nondegenerate triangles S in $L' \cap B_3(\rho)$ with vertices P and Q and* $\operatorname{area}(S) \leq v$ *is*

$$O\left(\frac{v \cdot \rho}{\operatorname{dist}(P, Q) \cdot \|a_L\|}\right).$$

Proof. By an affine mapping $f\colon L \longrightarrow \mathbb{Z}^2$ we transform the 2-maximal grid L in $\mathbb{Z}^3$ with primitive normal vector $a_L \in \mathbb{Z}^3$ (or any residue class L' of L) into the standard two-dimensional rectangular grid $\mathbb{Z}^2$ with basis $(1,0)^\top$ and $(0,1)^\top$. Points in $L \cap B_3(\beta)$ become points within an ellipsoid C. For a basis $a = (a_1, a_2, a_3)^\top \in \mathbb{Z}^3$, $b = (b_1, b_2, b_3)^\top \in \mathbb{Z}^3$ of the grid L, let $f(a) := (1,0)^\top$ and $f(b) := (0,1)^\top$. We can assume that $L' = L$, and that $P = (0,0,0)$ and $Q = \lambda \cdot a + \mu \cdot b$ (for some $\lambda, \mu \in \mathbb{Z}$) are the two given points. Via the mapping $f\colon L' \longrightarrow \mathbb{Z}^2$ we obtain the points $f(P) = P' = (0,0)$ and $f(Q) = Q' = (\lambda, \mu)$.

Points $P, Q, R \in L' \cap B_3(\rho)$ become the grid points $P', Q', R' \in C \cap \mathbb{Z}^2$ in the ellipsoid C. If $\operatorname{area}(P, Q, R) = v$, then $\operatorname{area}(P', Q', R') = v/\|a_L\|$, as can be easily seen.

Let $g = \gcd(\lambda, \mu)$, and set $\lambda' := \lambda/g$ and $\mu' := \mu/g$. The line ℓ (residue class) through the points P' and Q' in $\mathbb{Z}^2$ has the primitive normal vector $a_N := (\mu', -\lambda')^\top$.

To estimate the number of points $R \in L' \cap B_3(\rho)$ such that $\operatorname{area}(P, Q, R) \leq v$, we compute the number of points $R' \in C \cap \mathbb{Z}^2$ such that $\operatorname{area}(P', Q', R') \leq v/\|a_L\|$. The distance of R' to the line ℓ is at most $2 \cdot v/(\|a_L\| \cdot \operatorname{dist}(P', Q'))$. By Lemma 3.15

distinct residue classes ℓ' of ℓ have a distance which is a multiple of $1/\|a_N\|$; thus there are

$$O\left(\frac{v \cdot \|a_N\|}{\|a_L\| \cdot \operatorname{dist}(P', Q')}\right)$$

lines ℓ' with $R' \in \ell'$ to consider. Since the distance between any two points in $B_3(\rho)$ is at most $2 \cdot \rho$, the line ℓ intersects the ellipsoid C in two points with distance D, where

$$D = O\left(\frac{\rho \cdot \operatorname{dist}(P', Q')}{\operatorname{dist}(P, Q)}\right).$$

Every line ℓ' parallel to ℓ intersects the ellipsoid C in two points whose distance D' is at most D. To see this, consider the line ℓ'' obtained by reflecting the line ℓ' at ℓ. By symmetry, the line ℓ'' intersects the ellipsoid C in two points which also have distance D'. From the convexity of the ellipsoid it follows that $D' \le D$. By Lemma 3.16 the distance between points in $\ell' \cap \mathbb{Z}^2$ is a multiple of $\|a_N\|$, and we infer that $|\ell' \cap E \cap \mathbb{Z}^2| = O(D'/\|a_N\|) = O(D/\|a_N\|)$.

Thus, we have the following upper bound on the number of triangles in $L' \cap B_3(\rho)$ with area at most v and with fixed vertices P and Q:

$$O\left(\frac{v \cdot \|a_N\|}{\|a_L\| \cdot \operatorname{dist}(P', Q')} \cdot \frac{D}{\|a_N\|}\right) = O\left(\frac{v \cdot \rho}{\operatorname{dist}(P, Q) \cdot \|a_L\|}\right). \qquad \square$$

COROLLARY 5.4. *Let L be a 2-maximal grid in $\mathbb{Z}^3$ with primitive normal vector $a_L \in \mathbb{Z}^3$. For every residue class L' of L, the number of nondegenerate triangles S in $L' \cap B_3(\rho)$ with* $\operatorname{area}(S) \le v$ *is*

$$O\left(\frac{v \cdot \rho^4}{\|a_L\|^3}\right).$$

Proof. Since $|L' \cap B_3(\rho)| \le |L \cap B_3(\rho)|$ and L' is a residue class of L, we can assume that $L' = L$. By Lemma 3.18 we can assume that the grid L has a basis $q_1, q_2 \in \mathbb{Z}^3$ with $\|q_1\|, \|q_2\| = O(\rho)$. Fix a point $P \in L' \cap B_3(\rho)$; by Theorem 3.19(iii) there are $O(\rho^2/\|a_L\|)$ possibilities for this. For every integer $d \in \mathbb{N}$ there are at most $r_3(d; a_L)$ points Q in $L' \cap B_3(\rho)$ such that $(\operatorname{dist}(P, Q))^2 = d$. With $d = O(\rho^2)$, Lemma 5.3, and Corollary 3.23, the number of nondegenerate triangles S in the set $L' \cap B_3(\rho)$ with $\operatorname{area}(S) \le v$ is

$$\begin{aligned} O\left(\frac{\rho^2}{\|a_L\|} \cdot \sum_{d=1}^{O(\rho^2)} \frac{v \cdot \rho \cdot r_3(d; a_L)}{d^{1/2} \cdot \|a_L\|}\right) &= O\left(\frac{v \cdot \rho^3}{\|a_L\|^2} \cdot \sum_{d=1}^{O(\rho^2)} \frac{r_3(d; a_L)}{d^{1/2}}\right) \\ &= O\left(\frac{v \cdot \rho^4}{\|a_L\|^3}\right). \qquad \square \end{aligned}$$

LEMMA 5.5. *Let L be a 2-maximal grid L in $\mathbb{Z}^3$ with primitive normal vector $a_L \in \mathbb{Z}^3$. Then for every nondegenerate triangle S in L it is* $\operatorname{area}(S) \ge \|a_L\|/2$.

Proof. Let Q be a basis of L. The minimum area of a nondegenerate triangle in L is half of the volume of the fundamental parallelepiped F_Q, where $\operatorname{vol}(F_Q) = \|a_L\|$ by Lemma 3.16. $\square$

LEMMA 5.6. *Let L be a 2-maximal grid L in $\mathbb{Z}^3$ with primitive normal vector $a_L \in \mathbb{Z}^3$. Let L' be any residue class of L. Let $v > 0$ be a real number. The number of nondegenerate tetrahedra $S = \{p_0, \dots, p_3\}$ in $B_3(\rho) \cap \mathbb{Z}^3$ with $S \setminus \{p_3\} \subseteq L'$ and* $\operatorname{area}(S \setminus \{p_3\}) \le v$ *and* $\operatorname{vol}(S) \le \beta$ *is*

$$O\left(\frac{\beta \cdot v \cdot \rho^6}{\|a_L\|^4}\right).$$

Proof. By Lemma 3.18 we can assume that the grid L has a basis $q_1, q_2 \in \mathbb{Z}^3$, with $\|q_1\|, \|q_2\| = O(\rho)$. Let $S' = \{p_0, p_1, p_2\}$ be a nondegenerate triangle in $L' \cap B_3(\rho)$ with $\operatorname{area}(S') \le v$. By Corollary 5.4 there are $O(v \cdot \rho^4/\|a_L\|^3)$ of them. By Lemma 5.5 we have $\operatorname{area}(S') \ge \|a_L\|/2$. To select the point $p_3 \in B_3(\rho) \cap \mathbb{Z}^3$, the requirement $\operatorname{vol}(S' \cup \{p_3\}) \le \beta$ has to be satisfied; thus the distance between the point p_3 and the affine space defined by S' is $O(\beta/\|a_L\|)$. By Lemma 3.15 the distance between distinct residue classes of L is a multiple of $1/\|a_L\|$. By Theorem 3.19(iii) for every residue class L' of L the set $L' \cap B_3(\rho)$ contains $O(\rho^2/\|a_L\|)$ points. Hence, for a fixed triangle S', the point p_3 can be chosen in

$$O\left(\frac{\beta}{\|a_L\|} \cdot \|a_L\| \cdot \frac{\rho^2}{\|a_L\|}\right) = O\left(\frac{\beta \cdot \rho^2}{\|a_L\|}\right) \tag{7}$$

ways. Thus, the number of tetrahedra $S = \{p_0, \dots, p_3\}$ in $B_3(\rho) \cap \mathbb{Z}^3$ with $\operatorname{vol}(S) \le \beta$ and $S \setminus \{p_3\} \subseteq L'$ and $\operatorname{area}(S \setminus \{p_3\}) \le v$ is

$$O\left(\frac{v \cdot \rho^4}{\|a_L\|^3} \cdot \frac{\beta \cdot \rho^2}{\|a_L\|}\right) = O\left(\frac{\beta \cdot v \cdot \rho^6}{\|a_L\|^4}\right). \qquad \square$$

LEMMA 5.7. *Let L be a 2-maximal grid in $\mathbb{Z}^3$ with primitive normal vector $a_L \in \mathbb{Z}^3$. For every residue class L' of L the number of nondegenerate tetrahedra $S = \{p_0, p_1, p_2, p_3\} \subseteq B_3(\rho) \cap \mathbb{Z}^3$ with $S \setminus \{p_3\} \subseteq L'$ and* $\operatorname{vol}(S) \le \beta$ *is $O(\beta \cdot \rho^7/\|a_L\|^{7/2})$.*

Proof. From Lemmas 5.2 and 5.6 we infer that, for every residue class L' of a 2-maximal grid L in $\mathbb{Z}^3$ with primitive normal vector $a_L \in \mathbb{Z}^3$ and for every real $v > 0$, the number of tetrahedra $S = \{p_0, \dots, p_3\}$ in $B_3(\rho) \cap \mathbb{Z}^3$ with $S \setminus \{p_3\} \subseteq L'$ and $\operatorname{vol}(S) \le \beta$ is

$$O\left(\frac{\beta \cdot \rho^8}{v \cdot \|a_L\|^3} + \frac{\beta \cdot v \cdot \rho^6}{\|a_L\|^4}\right). \tag{8}$$

We have

$$\frac{\beta \cdot v \cdot \rho^6}{\|a_L\|^4} = \frac{\beta \cdot \rho^8}{v \cdot \|a_L\|^3} \qquad \text{if} \qquad v = \rho \cdot \|a_L\|^{1/2}.$$

For a given vector $a_L \in \mathbb{Z}^3$ we set $v(a_L) := \rho \cdot \|a_L\|^{1/2}$. Then, (8) becomes

$$O\left(\frac{\beta \cdot \rho^8}{v \cdot \|a_L\|^3} + \frac{\beta \cdot v \cdot \rho^6}{\|a_L\|^4}\right) = O\left(\frac{\beta \cdot \rho^7}{\|a_L\|^{7/2}}\right). \qquad \square$$

Now we can finish the proof of Theorem 5.1. By Lemma 3.18 we can assume that the grid L has a basis $q_1, q_2 \in \mathbb{Z}^3$ with $\|q_1\|, \|q_2\| = O(\rho)$; hence $\|a_L\| = O(\rho^2)$ by Theorem 3.19(i). By Theorem 3.19(ii), for a fixed primitive normal vector $a_L \in \mathbb{Z}^3$,

there are $O(\rho \cdot \|a_L\|)$ distinct residue classes L' of the grid L, which intersect $B_3(\rho)$ in a nonempty set. Summing over all possible grids L, we have with Lemma 5.7 that

$$N_3(\rho;\beta) = O\left(\sum_{\substack{a\in\mathbb{Z}^3 \\ \|a\|=O(\rho^2)}} \rho \cdot \|a\| \cdot \frac{\beta\cdot\rho^7}{\|a\|^{7/2}} \right) = O\left(\beta\cdot\rho^8 \cdot \sum_{\substack{a\in\mathbb{Z}^3 \\ \|a\|=O(\rho^2)}} \frac{1}{\|a\|^{5/2}} \right)$$
$$= O\left(\beta\cdot\rho^8 \cdot \sum_{d=1}^{O(\rho^4)} \frac{r_3(d)}{d^{5/4}} \right) = O(\beta\cdot\rho^9),$$

where the last equation follows with Corollary 3.21, i.e., $\sum_{d=1}^{n} r_3(d)/d^{5/4} = O(n^{1/4})$. This finishes the proof of Theorem 5.1. □

6. Properties of the hypergraph $\mathcal{G}(\beta)$. For some real number $\beta > 0$, which will be fixed below, we form a hypergraph $\mathcal{G}(\beta) = (V, \mathcal{E}_3 \cup \mathcal{E}_4)$ with the vertex set V being the set $B_3(\rho) \cap \mathbb{Z}^3$ of $\Theta(\rho^3)$ grid-points and $\mathcal{E}_i$ being the set of all i-element edges, $i = 3, 4$. The hypergraph $\mathcal{G}$ contains 3- and 4-element edges. The 4-element edges $E \in \mathcal{E}_4$ are determined by all 4-element subsets of V, no three of them on a line, which form a tetrahedron of volume at most β including degenerate tetrahedra. The 3-element edges $E' \in \mathcal{E}_3$ are formed by all collinear triples from $V = B_3(\rho)\cap\mathbb{Z}^3$. Then an independent set in this hypergraph $\mathcal{G}(\beta)$ corresponds to a set of points in $B_3(\rho)\cap\mathbb{Z}^3$, where all tetrahedra have volume bigger than β. In order to apply Theorem 2.2 we will show that the assumptions there are satisfied; i.e., we will give upper bounds on the numbers of 3- and 4-element edges and the numbers of 2-cycles among the 4-element edges. Set

$$\beta := \frac{\log n}{n^3} \cdot \rho^3,$$

where $\rho = n^{1+\varepsilon}$ for some fixed $\epsilon > 0$; thus $\beta = n^{3\varepsilon} \cdot \log n$.

First we estimate the average degree t^3 of the hypergraph $\mathcal{G} = (V, \mathcal{E}_4)$ among the 4-element edges. By Theorems 4.1 and 5.1 we can bound the number of 4-element edges in $\mathcal{G}$ by

$$|\mathcal{E}_4| = O(\rho^9 \cdot \log\rho + \beta\cdot\rho^9) = O(\beta\cdot\rho^9);$$

hence, with $|V| = \Theta(\rho^3)$, the average degree of $\mathcal{G}$ is

$$\frac{4\cdot|\mathcal{E}_4|}{|V|} = O\left(\frac{\beta\cdot\rho^9}{\rho^3}\right) = O\left(\beta\cdot\rho^6\right).$$

In our application of Theorem 2.2 we will calculate with an upper bound on t; thus from now on for some constant $c > 0$ we use

$$t^3 = c\cdot\beta\cdot\rho^6. \tag{9}$$

Next we will bound the number $|\mathcal{E}_3|$ of 3-element edges in $\mathcal{G}(\beta)$, that is, the number of collinear triples in $B_3(\rho)\cap\mathbb{Z}^3$.

We choose two points P and Q from $B_3(\rho)\cap\mathbb{Z}^3$ in $O(\rho^6)$ ways. There are $O(\rho)$ points in $B_3(\rho)\cap\mathbb{Z}^3$ on the line through P and Q; hence

$$|\mathcal{E}_3| = O(\rho^7)\ . \tag{10}$$

To satisfy the assumptions of Theorem 2.2, we need to have for some $\delta > 0$ that

$$|\mathcal{E}_3| = O(\rho^3 \cdot t^{2-\delta}) \,. \tag{11}$$

Then (11) is satisfied for $0 < \delta < 2\varepsilon/(2+3\varepsilon)$, as can be seen with (9) and (10) for the constant $c' = c^{2/3-\delta/3}$ from the following:

$$\rho^3 \cdot t^{2-\delta} = c' \cdot \beta^{2/3-\delta/3} \cdot \rho^{7-2\delta} = c' \cdot \rho^7 \cdot \left(\beta^{2/3-\delta/3} \cdot \rho^{-2\delta}\right)$$
$$= c' \cdot \rho^7 \cdot (\log n)^{2/3-\delta/3} \cdot n^{2\varepsilon-3\varepsilon\delta-2\delta} = \Omega(\rho^7) \,.$$

Next we will give upper bounds on the number of 2-cycles in our hypergraph $\mathcal{G} = (V, \mathcal{E}_4)$. We will distinguish two types of 2-cycles, namely, $(2,2)$-cycles and $(2,3)$-cycles. In the following we will always assume by Lemma 3.18 that the 2-maximal grids L in $\mathbb{Z}^3$ under consideration have a basis $q_1, q_2 \in \mathbb{Z}^3$, with $\|q_1\|, \|q_2\| = O(\rho)$; hence by Theorem 3.19(i) we have $\|a_L\| = O(\rho^2)$.

6.1. (2, 2)-cycles. Let us consider first the number $s_{2,2}(\mathcal{G})$ of $(2,2)$-cycles in our hypergraph $\mathcal{G} = (V, \mathcal{E}_4)$, that is, the number of pairs of tetrahedra in $B_3(\rho) \cap \mathbb{Z}^3$, which have exactly two vertices in common, and both tetrahedra have volume at most β.

We distinguish three cases: (a) both tetrahedra are degenerate, (b) one tetrahedron is degenerate and the other is nondegenerate, and (c) both tetrahedra are nondegenerate. The corresponding numbers of $(2,2)$-cycles are denoted by $s_{2,2}(\mathcal{G}; dd)$, $s_{2,2}(\mathcal{G}; dn)$, $s_{2,2}(\mathcal{G}; nn)$, respectively.

Case (a). Both tetrahedra are degenerate. By Theorem 4.1 there are $O\left(\rho^9 \cdot \log \rho\right)$ degenerate tetrahedra in the set $B_3(\rho) \cap \mathbb{Z}^3$. Fix one of these tetrahedra. The second degenerate tetrahedron is contained in a residue class M' of a 2-maximal grid M in $\mathbb{Z}^3$ and has two vertices in common with the first one, say, $P = (p_1, p_2, p_3) \in M'$ and $Q = (q_1, q_2, q_3) \in M'$. Fix a primitive normal vector $b_M := (b_1, b_2, b_3) \in \mathbb{Z}^3$ with $\|b_M\| = O(\rho^2)$, which belongs to a 2-maximal grid M in $\mathbb{Z}^3$, where $P, Q \in M'$ for some residue class M' of the grid M. If $P, Q \in M'$, then with $y_i := p_i - q_i$ for $i = 1, 2, 3$ it must hold that

$$b_1 \cdot y_1 + b_2 \cdot y_2 + b_3 \cdot y_3 = 0 \,,$$

where $(y_1, y_2, y_3) \neq (0, 0, 0)$. By Theorem 3.19(iii) the set $M' \cap B_3(\rho)$ contains $O(\rho^2/\|b_M\|)$ points; by Lemma 3.18 we can assume that M has a basis $q_1, q_2 \in \mathbb{Z}^3$ with $\|q_1\|, \|q_2\| = O(\rho)$. Having already fixed the vertices P and Q of the second degenerate tetrahedron, two further vertices from M' can be chosen in $O(\binom{\rho^2/\|b_M\|}{2})$ ways. Summing over all possible residue classes M' of 2-maximal grids M in $\mathbb{Z}^3$ with $P, Q \in M'$, we obtain, using Corollary 3.21, the following upper bound on the number of possibilities for the second tetrahedron, where, neglecting constant factors, we assume in the calculations that $y_3 \neq 0$:

$$\left(\sum_{\substack{b=(b_1,b_2,b_3)\in\mathbb{Z}^3;\|b\|=O(\rho^2) \\ b_1y_1+b_2y_2+b_3y_3=0}} \binom{\rho^2/\|b\|}{2} \right)$$
$$= O\left(\rho^4 \cdot \sum_{\substack{(b_1,b_2)\in\mathbb{Z}^2 \\ |b_1|,|b_2|=O(\rho^2)}} \frac{1}{b_1^2 + b_2^2 + (b_1 \cdot y_1/y_3 + b_2 \cdot y_2/y_3)^2} \right)$$

$$= O\left(\rho^4 \cdot \sum_{\substack{(b_1,b_2)\in\mathbb{Z}^2 \\ |b_1|,|b_2|=O(\rho^2)}} \frac{1}{b_1^2+b_2^2}\right) = O\left(\rho^4 \cdot \sum_{d=1}^{O(\rho^4)} \frac{r_2(d)}{d}\right) = O(\rho^4 \cdot \log\rho). \tag{12}$$

Hence the number $s_{2,2}(\mathcal{G}; dd)$ of pairs of degenerate tetrahedra in $B_3(\rho) \cap \mathbb{Z}^3$, which have two vertices in common, satisfies

$$s_{2,2}(\mathcal{G}; dd) = O\left(\rho^9 \cdot \log\rho \cdot \rho^4 \cdot \log\rho\right) = O\left(\rho^{13} \cdot (\log\rho)^2\right). \tag{13}$$

Case (b). One tetrahedron is degenerate and the other is nondegenerate and has volume at most β. By Theorem 5.1 the number of nondegenerate tetrahedra with volume at most β in $B_3(\rho) \cap \mathbb{Z}^3$ is $O(\beta \cdot \rho^9)$. Fix such a tetrahedron and fix two of its vertices, say, $P = (p_1, p_2, p_3)$ and $Q = (q_1, q_2, q_3)$, where $y_i := p_i - q_i$ for $i = 1, 2, 3$. As in case (a), for a primitive normal vector $b_M = (b_1, b_2, b_3) \in \mathbb{Z}^3$ with $\|b_M\| = O(\rho^2)$, using Theorem 3.19(i), we must have for the case that $P, Q \in M'$ for some residue class M' of M that

$$b_1 \cdot y_1 + b_2 \cdot y_2 + b_3 \cdot y_3 = 0.$$

Two further vertices of the second degenerate tetrahedron can be chosen from M' in $O(\binom{\rho^2/\|b_M\|}{2})$ ways; hence as in case (a) and using (12), altogether we have $O(\rho^4 \cdot \log\rho)$ possibilities for this. We infer for the number $s_{2,2}(\mathcal{G}; dn)$ of pairs of tetrahedra, where one is nondegenerate with volume at most β and the other is degenerate, the following upper bound:

$$s_{2,2}(\mathcal{G}; dn) = O\left(\beta \cdot \rho^9 \cdot \rho^4 \cdot \log\rho\right) = O\left(\beta \cdot \rho^{13} \cdot \log\rho\right). \tag{14}$$

Case (c). Both tetrahedra have volume at most β, are nondegenerate, and have two vertices in common. To count this number $s_{2,2}(\mathcal{G}; nn)$ of $(2,2)$-cycles, we choose a primitive normal vector $a_L \in \mathbb{Z}^3$ of a 2-maximal grid L in $\mathbb{Z}^3$ with $\|a_L\| = O(\rho^2)$. Then we fix a point $P \in \mathbb{Z}^3 \cap B_3(\rho)$. There is exactly one residue class L' of L with $P \in L'$. For fixed integers $d > 0$ consider a second point $Q \in L'$ with $(\mathrm{dist}(P, Q))^2 = d$, there are at most $r_3(d; a_L)$ of these points. The points P and Q are the two common vertices of the two tetrahedra.

Let $v > 0$ be a real number. By Lemma 5.3 there are $O(v \cdot \rho/(\|a_L\| \cdot d^{1/2}))$ points $R \in L' \cap B_3(\rho)$ such that $\mathrm{area}(P, Q, R) \le v$ and the triangle determined by P, Q, R is nondegenerate. Then the fourth point from $B_3(\rho) \cap \mathbb{Z}^3$ of a tetrahedron with volume at most β can be chosen in $O(\beta \cdot \rho^2/\|a_L\|)$ ways; see (7). If we assume that the third point $R \in L' \cap B_3(\rho)$ satisfies $\mathrm{area}(P, Q, R) > v$, then there are $O(\rho^2/\|a_L\|)$ choices for the point R and the fourth point from $B_3(\rho) \cap \mathbb{Z}^3$ can be chosen in $O(\beta \cdot \rho^2/v)$ ways; thus we have

$$O\left(\frac{\beta \cdot v \cdot \rho^3}{\|a_L\|^2 \cdot d^{1/2}} + \frac{\beta \cdot \rho^4}{v \cdot \|a_L\|}\right) \tag{15}$$

possibilities for the third and fourth vertices of the first tetrahedron. With $v(a_L) := \rho^{1/2} \cdot \|a_L\|^{1/2} \cdot d^{1/4}$ this upper bound (15) becomes

$$O\left(\frac{\beta \cdot \rho^{7/2}}{\|a_L\|^{3/2} \cdot d^{1/4}}\right). \tag{16}$$

Now we consider the second nondegenerate tetrahedron in $B_3(\rho) \cap \mathbb{Z}^3$ with the already fixed vertices $P = (p_1, p_2, p_3)$ and $Q = (q_1, q_2, q_3)$. A third vertex $R \in B_3(\rho) \cap \mathbb{Z}^3$ of the second tetrahedron determines uniquely a 2-maximal grid M in $\mathbb{Z}^3$, such that P, Q, R are contained in a residue class M' of M. These 2-maximal grids M in $\mathbb{Z}^3$ with primitive normal vector $b_M = (b_1, b_2, b_3) \in \mathbb{Z}^3$ with $\|b_M\| = O(\rho^2)$, where $P - Q \in M$ and $P, Q \in M'$, satisfy

$$b_1 \cdot y_1 + b_2 \cdot y_2 + b_3 \cdot y_3 = 0, \tag{17}$$

where $y_i := p_i - q_i$ for $i = 1, 2, 3$. Since the third point $R \in M$ of the nondegenerate tetrahedron satisfies $R \in B_3(\rho) \cap \mathbb{Z}^3$, there are only $O(\rho^3)$ choices for the primitive normal vector $b_M \in \mathbb{Z}^3$. Let $C \subseteq \mathbb{Z}^3$ be the set of all possible choices for b_M.

Having fixed P and Q, the number of possibilities to extend these two points to the second tetrahedron in $B_3(\rho) \cap \mathbb{Z}^3$ is by (16)

$$O\left(\sum_{b \in C} \frac{\beta \cdot \rho^{7/2}}{\|b\|^{3/2} \cdot d^{1/4}}\right) = O\left(\frac{\beta \cdot \rho^{7/2}}{d^{1/4}} \cdot \sum_{b \in C} \frac{1}{\|b\|^{3/2}}\right) = O\left(\frac{\beta \cdot \rho^{17/4}}{d^{1/4}}\right).$$

The last equality can be seen as follows. Since we already fixed the two points P and Q, there are $O(\rho^3)$ possibilities to choose a residue class M' (of a 2-maximal grid M in $\mathbb{Z}^3$) such that $P, Q \in M'$ and where $|M' \cap B_3(\rho)| \geq 3$. Assume that $y_3 \neq 0$. Then by (17) we have that $(b_1, b_2, b_3), (b_1, b_2, b_3') \in C$ implies that $b_3 = b_3'$. We infer using Corollary 3.21 that

$$\sum_{b=(b_1,b_2,b_3) \in C} \frac{1}{\|b\|^{3/2}} = O\left(\sum_{b=(b_1,b_2,b_3) \in C} \frac{1}{(b_1^2 + b_2^2)^{3/4}}\right) = O\left(\sum_{d=1}^{O(\rho^3)} \frac{r_2(d)}{d^{3/4}}\right) = O(\rho^{3/4}).$$

The second equality can be seen from the following.

LEMMA 6.1. *Let $S \subset \mathbb{Z}^2$ be a finite set and let $\alpha > 0$. Then it holds that*

$$\sum_{(s_1,s_2) \in S} \frac{1}{(s_1^2 + s_2^2)^{\alpha}} = O\left(\sum_{d=1}^{|S|} \frac{r_2(d)}{d^{\alpha}}\right).$$

Proof. This is due to the fact that the function $f(x) = 1/x$ is monotone decreasing and that $\sum_{d=1}^{N} r_2(d) = \theta(N)$ by Lemma 3.20; i.e., there are $\Theta(N)$ representations of positive integers $i < N$ as a sum of two squares. ∎

Thus, we infer with Corollaries 3.21 and 3.23 that

$$\begin{aligned}
s_{2,2}(\mathcal{G}; nn) &= O\left(\sum_{\substack{a \in \mathbb{Z}^3 \\ \|a\| = O(\rho^2)}} \rho^3 \cdot \sum_{d=1}^{O(\rho^2)} r_3(d; a) \cdot \frac{\beta \cdot \rho^{7/2}}{\|a\|^{3/2} \cdot d^{1/4}} \cdot \frac{\beta \cdot \rho^{17/4}}{d^{1/4}}\right) \\
&= O\left(\beta^2 \cdot \rho^{43/4} \cdot \sum_{\substack{a \in \mathbb{Z}^3 \\ \|a\| = O(\rho^2)}} \frac{1}{\|a\|^{3/2}} \cdot \sum_{d=1}^{O(\rho^2)} \frac{r_3(d; a)}{d^{1/2}}\right) \\
&= O\left(\beta^2 \cdot \rho^{47/4} \cdot \sum_{\substack{a \in \mathbb{Z}^3 \\ \|a\| = O(\rho^2)}} \frac{1}{\|a\|^{5/2}}\right) = O\left(\beta^2 \cdot \rho^{47/4} \cdot \sum_{d=1}^{O(\rho^4)} \frac{r_3(d)}{d^{5/4}}\right) \\
&= O(\beta^2 \cdot \rho^{51/4}). \qquad (18)
\end{aligned}$$

To satisfy the assumptions of Theorem 2.2, we must have for some suitable constant $\gamma > 0$ that

$$\begin{aligned} s_{2,2}(\mathcal{G}) &= s_{2,2}(\mathcal{G}; dd) + s_{2,2}(\mathcal{G}; dn) + s_{2,2}(\mathcal{G}; nn) \\ &= O\left(\rho^3 \cdot t^{5-\gamma}\right) = O\left(\rho^{13-2\gamma} \cdot \beta^{5/3-\gamma/3}\right), \end{aligned} \tag{19}$$

where $t = c^{1/3} \cdot \beta^{1/3} \cdot \rho^2$ by (9) with $\beta = \rho^3 \cdot \log n/n^3$ and $\rho = n^{1+\varepsilon}$ for some constant $\varepsilon > 0$.

Considering (13), (14), and (18), we have $\rho^{13} \cdot (\log \rho)^2 = O(\beta \cdot \rho^{13} \cdot \log \rho)$, and $\beta^2 \cdot \rho^{51/4} = O(\beta \cdot \rho^{13} \cdot \log \rho)$ for $0 < \varepsilon < 1/11$. Thus it suffices to consider only case (b). In this case (b) we infer with (14) for $0 < \gamma < 2\varepsilon/(2+3\varepsilon)$:

$$\frac{\beta \cdot \rho^{13} \cdot \log \rho}{\rho^{13-2\gamma} \cdot \beta^{5/3-\gamma/3}} = \frac{\rho^{2\gamma} \cdot \log \rho}{\beta^{2/3-\gamma/3}} = O\left(\frac{(\log n)^{1/3+\gamma/3}}{n^{2\varepsilon-3\varepsilon\gamma-2\gamma}}\right) = o(1). \tag{20}$$

Thus by (20) the upper bound (19) holds for $0 < \varepsilon < 1/11$ and $0 < \gamma < 2\varepsilon/(2+3\varepsilon)$.

6.2. (2, 3)-cycles. Let us now consider the number $s_{2,3}(\mathcal{G})$ of $(2,3)$-cycles in our hypergraph $\mathcal{G} = (V, \mathcal{E}_4)$, that is, the number of pairs of tetrahedra in $B_3(\rho) \cap \mathbb{Z}^3$, both with volume at most β, having exactly three vertices in common. As in the case of $(2,2)$-cycles, we distinguish three cases: (a) both tetrahedra are degenerate, (b) one tetrahedron is degenerate and the other one is nondegenerate, and (c) both tetrahedra are nondegenerate. The corresponding numbers of $(2,3)$-cycles are denoted by $s_{2,3}(\mathcal{G}; dd)$, $s_{2,3}(\mathcal{G}; nd)$, $s_{2,3}(\mathcal{G}; nn)$, respectively. We consider only those configurations where the three common points *do not* lie on a line, as care is taken of these triples by the 3-element edges of the hypergraph $\mathcal{G}(\beta)$.

Case (a). Both tetrahedra are degenerate and have three vertices in common, which do not lie on a line. Thus the two tetrahedra are contained in a unique residue class L' of a 2-maximal grid L in $\mathbb{Z}^3$ with $L' \cap B_3(\rho) \neq \emptyset$, determined by some primitive normal vector $a_L \in \mathbb{Z}^3$ with $\|a_L\| = O(\rho^2)$ by Theorem 3.19(i). By Theorem 3.19(iii) the set $L' \cap B_3(\rho)$ contains $O(\rho^2/\|a_L\|)$ points. We can choose the five vertices of the two tetrahedra in $O(\binom{\rho^2/\|a_L\|}{5})$ ways. By Theorem 3.19(ii), there are $O(\rho \cdot \|a_L\|)$ residue classes of L intersecting $B_3(\rho)$ in a nonempty set; hence we have for these pairs of tetrahedra the upper bound

$$\begin{aligned} s_{2,3}(\mathcal{G}; dd) &= O\left(\sum_{\substack{a \in \mathbb{Z}^3 \\ \|a\| = O(\rho^2)}} \rho \cdot \|a\| \cdot \binom{\rho^2/\|a\|}{5}\right) \\ &= O\left(\rho^{11} \cdot \sum_{\substack{a \in \mathbb{Z}^3 \\ \|a\| = O(\rho^2)}} \frac{1}{\|a\|^4}\right) = O\left(\rho^{11} \cdot \sum_{d=1}^{O(\rho^4)} \frac{r_3(d)}{d^2}\right) = O(\rho^{11}), \end{aligned} \tag{21}$$

since by Corollary 3.21 we have $\sum_{d=1}^{n} r_3(d)/d^2 = O(1)$.

Case (b). One tetrahedron is nondegenerate with volume at most β and the other one is degenerate, and they have three vertices in common. By Theorem 5.1 there are $O(\beta \cdot \rho^9)$ nondegenerate tetrahedra in $B_3(\rho) \cap \mathbb{Z}^3$ with volume at most β. Fix one of it and choose three of its vertices, say p_0, p_1, p_2, which are common to both tetrahedra. Since the first tetrahedron is nondegenerate, the points p_0, p_1, p_2 uniquely determine a residue class L' of a maximal grid L in $\mathbb{Z}^3$, and since the second tetrahedron is

degenerate, the fourth point p_3' of the second degenerate tetrahedron is contained in L'. With $|L' \cap B_3(\rho)| = O(\rho^2)$ there are $O(\rho^2)$ choices for the point p_3', and we obtain

$$s_{2,3}(\mathcal{G}; dn) = O(\beta \cdot \rho^9 \cdot \rho^2) = O(\beta \cdot \rho^{11}). \tag{22}$$

Case (c). Both tetrahedra are nondegenerate, each with volume at most β, and they have three vertices in common. Fix a 2-maximal grid L in $\mathbb{Z}^3$ with primitive normal vector $a_L \in \mathbb{Z}^3$, where $\|a_L\| = O(\rho^2)$, and then fix a residue class L' of L with $L' \cap B_3(\rho) \neq \emptyset$. We count the pairs of nondegenerate tetrahedra $S = \{p_0, p_1, p_2, p_3\}$ and $S' = \{p_0, p_1, p_2, p_3'\}$ in $B_3(\rho) \cap \mathbb{Z}^3$ with $p_0, p_1, p_2 \in L'$ and $\mathrm{vol}(S) \leq \beta$ and $\mathrm{vol}(S') \leq \beta$.

The number of nondegenerate triangles in $L' \cap B_3(\rho)$ with area at most v is $O(v \cdot \rho^4/\|a_L\|^3)$ by Corollary 5.4. A fourth point of a tetrahedron from $B_3(\rho) \cap \mathbb{Z}^3$ with volume at most β can be chosen in $O(\beta \cdot \rho^2/\|a_L\|)$ ways.

On the other hand, the number of triangles in $L' \cap B_3(\rho)$ with area at least v is $O(\binom{\rho^2/\|a_L\|}{3})$, and a fourth point of a tetrahedron from $B_3(\rho) \cap \mathbb{Z}^3$ with maximum volume β can be chosen in $O(\beta \cdot \rho^2/v)$ ways.

Altogether, using $v = v(a_L) = \rho^{2/3} \cdot \|a_L\|^{2/3}$, the number of such pairs of tetrahedra is

$$\begin{aligned} &O\left(\frac{v \cdot \rho^4}{\|a_L\|^3} \cdot \left(\frac{\beta \cdot \rho^2}{\|a_L\|}\right)^2 + \frac{\rho^6}{\|a_L\|^3} \cdot \left(\frac{\beta \cdot \rho^2}{v}\right)^2\right) \\ &= O\left(\frac{v \cdot \beta^2 \cdot \rho^8}{\|a_L\|^5} + \frac{\beta^2 \cdot \rho^{10}}{v^2 \cdot \|a_L\|^3}\right) = O\left(\frac{\beta^2 \cdot \rho^{26/3}}{\|a_L\|^{13/3}}\right). \end{aligned}$$

Summing over all grids L in $\mathbb{Z}^3$ with $\|a_L\| = O(\rho^2)$ and over all $O(\rho \cdot \|a_L\|)$ residue classes L' of L with $L' \cap B_3(\rho) \neq \emptyset$, we obtain by Corollary 3.21

$$\begin{aligned} s_{2,3}(\mathcal{G}; nn) &= O\left(\sum_{\substack{a \in \mathbb{Z}^3 \\ \|a\| = O(\rho^2)}} \rho \cdot \|a\| \cdot \frac{\beta^2 \cdot \rho^{26/3}}{\|a\|^{13/3}}\right) \\ &= O\left(\beta^2 \cdot \rho^{29/3} \cdot \sum_{\substack{a \in \mathbb{Z}^3 \\ \|a\| = O(\rho^2)}} \frac{1}{\|a\|^{10/3}}\right) = O\left(\beta^2 \cdot \rho^{29/3} \cdot \sum_{d=1}^{O(\rho^4)} \frac{r_3(d)}{d^{5/3}}\right) \\ &= O(\beta^2 \cdot \rho^{29/3}). \end{aligned} \tag{23}$$

To satisfy the assumptions in Theorem 2.2, we must have, for some suitable constant $\gamma > 0$, that

$$s_{2,3}(\mathcal{G}) = s_{2,3}(\mathcal{G}; dd) + s_{2,3}(\mathcal{G}; dn) + s_{2,3}(\mathcal{G}; nn) = O(\rho^3 \cdot t^{4-\gamma}), \tag{24}$$

where $t = c^{1/3} \cdot \beta^{1/3} \cdot \rho^2$ by (9); i.e., using the estimates (21), (22), and (23), we need for some $\gamma > 0$ the following:

$$\rho^{11} + \beta \cdot \rho^{11} + \beta^2 \cdot \rho^{29/3} = O\left(\rho^{11-2\gamma} \cdot \beta^{4/3-\gamma/3}\right),$$

where $\beta := \rho^3 \cdot \log n/n^3$ and $\rho = n^{1+\varepsilon}$ with $\varepsilon > 0$.

Since we have $\rho^{11} = O(\beta \cdot \rho^{11})$ and $\beta^2 \cdot \rho^{29/3} = O(\beta \cdot \rho^{11})$ for $0 < \varepsilon < 4/5$, it suffices to consider only case (b). For this case (b) with (22) and $0 < \gamma < \varepsilon/(2+3\varepsilon)$, we have

$$s_{2,3}(\mathcal{G}; dn) = O\left(\beta \cdot \rho^{11}\right) = O\left(\rho^{11-2\gamma} \cdot \beta^{4/3-\gamma/3}\right),$$

since

$$\frac{\beta \cdot \rho^{11}}{\rho^{11-2\gamma} \cdot \beta^{4/3-\gamma/3}} = \frac{\rho^{2\gamma}}{\beta^{1/3-\gamma/3}} = \frac{1}{(\log n)^{1/3-\gamma/3} \cdot n^{\varepsilon-3\gamma\varepsilon-2\gamma}} = o(1).$$

For $0 < \varepsilon < 1/11$ and $0 < \gamma < \varepsilon/(2+3\varepsilon)$, (24), (11), and (19) are satisfied; thus all assumptions of Theorem 2.2 are fulfilled. Now we apply this theorem to our hypergraph $\mathcal{G}(\beta) = (V, \mathcal{E}_3 \cup \mathcal{E}_4)$ with average degree $t^3 = O(\beta \cdot \rho^6)$ for the 4-element edges, see (9), and we find in time polynomial in $\rho = n^{1+\varepsilon}$ and hence in n an independent set in $\mathcal{G}(\beta)$ of size

$$\begin{aligned}\Omega\left(\frac{|V|}{t} \cdot (\log t)^{1/3}\right) &= \Omega\left(\frac{\rho^3}{\beta^{1/3} \cdot \rho^2} \cdot \left(\log(\beta^{1/3} \cdot \rho^2)\right)^{1/3}\right) \\ &= \Omega\left(\frac{\rho}{(\log n)^{1/3} \cdot n^{\varepsilon}} \cdot (\log n)^{1/3}\right) = \Omega(n).\end{aligned}$$

Thus we have found in polynomial time $\Omega(n)$ points in $B_3(\rho) \cap \mathbb{Z}^3$ such that the volume of every tetrahedron is bigger than $\rho^3 \cdot \log n/n^3$. After rescaling and adapting constant factors, we obtain n points in the unit cube $[0,1]^3$ such that the volume of every tetrahedron is $\Omega(\log n/n^3)$.

THE MINIMIZATION PROBLEM FOR BOOLEAN FORMULAS*

EDITH HEMASPAANDRA† AND GERD WECHSUNG‡

Abstract. More than a quarter of a century ago, the question of the complexity of determining whether a given Boolean formula is minimal motivated Meyer and Stockmeyer to define the polynomial hierarchy. This problem (in the standard formalized version—that of Garey and Johnson) has been known for decades to be coNP-hard and in $\mathrm{NP}^{\mathrm{NP}}$, and yet no one had even been able to establish (many-one) NP-hardness. In this paper, we show that and more: The problem in fact is (many-one) hard for parallel access to NP.

Key words. Boolean formula minimization, parallel access, computational complexity, polynomial hierarchy, reductions

1. Introduction.

More than a quarter of a century ago, Meyer and Stockmeyer defined the polynomial hierarchy [12]. They were led to this by looking at the language `Minimal`: the set of those Boolean formulas for which there does not exist a shorter equivalent formula. The best upper bound they could find for $\overline{\texttt{Minimal}}$ was an NP machine with access to an NP oracle. Thus, the class $\Sigma_2^p = \mathrm{NP}^{\mathrm{NP}}$ was born, and the rest of the polynomial hierarchy was defined analogously.

But what can one say about the complexity of $\overline{\texttt{Minimal}}$? Is it Σ_2^p-complete? Nobody knows. In fact, no better upper bound than Σ_2^p is known, and until the present paper no lower bounds were known. Similarly large gaps between upper and lower bounds occur in other standard definitions of the minimization problem for Boolean formulas. Typically, these problems are trivially in Σ_2^p and have trivial coNP lower bounds, and nothing better was known until the present paper. In this paper we study the complexity of these problems and prove much better lower bounds. Namely, we establish hardness for parallel access to NP in those cases where coNP was the best previously known lower bound, and we establish coNP-hardness for `Minimal`.

There exist different definitions for the minimization problem for Boolean formulas. We will look at the three classic definitions: the original Meyer and Stockmeyer definition [12], the definition from Stockmeyer's seminal polynomial hierarchy paper [15], and the definition from Garey and Johnson [5].

1. Meyer and Stockmeyer [12]. `Minimal`: Given a formula ϕ, is it true that there does not exist a formula equivalent to ϕ that is of smaller size than ϕ?

2. Garey and Johnson [5]. `Minimum Equivalent Expression` (`MEE`, for short): Given a Boolean formula ϕ and a nonnegative integer k, is it true that there exists a

Boolean formula of size at most k that is equivalent to ϕ?

3. Stockmeyer [15]. MEE restricted to formulas in DNF (disjunctive normal form) (here and in the rest of the paper, restrictions also apply to the minimum equivalent formula). This problem is called MIN in [15]; we will call it MEE_{DNF}: Given a Boolean formula ϕ in DNF and a nonnegative integer k, is it true that there exists a Boolean formula in DNF of size at most k that is equivalent to ϕ?

In all these cases, $Size(\phi)$ is defined as the number of occurrences of propositional variables in ϕ. Note that $Size(true) = Size(false) = 0$. Of course, Minimal and MEE depend on the underlying language. We will look at Boolean formulas built from propositional variables, the operators $\{\leftrightarrow, \rightarrow, \wedge, \vee, \neg\}$, and the constants *true* and *false*. However, we will show that our results are fairly robust in the sense that they hold for any truth-functionally complete subset of $\{\leftrightarrow, \rightarrow, \wedge, \vee, \neg, true, false\}$.

Before this paper, the only known results on the complexity of these problems were as follows:

1. Trivial Σ_2^p upper bounds for MEE, MEE_{DNF}, and $\overline{\text{Minimal}}$: Given a formula ϕ and integer k, guess a formula ψ of size at most k (guess a DNF formula for MEE_{DNF}, and guess ψ of size less than $Size(\phi)$ for $\overline{\text{Minimal}}$), and verify that ϕ and ψ are equivalent. Determining equivalence between two formulas is in coNP.

2. Trivial coNP lower bounds for MEE and MEE_{DNF}, by a reduction from "tautology for DNF formulas," since ϕ in DNF is a tautology iff ϕ with all variables set to *true* is true and ϕ has an equivalent formula of size 0.

Garey and Johnson [5] state that MEE is NP-hard, but by this they merely mean NP-*Turing*-hard. In this paper, when we speak of hardness, we always mean *many-one*-hardness.

The results of this paper are as follows:

1. Minimal is coNP-hard.
2. MEE and MEE_{DNF} are hard for parallel access to NP.
3. Minimal restricted to positive formulas is coNP-hard.
4. MEE restricted to positive formulas is NP-hard.

Papadimitriou and Zachos [14] introduced and discussed a complexity class capturing the power of parallel access to NP, denoted by $\text{P}_{||}^{\text{NP}}$: the class of problems that can be solved by a P machine with access to an NP oracle with the restriction that all the queries to the NP oracle are asked in parallel. Clearly, $\text{NP} \cup \text{coNP} \subseteq \text{P}_{||}^{\text{NP}} \subseteq \text{P}^{\text{NP}} \subseteq \text{NP}^{\text{NP}}$. The class has been further studied in [7, 11, 18, 19, 9]. $\text{P}_{||}^{\text{NP}}$ is extremely robust. In particular, $\text{P}_{||}^{\text{NP}}$ is the class of problems that can be solved in polynomial time by $O(\log n)$ sequential Turing queries to NP [7].

The results of this paper should be contrasted with a recent result of Agrawal and Thierauf [1], who showed that the Boolean Isomorphism problem, previously only known to be coNP-hard and in Σ_2^p, just like MEE, cannot be Σ_2^p-complete unless the polynomial hierarchy collapses. (See [2] for related problems.) Their result draws on recent work in learning theory [3]. However, our methods do not seem to apply to their case, nor does their method seem to work in our case.

The rest of the paper is organized as follows. The next section proves that MEE is NP-hard. It also shows that the same construction can be used to prove coNP-hardness for Minimal. Section 3 shows how to use the NP-hardness reduction for MEE in combination with a result of Wagner [18] to obtain the $\text{P}_{||}^{\text{NP}}$ lower bound for MEE. The last section describes how to adapt the proofs for MEE to MEE_{DNF}.

2. MEE is NP-hard. In this section, we prove that MEE is NP-hard by a reduction from Vertex Cover.

DEFINITION 2.1. `Vertex Cover`*: Given a graph $G = \langle V, E\rangle$ and a positive integer k, does G have a vertex cover of size $\leq k$; i.e., does there exist a set $W \subseteq V$ such that $||W|| \leq k$ and, for all edges $\{v, w\} \in E$, $\{v, w\} \cap W \neq \emptyset$?*

In the next section, we will use the following properties of the reduction from `Vertex Cover` to `MEE` to show that `MEE` is hard for parallel access to NP.

THEOREM 2.2. *There exists a polynomial-time computable function f such that for all graphs G, $f(G)$ is a Boolean formula, and for all positive integers k, G has a vertex cover of size $\leq k$ iff $f(G)$ has an equivalent formula of size $\leq k + m(1 + 2m)$, where m is the number of edges in G.*

Proof. Let $G = \langle V, E\rangle$ be a graph, and let k be a positive integer. Let $||V|| = n$ and $||E|| = m$. Without loss of generality, we assume that $V = \{1, \ldots, n\}$, that G has no isolated vertices, and that $k < n$.

We will use the following $n+2m^2$ propositional variables in the formula $\phi = f(G)$:

- a variable p_i for every vertex $i \in V$, and
- a set Q_e of $2m$ propositional variables for every edge $e \in E$.

Define $f(G) = \phi$ as follows:

$$\phi = \bigvee_{\{i,j\}\in E} \left(p_i \wedge p_j \wedge \bigwedge_{q\in Q_{\{i,j\}}} q \right).$$

The formula ϕ contains all the information about graph G. We will show that G has a vertex cover of size $\leq k$ iff ϕ has an equivalent formula of size $\leq k + m(1 + 2m)$. Since f is clearly computable in polynomial time, this will prove Theorem 2.2.

For the left-to-right direction, suppose that $\{\ell_1, \ldots, \ell_k\}$ is a vertex cover of G. Then for every edge $\{i, j\} \in E$, $\{i, j\} \cap \{\ell_1, \ldots, \ell_k\} \neq \emptyset$. Thus, we can partition the set of edges E into k disjoint sets $E_1, E_2, \ldots, E_k$ such that, for all $1 \leq i \leq k$, $e \in E_i$ implies that $\ell_i \in e$. (In general, it will not be the case that every edge incident with ℓ_i will belong to E_i, because the E_i's form a partition.)

Consider the following formula:

$$\phi' = \bigvee_{i=1}^{k} \left(p_{\ell_i} \wedge \bigvee_{\{\ell_i,j\}\in E_i} \left(p_j \wedge \bigwedge_{q\in Q_{\{\ell_i,j\}}} q \right) \right).$$

It is easy to see that ϕ' and ϕ are equivalent. In addition, $\mathit{Size}(\phi') = k + \Sigma_{i=1}^{k}(||E_i|| \cdot (1 + 2m)) = k + (\Sigma_{i=1}^{k}||E_i||) \cdot (1 + 2m)$. Since the E_i's form a partition of E, $\mathit{Size}(\phi') = k + m(1 + 2m)$.

This completes the proof of the left-to-right direction. It remains to show that if ϕ has an equivalent formula of size $\leq k + m(1 + 2m)$, then G has a vertex cover of size $\leq k$. We will first prove the following lemma, which will make the formula easier to handle.

In the remainder of the proof, let ϕ be the formula defined above. For each $e \in E$, let q_e be a new propositional variable. Define $\widehat{\phi}$ as follows:

$$\widehat{\phi} = \bigvee_{\{i,j\}\in E} (p_i \wedge p_j \wedge q_{\{i,j\}}).$$

LEMMA 2.3. *If $\langle \phi, k + m(1 + 2m)\rangle \in$ `MEE`, then $\widehat{\phi}$ has an equivalent formula $\widehat{\psi}$ such that $\mathit{Size}(\widehat{\psi}) \leq k + 2m$ and every q_e occurs exactly once in $\widehat{\psi}$.*

Proof. Let ψ be a formula such that $Size(\psi) \leq k + m(1+2m)$ and ψ is equivalent to ϕ. First note that all variables in ϕ occur at least once in ψ. Thus, there are exactly $n + 2m^2$ different variables in ψ.

Also note that for every edge $e \in E$, there exists a variable in Q_e that occurs exactly once in ψ. To see this, suppose for a contradiction that there exists some set Q_e such that all the variables of Q_e occur at least twice in ψ. Then $Size(\psi) \geq n + m \cdot 2m + 2m > k + m(1+2m)$.

For every $e \in E$, let $\widehat{q_e} \in Q_e$ occur exactly once in ψ. Let $\widehat{\psi}$ be the formula that results from ψ when we set every variable in $\bigcup_{e \in E} Q_e \backslash \{\widehat{q_e}\}$ to *true* and replace $\widehat{q_e}$ by q_e. $\widehat{\psi}$ is equivalent to $\widehat{\phi}$, and $Size(\widehat{\psi}) \leq Size(\psi) - m(2m-1) \leq k + m(1+2m) - m(2m-1) = k + 2m$, and every q_e occurs exactly once in $\widehat{\psi}$. □

For the remainder of the proof of Theorem 2.2, let $\widehat{\phi}$ be as defined before Lemma 2.3, let $\widehat{\psi}$ be equivalent to $\widehat{\phi}$, and for all $e \in E$, let q_e occur exactly once in $\widehat{\psi}$. To finish the proof of Theorem 2.2, we will show that if G does *not* have a vertex cover of size k, then $Size(\widehat{\psi}) > k + 2m$.

We will view $\widehat{\psi}$ as a binary tree. The nodes of the tree are labeled by operators, propositional variables, *true*, and *false*. We will freely identify node X in the tree with the formula represented by the subtree rooted at X. We adopt the convention that every node is an ancestor of itself.

LEMMA 2.4. *Let $e, f \in E$, let $i \in e$, $i \notin f$, and in the tree representing $\widehat{\psi}$,*

- *let X be the least common ancestor of the node labeled q_e and the node labeled q_f,*
- *let X_e be the child of X that is an ancestor of the node labeled q_e, and*
- *let X_f be the child of X that is an ancestor of the node labeled q_f.*

Then p_i occurs in X_e.

Proof. Since q_e and q_f occur only once in $\widehat{\psi}$, and since X and X_e (X and X_f) are on the path from the root to q_e (q_f), we have the following fact, which will be used repeatedly in the proof of Lemma 2.4.

FACT 2.5. *If the value of $q_e(q_f)$ is changed and this change causes the value of $\widehat{\psi}$ to change, then the values of X and X_e (X and X_f) change as well.*

Let $e = \{i, j\}$, and let $f = \{r, s\}$. We will allow freedom only in the assignments to propositional variables q_e, q_f, and p_i, and we will fix the assignments to all other variables in such a way that the following formula α is satisfied:

$$\alpha = p_j \wedge p_r \wedge p_s \wedge \bigwedge_{p \notin \{q_e, q_f, p_i, p_j, p_r, p_s\}} \neg p.$$

To prove Lemma 2.4, it is sufficient to consider only two cases, namely, that X is labeled $\wedge$ and that X is labeled $\leftrightarrow$. This is true since the connectives $\vee$ and $\rightarrow$ may be replaced by $\wedge$ and $\neg$ without an increase in the size of the formula (since $(p \vee q) \leftrightarrow \neg(\neg p \wedge \neg q)$ and $(p \rightarrow q) \leftrightarrow \neg(p \wedge \neg q)$).

Case 1: X is labeled $\wedge$. Consider what happens to X_e, X_f, X, and $\widehat{\psi}$ for the assignment that satisfies $\neg q_e \wedge \neg q_f \wedge p_i \wedge \alpha$. Note that $\neg\widehat{\psi}$ holds, and note that we have four different possibilities for the values of X_e, X_f, and X, since X iff $X_e \wedge X_f$.

Case 1.1: $\neg q_e \wedge \neg q_f \wedge p_i \wedge \alpha \rightarrow \neg X_e \wedge \neg X_f \wedge \neg X \wedge \neg\widehat{\psi}$. Applying Fact 2.5, we get

$$q_e \wedge \neg q_f \wedge p_i \wedge \alpha \rightarrow X_e \wedge \neg X_f \wedge X \wedge \widehat{\psi},$$

which contradicts the fact that X iff $X_e \wedge X_f$.

Case 1.2: $\neg q_e \wedge \neg q_f \wedge p_i \wedge \alpha \rightarrow X_e \wedge \neg X_f \wedge \neg X \wedge \neg\widehat{\psi}$. Applying Fact 2.5, we get

$$q_e \wedge \neg q_f \wedge p_i \wedge \alpha \rightarrow \neg X_e \wedge \neg X_f \wedge X \wedge \widehat{\psi},$$

which contradicts the fact that X iff $X_e \wedge X_f$.

Case 1.3: $\neg q_e \wedge \neg q_f \wedge p_i \wedge \alpha \rightarrow \neg X_e \wedge X_f \wedge \neg X \wedge \neg\widehat{\psi}$. Applying Fact 2.5, we get

$$\neg q_e \wedge q_f \wedge p_i \wedge \alpha \rightarrow \neg X_e \wedge \neg X_f \wedge X \wedge \widehat{\psi},$$

which contradicts the fact that X iff $X_e \wedge X_f$.

Case 1.4: The only remaining case is $\neg q_e \wedge \neg q_f \wedge p_i \wedge \alpha \rightarrow X_e \wedge X_f \wedge X \wedge \neg\widehat{\psi}$. Applying Fact 2.5, we get

$$q_e \wedge \neg q_f \wedge p_i \wedge \alpha \rightarrow \neg X_e \wedge X_f \wedge \neg X \wedge \widehat{\psi}.$$

For a contradiction, assume that p_i does not occur in X_e. Then we get

$$q_e \wedge \neg q_f \wedge \neg p_i \wedge \alpha \rightarrow \neg X_e \wedge \neg X \wedge \neg\widehat{\psi}.$$

The first term on the right-hand side is justified by the assumption that p_i does not occur in X_e, and $\neg X$ follows from $\neg X_e$. Making use of Fact 2.5, we get

$$q_e \wedge q_f \wedge \neg p_i \wedge \alpha \rightarrow \neg X_e \wedge X \wedge \widehat{\psi},$$

which contradicts the fact that X iff $X_e \wedge X_f$.

Case 2: X is labeled $\leftrightarrow$. Again, we will consider what happens for the assignment that satisfies $\neg q_e \wedge \neg q_f \wedge p_i \wedge \alpha$. We will write

$$\neg q_e \wedge \neg q_f \wedge p_i \wedge \alpha \rightarrow X_e^* \wedge X_f^* \wedge X^* \wedge \neg\widehat{\psi}, \tag{1}$$

where $X^* \in \{X, \neg X\}$, $X_e^* \in \{X_e, \neg X_e\}$, and $X_f^* \in \{X_f, \neg X_f\}$. Since X is labeled $\leftrightarrow$, we know that

$$X^* \text{ is true iff } X_e^* \leftrightarrow X_f^* \text{ is true.} \tag{2}$$

Applying Fact 2.5, we get

$$q_e \wedge \neg q_f \wedge p_i \wedge \alpha \rightarrow \neg X_e^* \wedge X_f^* \wedge \neg X^* \wedge \widehat{\psi}. \tag{3}$$

For a contradiction, assume that p_i does not occur in X_e. Then we get from (3) that

$$q_e \wedge \neg q_f \wedge \neg p_i \wedge \alpha \rightarrow \neg X_e^* \wedge X_f^+ \wedge X^+ \wedge \neg\widehat{\psi}. \tag{4}$$

The first term on the right-hand side is justified by (3) and the assumption that p_i does not occur in X_e. Since we do not know if p_i influences X_f or X, we cautiously write X_f^+ and X^+, where $X^+ \in \{X, \neg X\}$ and $X_f^+ \in \{X_f, \neg X_f\}$.

Making use of Fact 2.5, we get

$$q_e \wedge q_f \wedge \neg p_i \wedge \alpha \rightarrow \neg X_e^* \wedge \neg X_f^+ \wedge \neg X^+ \wedge \widehat{\psi}. \tag{5}$$

Case 2.1: $X^+ = X^*$ and $X_f^+ = X_f^*$. From (4) we get X^* is true and X_f^* is true, but X_e^* is false. This contradicts (2).

Case 2.2: $X^+ = \neg X^*$ and $X_f^+ = \neg X_f^*$. From (5) we get X^* is true and X_f^* is true, but X_e^* is false. This contradicts (2).

The remaining two cases need more work.

Case 2.3: $X^+ = X^*$ and $X_f^+ = \neg X_f^*$. We summarize the statements valid in this case.

$$\neg q_e \wedge \neg q_f \wedge p_i \wedge \alpha \rightarrow X_e^* \wedge X_f^* \wedge X^* \wedge \neg\widehat{\psi} \tag{1}$$

$$q_e \wedge \neg q_f \wedge p_i \wedge \alpha \rightarrow \neg X_e^* \wedge X_f^* \wedge \neg X^* \wedge \widehat{\psi} \tag{3}$$

$$q_e \wedge \neg q_f \wedge \neg p_i \wedge \alpha \rightarrow \neg X_e^* \wedge \neg X_f^* \wedge X^* \wedge \neg\widehat{\psi} \tag{4}$$

$$q_e \wedge q_f \wedge \neg p_i \wedge \alpha \rightarrow \neg X_e^* \wedge X_f^* \wedge \neg X^* \wedge \widehat{\psi} \tag{5}$$

Comparing (3) and (4), we see that both X_f and X depend on p_i. Since q_e does not have any influence on the dependency of X_f on p_i, we get the following from (1) by switching p_i to $\neg p_i$.

$$\neg q_e \wedge \neg q_f \wedge \neg p_i \wedge \alpha \rightarrow X_e^* \wedge \neg X_f^* \wedge \neg X^* \wedge \neg\widehat{\psi}. \tag{6}$$

The reason for X_e^* occurring on the right-hand side is that p_i does not occur in X_e. $\neg X^*$ follows from (2), which always has to be satisfied. It is clear that $\neg\widehat{\psi}$ occurs because the assignment that satisfies the left-hand side of (6) falsifies $\widehat{\psi}$.

If $\alpha = \mathit{true}$, the value of $\widehat{\psi}$ depends only on the values of X and p_i. However, because of (5), X^* and p_i are false and $\widehat{\psi}$ is true, but because of (6), X^* and p_i are false and $\widehat{\psi}$ is false. This is a contradiction.

Case 2.4: $X^+ = \neg X^*$ and $X_f^+ = X_f^*$. This case is treated in the same way as Case 2.3.

This completes the proof of Lemma 2.4 □

LEMMA 2.6. *Let X be an internal node in $\widehat{\psi}$, and let Y be a child of X. If*

$$\bigcap\{\{i,j\} \mid q_{\{i,j\}} \text{ occurs in } X\} = \emptyset,$$

then for all $\{i,j\} \in E$, if $q_{\{i,j\}}$ occurs in Y, then so do p_i and p_j.

Proof. Suppose $q_{\{i,j\}}$ occurs in Y. We will show that p_i occurs in Y. Because

$$\bigcap\{\{i,j\} \mid q_{\{i,j\}} \text{ occurs in } X\} = \emptyset,$$

there exists an edge $f \in E$ such that q_f occurs in X, and $i \notin f$.

Let Z be the least common ancestor of the nodes labeled $q_{\{i,j\}}$ and q_f, and let $Z_{\{i,j\}}$ be the child of Z that is an ancestor of the node labeled $q_{\{i,j\}}$. By Lemma 2.4, p_i occurs in $Z_{\{i,j\}}$. It remains to show that Y is an ancestor of $Z_{\{i,j\}}$. This is simple: Since there is only one node labeled $q_{\{i,j\}}$, X, Y, Z, and $Z_{\{i,j\}}$ all lie on the unique path from the root to the node labeled $q_{\{i,j\}}$. In addition, X is an ancestor of the node labeled q_f and is therefore an ancestor of Z. It follows that Y is an ancestor of $Z_{\{i,j\}}$. □

To finish the proof of Theorem 2.2, suppose that G does not have a vertex cover of size k. We need to show that $\mathit{Size}(\widehat{\psi}) > k + 2m$.

Let $Y_1, Y_2, \ldots, Y_r$ be all nodes in $\widehat{\psi}$ such that, for all $1 \leq \ell \leq r$,

- $\bigcap\{\{i,j\} \mid q_{\{i,j\}} \text{ occurs in } Y_\ell\} \neq \emptyset$, and
- if X is a proper ancestor of Y_ℓ, then $\bigcap\{\{i,j\} \mid q_{\{i,j\}} \text{ occurs in } X\} = \emptyset$.

The following hold:

- For every $e \in E$, the node labeled q_e has exactly one Y_ℓ as ancestor,
- $r > k$ (because the Y_ℓ's induce a vertex cover of size r), and
- if $q_{\{i,j\}}$ occurs in Y_ℓ, then so do p_i and p_j by Lemma 2.6.

It follows that

$$\begin{aligned} \mathit{Size}(\widehat{\psi}) &\geq m + \sum_{1 \leq \ell \leq r} \left|\left| \bigcup \{\{p_i, p_j\} \mid q_{\{i,j\}} \text{ occurs in } Y_\ell\} \right|\right| \\ &\geq m + \sum_{1 \leq \ell \leq r} (||\{q_e \mid q_e \text{ occurs in } Y_\ell\}|| + 1) \\ &= m + m + r \\ &> 2m + k. \end{aligned}$$

This completes the proof of Theorem 2.2. □

We conclude this section by using Theorem 2.2 to show that `Minimal` is coNP-hard.

THEOREM 2.7. `Minimal` *is* coNP*-hard.*

Proof. We will reduce the complement of `Vertex Cover` to `Minimal`. Let $G = \langle V, E\rangle$ be a graph, and let k be a positive integer. Let $||V|| = n$, $k < n$, let W be a set of $n - k - 1$ new vertices, and define $G' = \langle V \cup W, E \cup (V \times W)\rangle$.

The vertex covers for G' are exactly those sets of vertices that either contain V or are of the form $W \cup \widehat{V}$, where $\widehat{V}$ is a vertex cover for G. It follows that G does *not* have a vertex cover of size $\leq k$ iff all vertex covers for G' have size at least n, and the latter is true iff V is a vertex cover of minimum size for G'.

Applying Theorem 2.2, this holds iff the minimum size of a formula equivalent to $f(G')$ is $n + m(1 + 2m)$, where m is the number of edges in G'.

Writing $\{1, \ldots, n\}$ for V and $\{n+1, \ldots, 2n-k-1\}$ for W, $f(G')$ is the following formula:

$$\bigvee_{\{i,j\} \in E \cup (V \times W)} \left(p_i \wedge p_j \wedge \bigwedge_{q \in Q_{\{i,j\}}} q \right),$$

where for each edge e, Q_e consists of $2m$ new variables. Since V is clearly a vertex cover for G', the following formula ϕ' is equivalent to $f(G')$:

$$\phi' = \bigvee_{i=1}^{n} \left(p_i \wedge \bigvee_{\{i,j\} \in E, i<j} \left(p_j \wedge \bigwedge_{q \in Q_{\{i,j\}}} q \right) \right).$$

Note that $\mathit{Size}(\phi') = n + m(1 + 2m)$. It follows that $G = \langle V, E\rangle$ does *not* have a vertex cover of size $\leq k$ iff $\phi' \in$ `Minimal`. □

Since the reductions to `MEE` and `Minimal` construct formulas that use only $\wedge$ and $\vee$, and since the minimum size formulas (i.e., ϕ') in both constructions in this section also use only $\wedge$ and $\vee$, it is immediate that the results go through if we restrict the problems to positive formulas.

COROLLARY 2.8. `MEE` *restricted to positive formulas is* NP*-hard, and* `Minimal` *restricted to positive formulas is* coNP*-hard.*

Also note that formulas over $\{\vee, \wedge\}$ can in polynomial time be transformed into formulas over any truth-functionally complete subset of $\{\leftrightarrow, \rightarrow, \wedge, \vee, \neg, \mathit{true}, \mathit{false}\}$ without an increase in size. This immediately gives the following corollary.

COROLLARY 2.9. *For any truth-functionally complete subset of* $\{\leftrightarrow, \rightarrow, \wedge, \vee, \neg, \mathit{true}, \mathit{false}\}$, `MEE` *restricted to formulas over this subset is* NP*-hard, and* `Minimal` *restricted to formulas over this subset is* coNP*-hard.*

3. `MEE` is $\mathbf{P}_{||}^{\mathbf{NP}}$-hard.

In this section, we will prove the following theorem.

THEOREM 3.1. `MEE` *is* $\mathrm{P}_{||}^{\mathrm{NP}}$*-hard.*

Proof. We will use the following theorem from Wagner [18].

THEOREM 3.2 (Wagner [18]). *Let D be an* NP*-hard set, and let A be an arbitrary set. If there exists a polynomial-time computable function h such that*[1]

$$||\{i \mid x_i \in D\}|| \text{ is odd } \Leftrightarrow h(x_1, \ldots, x_{2k}) \in A$$

for all $k \geq 1$ and $x_1, x_2, \ldots, x_{2k} \in \Sigma^*$ with $\chi_D(x_1) \geq \chi_D(x_2) \geq \cdots \geq \chi_D(x_{2k})$, then A is $\mathrm{P}_{||}^{\mathrm{NP}}$*-hard.*[2] *($\chi_D$ is the characteristic function of D.)*

Thus, in our case it suffices to construct a polynomial-time computable function h such that

$$||\{i \mid \phi_i \in \mathrm{SAT}\}|| \text{ is odd } \Leftrightarrow h(\phi_1, \ldots, \phi_{2k}) \in \texttt{MEE}$$

for all $k \geq 1$ and conjunctive normal form (CNF) formulas $\phi_1, \phi_2, \ldots, \phi_{2k}$ with $\phi_{i+1} \in \mathrm{SAT} \Rightarrow \phi_i \in \mathrm{SAT}$ for all $i < 2k$.

Before we can attempt to construct h, we have to look carefully at the properties of the NP-hardness reduction to `MEE`. We introduce the following shorthand for the minimum size of a formula equivalent to ϕ.

DEFINITION 3.3. *Minsize*$(\phi) = \mathit{min}\{\mathit{Size}(\psi) \mid \psi \text{ equivalent to } \phi\}$.

LEMMA 3.4. *There exists a reduction g from* SAT *to* `MEE` *such that, for all CNF formulas ϕ, $g(\phi) = \langle \psi, k \rangle$, where ψ is a Boolean formula, k is a positive integer, and*

- $\neg\psi \in \mathrm{SAT}$,
- $\phi \in \mathrm{SAT} \Rightarrow$ *Minsize*$(\psi) = k$, *and*
- $\phi \notin \mathrm{SAT} \Rightarrow$ *Minsize*$(\psi) = k + 1$.

Proof. We may assume (see Papadimitriou and Yannakakis [13]) that there exists a polynomial-time computable function g' such that, for all CNF formulas ϕ, $g'(\phi) = \langle G, k \rangle$, where G is a graph, k is a positive integer, and

- if $\phi \in \mathrm{SAT}$, then the size of a minimum vertex cover of G is k, and
- if $\phi \notin \mathrm{SAT}$, then the size of a minimum vertex cover of G is $k + 1$.

Let f be the function from Theorem 2.2. Then, for all graphs G, $f(G)$ is a Boolean formula, and for all k, G has a vertex cover of size $\leq k$ iff $f(G)$ has an equivalent formula of size $\leq k + m(1 + 2m)$, where m is the number of edges in G.

It is immediate that, for all graphs G and for all k, the size of a minimum vertex cover of G is k iff *Minsize*$(f(G)) = k + m(1 + 2m)$, where m is the number of edges in G. In addition, since $k \geq 1$, *Minsize*$(f(G)) \geq 1$, and thus $f(G)$ is not equivalent to *true* or *false*. Hence, both $f(G), \neg f(G) \in \mathrm{SAT}$. Now define $g(\phi)$ as follows:

$$g(\phi) = \langle f(G), k + m(1 + 2m) \rangle, \text{ where } \langle G, k \rangle = g'(\phi). \qquad \square$$

In our proof of Theorem 3.1, we will use the following well-known fact.

FACT 3.5. *If ϕ and ψ are disjoint (i.e., the sets of propositional variables that occur in ϕ and ψ are disjoint), then*

---

[1] Since h is a variable-arity function, we mean that h's running time is polynomial in $2k + |x_1| + |x_2| + \cdots + |x_{2k}|$; see [8] for a discussion on why we have to be careful here.

[2] In fact, Wagner actually proves hardness for $\mathrm{P}_{\mathrm{bf}}^{\mathrm{NP}}$, but that class is now known to be equivalent to $\mathrm{P}_{||}^{\mathrm{NP}}$.

1. $Minsize(\phi \wedge \psi) = Minsize(\phi) + Minsize(\psi)$ *if* $\phi \in \mathrm{SAT}$ *and* $\psi \in \mathrm{SAT}$,
2. $Minsize(\phi \wedge \psi) = 0$ *if* $\phi \notin \mathrm{SAT}$ *or* $\psi \notin \mathrm{SAT}$,
3. $Minsize(\phi \vee \psi) = Minsize(\phi) + Minsize(\psi)$ *if* $\neg\phi \in \mathrm{SAT}$ *and* $\neg\psi \in \mathrm{SAT}$,
4. $Minsize(\phi \vee \psi) = 0$ *if* $\neg\phi \notin \mathrm{SAT}$ *or* $\neg\psi \notin \mathrm{SAT}$.

Now we are ready to prove Theorem 3.1. Let $k \geq 1$, and let $\phi_1, \phi_2, \ldots, \phi_{2k}$ be CNF formulas such that $\phi_{i+1} \in \mathrm{SAT} \Rightarrow \phi_i \in \mathrm{SAT}$ for all $i < 2k$. We have to construct a polynomial-time computable function h such that $||\{i \mid \phi_i \in \mathrm{SAT}\}||$ is odd iff $h(\phi_1, \ldots, \phi_{2k}) \in \mathtt{MEE}$. Note that, for all m, $||\{i \mid \phi_i \in \mathrm{SAT}\}|| = m$ iff $\phi_1, \phi_2, \ldots, \phi_m \in \mathrm{SAT}$ and $\phi_{m+1}, \ldots, \phi_{2k} \notin \mathrm{SAT}$. Therefore,

- if $||\{i \mid \phi_i \in \mathrm{SAT}\}||$ is even, then $\forall i$ ($\phi_{2i-1} \in \mathrm{SAT}$ iff $\phi_{2i} \in \mathrm{SAT}$), and
- if $||\{i \mid \phi_i \in \mathrm{SAT}\}||$ is odd, then $\exists i$ [($\phi_{2i-1} \in \mathrm{SAT}$ and $\phi_{2i} \notin \mathrm{SAT}$) and $\forall j \neq i$ ($\phi_{2j-1} \in \mathrm{SAT}$ iff $\phi_{2j} \in \mathrm{SAT}$)].

Let g be the reduction from Lemma 3.4. For all i, let $g(\phi_{2i-1}) = \langle \psi_{2i-1}, k_i \rangle$. Then $k_i \geq 1$ and

- $\neg\psi_{2i-1} \in \mathrm{SAT}$,
- $Minsize(\psi_{2i-1}) = k_i$ if $\phi_{2i-1} \in \mathrm{SAT}$, and
- $Minsize(\psi_{2i-1}) = k_i + 1$ if $\phi_{2i-1} \notin \mathrm{SAT}$.

Define $m = \Sigma_{i=1}^{k} Size(\phi_{2i}) + 1$.

In order to apply Fact 3.5, we will need to make all formulas disjoint. We will also need a number of disjoint copies of the same formula. Without loss of generality, suppose that, for all i, every propositional variable in ϕ_{2i} and ψ_{2i-1} is of the form p_ℓ for some ℓ. The propositional variables in our new formulas will be of the form $q_{\ell,i,j}$, $r_{\ell,i,j}$, and $w_{i,j}$.

- For all i, we need m disjoint copies of ψ_{2i-1}. For $1 \leq j \leq m$, let $\psi_{2i-1,j}$ be a copy of ψ_{2i-1} with every occurrence of a propositional variable p_ℓ replaced by $q_{\ell,i,j}$.
- For all i, let ϕ''_{2i} be a copy of ϕ_{2i} with every occurrence of a propositional variable p_ℓ replaced by $r_{\ell,i,j}$, and let

$$\phi'_{2i} = \phi''_{2i} \wedge w_{i,1} \wedge w_{i,2} \wedge \cdots \wedge w_{i,m}.$$

Since all these formulas are disjoint, and $\neg\psi_{2i-1} \in \mathrm{SAT}$, we obtain the following by applying Fact 3.5:

- $Minsize(\bigvee_{j=1}^{m} \psi_{2i-1,j}) = mk_i$ if $\phi_{2i-1} \in \mathrm{SAT}$,
- $Minsize(\bigvee_{j=1}^{m} \psi_{2i-1,j}) = mk_i + m$ if $\phi_{2i-1} \notin \mathrm{SAT}$,
- $Minsize(\phi'_{2i}) = 0$ if $\phi_{2i} \notin \mathrm{SAT}$, and
- $m \leq Minsize(\phi'_{2i}) \leq m + Size(\phi_{2i})$ if $\phi_{2i} \in \mathrm{SAT}$.

For $1 \leq i \leq k$, define

$$\xi_i = \bigvee_{j=1}^{m} \psi_{2i-1,j} \vee \phi'_{2i}.$$

Note that $\neg \bigvee_{j=1}^{m} \psi_{2i-1,j} \in \mathrm{SAT}$ and $\neg\phi'_{2i} \in \mathrm{SAT}$. This implies by Fact 3.5 that

$$Minsize(\xi_i) = Minsize\left(\bigvee_{j=1}^{m} \psi_{2i-1,j}\right) + Minsize(\phi'_{2i}).$$

It follows that, for all i,

- $Minsize(\xi_i) = mk_i$ if $\phi_{2i-1} \in \mathrm{SAT}$ and $\phi_{2i} \notin \mathrm{SAT}$, and

• $mk_i + m \leq \mathit{Minsize}(\xi_i) \leq mk_i + m + \mathit{Size}(\phi_{2i})$ if ($\phi_{2i-1} \in$ SAT iff $\phi_{2i} \in$ SAT).

Now we define the reduction

$$h(\phi_1, \phi_2, \ldots, \phi_{2k}) = \left\langle \bigvee_{i=1}^{k} \xi_i, m\Sigma_{i=1}^{k} k_i + km - 1 \right\rangle.$$

Clearly, h is computable in polynomial time. Note that, for all i, $\neg\xi_i \in$ SAT. Thus, $\mathit{Minsize}(\bigvee_{i=1}^{k} \xi_i) = \Sigma_{i=1}^{k} \mathit{Minsize}(\xi_i)$.

We need to show that $||\{i \mid \phi_i \in \text{SAT}\}||$ is odd iff $h(\phi_1, \ldots, \phi_{2k}) \in$ MEE.

($\Leftarrow$) Suppose that $h(\phi_1, \phi_2, \ldots, \phi_{2k}) \in$ MEE, and suppose for a contradiction that $||\{i \mid \phi_i \in \text{SAT}\}||$ is even. Then $\forall i$ ($\phi_{2i-1} \in$ SAT iff $\phi_{2i} \in$ SAT). It follows that, for all i, $\mathit{Minsize}(\xi_i) \geq mk_i + m$. And thus, $\mathit{Minsize}(\bigvee_{i=1}^{k} \xi_i) \geq m\Sigma_{i=1}^{k} k_i + km$. But that contradicts the assumption that $h(\phi_1, \phi_2, \ldots, \phi_{2k}) \in$ MEE.

($\Rightarrow$) Suppose $||\{i \mid \phi_i \in \text{SAT}\}||$ is odd. Let i be such that ($\phi_{2i-1} \in$ SAT and $\phi_{2i} \notin$ SAT) and $\forall j \neq i$ ($\phi_{2j-1} \in$ SAT iff $\phi_{2j} \in$ SAT). It follows that $\mathit{Minsize}(\xi_i) = mk_i$ and that, for all $j \neq i$, $\mathit{Minsize}(\xi_j) \leq mk_j + m + \mathit{Size}(\phi_{2j})$. Thus,

$$\begin{aligned}
&\mathit{Minsize}\left(\bigvee_{j=1}^{k} \xi_j\right) \\
&\leq mk_i + \Sigma_{j \neq i}(mk_j + m + \mathit{Size}(\phi_{2j})) \\
&\leq m\Sigma_{j=1}^{k} k_j + m(k-1) + \Sigma_{j=1}^{k} \mathit{Size}(\phi_{2j}) \\
&\leq m\Sigma_{j=1}^{k} k_j + m(k-1) + m - 1 \\
&= m\Sigma_{j=1}^{k} k_j + km - 1.
\end{aligned}$$

It follows that $h(\phi_1, \phi_2, \ldots, \phi_{2k}) \in$ MEE. □

Careful inspection of the construction shows that if $\mathit{Minsize}(\bigvee_{i=1}^{k} \xi_i) \leq m\Sigma_{i=1}^{k} k_i + km - 1$, then this is witnessed by a formula over $\{\wedge, \vee, \neg\}$. Such a formula can in polynomial time be transformed into an equivalent formula over any truth-functionally complete subset of $\{\leftrightarrow, \rightarrow, \wedge, \vee, \neg, \mathit{true}, \mathit{false}\}$ without an increase in size.

COROLLARY 3.6. *For any truth-functionally complete subset of* $\{\leftrightarrow, \rightarrow, \wedge, \vee, \neg, \mathit{true}, \mathit{false}\}$, MEE *restricted to formulas over this subset is* $\mathrm{P}_{||}^{\mathrm{NP}}$*-hard.*

4. The Complexity of $\mathtt{MEE}_{\mathtt{DNF}}$. In this section, we investigate the complexity of MEE restricted to formulas in DNF. Note that we cannot use the reduction from Theorem 2.2 to show that $\mathtt{MEE}_{\mathtt{DNF}}$ is NP-hard, since the equivalent formula of minimum size (ϕ') is definitely not in DNF.

In 1965, predating NP and NP-completeness, Gimpel [4] reduced the general set covering problem to the prime implicant covering problem. As pointed out in Garey and Johnson [5], this implicitly gives a reduction from the NP-complete problem `Minimum Cover` to `Minimum Disjunctive Normal Form`, a problem that is closely related to $\mathtt{MEE}_{\mathtt{DNF}}$. A very careful inspection of the reduction implicit in [4] shows that this reduction establishes the NP-hardness of $\mathtt{MEE}_{\mathtt{DNF}}$. (The NP-hardness of $\mathtt{MEE}_{\mathtt{DNF}}$ also follows from Hammer and Kogan's result that MEE restricted to Horn CNFs is NP-complete [6].)

Just as in the case for MEE, we can combine the properties of the NP-hardness reduction with Wagner's Theorem 3.2 to obtain a $\mathrm{P}_{||}^{\mathrm{NP}}$ lower bound.

THEOREM 4.1. $\mathtt{MEE}_{\mathtt{DNF}}$ *is* $\mathrm{P}_{||}^{\mathrm{NP}}$*-hard.*

After our results appeared in [10], Umans showed that $\mathtt{MEE}_{\mathtt{DNF}}$ is complete for Σ_2^p [16], and that $\mathtt{MEE}_{\mathtt{DNF}}$ is Σ_2^p-hard to approximate to within an n^ϵ factor [17]. Hence,

we will not include the proof of Theorem 4.1 here. However, our proof can be found in [10].

Acknowledgments. We would like to thank Harald Hempel, Jörg Rothe, and especially Lane Hemaspaandra for helpful discussions and comments. We also thank Lane Hemaspaandra for suggesting this topic. We gratefully acknowledge that the paper has benefited from suggestions of two anonymous referees.
