In section 2.3 we show how the robot recursively detects and explores an exhaustive system of groups of right and left reflex vertices. Groups of vertices that are on sufficiently different recursive levels give rise to base point sets whose $\mathcal{RCH}$s are mutually invisible. Therefore, the sum of their hulls' perimeters is less than the perimeter of the $\mathcal{RCH}$ of their union. In Lemma 2.6 we will show that each base point can see two points of the optimum watchman tour, W_{opt}, at an angle of 90°; therefore, all base points must be contained in the angle hull of W_{opt}. Consequently, the perimeter of the $\mathcal{RCH}$ of the base points must be less than the perimeter of the $\mathcal{RCH}$ of the angle hull of W_{opt}. The latter, in turn, can only be less than or equal to the perimeter of the $\mathcal{RCH}$ of W_{opt} itself, because the perimeter of the $\mathcal{RCH}$ of a connected object is no longer than the perimeter of the object itself. Now we can apply our angle hull result a second time in estimating the perimeter of the angle hull of W_{opt} against the length of W_{opt} itself. This way we have bounded the length of the whole exploration path walked by the robot by a multiple of the length of the optimum watchman path, W_{opt}.

Our analysis greatly benefits from this new geometric structure we propose to call the *angle hull*. Let D be a simple polygon contained in another simple polygon, P. Then the angle hull, $\mathcal{AH}(D)$, of D consists of all points in P that can see two points of D at an angle of 90°. The boundary of $\mathcal{AH}(D)$ can be described as the path of a diligent photographer who uses a 90° angle lens and wants to take a picture of D that shows as large a portion of D as possible but no walls of P. Before taking the picture, the photographer walks around D, in order to inspect all possible viewpoints.

In section 3 we prove that the photographer's path is at most twice as long as the perimeter of her model, D.

2. The strategy and its analysis. Let P be a simple polygon and let s be a point on its boundary. The *shortest path tree* of s consists of all shortest paths from s to the vertices of P. Its internal nodes are reflex vertices of P. Those vertices touching a shortest path from the right are called *right reflex vertices*; left reflex vertices are defined accordingly. If we follow the shortest path from s to reflex vertex v, one of its adjacent polygon edges remains invisible until v is actually reached. The extension into the polygon of this invisible edge is called a *cut* of P with respect to s.

Exploring a polygon P is equivalent to visiting all of its cuts with respect to the start point s.

Figure 2.1 shows an example of the *optimum watchman tour*, W_{opt}, containing a boundary point, s. Tan and Hirata [28] have provided an off-line algorithm for computing W_{opt} within time $O(n^2)$ for a polygon of n edges.

We say a vertex has been *discovered* after it has been visible at least once from the robot's current position. A reflex vertex is *unexplored* as long as its cut has not been reached, and *fully explored* thereafter.

In an unknown polygon, even exploring a single reflex vertex requires a little care. For example, one cannot afford to go straight to the vertex in order to get to its cut: The cut could be passing by the start point very closely, so that a much shorter path would be optimal.

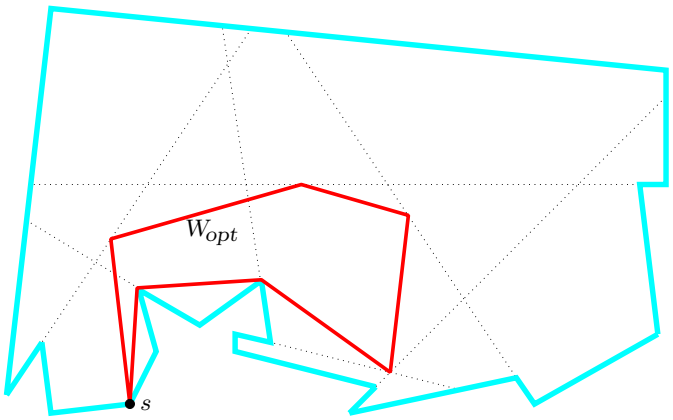

FIG. 2.1. *The optimum watchman tour visits all cuts of the polygon.*

We avoid this difficulty as follows. Whenever the robot wants to explore a right reflex vertex, r, visible from some local start point, p, it approaches r along the clockwise oriented circle *spanned* by p and by r, denoted by $\mathit{circ}\,(p, r)$, i.e., the smallest circle that contains p and r.

Consequently, when the robot reaches the cut of r at some point c, the ratio of the length of the circular arc from p to c over their euclidean distance is bounded by $\frac{\pi}{2} \approx 1.57$.

One might wonder if the subproblem of exploring a single vertex can be solved more efficiently by using curves other than circular arcs. This is, in fact, the case; Icking, Klein, and Ma [20] have shown that an optimum ratio of ≈ 1.212 is achieved by curves that result from solving certain differential equations. However, these curves are lacking a useful property possessed by circular arcs: The intersection point, c, of the circular arc with the cut is just the point on the cut closest to p, due to Thales's theorem.[2] This property turns out to be very helpful in our analysis.

In rectilinear polygons, the cut of each visible reflex vertex is known, and two cuts can cross only perpendicularly. This makes it possible to apply a simple greedy exploration strategy: The robot always walks to the cut of the next reflex vertex, in clockwise order, one of whose edges is invisible; see Deng, Kameda, and Papadimitriou [12].

For general polygons, this greedy approach is bound to fail, as Figure 2.2 illustrates. The example polygon shown there suggests exploring left and right reflex vertices separately. However, it is not really obvious how to do this in general, since, e.g., the existence of a left reflex vertex at the end of a long chain of right vertices is initially not known to the robot. Therefore, it seems necessary to partition left and right reflex vertices into compact groups that can be explored one by one.

2.1. Exploring a single vertex. The essential subtask of the robot's strategy is in exploring a single vertex. This is handled by the following procedure, *ExploreRightVertex*. We first list the complete pseudocode of the procedure, then we explain its steps and notation in detail.

[2]Thales's theorem: an angle inscribed in a semicircle is always a right angle.

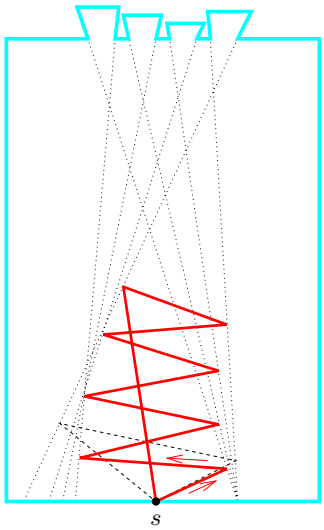

FIG. 2.2. *Visiting cuts in the order in which their vertices appear on the boundary does not lead to a competitive strategy.*

PROCEDURE *ExploreRightVertex* (**inout** *TargetList*, **inout** *ToDoList*);

BasePoint := *CP*;

Target := *First* (*TargetList*);

if *Target* not visible **then**
walk on shortest path from *BasePoint* to *Target*
until *Target* becomes visible;

Back := last vertex before *CP* on shortest path from *BasePoint* to *CP*;

walk clockwise along *circ* (*Back*, *Target*)
while maintaining *TargetList* and *ToDoList*

whenever *First* (*TargetList*) changes let *Target* := *First* (*TargetList*);
whenever *Back* becomes invisible update *Back*;

exceptions for walking along the circle:
if the boundary of P blocks the walk on the current circle **then**
walk clockwise along the boundary
until the circular walk is again possible;
if *Target* is becoming invisible **then**
walk towards *Target*
until the blocking vertex is reached;

until *Target* is fully explored;

end *ExploreRightVertex*;

We are using the abbreviation *CP* to denote the robot's current position. Procedure *ExploreRightVertex* works on two lists of vertices, *TargetList* and *ToDoList*. On entry, *TargetList* contains a list of right vertices, sorted in clockwise order along the boundary, that have already been discovered but not yet explored. When *ExploreRightVertex* is called for the very first time, *TargetList* contains exactly those right vertices that are visible from the start point, s, and have an invisible edge. *ToDo-*

List can be thought of as a long-term agenda that is passed to *ExploreRightVertex*; however, this procedure will only add to this list but not carry out one of the tasks.

In our pseudocode, *CP* (current position) is a global variable whose value can be changed only by **walk** statements. The robot's current position on calling *ExploreRightVertex* is called a *base point*.

The robot wants to explore the first vertex, *Target*, of *TargetList*. This vertex may have been discovered at an earlier stage, so that it may no longer be visible from the current position. In this case, the robot walks along the shortest path towards *Target* until it becomes visible again. Note that this shortest path is known to the robot; in fact a shortest path is always known between two points that have been seen (which would not be the case for polygons with holes).

Now the robot starts approaching *Target* along the circular arc spanned by the base point and by *Target*. On the way, a new right vertex, r, may be discovered. If one of its edges is invisible, r gets inserted into *TargetList*, provided that a certain criterion is met. Namely, the shortest path from the current *stage point*—a vertex defined one level up in the strategy—to r must not contain left turns. A right vertex that violates this criterion is ignored for now. A precise definition of a stage point is given in section 2.2.

It may happen that the vertex r newly discovered and inserted into *TargetList* comes before *Target* in clockwise order. In this case the robot ceases approaching its old target and starts exploring, from its current position, vertex r. This way, the vertex *Target* currently under exploration may repeatedly change.

It may also happen that the robot loses sight of the base point from which the current execution of procedure *ExploreRightVertex* has started. Namely, the robot's view of the base point may become obstructed by some left or right reflex vertex, b_1; examples will be shown in Figure 2.3. In this case, the exploration of the current *Target* no longer proceeds along the circle spanned by the base point and by *Target*; instead, it switches to the circle spanned by *Target* and by b_1. As the robot continues, its view of b_1 may become obstructed by some reflex vertex b_2, and so on. These reflex vertices, b_1, b_2,..., b_i define the shortest path from the base point to the robot's current position, and the robot explores *Target* along the circle spanned by *Target* and b_i. This last reflex vertex of the chain is named *Back* in the code. If the robot reaches the cut of *Target* at some point c, it arrives there at a right angle by the Thales property. Consequently, the shortest path in P from the base point to the cut goes through b_1, b_2,..., b_i and ends in c.

If the robot crosses the cut of a right vertex different from *Target* the former vertex is removed from *TargetList* because it has been explored on the way, this is done in the "while maintaining *TargetList*" step. Eventually, the target itself is deleted from the list when its cut has been reached.

When a right reflex vertex is explored, all of its children in the shortest path tree have already been discovered. Those right vertices having a left child are inserted into *ToDoList*, as candidates for future stages, together with references to their left children.

Finally, there are some exceptional events procedure *ExploreRightVertex* needs to take care of. If the robot's circular exploration path hits the boundary of the polygon, the robot follows the boundary until a circular path again becomes possible. If the robot's view of the target vertex is about to be blocked, the robot walks straight to the blocking vertex and continues from there on a circular path.

For ease of reference we summarize the rules by which *ExploreRightVertex* proceeds.

1. The current *target* vertex, i. e., the vertex whose cut we are intending to reach at the moment, is always the clockwise first among those right reflex vertices that have been discovered but not yet fully explored, i. e., the first element of *TargetList*. Only such right vertices can be in *TargetList* whose shortest paths from the stage point make only right turns.
2. To explore a right reflex vertex, r, we follow the clockwise oriented circle spanned by r and by the last vertex before CP on the shortest path from the base point to CP.
3. When the view to the current target vertex gets blocked (or when the boundary is hit) we walk straight towards the blocking vertex (or follow the boundary) until motion according to rule 2 becomes possible again.

Figure Figure 2.3 demonstrates how this strategy works. Initially, r_3 is the only right vertex visible; consequently, *TargetList* contains only r_3, and the robot's path begins with a circular arc spanned by s and by r_3. At point a, right vertex r_2 becomes visible. It is situated before r_3 on the boundary; therefore, the robot switches to exploring r_2, according to rule 1. Note that the circle spanned by s and by r_2 is passing through a, too, so that it is in fact possible to apply rule 2 at this point.

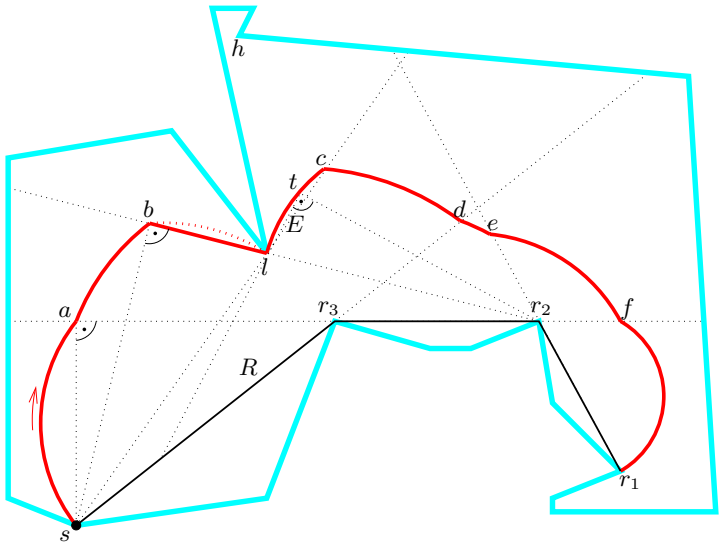

FIG. 2.3. *While executing ExploreRightVertex, the target vertex is initially r_3, then changes to r_2 and finally to r_1.*

At point b, vertex r_2 would become invisible if the robot were to follow the circular arc. But now rule 3 applies, causing the robot to walk straight to the left reflex vertex l. From there, a circular motion is again possible; but the shortest path from s to CP now contains vertex l. By rule 2, the robot continues its approach to r_2 along the arc spanned by l and by r_2.

Notice that at vertex l, also the right vertex h becomes visible, but it is ignored because its shortest path from s makes a left turn at l.

From c on, the shortest path to s is the line segment. Since the circle spanned by s and by r_2 is passing through c, the robot proceeds along that circle, applying rule 2.

At d, the shortest path to s changes again; now it contains vertex r_3. The robot walks along the circle spanned by r_3 and r_2, and gets to point e from which vertex r_1 becomes visible. From here, the robot explores r_1, following the circle spanned by r_3 and by r_1, the former changing to r_2 at f. Eventually, the robot arrives at r_1, thereby fully exploring r_1. Here procedure *ExploreRightVertex* terminates.

In order to provide an upper bound on the length of the resulting path we need to give the definition of the angle hull. A detailed discussion of this topic will follow in section 3.

Let D be a bounded, connected region in the plane. For convenience, we shall assume that D is a simple polygon, but our results can easily be generalized to curved objects by approximation. Now suppose that a photographer wants to take a picture of D that shows as large a portion of D as possible, but no white space. The photographer is using a fixed angle lens. For now, we assume that the angle equals 90°; later, at the end of section 3.2, we will see how to generalize to arbitrary angles.

Before taking the picture, the diligent photographer walks around D and inspects all possible viewpoints. We are interested in comparing the length of the photographer's path to the perimeter of the object, D.

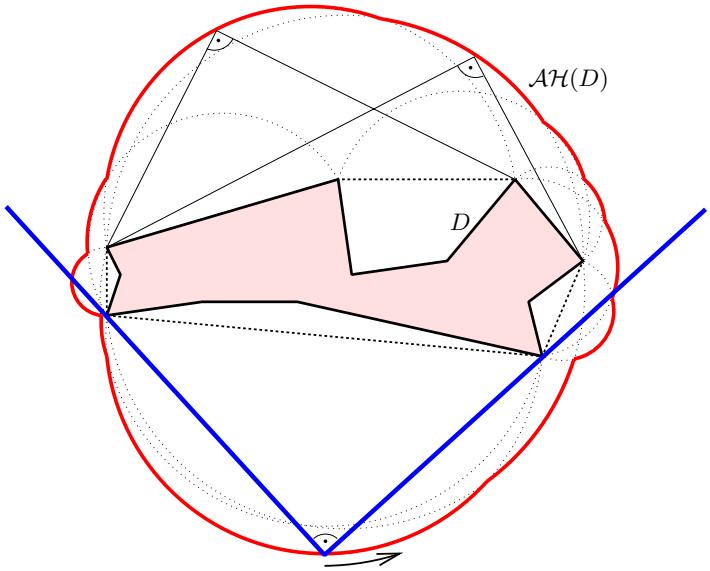

FIG. 2.4. *Drawing the angle hull $\mathcal{AH}(D)$ of a region D.*

In the simple outdoor setting there are no obstacles that can obstruct the photographer's view of D; this situation is depicted in Figure 2.4. At each point of the path, the two sides of the lens' angle touch the boundary of D from the outside, in general at a single vertex each.

While the right angle is touching two vertices, v and w, of D, its apex describes a circular arc spanned by v and w, as follows from Thales' theorem. All points enclosed by the photographer's path, and no other, can see two points of D at a 90° angle; we call this point set the *angle hull* of D and denote it by $\mathcal{AH}(D)$.

Only such vertices can be touched by the right angle that are situated on the convex hull of D. Consequently, the photographer's path depends on the convex hull, $\mathcal{CH}(D)$, of D, rather than on D itself, therefore we have $\mathcal{AH}(D) = \mathcal{AH}(\mathcal{CH}(D))$.

It is not hard to see that, without further obstacles, the perimeter of the angle hull is at most $\pi/2$ times the perimeter of D; the worst case occurs when D is a line segment or a rectangle; see [16].

However, for our application we need to analyze the indoor setting where D is contained in a simple polygon P whose edges give rise to visibility constraints. The photographer does not want any wall segments to appear in the picture; thus, the viewing angle can now be constrained in different ways: Either side may touch a convex vertex of D that is included in the angle, as before, or it may touch a reflex vertex of P that is excluded; see Figure 2.5.

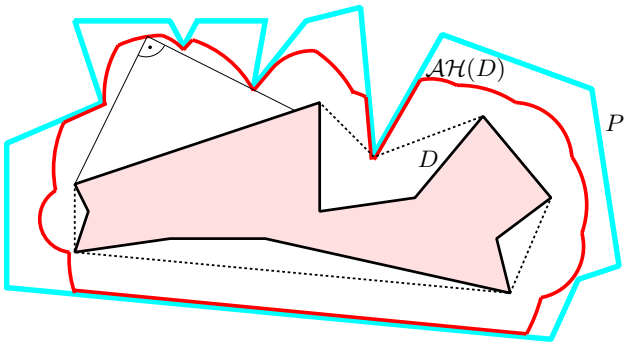

FIG. 2.5. *The angle hull $\mathcal{AH}(D)$ inside a polygon P.*

Any combination of these cases is possible.

As a consequence, the photographer's path contains circular arcs spanned by vertices of D and of P; in addition, it may contain segments of edges of P that prevent the photographer from stepping back far enough; see Figure 2.5.

Formally, we define the angle hull, $\mathcal{AH}(D)$, of D with respect to P to be the set of all points of P that can see two points of D at a right angle. Its boundary equals the photographer's path. In the indoor setting, the angle hull $\mathcal{AH}(D)$ depends only on the relative convex hull, $\mathcal{RCH}(D)$, of D; in other words $\mathcal{AH}(D) = \mathcal{AH}(\mathcal{RCH}(D))$.

In section 3 we show that the angle hull can have at most twice the perimeter of D.

Coming back to our exploration strategy, the crucial observation is that its path is essentially an angle hull (AH).

LEMMA 2.1. *Assume the robot starts at the base point and invokes procedure ExploreRightVertex. Suppose this procedure terminates with the robot reaching the cut of target vertex r_1 at point c. Then the shortest path, R, inside P from the base point to the cut also reaches the cut at c. Moreover the robot's path is part of the boundary of the angle hull $\mathcal{AH}(R)$ of R except for straight line segments leading to blocking vertices.*

Proof. In the discussion of procedure *ExploreRightVertex* above in this section, we have already shown that the robot's path and the shortest path to the cut arrive at the same point c.

Now let t be a point on the robot's path that is not contained on a straight line segment of the path. Assume that, at t, the robot is exploring right reflex vertex r_2, as in the example shown in Figure 2.3. Since r_2 and r_1 are in convex position relative to the base point, vertex r_2 lies on the shortest path, R, from the base point to r_1.

Now consider the shortest path, T, from the base point to t. As a consequence of rule 2 and by Thales' theorem, the last line segment, E, of T is perpendicular to the line through t and r_2. Since the backward prolongation of E is bound to hit R, we know that point t can see two points of R at a right angle. Thus, t belongs to the angle hull $\mathcal{AH}(R)$; it lies on the boundary because the angle's sides are both touching reflex vertices of P or endpoints of the path R. □

To estimate the length of the path from the base point to the cut we make use of the analysis of the angle hull from section 3.

LEMMA 2.2. *The robot's path from the base point to the cut of the target vertex explored by procedure ExploreRightVertex is not longer than twice the length of the shortest path.*

Proof. If the robot's path contains straight line segments leading to blocking vertices, like the segment from b to l in Figure 2.3, these segments are replaced by circular arcs in the angle hull $\mathcal{AH}(R)$. Thus, the robot's path to the cut of r_1 cannot be longer than the angle hull's perimeter. If it ends at the point r_1 itself, as in Figure 2.3, we can apply Theorem 3.5—which states that the arc length of the angle hull of a polygon D in P is less than twice as long as D's boundary—to the shortest path as D and obtain the desired upper bound.

If the robot reaches the cut of r_1 at some point different from r_1, we can arrive at the same conclusion using Corollary 3.6. □

It is important to note that procedure *ExploreRightVertex* ignores such vertices as h in Figure 2.3, whose shortest paths from the current stage point include left turns. Otherwise, it would not be clear how to apply Lemma 2.1.

There is a symmetric procedure *ExploreLeftVertex* which is identical to *ExploreRightVertex*, except that left/right and clockwise/counterclockwise are exchanged.

2.2. Exploring a group of vertices. Each exploration of a group of vertices starts from a *stage point*. The importance of stage points lies in the fact that they are visited by the optimum watchman tour, W_{opt}, too. The first stage point encountered is the robot's start point, s. All stage points are vertices of the shortest path tree of s; the shortest path from s to any vertex of a group leads through the group's stage point.

The exploration of a group of right vertices is performed by procedure *ExploreRightGroup*.

```
PROCEDURE ExploreRightGroup ( in TargetList, out ToDoList );
  StagePoint := CP;
  ToDoList := empty list;
  while TargetList is not empty do
    ExploreRightVertex (TargetList, ToDoList );
      (* CP is now on the cut, C, of the last target. *)
    walk to the point on C that is closest to StagePoint
      while maintaining TargetList and ToDoList;
  walk on the shortest path back to StagePoint;
end ExploreRightGroup;
```

The stage point of a right group is always a left vertex. Initially, *ToDoList* is empty, whereas *TargetList* contains a sorted list of unexplored right vertices whose shortest path from the base point makes only right turns. Among them are all unexplored right vertices visible from *StagePoint*.

Roughly, the group exploration proceeds by repeatedly calling procedure *ExploreRightVertex* introduced in section 2.1 until *TargetList* becomes empty. Afterwards, all right vertices initially present in *TargetList* have been explored, together with their *purely right descendants* in the shortest path tree of s. Here, vertex w is called a *purely right* descendant of vertex v in the shortest path tree of s if w is a right vertex and if the path from v to w makes only right turns. This set of vertices constitutes a *group*, by definition.

On returning from a call to *ExploreRightVertex* the robot has just explored the clockwise first vertex of *TargetList* and is now situated on this vertex's cut. Before it continues, the robot walks along this cut to the point closest to the stage point; this will be the base point in the next execution of *ExploreRightVertex*. The reason for this step will become clear in the proof of Lemma 2.5; essentially, it keeps the robot closer to the optimum watchman tour.

Once the last vertex of *TargetList* has been explored, the robot walks back to the stage point, thus completing the exploration of the group. Now *ToDoList* contains, of all right vertices explored, those who have left children, together with references to the latter.

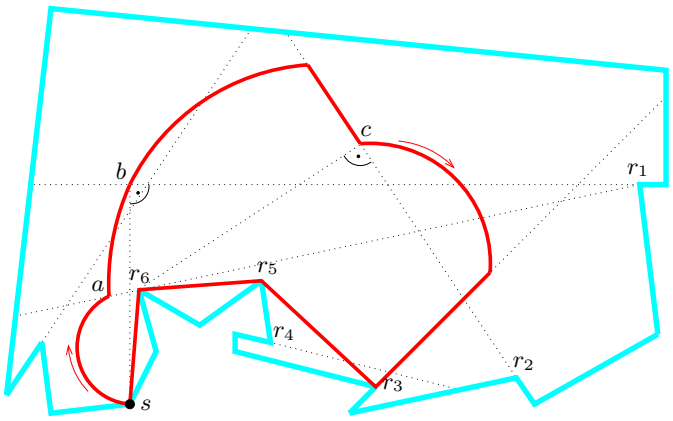

FIG. 2.6. *Exploring a group of right vertices.*

For an example, see Figure 2.6. Point s is the stage point and also the first base point, and *ExploreRightVertex* is called with *First* (*TargetList*) $= r_6$. While exploring r_6, point r_1 is discovered at point a and becomes *First* (*TargetList*). At $CP = b$ procedure *ExploreRightVertex* returns. Meanwhile, r_2 and r_5 have been added to *TargetList* while r_1 and r_6 have been removed. Point b is also the closest point to s on the current cut.

As we continue with exploring *First* (*TargetList*) $= r_2$, point r_5 gets explored on the way. Once the cut of r_2 is reached, we walk to c, the closest point to s on the cut. Similar for r_3; while walking along the cut to the point closest to s, which is r_3 itself, r_4 gets explored and no unexplored right vertices remain.

As before with *ExploreRightVertex*, for *ExploreRightGroup* we also have a symmetric counterpart, *ExploreLeftGroup*.

First we prove a useful structural result which says that the shortest paths to the base points fan out in the same order as the base points are generated.

LEMMA 2.3. *Suppose that procedure ExploreRightGroup generates the base points* $b_1, \ldots, b_m$ *in* m *consecutive calls of subroutine ExploreRightVertex. Then the*

shortest paths from the stage point to $b_1, \ldots, b_m$ are in clockwise order.

Proof. Let base point b_i be situated on the cut of right reflex vertex v_i. Since each call to *ExploreRightVertex* explores the clockwise first right vertex that is still unexplored, $v_1, \ldots, v_m$ appear in clockwise order on the boundary. The stage point must be situated below the cuts of v_i and v_{i+1} as these are unexplored right vertices. The same holds for the last point, p, the shortest paths from the stage point to b_i and b_{i+1} have in common. Moreover, b_i must be below the cut of v_{i+1} because the latter is still unexplored when the robot reaches b_i; see Figure 2.7. Since neither of the shortest paths nor the cut between v_i and b_i can be penetrated by the polygon's boundary, the claim follows. □

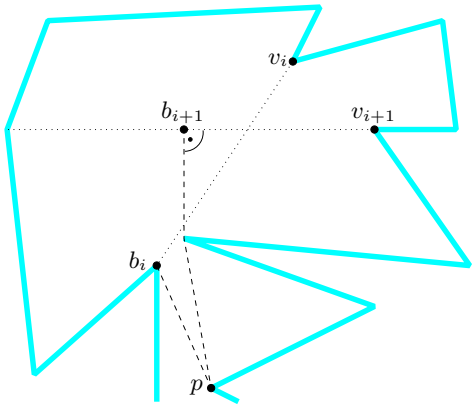

FIG. 2.7. *As seen from p, the shortest path to b_i runs to the left of the shortest path to b_{i+1}.*

Now we turn to analyzing the length of the path the robot spends on exploring a group of vertices.

LEMMA 2.4. *The robot's path between two consecutive base points is at most 3 times as long as the shortest path.*

Proof. Let us call the base points b_1 and b_2, and let c be the point where $cut(v_2)$ is reached. Then c is also the cut's closest point to b_1, by Lemma 2.1. By Lemma 2.2, the robot's path to c is not longer than twice the length of the shortest path from b_1 to c and therefore is also not longer than twice the length of the shortest path from b_1 to b_2; see Figure 2.8.

It remains to account for the walk along the cut from c to b_2. This line segment can be orthogonally projected onto the shortest path from b_1 to b_2 and, therefore, it must be shorter.

Observe that Figure 2.8 is in fact generic: As seen from s, the shortest path to b_1 runs to the left to the shortest path to b_2, by Lemma 2.3; base point b_1 must be located below the cut of v_2; the shortest paths from b_1 to c and from s to b_2 cannot cross because they are both shortest paths to this cut. □

The next steps consist of comparing the length of an *ExploreRightGroup* tour with the relative convex hull of the base points visited.

LEMMA 2.5. *The length of a path caused by a call to ExploreRightGroup does not exceed $3\sqrt{2}$ times the perimeter of the relative convex hull of the base points visited.*

Proof. Let sp be the stage point and $sp = b_0, \ldots, b_{m-1}, b_m = sp$ be the sequence of base points visited by *ExploreRightGroup*. Due to Lemma 2.3, $b_1, \ldots, b_{m-1}$ appear in clockwise order as leaves of the shortest path tree from sp to $b_1, \ldots, b_{m-1}$. So, even

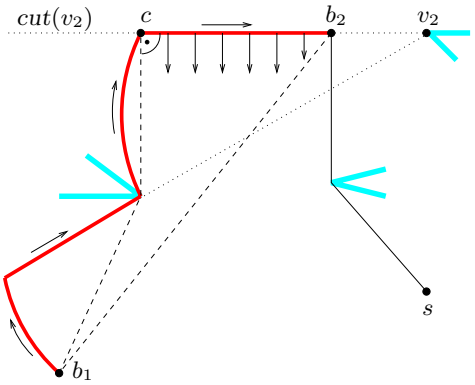

FIG. 2.8. *Line segment $c\,b_2$ must be shorter than the shortest path from b_1 to b_2.*

factor 3 of Lemma 2.4 would apply if all base points b_i were vertices of their relative convex hull, $\mathcal{RCH}$, in P. In the following we show how to reduce to this case.

Suppose that for $i \leq k-2$ the base points b_i and b_k are situated on the boundary of $\mathcal{RCH}$ and the points $b_{i+1}, \ldots, b_{k-1}$ in between are not. The shortest path from *sp* to the cut of each of them must have a right angle to the cut because of Lemma 2.1; see Figure 2.9.

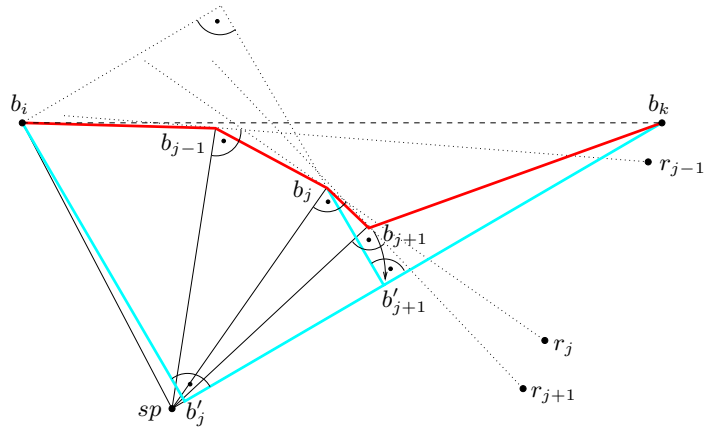

FIG. 2.9. *The cut of vertex r_j containing the base point b_j must not intersect the shortest path from sp to b_{j-1}.*

For $i < j < k$, the cut of b_j must pass above b_{j-1} because otherwise its cut would intersect every possible path from s to b_{j-1}, in particular the robot's path, contradicting the fact that vertex r_j is explored *after* r_{j-1}.

While maintaining these properties, we move the base points one after the other such that the path $b_i, \ldots, b_k$ becomes even longer. For all vertices v of this path, starting with b_{k-1} and going back to b_{i+1}, we do the following. If the path from b_i to b_k makes a left turn at v, like at b_{j+1} in Figure 2.9, then we move v to the point on the shortest path from *sp* to v's successor such that the left turn is a right angle; see b'_{j+1}. Note that every left turn must be an obtuse angle which again is due to the fact that the cut of b_j must pass above b_{j-1}. In case of a right turn we do nothing. Eventually, we end up with a path whose left turns are all right angles.

Now a maximal sequence of right turns, in the example the chain from b_i to b'_{j+1}, can be replaced by one left turn of 90° which is clearly longer than the chain, see b'_j and the rectangle with vertices b_i, b'_j, and b'_{j+1}. Finally, no right turn remains and the new path makes only one left turn of 90° for which the claim is obvious. □

In relating the robot's path to the optimum watchman tour, the following lemma is crucial.

LEMMA 2.6. *All base points are contained in the angle hull* $\mathcal{AH}(W_{opt})$.

Proof. A base point b is, by definition, the closest point to s of a cut. The optimum watchman tour W_{opt} connects the start point s to the cut. Let E be the last edge of the shortest path from s to the cut, i.e., to b.

In most cases, edge E is orthogonal to the cut. Then we have a right angle at b whose one side goes along the cut and touches W_{opt}, while the other side K extends edge E. Either the other endpoint of E equals s, so that K touches W_{opt} in s, or K separates s and the cut because P is simple, and W_{opt} must also be touched by K.

In the remaining case, when there is no right angle between edge E and the cut, point b must be one endpoint of the cut, i.e., it is the target vertex itself or the other endpoint. In both cases the inner angle between E and the cut is necessarily greater than 90°, otherwise there would be a shorter path to the cut. As before either E or its extension meets W_{opt}. □

2.3. Subdividing the polygon. Now we want to combine the exploration of several groups of vertices to finally explore the whole polygon P. This is done by making the *ExploreGroup*-procedures recursive.

```
PROCEDURE ExploreRightGroupRec ( in TargetList );
  ExploreRightGroup ( TargetList, ToDoList );    (*  ToDoList gets filled in. *)
  Clean up ToDoList:
    retain only those right vertices in ToDoList
    which are highest up in the shortest path tree;
  for all vertices v of ToDoList in clockwise order do
    walk on the shortest path to v;    (* connect stage points *)
    ExploreLeftGroupRec( {all known left descendants of v in counterclw. order} );
end ExploreRightGroupRec;
```

The task of *ExploreRightGroupRec* is to explore, from the current position *CP*, all vertices in the input parameter *TargetList* and everything behind.

ExploreRightGroupRec performs in three steps. The *TargetList* is handed over to *ExploreRightGroup*, so *CP* is the new stage point, and after the exploration we are back at this point. We are given a *ToDoList* of candidates for stage points in recursive explorations.

The next step is a necessary cleanup for the *ToDoList*, which contains all purely right descendants of the current stage point which have left children. Some of these right vertices are descendants of others in this list; they must be removed from the list. Only maximal (highest up) right vertices are retained; these will become stage points in further steps. To each of these future stage points we associate a list of all known left descendants that were referenced in *ExploreRightVertex* and *ExploreRightGroup*.

Finally, the remaining vertices in *ToDoList* are visited in clockwise order, at each vertex procedure *ExploreLeftGroupRec* is called to explore the list of all known left descendants (as *TargetList*) from there. *ExploreLeftGroupRec* is the symmetric counterpart of *ExploreRightGroupRec* with one particularity. In the **for** loop, the

vertices in *ToDoList* are also visited in clockwise order. The reason for this will become clear in the proof of Theorem 2.10.

To conclude the bottom-up presentation of our strategy, we show the main program. Its task is, of course, to explore a given polygon, P, starting at a boundary point, s. First, in a call to the nonrecursive *ExploreRightGroup*, the right vertices visible from s are explored. The next target list contains all left children of the right vertices just explored and the left vertices visible from s. All these, and everything behind, gets explored by a call to the recursive *ExploreLeftGroupRec* with this target list.

PROCEDURE *ExplorePolygon* (**in** P, **in** s);

ExploreRightGroup ({clockwise list of all right vertices visible from s}, *ToDoList*);

TargetList := {all left children of the vertices of *ToDoList*};

Add all left vertices visible from s into *TargetList* and sort counterclockwise;

ExploreLeftGroupRec (*TargetList*);

end *ExplorePolygon*;

Each call of *ExploreRightGroup* or *ExploreLeftGroup* generates a set of base points; the first base point of the set is the stage point. For estimating the length of the complete tour, we distribute all these sets into three categories.

The set of base points generated by the call of *ExploreRightGroup* in *ExplorePolygon* belongs to category 0. For the remaining sets, we use their level of recursion to determine their category: the set of base points generated by a call of *ExploreRightGroup* or *ExploreLeftGroup* at total recursion depth i belongs to category (i mod 3).

For example, the very first call of *ExploreLeftGroup* belongs to category 1, and the calls of *ExploreRightGroup* one level deeper belong to category 2. All calls of *ExploreLeftGroup* have an odd level, and all calls of *ExploreRightGroup* an even level.

A key observation is that two sets of base points of the same category will be mutually invisible; see Lemma 2.7 below. Thus the three categories will contribute a factor of 3 to the final analysis in Theorem 2.10 below.

One might wonder why the first nonrecursive call of *ExploreRightGroup* in procedure *ExplorePolygon* is necessary. Without this call the right vertices visible from s, and everything behind, would not be explored because procedure *ExploreLeftGroupRec* deals exclusively with left vertices visible from s and recursively with their offspring.

LEMMA 2.7. *The relative convex hulls of two sets of base points of the same category are mutually invisible, with a possible exception for their stage points.*

Proof. The recursion depths of two sets of base points, B_1 and B_2, of the same category differ by a multiple of 3, possibly 0, as explained above. Let $s_1 \neq s_2$ be the stage points of B_1, resp., B_2. We distinguish two cases depending on the shortest paths from s to s_1 and s_2.

If stage point s_1 is not on the shortest path from s to s_2 and vice versa then let s_0 be the vertex where the shortest paths from s to s_1 and s_2 separate. Without loss of generality we assume that s_2 is a left vertex and that the clockwise order on the boundary is s_0, s_1, s_2. The left picture in Figure 2.10 shows such a situation.

The base points of B_2 are on cuts of right vertices whose shortest paths from s_0 all pass through s_2. Therefore, the shortest path from s_0 to s_2 is invisible from any point of B_2, except s_2. But this shortest path separates B_2 from B_1, they are therefore mutually invisible, except for s_1 and s_2. This argument easily extends to the convex hulls as well.

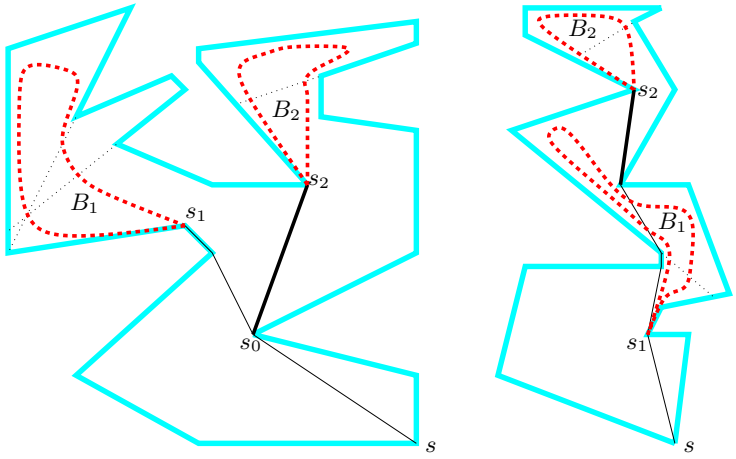

FIG. 2.10. *Base points in B_2 cannot see B_1, two cases.*

Otherwise assume that s_1 lies on the shortest path from s to s_2, see the right picture in Figure 2.10. Then the recursion depths of B_1 and B_2 differ by at least three. Similar to the previous case, no point of B_2 can see the shortest path from s_2 to its parent stage point, but this path definitely separates B_1 and B_2.

Note that a difference of three levels is really necessary. If B_2 is only two levels deeper than B_1 then the stage points s_1 and s_2 are of the same type and the parent stage point of s_2 can be a direct descendant of s_1, and therefore it can very well be contained in $\mathcal{RCH}(B_1)$. □

As a consequence, we conclude that the union of all base points of one category has no shorter perimeter than the perimeters of all of its sets of base points together. Let $\mathrm{per}(\mathcal{RCH}(A))$ denote the perimeter of the relative convex hull of set A.

LEMMA 2.8. *Let B_1 and B_2 be two sets of base points of the same category. Then we have $per(\mathcal{RCH}(B_1)) + per(\mathcal{RCH}(B_2)) \le per(\mathcal{RCH}(B_1 \cup B_2))$.*

As a consequence, we can estimate the path length caused by all calls of *ExploreRightGroup* or *ExploreLeftGroup* in the same category.

LEMMA 2.9. *The path length caused by all calls of ExploreRightGroup and ExploreLeftGroup in one category is less than $6\sqrt{2} \le 8.5$ times the length of W_{opt}.*

Proof. Let the category consist of sets B_i, $i = 1, \ldots,$ of base points. By Lemma 2.5, the length of the path created by one call of *ExploreRightGroup* or *ExploreLeftGroup* with set B_i is not greater than $3\sqrt{2}\,\mathrm{per}(\mathcal{RCH}(B_i))$.

The relative convex hulls $\mathcal{RCH}(B_i)$ are mutually invisible (Lemma 2.7); hence we conclude from Lemma 2.8 for the path length, L, caused by all calls of *ExploreRightGroup* or *ExploreLeftGroup* of this category,

$$L \le 3\sqrt{2} \sum_i \mathrm{per}(\mathcal{RCH}(B_i)) \le 3\sqrt{2}\,\mathrm{per}\left(\mathcal{RCH}\left(\bigcup_i B_i\right)\right).$$

All base points considered are contained in the angle hull of W_{opt}, as Lemma 2.6 has shown, hence the perimeter of their relative convex hull is shorter than the perimeter of $\mathcal{RCH}(\mathrm{AH}(W_{opt}))$.

The perimeter of $\mathcal{RCH}(\mathrm{AH}(W_{opt}))$ is not longer than the perimeter of the angle hull of W_{opt} itself. By Theorem 3.5 this is not greater than twice the length of W_{opt} and the claim follows. □

As the main result for our complete strategy, we obtain a factor of 26.5.

THEOREM 2.10. *For a polygon, P, and a start point s on the boundary of P, a procedure call ExplorePolygon(P, s) explores the polygon and returns to s. The total path length used is less than $(18\sqrt{2}+1) \leq 26.5$ times the length of the optimum watchman tour from s.*

Proof. Since we have three categories of base point sets, all *ExploreRightGroup* and *ExploreLeftGroup* calls together cause a path length of less than $3 \cdot 6\sqrt{2}|W_{opt}|$.

It remains to bound the path length caused by the walks during the **for** loops of *ExploreRightGroupRec* and *ExploreLeftGroupRec*. They connect only stage points by shortest paths, and all those stage points are visited in clockwise order along the boundary of P, independently of whether this is done in *ExploreRightGroupRec* or *ExploreLeftGroupRec*.

The optimum watchman path visits all stage points, and some of them even twice. In any case the sequence of stage points as they appear on the boundary of P is a subsequence of the boundary points of P that are visited by W_{opt} because W_{opt} can not properly cross itself. Therefore, we can be sure that all those walks together make up for an additional path length of at most $|W_{opt}|$. □

3. The angle hull. In on-line navigation algorithms for autonomous robots, analyzing the length of the robot's path is often a complicated issue. Sometimes, only the discovery of certain structural properties has led to a reasonably sharp analysis; see [1, 18, 19, 20] and Rote [24].

Here we provide a new result of this type. It is crucial in analyzing our on-line strategy of section 2, and it seems also to be interesting in its own right.

For convenience, we repeat the definition of the angle hull. Let D be a simply connected region contained in a simple polygon P, then the angle hull, $\mathcal{AH}(D)$, of D with respect to P consists of all points of P that can see two points of D at a right angle. Note that D itself is included in $\mathcal{AH}(D)$. The boundary of the angle hull was denoted the photographer's path of D in section 2.1; for an example see Figure 2.5.

We are now going to analyze the length of the photographer's path, i.e., the perimeter of the angle hull. In section 3.1 we show that, in the indoor setting, the angle hull may have twice the perimeter of D, in the limit. Then, in section 3.2, we prove that this is the worst that can happen.

3.1. The lower bound. We start with the proof that the angle hull of a set D contained in a polygon P can be twice as long as the perimeter of D. Our construction is rather simple, D is a line segment and P is a jagged halfcircle. Region D is called *relatively convex* iff $D = \mathcal{RCH}(D)$.

LEMMA 3.1. *Let $\varepsilon > 0$. There is a polygon, P, and a relatively convex region, D, inside P, for which the boundary of the angle hull $\mathcal{AH}(D)$ with respect to P is longer than $2 - \varepsilon$ times the boundary of D.*

Proof. As our region D, we take a horizontal line segment of length 1. Let p_0, $\ldots$, p_n be equidistant points on the halfcircle spanned by D, where p_0 and p_n are the endpoints of D; see Figure 3.1. From each point p_i we draw the right angle to the endpoints of D. Let P be the concatenation of the upper envelope of these angles and its reflection at D. Then we have $P = \mathcal{AH}(D)$ by construction. Let us analyze the upper envelope.

We will show that the length of the jagged line from p_0 to p_n is less than 2, but comes arbitrarily close to 2, as n increases. Let q_i be the intersection of the segments $p_0\,p_{i+1}$ and $p_i\,p_n$. If we rotate, for all i, the ascending segments $q_i\,p_{i+1}$ about p_0 onto D (see the dotted arcs in Figure 3.1), these segments cover disjoint pieces of D,

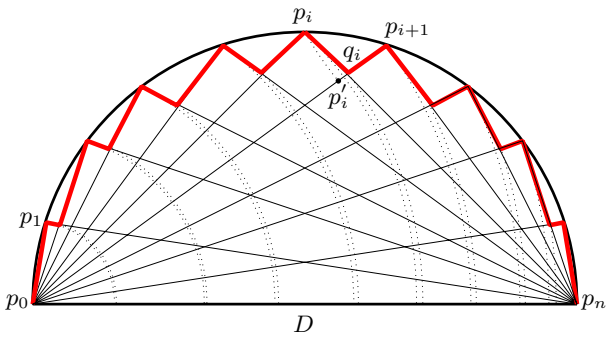

FIG. 3.1. *The boundary of the upper envelope of the right angles is less than* $2|D|$.

so the total length of all ascending segments is always less than 1. By symmetry, the same bound holds for the descending segments. It remains to show that the ascending length can come arbitrarily close to 1.

Consider the triangle $p_i\, q_i\, p'_i$, where p'_i is the orthogonal projection of p_i onto $p_0\, q_i$. Point p_0 is closer to p'_i than to p_i, so for the distances from p_0 to p_i and to q_i we have

$$|p_0\, q_i| - |p_0\, p_i| \le |p_0\, q_i| - |p_0\, p'_i| = |p'_i\, q_i| = |p_i\, q_i| \sin\frac{\pi}{2n}.$$

The total length of all ascending segments is therefore 1 minus the following rest:

$$\sum_i (|p_0\, q_i| - |p_0\, p_i|) \le \sin\frac{\pi}{2n} \sum_i |p_i\, q_i| \le \sin\frac{\pi}{2n}.$$

For $n \to \infty$, this tends to 0. The last inequality holds because $\sum_i |p_i\, q_i| \le 1$ is the length of all descending segments. □

The proof also works for nonequidistant points as long as the maximum distance between subsequent points tends to 0. We are obliged to Seidel [26] for this elegant proof of Lemma 3.1.

3.2. The upper bound. Interestingly, the same jagged lines as used in the proof of Lemma 3.1 are also very useful in the proof of the upper bound. For any circular arc C we can construct a jagged line by distributing auxiliary points along C and by taking the upper envelope of the right angles at these points whose sides pass through the two spanning vertices of C; see Figure 3.2. We denote with *jagged length*, $J(C)$, of C the limit of the lengths of these jagged lines as the maximum distance between subsequent points tends to 0. This limit is well defined, i.e., it does not depend on how the points are chosen. In the proof of Lemma 3.1 we have already seen how to determine this length by separately estimating the lengths of the ascending and descending segments. For the jagged length of a circular arc with diameter 1 from angle α to angle β (see Figure 3.2), we obtain analogously to the proof of Lemma 3.1

$$J(C) = \sin\beta - \sin\alpha - \cos\beta + \cos\alpha,$$

which can also be written as

$$J(C) = \int_\alpha^\beta (\cos\gamma + \sin\gamma)\, d\gamma\,.$$

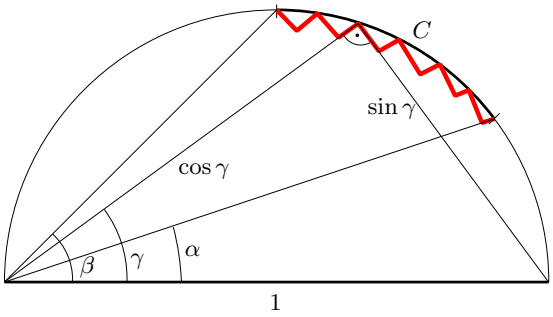

FIG. 3.2. *Analyzing the jagged length, $J(C)$, of a circular arc C.*

LEMMA 3.2. *The jagged length of an arc is always greater than the arc length itself.*

Proof. Consider a circle with diameter d and a circular arc a on its boundary. Two lines from an arbitrary point on the boundary through the endpoints of the arc always intersect in the same angle ϕ, by the generalized Thales's theorem. For the length of a, we have $|a| = \phi d$; see Figure 3.3.

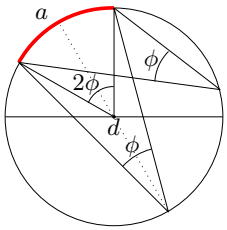

FIG. 3.3. $|a| = \phi d$.

So the arc length of the arc C in Figure 3.2 equals $\beta - \alpha$, and we have

$$J(C) = \int_\alpha^\beta (\cos\gamma + \sin\gamma)\, d\gamma \geq \int_\alpha^\beta 1\, d\gamma = \beta - \alpha\,;$$

the inequality follows from $\cos\gamma + \sin\gamma \geq 1$ for $\gamma \in [0, \frac{\pi}{2}]$. □

The integral form for the jagged length also has a geometric interpretation. Let us consider a right angle with slope γ contained in the halfcircle, as shown in Figure 3.2. The length of the two sides of the right angle equals $\cos\gamma + \sin\gamma$. If we define

$$C_\gamma := \begin{cases} \text{length of the right angle} & \text{if its apex is contained in } C, \\ 0 & \text{otherwise,} \end{cases}$$

we obtain the nice form

$$J(C) = \int_0^{\frac{\pi}{2}} C_\gamma\, d\gamma\,.$$

This form is used in the proof of the next lemma.

LEMMA 3.3. *Let D be a line segment, and let P be a surrounding polygon such that P and the angle hull $\mathcal{AH}(D)$ with respect to P touch only at vertices of P; see*

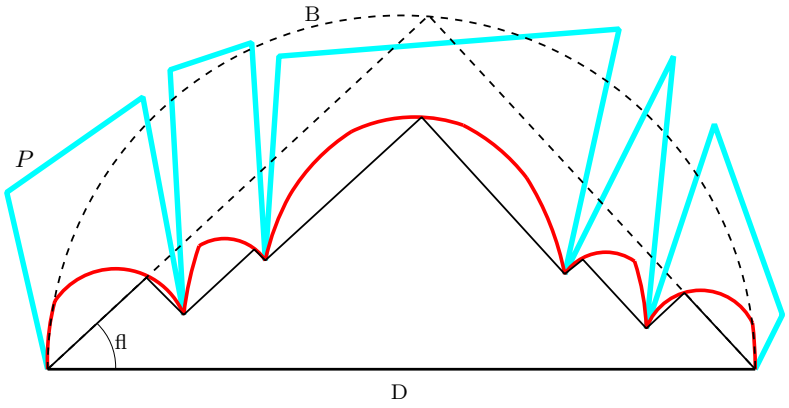

FIG. 3.4. *For a line segment D we have $J(\mathcal{AH}(D)) = J(B) = 2|D|$.*

Figure 3.4. *Then the arc length of $\mathcal{AH}(D)$ with respect to P from one endpoint of D to the other is less than $2|D|$.*

Proof. By Lemma 3.2, the arc length of $\mathcal{AH}(D)$ is certainly shorter than the jagged length of $\mathcal{AH}(D)$, i.e., the sum of the jagged lengths of all circular arcs of $\mathcal{AH}(D)$, and we obtain

$$\begin{aligned} \mathit{length}(\mathcal{AH}(D)) \le J(\mathcal{AH}(D)) &= \sum_{C\in\mathcal{AH}(D)} J(C) \\ &= \sum_{C\in\mathcal{AH}(D)} \int_0^{\frac{\pi}{2}} C_\gamma \, d\gamma = \int_0^{\frac{\pi}{2}} \left(\sum_{C\in\mathcal{AH}(D)} C_\gamma \right) d\gamma \,. \end{aligned}$$

But for any angle γ the sum over the lengths of the right angles of slope γ which are contained in the halfcircles of the different circular arcs of $\mathcal{AH}(D)$ is equal to the length, B_γ, of the big right angle in the halfcircle B spanned by the two endpoints of D, which means that

$$\int_0^{\frac{\pi}{2}} \left(\sum_{C\in\mathcal{AH}(D)} C_\gamma \right) d\gamma = \int_0^{\frac{\pi}{2}} B_\gamma \, d\gamma = J(B) = 2|D| \,. \qquad \square$$

Note that in the proof of Lemma 3.3 the halfcircle B does not depend on P, and $J(\mathcal{AH}(D)) = J(B)$ therefore means that the jagged lengths of the angle hulls of D for different surrounding polygons P are all identical! We may also say that we have bounded the length of the angle hull with respect to a surrounding polygon P by the jagged length of the angle hull without obstacles.

LEMMA 3.4. *The statement of Lemma* 3.3 *remains true if D is a convex chain instead of a line segment.*

Proof. We consider a convex chain, D, and a surrounding polygon, P, such that P and the angle hull $\mathcal{AH}(D)$ with respect to P touch only at vertices of P.

We make a construction similar to the proof of Lemma 3.3. For an angle γ we find the tangent to D with that slope. Starting with the touching vertex we go into direction γ until we hit an arc of the angle hull, then we turn by a right angle and go to the vertex of P (or D) that co-spans the current arc. Here we turn back to the original direction and continue accordingly to obtain a connected chain of right angles; see Figure 3.5.

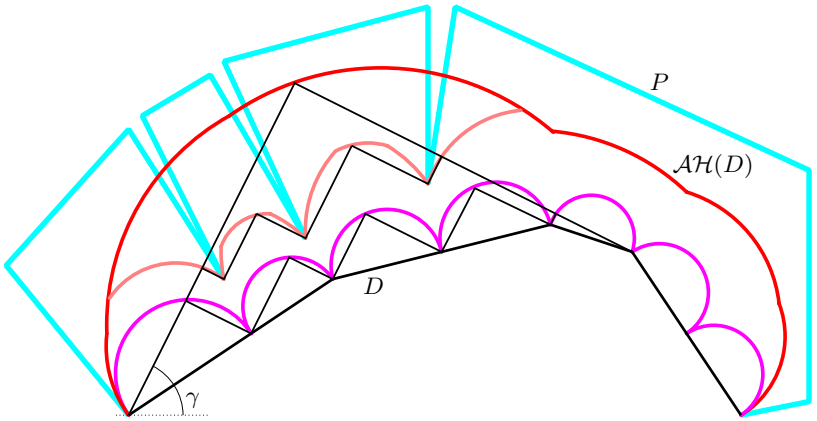

FIG. 3.5. *Three chains of right angles which are all of the same length.*

This chain has the same length as the two sides of the "unfolded" big right angle of slope γ which generates the angle hull without obstacles. As before, this shows that the jagged length of the angle hull does not depend on P.

Now it is not difficult to see how long it really is. Consider the set of halfcircles spanned by the segments of D. Analogously to the previous construction, we can construct the chain of right angles of slope γ below these halfcircles which again has the same length. But these right angles represent the jagged lengths of the isolated segments, and each of them equals twice the length of the segment, by Lemma 3.3. Therefore the total length of the angle hull of D is less than twice the length of D. □

To obtain our main result we need to consider an arbitrary surrounding polygon P that influences the angle hull not only with acute reflex vertices but also with its edges.

THEOREM 3.5. *Let P be a simple polygon containing a relatively convex polygon D. The arc length of the boundary of the angle hull, $\mathcal{AH}(D)$, with respect to P is less than* 2 *times the length of D's boundary. This bound is tight.*

The bound also holds if there are several obstacles instead of P that influence the angle hull and also if their boundaries consist of arbitrary curves.

Proof. Each convex chain of D can be treated separately because the angle hull must pass through the reflex vertices of D.

First, we consider the angle hull $\mathcal{AH}_1(D)$ with respect to only the vertices of P as obstacle points. Its arc length is less than $2|D|$, by Lemma 3.4.

Now also the edges come into play. The angle hull $\mathcal{AH}_2(D)$ with respect to the whole of P contains circular arcs and some pieces of P's edges, for an example see Figure 2.5. The circular arcs of $\mathcal{AH}_2(D)$ are also part of $\mathcal{AH}_1(D)$.

For every piece of an edge which contributes to $\mathcal{AH}_2(D)$, the piece's two endpoints are also on the boundary $\mathcal{AH}_1(D)$. Therefore, $\mathcal{AH}_2(D)$ can only be shorter than $\mathcal{AH}_1(D)$.

The bound is tight by Lemma 3.1.

The proof easily generalizes to the case of several obstacles around D that influence the angle hull instead of P. Indeed, we have never used the fact that the parts of P that are touching the angle hull are connected by edges of P. And if we have several obstacles, we can always connect them to a single one by edges which do not influence the angle hull.

The proof carries over to arbitrary curves by approximation of these curves with polygons. □

The following variation of Theorem 3.5 for an "incomplete angle hull" is used for analyzing the exploration strategy in section 2.

COROLLARY 3.6. *Consider a convex chain, D, from s to t and its angle hull from s to some point g. The jagged length of this part of the angle hull is bounded by twice the length of the shortest path around D from s to g.*

Proof. Let m be the last segment of D and let α be the angle between m and the last segment of the shortest path from s to g; see Figure 3.6.

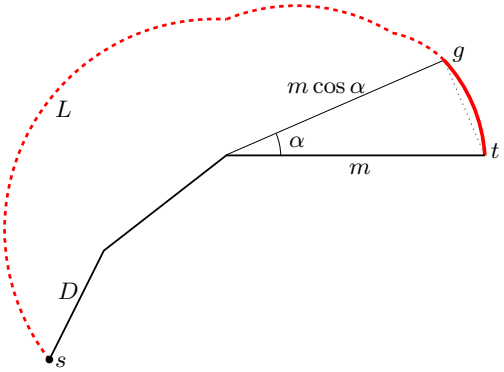

FIG. 3.6. *The cut of r_1 is reached at point g.*

The jagged length of the angle hull from g to t equals $m(1+\sin\alpha-\cos\alpha)$. The path, L, from the base point to g can therefore be estimated in the following way, using Theorem 3.5:

$$\begin{aligned} L &\le 2|D| - m(1+\sin\alpha-\cos\alpha) \\ &= 2(|D| - m + m\cos\alpha) + m(1-\cos\alpha-\sin\alpha) \\ &\le 2(|D| - m + m\cos\alpha). \end{aligned}$$

The last inequality holds because of $0 \le \alpha \le \frac{\pi}{2}$. But $|D| - m + m\cos\alpha$ is exactly the length of the shortest path from the base point to g. □

Remark. The result of Theorem 3.5 can be generalized to angles $\phi \neq 90°$. Namely, for the jagged length of a circular arc C spanned with fixed angle ϕ by a chord of length 1 from angle α to angle β we have

$$J_\phi(C) = (\sin\beta - \sin\alpha - \cos\beta + \cos\alpha)\frac{\cos\phi+1}{\sin^2\phi}$$

from which a tight factor of $2(\cos\phi+1)/\sin^2\phi$ follows; see [16] for this and other interesting extensions. Interestingly, the angle hull with respect to an arbitrary angle has independently been described, in a different context and without estimations about its length, by de Berg et al. [10]—this corresponds to our "outdoor setting"—and in the successor article by Cheong and van Oostrum [8] for the "indoor setting," i.e., with obstacles.

4. Conclusions. We have seen that a combination of suitable analysis techniques is necessary for proving an upper bound for the competitive factor of a rather simple strategy. Still, we believe that its actual performance, even in the worst case,

is considerably better than the proven bound. Establishing a lower bound for polygon exploration, higher than the trivial $(1+\sqrt{2})/2 \approx 1.207$, and closing the gap to the upper bound seem to be challenging problems.

There are many interesting variations and generalizations of the polygon exploration problem. For example, one could study different cost models for the robot's motion. Also, the case of polygons with holes deserves investigation. Here the off-line problem becomes NP-hard, by reduction from the traveling salesperson problem. Recently, Albers, Kursawe, and Schuierer [2] have shown that in a rectilinear environment no better competitive factor than $O(\sqrt{k})$ can be achieved for the on-line problem in the presence of k rectilinear holes, what was known before only for general polygons.

We have also introduced a new type of hull operator that suits us well in analyzing the on-line exploration strategy and that is interesting in its own right. Here we have analyzed the perimeter of the angle hull, $\mathcal{AH}(D)$, in terms of the perimeter of the region D. A number of interesting questions remain open: If we consider a subset of D, is the perimeter of its angle hull always shorter than the perimeter of $\mathcal{AH}(D)$? Does the iterated construction of the angle hull approximate a circle? How can angle hulls be generalized, and analyzed, in three dimensions?

Acknowledgment. We would like to thank the anonymous referees for their valuable comments.

ON THE COMPUTATIONAL COMPLEXITY OF UPWARD AND RECTILINEAR PLANARITY TESTING*

ASHIM GARG† AND ROBERTO TAMASSIA‡

Abstract. A directed graph is upward planar if it can be drawn in the plane such that every edge is a monotonically increasing curve in the vertical direction and no two edges cross. An undirected graph is rectilinear planar if it can be drawn in the plane such that every edge is a horizontal or vertical segment and no two edges cross. Testing upward planarity and rectilinear planarity are fundamental problems in the effective visualization of various graph and network structures. For example, upward planarity is useful for the display of order diagrams and subroutine-call graphs, while rectilinear planarity is useful for the display of circuit schematics and entity-relationship diagrams.

We show that upward planarity testing and rectilinear planarity testing are NP-complete problems. We also show that it is NP-hard to approximate the minimum number of bends in a planar orthogonal drawing of an n-vertex graph with an $O(n^{1-\epsilon})$ error for any $\epsilon > 0$.

1. Introduction.

Graph drawing addresses the problem of constructing geometric representations of abstract graphs and networks [6, 7]. It is an emerging area of research that combines flavors of topological graph theory and computational geometry. The automatic generation of drawings of graphs has important applications in key computer technologies such as software engineering, database design, visual interfaces, and computer-aided design.

Various graphic standards have been proposed for the representation of graphs in the plane. Usually, each vertex is represented by a point and each edge (u, v) is represented by a simple open Jordan curve joining the points associated with vertices u and v. A *straight-line* drawing maps each edge into a straight-line segment. A drawing is *planar* if no two edges cross. A graph (or digraph) is planar if it admits a planar drawing. A drawing of a digraph is *upward* if every edge is monotonically nondecreasing in the y-direction. A drawing of a digraph is *planar upward* if it is planar and upward. A digraph is *upward planar* if it admits a planar upward drawing. Figure 1.1(a) shows a planar straight-line upward drawing. An *orthogonal* drawing maps each edge into a chain of horizontal and vertical segments. A *rectilinear* drawing is an orthogonal straight-line drawing, i.e., a drawing where every edge is either a horizontal or a vertical segment. A graph is *rectilinear planar* if it admits a planar rectilinear drawing. Figure 1.1(b) shows a planar rectilinear drawing.

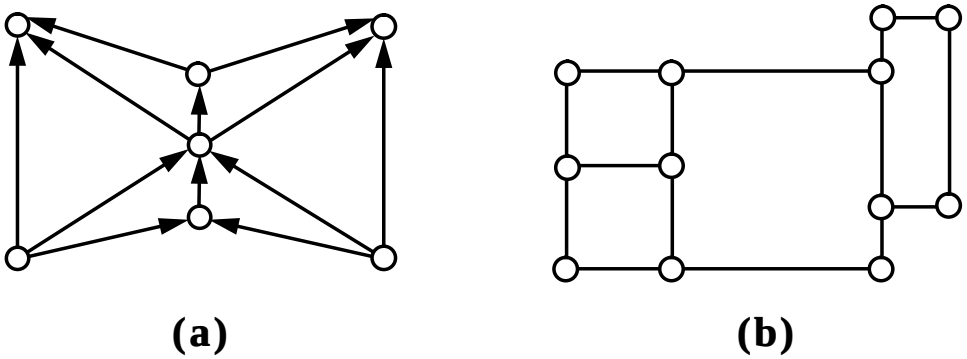

FIG. 1.1. *Examples of* (a) *a planar straight-line upward drawing of a digraph and* (b) *a planar rectilinear drawing of a graph.*

Testing upward planarity and rectilinear planarity are fundamental problems in the effective visualization of various graph and network structures. For example, upward planarity is useful for the display of order diagrams and subroutine-call graphs, while rectilinear planarity is useful for the display of circuit schematics and entity-relationship diagrams. In this paper, we show that the following two problems are NP-complete:

Upward planarity testing. Testing whether a digraph is upward planar.

Rectilinear planarity testing. Testing whether a graph is rectilinear planar.

These problems have challenged researchers in order theory, topological graph theory, computational geometry, and graph drawing for many years. Our intractability results motivate the following observations:

- Testing whether a graph admits a planar drawing or an upward drawing can be done in linear time. Combining the two properties makes the problem NP-hard.
- Every planar graph admits a planar straight-line drawing. Hence, we can say that planarity is equivalent to straight-line planarity, and both properties can be verified in linear time. We can view upward and rectilinear planarity as derived from straight-line planarity by adding further constraints, which apparently make the problem become much more difficult.

We also show that it is NP-hard to approximate the minimum number of bends in a planar orthogonal drawing of an n-vertex graph with an $O(n^{1-\epsilon})$ error for any $\epsilon > 0$.

Previous results on upward and rectilinear planarity testing are summarized below. In the rest of this section, we denote with n the number of vertices of the graph being considered.

Combinatorial results on upward planarity of covering digraphs of lattices were first given in [17, 24]. Further results on the interplay between upward planarity and ordered sets are surveyed by Rival [25, 26, 27]. Lempel, Even, and Cederbaum [18] relate the planarity of biconnected undirected graphs to the upward planarity of *st*-digraphs. A combinatorial characterization of upward planar digraphs is provided in [10, 16]; namely, a digraph is upward planar if and only if it is a spanning subgraph of a planar *st-digraph*. This characterization implies that upward planarity testing is in NP.

Di Battista, Liu, and Rival [9] show that every planar bipartite digraph is up-

ward planar. Papakostas [23] gives a polynomial-time algorithm for upward planarity testing of outerplanar digraphs. Bertolazzi and Di Battista [2] and Bertolazzi et al. [3] give a polynomial-time algorithm for testing upward planarity of triconnected digraphs and of digraphs with a fixed embedding. Concerning single-source digraphs, Thomassen [33] characterizes upward planarity in terms of forbidden circuits. Hutton and Lubiw [14] combine Thomassen's characterization with a decomposition scheme to test upward planarity of a single-source digraph in $O(n^2)$ time. Bertolazzi et al. [4] show that upward planarity testing of a single-source digraph can be done optimally in $O(n)$ time. They also give a parallel algorithm that runs in $O(\log n)$ time on a CRCW PRAM with $n \log\log n / \log n$ processors.

Di Battista and Tamassia [10] and Di Battista, Tamassia, and Tollis [11] give algorithms for constructing upward planar drawings of planar *st*-digraphs and investigate area bounds and symmetry display. Tamassia and Vitter [32] show that the above drawing algorithms can be efficiently parallelized. Upward planar drawings of series-parallel digraphs are studied in [1].

Regarding rectilinear planarity testing, Shiloach [28] and Valiant [34] show that any planar graph of degree at most 4 admits a planar orthogonal drawing. Vijayan and Wigderson [35] study structural properties of rectilinear planar drawings. From their results, the membership of rectilinear planarity testing in NP is easy to establish. Storer [29], Tamassia and Tollis [31], Liu et al. [20], Liu, Morgana, and Simeone [21, 22], Liu, Marchioro, and Petreschi [19], Even and Granot [12], Kant [15], and Biedl and Kant [5] give various techniques for constructing planar orthogonal drawings with $O(n)$ bends. Tamassia [30] gives an $O(n^2 \log n)$-time algorithm that constructs a planar orthogonal drawing with the minimum number of bends for an embedded planar graph. Di Battista, Liotta, and Vargiu [8] give polynomial-time algorithms for minimizing bends in planar orthogonal drawings of series-parallel and cubic graphs. The latter two results show that rectilinear planarity testing can be done in polynomial time for a fixed embedding or for special classes of graphs.

Our proof techniques are based on a two-phase reduction from the known NP-complete problem NOT-ALL-EQUAL-3-SAT. In the first phase, we reduce NOT-ALL-EQUAL-3-SAT to an auxiliary undirected flow problem. In the second phase, we reduce this undirected flow problem to the upward (or rectilinear) planarity testing of a special class of digraphs. The latter reduction is interesting on its own and provides new insights on the characterization by flow networks of the angles formed by the edges of upward planar drawings [2, 3] and orthogonal drawings [8, 30].

The rest of this paper is organized as follows. Preliminary definitions and results are provided in section 2. The reduction from NOT-ALL-EQUAL-3-SAT to the auxiliary flow problem is given in section 3. Sections 4 and 5 describe the reductions from the auxiliary flow problem to upward and rectilinear planarity testing, respectively. Conclusive remarks are given in section 6.

2. Preliminaries. We assume that the reader is familiar with the standard concepts and definitions on NP-completeness [13]. Our results use reductions from the following well-known NP-complete problem:

NOT-ALL-EQUAL-3-SAT. Given a set of clauses with three literals each, is there a truth assignment such that each clause has at least one *true* literal and one *false* literal?

An *embedding* of a planar graph is the collection of circular permutations of the edges incident upon each vertex in a planar drawing of the graph. An *embedded graph* is a planar graph equipped with an embedding. We do not distinguish between a

graph and its embedding if the embedding is unique and the meaning is clear from the context. A vertex has *degree d* if it has d edges incident upon it. A *degree-d* graph is one each of whose vertices has degree at most d.

We denote by $G - \{v\}$ the subgraph of graph G obtained by removing vertex v and its incident edges from G.

The *angles* of an embedded *undirected* graph are the pairs of consecutive edges incident on the same vertex. The *angles* of an embedded *directed* graph are the pairs of consecutive incoming and outgoing edges incident upon the same vertex. Such angles are mapped to geometric angles in a straight-line drawing of the graph.

A *labeled embedding* of an *undirected* graph G is an embedding of G in which each angle is assigned a label from the set $\{1, 2, 3, 4\}$. A *labeled embedding* of a *directed* graph G is an embedding of G in which each angle is assigned a label from the set $\{small, large\}$.

A *rectilinear embedding* of a graph G is a labeled embedding of G such that there exists a rectilinear drawing of G in which each angle labeled ℓ in the embedding measures $\ell\pi/2$ in the drawing. Each rectilinear embedding has a unique external face.

The following definitions are from [2, 3]. An *upward embedding* of a directed graph (digraph) $\vec{G}$ is a labeled embedding of $\vec{G}$ such that there exists a planar straight-line upward drawing of $\vec{G}$ where each angle labeled *small* has measure $< \pi$ and each angle labeled *large* has measure $> \pi$. Each upward embedding has a unique external face.

A *source* of a digraph $\vec{G}$ is a vertex with all outgoing edges, and a *sink* of $\vec{G}$ is a vertex with all incoming edges. A *switch* of $\vec{G}$ is a source or sink of $\vec{G}$. A source or sink of a face f of $\vec{G}$ is called a *local* source or sink of f. Note that a local switch of f may or may not be a switch of $\vec{G}$.

2.1. Upward and rectilinear embeddings. In this section, we give some lemmas on upward and rectilinear embeddings that will be used extensively in the proofs.

We first give some definitions. In an embedding of a digraph $\vec{G}$, a vertex is *bimodal* if its incident edges can be partitioned into two (possibly empty) sets of consecutive edges consisting of its incoming and outgoing edges, respectively. An embedding of $\vec{G}$ is *bimodal* if each vertex is bimodal.

Consider an assignment of labels from the set {*small*, *large*} to the angles of an embedding of $\vec{G}$. For a face f of the embedding, let $L(f)$ and $S(f)$ be the number of angles of f with label *large* and *small*, respectively. Face f is said to be *consistently assigned* if

$$L(f) - S(f) = \begin{cases} -2 & \text{if } f \text{ is an internal face,} \\ +2 & \text{if } f \text{ is the external face.} \end{cases}$$

An assignment of labels to the angles of an embedding of digraph $\vec{G}$ is a *consistent assignment* if

- all the angles at a nonsource or nonsink vertex of $\vec{G}$ are assigned label *small*,
- exactly one angle at a source or sink vertex of $\vec{G}$ is assigned label *large*, and
- each face is consistently assigned.

We paraphrase a result of [2, 3] in the following lemma.

LEMMA 2.1. *An embedding of a digraph $\vec{G}$ can be extended to an upward embedding if and only if it is bimodal and admits a consistent assignment of labels to its angles.*

Let G be an undirected graph of degree at most 4. Consider an assignment of labels from the set $\{1, 2, 3, 4\}$ to the angles of an embedding of G. For a face f of the embedding, let $N_i(f)$ be the number of angles of f with label i. Face f is said to be *consistently rectilinearly assigned* if

$$2 \cdot N_4(f) + N_3(f) - N_1(f) = \begin{cases} -4 & \text{if } f \text{ is an internal face,} \\ +4 & \text{if } f \text{ is the external face.} \end{cases}$$

An assignment of labels to the angles of an embedding of a graph G is a *consistent rectilinear assignment* if

- the sum of the labels of the angles around each vertex is 4, and
- each face is consistently rectilinearly assigned.

The following lemma is an immediate consequence of the results in [30, 35].

LEMMA 2.2. *An embedding of a graph G can be extended to a rectilinear embedding if and only if it admits a consistent rectilinear assignment of labels to its angles.*

2.2. Tendrils and wiggles. We now define several graphs that will be used as gadgets in our reductions.

Tendril T_k, for $k \geq 0$, is an acyclic digraph with two designated poles, a *source pole* denoted by s and a *sink pole* denoted by t, and is defined recursively as follows:

- Tendril T_0 consists of a single directed edge (s, t).
- Tendril T_1 is the 10-vertex graph shown in Figure 2.1(a).
- Tendril T_k is constructed from T_{k-1} by adding the graph H_k shown in Figure 2.1(b) to it by identifying edges (and their endpoints) e_{k-1} of T_{k-1} and f_k of graph H_k (Figure 2.1(c)).

It is easy to see that T_k has exactly $k + 1$ sources and $k + 1$ sinks. Figure 2.2(a) and Figure 2.2(b) show tendrils T_2 and T_3, respectively.

LEMMA 2.3. *Tendril T_k is upward planar and admits a unique upward embedding.*

Proof. We use induction on k. It is straightforward to verify that T_1 has a unique upward embedding by applying Lemma 2.1 to their $O(1)$ planar embeddings. Now suppose that T_{k-1} has a unique upward embedding. Again, it can be easily verified that H_k has a unique upward embedding by applying Lemma 2.1 to its $O(1)$ planar embeddings. Hence, for finding upward embeddings of T_k, we need only to consider the four planar embeddings of T_k obtained by flipping the upward embeddings of T_{k-1} and H_k around their common edge f_k. Applying Lemma 2.1 to the four faces containing both endpoints of f_k shows that only one of these four planar embeddings can be extended to an upward embedding of T_k. □

In the upward planar embedding of T_k, the external face consists of two paths, namely, the *outer* and *inner* paths, between s and t. The outer path has $2k$ large angles and no small angles, and the *inner path* has $2k$ small angles and no large angles. The outer and inner paths of T_2 are drawn with shaded and solid thick lines, respectively, in Figure 2.2(a). When T_k replaces an edge of an embedded planar digraph, the outer (inner) path becomes a subpath of a face f, and we say that the *contribution* of the outer (inner) path to f is $+2k$ $(-2k)$.

Figure 2.2(b) shows a *wiggle* W_k, which consists of a chain of $2k + 1$ edges whose orientations alternate along the chain. The two extreme vertices of W_k are called its *source* and *sink* poles, respectively, and are denoted by s and t, respectively. Later, in section 4, we will consider transformations where a directed edge (u, v) of an embedded digraph is replaced with W_k such that s is identified with u and t with v, and W_k

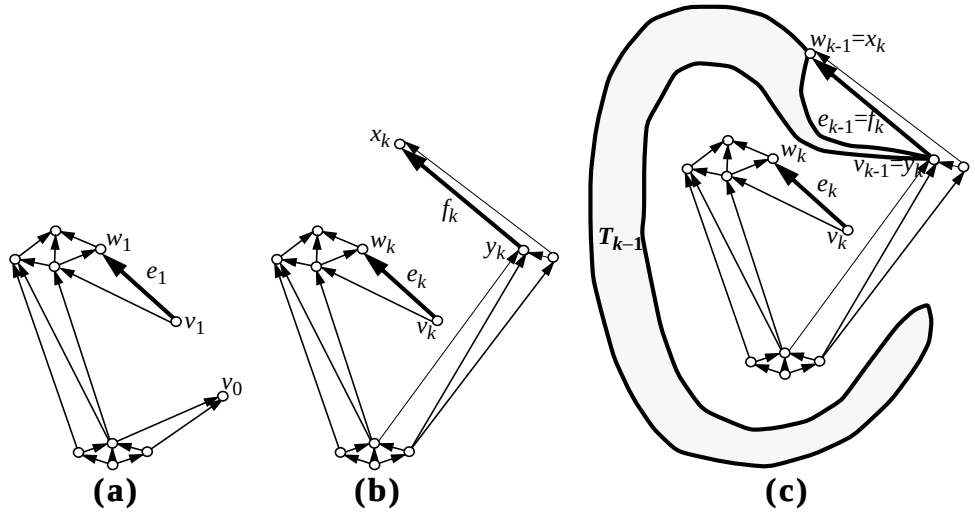

FIG. 2.1. (a) *Tendril* T_1*;* (b) *graph* H_k*;* (c) *constructing* T_k *from* T_{k-1}.

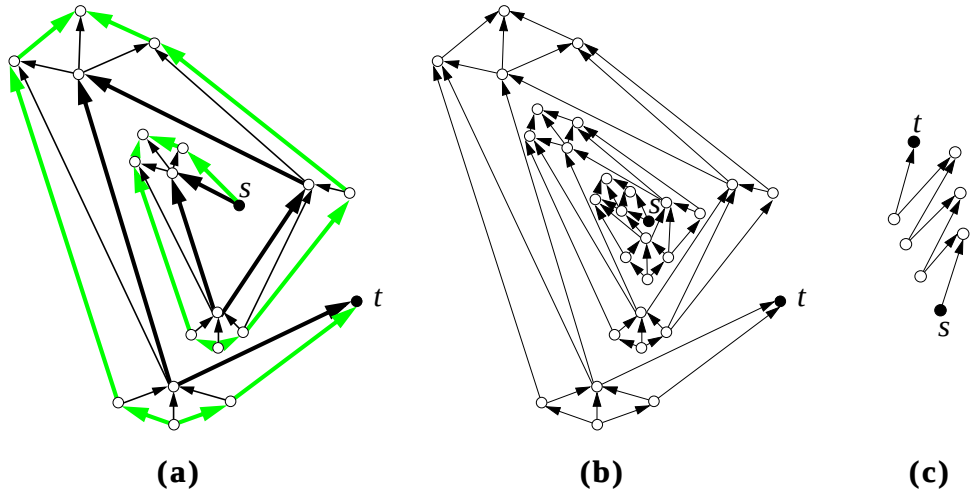

FIG. 2.2. *Examples of tendrils and wiggles:* (a) *tendril* T_2*;* (b) *tendril* T_3*;* (c) *wiggle* W_3*. The outer and inner paths of* T_2 *are drawn using shaded and solid thick lines, respectively.*

becomes a subpath of two faces f_1 and zz_2 in the new digraph. Given an upward embedding of W_k, we say that the *contribution* of W_k to face f_i, where $i = 1$ or 2, is equal to the number of large angles minus the number of small angles of W_k in f_i. Because each angle of W_k in f_i is either large or small, the contribution of W_k to f_i is an even number c, where $-2k \leq c \leq 2k$. Note that if W_k gives contribution c to face f_1 (f_2), it gives contribution $-c$ to face f_2 (f_1).

A *rectilinear tendril* T_k, for $k \geq 0$, is an undirected graph with two designated poles s and t, and is defined recursively as follows:

- T_0 consists of a single edge (s, t).
- T_1 is the 10-vertex graph with poles $s = s_1$ and $t = t_1$ shown in Figure 2.3(a).
- T_k is constructed from T_{k-1} by removing s_{k-1} and its incident edge and

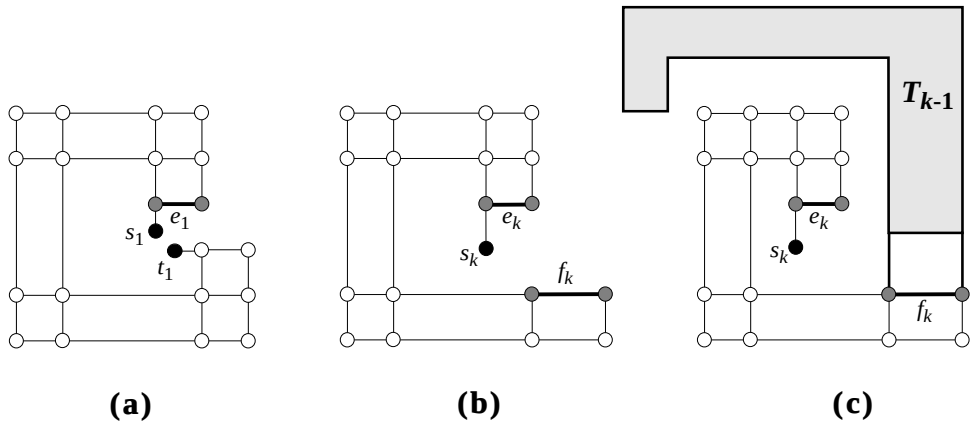

FIG. 2.3. (a) *Rectilinear tendril* T_1*;* (b) *graph* H_k*;* (c) *constructing* T_k *from* T_{k-1}.

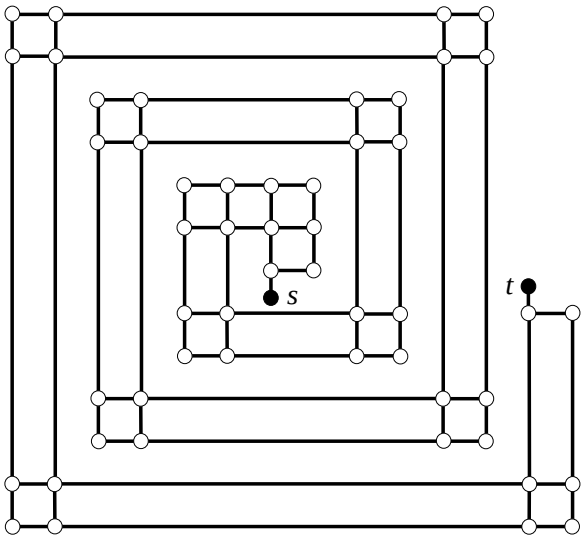

FIG. 2.4. *Rectilinear tendril* T_3.

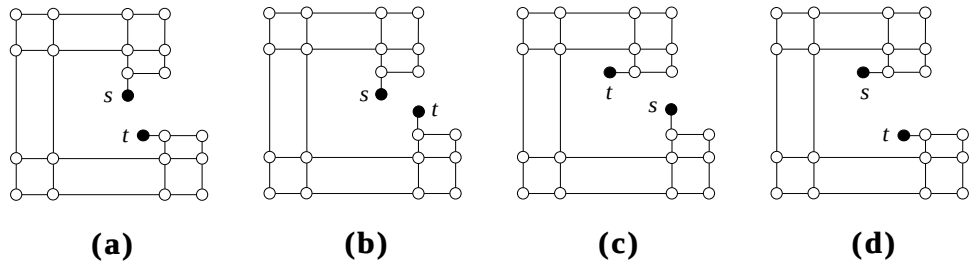

FIG. 2.5. *The four rectilinear embeddings of rectilinear tendril* T_1.

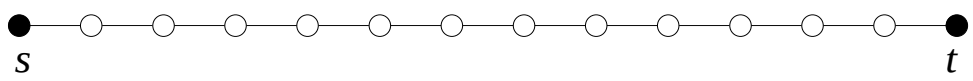

FIG. 2.6. *Rectilinear wiggle* W_3.

adding the graph H_k shown in Figure 2.3(b) to it by identifying its edge e_{k-1} with the edge f_k of H_k (Figure 2.3(c)). The poles of T_k are $s = s_k$ and $t = t_1$. Figure 2.4 shows rectilinear tendril T_3.

LEMMA 2.4. *Rectilinear tendril T_k is rectilinear planar and admits exactly four rectilinear embeddings.*

Proof. The proof has the same flavor as that of the proof of Lemma 2.3. We use induction on k and apply Lemma 2.2. □

Figure 2.5 shows the four rectilinear embeddings of T_1. An *external* path of T_k is a subpath from s to t of its external face in a rectilinear planar embedding of T_k. Notice that T_k has exactly two external paths.

A *rectilinear wiggle* W_k consists of a chain of $4k+1$ edges, and its two end vertices are called the *poles*. Figure 2.6 shows rectilinear wiggle W_3.

Later, in section 5, we will consider transformations where an edge (u, v) of an embedded graph is replaced with a rectilinear tendril T_k or wiggle W_k such that u and v are identified with the poles of T_k or W_k. Let f_1 and f_2 be the two faces of the new graph such that W_k or the external paths of T_k are subpaths of f_1 and f_2. The *contribution* of W_k or T_k to f_1 (f_2) is equal to the number of its angles labeled 3 minus the number of its angles labeled 1 that are in f_1 (f_2). Hence, the contribution of T_k to f_1 (f_2) is an integer c, where c is equal to one of $-(4k+2)$, $-(4k+1)$, $-4k$, $4k$, $4k+1$, and $4k+2$, and the contribution to f_2 (f_1) is $-c$. The contribution of W_k to f_1 (f_2) is an integer c, where $-4k \leq c \leq 4k$, and the contribution to f_2 (f_1) is $-c$.

3. An auxiliary flow problem. In this section, we define two auxiliary flow problems and show that they are equivalent to NOT-ALL-EQUAL-3-SAT under polynomial-time reductions.

A *switch-flow network* is an undirected flow network $\mathcal{N}$, where each edge is labeled with a range $[c' \cdots c'']$ of nonnegative integer values, called the *capacity range* of the edge. For simplicity, we denote the capacity range $[c \cdots c]$ with $[c]$. A *flow* for a switch-flow network is an orientation of and an assignment of integer "flow" values to the edges of the network. A *feasible flow* is a flow that satisfies the following two properties:

Range property. The flow assigned to an edge is an integer within the capacity range of the edge.

Conservation property. The total flow entering a vertex from the incoming edges is equal to the total flow exiting the vertex from the outgoing edges.

Starting from an instance $\mathcal{S}$ of NOT-ALL-EQUAL-3-SAT, we construct a switch-flow network $\mathcal{N}$ as follows (see Figures 3.1–3.2). Let the literals of $\mathcal{S}$ be denoted with $x_1, y_1, \ldots, x_n, y_n$, where $y_i = \overline{x_i}$, and let the clauses of $\mathcal{S}$ be denoted with $c_1, \ldots, c_m$. Let θ be a positive integer parameter. We denote with α_i and β_i (where $i = 1, \ldots, n$) the number of occurrences of literals x_i and y_i, respectively, in the clauses of $\mathcal{S}$. Note that $\sum_{i=1}^{n}(\alpha_i + \beta_i) = 3m$. Also, we define $\gamma_i = (2i-1)\theta$ and $\delta_i = 2i\theta$ ($i = 1, \ldots, n$). Network $\mathcal{N}$ has a *literal vertex* for each literal of $\mathcal{S}$ and a *clause vertex* for each clause of $\mathcal{S}$, plus a special dummy vertex z. There are three types of edges in $\mathcal{N}$ (see Figure 3.2):

Literal edges. Joining pairs of literals associated with the same boolean variable; the capacity range of literal edge (x_i, y_i) is $[\alpha_i\gamma_i + \beta_i\delta_i]$.

Clause edges. Joining each literal to each clause; the capacity range of clause edge (x_i, c_j) is $[\gamma_i]$ if $x_i \in c_j$ and $[0]$ otherwise. The capacity range of clause edge (y_i, c_j) is $[\delta_i]$ if $y_i \in c_j$ and $[0]$ otherwise.

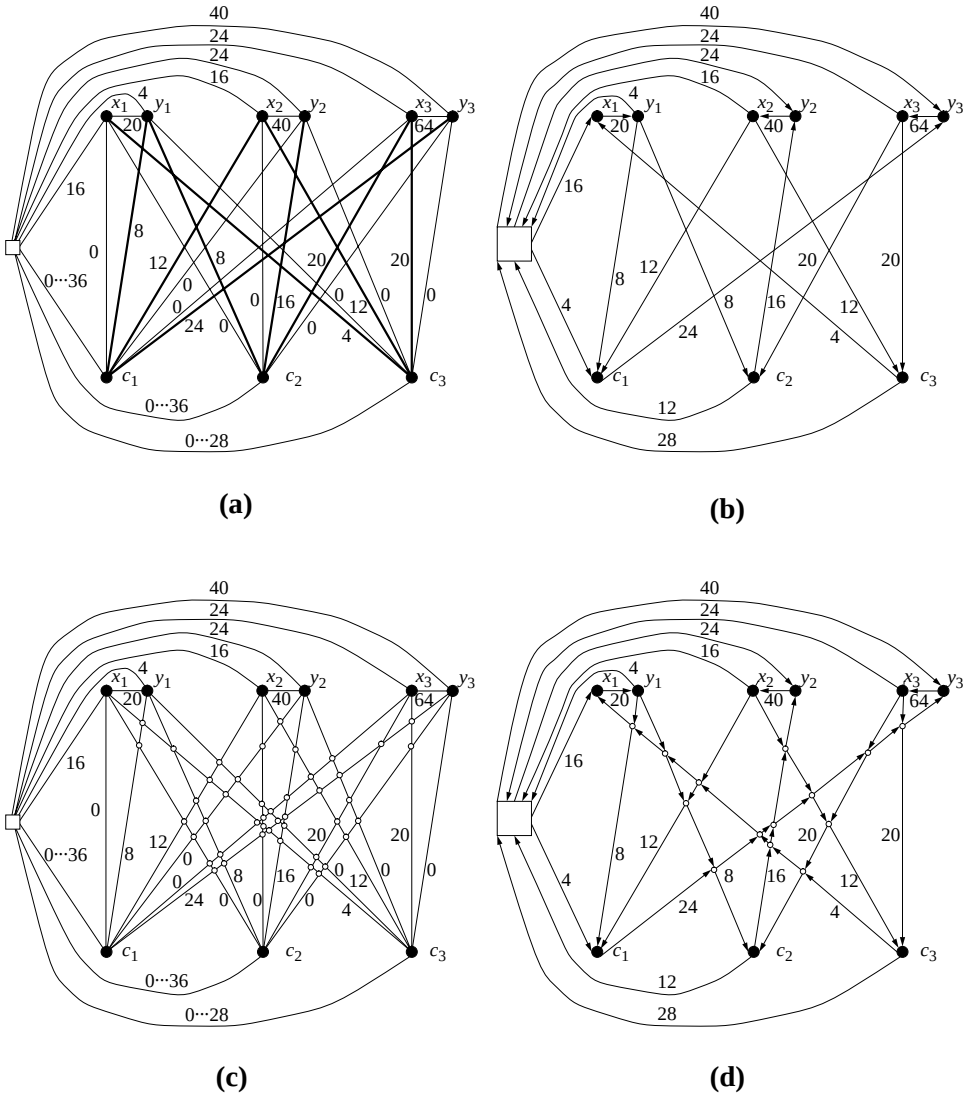

FIG. 3.1. (a) *Switch-flow network $\mathcal{N}$ with parameter $\theta = 4$ associated with the* NOT-ALL-EQUAL-3-SAT *instance $\mathcal{S}$ with clauses $c_1 = y_1x_2y_3$, $c_2 = y_1y_2x_3$, and $c_3 = x_1x_2x_3$. The clause edges with nonzero capacity range are shown with thick lines.* (b) *Feasible flow for $\mathcal{N}$ corresponding to the satisfying truth assignment (y_1, x_2, x_3) for $\mathcal{S}$. Only the edges with nonzero flow are shown.* (c) *Planar switch-flow network $\mathcal{P}$ associated with $\mathcal{S}$.* (d) *Feasible flow for $\mathcal{P}$ corresponding to the satisfying truth assignment (y_1, x_2, x_3) for $\mathcal{S}$. Only the edges with nonzero flow are shown.*

Dummy edges. Joining each literal and each clause to the dummy vertex; the capacity ranges of dummy edges (z, x_i) and (z, y_i) are $[\beta_i\delta_i]$ and $[\alpha_i\gamma_i]$, respectively. The capacity range of dummy edge (z, c_j) is $[0 \cdots \eta_j - 2\theta]$, where η_j is the sum of the capacities of the clause edges incident on c_j.

The construction of network $\mathcal{N}$ from $\mathcal{S}$ is straightforward, and we have the following lemma.

LEMMA 3.1. *Given an instance $\mathcal{S}$ of* NOT-ALL-EQUAL-3-SAT *with n variables and m clauses, the associated switch-flow network $\mathcal{N}$ has $O(n + m)$ vertices and $O(nm)$*

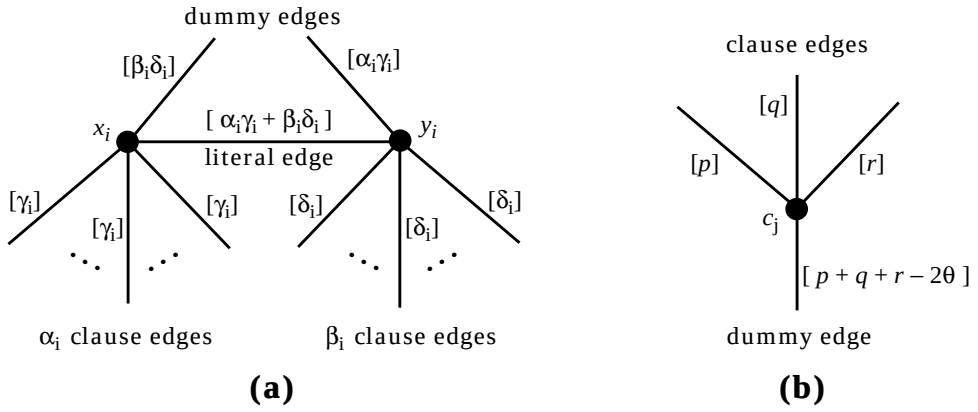

FIG. 3.2. *Schematic illustration of the edges incident on the literal and clause vertices of network N:* (a) *literal vertices x_i and y_i;* (b) *clause vertex c_j.*

edges and can be constructed in $O(nm)$ time.

A feasible flow in network $\mathcal{N}$ corresponds to a satisfying truth assignment for $\mathcal{S}$. Namely, we have that a literal is true whenever its incident literal edge is incoming in the feasible flow (see Figure 3.1(b)) and its incident clause edges with nonzero capacity range are outgoing. We formalize this correspondence in the following lemma.

LEMMA 3.2. *An instance $\mathcal{S}$ of* NOT-ALL-EQUAL-3-SAT *is satisfiable if and only if the associated switch-flow network $\mathcal{N}$ admits a feasible flow. Also, given a feasible flow for $\mathcal{N}$, a satisfying truth assignment for $\mathcal{S}$ can be computed in time $O(nm)$, where n and m are the number of variables and clauses of $\mathcal{S}$, respectively.*

Proof. If. Given a feasible flow in $\mathcal{N}$, we construct a truth assignment A by setting a literal *true* if its incident literal edge is incoming in the flow. We now show that this is a satisfying assignment. Clearly, the two literals x_i and y_i associated with the same boolean variable consistently receive opposite truth assignments.

Because of the conservation property, all the incident clause edges with nonzero capacity range of a *true* literal are outgoing, and the amount of flow in each of them is equal to the capacity. Conversely, if a literal is *false*, then because of the conservation property, all its incident clause edges with nonzero capacity range are incoming, and the amount of flow in each of them is equal to the capacity. The three clause edges with nonzero capacity range incident on a clause vertex c_j cannot be all incoming or all outgoing because of the conservation property at vertex c_j and the choice of the capacity range for the dummy edge incident on c_j. Therefore, three literals in c_j can not be all *true* or all *false*. Hence, A is a satisfying truth assignment for $\mathcal{S}$. Also, A can be constructed in time linear in the number of edges of $\mathcal{N}$, which is $O(nm)$.

Only if. Let A be a satisfying truth assignment of $\mathcal{S}$. We construct a feasible flow f in $\mathcal{N}$ from A. In this flow, we have the following:

- The amount of flow through the literal, clause, and the dummy edges incident on literal vertices is equal to their capacities. The flow, therefore, satisfies the range property in these edges.
- If a literal is true, then its incident literal edge is incoming and its incident clause edges with nonzero capacity range and its dummy edge are outgoing. If a literal is false then its incident literal edge is outgoing and its incident clause edges with nonzero capacity and its dummy edge are incoming. In either case, the amount of flow coming into a literal l_i is $\alpha_i\gamma_i + \beta_i\delta_i$, and

the amount of flow leaving it is $\alpha_i\gamma_i + \beta_i\delta_i$. Therefore, the flow satisfies the conservation property at these vertices.

- If the net flow entering a clause vertex through the clause edges is ν_j, then the flow leaving it through its dummy edge is ν_j. Conversely, if the net flow leaving a clause through the clause edges is ν_j, then the flow entering it through its dummy edge is ν_j. Since A is a satisfying assignment, the three clause edges with nonzero capacity range incident on a clause vertex cannot be all incoming or all outgoing. The magnitude of flow in a clause edge is at least θ. Therefore, the net flow coming into or leaving a clause vertex c_j through its clause edges is at most $\eta_j - 2\theta$. Hence, the conservation property at c_j and the range property in its dummy edge are both satisfied by the flow.
- We show now that the conservation property holds at the dummy vertex by using the following argument. By successive mergers of two nondummy vertices of $\mathcal{N}$ and elimination of the resultant self loops and the flow through them, we can reduce $\mathcal{N}$ into a graph with multiple edges between two vertices: the dummy vertex and another vertex u for which the conservation property holds. The net flow between these two vertices is same as in f. Since the conservation property holds for u and the dummy vertex is neither a source nor a sink, the conservation property holds for the dummy vertex also. □

Now, starting from $\mathcal{S}$, we construct a planar switch-flow network $\mathcal{P}$ (see Figure 3.1). We first construct a *layered drawing* $\psi_{\mathcal{N}}$ of $\mathcal{N}$ as follows (see Figure 3.1(a)):

- Each literal and clause edge is drawn as a straight line. The dummy edges are drawn as continuous curves.
- The clause vertices are horizontally aligned and ordered $c_1, c_2, \ldots, c_m$ from left to right.
- The literal vertices are horizontally aligned above the clause vertices and ordered $x_1, x_2, y_1, y_2, \ldots, x_m, y_m$ from left to right.
- There are crossings only between the clause edges. However, no more than two clause edges cross at the same point.

We next replace the crossings of $\psi_{\mathcal{N}}$ with vertices called the *crossing* vertices, thus splitting the clause edges at the crossing vertices. We call *fragment edges*, or simply *fragments*, the edges originated by the splitting of the clause edges. Each fragment edge inherits the capacity range of the originating clause edge. We define the *facial degree* of a vertex as the total number of edges in its incident faces.

LEMMA 3.3. *Given network $\mathcal{N}$ representing an instance $\mathcal{S}$ of* NOT-ALL-EQUAL-3-SAT *with $n \geq 3$ variables and $m \geq 3$ clauses, the associated planar switch-flow network $\mathcal{P}$ is triconnected, has $O(n^2m^2)$ vertices and edges, and can be constructed in $O(n^2m^2)$ time. Also, in the unique embedding of $\mathcal{P}$, the facial degree of each vertex is at most $7nm$.*

Proof. Let $\psi_{\mathcal{N}}$ be the layered drawing of $\mathcal{N}$ that is used to construct $\mathcal{P}$ (see Figure 3.1(a)). There are $O(n^2m^2)$ crossings in $\psi_{\mathcal{N}}$. Therefore, $\mathcal{P}$ has $O(n^2m^2)$ crossing vertices and fragment edges. Consequently, $\mathcal{P}$ has $O(n^2m^2)$ vertices and edges.

Now we show that $\mathcal{P}$ is triconnected. We denote by u_k the crossing vertex that corresponds to the crossing between the line joining c_k and y_n and the line joining c_{k+1} and x_1. We denote by v_k the crossing vertex that corresponds to the crossing between the line joining y_k and c_m and the line joining x_{k+1} and c_1. We call the vertices of type u_k and v_k the *bounding* crossing vertices of $\mathcal{P}$. No two bounding vertices are identical because they correspond to crossings between different pairs of

lines. Hence there are two vertex disjoint paths, $p = x_1 y_1 v_1 \dots x_k y_k v_k x_{k+1} \dots y_n$ and $q = c_1 u_1 c_2 \dots c_k u_k c_{k+1} \dots c_m$, in $\mathcal{P}$. Let a and b be two nondummy vertices of $\mathcal{P}$. From a and b, there are four vertex-disjoint paths p_a, q_a, p_b, and q_b such that p_a and q_a consist of the fragment edges of a clause edge incident upon a and connect a with a vertex of the paths p and q, respectively, and p_b and q_b consist of the fragment edges of a clause edge incident upon b and connect b with a vertex of the paths p and q, respectively. Notice that if a (b) is a literal vertex, then p_a (p_b) is empty; and if a (b) is a clause vertex, then q_a (q_b) is empty. Hence, between a and b there are two vertex-disjoint paths: one consisting of p_a, a subpath of p, and p_b, and the other consisting of q_a, a subpath of q, and q_b. Hence, graph $\mathcal{P} - \{z\}$ is biconnected. Now suppose, for contradiction, that $\mathcal{P}$ is not triconnected. Since the graph $\mathcal{P} - \{z\}$ is biconnected, z is not a member of a separating pair of $\mathcal{P}$. Let C_1 and C_2 be two connected components of $\mathcal{P}$ obtained after removing a separating pair. Suppose z is in C_1. Hence there are at most two vertex disjoint paths between z and the vertices in C_2. However, between z and a vertex w of $\mathcal{P} - \{z\}$, there are at least four vertex disjoint paths as follows:

- if w is a crossing vertex, then the four paths go through the endpoints of the two clause edges of $\mathcal{N}$ whose crossing is associated with v;
- if w is a clause vertex, then one path consists of the dummy edge incident upon w, and the other three paths go through three literal vertices; and
- if w is a literal vertex, then one path consists of the dummy edge incident upon w, and the other three paths go through three clause vertices.

Thus, we get a contradiction. Therefore $\mathcal{P}$ is triconnected.

Now we show that the facial degree of any vertex is at most $7nm$. All the faces incident on the dummy vertex z have at most four vertices: one is z, two of them are clause and/or literal vertices, and the fourth (if present) is a bounding crossing vertex. There are $n - 1 + m - 1$ bounding crossing vertices in $\mathcal{P}$. A simple counting argument, therefore, shows that the facial degree of z is equal to $3n + m + 2(n - 1 + m - 1) + 2 = 5n + 3m - 2$. Let f be a face that does not contain z. Face f contains at most two fragments of clause edges incident on the same clause or literal vertex. Hence, the number of edges in face f is at most $\min\{2 \cdot 2n, 2m\} = \min\{4n, 2m\}$. The degree of a nondummy vertex u is at most $\max\{2n + 1, m + 2, 4\}$, which is at most $\max\{2n + 1, m + 2\}$ for $n, m \geq 3$. Hence, the facial degree of u is at most $\max\{2n+1, m+2\} \cdot \min\{4n, 2m\} \leq (\max\{2n, m\}+2) \cdot \min\{4n, 2m\} = (\max\{2n, m\}+2) \cdot 2\min\{2n, m\} = 2(\max\{2n, m\} + 2)\min\{2n, m\} = 2\max\{2n, m\}\min\{2n, m\} + 4\min\{2n, m\} = 2(2nm) + 4\min\{2n, m\} = 4nm + \min\{8n, 4m\}$. Since $\min\{8n, 4m\}$ is at most $3nm$ for $n, m \geq 3$, we have that the facial degree of u is at most $4nm + 3nm = 7nm$. Since the facial degree of the dummy vertex is equal to $5n + 3m - 2$, we have that the facial degree of a vertex of $\mathcal{P}$ is at most $\max\{7nm, 5n + 3m - 2\}$, which is equal to $7nm$ for $n, m \geq 3$.

Finally, we show how to construct $\mathcal{P}$ from $\mathcal{N}$ in $O(n^2m^2)$ time. Suppose the literals are numbered from 1 to $2n$ so that literal $l_{2k-1} = x_k$ and $l_{2k} = y_k$. We inductively construct a layered drawing $\psi(k, m)$ of the subgraph of $\mathcal{N}$ induced by literals $l_1, \dots, l_k$ and clauses $c_1, \dots, c_m$ (see Figure 3.3). Drawing $\psi(2, m)$ is shown in Figure 3.3(a). Suppose we have already constructed drawing $\psi(k - 1, m)$ (see Figure 3.3(b)). We place literal l_k at the same height as l_{k-1} and sufficiently far to its right so that edge (l_k, c_1) intersects each clause edge of $\psi(k - 1, m)$ below its lowest crossing. Replacing the crossings of $\psi(2n, m)$ by crossing vertices gives us the planar network $\mathcal{P}$.

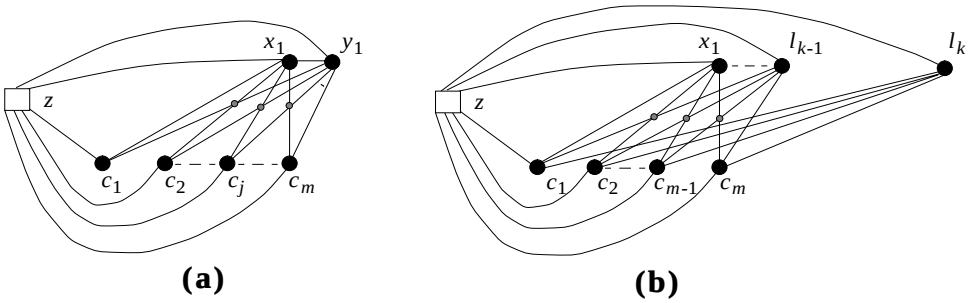

FIG. 3.3. *Proof of Lemma* 3.3: (a) *drawing* $\psi(2, m)$*;* (b) *drawing* $\psi(k, m)$*. The small circles show the lowest crossings of the clause edges in the drawing of* $\psi(k-1, m)$*.*

The construction of the network $\mathcal{P}$ does not require computing the exact coordinates of the vertices and crossings of $\psi(2n, m)$. In an actual implementation, $\mathcal{P}$ can be constructed directly by maintaining and updating at each inductive step a list of the lowest crossing vertices of the clause edges. The manipulation of this list takes constant time per crossing vertex and hence can be done in total $O(n^2m^2)$ time. The rest of the construction can also be carried out in $O(n^2m^2)$ time. □

LEMMA 3.4. *Network* $\mathcal{N}$ *admits a feasible flow if and only if network* $\mathcal{P}$ *admits a feasible flow, and a feasible flow for* $\mathcal{N}$ *can be computed from a feasible flow for* $\mathcal{P}$ *in* $O(n^2m^2)$ *time.*

Proof. Only if. Given a feasible flow in $\mathcal{N}$, we can get a feasible flow in $\mathcal{P}$ in which the flow through each fragment edge is the same as in the corresponding clause edge in $\mathcal{N}$, and the flow through the dummy and literal edges is same as in the corresponding edges in $\mathcal{N}$.

If. Suppose that $\mathcal{P}$ admits a feasible flow f. In f, at any crossing vertex, of the two fragment edges of a clause edge incident upon it, one is incoming and the other is outgoing. This is so because the fragment edges of different clause edges have different capacities and the conservation property is satisfied at the vertex. Consequently, all the fragment edges of a clause edge have the same flow. We can get a feasible flow in $\mathcal{N}$ in which the flow through a clause edge is same the as the flow in its fragment edges in f, and the flow through the dummy edges and the literal edges is the same as the flow in the corresponding edges in $\mathcal{P}$. □

By combining Lemmas 3.2, 3.3, and 3.4, we obtain the main result of this section.

THEOREM 3.5. *Given an instance* $\mathcal{S}$ *of* NOT-ALL-EQUAL-3-SAT *with* $n \geq 3$ *variables and* $m \geq 3$ *clauses, the associated planar switch-flow network* $\mathcal{P}$ *is triconnected, has* $O(n^2m^2)$ *vertices and edges, has facial degree at most* $7nm$*, and can be constructed in* $O(n^2m^2)$ *time. Instance* $\mathcal{S}$ *is satisfiable if and only if network* $\mathcal{P}$ *admits a feasible flow. Also, given a feasible flow for* $\mathcal{P}$*, a satisfying truth assignment for* $\mathcal{S}$ *can be computed in time* $O(n^2m^2)$*.*

4. Upward planarity testing. In this section, we show how to reduce the problem of computing a feasible flow in the planar switch-flow network associated with a NOT-ALL-EQUAL-3-SAT instance to the problem of testing the upward planarity of a suitable digraph.

Let $\mathcal{P}$ be the planar switch-flow network with parameter $\theta = 4$ associated with a NOT-ALL-EQUAL-3-SAT instance $\mathcal{S}$. Now we construct an orientation $\vec{\mathcal{P}}$ of $\mathcal{P}$ as follows (see Figure 4.1):

- Every literal edge (x_i, y_i) is oriented from x_i to y_i.

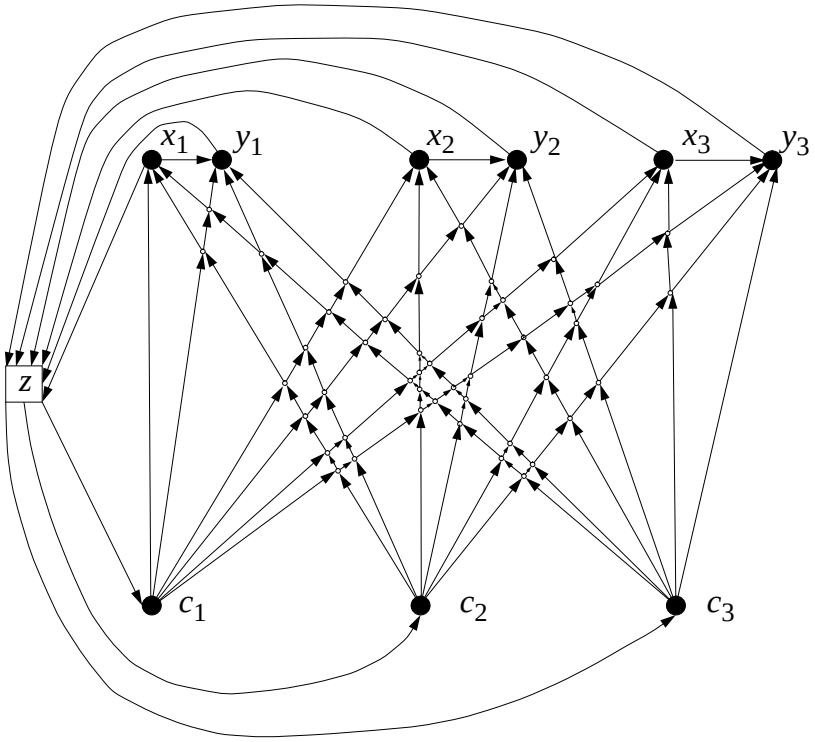

FIG. 4.1. *Orientation $\vec{\mathcal{P}}$ of the network $\mathcal{P}$ shown in Figure* 3.1(c).

- Every fragment edge is oriented "away from" the clause vertex and "towards" the literal vertex.
- Every dummy edge incident upon a literal vertex is oriented towards the dummy vertex, and every dummy edge incident upon a clause vertex is oriented towards the clause vertex.

LEMMA 4.1. *In digraph $\vec{\mathcal{P}}$, every vertex has at least one incoming and one outgoing edge, every directed cycle contains the dummy vertex, and there are exactly two faces that are directed cycles. Also, $\vec{\mathcal{P}}$ is bimodal and each face of $\vec{\mathcal{P}}$ consists of at most two directed paths.*

Proof. Let m be the number of clauses and n be the number of variables in $\mathcal{S}$. Let z be the dummy vertex of $\vec{\mathcal{P}}$.

Each crossing vertex has two incoming and two outgoing fragment edges. Each literal vertex y_i has $m+1$ incoming edges and one outgoing edge (to z). Each literal vertex x_i has m incoming edges and two outgoing edges (to z and y_i). Each clause vertex has $2n$ outgoing edges and one incoming edge (from z). The dummy vertex has $2n$ incoming edges and m outgoing edges. Therefore, each vertex has at least one incoming and one outgoing edge. It can easily be verified that each vertex of $\vec{\mathcal{P}}$ is bimodal, and hence $\vec{\mathcal{P}}$ is bimodal.

The digraph $\vec{\mathcal{P}} - \{z\}$ is upward planar with m sources, each being a clause vertex, and n sinks, each being a literal vertex y_i. Therefore, every directed cycle in $\vec{\mathcal{P}}$ contains z. There are exactly two faces in $\vec{\mathcal{P}}$ that that are directed cycles: one consisting of vertices x_1, z, and c_1, and the other consisting of vertices y_n, z, and c_m. It can be easily verified that the other faces of $\vec{\mathcal{P}}$ each consist of exactly two directed

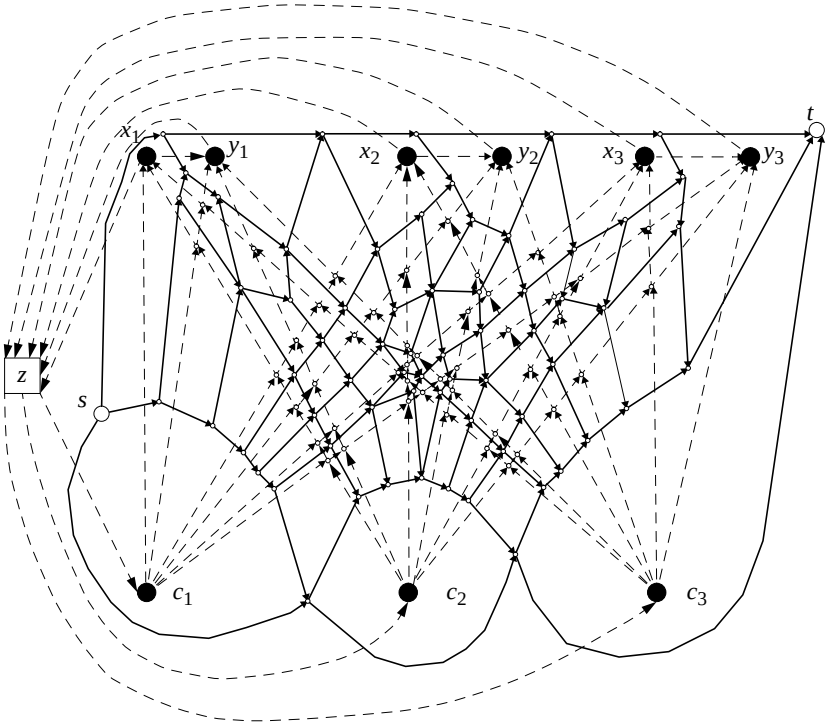

FIG. 4.2. *Dual digraph $\vec{\mathcal{D}}$ of the network $\vec{\mathcal{P}}$ shown in Figure* 4.1.

paths. □

Since $\mathcal{P}$ is triconnected (see Theorem 3.5), the planar embedding of $\mathcal{P}$ and the dual graph of $\mathcal{P}$ are unique. We construct the dual digraph $\vec{\mathcal{D}}$ of $\vec{\mathcal{P}}$ by taking the dual graph $\mathcal{D}$ of $\mathcal{P}$ and orienting every dual edge from the face on the left to the face on the right of the primal edge (see Figure 4.2).

LEMMA 4.2. *The dual digraph $\vec{\mathcal{D}}$ of $\vec{\mathcal{P}}$ is upward planar, triconnected, acyclic, and has exactly one source and one sink, denoted with s and t, both of which are on the same face. Also, each face of $\vec{\mathcal{D}}$ has exactly one source and one sink.*

Proof. Because $\vec{\mathcal{P}}$ is planar and triconnected (Theorem 3.5), so is its dual $\vec{\mathcal{D}}$. By Lemma 4.1, exactly two faces of $\vec{\mathcal{P}}$ are directed cycles. Hence, $\vec{\mathcal{D}}$ has exactly two switches, denoted by s and t (see Figure 4.2), respectively, corresponding to these two cycles. Switch s is a source vertex and corresponds to the face of $\vec{\mathcal{P}}$ that consists of the literal vertex x_1, dummy vertex z, and the clause vertex c_1. Switch t is a sink vertex and corresponds to the face of $\vec{\mathcal{P}}$ that consists of the vertices y_n, z, and c_m. Also notice that both s and t are on the face that is the dual of z. From Lemma 4.1, each face of $\vec{\mathcal{P}}$ consists of at most two directed paths, and hence each vertex of $\vec{\mathcal{D}}$ is bimodal. Therefore, $\vec{\mathcal{D}}$ is also bimodal. Again from Lemma 4.1, each vertex of $\vec{\mathcal{P}}$ is bimodal and none of them is a source or a sink. Hence, each face of $\vec{\mathcal{D}}$ has exactly one source and one sink. Since s and t are the only switches of $\vec{\mathcal{D}}$ and both of them are on the same face, it follows that there is a consistent assignment of labels to the angles of $\vec{\mathcal{D}}$ in which exactly two angles are labeled large, namely, the angles at s and t in their common face. Therefore, by Lemma 2.1, $\vec{\mathcal{D}}$ has an upward embedding and hence is upward planar. □

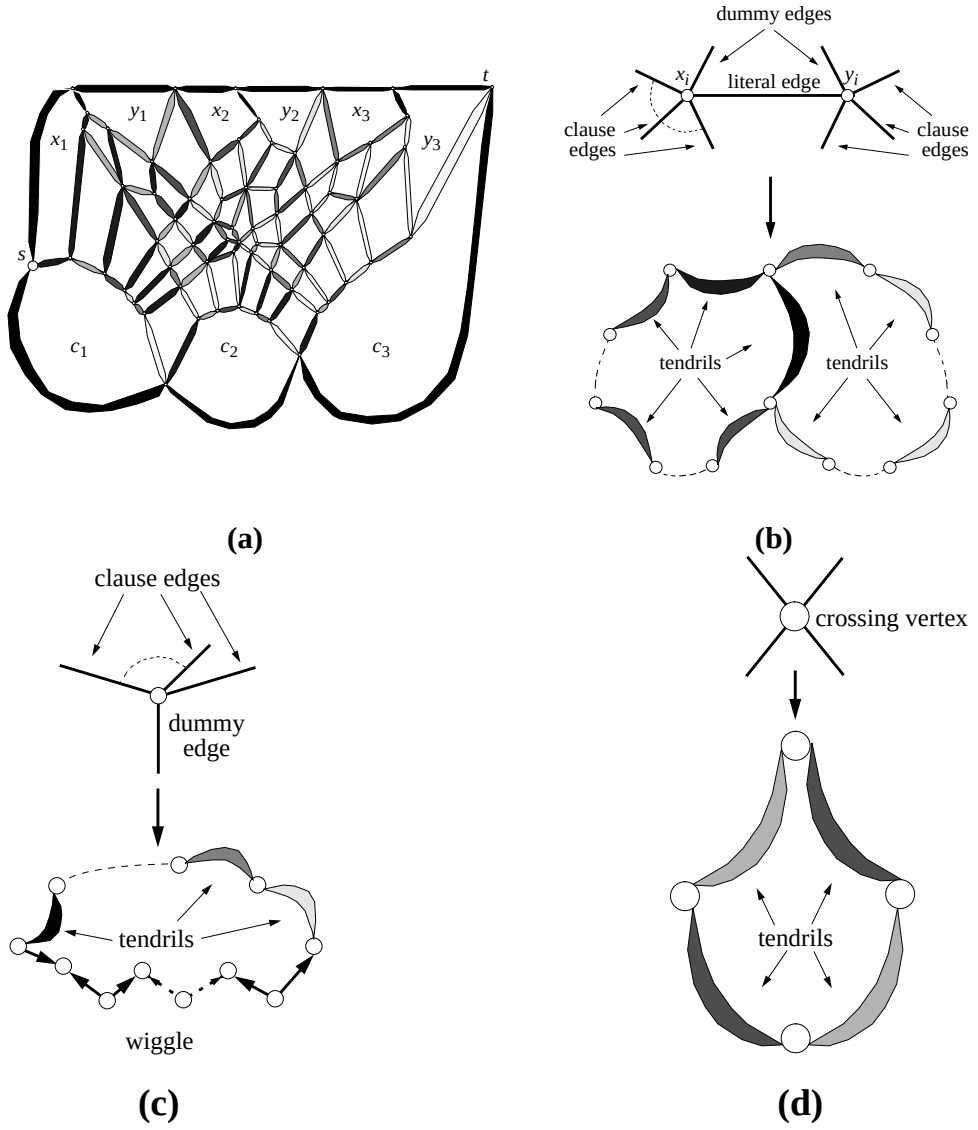

FIG. 4.3. (a) *Schematic illustration of digraph* $\vec{\mathcal{G}}$ *obtained from* $\vec{\mathcal{D}}$ *by replacing edges with tendrils and wiggles.* (b) *The two faces of* $\vec{\mathcal{G}}$ *associated with literal vertices* x_i *and* y_i *of* $\mathcal{P}$. (c) *The face of* $\vec{\mathcal{G}}$ *associated with a clause vertex of* $\mathcal{P}$. (d) *The face of* $\vec{\mathcal{G}}$ *associated with a crossing vertex of* $\mathcal{P}$.

Starting from digraph $\vec{\mathcal{D}}$, we construct a new digraph $\vec{\mathcal{G}}$ by replacing the edges of $\vec{\mathcal{D}}$ with subgraphs (tendrils or wiggles) as follows (see Figure 4.3):

- Every edge of $\vec{\mathcal{D}}$ that is the dual of a literal edge, fragment edge, or dummy edge incident on a literal vertex is replaced with tendril T_c, where $[c]$ is the capacity range of the dual edge. Notice that c is a multiple of parameter θ.
- Every edge of $\vec{\mathcal{D}}$ that is the dual of a dummy edge incident on a clause vertex is replaced with wiggle W_c, where $[0 \cdots c]$ is the capacity range of the dual edge.

A vertex of $\vec{\mathcal{G}}$ is a *primary* vertex if it is also a vertex of $\vec{\mathcal{D}}$, and is a *secondary* vertex otherwise. A face of an embedding of $\vec{\mathcal{G}}$ is a *secondary* face if it is bounded by the edges of the same tendril, and is a *primary* face otherwise. Figure 4.3(a) shows the primary faces of an embedding ψ of $\vec{\mathcal{G}}$ and the primary vertices of $\vec{\mathcal{G}}$; in this figure, the secondary faces of ψ and the secondary vertices of $\vec{\mathcal{G}}$ are hidden inside the shaded regions denoting the tendrils and the wiggles. We establish the following correspondence between the primary faces of an embedding ψ of $\vec{\mathcal{G}}$, the faces of $\vec{\mathcal{D}}$, and the vertices of $\vec{\mathcal{P}}$. Let f be a primary face of ψ; f corresponds to a face f' of $\vec{\mathcal{D}}$, namely, the one whose boundary edges were replaced by tendrils and wiggles to give f. Recall that $\vec{\mathcal{D}}$ is the dual digraph of $\vec{\mathcal{P}}$, and its faces correspond to the vertices of $\vec{\mathcal{P}}$. Therefore, f also corresponds to a vertex v of $\vec{\mathcal{P}}$, namely, the one that corresponds to f'. f is the *dummy face* of $\vec{\mathcal{G}}$ if v is the dummy vertex of $\vec{\mathcal{P}}$, and is a *nondummy* face otherwise. A *primary* angle a of f is its angle at a primary vertex u; a corresponds to an angle of f', namely, the one at u. A primary vertex of f is a *primary source* of f if it is also a source of f, and is a *primary sink* of f if it is also a sink of f.

There is no directed path from the sink pole to the source pole of a tendril or a wiggle. Therefore, $\vec{\mathcal{G}}$ is also acyclic. From Lemma 4.2 and the construction of digraph $\vec{\mathcal{G}}$, the following lemma is immediate.

LEMMA 4.3. *Digraph $\vec{\mathcal{G}}$ is planar and acyclic. All its embeddings can be obtained by choosing one of the two possible flips for each tendril and have the same set of secondary faces. Also, for every face f in an embedding of $\vec{\mathcal{G}}$, the following holds:*

- *if f is a secondary face, then it has exactly one source and exactly one sink;*
- *or else (f is a primary face), it has exactly one primary source and exactly one primary sink.*

We need the following technical lemma to prove Lemma 4.5.

LEMMA 4.4. *Let f be a primary face of an upward embedding ψ of $\vec{\mathcal{G}}$. Let $\tau(f)$ and $\omega(f)$ be the total contribution to f of its tendrils and wiggles, respectively. Then,*

$$|\tau(f) + \omega(f)| \leq \theta.$$

Proof. From Lemma 4.3, f has exactly one primary source s and exactly one primary sink t. In other words, f has exactly two primary angles. Let $\nu(f)$ be equal to the number of *large* primary angles minus the number of *small* primary angles of f. Clearly, $|\nu(f)| \leq 2$. Let us denote with $L(f)$ and $S(f)$, respectively, the number of *large* and *small* angles of f. Because ψ is an upward embedding, from Lemma 2.1 it follows that $|L(f) - S(f)| = 2$. An angle of f is either a primary angle of f or an angle of one of its tendrils and wiggles. Therefore, $L(f) - S(f) = \nu(f) + \tau(f) + \omega(f)$. Therefore, $\tau(f) + \omega(f) = L(f) - S(f) - \nu(f)$. Hence, $|\tau(f) + \omega(f)| = |L(f) - S(f) - \nu(f)| \leq |L(f) - S(f)| + |\nu(f)|$. Since $|\nu(f)| \leq 2$ and $|L(f) - S(f)| = 2$, we have that $|\tau(f) + \omega(f)| \leq 4$. Recall from the beginning of this section that $\theta = 4$. Hence, $|\tau(f) + \omega(f)| \leq \theta$. □

We are now ready to present Lemma 4.5.

LEMMA 4.5. *Digraph $\vec{\mathcal{G}}$ is upward planar if and only if its tendrils can be flipped and labels can be assigned to the angles of its wiggles such that for every primary face the total contribution to it of its tendrils and wiggles is zero.*

Proof. If. From Lemma 4.2, $\vec{\mathcal{D}}$ has an upward embedding $\psi_{\vec{\mathcal{D}}}$. Let g' be the external face of $\psi_{\vec{\mathcal{D}}}$. Let ψ be a labeled embedding of $\vec{\mathcal{G}}$ such that, for every face f of ψ,

- if f is a secondary face, then the angles of f are labeled *small*;
- or else (f is a primary face)

– the total contribution to it of its tendrils and wiggles is zero, and
– its primary angles have the same label as the corresponding angles of $\psi_{\vec{\mathcal{D}}}$.

Notice that such a ψ exists because the tendrils of $\vec{\mathcal{G}}$ can be flipped and labels can be assigned to the angles of the wiggles of $\vec{\mathcal{G}}$ such that for every primary face the total contribution to it of its tendrils and wiggles is zero.

Let g be the primary face of ψ that corresponds to g'. We now show that ψ is an upward embedding with g as its external face. From Lemma 2.1, this is equivalent to showing that each face of ψ is consistently assigned with g as the external face (see the definition of consistently assigned faces in section 2.1).

Let f be a face of ψ. If f is a secondary face, then, from Lemma 4.3, f has exactly one source and exactly one sink. Because both of them are labeled *small* and f is an internal face, f is consistently assigned.

If f is a primary face, then it corresponds to a face f' of $\psi_{\vec{\mathcal{D}}}$. Let d be an integer equal to the number of large angles minus the number of small angles of f. Define d' likewise for f'. Because the total contribution to f of its tendril and wiggles is zero, and the angles at its primary vertices have the same label as the corresponding angles of f', it follows that $d = d'$. Thus, since f' is consistently assigned, f is consistently assigned too.

Only if. Suppose $\vec{\mathcal{G}}$ has an upward embedding ψ. Let f be a face of ψ. Since ψ is an upward embedding, f is consistently assigned, and therefore, from Lemma 2.1, the difference of its large and small angles is 2. However, because f, in general, also has primary vertices, each one of which contributes a *large* or *small* angle to it, it may be possible that the total contribution to it of its tendrils and wiggles is not zero. However, using Lemma 4.5, we show now that $\vec{\mathcal{G}}$ admits a labeled embedding ψ' such that[1]

- ψ' has the same faces as ψ,
- the primary angles of ψ' are the same as those of ψ,
- the contribution of a tendril to a primary face f of ψ' is the same as its contribution to f in ψ,
- the contribution of a wiggle to a primary face f of ψ' *may be different* from its contribution to f in ψ, and
- for every primary face f of ψ', the total contribution to f of its tendrils and wiggles is zero.

(Thus, ψ' and ψ are the same except for a possible difference in the assignment of labels to the angles of their wiggles.)

Let f be a primary face of ψ (and therefore also of ψ'). Let $\tau(f)$ and $\omega(f)$ be the total contributions to f of its tendrils and wiggles, respectively, in ψ. Let $\tau'(f)$ and $\omega'(f)$ be the total contributions to f of its tendrils and wiggles, respectively, in ψ'. Our goal is to show that $\tau'(f) + \omega'(f) = 0$.

First of all, we notice that because ψ and ψ' have the same faces, $\tau(f) = \tau'(f)$.

We now describe the assignment of labels to the angles of the wiggles of ψ' and show that $\tau'(f) + \omega'(f) = 0$ with this assignment. We have the following three cases:

Case 1. f is a nondummy face and it corresponds to a literal vertex or a crossing vertex of $\vec{\mathcal{P}}$. Clearly, f has no wiggles. Therefore, $\omega'(f) = \omega(f) = 0$. Since $\omega(f) = 0$,

[1] By appropriately reassigning labels to the angles of those primary vertices that are endpoints of the wiggles, from ψ we can obtain an upward embedding in which for every primary face f the total contribution to f of its tendrils and wiggles is zero. However, for our purposes, it is sufficient to show the existence of a labeled embedding ψ', as described here.

from Lemma 4.4 it follows that $|\tau(f)| \leq \theta$. From the construction of graph $\vec{\mathcal{G}}$ and the fact that a tendril T_k gives a contribution equal to either $2k$ or $-2k$ to a face (see section 2.2), it follows that $|\tau(f)|$ is a multiple of 2θ. Therefore, $|\tau(f)| \leq \theta$ implies that $\tau(f)$ is equal to 0. Since $\tau'(f) = \tau(f)$, we have that $\tau'(f)$ is also equal to 0. Because $\omega'(f) = 0$, it follows that $\tau'(f) + \omega'(f) = 0$.

Case 2. f is a nondummy face and it corresponds to a clause vertex c_j of $\vec{\mathcal{P}}$. Clearly, f has exactly one wiggle w. In ψ', we assign labels to the angles of w such that $\omega'(f) = -\tau(f)$. As noted earlier, $\tau'(f) = \tau(f)$. Hence, $\tau'(f)+\omega'(f) = \tau(f)-\tau(f) = 0$ with this assignment of labels to w. Therefore, if we can show that it is possible to assign labels to the angles of w such that $\omega'(f) = -\tau(f)$, we are done.

Recall from the construction of network $\mathcal{N}$ from section 3 that the capacity range of the dummy edge incident on c_j is $[0 \cdots \eta_j - 2\theta]$, where η_j is the sum of the capacities of the clause edges incident on c_j. Also it follows from the construction of $\vec{\mathcal{G}}$ that w is a copy of the wiggle $w_{\eta_j - 2\theta}$. Because the magnitude of the contribution of a wiggle w_k to a face is at most $2k$ (see section 2.2), we have that $|\omega(f)| \leq 2(\eta_j - 2\theta)$. Therefore, if we are able to show that $|\tau(f)|$ is at most $2(\eta_j - 2\theta)$, then because $\tau(f)$ is an even number, and w can give any even valued contribution in the range $-2(\eta_j - 2\theta)$ to $2(\eta_j - 2\theta)$, we will be able to show that it is possible to assign labels to the angles of w such that the contribution of w to f is equal to $-\tau(f)$.

We now prove that $|\tau(f)|$ is at most $2(\eta_j - 2\theta)$. From the construction of $\vec{\mathcal{G}}$ and the fact that a tendril T_k gives a contribution equal to either $2k$ or $-2k$ to a face (see section 2.2), it follows that the maximum value of $|\tau(f)|$ is $2\eta_j$, and $|\tau(f)|$ is a multiple of 2θ. Therefore, either $|\tau(f)| = 2\eta_j$, or $|\tau(f)| = 2\eta_j - 2\theta$, or $|\tau(f)| \leq 2\eta_j - 4\theta$. However, because $|\omega(f)| \leq 2(\eta_j - 2\theta)$, from Lemma 4.4 it follows that $|\tau(f)| \leq 2(\eta_j - 2\theta) + \theta = 2\eta_j - 3\theta$. Hence, $|\tau(f)|$ cannot be equal to $2\eta_j$ or $2\eta_j - 2\theta$. Consequently, $|\tau(f)| \leq 2\eta_j - 4\theta = 2(\eta_j - 2\theta)$.

Case 3. f is the dummy face of ψ'. Let T be a tendril of $\vec{\mathcal{G}}$. If T contributes k to a primary face of ψ', it also contributes $-k$ to another primary face of ψ'. Therefore, the total contribution of the tendrils of ψ', when summed over all its primary faces, is 0. Similarly, the total contribution of the wiggles of ψ', when summed over all its primary faces, is 0. We have already shown by considering Cases 1 and 2 that if h is a nondummy face, then $\tau'(h) + \omega'(h) = 0$. Therefore, it follows that $\tau'(f) + \omega'(f) = 0$. □

THEOREM 4.6. *Given an instance $\mathcal{S}$ of* NOT-ALL-EQUAL-3-SAT *with n variables and m clauses and the associated planar switch-flow network $\mathcal{P}$, digraph $\vec{\mathcal{G}}$ associated with $\mathcal{S}$ and $\mathcal{P}$ has $O(n^3m^2)$ vertices and edges and can be constructed in $O(n^3m^2)$ time. Instance $\mathcal{S}$ is satisfiable and network $\mathcal{P}$ admits a feasible flow if and only if digraph $\vec{\mathcal{G}}$ is upward planar. Also, given an upward planar embedding for $\vec{\mathcal{G}}$, a feasible flow for $\mathcal{P}$ and a satisfying truth assignment for $\mathcal{S}$ can be computed in time $O(n^3m^2)$.*

Proof. Since $\theta = 4 = O(1)$, from the construction of $\vec{\mathcal{G}}$ we have that the number of vertices and edges in a tendril or a wiggle is $O(n)$. Since $\mathcal{P}$ has $O(n^2m^2)$ vertices and edges (see Theorem 3.5), $\vec{\mathcal{G}}$ has $O(n^3m^2)$ vertices and edges. $\mathcal{P}$ can be constructed from $\mathcal{S}$ in $O(n^2m^2)$ time (see Theorem 3.5), and $\vec{\mathcal{G}}$ can be constructed from $\mathcal{P}$ in $O(n^3m^2)$ time. Thus, we can construct $\vec{\mathcal{G}}$ from $\mathcal{S}$ in $O(n^3m^2)$ time.

We now show that instance $\mathcal{S}$ is satisfiable and network $\mathcal{P}$ admits a feasible flow if and only if digraph $\vec{\mathcal{G}}$ is upward planar.

We establish the following correspondences between digraph $\vec{\mathcal{G}}$ and network $\mathcal{P}$ (see Figure 4.3):

- The faces of $\vec{\mathcal{G}}$ correspond to the vertices of $\mathcal{P}$.
- The tendrils and wiggles of $\vec{\mathcal{G}}$ correspond to the the edges of $\mathcal{P}$.
- Flipping a tendril T_k of $\vec{\mathcal{G}}$ corresponds to orienting an edge e of $\mathcal{P}$, where e is the dual of the edge replaced by T_k in constructing $\vec{\mathcal{G}}$ from $\vec{\mathcal{D}}$. Edge e is oriented towards an endpoint v (which is a vertex of $\mathcal{P}$) if and only if v corresponds to f and T_k contributes $2k$ to f.
- The contribution of a tendril or wiggle U of $\vec{\mathcal{G}}$ corresponds to the flow in an edge e of $\mathcal{P}$. Here e is the dual of the edge which is replaced by U in constructing $\vec{\mathcal{G}}$ from $\vec{\mathcal{D}}$. The contribution of U to a face f is equal to the amount of the flow coming through e into the endpoint (of e) that corresponds to f.
- The balance of the contributions of the tendrils and wiggles to the faces of $\vec{\mathcal{G}}$ corresponds to the conservation of flow at the corresponding vertices of $\mathcal{P}$; i.e., the total contribution of the tendrils and wiggles to a face is zero if and only if there is a conservation of flow at its corresponding vertex in $\mathcal{P}$.

From Theorem 3.5, Lemma 4.5, and the correspondence established above between a feasible flow in $\mathcal{P}$ and the upward planarity of $\vec{\mathcal{G}}$, it follows that $\mathcal{S}$ is satisfiable and $\mathcal{P}$ admits a feasible flow if and only if $\vec{\mathcal{G}}$ is upward planar. It also follows that given an upward planar embedding for $\vec{\mathcal{G}}$, a feasible flow for $\mathcal{P}$ and a satisfying truth assignment for $\mathcal{S}$ can be computed in $O(n^3m^2)$ time. □

From Theorem 4.6, we conclude the following corollary.

COROLLARY 4.7. *Upward planarity testing is NP-complete.*

5. Rectilinear planarity testing. In this section, we show that rectilinear planarity testing is NP-complete by reducing the problem of computing a feasible flow in the planar switch-flow network associated with an instance of NOT-ALL-EQUAL-3-SAT to the problem of testing the rectilinear planarity of a suitable graph $\mathcal{G}$. The construction of $\mathcal{G}$ is similar to the construction of $\vec{\mathcal{G}}$ in section 4 and is carried out in several stages, where at each stage an intermediate graph is produced.

Let $\mathcal{S}$ be an instance of NOT-ALL-EQUAL-3-SAT with n variables and m clauses; let $\mathcal{P}$ be the associated planar switch-flow network of $\mathcal{S}$ with parameter $\theta = 4 + 37nm$ (see section 3).

Let $\mathcal{D}$ be the dual graph of $\mathcal{P}$. Starting from $\mathcal{D}$, we construct a degree-3 planar graph $\mathcal{F}$ using the following two-step process:

1. First, replace each vertex of $\mathcal{D}$ by a binary tree with d leaves. Let $\mathcal{E}$ be the resultant graph.
2. Next, replace each edge e of $\mathcal{E}$ with a chain c_e consisting of five edges. The middle edge of c_e is called the *representative* of e in $\mathcal{F}$.

Since $\mathcal{P}$ has $O(n^2m^2)$ vertices and edges, it follows that $\mathcal{D}$ and $\mathcal{F}$ also have $O(n^2m^2)$ vertices and edges each.

LEMMA 5.1. *Graph $\mathcal{F}$ has a unique planar embedding and admits a rectilinear embedding, which can be constructed in linear time.*

Proof. Since $\mathcal{D}$ has a unique planar embedding, it follows that $\mathcal{F}$ also has a unique planar embedding.

It is known that every degree-4 planar graph admits an orthogonal drawing with at most four bends per edge, which can be constructed in linear time (see, e.g., [31]). Hence, $\mathcal{E}$ also admits a planar orthogonal drawing R with at most four bends per edge. Because each edge e of $\mathcal{E}$ is replaced by a chain c_e in $\mathcal{F}$, from R we can construct a rectilinear embedding of $\mathcal{F}$ by replacing each bend of e by an intermediate vertex of c_e. □

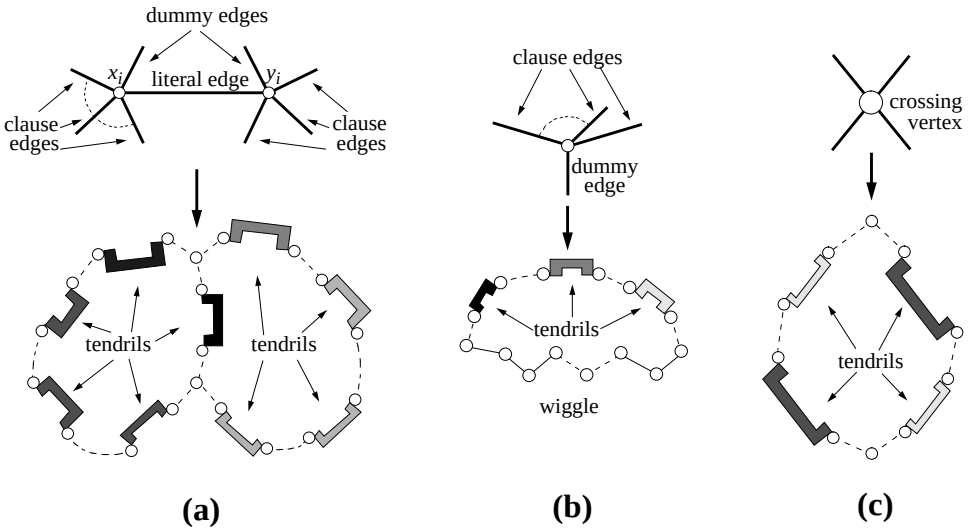

FIG. 5.1. *Schematic illustration of graph $\mathcal{G}$ obtained from $\mathcal{F}$ by replacing edges with rectilinear tendrils and wiggles:* (a) *the two faces of $\mathcal{G}$ associated with literal vertices x_i and y_i of $\mathcal{P}$;* (b) *the face of $\mathcal{G}$ associated with a clause vertex of $\mathcal{P}$;* (c) *the face of $\mathcal{G}$ associated with a crossing vertex of $\mathcal{P}$.*

We construct $\mathcal{G}$ from $\mathcal{F}$ by replacing the edges of $\mathcal{F}$ with subgraphs (rectilinear tendrils or wiggles) as follows (see Figure 5.1). Let e be an edge of $\mathcal{D}$ and *rep(e)* be the representative of e in $\mathcal{G}$.

- If e is the dual of a literal edge, fragment edge, or dummy edge incident on a literal vertex, then *rep(e)* is replaced with a rectilinear tendril T_c, where $[c]$ is the capacity range of the dual edge of e. Note that c is a multiple of parameter θ.
- If e is the dual of a dummy edge e' incident on a clause vertex, then *rep(e)* is replaced with a rectilinear wiggle W_c, where $[0 \cdots c]$ is the capacity range of the dual edge of e.

The vertices of $\mathcal{G}$ that are also vertices of $\mathcal{F}$ are called its *primary* vertices. We define the *primary*, *secondary*, *dummy*, and *nondummy* faces of $\mathcal{G}$ similar to their definition for $\vec{\mathcal{G}}$ in section 4 and also establish similar correspondences between the primary faces of an embedding ψ of $\mathcal{G}$, the faces of $\mathcal{F}$, and the vertices of $\mathcal{P}$.

By Lemma 5.1 and the construction of graph $\mathcal{G}$, all the embeddings of $\mathcal{G}$ are obtained by choosing one of the two possible flips for each rectilinear tendril.

Let ψ be a rectilinear embedding of $\mathcal{G}$. Recall that a rectilinear tendril T_k contributes one of $4k$, $4k+1$, $4k+2$, $-4k$, $-(4k+1)$, and $-(4k+2)$ to a face of $\mathcal{G}$. In ψ, the *significant* contribution of a rectilinear tendril T_k to a face is $4k$ if its contribution is one of $4k$, $4k+1$, and $4k+2$, and is $-4k$ otherwise. In ψ, the *significant* contribution of a rectilinear wiggle to a face is equal to its contribution to the face. Hence, the difference in the contribution and significant contribution of a tendril (wiggle) to a face of ψ is at most 2 (0). Also, the total significant contribution of the tendrils to a face of ψ is a multiple of 4θ. The *contribution* of a primary vertex to a face f of ψ is 1 if its angle in f is labeled 3, is -1 if its angle in f is labeled 1, and is 0 otherwise.

LEMMA 5.2. *If $n \geq 3$ and $m \geq 3$, then in a rectilinear embedding of $\mathcal{G}$ the magnitude of the total contribution of primary vertices to a nondummy face is at*

most $35nm$.

Proof. We show that, in a rectilinear embedding of $\mathcal{G}$, a nondummy face has at most $35nm$ primary vertices, and hence the magnitude of the total contribution of primary vertices to it is at most $35nm$.

Let f be a face of $\mathcal{D}$ with k vertices. Let f be the dual of vertex u of $\mathcal{P}$. Expanding a vertex of f with degree d by a binary tree adds at most $d-1$ vertices to f. Hence, expanding each vertex of f by a binary tree adds at most $r-k$ vertices to f, where r is the facial degree of u. Therefore, after step 1, f has at most $k+r-k=r$ vertices. Hence, after replacing each edge of f by a chain of five edges in step 2, f has at most $5r$ vertices. From Theorem 3.5, r is at most $7nm$ for $n, m \geq 3$. Hence, f has at most $35nm$ vertices in $\mathcal{G}$. □

LEMMA 5.3. *Let f be a primary face of a rectilinear embedding ψ of $\mathcal{G}$. Let $\tau(f)$ and $\omega(f)$ be the total significant contributions to f of its tendrils and wiggles, respectively. Then*

$$|\tau(f) + \omega(f)| \leq \theta.$$

Proof. Let $\nu(f)$ be equal to the number of primary angles labeled 3 minus the number of primary angles labeled 1 of f. Let $\tau'(f)$ and $\omega'(f)$ be the total contribution to f of its tendrils and wiggles, respectively. Let us denote with $N_3(f)$ and $N_1(f)$ the number of angles of f labeled 3 and 1, respectively. An angle of f is either a primary angle of f or an angle of one of its tendrils and wiggles. Therefore, $N_3(f) - N_1(f) = \nu(f) + \tau'(f) + \omega'(f)$. Hence, $\tau'(f) + \omega'(f) = N_3(f) - N_1(f) - \nu(f)$. Therefore, $|\tau'(f) + \omega'(f)| = |N_3(f) - N_1(f) - \nu(f)| \leq |N_3(f) - N_1(f)| + |\nu(f)|$. Because ψ is a rectilinear embedding, the sum of the labels of the angles around each vertex of ψ is equal to 4. Hence, because each angle of $\mathcal{G}$ has label at least 1, and each vertex of $\mathcal{G}$ has degree at least 2, no angle of $\mathcal{G}$ has label 4. Therefore, $N_4(f) = 0$. Hence, from Lemma 2.2, it follows that $|N_3(f) - N_1(f)| = 4$. Therefore, $|\tau'(f) + \omega'(f)| \leq 4 + |\nu(f)|$. Since the difference in the contribution and significant contribution of a tendril to a face of ψ is at most 2, and f has at most nm tendrils, we have that $|\tau(f)| \leq |\tau'(f)| + 2nm$. Since $\omega(f) = \omega'(f)$, it follows that $|\tau(f) + \omega(f)| \leq |\tau'(f) + \omega'(f)| + 2nm \leq 4 + |\nu(f)| + 2nm$. Since, from Lemma 5.2, $|\nu(f)| \leq 35nm$, we have that $|\tau(f) + \omega(f)| \leq 4 + 37nm$. Recall from the beginning of this section that $\theta = 4 + 37nm$. Hence, $|\tau(f) + \omega(f)| \leq \theta$. □

We are now ready to present Lemma 5.4.

LEMMA 5.4. *Graph $\mathcal{G}$ is rectilinear planar if and only if its tendrils can be flipped and labels can be assigned to the angles of its wiggles such that for every primary face the total significant contribution to it of its tendrils and wiggles is zero.*

Proof. If. From Lemma 5.1, $\mathcal{F}$ has a rectilinear embedding $\psi_{\mathcal{F}}$. Let g' be the external face of $\psi_{\mathcal{F}}$. Let ψ be a labeled embedding of $\mathcal{F}$ such that, for every face f of ψ,

- if f is a secondary face, then the angles of f are labeled 1,
- or else (f is a primary face)
  - the contribution of a tendril or a wiggle to f is equal to its significant contribution, and the total contribution to f of its tendrils and wiggles is zero, and
  - its primary angles have the same label as the corresponding angles of $\psi_{\mathcal{F}}$.

The rest of the proof uses the same arguments as those in the *if* part of the proof for Lemma 4.5 with the contribution of a tendril or wiggle replaced by the significant contribution of a rectilinear tendril or wiggle.

Only if. The proof uses Lemma 5.3 and the same arguments as those by the *only if* part of the proof for Lemma 4.5 with the contribution of a tendril or wiggle replaced by the significant contribution of a rectilinear tendril or wiggle. □

THEOREM 5.5. *Given an instance $\mathcal{S}$ of* NOT-ALL-EQUAL-3-SAT *with n variables and m clauses, graph $\mathcal{G}$ associated with $\mathcal{S}$ has $O(n^4m^3)$ vertices and edges and can be constructed in $O(n^4m^3)$ time. Instance $\mathcal{S}$ is satisfiable if and only if graph $\mathcal{G}$ is rectilinear planar. Also, given a rectilinear planar embedding for $\mathcal{G}$, a satisfying truth assignment for $\mathcal{S}$ can be computed in time $O(n^4m^3)$.*

Proof. Since $\theta = 4+37nm = O(nm)$, from the construction of $\mathcal{G}$ we have that the number of vertices and edges in a tendril or a wiggle is $O(n^2m)$. Since $\mathcal{P}$ has $O(n^2m^2)$ vertices and edges (see Theorem 3.5), $\mathcal{G}$ has $O(n^4m^3)$ vertices and edges. $\mathcal{P}$ can be constructed from $\mathcal{S}$ in $O(n^2m^2)$ time (see Theorem 3.5), and $\mathcal{G}$ can be constructed from $\mathcal{P}$ in $O(n^4m^3)$ time. Hence, we can construct $\mathcal{G}$ from $\mathcal{S}$ in $O(n^4m^3)$ time.

We now show that instance $\mathcal{S}$ is satisfiable and network $\mathcal{P}$ admits a feasible flow if and only if graph $\mathcal{G}$ is rectilinear planar.

We establish the following correspondences between graph $\mathcal{G}$ and network $\mathcal{P}$ (see Figure 5.1):

- The faces of $\mathcal{G}$ correspond to the vertices of $\mathcal{P}$.
- The rectilinear tendrils and wiggles of $\mathcal{G}$ correspond to the the edges of $\mathcal{P}$.
- Flipping a rectilinear tendril T_k of $\mathcal{G}$ corresponds to orienting an edge e of $\mathcal{P}$. Edge e is oriented towards an endpoint v (which is a vertex of $\mathcal{P}$) if and only if v corresponds to f and the significant contribution of T_k to f is $4k$.
- The significant contribution of a tendril or wiggle U of $\mathcal{G}$ corresponds to the flow in an edge e of $\mathcal{P}$. Edge e is the dual of the edge whose representative is replaced by U in constructing $\mathcal{G}$ from $\mathcal{F}$. The significant contribution of U to a face f is equal to the amount of the flow coming through e into the end point (of e) that corresponds to f.
- The balance of the significant contributions of the tendrils and wiggles to the faces of $\mathcal{G}$ corresponds to the conservation of flow at the corresponding vertices of $\mathcal{P}$, i.e., the total significant contribution of the tendrils and wiggles to a face f is zero if and only if there is a conservation of flow at its corresponding vertex in $\mathcal{P}$.

From Theorem 3.5, Lemma 5.4, and the correspondence established above between a feasible flow in $\mathcal{P}$ and the rectilinear planarity of $\mathcal{G}$, it follows that instance $\mathcal{S}$ is satisfiable and $\mathcal{P}$ admits a feasible flow if and only if graph $\mathcal{G}$ is rectilinear planar. It also follows that given a rectilinear planar embedding for $\mathcal{G}$, a satisfying truth assignment for $\mathcal{S}$ can be computed in time $O(n^4m^3)$. □

From Theorem 5.5 we conclude the following corollaries.

COROLLARY 5.6. *Rectilinear planarity testing is NP-complete.*

COROLLARY 5.7. *Computing a planar orthogonal drawing with the minimum number of bends is NP-hard.*

We can strengthen Corollary 5.7 as follows.

COROLLARY 5.8. *Let G be an n-vertex planar graph whose minimum number of bends in any planar orthogonal drawing is b^*. Computing a planar orthogonal drawing of G with $O(b^* + n^{1-\epsilon})$ bends is NP-hard for $\epsilon > 0$.*

Proof. Suppose there is a polynomial-time algorithm A that computes a planar orthogonal drawing of G with at most $c(b^* + n^{1-\epsilon})$ bends, where c is some constant. We can then use algorithm A to test in polynomial time whether graph G is rectilinear planar as follows. Construct a graph G' consisting of $K = \lceil (cn^{1-\epsilon})^{1/\epsilon} \rceil + 1$ copies of

G and give G' as an input to algorithm A. Clearly, G is rectilinear planar if and only if G' has a planar orthogonal drawing with fewer than K bends. Since G' has Kn vertices and $K > c(Kn)^{1-\epsilon}$, algorithm A computes a drawing of G' with fewer than K bends if and only if G is rectilinear planar. □

6. Conclusions. Finding efficient algorithms for upward and rectilinear planarity testing had been an open problem for many years. In this paper we have shown that a polynomial-time algorithm for either of these problems is unlikely to exist by proving that both problems are NP-complete. NP-completeness of rectilinear planarity testing also implies that the bend-minimization problem for planar orthogonal drawings is NP-hard.

Acknowledgments. We would like to thank Giuseppe Di Battista for useful discussions and Ivan Rival for comments on a preliminary version of this paper.

NEW ALGORITHMIC ASPECTS OF THE LOCAL LEMMA WITH APPLICATIONS TO ROUTING AND PARTITIONING*

TOM LEIGHTON†, CHI-JEN LU‡, SATISH RAO§, AND ARAVIND SRINIVASAN¶

Abstract. The Lovász local lemma (LLL) is a powerful tool that is increasingly playing a valuable role in computer science. The original lemma was nonconstructive; a breakthrough of Beck and its generalizations (due to Alon and Molloy and Reed) have led to constructive versions. However, these methods do not capture some classes of applications of the LLL. We make progress on this by providing algorithmic approaches to two families of applications of the LLL. The first provides constructive versions of certain applications of an extension of the LLL (modeling, e.g., hypergraph-partitioning and low-congestion routing problems); the second provides new algorithmic results on constructing disjoint paths in graphs. Our results can also be seen as constructive upper bounds on the integrality gap of certain packing problems. One common theme of our work is a "gradual rounding" approach.

Key words. disjoint paths, randomized rounding, integer programming

1. Introduction.

The Lovász local lemma (LLL) is a powerful tool that can be used to show the existence of various types of (discrete) structures [7]. Let e denote the base of natural logarithms and $E_1, E_2, \ldots, E_m$ be events with $\max_i \Pr[E_i] \leq p$. If each E_i is mutually independent of all but at most D of the other events E_j and if $ep(D+1) \leq 1$, then the key claim of the LLL (symmetric case) is that $\Pr[\bigwedge_{i=1}^{m} \overline{E_i}] \geq (1-ep)^m > 0$. See, e.g., [3, 19] for many applications of this. The term $(1-ep)^m$, though positive, is often "tiny," so the result does not directly imply an efficient algorithm to produce a structure that avoids all the E_i. Breakthroughs in this direction have been made by Beck [4] and generalized by Alon [1] and Molloy and Reed [18]. However, as mentioned in [4, 1, 18], certain classes of applications of the LLL are not covered by these results. One such class arises because the approaches of [4, 1, 18] require $pD^3 = \mathrm{O}(1)$; they require something close to "$pD^9 = \mathrm{O}(1)$" for some situations. More importantly, as sketched in section 4.1,

they do not guarantee polynomial-time algorithms in some settings where the underlying random variables have "large" ranges, even if $pD^c = \mathrm{O}(1)$ for an arbitrarily large constant c. Another such class involves some extensions of the LLL where $D \gg p^{-1}$. Here, we provide constructive approaches for certain instances of both of these classes; we now start with a framework that motivates many of the problems considered.

Let $[t] \doteq \{1, 2, \ldots, t\}$. The NP-hard *low-congestion routing* problem has attracted much attention, e.g., from the VLSI layout and network routing viewpoints [21, 11]. Given a graph $G = (V, E)$ and a collection $\mathcal{T} = \{(s_i, t_i) : i \in [k]\}$ of pairs of vertices in G, how do we construct an (s_i, t_i) path for each i so that the *congestion* (maximum number of paths using any given edge) C is minimized? The multicommodity flow relaxation of this problem is to send one unit of flow from s_i to t_i for each i; the resultant minimum *fractional congestion* (maximum amount of flow using any edge) y^* is a lower bound on C. Since this relaxation is, e.g., a linear program (LP), the corresponding optimal multicommodity flow can be found efficiently. Next suppose we do a flow decomposition: for each (s_i, t_i), we find a set of ℓ_i paths $P_{i,j}$ for $j \in [\ell_i]$, with positive flow values that sum to 1. We can assume without loss of generality (w.l.o.g.) that $\sum_{i \in [k]} \ell_i \leq m$, as each time we can select a path and assign it a flow that saturates at least one edge on it (see, e.g., [21]). Finally, we want to choose exactly one path for each pair to minimize the congestion C. The first two steps can be done efficiently, so the final step is our focus.

How large can C be as a function of y^* and of some other parameters of G? (Even the special case $y^* = \mathrm{O}(1)$ is of much interest; $C \leq \mathrm{O}(\log |V| / \log \log |V|)$ here [21]. This special case is related to several conjectures and results [23, 15, 17, 14].) Our first family of results, described in section 1.1, yields new constructive results for generalizations of this question. Our second family of results, discussed in section 1.2, is related to the question, How large can $y^* < 1$ be if we *require* that $C = 1$, i.e., if we need an edge-disjoint routing?

1.1. Routing, partitioning, and minmax integer programs. Our first family of results concerns *minmax integer programs* (MIPs) as defined in the following; these were named *minimax integer programs* in [25].

Definition 1.1. *An MIP has variables Y and $\{x_{i,j} : i \in [k], j \in [\ell_i]\}$, for some integers $\{\ell_i\}$. Let $N = \sum_{i \in [k]} \ell_i$ and let x denote the N-dimensional vector of the variables $x_{i,j}$ (arranged in any fixed order). An MIP seeks to minimize a real Y subject to:* (i) $\forall i \in [k]$ $\sum_{j \in [\ell_i]} x_{i,j} = 1$*;* (ii) *a system of linear inequalities $Ax \leq \vec{Y}$, where $A \in [0,1]^{m \times N}$ and $\vec{Y}$ is the m-dimensional vector with the variable Y in each component, and* (iii) $\forall i, j,\ x_{i,j} \in \{0, 1\}$.

For convenience, we will call (i) the equality constraints, (ii) the congestion constraints, and (iii) the integrality constraints.

Note that the final step of the low-congestion routing problem can be captured by this form of MIP: the binary variable $x_{i,j}$, for $i \in [k]$ and $j \in [\ell_i]$, indicates whether or not the path $P_{i,j}$ is chosen, and $A_{r,(i,j)}$, for $r \in [m]$, $i \in [k]$, and $j \in [\ell_i]$, indicates whether the edge r is in the path $P_{i,j}$. The MIP problem also arises from a canonical NP-hard hypergraph-partitioning problem [9], which can be applied to support some divide and conquer approaches [2, 12, 16]. We are given a set-system $H = (V, F)$, where $V = [k]$ and $F = \{S_1, \ldots, S_M\} \subseteq 2^V$. Given a positive integer ℓ, the problem is to partition V into ℓ parts, so that *each* S_j is "split well": we want a $\chi : V \to [\ell]$ that minimizes $Y = \max_{j \in [M], q \in [\ell]} |\{i \in S_j : \chi(i) = q\}|$. This is easily written as an MIP with $m = M\ell$.

In MIPs, two parameters, d and κ, are of particular importance to us. Let d denote the maximum number of nonzero entries in any column of the matrix A. In the context of the low-congestion routing problem, d is the length of the longest path among the paths $P_{i,j}$. Let $\kappa \geq 1$ be such that the minimum nonzero entry of A is κ^{-1}. As was for the low-congestion routing problem, an LP relaxation for an MIP is to remove the integrality constraints (iii). The resulting LP optimum y^* is a lower bound on Y. As MIPs are NP-hard, we seek approximation algorithms for them: we will present an efficient way of rounding an optimal solution to the LP. The current-best upper-bounds on Y (as a function of y^* and other parameters) are due to [25], improving on earlier work of [21]. In particular, Y has been shown to be "not much above" y^* if d is "small," i.e., if an MIP instance is *column-sparse*. However, these techniques are nonconstructive and are based on an extension of the LLL. Here, we make progress on the algorithmic aspect, i.e., we develop approximation algorithms for MIPs, by focusing on MIP instances where κ is not "too large": indeed, note that we have $\kappa = 1$ for MIPs with $\{0,1\}$ matrices A (e.g., for low-congestion routing and hypergraph-partitioning).

The previous-best result for general MIPs was nonconstructive and showed that $Y \leq y^*(1 + \mathrm{O}(L'(y^*, 1/(2d)))) + \mathrm{O}(1)$ [25], where L' is a function to be defined in section 2. Here, we present a deterministic polynomial-time algorithm that will produce an integral solution of value at most $y^*(1+\mathrm{O}(L'(y^*, 1/(d\kappa))))+\mathrm{O}(1)$. $L'(\mu, p)$ depends logarithmically on p^{-1}; thus, for families of MIPs where, e.g., κ grows at most as fast as poly(d), we match the previous-best results *constructively*, to within a constant factor. Also, for any family of MIPs where $y^* = \omega(\log(d+\kappa))$ as $d\kappa \to \infty$, our algorithm will produce an integral solution of value $y^*(1 + o(1))$ (e.g., in the hypergraph-partitioning problem, we can asymptotically constructively match the LP optimum if $\ell = o((\max_i |S_i|)/\log d)$, where d is the degree of H). For general MIPs, our improvement over the previous-best *constructive* result [21] is in, essentially, replacing m by $d\kappa$ in the integral solution produced: we get good improvements for MIP instances where $d\kappa \ll m$.

See [6] for recent related results on constructive results for families of MIPs.

1.2. Constructive sufficient conditions for disjoint paths. Suppose we require congestion $C = 1$ in the routing problem described before. Let $G = (V, E)$ with $|V| = n$ and $|E| = m$. Randomized rounding approaches show that if $y^* \leq a_0/\sqrt{m}$, then $C = 1$ is achievable constructively; on the other hand, there are instances where $y^* = \Theta(1/\sqrt{n})$ and $C \geq 2$ [11]. Thus, the gap is large in general. An interesting alternative parametrization is based on d, the length of a longest path in a fractional optimal solution; the existentially optimal result that $C = 1$ if $y^* \leq a_1/d$ has been shown via the LLL [14]. (a_0, a_1, a_2, etc. denote positive constants.) It would be of much interest to make this constructive. As mentioned above, the approaches of [4, 1, 18] do not seem to extend here. We get around this by an approach that generates a large number of paths according to a carefully chosen distribution. Though many of these paths could intersect, we show that if $y^* \leq a_2/(d \ln k)$, then we can locate an edge-disjoint collection within these paths with high probability (whp).

Thus, we present new algorithmic approaches to some classes of packing problems, where the previous-best results were nonconstructive, based on versions of the LLL.

2. Preliminaries. Let $X_1, X_2, \ldots, X_n$ be a sequence of independent random variables taking values from $[0,1]$ with $\mathrm{E}[X_i] = p_i$. Let $X \doteq \sum_{i\in[n]} X_i$ and $\mu \doteq$

$\mathrm{E}[X] = \sum_{i\in[k]} p_i$. Let S_b be the bth elementary symmetric polynomial, i.e.,

$$S_b(p_1,\ldots,p_n) \doteq \sum_{I\subseteq[k],|I|=b} \prod_{i\in I} p_i.$$

We summarize the large deviation bounds of Chernoff [5], Hoeffding [10], and Schmidt, Siegel, and Srinivasan [22] in the following lemmas.

LEMMA 2.1. *For $0 \le \delta \le 1$, $\Pr[|X-\mu| \ge \mu\delta] \le 2e^{-\mu\delta^2/3}$.*

LEMMA 2.2. *For $\delta \ge 0$, $\Pr[X \ge \mu(1+\delta)] \le S_{\lceil\mu\delta\rceil}(p_1,\ldots,p_n)/\binom{\mu(1+\delta)}{\lceil\mu\delta\rceil} \le H(\mu,\delta)$, where $H(\mu,\delta) \doteq (e^\delta/(1+\delta)^{(1+\delta)})^\mu$.*

For $p \in (0,1)$, let $L(\mu,p)$ be the smallest $\delta \ge 0$ such that $H(\mu,\delta) \le p$. It is not hard to see that

$$L(\mu,p) = \begin{cases} \Theta\left(\sqrt{\frac{\log p^{-1}}{\mu}}\right) & \text{if } \mu \ge \frac{1}{2}\log p^{-1}; \\ \Theta\left(\frac{\log p^{-1}}{\mu \log((\log p^{-1})/\mu)}\right) & \text{otherwise.} \end{cases}$$

In [25], a related bound $L'(\mu,p)$ was used, which was defined to be the smallest $\delta \ge 0$ such that $\lceil\mu\delta\rceil H(\mu,\delta) \le p$. So, for this δ, we have

$$\Pr[X \ge \mu(1+L'(\mu,p))] \le p/\lceil\mu\delta\rceil.$$

It can also be seen that

$$L'(\mu,p) = \begin{cases} \Theta\left(\sqrt{\frac{\log(\mu+p^{-1})}{\mu}}\right) & \text{if } \mu \ge \frac{1}{2}\log p^{-1}; \\ \Theta\left(\frac{\log p^{-1}}{\mu \log((\log p^{-1})/\mu)}\right) & \text{otherwise.} \end{cases}$$

3. Constructive approximations for minmax integer programs. We now present results for MIPs. Consider a generic MIP and its relaxation, as described in section 1. Let $\{x^*_{i,j} : i \in [k], j \in [\ell_i]\}$ denote the given optimal solution to the LP relaxation. Starting with this, the algorithm will construct a sequence of feasible solutions to the LP relaxation; variables $x_{i,j}$ that get rounded to 0 or 1 will never have their values realtered. There are two relevant parameters:

- ℓ: the maximum, over all $i \in [k]$, of the number of variables $x_{i,j}$ to be rounded[1];
- t: the maximum number of variables to be rounded in a row of congestion constraints.

We will show two ways to do the rounding. The first one has a slightly inferior performance and gives the following theorem.

THEOREM 3.1. *There exists a deterministic polynomial-time algorithm for finding a solution of value at most $y^*(1+O(L(y^*,1/(dt\ell))))$ for any given MIP.*

The dependency on $t\ell$ in Theorem 3.1 is undesirable, as $t\ell$ sometimes could be large. Next, we show how to do the rounding in several iterations, so that t and ℓ decrease in each iteration and finally reach $\mathrm{poly}(\kappa,d,y^*)$, with only a slight increase in y^*. Then we can apply Theorem 3.1 to get the following theorem. Note that $L(y^*,1/\mathrm{poly}(\kappa,d,y^*)) = O(L'(y^*,1/(d\kappa)))$.

THEOREM 3.2. *There exists a deterministic polynomial-time algorithm for finding a solution of value $y^*(1+O(L'(y^*,1/(d\kappa))))+O(1)$ for any given MIP.*

Next, we prove the above two theorems.

[1] We can assume w.l.o.g. that the LP optimal solution is a *basic* feasible solution, so $\ell \le m$ and $t \le m$.

3.1. Proof of Theorem 3.1. Independently for each $i \in [k]$, randomly round exactly one $x^*_{i,j}$ to 1, with $x^*_{i,j}$ chosen with probability $x^*_{i,j}$, and let $z_{i,j}$ be the random variable with the rounded value. Let z be the N-dimensional vector of the $z_{i,j}$'s. We say that a row $r \in [m]$ of the congestion constraints is *affected* by another row $r' \in [m]$ if the random variables $(Az)_r$ and $(Az)_{r'}$ are dependent, which occurs exactly when

$$\exists i \in [k],\ \exists j, j' \in [\ell_i] \text{ s.t. } A_{r,(i,j)}, A_{r',(i,j')} \neq 0, \text{ and } x^*_{i,j}, x^*_{i,j'} \notin \{0,1\}.$$

So each row can be affected by at most $D \doteq dt\ell$ other rows. For $r \in [m]$ and $i \in [k]$, define

$$Z_{r,i} \doteq \sum_{j \in [\ell_i]} A_{r,(i,j)} z_{i,j}.$$

Clearly, for each $r \in [m]$, $Z_{r,1}, \ldots, Z_{r,k}$ is a sequence of independent random variables taking values from $[0,1]$, with $\mathrm{E}[\sum_{i\in[k]} Z_{r,i}] = \mathrm{E}[(Az)_r] \leq y^*$, so

$$\Pr\left[\sum_{i\in[k]} Z_{r,i} > y^*\left(1 + L\left(y^*, \frac{1}{4D}\right)\right)\right] \leq \frac{1}{4D}.$$

By the LLL, there exists a rounding such that for every $r \in [m]$, $(Az)_r \leq y^*(1 + L(y^*, \frac{1}{4D}))$. We will follow the broad approach of [4, 1] to find a rounding such that for every $r \in [m]$,

$$(Az)_r \leq y^*\left(1 + O\left(L\left(y^*, \frac{1}{D}\right)\right)\right).$$

A direct application of the ideas of [4, 1] leads to $(Az)_r \leq cy^*(1 + L(y^*, \frac{1}{D}))$ for some constant $c > 1$, which is not sufficient for use in Theorem 3.2. A twist is needed to achieve our bound.

We first show a randomized algorithm and then derandomize it.

3.1.1. A randomized algorithm. For a row $r \in [m]$ and for $i \in [k], j \in [\ell_i]$ with $x^*_{i,j} \notin \{0,1\}$, we say that $z_{i,j}$ is a variable of r if $A_{r,(i,j)} > 0$. Consider the graph $G(V,E)$, where $V = [m]$ represents the m rows, and two nodes are adjacent iff one can be affected by the other. Note that each node has at most D neighbors. Let $G^{(a,b)}(V,E')$ be the graph with two nodes adjacent iff their distance is exactly a or b in G. Call a set of nodes in G an (a,b)-tree if they form a connected component in $G^{(a,b)}$. Call a node $r \in [m]$ *bad* if

$$(Az)_r = \sum_{i\in[k]} Z_{r,i} > y^*\left(1 + L\left(y^*, \frac{1}{6D^4}\right)\right),$$

which happens with probability at most $\frac{1}{6D^4}$. For a (1, 2)-tree T and a node $r \in [m]$, let $I_{r,T}$ denote the set of indices $i \in [k]$ such that $Z_{r,i}$ can be affected by rerounding variables in the rows represented by $T \setminus \{r\}$; i.e., $I_{r,T}$ is the set

$$\{i \in [k] : \exists r' \in T \setminus \{r\},\ \exists j, j' \in [\ell_i] \text{ s.t. } A_{r,(i,j)}, A_{r',(i,j')} \neq 0, \text{ and } x^*_{i,j}, x^*_{i,j'} \notin \{0,1\}\}.$$

Let $\overline{I}_{r,T} \doteq [k] \setminus I_{r,T}$. Call a node r *bad for* T if

$$\sum_{i\in\overline{I}_{r,T}} Z_{r,i} > \mathrm{E}\left[\sum_{i\in\overline{I}_{r,T}} Z_{r,i}\right] + y^* L\left(y^*, \frac{1}{6D^4}\right); \tag{3.1}$$

for any fixed r, r is bad for T with probability at most $\frac{1}{6D^4}$, by the definition of L. Call a (1, 2)-tree T *bad*, if every node $r \in T$ is either bad or bad for T.

The intuition is that our randomized rounding is unlikely to lead to large bad (1, 2)-trees and that variables in different bad (1, 2)-trees can be re-rounded separately. Our algorithm consists of at most three phases. In the first phase, we find a rounding such that all bad (1, 2)-trees have size at most $2D \log m / \log D$. Then we try to re-round variables in each bad (1, 2)-tree separately. If m is small, the rerounding can be done in the second phase. Otherwise we need another phase.

Phase 1. First we need a lemma.

LEMMA 3.3. *The probability that our randomized rounding leads to a bad* $(1,2)$*-tree of size at least* $2D \log m / \log D$ *is at most* $1/m$.

Proof. Let $u = 2 \log m / \log D$. As a (1, 2)-tree of size Du must contain a (2, 3)-tree of size u and two nodes of a (2, 3)-tree do not affect each other, a (1, 2)-tree of size Du is bad with probability at most $(\frac{1}{6D^4} + \frac{1}{6D^4})^u = (\frac{1}{3D^4})^u$. The number of (1, 2)-trees of size Du is at most $\frac{m}{(D^2-1)Du+1}\binom{D^3u}{u} < m(\frac{3D^3u}{u})^u = m(3D^3)^u$; see the appendix. Thus the probability that we get a bad (1, 2)-tree of size Du is at most

$$m(3D^3)^u \left(\frac{1}{3D^4}\right)^u \le m\left(\frac{1}{D}\right)^u \le \frac{1}{m}. \qquad \square$$

This gives us a randomized algorithm for finding a rounding with no large bad (1, 2)-trees. In section 3.1.2, we will show how to find such a rounding deterministically, by using the method of conditional probabilities [20].

Phase 2. Suppose we have found a rounding with no bad (1, 2)-tree of size Du. Consider a maximal bad (1, 2)-tree T. We will reround all variables in T using the same randomized approach as in Phase 1. Now the neighbors of T become *dangerous* as they are affected by T and could turn bad after the rerounding. Let $N(T)$ denote the set of T's neighbors. Note that nodes in T cannot be affected by other bad (1, 2)-trees and nodes in $N(T)$ are not dangerous for other bad (1, 2)-trees. So we can deal with each bad (1, 2)-tree separately.

For $r \in N(T)$, since T is maximal and $r \notin T$, we see from (3.1) that

$$\sum_{i \in \bar{I}_{r,T}} Z_{r,i} \le \mathrm{E}\left[\sum_{i \in \bar{I}_{r,T}} Z_{r,i}\right] + y^* L\left(y^*, \frac{1}{6D^4}\right). \tag{3.2}$$

After the rerounding, we call a node $r \in T \cup N(T)$ bad if

$$(Az)_r > y^*\left(1 + 2L\left(y^*, \frac{1}{6D^4}\right)\right).$$

For $r \in T$, this obviously happens with probability at most $\frac{1}{6D^4}$. For $r \in N(T)$, as $\sum_{i \in \bar{I}_{r,T}} Z_{r,i}$ is not affected, we get from (3.2) that r is bad only if

$$\sum_{i \in I_{r,T}} Z_{r,i} > \mathrm{E}\left[\sum_{i \in I_{r,T}} Z_{r,i}\right] + y^* L\left(y^*, \frac{1}{6D^4}\right),$$

which happens with probability at most $\frac{1}{6D^4}$.

$T \cup N(T)$ has at most $Du + D^2u = D(D+1)u$ nodes. Suppose $\sqrt{\log m / \log\log m} \le D$. Then $u = 2 \log m / \log D \le 5 \log m / \log\log m \le 5D^2$. So the probability of having

a bad node is at most

$$D(D+1)u\frac{1}{6D^4} < 5(D+1)D^3\frac{1}{6D^4} < 1.$$

We can find a good rerounding in deterministic polynomial time via the method of conditional probabilities. The proof is omitted here, as the idea is similar to that in section 3.1.2.

Otherwise, we have $D < \sqrt{\log m/\log\log m}$. Using a procedure similar to that in Phase 1, we can find a rerounding such that all bad (1, 2)-trees have size at most

$$O(D\log(D^2\log m)/\log D) = O(\sqrt{\log m\log\log m}/\log D).$$

Then we enter Phase 3.

Phase 3. The LLL shows that a good rerounding exists. Since (i) each bad (1, 2)-tree has at most $\beta = O(\sqrt{\log m\log\log m}/\log D)$ nodes, and (ii) $t \le D \le \sqrt{\log m/\log\log m}$, each bad (1, 2)-tree has at most $t\beta = O(\log m/\log D)$ variables. So, we can use an exhaustive search in deterministic poly(m) time to find a good rerounding such that for every $r \in [m]$,

$$(Az)_r \le y^*\left(1 + 3L\left(y^*, \frac{1}{6D^4}\right)\right).$$

3.1.2. Derandomization of Phase 1. Let R denote the set of all (1, 2)-trees of size $Du = 2D\log m/\log D$. From Lemma 3.3, a randomized rounding is unlikely to result in some tree in R being bad. How do we find a good rounding deterministically? The idea is to use the standard *method of conditional probabilities* with a pessimistic estimator [20]. For $i \in [k]$, let x_i^* denote the vector $(x^*_{i,1},\ldots,x^*_{i,\ell_i})$, and let z_i denote $(z_{i,1},\ldots,z_{i,\ell_i})$. We want to round x_i^* to z_i one at a time, subject to the equality constraints of the MIP. The value of z_i is chosen to minimize the probability of some tree in R being bad if we randomly round the remaining $x^*_{i+1},\ldots,x^*_k$, conditional on the previously chosen $z_1,\ldots,z_{i-1}$. The hope is that the final rounding is a good one because the final conditional probability, which is either 0 or 1, is at most the original unconditional one, which is less than 1. However, it is not easy to compute the exact conditional probability at each step. So we use a pessimistic estimator instead.

For $T \in R$, let T_{23} be an arbitrary maximal (2, 3)-tree in T. Suppose that we have already fixed $z_1,\ldots,z_i$. Then

$$\begin{aligned} P_i(z_1,\ldots,z_i) &\doteq \Pr_{z_{i+1},\ldots,z_k}[\exists T \in R, T \text{ is bad} \mid z_1,\ldots,z_i] \\ &\le \sum_{T\in R}\prod_{r\in T_{23}}\Pr_{z_{i+1},\ldots,z_k}[r \text{ is bad or bad for } T \mid z_1,\ldots,z_i]. \end{aligned}$$

Let $b \doteq \lceil y^*L(y^*, \frac{1}{6D^4})\rceil$ and $c \doteq y^*(1 + L(y^*, \frac{1}{6D^4}))$. Let $w_{r,T} \doteq \mathrm{E}[\sum_{j\in\overline{I}_{r,T}} Z_{r,j}] + y^*L(y^*, \frac{1}{6D^4})$, and let $S_b^r(I)$ denote S_b on input $(\mathrm{E}[Z_{r,v}] : v \in I)$, for $I \subseteq [k]$. Note that

$$\mathrm{E}[Z_{r,v}] = \begin{cases} \displaystyle\sum_{j\in[\ell_v]} A_{r,(v,j)}z_{v,j} & \text{if } z_v \text{ has been fixed,} \\ \displaystyle\sum_{j\in[\ell_v]} A_{r,(v,j)}x^*_{v,j} & \text{otherwise.} \end{cases}$$

Consider the following pessimistic estimator:

$$A_i(z_1,\dots,z_i) \doteq \sum_{T\in R}\prod_{r\in T_{23}}\left(\frac{S_b^r([k])}{\binom{c}{b}}+\frac{S_b^r(\overline{I}_{r,T})}{\binom{w_{r,T}}{b}}\right).$$

From Lemma 2.2, we have $P_i(z_1,\dots,z_i)\le A_i(z_1,\dots,z_i)$. Now,

$$\begin{aligned}A_i(z_1,\dots,z_i) &= \sum_{T\in R}\prod_{r\in T_{23}}\mathrm{E}_{z_{i+1}}\left[\frac{S_b^r([k])}{\binom{c}{b}}+\frac{S_b^r(\overline{I}_{r,T})}{\binom{w_{r,T}}{b}}\right]\\ &= \sum_{T\in R}\mathrm{E}_{z_{i+1}}\left[\prod_{r\in T_{23}}\left(\frac{S_b^r([k])}{\binom{c}{b}}+\frac{S_b^r(\overline{I}_{r,T})}{\binom{w_{r,T}}{b}}\right)\right]\\ &= \mathrm{E}_{z_{i+1}}[A_{i+1}(z_1,\dots,z_{i+1})],\end{aligned}$$

where the second equality is because two distinct nodes of T_{23} share no variable. We choose z_{i+1} to minimize $A_{i+1}(z_1,\dots,z_{i+1})$. Then we have

$$\frac{1}{m}\ge A_0\ge A_1(z_1)\ge\cdots\ge A_k(z_1,\dots,z_k)\ge P_k(z_1,\dots,z_k).$$

$P_k(z_1,\dots,z_k)$ is either 1 or 0 depending on whether or not the rounding results in a bad (2, 3)-tree of size u. As $P_k(z_1,\dots,z_k)<1$, we have found a rounding such that there is no bad (1, 2)-tree of size Du.

It remains to show that for any i and $z_1,\dots,z_i$, $A_i(z_1,\dots,z_i)$ can be computed efficiently. There are poly(m) number of (1, 2)-trees of size Du in R, and they can be enumerated in polynomial time (see appendix). Next, we show how to compute S_b efficiently. For any $y_1,\dots,y_k$, note that

$$S_b(y_1,\dots,y_k)=y_k\cdot S_{b-1}(y_1,\dots,y_{k-1})+S_b(y_1,\dots,y_{k-1}).$$

Thus, using a dynamic programming approach that is similar to the standard method of computing Pascal's triangle, we can compute S_b in deterministic polynomial time.

So A_i can be computed in deterministic polynomial time.

3.2. Proof of Theorem 3.2. Let $x=x^*$, $y=y^*$, and $D=dt\ell$. Note that we can just apply Theorem 3.1 if the following holds:

$$D\le\kappa^8d^8 \text{ or } D\le y^8 \text{ or } D\le c_0 \text{ or } D\le y^{-8/5}. \tag{3.3}$$

Here, c_0 is some absolute constant to be chosen after equation (3.6). So suppose (3.3) is not true; we will try to reduce D in several iterations to finally reach this condition. The idea is similar to that in [25], and we make the key observation that the approach of [25] can reduce not only ℓ but also t. So we can use the standard version of the LLL, instead of the generalization of the LLL developed in [25]. We consider two cases depending on the range of y.

Case 1. $y\ge 1$. We will scale up each $x_{i,j}$, do a rounding, and then normalize each $x_{i,j}$ back to satisfy the equality constraint. This is done as follows.

Recall the notion of randomized rounding of a real [21]: given a real $\alpha\ge 0$, we round it to $\lceil\alpha\rceil$ with probability $\alpha-\lfloor\alpha\rfloor$ and round it to $\lfloor\alpha\rfloor$ with probability $1-(\alpha-\lfloor\alpha\rfloor)$. Let $x'_{i,j}=x_{i,j}y^2\log^3 D$. We will randomly round each $x'_{i,j}$ *independently.* (Notice the difference from the rounding in Theorem 3.1.) Let $z_{i,j}$ be the random

variable taking the value $\lceil x'_{i,j} \rceil$ with probability $x'_{i,j} - \lfloor x'_{i,j} \rfloor$ and taking the value $\lfloor x'_{i,j} \rfloor$ with probability $\lceil x'_{i,j} \rceil - x'_{i,j}$. Note that $\mathrm{E}[z_{i,j}] = x'_{i,j}$; hence, for each $r \in [m]$, we have $\mathrm{E}[(Az)_r] \le y^3 \log^3 D$. Let R_r denote the bad event that

$$(Az)_r > y^3 \log^3 D \left(1 + L\left(y^3 \log^3 D, \frac{1}{6D^4}\right)\right),$$

with $\Pr[R_r] \le \frac{1}{6D^4}$. We will call events such as R_r as "type R" events. For each $i \in [k]$, we have $\mathrm{E}[\sum_{j \in [\ell_i]} z_{i,j}] = y^2 \log^3 D$; let S_i denote the bad event that

$$\left| \sum_{j \in [\ell_i]} z_{i,j} - y^2 \log^3 D \right| > 4y \log^2 D,$$

with $\Pr[S_i] \le \frac{1}{6D^4}$ from Lemma 2.1. Call these "type S" events.

Each type R event depends on at most dt type R events and at most t type S events. Each type S event depends on at most $d\ell$ type R events and on no other type S events. There are $m' = m + k$ bad events, each happening with probability at most $\frac{1}{6D^4}$, and each depending on at most D other bad events. From the LLL, there exists a rounding such that no bad event happens. An algorithm similar to that in the previous section can be used to find a good rounding in deterministic polynomial time, as sketched below. In Phase 1, we find a rounding such that all bad (1, 2)-trees have size at most $2D \log m' / \log D$. In Phase 2, either we can find a good rerounding and we are done, or we can find a rerounding such that all bad (1, 2)-trees are very small. Then we can use an exhaustive search to find a good rerounding in Phase 3. After this, we have that $\forall r \in [m]$,

$$(Az)_r \le y^3 \log^3 D(1 + O(1/(y^{1.5} \log D)))$$

and $\forall i \in [k]$,

$$\left| \sum_{j \in [\ell_i]} z_{i,j} - y^2 \log^3 D \right| \le O(y \log^2 D).$$

Then we do the normalization

$$x_{i,j} = \frac{z_{i,j}}{\sum_{v \in [\ell_i]} z_{i,v}}$$

to satisfy the equality constraints. Now for every $r \in [m]$,

$$(Ax)_r \le \frac{y^3 \log^3 D(1 + O(1/(y^{1.5} \log D)))}{y^2 \log^3 D(1 - O(1/(y \log D)))} = y\left(1 + O\left(\frac{1}{y \log D}\right)\right), \tag{3.4}$$

so the values $(Ax)_r$ increase just a little. Notice that each $z_{i,j}$ is a nonnegative integer. Thus, for each $i \in [k]$, the number of nonzero $z_{i,j}$ (or $x_{i,j}$), for $j \in [\ell_i]$, is at most

$$\sum_{j \in [\ell_i]} z_{i,j} = O(y^2 \log^3 D) = O(D^{1/4} \log^3 D), \tag{3.5}$$

since (3.3) is not true. (The constants hidden in the "big-Oh" notation in (3.4) and in (3.5), as well as in the remaining big-Oh upper bounds in this subsection, are all

absolute constants that are *independent* of c_0.) Next, recall that every nonzero entry of A is at least κ^{-1}. So, for each $r \in [m]$, the number of nonzero $A_{r,(i,j)}x_{i,j}$ is at most

$$\kappa(Az)_r = O(\kappa y^3 \log^3 D) = O(\kappa D^{3/8} \log^3 D).$$

The parameters ℓ and t drop to $O(D^{1/4} \log^3 D)$ and $O(\kappa D^{3/8} \log^3 D)$, respectively. Thus there is an absolute constant c_0', independent of c_0, such that the parameter D comes down to

$$\begin{aligned} c_0' d\kappa D^{5/8} \log^6 D &\le c_0' \kappa^{-1} D^{1/8} \kappa D^{5/8} \log^6 D \\ &= c_0' D^{3/4} \log^6 D, \end{aligned} \tag{3.6}$$

which is at most $D^{7/8}$ if we choose c_0 large enough such that $\forall D > c_0$, the bound $c_0' \log^6 D < D^{1/8}$ holds. Then repeating the above process $O(\log \log D)$ times will ensure that D becomes small enough to satisfy condition (3.3).

Finally, how large can y become? Suppose $y_0, y_1, \ldots, y_s$ are the successive values assumed by y, and $D_0, D_1, \ldots, D_s$ are the successive values assumed by D in the above process. We see from (3.6) that if c_0 is large enough, then $\log D_{i+1} \le (7/8) \log D_i$; hence, $\log D_i \ge (8/7)^{i-s} \log D_s$. Thus we see from (3.4) that

$$y_{i+1} \le y_i + O(1/\log D_i) \le y_i + O((7/8)^{s-i} (\log D_s)^{-1});$$

a telescoping sum shows that $y_s \le y_0 + O(1)$. Now that (3.3) holds and y has increased by at most a constant, we can apply Theorem 3.1.

Case 2. $y < 1$. The idea is the same here. The scaling up is now $x'_{i,j} = x_{i,j} y^{-1} \log^3 D$, for each $i \in [k]$ and $j \in [\ell_i]$, and the rounding and normalization are similar.

4. Constructive sufficient conditions for disjoint paths. We now move on to the problem of lower bounds on y^* in our low-congestion routing problem that can guarantee algorithmically that the integral congestion C is 1. Our main result here is Theorem 4.1. In typical applications of it, the parameter p is likely to be $o(1)$ or bounded away from 1. So, the term "$\lceil \ln p^{-1} \rceil$" can be taken to be "$\ln p^{-1}$" for a first reading.

As will be seen below, we will employ certain randomized rounding and "scaling up–randomized rounding–scaling down" ideas similar to those of section 3.2. Also, one of our original applications of Theorem 4.1 was for edge-disjoint paths in *expander graphs*; however, this problem has been completely recently resolved by Frieze [8]. In section 4.1, we discuss why approaches such as those of [4, 1, 18] do not appear to yield Theorem 4.1.

THEOREM 4.1. *There is a constant $c_1 > 0$ such that the following holds. Suppose we are given any (directed or undirected) graph G, any k (multi-)sets of paths in it, $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_k$, and any parameter $p \in (0,1)$. Let the paths in $\mathcal{P}_i$ be denoted $P_{i,j}$; let d be the maximum, over all i, j, of the length of $P_{i,j}$. Let each $P_{i,j}$ carry some nonnegative amount of flow such that* (i) *the total flow in each $\mathcal{P}_i$ is 1, and* (ii) *for each edge in G, the total flow using it is at most $c_1/(d\lceil \ln p^{-1} \rceil)$. Then, there is a randomized polynomial algorithm to pick one path each from at least $k(1-p)$ of the $\mathcal{P}_i$, such that all paths chosen are edge-disjoint whp. (If we want one path from each of the $\mathcal{P}_i$, we can set, e.g., $p = 1/(2k)$.)*

Specializing to the case where all paths in any given $\mathcal{P}_i$ connect the same pair of vertices, we get the following.

COROLLARY 4.2. *There is a constant $c_1 > 0$ such that the following holds. Suppose we are given any (directed or undirected) graph G, any collection $\mathcal{T} = \{(s_i, t_i) : i \in [k]\}$ of vertex-pairs in G, and any parameter $p \in (0,1)$. Suppose there is a unit flow from s_i to t_i for each i, such that the fractional congestion is at most $c_1/(d\lceil \ln p^{-1} \rceil)$; d denotes the length of a longest flow-path. Then, there is a randomized polynomial algorithm to pick an (s_i, t_i)-path for at least $k(1-p)$ indices i, such that all paths chosen are edge-disjoint whp. (If we want one (s_i, t_i)-path for each i, we can set $p = 1/(2k)$.)*

Remark. Our algorithm will be easily seen to run in polynomial time and will involve several random processes. For each process for which success or failure can be checked efficiently, we will just show that the process succeeds with constant probability. This suffices since, letting N denote the "input size" for the problem, we can repeat each such process, say $O(N)$ times, to drive the failure probability down to $2^{-\Theta(N)}$. Thus, our algorithm will succeed whp.

We now present the algorithm and proof for Theorem 4.1.

Proof. We will choose the constant $c_1 \in (0,1)$ sufficiently small. Let $z \doteq d\lceil \ln p^{-1} \rceil / c_1$; thus, the *fractional congestion* (maximum flow using any given edge) is at most $1/z$. There are three simple steps in the algorithm:

Step 1. This is a "scaling up–randomized rounding–scaling down" step, similar to the one employed in Cases 1 and 3 of section 3.2. Let n be the number of vertices in G. Recall the notion of randomized rounding of a real α [21] from Case 1 of section 3.2. For a suitably large absolute constant $c_2 > 2$ (say 20), we scale all the flow values by $c_2 z \ln n$, and then conduct randomized rounding independently on each flow value (i.e., for each path $P_{i,j}$). By a standard analysis via Lemmas 2.1 and 2.2, we have whp that

(P1) the total flow f_i in each $\mathcal{P}_i$ is such that $c_2 z(\ln n)/2 \le f_i \le 2c_2 z \ln n$, and

(P2) the total flow on any edge is at most $2c_2 \ln n$.

(This can also be derandomized easily by the method of conditional probabilities.) Dividing the flow value on each $P_{i,j}$ by f_i, we restore the property that the total flow value in each $\mathcal{P}_i$ is 1. Furthermore, the fractional congestion now is at most

$$2c_2 \ln n (\min_i f_i)^{-1} \le 2c_2 \ln n (c_2 z (\ln n)/2)^{-1} = 4/z. \tag{4.1}$$

Let $x \doteq \max_i f_i$; (P1) shows that

$$c_2 z(\ln n)/2 \le x \le 2c_2 z \ln n. \tag{4.2}$$

Since the randomized rounding leads to integral flow values, we see, for any i, that the number of flow-paths $P_{i,j}$ carrying nonzero flow now is at most f_i; hence, the maximum number of flow-paths $P_{i,j}$ carrying nonzero flow now, for any i, is at most x.

Step 2. Suppose, after the scaling-rounding-rescaling process of Step 1, that flow path $P_{i,j}$ carries a flow of value $g_{i,j} \ge 0$. For each (i,j), we proceed as follows. Let $g'_{i,j}$ be the largest multiple of $1/(2x)$ that is no larger than $g_{i,j}$; replace $P_{i,j}$ by $2xg'_{i,j}$ copies of itself, each of the copies carrying a flow of precisely $1/(2x)$. We refer to the new paths as $P'_{i,\ell}$. Fix i. How many flow paths do we have in any $\mathcal{P}_i$ now? Since each flow value is now exactly $1/(2x)$ and the total flow in $\mathcal{P}_i$ is now at most 1, this number can be at most $2x$. On the other hand, recall that $\sum_j g_{i,j} = 1$, and, as seen above, that there are at most x (nonzero-flow) paths $P_{i,j}$. Since $g'_{i,j} \ge g_{i,j} - 1/(2x)$, we see by summing that $\sum_j g'_{i,j} \ge 1 - x/(2x) = 1/2$. Thus, since each of the new

flow-paths carries a flow of exactly $1/(2x)$, there must be at least x many $P'_{i,j}$. So, for each i, the set A_i of flow-paths $P'_{i,j}$ is such that

$$x \le |A_i| \le 2x. \tag{4.3}$$

In the rest of the algorithm description, "flow paths" shall refer to these newly constructed flow paths $P'_{i,j}$.

Let y denote the maximum number of flow-paths $P'_{i,j}$ that use any given edge. Now, all paths $P'_{r,s}$ carry a flow of exactly $1/(2x)$. Thus, by (4.1),

$$y \le (4/z)/(1/(2x)) = 8x/z \le 8(2c_2 z \ln n)/z = 16c_2 \ln n, \tag{4.4}$$

the second inequality following from (4.2).

Step 3. Let $t \doteq \lceil \ln p^{-1} \rceil$. Independently for each $i \in [k]$, we do the following. For each i, we randomly select t flow-paths (without replacement) from among the collection of flow-paths $P'_{i,j}$. (The bounds $c_2 > 2$, (4.3), and (4.2) show that $|A_i| \ge z \ln n$. Now, $t = c_1 z/d \le z \ln n$ since $c_1 < 1$. So our random-selection process is well defined.) Call all the paths selected here *tentatively chosen*. We will say that two paths $P'_{a,b}$ and $P'_{r,s}$ are *neighbors* iff $a \ne r$ and $P'_{a,b}$ and $P'_{r,s}$ share a common edge.

Call $P'_{i,j}$ *bad* iff it and some neighbor of it are both tentatively chosen; call i dangerous iff all its t tentatively chosen paths $P'_{i,j}$ are bad. We will next prove Theorem 4.3; let us see why this will help us complete the proof of Theorem 4.1. As usual, the probability of 2/3 in Theorem 4.3 can be boosted by repeating the random process sufficiently many times. Thus, we will be able to efficiently (i) select some $T \subseteq [k]$ of cardinality at least $k(1-p)$, and (ii) pick one tentatively chosen $P'_{i,j}$ for each $i \in T$, such that all the paths picked are edge-disjoint. □

THEOREM 4.3. *If $c_1 > 0$ is sufficiently small, then with probability at least* 2/3*, the number of dangerous i is at most kp.*

Proof. Since each path passes through at most d edges and since each edge has at most y flow-paths using it (by definition of y), we see that each flow-path has at most dy neighbors. Fix i. We now bound the probability that i is dangerous. Suppose i is dangerous, and that it has a collection S of t bad paths $P'_{i,j}$. For each path in S, choose one among its bad neighbors arbitrarily. Suppose there are q such distinct bad neighbors $p_1, p_2, \ldots, p_q$ of the elements of S, where $1 \le q \le t$. We can represent this by an unordered q-tuple $\langle [S_1, p_1], [S_2, p_2], \ldots, [S_q, p_q] \rangle$, where (i) the sets S_j form a partition of S, and (ii) p_j is a bad neighbor of all elements of S_j. Consider any such fixed tuple $T = \langle [S_1, p_1], [S_2, p_2], \ldots, [S_q, p_q] \rangle$. Suppose, for some distinct indices $u_1, u_2, \ldots, u_r$, that the $t+q$ paths in T are ℓ_1 paths from A_{u_1}, ℓ_2 paths from A_{u_2}, …, ℓ_r paths from A_{u_r}. (The positive integers r and $\ell_1, \ell_2, \ldots, \ell_r$ are such that $\ell_j \le t$ and $\sum_j \ell_j = t+q$.) The probability of all of T's $(t+q)$ paths getting tentatively chosen is

$$\left(\prod_{j=1}^{r} \left[\binom{|A_{u_j}| - \ell_j}{t - \ell_j} \Big/ \binom{|A_{u_j}|}{t} \right] \right) \le \prod_{j=1}^{r} (t/|A_{u_j}|)^{\ell_j} \le \prod_{j=1}^{r} (t/x)^{\ell_j} = (t/x)^{t+q}; \tag{4.5}$$

the second inequality is a consequence of (4.3).

Fix q. We next upper-bound the number of possible unordered q-tuples $\langle [S_1, p_1], [S_2, p_2], \ldots, [S_q, p_q] \rangle$. To do so, we will bound the number of such *ordered* q-tuples, and divide the result by $q!$. Let us now bound the number of ordered q-tuples. Clearly, we may assume that each S_j is nonempty. We first fix the cardinalities of the S_j: this can be done in $\binom{t-1}{q-1}$ ways, since $\sum_j |S_j| = t$ and as each S_j is nonempty. Suppose

$|S_j| = t_j$. Recall from (4.3) that a member $P'_{i,\ell}$ of S_1 can be picked in at most $2x$ ways. Given this choice, since p_1 is a neighbor of $P'_{i,\ell}$, p_1 can be picked in at most dy ways. Next, since the remaining $t_1 - 1$ elements of S_1 are all neighbors of p_1, they can be picked in at most $\binom{dy}{t_1-1}$ ways. Thus, the number of ways of choosing $[S_1, p_1]$ is at most

$$(2x) \cdot (dy) \cdot \binom{dy}{t_1 - 1} \leq (2x) \cdot (dy)^{t_1}. \tag{4.6}$$

Arguing similarly for $[S_2, p_2], \ldots, [S_q, p_q]$, we see, for each fixed choice of $t_1, t_2, \ldots, t_q$, that the number of ordered q-tuples is at most $\prod_{j=1}^{q}((2x) \cdot (dy)^{t_j}) = (2x)^q \cdot (dy)^t \leq 2^t x^q \cdot (dy)^t$. Next, as seen above, (i) there are

$$\binom{t-1}{q-1} \leq \binom{t}{q} \leq e^q t^q / q^q \leq e^t t^q / q^q$$

ways of choosing the t_i; (ii) the number of unordered q-tuples is the number of ordered q-tuples divided by $q!$. Combining with (4.5), the probability of existence of some q-tuple is at most

$$c_3^t x^q (dy)^t (t/q)^q (t/x)^{t+q} / q! \leq c_4^t (t/q)^{2q} (tdy/x)^t, \tag{4.7}$$

where $c_3, c_4 > 0$ are absolute constants; in going from the left-hand side (l.h.s.) to the right-hand side (r.h.s.), we have used the fact that $q! \geq (q/e)^q \geq q^q/e^t$. By calculus, it is evident that $(t/q)^{2q} \leq e^{2t/e}$. Next, by recalling that $z = dt/c_1$ and by using the lower bound on x and upper bound on y from (4.2) and (4.4), we see from (4.7) that the probability of existence of some q-tuple is at most $(c_5 c_1)^t$, where c_5 is an absolute constant which, in particular, is independent of c_1. Finally, since q can only take t values—from 1 to t—the probability that i is dangerous is at most $t(c_5 c_1)^t$, which can be made, say, at most $p/3$ by taking c_1 appropriately small (recall that $t = \lceil \ln p^{-1} \rceil$). Thus, by Markov's inequality, the probability that there are more than kp dangerous i is at most $1/3$. □

We now sketch two ways in which the constant factor c_1 in Theorem 4.1 can be increased; however, these methods do not replace c_1 by any super-constant term. First, in (4.6), we can upper-bound $\binom{dy}{t_1-1}$ by $(dy)^{t_1-1}/(t_1-1)!$. More interestingly, we can include an additional element of randomness in Step 3 of our algorithm as follows, motivated by a "random permutation" idea of [24]. Choose a random permutation σ of all the paths $P_{i,j'}$, and call $P_{i,j'}$ bad iff it and some neighbor of it *that precedes* $P_{i,j'}$ *in* σ, are both tentatively chosen. Call i dangerous iff all its t tentatively chosen paths $P'_{i,j}$ are bad, and note that we can efficiently select one tentatively chosen path for each nondangerous index i, in such a way that these selected paths are edge-disjoint. This idea helps improve the constant c_1.

4.1. Comparison of Theorem 4.1 with previous methods. We now give a brief sketch of an approach of [18], which generalizes the basic algorithm of [4, 1] to cover many new applications. The reader is referred to these three beautiful papers for more details. Suppose we have a set $\mathcal{F} = \{f_1, f_2, \ldots, f_t\}$ of *independent* random variables, each f_j taking values in some domain of cardinality at most γ. Suppose we also have ("bad") events $E_1, E_2, \ldots, E_m$, such that each E_i is determined by the values of the variables in some $F_i \subseteq \mathcal{F}$. Define $u \doteq \max_i |F_i|$. Let us say that E_i *intersects* E_j iff $F_i \cap F_j \neq \emptyset$; we let D denote the maximum number of other E_j that any given E_i intersects. Let $q = \max_i \Pr[E_i]$. One of the main results of [18] is that if

$$qD^9 < 1/8, \tag{4.8}$$

then we can find an assignment for all the f_i in randomized poly$(m, t, \gamma^{uD \log\log m})$ time such that $\bigwedge_{i \in [m]} \overline{E_i}$ holds.

We now sketch this algorithm. A setting $\mathcal{A}$ of some of the random variables f_j is done in a way such that $\Pr[E_i|\mathcal{A}] \leq q^{2/3} \forall i$. More importantly, as seen in section 3.1.1, the problem of setting the remaining f_j gets split into different "components," where each component has at most $D \log m$ events E_i whp; we can handle each component separately. If need be, we repeat the above process, and end up whp with components of size $O(D \log(D \log m))$; the probability of each E_i conditional on the f_j fixed so far will be at most $q^{1/3}$. The LLL and (4.8) show that there is a setting of the variables in each component such that all the E_i are avoided. Since each component is quite small now, we can now conduct an exhaustive search separately in each component. In particular, if γ and u are "small," say bounded by a constant which is true for many applications of the LLL, the condition (4.8) that is somewhat stronger than the "$eq(D+1) \leq 1$" of the LLL, ensures a constructive version of the LLL. However, as pointed out in [18], if γ is "large," say $(t+m)^{\Theta(1)}$, this method does not guarantee polynomial-time algorithms.

Suppose we were to follow the methodology of [4, 1, 18] to try and prove Theorem 4.1. Motivated by the notation above, let us define γ to be the maximum number of paths in any (multi-)set $\mathcal{P}_i$. In Theorem 4.1, consider the case where we wish to choose one path from each $\mathcal{P}_i$; i.e., $p = \Theta(1/k)$. Combined with the work of [14], the approach sketched above would require that the fractional congestion in Theorem 4.1 be $O(1/d\gamma^c)$, for a certain constant $c > 0$; some basic features of the approaches of [4, 1, 18] make it potentially impossible to eliminate this constant. Thus, situations where γ is "large" pose problems if we use the approach of [4, 1, 18]. Via the approach of Step 1 of our algorithm for Theorem 4.1, we can reduce γ to $O(d \log n)$, but reducing γ to $o(d)$, say, is a challenging open problem. Also, as pointed out in [18] and above, situations where γ is "large," say $n^{\Theta(1)}$, do not necessarily admit of polynomial-time solutions via the approach of [4, 1, 18]. Thus, for instances where $\min\{\gamma, d\}$ is, say, $n^{\Theta(1)}$, it is not clear how to use the methods of [4, 1, 18] to derive polynomial-time algorithms.

5. Open questions. The following problems suggest themselves. Can we get a full algorithmic version of the result of [25]? That is, can we get rid of the "κ" term in Theorem 3.2? Another question is whether L' can be replaced by L in Theorem 3.2. Finally, in the notation of section 1.2, Corollary 4.2 shows that "$y^* \leq a_2/(d \ln k)$" is a sufficient condition for efficiently generating edge-disjoint paths. As pointed out in section 1.2, it would be of much interest to see if this can be improved to "$y^* \leq a_1'/d$" for some constant a_1'.

Appendix. The number of rooted u-node ordered d-ary trees. A rooted tree is called *ordered* if the relative order of each node's children is important; different relative orders give different trees. "d-ary" means that each tree node has at most d children.

The following lemma is well known; for an algebraic proof, see, for example, [13]. For $d = 2$, it gives a derivation of the Catalan number, which has a combinatorial proof using a reflection principle. With the help of David Mix Barrington, we generalize this idea to any d.

LEMMA A.1. *The number of rooted u-node ordered d-ary trees is* $\frac{1}{(d-1)u+1}\binom{du}{u}$.

Proof. Let A denote the set of such trees. Let B be the class of strings from $\{1, 2, \ldots, d\}^{du}$ generated by the following grammar:

$$T \to \lambda \mid 1T\,2T\,3T \cdots dT,$$

where λ denotes the empty string. For a tree in A, let us add imaginary edges to nodes, including leaves, so that each node has exactly d outgoing edges, labeled from 1 through d. Note that there are du edges now. Then one can show that $|B| = |A|$ as each string in B corresponds to the sequence of edge labels seen from a depth-first traversal of some tree in A. There is also a one-to-one correspondence between B and the class C of strings from $\{1, *\}^{du}$ generated by the following grammar:

$$S \to \lambda \mid 1S * S * S \cdots * S,$$

with $d-1$ $*$'s above. Another way to see directly why $|A| = |B| = |C|$ is that they all have the same recurrence relation and the same initial condition.

Let D denote the set of strings from $\{1, *\}^{du}$ with exactly u 1's. As $C \subseteq D$ and $|D| = \binom{du}{u}$, it remains to calculate $|D \setminus C|$. Let D' denote the set of strings from $\{1, *\}^{du}$ with exactly $u-1$ 1's. Clearly $|D'| = \binom{du}{u-1} = \frac{u}{(d-1)u+1}\binom{du}{u}$. Next, we show that $|D \setminus C| = (d-1)|D'|$.

It is not hard to verify that C contains exactly those strings in D satisfying the following *prefix condition*:

- In any prefix, the number of $*$'s is at most $d-1$ times the number of 1's.

Any string in $D \setminus C$ or D' must contain a prefix that first violates this condition. Let $w*$ be any such a prefix consisting of k 1's and $(d-1)k+1$ $*$'s, for some $k < u$, with w satisfying the prefix condition. There are exactly $\binom{du-(dk+1)}{u-k} = (d-1)\binom{du-(dk+1)}{u-k-1}$ strings in $D \setminus C$ having $w*$ as prefix, and there are exactly $\binom{du-(dk+1)}{u-k-1}$ strings in D' having $w*$ as prefix. Ranging through all such strings $w*$, every string in $D \setminus C$ is enumerated exactly once, and so is every string in D'. So, $|D \setminus C| = (d-1)|D'|$, and $|C| = |D| - |D \setminus C| = \frac{1}{(d-1)u+1}\binom{du}{u}$. □

The following corollary follows immediately.

COROLLARY A.2. *In a graph of m nodes and degree d, there are at most $s = \frac{m}{(d-1)u+1}\binom{du}{u}$ connected components of size u, and they can be enumerated in deterministic* poly(s) *time.*

Acknowledgment. We thank Alan Frieze for his helpful suggestions.

ADAPTIVE AND EFFICIENT ALGORITHMS FOR LATTICE AGREEMENT AND RENAMING*

HAGIT ATTIYA† AND ARIE FOUREN†

Abstract. In a shared-memory system, n independent asynchronous processes, with distinct names in the range $\{0,\ldots,N-1\}$, communicate by reading and writing to shared registers. An algorithm is *wait-free* if a process completes its execution regardless of the behavior of other processes. This paper considers wait-free algorithms whose complexity adjusts to the level of contention in the system: An algorithm is *adaptive* (to total contention) if its step complexity depends only on the actual number of active processes, k; this number is unknown in advance and may change in different executions of the algorithm.

Adaptive algorithms are presented for two important decision problems, *lattice agreement* and $(6k-1)$-*renaming*; the step complexity of both algorithms is $O(k \log k)$. An interesting component of the $(6k-1)$-renaming algorithm is an $O(N)$ algorithm for $(2k-1)$-renaming; this improves on the best previously known $(2k-1)$-renaming algorithm, which has $O(Nnk)$ step complexity.

The efficient renaming algorithm can be modified into an $O(N)$ implementation of atomic snapshots using *dynamic single*-writer multi-reader registers. The best known implementations of atomic snapshots have step complexity $O(N \log N)$ using *static single*-writer multi-reader registers, and $O(N)$ using *multi*-writer multi-reader registers.

Key words. shared-memory systems, wait-free computation, atomic read/write registers, renaming, lattice agreement, atomic snapshots

1. Introduction.

An asynchronous shared-memory system contains n processes running at arbitrary speeds and communicating by reading from and writing to shared registers; processes have distinct names in the range $\{0,\ldots,N-1\}$, $n \leq N$. In a *wait-free* algorithm, a process terminates in a finite number of steps, even if other processes are very slow, or even stop taking steps completely.

The step complexity of many wait-algorithms depends on N; for example, collecting up-to-date information from all processes typically requires reading array indexed with processes' names. Real distributed systems need to accommodate a large number of processes, i.e., N is large, while often only a small number of processes take part in the computation. For such systems, step complexity depending on n or N is undesirable; it is preferable to have step complexity which adjusts to the number of processes participating in the algorithm.

An algorithm is *adaptive* (to total contention) if its step complexity depends only on the total number of processes participating in the algorithm, denoted k; k is unknown in advance and it may change in different executions of the algorithm. The step complexity of an adaptive algorithm adjusts to the number of active processes: It is constant if a single process participates in the algorithm, and it gradually grows as the number of active processes increases.

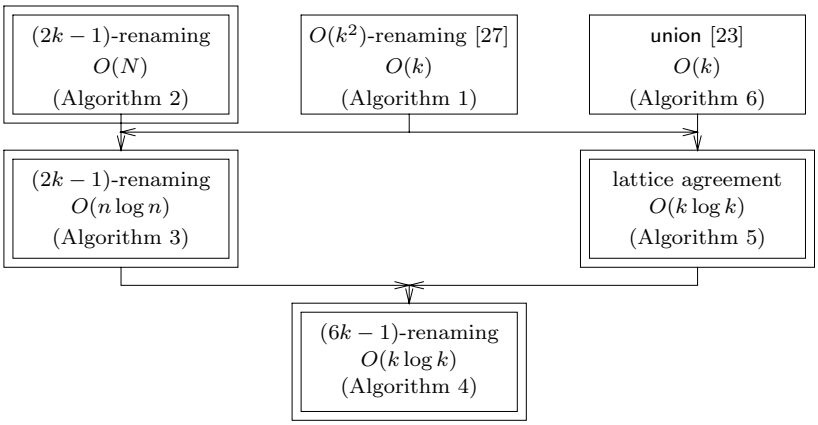

FIG. 1.1. *The algorithms presented in this paper; double boxes indicate the main results.*

A weaker guarantee is provided by *range-independent* algorithms whose step complexity depends only on n, the maximal number of processes; clearly, n is fixed for all executions.[1] The advantage of range-independent algorithms is quite restricted: They require a priori knowledge of n, which is often difficult to determine; moreover, their step complexity is not optimal when the actual number of participating processes is much lower than the upper bound. Yet, as we show, they can be useful tools in the construction of adaptive algorithms.

This paper presents adaptive wait-free algorithms for lattice agreement and renaming, using only read and write operations. Along the way, we improve the step complexity of nonadaptive algorithms for renaming. Figure 1.1 depicts the algorithms presented in this paper.

In the one-shot *M-renaming* problem [10], processes are required to choose distinct names in a range of size $M(k)$, for some bounded function M. This paper does not consider the more general *long-lived* renaming problem [9], in which processes repeatedly *acquire* and *release* names. Adaptive renaming can serve as an intermediate step in adaptive algorithms for other problems [9, 26, 27, 28]: The new names replace processes' original names, making the step complexity depend only on the number of active processes. Our algorithms employ this technique, as well as [6, 7].

An efficient adaptive algorithm for renaming could not be derived from known algorithms: The best previously known algorithm for renaming with linear name space [18] has $O(Nnk)$ step complexity, yielding $O(k^3)$ step complexity (at best) if it can be made adaptive. Thus, we first present a $(2k-1)$-renaming algorithm with $O(N)$ step complexity, which is neither adaptive nor range-independent. This algorithm is based on a new "shrinking network" construction, which we consider to be the novel algorithmic contribution of our paper.

The new linear renaming algorithm is employed in a range-independent algorithm for $(2k-1)$-renaming with $O(n \log n)$ step complexity. Processes start with an adaptive $O(k^2)$-renaming algorithm whose step complexity is $O(k)$; this is a simple modification of the range-independent renaming algorithm of Moir and Anderson [27]. Then, processes reduce the range of names in $O(\log n)$ iterations; each iteration uses our new linear renaming algorithm.

[1] Moir and Anderson [27] use the term "fast," which conflicts with other papers [3, 25].

The range-independent renaming algorithm is used to construct an adaptive $(6k-1)$-renaming algorithm with $O(k \log k)$ step complexity. In this algorithm, processes are partitioned into $O(\log k)$ disjoint sets according to views obtained from an adaptive lattice agreement algorithm (described below). This partition bounds the number of processes in each set and allows them to employ a range-independent $(2k-1)$-renaming algorithm designed for this bound. Different sets use disjoint name spaces; no coordination between the sets is required.

In the *lattice agreement* problem [15], processes obtain comparable (by containment) subsets of the set of active processes. A wait-free lattice agreement algorithm can be turned into a wait-free implementation of an *atomic snapshot* object, with $O(n)$ additional read/write operations [15]. Atomic snapshot objects allow processes to get instantaneous global views ("snapshots") of the shared memory, and thus they simplify the design of wait-free algorithms.

The step complexity of our adaptive algorithm for lattice agreement is $O(k \log k)$. In this algorithm, processes first obtain names in a range of size $O(k^2)$ using the simple algorithm with $O(k)$ step complexity. Based on its reduced name, a process enters an adaptive variant of the tree used in the lattice agreement algorithm of Inoue et al. [23].

Appendix C describes how the shrinking network is modified to get a lattice agreement algorithm with $O(N)$ step complexity, using *dynamic single*-writer single-reader registers; this gives an implementation of atomic snapshots with the same complexity. Previous implementations of atomic snapshots had either $O(N \log N)$ step complexity using *static single*-writer multi-reader registers [16] or $O(N)$ step complexity using *multi*-writer multi-reader registers [23].

The renaming problem was introduced and solved by Attiya et al. [10] for the message-passing model; Bar-Noy and Dolev [17] solved the problem in the shared-memory model. Burns and Peterson [19] considered the *l-assignment* problem—dynamic allocation of l distinct resources to processes. They present a wait-free l-assignment algorithm which assumes $l \geq 2k-1$, where k is the number of processes trying to acquire a resource. All these algorithms have exponential step complexity [21]. Borowsky and Gafni [18] present an algorithm for one-shot $(2k-1)$-renaming using $O(Nnk)$ read/write operations.

Anderson and Moir [9] define long-lived renaming and present range-independent algorithms for one-shot and long-lived renaming; their algorithms use test&set operations. Moir and Anderson [27] introduce a building block, later called a *splitter*, and employ it in range-independent algorithms for long-lived renaming, using read/write operations. Moir and Garay [28, 26] give a range-independent long-lived $O(kn)$-renaming algorithm, using only read/write operations. By combining with a long-lived $(2k-1)$-renaming algorithm [19] they obtain a range-independent long-lived $(2k-1)$-renaming algorithm; its step complexity is dominated by the exponential step complexity of Burns and Peterson's algorithm.

Herlihy and Shavit [22] show that one-shot renaming requires $2k-1$ names. This implies that our range-independent renaming algorithm provides an optimal name space. The name space provided by our adaptive renaming algorithm is not optimal $(M = 6k-1)$; still, it is linear in the number of active processes.

Following the original publication of our paper [12], Afek and Merritt [4] used our algorithms to obtain an adaptive wait-free $(2k-1)$-renaming algorithm, with $O(k^2)$ step complexity.

In another paper [13], we present an adaptive collect algorithm with $O(k)$ step complexity and derive adaptive algorithms for atomic snapshots, immediate snap-

shots, and $(2k-1)$-renaming. That paper emphasizes the modular use of a collect operation to make known algorithms adaptive; the algorithms have higher step complexity than those presented here.

Our algorithms adapt to the total number of participating processes, that is, if a process ever performs a step then it influences the step complexity of the algorithm throughout the execution. More useful are algorithms which adapt to the *current* contention and whose step complexity decreases when processes stop participating. Afek, Dauber, and Touitou [3] present implementations of long-lived objects which adapt to the current contention; they use load-linked and store-conditional operations. Recent papers present algorithms for long-lived renaming [2, 14], collect [6], and snapshots [7] which adapt to the current contention using only read/write operations.

Lamport [25] suggests a *mutual exclusion* algorithm which requires a constant number of steps when a single process wishes to enter the critical section, using read/write operations; when several processes compete for the critical section, the step complexity depends on the range of names. Alur and Taubenfeld [8] show that this behavior is inherent for mutual exclusion algorithms. Choy and Singh [20] present mutual exclusion algorithms whose *time complexity*—the time between consecutive entries to the critical section—is $O(k)$, using only read/write operations. Afek, Stupp, and Touitou [6] use an adaptive collect algorithm to derive an adaptive version of the bakery algorithm [24]; they present another mutual exclusion algorithm in [5]. Recently, Attiya and Bortnikov [11] presented a mutual exclusion algorithm whose time complexity is $O(\log k)$; this algorithm employs an unbalanced tournament tree with the same structure as our adaptive lattice agreement tree.

2. Preliminaries.

2.1. The model. In the shared-memory model, *processes* $p_0, \ldots, p_{n-1}$ communicate by applying *operations* on shared objects. A process p_i is modeled as a (possibly infinite) state machine; process p_i has a distinct name $id_i \in \{0, \ldots, N-1\}$, $n \leq N$.

The shared objects considered in this paper are *atomic read/write registers*, accessed by read and write operations. A read(R) operation does not change the state of R, and returns the current value stored in R; a write(v,R) operation changes the state of R to v. A *multi-writer multi-reader* register allows any process to perform read and write operations. A *single-writer multi-reader* register allows only a single process to perform write operations, and any process to perform read operation. A single-writer multi-reader register is *dynamic* if the identity of the single process writing to the register varies in different executions; otherwise, it is *static*.

An *event* is a computation step by a single process; the process determines the operation to perform according to its state, and its next state according to its state and the value returned by the operation. Computations in the system are captured as sequences of events. An *execution* α is a (finite or infinite) sequence of events $\phi_0, \phi_1, \phi_2, \ldots$. For every $r = 0, 1, \ldots$, if p_i is the process performing the event ϕ_r, then it applies a read or a write operation to a single register and changes its state according to its transition function. There are no constraints on the interleaving of events by different processes, reflecting the assumption that processes are *asynchronous* and there is no bound on their relative speeds.

Consider an execution α of some algorithm A. For process p_i, $step(A, \alpha, p_i)$ is the number of read/write operations p_i performs in α. The step complexity of A in α, denoted $step(A, \alpha)$, is the maximum of $step(A, \alpha, p_i)$ over all processes p_i. A process is *active* in α if it takes a step in α, that is, $step(A, \alpha, p_i) \neq 0$; $k(\alpha)$ denotes the number of active processes in α.

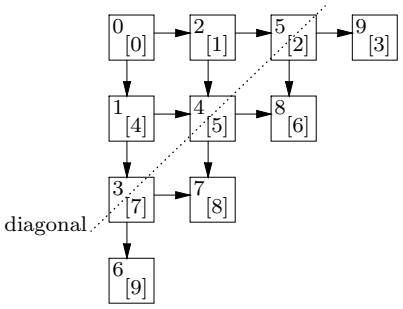

FIG. 2.1. *The grid used for $O(k^2)$-renaming (depicted for $n = 4$).*

Algorithm A is *range-independent* if there is a function $f : \mathcal{N} \mapsto \mathcal{N}$ such that in every execution α of A, $step(A, \alpha) \leq f(n)$. Namely, the step complexity of A in every execution is bounded by a function of the total number of processes (which is known in advance); it does not depend on the range of the initial names.

Algorithm A is *adaptive (to total contention)* if there is a function $f : \mathcal{N} \mapsto \mathcal{N}$ such that in every execution α of A, $step(A, \alpha) \leq f(k(\alpha))$. Namely, the step complexity of A in α is bounded by a function of the number of active processes in α. Clearly, the number of active processes is not known a priori.

A *wait-free* algorithm guarantees that every process completes its computation in a finite number of steps, regardless of the behavior of other processes. Since $k(\alpha)$ is bounded (by n) it follows that adaptive algorithms are wait-free.

2.2. Problems. The *M-renaming* problem [10] requires processes to choose distinct names in a range that depends only on the number of active processes. Namely, there is a function $M : \mathcal{N} \mapsto \mathcal{N}$ such that in every execution α, processes output distinct names in the range $\{0, \ldots, M(k(\alpha)) - 1\}$.

In the *lattice agreement* problem [15], every process p_i outputs V_i a subset of the active processes (e.g., a *view*) such that the following conditions hold:

Self-inclusion: $p_i \in V_i$ for every i.

Comparability: V_i and V_j are comparable (either $V_i \subseteq V_j$ or $V_j \subseteq V_i$) for every i and j.

2.3. Simple $O(k^2)$-renaming in $O(k)$ operations. The first step in our algorithms is a simple adaptive $O(k^2)$-renaming algorithm. This algorithm reduces the range of names to depend only on the number of active processes; later stages use these distinct names, without sacrificing the adaptiveness. We describe this algorithm first since it is employed in both adaptive algorithms presented in this paper.

The basic building block of this algorithm is the *splitter* of Moir and Anderson [27]. A process executing a splitter obtains **down**, **right**, or **stop**. At most one process obtains **stop** and when a single process executes the splitter it obtains **stop**; when two or more processes execute the splitter, not all of them obtain the same value. In this way, the set of processes accessing the splitter is "split" into smaller subsets.

As in [27], splitters are arranged in a grid of size $n \times n$ (Figure 2.1). A process starts at the upper left corner of the grid; the splitters direct the process either to continue (moving right or down in the grid), or to obtain the number associated with the current splitter. The grid spreads the processes so that each process eventually stops in a distinct splitter.

ALGORITHM 1. Adaptive $k(k+1)/2$-renaming.

```
Procedure Adaptive_k(k+1)/2-renaming()
private i, j: integer, initially 0                          // row and column indices
private move: {down, right, stop}, initially down           // direction
1.  while ( move ≠ stop ) do
2.      move := Splitter[i, j]()          // execute splitter in grid position (i, j)
3.      if ( move = down ) then i++                          // increase row
4.      if ( move = right ) then j++                         // increase column
5.  return((i + j)(i + j + 1)/2 + j)      // get a name based on the current splitter

Procedure Splitter[i, j]                                    // from Moir and Anderson [27]
    shared X[i, j]: {⊥} ∪ {0, ..., N − 1}, initially ⊥
    shared Y[i, j]: Boolean, initially false
1.  X[i, j] := id
2.  if ( Y[i, j] ) then return(right)
3.  else Y[i, j] := true
4.      if ( X[i, j] = id ) then return(stop)
5.      else return(down)
```

The difference between the algorithm of Moir and Anderson [27] and our algorithm is that they number splitters by *rows*, while we number splitters by *diagonals*. Splitter (i, j), in row i and column j, $0 \le i < n$ and $0 \le j < n$, is numbered $(i + j)(i + j + 1)/2 + j$. Figure 2.1 shows our numbering; the numbering of Moir and Anderson appears in square brackets.

Algorithm 1 presents pseudocode for the grid and for a splitter.[2]

We say that splitter (i, j) is $i + j$ *steps away* from splitter $(0, 0)$, the top left corner of the grid. As shown in [27, section 3.1], if k processes access the grid then each process stops after $O(k)$ operations in a distinct splitter which is at most $k - 1$ steps away from $(0, 0)$. A simple counting argument shows that these splitters have numbers in the range $\{0, \ldots, k(k + 1)/2 - 1\}$.

THEOREM 2.1. *Algorithm* 1 *solves* $k(k+1)/2$*-renaming with* $O(k)$ *step complexity.*

3. $(2k-1)$-renaming in $O(N)$ operations. As explained in the introduction, the step complexity of adaptive renaming depends on a new linear renaming algorithm, which is neither range-independent nor adaptive.

The algorithm is organized as a network of *reflectors*. A reflector has two distinguished entrances; a process accessing the reflector changes the direction of its movement if another process accessed the reflector, depending on the entrance through which it entered the reflector.

The network consists of N columns, numbered $0, \ldots, N - 1$, from left to right (see Figure 3.1). Column $c = 0, \ldots, N - 1$ contains $2c - 1$ reflectors, numbered $c, c - 1, \ldots, 0, -(c - 1), -c$, from top to bottom. Process q with name c starts at the topmost reflector of column c and descends through column c, until it sees another process accessing the same reflector. Then, q moves left to right towards column $N - 1$; q outputs the row on which it exits column $N - 1$.

[2] Algorithms declare private variables only if their usage in not obvious or their initial value is important.

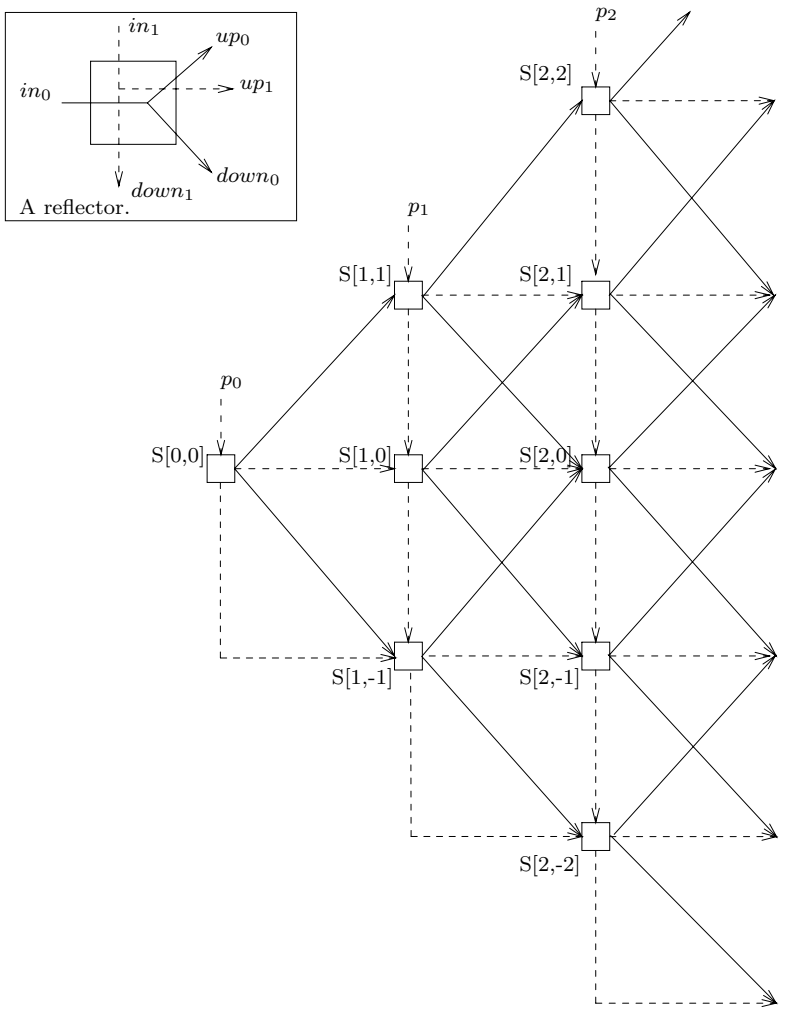

FIG. 3.1. *The network of reflectors for* $(2k-1)$*-renaming (depicted for* $n=3$*).*

For column c, S_{c-1} is the set of processes starting in columns $0,\ldots,c-1$. The main property of the network is that processes in S_{c-1} enter column c on distinct rows among the lowest $2|S_{c-1}|-1$ ones. Therefore, processes in S_{c-1} do not access the same reflectors in column c (or larger); they may interfere only with the single process descending through column c.

Process q descends through column c until it accesses a reflector in row r through which a process in S_{c-1} has passed; then, q moves to column $c+1$, remaining in row r. If process $p \in S_{c-1}$ accesses a reflector which q has passed, then p moves one row up to column $c+1$; if p accesses a reflector which q did not pass, then p moves one row down to column $c+1$. Therefore, processes in S_{c-1} which enter column c on rows $> r$ move one row up; processes in S_{c-1} which enter column c on rows $< r$ move one row down. Process q leaves on one of the free rows between the rows occupied by these two subsets of S_{c-1} (Figure 3.2(c)). Thus, processes in $S_c = S_{c-1} \bigcup \{q\}$ leave column c on distinct rows. Since the new names of the processes are the rows on which they leave the network, they output distinct names.

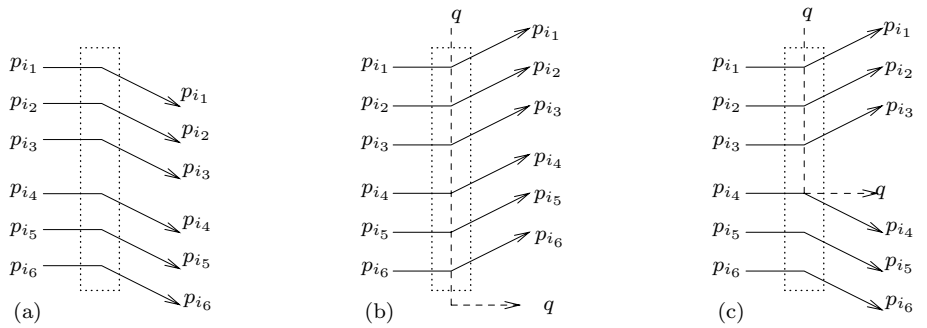

FIG. 3.2. *Illustration for the proof of Lemma* 3.3—*column* $c+1$.

The interaction of processes in column c guarantees that processes in S_{c-1} move to upper rows in column $c+1$ only if q is active; at most two additional rows are occupied (Figure 3.3(b)). If q is not active, then processes leave column c exactly on the same number of rows as they enter (Figure 3.3(a)). Thus, an active process causes at most two rows to be occupied; if there are k active processes, then they leave the network on the lowest $2k-1$ rows.

More formally, a reflector has two *entrances*, in_0 and in_1, two *lower exits*, $down_0$ and $down_1$, and two *upper exits*, up_0 and up_1. A process entering the reflector on entrance in_i leaves the reflector only on exits up_i or $down_i$ (see the top left corner of Figure 3.1). If a single process enters the reflector then it must leave on a lower exit, and at most one process leaves on a lower exit; it is possible that two processes entering the reflector will leave on upper exits. A reflector is easily implemented with two Boolean registers (see Algorithm 2).

The reflectors of column c, denoted $S[c,-c],\ldots,S[c,0],\ldots,S[c,c]$, are connected as follows:

- The upper exit up_0 of $S[c,r]$ is connected to entrance in_0 of $S[c+1,r+1]$.
- The upper exit up_1 of $S[c,r]$ is connected to entrance in_0 of $S[c+1,r]$.
- The lower exit $down_0$ of $S[c,r]$ is connected to entrance in_0 of $S[c+1,r-1]$.
- The lower exit $down_1$ of a reflector $S[c,r]$ is connected to entrance in_1 of reflector $S[c,r-1]$, if $r>-c$; if $r=-c$ (the lowest reflector of column c), then it is connected to entrance in_0 of reflector $S[c+1,r-1]$.

In Algorithm 2, a process with name c starts on entrance in_1 of the upper reflector of column c; it descends through column c (leaving on exit $down_1$) until it sees another

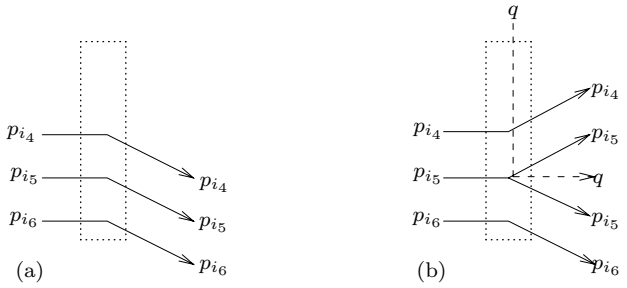

FIG. 3.3. *Illustration for the proof of Lemma* 3.4—*column* $c+1$.

ALGORITHM 2. $(2k-1)$-renaming.

```
Procedure shrink(name : 0, ..., N − 1)                    // renaming algorithm
private col, row: integer, initially name    // start on top reflector of column name
1.  while ( col = name ) do                          // descend through column name
2.      exit := reflector[row,col](1)                                // enter on in_1
3.      if ( exit = up_1 ) then col++
4.      else row−−                                                  // exit = down_1
5.          if ( row < −col ) then col++   // reached the lowest reflector in column
6.  while ( col < N ) do                          // move towards column N − 1
7.      exit := reflector[row, col](0)                               // enter on in_0
8.      if ( exit = up_0 ) then col++; row++;
9.      else col++; row−−;                                          // exit = down_0
10. return(row + N);

Procedure reflector(entrance r : 0,1)
1.  R_r := true ;
2.  if ( R_{1−r} = false ) then return(down_r)
3.  else return(up_r)
```

process or it reaches the bottom of the column. At this point, the process leaves on exit up_1 to the next column, and moves towards column $N-1$; in each column y, it enters exactly one reflector on entrance in_0; it leaves on exit up_0 if it sees another process, or on exit $down_0$, otherwise.

Suppose that p_j enters the reflector on entrance in_i, $i \in \{0,1\}$, and no process enters the reflector on entrance in_{1-i}. Since no process writes to R_{1-i}, p_j reads **false** from R_{1-i} and leaves the reflector on the lower exit, $down_i$. This implies the following lemma.

LEMMA 3.1. *If a single process enters a reflector, then it leaves on a lower exit.*

Similar arguments are used in the proof of the next lemma.

LEMMA 3.2. *If a single process enters a reflector on in_0 and a single process enters the reflector on in_1, then at most one process leaves the reflector on a lower exit.*

Proof. Assume that p_i enters the reflector on in_0 and p_j enters the reflector on in_1. If both processes read **true** from R_1 and R_0, then by the algorithm, $exit(p_i) = up_0$, $exit(p_j) = up_1$, and the lemma holds. Otherwise, without loss of generality, p_i reads **false** from R_1. Since p_i reads **false** from R_1, p_j writes to R_1 in line 1 after p_i reads R_1 at line 2. Therefore, p_j reads R_0 in line 2 after p_i writes to R_0 in line 1. Consequently, p_j obtains **true** from R_0 and by the algorithm, $exit(p_j) = up_1$, which proves the lemma. □

Recall that S_c contains the active processes starting on columns $0, \ldots, c$. For every process $p_i \in S_c$, let $row(p_i, c)$ be the value of the local variable *row* before p_i accesses the first reflector in column $c+1$. The next lemma shows that processes exit a column on distinct rows.

LEMMA 3.3. *For every pair of processes $p_i, p_j \in S_c$, $0 \le c < N$, $row(p_i, c) \neq row(p_j, c)$.*

Proof. The proof is by induction on the column c. In the base case, $c = 0$, the lemma trivially holds since only one process may access a reflector in column 0.

For the induction step, suppose that the lemma holds for column $c \ge 0$; there are

two cases.

Case 1. If no process starts on column $c+1$, then by the algorithm, no reflector in column $c+1$ is accessed on in_1. By Lemma 3.1, every process $p_i \in S_c$ leaves column $c+1$ on exit $down_0$. By the algorithm, we have

$$row(p_i, c+1) = row(p_i, c) - 1$$

(Figure 3.2(a)) and the lemma holds by the induction hypothesis.

Case 2. Suppose that process q starts on column $c+1$. Let $S[c+1, r']$ be the last reflector accessed by q in column $c+1$. That is, q leaves reflectors $S[c+1, c+1], \ldots, S[c+1, r'+1]$ on exits $down_1$; q does not access any of the reflectors $S[c+1, r'-1], \ldots, S[c+1, -(c+1)]$.

By Lemma 3.2, every process $p_i \in S_c$ which enters column $c+1$ on row $r'+1$ or higher, exits column $c+1$ on up_0, and we have

$$row(p_i, c+1) = row(p_i, c) + 1 > r' + 1.$$

By Lemma 3.1, every process $p_i \in S_c$ which enters column $c+1$ on row $r'-1$ or lower, exits column $c+1$ on $down_0$, and we have

$$row(p_i, c+1) = row(p_i, c) - 1 < r' - 1.$$

Now consider process q. By the algorithm, q leaves column $c+1$ either on exit $down_1$ of the lowest reflector in the column, $S[c+1, -(c+1)]$, or on exit up_1 of a reflector $S[c+1, r']$, where $-(c+1) \le r' \le c+1$.

If q leaves reflector $S[c+1, -(c+1)]$ on $down_1$ (Figure 3.2(b)), then by the algorithm,

$$row(q, c+1) = -(c+1) - 1 = r' - 1.$$

If there is a process $p_j \in S_c$ which also accesses $S[c+1, -(c+1)]$, then by Lemma 3.2, p_j leaves $S[c+1, -(c+1)]$ on exit up_0 and therefore,

$$row(p_j, c+1) = -(c+1) + 1 = r' + 1.$$

If q leaves reflector $S[c+1, r']$ on up_1 (Figure 3.2(c)), then by the algorithm, $row(q, c+1) = r'$. By Lemma 3.2, there is a process $p_j \in S_c$ which accesses $S[c+1, r']$; that is, $row(p_j, c) = r'$. By the algorithm

$$row(p_j, c+1) = \begin{cases} r' - 1 & \text{if } p_j \text{ leaves on } down_0, \\ r' + 1 & \text{otherwise.} \end{cases}$$

The induction hypothesis and the above equations imply that in all cases, $row(p_i, c+1) \neq row(p_j, c+1)$, for every pair of processes $p_i, p_j \in S_c$. □

Therefore, processes exit the network on different rows and hence obtain distinct names. The next lemma shows that processes in S_c leave column c on the lowest $2|S_c| - 1$ rows.

LEMMA 3.4. *For every process $p_i \in S_c$, $0 \le c < N$, $-(c+1) \le row(p_i, c) < -(c+1) + 2|S_c| - 1$.*

Proof. The proof is by induction on c. In the base case, $c = 0$. If there is a process p_i such that $id_i = 0$, then by Lemma 3.1, $exit(p_i, 0) = down_1$, since no process accesses reflector $S[0, 0]$ on in_0. Therefore, by the algorithm, we have $row(p_i, 0) = -1$, and the lemma holds.

For the induction step, suppose that the lemma holds for column $c \geq 0$; there are two cases.

Case 1. If no process starts on column $c+1$, then no process accesses reflectors in column $c+1$ on entrance in_1 (Figure 3.3(a)). Therefore, by Lemma 3.1, each process $p_i \in S_c$ exits column $c+1$ on $down_0$, and therefore, $row(p_i, c+1) = row(p_i, c) - 1$. By the induction hypothesis

$$row(p_i, c+1) = row(p_i, c) - 1 \geq -(c+1) - 1 = -((c+1)+1) \ .$$

Also, since $|S_{c+1}| = |S_c|$,

$$row(p_i, c+1) = row(p_i, c) - 1 < -(c+1) + 2|S_c| - 1 - 1 = -((c+1)+1) + 2|S_{c+1}| - 1 \ .$$

The lemma follows from these inequalities.

Case 2. Suppose that process q starts on column $c+1$. By the induction hypothesis, processes from S_c access only the lowest $2|S_c|-1$ reflectors in column $c+1$. Since no process accesses the upper reflectors $S[c+1, c+1], \ldots, S[c+1, -(c+1)+2|S_c|-1]$ on in_0, by Lemma 3.1, q accesses these reflectors until it reaches a reflector $S[c+1, r']$ accessed by another process, or until it reaches the lowest reflector $S[c+1, -(c+1)]$ in the column (Figure 3.3(b)). Therefore, q leaves column $c+1$ either on exit $down_1$ of reflector $S[c+1, -(c+1)]$ or on exit up_1 of a reflector $S[c+1, r']$, where $-(c+1) \leq r' < -(c+1) + 2|S_c| - 1$. By the algorithm, this implies

$$-((c+1)+1) \leq row(q, c+1) < -(c+1) + 2|S_c| - 1$$

since $S_{c+1} = S_c \cup \{q\}$, $|S_{c+1}| = |S_c| + 1$. Therefore,

$$-((c+1)+1) \leq row(q, c+1) < -((c+1)+1) + 2|S_{c+1}| - 2. \tag{3.1}$$

According to the algorithm, for each process $p_i \in S_c$,

$$row(p_i, c+1) = \begin{cases} row(p_i, c) + 1 & \text{if } exit(p_i, c+1) = up_0, \\ row(p_i, c) - 1 & \text{otherwise.} \end{cases}$$

Together with the induction hypothesis, this implies

$$row(p_i, c+1) \geq row(p_i, c) - 1 \geq -(c+1) - 1 = -((c+1)+1). \tag{3.2}$$

Also,

$$\begin{aligned} row(p_i, c+1) &\leq row(p_i, c) + 1 \\ &< -(c+1) + 2|S_c| - 1 + 1 \\ &= -((c+1)+1) + 1 + 2(|S_{c+1}| - 1) - 1 + 1 \\ &= -((c+1)+1) + 2|S_{c+1}| - 1. \end{aligned} \tag{3.3}$$

The lemma follows from inequalities (3.1), (3.2), and (3.3). □

Lemma 3.4 implies that processes leave the network on rows $-N, \ldots, -N + 2|S_{N-1}| - 2$. Since $|S_{N-1}| \leq k$, the names chosen in line 10 are in the range $\{0, \ldots, 2k-2\}$.

Process p_j accesses at most $2id_j + 1$ reflectors in column id_j, and exactly one reflector in each column $id_j + 1, \ldots, N-1$. Each reflector requires a constant number of operations, implying the next theorem.

THEOREM 3.5. *Algorithm 2 solves $(2k-1)$-renaming with step complexity $O(N)$.*

The network consists of $O(N^2)$ reflectors; each reflector is implemented with two registers. Register R_i of a reflector is written only by a process entering the reflector on entrance in_i. Entrance in_1 of a reflector is accessed only by the single process starting on this column, and entrance in_0 is accessed by at most one process (by Lemma 3.3). Therefore, we use $O(N^2)$ *dynamic* single-writer single-reader registers.

4. $(2k-1)$-renaming in $O(n \log n)$ operations. A range-independent $(2k-1)$-renaming can be obtained by combining adaptive $O(k^2)$-renaming and nonadaptive $(2k-1)$-renaming. First, the names are reduced into a range of size $O(n^2)$ (Algorithm 1); these names are used to enter the shrinking network of Algorithm 2, which reduces them into a range of size $(2k-1)$. The shrinking network is started with names of size $O(n^2)$, and hence, the step complexity of this simple algorithm is $O(n^2)$. The algorithm presented in this section obtains $O(n \log n)$ step complexity by reducing the name space gradually in $O(\log n)$ iterations. To do so, distinct copies of shrink (Algorithm 2) are associated with the vertices of a complete binary tree of height $\lceil \log n(n+1)/2 \rceil - 1 \approx 2 \log n$ (Figure 4.1). Each copy of shrink is designed for names in a range of size $4n-2$; that is, it employs a network with $4n-2$ columns.

A process starts Algorithm 3 by acquiring a name using $O(k^2)$-renaming; this name determines from which leaf to start. The process performs the shrinking network associated with each vertex v on the path from the leaf to the root, starting at a column which is determined by the name obtained at the previous vertex: If it ascends from the left subtree of v, then it starts at one of the first $2n-1$ columns of the network; otherwise, it starts at one of the last $2n-1$ columns. The process outputs the name obtained at the root.

The vertices of the tree are numbered in BFS order (Figure 4.1): The root is numbered 1; if vertex v is numbered ℓ, then its left child is numbered 2ℓ, and its right child is numbered $2\ell+1$. The copy of Algorithm 2 associated with a vertex numbered ℓ is denoted shrink$[\ell]$.

LEMMA 4.1. *For every vertex v, processes executing* shrink$[v]$ *obtain distinct temporary names in the range $\{0, \ldots, 2k-2\}$.*

Proof. The proof is by induction on d, the height of v. In the base case, $d = 0$. After executing Algorithm 1, processes get distinct names in the range $\{0, \ldots, k(k+1)/2-1\}$. Therefore, at most one process accesses v from the left executing shrink$[v]$ with temporary name 0, and at most one process accesses v from the right, executing shrink$[v]$ with temporary name $2n-1+0 = 2n-1$. Thus, they execute shrink$[v]$ with different temporary names in the range $\{0, \ldots, 4n-3\}$. Theorem 3.5 implies

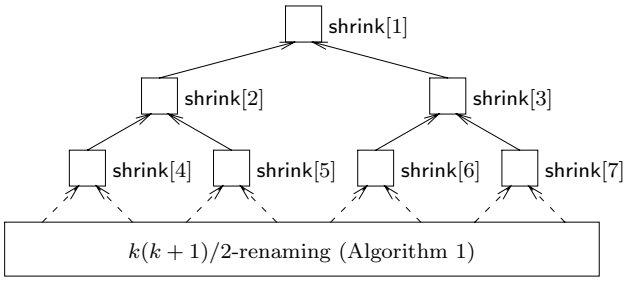

FIG. 4.1. *The range-independent algorithm for $(2k-1)$-renaming (depicted for $n = 3$).*

ALGORITHM 3. Range-independent $(2k-1)$-renaming for n processes.

```
Procedure indRenaming_n()
1.  temp-name := Adaptive_k(k+1)/2-renaming()                    // Algorithm 1
2.  ℓ := 2^h + ⌊temp-name/2⌋   // h = ⌈log n(n+1)/2⌉ − 1 is the height of the tree
3.  side := temp-name mod 2
4.  temp-name := 0
5.  while ( ℓ ≥ 1 ) do
6.      temp-name := shrink[ℓ](temp-name + side · (2n − 1))
7.      side := ℓ mod 2
8.      ℓ := ⌊ℓ/2⌋
9.  return(temp-name)
```

they obtain distinct names in the range $\{0, 1, 2\}$ and therefore, the lemma holds when $d = 0$.

For the induction step, assume the lemma holds for vertices at height d, and let v be a vertex at height $d + 1$. By the induction hypothesis and by the algorithm, processes accessing v from the left child have distinct temporary names in the range $\{0, \ldots, 2k-2\}$, and processes accessing v from the right child have distinct names in the range $\{2n-1, \ldots, 2n+2k-3\}$. Thus, processes execute shrink$[v]$ with distinct names in the range $\{0, \ldots, 4n-3\}$, and obtain distinct names in the range $\{0, \ldots, 2k-2\}$, by Theorem 3.5. □

Therefore, processes obtain distinct names in the range $\{0, \ldots, 2k-2\}$ after completing shrink at the root. A process performs shrink in $h = O(\log n)$ vertices of the tree, and each vertex requires $O(n)$ operations (Theorem 3.5). This implies the following theorem.

THEOREM 4.2. *Algorithm* 3 *solves* $(2k-1)$*-renaming with* $O(n \log n)$ *step complexity.*

5. $(6k-1)$-renaming in $O(k \log k)$ operations. In our adaptive $(6k-1)$-renaming algorithm, a process estimates the number of active processes and performs a copy of the range-independent $(2k-1)$-renaming algorithm (Algorithm 3) designed for this number. Processes may have different estimates of k, the number of active processes, and perform different copies of Algorithm 3. Instead of consolidating the names obtained in the different copies, disjoint name spaces are allocated to the copies.

The number of active processes is estimated by the size of a view obtained from lattice agreement; since views are comparable, the estimate is within a constant factor (see Lemma 5.1).

In Algorithm 4, process p_i belongs to a set S_j if the size of its view is in $(2^{j-1}, 2^j]$. For views obtained in lattice agreement, this partition guarantees that $|S_j| \leq 2^j$, for $j \leq \lceil \log n \rceil$; moreover, if the number of active processes is k, then $|S_j| = 0$, for $j > \lceil \log k \rceil$. There are $\lceil \log n \rceil + 1$ copies of Algorithm 3, denoted indRenaming$_{2^0}$, ..., indRenaming$_{2^{\lceil \log n \rceil}}$. Processes in S_j perform indRenaming$_{2^j}$, designed for 2^j processes, and obtain names in a range of size $2|S_j| - 1$. The name spaces for $S_0, \ldots, S_{\lceil \log n \rceil}$ do not overlap, and their size is linear k (Figure 5.1).

LEMMA 5.1. *If the views of processes in a set* S *satisfy the comparability and self-inclusion properties of lattice agreement, and the size of a view is at most* k*, then* $|S| \leq k$.

Proof. Assume V is the view with maximal size in S. Let V_i be the view of some process $p_i \in S$. The self-inclusion property implies that $p_i \in V_i$, and the comparability

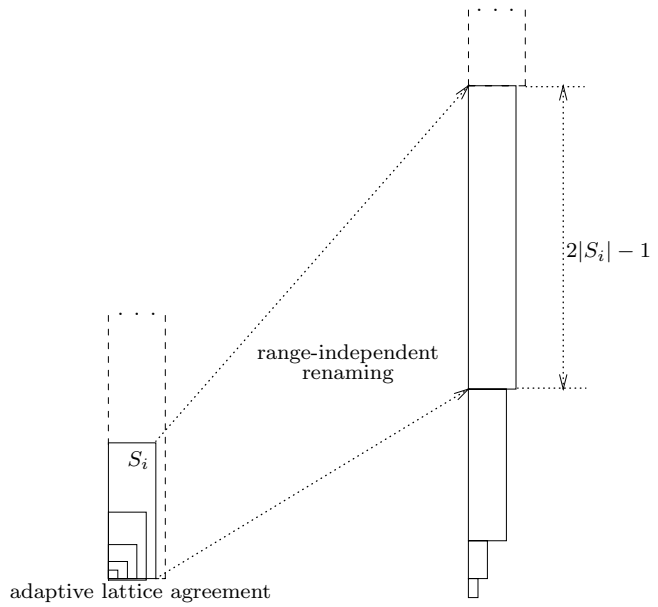

FIG. 5.1. *Adaptive* $(6k-1)$*-renaming.*

ALGORITHM 4. Adaptive $(6k-1)$-renaming.

```
1.  V := AdaptiveLA()                                  // Algorithm 5, presented below
2.  r := ⌈log |V|⌉
3.  temp-name := indRenaming_{2^r}()                   // Algorithm 3
4.  if ( r = 0 ) then return(temp-name)
5.  else return(temp-name + 2^{r+1})
```

property implies that $V_i \subseteq V$. Therefore, $S \subseteq V$, implying that $|S| \leq |V| \leq k$. □

By the algorithm, if process p_i is in S_j, then $|V_i| \leq 2^j$. Lemma 5.1 implies the next lemma.

LEMMA 5.2. *If there are* k *active processes, then* $|S_j| \leq 2^j$*, for* $0 \leq j \leq \lceil \log k \rceil$.

For every process p_i, $|V_i| \leq k$, since the views contain only active processes. Therefore, $p_i \in S_j$ only if $0 \leq j \leq \lceil \log k \rceil$, which implies the next lemma.

LEMMA 5.3. *If there are* k *active processes, then* $|S_j| = 0$ *for* $j > \lceil \log k \rceil$.

By Lemma 5.2, at most 2^j processes invoke $\mathsf{indRenaming}_{2^j}$. Therefore, process p_i invoking $\mathsf{indRenaming}_{2^j}$ obtains $\textit{temp-name}_i \in \{0, \ldots, 2 \cdot 2^j - 2\}$, by Theorem 4.2. By the algorithm, p_i returns $\textit{temp-name}_i + 2^{j+1} \in \{2^{j+1}, \ldots, 2^{j+2} - 2\}$.

The set of names returned by processes performing $\mathsf{indRenaming}_{2^j}$ is denoted $\textit{NameSpace}_j$; the next lemma follows from the algorithm.

LEMMA 5.4. (1) $\textit{NameSpace}_i \bigcap \textit{NameSpace}_j = \emptyset$*, for every* i *and* j*,* $0 \leq i < j \leq \lceil \log n \rceil$.

(2) $\bigcup_{i=0}^{m} \textit{NameSpace}_i \subseteq \{0, \ldots, 4 \cdot 2^m - 2\}$ *for every* $m \leq \lceil \log n \rceil$.

LEMMA 5.5. *If there are* k *active processes, then they return distinct names in the range* $\{0 \ldots 2^{\lceil \log k \rceil + 1} + 2k - 2\}$.[3]

[3]There are $\lceil \log k \rceil + 1$ names of the form $2^{j+2} - 1$, $0 \leq j \leq \lceil \log k \rceil$, which are not used. Therefore, the names obtained in the algorithm can be mapped into a name space of size $6k - \lceil \log k \rceil - 2$.

Proof. If two active processes, p_i and p_j, execute the same copy of indRenaming, then they obtain distinct names by Theorem 4.2; otherwise, they obtain distinct names, by Lemma 5.4(1).

By Lemma 5.3, processes invoke $\mathsf{indRenaming}_{2^j}$ only if $0 \leq j \leq \lceil \log k \rceil$. By Lemma 5.4(2), processes invoking $\mathsf{indRenaming}_{2^j}$, for $0 \leq j < \lceil \log k \rceil$, return names in the range $\{0, \ldots, 2^{\lceil \log k \rceil + 1} - 2\}$. By Theorem 4.2, a process p_i invoking the last nonempty copy $\mathsf{indRenaming}_{2^{\lceil \log k \rceil}}$ obtains a temporary name in the range $\{0, \ldots, 2k - 2\}$. By the algorithm, p_i returns a name in the range $\{2^{\lceil \log k \rceil + 1}, \ldots, 2^{\lceil \log k \rceil + 1} + 2k - 2\}$. Thus, the output names are in a range whose size is not greater than $2^{\lceil \log k \rceil + 1} + 2k - 1$. ∎

Since $6k - 1 \leq 2^{\lceil \log k \rceil + 1} + 2k - 1$, the correctness of the algorithm follows from Lemma 5.5.

If there are k active processes, then each process performs AdaptiveLA (presented in the next section) in $O(k \log k)$ operations. By Lemma 5.3, only copies of indRenaming for less than $2k$ processes are invoked. Therefore, a process completes indRenaming in $O(k \log k)$ operations.

THEOREM 5.6. *Algorithm* 4 *solves* $(6k-1)$*-renaming with* $O(k \log k)$ *step complexity.*

The upper bound on the size of the name space, $6k - 1$, is tight for Algorithm 4. Assume that all processes executing lattice agreement obtain the maximal view (with size k) and access $\mathsf{indRenaming}_{2^{\lceil \log k \rceil}}$. The processes leave the range $\{0, \ldots, 2^{\lceil \log k \rceil + 1} - 2\}$ unused (since it is unknown whether the previous copies of indRenaming are empty or not) and return names in the range $\{2^{\lceil \log k \rceil + 1}, \ldots, 2^{\lceil \log k \rceil + 1} + 2k - 2\}$. If k is not an integral power of 2, then the output names are in a range of size $\leq 2^{\log k + 2} + 2k - 1 = 6k - 1$. If k is an integral power of 2, then the output names are in a range of size $2^{\log k + 1} + 2k - 1 = 4k - 1$.

Merritt (private communication) noted that the names can be reduced by partitioning the active processes into sets of size $a^0, \ldots, a^j, \ldots$ for an integer $a > 2$. Active processes are partitioned into sets $S_0, \ldots, S_j, \ldots$; processes in S_j execute $\mathsf{adaptiveRenaming}_{a^j}$ designed for a^j participants and obtain new names in a range of size $2|S_j| - 1$. As in our algorithm, when k processes are active, $\mathsf{adaptiveRenaming}_{a^j}$ is accessed only for $0 \leq j \leq \lceil \log_a k \rceil$. Processes accessing copies $\mathsf{adaptiveRenaming}_{a^j}$, $0 \leq j < \lceil \log_a k \rceil$, obtain names in a space of size $\sum_{j=0}^{\lceil \log_a k \rceil - 1} (2a^j - 1) \leq 2\frac{a^{\lceil \log_a k \rceil} - 1}{a-1} \leq 2\frac{a^{\log_a k + 1} - 1}{a-1} = 2\frac{ka-1}{a-1}$, which tends to $2k$ when $a \to \infty$. Processes accessing the last nonempty copy, $\mathsf{adaptiveRenaming}_{a^{\lceil \log_a k \rceil}}$, obtain new names in a range of size $2k - 1$. Thus, the size of the total name space is $\leq 4k - 1$ when $a \to \infty$.

6. Lattice agreement in $O(k \log k)$ operations. Our lattice agreement algorithm is based on the algorithm of Inoue et al. [23]. In their algorithm, each process starts at a distinct leaf (based on its name) of a complete binary tree with height $\lceil \log N \rceil - 1$, and climbs up the tree to the root. At each vertex on the path, it performs a procedure which merges together two sets of views, each set containing only comparable views; this procedure is called union. At the leaf, the process uses its own name as input to union; at the inner vertices, it uses the view obtained in the previous vertex as input to union. The process outputs the view it obtains at the root.

Specifically, union takes two parameters, an input view V and an integer $side \in \{0, 1\}$, and returns an output view; its properties are specified by the next lemma [23, Lemma 6].

LEMMA 6.1. *If the input views of processes invoking* union *with* $side = 0$ *are*

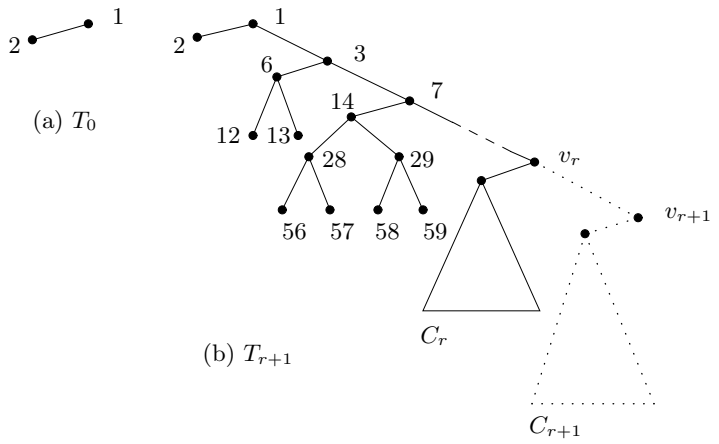

FIG. 6.1. *The unbalanced binary tree used in the adaptive lattice agreement algorithm.*

comparable and satisfy the self-inclusion property, and similarly for the input views of processes invoking union *with side* $= 1$*, then*

(1) *the output views of processes exiting* union *are comparable, and*

(2) *the output view of a process exiting* union *contains its input view.*

Appendix A describes union in detail, and explains the next lemma.

LEMMA 6.2. *The step complexity of* union *is* $O(k)$.

Our adaptive algorithm uses an unbalanced binary tree T_r defined inductively as follows. T_0 has a root v_0 with a single left child (Figure 6.1(a)). For $r \geq 0$, suppose T_r is defined with an identified vertex v_r, which is the last vertex in an in-order traversal of T_r; notice that v_r does not have a right child in T_r. T_{r+1} is obtained by inserting a new vertex v_{r+1} as the right child of v_r, and inserting a complete binary tree C_{r+1} of height $r+1$ as the left subtree of v_{r+1} (Figure 6.1(b)). By the construction, v_{r+1} is the last vertex in an in-order traversal of T_{r+1}.

The vertices of the tree are numbered as follows: The root is numbered 1; if a vertex is numbered ℓ, then its left child is numbered 2ℓ, and its right child is numbered $2\ell+1$ (Figure 6.1).

By the construction, the leaves of T_r are the leaves of the complete binary subtrees $C_0, C_1, \ldots, C_r$. Therefore, the total number of leaves in T_r is $\sum_{j=0}^{r} 2^j = 2^{r+1} - 1$. The following simple lemma, proved in Appendix B, states some properties of T_r.

LEMMA 6.3. *Let* w *be the* i*th leaf of* T_r*,* $1 \leq i \leq 2^{r+1} - 1$*, counting from left to right. Then*

(1) *the depth of* w *is* $2\lfloor \log i \rfloor + 1$*;*

(2) w *is numbered* $2^d(2^{d+2} - 3) + i$*, where* $d = \lfloor \log i \rfloor$.

Algorithm 5 uses $T_{2\log n - 1}$, which has $n^2 - 1$ leaves.[4] A process starts the algorithm by obtaining a new name in a range of size $k(k+1)/2$ (using Algorithm 1). This name determines the leaf at which the process starts to climb up the tree: A process with a new name x_i starts the algorithm at the x_ith leaf of the tree, counting from left to right. Since $k(k+1)/2 \leq n^2 - 1$ for all $n \geq 2$, $T_{2\log n - 1}$ have enough leaves for temporary names in a range of size $k(k+1)/2$. By Lemma 6.3, the x_ith leaf is numbered $2^d(2^{d+2} - 3) + x_i$, where $d = \lfloor \log x_i \rfloor$.

[4]For simplicity, we assume n is a power of 2.

ALGORITHM 5. Adaptive lattice agreement.

```
Procedure AdaptiveLA()
1.  temp-name := Adaptive_k(k+1)/2-renaming()+1          // Algorithm 1
2.  d := ⌊log temp-name⌋
3.  ℓ := 2^d(2^{d+2} − 3) + temp-name      // the leaf corresponding to temp-name
4.  V := {p_i}                                  // the input is the process's name
5.  while ( ℓ ≥ 1 ) do
6.      side := ℓ mod 2                                          // calculate side
7.      ℓ := ⌊ℓ/2⌋                                             // calculate father
8.      V := union[ℓ](V, side)
9.  return(V)
```

As in [23], a distinct copy of union is associated with each inner vertex of the tree. A process performs copies of union associated with the vertices along its path to the root, and returns the view obtained at the root.

Simple induction on the distance of a vertex v from the leaves shows that the views obtained by processes executing union at v satisfy the comparability and self-inclusion properties. In the base case, v is a leaf and the claim is trivial since a single process starts at each leaf; the induction step follows immediately from Lemma 6.1. Hence, the views obtained at the root have the lattice agreement properties.

If there are k active processes, process p_i gets a unique name $x_i \in \{1, \ldots, k(k+1)/2\}$ (line 1) and by Lemma 6.3(2), starts in a leaf ℓ of depth $2\lfloor \log x_i \rfloor + 1$ (line 3). Therefore, p_i accesses at most $2\lfloor \log x_i \rfloor + 1 \leq 2\lfloor \log k(k+1)/2 \rfloor + 1 \leq 4 \log k + 1$ vertices. At each vertex, the execution of union requires $O(k)$ operations (Lemma 6.2). Thus, the total step complexity of the algorithm is $O(k \log k)$, implying the following theorem.

THEOREM 6.4. *Algorithm 5 solves lattice agreement with $O(k \log k)$ step complexity.*

7. Discussion. This work presents *adaptive* wait-free algorithms, whose step complexity depends only on the number of active processes, for lattice agreement and $(6k-1)$-renaming in the read/write asynchronous shared-memory model; the step complexity of both algorithms is $O(k \log k)$.

Clearly, the complexities of our algorithms—the number of steps, the number and the size of registers used—can be improved. For example, an algorithm for $O(k)$-renaming with $O(k)$ step complexity would immediately yield a lattice agreement algorithm with the same step complexity. Also it would be interesting to see if ideas from our efficient algorithms can improve the complexities of algorithms which adapt to the current contention [2, 6].

Appendix A. Procedure union.

Procedure union (from [23]) takes two parameters, a view V and an integer $side \in \{0, 1\}$, and returns a view. Let S_b be the set of processes which call union with side b. If the input views of the processes in S_0 are comparable and the input views of the processes in S_1 are comparable (within each set separately), then *all* the views returned by union are comparable. In addition, the output view of each process contains its input view.

The procedure uses two shared arrays, $Views_0[1, \ldots, n+1]$ and $Views_1[1, \ldots, n+1]$, whose entries contain views (initially empty). Processes use two procedures:

WriteSet which writes a view into an array, and ReadSet which reads the view of maximal size written in an array.

A process invoking union with side b, first writes its input view V into $Views_b$ using WriteSet. Then the process repeatedly reads from the arrays $Views_0$ and $Views_1$ using ReadSet. If the last two reads from $Views_0$ return the same view, and the last two reads from $Views_1$ return the same view, then the process returns the union of these views. As in Afek et al. [1], if two nonoverlapping ReadSet operations return the same maximal view, then the maximal view does not change in between the operations. Since reads from $Views_0$ alternate with reads from $Views_1$, there is an execution interval during which $Views_0$ and $Views_1$ do not change. Therefore, the union of the last views read from the arrays is a snapshot of the maximal size views written in them. If the views written in each array are comparable, then the snapshots of the maximal views, returned by union, are also comparable.

The crux of the algorithm is how ReadSet and WriteSet guarantee linear step complexity. For $b = 0, 1$, the ℓth entry of $Views_b$ corresponds to the unique view of size ℓ in S_b. A process accesses each entry of $Views_b$ at most once. Towards this end, if a process reads a view V in ReadSet from an entry $i < |V|$, then it writes V into entries $i+1, \ldots, |V|$; this guarantees that V will not be overwritten by a smaller view and will be available for other processes. Furthermore, if the maximal size of views in S_b is k, then a process accesses only the first $k+1$ entries of $Views_b$. Thus, a process performs at most $O(|S_0 \bigcup S_1|)$ reads and writes.

The pseudocode appears in Algorithm 6.

In WriteSet(A, V), a process writes V to $A[1], A[2], \ldots, A[|V|]$ (in this order). When there are k active processes, $|V| \leq k$, and hence no process writes to $A[k+1]$.

In ReadSet(A, V), process p_i reads the entries of array A in increasing order of indices, until it reads $\emptyset$; by the property of WriteSet, p_i obtains $\emptyset$ after at most $k+1$ reads. If p_i reads a view W from $A[j]$, $j \leq |W|$, then p_i writes W to the array in the order $A[j+1], A[j+2], \ldots, A[|W|]$ (lines 4–6) and resumes reading from $A[|W|+1]$ (lines 7–11). This requires ReadSet to take an additional parameter V, the maximal view p_i has written or read so far.

Let V_i be the view returned by process p_i. Clearly, the step complexity of union is linear in $|V_i|$ (see [23, Lemma 9]). Since $V_i \subseteq S_0 \cup S_1$, the step complexity of union is $O(|S_0 \cup S_1|) = O(k)$, which implies Lemma 6.2.

Appendix B. Proof of Lemma 6.3.

(1) Suppose that w belongs to a C_d, $d \leq r$. The total number of leaves in $C_0, \ldots, C_{d-1}$ is $\sum_{j=0}^{d-1} 2^j = 2^d - 1$. Therefore, $2^d - 1 < i$. Since w belongs to C_d, $i \leq \sum_{j=0}^{d} 2^j = 2^{d+1} - 1$. Thus, $2^d \leq i < 2^{d+1}$, implying that $d = \lfloor \log i \rfloor$.

Consider the path from the root of T_r to w. The path has length $2d+1$: d edges on the path from the root of T_r to v_d, one edge connecting v_d and the root of C_d, and d edges on the path from the root of C_d to w. Since $d = \lfloor \log w_i \rfloor$, the length of the path is $2\lfloor \log i \rfloor + 1$.

(2) Define a binary string $b[1 \ldots 2d+1]$, which represents the path from the root of T_r to w, as follows: $b[1] = 1$; for any $1 \leq j < 2d+1$, $b[j+1] = 0$, if the $(j+1)$st vertex on the path is the left child of its parent; and $b[j+1] = 1$, otherwise.

The numbering of the vertices in T_r implies that the number of w is represented by the binary string $b[1 \ldots 2d+1]$. The d leftmost bits of b, corresponding to the path from the root of the tree to vertex v_d are $11 \ldots 1$, since all the vertices on the path are right children (see Figure 6.1(b)). The $(d+1)$st bit of b is 0, since the root of C_d

ALGORITHM 6. Procedure union (from [23]).

```
Procedure union(V: view, b: 0,1)                          // side parameter is b
1.  WriteSet(Views_b,V)
2.  current_b := V ; current_{1-b} := ∅
3.  repeat
4.      prev_0 := current_0 ; prev_1 := current_1
5.      current_0 := ReadSet(Views_0,prev_0)
6.      current_1 := ReadSet(Views_1,prev_1)
7.  until ( prev_0 = current_0 and prev_1 = current_1 )
8.  return(current_0 ∪ current_1)

Procedure WriteSet(A: array of registers, V: view)
1.  for j = 1 to |V| do A[j] := V

Procedure ReadSet(A: array of registers, prev: view)
1.  max := prev
2.  p := |max|
3.  while ( p ≤ |max| ) do
4.      for j = p + 1 to |max| do A[j] := max
5.      p := |max|
6.      repeat
7.          p := p + 1
8.          temp := A[p]
9.          if ( |temp| > p ) then max := temp
10.     until ( |max| > p or temp = ∅ )
11. return(max)
```

is the left child of v_d. It remains to calculate the d rightmost bits of b, corresponding to the path from the root of C_d to w.

The total number of leaves in $C_0, \ldots, C_{d-1}$ is $\sum_{j=0}^{d-1} 2^j = 2^d - 1$. Since w is the ith leaf in T_r, it is the $(i - (2^d - 1))$st leaf in C_d, counting from 1. Therefore, the d bits corresponding to the path from the root of C_d to w are the binary representation of the number $(i - (2^d - 1)) - 1$, that is, $(i - 2^d)_2$. Hence,

$$b[1 \ldots 2d+1] = \overbrace{11\ldots1}^{d}0 \cdot (i - 2^d)_2.$$

Therefore, the number of w is $(2^{d+1} - 1)2^{d+1} + i - 2^d = 2^d(2^{d+2} - 3) + i$.

Appendix C. Linear atomic snapshots.

This section presents a linear-time algorithm for lattice agreement using only dynamic single-writer single-reader registers; this algorithm is neither range-independent nor adaptive. It appears here because it is a simple modification of Algorithm 2, and it shows yet another interesting connection between renaming and lattice agreement.

The algorithm uses the network of reflectors of Figure 3.1. In the modified algorithm, reflectors help the processes to collect views, in addition to directing their movements. The modified reflector is implemented with two N-bit registers, R_0 and R_1, that can contain views. Initially, each register contains the empty view, $\emptyset$. A process entering the reflector on entrance in_i writes its local view into register R_i,

ALGORITHM 7. Linear lattice agreement.

```
Procedure LatticeAgreement(name_i : 0, ..., N − 1)
private col, row: integer, initially name_i  // start on top reflector of column name_i
private V, initially {p_i}                                          // the initial view
1.  while ( row = name_i ) do                  // descend through column name_i
2.      ⟨V, exit⟩ := reflector[row,col](V,1)                        // enter on in_1
3.      if ( exit = up_1 ) then col++;
4.      else                                                        // exit = down_1
5.          row−−;
6.          if ( row < −col ) then
7.              col++;                  // reached the lowest reflector in column
8.  while ( col < N ) do                       // move towards column N − 1
9.      ⟨V, exit⟩ := reflector[row,col](V,0)                        // enter on in_1
10.     if ( exit = up_0 ) then col++; row++;
11.     else col++; row−−;                                          // exit = down_0
12. return(V);

Procedure reflector(view V, entrance r: 0,1)
1.  R_r := V ;
2.  if ( R_{1−r} = ∅ ) then return(⟨V, down_r⟩)
3.  else return(⟨V ∪ R_{1−r}, up_r⟩)
```

and then reads the other register, R_{1-i}. If it is $\emptyset$, then the local view of the process does not change, and the process exits on $down_i$; otherwise, the process joins the view written in R_{1-i} with its local view and exits on up_i.

The algorithm which controls the processes' movements in the network remains exactly the same as in Algorithm 2. Processes leaving the network return their local views (instead of the row numbers, as in the renaming algorithm). Pseudocode appears in Algorithm 7; the numbers of the modified lines appear in bold.

For a process p_i and a reflector S, $V_{in}(p_i, S)$ and $V_{out}(p_i, S)$ are the views of p_i before and after accessing S, respectively. The following lemma is a modification of Lemma 3.1. The only difference is related to the process' view after accessing a reflector. By the algorithm, the local view of the process which reads $\emptyset$ from R_{1-i} does not change.

LEMMA C.1. *If a single process p_j enters a reflector S then p_j leaves S on a lower exit and $V_{out}(p_i, S) = V_{in}(p_i, S)$.*

The proof of the following lemma is similar to Lemma 3.2.

LEMMA C.2. *If a single process p_i enters a reflector S on in_0, and a single process p_j enters S on in_1, then*

(1) *at most one of the processes leaves S on a lower exit;*

(2) *if $p \in \{p_i, p_j\}$ goes down, then $V_{out}(p, S) = V_{in}(p, S)$;*

(3) *if $p \in \{p_i, p_j\}$ goes up, then $V_{out}(p, S) = V_{in}(p_i, S) \cup V_{in}(p_j, S)$.*

Recall that S_c is the set of processes which start execution on columns $0, \ldots, c$; let $V(p_i, c)$ be the view with which a process p_i exists column c. The next lemma shows that the views of processes exiting column c are comparable.

LEMMA C.3. *For every pair of processes $p_i, p_j \in S_c$, $0 \le c < N$, if $row(p_i, c) < row(p_j, c)$ then $V(p_i, c) \subseteq V(p_j, c)$.*

Proof. The proof is by induction on the column c. The lemma holds in the base

case, $c = 0$, since at most one process exits column 0. Suppose that the lemma holds for $c \geq 0$.

If there is no active process with name equal to $c+1$, then the reflectors in column $c+1$ are accessed only on entrances in_0. Therefore, by Lemma C.1, the local views of the processes S_c do not change in column $c+1$, and for every process $p_j \in S_c$, $row(p_j, c+1) = row(p_j, c) - 1$. In this case, the lemma holds by the induction hypothesis.

Otherwise, let q be an active process which starts on column $c+1$. Suppose that the last reflector accessed by q on column $c+1$ is $S[c+1, r']$, $-(c+1) \leq r' \leq c+1$. That is, q leaves reflectors $S[c+1, c+1], \ldots, S[c+1, r'+1]$ on $down_1$, and q does not access reflectors $S[c+1, r'-1], \ldots, S[c+1, -(c+1)]$. By Lemmas C.1 and C.2,

- for all $p_j \in S_c$ such that $row(p_i, c) < r'$

$$\begin{aligned} exit(p_i, c+1) &= down_0, \\ row(p_i, c+1) &= row(p_i, c) - 1, \\ V(p_i, c+1) &= V(p_i, c); \end{aligned} \tag{C.1}$$

- for all $p_j \in S_c$ such that $row(p_i, c) > r'$

$$\begin{aligned} exit(p_i, c+1) &= up_0, \\ row(p_i, c+1) &= row(p_i, c) + 1, \\ V(p_i, c+1) &= V(p_i, c) \cup \{q\}. \end{aligned} \tag{C.2}$$

By the algorithm, q leaves column $c+1$ either on exit $down_1$ of the lowest reflector $S[c+1, -(c+1)]$ in the column, or on exit up_1 of $S[c+1, r']$, where $-(c+1) \leq r' \leq c+1$.

If q leaves reflector $S[c+1, -(c+1)]$ on $down_1$, then by Lemma C.1, $row(q, c+1) = -(c+1) - 1$ and $V(q, c+1) = V(q, c)$. The lemma holds by the induction hypothesis and (C.2).

If q leaves reflector $S[c+1, r']$ on up_1, then there is a process $p_j \in S_c$ such that $row(p_j, c) = r'$, by Lemma C.1. By Lemma C.2, $V(q, c+1) = V(p_j, c) \cup \{q\}$. If p_j leaves column $c+1$ on up_0, then $V(p_j, c+1) = V(p_j, c) \cup \{q\}$ and $row(p_j, c+1) = row(p_j, c) + 1 = r' + 1$, by Lemma C.2. If p_j leaves column $c+1$ on $down_0$, then $V(p_j, c+1) = V(p_j, c)$ and $row(p_j, c+1) = r' - 1$, by Lemma C.2. In both cases, the lemma holds by the induction hypothesis, (C.1), and (C.2). □

Lemma C.3 with $c = N - 1$ implies that the local views of the processes leaving the network are comparable. Since p_i initial view contains its identifier and the local view never decreases, we have the self-inclusion property. The step complexity of the algorithm is calculated as in Theorem 3.5. The network contains $O(N^2)$ reflectors; each reflector uses two bounded dynamic single-writer single-reader registers. This proves the following theorem.

THEOREM C.4. *Algorithm 7 solves the lattice agreement problem with step complexity $O(N)$ using $O(N^2)$ dynamic single-writer single-reader registers of length N bits.*

Applying the transformation of [15], which requires $O(N)$ additional operations on single-writer multi-reader registers, we get the following result.

THEOREM C.5. *There is an implementation of an atomic snapshot object such that every operation on the object requires $O(N)$ read/write operations on dynamic single-writer multi-reader registers. The implementation uses $O(N^2)$ registers of length N bits.*

LEMMA C.6. *If the processes executing* RestrictedLA$_{2^j}$ *have distinct names in the range* $\{0, \ldots, 2^j - 1\}$*, then the following conditions hold for every vertex* v*:*

(1) *the output views of processes exiting* union *at* v *are comparable, and*

(2) *the output view of a process exiting* union *at* v *contains its input view.*

Proof. Assume the vertex v is numbered ℓ. Let $InView(v, p)$ and $OutView(v, p)$ be the local views of a process p before and after the execution of union$[\ell]$. Let $InViews_i(v)$ be the set of views of processes that invoke union$[\ell]$ with side i, $i = 0, 1$, and let $OutViews(v)$ be the set of views returned by union$[\ell]$.

The proof of the lemma is by induction on the height, h, of v. In the base case, $h = 0$, v is a leaf. At most one process accesses union$[\ell]$ on each of its entrances, since processes have distinct names in the range $\{0, \ldots, 2^j - 1\}$. Therefore, the views in $InViews_i(v)$ are comparable for $i = 0, 1$. Conditions (1) and (2) follow from Lemma 6.1.

For the induction step, suppose that the lemma holds for every vertex at height h; we prove that it also holds for a vertex v at height $h + 1$. Let u be the left child of v and let w be the right child of v. By the algorithm, $InViews_0(v) = OutViews(u)$ and $InViews_1(v) = OutViews(w)$.

Since u is at height h, the views in $OutViews(u)$ are comparable by the induction hypothesis; similarly, the views in $OutViews(w)$ are comparable. Therefore, the views in $OutViews(v)$ are comparable by Lemma 6.1. This proves condition (1).

If process p_i invokes union$[\ell]$ with side 0 then $InView(v, p_i) = OutView(u, p_i)$. By the induction hypothesis, $p_i \in OutView(u, p_i) = InView(v, p_i)$. By Lemma 6.1, $InView(v, p_i) \subseteq OutView(v, p_i)$, and hence $p_i \in OutView(v, p_i)$, which proves condition (2). A similar argument holds if p_i invokes union with side 1. ∎

ALGORITHMS FOR CAPACITATED VEHICLE ROUTING*

MOSES CHARIKAR†, SAMIR KHULLER‡, AND BALAJI RAGHAVACHARI§

Abstract. Given n identical objects (pegs), placed at arbitrary initial locations, we consider the problem of transporting them efficiently to n target locations (slots) with a vehicle that can carry at most k pegs at a time. This problem is referred to as k-delivery TSP, and it is a generalization of the traveling salesman problem. We give a 5-approximation algorithm for the problem of minimizing the total distance traveled by the vehicle.

There are two kinds of transportations possible—one that could drop pegs at intermediate locations and pick them up later in the route for delivery (preemptive) and one that transports pegs to their targets directly (nonpreemptive). In the former case, by exploiting the freedom to drop, one may be able to find a shorter delivery route. We construct a nonpreemptive tour that is within a factor 5 of the optimal preemptive tour. In addition we show that the ratio of the distances traveled by an optimal nonpreemptive tour versus a preemptive tour is bounded by 4.

Key words. vehicle routing, traveling salesman problem, approximation algorithms, graphs

1. Introduction.

Vehicle routing and delivery problems have been widely studied in computer science and operations research. Many of these problems are NP-hard, and a lot of research has been done on analyzing heuristics to find "good" solutions to these problems. These transportation problems occur in real life in areas such as robotics and transportation of packages. Methods for obtaining "good" solutions to the problems are of great practical significance. For example, Casco, Golden, and Wasil [9] report that combining deliveries and pickups for supermarkets led to an industry wide savings of $160 million a year. The problem that we consider in this paper is that of transporting a single commodity from a set of suppliers to a set of demand points using a vehicle of limited capacity.

One way to analyze the performance of a heuristic is to compute the worst-case ratio between the cost of a solution produced by the algorithm to the cost of an optimal solution. If this ratio is bounded by ρ, we refer to this algorithm as an approximation algorithm with performance ratio ρ or simply as a ρ-approximation algorithm.

***k*-delivery TSP.** Given n identical pegs placed at arbitrary locations, a vehicle with a maximum capacity of k pegs, and n slots (demand points), each requiring a peg, the problem is to find a shortest tour for the vehicle in which all the pegs can be transported to their slots without exceeding the capacity of the vehicle. This

problem is referred to as k-delivery TSP. The traveling salesman problem (TSP) is a special case of k-delivery TSP, since replacing each vertex of the TSP by a peg and a slot yields an instance of the 1-delivery TSP. In this instance, the vehicle has to simply find a shortest tour that visits all the pegs (i.e., a TSP solution), since any peg that is picked up by the vehicle can immediately be delivered to the slot in the same location. Therefore, the k-delivery TSP is NP-hard [16], even when $k = 1$. The distances between the given points satisfy the triangle inequality since the vehicle can always take a shortest path between any two points. Replacing the distances between each pair of points by the shortest-path distance between them ensures that the triangle inequality is satisfied.

Haimovich and Rinnooy Kan [17] studied a *special case* of this problem when all the pegs are located at one central depot and are delivered with a vehicle of capacity k. They provided an approximation algorithm that obtains a performance ratio of 3. For geometric graphs—graphs induced by points in the plane with Euclidean distances as edge-weights—they provided a polynomial-time approximation scheme for constant k. Christofides [11] surveyed various issues, including problem formulation and algorithms, related to the vehicle routing problem, where the vehicles originate at a central depot. Asano, et al. [6] gave a polynomial-time approximation scheme for the same special case in the geometric setting, when k is $O(\log n/\log\log n)$. Anily and Hassin [2] demonstrated an algorithm that obtains a ratio of 2.5 for the 1-delivery TSP. The first constant factor approximation algorithm for the general problem was given by Chalasani, Motwani, and Rao [10]. We will refer to their algorithm as the "CMR algorithm." They obtained an approximation ratio of 9.5. They also gave better algorithms for the cases $k = 1$ and $k = \infty$ that yield ratios of 2 in both cases. Independent of our work, Anily and Bramel [1] showed that a modification of the CMR algorithm improves the approximation ratio to $7 - \frac{3}{k}$. (In fact, we show that one can obtain a better bound of 6.5 by modifying the CMR approach.) They also gave another algorithm with an approximation ratio of $c(k) + \frac{1}{2}\log_2 k$, where $2 \le c(k) \le 3$.

Our results. We summarize the results presented in this paper below:

- For the k-delivery TSP, we provide a natural approximation algorithm that runs in polynomial time and show that its performance ratio is at most 5. Since the proof is complex, we first prove a simpler bound of 6.5; this proof contains some of the basic ideas.
- For geometrical instances, such as points in the plane, the algorithms of Arora [4, 5] and Mitchell [20] can be used to obtain an $(1+\epsilon)$ approximation of the TSP, and this leads to an approximation factor of $4(1+\epsilon)$ for these instances.
- We also describe a *simple* algorithm that finds a preemptive tour whose length is at most five times the length of an optimal preemptive tour. (We will shortly explain what we mean by a preemptive tour.)

Significance of our work. We explain below how our algorithm fundamentally differs from previous algorithms and why it is likely to return far better solutions in practice than they do. The previous methods for solving the general k-delivery TSP suffer from the following drawback. They start with two tours, one containing all the pegs (source nodes) and the other containing all the slots (delivery nodes). The basic idea is to traverse the cycle of pegs, collecting k pegs, then switch over to the other cycle and deliver the k pegs, repeating the process until all pegs are delivered. The delivery route thus alternates between the two cycles; it turns out that it is easy

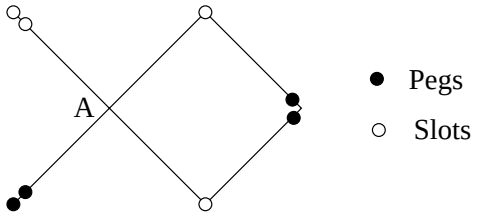

FIG. 1.1. *Example to show that intermediate drops help even for* $k = 2$.

to analyze the cost of shuttling between the cycles in this scheme. Such a scheme suffers from the drawback that the individual tours for the pegs and slots do not take advantage of the proximity of pegs and slots. In most instances, one can do better by alternating pickups and deliveries without waiting for the vehicle to become either completely full or completely empty. We derive a natural algorithm that *uses a single tour* containing all points, combining pickups and deliveries arbitrarily, and taking "corrective" action only when the vehicle becomes either full or empty. The main hurdle is in proving a good analysis of this more natural scheme. Our analysis shows significantly better approximation ratios for our algorithm than the previous algorithms. In addition, preliminary experimental studies show that our algorithm returns much better solutions.

Note. We will assume that we can start the vehicle's tour at any location. This is slightly different from previous work on this problem, which assumes that the starting point is fixed. With a fixed starting point, our method still applies with an additive factor of 1 in the approximation factors in the worst case.

Preemptive tours A fundamental issue is that of *preemptive* versus *nonpreemptive* traversals. In a preemptive traversal, pegs may be dropped at intermediate locations; in other words, we may pick up a peg and leave it at some location, and return later to collect it and deliver it. In a nonpreemptive solution, we carry a peg from its source to its destination without ever unloading it from the vehicle at intermediate nodes. The nature of the problem and algorithms can change if drops are permitted.

Figure 1.1 shows an example in which the best preemptive tour is shorter than the best nonpreemptive tour. The edges shown cost 1 unit each. A tour with a capacity-2 vehicle that leaves a peg at point A and delivers it later costs 8 units. If we are not allowed to drop a peg at intermediate locations, we incur a higher cost (regardless of where the tour starts), and an optimal nonpreemptive tour costs 10 units. This raises a very fundamental question—*what is the worst-case ratio of the cost of an optimal nonpreemptive tour to that of an optimal preemptive tour?* Our example shows that the ratio is at least $\frac{5}{4}$.

We show that the ratio between the optimal nonpreemptive and preemptive tours is at most 4 by showing that, given a preemptive tour of length L, we can find a nonpreemptive tour of length at most $4L$. This theorem is proven by using a variety of different ideas. One interesting method is a general technique for simulating a preemptive tour of a unit-capacity vehicle by a nonpreemptive tour *that travels the same distance* (Lemma 2.7).

Related work. A closely related problem is the *stacker-crane* problem. This problem also involves making deliveries with a vehicle of capacity k. In the stacker-crane problem, the objects are *not* identical and each object has a specific target

destination. The goal is to find a shortest tour that performs the transportation. For the unit-capacity case, Frederickson, Hecht, and Kim [15] gave an algorithm with an approximation factor of 1.8. For the case when the underlying metric is a tree, Frederickson and Guan [13, 14] have given fast algorithms to compute optimal solutions for the preemptive case and fast approximation algorithms for the nonpreemptive case. (The problems are NP-hard even for trees.) Knuth [19, section 5.4.8] discusses Karp's work [18] on the problem for paths and trees. Fast algorithms were given by Atallah and Kosaraju [7] for the cases in which the graph is either a simple cycle or path. The algorithms are slightly faster for the cases when drops are permitted. Frederickson [12] showed improved running times for a cycle when no drops are allowed. The issue of tours under various types of restrictions has also been investigated by Arkin, Hassin, and Klein [3].

Outline of the paper. In section 2 we describe an approximation algorithm for the k-delivery TSP that obtains an approximation ratio of 5. We first prove a simpler bound of 6.5 in section 2, and then, in section 3, we provide a better analysis of our algorithm. We also show how to "convert" a preemptive tour to a nonpreemptive tour. We prove that the total length of the nonpreemptive tour obtained by our algorithm is at most four times the length of the preemptive tour. In section 4, we describe a simple algorithm that finds a preemptive tour whose length is at most five times the length of an optimal preemptive tour.

Notation. An optimal nonpreemptive tour for the k-delivery TSP is denoted by C_k, and an optimal preemptive tour is denoted by C'_k. We will use C_k or C'_k to denote the length of the tour as well, and one can distinguish between the two meanings from the context.

2. An approximation algorithm for k-delivery TSP.

In this section, we provide an approximation algorithm and an analysis for its performance. We also show how to simulate a preemptive tour by a nonpreemptive tour. In particular, we show that $C_1 \leq kC'_k$ (Lemma 2.7). (This also shows the interesting result that $C_1 = C'_1, C_2 \leq 2C'_2, C_3 \leq 3C'_3$.)

We prove the following theorems.

THEOREM 2.1. *Consider an arbitrary instance of k-delivery TSP. There is a polynomial-time approximation algorithm that finds a nonpreemptive tour whose length is at most five times the length of an optimal tour (possibly preemptive). In the special case when the points are specified on the plane, and edge-costs are specified by Euclidean distances, the approximation ratio can be improved to $4(1+\epsilon)$ for any constant $\epsilon > 0$.*

THEOREM 2.2. *The length of an optimal nonpreemptive tour of a k-delivery TSP instance is at most four times the length of an optimal preemptive tour, i.e., $C_k \leq 4C'_k$.*

2.1. Overview of the algorithm. The main idea is the following: First construct a tour of *all* the given points. Starting from some initial vertex, we traverse the tour, picking up pegs, and delivering them to slots, on-line. In other words, when the vehicle passes through a node with a peg, it picks up the peg, and when it passes through a slot, it drops a peg there. We show that if the vehicle has unbounded capacity, then there is always a starting point such that the vehicle can complete all deliveries without ever running out of pegs. If the vehicle has bounded capacity k, the simple scheme outlined above does not work directly. We need to address the following two situations: (a) the vehicle is full when a peg is visited, and (b) the vehicle is empty when a slot is visited.

In the following discussion, we assume that k is even. We will later describe how to handle the case when k is odd. The performance ratio is at most $5\frac{1}{6}$ for odd k. We treat the vehicle as full when it has $k/2$ pegs on it, and the remaining capacity is used as a "buffer." The tour is broken up into segments of 3 kinds: (i) *neutral* segments with equal number of pegs and slots, (ii) *positive* segments that have $k/2$ more pegs than slots, and (iii) *negative* segments that have $k/2$ more slots than pegs. Neutral segments are processed as mentioned in the above scheme. In most practical situations, most parts of the tour constructed may be neutral segments, and in this case our algorithm would do very well since neutral segments are processed by traversing them only once. By definition, there are as many positive segments as negative segments. We compute a minimum-weight perfect matching between the positive and the negative segments. When the vehicle is passing through a positive segment on its tour, it delivers the excess pegs to the negative segment to which the positive segment is matched.

The main difficulty in analyzing such a scheme is that the cost of a matching between the positive and the negative segments has to be bounded with respect to an optimal tour. Note that the matching does not include all nodes in the original problem, and therefore it could possibly be arbitrarily expensive. Another complication is that the segments do not have the same number of points on them. The techniques used in the previous results [1, 10] do not yield a bound on the cost of such a matching. We show how to bound the cost of the matching with respect to an optimal tour and use it to derive a better approximation bound. We now describe the algorithm in detail.

2.2. The algorithm.

1. Construct a tour T that visits all the points.
2. Fix a reference point P on the tour T.
3. Traverse the tour T in some direction starting from P.
4. Compute the *excess* function $\text{EXCESS}(e)$ for each edge e of T. $\text{EXCESS}(e) = \text{PEGS}(e) - \text{SLOTS}(e)$, where $\text{PEGS}(e)$ is the number of pegs encountered before e is traversed, and $\text{SLOTS}(e)$ is defined analogously as the number of slots encountered before e.
5. For each value of $i \in [0, k/2)$ do
   (a) Break the tour into pieces by removing all edges with $\text{EXCESS}(e) \equiv i \bmod k/2$. Call these edges *cut* edges. Figure 2.1 shows a sample tour and a plot of the excess function for a counterclockwise traversal of the tour (with $k = 6$ and $i = 0$).
   (b) We get p-pieces (positive pieces), n-pieces (negative pieces), and 0-pieces (zero or neutral pieces) as follows.
   - A p-piece is one where the *excess* function is x on the cut edge preceding the piece and $x + k/2$ on the cut edge following the piece; for all edges e in the piece, $\text{EXCESS}(e) \in (x, x + k/2)$.
   - An n-piece is one where the *excess* function is x on the cut edge preceding the piece and $x - k/2$ on the cut edge following the piece; for all edges e in the piece, $\text{EXCESS}(e) \in (x - k/2, x)$.
   - A 0-piece is one where the *excess* function is x on the cut edge preceding the piece and x on the cut edge following the piece; for all edges e in the piece, either $\text{EXCESS}(e) \in (x - k/2, x)$ (such a piece is called *decreasing*) or $\text{EXCESS}(e) \in (x, x + k/2)$ (such a piece is called *increasing*).

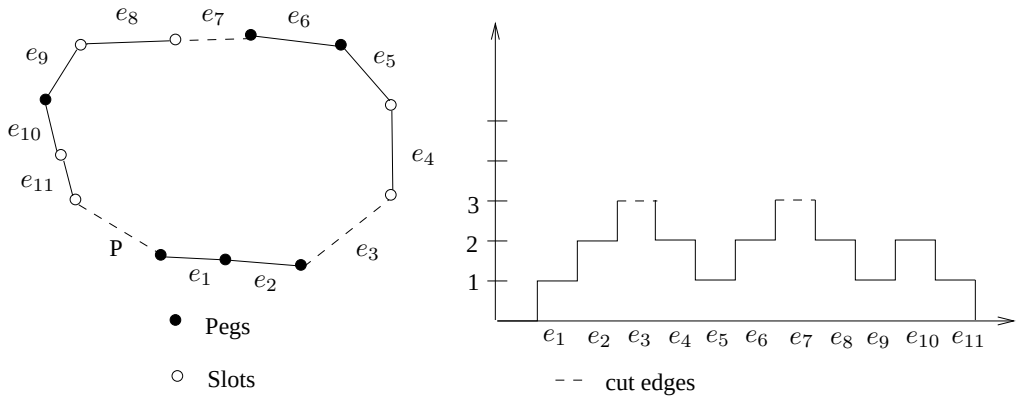

FIG. 2.1. *A tour and the excess function plotted for $k = 6$ and $i = 0$.*

(c) Compute a matching on the p- and n-pieces as follows:
- Construct a weighted bipartite graph $B = (V^+, V^-, E)$ on p- and n-pieces as follows: There is one vertex in V^+ for each p-piece and one vertex in V^- for each n-piece. For each p-piece u^+ and each n-piece w^-, the edge (u^+, w^-) has weight equal to the minimum-weight edge connecting a vertex in u^+ and a vertex in w^-.
- Compute a minimum-weight perfect matching M in the bipartite graph B. A p-piece and an n-piece that are matched to each other are said to form a p/n-pair.

(d) Now traverse the tour starting from any point in both clockwise and counterclockwise directions as follows (assume for now that we start each traversal at the beginning of a piece with exactly $k/2$ pegs; Lemma 2.3 shows how this assumption is unnecessary):
- On encountering a 0-piece, we move along the piece picking up pegs and delivering them. Since we start with $k/2$ pegs, we can do this in a single traversal and reach the end of the piece with $k/2$ pegs. Note that we leave the piece with $k/2$ pegs.
- When we encounter the first piece of a p/n-pair, we service the pair as follows: Suppose we encounter a p-piece P^+ which is matched with n-piece P^- by edge $e \in M$. Note that there must be an edge e' corresponding to e, such that e' connects some vertex in P^+ to some vertex in P^-, and the weight of e' is the same as that of e. Traverse P^+, performing pickups and deliveries, until e' is encountered. Now, move to the beginning of P^- and traverse P^- performing pickups and deliveries. Then move back to the point in P^+ where we left off and continue performing pickups and deliveries. Note that after servicing a p/n-pair in this way, we finish with $k/2$ pegs. The case when the n-piece is encountered before the p-piece is handled similarly.
- When we encounter the second piece of a p/n-pair, we simply traverse the piece without performing any pickups and deliveries (since it has already been serviced).

(e) For both of the tours (clockwise and counterclockwise) described above,

find a valid starting point (i.e., a starting point such that we never run out of pegs and the number of pegs carried is at most k). Lemma 2.3 guarantees the existence of such a starting point.

6. Return a shortest tour from amongst the k tours constructed (two for each $i \in [0, k/2)$).

2.3. Analysis: A weaker bound. We can prove an upper bound of 5 on the approximation ratio achieved by the above algorithm. Since the proof is complex, we prove a simpler bound of 6.5 that contains the basic ideas. In fact, for the simpler proof we can fix $i = 0$ in the above algorithm. To prove the better bound, we need to try all values of i. Section 3 contains the proof for the bound of 5. We also prove the relationship between the tour generated by the algorithm and C'_k (Theorem 2.2).

LEMMA 2.3. *A valid starting point is guaranteed to exist in step* 5(e) *of the algorithm.*

Proof. Suppose we started the tour constructed by the algorithm at the beginning of any piece with a vehicle preloaded with $k/2$ pegs. Then the following invariant is maintained throughout the tour: The vehicle has exactly $k/2$ pegs when it traverses a cut edge from one piece to another. We can verify that the number of pegs carried by the vehicle always lies in the interval $[0, k]$. This would be a valid tour except for the fact that we assumed that we initially started with $k/2$ pegs. Let $n(e)$ be the number of pegs carried by the vehicle as it traverses edge e (beginning with $k/2$ pegs). Consider the edge $e_{\min}$, where $n(e)$ reaches its minimum value, say, x (break ties arbitrarily). Suppose we start a new vehicle with no pegs from edge $e_{\min}$. Let $n'(e)$ be the number of pegs carried by the new vehicle as it traverses edge e. It can be verified that $n'(e) = n(e) - x$. By the choice of $e_{\min}$, this ensures that the number of pegs carried by the vehicle always lies in the interval $[0, k]$. This proves the existence of a valid starting point for the tour and, in fact, also gives a simple method to find such a starting point. □

Based on the above lemma, we can also show the following lemma.

LEMMA 2.4. *There is a polynomial-time approximation algorithm for the* ∞*-delivery TSP (i.e., the vehicle has infinite capacity) with a performance ratio of* 1.5. *For geometric instances on the plane, the approximation ratio is* $1 + \epsilon$ *for any* $\epsilon > 0$.

Proof. Let T_{OPT} be a minimum length tour of all the points. Since C'_k is a tour of the points, $T_{OPT} \leq C'_k$. The algorithm constructs a tour T of all the points. For the algorithm, we will assume that an α-approximation of the TSP tour is used, and therefore the weight of the tour is at most $\alpha T_{OPT} \leq \alpha C'_k$. If Christofides's algorithm is used, then $\alpha \leq 1.5$. For geometric instances, such as points in the plane, the algorithms of Arora [4, 5] and Mitchell [20] can be used to obtain a $(1 + \epsilon)$ approximation of the TSP tour. In this case, $\alpha = 1 + \epsilon$ for any constant $\epsilon > 0$. Using the same ideas as in the above lemma, we can show that there is always a valid starting point on this tour such that we never run out of pegs. □

In step 5(c) we find a matching M on the p- and n-pieces. We need to bound the weight of the matching M. We cannot bound the weight of the matching by the method used in [10] since the matching is not being computed in a graph that includes all the pegs and slots. We use a different approach to bound the weight of the matching.

Let A be a minimum-weight perfect matching between pegs and slots, where a peg must be matched to a slot. We use A to denote the matching and its weight. One can distinguish between the two meanings from the context.

2.3.1. Bounding the matching *A*. The following lemmas derive an upper bound on the ratio of the weight of matching A to the weight of an optimal preemptive solution. Even though there are other ways of proving this directly, these proof methods also show how to "simulate" a preemptive solution with a nonpreemptive solution.

Our main goal is to prove the following theorem.

THEOREM 2.5. $A \leq \frac{k}{2} C'_k$.

This theorem follows once we establish the following lemmas.

LEMMA 2.6 (see [10]). $A \leq \frac{1}{2} C_1$.

We now prove that a nonpreemptive unit-capacity vehicle can simulate a preemptive capacity-k vehicle with an increase of the length of the tour by a factor of k. One could attempt to prove this by walking around the cycle k times, but the problem is that we may attempt to pick up a peg that is not yet "available."

LEMMA 2.7. $C_1 \leq k \cdot C'_k$.

Proof. Consider a tour C'_k which delivers pegs to slots and is allowed intermediate dropping points. We will show that we can convert this tour into one of length $k \cdot C'_k$, where the pegs are carried to slots with no intermediate drops by a unit-capacity vehicle. Assume the vehicle of capacity k starts at s and returns to s.

We construct an auxiliary multigraph $G = (V, E)$ from the tour as follows. The vertex set of the graph is defined to be

$$V = \{s\} \cup \{x | x \text{ is an intermediate drop point}\}.$$

Imagine that we store the pegs on numbered compartments in the vehicle. The numbers are $1 \ldots k$. The tour starts from s and visits pegs/slots and intermediate drop points. We can view the tour as "segments," where it goes back and forth between the vertices of the graph we constructed (see Figure 2.2). We create k edges in G for each movement done by the vehicle between two vertices of G. Each edge corresponds to a numbered compartment. We associate with each such edge the pegs which were placed into this compartment and the slots which were serviced by removing a peg from this compartment. Thus each edge is associated with an alternating sequence of pegs and slots. As the vehicle moves from vertex x to vertex y of G, each numbered compartment undergoes the following various changes:

(1) Lose a peg. (Leave x with a peg; arrive at y with no peg.) The corresponding edge is associated with a peg/slot sequence of the form $sps \ldots ps$. (Here p represents a peg and s a slot.)
(2) Gain a peg. (Leave x with no peg; arrive at y with a peg.) The corresponding edge is associated with a sequence of the form $psp \ldots sp$.
(3) Move without carrying anything from x to y. (We may load and unload pegs in this compartment during the motion.) The corresponding edge is associated with a sequence of the form $psp \ldots ps$ (possibly empty).
(4) Move carrying a peg from a vertex to another vertex. (We may unload and load pegs in this compartment during the motion.) The corresponding edge is associated with a sequence of the form $sps \ldots sp$ (possibly empty).

Each edge corresponding to a compartment is a labeled edge in the multigraph. Type (1) edges are labeled as $-$ edges. Type (2) edges are labeled as $+$ edges. We subdivide edges of type (3) by a vertex xy. The edge from x to xy gets the label $+$, and the edge from xy to y is labeled as a $-$ edge. We subdivide edges of type (4) by a vertex xy. The edge from x to xy gets the label $-$, and the edge from xy to y is labeled as a $+$ edge. We can think of a $+$ edge as being associated with an odd length alternating

peg/slot sequence that begins and ends with a peg. Similarly, a $-$ edge can be thought of as being associated with an odd length alternating peg/slot sequence that begins and ends with a slot.

LEMMA 2.8. *For each vertex of the auxiliary multigraph G, the number of $+$ labels incident to it is equal to the number of $-$ labels incident to it.*

Proof. For each compartment, the contribution to the $+$ and $-$ label is the same. Consider a vertex v that is a dropping point. The number of pegs that are carried to it are carried away. (Formally, each vertex v occurs a number of times on the tour. There are 4 cases: (a) come with a peg, leave it here, and go $(+v+)$; (b) come with a peg, leave with a peg $(+v-)$; (c) come with no peg, go with no peg $(-v+)$; (d) come with no peg, go with a peg $(-v-)$. The number of cases (a) and (d) are the same since (a) increases peg count and (d) decreases peg count.) □

In order to construct a solution that does not drop pegs at intermediate locations, we need to construct an alternating sequence of pegs and slots which visits every peg and every slot. Find an Euler tour that alternates using $+$ and $-$ edges in this multigraph. (When we enter a vertex on a $+$ edge we can leave on a $-$ edge and vice versa.) The Euler tour can be interpreted as a nondrop tour solution for a vehicle with unit capacity. The unit-capacity vehicle simply traverses the edges in the order of the Euler tour. When we traverse a particular edge, we service the sequence of pegs and slots associated with that edge. The definition of $+$ and $-$ edges ensures that we encounter pegs and slots in an alternating fashion. This therefore gives a nondrop tour solution with unit capacity. This completes the proof of Lemma 2.7. □

We illustrate this construction by an example in Figure 2.2. Suppose we are given the preemptive tour that starts at s, pick up a peg on path A, and drop it off at the first drop off point. We then take the loop marked B performing one delivery, come back to pick up the dropped off peg, and take the loop marked C. We return with a peg, drop it off at the same place, and then take the path D, drop off a second peg, come back to pick up the first peg on path E, deliver it on path F, pick up the second peg, and take path G, returning to s.

Corresponding to this traversal, we construct the auxiliary multigraph G. We have three vertices to begin with. Path A gains a peg and is marked $+$. Path B is a loop on which we leave without a peg and return without a peg; we subdivide this edge and it is a $+-$ edge. Path C is a loop on which we leave with a peg and return with a peg, and so we subdivide it and mark it a $-+$ edge. In a similar manner we finish the construction of the multigraph. An Euler tour in this multigraph that alternates between $+$ and – edges is easy to find. This corresponds to a nonpreemptive traversal.

2.3.2. Bounding the matching M. Let W be a matching (which we call a *wiggly matching*) that matches pegs to slots such that all points are matched except for some $k/2$ pegs in each p-piece and $k/2$ slots in each n-piece. We use the *wiggly matching* to bound the cost of the matching M as follows.

LEMMA 2.9.

$$M \leq \frac{2}{k}(A + W). \tag{2.1}$$

Proof. Consider the symmetric difference of A and W. A is a perfect matching and W is a matching where all the pegs and slots in the 0-pieces are matched, and in each p- (n-) piece, there are $\frac{k}{2}$ unmatched pegs (slots). The symmetric difference has even length cycles and paths. Since A is a perfect matching, the symmetric difference

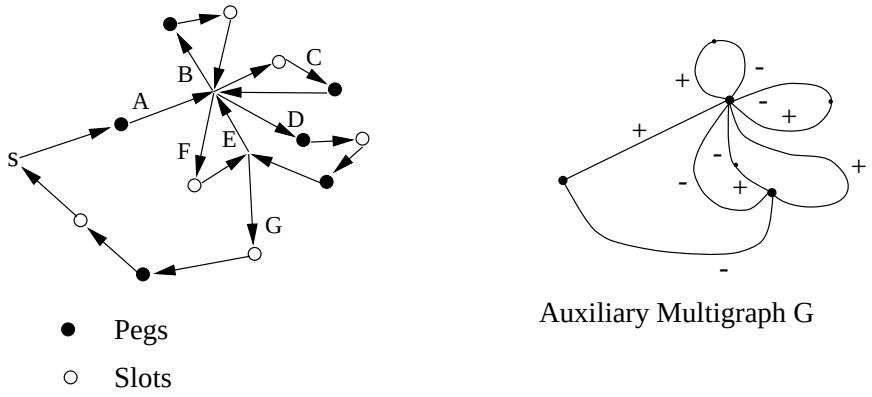

FIG. 2.2. *Illustrating construction of auxiliary multigraph $G = (V, E)$ for a unit-capacity vehicle.*

is a collection of disjoint augmenting paths (with respect to W) that start and end with edges from A at vertices of degree 1 in the graph $A \cup W$. The only vertices having degree 1 are pegs in the p-pieces and slots in the n-pieces. Each augmenting path with respect to W has a peg at one end and a slot at the other end. This gives us paths from pegs to slots such that each p-piece has $k/2$ paths emerging from it and each n-piece has $k/2$ paths ending on it. This collection of paths can be decomposed into $k/2$ perfect matchings between p- and n-pieces (because the edges of a d-regular bipartite graph can be decomposed into d perfect matchings [8]). It follows that the weight of the minimum-weight perfect matching on the p- and n-pieces is at most the average weight of the $\frac{k}{2}$ matchings we found. By triangle inequality, the weight of the symmetric difference is at most the sum of the weights of the matchings. This proves the lemma. □

Recall that T is the tour of all the points constructed by the algorithm. Let $T^{(\pm)}$ be the total length of the p/n-pieces and let $T^{(0)}$ be the total length of the 0-pieces. Let $T^{(C)}$ be the total length of the cut edges. Then $T = T^{(\pm)} + T^{(0)} + T^{(C)}$.

2.3.3. Bounding the matching W.

LEMMA 2.10. *There exists a wiggly matching (a matching that matches pegs to slots such that all points are matched except for some $k/2$ pegs in each p-piece and $k/2$ slots in each n-piece) W such that*

$$W \leq \frac{k}{2}\left(\frac{1}{2}T^{(\pm)} + T^{(0)}\right). \tag{2.2}$$

Proof. We will construct the *wiggly matching* separately for 0- and p/n-pieces. A 0-piece can be traversed in one of the two directions by a vehicle with no pegs initially such that pegs are picked up and delivered without having to back up. Suppose this vehicle operates like a stack, pushing and popping pegs. For each $j \in [0, k/2)$, consider the pegs which were placed in location j of this stack and the slots which were serviced by popping a peg from location j of this stack. This defines a path of the form $psp \ldots s$, where p stands for a peg and s stands for a slot. We match each peg on this path with the slot immediately following it. The total length of the matching edges is at most the length of the path. However, the length of the path is at most the length of the 0-piece. Since we construct $k/2$ paths, the total length of the matching within this 0-piece is at most $k/2$ times the length of the 0-piece.

A p-piece can be traversed (in either direction) by a vehicle with no pegs initially such that pegs are picked up and delivered without having to back up. The vehicle ends up with $k/2$ pegs at the end. Analogous to the construction for a 0-piece, we define a path corresponding to each location j of the stack. Each path is of the form $psp \dots sp$. Now we can match pegs with slots either starting from the left or the right. In either case, one peg is left unmatched. We choose the lower cost matching between the two. The total cost of the two matchings is exactly the cost of the path. Thus the smaller of the two matchings costs at most half the length of the path. Again the length of each path is at most the length of the p-piece. Since we construct $k/2$ paths, the total length of the matching within this p-piece is at most $k/4$ times the length of the p-piece. A similar construction can be done for n-pieces. Hence the lemma follows. □

Theorem 2.5 bounds the weight of the matching A to be at most $\frac{k}{2}C'_k$. Substituting into (2.1) for A from the theorem and for W from (2.2), we get

$$M \leq C'_k + \frac{1}{2}T^{(\pm)} + T^{(0)}. \tag{2.3}$$

Proof of Theorems 2.1 *and* 2.2. Note that in the two tours constructed by the algorithm, each 0-piece is traversed once and each cut edge is traversed once. Also the first of each p/n-pair is traversed once while the second is traversed thrice. Averaging over the two traversals, we charge each p/n-piece twice. Each edge in M is traversed twice.

Hence the average length of the two tours constructed is at most

$$\begin{aligned} 2M + T^{(0)} + 2T^{(\pm)} + T^{(C)} &\leq 2C'_k + 3T^{(0)} + 3T^{(\pm)} + T^{(C)} \\ &\leq 2C'_k + 3T \\ &\leq 2C'_k + 3\alpha C'_k = (2 + 3\alpha)C'_k. \end{aligned}$$

Since $\alpha \leq 1.5$, we obtain a worst-case approximation ratio of 6.5. We can also view this as a constructive proof bounding the ratio of C_k to C'_k. In that case $\alpha = 1$ and we obtain an upper bound of 5 on the ratio. In section 3 we show a bound of $(2+(2-\frac{4}{k^2})\alpha)C'_k$. Using this improved bound, we get an approximation ratio of 5, and we can bound the ratio of C_k to C'_k by 4. Also, for geometric instances (consisting of points in the plane with Euclidean distances), using an $(1+\epsilon)$-optimal tour [4, 5, 20] in the first step of the algorithm, we obtain a ratio of $4(1+\epsilon)$. □

If we are given a fixed starting point q, we obtain a tour that starts and ends at q as follows. We apply the algorithm as usual. Suppose this constructs a tour that starts and ends at q', which is a peg without loss of generality. We first move from q to q', traverse the tour constructed by the algorithm, and, on reaching q' again, move back to q. We pay an additional cost of twice the distance between q and q', which is at most the cost of the optimal tour, since the optimal tour includes two paths between q to q'. This adds 1 to our approximation ratios.

3. A better analysis. Notice that the previous analysis did not use the fact that we try different break points and average over them. We now present a better analysis that builds on the basic ideas from section 2.3 to show that the average tour length for the k tours constructed is actually at most $(2 + (2 - \frac{4}{k^2})\alpha)C'_k$.

Examining the proof of Lemma 2.10, we observe that the proof constructs $k/2$ paths within each piece of the tour. The contribution to the total length of the final tour is the average path length in the p/n-pieces plus twice the average path length in

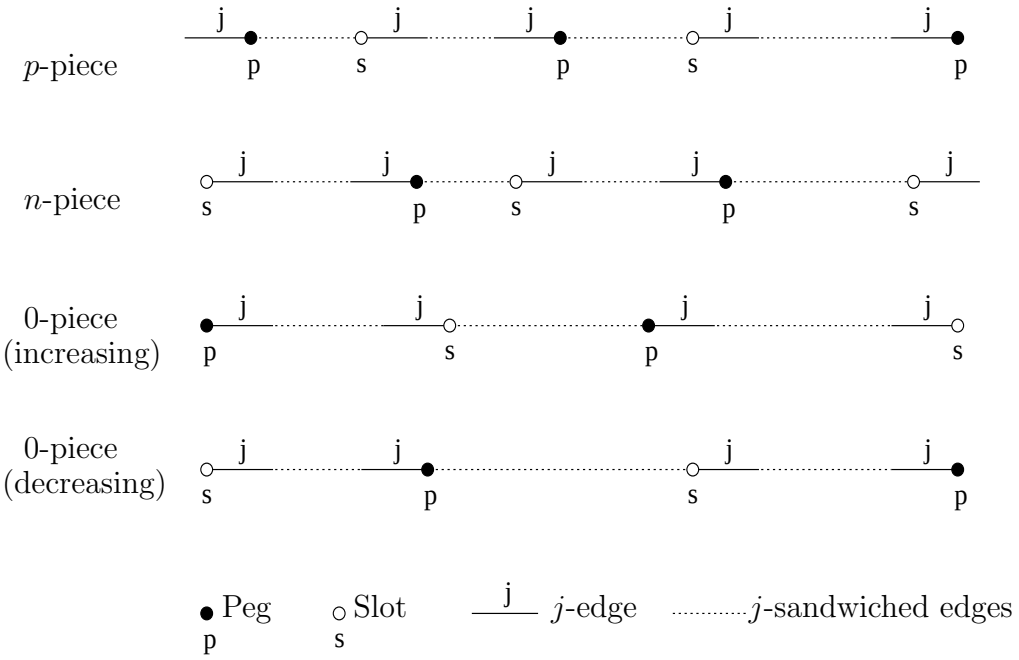

FIG. 3.1. *Illustrating the definition of paths in terms of the excess function.*

the 0-pieces. Here, "average" refers to the average length of the $k/2$ paths. The earlier proof bounded each path length by the length of the entire piece. We will improve the analysis by getting better estimates for the average path lengths by averaging over all values of i used to define the cut edges of the tour.

For a node v (peg or slot) in the tour T, define BEFORE(v) to be the edge preceding v in T and AFTER(v) to be the edge following v in T.

It will be useful to identify the paths constructed by the proof of Lemma 2.10 with the values of the *excess* function on edges within a piece. In the following discussion, we fix a value of i used to define the cut edges. For a given i, for every integer $j \in [0, k/2)$, we construct a path in each piece based on the values of the *excess* function as follows. An edge e is said to be a j-edge if EXCESS(e) $\equiv j \pmod{k/2}$.

For a p/n-piece, the path consists of the pegs p such that BEFORE(p) is a j-edge and the slots s such that AFTER(s) is a j-edge. For a 0-piece, we define the paths differently depending on whether the piece is *increasing* or *decreasing*. For an *increasing* 0-piece, the path consists of the pegs p such that AFTER(p) is a j-edge and the slots s such that BEFORE(s) is a j-edge. For a *decreasing* 0-piece, the path consists of the slots s such that AFTER(s) is a j-edge and the pegs p such that BEFORE(p) is a j-edge. See Figure 3.1 for an illustration of this definition of paths. Observe that by this definition, for all cases, the path for $j = i$ always has zero length. For a p-piece, it consists of a single peg. For an n-piece, it consists of a single slot. For a 0-piece, the path for $j = i$ is empty. The reader can verify that the paths constructed by this definition are identical to the paths constructed in the proof of Lemma 2.10.

Let $l_{ij}^{(\pm)}$ be the total length of the paths corresponding to j (by the above correspondence) within the p/n-pieces when i is used to define the cut edges. We define

$l_{ij}^{(0)}$ similarly for the paths within the 0-pieces.

Call an edge e in a piece *j-sandwiched* if e is not a j-edge and there is some j-edge before e and some j-edge after e in the piece. (The j-edges need not be immediately before and after e.) Note that the property of being a j-edge is independent of the value of i; however, the property of being a j-sandwiched edge depends on the value of i used to define the cut edges. In any piece, the path corresponding to j (described above) consists of j-sandwiched edges and j-edges Thus the length of this path is bounded by the sum of the total length of the j-sandwiched edges and the total length of the j-edges in the piece.

Let $p_{ij}^{(\pm)}$ be the total length of the j-sandwiched edges within the p/n-pieces when i is used to define the cut edges. We define $p_{ij}^{(0)}$ similarly for the 0-pieces. Let $q_{ij}^{(\pm)}$ be the total length of the j-edges within the p/n-pieces when i is used to define the cut edges. We define $q_{ij}^{(0)}$ similarly for the 0-pieces. By the above definitions, we have

$$l_{ij}^{(\pm)} \le p_{ij}^{(\pm)} + q_{ij}^{(\pm)},$$
$$l_{ij}^{(0)} \le p_{ij}^{(0)} + q_{ij}^{(0)}.$$

Also, when i is used to define the cut edges, let $T_i^{(\pm)}$ be the total length of the p/n-pieces, let $T_i^{(0)}$ be the total length of the 0-pieces, and let $T_i^{(C)}$ be the total length of the cut edges.

Note that

$$\sum_{j\neq i} q_{ij}^{(\pm)} = T_i^{(\pm)},$$
$$\sum_{j\neq i} q_{ij}^{(0)} = T_i^{(0)}.$$

Now, the analysis of the previous section bounded the average length of the two tours produced when a particular value of i is used to define the cut edges. In terms of the notation introduced, this bound can be written as

$$\begin{aligned}
&\frac{4}{k}A + \frac{2}{k}\sum_{j\neq i} l_{ij}^{(\pm)} + \frac{4}{k}\sum_{j\neq i} l_{ij}^{(0)} + 2T_i^{(\pm)} + T_i^{(0)} + T_i^{(C)} \\
&\le 2C'_k + \frac{2}{k}\sum_{j\neq i}\left(p_{ij}^{(\pm)} + q_{ij}^{(\pm)}\right) + \frac{4}{k}\sum_{j\neq i}\left(p_{ij}^{(0)} + q_{ij}^{(0)}\right) + 2T_i^{(\pm)} + T_i^{(0)} + T_i^{(C)} \\
&= 2C'_k + \frac{2}{k}\sum_{j\neq i} p_{ij}^{(\pm)} + \frac{4}{k}\sum_{j\neq i} p_{ij}^{(0)} + \left(2+\frac{2}{k}\right)T_i^{(\pm)} + \left(1+\frac{4}{k}\right)T_i^{(0)} + T_i^{(C)}.
\end{aligned}$$

Let L be the length of the constructed tour averaged over all the $k/2$ values of i. Summing up the above bound over all values of i, we get

$$\begin{aligned}
\frac{k}{2}L \le kC'_k + \underbrace{\frac{2}{k}\sum_i\sum_{j\neq i} p_{ij}^{(\pm)}}_{S_1} + \underbrace{\frac{4}{k}\sum_i\sum_{j\neq i} p_{ij}^{(0)}}_{S_2} + \left(2+\frac{2}{k}\right)\underbrace{\sum_i T_i^{(\pm)}}_{S_3} \\
+ \left(1+\frac{4}{k}\right)\underbrace{\sum_i T_i^{(0)}}_{S_4} + \underbrace{\sum_i T_i^{(C)}}_{S_5}.
\end{aligned} \tag{3.1}$$

We will compute a bound for sum of the last five terms of the right-hand side of (3.1) in terms of T.

Consider a particular edge e of the tour. Let us calculate its contribution to the various terms in (3.1). Suppose e is an r-edge. For each value of $i \in [0, k/2), i \neq r$, we scan to the left and right of e for the closest i-edges before and after e. Let A_i be the portion of the path between (and not including) these two i-edges. When i is chosen to define the cut edges of the tour, A_i is a (p/n- or 0-) piece. Accordingly, we label the segment A_i as p/n or 0. Note that we use the term segment as opposed to piece, as a segment A_i may or may not be a piece depending on the value used to define the cut edges.

Edge e contributes to $l_{ij}^{(\pm)}$ iff A_i is a p/n segment and e is j-sandwiched within A_i, i.e., iff A_j is completely contained within A_i. The edge e contributes to $l_{ij}^{(0)}$ iff A_i is a 0-segment and e is j-sandwiched within A_i, i.e., iff A_j is completely contained within A_i. The edge e contributes to $T_i^{(\pm)}$ iff A_i is a p/n segment and contributes to $T_i^{(0)}$ iff A_i is a 0-segment. It contributes to $T_i^{(C)}$ iff $i = r$.

Claim. If A_i is a p/n segment, it cannot be contained in any other segment A_j ($j \neq i$).

Proof. Since A_i is a p/n segment, the *excess* function changes by $k/2$ from one end to the other. Hence there must be some point within it where the *excess* function is $j \bmod k/2$. Hence one of the end points of A_j must be within A_i, proving the claim. □

Suppose x of the segments A_i are 0-segments and $(\frac{k}{2} - x - 1)$ of them are p/n segments. Let us calculate the number of times edge e is counted in the various terms in (3.1).

The contribution to S_1 is the number of pairs (A_j, A_i) such that A_j is contained in A_i and A_i is a p/n-segment By the above claim, A_j must be a 0-segment. Thus the number of such pairs is at most $x(\frac{k}{2} - x - 1)$. The contribution to S_2 is the number of pairs (A_j, A_i) such that A_j is contained in A_i and A_i is a 0-segment. By the above claim, A_j must be a 0-segment. Note that if A_j is contained in A_i, then A_i is not contained in A_j. Thus the number of such pairs is at most $\frac{x(x-1)}{2}$. The contribution to S_3 is $\frac{k}{2} - x - 1$. The contribution to S_4 is x. The contribution to S_5 is 1.

Thus the contribution of edge e to the sum of the last five terms in (3.1) is at most

$$\begin{aligned}&\frac{2}{k}x\left(\frac{k}{2} - x - 1\right) + \frac{4}{k}\frac{x(x-1)}{2} + \left(2 + \frac{2}{k}\right)\left(\frac{k}{2} - x - 1\right) + \left(1 + \frac{4}{k}\right)x + 1\\ &= k - \frac{2}{k} - \frac{2x}{k} \leq k - \frac{2}{k}.\end{aligned}$$

Hence the sum of the last five terms in (3.1) is at most $(k - \frac{2}{k})T$. Using this bound in (3.1), we get

$$\frac{k}{2}L \leq kC'_k + \left(k - \frac{2}{k}\right)T,$$

and hence

$$\begin{aligned}L &\leq 2C'_k + \left(2 - \frac{4}{k^2}\right)T\\ &\leq 2C'_k + \left(2 - \frac{4}{k^2}\right)\alpha C'_k.\end{aligned}$$

Since $\alpha = 1.5$, we obtain a $5 - \frac{6}{k^2}$-approximation algorithm. As before, we can also view this as a constructive proof bounding the ratio of C_k to C'_k. In that case $\alpha = 1$ and we obtain an upper bound of $4 - \frac{4}{k^2}$ on the ratio.

3.1. Odd values of k. When $k > 1$ is odd, we can use our algorithm using $k - 1$ as the capacity of the vehicle. Theorem 2.5 and Lemmas 2.6 and 2.7 are true for all values of k, independent of its parity. In Lemmas 2.9 and 2.10, k should be replaced by $k - 1$. If the proof is repeated with these modifications, the performance ratio increases by an additive term of $\frac{2}{k-1}$. The performance ratio in this case is at most $5 - \frac{6}{(k-1)^2} + \frac{2}{k-1} \leq 5.1667$.

4. A preemptive algorithm. In this section we describe a simple strategy that also achieves an approximation factor of 5 for the preemptive k-delivery TSP. Our algorithm outputs a preemptive solution (i.e., may drop pegs at intermediate locations during the course of the algorithm), and the length traveled by the vehicle is compared to the length of an optimal preemptive solution.

This algorithm is a modification of the strategy given by Chalasani, Motwani, and Rao [10].

4.1. The CMR Algorithm. We first review the algorithm given by Chalasani, Motwani, and Rao [10] for this problem. We then show that a modification of the algorithm improves the approximation ratio to 6.5 without preemption and 5 with preemption. We will assume for simplicity that n is a multiple of k and that k is even. The former assumption can be made to hold by adding at most $k - 1$ dummy peg/slot pairs.

1. Find tours (of almost minimum weight) T_p and T_s of the pegs and slots points, respectively. (This step could be implemented using Christofides's heuristic for the TSP.)
2. Break T_p and T_s into paths containing k vertices each, by deleting every kth edge from each cycle.
3. View each k-path as a "supernode" and construct an auxiliary complete bipartite graph which has one vertex for each of the supernodes in T_p and T_s. The weight of an edge in this bipartite graph is the shortest distance between a pair of points belonging to the respective supernodes.
4. Find a minimum-weight perfect matching M in this bipartite graph.
5. Traverse the tour T_p and at the end of each segment use the matching M to transport the k pegs to the corresponding delivery point (supernode) in T_s.

The total length of such a tour is shown to be at most $3T_p + 2T_s + 2M \leq 4.5C_k + 3C_k + \frac{2}{k}A$. As shown in [10], $A \leq kC_k$. Using Christofides's approximation for the TSP, T_p and T_s are at most $1.5C_k$. The approximation ratio obtained is therefore at most 9.5. For geometrical instances, such as points in the plane, the algorithms of Arora [4, 5] and Mitchell [20] can be used to obtain an $(1 + \epsilon)$ approximation of the TSP, and this leads to better approximation factors for these instances.

Theorem 2.5 shows that $A \leq \frac{k}{2}C'_k$. Since $C'_k \leq C_k$, we also have $A \leq \frac{k}{2}C_k$. Using this improved upper bound on the weight of A, the approximation ratio of the algorithm improves from 9.5 to 8.5. A small change to the algorithm improves it further to an approximation factor of 7 as follows. We can traverse T_p in two ways. A clockwise traversal and a counterclockwise traversal give us two tours whose total length is at most $4T_p + 4T_s + 4M \leq 12C_k + 4(\frac{C_k}{2})$. The smaller of these two tours has length at most the average of these two tour lengths, which is $7C_k$.

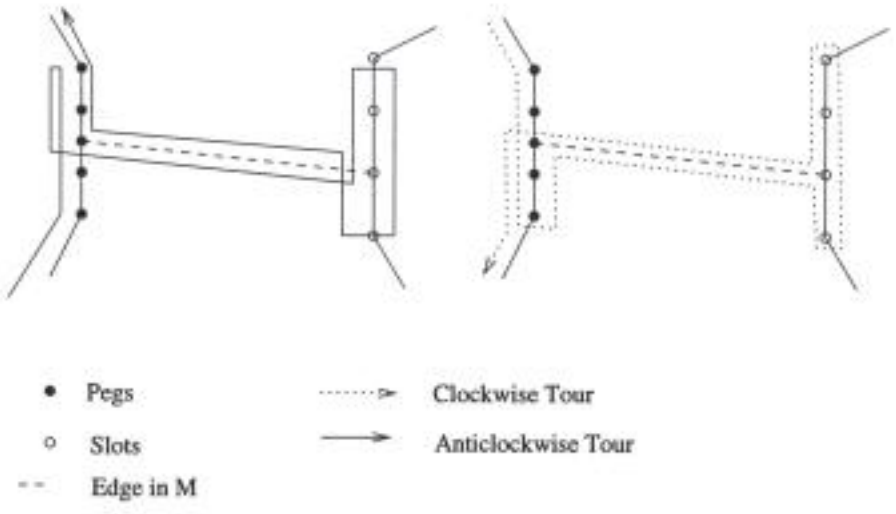

FIG. 4.1. *Two tours in T_p.*

Figure 4.1 illustrates why each segment of the tour T_p is charged at most four times by the two tours. Observe that each segment of T_p is traversed once in one of the tours and thrice in the other tour.

4.2. An improved nonpreemptive algorithm. We now present an improved algorithm that obtains an approximation ratio of 6.5.

1. Find tours T_p and T_s as before.
2. Break T_p and T_s into paths containing $k/2$ vertices each.
3. View each segment of T_p and T_s as a supernode and construct the auxiliary bipartite graph as before.
4. Find a minimum-weight perfect matching M in this auxiliary graph. Mark the segments of T_p sequentially as $B_1, B_2, \ldots$ around the cycle. Each edge in M matches a segment in T_p to a segment in T_s. Let the segment matched to $B_i, i = 1, 2, \ldots$, be called R_i, and let M_i be the edge of M connecting B_i and M_i.
5. The delivery schedule is as follows. Assume that the vehicle starts at the beginning of segment B_1 with $k/2$ pegs, and proceeds along T_p, picking the pegs in its path. For $i = 1, 2, \ldots$, when it reaches the vertex in B_i incident to the matched edge (M_i) in M, it travels across this edge and delivers to R_i the pegs that were collected from B_{i-1}. (When $i = 1$ we deliver the pegs we started with.) After delivering the pegs, it retraces back on M_i and continues along T_p.
6. Finally, when the vehicle returns to the starting location, it is carrying $k/2$ pegs. Lemma 2.3 guarantees that there exists a valid starting point on this traversal such that the vehicle never runs out of pegs or exceeds its carrying capacity.

The algorithm above generates a valid vehicle routing without violating the capacity constraints of the vehicle for the following reason. When it is on a segment

of B_i that precedes M_i on T_p, it is carrying $k/2$ pegs from B_{i-1} and the other pegs that have been collected from B_i. Since B_i has at most $k/2$ pegs, the total number of pegs that it is carrying does not exceed k. On reaching M_i, the vehicle goes to R_i and delivers the $k/2$ pegs that were collected from B_{i-1}. Therefore, when it returns to B_i and resumes its journey, it reaches the end of B_i with $k/2$ pegs that were on B_i.

The reason that the algorithm gives a better approximation ratio is as follows. Observe that the algorithm goes around T_p only once (except for segment B_1) instead of twice. This decreases the length traveled. However, the cost of M is now more since there are twice as many segments as before in each of T_s and T_p (because the segments have only $k/2$ vertices each).

Extending the analysis from the previous algorithm, we get $M \leq C'_k$. The vehicle traverses T_p once, T_s twice, and M twice. We get the following result: The distance traveled by the vehicle in the scheme devised by the above algorithm is at most $T_p + 2T_s + 2M+ \leq 6.5C_k$. Therefore, the approximation ratio is at most 6.5.

4.3. An improved preemptive algorithm. In this section, we consider the vehicle routing problem when the vehicle is allowed to drop some pegs at intermediate points in the route and pick them up later for delivery. We show that the previous algorithm can be modified into a preemptive algorithm with an approximation ratio of a little over 5.

In the previous algorithm, instead of delivering the pegs directly to the slots in R_i, when we cross M_i, we do the following: The vehicle crosses M_i and leaves $k/2$ pegs there to be delivered to the slots later. Once the tour along the peg cycle is completed, the vehicle switches to the slot tour, and delivers the pegs, but this time picking them up at intermediate points on the T_s as it reaches them. In all, the vehicle travels around each of the cycles T_p and T_s once each, twice around M, and once extra on the segments B_1 and R_1. By selecting B_1 and R_1 appropriately, over all possible segments, our algorithm obtains a tour with a ratio of $5 + k/n \approx 5$.

Acknowledgments. We are grateful to Greg Frederickson for useful discussions. We thank Shoshana Anily and Julien Bramel for making their paper available to us. We also thank Rafi Hassin for useful comments on an earlier draft of this paper.

OPTIMAL SAMPLING STRATEGIES IN QUICKSORT AND QUICKSELECT*

CONRADO MARTÍNEZ† AND SALVADOR ROURA†

Abstract. It is well known that the performance of quicksort can be improved by selecting the median of a sample of elements as the pivot of each partitioning stage. For large samples the partitions are better, but the amount of additional comparisons and exchanges to find the median of the sample also increases. We show in this paper that the optimal sample size to minimize the average total cost of quicksort, as a function of the size n of the current subarray size, is $a \cdot \sqrt{n} + o(\sqrt{n})$. We give a closed expression for a, which depends on the selection algorithm and the costs of elementary comparisons and exchanges. Moreover, we show that selecting the medians of the samples as pivots is not the best strategy when exchanges are much more expensive than comparisons. We also apply the same ideas and techniques to the analysis of quickselect and get similar results.

Key words. quicksort, quickselect, sorting, selection, sampling, median-of-$(2k+1)$, analysis of algorithms, divide-and-conquer

1. Introduction.

Quicksort [8] and quickselect [7] are among the most thoroughly studied algorithms. Quicksort sorts an array A of n elements by rearranging A around one of its elements—the *pivot*—so that the elements smaller than the pivot are to its left and larger elements are to its right. After the array has been partitioned, quicksort is recursively applied to the subarrays on either side of the pivot. Quickselect[1] selects the mth element (equivalently, the element of *rank* m in ascending order, the mth order statistic) out of n using the same divide-and-conquer principle. Once the array is partitioned and the pivot brought into its correct position, say j, either the sought element is the pivot ($m = j$) or the algorithm recursively continues in the appropriate subarray: the left subarray if $m < j$, the right subarray if $m > j$. Excellent sources for background information, implementation, variants, and their analysis include [3, 12, 13, 22, 23, 24].

In *median-of-three quicksort* [25] the pivot of each recursive stage is the median of a sample of three elements. This variant is easily generalized to select the $(k+1)$th element of a sample of size $s = 2k+1$ as the pivot. Van Emden [26] showed that the average number of comparisons to sort an array of size n is $q(k) \cdot n \ln n + \mathcal{O}(n)$, where $q(k)$ steadily decreases from $q(0) = 2$ to $q(\infty) = 1/\ln 2$. The median-of-three strategy also improves the performance of quickselect [10].

The basic problem with large samples is that the savings achieved because of more balanced partitions can be swamped in practice by the time spent in finding the median of the samples. This cost shows up in the lower order terms of the

[1] Also known as Hoare's FIND algorithm.

average performance of quicksort and quickselect and cannot be disregarded unless n is impractically large.

McGeoch and Tygar [17] analyzed the expected number of comparisons of quicksort for various sampling strategies. They considered fixed-size sampling and hybrid strategies, which first use a sample whose size is a function of the size of the array to be sorted, and fixed-size samples in subsequent recursive calls. They proved that these strategies are worse than using samples of size $\Theta(\sqrt{n}\,)$, where n denotes the size of the (sub-)array to be sorted in each recursive invocation.

We show in this paper that the optimal sample size as a function of the size n of the current subarray is $a \cdot \sqrt{n} + o(\sqrt{n}\,)$ and determine the value of the constant a in terms of the cost of the median-finding algorithm, taking into account the cost of comparisons and exchanges. Furthermore, we consider the more general setting where we pick the $(p+1)$th element in the sample with $0 \le p < \lfloor s/2 \rfloor$. (The case for $\lfloor s/2 \rfloor \le p < s$ reduces to the former by symmetry.)

This paper is organized as follows. In section 2 we set up the basic recurrences for quicksort and quickselect. In section 3 we analyze the variants with fixed-size sampling. We rederive known results such as those of van Emden [26] and those of quickselect with median-of-three [10]. As far as we know, our results regarding the total cost of quicksort and of quickselect with fixed $s > 3$ are original.

In section 4 we study the surprising behavior of quicksort when the cost of an exchange exceeds by far that of a comparison: on the one hand, the optimal value of p is not $p = \lfloor (s-1)/2 \rfloor$ but a function of the ratio between the cost of an exchange and the cost of a comparison; on the other hand, if we always select the medians of the samples as pivots, then fixed-size sampling is better than using samples whose sizes grow with n.

In sections 5 and 6 we tackle the study of the variants with sample sizes depending on n. We analyze quickselect first, since its analysis is easier. We prove in section 5 that if the size of the sample grows with n and is $o(n)$, then the average number of comparisons and exchanges to select an item of random rank are $2n + o(n)$ and $n/2 + o(n)$, respectively. By analyzing the lower order terms, we prove that the optimal sample size is $\Theta(\sqrt{n}\,)$ and give an explicit formula for the constant factor of the main term, which depends on the cost of the algorithm to select pivots and on the cost of elementary comparisons and exchanges.

We consider quicksort in section 6. We prove that when $s = \omega(1)$ and $s = o(n)$ the average number of comparisons is $n \log_2 n + o(n \log n)$ and the average number of exchanges is $\frac{1}{4} n \log_2 n + o(n \log n)$. Using similar techniques to those in section 5 we prove that the optimal sample size for quicksort is $\Theta(\sqrt{n}\,)$ as well and also find the constant factor of the main term. Moreover, we prove that the best pivots are the medians of the samples only when exchanges are not too expensive.

In section 7 we show that using fixed-size samples reduces the constant factor in the main term $\Theta(n^2)$ of the variance of quickselect. Another result with practical implications is that the variance of quickselect is $\mathcal{O}(\max\{n \cdot s, n^2/s\})$ when $s = \omega(1)$. For quicksort, we conjecture that similar results hold. We also discuss tuned implementations of partitioning for quicksort and quickselect, which avoid making redundant comparisons and exchanges.

A preliminary version of this work appears in [15] (see also [16, 20]). Some of the material there is also presented here, in order to make this paper more self-contained.

2. Preliminaries. A basic assumption of this paper is that s, the size of the samples, is a function of the size n of the (sub-)array to be sorted. We will not write

down the dependence of s on n most of the time, though. We also assume $s(n) = o(n)$ and, of course, $s(n) \geq 1$. Finally, we assume that the given array contains a random permutation of distinct elements.

We will denote p (respectively, q) the number of elements in the sample smaller than (respectively, larger than) the pivot. Therefore the pivot is the $(p+1)$th element $(0 \leq p < s)$ in the sample, and $q = s - 1 - p$. For the particular case where the pivot is the median of a sample of odd size, we write $s = 2k + 1$, where $k + 1$ is the rank of the pivot, with $p = q = k$.

Most analyses of quicksort and quickselect consider only the number of comparisons. In this paper, we investigate the average *total cost*, that is, the sum of the cost of comparisons and exchanges. We take the cost of a single comparison as the unit and denote ξ the cost of an exchange relative to that of a comparison.

Both quicksort and quickselect operate by selecting a pivot and then partitioning the current subarray w.r.t. the pivot. This requires $n + 1$ comparisons irrespective of s and p.[2] Let $\mathsf{X}(n, s, p)$ denote the average number of exchanges during a single partition stage. We consider here a very common partitioning algorithm, which scans the subarray from left to right until an element larger than the pivot is found, then from right to left until an element smaller than the pivot is found, then exchanges the two designated elements, and then iterates the process again. The partitioning ends when the two scanning pointers meet [22, 23, 24].[3] The following lemma provides the value of $\mathsf{X}(n, s, p)$ for any n, s, and p such that $0 \leq p < s \leq n$. Its proof is given in Appendix B.

LEMMA 1. *The average number of exchanges to partition a random array of size n when the pivot is the $(p+1)$th element of a sample of s elements is*

$$\mathsf{X}(n, s, p) = \frac{(p+1)(q+1)}{(s+1)(s+2)} \frac{(n+1)(n+2)}{n-1} - \frac{n}{n-1}.$$

Let $\mathsf{S}(s, p)$ denote the average total cost of the algorithm to select the $(p+1)$th out of s elements. (This algorithm may or may not be quickselect or one of its variants.) Efficient selection algorithms work in linear time on the average, so we can safely assume $\mathsf{S}(s, p) = \beta \cdot s + o(s)$ for some constant β that depends on the selection algorithm, the costs of comparisons and exchanges, and typically on the ratio $\psi = p/s$. For instance, if we count only comparisons ($\xi = 0$), then $\beta = \frac{3}{2} - \left|\frac{1}{2} - \psi\right|$ for Floyd–Rivest's SELECT [4], $\beta = 2 - 2(\psi \ln \psi + (1-\psi)\ln(1-\psi))$ for Hoare's quickselect [11], and $\beta = 2 + 3\psi(1-\psi)$ for quickselect with median-of-three [10]. An important assumption that we make is that the selection process preserves the randomness of the input array, copying the sample to a separate area if necessary. Otherwise, the recurrences below would not be accurate (see section 7.2).

Let $\pi_{n,j}^{(s,p)}$ be the probability that the $(p+1)$th element of a sample of s elements is the $(j+1)$th element of a random permutation of size n. It is clear that

$$\pi_{n,j}^{(s,p)} = \frac{\binom{j}{p}\binom{n-1-j}{q}}{\binom{n}{s}}, \qquad 0 \leq p < s \leq n, \quad 0 \leq j < n. \tag{2.1}$$

[2] If partitioning uses sentinels, then the number of comparisons can be reduced to $n - 1$, but the main conclusions of this work do not significantly change.

[3] For other randomness-preserving partitioning schemes (e.g., Lomuto's partition, as cited by Bentley [2]) the main conclusions of this paper apply with minor quantitative differences.

The denominator is the number of ways to pick a sample of size s out of n elements; the numerator is the number of ways to choose p elements smaller than the pivot times the number of ways to choose q elements larger than the pivot.

Now we are ready to set the recurrences for Q_n, the average total cost of quicksort, and, for F_n, the average total cost of quickselect averaged w.r.t. the n possible values of the rank of the sought element. F_n has been investigated in [14, 18, 19] as a particular case of *multiple quickselect* with $p = 1$ in the two last references. (There, p is the number of sought elements, not the number of elements smaller than the pivot within the sample.) The term *grand average* has been used to describe F_n and its generalizations for multiple quickselect (see, for instance, [13, 19]). Let $\mathsf{F}_n^{(m)}$ denote the cost of selecting the mth element out of n with quickselect and let F_n denote the cost of selecting an element of random rank. Then

$$F_n = \mathbb{E}[\mathsf{F}_n] = \frac{1}{n} \sum_{1 \le m \le n} \mathbb{E}\left[\mathsf{F}_n^{(m)}\right],$$

but the analogous equation does not hold for the random variables.

For quicksort using samples of size s, the nonrecursive cost of selecting the pivot (the pth element of the sample) and partitioning is

$$\mathsf{S}(s,p) + n + 1 + \mathsf{X}(n,s,p) \cdot \xi,$$

and hence

$$\begin{aligned} Q_n &= \mathsf{S}(s,p) + n + 1 + \mathsf{X}(n,s,p) \cdot \xi \\ &\quad + \sum_{0 \le j < n} \Pr\{\text{the pivot is the } (j+1)\text{th}\} \cdot (Q_j + Q_{n-1-j}) \\ &= \mathsf{S}(s,p) + n + 1 + \mathsf{X}(n,s,p) \cdot \xi + \sum_{0 \le j < n} \left(\pi_{n,j}^{(s,p)} + \pi_{n,n-1-j}^{(s,p)}\right) \cdot Q_j, \end{aligned} \tag{2.2}$$

where we have used obvious symmetries in the last step.

The recurrence for F_n is a bit more involved. The nonrecursive cost is the same as in quicksort. However, the probability that a recursive call with an instance of size j is made is now $\pi_{n,j}^{(s,p)} \cdot \frac{j}{n}$, as we are looking for an element of random rank. Hence, applying the same symmetries as in the recurrence for quicksort,

$$F_n = \mathsf{S}(s,p) + n + 1 + \mathsf{X}(n,s,p) \cdot \xi + \sum_{0 \le j < n} \frac{j}{n} \left(\pi_{n,j}^{(s,p)} + \pi_{n,n-1-j}^{(s,p)}\right) \cdot F_j. \tag{2.3}$$

3. Fixed-size samples. We consider here the solution of (2.2) and (2.3) when $s = \Theta(1)$. This analysis is almost straightforward using the continuous master theorem (CMT) [20, 21]. We briefly review this theorem (Theorem 18) and the necessary definitions in Appendix A for the reader's convenience.

First of all, the *toll function* (the nonrecursive cost) t_n in the recurrences for Q_n and F_n is

$$t_n = \left(1 + \frac{(p+1)(q+1)}{(s+1)(s+2)} \cdot \xi\right) \cdot n + \mathcal{O}(1).$$

Notice that $\mathsf{S}(s,p)$ and several other terms are accounted for in the $\mathcal{O}(1)$-term above. Now we tackle the analysis of quicksort. The first step to apply the CMT

requires that we compute the *shape function* $w^{(s,p)}(z)$ of the recurrence, which essentially is a continuous approximation of the discrete weights. In our instance we have

$$w^{(s,p)}(z) = \lim_{n\to\infty} n \cdot \left(\pi^{(s,p)}_{n,z\cdot n} + \pi^{(s,p)}_{n,n-1-z\cdot n}\right) = \frac{s!}{p!\,q!}\left(z^p(1-z)^q + z^q(1-z)^p\right).$$

Since t_n is linear, the limiting const-entropy is evaluated as $\mathcal{H}(s,p) = 1 - \int_0^1 z^1\, w^{(s,p)}(z)\, dz = 0$ for all s and p. Hence, Case 2 of the CMT states that $Q_n = t_n \cdot \ln n / \operatorname{VE}(s,p)$, where $\operatorname{VE}(s,p)$ denotes the limiting log-entropy. We use $\operatorname{VE}(s,p)$ for this value after van Emden, who first used this function for the particular case where $p = q = k$ and $\xi = 0$ [26]. Proposition 19(b) in Appendix B is useful in the following computation:

$$\operatorname{VE}(s,p) \stackrel{\triangle}{=} -\int_0^1 z^1 \ln z \cdot w^{(s,p)}(z)\, dz = H_{s+1} - \frac{(p+1)H_{p+1} + (q+1)H_{q+1}}{s+1},$$

where $H_n = \sum_{1\le j\le n} 1/j = \ln n + \gamma + \mathcal{O}(1/n)$ denotes the nth *harmonic number*, and $\gamma = 0.577\ldots$ is Euler's constant. Therefore, $Q_n = q_\xi(s,p)\cdot n\ln n + o(n\log n)$, where

$$q_\xi(s,p) \stackrel{\triangle}{=} \left(1 + \frac{(p+1)(q+1)}{(s+1)(s+2)}\cdot\xi\right) / \operatorname{VE}(s,p). \tag{3.1}$$

It is possible to get more information about Q_n by subtracting the main order term from Q_n and setting up a recurrence for the remaining part, i.e., for $R_n = Q_n - q_\xi(s,p)\, nH_n$. Applying the CMT again we get $R_n = \mathcal{O}(n)$. As a conclusion we have the following theorem.

THEOREM 2. *The average total cost of quicksort with fixed-size samples is* $Q_n = q_\xi(s,p)\cdot n\ln n + \mathcal{O}(n)$.

The analysis of quickselect follows similar steps. Computing the shape function yields[4] $w^{(s,p)}(z) = s!/(p!\,q!)\left(z^{p+1}(1-z)^q + z^{q+1}(1-z)^p\right)$. The limiting const-entropy is now

$$\mathcal{H}(s,p) = 1 - \frac{(p+1)(p+2)+(q+1)(q+2)}{(s+1)(s+2)} = \frac{2(p+1)(q+1)}{(s+1)(s+2)},$$

which is strictly positive for every s and p. Therefore $F_n = f_\xi(s,p)\cdot n + o(n)$, where

$$f_\xi(s,p) \stackrel{\triangle}{=} \left(1 + \frac{(p+1)(q+1)}{(s+1)(s+2)}\cdot\xi\right) / \mathcal{H}(s,p) = \frac{(s+1)(s+2)}{2(p+1)(q+1)} + \frac{\xi}{2}.$$

As before, we can estimate the lower order terms of F_n by iteratively using the CMT. Applying it twice, we get a precise asymptotic estimate for the second order term and the order of magnitude of the third order term (see [16] or [20] for additional details).

THEOREM 3. *The average total cost of quickselect with fixed-size samples is*

$$F_n = f_\xi(s,p)\cdot n + \left(\mathsf{S}(s,p) - 2 - \xi - \frac{3(q+1) - p(q+5)}{(s+1)(s+2)}\cdot\xi\right)\cdot\frac{\ln n}{VE(s,p)} + \mathcal{O}(1).$$

[4] We use the same symbol to denote quickselect's shape function and quicksort's shape function, even though they are different.

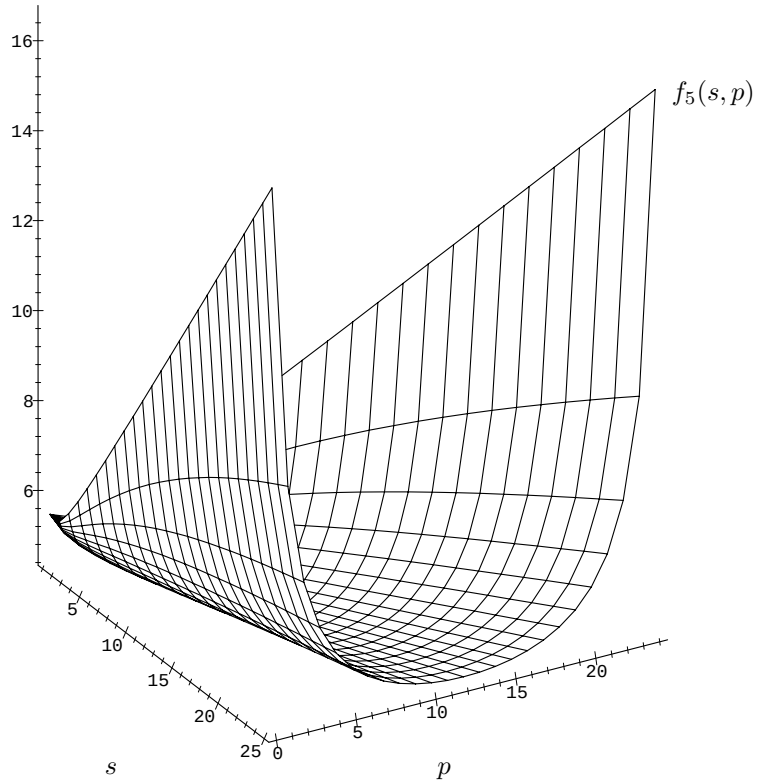

FIG. 1. *Values of* $f_5(s,p)$.

In section 4 we examine in depth the behavior of $q_\xi(s,p)$, the constant factor of the main term of Q_n. The behavior of $f_\xi(s,p)$ in the main term of F_n is much simpler. For any fixed s, the value of p that minimizes $f_\xi(s,p)$ is $p=(s-1)/2$ if s is odd, and $p=(s-2)/2$ (also $p=s/2$ by symmetry) if s is even, regardless of the value of ξ. Figure 1 depicts a typical situation with $\xi=5$. Moreover, for any $k\geq 0$ we have that $f_\xi(2k+1,k)=f_\xi(2k+2,k)=2+1/(k+1)+\xi/2$ is a decreasing function of k. Hence, our best choice for p is always the median of the sample and to let s be "as large as possible." In section 5 we precisely characterize the best way to do this.

4. Exchanges in quicksort with fixed-size sampling. In this section we study which values of s and p minimize the constant factor $q_\xi(s,p)$ of the $n\ln n$-term in the average cost of quicksort with fixed-size sampling. Given s and ξ, let $p^*(s,\xi)$ be the rank of the optimal pivot. For moderately large values of ξ (this includes the case $\xi=0$, where we take into account only comparisons) the optimal pivot is $p^*=\lfloor (s-1)/2\rfloor$, and $q_\xi(2k+1,k)$ is a strictly decreasing function of k. By contrast, for large values of ξ the best fixed-size strategy is indeed to have large samples, but the pivot should be an element of rank $p^*\neq\lfloor (s-1)/2\rfloor$.

For convenience we will work with the quotients $\psi=p/s$ rather than with the actual ranks p for the rest of this section. Figure 2 shows the function $q_{30}(s,p)$ with two valleys symmetrically disposed at both sides of the line $\psi=1/2$. For each s, we take the smallest p with minimum $q_{30}(s,p)$ to define ψ^*, which is clearly smaller than

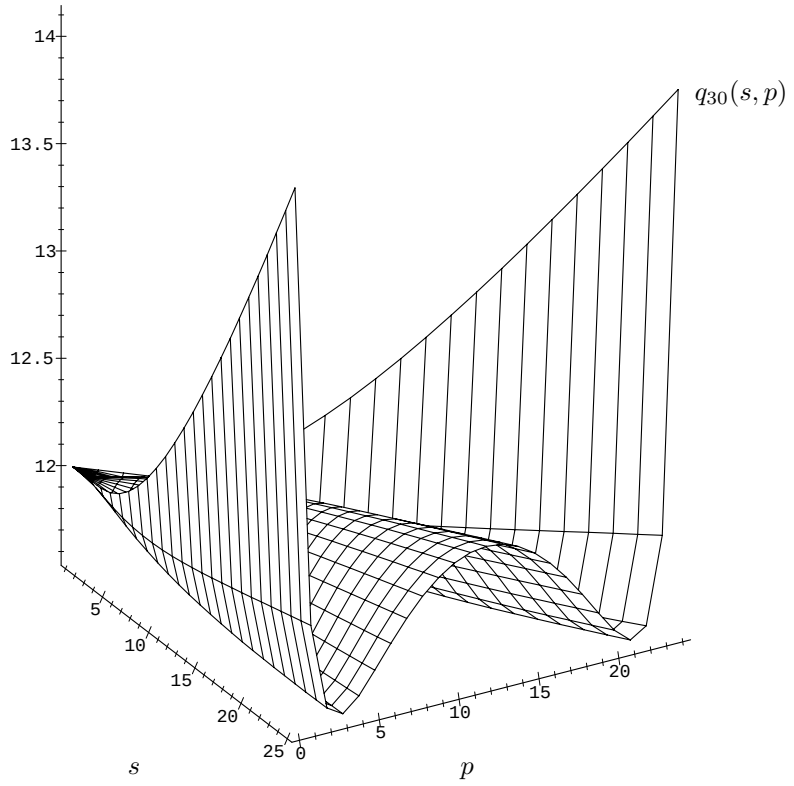

FIG. 2. *Values of* $q_{30}(s,p)$.

1/2.

In Figure 3 we plot the (scaled) values of the function

$$q_\xi(\psi) \stackrel{\triangle}{=} \lim_{s\to\infty} q_\xi(s, \psi\cdot s + o(s)) = -\frac{1+\psi(1-\psi)\xi}{\psi\ln\psi + (1-\psi)\ln(1-\psi)}$$

for $\xi = 0, 5, 15, 20$, and 30. Note that the denominator is, besides the limiting value $\lim_{s\to\infty} \mathrm{VE}(s, \psi\cdot s)$, the entropy for the probabilities ψ and $1-\psi$ (with the minus sign). It appears often enough to deserve a special name: for $0 < x < 1$, let

$$h(x) \stackrel{\triangle}{=} -x\ln x - (1-x)\ln(1-x). \tag{4.1}$$

The function is symmetric around $\psi = 1/2$ with only one minimum located at $\psi^* = 1/2$ when ξ is not larger than a threshold value τ; otherwise, we have a local maximum at $\psi = 1/2$ and two absolute minima at $\psi^* < 1/2$ and at $1-\psi^* > 1/2$. In this last case ψ^* is the unique solution in the interval $(0, 1/2)$ of the equation $\partial q_\xi(\psi)/\partial\psi = 0$, or, equivalently, of

$$\ln\psi + \xi\,\psi^2\ln\psi = \ln(1-\psi) + \xi(1-\psi)^2\ln(1-\psi). \tag{4.2}$$

The threshold value τ is given by the solution of the equation

$$\left.\frac{\partial^2 q_\xi(\psi)}{\partial\psi^2}\right|_{\psi=1/2} = 0,$$

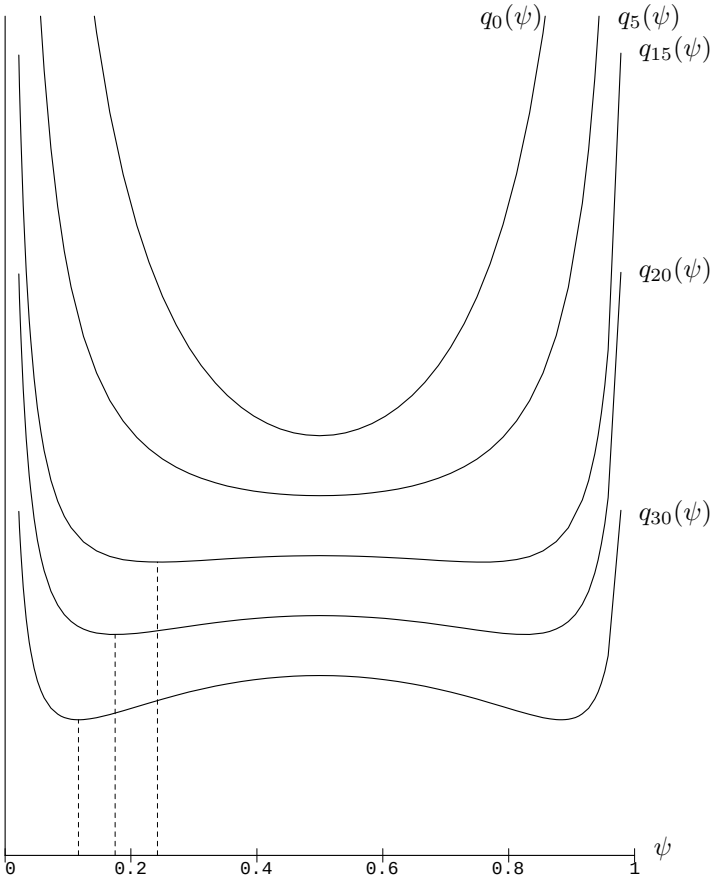

FIG. 3. *Values of* $q_\xi(\psi)$ *for* $\xi = 0, 5, 15, 20,$ *and* 30.

which is $\tau = 4/(2\ln 2 - 1) \approx 10.35480$. In Figure 4 we see that $\psi^*(\xi) = 1/2$ for $\xi \in [0, \tau]$, whereas $\psi^*(\xi)$ strictly decreases for $\xi > \tau$, tending to 0 as ξ grows.

For large s we know that p^* is roughly $\psi^* \cdot s$. However, now the question is whether taking large samples is the best choice (on the asymptotic regime) among fixed-size sampling strategies. The next theorem states just that.

THEOREM 4. *For any* s *and* p, $q_\xi(s,p) > q_\xi(\psi^*)$.

Proof. Let $u(z) = s!/p!\,q! \cdot z^p(1-z)^q$. From (3.1) and Proposition 19, we have

$$q_\xi(s,p) = \frac{\int_0^1 u(z)\,(1 + z(1-z)\xi)\,dz}{\int_0^1 u(z)h(z)\,dz}.$$

We will use the following fact: Let $f(z)$, $g(z)$ be positive functions over the interval $[0,1]$. Let z^* be the location of a minimum of $f(z)/g(z)$, and assume $0 < z^* < 1$ and $g(z) \neq 0$ for $0 < z < 1$. Then, as $f(z) \geq g(z)f(z^*)/g(z^*)$ and $u(z)$ is also positive in the interval $[0,1]$, it follows that

$$\frac{\int_0^1 u(z)f(z)\,dz}{\int_0^1 u(z)g(z)\,dz} \geq \frac{\int_0^1 u(z)\,[g(z)f(z^*)/g(z^*)]\,dz}{\int_0^1 u(z)g(z)\,dz} = \frac{f(z^*)}{g(z^*)}.$$

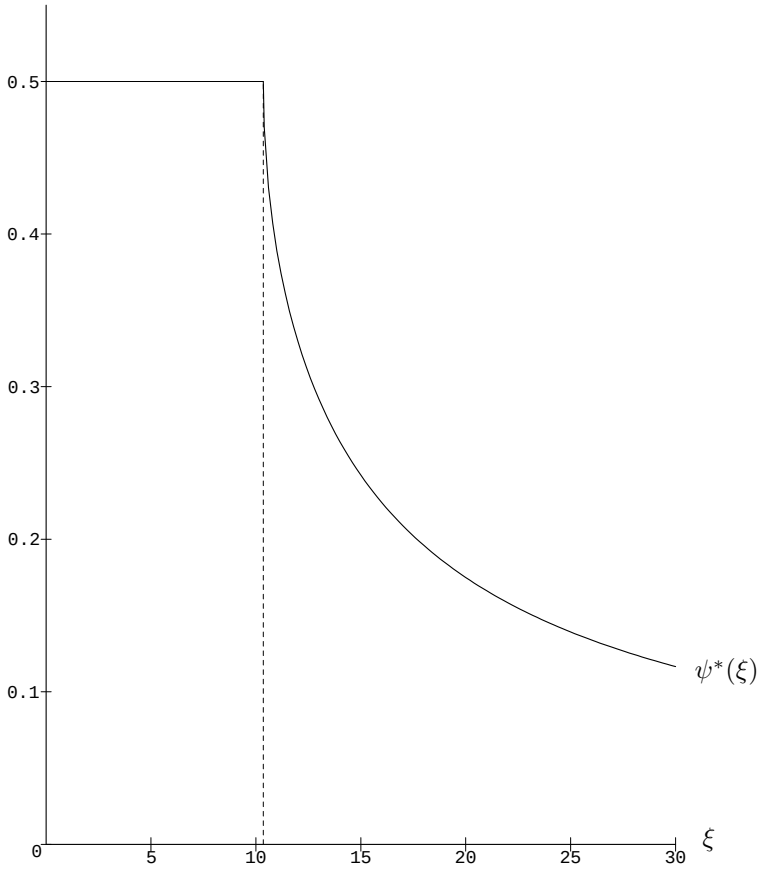

FIG. 4. *Values of* $\psi^*(\xi)$.

Now taking $f(z) = 1+z(1-z)\xi$, $g(z) = h(z) = -z\ln z-(1-z)\ln(1-z)$, and since ψ^* is the minimum of $q_\xi(\psi) = f(\psi)/g(\psi)$, we have $q_\xi(s,p) \geq q_\xi(\psi^*)$, and the statement of the theorem is almost proved. Finally, notice that for any ξ there is always an interval $[\psi_1, \psi_2]$ with $0 \leq \psi_1 < \psi_2 \leq 1$ such that $q_\xi(\psi) > q_\xi(\psi^*(\xi))$ and $u(z) > 0$ for every ψ in (ψ_1, ψ_2). Thus $q_\xi(s,p) > q_\xi(\psi^*)$. □

An intuitive explanation for the theorem above goes as follows. Assume that we had a black-box routine such that, given an array of size n and a value $0 < \psi < 1$, it returned the $\lfloor\psi \cdot n\rfloor$th element in the array *at no cost*. Using such a routine (with some fixed ψ) in the pivot-finding stage of quicksort provides a variant of quicksort with toll function $(1 + \psi(1-\psi)\xi)$, log-entropy $h(\psi)$, and average total cost $q_\xi(\psi)\, n\ln n + o(n\log n)$. Thus the optimal choice for ψ is ψ^*. Now, as we are deprived from such a routine, we try to get the best possible estimate of the $\lfloor\psi^* \cdot n\rfloor$th element in the array, which can be done by taking large samples and selecting the $\lfloor\psi^* \cdot s\rfloor$th element.

Several remarks are in order. On the one hand, the fact that ψ^* tends to 0 as ξ tends to ∞ can be informally described as a smooth transition from quicksort to selection sort. Selection sort is a good sorting method when exchanges are extremely expensive because it minimizes their number, and quicksort behaves exactly as selec-

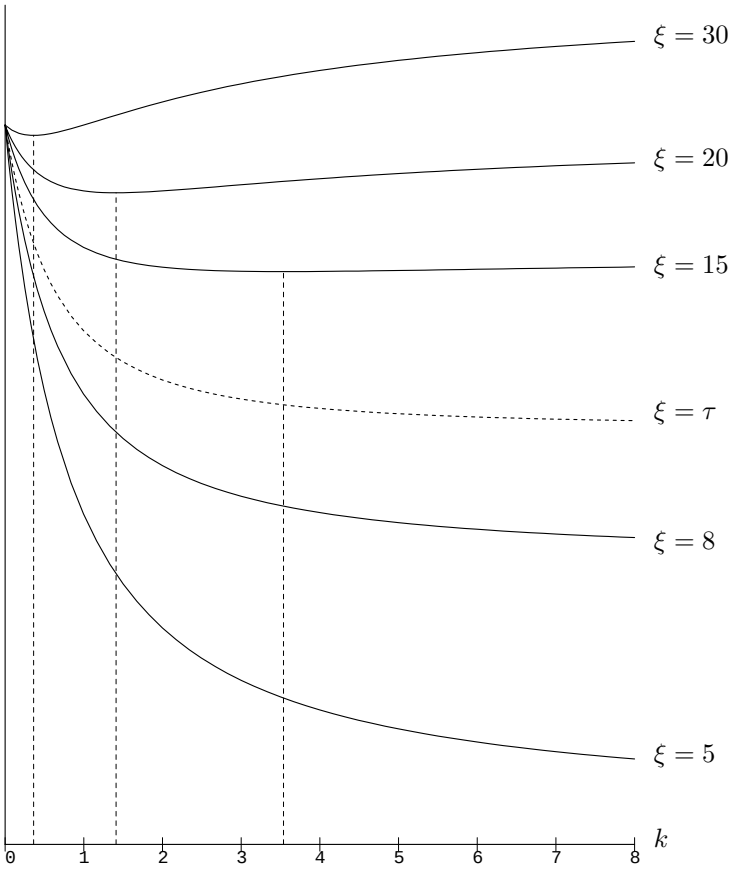

FIG. 5. *Values of* $q_\xi(k)$ *for* $\xi = 5,\ 8,\ \tau,\ 15, 20,$ *and* 30.

tion sort when the smallest element in the array is always selected as the pivot. On the other hand, we should be aware that the analysis of the case $\xi > \tau$ is mainly of theoretical interest, since we should sort an array of pointers to the actual records rather than sorting the records themselves if data movements were too expensive.

Now we restrict our attention to the variants of quicksort that always take the medians of samples of fixed size as the pivots (and therefore are not the best theoretical alternatives when $\xi > \tau$); that is, we take $s = 2k + 1$ and $p = q = k$ for some $k \geq 0$. This time we have

$$q_\xi(k) \stackrel{\triangle}{=} q_\xi(2k+1, k) = \frac{1 + (k+1)/(4k+6) \cdot \xi}{H_{2k+2} - H_{k+1}}.$$

The (scaled) shape of this function is shown in Figure 5 for several values of ξ. The plot actually depicts the extension of $q_\xi(k)$ to the real numbers using the continuous function $\Psi(z) = d \ln \Gamma(z)/dz$; recall that $\Psi(n+1) = H_n - \gamma$ for positive integers [1]. For $\xi = 5$, $\xi = 8$, and $\xi = \tau$ (dashed in the figure) the function $q_\xi(k)$ steadily decreases with k in accordance with what we know. This behavior changes as soon as $\xi > \tau$, as $q_\xi(k)$ has one minimum at finite distance $k^*(\xi)$. Observe in Figure 5 that the location of the minima (which is shown for $\xi = 15$, 20, and 30) tends to 0

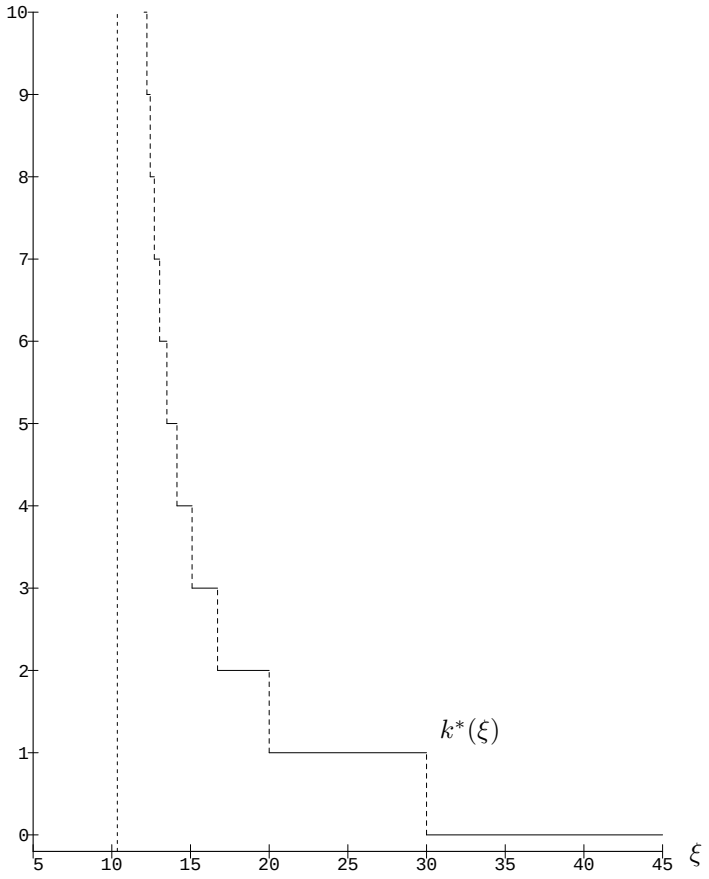

FIG. 6. *Values of* $k^*(\xi)$.

when ξ grows.

Figure 6 shows the function $k^*(\xi)$. There is a vertical asymptote as $\xi \to \tau^+$. For values of ξ larger than 30 we have $k^* = 0$ (plain quicksort). Note that k^* is not well defined for some values of ξ. For instance, 1 and 2 compete as optimal choices for k when $\xi = 20$.

The function

$$\xi^*(k) \triangleq \frac{4}{4(H_{2k} - H_k)\frac{k+1}{2k+3} - 1 + \frac{1}{2k+1}}$$

is the pseudoinverse of $k^*(\xi)$ in the sense that k is the optimal choice if ξ belongs to the open interval $(\xi^*(k+1), \xi^*(k))$. Therefore, $q_{\xi^*(k)}(k) = q_{\xi^*(k)}(k-1)$ for any $k > 0$. For instance, we have $k^* = 1$ when $20 < \xi < 30$ because $\xi^*(2) = 20$ and $\xi^*(1) = 30$. By convention we take $\xi^*(0) = \infty$.

As a conclusion, we could say that a good estimation of the median of the (sub-) array is always profitable as far as comparisons are concerned. However, regarding exchanges we have a trade-off between the short-term profit of selecting a pivot far away from the median (since only a few exchanges would be needed in that stage) and the long-term gains of selecting a pivot closer to the median (since an even

partition means fewer recursive stages and fewer exchanges to be done in the long run). Roughly speaking, this is why small samples—and consequently, poor estimations of the medians—are preferable when the important quantity to minimize is the number of exchanges, i.e., when ξ is large.

5. Optimal samples for quickselect. We already know from section 3 that selecting the medians of the samples is the best choice to minimize the average cost of quickselect. Therefore, we will assume $s = 2k+1$ and $p = q = k$ for the rest of this section, and we will simplify the notation for functions like $\mathsf{X}(n, 2k+1, k)$, writing $\mathsf{X}(n, k)$ instead. Here we will consider the case where $k = k(n)$ is a function of the current subarray size n.

In principle it pays to have samples as large as possible. However, if $s = \Theta(n)$ the average total cost is not optimal, since the cost of the selection of the pivot is of the same order of magnitude as the cost of the partition. Hence, we shift our attention towards samples whose size increases with n but are sublinear, that is, $s = \omega(1)$ and $s = o(n)$.

Under the hypotheses above, $s \to \infty$ when $n \to \infty$, so the coefficient of n in F_n should be the limit of $f_\xi(s, s/2)$ for $s \to \infty$. The following theorem rigorously establishes our intuition. The CMT itself cannot be applied here because the shape function for this case is not well defined; we require more basic results that we also review in Appendix A.

THEOREM 5. *Let $s = 2k+1$ and $p = q = k$, where $k = \omega(1)$ and $k = o(n)$. Then the average total cost of quickselect to find an element of random rank out of n is $F_n = (2 + \xi/2)\, n + o(n)$.*

Proof. Let $F_n(t)$ be the average total cost of quickselect when we use samples of fixed size $2t+1$, and let $\pi^{(t)}_{n,j} = \pi^{(2t+1,t)}_{n,j}$. The const-entropy associated to $F_n(t)$ (see Appendix A) is

$$\mathcal{H}_n(t) = 1 - \frac{2}{n^2} \sum_{0 \le j < n} j^2\, \pi^{(t)}_{n,j} + o(1),$$

which by Proposition 21 in Appendix B has limit $\mathcal{H}(t) = \lim_{n\to\infty} \mathcal{H}_n(t) = 1/2 - 1/(4t+6)$. Fix any $t' \ge t$. Since x^2 is a convex function, the probabilities $\pi^{(.)}_{n,j}$ are symmetric in j and $n-1-j$, and the weights for t' are more concentrated around $(n-1)/2$ than the weights for t, it follows that $\sum_{0\le j<n} j^2 \pi^{(t')}_{n,j} \le \sum_{0\le j<n} j^2 \pi^{(t)}_{n,j}$, and hence $\mathcal{H}_n(t') \ge \mathcal{H}_n(t)$ if n is large enough.

On the other hand, the const-entropy associated to F_n is

$$\mathcal{H}_n = 1 - \frac{2}{n^2} \sum_{0 \le j < n} j^2 \pi^{(k(n))}_{n,j} + o(1).$$

Since $k = \omega(1)$, for any fixed t we have $k(n) > t$ and $\mathcal{H}_n \ge \mathcal{H}_n(t)$ as long as n is large enough. Hence $\mathcal{H} = \lim_{n\to\infty} \mathcal{H}_n \ge \lim_{n\to\infty} \mathcal{H}_n(t) = \mathcal{H}(t)$. Moreover, $\mathcal{H} \ge 1/2 - 1/(4t+6)$ for any t, so $\mathcal{H} \ge 1/2$. Furthermore, the upper bound $\mathcal{H}_n \le 1/2$ can be easily derived using the probabilities

$$\pi_{n,j} = \begin{cases} 1 & \text{if } j = \lfloor (n-1)/2 \rfloor, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore, $\mathcal{H} = 1/2$. Since under the hypotheses the toll function is $t_n = (1 + \xi/4) \cdot n + o(n)$, we can conclude from (A.2) that $F_n = (1 + \xi/4)\, n/\,\mathcal{H} + o(n) = (2 + \xi/2)\, n + o(n)$. ∎

If we consider only comparisons ($\xi = 0$) Theorem 5 states that the average cost of quickselect is $2n+o(n)$, well above the $1.25n+o(n)$ comparisons needed on average to locate an element of random rank using Floyd and Rivest's SELECT algorithm [4] but well below the $3n + o(n)$ comparisons of standard quickselect. Using rather different techniques than ours, Grübel [6] has shown that $\mathsf{W}_n = \sup_{1\le m\le n}\{\mathsf{F}_n^{(m)}\}$ converges in probability to $2n$ if $k = \omega(1)$ and $k = o(\frac{n}{\log n})$.

Theorem 5 leaves open which is the optimal sample size. To find it we introduce the function

$$\mathcal{F}(n,k) = -\frac{1}{2} + \sum_{0\le j<n} \frac{j^2}{n^2}\left(\pi_{n,j}^{(k)} + \pi_{n,n-1-j}^{(k)}\right) = -\frac{1}{2} + \frac{2}{n^2}\sum_{0\le j<n} j^2\pi_{n,j}^{(k)},$$

which is only a slight variation of the const-entropy associated to F_n (see the proof of Theorem 5). As $k = \omega(1)$ and $k = o(n)$, we have $F_n = (2+\xi/2)\cdot n + G_n$ for some function $G_n = o(n)$. Substituting in the recurrence for F_n we get

$$F_n = n+1+\mathsf{S}(k)+\mathsf{X}(n,k)\cdot\xi+2\sum_{0\le j<n}\frac{j}{n}\pi_{n,j}^{(k)}G_j+(1+\xi/4)\cdot n+(2+\xi/2)\cdot\mathcal{F}(n,k)\cdot n.$$

The asymptotic behavior of $\mathsf{X}(n,k)$ and $\mathcal{F}(n,k)$ when k grows with n is stated in the following lemmas.

LEMMA 6. *If $k = \omega(1)$ and $k = o(n)$, then*

$$\mathsf{X}(n,k) = \frac{n}{4} - \frac{n}{8k} + \Theta\left(\frac{n}{k^2}\right).$$

Proof. Setting $s = 2k+1$ and $p = k$ in Lemma 1 yields

$$\mathsf{X}(n,k) = \frac{(k+1)n^2 - (k+3)n + (2k+2)}{2(2k+3)(n-1)}.$$

Now it is a simple matter to rewrite the equality above to get the statement of the lemma. □

LEMMA 7. *If $k = \omega(1)$ and $k = o(n)$, then*

$$\mathcal{F}(n,k) = \frac{1}{4k} + \Theta(\max\{1/k^2, 1/n\}).$$

Proof. Setting $s = 2k+1$ and $p = k$ in Proposition 21 of Appendix B we get

$$\mathcal{F}(n,k) = \frac{1}{4k} - \frac{3}{4k(2k+3)} - \frac{3}{2n} + \frac{3}{2(2k+3)n} + \frac{1}{(2k+3)n^2}.$$ □

Since $G_n = o(F_n)$, it is rather intuitive that the contribution of the sum of G_j's to the asymptotic location of k^* is irrelevant. The argument can be formalized as follows. Fix any $\delta > 0$. By hypothesis, there exists some N such that $|G_j| \le \delta\cdot j$ for every $j \ge N$. On the other hand, we are assuming $k = \omega(1)$, so for large n we have $k \ge N$ and $\pi_{n,j}^{(k)} = 0$ for every $j < N$. Therefore,

$$2\sum_{0\le j<n}\frac{j}{n}\cdot\pi_{n,j}^{(k)}\cdot|G_j| \le 2\delta\cdot\sum_{0\le j<n}\frac{j^2}{n}\cdot\pi_{n,j}^{(k)} = \left(\delta\cdot\mathcal{F}(n,k)+\frac{\delta}{2}\right)\cdot n$$

when n is large enough. Thus

$$F_n = n + 1 + \mathsf{S}(k) + \mathsf{X}(n,k) \cdot \xi + E_1(n) \cdot n + E_2(n) \cdot \mathcal{F}(n,k) \cdot n, \tag{5.1}$$

where we have the bounds $(1+\xi/4)-\delta/2 \leq E_1(n) \leq (1+\xi/4)+\delta/2$ and $(2+\xi/2)-\delta \leq E_2(n) \leq (2+\xi/2)+\delta$. Notice that the bounds for $E_1(n)$ and $E_2(n)$ do not depend on k. Moreover, $\mathsf{S}(k) \sim 2\beta\, k$ for some constant β, where β depends on the chosen selection algorithm. Then it is easy to see that, for large n, k^* belongs to the interval $[k_1, k_2]$, where k_1 minimizes the function of k

$$2(1+\delta)\,\beta\, k - \frac{(1+\delta)\cdot\xi}{8k} \cdot n + \left[\left(2+\frac{\xi}{2}\right) - \delta\right] \frac{(1-\delta)}{4k} \cdot n,$$

that we obtain by plugging the asymptotic estimates of $\mathsf{S}(k)$, $\mathsf{X}(n,k)$, and $\mathcal{F}(n,k)$ and the lower bounds on $E_1(n)$ and $E_2(n)$ in (5.1), disregarding those terms not depending on k. Similarly, k_2 minimizes the function of k

$$2(1-\delta)\,\beta\, k - \frac{(1-\delta)\cdot\xi}{8k} \cdot n + \left[\left(2+\frac{\xi}{2}\right) + \delta\right] \frac{(1+\delta)}{4k} \cdot n.$$

This yields

$$k_1 = \sqrt{\frac{((4+\xi)-2\delta)(1-\delta)-(1+\delta)\cdot\xi}{16(1+\delta)\beta}} \cdot \sqrt{n},$$

$$k_2 = \sqrt{\frac{((4+\xi)+2\delta)(1+\delta)-(1-\delta)\cdot\xi}{16(1-\delta)\beta}} \cdot \sqrt{n}.$$

The reasoning above holds for every $\delta > 0$, no matter how small we choose it. Therefore, we can conclude the following theorem.

THEOREM 8. *Let $s^* = 2k^* + 1$ be the optimal sample size w.r.t. the average total cost of quickselect to select a random element when the median of the sample is used as the pivot. Then $k^* = \sqrt{n/4\beta} + o(\sqrt{n}\,)$.*

The procedure that we have just outlined here will be used again in section 6. Observe that it has been enough to consider the main terms of $\mathsf{S}(k)$, $\mathsf{X}(n,k)$, and $\mathcal{F}(n,k)$ to find the main term of k^*. In section 6 we will avoid dealing with the tedious details by disregarding terms of small order and by obtaining minima as if these terms did not exist. We have already shown here that it can be done safely and yields asymptotically valid conclusions.

Finally, notice that $\Theta(\sqrt{n}\,)$-sampling improves the worst-case complexity of quickselect from $\Theta(n^2)$ to $\Theta(n^{3/2})$; the same happens with quicksort [17]. This is valid no matter what the rank of the sought element is and even if the selection of pivots is made using an algorithm with quadratic worst case.

6. Optimal samples for quicksort. As shown in section 4, picking the median of the sample as the pivot is not always the best choice. Therefore, we set $p = \psi \cdot s + o(s)$ for some fixed $0 < \psi \leq 1/2$. We do not necessarily assume $\psi = \psi^*(\xi)$.

The following theorem provides the main term of the total cost of quicksort when we make the size of the sample grow with the size of the input. The proof (which we do not give here) uses an argument quite similar to that of Theorem 5, finding matching lower and upper bounds for the limiting log-entropy of Q_n. (For further details see [16, 20].)

THEOREM 9. *Let $p = \psi \cdot s + o(s)$, where $0 < \psi < 1$ and $s = \omega(1)$ and $s = o(n)$. Then the average total cost of quicksort is $Q_n = q_\xi(\psi) \cdot n \ln n + o(n \log n)$.*

If we measure only the number of comparisons ($\xi = 0$), the theorem above states that *any* sample size $s = \omega(1)$ and $s = o(n)$ with $\psi = 1/2$ is asymptotically optimal w.r.t. the main term of quicksort, as the expected number of comparisons for all of them is $Q_n \sim n \log_2 n$.

To investigate the optimal sample size we will assume $p = \lceil \psi \cdot (s+1) \rceil - 1$, but any other discretization satisfying $\lim_{s\to\infty}(p/s) = \psi$ would yield similar results.

Let us introduce

$$\mathcal{Q}(n, s, \psi) = -\left(H_n - h(\psi)\right) \frac{n-1}{n} + \sum_{0 \le j < n} \left(\pi_{n,j}^{(s,p)} + \pi_{n,n-1-j}^{(s,p)}\right) \frac{jH_j}{n},$$

where $h(x) = -x \ln x - (1-x)\ln(1-x)$ (see (4.1)). The function $\mathcal{Q}(n, s, \psi)$ plays a role analogous to that of $\mathcal{F}(n, k)$ in the analysis of quickselect. By Theorem 9 we can decompose Q_n as $Q_n = q_\xi(\psi)\, nH_n + R_n$, where $R_n = o(n \log n)$. The recurrence for quicksort (2.2) can be then rewritten as

$$\begin{aligned} Q_n = {} & \mathsf{S}(s, \psi) + n + 1 + \mathsf{X}(n, s, \psi) \cdot \xi + \sum_{0 \le j < n} \left(\pi_{n,j}^{(s,p)} + \pi_{n,n-1-j}^{(s,p)}\right) \cdot R_j \\ & + \Big(H_n - h(\psi)\Big) \cdot q_\xi(\psi) \cdot (n-1) + \mathcal{Q}(n, s, \psi) \cdot q_\xi(\psi) \cdot n. \end{aligned}$$

Let $\chi_\psi(s)$ be the oscillating factor induced by taking ceilings: $\chi_\psi(s) = \lceil \psi \cdot (s+1) \rceil - \psi \cdot (s+1)$. We have the following lemma for the asymptotic behavior of $\mathcal{Q}(n, s, \psi)$.

LEMMA 10. *If $s = \omega(1)$, $s = o(n)$, and $p = \lceil \psi \cdot (s+1) \rceil - 1$ for some ψ such that $0 < \psi \le 1/2$, then $\mathcal{Q}(n, s, \psi) = 1/2s - (\ln(1-\psi) - \ln\psi) \cdot \chi_\psi(s)/s + \mathcal{O}\left(\max\left\{1/n, 1/s^2\right\}\right)$.*

Proof. Using Proposition 20(b) in Appendix B yields

$$\begin{aligned} \sum_{0 \le j < n} \left(\pi_{n,j}^{(s,p)} + \pi_{n,n-1-j}^{(s,p)}\right) jH_j = {} & \left(H_n - \mathrm{VE}(s, p)\right) \cdot (n-1) \\ & + \frac{p+1}{s+1}(H_{p+1} - H_{q+1}) + \frac{q+1}{s+1}(H_{q+1} - H_{p+1}) + \frac{1}{p+1} + \frac{1}{q+1} - \frac{2}{s+1} - 1. \end{aligned}$$

The last four terms above are $\mathcal{O}(1)$. On the other hand, from the equalities $p + 1 = \psi \cdot (s+1) + \chi_\psi(s)$, $H_n = \ln n + \gamma + 1/(2n) + \Theta(n^{-2})$, and $\ln(1 + 1/x) = 1/x + \Theta(x^{-2})$, it is not difficult to deduce that

$$\begin{aligned} & -H_{s+1} + \frac{p+1}{s+1} \cdot H_{p+1} + \frac{q+1}{s+1} \cdot H_{q+1} \\ & = -h(\psi) + \frac{1}{2s} - \Big(\ln(1-\psi) - \ln\psi\Big) \frac{\chi_\psi(s)}{s} + \Theta\left(\frac{1}{s^2}\right), \end{aligned}$$

and the lemma follows after a few simple manipulations. ∎

The factor $\ln(1-\psi) - \ln\psi$ in the statement of Lemma 10 is zero only when $\psi = 1/2$. Therefore, the perturbation $\chi_\psi(s)/s$ has to be taken into account whenever we are not selecting the median of the sample as the pivot.

As pointed out in section 2, $\mathsf{S}(s, p)$ is linear with the constant of proportionality typically dependent on the quotient $\psi = p/s$. Thus we assume $\mathsf{S}(s, p) = \mathsf{S}(s, \psi) = \beta \cdot s + o(s)$ for some constant $\beta = \beta(\psi)$. We also need the asymptotic properties of

$\mathsf{X}(n, s, \psi)$ given in the next lemma. It extends Lemma 6 for $\psi < 1/2$. The proof, very similar to others in this work, is omitted.

LEMMA 11. *If $s = \omega(1)$, $s = o(n)$, and $p = \lceil \psi \cdot (s+1) \rceil - 1$ for some ψ such that $0 < \psi \leq 1/2$, then*

$$\mathsf{X}(n, s, \psi) = \psi(1-\psi)n\left(1 - \frac{1}{s}\right) + (1-2\psi)\cdot\chi_\psi(s)\cdot\frac{n}{s} + \mathcal{O}\left(\max\left\{n/s^2, 1\right\}\right).$$

Therefore, by a reasoning identical to that of section 5, we can obtain the leading term of the optimal sample size s^* by minimizing

$$\beta\cdot s + \frac{n}{s}\cdot\left(\frac{q_\xi(\psi)}{2} - \psi\cdot(1-\psi)\cdot\xi\right) + \frac{n}{s}\cdot\Big((1-2\psi)\cdot\xi - (\ln(1-\psi) - \ln\psi)\cdot q_\xi(\psi)\Big)\cdot\chi_\psi(s). \tag{6.1}$$

We will consider two variants of quicksort with sample sizes depending on n. The first one is setting $\psi = \psi^*(\xi)$, i.e., choosing the optimal ratio p/s, and the second one is setting $\psi = 1/2$, that is, always picking the median of the sample (if $\xi \leq \tau$, both variants are identical, as $\psi^* = 1/2$ in this case). Fortunately, in any of these two variants the last term of (6.1) vanishes because of (4.2). Therefore, we can follow similar steps to those in the analysis of quickselect to obtain the two theorems below.

THEOREM 12. *Let s^* denote the optimal sample size w.r.t. Q_n when we use the $\lceil \psi^*(s+1) \rceil$th element of the sample as the pivot. Then*

$$s^* = \sqrt{\left(\frac{q_\xi(\psi^*)}{2} - \psi^*\cdot(1-\psi^*)\cdot\xi\right)\frac{1}{\beta(\psi^*)}}\cdot\sqrt{n} + o\left(\sqrt{n}\right).$$

THEOREM 13. *Let s^* denote the optimal sample size w.r.t. Q_n when the median of the sample is used as the pivot. Then*

$$s^* = \sqrt{\left(\frac{4 - (2\ln 2 - 1)\cdot\xi}{8\ln 2}\right)\frac{1}{\beta(1/2)}}\cdot\sqrt{n} + o\left(\sqrt{n}\right).$$

Notice that Theorem 13 makes no sense when $\xi > \tau$, as the factor multiplying $\sqrt{n}$ would be the square root of a negative number. This provides a further check for the conclusions of section 4 and is consistent with the observation that the optimal samples in that situation have constant size.

In [17] a dynamic-programming algorithm was used to compute several exact values of the optimal sample size for quicksort to minimize the average number of comparisons, assuming that standard quickselect was the median-finding algorithm. The authors reported that their data suggests a best power-law fit proportional to $n^{0.588}$. Also, for a tuned variant of quicksort (see section 7.2) they found that the best fit is proportional to at least $n^{0.475}$.

Figure 7 shows those exact values as a staircase plot. The continuous curve is the leading term of the optimal sample size s^* as stated by Theorem 13, setting $\xi = 0$ (minimize comparisons) and $\beta(1/2) = 2(1 + \ln 2)$ (use standard Hoare's quickselect algorithm). It is in very good accordance with the exact values, even for small values of n. We conjecture that the $o(\sqrt{n})$ term in s^* is actually $\Theta(1)$.

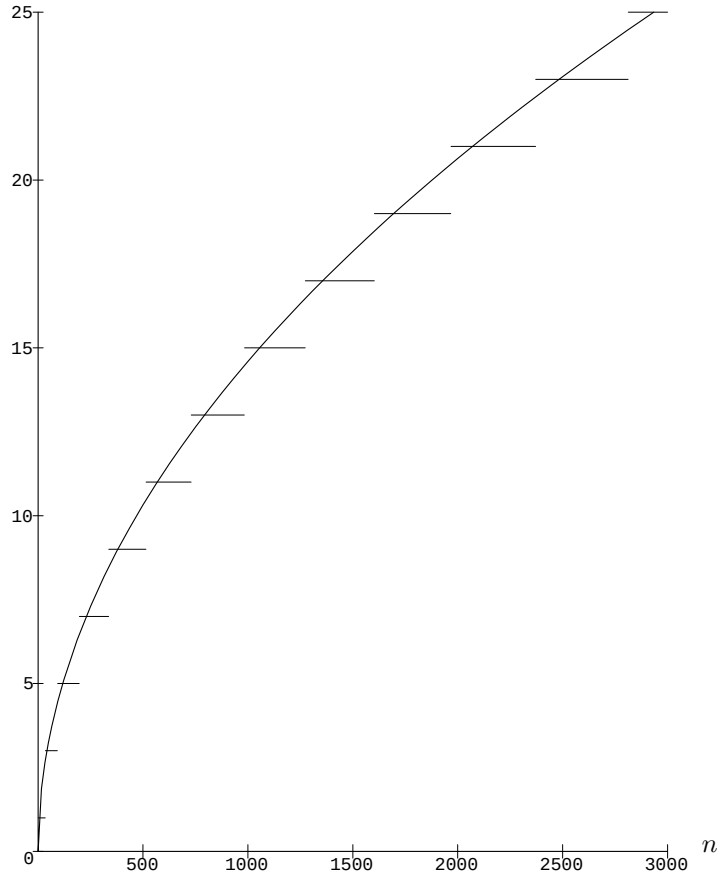

FIG. 7. *Exact values of the optimal samples to minimize the average number of comparisons compared with the main term of s^* (Theorem 13).*

7. Related issues.

7.1. Variance of quickselect. The variance of the number of comparisons of standard quickselect is $\Theta(n^2)$ [14] (see also [9, 18]). Thus, there is a low but nonnegligible probability that the number of comparisons actually made is much larger than the expected number. In this subsection we will study the variance of the number of comparisons of quickselect with sampling, specifically, for the case where the selected pivot is the median of the sample. This analysis is somewhat more complicated than the analysis of its expected performance.

It is worth noting again that we are investigating here the variance of the cost of quickselect when the rank of the sought element is given by a uniformly distributed random variable, not the average of the variances of the costs of selecting each element (see the remark on page 2).

We assume that the median-finding algorithm to select the pivots has quadratic variance. (If the variance were subquadratic, the basic conclusions of this section would not change.) A key observation that makes the analysis relatively simple is that the number of comparisons needed to select the pivot, the number of comparisons made to partition the array, and the number of comparisons made in further

invocations of quickselect in smaller subarrays are mutually independent. If the random variable Z_n is the sum of two independent random variables, X_n and Y_n, and $\{A_j\}_{0\le j<n}$ is a family of independent events, then

$$\begin{aligned}\mathbb{E}\big[Z_n^2\big] &= \mathbb{E}\big[(X_n+Y_n)^2\big] = \mathbb{E}\big[X_n^2\big] + 2\,\mathbb{E}[X_n]\,\mathbb{E}[Y_n] + \mathbb{E}\big[Y_n^2\big] \\ &= \mathbb{E}\big[X_n^2\big] + 2\,\mathbb{E}[X_n]\,(\mathbb{E}[Z_n] - \mathbb{E}[X_n]) + \mathbb{E}\big[Y_n^2\big] \\ &= 2\,\mathbb{E}[X_n]\,\mathbb{E}[Z_n] + \mathbb{E}\big[X_n^2\big] - 2\,\mathbb{E}[X_n]^2 + \sum_{0\le j<n} \Pr\{A_j\}\,\mathbb{E}\big[Y_n^2 \mid A_j\big]\,.\end{aligned}$$

Applying the equation above with

X_n = number of comparisons made to select the pivot and partition the array,
Y_n = number of comparisons made in further recursive invocations,

and A_j = "the pivot is the $(j+1)$th", we can easily obtain recurrences for $F_n^{(2)}$, the second moment of the number of comparisons made by quickselect to find an element of random rank out of n. We first consider the situation where $s = 2k+1 = \Theta(1)$. Then the recurrence for $F_n^{(2)}$ is

$$\begin{aligned}F_n^{(2)} &= 2(n+\Theta(1))F_n - (n+\Theta(1))^2 + \sum_{0\le j<n} w_{n,j}^{(k)} F_j^{(2)} \\ &= \frac{3k+5}{k+1}\,n^2 + \mathcal{O}(n) + \sum_{0\le j<n} w_{n,j}^{(k)} F_j^{(2)}.\end{aligned}$$

The weights and shape function are the same as for the analysis of the expected cost of quickselect with fixed-size samples, but the toll function is now quadratic. Therefore, the limiting const-entropy is

$$\mathcal{H}(k) = 1 - \frac{k+3}{2(2k+3)} = \frac{3(k+1)}{2(2k+3)},$$

and $F_n^{(2)} = (3k+5)(4k+6)n^2/(3(k+1)^2) + o(n^2)$. Finally, subtracting F_n^2 from $F_n^{(2)}$ we get the variance of quickselect.

THEOREM 14. *The variance of the number of comparisons made by quickselect when using samples of fixed size $s = 2k+1$ is*

$$V_n = \frac{2k+3}{3(k+1)^2}\,n^2 + o(n^2) = \left(\frac{2}{3k} + \mathcal{O}\left(\frac{1}{k^2}\right)\right) n^2 + o(n^2).$$

As expected, sampling not only reduces the expected number of comparisons, it also reduces its variance: if $v(k)$ denotes the coefficient of n^2 in V_n, we have $v(0) = 1, v(1) = 5/12, v(2) = 7/27\ldots$, and $\lim_{k\to\infty} v(k) = 0$. This suggests that for samples of increasing size ($k = \omega(1)$, $k = o(n)$) the variance is $o(n^2)$. Indeed, this is what actually happens.

The analysis of this case goes along the same lines as the analysis of the expected value F_n in section 5. Similar techniques to those used in the proof of Theorem 5 yield here that the limiting entropy associated to $F_n^{(2)}$ is $\mathcal{H} = 3/4$. Since the toll function is $3n^2 + o(n^2)$, we have $F_n^{(2)} = 4n^2 + o(n^2)$, and the variance is $V_n = F_n^{(2)} - F_n^2 = 4n^2 + o(n^2) - (2n + o(n))^2 = o(n^2)$.

A refinement of this calculation is possible since we know that, because of (5.1), $F_n = 2n + n/(2k) + \Theta(k) + \Theta\left(n/k^2\right)$. Substituting this estimate into the recurrence for $F_n^{(2)}$ and using $F_j^{(2)} \sim 4j^2$ to compute $\sum_{0\le j<n} w_{n,j}^{(k)} F_j^{(2)}$, we get $F_n^{(2)} = 4n^2 + \Theta\left(\max\left\{nk, n^2/k\right\}\right)$. We thus have the following theorem.

THEOREM 15. *The variance V_n of the number of comparisons made by quickselect when the samples are of size $2k+1$, where $k = \omega(1)$ and $k = o(n)$, is $V_n = \mathcal{O}\left(\max\left\{n^2/k, nk\right\}\right)$.*

Notice that the upper bound given above is $o(n^2)$ for any k such that $k = \omega(1)$ and $k = o(n)$. When $k = \Theta(\sqrt{n}\,)$ the variance is $\mathcal{O}(n^{3/2})$ and the standard deviation is $\mathcal{O}(n^{3/4})$. This is the right choice, since it simultaneously minimizes the average number of comparisons (Theorem 8) and the order of magnitude of the variance.

Concerning quicksort, we have not been able to analyze the effect of sampling in the variance of the number of comparisons. We conjecture that for $s = \omega(1)$ and $s = o(n)$ the variance of the number of comparisons satisfies $V_n = \mathcal{O}\left(\max\left\{n^2/s, ns\right\}\right)$, as in Theorem 15.

7.2. Tuning performance. We might avoid redundant comparisons and exchanges as follows [17]: if the input subarray is $A[l\,..\,u]$, we would take the segments $A[l\,..\,l+p]$ and $A[u-q+1\,..\,u]$ as our sample of $s = s(u-l+1)$ elements and apply a slightly modified version of quickselect, which would bring the $(p+1)$th element of the sample to $A[l]$, and put all smaller elements in $A[l+1\,..\,l+p]$ and all larger elements in $A[u-q+1\,..\,u]$. Then the partition of $A[l\,..\,u]$ around the pivot at $A[l]$ would initially set the left scanning pointer to $l+p+1$ and the right scanning pointer to $u-q$. The number of comparisons would then be reduced to $n+2-s$.

This selection-plus-partition combination is more efficient than the standard mechanism assumed in previous sections, but it does not preserve randomness, because the selection of the pivot reorganizes the elements of the sample. There seems not to exist—for general s—an efficient way to perform selection in-place and partition without redundant comparisons and exchanges while preserving randomness. However, we disregard the small amount of sortedness that the selection process introduces and assume that (2.2) and (2.3) are still valid, yielding at least good approximate results.

The steps and computations are absolutely analogous to those of previous sections. The results are, qualitatively speaking, identical. For instance, a straightforward computation—very similar but even simpler than that in the proof of Lemma 1 (see Appendix B)—yields

$$\mathsf{X}(n,s,p) = \frac{(p+1)(q+1)}{(s+1)(s+2)}(n-1-s) \qquad \text{if } s < n.$$

We present here a couple of results for these tuned variants of quickselect and quicksort.

THEOREM 16. *Let $s^* = 2k^*+1$ be the optimal sample size w.r.t. the average total cost of the tuned variant of quickselect to select a random element when the median of the sample is used as pivot. Then $k^* = \sqrt{n/(4\beta - 4 - \xi)} + o\left(\sqrt{n}\,\right)$.*

THEOREM 17. *Let s^* be the optimal sample size w.r.t. the average total cost of the tuned variant of quicksort when the $\lceil \psi^*(s+1)\rceil$th element of the sample is used as the pivot. Then*

$$s^* = \sqrt{\frac{q_\xi(\psi^*)/2 - \psi^*(1-\psi^*)\cdot\xi}{\beta(\psi^*) - 1 - \psi^*(1-\psi^*)\cdot\xi}} \cdot \sqrt{n} + o\left(\sqrt{n}\,\right).$$

Appendix A. The CMT. We briefly review in this appendix the CMT; since no proofs are given here, we refer the reader to [20, 21] for a detailed treatment.

Consider a recurrence like

$$F_n = t_n + \sum_{0 \le j < n} w_{n,j} F_j, \qquad n \ge n_0, \tag{A.1}$$

where t_n is the so-called *toll function* and the quantities $w_{n,j} \ge 0$ are called *weights*. This recurrence is a *divide-and-conquer recurrence* if and only if the following conditions hold:

1. There exists the limiting value $W = \lim_{n\to\infty} \sum_{0\le j<n} w_{n,j}$.
2. The sequence $W_n = \sum_{0\le j<n} w_{n,j}$ converges to W fast enough, namely,

$$|W_n - W| = \mathcal{O}(n^{-c})$$

for some constant $c > 0$.

3. The sequence

$$Z_n = \frac{1}{W_n} \cdot \sum_{0 \le j < n} w_{n,j} \cdot \frac{j}{n}$$

is strictly bounded above by 1 for sufficiently large n.

While the weights $w_{n,j}$ represent the (average) number of recursive calls made to subproblems of size j when the given instance is of size n, W_n is the (average) number of recursive calls made for instances of size n and Z_n is the average size (as a fraction of n) of the subproblems.

THEOREM 18 (CMT). *Let F_n be the solution of* (A.1)*, where $t_n \sim K n^a \log^b n$ for some constants K, $a \ge 0$, and $b > -1$, and let $w(z)$ be a real function over $[0,1]$ such that*

$$\sum_{0 \le j < n} \left| w_{n,j} - \int_{j/n}^{(j+1)/n} w(z)\, dz \right| = \mathcal{O}(n^{-d})$$

for some constant $d > 0$. Let $\phi(x) = \int_0^1 z^x\, w(z)\, dz$ and define $\mathcal{H} = 1 - \phi(a)$. Then

1. *if $\mathcal{H} > 0$, then $F_n \sim t_n \,/\, \mathcal{H}$;*
2. *if $\mathcal{H} = 0$, then $F_n \sim t_n \ln n \,/\, \mathcal{H}'$, where $\mathcal{H}' = -(b+1) \int_0^1 z^a \ln z\, w(z)\, dz$;*
3. *if $\mathcal{H} < 0$, then $F_n = \Theta(n^\alpha)$, where α is the unique real solution of $\phi(x) = 1$.*

The proof of this theorem is based upon more basic and technical results which are also useful to solve or show particular properties of divide-and-conquer recurrences which do not satisfy the hypothesis of the CMT, e.g., for recurrences for which a shape function $w(z)$ cannot be found.

We next consider an example of the results mentioned above. These results have already been used in sections 5 and 6.

Given a function $\gamma_n > 0$ such that $\gamma_n = o(n^\sigma)$ and $\gamma_n = \omega(n^{-\sigma})$ for any $\sigma > 0$ and a toll function t_n, γ_n is a *bounding function* of t_n if and only if there exist a constant $n_\gamma \ge 1$ and a strictly positive nonincreasing function $\beta(z)$ in $[0,1]$ such that $t_n\gamma_n - t_j\gamma_j \ge \beta(j/n) \cdot t_n$ for all $n > n_\gamma$ and for all $n_\gamma \le j < n$.

Given a divide-and-conquer recurrence (A.1) for F_n and a bounding function γ_n of the toll function t_n, the *entropy* $\mathcal{H}_n^{(\gamma)}$ of F_n with respect to γ_n (or γ-entropy of F_n, for short) is

$$\mathcal{H}_n^{(\gamma)} = \gamma_n - \sum_{n_\gamma \le j < n} w_{n,j} \cdot \frac{t_j}{t_n} \cdot \gamma_j.$$

Also, we define the *limiting* γ*-entropy* as $\mathcal{H}^{(\gamma)} = \lim_{n\to\infty} \mathcal{H}_n^{(\gamma)}$ if it exists. Then it is possible to prove that

$$F_n \sim t_n \gamma_n \,/\, \mathcal{H}^{(\gamma)}\,. \tag{A.2}$$

The CMT provides an easy way to determine a bounding function and to compute the limiting value of the corresponding entropy under appropriate circumstances. Notice that $\mathcal{H} \equiv \mathcal{H}^{(1)}$ is the limiting const-entropy and $\mathcal{H}' \equiv \mathcal{H}^{(\ln)}$ is the limiting log-entropy.

Appendix B. Combinatorial identities and proofs. In this appendix we collect several standard results for Beta integrals (see, for instance, [1]) and their discrete analogues, which easily follow from basic results in discrete calculus (see, for instance, [5]). We therefore leave the first two propositions without proof.

We also prove Lemma 1 in this appendix.

PROPOSITION 19.

$$\text{(a)} \qquad \int_0^1 z^\alpha (1-z)^\beta \, dz = \frac{\alpha!\beta!}{(\alpha+\beta+1)!},$$

$$\text{(b)} \qquad -\int_0^1 z^\alpha (1-z)^\beta \, \ln z \, dz = \frac{\alpha!\beta!}{(\alpha+\beta+1)!}(H_{\alpha+\beta+1} - H_\alpha).$$

For any real x and integer $\ell \ge 0$, $x^{\underline{\ell}} = x \cdot (x-1) \cdots (x-\ell+1)$ will denote the ℓth *falling factorial* of x [5]. Many of the computations in this work involve evaluating sums of the type

$$\sum_{0\le j<n} g(j,n) \binom{j}{p} \binom{n-1-j}{q} = \frac{1}{p!\,q!} \sum_{0\le j<n} g(j,n)\, j^{\underline{p}}\, (n-1-j)^{\underline{q}}$$

for some appropriate function $g(j,n)$. For instance, to evaluate $\mathsf{X}(n,s,p)$ we use $g = j(n-1-j)$, for $\mathcal{F}(n,k)$ we use $g = j^2$, and for $\mathcal{Q}(n,\psi)$ we use $g = jH_j$.

Proposition 20 is helpful in coping with these sums. Notice the parallelism with Proposition 19.

PROPOSITION 20.

$$\text{(a)} \quad A_{\ell,m}(n) = \sum_{0\le j<n} j^{\underline{\ell}} (n-1-j)^{\underline{m}} = \ell!\, m! \binom{n}{\ell+m+1},$$

$$\text{(b)} \quad B_{\ell,m}(n) = \sum_{0\le j<n} j^{\underline{\ell}} (n-1-j)^{\underline{m}} H_j = \ell!\, m! \binom{n}{\ell+m+1} (H_n - H_{\ell+m+1} + H_\ell)\,.$$

The following intermediate result, which is used in section 5, is just an example of the usefulness of the proposition above. Similar intermediate results in the analysis of quicksort (section 6) follow also from Proposition 20(b).

PROPOSITION 21. *For all s and p such that $0 \le p < s$,*

$$(s+1)(s+2)\sum_{0\le j<n} j^2\left(\pi_{n,j}^{(s,p)} + \pi_{n,n-1-j}^{(s,p)}\right) = \big((p+1)(p+2)+(q+1)(q+2)\big)n^2 - 6(p+1)(q+1)n + (p-q)^2 + (s+1).$$

Proof. Apply Proposition 20(a) twice, using $j^2 = (j-x)(j-1-x)+(2x+1)(j-x)+x^2$, with $x=p$ the first time and with $x=q$ the second time. □

We end this appendix with a proof of Lemma 1, which gives a closed expression for $\mathsf{X}(n,s,p)$.

Proof of Lemma 1. Here we assume that the subarray to be partitioned contains the pivot in its first position. If the pivot ends at $A[j+1]$ after partitioning and there were t elements in $A[2\,..\,j+1]$ greater than the pivot, then exactly t swaps were needed to arrange the array. (We do not count the one or two additional swaps just before and after the partitioning.) The probability of this to happen is

$$\frac{\binom{j}{j-t}\binom{n-1-j}{t}}{\binom{n-1}{j}},$$

by an argument largely analogous to the one used to obtain the value of $\pi_{n,j}^{(s,p)}$ in (2.1). Thus

$$\mathsf{X}(n,s,p) = \sum_{0\le j<n} \pi_{n,j}^{(s,p)} \sum_t t\cdot \frac{\binom{j}{j-t}\binom{n-1-j}{t}}{\binom{n-1}{j}}.$$

We can now use the "derivative" of Vandermonde's convolution [5],

$$\sum_t t\binom{b}{c-t}\binom{a}{t} = a\binom{a+b-1}{c-1},$$

to get

$$\mathsf{X}(n,s,p) = \sum_{0\le j<n} \pi_{n,j}^{(s,p)} \cdot \frac{j(n-1-j)}{(n-1)}.$$

Finally, using the equality $j(n-1-j) = (j-p)(n-1-j-q)+(j-p)(q-p)+(pn-p^2-p)$ yields

$$\mathsf{X}(n,s,p) = \frac{A_{p+1,q+1}(n) + (q-p)\cdot A_{p+1,q}(n) + (pn-p^2-p)\cdot A_{p,q}(n)}{p!\,q!\,(n-1)\binom{n}{s}},$$

where $P_{p,q}(n)$ is as in Proposition 20(a). The rest of the proof is a simple matter of computation. □

Acknowledgments. We thank H.-K. Hwang for various useful comments and suggestions, especially for encouraging us to study the variance of quicksort and quickselect. We also wish to thank the anonymous referees of this paper for their comments and useful suggestions.

THE COMPACTNESS OF INTERVAL ROUTING FOR ALMOST ALL GRAPHS*

CYRIL GAVOILLE† AND DAVID PELEG‡

Abstract. Interval routing is a compact way of representing routing tables on a graph. It is based on grouping together, in each node, destination addresses that use the same outgoing edge in the routing table. Such groups of addresses are represented by some intervals of consecutive integers. We show that almost all the graphs, i.e., a fraction of at least $1 - 1/n^2$ of all the n-node graphs, support a shortest path interval routing with *three* intervals per outgoing edge, even if the addresses of the nodes are arbitrarily fixed in advance and cannot be chosen by the designer of the routing scheme. In case the addresses are initialized randomly, we show that *two* intervals per outgoing edge suffice, and, conversely, that two intervals are required for almost all graphs. Finally, if the node addresses can be chosen as desired, we show how to design in polynomial time a shortest path interval routing with a *single* interval per outgoing edge for all but at most $O(\log^3 n)$ outgoing edges in each node. It follows that almost all graphs support a shortest path routing scheme which requires at most $n + O(\log^4 n)$ bits of routing information per node, improving on the previous upper bound.

Key words. interval routing, compact routing, random graphs

1. Introduction.

1.1. Background. A *universal routing strategy* is an algorithm which generates a routing scheme for every given network. One type of trivial universal routing strategy is based on schemes that keep in each node a full routing table which specifies an output port for every destination. Though this strategy can guarantee routing along shortest paths, each router has to locally store $\Theta(n \log d)$ bits of information, where d is the degree of the router (i.e., the number of output ports) and n is the number of nodes in the network.

The *interval routing scheme* [9, 10] is a compact routing scheme, i.e., a routing scheme that needs to keep only a small amount of information in each node to route messages correctly through the network. The idea of this scheme is to label the n nodes of the network with unique integers from $\{1, \ldots, n\}$ and to label the outgoing arcs in every node with a set of intervals forming a partition of the name range. The routing process sends a message on the unique outgoing arc labeled by an interval that contains the destination label. While the preprocessing stage of such a routing scheme (which is performed once in the initialization of the network) might be complex, the delivery protocol consists of simple decision functions which can be implemented with $O(kd \log n)$ bits in each node of degree d, where k is the maximum number of intervals assigned to an arc. Such a routing scheme supports a compact implementation whenever k is small in comparison with n or d.

In [8], it is shown that there is no universal routing strategy that can guarantee a shortest path routing scheme with less than $\Omega(n \log d)$ bits per node for all the n-node networks of maximum degree d. This result means that there is some worst-case network where for any shortest path routing function, the number of bits required to be stored in a router is not significantly smaller than the size of a routing table, whatever the node labeling (from the range $\{1, \ldots, n\}$) and the shortest paths are. Fortunately, such a problematic situation where the routing tables cannot be compressed occurs for a limited number of worst-case networks only.

In particular, in [3], it is shown that for almost all the n-node networks the size of the routing tables can be reduced to $O(n)$ bits per node. More precisely, it is shown that all labeled graphs but a $1/n^3$ fraction can be routed with a scheme that uses $3n + o(n)$ bits of information, under the assumption that nodes are randomly labeled in the range $\{1, \ldots, n\}$, and that every node knows its neighbors for "free," or that the port assignment may be changed. Moreover, if, during the initialization process of the network, nodes can be relabeled with binary string of length $c \log^2 n + o(\log^2 n)$ bits[1] (for constant $c > 3$), then $c \log^2 n$ bits per node suffice to route along the shortest paths for almost all networks.

1.2. Definitions and results. In this paper, we consider shortest path routing schemes only. An undirected graph $G = (V, E)$ represents the classic model of the underlying topology of the network. An n-node graph G with the nodes labeled by labels from the set $\{1, \ldots, n\}$ is said to *support a k-interval routing scheme* (k-IRS for short) if there exists an interval routing scheme $\mathcal{R}$ for G with the property that for every (directed) edge e, the set of node labels to which $\mathcal{R}$ routes messages via e is composed of at most k intervals. (An interval means a set of consecutive integers taken from $\{1, \ldots, n\}$, where n and 1 are considered to be consecutive.)

Our goal is to find a labeling of the nodes and a shortest path system in order to minimize the maximum number of intervals assigned to the edges of the graph. We distinguish three models depending on the freedom we have in labeling the nodes.

1. *Adversary.* Labels are fixed in advance (by an adversary) and cannot be permuted.
2. *Random.* Labels are randomly permuted.
3. *Designer.* Labels can be chosen (by the routing designer) in order to achieve the smallest possible number of intervals.

In all three models, the routing designer has the freedom of selecting the shortest paths to be used.

Corresponding to these three models, we introduce the following three parameters. We denote by $\mathrm{IRS}_A(G)$ the smallest integer k such that G supports a k-IRS in the adversary model (namely, for every arbitrary labeling of the nodes). We denote by $\mathrm{IRS}_R(G)$ the smallest k such that G supports a k-IRS in the random model (namely, given a random labeling of the nodes of G) with high probability. Finally, we denote by $\mathrm{IRS}(G)$ the smallest k such that G supports a k-IRS in the designer model (namely, under some specifically chosen node labeling of G). Clearly, $\mathrm{IRS}(G) \leqslant \mathrm{IRS}_R(G) \leqslant \mathrm{IRS}_A(G)$ for every graph G.

The parameter $\mathrm{IRS}(G)$, sometimes called the *compactness* of the scheme, has been computed for many classes of graphs (see [6] for a recent overview). Notably, in [7] it is shown that for every G, $\mathrm{IRS}_R(G) < n/4 + o(n)$, whereas there exists some worst-case G_0 such that $\mathrm{IRS}(G_0) > n/4 - o(n)$. However, as shown in this paper, the

[1] Where hereafter log denotes the logarithm in base 2.

situation is considerably better for the "average" case. Specifically, we will see that $\mathrm{IRS}(G) \leqslant 2$ for a fraction of at least $1 - 1/n^2$ of all the n-node labeled graphs.

Technically, we use random graphs instead of the Kolmogorov random graphs used in [3]. A discussion about the relationships between random and Kolmogorov random graphs can be found in [4]. The class $\mathcal{G}_{n,p}$ denotes the classic model of n-node labeled random graphs, where $0 \leqslant p \leqslant 1$ represents the probability of having an edge between any two nodes. Clearly, a random graph $G \in \mathcal{G}_{n,1/2}$ has a given property $\mathcal{P}$ with probability α if and only if $\mathcal{P}$ holds for a fraction of α of all the n-node labeled graphs. Interval routing on random graphs has been first investigated in [5], where some lower bounds are given for $\mathrm{IRS}(G)$ for $G \in \mathcal{G}_{n,p}$. More precisely, it is shown therein that for $p = n^{-1+1/s}$ for integer $s > 0$, such that there exists some $\varepsilon > 0$ satisfying $(\ln^{1+\varepsilon} n)/n < p < n^{-1/2-\varepsilon}$, a graph $G \in \mathcal{G}_{n,p}$ satisfies

$$\mathrm{IRS}(G) \;\geqslant\; \frac{1}{10}\, n^{1-6/\ln(np)-\ln(np)/\ln n} \tag{1.1}$$

with high probability. It is also shown that for some $p = n^{-1+1/\Theta(\sqrt{\log n})}$, a graph $G \in \mathcal{G}_{n,p}$ satisfies $\mathrm{IRS}(G) = \Omega(n^{1-1/\Theta(\sqrt{\log n})})$ with high probability. In this paper, we investigate the case where p is a fixed constant, e.g., $p = 1/2$, in order to establish some average results on the total space of n-node graphs. (Note that for constant p, (1.1) cannot be used since in this case p lies outside the validity range.)

The following table presents our results for each model. The results of the table are proved for a fraction of at least $1 - 1/n^2$ of all the n-node labeled graphs.

Label select	Designer	Random	Adversary
Upper bound	$\mathrm{IRS} \leqslant 2$	$\mathrm{IRS}_R \leqslant 2$	$\mathrm{IRS}_A \leqslant 3$
Lower bound	$\mathrm{IRS} \geqslant 1$	$\mathrm{IRS}_R \geqslant 2$	$\mathrm{IRS}_A \geqslant 3$

At this time, we are still unable to decide whether $\mathrm{IRS}(G) = 1$ or 2 for almost every graph G in the model where both the node labels and the shortest path system can be chosen in advance by the designer. However, we present a polynomial time algorithm to design a 2-IRS for all graphs but a $1/n$ fraction such that for every node, all its outgoing edges are labeled with a single interval, except for up to $O(\log^3 n)$ edges where two intervals are required. It follows that almost every graph supports a shortest path routing scheme that can be implemented with $n + O(\log^4 n)$ bits, improving on the best known result (cf. [3]). Note that our result is stated with the assumption that nodes can be permuted but without the assumption that nodes know their neighbors.

2. Randomly assigned node labels. In this section, we show that in the random model, almost every graph G satisfies $\mathrm{IRS}_R(G) = 2$. This implies, in particular, that almost every graph G satisfies $\mathrm{IRS}(G) \leqslant 2$. This is done by showing that, with probability at least $1 - 1/n^2$, a random graph G from $\mathcal{G}_{n,1/2}$ satisfies $\mathrm{IRS}_R(G) = 2$. Actually, we show that the result holds for the class $\mathcal{G}_{n,p}$ of random graphs for each fixed probability $0.45 < p < 1$.

2.1. Upper bound. In this subsection, we shall prove that $\mathrm{IRS}_R(G) \leqslant 2$. Assume the node labels $\{1, \ldots, n\}$ are assigned randomly for the graph G. In that case, given that G is a random graph in $\mathcal{G}_{n,p}$, we may assume that the nodes are first marked by the labels 1 through n, and only then we draw the edges randomly and uniformly with probability p.

For random graphs selected from $\mathcal{G}_{n,p}$, we have the following simple bounds.[2] We denote by $\Gamma(v)$ the set composed of v and of its neighbors.

LEMMA 2.1. *With probability at least* $1 - 1/n^3$, *and for every fixed* $0 < p < 1$, *a random graph* $G \in \mathcal{G}_{n,p}$ *is of diameter* 2, *and for every node* $v \in V$,

$$np - 3\sqrt{n \ln n} \leqslant |\Gamma(v)| \leqslant np + 3\sqrt{n \ln n}.$$

Let $\mathcal{E}_A$ denote the event that the random graph at hand does not satisfy the properties asserted in Lemma 2.1. Henceforth, we ignore that possibility and restrict our attention to $\overline{\mathcal{E}_A}$.

For notational convenience, we identify nodes with their labels, i.e., denote $V = \{1, \ldots, n\}$.

Consider a node $v_0 \in V$. We need to argue that with high probability, the edges of v_0 can be labeled with at most two intervals per edge so that for every possible destination $v_d \in V$, the selected edge is along a shortest path from v_0 to v_d.

Let $A = \Gamma(v_0) \setminus \{v_0\}$ and $B = V \setminus \Gamma(v_0)$. Since G satisfies the event $\overline{\mathcal{E}_A}$,

$$np - 3\sqrt{n \ln n} - 1 \leqslant |A| \leqslant np + 3\sqrt{n \ln n}, \tag{2.1}$$

$$n(1-p) - 3\sqrt{n \ln n} \leqslant |B| \leqslant n(1-p) + 3\sqrt{n \ln n}. \tag{2.2}$$

Let

$$C = \{v \in B \mid v + 1 \in A \text{ and } (v, v+1) \in E\}.$$

LEMMA 2.2. *With probability at least* $1 - 1/n^3$, *the size of the set* C *is bounded by*

$$n(1-p)p^2 - 5\sqrt{n \ln n} \leqslant |C| \leqslant n(1-p)p^2 - 5\sqrt{n \ln n}.$$

Proof. Consider a vertex $v \in B$, and let I_v denote the event that $v \in C$. This event happens precisely if $v + 1 \in A$ and $(v, v+1) \in E$. These two subevents are independent and both occur with probability p, and hence $\mathbb{P}(I_v) = p^2$. Also note that the events I_v for $v \in B$ are mutually independent. Let Z be a random variable denoting the size of $|C|$. Then $Z = \sum_{v \in B} z_v$, where z_v is the characteristic random variable of the event I_v. Hence, Z is the sum of $|B|$ mutually independent Bernoulli variables, and its expected value is $\mathbb{E}(Z) = |B|p^2$, and hence applying Chernoff's bound (cf. [1]) we get

$$\begin{aligned}\mathbb{P}\left(Z \geqslant n(1-p)p^2 + 5\sqrt{n \ln n}\right) &\leqslant \mathbb{P}\left(Z \geqslant \mathbb{E}(Z) + 2\sqrt{n \ln n}\right) \\ &\leqslant \exp\left(-\frac{\left(2\sqrt{n \ln n}\right)^2}{n}\right) \leqslant \frac{1}{n^4}\end{aligned}$$

and

$$\mathbb{P}\left(Z \leqslant n(1-p)p^2 - 5\sqrt{n \ln n}\right) \leqslant \frac{1}{n^4},$$

and the lemma follows. ∎

[2] We state a variant of the bounds suitable to our needs and make no attempt to optimize them; see [2] for sharper statements.

Let $\mathcal{E}_B$ denote the event that the random graph at hand does not satisfy the property asserted in Lemma 2.2 for *some* node v_0. Note that the probability for this event is bounded above by $1/n^3$. Henceforth, we ignore that possibility and restrict our attention to $\overline{\mathcal{E}_B}$.

Let us now define one interval per emanating edge of v_0 to take care of routing to the nodes in $A \cup C$. For every node $w \in A$, mark the edge (v_0, w) by the interval $[w-1, w]$ if $w - 1 \in C$ and by the interval $[w]$ if $w - 1 \notin C$.

It is thus left to show how the remaining interval per edge of v_0 can be used to route optimally towards the nodes in $X = B \setminus C$. This is done as follows. Let $X = \{x_1, \ldots, x_m\}$. Note that since G satisfies the events $\overline{\mathcal{E}_A}$ and $\overline{\mathcal{E}_B}$,

$$n(1-p)(1-p^2) - 8\sqrt{n \ln n} \;\leqslant\; m \;\leqslant\; n(1-p)(1-p^2) + 8\sqrt{n \ln n}.$$

We now describe a process for selecting a subset of A, denoted $Y = \{y_1, \ldots, y_m\} \subseteq A$, such that there is an edge $(x_i, y_i) \in E$ for every $1 \leqslant i \leqslant m$. Once this is done, we mark each edge (v_0, y_i) by the interval $[x_i]$, thus completing our task.

The selection process is a straightforward greedy one. Let $Q = A$. Having already selected $y_1, \ldots, y_{i-1}$, the ith step consists of selecting y_i to be some arbitrary neighbor of x_i in Q and discarding y_i from Q. If, at any stage, the node x_i considered by the process has no neighbors in the remaining set Q, then the process fails and we abort our attempt to provide a 2-IRS for G.

We need to argue that with very high probability, the process does not fail. Let F_i be the event that the process fails in the ith step. Note that at the beginning of step i the current set Q is of size

$$\begin{aligned} |Q| \;=\; |A| - (i-1) &\geqslant |A| + 1 - m \\ &\geqslant np - n(1-p)(1-p^2) - 11\sqrt{n \ln n} \\ &\geqslant \frac{n}{2}\left(p - (1-p)(1-p^2)\right) \end{aligned}$$

for sufficiently large n.

Let

$$f(p) \;=\; p - (1-p)(1-p^2) \;=\; -p^3 + p^2 + 2p - 1.$$

Then $f'(p) = -3p^2 + 2p + 2$, which is positive for $0 < p < 1$. Therefore, f increases on this range. Note that[3] $f(0.45) > 0.01$. Therefore, for $0.45 < p < 1$, and for sufficiently large n, $|Q| > n/200$.

Event F_i occurs only if x_i is not connected to any node of Q. This is the intersection of $|Q|$ independent events of probability $1 - p$ each, and hence

$$\mathbb{P}(F_i) \;\leqslant\; (1-p)^{n/200} \;<\; c^{-n}$$

for constant $c > 1$. Let $\mathcal{E}_F(v_0)$ denote the event that the process fails for v_0. This event occurs if for some $x_i \in X$, no remaining common neighbors of v_0 and x_i could be found, i.e., $\mathcal{E}_F(v_0) = \bigcup_i F_i$. We have $\mathbb{P}(\mathcal{E}_F(v_0)) < m\, c^{-n}$. It follows that for a sufficiently large n, the event $\mathcal{E}_F = \bigcup_{v_0} \mathcal{E}_F(v_0)$ has probability $\mathbb{P}(\mathcal{E}_F) \leqslant 1/n^3$.

Combining all possible failure events (namely, $\mathcal{E}_A \cup \mathcal{E}_B \cup \mathcal{E}_F$), we get that for sufficiently large n, the probability that our process fails to generate an interval routing

[3] Actually, the root of $f(p) = 0$, for $0 < p < 1$, is $p_0 \approx 0.445041$.

scheme for the graph with two intervals per edge is bounded from above by $1/n^2$. We remark that all the intervals considered here are *linear*, i.e., of the type $[a, b]$ with $a \leqslant b$, and are *strict*, i.e., do not include the label of the node itself.

THEOREM 2.3. *For sufficiently large n, and for every fixed $0.45 < p < 1$, a random graph $G \in \mathcal{G}_{n,p}$ satisfies $\mathrm{IRS}_R(G) \leqslant 2$ with probability at least $1 - 1/n^2$.* □

2.2. Lower bound. In this subsection, we prove that $\mathrm{IRS}_R(G) \geqslant 2$ for almost every graph G for a random assignment of node labels.

Again, we assume the node labels $\{1, \ldots, n\}$ are assigned randomly for the graph G, so given that G is a random graph in $\mathcal{G}_{n,p}$, for p fixed, we may assume that the nodes are first labeled 1 through n and the edges are randomly drawn only later. As in the previous subsection, we assume the event $\overline{\mathcal{E}_A}$.

We need to show that with high probability, a single interval per edge will not be sufficient for producing shortest paths.

Consider a node $x \in \{1, \ldots, n\}$. Suppose that x is connected to $x + 1$ and $x + 3$ and that $x + 2$ is not connected to any node from $\{x, x + 1, x + 3\}$. Let $I(x, u)$ be the interval assigned to the edge (x, u) that contains $x + 2$. Since the diameter of G is 2, it follows that $u \notin \{x + 1, x + 2, x + 3\}$. $I(x, u)$ must contain u and $x + 2$, but neither $x + 1$ nor $x + 3$, which are connected to x. This contradicts the fact that $I(x, u)$ is composed of a single interval.

Let $x_i = 4i - 3$, for every $i \in \{1, \ldots, m\}$, with $m = \lfloor n/4 \rfloor$. Let K_i denote the event x_i as in the previous configuration, and let $\mathcal{E}_K$ denote the event that there exists an event K_{i_0} that occurs. Note that by the above discussion, the probability of $\mathrm{IRS}_R(G) > 1$ (under the event $\overline{\mathcal{E}_A}$) is lower bounded by $\mathbb{P}(\mathcal{E}_K)$.

Let Z_i be the characteristic random variable of the event K_i, and $Z = \sum_{i=1}^{m} Z_i$. The events K_i are independent, and each one occurs with probability $p^2(1 - p)^3$. Therefore, $\mathbb{P}(Z = 0) = (1 - p^2(1 - p)^3)^m < 1/n^3$ for a sufficiently large n. It follows that $\mathbb{P}(\mathcal{E}_K) \geqslant 1 - 1/n^3$.

THEOREM 2.4. *For sufficiently large n, and for every fixed $0 < p < 1$, a random graph $G \in \mathcal{G}_{n,p}$ satisfies $\mathrm{IRS}_R(G) \geqslant 2$ with probability at least $1 - 1/n^2$.* □

3. Adversely assigned labels. Next we assume the adversary model, in which the assignment of the node labels $\{1, \ldots, n\}$ to nodes is done by an adversary, aiming to cause the routing scheme to use the maximum number of intervals. We show that almost every graph G satisfies $\mathrm{IRS}_A(G) = 3$.

3.1. Upper bound. We start by showing that with probability at least $1 - 1/n^2$, a random graph G from $\mathcal{G}_{n,p}$ satisfies $\mathrm{IRS}_A(G) \leqslant 3$, for every fixed probability p, $1/3 < p < 1$. More generally, we show that for each integer $k \geqslant 2$, $\mathrm{IRS}_A(G) \leqslant k$ with probability at least $1 - 1/n^2$ for $G \in \mathcal{G}_{n,p}$, for each fixed p, $1/k < p < 1$.

Once again, by Lemma 2.1, we are allowed to restrict our attention to the event $\overline{\mathcal{E}_A}$, and assume the graph $G = (V, E)$ at hand is of diameter 2, and such that for every node $v \in V$, $np - 3\sqrt{n \ln n} \leqslant |\Gamma(v)| \leqslant np + 3\sqrt{n \ln n}$.

Consider a node $v_0 \in V$ and an integer $k \geqslant 2$. We need to argue that with high probability, the edges of v_0 can be labeled with at most k intervals per edge so that for every possible destination $v_d \in V$, the selected edge is along a shortest path from v_0 to v_d.

Let $A = \Gamma(v_0) \setminus \{v_0\}$ and $B = V \setminus \Gamma(v_0)$. Let us first define one interval per emanating edge of v_0 to take care of routing to the nodes of A. Namely, for every node $w \in A$, mark the edge (v_0, w) by the interval $[w]$. It is left to show how the

remaining $k-1$ intervals per edge of v_0 can be used to route optimally towards the nodes of B.

This is done as follows. Let $B = \{b_1, \ldots, b_m\}$. Recall that A and B satisfy inequalities (2.1) and (2.2). We now describe a process for selecting an intermediate node $a_i \in A$ for every $1 \leqslant i \leqslant m$ such that the routing from v_0 to b_i will go through a_i. For this, we need to ensure that there is an edge $(a_i, b_i) \in E$ for every $1 \leqslant i \leqslant m$. Once this is done, we mark each edge (v_0, a_i) by the interval $[b_i]$, thus completing our task.

The selection process is similar to the greedy process of section 2.1. Let $Q = A$, and define a counter $C(a)$ for each node $a \in A$, initially setting all counters to zero. Having already selected $a_1, \ldots, a_{i-1}$, the ith step consists of selecting a_i to be some arbitrary neighbor of b_i in Q, increasing the counter $C(a_i)$ by one, and discarding a_i from Q if the counter has reached $k-1$. If, at any stage, the node b_i considered by the process has no neighbors in the remaining set Q, then the process fails and we abort our attempt to provide a k-IRS for G.

We need to argue that with high probability, the process does not fail. Let F_i be the event that the process fails in the ith step. Note that at the beginning of step i the counters sum up to $i-1$, and hence at most $\lfloor (i-1)/(k-1) \rfloor$ nodes were discarded from Q, so the current set Q is of size

$$\begin{aligned} |Q| \;\geqslant\; |A| - \left\lfloor \frac{i-1}{k-1} \right\rfloor &> |A| - \frac{|B|}{k-1} \\ &> np - \frac{n(1-p)}{k-1} - 6\sqrt{n \ln n} - 1 \\ &> \frac{n}{2}\left(p - \frac{1-p}{k-1}\right) \end{aligned}$$

for sufficiently large n. Since $p > 1/k$, and $k > 1$, it implies that

$$p - \frac{1-p}{k-1} \;>\; 0.$$

Therefore, there is a constant $\alpha > 0$ such that for sufficiently large n, $|Q| > \alpha n$.

Event F_i occurs only if b_i is not connected to any node of Q. This is the intersection of $|Q|$ independent events of probability $1-p$ each, and hence $\mathbb{P}(F_i) \leqslant (1-p)^{\alpha n} < c^{-n}$, for constant $c > 1$. Letting $\mathcal{E}_F(v_0)$ denote the event that the process fails for v_0, i.e., $\mathcal{E}_F(v_0) = \bigcup_i F_i$, we have $\mathbb{P}(\mathcal{E}_F(v_0)) \leqslant m\, c^{-n}$. It follows that for a sufficiently large n, the event $\mathcal{E}_F = \bigcup_{v_0} \mathcal{E}_F(v_0)$ has probability $\mathbb{P}(\mathcal{E}_F) \leqslant 1/n^3$.

Combining all possible failure events (namely, $\mathcal{E}_A \cup \mathcal{E}_F$), we get that the probability that our process fails to generate an interval routing scheme for the graph with three intervals per edge is bounded from above by $1/n^2$. We remark that all the intervals used in the scheme are linear and strict.

THEOREM 3.1. *For sufficiently large n, for every integer $k \geqslant 2$, and for every fixed p in the range $1/k < p < 1$, a random graph $G \in \mathcal{G}_{n,p}$ satisfies $\mathrm{IRS}_A(G) \leqslant k$ with probability at least $1 - 1/n^2$.* □

In particular, a graph $G \in \mathcal{G}_{n,1/2}$ satisfies $\mathrm{IRS}_A(G) \leqslant 3$ with probability at least $1 - 1/n^2$.

3.2. Lower bound. We restrict our attention to random graph $G \in \mathcal{G}_{n,1/2}$ and show that $\mathrm{IRS}_A(G) \geqslant 3$ with probability at least $1 - 1/n^2$. As in the previous sections, we assume the event $\overline{\mathcal{E}_A}$; i.e., G has diameter 2.

The main idea is the following. Consider a node v such that $|\Gamma(v)| = d+1$, for some suitable integer $d < n/2$, and let $A = \Gamma(v) \setminus \{v\}$, and $B = V \setminus \Gamma(v)$. Now suppose that $A = \{a_1, \ldots, a_d\}$, and $C = \{b_1, \ldots, b_{d+1}\} \subset B$ such that the following two assumptions hold:

(A1) For every $i \in \{1, \ldots, d\}$, a_i is connected to neither b_i nor b_{i+1}.

(A2) The adversary has labeled the nodes by $a_i = 2i$ and $b_i = 2i-1$ for all $i \in \{1, \ldots, d\}$. (The other nodes have arbitrary labels.)

Since $|A| < |C|$, for every shortest path routing there exist two nodes $b, b' \in C$, $b < b'$, that are reached from v through the same $a \in A$. Thus the set $I_{v,a}$ that labels the edge (v, a) contains a, b, b'. However, $a-1, a+1 \notin I_{v,a}$, and by assumption (A1) $b+1, b'-1 \notin I_{v,a}$. It forces at least three linear intervals for $I_{v,a}$.

However, if the labeling is allowed to be nonstrict and nonlinear, $b = 1$, $b' = n-1$, and $v = n \in I_{v,a}$, it is possible to have b and b' in a single *wraparound* interval which does not contain $b+1$ and $b'-1$. For example, $I_{v,a} = [a] \cup [b', b]$. In order to strengthen our lower bound we will show that, actually, with high probability this node labeling implies three intervals, even if the intervals used are nonstrict and nonlinear. Indeed, it suffices to show that there is a node $b'' \in B \setminus C$ that is not connected to a. From the definition of the node labeling $b < b' < b''$. Therefore, even if $b = 1$ and $v \in I_{v,a}$, the set $I_{v,a}$ cannot contain the subinterval $[b', b]$ since it would contain b''.

First, we prove[4] that with high probability there must be some node v such that $|\Gamma(v)| \leqslant n/2 - 16\log^2 n$.

LEMMA 3.2. *With probability at least* $1 - 1/n^3$*, there exists a node* v *such that* $|\Gamma(v)| \leqslant n/2 - 16\log^2 n$.

Proof. For every node v, let $\deg(v) = |\Gamma(v)| - 1$. Consider an arbitrary $v \in V$. Note that $\deg(v)$ is the sum of $n-1$ independent Bernoulli random variables each of probability $1/2$. Therefore,

$$\mathbb{P}(\deg(v) = i) \;=\; \frac{\binom{n-1}{i}}{2^{n-1}}.$$

For notational convenience, let $m = n-1$. For every integer h, $0 < h < m/2$,

$$\begin{aligned}
\mathbb{P}(\deg(v) < m/2 - h) &= \frac{1}{2^m} \sum_{i=0}^{m/2-h-1} \binom{m}{i} \\
&= \frac{1}{2^m} \left(\sum_{i=0}^{m/2} \binom{m}{i} - \sum_{i=m/2-h}^{m/2} \binom{m}{i} \right) \\
&\geqslant \frac{1}{2^m} \left(2^{m-1} - \sum_{i=m/2-h}^{m/2} \binom{m}{i} \right).
\end{aligned}$$

By the Stirling formula, $\binom{m}{m/2} \leqslant c \cdot 2^m/\sqrt{m}$ for some constant $c > 0$. Also, $\binom{m}{i} \leqslant \binom{m}{m/2}$ for every $0 \leqslant i \leqslant m$. Hence,

$$\begin{aligned}
\mathbb{P}(\deg(v) < m/2 - h) &\geqslant \frac{1}{2^m} \left(2^{m-1} - (h+1)c \cdot 2^m/\sqrt{m} \right) \\
&\geqslant \frac{1}{2} - \frac{(h+1)c}{\sqrt{m}}.
\end{aligned}$$

[4] Again, making no attempt to optimize the constants involved in the calculations.

Hence, for $h = 16\log^2 n + 1$, we have $\mathbb{P}(\deg(v) < m/2 - h) \geqslant 1/4$ for sufficiently large n. The probability that all the nodes have degree at least $m/2 - h$ is thus bounded by $(3/4)^n \leqslant 1/n^3$ for sufficiently large n. Hence, with probability at least $1 - 1/n^3$ there exists a node v such that $\deg(v) \leqslant n/2 - 16\log^2 n - 1$, and the lemma follows. □

Hence, we have $|B| - |A| \geqslant 32\log^2 n$. Define a "walk" in G such that any two consecutive nodes of the walk are nonadjacent, as follows. Start the walk at an arbitrary node b_1 of B, continuing to an arbitrary nonneighbor a_1 in A, from there back to an arbitrary nonneighbor b_2 in B, and so on. Continue in that fashion for the first $|A| - \lceil 8\log n\rceil$ "double steps" (each consisting of two substeps, from B to A and back to B) and ending at some node $a_t \in A$.

LEMMA 3.3. *With probability at least $1 - 1/n^3$, the walk does not get stuck during its first $|A| - \lceil 8\log n\rceil$ steps.*

Proof. First, consider a random v. Let $Q_B = B$ and $Q_A = A$. Having already selected $b_1, a_1, \ldots, b_{i-1}, a_{i-1}$, the ith step of the walk consists of choosing an arbitrary $b_i \in Q_B \setminus \Gamma(a_{i-1})$ and discarding b_i from Q_B. It fails if $|Q_B \setminus \Gamma(a_{i-1})| = 0$, i.e., if a_{i-1} is connected to all nodes of Q_B. Let F_B^i be this failure event. This event is the intersection of $|Q_B|$ independent events of probability $1/2$ each. Note that at any step $|Q_B| \geqslant |B| - |A| \geqslant 32\log^2 n$; thus

$$\mathbb{P}(F_B^i) \;\leqslant\; \left(\frac{1}{2}\right)^{32\log^2 n} \;<\; \frac{1}{n^{32}}.$$

Then we choose $a_i \in Q_A \setminus \Gamma(b_i)$, discarding a_i from Q_A. Let F_A^i denote the event "$|Q_A \setminus \Gamma(b_i)| = 0$." It occurs if b_i is connected to all nodes of Q_A. This is the intersection of $|Q_A|$ independent events of probability $1/2$ each. Since $|Q_A| \geqslant 8\log n$,

$$\mathbb{P}(F_A^i) \;\leqslant\; \left(\frac{1}{2}\right)^{8\log n} \;=\; \frac{1}{n^8}.$$

Thus letting $F_i = F_A^i \cup F_B^i$ be the event that the walk fails at the ith step, we have

$$\mathbb{P}(F_i) \;<\; \frac{2}{n^8}.$$

Therefore, the walk fails within the first $|A| - \lceil 8\log n\rceil < n/2$ steps with probability

$$\mathbb{P}\left(\bigcup_i F_i\right) \;<\; \frac{1}{n^7}.$$

Finally, the probability that the walks from any of the nodes v fails is bounded by

$$\mathbb{P}\left(\bigcup_v \bigcup_i F_i\right) \;<\; \frac{1}{n^3}. \qquad \square$$

Let $\mathcal{E}_W$ denote the event that G does not satisfy the property asserted in Lemma 3.3. Henceforth, we ignore that possibility and restrict our attention to $\overline{\mathcal{E}_W}$.

Let the first segment of the walk consist of the following sequence of nodes:

$$b_1, a_1, b_2, a_2, \ldots, b_t, a_t.$$

At the end of the first stage, there are only $k = d - t = \lceil 8 \log n \rceil$ nodes remaining in A, $a_{t+1}, \ldots, a_d$, and more than $32 \log^2 n$ nodes in B. Partition the remaining nodes of B arbitrarily into $k+1$ groups of $4 \log n$ nodes each, denoted by $B_{t+1}, \ldots, B_{d+1}$. (The last group may be larger.)

The only thing that remains to do is to pick in each set B_i a distinct node b_i that neighbors both a_{i-1} and a_i, for $i \in \{t+1, \ldots, d\}$. The resulting second segment of the walk would be

$$b_{t+1}, a_{t+1}, \ldots, b_d, a_d.$$

This can be done with high probability again. (For the last step, of choosing b_{d+1}, we need only to verify that it neighbors a_d.)

LEMMA 3.4. *With probability at least* $1 - 1/n^3$, *the second segment of the walk can be completed successfully.*

Proof. The formal proof requires some care, since it is necessary to show that the events are independent. In particular, for the second stage, we are left with some nodes in A which were not chosen completely randomly, since these are nodes that perhaps were not connected to various nodes along the first segment of the walk. However, the events we look at in the second stage are independent of the events considered earlier. In particular, for each a_i and each $b \in B_i$, the events considered are "a_i is connected to b" and "a_{i-1} is connected to b," and these events are indeed independent of any event considered in the first stage, and of each other. Moreover, the probability of each such event is exactly $1/2$. Therefore,

$$\mathbb{P}(B_i \cap \Gamma(a_i) = \varnothing) \;\leqslant\; \frac{1}{2^{4 \log n}} \;=\; \frac{1}{n^4},$$

and similarly

$$\mathbb{P}(B_i \cap \Gamma(a_{i-1}) = \varnothing) \;\leqslant\; \frac{1}{n^4}.$$

Hence, letting $\mathcal{E}_{W'}$ denote the event that the property asserted in the lemma does not hold, we have

$$\mathbb{P}(\mathcal{E}_{W'}) \;\leqslant\; \frac{2(d-t)}{n^4} \;\leqslant\; \frac{1}{n^3}. \qquad \square$$

The combined path now consists of all nodes of A and $|A| + 1$ nodes of B, and the proof follows for linear intervals. To show that the lower bound holds also for nonstrict and nonlinear intervals, it remains to show the following lemma.

LEMMA 3.5. *With probability at least* $1 - 1/n^3$, *there is no node* $a \in A$ *connected to all nodes of* $B \setminus \{b_1, \ldots, b_{d+1}\}$.

Proof. Let $C = \{b_1, \ldots, b_{d+1}\}$. The probability that all the nodes of $B \setminus C$ are connected to a random node $a \in A$ is

$$\left(\frac{1}{2}\right)^{|B \setminus C|} \;<\; \frac{1}{n^4}$$

since $|B \setminus C| > 4 \log n$. Therefore, the probability that at least one node of A is connected to all of them of $B \setminus C$ is upper bounded by $|A|/n^4 < 1/n^3$. $\square$

Combining all possible failure events (namely, $\mathcal{E}_A$, Lemma 3.2, $\mathcal{E}_W$, Lemma 3.4, and Lemma 3.5), we obtain the following theorem.

THEOREM 3.6. *For sufficiently large* n, *with probability at least* $1 - 1/n^2$, *a random graph* $G \in \mathcal{G}_{n,1/2}$ *satisfies* $\mathrm{IRS}_A(G) \geqslant 3$. $\square$

4. Designer chosen labels. We next assume the designer model, in which the assignment of the node labels $\{1,\ldots,n\}$ to nodes is done by the designer of the routing scheme, aiming to minimize the number of intervals used by the routing scheme.

In this case, the only lower bound we have at the moment is the trivial $\mathrm{IRS}(G) \geqslant 1$ for every graph G. In the opposite direction, we are also unable so far to prove an upper bound of 1 on the maximum number of intervals per edge.

However, we will show that it is possible to assign the node labels in such a way that, while some edges might still require two intervals, the number of such violations will be very small, and more specifically, bounded by $O(\log^3 n)$ with high probability. In this section, we restrict our attention to the case $p = 1/2$, so $G \in \mathcal{G}_{n,1/2}$.

The idea behind the selection process is the following. Suppose that the node set of the given random graph is partitioned into cliques $V = C_1 \cup \cdots \cup C_m$. Label the nodes of V according to this partition, so that the nodes of each clique C_i are numbered consecutively. Now use this partition to define the routing scheme as follows. Consider a sender v_0. Suppose that $v_0 \in C_J$, and consider some other clique C_I. The central property we rely upon is that if v_0 is adjacent to *some* of the nodes of C_I, then all the nodes of C_I can be provided for using a single interval on each edge going from v_0 to the nodes of C_I, as follows. Let $C_I = \{p, p+1, \ldots, q\}$. If v_0 has a unique neighbor ℓ in C_I, then mark the edge from v_0 to ℓ by the interval $[p,q]$. Otherwise, suppose v_0 has neighbors $\ell_1 < \ell_2 < \cdots < \ell_k$ in C_I. Then the edges $e_j = (v_0, \ell_j)$ leading from v_0 to these nodes can be labeled by intervals $I(e_j)$, as follows:

$$I(e_j) = \begin{cases} [p, \ell_2 - 1], & j = 1, \\ [\ell_j, \ell_{j+1} - 1], & 1 < j < k, \\ [\ell_k, q], & j = k. \end{cases}$$

Note that this choice of intervals also takes care of the special case of $C_I = C_J$ itself, where every node other than v_0 itself is a neighbor of v_0.

Thus we are left only with the need of handling the cliques C_i, none of whose nodes are adjacent to v_0. Call these cliques the "remote" cliques. The nodes of these remote cliques must be reached through nodes of other cliques, potentially using additional intervals, and at worst using a unique new interval for each node. It is thus required to bound from above the maximum number of nodes in the remote cliques. Towards this goal, we rely intuitively on the fact that large cliques are unlikely to be remote. More precisely, the probability that a clique of size k is remote is roughly $1/2^k$. It thus becomes necessary to explore the distribution of clique sizes in a clique partition of random graphs or at least generate partitions with favorable size distributions.

We make use of the following two properties of random graphs. (In the following, the function log denotes the logarithm in base 2.) First, regarding the size of the maximum clique, we have (cf. Chapt. XI.1 of [2]) the following lemma.

LEMMA 4.1. *With probability at least* $1 - 1/n^{\log\log n}$, *the maximum clique in a random graph* $G \in \mathcal{G}_{n,1/2}$ *is of size at most* $2\log n$.

Let $\mathcal{E}_C$ denote the event that the random graph at hand does not satisfy the property asserted in Lemma 4.1. Henceforth, we ignore that possibility and restrict our attention to $\overline{\mathcal{E}_C}$. As before, we also restrict ourselves to $\overline{\mathcal{E}_A}$.

Second, we make use of a natural technique for generating a clique partition of a given graph. This technique is the "mirror image" of the greedy algorithm often used to generate a legal coloring for a graph. This simple algorithm operates as follows. Start by ordering the nodes arbitrarily, numbering them as $1, 2, \ldots, n$. Assign the nodes to cliques $C_1, C_2, \ldots, C_n$ one by one, assigning each node to the

smallest-indexed admissible clique. Node 1 is thus assigned to C_1, node 2 is assigned to C_1 if it is a neighbor of node 1, otherwise it is assigned to C_2, and so on. It is known (cf. Chapt. XI.3 of [2]) that with high probability this process will pack the nodes of the given random graph G in fewer than $n/\log n$ cliques. Moreover, analyzing the process in more detail, we will derive bounds on the number of small cliques generated. Specifically, there will be no more than $2^k \log n$ cliques of size k with high probability. Coupled with Lemma 4.1, this can be used to show that the total number of nodes in remote cliques is bounded (with high probability) by about

$$\sum_{k=1}^{2\log n} k \cdot \frac{1}{2^k} \cdot 2^k \log n = O(\log^3 n).$$

The problem that makes formalizing this argument somewhat more difficult is that once the partition is calculated, the graph can no longer be treated as random, as the fact, say, that v_0 is not in the clique C_i bears some implications on the probability that v_0 is connected to some node of C_i and prevents us from assuming that all the events considered in the analysis are independent. Nevertheless, the dependencies can be bounded and turn out to have little effect on the resulting probabilities.

Let us fix our attention on a node v_0, belonging to the clique C_J, and on another clique C_I. We would like to bound the probability that v_0 is not connected to any node of C_I.

For every clique C_i and node $v \in V$, partition C_i into $C_i = \mathcal{B}_i(v) \cup \mathcal{A}_i(v)$, where $\mathcal{B}_i(v)$ consists of all the nodes that entered C_i *before* v was considered by the algorithm, namely, $\mathcal{B}_i(v) = \{w \in C_i \mid w < v\}$, and $\mathcal{A}_i(v) = C_i \setminus \mathcal{B}_i(v)$, the nodes added to C_i *after* v was added to some clique. Let $\beta_i(v) = |\mathcal{B}_i(v)|$ and $\alpha_i(v) = |\mathcal{A}_i(v)|$. In particular, let $\mathcal{B} = \mathcal{B}_I(v_0)$, $\mathcal{A} = \mathcal{A}_I(v_0)$, $\beta = \beta_I(v_0)$, and $\alpha = \alpha_I(v_0)$.

LEMMA 4.2. *If $I < J$, then the probability that C_I is remote from v_0 is at most $1/2^{|C_I|-1}$.*

Proof. We will actually prove the somewhat stronger claim that if $I < J$, then the probability that v_0 is not connected to any node in C_I is $\frac{1}{2^\alpha(2^\beta-1)}$ that is at most $1/2^{|C_I|-1}$ because $\beta \geqslant 1$.

Since $I < J$, when the greedy algorithm considered v_0, it had to examine (and reject) the possibility of adding it to C_I before actually adding it to C_J. The fact that v_0 was not added to C_I implies that there is some node in $\mathcal{B}$ that does not neighbor v_0. However, of all 2^β possible connection configurations between v_0 and the nodes of $\mathcal{B}$, the event $\mathcal{E}_N =$ "v_0 has a nonneighbor in $\mathcal{B}$" excludes only the possibility that v_0 neighbors all nodes of $\mathcal{B}$ and leaves us with $2^\beta - 1$ other possibilities. Hence, conditioned on $\mathcal{E}_N$, we have

$$\mathbb{P}(v_0 \text{ has no neighbors in } \mathcal{B}) \;=\; \frac{1}{2^\beta - 1}.$$

As for the nodes of $\mathcal{A}$, each such node v was added to C_I after v_0 was considered, and since $I < J$, the decision to add v into C_I was reached before considering clique C_J, and hence it was independent of the existence (or nonexistence) of the edge (v, v_0). Hence,

$$\mathbb{P}(v_0 \text{ has no neighbors in } \mathcal{A}) \;=\; \frac{1}{2^\alpha}.$$

The lemma follows. ∎

LEMMA 4.3. *If $I > J$, then the probability that C_I is remote from v_0 is at most*

$$\frac{1}{2^\beta} \cdot \prod_{v \in \mathcal{A}} \frac{2^{\beta_J(v)-1}}{2^{\beta_J(v)}-1}.$$

Proof. Since $I > J$, when the greedy algorithm considered each node v of C_I, it had to first examine (and reject) the possibility of adding it to C_J. For $v \in \mathcal{B}$, the decision not to add v to C_I was clearly independent of the edge (v, v_0). (Note that in fact $v_0 \in \mathcal{A}_J(v)$.) Hence,

$$\mathbb{P}(v_0 \text{ has no neighbors in } \mathcal{B}) \;=\; \frac{1}{2^\beta}.$$

It remains to consider nodes $v \in \mathcal{A}$.

The fact that a node $v \in \mathcal{A}$ was not added to C_J implies that there exists a node in $\mathcal{B}_J(v)$ that does not neighbor v. However, again, of all $2^{\beta_J(v)}$ possible connection configurations between v and the nodes of $\mathcal{B}_J(v)$, the event $\mathcal{E}_N(v)$ = "v has a nonneighbor in $\mathcal{B}_J(v)$" excludes only the possibility that v neighbors all nodes of $\mathcal{B}_J(v)$ and leaves us with $2^{\beta_J(v)} - 1$ other possibilities. Of those, v neighbors v_0 in exactly $2^{\beta_J(v)-1}$ possibilities. Hence, conditioned on $\mathcal{E}_N(v)$, the probability that v does not neighbor v_0 is $\frac{2^{\beta_J(v)-1}}{2^{\beta_J(v)}-1}$. Hence,

$$\mathbb{P}(v_0 \text{ has no neighbors in } \mathcal{A}) \;=\; \prod_{v \in \mathcal{A}} \frac{2^{\beta_J(v)-1}}{2^{\beta_J(v)}-1}.$$

The lemma follows. □

The product appearing in the bound of Lemma 4.3 is small only when the values $\beta_J(v)$ involved in it are sufficiently large. Fortunately, there cannot be too many nodes v with small $\beta_J(v)$ values, as we prove next.

For integer $k \geqslant 1$, let $X_J(k)$ denote the set of nodes v that were considered by the algorithm during the period when C_J contained exactly k nodes and were rejected from C_J. In particular, we are interested in the collection of such nodes for small values of k, i.e., $\hat{X} = \bigcup_{k=1}^{\log\log n} X_J(k)$.

COROLLARY 4.4. *Suppose that the clique C_I, $I > J$, contains no node from $\hat{X}$. Then the probability that v_0 is not connected to any node in C_I is at most $\gamma/2^{|C_I|}$ for some fixed constant $\gamma > 1$.*

Proof. Under the assumption of the corollary, $\beta_J(v) > \log\log n$ for every $v \in \mathcal{A}$. Therefore,

$$\frac{2^{\beta_J(v)-1}}{2^{\beta_J(v)}-1} \;=\; \frac{1}{2}\left(1 + \frac{1}{2^{\beta_J(v)}-1}\right) \;\leqslant\; \frac{1}{2}\left(1 + \frac{1}{2^{\log\log n+1}-1}\right) \;\leqslant\; \frac{1}{2}\left(1 + \frac{1}{\log n}\right).$$

The bound of Lemma 4.3 thus becomes

$$\frac{1}{2^\beta} \cdot \left(\frac{1}{2}\left(1 + \frac{1}{\log n}\right)\right)^\alpha.$$

As the size of the maximum clique in a random graph is at most $2\log n$ (with probability at least $1 - 1/n^{\log\log n}$), this bound is no greater than

$$\frac{1}{2^\beta} \cdot \frac{1}{2^\alpha}\left(1 + \frac{1}{\log n}\right)^{2\log n} \;\leqslant\; \frac{1}{2^{\beta+\alpha}} \cdot e^2,$$

and the claim follows. □

LEMMA 4.5. *With probability at least* $1-1/n^3$, *the set* $X_J(k)$ *is of size* $|X_J(k)| \leqslant 2^{k+2}\ln n$ *for every* $k \geqslant 1$.

Proof. Suppose that $|X_J(k)| > 2^{k+2}\ln n$. For every $v \in X_J(k)$, the probability for v not joining C_J (on account of a missing edge from v to some node in C_J) is $1-1/2^k$. Thus the probability of all of those nodes being rejected from C_J is

$$\left(1-\frac{1}{2^k}\right)^{|X_J(k)|} \;<\; \left(1-\frac{1}{2^k}\right)^{2^{k+2}\ln n} \;\leqslant\; e^{-4\ln n} \;=\; \frac{1}{n^4}.$$

Summing these probabilities over all k yields the desired claim. □

Let $\mathcal{E}_D$ denote the event that the random graph at hand does not satisfy the property asserted in Lemma 4.5. Henceforth, we ignore that possibility and restrict our attention to $\overline{\mathcal{E}_D}$. Under this restriction, the size of the set $\hat{X}$ is bounded above by

$$|\hat{X}| \leqslant \sum_{k=1}^{\log\log n} 2^{k+2}\ln n = O(\log^2 n).$$

It remains to bound the number of remote cliques C_I (that have no neighbor of v_0). Let $f(k)$ denote the number of cliques of size k.

LEMMA 4.6. *With probability at least* $1-1/n^2$, $f(k) \leqslant 2^{k+2}\ln n$ *for every* $k \geqslant 1$.

Proof. Let us bound the probability of the event that there are more than $2^{k+1}\log n$ cliques of size k, $C_{i_1},\ldots,C_{i_{f(k)}}$. Let $m = 2^{k+2}\ln n$ and consider the time when clique C_{i_m} was formed by the greedy algorithm (for the purpose of hosting the currently inspected node v'). For any node v considered after v', the probability that it could not have joined the clique C_{i_j} is

$$1-\frac{1}{2^{\beta_{i_j}(v)}} \;\leqslant\; 1-\frac{1}{2^k}.$$

Hence, the probability that v could not have joined any of those m cliques is at most

$$\left(1-\frac{1}{2^k}\right)^m \;\leqslant\; \left(1-\frac{1}{2^k}\right)^{2^{k+2}\ln n} \;\leqslant\; e^{-4\ln n} \;=\; \frac{1}{n^4}.$$

Consequently, the probability that any of the remaining nodes to be considered by the algorithm after v' could not join an existing clique, and a new clique must be formed, is at most $1/n^3$. Summing these probabilities for every k, the lemma follows. □

Let $\mathcal{E}_H$ denote the event that the random graph at hand does not satisfy the property asserted in Lemma 4.6. Henceforth, we ignore that possibility and restrict our attention to $\overline{\mathcal{E}_H}$.

LEMMA 4.7. *The number of remote cliques is at most* $O(\log^2 n)$ *with probability* $1-1/n^2$.

Proof. Assuming event $\overline{\mathcal{E}_D}$, the total number of remote cliques that contain a node of $\hat{X}$ is at most $O(\log^2 n)$. It remains to count the remote cliques among the cliques that do not contain any node of $\hat{X}$. The probability of such a clique C_I being remote is bounded, in Lemma 4.2 and Corollary 4.4, by $\delta/2^{|C_I|}$ for some constant $\delta > 1$.

For every clique C_i of size k, let R_i be the event that C_i is remote. Let R be a random variable representing the number of remote cliques of size k, and let $f_R(k)$

denote its expectation. Since R is the sum of $f(k)$ Bernoulli random variables R_i, each with probability $\delta/2^k$, $f_R(k)$ is at most $\delta f(k)/2^k$. Assuming event $\overline{\mathcal{E}_H}$, we have

$$f_R(k) \leqslant \frac{\delta 2^{k+2} \ln n}{2^k} = 4\delta \ln n.$$

Applying Chernoff's bound, we get that

$$\mathbb{P}(R \geqslant 8\delta \ln n) < \exp(-2\delta \ln n) = n^{-2\delta} < \frac{1}{n^2}.$$

Hence, for the cliques not containing any nodes from $\hat{X}$, with probability at least $1-1/n^2$, the total number of remote cliques of any size k is bounded (recalling Lemma 4.1) by $O(\log^2 n)$.

Combining both clique types together, we get the claim of the lemma. □

It follows that for every v_0, the number of "problematic" nodes (namely, those of remote cliques) that need to be assigned an individual interval is bounded by $O(\log^3 n)$ with probability $1 - 1/n$.

Combining all possible failure events (namely, $\mathcal{E}_A \cup \mathcal{E}_C \cup \mathcal{E}_D \cup \mathcal{E}_H$), we get that for a random graph in $\mathcal{G}_{n,1/2}$, with probability at least $1-1/n$, it is possible to assign node labels and design an interval routing scheme in such a way that for every node v_0, there is a single interval on every edge except at most $O(\log^3 n)$ edges with two intervals each. (Spreading the problematic nodes so that each adds an interval to a different edge is done by a greedy process similar to those of sections 2.1 and 3.) We remark that the intervals used in the scheme are linear and strict.

THEOREM 4.8. *For sufficiently large n, with probability at least $1-1/n$, a random graph $G \in \mathcal{G}_{n,1/2}$ can be given an assignment of node labels and a shortest path interval routing scheme (polynomial time constructible) using a single interval per edge, except for at most $O(\log^3 n)$ edges per node where two intervals must be used.* □

COROLLARY 4.9. *For almost every n-node graph G there exists an assignment of node labels from the set $\{1, \ldots, n\}$ and a shortest path routing scheme using at most $n + O(\log^4 n)$ bits of information per node. Moreover, the routing scheme is constructible in polynomial time.*

Proof. Assume G satisfies Theorem 4.8. The interval routing scheme on G can be implemented in each node by a table of $O(\log^3 n)$ integers and a binary vector of n bits. Indeed, every 1-IRS can be implemented in each node in $n + O(\log n)$ bits (cf. [6]). Note that the $O(\log^3 n)$ problematic nodes contribute for at most $O(\log^3 n)$ single intervals, each one composed of exactly one node label. We store in a table of $O(\log^3 n)$ entries the label of these nodes and the output port number that makes an overhead of $O(\log^4 n)$ bits in total. These nodes are treated as exceptions and checked first in the routing process. Therefore, the label of these nodes can be merged to the remaining intervals in order to simulate a 1-IRS. □

Acknowledgment. The authors thank the anonymous referee for calling their attention to some inaccuracies in the original version of the paper and making a number of suggestions that improved the presentation.

TOPOLOGICAL LOWER BOUNDS ON ALGEBRAIC RANDOM ACCESS MACHINES*

AMIR M. BEN-AMRAM† AND ZVI GALIL†

Abstract. We prove general lower bounds for set recognition on random access machines (RAMs) that operate on real numbers with algebraic operations $\{+, -, \times, /\}$, as well as RAMs that use the operations $\{+, -, \times, \lfloor\ \rfloor\}$. We do it by extending a technique formerly used with respect to algebraic computation trees. In the case of algebraic computation trees, the complexity was related to the number of connected components of the set W to be recognized. For RAMs, four similar results apply to the number of connected components of W°, the topological interior of W. Two results use $(\overline{W})^\circ$, the interior of the topological closure of W.

We present theorems that can be applied to a variety of problems and obtain lower bounds, many of them tight, for the following models:

1. A RAM which operates on real numbers, using integers to address memory and either the operations $\{+, -, \times, /\}$ or $\{+, -, \times, \lfloor\ \rfloor\}$.

2. A RAM of each of the above instruction sets, extended by allowing arbitrary real numbers to be used as memory addresses and adding a test-for-integer instruction.

3. A RAM of each of the above instruction sets which can compute with arbitrary real numbers, as well as use them for memory addressing, while the input is restricted to the integers. (For one result on this model, we require that all program constants be rational.)

Key words. algebraic computation trees, element distinctness, knapsack, component counting arguments

1. Introduction.

Consider a set $W \subset \Re^n$ and the problem of recognizing W. Ben-Or proved that an algebraic computation tree recognizing W requires height that is at least a logarithm of the number of path-connected components[1] of W [2]. For the exact statement see Theorem 3.1 in section 3. Yao proved that under certain conditions, an ACT recognizing *integer* elements of W requires a height that is at least a logarithm of the number of connected components of W that have a nonempty interior [19]. For the exact statement see Theorem 3.2 in section 3. The question we ask and answer in this paper is, Can we prove similar results for random access machine models with powerful instruction sets?

A well-known example, the element distinctness problem, is defined by $W = \{x \in \Re^n |\ x_i \neq x_j \text{ for } 1 \leq i \neq j \leq n\}$. Both Ben-Or and Yao used their theorems to obtain (as an easy corollary) an $\Omega(n \log n)$ lower bound on the height of a computation tree that solves this problem. However on a random access machine (RAM), the problem can be easily solved in time $O(n)$ by storing a flag in address x_i for $i = 1, \ldots, n$. This indicates that perhaps the answer to our question above is negative. On the other hand, this solution may perhaps be ruled out: If the x_i are real numbers, can we expect to be able to use them as memory addresses? We return to this question,

[1]It turns out that in applying this result, as well as all other theorems given in this paper, it never becomes necessary to distinguish path-connectedness from connectedness. Therefore, we neglect this distinction througout.

for the case of real-number input, later on. However, in the case of integer input, the objection does not arise, so in this setting it is clear that the applicability of computation-tree lower bounds to the RAM should be questioned. Interestingly, our results for the integer-constrained model are obtained using the techniques developed for the unconstrained case.

We start by making a couple of simple observations concerning Ben-Or's and Yao's theorems. We show that Ben-Or's theorem still holds if, instead of counting the connected components of W, we count those of W°, the interior of W. For some sets, this yields a stronger result; for others, the original version is stronger. We can also make the same modification to Yao's theorem, obtaining a result which is always at least as strong as in his formulation, and further gives these two theorems a more similar form. The importance of these observations is that they hint that one may obtain results on the complexity of recognizing W by counting the components of a *different, related set*; this twist turns out to be crucial for our results on random access machines.

Our first new results are corresponding theorems for the real-number algebraic RAM, i.e., a RAM with operations $\{+, -, \times, /\}$. We consider two main variants of this model. In the standard variant, only integers may be used to address memory locations. For this variant, we prove that recognizing W requires time that is at least a logarithm of the number of connected components of W°, as in our version of Ben-Or's theorem.

Referring again to the element distinctness problem, the proofs of the lower bounds in [2] and [19] use a set W such that both W and W° have $n!$ connected components. Thus the lower bound of $\Omega(n \log n)$ time applies to this model.

We also consider a "nonstandard" model which allows arbitrary real numbers to be used as addresses. For this model we prove that the time to recognize W is at least a logarithm of the number of connected components of $(\overline{W})^\circ$, the interior of the closure of W. The result also holds if an instruction is added to the model, which tests (at unit cost) whether a given value is an integer.

In the case of Element Distinctness, it turns out that $(\overline{W})^\circ$ consists of a single component. This explains why the lower bound for Element Distinctness cannot be obtained under this model, and indeed it supports the fast algorithm suggested above.

We also show that under conditions similar to those required by Yao, recognizing integer elements of W requires at least a logarithm of the number of connected components of $(\overline{W})^\circ$, just as in the case of real input.

We proceed to consider the truncation operation, also known as *floor*. We show that results very similar to the above three propositions also hold for corresponding models with operations $\{+, -, \times, \lfloor\ \rfloor\}$. Note that the integrality-test operation, allowed in one of the previous results, can be simulated in a straightforward way using *floor*; however, incorporating the full power of *floor* in our theorems forces us to leave *division* out. This is justified by the fact that certain problems (subject to our previous lower bounds) have faster algorithms on the model that combines *floor* with division. A well-known example is Gonzalez's algorithm for the *max gap* problem [16] which runs in linear time, contrasting an $\Omega(n \log n)$ lower bounds given by our theorems. Another example of this kind is a linear-time algorithm for the decision problem Min Gap, which is given in the appendix.

The six lower-bound theorems are given in section 3.

In section 4 we consider a dozen of examples of set-recognition problems. In some cases the lower bounds proved for algebraic computation trees also apply to random

access machines, while in some other cases they do not. In most of the latter cases, we are able to show that like in the case of element distinctness, a linear time algorithm exists on the RAM. The two exceptions are the knapsack problem and the generalized knapsack problem. We remark that in these two problems the computation-tree lower bound is larger than $O(n \log n)$. The significance of this fact will be seen later on.

Sections 5–7 are concerned with proving the above theorems. An important tool in the proofs is a technique that was introduced by Paul and Simon [15]. Informally, if a RAM recognizes a set W in time bounded by t, we are able to build a computation tree of height t that recognizes a set V, such that V approximates W in a certain sense. We develop this basic idea into six lemmas that are used in the proofs of the six theorems. An additional idea which is used in the last result, involving the truncation operation in conjunction with integer input, draws from work of Lürwer-Brüggemeier and Meyer auf der Heide [9]. This result requires that the program only use rational constants.

We now review some related results. Paul and Simon applied their technique to prove that arithmetic RAMs (later extended to algebraic RAMs [5]) do not perform better than decision trees for certain problems where decision-tree lower bounds are known (e.g., sorting). Using the same technique, Klein and Meyer auf der Heide extended in [8] the $\Omega(n^2)$ lower bound for *knapsack* (which was known for computation trees [6]) to a RAM which can only add and subtract (but not multiply or divide), and in [12] a generalized knapsack problem was considered. These papers already used component counting together with the Paul–Simon technique, but in a direct fashion (i.e., they count the components of W). This is made possible by the simple structure of sets recognized by this restricted model.

In another paper [13], Meyer auf der Heide stated a result that allows lower bounds for computation trees to be converted to RAM lower bounds, where the RAM may use all the operations that are allowed in the computation tree; hence, in our case, it may be used to infer lower bounds for algebraic RAMs. The result is given by the following lemma.

LEMMA 1.1. *Given a real-number RAM program P, we can construct an algebraic computation tree T that computes the same function, and whenever P takes t time units to process a certain input, the corresponding path in the tree is of length $O(t \log(n + t))$.*

A detailed proof is given in [1]. From this lemma it follows that a lower bound of $f(n)$ for a computation tree implies a lower bound of $\Omega(f(n)/\log(n + f(n)))$ for the RAM. Thus this theorem implies a nonlinear lower bound for the RAM only if the computation-tree lower bound is larger than $\Omega(n \log n)$, and it can never show that the complexity on the RAM is the same as in an algebraic computation tree. These gaps may be closed by our results.

The power of *floor* in computation trees has been investigated in numerous papers [3, 4, 5, 7, 9, 10, 11]; Mansour, Schieber, and Tiwari [10] also extend their lower bound technique to random access machines. It applies to a rational-number RAM with operations $\{+, -, \times, /, \lfloor\ \rfloor\}$ and an initially zero memory. This result, and most of the others, relate to problems where the time of computation depends on the size of the input value or values. In contrast, in this paper we consider *genuinely time-bounded computations* [13], namely programs whose running time is bounded by a function of n, the number of input values. Among the above papers, lower bounds for genuinely time-bounded computations appear only in [9].

All of the above results do not allow the RAM to use preinitialized tables. On the

contrary, all our lower bounds allow the program to make use of finite tables, whose size and contents may depend on n. This means, in particular, that they apply to nonuniform programs in the usual sense (i.e., the program code depends on n).

In our lower bounds for problems with real input, we allow an even stronger model: All memory cells of integer addresses may be assumed to contain initial values that depend on n. This very strong extension cannot be allowed when the input is an integer, for then it allows every problem to be solved in linear time. We sketch the way this can be done: First encode the input n-tuple in a single number, using repeated application of a standard pairing function; e.g., $\pi(x, y) = (x+y)^2 + x$. Then use this number to index an infinite table that contains all the right answers. The correctness of the procedure follows from the injectivity of the pairing function.

2. Preliminaries. In this section we define our models of computation and list some mathematical notation used in expressing the results as well as in the proofs.

2.1. Models of computation. An *algebraic computation tree* models a computational process in which each step has one of the following types: (i) an assignment $z \leftarrow u$; (ii) an arithmetic operation $z \leftarrow u \circ w$, where $\circ \in \{+, -, \times, /\}$; (iii) a comparison $u : 0$. The variables u, w stand for either input variables (denoted $x_1, \ldots, x_n$) or the results of prior computation, while z stands for a new variable name (thus every variable is only assigned once).

Computation starts at the root and proceeds down the tree as follows: Each arithmetic node has one child, which is its successor. Each comparison node has three children associated with the possibilities $>$, $<$, and $=$. Computation proceeds along the appropriate branch. Each leaf is labeled with a constant or a variable that represents the output of the computation. An algebraic computation tree is said to *recognize a set* if each output is a 0 or a 1, where the value of 1 represents acceptance. (Note that we may assume that the output value is a constant rather than a variable; otherwise, add a test, and have distinct leaves for acceptance and rejection.) The tree is said to recognize $W \subseteq \Re^n$ when an accepting leaf is reached if and only if $(x_1, \ldots, x_n) \in W$. The tree is said to recognize W for a restricted set of inputs (e.g., the integers) if the last condition is fulfilled for inputs of this set; it does not matter which leaf is reached for other inputs.

We denote by $h(T)$ the height of the tree T, which represents the worst-case time complexity of the computation described by T (more precisely, an upper bound on it; the height is precisely the worst-case time, if every leaf is reachable).

All *RAMs* share the following structure. The machine consists of a processing unit and a memory unit. The processing unit runs the program; to this end it contains a "program counter" that points to the next instruction to be executed. (The different instructions are described below.) It also makes use of a finite set of *operating registers* $r_1, \ldots, r_k$, whose number is fixed for any given program, as they can only be accessed by being named in an instruction. These registers are used for all arithmetics and tests, leaving the *memory* with the sole role of data storage.

This description is still quite general and is made specific by the choice of three parameters.

The *domain* $\mathcal{D}$ is the set of values that may be manipulated by the machine as "units of data." Every memory cell or operating register holds one element of $\mathcal{D}$. This set is the integers or natural numbers in classical RAM models and the real numbers or rational numbers in the models considered in this paper.

The *address space* $\mathcal{A}$ is the set of values that may be used as memory addresses. Thus the size of memory is $|\mathcal{A}|$, and the standard idealized model uses $\mathcal{A} = \mathbb{N}$. In

case that $\mathcal{A}$ is strictly contained in $\mathcal{D}$, a program may *fault* by attempting to use a value in $\mathcal{D} \setminus \mathcal{A}$ as an address. In this case the program may be considered invalid, or we may consider its result to be $\perp$.

The *set of primitives* $\mathcal{F}$ defines the functions that can be computed by the so-called arithmetic instructions. We call the RAM *algebraic* if $\mathcal{F}$ consists of the field operations $\{+, -, \times, /\}$. In this paper, we will also consider the nonalgebraic operations $\lfloor\ \rfloor$ (truncation to an integer) and $\chi_{\mathbb{Z}}$. (The characteristic function of $\mathbb{Z}$ can be used to test whether a given value is an integer.)

The instruction set of the RAM contains the following groups. In the notation for instructions, r_i, r_j, r_k are register names; x is a constant from $\mathcal{D}$. The notation $\langle r_i \rangle$ refers to the memory cell whose address is given by the contents of r_i.

Direct assignments:

$$r_i \leftarrow x$$
$$r_i \leftarrow r_j$$

Memory access:

$$\langle r_i \rangle \leftarrow r_j$$
$$r_j \leftarrow \langle r_i \rangle$$

Flow control instructions:

jump *label*
if $r_i \bowtie r_j$ jump *label*
$\bowtie \in \{=, <, \leq, \ldots\}$
halt

Arithmetic instructions:

$$r_i \leftarrow r_j + r_k$$
$$r_i \leftarrow r_j - r_k$$

etc., as provided by $\mathcal{F}$.

For every RAM program, the initial contents of memory cells is assumed to be zero, except for those that hold the input, and possibly another set of cells, whose contents and size may depend on n but not on the input values; thus we allow nonuniform solutions. Finally, *set recognition* by a RAM is defined as for a computation tree.

We use the notation (D, A, F)-RAM for a model where $\mathcal{D}$, $\mathcal{A}$, and $\mathcal{F}$ have the values D, A, and F, respectively.

A *real-number RAM* is a RAM where $\mathcal{D} = \Re$. Its main justification is as a convenient model for studying problems on real numbers, e.g., in computational geometry; but it is possible that a problem on integer inputs will be solved faster by a program which uses the power of the real-number RAM. Thus, we consider the real-number RAM also in conjunction with integer-constrained problems. (In fact, geometrical problems are often encountered in practice with integer-constrained input, because of the use of raster devices and digitized data.)

We consider two variants of the real-number RAM. The "standard" version has $\mathcal{A} = \mathbb{N}$, while a stronger, nonstandard version has $\mathcal{A} = \Re$. The last choice seems at first to be a far-fetched idealization; however, it may not be so far-fetched in practice. One may think of the real-number RAM as an abstraction of an actual computer

which works with a finite representation of real values, say in floating point. In this case, these representations may be used to address an ordinary random-access memory. Another justification for using an idealized model is that it is elucidates problems; and in fact, it is via our analysis of this model that some of our best results for integer-constrained input (even on the integer RAM) have been obtained.

Finally, in certain results, we are able to allow the program to initialize all integer-addressed memory cells at no cost. This is a stronger extension than ordinary use of finite tables.

2.2. Various notation and terms. For a set $W \subseteq \Re^n$, let $\beta(W)$ be the number of connected components in W. As customary, we denote by W° the topological interior of W, and by $\overline{W}$ its closure. (We use the usual Euclidean topology.) The boundary of W is $\partial W = \overline{W} \setminus W^\circ$ and is a boundary set, i.e., a set of empty interior. (So far, the definitions apply to any metric space.)

A set $W \subseteq \Re^n$ is called *scale invariant* if $\mathbf{x} \in W$ implies $\lambda\mathbf{x} \in W$ for all real $\lambda > 0$. A set $W \subseteq \Re^n$ is said to be *rationally dispersed* if, for every $\mathbf{x} \in \Re^n$ and $\varepsilon > 0$, there is a rational point $\mathbf{z}$ such that $\|\mathbf{z} - \mathbf{x}\| < \varepsilon$ and $(\mathbf{z} \in W \iff \mathbf{x} \in W)$.

We denote by $\hat{\beta}(W)$ is the number of connected components of W which have nonempty interior (called *primary*).

For real $\lambda > 0$, let $B(\lambda, \mathbf{x})$ be the open ball of radius λ centered at $\mathbf{x}$. For $W \subseteq \Re^n$, and $\mathbf{x} \in \Re^n$, we define

$$\tilde{\beta}(W, \mathbf{x}) = \limsup_{\lambda \to 0^+} \beta(W \cap B(\lambda, \mathbf{x}))$$

and

$$\tilde{\beta}(W) = \tilde{\beta}(W, \mathbf{0}),$$

where $\mathbf{0}$ denotes the origin of $\Re^n$.

The following constants appear in our theorems: $c_1 = \frac{1}{1+2\log_2 3}$ and $c_2 = 1 + \frac{\log_2 3}{1+2\log_2 3}$.

3. Lower-bound theorems. In this section we give a list of lower-bound theorems: first, we give results on computation trees, following Ben-Or [2] and Yao [19].

THEOREM 3.1 (Ben-Or). *Let T be an algebraic computation tree that recognizes $W \subseteq \Re^n$. Then*

$$h(T) \geq \log_9 \beta(W) - \frac{1}{2}n.$$

A simple modification of Ben-Or's proof (which we give below) proves the following theorem.

THEOREM 3.1′. *Let T be an algebraic computation tree that recognizes $W \subseteq \Re^n$. Then $h(T) \geq \log_9 \max(\beta(W^\circ), \beta(W)) - \frac{1}{2}n$.*

Theorem 3.1′ gives a stronger result for some sets, where $\beta(W^\circ) > \beta(W)$. (There are sets where it is smaller; this the reason for the max operator.)

THEOREM 3.2 (Yao). *Let $W \subseteq \Re^n$ be scale invariant and rationally dispersed. If T is an algebraic computation tree that recognizes W for integer input, then*

$$h(T) \geq c_1(\log_2 \hat{\beta}(W) - 1) - c_2 n.$$

A simple modification of Yao's proof (which we give below) yields the following theorem.

THEOREM 3.2′. *Let $W \subseteq \Re^n$ be scale invariant and rationally dispersed. If T is an algebraic computation tree that recognizes W for integer input, then*

$$h(T) \geq c_1(\log_2 \beta(W^\circ) - 1) - c_2 n.$$

This modification always gives a result stronger or equal to the former (see Lemma 5.7 in section 5).

The main results of this paper are theorems for various RAM variants. To clarify the picture, we give a summary of the results in Table 1. In this table, only the leading term of the lower bound is given, without constant coefficient and other details. The table also includes comments on the question, Could it be possible to obtain stronger results by allowing larger sets of addresses, operations, etc.? The precise statement of the lower bound results is given by the theorems below.

THEOREM 3.3. *Let $W \subseteq \Re^n$. If W is recognized in time $t(n)$ on $(\Re, \mathbb{N}, \{+, -, \times, /\})$-RAM, then*

$$t(n) \geq \log_9 \beta(W^\circ) - \frac{1}{2}n\,.$$

The program may specify arbitrary initial values for all memory cells.

THEOREM 3.4. *Let $W \subseteq \Re^n$. If W is recognized in time $t(n)$ on $(\Re, \Re, \{+, -, \times, /, \chi_{\mathbb{Z}}\})$-RAM, then*

$$t(n) \geq \log_9 \beta((\overline{W})^\circ) - \frac{1}{2}n\,.$$

The program may specify arbitrary initial values for all memory cells of integer addresses.

THEOREM 3.5. *Let $W \subseteq \Re^n$ be scale invariant and rationally dispersed. If W is recognized for integer input in time $t(n)$ on $(\Re, \Re, \{+, -, \times, /, \chi_{\mathbb{Z}}\})$-RAM, then*

$$t(n) \geq c_1(\log_2 \beta((\overline{W})^\circ) - 1) - c_2 n\,.$$

The program may use a finite initialized table.

THEOREM 3.6. *Let $W \subseteq \Re^n$. If W is recognized in time $t(n)$ on $(\Re, \mathbb{N}, \{+, -, \times, \lfloor\ \rfloor\})$-RAM, then*

$$t(n) \geq \frac{1}{3}(\log_9 \max(\tilde{\beta}(W^\circ), \tilde{\beta}(W)) - 1) - \frac{5}{6}n.$$

The program may specify arbitrary initial values for all memory cells.

THEOREM 3.7. *Let $W \subseteq \Re^n$. If W is recognized in time $t(n)$ on $(\Re, \Re, \{+, -, \times, \lfloor\ \rfloor\})$-RAM, then*

$$t(n) \geq \frac{1}{3}(\log_9 \tilde{\beta}((\overline{W})^\circ) - 1) - \frac{5}{6}n\,.$$

The program may specify arbitrary initial values for all memory cells of integer addresses.

THEOREM 3.8. *Let $W \subseteq \Re^n$ be scale invariant and rationally dispersed. If W is recognized for integer input in time $t(n)$ on $(\mathbb{Q}, \mathbb{Q}, \{+, -, \times, \lfloor\ \rfloor\})$-RAM, then*

$$t(n) \geq \frac{1}{2}c_1(\log_2 \beta((\overline{W})^\circ) - 1) - \frac{1}{2}c_2 n\,.$$

The program may use a finite initialized table.

TABLE 1
RAM lower bounds.

$\Re^n$	$\Re$	$\Re$	$\{+,-,\times,/,\chi_{\mathbb{Z}}\}$	$\aleph_0$	$\log \beta((\overline{W})^\circ)$
$\mathbb{Z}^n$	$\Re$	$\Re$	$\{+,-,\times,/,\chi_{\mathbb{Z}}\}$	finite$^{(2)}$	$\log \beta((\overline{W})^\circ)$
$\Re^n$	$\Re$	$\mathbb{N}^{(1)}$	$\{+,-,\times,\lfloor\ \rfloor\}$	$\aleph_0$	$\log \max(\tilde{\beta}(W^\circ), \tilde{\beta}(W))$
$\Re^n$	$\Re$	$\Re$	$\{+,-,\times,\lfloor\ \rfloor\}$	$\aleph_0$	$\log \tilde{\beta}((\overline{W})^\circ)$
$\mathbb{Z}^n$	$\mathbb{Q}^{(3)}$	$\mathbb{Q}$	$\{+,-,\times,\lfloor\ \rfloor\}$	finite$^{(2)}$	$\log \beta((\overline{W})^\circ)$

(1) Cannot allow $\Re$ here, as shown by the element distinctness problem.
(2) Cannot allow $\aleph_0$ here, as illustrated in the introduction.
(3) $\Re$ could possibly be allowed (open problem).

4. Applications. We give some examples of problems for which lower bounds can be proved as corollaries of our theorems. Each problem is presented as a set recognition problem, the set always denoted by W.

In applying Theorems 3.5 and 3.8, we have to make sure that the set in question is rationally dispersed as well as scale invariant. All the sets we consider will be of this type. This will also facilitate the application of Theorems 3.6 and 3.7, where $\tilde{\beta}$ is used instead of β, due to the following simple property.

FACT 4.1. *If W is scale invariant, then $\beta(W) = \tilde{\beta}(W)$.*

Interestingly, all the sets that appear in our list of examples but one belong to a special family, where the desired features can be proved to hold in general.

LEMMA 4.2. *Let W be a subset of $\Re^n$ that is defined by a Boolean combination of linear homogeneous (in)equalities with integer coefficients. Then W is scale invariant and rationally dispersed.*

Proof. According to the assumptions of the lemma, there are homogenous linear forms $l_1, \ldots, l_r$, of integer coefficients, such that W is defined by a Boolean combination of the formulae: $(l_i > 0)$, $(l_i = 0)$, and $(l_i < 0)$, where $1 \le i \le r$.

Homogenity of the l_i implies that replacing $\mathbf{x}$ with $\lambda\mathbf{x}$, for any real $\lambda > 0$, does not change the truth value of any of the (in)equalities. Hence W is scale invariant. We now prove rational dispersal. Let $\mathbf{x} \in W$ and $\varepsilon > 0$. We have to prove the existence of a rational point $\mathbf{z}$ such that $\|\mathbf{z} - \mathbf{x}\| < \varepsilon$ and $\mathbf{z} \in W$. We do not have to treat the case $\mathbf{x} \notin W$ separately, because the complement of W is also a Boolean combination of the same inequalities.

We make the following nonrestrictive assumptions on the formula defining W.

(1) There are no negations. (To achieve this, replace $\neg(l_i = 0)$ by $(l_i < 0) \vee (l_i > 0)$, etc.)

(2) All inequalities are of the form $l_i > 0$. (Otherwise use $-l_i$ instead.)

Now assume that $\mathbf{x}$ is in W because it satisfies the following conditions:

$$l_1 > 0, \ldots, l_r > 0, l_{r+1} = 0, \ldots, l_{r+s} = 0\,.$$

Because of assumption (1), every point that satisfies these conditions will also be in W. Let S be the set defined by the inequalities alone; it is a nonempty, open set. In particular, there is a neighborhood of $\mathbf{x}$, say of radius ε_1, that lies entirely in S.

Next we concentrate on the equalities. These s equations define a nonempty linear subspace L of $\Re^n$, say of dimension k. By elementary linear algebra, we can express this subspace as the graph of a linear function of k *independent* variables. Without

†No lower bound from Theorem 3.3, but $\Omega(n \log n)$ from Theorem 3.6.

‡From Meyer auf der Heide's Lemma (section 1).

loss of generality, let these variables be $x_1, \ldots, x_k$; then L is defined by

$$\begin{pmatrix} x_{k+1} \\ \vdots \\ x_n \end{pmatrix} = A \begin{pmatrix} x_1 \\ \vdots \\ x_k \end{pmatrix},$$

where A is an $(n-k) \times k$ matrix.

Recall that all the l_i have integer coefficients. This implies that the coefficients of A are all rational. Therefore, if we choose rational values $(z_1, \ldots, z_k)$ for the independent variables, multiplying by A to obtain the other coordinates will yield a rational point $\mathbf{z} \in L$. Furthermore, this transformation is obviously continuous, which goes to say that by choosing $(z_1, \ldots, z_k)$ sufficiently close to $(x_1, \ldots, x_k)$, we can make the point $\mathbf{z}$ arbitrarily close to the point $\mathbf{x}$. Since rational points exist arbitrarily close to $(x_1, \ldots, x_k)$, we can make $\mathbf{z}$ rational and satisfy $\|\mathbf{z} - \mathbf{x}\| < \min(\varepsilon, \varepsilon_1)$. This implies that $\mathbf{z} \in S$; hence $\mathbf{z} \in L \cap S \subseteq W$ and satisfies $\|\mathbf{z} - \mathbf{x}\| < \varepsilon$. □

The results described in this section are summarized in Table 2. For every problem we consider, this table gives three complexity results: the complexity in the algebraic computation-tree model and in two groups of RAM model. The "weak" group contains the RAMs with integer addresses that are required to handle real input. For this group the lower bounds are determined by $\log \beta(W^{\circ})$. The "strong" group contains the RAMs with real addresses that are required to handle either real or integer input. For this group, lower bounds are determined by $\log \beta((\overline{W})^{\circ})$. We remark that the upper-bound results do no require the use of noninteger addresses if the input is integer.

EXAMPLE 1 (set disjointness). *Given two sets* $A = \{x_1, \ldots, x_n\}$ *and* $B = \{y_1, \ldots, y_n\}$, *decide whether* A *and* B *are disjoint.*

Here

$$W = \{\, (\mathbf{x}, \mathbf{y}) \in \Re^{2n} : \prod_{1 \le i,j \le n} (x_i - y_j) \neq 0 \,\}.$$

It is open and has $(n!)^2$ components, so an $\Omega(n \log n)$ bound on computation trees follows from Ben-Or's theorem and similarly from Yao's for the case of integer inputs. This is tight, as the problem can be solved by sorting and merging. The same lower bounds follow from Theorems 3.3 and 3.6. On the contrary, in the other models it can be solved in linear time with a straightforward use of indirect addressing. Indeed, $\overline{W} = \Re^{2n}$ (there is a point in W arbitrarily close to every point in $\Re^{2n}$) so $(\overline{W})^\circ$ has a single component.

EXAMPLE 2 (sign of resultant). *Given $x_1, \ldots, x_n; y_1, \ldots, y_n$, decide whether*

$$RES(\mathbf{x}, \mathbf{y}) = \prod_{i,j} (x_i - y_j) > 0.$$

Ben-Or proved an $\Omega(n \log n)$ lower bound for this problem, which also holds in Yao's model. A matching upper bound can be obtained by sorting and merging.

COROLLARY 4.3. *Sign of Resultant requires $\Omega(n \log n)$ time in all the models considered in Theorems* 3.3–3.8.

Proof. Here

$$W = \left\{ (\mathbf{x}, \mathbf{y}) \in \Re^{2n} : \prod_{1 \le i,j \le n} (x_i - y_j) > 0 \right\}.$$

W is clearly open, and

$$\overline{W} = \left\{ (\mathbf{x}, \mathbf{y}) \in \Re^{2n} : \prod_{1 \le i,j \le n} (x_i - y_j) \ge 0 \right\}.$$

We now show that each point where the resultant equals 0 is a boundary point of this set. Indeed, let $(\mathbf{x}; \mathbf{y})$ be such a point; then there are indices k, l such that $x_k = y_l$. Let

$$0 < \delta < \tfrac{1}{4} \min\{|y_j - x_i| : y_j - x_i \neq 0\}$$

and replace each x_i with $x_i + \delta$. This results in a nonzero resultant. If it is negative, we obtained a point outside W. As δ tends to zero, this point gets arbitrarily close to $(\mathbf{x}; \mathbf{y})$; thus $(\mathbf{x}, \mathbf{y})$ is a boundary point. If the resultant is positive, replace x_k with $x_k + \delta$, y_l with $y_l + 2\delta$, and x_i, for all $i \neq k$, with $x_i + 3\delta$. This inverts the sign of exactly one of the differences $x_i - y_j$, namely the difference $x_k - y_l$. We obtain a point where the resultant is negative, which can be arbitrarily close to $(\mathbf{x}; \mathbf{y})$.

Removing the boundary points, we obtain $(\overline{W})^\circ = W$. The proof is completed by showing that this set has at least $(n-1)!$ connected components.

Let $\mathbf{x} = (0, 2, \ldots, 2n-2)$ and $\mathbf{y} = (1, 3, \ldots, 2n-1)$. If $RES(\mathbf{x}, \mathbf{y}) > 0$, set x_n to $2n$; this inverts the sign of just one difference $(x_n - y_n)$ and hence the sign of $RES(\mathbf{x}, \mathbf{y})$. Now, replacing $(y_1, \ldots, y_{n-1})$ by an arbitrary permutation of these values will preserve the sign of $RES(\mathbf{x}, \mathbf{y})$. We thus obtain $(n-1)!$ distinct points in W. Let $\mathbf{u}$ and $\mathbf{v}$ be two such points. Say they differ in the value of y_j for some $1 \le j \le n-1$. Then there is an i such that $x_i - y_j$ is positive at one of the points (say $\mathbf{u}$) and negative at the other ($\mathbf{v}$). On any path connecting $\mathbf{u}$ and $\mathbf{v}$ there must be a point where $x_i - y_j = 0$; this point does not belong to W. Hence $\mathbf{u}$ and $\mathbf{v}$ belong to distinct connected components, and $\beta(W) \ge (n-1)!$. □

EXAMPLE 3 (element distinctness). *Given $x_1, x_2, \ldots, x_n$, decide whether these n numbers are all distinct.*

EXAMPLE 4 (min gap). *Given $n+1$ numbers $x_1, \ldots, x_n, t$, decide if the minimum difference between a pair of these numbers is bounded above by t.*

Frequently this problem is presented in a computational form, where the minimum gap has to be reported; the above decision problem is obviously not harder, and for it we give a lower bound that matches an upper bound known for the computational problem.

Yao's theorem gives an $\Omega(n \log n)$ lower bound for Element Distinctness on computation trees, even when restricted to integer inputs. Since Element Distinctness is a special case of Min Gap ($t = 0$), the same lower bound applies to Min Gap. As there is a matching upper bound (by sorting the numbers), the complexity of both problems for the algebraic computation tree is $\Theta(n \log n)$. The lower bound for Min Gap holds for all our RAM models as well as we will shortly demonstrate.

The situation for Element Distinctness is different: We show that the $\Omega(n \log n)$ lower bound holds in the "weak" models. The "strong" models can solve the problem in linear time, with a straightforward use of indirect addressing. Thus the latter models separate the complexities of the two problems.

COROLLARY 4.4. *Min Gap requires $\Omega(n \log n)$ time in all the models considered in Theorems* 3.3–3.8. *Element Distinctness requires $\Omega(n \log n)$ time in the models with integer addresses.*

Proof. The corollary follows by showing that for Element Distinctness, W° has $n!$ components, while for Min Gap, the same is true for $(\overline{W})^\circ$.

For Element Distinctness we have

$$W = \{\, (\mathbf{x} \in \Re^n : (\forall\, 1 \le i < j \le n)\ x_i \ne x_j \,\}.$$

This set is clearly open, so $W^\circ = W$. To see that the number of components of W is at least $n!$, consider points $\mathbf{x}$ such that $(x_1, \ldots, x_n)$ is a permutation of $(1, 2, \ldots, n)$; $\mathbf{x} \in W$, and there are $n!$ such points. We show that each of them lies in a distinct component. Let $\mathbf{u}$, $\mathbf{v}$ be distinct points from this set. Let $i_1, i_2, \ldots, i_n$ be such that $u_{i_k} = k$. Since $\mathbf{v}$ is a different permutation, there will be a first k such that $v_{i_k} \ne k$. Necessarily $v_{i_k} > k$. For another position i_l, $l \ne k$, we will have $v_{i_l} = k$. Consider the function $f(\mathbf{x}) = x_{i_l} - x_{i_k}$. We have $f(\mathbf{u}) > 0$ and $f(\mathbf{v}) < 0$ and f is continuous, therefore every path connecting $\mathbf{u}$ and $\mathbf{v}$ must contain a point where $x_{i_l} = x_{i_k}$, a point not in W.

In contrast, $\overline{W} = \Re^n$, so $(\overline{W})^\circ$ has a single component. No wonder that the lower bound collapses for the strong models.

Consider now the Min Gap problem. We have

$$W = \{\, (\mathbf{x}, t) \in \Re^{n+1} : (\exists\, 1 \le i < j \le n)\, |x_i - x_j| \le t \,\}.$$

Clearly, recognizing W has the same complexity as recognizing its complement W', and adding the requirement $t \ge 0$ does not change the complexity of recognizing the set. Clearly,

$$W' = \{\, (\mathbf{x}, t) \in \Re^n : (\forall\, 1 \le i < j \le n)\, |x_i - x_j| > t \,\}$$

and

$$\overline{W' \cap \{t \ge 0\}} = \{\, (\mathbf{x}, t) \in \Re^n : t \ge 0, (\forall\, 1 \le i < j \le n)\, |x_i - x_j| \ge t \,\}.$$

Now, if $t > 0$, the points that satisfy one of these inequalities in the weak sense are boundary points. The points where $t = 0$ are all boundary points. Hence

$$(\overline{W' \cap \{t \geq 0\}})^\circ = \{\, (\mathbf{x}, t) \in \Re^n : t > 0, (\forall\, 1 \leq i < j \leq n)\, |x_i - x_j| > t \,\} = W'.$$

This set has $n!$ components. (Let $\mathbf{x}$ be a permutation of $(2t, 4t, \ldots, 2nt)$; each permutation lies in a distinct component.) □

EXAMPLE 5 (max gap). *Given $n+1$ numbers $x_1, \ldots, x_n, \varepsilon$, decide whether the x_i can be permuted into a nondecreasing sequence such that the gap between each pair of consecutive elements is bounded above by ε.*

Again, frequently we are asked to find out the maximum gap; this decision problem is not harder, and the lower bound that we give matches the upper bound for the computational version.

The theorems of Ben-Or and Yao yield lower bounds of $\Omega(n \log n)$ for Max Gap on algebraic computation trees (resp., with integer input). Clearly, Max Gap can be solved in $O(n \log n)$ time by sorting the numbers. The same lower bound holds for RAMs.

COROLLARY 4.5. *Max Gap requires $\Omega(n \log n)$ time in all the models considered in Theorems* 3.3–3.8.

Proof. We consider a restricted problem in which we have to decide whether the following conditions hold simultaneously: (1) the maximum gap is less than ε; (2) the difference between the maximum and minimum of this set is greater than $(n - 1.5)\varepsilon$. (Checking the last condition obviously takes linear time.) Let S_n be the set of permutations over $\{1, 2, \ldots, n\}$. In this problem,

$$W = \{\, (\mathbf{x}, \varepsilon) \in \Re^{n+1} : (\exists \sigma \in S_n)\, x_{\sigma(n)} - x_{\sigma(1)} > (n - 1.5)\varepsilon \\ \wedge\, (\forall j < n)\, x_{\sigma(j)} \leq x_{\sigma(j+1)} < x_{\sigma(j)} + \varepsilon \,\}.$$

Clearly,

$$\overline{W} = \{\, (\mathbf{x}, \varepsilon) \in \Re^{n+1} : (\exists \sigma \in S_n)\, x_{\sigma(n)} - x_{\sigma(1)} \geq (n - 1.5)\varepsilon \\ \wedge\, (\forall j < n)\, x_{\sigma(j)} \leq x_{\sigma(j+1)} \leq x_{\sigma(j)} + \varepsilon \,\}.$$

Each point of this set such that $\varepsilon = 0$ is a boundary point, since ε cannot be negative. For $\varepsilon > 0$, we show now that the points where at least one of the inequalities holds weakly are boundary points. Let $(\mathbf{x}, \varepsilon)$ be such a point. We show that there are points, arbitrarily close to it, not in $\overline{W}$. For simplicity, assume that the appropriate σ for this point is the identity, i.e., $x_1 \leq x_2 \leq \cdots \leq x_n$. First note that the condition $x_j = x_{j+1}$ cannot hold for any j since otherwise, $x_n - x_1 \geq (n - 1.5)\varepsilon$ implies that at least one gap exceeds ε. If $x_n - x_1 = (n - 1.5)\varepsilon$, then for all small enough $\delta > 0$, $(x_1, \ldots, x_n - \delta)$ is not in $\overline{W}$. Next, if $x_{j+1} = x_j + \varepsilon$, for all small enough $\delta > 0$ the point $(x_1, \ldots, x_j, x_{j+1} + \delta, x_{j+2}, \ldots, x_n)$ is not in $\overline{W}$.

We conclude that

$$(\overline{W})^\circ = \{\, (\mathbf{x}, \varepsilon) \in \Re^{n+1} : (\exists \sigma \in S_n)\, x_{\sigma(n)} - x_{\sigma(1)} > (n - 1.5)\varepsilon \\ \wedge (\forall j < n)\, x_{\sigma(j)} < x_{\sigma(j+1)} < x_{\sigma(j)} + \varepsilon \,\}.$$

The proof is completed by observing that this set has $n!$ components. (Each permutation of $(\varepsilon, 2\varepsilon, \ldots, n\varepsilon)$ belongs to a distinct component.) □

EXAMPLE 6 (uniform gap). *Given $n+1$ numbers $x_1, x_2, \ldots, x_n, \varepsilon$ decide whether the x_i can be permuted into a nondecreasing sequence where the gap between each pair of consecutive elements is ε.*

Here

$$W = \{\, (\mathbf{x}, \varepsilon) \in \Re^{n+1} : (\exists \sigma \in S_n)\, (\forall j < n)\, x_{\sigma(j+1)} = x_{\sigma(j)} + \varepsilon \,\}.$$

W has $n!$ components (given by permutations of $(\varepsilon, 2\varepsilon, \ldots, n\varepsilon)$), while W° is empty. Thus, Ben-Or's theorem implies an $\Omega(n \log n)$ bound for an algebraic computation tree solving Uniform Gap on real input, while Yao's theorem fails to provide a lower bound. The same happens with all our theorems but one.

COROLLARY 4.6. *Uniform Gap requires* $\Omega(n \log n)$ *time on a* $(\Re, \mathbb{N}, \{+, -, \times, \lfloor\ \rfloor\})$*-RAM.*

The result follows from the appearance of $\log \tilde{\beta}(W)$ in Theorem 3.6. We conjecture that the same is true for the model of Theorem 3.3, but our theorem does not prove it as it only refers to $\beta(W^\circ)$. In contrast, in the four "strong" models, the problem can be solved in linear time: Compute the minimum of the $\{x_i\}$, m. Then by means of indirect addressing check whether the rest of the set equals $\{m+\varepsilon, m+2\varepsilon, \ldots, m+(n-1)\varepsilon\}$.

Uniform Gap relates to Max Gap in a way that resembles the relationship of Element Distinctness to Min Gap. On one hand, a nonlinear lower bound for Uniform Gap implies the same lower bound for Max Gap, because Uniform Gap can be efficiently reduced to the latter. In fact, the answer to Uniform Gap is "yes" if and only if the answer to Max Gap on $x_1, \ldots, x_n$ is ε, and the difference between the minimum and the maximum of this set is $(n-1)\varepsilon$. Thus, when there is an $\Omega(n \log n)$ bound for Uniform Gap, the complexity of both problems coincides, and this happens for algebraic computation trees, over real input, and for the model of the above corollary. On the contrary, as with Element Distinctess and Min Gap, the "strong" models separate the complexities of the two problems.

EXAMPLE 7 (sign of permutation). *Given* $x_1, \ldots, x_n$ *decide whether there exists an even permutation* σ *such that* $x_{\sigma(1)} < x_{\sigma(2)} < \cdots < x_{\sigma(n)}$.

Here

$$W = \left\{ \mathbf{x} \in \Re^n : \prod_{i<j} (x_j - x_i) > 0 \right\}.$$

Yao showed that this problem requires $\Omega(n \log n)$ in an algebraic computation tree, even for integer input, and we show that the same holds for the RAM models.

COROLLARY 4.7. *Sign of permutation requires* $\Omega(n \log n)$ *time in all the models considered in Theorems* 3.3–3.8.

Proof. We have

$$\overline{W} = \left\{ \mathbf{x} \in \Re^n : \prod_{i<j} (x_j - x_i) \geq 0 \right\}.$$

We next prove that each point where equality holds is a boundary point of this set. Therefore, $(\overline{W})^\circ = W$ and has $\frac{n!}{2}$ components. (Each even permutation of $(1, 2, \ldots, n)$ represents a distinct component.) To complete the proof, let $(x_1, \ldots, x_n)$ be a point such that $\prod_{i<j}(x_j - x_i) = 0$; thus the coordinates are not all distinct. Without loss of generality, assume $x_1 \leq x_2 \leq \cdots \leq x_n$ and let k satisfy $x_k = x_{k+1}$. For every $\delta > 0$, consider the point

$$\mathbf{y}_\delta = (x_1 + \delta, \ldots, x_{k-1} + (k-1)\delta, x_k + (k+1)\delta, x_{k+1} + k\delta, x_{k+2} + (k+2)\delta, \ldots, x_n + n\delta)\,.$$

The difference $y_j - y_i$ is positive for all $j > i$ except $i = k, j = k+1$, where it is negative. Therefore, $\prod_{i<j}(y_j - y_i) < 0$ and $\mathbf{y} \notin \overline{W}$. However, when $\delta \to 0$, $\mathbf{y} \to \mathbf{x}$. Thus $\mathbf{x}$ is a boundary point of $\overline{W}$. □

EXAMPLE 8 (convex hull). *Given n points in the plane, decide whether they all lie on the convex hull of the set.*

Yao considered a slightly different version of this problem, where we have to decide whether the convex hull has n vertices (which means that all the points lie on the hull and are also in general position). Yao gave an $\Omega(n \log n)$ lower bound for a computation tree that solves this problem, even for integer inputs. The same lower bound for our version of the problem follows by Theorem 3.2′. In this case $W \subseteq \Re^{2n}$ is the set of all points $(x_0, y_0, \ldots, x_{n-1}, y_{n-1})$ for which there exists a permutation σ on $(0, 1, \ldots, n-1)$ such that, for all $0 \le i < n$,

$$\begin{vmatrix} 1 & x_{\sigma(i)} & y_{\sigma(i)} \\ 1 & x_{\sigma(i+1) \bmod n} & y_{\sigma(i+1) \bmod n} \\ 1 & x_{\sigma(i+2) \bmod n} & y_{\sigma(i+2) \bmod n} \end{vmatrix} \ge 0.$$

W° has $(n-1)!$ components and is scale invariant and rationally dispersed [17, 19]. W is closed, so the same holds for $(\overline{W})^\circ$, and the lower bound applies to the various RAM models as well.

EXAMPLE 9 (knapsack). *Given numbers $x_1, \ldots, x_n$ and $M > 0$ decide if there exists some subset $S \subseteq \{1, 2, \ldots, n\}$ such that*

$$\sum_{i \in S} x_i = M.$$

EXAMPLE 10 (generalized knapsack). *Given numbers $x_1, \ldots, x_n$ and $M > 0$ decide if there exists a vector $v \in \{0 \ldots k\}^n$ such that the inner product $x \cdot v = M$. (For $k = 1$ this is the original problem.)*

EXAMPLE 11 (approximate generalized knapsack). *Given numbers $x_1, \ldots, x_n$ and $M > 0$ decide if there exists a vector $v \in \{0 \ldots k\}^n$ such that*

$$|x \cdot v - M| \le \varepsilon M,$$

where $k \in \mathbb{N}$, $\varepsilon > 0$ are fixed constants.

Let $\mathcal{P}$ denote the spatial partition induced on $\Re^{n+1}$ by the hyperplanes $v \cdot x = M$, for all $v \in \{0 \ldots k\}^n$. Meyer auf der Heide [12] shows that $\mathcal{P}$ consists of at least $(k+1)^{(n(n-1)/2)}/(2^n - 1)$ connected regions. He uses this fact to give a lower bound on computation-tree complexity for the generalized knapsack problem. (For the original knapsack problem, lower bounds are given in [2, 19].) We start with the approximate problem, for which we obtain a lower bound in all of the RAM models.

COROLLARY 4.8. *On all the models considered in Theorems 3.3–3.8, the complexity of the approximate knapsack problem is $\Omega(n^2 \log(k+1))$.*

Proof. Let W' be the complement of the set to be recognized. A lower bound for recognizing W' is a lower bound for recognizing W.

$$W' = \{(x_1, \ldots, x_n, M) : |v \cdot x - M| > \varepsilon M \quad \forall v \in \{0 \ldots k\}^n\}.$$

It is easy to show that $(\overline{W'})^\circ = W'$, and that if ε is small enough, then a component of W' exists within each region of $\mathcal{P}$. Thus, $\beta((\overline{W'})^\circ) \ge (k+1)^{(n(n-1)/2)}/(2^n - 1)$ and the lower bound follows. □

The exact problems differ from the approximate ones by setting $\varepsilon = 0$. This change invalidates the results using $(\overline{W'})^\circ$, because it becomes $\Re^n$. However, $(W')^\circ = W'$, so the above lower bound stays valid for the RAMs with integer addresses. We remark that for the stronger models, it is possible to obtain (weaker) lower bounds using a technique Meyer auf der Heide's lemma (section 1). The results are $\Omega(n^2/\log n)$ for Exact Knapsack and $\Omega(n^2 \log(k+1)/(\log n + \log\log(k+1)))$ for Exact Generalized Knapsack.

5. Background for Proofs. In this section we group a few definitions, facts and lemmas that are useful for the forthcoming proofs. We start with some point-set topology.

FACT 5.1. *Every connected component of an open set is open.*

FACT 5.2. *If $U \subseteq V$, then every connected component of U is contained within a component of V.*

LEMMA 5.3. *Let W, A be subsets of some metric space such that A is closed and has empty interior. Then*

$$(\overline{W \setminus A})^\circ = (\overline{W})^\circ = (\overline{W \cup A})^\circ.$$

Proof. The first equality follows from the second by substituting $W \setminus A$ for W. We now prove the second one. We obviously have $\overline{W} \subseteq \overline{W \cup A}$. Therefore also $(\overline{W})^\circ \subseteq (\overline{W \cup A})^\circ$. To prove inclusion in the other direction, note that

$$\overline{(W \cup A)} = \overline{W} \cup \overline{A} = \overline{W} \cup A\,.$$

Let $x \in (\overline{W \cup A})^\circ = (\overline{W} \cup A)^\circ$. Since $x \in (\overline{W} \cup A)^\circ$, there exists a ball $B \subseteq \overline{W} \cup A$ that includes x. We distinguish two cases.

Case 1: $x \notin A$. A is closed, so $B \setminus A$ is an open set, contains x, and is contained in $\overline{W}$. This shows that $x \in (\overline{W})^\circ$.

Case 2: $x \in A$. Since A has empty interior, $B \subseteq \overline{B \setminus A}$. Since B is open, this implies $B \subseteq (\overline{B \setminus A})^\circ$. Thus $x \in (\overline{B \setminus A})^\circ$. But $B \setminus A \subseteq \overline{W}$, so $(\overline{B \setminus A})^\circ \subseteq (\overline{W})^\circ$. □

LEMMA 5.4. *Let $X \subseteq \Re^n$, B an open ball in $\Re^n$. Then*

$$(\overline{X})^\circ \cap B = (\overline{X \cap B})^\circ.$$

Proof. Because B is open, we have

$$\overline{X} \cap B \subseteq \overline{X \cap B}.$$

Hence,

$$(\overline{X})^\circ \cap B = (\overline{X})^\circ \cap B^\circ = (\overline{X} \cap B)^\circ \subseteq (\overline{X \cap B})^\circ.$$

On the other hand, because B is a ball, $(\overline{B})^\circ = B$; hence

$$(\overline{X \cap B})^\circ \subseteq (\overline{X} \cap \overline{B})^\circ = (\overline{X})^\circ \cap (\overline{B})^\circ = (\overline{X})^\circ \cap B.$$

Combining the two inclusions, we have

$$(\overline{X})^\circ \cap B = (\overline{X \cap B})^\circ\,. \qquad \square$$

LEMMA 5.5. *Let W be an open set. Then*

$$\beta((\overline{W})^\circ) \leq \beta(W).$$

Proof. We show that each component of $(\overline{W})^\circ$ contains at least one component of W. In fact, since $W \subseteq \overline{W}$, we also have $W \subseteq (\overline{W})^\circ$. Thus a component of W must be contained within a component of $(\overline{W})^\circ$. It remains to show that each component C of $(\overline{W})^\circ$ contains at least one point of W. To this end, observe that $\overline{W} = W \cup \partial W$, so $W \supseteq \overline{W} \setminus \partial W$; hence

$$C \cap W \supseteq C \cap (\overline{W} \setminus \partial W) = (C \cap \overline{W}) \setminus (C \cap \partial W) = C \setminus \partial W$$

and this is not empty since a boundary set cannot contain C. □

LEMMA 5.6. *Let W be an open set and A a boundary set. Then*

$$\beta(W \setminus A) \geq \beta(W).$$

Proof. We show that each component of W contains at least one component of $W \setminus A$. In fact, since $W \setminus A \subseteq W$, every component of $W \setminus A$ must be contained within a component of W. It remains to show that for each component C of W contains at least one point of $W \setminus A$. This follows since otherwise, we would have $C \subseteq A$, but C is open and A is a boundary set, a contradiction. □

LEMMA 5.7. *For any set W, $\hat{\beta}(W) \leq \beta(W^\circ)$.*

Proof. Recall that $\hat{\beta}(W)$ is the number of components of W that have a nonempty interior. Let C be such a component; we show that it contains at least one component of W°. This establishes the desired inequality. In fact, it suffices to prove that $C \cap W^\circ$ is not empty, because once C contains one point of W°, it will contain the whole component of this point (Fact 5.2).

Now, $W^\circ = W \setminus \partial W$. Therefore $C \cap W^\circ = C \setminus \partial W$. Since C has a nonempty interior, it cannot be contained in ∂W; hence the last set is not empty. □

We now move on to properties of polynomials and rational functions on $\Re^n$. We will be particularly interested in the existence of integer points on the graphs of such functions.

DEFINITION 5.8. *An algebraic variety in $\Re^n$ is the set of common zeros of a finite set of polynomials; in other words, it is the set of points satisfying a finite set of algebraic equations.*

The adjective *algebraic* is often omitted, since we do not consider other types of "varieties." A variety is called *nontrivial* if it is different from $\Re^n$. Here are some important properties.

FACT 5.9. *Every finite union or intersection of algebraic varieties is itself a variety. Every nontrivial algebraic variety is a closed boundary set.*

DEFINITION 5.10. *A function of the form P/Q, where P and Q are (multivariate) polynomials, is called rational.*

LEMMA 5.11. *Any function that can be computed from $x_1, \ldots, x_n$ using the operations $\{+, -, \times, /\}$ is rational.*

Proof. The coordinate functions $I_k(\mathbf{x}) = x_k$ are rational. The result follows by induction on the number of operations, using the following identities:

$$\begin{aligned} \tfrac{P}{Q} \pm \tfrac{R}{T} &= \tfrac{PT \pm RQ}{QT}, \\ \tfrac{P}{Q} \cdot \tfrac{R}{T} &= \tfrac{PR}{QT}, \\ \tfrac{P}{Q} \Big/ \tfrac{R}{T} &= \tfrac{PT}{QR}. \end{aligned}$$ □

Standard notation is $\Re[\mathbf{x}]$ for the ring of polynomials in $\mathbf{x}$ with coefficients from $\Re$, and $\Re(\mathbf{x})$ for the corresponding field of rational functions.

LEMMA 5.12. *Let $f : \Re^n \to \Re$ be rational. Assume that there is an open nonempty subset of $\Re^n$ on which f only assumes integer values. Then f is constant throughout its domain of definition D_f.*

Proof. Note first that f is continuous on every path-connected component of D_f. Assume that $O \subseteq \Re^n$ is an open subset as described. Let $\mathbf{x}_0 \in O$, and $y = f(\mathbf{x}_0)$. By the assumption, $y \in \mathbb{Z}$. Let $O_1 \subseteq O$ be the path-connected component of O that contains $\mathbf{x}_0$. By Fact 5.1, O_1 is an open set. If for some $\mathbf{x}_1 \in O_1$, $f(\mathbf{x}_1) \neq f(\mathbf{x}_0)$, it follows from continuity of f that there is $\mathbf{x}_2 \in O$ such that $f(\mathbf{x}_2) \notin \mathbb{Z}$, contradicting the assumption. Therefore, $f \equiv f(\mathbf{x}_0)$ throughout O_1.

Express f as P/Q where P,Q are polynomials. We obtain that for all $\mathbf{x} \in O_1$,

$$P(\mathbf{x})/Q(\mathbf{x}) = f(\mathbf{x}_0), \tag{1}$$

i.e.,

$$P(\mathbf{x}) - f(\mathbf{x}_0)Q(\mathbf{x}) = 0\,. \tag{2}$$

In the last equation, the left-hand side is a polynomial; a polynomial that is zero on an open set must be the zero polynomial. Therefore, (1) is an identity, and the same goes for (2) (within D_f). □

DEFINITION 5.13. *A set $H \subseteq \Re^n$ is a bale if there is a finite set of polynomials $\{ P_i, Q_i,\ i \in I \}$ such that*

$$H = \bigcup_{i \in I} \left\{ \mathbf{x} \in \Re^n : \left(\frac{P_i(\mathbf{x})}{Q_i(\mathbf{x})} \in \mathbb{Z} \right) \vee (Q_i(\mathbf{x}) = 0) \right\}.$$

The above bale is denoted by $\mathcal{B}(P_i, Q_i, i \in I)$. If there is only one pair of polynomials P, Q we write $\mathcal{B}(P, Q)$. A bale is called *nontrivial* if it is different from $\Re^n$. The following observations are important for our proofs.

FACT 5.14. *Every algebraic variety in $\Re^n$ is a bale. A finite union of bales is a bale. Every nontrivial bale is a closed boundary set.*

Proof. For the first claim, note that an algebraic variety in $\Re^n$ can be described as the zero set of a single polynomial (the sum of squares of the defining polynomials). Call this polynomial Q. The zero-set of Q is exactly the bale $\mathcal{B}(Q/2, Q)$. The second claim is immediate from the definition. For the third, let $H = \mathcal{B}(P, Q)$. It is enough to prove the claim for such a bale because a finite union of closed boundary sets is a closed boundary set. H is, by definition, a countable union of varieties (namely, $\{Q_i(\mathbf{x}) = 0\}$, and $\{P_i(\mathbf{x}) = kQ_i(\mathbf{x})\}$ for all $k \in \mathbb{Z}$). Each of them is a boundary set so, by Baire's category theorem, so is their union. To show that H is closed, we prove that $\Re^n \setminus H$ is open: let $\mathbf{y} \in \Re^n \setminus H$. Then $Q(\mathbf{y}) \neq 0$. By continuity of Q, there is a neighborhood $\mathcal{N}$ of $\mathbf{y}$ in which $Q \neq 0$. Also $\frac{P(\mathbf{y})}{Q(\mathbf{y})} \notin \mathbb{Z}$. By continuity of P/Q in $\mathcal{N}$, there is a neighborhood of $\mathbf{y}$ in which $\frac{P(\mathbf{y})}{Q(\mathbf{y})} \notin \mathbb{Z}$. Thus there exists a neighborhood of $\mathbf{y}$ contained in $\Re^n \setminus H$. □

DEFINITION 5.15. *For two functions f, g we write $f \prec g$ if f is defined at least where g is and $f_{|domg} = g$.*

DEFINITION 5.16. *A subset of $\Re^n$ is called large if it is not contained in any nontrivial algebraic variety.*

Note that a large set is necessarily infinite, since every finite set of points is a nontrivial variety. Furthermore, every finite union of nontrivial varieties is a nontrivial variety; hence no large set can be covered by finitely many nontrivial varieties.

THEOREM 5.17. *Let $r \in \Re(\mathbf{x})$ be a rational function. If there is a large set $B \subseteq \mathbb{Z}^n$ such that $r(B) \subseteq \mathbb{Z}$, then there are $P, Q \in \mathbb{Z}[\mathbf{x}]$ such that $P/Q \prec r$.*

Informally, if a rational function (with coefficients from $\Re$) has an integer value in "many" integer points, then the coefficients may be safely assumed to be from $\mathbb{Z}$.

Proof. Every rational function has a *reduced* form, in which the nominator and denominator are relatively prime polynomials. Every other form has larger degree in both polynomials. The reduced denominator is a divisor of any other possible denominator, and hence the reduced fraction will be defined whenever the nonreduced form is as follows: symbolically, if R_1/R_2 is the reduced form of r, then $R_1/R_2 \prec r$. Let $d_i = \deg R_i$. Then R_1/R_2 is completely specified by $d = d_1+d_2+2$ real coefficients, $(a_1, \ldots, a_d)$. The relation $r(\mathbf{x}) = y$ can be rewritten as $R_1(\mathbf{x}) = yR_2(\mathbf{x})$, an equation linear in $(a_1, \ldots, a_d)$. Every point of B gives rise to such an equation; we obtain an infinite set E of linear equations which have a common solution, hence a set of solutions which is a linear subspace of $\Re^d$. Let e be the dimension of this subspace; then we may select $d - e$ equations from E that suffice to determine the required subspace.

The equations in question have integer coefficients; therefore, they can be solved over the rationals. We obtain a rational vector of coefficients $(a_1, \ldots, a_d)$. Multiplying by a common denominator we can assume the a_i to be integer. (Note that the equations are homogeneous.) We thus obtain a function P/Q, with $P, Q \in \mathbb{Z}[\mathbf{x}]$, that coincides with R on B. Thus, $R_1Q - R_2P = 0$ on B, but by the assumption on B, the polynomial $R_1Q - R_2P$ must be the zero polynomial. Hence $P/Q = R_1/R_2$ wherever both are defined. Moreover, since R_1/R_2 is reduced, and P, Q are constrained by the same degrees as R_1, R_2, we must have $(P, Q) = c(R_1, R_2)$ for a scalar c. Thus P/Q coincides precisely with R_1/R_2. □

In what follows, we use the letter t to denote a scalar variable (in contrast with the boldface letters, such as $\mathbf{x}$, that designate vector variables). By $\mathbb{Z}^+$ we denote, as usual, the set of positive integers.

LEMMA 5.18. *Let $P \in \mathbb{Q}[t]$. Then*

(i) *there is a rational $0 < q \leq 1$ such that $P(\mathbb{Z}) \subseteq q\mathbb{Z}$;*

(ii) *there is an integer $a > 0$ such that either $P(a\mathbb{Z}) \subseteq \mathbb{Z}$ or $P(a\mathbb{Z}) \cap \mathbb{Z} = \emptyset$.*

Proof. Assume $P \not\equiv 0$ (otherwise the statements are trivial). The nonzero coefficients of P are all rational so they have a common denominator $d > 0$. We choose $q = 1/d$ and $a = d$. We leave it to the reader to verify the claims. □

DEFINITION 5.19. *A ray in $\Re^n$ is a set of the form $\{t\mathbf{c} : t > 0\}$ for $\mathbf{c} = (c_1, c_2, \ldots, c_n) \neq \mathbf{0}$.*

The vector $(c_1, \ldots, c_n)$ is *a coordinate vector* for the ray. In fact, every point on the ray can serve as coordinate vector.

Let $f : \Re^n \to \Re^n$, and let K be a ray. We denote by $f_{|K}$ the function of a single variable obtained by restricting f to K; thus $f_{|K}(t) = f(t\mathbf{c})$, where $\mathbf{c}$ is a chosen coordinate vector for K. When we want to be specific about the choice of $\mathbf{c}$, we write $f_{\mathbf{c}}(t)$ for $f(t\mathbf{c})$. It is easy to see that if f is a polynomial, so is $f_{\mathbf{c}}$ for any $\mathbf{c} \in K$.

The following is almost too obvious to state.

FACT 5.20. *A set in $\Re^n$ is scale invariant if and only if it is a union of rays (plus possibly the origin).*

LEMMA 5.21. *Let H be an algebraic variety in $\Re^n$ and $K \subseteq \Re^n$ a ray. Then $H \cap K$ either equals K or is finite.*

Proof. Let $\mathbf{c}$ be a coordinate vector for K; substitute $\mathbf{x} = t\mathbf{c}$ in all the polynomials defining H. We obtain a set of monovariate polynomials that define $H \cap K$. However,

a monovariate polynomial either is identically zero or has finitely many zeros. The lemma follows. □

A ray is called *rational* if it has a rational coordinate vector (which amounts to saying that it contains a rational point). We denote the set of rational rays in $\Re^n$ by $\mathcal{Q}^{(n-1)}$. (The superscript reminds us that this set is an $(n-1)$-dimensional vector space, but this is not important for our discussion.) Subsets of $\mathcal{Q}^{(n-1)}$ are often denoted by Γ.

LEMMA 5.22. *Let $\Gamma \subseteq \mathcal{Q}^{(n-1)}$, and for all $K \in \Gamma$ let $S(K) \subseteq K \cap \mathbb{Z}^n$ be infinite. If $\bigcup_{K\in\Gamma} K$ is large, then $\bigcup_{K\in\Gamma} S(K)$ is also large.*

Proof. We prove the contrapositive: Assume that there is a nontrivial variety H such that $\bigcup_{K\in\Gamma} S(K) \subseteq H$. Thus, every ray $K \in \Gamma$ intersects with H infinitely often. By Lemma 5.21, $K \subseteq H$. Hence $\bigcup_{K\in\Gamma} K \subseteq H$. □

DEFINITION 5.23. *The function $f : \Re \to \Re$ is periodically integral (p.i.) if there is $a \in \mathbb{Z}^+$ such that $f(a\mathbb{Z}^+) \subseteq \mathbb{Z}$. We say that f is periodically nonintegral (p.n.i.) if there $a \in \mathbb{Z}^+$, such that $f(a\mathbb{Z}^+) \subseteq \Re \setminus \mathbb{Z}$.*

LEMMA 5.24. *If f is not periodically (non)integral, then there is an infinite set $S \subseteq \mathbb{Z}^+$ such that $f(S)$ lies outside (inside) of $\mathbb{Z}$.*

We omit the easy proof. It is also easy to see that, if $f(t)$ is p.i. (p.n.i.), then $f(qt)$ is p.i. (p.n.i.) for any $q \in \mathbb{Q}^+$. The following is an immediate consequence.

LEMMA 5.25. *Let $K \in \mathcal{Q}^{(n-1)}$ and $f : \Re^n \to \Re$. Then $f_{|\mathbf{y}}$ is p.i. (p.n.i.) for some $\mathbf{y} \in K \cap \mathbb{Q}^n$ if and only if it is p.i. (p.n.i.) for all such $\mathbf{y}$.*

In view of this lemma, we can use the expression "$f_{|K}$ is p.i. (p.n.i)" without specifying the coordinates used for K. Another easy observation is that a function may be either p.i. or p.n.i. but not both. There are also functions that are neither; as the next lemma shows, this does not occur for polynomials from $\mathbb{Q}[t]$.

LEMMA 5.26. *A polynomial in $\mathbb{Q}[t]$ is p.i. if and only if its constant term is an integer. It is p.n.i. otherwise.*

Proof. Let $Q(t) = c_0 + c_1 t + \cdots + c_d t^d \in \mathbb{Q}[t]$. Assume first that c_0 is an integer; let d be the common denominator of $c_1, \ldots, c_d$. Then $Q(d\mathbb{Z}^+) \subseteq \mathbb{Z}$. On the other hand, if $c_0 \notin \mathbb{Z}$, then $Q(dm) \notin \mathbb{Z}$ for all $m \in \mathbb{Z}$. □

DEFINITION 5.27. *Let $S \subseteq \Re$ and $x \in \Re$. The distance $d(x, S)$ is defined as* $\inf_{s\in S} |x - s|$.

We are now prepared to prove a useful theorem about rational functions and their behavior on rational rays.

THEOREM 5.28. *For $r \in \Re(\mathbf{x})$ let Γ (resp., Δ) be the set of rays $K \in \mathcal{Q}^{(n-1)}$ such that $r_{|K}$ is periodically (non)integral. Then either $\bigcup_{K\notin\Gamma} K$ or $\bigcup_{K\notin\Delta} K$ is contained in a nontrivial, scale-invariant bale.*

Proof. Fix r, and hence Γ and Δ, as in the theorem. To prove the theorem, we assume

(∗) $\bigcup_{K\notin\Delta} K$ is not contained in any nontrivial, scale-invariant bale.

We will prove that $\bigcup_{K\notin\Gamma} K$ is contained in a nontrivial scale-invariant variety.

For every $K \notin \Delta$, let $S(K)$ be the following set, implied by Lemma 5.24: $S(K) \subseteq K \cap \mathbb{Z}^n$, it is infinite, and $f(\mathbf{x}) \in \mathbb{Z}$ for all $\mathbf{x} \in S(K)$.

From our assumption (∗) and Lemma 5.22, $\bigcup_{K\notin\Delta}(S(K))$ is a large set. Note that this is a set of integer points where r assumes an integer value. Its existence implies, by Theorem 5.17, that we may assume r to be of the form P/Q, where P and Q have integer coefficients.

We now consider the restrictions of r, P, and Q to a single rational ray $K \notin \Delta$,

using for coordinates an arbitrary point $\mathbf{c} \in K \cap \mathbb{Q}^n$. We have

$$r_{\mathbf{c}} = \frac{P_{\mathbf{c}}}{Q_{\mathbf{c}}},$$

where $P_{\mathbf{c}}$, $Q_{\mathbf{c}}$ are univariate polynomials. Applying polynomial division to divide $P_{\mathbf{c}}$ by $Q_{\mathbf{c}}$, we obtain a quotient $S^{(\mathbf{c})}(t)$ and a remainder $R^{(\mathbf{c})}$. The remainder is a polynomial of degree less than $\deg Q_{\mathbf{c}}$, and

$$r_{\mathbf{c}}(t) = S^{(\mathbf{c})}(t) + \frac{R^{(\mathbf{c})}(t)}{Q_{\mathbf{c}}(t)}\,. \tag{3}$$

Since $\deg R^{(\mathbf{c})} < \deg Q_{\mathbf{c}}$, the right-hand term converges to zero as $t \to \infty$. Applying Lemma 5.18 (part i), we obtain a rational $0 < q \leq 1$ such that for integer t, $S^{(\mathbf{c})}(t) \in q\mathbb{Z}$. Combining with (3), we have (for integer t large enough)

$$d(r_{\mathbf{c}}(t), q\mathbb{Z}) = \left| \frac{R^{(\mathbf{c})}(t)}{Q_{\mathbf{c}}(t)} \right|.$$

Since $r_{|K}$ is not p.n.i., there are infinitely many $t \in \mathbb{Z}^+$ such that $r_{\mathbf{c}}(t) \in \mathbb{Z}$, i.e., $d(r_{\mathbf{c}}(t), q\mathbb{Z}) = 0$. Thus we must have

$$\frac{R^{(\mathbf{c})}(t)}{Q_{\mathbf{c}}(t)} = 0$$

for such t, but then $R^{(\mathbf{c})}$ must be the zero polynomial. In other words, the polynomial $Q_{\mathbf{c}}$ is a divisor of $P_{\mathbf{c}}$.

Denote by $\sigma_i^{(\mathbf{c})}$ the coefficient of t^i in $S^{(\mathbf{c})}(t)$. We know that the latter polynomial is not p.n.i.; by Lemma 5.26, $\sigma_0^{(\mathbf{c})}$ is an integer. Recall that

$$P_{\mathbf{c}}(t) = P(c_1 t, c_2 t, \ldots, c_n t) = \sum_i p_i(c_1, \ldots, c_n) t^i,$$

where each p_i is a polynomial in $c_1, \ldots, c_n$ (in fact a homogenous polynomial of degree i). Similarly let us write

$$Q_{\mathbf{c}}(t) = \sum_i q_i(c_1, \ldots, c_n) t^i.$$

Note that the $S^{(\mathbf{c})}$ is defined by the equation

$$P_{\mathbf{c}} = Q_{\mathbf{c}} \cdot S^{(\mathbf{c})}\,.$$

By comparing corresponding coefficients, we convert this equation to the linear system (in the unknowns $\sigma_j^{(\mathbf{c})}$)

$$\begin{aligned}
p_0(\mathbf{c}) &= q_0(\mathbf{c})\sigma_0^{(\mathbf{c})}, \\
p_1(\mathbf{c}) &= q_1(\mathbf{c})\sigma_0^{(\mathbf{c})} + q_0(\mathbf{c})\sigma_1^{(\mathbf{c})}, \\
p_2(\mathbf{c}) &= q_2(\mathbf{c})\sigma_0^{(\mathbf{c})} + q_1(\mathbf{c})\sigma_1^{(\mathbf{c})} + q_0(\mathbf{c})\sigma_2^{(\mathbf{c})}, \\
&\;\;\vdots \\
&\;\;\vdots \\
&\;\;\vdots
\end{aligned} \tag{4}$$

If $q_0 \neq 0$, these equations are easy to solve:

$$\begin{aligned} \sigma_0^{(\mathbf{c})} &= \frac{p_0(\mathbf{c})}{q_0(\mathbf{c})}, \\ \sigma_1^{(\mathbf{c})} &= \frac{p_1(\mathbf{c})}{q_0(\mathbf{c})} - \frac{q_1(\mathbf{c})}{q_0(\mathbf{c})}\sigma_0^{(\mathbf{c})}, \\ &\vdots \end{aligned} \tag{5}$$

If $q_0(\mathbf{c}) = 0$, the first equation degenerates, so we proceed to the following equations. If $q_1(c) \neq 0$, we obtain

$$\sigma_0^{(\mathbf{c})} = \frac{p_1(\mathbf{c})}{q_1(\mathbf{c})}$$

and so on. To sum up, the form of the solution depends on the first polynomial of $q_0, q_1, \ldots$ which does not vanish at $\mathbf{c}$. The first q_i which has nonzero value is used as the denominator in a solution similar to (5). In particular, the solution for $\sigma_0^{(\mathbf{c})}$ is $\frac{p_i(\mathbf{c})}{q_i(\mathbf{c})}$.

To add some formal notation to the above discussion, let $\mathcal{V}(q)$ be the zero set of the polynomial q. We define

$$H_i = \left(\bigcap_{j<i} \mathcal{V}(q_j) \right) \setminus \mathcal{V}(q_i)$$

(with obvious modifications for the first and last i). H_i is the set of points $\mathbf{c}$ for which q_i is the denominator in the solution. It is easy to verify, that there is at most one index k such that H_k is a large set. In fact, $H_k = \Re^n - \mathcal{V}(q_k)$.

Note that each of the polynomials q_i is homogenous of degree i. It follows, that $\mathcal{V}(q_k)$ is scale invariant, and so is its complement H_k.

One must not forget that in the system (4) there are more equations than unknowns. It is possible that such a system will not have any solution. This occurs when the solution obtained from some of the equations does not fulfill the other equations. Note, however, that once the solutions for σ_i are substituted in the other equations, they become algebraic equations in $(c_1, \ldots, c_n)$. Thus, to every H_i we have an associated variety G_i that restricts the solution.

We argued before that every $\mathbf{c} \in \bigcup_{K \notin \Delta}(S(K))$ gives rise to divisibility of $P_{\mathbf{c}}$ by $Q_{\mathbf{c}}$, i.e., enables a solution of (4). Hence

$$\bigcup_{K \notin \Delta} (S(K)) \subseteq \bigcup_i (H_i \cap G_i) .$$

The set on the left-hand side is known to be large, so the set on the right-hand side must also be large. We conclude that there is a k such that $H_k \cap G_k$ is large. Then H_k is the unique large set mentioned above, and G_k is trivial, i.e., $H_k \cap G_k = H_k$.

We now get rid of the specific ray K we chose before, and consider the relationship of a general ray K to the set H_k. Since H_k is scale invariant, a ray is either contained in this set or disjoint from it. Let $K \subseteq H_k \, (= H_k \cap G_k)$. Pick a point $\mathbf{c} \in K \cap \mathbb{Q}^n$.

By definition of H_k and G_k, (2) can be solved for $\mathbf{c}$ and produce a polynomial $S^{(\mathbf{c})}$ such that $r_{\mathbf{c}} = S^{(\mathbf{c})}$.

The set of points on which $\sigma_0^{(\mathbf{c})}$ obtains integer values is contained in $\mathcal{B}(p_k, q_k)$. (Note that this bale also includes the case $q_k = 0$.) We argued above that for $K \notin \Delta$ and $\mathbf{c} \in S(K)$, $\sigma_0^{(\mathbf{c})}$ is an integer. Thus

$$\bigcup_{K \notin \Delta} S(K) \subseteq \mathcal{B}(p_k, q_k).$$

Since p_i and q_i are both homogenous, $\mathcal{B}(p_k, q_k)$ is scale invariant and contains all of $\bigcup_{K \notin \Delta} K$. This is a contradiction to our opening assumption $(*)$, unless the bale is trivial. A trivial bale satisfies $p_k(\mathbf{c})/q_k(\mathbf{c}) \in \mathbb{Z}$ for every $\mathbf{c}$ such that $q_k(\mathbf{c}) \neq 0$, i.e., for $\mathbf{c} \in H_k$. We conclude that $r_{|K}$ is p.i. for every ray contained in H_k. In other words, $\bigcup_{K \notin \Gamma} K \subseteq \mathcal{V}(q_k)$, a nontrivial scale-invariant variety. □

DEFINITION 5.29. *Let $P(\mathbf{x}) \in \Re[\mathbf{x}]$. We define $\psi(P)(\mathbf{x}) = \lim_{\lambda \to 0} \lambda^s P(\mathbf{x}/\lambda)$ where $s = \deg P$. That is, $\psi(P)$ is the sum of monomials in P of leading degree. For any rational function $r = P/Q$ where $P, Q \in \Re[\mathbf{x}]$, $\psi(r)(\mathbf{x}) \stackrel{\text{def}}{=} \psi(P)(\mathbf{x})/\psi(Q)(\mathbf{x})$.*

ψ is a "homogenizing operator" on polynomials and rational functions.

LEMMA 5.30. *If a set of rays in $\Re^n$ is contained in some nontrivial algebraic variety, then it is contained in a nontrivial, scale-invariant one.*

Proof. Let Γ be the set of rays and V a variety that contains it. Let $p_1, \ldots, p_k$ be the polynomials defining V. Let $\psi(V)$ be defined by $\psi(p_1) = 0, \ldots, \psi(p_k) = 0$. Clearly, $\psi(V)$ is scale invariant. We first claim that it is nontrivial: for $\psi(V)$ to be trivial, at least one of its defining polynomials must be identically zero. But $\psi(p_i) \equiv 0$ if and only if $p_i \equiv 0$. It rests to show that $\Gamma \subseteq \psi(V)$. To see this, let $K \in \Gamma$; then $K \subseteq V$, so $p_{i|K} \equiv 0$ for every i. In particular,

$$\lim_{\lambda \to 0} \lambda^s p_{i|K}(t/\lambda) = 0$$

for every t; i.e., $\psi(p_i)_{|K} \equiv 0$. Thus $K \subseteq \psi(V)$. □

6. Translating RAM programs into computation trees. The foundation for the proof of all our lower-bound theorems for RAMs is a way of translating a RAM program into a computation tree that computes the same function for almost all inputs (or almost all inputs within a certain neighborhood). The precise statement varies from theorem to theorem, and accordingly we present six different lemmas, that prepare the ground for our six theorems.[2] The starting point for these proofs is the technique of Paul and Simon [15]. The first lemma below is "almost" proved in their work.

LEMMA 6.1. *Let P be a $(\Re, \Re, \{+, -, \times, /\})$-RAM program that recognizes a set $W \subseteq \Re^n$ in time bounded by t. The initial contents of the random access memory are assumed to be zero except for a finite set of cells. Then P can be transformed into an algebraic computation tree, recognizing a set V, such that the following hold:*

(1) *$h(T) \leq t$;*

(2) *V is an open set;*

(3) *there exists a nontrivial algebraic variety H such that $W \cup H = V \cup H$.*

Proof. We make the following nonrestrictive assumptions on the program. The input variables, $x_1, \ldots, x_n$, reside in addresses $1, 2, \ldots, n$ of the random access memory. The program has access to a fixed set of *registers* $r_1, \ldots, r_k$ which are not in

[2]Note that the order of the lemmas does not correspond to the order of the theorems; it was chosen to facilitate the presentation of the proofs.

the random access memory and on which arithmetics and tests are performed, while main memory is accessed explicitly only by instructions that transfer the contents of a register into memory, or vice versa. These instructions can use *direct addressing* (the address is a program constant) or *indirect addressing* (the address is given in a specified register). The registers must be explicitly initialized, while the memory is preset to the program-determined values. Finally, we assume that the program ends with an output instruction that specifies the result of the computation (say, by naming a register).

We begin by representing P in tree form in the standard way, which involves unrolling loops, so that control only flows from root to leaves. This tree is potentially infinite; however, since we assume that the time complexity of the program is bounded by t, we may prune the tree at height t, without interfering with its correctness. The nodes of this tree are labeled with instructions of the program. To make it a computation tree, we have to replace all references to registers and memory locations with named variables. The variable names will be u_1, u_2, etc.

We start by replacing each left-hand occurrence of a register name by a unique variable name u_i. Next, we replace all right-hand occurrences in accordance with the closest preceding left-hand replacement. (Since we assume that registers must be initialized explicitly, there will always be one.)

Our main concern is handling memory references. We will use additional new variables to represent values stored in memory (except for the initial values). In order to determine the target of a memory reference, we have to find out whether the value used for addressing (itself the result of prior computation) coincides with the address used in a preceding memory reference. Since in our model $\mathcal{F} = \{+, -, \times, /\}$, all functions that can be computed by a straight-line sequence of instructions are rational functions from $\Re(\mathbf{x})$. Therefore, in order to analyze the memory references of the program, we represent each value computed as a rational function.

Recall that register names have already been replaced with variable names; thus it rests to handle memory access instructions, which can take one of four possible forms (here a represents a real constant):

(i) $\langle a \rangle \leftarrow u_i$
(ii) $\langle u_j \rangle \leftarrow u_i$
(iii) $u_i \leftarrow \langle a \rangle$
(iv) $u_i \leftarrow \langle u_j \rangle$

In order to analyze the memory references we apply the following analysis procedure to the whole tree. The procedure handles the nodes of the tree in a top-down order. With each node ν that sets a variable u_i we associate a function $f_i \in \Re(\mathbf{x})$ that represents the value assigned. With nodes representing STORE instructions (types (i) and (ii)), we also associate a function g_i that represents the address accessed. Later, we will change a STORE instruction into an assignment to a unique variable. This variable will be used in subsequent LOAD instructions only if the functions that describe the addresses accessed in the STORE and the subsequent LOAD are identical. This is a "rough" analysis, because if nonidentical functions yield the same address, our analysis will be incorrect; the inputs where such a failure happens will create the difference between V (the set recognized by the computation tree) and W (the set recognized by P).

The following rules are applied to each node, according to the type of instruction it represents.

(1) A decision node: no special handling.

(2) An assignment

$$u_i \leftarrow a, \qquad \text{where } a \in \Re.$$

We define $f_i = a$.
(3) An assignment

$$u_i \leftarrow u_j.$$

We define $f_i = f_j$. Note that f_j must have already been defined.
(4) A computational instruction

$$u_i \leftarrow u_j \circ u_k, \qquad \text{where } \circ \in \{+, -, \times, /\}.$$

We define $f_i = f_j \circ f_k$. Note that f_j and f_k must have been already defined.

(5) For a STORE instruction of type (i), we replace the left-hand side with a new variable u_k; we define $f_k = f_i$ and $g_k = a$.

(6) For a STORE instruction of type (ii), we replace the left-hand side with a new variable u_k; we define $f_k = f_i$ and $g_k = f_j$.

(7) For a LOAD instruction of type (iii), we look for the closest ancestor of the current node that represents an instruction of type (i) or (ii) and has $g_k = a$. If we find such a node, we replace the right-hand side of the assignment with u_k. If we do not, and $a \in \{1, \ldots, n\}$, we replace the right-hand side with x_a. Otherwise, we replace it with a constant that is the initial value of memory address a (either specified explicitly by the program or the default value zero).

(8) For a LOAD instruction of type (iv), we look for the closest ancestor of the current node that represents an instruction of type (i) or (ii) and has $g_k = f_j$. If we find such a node, we replace the right-hand side of the assignment with u_k. If we do not, and $f_j \in \{1, \ldots, n\}$, we replace the right-hand side with x_{f_j}. Otherwise, if $f_j = a$ where a is one of the addresses initialized to a nonzero value, we replace the right-hand side with this value. In all other cases we replace the right-hand side with a zero.

In cases (1) through (6), it is clear that the function f_i represents correctly the value of u_i (assuming ancestors were handled correctly). Only cases (7)–(8) require finer consideration. The analysis of case (7) is correct, provided that the input vector $\mathbf{x}$ does not mislead us by satisfying an equation $g_k(\mathbf{x}) = a$ which is not an identity. Similarly, the analysis of case (8) is correct, provided that the input vector $\mathbf{x}$ does not mislead us by satisfying a nontrivial equation among $g_k(\mathbf{x}) = f_j(\mathbf{x})$, $f_j(\mathbf{x}) = 1, \ldots, f_j(\mathbf{x}) = n$, and $f_j(\mathbf{x}) = a$, where a is one of the addresses initialized to a nonzero value. Note that the set of misleading $\mathbf{x}$ values is defined by a finite number of equations in rational functions. Each equation of rational functions, say

$$\frac{P(\mathbf{x})}{Q(\mathbf{x})} = \frac{R(\mathbf{x})}{S(\mathbf{x})}$$

(P, Q, R, and S are polynomials), can be rewritten as

$$PS - RQ = 0 \tag{6}$$

(possibly adding solutions where one of the denominators is zero). This way we obtain a set H_1, defined by a finite number of polynomial equations, i.e., an algebraic variety, that contains all the misleading $\mathbf{x}$ values. H_1 is a nontrivial variety, for the defining

equations are never identities. For every $\mathbf{x} \in \Re \setminus H_1$, the computation tree obtained simulates the RAM program faithfully.

For every decision node $u_i : u_j$, we can now write the comparison in terms of rational functions $f_i : f_j$. If this comparison happens to be trivial (has only one possible outcome), we delete the decision node, keeping the only child that is reached. For every remaining decision node, we remove the branch of equality. Namely, we use the form of decision nodes with three children ($<$, $=$, and $>$) and replace every subtree rooted at $=$ with a rejecting leaf. Let H_2 be the set of inputs that satisfy one or more of the equations $f_i = f_j$ (rewritten as in (6)); H_2 is a nontrivial algebraic variety.

Following the last change, we obtain a tree T that simulates P faithfully if the input is not in $H = H_1 \cup H_2$.

Let V be the set recognized by T. Now, V is an open set because it is defined by strict polynomial inequalities. If $\mathbf{x} \in W \cup H$, then either $\mathbf{x} \in H$ or $\mathbf{x} \in W \setminus H$. In the latter case, $\mathbf{x}$ is accepted by the program P; moreover the tree simulates P faithfully on $\mathbf{x}$ and therefore accepts it. Thus $\mathbf{x} \in V$. Similarly, if $\mathbf{x} \in V \setminus H$, then $\mathbf{x} \in W$. We have proved the lemma. □

LEMMA 6.2. *Let P be a $(\Re, \Re, \{+, -, \times, /, \chi_{\mathbb{Z}}\})$-RAM program that recognizes a set $W \subseteq \Re^n$ in time bounded by t. The initial contents of the memory cells of integer addresses may be arbitrarily specified by P. Then P can be transformed into an algebraic computation tree recognizing a set V, such that the following hold:*

(1) *$h(T) \leq t$;*

(2) *V is an open set;*

(3) *there exists a nontrivial bale H such that $V \cup H = W \cup H$.*

Proof. We point out only the differences from the proof of Lemma 6.1. The extensions allowed by our RAM are integrality testing and free initialization of all integer-addressed cells. We consider the latter extension first. It affects the proof of Lemma 6.1 by introducing infinitely many equations for misleading inputs (only for case 8). These are the equations:

$$\{f_j(\mathbf{x}) = a : a \text{ is an initialized address}\}.$$

Since f_j is a rational function, the solutions of these equations belong to the bale $\mathcal{B}(P, Q)$ where $P/Q = f_j$. The other prohibited equations define algebraic varieties, which are a special case of bale. Thus the total set of misleading inputs is contained in a finite union of bales, i.e., in a bale. We initially define H_1 to be this bale.

We proceed to handle tests of the two kinds: ordinary comparisons are handled as before, giving rise to the set H_2. Now we also have integrality tests. Here we distinguish two cases. For a given integrality-testing node, it is possible that the test passes for all input that arrives there (i.e., only integers are ever tested). If this is the case, the node is simply eliminated, and only the "yes" branch kept. Otherwise, we eliminate the node as well but keep the "no" branch instead; to maintain correctness, we forbid all input that passes the test. Since the variable tested has already been associated with a rational function, the set of inputs that pass the test forms a bale (and not the trivial one, because some inputs do not pass). Call this bale H_3. We let $H = H_1 \cup H_2 \cup H_3$. □

LEMMA 6.3. *Let P be a $(\Re, \mathbb{N}, \{+, -, \times, /\})$-RAM program that recognizes a set $W \subseteq \Re^n$ in time bounded by t. The initial contents of the random access memory may be arbitrarily specified by P. Then P can be transformed into an algebraic computation tree recognizing a set V, such that the following hold:*

(1) $h(T) \leq t$;
(2) V *is an open set;*
(3) *there exists a boundary set* A *such that* $V \cup A = W^\circ$.

Proof. T is obtained from P much as in the proof of Lemma 6.1, with a difference only in the handling of indirect addressing operations. Here, we treat every memory access as a direct addressing one. For the constant address, we use the value of the function g_k at an arbitrary point of its domain of definition.

We now elaborate the effects of this change. Recall that in the process that derives T from the program tree, certain parts of the tree have been removed. First, we remove all branching nodes where there is only one possible outcome (with no effect on the computation). Next, every node, that is reached on a nontrivial equality, is replaced by a rejecting leaf. (This change gives rise to the set H_2.)

Therefore, it suffices to consider indirect addressing nodes in those parts of the tree that are not eliminated. Let ν be such a node and D_ν be the set of inputs $\mathbf{x} \in \Re^n$ that arrive at ν (more precisely, the computation on $\mathbf{x}$ arrives at ν). This set is defined by the branching conditions on the path to ν, which are all strict inequalities among polynomials; it is therefore an open set. Let f be the function, that yields the address for the memory access at ν. It is a rational function, and its value must be integer for all $\mathbf{x} \in D_\nu$; otherwise the program would not be valid. By Lemma 5.12, f is constant throughout its domain of definition, justifying the change described above.

After replacing register names with variables, we proceed to replace memory access operations with assignments. In the proof of Lemma 6.1, we argued that this substitution is safe for input $\mathbf{x}$ unless $\mathbf{x}$ satisfies one of a certain set of nontrivial equations, giving rise to a variety of "misleading input" H_1. The equations test whether the memory address coincides with an address accessed in some prior node or with a preset location. In the current construction we have changed all address expressions into constants: thus the equations in question become relations between constants. They can hold for $\mathbf{x}$ if and only if they are identities, but identities were not included in the definition of H_1. The set corrseponding to H_1 for the current construction is thus empty.

We conclude that T simulates P faithfully if the input is not in H_2. All inputs in H_2 are rejected; therefore, every input accepted by T is indeed in W, and we obtain

$$\begin{aligned} V \subseteq & W^\circ \subseteq W \subseteq V \cup H_2 \\ \Rightarrow \quad & W^\circ = V \cup (W^\circ \cap H_2)\,. \end{aligned}$$

We thus let $A = W^\circ \cap H_2$. Since H_2 is a boundary set, so is A. □

LEMMA 6.4. *Let* P *be a* $(\Re, \Re, \{+, -, \times, /, \chi_{\mathbb{Z}}\})$*-RAM program that recognizes a set* $U \subseteq \Re^n$ *in time bounded by* t. *The initial contents of the random access memory are assumed to be zero except for a finite set of cells. Then* P *can be transformed into an algebraic computation tree recognizing a set* V, *such that the following hold:*

(1) $h(T) \leq t$;
(2) V *is an open set;*
(3) *there exists a nontrivial, scale-invariant bale* B *such that for all* $K \in \mathcal{Q}^{(n-1)}$, *where* $K \not\subseteq B$, $\exists a_K \in \mathbb{Z}^+$ *such that for all* $\mathbf{x} \in (K \cap a_K \mathbb{Z}^n), \mathbf{x} \in U \Leftrightarrow \mathbf{x} \in V$.

Proof. We extend the construction of Lemma 6.1 to handle the integrality predicate. This extension will introduce the bale mentioned in the lemma. We consider first the case where the integrality predicate is not used by the program; then we can apply Lemma 6.1 and obtain a variety H such that $U \cup H = V \cup H$. Let Γ be the set of rays K wholly contained in H. By Lemma 5.30, Γ may be completed to a nontrivial,

scale-invariant variety which we now call B. Consider a rational ray $K \not\subseteq B$. Only a finite number of points from K may be contained in H (Lemma 5.21). The conclusion of our lemma is immediate.

We proceed to programs with integrality tests $\chi_{\mathbb{Z}}$. This operation is represented in the program tree by a branching node, where the branch labeled *yes* is taken if and only if the register tested contains an integer. Note that the construction of Lemma 6.1 gives no special treatment to decision nodes of any kind, so it can be carried out in the extended model with no change. We deal with integrality tests after performing the original construction as described for Lemma 6.1. Consider now a $\chi_{\mathbb{Z}}$-node ν, the first such node on its path. The register name it used has been replaced by a variable u_i, and a rational function f_i has been found that represents the value of u_i on "safe" input. Because there are no $\chi_{\mathbb{Z}}$ nodes before ν, the safety requirement applying to f_i is the same as in Lemma 6.1, i.e., input $\notin H$.

Let

$$\Gamma_i = \{K \in \mathcal{Q}^{(n-1)} : f_{i|K} \text{ is p.i.}\}$$

and similarly

$$\Delta_i = \{K \in \mathcal{Q}^{(n-1)} : f_{i|K} \text{ is p.n.i.}\}.$$

Theorem 5.28 shows that either $\bigcup_{K \notin \Gamma_i} K$ or $\bigcup_{K \notin \Delta_i} K$ is contained in a nontrivial, scale-invariant bale. We add this bale to B. (A union of two nontrivial, scale-invariant bales is once again such a bale.)

First assume that $\bigcup_{K \notin \Gamma_i} K \subseteq B$. Then we remove the decision done and keep only the *yes* branch. The change is safe on input $\mathbf{x}$, provided that $f_i(\mathbf{x}) \in \mathbb{Z}$. Now if $K \not\subseteq B$ then $K \in \Gamma_i$, so f_i is p.i. on K. Thus there is an $a_i^K \in \mathbb{Z}^+$, such that the modified tree handles $\mathbf{x}$ correctly if $\mathbf{x} \in K \cap a_i^K \mathbb{Z}^n$.

In the other case we have $\bigcup_{K \notin \Delta_i} K \subseteq B$. Then we remove the decision done and keep only the *no* branch. The safety argument is similar.

We complete the construction by setting a_K, for every $K \not\subseteq B$, to be a common multiple of the a_i^K associated with all the nodes eliminated. □

LEMMA 6.5. *Let P be a $(\Re, \Re, \{+, -, \times, \lfloor\ \rfloor\})$-RAM program that recognizes a set $W \subseteq \Re^n$ in time bounded by t. The initial contents of the random access memory cells of integer addresses may be arbitrarily specified by P. Then there exists a constant $\lambda_0 > 0$ such that for all $0 < \lambda < \lambda_0$, P can be transformed into an algebraic computation $T = T_\lambda$ such that the following conditions hold:*

(1) *$h(T) \leq 3t + 2n + 1$;*

(2) *T recognizes an open set V;*

(3) *there exists a boundary set A such that $V \cup A = (W \cup A) \cap B(\lambda, \mathbf{0})$.*

Proof. We start by constructing a computation tree, T_0, from P, much as in the proofs of Lemmas 6.1 and 6.2. As in the former constructions, we associate with each variable u_i a function f_i that represents the value assigned to that variable. However, this time, the function will be a polynomial. In fact, the computation tree that we derive only includes the operations $\{+, -, \times\}$. Floor operations are eliminated in course of the construction, and it is their elimination that necessitates restricting the input to the neighborhood $B(\lambda, \mathbf{0})$. The constant λ_0 is derived in the construction.

The first stage, as in the former lemmas, involves unfolding the program to tree form and replacing register names by variables, obtaining the program tree T_P of height t. This tree may now include operations $u_i \leftarrow \lfloor u_j \rfloor$. These nodes are handled

specially as described below. With each such node, a constant λ_i is associated, in addition to the function f_i. The construction proceeds top-down, applying the following rules to each node according to its type.

(1) A decision node: no special handling.

(2) An assignment

$$u_i \leftarrow a, \qquad \text{where } a \in \Re.$$

We define $f_i = a$.

(3) An assignment

$$u_i \leftarrow u_j.$$

We define $f_i = f_j$. Note that f_j must have already been defined.

(4) An arithmetic instruction

$$u_i \leftarrow u_j \circ u_k, \qquad \text{where } \circ \in \{+, -, \times\}.$$

We define $f_i = f_j \circ f_k$. Note that f_j and f_k must have been already defined, and that the resulting function is a polynomial.

(5) A truncation instruction

$$u_i \leftarrow \lfloor u_j \rfloor.$$

Let $c_j = f_j(\mathbf{0})$. We distinguish two cases.

(5.1) $c_j \notin \mathbb{Z}$, i.e., $\lfloor c_j \rfloor < c_j < \lceil c_j \rceil$. By continuity of f_j, we choose $\lambda_i > 0$ such that for all $\mathbf{x} \in B(\lambda_i, \mathbf{0})$ we have $\lfloor c_j \rfloor < f_j(\mathbf{x}) < \lceil c_j \rceil$. Hence, $\lfloor f_j(\mathbf{x}) \rfloor = \lfloor c_j \rfloor$ for all such $\mathbf{x}$. We relabel the current node with the instruction

$$u_i \leftarrow \lfloor c_j \rfloor$$

and set $f_i = \lfloor c_j \rfloor$.

(5.2) $c_j \in \mathbb{Z}$. By continuity of f_j, we choose $\lambda_i > 0$ such that for all $\mathbf{x} \in B(\lambda_i, \mathbf{0})$ we have $c_j - 1 < f_j(\mathbf{x}) < c_j + 1$. Hence, $\lfloor f_j(\mathbf{x}) \rfloor \in \{c_j - 1, c_j\}$ for all such $\mathbf{x}$. We replace the current node with a branching structure, which tests the value of $f_j(\mathbf{x})$ to determine which of the two possibilities is appropriate, and proceed accordingly. This transformation is shown in Figure 1, where T_1' (resp., T_1'') represents a copy of T_1 with new (primed; resp., double-primed) variable names; u_k is an additional variable not in the original tree. The functions f_k, f_i and $f_{i'}$ are now defined as in case (2).

The rest of the nodes, representing LOAD and STORE operations, are replaced with assignment operations just as in the proof of Lemma 6.2. This results in the definition of a "forbidden bale" H. This set contains all input values for which memory references were not resolved correctly. The resulting tree T_0 simulates the RAM program faithfully provided that the input is not in H, *and* the replacement of floor operations is correct. The latter condition will be fulfilled if $\mathbf{x} \in B(\lambda_0, \mathbf{0})$ where λ_0 is the minimum over the λ_i defined. (If none were defined, which means that there were no floor operations, λ_0 can be chosen arbitrarily.)

We conclude the construction by eliminating redundant comparisons and then replacing every $=$-branch (in the comparison nodes that remained) with a rejecting leaf. These equality branches define another variety, H_2, which contains input which we may unjustly reject. The effect of the last change is that the set V_1 accepted by the resulting tree T_1 is open. It also satisfies, for $H = H_1 \cup H_2$, and for every $0 < \lambda < \lambda_0$,

$$(V_0 \cup H) \cap B(\lambda, \mathbf{0}) = (W \cup H) \cap B(\lambda, \mathbf{0}).$$

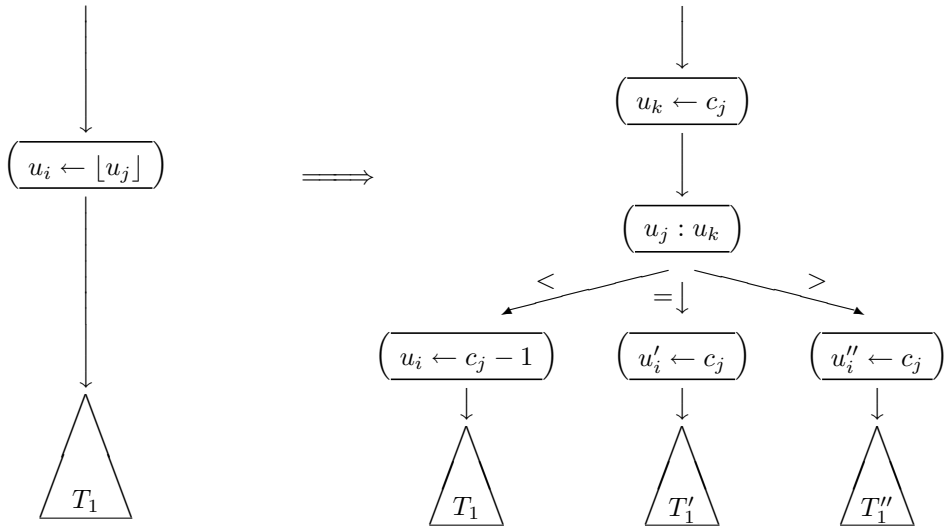

FIG. 1. *Transformation of truncation nodes.*

It is easy to see that $h(T_1) \leq 3t$. We now extend T_1 to the desired tree T by inserting, before the root of T_1, a series of nodes that compute

$$\|\mathbf{x}\| = \left(\sum_{i=1}^{n} x_i^2 \right),$$

and finally compare this value with λ. The branch for $\|\mathbf{x}\| < \lambda$ is connected to the root of T_1; the other branches reject. It is clear that the resulting tree recognizes the set $V = V_1 \cap B(\lambda, \mathbf{0})$. Let $A = H \cap B(\lambda, \mathbf{0})$. It is easy to verify that parts (2) and (3) of the lemma is satisfied. Verifying part (1) is also straightforward. □

LEMMA 6.6. *Let P be a $(\Re, \mathbb{N}, \{+, -, \times, \lfloor\ \rfloor\})$-RAM program that recognizes a set $W \subseteq \Re^n$ in time bounded by t. The initial contents of the random access memory may be arbitrarily specified by P. Then there exists a constant $\lambda_0 > 0$ such that for all $0 < \lambda < \lambda_0$, P can be transformed into an algebraic computation tree $T = T_\lambda$ such that the following hold:*

(1) *$h(T) \leq 3t + 2n + 1$;*
(2) *T recognizes an open set V;*
(3) *there exists a boundary set H such that $V \cup H = W^\circ \cap B(\lambda, \mathbf{0})$.*

We omit details of the proof, which is a straightforward combination of the proofs of Lemmas 6.5 and 6.3.

LEMMA 6.7. *Let P be a $(\mathbb{Q}, \mathbb{Q}, \{+, -, \times, \lfloor\ \rfloor\})$-RAM program that recognizes a set $U \subseteq \mathbb{Q}^n$ in time bounded by t. The initial contents of the random access memory are assumed to be zero except for a finite set of cells. Then P can be transformed into an algebraic computation tree T recognizing a set $V \subseteq \Re^n$, such that the following hold:*

(1) *$h(T) \leq 2t$;*
(2) *V is an open set;*
(3) *there exist a nontrivial algebraic variety H and a constant $a \in \mathbb{Z}^+$ such that*

$$V \cap (a\mathbb{Z}^n \setminus H) = U \cap (a\mathbb{Z}^n \setminus H).$$

Proof. We construct T from P in a way similar to the construction of Lemma 6.1. As in the previous constructions, we associate with each variable u_i a function f_i that represents the value assigned to that variable. This time, this function will not be a rational function but a polynomial. Thus only the operations $\{+, -, \times\}$ take part in these functions; floor operations will be eliminated. We will define the constant a and show that these functions represent the computation precisely enough for input in $a\mathbb{Z}^n$.

As usual we start by representing the program as a tree, renaming registers to unique variables. In this tree, there still are operations of the form $u_i \leftarrow \lfloor u_j \rfloor$. These operations have to be replaced by algebraic operations. The idea that allows this is as follows. If only the operations $\{+, -, \times\}$ had been used, all functions computed by the program would have been polynomials. We study the effect of applying the truncation operation to a polynomial. Consider for simplicity a univariate polynomial $c_k x^k + \cdots + c_1 x + c_0$. All c_j are rational. Let d be the common denominator of $\{c_1, \ldots, c_k\}$. Then, if x is divisible by d, the fractional part of this polynomial is determined by the constant c_0. Thus, computing the "floor" of this expression is achieved by subtracting a fixed constant. Hence, for input suitably restricted, we can replace this truncation operation with subtraction. In this way, we eliminate one by one all the truncation operations in the tree.

More precisely, we now associate with each variable u_i an integer a_i (in addition to the function f_i which is used as before). The construction proceeds top-down, applying the following rules to each node according to its type.

(1) A decision node: no special handling.

(2) An assignment

$$u_i \leftarrow c, \qquad \text{where } c \in \mathbb{Q}.$$

We define $f_i = c$ and $a_i = 1$.

(3) An assignment

$$u_i \leftarrow u_j.$$

We define $f_i = f_j$ and $a_i = 1$. Note that f_j must have already been defined.

(4) An instruction

$$u_i \leftarrow u_j \circ u_k, \qquad \text{where } \circ \in \{+, -\}.$$

We define $f_i = f_j \circ f_k$, and $a_i = 1$. Note that f_j and f_k must have been already defined and that the resulting function is a polynomial.

(5) A multiplication instruction

$$u_i \leftarrow u_j \cdot u_k.$$

We define $f_i = f_j \cdot f_k$. Note that f_j and f_k must have been already defined and that the resulting function is a polynomial. We define a_i to be the least common denominator of the constant terms of the polynomials f_j, f_k.

(6) A truncation instruction

$$u_i \leftarrow \lfloor u_j \rfloor.$$

Let c_j be the constant term of f_j. We replace this node by two nodes, labeled with the instructions

$$u_k \leftarrow c_j - \lfloor c_j \rfloor$$
$$u_i \leftarrow u_j - u_k$$

(u_k is a new variable). Note that this is a correct replacement for the truncation instruction, provided that f_j represents correctly the value of u_j and that the non-constant part of f_j is integer. We define f_i, f_k and a_i, a_k accordingly.

The rest of the nodes, representing LOAD and STORE operations, are handled exactly as in the Paul–Simon construction. a_i is defined as 1 for all of these instructions. This results in the definition of a "forbidden variety" H_1 in the usual way, which contains all input values for which memory references were not resolved correctly. We obtain that the tree simulates the RAM program faithfully, provided that the input is not in H_1 *and* the replacement of floor operations is correct. To this end we define a to be the product of all the a_i. We claim that if the input belongs to $a\mathbb{Z}^n$, then these replacements are correct. As above, we denote by c_j the constant term of f_j. We assume for simplicity that the variables are numbered so that the variables defined before u_i (that is, in ancestors thereof) have lower indices.

CLAIM 6.8. *Let $\mathbf{x} \in a\mathbb{Z}^n \setminus H_1$. On input $\mathbf{x}$, the value assigned to u_i is $f_i(\mathbf{x})$, for every u_i in T. The value of $f_i(\mathbf{x}) - c_i$ is an integer divisible by the $d_i = a/(a_1 \cdot \cdots \cdot a_i)$.*

Hence the replacement of all floor operations is correct for such $\mathbf{x}$.

The claim is proved by induction, starting at the root of the tree. For variables defined by case (2) it is immediate. For variables defined by cases (3)–(4) the claim follows from the inductive assumption regarding u_j and u_k. Consider case (5). It is clear that if the values assigned to u_j and u_k are, respectively, $f_j(\mathbf{x})$ and $f_k(\mathbf{x})$, then the value assigned to u_i is $f_i(\mathbf{x})$. Now

$$f_i(\mathbf{x}) - c_i = f_j(\mathbf{x}) \cdot f_k(\mathbf{x}) - c_j c_k = (f_j(\mathbf{x}) - c_j) f_k(\mathbf{x}) + c_j (f_k(\mathbf{x}) - c_k).$$

The inductive assumption shows that $f_j(\mathbf{x}) - c_j$ is a multiple of $d_j = a/(a_1 \cdots a_j)$, and hence of $d_{i-1} = a/(a_1 \cdots a_{i-1})$. By the definition of a_i, it is the common denominator of the rational numbers $f_k(\mathbf{x})$ and $f_j(\mathbf{x})$. Thus $(f_j(\mathbf{x}) - c_j) f_k(\mathbf{x})$ is a multiple of $d_{i-1}/a_i = d_i$. The same holds for $c_j(f_k(\mathbf{x}) - c_k)$.

In case (6) the inductive assumption shows that the value of u_j is $f_j(\mathbf{x})$ and that $f_j(\mathbf{x}) - c_j$ is a whole number; thus the fractional part of u_j is indeed $c_j - \lfloor c_j \rfloor$. It follows that the new instructions compute u_i correctly (for this input).

STORE and LOAD instructions were replaced by regular assignments; the claim thus holds, as it does for regular assignments, as long as the replacement is valid. We know (see Lemma 6.1) that it is valid for input not in H_1. This concludes the proof of the claim.

Our construction is concluded, as in Lemma 6.1, by deleting trivial comparisons and replacing equality branches that remain by a rejecting leaf. This gives rise to the nontrivial variety H_2. As usual, we define $H = H_1 \cup H_2$. Now, the set V recognized by the resulting tree is an open set. If $\mathbf{x} \in U \cap (a\mathbb{Z}^n \setminus H)$, Claim 6.8 applies to $\mathbf{x}$, showing that the tree is faithful to the program. From $\mathbf{x} \in U$ it follows that $\mathbf{x} \in V$. We have thus shown

$$U \cap (a\mathbb{Z}^n \setminus H) \subseteq V \cap (a\mathbb{Z}^n \setminus H).$$

The reverse containment is similarly proved. □

7. Proofs of lower bound theorems.

7.1. Extending Ben-Or's theorem. Theorem 3.1 is a direct consequence of the following lemma [2].

LEMMA 7.1. *Let T be an algebraic computation tree recognizing $W \subseteq \Re^n$. Then $\beta(W) \leq 9^{h(T)} 3^n$.*

Ben-Or proves this lemma by applying, in an elegant way, results of Milnor [14] and Thom [18] on the topology of varieties. Using this lemma we can also prove Theorem 3.1′. Let T be a computation tree that recognizes W. Let T' be obtained from T by rejecting all nontrivial equalities (as in the proof of Lemma 6.4). Note that $h(T') \leq h(T)$. Let V be the set recognized by T'; obviously $V \subseteq W$ and is open. Thus $V \subseteq W^\circ$. In fact, $V = W^\circ \setminus H$ where H is the union of all (nontrivial) varieties defined by the equalities affected. Combining Lemma 7.1 with Lemma 5.6 we have

$$\beta(W^\circ) \leq \beta(V) \leq 9^{h(T')}3^n \leq 9^{h(T)}3^n,$$

whereby

$$h(T) \geq \log_9 \beta(W^\circ) - \frac{1}{2}n.$$

Theorem 3.1′ follows.

7.2. Proof of Theorem 3.3. Consider a $(\Re, \mathbb{N}, \{+, -, \times, /\})$-RAM program P recognizing W in time t. Let T and V be given by Lemma 6.3. By the last lemma,

$$\beta(V) \leq 9^t 3^n.$$

Using Lemmas 6.3 and 5.6,

$$\beta(V) \geq \beta(W^\circ).$$

Combining the two inequalities we have

$$9^t 3^n \geq \beta(W^\circ).$$

Theorem 3.3 follows.

7.3. Proof of Theorem 3.4. Consider an $(\Re, \Re, \{+, -, \times, /, \chi_{\mathbb{Z}}\})$-RAM program P recognizing W in time t. Let T, V, and H be given by Lemma 6.2. By Lemma 7.1,

$$\beta(V) \leq 9^t 3^n.$$

Using Lemmas 6.2 and 5.3,

$$(\overline{W})^\circ = (\overline{W \cup H})^\circ = (\overline{V \cup H})^\circ = (\overline{V})^\circ,$$

and by Lemma 5.5,

$$\beta((\overline{W})^\circ) = \beta((\overline{V})^\circ) \leq \beta(V) \leq 9^t 3^n.$$

Theorem 3.4 follows.

7.4. Proof of Theorem 3.6. For simplicity we assume $\tilde{\beta}(W^\circ)$ and $\tilde{\beta}(W)$ to be finite. If one of them is infinite the theorem claims that there is no genuinely time-bounded program for recognizing W, and the proof is a simple extension of the finite case.

Consider a $(\Re, \mathbb{N}, \{+, -, \times, \lfloor\ \rfloor\})$-RAM program P recognizing W in time t. Let λ_0 be given by Lemma 6.6. Since the limit $\tilde{\beta}(W^\circ)$ is finite, there is a number $0 < \lambda < \lambda_0$

such that $\beta(W^\circ \cap B(\lambda, \mathbf{0})) = \tilde{\beta}(W^\circ)$. Pick $T = T_\lambda$ as in Lemma 6.6, and let V be the set T recognizes. By Lemma 7.1,

$$\beta(V) \leq 9^{3t+2n+1}3^n = 9^{3t+1}3^{5n}.$$

Using Lemmas 6.6 and 5.6,

$$\beta(V) \geq \beta(W^\circ \cap B(\lambda, \mathbf{0})) = \tilde{\beta}(W^\circ).$$

Combining the two inequalities we have

$$9^{3t+1}3^{5n} \geq \tilde{\beta}(W^\circ)$$

or

$$t \geq \frac{1}{3}(\log_9 \tilde{\beta}(W^\circ) - 1) - \frac{5}{6}n.$$

A similar reasoning gives the same inequality with W instead of W°, and together they prove Theorem 3.6.

7.5. Proof of Theorem 3.7. As above, we assume $\tilde{\beta}((\overline{W})^\circ)$ to be finite. Consider a $(\Re, \Re, \{+, -, \times, \lfloor\ \rfloor\})$-RAM program P recognizing W in time t. Let λ_0 be given by Lemma 6.5. Since the limit $\tilde{\beta}(W^\circ)$ is finite, there is a number $0 < \lambda < \lambda_0$ such that $\beta(W^\circ \cap B(\lambda, \mathbf{0})) = \tilde{\beta}(W^\circ)$. Pick T, V and A as in Lemma 6.5. By Lemmas 5.5 and 7.1,

$$\beta((\overline{V})^\circ) \leq \beta(V) \leq 9^{3t+2n+1}3^n = 9^{3t+1}3^{5n}\,.$$

On the other hand,

$$\begin{aligned}
(\overline{W})^\circ \cap B(\lambda, \mathbf{0}) &= (\overline{W \cup A})^\circ \cap B(\lambda, \mathbf{0}) && \text{(Lemma 5.3)} \\
&= (\overline{(W \cup A) \cap B(\lambda, \mathbf{0})})^\circ && \text{(Lemma 5.4)} \\
&= (\overline{V \cup A})^\circ && \text{(Lemma 6.5)} \\
&= (\overline{V})^\circ.
\end{aligned}$$

Combining the last results we have

$$9^{3t+1}3^{5n} \geq \tilde{\beta}((\overline{W})^\circ).$$

Theorem 3.7 follows.

7.6. Extending Yao's lower bound. We start by reviewing Yao's proof of Theorem 3.2, and extend it to prove both Theorem 3.2 and Theorem 3.2′. We denote by $\mathcal{A}_{\mathbb{Z}^n, W}$ the class of algebraic computation trees that recognize the set $W \subseteq \Re^n$ when restricted to input in $\mathbb{Z}^n$.

Let $T \in \mathcal{A}_{\mathbb{Z}^n, W}$. With any node ν in T that represents an assignment or a computation, we associate a rational function r_ν that represents the value assigned or computed. Namely, if a constant if assigned, r_ν is this constant. If a previous variable is assigned, which was itself defined at node μ, then $r_\nu = r_\mu$. A computation node is handled as follows. Consider a node labeled with $u \leftarrow z \circ w$, where z, w are defined at nodes μ, τ, respectively. Then $r_\nu = r_\mu \circ r_\tau$ $(\circ \in \{+, -, \times, /\})$.

We define p_ν and q_ν to be polynomials such that $r_\nu = p_\nu/q_\nu$. These polynomials are defined in the natural way, e.g., in case $r_\nu = r_\mu \times r_\tau$ we have $p_\nu = p_\mu p_\tau$ and $q_\nu = q_\mu q_\tau$.

For any leaf $l \in T$, we denote by $\xi_{T,l}$ the path from the root of T to l. For $\alpha \in \{0,1\}$, let L_α be the set of leaves l such that the output of l is α and such that $\xi_{T,l}$ traverses no arcs labeled "=". Let $S_{T,l}$ be the set of $\mathbf{x} \in \Re^n$ that will trace the path $\xi_{T,l}$ in T.

DEFINITION 7.2. *T is called* normal *if, for every leaf l, the sequence of operations from the root to l has the form*

$$\begin{aligned} &z_1 \leftarrow u_1\ op_1\ w_1,\\ &z_1 : 0,\\ &z_2 \leftarrow u_2\ op_2\ w_2,\\ &z_2 : 0,\\ &\quad\cdot\\ &\quad\cdot\\ &\quad\cdot\\ &z_m \leftarrow u_m\ op_m\ w_m,\\ &z_m : 0, \end{aligned}$$

where $m \geq n$; for $1 \leq i \leq m$, $op_i \in \{+,-,\times,/\}$, every u_i and w_i is either a constant or an element of $\{z_1, z_2, \ldots, z_{i-1}\} \cup \{x_1, \ldots, x_n\}$, and for $1 \leq j \leq n$, $u_j = x_j$, $w_j = 1$ and $op_j = \times$.

DEFINITION 7.3. *T is* irredundant *if every node u can be traversed by some input $\mathbf{x} \in \mathbb{Z}^n$, and every computation node $\nu \in T$ computes a function r_ν which is not constant.*

DEFINITION 7.4. *A* regular *computation tree is one that is normal and irredundant.*

LEMMA 7.5 (Yao). *For every $T \in \mathcal{A}_{\mathbb{Z}^n,W}$ there exists $T' \in \mathcal{A}_{\mathbb{Z}^n,W}$ such that T' is regular and $h(T') \leq 2h(T) + 2n$.*

Proof. Add the sequence of instructions $z_i \leftarrow x_i \times 1$, $i = 1, \ldots, n$, at the beginning; expand each internal node into a computation node $z_i \leftarrow \cdots$ followed immediately by a branching node $z_i : 0$. Find the function r_ν computed at every node. For functions that are constant, remove this node (and the succeeding test), leaving only the correct branch of the test, and replace future references to the variable computed by the corresponding constant. Now prune away all the branches in the tree that are not traversed by any input $\mathbf{x} \in \mathbb{Z}^n$. □

We now define an operator ϕ, that translates every regular computation tree into a related decision tree. The technique developed by Yao gives a lower bound on the height of $\phi(T)$ from the topology of the set it recognizes. We further relate this set to the set recognized by T in order to derive a lower bound for the latter.

The following definition is repeated here for convenience.

DEFINITION 5.29. *Let $P(\mathbf{x}) \in \Re[\mathbf{x}]$. We define $\psi(P)(\mathbf{x}) = \lim_{\lambda \to 0} \lambda^s P(\mathbf{x}/\lambda)$ where $s = \deg P$. That is, $\psi(P)$ is the sum of monomials in P of leading degree. For any rational function $r = P/Q$ where $P, Q \in \Re[\mathbf{x}]$, let $\psi(r)(\mathbf{x}) = \psi(P)(\mathbf{x})/\psi(Q)(\mathbf{x})$.*

DEFINITION 7.6. *For any regular T, $\phi(T)$ is the decision tree obtained from T as follows. For each branching node ν of T, group the pair $(\mu = parent[\nu], \nu)$ into one node $\phi(\nu)$. Associate it with the test $\psi(p_\mu)(\mathbf{x}) \cdot \psi(q_\mu)(\mathbf{x}) : 0$. The three children of this node (labeled <,=,>) are obtained from the corresponding children in T.*

LEMMA 7.7 (Yao). *Let T be regular. For any leaf $l \in L_0(T) \cup L_1(T)$, we have $\beta(S_{\phi(T),\phi(l)}) \leq 2 \cdot 3^{n+h(T)}$.*

Note that $L_0(T) \cup L_1(T)$ is the set of leaves l such that the path to l traverses no arc labeled "=".

LEMMA 7.8 (Yao). *Let $W \subseteq \Re^n$ be scale invariant and rationally dispersed, and let $T' \in \mathcal{A}_{\mathbb{Z}^n,W}$. Then there is a boundary set A such that*

$$\bigcup_{l \in L_1(T)} S_{\phi(T'),\phi(l)} = W \setminus A\,.$$

For proofs of both lemmas see [19].

We now prove Theorems 3.2 and 3.2′.

Let $T \in \mathcal{A}_{\mathbb{Z}^n,W}$. Let T' be the regular tree provided by Lemma 7.5. By definition of $L_1(T')$, the set $\bigcup_{l \in L_1(T')} S_{\phi(T'),\phi(l)}$ is open. Thus Lemma 7.8 can be strengthened to

$$\bigcup_{l \in L_1(T')} S_{\phi(T'),\phi(l)} = W^\circ \setminus A.$$

Therefore Lemma 5.6 shows that

$$\beta\left(\bigcup_{l \in L_1(T')} S_{\phi(T'),\phi(l)}\right) \geq \beta(W^\circ).$$

By the definition of a normal tree, together with Lemma 7.5, we have

$$|L_1(T')| \leq 2^{h(T')/2} \leq 2^{h(T)+n}.$$

We now combine the last two inequalities with Lemma 7.7:

$$\beta(W^\circ) \leq |L_1(T')| \cdot 2 \cdot 3^{n+h(T')} \leq 2^{h(T)+n+1} \cdot 3^{3n+2h(T)},$$

hence

$$h(T) \geq c_1(\log_2 \beta(W^\circ) - 1) - c_2 n.$$

This proves Theorem 3.2′ directly and Theorem 3.2 as a consequence (since $\beta(W^\circ) \geq \hat{\beta}(W)$).

7.7. Proof of Theorem 3.5. Consider a $(\Re, \Re, \{+, -, \times, /, \chi_{\mathbb{Z}}\})$-RAM program P that recognizes W in time t for integer inputs. W is assumed to be scale invariant and rationally dispersed. Let U be the set of real-valued inputs accepted by P. Correctness of the program means $U \cap \mathbb{Z}^n = W \cap \mathbb{Z}^n$. Let T, V and B be given by Lemma 6.4. Let T' be a regular computation tree obtained from T (and recognizing the same set V) such that $h(T') \leq 2t + 2n$.

LEMMA 7.9. *There is a closed boundary set A such that*

$$\left(\bigcup_{l \in L_1(T')} S_{\phi(T'),\phi(l)}\right) \setminus A = W \setminus A.$$

Proof. Let H be the set of $\mathbf{x} \in \Re^n$ that satisfy $\psi(p_\nu)(\mathbf{x}) \cdot \psi(q_\nu)(\mathbf{x}) = 0$ for some branching node ν in T'. H is an algebraic variety and, by the regularity of T', is nontrivial. Since the operator ψ yields homogenous polynomials, H is scale invariant. Let

$A = B \cup H \cup \{\mathbf{0}\}$. Then A is a scale-invariant, closed boundary set. Let $\mathbf{x} \in \Re^n \setminus A$. Then $\mathbf{x} \in S_{\phi(T'),\phi(l)}$ for $l \in L_1(T') \cup L_0(T')$. We wish to prove that $\mathbf{x} \in W$ if and only if $l \in L_1(T')$.

We consider first the case $\mathbf{x} \in W$. The set $S_{\phi(T'),\phi(l)}$ is open (it is defined by strict inequalities), so $S_{\phi(T'),\phi(l)} \setminus A$ is open too, and $\mathbf{x}$ belongs in it. Hence we can choose $\varepsilon > 0$ such that the ε-neighborhood of $\mathbf{x}$ will be contained within this set. Since W is rationally dispersed, we can pick $\mathbf{y} \in \mathbb{Q}^n$ such that $\|\mathbf{y} - \mathbf{x}\| < \varepsilon$ and $\mathbf{y} \in W$. Let $N_0 > 0$ be an integer such that $N_0\mathbf{y} \in \mathbb{Z}^n$. Since W is scale invariant, we have, for all integer $k > 0$, $kN_0\mathbf{y} \in W$; hence also $kN_0\mathbf{y} \in U$. Since $\mathbf{y} \notin A$, in particular $\mathbf{y} \notin B$, and by Lemma 6.4 there is an integer $a > 0$ such that, for all $k \in \mathbb{Z}^+, kaN_0\mathbf{y} \in V$. We now choose an integer $N = kaN_0$ with k large enough to make, for all $\nu \in \xi_{T,l}$,

$$\operatorname{sign}(r_\nu(N\mathbf{y})) = \operatorname{sign}\left(\frac{1}{N^d} r_\nu(N\mathbf{y})\right) = \operatorname{sign}(\psi(r_\nu)(\mathbf{y}))$$

(such k exists by the definition of ψ). The above equation implies that $N\mathbf{y}$ will follow the same path in T' as $\mathbf{y}$ does in $\phi(T')$. Since $\mathbf{y}$ reaches leaf $\phi(l)$ in $\phi(T')$, $N\mathbf{y}$ will reach leaf l in T'. Since $N\mathbf{y} \in V \cap \mathbb{Z}^n$, we have $l \in L_1(T')$.

For $\mathbf{x} \notin W$, similar arguments show that $l \in L_0(T')$, hence $\mathbf{x} \notin \bigcup_{l \in L_1(T')} S_{\phi(T'),\phi(l)}$. The conclusion of the lemma folows. □

Combining the last result with Lemmas 5.3 and 5.5, we have

$$\beta\left(\bigcup_{l \in L_1(T')} S_{\phi(T'),\phi(l)}\right) \geq \beta\left(\left(\overline{\bigcup_{l \in L_1(T')} S_{\phi(T'),\phi(l)}}\right)^\circ\right) = \beta((\overline{W})^\circ)$$

and by applying Lemma 7.7, as in the preceding proof, we obtain

$$\beta((\overline{W})^\circ) \leq 2^{t+n+1} \cdot 3^{3n+2t},$$

completing the proof of Theorem 3.5.

7.8. Proof of Theorem 3.8. The proof of Theorem 3.8 is very similar to the last proof. However, since there are some technical differences, we give the proof in whole.

LEMMA 7.10. *Let $W \subseteq \Re^n$ be scale invariant and rationally dispersed, H a nontrivial algebraic variety in $\Re^n$. For any $\mathbf{x} \in \Re^n \setminus (H \cup \{\mathbf{0}\})$ and $\varepsilon > 0$, there exists a rational point $\mathbf{y} \neq \mathbf{0}$ and an integer $N_0 > 0$, such that $\|\mathbf{y} - \mathbf{x}\| < \varepsilon$, $N_0\mathbf{y}$ has integer coordinates, and for every positive multiple kN_0 we have $kN_0\mathbf{y} \notin H$ and $kN_0\mathbf{y} \in W \iff \mathbf{x} \in W$.*

Proof. Without loss of generality, let us assume that H contains the origin. Let $\mathbf{x} \in \Re^n \setminus H$. The latter is an open set, so there is a neighborhood $\mathcal{N}$ of $\mathbf{x}$ that is disjoint from H. Assume that $\mathbf{x} \in W$ (the other case is treated analogously). Since W is rationally dispersed, W contains rational points arbitrarily close to $\mathbf{x}$. Choose $\mathbf{y}$ as such a point that belongs to $\mathcal{N}$, and satisfies $\|\mathbf{y} - \mathbf{x}\| < \varepsilon$. Then $\mathbf{y} \in W \setminus H$. Let L be the line $\{\lambda\mathbf{y}, \lambda \in \Re\}$. Consider the set $N_H = \{\, N > 0 : N\mathbf{y} \in H \,\}$. We have $N_H\mathbf{y} \subseteq L \cap H$. Since $\mathbf{y} \notin H$, L cannot be contained in H. Hence by Lemma 5.21, $L \cap H$ is finite; hence also $N_H\mathbf{y}$ is. Note that since $\mathbf{y}$ is rational, there are infinitely many $N > 0$ such that $N\mathbf{y} \in \mathbb{Z}^n$. Choose N_0 to be such a number, greater than the maximum of N_H. The statement of the lemma is fulfilled. □

Consider a $(\mathbb{Q}, \mathbb{Q}, \{+, -, \times, \lfloor\ \rfloor\})$-RAM program P that recognizes W in time t for integer inputs. W is assumed to be scale invariant and rationally dispersed. Let

U be the set of rational input vectors accepted by P. Correctness of the program means $U \cap \mathbb{Z}^n = W \cap \mathbb{Z}^n$. Let T, V, H, and a be given by Lemma 6.7. Let T' be a regular computation tree obtained from T (and recognizing the same set V) such that $h(T') \leq 2t + 2n$.

LEMMA 7.11. *There is a closed boundary set A such that*

$$\left(\bigcup_{l \in L_1(T')} S_{\phi(T'),\phi(l)} \right) \setminus A = W \setminus A\,.$$

Proof. Let H_1 be the set of $\mathbf{x} \in \Re^n$ that satisfy $\psi(p_\nu)(\mathbf{x}) \cdot \psi(q_\nu)(\mathbf{x}) = 0$ for some branching node ν in T'. H_1 is an algebraic variety and, by the regularity of T', is nontrivial. Let $A = H \cup H_1$. Then A is a closed boundary set. Let $\mathbf{x} \in \Re^n \setminus A$. Then $\mathbf{x} \in S_{\phi(T'),\phi(l)}$ for $l \in L_1(T') \cup L_0(T')$. We wish to prove that $\mathbf{x} \in W$ if and only if $l \in L_1(T')$.

First, we assume $\mathbf{x} \in W$. The set $S_{\phi(T'),\phi(l)} \setminus A$ is open and contains $\mathbf{x}$, so we can choose $\varepsilon > 0$ such that the ε-neighborhood of $\mathbf{x}$ will be contained within this set. Pick $\mathbf{y}$ and N_0 as provided by Lemma 7.10. Then $\mathbf{y} \in S_{\phi(T'),\phi(l)}$, and for all $k > 0$, $kN_0\mathbf{y} \in W \setminus H$; this implies, by Lemma 6.7, that

$$\forall k \in \mathbb{Z}^+ \quad kaN_0\mathbf{y} \in U \iff kaN_0\mathbf{y} \in V\,. \tag{7}$$

We now choose an integer $N = kaN_0$ with k large enough to make, for all $\nu \in \xi_{T,l}$,

$$sign(r_\nu(N\mathbf{y})) = sign\left(\frac{1}{N^d} r_\nu(N\mathbf{y})\right) = sign(\psi(r_\nu)(\mathbf{y})).$$

This implies that $N\mathbf{y}$ will follow the same path in T' as $\mathbf{y}$ does in $\phi(T')$. Since $\mathbf{y}$ reaches leaf $\phi(l)$ in $\phi(T')$, $N\mathbf{y}$ will reach leaf l in T'. Since $N\mathbf{y} \in W \cap \mathbb{Z}^n$, we also have $N\mathbf{y} \in U \cap \mathbb{Z}^n$, and (7) shows that $N\mathbf{y} \in V$. Thus $l \in L_1(T')$.

For $\mathbf{x} \notin W$, similar arguments show that $l \in L_0(T')$; hence $\mathbf{x} \notin \bigcup_{l \in L_1(T')} S_{\phi(T'),\phi(l)}$. The conclusion of the lemma follows. ∎

Combining the last result with Lemmas 5.3 and 5.5, we have

$$\beta\left(\bigcup_{l \in L_1(T')} S_{\phi(T'),\phi(l)} \right) \geq \beta\left(\left(\overline{\bigcup_{l \in L_1(T')} S_{\phi(T'),\phi(l)}} \right)^\circ \right) = \beta((\overline{W})^\circ),$$

and by applying Lemma 7.7, as in the preceding proofs, we obtain

$$\beta((\overline{W})^\circ) \leq 2^{h(t)+n+1} \cdot 3^{3n+2h(T)} \leq 2^{2t+n+1} \cdot 2^{3n+4t},$$

completing the proof of Theorem 3.8.

8. Conclusion. In this paper we showed how topological arguments, previously used to achieve lower bounds for algebraic computation trees, can be applied to random access machines. We considered machines with standard memory access (using integer addresses) and nonstandard models that may use arbitrary real addresses. We considered the case of real-number input as well as that of integer input, and instruction sets $\{+, -, \times, /\}$ and $\{+, -, \times, \lfloor\ \rfloor\}$. Our first lower bounds for these models (Theorems 3.3 and 3.6, resp.) show that when problems with real input are considered, it is hard to make effective use of integer addresses within these models. This is one motivation for studying the nonstandard model.

If the model is extended with the integrality predicate (which is not an algebraic function), some problems may be solved faster without resorting to noninteger addresses. For example, Uniform Gap can be solved in linear time. Theorem 3.4 gives a class of problems that cannot benefit this way. An even stronger extension is adding the truncation ("floor") operation. Together with division, it allows a linear-time solution to Max Gap and to Min Gap. Obtaining a better characterization of the power of this instruction set is a challenging open problem. Another open problem is to close the gap that remains between even the algebraic RAM and computation trees regarding bounds for the knapsack and generalized knapsack problems. (In fact, even the computation-tree bound is not known to be tight.)

Finally, another extension of this research is to use other topological properties of the set, besides the number of connected components. Yao [20] obtained new lower bounds for algebraic computation trees using higher Betti numbers of W (the number of path-connected components is the 0th Betti number). In particular he obtained an $\Omega(n \log(n/k) - cn)$ lower bound for the following.

EXAMPLE 12 (generalized element distinctness). *Given $x_1, x_2, \ldots, x_n$, decide whether some k of these n numbers are equal.*

This result can be easily applied to the models of Theorems 3.3 and 3.6, since their proofs give a direct reduction of the RAM program to an algebraic computation tree. However, for the other models, making use of this result for RAM programs is still an open problem.

9. Appendix. An algorithm using truncated division. The Min Gap decision problem calls for deciding whether, in an array of input numbers, there are two whose difference is bounded by an input value t. In section 3, we have shown that the algebraic RAM, as well as the RAM with floor but without division, require $\Omega(n \log n)$ time to solve this problem even with $\mathcal{A} = \Re$. This appendix gives a simple linear-time algorithm to solve this problem on a $(\Re, \mathbb{N}, \{+, -, \times, /, \lfloor\ \rfloor\})$-RAM with an initially zero memory.

ALGORITHM 1. MIN GAP DECISION.
Input: Real numbers $x_1, \ldots, x_n$ and $t > 0$.
Output: If there is a pair $i \neq j$ such that $|x_i - x_j| \leq t$, the algorithm outputs such a pair; otherwise it asserts that there is none.
Method: We partition the real line into intervals of length t and use the following fact: If there is a pair of points from the given set whose difference is bounded by t, then these points occupy either the same interval or two consecutive ones. Furthermore, if no pair satisfies the first condition, detecting the second is easy since each interval contains at most a single point.

A detailed program appears in Figure 2. In this program, we assume that uses of indirect addressing in the algorithm do not collide with any variables; assumptions which can be removed with standard programming techniques. Finally, we assume

the points x_i have been translated, if necessary, so that their minimum is zero. The notation $\langle a \rangle$ is used for the memory cell whose address is a.

```

SUCCINCT REPRESENTATION OF BALANCED PARENTHESES AND STATIC TREES*

J. IAN MUNRO† AND VENKATESH RAMAN‡

Abstract. We consider the implementation of abstract data types for the static objects: binary tree, rooted ordered tree, and a balanced sequence of parentheses. Our representations use an amount of space within a lower order term of the information theoretic minimum and support, in constant time, a richer set of navigational operations than has previously been considered in similar work. In the case of binary trees, for instance, we can move from a node to its left or right child or to the parent in constant time while retaining knowledge of the size of the subtree at which we are positioned. The approach is applied to produce a succinct representation of planar graphs in which one can test adjacency in constant time.

Key words. abstract data type, succinct representation, binary trees, balanced parenthesis, rooted ordered trees, planar graphs

1. Introduction.

The binary tree is among the most fundamental of data structures. While it is often the case that substantial amounts of data are associated with each node, there are also important cases in which there is little enough so that the representation of the tree with two $\lg n$ [1] bit pointers per node is a substantial, or even dominant, component of the total storage cost of a system. As there are $C_n \equiv \binom{2n}{n}/(n+1)$ or about $2^{2n}/n^{3/2}$ binary trees on n nodes, $2n$ bits are necessary (ignoring logarithmic terms) to encode an arbitrary binary tree. It is also easy to come up with a $2n$ bit representation of an n-node binary tree using a balanced nested parenthesis sequence. (Do a preorder traversal of the tree outputting an open parenthesis when visiting a node for the first time and a matching closing parenthesis when visiting it again after visiting the nodes of its subtree. Note that in this representation it is not possible to distinguish a node having a left child but not a right child from one having a right child but not a left child, but we will deal with this in section 3.2). A greater challenge is to come up with an optimal representation where the navigation around the tree, or for that matter the parentheses, can be done efficiently. Jacobson [13] proposed a method achieving the information theoretically optimal bound to within a lower order term. His interest, like ours, was in representing static data structures succinctly while still permitting the natural operations of navigating around the structure to be performed quickly. His encoding permitted the operations to move to the parent or either child of a given node, upon inspection of $\Theta(\lg n)$ bits. There are two shortcomings with this approach. First, the bits inspected are by no means localized. At one point a "binary search" of $\Theta(\lg^2 n)$ bits is per-

[1] We use lg to denote the ceiling of the logarithm base 2 and $\lg^2$ to denote its square.

formed. Hence, the runtime is certainly not constant, even if a single operation were to permit the inspection of $\lg n$ consecutive bits. While this difficulty can be overcome (by an approach of the first author appearing only in [6]), the second shortcoming is really the one which inspired our work. In a number of applications, the retention of the size of the subtree, rooted at the current node, is essential. For example, in using a binary trie as an index for full text search, one is given a query phrase and traces down the index trie following the bit pattern of the query. Where one runs out of query bits, the entire subtree rooted at the current node corresponds to the set of matches of the query in the text. When this subtree is large, it is crucial that the system be able to announce the number of matches without enumerating them all. For example, the word "the" occurs 2,744,347 times in the Oxford English Dictionary.

Clark and Munro [7] used a $3n$ bit encoding of a binary tree to demonstrate the viability of succinct tree representations for indexing large text files. The encoding they used, however, had three other important features: two good and one bad. First, it was based on explicitly giving the size of one subtree at each node; hence, keeping track of the size of a subtree was a by-product of moving down the tree. Second, the structural information needed at any time was, more or less, together. This meant that, if one considered a model under which a word is a sequence of $\lg n$ consecutive bits, the basic (arithmetic and bitwise logical) operations could be performed in constant time. The shortcoming of the technique was that it did not support efficient determination of the parent of a given node.

In this paper, we give an encoding for arbitrary binary trees on n nodes, using $2n + o(n)$ bits under this $\lg n$ bit word RAM model. As in [3], for convenience we count the space in terms of bits instead of words, and we assume that all standard operations on words can be performed in constant time. Our representation for binary trees supports all four operations: *left child*, *right child*, *parent*, and *size*. This method, along with all others mentioned, maps the nodes of the tree onto the integers $1, \ldots, n$, and hence all are appropriate for applications in which data is to be associated with nodes or leaves.

Despite the motivation for our work coming initially from the binary tree application, our technique focuses first on the problem of an optimal representation of balanced sequences of parentheses. As the class of such strings of length $2n$ is isomorphic to the class of binary trees on n nodes, it is convenient to let n denote the number of open parentheses, or half the string length. Jacobson [13] also considered this problem and proposed what seems to be a $10n + o(n)$ bit solution, a factor of 5 times the optimal. His solution supports the following operations:

- *findclose(i)*. Find the position of the closing parenthesis that matches the open parenthesis in position i.
- *findopen(i)*. Find the position of the open parenthesis that matches the closing parenthesis in position i.
- *excess(i)*. Find the difference of the number of open parentheses and the number of closing parentheses from the beginning to position i.

As with his solution to the tree representation problem, these operations require the inspection of $\Theta(\lg n)$ bits. Our solution uses space which is within a lower order term of the information theoretic $2n$ bits, and all operations can be performed in constant time in our model. One other operation is also necessary for our tree representation and so, again in constant time, we support the following:

- *enclose(i)*. Given a parenthesis pair whose open parenthesis is in position i, find its closest enclosing matching parenthesis pair, if it exists.

Throughout the paper, by the term "position" of a parenthesis, we mean the index to the location (in the given parenthesis sequence) of the parenthesis from the beginning. Given a bitstring, $rank(x)$, the rank of the bit at position x is the number of 1's up to and including the position x, and $select(i)$ is the position of the ith 1 in the bitstring. These two operations can be supported in constant time for an n bit string using $o(n)$ bits of extra space (see [13, 15]). When referring to elements stored in an array (or a sequence), we will speak of the array (sequence) as going from left to right.

The next section discusses our implementation of a sequence of balanced parentheses, and section 3 discusses our representations for static trees. Section 4 gives an efficient representation of bounded page number graphs, including planar graphs. Section 5 presents some concluding remarks and some recent work based on the preliminary version of this work.

2. Balanced parentheses. Here we are given a balanced sequence of parenthesis of length $2n$, so there are n open and n closing parentheses. We want to use an auxiliary storage of $o(n)$ bits to answer standard operations in constant time. Jacobson [13] first breaks the given sequence into blocks of length $\lg n$. Therefore, simply keeping $\Theta(\lg n)$ bits of information with each block contributes heavily to the lead term ($\Theta(n)$ term) of the amount of storage required. We get around the problem by using three levels of blocking. First, we break the sequence into "big blocks" of size $b = \lg^2 n$. This permits a constant number of references to be stored with each big block. It does, however, preclude scanning the entire block in constant time and thus forces the notion of a small block. Each big block is divided into "small blocks" of size $\lg^2 b = 4(\lg \lg n)^2$. As a *local* reference to a parenthesis in a big block requires only $2 \lg \lg n$ bits, such a reference to a single parenthesis can be stored for each small block. Finally, small blocks are further subdivided into "tiny blocks" of length $2 \lg \lg n$. These are so small that we can afford a single table with an entry for every possible distinct tiny block.

To help answer queries, we associate some auxiliary storage with each of these blocks. A similar but two level storage has been used to succinctly represent sets of a finite universe to support membership [3] and to represent bitstrings to support the operations rank and select [13, 15].

We gear our description of our auxiliary storage to answer the operation *findclose(i)* which finds the matching closing parenthesis for the open parenthesis in position i. Some of the other operations, such as *excess(i)*, are required along the way, while others, such as *enclose(i)*, can be implemented using the *findclose(i)* operation. We will specifically address these operations later.

Using the terminology of Jacobson, we call a parenthesis *far* if its matching parenthesis lies outside its block. A far open (closing) parenthesis is a *pioneer* if its matching parenthesis lies in a different block than that of the immediately previous (next) far open (closing) parenthesis in the sequence from the beginning. (Note that the matching parenthesis of a pioneer may or may not be a "pioneer" itself.) These two definitions are general enough that we can, and we will, use them with respect to any of the block sizes: big, small, or tiny. However, until otherwise noted the terms will be used in the context of big blocks. For example, the matching parenthesis of a far parenthesis lies outside its "big block." With each pioneer parenthesis, we keep the position of its matching parenthesis. For any other parenthesis, we will keep sufficient information to find

- its immediately preceding pioneer parenthesis in the sequence; and
- its matching parenthesis, given the matching parenthesis of its pioneer.

In our auxiliary storage structure, there are two types of information stored. In the first type, we keep some information with each block (big, small, or tiny). This is stored in three arrays, one indexed by the big blocks, one by the small blocks, and one by the tiny blocks. Each cell of each array contains all information stored with the corresponding block in an arbitrary but fixed sequence. The second type of information is stored only for specific parentheses or blocks. Each such information is stored in an efficient hash table (see [8, 19]), each cell of which consists of a position of the specific parentheses or the block, along with all the information stored with the corresponding parenthesis or the block. Given a position (of a parenthesis or a block), its membership can be found in constant time in such a hash table. For example, the position of the matching parenthesis for every pioneer parenthesis is stored in such a hash table, each cell of which consists of a position of a pioneer parenthesis along with the position of its matching parenthesis. We will call that table the pioneer table p. Given the position of a parenthesis, it can be checked in constant time, whether or not it is a pioneer, by checking for its membership in this hash table.

Now we begin the complete description of our auxiliary storage which consists of the following:

- With every pioneer parenthesis, we keep the position of its matching parenthesis in the table p.
- With every big block, we keep
  - the position of the immediately preceding pioneer (i.e., the pioneer immediately to the left of the block) and
  - the excess, namely, the number of open parentheses minus the number of closing parentheses up to the position of the first parenthesis, in the block.

  We will call the array containing this information B.
- With every small block within a big block, we keep
  - the position of the immediately preceding pioneer inside the big block (and a string of 0's if there is no pioneer to its left in the big block) and
  - the excess at that position starting from the beginning of its big block. (This value could be negative.)

  We will call the array containing this information b.
- With every small block containing a pioneer, we will keep a bitstring whose length equals the size of the small block. The ith bit in the bitstring is 1 if the corresponding parenthesis is a pioneer in the small block, and 0 otherwise. The hash table containing this information is called bp.

In addition, for every possible bitstring of length $4(\lg \lg n)^2$, and for every position in that string, we create a table entry. There are two values in each table entry: one giving the position of the preceding 1 in that string (a string of 0's if there is no 1 to the left of that position) and the other giving the excess (the number of 0's minus the number of 1's) in binary at the given position inside that string. (Again this value could be negative.) We will call this table st.

Note that we have not yet associated any storage with individual tiny blocks. We will do this later.

We claim that the storage used so far is $o(n)$ and is sufficient to find, for every far parenthesis, its target big block and the excess at its position in constant time.

2.1. Finding the target big block of the matching parenthesis. As Jacobson [13] noted, if there are b blocks, there are at most $2b-3$ pioneers, and so we have $O(n/\lg^2 n)$ pioneer parentheses. Hence, the hash table p that stores the location of

the matching parenthesis of every pioneer parenthesis takes $O(n/\lg n)$ bits. It is also clear that the total space occupied by the table B is $O(n/\lg n)$ bits. As the address of the previous pioneer inside the big block, and the excess inside the big block at that position, for every small block, take $O(\lg\lg n)$ bits, and the number of small blocks is $O(n/(\lg\lg n)^2)$, the total space to store these values in the table b is $O(n/\lg\lg n)$ bits. The number of small blocks with pioneers is at most $O(n/\lg^2 n)$, and so the hash table bp storing the bitstring of pioneers take at most $O(n/\lg n)$ bits. The total number of entries in the table st is $O((\lg n)^{4\lg\lg n}(\lg\lg n)^2)$, and each table entry takes $O(\lg\lg\lg n)$ bits for a total of $O((\lg n)^{4\lg\lg n}(\lg\lg n)^2\lg\lg\lg n)$ bits of storage for the table st.

Now we can find the preceding pioneer parenthesis for a given far parenthesis in position i in constant time as follows:

- Given the position i, first check, by consulting the hash table bp containing the (addresses of the small blocks having pioneers and the) bitstring of pioneers, whether the small block to which i belongs has a pioneer.
- If there is a pioneer in the small block, then a table lookup in the st table, at the position given by the bitstring of pioneers in that small block and its position i, gives the position of the previous pioneer if there is one to its left in the small block.
- If there is no pioneer in the small block to the left of i, then the appropriate position in the array b gives the position of the previous pioneer in that big block. If that is simply a string of 0's, then there is no pioneer in the big block to the left of this small block. In that case, the appropriate index in array B gives the position of the pioneer previous to the position i.

A completely analogous strategy finds the excess at the given position. Here we don't need to consult a hash table first, and we have to treat the open parenthesis as a 0 and a closing parenthesis as a 1 to index into the table st for the table look up. Three words (an entry in table st and appropriate locations in arrays b and B) have to be inspected and the resulting values summed up to get the answer. Once we find the preceding pioneer parenthesis of a given far parenthesis, we find the matching parenthesis of the pioneer from the pioneer hash table p. From that, we know the target big block of the matching parenthesis of the given far parenthesis. Thus we have the following lemma.

LEMMA 1. *Given a sequence of balanced parentheses of length $2n$, and a far parenthesis (i.e., one whose matching parenthesis lies outside its block), the target block of its matching parenthesis and the excess at its position can be found in constant time using $o(n)$ bits of auxiliary information.*

2.2. Finding the matching parenthesis of a far parenthesis. Let us call the "excess" value to which we have been referring the *left excess* and retain, also in $o(n)$ auxiliary storage, similar information regarding the "excess" of the reversal of the given sequence. Then the *right excess* at a position is defined and determined in the analogous way. More specifically, the right excess at a given position i is the number of closing parentheses minus the number of open parentheses starting from the end of the string to the position i. Now, given a far open parenthesis with left excess e at its position, its matching parenthesis in the target big block is the first (from the left) closing parenthesis with right excess e. (Note that there may be several parentheses with the same excess and the first one will necessarily be far.) To compute this information, we need something similar to the inverse of the excess operation: given an excess value and a block, we want to find the first far parenthesis with that excess value in that block.

We can first subtract from e, the right excess (from the end of the string until the beginning of the next block) stored with the next block. What we now require is the first far closing parenthesis with the residual right excess in the target block. Though arrays B and b have the excess information for each of the big and small blocks, it is not enough to simply consult them and/or scan a small block to find the answer. To handle this problem, we create another auxiliary storage. Note that the excess within a big block is at most $\lg^2 n$. With each big block, we keep an array f of answers (the first far closing parenthesis with that excess) for every $\sqrt{\lg n}$ excesses inside the block. This requires $\lg \lg n$ bits for each answer and thus $O(n \lg \lg n / \sqrt{\lg n})$ bits in total. Now to find the parenthesis with a specified excess not a multiple of $\sqrt{\lg n}$, one has to scan the portion between the answers corresponding to the closest multiples of $\sqrt{\lg n}$ to the given excess. If this portion between the two consecutive answers is of size at most $(\lg n)/2$, then we can solve this problem by keeping a table f_1 of answers for every such string for every position. Since there are $\sqrt{n}$ strings of size $(\lg n)/2$, this takes $O(\sqrt{n} \lg n \lg \lg n)$ bits in total. If, on the other hand, the portion between two consecutive answers is larger than $(\lg n)/2$, then we keep the answer for *every* intermediate excess (between the two closest $\sqrt{\lg n}$ multiples) for each such portion. There are $O(\sqrt{\lg n})$ answers for every such portion requiring a total of $O(\sqrt{\lg n} \lg \lg n)$ bits for each such portion. Since there can be at most $2n/\lg n$ such portions, the total space requirement for these values is at most $O(n \lg \lg n / \sqrt{\lg n})$ bits. This information can be stored in an efficient hash table f_3, one for each block, where each cell of the hash table contains the position of the "large" portion (portion of length more than $(\lg n)/2$) between two consecutive answers, along with $O(\sqrt{\lg n} \lg \lg n)$ bits for each such portion. Since there are at most $\lg^{1.5} n$ portions (between two consecutive answers) for each block, the position information for each portion takes only $1.5 \lg \lg n$ bits. Note that at most $2 \lg n$ such portions are large in each block.

Thus in constant time, we can find the matching closing parenthesis for a far open parenthesis using $o(n)$ auxiliary bits of space. A completely analogous strategy finds the matching open parenthesis for a far closing parenthesis. Along the way, we also saw that we can find the excess value at any position in constant time. Thus we have the following lemma.

LEMMA 2. *Given a sequence of balanced parentheses of length $2n$, and a far parenthesis (i.e., one whose matching parenthesis lies outside its block), the position of its matching parenthesis can be found in constant time using $o(n)$ bits of auxiliary information.*

Now we need only to explain how to implement the enclose operation and to deal with parentheses which are not far.

2.3. The enclose operation. Here we outline a method of finding the closest enclosing parentheses for a given matching parenthesis pair at positions i and j. Suppose the parenthesis at position i has left excess e at that position. If e is 0, then there is no enclosing parenthesis. Otherwise, the closing parenthesis of the answer (the closest enclosing parenthesis) is the first far closing parenthesis in the block of j (or its next block having a far parenthesis) with right excess $e - 1$. This can be found, by the method described earlier, to find the first far closing parenthesis with a given excess and a target block. Sometimes the excess $e - 1$ may not be in the block containing j. For this, with every block, we keep a pointer to the far parenthesis that has right excess one less than the minimum in that block. This requires an additional $O(n/\lg n)$ bits. Once we find the closing parenthesis in the answer, its matching parenthesis can be found in constant time using the *findopen* operation. Thus we

have the following lemma.

LEMMA 3. *Given a sequence of balanced parentheses of length* $2n$*, the "enclose(i)" operation, that finds the closest enclosing parentheses for the given matching parenthesis pair whose open parenthesis is at position* i*, can be supported in constant time using* $o(n)$ *bits of auxiliary information.*

2.4. Checking if a parenthesis is far. To check whether a given parenthesis has its matching pair inside a big block, i.e., to check whether it is far (with respect to a big block), we run exactly the procedure outlined in sections 2.1 and 2.2 within a big block with the "small blocks" playing the role of "big blocks" and the "tiny blocks" playing the role of "small blocks." There is one difference though, and that is that the initial entire sequence is a balanced sequence, whereas the sequence inside the big block may not be. This can be easily taken care of by imagining two blocks, one before and one after the big block, with the required number of open and closing parentheses, respectively, to make the augmented sequence balanced. There is no need to keep any auxiliary storage with these imaginary blocks. Furthermore, whenever a parenthesis is found to have its matching parenthesis in the imaginary blocks, then we know that it is far. The rest of the argument goes through as before. For completion, we give a complete description and the auxiliary storage count for this below, omitting just the names of individual auxiliary tables and arrays.

We first fix a big block (the big block in which the given parenthesis resides) and speak of "far" and "pioneer" parentheses with respect to the small blocks within the big block. Note that the sequence inside the big block will, in general, not be balanced; and so we *imagine* augmenting it with a block preceding it, and one succeeding it, to make it balanced. Therefore, the parentheses whose matching pairs lie in the imaginary blocks are the far ones in which we are interested. In fact, some of these will be pioneers with respect to the small blocks. In addition to the storage described earlier, our auxiliary storage is analogous to that previously described for the full structure and consists of the following. (Note that in the discussion below 'far' and 'pioneer' are with respect to the small blocks within the big block.)

- With every pioneer parenthesis, store the position of its matching parenthesis. For those pioneer parentheses whose matching pairs are not in the big block, i.e., for those that are far, we simply indicate it by a special bit. If we hit such a parenthesis, then we immediately know that it is far.
- With every small block, we keep
  - the position of the immediately preceding pioneer in the big block (i.e., the immediate pioneer to the left of the block) and
  - the excess, namely, the number of open parentheses minus the number of closing parentheses up to the position of the first parenthesis, in the big block.
- With every tiny block within a small block, we keep
  - the excess at that position starting from the beginning of the small block it belongs to and
  - the position of the immediately preceding pioneer inside the small block (and 0 if there is no pioneer to its left in the small block)
- With every tiny block containing a pioneer, we will keep a bitstring whose length is the size of the tiny block. The ith bit in the bitstring is 1 if the corresponding parenthesis is a pioneer in the small block, and 0 otherwise.

Furthermore, for every possible bitstring of length $2(\lg \lg n)$, and for every position in that string, we create a table entry. There are two values in each table entry: one

giving the position in that string of the preceding 1 in that string (0 if there is no 1 to the left of that position) and the other giving the excess (the number of 0's minus the number of 1's) at the given position inside that string. (This value could be negative.)

We show that the storage used is $o(n)$, and it suffices to identify in constant time whether a given parenthesis is far with respect to its big block.

As there are $O(\lg^2 n/(\lg\lg n)^2)$ small blocks inside a big block, there are $O(n/(\lg\lg n)^2)$ pioneer parentheses in total. The space to store the matching parenthesis of each pioneer parenthesis is $O(\lg\lg n)$ bits, thus requiring a total of $O(n/\lg\lg n)$ bits for the hash table storing the addresses of these pioneers. It is also clear that the total space for the values associated with every small block is also $O(n/\lg\lg n)$. As the values (address of the previous pioneer inside the small block and the excess inside the small block) at the tiny blocks take $O(\lg\lg\lg n)$ bits each, and the number of tiny blocks is $O(n/\lg\lg n)$, the total space to store these values is $O(n\lg\lg\lg n/\lg\lg n)$ bits. The number of tiny blocks with pioneers is at most $O(n/(\lg\lg n)^2)$, and so the bitstring of pioneers take at most $O(n/\lg\lg n)$ bits in the hash table storing these bitstrings. The total number of table entries is $O(\lg^2 n\lg\lg n)$, and each table entry takes $O(\lg\lg\lg n)$ bits for a total of $O(\lg^2 n\lg\lg n\lg\lg\lg n)$ bits.

A completely analogous procedure as described earlier can find the target small block, if it exists, for a far (with respect to small blocks) open parenthesis in constant time. If the target block happens to be one of those imaginary blocks, we are through. Otherwise, given the excess and the target small block, to find the answer within the small block, a similar strategy used for the big blocks require another auxiliary storage of $o(n)$ bits. The size of each big block is $b = \lg^2 n$ and the size of each small block is $\lg^2 b$. Therefore, if we keep an auxiliary storage for answers analogous to the one described earlier, by replacing n by b, then the required storage will be $o(b)$ bits for each big block, thus resulting in $o(n)$ bits overall. (This turns out to be $O(n\lg\lg\lg n/\sqrt{\lg\lg n})$.)

To check whether a given parenthesis has its matching pair inside a small block (of size $4(\lg\lg n)^2$), we can have a table of all such parenthesis strings and answers for each position in that string. This requires only $O((\lg n)^{4\lg\lg n}(\lg\lg n)^2\lg\lg\lg n)$ bits. Thus we have the following lemma.

LEMMA 4. *Given a sequence of balanced parentheses of length $2n$, and an open or closing parenthesis, it can be checked in constant time using $o(n)$ bits of auxiliary information whether the parenthesis is far, i.e., whether its matching parenthesis is outside its block.*

2.5. Putting things together. To summarize, given an open parenthesis, we first check whether it has a matching pair in its small block using a table of answers. If not, we check whether it has a matching pair in its big block using the procedure described in section 2.4 using the small and tiny block divisions. Otherwise, it is far and so we use the procedure outlined in the proof of Lemma 2 using the big and small block divisions to find its matching parenthesis. A completely analogous strategy works to find the excess value at each position. Thus we have the following theorem.

THEOREM 1. *Given a sequence of balanced parentheses of length $2n$, using $o(n)$ auxiliary bits, we can perform the operations findclose(i), findopen(i), excess(i), and enclose(i) in constant time.*

3. Static trees.

3.1. Rooted ordered trees. To represent a general rooted ordered tree (where each node could have an unbounded number of children), we use the isomorphism

between general ordered trees and balanced parenthesis expressions. Here, in performing a preorder traversal of the general tree starting from the root, we write an open parenthesis when the node is first encountered, going down the tree, and then a closing parenthesis while going up after traversing its subtree. For example, the rooted ordered tree of Figure 3.1(b) is represented by the parenthesis sequence in Figure 3.1(c). With this representation, we make the following observations. We represent a node by its corresponding open parenthesis.

- The parent of a given node is given by the closest parenthesis pair enclosing the parenthesis pair corresponding to the given node.
- The subtree of a given node x consists of all nodes represented by parenthesis pairs in the sequence starting from the open parenthesis corresponding to x to its matching closing parenthesis. Hence, the subtree size is simply half the difference between the indices of x's closing parenthesis and open parenthesis (both end points included).
- The ith child of a node x can be obtained as follows. If the parenthesis next to x's open parenthesis is a closing parenthesis, then x has no children. Otherwise, that open parenthesis next to x's and its matching closing parenthesis form the first child of x, the next parenthesis (if it is open) and its matching parenthesis form the second child of x, and so on. In this process, using the $findclose$ operation at most $i-1$ times starting from the open parenthesis next to that of x, we find the open parenthesis of the ith child or find that x has no ith child.

  In a similar fashion, given a node x, we can find its left or right sibling in constant time as follows. First apply $findclose(x)$ operation to find the matching parenthesis of the open parenthesis corresponding to x. If the parenthesis next to that is an open parenthesis, then it is the parenthesis corresponding to x's right sibling. Similarly, if the parenthesis before the open parenthesis corresponding to x is a closing parenthesis, its matching parenthesis gives the parenthesis corresponding to x's left sibling.

Note that we require that a node be given by the position of its open parenthesis in the sequence. Given an open parenthesis at position p in the sequence we can find, in constant time, the (preorder) index of the node corresponding to it as follows. The preorder index of the corresponding node is simply the number of open parentheses up to but not including position p. (The root has preorder index 0.) This can be found in one of two ways: we can simply use the rank function (previously defined as the number of 1's up to a given position, and detailed in [13, 6]) on the given sequence and find the rank of the current open parenthesis. The other option is to use the excess operation and find the excess e at p. If there are i open parentheses and j closing parentheses up to position p, then $i+j=p$, and $i-j=e$. Therefore, we can compute i if we know p and e. Similarly, the position of the open parenthesis corresponding to a node whose preorder index is i can be obtained by a select operation on the string representing the tree. More precisely, it is the $(i+1)$st open parenthesis in the parenthesis representation of the tree.

Thus we have the following theorem.

THEOREM 2. *Given a static rooted ordered tree on n nodes, we can represent it using $2n + o(n)$ bits in such a way that given a node x (by its preorder index), we can find its parent and its subtree size in constant time and find its ith child in $O(i)$ time.*

3.2. Binary trees. A binary tree is not just a special case of an ordered rooted tree, as there is a distinction between a node having a left child but no right child

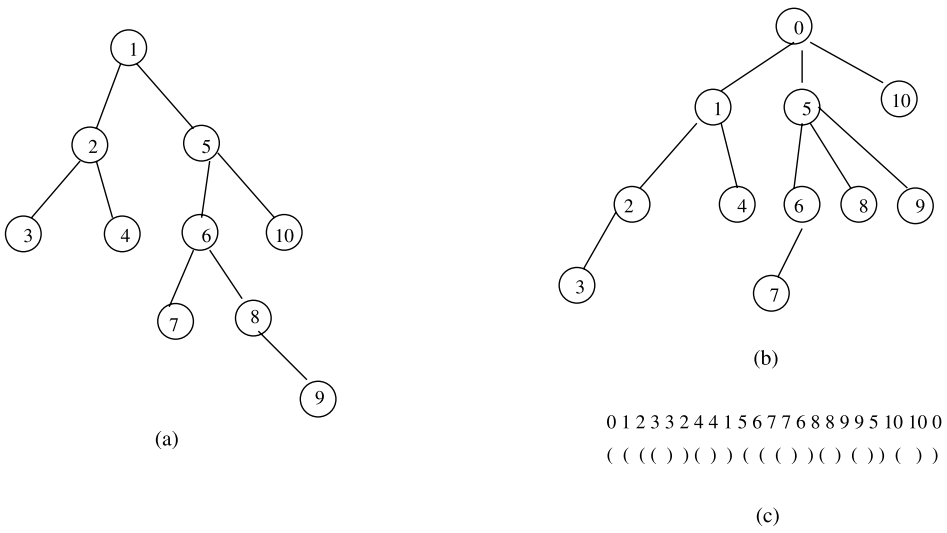

FIG. 3.1. (a) *The given binary tree on* 10 *nodes.* (b) *Equivalent rooted ordered tree.* (c) *The parenthesis representation.*

and one with a right child but no left child. We can, however, take advantage of a well-known isomorphism between these classes. Here the ordered tree has a root which does not correspond to any node in the binary tree. Beyond this, the left child of a node in the binary tree corresponds to the leftmost child in the ordered tree of the corresponding node, and the right child in the binary tree corresponds to the next sibling to the right in the ordered tree. As a consequence, the root of the binary tree corresponds to the leftmost child of the root of the ordered tree. (See, for example, Figures 3.1(a) and 3.1(b).) This isomorphism is often used to map the ordered tree to a binary tree and thus permit the representation of the ordered tree in nodes of a fixed size (i.e., two pointers). We use the isomorphism in the opposite direction as, together with the representation for rooted ordered trees, it enables us to store subtrees in contiguous segments and thus infer the size of a subtree.

We can therefore represent the given binary tree by this sequence of balanced parentheses of length $2n+2$. In fact, $2n$ bits are sufficient as the first open parenthesis along with its matching parenthesis is redundant. For example, the binary tree in Figure 3.1(a) is represented by the parenthesis sequence given in Figure 3.1(c).

By convention, we will denote a given node by the corresponding open parenthesis in the sequence. Then the following facts follow immediately for the binary tree representation by the parenthesis sequence:

- If the symbol following the open parenthesis corresponding to a given node is an open parenthesis, then it corresponds to the left child of the node. Otherwise, the left child is absent.
- To find the right child, if it exists, find the matching parenthesis of the open parenthesis corresponding to the given node. If the following symbol is an open parenthesis, then that is the parenthesis corresponding to the right child of the given node. Otherwise, there is no right child.
- To find the parent of a given node, if the symbol before the parenthesis corresponding to the node is an open parenthesis, then that is its parent. If there is no symbol before, then it is the root. Otherwise, the symbol before

is the closing parenthesis of its left sibling in the general ordered tree. Find its matching open parenthesis, that is, the parenthesis corresponding to its parent in the binary tree.

- The subtree rooted at a node x in the binary tree consists of all nodes in the subtrees rooted at x and at its right siblings in the general tree. In the parenthesis notation, this corresponds to all parentheses pairs from x's open parenthesis to (but not including) the closing parenthesis of x's parent in the general tree. However, x's parent parentheses are the closest enclosing parentheses of x's parentheses. Therefore, given x's open parenthesis, we can find the closest enclosing parentheses using the enclose operation, and thus we can obtain the parentheses corresponding to the nodes in the entire subtree rooted at x. The size of the subtree rooted at x is simply half the difference between the indices of the closing parenthesis of x's parent (excluding it) and the open parenthesis of x.

Thus we have the following theorem.

THEOREM 3. *Given a static binary tree on n nodes, we can represent it using $2n + o(n)$ bits such that given a node in the tree, we can find the left child, right child, and parent of the node if they exist and the size of the subtree rooted at that node in constant time.*

As before, here also a node must be given by the position of its open parenthesis in the sequence, or by its preorder index in the binary tree. It can be verified that we can obtain one from the other in constant time using rank and select operations.

4. Planar graphs. To represent a planar graph efficiently, it is tempting to use the fact [18] that any planar graph can be partitioned into at most three edge-disjoint spanning forests and use our succinct representation to represent the trees of each forest. However, note that our representation for trees is for unlabeled trees and it gives an implicit labeling (based on the preorder traversal of the tree). It is not clear that there is a partition of a planar graph into spanning forests which maintains consistency of the vertex labeling when the vertices of a forest are labeled by our representation. Hence, we resort to the approach of Jacobson [13] and use an edge partition of a planar graph which does maintain the same vertex labeling in each part of the partition. Such a partition is a partition of the edges into *pages* (defined below). Since in linear time planar graphs can be embedded in four pages [22], this leads to a succinct and quickly found representation for planar graphs.

Jacobson first gives a representation for one-page graphs and generalizes to graphs with bounded number of pages. His representation for one-page graphs uses his parentheses representation and hence is fairly inefficient in terms of space. Our parenthesis representation gives an immediate reduction in the higher order term for the number of bits used. Furthermore, as we have expanded the types of operations that can be handled in our implementation, we represent one page graphs differently, resulting in further reduction in space. We give details after defining the term "page." We use the terminology of Bernhart and Kainen [2], as did Jacobson [13].

A *k-page book embedding* of a graph $G = (V, E)$ is a printing order of V (a permutation specifying the ordering of the nodes along the spine of a book), plus a partition of E into k *pages*. The edges on a given page must not intersect, and all pages share the same printing order of the nodes. The *page number* of a graph G is the minimum number of pages in any book embedding of G.

4.1. One-page graphs. When the book is drawn so that the spine is horizontal, then the edges form a nesting structure as in a balanced string of parentheses (see Figure 4.1).

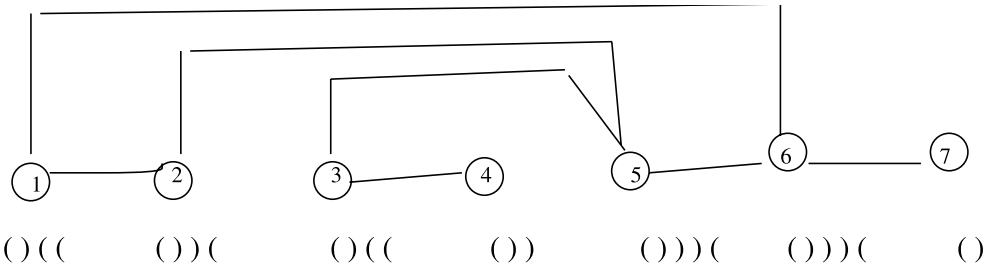

FIG. 4.1. *A one-page graph and its parenthesis representation. (The graph has seven vertices and seven edges.)*

Our representation by a balanced parentheses sequence is as follows. We represent every node and every edge by a matching pair of open and closing parentheses. We associate with every node j its representative matching pair of parentheses followed by a sequence of (single) parentheses for every edge incident on j. The open parenthesis corresponding to an edge $(i, j), i < j$, is in the sequence of parentheses associated with the node i, and the matching closing parenthesis is with the sequence associated with the node j. Thus with respect to a vertex i, we have the following: a matching pair of parentheses to represent node i, a sequence of closing parentheses in decreasing order of their other end points for edges incident on i whose other end points are less than i, followed by a sequence of open parentheses in increasing order of their other end points for edges incident on i whose other end points are greater than i. We concatenate the sequences with respect to every vertex in the order of vertices in the spine (see Figure 4.1). In our representation, a pair of adjacent symbols forms a matching pair of parentheses if and only if the pair represents a node in the one-page graph.

Clearly, this representation uses $2m + 2n$ bits, where m is the number of edges (which is $O(n)$) and n is the number of vertices in the graph. In fact, $2m + 2n - 2$ bits are sufficient as the first matching pair representing the first vertex is redundant.

In this representation, given the label of a node, its matching parenthesis pair in the sequence can be found using a select operation by denoting the adjacent parenthesis pairs (both open and closing) by a single 1 and the other (either open or closing) parenthesis by a 0. Conversely, given a parenthesis pair corresponding to a node, we can find its label by using a rank operation (which counts the number of 1s up to a position in a bit string) in a similar way. Furthermore, the neighbors of a vertex are immediately after its corresponding matching parentheses pair. Thus in time proportional to the degree of the vertex, we can find all the neighbors of a vertex using our parentheses sequence operations ($findopen()$ and $findclose()$). If we just want the degree of the vertex, we can use the rank and select operation to first find the parenthesis pair corresponding to the next vertex in the spine; the difference in the indices between the pairs corresponding to the two vertices gives the degree of the vertex.

To find whether nodes i and j ($i < j$ in the spine order) are adjacent in the graph, we can adapt the method of Jacobson [12] given for his representation. Simply find the matching parenthesis of the first open parenthesis after the pair corresponding to vertex i. If its position is before the position of the pair corresponding to vertex j, then i and j are not adjacent. If it corresponds to an edge incident on j, then i and j are adjacent. Otherwise, find the matching open parenthesis of the last closing

parenthesis after the pair corresponding to vertex j. If it corresponds to an edge incident on i, then i and j are adjacent. Otherwise, they are not. It can be verified that a constant number of rank and select computations are sufficient to perform these operations. Thus we have the following theorem.

THEOREM 4. *A one-page multigraph on n vertices and m edges can be represented using $2n + 2m + o(n + m)$ bits in such a way that the adjacency of a pair of vertices, and the degree of any given vertex, can be found in constant time, and the neighbors of a vertex can be produced in time proportional to the degree of the vertex.*

4.2. Graphs with more than one page. The generalization to graphs with more than one page is direct. We simply represent each page (which is a one-page graph) separately using the representation of section 4.1 and concatenate them together. As all pages share the same printing order of the vertices, the matching pair corresponding to each vertex appears in all pages. Therefore, if the graph has k pages, a vertex requires $2k$ bits, whereas an edge requires only 2 bits. Thus the parenthesis representation requires $2kn + 2m$ bits. The address of the beginning of each page can be stored separately in $k \lg n$ bits. The adjacency of a pair can be checked in $O(k)$ time by checking it in each page. Similarly, the degree of a vertex can be found in $O(k)$ time. The neighbors of a vertex can be listed out by following through the adjacency list in each page, in $O(k + d)$ time, where d is the degree of the vertex.

In particular for planar graphs (which can be embedded in four pages [22]), our representation requires $8n + 2m$ bits (ignoring lower order terms), requiring only a constant factor increase in the time spent. Thus we have the following theorem.

THEOREM 5. *A k page graph on n vertices and m edges can be represented using $2kn + 2m + o(nk + m)$ bits in such a way that adjacency between a pair of vertices and the degree of a vertex can be found in $O(k)$ time, and the neighbors of a vertex x can be listed out in $O(d(x)+k)$ time where $d(x)$ is the degree of the vertex x. In particular, a planar graph on n vertices and m edges can be represented using $8n + 2m + o(n)$ bits so as to test adjacency of a pair in constant time.*

5. Concluding remarks and further work. We have given the first representation for static binary trees on n nodes that uses the information theoretically optimum $2n + o(n)$ bits and still supports the *left child, right child, parent*, and the *subtree size* operations in constant time. Our representation simply uses the natural preorder traversal sequence. We also gave the first information theoretically optimum representation for a balanced sequence of parenthesis supporting several natural operations in constant time.

A related, but restricted, scheme for static binary trees has been implemented by Chupa [5]. The operations of moving up or down the tree are amazingly fast, though that scheme does not support finding the size of a subtree. We also note that a tree must have more than 10 million nodes before the total number of bits used, including those noteworthy "lower order terms," is less than three times the size of the tree. We feel the method discussed here will be comparable in implementation, while supporting a full range of motion in the tree.

Based on the preliminary report of our work, a number of related advances have been made. Our representation actually supports more operations than we have described here. For example, given a node, suppose we want to find the leftmost leaf in the subtree rooted at that node. In the parenthesis representation of the ordered tree corresponding to the binary tree, this is simply the node corresponding to the matching parenthesis pair in which the matching parentheses are adjacent and is the first such pair after the open parenthesis corresponding to the node. By considering

the adjacent matching parenthesis pairs as representing 1's and the other parentheses as representing 0's, this operation is simply a computation of rank and select in the parenthesis sequence. In a very similar way, we can find the rightmost leaf in the subtree rooted at any given node. Using these operations and our representation of static trees, Munro, Raman, and Rao [16] have demonstrated very efficient representations of suffix trees for text searching. The time and space bound for the suffix tree operations are further improved by Grossi and Vitter [9].

For rooted ordered trees (also known as ordinal trees), our representation takes $O(i)$ time to find the ith child of a given node, though every other navigational operation takes only a constant time. Benoit et al. [1] have reported a representation for ordinal trees in which this operation, besides the other constant time operations we support, can be performed in constant time. They have also generalized our binary tree representation for k-ary (cardinal) trees (where one or more subtrees of a node can be empty). Their representation uses $2n + n\lceil \lg k \rceil$ bits and supports searching for the child labeled i in $O(\lg \lg k)$ time while supporting all other navigational operations in constant time. Raman and Rao [20] have improved the time for searching the child labeled i to $O(\lg \lg \lg k)$ time while maintaining every other feature of the structure of Benoit et al. [1].

We have employed our parenthesis based operations to represent a planar graph on n vertices and m edges using $8n + 2m$ bits still supporting adjacency and degree queries in constant time. The space used is at most $14n$ (ignoring lower order terms), as m is at most $3n$. This is a drastic reduction from $64n$ bits required in Jacobson's representation of planar graphs [12] and is much closer to the $3.58m$ bits representation of planar graphs by Keeler and Westbrook [14], which does not allow efficient search operations. Using a more efficient representation for multiple parenthesis sequences, and a canonical ordering of planar graphs, Chuang et al. [4] have improved this space requirement to $2m + (5 + \frac{1}{k})n + o(m + n)$ bits for any constant $k > 0$ with the same query support. The bit count can be further reduced if only adjacency queries are supported in constant time, or if G is simple, triconnected, or triangulated [4]. For recent work on efficient representation of special classes of planar graphs (where the emphasis is on fast encoding and decoding rather than the navigational operations on the compressed representation), see [10] or [11].

More recently, Munro, Raman, and Storm [17] have found a succinct representation for dynamic binary trees where updates can be supported in $O(\lg^2 n)$ amortized time. The basic approach taken in that work is quite different from that used here. Furthermore, it is not clear that it can be adapted to deal with the auxiliary functions we can support with the approach developed here.

Acknowledgments. We thank Meng He for pointing out an error in the *double enclose* operation reported in the earlier version and the referees for their comments that greatly helped improve the presentation of the paper.

TEMPORAL LOGIC AND SEMIDIRECT PRODUCTS: AN EFFECTIVE CHARACTERIZATION OF THE UNTIL HIERARCHY*

DENIS THÉRIEN† AND THOMAS WILKE‡

Abstract. We reveal an intimate connection between semidirect products of finite semigroups and substitution of formulas in linear temporal logic. We use this connection to obtain an algebraic characterization of the until hierarchy of linear temporal logic. (The kth level of that hierarchy is comprised of all temporal properties that are expressible by a formula of nesting depth k in the until operator.) Applying deep results from finite semigroup theory we are able to prove that each level of the until hierarchy is decidable. By means of Ehrenfeucht–Fraïssé games, we extend the results from linear temporal logic over finite sequences to linear temporal logic over infinite sequences.

Key words. linear temporal logic, until hierarchy, substitution, finite semigroups, pseudovarieties of semigroups, aperiodic semigroups, semidirect products

1. Introduction.

Linear temporal logic is a language for expressing relationships between the order of events occurring over time. It is used in various areas of computer science as different as computer-aided verification (temporal logic as a specification language for reactive and concurrent systems) and databases (temporal logic to represent knowledge involving time and to deduct on time-dependent data). Its basic operators (modalities) are "next," "eventually," and "until," of which "until" is the most powerful one.[1] The latter observation has led to a classification of temporal properties according to the nesting depth in the until operator required to express them. In [8], it was shown that the resulting hierarchy, the so-called until hierarchy, is strict. In fact, "counting up to k" requires nesting depth k in the until operator (and nesting depth k is enough to express this property).

In this paper we show that the "until depth" of a given property (i.e., the lowest level of the until hierarchy the property belongs to) is effectively computable, both in the case where temporal logic is interpreted in finite sequences and in the case where it is interpreted in infinite sequences. This answers a question left open in [6] and [8].

Our approach to the computational problem of determining the until depth of a given property of finite sequences follows a well-known and established pattern. In a first step, we define a hierarchy of finite semigroups and prove that this hierarchy is tightly connected with the until hierarchy: a temporal property belongs to the kth level of the until hierarchy if and only if its syntactic semigroup (the transformation

[1] If one chooses the right variant of the until operator, the other two operators become superfluous; i.e., they are no longer needed to achieve the full power of temporal logic.

semigroup of its minimal automaton) belongs to the kth level of the hierarchy of semigroups. In a second step, we show that for a finite semigroup one can effectively compute the lowest level of the hierarchy of semigroups to which it belongs. This yields the desired result, as the syntactic semigroup of a given temporal property can be computed effectively.

It is in the first step of the above process where we introduce new methodology. We develop a completely new approach to understanding semidirect products. We prove that semidirect products can be characterized in terms of substitution of formulas of linear temporal logic. Under reasonably weak assumptions, the semidirect product of two classes of semigroups corresponds to the set of formulas that are obtained by substituting formulas corresponding to the second class for atomic formulas in formulas corresponding to the first class. This is what we call the "semidirect product/substitution principle."

In the second step of the above process, we apply results from [18] and an intricate decidability criterion from [19] involving graph congruences to prove that each level of the hierarchy of semigroups in question is decidable.

The extension to the case where temporal logic is interpreted in infinite sequences is achieved by means of the Ehrenfeucht–Fraïssé game developed in [8]. This game gives us a way to approach the until hierarchy over infinite sequences from an algebraic point of view. We prove that the situation is exactly as in the case of finite sequences: a temporal property of infinite sequences belongs to the kth level of the until hierarchy if and only if its syntactic semigroup (in the sense of [2]) belongs to the kth level of the same semigroup hierarchy as above. The decidability result is then merely a corollary.

Temporal logic, first-order logic over unary predicates with total ordering, and star-free expressions are known to have the same expressive power on both finite sequences and on infinite sequences [15, 9, 11, 10, 22]. Each of the mutually equivalent formalisms motivates its own hierarchy: the until hierarchy, the quantifier-alternation hierarchy, and the dot-depth hierarchy [5]. The two latter are strict [3] and identical [23], whereas [8] describes a family of properties that separates the levels of the until hierarchy but is contained in the second level of the quantifier-alternation/dot-depth hierarchy. It is a long standing problem whether the "dot depth" of a star-free language is computable.

Star-free languages, and hence the class of all temporal properties, have also been shown to correspond to aperiodic (group-free) semigroups [15, 13]. The semigroup-theoretic characterization of the until hierarchy we give in this paper has a natural interpretation as a hierarchy for aperiodic semigroups, which is closely related to the Krohn–Rhodes decomposition theorem. This theorem is the most powerful tool for decomposing finite semigroups (respectively, finite automata).

In [4] it is shown that level 0 of the until hierarchy over finite sequences is decidable. In [6] the hierarchy of semigroups we consider is defined, and partial results about its relation to the until hierarchy over finite sequences are obtained. (For more details, see the remark right after Theorem 4.7.)

In section 2, we provide background on temporal logic and recall the definition of the until hierarchy over finite sequences. In section 3, we establish the connection between semidirect products and substitution. In section 4, we characterize the until hierarchy over finite sequences algebraically and show how the desired decidability result follows. In section 5, our results are extended to infinite sequences. Section 6 contains open problems.

This is a completely revised version of our technical report [20] and our conference

paper [21].

For finite semigroup theory, the reader is referred to the excellent monograph [1], from where our notation also stems. The book [14] provides background on the algebraic theory of regular languages. The handbook chapters [7] and [24] survey temporal logic and the theory of regular ω-languages.

2. Future temporal logic on strings and the until hierarchy. A *future temporal logic (FTL) formula* over a finite set P of propositional variables is built from the elements of P and the logical constant TRUE using the boolean connectives $\neg$ and $\vee$ and the usual temporal logic operators $\bigcirc$ (next), $\Diamond$ (eventually), and U (until), the two former of which are unary operators and the latter of which is a binary operator written in infix notation.

FTL formulas over a set P of propositional variables are interpreted in strings over an alphabet denoted Σ_P, which consists of all subsets of P. Given a string u, its length is denoted by $|u|$, and its positions are numbered 0, 1, 2, ..., $|u|-1$. The symbol at position i is denoted $u(i)$.

Given a string $u \in \Sigma_P^+$ and a position $i < |u|$, one defines what it means for an FTL formula φ over P to be true in u at i, in symbols $(u,i) \models \varphi$. In this paper, we adopt the following conventions:

- $(u,i) \models$ TRUE,
- $(u,i) \models p$ if $p \in u(i)$,
- $(u,i) \models \neg\varphi$ if not $(u,i) \models \varphi$,
- $(u,i) \models \varphi_1 \vee \varphi_2$ if $(u,i) \models \varphi_1$ or $(u,i) \models \varphi_2$,
- $(u,i) \models \bigcirc\varphi$ if $i+1 < |u|$ and $(u,i+1) \models \varphi$,
- $(u,i) \models \Diamond\varphi$ if there exists j with $i \leq j < |u|$ such that $(u,j) \models \varphi$,
- $(u,i) \models \varphi_1 \,\mathsf{U}\, \varphi_2$ if there exists j with $i \leq j < |u|$ such that $(u,i') \models \varphi_1$ for every i' with $i \leq i' < j$ and $(u,j) \models \varphi_2$.

Given an FTL formula φ, we write $u \models \varphi$ and say that u is a model of φ if $(u,0) \models \varphi$. We write $L(\varphi)$ for the set of all models of φ, i.e., $L(\varphi) = \{u \in \Sigma_P^+ \mid u \models \varphi\}$. We say that φ expresses $L(\varphi)$.

Similarly, we say that a language L is expressible in FTL if there exists an FTL formula φ such that $L = L(\varphi)$. Given a class Φ of FTL formulas, we write $L(\Phi)$ for $\{L(\varphi) \mid \varphi \in \Phi\}$.

In some of the commonly accepted definitions of the semantics of the eventually operator the value of j is restricted to positions strictly larger than i. For the until operator, a similar restriction of i' to the values strictly between i and j has been considered. The until depth of a language, however, does not depend on which of the four possible combinations is actually chosen. (For a formal definition of until depth, see below.)

The *until depth* of an FTL formula is its nesting depth in terms of the until operator. When φ is a formula, $\mathrm{ud}(\varphi)$ denotes its until depth. Formally, the until depth is defined inductively by

$$\begin{aligned}
\mathrm{ud}(\text{TRUE}) &= 0,\\
\mathrm{ud}(p) &= 0 \qquad \text{for } p \in P,\\
\mathrm{ud}(\neg\varphi) &= \mathrm{ud}(\varphi),\\
\mathrm{ud}(\varphi_1 \vee \varphi_2) &= \max\{\mathrm{ud}(\varphi_1), \mathrm{ud}(\varphi_2)\},\\
\mathrm{ud}(\bigcirc\varphi) &= \mathrm{ud}(\varphi),\\
\mathrm{ud}(\Diamond\varphi) &= \mathrm{ud}(\varphi),
\end{aligned}$$

$$\mathrm{ud}(\varphi_1 \,\mathsf{U}\, \varphi_2) = \max\{\mathrm{ud}(\varphi_1), \mathrm{ud}(\varphi_2)\} + 1.$$

The class of all FTL formulas of until depth at most k is denoted by $\mathtt{Ut}_k$. That is, a language L belongs to $L(\mathtt{Ut}_k)$ if and only if it is expressed by some FTL formula of until depth at most k. The until hierarchy is the sequence $L(\mathtt{Ut}_0)$, $L(\mathtt{Ut}_1)$, $L(\mathtt{Ut}_2)$, ... In [8], it is shown that this hierarchy is strict in the following sense: $L(\mathtt{Ut}_0) \subsetneq L(\mathtt{Ut}_1) \subsetneq L(\mathtt{Ut}_2) \subsetneq \cdots$.

The main result of this paper is Corollary 4.18, which states that given an FTL formula φ or a regular language L expressible in FTL, one can compute the lowest level of the until hierarchy $L(\varphi)$ (respectively, L) belongs to, i.e., the smallest k such that $L(\varphi) \in L(\mathtt{Ut}_k)$ (respectively, $L \in L(\mathtt{Ut}_k)$). Theorem 5.9 states the same result for ω-words instead of strings.

3. Substitution and semidirect products. This section builds the core of the paper. It provides the correspondence between semidirect products of pseudovarieties of semigroups and substitution in past temporal logic formulas.

3.1. Past temporal logic. *Past temporal logic (PTL) formulas* are built exactly as FTL formulas but use a corresponding set of reversed operators: instead of $\bigcirc$, $\Diamond$, and U, PTL formulas use $\ominus$ (previously), $\diamondminus$ (sometime in the past, once upon a time), and S (since). The semantics of PTL formulas is defined analogously to the semantics of FTL formulas: in the above definition for FTL, every temporal operator is replaced by its reversed form, and every condition that involves the ordering is replaced by the symmetric condition

- $(u, i) \models \ominus\varphi$ if $i > 0$ and $(u, i-1) \models \varphi$,
- $(u, i) \models \diamondminus\varphi$ if there exists j with $j \leq i$ such that $(u, j) \models \varphi$,
- $(u, i) \models \varphi_1 \,\mathsf{S}\, \varphi_2$ if there exists j with $j \leq i$ such that $(u, i') \models \varphi_1$ for every i' with $j < i' \leq i$ and $(u, j) \models \varphi_2$.

Given a PTL formula φ over a set P of propositional variables and $u \in \Sigma_P^+$, we write $u \models \varphi$ and say that u is a model of φ if $(u, |u| - 1) \models \varphi$. As a consequence, if u is a string and v its reverse, and if φ is an FTL formula and ψ its reversed counterpart (obtained by replacing every operator by its reversal), then $u \models \varphi$ if and only if $v \models \psi$.

Abusing notation, we use $L(\varphi)$ to denote the set of models of both FTL and PTL formulas, although there are formulas that are FTL and PTL formulas at the same time and their respective sets of models are distinct; consider, e.g., the atomic formula p. It will, however, always be clear from the context whether we view a given formula as an FTL or a PTL formula. Similarly, we use $L(\Phi)$ to also denote the class of all languages expressible by some PTL formula from Φ.

The *since depth* of a PTL formula is its nesting depth in terms of the since operator; we denote the class of all PTL formulas of since depth at most k by $\mathtt{Sn}_k$. It should be clear that a language belongs to $L(\mathtt{Ut}_k)$ if and only if its reverse belongs to $L(\mathtt{Sn}_k)$.

3.2. Definition of substitution. If φ is a PTL formula over a set of propositions P and $(\psi_p)_{p \in P}$ a family of PTL formulas over Q, then $\varphi[p \mapsto \psi_p]$ stands for the PTL formula over Q obtained from φ by simultaneously replacing every occurrence of a propositional variable $p \in P$ by ψ_p.

Formally, substitution is defined by

$$\textsc{True}[p \mapsto \psi_p] = \textsc{True}, \tag{3.1}$$

$$p'[p \mapsto \psi_p] = \psi_{p'} \qquad \text{for } p' \in P, \tag{3.2}$$

$$\neg\varphi[p \mapsto \psi_p] = \neg(\varphi[p \mapsto \psi_p]), \tag{3.3}$$

$$\varphi_1 \vee \varphi_2[p \mapsto \psi_p] = (\varphi_1[p \mapsto \psi_p]) \vee (\varphi_2[p \mapsto \psi_p]), \tag{3.4}$$

$$\ominus\varphi[p \mapsto \psi_p] = \ominus(\varphi[p \mapsto \psi_p]), \tag{3.5}$$

$$\diamondminus\varphi[p \mapsto \psi_p] = \diamondminus(\varphi[p \mapsto \psi_p]), \tag{3.6}$$

$$\varphi_1 \mathsf{S} \varphi_2[p \mapsto \psi_p] = (\varphi_1[p \mapsto \psi_p]) \mathsf{S} (\varphi_2[p \mapsto \psi_p]). \tag{3.7}$$

3.3. Basic properties of substitution. Obviously, substitution is associative.

REMARK 1 (associativity of substitution). *Let φ be a PTL formula over P, $\{\psi_p\}_{p\in P}$ a family of PTL formulas over Q, and $\{\chi_q\}_{q\in Q}$ a family of PTL formulas over R.*

Then

$$\varphi[p \mapsto \psi_p[q \mapsto \chi_q]] = \varphi[p \mapsto \psi_p][q \mapsto \chi_q]. \tag{3.8}$$

In first-order logic, the most important property of substitution is described by the so-called substitution lemma. There is an analogue with temporal logic. For a family $(\psi_p)_{p\in P}$ of PTL formulas over Q and a string $u \in \Sigma_Q^+$, define a string over Σ_P, denoted $u[p \mapsto \psi_p]$, as follows: $u[p \mapsto \psi_p] = v_0 \dots v_{|u|-1}$ where $v_i = \{p \in P \mid (u, i) \models \psi_p\}$. Using this notation, the substitution lemma for temporal logic can be stated as follows.

LEMMA 3.1 (substitution lemma for PTL). *Let φ be a PTL formula over P and $(\psi_p)_{p\in P}$ a family of PTL formulas over Q.*

For every string u over Σ_Q and every position $i < |u|$, the following then holds:

$$(u, i) \models \varphi[p \mapsto \psi_p] \qquad \textit{if and only if} \qquad (u[p \mapsto \psi_p], i) \models \varphi. \tag{3.9}$$

This can be proven by a straightforward induction on the structure of φ.

An immediate consequence of the substitution lemma is the following corollary.

COROLLARY 3.2. *Let φ and φ' be PTL formulas over P, and $\{\psi_p\}_{p\in P}$ and $\{\psi'_p\}_{p\in P}$ families of PTL formulas over Q, such that $L(\varphi) = L(\varphi')$ and $L(\psi_p) = L(\psi'_p)$ for every $p \in P$.*

Then $L(\varphi[p \mapsto \psi_p]) = L(\varphi'[p \mapsto \psi'_p])$.

3.4. Substitution and sequential functions. Recall that a function $\sigma\colon A^+ \to B^+$ is called a sequential function if it is realized by a transducer. A transducer is a tuple

$$(\mathcal{Q}, A, B, s_I, \delta, \lambda), \tag{3.10}$$

where $\mathcal{Q}$ is a finite set of states, $q_I \in \mathcal{Q}$ is the initial state, A and B are alphabets, $\delta\colon \mathcal{Q} \times A \to \mathcal{Q}$ is a transition function, and $\lambda\colon \mathcal{Q} \times A \to B^+$ is an output function. The transition function δ is inductively extended to a function $\mathcal{Q} \times A^+ \to \mathcal{Q}$ by setting $\delta(q, wa) = \delta(\delta(q, w), a)$. The function $\sigma\colon A^+ \to B^+$ realized by the transducer is inductively defined by

$$\begin{aligned} \sigma(a) &= \lambda(q_I, a) && \text{for } a \in A, \\ \sigma(wa) &= \sigma(w)\,\lambda(\delta(q_I, w), a) && \text{for } a \in A,\ w \in A^+. \end{aligned}$$

A transducer as in (3.10) is called synchronous if $\lambda(q, a) \in B$ for all $q \in \mathcal{Q}$, $a \in A$. Accordingly, a sequential function is called synchronous if it is realized by a synchronous transducer.

Under a certain proviso inverse images of synchronous sequential functions can be described by substitution.

LEMMA 3.3. *Let $\sigma\colon \Sigma_Q^+ \to \Sigma_P^+$ be a synchronous sequential function and $\{\psi_p\}_{p\in P}$ a family of PTL formulas over Q such that*

$$\sigma^{-1}(L(p)) = L(\psi_p) \tag{3.11}$$

for every $p \in P$.

Then, for every PTL formula φ over P,

$$\sigma^{-1}(L(\varphi)) = L(\varphi[p \mapsto \psi_p]). \tag{3.12}$$

Proof. The proof is by induction on the structure of φ. The base case is trivial. In the induction step, we have to consider boolean connectives and temporal operators. Boolean connectives are dealt with easily, because inverse functions respect boolean operations. Of the three temporal operators, we consider only "since," which requires the most involved argument. Given a string u and a position $i < |u|$, we will use $u[0,i]$ to denote the prefix $u(0)\dots u(i)$ of u. Observe that, in general, $u[0,i] \models \varphi$ is equivalent to $(u,i) \models \varphi$ for every PTL formula φ.

Assume φ is of the form $\varphi_1 \mathsf{S} \varphi_2$, and let u be an arbitrary string over Σ_Q. Let $v = \sigma(u)$. Then, since σ is assumed to be synchronous, $|v| = |u|$. The string u belongs to $\sigma^{-1}(L(\varphi_1 \mathsf{S} \varphi_2))$ if and only if there exists $i < |v|$ such that

- $v[0,i] \models \varphi_2$ and
- $v[0,j] \models \varphi_1$ for every j with $i < j < |v|$.

By induction hypothesis, we know that $v[0,i] \models \varphi_2$ if and only if $u[0,i] \models \varphi_2[p \mapsto \psi_p]$. (Observe that, since σ is synchronous, $\sigma(u[0,i]) = v[0,i]$.) Similarly, $v[0,j] \models \varphi_1$ if and only if $u[0,j] \models \varphi_1[p \mapsto \psi_p]$ for every $j < |u|$. Therefore, the above assertion is equivalent to the existence of $i \le |u|$ such that

- $u[0,i] \models \varphi_2[p \mapsto \psi_p]$ and
- $u[0,j] \models \varphi_1[p \mapsto \psi_p]$ for every j with $i < j$.

According to the semantics of PTL formulas, the latter is true if and only if $u \models (\varphi_1[p \mapsto \psi_p]) \mathsf{S} (\varphi_2[p \mapsto \psi_p])$. However, in view of (3.7), $(\varphi_1[p \mapsto \psi_p]) \mathsf{S} (\varphi_2[p \mapsto \psi_p])$ is the same as $(\varphi_1 \mathsf{S} \varphi_2)[p \mapsto \psi_p]$. □

The previous lemma actually holds under seemingly weaker assumptions; besides (3.11) we need only that σ is *length-preserving,* i.e., that σ satisfies $|\sigma(u)| = |u|$ for every $u \in \Sigma_Q^+$, and that it *respects prefixes* in the following sense: $\sigma(uv) \in \sigma(u)\Sigma_P^+$ for all $u, v \in \Sigma_Q^+$. It is, however, easy to see that if these conditions are met, then σ is a synchronous sequential function.

3.5. Substitution and homomorphisms. One way to interpret Lemma 3.3 is to say that substitution can (in many cases) be regarded as applying the inverse of a sequential function. If the substituents are very simple, substitution can even be explained using homomorphisms.

LEMMA 3.4. *Let φ be a PTL formula over P and $\{\psi_p\}_{p\in P}$ a P-indexed family of PTL formulas over Q. Furthermore, assume each formula ψ_p is a disjunction of propositional variables from Q.*

Then $L(\varphi[p \mapsto \psi_p])$ is the preimage of $L(\varphi)$ under a homomorphism $\Sigma_Q^+ \to \Sigma_P^+$.

By convention, an empty disjunction is FALSE.

Proof. For every $p \in P$, let D_p denote the set of disjuncts of ψ_p. Consider the homomorphism $g\colon \Sigma_Q^+ \to \Sigma_P^+$ defined by $g(b) = \bigcup\{p \mid D_p \cap b \neq \emptyset\}$. Let $v \in \Sigma_Q^*$ and $b \in \Sigma_Q$, and assume $g(vb) = ua$ where $a \in \Sigma_P$. Then $p \in a$ if and only if there exists

$q \in b$ such that $q \in D_p$. The latter is equivalent to $vb \models \psi_p$. Thus, $g^{-1}(L(p)) = L(\psi_p)$, and we can apply Lemma 3.3 to conclude $g^{-1}(L(\varphi)) = L(\varphi[p \mapsto \psi_p])$. □

This lemma can be strengthened.

LEMMA 3.5. *Let φ be a PTL formula over P and $\{\psi_p\}_{p\in P}$ a P-indexed family of PTL formulas over Q. Furthermore, assume each formula ψ_p is a boolean combination of propositional variables from Q (i.e., a propositional formula).*

Then $L(\varphi[p \mapsto \psi_p])$ is the preimage of $L(\varphi)$ under a homomorphism $\Sigma_Q^+ \to \Sigma_P^+$.

Proof. For $b \in \Sigma_Q$, let α_b be a propositional formula such that $L(\alpha_b) = \Sigma_Q^* b$. For each $p \in P$, define a formula μ_p over Σ_Q (!) as follows. Let μ_p be the disjunction of all $b \in \Sigma_Q$ such that α_b implies ψ_p (as a propositional formula). Then, $L(\psi_p) = L(\mu_p[b \mapsto \alpha_b])$, and thus $L(\varphi[p \mapsto \psi_p]) = L(\varphi[p \mapsto \mu_p][b \mapsto \alpha_b])$. Write φ' for $\varphi[p \mapsto \mu_p]$. By the previous lemma, $L(\varphi') = g^{-1}(L(\varphi))$ for some homomorphism $g\colon \Sigma_{\Sigma_Q}^+ \to \Sigma_P^+$.

Now consider the homomorphism $h\colon \Sigma_Q^+ \to \Sigma_{\Sigma_Q}^+$ defined by $h(b) = \{b\}$. Trivially, $h^{-1}(L(b)) = L(\alpha_b)$. Lemma 3.3 then implies $L(\varphi'[b \mapsto \alpha_b]) = h^{-1}(L(\varphi'))$, which means $L(\varphi[p \mapsto \psi_p]) = h^{-1}(g^{-1}(L(\varphi)))$. □

3.6. Substitution on classes of formulas. Pseudovarieties of semigroups are classes of finite semigroups closed under homomorphic images, finite direct products, and subsemigroups; see [1, p. 53]. With each such class $\mathbf{V}$, we associate the class $L(\mathbf{V})$ of all languages over alphabets of the form Σ_P that are recognized by elements from $\mathbf{V}$. Recall that a language $L \subseteq A^+$ is said to be recognized by a semigroup S if there exists a semigroup homomorphism $h\colon A^+ \to S$ and a subset $F \subseteq S$ such that $L = h^{-1}(F)$, i.e., if L is the preimage of some subset of S under h.

Complex pseudovarieties of semigroups are often decomposed using semidirect products; that is, they are described as a semidirect product of simpler pseudovarieties. As usual, we denote the semidirect product of two pseudovarieties $\mathbf{V}$ and $\mathbf{W}$ by $\mathbf{V} * \mathbf{W}$; see [1, pp. 266, 269].

On classes of formulas, we now define an operation, denoted $\star$, which corresponds to the semidirect product on classes of semigroups, as we will see below in Theorem 3.6.

Given classes Φ and Ψ of PTL formulas, we define $\Phi \star \Psi$ to contain all formulas that are boolean combinations of formulas from Ψ and formulas that can be written in the form $\varphi[p \mapsto \psi_p]$ where $\varphi \in \Phi$ and the ψ_p's themselves are boolean combinations of formulas from Ψ and propositional variables.

Before we investigate the close connection between $\star$ and $*$, let us observe that $\star$ is a convenient tool for defining classes of formulas. Using $\star$, for instance, the kth level of the since hierarchy can be expressed in terms of its first level:

$$\mathtt{Sn}_k = \underbrace{\mathtt{Sn}_1 \star \cdots \star \mathtt{Sn}_1}_{k \text{ factors}} \qquad \text{for } k > 0. \tag{3.13}$$

Notice that $\star$ is associative. Therefore grouping is not necessary in the above equation.

As is usual with associative binary operations, we allow ourselves to use exponentiation to denote "iterated multiplication"; e.g., we allow ourselves to write $\mathtt{Sn}_1^k$ for the right-hand side of the above equation.

3.7. The semidirect product/substitution principle. In this section we relate the two operations $\star$ and $*$ to each other. There are two parts to this relation, Propositions 3.8 and 3.10. Combined into one statement, they yield the following concise theorem. The set of all PTL formulas without occurrence of $\diamond$ and S is denoted by $\mathtt{Pv}$.

THEOREM 3.6 (semidirect product/substitution principle, SSP). *Let* $\mathbf{V}$, $\mathbf{W}$ *be pseudovarieties of semigroups and* Φ, Ψ *classes of PTL formulas such that* $L(\mathbf{V}) = L(\Phi)$ *and* $L(\mathbf{W}) = L(\Psi)$.

If $L(\Phi \star \mathtt{P}\mathbf{v} \star \Psi) \subseteq L(\Phi \star \Psi)$, *then*

$$L(\mathbf{V} * \mathbf{W}) = L(\Phi \star \Psi). \tag{3.14}$$

The theorem follows from Propositions 3.8 and 3.10 below, each of which proves one inclusion of (3.14).

In the proof of Proposition 3.8 we will make use of the following fact about wreath products (see [1, pp. 265, 266]) and regular languages (see, e.g., [14]). (Wreath products are closely related to semidirect products and come in handy whenever one works with transformation semigroups.) Recall that the transformation semigroup of a transducer as in (3.10) is (Q, T), where T is the subsemigroup of Q^Q generated by $q \mapsto \delta(q, a)$ for $a \in A$.

PROPOSITION 3.7. *Let* $\sigma\colon A^+ \to B^+$ *be a sequential function given by a transducer whose transformation semigroup is* $(\mathcal{Q}, T)$, *and let* $L \subseteq B^+$ *be a language recognized by a semigroup* S.

Then $\sigma^{-1}(L)$ *is recognized by the semigroup of* $(S^1, S) \circ (\mathcal{Q}, T)$, *which is isomorphic to a particular semidirect product* $S^{\mathcal{Q}} * T$.

The inclusion from right to left in (3.14) now follows from the following proposition.

PROPOSITION 3.8 (SSP I). *Let* $\mathbf{V}$, $\mathbf{W}$ *be pseudovarieties of semigroups and* Φ, Ψ *classes of PTL formulas such that* $L(\mathbf{V}) = L(\Phi)$ *and* $L(\mathbf{W}) = L(\Psi)$.

Then

$$L(\Phi \star \Psi) \subseteq L(\mathbf{V} * \mathbf{W}). \tag{3.15}$$

Proof. Assume $\varphi \in \Phi$ is a formula over P and $\{\psi_p\}_{p \in P}$ is a family of formulas over Q where each ψ_p is a boolean combination of propositional variables and formulas from Ψ. We will show that $L(\varphi[p \mapsto \psi_p])$ is recognized by an element of $\mathbf{V} * \mathbf{W}$. This is enough for two reasons. First, $\mathbf{W} \subseteq \mathbf{V} * \mathbf{W}$ holds for arbitrary pseudovarieties of semigroups, unless $\mathbf{V}$ is the empty pseudovariety or the pseudovariety consisting of the empty semigroup only. This means $L(\mathbf{W}) \subseteq L(\mathbf{V} * \mathbf{W})$. Second, $L(\mathbf{V} * \mathbf{W})$ is closed under boolean combinations, as $L(\mathbf{U})$ is closed under boolean combinations for any arbitrary pseudovariety $\mathbf{U}$ of semigroups.

Let $Q = \{q_0, \ldots, q_{m-1}\}$ and assume $\psi_p = \alpha_p(q_0, \ldots, q_{m-1}, \mu_0, \ldots, \mu_{n-1})$, where α_p is a boolean combination and the μ_j's are from Ψ. Since $\mathbf{W}$ is assumed to be a pseudovariety, we can find a single semigroup $T \in \mathbf{W}$ and a homomorphism $h\colon \Sigma_Q^+ \to T$ such that every language $L(\mu_j)$ is recognized by h; i.e., for every $j < n$ there exists $F_j \subseteq T$ such that $L(\mu_j) = h^{-1}(F_j)$. For every $j < n$, let ν_j be the formula $\bigvee_{t \in F_j} t$. And for each $t \in T$, let κ_t be a formula over Q from Ψ such that $L(\kappa_t) = h^{-1}(t)$. Then

$$L(\psi_p) = L(\alpha_p(\bar{q}, \bar{\nu})[q/t \mapsto q/\kappa_t]), \tag{3.16}$$

where $[q/t \mapsto q/\kappa_t]$ means that every element from Q is replaced by itself and every element from t is replaced by κ_t; overstriking indicates a sequence of formulas.

Write β_p for $\alpha_p(\bar{q}, \bar{\nu})$. Then

$$L(\varphi[p \mapsto \psi_p]) = L(\varphi[p \mapsto \beta_p][q/t \mapsto q/\kappa_t]). \tag{3.17}$$

Denote $\varphi[p \mapsto \beta_p]$ by φ'. From Lemma 3.4, we can conclude that $L(\varphi')$ is recognized by an element of $\mathbf{V}$, say S, as $L(\mathbf{V})$ is closed under inverse images.

Consider the sequential function σ defined by the transducer

$$(T^1, \Sigma_Q, \Sigma_{T\cup Q}, 1, \delta, \lambda) \tag{3.18}$$

as specified through

$$\delta(t, a) = t\,h(a), \tag{3.19}$$

$$\lambda(t, a) = \{t\,h(a)\} \cup a \qquad \text{for } t \in T^1,\ a \in \Sigma_Q. \tag{3.20}$$

The transformation semigroup of this transducer is isomorphic to (T^1, T). We have $\sigma(ua) \in \Sigma_T^*(\{h(ua)\} \cup a)$ for $u \in \Sigma_Q^*$, $a \in \Sigma_Q$, i.e., $\sigma^{-1}(L(t)) = h^{-1}(t)$ for every $t \in T$, hence $\sigma^{-1}(L(t)) = L(\kappa_t)$ for every $t \in T$. Also, $\sigma^{-1}(L(q)) = L(q)$ for every $q \in Q$. Thus, by Lemma 3.3, $L(\varphi'[q/t \mapsto q/\kappa_t]) = \sigma^{-1}(L(\varphi'))$. On the other hand, $\sigma^{-1}(L(\varphi'))$ is recognized by the semigroup of $(S^1, S) \circ (T^1, T)$ according to Proposition 3.7. Hence, $L(\varphi'[q/t \mapsto q/\kappa_t])$ is recognized by $S^{S^1} * T$, which is an element of $\mathbf{V} * \mathbf{W}$. □

To prove the other inclusion of (3.14), we need the so-called wreath product principle, introduced in [17]. For use with temporal logic, it can be formulated as follows.

PROPOSITION 3.9 (wreath product principle). *Let $L \subseteq \Sigma_P^+$ be a language recognized by the semigroup of a wreath product $(\mathcal{P}, S) \circ (\mathcal{Q}, T)$ of transformation semigroups via a homomorphism $h\colon \Sigma_P^+ \to S^{\mathcal{Q}} * T$. Denote the projection of h onto the second component by h_2, and let $R = T^1 \cup P$. Define $\sigma\colon \Sigma_P^+ \to \Sigma_R^+$ by $\sigma(a_0 \dots a_{n-1}) = b_0 \dots b_{n-1}$, where $b_i = \{h_2(a_0 \dots a_{i-1})\} \cup a_i$. (By convention, $h(\epsilon) = 1$.)*

This function is a synchronous sequential function which can be realized by a transducer whose transformation semigroup is T's right regular representation.

The language L is a boolean combination of languages of the following two types:

(i) *languages of the form $h_2^{-1}(t)$ for some $t \in T$;*

(ii) *languages of the form $\sigma^{-1}(V)$ where $V \subseteq \Sigma_R^+$ is recognized by S.*

The other inclusion of (3.14) follows from the following proposition.

PROPOSITION 3.10 (SSP II). *Let $\mathbf{V}$, $\mathbf{W}$ be pseudovarieties of semigroups and Φ, Ψ classes of PTL formulas such that $L(\mathbf{V}) = L(\Phi)$ and $L(\mathbf{W}) = L(\Psi)$.*

Then

$$L(\mathbf{V} * \mathbf{W}) \subseteq L(\Phi \star \mathtt{Pv} \star \Psi). \tag{3.21}$$

Proof. Assume $L \subseteq \Sigma_P^+$ is a language recognized by an element of $\mathbf{V} * \mathbf{W}$. There exist transformation semigroups $(\mathcal{P}, S)$ and $(\mathcal{Q}, T)$ with $S \in \mathbf{V}$ and $T \in \mathbf{W}$ such that L is recognized by the semigroup of $(\mathcal{P}, S) \circ (\mathcal{Q}, T)$ via some homomorphism $h\colon \Sigma_P^+ \to S^{\mathcal{Q}} * T$.

Let R, h_2, and σ be as in Proposition 3.9. It is enough to show that the two types of languages described in Proposition 3.9 can be defined by formulas from $\Phi \star \mathtt{Pv} \star \Psi$.

Clearly, every language of type (i) is definable by a formula from Ψ. To complete the proof, we show that every language of type (ii) is definable by a formula from $\Phi \star \mathtt{Pv} \star \Psi$.

Let $V \subseteq \Sigma_R^+$ be a language recognized by S. By assumption, there exists a formula $\varphi \in \Phi$ such that $V = L(\varphi)$. Also, for every $t \in T$, there exists a formula $\mu_t \in \Psi$ such that $h_2^{-1}(t) = L(\mu_t)$.

We want to apply Lemma 3.3. For every $r \in R$, we construct a formula ψ_r such that $\sigma^{-1}(L(r)) = L(\psi_r)$. By definition of σ, the ψ_r's can be chosen as follows:

$$\psi_r = \begin{cases} r & \text{if } r \in \mathcal{P}, \\ \ominus \mu_r & \text{if } r \in T \setminus \{1\}, \\ \ominus \mu_1 \wedge \neg \ominus \textsc{True} & \text{if } r = 1 \text{ and } 1 \in T, \\ \neg \ominus \textsc{True} & \text{if } r = 1 \text{ and } 1 \notin T. \end{cases}$$

(Notice that $\neg\ominus\textsc{True}$ defines the set of all strings of length exactly 1.) We can now apply Lemma 3.3 and conclude $\sigma^{-1}(L(\varphi)) = L(\varphi[r \mapsto \psi_r])$, hence $\sigma^{-1}(V) = L(\varphi[r \mapsto \psi_r])$. Obviously, every formula ψ_r belongs to $\mathtt{Pv} \star \Psi$ or else is atomic. □

4. Since and until hierarchy. In this section, we first obtain an algebraic characterization of the levels of the since hierarchy and will then be able to deduce that each level of this hierarchy is decidable. By the symmetry between FTL and PTL, this also implies that the until hierarchy is decidable.

There are essentially two ways of obtaining an effective characterization of the since hierarchy. In the first approach, one first shows that the kth level of the since hierarchy is characterized by the left-hand side of (4.30), then shows (4.30), and finally proves that membership in the pseudovariety on the right-hand side of (4.30) is decidable. This approach was taken in our technical report [20] and relies heavily on fundamental results from [16]. The second approach is taken here. In it most of the algebraic arguments from [16] are replaced by syntactic/logical arguments. In that way, some of the results from [16] can actually be reproved, which is demonstrated in section 4.4.

4.1. A normal form for PTL. We first prove a strong normal form for temporal logic which replaces the complicated algebraic argument of section 6.1 of our technical report [20]. The normal form is established by syntactic means.

The observation that in PTL application of the previously operator can be restricted to propositional variables or negated propositional variables is folklore. It follows from the following (almost obvious) lemma.

LEMMA 4.1 (switching rules for $\ominus$). *For arbitrary PTL formulas φ and ψ,*

$$\begin{aligned} L(\ominus(\varphi_1 \,\mathsf{S}\, \varphi_2)) &= L(\ominus\varphi_1 \,\mathsf{S}\, \ominus\varphi_2), \\ L(\ominus \diamondminus \varphi) &= L(\diamondminus \ominus \varphi), \\ L(\ominus(\varphi \vee \psi)) &= L(\ominus\varphi \vee \ominus\psi), \\ L(\ominus\neg\varphi) &= L(\neg\ominus\varphi \wedge \ominus\textsc{True}). \end{aligned}$$

Writing $\mathtt{On}$ (reminding of "once upon a time") for the class of all PTL formulas not using S and $\ominus$, we obtain as an immediate consequence the following identity:

$$L(\mathtt{Sn}_0) = L(\mathtt{On} \star \mathtt{Pv}). \tag{4.1}$$

We will extend this to any level of the since hierarchy. Let $\underline{\mathtt{Sn}}_k$ denote all formulas in $\mathtt{Sn}_k$ that don't use $\ominus$ or $\diamondminus$. Then we have the following theorem.

THEOREM 4.2. *For every $k \geq 0$,*

$$L(\mathtt{Sn}_k) = L(\mathtt{On} \star \underline{\mathtt{Sn}}_k \star \mathtt{Pv}). \tag{4.2}$$

In other words,

$$L(\mathtt{Sn}_k) = L(\mathtt{On} \star \underline{\mathtt{Sn}}_1^k \star \mathtt{Pv}) \qquad \text{for } k \geq 0. \tag{4.3}$$

Obviously, it is enough to prove (4.2) for $k = 1$. However, this follows immediately from Lemmas 4.1 and 4.3. The operator $\boxminus$ is defined by $\boxminus\varphi = \neg\diamondminus\neg\varphi$, and using it makes the formulas in Lemma 4.3 more readable.

LEMMA 4.3 (switching rules for $\diamondminus$ and S). *For arbitrary PTL formulas φ, ψ, and ρ,*

$$\begin{aligned}
L((\varphi \wedge \psi)\ \mathsf{S}\ \rho) &= L((\varphi\ \mathsf{S}\ \rho) \wedge (\psi\ \mathsf{S}\ \rho)),\\
L((\varphi\ \mathsf{S}\ (\psi \vee \rho)) &= L((\varphi\ \mathsf{S}\ \psi) \vee (\varphi\ \mathsf{S}\ \rho)),\\
L((\varphi \vee \diamondminus q)\ \mathsf{S}\ \rho) &= L((\varphi\ \mathsf{S}\ \rho) \vee \diamondminus(\diamondminus q \wedge \ominus(\varphi\ \mathsf{S}\ \rho))),\\
L((\varphi \vee \boxminus\psi)\ \mathsf{S}\ \rho) &= L((\varphi\ \mathsf{S}\ \rho) \vee (\diamondminus\rho \wedge \boxminus(\varphi \vee \boxminus\psi))),\\
L(\varphi\ \mathsf{S}\ (\psi \wedge \diamondminus\rho)) &= L((\varphi\ \mathsf{S}\ \psi) \wedge \diamondminus(\psi \wedge \diamondminus\rho)),\\
L(\varphi\ \mathsf{S}\ (\psi \wedge \boxminus\rho)) &= L(\varphi\ \mathsf{S}\ (\psi \wedge \rho) \wedge \boxminus(\boxminus\rho \vee (\varphi \wedge \varphi\ \mathsf{S}\ (\psi \wedge \rho)))).
\end{aligned}$$

Proof. We prove only the inclusion from right to left in the last equation, which is the only nontrivial assertion. Write φ_L and φ_R for the left- and right-hand sides of this equation, respectively.

Assume $u \models \varphi_R$. Then there exists a position i in u such that

$$(u, i) \models \psi, \tag{4.4}$$

$$(u, i) \models \rho, \tag{4.5}$$

$$(u, j) \models \varphi \qquad \text{for every } j \text{ with } i < j < |u|. \tag{4.6}$$

Fix i to be the minimal such position. Clearly, if $(u, i) \models \boxminus\rho$, then $u \models \varphi_L$. Therefore, for the rest, we assume

$$(u, i) \not\models \boxminus\rho \tag{4.7}$$

and show this assumption leads to a contradiction. As the second conjunct of φ_R holds at i, but $\boxminus\rho$ does not, we conclude

$$(u, i) \models \varphi. \tag{4.8}$$

Also, $i > 0$ and

$$(u, i-1) \not\models \boxminus\rho \tag{4.9}$$

because otherwise $\boxminus\rho$ would hold at i (cf. (4.5)). Hence,

$$(u, i-1) \models \varphi\ \mathsf{S}\ (\psi \wedge \rho), \tag{4.10}$$

again because the second conjunct of φ_R holds at i, but $\boxminus\rho$ does not. Thus there exists a position i' with $i' < i$ such that

$$(u, i') \models \psi, \tag{4.11}$$

$$(u, i') \models \rho, \tag{4.12}$$

$$(u, j) \models \varphi \qquad \text{for every } j \text{ with } i' < j < i. \tag{4.13}$$

From (4.6) and (4.8) we conclude that instead of (4.13) we even have

$$(u, j) \models \varphi \qquad \text{for every } j \text{ with } i' < j < |u|. \tag{4.14}$$

Therefore (4.11), (4.12), and (4.14) show that i was not chosen minimal—a contradiction. □

4.2. Characterization of small classes. Before we can give an algebraic characterization of the levels of the since hierarchy, we need to characterize classes of languages expressible by very simple formulas.

We recall some terminology and notation, following [1]. $\mathrm{B}(1,2)^1$ stands for the semigroup $\{1, a, b\}$ whose multiplication is given by $xa = a$, $xb = b$, and $x1 = x$ for all $x \in \{1, a, b\}$. The subsemigroups $\{a, b\}$ and $\{1, a\}$ of $\mathrm{B}(1,2)^1$ are denoted by $\mathrm{B}(1,2)$ and Sl_2, respectively.

Given a class $\mathcal{C}$ of finite semigroups, $V(\mathcal{C})$ denotes the smallest pseudovariety of semigroups containing $\mathcal{C}$, and $V^*(\mathcal{C})$ denotes the smallest pseudovariety of semigroups closed under semidirect products that contains $\mathcal{C}$. Given a pseudovariety $\mathbf{V}$ of semigroups, $\mathbf{V}^n$ stands for the iterated semidirect product $\mathbf{V} * \cdots * \mathbf{V}$ with n factors, and $\mathbf{LV}$ stands for the class of all finite semigroups whose submonoids belong to $\mathbf{V}$.

For $n \geq 1$, $\mathbf{D}_n$ is the pseudovariety of semigroups defined by the equation

$$yx_1 \dots x_n = x_1 \dots x_n \tag{4.15}$$

and

$$\mathbf{D} = \bigcup_{n>0} \mathbf{D}_n. \tag{4.16}$$

$\mathbf{R}$ is the pseudovariety of all $\mathcal{R}$-trivial finite semigroups, $\mathbf{SL}$ is the pseudovariety of all finite semilattices, and $\mathbf{MD_1}$ is the pseudovariety of semigroups generated by all semigroups of the form S^1 with $S \in \mathbf{D_1}$.

Equivalent descriptions of $\mathbf{D_1}$, $\mathbf{SL}$, $\mathbf{R}$, $\mathbf{MD_1}$, and $\mathbf{LR}$ are (see, e.g., [1])

$$\mathbf{D_1} = V(\{\mathrm{B}(1,2)\}), \tag{4.17}$$

$$\mathbf{SL} = V(\{\mathrm{Sl}_2\}), \tag{4.18}$$

$$\mathbf{D} = V^*(\mathbf{D_1}), \tag{4.19}$$

$$\mathbf{R} = V^*(\mathbf{SL}), \tag{4.20}$$

$$\mathbf{MD_1} = V(\{\mathrm{B}(1,2)^1\}), \tag{4.21}$$

$$\mathbf{LR} = V^*(\{\mathrm{B}(1,2), \mathrm{Sl}_2\}) \;=\; \mathbf{R} * \mathbf{D}. \tag{4.22}$$

Equation (4.22) is from [16].

We first characterize the class of temporal logic formulas that corresponds to the pseudovariety $\mathbf{D}$.

LEMMA 4.4. $L(\mathtt{Pv}) = L(\mathbf{D})$.

Proof. A language $L \subseteq \Sigma_P^+$ belongs to $L(\mathbf{D})$ if and only if L is a boolean combination of singleton sets $\{u\}$ and languages of the form $\Sigma_P^* u$ for $u \in \Sigma_P^+$. This follows almost immediately from (4.15) and (4.16); see also [14].

For each $a \in \Sigma_P$ let α_a be a propositional formula such that $L(\alpha_P) = \Sigma_P^* a$. Assume u is a nonempty word over Σ_P^+ of length n. Then

$$L(\alpha_{u(n-1)} \wedge \ominus(\alpha_{u(n-2)} \wedge \ominus(\alpha_{u(n-3)} \wedge \dots (\alpha_{u(0)} \wedge \neg\ominus \textsc{True})))) = \{u\}. \tag{4.23}$$

Similarly,

$$L(\alpha_{u(n-1)} \wedge \ominus(\alpha_{u(n-2)} \wedge \ominus(\alpha_{u(n-3)} \wedge \dots \alpha_{u(0)}))) = \Sigma_P^* u. \tag{4.24}$$

Thus, $L(\mathbf{D}) \subseteq L(\mathtt{Pv})$.

For the other direction, recall that by Lemma 4.1, every formula in $\mathtt{Pv}$ is equivalent to a formula which is a boolean combination of formulas of the form $\ominus\ominus\ldots\ominus p$ or $\ominus\ominus\ldots\ominus\textsc{True}$. Now observe that

$$L(\ominus\ominus\ldots\ominus p) = \bigcup_u \Sigma^* u, \tag{4.25}$$

where u ranges over all words of length $n+1$ with $p \in u(n)$ and where n is the number of times the previously operator is applied in the formula on the left-hand side. Dropping the restriction "$p \in u(n)$" leads to an expression equivalent to $\ominus\ominus\ldots\ominus\textsc{True}$. This shows $L(\mathtt{Pv}) \subseteq L(\mathbf{D})$. □

Next, we characterize $\mathbf{MD_1}$.

LEMMA 4.5.

1. *A language over A is recognized by $\mathrm{B}(1,2)^1$ if and only if it is of the form A^*BC^* for some $B, C \subseteq A$.*

2. *A language over A is recognized by a semigroup in $\mathbf{MD_1}$ if and only if it is a boolean combination of languages of the form A^*BC^* for sets $B, C \subseteq A$.*

3. $L(\underline{\mathtt{Sn}}_1) = L(\mathbf{MD_1})$.

See also Lemma 1.3 in [4].

Proof. For the proof of part 1, let $h\colon A^+ \to \mathrm{B}(1,2)^1$ be a homomorphism. Set $M_s = h^{-1}(s) \cap A$ for every $s \in \mathrm{B}(1,2)^1$. Then $h^{-1}(a) = A^*M_aM_1^*$, $h^{-1}(b) = A^*M_bM_1^*$, and $h^{-1}(1) = M_1^+$. Therefore, every language recognized by $\mathrm{B}(1,2)^1$ is already of the form A^*BC^* for $B, C \subseteq A$. On the other hand, for every possible choice of $B, C \subseteq A$, the set A^*BC^* is recognized by $\mathrm{B}(1,2)^1$, as can be seen as follows. The claim is trivial if $B = \emptyset$. If $B \neq \emptyset$, consider the homomorphism $h\colon A^+ \to \mathrm{B}(1,2)^1$ defined by

$$h(c) = \begin{cases} a & \text{if } c \in B, \\ 1 & \text{if } c \in C \setminus B, \\ b & \text{otherwise.} \end{cases}$$

Then $h^{-1}(a) = A^*BC^*$.

For the proof of part 2 observe that since $\mathbf{MD_1}$ is generated by $\mathrm{B}(1,2)^1$, a language is recognized by an element of $\mathbf{MD_1}$ if and only if it is a boolean combination of languages recognized by $\mathrm{B}(1,2)^1$. Therefore the claim follows from part 1.

Part 3 is a trivial consequence of part 2 in view of the following equation, where $B = \{b_1, \ldots, b_m\}$ and $C = \{c_1, \ldots, c_n\}$ are (possibly empty) subsets of A.

$$L((c_1 \vee c_2 \vee \cdots \vee c_n)\ \mathsf{S}\ (b_1 \vee b_2 \vee \cdots \vee b_m)) = A^*BC^*. \tag{4.26}$$

Recall also that every formula in $\underline{\mathtt{Sn}}_1$ is equivalent to a boolean combination of formulas as in (4.26) and atomic formulas. □

The next pseudovariety we consider is $\mathbf{R}$. Let $\mathtt{WOn}$ ("$\mathtt{W}$" suggesting "weak") denote the class of formulas that are boolean combinations of formulas $\diamondsuit\varphi$ where φ belongs to $\mathtt{On}$. Similarly, let $\mathtt{WOn}_1$ denote the set of all formulas from $\mathtt{WOn}$ of nesting depth at most 1 in $\diamondsuit$; i.e., a formula belongs to $\mathtt{WOn}_1$ if and only if it is a boolean combination of formulas $\diamondsuit\varphi$ where φ is propositional.

LEMMA 4.6.

1. *A language over A^+ is recognized by* Sl_2 *if and only if it is of the form A^*BA^* for some $B \subseteq A$ or the complement of such a language.*
2. $L(\mathtt{WOn}_1) = L(\mathbf{SL})$.
3. $L(\mathtt{WOn}) \subseteq L(\mathbf{R})$.
4. $L(\mathbf{R}) \subseteq L(\mathtt{WOn} \star \mathtt{Pv})$.

Proof. The proof of part 1 follows the pattern of the proof of the first part of the previous lemma. Part 2 follows from part 1, as a language is a boolean combination of languages of the form A^*BA^* if and only if it is a boolean combination of languages of the form A^*bA^* for $b \in A$.

For the proof of part 3, we first show $L(\mathtt{WOn}_1^k) \subseteq L(\mathbf{SL}^k)$ for every $k > 0$. The induction base follows from part 2. For the inductive step, assume $L(\mathtt{WOn}_1^k) \subseteq L(\mathbf{SL}^k)$ for some k. Let Φ be the set of all PTL formulas φ such that $L(\varphi) \in L(\mathbf{SL}^k)$. Then, by the inductive assumption, $\mathtt{WOn}_1^k \subseteq \Phi$. Moreover,

$$\begin{array}{rcll} L(\mathtt{WOn}_1^{k+1}) & = & L(\mathtt{WOn}_1 \star \mathtt{WOn}_1^k) & \\ & \subseteq & L(\mathtt{WOn}_1 \star \Phi) & \text{Definition of } \Phi \\ & \subseteq & L(\mathbf{SL} * \mathbf{SL}^k) & \text{SSP I} \\ & = & L(\mathbf{SL}^{k+1}). & \end{array}$$

The claim now follows from (4.20).

For the proof of part 4, we first show $L(\mathbf{SL}^k) \subseteq L(\mathtt{WOn}_1^k \star \mathtt{Pv})$ for $k > 0$. The induction base follows from part 2. For the inductive step, assume $L(\mathbf{SL}^k) \subseteq L(\mathtt{WOn}_1^k \star \mathtt{Pv})$ for some k. Let Φ be the set of all formulas $\varphi \in \mathtt{WOn}_1^k \star \mathtt{Pv}$ such that $L(\varphi) \in L(\mathbf{SL}^k)$. Then, by the inductive assumption, $L(\mathbf{SL}^k) = L(\Phi)$. Moreover,

$$\begin{array}{rcll} L(\mathbf{SL}^{k+1}) & = & L(\mathbf{SL} * \mathbf{SL}^k) & \\ & \subseteq & L(\mathtt{WOn}_1 \star \mathtt{Pv} \star \Phi) & \text{SSP II} \\ & \subseteq & L(\mathtt{WOn}_1 \star \mathtt{Pv} \star \mathtt{WOn}_1^k \star \mathtt{Pv}) & \text{Definition of } \Phi \\ & = & L(\mathtt{WOn}_1 \star \mathtt{WOn}_1^k \star \mathtt{Pv}) & \text{Lemma 4.1} \\ & = & L(\mathtt{WOn}_1^{k+1} \star \mathtt{Pv}). & \end{array}$$

The claim of part 4 now follows from (4.20). □

It is not true that $L(\mathtt{WOn}) = L(\mathbf{R})$, and neither is it true that $L(\mathbf{R}) = L(\mathtt{WOn} \star \mathtt{Pv})$. Just note that $L(\ominus \diamondsuit p) \in L(\mathbf{R}) \setminus L(\mathtt{WOn})$ and $L(p) \in L(\mathtt{WOn} \star \mathtt{Pv}) \setminus L(\mathbf{R})$. We mention without proof that $L(\mathbf{R})$ is the set of all languages that are expressible via a formula which is a boolean combination of formulas $\diamondsuit\varphi$, where φ is a PTL formula using the combined operator $\ominus\diamondsuit$ as the only temporal operator.

4.3. Characterization of the hierarchies. We can now give an algebraic characterization of the since hierarchy.

THEOREM 4.7 (characterization of since hierarchy). *For every $k \geq 0$,*

$$L(\mathtt{Sn}_k) = L(\mathbf{R} * \mathbf{MD}_1^k * \mathbf{D}). \tag{4.27}$$

The case $k = 0$ is Theorem 4.2 in [4]. Theorem 1.1 in Chapter 7 of [6] states $L((\mathbf{R} * \mathbf{MD_1})^k * \mathbf{LR}) \subseteq L(\mathtt{Sn}_k)$, which is the inclusion from right to left in (4.27).

A somewhat weaker version of the inclusion from right to left is Theorem 1.1 in Chapter 7 of [6].

Proof. By induction on k, we first prove

$$L(\underline{\mathtt{Sn}}_1^k \star \mathtt{Pv}) = L(\mathbf{MD}_1^k * \mathbf{D}) \tag{4.28}$$

for $k \geq 0$.

The induction base is Lemma 4.4. For the inductive step, assume (4.28) holds for some $k \geq 0$. Clearly, $L(\underline{\mathtt{Sn}}_1^{k+1} \star \mathtt{Pv}) = L(\underline{\mathtt{Sn}}_1 \star \underline{\mathtt{Sn}}_1^k \star \mathtt{Pv})$. From Lemma 4.5, we know $L(\underline{\mathtt{Sn}}_1) = L(\mathbf{MD_1})$. Lemma 4.1 tells us $L(\underline{\mathtt{Sn}}_1 \star \mathtt{Pv} \star \underline{\mathtt{Sn}}_1^k \star \mathtt{Pv}) \subseteq L(\underline{\mathtt{Sn}}_1^{k+1} \star \mathtt{Pv})$. Using SSP, we obtain $L(\underline{\mathtt{Sn}}_1^{k+1} \star \mathtt{Pv}) = L(\mathbf{MD}_\mathbf{1}^{k+1} * \mathbf{D})$.

The rest of the proof consists of the following chain of inclusions, where Φ stands for the set of all formulas from $\mathtt{Sn}_0$ that are recognized by an element of $\mathbf{R}$:

$$\begin{array}{rcll}
L(\mathtt{Sn}_k) & = & L(\mathtt{On} \star \underline{\mathtt{Sn}}_1^k \star \mathtt{Pv}) & \text{Theorem 4.2} \\
& = & L(\mathtt{WOn} \star \underline{\mathtt{Sn}}_1^k \star \mathtt{Pv}) & \text{Definition of } \star \\
& \subseteq & L(\Phi \star \underline{\mathtt{Sn}}_1^k \star \mathtt{Pv}) & \text{Lemma 4.6} \\
& = & L(\mathbf{R} * \mathbf{MD}_\mathbf{1}^k * \mathbf{D}) & \text{SSP and (4.28)} \\
& \subseteq & L(\Phi \star \mathtt{Pv} \star \underline{\mathtt{Sn}}_1^k \star \mathtt{Pv}) & \text{SSP II} \\
& \subseteq & L(\mathtt{WOn} \star \mathtt{Pv} \star \underline{\mathtt{Sn}}_1^k \star \mathtt{Pv}) & \text{Lemma 4.6} \\
& = & L(\mathtt{WOn} \star \underline{\mathtt{Sn}}_1^k \star \mathtt{Pv}) & \text{Lemma 4.1} \\
& = & L(\mathtt{On} \star \underline{\mathtt{Sn}}_1^k \star \mathtt{Pv}) & \text{Definition of } \star \\
& = & L(\mathtt{Sn}_k) & \text{Theorem 4.2.}
\end{array}$$

This completes the proof. □

Using $\mathcal{C}^\rho$ to denote the class of all semigroups for which the reverse belongs to a given class $\mathcal{C}$, we immediately get the following theorem.

THEOREM 4.8 (characterization of until hierarchy). *For every $k \geq 0$,*

$$L(\mathtt{Ut}_k) = L((\mathbf{R} * \mathbf{MD}_\mathbf{1}^k * \mathbf{D})^\rho). \tag{4.29}$$

4.4. Algebraic implications. In this section, we deviate a little from our main route. The purpose is to explain what can be concluded from the previous theorem from a semigroup-theoretic point of view. We prove a switching rule and explain the connection to the Krohn–Rhodes theorem.

The following switching rule is slightly weaker than the switching rule from Theorem 9 in [20], which we used when we proved the decidability of the until hierarchy for the first time and which was derived from fundamental results in [16].

THEOREM 4.9. $\mathbf{MD_1} * \mathbf{R} \subseteq \mathbf{R} * \mathbf{MD_1} * \mathbf{D}$.

Proof. Clearly, $\mathbf{MD_1} * \mathbf{R} \subseteq \mathbf{MD_1} * \mathbf{R} * \mathbf{D}$. Thus, using SSP, Lemmas 4.5, and Theorem 4.7, $L(\mathbf{MD_1} * \mathbf{R} * \mathbf{D}) \subseteq L(\underline{\mathtt{Sn}}_1 \star \mathtt{Sn}_0)$. The latter is the same as $L(\mathtt{Sn}_1)$, which, by Theorem 4.7, is identical with $L(\mathbf{R} * \mathbf{MD_1} * \mathbf{D})$. The claim now follows from Eilenberg's variety theorem, which, among other things, states that if $\mathbf{V}$ and $\mathbf{W}$ are pseudovarieties of semigroups such that $L(\mathbf{V}) = L(\mathbf{W})$, then $\mathbf{V} = \mathbf{W}$. □

The next theorem gives an alternative description of $\mathbf{R} * \mathbf{MD}_\mathbf{1}^k * \mathbf{D}$.

THEOREM 4.10. *For $k \geq 0$,*

$$\mathbf{LR} * (\mathbf{MD_1} * \mathbf{LR})^k = \mathbf{R} * \mathbf{MD}_\mathbf{1}^k * \mathbf{D}. \tag{4.30}$$

Proof. The case $k = 0$ is (4.22). For $k > 0$ observe that $\mathbf{LR} = \mathbf{LR} * \mathbf{LR}$ by definition. Therefore $\mathbf{LR} * (\mathbf{MD_1} * \mathbf{LR})^k = (\mathbf{LR} * \mathbf{MD_1} * \mathbf{LR})^k$ for $k > 0$. By SSP, we have $L(\mathbf{LR} * \mathbf{MD_1} * \mathbf{LR}) = L(\mathtt{Sn}_0 \star \underline{\mathtt{Sn}}_1 \star \mathtt{Sn}_0)$. However, the latter is the same as $L(\mathtt{Sn}_1)$. We thus conclude $L(\mathbf{LR} * (\mathbf{MD_1} * \mathbf{LR})^k) = L(\mathtt{Sn}_k)$. This implies the claim in view of Theorem 4.7. □

The Krohn–Rhodes theorem states that the pseudovariety $\mathbf{A}$, the class of all finite semigroups containing no nontrivial group, is identical with $V^*(\{\mathrm{B}(1,2)^1\})$. In view of this, it is only natural to classify a semigroup S of $\mathbf{V}$ according to how often the

semidirect product operation and the use of direct products of $\mathrm{B}(1,2)^1$ alternate in a decomposition of S. We get a hierarchy of pseudovarieties, the kth level given by

$$V^*(\{\mathrm{B}(1,2), \mathrm{Sl}_2\}) * (V(\{\mathrm{B}(1,2)^1\}) * V^*(\{\mathrm{B}(1,2), \mathrm{Sl}_2\}))^k. \tag{4.31}$$

(Recall that B(1,2) and Sl_2 are the only nontrivial factors of $\mathrm{B}(1,2)^1$.) Using the notation introduced above, we can as well write $\mathbf{LR} * (\mathbf{MD_1} * \mathbf{LR})^k$. The previous theorem now tells us that this hierarchy corresponds to the since hierarchy of temporal logic.

4.5. Decidability. Before we can prove the decidability of the levels of the since hierarchy, we need to recall some facts from finite semigroup theory.

The first lemma gives a description of $\mathbf{MD_1}$ and is folklore.

LEMMA 4.11. *A finite semigroup belongs to* $\mathbf{MD_1}$ *if and only if it satisfies*

$$xyx = yx, \tag{4.32}$$

$$x^2 = x. \tag{4.33}$$

Recall that a pseudovariety $\mathbf{V}$ of semigroups is called locally finite if for every $m > 0$ there exists a finite semigroup $F_m \in \mathbf{V}$ such that every semigroup from $\mathbf{V}$ generated by at most m elements is a homomorphic image of F_m. The semigroup F_m is then unique up to isomorphism and is denoted by $F_m\mathbf{V}$.

We say a pseudovariety $\mathbf{V}$ of semigroups is *effectively locally finite* if it is locally finite and $m \mapsto F_m\mathbf{V}$ is computable.

The following proposition can be found, for instance, in [18], as Proposition 6.2, and in [1], as Theorem 10.2.1.

PROPOSITION 4.12. *If* $\mathbf{V}$ *and* $\mathbf{W}$ *are effectively locally finite pseudovarieties of semigroups, then* $\mathbf{V} * \mathbf{W}$ *is effectively locally finite.*

The next proposition is Theorem 5.7 from [18].

PROPOSITION 4.13 (Straubing). *If* $\mathbf{V}$ *is a pseudovariety of semigroups, then* $S \in \mathbf{V} * \mathbf{D}$ *if and only if* $S \in \mathbf{V} * \mathbf{D}_{|S|}$.

The last fact we need is an obvious consequence of results in [19] on graph congruences.

THEOREM 4.14 (Thérien,Weiss). *If* $\mathbf{V}$ *and* $\mathbf{W}$ *are pseudovarieties such that*

- $\mathbf{LV} = \mathbf{V} * \mathbf{D}$,
- $\mathbf{V}$ *is decidable, and*
- $\mathbf{W}$ *is effectively locally finite,*

then $\mathbf{V} * \mathbf{W}$ *is decidable.*

The decision procedure we have in mind is the obvious modification of the procedure described under (ii) in Example 2.5 of [19]. Its correctness follows from Theorem 2.8 in [19].

We can now approach the decidability of the since hierarchy.

PROPOSITION 4.15. *Let* $k \geq 0$, $l \geq 1$. *The pseudovariety* $\mathbf{MD}_1^k * \mathbf{D}_l$ *is effectively locally finite.*

Proof. From (4.15) it is clear that $F_m\mathbf{D}_l$ is finite for $m, l \geq 1$. From Lemma 4.11 it is clear that $\mathbf{MD_1}$ is effectively locally finite. Therefore, by repeated application of Proposition 4.12, we obtain that $\mathbf{MD}_1^k * \mathbf{D}_l$ is effectively locally finite. □

THEOREM 4.16. *Let* $k \geq 0$. *The problem of determining whether a given finite semigroup* S *belongs to* $\mathbf{R} * \mathbf{MD}_1^k * \mathbf{D}$ *is decidable.*

Proof. In order to check whether $S \in \mathbf{R} * \mathbf{MD}_1^k * \mathbf{D}$, according to Proposition 4.13, we have only to check for $S \in \mathbf{R} * \mathbf{MD}_1^k * \mathbf{D}_{|S|}$. This is effective by Theorem 4.14 and Proposition 4.15 in view of (4.22). □

This finally yields the following theorem.

THEOREM 4.17 (decidability of until hierarchy).

1. *Let $k \geq 0$. The problems of determining whether a regular language belongs to $L(\mathtt{Ut}_k)$ is decidable.*

2. *The problem of determining the smallest number k such that a given regular language belongs to $L(\mathtt{Ut}_k)$ can be solved effectively.*

Proof. In order to determine whether $L \in L(\mathtt{Ut}_k)$ for a given regular language L, say, represented by a finite automaton, one first computes its minimal automaton $\mathfrak{A}$. The next step is to compute the transformation semigroup S of $\mathfrak{A}$. Using Theorem 4.16, it is then checked whether $S \in (\mathbf{R} * \mathbf{MD}_1^k * \mathbf{D})^\rho$, which is also the answer to the question, as can be seen as follows. First, the semigroup S is isomorphic to the syntactic semigroup of L. Second, since $(\mathbf{R} * \mathbf{MD}_1^k * \mathbf{D})^\rho$ is a pseudovariety of semigroups, $L \in L((\mathbf{R} * \mathbf{MD}_1^k * \mathbf{D})^\rho)$ if and only if $S \in (\mathbf{R} * \mathbf{MD}_1^k * \mathbf{D})^\rho$. Third, $L \in L(\mathtt{Ut}_k)$ if and only if $L \in L((\mathbf{R} * \mathbf{MD}_1^k * \mathbf{D})^\rho)$ by Theorem 4.8.

The second part follows immediately from part 1, as the decision procedures described in the proof of Theorem 4.16 are uniform in k, and one can a priori check whether a given language L is at all expressible in FTL. See [9, 15, 11]. □

COROLLARY 4.18. *The problem of determining the smallest number k such that the language defined by a given FTL formula belongs to $L(\mathtt{Ut}_k)$ can be solved effectively.*

Proof. It suffices to note that given an FTL formula φ it is easy to compute a finite automaton that recognizes the language defined by φ; see, for instance, [25] for the case of ω-words. □

Obviously, analogues of the previous two results hold for the since hierarchy.

5. Extension to ω-words. In this chapter we extend the algebraic characterization of the until hierarchy and its decidability to the situation where temporal logic formulas are interpreted in ω-words instead of strings (which is often enough the case, especially when temporal logic is used to specify the behavior of reactive systems).

It should be clear how the definitions of section 2 carry over to ω-words. To distinguish between the two settings we will write $L_\omega(\varphi)$ to denote the set of all ω-models of an FTL formula and keep writing $L(\varphi)$ for the set of all string models of an FTL formula.

5.1. Regular ω-languages. We recall some basic facts about the algebraic treatment of regular ω-languages.

Let $L \subseteq A^\omega$. The *syntactic congruence* of L, as defined in [2] and denoted by $\equiv_L$, is the binary relation on A^+ that relates u and v if and only if

$$(\forall x, y \in A^*)\,(x(uy)^\omega \in L \leftrightarrow x(vy)^\omega \in L) \tag{5.1}$$

and

$$(\forall x, y \in A^*)\,(\forall z \in A^+)\,(xuyz^\omega \in L \leftrightarrow xvyz^\omega \in L). \tag{5.2}$$

Given an arbitrary congruence $\equiv$ on A^+, we define a similarity relation $\sim$ on A^ω as follows: $\alpha \sim \beta$ if and only if there exist decompositions $\alpha = u_0u_1u_2\ldots$ and $\beta = v_0v_1v_2\ldots$ such that $u_i \equiv v_i$ for $i \geq 0$.

For a given language $L \subseteq A^\omega$, we denote by $\sim_L$ the similarity relation induced by $\equiv_L$. The following crucial property of the syntactic congruence of a regular ω-language goes back to [2] and [12].

LEMMA 5.1 (Arnold, Pécuchet). *Let $L \subseteq A^\omega$ be regular and $\sim_L$ the similarity relation induced by $\equiv_L$.*

If $\alpha \sim_L \beta$, then $\alpha \in L$ if and only if $\beta \in L$.

5.2. The Ehrenfeucht–Fraïssé game for FTL. As our main tool we will use a combinatorial description of the Ehrenfeucht–Fraïssé game of [8]. In fact, we will use the following definition of game equivalence.

Let $x, y \in \Sigma_P^+ \cup \Sigma_P^\omega$, $i < |x|$, and $j < |y|$.

We define $(x,i) \equiv_k^l (y,j)$ to hold if and only if the following conditions and their symmetric counterparts (where the roles of (x,i) and (y,j) are interchanged) are met.

Initial condition: $x(i) = y(j)$.

Next condition, required if $l > 0$: If $i+1 < |x|$, then $j+1 < |y|$ and $(x, i+1) \equiv_k^{l-1} (y, j+1)$.

Eventually condition, required if $l > 0$: For every i' with $i \le i' < |x|$, there exists j' with $j \le j' < |y|$ such that $(x,i') \equiv_k^{l-1} (y,j')$.

Until condition, required if $k > 0$: For every i' with $i \le i' < |x|$, there exists j' with $j \le j' < |y|$ such that

(UC1) if $i' = i$, then $j' = j$;

(UC2) $(x,i') \equiv_{k-1}^l (y,j')$;

(UC3) for every j'' with $j \le j'' < j'$, there exists i'' with $i \le i'' < i$ such that $(x,i'') \equiv_{k-1}^l (y,j'')$.

We write $x \equiv_k^l y$ for $(x,0) \equiv_k^l (y,0)$.

For a game-theoretic interpretation of $\equiv_k^l$, see [8].

To describe the connection of $\equiv_k^l$ with temporal logic, we need the notion of residual depth.

The *residual depth* of a FTL formula φ, denoted by $\mathrm{rd}(\varphi)$, is defined to be the depth of the formula in terms of the FTL operators other than U:

$$\begin{aligned}
\mathrm{rd}(\textsc{True}) &= 0,\\
\mathrm{rd}(p) &= 0 \qquad \text{for } p \in P,\\
\mathrm{rd}(\neg\varphi) &= \mathrm{rd}(\varphi),\\
\mathrm{rd}(\varphi_1 \vee \varphi_2) &= \max\{\mathrm{rd}(\varphi_1), \mathrm{rd}(\varphi_2)\},\\
\mathrm{rd}(\bigcirc\varphi) &= \mathrm{rd}(\varphi) + 1,\\
\mathrm{rd}(\Diamond\varphi) &= \mathrm{rd}(\varphi) + 1,\\
\mathrm{rd}(\varphi_1 \,\mathsf{U}\, \varphi_2) &= \max\{\mathrm{rd}(\varphi_1), \mathrm{rd}(\varphi_2)\}.
\end{aligned}$$

The set $\mathtt{Ut}_{k,l}$ is defined to be the set of all FTL formulas of until depth at most k and residual depth at most l.

The following theorem is an adapted version of Theorem 2.1 from [8].

THEOREM 5.2 (Etessami, Wilke; soundness and completeness). *Let $x, y \in \Sigma_P^+ \cup \Sigma_P^\omega$ and $k, l \ge 0$.*

Then $x \equiv_k^l y$ if and only if x and y are models of the same $\mathtt{Ut}_{k,l}$-formulas over P.

The following lemma states that game equivalence is a congruence relation; in fact, it is a Ramsey congruence in the sense of [26]. The proof is straightforward but lengthy. The interested reader is referred to our technical report [20].

LEMMA 5.3 (congruence property). *Let $k, l \geq 0$.*

1. *The binary relation $\equiv_k^l$ restricted to Σ_P^+ is a congruence relation. That is, $\equiv_k^l$ restricted to Σ_P^+ is an equivalence relation and whenever $u \equiv_k^l v$ and $u' \equiv_k^l v'$ for $u, u', v, v' \in \Sigma_P^+$, then $uu' \equiv_k^l vv'$.*
2. *Let $u, v \in \Sigma_P^+$ and $\alpha, \beta \in \Sigma_P^\omega$. If $u \equiv_k^l v$ and $\alpha \equiv_k^l \beta$, then $u\alpha \equiv_k^l v\beta$.*
3. *If $u, v \in \Sigma_P^+$ such that $u \equiv_k^l v$, then $u^\omega \equiv_k^l v^\omega$.*

To conclude this section about game equivalence, we note the following remark.

REMARK 2. *Let $k, l \geq 0$, $x, y \in \Sigma_P^\infty$, $i < |x|$, and $j < |y|$. Assume $u, v \in \Sigma_P^*$ and $(x, i) \equiv_k^l (y, j)$.*

Then $(ux, |u| + i) \equiv_k^l (vy, |v| + j)$.

5.3. Reduction to strings. Using game equivalence we can now characterize the levels of the until hierarchy for ω-words. We start with a lemma.

LEMMA 5.4. *Let $k, l \geq 0$ and $u, v \in \Sigma_P^+$ be such that $u \equiv_k^l v$. For all $x, y \in \Sigma_P^*$ and $z \in \Sigma_P^+$,*

$$x(uy)^\omega \equiv_k^l x(vy)^\omega, \tag{5.3}$$

$$xuyz^\omega \equiv_k^l xvyz^\omega. \tag{5.4}$$

Proof. Relation (5.4) follows immediately from Lemma 5.3 (part 2) and Remark 2.

By part 1 of the same lemma, we obtain $uy \equiv_k^l vy$. Thus, by part 3 of that lemma, $(uy)^\omega \equiv_k^l (vy)^\omega$. Another application of part 2 finally yields $x(uy)^\omega \equiv_k^l x(vy)^\omega$. □

The next proposition states that if a regular ω-language belongs to the kth level of the until hierarchy, then so do the classes of its syntactic congruence relation.

PROPOSITION 5.5. *Let $k \geq 0$ and $L \subseteq \Sigma_P^\omega$ such that $L \in L_\omega(\mathtt{Ut}_k)$. Each class of $\equiv_L$ belongs to $L(\mathtt{Ut}_k)$.*

Proof. There exists l such that L belongs to $L_\omega(\mathtt{Ut}_{k,l})$. We claim that every class of the syntactic congruence of L belongs to $L(\mathtt{Ut}_{k,l})$.

We need only to show that for all $u, v \in \Sigma_P^+$ the following holds. If $u \equiv_k^l v$, then $u \equiv_L v$. Therefore assume $u \equiv_k^l v$, and let $x, y \in \Sigma_P^*$ and $z \in \Sigma_P^+$.

Assume $x(uy)^\omega \in L$. From Lemma 5.4, we know $x(uy)^\omega \equiv_k^l x(vy)^\omega$. Thus, since $L \in L_\omega(\mathtt{Ut}_{k,l})$, $x(vy)^\omega \in L$. By symmetry, if $x(vy)^\omega \in L$, then $x(uy)^\omega \in L$. Similarly, using (5.4) instead of (5.3), one shows $xuyz^\omega \in L$ if and only if $xvyz^\omega \in L$. Therefore (5.1) and (5.2) hold, which means $u \equiv_L v$. □

The converse of the previous proposition is also true and is the crucial observation of this section. It is more difficult to prove, and we will dedicate almost the entire rest of this section to it.

LEMMA 5.6. *Let $k, l \geq 0$, $p = k + l + 1$, and $u, v \in \Sigma_P^*$ and $w \in \Sigma_P^+$ such that $uw^\omega \equiv_k^l vw^\omega$. Then $uw^p \equiv_k^l vw^p$.*

Proof. We prove by induction on $k' + l'$ that the following is true for $k' \leq k$, $l' \leq l$ and $i, j \geq 0$: if $(uw^\omega, i) \equiv_{k'}^{l'} (vw^\omega, j)$, $i \leq |u| + (k - k' + l - l')|w|$, and $j \leq |v| + (k - k' + l - l')|w|$, then $(uw^p, i) \equiv_{k'}^{l'} (vw^p, j)$.

Write x, y, α, and β for uw^p, vw^p, uw^ω, and vw^ω.

Induction base, $k' + l' = 0$. This is trivial.

Induction step, $k' + l' > 0$. We consider the various conditions.

Initial condition. Clearly, this condition is satisfied.

Next condition. Clearly, $(\alpha, i+1) \equiv_{k'}^{l'-1} (\beta, j+1)$, hence $(x, i+1) \equiv_{k'}^{l'-1} (y, j+1)$ by induction hypothesis.

Eventually condition. Let i' be such that $i \leq i' < |x|$. We distinguish two cases.

First case, $i < |u|$. Since $(\alpha, i) \equiv_{k'}^{l'} (\beta, j)$, there exists j' such that $(\alpha, i') \equiv_{k'}^{l'} (\beta, j')$. By Remark 2, we can assume $j' < |v| + (k - k' + l - l' + 1)|w|$. Thus we can apply the induction hypothesis and find $(x, i') \equiv_{k'}^{l'-1} (y, j')$.

Second case, $i' \geq |u|$. This case is simple, as we can choose $j' = |v| + i' - |u|$.

Until condition. Let i' be such that $i \leq i' < |x|$. Since $(\alpha, i) \equiv_{k'}^{l'} (\beta, j)$, there exists j' such that (UC1)–(UC3) hold for α, β, k', and l' instead of x, y, k, and l.

By Remark 2, we can find j_1 such that $j \leq j_1 < |v| + (k - k' + l - l' + 1)|w|$, $j_1 \leq j$, and $(\beta, j') \equiv_{k'-1}^{l'} (\alpha, j_1)$. We claim that (UC1)–(UC3) then hold for k', l', x, y, and j_1 instead of k, l, x, y, and j'.

(UC1) is trivially satisfied, as we know that if $i = i'$, then $j' = j$, and that $j \leq j_1 \leq j'$. By definition of j_1, we know $(\alpha, i') \equiv_{k'-1}^{l'} (\beta, j_1)$, hence, by induction hypothesis, $(x, i') \equiv_{k'-1}^{l'} (y, j_1)$. Therefore (UC2) is satisfied.

To verify (U3), let j'' be such that $j \leq j'' < j_1$. If $j'' \geq |v|$, we simply take $i'' = |u| + j'' - |v|$. In the other case, if $j'' < |v|$, there is i'' such that $i \leq i'' < i$ and $(\alpha, i'') \equiv_{k'-1}^{l'} (\beta, j'')$. We can assume $i'' < |u| + (k - k' + l - l' + 1)|w|$. The induction hypothesis then yields $(x, i'') \equiv_{k'-1}^{l'} (y, j'')$. ∎

We denote by $\sim_k^l$ the similarity relation induced by $\equiv_k^l$.

PROPOSITION 5.7. *Let* $k, l \geq 0$, *and* $s, t, u, v \in \Sigma_P^+$ *such that* $st^\omega \equiv_k^{l+2} uv^\omega$. *Then there exists* $\gamma \in \Sigma_P^\omega$ *such that* $st^\omega \sim_k^l \gamma \sim_k^l uv^\omega$.

Proof. Write α and β for st^ω and uv^ω, respectively.

We first argue that we can assume $t^\omega \equiv_k^l v^\omega$.

Since we have $st^\omega \equiv_k^{l+2} uv^\omega$, there exists j such that $(st^\omega, |s|) \equiv_k^{l+1} (uv^\omega, j)$. Consequently, there exists i' such that $(st^\omega, |s| + i') \equiv_k^l (uv^\omega, j + |u|)$. By Remark 2, we can assume $i' < |t|$ and $j < |v|$. Write v', v'', t', t'' for $v(0, i'')$, $v(i'', |v|)$, $t(0, j')$, and $t(j', |t|)$. Then $uv^\omega = uv'(v''v')^\omega$ and $st^\omega = st'(t''t')^\omega$, where $(v''v')^\omega \equiv_k^l (t''t')^\omega$. We can thus replace u by uv', v by $v''v'$, s by st', and t by $t''t'$ in order to achieve $t^\omega \equiv_k^l v^\omega$.

Let $p = k + l + 1$. Set $\gamma = s(t^p v^p)^\omega$. We prove that this choice is correct.

We first show $\alpha \sim_k^l \gamma$. Let $u_0 = st^p$, $v_0 = st^p$, $u_i = t^{2p}$ for $i > 0$, and $v_i = v^p t^p$ for $i > 0$. Then $\alpha = u_0 u_1 u_2 \ldots$ and $\gamma = v_0 v_1 v_2 \ldots$. Trivially, $u_0 \equiv_k^l v_0$. Moreover,

$$v^p t^\omega \equiv_k^l v^p v^\omega = v^\omega \equiv_k^l t^\omega = t^p t^\omega, \tag{5.5}$$

where the first equivalence follows from Lemma 5.3 and the second one holds by assumption. Therefore Lemma 5.6 yields $v^p t^p \equiv_k^l t^p t^p$, hence $u_i \equiv_k^l v_i$ for $i > 0$, thus $\alpha \sim_k^l \gamma$.

We finally show $\gamma \sim_k^l \beta$. Let $u_0 = st^p v^p$, $v_0 = uv^p$, $u_i = t^p v^p$ for $i > 0$, and $v_i = v^{2p}$ for $i > 0$. Then $\gamma = u_0 u_1 u_2 \ldots$ and $\beta = v_0 v_1 v_2 \ldots$. As in the previous paragraph, we obtain $u_i \equiv_k^l v_i$ for $i > 0$. In order to prove $u_0 \equiv_k^l v_0$, we first observe

$$t^\omega = st^\omega \equiv_k^l uv^\omega, \tag{5.6}$$

where the first equivalence follows from Lemma 5.3 and the second one holds by assumption. From Lemma 5.6, we can thus conclude $st^p v^p \equiv_k^l uv^p$, which means $u_0 \equiv_k^l v_0$. ∎

We can now prove the following theorem.

THEOREM 5.8 (characterization of until hierarchy over infinite sequences). *Let* $k \geq 0$ *and* $L \subseteq \Sigma_P^\omega$ *regular. The following are equivalent.*

- $L \in L_\omega(\mathtt{Ut}_k)$.
- *Each equivalence class of* $\equiv_L$ *belongs to* $L(\mathtt{Ut}_k)$.

Proof. One direction is Proposition 5.5. For the other direction, assume that each class of $\equiv_L$ belongs to $L(\mathtt{Ut}_k)$. Since L is regular, $\equiv_L$ has only finitely many classes, and there thus exists $l \geq 0$ such that each class of $\equiv_L$ belongs to $L(\mathtt{Ut}_{k,l})$. We will prove that L belongs to $L(\mathtt{Ut}_{k,l+2})$.

For $\alpha, \beta \in \Sigma_P^\omega$ such that $\alpha \equiv_k^{l+2} \beta$, we have to show that $\alpha \in L$ if and only if $\beta \in L$.

Since all classes of $\equiv_k^{l+2}$ on Σ_P^ω are regular ω-languages, it is enough to consider only ultimately periodic words; that is, we can assume that α and β are of the form st^ω and uv^ω, respectively. (Recall that every nonempty regular ω-language contains an ultimately periodic word.)

By Proposition 5.7, there exists γ such that $\alpha \sim_k^l \gamma \sim_k^l \beta$. Since we assume that every class of $\equiv_L$ belongs to $L_\omega(\mathtt{Ut}_k)$, $\equiv_L$ is at least as coarse as $\equiv_k^l$, which implies that we also have $\alpha \sim_L \gamma \sim_L \beta$. We can now apply Lemma 5.1 and obtain $\alpha \in L$ if and only if $\gamma \in L$ if and only if $\beta \in L$. □

We can finally prove the counterpart to Theorem 4.17 and Corollary 4.18.

THEOREM 5.9 (decidability of until hierarchy over infinite sequences).

1. *Let $k \geq 0$. The problem of determining whether a given regular ω-language belongs to $L^\omega(\mathtt{Ut}_k)$ is decidable.*

2. *The problem of determining the smallest number k such that a given regular ω-language belongs to $L^\omega(\mathtt{Ut}_k)$ can be solved effectively.*

3. *The problem of determining the smallest number k such that a given FTL formula is equivalent over ω-words to an FTL formula of until depth at most k can be solved effectively.*

Proof. In order to check whether a given regular ω-language L belongs to $L^\omega(\mathtt{Ut}_k)$ one first computes a representation of its syntactic congruence as a finite automaton $\mathfrak{A}$ (on strings). The next step is to compute the transformation semigroup S of $\mathfrak{A}$. Using Theorem 4.16, one then checks whether $S \in (\mathbf{R} * \mathbf{MD_1} * \mathbf{D})^\rho$, which is also the answer to the question, as can be seen as follows. The semigroup is equivalent to $\Sigma_P^+/\equiv_L$, the syntactic semigroup of L. Since $(\mathbf{R} * \mathbf{MD_1} * \mathbf{D})^\rho$ is a pseudovariety of semigroups, each class of $\equiv_L$ belongs to $L((\mathbf{R} * \mathbf{MD_1} * \mathbf{D})^\rho)$ if and only if $S \in (\mathbf{R} * \mathbf{MD_1} * \mathbf{D})^\rho$. Now recall that Theorem 4.8 says that $L((\mathbf{R} * \mathbf{MD_1} * \mathbf{D})^\rho) = L(\mathtt{Ut}_k)$ and that Theorem 5.8 says that $L \in L^\omega(\mathtt{Ut}_k)$ if and only if every equivalence class of $\equiv_L$ belongs to $L(\mathtt{Ut}_k)$. □

6. Problems. We would like to conclude this paper with a list of problems.

PROBLEM 1. *Determine the complexity of the decision problems considered in this paper. It is not even obvious that the procedure described in the proof of Theorem* 4.16 *has an elementary upper bound.*

PROBLEM 2. *Extend our results to the combined until/since hierarchy.*

PROBLEM 3. *Find a description of the kth level of the until hierarchy in terms of structural properties of the corresponding minimal automata, as for instance given in* [4] *for until depth* 0.

PARALLEL QUANTUM COMPUTATION AND QUANTUM CODES*

CRISTOPHER MOORE† AND MARTIN NILSSON‡

Abstract. We study the class **QNC** of efficient parallel quantum circuits, the quantum analog of **NC**. We exhibit several useful gadgets and prove that various classes of circuits can be parallelized to logarithmic depth, including circuits for encoding and decoding standard quantum error-correcting codes, or, more generally, any circuit consisting of controlled-not gates, controlled π-shifts, and Hadamard gates. Finally, while we note the exact quantum Fourier transform can be parallelized to linear depth, we conjecture that neither it nor a simpler "staircase" circuit can be parallelized to less than this.

Key words. quantum circuits, parallel computation, quantum complexity classes, quantum error-correcting codes, group theory

1. Introduction.

Much of computational complexity theory has focused on the question of what problems can be solved in polynomial time. Shor's quantum factoring algorithm [22] suggests that quantum computers might be more powerful than classical computers in this regard, i.e., that **BQP** might be a larger class than **P**, or rather **BPP**, the class of problems solvable in polynomial time by a classical probabilistic Turing machine with bounded error.

A finer distinction can be made between **P** and the class **NC** of efficient parallel computation, namely the subset of **P** of problems which can be solved by a parallel computer with a polynomial number of processors in *polylogarithmic* time, $\mathcal{O}(\log^k n)$ time for some k, where n is the number of bits of the input [18]. Equivalently, **NC** problems are those solvable by Boolean circuits with a polynomial number of gates and polylogarithmic depth.

This distinction seems especially relevant for quantum computers, where decoherence makes it difficult to do more than a limited number of computation steps reliably. Since decoherence due to storage errors is essentially a function of time, we can avoid it by doing as many of our quantum operations at once as possible. (Then again, gate errors will typically get worse since parallel algorithms often involve more gates, and gate errors are typically the dominant source of decoherence in current models of quantum computation such as bulk-spin NMR [9]. In addition, using a large number of work qubits may worsen decoherence and storage errors as well.)

In this paper, we initiate the study of **QNC**, the quantum analog of **NC**, and prove a number of elementary results. Our main theorem is that circuits consisting of controlled-not gates, controlled π-shifts, and Hadamard gates can be parallelized to logarithmic depth. This includes circuits for encoding and decoding standard

quantum error-correcting codes. We end with a conjecture that neither an exact quantum Fourier transform nor a simple "staircase" circuit can be parallelized to less than linear depth. While this would not show that **QNC** $<$ **QP**, it would certainly suggest that not all quantum algorithms can be parallelized.

In another paper [17], one of us explores quantum analogs of $\mathbf{AC}^0$ and $\mathbf{ACC}^0$, the subsets of **NC** consisting of constant-depth circuits with AND, OR, and MOD gates of arbitrary fan-in. Some further results on $\mathbf{QAC}^0$ and $\mathbf{QACC}^0$ can be found in [11, 12].

2. Definitions. We define quantum operators and quantum circuits as follows.

DEFINITION 1. *A* quantum operator *on n qubits is a unitary rank-$2n$ tensor U where $U^{b_1 b_2 \dots b_n}_{a_1 a_2 \dots a_n}$ is the amplitude of the incoming and outgoing truth values being $a_1, a_2, \dots, a_n$ and $b_1, b_2, \dots, b_n$, respectively, with $a_i, b_i \in \{0, 1\}$ for all i. However, we will usually write U as a $2^n \times 2^n$ unitary matrix U_{ab} where a and b's binary representations are $a_1 a_2 \cdots a_n$ and $b_1 b_2 \cdots b_n$, respectively.*

A one-layer circuit *consists of the tensor product of one- and two-qubit gates, i.e., rank* 2 *and* 4 *tensors, or* 2×2 *and* 4×4 *unitary matrices. This is an operator that can be carried out by a set of simultaneous one-qubit and two-qubit gates, where each gate couples a disjoint set of qubits.*

A quantum circuit of depth k *is a quantum operator written as the product of k one-layer circuits.*

Here we are allowing arbitrary two-qubit gates. If we like, we can restrict this to *controlled-U gates*, of the form

$$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & u_{11} & u_{12} \\ 0 & 0 & u_{21} & u_{22} \end{pmatrix},$$

or more stringently to the *controlled-not* gate

$$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}.$$

For these, we will call the first and second qubits the *input* and *target* qubits, respectively; however, they do not really leave the input qubit unchanged, since they entangle it with the target.

Since either of these can be combined with one-qubit gates to simulate arbitrary two-qubit gates [1], these restrictions would just multiply our definition of depth by a constant. The same is true if we wish to allow gates that couple $k > 2$ qubits as long as k is constant, since any k-qubit gate can be simulated by $2^{\mathcal{O}(k)}$ two-qubit gates [1].

In order to design a shallow parallel circuit for a given quantum operator, we want to be able to use additional qubits or "ancillae" as workspace in the computation, equivalent to additional processors in a parallel quantum computer. However, to be able to correctly measure the computer's output, we have to make sure that the ancillae qubits are not entangled with the qubits of the final state that we care about. The easiest way to ensure this is to demand that the ancillae start and end in a pure state $|0\rangle$, so that the desired operator appears as the diagonal block of the operator

performed by the circuit on the subspace where the ancillae are zero. This also allows ancillae to be reused, which is important if we are going to compose two separately parallelized operators.

Note that although we do not explicitly allow measurement as an operator in our circuit, measurements can be treated as interactions with additional ancillae which represent the environment.

Then in analogy with **NC** we propose the following definition.

DEFINITION 2. *Let F be a family of quantum operators, where F_n is a $2^n \times 2^n$ unitary matrix on n qubits. We say that F_n is* embedded *in an operator M with m ancillae if M is a $2^{m+n} \times 2^{m+n}$ unitary matrix which preserves the subspace where the ancillae are zero, and if M is identical to $F_n \otimes \mathbf{1}^{2^m}$ on this subspace.*

Then $\mathbf{QNC} = \cup_k \mathbf{QNC}^k$, where $\mathbf{QNC}^k$ is the class of operators parallelizable to $\mathcal{O}(\log^k n)$ depth with a polynomial number of ancillae. That is, F is in $\mathbf{QNC}^k$ if, for all n, F_n can be embedded in a circuit of depth at most $c_1 \log^k n$ with at most $c_2 n^j$ ancillae, where c_1, c_2, and j are constants.

Here we are defining **QNC** as a class of quantum operators. We can extend this to functions and decision problems by embedding them in reversible functions first.

DEFINITION 3. *If ϕ is a Boolean function with n inputs and k outputs, define its* reversible version *ϕ' as the reversible Boolean function on $n + k$ bits defined by $\phi'(x, y) = (x, y \oplus \phi(x))$, where $\oplus$ is bitwise exclusive-or. Thus ϕ' keeps the input x, and xors y with the output $\phi(x)$. We can write ϕ' as a $2^n \times 2^n$ matrix with Boolean values, and we say that a Boolean function is in* **QNC** *if its reversible version is.*

We can consider various definitions of probabilistic acceptance and obtain the classes **EQNC**, **BQNC**, and **PrQNC** in nomenclature drawn from [21, 25]. **EQNC** accepts exactly, i.e., with probability 1, if the input is in the language and 0 otherwise. **BQNC** accepts with two-sided bounded probability $P \geq 2/3$ if the input is in the language and $P \leq 1/3$ if it is not. **PrQNC** accepts with probability $P > 1/2$ if the input is in the language and $P \leq 1/2$ if it is not.

With this definition, it is easy to see that $\mathbf{NC} \subset \mathbf{EQNC}$, since **EQNC** includes reversible Boolean circuits composed, say, of Toffoli gates, and a Boolean circuit of depth d and width w can be converted to a reversible one of depth $2d - 1$ with wd ancillae. Each gate is given its own ancilla which is xored with the gate's output. After obtaining the output of the circuit, we go through the layers of the circuit in reverse order to return the ancillae to zero.

For an upper bound, it is clear that $\mathbf{QNC} \subset \mathbf{QP}$ for the various definitions of acceptance, but it would be very nice if a sufficiently uniform quantum circuit could be evaluated by a quantum Turing machine with space equal to the circuit's depth, where by "uniform" we mean that there is, say, a classical DLOGTIME algorithm for describing the set of gates of the circuit.[1] This would be a quantum analog of Borodin's result [2] that $\mathbf{NC}^k \subset \mathbf{DSPACE}(\log^k n)$, and results of Watrous [25] would then imply that

$$\mathbf{EQNC}^k \subset \mathbf{PrQNC}^k \subset \mathbf{PrQSPACE}(\log^k n) \subset \mathbf{DSPACE}(\log^{2k} n).$$

If this is true, **QNC** can be simulated by classical circuits with polylogarithmic depth and quasipolynomial width, i.e., $\mathcal{O}(2^{\log^{\mathcal{O}(1)} n})$. However, even in the classical probabilistic case an analog of Borodin's result is not known.

[1] It would be nice to define uniformity in terms of quantum machines rather than classical ones. This would presumably allow the circuit itself to be in a superposition of multiple topologies, which a physicist might call a "second quantized" computation.

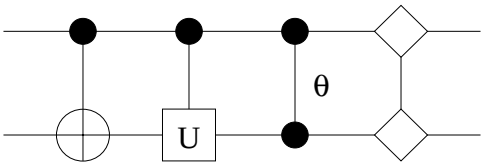

FIG. 1. *Our notation for controlled-not, controlled-U, symmetric phase shift, and arbitrary diagonal gates.*

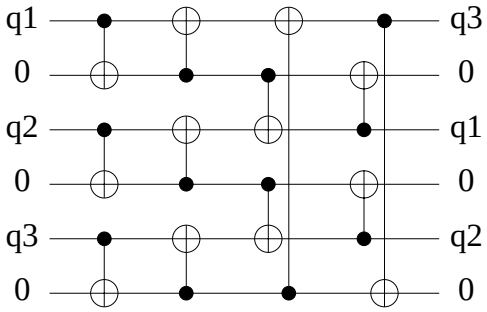

FIG. 2. *Permuting n qubits in four layers using n ancillae. In this example, the three qubits are rotated.*

We will use the notation in Figure 1 for our various gates: the controlled-not and controlled-U, the symmetric phase shift

$$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & e^{i\theta} \end{pmatrix},$$

and arbitrary diagonal gates

$$\begin{pmatrix} e^{i\omega_{00}} & 0 & 0 & 0 \\ 0 & e^{i\omega_{01}} & 0 & 0 \\ 0 & 0 & e^{i\omega_{10}} & 0 \\ 0 & 0 & 0 & e^{i\omega_{11}} \end{pmatrix}.$$

3. Permutations. In classical circuits, one can move wires around as much as one likes. In a quantum computer, it may be more difficult to move a qubit from place to place. However, we can easily do arbitrary permutations in constant depth.

PROPOSITION 1. *Any permutation of n qubits can be performed in four layers of controlled-not gates with n ancillae, or in six layers with no ancillae.*

Proof. The first part is obvious; simply copy the qubits into the ancillae, cancel the originals, recopy them from the ancillae in the desired order, and cancel the ancillae. An example is shown in Figure 2.

Without ancillae, we can use the fact that any permutation can be written as the composition of two involutions, i.e., two sets of disjoint transpositions. To see this, first decompose it into a product of disjoint cycles, and then note that a cycle is the composition of two reflections, as shown in Figure 3. Two qubits can be switched with three layers of controlled-not gates as shown in Figure 4, so any permutation

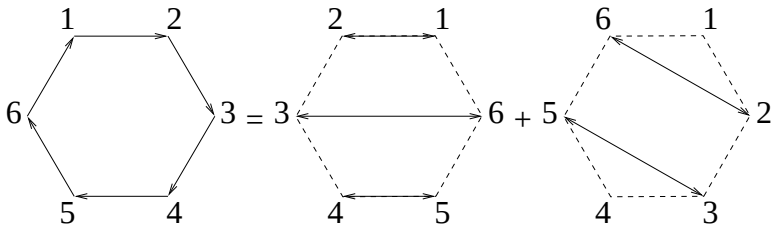

FIG. 3. *Any cycle, and therefore any permutation, is the composition of two sets of disjoint transpositions.*

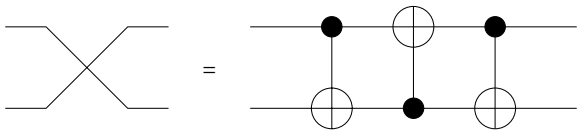

FIG. 4. *Switching two qubits with three controlled-nots.*

can be done in six layers. □

4. Fan-out. To make a shallow parallel circuit, it is often important to *fan out* one of the inputs into multiple copies. The controlled-not gate can be used to copy a qubit onto an ancilla in the pure state $|0\rangle$ by making a nondestructive measurement

$$(\alpha|0\rangle + \beta|1\rangle) \otimes |0\rangle \;\rightarrow\; \alpha|00\rangle + \beta|11\rangle.$$

Note that the final state is not a tensor product of two independent qubits, since the two qubits are completely entangled. Making an unentangled copy requires nonunitary, and in fact nonlinear, processes since

$$(\alpha|0\rangle + \beta|1\rangle) \otimes (\alpha|0\rangle + \beta|1\rangle) = \alpha^2|00\rangle + \alpha\beta(|01\rangle + |10\rangle) + \beta^2|11\rangle$$

has coefficients quadratic in α and β. This is one form of the "no cloning" theorem of quantum mechanics [26].

This means that disentangling or *uncopying* the ancillae by the end of the computation, and returning them to their initial state $|0\rangle$, is a nontrivial and important part of a quantum circuit. There are, however, some special cases where this can be done easily.

Suppose we have a series of n controlled-U gates all with the same input qubit. Rather than applying them in series, we can *fan out* the input into n copies by splitting it $\log_2 n$ times, apply them to the target qubits, and uncopy them afterward, thus reducing the circuit's depth to $\mathcal{O}(\log n)$ depth.

PROPOSITION 2. *A series of n controlled-U gates with arbitrarily varying U coupling the same input to n target qubits can be parallelized to $\mathcal{O}(\log n)$ depth with $\mathcal{O}(n)$ ancillae.*

Proof. The circuit in Figure 5 copies the input onto $n-1$ ancillae, applies all the controlled-U gates simultaneously, and uncopies the ancillae back to their original state. Its total depth is $2\log_2 n + 1$. □

This kind of symmetric circuit, in which we uncopy the ancillae to return them to their original state, is similar to circuits designed by the reversible computation group at MIT [8] for reversible classical computers.

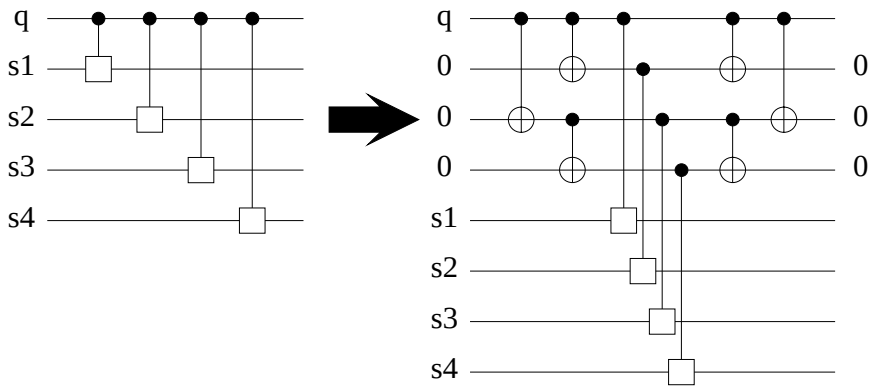

FIG. 5. *Parallelizing n controlled gates on a single input qubit q to $\mathcal{O}(\log n)$ depth.*

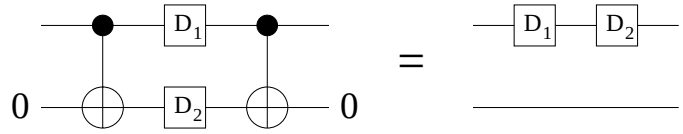

FIG. 6. *Using entanglement to parallelize diagonal operators.*

5. Fan-in: Diagonal and mutually commuting gates. Fan-in seems more difficult in general. Classically, we can calculate the composition of n operators in $\mathcal{O}(\log n)$ time by composing them in pairs; but since matrix multiplication is quadratic, it is unclear when we can do this with unitary linear operators. One special case where it is possible is if all the gates are diagonal.

PROPOSITION 3. *A series of n diagonal k-qubit operators on the same k qubit(s) can be parallelized to $\mathcal{O}(\log n) + 2^{\mathcal{O}(k)}$ depth with $\mathcal{O}(kn)$ ancillae.*

Proof. Here the entanglement between two copies of a qubit becomes an asset. Since diagonal matrices do not mix Boolean states with each other, we can act on one or more qubits and an entangled copy of them with two diagonal matrices D_1 and D_2 as in Figure 6. When we uncopy the ancilla(e), we have the same effect as if we had applied both matrices to the original qubit(s). Then the same kind of circuit as in Proposition 2 works, as shown in Figure 7, in which we make n copies of each of the k qubits, and apply the operators simultaneously. From [1] and Propositions 7 and 8 below, the depth of an arbitrary k-qubit diagonal operator is $2^{\mathcal{O}(k)}$. □

Since matrices commute if and only if they can be simultaneously diagonalized, we can generalize this to the case where a set of controlled-U gates applied to the same target qubit(s) have mutually commuting U's.

PROPOSITION 4. *A series of of n controlled-U gates acting on the same k target qubit(s), where the U's are mutually commuting operators on k qubits, can be parallelized to $\mathcal{O}(\log n) + 2^{\mathcal{O}(k)}$ depth with $\mathcal{O}(kn)$ ancillae.*

Proof. Since the U's all commute, they can be simultaneously diagonalized by some 2×2 unitary operator T. Apply $T^\dagger$ to the target qubit(s), parallelize the circuit using Proposition 3, and put the target qubit(s) back in the original basis by applying T. This is all done with a circuit of depth $2 \log_2 n + 2 \operatorname{depth}(T) + \operatorname{depth}(D)$. From [1] and Propositions 7 and 8 below, $\operatorname{depth}(T)$ and $\operatorname{depth}(D)$ are both $2^{\mathcal{O}(k)}$. □

As an example, in Figure 8 we show a circuit that applies the qth power of an

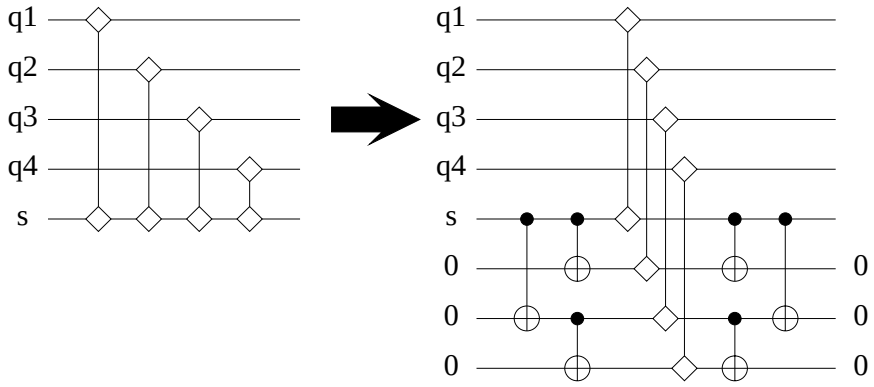

FIG. 7. *Parallelizing n diagonal gates on a single qubit as in Proposition* 2.

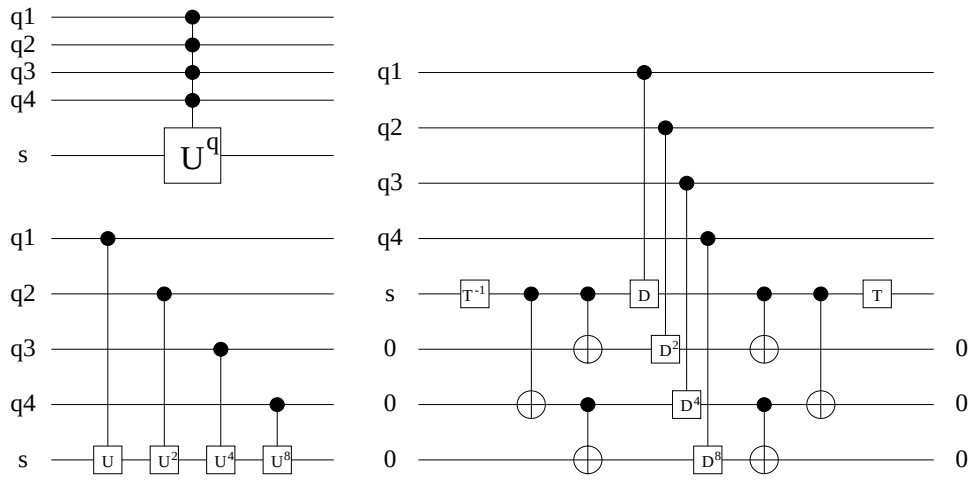

FIG. 8. *Applying an operator U q times, where q is given in binary by the input qubits.*

operator U to a target qubit, where $0 \leq q < 2^p$ is given by p input qubits as a binary integer. We can do this because $U^q = T^\dagger D^q T$.

We can extend this to circuits in general whose gates are mutually commuting, which includes diagonal gates. Note that when we say two gates commute, we mean as applied to particular qubits; for instance, controlled-not gates commute with each other if their input qubits or target qubits are the same, or if they are applied to disjoint pairs of qubits, but not if they overlap in other ways.

PROPOSITION 5. *A circuit of any size on n qubits, consisting of diagonal or mutually commuting gates, each of which couples at most k qubits, can be parallelized to depth* $\mathcal{O}(n^{k-1})2^{\mathcal{O}(k)}$ *with no ancillae, and to depth* $\mathcal{O}(k \log n) + 2^{\mathcal{O}(k)}$ *with* $\mathcal{O}(n^k)$ *ancillae. Therefore, any family of such circuits with constant k is in* $\mathbf{QNC}^1$.

Proof. Since all the gates commute, we can sort them by which qubits they couple and obtain a compressed circuit with one gate for each k-tuple. This gives $\binom{n}{k} = \mathcal{O}(n^k)$ gates, but by performing groups of n/k disjoint gates simultaneously we can do all of them in $\mathcal{O}(n^{k-1})$ layers.

By making $\frac{k}{n}\binom{n}{k} = \mathcal{O}(n^{k-1})$ of each qubit, we can apply each of these $\mathcal{O}(n^k)$

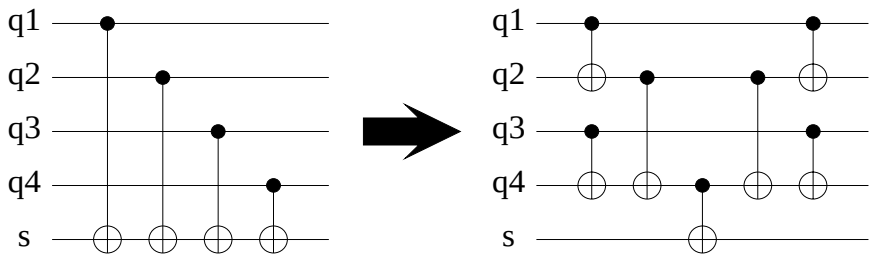

FIG. 9. *Parallelizing n controlled-not gates to $\mathcal{O}(\log n)$ depth by adding them in pairs.*

gates to a disjoint set of copies as in Propositions 3 and 4. This takes $\mathcal{O}(k \log n)$ layers of controlled-not gates.

As in Propositions 3 and 4, the layers coupling a given set of k qubits in the first case, and the operators T and D in the second case, both have depth $2^{\mathcal{O}(k)}$ in general. This is less obvious in the case of a mutual diagonalization operator T for a pair of overlapping but commuting gates. Suppose that two commuting k-qubit gates U and V overlap on some qubits we index with j, m, so that we can write them as tensor products along two different "boundaries," $U_{ij}^{lm}\delta_k^n$ and $\delta_i^l V_{jk}^{mn}$, where δ is the identity matrix. We state without proof that they can then both be diagonalized by an operator of the form $T_{ijk}^{lmn} = X_i^l Y_j^m Z_k^n$. Since this is the tensor product of three operators, each operating on k or fewer qubits, T has depth $2^{\mathcal{O}(k)}$ as before. This completes the proof. □

It comes as no surprise that gates can be performed simultaneously if they commute with each other. Proposition 5 simply confirms this intuition. Note that we could allow $k = \mathcal{O}(\log \log n)$ if we are willing to have a quasi-polynomial number of ancillae, or if the circuit is of polynomial size, in which case there are only a polynomial number of ancillae. In both cases the depth remains polylogarithmic.

6. Circuits of controlled-not gates. We can also fan in controlled-not gates. Figure 9 shows how to implement n controlled-not gates on the same target qubit in depth $2 \log_2 n + 1$. We construct the exclusive-or of subsets of the inputs by combining them in pairs.

We can use a generalization of this circuit to show that any circuit composed entirely of controlled-not gates can be parallelized to logarithmic depth.

PROPOSITION 6. *A circuit of any size on n qubits composed entirely of controlled-not gates can be parallelized to $\mathcal{O}(\log n)$ depth with $\mathcal{O}(n^2)$ ancillae. Therefore, any family of such circuits is in* $\mathbf{QNC}^1$.

Proof. First, note that there are a finite number of such circuits for a given n. In any circuit of controlled-not gates, if the n input qubits have binary values and are given by an n-dimensional vector q, then the output can be written Mq, where $M \in GF(2)$ is an $n \times n$ matrix over the integers mod 2. Each of the output qubits can be written as a sum of up to n inputs, $(Mq)_i = \sum_k q_{j_k}$, where the j_k are those j for which $M_{ij} = 1$.

We can break these sums down into binary trees. Let W_n be the complete output sums, $W_{n/2}$ be their left and right halves consisting of up to $n/2$ inputs, and so on down to single inputs. There are less than n^2 such intermediate sums W_k with $k > 1$. We assign an ancilla to each one, and build them up from the inputs in $\log_2 n$ stages, adding pairs from W_k to make W_{2k}. The first stage takes $\mathcal{O}(\log n)$ time and an

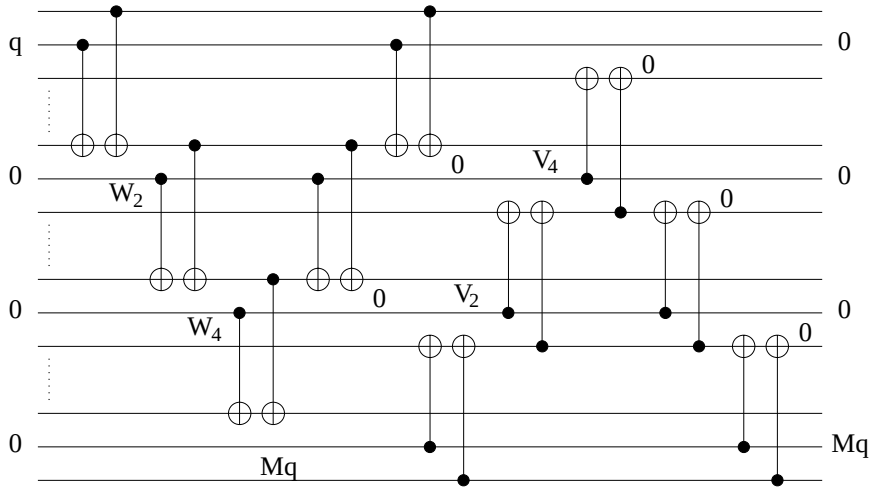

FIG. 10. *Parallelizing an arbitrary circuit of controlled-not gates to logarithmic depth.*

additional $\mathcal{O}(n^2)$ ancillae, since we may need to make $\mathcal{O}(n)$ copies of each input, but each stage after that can be done in depth 2.

To cancel the ancillae, we use the same cascade in reverse order, adding pairs from W_k to cancel W_{2k}. This leaves us with the input q, the output Mq, and the ancillae set to zero.

Now we use the fact that, since the circuit is unitary, M is invertible. Thus we can recalculate the input $q = M^{-1}(Mq)$ and cancel it. We use the same ancillae in reverse order, building the inputs q out of Mq with a series of partial sums $V_2, V_4, \ldots$, cancel q, and cancel the ancillae in reverse as before. All this is illustrated in Figure 10.

This leaves us with the output Mq and all other qubits zero. With four more layers as in Proposition 1, we can shift the output back to the input qubits, and we are done. □

This result is hardly surprising; after all, these circuits are reversible Boolean circuits, and any classical circuit composed of controlled-not gates is in $\mathbf{NC}^1$ (in fact, in the class $\mathbf{ACC}^0[2]$ of constant-depth circuits with sum mod 2 gates of unbounded fan-in). We just did a little extra work to disentangle the ancillae.

7. Controlled-not gates and phase shifts. We have shown that circuits composed of diagonal or controlled-not gates can be parallelized. It is reasonable to ask whether Propositions 5 and 6 can be combined, that is, whether arbitrary circuits composed of controlled-not gates and diagonal operators can be parallelized to logarithmic depth. In this section, we will show that this is not the case.

PROPOSITION 7. *Any diagonal unitary operator on n qubits can be performed by a circuit consisting of an exponential number of controlled-not gates and one-qubit diagonal gates and no ancillae.*

Proof. Any diagonal unitary operator on n qubits consists of 2^n phase shifts,

$$\begin{pmatrix} e^{i\omega_{000}} & & \\ & \ddots & \\ & & e^{i\omega_{111}} \end{pmatrix}.$$

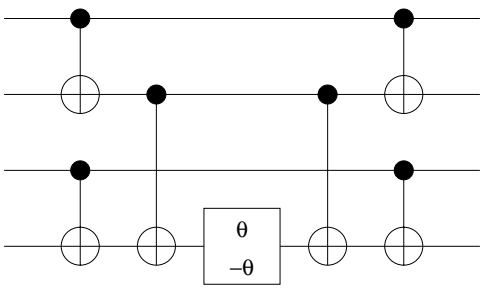

FIG. 11. *A circuit for the phase shift $\theta\mu_s$, i.e., a phase shift of $+\theta$ if the number of true qubits is even and $-\theta$ if it is odd.*

If we write the phase angles as a 2^n-dimensional vector ω, then the effect of composing two diagonal operators is simply to add these vectors mod 2π.

For each subset s of the set of qubits, let μ_s be the 2^n-dimensional vector whose ith component is $+1$ if the number of true qubits in $i \cap s$ is even, and -1 if it is odd. If $s = \{1 \cdots n\}$, for instance, μ_s is the aperiodic Morse sequence $(+1, -1, -1, +1, \ldots)$ when written out as a 2^n-dimensional vector, but it really just means giving the odd and even corners of the Boolean n-cube opposite signs.

It is easy to see that the μ_s for all $s \subset \{1 \cdots n\}$ are linearly independent and form the Hadamard, or Fourier, basis of $\mathbb{R}^{2^n}$. Moreover, while diagonal gates coupling k qubits can only perform phase shifts spanned by those μ_s with $|s| \leq k$, a circuit like that in Figure 11 can perform a phase shift proportional to μ_s for any given s (incidentally, in depth $\mathcal{O}(\log |s|)$ with no ancillae). Therefore, a series of 2^n such circuits, one for each subset of $\{1 \cdots n\}$, can express any diagonal unitary operator. □

This exponential bound is necessary in the worst case.

PROPOSITION 8. *There are diagonal operators that cannot be parallelized to less than exponential depth with a polynomial number of ancillae.*

Proof. Consider setting up a mapping between circuits and operators. A diagonal unitary operator on n qubits is described by 2^n eigenvalues which lie on the unit circle, so the set of such operators is isomorphic to a 2^n-dimensional torus. On the other hand, a circuit of depth d with m ancillae is described by only $\mathcal{O}(d(m+n))$ complex numbers, and the circuit can take one of $2^{\mathcal{O}(d(m+n)\log(m+n))}$ discrete topologies. Thus the set of such circuits is isomorphic to a union of $2^{\mathcal{O}(d(m+n)\log(m+n))}$ complex manifolds, each of which has $\mathcal{O}(d(m+n))$ dimensions. Since the map between circuits and operators is easily seen to be continuous, in order for this map to be surjective we need $2^n = \mathcal{O}(d(m+n))$ and so at least one of m or d must be exponential in n. □

However, the next proposition shows that this will not help us distinguish **QP** from **QNC**. In fact, for circuits consisting of controlled-nots and diagonal gates, **QP** and **QNC** are identical.

PROPOSITION 9. *Any circuit on n qubits consisting of controlled-not gates and m diagonal operators coupling k qubits each can be parallelized to $\mathcal{O}(2^k \log n)$ depth with $\mathcal{O}(\max(kmn, n^2))$ ancillae, using gates that couple a constant number of qubits. Therefore, any such circuit of polynomial size $\mathcal{O}(n^c)$ can be parallelized to $\mathcal{O}(2^k \log n)$ depth with $\mathcal{O}(kn^{c+1})$ ancillae, any family of such circuits with constant k is in $\mathbf{QNC}^1$, and any family with $k = \mathcal{O}(\log \log n)$ is in* **QNC**.

Proof. Any such circuit can be written as the product of a circuit of controlled-

not gates and a diagonal matrix that takes care of the phase shifts. The first part we can parallelize as in Proposition 6 to $\mathcal{O}(\log n)$ depth and $\mathcal{O}(n^2)$ ancillae. However, Proposition 8 shows that diagonal matrices cannot be parallelized in general, so we have to look at the circuit more closely.

We can write the circuit we are trying to parallelize as a product $M = M_0 P_1 M_1 P_2 M_2 \cdots P_m M_m$, where the M_i consist only of controlled-not gates and the P_i are the diagonal operators. By passing the P's through the M's to the right end of the circuit, we can write

$$M = M_0 \cdots M_m \cdot D_1 \cdots D_m,$$

where D_i is the diagonal operator

$$D_i = (M_i \cdots M_m)^\dagger P_i (M_i \cdots M_m).$$

In other words, D_i calculates what state the controlled-not circuit was in when P_i was applied, applies it, and uncalculates.

Each one of the k qubits coupled by P_i is the exclusive-or of some subset of the inputs and can be calculated with a binary tree of $\mathcal{O}(n)$ ancillae as in Proposition 6. Finally, by Proposition 3 we can apply all the D_i at once, by making m copies of the system's entire state. Thus the total number of ancillae needed is $\mathcal{O}(kmn)$, or $\mathcal{O}(kn^{c+1})$ if $m = \mathcal{O}(n^c)$.

Finally, Propositions 7 and 8 show that each diagonal gate takes depth $\mathcal{O}(2^k)$ to perform with diagonal gates coupling a constant number of qubits. Thus the depth is $\mathcal{O}(\log n)$ if k is constant, and $\mathcal{O}(\log^{\mathcal{O}(1)} n)$ if $k = \mathcal{O}(\log \log n)$. □

8. The Hadamard gate and quantum codes. So far, all the circuits we have looked at are essentially classical; each row and each column has only one nonzero entry, so they are just reversible Boolean functions with phase shifts. Obviously, any interesting quantum algorithm will involve mixing between different Boolean states.

The simplest such operator is the *Hadamard gate* $R = \frac{1}{\sqrt{2}}\left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)$.By applying it to all n qubits of a state $|000\cdots0\rangle$, we can prepare them in a superposition of all 2^n possible states. It is used, along with phase shifts, in the standard circuit (shown below in Figure 19) for the quantum Fourier transform; in fact, it is itself the quantum Fourier transform on $\mathbb{Z}_2$.

We will call a controlled-U gate a *controlled-Pauli gate* if U is one of the Pauli matrices $\sigma_x = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, $-i\sigma_y = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$, or $\sigma_z = \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$. Note that a controlled-X is simply a controlled-not, a controlled-Z is just the symmetric π-shift, and this real version of the controlled-Y is their product.

The π-shift can be written in terms of a controlled-not by conjugating the target with R. Conjugating the input qubit instead gives us the π-shift in the Hadamard basis, which is a symmetric gate

$$\frac{1}{2}\begin{pmatrix} 1 & 1 & 1 & -1 \\ 1 & 1 & -1 & 1 \\ 1 & -1 & 1 & 1 \\ -1 & 1 & 1 & 1 \end{pmatrix}.$$

We call this the w-gate, pronounced "wiggle," and notate it as in Figure 12.

Then we have the following proposition.

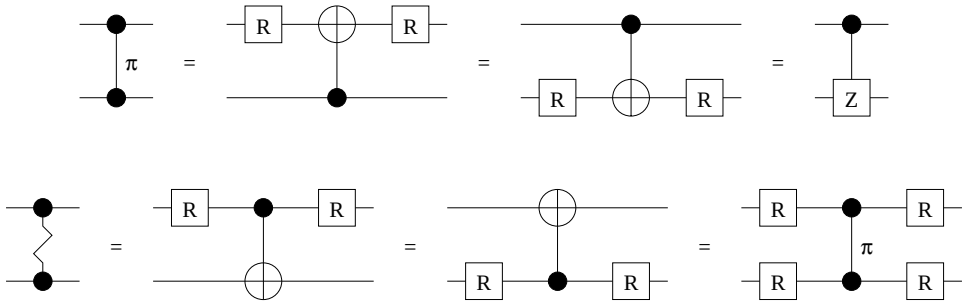

FIG. 12. *Relations between the π-shift, the controlled-not, and the w gate, which we notate with a wiggle.*

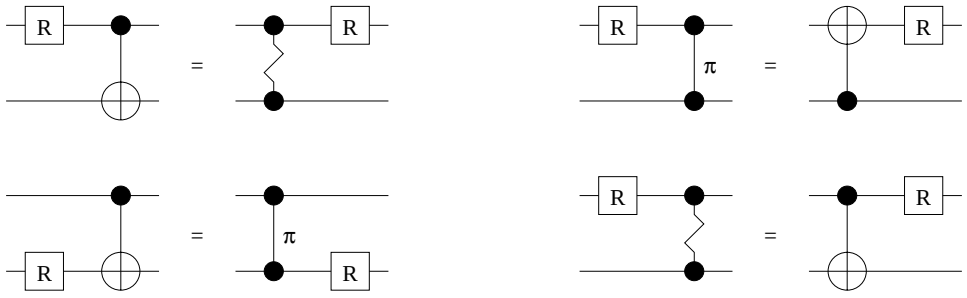

FIG. 13. *Step 1: combing R's to the right through controlled-nots, π-shifts, and w gates.*

PROPOSITION 10. *Circuits of any size consisting of controlled-Pauli gates and the Hadamard gate R can be parallelized to $\mathcal{O}(\log n)$ depth with $\mathcal{O}(n^2)$ ancillae. Thus any family of such circuits is in* $\mathbf{QNC}^1$.

Proof. We will use the algebraic relations between these gates to arrange them into easily parallelizable groups. The relations shown in Figures 12–15 can be verified by multiplying the 4×4 or 8×8 matrices corresponding to these gates.

In step 1, we move Hadamard gates to the right through the other gates as shown in Figure 13. Since $R^2 = \mathbf{1}$, this leaves a circuit of controlled-nots, π-shifts, and w-gates, followed by a single layer of R's and identities.

In step 2, we arrange π-shifts and w-gates into three groups: a set of π-shifts, a set of w's, and another set of π-shifts, with controlled-nots interspersed throughout. We can do this because these gates commute when applied to different pairs of qubits (up to the creation of an additional controlled-not) and generate a finite group when applied to the same pair. Specifically, if we call the 4×4 matrix of the π-shift z, then z and w obey the relations $z^2 = w^2 = 1$ and $wzw = zwz$, and generate the permutation group on three elements $S_3 = \{1, z, w, zw, wz, zwz\}$. Thus a group of z's, a group of w's, and a group of z's are sufficient to generate all possible products of these. These relations are shown in Figure 14.

In step 3, we pull the controlled-nots to the left through the z's and w's as shown in Figure 15. This makes some additional symmetric gates, but always of the same type we pull through, so the grouping of z's, w's, and z's is not disturbed. (We also sometimes create single-qubit gates X and Z, but these can be thought of as controlled-nots or π-shifts whose control qubit is always true.)

Finally, we note that since w is simply z in the Hadamard basis as shown in

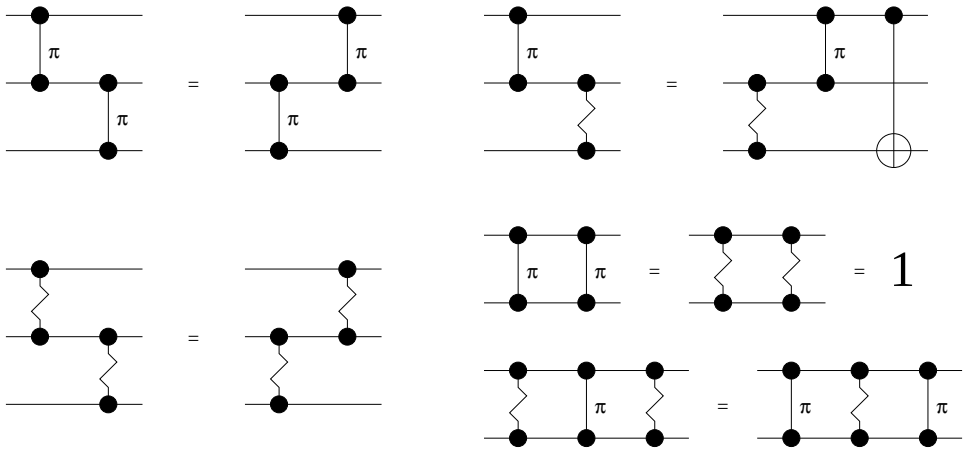

FIG. 14. *Step 2: commuting π-shifts and w's past each other, and combining them into 1, z, w, zw, wz, or zwz.*

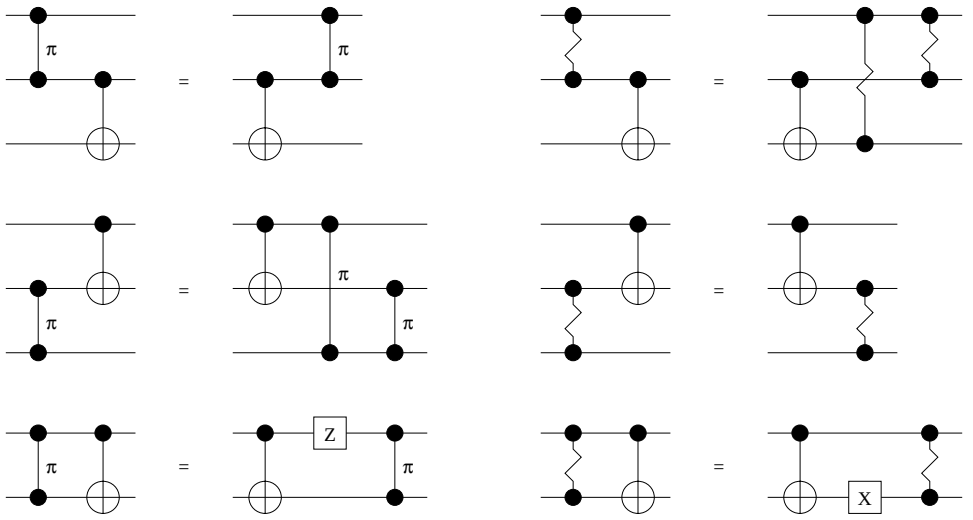

FIG. 15. *Step 3: commuting π-shifts and w's past controlled-nots.*

Figure 12, we can write the group of w's as a group of z's conjugated with R on every qubit. We are left with a circuit of controlled-not gates, followed by three groups of π-shifts separated by two layers of R's, and a single layer of possible R's as shown schematically in Figure 16.

Propositions 5 and 6 show how to parallelize circuits of π-shifts and of controlled-nots to $\mathcal{O}(\log n)$ depth with $\mathcal{O}(n^2)$ ancillae, and the theorem is proved. □

With a little extra work we should also be able to include the one-qubit $\pi/2$ shift $P = \left(\begin{smallmatrix} 1 & 0 \\ 0 & i \end{smallmatrix}\right)$, also known as the "square-root-of-not." This would give us the *Clifford group*, which is the normalizer of the group of tensor products of Pauli matrices. In fact, some of the relations we have used here are equivalent to those used by Gottesman to derive the Heisenberg representation of circuits in the Clifford group [10]. Figure 17 shows some relations between the P gate and the controlled-not, π-shift, and w, but so far we have not found a way to use these in a way analogous to Proposition 10.

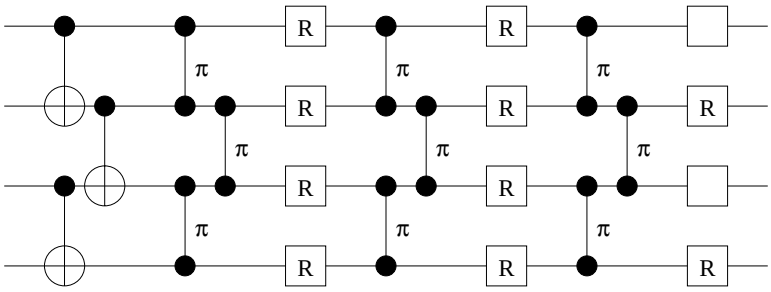

FIG. 16. *The kind of circuit we are left with after steps* 1, 2, *and* 3, *and after writing the* w*'s as* π*-shifts conjugated by* R.

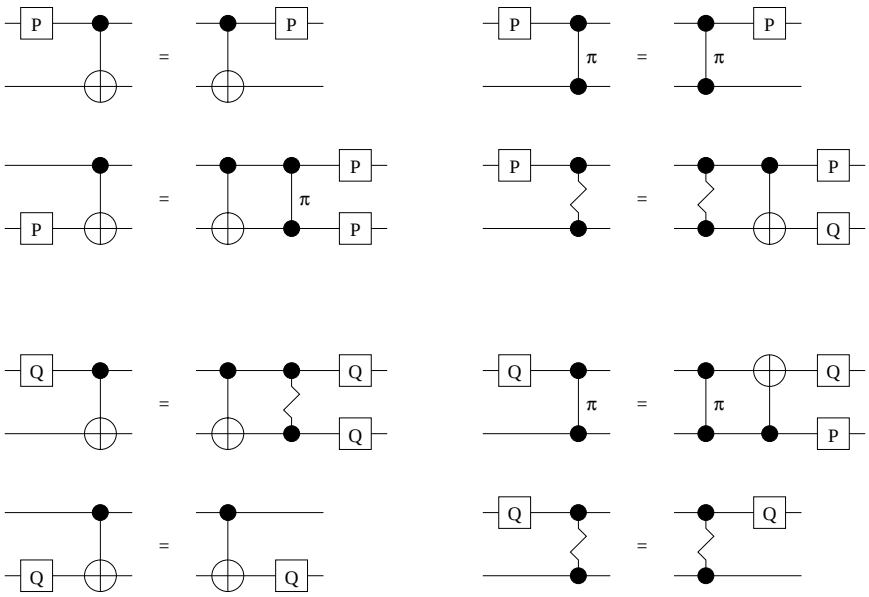

FIG. 17. *Relations between the* P *and the controlled-not,* π*-shift, and* w. *Here* $Q = RPR$, *the* P *gate conjugated with a Hadamard gate.*

The reader can experience our frustration by trying to use these relations to move two P gates, one on each qubit, rightward through a w. The result is an endless loop. In fact, computational search shows that this circuit cannot be written as any product of controlled-nots and π-shifts followed by any pair of one-qubit gates. This indicates that P gates are more difficult to pull out of a circuit than, say, Hadamard gates are. However, we are hopeful enough to conjecture that Proposition 10 can be generalized to include the P gate as well.

There may be other interesting finite subgroups of $O(2^n)$ that we can parallelize. However, even small additions to the Clifford group result in a dense set of operators and hence universal computation. This is because the controlled-Z gate is the only two-qubit phase shift whose conjugate by a controlled-not can be expressed with two- and one-qubit gates, just as P and Z are the only one-qubit phase shifts whose conjugate by a controlled-not can be expressed with themselves and controlled-Z gates. Other phase shifts generate three- and more-qubit interactions when they are

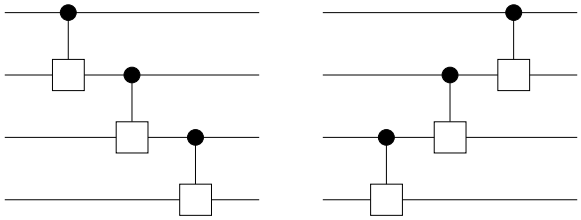

FIG. 18. *These "staircase" circuits seem hard to parallelize unless the operators are purely diagonal or off-diagonal.*

commuted through controlled-nots. The controlled-P gate, for instance, generates the Toffoli gate [1] and hence irrational rotations and a dense set of operators [19].

In any case, Proposition 10 gives us the following corollary.

COROLLARY 1. *Additive (or "stabilizer") quantum error-correcting codes are in* $\mathbf{QNC}^1$*, in the sense that encoding and decoding families of such codes with* n*-qubit code words can be done in* $\mathcal{O}(\log n)$ *depth and* $\mathcal{O}(n^2)$ *ancillae.*

Proof. Since the Pauli matrices σ_x and σ_z generate bit errors and phase errors, respectively, circuits for quantum codes such as those in [23, 14, 3, 7] are composed of controlled-Pauli and Hadamard gates. By a result of Rains [20], additive quantum codes are always equivalent to real ones, so the real version of the controlled-Y gate is sufficient. □

In fact, Cleve and Gottesman [4] and Steane [24] have shown that circuits for additive quantum codes can be constructed out of controlled-Pauli gates, where Hadamard gates appear only in one or two layers. Thus Proposition 9 is already enough to parallelize these circuits.

9. The quantum Fourier transform and the staircase circuit. A simple, perhaps minimal, example of a quantum circuit that seems hard to parallelize is the "staircase" circuit shown in Figure 18. This kind of structure appears in the standard circuit for the quantum Fourier transform (QFT), which has $\mathcal{O}(n^2)$ gates [6, 22]. Careful inspection shows that the QFT can in fact be parallelized to $\mathcal{O}(n)$ depth as shown in Figure 19 (an upside-down version of which appears in [13]), but it seems difficult to do any better.

Cleve and Watrous [5] have shown that fast parallel circuits exist for an approximate QFT, with error small enough to implement Shor's factoring algorithm; this shows that factoring is in $\mathbf{ZPP}^{\mathbf{BQNC}}$ and leaves iterated exponentiation as the main bottleneck. They also showed that any constant-error circuit must have depth at least $\mathcal{O}(\log n)$. However, the question of whether the *exact* QFT can be parallelized remains open, and we give the following conjecture.

Conjecture 1. Staircase circuits composed of controlled-U gates other than diagonal or off-diagonal gates (i.e., other than the special cases handled in Propositions 5 and 6) cannot be parallelized to less than linear depth, and neither can the exact quantum Fourier transform.

Since many different quantum operators can be used to solve a problem, proving this conjecture would *not* establish that $\mathbf{QNC} < \mathbf{QP}$ (which, if it were true, would also imply $\mathbf{NC} < \mathbf{PSPACE}$). However, it would certainly shed light on why quantum algorithms can be difficult to parallelize.

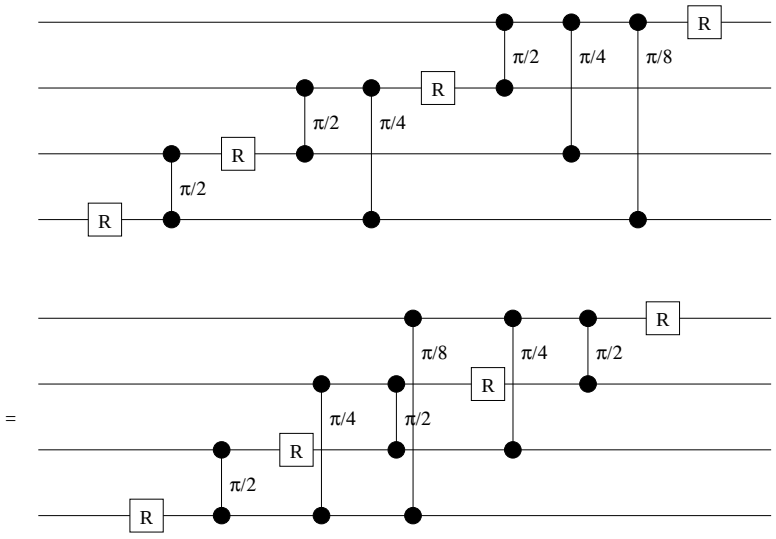

FIG. 19. *The standard circuit for the exact quantum Fourier transform on n qubits can be carried out in $2n-1$ layers. Can it be parallelized to less than linear depth?*

10. Conclusion. We conclude with some questions for further work.

Is **QNC**, or even **EQNC**, contained in **P**? Watrous's results on space-bounded quantum complexity classes [25] show that $\mathbf{QL} \subset \mathbf{NC}^2$, but no quantum analog of Borodin's equivalence [2] between depth and space is known. **BQNC** and **BPP**, or **EQNC** and **P**, might be incomparable.

Does parallelizing the encoding and decoding of error-correcting codes help reduce the error threshold for reliable quantum computation, at least in regimes where storage errors are more significant than gate errors?

Quantum context-free languages have been defined in [15], where it is shown that they are strictly more powerful than classical ones. Parsing classical context-free languages is in **NC**. Is quantum parsing, i.e., producing derivation trees with the appropriate amplitudes, in **QNC**?

Finally, can the reader show that the staircase circuit or the exact QFT cannot be parallelized?

ANALYSIS OF TIMING-BASED MUTUAL EXCLUSION WITH RANDOM TIMES*

ELI GAFNI† AND MICHAEL MITZENMACHER‡

Abstract. Various timing-based mutual exclusion algorithms have been proposed that guarantee mutual exclusion if certain timing assumptions hold. In this paper, we examine how these algorithms behave when the time for the basic operations is governed by probability distributions. In particular, we are concerned with how often such algorithms succeed in allowing a processor to obtain a critical region and how this success rate depends on the random variables involved. We explore this question in the case where operation times are governed by exponential and gamma distributions, using both theoretical analysis and simulations.

Key words. mutual exclusion, timed mutual exclusion, Markov chains, locks

1. Introduction.

A good design methodology for developing distributed algorithms, as advocated by Liskov [10], is to assume the worst and hope for the best. In assuming the worst, one designs an algorithm which is safe regardless of the amount of time each operation takes. In hoping for the best, one designs the algorithm to optimize some utility function under certain timing assumptions.

A nice example of such a design is the mutual exclusion algorithm of Lynch and Shavit [12]. We describe the algorithm here at a high level; definitions of the relevant terms appear in section 2.1. The Lynch and Shavit algorithm for mutual exclusion is designed to cope with variations in timing of read and write operations. It combines previous mutual exclusion algorithms of Fischer [5] and Lamport [8] in a clever way in order to guarantee mutual exclusion and weak deadlock-freedom, as well as guarantee deadlock-freedom if certain timing constraints are met. Specifically, the algorithm is guaranteed to avoid deadlock if all steps of a process take time in a fixed range $[c_1, c_2]$. Given these timing constraints, specific pauses depending on the bounds c_1 and c_2 are added into the program for each process; these pauses ensure deadlock-freedom. Note that deadlock-freedom comes at a price, namely, the introduction of pauses that delay the completion of operations. In practice, detecting deadlock and breaking it are very costly in terms of time, and therefore a good design should ensure that deadlock never or rarely happens.

It is reasonable to assume that hard timing constraints will rarely or never be violated in the case of interprocess communication through a standard shared memory, such as when processes are running on machines in the same room. The gap between

the minimum and maximum memory reaction time is likely to be sufficiently small enough that pauses based on these timing constraints will generally yield only a small performance penalty. With the rise of fast networks and the Internet, however, there are alternative situations where processors may communicate through a much slower and more variable shared memory medium. For example, interprocess communication can be accomplished via servers reading and writing shared disk pages from a shared farm of disks accessible over a network. The mechanisms for using shared disks in this manner exist today and are described in several works on storage area networks [3, 4, 9, 14]. Indeed, storage area networks offer a shared memory that is cheap, reliable, and large; moreover, with regard to the design of distributed algorithms, the physical model of this architecture is close to the abstract model of shared memory. Operations on a disk-based shared memory might be slow and have large variance; moreover, its timing may not be well understood. Making hard timing assumptions that are guaranteed to hold may entail prohibitively long timeouts or self-delays for practice.

An alternative application that we envision involves multiple processes interacting via the Internet, such as in an auction on eBay. In such a scenario, the number of processes interacting may be extremely large. Also, while operations on shared memory may be instantaneous, users cannot expect response times on the order of shared memory systems, since Internet progagation delay will dominate.

Therefore, we are motivated to expand the analysis of the performance of mutual exclusion algorithms based on shared memory to systems that can potentially have long delays, so that the bounded timing model is not applicable. In many cases, even when timing bounds may prove problematic, knowledge of the distribution of operation times may be possible through systematic study. Consequently, we suggest introducing a probabilistic analysis of mutual exclusion algorithms under random delays.

Besides the above motivation, once we considered the idea of probabilistic analysis, it occurred to us that randomized algorithms for mutual exclusion may be more efficient than previous algorithms even in the context of fast shared memories. Instead of having algorithms introduce deterministic pauses designed for the worst case in order to guarantee mutual exclusion, using shorter pauses with random times may lead to better practical performance. The hope is that smaller random delays will avoid deadlock often enough that it will be more efficient to use small random delays and a mechanism for breaking deadlock than a slower deadlock-free algorithm. This approach may allow tradeoffs between correctness properties and efficiency.

A further motivation for introducing probabilistic models into this area is simply to gain more insight into the features of these algorithms. In particular, our analysis demonstrates that an appropriate pause (even one that lasts a random time) can dramatically change an algorithm's behavior.

We further note that the probabilistic framework we introduce is reminiscent of similar work on contention resolution in multiaccess channels. The contention resolution framework has proven highly successful. (See the notes in [6] or references from [7] or [13].) We suspect that this direction may therefore prove worthwhile in the context of mutual exclusion or other distributed algorithms as well. For example, since the publication of the original version of this paper, a similar probabilistic framework was used by Aspnes to study a deterministic consensus algorithm against an adversary who cannot control random timing noise introduced by the system [2].

In this paper, we focus on the case where operation times have the exponential

distribution. This distribution has properties which prove handy for analysis. Moreover, although the assumption of exponential distributions is not correct in practice, algorithms that behave well under the exponential distribution are generally assumed (whether correctly or not) to behave well under "reasonable" distributions. Thus they make an appropriate starting point for this analysis. We also examine the case where operation times have a gamma distribution, both to offer more insight and to avoid the problem of drawing conclusions specific to the exponential distribution.

We refer to the basic unit of much of our analysis as a *lock*. Loosely speaking, for our purposes a lock is a shared variable that can be inspected (or read, to see if it is clear), written (to attempt to take control), and read (to see if control has been obtained). A processor successfully passes through a lock if it finds it clear on inspection, writes its processor ID to it, and reads back its processor ID. Note that a processor may pause, or self-delay, between any of these steps. A lock is a basic unit in Fischer's mutual exclusion algorithm [5], which we describe in section 2.1. Studying locks provides us with the means and insight to study variations on the algorithm of Lynch and Shavit [12].

We are interested in answers to questions such as the following:

1. How often do locks succeed, and how does this depend on the underlying distributions?
2. Are we better off with one lock with a long pause or two consecutive locks with smaller pauses?
3. How should lock constructions be combined in this setting?

In this paper, we focus on the analysis of the basic lock construction and explore the behavior of these locks and some of our questions with simulations. As a by-product of our work, we explore the behavior of several simple but interesting Markov chains. We believe that further, more detailed analysis of these Markov chains would be interesting, not only because of their connection to timed mutual exclusion algorithms, but also in and of themselves.

Because we focus on the simple lock mechanism, the analysis in this version of the paper is essentially self-contained. However, we encourage the interested reader to peruse the work by Lynch and Shavit on timing-based mutual exclusion [12] for more details on Lamport's algorithm, Fischer's algorithm, and their combination, in order to put this work in context.

2. Background.

2.1. Definitions. For completeness, we describe the basic definitions associated with the mutual exclusion problem. Here we generally follow the definitions and notation of [12]. (See also [11] for extensive references and related work.)

A mutual exclusion algorithm arbitrates among n sequential threads of control, or processes. Processes communicate by reading and writing in some form of shared memory. Read and write operations on this memory are assumed to execute instantaneously; that is, they happen atomically on memory locations. The process itself, however, might not obtain the result of the read or write until some future time, depending on the architecture of the system. For our purposes, the program associated with each process has a form as given in Figure 1. In particular, a process has an associated *critical region*. A system is said to *satisfy mutual exclusion* if in any reachable system state at most one user is in its critical region. Note that the *trying region* and the *exit region* are used to coordinate entry to and exit from the critical region; the *remainder region* is where all other work is done.

```
Basic process
p: current process index

repeat forever:
  remainder region
  trying region
  critical region
  exit region
end repeat;
```

FIG. 1. *Basic process program.*

Two other properties are useful to consider. A system is said to be *weakly deadlock-free* if when any single process's trying region is concurrent only with the remainder regions of other processes, then its trying region terminates, and similarly if when any single process's exit region is concurrent only with the remainder region of other processes, then its exit region terminates. This property corresponds to the requirement that if a process runs alone, it accesses the critical region. The stronger property of being *deadlock-free*, which corresponds to the requirement that the system progress, requires that

- if some process is in the trying region and no process is in the critical region, then subsequently some process enters the critical region; and
- if some process is in the exit region, then subsequently some process enters the remainder region.

The algorithm of Lynch and Shavit relies on Lamport's fast mutual exclusion algorithm [8] to guarantee that mutual exclusion is never violated. (See Figure 2.) It also relies on Fischer's timed mutual exclusion algorithm [5] to provide Lamport's algorithm the environment it requires for deadlock-freedom, namely, a single contender. (See Figure 3.) We discuss the combined algorithms in section 4. Proofs of these properties appear in [12].

Note the appearance of a pause in Fischer's timed mutual exclusion algorithm. The point of the pause is as follows: suppose each *step* of a process, corresponding to a line of code, takes time bounded between $[c_1, c_2]$ for some positive finite values c_1 and c_2. Then if the pause time corresponds to at least $\lceil c_2/c_1 \rceil$ steps (using for example no-op operations), so that the pause takes time at least c_2, then Fischer's algorithm guarantees both mutual exclusion and deadlock-freedom.

2.2. Properties of the exponential distribution. Recall that a random variable that is exponentially distributed with mean μ is defined by its probability density function, $f(x) = (1/\mu)\mathrm{e}^{-x/\mu}$. The exponential distribution proves convenient for theoretical study because of its special properties. We briefly note these properties here and make use of them without further reference throughout this paper.

- *Memoryless property.* Suppose that the time until an event is determined by an exponential random variable with mean μ. Given that the event has not yet happened, the remaining time until the event happens is still an exponential random variable with mean μ.
- *Minimum property.* Suppose that the times until each of k events are determined by independent exponential random variables with mean μ. Then the time until the first of these events occurs is exponential with mean $\frac{\mu}{k}$.

FIG. 3. *Fischer's timed mutual exclusion algorithm.*

- *Fairness property.* Suppose that the times until events A and B are determined by independent exponential random variables with means μ_1 and μ_2, respectively. Then event A occurs first with probability $\frac{\mu_2}{\mu_1+\mu_2}$.

2.3. How many pass through? We begin by considering a basic unit for mutual exclusion algorithms, namely, a *lock*. A lock access protocol consists of an *inspect* phase (which is an initial read of the shared variable that comprises the lock), a *write* phase, and a final *read* phase. A processor inspects the lock to see if it is clear; it attempts to write its processor ID to the lock; and then it passes through the lock successfully if it reads its own ID. A processor that successfully passes through the lock eventually clears the shared variable so that others may pass through; until this occurs, the processor is said to own the lock. Mutual exclusion is guaranteed as long as no two processors believe they own the lock at the same time. Recall that a lock is the mechanism behind Fischer's algorithm, as seen in Figure 3. Also, Fischer's mutual exclusion algorithm also allows for pauses. We begin our analyses without considering the effect of a pause; however, we return to consider the pause later in the paper.

We will often compare the behavior of a lock with a *double lock*, by which we mean two successive back-to-back locks, each with its own shared variable. When a processor passes through the first lock of a double lock, it then begins the inspection phase for the second lock of the double lock. A processor is said to own a double lock only after it has passed through the second lock, and mutual exclusion is guaranteed as long as no two processors believe they own the lock at the same time. A natural question we consider here is whether using two short locks in a double lock might be better than using a long single lock.

We denote the three phases by I, W, and R, respectively. In this section, unless otherwise stated, we assume that the times for each of these actions are exponentially distributed, with means i, w, and r respectively, where the values of i, w, and r are fixed constants (independent of the number of processors in the system). For convenience, we scale so that $w = 1$ unless otherwise noted.

We emphasize that an operation is meant to take place *atomically* (that is instantaneously, from the point of view of the processes) at the end of the time interval corresponding to the operation. That is, the fact that operations take time to complete is not to suggest that they do not take place atomically, but only that there is a delay between when an operation is initiated by a processor and when it completes. One way to view this model is that operations initiated by a processor are scheduled in some way, say, on a shared disk system. The scheduling causes a random delay between when an operation is initiated and when it is completed. A processor sees the results of an operation as soon as it is completed.

We begin by presenting some simple arguments regarding how many processors complete successive stages of a lock in the face of contention. These arguments do not answer our main question, which is how often just one processor successfully obtains a lock in the face of contention. They do, however, introduce the flavor of our arguments and provide some initial insight.

THEOREM 1. *Consider a situation where n processors begin inspecting a free lock at the same time. Then, with probability bounded below by some constant, at least $\Omega(\sqrt{n/i})$ processors complete the inspection stage before the first write completes.*

Remark. The assumption that the processors begin at the same time is for convenience; since all times are exponentially distributed, as long as a write has not occurred, we may take any instant when n processors are in the I stage as the beginning.

Proof. We derive a recursive function p_j describing the probability that at least j processors successfully inspect the lock before the first write. Suppose that jth inspection has just completed, and no writes have yet occurred. Then the time until the next inspection completes is exponentially distributed with mean $i/(n-j)$, as there are $n-j$ processors remaining. The time until the first write completes is exponentially distributed with mean $1/j$, as there are j processors attempting a write. Hence, the probability that another inspection completes before the first write is $\frac{n-j}{ij+n-j}$. Recursively, then, we have $p_1 = 1$ and $p_{j+1} = p_j \frac{n-j}{ij+n-j}$.

Let $z = \sqrt{n/i}$. Then

$$\begin{aligned} p_{z+1} &= \prod_{1 \le j \le z} \frac{n-j}{ij+n-j} \\ &= \prod_{1 \le j \le z} \left(1 - \frac{ij}{ij+n-j}\right) \end{aligned}$$

$$\geq \prod_{1 \leq j \leq z} \left(1 - \frac{ij}{(1-\epsilon)n}\right)$$

for an ϵ that goes to 0 as n gets large. Hence,

$$p_{z+1} \geq \prod_{1 \leq j \leq z} \left(1 - \frac{ij}{(1-\epsilon)n}\right) \geq \left(1 - \frac{1}{(1-\epsilon)z}\right)^z,$$

which is arbitrarily close to $\mathrm{e}^{-1/(1-\epsilon)}$ for sufficiently large n. This demonstrates that with at least some constant probability, at least $\Omega(\sqrt{n/i})$ processors complete the I stage. □

It is easy to extend the proof of Theorem 1 to show that the expected number of processors that complete their I stage before the first write is actually $\Theta(\sqrt{n/i})$.

THEOREM 2. *Consider the setting of Theorem* 1. *The expected number of processors that complete the inspection stage before the first write is* $\Theta(\sqrt{n/i})$.

Proof. The lower bound follows from Theorem 1. For the upper bound, note that the expected number of processors to complete the inspection stage before the first write is $\sum_{m \geq 1} p_m$. Let $z = \sqrt{n/i}$; then for any integer $k \geq 1$, for y such that $zk < y \leq z(k+1)$,

$$p_y = \prod_{1 \leq j \leq y-1} \frac{n-j}{ij+n-j} \leq \prod_{z \leq j \leq y-1} \frac{n}{ij+n} \leq \left(1 + \frac{1}{z}\right)^{-(k-1)z} < 2^{-k+1}.$$

It follows that $\sum_{m \geq 1} p_m < 3\sqrt{n/i}$. □

In fact, asymptotically exact formulae can be found with some work. We demonstrate this for the case $i = 1$, which yields an interesting result, although the same technique applies for other cases. When $i = 1$, we have $p_k = \prod_{1 \leq j \leq k-1} \frac{n-j}{n}$, and the expected number of processors that complete the I stage before the first write is $E_I = \sum_{k=1}^{n} p_k$. Consider plotting the points $((k-1)/n, np_k)$ in the first quadrant of the Euclidean plane for $k = 1, \ldots, n$. The area under the successive axes-parallel rectangles defined by these points equals the desired expectation E_I. Moreover, the area of these rectangles approximates the area under a curve passing through these points. Defining a curve that passes through these points is difficult, but we can find a curve that nearly passes through these points quite easily. Consider moving from $(x, y) = ((k-1)/n, np_k)$ to $(k/n, np_{k+1})$. Note that as we move $\Delta x = 1/n$ on the x-axis, the corresponding y-value drops by $\Delta y = -(x + \Delta x)y$. Hence, our points are well approximated by the curve defined by the differential equation $dy/dx = -nxy$ and the boundary condition $y(0) = n$. This curve is just $y = n\mathrm{e}^{-nx^2/2}$. The area under the curve is

$$\int_0^1 n\mathrm{e}^{-nx^2/2} dx = \sqrt{\frac{\pi n}{2}} + O(1).$$

Hence, if n processors begin an I stage, then (up to lower order terms) on average $\sqrt{\frac{\pi n}{2}}$ processors complete their inspection before the first write occurs.

This argument for $i = 1$ can be formalized by noting that

$$p_k = \prod_{1 \leq j \leq k-1} \frac{n-j}{n} \leq \prod_{1 \leq j \leq k-1} \mathrm{e}^{-j/n} = \mathrm{e}^{-k(k-1)/2n} \leq \mathrm{e}^{-(k-1)^2/2n}.$$

It easily follows that $\sum_{k=1}^{n} p_k$ is bounded above by

$$1 + \int_0^n \mathrm{e}^{-x^2/2n} dx = \int_0^1 n\mathrm{e}^{-nx^2/2} dx + O(1).$$

Similarly, using $1 - x \geq \mathrm{e}^{-x-x^2}$ for $0 \leq x \leq 1/2$, we have for $k \leq n/2$

$$p_k = \prod_{1 \leq j \leq k-1} \frac{n-j}{n} \geq \prod_{1 \leq j \leq k-1} \mathrm{e}^{-j/n - j^2/n^2} \geq \mathrm{e}^{-k(k-1)/2n - k(k-1)(2k-1)/6n^2}$$
$$\geq \mathrm{e}^{-k^2/2n - k^3/3n^2}.$$

It follows that $\sum_{k=1}^{n} p_k$ is bounded below by $\int_0^{1/2} n\mathrm{e}^{-nx^2/2 - nx^3/3} dx + O(1)$, and it can be checked that this is equal to $\int_0^1 n\mathrm{e}^{-nx^2/2} dx + O(1)$. (For example, split the integral into two parts, the first covering the range $[0, n^{-5/12}]$ and the second $[n^{-5/12}, 1/2]$. The cubic term is lower order in the exponent in the first range and can be absorbed in the $O(1)$. Similarly, the exponential term in the second range is small enough to be absorbed in the $O(1)$, which also explains why the difference between integrating to $1/2$ and integrating to 1 can be dismissed.)

THEOREM 3. *Consider a situation where n processors begin to write to a lock at the same time. Then on average $\Theta(\ln(rn)/r)$ read their own value, and in fact $\Theta(\ln(rn)/r)$ read their own value with probability $1 - o(1)$.*

Proof. The time between the jth and $(j+1)$st write is exponentially distributed with mean $1/(n-j)$. Hence, the probability that the processor that makes the jth write reads its own value is

$$\frac{\frac{1}{n-j}}{r + \frac{1}{n-j}} = \frac{1}{r(n-j)+1}.$$

The expected number of processors that read their own value is therefore

$$\sum_{j=1}^{n} \frac{1}{r(n-j)+1}.$$

When $r = 1$, this is simply $\sum_{j=1}^{n} 1/j = H(n) \approx \ln n$. Otherwise, bounding the sum by appropriate integrals we have

$$\int_{x=1}^{n} \frac{1}{xr+1} dx \leq \sum_{j=1}^{n} \frac{1}{r(n-j)+1} \leq 1 + \int_{x=0}^{n} \frac{1}{xr+1} dx,$$

and hence

$$\frac{\ln(rn+1)}{r} - \frac{\ln(r+1)}{r} \leq \sum_{j=1}^{n} \frac{1}{r(n-j)+1} \leq 1 + \frac{\ln(rn+1)}{r}.$$

The argument can be easily extended to show that the number of processors that read their own value is $\Theta(\ln n)$ with high probability. Let X_j be the event that the processor that makes the jth write reads its own value. Under the assumption of exponentially distributed read and write times, the X_j are independent. Letting

$X = \sum_{j=1}^{n} X_j$, we may use the standard Chernoff bound (see, for example, Corollary A.14 of [1])

$$\Pr(|X - E[X]| \geq \epsilon E[X]) \leq 2\mathrm{e}^{-\epsilon^2 E[X]/3}.$$

Hence, for any fixed r the probability of X deviating from the mean by more than $\epsilon E[X]$ falls inverse polynomially in n, proving the theorem. □

From Theorems 1 and 3 we immediately obtain as a corollary that two locks are significantly better than one, in terms of the number of processors that can get through (in the case of no pauses). Specifically, for a single lock with all times having the same mean, $\Theta(\sqrt{n})$ processors inspect the free lock before a write occurs with constant probability. Of these processors, with high probability $\Theta(\ln \sqrt{n}) = \Theta(\ln n)$ then read their own values and hence pass through the lock. For a double lock, from Theorem 3, with high probability $\mathrm{O}(\ln n)$ get through the first lock, and hence with high probability at most $\mathrm{O}(\ln \ln n)$ pass through the second. Note that changing the mean times for the I, W, or R operations (while keeping them constant) changes only these expressions by constant factors, and hence this remains true even if the average time to pass through the lock is the same in both scenarios. Hence, in the face of sufficiently large contention, double locks are much better with regard to the number of processors that pass through (on average, with no pauses).

2.4. How often does one pass through? Showing that on average fewer processors pass through a double lock than a long single lock does not really answer our question of which is better. The proper measure of performance is how often a lock successfully allows only one processor through. We now focus on this variable. First, we show that for a single lock with exponentially distributed read and write times (and no pause), a single lock can perform quite poorly under high contention.

THEOREM 4. *Consider a single lock with n processors beginning a write at the same time. The probability that just a single processor reads its own value is $O(\sqrt[r]{1/rn})$.*

Proof. We begin with the case $r = 1$. Recall from Theorem 3 that the jth processor to write reads its own value with probability $1/(r(n-j)+1)$ and that all such events can be treated as independent. Clearly, the last processor to write will read its own value. The probability that it is the only one to do so is

$$\left(1 - \frac{1}{2}\right)\left(1 - \frac{1}{3}\right)\cdots\left(1 - \frac{1}{n}\right) = \frac{1}{2}\frac{2}{3}\cdots\frac{n-1}{n} = \frac{1}{n}.$$

Thus, when $r = 1$, the probability that only one processor believes it obtains the lock is $1/n$. For a general r, this probability is

$$\begin{aligned}\prod_{j=1}^{n-1}\left(1 - \frac{1}{r(n-j)+1}\right) &\leq \prod_{i=1}^{n-1}\mathrm{e}^{-1/(r(n-i)+1)} \\ &= \mathrm{e}^{-\sum_{i=1}^{n-1} 1/(r(n-i)+1)} \\ &\leq \mathrm{e}^{-1-(\ln(rn)+1)/r},\end{aligned}$$

and the last term is $O(\sqrt[r]{1/rn})$. □

The result of Theorem 4 demonstrates how the probability of success increases with r and decreases with n. Although increasing r substantially increases the probability of just one processor successfully obtaining the lock, as n grows large, for any fixed r this probability falls to 0.

We now consider the probability of exactly one processor taking control of a double lock. Under a reasonable assumption, we find that in this case, the probability that a single processor obtains the lock is bounded below by a constant, *regardless of how n grows.* This result is somewhat surprising, given the previous result for a single lock.

In this setting, we adopt the following assumption: once a processor passes through the second lock, it will hold that lock for a reasonably long amount of time. Hence, if one processor writes to the second lock before any others read it, we assume that this processor does not clear the second lock until well after all others read that it has possession. This assumption simplifies the problem, as now we need to consider only the problem of whether one processor writes to the second lock before any others read it. It is also reasonable, since a lock is held long enough so that the critical region can be executed.

THEOREM 5. *Let n processors begin a write for a first lock of a double lock at the same time. Then with probability bounded below by some constant, one processor writes to obtain the second lock before any other processors successfully pass through the first lock.*

Proof. The intuition behind the theorem is relatively simple. With some constant probability, one lucky processor passes through the first lock quickly. It then writes to obtain the second lock before any other lucky processors can pass through the first lock. We now formalize this intuition. We first consider the case where $i = r = w = 1$ for convenience. Also, we assume all relevant quantities are integers and avoid floor and ceiling notation for convenience as well.

The jth processor to write passes through the first lock with probability $\frac{1}{n-j+1}$. Hence the probability that none of the first $n/2$ processors passes through the first lock is

$$\prod_{j=1}^{n/2}\left(1-\frac{1}{n-j+1}\right)=\frac{n-1}{n}\frac{n-2}{n-1}\cdots\frac{n/2}{n/2+1}=\frac{1}{2}.$$

Similarly, the probability that exactly one of the first $n/2$ processors passes through the first lock is

$$\sum_{j=1}^{n/2}\left[\frac{\frac{1}{n-j+1}}{1-\frac{1}{n-j+1}}\prod_{k=1}^{n/2}\left(1-\frac{1}{n-k+1}\right)\right]=\frac{1}{2}\sum_{j=1}^{n/2}\frac{1}{n-j}\geq\frac{\ln 2}{2}-o(1).$$

Now suppose exactly one processor from the first $n/2$ passes through the first lock; let it be the jth to write. We now lower bound the probability this processor writes to obtain the second lock before any other processor passes through the first lock. To do so, this processor must complete both an I and W operation. Since all operation times are exponential, with constant probability both these operations complete before the $(7n/8)$th processor completes its write to the first lock. This is clear since with probability 1/2, the I operation occurs before 1/2 of the remaining $n-j$ writes to the first lock. Assuming this happens, with probability 1/2 again, the second W operation completes before 1/2 the remaining writes to the first lock. Hence, with the probability 1/4, the jth processor finishes the I and W operation for the second lock by the time processor $j+(n-j)/2+(1/2)(n-(j+(n-j)/2))$ writes to the first lock. Since $j \leq n/2$, we have that with constant probability the jth processor finishes the I and W operation for the second lock by the time the $(7n/8)$th

processor writes to the first lock. Now, however, by the same argument as previously, the probability that no processors from the $(n/2)$nd to the $(7n/8)$th finish their first write and pass through to the second lock is

$$\prod_{i=n/2+1}^{7n/8}\left(1-\frac{1}{n-i+1}\right)=\frac{1}{4}.$$

Because of the memorylessness of the exponential distribution, all of these events can be treated as independent, and hence with probability bounded below by some constant a single processor successfully writes to the second lock as in the statement of the theorem.

When r and i are fixed constants other than 1, the same argument suffices; various constants in the argument must be changed to reflect the change in r and i. We sketch the required changes. The jth processor passes through the first lock with probability $\frac{1}{1+r(n-j)}$. Hence, the probability that none of the first $n/2$ processors passes through the first lock is

$$\prod_{j=1}^{n/2}\left(1-\frac{1}{r(n-j)+1}\right).$$

We may bound this by noting $1-x\geq \mathrm{e}^{-x-x^2}$ for $0\leq x\leq 1/2$. Hence,

$$\begin{aligned}\prod_{j=1}^{n/2}\left(1-\frac{1}{r(n-j)+1}\right)&\leq\prod_{j=1}^{n/2}\mathrm{e}^{-1/(r(n-j)+1)-1/(r(n-j)+1)^2}\\&=\mathrm{e}^{\sum_{j=1}^{n/2}-1/r(n-j)}(1-o(1))\\&=\mathrm{e}^{-(H(n-1)-H(n/2))/r}(1-o(1))\\&=2^{-1/r}(1-o(1)).\end{aligned}$$

Similarly, the probability that exactly one such processor passes through the first lock is

$$\begin{aligned}\sum_{j=1}^{n/2}\left[\frac{\frac{1}{r(n-j)+1}}{1-\frac{1}{r(n-j)+1}}\prod_{k=1}^{n/2}\left(1-\frac{1}{r(n-k)+1}\right)\right]&=2^{-1/r}\sum_{j=1}^{n/2}\frac{1}{r(n-j)}(1-o(1))\\&=\frac{2^{-1/r}\ln 2}{r}(1-o(1)).\end{aligned}$$

Now suppose exactly one processor passes through the first lock. For this processor to write to obtain the second lock before any other processor passes through the first lock, it must complete both an I and W operation. Since all operation times are exponential, with constant probability both these operations complete before the (αn)th processor completes its write for some constant α depending on i. However, the probability that no processors from the $(n/2)$nd to the (αn)th finish their first write and pass through to the second lock is

$$\prod_{j=n/2+1}^{\alpha n}\left(1-\frac{1}{r(n-j)+1}\right),$$

which can be bounded above and below by some constant independent of n. Hence, again with probability bounded below by some constant, a single processor successfully writes to the second lock as in the statement of the theorem. □

The rather loose analysis of Theorem 5 greatly underestimates the probability that a single processor successfully writes to the second lock before all others. The true probabilities are best determined by simulations, and hence we return to this question in section 5.

We also note that another way to gain better insight into the exact probability that a single processor successfully passes through the double lock is to consider the underlying Markov chain. For instance, this chain can easily be represented as a six-dimensional Markov chain, where each dimension tracks the number of processors in each state. Examining this Markov chain could lead to provable bounds on various probabilities associated with the lock's behavior. Of course, a complete analysis of this complex chain appears rather difficult. We therefore feel that our intuitive proof, combined with simulation results, is a natural approach to the problem.

Given that two locks have a different behavior than one, one might naturally ask whether three (or more) locks have a different behavior than two. Using induction and the above results one can show that using $2k$ consecutive locks, the probability of more than one processor successively passing through is at most γ^k for some constant γ. Could the behavior be even better than exponentially decreasing? We show that the answer to this question is negative by considering the limiting case where just two processors start together at the first lock.

THEOREM 6. *Consider two processors starting at a sequence of k locks. Then the probability that both processors pass through the final lock is at least β^k for some constant β depending on i, w, and r.*

Proof. We first show that the probability that two processors "follow each other" through the lock is a constant. That is, consider the following sequence of events:

1. Both processors inspect the lock before either writes.
2. The first processor to complete a write to the lock reads back its value before the other processor completes its write to the lock.
3. The second processor to complete a write to the lock reads back its value before the other processor inspects the subsequent lock.

If these events occur, because of the memorylessness property of the exponential distribution, the two processors are then in a similar state as though they had both just begun competing for the subsequent lock. It is clear that the intersection of these events hold with constant probability. In fact, by the fairness property and the memorylessness property, we can calculate that all of these events occur with probability β, where

$$\beta = \frac{w}{i+w}\frac{w}{r+w}\frac{i}{i+w}\frac{i}{i+r}.$$

By induction, the probability of both processors passing together through k consecutive locks is at least β^k. □

Thus, for any number of successive locks in this setting, the best one can hope for is a failure probability that decreases exponentially in the number of locks.

3. The gamma distribution. While the previous section, in which we considered exponential random variables, showed that a double lock is better than a single lock, the results must of course be taken in context. Since we know that in the case where all times are deterministic (and, for example, all operations require the same

time) that a single lock is sufficient, it becomes interesting to consider how strongly this behavior depends on the underlying distribution. We offer some insight into this problem by considering the *gamma distribution*. Recall that a gamma distribution is the sum of a number of independent exponential random variables (of the same mean). For example, a gamma(2) distributed random variable with mean 1 is the sum of two exponential random variables, each with mean 1/2.

We show that for a gamma(2) distribution, the probability that only a single processor obtains a single lock is bounded below by a constant independent of n, the number of processors contending for the lock. Hence, in this case, a single lock behaves more like a double lock under the exponential distribution.

The intuition behind this performance is as follows. Consider the case where n processors are initiating the write stage for the lock at the same time. We may think of the write phase for a processor as consisting of two subphases, each corresponding to an exponentially distributed amount of time. Let us say that a processor is *half-done* with the write stage if it has completed its first subphase, *done* or *completed* if its write is fully complete, and *unstarted* if it is not yet even half-done. Before the first processor to complete a write finishes the write, several processors will be half-done. The number of processors half-done with their write are very likely to prevent this first processor from reading its value, for it is very likely that one of these half-done processors will complete its write before this processor can finish its read. This situation, where half-done writes overwrite completed writes before the corresponding read finishes, is likely to occur until few processors remain to complete their writes. When there are few processors remaining, it is possible for a read to complete before the processor value is overwritten, but this happens only with constant probability.

We present the above argument more formally in the theorem below for the case where reads and writes execute with the same average time. For convenience, we take this mean to be 2.

THEOREM 7. *Consider n processors beginning the write for a single lock, where the times for writes and reads have independent gamma(2) distributions with mean 2. Then a single processor reads its own value with probability bounded below by some constant.*

Proof. We assume that n is sufficiently large throughout. We wish to show that only the last processor to write its value reads its own value with constant probability. The proof is divided into three parts, corresponding to the beginning, the middle, and the end of the process.

For the beginning, we wish to show that with constant probability, by the time the first write completes, with constant probability there are at least $6\sqrt{n}$ processors that are half-done. This will ensure that sufficiently many half-done processors are around to block the completion of any write for all but the end of the process. Consider the time until the first write completes. Let p_j be the probability that at least j processors are at least half-done by this point. By the same argument as Theorem 1, $p_1 = 1$ and $p_{j+1} = p_j \frac{n-j}{n}$. It is straightforward to use this recurrence in a manner similar to Theorem 1 to show that at least $6\sqrt{n}$ are half-done when the first write completes with constant probability. (Note that, if we wished to bound this probability, we might do better to consider explicitly the behavior of the process until the first few writes complete; however, for our purposes the above is sufficient.)

For the middle, we show that with constant probability, conditioned on the fact that at least $6\sqrt{n}$ half-done processors exist at the time the first write completes, there are always many half-done processors until the very end of the process. Explicitly,

we claim that with constant probability there are always at least $2\sqrt{n}$ processors half-done with their writes as long as there are at least $10\sqrt{n}$ unstarted processors. This is easily seen by making a stochastic comparison with the number of half-done processors and a simple random walk. When there are u unstarted processors and h half-done processors, the probability that h increases (and u decreases) is $\frac{u}{h+u}$, and the probability that h decreases (and u stays the same) is $\frac{h}{h+u}$. Moreover, because all distributions are exponential, each step is independent. In particular, when $u \geq 10\sqrt{n}$ and $h < 10\sqrt{n}$, the number of half-done processors h is biased upwards.

Now consider an unbiased random walk that starts at $6\sqrt{n}$ with boundaries at $2\sqrt{n}$ and $10\sqrt{n}$ that runs for $2n$ steps. We claim that it is more likely that h is at least $2\sqrt{n}$ until there are $10\sqrt{n}$ unstarted processors than that this unbiased random walk reaches the boundary $2\sqrt{n}$. This follows from a standard stochastic domination argument; the value h also begins at $6\sqrt{n}$, it changes less than $2n$ times, and it is always more likely to increase than the unbiased random walk. Standard results in probability theory now yield that the random walk (and hence h) stays above $2\sqrt{n}$ with constant probability.

This is most easily seen by noting that for the walk to reach $2\sqrt{n}$, it must fall $2\sqrt{n}$ in either the first n or the last n steps. Let $X_i = 1$ if a walk of n steps goes up on the ith step, and let $X_i = -1$ if it goes down on the ith step. Then from Theorem A.1 of [1], which is derived in a manner similar to Chernoff bounds, the probability that $\sum_{i=1}^{n} X_i \leq 2\sqrt{n}$ is at most e^{-2}. By a union bound, the probability that the walk falls $2\sqrt{n}$ in either the first n or the last n steps is at most $2\mathrm{e}^{-2}$.

Now, conditioned on all of the above, up to the point where there are $10\sqrt{n}$ unstarted processors, with constant probability no processor will read its own value. For to do so, any such processor must complete two read phases before any of the half-done writes complete. In each case the probability of doing so is $(\frac{1}{2\sqrt{n}})^2 = \frac{1}{4n}$, and hence by the union bound with probability at least $\frac{3}{4}$ no processor to this point reads its own value.

We clarify that this statement follows using conditional probabilities, not a union bound. That is, we define the following: let A be the event that $6\sqrt{n}$ processes are half-done when the first write completes. Let B be the event that at least $2\sqrt{n}$ processes are half-done as long as there are at least $10\sqrt{n}$ unstarted processes. Let C be the event that, up to the point where there are $10\sqrt{n}$ unstarted processes, no processor reads its own value. Then

$$\Pr(C) \geq \Pr(C|B) \cdot \Pr(B|A) \cdot \Pr(A),$$

and we have shown that all of the above on the right-hand side are constants.

We now need to consider the end of the process. To see what happens toward the end of the process, consider what would happen if the system began with all processors half-done with their writes. The jth processor to complete its write would then successfully read its own value if it completed two read phases before any of the half-done writes completed, which occurs with probability $(\frac{1}{n-j+1})^2$. Hence, the probability that any processor other than the last to write would read its own value would be at most $\sum_{j=1}^{n-1}(\frac{1}{n-j+1})^2 < \frac{6}{\pi^2}$. (We elaborate on this in Theorem 8.)

In the actual process, we have already seen that all behaves well up to the point when there are $10\sqrt{n}$ unstarted processors. After this point, we claim the system behaves similarly to one where all remaining processors begin half-done with their writes. Specifically, we show that at the last point in time when there are k processors left unstarted, there are at least $k \log n/2$ processors left with probability $1 - o(1)$ for

all k from 1 to $10\sqrt{n}$. This implies that at the end of the process, we always have that most processors are half-done, which will suffice.

Let us consider the specific case where $k = 1$. The probability that the $(n-j)$th processor to become half-done has not yet completed at the first time when there is one processor left unstarted is just $1/(j+1)$. Hence, the expected number of half-done processors at the point where there is just one unstarted processor is approximately $H(n) \approx \log n$. Moreover, the events (that the jth processor to become half-done has not yet completed) are independent, so we may apply Chernoff bounds. Hence, we find the probability that there are not at least $\log n/2$ half-done processors is at most $1/n^{1/16}$.

We may attack larger k similarly. The probability that the $(n-j)$th processor to become half-done has not yet completed while there are k processors left unstarted is just $k/(j+1)$. Hence, the expected number of half-done processors at the point where there are k unstarted processors is approximately $k(H(n) - H(k)) \approx k \log(n/k)$. For $k \leq \log n$, a Chernoff bounds yields that the probability that there are not at least $k \log(n/k)/2$ half-done processors is at most $1/n^{1/16}$. For $\log n \leq k \leq 10\sqrt{n}$, Chernoff bounds yield that the probability that there are not at least $k \log(n/k)/2$ half-done processors is at most $n^{-\log n/8}$. Using a union bound, we find that, for all k from 1 to $10\sqrt{n}$, at the last point in time when there are k process left unstarted, there are at least $k \log(n/k)/2$ half-done processors left with probability $1 - o(1)$.

Let us temporarily assume that this is the case. Let $u(j)$ be the number of unstarted processors when the jth processor to write completes its write. Then the probability that the jth processor to write reads its own value is at most

$$\left(\frac{1}{n-j-u(j)+1}\right)^2.$$

We are interested only in the situation when $u(j) \leq 10\sqrt{n}$. Hence, the probability that some processor reads its own value when $u(j) \leq 10\sqrt{n}$ is bounded above by

$$\sum_{j=1}^{n-1} \left(\frac{1}{n-j-\min(10\sqrt{n}, u(j))+1}\right)^2.$$

Note that summing to $n-1$ is clearly overcounting. Also, with high probability, for $j = n - \log n/2$ to $n-1$ the value of $u(j)$ is 0. It follows that with high probability the above sum is just

$$\sum_{j=1}^{n-1} \left(\frac{1}{n-j+1}\right)^2 + o(1) < \frac{6}{\pi^2} + o(1),$$

where the $o(1)$ term corrects for the $\min(10\sqrt{n}, u(j))$ term.

To show that this suffices, let D be the event that, from the point where there are $10\sqrt{n}$ unstarted processes, no processor except the last reads its own value. Let E be the event that for all k from 1 to $10\sqrt{n}$, when there are k processors left unstarted, there are at least $k \log(n/k)/2$ processors left. Finally, let S be the successful event that no processor except the last reads its own value.

Then

$$\Pr(S) = \Pr(D \wedge C) \geq \Pr(D \wedge C \wedge E) = \Pr(D|C \wedge E) \cdot \Pr(C \wedge E).$$

The argument regarding the end of the process shows that $\Pr(D|C \wedge E)$ is bounded below by a constant. Also, $\Pr(C \wedge E)$ is bounded below by a constant, since $\Pr(C)$ is and $\Pr(E)$ is $1 - o(1)$. Hence, $\Pr(S)$ is bounded below by a constant and the theorem is proven.

To summarize, we find that in the very beginning no processors pass through the lock with high probability, and several processors become half-done with their writes. Conditioned on this, with constant probability the number of processors half-done with their writes remains high, and hence no processors pass through the lock in the middle. Finally, at the end, with high probability we are always in a state where "almost all" of the processors are half-done. By combining all of the conditioning appropriately, we find that no processor except the last passes through the lock at the end with probability bounded below by a constant. □

The proof of Theorem 7 is somewhat limiting, in that the read and write times are taken to be equal, and in practice one may desire a different initial state, such as when all processors start at the inspect phase. It appears that the theorem above should hold for more general cases; however, writing an appropriate generalization appears difficult. Finding a more elementary proof therefore remains an interesting question.

Theorem 7 has an interesting implication. Because a gamma(2) distribution is just the sum of two exponential distributions, we could easily turn a setting with exponentially distributed read and write times into one with gamma(2) distributed read and write times. Each read and write operation would simply be preceded by a "dummy" read or write operation. If the operations are uncorrelated, this effectively changes the distributions from exponential to gamma(2). Although this doubles the average time to obtain a lock, it changes the probability that a single processor successfully accesses the lock from a diminishing function of the number of processors n to something bounded below by a constant.

In fact, the dummy read or write operations are equivalent to a pause operation, where a pause takes a random amount of time. In Fischer's algorithm, only the read and not the write operation is delayed in this manner. It is therefore natural to now consider the case of Fischer's algorithm, where all operation times are exponential and there is a pause before the final read.

THEOREM 8. *Consider n processors beginning the write for a single lock, where writes and reads have independent exponential distributions with mean* 1, *and there is a pause before each final read of time that is also independent and exponentially distributed with mean* 1. *Then a single processor reads its own value with probability* $\frac{n+1}{2n}$.

Proof. For the jth processor to complete its write to read its own value, the corresponding pause and read operation must occur before any other writes occur. This happens with probability $(\frac{1}{n-j+1})^2$. Hence, all but the last processor to write fail to pass through the lock with probability

$$\begin{aligned}\prod_{j=2}^{n}\left(1-\frac{1}{j^2}\right) &= \prod_{j=2}^{n}\frac{j^2-1}{j^2}\\ &= \frac{\prod_{j=2}^{n}(j-1)\prod_{j=2}^{n}(j+1)}{\prod_{j=2}^{n}j\prod_{j=2}^{n}j}\\ &= \frac{n+1}{2n}.\end{aligned}$$

□

Theorem 8 demonstrates the importance of the pause operation in the context of Fischer's algorithm in the case of exponentially distributed operation times. The pause leads to a completely different type of behavior, avoiding conflict in the critical region over half of the time.

It is worth noting also that the approach to lower bound the failure probability for multiple locks from Theorem 6 can be extended to the case where operation times have the gamma distribution as well. Again, we just imagine two processors following each other through the proper stages and use the properties of the exponential distributions. Hence, the best we could hope for is a failure probability that decreases exponentially with the number of sequential locks.

4. Two protocols. We now apply some of the previous results in considering the performance of two mutual exclusion algorithms first suggested by Lynch and Shavit [12]. Both provide mutual exclusion and weak deadlock-freedom.

The first protocol we consider, given in Figure 4, is the combined Fischer–Lamport algorithm presented as Algorithm 3 in [12]. It uses two registers. We also consider an algorithm using three registers also discussed in [12] that is obtained by directly replacing the critical region of Fischer's algorithm with a Lamport style algorithm for mutual exclusion, as shown in Figure 5.

The scheme using three registers (FL2) behaves similarly to a double lock. The first lock is represented by the x register, and the second "lock" consists of both the y and z registers. Hence, with exponential service times, even without a pause, we would expect a constant probability for some processor to successfully execute the critical region on each trial. The logic is the same as that of Theorem 5; one fortunate early processor passes through the lock represented by register x and then reaches the critical region before another processor can block it.

The scheme using two registers behaves essentially like a single lock on the register x with the additional register y to ensure that only a single processor enters the critical region. It follows immediately from Theorem 8 that if the operation times are independently and exponentially distributed (including the pause), then a single

FIG. 5. *A direct Fischer–Lamport combination.*

processor passes through the x lock and hence successfully executes the critical region with probability bounded below by some constant. Similarly, it is easy to show that the probability of a processor obtaining the critical region goes to 0 as the number of processors increases when the pause is removed. We formalize this explicitly.

THEOREM 9. *Consider n processors beginning at L in the algorithm FL*1 *of Figure* 4. *If writes and reads have independent exponential distributions with mean* 1, *and the pause takes time* 0 *(i.e., no pause), then the probability that any processor enters the critical region is $o(1)$.*

Proof. As usual, we assume that n is sufficiently large throughout. First, we note that with high probability $(1-o(1))$, at least $\Omega(\sqrt[3]{n})$ of the n processors starting at L reach the write step, as can be seen using the argument of Theorem 1 with $z = n^{1/3}$. We may therefore assume that we begin with $m = \Omega(\sqrt[3]{n})$ processors at the write stage.

We derive two bounds. The first shows that processors that complete the write to x early are unlikely to reach the critical region, and the second shows that processors that complete the write to x late are unlikely to reach the critical region.

The jth processor to write its own value in register x must read back its value, read register y, write register y, and read its own value again before any other processor writes to register x to obtain the critical region. By now familiar reasoning, the probability of all of these events occurring is $1/(m-j+1)^4$. By the union bound, the probability that any of first $m - m^{1/3}$ processors that write to register x read back its own value is

$$\sum_{j=1}^{m-m^{1/3}} \frac{1}{(m-j+1)^4} = o(1).$$

For the second bound, we consider the final $m^{1/3}$ processors that write their values into register x. Note that the jth processor to write its own value in register x can

reach the critical region only if no processor writes the value 1 on register y before this processor can read the register y. Consider the first $m - 5m^{1/3}$ processors. We claim that with probability $1 - o(1)$, one of these processors writes a 1 on register y before any of the final $m^{1/3}$ processors to write into register x reads register y.

By the same argument as Theorem 4, the probability that none of the first $m - 5m^{1/3}$ reads back its value from register x and proceeds to write to register y is

$$\left(1 - \frac{1}{(5m^{1/3}+1)}\right) \cdots \left(1 - \frac{1}{m}\right) = \frac{1}{5m^{1/3}} = o(1).$$

Hence, with probability $1-o(1)$ at least one processor attempts a write to y. Consider any such processor. For it to fail to write before the $(m - m^{1/3})$rd write to x, either y must have already been written over with a 1 (in which case we are done), or one the following events must occur:

- the read of y must occur after the $(m - 3m^{1/3})$rd write to x;
- the read of y occurs before the $(m - 3m^{1/3})$rd write to x and the write to y occurs after the $(m - m^{1/3})$rd write to x.

Since all operation times have the same mean, the probability of the first event is at most $1/2m^{1/3}$, and the probability of the second event is at most $1/2m^{1/3}$. By a union bound, the probability y still holds the value 0, for any of the last $(m - m^{1/3})$ writes is thus only $o(1)$.

Hence, considering both cases, a processor successfully enters the critical region with probability only $o(1)$. □

We note that we have not attempted to optimize the bounds of Theorem 9. A tight analysis would be interesting.

5. Simulations. In this section, we present the results of simulations of locks and double locks with varying service times, as well as examine the performance of some mutual exclusion algorithms that use locklike structures. The goal of this section is to demonstrate that our previous theorems accurately describe perceived performance, as well as gain more insight into the actual performance of mutual exclusion algorithms under these distributions.

We simulated single and double locks using operation times with an exponential distribution, a gamma(2) distribution, and a gamma(3) distribution. For the double lock, all operations have the same mean time, which we scale to be 1. For the single lock, we have simulated two cases: one where all operations have the same mean time, and one where the final read operation has mean 4, so that the total average time for a lock to try a processor is the same as that for a double lock. We call this a *long lock*. Each data point represents the fraction of 10,000 trials for which a single processor successfully passed through the lock.

The results are presented in Figure 6. We point out some features of interest. As expected, we find that a double lock dramatically outperforms a single lock in the case of the exponential distribution. Moreover, the poor performance of a single lock as the contention grows is clear. For the gamma distributions, however, the single lock performance does not deteriorate with contention, as expected. With a gamma(3) distribution, a single long lock outperforms a double lock.

Interestingly, the behavior as the number of processors increases is different for the three distributions. For the exponential distribution, the probability of success appears to decrease monotonically in the number of processors, while for the gamma(3) distribution the probability appears to increase monotonically in the number of processors. Meanwhile, for the gamma(2) distribution, the probability is nonmonotonic

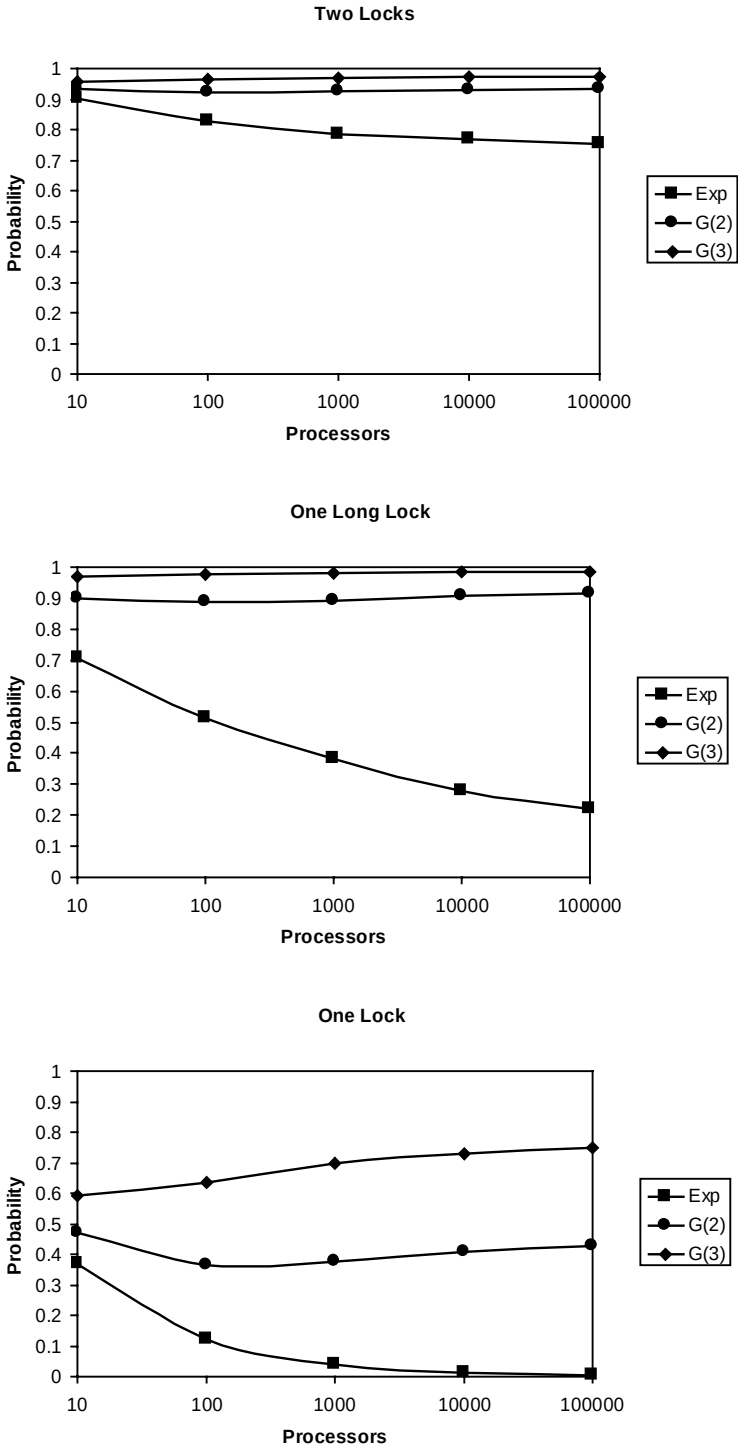

FIG. 6. *Comparing the behavior of a single lock and a double lock.*

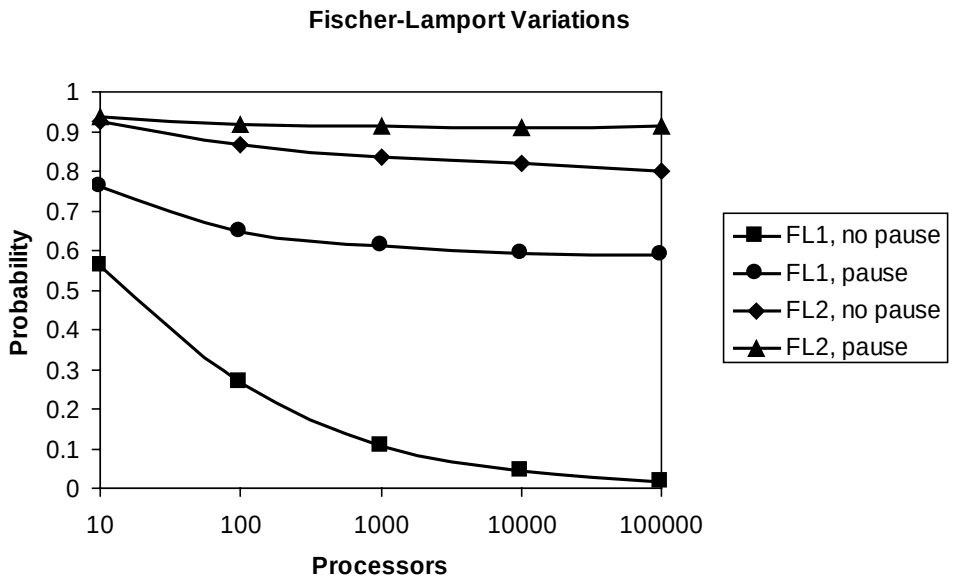

FIG. 7. *Comparing combined mutual exclusion algorithms.*

in the number of processors. This behavior may be worthy of future study, if only as a mathematical curiosity.

We also present some results for the mutual exclusion algorithms of section 4 in Figure 7. For these results, the distribution of the time for all operations is taken to be exponential with mean 1.

Note the dramatic effect of the pause in the performance of FL1. This is not surprising, given the analysis of section 4. Also, note that with the pause the FL1 algorithm succeeds a little more than 1/2 of the time. A rough approximation of this behavior is derivable from Theorem 8. Slightly over 1/2 of the time, a single processor will pass through the first lock. When multiple processors pass through the first lock, sometimes one will reach the critical region before any other processor can block it; this accounts for the additional probability of success. The mutual exclusion algorithm FL2 performs better, but of course it uses an extra register, and on average more time, since more reads and writes are performed by each processor. Tighter analyses or exhaustive simulations of the behavior of these algorithms might lead to a better comparison. It seems difficult to develop a more general statement as to which algorithm is preferable, as the decision may simply depend on the underlying timing distributions.

6. Conclusions and open questions. We have examined the behavior of timed locks under simple distributions, including exponential and gamma distributions, using both theoretical analysis and simulations. In particular, we have focused on the question of whether two locks are better than one and shown how it may depend on the distribution of the completion time of operations. We have also considered how this affects the design of mutual exclusion algorithms. Our work represents the first step toward designing a mutual exclusion algorithm based on random times that offers better performance in realistic situations than algorithms designed for the worst case.

We believe there are several ways to extend this work. A better understanding of the Markov chains underlying double or more extensive sequences of locks would

be interesting. For example, it would be appealing to determine with some accuracy the probability that only one processor passes through a double lock (even if only in the limiting case) by analyzing the underlying Markov chain in a more careful manner. Also, it would be worthwhile to understand the behavior of timed locks under more general distributions. In particular, truncated distributions where events occur within some bounded period of time may provide a more realistic description of actual behavior. Situations where the read and write times are somehow correlated may also be more realistic.

A CHARACTERIZATION OF EVENTUAL BYZANTINE AGREEMENT*

JOSEPH Y. HALPERN†, YORAM MOSES‡, AND ORLI WAARTS§

Abstract. We investigate eventual Byzantine agreement (EBA) in the crash and omission failure modes. The emphasis is on characterizing optimal EBA protocols in terms of the states of knowledge required by the processors in order to attain EBA. It is well known that common knowledge among the nonfaulty processors is a necessary and sufficient condition for attaining *simultaneous* Byzantine agreement (SBA). We define a new variant that we call *continual* common knowledge and use it to provide necessary and sufficient conditions for attaining EBA. Using this characterization, we provide a technique that allows us to start with any EBA protocol and convert it to an optimal EBA protocol using a two-step process.

Key words. fault-tolerance, eventual Byzantine agreement, common knowledge, continual common knowledge, optimal protocol

1. Introduction.

In a distributed system, it is important to be able to design protocols that attain their goals despite the presence of unreliable components. The essence of the difficulties in doing this is captured by the well-studied problem of *Byzantine agreement* (BA), first introduced in [17]. Roughly speaking, a BA protocol provides a means for n processors, at most t of which may be faulty, to agree on a value in such a way that all nonfaulty processors decide on the same value, and when all processors start with the same initial value, the nonfaulty processors decide on this value. The version of the problem formulated in [17] did not require all processors to decide on the value simultaneously, yet the algorithms given in [17] (and many later papers) had the property that the processors did indeed decide simultaneously. In [3], it was pointed out that requiring simultaneous agreement could significantly affect the problem. Since then, both simultaneous Byzantine agreement (SBA), where processors are required to decide simultaneously, and eventual Byzantine agreement (EBA), where they are not, have received a great deal of attention.

We will be particularly interested here in the problem of reaching EBA as quickly as possible. The number of rounds it takes for a protocol to reach a decision depends in general on the pattern of failures, that is, on how and when failures occur. Thus, roughly speaking, we say that protocol P_1 *dominates* protocol P_2 if every nonfaulty

processor in a run of P_1 decides at least as soon as it does in the *corresponding* run of P_2 (where two runs are said to correspond if the initial values of all processors and the pattern of failures are the same in both); we say that P_1 *strictly dominates* P_2 if it dominates P_2 and in some run of P_1 at least one nonfaulty processor decides earlier than it does in the corresponding run of P_2. A protocol is *optimal* if it is not strictly dominated by another protocol; an *optimum* protocol is one that dominates every other protocol.

Optimum protocols are given for SBA in the case of *crash failures* [5], where a processor that is faulty sends no messages after it has failed, and in the case of the more general *(sending) omission* failures [14], where a processor may continue to send messages after it has failed. The construction of these protocols, as well as the analysis of their optimality, is done in terms of reasoning about knowledge [8, 6]. The key observation is that simultaneous actions are intimately related to *common knowledge*: it can be shown that a necessary and sufficient condition for optimal SBA is that the nonfaulty processors decide once they have common knowledge of a particular initial value.

By definition of EBA, different processors have the freedom to decide at different times. This freedom makes it possible to construct EBA protocols that typically decide much faster than SBA protocols [3]; it is also the cause of a number of subtle, but significant, differences between SBA and EBA. In particular (as already pointed out in [14]), although there are *optimal* protocols for EBA there are no *optimum* protocols for EBA.

Our goal here is to better understand the structure of EBA protocols and, in particular, optimal EBA protocols. A decision is made in an optimum SBA protocol as soon as common knowledge of some initial value is attained. This suggests that in an optimal EBA protocol, a decision should be made when some variant of common knowledge of an initial value is attained. A number of variants of common knowledge are discussed in [8]. Perhaps the most plausible candidate is *eventual* common knowledge. A fact φ is common knowledge if everyone knows that everyone knows that everyone knows ... φ; similarly, φ is eventual common knowledge essentially if eventually everyone will know that eventually everyone will know ... φ. However, a closer inspection shows that eventual common knowledge is an insufficient basis for decision in EBA. Specifically, it is not safe for a processor to decide as soon as it knows that some initial value is eventual common knowledge. For example, consider a protocol where a processor decides on the value v ($v \in \{0, 1\}$) once it knows that there is eventual common knowledge that someone started with initial value v. It is quite possible that at some point, processor i knows that there is eventual common knowledge that some initial value was 0 and does not know that there is eventual common knowledge that some initial value was 1, while processor j knows that there is eventual common knowledge that some initial value was 1 and does not know that there is eventual common knowledge that some initial value was 0. Thus, the obvious decision rule based on eventual common knowledge leads to inconsistency. (Note that, by way of contrast, with common knowledge it is the case that if one processor has common knowledge of φ, then all the processors do, so it is possible to define a consistent decision rule using common knowledge, for example, deciding on 0 if it is common knowledge that some initial value was 0 and deciding on 1 if it is common knowledge that some initial value was 1 and it is not common knowledge that some initial value was 0.)

One way to deal with the inconsistency described above is to require a processor

to decide 0 when it knows that there is eventual common knowledge that some initial value was 0 but to decide 1 only when it knows that there will *never* be eventual common knowledge that some initial value was 0. Although this state of knowledge is indeed sufficient for consistency, it does not guarantee optimality. That is, this protocol can be modified so that processors will be able to decide 1 earlier while still preserving consistency.

What is needed here is some condition that says "decide 1 as long as you are sure that everybody that ever knows there is eventual common knowledge that some initial value was 0 also knows (at the same time) that there is eventual common knowledge that some initial value was 1 and hence can decide 1." It turns out that in order to capture this type of condition, we need a new variant of common knowledge that we call *continual common knowledge*. Roughly speaking, a fact φ is continual common knowledge if throughout the run everyone knows that throughout the run everyone knows that ... φ.

We show that continual common knowledge plays a role in EBA that is somewhat analogous to that played by common knowledge in SBA. In particular, we can characterize the state of knowledge needed to attain EBA in terms of continual common knowledge, although it turns out that the precise characterization is more complicated than that of SBA. Using our characterization, we are also able to characterize optimal EBA protocols. Moreover, we provide a general technique for converting *any* EBA protocol P to an optimal EBA protocol P' dominating P. All of the analysis and the conversion is done at the knowledge level by working with high-level protocols with tests for knowledge.

This paper is organized as follows. In the next section we present our formal model of protocols and review the basic definitions of BA. In section 3, we review the knowledge formalism and introduce the notion of continual common knowledge. In section 4 we show that continual common knowledge is both a necessary and sufficient state of knowledge for an agreement protocol. We use these results in section 5 to characterize optimal knowledge-based protocols for EBA and then use our characterization to show how we can construct optimal EBA protocols, starting with arbitrary EBA protocols. Section 6 uses the technique described in section 5 to construct examples of optimal protocols, including a polynomial time optimal EBA protocol for the case of crash failures. We conclude with some discussion in section 7.

2. BA and full-information protocols. In this section, we review the BA problem, define the notion of optimality we are interested in, present our formal model of protocols, and show that, if optimality is our only concern, we can restrict attention to special protocols known as *full-information protocols*.

2.1. The BA problem. Suppose we are given a system with n processors, at most t of which might be faulty. Each processor i has an initial value $v_i \in V$. A *BA protocol* is one that satisfies the following properties:

1. *Decision.* Every nonfaulty processor i eventually decides (irreversibly) on a value $y_i \in V$.
2. *Consistency.* All nonfaulty processors decide on the same value.
3. *Validity.* If a nonfaulty processor decides v, then v must be the initial value of some processor.

The problem as stated above is actually EBA. In order to define SBA, we need to add one more condition:

4. *Simultaneity.* All the nonfaulty processors decide at the same round.

For simplicity, in this paper we focus on the case of *binary agreement*, where $V = \{0, 1\}$. Extending our methods to the case where $|V| > 2$ is straightforward.

It is well known that the BA problem is sensitive to the types of failures that might occur. We consider two basic failure modes in this paper:

1. *Crash failures.* A faulty processor behaves according to the protocol, except that it might commit a crash failure at an arbitrary round $k > 0$. If a processor commits a crash failure in round k (or simply *fails* in round k), then it obeys its protocol in all rounds preceding round k, it does not send any message in the rounds following k, and in round k it sends an arbitrary (not necessarily strict) subset of the messages it is required to send by its protocol.
2. *Omission failures.* A faulty processor behaves according to the protocol, except that it may omit sending an arbitrary set of message in any given round. (What we are calling "omission failures" here are what were termed *sending omission failures* in [14]; we do not consider *general omission failures* [18] here, where a processor may omit receiving a message as well as omitting to send one.)

We do not consider the more general *Byzantine failures*, where faulty processors may behave arbitrarily.

The first subtlety in comparing EBA and SBA already arises when we consider what we mean by a *nonfaulty* processor. Should we consider a processor that fails at some point in a run as faulty only after it has actually displayed faulty behavior, or should it be considered faulty throughout the run? In the case of SBA both interpretations work, while for EBA the distinction matters. Since all *nonfaulty* processors are required to decide consistently, if we choose the first interpretation, then a processor can decide on some value only when it is guaranteed that even if it fails after its decision, all nonfaulty processors will finally decide upon the same value. On the other hand, choosing the second interpretation enables the processor to decide on a value as long as it knows that, provided that it does not fail, all nonfaulty processors will decide on the same value. Clearly, in the crash or omission failure modes, when considering protocols in which the processors do not send any message after they decide, there is essentially no difference between these choices. Consequently, there is no difference between the choices in the case of SBA. However, there is a substantial difference in the case of EBA. For the purposes of this paper, we call a processor "nonfaulty" in a particular run only if it is nonfaulty throughout the run. This usage is consistent with the usual usage in other papers on EBA for crash and omission failures (see, e.g., [7, 11, 18]), although it differs somewhat from that of [5], where Dwork and Moses concentrate on the set of "active" processors, which can decrease over time.

Notice that in EBA we require all the nonfaulty processors to eventually decide on some value. It is occasionally useful to consider weaker notions. An *agreement protocol* is a protocol that satisfies the following two properties:

2′. *Weak consistency.* Nonfaulty processors do not decide on different values.

3′. *Weak validity.* If all initial values v_i are identical, then all nonfaulty processors that decide, decide v_i.

Note that an agreement protocol does not necessarily satisfy the decision property; a nonfaulty processor may not decide at all.

We discussed the notion of one protocol dominating another in the introduction; we will provide a formal definition of it in the next section. An *optimal protocol*

for EBA (SBA, agreement, etc.) is one that is not strictly dominated by any other protocol. An *optimum protocol* is one that dominates every other protocol. Although it is possible to find optimum protocols for SBA [5, 14], this is not the case for EBA. We give a proof here for the sake of completeness.

PROPOSITION 2.1 (see [14]). *There are no optimum EBA protocols.*

Proof. Consider a variant of an EBA protocol for the crash failure mode that was first introduced in [11]. When a processor first learns that some processor has an initial value of 0, it decides 0, relays 0 (i.e., sends 0 to all the other processors), and halts; if by time $t+1$ a processor does not know of any processors with initial value 0, it decides 1 and halts. It is easy to see that this protocol achieves EBA. Moreover, all nonfaulty processors with initial value 0 decide at time 0. Call this protocol $P0$. There is a symmetric protocol $P1$ where the roles of 0 and 1 are reversed. In $P1$, all nonfaulty processors with initial value 1 decide at time 0. An optimum EBA protocol would have to dominate both $P0$ and $P1$. Thus, in an optimum EBA protocol, all processors would have to decide at time 0. However, this is provably impossible [4]. □

This proof shows even more. Since it is well known [4] that in any EBA protocol there will always be some run in which some processor takes $t+1$ rounds to decide, it follows that given any EBA protocol P, there must be some run in which some processor takes at least $t+1$ rounds longer to decide than it does in one of $P0$ and $P1$. Thus, no protocol is guaranteed to even be close to optimum in all runs.

2.2. Optimal protocols: An example. We have just seen that there is no hope of obtaining optimum protocols for EBA. The existence of optimal protocols is, however, guaranteed. Intuitively, the reason is that there are a finite number of initial configurations of votes and a finite number of behaviors of faulty processors in the first k rounds for every finite k. An easy application of König's lemma thus shows that there must be a bound on the time at which all processors halt in all executions of any given EBA protocol. Thus, there cannot exist an infinite sequence $P_1, P_2, \ldots$ of correct EBA protocols where P_{i+1} strictly dominates P_i. It follows that if we start with an EBA protocol and repeatedly generate a strictly dominating protocol, then this process will terminate after a finite number of steps. Moreover, the last protocol in this process will be optimal.

One of the main results of this paper is an effective method of generating an optimal protocol dominating a given protocol. We now describe a simple optimal protocol in the crash failure mode that is generated in this way. Consider the protocol $P0$ defined in the proof of Proposition 2.1. In this protocol, processors decide 0 and send 0 to everyone else as soon as they learn that some processor had initial value 0. A processor that has not learned about a value of 0 by time $t+1$ decides 1 at time $t+1$. While this protocol is fairly efficient, it is not optimal.

Clearly, the fact that some processor had an initial value of 0 is propagated as fast as possible in this protocol. It follows that no correct EBA protocol can decide 0 any faster than $P0$ does because, by the specification of EBA, in order to decide 0, it is necessary that some processor started with an initial value of 0, and in $P0$, processors decide 0 as soon as they learn that some processor had an initial value of 0. How about deciding on 1? Here, it seems, the protocol $P0$ is not being as efficient as possible. For example, we know from the specification of EBA that if all initial values are 1, then a decision of 1 is forced. Obviously, in order to reach this decision as soon as possible in runs with no failures, a processor should notify the other processors in the first round about its having an initial value of 1 as well as about its having an

initial value of 0.

One way to get an optimal EBA protocol is to get a rule for deciding 1 as soon as possible without changing the rule used by $P0$ for deciding on 0. We now design a protocol with this property. The idea is that processors decide 1 as soon as they know that nobody is ever going to know that some processor had an initial value of 0. The protocol uses the same rule for deciding on 0 as $P0$. The rule for deciding on 1 is based on the observation that processor i knows that no nonfaulty processor will ever know that some processor had an initial value of 0 if either

(a) processor i knows that all initial values are 1 or
(b) every processor sends a message to all processors in every round telling them which initial values each processor has (as far as it knows), i hears from the same set of processors in two consecutive rounds, and i still does not know that some processor had an initial value of 0.

Thus, each processor i maintains a list of the initial values it knows about and sends this list to all other processors in every round. It decides 1 and communicates for one more round if one of the two properties above holds. We call this protocol $P0_{\text{opt}}$. It is easy to check that by time $t+1$, either processor i will learn that some processor had an initial value of 0, or one of the properties (a) or (b) above holds. $P0_{\text{opt}}$ thus dominates $P0$. Indeed, as we formally show in section 6, $P0_{\text{opt}}$ is an optimal EBA protocol for the crash failure mode. In fact, it is the unique optimal protocol dominating $P0$.

2.3. Protocols and systems. Up to now we have spoken informally of "protocols." We now give a more formal definition of the model and notions involved along the lines of [5, 14, 6]; the interested reader is referred to [6] for more detail.

We consider a synchronous distributed system consisting of a finite collection of $n \geq 2$ processors (automata) $\{i_1, \ldots, i_n\}$, each pair of which is connected by a two-way communication link. The processors share a global clock that starts out at time 0 and advances by increments of one. Communication in the system proceeds in a sequence of *rounds*, with round k taking place between time $k-1$ and time k. In each round, every processor first sends the messages it needs to send to other processors and then receives the messages that were sent to it by other processors in the same round. The identity of the sender and destination of each message, as well as the round in which it is sent, are assumed to be part of the message.

We think of the processors as following a *protocol*, which specifies the actions of each of the nonfaulty processors as a *deterministic* function of the processor's local state.[1]

A *run* of a protocol is a complete description of the system at each time step. This includes each processor's initial state the messages sent in every round, the decisions taken by the processors, and the behavior of the faulty processors. We assume that at every point in time each processor has a well-defined local state, which is recorded in the run and which the protocol uses to determine the actions that the processor takes. A *point* is a pair (r, k) consisting of a run r and a time k. We use $r_i(k)$ to denote processor i's local state at the point (r, k). For technical reasons, it is convenient to assume that communication happens during a round (that is, between two points (r, m) and $(r, m+1)$) but that a decision is actually made at a given point, not during the round. Thus, we talk about a message being sent in round k and a decision being

[1] As discussed in detail in [14], a protocol is typically stated in terms of parameters n and t, standing for the number of processors, and an upper bound on the number of failures. We do not represent this explicitly here, since this fact does not affect our results in this paper.

made at time k (of some run r). For simplicity, we assume that the only possible outputs (decisions) are 0 and 1, and that a processor can output at most one of these values at a given time. A *system* $\mathcal{R}$ is just a set of runs. We can associate with a protocol P the systems $\mathcal{R}_P^{cr}(n,t)$ for all $n \geq t \geq 0$, consisting of its possible runs with n processors in which no more than t processors crash. We similarly associate with P the analogous systems $\mathcal{R}_P^{om}(n,t)$ corresponding to the omissions failure model. We omit the parameters of n and t as the results are typically independent of these values. Similarly, for the most part, our results do not depend on whether we consider crash failures or omission failures. We omit the superscript and just write $\mathcal{R}_P$ whenever the type of failure is not relevant to the discussion.

As discussed in the previous section, we say that a processor is *nonfaulty* in a given run if it follows the protocol throughout the run. Since we are considering only crash and omission failures here, if i is a faulty processor in a run r, then its faulty behavior can be characterized by describing to which processes i omits sending required messages at each round. The *failure pattern* of a run contains the faulty behavior of all the processors that fail in the run. (A more detailed and formal exposition of the model can be found in [6, 14]; this brief exposition should suffice for stating and proving our results.)

The list of processors' initial states is the system's *initial configuration*. A protocol P, an initial configuration, and a failure pattern uniquely determine a run. Two runs r and r' of protocols P and P' are called *corresponding runs* if they have the same initial configuration and result from the same failure pattern. Two points (r,m) and (r',m') of protocols P and P' are *corresponding points* if r and r' are corresponding runs of the two protocols and $m = m'$. As we said in the introduction, given two protocols P and P', we say that P *dominates* P' if every nonfaulty processor that makes a decision (i.e., outputs 0 or 1 at some point in a run) in a run r' of P' also does so in the corresponding run r of P, and in fact decides at least as soon in r as it does in r'. We say P *strictly dominates* P' if P dominates P' and in some run r of P there is a nonfaulty processor that decides sooner in r than it does in the corresponding run of P'.

Notice that our definition of "dominate" focuses on when the processors decide and not when they halt. However, in all our protocols the processors can always halt after they know that all the nonfaulty processors have decided. In many cases they can in fact halt one round after they decide. Thus, we ignore issues of termination here and assume that protocols run forever.

2.4. Full-information protocols. We now review the notion of a full-information protocol and some of its implications. The treatment in this section follows the lines of [2].

A protocol is said to be a *full-information* protocol if each processor is required to send its current state to all processors at each round. The state of a processor in a full-information protocol consists of the processor's name, initial state, message history, and the time on the global clock. Thus, the states of processors following a full-information protocol are completely independent of their final decisions; at corresponding points in two full-information protocols, processors have the same states. Indeed, the only way in which full-information protocols can differ is in the decisions made by the processors.

Intuitively, the states of the processors in a full-information protocol make the finest possible distinctions among histories. That is why the full-information protocol is particularly well suited for proving possibility and impossibility of achieving certain

goals in distributed systems, and for the design and analysis of distributed protocols. The following proposition, essentially due to Coan [2], and corollary formalize this intuition.

PROPOSITION 2.2. *Let P be an arbitrary protocol in a system with omission (resp., crash) failures. Then for each processor i there is a function f_i from i's state in a full-information protocol F to its state in P such that for every pair (r, m) and (r', m) of corresponding points of F and P, we have $f_i(r_i(m)) = r'_i(m)$.*

As an immediate consequence, we get the following corollary.

COROLLARY 2.3. *Let P be an arbitrary protocol in a system with omission (resp., crash) failures. Then there is a full-information protocol that dominates P.*

This proposition shows that, just as in [5, 14] for the case of SBA, we can restrict attention to full-information protocols when looking for optimal EBA protocols.

3. Continual common knowledge. As we mentioned in the introduction, we want to perform a knowledge-theoretic analysis of EBA. In the case of SBA, the notion of common knowledge was shown to be central, and its use facilitated the construction of optimal (indeed optimum) protocols. A similar role for EBA will be played by the notion of continual common knowledge, which is a strengthening of common knowledge. Our purpose in this section is to define continual common knowledge and present some of its most useful properties. To do so, we start by describing the knowledge formalism and give definitions and properties of knowledge, belief, and common knowledge. The reader familiar with these notions can skip directly to section 3.2.

3.1. The knowledge formalism. We want to be able to reason about the states of knowledge of the processors in the system. In order to do so, we use the formalism first introduced in [8].

We start with a collection of basic facts (which can essentially be thought of as primitive propositions). For each such basic fact, it will typically be clear whether or not it is true at a given point.[2] We define various basic facts as we go along. Among the basic facts of interest is $\exists 0$, which is true at a point (r, k) in $\mathcal{R}$ if some processor started with initial value 0 in r; we similarly define $\exists 1$. We close this language under the standard Boolean connectives $\wedge$, $\neg$, and $\Rightarrow$, interpreted as conjunction, negation, and implication, as well as various knowledge operators. The basic operator is K_i, where $K_i\varphi$ is read "processor i knows φ."

A processor is said to *know* a fact at a given point (r, m) exactly if the fact holds at all of the points in which the processor has the same state as at (r, m). Thus, we have $(\mathcal{R}, r, m) \models K_i\varphi$ if $(\mathcal{R}, r', m') \models \varphi$ for all points (r', m') such that $r_i(m) = r'_i(m')$. Given a system $\mathcal{R}$, a formula φ is said to be *valid in* $\mathcal{R}$, denoted $\mathcal{R} \models \varphi$, if it holds at all points in $\mathcal{R}$. It is well known that our definition of knowledge satisfies the axioms of the modal logic S5.

PROPOSITION 3.1 (see [9]). *For every system $\mathcal{R}$ we have*

(a) *if $\mathcal{R} \models \varphi$, then $\mathcal{R} \models K_i\varphi$ (knowledge generalization);*
(b) *$\mathcal{R} \models (K_i\varphi \wedge K_i(\varphi \Rightarrow \psi)) \Rightarrow K_i\psi$ (distribution axiom);*
(c) *$\mathcal{R} \models K_i\varphi \Rightarrow \varphi$ (knowledge axiom);*
(d) *$\mathcal{R} \models K_i\varphi \Rightarrow K_iK_i\varphi$ (positive introspection axiom);*

[2] Strictly speaking, we need not just the system, but an *interpreted system*, which is a system together with an *interpretation* of the primitive propositions (see [6] for details). In this paper the basic facts of interest are few and their interpretation will be clear from context, so we do not explicitly use interpretations here.

(e) $\mathcal{R} \models \neg K_i\varphi \Rightarrow K_i\neg K_i\varphi$ *(negative introspection axiom).*

Having defined knowledge for individual processors, we now extend this definition to states of knowledge of a group of processors. We are mainly interested in the state of knowledge called *common knowledge*, since this has been shown to be closely related to coordination and agreement [8]. Given a set G of processors, let $E_G\varphi$ be an abbreviation for $\wedge_{i\in G}K_i\varphi$. Thus, $E_G\varphi$ holds if every processor in G knows φ. $C_G\varphi$ (φ is common knowledge among the processors in G) holds if everyone in G knows φ, everyone knows that everyone knows, and so on. Formally, taking $E_G^1\varphi$ to be an abbreviation for $E_G\varphi$ and $E_G^{k+1}\varphi$ to be an abbreviation for $E_GE_G^k\varphi$, we define

$$(\mathcal{R}, r, m) \models C_G\varphi \text{ iff } (\mathcal{R}, r, m) \models E_G^k\varphi \text{ for } k = 1, 2, 3, \ldots.$$

In the analysis in [5, 14] of SBA, the key concept is not common knowledge among a fixed set G of processors but common knowledge among the nonfaulty processors. The set of nonfaulty processors is a *nonrigid* set: its elements vary from one point to another. Formally, given a system $\mathcal{R}$, a nonrigid set $\mathcal{S}$ of processors in the system is a function associating with every point of the system a subset of the processors. In other words, $\mathcal{S}(r, m)$ is a (possibly different) set of processors for every point (r, m) of $\mathcal{R}$. We denote by $\mathcal{N}$ the nonrigid set of nonfaulty processors. Since a nonfaulty processor does not necessarily know that it is nonfaulty, we would like a notion of knowledge that is appropriate even when processors are not guaranteed to know whether they belong to the nonrigid set. Thus, following [14], given a nonrigid set $\mathcal{S}$ and a processor i, we define $B_i^{\mathcal{S}}\varphi = K_i(i \in \mathcal{S} \Rightarrow \varphi)$. More formally,

$$\begin{aligned}(\mathcal{R}, r, m) \models B_i^{\mathcal{S}}\varphi \text{ iff } &(\mathcal{R}, r', m') \models \varphi \text{ for all } (r', m')\\ &\text{such that } r_i(m) = r_i'(m') \text{ and } i \in \mathcal{S}(r', m').\end{aligned}$$

In other words, $B_i^{\mathcal{S}}\varphi$ holds if i knows that *if it is in* $\mathcal{S}$, then φ holds. This way of defining belief is a special case of a notion of belief defined by Moses and Shoham [13]. As they show, $B_i^{\mathcal{S}}$ behaves much like knowledge. The following proposition summarizes some of its properties.

PROPOSITION 3.2 (see [13]). *For every system* $\mathcal{R}$ *we have*

(a) *if* $\mathcal{R} \models (i \in \mathcal{S}) \Rightarrow \varphi$, *then* $\mathcal{R} \models B_i^{\mathcal{S}}\varphi$;
(b) $\mathcal{R} \models (B_i^{\mathcal{S}}\varphi \wedge B_i^{\mathcal{S}}(\varphi \Rightarrow \psi)) \Rightarrow B_i^{\mathcal{S}}\psi$;
(c) $\mathcal{R} \models i \in \mathcal{S} \Rightarrow (B_i^{\mathcal{S}}\varphi \Rightarrow \varphi)$;
(d) $\mathcal{R} \models B_i^{\mathcal{S}}\varphi \Rightarrow B_i^{\mathcal{S}}B_i^{\mathcal{S}}\varphi$;
(e) $\mathcal{R} \models \neg B_i^{\mathcal{S}}\varphi \Rightarrow B_i^{\mathcal{S}}\neg B_i^{\mathcal{S}}\varphi$;
(f) $\mathcal{R} \models K_i\varphi \Rightarrow B_i^{\mathcal{S}}\varphi$.

Properties (a), (b), (d), (e) are the obvious analogues of the corresponding properties in Proposition 3.1. Property (c) characterizes what is considered to be the key difference between knowledge and belief. By definition, it is impossible to know something which is false, while it is possible to have false beliefs. Thus, $B_i^{\mathcal{S}}$ can be considered to be a notion of belief, but a special one, in that a processor in $\mathcal{S}$ cannot have false beliefs. An extreme case that will appear in our technical analysis is when a processor knows that it is *not* in the set $\mathcal{S}$. When this happens, the processor believes everything:

$$\models \quad K_i(i \notin \mathcal{S}) \Rightarrow B_i^{\mathcal{S}}\varphi.$$

We define $E_{\mathcal{S}}\varphi$ as $\bigwedge_{i\in\mathcal{S}} B_i^{\mathcal{S}}\varphi$. In other words, *everyone in* $\mathcal{S}$ *knows* φ if every processor in $\mathcal{S}$ knows that if it is in $\mathcal{S}$, then φ holds. Notice that if $\mathcal{S}(r, m)$ is empty, then, by definition, $E_{\mathcal{S}}\varphi$ holds at (r, m) (for all formulas φ).

The notion of $C_{\mathcal{S}}\varphi$ is now defined as an infinite conjunction in terms of $E_{\mathcal{S}}\varphi$. Defining $E_{\mathcal{S}}^{k+1}\varphi$ inductively as an abbreviation for $E_{\mathcal{S}}E_{\mathcal{S}}^{k}\varphi$, we have

$$(\mathcal{R}, r, m) \models C_{\mathcal{S}}\varphi \quad \text{iff} \quad (\mathcal{R}, r, m) \models E_{\mathcal{S}}^{k}\varphi \text{ for } k = 1, 2, \ldots.$$

It is easy to see that if $\mathcal{S}$ is the constant function that always returns G, then $C_{\mathcal{S}}\varphi$ is equivalent to $C_G\varphi$. Thus, this definition of $C_{\mathcal{S}}\varphi$ extends the original definition of $C_G\varphi$ to nonrigid sets.

For the sake of completeness, we briefly mention the formal definition of the linear-time temporal operator $\Diamond$ (standing for "eventually") and its dual $\Box$ ("henceforth") in our setting. These operators will be used later on; for details about linear-time temporal logic, see [12]:

$$(\mathcal{R}, r, m) \models \Diamond\varphi \quad \text{iff} \quad (\mathcal{R}, r, m') \models \varphi \text{ for some } m' \geq m,$$

$$(\mathcal{R}, r, m) \models \Box\varphi \quad \text{iff} \quad (\mathcal{R}, r, m') \models \varphi \text{ for all } m' \geq m.$$

3.2. Eventual common knowledge and agreement. As shown in [5, 14], common knowledge among the nonfaulty processors is just the right tool for characterizing optimal SBA. It is not quite right for EBA though, since in EBA it is clear that a processor can decide 0 (or 1) well before it knows that other processors know about this value and thus, a fortiori, before this value is common knowledge. As we said in the introduction, we might have hoped that *eventual common knowledge* would be the appropriate replacement for common knowledge, but that does not quite work.

To understand why, consider the following full-information protocol F_0 that uses eventual common knowledge in its decision rule. While we have not given a formal definition of eventual common knowledge here (one can be found in [6, 9]), for the purposes of this discussion it suffices to know that if φ eventually becomes common knowledge, then it is eventual common knowledge. That is, if we denote eventual common knowledge of φ by $C^{\Diamond}\varphi$, then $\Diamond C\varphi \Rightarrow C^{\Diamond}\varphi$ is valid. According to F_0, a processor decides 0 when it knows there is eventual common knowledge that some initial value was 0 (i.e., when it knows that $C^{\Diamond}\exists 0$ holds) and decides 1 when it knows not only that there is eventual common knowledge that some initial value was 1, but also that there can never be eventual common knowledge that some initial value was 0 (i.e., when it knows that $C^{\Diamond}\exists 1 \wedge \Box\neg C^{\Diamond}\exists 0$ holds). Clearly F_0 is an agreement protocol.

Although the state of knowledge required for decision according to this rule is sufficient for agreement, it is not necessary. Just as in the case of the protocol $P0$ of section 2.2, it is possible to decide 1 earlier than F_0. For example, consider a run of the full-information protocol in the omission failure mode, in which all processors start with initial value 1, there are t faulty processors, and the t faulty processors send no messages in the first two rounds. Techniques of [14] show that in this case it is common knowledge at the end of the second round that there exists an initial value of 1 (indeed, the values of all nonfaulty processors are common knowledge), but no processor knows that all initial values are 1. Indeed, each processor considers it possible that one of the faulty processors has an initial value of 0 and that it will send it to some nonfaulty processor in the third round. The analysis in [14] can be used to show that, should such a message be received in the third round, the existence of a value of 0 will become common knowledge (and thus also be eventual common knowledge) at the end of the fourth round. Thus, according to the protocol F_0, no nonfaulty processor decides at the end of the second round in such a run. However, it is not hard to construct a protocol which dominates F_0 and does decide at this point.

To understand how this can be done, note that the reason we require a processor to wait until it knows that $C^\diamond\exists 1 \wedge \Box\neg C^\diamond\exists 0$ holds before it decides 1 is that otherwise we may have inconsistency: some processor may decide 0 while another may decide 1. Can we decide earlier while still avoiding inconsistency? One thought might be to have a processor decide 1 if it knows that $C^\diamond\exists 1$ holds and that every nonfaulty processor that learns $C^\diamond\exists 0$ does so after it learns $C^\diamond\exists 1$. However, to avoid inconsistency, we then have to modify the rule for deciding 0 so that a processor decides 0 if it knows that $C^\diamond\exists 0$ holds and it considers it possible that some nonfaulty processor will learn $C^\diamond\exists 0$ no later than $C^\diamond\exists 1$. It is easy to see that this gives us an agreement protocol: it is impossible for one nonfaulty processor to decide 0 and another to decide 1. Moreover, it is not hard to show that this protocol dominates F_0: all processors decide no later in runs of this protocol than in the corresponding run of F_0 (although their decisions in corresponding runs may be different).

This protocol itself can be improved though by refining the rule for deciding 0 in a similar fashion. It turns out that an optimal protocol is obtained when the process of refining the decision rules reaches a fixed point. These ideas can be formally captured by use of a new state of knowledge that we call *continual common knowledge*. This is the subject of the next section.

3.3. The definition of continual common knowledge. Roughly speaking, a fact φ is continual common knowledge in a run r among the processors in the nonrigid set $\mathcal{S}$ if, at all points (r, m'), every processor that belongs to $\mathcal{S}(r, m')$ knows that at every point in the run every processor that belongs to $\mathcal{S}$ at that point knows that ... φ holds. More formally, we first define

$$(\mathcal{R}, r, m) \models \boxdot\psi \quad \text{iff} \quad (\mathcal{R}, r, m') \models \psi \ \text{ for all } m' \geq 0.$$

Thus, $\boxdot$ is analogous to the standard temporal logic operator $\Box$, except that instead of restricting attention to the present and future as we do with $\Box$, with $\boxdot$ we consider all times past, present, and future. Note that $(\mathcal{R}, r, m) \models \boxdot\psi$ iff $(\mathcal{R}, r, 0) \models \Box\psi$.

We define $E^{\boxdot}_{\mathcal{S}}\varphi$ as an abbreviation for $\boxdot E_{\mathcal{S}}\varphi$. In other words, $E^{\boxdot}_{\mathcal{S}}\varphi$ holds at the point (r, m) if for all times m', every processor in $\mathcal{S}(r, m')$ knows at time m' that if it is in $\mathcal{S}$, then φ holds. The twist here is, of course, that because $\mathcal{S}$ is nonrigid, the members of $\mathcal{S}(r, m')$ may be different for different values of r and m'. Notice that if $\mathcal{S}(r, m')$ is empty for all $m' \geq 0$, then by definition $E^{\boxdot}_{\mathcal{S}}\varphi$ holds at (r, m) (and, in fact, throughout the run r).

The notion of continual common knowledge of φ is now defined as an infinite conjunction in terms of $E^{\boxdot}_{\mathcal{S}}\varphi$. Defining $(E^{\boxdot}_{\mathcal{S}})^{k+1}\varphi$ inductively as an abbreviation for $E^{\boxdot}_{\mathcal{S}}(E^{\boxdot}_{\mathcal{S}})^k\varphi$, we define

$$(\mathcal{R}, r, m) \models C^{\boxdot}_{\mathcal{S}}\varphi \quad \text{iff} \quad (\mathcal{R}, r, m) \models (E^{\boxdot}_{\mathcal{S}})^k\varphi \text{ for every } k \geq 1.$$

Thus, $C^{\boxdot}_{\mathcal{S}}\varphi$ holds if at all times everyone in $\mathcal{S}$ knows that at all times everyone in $\mathcal{S}$ knows that ... φ holds. We remark that just as $C_{\mathcal{S}}\varphi$ can be shown to be a greatest fixed point of the equation $X \Leftrightarrow E_{\mathcal{S}}(\varphi \wedge X)$ [6, 8], so $C^{\boxdot}_{\mathcal{S}}\varphi$ is the greatest fixed point of the equation $X \Leftrightarrow E^{\boxdot}_{\mathcal{S}}(\varphi \wedge X)$; we omit further details here.

We can characterize continual common knowledge as follows. A point (r', m') is said to be $\mathcal{S}$-$\boxdot$-*reachable in k steps* from a point (r, m) if there exist runs $r^0, \ldots, r^k$, times $m_0, m'_0, \ldots, m_{k-1}, m'_{k-1}$, and processors $i_0, \ldots, i_{k-1}$ such that $r^0 = r$, $r^k = r'$, $m'_{k-1} = m'$, and, for $j = 0, \ldots, k-1$, we have that $i_j \in \mathcal{S}(r^j, m_j) \cap \mathcal{S}(r^{j+1}, m'_j)$

and $r_{i_j}^j(m_j) = r_{i_j}^{j+1}(m'_j)$.[3] We say that (r', m') is $\mathcal{S}$-$\boxdot$-*reachable from* (r, m) if it is $\mathcal{S}$-$\boxdot$-reachable from (r, m) in k steps for some k. It is not too hard to check that the following proposition holds.

PROPOSITION 3.3. $(\mathcal{R}, r, m) \models (E_{\mathcal{S}}^{\boxdot})^k \varphi$ *iff* $(\mathcal{R}, r', m') \models \varphi$ *for all points* (r', m') *that are* $\mathcal{S}$-$\boxdot$-*reachable from* (r, m) *in* k *steps.*

COROLLARY 3.4. $(\mathcal{R}, r, m) \models C_{\mathcal{S}}^{\boxdot} \varphi$ *iff* $(\mathcal{R}, r', m') \models \varphi$ *for all points* (r', m') *that are* $\mathcal{S}$-$\boxdot$-*reachable from* (r, m).

We remark that this result is a variant of the characterization of $C_{\mathcal{S}}\varphi$ given in [5]. Using that characterization, it was shown that $C_{\mathcal{S}}$ satisfies all the S5 axioms except the knowledge axiom[4] and that $C_{\mathcal{S}}\varphi \Rightarrow \varphi$ holds at points where $\mathcal{S}$ is nonempty.[5] $C_{\mathcal{S}}$ was also shown to satisfy two additional properties, known as the *induction rule* and the *fixed-point axiom*. Using Corollary 3.4, we can prove the analogous properties for continual common knowledge.

LEMMA 3.5. *For every system* $\mathcal{R}$ *we have that*

(a) *if* $\mathcal{R} \models \varphi$, *then* $\mathcal{R} \models C_{\mathcal{S}}^{\boxdot} \varphi$ *(common knowledge generalization);*
(b) $\mathcal{R} \models (C_{\mathcal{S}}^{\boxdot} \varphi \wedge C_{\mathcal{S}}^{\boxdot} (\varphi \Rightarrow \psi)) \Rightarrow C_{\mathcal{S}}^{\boxdot} \psi$ *(distribution axiom);*
(c) $\mathcal{R} \models C_{\mathcal{S}}^{\boxdot} \varphi \Rightarrow C_{\mathcal{S}}^{\boxdot} C_{\mathcal{S}}^{\boxdot} \varphi$ *(positive introspection);*
(d) $\mathcal{R} \models \neg C_{\mathcal{S}}^{\boxdot} \varphi \Rightarrow C_{\mathcal{S}}^{\boxdot} \neg C_{\mathcal{S}}^{\boxdot} \varphi$ *(negative introspection);*
(e) $\mathcal{R} \models C_{\mathcal{S}}^{\boxdot} \varphi \Leftrightarrow E_{\mathcal{S}}^{\boxdot} (\varphi \wedge C_{\mathcal{S}}^{\boxdot} \varphi)$ *(fixed-point axiom);*
(f) *if* $\mathcal{R} \models \varphi \Rightarrow E_{\mathcal{S}}^{\boxdot} (\varphi \wedge \psi)$, *then* $\mathcal{R} \models \varphi \Rightarrow C_{\mathcal{S}}^{\boxdot} \psi$ *(induction rule);*
(g) $\mathcal{R} \models C_{\mathcal{S}}^{\boxdot} \varphi \Rightarrow \boxdot C_{\mathcal{S}}^{\boxdot} \varphi$;
(h) $\mathcal{R} \models (i \in \mathcal{S}) \Rightarrow (C_{\mathcal{S}}^{\boxdot} \varphi \Leftrightarrow B_i^{\mathcal{S}} C_{\mathcal{S}}^{\boxdot} \varphi)$.

Proof. The proof of parts (a)–(f) is essentially identical to the proof of the analogous properties for $C_{\mathcal{S}}$ in [5], so it is omitted here. Part (g) follows from the observation that for all m, m', the set of points $\mathcal{S}$-$\boxdot$-reachable from (r, m) and (r, m') is identical. Part (h) follows easily from part (e) and part (c) of Proposition 3.2. We leave details to the reader. □

It is easy to see that $\models C_{\mathcal{S}}^{\boxdot} \varphi \Rightarrow C_{\mathcal{S}}\varphi$ for all formulas φ. It is also not hard to show that the converse does not hold in general. Thus, continual common knowledge is a variant of common knowledge that is strictly stronger than common knowledge.

4. Continual common knowledge and agreement. In this section, we begin our analysis of EBA in terms of continual common knowledge. Let $decide_i(y)$, $y = 0, 1$, be the basic fact which is true at all points where processor i decides y. Since the truth of $decide_i(y)$ at a point depends only on processor i's local state at that point, when $decide_i(y)$ holds, processor i knows it. Moreover, since we have assumed that a processor cannot output 0 and 1 at the same time, we cannot have both $decide_i(0)$ and $decide_i(1)$ holding at any point. Combining these observations with parts (c) and (f) of Proposition 3.2, we immediately get the following result.

[3] The particular models we consider in this paper are *synchronous*, which means that if $r_j(m) = r_j(m')$, then $m = m'$. In synchronous models, we can simplify the notion of reachability slightly because we can take $m_i = m'_i$ for $i = 0, \ldots, k-1$.

[4] The modal system satisfying precisely these properties is known as K45 [1].

[5] Actually, in [5] it is claimed that $C_{\mathcal{S}}$ even satisfies the knowledge axiom. This is indeed the case in the particular application in [5], in which the nonrigid sets $\mathcal{S}$ of interest are always nonempty. However, $C_{\mathcal{S}}$ does not satisfy the knowledge axiom in the more general case in which the nonrigid set might occasionally be empty.

PROPOSITION 4.1. *Let $\mathcal{N}$ stand for the set of nonfaulty processors. If P is an agreement protocol, then for $y = 0, 1$ we have*

(a) $\mathcal{R}_P \models \mathit{decide}_i(y) \Rightarrow \neg \mathit{decide}_i(1-y)$;
(b) $\mathcal{R}_P \models (K_i \mathit{decide}_i(y) \Leftrightarrow \mathit{decide}_i(y)) \wedge (K_i \neg \mathit{decide}_i(y) \Leftrightarrow \neg \mathit{decide}_i(y))$;
(c) $\mathcal{R}_P \models i \in \mathcal{N} \Rightarrow ((B_i^{\mathcal{N}} \mathit{decide}_i(y) \Leftrightarrow \mathit{decide}_i(y)) \wedge (B_i^{\mathcal{N}} \neg \mathit{decide}_i(y) \Leftrightarrow \neg \mathit{decide}_i(y)))$.

Another property of agreement protocols that we will use later on is the following.

LEMMA 4.2. *Let P be an agreement protocol and assume that i, j are nonfaulty in run r of P. Then for all times m we have $(\mathcal{R}_P, r, m) \models \mathit{decide}_i(0) \Rightarrow \boxdot \neg \mathit{decide}_j(1)$.*

Proof. The result is immediate from the definitions. □

We want to focus on the decisions made according to protocol P. To do this, the following definitions will be helpful. We say that a *decision set* $\mathcal{A}$ is a tuple $(\mathcal{A}_1, \ldots, \mathcal{A}_n)$, where $\mathcal{A}_i$ is a subset of processor i's states. We think of the $\mathcal{A}_i$ component of a decision set as consisting of all the states where processor i has decided on a particular value. A *decision pair* is a pair $(\mathcal{Z}, \mathcal{O})$ of decision sets. Intuitively, $\mathcal{Z}$ (for *zero*) describes the local states of processors at points where they are deciding or have decided on 0, while $\mathcal{O}$ (for *one*) describes the analogous states for a decision of 1. We say that $(\mathcal{Z}, \mathcal{O})$ *is the decision pair for protocol P* if $\mathcal{Z}_i$ consists of the local states at which processor i decides or has decided 0 when executing the protocol P, and $\mathcal{O}_i$ consists of the local states at which processor i decides or has decided 1. Typically, we shall describe a decision set such as $\mathcal{Z}_i$ or $\mathcal{O}_i$ by a formula of the form $K_i\varphi$ or $B_i^{\mathcal{N}}\psi$. Given a system, the decision set is then the set of local states in the system at which the formula is satisfied. For example, the decision set defined by $K_i\varphi$ is $\{r_i(m) : (\mathcal{R}, r, m) \models K_i\varphi\}$; similarly, the set defined by $B_i^{\mathcal{N}}\psi$ is $\{r_i(m) : (\mathcal{R}, r, m) \models B_i^{\mathcal{N}}\psi\}$.

Recall that $\mathcal{N}$ denotes the set of nonfaulty processors. Given a decision set $\mathcal{A}$, let $\mathcal{N} \wedge \mathcal{A}$ denote the nonrigid set described by

$$(\mathcal{N} \wedge \mathcal{A})(r, m) = \{i : i \in \mathcal{N}(r, m) \text{ and } r_i(m) \in \mathcal{A}_i\}.$$

With this machinery, we can now give a necessary condition for agreement.

PROPOSITION 4.3. *Let P be an agreement protocol with decision pair $(\mathcal{Z}, \mathcal{O})$. Then*

(a) $\mathcal{R}_P \models \mathit{decide}_i(0) \Rightarrow B_i^{\mathcal{N}}(\exists 0 \wedge \neg \mathit{decide}_i(1) \wedge C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}} \exists 0)$;
(b) $\mathcal{R}_P \models \mathit{decide}_i(1) \Rightarrow B_i^{\mathcal{N}}(\exists 1 \wedge \neg \mathit{decide}_i(0) \wedge C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}} \exists 1)$.

Proof. We prove part (a); the proof of (b) is completely symmetric. The argument is split into showing that $\mathit{decide}_i(0)$ implies belief in each of the three conjuncts. Suppose that $(\mathcal{R}_P, r, m) \models \mathit{decide}_i(0)$. By Proposition 4.1(b) we have that $(\mathcal{R}_P, r, m) \models K_i \mathit{decide}_i(0)$. From Proposition 3.2(f) we obtain that $(\mathcal{R}_P, r, m) \models B_i^{\mathcal{N}} \mathit{decide}_i(0)$. The weak validity property for P implies that $\mathcal{R}_P \models (i \in \mathcal{N}) \Rightarrow (\mathit{decide}_i(0) \Rightarrow \mathit{exist}(0))$. By Proposition 3.2(a) we have that $(\mathcal{R}_P, r, m) \models B_i^{\mathcal{N}}(\mathit{decide}_i(0)) \Rightarrow \mathit{exist}(0))$, and it follows by the distribution axiom for $B_i^{\mathcal{N}}$ (Proposition 3.2(b)) that $(\mathcal{R}_P, r, m) \models B_i^{\mathcal{N}} \mathit{exist}(0)$. Similarly, we explicitly assumed that a processor cannot at once decide on two values, and hence $\mathcal{R}_P \models \mathit{decide}_i(0) \Rightarrow \neg \mathit{decide}_i(1)$. As before, this implies that $(\mathcal{R}_P, r, m) \models B_i^{\mathcal{N}}(\mathit{decide}_i(0) \Rightarrow \neg \mathit{decide}_i(1))$, and the distribution axiom yields belief in the second conjunct: $(\mathcal{R}_P, r, m) \models B_i^{\mathcal{N}} \neg \mathit{decide}_i(1)$. It remains to show that $(\mathcal{R}_P, r, m) \models B_i^{\mathcal{N}} C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}} \exists 0$. Let (r', m) be a point such that $r'_i(m) = r_i(m)$ and $i \in \mathcal{N}(r', m)$. Since $r'_i(m) = r_i(m)$ we have by Proposition 4.1 that $(\mathcal{R}_P, r', m) \models \mathit{decide}_i(0)$. Lemma 4.2 implies that $(\mathcal{R}_P, r', m) \models \boxdot \neg \mathit{decide}_j(1)$ for every nonfaulty processor j. Thus, for all $m' \geq 0$, we have that $(\mathcal{N} \wedge \mathcal{O})(r', m') = \emptyset$. By definition of

continual common knowledge, this immediately implies that $(\mathcal{R}_P, r', m) \models C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0$. It follows by definition of $B_i^{\mathcal{N}}$ that $(\mathcal{R}_P, r, m) \models B_i^{\mathcal{N}} C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0$ as desired, and we are done. □

Proposition 4.3 shows that in order to decide 0, processor i must believe, not surprisingly, that some initial value was 0 and that it does not decide 1. More interesting is the fact that it also must believe that it is continual common knowledge among the nonfaulty processors that eventually decide 1 that there is an initial value of 0. A moment's thought will show that this is true simply because, in an agreement protocol, if a nonfaulty processor decides 0 in run r it believes that there are no nonfaulty processors that decide 1, so $(\mathcal{N}\wedge\mathcal{O})(r,m) = \emptyset$ for all m. Nevertheless, this characterization is of interest because for optimal protocols this condition will turn out to be necessary and sufficient. We now show that a closely related condition is sufficient for agreement in general.

PROPOSITION 4.4. *Let P be a protocol with decision pair $(\mathcal{Z}, \mathcal{O})$ such that either*

(a) $\mathcal{R}_P \models \mathit{decide}_i(0) \Rightarrow B_i^{\mathcal{N}}\exists 0$ *and*

(b) $\mathcal{R}_P \models \mathit{decide}_i(1) \Leftrightarrow B_i^{\mathcal{N}}(\exists 1 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{Z}}\exists 1)$

or

(a′) $\mathcal{R}_P \models \mathit{decide}_i(0) \Leftrightarrow B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0)$ *and*

(b′) $\mathcal{R}_P \models \mathit{decide}_i(1) \Rightarrow B_i^{\mathcal{N}}\exists 1$.

Then P is an agreement protocol.

Proof. We prove the first claim regarding the pair (a) and (b), as the other part is again completely symmetric. Assume that P satisfies (a) and (b). We first show that P satisfies weak validity. Let i be a nonfaulty processor in the run r. We claim that i can decide only on a value that appeared as one of the initial values. Assume that i decides 0 in r. Part (a) implies that i believes $\exists 0$ at that point. By Proposition 3.2(c) we have that $\exists 0$ indeed holds at that point, which implies that some initial value was 0. Similarly, if i decides 1, then part (b) implies that i believes 1 and similarly at least one initial value was 1. It remains to show weak consistency. Assume by way of contradiction that in a run r of $\mathcal{R}_P$ nonfaulty processor i decides 0 at (r,m), while nonfaulty processor j decides 1 at (r,m'). Part (b) implies that $(\mathcal{R}_P, r, m') \models (j \in \mathcal{N}) \wedge B_j^{\mathcal{N}} C^{\boxdot}_{\mathcal{N}\wedge\mathcal{Z}}\exists 1$. Since the belief of a nonfaulty processor is guaranteed to be true we have that $(\mathcal{R}_P, r, m') \models C^{\boxdot}_{\mathcal{N}\wedge\mathcal{Z}}\exists 1$. By Lemma 3.5(g) we have that $(\mathcal{R}_P, r, m) \models C^{\boxdot}_{\mathcal{N}\wedge\mathcal{Z}}\exists 1$ holds as well. From the fact that i decides 0 at (r,m) it follows that $i \in \mathcal{N}\wedge\mathcal{Z}(r,m)$. The fixed-point axiom for continual common knowledge (Lemma 3.5(e)) implies that $(\mathcal{R}_P, r, m) \models B_i^{\mathcal{N}}(\exists 1 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{Z}}\exists 1)$. We can now apply property (b) to i at (r,m) and conclude that i decides 1 at that point, contradicting the assumption that i decides 0 there. □

We remark that the asymmetry between the decision sets for 0 and 1 in Proposition 4.4 is essential. While the conditions in Propositions 4.3 and 4.4 are not identical, once we move to *optimal* protocols, we will be able to get a single necessary and sufficient condition, expressed in terms of continual common knowledge, that characterizes optimality.

5. Constructing and characterizing optimal agreement. It is not too hard to show that for optimal agreement protocols the implications ("⇒") in parts (a) and (b) of Proposition 4.3 become equivalences ("⇔"). More importantly, we can show that if "sufficient information" is transmitted, as is the case in a full-information protocol, then a protocol satisfying these conditions is optimal. These points are made precise and proved in this section. In the process, we also show how to construct an optimal protocol dominating any given protocol.

From here on in, we focus on full-information protocols. As we indicated in section 2.4, full-information protocols are all we need to consider if we are interested in optimal protocols for EBA. We use $FIP(\mathcal{Z},\mathcal{O})$ to denote the (unique) full-information protocol with decision pair $(\mathcal{Z},\mathcal{O})$. We will be focusing on protocols of the form $FIP(\mathcal{Z},\mathcal{O})$ in the rest of our analysis. Notice that for any pair of protocols of this form, there is a one-to-one and onto mapping from the runs of the first protocol to corresponding runs of the second protocol. The only possible difference between corresponding runs is in what decisions are made and when they are taken; the same messages are sent at the same times, and the same processors fail in the same way and at the same time. As a result, we can assume without loss of generality that all decision sets $\mathcal{A}$ that we consider are defined in terms of the initial configuration and the pattern of messages that are communicated. More formally, we assume that all sets $\mathcal{A}$ that we consider for decision sets $\mathcal{Z}$ and $\mathcal{O}$ have the property that if F and F' are full-information protocols and r and r' are corresponding runs in $\mathcal{R}_F$ and $\mathcal{R}_{F'}$, respectively, then $r_i(m) \in \mathcal{A}$ iff $r'_i(m) \in \mathcal{A}$. We use this observation in our construction of optimal EBA protocols. During the construction, we start with one full-information protocol and then modify its decision pair to get another full-information protocol. After a finite number of modifications, we end up with an optimal protocol.

When we represent full-information protocols in this way, the sets determining the decision pair can be specified in a fairly flexible manner. For example, we will often use knowledge formulas to describe these sets. As long as these formulas talk about initial values (and not decisions), they will be uniquely determined by the communication that takes place in the run and thus result in a well-defined protocol. For example, a formula such as $B_i^{\mathcal{N}}\exists 0$ uniquely specifies a set of local states for processor i in runs of full-information protocols of this form. It can therefore be used to specify a decision set in a decision pair.

The following result is the core of our technique for constructing optimal protocols. It provides a knowledge-theoretic method for constructing protocols that dominate a given (full-information) agreement protocol and plays a key role in our characterization of optimal agreement protocols. It can be viewed as a formalization of some of the intuitions presented in section 3.2.

PROPOSITION 5.1. *Let $F = FIP(\mathcal{Z},\mathcal{O})$ be a full-information agreement protocol, and define $F' = FIP(\mathcal{Z}',\mathcal{O}')$ and $F'' = FIP(\mathcal{Z}'',\mathcal{O}'')$, where*

$$\mathcal{Z}'_i = B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0) \quad \text{and} \quad \mathcal{O}'_i = B_i^{\mathcal{N}}(\exists 1 \wedge \neg C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0),$$

while

$$\mathcal{O}''_i = B_i^{\mathcal{N}}(\exists 1 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{Z}}\exists 1) \quad \text{and} \quad \mathcal{Z}''_i = B_i^{\mathcal{N}}(\exists 0 \wedge \neg C^{\boxdot}_{\mathcal{N}\wedge\mathcal{Z}}\exists 1).$$

Then F' and F'' are both agreement protocols that dominate F.

Proof. The case of $F'' = FIP(\mathcal{Z}'',\mathcal{O}'')$ is symmetric to that of $F' = FIP(\mathcal{Z}',\mathcal{O}')$; we prove for F'.

First note that $\models C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0 \Leftrightarrow \boxdot C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0$, and hence $C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0$ is a property of runs. The property $\mathcal{Z}'_i$ can hold at a point in a run only if the run satisfies $C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0$, while $\mathcal{O}'_i$ can hold only if $\neg C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0$ does. It follows that nonfaulty processors cannot reach different decisions in the same run of F', and so weak agreement holds. In addition, since $\models \mathcal{Z}'_i \Rightarrow \exists 0$ and $\models \mathcal{O}'_i \Rightarrow \exists 1$, weak validity is guaranteed. It follows that F' is an agreement protocol. It remains to show that F' dominates F.

Let r be a run of $\mathcal{R}_F$, and let r' be the corresponding run in $\mathcal{R}_{F'}$. First, suppose that $(\mathcal{R}_F, r, m) \models \mathit{decide}_i(1) \wedge (i \in \mathcal{N})$. We want to show that processor i decides by time m in r'. If i decides in r' before time m we are done. Assume not. Clearly, either (a) $(\mathcal{R}_F, r, m) \models C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0$ or (b) $(\mathcal{R}_F, r, m) \models \neg C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0$. If (a) holds, then $r_i(m) \in (\mathcal{N} \wedge \mathcal{O})$ and by Lemma 3.5(e) we have that

$$(\mathcal{R}_F, r, m) \models B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0).$$

Thus, by definition of $\mathcal{Z}'$,we have that $r_i(m) \in \mathcal{Z}'_i$. If (b) holds, a similar argument shows that $(\mathcal{R}_F, r, m) \models B_i^{\mathcal{N}}\neg C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0$. In addition, since F is an agreement protocol, it follows from the fact that i decides 1 at (r, m) that $(\mathcal{R}_F, r, m) \models B_i^{\mathcal{N}}\exists 1$. Therefore, $(\mathcal{R}_F, r, m) \models B_i^{\mathcal{N}}(\exists 1 \wedge \neg C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0)$, and so $r_i(m) \in \mathcal{O}'_i$. Thus, $r'_i(m) \in (\mathcal{Z}'_i \cup \mathcal{O}'_i)$ so that in either case processor i decides at $r'_i(m)$.

Now suppose that $(\mathcal{R}_F, r, m) \models \mathit{decide}_i(0) \wedge (i \in \mathcal{N})$. Then by Proposition 4.3, we also have $(\mathcal{R}_F, r, m) \models B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0)$. Therefore, by definition, $r_i(m) \in \mathcal{Z}'_i$, and again it follows that processor i decides at least as soon in r' as in r. □

Proposition 5.1 suggests a way to construct an optimal agreement protocol. Namely, start with a full-information agreement protocol $F = \mathit{FIP}(\mathcal{Z}, \mathcal{O})$. Then construct a new protocol $F^1 = \mathit{FIP}(\mathcal{Z}^1, \mathcal{O}^1)$, where

$$\begin{aligned}\mathcal{Z}_i^1 &= B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0) \text{ and}\\ \mathcal{O}_i^1 &= B_i^{\mathcal{N}}(\exists 1 \wedge \neg C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0).\end{aligned}$$

Notice that the new protocol is completely determined by the formula decision set $\mathcal{O}$ of the original protocol. We then proceed to create a second protocol $F^2 = \mathit{FIP}(\mathcal{Z}^2, \mathcal{O}^2)$, where

$$\begin{aligned}\mathcal{Z}_i^2 &= B_i^{\mathcal{N}}(\exists 0 \wedge \neg C^{\boxdot}_{\mathcal{N}\wedge\mathcal{Z}^1}\exists 1) \text{ and}\\ \mathcal{O}_i^2 &= B_i^{\mathcal{N}}(\exists 1 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{Z}^1}\exists 1).\end{aligned}$$

Protocol F^2 is thus completely determined by $\mathcal{Z}^1$. We can, of course, continue in this fashion and define protocols $F^{2,1}, F^{2,2}, \ldots$. By Proposition 5.1, each new protocol we construct dominates the previous ones. By the observations in section 2.2, if we start with an EBA protocol, this process eventually terminates, giving us an optimal EBA protocol. However, it is far from clear how long it takes this process to terminate (or if it even terminates at all if we start with an arbitrary agreement protocol). We now show that, in fact, the process always terminates in two steps, so the resulting protocol F^2 is indeed optimal. (Of course we can also show that the analogous construction, exchanging the roles of $\mathcal{Z}$ and $\mathcal{O}$, results in an optimal protocol.)

THEOREM 5.2. *Let $F = \mathit{FIP}(\mathcal{Z}, \mathcal{O})$ be an agreement protocol, and let F^1 and F^2 be as described above. Then F^2 is an optimal agreement protocol. Moreover, if F is an EBA protocol, then F^2 is an optimal EBA protocol dominating F.*

Proof. Suppose that F^2 is not optimal and that F^3 dominates F^2. Proposition 5.1 implies that F^2 dominates both F and F^1. Therefore, F^3 must also dominate both F and F^1. By Lemma 5.3, if processor i decides 0 at the point (r', m) of $\mathcal{R}_{F^3}$, it must be the case that $(\mathcal{R}_{F^3}, r', m) \models B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0)$. Thus, by definition of $\mathcal{Z}_i^1$, processor i decides at the corresponding point of $\mathcal{R}_{F^1}$ (if it has not done so earlier in the run). Since F^2 dominates F^1, it must be the case that processor i has also decided by the corresponding point of $\mathcal{R}_{F^2}$. Similarly, since F^3 dominates F^1, if processor i decides 1 at the point (r', m), then $(\mathcal{R}_{F^3}, r', m) \models B_i^{\mathcal{N}}(\exists 1 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{Z}^1}\exists 1)$. By definition of $\mathcal{O}_i^2$, it must be the case that processor i has decided by the corresponding point

in $\mathcal{R}_{F^2}$. We conclude that F^2 dominates F^3. Since F^3 was chosen as an arbitrary protocol dominating F^2, it follows that F^2 is indeed optimal.

Notice that, in general, F^2 is not necessarily an EBA protocol because not all the nonfaulty processors necessarily decide. However, if the protocol F we started out with is an EBA protocol, then every protocol dominating F must satisfy the decision condition of EBA. In this case, then, F^2 will in fact be an optimal EBA protocol dominating F. □

To complete the proof of Theorem 5.2, we need a technical lemma that relates the stopping conditions of two protocols F and F', where F' dominates F. It describes the state of knowledge that must hold in a run of F' in which the decision value is different from that of the corresponding run of F.

LEMMA 5.3. *Let $F = FIP(\mathcal{Z}, \mathcal{O})$ and $F' = FIP(\mathcal{Z}', \mathcal{O}')$ be full-information agreement protocols such that F' dominates F. Then we must have*

(a) $\mathcal{R}_{F'} \models decide_i(0) \Rightarrow B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}} \exists 0)$;

(b) $\mathcal{R}_{F'} \models decide_i(1) \Rightarrow B_i^{\mathcal{N}}(\exists 1 \wedge C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}} \exists 1)$.

Proof. The proofs of (a) and (b) are identical, so we prove only (a). The fact that $\mathcal{R}_F \models decide_i(0) \Rightarrow B_i^{\mathcal{N}} \exists 0$ follows from the fact that F' is an agreement protocol. Therefore, it suffices to show that $\mathcal{R}_{F'} \models decide_i(0) \Rightarrow B_i^{\mathcal{N}} C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}}(\exists 0)$. Proposition 4.3 implies that $\mathcal{R}_{F'} \models decide_i(0) \Rightarrow B_i^{\mathcal{N}} C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}'}(\exists 0)$. We need to show that the same result holds with $\mathcal{O}'$ replaced by $\mathcal{O}$.

Let $decide(0)$ denote the basic fact that is true at a point (r, m) in $\mathcal{R}_{F'}$ exactly if some nonfaulty processor decides 0 at some point in r. It is clearly the case that $\mathcal{R}_{F'} \models decide_i(0) \Rightarrow B_i^{\mathcal{N}} decide(0)$, since if $decide_i(0)$ holds, then i knows $decide_i(0)$, and hence in particular i knows that if i is nonfaulty, then $decide(0)$ holds. To complete the proof, it remains to prove the following.

Claim. $\mathcal{R}_{F'} \models decide(0) \Rightarrow C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}} \exists 0$.

Proof. Since F' satisfies weak validity, it is easy to check that $\mathcal{R}_{F'} \models decide(0) \Rightarrow \exists 0$. It therefore suffices to prove that $\mathcal{R}_{F'} \models decide(0) \Rightarrow C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}} decide(0)$. Using the induction rule (part (f) of Lemma 3.5), it suffices to show that

$$\mathcal{R}_{F'} \models decide(0) \Rightarrow E^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}} decide(0).$$

To see this, assume that $(\mathcal{R}_{F'}, r', m) \models decide(0)$ and $j \in (\mathcal{N} \wedge \mathcal{O})(r', m')$ for some point (r', m') in the run r'. We need to show that $(\mathcal{R}_{F'}, r', m') \models B_j^{\mathcal{N}} decide(0)$. Let r be the run of $\mathcal{R}_F$ that corresponds to r'. Since $F = FIP(\mathcal{Z}, \mathcal{O})$, if processor j decides in run r at all, it does so at the first time m such that $r_j(m) \in \mathcal{O}_j$. Since $j \in (\mathcal{N} \wedge \mathcal{O})(r', m')$, it follows that $r'_j(m') = r_j(m') \in \mathcal{O}_j$. Thus, processor j decides no later than at time m' in run r. Since F' dominates F, processor j must decide no later than at time m' in run r' either. Since j is nonfaulty in r', and the nonfaulty processors decide 0 in r', it follows that j decides 0 in r' at some time $m'' \leq m'$. Thus, we have $(\mathcal{R}_{F'}, r', m'') \models decide_j(0)$, from which it follows that $(\mathcal{R}_{F'}, r', m'') \models B_j^{\mathcal{N}} decide(0)$. Finally, since in a full-information protocol processors keep track of their history in their local state, it follows that once processor j believes that $decide(0)$ holds, it will continue to believe this at all points in the future. (Technically, the property of *no forgetting* or *perfect recall* holds in full-information protocols [10].) Thus, $(\mathcal{R}_{F'}, r', m') \models B_j^{\mathcal{N}} decide(0)$, as desired. □

To complete the section, we now show that, as claimed earlier, the necessary conditions of Proposition 4.3 actually characterize optimal (full-information) agreement protocols.

THEOREM 5.4. *Let $F = FIP(\mathcal{Z}, \mathcal{O})$ be a full-information agreement protocol. Then F is optimal iff both of the following conditions hold:*

(a) $\mathcal{R}_F \models i \in \mathcal{N} \Rightarrow (\mathit{decide}_i(0) \Leftrightarrow B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0 \wedge \neg \mathit{decide}_i(1)))$,
(b) $\mathcal{R}_F \models i \in \mathcal{N} \Rightarrow (\mathit{decide}_i(1) \Leftrightarrow B_i^{\mathcal{N}}(\exists 1 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{Z}}\exists 1 \wedge \neg \mathit{decide}_i(0)))$.

Proof. For the "only if" direction, we prove only (a) here; the proof of (b) is analogous. Since F is an agreement protocol, it follows from Proposition 4.3 that

$$\mathcal{R}_F \models \mathit{decide}_i(0) \Rightarrow B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0 \wedge \neg \mathit{decide}_i(1)).$$

Hence it is enough to prove that

$$\mathcal{R}_F \models i \in \mathcal{N} \Rightarrow (B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0 \wedge \neg \mathit{decide}_i(1)) \Rightarrow \mathit{decide}_i(0)).$$

Suppose that

$$(\mathcal{R}_F, r, m) \models i \in \mathcal{N} \wedge B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0 \wedge \neg \mathit{decide}_i(1)).$$

Let $\mathcal{Z}_i' = B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0)$ and $\mathcal{O}_i' = B_i^{\mathcal{N}}(\exists 1 \wedge \neg C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0)$, and consider the protocol F' defined by $F' = \mathit{FIP}(\mathcal{Z}', \mathcal{O}')$. Proposition 5.1 shows that F' is an agreement protocol that dominates F. Therefore, for F to be optimal, it must dominate F' as well.

Let (r', m) be the point of $\mathcal{R}_{F'}$ corresponding to (r, m). Since $(\mathcal{R}_F, r, m) \models B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0 \wedge \neg \mathit{decide}_i(1))$, we have that $r_i(m) \in \mathcal{Z}_i'$. From $r_i(m) = r_i'(m)$, it follows that $r_i'(m) \in \mathcal{Z}_i'$ so that processor i decides or has decided by (r', m) in protocol F'. Since F is optimal by assumption, we have that processor i must also decide by (r, m). Thus, $(\mathcal{R}_F, r, m) \models \mathit{decide}_i(0) \vee \mathit{decide}_i(1)$. However, since $(\mathcal{R}_F, r, m) \models i \in \mathcal{N} \wedge B_i^{\mathcal{N}}\neg \mathit{decide}_i(1)$, it follows by Proposition 4.1(c) that $(\mathcal{R}_F, r, m) \models \neg \mathit{decide}_i(1)$, and hence $(\mathcal{R}_F, r, m) \models \mathit{decide}_i(0)$ as desired.

For the "if" direction, suppose that both (a) and (b) hold. Proposition 2.3 implies that it is enough to show that F dominates any full-information agreement protocol F' that dominates it. Therefore, suppose F' dominates F. Let r' be a run of $\mathcal{R}_{F'}$, and let r be the corresponding run in $\mathcal{R}_F$. First, suppose that $(\mathcal{R}_{F'}, r', m) \models i \in \mathcal{N} \wedge \mathit{decide}_i(0)$. We want to show that processor i decides by time m in r. The proof that the same happens if $\mathit{decide}_i(1)$ holds is identical and hence is omitted. By Lemma 5.3, we have

$$(\mathcal{R}_{F'}, r', m) \models B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0).$$

Since (r, m) and (r', m) are corresponding points of $\mathcal{R}_F$ and $\mathcal{R}_{F'}$, we have that

$$(\mathcal{R}_F, r, m) \models B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0).$$

If, in addition, $(\mathcal{R}_F, r, m) \models \mathit{decide}_i(1)$, then processor i decides by time m in run r. On the other hand, if $(\mathcal{R}_F, r, m) \models \neg \mathit{decide}_i(1)$, then Proposition 4.1 implies that $\mathcal{R}_F \models \neg \mathit{decide}_i(1) \Rightarrow B_i^{\mathcal{N}}\neg \mathit{decide}_i(1)$, so

$$(\mathcal{R}_F, r, m) \models B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N}\wedge\mathcal{O}}\exists 0 \wedge \neg \mathit{decide}_i(1)).$$

From assumption (a), it follows that $(\mathcal{R}_F, r, m) \models \mathit{decide}_i(0)$, and thus we again get that processor i decides by time m in run r. □

6. Examples of optimal protocols. In this section, we apply the technique of Theorem 5.2 to construct some optimal agreement protocols. We start with an agreement protocol $F(\mathcal{Z}, \mathcal{O})$ and proceed as described in section 5. Though each protocol constructed in this way is optimal, different choices of $\mathcal{Z}$ and $\mathcal{O}$ yield optimal

protocols with different properties and different performance. Moreover, even if we start with the same basic protocol, the protocol we end up with depends on the failure mode considered. This stems from a subtle point that has not arisen in our treatment so far. Up until now, we have ignored the issue of whether we are dealing with crash failures or omission failures. Notice, however, that the sets $\mathcal{Z}_i^1$, $\mathcal{O}_i^1$, $\mathcal{Z}_i^2$, and $\mathcal{O}_i^2$ are defined in terms of what processors know at certain points. Of course, what they know at a given point will depend in part on whether we are dealing with crash failures or omission failures. Suppose, for example, we start with an agreement protocol F that works in the case of omission failure. Then it clearly also works in the case of crash failures. However, $\mathcal{R}_F^{cr}(n,t)$ and $\mathcal{R}_F^{om}(n,t)$ are different systems. Thus, we have different decision pairs $(\mathcal{Z}^{cr}, \mathcal{O}^{cr})$ and $(\mathcal{Z}^{om}, \mathcal{O}^{om})$, depending on whether we consider crash failures or omission failures. Because there are more runs in $\mathcal{R}_F^{om}$ than $\mathcal{R}_F^{cr}$, it follows that $\mathcal{Z}_i^{cr} \subseteq \mathcal{Z}_i^{om}$ and $\mathcal{O}_i^{cr} \subseteq \mathcal{O}_i^{om}$. However, once we apply the procedure of Proposition 5.1 to these sets, we may no longer have, for example, $(\mathcal{Z}_i')^{cr} \subseteq (\mathcal{Z}_i^1)^{om}$. Nevertheless, all the results from section 5 apply whether we are working with crash failures or omission failures, so we continue to suppress the failure mode here. However, as we shall see, the issue of the failure mode plays a major role in starting with the same protocol; our techniques lead to different protocols depending on the type of failures considered. Since many of the proofs in this section are lengthy and provide less insight than the ones in the previous sections, we defer them to the appendix.

6.1. A simple optimal protocol. A particularly trivial agreement protocol is one in which no processor ever decides. Let F^Λ be the full-information protocol in which no processor ever decides. That is, we define $\mathcal{Z}_i^\Lambda = \mathcal{O}_i^\Lambda = \emptyset$ for $i = 1, \ldots, n$, and let $F^\Lambda = FIP(\mathcal{Z}^\Lambda, \mathcal{O}^\Lambda)$. Suppose we apply our optimization technique to F^Λ.

The first step of the construction consists of having the processors decide 0 as soon as possible, given the criterion for deciding 1. Thus,

$$\mathcal{Z}_i^{\Lambda,1} = B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}^\Lambda} \exists 0) \text{ and}$$
$$\mathcal{O}_i^{\Lambda,1} = B_i^{\mathcal{N}}(\exists 1 \wedge \neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}^\Lambda} \exists 0).$$

Since in F^Λ nonfaulty processors never decide 1, we have that $\mathcal{R}_{F^\Lambda} \models \boxdot(\mathcal{N} \wedge \mathcal{O}^\Lambda = \emptyset)$, and hence also $\mathcal{R}_{F^\Lambda} \models C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}^\Lambda} \exists 0$. It follows that $\mathcal{Z}_i^{\Lambda,1} = B_i^{\mathcal{N}} \exists 0$ and $\mathcal{O}_i^{\Lambda,1} = B_i^{\mathcal{N}}(\exists 1 \wedge \mathit{false})$, which is equivalent to $B_i^{\mathcal{N}} \mathit{false}$.

The second step of the construction optimizes the decision on 1, given the definition of $\mathcal{Z}^{\Lambda,1}$. Following Proposition 5.1, we define

$$\mathcal{Z}_i^{\Lambda,2} = B_i^{\mathcal{N}}(\exists 0 \wedge \neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}} \exists 1) \text{ and}$$
$$\mathcal{O}_i^{\Lambda,2} = B_i^{\mathcal{N}}(\exists 1 \wedge C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}} \exists 1).$$

We denote $FIP(\mathcal{Z}^{\Lambda,2}, \mathcal{O}^{\Lambda,2})$ by $F^{\Lambda,2}$.

The analysis we have performed so far applies equally well to both the crash and the omission failure mode. Thus, $F^{\Lambda,2}$ is an optimal agreement protocol in both cases. As we shall see, however, while F^Λ behaves in essentially the same way in both settings, the properties of $F^{\Lambda,2}$ are dramatically different in the two failure modes. The crux of the analysis will involve figuring out when $\mathcal{Z}^{\Lambda,2}$ and $\mathcal{O}^{\Lambda,2}$ hold in runs of $F^{\Lambda,2}$. This, in turn, will be determined by when $C^{\boxdot}_{\mathcal{N} \wedge B^{\mathcal{N}} \exists 0} \exists 1$ holds.

We begin with an analysis of $F^{\Lambda,2}$ in the crash failure mode. As the next theorem shows, $F^{\Lambda,2}$ is quite simple in this case.

THEOREM 6.1. *In the crash failure mode,* $F^{\Lambda,2} = FIP(\mathcal{Z}^{cr}, \mathcal{O}^{cr})$, *where* $\mathcal{Z}_i^{cr} = B_i^{\mathcal{N}} \exists 0$ *and* $\mathcal{O}_i^{cr} = B_i^{\mathcal{N}}((\mathcal{N} \wedge \mathcal{Z}^{cr}) = \emptyset)$.

Proof. The proof can be found in the appendix. □

It is easy for processor i to compute when it should decide 0 according to $F^{\Lambda,2}$ in the crash failure mode: it decides 0 if it ever hears about a 0 from any processor. It also turns out to be easy for processor i to compute when to decide 1. According to Theorem 6.1, it should decide 1 when it believes that $\mathcal{N} \wedge \mathcal{Z}^{cr} = \emptyset$, that is, when it believes that no nonfaulty processor knows that some processor started with 0. The relevant conditions for this to be the case are precisely those given for the protocol $P0_{\text{opt}}$ described in the introduction. As we prove in Theorem 6.2, processor i decides 1 according to the protocol when it either knows that all initial values are 1 or it hears from the same set of processors in two consecutive rounds and still does not know that some processor had an initial value of 0. Thus, $P0_{\text{opt}}$ and $F^{\Lambda,2}$ are essentially equivalent protocols. The same decisions are made by all processors at corresponding points of the systems generated by the two protocols in the crash failure mode. (The two protocols are not identical because $F^{\Lambda,2}$ is a full-information protocol, while in $P0_{\text{opt}}$ the processors send much shorter messages.) It follows from this that not only is $F^{\Lambda,2}$ an optimal agreement protocol (this already follows from Theorem 5.2), but it is also an optimal EBA protocol.

THEOREM 6.2. *In the crash failure mode, the same decisions are made by nonfaulty processors at corresponding points of the protocols* $P0_{\text{opt}}$ *and* $F^{\Lambda,2}$. *Thus, both* $F^{\Lambda,2}$ *and* $P0_{\text{opt}}$ *are optimal EBA protocols for the crash failure mode.*

Proof. The proof can be found in the appendix. □

Since $P0_{\text{opt}}$ can be implemented using messages of linear size, $F^{\Lambda,2}$ gives us an efficient optimal EBA protocol in the crash failure mode. The situation is very different in the case of omission failures. While $F^{\Lambda,2}$ is still an optimal agreement protocol, and an analysis similar to that carried out for the case of crash failures can be used to show that it has an efficient implementation, it is no longer an EBA protocol. There are runs in which it never halts.

PROPOSITION 6.3. *If* $t > 1$ *and* $n \geq t + 2$, *then there are runs of* $F^{\Lambda,2}$ *in* $\mathcal{R}^{om}$ *in which the nonfaulty processors do not decide.*

Proof. The proof can be found in the appendix. □

6.2. Optimal EBA for omission failures. As the proof of Proposition 6.3 shows, the reason that $F^{\Lambda,2}$ does not necessarily terminate in the presence of omission failures is that there is no bound on the time at which a processor can learn that there exists an initial value of 0. Clearly, if we start out with a terminating protocol and find an optimal protocol that dominates it, then the optimal protocol we obtain will also be terminating. We now use a well-known approach to generate a (terminating) EBA protocol in the omission failure mode. Intuitively, we say that a processor *accepts* 0 in round m only if this value was transferred by a chain of $m - 1$ distinct processors (cf. [4]). Formally, we say that a 0-*chain* exists at the point (r, m) full-information F iff there is a sequence of m distinct processors $i_1, \ldots, i_m$, such that i_1 has initial value 0, i_{k+1} received a message from i_k at round k and $(\mathcal{R}_F, r, k) \models \neg B_{i_{k+1}}^{\mathcal{N}}(i_k \notin \mathcal{N})$, and i_m is nonfaulty. We say that $(\mathcal{R}_F, r, m) \models \exists 0^*$ if there is a 0-chain at some point (r, m') with $m' \leq m$.

Let $\mathcal{Z}_i^0 = B_i^{\mathcal{N}} \exists 0^*$ and $\mathcal{O}_i^0 = B_i^{\mathcal{N}} \neg \exists 0^*$, and consider the protocol $FIP(\mathcal{Z}^0, \mathcal{O}^0)$. It is easy to see that this is an agreement protocol. The following proposition shows that it is actually an EBA protocol.

PROPOSITION 6.4. *In a run* r *of* $FIP(\mathcal{Z}^0, \mathcal{O}^0)$ *in the omission failure mode where*

f processors actually fail, all nonfaulty processors decide by time $f+1$.

Proof. The proof can be found in the appendix. □

Clearly $FIP(\mathcal{Z}^0, \mathcal{O}^0)$ satisfies the validity and consistency conditions, so we immediately get the following corollary.

COROLLARY 6.5. *$FIP(\mathcal{Z}^0, \mathcal{O}^0)$ is an EBA protocol.*

We can now apply the construction of Theorem 5.2 to $FIP(\mathcal{Z}^0, \mathcal{O}^0)$ to get an optimal EBA protocol that dominates it. The description of the protocol that we get using the construction can be simplified somewhat. Let $\mathcal{Z}^* = B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}^0} \exists 0)$, $\mathcal{O}^* = B_i^{\mathcal{N}}(\exists 1 \wedge \neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{O}^0} \exists 0)$, and $F^* = FIP(\mathcal{Z}^*, \mathcal{O}^*)$.

PROPOSITION 6.6. *F^* is an optimal EBA in the omission failure mode that dominates $FIP(\mathcal{Z}^0, \mathcal{O}^0)$.*

Proof. The proof can be found in the appendix. □

Note that the decision rules in F^* involve explicit tests for knowledge. Although it is not hard to show that these tests can be implemented effectively (by which we mean that the tests are decidable in principle; in fact, this can be done in PSPACE [5]), we do not know if they can be implemented efficiently, even in the case of crash failures. The question of whether there exists a polynomial-time protocol that is optimal for EBA in the case of omission failures is still open; we conjecture that such a protocol does exist. (We remark that in [5, 14], polynomial time protocols that are optimum for SBA in the case of crash and omission failures are given.)

7. Conclusions. This paper completely characterizes optimal EBA protocols in the case of crash and omission failures. It involves a new variant of common knowledge—*continual common knowledge*—in an essential way. Interestingly, continual common knowledge is a stronger state of knowledge than common knowledge. By contrast, all other variants of common knowledge considered in the literature (cf. [8, 16]) are weakenings of common knowledge. The characterization is far from trivial. While it would in principle be possible to characterize and prove these properties without using knowledge, we conjecture that it would be rather difficult.

Our results can be extended in a number of ways. First, although we have considered here only crash and omission failures, we believe that our results should be extendible to the case of Byzantine failures, once a reasonable notion of corresponding runs and protocols is given for that model. Second, although we assumed here that the processors are synchronous, our knowledge analysis is also valid for asynchronous systems (except for the implementations in section 6, of course). Third, although this paper focuses on EBA and agreement protocols, it is straightforward to extend our results to general coordination problems along the lines of [14], including ones in which *all* processors (and not only the nonfaulty ones) are required to act consistently. (Problems of the latter type are said to require *uniform agreement*.) Neiger and Bazzi [15] consider these issues, using an approach based on ours. They consider agreement in synchronous and asynchronous systems, and study both uniform and nonuniform agreement. In addition, they look at cases where explicit termination, as well as agreement, is required. To handle termination and agreement, they define a notion of *extended knowledge*, which is essentially a combination of continual common knowledge and eventual common knowledge.

An interesting question left open is whether our two-step optimizing process can be done in a computationally efficient manner. Our examples in section 6 show that in some cases we can obtain efficient optimal EBA protocols. However, a naive evaluation of the formulas used in the optimization process does not guarantee computationally efficient results.

Appendix. Proofs. In this appendix, we prove the results in section 6. For the convenience of the reader, we repeat the statements of the results.

THEOREM 6.1. *In the crash failure mode,* $F^{\Lambda,2} = FIP(\mathcal{Z}^{cr}, \mathcal{O}^{cr})$, *where* $\mathcal{Z}_i^{cr} = B_i^{\mathcal{N}}\exists 0$ *and* $\mathcal{O}_i^{cr} = B_i^{\mathcal{N}}((\mathcal{N} \wedge \mathcal{Z}^{cr}) = \emptyset)$.

Theorem 6.1 follows immediately from the next two lemmas. The first shows that $\mathcal{Z}_i^{\Lambda,2} = B_i^{\mathcal{N}}\exists 0$, and the second shows that $\mathcal{O}_i^{\Lambda,2} = B_i^{\mathcal{N}}((\mathcal{N} \wedge \mathcal{Z}^{cr}) = \emptyset)$. This shows that $\mathcal{Z}^{\Lambda,2} = \mathcal{Z}^{cr}$ and $\mathcal{O}^{\Lambda,2} = \mathcal{O}^{cr}$, proving the theorem. To simplify notation in the proofs, we denote the system $\mathcal{R}^{cr}_{F^{\Lambda,2}}$ obtained by running protocol $F^{\Lambda,2}$ in the crash failure mode by $\mathcal{R}^{cr}$.

LEMMA A.1. *In* $\mathcal{R}^{cr}$, $\mathcal{Z}_i^{\Lambda,2} = B_i^{\mathcal{N}}\exists 0$.

Proof. Recall that $\mathcal{Z}_i^{\Lambda,2} = B_i^{\mathcal{N}}(\exists 0 \wedge \neg C^{\boxdot}_{\mathcal{N}\wedge \mathcal{Z}^{\Lambda,1}}\exists 1)$ and that $\mathcal{Z}_i^{\Lambda,1} = B_i^{\mathcal{N}}\exists 0$. Clearly $\mathcal{Z}_i^{\Lambda,2} \subseteq B_i^{\mathcal{N}}\exists 0$. For the opposite containment, suppose $(\mathcal{R}^{cr}, r, m) \models B_i^{\mathcal{N}}\exists 0$. We want to show that $(\mathcal{R}^{cr}, r, m) \models B_i^{\mathcal{N}}(\exists 0 \wedge \neg C^{\boxdot}_{\mathcal{N}\wedge \mathcal{Z}^{\Lambda,1}}\exists 1)$. Therefore, suppose that $r_i(m) = r'_i(m)$ and i is nonfaulty in r'. We must show that $(\mathcal{R}^{cr}, r', m) \models \neg C^{\boxdot}_{\mathcal{N}\wedge \mathcal{Z}^{\Lambda,1}}\exists 1$. Since $(\mathcal{R}^{cr}, r', m) \models i \in \mathcal{N} \wedge B_i^{\mathcal{N}}\exists 0$, it certainly suffices to show that

$$\mathcal{R}^{cr} \models (i \in \mathcal{N} \wedge B_i^{\mathcal{N}}\exists 0) \Rightarrow \neg C^{\boxdot}_{\mathcal{N}\wedge \mathcal{Z}^{\Lambda,1}}\exists 1.$$

To show this, we prove by induction on k that for all runs r' of $\mathcal{R}^{cr}$ and processors i that are nonfaulty in r', if $(\mathcal{R}^{cr}, r', k) \models B_i^{\mathcal{N}}\exists 0$, then there is a point $(\hat{r}, k)$ that is $(\mathcal{N} \wedge B^{\mathcal{N}}\exists 0)$-$\boxdot$-reachable from (r', k) such that $(\mathcal{R}^{cr}, \hat{r}, k) \models \neg\exists 1$.

Suppose that $k = 0$. Since i does not believe it is faulty, $B_i^{\mathcal{N}}\exists 0$ holds only if i's initial value is 0. Let $\hat{r}$ be the run where all processors have initial values 0 and no processor fails. Clearly, $(\hat{r}, 0)$ has the desired properties.

For the inductive step, let $k > 0$ and assume that the claim has been shown for all $k' < k$. If $(\mathcal{R}^{cr}, r', k') \models B_i^{\mathcal{N}}\exists 0$ for some time $k' < k$, then the point (r', k') is clearly $(\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1})$-$\boxdot$-reachable from (r', k), and the claim follows from the induction hypothesis for (r', k') and the transitivity of reachability.

Now suppose that $(\mathcal{R}^{cr}, r', k') \not\models B_i^{\mathcal{N}}\exists 0$ for all $k' < k$. Since $(\mathcal{R}^{cr}, r', k) \models B_i^{\mathcal{N}}\exists 0$, i must have received a value of 0 in one of the messages sent to it in round k, say, from processor j. Since we are in the crash failure mode, if processor i receives a round k message from j, then all other processors received messages from j in all rounds preceding round k. Thus, i does not know at the point (r', k) that j is faulty. Hence, there must be a run r'' in which both i and j are nonfaulty such that $r'_i(k) = r''_i(k)$ and $r'_j(k-1) = r''_j(k-1)$. It follows that $(\mathcal{R}^{cr}, r'', k-1) \models (j \in \mathcal{N}) \wedge B_j^{\mathcal{N}}\exists 0$. Moreover, by construction, $(r'', k-1)$ is $(\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1})$-$\boxdot$-reachable from (r', k) (since $\mathcal{Z}_j^{\Lambda,1} = B_j^{\mathcal{N}}\exists 0$). The claim now follows from the inductive hypothesis for $k-1$ (with respect to r'' and j), and (as before) from the transitivity of reachability. ∎

We now consider $\mathcal{O}^{\Lambda,2}$.

LEMMA A.2. *In* $\mathcal{R}^{cr}$, $\mathcal{O}_i^{\Lambda,2} = B_i^{\mathcal{N}}((\mathcal{N} \wedge \mathcal{Z}^{cr}) = \emptyset)$.

Proof. Recall that $\mathcal{O}_i^{\Lambda,2} = B_i^{\mathcal{N}}(\exists 1 \wedge C^{\boxdot}_{\mathcal{N}\wedge \mathcal{Z}^{\Lambda,1}}\exists 1)$. Observe that $\mathcal{R}^{cr} \models C^{\boxdot}_{\mathcal{N}\wedge \mathcal{Z}^{\Lambda,1}}\exists 1 \Leftrightarrow \boxdot((\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}) = \emptyset)$. The $\Leftarrow$ direction is immediate, since $\boxdot(\mathcal{S} = \emptyset) \Rightarrow C^{\boxdot}_{\mathcal{S}}\varphi$ is valid for any nonrigid set $\mathcal{S}$ and formula φ. The proof of Lemma A.1 shows that $\mathcal{R}^{cr} \models C^{\boxdot}_{\mathcal{N}\wedge \mathcal{Z}^{\Lambda,1}}\exists 1 \Rightarrow ((\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}) = \emptyset)$. It is immediate that $\mathcal{R}^{cr} \models \boxdot C^{\boxdot}_{\mathcal{N}\wedge \mathcal{Z}^{\Lambda,1}}\exists 1 \Rightarrow \boxdot((\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}) = \emptyset)$. Since $C^{\boxdot}_{\mathcal{S}}\varphi \Rightarrow \boxdot C^{\boxdot}_{\mathcal{S}}\varphi$ is valid for all nonrigid sets $\mathcal{S}$ and formulas φ (Lemma 3.5), the result follows.

To complete the proof it suffices to show that

$$\mathcal{R}^{cr} \models B_i^{\mathcal{N}}(\exists 1 \wedge \boxdot((\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}) = \emptyset)) \Leftrightarrow B_i^{\mathcal{N}}((\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}) = \emptyset).$$

Setting $\psi = ((\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}) = \emptyset)$, this claim has the form

$$\mathcal{R}^{cr} \models B_i^{\mathcal{N}}(\exists 1 \wedge \boxdot \psi) \Leftrightarrow B_i^{\mathcal{N}} \psi.$$

The $\Rightarrow$ direction is straightforward, following from the validity $\models \boxdot \psi \Rightarrow \psi$ and the monotonicity of $B_i^{\mathcal{N}}$. The other direction uses properties of the crash failure mode.

Assume that i is nonfaulty and that $(\mathcal{R}^{cr}, r, m) \models B_i^{\mathcal{N}}((\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}) = \emptyset)$. Since $\mathcal{Z}_i^{\Lambda,1} = B_i^{\mathcal{N}} \exists 0$, this clearly implies that $(\mathcal{R}^{cr}, r, m) \models \neg B_i^{\mathcal{N}} \exists 0$, and hence i's own initial value could not have been 0; thus, $B_i^{\mathcal{N}} \exists 1$ holds. It remains to show that $(\mathcal{R}^{cr}, r, m) \models B_i^{\mathcal{N}} \boxdot \psi$. Therefore, suppose $r_i(m) = r'_i(m)$ and i is nonfaulty in both r and r'. Note that $(\mathcal{R}^{cr}, r', m) \models B_i^{\mathcal{N}} \psi$. We must show that $(\mathcal{R}^{cr}, r', m) \models \boxdot \psi$. Clearly $(\mathcal{R}^{cr}, r', m') \models \psi$ for $m' < m$, for if a nonfaulty processor j believed $\exists 0$ at a time $m' < m$, this fact would have appeared in j's message to i in round $m' + 1 \leq m$, and hence i would already know about the 0 at time m in r', contradicting the fact that $(\mathcal{R}^{cr}, r', m) \models \psi$. Since $(\mathcal{R}^{cr}, r', m) \models B_i^{\mathcal{N}} \psi$ and $i \in \mathcal{N}$, it follows that $(\mathcal{R}^{cr}, r', m) \models \psi$. Notice that, since we are in the crash failure mode, a processor that is known by i to be faulty at time m cannot send messages after round m. Moreover, for i to believe ψ at (r', m), it must be the case that no processor not known by i to be faulty knows $\exists 0$ at (r', m). (The formal proof of this is identical to that of the proof of Theorem 5 in [5].) It immediately follows that, because we are in the crash failure mode, no nonfaulty processor will know $\exists 0$ at any later time $m' > m$ in r'. □

THEOREM 6.2. *In the crash failure mode, the same decisions are made by nonfaulty processors at corresponding points of the protocols* $P0_{\text{opt}}$ *and* $F^{\Lambda,2}$. *Thus, both* $F^{\Lambda,2}$ *and* $P0_{\text{opt}}$ *are optimal EBA protocols for the crash failure mode.*

Proof. Recall that information about the existence of a value of 0 and about the identity of processors that started out with 1 are forwarded in $P0_{\text{opt}}$ as fast as in a full-information protocol. Moreover, in $P0_{\text{opt}}$ every processor sends a message to all other processors in every round. As a result, a straightforward inductive argument shows that for every pair of corresponding runs r of $\mathcal{R}^{cr}_{P0_{\text{opt}}}$ and r' of $\mathcal{R}^{cr}_{FL^2}$, every processor i nonfaulty in these runs, and every time $m \geq 0$, we have that (1) $B_i^{\mathcal{N}} \exists 0$ holds at (r, m) exactly if it holds at (r', m), (2) $B_i^{\mathcal{N}} \neg \exists 0$ holds at (r, m) exactly if it holds at (r', m), and (3) i receives messages from the same set of processors in round m of r and in round m of r'.

Since in both protocols a nonfaulty processor i decides 0 exactly when $B_i^{\mathcal{N}} \exists 0$ first holds, it follows that decisions on 0 take place at corresponding points of the two systems. To complete the proof, we need to show that nonfaulty processors decide 1 at corresponding points of the two systems as well. Notice that the condition $\mathcal{O}_i^{\Lambda,2} = B_i^{\mathcal{N}}((\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}) = \emptyset)$ holds exactly if i knows that no nonfaulty processor can know of a value of 0. It remains to show that this holds at a point of $\mathcal{R}^{cr}_{F^{\Lambda,2}}$ exactly if one of the conditions (a) and (b) defining the decision on 1 in $P0_{\text{opt}}$ holds in the corresponding point of $\mathcal{R}^{cr}_{P0_{\text{opt}}}$.

We first argue that if the nonfaulty processor i does not decide 1 at the point (r, m) of $\mathcal{R}^{cr}_{P0_{\text{opt}}}$, then it does not do so in the corresponding point (r', m) of $\mathcal{R}^{cr}_{F^{\Lambda,2}}$. The case $m = 0$ is straightforward, since processor i has no information about values of other processors. Thus, it must consider it possible that some nonfaulty processor i_1 has initial value 0, so $\mathcal{O}_i^{\Lambda,2}$ cannot hold at $(r', 0)$ (since $\mathcal{Z}_i^{\Lambda,1} = B_i^{\mathcal{N}} \exists 0$). Now suppose that $m \geq 1$. Notice that if neither (a) nor (b) holds for i at all points (r, m') with $m' \leq m$, then there is a sequence $i_1, i_2, \ldots, i_m$ of processors such that, for all $k < m$, in round k processor i_k crashes and sends no messages to processors that survive round k, except possibly to i_{k+1}. In addition, processor i_m crashes in round m without sending

a message to i. It follows that there is a run r'' in which (i) i_1 has initial value 0, (ii) for all $k < m$ we have that i_k sends a message only to i_{k+1} in round k, (iii) the same processors are nonfaulty in r and in r'', (iv) $r_j(k) = r''_j(k)$ for all $k < m$ and all processors j nonfaulty in r (and hence also in r''), and finally (v) i_m sends a message in round m of r'' to all nonfaulty processors $j' \neq i$. Thus, $r''_i(m) = r_i(m)$ and at (r'', m) there are nonfaulty processors that know $\exists 0$. Since r' is a run of a full-information protocol in which the same processors are nonfaulty as in r, it follows that $\mathcal{O}_i^{\Lambda,2}$ will not hold at (r', m) as well, so i does not decide 1 at (r', m).

To complete the proof, we argue that if i decides 1 at the point (r, m) of $P0_{\mathrm{opt}}$, then it also does so at the corresponding point (r', m) of $F^{\Lambda,2}$. By fact (1) above, if condition (a) holds, so that i knows at (r, m) that all initial values were 1, then it knows this fact at (r', m) as well; as a result, i knows nobody can know $\exists 0$, so $\mathcal{O}_i^{\Lambda,2}$ holds.

Suppose that condition (b) holds at (r, m); we need to show that in (r', m) process i believes that $\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1} = \emptyset$. Since condition (b) holds at (r, m), then i does not know $\exists 0$ at (r, m), and i received messages from the same set G of processors in rounds $m-1$ and m of r. By facts (1) and (3) above, the same is true for r' as well. In the crash failure mode, a processor whose round $m-1$ message to i is not delivered is definitely silent from round m on. Hence, no processor other than those in G sends (or receives) messages in round m of r'. Since $F^{\Lambda,2}$ is a full-information protocol, it follows that if the set of messages sent by the processors in G in round m does not contain information about the existence of a value of 0, then nobody knows $\exists 0$ at time (r', m). Finally, by assumption, processor i receives all messages from processors in G in round m and still does not know that $\exists 0$ holds there. We conclude that $\mathcal{O}_i^{\Lambda,2}$ holds at (r', m), and we are done. □

We next want to prove that in the omission failure mode, $F^{\Lambda,2}$ does not hold. We first need to get some insight into $\mathcal{Z}^{\Lambda,1}$ in the case of omission failures. The following is a variant of Lemma A.1 modified to suit the omission failure model.

LEMMA A.3. *Suppose that $n \geq t+2$, r is a run of $\mathcal{R}^{om}$ in which fewer than t processors fail, and i is nonfaulty in r. Then for all times $m \geq 0$ we have that $(\mathcal{R}^{om}, r, m) \models B_i^{\mathcal{N}} \exists 0 \Rightarrow \neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}} \exists 1$.*

Proof. We proceed by induction on k to show that if k is the first time in r such that $(\mathcal{R}^{om}, r, k) \models B_i^{\mathcal{N}} \exists 0$, then $(\mathcal{R}^{om}, r, k) \models \neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}} \exists 1$. This suffices since if $\neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}} \exists 1$ is true at (r, k), it is true at (r, m) for all m by part (g) of Lemma 3.5. If $k = 0$, it must be the case that i has initial value 0, and hence its state at $(r, 0)$ is the same as at $(r', 0)$, where r' is the run in which no processor started with initial value 1 and all processors are nonfaulty. Since $\exists 1$ does not hold at $(r', 0)$ and i is nonfaulty at both $(r, 0)$ and $(r', 0)$, then by Proposition 3.3 it follows that $(\mathcal{R}^{om}, r, 0) \models \neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}} \exists 1$.

Now suppose that $k > 1$ and the induction hypothesis holds for $k-1$. Then i must have received a 0 from some processor j in round k of r. If i does not know that j is faulty, then let r' be a run with the same failure pattern as r, except that processor j is nonfaulty. (In particular, $r' = r$ if j is nonfaulty in r.) Since $(\mathcal{R}^{om}, r', k') \models B_j^{\mathcal{N}} \exists 0$ for some $k' < k$, by the induction hypothesis $(\mathcal{R}^{om}, r', k') \models \neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}} \exists 1$. The claim follows since (r, k) is $(\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1})$-$\boxdot$-reachable from (r', k'). If i does consider j to be faulty at (r, k), consider a run r' that is identical to r up to time k, except that there is a processor j'' faulty in r' that fails for the first time in round k of r and sends messages to all processors in round k, except some nonfaulty processor $j' \neq i$. Note that this means that $r_i(k) = r'_i(k)$. (Such processors j' and j'' exist because,

by assumption, $n \geq t+2$, and less than t processors fail in r.) Finally, consider a run r'' which is identical to r' up to time k, except that whichever processor sent j a message saying $\exists 0$ in r at round $k-1$ also sends it to j', and at round k, and all processors send the same messages in r' and r'', except that j' sends i a message saying $\exists 0$. Note that $r'_j(k) = r''_j(k)$. Now, by construction, i learns about $\exists 0$ in r'' from a processor which it does not know to be faulty. Thus, by the earlier argument, $(\mathcal{R}^{om}, r'', k) \models \neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}} \exists 1$. The induction hypothesis carries us through as above, and we are done. □

PROPOSITION 6.3. *If $t > 1$ and $n \geq t+2$, then there are runs of $F^{\Lambda,2}$ in $\mathcal{R}^{om}$ in which the nonfaulty processors do not decide.*

Proof. Consider the run r where all the processors start with 1, processor 1 is faulty and never sends messages to any processor, and no other processors fail. Clearly, the weak validity condition implies that any nonfaulty processor which decides in r must decide 1. We now show that no nonfaulty processor can ever decide 1 in r. Assume that a nonfaulty processor i decides 1 at (r, m) for some m. Then, by definition, $\mathcal{O}^2_i$ holds at (r, m). Let r' be a run of R^{om} in which processor 1 is the only faulty processor and where the first m rounds of r' differ from those of r only in the following two ways: (a) processor 1 has initial value 0, and (b) exactly one message sent by processor 1 is delivered in r'; it is a message sent in round m to some nonfaulty processor $j \neq i$. Clearly, $r_i(m) = r'_i(m)$. It follows that $\mathcal{O}^2_i$, which depends only on i's local state, holds at (r', m) as well. By definition of $\mathcal{O}^2_i$, we thus have that $(\mathcal{R}^{om}, r', m) \models B^{\mathcal{N}}_i C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}} \exists 1$. Since i is nonfaulty in r', we have that

$$(R^{om}, r', m) \models C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}} \exists 1.$$

Notice, however, that in r' the nonfaulty processor $j \neq i$ receives a message reporting a value of 0 from processor 1 in round m. As a result, we have that $(R^{om}, r', m) \models B^{\mathcal{N}}_j \exists 0$. Applying Lemma A.3 with respect to r' and j now yields $(R^{om}, r', m) \models \neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^{\Lambda,1}} \exists 1$, giving us a contradiction. □

PROPOSITION 6.4. *In a run r of FIP($\mathcal{Z}^0, \mathcal{O}^0$) in the omission failure mode where f processors actually fail, all nonfaulty processors decide by time $f+1$.*

Proof. Let $F = FIP(\mathcal{Z}^0, \mathcal{O}^0)$. Suppose that r is a run in $\mathcal{R}^{om}_F$ in which f processors fail. Then, for each nonfaulty processor i, there is a round $m \leq f+1$ such that the only processors from which i does not receive a message in round m are ones that did not send it a message in some earlier round. Since a nonfaulty processor sends its state to everybody at each round, if processor j does not send a message to i in round $m' < m$, in round m (in fact, in all rounds between m' and m) i tells all processors that j is faulty. Thus, for each such j, we have

$$(\mathcal{R}^{om}_F, r, m) \models B_i(E_{\mathcal{N}}(j \notin \mathcal{N})).$$

We claim that $(\mathcal{R}^{om}_F, r, m) \models B^{\mathcal{N}}_i \exists 0^* \vee B^{\mathcal{N}}_i \neg \exists 0^*$, so that i decides at (r, m). Clearly, if i receives a message in round m from some processor j that is not known by i to be faulty which implies $\exists 0^*$, then $(\mathcal{R}^{om}_F, r, m) \models B^{\mathcal{N}}_i \exists 0^*$, and i can decide 0. Otherwise, we claim that $(\mathcal{R}^{om}_F, r, m) \models B^{\mathcal{N}}_i \neg \exists 0^*$. Suppose by way of contradiction that there exists a run r' such that $r'_i(m) = r_i(m)$, i is nonfaulty in r', and $(\mathcal{R}^{om}_F, r', m) \models \exists 0^*$. Thus, there must be a 0-chain in r' ending with some nonfaulty processor j at some time $m' \leq m$. Thus, j hears $\exists 0^*$ at some round $m' \leq m$. If $m' < m$, since j is nonfaulty in r', it will tell i $\exists 0^*$ in round $m'+1$ of r', so there will be a 0-chain ending with i at $(r', m'+1)$. Thus, i decides 0 at $(r', m'+1)$. Since $r_i(m) = r'_i(m)$ and F is a full-information protocol, we must have $r_i(m'+1) = r'_i(m'+1)$, and i decides 0

at $(r, m'+1)$, contradicting our assumption. Therefore, suppose that j hears $\exists 0^*$ in round m from j'. Thus, j considers j' to be nonfaulty at (r', m). However, this means that i must consider j' to be nonfaulty at $(r', m-1)$ (and hence at $(r, m-1)$), since otherwise i would tell j that j' was faulty in round m of r'. By choice of (r, m), i must also hear from j' in round m of r. Since $r_i(m) = r'_i(m)$, i also hears from j' in round m of r' and gets the same message in both r and r'. Again, this means that i hears $\exists 0^*$ in r, a contradiction. □

PROPOSITION 6.6. *F^* is an optimal EBA in the omission failure mode that dominates FIP($\mathcal{Z}^0, One^0$).*

Proof. Applying the first step of our construction, optimizing the decision on 1, given the rule in $F(\mathcal{Z}^0, \mathcal{O}^0)$ for deciding 0, we get

$$\mathcal{Z}_i^1 = B_i^{\mathcal{N}}(\exists 0 \wedge \neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^0} \exists 1) \text{ and}$$
$$\mathcal{O}_i^1 = B_i^{\mathcal{N}}(\exists 1 \wedge C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^0} \exists 1).$$

We claim that $\mathcal{Z}^1 = \mathcal{Z}^1$ and $\mathcal{O}^1 = \mathcal{O}^0$. This follows from the next two lemmas.

LEMMA A.4. *Let F be any full-information protocol. Then*

$$\mathcal{R}_F^{om} \models C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^0} \exists 1 \Leftrightarrow \boxdot(\mathcal{N} \wedge \mathcal{Z}^0) = \emptyset.$$

Proof. The "if" direction follows immediately from the definition, so we prove the "only if" direction. Assume that $(\mathcal{R}_F^{om}, r, m) \models \neg \boxdot(\mathcal{N} \wedge \mathcal{Z}^0) = \emptyset$. Then there is a first time $l = l(r)$ at which we have $(\mathcal{R}_F^{om}, r, l(r)) \models (\mathcal{N} \wedge \mathcal{Z}^0) \neq \emptyset$. We prove by induction on $l(r)$ that $C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^0} \exists 1$ does not hold in r. If $l(r) = 0$, since $\mathcal{Z}_i^0 = B_i^{\mathcal{N}} \exists 0^*$, it must be the case that all the nonfaulty processors in r have initial value 0. Thus, all the nonfaulty processors in r initially consider it possible that $\neg \exists 1$ holds; the result follows immediately.

Now suppose that $l(r) > 0$ and the induction hypothesis holds for $l(r)-1$. Suppose $B_i^{\mathcal{N}} \exists 0^*$ holds at $(r, l(r))$ for some nonfaulty processor i. Then there must be some processor j that is not known to i as faulty at (r, l) that tells i $B_j^{\mathcal{N}} \exists 0^*$ in round l of r. Let r' be the run with the same failure pattern and initial states as r, except that j is nonfaulty in r'. It is easy to see that $r_i(l(r)) = r'_i(l(r))$. However, $l(r') = l(r) - 1$, and hence by the induction hypothesis $C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^0} \exists 1$ does not hold in r'. By Proposition 3.3, it follows that $C^{\boxdot}_{\mathcal{N} \wedge B^{\mathcal{N}} \exists 0^*} \exists 1$ does not hold in r either, and we are done. □

Lemma A.4 implies that $\mathcal{Z}^1, \mathcal{O}^1$ reduce to

$$\mathcal{Z}_i^1 \equiv B_i^{\mathcal{N}}(\exists 0 \wedge \neg \boxdot((\mathcal{N} \wedge \mathcal{Z}^0) = \emptyset)) \text{ and}$$
$$\mathcal{O}_i^1 \equiv B_i^{\mathcal{N}}(\exists 1 \wedge \boxdot((\mathcal{N} \wedge \mathcal{Z}^0) = \emptyset)).$$

As the following lemma shows, even further simplification is possible.

LEMMA A.5. *Let F be any full-information protocol. Then*

$$\mathcal{R}_F^{om} \models B_i^{\mathcal{N}}(\exists 0 \wedge \neg \boxdot((\mathcal{N} \wedge \mathcal{Z}^0) = \emptyset)) \Leftrightarrow B_i^{\mathcal{N}}(\exists 0^*)$$

and

$$\mathcal{R}_F^{om} \models B_i^{\mathcal{N}}(\exists 1 \wedge \boxdot((\mathcal{N} \wedge \mathcal{Z}^0) = \emptyset)) \Leftrightarrow B_i^{\mathcal{N}}(\neg \exists 0^*).$$

Proof. We first need the following claim.

Claim. $\mathcal{R}_F^{om} \models (\mathcal{N} \wedge \mathcal{Z}^0) \neq \emptyset \Leftrightarrow \exists 0^*$.

Clearly, if $\exists 0^*$ holds at (r, m), then there is a 0-chain ending at some nonfaulty processor j at some point (r, m') with $m' \leq m$. Then $j \in (\mathcal{N} \wedge \mathcal{Z}^0)(r, m'')$ for all

$m'' \geq m'$. Conversely, if $j \in (\mathcal{N} \wedge \mathcal{Z}^0)(r,m)$, then $B_j^{\mathcal{N}}(\exists^* 0)$ holds at (r,m), and j is nonfaulty in r. Thus, $\exists^* 0$ holds at (r,m) too. This completes the proof of the claim.

For the first half of the lemma, $B_i^{\mathcal{N}}(\exists 0^*)$ clearly implies $B_i^{\mathcal{N}}(\exists 0)$. It is immediate from the claim that $\mathcal{R}_F^{om} \models B_i^{\mathcal{N}}(\exists 0^*) \Rightarrow B_i^{\mathcal{N}}(\neg\boxdot((\mathcal{N} \wedge \mathcal{Z}^0) = \emptyset))$. For the converse, the claim implies that $\mathcal{R}_F^{om} \models B_i^{\mathcal{N}}(\neg\boxdot((\mathcal{N} \wedge \mathcal{Z}^0) = \emptyset)) \Rightarrow B_i^{\mathcal{N}}(\neg\boxdot\neg\exists^* 0)$. However, it should be clear that the only way processor i can believe that $\exists 0^*$ holds at some point in a run r is if i currently believes $\exists 0^*$ holds.

For the second half of the lemma, note that it is immediate from the claim that $\mathcal{R}_F^{om} \models B_i^{\mathcal{N}}(\exists 1 \wedge \boxdot((\mathcal{N} \wedge \mathcal{Z}^0) = \emptyset)) \Rightarrow B_i^{\mathcal{N}}(\neg\exists 0^*)$. For the converse, suppose that $(\mathcal{R}_F^{om}, r, m) \models B_i^{\mathcal{N}}(\neg\exists 0^*)$. Clearly, this means that processor i must have an initial value of 1 in r, so $(\mathcal{R}_F^{om}, r, m) \models B_i^{\mathcal{N}}\exists 1$. To see that $(\mathcal{R}_F^{om}, r, m) \models B_i^{\mathcal{N}}(\boxdot((\mathcal{N} \wedge \mathcal{Z}^0) = \emptyset))$, suppose not. Then, by the claim, there is some time m' such that $(\mathcal{R}_F^{om}, r, m') \models B_i^{\mathcal{N}}(\exists 0^*)$. Since $(\mathcal{R}_F^{om}, r, m) \models B_i^{\mathcal{N}}(\neg\exists 0^*)$, we must have $m' > m$. However, this means that i believes at (r,m') there is a 0-chain with m' processors. Let i_m and i_{m+1} be the mth and $(m+1)$st processors in that chain. Processor i must believe at time m that i_m is faulty, otherwise we would not have $(\mathcal{R}_F^{om}, r, m) \models B_i^{\mathcal{N}}(\neg\exists 0^*)$. However, this means that i would tell i_{m+1} in round $m+1$ that i_m is faulty, contradicting the existence of the 0-chain. This completes the proof of the lemma. □

From Lemmas A.4 and A.5, we have that

$$\mathcal{Z}_i^1 \equiv B_i^{\mathcal{N}}\exists 0^* \text{ and}$$
$$\mathcal{O}_i^1 \equiv B_i^{\mathcal{N}}\neg\exists 0^*.$$

Now we apply the second step of our construction and obtain

$$\mathcal{Z}_i^2 = B_i^{\mathcal{N}}(\exists 0 \wedge C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^0}\exists 0) \text{ and}$$
$$\mathcal{O}_i^2 = B_i^{\mathcal{N}}(\exists 1 \wedge \neg C^{\boxdot}_{\mathcal{N} \wedge \mathcal{Z}^0}\exists 0).$$

Thus, $F^* = FIP(\mathcal{Z}^*, \mathcal{O}^*)$. By Theorem 5.2, F^* dominates $FIP(\mathcal{Z}^0, \mathcal{O}^0)$. □

EVASIVENESS OF SUBGRAPH CONTAINMENT AND RELATED PROPERTIES*

AMIT CHAKRABARTI†, SUBHASH KHOT†, AND YAOYUN SHI†

Abstract. We prove new results on evasiveness of monotone graph properties by extending the techniques of Kahn, Saks, and Sturtevant [*Combinatorica*, 4 (1984), pp. 297–306]. For the property of containing a subgraph isomorphic to a fixed graph, and a fairly large class of related n-vertex graph properties, we show evasiveness for an arithmetic progression of values of n. This implies a $\frac{1}{2}n^2 - O(n)$ lower bound on the decision tree complexity of these properties.

We prove that properties that are preserved under taking graph minors are evasive for all sufficiently large n. This greatly generalizes a theorem due to Best, van Emde Boas, and Lenstra [*A Sharpened Version of the Aanderaa–Rosenberg Conjecture*, Report ZW 30/74, Mathematisch Centrum, Amsterdam, The Netherlands, 1974] which states that planarity is evasive. We prove a similar result for bipartite subgraph containment.

1. Introduction.

Suppose we have an input graph G and are required to decide whether or not it has a certain (isomorphism invariant) property P. The graph is given by an oracle which answers queries of the form "Is (x, y) an edge of G?" A *decision tree algorithm* for P is a strategy that specifies a sequence of such queries to the oracle, where each query may depend upon the outcomes of the previous ones, terminating when sufficient information about G has been obtained to decide whether or not P holds for G. The *cost* of such a decision tree algorithm is the worst case number of queries that it makes. The *decision tree complexity* of P is the minimum cost of any decision tree algorithm for P.

Since an n-vertex graph has $\frac{1}{2}n(n-1)$ vertex pairs each of which could either be an edge or not, it is clear that any property of n-vertex graphs has complexity at most $\frac{1}{2}n(n-1)$. If a property happens to have complexity *exactly* $\frac{1}{2}n(n-1)$, then it is said to be *evasive*.[1]

A property of n-vertex graphs is said to be *monotone* if, starting with a graph which has the property, the addition of edges does not destroy the property. It is said to be *nontrivial* if there exists an n-vertex graph which has the property and one which does not. Connectedness, nonplanarity, non-k-colorability, and the property of containing a perfect matching are all examples of nontrivial monotone properties (for sufficiently large n). Rosenberg [7] attributes to Karp the following conjecture which, remarkably, remains open even today.

KARP CONJECTURE. *Every nontrivial monotone graph property is evasive.*

[1]Some authors call such properties "elusive" instead of evasive.

As a first step towards a resolution of this conjecture, Rivest and Vuillemin [6] proved that such properties have complexity at least $n^2/16$, thereby settling the Aanderaa–Rosenberg conjecture [7] of an $\Omega(n^2)$ complexity lower bound. The next big advance was the work of Kahn, Saks, and Sturtevant [4], where an interesting *topological approach* was used to prove that the Karp Conjecture holds whenever n is a prime power. Triesch [8, 9] used this approach, together with complicated algebraic constructions, to prove the evasiveness of some special classes of properties: specifically, these papers established evasiveness of graph properties that are always false when (i) the graph contains either a 3-cycle or a 4-cycle, and when (ii) the graph is not bipartite, respectively. Similar topological ideas were used by Yao [10] to prove a related result, namely, that nontrivial monotone *bipartite* graph properties are always evasive. Prior to the work of Kahn, Saks, and Sturtevant [4], adversarial strategies had been devised to prove the evasiveness, for all n, of certain specific graph properties (see, e.g., [1], [5], and [3, Ch. 8]). These strategies worked for the properties of acyclicity, connectedness, 2-connectedness, planarity, and simple variants on these. The most sophisticated of these adversarial strategies was one used by Bollobás [2] to prove the evasiveness of the property of containing a k-clique, for any k, $2 \leq k \leq n$.

Let H be any fixed graph. For n-vertex graphs, let Q_n^H denote the property of containing H as a subgraph (not necessarily as an induced subgraph). From the work of Bollobás [2] we know that Q_n^H is evasive for all n in the special case when H is a complete graph. This raises the natural question "What can we say about general H?"

In this paper, we study this question and some related ones, extending the topological approach of [4] to a fairly general class of graph properties. For each of these properties, we draw stronger inferences than [4]. Our main theorem is stated below.

THEOREM 1.1 (main theorem). *For any fixed graph H there exists an integer r_0 with the following property. Suppose $n = \sum_{i=1}^{r} q^{\alpha_i}$, where q is a prime power, $q \geq |H|$, each $\alpha_i \geq 1$, and $r \equiv 1 \pmod{r_0}$. Then Q_n^H is evasive.*

In order to understand the significance and strength of this theorem, consider the following statements (proven in this paper). Each of these statements follows either from the main theorem or from the techniques used in proving it.

1. For any graph H, there is an *arithmetic progression* such that Q_n^H is evasive for all n in the progression. Note that this is a much stronger inference than can be drawn by applying the results of [4].

2. The decision tree complexity of Q_n^H is $\frac{1}{2}n^2 - O(n)$. This bound does not follow from the results of [4].

3. If the graph H is *bipartite*, then Q_n^H is evasive for large enough n.

4. Any n-vertex nontrivial graph property that is preserved under taking graph minors is evasive for large enough n. This includes lots of very natural graph properties such as embeddability on any surface, outerplanarity, linkless embeddability in $\mathbf{R}^3$, the property of being a series-parallel graph, etc. Thus, our result generalizes a result of Best, van Emde Boas, and Lenstra [1], who show that planarity is evasive.

5. Any monotone boolean combination of the properties Q_n^H for several different graphs H still satisfies our main theorem. Thus, for example, if H_1, H_2, and H_3 are fixed graphs, then the property of containing as subgraph either H_1 or both of H_2 and H_3 is still evasive for those n which satisfy the conditions of the main theorem.

The remainder of the paper is organized as follows. In section 2 we review the basics of the topological approach of Kahn, Saks, and Sturtevant [4], establishing a connection between proving evasiveness of monotone properties and computing Euler

characteristics of abstract complexes. Then in section 3 we define a certain auxiliary property of graphs and prove a technical result (called the main lemma) about this property. This result is then used in section 4 to prove our main theorem. In section 5, we provide proofs for the additional results itemized above. We end with some concluding remarks in section 6.

Notations, terminology, and conventions. We call a graph *trivial* if it has no edges. Throughout this paper, all graphs will be assumed to be nontrivial, to have no loops, and to have no parallel edges. For a graph G, $|G|$ will denote the number of vertices in G, also called the *size* of G, $V(G)$ will denote its vertex set, $E(G)$ its edge set, $\mathrm{chr}(G)$ its chromatic number, and $\mathrm{clq}(G)$ the size of its largest clique. Graphs which occur as "input graphs" on which boolean properties are to be tested are assumed to always be vertex-labeled. All other graphs are assumed to be unlabeled, unless otherwise specified. When we speak of an "edge" in an input graph, we really mean an unordered vertex pair which may or may not be an edge.

2. Review of the topological approach. A property of m boolean variables $x_1, \ldots, x_m$ is a function $P : \{0,1\}^m \to \{0,1\}$; we say that the m-tuple $(x_1, \ldots, x_m)$ has (or satisfies) property P if $P(x_1, \ldots, x_m) = 1$. We say that P is *monotone* if for every m-tuple $(x_1, \ldots, x_m)$ that satisfies P, increasing any x_i from 0 to 1 yields an m-tuple that also satisfies P. We say that P is *evasive* if any decision tree algorithm for P has cost m. In our study of graph properties, the variables will be unordered pairs of vertices (i.e., potential edges of the graph) and P will be required to be invariant under relabelings of the graph.

Let $[m]$ denote the set $\{1, 2, \ldots, m\}$ and consider the collection of subsets $S \subseteq [m]$ with the following property: setting the variables indexed by S to 1 and those indexed by $[m] \setminus S$ to 0 yields an m-tuple which *does not satisfy* P. Since P is monotone, this collection of sets is downward closed under set inclusion. Recall that such a downward closed collection of sets is called an *abstract complex* and that the sets in this collection are called the *faces* of the complex. This observation motivates the following definition.

DEFINITION 2.1. *If P is monotone, then the abstract complex associated with P, denoted $\Delta(P)$, is defined as follows:*

$$\Delta(P) = \{S \subseteq [m] \,:\, \text{If } x_i = 1 \iff i \in S, \text{ then } (x_1, \ldots, x_m) \text{ does not satisfy } P\}.$$

Associated with an abstract complex Δ is a topologically important number called its *Euler characteristic* which is denoted $\chi(\Delta)$ and is defined as follows:

$$\chi(\Delta) = \sum_{\emptyset \neq F \in \Delta} (-1)^{|F|-1}. \tag{1}$$

Kahn, Saks, and Sturtevant [4] showed that nonevasiveness of P has topological consequences for $\Delta(P)$. The following theorem is implicit in their work.

THEOREM 2.2 (Kahn, Saks, and Sturtevant [4]). *If the monotone property P is not evasive, then $\chi(\Delta(P)) = 1$.*

For our result, we shall need to use a stronger theorem which can also be found in [4]. Let Δ be an abstract complex defined on $[m]$ and let Γ be a finite group which acts on the set $[m]$, preserving the faces of Δ. The action partitions $[m]$ into orbits, say $A_1, \ldots, A_k$. We use the action of Γ to define another abstract complex Δ_Γ on $[k]$ as follows:

$$\Delta_\Gamma = \left\{ S \subseteq [k] \,:\, \bigcup_{i \in S} A_i \in \Delta \right\}. \tag{2}$$

Sometimes, as is the case with our work, it is not easy to say much about $\Delta(P)$ for a monotone property P. However, it is possible to find some group Γ such that its action produces a more understandable abstract complex $(\Delta(P))_\Gamma$. The next theorem, the most important tool in [4], says that if Γ has certain rather restrictive properties, then nonevasiveness of P has a topological consequence on this new complex.

THEOREM 2.3 (Kahn, Saks, and Sturtevant [4]). *Suppose Γ has a normal subgroup Γ_1 which is such that $|\Gamma_1|$ is a prime power and the quotient group Γ/Γ_1 is cyclic. Then if P is not evasive, we have $\chi((\Delta(P))_\Gamma) = 1$.*

An application of this result leads to the following theorem which is the main result of [4].

THEOREM 2.4 (Kahn, Saks, and Sturtevant [4]). *Let P_n be a nontrivial monotone property of n-vertex graphs. If n is a prime power, then P_n is evasive.*

In order to derive Theorem 2.4 from Theorem 2.3, Kahn, Saks, and Sturtevant [4] construct a group which acts on the vertices of the input graph and thus, indirectly, on the edges. The number theoretic constraint on n is a consequence of the fact that this action depends crucially on being able to view the vertices of the graph as elements of a finite field. Our approach to proving evasiveness for more general n will be to devise a more sophisticated group action. Before we do so, we will need an auxiliary result which we shall establish in the next section.

3. The main lemma. Consider the following operation on a graph G. Let the vertices of G be colored, using *all* the colors in some set C, so that no two adjacent vertices get the same color. Let G' be a graph with vertex set C where two distinct vertices $c_1, c_2 \in C$ are adjacent iff the coloring assigns colors c_1 and c_2 to the end points of some edge in G. We shall call G' a *compression of graph G induced by coloring C*. If there exists a C which induces a compression G' of G, we shall write $G' \lhd G$.

DEFINITION 3.1. *A family $\mathcal{F}$ of graphs is said to be closed under compression if for graphs G, H such that $G \in \mathcal{F}$ and $H \lhd G$ we have $H \in \mathcal{F}$.*

Let $\mathcal{F}$ be a nonempty finite family of (nontrivial) graphs that is closed under compression. The property $P_n^{\mathcal{F}}$ that an input graph G on n vertices contains some member of $\mathcal{F}$ as a subgraph is clearly nontrivial, for n large enough, and monotone. Let $\Delta_n^{\mathcal{F}}$ be the abstract complex associated with this property and let $\chi_n = \chi(\Delta_n^{\mathcal{F}})$ be the Euler characteristic of this complex.

The purpose of this section is to establish that for any such family $\mathcal{F}$, we have $\chi_n \neq 1$ infinitely often. Let us set

$$T = 2^{2^t}, \text{ where } t \text{ is the smallest integer such that } T \geq \min_{F \in \mathcal{F}} |F|. \tag{3}$$

We shall prove the following lemma.

LEMMA 3.2 (main lemma). *If $n \equiv 1 \pmod{T-1}$, then $\chi_n \equiv 0 \pmod 2$.*

Since we care only about $\chi_n \bmod 2$, we can use the fact that addition and subtraction are equivalent mod 2 in (1) to get[2]

$$\chi_n \equiv \#\{G \,:\, G \text{ is nontrivial and does not satisfy } P_n^{\mathcal{F}}\} \pmod 2. \tag{4}$$

[2]Note that we are counting not graphs, but labeled graphs.

Consider n-vertex input graphs with vertices labeled with integers from 0 to $n-1$. For $n > T$, let us define a group action on such graphs as follows. For $a, b \in \{0, 1, 2, \ldots, T-1\}$ and a odd, let permutation $\phi_{a,b}$ be defined by mapping vertex i to vertex $(ai + b) \bmod T$ for $i \in \{0, 1, \ldots, T-1\}$. The other $n - T$ vertices are left fixed. It is routine to check that the set of all these permutations forms a group Φ under composition, thereby defining a group action on the labeled vertices. This action induces an action on graphs in the obvious manner, thereby partitioning the set of all labeled n-vertex graphs into orbits. Since the order $|\Phi|$ of the group is $T^2/2$, a power of 2, each orbit has size a power of 2. Therefore, (4) can be modified to

$$\chi_n \equiv \#\left\{G : \begin{array}{c} G \text{ is nontrivial, invariant under} \\ \Phi \text{ and does not satisfy } P_n^{\mathcal{F}} \end{array}\right\} \pmod 2. \tag{5}$$

The action of Φ on the vertices also induces an action on edges (or rather, on unordered pairs of distinct vertices, each of which may or may not be an edge), not to be confused with the action on labeled graphs mentioned above. Therefore the set of edges amongst vertices $0, 1, \ldots, T-1$ is partitioned into orbits. Since any odd integer is invertible mod T, we get 2^t orbits $E_0, E_1, \ldots, E_{2^t-1}$, where

$$E_i = \{(x, y) : 0 \le x < y < T, \;\; y - x = 2^i k \text{ for some odd number } k\} \; . \tag{6}$$

Let G be an invariant graph. From now on, let us refer to the vertices $0, 1, \ldots, T-1$ as *left vertices* and the rest as *right vertices*. Let G_{left} and G_{right} denote the subgraphs of G induced by the left and right vertices, respectively. By invariance of G, the set of right vertices adjacent to any left vertex is the same for each left vertex; let $\mathcal{R}(G)$ denote this set. Also, the set of edges $E(G_{\text{left}})$ is the union of a certain number of the orbits E_i; let $\text{orb}(G)$ denote this number. We shall show that whether or not G has the property $P_n^{\mathcal{F}}$ is completely determined once $G_{\text{right}}, \mathcal{R}(G)$ and this number $\text{orb}(G)$ are fixed; the specific G_{left} does not matter.

LEMMA 3.3. *For any invariant G, we have* $\text{chr}(G_{\text{left}}) = \text{clq}(G_{\text{left}}) = 2^{\text{orb}(G)}$.

Proof. Let $I \subseteq \{0, 1, \ldots, 2^t - 1\}$ be such that $E(G_{\text{left}}) = \bigcup_{i \in I} E_i$; then we have $|I| = \text{orb}(G)$. Consider two vertices x, y of G_{left}. If their binary representations agree on the bit positions indexed by I, then $x - y = \sum_{i \in I'} \pm 2^i$ for some set I' disjoint from I. By (6), this implies $(x, y) \notin E(G_{\text{left}})$. Therefore, the vertices of G_{left} can be partitioned into $2^{|I|}$ independent sets; thus $\text{chr}(G_{\text{left}}) \le 2^{\text{orb}(G)}$. On the other hand, if x, y are such that the bits in positions outside I are all zero, then $x - y = \sum_{i \in I''} \pm 2^i$ for some $I'' \subseteq I$, which by (6) implies that $(x, y) \in E(G_{\text{left}})$. Therefore, G_{left} has a clique of size $2^{|I|} = 2^{\text{orb}(G)}$. The lemma follows. □

LEMMA 3.4. *Let G_1, G_2 be two invariant n-vertex labeled graphs with $G_{1,\text{right}} = G_{2,\text{right}}$, $\mathcal{R}(G_1) = \mathcal{R}(G_2)$, and $\text{orb}(G_1) = \text{orb}(G_2)$. Then G_1 has property $P_n^{\mathcal{F}}$ iff G_2 does.*

Proof. Suppose G_1 has property $P_n^{\mathcal{F}}$; we shall show that G_2 does too. Suppose G_1 contains $F \in \mathcal{F}$ as a subgraph. We fix a particular occurrence of F within G_1 so that we can talk about $F_{\text{left}}, F_{\text{right}}$ and $\mathcal{R}(F) := \mathcal{R}(G_1) \cap V(F)$.

Using Lemma 3.3 and the hypothesis, we obtain $\text{chr}(F_{\text{left}}) \le \text{chr}(G_{1,\text{left}}) = \text{clq}(G_{2,\text{left}})$. Let $h = \text{chr}(F_{\text{left}})$; from the above inequality it is clear that $G_{2,\text{left}}$ contains K_h as a subgraph. Fix a particular occurrence of K_h and, starting with the graph F_{right}, connect each of the h left vertices in this occurrence to each vertex in $\mathcal{R}(F)$. Let F' be the resulting graph. Since $\mathcal{R}(F) \subseteq \mathcal{R}(G_1) = \mathcal{R}(G_2)$ and since F_{right} is a subgraph of $G_{1,\text{right}} = G_{2,\text{right}}$, it follows that F' is a subgraph of G_2.

Consider the following coloring of the graph F: we use h colors for its left vertices and color each right vertex with a distinct color, never using any of these h colors. Let $F'' \lhd F$ be the compression of F induced by this coloring. It is not hard to see that F'' is a subgraph of F' and therefore of G_2. Since $\mathcal{F}$ is closed under compression, $F'' \in \mathcal{F}$. Therefore G_2 has property $P_n^{\mathcal{F}}$. □

LEMMA 3.5. *For $n \geq T = 2^{2^t}$, we have $\chi_n \equiv \chi_{n-T+1} \pmod 2$.*

Proof. Let k be a fixed integer with $0 \leq k \leq 2^t$. Recall that the group action induced on the edges creates 2^t orbits. Consider the family of all n-vertex invariant graphs G with $\mathcal{R}(G)$ and G_{right} fixed, and $\text{orb}(G) = k$. By Lemma 3.4, either all graphs in this family have property $P_n^{\mathcal{F}}$ or none of them does. The size of this family is $\binom{2^t}{k}$ which is even if $k \neq 0$ and $k \neq 2^t$. If $k = 2^t$, G_{left} is a complete graph, and so G contains a clique of size T. From (3), we see that G has property $P_n^{\mathcal{F}}$. Therefore, by (5),

$$\chi_n \equiv \#\left\{ G : \begin{array}{c} \text{orb}(G) = 0 \text{ and } G \text{ is nontrivial,} \\ \text{invariant, and does not satisfy } P_n^{\mathcal{F}} \end{array} \right\} \pmod 2. \tag{7}$$

Suppose we take such a G with $\text{orb}(G) = 0$ and collapse all its left vertices into one vertex which we connect to every vertex in $\mathcal{R}(G)$ and to no others, thereby yielding a graph $\hat{G}$. This gives a bijection from n-vertex invariant graphs G with $\text{orb}(G) = 0$ to $(n - T + 1)$-vertex graphs.

It is clear that if $\hat{G}$ has property $P_{n-T+1}^{\mathcal{F}}$, then G has property $P_n^{\mathcal{F}}$. Now suppose G has property $P_n^{\mathcal{F}}$ and let $F \in \mathcal{F}$ be a subgraph of G. Since $\text{orb}(G) = 0$, the vertices in F_{left} form an independent set; thus we may color them all with one color and then color each remaining vertex of F with a distinct color different from the one just used. This coloring produces a compression $\hat{F} \lhd F$ which clearly is a subgraph of $\hat{G}$. Since $\mathcal{F}$ is closed under compression, we have $\hat{F} \in \mathcal{F}$ and so $\hat{G}$ has property $P_{n-T+1}^{\mathcal{F}}$. Thus our bijection respects the relevant property and this completes the proof. □

We now have all the pieces needed for the following proof.

Proof of Lemma 3.2. Set $n = T = 2^{2^t}$. The only way for an n-vertex graph to have $\text{orb}(G) = 0$ is for it to have no edges. Using (7), this implies $\chi_T \equiv 0 \pmod 2$. Invoking Lemma 3.5 completes the proof. □

4. Proof of the main theorem. We now return to proving Theorem 1.1. According to the theorem's hypotheses

$$n = \sum_{i=1}^{r} q^{\alpha_i}, \tag{8}$$

where q is a prime power, $q \geq |H|$, each $\alpha_i \geq 1$, and $r \equiv 1 \pmod{r_0}$. Our goal is to show that Q_n^H is evasive under these hypotheses for some choice of r_0.

The chief difficulty in applying the topological approach outlined in section 2 lies in having to construct a group action natural enough for the property under consideration and satisfying the stringent conditions on the underlying group necessary for Theorem 2.3 to apply. In this section we shall come up with a group action that allows us to "merge together" big clusters of vertices in our graph, in the process changing the property under consideration from Q_n^H to $P_r^{\mathcal{F}}$ for some family $\mathcal{F}$ of graphs, r being as in (8).

We partition the vertex set of our n-vertex graph into clusters $V_1, \ldots, V_r$, with $|V_i| = q^{\alpha_i}$, and identify vertices in V_i with elements of the finite field $\mathbb{F}_{q^{\alpha_i}}$. Define a

permutation group Γ on the vertices as follows:

$$\Gamma = \{\langle a, b_1, b_2, \ldots, b_r\rangle \ : \ a \in \mathbb{F}_q^*,\ b_i \in \mathbb{F}_{q^{\alpha_i}}\}\ , \tag{9}$$

where $\langle a, b_1, b_2, \ldots, b_r\rangle$ denotes a permutation which sends $x \in V_i = \mathbb{F}_{q^{\alpha_i}}$ to $ax + b_i \in V_i$. Let $\Gamma_1 = \{\langle 1, b_1, \ldots, b_r\rangle \ : \ b_i \in \mathbb{F}_{q^{\alpha_i}}\}$. It is easy to check that Γ_1 is a normal subgroup of Γ, $|\Gamma_1| = q^{\alpha_1+\cdots+\alpha_r}$, a prime power, and $\Gamma/\Gamma_1 \cong \mathbb{F}_q^*$, a cyclic group. Thus Γ satisfies the hypotheses of Theorem 2.3.

As in section 3, the action of Γ induces a group action on the edges and thus partitions the edges into orbits. Let $\mathcal{A}$ denote the set of these orbits and let $\Delta = \Delta(Q_n^H)$ denote the abstract complex associated with property Q_n^H. Define a complex Δ_Γ on $\mathcal{A}$ as in (2):

$$\Delta_\Gamma = \left\{\mathcal{D} \subseteq \mathcal{A} \ : \ \bigcup_{A\in\mathcal{D}} A \ \in \Delta\right\}. \tag{10}$$

Our intention is to show that the Euler characteristic $\chi(\Delta_\Gamma) \neq 1$. By Theorem 2.3, evasiveness of Q_n^H will follow. To this end, let us investigate what the faces of Δ_Γ look like. Call an edge an *intracluster edge* if both its end points lie in the same V_i for some i; otherwise, call the edge an *intercluster edge*.

LEMMA 4.1. *An orbit containing an intracluster edge is not contained in any face of* Δ_Γ.

Proof. Let $A \in \mathcal{A}$ be the orbit of the intracluster edge (u, v), $u, v \in V_i$. Then $A = \{(au + b, av + b) \ : \ b \in \mathbb{F}_{q^{\alpha_i}},\ a \in \mathbb{F}_q^*\}$. Set $w = v - u$. Then $(0, w) \in A$. Consider the set of vertices $X = \{wz \ : \ z \in \mathbb{F}_q\}$. For $0 \neq x \in X$ we clearly have $(0, x) \in A$. Thus for any pair of distinct vertices $x_1, x_2 \in X$, we have $(0, x_2 - x_1) \in A$, whence $(x_1, x_2) \in A$. So A contains all edges among vertices in X. Since $|X| = q \geq |H|$, the orbit A contains H as a subgraph. By definition, Δ cannot contain a face that includes A and so no face of Δ_Γ can contain A. ∎

If $u \in V_i, v \in V_j, i < j$, then the orbit of the intercluster edge (u, v) is the set E_{ij} of all edges between V_i and V_j. Let $\mathcal{E} = \{E_{ij} |\ i < j\} \subseteq \mathcal{A}$. From the preceding lemma and (10) it is clear that

$$\Delta_\Gamma = \left\{\mathcal{D} \subseteq \mathcal{E} \ : \ \bigcup_{A\in\mathcal{D}} A \ \in \Delta\right\}. \tag{11}$$

Let $\mathcal{D}$ be any subset of $\mathcal{E}$. Then $G_\mathcal{D} = \bigcup_{A\in\mathcal{D}} A$ is a graph on n vertices with no intracluster edges and such that if $i \neq j$, the edges between V_i and V_j are either all present or all absent. Define a graph $\hat{G}_\mathcal{D}$ on r vertices $v_1, \ldots, v_r$ such that (v_i, v_j) is an edge iff all edges between V_i, V_j are present in $G_\mathcal{D}$.

Let $\mathcal{T}_H$ denote the family of all graphs $\hat{H}$ such that $\hat{H} \lhd H$. It is easy to check that $\mathcal{T}_H$ is closed under compression (refer to Definition 3.1). The following lemma is simple to prove and connects this section with section 3.

LEMMA 4.2. *H is a subgraph of $G_\mathcal{D}$ iff there is a $\hat{H} \in \mathcal{T}_H$ such that $\hat{H}$ is a subgraph of $\hat{G}_\mathcal{D}$. In other words, $G_\mathcal{D}$ satisfies Q_n^H iff $\hat{G}_\mathcal{D}$ satisfies $P_r^{\mathcal{T}_H}$.*

Proof. Suppose H is a subgraph of $G_\mathcal{D}$. Consider the following coloring of $G_\mathcal{D}$: all vertices in a cluster are colored the same and no two clusters use the same color. This is a valid coloring since each cluster of vertices is an independent set. This coloring induces a coloring of H which in turn induces a compression $\hat{H} \lhd H$. Clearly, this $\hat{H}$ is a subgraph of $\hat{G}_\mathcal{D}$.

Now suppose $\hat{H} \lhd H$ is a subgraph of $\hat{G}_{\mathcal{D}}$. Consider the graph H_1 with vertices in $\cup_{i=1}^{r} V_i$ formed by taking all edges in E_{ij} whenever v_i and v_j are adjacent in $\hat{H}$. Since each $|V_i| \geq q \geq |H|$, a straightforward argument shows that H is a subgraph of H_1, and therefore of $G_{\mathcal{D}}$. □

We are ready to prove our main theorem.

Proof of Theorem 1.1. Suppose Q_n^H is not evasive. From Theorem 2.3, we have $\chi(\Delta_\Gamma) = 1$. If $r = 1$, there is only one cluster, so by Lemma 4.1 we have $\Delta_\Gamma = \{\emptyset\}$, whence $\chi(\Delta_\Gamma) = 0$, a contradiction. Therefore $r > 1$. Equation (11) and Lemma 4.2 imply that there is a one-to-one correspondence between faces of Δ_Γ and nontrivial r-vertex graphs not satisfying property $P_r^{\mathcal{T}_H}$. Hence the abstract complex Δ_Γ is the same as the abstract complex $\Delta_r^{\mathcal{T}_H}$ defined in section 3. It follows from the definition of compression that $\mathcal{T}_H$ contains the complete graph on $\mathrm{chr}(H)$ vertices and contains no smaller graph. Therefore, (3) yields $t = \lceil \lg \lg \mathrm{chr}(H) \rceil$. Setting $r_0 = 2^{2^t} - 1$ and applying Lemma 3.2 we have $\chi(\Delta_r^{\mathcal{T}_H}) \neq 1$ and so $\chi(\Delta_\Gamma) \neq 1$, a contradiction. □

5. Consequences and extensions. Our techniques enable us to prove certain results with "cleaner" statements than our main Theorem 1.1; we prove four such results below. The first two are simple corollaries of Theorem 1.1 while the other two can easily be proved using the machinery of its proof. Finally, we present an interesting generalization of our main theorem.

THEOREM 5.1. *For any graph H there exist infinitely many primes p with the following property: for all sufficiently large n divisible by p, the property Q_n^H is evasive.*

Remark. Note that this establishes the evasiveness of Q_n^H for an arithmetic progression of values of n.

Proof. Choose an integer t such that $T = 2^{2^t}$ is at least $|H|$. By Dirichlet's theorem there exist infinitely many primes p such that $p \equiv 2 \pmod{T-1}$. Fix one such $p \geq T$ and pick any $n \geq p^2(T-1)$ divisible by p. Now $p-1$ is relatively prime to $T-1$; therefore there is an integer x such that $x(p-1) \equiv n/p - 1 \pmod{T-1}$ and $0 \leq x < T-1$. From the lower bound on n we have $n/p - px > 0$. Therefore we can write

$$n = \sum_{i=1}^{x} p^2 + \sum_{i=1}^{n/p-px} p,$$

which is an expression of n as a sum of powers of p. The number of summands in this expression is $x + n/p - px \equiv 1 \pmod{T-1}$. Since $p \geq T \geq |H|$, we can apply Theorem 1.1 to conclude that Q_n^H is evasive. □

COROLLARY 5.2. *For any graph H there exists a constant $c = c(H)$ such that for all sufficiently large n, the decision tree complexity of Q_n^H is at least $\frac{1}{2}n^2 - cn$.*

THEOREM 5.3. *If the graph H is bipartite, then Q_n^H is evasive for all sufficiently large n.*

Proof. Since $\mathrm{chr}(H) = 2$, in the proof of Theorem 1.1, using the notation of that proof, we may take $t = 0$ which gives $r_0 = 1$. The condition $r \equiv 1 \pmod{r_0}$ is now trivially satisfied. The condition on n becomes a simple requirement that n be divisible by a prime power $q \geq |H|$. However, if n is sufficiently large, then it clearly satisfies this condition. □

THEOREM 5.4. *Let $\mathcal{M}$ be an infinite minor-closed family of graphs that does not include all graphs. For n-vertex graphs, let $R_n^{\mathcal{M}}$ be the property of being in $\mathcal{M}$. Then $R_n^{\mathcal{M}}$ is evasive for all sufficiently large n.*

Remark. Planarity was already known to be evasive [1]. This result is a major generalization. However, it is not the strongest possible generalization to "minor-closed" properties, since planarity has been proven evasive whenever n is large enough for it to be a nontrivial property (i.e., $n \geq 5$).

Proof. Let H be a graph not in $\mathcal{M}$ with minimum size and let $h = |H|$. Then H is a minor of both the complete graph K_h and the complete bipartite graph $K_{h,h}$; therefore no graph in $\mathcal{M}$ can contain either K_h or $K_{h,h}$ as a subgraph.

Suppose n is divisible by a prime power $q \geq h$, a condition that always holds if n is sufficiently large. Following the argument of section 4 we divide the labeled vertices of the candidate graph G into clusters of size q and consider the orbits of the edges created by the action of the group Γ described there. Let Δ be the abstract complex associated *with the negation*[3] *of* $R_n^{\mathcal{M}}$. An orbit containing an intracluster edge cannot be included in a face of Δ_Γ because its edges, if present, would create a K_q subgraph. An orbit containing an intercluster edge cannot be included either because its edges, if present, would create a $K_{q,q}$ subgraph. Thus, $\Delta_\Gamma = \{\emptyset\}$ and so $\chi(\Delta_\Gamma) = 0 \neq 1$. By Theorem 2.3, the negation of $R_n^{\mathcal{M}}$ is evasive and therefore so is $R_n^{\mathcal{M}}$. □

The next theorem generalizes our main theorem and can be proved essentially using the same argument as that for the main theorem.

THEOREM 5.5. *Let $f : \{0,1\}^k \to \{0,1\}$ be a nontrivial monotone boolean function and let $H_1, \ldots, H_k$ be arbitrary graphs. Define the composite property $Q_n = f(Q_n^{H_1}, \ldots, Q_n^{H_k})$. Then there exists an integer r_0 with the following property. Suppose $n = \sum_{i=1}^{r} q^{\alpha_i}$, where q is a prime power, $q \geq \max_{1 \leq i \leq k} |H_i|$, each $\alpha_i \geq 1$, and $r \equiv 1 \pmod{r_0}$. Then Q_n is evasive.*

Remark. This theorem shows, for instance, that properties like "G either contains H_1 as a subgraph or else contains both H_2 and H_3 as subgraphs" are evasive for several values of n. This theorem has corollaries similar to Theorem 5.1 and Corollary 5.2.

6. Concluding remarks. The major open question in the area of decision tree complexity of graph properties is to settle the Karp Conjecture. The pioneering work of Kahn, Saks, and Sturtevant [4] has given us a possible direction to follow in attempting to settle this conjecture. Our work takes steps in this direction by extending their topological approach to prove stronger results for a fairly general class of graph properties.

An obvious open question raised by our work is "How far can one enlarge the set of values of n for which our results hold?" We conjecture that in the notation of section 3, we have $\chi_n \neq 1$ for large enough n. If proved true, this conjecture would remove all number theoretic restrictions in the main theorem.

Acknowledgments. We would like to express our sincere thanks to Professors Sanjeev Arora, Bernard Chazelle, and Andrew Yao for their valuable comments and suggestions.

COMPRESSIBILITY AND RESOURCE BOUNDED MEASURE*

HARRY BUHRMAN† AND LUC LONGPRÉ‡

Abstract. We give a new definition of resource bounded measure based on compressibility of infinite binary strings. We prove that the new definition is equivalent to the one commonly used. This new characterization offers us a different way to look at resource bounded measure, shedding more light on the meaning of measure zero results and providing one more tool to prove such results. The main contribution of the paper is the new definition and the proofs leading to the equivalence result. We then show how this new characterization can be used to prove that the class of linear autoreducible sets has p- measure 0. We also prove that the class of sets that are truth-table reducible to a p-selective set has p-measure 0 and that the class of sets that Turing reduce to a subpolynomial dense set has p-measure 0. This strengthens various results.

Key words. resource bounded measure, Kolmogorov complexity, compressibility

1. Introduction.

While Lebesgue measure has been used in mathematics since the previous century, and while it has been used earlier this century to study randomness in infinite strings [19], its notable appearance in complexity theory is in the formalization of "random oracles." Bennett and Gill [5] showed, for example, that relative to a random oracle A, $\mathrm{P}^A \neq \mathrm{NP}^A$. The statement about the random oracle is formalized as follows: the class of sets A such that $\mathrm{P}^A = \mathrm{NP}^A$ has Lebesgue measure zero.

When dealing with uncountable classes, measure zero is an intuitively appealing concept to formalize the idea that sets having a certain property are rare. But the concept seems to fall apart when dealing with countable classes, since all of these have Lebesgue measure zero. For example, how would we formalize the statement "most recursive oracles separate P from NP"?

In order to formalize this kind of statement, Lutz introduced resource bounded measure [14]. A more useful definition based on resource bounded martingales appeared in [15]. With resource bounded measure, one is able to formally state results of the type "most languages in class $\mathcal{C}$ have property P." These notions turned out to be quite useful in complexity, as witnessed by a stream of results in recent years (for example, see [9, 10, 16, 18, 17, 3, 4, 1]).

In this paper, we offer a different definition of resource bounded measure, equivalent to that of Lutz in [15]. We say that a set is $t(n)$-compressible if its characteristic sequence can be compressed and uncompressed in time $t(n)$. The precise definition is given in section 4. A class of sets has p-measure zero if all the sets in the class are n^k-compressible for some fixed k. This new characterization has several advantages.

(i) This new characterization may allow more intuitive proofs of results about resource bounded measure.

(ii) A result claiming that a class of set does not have p-measure zero is usually seen as an abundance result. How should this abundance be interpreted? The new characterization explains in a precise way what is meant: the sets in the class cannot all be compressed with a fixed polynomial-time bound.

(iii) While the martingale characterization was not directly applicable to classes below E, Mayordomo [21] gave a definition applicable to PSPACE, and Allender and Strauss [1] gave a definition applicable to P and other subexponential classes. Further related work on this can be found in [24, 8]. Although similar technical problems arise with our definition, it may offer other alternatives for defining measures applicable to subexponential classes.

A corollary of the proof of equivalence is as follows: a class $\mathcal{C}$ has p-measure zero in E if and only if all the sets in $\mathcal{C}$ are n^k-compressible for some fixed k. The n^k-compressible sets form a proper hierarchy, and E is not included in any fixed level of that hierarchy. Moreover, if we define $\mathrm{Comp}(n^k)$ as the class of sets in E that are n^k-compressible, then $\mathrm{E} = \cup_k \mathrm{Comp}(n^k)$. So the abundance meaning can be understood as follows: a class of sets X has p-measure 0 in E if and only if $X \cap \mathrm{E}$ is included in a fixed level of that hierarchy, while the hierarchy is itself infinite.

It should be noted that equivalence between a classical constructive measure and a definition based on Kolmogorov complexity has been studied in the context of random sequences. Martin-Löf's definition of random sequences [19] based on constructive measure is equivalent to a subsequent definition using incompressibility in the sense of a version of prefix Kolmogorov complexity due to Levin [12]. See also Schnorr [22] for a similar theorem. We refer the reader to the book by Li and Vitányi [13] for a more detailed account.

There is also a way to define compressibility in the nonuniform context and prove that Lebesgue measure zero is equivalent to that kind of compressibility [11].

Next we will use the new characterization to prove the following results:

(i) The class of $c \cdot n$ autoreducible sets has p-measure 0.

(ii) The class of sets that are polynomial-time truth-table reducible to a p-selective set has p-measure 0. It follows immediately that there is no p-selective set that is hard for E under polynomial-time truth-table reductions.

(iii) The class of sets that are Turing reducible to a set with subpolynomial density has p-measure 0. This strengthens the results in [6].

2. Preliminaries. Let $\Sigma = \{0, 1\}$. Strings are elements of $\Sigma^*$and are denoted by lower case letters $x, y, u, v, \ldots$. Infinite strings are elements of Σ^∞ and are denoted by lower case Greek letters. The empty string is λ. For any string x, the length of a string is denoted by $|x|$, $x[i..j]$ is the substring of x from index i to index j inclusively, $x[i]$ stands for $x[i..i]$, $x = x[0..|x| - 1]$, and if $j < i$, then $x[i..j]$ is λ. For two strings x and y, $x \sqsubseteq y$ if y is an extension of x. Subsets of Σ^* are denoted by capital letters $A, B, C, S, \ldots$. The set $\Sigma^* - A$ is denoted by $\overline{A}$. The complement of a class of sets X is $X^c = \{A \subseteq \Sigma^* | A \notin X\}$. For a set A we use $A^{=n}(A^{\leq n})$ to denote the subset of all strings in A having length equal to n ($\leq n$, resp.). We use χ_A to denote the infinite binary string where bit i is 1 if and only if string $x_i \in A$, for a standard enumeration $\{x_i\}$ of finite binary strings. With any infinite binary string, we can associate a real between 0 and 1 through the natural binary expansion. This mapping is one-to-one except on multiples of powers of 2 (dyadic rationals or dyadic numbers). With each finite binary string x, we can associate an interval I_x

that corresponds to the set of all reals associated with possible infinite extensions of x. In this paper, intervals over the reals are half-open intervals, so I_x excludes its right boundary. For an interval I over the reals, $\mu(I)$ is the length of the interval. For any set A, the cardinality of A is denoted by $\|A\|$. We define C_w, the cylinder generated by w, as the class of languages $\{\alpha \in \Sigma^\infty | w \sqsubseteq \alpha\}$. We fix a pairing function $\lambda xy.\langle x, y\rangle$ that is computable in polynomial time from $\Sigma^* \times \Sigma^*$ to Σ^*. Without loss of generality, we assume that the pairing function respects the length of its arguments (i.e., $|x| + |y| \leq |\langle x, y\rangle| \leq 2(|x| + |y|)$). We assume that the reader is familiar with the standard Turing machine model. The class p is the class of all polynomials.

3. Resource bounded measure. We use the definition of resource bounded measure based on martingales.

Let $D = \{m2^{-n} | m, n \in N\}$ be the set of nonnegative dyadic rationals.

DEFINITION 1. *A* martingale *is a function $d : \Sigma^* \to D$ with the property that, for all $w \in \Sigma^*$,*

$$d(w) = \frac{d(w0) + d(w1)}{2}.$$

DEFINITION 2. *A martingale* succeeds *on language $A \subseteq \Sigma^*$ if*

$$\limsup_{n\to\infty} d(\chi_A[0..n-1]) = \infty.$$

A martingale d is p-computable, and we call it a p-martingale, if $d(w)$ can be computed in time polynomial in $|w|$.

The intuition behind this definition is a game where a player is trying to predict the next bit by looking at all the bits that have been produced so far. The player starts with an initial capital $d(\lambda)$ and can decide to bet an amount of money which is at most the current capital. If the predicted bit is correct, the capital increases by the amount bet, and if it's incorrect, the capital decreases by that same amount. The function d models the current capital of the betting strategy after having seen a finite binary string.

Lutz [15] defined a martingale to give a real value and required computations of the martingale to approximate the real value by using dyadic rationals. But, as shown independently by Mayordomo [21] and by Juedes and Lutz [10], defining the martingale directly with the dyadic rationals provides an equivalent definition of resource bounded measure. Moreover, without loss of generality, we may assume that $d(w)$ is a dyadic number $m2^{-n}$ such that $n < |w|$.

DEFINITION 3. *A class X of languages has p-measure 0, and we write $\mu_p(X) = 0$, if there is a p-martingale d that succeeds on every element of X.*

DEFINITION 4. *A class X of languages has p-measure 1, and we write $\mu_p(X) = 1$, if $\mu_p(X^c) = 0$.*

4. Compressibility. Compressibility of finite strings is usually defined using Kolmogorov complexity. There are various problems in defining compressibility of infinite strings in terms of the Kolmogorov compressibility of its prefixes, mainly because no string has all of its prefixes completely incompressible. We define compressibility of an infinite string by using another infinite string that can generate it, with the compressibility calculated as the amount of the prefix of the compressed string that is needed to reproduce a prefix of the uncompressed string. For the time bounded version, we also need that the compressed string can be efficiently computed, at least in some weak sense.

Results in this paper are in terms of p-measure, which is appropriate for studying abundance with respect to E. The obvious extension to p_2, the class of functions of the form $2^{\log^c n}$ and EXP also holds.

DEFINITION 5. *An infinite string $\omega \in \{0,1\}^\infty$ is f-compressible if $\exists \kappa \in \{0,1\}^\infty$ such that the following conditions hold.*

1. *(Uncompression) There is a Turing machine M that, given $\kappa[0..j]$, outputs a prefix $\omega[0..i]$ of ω in time at most $f(i+j)$, such that the value $i-j$ is not bounded by any constant.*

2. *(Compression) There is a Turing machine M' that, given $\omega[0..i]$, uses at most $f(i)$ time to output a finite number of strings, one of which is a prefix $\kappa[0..j']$ such that M, on input $\kappa[0..j']$, outputs a prefix of ω that is a proper extension of $\omega[0..i]$ consistent with ω.*

(Note: We could also add the restriction have that $i-j'$ is not bounded by any constant. By the composition of uncompression and compression, it would turn out to be an equivalent definition.)

We show in section 5 (Theorem 7) that

$$\mu_p(\mathcal{C}) = 0 \;\Rightarrow\; (\exists f \in p)(\forall A \in \mathcal{C})\;\; \chi_A \text{ is } f\text{-compressible},$$

and in section 6 (Theorem 9) that

$$(\exists f \in p)(\forall A \in \mathcal{C})\;\; \chi_A \text{ is } f\text{-compressible} \Rightarrow \mu_p(\mathcal{C}) = 0.$$

These two theorems together show that the definition of p-measure zero in terms of our compressibility definition is equivalent to that of Lutz in [15].

5. Measure zero implies compressibility. We have defined measure zero using basic martingales. We will need a few more properties of the martingales to prove that measure zero implies compressibility. The following shows that such special properties can be assumed without loss of generality.

LEMMA 6. *If $\mu_p(\mathcal{C}) = 0$, then there exists a p-martingale d that succeeds on every element of $\mathcal{C}$ and satisfies the following properties:*

1. $d(\lambda) = 1$,
2. *$d(x)$ is a dyadic number $m2^{-n}$ such that $n \le |x| + 4$,*
3. *$(\forall x, y)\ d(x)/4 \le d(xy)$, where y is a finite binary string,*
4. *$(\forall x, b)\ d(xb) \le (7/4)d(x)$, where b is a bit.*

Proof. Let d be a martingale witnessing that $\mu_p(\mathcal{C}) = 0$. Define a martingale d' in the following way. Given a finite string x, let $i_0 = -1$, and for $k \ge 1$, let i_k be the smallest integer, if it exists, such that

$$\frac{d(x[0..i_k])}{d(x[0..i_{k-1}])} \ge 2.$$

Define

$$\begin{aligned} d'(\lambda) &= 1, \\ d'(x) &= d'(x[0..i_k]) - 1/4 + (1/4)d(x)/d(x[0..i_k]), \\ &\qquad \text{where } k \text{ is the largest integer such that} \\ &\qquad x[0..i_k] \text{ is a proper prefix of } x. \end{aligned}$$

Informally, d' starts with \$1.00 on λ, and its betting strategy on successively longer prefixes of the characteristic function of a set A is to keep part of its capital

frozen and use the rest to bet in proportion with the d strategy. The amount of frozen capital is revised each time d has doubled its capital. At that time, all the capital is frozen except for \$0.25, which is kept for betting. Each time d is doubled, d' earns \$0.25. If d is successful on A, the doubling occurs infinitely often, so d' is unbounded as well, and is thus successful.

Although d' does not meet property 2 of the lemma, we show next that it meets stronger versions of properties 3 and 4:

(i) $(\forall x, y)\ (3/5)d'(x) \leq d'(xy)$, where y is a finite binary string,

(ii) $(\forall x, b)\ d'(xb) \leq (7/5)d'(x)$, where b is a bit.

To see this, let k_1 be the largest integer such that $xy[0..i_{k_1}]$ is a (not necessarily proper) prefix of xy, where indices i_k are defined as above. Similarly, let k_2 be the largest integer such that $x[0..i_{k_2}]$ is a (not necessarily proper) prefix of x. If $xy = xy[0..i_{k_1}]$, then the first equality below holds trivially. Otherwise, it holds by the definition of d'. A similar argument goes for the second equality:

$$\begin{aligned} d'(xy) &= d'(xy[0..i_{k_1}]) - 1/4 + (1/4)d(xy)/d(xy[0..i_{k_1}]), \\ d'(x) &= d'(xy[0..i_{k_2}]) - 1/4 + (1/4)d(x)/d(xy[0..i_{k_2}]). \end{aligned}$$

Now, notice that for any x, the function $f(k) = d(x[0..i_k])$ is monotonically increasing, so $d(x[0..i_{k_1}]) \geq 1$. Notice also that $d'(xy[0..i_{k_2}]) \leq d'(xy[0..i_{k_1}])$ because $i_{k_2} \leq i_{k_1}$ and by monotonicity. Finally, notice that $d(x)/d(x[0..i_{k_2}]) < 2$, because if it were ≥ 2, then k_2 would not, by our definition, be the largest of indices i_k. With these observations, we can derive

$$\begin{aligned} d'(xy) - (3/5)d'(x) &= d'(xy[0..i_{k_1}]) - 1/4 + (1/4)d(xy)/d(xy[0..i_{k_1}]) \\ &\quad -(3/5)d'(xy[0..i_{k_2}]) + 3/20 - (3/20)d(x)/d(x[0..i_{k_2}]) \\ &\geq d'(xy[0..i_{k_2}]) - 1/4 + (1/4)d(xy)/d(xy[0..i_{k_1}]) \\ &\quad -(3/5)d'(xy[0..i_{k_2}]) + 3/20 - (3/20)d(x)/d(x[0..i_{k_2}]) \\ &= (2/5)d'(xy[0..i_{k_2}]) - 1/4 + (1/4)d(xy)/d(xy[0..i_{k_1}]) \\ &\quad +3/20 - (3/20)d(x)/d(x[0..i_{k_2}]) \\ &\geq 2/5 - 1/4 + 0 + 3/20 - (3/20) * 2 \\ &= 0. \end{aligned}$$

The other property can be proved in a similar fashion. Let k_1 be the largest integer such that $x[0..i_{k_1}]$ is a (not necessarily proper) prefix of x. Then

$$\begin{aligned} d'(xb) &= d'(xb[0..i_{k_1}]) - 1/4 + d(xb)/4d(x[0..i_{k_1}]), \\ d'(x) &= d'(xb[0..i_{k_1}]) - 1/4 + d(x)/4d(x[0..i_{k_1}]), \end{aligned}$$

and we can conclude that

$$\begin{aligned} d'(xb) - (7/5)d'(x) &= d'(xb[0..i_{k_1}]) - (7/5)d'(xb[0..i_{k_1}]) - 1/4 + 7/20 \\ &\quad +d(xb)/4d(x[0..i_{k_1}]) - (7/20)d(x)/d(x[0..i_{k_1}]) \\ &\leq -(2/5)d'(xb[0..i_{k_1}]) + 1/10 + 2d(x)/4d(x[0..i_{k_1}]) \\ &\quad -(7/20)d(x)/d(x[0..i_{k_1}]) \\ &\leq -(2/5) + 1/10 + (3/20)d(x)/d(x[0..i_{k_1}]) \\ &\leq -(2/5) + 1/10 + 3/10 \\ &= 0. \end{aligned}$$

Now, define martingale d'' as follows. Define $d''(\lambda) = 1$. If $d'(x) > d'(\tilde{x})$, where $\tilde{x}$ is x where the last bit is flipped from 0 to 1 or from 1 to 0, then $d''(x)$ is the value $d'(x)$ approximated downwards to the closest dyadic number of the form $m2^{-n}$, where $n \leq |x| + 4$. Otherwise, it is approximated upwards. The loss of capital for d'' compared to d' is at most $2^{-|x|-4}$ when betting on x, which totals to at most $\Sigma_{i=1}^{\infty} 1/2^{i+4} = 1/16$ cumulatively. Also, because $d'(\lambda) = 1$ for all y, $d'(y) \geq 3/5$, so for all y, $(15/16)d'(y) \leq d''(y) \leq (17/16)d'(y)$. Combining this and the property of d' above, we get all properties 1, 2, 3, and 4 of the lemma. □

THEOREM 7. $\mu_p(\mathcal{C}) = 0 \Rightarrow (\exists f \in p)(\forall A \in \mathcal{C})$ χ_A *is* f*-compressible.*

Proof. Assume that $\mu_p(\mathcal{C}) = 0$ and let d be a p-martingale as in Lemma 6. Let $A \in \mathcal{C}$ and let $\omega = \chi_A$. If A is finite or cofinite, then χ_A is obviously f-compressible, so without loss of generality, assume A is neither finite nor cofinite. We need an infinite string κ to encode ω. We can interpret ω as the encoding of a real in the half-open interval $[0, 1)$. In the following arguments, all intervals have a boundary at dyadic numbers. Since we assume A is neither finite nor cofinite, ω is not the binary expansion of a dyadic number, so its binary expansion will never fall on the extremity of any interval. In a standard encoding, all infinite strings starting with 0 encode reals in the first half of the interval, and strings starting with 1 encode reals in the right half of the interval. We will create an encoding scheme that possibly moves this halfway border. If $d(0) > d(1)$, then the binary expansion of reals in an interval larger than $1/2$ will be used to encode reals between 0 and 0.5. Similarly, if $d(x0) > d(x1)$, then the size of the interval reserved to encode reals that extend $x0$ will be larger than that of extensions of $x1$. The idea is to keep an interval of reals to encode extensions such that the size of the interval is proportionally related to the current capital with the current betting strategy of the martingale. Intuitively, large intervals can be described with few bits, so a winning strategy will result in compression.

More formally, let g be a function from finite binary strings to half-open intervals in $[0, 1)$ defined as follows:

$$\begin{aligned} g(\lambda) &= [0, 1), \\ g(x0) &= \text{the left part of } g(x) \text{ of size } d(x0)/2^{|x0|}, \\ g(x1) &= g(x) - g(x0). \end{aligned}$$

The following lemma has a straightforward proof by induction on the length of the strings. The proof is omitted.

LEMMA 8. $\mu(g(x)) = d(x)/2^{|x|}$.

Since $g(xb)$ is a subinterval of $g(x)$ and since property 4 of Lemma 6 ensures that $\lim_{n\to\infty} \mu(g(\omega[0..n])) = 0$, an infinite sequence can be associated with the real r defined by $r = \lim_{n\to\infty} g(\omega[0..n])$. Since ω is not a dyadic number, r is not a dyadic number, and hence r has a unique binary expansion. Let κ be the binary expansion of r. We now have to show that κ is a valid compression of ω.

To generate $\omega[0..i]$ from $\kappa[0..j]$, simulate the martingale starting at λ on successively longer strings. Suppose we have generated the string x so far. If $g(x0)$ contains $I_{\kappa[0..j]}$, then append 0 to x. If $g(x1)$ contains $I_{\kappa[0..j]}$, then append 1 to x. Continue until $I_{\kappa[0..j]}$ is not contained in either of the intervals. At the end of this process, we have a string x such that $g(x)$ contains $I_{\kappa[0..j]}$. By the definition of κ, x is a prefix of ω, say $x = \omega[0..i]$.

To generate $\kappa[0..j]$ from $\omega[0..i]$, we compute the list of all possible strings that encode extensions of $\omega[0..i]0$ and of $\omega[0..i]1$. Let $I = g(\omega[0..i]0)$. Since $d(\omega[0..i]0)$ is a dyadic number $m2^{-n}$, where $n \leq |\omega[0..i]0| + 4 = i + 6$, and since $\mu(I) =$

$d(\omega[0..i]0)/2^{i+2}$, the borders of I can be expressed by dyadic numbers $m2^{-n}$, where $n \leq 2i+8$. The interval I can be covered exactly by a set of at most $2(2i+8)$ intervals each expressible as I_x for some x. This is done by starting from a point inside the interval which is expressible by a dyadic number $m2^{-n}$, where n is the smallest. Covering the part of I on the left of that point can be done with a set of at most $2i+8$ intervals because each interval chosen decreases in size by at least half and covers at least half of the remaining gap. Covering the part of I on the right of that point can be done with another set of at most $2i+8$ intervals. Interval $g(\omega[0..i]1)$ can be covered similarly. Output the set of all strings x such that I_x is one of the intervals needed for the above covering. All of them generate proper extensions of $\omega[0..i]$ via our uncompression algorithm, and one of them is a prefix of κ.

It remains to show that $i-j$ is not bounded by any constant, where i is the index of the last bit produced by the uncompression algorithm M on $\kappa[0..j]$. Select j such that M on $\kappa[0..j]$ produces $\omega[0..i]$ and such that M on $\kappa[0..j-1]$ produces a proper prefix of $\omega[0..i]$. Since M produces $\omega[0..i]$ on $\kappa[0..j]$, $g(\omega[0..i])$ includes $I_{\kappa[0..j]}$. Since M produces a proper prefix of $\omega[0..i]$ on $\kappa[0..j-1]$, $g(\omega[0..i])$ does not contain $I_{\kappa[0..j-1]}$. Interval $g(\omega[0..i])$ can be partitioned into 3 intervals: L, $I_{\kappa[0..j]}$, and R, where L (resp., R) corresponds to the reals in $g(\omega[0..i])$ that are smaller (resp., greater) than those in $I_{\kappa[0..j]}$. Assume that $\kappa[j]=0$. The case where $\kappa[j]=1$ is similar. Then, R is an interval included in $I_{\kappa[0..j-1]1}$ because $g(\omega[0..i])$ does not include $I_{\kappa[0..j-1]}$. So, $\mu(R) \leq \mu(\kappa[0..j])$. Because $g(\omega[0..i]0)$ intersects $I_{\kappa[0..j]}$, we can derive the following upper bound for the size of L:

$$\begin{aligned}
\mu(L) &\leq \mu(g(\omega[0..i]0)) \\
&= d(\omega[0..i]0)/2^{i+2} \\
&\leq (7/4)d(\omega[0..i])/2^{i+2} \\
&\leq 7d(\omega[0..i]1)/2^{i+2} \\
&= 7\mu(g(w[0..i]1)) \\
&\leq 7(\mu(I_{\kappa[0..j]}) + \mu(R)), \\
\mu(g(\omega[0..i])) &= \mu(L) + \mu(I_{\kappa[0..j]}) + \mu(R) \\
&\leq 8(\mu(I_{\kappa[0..j]}) + \mu(R)) \\
&\leq 16\mu(I_{\kappa[0..j]}).
\end{aligned}$$

But $\mu(g(\omega[0..i])) = d(\omega[0..i])/2^{i+1}$ and $\mu(I_{\kappa[0..j]}) = 1/2^{j+1}$, so we get

$$\begin{aligned}
d(\omega[0..i])/2^{i+1} &\leq 16/2^{j+1}, \\
d(\omega[0..i]) &\leq 2^{i-j+4}, \\
\log(d(\omega[0..i])) - 4 &\leq i-j.
\end{aligned}$$

Since the martingale is successful, $d(\omega[0..i])$ is unbounded and hence so is $i-j$. □

6. Compressibility implies measure zero. We now need to show the opposite implication to show the equivalence between compressibility and measure zero.

THEOREM 9. $(\exists f \in p)(\forall A \in \mathcal{C})$ χ_A *is* f*-compressible* $\Rightarrow \mu_p(\mathcal{C}) = 0$.

Proof. Let f be bounded by $n^k + k$, and assume that for each $A \in \mathcal{C}$, χ_A is f-compressible. For each $A \in \mathcal{C}$, we build below a martingale that succeeds on A and is $n^k + k$ time computable. Since $n^k + k$ time bounded martingales are easily enumerable for a fixed k, $\mathcal{C}$ is a p-union of p-measure 0 sets, so $\mu_p(\mathcal{C}) = 0$. (To build a p-union of p-measure 0 sets, we need to build a sequence of martingales $d_1, d_2, \ldots$

witnessing that the sets have p-measure 0 and a uniform algorithm that receives k and x as input and computes $d_k(x)$ in time polynomial in both k and x. See [15] for more details and a proof of this.)

Let $A \in \mathcal{C}$ be a set such that χ_A is f-compressible. Assume we have algorithms to compress $\omega = \chi_A$. Let's say algorithm B_1 (compress) computes κ from ω and algorithm B_2 (uncompress) computes ω from κ. We build a p-martingale. Suppose we are given $\omega[0..i]$. Let S_0 be $\{\lambda\}$. To form S_j from S_{j-1}, simulate B_1 on $\omega[0..j]$. From the strings output by B_1, keep only those that are extensions of strings in S_{j-1}. For each remaining string x, if $B_2(x)$ is not a proper extension of $\omega[0..j]$, then discard it. Otherwise, replace it by its smallest prefix y such that B_2 on y is a proper extension of $\omega[0..j]$. Call the set of remaining strings S_j.

Compute strings in S_i. Separate the strings in S_i into two groups, those that predict (via B_2) a 0 and those that predict a 1. Call these groups G_0 and G_1. Let each string vote for the next bit. The relative weight of each vote depends on the length of the string: the shorter the string, the more weight. Let $s_i = \Sigma_{x_k \in S_i} 2^{-|x_k|}$. Let $b_0 = \Sigma_{x_k \in G_0} 2^{-|x_k|}$. Let $b_1 = \Sigma_{x_k \in G_1} 2^{-|x_k|}$. Then $d(\omega[0..i]0) = d(\omega[0..i])(1 + (b_0 - b_1)/s_i)$ and $d(\omega[0..i]1) = d(\omega[0..i])(1 + (b_1 - b_0)/s_i)$.

We claim that for any i, $d(\omega[0..i]) \geq \sum_{x_k \in S_i} 2^{i-|x_k|} = 2^i s_i$. This can be proven by induction on i. The statement is true for $i = 0$, assuming initial capital of 1. Assume it's true up to i. At step $i+1$, without loss of generality, suppose $\omega[i+1] = 0$. Let $r = b_0/s_i$. Then, $d(\omega[1..i]0) = 2rd(\omega[0..i])$. This is greater than or equal to $2r2^i s_i = 2^{i+1} r s_i$, by the induction hypothesis. Thus, the proof of the claim is complete if we show that rs_i is greater than or equal to s_{i+1}. But rs_i is just b_0, and because strings in S_{i+1} are extensions of strings in G_0, b_0 is no smaller than s_{i+1}.

Now, let k be an arbitrary value, and let j be such that algorithm B_2 computes $\omega[0..i]$ from $\kappa[0..j]$ such that $i - j > k$. By the assumption on compressibility, such a j must exist. Our construction guarantees that $\kappa[0..j]$ is in S_{i-1}. By the claim above, $d(\omega[0..i-1]) \geq \sum_{x_k \in S_{i-1}} 2^{i-1-|x_k|} \geq 2^{i-1-|\kappa[0..j]|} \geq 2^{i-j-2} \geq 2^{k-2}$. This shows that the capital is unbounded, so the martingale succeeds. □

7. Applications of the new characterization. In this section we give some examples of how the new characterization can be applied. In each case we use Theorem 9 to prove that some class has p-measure zero. In other words, to show that a class has p-measure zero, we show that every set in the class can be f-compressed, where f is a polynomial not depending on the particular set being compressed.

DEFINITION 10. *A set A is* P-immune *if no infinite subset of A is in* P.

DEFINITION 11. *A set A is* P-bi-immune *if both A and $\overline{A}$ are* P*-immune.*

THEOREM 12 (see [20]). *The class of non-*P*-bi-immune sets has p-measure* 0.

Proof. Let A be an arbitrary non-P-bi-immune set and suppose there is an infinite set $C \subseteq A$ where C is in DTIME(n^k). (The case where $C \subseteq \overline{A}$ is analogous.) If $A \in P$, then χ_A can obviously be compressed. Otherwise, the compressed characteristic sequence of A is the concatenation of the bits $\chi_A(x)$ with $x \notin C$. Since C is infinite, the compression is unbounded.

To uncompress $\kappa[0..j]$ into $\chi_A[0..i]$, for each string x in lexicographic order, if $x \in C$, append 1, else append the next bit of κ. Continue until the bits of $\kappa[0..j]$ are exhausted. This requires $i+1$ tests of membership in C, for strings of length $O(\lg i)$. The total time is in $O(i \lg^k i) \subseteq O(i^2)$.

To compress $\chi_A[0..i]$, just remove the bits corresponding to elements of C. Then create two strings by adding a 0 and a 1. One of the two strings will uncompress into the correct extension of $\chi_A[0..i]$. This can also be done in time $O(i^2)$.

(From the time analysis, we can see that the theorem holds even for larger run times than P.) □

The next theorem investigates the class of sets that are autoreducible [2]. A set A is *autoreducible* if there is a polynomial-time oracle Turing machine that accepts A with A as oracle provided that, on input x, it never queries x to the oracle.

THEOREM 13. *For any fixed constant c, the class of sets that are autoreducible via oracle machines that query no more than $c \cdot |x|$ queries on input x has p-measure 0.*

Proof. Let A be an arbitrary set in the class mentioned in the statement of the theorem. Let $n_0 = 4$ and $n_{k+1} = n_k^{\log n_k}$. For k large enough, an autoreduction on 0^{n_k} will never query a string of size $\geq n_{k+1}$.

To compress $\chi_A[0..i]$, substitute the bit for 0^{n_k} by a sequence of bits corresponding to the answers to all queries of strings y for $y > 0^{n_k}$ in the lexicographic ordering. This results in a local expansion of χ_A. Then, remove from χ_A all the bits corresponding to those large queries. Overall, we removed the bit for 0^{n_k} and moved some other bits around in χ_A. This results in one bit of compression for each section of χ_A corresponding to strings between 0^{n_k} and $0^{n_{k+1}}$. Since this is done for each k, the number of bits of compression is unbounded.

To uncompress $\kappa[0..j]$, simulate the autoreduction machine on strings of the form 0^{n_k}, for successive k, using the appropriate bits of $\kappa[0..j]$ to answer the queries. This generates the missing bits and allows reordering of the other bits into $\chi_A[0..i]$. The time for uncompression includes the time for the autoreduction on strings of the form 0^{n_k}, which is polynomial in $\lg i$, and the time for reordering the bits, which is in $O(i)$.

To compress $\chi_A[0..i]$, if i does not represent a string of size n_k for some k, the compression is straightforward. Otherwise, the string $\chi_A[0..i]$ may not contain all the bits that are needed for the substitution in the position corresponding to string 0^{n_k}. For this case, substitute the bit by all possible sequences of cn_k bits, giving 2^{cn_k} candidate compressions. For each candidate compression, generate the rest of the bits according to the autoreduction using the sequence included. The time for the autoreduction is polynomial in n_k, and since $n_k \leq \lg(i+2)$, each candidate compression can be generated in linear time, and the total time is $O(i2^{c \lg i}) = O(i^{c+1})$. □

The next theorem deals with p-selective sets, introduced by Selman [23]. A set A is p-selective if there is a polynomial-time selector function f such that (1) $f(x,y) \in \{x,y\}$ and (2) if $x \in A$ or $y \in A$, then $f(x,y) \in A$. Intuitively, $f(x,y)$ hands back the most likely of x or y to be in A. We will use the following lemma.

LEMMA 14 (see [7]). *Let A be a p-selective set. Any finite set X can be ordered in polynomial time, using the p-selector, as follows: $\{x_1, \ldots, x_k\} = X$ such that $x_i \in A$ implies $x_j \in A$ for all $j \geq i$.*

THEOREM 15. *The class of sets that are polynomial-time truth-table reducible to a p-selective set has p-measure 0.*

Proof. Let A be polynomial-time truth-table reducible to a p-selective set S via reduction r. Assume that the reduction r runs in time n^k and that the p-selector function f also runs in time n^k. Let $n_j = 2^j$ for some integer j. We compress $\chi_A[2^{n_j} - 1..2^{n_j+1} - 2]$ (corresponding to strings of length n_j) into a string s_j as follows. Let S_j be the set of all queries to S generated by applying reduction r on all strings of length n_j. This set has at most $2^{n_j} n_j^k \leq 2^{2n_j}$ strings. Let s_j be the binary string of length $2n_j$ encoding $\|S_j \cap S\|$. The compressed string κ is χ_A, where for each n_j, $\chi_A[2^{n_j} - 1..2^{n_j+1} - 2]$ has been replaced by s_j. This will result

in an unbounded compression.

To recover a piece of χ_A that has been replaced by s_j, simulate the reduction r on every string of length n_j and collect all queries to form S_j. Then sort S_j by using the p-selector as a string comparator. (This sorting is possible, using the lemma above.) By the property of the p-selector, if s_j encodes m, then the m largest strings of S_j according to our sort are in S. Use this information about S and the reduction to S to compute the membership of all strings of length n_j in A. This requires 2^{n_j} applications of the reduction r, each using n_j^k time, and then $O(n_j 2^{n_j})$ comparisons for sorting, each comparison being an application of f using n_j^k time. If this process produces $\chi_A[0..i]$, the largest j for which this is done is $j = \lfloor \lg\lg((i+2)/2) \rfloor$. This process can be done in time 2^{2n_j} for each j, and the total process will recover $\chi_A[0..i]$ in time $\Sigma_{j \le \lfloor \log\log((i+2)/2) \rfloor} 2^{2n_j} \in O(i^2)$.

To compute κ, we only need to compute candidates for κ, one of which is the correct one. Generate all possible candidates. Starting from $\chi_A[0..i]$, the largest j for which s_j needs to be computed is $j = \lfloor \lg\lg(i+2) \rfloor$. The number of undetermined bits is at most $\Sigma_{j \le \lfloor \lg\lg(i+2) \rfloor} 2n_j \le 4\log(i+2)$, so the number of possible candidates is in $O(i^4)$. (Although not necessary here, it is possible to reduce the time to $O(i^2)$ by putting the indices n_j at 2^{2^j} instead of 2^j.) □

COROLLARY 16. *There is no p-selective set that is hard for E under polynomial-time truth-table reductions.*

Proof. E does not have p-measure 0 [16]. □

The next result shows that the class of sets that reduce by Turing reductions to a set that has subpolynomial density has p-measure 0. A function is subpolynomial if $\forall \epsilon \; \exists n_0 \; \forall n > n_0 : f(n) < n^\epsilon$.

THEOREM 17. *Let f be a subpolynomial function. The class of sets that Turing reduce to a set S with density f (i.e., $\|S^{\le n}\| \le f(n)$) has p-measure 0.*

Proof. Let $A \le_T^p S$, where S has density $f(n)$, via machine M_T in time $p(n)$. Again we have to show that the characteristic sequence of A can be compressed and uncompressed. We consider $w = \chi_A[2^n - 1..2^{n+1} - 2]$, corresponding to strings of size n. We will compress the first n bits of w. Each string x of length n is mapped by M_T to at most $p(n)$ many different queries, provided that the answers to these queries are known. We replace the first n bits of w by pairs of the form $\langle i, j \rangle$, meaning that the jth query asked by M_T on the ith string of length n is in S. The number of bits needed to write these pairs is $O(f(p(n)) \log n)$, which is less than n because f is subpolynomial. To uncompress, simulate M_T on all those n strings of length n, using the compressed string to answer queries to S. To compress, generate all possible sequences of pairs. This results in at most $2^{O(f(p(n))) \log n}$ possible extensions, with the hidden constant in the exponent not depending on A. Only output the ones that are consistent with the known part of χ_A. One of the possibilities has to be a prefix of κ. □

COROLLARY 18 (see [6]). *There is no Turing hard set for E with subpolynomial density.*

Acknowledgments. We would like to thank Paul Vitányi for suggesting that we look at a Kolmogorov type of characterization of resource bounded measure. We would like to thank Martin Strauss for useful discussions that led us to improved results, and David Martin for his useful comments. We also would like to thank A. M. Bobu for hosting the meeting that enabled us to initiate this research.

RESOURCE-BOUNDED KOLMOGOROV COMPLEXITY REVISITED*

HARRY BUHRMAN†, LANCE FORTNOW‡, AND SOPHIE LAPLANTE§

Abstract. We take a fresh look at **CD** complexity, where $\mathbf{CD}^t(x)$ is the size of the smallest program that distinguishes x from all other strings in time $t(|x|)$. We also look at **CND** complexity, a new nondeterministic variant of **CD** complexity, and time-bounded Kolmogorov complexity, denoted by **C** complexity.

We show several results relating time-bounded **C**, **CD**, and **CND** complexity and their applications to a variety of questions in computational complexity theory, including the following:

- Showing how to approximate the size of a set using **CD** complexity without using the random string as needed in Sipser's earlier proof of a similar result. Also, we give a new simpler proof of this result of Sipser's.
- Improving these bounds for almost all strings, using extractors.
- A proof of the Valiant–Vazirani lemma directly from Sipser's earlier **CD** lemma.
- A relativized lower bound for **CND** complexity.
- Exact characterizations of equivalences between **C**, **CD**, and **CND** complexity.
- Showing that satisfying assignments of a satisfiable Boolean formula can be enumerated in time polynomial in the size of the output if and only if a unique assignment can be found quickly. This answers an open question of Papadimitriou.
- A new Kolmogorov complexity-based proof that $\mathbf{BPP} \subseteq \Sigma_2^p$.
- New Kolmogorov complexity based constructions of the following relativized worlds:
  - There exists an infinite set in **P** with no sparse infinite **NP** subsets.
  - **EXP** = **NEXP** but there exists a **NEXP** machine whose accepting paths cannot be found in exponential time.
  - Satisfying assignments cannot be found with nonadaptive queries to **SAT**.

Key words. computational complexity, Kolmogorov complexity, CD complexity

1. Introduction.

Originally designed to measure the randomness of strings, Kolmogorov complexity has become an important tool in computability and complexity theory. A simple lower bound showing that there exist random strings of every length has had several important applications (see [19, Chapter 6]).

Early in the history of computational complexity theory, many people naturally looked at resource-bounded versions of Kolmogorov complexity. This line of research was initially fruitful and led to some interesting results. In particular, Sipser [24] invented a new variation of resource-bounded complexity, called **CD** complexity, where one considers the size of the smallest program that accepts one specific string and no others. Sipser used **CD** complexity for the first proof that **BPP** is contained in the polynomial-time hierarchy.

Complexity theory has marched on for the past two decades, but resource-bounded Kolmogorov complexity has seen little interest. Now that computational complexity theory has matured a bit, we ought to look back at resource-bounded Kolmogorov complexity and see what new results and applications we can draw from it.

First, we use algebraic techniques to give a new upper bound lemma for **CD** complexity, without the additional advice required of Sipser's lemma [24]. With this lemma, we can measure the approximate size of a set using **CD** complexity.

We obtain better bounds on **CD** complexity using extractor graphs. These graphs are usually used for derandomization. However, these improved bounds apply only to most of the strings.

We also give a new, simpler proof of Sipser's lemma and show how it implies the important Valiant–Vazirani lemma [27] that randomly isolates satisfying assignments. Surprisingly, Sipser's paper predates the result of Valiant and Vazirani.

We define **CND** complexity as a variation of **CD** complexity where we allow nondeterministic computation. We prove a lower bound for **CND** complexity where we show that there exists an infinite set A such that every string in A has high **CND** complexity even if we allow access to A as an oracle. We use this lemma to prove some negative results on nondeterministic search vs. deterministic decision.

Once we have these tools in place, we use them to unify several important theorems in complexity theory. We answer an open question of Papadimitriou [22] by characterizing exactly when the set of satisfying assignments of a formula can be enumerated in output polynomial time. We also give straightforward proofs that **BPP** is in Σ_2^p (first proven by Gács (see [24])) and create relativized worlds where assignments to **SAT** cannot be found with nonadaptive queries to **SAT** (first proven by Buhrman and Thierauf [4]), and where **EXP** = **NEXP** but there exists a **NEXP** machine whose accepting paths cannot be found in exponential time (first proven by Impagliazzo and Tardos [15]).

These results in their original form require a great deal of time to fully understand the proofs because either the ideas and/or technical details are quite complex. We show that by understanding resource-bounded Kolmogorov complexity, one can see full and complete proofs of these results without much additional effort. We also look at when polynomial-time **C**, **CD**, and **CND** complexity coincide. We give a precise characterization of when we have equality of these measures, and some interesting consequences thereof.

2. Preliminaries. We use basic concepts and notation from computational complexity theory texts like Balcázar, Díaz, and Gabarró [1] and Kolmogorov complexity from the excellent book by Li and Vitányi [19]. We use $|x|$ to represent the length of a string x and $\|A\|$ to represent the number of elements in the set A. $A^{=n}$ is the set of strings in A of length n. $[N]$ denotes the set of integers between 1 and N. All of the logarithms are base 2.

Formally, we define the Kolmogorov complexity function $\mathbf{C}_\phi(x|y)$ by

$$\mathbf{C}_\phi(x|y) = \min_p\{|p| : \phi(p, y) = x\}.$$

There exists a universal machine U such that for all ϕ there is a constant c such that, for all x and y, $\mathbf{C}_U(x|y) \leq \mathbf{C}_\phi(x|y) + c$. We fix such a U and let $\mathbf{C}(x|y) = \mathbf{C}_U(x|y)$. We define unconditional Kolmogorov complexity by $\mathbf{C}(x) = \mathbf{C}(x|\epsilon)$.

A few basic facts about Kolmogorov complexity follow:

- The choice of U affects the Kolmogorov complexity by at most an additive constant.

- For some constant c, $\mathbf{C}(x) \leq |x| + c$ for every x.
- For every n and every y, there is an x such that $|x| = n$ and $\mathbf{C}(x|y) \geq n$.

We will also use time-bounded Kolmogorov complexity. Fix a fully time-constructible function $t(n) \geq n$. We define the $\mathbf{C}^t(x|y)$ complexity function as

$$\mathbf{C}^t(x|y) = \min_p\{|p| : U(p, y) = x \text{ and } U(p) \text{ runs in at most } t(|x| + |y|) \text{ steps}\}.$$

As before, we let $\mathbf{C}^t(x) = \mathbf{C}^t(x|\epsilon)$. A different universal U may affect the complexity by at most a constant additive term and the time by a $\log(t)$ factor.

While the usual Kolmogorov complexity asks about the smallest program to *produce* a given string, we may also want the smallest program to *distinguish* a string. While this difference affects the unbounded Kolmogorov complexity by only a constant, it can make a difference for the time-bounded case. Sipser [24] defined the distinguishing complexity $\mathbf{CD}^t$ by

$$\mathbf{CD}^t(x|y) = \min_p \left\{ |p| : \begin{array}{l} (1)\ U(p, x, y) \text{ accepts} \\ (2)\ U(p, z, y) \text{ rejects for all } z \neq x \\ (3)\ U(p, z, y) \text{ runs in } \leq t(|z|+|y|) \text{ steps for all } z \in \Sigma^* \end{array} \right\}.$$

When the auxiliary input string y is the empty string, we write $\mathbf{CD}^t(x)$.

We fix a universal nondeterministic Turing machine, U_n. We define the nondeterministic distinguishing complexity $\mathbf{CND}^t$ by

$$\mathbf{CND}^t(x|y) = \min_p \left\{ |p| : \begin{array}{l} (1)\ U_n(p, x, y) \text{ accepts} \\ (2)\ U_n(p, z, y) \text{ rejects for all } z \neq x \\ (3)\ U_n(p, z, y) \text{ runs in } \leq t(|z|+|y|) \text{ steps for all } z \in \Sigma^* \end{array} \right\}.$$

In this definition, we mean that the nondeterministic Turing machine accepts or rejects in the usual sense of nondeterministic computation. Once again we let $\mathbf{CND}^t(x) = \mathbf{CND}^t(x|\epsilon)$.

We can also allow for relativized Kolmogorov complexity. For example, $\mathbf{CD}^{t,A}(x|y)$ is defined as above except that the universal machine U has access to A as an oracle.

One can distinguish a string by generating it and then comparing it with the input, as stated in the following lemma.

LEMMA 2.1. *For all t $\exists c$ for all x, y : $\mathbf{CD}^{ct\log t}(x \mid y) \leq \mathbf{C}^t(x \mid y) + c$, where c is a constant.*

Likewise, every deterministic computation is also a nondeterministic computation, hence the lemma that follows.

LEMMA 2.2. *For all t $\exists c$ for all x, y : $\mathbf{CND}^{ct\log t}(x \mid y) \leq \mathbf{CD}^t(x \mid y) + c$.*

In section 7 we examine the consequences of the converses of these lemmas.

3. Approximating sets with distinguishing complexity. In this section we derive a lemma that enables one to approximate deterministically the density of a set, using polynomial-time distinguishing complexity. The technique we use of considering values modulo a prime is reminiscent of the hashing via the division method (see [17, p. 515]).

LEMMA 3.1. *Let $S = \{x_1, \ldots, x_d\} \subseteq \{0, \ldots, 2^n - 1\}$. For all $x_i \in S$ and at least half of the primes $p \leq 4dn^2$, $x_i \not\equiv x_j \bmod p$ for all $j \neq i$.*

Proof. For each $x_i, x_j \in S$, $i \neq j$, it holds that for at most n different prime numbers p, $x_i \equiv x_j \bmod p$ by the Chinese remainder theorem. (Alternatively, $|x_i - x_j| < 2^n$, so it can not have more than n prime factors.) For x_i there are at most dn

primes p such that $x_i \equiv x_j \bmod p$ for some $x_j \in S$. The prime number theorem [14] (see also [13]) states that for any m there are approximately $m/\ln(m) > m/\log(m)$ primes less than m. There are at least $4dn^2/\log(4dn^2) > 2dn$ primes less than $4dn^2$. So at least half of these primes p must have $x_i \not\equiv x_j \bmod p$ for all $j \neq i$. □

LEMMA 3.2. *Let A be any set. For all strings $x \in A^{=n}$ it holds that $\mathbf{CD}^{p,A^{=n}}(x) \leq 2\log(\|A^{=n}\|) + O(\log(n))$ for some polynomial p.*

Proof. Fix n and let $S = A^{=n}$. Fix $x \in S$ and a prime p_x fulfilling the conditions of Lemma 3.1 for x.

The $\mathbf{CD}^{poly,A}$ program for x works as follows:

input y
If $y \notin A^{=n}$ then **reject**
else if $y \bmod p_x = x \bmod p_x$ then **accept**
else **reject**

The size of the above program is $|p_x| + |x \bmod p_x| + O(1)$. This is $2\log(\|A\|) + O(\log(n))$. It is clear that the program runs in polynomial time and accepts only x. □

We note that Lemma 3.2 also works for $\mathbf{CND}^p$ complexity for some polynomial p.

Buhrman, Laplante, and Miltersen [3] show that Lemma 3.2 is tight.

THEOREM 3.3 (Buhrman–Laplante–Miltersen). *For every polynomial p and sufficiently large n there exists a set of strings $A \subseteq \{0,1\}^n$ containing more than $2^{n/50}$ strings such that there is an x in A with*

$$\mathbf{CD}^{p,A}(x) \geq 2\log(\|A^{=n}\|) - O(1).$$

COROLLARY 3.4. *Let A be a set in $\mathbf{P}$. For each string $x \in A$ it holds that $\mathbf{CD}^p(x) \leq 2\log(\|A^{=n}\|) + O(\log(n))$ for some polynomial p.*

Proof. We will use the same scheme as in Lemma 3.2, now using that $A \in \mathbf{P}$ and specifying the length of x, yielding an extra $\log(n)$ term for $|x|$ plus an additional $2\log\log(n)$ penalty for concatenating the strings. □

Theorem 3.3 also gives a relativized tightness result for Corollary 3.4.

COROLLARY 3.5.

1. *A set S is sparse if and only if, for all $x \in S$, $\mathbf{CD}^{p,S}(x) \leq O(\log(|x|))$ for some polynomial p.*
2. *A set $S \in \mathbf{P}$ is sparse if and only if, for all $x \in S$, $\mathbf{CD}^p(x) \leq O(\log(|x|))$ for some polynomial p.*
3. *A set $S \in \mathbf{NP}$ is sparse if and only if, for all $x \in S$, $\mathbf{CND}^p(x) \leq O(\log(|x|))$ for some polynomial p.*

Proof. Lemma 3.2 yields that all strings in a sparse set have $O(\log(n))$ $\mathbf{CD}^p$ complexity. On the other hand, simple counting shows that for any set A there must be a string $x \in A$ such that $\mathbf{CND}^A(x) \geq \log(\|A^{=|x|}\|)$. □

3.1. Sipser's lemma. We can also use Lemma 3.1 to give a simple proof of the following important result due to Sipser [24].

LEMMA 3.6 (Sipser). *For every polynomial-time computable set A there exists a polynomial p and constant c such that for every n, for most r in $\Sigma^{p(n)}$ and every $x \in A^{=n}$,*

$$\mathbf{CD}^{p,A^{=n}}(x|r) \leq \log(\|A^{=n}\|) + c\log(n).$$

Proof. For each k, $1 \leq k \leq n$, let r_k be a list of $4k(n+1)$ randomly chosen numbers less than 2^k. Let r be the concatenation of all of the r_k.

Fix $x \in A^{=n}$. Let $d = \|A^{=n}\|$. Fix k such that $2^{k-1} < 4dn^2 \leq 2^k$. Consider one of the numbers y listed in r_k. By the prime number theorem [13], the probability that y is prime and less than $4dn^2$ is at least $1/2\log(4dn^2)$. The probability that y fulfills the conditions of Lemma 3.1 for x is at least $1/4\log(4dn^2) > 1/4k$. With probability about $1 - 1/e^{n+1} > 1 - 1/2^{n+1}$, we have that some y in r_k fulfills the conditions of Lemma 3.1.

With probability at least $1/2$, for every $x \in A$ there is some y listed in r_k fulfilling the conditions of Lemma 3.1 for x.

We can now describe x by x mod y and the pointer to y in r. □

Note. Sipser's original proof gives a tighter bound than $c\log(n)$, but for most applications the additional $O(\log(n))$ additive factor makes no substantial difference.

Comparing our Lemma 3.2 with Sipser's lemma (Lemma 3.6), we are able to eliminate the random string required by Sipser at the cost of an additional $\log(\|A^{=n}\|)$ bits.

4. Approximating sets with extractors. By using extractors, we can obtain nearly the bound of Sipser's lemma 3.6 without the random string it requires. However, our result only works for most strings in A.

THEOREM 4.1. *For any set A and any function $\varepsilon(n)$ there is a polynomial p such that for all n and for all but a $2\varepsilon(n)$ fraction of the $x \in A^{=n}$,* $\mathbf{CD}^{p,A^{=n}}(x) \leq \log\|A^{=n}\| + \log^{O(1)}(n/\varepsilon(n))$.

We give a nondeterministic version of this result and give a bound on **CND** complexity. We also give a randomized version of these theorems, stating that the shorter string can be chosen at random and the probability of getting a short string which encodes as much information as the original string is bounded away from $1/2$.

4.1. Extractors. An extractor can be thought of as a bipartite graph, whose first color class is larger than the second color class. By convention, we think of the first color class as being on the left, and the second on the right. The vertices on the left side are all the strings of length n, so the first color class can be equated with the set $[N]$, where $N = 2^n$. Likewise, the vertices on the right side of the graph are labeled by strings of length $m \leq n$, so we let $M = 2^m$, and $[M]$ is equated with the vertices in the second color class.

4.1.1. Distributions. We will be choosing a node on the left side of the graph at random according to a distribution X. The result of choosing a neighbor uniformly at random in the graph will produce a distribution Y on vertices on the right.

The *min-entropy* of a distribution X over $[N]$ is defined as $\min\{-\log_2(X(x))|x \in [N]\}$. The min-entropy of X can be thought of as a measure of the randomness present in a string x chosen according to X.

A distribution Y is said to be ε-close to Z if both distributions are over the same space $[M]$, and such that for any $S \subseteq [M]$, $|Y(S) - Z(S)| \leq \varepsilon$.

4.1.2. Definition of extractors. A bipartite graph G with (independent) vertex sets $[N]$ and $[M]$, $N = 2^n, M = 2^m$, and for which the degree of all the vertices in the first color class is bounded by $D = 2^d$, is an $(n, k, d, m, \varepsilon)$ *extractor* if, given any distribution X on the N vertices whose min-entropy is at least k, the result of choosing an x according to this distribution and a random neighbor y of x in the graph is ε-close to the uniform distribution over $[M]$. In our setting, the distribution X will be the uniform distribution over a subset $A \subseteq [N]$, so k will be $\log(\|A\|)$.

$\Gamma(x)$ denotes the set of neighbors of x in G when x is a vertex on the left side of the graph. The number of edges originating at some vertex x on the left side of

the graph is called the *outdegree* of x, whereas the number $w(y)$ of edges adjacent with a vertex y on the right side of the graph is called the *indegree* (or weight) of y. $G(x,r)$ represents the rth neighbor of x in the graph, where multiple edges are allowed. When y is a vertex on the right side of the graph, $\Gamma_A^{-1}(y)$ is the subset of preimages of y which lie in A. The notation extends to sets in the natural way.

4.1.3. Best-known explicit constructions. The results we state are subject to improvement if better explicit extractor constructions are found. We have stated our results in general terms so that new results on extractors will be immediately applicable.

The current best-known explicit constructions for extractors are due to Ta-Shma [25], Zuckerman [29], Trevisan [26], and Raz, Reingold, and Vadhan [23]. The extractors best suited for our purposes are the ones which can be constructed for any k, and with $m = k$, with the smallest amount of additional randomness. We illustrate our results with the parameters obtained from Ta-Shma's construction.

THEOREM 4.2 (Ta-Shma). *There is an explicit construction that, for every n and for any function $\varepsilon(n)$ and every $m = m(n) \le n$, yields an extractor with parameters $(n, m, \log^{O(1)}(n/\varepsilon(n)), m, \varepsilon(n))$.*

It is useful to compare this construction to the current lower bound on extractors, due to Nisan and Zuckerman [20].

THEOREM 4.3 (Nisan–Zuckerman). *There is a constant c such that for all $n, m, k \le n-1$, $\varepsilon < 1/2$, if there is an extractor whose parameters are $(n, k, d, m, \varepsilon)$, then it must be the case that $d \ge \min\{m, c\log(n/\varepsilon)\}$.*

This lower bound also gives a good indication as to the limits of the techniques described in this paper.

4.2. Extracting CD complexity. Theorem 4.1 follows immediately from the following result, using the explicit extractor construction of Ta-Shma. For this theorem we assume that there is an explicit extractor construction whose parameters are $(n, k, d, m, \varepsilon)$, and we write $M = 2^m$.

THEOREM 4.4. *Fix a set A, a polynomial $q(n)$, and $\varepsilon = \varepsilon(n)$. Then there is a polynomial $p(n)$ such that for all n and for all but a 2ε fraction of the $x \in A^{=n}$, there is a y such that*

1. $|y| = m$,
2. $\mathbf{C}^p(y|x) \le d + O(1)$,
3. $\mathbf{CD}^{p,A^{=n}}(x) \le \mathbf{C}^q(y) + 3d + 2\log(\|A^{=n}\|/M) + c\log(n + d + \log(\|A^{=n}\|/M)) + O(1)$,

where the underlying extractor's parameters are determined by n and $k = \log(\|A^{=n}\|)$, and c is a small absolute constant.

For the remainder of this section, we fix n and we let $S = \|A^{=n}\|$. In our setting, we will think of the set $A^{=n}$ as defining a distribution of min-entropy $k = \log(S)$. The string x represents an element of $A^{=n}$ and y is one of its neighbors in the graph G. Hence y has length m; computing y from x requires knowing only a short ("random") string of length d. As we will see, y together with some short additional distinguishing information will suffice to distinguish the string x (in the sense of **CD** complexity).

The following lemmas are at the heart of the argument. They allow us to upper-bound the number of "bad" elements in $A^{=n}$, where "bad" means the strings x for which Theorem 4.4 will not apply.

In order to get a short description for x, we need to find a string y in its range which has small indegree (counting only those edges originating in $A^{=n}$).

In Lemma 4.5, we use the properties of the extractor to obtain an upper bound on the number of y which have large indegree. In the statement of the lemma, we use the variable w_0 to represent the threshold on degree: any vertex with degree larger than w_0 has large degree. A typical value for w_0 is twice the average degree of the graph.

Lemma 4.6 gives an upper bound on the number of x on the left side of the extractor whose neighbors all lie within a small subset of the right side of the graph. When the small subset is the set of vertices with large indegree, these x are the "bad" x to which the theorem will not apply.

LEMMA 4.5. *Consider the restriction of the extractor to the set of edges originating in $A^{=n}$. Recall that the degree of the graph is bounded by $D = 2^d$. In this restricted graph, let w_0 be an indegree threshold, $\frac{DS}{M} < w_0 \leq DS$, and Y be a subset of vertices on the right-hand side of the extractor graph. If for all $y \in Y$, $w(y) > w_0$, then $\|Y\| \leq \varepsilon \left(\frac{w_0}{DS} - \frac{1}{M}\right)^{-1}$.*

Proof. Let Y be the set of vertices whose indegree (in the restricted graph) exceeds w_0. Because the graph is an extractor, it must be the case that $\varepsilon \geq \frac{w(Y)}{\Gamma(A^{=n})} - \frac{\|Y\|}{M} \geq \frac{w(Y)}{DS} - \frac{\|Y\|}{M}$. Since $w(Y) \geq w_0\|Y\|$, we get $\|Y\| \leq \varepsilon \left(\frac{w_0}{DS} - \frac{1}{M}\right)^{-1}$ as claimed. □

LEMMA 4.6. *In the restricted graph, if Y is a set on the right side of the graph, then*

$$\|\{x \in A^{=n} : \Gamma(x) \subseteq Y\}\| \leq \left(\varepsilon + \frac{\|Y\|}{M}\right) S.$$

Proof. Let $X = \{x \in A^{=n} : \Gamma(x) \subseteq Y\}$. The distribution which consists of picking a random element of $A^{=n}$ and then choosing a random neighbor gives measure at least $\|X\|/S$ to the set Y. Because of the extractor property, $\frac{\|X\|}{S} - \frac{\|Y\|}{M} \leq \varepsilon$. □

To conclude, we give the proof of Theorem 4.4.

Proof. Let A be a set and ε, n be given as in the statement of the theorem. By Lemma 4.5, applied with $w_0 = 2DS/M$ ($D = 2^d$), and Lemma 4.6 with Y as in the hypothesis of Lemma 4.5, the size of the subset $B \subseteq A^{=n}$ such that for all $x \in B$, for all $y \in \Gamma(x)$, y has indegree at least w_0 can have size at most $2\varepsilon S$. Therefore for all but $2\varepsilon S$ of the x in $A^{=n}$, there is a y in its range whose indegree is at most $2DS/M$. For each such x, let r_x be the label of one of the edges in G which connects x to such a y. We need to verify 3 properties for each of these pairs x, y.

1. $|y| = m$: This is by choice of the extractor G.
2. $\mathbf{C}^p(y|x) \leq d + O(1)$: $y = G(x, r_x)$ for some $r_x \in \Sigma^d$, so the algorithm to print y will contain an encoding of r_x and on input x computes $G(x, r_x)$ and output the result.
3. $\mathbf{CD}^{p,A^{=n}}(x) \leq \mathbf{C}^q(y) + 3d + 2\log(S/M) + c\log(n) + O(1)$: The program to recognize x will contain an encoding for an r_x and y for which $G(x, r_x) = y$ and the indegree of y is at most $2DS/M$. It must also contain a distinguishing program p_x, which recognizes x among the $2DS/M$ vertices on the left originating in A that are adjacent to y. (The encoding of r_x is required to test that x is adjacent to y, but may be omitted if the degree of the graph is polynomial. This is not the case in the current explicit, efficient extractors, whose degree is on the order of $2^{\log^{O(1)}(n)}$.) The length of p_x is bounded by $2\log(2DS/M) + O(\log(n + \log(2DS/M)))$, by Lemma 3.2. (An additional logarithmic term is needed to encode the lengths of the various components of the encoding, but this is bundled in the O notation.)

The algorithm follows:

input z
If $z \notin A^{=n}$ then **reject**
else if $G(z, r_x) \neq y$ then **reject**
else if $p_x(z) = 1$ then **accept**
else **reject**

So the program requires an encoding of y, r, and the distinguishing program p_x, for a total length of $\mathbf{C}^q(y) + d + 2\log(2DS/M) + c\log(n + \log(2DS/M)) + O(1)$. □

4.3. Extracting CND complexity. A statement analogous to Theorem 4.4 can be made for **CND** complexity. Using a slight variant of the proof of Theorem 4.4, we can get a bound which is smaller by a term of d. Also, in the upper bound, $\mathbf{CD}^q(y)$ is used instead of the possibly larger term $\mathbf{C}^q(y)$.

THEOREM 4.7. *Fix a set A in* **NP**, *a polynomial $q(n)$, and $\varepsilon = \varepsilon(n)$. Then there is a polynomial $p(n)$ such that for every n and for all but a 2ε fraction of the $x \in A^{=n}$, there is a y such that*

1. $|y| = \log(\|A^{=n}\|)$,
2. $\mathbf{C}^p(y|x) \leq d + O(1)$,
3. $\mathbf{CND}^p(x) \leq \mathbf{CD}^q(y) + 2d + c\log(n + d) + O(1)$.

The proof is essentially the same as that of Theorem 4.4. To simplify the notation, we make the assumption that the extractor used achieves $k = m$, as does Ta-Shma's construction. To obtain property 3, we need only guess y and verify our guess using a distinguishing program for y whose length is bounded by $\mathbf{CD}^q(y)$. Likewise, we can simply guess r, omit its encoding, and use the distinguishing program p to verify our guess for r.

4.4. Randomly extracting CD complexity. Another variant that saves a $d = \log(D)$ term is to choose a counterpart y to a string x in a set in **P** at random. We will require only that, for most x, at least half of the edges from x map to a "good" y. Although this comes at the cost of applying only to "most" strings x, this improves upon the result of Sipser [24] by reducing the length of the random string from $n^{O(1)}$ to $\log^{O(1)}(n/\varepsilon)$. The proof is similar to that of Theorem 4.4; it requires only a slight modification to the counting argument.

THEOREM 4.8. *Fix a set A in* **P**, *a polynomial $q(n)$, and a function $\varepsilon(n)$. Then there is a polynomial $p(n)$ such that for every n and for all but a $4\varepsilon(n)$ fraction of the $x \in A^{=n}$, and at least half of the strings r of length d, there is a y such that*

1. $|y| = \log(\|A^{=n}\|)$,
2. $\mathbf{C}^p(y|x, r) \leq O(1)$,
3. $\mathbf{CD}^p(x|r) \leq \mathbf{C}^q(y) + 2d + 2\log(n + d) + O(1)$.

5. Extracting random strings. In the previous section, we used the fact that the strings examined were in a small set of bounded complexity, and we showed the existence of strings for which the mutual information was roughly the **CND** complexity of the original string. Here we use extractor techniques to a achieve a slightly different goal. We obtain an *incompressible* string whose length is close to the **CD** complexity of x and which can be computed from x using only $\log(n/\varepsilon)$ bits.

In the case of unbounded Kolmogorov complexity, it is easy to see that the following proposition is true.

PROPOSITION 5.1 (see [19, Example 2.1.5, p. 102]). *For any string x of length n, there is a y such that*

1. $|y| = \mathbf{C}(x)$,
2. $\mathbf{C}(y|x) \leq \log(n)$,
3. $\mathbf{C}(y) > |y| - O(1)$.

Namely, y is a minimal-length program for x and can be obtained from x by dovetailing, given the value of $\mathbf{C}(x)$. In the time-bounded setting, however, this argument fails, since dovetailing would take too much time. Our use of extractors is far afield from the above approach, yet it yields results surprisingly close to Proposition 5.1. (Nonexplicit extractors actually allow us to give an alternate proof of Proposition 5.1, although this is more an artifact than a useful new proof.)

THEOREM 5.2. *For any polynomial $q(n)$ and function $\varepsilon(n)$, there exists a polynomial $p(n)$ such that for any string x of length n there is a string y such that*

1. $|y| = \mathbf{CND}^p(x)/2 - c_1 \log(n)$,
2. $\mathbf{C}^p(y|x) \leq \log^{c_2}(n/\varepsilon(n))$,
3. $\mathbf{C}^q(y) > |y| - c_\varepsilon$,

where c_1, c_2 are absolute constants and c_ε depends only on ε.

Instead of giving the proof of Theorem 5.2, we prove the result in the following more general form, which may be improved as explicit extractor constructions are improved.

THEOREM 5.3. *For any polynomial $q(n)$ and $\varepsilon = \varepsilon(n)$, there exists a polynomial $p(n)$ such that for any string x there is a string y such that*

1. $|y| = m$,
2. $\mathbf{C}^p(y|x) \leq d + c_1$,
3. $\mathbf{C}^q(y) > |y| - c_\varepsilon$.

In the statement above, c_1 is an absolute constant, c_ε is a constant depending only on ε, $k = \frac{1}{2}(\mathbf{CND}^{2^d \cdot p}(x) - 2\log(n) - c_1 - 1)$ and $(n, k, d, m, \varepsilon)$ are the parameters of an explicit extractor.

Theorem 5.2 follows by applying Theorem 5.3 with parameters obtained from Ta-Shma's extractor [25].

Proof (sketch). Consider a family of extractors with parameters $n, k, m(k)$. Fix any n, k and let $G = G_{n,k,m}$, $m = m(k)$, be the extractor with parameters n, m, k. (Later we will fix k to be a specific value.) Let $A_{n,m} = \{x | \Gamma(x) \subseteq \mathbf{C}[q(n), m - c_\varepsilon]\}$, where $\mathbf{C}[t, l] = \{z | \mathbf{C}^t(z) \leq l\}$, and let c_ε be chosen so that $c_\varepsilon > \log(\frac{1}{1-\varepsilon})$ for large enough n.

The fact that G is an extractor prohibits the set $A_{n,m}$ from being large, as we see now. If $\|A_{n,m}\| > 2^k$, then by the properties of the extractor,

$$1 - \varepsilon \leq \frac{\|\mathbf{C}[q(n), m - c_\varepsilon]\|}{2^m}.$$

But $\|\mathbf{C}[q(n), m - c_\varepsilon]\| \leq 2^{m - c_\varepsilon}$, and we have chosen $c_\varepsilon > \log(\frac{1}{1-\varepsilon})$ in order to get a contradiction. Hence we must conclude that $\|A_{n,m}\| \leq 2^k$.

Now we may apply Lemma 3.2 for **CND** to conclude that all $x \in A_{n,m}$ must have small **CND** complexity. First notice that verifying membership in $A_{n,m}$ is in NTIME$[2^d \cdot p]$ for some polynomial p, since it suffices to guess, for each neighbor y of x in $G_{n,m}$, a program of length $m - c_\varepsilon$ which prints out y. Hence, there exists a constant c_1 such that for every $x \in A_{n,m}$, $\mathbf{CND}^{2^d \cdot p}(x) \leq 2\log(\|A_{n,m}\|) + 2\log(n) + c_1$.

Now consider x with respect to the extractor $G_{n,\hat{k},m(\hat{k})}$, where

$$\hat{k} = \frac{1}{2}\left(\mathbf{CND}^{2^d \cdot p}(x) - 2\log(n) - c_1 - 1\right)$$

and m is maximal for this k. By the observation above, it must be the case that $x \notin A_{n,m}$. Therefore there must be a y not in $\mathbf{C}[q(n), m - c_\varepsilon]$ to which x is mapped under $G_{n,k,m}$. It is easy to verify that y satisfies the properties claimed in the statement of the theorem. □

6. Lower bounds. In this section we show that there exists an infinite set A such that every string in A has high **CND** complexity, even relative to A.

Fortnow and Kummer [8] prove the following result about relativized **CD** complexity.

THEOREM 6.1. *There is an infinite set A such that for every polynomial p, $\mathbf{CD}^{p,A}(x) \geq |x|/5$ for almost all $x \in A$.*

We extend and strengthen their result for **CND** complexity.

THEOREM 6.2. *There is an infinite set A such that $\mathbf{CND}^{2^{\sqrt{|x|}},A}(x) \geq |x|/4$ for all $x \in A$.*

The proof of Fortnow and Kummer of Theorem 6.1 uses the fact that one can start with a large set A of strings of the same length such that any polynomial-time algorithm on an input x in A cannot query any other y in A. However, a nondeterministic machine may query every string of a given length. Thus we need a more careful proof.

This proof is based on the proof of a result due to Goldsmith, Hemachandra, and Kunen [9], which we obtain as Corollary 6.3 below. In section 9, we will also describe a rough equivalence between this result and an "X-search" theorem of Impagliazzo and Tardos [15].

Proof of Theorem 6.2. We create our set A in stages. In stage k, we pick a large n and add to A a nonempty set of strings B of length n such that for all nondeterministic programs p running in time $2^{\sqrt{n}}$ such that $|p| < n/4$, $p^{B \cup A}$ accepts either zero or more than one string in A. We first create a B that makes as many programs as possible accept zero strings in B. After that, we carefully remove some strings from B to guarantee that the rest of the programs accept at least two strings.

Let P be the set of nondeterministic programs of size less than $n/4$. We have $\|P\| < 2^{n/4}$. We will clock all of these programs so that they will reject if they take time more than $2^{\sqrt{n}}$. We also assume that on every program p in P, input x and oracle O, $p^O(x)$ queries x.

Let $v = 2^{\sqrt{n}+1}\|P\|$ and $w = \|P\|v2^{\sqrt{n}}$. Pick sets $\Delta \subseteq P$ and $H \subseteq \Sigma^n$ that maximize $\|\Delta\| + \|H\|$ such that $\|H\| \leq w\|\Delta\|$, and for all $X \subseteq \Sigma^n - H$ and $p \in \Delta$, $X \cap p^{A \cup X} = \emptyset$.

Note that $H \neq \Sigma^n$ since $\|H\| \leq w\|\Delta\| \leq w\|P\| \leq 2^{2\sqrt{n}+1}2^{3n/4} < 2^n$. Since some small program p always accepts, we have that $\Delta \neq P$.

Our final B will be a subset of $\Sigma^n - H$, which guarantees that for all $p \in \Delta$, $p^{A \cup B}$ will not accept any strings in B. We will create B such that for all $p \in P - \Delta$, $p^{A \cup B}$ accepts at least two strings in B. Initially let $B = \Sigma^n - H$. For each $p \in P - \Delta$ and for each integer i, $1 \leq i \leq v$, do the following:

- Pick a minimal $X \subseteq B$ such that for some $y \in X$, $p^{A \cup X}(y)$ accepts.
- Fix an accepting path and let Q_{p_i} be all the queries made on that path. Let $y_{p,i} = y$, $X_{p,i} = X$, and $B = B - Q_{p,i}$.

Note that $\|Q_{p,i}\| \leq 2^{\sqrt{n}}$. We remove no more than $\|P\|v2^{\sqrt{n}} \leq w$ strings in total. So if we cannot find an appropriate X, we have violated the maximality of $\|\Delta\| + \|H\|$. Note that $y_{p,i} \in X_{p,i} \subseteq Q_{p,i}$ and all of the $X_{p,i}$ are disjoint.

Initially set all of the $X_{p,i}$ as unmarked. For each $p \in P - \Delta$ do the following twice:

• Pick an unmarked $X_{p,i}$. Mark all $X_{q,j}$ such that $X_{q,j} \cap Q_{p,i} \neq \emptyset$.
Let $B = B \cup X_{p,i}$.

We have that $y_{p,i} \in B$ and $p^{A \cup B}(y_{p,i})$ accepts for every $X_{p,i}$ processed.

At most $2 \cdot 2^{\sqrt{n}} \|P\| - 1 < v$ of the $X_{q,j}$'s get marked before we have finished; we always can find an unmarked $X_{p,i}$.

Finally, note that $B \subseteq \Sigma^n - H$ and for every $p \in P - \Delta$ we have at least two $y \in B$ such that $p^{A \cup B}(y)$ accepts. Since $P - \Delta \neq \emptyset$, this also guarantees that $B \neq \emptyset$. Thus we have fulfilled the requirements for stage k. □

Using Theorem 6.2 we get the following corollary first proved by Goldsmith, Hemachandra, and Kunen [9].

COROLLARY 6.3 (Goldsmith–Hemachandra–Kunen). *Relative to some oracle, there exists an infinite polynomial-time computable set with no infinite sparse* **NP** *subsets.*

Proof. Let A from Theorem 6.2 be both the oracle and the set in P^A. Suppose A has an infinite sparse subset S in NP^A. Pick a large x such that $x \in S$. Applying Corollary 3.5 (3), it follows that $\mathbf{CND}^{A,p}(x) \leq O(\log(n))$. This contradicts the fact that $x \in S \subseteq A$ and Theorem 6.2. □

Actually, the above argument shows something stronger.

COROLLARY 6.4. *Relative to some oracle, there exists an infinite polynomial-time computable set with no infinite subset in* **NP** *of density less than* $2^{n/9}$.

It remains open whether Corollary 6.4 holds for $2^{\delta n}$ for $\frac{1}{9} < \delta < 1$.

7. CD vs. C and CND. This section deals with the consequences of the assumption that one of the complexity measures **C**, **CD**, and **CND** coincides for polynomial time. We will see that these assumptions are equivalent to well-studied complexity-theoretic assumptions. This allows us to apply the machinery developed in the previous sections. We will use the following function classes.

DEFINITION 7.1.

1. *The class* $\mathbf{FP}^{\mathbf{NP}[\log(n)]}$ *is the class of functions computable in polynomial time that can adaptively access an oracle in* **NP** *at most* $c\log(n)$ *times, for some* c.
2. *The class* $\mathbf{FP}_{tt}^{\mathbf{NP}}$ *is the class of functions computable in polynomial time that can nonadaptively access an oracle in* **NP**.

THEOREM 7.2. *The following are equivalent:*

1. *For all* p_2 $\exists p_1$, c *for all* $x, y : \mathbf{C}^{p_1}(x \mid y) \leq \mathbf{CND}^{p_2}(x \mid y) + c\log(|x| + |y|)$.
2. *For all* p_2 $\exists p_1$, c *for all* $x, y : \mathbf{CD}^{p_1}(x \mid y) \leq \mathbf{CND}^{p_2}(x \mid y) + c\log(|x| + |y|)$.
3. $\mathbf{FP}^{\mathbf{NP}[\log(n)]} = \mathbf{FP}_{tt}^{\mathbf{NP}}$.

Proof. (1 ⇒ 2) is trivial.

(2 ⇒ 3) We will first need the following lemma due to Lozano (see [16, pp. 184–185]).

LEMMA 7.3. $\mathbf{FP}^{\mathbf{NP}[\log(n)]} = \mathbf{FP}_{tt}^{\mathbf{NP}}$ *if and only if for every* f *in* $\mathbf{FP}_{tt}^{\mathbf{NP}}$ *there exists a function* $g \in \mathbf{FP}$ *that generates a polynomial-size set such that* $f(x) \in g(x)$.

In the following, let $f \in \mathbf{FP}_{tt}^{\mathbf{NP}}$. Let $f(x) = y$. We will see that there exists a p and c such that $\mathbf{CND}^p(y \mid x) \leq c\log(|x|)$. We can assume that the machine computing $f(x)$ produces a list of queries $Q = \{q_1, \ldots, q_l\}$ to **SAT**. Let w be the exact number of queries in Q that are in **SAT**. Thus $w = \|Q \bigcap \mathbf{SAT}\|$. Given x, consider the following $\mathbf{CND}^p$ program:

Input z.
Use $f(x)$ to generate Q.
Guess $q^1, \ldots, q^w \in Q$ that are in **SAT**

Guess satisfying assignments for $q^1, \ldots, q^w$.
Reject if not all $q^1, \ldots, q^w$ are satisfiable.
Compute $f(x)$ with $q^1, \ldots, q^w$ answered **yes**
and $q_j \in Q \setminus \{q^1, \ldots, q^w\}$ answered **no**.
Accept if and only if $f(x) = z$.

The size of the above program is $c\log(|x|)$, accepts only y, and runs in time p, for some polynomial p and constant c depending only on f. Also, it follows that all the prefixes of y have $\mathbf{CND}^p$ complexity bounded by $c\log(|x|) + \log(|x|) + O(1)$. By assumption there exists a polynomial p' and constant d such that $\mathbf{CD}^{p'}(z \mid x) \leq d\log(|x|)$ for z a prefix of y. For each of these z there is some program r such that

1. $|r| \leq d\log(|x|)$,
2. $U(r, z, x)$ accepts,
3. $U(r, u, x)$ rejects for each $u \neq z$, and
4. $U(r, u, x)$ runs in time at most $p'(|x|)$ for each $|u| \leq |x|$.

We can use the following procedure to enumerate possibilities for y.

Let $S_0 = \{\epsilon\}$.
For $m = 1$ to $|y|$.
Let S'_m consist of all strings u of length m such that
u extends some string in S_{m-1}.
Let S_m consist of all strings u in S'_m such that
there is some r, $|r| \leq d\log(|x|)$,
such that $U(r, u, x)$ accepts in $p'(|x|)$ steps, and
for all $v \in S'_m - \{u\}$, $U(r, v, x)$ does not accept in $p'(|x|)$ steps.

Note for all m, S_m and S'_m will have size bounded by $2|x|^d$, so the above algorithm runs in polynomial time. By our discussion, y will belong to $S_{|y|}$, so it follows (using Lemma 7.3) that $\mathbf{FP}^{\mathbf{NP}[\log(n)]} = \mathbf{FP}^{\mathbf{NP}}_{tt}$.

($3 \Rightarrow 1$) Let y be a string such that $\mathbf{CND}^{p'}(y \mid x) = k$. Let e be the program of length k that witnesses this. Consider the following function:

$$f(\langle e, 0^l, 0^m, x\rangle) = w_1 w_2 \ldots w_m,$$

where

$$w_i = \begin{cases} 1 & \text{if there is a } z \text{ of length } m \text{ with the } i\text{th bit equal to one} \\ & \text{such that } U_n(e, z, x) \text{ nondeterministically accepts in } l \text{ steps,} \\ 0 & \text{otherwise.} \end{cases}$$

Note that if e is a **CND** program that runs in l steps, then it accepts exactly one string, w of length m. Hence $f(\langle r, 0^{p'(|y|+|x|)}, 0^{|y|}, x\rangle) = y$. It is not hard to see that, in general, f is in $\mathbf{FP}^{\mathbf{NP}}_{tt}$ and by assumption in $\mathbf{FP}^{\mathbf{NP}[\log(n)]}$ via machine M. Next, given $e = r$, $m = |y|$, $l = p'(|y| + |x|)$, x, and the $c\log(|y| + |x|)$ answers to the **NP** oracle that M makes, we can generate y in polynomial time. We have that $\mathbf{C}^p(y \mid x) \leq \mathbf{CND}^{p'}(y \mid x) + c\log(|y| + |x|)$. □

For the next corollary we will use some results from [16]. We will use the following class of limited nondeterminism defined in [6].

DEFINITION 7.4. *Let $f(n)$ be a function from $\mathbb{N} \mapsto \mathbb{N}$. The class $\mathbf{NP}[f(n)]$ denotes that class of languages that are accepted by polynomial-time bounded nondeterministic machines that, on inputs of length n, make at most $f(n)$ nondeterministic moves.*

Jenner and Torán [16] show a series of consequences of the assumption $\mathbf{FP}^{\mathbf{NP}[\log(n)]} = \mathbf{FP}_{tt}^{\mathbf{NP}}$. By Theorem 7.2 we also get these consequences from a collapse of **CD** and **CND** complexity.

COROLLARY 7.5. *If for all* p_2 $\exists p_1, c$ *for all* x, y : $\mathbf{CD}^{p_1}(x \mid y) \leq \mathbf{CND}^{p_2}(x \mid y) + c\log(|x| + |y|)$, *then for any* k

1. $\mathbf{NP}[\log^k(n)]$ *is included in* $\mathbf{P}$,
2. $\mathbf{SAT} \in \mathbf{NP}[\frac{n}{\log^k(n)}]$,
3. $\mathbf{SAT} \in \mathbf{DTIME}(2^{n^{O(1/\log\log(n))}})$,
4. *there exists a polynomial* q *such that for every* m *formulae* $\phi_1, \ldots, \phi_m$ *of* n *variables, each such that at least one is satisfiable, there exists an* i *such that* ϕ_i *is satisfiable and*

$$\mathbf{CND}^q(\phi_i | \langle \phi_1, \ldots, \phi_m \rangle) \leq O(\log\log(n+m)).$$

The last consequence simply restates one of the Jenner–Torán results in the notation of this paper.

We can use Corollary 7.5 to get a complete collapse if there is only a constant difference between **CD** and **CND** complexity.

THEOREM 7.6. *The following are equivalent:*

1. *For all* p_2 $\exists p_1, c$ *for all* $x, y : \mathbf{C}^{p_1}(x \mid y) \leq \mathbf{CND}^{p_2}(x \mid y) + c$.
2. *For all* p_2 $\exists p_1, c$ *for all* $x, y : \mathbf{CD}^{p_1}(x \mid y) \leq \mathbf{CND}^{p_2}(x \mid y) + c$.
3. $\mathbf{P} = \mathbf{NP}$.

Proof (sketch). $(1 \Rightarrow 2)$ and $(3 \Rightarrow 1)$ are easy.

$(2 \Rightarrow 3)$ By combining Corollary 7.5(4) with the assumption, we have for any formula $\phi_1, \ldots, \phi_m$, where at least one is satisfiable, that

$$\mathbf{CD}^{p_1}(\phi_i | \langle \phi_1, \ldots, \phi_m \rangle) \leq c\log\log(n+m)$$

for some satisfiable ϕ_i. We can enumerate all the programs p of length at most $c\log\log(n+m)$ and find all the formula ϕ_i such that $p(\phi_i, \langle \phi_1, \ldots, \phi_m \rangle) = 1$ and $p(\phi_j, \langle \phi_1, \ldots, \phi_m \rangle) = 0$ for $j \neq i$.

Thus, given $\phi_1, \ldots, \phi_m$, we can, in polynomial time, create a subset of size $\log^c(n+m)$ that contains a satisfiable formula if the original list did. We then apply a standard tree-pruning algorithm to find the satisfying assignment of any satisfiable formula. □

A simple modification of the proof shows that Theorem 7.6 holds if we replace the constant c with $a\log(n)$ for any $a < 1$.

For the next corollary we will need the following definition (see [7]).

DEFINITION 7.7. *A promise problem is a pair of sets* (Q, R). *A set* L *is called a solution to the promise problem* (Q, R) *if the following property holds: for all* $x(x \in Q \Rightarrow (x \in L \Leftrightarrow x \in R))$. *For any function* f, $f\mathbf{SAT}$ *denotes the set of Boolean formulas with at most* $f(n)$ *satisfying assignments for formulae of length* n.

The next theorem states that nondeterministic computations that have few accepting computations can be "compressed" to nondeterministic computations that have few nondeterministic moves if and only if $\mathbf{C}^{poly} \leq \mathbf{CD}^{poly}$.

THEOREM 7.8. *The following are equivalent:*

1. *For all* p_2 $\exists p_1, c$ *for all* $x, y : \mathbf{C}^{p_1}(x \mid y) \leq \mathbf{CD}^{p_2}(x \mid y) + c$.
2. $(1\mathbf{SAT}, \mathbf{SAT})$ *has a solution in* $\mathbf{P}$.
3. *For all time constructible* f, $(f\mathbf{SAT}, \mathbf{SAT})$ *has a solution in* $\mathbf{NP}[2\log(f(n)) + O(\log(n))]$.

Proof. ($1 \iff 2$) This was proven in [8].

($3 \Rightarrow 2$) Take $f(n) = 1$ and the fact [6] that $\mathbf{NP}[O(\log(n))] = \mathbf{P}$.

($2 \Rightarrow 3$) Let ϕ be a formula with at most $f(|\phi|)$ satisfying assignments. Lemma 3.2 yields that for every satisfying assignment a to ϕ, there exists a polynomial p such that $\mathbf{CD}^p(a \mid \phi) \leq 2\log(f(|\phi|)) + O(\log(|\phi|))$. Hence (using that $1 \iff 2$) it follows that $\mathbf{C}^{p'}(a \mid \phi) \leq 2\log(f(|\phi|)) + c\log(|\phi|)$ for some constant c and polynomial p'. The limited nondeterministic machine now guesses a $\mathbf{C}^{p'}$ program e of size at most $2\log(f(|\phi|)) + c\log(|\phi|)$, runs it (relative to ϕ), and accepts if and only if the generated string is a satisfying assignment to ϕ. ∎

COROLLARY 7.9. $\mathbf{FP}^{\mathbf{NP}[\log(n)]} = \mathbf{FP}_{tt}^{\mathbf{NP}}$ *implies the following:*

1. *For any k, the promise problem $(2^{\log^k(n)}\mathbf{SAT}, \mathbf{SAT})$ has a solution in $\mathbf{P}$.*
2. *For any k, the class of languages that is accepted by nondeterministic machines that have at most $2^{\log^k(n)}$ accepting paths on inputs of length n is included in $\mathbf{P}$.*

Proof. This follows from Theorem 7.2, Theorem 7.8, and Corollary 7.5. ∎

8. Satisfying assignments. We show several connections between **CD** complexity and finding satisfying assignments of Boolean formulae. By Cook's theorem [5], finding satisfying assignments is equivalent to finding accepting computation paths of any **NP** computation.

8.1. Enumerating satisfying assignments. Papadimitriou [22] mentioned the following proposition.

PROPOSITION 8.1. *There exists a Turing machine that, given a formula ϕ, will output the set A of satisfying assignments of ϕ in time polynomial in $|\phi|$ and $\|A\|$.*

We can use **CD** complexity to show the following.

THEOREM 8.2. *Proposition* 8.1 *is equivalent to* $(1\mathbf{SAT}, \mathbf{SAT})$ *having a solution in* $\mathbf{P}$.

In Proposition 8.1, we do not require the machine to halt after printing out the assignments. If the machine is required to halt in time polynomial in ϕ and $\|A\|$, we have that Proposition 8.1 is equivalent to $\mathbf{P} = \mathbf{NP}$.

Proof of Theorem 8.2. The implication of $(1\mathbf{SAT}, \mathbf{SAT})$ having a solution in $\mathbf{P}$ is straightforward. We concentrate on the other direction.

Let $d = \|A\|$. By Lemma 3.2 and Theorem 7.8 we have that for every element x of A, $\mathbf{C}^q(x|\phi) \leq 2\log(d) + c\log(n)$ for some polynomial q and constant c. We simply now try every program p in length-increasing order and enumerate $p(\phi)$ if it is a satisfying assignment of ϕ. ∎

8.2. Computing satisfying assignments. In this section we turn our attention to the question of the complexity of generating a satisfying assignment for a satisfiable formula [28, 12, 21, 2]. It is well known [18] that one can generate (the leftmost) satisfying assignment in $\mathbf{FP}^{\mathbf{NP}}$. A tantalizing open question is whether one can compute some (not necessarily the leftmost) satisfying assignment in $\mathbf{FP}_{tt}^{\mathbf{NP}}$. Formalizing this question, we define the function class $\mathbf{F}_{sat}$ by $f \in \mathbf{F}_{sat}$ if, when $\varphi \in \mathbf{SAT}$, $f(\varphi)$ is a satisfying assignment of φ.

The question now becomes $\mathbf{F}_{sat} \bigcap \mathbf{FP}_{tt}^{\mathbf{NP}} = \emptyset$? Translating this to a **CND** setting, we have the following lemma.

LEMMA 8.3. $\mathbf{F}_{sat} \bigcap \mathbf{FP}_{tt}^{\mathbf{NP}} \neq \emptyset$ *if and only if for all $\phi \in \mathbf{SAT}$ there exists a satisfying assignment a of ϕ such that $\mathbf{CND}^p(a \mid \phi) \leq c\log(|\phi|)$ for some polynomial p and constant c.*

Lemma 8.3 relativizes when we consider a relativized version of $\mathbf{SAT}^A$ [10] by adding a series of extra predicates $A_0, A_1, A_2, \ldots$ such that $A_n(x_1, \ldots, x_n)$ is true if $x_1, \ldots, x_n$ is in A.

Toda and Watanabe [28] showed that, relative to a random oracle, $\mathbf{F}_{sat} \bigcap \mathbf{FP}_{tt}^{\mathbf{NP}} \neq \emptyset$. On the other hand, Buhrman and Thierauf [4] showed that there exists an oracle where $\mathbf{F}_{sat} \bigcap \mathbf{FP}_{tt}^{\mathbf{NP}} = \emptyset$. Their result also holds relative to the set constructed in Theorem 6.2.

THEOREM 8.4. *Relative to the set A constructed in Theorem* 6.2, $\mathbf{F}_{sat} \bigcap \mathbf{FP}_{tt}^{\mathbf{NP}} = \emptyset$.

Proof. For some n, let ϕ be the formula on n variables such that $\phi(x)$ is true if and only if $x \in A$. Suppose $\mathbf{F}_{sat} \bigcap \mathbf{FP}_{tt}^{\mathbf{NP}} \neq \emptyset$. It now follows by Lemma 8.3 that there exists an $x \in A$ such that $\mathbf{CND}^{p,A}(x) \leq O(\log(|x|))$ for some polynomial p, contradicting the fact that for all $x \in A$, $\mathbf{CND}^{2^{\sqrt{|x|}},A}(x) \geq |x|/4$. □

8.3. Isolating satisfying assignments. In this section we take a Kolmogorov complexity view of the statement and proof of the famous Valiant–Vazirani lemma [27]. The Valiant–Vazirani lemma gives a randomized reduction from a satisfiable formula to another formula that, with a nonnegligible probability, has exactly one satisfying assignment.

We state the lemma in terms of Kolmogorov complexity.

LEMMA 8.5. *There is some polynomial p such that for all ϕ in* **SAT** *and all r such that $|r| = p(|\phi|)$ and $\mathbf{C}(r) \geq |r|$ there is some satisfying assignment a of ϕ such that $\mathbf{CD}^p(a|\langle \phi, r \rangle) \leq O(\log(|\phi|))$.*

The usual Valiant–Vazirani lemma follows from the statement of Lemma 8.5 by choosing r and the $O(\log(|\phi|))$-size program randomly.

We show how to derive the Valiant–Vazirani lemma from Sipser's lemma (see Lemma 3.6). Note that Sipser's result predates Valiant–Vazirani by a couple of years.

Proof of Lemma 8.5. Let $n = |\phi|$. Consider A, the set of satisfying assignments of ϕ. We can apply Lemma 3.6 conditioned on ϕ using part of r as the random strings. Let $d = \lfloor \log(\|A\|) \rfloor$. We get that every element of A has a **CD** program of length bounded by $d + c\log(n)$ for some constant c. Since two different elements from A must have different programs, we have at least $1/n^c$ of the strings of length $d + c\log(n)$ that must distinguish some assignment in A.

We use the rest of r to list n^{2c} different strings of length $d + c\log(n)$. Since r is random, one of these strings w must be a program that distinguishes some assignment a in A. We can give a **CD** program for a in $O(\log(n))$ bits by giving d and a pointer to w in r. □

9. Search vs. decision in exponential time. If $\mathbf{P} = \mathbf{NP}$, then given a satisfiable formula, one can use binary search to find the assignment.

One might expect a similar result for exponential-time computation, i.e., if $\mathbf{EXP} = \mathbf{NEXP}$, then one should find a witness of a **NEXP** computation in exponential time. However, the proof for polynomial time breaks down because as one does the binary search the input questions get too long. Impagliazzo and Tardos [15] give relativized evidence that this problem is indeed hard.

THEOREM 9.1 (see [15]). *There exists a relativized world where $\mathbf{EXP} = \mathbf{NEXP}$, but there exists a* **NEXP** *machine whose accepting paths cannot be found in exponential time.*

We can give a short proof of this theorem using Theorem 6.2.

Proof of Theorem 9.1. Let A be from Theorem 6.2.

We will encode a tally set T such that $\mathbf{EXP}^{A\oplus T} = \mathbf{NEXP}^{A\oplus T}$. Let M be a nondeterministic oracle machine such that M runs in time 2^n and, for all B, M^B is $\mathbf{NEXP}^B$-complete.

Initially let $T = \emptyset$. For every string w in lexicographic order, put 1^{2w} into T if $M^{A\oplus T}(x)$ accepts.

Let $B = A\oplus T$ at the end of the construction. Since $M(w)$ could only query strings with length at most $2^{|w|} \leq w$, this construction will give us $\mathbf{EXP}^B = \mathbf{NEXP}^B$.

We will show that there exists a $\mathbf{NEXP}^B$ machine whose accepting paths cannot be found in time that is exponential relative to B.

Consider the $\mathbf{NEXP}^B$ machine M that on input n guesses a string y of length n and accepts if y is in A. Note that M runs in time $2^{|n|} \leq n$.

Suppose accepting computations of M^B can be found in time $2^{|n|^k} = 2^{\log^k(n)}$ relative to B. By Theorem 6.2, we can fix some large n such that $A^{=n} \neq \emptyset$ and, for all $x \in A^{=n}$,

$$\mathbf{CND}^{2^{\log^k(n)},A}(x) \geq n/4. \tag{9.1}$$

Let $w_i = \|\{1^m \mid 1^m \in T \text{ and } 2^i < m \leq 2^{i+1}\}\|$. We will show the following lemma.

LEMMA 9.2.

$$\mathbf{CND}^{2^{\log^k(n)},A}\left(x|w_1,\ldots,w_{\log^k(n)}\right) \leq \log(n) + O(1).$$

Assuming Lemma 9.2, Theorem 9.1 follows since, for each i, $|w_i| \leq i+1$. We thus have our contradiction with (9.1). □

Proof of Lemma 9.2. We will construct a program p^A to nondeterministically distinguish x. We use $\log(n)$ bits to encode n. First p will reconstruct T using the w_i's.

Suppose we have reconstructed T up to length 2^i. By our construction of T, strings of T of length at most 2^{i+1} can only depend on oracle strings of length at most $2^{i+1}/2 = 2^i$. We guess w_i strings of the form 1^m for $2^i < m \leq 2^{i+1}$ and nondeterministically verify that these are the strings in T. Once we have T, we also have $B = A \oplus T$, so in time $2^{\log^k(n)}$, we can find x. □

Impagliazzo and Tardos [15] prove Theorem 9.1 using an "X-search" problem. We can also relate this problem to **CND** complexity and Theorem 6.2.

DEFINITION 9.3. *The X-search problem has a player who, given N input variables not all zero, wants to find a one. The player can ask r rounds of l parallel queries of a certain type each and wins if the player discovers a one.*

Impagliazzo and Tardos [15] use the following result about the X-search problem to prove Theorem 9.1.

THEOREM 9.4 (see [15]). *If the queries are restricted to k-DNFs and $N > 2(klr)^2(l+1)^r$, then the player will lose on some nonzero setting of the variables.*

One can use a proof similar to that of Theorem 9.1 to prove a similar bound for Theorem 9.4: one just needs to apply Theorem 6.2 relative to the strategy of the player.

One can also use Theorem 9.4 to prove a weaker version of Theorem 6.2. Pick a large n and a time bound t. Let $N = 2^n$ and suppose for all $B \subseteq \Sigma^n$ there is an x in B, $\mathbf{CND}^{t,B}(x) \leq w$. Let $N = 2^n$.

For a fixed B and x, let p be the **CND** program that distinguishes x. Nondeterministically we can find the ith bit of x using t queries to B by guessing x

and the accepting computation of $U_n(p,x)$. We can express this computation as the complement of a t-**DNF** question.

We now build a strategy for X-search: Try all p and i, $|p| \leq 2^{|p|}$ and $1 \leq i \leq n$, in the first round using the t-**DNF** described above. This gives us a list of $2^{|p|}$ possible x's. We just try them all.

This solves the X-search problem using $k = t$, $l = n2^{|w|}$, and $r = 2$. By Theorem 9.4 we have $N \leq 2(tn2^w2)^2(n2^w)^2$. Taking logarithms we get $n \leq 2(\log t + \log n + w + \log 2) + 2(\log n + w)$. Thus we have a contradiction whenever $w = an$ and $t = 2^{bn}$ for $4a + 2b < 1$. In particular this gives us an infinite set A such that $\mathbf{CND}^{2^{n^{1/6}},A}(x) \geq |x|/7$ for all x in A.

10. BPP in the second level of the polynomial hierarchy. One of the applications of Sipser's [24] randomized version of Lemma 3.2 is the proof that **BPP** is in Σ_2^p. We will show that the approach taken in Lemma 3.2 yields a new proof of this result. We will first prove the following variation of Lemma 3.1.

LEMMA 10.1. *Let $S = \{x_1, \ldots, x_d\} \subseteq \{0, \ldots, n-1\}$. There exists a prime number p such that for all $x_i, x_j \in S$ $(i \neq j), x_i \not\equiv x_j \bmod p$, and such that $p \leq 2d^2 \log(n)$.*

Proof. We consider only prime numbers between c and $2c$. For $x_i, x_j \in S$ it holds that, for at most $\log_c(n) = \frac{\log(n)}{\log(c)}$ different prime numbers p, $x_i \equiv x_j \bmod p$. Moreover, there are at most $d(d-1)$ different pairs of strings in S, so there exists a prime number p among the first $d(d-1)\frac{\log(n)}{\log(c)} + 1$ prime numbers such that, for all $x_i, x_j \in S (i \neq j)$, it holds that $x_i \not\equiv x_j \bmod p$. Applying again the prime number theorem [13], it follows that if we take $c > d(d-1)\log(n)$, then $p \leq 2d^2 \log(n)$. ∎

The idea is to use Lemma 10.1 as a way to approximate the number of accepting paths of a **BPP** machine M. Note that the set of accepting paths $\mathbf{ACCEPT}_{M(x)}$ of M on x is in **P**. If this set is "small," then there exists a prime number satisfying Lemma 10.1. On the other hand, if the set is "big," no such prime number exists. This can be verified in Σ_2^p: There exists a number p such that for all pairs of accepting paths x_i, x_j of M, $x_i \not\equiv x_j \bmod p$. In order to apply this idea, we need the gap between the number of accepting paths when x is in the set and when it is not to be a square: if x is not in the set, then $\|\mathbf{ACCEPT}_{M(x)}\| \leq k(|x|)$, and if x is in the set, $\|\mathbf{ACCEPT}_{M(x)}\| > k^2(|x|)$. We will apply Zuckerman's oblivious sampler construction [29] to obtain this gap.

THEOREM 10.2. *Let M be a probabilistic machine that witnesses that some set A is in* **BPP**. *Assume that $M(x)$ uses m random bits. There exists a machine M' that uses $3m + 9m^{1-\frac{1}{2\log^*(m)}}$ random bits such that if $x \in A$, then $\Pr[M'(x)$ accepts$] > 1 - \frac{1}{2^{2m}}$, and if $x \notin A$, then $\Pr[M'(x)$accepts$] < \frac{1}{2^{2m}}$.*

Proof. Use the sampler in [29] with $\epsilon < 1/6$, $\gamma = \frac{1}{2^{2m}}$, and $\alpha = 3m^{-\frac{1}{2\log^*(m)}}$.

Let $A \in \mathbf{BPP}$ be witnessed by probabilistic machine M. Apply Theorem 10.2 to obtain M'. The Σ_2^p algorithm for $\overline{A}$ works as follows:

input x

Guess $p \leq 2^{2m+18m^{1-\frac{1}{2\log^*(m)}}}(3m + 9m^{1-\frac{1}{2\log^*(m)}})$

If for all $u, v \in \mathbf{ACCEPT}_{M'(x)}$ $u \not\equiv v \bmod p$ **accept** else **reject**

If $x \in \overline{A}$, then $\|\mathbf{ACCEPT}_{M'(x)}\| \leq 2^{m+9m^{1-\frac{1}{2\log^*(m)}}}$, and Lemma 10.1 guarantees that the above program accepts. On the other hand, if $x \in A$, then $\|\mathbf{ACCEPT}_{M'(x)}\| >$

$2^{3m+9m^{1-\frac{1}{2\log^*(m)}}-1}$ and for every prime number

$$p \leq 2^{2m+18m^{1-\frac{1}{2\log^*(m)}}}(3m+9m^{1-\frac{1}{2\log^*(m)}})$$

there will be a pair of strings in $\mathbf{ACCEPT}_{M'(x)}$ that are not congruent modulo p. This follows because for every number $p \leq 2^{2m+18m^{1-\frac{1}{2\log^*(m)}}}(3m+9m^{1-\frac{1}{2\log^*(m)}})$ at most $2^{2m+18m^{1-\frac{1}{2\log^*(m)}}}(3m+9m^{1-\frac{1}{2\log^*(m)}})$ different u and v it holds that $u \not\equiv v \bmod p$. □

Goldreich and Zuckerman [11] independently used Zuckerman's sampler [29] to give another proof that **BPP** is in Σ_2^p.

Acknowledgments. We would like to thank José Balcázar, Leen Torenvliet, and David Zuckerman for their comments on this subject. We thank John Tromp for the current presentation of the proof of Lemma 3.2. We thank Richard Beigel, Bill Gasarch, Stuart Kurtz, Amber Settle, Leen Torenvliet, and the two anonymous referees for comments on earlier drafts.

SEPARATION OF NP-COMPLETENESS NOTIONS*

A. PAVAN† AND ALAN L. SELMAN‡

Abstract. We use hypotheses of structural complexity theory to separate various NP-completeness notions. In particular, we introduce an hypothesis from which we describe a set in NP that is $\leq^{\mathrm{P}}_{\mathrm{T}}$-complete but not $\leq^{\mathrm{P}}_{tt}$-complete. We provide fairly thorough analyses of the hypotheses that we introduce.

Key words. Turing completeness, truth-table completeness, many-one completeness, p-selectivity, p-genericity

AMS subject classification. 68Q15

1. Introduction.

Ladner, Lynch, and Selman [LLS75] were the first to compare the strength of polynomial-time reducibilities. They showed, for the common polynomial-time reducibilities, Turing ($\leq^{\mathrm{P}}_{\mathrm{T}}$), truth-table ($\leq^{\mathrm{P}}_{tt}$), bounded truth-table ($\leq^{\mathrm{P}}_{btt}$), and many-one ($\leq^{\mathrm{P}}_{m}$), that

$$\leq^{\mathrm{P}}_{m} \prec \leq^{\mathrm{P}}_{btt} \prec \leq^{\mathrm{P}}_{tt} \prec \leq^{\mathrm{P}}_{\mathrm{T}},$$

where $\leq^{\mathrm{P}}_{r} \prec \leq^{\mathrm{P}}_{s}$ means that $\leq^{\mathrm{P}}_{r}$ is *properly stronger* than $\leq^{\mathrm{P}}_{s}$; that is, $A \leq^{\mathrm{P}}_{r} B$ implies $A \leq^{\mathrm{P}}_{s} B$, but the converse does not hold. In each case, the verifying sets belong to $\mathrm{E} = \mathrm{DTIME}(2^n)$. Ladner, Lynch, and Selman raised the obvious question of whether reducibilities differ on NP. If there exist sets A and B in NP (other than the empty set or Σ^*) such that $A \leq^{\mathrm{P}}_{\mathrm{T}} B$ but $A \not\leq^{\mathrm{P}}_{m} B$, then, of course, $\mathrm{P} \neq \mathrm{NP}$ follows immediately. With this in mind, they conjectured that $\mathrm{P} \neq \mathrm{NP}$ implies that $\leq^{\mathrm{P}}_{\mathrm{T}}$ and $\leq^{\mathrm{P}}_{m}$ differ on NP.

In the intervening years, many results have explained the behavior of polynomial-time reducibilities within other complexity classes and have led to a complete understanding of the completeness notions that these reducibilities induce. For example, Ko and Moore [KM81] demonstrated the existence of $\leq^{\mathrm{P}}_{\mathrm{T}}$-complete sets for EXP that are not $\leq^{\mathrm{P}}_{m}$-complete. Watanabe [Wat87] extended this result significantly, showing that $\leq^{\mathrm{P}}_{1-tt}$-, $\leq^{\mathrm{P}}_{btt}$-, $\leq^{\mathrm{P}}_{tt}$-, and $\leq^{\mathrm{P}}_{\mathrm{T}}$-completeness for EXP are mutually different, while Homer, Kurtz, and Royer [HKR93] proved that $\leq^{\mathrm{P}}_{m}$- and $\leq^{\mathrm{P}}_{1-tt}$-completeness are identical.

However, there have been few results comparing reducibilities within NP, and we have known very little concerning various notions of NP-completeness. It is surprising that no NP-complete problem has been discovered that requires anything other than many-one reducibility for proving its completeness. The first result to distinguish reducibilities within NP is an observation of Wilson in one of Selman's papers on p-selective sets [Sel82]. It is a corollary to results there that if NE$\cap$*co*-NE $\neq$ E, then there exist sets A and B belonging to NP such that $A \leq^{\mathrm{P}}_{ptt} B$, $B \leq^{\mathrm{P}}_{tt} A$, and $B \not\leq^{\mathrm{P}}_{ptt} A$, where

$\leq^{\mathrm{P}}_{ptt}$ denotes positive truth-table reducibility. Regarding completeness, Longpré and Young [LY90] proved that there are $\leq^{\mathrm{P}}_{m}$-complete sets for NP for which $\leq^{\mathrm{P}}_{\mathrm{T}}$-reductions to these sets are *faster*, but they did not prove that the completeness notions differ. The first to give technical evidence that $\leq^{\mathrm{P}}_{\mathrm{T}}$- and $\leq^{\mathrm{P}}_{m}$-completeness for NP differ are Lutz and Mayordomo [LM96], who proved that if the p-measure of NP is not zero, then there exists a $\leq^{\mathrm{P}}_{3\text{-}tt}$-complete set that is not $\leq^{\mathrm{P}}_{m}$-complete. Ambos-Spies and Bentzien [ASB00] extended this result significantly. They used an hypothesis of resource-bounded category theory that is weaker than that of Lutz and Mayordomo to separate nearly all NP-completeness notions for the bounded truth-table reducibilities.

It has remained an open question as to whether we can separate NP-completeness notions without using hypotheses that involve essentially stochastic concepts. Furthermore, the only comparisons of reducibilities within NP known to date have been those just listed.

Here we report some exciting new progress on these questions. Our main new result introduces a strong, but reasonable, hypothesis to prove existence of a $\leq^{\mathrm{P}}_{\mathrm{T}}$-complete set in NP that is not $\leq^{\mathrm{P}}_{tt}$-complete. Our result is the first to provide evidence that $\leq^{\mathrm{P}}_{tt}$-completeness is weaker than $\leq^{\mathrm{P}}_{\mathrm{T}}$-completeness. Let Hypothesis H be the following assertion: There is a UP-machine M that accepts 0^* such that (i) no polynomial time-bounded Turing machine correctly computes infinitely many accepting computations of M, and (ii) for some $\epsilon > 0$, no 2^{n^ϵ} time-bounded Turing machine correctly computes all accepting computations of M. Hypothesis H is similar to, but seemingly stronger than, hypotheses considered by researchers previously, notably Fenner et al. [FFNR96], Hemaspaandra, Rothe, and Wechsung [HRW97], and Fortnow, Pavan, and Selman [FPS99].

This result is especially interesting because the measure theory and category theory techniques seem to be successful primarily for the nonadaptive reducibilities. We will prove an elegant characterization of the genericity hypothesis of Ambos-Spies and Bentzien and compare it with Hypothesis H. Here, somewhat informally, let us say this: The genericity hypothesis asserts existence of a set L in NP such that no 2^{2n} time-bounded Turing machine can correctly *predict* membership of infinitely many x in L from the initial characteristic sequence $L|x = \{y \in L \mid y < x\}$. That is, L is almost-everywhere unpredictable within time 2^{2n}. Clearly, such a set L is 2^{2n}-bi-immune. In contrast, we show that Hypothesis H holds if there is a set L in UP$\cap$co-UP such that L is P-bi-immune and $L \cap 0^*$ is not in DTIME(2^{n^ϵ}) for some $\epsilon > 0$. Thus, we replace "almost-everywhere unpredictable" with P-bi-immunity and we lower the time bound from 2^{2n} to 2^{n^ϵ}, but we require L to belong to UP $\cap$ co-UP rather than NP.

We prove several other separations as well and some with significantly weaker hypotheses. For example, we prove that NP contains $\leq^{\mathrm{P}}_{\mathrm{T}}$-complete sets that are not $\leq^{\mathrm{P}}_{m}$-complete, if NP $\cap$ co-NP contains a set that is 2^{n^ϵ}-bi-immune, for some $\epsilon > 0$.

2. Preliminaries. We use standard notation for polynomial-time reductions [LLS75], and we assume that readers are familiar with Turing, $\leq^{\mathrm{P}}_{\mathrm{T}}$, and many-one, $\leq^{\mathrm{P}}_{m}$, reducibilities. A set A is *truth-table* reducible to a set B (in symbols $A \leq^{P}_{tt} B$) if there exist polynomial-time computable functions g and h such that on input x, $g(x)$ is a set of queries $Q = \{q_1, q_2, \cdots, q_k\}$, and $x \in A$ if and only if $h(x, B(q_1), B(q_2), \cdots, B(q_k)) = 1$. The function g is the *truth-table generator* and h is the *truth-table evaluator*. For a constant $k > 0$, A is *k-truth-table* reducible to B ($A \leq^{P}_{k\text{-}tt} B$) if for all x, $\|Q\| = k$, and A is *bounded-truth-table* reducible to B ($A \leq^{\mathrm{P}}_{btt} B$) if there is a constant $k > 0$ such that $A \leq^{P}_{k\text{-}tt} B$. Given a polynomial-time reducibility $\leq^{\mathrm{P}}_{r}$, recall that a set S is

$\leq_r^{\mathrm{P}}$-complete for NP if $S \in \mathrm{NP}$ and every set in NP is $\leq_r^{\mathrm{P}}$-reducible to S.

Recall that a set L is *p-selective* if there exists a polynomial-time computable function $f : \Sigma^* \times \Sigma^* \to \Sigma^*$ such that for all x and y, $f(x,y) \in \{x,y\}$ and $f(x,y)$ belongs to L if either $x \in L$ or $y \in L$ [Sel79]. The function f is called a *selector* for L.

Given a finite alphabet Σ, let Σ^ω denote the set of all strings of infinite length of order type ω. For $r \in \Sigma^* \cup \Sigma^\omega$, the standard left cut of r [Sel79, Sel82] is the set

$$L(r) = \{x \mid x < r\},$$

where $<$ is the ordinary dictionary ordering of strings with 0 less than 1. It is obvious that every standard left cut is p-selective with selector $f(x,y) = \min(x,y)$.

Given a p-selective set L such that the function f defined by $f(x,y) = \min(x,y)$ is a selector for L, we call f a *min-selector* for L. We will use the following simplified version of a lemma of Toda [Tod91]. Let $\perp$ be a special symbol such that $\perp \leq x$ for all $x \in \Sigma^*$.

LEMMA 2.1. *Let L be a p-selective set with a min-selector f. For any finite set Q there exists a string $z \in Q \cup \{\perp\}$ such that $Q \cap L = \{y \in Q \mid y \leq z\}$ and $Q \cap \overline{L} = \{y \in Q \mid y > z\}$. The string z is called a "pivot" string.*

Now we review various notions related to almost-everywhere hardness. A language L is *immune* to a complexity class $\mathcal{C}$, or $\mathcal{C}$-*immune*, if L is infinite and no infinite subset of L belongs to $\mathcal{C}$. A language L is *bi-immune* to a complexity class $\mathcal{C}$, or $\mathcal{C}$-*bi-immune*, if L and $\overline{L}$ are both immune to $\mathcal{C}$. Then, L is *bi-immune* to $\mathcal{C}$ if and only if L is infinite, no infinite subset of L belongs to $\mathcal{C}$, and no infinite subset of $\overline{L}$ belongs to $\mathcal{C}$. A language is $\mathrm{DTIME}(T(n))$-*complex* if L does not belong to $\mathrm{DTIME}(T(n))$ almost everywhere; that is, every Turing machine M that accepts L runs in time greater than $T(|x|)$ for all but finitely many words x. Balcázar and Schöning [BS85] proved that for every time-constructible function T, L is $\mathrm{DTIME}(T(n))$-complex if and only if L is bi-immune to $\mathrm{DTIME}(T(n))$.

Given a time bound $T(n)$, a language L is $T(n)$-*printable* if there exists a $T(n)$ time-bounded Turing machine that, on input 0^n, prints all elements of $L \cap \Sigma^{=n}$ [HY84]. A set S is $T(n)$-*printable-immune* if S is infinite and no infinite subset of S is $T(n)$-printable.

In order to compare our hypotheses with the genericity hypothesis we describe time-bounded genericity [ASFH87]. For this purpose, we follow the exposition of Ambos-Spies, Neis, and Terwijn [ASNT96]. Given a set A and string x, $A|x = \{y \mid y < x \text{ and } y \in A\}$. Let $\Sigma^* = \{z_n\}_n$, where z_n is the nth string in lexicographic order. We identify the initial segment $A|z_n$ with its characteristic sequence; i.e., $A|z_n = A(z_0) \cdots A(z_{n-1})$. A *condition* is a set $C \subseteq \Sigma^*$. *A meets C* if for some x, the characteristic sequence $A|x \in C$. C is *dense along A* if for infinitely many strings x there exists $i \in \{0,1\}$ such that the concatenation $(A|x)i \in C$. Then, the set A is $\mathrm{DTIME}(t(n))$-*generic* if A meets every condition $C \in \mathrm{DTIME}(t(n))$ that is dense along A. To simplify the notation, we say that A is $t(n)$-*generic* if it is $\mathrm{DTIME}(t(n))$-generic.

Finally, we briefly describe the Kolmogorov complexity of a finite string. Later we will use this in an oracle construction. The interested reader should refer to Li and Vitányi [LV97] for an in-depth study. Fix a universal Turing machine U. Given a string x and a finite set $S \subseteq \Sigma^*$, the *Kolmogorov complexity of x with respect to S* is defined by

$$K(x|S) = \min\{|p| \mid U(p,S) = x\}.$$

If $S = \emptyset$, then $K(x|S)$ is called the *Kolmogorov complexity* of x, denoted $K(x)$. We will also use time-bounded Kolmogorov complexity $K^t(x)$. For this definition, we require that $U(p)$ runs in at most $t(|x|)$ steps.

3. Separation results. Let Hypothesis H be the following assertion.

Hypothesis H. There is a UP-machine M that accepts 0^* such that

1. no polynomial time-bounded Turing machine correctly computes infinitely many accepting computations of M, and
2. for some $\epsilon > 0$, no 2^{n^ϵ} time-bounded Turing machine correctly computes all accepting computations of M.

THEOREM 3.1. *If Hypothesis* H *is true, then there exists a* $\leq^{\mathrm{P}}_{\mathrm{T}}$*-complete language for* NP *that is not* $\leq^{\mathrm{P}}_{tt}$*-complete for* NP.

Proof. Let $\epsilon > 0$, and let M be a UP-machine that satisfy the conditions of Hypothesis H. For each $n \geq 0$, let a_n be the unique accepting computation of M on 0^n, and let $l_n = |a_n|$. Define the language

$$L_1 = \{\langle x, a_n\rangle \mid |x| = n, \text{ and } x \in \mathrm{SAT}\}.$$

Define the infinite string $a = a_1 a_2 \ldots$, and define

$$L_2 = L(a) = \{x \mid x < a\}$$

to be the standard left-cut of a.

We define $L = L_1 \oplus L_2$ to be the disjoint union of L_1 and L_2. We will prove that L is $\leq^{\mathrm{P}}_{\mathrm{T}}$-complete for NP but not $\leq^{\mathrm{P}}_{tt}$-complete.

LEMMA 3.2. *L is $\leq^{\mathrm{P}}_{\mathrm{T}}$-complete for* NP.

Proof. It is clear that L belongs to NP. The following reduction witnesses that $\mathrm{SAT} \leq^{\mathrm{P}}_{\mathrm{T}} L$: Given an input string x, where $|x| = n$, use a binary search algorithm that queries L_2 to find a_n. Then, note that $x \in \mathrm{SAT}$ if and only if $\langle x, a_n\rangle$ belongs to L_1. □

LEMMA 3.3. *L is not $\leq^{\mathrm{P}}_{tt}$-complete for* NP.

Proof. Assume that L is $\leq^{\mathrm{P}}_{tt}$-complete for NP. Define the set

$$S = \{\langle 0^n, i\rangle \mid \text{ the } i\text{th bit of } a_n = 1\}.$$

Clearly, S belongs to NP. Thus, by our assumption, there is a $\leq^{\mathrm{P}}_{tt}$-reduction $\langle g, h\rangle$ from S to L. Given this reduction, we will derive a contradiction to Hypothesis H.

Consider the following procedure $\mathcal{A}$:

1. Input 0^n.
2. Compute the sets $Q^j = g(\langle 0^n, j\rangle)$ for $1 \leq j \leq l_n$. Let $Q = \bigcup\{Q^j \mid 1 \leq j \leq l_n\}$.
3. Let Q_1 be the set of all queries in Q to L_1, and let Q_2 be the set of all queries in Q to L_2 ($Q = Q_1 \cup Q_2$).
4. If Q_1 contains a query $\langle x, a_t\rangle$, where $t \geq n^\epsilon$, then output "Unsuccessful" and Print a_t, else output "Successful."

Observe that this procedure runs in polynomial time. We treat two cases, namely, $\mathcal{A}(0^n)$ is either unsuccessful, for infinitely many n, or it is successful for all but finitely many n.

CLAIM 1. *If the procedure $\mathcal{A}(0^n)$ is unsuccessful for infinitely many n, then there is a polynomial time-bounded Turing machine that correctly computes infinitely many accepting computations of M, thereby contradicting Clause* 1 *of Hypothesis* H.

Proof. If $\mathcal{A}(0^n)$ is unsuccessful, then it outputs a string a_t such that $t \geq n^\epsilon$. Hence, if $\mathcal{A}(0^n)$ is unsuccessful for infinitely many n, then for infinitely many t there

exists an n, where $n \leq t^{1/\epsilon}$, and $\mathcal{A}(0^n)$ outputs a_t. The following procedure uses this observation to compute infinitely many accepting computations of M in polynomial time.

input 0^t;
for $j = 1$ to $j = t^{1/\epsilon}$ **do**
    if $\mathcal{A}(0^j)$ outputs a_t
        then output a_t and halt.

The procedure runs in polynomial time because the procedure $\mathcal{A}(0^j)$ runs in polynomial time. □

CLAIM 2. *If $\mathcal{A}(0^n)$ is successful for all but finitely many n, then there is a 2^{n^ϵ} time-bounded Turing machine that correctly computes all accepting computations of M, thereby contradicting Clause* 2 *of Hypothesis* H.

Proof. We will demonstrate a procedure $\mathcal{B}$ such that for each n, if $\mathcal{A}(0^n)$ is successful, then $\mathcal{B}$ on input 0^n outputs the accepting computation of M on 0^n in 2^{n^ϵ} time.

If $\mathcal{A}(0^n)$ is successful, then no member of the set Q_1 is of the form $\langle x, a_t\rangle$ where $t \geq n^\epsilon$. We begin our task with the following procedure $\mathcal{C}$ that for each query $q = \langle y, z\rangle$ in Q_1 decides whether $q \in L_1$.

1. Input $q = \langle y, z\rangle$.
2. If $z \neq a_t$ for any t, then $\langle y, z\rangle$ does not belong to L_1. (This can be determined in polynomial time.)
3. If $z = a_t$, where $t \leq n^\epsilon$, then $\langle y, z\rangle$ belongs to L_1 only if $|y| = t$ and y belongs to SAT. (Since $t \leq n^\epsilon$ this step can be done in time 2^{n^ϵ}.)

Thus, $\mathcal{C}$ decides membership in L_1 for all queries q in Q_1. Therefore, if for each query q in Q_2, we can decide whether q belongs to L_2, then the evaluator h can determine whether each input $\langle 0^n, j\rangle$, $1 \leq j \leq l_n$, belongs to S. That is, if for each query q in Q_2, we can decide whether q belongs to L_2, then we can compute a_n. We can accomplish this using a standard proof technique for p-selective sets [HNOS96, Tod91]. Namely, since L_2 is a standard left-cut, by Lemma 2.1, there exists a pivot string z in $Q_2 \cup \{\perp\}$ such that $Q_2 \cap L_2$ is the set of all strings in Q_2 that are less than or equal to z. We do not know which string is the pivot string, but there are only $\|Q_2\|$ choices, which is bounded by a polynomial in n. Thus, procedure $\mathcal{B}$ on input 0^n proceeds as follows to compute a_n: For each possible choice of pivot and the output from procedure $\mathcal{C}$, the evaluator h computes a possible value for each jth bit of a_n. There are only a polynomial number of possible choices of a_n because there are only a polynomial number of pivots. $\mathcal{B}$ verifies which choice is the correct accepting computation of M on 0^n and outputs that value. Finally, we have only to note that the entire process can be carried out in 2^{n^ϵ} steps. This completes the proof of our claim. □

Lemma 3.3 follows from Claims 1 and 2, and the theorem follows from Lemmas 3.2 and 3.3. □

Let Hypothesis H′ be the following assertion.

Hypothesis H′. There is an NP-machine M that accepts 0^* such that for some $0 < \epsilon < 1$, no 2^{n^ϵ} time-bounded Turing machine correctly computes infinitely many accepting computations of M.

THEOREM 3.4. *If Hypothesis* H′ *is true, then there exists a Turing complete language for* NP *that is not* $\leq_m^{\mathrm{P}}$*-complete for* NP.

Proof. Let $0 < \epsilon < 1$, and let M be an NP-machine that satisfy the conditions of Hypothesis H′. For each $n \geq 0$, let a_n be the lexicographically maximum accepting

input 0^n;
$y := \lambda$;
Repeat l_n times
  begin
  $x_0 := f(\langle 0^n, y0\rangle)$;
  $x_1 := f(\langle 0^n, y1\rangle)$;
  if both x_0 and x_1 are queries to L_2
    then if $x_0 \le x_1$
      then $y := y0$
      else $y := y1$
    else {At least one of x_0 and x_1 is a query to L_1; let $b \in \{0,1\}$ be the least index such that x_b queries L_1, and let $x_b = \langle z, u\rangle$.}
      if u is not an accepting computation of M {thus, $x_b \notin L_1$}
        then $y = y\bar{b}$
        else {u is an accepting computation of M on some string 0^t}
          if $t \ge n^\epsilon$
            then output "Unsuccessful," print u, and terminate
            else $\{t < n^\epsilon\}$
              if $|z| = t^\epsilon/2$ and $z \in$ SAT {thus, $x_b \in L_1$}
                then $y := yb$
                else $\{x_b \notin L_1\}$ $y := y\bar{b}$
  end;
output "Successful" and print y.

FIG. 3.1. *Procedure* $\mathcal{D}$.

computation of M on 0^n, and let $|a_n| = l_n$. Define the language

$$L_1 = \{\langle x, u\rangle \mid |x| = n,\ u \text{ is an accepting computation of } M \text{ on } 0^m,\ n = m^\epsilon/2,\ \text{and } x \in \text{SAT}\}.$$

Let $a = a_1 a_2 a_3 \cdots$, and define

$$L_2 = L(a) = \{x \mid x < a\}.$$

Define $L = L_1 \oplus L_2$.

It is easy to see, as in the previous argument, that L is $\le_{\mathrm{T}}^{\mathrm{P}}$-complete for NP. In order to prove that L is not $\le_m^{\mathrm{P}}$-complete, we define the set

$$S = \{\langle 0^n, y\rangle \mid y \text{ is a prefix of an accepting computation of } M \text{ on } 0^n\},$$

which belongs to NP, and assume there is a $\le_m^{\mathrm{P}}$-reduction f from S to L. Consider the procedure $\mathcal{D}$ in Figure 3.1: First we will analyze the running time and then we treat two cases, namely, $\mathcal{D}(0^n)$ is either successful for infinitely many n, or it is unsuccessful for all but finitely many n.

CLAIM 3. *The above procedure halts in* $O(l_n 2^{n^{\epsilon^2}/2})$ *steps.*

Proof. Consider an iteration of the repeat loop. The most expensive step is the test of whether "$z \in$ SAT." This test occurs only when $|z| = t^\epsilon/2$ and $t < n^\epsilon$. Hence we can decide whether z belongs to SAT in $2^{n^{\epsilon^2}/2}$ steps. All other steps take polynomial time. Hence the time taken by the procedure is $O(l_n 2^{n^{\epsilon^2}/2})$. ∎

Since $0 < \epsilon < 1$, the running time of procedure $\mathcal{D}$ is bounded by 2^{n^ϵ}.

CLAIM 4. *If $\mathcal{D}(0^n)$ is successful for infinitely many n, then there is a 2^{n^ϵ}-time-bounded Turing machine that correctly computes infinitely many accepting computations of M.*

Proof. We demonstrate that if $\mathcal{D}$ is successful on an input 0^n, then the string that is printed is an accepting computation of M on 0^n. In order to accomplish this, we prove by induction that y is a prefix of an accepting computation of M on 0^n during every iteration of the repeat loop (i.e., a loop invariant). Initially, when $y = \lambda$, this is true. Assume that y is a prefix of an accepting computation of M at the beginning of an iteration. Then, at least one of $f(\langle 0^n, y0\rangle) = x_0$, $f(\langle 0^n, y1\rangle) = x_1$ must belong to L. If both x_0 and x_1 are queries to L_2, then the smaller of x_0 and x_1 belongs to L_2 because L_2 is p-selective. Thus, in this case, the procedure extends y correctly. If at least one of x_0 and x_1 is a query to L_1, then the procedure determines whether $x_b \in L_1$, where x_b is the query to L_1 with least index. If x_b belongs to L, then $\langle 0^n, yb\rangle \in S$. Hence, yb is a prefix of an accepting computation. If $x_b \notin L$, then $x_{\bar{b}}$ belongs to L because at least one of x_b or $x_{\bar{b}}$ belongs to L. Thus, in this case, $y\bar{b}$ is a prefix of an accepting computation. This completes the induction argument.

The loop repeats l_n times. Therefore, the final value of y, which is the string that $\mathcal{D}$ prints, is an accepting computation. □

CLAIM 5. *If $\mathcal{D}(0^n)$ is unsuccessful for all but finitely many n, then there is a 2^{n^ϵ}-time-bounded Turing machine that correctly computes infinitely many accepting computations of M.*

Proof. The proof is similar to the proof of Claim 1. The following procedure computes infinitely many accepting computations of M.

input 0^n;
for $j = 1$ to $j = n^{1/\epsilon}$ **do**
    if $\mathcal{D}(0^j)$ outputs u and u is an accepting computation of M on 0^n
        then print u and terminate.

The running time of this algorithm can be bounded as follows: The procedure $\mathcal{D}(0^j)$ runs in time $l_j 2^{j^{\epsilon^2}/2}$ steps. So the total running time is $\sum_1^{n^{1/\epsilon}} l_j 2^{j^{\epsilon^2}/2} = O(2^{n^\epsilon})$. □

Since the cases treated both by Claims 4 and 5 demonstrate Turing machines that correctly compute infinitely many accepting computations of M in 2^{n^ϵ} time, we have a contradiction to Hypothesis H′. Thus L is not $\leq_m^{\mathrm{P}}$-complete for NP. □

The following results give fine separations of polynomial-time reducibilities in NP from significantly weaker hypotheses. Moreover, they follow readily from results in the literature.

THEOREM 3.5. *If there is a tally language in* UP − P, *then there exist two languages L_1 and L_2 in* NP *such that $L_1 \leq_{tt}^{\mathrm{P}} L_2$, $L_2 \leq_{\mathrm{T}}^{\mathrm{P}} L_1$, but $L_1 \not\leq_{btt}^{\mathrm{P}} L_2$.*[1]

Proof. Let L be a tally language in UP − P. Let R be the polynomial-time computable relation associated with the language L. Define

$$L_1 = \{\langle 0^n, y\rangle \mid \exists w, R(0^n, w) \text{ and } y \leq w\}$$

and

$$L_2 = \{\langle 0^n, i\rangle \mid \exists w, R(0^n, w) \text{ and } i\text{th bit of } w \text{ is one}\}.$$

[1] The class of all languages that are $\leq_{\mathrm{T}}^{\mathrm{P}}$-equivalent to L_1 is a noncollapsing degree.

It is clear that L_1 is $\leq^{\mathrm{P}}_{tt}$-reducible to L_2. To see that L_2 is $\leq^{\mathrm{P}}_{\mathrm{T}}$-reducible to L_1, implement a binary search algorithm that accesses L_1 to determine the unique witness w such that $R(0^n, w)$ and then find the ith bit.

Observe that L_2 is a sparse set. Ogiwara and Watanabe [OW91] call L_1 the *left set* of L, and they and Homer and Longpré [HL94] proved for every L in NP that if the left set of L is $\leq^{\mathrm{P}}_{btt}$-reducible to a sparse set, then L is in P. Hence $L_1 \not\leq_{btt} L_2$. □

We now prove that Turing and truth-table reducibilities also differ in NP under the same hypothesis.

THEOREM 3.6. *If there is a tally language in* $\mathrm{UP} - \mathrm{P}$*, then there exist two languages* L_1 *and* L_2 *in* NP *such that* $L_1 \leq^{\mathrm{P}}_{\mathrm{T}} L_2$*, but* $L_1 \not\leq^{\mathrm{P}}_{tt} L_2$*.*

Proof. Hemaspaandra et al. [HNOS96] proved that the hypothesis implies existence of a tally language L in $\mathrm{UP}-\mathrm{P}$ such that L is not $\leq^{\mathrm{P}}_{tt}$-reducible to any p-selective set. In the same paper they also showed, given a tally language L in $\mathrm{NP} - \mathrm{P}$, how to obtain a p-selective set S such that L is $\leq^{\mathrm{P}}_{\mathrm{T}}$-reducible to S. Combining the two results we obtain the theorem. □

4. Analysis of the hypotheses. This section contains a number of results that help us to understand the strength of Hypotheses H and H′.

4.1. Comparisons with other complexity-theoretic assertions. We begin with some equivalent formulations of these hypotheses and then relate them to other complexity-theoretic assertions. The question of whether P contains a P-printable-immune set was studied by Allender and Rubinstein [AR88], and the equivalence of items 1 and 3 in the following theorem is similar to results of Hemaspaandra, Rothe, and Wechsung [HRW97] and Fortnow, Pavan, and Selman [FPS99]. The second item is similar to the characterization of Grollmann and Selman [GS88] of *one-one, one-way* functions with the addition of the attribute *almost-always one-way* of Fortnow, Pavan, and Selman.

THEOREM 4.1. *The following statements are equivalent:*

1. *There is a language* L *in* P *that contains exactly one string of every length such that* L *is* P*-printable-immune and, for some* $\epsilon > 0$*,* L *is not* 2^{n^ϵ}*-printable.*
2. *There exists a polynomial-bounded, one-one, function* $f : 0^* \to \Sigma^*$ *such that* f *is almost-everywhere not computable in polynomial time, for some* $\epsilon > 0$*,* f *is not computable in time* 2^{n^ϵ}*, and the graph of* f *belongs to* P.[2]
3. *Hypothesis* H *is true for some* $\epsilon > 0$*.*

Proof. Let L satisfy item 1. In order to prove item 2, define

$$f(0^n) = \text{ the unique string of length } n \text{ that belongs to } L.$$

Clearly, f is polynomial-bounded and one-one. The graph of f belongs to P because L belongs to P. Suppose that M is a Turing machine that computes f and that runs in polynomial time on infinitely many inputs. Then, on these inputs, M prints $L \cap \Sigma^n$. Similarly, f is not computable in time 2^{n^ϵ}.

Let f satisfy item 2. To prove that item 3 holds, define a UP-machine M to accept 0^* as follows: On input 0^n, M guesses a string y of length within the polynomial bound of f and accepts if and only if $\langle 0^n, y\rangle \in \mathit{graph}(f)$. The rest of the proof is clear.

Now we prove that item 3 implies item 1. Let M be a UP-machine that satisfies item 3, i.e., that satisfies the conditions of Hypothesis H. Let a_n be the unique accepting computation of M on 0^n, and let $|a_n| = n^l$. Let r_n be the rank of a_n among

[2] f is *polynomial-bounded* if for some polynomial q, for all x, $|f(x)| \leq q(|x|)$.

all strings of length n^l. Now we define L as follows: Given a string x, if $|x| = n^l$ for some n, then x belongs to L if and only if $x = a_n$. If $(n-1)^l < |x| < n^l$, then x belongs to L if and only if the rank of x (among all the string of length $|x|$) is r_{n-1}. It is clear that $L \in \mathrm{P}$ and has exactly one string per each length. We claim that L is P-printable-immune and is not 2^{n^ρ}-printable, where $\epsilon = l\rho$. Any machine that prints infinitely many strings of L in polynomial time can be used to print infinitely many accepting computations of M in polynomial time. Thus L is P-printable-immune. Any machine that prints all the strings of L in 2^{n^ρ} time can be used to print all the accepting computations of M in 2^{n^ϵ} time. Thus L is not 2^{n^ρ}-printable. □

We prove the following theorem similarly.

THEOREM 4.2. *The following statements are equivalent:*

1. *There is a language L in* P *that contains* at least *one string of every length such that, for some $\epsilon > 0$, L is 2^{n^ϵ}-printable-immune.*
2. *There is a polynomial-bounded, multivalued function $f : 0^* \to \Sigma^*$ such that every refinement of f is almost-everywhere not computable in 2^{n^ϵ}-time, and the graph of f belongs to* P.
3. *Hypothesis* H′ *holds for some $\epsilon > 0$.*

Next we compare our hypotheses with the following complexity-theoretic assertions:

1. For some $\epsilon > 0$, there is a P-bi-immune language L in UP ∩ co-UP such that $L \cap 0^*$ is not in DTIME(2^{n^ϵ}).
2. For some $\epsilon > 0$, there is a language L in UP ∩ co-UP such that L is not in DTIME(2^{n^ϵ}).
3. For some $\epsilon > 0$, there is a 2^{n^ϵ}-bi-immune language in NP ∩ co-NP.

THEOREM 4.3. *Assertion* 1 *implies Hypothesis* H *and Hypothesis* H *implies assertion* 2.

Proof. Let L be a language in UP ∩ co-UP that satisfies assertion 1. Define M to be the UP-machine that accepts 0^* as follows: On input 0^n, nondeterministically guess a string w. If w either witnesses that 0^n is in L or witnesses that 0^n is in $\overline{L}$, then accept 0^n. It is immediate that M satisfies the conditions of Hypothesis H.

To prove the second implication, let M be a UP-machine that satisfies the conditions of Hypothesis H. Let a_n denote the unique accepting computation of M on 0^n and define

$$L = \{\langle 0^n, x\rangle \mid x \leq a_n\}.$$

It is clear that $L \in \mathrm{UP} \cap \text{co-UP}$. If $L \in \mathrm{DTIME}(2^{n^\epsilon})$, then a binary search algorithm can correctly compute a_n, for every n, in time 2^{n^ϵ}. This would contradict Hypothesis H. Hence, $L \notin \mathrm{DTIME}(2^{n^\epsilon})$. □

The discrete logarithm problem is an interesting possible witness for assertion 2. The best known deterministic algorithm requires time greater than $2^{n^{\frac{1}{3}}}$ [Gor93]. Thus, the discrete logarithm problem is a candidate witness for the noninclusion UP ∩ co-UP $\not\subseteq$ DTIME(2^{n^ϵ}) for any $0 < \epsilon \leq \frac{1}{3}$.

COROLLARY 1. *If, for some $\epsilon > 0$,* UP ∩ co-UP *has a 2^{n^ϵ}-bi-immune language, then $\leq^{\mathrm{P}}_{\mathrm{T}}$-completeness is different from $\leq^{\mathrm{P}}_{tt}$-completeness for* NP.

THEOREM 4.4. *Assertion* 3 *implies Hypothesis* H′.

COROLLARY 2. *If, for some $\epsilon > 0$,* NP ∩ co-NP *has a 2^{n^ϵ}-bi-immune language, then $\leq^{\mathrm{P}}_{\mathrm{T}}$-completeness is different from $\leq^{\mathrm{P}}_{m}$-completeness for* NP.

4.2. Comparisons with genericity. The genericity hypothesis of Ambos-Spies and Bentzien [ASB00], which they used successfully to separate NP-completeness notions for the bounded-truth-table reducibilities, states that "NP contains an n^2-generic language." Our next result enables us to compare this with our hypotheses.

We say that a deterministic oracle Turing machine M is a *predictor* for a language L if for every input word x, M decides whether $x \in L$ with oracle $L|x$. L is *predictable in time* $t(n)$ if there is a $t(n)$ time-bounded predictor for L. We define a set L to be *almost-everywhere unpredictable in time* $t(n)$ if every predictor for L requires more than $t(n)$ time for all but finitely many x. This concept obviously implies DTIME($t(n)$)-complex almost everywhere, but the converse does not hold.

PROPOSITION 4.5. EXP *contains languages that are* DTIME(2^n)*-complex but* not *almost-everywhere unpredictable in time* 2^n.

Let $L \in$ EXP be DTIME(2^n)-complex [GHS91]. Then $L \oplus L$ satisfies the conditions of the proposition. Now we state our characterization of $t(n)$-genericity.

THEOREM 4.6. *Let $t(n)$ be a polynomial. A decidable language L is $t(n)$-generic if and only if it is almost-everywhere unpredictable in time $t(2^n - 1)$.*

Proof. Assume that L is not almost-everywhere unpredictable in time $t(2^n - 1)$, and let M be a predictor for L that for infinitely many strings x runs in time $t(2^n - 1)$. Define a condition C so that the characteristic sequence

$$(L|x)\overline{x} \in C \Leftrightarrow M \text{ with oracle } L|x \text{ runs in time } t(2^{|x|} - 1) \text{ on input } x,$$

where $\overline{x} = \neg(M \text{ accepts } x)$. Then, C is dense along L because M correctly predicts whether $x \in L$ for infinitely many x. It is easy to see that $C \in$ DTIME($t(n)$). However, L is not $t(n)$-generic because we defined C so that L does not meet C.

Assume that L is not $t(n)$-generic, and let $C \in$ DTIME($t(n)$) be a condition that is dense along L such that L does not meet C. Let T be a deterministic Turing machine that halts on all inputs and accepts L. Define a predictor M for L to behave as follows on input x with oracle $A|x$: If $(A|x)1 \in C$, then M rejects x, and if $(A|x)0 \in C$, then M accepts x. If neither holds, then M determines membership in L by simulating T on x. Since L does not meet C, M is a predictor for L. Since C is dense along L and L does not meet C, for infinitely many x, either $(A|x)1 \in C$ or $(A|x)0 \in C$, and in each of these cases, M runs for at most $t(2 \cdot 2^{|x|})$ steps. Since $t(n)$ is a polynomial function, by the linear speedup theorem [HS65], there is a Turing machine that is equivalent to M that runs in time $t(2^{|x|} - 1)$. □

COROLLARY 4.7. NP *contains an n^2-generic language if and only if* NP *contains a set that is almost-everywhere unpredictable in time* 2^{2n}.

By Theorem 4.4, Hypothesis H′ holds if NP ∩ co-NP contains a set that, for some $\epsilon > 0$, is 2^{n^ϵ}-bi-immune. So, Hypothesis H′ requires bi-immunity, which is weaker than almost-everywhere unpredictability, and the time bound is reduced from 2^{2n} to 2^{n^ϵ}. On the other hand, we require the language to belong to NP ∩ co-NP instead of NP. Similarly, when we consider Hypothesis H, we require the language to be P-bi-immune and not in DTIME(2^{n^ϵ}), whereas now we require the language to be in UP ∩ co-UP. Moreover, the conclusion of Theorem 3.1 is not known to follow from the genericity hypothesis. At the same time, we note that the genericity hypothesis separates several bounded-truth-table completeness notions in NP that do not seem obtainable from our hypotheses.

4.3. Relativization.

THEOREM 4.8. *There exists an oracle relative to which the polynomial hierarchy is infinite and Hypotheses* H *and* H′ *both hold.*

Proof. Define Kolmogorov random strings $r_0, r_1, \ldots$ as follows: r_n is the first string of length n such that

$$K^{2^n}(r_n \mid r_0, r_1, \ldots, r_{n-1}) > n/2.$$

Then, define the oracle $A = \{r_n \mid n \geq 0\}$.

Define M to be an oracle Turing machine that accepts 0^* with oracle A as follows: On input 0^n, guess a string y of length n. If $y \in A$, then accept. M is a UP^A-machine that accepts 0^* because A contains exactly one string of every length.

Now we show that no 2^{n^ϵ} oracle Turing machine with oracle A, for any $0 < \epsilon < 1$, correctly computes infinitely many accepting computations of M. Observe that relative to A, this implies both Hypotheses H and H$'$. Suppose otherwise, and let T be such an oracle Turing machine. The gist of the remainder of the proof is that we will show how to simulate T without using the oracle, and that will contradict the randomness of r_n.

Suppose that $T^A(0^n) = r_n$. Let $l = 3n^\epsilon$. Then we simulate this computation without using an oracle as follows:

1. Compute $r_0, r_1, \ldots, r_{l-1}$. Do this iteratively: Compute r_i by running every program (with input strings $r_0, r_1, \ldots, r_{i-1}$) of length $\leq i/2$ for 2^i steps. Then r_i is the first string of length i that is not output by any of these programs. Note that the total time for executing this step is

$$l 2^{l/2} 2^l \leq l 2^{3l/2} \leq 2^{5n^\epsilon}.$$

2. Simulate T on input 0^n, except replace all oracle queries q by the following rules: If $|q| < l$, answer using the previous computations. Otherwise, just answer "no."

If the simulation is correct (i.e., the rules in step 2 correctly answer each query q to A), then this procedure outputs r_n without using the oracle. The running time of this procedure on input 0^n is $2^{5n^\epsilon} + 2^{n^\epsilon}$, which is less than 2^n. So we can describe r_n by a string of length $O(\log n)$, namely a description of T and 0^n. This contradicts the definition of r_n.

We need to show that the simulation is correct. The simulation can only be incorrect if $|q| \geq l$ and $q = r_m$ for some $m > l$. Let r_m be the first such query. This yields a short description of r_m, given $r_0, r_1, \ldots, r_{l-1}$. Namely, the description consists of the description of T (a constant), the description of 0^n ($\log n$ bits), and the description of the number j such that $q = r_m$ is the jth query (at most n^ϵ). Thus, the length of the description is $O(n^\epsilon)$. Since $l = 3n^\epsilon$, it follows that the length of the description of r_m is less than $m/2$. The running time of T, given $r_0, r_1, \ldots, r_{l-1}$, is 2^{n^ϵ}, which is less than 2^m. (The reason is that the first step in the simulation of T is not needed.) Therefore, the simulation is correct.

Finally, because A is a sparse set, using results of Balcázar, Book, and Schöning [BBS86], there is an oracle relative to which the hypotheses holds and the polynomial hierarchy is infinite. □

Hypothesis H fails relative to any oracle for which P = NP ∩ co-NP [BGS75]. Fortnow and Rogers [FR94] obtained an oracle relative to which NP ≠ co-NP and Hypothesis H$'$ fails. We know of no oracle relative to which P ≠ NP, and every $\leq^{\mathrm{P}}_{\mathrm{T}}$-complete set is $\leq^{\mathrm{P}}_m$-complete.

4.4. Extensions. The extensions in this section are independently observed by Regan and Watanabe [RW01]. In Hypothesis H we can replace the UP-machine by

an NP-machine under a stronger intractability assumption. Consider the following hypothesis: There is an NP-machine M that accepts 0^* such that

1. no probabilistic polynomial time-bounded Turing machine correctly outputs infinitely many accepting computations with nontrivial (inverse polynomial) probability, and
2. for some $\epsilon > 0$, no 2^{n^ϵ} time-bounded Turing machine correctly computes all accepting computations with nontrivial probability.

We can prove that Turing completeness is different from truth-table completeness in NP under the above hypothesis. The proof uses the randomized reduction of Valiant and Vazirani [VV86] that isolates the accepting computations. We define L as in the proof of Theorem 3.4. Let

$$S = \{\langle 0^n, k, r_1, r_2, \cdots, r_k, i\rangle \mid \exists v \text{ such that } v \text{ is an accepting computation of } M,$$
$$v.r_1 = v.r_2 = \cdots = v.r_k = 0, \text{ and the } i\text{th bit of } v = 1\},$$

where $v.r_i$ denotes the inner product over GF[2].

Valiant and Vazirani showed that if we randomly pick $r_1, r_2, \ldots, r_k$, then with a nontrivial probability there exists exactly one accepting computation v of M whose inner product with each r_i is 0. Thus, for a random choice of $r_1, \ldots, r_k$, there is exactly one witness v for $\langle 0^n, k, r_1, \ldots, r_k, i\rangle$. The rest of the proof is similar to that of Theorem 3.1.

We also note that we can replace the UP-machine in Hypothesis H with a FewP-machine.

APPROXIMATION ALGORITHMS FOR SINGLE-SOURCE UNSPLITTABLE FLOW*

STAVROS G. KOLLIOPOULOS† AND CLIFFORD STEIN‡

Abstract. In the *single-source unsplittable flow* problem, we are given a network G, a source vertex s, and k commodities with sinks t_i and real-valued demands ρ_i, $1 \leq i \leq k$. We seek to route the demand ρ_i of each commodity i along a single s-t_i flow path so that the total flow routed across any edge e is bounded by the edge capacity u_e. The conceptual difficulty of this NP-hard problem arises from combining packing constraints due to the existence of capacities with path selection in a graph of arbitrary topology. In this paper we give a generic framework, which yields approximation algorithms that are simpler than those previously known and achieve significant improvements upon the approximation ratios. Our framework, with appropriate subroutines, applies to all optimization versions previously considered and, unlike previous work, treats in a unified manner directed and undirected graphs. We provide extensions of our algorithms which yield the best possible approximation guarantees for restricted sets of demand values and an associated scheduling problem.

Key words. approximation algorithms, network algorithms, routing, network flow, unsplittable flow, disjoint paths, parallel machine scheduling

1. Introduction.

In the *single-source unsplittable flow* problem (UFP), we are given a network $G = (V, E, u)$, a source vertex s, and a set of k commodities with sinks $t_1, \ldots, t_k$ and associated real-valued demands $\rho_1, \ldots, \rho_k$. We seek to route the demand ρ_i of each commodity i along a single s-t_i flow path so that the total flow routed across any edge e is bounded by the edge capacity u_e. See Figure 1 for an example instance. The minimum edge capacity is assumed to have value at least $\max_i \rho_i$. The requirement of routing each commodity on a single path bears resemblance to integral multicommodity flow and in particular to the multiple-source edge-disjoint path problem. For the latter problem, a large amount of work exists either for solving exactly interesting special cases (e.g., [9, 37, 36]) or for approximating, with limited success, various objective functions (e.g., [35, 11, 24, 25, 22]). Further, shedding light on single-source unsplittable flow may lead to a better understanding of multiple-source disjoint-path problems. From a different perspective, UFP can be approached as a variant of standard, single-commodity, maximum flow since in both problems there is one source for the flow. From this point of view, UFP generalizes single-source edge-disjoint paths. UFP is also important as a unifying framework for a variety of scheduling and load balancing problems [23]. It can be used to model bin packing

[23] and certain scheduling problems on parallel machines [32]. Another possible application for UFP is in virtual-circuit routing, where the source would represent a node wishing to multicast data to selected sinks. The conceptual difficulty in UFP arises from combining packing constraints due to the existence of capacities with path selection in a graph of arbitrary topology.

The feasibility question for UFP, i.e., can all commodities be routed unsplittably, is strongly NP-complete [22]. We focus thus on efficient algorithms to obtain approximate solutions. For a minimization (resp., maximization) problem, a *ρ-approximation algorithm,* $\rho > 1$ (resp., $\rho < 1$), outputs in polynomial time a solution with objective value at most (resp., at least) ρ times the optimum. Three main optimization versions of unsplittable flow can be defined.

Minimum congestion. Find an unsplittable flow f satisfying all demands, which minimizes *congestion,* i.e., the quantity $\max\{\max_e\{f_e/u_e\}, 1\}$. That is, the minimum congestion is the smallest number $\alpha \geq 1$ such that if we multiplied all capacities by α, f would satisfy the capacity constraints. The congestion metric was a primary test bed for the randomized rounding technique of Raghavan and Thompson [35] and has been studied extensively for its connections to multicommodity flow and cuts (e.g., [31, 21, 30, 20]).[1]

Maximum routable demand. Route unsplittably a subset of the commodities of maximum total demand, while respecting capacity constraints.

Minimum number of rounds. Partition the commodities into a minimum number of sets, called *rounds,* so that commodities assigned to the same round can be routed

[1] In [30] congestion is defined as $\max_e\{f_e/u_e\}$. In this setting a congestion of $\lambda \in (0, 1)$ implies that it is possible to multiply all demands by $1/\lambda$ and still satisfy them by a flow which respects the capacity constraints. Algorithmically the two definitions are equivalent: with a polynomial number of invocations of an algorithm which minimizes congestion according to our definition, one can minimize congestion according to the definition in [30].

unsplittably without violating the capacity constraints.

The randomized rounding technique applies to the more general multiple-source unsplittable flow problem and provides an $O(\log|E|/\log\log|E|)$ approximation for congestion; for the maximum demand and minimum number of rounds versions, it can give meaningful approximations only when the minimum capacity value is $\Omega(\log|E|)$ times the value of the maximum demand [35, 34]. Kleinberg [22, 23] was the first to consider the UFP as a distinct problem and gave constant-factor approximation algorithms for all three optimization versions presented above, on both directed and undirected graphs.

Our results. We give a new approach for single-source unsplittable flow that has three main advantages.

- The algorithms are simple and do not need the machinery developed in [23].
- Our approach treats directed and undirected graphs in a unified manner.
- We obtain significant improvements upon the approximation ratios for all three optimization versions.

Our algorithms follow the same *grouping-and-scaling* technique. We first find a maximum flow. This relaxation is a "splittable" solution, i.e., it allows the demand for a commodity to be split along more than one path. As in the previous work [23], we use the maximum flow solution as a guide for the discovery of an unsplittable routing. However, we use this solution in a much stronger way: we employ information from maximum flow to *allocate capacity* to a set of subproblems, where each subproblem G^i contains commodities with demands in a fixed range. For each subproblem G^i, a near-optimal routing g^i is separately computed by exploiting the fact that demands are close in range. These solutions are then combined by superimposing the g^i's on the original graph. Since we are interested in constant-factor approximations, when combining the solutions it is important to avoid an additive deterioration of the approximation guarantees obtained for each individual G^i. One of our conceptual contributions lies in showing that this is possible, given an appropriate initial capacity allocation. Combining solutions presents different challenges for the maximum demand and minimum number of rounds versions of our algorithms as opposed to minimizing congestion. In the congestion version, increasing the original edge capacities as the routings g^i are superimposed on G only affects the approximation ratio. For the other two versions, it would be infeasible to do so. We note that a grouping scheme on the commodities is also used in [23], though in a more complicated way; ours is based solely on demand values and does not require any topological information from the graph. We now elaborate on the approximation ratios we obtain.

Minimum congestion. We give a 3-approximation algorithm for both directed and undirected graphs. The bounds known before our work were 16 for the directed and 8.25 for the undirected case [23]. In the first publication of this work [27] we gave PARTITION, a 4-approximation algorithm and obtained also a $10/3 = 3.33\ldots$ bound[2] for a more elaborate version of PARTITION. Dinitz, Garg, and Goemans recently obtained a new 2-approximation result (appearing in [5]). Following this development we further refined our 10/3-approximation algorithm and obtained H_PARTITION, a 3-approximation algorithm appearing also in [26]. In this paper we describe both PARTITION and H_PARTITION. Algorithm H_PARTITION also exploits the grouping and scaling technique by scaling demands in a fixed range to the same value. However, instead of producing "in parallel" an unsplittable solution for all the ranges, H_PARTITION outputs the partial routings g^i by iteratively improving the quality

[2]Erroneously reported in [27] as 3.23.

of the solution to a maximum flow relaxation. The quality of the latter solution is characterized by the minimum amount of flow routed along a single path to any commodity which has not been routed yet unsplittably.

Minimizing congestion and cost. A natural optimization question arises when routing a unit of flow through edge e incurs cost c_e. The objective is to find an unsplittable flow that minimizes the total cost. More precisely, if z is the optimal congestion, define the optimal cost to be the minimum cost of an unsplittable flow that is feasible with respect to the capacity function zu. Since UFP without costs is already NP-hard, we aim for a bicriteria approximation of cost and congestion. Our approach gives the first constant-factor approximation for minimum-cost, minimum-congestion unsplittable flow on directed graphs; it also improves considerably upon the constants known for the minimum cost version on undirected graphs. In particular, existing results for undirected graphs [23] give a simultaneous $(7.473, 10.473)$ approximation for cost and congestion. We provide a $(2, 3)$ simultaneous approximation on both directed and undirected graphs. Moreover, we show how to obtain a $1 + \delta$ approximation for cost, for any $\delta > 0$, at the expense of a larger constant factor for congestion.

Maximum routable demand. We show how to route at least .075, i.e., 7.5% of the optimum. In [23] the constant is not given explicitly, but it can be as low as .031 for undirected graphs and on the order of 10^{-9} for directed graphs.

Minimum number of rounds. We show how to route all the demands in at most 13 times the optimum number of rounds, an improvement upon the 32 upper bound given in [23]. A guarantee of routing in x rounds implies that at least $1/x$ of the total demand is routed in some round. Kleinberg's 32-approximation algorithm for rounds can be seen to imply a $1/32 = 0.03125$ approximation for routable demand when the cut condition is met, i.e., when the maximum flow relaxation satisfies all demands. Accordingly we obtain a $1/13 = .0769$ approximation for routable demand under the cut condition. We elaborate on this observation in section 8.

We emphasize that our algorithms for all three different versions are simple and make use of the same generic framework. Although they are presented separately for ease of exposition, they could all be stated in terms of one algorithm, with different subroutines invoked for subproblems. The dominant computational steps are maximum flow and flow decomposition; these are tools that work well on both directed and undirected graphs. In [23] it is noted that "the disjoint paths problem is much less well understood for directed than it is for undirected graphs ... in keeping with the general principle we will find that the algorithms we obtain for directed graphs will be more complicated."

Generalizations. The algorithmic techniques we introduce are quite general and can be applied to related problems. We show how to use them to obtain a constant-factor approximation for minimum congestion on a network, where the minimum edge capacity can be arbitrarily low with respect to the maximum demand. This is the first result of this type that we are aware of. In subsequent work [28], we show how to apply the algorithmic techniques developed here for UFP to obtain improved approximations for classes of packing integer programs and multiple-source unsplittable flow. On the negative side, we show in this paper that for the unsplittable flow problem with two sources on a directed network, no ρ-approximation with $\rho < 2$ can be achieved for congestion, unless P = NP, even when all the demands and capacities have value 1. This gives an idea of how hard it might be to formulate an approximate version of the fundamental Theorem 2.1 that we use in our single-source algorithms.

Applications to scheduling. We also examine applications of unsplittable flow to scheduling problems. A lower bound of 3/2 exists for the approximability of mini-

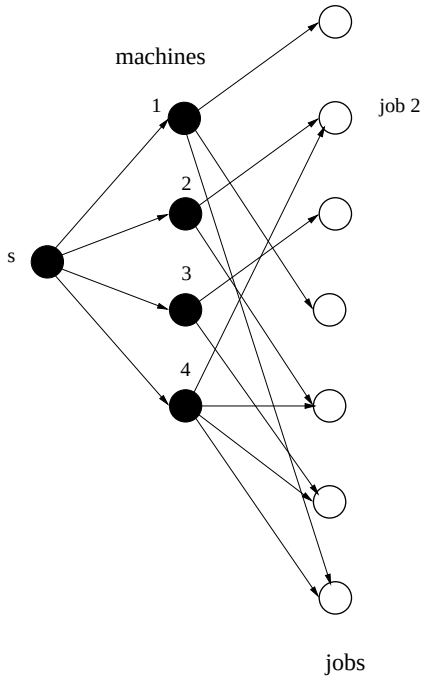

FIG. 2. *Reduction of the scheduling problem to* UFP. *Job* 2 *can be processed only on machines* 2 *and* 4. *The capacity of the edges connecting* s *to the machine vertices is equal to a makespan estimate.*

mum makespan on parallel machines when a job j can be processed only on a subset $M(j)$ of the available machines [32]. Let $\mathcal{S}$ denote this scheduling problem. The 2-approximation algorithm of Lenstra, Shmoys, and Tardos [32] or Shmoys and Tardos [38] for the more general problem of scheduling on unrelated machines is the best known for $\mathcal{S}$. On the other hand an approximation-preserving reduction is known to exist from $\mathcal{S}$ to single-source unsplittable flow (see Figure 2) [23], so the 3/2 lower bound for $\mathcal{S}$ [32] applies to single-source unsplittable flow as well. The lower bound holds when processing times (or demands) take the values p or $2p$ for some $p > 0$. We provide an additive p approximation for this restricted unsplittable flow problem, which corresponds to a ratio of at most 3/2. This is the best possible approximation ratio for the problem unless P = NP. Improved approximation factors are also obtained for the more general case, in which all demand values are powers of 1/2.

The outline of this paper is as follows. In section 2 we present definitions and a basic theorem from flow theory. In section 3 we provide a $(4 + o(1))$-approximation algorithm for congestion, which introduces our basic techniques. In section 4 we provide the improved 3-approximation. In section 5 we give the approximation algorithm for minimum congestion unsplittable flow with arbitrarily small capacities. In section 6 we present the simultaneous cost-congestion approximation. In sections 7 and 8 the approximation algorithms for maximum total demand and minimum number of rounds are presented. In section 9 we present the hardness result for 2-source unsplittable flow. Finally, in section 10 we examine the connection between UFP and scheduling problems. A preliminary version of the material in this paper appeared in [27]. Experimental results on implementations of our algorithms appeared in [29]. Af-

ter the first publication of this work, Dinitz, Garg, and Goemans obtained improved approximation ratios by using a different approach [5], and Skutella gave improved results for the simultaneous optimization of cost and each of the three metrics [39].

2. Preliminaries. All logarithms in this paper are base 2 unless otherwise noted. A *single-source unsplittable flow problem* (UFP) $(G, s, \mathcal{T})$ is defined on a capacitated network $G = (V, E, u)$ where a subset $\mathcal{T} = \{t_1, \ldots, t_k\}$ of V is the set of *sinks*; each edge e has a real-valued capacity u_e; each sink t_i has a real-valued demand ρ_i. The pair (t_i, ρ_i) defines the *commodity* i. To avoid cumbersome notation, we occasionally use the set $\mathcal{T}$ to denote the set of commodities. We assume in our definition that each vertex in V hosts at most one sink; the input network can always be transformed to fulfill this requirement. A *source* vertex $s \in V$ is specified. For any $I \subseteq \mathcal{T}$, a *partial routing* is a set of $|I|$ s-t_i paths, in which path P_i is used to route ρ_i amount of flow from s to t_i for each $t_i \in I$. A partial routing that contains a path to each sink in $\mathcal{T}$ is simply called a *routing.* Given a routing g, the flow g_e through edge e is equal to $\sum_{P_i \in g | P_i \ni e} \rho_i$. A (partial) routing g for which $g_e \leq u_e$ for each edge e is a *(partial) unsplittable flow.* A *fractional routing* is a set of flow paths, satisfying capacity constraints, in which the flow to each sink is split along potentially many paths. A fractional routing can be computed by standard maximum flow. Thus we shall refer to a fractional routing satisfying all demands of the underlying UFP as a *feasible fractional flow solution.* For clarity we will also refer to a standard maximum flow as *fractional maximum flow.* We assume that a UFP input meets the following two requirements:

Cut condition. There is a feasible fractional flow solution.

Balance condition. All demands have value at most 1 and the minimum edge capacity is 1.

The first requirement is introduced only for simplicity. For each of the optimization metrics studied, an optimal fractional solution, potentially violating the unsplittability requirement, can be efficiently found. Since our analysis uses the fractional optima as lower bounds, our approximation results hold without the cut condition. For the balance condition, we note that the actual numerical value of 1 is not crucial; demands and capacities can be scaled without affecting solutions. The important requirement is that the minimum capacity is greater than or equal to the maximum demand. We will explicitly state it when we deal with a UFP in which the minimum capacity can be arbitrarily small. Finally, the *k-source unsplittable flow problem* (k-UFP) is similarly defined, but now $k > 1$ sources exist and demands are defined for pairs (s_i, t_i) of sources and sinks. Unless otherwise stated, we use n, m to denote $|V|, |E|$, respectively.

The following theorem is an easy consequence of the well-known augmenting path algorithm [7, 6] and will be of use. It was also used as part of the approximation techniques in [23] and is a consequence of the integrality property for maximum flow with all demands and capacities scaled by σ.

THEOREM 2.1. *Let $(G = (V, E, u), s, \mathcal{T})$ be a* UFP *on an arbitrary network G with all demands ρ_i, $1 \leq i \leq k$, equal to the same value σ, and edge capacities u_e equal to integral multiples of σ for all $e \in E$. If there is a fractional flow of value f, then there is an unsplittable flow of value at least f. This unsplittable flow can be found in $O(km)$ time, where k is the number of sinks in $\mathcal{T}$.*

We defined a routing as a collection of flow paths; it can equivalently be represented as an *edge flow,* i.e., a collection of functions assigning flow values to each edge. Conversely, an edge flow, whether fractional or unsplittable, can be represented

as a path flow. In particular our algorithms will make use of the well-known *flow decomposition theorem* [2]. Given problem $(G, s, \mathcal{T})$ let a fractional flow solution f be represented as an assignment of flow values to edges. Then one can find, in $O(nm)$ time, a representation of f as a path and cycle flow, where the paths join s to sinks in $\mathcal{T}$. In the remainder of the paper, we will assume that the cycles are deleted from the output of a flow decomposition. The flow decomposition theorem trivially applies also to transforming an unsplittable flow from edge representation to a path representation. We will point out cases in which outputting the unsplittable flow as an edge flow results in faster algorithms.

3. The approximation algorithm for minimum congestion. In this section we give a $(4 + o(1))$-approximation algorithm for minimizing congestion. In section 4 we show how to improve the approximation guarantee to 3. All our results can be seen to hold for minimizing *absolute congestion* as well, defined as $\max\{\max_e\{f_e\}, 1\}$. The same algorithm works on both directed and undirected graphs with the same performance guarantee. The algorithm works by partitioning the original UFP into subproblems, each containing only demands in a fixed range. We use an initial maximum flow solution to allocate capacity to different subproblems. Capacities in the subproblems are arbitrary and may violate the balance condition. The subproblems are separately solved by introducing bounded congestion; the partial solutions are then combined by superimposing on the original network G the flow paths obtained in the respective routings. The combination step will have a subadditive effect on the total congestion and thus near-optimality of the global solution is achieved.

We present first two simple lemmas for cases in which demands are bounded. They will be used to provide subroutines to the final algorithm.

LEMMA 3.1. *For a* UFP *with demands in the interval* $(0, \alpha]$, *there is an algorithm,* α-ROUTING, *which finds, in time* $O(n + m)$, *an unsplittable routing in which the flow through each edge is at most* $n\alpha$.

Proof. Algorithm α-ROUTING works as follows. A depth first search from the source s gives a path from s to each of the at most n sinks. For each sink t_i, route, along the corresponding path, flow equal to the demand $\rho_i \leq \alpha$. □

Given a real number interval with endpoints a and b, $0 < a < b$, the *ratio* $r(a, b)$ of the interval is b/a. The following fact is also used in [23]; we include a proof for the sake of completeness.

LEMMA 3.2 (see [23]). *Given a* UFP $\Pi = (G, s, \mathcal{T})$, *with demands in the interval* $(a, b]$ *and arbitrary capacities, there is an algorithm,* INTERVAL_ROUTING, *which finds in polynomial time an unsplittable routing* g, *such that for all edges* e, $g_e \leq r(a, b)u_e + b$.

Remark. The statement of the lemma holds also when demands lie in the interval $[a, b]$.

Proof. Let f be a feasible fractional solution to Π. Round all demands up to b and call Π' the resulting UFP instance. To obtain a feasible fractional solution for Π', it suffices to multiply the flow f_e and the capacity u_e on each edge e by a factor of at most $r(a, b)$. Further round all capacities up to the closest multiple of b by adding at most b. The new edge capacities are now at most $r(a, b)u_e + b$. By Theorem 2.1 an unsplittable routing for Π' can now be found in polynomial time. Algorithm INTERVAL_ROUTING finds first this unsplittable routing g' for Π'. To obtain an unsplittable routing g for Π, from each path in g', the flow in excess of the demands in $\mathcal{T}$ is removed. □

We are now ready to present Algorithm PARTITION in Figure 3. Algorithm PARTITION takes as input a UFP $(G, s, \mathcal{T})$, together with a set of parameters $\xi, \alpha_1, \ldots, \alpha_\xi$,

ALGORITHM PARTITION$(G = (V, E, u), s, \mathcal{T}, \xi, \alpha_1, \ldots, \alpha_\xi)$

***Step* 1.** Find a feasible fractional solution f.

***Step* 2.** Define a partition of the $(0, 1]$ interval into ξ consecutive subintervals $(0, \alpha_1], (\alpha_1, \alpha_2], \ldots, (\alpha_{\xi-1}, \alpha_\xi]$, $\alpha_\xi = 1$. Construct ξ copies of G where the set of sinks in G_i, $1 \le i \le \xi$, is the subset $\mathcal{T}_i$ of $\mathcal{T}$ with demands in the interval $(\alpha_{i-1}, \alpha_i]$. Using flow decomposition determine for each edge e the amount u_e^i of u_e used by f to route flow to sinks in $\mathcal{T}_i$. Set the capacity of edge e in G_i to u_e^i.

***Step* 3.** Invoke INTERVAL_ROUTING on each G_i, $2 \le i \le \xi$, to obtain an unsplittable routing g^i. Invoke α-ROUTING on G_1 to obtain an unsplittable routing g^1.

***Step* 4.** Output routing g, the union of the path sets g^i, $1 \le i \le \xi$.

FIG. 3. *Algorithm* PARTITION.

that will determine the exact partitioning scheme. Subsequently we show how to choose these parameters so as to optimize the approximation ratio. The algorithm outputs an unsplittable routing g. The two previous lemmas will be used to provide subroutines. Recall that in a UFP demands lie in the interval $(0, 1]$ and capacities are at least 1.

We need to examine the effect of the combination on the total congestion.

LEMMA 3.3. *Algorithm* PARTITION *outputs an unsplittable routing g with congestion at most*

$$n\alpha_1 + \max_{2 \le i \le \xi} \{r(\alpha_{i-1}, \alpha_i)\} + \sum_{i=2}^{\xi} \alpha_i.$$

The running time of PARTITION *is $O(T_1(n, m) + nm + m\xi)$ where $T_1(n, m)$ is the time to solve a fractional maximum flow problem.*

Proof. In order to determine in Step 2 the capacity u_e^i of edge e in the ith copy G_i, $1 \le i \le \xi$, of G we use the flow decomposition theorem [8]. Any flow along cycles given by the decomposition theorem is discarded since it does not contribute to the routing of demands. We focus on the congestion of a particular edge e. By Lemma 3.2 algorithm INTERVAL_ROUTING finds an unsplittable routing in G_i, $2 \le i \le \xi$, at Step 3 by pushing through edge e at most $r(\alpha_{i-1}, \alpha_i)u_e^i + \alpha_i$ units of flow. By Lemma 3.1 algorithm α-ROUTING pushes at most $n\alpha_1$ units of flow through edge e to find a routing on G_1. At Step 4 the superposition of the routings g^i gives an approximate unsplittable solution g, in which, for each edge e,

$$\begin{aligned} g_e &\le n\alpha_1 + \sum_{i=2}^{\xi} u_e^i r(\alpha_{i-1}, \alpha_i) + \sum_{i=2}^{\xi} \alpha_i \\ &\le n\alpha_1 + \max_{2 \le i \le \xi} \{r(\alpha_{i-1}, \alpha_i)\} \sum_{i=2}^{\xi} u_e^i + \sum_{i=2}^{\xi} \alpha_i \\ &\le n\alpha_1 u_e + \max_{2 \le i \le \xi} \{r(\alpha_{i-1}, \alpha_i)\} u_e + \sum_{i=2}^{\xi} \alpha_i u_e. \end{aligned}$$

The last step follows because $\sum_{i=2}^{\xi} u_e^i \leq u_e$ from the feasibility of f, and $u_e \geq 1$, and thus the congestion bound in the lemma follows.

As for the running time, finding the fractional flow in Step 1 requires $T_1(n,m)$ time. Flow decomposition can be done in $O(nm)$ time [2], thus the running time of Step 2 is $O(nm + m\xi)$. Implementing INTERVAL_ROUTING with the augmenting path algorithm gives total running time $O(km)$ for all the $\xi - 1$ invocations at Step 3. This time includes the time required by flow decomposition to output each partial routing in a path representation. The reason is that by Theorem 2.1 the algorithm takes $O(m)$ time per sink. The total number of sinks in the ξ subproblems is $k \leq n$. Hence the total running time of PARTITION is $O(T_1(n,m) + nm + m\xi)$. □

In order to substantiate the approximation factor we need to come up with a partitioning scheme to be used at Step 2 of algorithm PARTITION. The following theorem is the main result of this section.

THEOREM 3.1. *Given a* UFP Π*, algorithm* PARTITION *finds a* $(4+\varepsilon)$*-approximation for relative congestion for any* $\varepsilon > 0$*. The running time of the algorithm is* $O(T_1(n,m) + nm + m\log(n/\varepsilon))$*, where* $T_1(n,m)$ *is the time to solve a fractional maximum flow problem.*

Proof. At Step 2 of PARTITION, partition the interval $(0,1]$ of demand values into ξ geometrically increasing subintervals

$$(0, 1/2^{\xi-1}], \ldots, (1/2^{i+1}, 1/2^i], \ldots, (1/2^2, 1/2], (1/2, 1]$$

such that $1/2^{\xi-1} \leq \varepsilon/n$. Thus it suffices for ξ to be $\Theta(\log(n/\varepsilon))$. By Lemma 3.3, the congestion of the routing g returned at Step 4 of the algorithm is at most $n\frac{\varepsilon}{n} + 2 + \sum_{i=0}^{\xi-2} \frac{1}{2^i} < 4 + \varepsilon$. □

In order to achieve $\varepsilon = o(1)$, it suffices to set $1/2^{\xi-1} \leq 1/n^c$, $c > 1$. Obtaining a better $o(1)$ factor is straightforward by increasing the number of intervals. A fractional maximum flow can be found by the push-relabel method of Goldberg and Tarjan [13], whose currently fastest implementation has running time $T_1(n,m) = O(nm \log_{\frac{m}{n\log n}} n)$ [19]. In that case even when our algorithm is used to obtain a $(4 + \frac{1}{2^n})$-approximation, the running time is dominated by a single maximum flow computation. Alternatively, the new maximum flow algorithm of Goldberg and Rao [12] with $T_1(n,m) = O(\min(n^{2/3}, m^{1/2}) m \log(\frac{n^2}{m}) \log U)$ may be used, if edge capacities can be expressed as integers in a range $[1, \ldots, U]$. We point out that if an edge representation of the output routing suffices, the Goldberg–Rao algorithm can be used to surpass the $O(nm)$ bottleneck.

THEOREM 3.2. *If an edge-representation of the output routing is sought, algorithm* PARTITION *can be implemented to run in* $O(\log(n/\varepsilon) \min(n^{2/3}, m^{1/2}) m \log(\frac{n^2}{m}) \log(UD))$ *time, assuming in the original network we have integral capacities in the range* $[1, \ldots, U]$ *and the minimum demand is* $1/D$ *for* $D \in Z_{>0}$*.*

Proof. The flow decomposition computation in Step 2 of PARTITION can be replaced by $\xi = O(\log(n/\varepsilon))$ maximum flow computations; in the ith such computation only the set of sinks $\mathcal{T}_i$, as defined in Step 3, with demand values in the corresponding subinterval is included.

The first maximum flow computation has available on each edge the capacity used by the original fractional solution f. The flow found at the ith computation is subtracted from the capacity allotted to the $(i+1)$st computation. Intuitively, this iterative procedure is correct for the same reason that standard flow decomposition is correct. In the latter case, flow is subtracted along a single path (or cycle) at each

iteration. In each iteration of our scheme, we use Goldberg–Rao to find in one "shot" all the flow paths leading to sinks with demand values in a given subinterval and remove their capacity. It is enough to show that implementing flow decomposition by successive invocations of Goldberg–Rao maintains the following invariant.

INV: After the ith Goldberg–Rao flow computation, the available capacity across any cut (S, T) with $s \in S$ is equal to the sum of the demand values of the sinks in $T \cap (\mathcal{T} - \cup_{j \le i} \mathcal{T}_j)$.

The induction hypothesis is that INV is true after the end of the $(i-1)$st iteration. Across a given (S, T) cut the available capacity is equal to the sum of the demand values of the sinks in $T \cap (\mathcal{T} - \cup_{j < i} \mathcal{T}_j)$. Goldberg–Rao will make unusable during the ith invocation an amount of cut capacity equal to the sum of the demand values of the sinks in $T \cap \mathcal{T}_i$. Hence INV will be true after the ith iteration as well.

Also the INTERVAL_ROUTING subroutine at Step 3 can be implemented by the Goldberg–Rao algorithm yielding an edge-only representation of the partial routing. Finally, the demand value of a sink can be represented as the capacity of the unique edge leading to it. Multiplying demands and capacities by D results in a network with integral capacities in the range $[1, \ldots, UD]$. □

Although in the next section we improve upon the 4-approximation, algorithm PARTITION introduces some of the basic ideas behind all of our algorithms. For this reason a demonstration of the algorithm execution on an example instance follows in Figures 4–7. In these figures, numbers on vertices denote demands while numbers on edges denote capacities. The capacities on the original input are equal to 1. Flow paths are depicted as lines parallel to the original edges. Solid and dashed flow paths carry 1 and 1/2 units of flow, respectively.

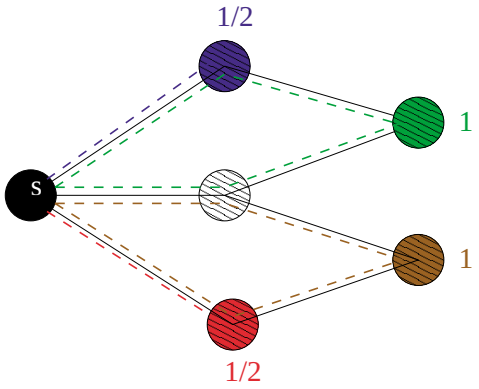
4. A 3-approximation algorithm for congestion. An improved approximation algorithm can be obtained by combining the partitioning idea above with a more careful treatment of the subproblems. At the first publication of our results [27] we obtained a $(10/3 + o(1))$-approximation. Subsequently we improved our scheme to obtain a 3 ratio; prior to this improvement, a 2-approximation for UFP was independently obtained by Dinitz, Garg, and Goemans [5]; see also [26].

We give first a specialized version of Lemma 3.2 to be used in the new algorithm.

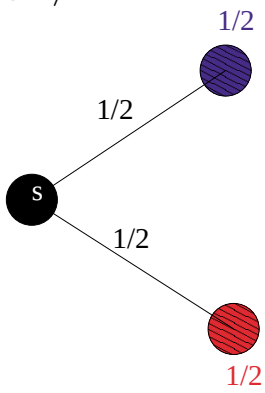
LEMMA 4.1. *Let $\Pi = (G, s, \mathcal{T})$ be a* UFP *in which all demands have value $1/2^x$ for $x \in N$, and all capacities are multiples of $1/2^{x+1}$, and let f be a fractional flow solution such that the flow f_e through any edge is a multiple of $1/2^{x+1}$. We can find in polynomial time an unsplittable routing g where the flow g_e through an edge e is at most $f_e + 1/2^{x+1}$.*

Algorithm PARTITION finds a routing for each subproblem by scaling up subproblem capacities to ensure they conform to the requirements of Lemma 3.2. The new algorithm operates in phases, during which the number of distinct paths used to route flow for a particular commodity is progressively decreased. Call *granularity* the minimum amount of flow routed along a single path to any commodity which has not been routed yet unsplittably. Algorithm PARTITION starts with a fractional solution of arbitrary granularity and, in essentially one step per commodity, rounds this fractional solution to an unsplittable one. In the new algorithm, we delay the rounding process in the sense that we keep computing a fractional solution of successively increasing granularity. The granularity will always be a power of 1/2, and this unit will be doubled after each iteration. Once the granularity surpasses $1/2^x$, for some x, we guarantee that all commodities with demands $1/2^x$ or less have already been routed unsplittably. Each iteration improves the granularity at the expense of increasing the

Fractional Solution:



Subproblem G^1 for demands of 1/2:



Subproblem G^2 for demands of 1:

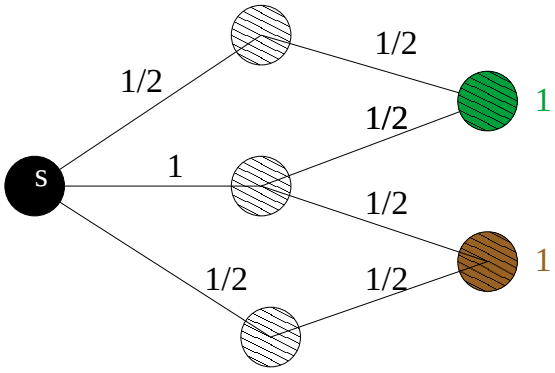


FIG. 4. *Algorithm* PARTITION *Demonstration* I. *Numbers on the edges and the vertices denote capacities and demands, respectively. Original input capacities are* 1. *Flow paths are depicted as lines parallel to the original edges. Solid and dashed flow paths carry* 1 *and* 1/2 *units of flow, respectively.*

congestion. The method has the advantage that, by Lemma 4.1, a fractional solution of granularity $1/2^x$ requires only a $1/2^x$ additive offset to current capacities to find a new flow of granularity $1/2^{x-1}$. Therefore, if the algorithm starts with a fractional

Scale up capacities for G^1 to $2u_e^1 + (1/2)$. Unsplittable solution:

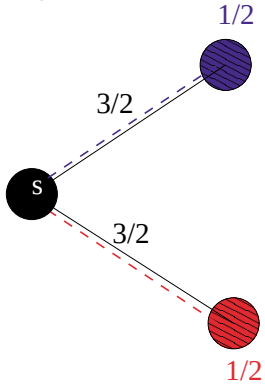

FIG. 5. *Algorithm* PARTITION *Demonstration* II. *Numbers on the edges and the vertices denote capacities and demands, respectively. Original input capacities are* 1. *Flow paths are depicted as lines parallel to the original edges. Solid and dashed flow paths carry* 1 *and* 1/2 *units of flow, respectively.*

Scale up capacities for G^2 to $2u_e^2 + 1$. Unsplittable solution:

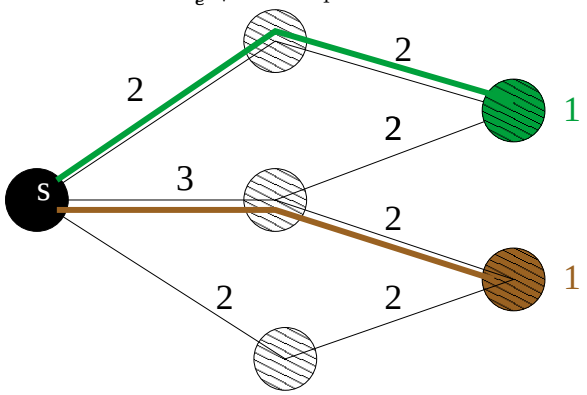

FIG. 6. *Algorithm* PARTITION *Demonstration* III. *Numbers on the edges and the vertices denote capacities and demands, respectively. Original input capacities are* 1. *Flow paths are depicted as lines parallel to the original edges. Solid and dashed flow paths carry* 1 *and* 1/2 *units of flow, respectively.*

solution of granularity $1/2^\lambda$, for some potentially large λ, the total increase to an edge capacity from then on would be at most $\sum_{j=1}^{j=\lambda} 1/2^j < 1$. Expressing the granularity in powers of $1/2$ requires an initial rounding of the demand values; this rounding will force us to scale capacities by at most a factor of 2. We first provide an algorithm for the case in which demand values are powers of $1/2$. The algorithm for the general case will then follow easily.

THEOREM 4.1. *Let* $\Pi = (G = (V, E, u), s, \mathcal{T})$ *be a* UFP *in which all demand values are of the form* $2^{-\nu}$ *with* $\nu \in N$, *the maximum demand value is denoted by* $\rho_{\max}$, *and the minimum demand value is denoted by* $\rho_{\min}$. *There is an algorithm,* 2H_PARTITION, *which obtains in polynomial time an unsplittable routing such that the flow through any edge* e *is at most* $zu_e + \rho_{\max} - \rho_{\min}$ *where* z *is the optimum congestion.*

Superimpose the two solutions to obtain final solution:

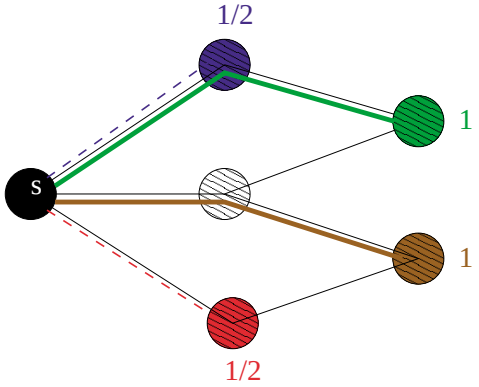

FIG. 7. *Algorithm* PARTITION *Demonstration* IV. *Numbers on the edges and the vertices denote capacities and demands, respectively. Original input capacities are* 1. *Flow paths are depicted as lines parallel to the original edges. Solid and dashed flow paths carry* 1 *and* 1/2 *units of flow, respectively. Final congestion is* 3/2.

Remark. We first obtained a relative $(1+\rho_{\max}-\rho_{\min})$-approximation for the case with demand values in $\{1/2, 1\}$ in [27]. Dinitz, Garg, and Goemans [5] first extended that theorem to arbitrary powers of 1/2 to obtain a $u_e+\rho_{\max}-\rho_{\min}$ absolute guarantee on the flow through edge e. Their derivation uses a different approach.

Proof. We describe the algorithm 2H_PARTITION. The crux of the algorithm is a relaxed decision procedure that addresses the question, Is there an unsplittable flow after scaling all the input capacities by x? The procedure will either return no or will output a solution where the flow through edge e is at most $xu_e + \rho_{\max} - \rho_{\min}$. Embedding the relaxed decision procedure in a binary search completes the algorithm. See [15] for background on relaxed decision procedures. The following claim will be used to show the correctness of the procedure.

CLAIM 4.1. *Given a* UFP Π *with capacity function* r, *all demands of the form* $2^{-\nu}$, $\nu \in N$, *and minimum demand* $2^{-\lambda}$, *let* Π' *be the modified version of* Π *in which each edge capacity* r_e *has been rounded down to the closest multiple* r'_e *of* $1/2^{\lambda}$. *If the optimum congestion is* 1 *for* Π, *the optimum congestion is* 1 *for* Π' *as well.*

Proof of claim. Let G be the network with capacity function r and G' be the network with rounded capacities r'. The amount $r_e - r'_e$ of capacity will be unused by any optimal unsplittable flow in G. The reason is that the sum $\sum_{i\in S} 1/2^i$ for any finite multiset $S \subset N$ is equal to a multiple of $1/2^{i_0}$, $i_0 = \min_{i\in S}\{i\}$. □

We describe now the relaxed decision procedure. Let u' denote the scaled capacity function xu. Let $\rho_{\min} = 1/2^{\lambda}$. The relaxed decision procedure is broken into at most $\lambda - \log(\rho_{\max}^{-1}) + 1$ iterations; each iteration aims to double the granularity.

During the first iteration, split each commodity in $\mathcal{T}$, called an *original commodity*, with demand $1/2^y$, $0 \le y \le \lambda$, into $2^{\lambda-y}$ *virtual commodities* each with demand $1/2^{\lambda}$. Call the resulting set of commodities $\mathcal{T}_1$. Round down all capacities to the closest multiple of $1/2^{\lambda}$. By Theorem 2.1 we can find an unsplittable flow solution $f^0 \equiv g^1$, for $\mathcal{T}_1$, in which the flow through any edge is a multiple of $1/2^{\lambda}$. If this solution does not satisfy all demands, the decision procedures returns no; by Claim 4.1 no unsplittable solution is possible without increasing the capacities u'. Otherwise the decision procedure continues to iterate as described below. We denote by u_e^i, $i \ge 1$, the flow through edge e at the end of the ith iteration. Observe that f^0 is a fractional solution

for the set of original commodities as well, a solution with granularity $1/2^{\lambda}$. The flow u_e^1 through an edge is trivially $f_e^0 \leq u'_e \leq u_e$.

At iteration $i > 1$, the following steps are taken.

Step i1. Extract from g^{i-1}, using flow decomposition, the set of flow paths f^{i-1} used to route the set S_{i-1} of virtual commodities in $\mathcal{T}_{i-1}$ which correspond to original commodities in $\mathcal{T}$ with demand $1/2^{\lambda-i+1}$ or higher.

Step i2. Pair up the virtual commodities in S_{i-1} corresponding to the same original commodity. Call the resulting set of virtual commodities $\mathcal{T}_i$.

Step i3. Find an unsplittable routing g^i for $\mathcal{T}_i$.

At Step i2, pairing is possible since the demand of an original commodity is inductively an even multiple of the demands of the virtual commodities. $\mathcal{T}_i$ will contain virtual commodities with demand $1/2^{\lambda-i+1}$. For Step i3 observe that the set of flow paths f^{i-1} is a fractional solution for the commodity set $\mathcal{T}_i$. Inductively each flow path in f^{i-1} carries flow which is a multiple of $1/2^{\lambda-i+2}$. By Lemma 4.1, we can find an unsplittable routing g^i for $\mathcal{T}_i$ such that the flow g_e^i through an edge e is at most

$$f_e^{i-1} + 1/2^{\lambda-i+2}.$$

After the ith iteration the granularity has been doubled to $1/2^{\lambda-i+1}$. A crucial observation is that from this quantity, g_e^i, only an amount of at most $1/2^{\lambda-i+2}$ corresponds to new flow, added to e during iteration i. It is easy to see that during the execution of the procedure the following two invariants are maintained.

*INV*1: After iteration i, all original commodities with demands $1/2^{\lambda-i+1}$ or less have been routed unsplittably.

*INV*2: After iteration $i > 1$, the total flow u_e^i through edge e, which is due to all i first iterations, satisfies the relation

$$u_e^i \leq u_e^{i-1} + 1/2^{\lambda-i+2}.$$

Given that $u_e^1 = u'_e$, the total flow through e used to route unsplittably all commodities in $\mathcal{T}$ is at most

$$u'_e + \sum_{i=2}^{\lambda-\log(\rho_{\max}^{-1})+1} 1/2^{\lambda-i+2} = xu_e + \rho_{\max} - 1/2^{\lambda} = xu_e + \rho_{\max} - \rho_{\min}.$$

Therefore the relaxed decision procedure returns the claimed guarantee. For the running time, we observe that in each of the $l = \lambda - \log(\rho_{\max}^{-1}) + 1$ iterations, the number of virtual commodities appears to be $O(k2^l)$, where k is the number of the original commodities. We opted to present a "pseudopolynomial" version of the decision procedure for clarity. There are two approaches to ensure polynomiality of our method. One is to consider only demands of value $1/2^{\lambda} > 1/n^d$ for some $d > 1$. It is known [27] that we can route the very small demands while affecting the approximation ratio by an $o(1)$ factor. The other approach relies on changing the units at which demands and capacities are expressed. During iteration i scale all demands up by multiplying by a factor of $2^{\lambda-i+1}$. This means that all demands of value $1/2^{\lambda-i+1}$ are now demands of 1. The different virtual commodities hosted by the same sink t are not represented explicitly. Their number will be equal to the total demand of t under the new units. Lemma 4.1 requires the capacity of each edge e to be a multiple $d_e(1/2^{\lambda-i+1})$ of $1/2^{\lambda-i+1}$; change this capacity to d_e. An integral

solution to the problem after remapping demands and capacities in the manner described corresponds to an unsplittable one for the virtual commodities of demand $1/2^{\lambda-i+1}$. □

Recall that for a given UFP we assume that the cut condition holds. In the proof of Theorem 4.1 one can avoid the binary search if all the capacities are multiples of $2^{-\lambda}$. In particular, integral capacities fulfill this requirement. Together with the cut condition, the extra condition implies that under the original capacity function u, a routing g^1 which satisfies all the demands in $\mathcal{T}_1$ can always be found. This gives the following corollary.

COROLLARY 4.1. *Let $\Pi = (G = (V, E, u), s, \mathcal{T})$ be a* UFP *in which all demand values are of the form $2^{-\nu}$ with $\nu \in N$, the maximum demand value is denoted by $\rho_{\max}$, and the minimum demand value is denoted by $\rho_{\min}$. If all capacity values are multiples of $\rho_{\min}$, algorithm* 2H_PARTITION *will obtain in polynomial time an unsplittable routing such that the flow through any edge e is at most $u_e + \rho_{\max} - \rho_{\min}$.*

THEOREM 4.2. *Let $\Pi = (G = (V, E, u), s, \mathcal{T})$ be a* UFP *with maximum and minimum demand values $\rho_{\max}$ and $\rho_{\min}$, respectively. There is an algorithm,* H_PARTITION, *which obtains in polynomial time a*

$$\min\{3 - \rho_{\min}, 2 + 2\rho_{\max} - \rho_{\min}\}$$

approximation for congestion.

Proof. We describe the algorithm H_PARTITION. Round up each demand to its closest power of 1/2. Call the resulting UFP Π' with sink set $\mathcal{T}'$. Multiply all capacities in Π' by at most 2 and let u' denote the resulting capacity function in Π'. Then there is a fractional feasible solution f' to Π'. The purpose of the rounding is to always be able to express the granularity as a power of 1/2. The remainder of the proof consists of finding an unsplittable solution to Π'; this solution can be efficiently converted to an unsplittable solution to Π without further capacity increase. Such a solution to Π' can be found by the algorithm 2H_PARTITION from Theorem 4.1. Observe that the optimum congestion for Π' is at most z, the optimum congestion for Π. 2H_PARTITION will route through edge e flow that is at most

$$zu'_e + \rho'_{\max} - \rho'_{\min} \leq 2zu_e + \rho'_{\max} - \rho'_{\min},$$

where $\rho'_{\max}$ and $\rho'_{\min}$ denote the maximum and minimum demand values in Π'. But $\rho'_{\max} < 2\rho_{\max}$, $\rho'_{\max} \leq 1$, and $\rho'_{\min} \geq \rho_{\min}$ from the construction of Π'. Therefore $\rho'_{\max} - \rho'_{\min} \leq 1 - \rho_{\min}$ and $\rho'_{\max} - \rho'_{\min} \leq 2\rho_{\max} - \rho_{\min}$. Dividing the upper bound on the flow by $zu_e \geq 1$ yields the claimed guarantees on congestion. □

5. Minimizing congestion with arbitrary capacities. We examine here UFP in its full generality, when demands lie in $(0, 1]$ and capacities in $(0, \infty)$. In particular, let $1/D$ be the minimum demand value for a real $D \geq 1$. We assume without loss of generality that $u_e \geq 1/D$ for all e, since the optimal solution will not use any edge violating this condition. Our approximation algorithm will have time complexity polynomial in $\lfloor \log D \rfloor$. In subsequent sections we return to the original balance condition on the capacity values as stated in section 2.

The essential modification required in algorithm PARTITION is at Step 1. We compute a feasible fractional solution such that the flow of commodity i through edge e is set to 0 if $\rho_i > u_e$. These constraints can be easily enforced, for example, in a linear programming formulation. The resulting problem formulation is a valid relaxation of the original problem and the unsplittable optimum is not affected by the additional

constraints. A second modification is that no subproblem is constructed for a range of the form $(0, \alpha_1]$. The first subinterval of the decomposition is $[a_1, a_2]$ with $a_1 = 1/D$. The analysis of the performance guarantee is largely the same. Let L_PARTITION be the modified algorithm as outlined above. We maintain the notation of PARTITION for the decomposition parameters.

LEMMA 5.1. *Algorithm* L_PARTITION *runs in polynomial time and outputs an unsplittable routing g with total flow through edge e at most* $\max_{2\le i\le\nu}\{r(\alpha_{i-1}, \alpha_i)\}u_e + \sum_{i=2}^{\nu}\alpha_i$, *where* $u_e \in (\alpha_{\nu-1}, \alpha_\nu]$, $\nu \le \xi$.

Proof. The proof is similar to that of Lemma 3.3. The additional observation is that because of the new constraints in the fractional relaxation, during Step 2 of the algorithm edge e is not included in any graph G_i with $i \ge \nu$. □

THEOREM 5.1. *Given* UFP Π *with arbitrary capacities and minimum demand value* $\rho_{\min} = 1/D$, $D \ge 1$, *algorithm* L_PARTITION *finds a* $(5.8285 - 1.4144\rho_{\min})$*-approximation for congestion. The algorithm runs in polynomial time.*

Proof. We instantiate the partitioning scheme as follows. The parameter $r > 1$, to be chosen later, is the ratio of the geometrically decreasing intervals. (In the proof of Theorem 3.1, $r = 2$.) We partition the interval $[1/D, 1]$ of demands into $O(\log_r D)$ geometrically increasing subintervals:

$$[1/D, 1/r^{\lfloor \log_r D\rfloor}], \ldots, (1/r^{i+1}, 1/r^i], \ldots, (1/r, 1].$$

By Lemma 5.1 the total flow through an edge e such that $1/r^{i+1} < u_e \le 1/r^i$ is at most

$$ru_e + \sum_{j=i}^{\lfloor \log_r D\rfloor} 1/r^j = ru_e + \frac{r}{r^i(r-1)} - \frac{1}{(r-1)r^{\lfloor \log_r D\rfloor}} \le ru_e + \frac{r^2 u_e}{r-1} - \frac{u_e}{(r-1)D}.$$

Thus we obtain a congestion of $\frac{2r^2-r}{r-1} - \frac{1}{(r-1)D}$. Selecting $r = 1.707$, yields $5.8285 - 1.4144\rho_{\min}$. This analysis hinges on the fact that $u_e \le 1$. The total flow through an edge e with $u_e > 1$ will be

$$ru_e + \sum_{j=0}^{\lfloor \log_r D\rfloor} 1/r^j < ru_e + \frac{r}{r-1}u_e,$$

which is at most $4.12143u_e$ when $r = 1.707$. Since $\rho_{\min} \le 1$, $4.12143 < 5.8285 - 1.4144\rho_{\min}$. □

6. Minimum-cost unsplittable flow. In this section we examine the problem of finding a minimum-cost unsplittable flow for $(G, s, \mathcal{T})$ when a cost $c_e \ge 0$ is associated with each edge e. The cost $c(P)$ of a path P is $\sum_{e\in P} c_e$. The *cost of a routing* is defined as $\sum_{t_i\in\mathcal{T}} \rho_i c(P_i)$. Similarly we define the *cost of an unsplittable flow* to be the cost of the corresponding routing. The optimization problem we consider is defined as follows: find among all routings of minimum congestion the one of minimum cost. Given that this problem has two objectives, we give a bicriteria (α, β)-approximation which finds an unsplittable routing with (i) congestion β times the optimum congestion z and (ii) cost α times the minimum cost of an unsplittable flow which is feasible with respect to the capacity function zu.

We show how to modify algorithm PARTITION to invoke a minimum-cost flow subroutine instead of maximum flow routines. Since PARTITION works on both directed and undirected graphs the same holds for the new algorithm. First we need the analogue of Theorem 2.1.

THEOREM 6.1. *Let $(G = (V, E, u), s, \mathcal{T})$ be a* UFP *with costs on an arbitrary network G with all demands ρ_i, $1 \le i \le k$, equal to the same value σ and edge capacities u_e equal to integral multiples of σ for all $e \in E$. There is a maximum fractional flow of minimum cost that is an unsplittable flow. Moreover, this unsplittable flow can be found in polynomial time.*

This theorem is an easy consequence of the well-known successive shortest path algorithm for minimum-cost flow (developed independently by [17, 16, 3]), and it is a corollary of the integrality property of minimum-cost flow, with integral units scaled by σ.

Two lemmas for the analysis follow. They generalize Lemmas 3.1 and 3.2 to accommodate costs.

LEMMA 6.1. *Given a minimum-cost* UFP *with demands in the interval $(0, \alpha]$ and a fractional solution f with cost $c(f)$, there is an algorithm, α-*C_ROUTING, *which finds an unsplittable routing of cost at most $c(f)$, such that the flow through an edge is at most $n\alpha$. The running time of the algorithm is $O(n \log n + m)$.*

Proof. Algorithm α-C_ROUTING works as follows. Find shortest paths from s to all the sinks in G using Dijkstra's algorithm [4, 10]. For each sink t_i route on the shortest path from s flow equal to the demand ρ_i. □

LEMMA 6.2. *Let a minimum-cost* UFP Π *have demands in the interval $(a, b]$, arbitrary capacities, and a fractional solution f of cost $c(f)$. There is an algorithm,* C_INTERVAL_ROUTING, *which finds in polynomial time an unsplittable routing of cost at most $r(a, b)c(f)$ such that the flow through an edge e is at most $r(a, b)u_e + b$.*

Proof. The proof is similar to that of Lemma 3.2, but we use Theorem 6.1 instead of Theorem 2.1. Round up all the demands to b and call Π' the resulting problem. By multiplying the flow f_e and the capacity u_e on each edge e by at most $r(a, b)$, we obtain a feasible fractional solution f' for Π'; the cost of f' is at most $r(a, b)c(f)$. Now add at most b to each edge capacity so that it becomes a multiple of b. Find an unsplittable routing by using Theorem 6.1. The cost of the unsplittable routing is at most equal to the cost of the fractional solution f'. □

Algorithm C_PARTITION takes the same steps as PARTITION, with two differences in Steps 1 and 3. At Step 1 of C_PARTITION a fractional minimum-cost solution f is found. At Step 3 we invoke C_INTERVAL_ROUTING instead of INTERVAL_ROUTING. C_INTERVAL_ROUTING is implemented with the successive shortest paths algorithm for minimum-cost flow. Finally algorithm α-C_ROUTING is used to compute a routing for graph G_1 of the decomposition. We keep the same notation for the partitioning scheme. The proof is very similar to that of Lemma 3.3, and we omit it.

LEMMA 6.3. *Algorithm* C_PARTITION *outputs an unsplittable routing g with congestion at most*

$$n\alpha_1 + \max_{2 \le i \le \xi} \{r(\alpha_{i-1}, \alpha_i)\} + \sum_{i=2}^{\xi} \alpha_i$$

and cost at most $\max_{2 \le i \le \xi}\{r(\alpha_{i-1}, \alpha_i)\}c(f)$, where $c(f)$ is the minimum cost of a fractional solution. The running time of C_PARTITION *is $O(T_2(n, m) + nm + m\xi)$ where $T_2(n, m)$ is the time to solve a fractional minimum-cost flow problem.*

Using the same partitioning scheme as in Theorem 3.1 we obtain the following.

THEOREM 6.2. *Given a minimum-cost* UFP Π, *we can obtain a simultaneous $(2, 4 + \varepsilon)$-approximation for cost and congestion, for any $\varepsilon > 0$. The running time of the algorithm is $O(T_2(n, m) + nm + m \log(n/\varepsilon))$ where $T_2(n, m)$ is the time to solve a fractional minimum-cost flow problem.*

We observe that the approximation factor for the cost in the above algorithm is the ratio of the subintervals used in the partitioning scheme. By increasing the constant for congestion we can improve upon the cost approximation.

THEOREM 6.3. *Given a minimum-cost* UFP Π *we can obtain a simultaneous* $(1+\delta, 2+\frac{\delta^2+1}{\delta}+\varepsilon)$*-approximation for cost and relative congestion for any* $\delta, \varepsilon > 0$. *The running time of the algorithm is* $O(T_2(n,m) + m\log(n/\varepsilon))$, *where* $T_2(n,m)$ *is the time to solve a fractional minimum-cost flow problem.*

Proof. The new algorithm is the same as C_PARTITION except for the partitioning scheme. The interval $(0,1]$ of demands is partitioned into ξ geometrically increasing subintervals

$$(0, 1/(\delta+1)^{\xi-1}], \ldots, (1/(\delta+1)^{i+1}, 1/(\delta+1)^i], \ldots, (1/(\delta+1)^2, 1/(\delta+1)], (1/(\delta+1), 1]$$

such that $1/(\delta+1)^{\xi-1} \le \varepsilon/n$. According to this scheme, by Lemma 6.3 the approximation ratio for the cost will be $1+\delta$ and the approximation ratio for the congestion will be at most

$$\begin{aligned} 1 + \delta + \sum_{i=0}^{\xi-2} \frac{1}{(\delta+1)^i} + \varepsilon \\ \le 1 + \delta + \frac{1+\delta}{\delta} + \varepsilon \\ = 2 + \frac{\delta^2+1}{\delta} + \varepsilon. \end{aligned}$$

□

Currently the best time bound $T_2(n,m)$ for fractional minimum-cost flow is

$$O(\min\{nm\log(n^2/m)\log(nC), nm(\log\log U)\log(nC), (m\log n)(m + n\log n)\})$$

due to [14, 1, 33]. Finally, by modifying the congestion algorithm of Theorem 4.2, it is easy to see how to obtain a $(2,3)$ simultaneous approximation for cost and congestion. The essential modification to H_PARTITION lies in the use of the minimum-cost analogue to Lemma 4.1.

LEMMA 6.4. *Let* $\Pi = (G, s, \mathcal{T})$ *be a minimum-cost* UFP *in which all demands have value* $1/2^x$ *for* $x \in N$ *and all capacities are multiples of* $1/2^{x+1}$, *and let* f *be a fractional flow solution of cost* $c(f)$ *such that the flow* f_e *through any edge is a multiple of* $1/2^{x+1}$. *We can find in polynomial time an unsplittable routing* g *of cost at most* $c(f)$ *such that the flow* g_e *through an edge* e *is at most* $f_e + 1/2^{x+1}$.

THEOREM 6.4. *Let* Π *be a minimum-cost* UFP, *with maximum and minimum demand values* $\rho_{\max}$ *and* $\rho_{\min}$, *respectively. We can obtain in polynomial time a simultaneous*

$$(2, \min\{3 - \rho_{\min}, 2 + 2\rho_{\max} - \rho_{\min}\})$$

approximation for cost and congestion.

7. Maximizing the routable demand. In this section we turn to the maximization problem of finding a routable subset of sinks with maximum total demand. Let the *value* of a (partial) routing be the sum of the demands of the commodities being routed. We seek a routing of maximum value such that the capacity constraints are satisfied. We obtain a .075 approximation which is slightly improved in the next section to .0769 as an indirect application of the algorithm for minimizing the number

of rounds; the latter algorithm uses subroutines from matroid theory. In contrast to most of the results in this paper, the cut condition is a necessary prerequisite for the .0769-approximation. Therefore the .075-approximation is our most generally applicable algorithm for maximum demand. The exposition in the present section introduces in a direct fashion the general technique while the algorithm invokes only maximum flow subroutines. Note that if the value definition was relaxed to take into account paths carrying flow to commodities without fully satisfying the respective demands, a c-approximation, $c > 1$, for congestion would imply a $1/c$-approximation for this relaxed maximization problem.

Let $(G, s, \mathcal{T})$ be the given UFP. Consider splitting the interval $(0, 1]$ of demands into two intervals, $(0, \alpha]$ and $(\alpha, 1]$, for an appropriate *breakpoint* α. We will give separate constant-factor approximation algorithms for each of the two resulting problems. At least one of the two intervals contains at least half of the total demand in $\mathcal{T}$, so we obtain a constant-factor approximation for the entire problem. This was also the high-level approach used in [23]. In fact, in order to route the demands in the subinterval $(\alpha, 1]$ we will use an intuitive algorithm developed by Kleinberg [23]. For the demands in $(0, \alpha]$, we show how a partitioning scheme, similar to the one used for minimizing congestion, can give a simple algorithm with a constant performance guarantee. For our partitioning scheme to succeed in the maximization setting, it is essential to have the maximum demand bounded away from 1. Hence the different treatment for $(0, \alpha]$ and $(\alpha, 1]$.

Let $\alpha^f(G, s, \mathcal{T})$ denote the total demand routed by a fractional solution f. For any given UFP we will use $\alpha^f(G, s, \mathcal{T})$, with f a fractional solution of maximum value, as an upper bound to measure the quality of our approximation.

The following lemma, shown in [23], will be used for demands in $(\alpha, 1]$. The spirit of the proof is similar to that of Lemma 3.2.

LEMMA 7.1 (see [23]). *Given a* UFP $\Pi = (G, s, \mathcal{T})$ *with demands in the interval* $(a, b]$, *there is an algorithm,* K_ROUTING, *which finds a partial unsplittable flow* g *of value at least* $\frac{1}{2}[r(a, b)]^{-1}\alpha^f(G, s, \mathcal{T})$. *The algorithm runs in polynomial time.*

Adapting the proof of Lemma 7.1 we can show a slightly different lemma, which will be also of use in our algorithm. We include the proof for the sake of completeness.

LEMMA 7.2. *Given a* UFP $\Pi = (G, s, \mathcal{T})$ *with demands in the interval* $(a, b]$ *and capacities that are multiples of* b, *there is an algorithm,* M_ROUTING, *which finds, in polynomial time, a partial unsplittable flow* g *of value at least* $[r(a, b)]^{-1}\alpha^f(G, s, \mathcal{T})$, *where* f *is a fractional solution to* Π.

Proof. We outline algorithm M_ROUTING. Round down all demands to a. Multiply all capacities in G by $[r(a, b)]^{-1} < 1$. Let $\Pi' = (G', s, \mathcal{T}')$ be the resulting problem. We show that Π' has a fractional solution f' of value $\alpha^{f'}(G', s, \mathcal{T}') \geq [r(a, b)]^{-1}\alpha^f(G, s, \mathcal{T})$: multiply the flow pushed by f on each edge by $[r(a, b)]^{-1}$ and let f' be the resulting fractional flow. Clearly f' does not route more than a units of flow to any sink in $\mathcal{T}'$ and respects the capacities in G', so it is feasible for Π'.

We now show how to obtain a partial unsplittable solution for Π of value at least $\alpha^{f'}(G', s, \mathcal{T}')$. In G all capacities are multiples of b so in G' they are multiples of a. But all demands in G' are a so by Theorem 2.1 there is an unsplittable flow g' of value at least $\alpha^{f'}(G', s, \mathcal{T}')$. Multiplying the flow on each path in g' by a factor of at most $r(a, b)$ gives a partial unsplittable flow g for Π, respecting the capacities in G and of value at least $\alpha^{f'}(G', s, \mathcal{T}')$. ∎

We now outline our approach for the second half of the problem, namely the demands in $(0, \alpha]$. Our aim is to use a partitioning scheme as in the congestion case:

ALGORITHM M_PARTITION$(G=(V,E,c), s, \mathcal{T}, \xi, \alpha_1, \ldots, \alpha_\xi, x)$

***Step* 1.** Find a feasible fractional solution f.

***Step* 2.** Let x be a constant, $0 < x < 1$. Define a partition of the $(0,1]$ interval into ξ consecutive subintervals $(0,\alpha_1], (\alpha_1,\alpha_2], \ldots, (\alpha_{\xi-1},\alpha_\xi]$, $\alpha_\xi = 1$, such that $\sum_{i=1}^{\xi-1} \alpha_i \leq x$. Construct $\xi - 1$ copies of G where the set of sinks in G_i, $2 \leq i \leq \xi$, is the subset $\mathcal{T}_i$ of $\mathcal{T}$ with demands in the interval $(\alpha_{i-1}, \alpha_i]$. Using flow decomposition determine for each edge e the amount c_e^i of u_e used by f to route flow to sinks in $\mathcal{T}_i$.

***Step* 3.** Set the capacity of edge e in G_i, $2 \leq i \leq \xi - 1$, equal to the smallest multiple of α_i greater than or equal to $(1-x)c_e^i$. Set the capacity of edge e in G_ξ to u_e.

***Step* 4.** Invoke M_ROUTING on each G_i, $2 \leq i \leq \xi - 1$, to obtain a partial unsplittable flow g^i. Invoke K_ROUTING on G_ξ to obtain a partial unsplittable flow g^ξ.

***Step* 5.** Set partial routing g to be the union of the path sets g^i, $2 \leq i \leq \xi - 1$. Of the two partial routings g and g^ξ output the one of greater value.

FIG. 8. *Algorithm* M_PARTITION.

partition the interval $(0, \alpha]$ of demand values into subintervals and generate an appropriate subproblem for each subinterval. We would like to find a near-optimal solution to each subproblem, by exploiting Lemma 7.2. Ideally, we could then combine these near-optimal solutions to the subproblems to obtain a close-to-maximum unsplittable flow for the original problem. However, in the congestion version, only a fraction of the capacity of an edge is assigned initially to each subproblem, a fraction determined by flow decomposition. On the other hand, in order to make use of Lemma 7.2 on each subproblem, we require capacities to be multiples of the maximum demand. In the congestion algorithm, adding the necessary amount to each capacity only increased the approximation ratio. In the current setting we are not allowed to increase the original input capacities, as this would violate feasibility. To circumvent this difficulty we scale down the fractional solution to the original problem. On each edge a constant fraction of the edge capacity is then left unused and can provide the required extra capacity for the subproblems. The scaling of the fractional solution by a $1-x$ factor, for appropriately chosen x, will incur a scaling by the same factor to the approximation ratio, as the value of the final routing is given in terms of the value $\alpha^f(G, s, \mathcal{T})$ of the maximum flow with which we begin. We give the general algorithm in Figure 8. It takes as input a UFP $(G, s, \mathcal{T})$ together with a set of parameters $x, \xi, \alpha_1, \ldots, \alpha_\xi$ that will determine the exact partitioning scheme. The breakpoint α will be $\alpha_{\xi-1}$ with α_ξ set to 1. Subsequently we show how to choose these parameters so as to optimize the approximation ratio. The algorithm outputs a partial routing.

By Lemma 7.1, partial routing g^ξ computed in Step 4 is a partial unsplittable flow, which respects the capacities. We need to establish this fact for partial routing g computed in Step 5 as well and also get an estimate of its value. Note that algorithm M_PARTITION does not route any demands in $(0, \alpha_1]$. Let $\alpha^f(G, s, \mathcal{T}_i)$ denote the flow routed by the fractional solution to demands in the interval $(\alpha_{i-1}, \alpha_i]$.

LEMMA 7.3. *Partial routing g found by algorithm* M_PARTITION *is a partial*

unsplittable flow of value at least

$$\min_{2\le i\le \xi-1}\{[r(\alpha_{i-1},\alpha_i)]^{-1}\}(1-x)\alpha^f\left(G,s,\bigcup_{2\le i\le \xi-1}\mathcal{T}_i\right).$$

Moreover, g respects the capacity constraints in G. The running time of M_PARTITION *is $O(T_1(n,m)+nm+m\xi)$, where $T_1(n,m)$ is the time to solve a fractional maximum flow problem.*

Proof. We examine first the value of g. Let f_i^x be the fractional optimal flow on G_i. By Lemma 7.2 the value of the partial routing g_i, $2\le i\le \xi-1$, found at Step 5, is at least $[r(\alpha_{i-1},\alpha_i)]^{-1}f_i^x$. By the capacity assignment in G_i, $\alpha^{f_i^x}(G,s,\mathcal{T}_i)\ge (1-x)\alpha^f(G,s,\mathcal{T}_i)$. Hence the value of the partial routing g^i is at least

$$(1-x)[r(\alpha_{i-1},\alpha_i)]^{-1}\alpha^f(G,s,\mathcal{T}_i).$$

Since $\alpha^f(G,s,\bigcup_{2\le i\le \xi-1}\mathcal{T}_i)=\sum_{i=2}^{i=\xi-1}\alpha^f(G,s,\mathcal{T}_i)$, the claim on the value follows.

For the capacity constraints, the aggregate capacity used in all partial routings g^i, $2\le i\le \xi-1$, on any edge e, is by Step 4 at most $(1-x)\sum_{i=2}^{i=\xi-1}c_e^i+\sum_{i=2}^{i=\xi-1}\alpha_i$. By Step 2, $\sum_{i=2}^{\xi-1}\alpha_i\le x$ and $\sum_{i=2}^{i=\xi-1}c_e^i\le u_e$. Thus, the aggregate capacity used by g is at most $(1-x)u_e+x\le u_e$. The running time follows in the same manner as in Lemma 3.3. ∎

It remains to choose the parameters x,ξ, and the α_i of the partitioning and to account for the "missing" flow $\alpha^f(G,s,\mathcal{T}_1)$. Without loss of generality we assume that there is one demand in $\mathcal{T}$ of value 1. Otherwise we can rescale the interval of demands. Thus $\alpha^f(G,s,\mathcal{T})$ is at least 1.

THEOREM 7.1. *Let x_1,x_2,x_3 be constants in $(0,1)$ such that $x_3=x_1(1-x_2)$. Given a* UFP $\Pi=(G,s,\mathcal{T})$ *and choosing parameters based on x_1,x_2,x_3, algorithm* M_PARTITION *finds a $\beta(1-\varepsilon)$-approximation for maximum routable demand for any $0<\varepsilon<\beta$ and $\beta=\min\{(1-x_1)x_2/2,x_3/4\}$. The running time of the algorithm is $O(T_1(n,m)+nm+m\log(n/\varepsilon))$ where $T_1(n,m)$ is the time to solve a fractional maximum flow problem.*

Proof. At Step 3 of M_PARTITION, partition the interval $(0,1]$ of demand values into ξ geometrically increasing subintervals

$$(0,x_3(x_2)^{\xi-2}],\ldots,(x_3(x_2)^{i+1},x_3(x_2)^i],\ldots,(x_3x_2,x_3],(x_3,1]$$

such that $x_3(x_2)^{\xi-2}\le\varepsilon/n$. Thus it suffices for ξ to be $\Theta(\log n/\varepsilon)$. The flow $\alpha^f(G,s,\mathcal{T}_1)$ is at most ε so

$$\alpha^f\left(G,s,\bigcup_{2\le i\le \xi}\mathcal{T}_i\right)\ge\alpha^f(G,s,\mathcal{T})-\varepsilon\ge(1-\varepsilon)\alpha^f(G,s,\mathcal{T}).$$

Achieving therefore a β-approximation to $\alpha^f(G,s,\bigcup_{2\le i\le \xi}\mathcal{T}_i)$ will yield the claimed $\beta(1-\varepsilon)$ ratio.

Set parameter x in the algorithm to x_1. Note that by the choice of x_3 the sum $\sum_{i=0}^{i=\xi-2}x_3(x_2)^i$ is at most x_1 as required by the algorithm. By Lemma 7.3, the partial unsplittable flow g found by M_PARTITION is a $(1-x_1)x_2$-approximation to $\alpha^f(G,s,\bigcup_{2\le i\le \xi-1}\mathcal{T}_i)$. By Lemma 7.1, the partial unsplittable flow g^ξ is a $x_3/2$-approximation to $\alpha^f(G,s,\mathcal{T}_\xi)$. Choosing of the two the one of greatest value at Step 5 yields a β-approximation to $\alpha^f(G,s,\bigcup_{2\le i\le \xi}\mathcal{T}_i)$. ∎

By choosing x_1,x_2, and x_3 to be $4/10,1/4$, and $3/10$, respectively, we obtain $(1-x_1)x_2=x_3/2=0.15$. Accordingly, $\beta=.075$.

8. Minimizing the number of rounds. In this section we examine the problem of routing in rounds. A partitioning of the set of sinks into a minimum number of communication rounds is sought so that the set of terminals assigned to each round is routable under the capacity constraints. The requirement to satisfy the capacity constraints leads to a high-level treatment similar to the one for the maximum demand metric. We split the interval of demand values into $(0, \alpha]$ and $(\alpha, 1]$, for an appropriate breakpoint α, and give a constant-factor approximation for each of the two resulting problems. Demands in $(0, \alpha]$ will be processed under a partitioning scheme that will generate subproblems. In the subproblems, we relax the capacities to allow congestions of up to $1/(1-x)$ in order to free up capacity that we can reallocate conveniently among subproblems. This scaling will be reflected in an increase on the approximation ratio by $1/(1-x)$. Intuitively, since we are using paths from the fractional solution in the unsplittable routings, when the fractional solution carries $(1-x)$ times less flow for each commodity, we need more rounds.

Recall that the input UFP comes with the assumption that a fractional solution with relative congestion 1 exists, i.e., the cut condition holds. In this section we will generate subproblems on which this assumption does not hold. Therefore we introduce notation $\zeta^f(G, s, \mathcal{T})$ for the congestion of a *fractional* solution f to a UFP $(G, s, \mathcal{T})$. Note that if f is a fractional solution of minimum congestion for a problem $(G, s, \mathcal{T})$, the quantity $\lceil \zeta^f(G, s, \mathcal{T}) \rceil$ is a lower bound on the minimum number of rounds, which we denote by $\chi(G, s, \mathcal{T})$. Our analysis bounds the number of rounds against $\zeta^f(G, s, \mathcal{T})$, which we have assumed to be 1 (because of the cut condition). But since $\chi(G, s, \mathcal{T}) \geq \lceil \zeta^f(G, s, \mathcal{T}) \rceil$, the approximation ratio holds even if we drop this assumption. For the sake of clarity we include $\zeta^f(G, s, \mathcal{T})$ in the approximation guarantees because we find that the rounds metric is the least intuitive of the three metrics as far as validity of the approximations without the cut condition is concerned.

We employ a subroutine that we call KR_ROUTING (see Lemma 5.3 in [23]) and a variant R_ROUTING to deal with subproblems having demands in a bounded range. The subroutines are similar in spirit to the subroutines K_ROUTING and M_ROUTING used for the maximum demand metric; however, their basic ingredient is not Theorem 2.1. Maximum flow integrality is not useful in the rounds setting and instead a result from [23] is used, given as Theorem 8.1 below. The proof of the latter theorem uses results from matroid theory.

THEOREM 8.1 (see [23]). *Given a* UFP $(G, s, \mathcal{T})$ *with all demands equal to* σ *and all capacities multiples of* σ, $\lceil \zeta^f(G, s, \mathcal{T}) \rceil = \chi(G, s, \mathcal{T})$. *Moreover, a routing in* $\chi(G, s, \mathcal{T})$ *rounds can be found in polynomial time.*

LEMMA 8.1 (see [23]). *Let* $\Pi = (G, s, \mathcal{T})$ *be a* UFP *with demands in the interval* $(a, b]$ *and* f *a corresponding fractional solution. There is a polynomial-time algorithm,* KR_ROUTING, *which routes* Π *in at most* $\lceil 2r(a, b)\zeta^f(G, s, \mathcal{T}) \rceil$ *rounds.*

Again we can adapt the proof of Lemma 8.1 to show a slightly different result.

LEMMA 8.2. *Let* $\Pi = (G, s, \mathcal{T})$ *be a* UFP *with demands in the interval* $(a, b]$, *and capacities multiples of* b, *and* f *a corresponding fractional solution not necessarily respecting capacities. There is a polynomial-time algorithm,* R_ROUTING, *which routes* Π *in at most* $\lceil r(a, b)\zeta^f(G, s, \mathcal{T}) \rceil$ *rounds.*

Proof. We outline algorithm R_ROUTING. Round all the demands up to b. Call Π' the resulting problem and f' a corresponding fractional solution not necessarily respecting capacities. In Π' all demands are equal to b and all capacities are multiples of b; therefore by Theorem 8.1 we can route in $\chi(\Pi') = \lceil \zeta^{f'}(\Pi') \rceil$ rounds and use the paths from this routing to route Π. Clearly, the paths used in each round respect the

capacity constraints in $(G, s, \mathcal{T})$. This completes the description of the algorithm.

It remains to demonstrate a suitable f', which will help us to upper bound $\zeta^{f'}(\Pi')$ in terms of $\zeta^f(G, s, \mathcal{T})$. Decompose the flow f for Π and consider the paths routing demand to a particular sink t_i. Multiply the flow on each path by the same constant (no greater than b/a) so that b units of flow are routed to each t_i. Do this for all sinks. Let f' be the resulting fractional solution; f' satisfies all the demands for Π' and has congestion $\zeta^{f'}(\Pi')$ at most $r(a, b)\zeta^f(G, s, \mathcal{T})$. □

Our algorithm R_Partition and its analysis are very similar to M_Partition up to the subroutine level. When dealing with $(\alpha_1, \alpha_{\xi-1}]$, we scale down the fractional capacity on each edge by $(1 - x)$, thereby inducing congestion of up to $1/(1 - x)$ in the subproblems, in order that we can reallocate capacity among the subproblems to satisfy the hypotheses of Lemma 8.2. Steps 1 through 3 are exactly the same for both algorithms. In Step 4 routines R_Routing and KR_Routing are invoked on G_i, $2 \le i \le \xi - 1$, and G_ξ, respectively. Algorithm R_Routing outputs for each G_i, $2 \le i \le \xi - 1$, a set of paths $\mathcal{P}_{ij}$ to be used on round j. Let j^* be the maximum number of rounds output from R_Routing for any G_i, $2 \le i \le \xi - 1$. During round j, $1 \le j \le j^*$, we route along all paths in $\bigcup_i \mathcal{P}_{ij}$. Subsequently we route the demands in $(0, \alpha_1]$ and $(\alpha_{\xi-1}, 1]$ in two separate sets of rounds. Recall that $\zeta^f(G, s, \mathcal{T}_i)$ is the minimum congestion for routing demands fractionally in $\mathcal{T}_i$ on the original unscaled capacities and thus is equal to 1. The following lemma accounts for the rounds needed to route all demands except for the ones in the $(0, \alpha_1]$.

Lemma 8.3. *Algorithm* R_Partition *runs in polynomial time and routes the demands in* $(\alpha_1, 1]$ *in at most*

$$\max_{2 \le i \le \xi - 1} \left\{ \left\lceil \frac{1}{1 - x} r(\alpha_{i-1}, \alpha_i) \zeta^f(G, s, \mathcal{T}_i) \right\rceil \right\} + \left\lceil 2r(a_{\xi-1}, 1)\zeta^f(G, s, \mathcal{T}_\xi) \right\rceil$$

rounds.

Proof. For the number of rounds to route demands in $(\alpha_i, \alpha_{i+1}]$, $1 \le i \le \xi - 2$, we note that Lemma 8.2 applies in the corresponding subproblems. A fractional solution satisfying all demands in subproblem G_i would have to potentially introduce congestion given that at Step 3 we assign capacity to edge e in G_i which is as low as $(1 - x)c_e^i$. There is a fractional solution f_i to G_i with congestion at most $\frac{1}{1-x}\zeta^f(G, s, \mathcal{T}_i)$, obtained by setting $f_e^i = c_e^i$. Therefore, the number of rounds for a subproblem is at most $\lceil \frac{1}{1-x} r(\alpha_{i-1}, \alpha_i)\zeta^f(G, s, \mathcal{T}_i) \rceil$. By the same argument as in Lemma 7.3, the aggregate capacity on any edge e used on all these subproblems does not exceed u_e. Thus during the same round j, $1 \le j \le j^*$, we can route all paths in $\bigcup_{2 \le i \le \xi - 1} \mathcal{P}_{ij}$.

To route the demands in $(\alpha_{\xi-1}, 1]$ we need by Lemma 8.1 at most an additional $\lceil 2r(a_{\xi-1}, 1)\zeta^f(G, s, \mathcal{T}_\xi) \rceil$ number of rounds. □

By choosing $\alpha_1 \le 1/n$, all the demand in $(0, \alpha_1]$ can be routed in one round, by Lemma 3.1.

Theorem 8.2. *Let* x_1, x_2, x_3 *be constants in* $(0, 1)$ *so that* $x_3 = x_1(1 - x_2)$. *Given a* Ufp $\Pi = (G, s, \mathcal{T})$, *we can obtain in polynomial time a* β*-approximation for minimum number of rounds where* $\beta = \lceil 1/(1 - x_1)x_2 \rceil + \lceil 2/x_3 \rceil + 1$.

Proof. The partitioning scheme is the same as in the proof of Theorem 7.1 with $\varepsilon = 1$. The demands in $(0, x_3(x_2)^{\xi-2}]$ are small enough to be routed in one round using the algorithm α-Routing from Lemma 3.1. Substituting x_1, x_2, x_3 in the number of rounds given by Lemma 8.3 and adding one extra round for the demands in $(0, x_3(x_2)^{\xi-2}]$ complete the proof. □

By choosing x_1, x_2, x_3 to be $1/2, 1/2$, and $1/4$, respectively, we obtain $\beta = 13$.

Routing all commodities in x rounds implies that during one round at least a $1/x$ fraction of the total demand is routed. If for the problem $\Pi = (G, s, \mathcal{T})$ we begin with $\zeta^f(G, s, \mathcal{T}) = 1$, i.e., the cut condition is met, Theorem 8.2 implies that we can route all commodities in at most 13 rounds. During one of those at least $1/13 = .0769$ of the total demand is routed.

COROLLARY 8.1. *Given a* UFP $\Pi = (G, s, \mathcal{T})$ *which satisfies the cut condition, we can obtain in polynomial time a* .0769*-approximation for maximizing routable demand.*

Observe that Theorem 7.1 guarantees routing at least .075 of $\alpha^f(G, s, \mathcal{T})$, which is an upper bound on the maximum routable demand but less than the total demand if the cut condition is not met. We do not see how to apply Theorem 8.2 to obtain a guarantee for maximum demand when the cut condition is violated.

9. A hardness result for unsplittable flow. In this section we consider the hardness of approximation for minimum congestion unsplittable flow on a directed network with 2 sources (2-UFP). We give a gap-preserving reduction from the NP-complete problem 3-D MATCHING [18]. Our reduction establishes that it is NP-hard to achieve an approximation ratio better than 2 for 2-UFP. In the 3-D MATCHING problem, we are given a set $M \subseteq A \times B \times C$, where A, B, and C are disjoint sets each of cardinality n. The objective is to find a *perfect matching,* i.e., a subset $M' \subseteq M$ such that $|M'| = n$ and no two elements of M' agree in any coordinate. In our reduction we use ideas from Theorem 5 in [32].

LEMMA 9.1. *Given an instance* I *of* 3-D MATCHING, *we can obtain in polynomial time an instance* I' *of* 2-UFP *on a directed network such that*

$$I \in \text{3-D MATCHING} \Rightarrow OPT(I') = 1,$$

$$I \notin \text{3-D MATCHING} \Rightarrow OPT(I') \geq 2.$$

Proof. Let $A = \{a_1, \ldots, a_n\}$, $B = \{b_1, \ldots, b_n\}$, and $C = \{c_1, \ldots, c_n\}$ so that the m triples in I are of the form (a_i, b_j, c_k). We show how to construct a directed network G for the corresponding instance I' of unsplittable flow. G contains two source vertices s_d and s_c. For each a_i occurring in t_i triples in I, G contains $t_i - 1$ vertices called the *dummies.* We denote as $\bar{d_{i\tau}}$, $1 \leq \tau \leq t_i - 1$, the dummy vertices corresponding to a_i. For each element b_j and c_k in I, we have, respectively, a vertex b_j and $\bar{c_k}$ in I'. We refer collectively to the $2n$ vertices b_j, $\bar{c_k}$, $1 \leq j, k \leq n$, as *b-* and *c-type vertices,* respectively. There are m commodities corresponding to terminal pairs $(s_c, \bar{c_k})$, $1 \leq k \leq n$, and $(s_d, \bar{d_{i\tau}})$, $1 \leq i \leq n, 1 \leq \tau \leq t_i - 1$, and they have demand 1 each. We use the bar symbol to emphasize that a vertex has a nonzero demand. All the edges in G have capacity 1.

For each of the m triples in I there will be a *triple gadget* (see Figure 9) in G. Let the μth triple be (a_i, b_j, c_k). The gadget for μ contains two dedicated vertices: x_μ and y_μ. The edges of the gadget are (x_μ, y_μ), (b_j, x_μ), $(y_\mu, \bar{c_k})$ and there is an edge from y_μ to each $\bar{d_{i\tau}}$, $1 \leq \tau \leq t_i - 1$. This completes the description of a gadget. For convenience let us identify a gadget with the triple it represents. Finally, an edge is directed from s_d to each x_μ, $1 \leq \mu \leq m$, and from s_c to each b_j, $1 \leq j \leq n$.

Since all demands and capacities are 1, each feasible unsplittable flow is simply a set of disjoint source-sink paths each carrying unit flow. Note that each flow path must pass through some gadget μ and in particular through the edge (x_μ, y_μ) of the gadget.

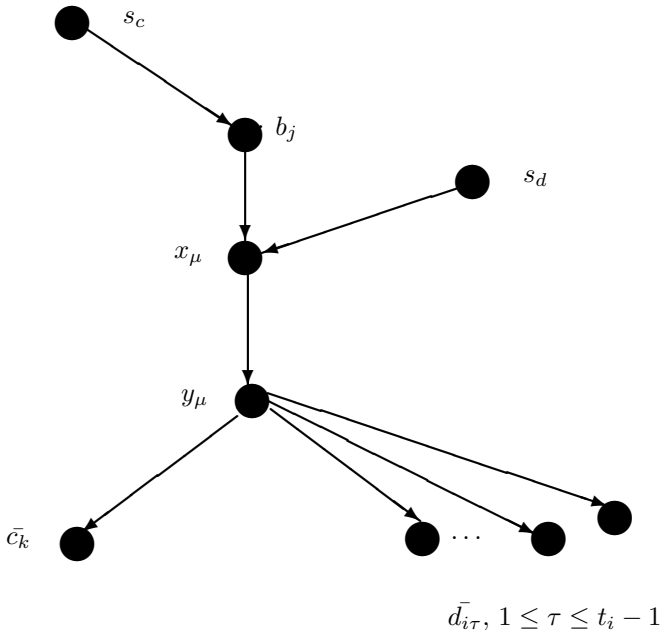

FIG. 9. *Gadget corresponding to the μth triple (a_i, b_j, c_k) together with the edges connecting it to the two sources.*

If I contains a three-dimensional (3-D) perfect matching M', it is straightforward to construct an unsplittable flow g in G with congestion 1. Flow g uses the n gadgets corresponding to triples in M' to satisfy the demands of vertices $\bar{c_k}$, $1 \le k \le n$. The remaining gadgets are used to route 1 unit of flow each (via vertex y_μ for the μth gadget) to a dummy vertex. Since M' is a matching, only one of the t_i gadgets associated with a_i, for any i, is used to route flow to a c-type vertex. As a result, for any i, there are $t_i - 1$ gadgets available to route the dummy vertices associated with a_i.

We show now that if I' has an unsplittable flow g', which satisfies the capacity constraints, then I contains a 3-D perfect matching. Let Γ be the set of n gadgets used by g' to route flow to c-type vertices. We claim that Γ forms a 3-D perfect matching in I. For each $1 \le i \le n$, each dummy vertex $\bar{d_{i\tau}}$ $(1 \le \tau \le t_i - 1)$ requires one flow path, so only one gadget in Γ corresponds to α_i. Each node b_i has in-degree 1, so only one gadget in Γ contains b_i, and the demand at each node c_i is 1, so only one gadget in Γ contains c_i. □

The ensuing theorem is an immediate consequence of Lemma 9.1.

THEOREM 9.1. *No ρ-approximation algorithm, $\rho < 2$, exists for* 2-UFP *on directed graphs unless $P = NP$. The result holds even when all capacities and demands are equal to* 1.

10. Restricted sets of demands and applications to scheduling. In this section we examine connections between unsplittable flow and scheduling problems. Consider the scheduling problem $\mathcal{S}$ defined as follows. A set J of jobs is to be scheduled on a set M of parallel nonidentical machines. A job j can be scheduled to run with

processing time p_j on a set of machines $M(j)$ and has processing time ∞ on all machines in $M - M(j)$. In other words, it is technologically infeasible for job j to run on machines in $M - M(j)$. The objective is to find a schedule which minimizes the *makespan,* i.e., the maximum completion time of a job. $\mathcal{S}$ is a special case of minimizing makespan on unrelated machines. In the unrelated machine setting, job j has a machine-dependent processing time p_{ij} on $i \in M$. The best approximation algorithm known for $\mathcal{S}$ is the 2-approximation for unrelated machine scheduling [32, 38]. From a straightforward modification to Theorem 5 in [32], the following hardness result is obtained.

THEOREM 10.1 (see [32]). *Unless $P = NP$, no approximation better than $3/2$ exists for $\mathcal{S}$ with processing times from the set $\{1, 2, \infty\}$.*

Kleinberg [23] gave an approximation-preserving reduction from $\mathcal{S}$ to minimum congestion unsplittable flow on a three-level directed graph G. A source vertex has edges directed to vertices representing the machines. The vertex set of G contains also one vertex for each job. Machine vertex i has an edge directed to job vertex j if and only if $i \in M(j)$. The edges out of the source have capacity T and the edges into the job vertices have infinite capacity. Finally each job vertex has demand equal to p_j. An unsplittable routing in G where at most ρT amount of flow is pushed through any edge corresponds to a schedule with makespan ρT for $\mathcal{S}$. See Figure 2 for an example network.

Consider a UFP on an arbitrary network with demands p and $2p$, for some $p > 0$. This includes the family of networks obtained for the scheduling problem with processing times $\{1, 2, \infty\}$. As a corollary to Theorem 4.1 and Corollary 4.1 we obtain a tight approximation ratio of $3/2$. The lower bound comes from Theorem 10.1.

COROLLARY 10.1. *Given a* UFP $\Pi = (G, s, \mathcal{T})$ *with demands from the set $\{p, 2p\}$, $0 < p \leq 1/2$, there is an algorithm to find in polynomial time an unsplittable routing where the flow through an edge e is at most $zu_e + p$, where z is the optimal congestion. If all capacities are multiples of p the flow is at most $u_e + p$. Thus the approximation ratio for congestion is at most $3/2$. This is best possible, unless $P = NP$.*

COROLLARY 10.2. *For problem $\mathcal{S}$ with processing times from $\{p, 2p, \infty\}$ there is a polynomial-time algorithm, which outputs a schedule within an additive p of the optimum makespan. The approximation ratio is at most $3/2$ and this is best possible, unless $P = NP$.*

It is instructive to consider the action taken by algorithm 2H_PARTITION on the UFP resulting from scheduling problem $\mathcal{S}$. The algorithm splits each job of processing time $2p$ into two virtual jobs each of processing time p. Then a schedule g_1 with optimum makespan is computed for the resulting instance. In the scheduling context, when all the jobs have the same processing time, an optimum schedule can be found by solving an assignment problem. Schedule g_1 corresponds to a half-integral superoptimal solution for $\mathcal{S}$. In the second phase of 2H_PARTITION this half-integral solution is rounded to an integral one.

The results of Corollary 10.1 can be generalized to the following.

COROLLARY 10.3. *Given a* UFP $\Pi = (G, s, \mathcal{T})$, *with demands from the set $\{p, Cp\}$, $C > 1, 1/C \geq p > 0$, there is an algorithm to find in polynomial time an unsplittable routing where the flow through an edge e is at most $zu_e + (C-1)p$, where z is the optimal congestion. If all capacities are multiples of p the flow is at most $u_e + (C-1)p$. Thus the approximation ratio for congestion is at most $2 - \frac{1}{C}$.*

We now proceed to examine the case in which the demands lie in the interval $[p, Cp]$, $p > 0$. Lemma 3.2 would give in this setting a $(C+1)$-approximation for

congestion, since the minimum capacity is now Cp. We show how to achieve a C-approximation, the same as the ratio of the interval.

THEOREM 10.2. *Given a* UFP $\Pi = (G, s, \mathcal{T})$ *with demands from the interval* $[p, Cp]$, $C > 1, p > 0$, *there is an algorithm to find in polynomial time an unsplittable routing where the flow through an edge* e *is at most* Cu_e.

Proof. As in the proof of Theorem 4.1 we assume without loss of generality that Π has an unsplittable routing with congestion 1. Otherwise one can use the algorithm we propose as a C-relaxed decision procedure [15] in conjunction with a binary search for the optimum congestion to obtain the claimed approximation. The algorithm is as follows. Round all demands down to p. Call the resulting problem Π'. Since an unsplittable flow solution exists for Π, one exists for Π' as well. Rounding down the capacities of edges to the closest multiple of p does not affect the existence of this solution. But for Π' all demands are p and all capacities are multiples of p. Therefore, by Theorem 2.1 we can find an unsplittable flow solution g' in polynomial time. To obtain from g' an unsplittable routing for Π it suffices to increase the flow along paths in g' that lead to sinks in $\mathcal{T}$ with demands more than p. The increase will be at most by a multiplicative factor of C on each path, hence the approximation theorem. ∎

Interestingly, the approach in Theorem 10.2 does not seem to yield an improvement on the result of Lemma 3.3. For problem Π' in the proof above, the capacities are already multiples of p, an assumption we cannot make in the setting of Lemma 3.2.

Acknowledgments. Thanks to Aravind Srinivasan for useful discussions and to Michel Goemans for sending us a copy of [5]. We also wish to thank the two anonymous referees for their comments that substantially improved the presentation and led to a strengthening of Theorem 5.1.

PROOF TECHNIQUES FOR CRYPTOGRAPHIC PROCESSES*

MICHELE BOREALE†, ROCCO DE NICOLA†, AND ROSARIO PUGLIESE†

Abstract. Contextual equivalences for cryptographic process calculi, like the spi-calculus, can be used to reason about correctness of protocols, but their definition suffers from quantification over all possible contexts. Here, we focus on two such equivalences, namely may-testing and barbed equivalence, and investigate tractable proof methods for them. To this aim, we design an enriched labelled transition system, where transitions are constrained by the knowledge the environment has of names and keys. The new transition system is then used to define a trace equivalence and a weak bisimulation equivalence that avoid quantification over contexts. Our main results are soundness and completeness of trace and weak bisimulation equivalence with respect to may-testing and barbed equivalence, respectively. They lead to more direct proof methods for equivalence checking. The use of these methods is illustrated with a few examples concerning implementation of secure channels and verification of protocol correctness.

1. Introduction.

Recently, there has been much interest in using formal methods for analyzing cryptographic protocols. Here, we focus on a specific approach, which aims at modeling protocols as concurrent processes, described as terms of a process calculus (e.g., the spi-calculus [7, 5], a cryptographic version of the π-calculus [17, 18]). As an example, consider the very simple protocol where two principals A and B share a private key k, and A wants to send B a datum d encrypted under k through a public channel c:

$$\text{Message 1} \qquad A \to B\colon \{d\}_k \text{ on } c.$$

This informal notation can be expressed in the spi-calculus as follows:

$$\begin{aligned} A(d) &\stackrel{\text{def}}{=} \overline{c}\{d\}_k.\mathbf{0}, \\ B &\stackrel{\text{def}}{=} c(x).F(x), \\ P(d) &\stackrel{\text{def}}{=} (\nu\, k)(A(d) \mid B). \end{aligned}$$

Here, $\overline{c}\{d\}_k.$ means *output* of message $\{d\}_k$ at channel c and $\mathbf{0}$ stands for *termination*. The prefix $c(x).$ indicates the intention to *input* a message at channel c and to bind it to x, and $F(x)$ is some expression describing the behavior of B after the reception of x. The whole protocol $P(d)$ is the *parallel composition* $A(d) \mid B$, with the *restriction* $(\nu\, k)$ indicating that the key k is known only to $A(d)$ and B.

The main advantage of this kind of description is that process calculi have formal yet simple semantics that permit rendering rigorously such notions as "attacker" and "secrecy." Continuing with the example above, a way of asserting that $P(d)$ keeps d secret is requiring that $P(d)$ be *equivalent* to $P(d')$ for every other d'. An appropriate notion of equivalence is *may-testing* [11, 8, 7]; its intuition is precisely that no external context (which in the present setting can be read as "attacker") may notice any

difference when running in parallel with $P(d')$ or $P(d)$. A similar intuition is supported by other contextual equivalences, like *barbed equivalence* [19]. While rigorous and intuitive, the definitions of these equivalences suffer from universal quantification over contexts (attackers) that makes equivalence checking very hard. It is then important to devise proof techniques that avoid such quantification. Results in this direction have been obtained for traditional process calculi (for example, in CCS [11, 15] and in π-calculus [17, 18], may-testing is easily proven to coincide with trace equivalence), but little has been done for cryptographic calculi.

In this paper, we consider may-testing and barbed equivalence for a variant of the spi-calculus with shared-key encryption primitives [7]. We develop an "environment-sensitive" labeled transition system (lts), whose transitions are constrained by the knowledge that the environment has of names and keys. A trace-based equivalence and a purely coinductive notion of weak bisimulation, which avoid quantification over contexts, are defined on the new lts, and it is shown that they are in agreement with may-testing and barbed equivalence, respectively. A more detailed account of our work follows.

The handling of names is a crucial aspect in the semantics of process calculi. Let us first consider the nature of the transitions in the noncryptographic π-calculus. There are three kinds of basic moves which correspond to output of a message, input of a message, and internal computation. An output transition like $P \xrightarrow{(\nu\, b)\overline{a}\langle b\rangle} P'$ says that process P passes a *new* (or *fresh*; $(\nu\,\cdot)$ means "new") name b to the environment along channel a and becomes P' in doing so. The environment can use at will names it has got to know. For example, the two-step sequence $P \xrightarrow{(\nu\, b)\overline{a}\langle b\rangle} P' \xrightarrow{b\, c} P''$ (where $b\,c$ means "input c along b") is possible. In general, if a process is ready to perform some action, the environment will always be able to react. The reason is that, in the π-calculus, environment and process share at each stage the *same* knowledge of names. Thus, to determine whether two processes are, say, may-testing equivalent, it is sufficient to establish that they can perform the *same* sequences of (input/output) actions.

The correspondence between environment and process knowledge is lost when moving to the spi-calculus, i.e., when adding encryption and decryption primitives to the π-calculus. Indeed, two new facts must be taken into account.

(a) When the environment receives a new name encrypted under a fresh key, it does not acquire the knowledge of that name immediately. For instance, after P outputs a new name b encrypted under a fresh key k (written $P \xrightarrow{(\nu\, b,k)\overline{a}\langle\{b\}_k\rangle} P'$), name b is part of the knowledge of P' but not part of the knowledge of the environment. Thus, if P' is willing to input something at b (say $P' = b(c).P''$), the environment cannot satisfy P''s expectations: a sequence like $P \xrightarrow{(\nu\, b,k)\overline{a}\langle\{b\}_k\rangle} P' \xrightarrow{b\, c} P''$ (that is possible in the traditional-style transition system) cannot be considered as meaningful in the spi-calculus. For similar reasons, a sequence like $P \xrightarrow{(\nu\, b,k)\overline{a}\langle\{b\}_k\rangle} P' \xrightarrow{a'\, b} P''$, where the environment is expected to send back the cleartext b, cannot be considered as meaningful.

(b) Equivalent processes need not exhibit the same sequences of transitions. The process that performs the single output $(\nu\, k)\overline{a}\langle\{b\}_k\rangle$ and terminates, and the one that performs $(\nu\, k)\overline{a}\langle\{c\}_k\rangle$ and terminates, are equivalent because messages $\{b\}_k$ and $\{c\}_k$ cannot be distinguished by the environment (as it

cannot open something encrypted with k). However, the two messages could be distinguished if the environment got the key k. Thus, the two processes $(\nu\, k)\overline{a}\{b\}_k.\,\overline{a}k.\,\mathbf{0}$ and $(\nu\, k)\overline{a}\{c\}_k.\,\overline{a}k.\,\mathbf{0}$ are not equivalent.

To cope with these issues and recover the correspondence between environment and process actions, we introduce an enriched lts that explicitly keeps track of the environment's knowledge. The states of the new lts are *configurations* $\sigma \rhd P$, where P is a process and σ is the current environment's knowledge, modeled as a mapping from a set of variables to a set of messages. Informally, σ plays the role of a database storing the messages received by the environment; each entry of the database is referenced by a distinct variable. Transitions represent interactions between the environment and the process and take the form

$$\sigma \rhd P \overset{\mu}{\underset{\delta}{\longmapsto}} \sigma' \rhd P',$$

where μ is the action of process P and δ is the "complementary" *environment action*.

We have three different kinds of situations.

1. The process performs an output and the environment an input. As a consequence, the environment's knowledge gets updated. For instance,

$$\sigma \rhd P \overset{(\nu\, \widetilde{b})\overline{a}\langle M\rangle}{\underset{z(x)}{\longmapsto}} \sigma[M/x] \rhd P'.$$

   Here $\sigma[M/x]$ is the update of σ with the new entry $[M/x]$ for a fresh variable x. Moreover, $\widetilde{b}$ is the set of new names the process has just created. For the transition to take place, channel a must belong to the knowledge of σ, which in this case amounts to saying that $\sigma(z) = a$.
2. The process performs an input and the environment an output. As discussed previously, messages from the environment cannot be arbitrary. They must be built, via encryption and decryption, using only the knowledge stored in σ. Thus, a transition might be

$$\sigma \rhd P \overset{a\, M}{\underset{(\nu\, \widetilde{b})\overline{z}\langle\zeta\rangle}{\longmapsto}} \sigma[\widetilde{b}/\widetilde{b}] \rhd P'.$$

   Informally, $\widetilde{b}$ is the set of new names the environment has just created and added to its knowledge, while ζ is an expression describing how M has been built out of σ and $\widetilde{b}$. For example, if $\sigma(x_1) = \{c\}_k$, $\sigma(x_2) = k$, and $M = c$, then ζ might be $\mathtt{dec}_{x_2}(x_1)$, indicating that message c results from decrypting the x_1-entry using the x_2-entry as a key. Again, a must belong to the knowledge of σ; thus $\sigma(z) = a$.
3. The process performs an internal move and the environment does nothing:

$$\sigma \rhd P \overset{\tau}{\underset{-}{\longmapsto}} \sigma \rhd P'.$$

When defining trace and bisimulation semantics (section 3) on the top of the new lts, the point of view is taken that *equivalent configurations should exhibit the same environment actions*. As an example, take σ with entries $\sigma(x) = a$, $\sigma(y) = b$, and $\sigma(z) = c$ and consider the configurations $C_1 \overset{\text{def}}{=} \sigma \rhd (\nu\, k)\overline{a}\{b\}_k.\,\mathbf{0}$ and $C_2 \overset{\text{def}}{=} \sigma \rhd (\nu\, k)\overline{a}\{c\}_k.\,\mathbf{0}$.

These configurations are both trace and bisimulation equivalent, because the only transitions they have are

$$C_1 \xmapsto[x(w)]{(\nu\, k)\overline{a}\langle\{b\}_k\rangle} \sigma[\{b\}_k/w] \rhd \mathbf{0}$$

and

$$C_2 \xmapsto[x(w)]{(\nu\, k)\overline{a}\langle\{c\}_k\rangle} \sigma[\{c\}_k/w] \rhd \mathbf{0},$$

which exhibit the same environment action, $x(w)$. On the other hand, as discussed above, $C_3 \stackrel{\text{def}}{=} \sigma \rhd (\nu\, k)\overline{a}\{b\}_k.\, \overline{a}k.\, \mathbf{0}$ and $C_4 \stackrel{\text{def}}{=} \sigma \rhd (\nu\, k)\overline{a}\{c\}_k.\, \overline{a}k.\, \mathbf{0}$ should not be regarded as equivalent. Indeed, after two steps, C_3 reaches a state where the environment is $\sigma[\{b\}_k/w][k/v]$, which cannot be considered "equivalent" to the environment reachable from C_4, i.e., $\sigma[\{c\}_k/w][k/v]$: The decryption of the entry w, which is now possible because k is known, yields distinct names, b and c, in the two cases. Equivalence on environments is a notion crucial to our approach and will be formalized in terms of logical equivalence. For both trace and bisimulation equivalence, we shall insist that *matching transitions should take equivalent environments to equivalent environments.* We shall show that these equivalences imply their contextual counterparts (soundness); hence the former can be used as proof techniques for the latter. The converse implication (completeness) is also proven for trace equivalence. As to bisimulation, we establish completeness relative to a broad class of processes (which includes all the *image-finite* ones [15]).

Trace and bisimulation equivalences avoid quantification over contexts and only require considering transitions of the enriched lts. As such, they make reasoning on processes much easier than the contextual definitions. While trace semantics are sufficient for expressing many security properties (especially those of secrecy and authenticity [7]), bisimulation is sometimes preferable because it embodies a notion of fairness and is supported by a nice, purely coinductive proof technique. The latter can be enhanced by tailoring, as we do, some "up to" techniques [22, 10] to the cryptographic setting. Another advantage of our semantics is the congruence rules that make compositional proofs possible. The use of trace and bisimulation semantics as proof techniques is illustrated with a few examples; some of them concern the problem of implementing secure channels using encrypted public channels (like in [4]). Some of the equalities we establish are hard and lengthy to prove if relying on the original, contextual definitions (see, e.g., the secure channel implementations in section 5).

The rest of the paper is organized as follows. The language is presented in section 2; there, we also introduce the contextual semantics: may-testing and barbed equivalences. Section 3 introduces the new lts for the spi-calculus and, based on that, trace and bisimulation semantics. In section 4, we establish soundness and completeness of trace semantics with respect to may-testing and of bisimulation with respect to barbed equivalence. Section 5 presents a number of properties of trace and bisimulation semantics and their applications. In section 6, we present the extension of the theory to a richer calculus, which permits handling pairs of messages. Comparisons to related works and a few concluding remarks are reported in section 7. The most technical proofs and definitions are relegated to appendices A, B, and C.

2. The language. We first present syntax and (conventional) operational semantics of the language, which is a variant of the spi-calculus. We then define the

contextual semantics: may-testing and barbed equivalence. In the definition of the language, there are a few implicit assumptions on the underlying system of shared-key cryptography. We make them explicit below:

1. A message M encrypted under a key k, written $\{M\}_k$, can only be decrypted using k. The only way to produce the ciphertext $\{M\}_k$ is to encrypt M under k. If k is secret, the attacker cannot guess or forge k (*perfect encryption*).
2. There is enough redundancy in the structure of messages to tell whether decryption of a message with a given key has actually succeeded or not.
3. There is enough redundancy in the structure of messages to tell their role (key or compound ciphertext).
4. The only way to form a new key is to get a fresh name from a primitive set of *names*.

These assumptions are quite common in the literature. In particular, the first two are also found in the original spi-calculus [7]. The third and fourth assumptions might be regarded as a limitation over the practice of crypto-protocols, where new keys are sometimes formed by assembling pieces of old messages together (especially if random bits are considered as an expensive resource). However, many interesting protocols do fulfill these assumptions.

2.1. Syntax. The syntax of the calculus is summarized in Figure 1. A countable set $\mathcal{N}$ of *names* $a, b \ldots, h, k, \ldots, x, y, z \ldots$ is assumed. Names can be used as communication channels, primitive data, or encryption keys: we do not distinguish between these three kinds of objects (in notation, we prefer letters $h, k, \ldots$ when we want to stress the use of a name as a key). In the standard π-calculus, names are the only transmissible objects. In the spi-calculus the possibility has been added to communicate *messages* obtained via shared-key encryption: message $\{M\}_k$ represents the ciphertext obtained by encrypting message M under key k, using a shared-key encryption system. Encryptions can be arbitrarily nested. *Expressions* are obtained by applying encryption and decryption operators to names and ciphertexts. For example, the result of evaluating $\mathtt{dec}_\eta(\zeta)$ is the text obtained by decrypting the ciphertext ζ using the value of η as a key. Expressions are also used to represent dummy terms that can be generated at run but do not represent proper messages (such as $\{a\}_{\{b\}_k}$, where a compound term $\{b\}_k$ is used as a key instead of an atomic name). Logical *formulae* generalize the usual equality operator of the π-calculus with a predicate $name(\cdot)$, which tests for the format of the argument (plain name or a compound ciphertext), and with a `let` construct that binds the value of some expression ζ to a name z. *Processes* are built using a set of operators which include those from the standard π-calculus, plus two new operators: boolean guard and a `let` construct. An informal explanation of the operators might be the following:

- $\mathbf{0}$ is the process that does nothing.
- $\eta(x).P$ represents input of a generic message x along η: the only useful case is when η is a name; otherwise the whole process is stuck.
- $\overline{\eta}\zeta.P$ represents output of ζ along η: the only useful case is when η is a name and ζ is a message; otherwise the whole process is stuck.
- $P + Q$ can behave either as P or Q: the choice might be triggered either by the environment, or by internal computations of P or Q.
- $P \mid Q$ is the parallel execution of P and Q.
- $(\nu\, a)P$ creates a new name a which is only known to P.
- $!\,P$ behaves like unboundedly many copies of P running in parallel, i.e., $P \mid P \mid P \mid \cdots$.

$a, b \ldots, h, k, \ldots, x, y, z \ldots$			*names* $\mathcal{N}$
M, N	::=	$a \mid \{M\}_k$	*messages* $\mathcal{M}$
η, ζ	::=	$a \mid \{\eta\}_\zeta \mid \mathtt{dec}_\eta(\zeta)$	*expressions* $\mathcal{Z}$
ϕ, ψ	::=	$\sharp \mid name(\zeta) \mid [\zeta = \eta] \mid \mathtt{let}\ z = \zeta\ \mathtt{in}\ \phi \mid \phi \wedge \psi \mid \neg\phi$	*formulae* Φ
P, Q	::=		*processes* $\mathcal{P}$
		$\mathbf{0}$	(*null*)
	|	$\eta(x).\, P$	(*input prefix*)
	|	$\overline{\eta}\zeta.\, P$	(*output prefix*)
	|	$P + Q$	(*nondeterministic choice*)
	|	$P \mid Q$	(*parallel composition*)
	|	$(\nu\, a)P$	(*restriction*)
	|	$!\, P$	(*replication*)
	|	ϕP	(*boolean guard*)
	|	$\mathtt{let}\ z = \zeta\ \mathtt{in}\ P$	(*encryption/decryption*)

It is assumed that $\mathtt{dec}_\cdot(\cdot)$ does not occur in $name(\zeta)$, $[\zeta = \eta]$, $\eta(x).$, and $\overline{\eta}\zeta.$. Operators $a(x).\cdot$, $(\nu\, a)\cdot$, and $\mathtt{let}\ z = \zeta\ \mathtt{in}\ \cdot$ are *binders*, with the obvious scope, for names x, a, and z, respectively. In $\mathtt{let}\ z = \zeta\ \mathtt{in}\ \cdot$, it is assumed that z does not appear in ζ.

FIG. 1. *Syntax of the calculus.*

- ϕP behaves like P if the formula ϕ is logically true; otherwise it is stuck.
- $\mathtt{let}\ z = \zeta\ \mathtt{in}\ P$ attempts evaluation of ζ: if the evaluation succeeds, the result is bound to z within P; otherwise the whole process is stuck.

There are a few differences from Abadi and Gordon's spi-calculus [7]. In particular, the differences are as follows:

- Our decryption keys cannot be compound messages, as already noted.
- For decryption, we use a "let" construct instead of the "case" construct of [7]. This enables us to write process expressions in a more compact form; for instance, the spi-calculus process $\mathtt{case}\ M\ \mathtt{of}\ \{k\}_h\ \mathtt{in}\ (\mathtt{case}\ N\ \mathtt{of}\ \{z\}_k\ \mathtt{in}\ P)$ can be written as $\mathtt{let}\ z = \mathtt{dec}_{\mathtt{dec}_h(M)}(N)\ \mathtt{in}\ P$ in our syntax.
- We have included a nondeterministic choice $+$, which is sometimes useful for specification purposes. Another, technical, reason for including $+$ in the language is that this operator appears to be necessary when proving coincidence of barbed equivalence and bisimilarity.
- We do not consider public key and hash functions, which are present in the original spi-calculus.

A minor difference is that the syntax above does not mention *tuples*, which we have preferred to treat separately (in section 6). This permits a cleaner presentation of the overall approach.

We shall often abbreviate $\alpha.\mathbf{0}$ as α, where α is an input or output prefix, and $(\nu\, a)(\nu\, b)P$ as $(\nu\, a, b)P$. We shall use the tilde $\widetilde{\cdot}$ to denote tuples of objects (e.g., $\widetilde{x}$ is a generic tuple of names); this will sometimes be written as $\widetilde{x}_{i \in I}$, for an appropriate index-set I. If $\widetilde{x} = (x_1, \ldots, x_n)$ and $\widetilde{y} = (y_1, \ldots, y_m)$, then $\widetilde{x}\widetilde{y}$ will denote the tuple

$(x_1, \ldots, x_n, y_1, \ldots, y_m)$. When convenient, we shall regard a tuple simply as a set (writing, e.g., $\widetilde{x} \subseteq S$ to mean that all components of $\widetilde{x}$ are in S). All our notations are extended to tuples componentwise. In particular, if $\widetilde{k} = (k_1, \ldots, k_n)$, then $\{M\}_{\widetilde{k}}$ means $\{\cdots\{M\}_{k_1}\cdots\}_{k_n}$ and $\mathtt{dec}_{\widetilde{k}}(M)$ means $\mathtt{dec}_{k_n}(\cdots\mathtt{dec}_{k_1}(M)\cdots)$.

Notions of *free names* of a process P, $fn(P)$, of *bound names* of P, $bn(P)$, and of alpha-equivalence arise as expected; $n(P)$ is $fn(P) \cup bn(P)$. Often, we shall write $fn(P, Q)$ in place of $fn(P) \cup fn(Q)$ (similarly for $bn(\cdot)$ and $n(\cdot)$). Similar notations are used for formulae, expressions, and messages.

A *substitution* σ is a finite partial map from $\mathcal{N}$ to the set of messages $\mathcal{M}$. The domain and proper codomain of σ are written $dom(\sigma)$ and $range(\sigma)$, respectively. We let $n(\sigma) = dom(\sigma) \cup (\cup_{M \in range(\sigma)} n(M))$. Given a tuple of distinct names $\widetilde{x} = (x_1, \ldots, x_n)$ and a tuple of messages $\widetilde{M} = (M_1, \ldots, M_n)$, the substitution mapping each x_i to M_i will be sometimes written as $[\widetilde{M}/\widetilde{x}]$ or $[{}^{M_i}/_{x_i}]_{i \in 1..n}$. When $\widetilde{x} \cap dom(\sigma) = \emptyset$, we write $\sigma[\widetilde{M}/\widetilde{x}]$ for the substitution σ', which is the union of σ and $[\widetilde{M}/\widetilde{x}]$ (in this case we say that σ' *extends* σ). For a given $V \subseteq_{\text{fin}} \mathcal{N}$, we write ϵ_V for the substitution with $dom(\epsilon_V) = V$ that acts as the identity on V. For any term (name/expression/formula/process) t, $t\sigma$ denotes the term obtained by simultaneously replacing each $x \in fn(t) \cap dom(\sigma)$ with $\sigma(x)$, with renaming of bound names of t possibly involved to avoid captures.

2.2. Operational semantics. The (conventional) operational semantics defined below only accounts for process intentions. In fact, the subsequent definitions of contextual equivalences use only the part of this semantics that describes "internal computation" (denoted by $\xrightarrow{\tau}$) of processes.

First, we need two evaluation functions: one for expressions, the other for formulae. The *evaluation function for expressions*, $\widehat{\cdot} : \mathcal{Z} \to \mathcal{M} \cup \{\bot\}$ (where $\bot$ is a distinct symbol) is defined by induction on ζ as follows:

- $\widehat{a} = a$,
- $\widehat{\{\zeta_1\}_{\zeta_2}} = \begin{cases} \{M\}_k & \text{if } \widehat{\zeta_1} = M \text{ and } \widehat{\zeta_2} = k \in \mathcal{N}, \text{ for some } M \text{ and } k, \\ \bot & \text{otherwise,} \end{cases}$
- $\widehat{\mathtt{dec}_{\zeta_2}(\zeta_1)} = \begin{cases} M & \text{if } \widehat{\zeta_1} = \{M\}_k \text{ and } \widehat{\zeta_2} = k \in \mathcal{N}, \text{ for some } M \text{ and } k, \\ \bot & \text{otherwise.} \end{cases}$

Note that the evaluation of an expression "fails," i.e., returns the value $\bot$, whenever an encryption/decryption with something different from a name is attempted, or whenever a decryption with something different from the encryption key is attempted. For instance, the evaluation of $\{a\}_{\{b\}_c}$ and $\mathtt{dec}_b(\{a\}_c)$ is $\bot$, while $\mathtt{dec}_c(\{a\}_c)$ evaluates to a.

The *evaluation function for formulae*, $[\![\cdot]\!] : \Phi \to \{tt, ff\}$, is defined by induction on ϕ. The only nonstandard clauses are those for $name(\zeta)$ and for $\mathtt{let}\ z = \zeta\ \mathtt{in}\ \phi$:

- $[\![name(\zeta)]\!] = \begin{cases} tt & \text{if } \zeta \in \mathcal{N}, \\ ff & \text{otherwise,} \end{cases}$
- $[\![\mathtt{let}\ z = \zeta\ \mathtt{in}\ \phi]\!] = \begin{cases} [\![\phi[\widehat{\zeta}/z]]\!] & \text{if } \widehat{\zeta} \neq \bot, \\ ff & \text{otherwise.} \end{cases}$

For any substitution σ, $\sigma \models \phi$ means that $[\![\phi\sigma]\!] = tt$.

The operational semantics is defined by the early-style inference rules of Figure 2. All rules but the last two are standard from π-calculus. Rule (GUARD) says that process ϕP behaves like P, provided that ϕ evaluates to true; otherwise, process ϕP is stuck. Rule (LET) attempts evaluation of expression ζ: if the evaluation succeeds,

(Inp) $a(x).\,P \xrightarrow{a\,M} P[M/x]$ (Out) $\overline{a}M.\,P \xrightarrow{\overline{a}\langle M\rangle} P$

(Sum) $\dfrac{P \xrightarrow{\mu} P'}{P+Q \xrightarrow{\mu} P'}$ (Rep) $\dfrac{P \mid !\,P \xrightarrow{\mu} P'}{!\,P \xrightarrow{\mu} P'}$

(Par) $\dfrac{P \xrightarrow{\mu} P'}{P \mid Q \xrightarrow{\mu} P' \mid Q}$ (Com) $\dfrac{P \xrightarrow{(\nu\,\widetilde{b})\overline{a}\langle M\rangle} P' \qquad Q \xrightarrow{a\,M} Q'}{P \mid Q \xrightarrow{\tau} (\nu\,\widetilde{b})(P' \mid Q')}$

(Res) $\dfrac{P \xrightarrow{\mu} P'}{(\nu\,c)P \xrightarrow{\mu} (\nu\,c)P'}\ c \notin n(\mu)$ (Open) $\dfrac{P \xrightarrow{(\nu\,\widetilde{b})\overline{a}\langle M\rangle} P'}{(\nu\,c)P \xrightarrow{(\nu\,\widetilde{b}c)\overline{a}\langle M\rangle} P'}\ c \neq a, c \in n(M) - \widetilde{b}$

(Guard) $\dfrac{[\![\,\phi\,]\!] = tt \qquad P \xrightarrow{\mu} P'}{\phi P \xrightarrow{\mu} P'}$ (Let) $\dfrac{\widehat{\zeta} \neq \bot \qquad P[\widehat{\zeta}/z] \xrightarrow{\mu} P'}{\texttt{let}\ z = \zeta\ \texttt{in}\ P \xrightarrow{\mu} P'}$

FIG. 2. *Operational semantics (symmetric versions of* (Sum)*,* (Par)*, and* (Com) *omitted).*

then process $\texttt{let}\ z = \zeta\ \texttt{in}\ P$ behaves like process $P[\widehat{\zeta}/z]$; otherwise, $\texttt{let}\ z = \zeta\ \texttt{in}\ P$ is stuck.

Process *actions* (i.e., labels of the transition system), ranged over by $\mu, \lambda, \ldots$, can be of three forms: τ (internal action), $a\,M$ (input at a where message M is received), and $(\nu\,\widetilde{b})\overline{a}\langle M\rangle$ (output at a where message M containing the fresh, private names $\widetilde{b}$ is sent). We shall write $\overline{a}\langle M\rangle$ instead of $(\nu\,\widetilde{b})\overline{a}\langle M\rangle$ whenever $\widetilde{b} = \emptyset$. Input and output actions will be called *visible* actions. We use s to range over sequences of visible actions (traces), and write $\Longrightarrow$ or $\stackrel{\epsilon}{\Longrightarrow}$ to denote the reflexive and transitive closure of $\xrightarrow{\tau}$ and, inductively, $\stackrel{s}{\Longrightarrow}$ for $\Longrightarrow\xrightarrow{\mu}\stackrel{s'}{\Longrightarrow}$ when $s = \mu \cdot s'$. $P \stackrel{s}{\Longrightarrow}$ will stand for "there is P' such that $P \stackrel{s}{\Longrightarrow} P'$ for some P."

From now on, we shall adopt the following convention.

Convention 2.1. We identify alpha-equivalent processes and formulae. Moreover, both in actions and in sequences of actions, *we shall assume that bound names can be freely renamed with fresh names*. In particular, we shall always assume that bound names are distinct from each other and from the free names and are not touched by substitutions.

2.3. May-testing and barbed equivalence. We instantiate the general framework of may-testing [11] to our calculus. *Observers*, ranged over by $O, O', \ldots$, are processes that can perform a distinct "success" action ω. Informally, the latter is used to signal that the observed process has passed a test. For instance, the observer $(\nu\,b)\overline{a}b.\,b(x).\,[x = c]\omega$, when run in parallel with any process, tests for the ability of the process to receive a new name b on channel a and then to send name c along b. The may-testing preorder is defined in terms of the ability of processes to pass tests proposed by observers. Since we work in a nondeterministic setting, a process *may* or *may not* pass a specific test. If one interprets "passing a test" as "revealing a piece of information," then two processes that may pass the same tests may potentially reveal the same information to observers. As such, they should be considered as equivalent from a security point of view. We can formalize this concept solely in terms of sequences of internal computations ($\Longrightarrow$) and success action (ω).

DEFINITION 2.2 (may-testing preorder). *$P \lesssim Q$ if, for every observer O, $P \mid O \stackrel{\omega}{\Longrightarrow}$ implies $Q \mid O \stackrel{\omega}{\Longrightarrow}$.*

The equivalence obtained as the kernel of the preorder $\lesssim$ is denoted by $\simeq$ ($\simeq = \lesssim \cap \lesssim^{-1}$) and is called *testing equivalence*.

The intuition behind barbed equivalence [19] is somehow similar to that of testing, but is based on a notion of step-by-step simulation between two processes. Throughout the rest of the paper, we say that a process P *commits to* a, and write $P \downarrow a$, if $P \xrightarrow{a\,M}$ or $P \xrightarrow{(\nu\,\widetilde{b})\overline{a}\langle M\rangle}$ for some M and $\widetilde{b}$. We also write $P \Downarrow a$ if $P \Longrightarrow P'$ and $P' \downarrow a$ for some P'.

DEFINITION 2.3 (barbed equivalence). *A symmetric relation $\mathcal{S} \subseteq \mathcal{P} \times \mathcal{P}$ is a* barbed bisimulation *if whenever $P\mathcal{S}Q$ holds true, then*

1. *for each P', if $P \xrightarrow{\tau} P'$, then there is Q' such that $Q \Longrightarrow Q'$ and $P'\mathcal{S}Q'$, and*
2. *for each a, if $P \downarrow a$, then $Q \Downarrow a$.*

Barbed bisimilarity*, written $\dot{\cong}$, is the largest barbed bisimulation relation. Two processes P and Q are* barbed equivalent*, written $P \cong Q$, if for all R we have that $P \mid R \dot{\cong} Q \mid R$.*

It is worthwhile to notice that neither $\lesssim$ nor $\cong$ are (pre)congruences, because they are not preserved by input prefix. This is standard in name-passing languages (see, e.g., [17, 18, 10]).

3. Trace and bisimulation semantics. In this section we shall first introduce an "environment-sensitive" lts for our calculus and then define trace and bisimulation equivalences over the new lts.

3.1. An environment-sensitive lts. States are *configurations* of the form $\sigma \rhd P$, where P is a process and where substitution σ represents the environment (from now on, terms "substitution" and "environment" will be used interchangeably). Transitions take the form

$$\sigma \rhd P \stackrel{\mu}{\underset{\delta}{\longmapsto}} \sigma' \rhd P'$$

and represent atomic interactions between process P and environment σ, μ is the process action (i.e., input, output, or τ), and δ is the complementary *environment action*. The latter can be of three forms, output, input and "no action":

$$\delta ::= (\nu\,\widetilde{b})\overline{\eta}\langle\zeta\rangle \quad | \quad \eta(x) \quad | \quad -\,.$$

The upper transition labels are not strictly necessary for the development of our theory. However, they are useful because they show the process action that triggers the transition.

Free names and bound names of δ are defined as expected, in particular $bn(\eta(x)) = \{x\}$. The *visible* environment actions are input and output. We shall use u to range over sequences of visible environment actions. The inference rules for the transition relation $\stackrel{\mu}{\underset{\delta}{\longmapsto}}$ are displayed in Figure 3. Note that judgements from the conventional transition system are used in the premises.

In rule (E-OUT), the environment receives a message M and updates its knowledge accordingly. For the transition to take place, channel a must belong to the knowledge of the environment; thus η is some expression describing how a can be obtained out of σ (this is what $\widehat{\eta\sigma} = a$ means). In rule (E-INP), the environment

It is assumed that $n(\eta) \subseteq dom(\sigma)$ and that names in $\widetilde{b}$ are fresh for σ and P.

$$\text{(E-Out)}\quad \frac{P \xrightarrow{(\nu\,\widetilde{b})\overline{a}\langle M\rangle} P' \qquad \widehat{\eta\sigma} = a}{\sigma \rhd P \overset{(\nu\,\widetilde{b})\overline{a}\langle M\rangle}{\underset{\eta(x)}{\longmapsto}} \sigma[M/x] \rhd P'} \qquad \text{(E-Tau)}\quad \frac{P \xrightarrow{\tau} P'}{\sigma \rhd P \overset{\tau}{\underset{-}{\longmapsto}} \sigma \rhd P'}$$

$$\text{(E-Inp)}\quad \frac{P \xrightarrow{a\,M} P' \qquad \widehat{\eta\sigma} = a \qquad M = \widehat{\zeta\sigma} \qquad \widetilde{b} \stackrel{\text{def}}{=} (n(\zeta) - dom(\sigma))}{\sigma \rhd P \overset{a\,M}{\underset{(\nu\,\widetilde{b})\overline{\eta}\langle\zeta\rangle}{\longmapsto}} \sigma[\widetilde{b}/\widetilde{b}] \rhd P'}$$

FIG. 3. *Rules for the environment-sensitive lts.*

sends a message M to the process. Expression ζ describes how message M is built out of σ and $\widetilde{b}$. The update $[\widetilde{b}/\widetilde{b}]$ records the creation of the new names $\widetilde{b}$.[1] As in the previous rule, a must belong to the knowledge of σ.

In the following, we write $\Longmapsto$ to denote the reflexive and transitive closure of $\overset{\tau}{\underset{-}{\longmapsto}}$ and, inductively, write $\overset{s}{\underset{u}{\Longmapsto}}$ for $\Longmapsto \overset{\mu}{\underset{\delta}{\longmapsto}} \overset{s'}{\underset{u'}{\Longmapsto}}$ when $s = \mu \cdot s'$ and $u = \delta \cdot u'$.

3.2. Trace and bisimulation semantics. In order to define observational semantics based on $\overset{\mu}{\underset{\delta}{\longmapsto}}$, we have to precisely define when two environments, represented by substitutions σ and σ', can be considered as equivalent. Informally, two environments σ and σ' are equivalent whenever they are logically indistinguishable.

DEFINITION 3.1 (equivalence on environments). *Two substitutions σ and σ' are* equivalent, *written $\sigma \sim \sigma'$, if $dom(\sigma) = dom(\sigma')$ and, for each formula ϕ with $fn(\phi) \subseteq dom(\sigma)$, it holds that $\sigma \models \phi$ if and only if $\sigma' \models \phi$.*

This logical characterization is difficult to check, as it contains a quantification on all formulae. Below, we shall give an equivalent definition that is easy to check. To do this, we start by making precise the concept of knowledge of an environment σ, that is, all the information that can be deduced from σ.

DEFINITION 3.2 (decryption closure and knowledge). *Let W be a set of messages. The* decryption closure *of W, written $dc(W)$, is the set of messages defined inductively as follows:*

(i) *$W \subseteq dc(W)$, and*
(ii) *if $k \in dc(W)$ and $\{M\}_k \in dc(W)$, then $M \in dc(W)$.*

The knowledge *of W, written $kn(W)$, is the set of names in $dc(W)$, i.e., $kn(W) \stackrel{\text{def}}{=} dc(W) \cap \mathcal{N}$. Let σ be a substitution; we let $dc(\sigma) \stackrel{\text{def}}{=} dc(range(\sigma))$ and $kn(\sigma) \stackrel{\text{def}}{=} kn(range(\sigma))$.*

Note that $kn(\sigma)$ can be computed in a finite number of steps. For instance, it is not difficult to see that $kn([\{b\}_l/w, \{a\}_k/x, \{k\}_h/y, h/z]) = \{a, h, k\}$. Next, we list some notational shorthand.

- Given any substitution $\sigma = [M_i/x_i]_{i \in I}$ and $i \in I$, we denote by $core(\sigma, x_i)$ what is left of M_i after decrypting as much as possible using the keys in $kn(\sigma)$. Formally, we define $core(\sigma, x_i)$ as the message N such that, for some $\widetilde{k} \subseteq kn(\sigma)$, it holds $M_i = \{N\}_{\widetilde{k}}$ and either N is a name, or $N = \{N'\}_h$

[1] Actually, any update $[\widetilde{b}/\widetilde{x}]$—with $\widetilde{x}$ a tuple of fresh names—could have been used instead.

for some N' and $h \notin kn(\sigma)$. For example, given $\sigma = [\{a\}_{hk}/x_1, k/x_2]$, then $core(\sigma, x_1) = \{a\}_h$ and $core(\sigma, x_2) = k$.

- Given a tuple $\widetilde{x} = x_{i \in I}$ and a tuple of indices $\widetilde{\jmath} = (j_1, \ldots, j_k) \subseteq I$, we let $\widetilde{x}[\widetilde{\jmath}]$ denote the tuple $(x_{j_1}, \ldots, x_{j_k})$. For instance, if $\widetilde{x} = (x_1, x_2, x_3)$ and $\widetilde{\jmath} = (3, 1, 1, 2)$, then $\widetilde{x}[\widetilde{\jmath}] = (x_3, x_1, x_1, x_2)$.

We are now set to give an alternative definition of equivalence on environments. The intuition behind the definition below is that, for any two equivalent environments, it should not be possible to tell apart two messages M_i and M'_i referenced by the same variable x_i by (a) trying decryption with different keys, (b) format mismatch (name vs. compound ciphertext), or (c) syntactic comparison.

DEFINITION 3.3 (equivalence on environments: alternative definition). *Let $\sigma = [M_i/x_i]_{i \in I}$ and $\sigma' = [M'_i/x_i]_{i \in I}$ be two substitutions with the same domain. For each $i \in I$, let $N_i = core(\sigma, x_i)$ and $N'_i = core(\sigma', x_i)$, and let $\widetilde{N} = N_{i \in I}$ and $\widetilde{N}' = N'_{i \in I}$. We write $\sigma \sim' \sigma'$ if for each $i \in I$ the following three conditions hold:*

(a) *for some tuple of indices $\widetilde{\jmath_i} \subseteq I$, it holds that $M_i = \{N_i\}_{\widetilde{N}[\widetilde{\jmath_i}]}$ and $M'_i = \{N'_i\}_{\widetilde{N}'[\widetilde{\jmath_i}]}$;*

(b) *$N_i \in \mathcal{N}$ if and only if $N'_i \in \mathcal{N}$;*

(c) *for each $j \in I$, it holds that $N_i = N_j$ if and only if $N'_i = N'_j$.*

As an example, $\sigma_1 = [b/x_1, c/x_2, \{b\}_k/x_3]$ and $\sigma_2 = [b/x_1, c/x_2, \{c\}_k/x_3]$ are equivalent. On the contrary, $\sigma_3 = \sigma_1[k/x_4]$ and $\sigma_4 = \sigma_3[k/x_4]$ are not equivalent, because $core(\sigma_3, x_3) = b = core(\sigma_3, x_1)$, while $core(\sigma_4, x_3) = c \neq core(\sigma_4, x_1)$; thus condition (c) is violated.[2] Also note that equivalent environments need not have the same $kn(\cdot)$: for instance, the environments $[\{b\}_{kh}/x_1, h/x_2]$ and $[\{b\}_{k'h'}/x_1, h'/x_2]$ are equivalent, though they have different knowledge. Environment pairs of this sort may arise when comparing two processes (this is due to the interplay between encryption and restriction—see Example 3.9).

The following theorem, whose proof can be found in Appendix A, allows us to freely interchange the use of $\sim$ and of $\sim'$ in the rest of the paper.

THEOREM 3.4 (coincidence of $\sim$ and $\sim'$). *For any two substitutions σ and σ', it holds that $\sigma \sim \sigma'$ if and only if $\sigma \sim' \sigma'$.*

We are now ready to define a trace-based preorder. Recall that the bound names of s and u below are assumed to be fresh. A similar remark applies to μ and δ in Definition 3.8.

DEFINITION 3.5 (trace preorder). *Let $\sigma_1 \sim \sigma_2$. Given two processes P and Q, we write $(\sigma_1, \sigma_2) \vdash P \ll Q$ if, whenever $\sigma_1 \rhd P \stackrel{s}{\underset{u}{\Longrightarrow}} \sigma'_1 \rhd P'$, there are s', σ'_2, and Q' such that $\sigma_2 \rhd Q \stackrel{s'}{\underset{u}{\Longrightarrow}} \sigma'_2 \rhd Q'$ and $\sigma'_1 \sim \sigma'_2$.*

Note that, when comparing configurations, just the lower transition labels are considered, while the upper labels (in s and s') are ignored. We give them to help in reading the definition. We revise below the example given in the introduction.

EXAMPLE 3.6. *Define $\sigma = [a/x, b/y, c/z]$. Then $\sigma \rhd (\nu\, k)\overline{a}\{b\}_k$ and $\sigma \rhd (\nu\, k)\overline{a}\{c\}_k$ are $\ll$-equivalent. On the contrary, $\sigma \rhd (\nu\, k)\overline{a}\{b\}_k.\overline{a}k$ and $\sigma \rhd (\nu\, k)\overline{a}\{c\}_k.\overline{a}k$ are not*

[2] In general, once $kn(\sigma_1)$ and $kn(\sigma_2)$ have been computed, $\sigma_1 \sim' \sigma_2$ can be very easily checked. In particular, the existential on (a) does not imply any search among the tuples $\widetilde{\jmath}$. Given $i \in I$, we just choose any tuple $\widetilde{\jmath_i}$ s.t. $M_i = \{N_i\}_{\widetilde{N}[\widetilde{\jmath}_i]}$ and check whether $M'_i = \{N'_i\}_{\widetilde{N}'[\widetilde{\jmath}_i]}$. If this is the case, then condition (a) is verified for i; otherwise, we can immediately conclude that $\sigma \not\sim' \sigma'$. Indeed, if condition (a) were validated by a different tuple $\widetilde{\jmath}'$, then we would get that $\widetilde{N}[\widetilde{\jmath_i}] = \widetilde{N}[\widetilde{\jmath}'_i]$, but $\widetilde{N}'[\widetilde{\jmath_i}] \neq \widetilde{N}'[\widetilde{\jmath}'_i]$; thus condition (c) would be violated.

related, because $\sigma[\{b\}_k/v,\, k/w] \not\sim \sigma[\{c\}_k/v,\, k/w]$ *for any fresh* v, w.

EXAMPLE 3.7. *A subtler example. Consider*

$$P \stackrel{\text{def}}{=} (\nu\, a, k)\overline{c}\{k\}_k.\overline{c}a \qquad \text{and} \qquad Q \stackrel{\text{def}}{=} (\nu\, a, k)\overline{c}\{k\}_{ak}.\overline{c}a.$$

It is easy to check that, for $\sigma \stackrel{\text{def}}{=} [c/c]$, *it holds both that* $(\sigma, \sigma) \vdash P \ll Q$ *and that* $(\sigma, \sigma) \vdash Q \ll P$. *The difference between* P *and* Q *is that* Q*'s first message contains a private name* (a) *that is later disclosed to the environment; however, the environment cannot detect this difference without the key* k, *which is never disclosed. Indeed,* P *and* Q *are may (and barbed) equivalent.*

More examples will be given in section 5. Let us switch to bisimulation. In what follows, $\sigma \rhd P \stackrel{\widehat{\mu}}{\stackrel{\Longrightarrow}{\scriptstyle\delta}} \sigma' \rhd P'$ stands for $\sigma \rhd P \stackrel{\mu}{\stackrel{\Longrightarrow}{\scriptstyle\delta}} \sigma' \rhd P'$ if $\mu \neq \tau$, and for $\sigma \rhd P \Longrightarrow \sigma' \rhd P'$ if $\mu = \tau$ (the $\widehat{\cdot}$ defined here has of course nothing to do with the evaluation function on expressions defined in the previous section). We say that a pair of configurations $(\sigma_1 \rhd P, \sigma_2 \rhd Q)$ is *compatible* if σ_1 and σ_2 are equivalent. A relation $\mathcal{R}$ is *compatible* if it only contains compatible pairs of configurations. Given a binary relation $\mathcal{R}$, we write $(\sigma_1, \sigma_2) \vdash P\,\mathcal{R}\,Q$ if $(\sigma_1 \rhd P\,,\, \sigma_2 \rhd Q) \in \mathcal{R}$.

DEFINITION 3.8 (weak bisimulation). *Let* $\mathcal{R}$ *be a binary compatible relation of configurations. We say that* $\mathcal{R}$ *is a* weak bisimulation *if, whenever* $(\sigma_1, \sigma_2) \vdash P\,\mathcal{R}\,Q$ *and* $\sigma_1 \rhd P \stackrel{\mu}{\stackrel{\longmapsto}{\scriptstyle\delta}} \sigma_1' \rhd P'$, *there are* μ', σ_2', *and* Q' *such that* $\sigma_2 \rhd Q \stackrel{\widehat{\mu'}}{\stackrel{\Longrightarrow}{\scriptstyle\delta}} \sigma_2' \rhd Q'$ *and* $(\sigma_1', \sigma_2') \vdash P'\,\mathcal{R}\,Q'$, *and the converse on the transitions of* Q *and* P. Bisimilarity, *written* $\approx$, *is the largest weak bisimulation relation.*

EXAMPLE 3.9. *This example shows that, when establishing process equivalence, pairs of equivalent environments with different* $kn(\cdot)$ *may arise, even when starting from a pair of identical environments. Consider*

$$P \stackrel{\text{def}}{=} (\nu\, a, k)\overline{c}\{k\}_k.\overline{c}a.\overline{a}c \qquad \text{and} \qquad Q \stackrel{\text{def}}{=} (\nu\, a, k)\overline{c}\{k\}_{ak}.\overline{c}a.\overline{a}c,$$

and let $\sigma \stackrel{\text{def}}{=} [c/c]$. *It is easy to see that* $(\sigma, \sigma) \vdash P \approx Q$. *In particular, the move*

$$\sigma \rhd P \stackrel{(\nu\, k)\overline{c}\langle\{k\}_k\rangle}{\stackrel{\longmapsto}{\scriptstyle c(x)}} \sigma[\{k\}_k/x] \rhd (\nu\, a)\overline{c}a.\overline{a}c \stackrel{\text{def}}{=} P'$$

is matched by

$$\sigma \rhd Q \stackrel{(\nu\, k,a)\overline{c}\langle\{k\}_{ak}\rangle}{\stackrel{\longmapsto}{\scriptstyle c(x)}} \sigma[\{k\}_{ak}/x] \rhd \overline{c}a.\overline{a}c \stackrel{\text{def}}{=} Q',$$

where $(\sigma[\{k\}_k/x], \sigma[\{k\}_{ak}/x]) \vdash P' \approx Q'$. *Thus, the move*

$$\sigma[\{k\}_k/x] \rhd P' \stackrel{(\nu\, b)\overline{c}\langle b\rangle}{\stackrel{\longmapsto}{\scriptstyle c(y)}} \sigma[\{k\}_k/x,\, b/y] \rhd \overline{b}c \stackrel{\text{def}}{=} P''$$

(where we have alpha-renamed a *into a fresh* b*) must be matched by*

$$\sigma[\{k\}_{ak}/x] \rhd Q' \stackrel{\overline{c}\langle a\rangle}{\stackrel{\longmapsto}{\scriptstyle c(y)}} \sigma[\{k\}_{ak}/x,\, a/y] \rhd \overline{a}c \stackrel{\text{def}}{=} Q'',$$

where $(\sigma[\{k\}_k/x,\, b/y], \sigma[\{k\}_{ak}/x,\, a/y]) \vdash P'' \approx Q''$. *In particular, the process action* $\overline{b}\langle c\rangle$ *originating from* P'' *is matched by the process action* $\overline{a}\langle c\rangle$ *originating from* Q''.

To end the section, we note that bisimilarity $\approx$ is strictly included in the trace preorder $\ll$. This fact holds for labelled transition systems in general; it is not specific to cryptography. As an example, it is easily checked that if $V = \{a, b, c\}$, then

$$(\epsilon_V, \epsilon_V) \vdash P \stackrel{\text{def}}{=} \overline{a}a.(\nu\, z)((\overline{z}z.\overline{b}b \,|\, \overline{z}z.\overline{c}c) \,|\, z(x)) \ll (\nu\, z)((\overline{z}z.\overline{a}a.\overline{b}b \,|\, \overline{z}z.\overline{a}a.\overline{c}c) \,|\, z(x)) \stackrel{\text{def}}{=} Q$$

but

$$(\epsilon_V, \epsilon_V) \vdash P \not\approx Q.$$

Indeed, $\epsilon_V \rhd P$ has an $\overline{a}a$-move that $\epsilon_V \rhd Q$ cannot match.

4. Soundness and completeness. In this section we show the agreement between the contextual semantics of section 2 and the semantics based on the environment-sensitive lts of section 3. More precisely, we will prove that

- the trace preorder ($\ll$) coincides with the may-testing preorder ($\sqsubseteq_{\approx}$), and
- bisimilarity ($\approx$) is included in barbed equivalence ($\cong$), while the opposite inclusions hold for the class of structurally image-finite processes (defined later in this section).

The inclusions $\ll \subseteq$, $\sqsubseteq_{\approx}$, and $\approx \subseteq \cong$ will be referred to as *soundness*, while the opposite inclusions will be referred to as *completeness*. There are a few basic ingredients for the proofs of soundness and completeness, which we list below. First, it is technically convenient to introduce a notion of structural equivalence, $\equiv$, in the same vein of [16].

DEFINITION 4.1 (structural equivalence). Structural equivalence *is the least equivalence relation $\equiv$ over processes that is preserved by parallel composition and restriction and satisfies the structural laws of* [16], *i.e.,*

- the monoid laws for parallel composition*:* $P \mid \mathbf{0} \equiv P$, $P \mid Q \equiv Q \mid P$, *and* $P \mid (Q \mid R) \equiv (P \mid Q) \mid R$,
- the laws for restriction*:* $(\nu\, b)\mathbf{0} \equiv \mathbf{0}$, $(\nu\, a)(\nu\, b)P \equiv (\nu\, b)(\nu\, a)P$, *and* $(\nu\, a)(P|Q) \equiv P \mid (\nu\, a)Q$ *if* $a \notin fn(P)$,
- the law for replication*:* $!P \equiv P \mid !P$,

plus the law

$$(\texttt{let}\ z = \zeta\ \texttt{in}\ P) \equiv P[\widehat{\zeta}/z] \quad \text{if } \widehat{\zeta} \neq \perp.$$

A property of structural equivalence that we shall use extensively in what follows is that $\equiv$ commutes with $\xrightarrow{\mu}$; i.e., if $P \equiv Q$ and $P \xrightarrow{\mu} P'$, then there exists Q' such that $Q \xrightarrow{\mu} Q'$ and $P' \equiv Q'$ (the proof goes by inspection of the rules; see also [16]).

The key to soundness is the following proposition that relates equivalence on environments ($\sim$) to the (conventional) operational semantics of Figure 2 (its proof can be found in Appendix B).

PROPOSITION 4.2. *Consider two equivalent substitutions, σ_1 and σ_2. Let R be any process or observer such that $fn(R) \subseteq dom(\sigma_1)$.*

(1) *Suppose that $R\sigma_1 \xrightarrow{(\nu\, b)\overline{a}\langle M\rangle} R_1$. Then* (i) *there is η such that (s.t.) $n(\eta) \subseteq dom(\sigma_1)$ and $\widehat{\eta\sigma_1} = a$;* (ii) *there are ζ and R' s.t. $fn(\zeta, R') \subseteq dom(\sigma_1) \cup \widetilde{b}$, $M = \widehat{\zeta\sigma_1}$, and $R_1 \equiv R'\sigma_1$;* (iii) *it holds that $R\sigma_2 \xrightarrow{(\nu\, \widetilde{b})\overline{a'}\langle M'\rangle} R_2$, where $a' = \widehat{\eta\sigma_2}$, $M' = \widehat{\zeta\sigma_2}$, and $R_2 \equiv R'\sigma_2$.*

(2) *Suppose that* $R\sigma_1 \xrightarrow{a\,M} R_1$. *Then* (i) *there is* η *s.t.* $n(\eta) \subseteq dom(\sigma_1)$ *and* $\widehat{\eta\sigma_1} = a$; (ii) *given any fresh* y *and* $\sigma_1' \stackrel{\text{def}}{=} \sigma_1[M/y]$, *there is* R' *s.t.* $fn(R') \subseteq dom(\sigma_1')$ *and* $R_1 \equiv R'\sigma_1'$; (iii) *for any* M', *it holds that* $R\sigma_2 \xrightarrow{a'\,M'} R_2$, *where* $a' = \widehat{\eta\sigma_2}$, $R_2 \equiv R'\sigma_2'$, *and* $\sigma_2' \stackrel{\text{def}}{=} \sigma_2[M'/y]$.

(3) *Suppose that* $R\sigma_1 \xrightarrow{\mu} R_1$ *with* $\mu = \tau$ *or* $\mu = \omega$. *Then* (i) *there is* R' *s.t.* $fn(R') \subseteq dom(\sigma_1)$ *and* $R_1 \equiv R'\sigma_1$; (ii) *we have* $R\sigma_2 \xrightarrow{\mu} R_2$, *where* $R_2 \equiv R'\sigma_2$.

The main ingredient for completeness is the notion of a *characteristic formula* of an environment σ, written ϕ_σ. The exact definition of ϕ_σ can be found in Appendix A. Here, we only wish to recall the properties that will be used below. It holds that $n(\phi_\sigma) \subseteq dom(\sigma)$ and that $\sigma \models \phi_\sigma$; moreover, the following crucial theorem (whose proof can be found in Appendix A) says that ϕ_σ characterizes all and only those environments σ' equivalent to σ.

THEOREM 4.3. *Let* σ *and* σ' *be two substitutions such that* $dom(\sigma) = dom(\sigma')$. *We have that* $\sigma \sim \sigma'$ *if and only if* $\sigma' \models \phi_\sigma$.

We will now proceed to prove soundness and completeness, first for may-testing and then for barbed equivalence.

4.1. May-testing and trace semantics.

Soundness. It is convenient to prove soundness of $\ll$ with respect to a notion more general than $\sqsubseteq$, which is introduced below.

DEFINITION 4.4 (generalized may-testing). *For equivalent* σ_1 *and* σ_2, *we write* $(\sigma_1, \sigma_2) \vdash P \sqsubseteq Q$ *if, for each observer* O *with* $fn(O) \subseteq dom(\sigma_1)$, $P \mid O\sigma_1 \stackrel{\omega}{\Longrightarrow}$ *implies* $Q \mid O\sigma_2 \stackrel{\omega}{\Longrightarrow}$.

The above definition subsumes that of may preorder, as $P \sqsubseteq Q$ holds if and only if $(\epsilon_V, \epsilon_V) \vdash P \sqsubseteq Q$ for some $V \supseteq fn(P, Q)$. The "only if" part of this statement is trivial. To see that the "if" part is true, use the fact that, for any R and O, $R \mid O \stackrel{\omega}{\Longrightarrow}$ if and only if $(\nu\,\widetilde{b})(R \mid O) \equiv R \mid (\nu\,\widetilde{b})O \stackrel{\omega}{\Longrightarrow}$, where $\widetilde{b} = fn(O) - fn(R)$.

We need some properties of sequences of transitions. To state these properties we introduce some additional notions.

NOTATION 4.5. *Given two process actions* μ *and* λ, *we write* $\mu \underline{compl}\, \lambda$ *when* $\mu = a\,M$ *and* $\lambda = (\nu\,\widetilde{b})\overline{a}\langle M\rangle$, *or vice versa, for some* a, $\widetilde{b}$, *and* M. *The notation extends to sequences of visible actions of the same length (*$s \underline{compl}\, r$*) as expected.*

Note that whenever $P \mid O \stackrel{\omega}{\Longrightarrow}$, we can find s and r (possibly empty) s.t. $P \stackrel{s}{\Longrightarrow}$, $O \stackrel{r\omega}{\Longrightarrow}$, and $s \underline{compl}\, r$. Conversely, $P \stackrel{s}{\Longrightarrow}$ and $O \stackrel{r\omega}{\Longrightarrow}$ with $s \underline{compl}\, r$ can be composed to yield $P \mid O \stackrel{\omega}{\Longrightarrow}$.

DEFINITION 4.6. *Given an environment action* δ *and an environment* σ, $\widehat{\delta\sigma}$ *is the process action defined as*

$$\widehat{\delta\sigma} = \begin{cases} (\nu\,\widetilde{b})\overline{a}\langle M\rangle & \text{if } \delta = (\nu\,\widetilde{b})\overline{\eta}\langle\zeta\rangle,\ \widehat{\eta\sigma} = a, \text{ and } M = \widehat{\zeta\sigma}, \\ a\,M & \text{if } \delta = \eta(x),\ \widehat{\eta\sigma} = a, \text{ and } M = x\sigma, \\ \textit{undefined} & \textit{otherwise.} \end{cases}$$

Given a trace u *with* $n(u) \subseteq dom(\sigma)$, $\widehat{u\sigma}$ *is defined as expected.*

For proving the soundness theorem we make use of the following three auxiliary lemmas whose proofs can be found in Appendix B. The first lemma is a generalization of Proposition 4.2 to sequences of transitions.

LEMMA 4.7. *Suppose $\sigma_1 \sim \sigma_2$ and let O be any observer such that $fn(O) \subseteq dom(\sigma_1)$. Suppose that $O\sigma_1 \stackrel{r}{\Longrightarrow} O_1$, where, for some u and σ_1' extending σ_1, it is $r = \widehat{u\sigma_1'}$. Then, there is O' with $fn(O') \subseteq dom(\sigma_1')$ such that $O_1 \equiv O'\sigma_1'$. Furthermore, for any σ_2' extending σ_2 and such that $\sigma_2' \sim \sigma_1'$, it holds that $O\sigma_2 \stackrel{r'}{\Longrightarrow} \equiv O'\sigma_2'$, with $r' = \widehat{u\sigma_2'}$.*

The next lemma gives a sufficient condition to infer the existence of a sequence of transitions $\sigma \rhd P \stackrel{s}{\underset{u}{\models\!\Longrightarrow}} \sigma' \rhd P'$.

LEMMA 4.8. *Consider σ, P, and any observer O with $fn(O) \subseteq dom(\sigma)$. Suppose that $P \stackrel{s}{\Longrightarrow} P'$ and that $O\sigma \stackrel{r}{\Longrightarrow}$ with $s \underline{compl}\, r$. Then there are u and σ' extending σ such that $r = \widehat{u\sigma'}$ and $\sigma \rhd P \stackrel{s}{\underset{u}{\models\!\Longrightarrow}} \sigma' \rhd P'$.*

Finally, a simple result relates the form of s to that of u in a sequence of transitions $\stackrel{s}{\underset{u}{\models\!\Longrightarrow}}$.

LEMMA 4.9. *Suppose that $\sigma \rhd P \stackrel{s}{\underset{u}{\models\!\Longrightarrow}} \sigma' \rhd P'$. Then it holds that $P \stackrel{s}{\Longrightarrow} P'$, that σ' extends σ, and that $s \underline{compl}\, r$, where $r = \widehat{u\sigma'}$.*

We can now state and prove the soundness theorem.

THEOREM 4.10 (soundness of trace semantics). *If $(\sigma_1, \sigma_2) \vdash P \ll Q$, then $(\sigma_1, \sigma_2) \vdash P \stackrel{\cdot}{\lesssim} Q$.*

Proof. Suppose that $(\sigma_1, \sigma_2) \vdash P \ll Q$ and let O be any observer with $fn(O) \subseteq dom(\sigma_1)$. Suppose that $P \mid O\sigma_1 \stackrel{\omega}{\Longrightarrow}$; we have to show that $Q \mid O\sigma_2 \stackrel{\omega}{\Longrightarrow}$. Since $P \mid O\sigma_1 \stackrel{\omega}{\Longrightarrow}$ we can find P', s, and r such that

$$P \stackrel{s}{\Longrightarrow} P' \text{ and } O\sigma_1 \stackrel{r\omega}{\Longrightarrow} \text{ with } s \underline{compl}\, r.$$

(As usual, we suppose that $bn(s, r)$ are fresh.) Due to Lemma 4.8, we can find u and σ_1' extending σ_1 such that

$$\sigma_1 \rhd P \stackrel{s}{\underset{u}{\models\!\Longrightarrow}} \sigma_1' \rhd P' \text{ and } r = \widehat{u\sigma_1'}\,.$$

Thus, by hypothesis, there are s', σ_2' extending σ_2 and Q' such that

$$\sigma_2 \rhd Q \stackrel{s'}{\underset{u}{\models\!\Longrightarrow}} \sigma_2' \rhd Q' \text{ with } \sigma_1' \sim \sigma_2'\,.$$

Moreover, due to Lemma 4.9, it holds that $Q \stackrel{s'}{\Longrightarrow} Q'$ and $s' \underline{compl}\, r'$, where $r' = \widehat{u\sigma_2'}$. From Lemma 4.7 applied to $O\sigma_1 \stackrel{r\omega}{\Longrightarrow}$ and to σ_2', we get that $O\sigma_2 \stackrel{r'\omega}{\Longrightarrow}$. From this fact, $Q \stackrel{s'}{\Longrightarrow} Q'$, and $s' \underline{compl}\, r'$, we get the wanted $Q \mid O\sigma_2 \stackrel{\omega}{\Longrightarrow}$. □

Completeness. We begin by introducing some notation. We write $\langle\overline{\eta}\zeta\rangle.P$ instead of $\texttt{let}\ z_1 = \eta\ \texttt{in}\ (\texttt{let}\ z_2 = \zeta\ \texttt{in}\ \overline{z_1}z_2.P)$ and $\langle\eta(x)\rangle.P$ instead of $\texttt{let}\ z = \eta\ \texttt{in}\ z(x).P$ (z, z_1, and z_2 fresh). The *output-bound names* of δ, $obn(\delta)$, are defined as follows: $obn((\nu\,\widetilde{b})\overline{\eta}\zeta) = \widetilde{b}$ and $obn(\delta) = \emptyset$ if δ is not an output action. This notation extends to traces ($obn(u)$) as expected. Given u and σ, we say that u *is consistent with* σ if (i) $n(u) \subseteq dom(\sigma)$; (ii) σ extends $[\widetilde{b}/\widetilde{b}]$, where $\widetilde{b} = obn(u)$; and (iii) $\widehat{u\sigma}$ is defined.

Based on ϕ_σ, we can define a class of canonical observers $o(u, \sigma)$, depending on specific u and σ.

DEFINITION 4.11 (canonical observers). *Consider u consistent with σ. The observers $o(u,\sigma)$ are defined by induction on u as follows:*

$$\begin{array}{rcl} o(\epsilon,\sigma) & \stackrel{\text{def}}{=} & \phi_\sigma \omega, \\ o((\nu\, \widetilde{b})\overline{\eta}\langle\zeta\rangle \cdot u, \sigma) & \stackrel{\text{def}}{=} & (\nu\, \widetilde{b})\, \langle\overline{\eta}\zeta\rangle.o(u,\sigma), \\ o(\eta(x)\cdot u,\sigma) & \stackrel{\text{def}}{=} & \langle\eta(x)\rangle.o(u,\sigma). \end{array}$$

Note that $fn(o(u,\sigma)) \subseteq dom(\sigma) - bn(u)$. We now need two technical lemmas.

LEMMA 4.12. *Consider u consistent with σ. Let σ_0 be the restriction of σ to $dom(\sigma) - bn(u)$.*

1. *We have $o(u,\sigma)\sigma_0 \stackrel{r\omega}{\Longrightarrow}$, where $r = \widehat{u\sigma}$.*
2. *Consider any $\sigma_0' \sim \sigma_0$. If $o(u,\sigma)\sigma_0' \stackrel{r\omega}{\Longrightarrow}$, then (up to the renaming of bound names of r) $r = \widehat{u\sigma'}$ for some σ' extending σ_0' and s.t. $\sigma \sim \sigma'$.*

Proof. Both parts are proven by straightforward induction on u and relying on Theorem 4.3 for the base case. □

LEMMA 4.13. *Consider P, σ, and σ' extending σ. Suppose that $P \stackrel{s}{\Longrightarrow} P'$, with $s \underline{\ compl\ } \widehat{u\sigma'}$, for some u consistent with σ' and s.t. $bn(u) = dom(\sigma') - dom(\sigma)$. Then $\sigma \rhd P \stackrel{s}{\underset{u}{\models\!\Longrightarrow}} \sigma' \rhd P'$.*

Proof. The proof may be made by straightforward induction based on u, which relies on Proposition 4.2. □

We are now ready to prove completeness.

THEOREM 4.14 (completeness for may-testing). *If $(\sigma_1,\sigma_2) \vdash P \sqsubseteq Q$, then $(\sigma_1,\sigma_2) \vdash P \ll Q$.*

Proof. Suppose that $(\sigma_1,\sigma_2) \vdash P \sqsubseteq Q$ and that $\sigma_1 \rhd P \stackrel{s}{\underset{u}{\models\!\Longrightarrow}} \sigma_1' \rhd P'$, where as usual $bn(s,u)$ are taken fresh. We have to show that for some s', σ_2', and Q' it holds that $\sigma_2 \rhd Q \stackrel{s'}{\underset{u}{\models\!\Longrightarrow}} \sigma_2' \rhd Q'$ and $\sigma_1' \sim \sigma_2'$.

Due to Lemma 4.9, we know that $s \underline{\ compl\ } r \stackrel{\text{def}}{=} \widehat{u\sigma_1'}$. Furthermore, it is easy to show that u is consistent with σ_1'. Since σ_1 is the restriction of σ_1' to $dom(\sigma_1') - bn(u)$, by virtue of Lemma 4.12(1) we get that $o(u,\sigma_1')\sigma_1 \stackrel{r\omega}{\Longrightarrow}$. From this, $P \stackrel{s}{\Longrightarrow} P'$, and $s \underline{\ compl\ } r$, we get that $P \mid o(u,\sigma_1')\sigma_1 \stackrel{\omega}{\Longrightarrow}$. Thus, by hypothesis, we also have $Q \mid o(u,\sigma_1')\sigma_2 \stackrel{\omega}{\Longrightarrow}$. This implies that there are s', Q', and r' such that

$$Q \stackrel{s'}{\Longrightarrow} Q' \text{ and } o(u,\sigma_1')\sigma_2 \stackrel{r'\omega}{\Longrightarrow} \text{ with } s' \underline{\ compl\ } r' .$$

From this and Lemma 4.12(2), we obtain that $r' = \widehat{u\sigma_2'}$, for some σ_2' extending σ_2 and s.t. $\sigma_1' \sim \sigma_2'$. From this fact, $Q \stackrel{s'}{\Longrightarrow} Q'$, and Lemma 4.13, we get the desired $\sigma_2 \rhd Q \stackrel{s'}{\underset{u}{\models\!\Longrightarrow}} \sigma_2' \rhd Q'$. □

4.2. Barbed equivalence and bisimilarity.

Soundness. It is convenient to generalize Definition 2.3 of barbed equivalence.

DEFINITION 4.15 (generalized barbed equivalence). *Let $\sigma_1 = [M_i/x_i]_{i\in I}$ and $\sigma_2 = [M_i'/x_i]_{i\in I}$ be equivalent substitutions. For each $i \in I$, let $N_i = core(\sigma_1, x_i)$ and $N_i' = core(\sigma_2, x_i)$. A binary relation $\mathcal{S}$ of processes is a (σ_1,σ_2)-*barbed bisimulation *if, whenever $P\mathcal{S}Q$ holds true,*

1. *for each P', if $P \stackrel{\tau}{\longrightarrow} P'$, then there is Q' such that $Q \Longrightarrow Q'$ and $P'\mathcal{S}Q'$, and*

2. *for each* $i \in I$, *if* $P \downarrow N_i$, *then* $Q \Downarrow N'_i$

and the converse on the transitions and commitments of Q *and* P.

Two processes P *and* Q *are* (σ_1, σ_2)-barbed bisimilar, *written* $(\sigma_1, \sigma_2) \vdash P \mathrel{\dot{\cong}} Q$, *if* (P, Q) *belongs to the largest* (σ_1, σ_2)*-barbed bisimulation.*

Two processes P *and* Q *are* (σ_1, σ_2)-barbed equivalent, *written* $(\sigma_1, \sigma_2) \vdash P \cong Q$, *if for all* R *with* $fn(R) \subseteq dom(\sigma_1)$ *we have that* $(\sigma_1, \sigma_2) \vdash P \mid R\sigma_1 \mathrel{\dot{\cong}} Q \mid R\sigma_2$.

Note the differences of this definition from Definition 2.3. First, the "barbs" (the $\downarrow$ predicate) are only checked relative to those names that are known to the environments, which are precisely those N_i's and those N'_i's that are in $\mathcal{N}$. Second, for each $i \in I$, names N_i and N'_i are not required to be the same, but are just required to be the "cores" of the same environment entry x_i. Most important, $\mathrel{\dot{\cong}}$ is just closed under those contexts that can be obtained via instantiation with σ_1 and σ_2. Of course, $P \cong Q$ holds if and only if $(\epsilon_V, \epsilon_V) \vdash P \cong Q$ for some V containing $fn(P, Q)$.

The purely coinductive formulation of $\approx$ given in Definition 3.8 gives us a powerful proof technique when proving equalities between two processes: it is sufficient to exhibit *any* bisimulation relation containing the given pair. This technique can be enhanced using the so-called *up to* techniques (similar to those in, e.g., [22, 10]), which often permit one to reduce the size of the relation to exhibit. We introduce below some useful up to techniques, which will be used in later proofs and examples. *Up to structural equivalence* allows one to freely identify structurally equivalent processes; *up to weakening* permits discarding environment entries, while *up to contraction* permits adding redundant (hence harmless) entries to the environments. Finally, *up to restriction* and *up to parallel composition* permit cutting away top-level restrictions and common parallel contexts, respectively, in process derivatives.

DEFINITION 4.16 (up to techniques). *Given a compatible relation* $\mathcal{R}$, *define* $\mathcal{R}_t$, *for* $t \in \{s, w, c, r, p\}$, *as the least binary relations over configurations that satisfy the following rules:*

- *up to structural equivalence:*
$$\frac{P' \equiv P,\ Q' \equiv Q \text{ and } (\sigma_1, \sigma_2) \vdash P' \,\mathcal{R}\, Q'}{(\sigma_1, \sigma_2) \vdash P \,\mathcal{R}_s\, Q};$$

- *up to weakening:*
$$\frac{(\sigma_1[\widetilde{M}/\widetilde{x}], \sigma_2[\widetilde{M'}/\widetilde{x}]) \vdash P \,\mathcal{R}\, Q}{(\sigma_1, \sigma_2) \vdash P \,\mathcal{R}_w\, Q};$$

- *up to contraction:*
$$\frac{(\sigma_1, \sigma_2) \vdash P \,\mathcal{R}\, Q,\ \perp \notin \widetilde{\widetilde{\zeta}\sigma_1} \text{ and } n(\widetilde{\zeta}) - dom(\sigma_1) \text{ are fresh for } \sigma_1,\ \sigma_2,\ P, \text{ and } Q}{(\sigma_1[\widetilde{\widetilde{\zeta}\sigma_1}/\widetilde{y}], \sigma_2[\widetilde{\widetilde{\zeta}\sigma_2}/\widetilde{y}]) \vdash P \,\mathcal{R}_c\, Q};$$

- *up to restriction:*
$$\frac{\widetilde{h} \cap n(\sigma_1) = \emptyset\ ,\ \widetilde{k} \cap n(\sigma_2) = \emptyset \text{ and } (\sigma_1, \sigma_2) \vdash P \,\mathcal{R}\, Q}{(\sigma_1, \sigma_2) \vdash (\nu\, \widetilde{h}) P \,\mathcal{R}_r\, (\nu\, \widetilde{k}) Q};$$

- *up to parallel composition:*
$$\frac{A \equiv P \mid R\sigma_1,\ B \equiv Q \mid R\sigma_2 \text{ and } (\sigma_1, \sigma_2) \vdash P \,\mathcal{R}\, Q \text{ and } fn(R) \subseteq dom(\sigma_1)}{(\sigma_1, \sigma_2) \vdash A \,\mathcal{R}_p\, B}.$$

A relation $\mathcal{R}$ is a weak bisimulation up to structural equivalence *if $\mathcal{R}$ satisfies the definition of weak bisimulation (Definition* 3.8*), but with the condition on the derivatives "$(\sigma_1', \sigma_2') \vdash P' \,\mathcal{R}\, Q'$" replaced by the weaker "$(\sigma_1', \sigma_2') \vdash P' \,\mathcal{R}_s\, Q'$." Weak bisimulation* up to weakening, contraction, restriction, *and* parallel composition *are defined similarly.*

Thus an up to technique t is essentially a functional $(\cdot)_t$ from compatible relations to compatible relations. We say that an up to technique t is *sound* if, whenever $\mathcal{R}$ is a bisimulation up to t, then $\mathcal{R} \subseteq \approx$. Our first task is therefore to prove that the techniques we have defined above are sound. Next, it should be obvious that different up to techniques can be combined to get new techniques. As an example, weak bisimulation up to parallel composition and contraction is defined by replacing $(\sigma_1', \sigma_2') \vdash P' \mathcal{R} Q'$ with $(\sigma_1', \sigma_2') \vdash P' (\mathcal{R}_p)_c Q'$ in Definition 3.8. Formally, a combination of techniques is a composition of the corresponding functionals (see [22]). The results of [22] ensure that, if the techniques we have introduced in Definition 4.16 are sound, then any combination of them is sound too.[3] The next proposition, whose proof can be found in Appendix B, states the soundness of our up to techniques.

PROPOSITION 4.17. *Let $\mathcal{R}$ be a weak bisimulation up to structural equivalence (resp., weakening, contraction, restriction, parallel composition). Then $\mathcal{R} \subseteq \mathcal{R}_s \subseteq \approx$ (resp., $\mathcal{R} \subseteq \mathcal{R}_t \subseteq \approx$, for $t = w, c, r, p$).*

We are now ready to prove the soundness theorem.

THEOREM 4.18 (soundness of weak bisimilarity). *Let P and Q be processes and σ_1 and σ_2 be equivalent substitutions. If $(\sigma_1, \sigma_2) \vdash P \approx Q$, then $(\sigma_1, \sigma_2) \vdash P \cong Q$.*

Proof. Note that $\approx$ is trivially a weak bisimulation up to parallel composition; thus $(\approx)_p \subseteq \approx$ due to Proposition 4.17. Hence $(\sigma_1, \sigma_2) \vdash P \approx Q$ implies $(\sigma_1, \sigma_2) \vdash P \mid R\sigma_1 \approx Q \mid R\sigma_2$ for each R with $fn(R) \subseteq dom(\sigma_1)$. Since $\approx$ is finer than $\dot{\cong}$, this fact implies the wanted $(\sigma_1, \sigma_2) \vdash P \cong Q$. □

Completeness. We shall prove completeness of $\approx$ relative to a class of processes that have an image-finiteness property (defined below). This property makes the proof relatively simple (and not far from, e.g., the proof for asynchronous bisimilarity given in [3]). On the other hand, the class of processes enjoying the property is broad enough to ensure that $\approx$ is a fairly general proof technique. At present, we do not know whether the proof can be extended to the full language.

Formally, a process P is *structurally image-finite* if, for each visible trace s, the set of equivalence classes $\{P' : P \stackrel{s}{\Longrightarrow} P'\}/\equiv$ is finite. Note that this notion is slightly more general than the usual image-finiteness (as considered, e.g., in [3]). This is due to our use of $\equiv$ to quotient the set of s- derivatives. As an example, process $P \stackrel{\text{def}}{=} !\, a(x).\bar{b}x$ is structurally image-finite but not image-finite; indeed, for each s, P has infinitely many s-derivatives, which are, however, finite up to structural equivalence (use the law $!\, P \mid P \equiv !\, P$). On the contrary, process $Q \stackrel{\text{def}}{=} !\, (\tau.\overline{a} + \tau.\overline{b})$ is not structurally image-finite (hence not image-finite); for instance, for any $n, m \geq 0$, Q has an ϵ-derivative of the form $\overline{a} \mid \cdots \mid \overline{a} \mid \overline{b} \mid \cdots \mid \overline{b} \mid Q$, with n $\overline{a}$'s and m $\overline{b}$'s in parallel.

Next, it is convenient to introduce a chain of relations $\approx_i$, $i \geq 0$, which are used to approximate bisimilarity $\approx$ over configurations. In what follows, $|E|$ is used to denote the syntactic size of some term E. Given any σ, we let $rk(\sigma) \stackrel{\text{def}}{=} |\phi_\sigma|$.

[3] Technically, our techniques enjoy the "respectfulness" property of [22] with respect to the transition relation $\vdash \stackrel{\mu}{\underset{\delta}{\longrightarrow}}$.

DEFINITION 4.19. *The binary relations $\approx_i$ over configurations are defined by induction on i as follows:*

- $(\sigma_1, \sigma_2) \vdash P \approx_0 Q$ *if* $\sigma_1 \sim \sigma_2$;
- $(\sigma_1, \sigma_2) \vdash P \approx_i Q$, *for* $i > 0$ *and* $\sigma_1 \sim \sigma_2$ *if, whenever* $\sigma_1 \rhd P \stackrel{\mu}{\underset{\delta}{\longmapsto}} \sigma_1' \rhd P'$ *with* $|\delta| \leq i$ *and* $rk(\sigma_1') \leq i$, *there are* μ', σ_2', *and* Q' *s.t.* $\sigma_2 \rhd Q \stackrel{\hat{\mu}}{\underset{\delta}{\Longmapsto}} \sigma_2' \rhd Q'$, $rk(\sigma_2') \leq i$, *and* $(\sigma_1', \sigma_2') \vdash P' \approx_{i-1} Q'$, *and the converse on the transitions of* Q *and* P.

We let $\approx_\omega \stackrel{\text{def}}{=} \cap_{i \geq 0} \approx_i$.

The following is a variation on a standard result for bisimulation (see, e.g., [15, 21]).

LEMMA 4.20. *Let* P *and* Q *be structurally image-finite processes. Then* $(\sigma_1, \sigma_2) \vdash P \approx Q$ *if and only if* $(\sigma_1, \sigma_2) \vdash P \approx_\omega Q$.

We now show that $\cong$ implies $\approx_\omega$, from which completeness of $\approx$ for structurally image-finite processes will follow. In order to do this, we exploit the formula ϕ_σ and define a class of canonical contexts $R_{i,\sigma}$, depending on some $i \geq 0$ and σ, which can be used to test whether two configurations are related by $\approx_i$. In what follows, we shall use some of the process notation introduced at the beginning of the subsection on completeness for may-testing. Furthermore, we shall sometimes omit the object part of action prefixes, writing, e.g., $\overline{c}$ instead of $\overline{c}x$, when x is not relevant. We will let $\tau.P$ denote the process $(\nu\, c)(c.P \,|\, \overline{c})$ $(c \notin fn(P))$ and, for any finite set of processes $\{P_1, \ldots, P_k\}$, we will let $\sum \{P_1, \ldots, P_k\}$ denote the process $P_1 + \cdots + P_k$ (the exact way the summands are arranged does not matter).

DEFINITION 4.21 (canonical contexts). *Define the processes* $R_{i,\sigma}$, *for* $i \geq 0$, *by induction on* i *as follows.* $R_{0,\sigma} \stackrel{\text{def}}{=} \mathbf{0}$ *and, for* $i > 0$,

$$
\begin{array}{rcl}
R_{n,\sigma} & \stackrel{\text{def}}{=} & \sum \left\{ R_\eta^{inp} + R_\eta^{out} \;:\; n(\eta) \subseteq dom(\sigma),\, \widehat{\eta\sigma} \in \mathcal{N} \text{ and } |\eta| < i \right\} + R_\epsilon + \overline{e}_i, \text{where} \\
R_\eta^{inp} & \stackrel{\text{def}}{=} & \langle \eta(x) \rangle . \sum \left\{ \phi_{\sigma'} \big(\overline{f}_{\eta,\phi_{\sigma'},i} + \tau.R_{i-1,\sigma'} \big) \;: \right. \\
 & & \qquad \left. \text{there is } M \text{ s.t. } \sigma' = \sigma[M/x], \text{ and } rk(\sigma') \leq i \right\}, \\
R_\eta^{out} & \stackrel{\text{def}}{=} & \sum \left\{ (\nu\, \widetilde{b}) \langle \overline{\eta} \zeta \rangle . \big(\overline{g}_{\eta,\zeta,i} + \tau.R_{i-1,\sigma'} \big) \;: \right. \\
 & & \qquad \left. fn\big((\nu\, \widetilde{b})\big) \overline{\eta} \langle \zeta \rangle \subseteq dom(\sigma), \sigma' = \sigma[\widetilde{b}/\widetilde{b}] \text{ and } |\zeta| < i \right\}, \\
R_\epsilon & \stackrel{\text{def}}{=} & \tau.\big(\overline{h}_i + \tau.R_{i-1,\sigma} \big),
\end{array}
$$

where the names e_j, $f_{\eta,\phi_{\sigma'},j}$, $g_{\eta,\zeta,j}$, *and* h_j *(*$0 \leq j \leq i$*) are all distinct and fresh.*

Note that, in the above definition, the sum in R_η^{inp} is finite because, for fixed $\widetilde{x}$ and i, there are finitely many ϕ_σ's and $R_{i,\sigma}$ s.t. $dom(\sigma) = \widetilde{x}$ and $rk(\sigma) \leq i$ (this is formally proven by induction on i). The sum in R_η^{out} is finite as well, because actions $(\nu\, \widetilde{b})\overline{\eta}\langle\zeta\rangle$ are considered up to alpha-equivalence. Note also that $fn(R_{i,\sigma}) \subseteq dom(\sigma) \cup \widetilde{l}$, where $\widetilde{l}$ is the set of all names e_j, $f_{\eta,\phi_{\sigma'},j}$, $g_{\eta,\zeta,j}$, and h_j $(0 \leq j \leq i)$ occurring in $R_{i,\sigma}$.

An easy lemma on characteristic formulae follows; its proof can be found in Appendix B.

LEMMA 4.22. *If* $\sigma \sim \sigma'$, *then* $rk(\sigma) = rk(\sigma')$.

We are now ready to prove completeness.

THEOREM 4.23 (completeness for barbed equivalence). *Let* P *and* Q *be structurally image-finite processes. If* $(\sigma_1, \sigma_2) \vdash P \cong Q$, *then* $(\sigma_1, \sigma_2) \vdash P \approx Q$.

Proof. By virtue of Lemma 4.20, it is sufficient to prove that for each $i \geq 0$ it holds $(\sigma_1, \sigma_2) \vdash P \approx_i Q$. Consider R_{i,σ_1} and let $\rho_1 \stackrel{\text{def}}{=} \sigma_1[\widetilde{l}/\widetilde{l}]$ and $\rho_2 \stackrel{\text{def}}{=} \sigma_2[\widetilde{l}/\widetilde{l}]$, where $\widetilde{l}$ is the set of all names e_j, $f_{\eta,\phi_{\sigma'},j}$, $g_{\eta,\zeta,j}$, and h_j $(0 \leq j \leq i)$ occurring in R_{i,σ_1}

(we suppose that $\widetilde{l}$ has been chosen fresh for σ_1, σ_2, P, and Q). We prove that if $(\rho_1,\rho_2) \vdash (P \mid R_{i,\sigma_1}\sigma_1) \mathrel{\dot\cong} (Q \mid R_{i,\sigma_1}\sigma_2)$, then $(\sigma_1,\sigma_2) \vdash P \approx_i Q$. From this fact and $(\sigma_1,\sigma_2) \vdash P \cong Q$, the thesis will follow (note that $(\sigma_1,\sigma_2) \vdash P \cong Q$ trivially implies $(\rho_1,\rho_2) \vdash P \cong Q$).

We proceed by induction on i. The case $i = 0$ is trivial; thus suppose $i > 0$. We only consider the case of a (C-Inp) transition, that is,

$$\sigma_1 \rhd P \xmapsto[\eta(x)]{(\nu\,\widetilde{b})\overline{a}\langle M\rangle} \sigma_1' \rhd P' \tag{1}$$

with $|\eta(x)| \le i$, $\sigma_1' = \sigma_1[^M\!/_x]$, and $rk(\sigma_1') \le i$, as the other cases are similar or easier. We show the existence of a transition of $\sigma_2 \rhd Q$ that matches this one. From (1) above, we can infer that

$$P \mid R_{i,\sigma_1}\sigma_1 \xrightarrow{\tau} (\nu\,\widetilde{b})\left(P' \mid \left(\phi_{\sigma_1'}\left(\overline{f}_{\eta,\phi_{\sigma_1'},i} + \tau.R_{i-1,\sigma_1'}\right)\right)\sigma_1'\right) \stackrel{\text{def}}{=} A.$$

Since $(\rho_1,\rho_2) \vdash P \mid R_{i,\sigma_1}\sigma_1 \mathrel{\dot\cong} Q \mid R_{i,\sigma_1}\sigma_2$ and $A \downarrow f_{\eta,\phi_{\sigma_1'},i}$, we deduce the existence of a transition

$$Q \mid R_{i,\sigma_1}\sigma_2 \Longrightarrow (\nu\,\widetilde{b}')\left(Q' \mid \left(\phi_{\sigma_1'}\left(\overline{f}_{\eta,\phi_{\sigma_1'},i} + \tau.R_{i-1,\sigma_1'}\right)\right)\sigma_2'\right) \stackrel{\text{def}}{=} B$$

with $(\rho_1,\rho_2) \vdash A \mathrel{\dot\cong} B$ and $B \downarrow f_{\eta,\phi_{\sigma_1'},i}$, where $\sigma_2' = \sigma_2[^{M'}\!/_x]$, for some M' s.t. $Q \xRightarrow{(\nu\,\widetilde{b}')\overline{a'}\langle M'\rangle} Q'$ ($a' = \widehat{\eta\sigma_2}$). Hence

$$\sigma_2 \rhd Q \xRightarrow[\eta(x)]{(\nu\,\widetilde{b}')\overline{a'}\langle M'\rangle} \sigma_2' \rhd Q'. \tag{2}$$

Moreover, since $B \downarrow f_{\eta,\phi_{\sigma_1'},i}$, it holds that $\sigma_2' \models \phi_{\sigma_1'}$.

Now, from $A \xrightarrow{\tau} \equiv (\nu\,\widetilde{b})\big((P' \mid R_{i-1,\sigma_1'})\sigma_1'\big) \stackrel{\text{def}}{=} A'$ we deduce that $B \Longrightarrow B'$ with $(\rho_1,\rho_2) \vdash A' \mathrel{\dot\cong} B'$. Since $A' \downarrow e_{i-1}$, it must hold that $B' \Downarrow e_{i-1}$; hence we must have $B' \equiv (\nu\,\widetilde{b}')\big((Q'' \mid R_{i-1,\sigma_1'})\sigma_2'\big)$ with $Q' \Longrightarrow Q''$. We can strip the restrictions $(\nu\,\widetilde{b})$ and $(\nu\,\widetilde{b}')$ away from $(\rho_1,\rho_2) \vdash A' \mathrel{\dot\cong} B'$ and deduce that

$$(\rho_1,\rho_2) \vdash (P' \mid R_{i-1,\sigma_1'}\sigma_1') \mathrel{\dot\cong} (Q'' \mid R_{i-1,\sigma_1'}\sigma_2'),$$

which, by induction, implies that $(\sigma_1',\sigma_2') \vdash P' \approx_{i-1} Q''$. Now, from $Q' \Longrightarrow Q''$ and transition (2), we deduce

$$\sigma_2 \rhd Q \xRightarrow[\eta(x)]{(\nu\,\widetilde{b}')\overline{a'}\langle M'\rangle} \sigma_2' \rhd Q''\,.$$

We show that this transition matches (1). Indeed, we have that $\sigma_1' \sim \sigma_2'$ (by $\sigma_2' \models \phi_{\sigma_1'}$ and Theorem 4.3), that $rk(\sigma_2') = rk(\sigma_1') \le i$ (Lemma 4.22), and that $(\sigma_1',\sigma_2') \vdash P' \approx_{i-1} Q''$. □

5. Applications. In this section we first give some properties which are useful when reasoning on cryptographic processes and then use them in a few examples.

Let **rel** $\in \{\approx, \ll\}$.

(C-INP) Suppose that for all ζ such that $\widetilde{y} \stackrel{\text{def}}{=} (n(\zeta) - dom(\sigma_1))$ are fresh and $\widehat{\zeta\sigma_1} \neq \bot$ it holds that $(\sigma_1[\widetilde{y}/\widetilde{y}], \sigma_2[\widetilde{y}/\widetilde{y}]) \vdash P[\widehat{\zeta\sigma_1}/x]$ **rel** $Q[\widehat{\zeta\sigma_2}/x]$.
Suppose $a_i = \widehat{\eta\sigma_i}$ $(i = 1, 2)$ with $n(\eta) \subseteq dom(\sigma_1)$.
Then $(\sigma_1, \sigma_2) \vdash a_1(x).P$ **rel** $a_2(x).Q$.

(C-OUT) Suppose that $(\sigma_1[M_1/x], \sigma_2[M_2/x]) \vdash P$ **rel** Q and that $a_i = \widehat{\eta\sigma_i}$ $(i = 1, 2)$ with $n(\eta) \subseteq dom(\sigma_1)$.
Then $(\sigma_1[M_1/x], \sigma_2[M_2/x]) \vdash \overline{a}_1 M_1.P$ **rel** $\overline{a}_2 M_2.Q$.

(C-PAR) Suppose that $fn(R) \subseteq dom(\sigma_1)$ and $(\sigma_1, \sigma_2) \vdash P$ **rel** Q.
Then $(\sigma_1, \sigma_2) \vdash P \mid R\sigma_1$ **rel** $Q \mid R\sigma_2$.

(C-RES) Suppose that $(\sigma_1, \sigma_2) \vdash P$ **rel** Q, that $\widetilde{k} \cap n(\sigma_1) = \emptyset$, and that $\widetilde{h} \cap n(\sigma_2) = \emptyset$.
Then $(\sigma_1, \sigma_2) \vdash (\nu\,\widetilde{k})P$ **rel** $(\nu\,\widetilde{h})Q$.

FIG. 4. *Some congruence rules for* $\ll$ *and* $\approx$.

5.1. Some useful laws. We start by stating some simple properties.

PROPOSITION 5.1. *Let* **rel** $\in \{\approx, \ll\}$.

- (Reflexivity) *For any* σ *and* P, $(\sigma, \sigma) \vdash P$ **rel** P.
- (Transitivity) *If* $(\sigma_1, \sigma_2) \vdash P$ **rel** Q *and* $(\sigma_2, \sigma_3) \vdash Q$ **rel** R, *then* $(\sigma_1, \sigma_3) \vdash P$ **rel** R.
- (Weakening) *Suppose that* $(\sigma_1[M/x], \sigma_2[N/x]) \vdash P$ **rel** Q. *Then* $(\sigma_1, \sigma_2) \vdash P$ **rel** Q.
- (Contraction) *Suppose that* $(\sigma_1, \sigma_2) \vdash P$ **rel** Q *and consider any* ζ *such that* $n(\zeta) \subseteq dom(\sigma_1)$ *and* $\widehat{\zeta\sigma_1} \neq \bot$. *Then* $(\sigma_1[\widehat{\zeta\sigma_1}/x], \sigma_2[\widehat{\zeta\sigma_2}/x]) \vdash P$ **rel** Q.
- (Structural equivalence) *Suppose that* $P \equiv Q$. *Then for any* σ, $(\sigma, \sigma) \vdash P$ **rel** Q.

Proof. Reflexivity, transitivity, and structural equivalence are trivial. The other cases are consequences of Proposition 4.17 for $\approx$. For $\ll$, the proof becomes trivial when one switches to the original definition of $\lesssim$; for contraction, note that $O\sigma_i[\widehat{\zeta\sigma_i}/x] \equiv (\texttt{let}\ x = \zeta\ \texttt{in}\ O)\sigma_i$ for $i = 1, 2$ and $fn(O) \subseteq dom(\sigma_i)$. ∎

Some congruence laws are listed in Figure 4. These laws are very useful (especially (C-PAR) and (C-RES)) because they permit a kind of compositional reasoning, as we shall see in later examples in this section.

PROPOSITION 5.2. *The laws listed in Figure* 4 *are correct.*

Proof. The proof for (C-INP) and (C-OUT) is trivial. Laws (C-PAR) and (C-RES) are a consequence of Proposition 4.17 in the case of $\approx$. In the case of $\ll$, the proof becomes trivial if one switches to the original definition of $\lesssim$. ∎

We shall also need a few rules to reason on environments. They are given in the following two lemmas (whose proofs can be found in Appendix A). The first lemma characterizes $kn(\sigma)$ in terms of the expressions that can be formed using the variables in $dom(\sigma)$.

LEMMA 5.3. *Let* σ *be an environment. Then* $kn(\sigma) = \{\widehat{\zeta\sigma} \in \mathcal{N} : n(\zeta) \subseteq dom(\sigma)\}$.

The next lemma is about the effect of evaluating the same expression ζ under two

equivalent environments, σ and σ'.

LEMMA 5.4. *Let $\sigma = [M_i/x_i]_{i\in I}$ and $\sigma' = [M'_i/x_i]_{i\in I}$ be two substitutions s.t. $\sigma \sim' \sigma'$. Define $\widetilde{N} = core(\sigma, x_i)_{i\in I}$ and $\widetilde{N}' = core(\sigma', x_i)_{i\in I}$. For each ζ s.t. $n(\zeta) \subseteq \widetilde{x}$, either*

(a) *$\widehat{\zeta\sigma} = \widehat{\zeta\sigma'} = \bot$, or*

(b) *there are $i \in I$ and a tuple $\widetilde{\jmath} \subseteq I$ such that $\widehat{\zeta\sigma} = \{N_i\}_{\widetilde{N}[\widetilde{\jmath}]}$ and $\widehat{\zeta\sigma'} = \{N'_i\}_{\widetilde{N}'[\widetilde{\jmath}]}$.*

We end this subsection with a small example (borrowed from [6]) that shows the use of our congruence laws.

EXAMPLE 5.5. *Let us consider the processes $P \stackrel{\text{def}}{=} (\nu\, k)\overline{c}\{d\}_k.\, c(x).\, [x = k]\overline{c}\{d\}_k$ and $Q \stackrel{\text{def}}{=} (\nu\, k)\overline{c}\{d\}_k.\, c(x)$. Process P creates a private key k, sends d encrypted under k, listens for an input, and if it receives k, then resends $\{d\}_k$. Process Q behaves like P, but, after the reception of one message, it becomes stuck. Since k is a private key that is never disclosed to the environment, P will never receive k back at c; as a consequence the matching $[x = k]$ will never become true. Therefore P and Q should be considered as equivalent. Let $V = fn(P, Q) = \{c, d\}$; we want to show that $(\epsilon_V, \epsilon_V) \vdash P \simeq Q$.*

We can prove that $(\epsilon_V, \epsilon_V) \vdash Q \ll P$ by simply noting that traces of Q are also traces of P. To prove that $(\epsilon_V, \epsilon_V) \vdash P \ll Q$, let z be any fresh name and let $\sigma \stackrel{\text{def}}{=} \epsilon_V[\{d\}_k/z]$. The crucial step is showing that

$$(\sigma, \sigma) \vdash c(x).\, [x = k]\overline{c}\{d\}_k \ll c(x).$$

Indeed, for any ζ with $\widetilde{y} \stackrel{\text{def}}{=} (n(\zeta) - dom(\sigma))$ fresh, it holds that $\widehat{\zeta\sigma[\widetilde{y}/\widetilde{y}]} = \widehat{\zeta\sigma} \neq k$ (because of $k \notin kn(\sigma)$ and of Lemma 5.3); hence we have $(\sigma[\widetilde{y}/\widetilde{y}], \sigma[\widetilde{y}/\widetilde{y}]) \vdash [\widehat{\zeta\sigma} = k]\overline{c}\{d\}_k \ll \mathbf{0}$. The thesis for this step follows by using (C-INP). *Now, using* (C-OUT), *we have that*

$$(\sigma, \sigma) \vdash \overline{c}\{d\}_k.\, c(x).\, [x = k]\overline{c}\{d\}_k \ll \overline{c}\{d\}_k.\, c(x).$$

The thesis follows from this fact, using first weakening and then (C-RES).

5.2. Secure channels implementation. In the following examples, we show the use of our framework for proving security properties of communication protocols. In the same vein of [1, 4], the idea is that of implementing communication on secure (private) channels by means of encrypted communication on public channels. Let us consider the π-calculus process:

$$P \stackrel{\text{def}}{=} (\nu\, c)(\overline{c}d \mid c(z).\, R),$$

where c does not occur in R. Process P creates a private channel c which is used to transmit name d. Communication on c is secure because no execution context knows c. Since P consists of two concurrent subprocesses, the actual implementation could allocate them onto two different computers, whose interconnections are not guaranteed to be secure. Communication on c has to be implemented in terms of lower-level, encrypted communication on some public channel, say p. Thus, process P might be implemented as

$$I_P \stackrel{\text{def}}{=} (\nu\, k_c)(\overline{p}\{d\}_{k_c} \mid p(x).\mathtt{let}\ z = \mathtt{dec}_{k_c}(x)\ \mathtt{in}\ R) \qquad (k_c,\, x \notin fn(R)).$$

In I_P, name k_c is a private encryption key that corresponds to channel c. The behavior of the process is as follows: the process $\overline{p}\{d\}_{k_c}$ sends d encrypted under k_c, while $p(x).\texttt{let } z = \texttt{dec}_{k_c}(x) \texttt{ in } R$ tries to decrypt a ciphertext x received at p. If the decryption succeeds, a cleartext is obtained and bound to z and the process behaves like R, otherwise the process is stuck. Note that this implementation does not guarantee that d will eventually be passed to R: message $\{d\}_{k_c}$ could be captured by some context (attacker) listening at p. The last example of this section shall present an implementation that solves this problem.

A secrecy property. Assume that R keeps z secret under any context; i.e., for every d and d', and $\sigma_1 \sim \sigma_2$, it holds that $(\sigma_1, \sigma_2) \vdash R[d/z] \simeq R[d'/z]$. Under this hypothesis, we want to prove that the implementation scheme for P preserves secrecy. To see this, we consider a generic d', let $Q \stackrel{\text{def}}{=} (\nu\, c)(\overline{c}d' \mid c(z).\, R)$, and show that

$$(\epsilon_V, \epsilon_V) \vdash I_P \simeq I_Q,$$

where I_Q is the obvious implementation of Q and $V = fn(I_P, I_Q)$. In order to prove this, let y be any fresh name and define $\sigma_1 \stackrel{\text{def}}{=} \epsilon_V[\{d\}_{k_c}/y]$ and $\sigma_2 \stackrel{\text{def}}{=} \epsilon_V[\{d'\}_{k_c}/y]$. First, rule (C-Inp) allows one to prove that

$$(\sigma_1, \sigma_2) \vdash (p(x).\texttt{let } z = \texttt{dec}_{k_c}(x) \texttt{ in } R) \simeq (p(x).\texttt{let } z = \texttt{dec}_{k_c}(x) \texttt{ in } R).$$

To prove this, one exploits two facts: (1) for any ζ s.t. $n(\zeta) - dom(\sigma_1)$ are fresh, if $\widehat{\zeta\sigma_1} = \{M\}_{k_c}$, then $M = d$ and $\widehat{\zeta\sigma_2} = \{d'\}_{k_c}$ (by Lemma 5.4(b) and $k_c \notin kn(\sigma_1)$); (2) $R[d/z]$ is may-equivalent to $R[d'/z]$ under σ_1 and σ_2. These facts and (C-Par) can be used to infer that

$$\begin{aligned}&(\sigma_1, \sigma_2) \vdash (\overline{p}\{d\}_{k_c} \mid p(x).\texttt{let } z = \texttt{dec}_{k_c}(x) \texttt{ in } R)\\ &\simeq (\overline{p}\{d'\}_{k_c} \mid p(x).\texttt{let } z = \texttt{dec}_{k_c}(x) \texttt{ in } R).\end{aligned}$$

Finally, the desired claim follows by applying weakening and then (C-Res) (with $(\nu\, k_c)$) to the equality above.

Preservation of may semantics. Here we show that the previous implementation scheme also preserves may semantics. We relax the hypothesis that R keeps name z secret and, for the sake of simplicity, assume that $R \stackrel{\text{def}}{=} \overline{b}z$. In π-calculus, process P is may-equivalent to process $\overline{b}d$. We want to show that the implementations of P and of process $\overline{b}d$ are still may-equivalent, under the assumption that the communication channel p is both *asynchronous* and *noisy*. Thus, the actual implementation also includes a buffer $B \stackrel{\text{def}}{=}\!!p(x).\overline{p}x$ and a noise generator $N \stackrel{\text{def}}{=}\!!(\nu\, k)\overline{p}\{k\}_k$ for p. Both noise and asynchrony are necessary to prevent the execution context from detecting traffic on the public channel p. Let $V = fn(I_P, \overline{b}d, N, B)$. To sum up, we want to show that

$$(\epsilon_V, \epsilon_V) \vdash (I_P \mid N \mid B) \simeq (\overline{b}d \mid N \mid B). \tag{3}$$

(Note that this equation is *not* valid for $\approx$.) We do this in two steps.

- First, we prove that $(\epsilon_V, \epsilon_V) \vdash \overline{b}d \mid N \mid B \ll I_P \mid N \mid B$. The only possible trace for the configuration $\epsilon_V \rhd \overline{b}d$ is

$$\epsilon_V \rhd \overline{b}d \stackrel{\overline{b}d}{\underset{b(x)}{\longmapsto}} \epsilon_V[d/x] \rhd \mathbf{0}.$$

Configuration $\epsilon_V \rhd I_P$ can simulate the action above by first communicating $\{d\}_{k_c}$ on p, and then decrypting $\{d\}_{k_c}$:

$$\epsilon_V \rhd I_P \stackrel{\overline{b}d}{\stackrel{\Longrightarrow}{b(x)}} \epsilon_V[d/x] \rhd (\nu\, k_c)\mathbf{0}.$$

Hence, $(\epsilon_V, \epsilon_V) \vdash \overline{b}d \ll I_P$, and the thesis follows by applying law (C-Par) in Figure 4.

- Let us now prove that $(\epsilon_V, \epsilon_V) \vdash I_P \mid N \mid B \ll \overline{b}d \mid N \mid B$. Let y be any fresh name and let $\sigma \stackrel{\text{def}}{=} \epsilon_V[\{d\}_{k_c}/y]$.
  - The crucial step is showing that

    $$(\sigma, \sigma) \vdash p(x).\texttt{let}\ z = \texttt{dec}_{k_c}(x)\ \texttt{in}\ \overline{b}z \ll p(x).\overline{b}d. \tag{4}$$

    Indeed, taking any ζ such that $\widetilde{w} \stackrel{\text{def}}{=} (n(\zeta) - dom(\sigma))$ are fresh names and such that $\widehat{\zeta\sigma} \neq \perp$, we have $(\sigma[\widetilde{w}/\widetilde{w}], \sigma[\widetilde{w}/\widetilde{w}]) \vdash \texttt{let}\ z = \texttt{dec}_{k_c}(\widehat{\zeta\sigma})\ \texttt{in}\ \overline{b}z \ll \overline{b}d$. In fact, the only case in which $\texttt{dec}_{k_c}(\widehat{\zeta\sigma})$ does not evaluate to $\perp$ is when $\widehat{\zeta\sigma} = \{d\}_{k_c}$ (Lemma 5.4(b) and $k_c \notin kn(\sigma)$), which implies $\texttt{let}\ z = \texttt{dec}_{k_c}(\widehat{\zeta\sigma})\ \texttt{in}\ \overline{b}z \equiv \overline{b}d$. Then (4) above follows, using (C-Inp).
  - Now, using (C-Par) and (4) above, we have that

    $$(\sigma, \sigma) \vdash \overline{p}\{d\}_{k_c} \mid (p(x).\texttt{let}\ z = \texttt{dec}_{k_c}(x)\ \texttt{in}\ \overline{b}z) \ll \overline{p}\{d\}_{k_c} \mid p(x).\overline{b}d;$$

    hence, by weakening and (C-Res), we have that

    $$\begin{aligned}(\epsilon_V, \epsilon_V) \vdash\ & (\nu\, k_c)(\overline{p}\{d\}_{k_c} \mid p(x).\texttt{let}\ z = \texttt{dec}_{k_c}(x)\ \texttt{in}\ \overline{b}z) \\ & \ll (\nu\, k_c)(\overline{p}\{d\}_{k_c} \mid p(x).\overline{b}d) \equiv (\nu\, k_c)(\overline{p}\{d\}_{k_c}) \mid p(x).\overline{b}d.\end{aligned}$$

    In the last step we have used a structural law for restriction ($(\nu\, a)(A_1|A_2) \equiv ((\nu\, a)A_1) \mid A_2$ if $a \notin fn(A_2)$). Using (C-Par) again, we can put the context $N \mid B$ in parallel with the two processes:

    $$\begin{aligned}(\epsilon_V, \epsilon_V) \vdash\ & (\nu\, k_c)(\overline{p}\{d\}_{k_c} \mid p(x).\texttt{let}\ z = \texttt{dec}_{k_c}(x)\ \texttt{in}\ \overline{b}z) \mid N \mid B \\ & \ll (\nu\, k_c)(\overline{p}\{d\}_{k_c}) \mid p(x).\overline{b}d \mid N \mid B.\end{aligned}$$

    Now, $(\nu\, k_c)(\overline{p}\{d\}_{k_c})$ in the right-hand side above can be turned into a particle of noise, because $(\epsilon_V, \epsilon_V) \vdash (\nu\, k_c)(\overline{p}\{d\}_{k_c}) \simeq (\nu\, k)(\overline{p}\{k\}_k)$. Using the structural law for replication ($!A \equiv A \mid !A$), this particle of noise can be absorbed by N; hence

    $$(\epsilon_V, \epsilon_V) \vdash (\nu\, k_c)(\overline{p}\{d\}_{k_c}) \mid p(x).\overline{b}d \mid N \mid B \ \simeq\ p(x).\overline{b}d \mid N \mid B.$$

    Moreover, as an instance of a general law for asynchronous channels, we have that

    $$(\epsilon_V, \epsilon_V) \vdash\ p(x).\overline{b}d \mid B \ll \overline{b}d \mid B,$$

    and the thesis easily follows by (C-Par).

Ensuring message delivery. We consider a more sophisticated implementation scheme for process P and prove that (under a fairness assumption) this scheme guarantees that a message sent on channel c is eventually delivered. Again, we implement c with an asynchronous and noisy public channel p. This time, however, we need a more complex source of noise, $N \stackrel{\text{def}}{=} !(\nu\, k)!\overline{p}\{k\}_k$. Note the difference from the previous example: N can now spawn at any time a process $(\nu\, k)!\overline{p}\{k\}_k$ which emits a constant noise $\{k\}_k$ at p. The buffer B for p is still $B \stackrel{\text{def}}{=} !p(x).\overline{p}x$.

In this example, we shall use recursive definitions of agent constants of the kind $A \Longleftarrow S$, where A is an agent constant that may appear in the process expression S (these can be taken as primitive—the theory extends smoothly—or can be coded up using replication like in [15]). We also use the shorthand "$\texttt{let}\ z = \zeta\ \texttt{in}\ A\ \texttt{else}\ B$" for "$(\texttt{let}\ z = \zeta\ \texttt{in}\ A) + \neg(\texttt{let}\ z = \zeta\ \texttt{in}\ \not{t})B$."

The implementation of P is the process

$$I_P \stackrel{\text{def}}{=} (\nu\, k_c)\big(!\overline{p}\{d\}_{k_c} \mid R\big), \qquad \text{where}$$
$$R \Longleftarrow p(x).\texttt{let}\ z = \texttt{dec}_{k_c}(x)\ \texttt{in}\ \overline{b}z\ \texttt{else}\ (\overline{p}x \mid R).$$

Component $!\overline{p}\{d\}_{k_c}$ constantly emits d encrypted under key k_c on p, while R repeatedly tries to decrypt a ciphertext x received on p using k_c. When the decryption succeeds, the cleartext is sent on b.

Let $V = fn(I_P, \overline{b}d, B, N)$; we want to prove that

$$(\epsilon_V, \epsilon_V) \vdash (I_P \mid B \mid N) \approx (\overline{b}d \mid B \mid N).$$

In order to see this, define $\sigma_1 \stackrel{\text{def}}{=} \epsilon_V[\{d\}_{k_c}/y]$ and $\sigma_2 \stackrel{\text{def}}{=} \epsilon_V[\{k\}_k/y]$ (y fresh). We first show that

$$(\sigma_1, \sigma_2) \vdash T \stackrel{\text{def}}{=} (!\overline{p}\{d\}_{k_c} \mid R \mid B \mid N) \approx (\overline{b}d \mid !\overline{p}\{k\}_k \mid B \mid N) \stackrel{\text{def}}{=} U, \tag{5}$$

from which the thesis will follow by first applying weakening to discard the y-entry, then (C-Res) (with $(\nu\, k_c)$ on the left-hand side and $(\nu\, k)$ on the right-hand side), and then the structural laws for restriction and the structural law for replication ($N \mid (\nu\, k)!\overline{p}\{k\}_k \equiv N$) on the right-hand side. To prove (5), we consider a relation $\mathcal{R}$ consisting of *three* pairs (w is fresh):

$$\mathcal{R} = \Big\{ \big(\sigma_1 \rhd T,\, \sigma_2 \rhd U\big),\ \big(\sigma_1 \rhd \overline{b}d,\, \sigma_2 \rhd \overline{b}d\big),\ \big(\sigma_1[d/w] \rhd \mathbf{0},\, \sigma_2[d/w] \rhd \mathbf{0}\big) \Big\}$$

and show that $\mathcal{R}$ is a weak bisimulation up to parallel composition and contraction. The proof consists of analyzing every transition of $\sigma_1 \rhd T$ and $\sigma_2 \rhd U$ and of showing that a matching transition exists in the other configuration in each case. In particular, note the following:

- transitions of $\sigma_1 \rhd T$ originating from $!\overline{p}\{d\}_{k_c}$ are matched up to contraction via transitions from $!\overline{p}\{k\}_k$ in $\sigma_2 \rhd U$, and vice-versa;
- the transition of $\sigma_1 \rhd T$ originating from $R \xrightarrow{p\,\{d\}_{k_c}} \equiv \overline{b}d$ is matched up to parallel composition via $B \xrightarrow{p\,\{k\}_k} \overline{p}\{k\}_k \mid B$ in $\sigma_2 \rhd U$—to see this, first note that $\overline{p}\{k\}_k \mid !\overline{p}\{k\}_k \equiv !\overline{p}\{k\}_k$, and then cut away the parallel contexts $!\overline{p}\{d\}_{k_c} \mid B \mid N$ (from the left-hand side) and $!\overline{p}\{k\}_k \mid B \mid N$ (from the right-hand side);

- a transition of $\sigma_1 \rhd T$ originating from $R \xrightarrow{p\,M} \equiv \overline{p}M \mid R$, with $M = \widehat{\zeta\sigma_1} \neq \{d\}_{k_c}$, is matched up to parallel composition and contraction via a transition $B \xrightarrow{p\,M'} \equiv \overline{p}M' \mid B$ in $\sigma_2 \rhd U$, where $M' = \widehat{\zeta\sigma_2}$ (contraction may be used to discard any new name introduced by ζ);
- the transition of $\sigma_2 \rhd U$ originating from $\overline{b}d \xrightarrow{\overline{b}\langle d\rangle} \mathbf{0}$ is matched up to parallel composition via a communication between R and $!\overline{p}\{d\}_{k_c}$, followed by a $\overline{b}\langle d\rangle$-transition in $\sigma_1 \rhd T$.

Communications between R and $!\overline{p}\{d\}_{k_c}$ or R and N are treated as in the second and in the third item above, respectively. It should be now obvious how the other transitions match with each other.

5.3. Verification of a small protocol. Consider a system where two agents A and B share two secret keys, k_{AS} and k_{BS}, respectively, with a server S. The purpose of the protocol is to establish a new secret key k between A and B, which A may use to pass some confidential information d to B. This is achieved with a version of the Wide Mouthed Frog Protocol (see, e.g., [7]). For the sake of simplicity, we suppose that the protocol is always started by A and that all communications occur on a public channel, say p. Informally, the protocol can be described as follows:

$$\begin{array}{lll} \text{Message 1} & A \longrightarrow S: & \{k\}_{k_{AS}} \\ \text{Message 2} & S \longrightarrow B: & \{k\}_{k_{BS}} \\ \text{Message 3} & A \longrightarrow B: & \{d\}_k. \end{array}$$

Our intent here is to verify one run of the protocol (that is, we do not consider the case of multiple agents simultaneously executing the protocol). In our language, the above notation translates to a process $P(d)$ defined as follows (using the notation $R(w)$ to stress that name w may occur free in R, and, for any M, abbreviating $R[M/w]$ as $R(M)$; bound names are all distinct):

$$\begin{array}{rcl} A(d) & \stackrel{\text{def}}{=} & \overline{p}\{k\}_{k_{AS}}.\overline{p}\{d\}_k.\mathbf{0}, \\ S & \stackrel{\text{def}}{=} & p(x).\mathtt{let}\ x' = \mathtt{dec}_{k_{AS}}(x)\ \mathtt{in}\ \overline{p}\{x'\}_{k_{BS}}.\mathbf{0}, \\ B & \stackrel{\text{def}}{=} & p(y).\mathtt{let}\ y' = \mathtt{dec}_{k_{BS}}(y)\ \mathtt{in}\ p(z).\mathtt{let}\ z' = \mathtt{dec}_{y'}(z)\ \mathtt{in}\ \mathbf{0}, \\ P(d) & \stackrel{\text{def}}{=} & (\nu\, k_{AS},\, k_{BS})\big(((\nu\, k)A(d)) \mid S \mid B\big). \end{array}$$

Here we assume that A, S, and B terminate after the exchange of message 3: this assumption simplifies the reasoning below and seems sensible, because the correctness of the protocol should be assessed independently of the subsequent behavior of the participants. In what follows, following Abadi and Gordon [7], we use the contextual equivalence $\cong$ to express the properties of secrecy and integrity of $P(d)$ (below, we suppose by alpha-equivalence that names k_{AS}, k_{BS}, k, x, x', y, y', z, z' do not occur in messages M and M'):

Secrecy (“$P(d)$ does not leak d”).
For any M and M', it holds that $P(M) \cong P(M')$.

Integrity (“if B accepts a message $\{N\}_k$ then $N = d$”).
For any M, it holds that $P(M) \cong P^M_{spec}$, where

$$\begin{array}{rcl} P^M_{spec} & \stackrel{\text{def}}{=} & (\nu\, k_{AS},\, k_{BS})\big(((\nu\, k)A(d)) \mid S \mid B^M_{spec}\big), \\ B^M_{spec} & \stackrel{\text{def}}{=} & p(y).\mathtt{let}\ y' = \mathtt{dec}_{k_{BS}}(y)\ \mathtt{in}\ p(z).\mathtt{let}\ z' = \mathtt{dec}_{y'}(z)\ \mathtt{in}\ [z' \neq M]\,\overline{p}\,\mathtt{err}.\mathbf{0}. \end{array}$$

Output of name `err` on p is used to signal a violation of integrity, i.e., that some message $\{N\}_k$ with $N \neq M$ has been accepted. The fact that $P(M)$ and P^M_{spec} are

equivalent means that action $\overline{p}\langle \mathtt{err} \rangle$, hence the violation, never occurs (in this point our formalization differs a little from Abadi and Gordon's). Fix M and M' and let $V \stackrel{\text{def}}{=} fn(P(M), P(M'))$. By virtue of our soundness results for secrecy it will be sufficient to show that

$$(\epsilon_V, \epsilon_V) \vdash P(M) \approx P(M'), \tag{6}$$

while, for integrity, it will be sufficient to establish that

$$(\epsilon_{V \cup \{\mathtt{err}\}}, \epsilon_{V \cup \{\mathtt{err}\}}) \vdash P(M) \approx P_{spec}(M). \tag{7}$$

We will prove the above equalities by reasoning compositionally on processes. To do this, we first show a compositionality result for $\approx$. Let us say that a process R is σ-*safe* if for each s, whenever $\sigma \rhd R \stackrel{s}{\underset{u}{\Longrightarrow}} \sigma' \rhd R' \stackrel{(\nu\, \widetilde{b})\overline{a}\langle M \rangle}{\underset{\eta(x)}{\Longrightarrow}}$, then $M \in dc(\sigma')$ (hence $\widetilde{b} = \emptyset$). Intuitively, R is σ-safe if R cannot increase the knowledge of σ. The following proposition strengthens the congruence rule for parallel composition (C-Par), under the assumption that the involved processes are safe for the appropriate environments (the proof is in Appendix B).

Proposition 5.6. *Suppose that* $(\sigma_1, \sigma_2) \vdash Q_1 \approx Q_2$ *and that* $(\sigma_1, \sigma_2) \vdash R_1 \approx R_2$. *Suppose that, for* $i = 1, 2$, Q_i *and* R_i *are* σ_i*-safe. Then* $(\sigma_1, \sigma_2) \vdash Q_1 \mid R_1 \approx Q_2 \mid R_2$.

Let us examine secrecy first. Define

$$\sigma \stackrel{\text{def}}{=} \epsilon_V[\{k\}_{k_{AS}}/x_1,\ \{k\}_{k_{BS}}/x_2,\ \{M\}_k/x_3] \qquad \text{and}$$
$$\sigma' \stackrel{\text{def}}{=} \epsilon_V[\{k\}_{k_{AS}}/x_1,\ \{k\}_{k_{BS}}/x_2,\ \{M'\}_k/x_3].$$

Clearly, $\sigma \sim \sigma'$. As a first step, check that

$$\begin{array}{lrcl} (\sigma, \sigma') \vdash & A(M) & \approx & A(M'), \\ (\sigma, \sigma') \vdash & S & \approx & S, \\ (\sigma, \sigma') \vdash & B & \approx & B. \end{array}$$

The first equality follows from (C-Out), while the second and the third follow from (C-Inp) and Lemma 5.4. For instance, to establish the second equality, Lemma 5.4 is first used to check that whenever names $n(\zeta) - dom(\sigma)$ are fresh and $\widehat{\zeta\sigma_i} = \{N\}_{k_{BS}}$, then $N = k$; then (C-Inp) is applied. Next, it is easy to see that $A(M)$ is σ-safe and that $A(M')$ is σ'-safe, while S and B are both σ- and σ'-safe (again, this requires the use of Lemma 5.4). Applying Proposition 5.6, we can infer that

$$(\sigma, \sigma') \vdash A(M) \mid S \mid B \approx A(M') \mid S \mid B.$$

Next, apply weakening (so as to discard entries x_1, x_2, and x_3) and then (C-Res) with $(\nu\, k)$ and a structural law $((\nu\, a)(Q \mid R) \equiv ((\nu\, a)Q) \mid R$ if $a \notin fn(R))$ and deduce that

$$(\epsilon_V, \epsilon_V) \vdash ((\nu\, k)A(M)) \mid S \mid B \approx ((\nu\, k)A(M')) \mid S \mid B.$$

Finally apply (C-Res) with $(\nu\, k_{AS},\ k_{BS})$ to get the desired (6).

As to integrity, let $\sigma \stackrel{\text{def}}{=} \epsilon_{V \cup \{\mathtt{err}\}}[\{k\}_{k_{AS}}/x_1,\ \{k\}_{k_{BS}}/x_2,\ \{M\}_k/x_3]$. First, the crucial point is that $(\sigma, \sigma) \vdash B \approx B^M_{spec}$ (use twice Lemma 5.4 and (C-Inp)). Next, note that B, B^M_{spec}, A, and S are all σ-safe (use Lemma 5.4 again). Thus we can compose these processes and proceed like in the case of secrecy to obtain (7).

6. A calculus with pairs. Our most relevant omission from the calculus of Abadi and Gordon has been *pairing*, that is, the possibility of transmitting pairs of messages of the form $\langle M_1, M_2\rangle$. It is, however, easy to extend our theory to a calculus with pairs: The necessary modifications are reported below.

The syntax of messages and of expressions is extended by introducing appropriate constructors and selectors for pairs:

$$\begin{array}{rcl} M & ::= \ldots & \mid \quad \langle M_1, M_2\rangle, \\ \zeta & ::= \ldots & \mid \quad \pi_1(\zeta) \mid \pi_2(\zeta) \mid \langle \zeta_1, \zeta_2\rangle\,. \end{array}$$

The evaluation functions for expressions and formulae are extended accordingly (for example, $\pi_1(\widehat{\{a\}_k}) = \bot$). The definition of $dc(\cdot)$ is extended with the clause: if $\langle M_1, M_2\rangle \in dc(S)$, then $M_1, M_2 \in dc(S)$. The definition of *core* needs to be revised; informally, a message M can now have several cores, which are found at different positions inside M. If we code a position inside M as a string $p \in \{l, r\}^*$ (that is, a path through the nested pairs of M), then the core of M at position p with respect to σ, written $M[\sigma, p]$, can be formally defined as follows by induction on M:

- $a[\sigma, p] = \begin{cases} a & \text{if } p = \epsilon, \\ \bot & \text{otherwise,} \end{cases}$
- $\{M\}_k[\sigma, p] = \begin{cases} \{M\}_k & \text{if } k \notin kn(\sigma) \text{ and } p = \epsilon, \\ M[\sigma, p] & \text{if } k \in kn(\sigma), \\ \bot & \text{otherwise,} \end{cases}$
- $\langle M_1, M_2\rangle[\sigma, p] = \begin{cases} M_1[\sigma, p'] & \text{if } p = lp', \\ M_2[\sigma, p'] & \text{if } p = rp', \\ \bot & \text{otherwise.} \end{cases}$

As an example, consider message $M = \langle\langle\{b\}_{hk}, \{c\}_k\rangle, k\rangle$ and substitution $\sigma = [^{M}/_{x}, ^{\{h\}_d}/_{y}]$. We have $dc(\sigma) = \{M, M', k, \{h\}_d, \{b\}_{hk}, \{b\}_h, \{c\}_k, c\}$, where $M' = \langle\{b\}_{hk}, \{c\}_k\rangle$, and $kn(\sigma) = \{k, c\}$. Moreover, we have that $M[\sigma, r] = k$, $M[\sigma, ll] = \{b\}_h$, $M[\sigma, lr] = c$, and $M[\sigma, p] = \bot$ for $p \notin \{r, ll, lr\}$. Note also that the same would hold for every substitution σ' such that $kn(\sigma) = kn(\sigma')$.

Every core in $\sigma = [^{M_i}/_{x_i}]_{i\in I}$ is now determined by an index pair (index i, position p) which we write as ip. The following notation is useful: given a function f defined over $I \times \{l, r\}^*$ and a tuple of index pairs $\widetilde{\jmath} = (i_1p_1, \ldots, i_kp_k)$, we let $f[\widetilde{\jmath}]$ denote the tuple $(f_{i_1p_1}, \ldots, f_{i_kp_k})$ (we write f_{xy} instead of $f(x, y)$ for function application). We can now give the new definition of $\sim$.

Definition 6.1 (equivalence on environments: pairing). *Consider two substitutions $\sigma_1 = [^{M_i}/_{x_i}]_{i\in I}$ and $\sigma_2 = [^{M'_i}/_{x_i}]_{i\in I}$. Let $\widetilde{N}, \widetilde{N}' : I \times \{l, r\}^* \to \mathcal{M} \cup \{\bot\}$ be the functions defined as $N_{ip} \stackrel{\text{def}}{=} M_i[\sigma_1, p]$ and $N'_{ip} \stackrel{\text{def}}{=} M'_i[\sigma_2, p]$ for each index pair ip. We write $\sigma_1 \sim' \sigma_2$ if and only if for each $i \in I$ the following three conditions hold:*

(a) $(\sigma_1, \sigma_2) \vdash M_i \sim M'_i$;

(b) *for each p, $N_{ip} \in \mathcal{N}$ if and only if $N'_{ip} \in \mathcal{N}$;*

(c) *for each p, $j \in I$, and q, $N_{ip} = N_{jq}$ if and only if $N'_{ip} = N'_{jq}$,*

where the predicate $(\sigma_1, \sigma_2) \vdash M \sim M'$ (a recursive version of condition (a) in the old definition) is defined by induction on M as follows:

> *$(\sigma_1, \sigma_2) \vdash M \sim M'$ if and only if there is a tuple $\widetilde{\jmath}$ of index pairs such that $M = \{M_0\}_{\widetilde{N}[\widetilde{\jmath}]}$ and $M' = \{M'_0\}_{\widetilde{N}'[\widetilde{\jmath}]}$ for some M_0, M'_0 such that either* (i) *$M_0 = N_{ip}$ and $M'_0 = N'_{ip}$ for some i and p, or* (ii) *$M_0 = \langle M_1, M_2\rangle$, $M'_0 = \langle M'_1, M'_2\rangle$, and $(\sigma_1, \sigma_2) \vdash M_j \sim M'_j$ for $j = 1, 2$.*

Note that the new definition of $\sim'$ is still effective, because for each $i \in I$ there are finitely many p's s.t. $N_{ip} \neq \bot$ (not more than $|M_i|$). With the new definitions, the results we obtained in the previous sections carry over smoothly, modulo a few notational changes. For instance, the crucial Lemma 5.4 now enjoys the more compact formulation that takes advantage of the predicate $(\sigma_1, \sigma_2) \vdash M \sim M'$:

> Suppose that $\sigma_1 \sim \sigma_2$ and that $n(\zeta) \subseteq dom(\sigma_1)$. Then either $\widehat{\zeta\sigma_1} = \widehat{\zeta\sigma_2} = \bot$ or $(\sigma_1, \sigma_2) \vdash \widehat{\zeta\sigma_1} \sim \widehat{\zeta\sigma_2}$,

The changes in the other statements and proofs are obvious and omitted, with the exception of the construction of ϕ_σ, which is given in Appendix C.

EXAMPLE 6.2. *The following example is used by Abadi and Gordon to discuss the incompleteness of their proof technique for cryptographic protocols,* framed bisimulation [6]. *Processes P and Q defined below are not equated by framed bisimilarity, but Abadi and Gordon conjecture that they are barbed congruent (hence barbed- and testing-equivalent). Here, we indeed prove that P and Q are barbed equivalent: this fact confirms that framed bisimulation is not complete with respect to barbed equivalence.*

Fix some name 0 *and define (writing $\{A, B\}_c$ instead of $\{\langle A, B\rangle\}_c$)*

$$\begin{array}{rcl} P & \stackrel{\text{def}}{=} & (\nu\, k, k_{01})\ \ \overline{c}\{k_{01}\}_k.\, c(x).P', \\ Q & \stackrel{\text{def}}{=} & (\nu\, k, k_0, k_1)\ \ \overline{c}\{k_0, k_1\}_k.\, c(x).Q', \end{array}$$

where

$$\begin{array}{rcl} P' & \stackrel{\text{def}}{=} & [x = 0]\overline{c}k_{01} \ \mid\ [x \neq 0]\overline{c}k_{01}, \\ Q' & \stackrel{\text{def}}{=} & [x = 0]\overline{c}k_0 \ \mid\ [x \neq 0]\overline{c}k_1, \end{array}$$

for fresh and distinct k, k_0, k_1, and k_{01}. The difference between P and Q is that P discloses a single secret k_{01}, whereas Q may disclose either secret k_0 or secret k_1, but not both. The environment cannot detect this difference, because key k, under which the first message is encrypted, is never disclosed. To prove this, take $V = fn(P, Q)$ and let $\sigma_1 \stackrel{\text{def}}{=} \epsilon_V[\{k_{01}\}_k/y]$ and $\sigma_2 \stackrel{\text{def}}{=} \epsilon_V[\{k_0, k_1\}_k/y]$. Clearly $\sigma_1 \sim \sigma_2$ and, furthermore, for each ζ s.t. $\widetilde{w} \stackrel{\text{def}}{=} n(\zeta) - dom(\sigma_1)$ are fresh names and $\widehat{\zeta\sigma_1} \neq \bot$, we have that

$$(\sigma_1[\widetilde{w}/\widetilde{w}], \sigma_2[\widetilde{w}/\widetilde{w}]) \vdash P'[\widehat{\zeta\sigma_1}/x] \ \approx\ Q'[\widehat{\zeta\sigma_2}/x].$$

In fact, it holds both that $\sigma_1[\widetilde{w}/\widetilde{w}][k_{01}/z] \sim \sigma_2[\widetilde{w}/\widetilde{w}][k_0/z]$ and that $\sigma_1[\widetilde{w}/\widetilde{w}][k_{01}/z] \sim \sigma_2[\widetilde{w}/\widetilde{w}][k_1/z]$, for any fresh z. Therefore, whether $\widehat{\zeta\sigma_1}$ is equal to 0 *or not, we can infer the equivalence above. $(\epsilon_V, \epsilon_V) \vdash P \approx Q$ then follows by applying to the equivalence above first law* (C-INP)*, then law* (C-OUT)*, then weakening to discard the y-entry of the two environments, and finally law* (C-RES) *with $(\nu\, k, k_{01})$ on the left-hand side and $(\nu\, k, k_0, k_1)$ on the right-hand side. Thus we can conclude that $P \cong Q$.*

7. Final remarks and related work. We have studied contextual equivalences and relative proof techniques for a variant of the spi-calculus, an extension of the π-calculus proposed by Abadi and Gordon [7]. We have considered a few examples of verification, concerning secure channels implementation and protocol security, which demonstrate how these techniques can be used in practice.

In this paper, we have applied our techniques to small examples, as the emphasis was more on theory. However, we believe that our methodology can be used to reason on more complex systems. In this respect, a major advantage of our approach is the

possibility of compositional reasoning offered by a set of congruence laws. A further step in this direction would be the design of a sound and complete proof system for the considered equivalences. Another direction for future research is the study of algorithms for mechanical equivalence checking (especially in the case of bisimilarity). We are also considering extensions of the theory to public keys and digital signatures. A subtle point that remains to be solved is in connection with the so-called "known plaintext attack"; for instance, knowing a, b, and a public key k^+, an attacker could distinguish by comparison $\{b\}_{k^+}$ from $\{a\}_{k^+}$, even without knowing the private key k^- that "opens" these messages. As a consequence, and in contrast with the shared key case, two environments like $\sigma = [a/x, \{a\}_{k^+}/y]$ and $\sigma' = [a/x, \{b\}_{k^+}/y]$ cannot be regarded as equivalent.

The relevance of may-testing to the analysis of security properties was first pointed out by Abadi and Gordon in [7]. May-testing was originally introduced for CCS in [11], and subsequently studied for the π-calculus in [8].

Two papers closely related to our work are [10] and [6]. In [10], Boreale and Sangiorgi introduce an lts for a typed version of π-calculus, where the environment's input/output capabilities on names are explicitly described and updated. Here, we use a similar approach to model the environment's knowledge about names and keys.

Abadi and Gordon present in [6] *framed bisimulation*, a proof technique to analyze cryptographic protocols. In framed bisimulation, when comparing two processes P and Q, a *frame-theory pair* (fr, th) is used to represent the knowledge of P's and Q's environments. A judgement $(fr, th) \vdash M \leftrightarrow N$ is also introduced to express that the effect of message M on P's environment is the same as the effect of message N on Q's environment. The judgement is used to check indistinguishability of messages M and N that are exchanged by P and its environment and by Q and its environment. In our case, the indistinguishability of M and N is guaranteed by requiring matching transitions to exhibit the same environment action and to take equivalent environments into equivalent environments. This results in a relevant difference between the work in [6] and ours when considering output transitions. In our case, given an output transition, it is sufficient to check (like in standard bisimilarity) whether the other configuration can perform a matching output transition. Output transitions are, at least for finite-control processes, finitely many. In the case of [6], one must also build a new frame-theory pair that relates N to M and consistently extends the old one; this might be not completely trivial [12]. Moreover, in [6] there seem to be very few tools for compositional reasoning (congruence laws) and no obvious way of tailoring the "up to" techniques to their setting. Finally, as shown in Example 6.2, framed bisimulation is not complete for barbed equivalence.

The process algebraic approach to cryptographic protocols has also been followed by Roscoe [20], Lowe [14], and Schneider [23], all of whom consider model-checking of security protocols in a CSP-based framework. This approach requires explicitly designing a specific (powerful enough) attacker and carrying out the analysis with it. Of course, there is always a certain amount of arbitrariness in determining the attacker; any modification of the attacker would require a new analysis. In our paper, like in [7], a more radical approach is taken: the attacker may be *any* process that can be defined in spi-calculus.

In [2], Abadi presents an approach to secrecy that combines the spi-calculus and the use of type systems: the idea is that a process $P(d)$ that type-checks guarantees secrecy of d (in a sense made precise via testing equivalence).

All the approaches mentioned so far, including ours, work under a perfect en-

cryption hypothesis: this prevents the attacker from, for example, randomly guessing some bits of a secret key, or performing statistical analysis of messages. A first step towards relaxing this hypothesis has been made in [13], where probabilistic versions of the spi-calculus and of testing equivalence are introduced. Further research is required for a fuller understanding of these notions and for devising techniques to reason over them.

Appendix A. Results on environment equivalence. In this appendix we keep the definitions of $\sim$ (Definition 3.1) and of $\sim'$ (Definition 3.3) separate and introduce the notion of characteristic formula, ϕ_σ. The main steps taken here are

1. ϕ_σ characterizes all and only those environments $\sim'$-equivalent to σ (Theorem A.11);
2. using 1, one proves that $\sim$ and $\sim'$ coincide (Theorem 3.4/Theorem A.13);
3. hence, ϕ_σ characterizes all and only those environments $\sim$-equivalent to σ (Theorem 4.3/Theorem A.14).

Along the way, a few properties of $\sim$ are established which are of independent interest and are useful for the examples of section 5 (Lemma 5.3 and Lemma 5.4).

First we show that evaluation $\widehat{\cdot}$ commutes with substitution.

LEMMA A.1. *Let ζ and η be two expressions and σ a substitution. If $x \notin dom(\sigma)$, $n(\zeta) \subseteq dom(\sigma) \cup \{x\}$, and $n(\eta) \subseteq dom(\sigma)$, then $\zeta\sigma\widehat{[\widehat{\eta\sigma}/x]} = (\zeta\widehat{[\eta/x]})\sigma$.*

Proof. The proof follows from a straightforward induction on ζ. □

The following lemma establishes a first relationship between ζ-expressions and the decryption closure $dc(\cdot)$, and between the knowledge $kn(\cdot)$ and the set of *cores* of σ.

LEMMA A.2. *Let $\sigma = [M_i/x_i]_{i\in I}$.*

(1) *If $M \in dc(\sigma)$, then there is ζ s.t. $n(\zeta) \subseteq dom(\sigma)$ and $\widehat{\zeta\sigma} = M$.*

(2) *If $a \in kn(\sigma)$, then $a = core(\sigma, x_i)$ for some $i \in I$.*

Proof. Part (1) is easily proven by induction on the definition of $dc(\cdot)$. Part (2) follows from the following statement, easily proven by induction on the definition of $dc(\cdot)$: If $M \in dc(\sigma)$, then there are $i \in I$ and $\widetilde{k}$ s.t. $M = \{core(\sigma, x_i)\}_{\widetilde{k}}$. □

We proceed by showing that the knowledge $kn(\sigma)$ of σ is precisely the set of those names that can be obtained by arbitrary combinations of encryption and decryption operations (represented by ζ-expressions), starting from messages stored in σ.

LEMMA A.3 (see Lemma 5.3). *Let σ be a substitution. Then $kn(\sigma) = \{\widehat{\zeta\sigma} \in \mathcal{N} : n(\zeta) \subseteq dom(\sigma)\}$.*

Proof. That $kn(\sigma) \subseteq \{\widehat{\zeta\sigma} \in \mathcal{N} : n(\zeta) \subseteq dom(\sigma)\}$ is a consequence of Lemma A.2(1). We now prove the opposite inclusion. Consider the set $S \stackrel{\text{def}}{=} \{\widehat{\zeta\sigma} \neq \bot : n(\zeta) \subseteq dom(\sigma)\}$ and the set $T \stackrel{\text{def}}{=} \{\{M\}_{\widetilde{k}} : M \in dc(\sigma) \text{ and } \widetilde{k} \subseteq kn(\sigma)\}$. We prove that $S \subseteq T$, from which the thesis follows, because $S \cap \mathcal{N} = \{\widehat{\zeta\sigma} \in \mathcal{N} \mid n(\zeta) \subseteq dom(\sigma)\}$ and $T \cap \mathcal{N} = kn(\sigma)$. The proof proceeds by induction on the structure of ζ. We explicitly show only the case $\zeta = \mathtt{dec}_{\zeta_1}(\zeta_2)$, as the other cases are similar or easier. Let $\widehat{\zeta\sigma} = M$. Since $\widehat{\zeta\sigma} \neq \bot$, there is a name k such that $\widehat{\zeta_2\sigma} = \{M\}_k$ and $\widehat{\zeta_1\sigma} = k$. By induction, we can assume that $\{M\}_k \in T$, which, by definition of T, implies that there are $M' \in dc(\sigma)$ and $\widetilde{h} \subseteq kn(\sigma)$ such that $\{M\}_k = \{M'\}_{\widetilde{h}}$. Hence $M = \{M'\}_{\widetilde{h}'}$, for $\widetilde{h}'$ such that $\widetilde{h} = \widetilde{h}'k$, and the thesis follows. □

The next lemma is about the effect of applying two $\sim'$-equivalent substitutions σ and σ' onto the same expression ζ.

LEMMA A.4 (see Lemma 5.4). *Let $\sigma = [M_i/x_i]_{i\in I}$ and $\sigma' = [M'_i/x_i]_{i\in I}$ be two*

substitutions such that $\sigma \sim' \sigma'$. *Define* $\widetilde{N} = core(\sigma, x_i)_{i\in I}$ *and* $\widetilde{N}' = core(\sigma', x_i)_{i\in I}$. *For each* ζ *s.t.* $n(\zeta) \subseteq \widetilde{x}$, *either*

(a) $\widehat{\zeta\sigma} = \widehat{\zeta\sigma'} = \bot$, *or*

(b) *there are* $i \in I$ *and a tuple* $\widetilde{\jmath} \subseteq I$ *such that* $\widehat{\zeta\sigma} = \{N_i\}_{\widetilde{N}[\widetilde{\jmath}]}$ *and* $\widehat{\zeta\sigma'} = \{N'_i\}_{\widetilde{N}'[\widetilde{\jmath}]}$.

Proof. The proof proceeds by induction on ζ. We explicitly consider only the case $\zeta = \mathtt{dec}_{\zeta_2}(\zeta_1)$; the other cases are similar or easier. If $\widehat{\zeta_1\sigma} = \bot$ or $\widehat{\zeta_2\sigma} = \bot$, then by induction hypothesis it easily follows that $\widehat{\zeta\sigma} = \widehat{\zeta\sigma'} = \bot$. Otherwise, by induction hypothesis we have that for some tuples $\widetilde{\jmath}, \widetilde{\ell} \subseteq I$ and indices $i, j \in I$

$$\begin{array}{rclcrcl} \widehat{\zeta_1\sigma}, & = & \{N_i\}_{\widetilde{N}[\widetilde{\jmath}]}, & & \widehat{\zeta_1\sigma'}, & = & \{N'_i\}_{\widetilde{N}'[\widetilde{\jmath}]}, \\ \widehat{\zeta_2\sigma} & = & \{N_j\}_{\widetilde{N}[\widetilde{\ell}]}, & & \widehat{\zeta_2\sigma'} & = & \{N'_j\}_{\widetilde{N}'[\widetilde{\ell}]}. \end{array}$$

There are two cases:

- $\widetilde{\ell} \neq \emptyset$ or $N_j \notin \mathcal{N}$. Then by definition $\widehat{\zeta\sigma} = \widehat{\zeta\sigma'} = \bot$ (note that $N_j \notin \mathcal{N}$ implies $N'_j \notin \mathcal{N}$, because $\sigma \sim' \sigma'$).
- $\widetilde{\ell} = \emptyset$ and $N_j = a \in \mathcal{N}$. Hence $N'_j = a' \in \mathcal{N}$, because $\sigma \sim' \sigma'$. Now, if the last component of $\widetilde{\jmath}$ is some j' s.t. $N_{j'} = a$, say $\widetilde{\jmath} = (\widetilde{\jmath}', j')$, then it is also $N'_{j'} = a'$, because $\sigma \sim' \sigma'$; thus $\widehat{\zeta\sigma} = \{N_i\}_{\widetilde{N}[\widetilde{\jmath}']}$ and $\widehat{\zeta\sigma'} = \{N'_i\}_{\widetilde{N}'[\widetilde{\jmath}']}$, which is the desired claim for this case. Otherwise, $\widehat{\zeta\sigma} = \widehat{\zeta\sigma'} = \bot$. ∎

The intuition underlying the following lemma is that $\sim'$-equivalence is preserved when uniformly adding entries to two equivalent environments.

LEMMA A.5. *If* $\sigma_1 \sim' \sigma_2$, *then* $\sigma_1[\widehat{\zeta\sigma_1}/y] \sim' \sigma_2[\widehat{\zeta\sigma_2}/y]$, *provided that* $\widehat{\zeta\sigma_1} \neq \bot$ *and that* $n(\zeta) \subseteq dom(\sigma_1)$.

Proof. Apply Lemma 5.4 to σ_1, σ_2, and ζ. The thesis then follows by definition of $\sim'$. ∎

We can now prove that $\sim'$ implies $\sim$.

LEMMA A.6. *Let* σ *and* σ' *be two substitutions. If* $\sigma \sim' \sigma'$, *then* $\sigma \sim \sigma'$.

Proof. Suppose that $\sigma \sim' \sigma'$. We must show that for each ϕ with $fn(\phi) \subseteq dom(\sigma)$ it holds that $\sigma \models \phi$ if and only if $\sigma' \models \phi$. The proof proceeds by induction on ϕ. Here, we explicitly consider only the case where ϕ is $\mathtt{let}\ z = \zeta\ \mathtt{in}\ \phi'$, as the other cases are similar or easier. By definition, $\sigma \models \mathtt{let}\ z = \zeta\ \mathtt{in}\ \phi'$ means that $\widehat{\zeta\sigma} \neq \bot$ and that $\sigma[\widehat{\zeta\sigma}/z] \models \phi'$. Now, we have that $\widehat{\zeta\sigma'} \neq \bot$ (Lemma A.4) and $\sigma[\widehat{\zeta\sigma}/z] \sim \sigma'[\widehat{\zeta\sigma'}/z]$ (Lemma A.5). By induction, $\sigma'[\widehat{\zeta\sigma'}/z] \models \phi'$ and we can conclude that $\sigma' \models \mathtt{let}\ z = \zeta\ \mathtt{in}\ \phi'$. ∎

We proceed now to showing the converse implication, that $\sim$ implies $\sim'$. Two crucial ingredients for the proof will be the notion of the *characteristic formula* of an environment σ, ϕ_σ, and Theorem A.11, which will give a logical characterization of $\sim'$. We need some notational shorthand.

NOTATION A.7.

- "$\mathtt{let}_{j\in 1..k}\ z_j = \zeta_j\ \mathtt{in}\ \phi$" *stands for* "$\mathtt{let}\ z_1 = \zeta_1\ \mathtt{in}\ (\cdots(\mathtt{let}\ z_k = \zeta_k\ \mathtt{in}\ \phi)\cdots)$."
- "$\zeta \neq \bot$" *stands for* "$\mathtt{let}\ z = \zeta\ \mathtt{in}\ tt$", *for any* z, *and* "$\zeta = \bot$" *stands for* "$\neg(\zeta \neq \bot)$."
- "$w \in \{M_1, \ldots, M_m\}$" *stands for* "$\bigvee_{j=1}^{m}[w = M_j]$."

DEFINITION A.8 (characteristic formula). *Let* $\sigma = [{}^{M_i}/_{x_i}]_{i\in I}$ *be a substitution. For each* $i \in I$, *let* $N_i = core(\sigma, x_i)$ *and let* ζ_i *be the least*[4] *expression such that*

[4]With respect to some fixed total ordering of expressions.

$$\texttt{let}_{j\in I}\ z_j = \zeta_j\ \texttt{in}\ \Big[$$

$$(*)\quad \bigwedge_{i,j\in I}[\texttt{dec}_{z_j}(z_i) = \bot] \wedge$$

$$(a)\quad \bigwedge_{i\in I}[x_i = \{z_i\}_{\widetilde{z[\mathfrak{j}_i]}}] \wedge$$

$$(b)\quad \bigwedge_{N_i\in\mathcal{N}} name(z_i) \ \wedge\ \bigwedge_{N_i\notin\mathcal{N}} \neg name(z_i) \wedge$$

$$(c)\quad \bigwedge_{i,j\in I \text{ s.t. } N_i=N_j}[z_i = z_j] \ \wedge\ \bigwedge_{i,j\in I \text{ s.t. } N_i\neq N_j}[z_i \neq z_j]$$

$$\Big]$$

FIG. 5. *The formula* ϕ_σ.

$n(\zeta_i) \subseteq \widetilde{x}$ *and* $\widehat{\zeta_i\sigma} = N_i$. *Let* $\widetilde{N} = N_{i\in I}$ *and* $\widetilde{\zeta} = \zeta_{i\in I}$. *Finally, for each* $i \in I$, *let* $\widetilde{\mathfrak{j}_i} \subseteq I$ *be a tuple such that* $M_i = \{N_i\}_{\widetilde{N[\mathfrak{j}_i]}}$. *The formula* ϕ_σ *is then defined as in Figure* 5.

About Definition A.8 we have the following.

REMARK A.9. *Note that the expressions* $\zeta_{i\in I}$ *mentioned in the definition above do exist by virtue of Lemma* A.2(1). *Furthermore, we are allowed to assume that* $M_i = \{N_i\}_{\widetilde{N[\mathfrak{j}_i]}}$, *for some tuple* $\widetilde{\mathfrak{j}_i}$, *because, by virtue of Lemma* A.2(2), $kn(\sigma) \subseteq \widetilde{N}$. *Finally, note that* $fn(\phi_\sigma) \subseteq dom(\sigma)$ *and that* $\sigma \models \phi_\sigma$.

The next lemma gives conditions under which a tuple of messages $\widetilde{Z}$ can be identified as the tuple of "cores" of a given σ.

LEMMA A.10. *Consider* $\sigma = [^{M_i}/_{x_i}]_{i\in I}$ *and a tuple* $\widetilde{Z} = Z_{i\in I}$ *s.t.* $\widetilde{Z} \subseteq dc(\sigma)$. *Suppose that the following two conditions hold:*

(a) *for each* $i, j \in I$, $\widehat{\texttt{dec}_{Z_j}(Z_i)} = \bot$;
(b) *for each* $i \in I$, *there is a tuple* $\widetilde{\mathfrak{j}} \subseteq I$ *s.t.* $M_i = \{Z_i\}_{\widetilde{Z[\mathfrak{j}]}}$.

Then $\widetilde{Z} = core(\sigma, x_i)_{i\in I}$.

Proof. The proof consists of two steps.

- We first show that $kn(\sigma) \subseteq \widetilde{Z}$. To this end, consider the set of messages $T \stackrel{\text{def}}{=} \{N : \{N\}_{\widetilde{k}} = M_i \text{ for some } i \in I \text{ and } \widetilde{k} \subseteq \widetilde{Z}\}$. First, one proves by induction on the definition of $dc(\cdot)$ that $dc(\sigma) \subseteq T$. Then, it is easy to see that $T \cap \mathcal{N} \subseteq \widetilde{Z}$: indeed, if $\{a\}_{\widetilde{k}} = M_i$ for some $\widetilde{k} \subseteq \widetilde{Z}$, then it also holds that $\{a\}_{\widetilde{k}} = \{Z_i\}_{\widetilde{Z[\mathfrak{j}]}}$ (condition (b)), which, by virtue of condition (a), implies $a = Z_i$. Therefore we can conclude $\widetilde{Z} \supseteq kn(\sigma)$.
- Let $\widetilde{N} = core(\sigma, x_i)_{i\in I}$ and take any $i \in I$; we show that $Z_i = N_i$. By definition of *core* and by condition (b), we have that $M_i = \{N_i\}_{\widetilde{h}} = \{Z_i\}_{\widetilde{Z[\mathfrak{j}]}}$ for some tuple $\widetilde{\mathfrak{j}} \subseteq I$ and $\widetilde{h} \subseteq kn(\sigma)$. There are two cases:
  - $Z_i = \{N_i\}_{\widetilde{k}}$ with $(\widetilde{k}, \widetilde{Z}[\widetilde{\mathfrak{j}}]) = \widetilde{h}$. Since $\widetilde{k} \subseteq kn(\sigma)$ (as $\widetilde{h} \subseteq kn(\sigma)$), due to $kn(\sigma) \subseteq \widetilde{Z}$ and condition (a), we deduce that $\widetilde{k} = \emptyset$; hence $Z_i = N_i$.
  - $N_i = \{Z_i\}_{\widetilde{k}}$ with $(\widetilde{k}, \widetilde{h}) = \widetilde{Z}[\widetilde{\mathfrak{j}}]$. Again, we have that $\widetilde{k} \subseteq kn(\sigma)$ (as $\widetilde{k} \subseteq \widetilde{Z} \cap \mathcal{N}$ and $\widetilde{Z} \subseteq dc(\sigma)$); hence, by definition of *core*, we get $\widetilde{k} = \emptyset$, and hence $Z_i = N_i$. □

We arrive at the crucial result on $\sim'$ and characteristic formulae.

THEOREM A.11. *Let σ and σ' be two substitutions such that $dom(\sigma) = dom(\sigma')$. We have that $\sigma \sim' \sigma'$ if and only if $\sigma' \models \phi_\sigma$.*

Proof. The "only if" part is a consequence of Lemma A.6 (as $\sigma \models \phi_\sigma$). Let us see the "if" part. Suppose that $\sigma = [M_i/x_i]_{i\in I}$, and take any $\sigma' = [M'_i/x_i]_{i\in I}$ s.t. $\sigma' \models \phi_\sigma$: we show that $\sigma' \sim \sigma$. With the notation of Figure 5, let $Z_i = \widehat{\zeta_i\sigma'}$ and $\widetilde{Z} = Z_{i\in I}$. From $\sigma' \models \phi_\sigma$, we deduce that $\bot \notin \widetilde{Z}$ and that $\sigma'[\widetilde{Z}/\tilde{z}] \models (*) \wedge$ (a) $\wedge$ (b) $\wedge$ (c). Now, we have that

- $\sigma'[\widetilde{Z}/\tilde{z}] \models (*)$ means that for each $i, j \in I$, $\widehat{\mathtt{dec}_{Z_j}(Z_i)} = \bot$;
- $\sigma'[\widetilde{Z}/\tilde{z}] \models$ (a) means that for each $i \in I$ there is a tuple $\tilde{\jmath} \subseteq I$ s.t. $M'_i = \{Z_i\}_{\widetilde{Z[\tilde{\jmath}]}}$.

The above two facts and Lemma A.10 imply that $\widetilde{Z} = core(\sigma', x_i)_{i\in I}$. Thus $\sigma'[\widetilde{Z}/\tilde{z}] \models$ (a) $\wedge$ (b) $\wedge$ (c) precisely says that $\sigma \sim \sigma'$. □

We can prove that $\sim$ implies $\sim'$.

LEMMA A.12. *Let σ and σ' be substitutions. If $\sigma \sim \sigma'$, then $\sigma \sim' \sigma'$.*

Proof. By definition, $fn(\phi_\sigma) \subseteq dom(\sigma)$ and $\sigma \models \phi_\sigma$. Hence, by hypothesis, $\sigma' \models \phi_\sigma$, and the thesis immediately follows from Theorem A.11. □

The coincidence of $\sim$ and $\sim'$ is now an immediate consequence of Lemma A.6 and of Lemma A.12.

THEOREM A.13 (see Theorem 3.4). *Let σ and σ' be substitutions. Then $\sigma \sim \sigma'$ if and only if $\sigma \sim' \sigma'$.*

The following important property of characteristic formulae is an immediate consequence of Theorem A.11 and of Theorem A.13.

THEOREM A.14 (see Theorem 4.3). *Let σ and σ' be substitutions such that $dom(\sigma) = dom(\sigma')$. We have that $\sigma \sim \sigma'$ if and only if $\sigma' \models \phi_\sigma$.*

We end the section with two technical lemmas. The first lemma is useful for manipulating environments: it says that equivalence is preserved when uniformly removing entries from two equivalent environments. Its proof is an easy consequence of the definition of $\sim$.

LEMMA A.15. *If $\sigma_1[M/y] \sim \sigma_2[M'/y]$, then $\sigma_1 \sim \sigma_2$.*

The second lemma is about the size of characteristic formulae (recall that $rk(\sigma) = |\phi_\sigma|$).

LEMMA A.16 (see Lemma 4.22). *If $\sigma \sim \sigma'$, then $rk(\sigma) = rk(\sigma')$.*

Proof. Referring to the notation of Definition A.8, note that the size of ϕ_σ and $\phi_{\sigma'}$ may only differ due a different choice of some ζ_i, $i \in I$. But Lemma A.4(a) (which ensures that the same ζ_i's can be used in both ϕ_σ and $\phi_{\sigma'}$) and the requirement of minimality imply that the ζ_i's in ϕ_σ and those in $\phi_{\sigma'}$ are actually the same. □

Appendix B. Results on trace and bisimulation semantics. We begin the section with a crucial result on operational semantics.

PROPOSITION B.1 (see Proposition 4.2). *Consider two equivalent substitutions σ_1 and σ_2. Let R be any process or observer s.t. $fn(R) \subseteq dom(\sigma_1)$.*

1. *Suppose that $R\sigma_1 \xrightarrow{(\nu\, \widetilde{b})\overline{a}\langle M\rangle} R_1$. Then* (i) *there is η with $n(\eta) \subseteq dom(\sigma_1)$ s.t. $\widehat{\eta\sigma_1} = a$;* (ii) *there are ζ and R' with $fn(\zeta, R') \subseteq dom(\sigma_1) \cup \widetilde{b}$ s.t. $M = \widehat{\zeta\sigma_1}$, and $R_1 \equiv R'\sigma_1$;* (iii) *it holds that $R\sigma_2 \xrightarrow{(\nu\, \widetilde{b})\overline{a'}\langle M'\rangle} R_2$, where $a' = \widehat{\eta\sigma_2}$, $M' = \widehat{\zeta\sigma_2}$, and $R_2 \equiv R'\sigma_2$.*
2. *Suppose that $R\sigma_1 \xrightarrow{a\, M} R_1$. Then* (i) *there is η with $n(\eta) \subseteq dom(\sigma_1)$ s.t.*

$\widehat{\eta\sigma_1} = a$; (ii) *given any fresh* y *and* $\sigma_1' \stackrel{\text{def}}{=} \sigma_1[M/y]$, *there is* R' *with* $fn(R') \subseteq dom(\sigma_1')$ *s.t.* $R_1 \equiv R'\sigma_1'$; (iii) *for any* M', *it holds that* $R\sigma_2 \xrightarrow{a'\,M'} R_2$, *where* $a' = \widehat{\eta\sigma_2}$ *and* $R_2 \equiv R'\sigma_2'$ *with* $\sigma_2' \stackrel{\text{def}}{=} \sigma_2[M'/y]$.

3. *Suppose that* $R\sigma_1 \xrightarrow{\mu} R_1$ *with* $\mu = \tau$ *or* $\mu = \omega$. *Then* (i) *there is* R' *with* $fn(R') \subseteq dom(\sigma_1)$ *such that* $R_1 \equiv R'\sigma_1$; (ii) *we have* $R\sigma_2 \xrightarrow{\mu} R_2$, *where* $R_2 \equiv R'\sigma_2$.

Proof. The proof follows from an induction on the derivation of $R\sigma \xrightarrow{\mu} R_1$. Here, we explicitly consider only the case where the last rule applied is (LET), which is the most delicate.

Suppose that R is $\texttt{let}\ z = \xi\ \texttt{in}\ P$ and that $R \xrightarrow{\mu} R_1$ is inferred via (LET) from the premise $P\rho_1 \xrightarrow{\mu} R_1$, where $\rho_1 \stackrel{\text{def}}{=} \sigma_1[\widehat{\xi\sigma_1}/z]$ $(\widehat{\xi\sigma_1} \neq \bot)$. Depending on the form of μ, we have three cases; here we consider only the case when μ is an output, say $\mu = (\nu\,\widetilde{b})\overline{a}\langle M\rangle$. Since $\widehat{\xi\sigma_2} \neq \bot$ (Lemma A.4), we can define $\rho_2 \stackrel{\text{def}}{=} \sigma_2[\widehat{\xi\sigma_2}/z]$. Since $\rho_1 \sim \rho_2$ (Lemma A.5), by induction hypothesis applied to the premise $P\rho_1 \xrightarrow{\mu} R_1$ we have that

(j) there is η' with $dom(\eta') \subseteq dom(\rho_1)$ and $\widehat{\eta'\rho_1} = a$;

(jj) there are ζ' and R'' with $fn(\zeta', R'') \subseteq dom(\rho_1) \cup \widetilde{b}$ s.t. $M = \widehat{\zeta'\rho_1}$ and $R_1 \equiv R''\rho_1$;

(jjj) $P\rho_2 \xrightarrow{(\nu\,\widetilde{b})\overline{a'}\langle M'\rangle} R_2$, where $a' = \widehat{\eta'\rho_2}$, $M' = \widehat{\zeta'\rho_2}$, and $R_2 \equiv R''\rho_2$.

Define $\eta \stackrel{\text{def}}{=} \eta'[\xi/z]$, $\zeta \stackrel{\text{def}}{=} \zeta'[\xi/z]$, and $R' \stackrel{\text{def}}{=} \texttt{let}\ z = \xi\ \texttt{in}\ R''$. Then we have that $\widehat{\eta\sigma_1} = a$, $\widehat{\zeta\sigma_1} = M$ (Lemma A.1) and that $R'\sigma_1 \equiv R_1$: this proves parts (i) and (ii) of the claim. Similarly, it holds that $\widehat{\eta\sigma_2} = a'$ and $\widehat{\zeta\sigma_2} = M'$ and that $R'\sigma_2 \equiv R_2$. Part (iii) follows from these equalities and applying (LET) to transition $P\rho_2 \xrightarrow{(\nu\,\widetilde{b})\overline{a'}\langle M'\rangle} R_2$. □

B.1. Trace semantics.

LEMMA B.2 (see Lemma 4.7). *Suppose* $\sigma_1 \sim \sigma_2$ *and let* O *be any observer such that* $fn(O) \subseteq dom(\sigma_1)$. *Suppose that* $O\sigma_1 \stackrel{r}{\Longrightarrow} O_1$, *where, for some* u *and* σ_1' *extending* σ_1, *we have* $r = \widehat{u\sigma_1'}$. *Then, there is* O' *with* $fn(O') \subseteq dom(\sigma_1')$ *s.t.* $O_1 \equiv O'\sigma_1'$. *Furthermore, for any* σ_2' *extending* σ_2 *and s.t.* $\sigma_2' \sim \sigma_1'$, *it holds that* $O\sigma_2 \stackrel{r'}{\Longrightarrow} \equiv O'\sigma_2'$, *with* $r' = \widehat{u\sigma_2'}$.

Proof. The proof consists in iterating the statement of Proposition 4.2. Formally one proceeds by induction on trace u. We only examine the case when $u = u' \cdot \eta(x)$. For any substitution σ, let us write σ^{-x} for the substitution that behaves like σ but is undefined on x. Then we can write $r = \widehat{u'\sigma_1'^{-x} \cdot \eta(x)\sigma_1'} \stackrel{\text{def}}{=} s \cdot aM$ for $\widehat{\eta\sigma_1^{-x}} = a$ and $M = x\sigma_1'$, and similarly $r' = \widehat{u'\sigma_2'^{-x} \cdot \eta(x)\sigma_2'} \stackrel{\text{def}}{=} s' \cdot a'M'$ for $\widehat{\eta\sigma_2^{-x}} = a'$ and $M' = x\sigma_2'$ (recall that, by our convention on bound names, name x does not occur in u'). Applying induction and Proposition 4.2(2) and (3), the sequence of transitions $O\sigma_1 \stackrel{r}{\Longrightarrow} O_1$ can be decomposed as follows, for suitable O'' with $fn(O'') \subseteq dom(\sigma_1'^{-x})$, and O''' and O' with $fn(O''', O') \subseteq dom(\sigma_1')$:

$$O\sigma_1 \stackrel{s}{\Longrightarrow} \equiv O''\sigma_1'^{-x} \xrightarrow{aM} \equiv O'''\sigma_1' \Longrightarrow \equiv O'\sigma_1' \equiv O_1.$$

Similarly,

$$O\sigma_2 \stackrel{s'}{\Longrightarrow} \equiv O''\sigma_2'^{-x} \xrightarrow{a'M'} \equiv O'''\sigma_2' \Longrightarrow \equiv O'\sigma_2'$$

is inferred, again using induction and Proposition 4.2(2) and (3) (note that $\sigma_1^{'-x} \sim \sigma_2^{'-x}$ by Lemma A.15). This implies $O\sigma_2 \stackrel{r'}{\Longrightarrow} \equiv O'\sigma_2'$, which concludes the proof for this case. □

LEMMA B.3 (see Lemma 4.8). *Consider σ, P and any observer O with $fn(O) \subseteq dom(\sigma)$. Suppose that $P \stackrel{s}{\Longrightarrow} P'$ and that $O\sigma \stackrel{r}{\Longrightarrow}$ with $s \underline{compl}\, r$. Then there are u and σ' extending σ such that $r = \widehat{u\sigma'}$ and $\sigma \rhd P \stackrel{s}{\underset{u}{\Longmapsto}} \sigma' \rhd P'$.*

Proof. The proof consists of iterating the following two statements (the first one is an easy consequence of Proposition 4.2):

1. Suppose that $P \stackrel{\mu}{\longrightarrow} P'$ ($\mu \neq \tau$). Suppose that, for some observer O with $fn(O) \subseteq dom(\sigma)$, it holds that $O\sigma \stackrel{\lambda}{\longrightarrow} O_1$, with $\mu \,\underline{compl}\, \lambda$. Then there are σ' extending σ, δ, and O' with $fn(O') \subseteq dom(\sigma')$ s.t. $\sigma \rhd P \stackrel{\mu}{\underset{\delta}{\longmapsto}} \sigma' \rhd P'$ with $\lambda = \widehat{\delta\sigma'}$ and $O_1 \equiv O'\sigma'$.
2. Suppose that $P \stackrel{\tau}{\longrightarrow} P'$. Then $\sigma \rhd P \stackrel{\tau}{\underset{-}{\longmapsto}} \sigma \rhd P'$. □

LEMMA B.4 (see Lemma 4.9). *Suppose that $\sigma \rhd P \stackrel{s}{\underset{u}{\Longmapsto}} \sigma' \rhd P'$. Then it holds that $P \stackrel{s}{\Longrightarrow} P'$, that σ' extends σ, and that $s \,\underline{compl}\, r$, where $r = \widehat{u\sigma'}$.*

Proof. The proof follows by an easy induction on u. □

B.2. Bisimilarity.

PROPOSITION B.5 (see Proposition 4.17). *Let $\mathcal{R}$ be a weak bisimulation up to structural equivalence (resp., weakening, contraction, restriction, parallel composition). Then $\mathcal{R} \subseteq \mathcal{R}_s \subseteq \approx$ (resp., $\mathcal{R} \subseteq \mathcal{R}_t \subseteq \approx$, for $t = w, c, r, p$).*

Proof. It is obvious from the definition that $\mathcal{R} \subseteq \mathcal{R}_t$ for any t. Let us examine the other inclusion. For $t \in \{s, w, c\}$ the proof simply consists in showing that $\mathcal{R}_t$ is a weak bisimulation. This is straightforward by relying on the fact that $(\mathcal{R}_t)_t = \mathcal{R}_t$; in the case $t = c$, we also use the fact that, when $\bot \notin \widehat{\widetilde{\zeta}\sigma}$ and $n(\widetilde{\zeta}) \subseteq dom(\sigma)$, it holds $\sigma[\widehat{\widetilde{\zeta}\sigma}/\widetilde{y}] \rhd P \stackrel{\mu}{\underset{\delta}{\longmapsto}} \sigma'[\widehat{\widetilde{\zeta}\sigma}/\widetilde{y}] \rhd P'$ if and only if $\sigma \rhd P \stackrel{\mu}{\underset{\delta'}{\longmapsto}} \sigma' \rhd P'$, where if δ is an input, then $\delta' = \delta[\widetilde{\zeta}/\widetilde{y}]$; if δ is an output, then $\delta' = (\nu\, \widetilde{b})\delta[\widetilde{\zeta}/\widetilde{y}]$, with $\widetilde{b} = n(\zeta) - dom(\sigma)$, and $\delta' = \delta$ otherwise (the proof of this fact uses Lemma A.1). Next, we examine in more detail the two most interesting cases, up to restriction and parallel composition.

- *Up to restriction.* The proof is a variation on the proof for π-calculus found, e.g., in [22]. In order to cope with the fact that the output of a name which is bound by a restriction (like k in $(\nu\, k)\overline{a}k.P$) gives rise to infinitely many transitions, all of which differ by some injective renaming of this bound name, it is convenient to introduce bisimulation *up to injective renaming*.
  A substitution of names $\rho : \mathcal{N} \to \mathcal{N}$ is *injective on* $V \subseteq \mathcal{N}$ if for each $x, y \in V$, $x\rho = y\rho$ implies $x = y$; given any $\sigma = [M_i/x_i]_{i \in I}$, we denote by $\sigma \circ \rho$ the substitution $[M_i\rho/x_i]_{i \in I}$. We adapt the definition in [22] to our setting and define up to injective renaming as the technique that corresponds to the functional $(\cdot)_{in}$ defined by the rule

$$\frac{(\sigma_1, \sigma_2) \vdash P_1 \,\mathcal{R}\, P_2 \qquad \rho_i \text{ injective on } \cup_{i=1,2}\, n(\sigma_i) \cup fn(P_i)}{(\sigma_1 \circ \rho_1, \sigma_2 \circ \rho_2) \vdash P_1\rho_1 \,\mathcal{R}_{in}\, P_2\rho_2}\,.$$

  It is straightforward to show that if $\mathcal{R}$ is a bisimulation up to injective renaming then $\mathcal{R}_{in} \subseteq \approx$ (this relies on the fact that the both the transition

relation $\xrightarrow{\mu}$ and the relation $\sim$ on environments are preserved by injective renaming). Next, it is easy to show that if $\mathcal{R}$ is a bisimulation up to restriction, then $\mathcal{R}_r$ is a bisimulation up to injective renaming (the proof also uses the fact that $(\mathcal{R}_r)_r = \mathcal{R}_r$); thus we have that $\mathcal{R}_r \subseteq \approx$.

- *Up to parallel composition.* We will show that $\mathcal{R}_p$ is a weak bisimulation up to weakening, restriction, and structural equivalence. Since these techniques have already been proven sound, this implies $\mathcal{R}_p \subseteq \approx$. Suppose that $(\sigma_1, \sigma_2) \vdash A \,\mathcal{R}_p\, B$, with $A \equiv P \mid R\sigma_1$ and $B \equiv Q \mid R\sigma_2$ as given by the definition of $\mathcal{R}_p$. One analyzes the possible transitions from $\sigma_1 \rhd A$ and in each case finds a matching (weak) transition from $\sigma_2 \rhd B$.
  We examine only the most delicate case, which is when P and $R\sigma_1$ interact with each other:

$$\sigma_1 \rhd A \overset{\tau}{\underset{-}{\longmapsto}} \sigma_1 \rhd A',$$

  where $A \equiv P \,|\, R\sigma_1 \xrightarrow{\tau} (\nu\, \widetilde{h})(P' \,|\, R_1) \equiv A'$, $P \xrightarrow{(\nu\, \widetilde{h})\overline{a}\langle M\rangle} P'$, and $R\sigma_1 \xrightarrow{a\, M} R_1$. By virtue of Proposition 4.2(2)(i) applied to $R\sigma_1 \xrightarrow{a\, M} R_1$, there must be some η with $n(\eta) \subseteq dom(\sigma_1)$ s.t. $\widehat{\eta\sigma_1} = a$. Since $(\sigma_1, \sigma_2) \vdash P \,\mathcal{R}\, Q$ and $\mathcal{R}$ is a bisimulation up to parallel composition, it holds that $Q \xRightarrow{(\nu\, \widetilde{k})\overline{a'}\langle M'\rangle} Q'$ with $a' = \widehat{\eta\sigma_2}$ and $(\sigma_1[M/x], \sigma_2[M'/x]) \vdash P' \,\mathcal{R}_p\, Q'$ (x fresh). Moreover, by virtue of Proposition 4.2(2)(iii) applied to $R\sigma_1 \xrightarrow{a\, M} R_1$ and M', there is R' with $fn(R') \subseteq dom(\sigma_1) \cup \{x\}$ s.t. $R_1 \equiv R'\sigma_1[M/x]$ and $R\sigma_2 \xrightarrow{a'\, M'} \equiv R'\sigma_2[M'/x]$. Hence

$$Q \mid R\sigma_2 \equiv B \Longrightarrow B' \equiv (\nu\, \widetilde{k})(Q' \mid R'\sigma_2[M'/x]).$$

  By definition, $(\sigma_1[M/x], \sigma_2[M'/x]) \vdash (P' \mid R'\sigma_1[M/x]) \,\mathcal{R}_p\, (Q' \mid R'\sigma_2[M'/x])$ (here we have used the fact that $(\mathcal{R}_p)_p = \mathcal{R}_p$ for any $\mathcal{R}$); hence, by weakening (to discard the x-entries) and restriction, we get that

$$(\sigma_1, \sigma_2) \vdash (\nu\, \widetilde{h})(P' \mid R'\sigma_1[M/x]) \;((\mathcal{R}_p)_w)_r\; (\nu\, \widetilde{k})(Q' \mid R'\sigma_2[M'/x]).$$

  Finally, by structural equivalence, $(\sigma_1, \sigma_2) \vdash A'(((\mathcal{R}_p)_w)_r)_s B'$, which is the desired claim for this case. □

The following proposition strengthens the congruence rule for parallel composition (C-Par), under the assumption that the involved processes are safe for the appropriate environments. Recall that a process R is *σ-safe* if for each s, whenever $\sigma \rhd R \overset{s}{\underset{u}{\Longmapsto}} \sigma' \rhd R' \overset{(\nu\, \widetilde{b})\overline{a}\langle M\rangle}{\underset{\eta(x)}{\Longmapsto}}$, then $M \in dc(\sigma')$ (hence $\widetilde{b} = \emptyset$).

Proposition B.6 (see Proposition 5.6). *Suppose that $(\sigma_1, \sigma_2) \vdash Q_1 \approx Q_2$ and that $(\sigma_1, \sigma_2) \vdash R_1 \approx R_2$. Suppose that, for $i = 1, 2$, Q_i and R_i are σ_i-safe. Then $(\sigma_1, \sigma_2) \vdash Q_1 \mid R_1 \approx Q_2 \mid R_2$.*

Proof. Consider the relation $\mathcal{R}$ defined by

$$(\sigma_1, \sigma_2) \vdash (Q_1 \mid R_1)\ \mathcal{R}\ (Q_2 \mid R_2) \quad \text{if and only if}$$
$$\text{(a) } (\sigma_1, \sigma_2) \vdash Q_1 \approx Q_2 \text{ and } (\sigma_1, \sigma_2) \vdash R_1 \approx R_2,$$
$$\text{(b) for } i = 1, 2,\ Q_i \text{ and } R_i \text{ are } \sigma_i\text{-safe.}$$

One shows that $\mathcal{R}$ is a weak bisimulation. Suppose that $(\sigma_1, \sigma_2) \vdash Q_1 \mid R_1 \,\mathcal{R}\, Q_2 \mid R_2$. We only examine the most delicate case, that is, when Q_1 and R_1 interact with one

another. Thus, suppose that

$$\sigma_1 \rhd Q_1 \mid R_1 \stackrel{\tau}{\longmapsto} \sigma_1 \rhd (\nu\, \widetilde{h})(Q_1' \mid R_1'), \tag{8}$$

where $Q_1 \xrightarrow{(\nu\, \widetilde{h})\overline{a}\langle M\rangle} Q_1'$ and $R_1 \xrightarrow{a\, M} R_1'$ (the other cases follow by symmetry). Note that it must be $\widetilde{h} = \emptyset$, because $M \in dc(\sigma_1)$. Since $(\sigma_1, \sigma_2) \vdash Q_1 \approx Q_2$, we get that $Q_2 \xRightarrow{(\nu\, k)\overline{a'}\langle M'\rangle} Q_2'$, for some a', M', and Q_2', s.t. $(\sigma_1', \sigma_2') \vdash Q_1' \approx Q_2'$ (here $\sigma_1' \stackrel{\text{def}}{=} \sigma_1[M/x]$ and $\sigma_2' \stackrel{\text{def}}{=} \sigma_2[M'/x]$, for a fresh x). Also in this case, $\widetilde{k} = \emptyset$, because $M' \in dc(\sigma_2)$.

Now, since $M \in dc(\sigma_1)$, there is ζ s.t. $n(\zeta) \subseteq dom(\sigma_1)$ and $M = \widehat{\zeta\sigma_1}$ (Lemma A.2(1)). From Lemma A.4, it follows that $\widehat{\zeta\sigma_1} = \{N_i\}_{\widetilde{N}[\widetilde{\jmath}]}$ and that $\widehat{\zeta\sigma_2} = \{N_i'\}_{\widetilde{N}'[\widetilde{\jmath}]}$, for appropriate indices $i, \widetilde{\jmath}$ and cores $\widetilde{N}$ and $\widetilde{N}'$. Hence, from $\sigma_1' \sim \sigma_2'$, we get that $M' = \{N_i'\}_{\widetilde{N}'[\widetilde{\jmath}]}$; hence $M' = \widehat{\zeta\sigma_2}$. Similarly, one finds an η s.t. $n(\eta) \subseteq dom(\sigma_1)$ and $a = \widehat{\eta\sigma_1}$ and $a' = \widehat{\eta\sigma_2}$.

Now, using the facts on M and M' established above, from $R_1 \xrightarrow{a\, M} R_1'$ we deduce $\sigma_1 \rhd R_1 \stackrel{a\, M}{\longmapsto_{\overline{\eta}\zeta}} \sigma_1 \rhd R_1'$; hence, from $(\sigma_1, \sigma_2) \vdash R_1 \approx R_2$, we get $\sigma_2 \rhd R_2 \stackrel{a'\, M'}{\Longmapsto_{\overline{\eta}\zeta}} \sigma_2 \rhd R_2'$, where $(\sigma_1, \sigma_2) \vdash R_1' \approx R_2'$. Combining $Q_2 \xRightarrow{\overline{a'}\langle M'\rangle} Q_2'$ and $R_2 \xRightarrow{a'\, M'} R_2'$, we get $Q_2 \mid R_2 \Longrightarrow Q_2' \mid R_2'$; hence

$$\sigma_2 \rhd Q_2 \mid R_2 \stackrel{\tau}{\Longmapsto} \sigma_2 \rhd Q_2' \mid R_2'\,.$$

To see that the above weak transition matches (8), let us check conditions (a) and (b) of the definition of $\mathcal{R}$. Indeed, $(\sigma_1, \sigma_2) \vdash Q_1' \approx Q_2'$ (by $(\sigma_1', \sigma_2') \vdash Q_1' \approx Q_2'$ and weakening) and $(\sigma_1, \sigma_2) \vdash R_1' \approx R_2'$ imply condition (a); moreover, for $i = 1, 2$, R_i' and Q_i' are σ_i-safe, because R_i and Q_i are; thus condition (b) is true. ∎

Appendix C. Characteristic formula: Calculus with pairing.

DEFINITION C.1. *Let $\sigma = [M_i/x_i]_{i\in I}$ be a substitution. For each $i \in I$ and $p \in \{l, r\}^*$, let*

- *N_{ip} be $M_i[\sigma, p]$;*
- *ζ_{ip} be the least expression s.t. $n(\zeta_{ip}) \subseteq \widetilde{x}$ and $\widehat{\zeta_{ip}\sigma} = N_{ip}$;*
- *z_{ip} be some fixed fresh name.*

Let $\widetilde{N}$ be the function that maps each ip to N_{ip}, $\widetilde{\zeta}$ be the function that maps each ip to ζ_{ip}, and $\widetilde{z}$ be the function that maps each ip to z_{ip} ($\widetilde{z}$ will also denote the set of all z_{ip}'s). Let ρ_σ be the substitution that maps each z_{ip} to N_{ip} if $N_{ip} \neq \perp$.

Finally, for any $i \in I$, let M_i^σ be a message s.t. $n(M_i^\sigma) \subseteq \{z_{ip} : p \in \{l, r\}^*\}$ and $(M_i^\sigma)\rho_\sigma = M_i$. The formula ϕ_σ is then defined as in Figure 6.

The existence of expressions ζ_{ip} can be easily proven by relying on (the analogue of) Lemma A.2, while in the case of the M_i^σ, it is sufficient to prove that for each $M \in dc(\sigma)$ there is M' with $n(M') \subseteq \widetilde{z}_{ip}$ s.t. $M'\rho_\sigma = M$ (induction on M). The interested reader can easily supply the details. Note that $fn(\phi_\sigma) \subseteq dom(\sigma)$ and that $\sigma \models \phi_\sigma$.

The proof of Theorem A.11 is easily extended via the following lemma (the analogue of Lemma A.10), where we refer to the notation introduced in Definition C.1.

LEMMA C.2. *Consider $\sigma = [M_i/x_i]_{i\in I}$ and $\sigma' = [M_i'/x_i]_{i\in I}$, and let ρ' be a substitution s.t. $dom(\rho') = dom(\rho_\sigma)$ and $\widetilde{Z} \stackrel{\text{def}}{=} range(\rho') \subseteq dc(\sigma')$. Suppose that the following two conditions hold:*

$$
\begin{array}{ll}
 & \mathtt{let}_{N_{jq}\neq\perp}\ z_{jq} = \zeta_{jq}\ \mathtt{in}\ \Big[\\
(*) & \bigwedge_{N_{ip},N_{jq}\neq\perp} [\mathtt{dec}_{z_{jq}}(z_{ip}) = \perp]\ \wedge [\pi_1(z_{ip}) = \perp]\ \wedge\ [\pi_2(z_{ip}) = \perp] \wedge \\
(a) & \bigwedge_{i\in I} [x_i = M_i^\sigma] \wedge \\
(b) & \bigwedge_{N_{ip}\in\mathcal{N}} name(z_{ip})\ \wedge \bigwedge_{N_{ip}\neq\perp \text{ and } N_{ip}\notin\mathcal{N}} \neg name(z_{ip}) \wedge \\
(c) & \bigwedge_{N_{ip},N_{jq}\neq\perp \text{ and } N_{ip}=N_{jq}} [z_{ip} = z_{jq}]\ \wedge \bigwedge_{N_{ip},N_{jq}\neq\perp \text{ and } N_{ip}\neq N_{jq}} [z_{ip} \neq z_{jq}] \\
 & \qquad\qquad \Big]
\end{array}
$$

FIG. 6. *The formula ϕ_σ (calculus with pairing).*

(a) *for each Z_1, $Z_2 \in \widetilde{Z}$, $\widehat{\mathtt{dec}_{Z_2}(Z_1)} = \perp$ and Z_1 is not a pair;*
(b) *for each $i \in I$, it holds that $M_i' = (M_i^\sigma)\rho'$.*

Then for each i and p s.t. $M_i'[\sigma', p] \neq \perp$, it holds that $M_i'[\sigma', p] = \rho'(z_{ip})$. Furthermore, for each $i \in I$ it holds that $(\sigma, \sigma') \vdash M_i \sim M_i'$.

Proof. We just outline the proof. There are three steps:

- $kn(\sigma') \subseteq \widetilde{Z}$. To prove this, consider the set $T \stackrel{\text{def}}{=} \{M\rho' : n(M) \subseteq dom(\rho')\}$ and show that $dc(\sigma') \subseteq T$ (by induction on the definition of $dc(\cdot)$). The thesis then follows because $T \cap \mathcal{N} \subseteq \widetilde{Z}$.
- For any M and context $C[\cdot]$ (a message with a "hole"), if $C[M] = M_i^\sigma$ and $(M\rho')[\sigma', p] \neq \perp$, then $(M\rho')[\sigma', p] = \rho'(z_{i(qp)})$, where q is the position of the hole $[\cdot]$ inside $C[\cdot]$ (this implies $M_i'[\sigma', p] = \rho'(z_{ip})$ when $C[\cdot]$ is the empty context $[\cdot]$). The proof of this fact proceeds by induction on M and relies, for the base case, on the fact that $kn(\sigma') \subseteq \widetilde{Z}$.
- For any M that is a submessage of M_i^σ, it holds that $(\sigma, \sigma') \vdash M\rho_\sigma \sim M\rho'$ (this implies $(\sigma, \sigma') \vdash M_i \sim M_i'$ when M is M_i^σ, by virtue of hypothesis (b)). The proof of this fact proceeds by induction on M, and relies on the fact that $M_i'[\sigma', p] = \rho'(z_{ip})$, which has been proven above. ∎

Acknowledgments. We would like to thank the anonymous referees for helpful comments. Discussions with Martin Abadi, Cedric Fournet, and Andrew Gordon have helped us to improve the paper.

CORRIGENDUM: PROXIMITY IN ARRANGEMENTS OF ALGEBRAIC SETS*

J. H. RIEGER†

Abstract. This erratum corrects an error found in [J. H. Rieger, *SIAM J. Comput.*, 29 (1999), pp. 433–458].

PII. S0097539700380201

At present, it is not known whether the singular stratification of a real algebraic hypersurface $\hat{\mathcal{B}} \subset \mathbb{R}^d$ has $O((\deg \hat{\mathcal{B}})^d)$ strata, contrary to the statement in parentheses on the bottom of [1, p. 440].

As a consequence, the upper bounds for the number of connected regions of $\mathbb{R}^d \setminus \mathcal{B}$ and for the size of $\mathcal{A}(\mathcal{B})$ stated in Propositions 2.2, 3.1(iii), and 3.2(iii) are only valid for the number of regions of $\mathbb{R}^d \setminus \mathcal{B}$ but not for the size of $\mathcal{A}(\mathcal{B})$.

CORRIGENDUM: EDGE-DISJOINT PATHS IN EXPANDER GRAPHS*

ALAN FRIEZE†

PII. S0097539701395097

We would like to correct a small error involving some conditioning in the argument of [1]. It arose from trying to oversimplify the algorithm and proof. We are given an expander graph $G = (V, E)$ and κ pairs of vertices a_i, b_i, $i = 1, 2, \ldots, \kappa$, which must be joined by edge-disjoint paths.

As part of the algorithm we partition E into a number of sets E_i, $i = 1, 2, \ldots, k$, such that each $G_i = (V, E_i)$ has some guaranteed expansion properties. The next step is to generate two random sets $\tilde{A}, \tilde{B}$ of κ vertices in V. We then join $A = \{a_1, a_2, \ldots, a_\kappa\}$ to $\tilde{A}$ using a network flow algorithm on the graph G_1 and $B = \{b_1, b_2, \ldots, b_\kappa\}$ to $\tilde{B}$ using a network flow algorithm on the graph G_2. The endpoints of the paths produced are then relabelled $\tilde{a}_i, \tilde{b}_i, i = 1, 2, \ldots, \kappa$. This constitutes Phase 1. The task now is to join the random pairs $\tilde{a}_i, \tilde{b}_i$, $i = 1, 2, \ldots, \kappa$, by edge-disjoint paths using graphs G_i, $i \geq 3$.

The paper then claims it is sufficient to (try to) join $\tilde{a}_i$ to $\tilde{b}_i$ for $i = 1, 2, \ldots, \kappa$ by a shortest path in G_3. If we fail to find a path we put the pair into a set L which will be dealt with later. The pairs are considered in this order, and it is crucial for the analysis that when we come to consider $\tilde{a}_i$ or $\tilde{b}_i$ this vertex can be considered to be uniformly chosen from some large set, i.e., of size order n, *independent of the previous history.* This is true looking at each sequence $\tilde{a}_1, \tilde{a}_2, \ldots, \tilde{a}_\kappa$ and $\tilde{b}_1, \tilde{b}_2, \ldots, \tilde{b}_\kappa$ individually, and we tried to argue that this was sufficient:

"It is important to note here that regardless of the history of Phase 1, $\tilde{A}$ is a random set and we can assume that $\tilde{a}_1, \tilde{a}_2, \ldots, \tilde{a}_\kappa$ is a random ordering of its elements. (Phase 1 may cause some correlation between the orderings of $\tilde{A}, \tilde{B}$, but we compute the contribution of each set separately.)"

This is not actually true. The problem is that knowing $\tilde{a}_1, \tilde{a}_2, \ldots, \tilde{a}_i, \tilde{b}_1, \tilde{b}_2, \ldots, \tilde{b}_{i-1}$ we do learn something about the distribution of $\tilde{b}_i$.

Fortunately, there is a simple way of dealing with this problem. We can generate $x_1, x_2, \ldots, x_\kappa$ uniformly at random from V and then (try to) join $\tilde{a}_i$ to x_i, $i = 1, 2, \ldots, \kappa$, using the graph G_3 and then (try to) join $\tilde{b}_i$ to x_i, $i = 1, 2, \ldots, \kappa$, using the graph G_4. We can then analyze the joining of the $\tilde{a}_i$'s to the x_i's separately from the joining of the $\tilde{b}_i$'s to the x_i's and add up the separate contributions to the set L. It is now the case that when considering, say, the pairs $\tilde{a}_i, x_i$ in sequence, they are independently chosen from large sets.

A LAYERED ANALYSIS OF CONSENSUS*

YORAM MOSES† AND SERGIO RAJSBAUM‡

Abstract. This paper introduces a simple notion of *layering* as a tool for analyzing well-behaved runs of a given model of distributed computation. Using layering, a model-independent analysis of the consensus problem is performed and then applied to proving lower bounds and impossibility results for consensus in a number of familiar and less familiar models. The proofs are simpler and more direct than existing ones, and they expose a unified structure to the difficulty of reaching consensus. In particular, the proofs for the classical synchronous and asynchronous models now follow the same outline. A new notion of connectivity among states in runs of a consensus protocol, called *potence connectivity*, is introduced. This notion is more general than previous notions of connectivity used for this purpose and plays a key role in the uniform analysis of consensus.

Key words. distributed systems, shaved-memory systems, topology, consensus, impossibility results, lower bounds

1. Introduction.

For almost two decades now, the consensus problem has played a central role in the study of fault-tolerant distributed computing, e.g., [33, 18, 19, 15, 20, 29, 22, 9, 13]. It has clearly received the greatest amount of attention of any problem treated in the theoretical literature on distributed computing and has been studied in a large variety of models and under many types of failure assumptions. The structure of the consensus problem in different settings is frequently based on closely related notions. However, proofs for different models are often based on distinct and somewhat ad hoc techniques. In particular, there have been considerable differences between the study of consensus in asynchronous models and its study in synchronous and partially synchronous ones.

In order to cope with the proliferation of distributed computing models, researchers have proposed a variety of simulations between models. The aim is to establish a relation (often of equivalence) between the possibility of solving problems of certain types in different models. This is used to establish impossibility results in particular models or to provide a systematic way to transform protocols written in one model into protocols for another model. Various such simulations have been given, e.g., between shared memory and message passing [3]; between snapshot shared memory and read/write shared memory [1]; between immediate snapshot shared memory and read/write shared memory [10, 11]; between synchronous and asynchronous message passing [6]; and between two shared-memory models of different resilience [12].

This paper attempts to present a uniform approach to the study of solvability of consensus in various models of computation in which, intuitively, crash failure

behavior can occur. That is, where a process can be silenced from some point on in an execution and thus appear as if it has crashed. The standard forms of malicious (Byzantine) faults [33], in which faulty processes may behave in an arbitrary manner, satisfy the crashlike behavior condition, as do models of omission failures and, of course, the usual models of crash failures. Our results apply even to situations in which there are only link failures [35], provided there are sufficiently many of them to enable the environment to silence a process.

We start by presenting an alternative proof of the impossibility of consensus in the asynchronous shared-memory model treated by Loui and Abu-Amara [29]. This proof is based on a new notion of connectivity which we call *potence connectivity* and on an analysis based on a nicely structured subset of the runs. This subset consists of runs that are obtained by imposing a round-by-round *layering* structure on the model. Roughly, we use layerings in the following sense. Given a model of distributed computation, we identify particular legal sequences of actions for the scheduler, each of which we think of as generating a "layer." We require that any way of performing such layers repeatedly starting from a legal initial state will result in a legal run in the model. Thus, in a precise sense, such a layering can be viewed as defining a submodel of the original model.[1] Any protocol for the original model translates directly to one in the submodel. Moreover, the model and submodel generally share many features. In particular, lower bounds and impossibility results proven for the submodel translate directly into the original model. The use of layerings facilitates performing round-by-round analysis: Almost all of our results regarding consensus will follow from analyzing a single layer of computation.

The benefit of working in a submodel or a set of runs with a simpler structure than that of the original model is well known; some recent examples are [4, 10, 11, 9, 27, 34].

In this paper we concentrate on proving lower bounds and impossibility results for the consensus problem; in a sequel paper (as briefly described in [32]) we show how the ideas of this paper extend naturally to other decision tasks and are useful also to prove solvability results. First, we perform an abstract and model-independent analysis of consensus using layering. Based on this analysis, implications for specific models are obtained by demonstrating that appropriate layerings can be defined in the model. We exemplify this approach by applying it to the following models: Shared-memory asynchronous model with one crash failure, message-passing asynchronous model with one crash failure, message-passing synchronous model with one mobile failure, and message-passing synchronous model with t crash failures.

For the asynchronous models, we describe two styles of layerings: the *synchronic* and the *permutation* layering. The synchronic layerings we consider define submodels of the asynchronous models that are very close in structure to being synchronous, thereby defining "almost synchronous" submodels of the asynchronous models. Indeed, we show that synchronic layerings can be applied to the synchronous message-passing model too. The permutation layering is inspired by the immediate snapshot wait-free model of [10, 34], although we define it both for the message-passing and for the shared-memory models, both 1-resilient. This appears to be the first variant of the immediate snapshot model suggested for a message-passing model.

Regarding consensus, we provide the following:

- New, simple and uniform lower bound and impossibility proofs for the standard synchronous and asynchronous models. In particular, we show a simple

[1] Layering saves us the trouble of explicitly defining the submodel as a model of computation with a new transition function, new actions, etc.

bivalence-style proof for the synchronous case, and a direct round-by-round construction of a bivalent run (not employing a critical state argument) in asynchronous cases.

- Stronger impossibility results with respect to submodels of the full asynchronous models, in which there is only a small degree of asynchrony. These demonstrate how little asynchrony is needed to make consensus unsolvable.

In a sequel paper we show that the asynchronous models are equivalent in terms of the 1-resilient solvability of decision tasks. In particular, the slightly asynchronous submodels are no more powerful than the fully asynchronous ones. Moreover, in a precise sense, these models are strictly stronger than what can be done t-resiliently in t rounds of the standard synchronous model.

We consider the layering technique to be useful in a number of ways:

- It provides a tool for performing model-independent round-by-round analysis of decision tasks and related problems.
- Results are obtained directly and not by means of specially tailored reductions.
- Popular topological treatments (e.g., [25, 10, 26, 34]) focus on the local *final* states of processes. We consider states at intermediate stages of the computation as well. Moreover, the state of the environment is represented as an explicit component in the global state, which facilitates the treatment of message-passing as well as shared-memory models.
- We make use of a novel notion of *potence connectivity* of a set of states, whose definition depends on the decisions taken by the protocol in the possible futures of these states. In addition we use the more traditional notion of connectivity based on indistinguishability of states. The combined use of the two notions proved very useful for unifying the analysis of consensus in the synchronous and asynchronous models.

Our analysis in this paper concentrates on the consensus problem. By focusing on this "basic" case we obtain a direct and uniform analysis in simple and elementary terms. The proofs of all of our results are short and rather straightforward, which suggests to us that the notions we use are fairly natural. We believe that, with small modifications, the same type of analysis and style of reasoning can be applied to study more general problems involving topological connectivity of higher dimensionality (e.g., [25]).

There are two other papers that attempt to unify synchronous and asynchronous models in a round-by-round style. The research project of [21], concurrent and independent to ours, is based on a notion of *fault detectors*. Then there is the work of [24], which uses topological techniques in synchronous, asynchronous, and partially synchronous message-passing systems, with applications to set-consensus. There are two other papers that independently discovered bivalence arguments for the synchronous consensus lower bound: in the randomized setting there is [7], while in the deterministic setting (same as our application in section 7.2) there is [2]. A different abstract model based on the runs of a distributed system is proposed in [30]. Recently our layering technique was used to prove a synchronous lower bound for uniform consensus [28].

This paper is organized as follows. In section 2 we define the consensus problem and the basic elements of a distributed computing model, such as processes, environment (which can be used to model different communication mechanisms), states, actions, runs, and failures. In section 3 we illustrate the layering approach in the

concrete setting of an asynchronous shared-memory system by proving the impossibility of consensus. The notion of potence of a state is introduced here. This section provides a complete example of the use of our ideas; a reader uninterested in the full generality of the approach developed in the remaining of the paper could stop here. In section 4 we present a generic framework for defining models of a distributed system. As an example, we show how the synchronous mobile failures model is captured in our abstract framework. In section 5 we develop the generic setting for using potence connectivity to study consensus in the presence of crashlike failure behavior. In addition, the connection between potence connectivity and earlier notions of connectivity is formalized and proven. In section 6 we introduce layering in the generic setting, and its basic properties. In section 7.1 we illustrate the ideas with an impossibility result in the mobile failures (synchronous) model, demonstrating that asynchrony is not necessary in order to make consensus impossible. In section 7.2 we apply our framework to provide a new proof for the classic synchronous message-passing model. More applications are presented in section 8 for asynchronous systems, where various particular layerings are described. The conclusions are in section 9.

2. Preliminaries.

2.1. Consensus. In the consensus problem, we start out in an initial state in which the local state of a process i consists of a binary *initial value* variable $\mathtt{v}_i \in \{0,1\}$ and an undefined write-once *decision* variable $\mathtt{d}_i = \perp$. All communication channels (if any exist) are empty, and shared variables (if any exist) all have an undefined value of $\perp$. We denote the set of (all 2^n) initial states of consensus by Con_0. A protocol for consensus is a deterministic protocol D all of whose runs satisfy the following three properties:

Agreement: All nonfaulty processes reach the same decision.

Decision: Every nonfaulty process irrevocably *decides* on a value.

Validity: In runs in which all processes start with the same initial value w, the value that the nonfaulty processes decide on is w.

As presented, the consensus problem is well defined only once we have provided a model of computation. In this model, we must, in particular, define the structure of local and global states, as well as what protocols are and how they generate runs (computations).

In addition, we need to define when a process is faulty in a run, since the consensus problem distinguishes between the behavior of faulty processes and that of nonfaulty ones. In section 2.2 we introduce the most basic elements of a distributed system: states, actions, and runs.[2] Then in section 2.3, we consider the notion of a system, which is simply a set of runs of the model with an associated definition of who is faulty in each of the runs.

2.2. States, actions, and runs. Throughout the paper we will assume there is a fixed finite set of $n \geq 2$ processes, which we shall denote by $1, 2, \ldots, n$, and an *environment,* denoted by e, which is used to model aspects of the system that are not modeled as being part of the activity or state of the processes. For example, we will model the communication channels or shared variables as being part of the environment's state. In addition, we will assume that various nondeterministic choices such as various delays and failures are actions performed by the environment. (What

[2]Our modeling here and in section 4.1 is based on the work of [36], which in turn extends the modeling style of [17].

are typically thought of as actions of the "scheduler" or the "adversary" we model as actions of the environment.)

For every $i \in \{e, 1, 2, \ldots, n\}$, we assume there is a set L_i consisting of all possible *local states* for i. The set of *global states,* which we will simply call *states*, will consist of

$$\mathcal{G} \;=\; L_e \times L_1 \times \cdots \times L_n.$$

We denote by x_i the local state of i in the state x.

In a given setting, every $i \in \{e, 1, 2, \ldots, n\}$ is associated with a nonempty set ACT_i of possible actions. Intuitively, these may include shared-memory operations that the process can perform, messages the process sends, and any internal bookkeeping operations or computations the process may perform. In principle, a single action can cause a number of operations to take place. However, the important point is that the decision to perform this action is taken atomically. We find it convenient to model the environment as performing actions as well. Depending on the model, the environment's actions may involve the delivery of messages, the loss of messages, determining what failures happen and when they occur, resolving race conditions, etc. We also think of the environment as being in charge of *scheduling* the processes, determining which processes are to move in each round of the computation. A *scheduling action* is a set $\mathsf{Sched} \subseteq \{1, \ldots, n\}$ of the processes that are scheduled to move next. We assume the existence of a set $\mathsf{act_e}$ describing the aspects of the environment's actions that handle everything other than the scheduling of processes. Without loss of generality we will assume that an environment's action (an element in ACT_e) is a pair (Sched, a), where Sched is a scheduling action and $a \in \mathsf{act_e}$. A *joint action* is a pair $\bar{\mathsf{a}} = (\epsilon, \mathbf{a})$, where $\epsilon = (\mathsf{Sched}, a)$ is in ACT_e, and $\mathbf{a}$ is a function with domain Sched such that $\mathbf{a}(i) \in \mathsf{ACT}_i$ for each $i \in \mathsf{Sched}$. Thus, $\bar{\mathsf{a}}$ specifies an action for the environment (via $\mathbf{a}$) and an action for every process that is scheduled to move. We define the set of joint actions by $\overline{\mathsf{ACT}}$. Clearly, $\overline{\mathsf{ACT}}$ is determined by a collection of action sets $\{\mathsf{ACT}_i\}_{i=1,\ldots,n}$ and a set $\mathsf{act_e}$. Roughly speaking, joint actions are the events that cause the global state to change into a new state. Thus, for example, a joint action in which process i sends j a message m, and the environment delivers the message m' to process i' will typically cause the local state of i' to change, as well as modifying the state of the communication channel between i and j (this state will be part of the environment's local state). This is formally captured by the notion of a *transition function*, which is a function $\tau : \mathcal{G} \times \overline{\mathsf{ACT}} \to \mathcal{G}$ from global states and joint actions to global states, describing how a joint action transforms the global state.

A *deterministic protocol* for i is a function $P_i : L_i \to \mathsf{ACT}_i$ specifying the action that i is ready to perform in every state of L_i. A *nondeterministic protocol* for i is a function $P_i : L_i \to 2^{\mathsf{ACT}_i} \setminus \emptyset$ specifying for every state of L_i a nonempty set of actions, one of which i must perform in that state. In this paper, we will focus our attention on the case in which the processes follow deterministic protocols, while the environment may follow a nondeterministic protocol.[3]

Intuitively, we think of a run as consisting of an infinite sequence of global states and the joint actions that cause the transitions among them. Notice that once we fix a

[3]The assumption that the environment's protocol may be nondeterministic is necessary for a faithful description of many models of interest. The assumption that processes follow deterministic protocols is without loss of generality in this paper, in which we are interested in worst-case lower bounds and impossibility results. It is well known and straightforward to show that any result of this type for a protocol for consensus in a given model that is proved for deterministic protocols applies to the more general class of nondeterministic protocols as well.

deterministic protocol $D = (D_1, \ldots, D_n)$ for the processes, an action $\epsilon = (\mathsf{Sched}, a)$ of the environment uniquely determines the joint action $\bar{\mathsf{a}} = (\epsilon, \mathbf{a})$ that will be performed in a given (global) state x: the set Sched determines the processes that participate in the joint action, and $\mathbf{a}(i) = D_i(x_i)$ for each $i \in \mathsf{Sched}$. Proving lower bound and impossibility results can often be thought of as showing that the adversary, which here is the environment, always has a strategy that can guarantee the desired bad behavior. With this end in mind, we will represent a joint action by specifying the environment action that determines it. Formally, we model a *run* over $\mathcal{G}$ and ACT_e as a pair $R = (r, \alpha)$, where $r : N \to \mathcal{G}$ is a function from the natural numbers to $\mathcal{G}$ defining an infinite sequence of states of $\mathcal{G}$, and $\alpha : N \to \mathsf{ACT}_e$ defines a corresponding sequence of environment actions. The intuition will be that the joint action caused by $\alpha(k)$ and the underlying protocol leads us from a state $r(k)$ to a state $r(k+1)$. As we will see later on, once we fix a model of computation and a protocol D for the processes to follow, there will be additional conditions relating the sequences r and α. These conditions guarantee, for example, that the actions recorded by α do indeed cause the transitions among the corresponding states recorded by r. The state $r(0)$ is called the *initial state* of the run R. We denote by $r(k)_i$ (resp., $r(k)_e$) the local state of process i (resp., of the environment) in $r(k)$.

An *execution* is a finite or infinite subinterval of a run, starting and ending in a state, as described next. For a run $R = (r, \alpha)$ and a pair $m \leq m'$ where m is finite and m' is finite or infinite, we denote by $R[m, m']$ the execution starting at the state $r(m)$ and ending in $r(m')$ and behaving as R does between them. Formally, $R[m, m'] = (\sigma, \beta)$ where σ has domain $[0, m' - m]$ and β has domain $[0, m' - m - 1]$, and they satisfy $\sigma(k) = r(m + k)$ and $\beta(k) = \alpha(m + k)$ for every k in their respective domains. Notice that, in principle, the same execution can occur in different runs, and for that matter even at different times. A *suffix* of a run R is an execution of the form $R[m, \infty]$ for some finite m; similarly, a *prefix* of R is an execution of the form $R[0, m]$.

Given an execution R (possibly consisting of just one state), let us denote by $R \odot \epsilon$ the execution that results from extending R by having the environment perform the action ϵ. In models in which performing a joint action at a state results in a unique next state (which will invariably be the case in this paper), every run of a deterministic protocol D can be represented in the form $x \odot \epsilon_1 \odot \epsilon_2 \odot \cdots$ where x is an initial state and ϵ_i is an environment action, for every integer $i \geq 0$.

2.3. Systems and failures. We define a *system* to be a pair $(\mathcal{R}, \mathsf{Faulty})$ where $\mathcal{R}$ is a set of runs and Faulty is a predicate on processes and runs of $\mathcal{R}$. In what follows, $\mathsf{Faulty}(i, R)$ will be taken to mean that i is faulty in the run R. We often focus on the runs of a system $\mathcal{S} = (\mathcal{R}, \mathsf{Faulty})$ and write $R \in \mathcal{S}$ as shorthand for $R \in \mathcal{R}$. Notice that Faulty determines who is faulty in a run as a function of the *whole* infinite run. Obviously, in some models of distributed computation it is possible to determine that a process is faulty by considering only a prefix of the run, sometimes even a single state. In other cases, however, the full history of the run is needed in order to determine who is faulty (this is the case, for example, in the asynchronous models of [20, 29]).

With respect to a system $\mathcal{S}$, a state y is said to *extend* the state x if there is a finite execution in some run of $\mathcal{S}$ that starts in x and ends in y. A run R is said to *contain* a state x if x is one of the global states in R. For conciseness, we will use terminology such as *a state x of $\mathcal{S}$*, when we mean a state x appearing in a run of $\mathcal{S}$, or *an initial state of $\mathcal{S}$*, when we mean a state appearing as an initial state in a run

of $\mathcal{S}$. By convention, x extends x for every state x of $\mathcal{S}$.

3. Proving impossibility using layering. Our purpose in this section is to give a simple and elegant proof of the Fischer, Lynch, and Patterson impossibility result for consensus [20], based on the notion of layering. This concrete example serves to introduce the more general ideas developed in the rest of the paper. We will present the proof for the asynchronous shared-memory model [29]. Later on in the paper we will describe the properties that play a role in the proof. The standard asynchronous shared-memory model is well known, and detailed formal descriptions can be found in textbooks such as [5, 31]. We now briefly review the features of the model that are relevant for the analysis presented in this section.

We assume the standard asynchronous shared-memory model where n processes, $n \geq 2$, communicate by reading and writing to single-writer/multi-reader, shared variables, and one process can crash. A (global) *state* x of the system is a tuple specifying a local state x_i for every process i, and the state of the environment, which in this case consists of the assignment of values to the shared variables, as well as the set of pending shared-memory operations, and the set of pending reports for read operations that have been recorded (the value has been read) but not yet reported to the reading process. The pending operations are the read and write operations that have been issued for these variables and have not yet taken effect.

The sets ACT_i and ACT_e of the actions of the processes and the environment are defined as follows. A process performs an action only when it is scheduled to move. This action is either a local operation, a read of a shared variable (belonging to it or to some other process), or a write to one of its own variables. An action of the environment can have one of three forms: (a) scheduling a process to move—resulting in the process performing an action, (b) performing a pending shared-memory operation, or (c) reporting the value read in a recorded read operation to the reading process.

A process that is scheduled to move only a finite number of times in a given run R is said to have *crashed*. We define $\mathsf{Faulty}(i, R)$ to hold, and we consider i to be *faulty in* R exactly if i crashes in R. (Notice that in this model, there is no way to determine at a finite state x that a given process is faulty in the run; a process can always "recover" in the future.) As mentioned earlier, we consider deterministic protocols without loss of generality, because any nondeterministic protocol that solves consensus in this model can, by fixing the nondeterministic choices in a fixed arbitrary way, be turned into a deterministic protocol solving it.

A run of a given deterministic protocol D in this model is a run $R = (r, \alpha)$ satisfying the following:

(i) $r(0) \in \mathsf{Con}_0$,

(ii) each process follows its protocol, and every pair of consecutive states are related according to the operations that take place as scheduled by the environment.

If in addition

(iii) every read and write action issued is eventually serviced appropriately by the environment, and

(iv) at most one process fails in R,

then we say that the run is *admissible*. Let $\mathcal{S}(D)$ be the system consisting of the set of all admissible runs of D and the predicate Faulty described above. Now, the consensus problem is well defined: D solves consensus if all runs of $\mathcal{S}(D)$ satisfy agreement, decision, and validity with failures as defined by Faulty.

3.1. Layers in the shared-memory model. We define a *layer* to consist of a finite sequence of environment actions. Our intention is to focus on runs of a protocol that are generated by a particular set of layers. If the set of layers is chosen appropriately, these runs can have structural properties that will simplify their analysis.

We define the set L^{rw} of layers in the asynchronous shared-memory model to consists of all layers of the forms

- $[p_1, \ldots, p_n]$ and
- $[p_1, \ldots, p_{n-1}]$,

where the p_i's are process names (elements of $\{1, \ldots, n\}$), and the names appearing in a given layer are pairwise distinct. We think of layers of the first type as *full* layers, since in such a layer every process moves. Layers of the second type enable the environment to "silence" a process from any point in the computation; this will play an important role in determining the "topological" properties of the layered runs (e.g., in Lemma 3.4(b)). A layer specifies a linear ordering in which the environment schedules the processes to move. In a given layer, whenever a process p_i is scheduled to move, it performs a single action, and this action (internal, a read or a write) is serviced (i.e., the read or write action is performed and, in the case of a read, the value that was read is reported to the reader) before the next process moves. Since in our model every process can be scheduled to move at any state (although in some cases the pending operation may just be a "skip" internal operation), the sequence of environment actions described in a layer of L^{rw} can be applied at every state. The intuition behind the definition of L^{rw} is that a layer consists of a "round" in which at least $n-1$ processes get to move (sequentially). Notice that in an infinite sequence of layers, at least $n-1$ process names appear infinitely often. The layers just defined are designed to ensure that each layer contributes towards the fairness conditions (iii) and (iv). As a result, every run generated by an infinite sequence of such layers is admissible. Notice that a layer of the first type is specified by a permutation on $\{1, \ldots, n\}$. We will find it useful to identify a layer of the first type with the corresponding permutation. Because of this connection we call this layering a *permutation layering*.

Once we have fixed the protocol D, we can think of a layer $L \in \mathsf{L}^{rw}$ as an individual "higher-level" action by the environment. An individual environment step in a run would then consist of performing a whole layer. We define *an* L^{rw}*-run of* D to be a run of the form

$$x^0 \odot L_1 \odot L_2 \odot \cdots,$$

where $x^0 \in \mathsf{Con}_0$ and $L_i \in \mathsf{L}^{rw}$ for every $i \geq 1$. More formally, let us denote by $x \cdot L$ the state that is reached at the end of an execution that starts in x, where the processes follow D and the environment performs actions according to L. The L^{rw}-run depicted above is a run $R_{\mathsf{L}} = (r_{\mathsf{L}}, \alpha)$ with $\alpha = (L_1, L_2, \ldots)$ and $r_{\mathsf{L}} = (x^0, x^1, \ldots)$ where for $i \geq 0$ we inductively define $x^{i+i} = x^i \cdot L_{i+1}$. Thus, in an L^{rw}-run, we view the environment as performing actions consisting of whole layers, and we ignore the intermediate states that arise "in the middle" of a layer.

Notice that every L^{rw}-run R_{L} of D corresponds to a unique run $R \in \mathcal{S}(D)$ that is obtained from R_{L} by "expanding" the layers into the detailed sequence of environment actions they describe, and adding the intermediate states. We call a process *faulty* in R_{L} if it is faulty in the corresponding run R. We denote by $\mathcal{S}_{\mathsf{L}}(D)$ the system consisting of the L^{rw}-runs of D, with this definition of failures. The argument above that executing an infinite number of L^{rw} layers yields an admissible run can now be formalized as follows.

LEMMA 3.1. *For every run $R_{\mathsf{L}} \in \mathcal{S}_{\mathsf{L}}(D)$, the run $R \in \mathcal{S}(D)$ corresponding to R_{L} is admissible.*

Proof. By definition of R_{L}, the corresponding run R is clearly a run of D in the model. It is admissible because (a) by definition of the layers, each read and write action that is performed by a process is serviced immediately, and (b) at most one process can fail in R because in each of the infinite sequence of layers that generate R at least $n-1$ of the n processes is scheduled to perform an action; hence, at most one process can move only a finite number of times in R. □

3.2. Potence connectivity. Recall that decisions made by the processes appear in their local states from the point of decision on. Therefore, any infinite subsequence of the states of a run will contain the information about the decisions that the different processes perform in the run. Thus, we do not lose information about the decision values by considering the states of an L^{rw}-run instead of looking at the full detail of the run corresponding to it. If a protocol D solves consensus in the asynchronous model just described, it must do so in *every* admissible run. It follows that in every L^{rw}-run of D the nonfaulty processes must decide on a value $v \in \{0,1\}$. A crucial role in the proof of impossibility of consensus in the asynchronous shared-memory model is played by the decision values that are possible in the future of a given global state. This is captured by the notion of the *potential valence* (or *potence* for short)[4] of a state with respect to a set of runs.

DEFINITION 3.2. *A state x is* w-potent *with respect to a system $\mathcal{S}$ if x is a state of a run $R \in \mathcal{S}$ in which at least one nonfaulty process decides w. The state x is* bipotent *if it is both* 0*-potent and* 1*-potent.*

When discussing potence, we sometimes omit the system $\mathcal{S}$ when it is clear from context. Notice that if a state x is w-potent (resp., bipotent) with respect to $\mathcal{S}_{\mathsf{L}}(D)$, then it is guaranteed to be w-potent (resp., bipotent) with respect to $\mathcal{S}(D)$: If R_{L} is the witness proving that x is w-potent in $\mathcal{S}_{\mathsf{L}}(D)$, then x appears in the run $R \in \mathcal{S}(D)$ corresponding to R_{L}, and R is a witness to w-potence of x with respect to $\mathcal{S}(D)$. Clearly, the converse need not hold. Bipotent states play an important role in delaying (or precluding) consensus, as we shall see in the next section. Our goal will be to show that every consensus protocol must have a run where agreement is not reached. We will do this in the next section by demonstrating that every protocol for consensus must have a run whose states are all bipotent. Such a run we call a *bipotent run.* The notion of *potence connectivity* is a powerful tool for proving this and other impossibility results.

DEFINITION 3.3. *With respect to a system $\mathcal{S}$,*

(i) *two states x and y have* shared potence*, denoted by $x \sim_p y$, if both are w-potent for some $w \in \{0,1\}$;*

(ii) *a set of states X is* potence connected *if the graph $(X, \sim_p)$ induced by $\sim_p$ on X is connected.*

Potence connectedness is not a very strong condition. Indeed, it is easy to check that a set X of states is potence connected exactly if either (i) for some value w, all states of X are w-potent, or (ii) there exists at least one bipotent state in X. Equivalently, X is not potence connected exactly if X contains both 0-potent and 1-potent states but does not contain a bipotent state.

[4] In [32] we used the term *valence* instead of potence. This is changed here because the term valence is used slightly differently in the literature, starting with [20]. Briefly, a state is said to be w-valent if *all* extensions decide w. (However, bivalent is equivalent to bipotent.) We thank Gerard Tel for suggesting the term.

The following criterion will serve us to prove that two states have shared potence.

LEMMA 3.4. *Assume the protocol D satisfies the decision property, and let x and x' be states of $\mathcal{S}_{\mathsf{L}}(D)$. If there are states $y, y' \in \mathcal{S}_{\mathsf{L}}(D)$, where y extends x and y' extends x', such that y and y' differ at most in the local state of a single process, then $x \sim_p x'$ with respect to $\mathcal{S}_{\mathsf{L}}(D)$.*

Proof. Let R_x be an execution in $\mathcal{S}_{\mathsf{L}}(D)$ that ends in state x, and let $R_{x'}$ be one that ends in x'. Since y extends x, there is a finite sequence of layers σ such that $R_x \odot \sigma$ ends in y, and a corresponding sequence σ' such that $R_{x'} \odot \sigma'$ ends in y'. By assumption, we have that y and y' differ at most in the local state of process p. Choose a layer $L \in \mathsf{L}^{rw}$ in which p is not scheduled to move. We extend each state by applying L repeatedly. There are two runs $R, R' \in \mathcal{S}_{\mathsf{L}}(D)$ such that $R = R_x \odot \sigma \odot L^\infty$ and $R' = R_{x'} \odot \sigma' \odot L^\infty$. Both are clearly runs of $\mathcal{S}_{\mathsf{L}}(D)$, and in both runs process p is faulty and the rest are not faulty. A straightforward induction on the number of actions performed by the environment shows that all processes other than p have the same local state history in the suffix of R starting at y as they do in corresponding points in the suffix of R' starting at y'. It follows that the nonfaulty processes reach the same decision in both. Since D satisfies the decision property, decisions are reached by the nonfaulty processes in these runs, and we have that $x \sim_p x'$. □

Lemma 3.4 directly captures as particular instances many useful cases. Thus, for example, it implies that if x extends y, then they have a shared potence. Similarly, if a state z extends both x and y, then $x \sim_p y$. A third useful instance is that if x and y differ only in the local state of one process, then $x \sim_p y$.

The crux of the impossibility proof is captured in the following lemma, which shows that the set of successors of a state in $\mathcal{S}_{\mathsf{L}}(D)$ is guaranteed to be potence connected.

LEMMA 3.5. *Assume D satisfies the decision property. For every state x of $\mathcal{S}_{\mathsf{L}}(D)$, the set of states $\mathsf{L}^{rw}(x) = \{y \mid y = x \cdot L,$ for some $L \in \mathsf{L}^{rw}\}$ is potence connected with respect to $\mathcal{S}_{\mathsf{L}}(D)$.*

Proof. We start by showing two cases in which states of $\mathsf{L}^{rw}(x)$ have a shared potence, from which the result will follow. For every permutation $p_1, p_2, \ldots, p_n$ of $\{1, \ldots, n\}$ we claim that the following holds:

(i) $x \cdot [p_1, \ldots, p_{n-1}] \ \sim_p \ x \cdot [p_1, \ldots, p_n]$.

This is true by Lemma 3.4 because there is a state of $\mathcal{S}_{\mathsf{L}}(D)$ that extends both states. This state results from extending the first state by applying the layer $L = [p_n, p_1, \ldots, p_{n-1}]$, and it also results from extending the second state by $L' = [p_1, \ldots, p_{n-1}]$. Clearly,

$$x \cdot [p_1, \ldots, p_{n-1}] \cdot [p_n, p_1, \ldots, p_{n-1}] \quad = \quad x \cdot [p_1, \ldots, p_n] \cdot [p_1, \ldots, p_{n-1}],$$

since in both cases exactly the same actions take place in the same order in the two layers following x.

For a permutation $\pi = [p_1, \ldots, p_n]$, we denote the permutation $[p_1, \ldots, p_{k-1}, p_{k+1}, p_k, p_{k+2}, \ldots, p_n]$ that is obtained by transposing the kth and $(k+1)$st elements of π by $\mathsf{Tr}(k, \pi)$. We claim the following.

(ii) Let π be a full layer and $k \in \{1, \ldots, n-1\}$. Then $x \cdot \pi \quad \sim_p \quad x \cdot \mathsf{Tr}(k, \pi)$.

Let $y = x \cdot \pi$ and $y' = x \cdot \mathsf{Tr}(k, \pi)$. In moving from x to both y and y', every individual process performs the same action. Recall that in our model each shared variable can be written by a single process. Thus, every process that executes a write writes the same value in both cases, and the state of the shared memory is the same in y and in y'. In addition, every process except possibly for p_k and p_{k+1} end

up in the same local state in y and in y'. Now, if both processes perform a read or both perform a write, each of them will end up in the same local state in y and in y'. Finally, if one of them executes a read and the other a write, only the reading process may end up in a different state in y and in y'. It follows that y and y' differ at most in the local state of one process, so $y \sim_p y'$ by Lemma 3.4.

The potence connectivity of $\mathsf{L}^{rw}(x)$ follows: A well-known property of the group of permutations is that we can transform any permutation π of $\{1, \ldots, n\}$ to any other permutation π' using a finite number of single transpositions $\mathsf{Tr}(k, \pi)$ as in (ii). Thus, by transitivity of connectivity we have that all states $x \cdot \pi$ obtained from x by a full layer are potence connected. Each of the remaining states of $\mathsf{L}^{rw}(x)$ is obtained by a layer $[p_1, \ldots, p_{n-1}]$ and is connected to the rest by part (i). □

The last connectivity property is implicit in [20].

LEMMA 3.6. *If D satisfies the decision property, then Con_0 is potence connected with respect to $\mathcal{S}_{\mathsf{L}}(D)$.*

Proof. In this proof, given a state z we denote by z_j the local state of process j in the state z. Let $x, y \in \mathsf{Con}_0$, and for every $0 \leq m \leq n$ define x^m by setting

$$x_j^m = \begin{cases} y_j & \forall j \leq m, \text{ and} \\ x_j & \forall j > m. \end{cases}$$

Clearly, $x^m \in \mathsf{Con}_0$, and it is easy to check that $x^0 = x$ and $x^n = y$. Moreover, for every $0 < l \leq n$ we have that x^{m-1} and x^m differ exactly in the local state of process m. Con_0 is a subset of the states of $\mathcal{S}_{\mathsf{L}}(D)$. Hence, by Lemma 3.4 we have that $x^{m-1} \sim_p x^m$. It follows that x and y are potence connected and we are done. □

3.3. Using bipotence to prove impossibility. In the previous section we used the decision requirement of consensus, together with the possibility of having one process crash, to establish connectivity properties. In this section we show how these properties, together with the agreement and validity requirements of consensus, imply the impossibility result. We start by demonstrating that bipotent states can play a role in delaying, or precluding, consensus.

LEMMA 3.7. *Assume that the protocol D satisfies the agreement and decision properties. If a state x of $\mathcal{S}_{\mathsf{L}}(D)$ is bipotent with respect to $\mathcal{S}_{\mathsf{L}}(D)$, then no process has decided in x.*

Proof. Assume by way of contradiction that i has decided on value w in x. Since x is bipotent, there is a run $R \in \mathcal{S}_{\mathsf{L}}(D)$ containing x in which some process, say j, decides $1 - w$. Let y be a state of this run extending x in which j has already decided $1 - w$. Thus, at y processes i and j have (irrevocably) decided on different values. Let P be a prefix of this run that ends in y, and let $L \in \mathsf{L}^{rw}$ be any full layer. The run $R' = P \odot L^\infty$ is a run of $\mathcal{S}_{\mathsf{L}}(D)$ in which i decides w, process j decides $1 - w$, and both are nonfaulty (they move infinitely often). Processes i and j similarly decide w and $1 - w$, respectively, in the run $\hat{R} \in \mathcal{S}(D)$ corresponding to R', contradicting the assumption that D satisfies the agreement property. □

The following lemma is the basis for the impossibility proof.

LEMMA 3.8. *Let X be a potence connected (with respect to $\mathcal{S}_{\mathsf{L}}(D)$) set of states of $\mathcal{S}_{\mathsf{L}}(D)$. If X contains both 0-potent and 1-potent states, then there is a bipotent state in X.*

Proof. Let X^0 be the subset of X consisting of 0-potent states, while X^1 is the subset of 1-potent states. By assumption, both subsets are nonempty. It thus follows that there must be an edge $x^0 \sim_p x^1$ with $x^0 \in X^0$ and $x^1 \in X^1$ (otherwise X is not potence connected).

Since $x^0 \sim_p x^1$, the states x^0 and x^1 have a shared potence. If their shared potence is 0, then x^1 is bipotent, while if the shared potence is 1, then x^0 is bipotent. In either case there is a bipotent state in X, as desired. □

We can use Lemma 3.6 to obtain a bipotent initial state x^0, a well-known result of [20].

LEMMA 3.9. *If D satisfies the decision and validity properties, then the set Con_0 contains a bipotent state with respect to $\mathcal{S}_{\mathsf{L}}(D)$.*

Proof. Let $x^0 \in \mathsf{Con}_0$ be the initial state in which all initial values are 0, and let x^1 be the corresponding state with all values 1. By the validity condition in every admissible run of D starting in the state x^0 (resp., x^1) the nonfaulty processes decide 0 (resp., 1). Since L^{rw}-runs correspond to admissible runs, and there is an L^{rw}-run starting in x^0 and an L^{rw}-run starting in x^1, x^0 is 0-potent and x^1 is 1-potent. By Lemma 3.6 Con_0 is potence connected, and thus by Lemma 3.8 we obtain that there is a bipotent state in Con_0. □

LEMMA 3.10. *Every protocol D that satisfies decision and validity has a bipotent run in $\mathcal{S}_{\mathsf{L}}(D)$.*

Proof. By Lemma 3.9, there is a bipotent state, say x^0, in Con_0. We will construct a sequence of bipotent states $x^1, x^2, \ldots, x^k, \ldots$ and a corresponding sequence of layers $L_1, L_2, \ldots, L_k, \ldots$ such that $x^{i+1} = x^i \cdot L_{i+1}$ for all $i \geq 0$. The desired run will be

$$R_{\mathsf{L}} = x^0 \odot L_1 \odot L_2 \odot \cdots \odot L_k \odot \cdots.$$

It remains to define the two sequences. We will define the layers L_i and the states x^i by induction on i. Notice that x^0 is bipotent. Let $k \geq 0$, and assume that we have constructed sequences $L_1, L_2, \ldots, L_k$ and $x^1, x^2, \ldots, x^k$ with the desired properties. In particular, x^k is a bipotent state. Since D satisfies decision, we have by Lemma 3.5 that $\mathsf{L}^{rw}(x^k)$ is potence connected. Since x^k is bipotent, $\mathsf{L}^{rw}(x^k)$ contains both 0-potent and 1-potent states. It follows from Lemma 3.8 that there is a bipotent state $y \in \mathsf{L}^{rw}(x^k)$. Since $y \in \mathsf{L}^{rw}(x^k)$ we have by the definition of $\mathsf{L}^{rw}(x^k)$ that $y = x^k \cdot L$ for some layer L. Set $L_{k+1} = L$ and $x^{k+1} = y$. □

We conclude the following.

THEOREM 3.11. *There is no 1-resilient consensus protocol in the asynchronous shared-memory model.*

Proof. We need to show that no protocol D can satisfy all three properties of consensus: decision, validity, and agreement. Assume that D satisfies decision and validity. By Lemma 3.10 there is a bipotent run $R \in \mathcal{S}_{\mathsf{L}}(D)$. This run has an infinite number of bipotent states. If D were to satisfy agreement as well, we have by Lemma 3.7 that no process could have decided in a bipotent state. But then no process would ever decide in the run R, and hence no process would ever decide in the corresponding run of $\mathcal{S}(D)$, contradicting the assumption that D satisfies the decision property. □

3.4. Discussion. In this section we have used layering to provide an alternative proof of the impossibility of consensus in the asynchronous shared-memory model. Our proof differs from those of [20, 29] in a number of ways. First, it does not depend on a "critical state" argument; rather, it constructs a bipotent run inductively one state (or rather one layer) at a time. A subtle aspect of the standard proofs is proving that prefixes of a run can be extended into full runs in a manner that satisfies the fairness (or admissibility) conditions. In our case this is simplified by having each layer contribute "enough" to the fairness conditions to guarantee that any run constructed as a sequence of layers is admissible. We have attempted to provide a proof that

makes fairly limited and local use of the particular properties of the model. As a result, as we shall see in the following, the same proof outline is applicable to the analysis of consensus in other models. Thus, we believe that the notions of potence connectivity and layering capture some of the topological structure underlying the consensus problem (and more generally 1-resilient solvability, as described in [32]). For example, the layering approach can be used to prove global connectivity properties of a model, as opposed to the approach described in this section, which shows connectivity of successors of a state; more about this is in section 9.

We next provide a more general framework and show how the notions of potence and layering and the proof outline just given can be applied more broadly. We start by describing how to model different types of distributed systems in a general fashion.

4. Layering consensus in general models. We now consider how layering can be used to analyze consensus for a variety of models. We start by defining models of distributed systems in a more general manner, and we show how layering can be applied to consensus in such generic models.

4.1. Models of distributed computation. Using the notions of section 2.2, we define a generic model of computation. A *model of distributed computation* is determined by sets L_i, $i \in \{e, 1, 2, \ldots, n\}$, of local states for the processes and the environment, and corresponding sets of actions ACT_i, for every $i \in \{e, 1, 2, \ldots, n\}$, and by a tuple $M = (\mathcal{G}_0, P_e, \tau, \Psi, \mathsf{FGen})$, where the following hold:

- $\mathcal{G}_0 \subseteq \mathcal{G}$ is called the set of *initial states*. The identity of $\mathcal{G}_0$ will depend on the type of analysis for which the model is introduced. When we focus on a particular problem such as consensus, $\mathcal{G}_0$ is the set Con_0 of initial states for consensus.
- P_e is a (nondeterministic) protocol for the environment.
- τ is a transition function.
- Ψ is a set of runs over $\mathcal{G}$ and ACT_e, such that for every pair of runs R and R' that have a suffix in common, $R \in \Psi$ if and only if $R' \in \Psi$. The set Ψ is called the set of *admissible* runs in the model. This is a tool for specifying fairness properties of the model. For example, properties such as "every message sent is eventually delivered" or "every process moves infinitely often" are enforced by allowing as admissible only runs in which these properties hold. The condition we have on Ψ being determined by the suffixes of its runs ensures that admissibility depends only on the infinitary behavior of the run.
- FGen is a function that, for each protocol D gives a predicate Faulty_D defined on the runs of D in M (defined below). We remark that the dependence of the Faulty_D on the protocol is useful when we want to capture the idea that a process is faulty if it deviates from the protocol it is supposed to follow. This is relevant for handling malicious failures, for example.

We say that a run $R = (r, \alpha)$ is a *run of the protocol* $D = (D_1, \ldots, D_n)$ *in* $M = (\mathcal{G}_0, P_e, \tau, \Psi, \mathsf{FGen})$ when

(i) $r(0) \in \mathcal{G}_0$, so that R begins in a legal initial state according to M,
(ii) $\alpha(k) \in P_e(r(k)_e)$ for all k,
(iii) $r(k+1) = \tau(r(k), (\alpha(k), \mathbf{a}^k))$ holds for all $k \geq 0$, where the domain of $\mathbf{a}^k$ is the set Sched in $\alpha(k)$, and $\mathbf{a}^k_i = D_i(r(k)_i)$ for every $i \in \mathsf{Sched}$,[5] and

[5]Given this choice, any deviations of a process from the protocol, as may happen in a model with malicious failures, will need to be modeled as resulting from the environment's actions. The behavior of faulty processes in such a case will be controlled by the environment.

(iv) $R \in \Psi$, so that R is admissible.

Condition (ii) implies that the environment's action at every state of R is legal according to its protocol P_e, and condition (iii) states that the state transitions in R are according to the transition function τ, assuming that the joint action is the one determined by the environment's action and the actions that the protocol D specifies for the processes that are scheduled to move. A run satisfying properties (i)–(iii) but not necessarily the admissibility condition (iv) is called *a run of D consistent with M*. It is a run in which the initial state and local transitions are according to D and M, but the admissibility conditions imposed by Ψ are not necessarily satisfied. We will find it useful to consider such runs in section 6.

The notions of models and protocols give us a way of focusing on a special class of systems, resulting from the execution of a given protocol in a particular model. We denote by $\mathcal{S}(D, M, I)$ the system $(\mathcal{R}, \mathsf{Faulty})$, where $\mathcal{R}$ is the set of all runs of protocol D in the model M that start in initial states from a set I, where $I \subseteq \mathcal{G}_0$, and $\mathsf{Faulty} = \mathsf{FGen}^M(D)$.

We say that a system $\mathcal{S}$ satisfies the *pasting property* if, for every pair $R = (r, \alpha)$ and $R' = (r', \alpha')$ of runs of $\mathcal{S}$ such that $r(m) = r'(m')$ for some integers m, m', there is a run R'' of $\mathcal{S}$ such that $R''[0, m] = R[0, m]$ and $R''[m, \infty] = R'[m', \infty]$. Intuitively, the pasting property says that we can "paste" any prefix ending in a state x with a suffix starting in x, and obtain a run of $\mathcal{S}$. In a sense, this means that all of the information that is relevant to determining the future of a state is included in the state.

It is straightforward to show the following.

LEMMA 4.1. *Every system of the form $\mathcal{S} = \mathcal{S}(D, M, I)$ has the pasting property.*

Proof. Assume that $R = (r, \alpha)$ and $R' = (r', \alpha)$ are runs of $\mathcal{S}$, and that $r(m) = r'(m')$, and let R'' be defined as in the definition of the pasting property. We need to show that R'' satisfies conditions (i)–(iv) above. For condition (i), $r''(0) = r(0)$ and $r(0) \in \mathcal{G}_0$ since R satisfies condition (i). For $k < m$, we have that $r''(k) = r(k)$, $\alpha''(k) = \alpha(k)$, and $r''(k+1) = r(k+1)$. Therefore properties (ii) and (iii) follow for $k < m$ from the fact that they hold for R. Similarly, for $k \geq m$, $r''(k) = r'(m'+k-m)$, $\alpha''(k) = \alpha'(m'+k-m)$, and $r''(k+1) = r'(m'+k+1-m)$ so that (ii) and (iii) for these values of k follow from the fact that they hold for the run R' (at time $m'+k-m$). Finally, $R''[m, \infty] = R'[m', \infty]$, so that R'' and R' have a suffix in common. Since $R' \in \Psi$, it thus follows that $R'' \in \Psi$ so R'' satisfies (iv), and we are done. □

Finally, recall that the definition of consensus depends in an essential way on the behavior of the nonfaulty processes. Since we have a very general notion of a Faulty predicate that may depend on the model, we will restrict attention to cases in which the notion of failures is not completely out of hand. A predicate Faulty defined for the runs of a system $\mathcal{S}$ induces a notion of a process being *failed at a state* (with respect to $\mathcal{S}$). We say that a process i is *failed at state x* if i is faulty in all runs of $\mathcal{S}$ containing x. Otherwise i is *nonfailed* at x.

DEFINITION 4.2. *A system $\mathcal{S} = (\mathcal{R}, \mathsf{Faulty})$ satisfies* fault independence *if the following hold:*

(i) *For every state x of $\mathcal{S}$ there is a run $R^x \in \mathcal{S}$ in which x appears, such that the only processes that fail in R^x are those that are already failed at x.*
(ii) *No process is failed at an initial state of $\mathcal{S}$.*
(iii) *If R and R' have a common suffix, then the same processes fail in both runs.*
(iv) *At most $n-1$ processes fail in any run $R \in \mathcal{S}$.*

Part (i) is formally captured by the condition

$$(\forall x \text{ of } \mathcal{S})(\exists R^x \in \mathcal{S})\forall i\,[\mathsf{Faulty}(i, R^x) \text{ iff } i \text{ is failed at } x].$$

The intuition here is that every instance of faulty behavior should be the result of the failure of some component in the system. If there is an extension of a state in which one component fails and another does not, and there is a different execution where the second component fails but the first one does not, then there should be a third execution where neither one fails. Failures are thus independent in this sense. Part (ii) implies that for any initial state x and every process i, there is a run R^x containing x where i is nonfaulty. (Of course there may be another such run where i is faulty.) Part (iii) is included because the failures we are interested in (e.g., crashes) are determined by the infinite part (i.e., suffix) of a run. Notice that there are failure models in which a failure can be committed at a given point in time and not be reflected in the processes' states at a later time. This could cause two runs to have the same suffix while a particular process behaves in a faulty manner in one of the runs but not in the other. However, by appropriately modeling the environment's state to keep track of such failures, part (iii) can be guaranteed in such models as well. Part (iv) allows us to concentrate on runs where at least one process did not fail.

All systems we will consider are assumed to satisfy fault independence.

4.2. Example: The mobile failures model. We illustrate the use of the abstract framework just described by describing a synchronous model with a *single mobile failure* [35]. The model is the standard synchronous message-passing model in which communication proceeds in lockstep rounds; in every round each process can send a message to each of the other processes, and messages are delivered in the round they are sent with no corruptions. The failure assumption is that in every round m there can be at most one process i_m some of whose messages are lost. The set of messages lost by this process in the round in question is arbitrary. We use the term *mobile failure* because the identity of the process whose messages may be lost can change from one round to the next.

We now sketch how this model, which we denote by $M^{\mathsf{m}} = (\mathcal{G}_0^{\mathsf{m}}, P_e^{\mathsf{m}}, \tau^{\mathsf{m}}, \Psi^{\mathsf{m}}, \mathsf{FGen}^{\mathsf{m}})$, can be represented in terms of our formalism. The environment's state is assumed to be the same in all states of $\mathcal{G}_0^{\mathsf{m}}$. The environment's protocol P_e^{m} is uniform at all states: nondeterministically choose a process $i \in \{1, \ldots, n\}$ and a set $T \subseteq \{1, \ldots, n\}$ and perform the action $(\{1, \ldots, n\}, (i, T))$. Notice that in all cases $\mathsf{Sched} = \{1, \ldots, n\}$ so that, intuitively, all processes are scheduled to move in every round. The action $a = (i, T)$ specifies that any message sent from i to members of T will be lost. The actions a process can perform in this model specify a list of at most one message to be sent to each process in the current round. Thus, given a protocol $D = (D_1, \ldots, D_n)$ for the processes, for every state x the protocol D_i for i defines an action $D_i(x_i)$ that specifies what is its next state and the messages that i sends in that state.

Given a state x and a joint action $\bar{\mathsf{a}} = (a_e, \mathbf{a})$, $a_e = (\{1, \ldots, n\}, (j_0, T_0))$, the transition function τ^{m} updates the local state of a process i as a function of its current action, $D_i(x_i)$, and the list of messages that are sent to it in the current round that are not blocked (i.e., the list of messages sent to i by processes j according to $D_j(x_j)$ except that if $i \in T_0$, we ignore any message that may be sent by $j = j_0$).

The set Ψ^{m} makes no restrictions whatsoever: it consists of all possible runs consistent with M^{m}. Finally, $\mathsf{FGen}^{\mathsf{m}}(D)(i, R) = \mathit{false}$ for all processes i, runs R, and

protocols D; in this model, no process is ever considered faulty.[6]

Note that M^{m} satisfies fault independence. Namely, consider any system $\mathcal{S} = \mathcal{S}(D, M^{\mathsf{m}}, I)$. All properties of Definition 4.2 hold trivially for $\mathcal{S}$, because no processes are ever considered faulty in M^{m}.

5. Abstract impossibility framework for consensus. We are now ready to initiate a general model-independent analysis of the consensus problem. We will attempt to show that the general structure of the proof we presented in section 3 is widely applicable. As in section 2.1, we will assume a uniform set Con_0 of initial states for consensus. The local state of every process i in a state x of Con_0 consists of two distinct variables, $\mathtt{v}_i$ and $\mathtt{d}_i$. The first has a binary value and is considered i's *initial value* for the purpose of the consensus procedure. The second is a write-once variable that appears in all of i's local states and is initially undefined (i.e., initially $\mathtt{d}_i = \perp$). The environment's state is assumed to be the same in all states of Con_0.

In what follows, we shall focus on systems that are compatible with the consensus problem. We call a system $\mathcal{S} = \mathcal{S}(D, M, I)$ a *system for consensus* if (i) the set I of initial states in $\mathcal{S}$ is Con_0 and (ii) the local state x_i of every process i in each state x of $\mathcal{S}$ contains the variable $\mathtt{d}_i$, and in all runs the variable $\mathtt{d}_i$ is write-once. A model $M = (\mathcal{G}_0, P_e, \tau, \Psi, \mathsf{FGen})$ is a *model for consensus* if $\mathsf{Con}_0 \subseteq \mathcal{G}_0$ and every system of the form $S(D, M, \mathsf{Con}_0)$ is a system for consensus.

All models are models for consensus satisfying fault independence.

The consensus problem in section 2.1 is now well defined with respect to a general model M: a protocol D solves consensus if all the runs of the system $\mathcal{S}(D, M, \mathsf{Con}_0)$ satisfy agreement, decision, and validity, where faulty processes are defined according to the function $\mathsf{Faulty}_D = \mathsf{FGen}(D)$.

5.1. Potence and bipotence in general models. Recall the definitions of w-potence and bipotence with respect to a system $\mathcal{S}$ of section 3.2. In particular, they hold for $\mathcal{S} = \mathcal{S}(D, M, I)$. In this section we consider two useful ways to show that $x \sim_p y$ in general models. We start with some specific conditions under which analogues to Lemma 3.4 hold.

LEMMA 5.1. *Assume that $\mathcal{S}$ satisfies decision and let x, y, z be states of $\mathcal{S}$.*

(i) *For $v \in \{0, 1\}$, if z is v-potent and z extends y, then y is also v-potent.*

(ii) *If z extends both x and y, then $x \sim_p y$.*

Proof. For part (i), assume z is v-potent. Then there exists a run $R = (r, \alpha)$ of $\mathcal{S}$ and a time $m \geq 0$ such that $r(m) = z$ and some nonfaulty process i in R decides v. Since z extends y, there is a run $R' = (r', \alpha')$ and there are times $k' \geq k \geq 0$ such that $r'(k) = y$ and $r'(k') = z$, in which the only processes that fail are those that are already failed at z (fault independence (i) and (iii)). Consider the run R'' obtained by pasting the prefix $R'[0, k']$ with the suffix $R[m, \infty]$. Since the system $\mathcal{S}$ satisfies the pasting property (by Lemma 4.1), R'' is a run of $\mathcal{S}$. Process i reaches the same decisions in R and in R'' (decisions are write-once and the $\mathtt{d}_i$ variable appears in all of i's local states). Since R and R'' have a common suffix, the same processes fail in both runs (fault independence (iii)). It follows that i is a nonfaulty process deciding v in R''. The state y is therefore v-potent and we are done.

[6] This assumption is made for simplicity. Notice that the process i_m, some of whose messages may be lost in a given round m, still receives all messages sent to it. This process should therefore not be at a disadvantage when it comes to being able to decide on the consensus value. The same analysis and conclusions as we present here would hold if, for example, we would assume that a process that is silenced from some point on in a given run is considered faulty in that run.

We now show part (ii). Since $\mathcal{S}$ satisfies the decision property, every state of $\mathcal{S}$, including z in particular, is either 0-potent or 1-potent (or both). Assume that z is v-potent. By part (i) y is v-potent, and by the same argument x is v-potent as well. Hence $x \sim_p y$ and we are done. □

Recall that a run is bipotent if all of its states are bipotent. An important consequence of the agreement property is that a consensus protocol cannot terminate while in a bipotent state. As a result, if a protocol has a bipotent run, then it cannot solve consensus. This is an important feature underlying impossibility proofs for consensus. We now capture these claims as they apply to general models more formally. One feature of many popular models, including the common asynchronous ones, is that the failure of a process is not determined in finite time. We say that a system $\mathcal{S}$ displays *no finite failure* if, for all states x of $\mathcal{S}$, no process is failed at x. Namely, for every process i, there is a run containing x in which i is nonfaulty. For such systems we have the following lemma, which is a slight generalization of Lemma 3.7 and whose proof has the same structure.

LEMMA 5.2. *Let $\mathcal{S}$ satisfy the agreement requirement and assume there is a bipotent run $R^b \in \mathcal{S}$. If $\mathcal{S}$ displays no finite failure then $\mathcal{S}$ does not satisfy the decision property.*

Proof. We will show that if a state x of $\mathcal{S}$ is bipotent, then no process has decided by x. The claim follows, since in a bipotent run no process will ever decide, and we have by the fault independence assumption part (iv) that there must be at least one nonfaulty process in R^b.

Assume by way of contradiction that x is bipotent and i is decided at x. Let its decision at x be $\mathtt{d}_i = w \neq \perp$. Since x is bipotent, there is a run R containing x in which some process, say j, decides $1 - w$. It follows that there is in R a state y extending x in which $\mathtt{d}_j = 1 - w$. Since $\mathcal{S}$ displays no finite failure, both i and j are nonfailed at y. By the fault independence assumption part (i), there is a run R' containing y in which both i and j are nonfaulty. Since $\mathtt{d}_i$ and $\mathtt{d}_j$ are write-once, however, in R' process i decides w while j decides $1-w$, contradicting the assumption that $\mathcal{S}$ satisfies the agreement property. □

Lemma 5.2 clearly demonstrates that consensus cannot be attained at a bipotent state of a system that displays no finite failure. The following lemma shows that a consensus protocol is still unable to terminate in a bipotent state even in systems in which failures can be observed in finite time.

LEMMA 5.3. *Let $\mathcal{S}$ be a system satisfying the agreement requirement and assume that no more than $t < n$ processes fail in any run of $\mathcal{S}$. If x is a bipotent state of $\mathcal{S}$ then at least $n - t$ nonfailed processes at x have not decided by x.*

Proof. Since x is bipotent, there is a run R^0 containing x in which at least one nonfaulty process decides 0. The set P_0 of nonfaulty processes in R^0 consists of at least $n-t$ processes. They are all nonfailed at x, and by the agreement property none of them has decided 1 by x. By symmetry of 0 and 1, we obtain the existence of a set P_1 of at least $n - t$ nonfailed processes at x that have not decided 0 by x. By the fault independence property part (i), there is a run $\hat{R}$ containing x in which the only processes that fail are the ones that are already failed at x. All processes in $P_0 \cup P_1$ are nonfaulty in $\hat{R}$. By the agreement property, there is at most one value $w \in \{0, 1\}$ on which nonfaulty processes decide in $\hat{R}$. If nonfaulty processes do not decide 0 in $\hat{R}$, then no process in P_0 has decided by x, and if they do not decide 1 in $\hat{R}$, then no process in P_1 has decided by x. In either case, the claim holds. □

5.2. Potence connectivity revisited. The central role played by connectivity in the analysis of consensus and decision problems in general has been observed by many authors starting with [18]. The traditional notion of connectivity in the literature [18, 31, 35] is based on comparing the local states of processes in the *current* (global) state: Two states are similar if they share enough structure (e.g., equal environment and process states), and the transitive closure of this binary relation provides a corresponding notion of (similarity-based) connectivity. In contrast, the shared potence of states depends on their possible future extensions, and hence so is potence connectivity. Clearly, a notion of the first kind is independent of the protocol used, while potence connectivity is protocol dependent. It is our view that potence connectivity plays a crucial role in the structure of consensus. In addition to generalizing our treatment of potence connectivity slightly, in this section we will draw a formal connection between similarity connectivity and potence connectivity. Intuitively, we will show that in models in which the environment can always silence an arbitrary process, similarity connectivity yields potence connectivity. Similarity-based connectivity will thus prove to be a useful tool for showing potence connectivity.

Similarity connectivity + crashlike behavior $\Rightarrow$ potence connectivity. Many failure models considered in the study of fault tolerance allow faulty behavior in which the state of a process is "hidden" from some point on. Usually this happens as a result of a process crash, but it can also be the result of the process's memory being erased, for example. When such hiding can occur, states that differ only in the local state of one process will often have a shared potence. It follows that there is a connection between similarity of states and potence connectivity. We now formalize this connection.

The state of the environment is often best described as a tuple of distinct components, each accounting for a separate aspect of the system. In some models, part of the components of the state of the environment can affect only the state of a single process. For example, in a shared-memory model, if there is a variable that can be read *only* by process j, then it can affect only j. A similar situation occurs in the message-passing model, when a channel contains messages that were all sent to j. We call such components *j-components*. Clearly, in some models the environment state has no j-components. When they do exist, the following notions depend on a clear definition of these components. Two environment states are said to *agree modulo j* if they are the same except, possibly, for their j-components. We say that two states x and y *agree modulo j* if $x_i = y_i$ for all $i \neq j$ and their environment states x_e and y_e agree modulo j. The intuition is that if process j can somehow be "silenced" or if its local state can be "hidden" and not observed by others in the future, runs resulting from both states will be the same from the point of view of the other processes. In models in which there are no j-components to the environment's state, states x and y that agree modulo j differ at most in the identity of process j's local state.

DEFINITION 5.4 (similarity). *With respect to a system $\mathcal{S}$,*

(i) *states x and y are* similar*, denoted by $x \sim_s y$, if there is a process j such that* (a) *the states x and y agree modulo j and* (b) *there exists $i \neq j$ that is nonfailed in both x and y,*

(ii) *a set of states X is* similarity connected *if the graph $(X, \sim_s)$ induced by $\sim_s$ on X is connected.*

A well-known and useful property of the initial states for consensus, Con_0, is given by the following lemma.

LEMMA 5.5. *The set Con_0 is similarity connected.*

Proof. To prove that Con_0 is similarity connected we will show that every two initial states $x, y \in \mathsf{Con}_0$ are connected by a sequence of states in which each pair of neighbors are similar. Choose $x, y \in \mathsf{Con}_0$. For $0 \leq l \leq n$, define x^l by setting

$$x_j^l = \begin{cases} y_j & \forall j \leq l, \text{ and} \\ x_j & \forall j > l. \end{cases}$$

(Recall that $x_e = y_e$ by definition of Con_0.) Clearly, $x^l \in \mathsf{Con}_0$, and it is easy to check that $x^0 = x$ and $x^n = y$. Moreover, for every $0 < l \leq n$ we have that x^{l-1} and x^l agree modulo l, since the local states of the environment and of all processes, except possibly that of l, are equal. The assumption that no process is failed in an initial state (fault independence (ii)), and the fact that $n \geq 2$, imply that there is a process $i \neq l$ that is nonfailed in both x^{l-1} and x^l, and hence these two states are similar. ∎

We now formalize the intuition that similarity connectedness yields potence connectedness when processes may crash.

DEFINITION 5.6 (crashlike behavior). *Let X be a set of states of the system $\mathcal{S}$. We say that $\mathcal{S}$* displays crashlike behavior *with respect to X if the following condition holds. For every $x, y \in X$ and process j, if x and y agree modulo j, then there exist in $\mathcal{S}$ runs R^x and R^y and times $m_x, m_y \geq 0$ such that*

(i) *$r^x(m_x) = x$ and $r^y(m_y) = y$,*
(ii) *$r^x(m_x + k)$ and $r^y(m_y + k)$ agree modulo j for all $k \geq 0$, and*
(iii) *every process $i \neq j$ that is not failed in x and in y is nonfaulty in R^x and in R^y.*

It is worth noting that the abstract definition of crashlike behavior is not restricted to crash failures. What the definition requires is that the state of j may be "hidden" from the rest of the processes indefinitely from some point. This can happen in models of process failures such as crash, omission, or Byzantine failures. It can also happen in models of link failures [35] or even in some cases when a failure may simply change the local state of a process, thereby effectively corrupting or erasing its memory.

A very useful relation between potence connectedness and similarity connectedness is given by the following lemma.

LEMMA 5.7. *Let $\mathcal{S}$ be a system satisfying the decision property, and let X be a similarity connected set of states of $\mathcal{S}$. If $\mathcal{S}$ displays crashlike behavior with respect to X, then X is potence connected.*

Proof. Since similarity connectedness is the transitive closure of $\sim_s$ and potence connectedness is the transitive closure of $\sim_p$, it suffices to show that for all $x, y \in X$, if $x \sim_s y$, then $x \sim_p y$. Assume $x \sim_s y$ and $\mathcal{S}$ displays crashlike behavior with respect to $X \supseteq \{x, y\}$. Then there exists a process j such that (i) the states x and y agree modulo j and (ii) there exists a process $i \neq j$ that is nonfailed in both x and y. Since $\mathcal{S}$ displays crashlike behavior with respect to $\{x, y\}$, part (i) implies that there exist in $\mathcal{S}$ runs R^x and R^y and times $m_x, m_y \geq 0$ such that (a) $r^x(m_x) = x$ and $r^y(m_y) = y$, (b) $r^x(m_x + k)$ and $r^y(m_y + k)$ agree modulo j for all $k \geq 0$, and (c) every process $i \neq j$ that is nonfaulty in x and in y is nonfaulty in R^x and in R^y. Moreover, by (ii), there is at least one such nonfaulty process i. Since $\mathcal{S}$ satisfies the decision requirement, process i eventually decides in both runs. Let w be the value that i decides in R^x. Because $\mathtt{d}_i$ is write-once and appears in all local states of i, and since $r^x(m_x + k)_i = r^y(m_y + k)_i$ for all $k \geq 0$, we conclude that process i decides on w in R^y as well. It follows that both x and y are w-potent, and hence $x \sim_p y$. ∎

Notice that Lemma 3.8 holds also for a general model M. Also, recall from the

proof of Lemma 3.9 that when decision and validity hold, the initial state with all initial values 0 is 0-potent, while the one with all values 1 is 1-potent; this holds in the generic setting due to fault independence. Thus, an immediate consequence of Lemmas 3.8, 5.5, and 5.7 is a generalization of the well-known fact from [20] that when even a single process can crash, there must be a bipotent initial state for consensus.

THEOREM 5.8. *Let $\mathcal{S}$ be a system for consensus satisfying the decision and validity conditions. If $\mathcal{S}$ displays crashlike behavior with respect to Con_0, then there is a bipotent initial state in $\mathcal{S}$.*

6. Layering. In section 3.1 we defined a set of layers to facilitate the analysis of particular well-behaved runs of the shared-memory model. We now consider a similar operation for general models. Recall that given a finite execution R we denote by $R \odot \epsilon$ the execution that results from extending R by having the environment perform $\epsilon = (\mathsf{Sched}, a)$ in its final state. A run of $\mathcal{S} = \mathcal{S}(D, M, I)$ can thus be represented in the form $x \odot \epsilon_0 \odot \epsilon_1 \odot \cdots$, where $x \in I$ and $\epsilon_i \in \mathsf{ACT}_e$ for $i \geq 0$.

In some cases we are interested in single actions of the environment, while in others we may be interested in thinking of sequences of such actions as constituting a "round" or "layer" of the computation. In such cases, we will be interested only in those states that appear at the end of layers, and we want to ignore the intermediate states. Given a model $M = (\mathcal{G}_0, P_e, \tau, \Psi, \mathsf{FGen})$, we define a *layer* over ACT_e to be a nonempty finite sequence $\ell = \epsilon_1, \epsilon_2, \ldots, \epsilon_k$ of actions of the environment, $\epsilon_i \in \mathsf{ACT}_e$. If a protocol D is specified, given a state x, the round ℓ would lead from x to the state at the end of $x \odot \epsilon_1 \odot \epsilon_2 \odot \cdots \odot \epsilon_k = x \odot \ell$, provided each ϵ_i is an action that can be executed according to the environment protocol in the state at the end of $x \odot \epsilon_1 \odot \epsilon_2 \odot \cdots \odot \epsilon_{i-1}$. In this case we say that ℓ is *executable* at x. We denote the state at the end of the execution $x \odot \ell$ by $x \cdot \ell$.

One of the principles behind the use of layers and layerings is that we would like to ignore small steps and intermediate states and center our attention on interesting landmarks in the computation. Given a set of layers L, we define an L-*run* to be a pair $R_{\mathsf{L}} = (r_{\mathsf{L}}, \alpha_{\mathsf{L}})$, where $r_{\mathsf{L}} : N \to \mathcal{G}$ defines an infinite sequence of states of $\mathcal{G}$, and $\alpha_{\mathsf{L}} : N \to \mathsf{L}$ is a sequence of layers. We will be interested in L-runs that describe runs of a system $\mathcal{S} = \mathcal{S}(D, M, I)$. We say that a run $R = (r, \alpha)$ of $\mathcal{S}$ *corresponds to* an L-run $R_{\mathsf{L}} = (r_{\mathsf{L}}, \alpha_{\mathsf{L}})$ if there is an infinite sequence $i_0 < i_1 < \cdots < i_k < \cdots$, such that $i_0 = 0$ and for all $k \geq 0$ we have both (a) $r(i_k) = r_{\mathsf{L}}(k)$ and (b) the sequence $\alpha(i_k), \alpha(i_k + 1), \ldots, \alpha(i_{k+1} - 1)$ is exactly the layer $\alpha_{\mathsf{L}}(k)$.

Intuitively, an L-run is a run that is obtained by starting at some initial state and repeatedly performing layers of L. The run R_{L} keeps track of the specific sequence of layers used, and of the states at the end of layers. Thus, the view presented in R_{L} is that the actions that the environment performs are in the form of whole layers. It is easy to check that there can be at most one run R corresponding to a given R_{L} in the system $\mathcal{S}(D, M, I)$. Suppose that $r_{\mathsf{L}}(0) \in I$ and for every $m \geq 0$ there is an execution $x^m \odot \ell_m$ in $\mathcal{S} = \mathcal{S}(D, M, I)$, where $x^m = r_{\mathsf{L}}(m)$ and $\ell_m = \alpha_{\mathsf{L}}(m)$. In this case, there is a unique run R of D consistent with M that corresponds to R_{L}. Notice, however, that R might still not be a run of D in M, because it may fail to satisfy the fairness condition Ψ of M. We will be interested in sets L of layers in which this cannot happen.

DEFINITION 6.1. *A nonempty set L of layers is called a* layering *of a model M if, for every protocol D, the following condition holds. Every run R of D consistent with M that corresponds to an L-run R_{L} is a run of D in M.*

Notice that for every set of layers, L, we can consider the runs of a protocol D in

which the environment performs actions according to the layers in this set. A set of layers is a layering if it satisfies the property that *every* run obtained by performing an infinite sequence of layers of L must satisfy the fairness conditions imposed by M, as specified by its admissibility condition Ψ. Roughly speaking, then, each layer must carry out a sufficient amount of work to guarantee that the fairness requirements imposed by Ψ are ultimately satisfied.

Given a system $\mathcal{S} = \mathcal{S}(D, M, I)$ and a layering L of M, we define the corresponding layered system $\mathcal{S}_{\mathsf{L}} = \mathcal{S}_{\mathsf{L}}(D, M, I)$ by

$$\mathcal{S}_{\mathsf{L}} = \{R_{\mathsf{L}} \mid \text{there is a run } R \text{ of } \mathcal{S} \text{ that corresponds to } R_{\mathsf{L}}\},$$

with Faulty predicate as follows. Since every run R_{L} of $\mathcal{S}_{\mathsf{L}}$ has associated a unique run R of the original system $\mathcal{S}$, the Faulty_D predicate from M can be extended to the runs of $\mathcal{S}_{\mathsf{L}}$ by defining $\mathsf{Faulty}_D(R_{\mathsf{L}}) = \mathsf{Faulty}_D(R)$ for all runs $R_{\mathsf{L}} \in \mathcal{S}_{\mathsf{L}}$. Thus, to figure out who the faulty processes in a run of $\mathcal{S}_{\mathsf{L}}$ are, we check the corresponding run of $\mathcal{S}$. Notice, however, that fault independence of $\mathcal{S}$ does not necessarily imply fault independence of $\mathcal{S}_{\mathsf{L}}$.

DEFINITION 6.2. *A* layering L *of a model* M satisfies fault independence *if every system of the form* $\mathcal{S}_{\mathsf{L}}(D, M, I)$ *satisfies fault independence.*

There are several obvious close correspondences between $\mathcal{S}_{\mathsf{L}}$ and $\mathcal{S}$ that follow directly from the definition of $\mathcal{S}_{\mathsf{L}}$ in terms of the runs of $\mathcal{S}$. First of all, $\mathcal{S}_{\mathsf{L}}$ inherits a number of "universal" properties from $\mathcal{S}$: Each of the properties of decision, agreement, and validity is satisfied by $\mathcal{S}_{\mathsf{L}}$ if it is satisfied by $\mathcal{S}$. In the other direction, "existential" properties of $\mathcal{S}_{\mathsf{L}}$ pass on to $\mathcal{S}$: If a state x is bipotent with respect to $\mathcal{S}_{\mathsf{L}}$, then it is bipotent with respect to $\mathcal{S}$. Moreover, if R_{L} is a bipotent run of $\mathcal{S}_{\mathsf{L}}$, then the run R of $\mathcal{S}$ that corresponds to R_{L} is a bipotent run with respect to $\mathcal{S}$.

Our use of layering to prove lower bound and impossibility results for consensus will be based on the close correspondence between $\mathcal{S}_{\mathsf{L}}$ and $\mathcal{S}$. The general idea is to assume there is a protocol D solving consensus in some particular model M. An appropriate layering L for M is then defined, for which it can be shown that there is a bipotent run (or in the case of a lower bound a bipotent prefix of a run) in $\mathcal{S}_{\mathsf{L}} = \mathcal{S}_{\mathsf{L}}(D, M, \mathsf{Con}_0)$.

For every state x of $\mathcal{S}_{\mathsf{L}}$ we define $\mathsf{L}(x)$ to be the set of the successors of x in $\mathcal{S}_{\mathsf{L}}$. More formally,

$$\mathsf{L}(x) = \{x \cdot \ell \mid \ell \in \mathsf{L} \text{ and } x \odot \ell \text{ is an execution of } \mathcal{S}_{\mathsf{L}}\}.$$

Provided the layering L guarantees that $\mathsf{L}(x)$ is potence connected, we can use the following theorem to prove the existence of a bipotent run in $\mathcal{S} = \mathcal{S}(D, M, \mathsf{Con}_0)$. We can then apply Lemma 5.2 to show that the protocol D does not solve consensus.

THEOREM 6.3. *Let* L *be a layering of* M *satisfying fault independence, and let* $\mathcal{S} = \mathcal{S}(D, M, \mathsf{Con}_0)$ *be a system for consensus satisfying the decision condition. Consider the layered system* $\mathcal{S}_{\mathsf{L}} = \mathcal{S}_{\mathsf{L}}(D, M, \mathsf{Con}_0)$*, and assume that there is a bipotent initial state in* $\mathcal{S}_{\mathsf{L}}$*. If, for every state* x *of* $\mathcal{S}_{\mathsf{L}}$ *the set* $\mathsf{L}(x)$ *is potence connected in* $\mathcal{S}_{\mathsf{L}}$*, then there is a bipotent run in the original system* $\mathcal{S}$*.*

Proof. We will construct a bipotent L-run R^b_{L} in $\mathcal{S}_{\mathsf{L}}$, and the corresponding run R^b will be a bipotent run in $\mathcal{S}$. We obtain this run by starting from a bipotent initial state x^0 and constructing an infinite sequence of layers $\ell_0, \ell_1, \ldots$ from L, such that the state $x^m = x^0 \cdot \ell_0 \cdot \ldots \cdot \ell_{m-1}$ is bipotent with respect to $\mathcal{S}_{\mathsf{L}}$ for all $m \geq 0$. By construction, for all $m \geq 0$ we will have that $x^m \odot \ell_m$ is an execution in $\mathcal{S}_{\mathsf{L}}$, since it will be taken from $\mathsf{L}(x^m)$. This means that it is consistent with D and M to execute

the sequence of environment actions ℓ_m, and corresponding protocol actions starting in x^m, leading to x^{m+1}. Hence the run

$$R^b = x^0 \odot \ell_0 \odot \ell_1 \odot \cdots$$

will be a run of D consistent with M. The fact that L is a layering of M will then imply that R^b is a run of $\mathcal{S}(D, M, \mathsf{Con}_0)$. Recall that a bipotent state of $\mathcal{S}_\mathsf{L}$ is necessarily also a bipotent state of $\mathcal{S}$. Moreover, if a state of a run R is bipotent, then all states preceding x in R are also bipotent, by Lemma 5.1(i). Since there are infinitely many bipotent states in R^b (all the states x^m from the construction), it follows that all states of R^b are bipotent, so that R^b is a bipotent run of $\mathcal{S}$.

It remains to define x^0 and the sequence of layers ℓ_k. By assumption, there is a bipotent initial state in $\mathcal{S}_\mathsf{L}$. We shall choose this state to be x^0. Assume inductively we have chosen $\ell_0, \ldots, \ell_{m-1}$ so that $x^m = x^0 \cdot \ell_0 \cdot \cdots \cdot \ell_{m-1}$ is bipotent (with respect to $\mathcal{S}_\mathsf{L}$). Since x^m is bipotent, the set $\mathsf{L}(x^m)$ contains both 0-potent and 1-potent states. By assumption, $\mathsf{L}(x)$ is potence connected for every state x of $\mathcal{S}_\mathsf{L}$, and hence in particular $\mathsf{L}(x^m)$ is potence connected. It follows by Lemma 3.8 that there is a bipotent state $x' \in \mathsf{L}(x^m)$. By definition of $\mathsf{L}(x^m)$ there must also be a layer $\ell' \in \mathsf{L}$ such that $x' = x^m \cdot \ell'$. Set $\ell_m = \ell'$, and let $x^{m+1} = x^0 \cdot \ell_0 \cdot \cdots \cdot \ell_{m-1} \cdot \ell_m$. Clearly, $x^{m+1} = x^m \cdot \ell_m = x^m \cdot \ell' = x'$. It follows that x^{m+1} is bipotent, and we are done. □

We have essentially completed the description of our abstract framework for proving impossibility of consensus. Given a model M, the strategy would be to choose an appropriate layering L for M. With respect to an arbitrary protocol D, we use Theorem 5.8 to prove the existence of a bipotent initial state, and use Theorem 6.3 to extend this state into a bipotent run. Finally, from Lemmas 5.2 or 5.3 we conclude that this run is a counterexample to the decision property of consensus. We now apply this scheme to prove impossibility of consensus and lower bounds for models with synchronous message passing.

7. Synchronous message passing. We present two applications of the general framework to synchronous models: first for mobile failures and then for the classic crash failure model.

7.1. Impossibility for mobile failures. We illustrate the use of the abstract framework just described by proving a new impossibility result for consensus in the presence of a single mobile failure in the synchronous model. This model, denoted $M^\mathsf{m} = (\mathcal{G}_0^\mathsf{m}, P_e^\mathsf{m}, \tau^\mathsf{m}, \Psi^\mathsf{m}, \mathsf{FGen}^\mathsf{m})$, is described in section 4.2. Recall that M^m is the standard synchronous model with the failure assumption that in every round m there can be at most one process i_m some of whose messages are lost. The environment's protocol P_e^m is uniform in all states: nondeterministically choose a process $i \in \{1, \ldots, n\}$ and a set $T \subseteq \{1, \ldots, n\}$ and perform the action $(\{1, \ldots, n\}, (i, T))$, denoted simply by (i, T); all processes are scheduled to move in every round. The messages from i to members of T will be lost. Recall that Ψ^m makes no restrictions whatsoever: it consists of all possible runs consistent with M^m, and $\mathsf{FGen}^\mathsf{m}(D)(j, R) = \mathit{false}$ for all processes j, runs R, and protocols D.

To get the following impossibility result in M^m, we assume for contradiction that there is a protocol D solving consensus, and prove three basic claims:

(i) there exists a layering L for M^m that satisfies fault independence;
(ii) $\mathcal{S}_\mathsf{L} = \mathcal{S}_\mathsf{L}(D, M^\mathsf{m}, \mathsf{Con}_0)$ displays crashlike behavior with respect to every subset X of its states; and
(iii) for every state x in a layer of $\mathcal{S}_\mathsf{L}$, the set $\mathsf{L}(x)$ is potence connected.

The following proof establishes these claims in detail. The general scheme will be the same in the next sections (and we will not include as many details).

THEOREM 7.1. *No protocol solves the consensus problem in* M^{m}.

Proof. We start by choosing a layering for M^{m}. Each layer in this case will consist of a single action of the environment. We use $[k]$ to denote the set $\{1, \ldots, k\}$, with $[0]$ denoting the empty set. Define $\mathsf{L} = \{(i, [k]) : 1 \leq i \leq n \text{ and } 0 \leq k \leq n\}$. To see that L is a layering of M^{m}, observe that every layer is an action of the environment and the admissibility condition Ψ^{m} in this model makes no restrictions. Hence, for every protocol D, every run resulting from an infinite sequence of layers of L is immediately a run of M^{m} as desired. Moreover, L satisfies (trivially) fault independence because no processes are ever considered faulty in M^{m}.

Assume by way of contradiction that there is a protocol D solving consensus in M^{m}. Then the system $\mathcal{S} = \mathcal{S}(D, M^{\mathsf{m}}, \mathsf{Con}_0)$ is a system for consensus that satisfies decision, agreement, and validity. Given that no process is ever considered faulty in this model, we have by Lemma 5.2 that if there is a bipotent run in $\mathcal{S}$, then the decision property must fail in $\mathcal{S}$, contradicting the assumption that D solves consensus. We will complete the proof by demonstrating the existence of a bipotent run in $\mathcal{S}$ via Theorem 6.3. Hence, we next consider the layered system $\mathcal{S}_{\mathsf{L}} = \mathcal{S}_{\mathsf{L}}(D, M^{\mathsf{m}}, \mathsf{Con}_0)$.

Our next goal is to show that there is a bipotent initial state in $\mathcal{S}_{\mathsf{L}}$. Notice that, by definition of L, the environment is able to "silence" any given process j from a given state on, simply by performing the layer $(j, [n])$ in all subsequent rounds. The other processes will have no way to learn anything about j's state. It immediately follows that $\mathcal{S}_{\mathsf{L}}$ displays crashlike behavior with respect to every subset X of its states. More precisely, we verify that Definition 5.6 holds. Let x, y be two states in a layer of $\mathcal{S}_{\mathsf{L}}$, such that x and y agree modulo j. Let $\hat{R}^x$ and $\hat{R}^y$ be prefixes of L-runs ending in x and y, respectively. Then the L-runs $R^x = \hat{R}^x \odot (j, [n])^\infty$ and $R^y = \hat{R}^y \odot (j, [n])^\infty$ are in $\mathcal{S}_{\mathsf{L}}$. Letting $R^x = (r^x, \alpha^x)$ and $R^y = (r^y, \alpha^y)$, it is straightforward to verify that there are times $m_x, m_y \geq 0$ such that

(i) $r^x(m_x) = x$ and $r^y(m_y) = y$,
(ii) $r^x(m_x + k)$ and $r^y(m_y + k)$ agree modulo j for all $k \geq 0$, and
(iii) every process $i \neq j$ that is not failed in x and in y is nonfaulty in R^x and in R^y.

Recall that $\mathcal{S}$ is a system for consensus satisfying decision and validity. As mentioned above, $\mathcal{S}_{\mathsf{L}}$ inherits these properties from $\mathcal{S}$. It now follows from Theorem 5.8 that there is a bipotent initial state in $\mathcal{S}_{\mathsf{L}}$.

We are finally in a position to apply Theorem 6.3 to derive the existence of a bipotent run R^b in $\mathcal{S}_{\mathsf{L}}$. To do so, we still need to show that for every state x of $\mathcal{S}_{\mathsf{L}}$, the set $\mathsf{L}(x)$ is potence connected. For every pair of processes j, j' we have that $x \cdot (j, [0]) = x \cdot (j', [0])$ because in both cases no messages are lost in the round following x. It follows that $x \cdot (j, [0]) \sim_s x \cdot (j', [0])$. Moreover, for every $k < n$ we have that $x \cdot (j, [k]) \sim_s x \cdot (j, [k+1])$, because the two states can differ only in the state of process $k + 1$. It follows that $\mathsf{L}(x)$ is similarity connected for all x. That $\mathsf{L}(x)$ is potence connected now follows from Lemma 5.7, since $\mathcal{S}$ displays crashlike behavior with respect to $\mathsf{L}(x)$. We thus obtain that there exists a bipotent run R^b in $\mathcal{S}_{\mathsf{L}}$, and the run of $\mathcal{S}$ that corresponds to R^b is bipotent with respect to $\mathcal{S}$, as desired. ∎

Theorem 7.1 illustrates the fact that it doesn't take much to make consensus impossible. The adversary in M^{m} has fairly limited powers. Furthermore, we obtained the impossibility with a layering that restricts the adversary even more. We remark that this result can be obtained by a modification of the proof of a theorem by Santoro

and Widmayer in [35]. Their analysis involved attaining consensus in the presence of communication link failures. Their proof is the only one we have found that predates this paper and that uses a bipotence-based argument in the style of Fischer et al. [20] in the synchronous context.

7.2. The synchronous lower bound. The analysis we performed for the mobile failure model M^{m} in the synchronous case should, intuitively, apply equally well to the standard t-resilient case in the synchronous model. In this model there is a bound of t on the total number of processes who may fail in the run, and a process some of whose messages are lost is considered faulty. The well-known lower bound for this case (originally due to [18, 15]) states that every consensus protocol must require at least $t + 1$ rounds in its worst-case run. Roughly speaking, any prefix consisting of t rounds of a run of M^{m} can be viewed as a prefix of a run in the standard omissions failure model with at most t failures. (Formally, the only modification required would be to have the environment's state record processes that have omitted in the past.) The impossibility of solving consensus in M^{m} therefore immediately implies that there can be no protocol solving consensus in t rounds in the omissions model. For if one existed, it would also solve consensus in M^{m}. This argument immediately implies the $(t+1)$-round lower bound for the omissions and Byzantine failure models. We cannot, however, use the impossibility for M^{m} to derive the lower bound for the crash failure model. Nevertheless, even in the crash failure model one might expect to prove that there will exist a bipotent state at the end of round t, and thus derive the $(t + 1)$-round lower bound just as in our analysis for M^{m}. A close inspection, however, shows that things are not *that* simple. There will typically not need to be a bipotent state at the end of round t. But the essence of this idea still works.

We shall now provide the lower bound analysis for the crash failure model and a number of related failure models at once. We assume the failure model satisfies the following: (i) in the first round in which a process fails, the environment can block the delivery of an arbitrary subset of its messages; (ii) the environment can silence a faulty process forever in all rounds after the first one in which it fails; and (iii) the environment's local state keeps track of the processes that have failed. It is easy to check that it satisfies fault independence. The layers we will focus on will consist of single environment actions, each corresponding to a single round of the synchronous model. Specifically, we consider two kinds of actions by the environment:

- clean This environment action, applicable at all states, involves no new process failure. Messages of failed processes are not delivered, but all messages of nonfailed processes are delivered.
- (j, k) This action is applicable to a state x only if fewer than t processes are failed at x, and process j is not failed at x. As before, messages of failed processes are not delivered, while all messages of nonfailed processes other than j are delivered. The messages of j act as with the action $(j, [k])$ in M^{m}: Those addressed to processes up to and including k are not delivered, while the others are delivered.

We denote the layering consisting of all actions of these types by L^t. Notice that the number of processes that fail in a run of $\mathcal{S}_{\mathsf{L}^t}$ is at most t, since once t processes are failed at a state, all later layers will be clean. It is now straightforward to show the following.

LEMMA 7.2. *Let M be one of the standard synchronous t-resilient models with either crash, omission, or Byzantine failures. Let D be a protocol for the processes in the model M, and let $\mathcal{S} = \mathcal{S}(D, M, \mathsf{Con}_0)$. Finally, let x be a state of $\mathcal{S}_{\mathsf{L}^t}$. Then*

(i) L^t *is a layering of* M *that satisfies fault independence;*
(ii) *for every state* x *of* $\mathcal{S}_{\mathsf{L}^t}$ *the set* $\mathsf{L}^t(x)$ *is similarity connected; and*
(iii) *if no more than* $t-2$ *processes are failed at* x, $\mathsf{L}^t(x)$ *is potence connected.*

Proof. For part (i), recall that in a run of $\mathcal{S}_{\mathsf{L}^t}$ the number of failed processes does not exceed t. Moreover, every L^t action is a legal action for the environment in the model M. It follows that L^t is a layering of $\mathcal{S}$. Also, it is easy to check fault independence.

Part (ii) follows the pattern from M^{m}: If t processes are failed at x, then the set $\mathsf{L}^t(x)$ consists of the singleton state $x \odot \mathsf{clean}$ and is hence trivially similarity connected. If fewer than t processes are failed at x, then $\mathsf{L}^t(x) = \{x \odot \mathsf{clean}\} \cup \{x \odot (j,k) | j \text{ not failed in } x\}$. It is straightforward to check that $x \odot (j,k) \sim_s x \odot (j,k+1)$ for all j and $k < n$; additionally, $x \odot \mathsf{clean} \sim_s x \odot (j,0)$. It follows that $\mathsf{L}^t(x)$ is similarity connected in either case.

Finally, for part (iii), notice that $\mathcal{S}_{\mathsf{L}^t}$ displays crashlike behavior with respect to every set X consisting of states in each of which at most $t-1$ processes are failed. Since an L^t-action fails at most one new process, if at most $t-2$ processes are failed in x, then $\mathsf{L}^t(x)$ is similarity connected by part (ii), and at most $t-1$ processes are failed in any given state of $\mathsf{L}^t(x)$. It now follows from Lemma 5.7 that $\mathsf{L}^t(x)$ is potence connected and we are done. ∎

We thus have the following lemma.

LEMMA 7.3. *Consider the system* $\mathcal{S}_{\mathsf{L}^t} = \mathcal{S}_{\mathsf{L}^t}(D, M, \mathsf{Con}_0)$. *Let* x^0 *be a bipotent state in a layer of* $\mathcal{S}_{\mathsf{L}^t}$ *in which no more than* f *processes are failed. Then there is an* L^t*-execution with states* $x^0, x^1, \ldots, x^{t-f-1}$, *such that* x^{t-f-1} *is bipotent and no more than* $t-1$ *processes are failed in* x^{t-f-1}.

Proof. We prove by induction on m, for $0 \le m \le t-f-1$, that an execution of the desired form exists, with x^m bipotent and where no more than $m+f$ processes are failed in x^m. The basis $m=0$ holds by assumption. Assume inductively that the claim holds for $m < t-f-1$. Thus, we have that $m+f < t-1$ processes are failed in x^m. By Lemma 7.2(iii) we have that $\mathsf{L}^t(x^m)$ is potence connected, and by an argument similar to the one in the proof of Theorem 6.3, there is a bipotent state $x^{m+1} \in \mathsf{L}^t(x^m)$. By definition of L^t, the number of failed processes in x^{m+1} is at most $m+f+1 \le t$. ∎

Since Theorem 5.8 guarantees the existence of a bipotent initial state with $f=0$ failed processes, Lemma 7.3 immediately implies the existence of a bipotent state x^{t-1} at the end of round $t-1$. By Lemma 5.3, this gives us a t-round lower bound for consensus. The true $(t+1)$-round lower bound is obtained by showing that two rounds are still necessary after a bipotent state.

LEMMA 7.4. *Under the conditions of Lemma* 7.2, *assume that* $t \le n-2$ *and let* D *be a protocol for consensus. If* $\hat{x}$ *is a bipotent state in a layer of* $\mathcal{S}_{\mathsf{L}^t}$, *then there is a state* $y \in \mathsf{L}^t(\hat{x})$ *in which at least one nonfailed process has not decided.*

Proof. Notice that a state x with t failed processes cannot be bipotent, since there is a unique infinite L^t extension starting at x. Hence, to be bipotent, the state $\hat{x}$ can have no more than $t-1$ failed processes. By Lemma 7.2(ii), we have that $\mathsf{L}^t(\hat{x})$ is similarity connected. Since $\hat{x}$ is bipotent, there are states $y^0, y^1 \in \mathsf{L}^t(\hat{x})$ such that y^0 is 0-potent and y^1 is 1-potent. The similarity connectivity of $\mathsf{L}^t(\hat{x})$ implies the existence of states $z^0, z^1 \in \mathsf{L}^t(\hat{x})$ (not necessarily distinct) satisfying $z^0 \sim_s z^1$ that are 0- and 1-potent, respectively. Recall that all states of $\mathcal{S}_{\mathsf{L}^t}$ have at most t faulty processes. Since $t \le n-2$ and z^0 and z^1 agree modulo j for some j, it follows that there is at least one process $i \ne j$ such that i is not failed in both states and $z_i^0 = z_i^1$. Assume by way of

contradiction that every nonfailed process is decided in both z^0 and z^1. In particular, i is decided, say with value v. Agreement implies that in both states, every nonfailed process decides v. It follows that both z^0 and z^1 are v-potent, and neither of them is $(1-v)$-potent, contradicting the assumption that one of them is 0-potent and the other is 1-potent. □

We can now put the two results together and obtain the desired lower bound.

THEOREM 7.5. *Let $t \leq n-2$. Every t-resilient protocol for consensus in synchronous models where faulty processes can either crash, omit, or behave in a Byzantine fashion has a run in which decision requires at least $t+1$ rounds. Moreover, for $t = n-1$, every such protocol has a run in which decision requires at least t rounds.*

This result was first proved for crash failures by Dolev and Strong [15], and the latest version of the proof is in [16]. Our proof here is the first one we are aware of that is in the style and spirit of the impossibility proofs for the asynchronous case.[7] Moreover, we feel that it is even simpler than the one of [16]. In addition to generalizing the lower bound for t-resilient consensus, we feel that our proof provides further insight into the structure of consensus protocols in this model. Let us briefly consider an example. It is well known [33] that there are t-resilient consensus protocols that are guaranteed to decide in precisely $t+1$ rounds. Thus, the worst-case lower bound of Dolev and Strong is tight. We call a protocol in which consensus is always reached in at most $t+1$ rounds *fast*. We can now show the following.

LEMMA 7.6. *Let D be a fast t-resilient consensus protocol. For every execution with states $x^0, x^1, \ldots, x^k, x^{k+1}$ of D, if at most k processes have failed by x^k, and the $(k+1)$st round is failure-free, then x^{k+1} cannot be bipotent.*

Proof. By assumption, only k processes have failed by x^{k+1}. If x^{k+1} is bipotent, then by Lemma 7.3 it can be extended to a run with a bipotent state x^t at the end of t rounds. By Lemma 7.4, two more rounds are necessary for agreement in the worst case, contradicting the assumption that D is fast. □

Clearly, Lemma 7.3 also partially describes the situation in runs in which potentially more than one process can crash in a given round. It matches the upper (and lower) bounds given in [16], which show roughly that if in some execution $k+w$ crashes are detected by the end of round k, then agreement can be secured by the end of round $t+1-w$. Hence, by allowing $k+w$ crashes by the end of round k, the environment has essentially "wasted" w faults in its quest to delay agreement. Lemma 7.3 guarantees that the environment has not lost more than w rounds in this case.

8. Asynchronous message passing. In section 3 we illustrated the layering technique by proving impossibility of consensus in the asynchronous shared memory model. The proof was based on a "permutation layering," in which processes move one at a time and there is very little concurrency. Our proof of impossibility for M^{m}, on the other hand, considered every synchronous round to be a layer, and such a layer contains a great deal of concurrency. In this section we apply our framework to prove impossibility for the asynchronous message-passing model. We will give two proofs: one using a permutation layering based on the proof of section 3 and the other using a "synchronic layering," which is very close to the layering used in the synchronous model M^{m}. We do this to illustrate the closeness of the different models and to show the choice and flexibility that are often provided by the layering technique.

[7] We have recently been informed that Aguilera and Toueg [2] have independently and slightly later given a proof for this result using a bipotence argument. The structure of their proof is similar to ours. Bar-Joseph and Ben-Or also reported having found some of the arguments in [7].

As we have already seen in the shared-memory case, in asynchronous models "slow" behavior of processes can be used to imitate the omitting behavior in M^{m}. The small but crucial difference now will be that, in the asynchronous model, delayed messages will nevertheless eventually be delivered or, similarly, a slow process that is about to write a variable will ultimately write the value. In the synchronous model M^{m}, the lost messages are gone forever. Hence, to perform a careful analysis of the round by round evolution, we need to consider as part of the state (i.e., in the environment's local state) the status of the messages in transit or, similarly, the current values of shared variables. In this sense, our treatment goes slightly beyond the scope of most of the recent work on topological approaches, in which the state of the environment does not play a role, and asynchronous message-passing models are often somewhat subtle to deal with.

Consider the standard (see, for example, [20, 31]) asynchronous message-passing model M^{mp} in which processes communicate by message passing and both processes and communication are asynchronous. A process is faulty if it is scheduled to move only a finite number of times in an infinite run. The celebrated result of Fischer, Lynch, and Paterson [20] proving the impossibility of solving consensus in the presence of a single crash failure was carried out in this model. In the asynchronous message-passing model M^{mp}, an action for i is a pair: it contains a local action on the variables of the local state, and a communication action, which is either skip_i that does nothing, or is a $\mathsf{send}_i(j, m)$ action, specifying the sending of the message m to process j. The effect of a $\mathsf{send}_i(m, j)$ action is to change the environment's state by recording the new message as being in the channel between i and j. For the definition of similarity among states in this model, we consider the j-component of the environment's state to consist of the set of channels whose destinations are process j. Since channels are point-to-point in this model, components corresponding to different processes are disjoint. The environment's actions consist of either scheduling a process i to move, or delivering a set of one or more messages that have been sent and not yet delivered to their destination. The fairness conditions in this model are that (a) at most one process can fail in any given run and (b) every message that is sent to a process that does not fail in the run must eventually be delivered.

In this model we consider a layering L^{mp} consisting of all layers of the following three types:

- $[p_1, \ldots, p_n]$,
- $[p_1, \ldots, p_{n-1}]$, and
- $[p_1, \ldots, p_{k-1}, \{p_k, p_{k+1}\}, p_{k+2}, \ldots, p_n]$ with $k < n$.

The first two layers are of the same form as in the layering L^{rw} for the shared-memory model. In a layer of L^{mp}, when a process i is scheduled to *move* it first performs its action, and then it receives all the messages that have been sent to i by that point and have not yet been delivered (if any exist). The third type of layer is considered a *full* layer, since it involves all processes as the first type does. In this case, the processes take steps in the linear order given by the sequence, except that p_k and p_{k+1} move *concurrently*. Thus, a message sent by one of these two processes to the other will not be delivered in the current layer. The reason we use the new third type of layer is that with this particular layering, a transposition in a layer of the first two types can change the local state of both p_k and p_{k+1}. Whereas in the case of L^{rw} a move by a process involved either a read or a write, in L^{mp} when a process moves it may both send a message and receive messages. Adding a layer of the third type enables us to take smaller steps, in which at most one process at a

time will change its state. We identify a layer of the first type with the corresponding permutation on $\{1,\ldots,n\}$. For a permutation $\pi = [p_1,\ldots,p_n]$, we denote the layer $[p_1,\ldots,p_{k-1},\{p_k,p_{k+1}\},p_{k+2},\ldots,p_n]$ of the third type by $\pi_{\{k,k+1\}}$. Notice that the set notation in layers of the third type is justified, since the exact same sequence of operations occurs in $\pi_{\{k,k+1\}}$ and $\pi_{\{k+1,k\}}$. Hence, for every state x of $\mathcal{S}_{\mathsf{L}^{mp}}(D)$ and permutation π we have that $x \cdot \pi_{\{k,k+1\}} = x \cdot \pi_{\{k+1,k\}}$.

We can show the following.

LEMMA 8.1. *Let D be a protocol for the processes in the model M^{mp}.*

(i) *L^{mp} is a layering of M^{mp} that satisfies fault independence;*

(ii) *$\mathcal{S}_{\mathsf{L}^{mp}} = \mathcal{S}_{\mathsf{L}^{mp}}(D, M^{mp}, \mathsf{Con}_0)$ displays crashlike behavior with respect to every subset X of its states; and*

(iii) *for every state x in a layer of $\mathcal{S}_{\mathsf{L}^{mp}}$, the set $\mathsf{L}^{mp}(x)$ is potence connected.*

Proof. (i) Let R be an L^{mp}-run. By definition, R consists of an infinite sequence of layers from L^{mp}. Since in each layer L of L^{mp} at least $n-1$ processes move, in an infinite number sequence there can be at most one process that fails to take an infinite number of steps. It follows that at most one process can be faulty in R. Since a process that moves receives all of the pending messages sent to it, all messages sent to nonfaulty processes in R are delivered. It follows that the run R' that corresponds to R is admissible. It is, in addition, easy to check that L^{mp} satisfies fault independence, since M^{mp} satisfies no finite failure.

Part (ii) follows from the fact that the environment can halt the operation of an arbitrary process j at any given state by repeatedly performing layers of the form $[1,2,\ldots,j-1,j+1,\ldots,n]$ from that state on.

It remains to show part (iii). First notice that just as in the case of L^{rw} we have that

$$x \cdot [p_1,\ldots,p_{n-1}] \cdot [p_n,p_1,\ldots,p_{n-1}] \quad = \quad x \cdot [p_1,\ldots,p_n] \cdot [p_1,\ldots,p_{n-1}],$$

since in both cases exactly the same actions take place in the same order in the two layers following x. Lemma 5.1(ii) implies that $x \cdot [p_1,\ldots,p_n] \sim_p x \cdot [p_1,\ldots,p_{n-1}]$, and it follows that every state of $\mathsf{L}^{mp}(x)$ obtained from x by a layer of the second type is potence connected to a state obtained by a (full) layer of the first type. Let X_f be the subset of $\mathsf{L}^{mp}(x)$ consisting of states of the form $x \odot \mathsf{L}$, where L is a full layer. It remains to show that X_f is potence connected. Since, by part (ii), $\mathcal{S}_{\mathsf{L}^{mp}}(D)$ displays crashlike behavior with respect to X_f, Lemma 5.7 implies that it suffices to show that the set X_f is similarity connected.

We first claim that, for a full layer $L = \pi$ of the first type and an index $k < n$, we have that

$$x \cdot \pi \quad \sim_s \quad x \cdot \pi_{\{k,k+1\}}.$$

To see why, recall that according to the environment's actions in a layer of the types we are considering, a process that is scheduled first performs its action and then receives the messages that were sent to it and are still in transit. Thus, the actions of a process p_j in the layer $x \odot \pi$ depend only on p_j's local state in x. It now follows that every process p_i with $i \neq k+1$ performs the same actions and receives the same messages in the layer following x in both $x \odot \pi$ and $x \odot \pi_{\{k,k+1\}}$. The only process whose state at the end of the layer may differ in the two cases is p_{k+1}. If p_k sends p_{k+1} a message, it will be delivered in the first case and will remain in the channel from p_k to p_{k+1} in the second case. Since the channel from p_k to p_{k+1} is part of the

p_{k+1}-component of the environment's state,[8] the two states agree modulo p_{k+1} and are thus similar. The claim follows.

Finally, we use this last claim to argue as in the shared-memory case. Recall (proof of Lemma 3.5) that $\mathsf{Tr}(k,\pi)$ is the permutation obtained by transposing the kth and $(k+1)$st elements in π. Since the order of the concurrent processes in a layer of the third type is immaterial and since $\pi_{\{k+1,k\}} = \mathsf{Tr}(k,\pi)_{\{k,k+1\}}$ we obtain

$$x \cdot \pi \quad \sim_s \quad x \cdot \pi_{\{k,k+1\}} \quad = \quad x \cdot \pi_{\{k+1,k\}} \quad = \quad x \cdot \mathsf{Tr}(k,\pi)_{\{k,k+1\}} \quad \sim_s \quad x \cdot \mathsf{Tr}(k,\pi),$$

and we are done, since any layer of the first type can be transformed into any other by a sequence of transpositions. □

Given Lemma 8.1, we can use Theorem 6.3 which, together with Theorem 5.8 and Lemma 5.2, now yields the following.

THEOREM 8.2. *No protocol solves the consensus problem in M^{mp}.*

Observe that the layers in a given layering need not be of the same length. Indeed, we saw both full and nonfull layers being used in the permutation layerings above. In addition, in the permutation layerings we discussed above each process performed at most one action in a layer. This was chosen for simplicity. In [32], other variants of permutation layerings are given in which a process may perform many actions in a layer.

8.1. A synchronic layering. We now sketch a second type of layering for the asynchronous models we have considered. This one, which we call the *synchronic* layering, imitates the synchronous model and yields layered systems of M^{mp} whose runs are very close in structure to those of M^{m}. We shall describe it for the message-passing model, and a completely analogous treatment works for the asynchronous shared memory model sketched in section 3 as well.

The synchronic layering, denoted by L^s, is defined as follows. The layers are denoted by (j,A) or (j,k) with $1 \le j \le n$ and $0 \le k \le n$. In the sequence (j,A), all processes except j move, and then they all receive whatever outstanding messages are addressed to them (including messages that have just been sent). The "A" in (j,A) stands for process j being *absent* from the layer. In an action of the form (j,k), all n processes move simultaneously, and then all outstanding messages to the processes are delivered as before, with one exception: If j's current action is $\mathsf{send}_j(\ell,m)$ and $\ell \le k$, then this message remains outstanding and is not delivered. Notice that the actions $(j,0)$ are all identical and independent of j; they are written this way for ease of exposition. We think of j as being the "slow" process in the layer defined by (j,n) or (j,A).

As with the permutation layering, a layer in the synchronic case contributes sufficiently to the fairness requirements made by the model: At least $n-1$ processes get to move in every layer, and all messages that have been sent by the previous layer to a process that moves are guaranteed to be delivered by the end of the current layer. It follows that L^s is a layering of M^{mp}, and it is easy to check that it satisfies fault independence. Crashlike behavior is immediate as well. To complete the impossibility argument, one needs to show that $\mathsf{L}^s(x)$ is potence connected. The argument for this uses elements from the proof for M^{m} and from the proof in the case of permutation layerings. For every j and every $k < n$, the states $x \odot (j,k)$ and $x \odot (j,k+1)$ agree

[8] This is the place where we make use of the notion of j-component in the definition of similarity. Intuitively, we expect this will be needed whenever message-passing models are considered, in which messages can be delayed in the channels for more than one "round."

modulo process $k+1$; they can differ at most in the state of $k+1$ and of the channel from j to $k+1$, which is part of the $k+1$-component of the state. It follows that the set of states of the form $x \odot (j,k)$ is similarity connected, and by Lemma 5.7 this set is also potence connected.

The argument that all of $\mathsf{L}^s(x)$ is potence connected uses the diamond property that

$$x \odot (j,n) \odot (j,A) \quad = \quad x \odot (j,A) \odot (j,0).$$

To see why this equality is true, notice that in both $x \odot (j,n)$ and $x \odot (j,A)$ no process receives a message from j in the last round. These messages are sent, based on j's local state in x, in the last round of $x \odot (j,n)$, but are only received in the following round. In the last round of $x \odot (j,A) \odot (j,0)$ process j sends messages to everyone, and these messages are all received in that round. Notice, however, that these messages are sent before j has received any new messages following the state x. Hence, the messages it sends are again based on j's local state in x. It follows that the same messages are sent by j in the last round of $x \odot (j,A) \odot (j,0)$ and in the last round of $x \odot (j,n)$. Moreover, in both cases these messages are received in the second round following x. It follows that $x \odot (j,n) \odot (j,A)$ and $x \odot (j,A) \odot (j,0)$ are equal.

9. Conclusions. Roughly speaking, we have seen that invariably, when the processes follow a protocol D in a given model M, the environment has a simple best strategy to delay consensus: Start with a bipotent state and, for as long as possible, find a layer that will cause a transition from the current bipotent state to a successor state that is also bipotent. If there exists a layering function L for which $L(x)$ can be shown to be potence connected for all x, then we obtain impossibility. For lower bounds the analogy is almost (but not quite) complete.

Interestingly, some of the layering functions for the different models turn out to be extremely similar. Moreover, we believe that the vast majority of lower bounds and impossibility results for consensus in the different models can be cast in terms of such layering functions, with essentially the same proof. We feel that this uniformity provides new insight into the inherent structure of the consensus problem and helps pinpoint, in a fairly model-independent way, the reason why consensus is difficult.

Our analysis emphasized and focused on the role of connectivity in the structure of consensus. Indeed, it is straightforward to convert our proofs of the existence of a bipotent state to ones that show the following, roughly: For a set X of states and a layering function L, define $L(X) = \cup_{x \in X} L(x)$. Let $X_0 = \mathsf{Con}_0$, and inductively define $X_{k+1} = L(X_k)$. The proof of Lemma 5.8 shows that X_0 is similarity connected and potence connected (in the presence of a single failure). For the layering functions we have been discussing it is not hard to modify our proofs to show that, roughly, if X_k is potence connected then so is X_{k+1}. Therefore, we have two possible styles of proofs. First is the FLP [20] style, which we followed in the paper. The strategy in this case is to show that there is a bipotent initial state and then find a sequence of successor bipotent states by proving *locally* the connectivity of the successors of a bipotent state. The other, more *global*, type of proof is closer to the topological approach of works such as [10, 26, 23, 34] and, in particular, [24]. It shows that each layer X_k is connected, and since it has at least one 0-potent and one 1-potent state, then it must have a bipotent state. The connectivity of these sets is essentially a topological property (although clearly the analysis involves no deep topology). As long as these sets are connected, Lemma 3.8 guarantees that there is a bipotent state in the set.

In this paper we dealt with consensus only, but the connectivity properties we prove hold for arbitrary decision problems as well, and we pursue this line further in a sequel paper (as described in [32]), where we show how our work generalizes the necessary conditions of [8] to other models, perhaps more remarkably to the synchronous model.

It is often useful to ask what knowledge [17] about the state is required by a process in order to be able to reach a decision. We note that once the protocol is fixed, as long as the state is bipotent, even an observer with complete information about the state cannot determine the final outcome. In a precise sense, no knowledge about the actual state can help the process decide at that point. Indeed, this has been formally captured in Lemma 5.3. Once the state ceases to be bipotent (and becomes "unipotent"), however, information about the state can be of use in determining what value a process should decide on. In fact, the proof of Lemma 7.4 shows that at the first instant along a run in which the state ceases to be bipotent in the t-resilient synchronous case, there are often many processes who have insufficient knowledge to be able to decide. An additional round is sufficient for providing them with this knowledge, in which case they can safely decide. In summary, as long as the state is bipotent, there are "structural" reasons why decisions cannot be taken. After that, the reasons merely involve disseminating the relevant information to all relevant parties. In particular, in the $(t+1)$-round lower bound (Theorem 7.5), t rounds are paid on account of topological reasons (the need to disconnect the set of global states), while an additional round is paid on account of the insufficient knowledge available after t rounds. A similar phenomena may occur in other topology-related problems, such as the k-set consensus problem in the synchronous case [14], where the tight lower bound is $\lfloor t/k \rfloor + 1$ rounds.

Acknowledgments. We would like to thank Juan Garay for bringing to our attention the mobile failure model and the related reference [35]. Special thanks to Eric Ruppert for pointing out an error in the definition of the message-passing asynchronous layering in [32]. We thank Marcos Aguilera, Bernadette Charron-Bost, Idit Keidar, and the referees for a very careful reading of an earlier version of the paper and many useful comments.

ON BINARY SEARCHING WITH NONUNIFORM COSTS*

EDUARDO S. LABER†, RUY L. MILIDIÚ†, AND ARTUR A. PESSOA†

Abstract. Let us consider an ordered vector $A[1:n]$. If the cost of testing each position is similar, then the standard binary search is the best strategy to search the vector. This is true in both the average and worst case. However, if the costs are nonuniform, then the best strategy is not necessarily the standard binary search. The best algorithm to construct a strategy that minimizes the expected search cost runs in $O(n^3)$ time and requires $O(n^2)$ space. The same complexities hold for the best algorithm to construct a strategy that minimizes the worst case search cost.

Here, we show how to efficiently construct search strategies that are at most at a constant factor from the optimal one. These constructions take linear time and use only linear space. For both the problem of minimizing the expected search cost, under uniform access probabilities, and the problem of minimizing the worst case search cost, we present algorithms that require $O(n)$ space and give a $(2+\epsilon+o(1))$-approximated solution in $O(n)$ time for any fixed value of $\epsilon > 0$.

1. Introduction.

Let $A = [a_1 < \cdots < a_n]$ be an ordered list of keys with each key having an associated access cost $c(a_i)$. Any search strategy for A can be represented by a binary search tree (BST) with n nodes, where each node corresponds to a key of A. Let $N(a_i, T)$ be the set of ancestors of node a_i in a BST T. The cost of searching a key a in a BST T is defined by

$$\sum_{x \in N(a,T)} c(x).$$

The average cost problem (ACP) for the input list A consists of finding a BST T^* that minimizes the expected search cost

$$EC(T) = \frac{1}{n} \sum_{i=1}^{n} \sum_{x \in N(a_i,T)} c(x) \tag{1}$$

in the set of all BSTs for A. Observe that we are assuming uniform access probabilities. We can discard the $1/n$ factor and reformulate the ACP as follows: find a BST T^* that minimizes the search cost

$$c(T) = \sum_{i=1}^{n} \sum_{x \in N(a_i,T)} c(x) \tag{2}$$

in the set of all BSTs for A.

On the other hand, the worst cost problem (WCP) for the input list A consists of finding the BST T^* that minimizes the worst case access cost

$$w(T) = \max_{i=1,\ldots,n} \left\{ \sum_{x \in N(a_i,T)} c(x) \right\} \tag{3}$$

in the set of all BSTs for A. Throughout this paper, we assume without loss of generality that $\sum_{i=1}^{n} c(a_i) = 1$.

Although the problem of searching a sorted array with nonuniform access costs is a basic problem, an efficient solution for it (in the sense of many applications) is not known. In [3], Knight uses dynamic programming to devise an $O(n^3)$ time algorithm that requires $O(n^2)$ space to construct a search strategy that minimizes the expected access cost, where n is the number of array positions. His motivation is to solve a filter design problem. Knight also considers the particular cost structure where the cost of accessing the ith key is $c_i = i^k$ for a fixed integer value of k. In this case, he proves that the expected cost of a standard binary search is at most at a constant factor from the expected cost of an optimal strategy.

In [7], Navarro et al. considered a more general problem, where the access cost of a position depends on the previously accessed position. Their motivation was to minimize the time spent by the disk head during a search on a text indexed by a suffix array. If the disk head is on track i, then it requires time $c(i, j)$ to go to track j. They also used dynamic programming to devise two algorithms: one to minimize the expected search cost and another to minimize the worst case search cost. Both algorithms run in $O(n^3)$ time with $O(n^2)$ space requirement. For a particular cost structure that arises on a tape search problem, Wachs [9] extended Yao quadrangle inequalities [10] to obtain an $O(n^2)$ time algorithm to construct an optimal search strategy.

As far as we know, all the algorithms proposed to construct optimal strategies for searching on a sorted array with nonuniform costs are based on dynamic programming. As a consequence, they do not give much insight on the combinatorial structure of the optimal search strategy. Moreover, these algorithms run in $\Omega(n^2)$ time, which is extremely slow for several applications. On the other hand, simpler and faster strategies, such as the standard binary search or a greedy strategy that always accesses the "cheapest" position, achieve only good results for particular cost structures. In a recent paper [5], the authors proposed an $O(n^2)$ time algorithm that constructs a strategy whose expected cost, under uniform access probabilities, is at most at a $O(\log n)$ factor from the optimal one. In this case, no particular cost structure is assumed.

1.1. Results. In this paper, our major contribution is to efficiently construct search strategies that are at most at a constant factor from the optimal one without assuming anything about the cost structure. These constructions take linear time and use only linear space.

We propose two algorithms: ACT and WCT. ACT requires $O(n)$ space and gives a $(2+\epsilon+o(1))$-approximated solution for the ACP in $O(n)$ time for any fixed value of $\epsilon > 0$. On the other hand, WCT also requires $O(n)$ space and gives a $(2 + \epsilon + o(1))$-approximated solution for the WCP in $O(n)$ time for any fixed value of $\epsilon > 0$.

1.2. Notation. Let L be a contiguous sublist of the input list A. We use the following notation throughout this paper:

$c(L)$: search cost of the BST constructed by ACT for the sublist L;
$w(L)$: worst case cost of the BST constructed by WCT for the sublist L;
ACP(L): average cost problem (ACP) for the input sublist L;
WCP(L): worst cost problem (WCP) for the input sublist L;
$c^*(L)$: search cost of an optimal solution for ACP(L);
$w^*(L)$: worst case access cost of an optimal solution for WCP(L).

A strictly BST is a BST where every internal node has exactly two children. The level of a node v in a BST T is the number of edges in the path that connects v to the root of T. Let us define the concept of ancestor in a tree. Every node is an ancestor of itself. If s is a node, then the parent of any ancestor of s is also an ancestor of s. We say that a node s_1 is a strict ancestor of a node s_2 if and only if s_1 is an ancestor of s_2 and $s_2 \neq s_1$.

1.3. Paper organization. This paper is organized as follows. In section 2, we detail the algorithms ACT and WCT. In section 3, we introduce the partitioning technique and prove lower bounds on both $c^*(L)$ and $w^*(L)$. In section 4, we analyze the ACT algorithm. In section 5, we analyze the WCT algorithm. In section 6, we describe how the two algorithms can be implemented in linear time. Finally, in section 7 we present our conclusions and some open questions.

2. The algorithms. Both ACT and WCT try to balance the following goals:
(i) test the keys with small access costs first;
(ii) produce a reasonably balanced BST.

For that, each key in the input list is ranked according to its cost. In order to construct a BST, both algorithms use a "smallest-rank-first" rule; that is, the keys with smaller ranks are always searched before those with greater ranks. This rule reflects goal (i). Goal (ii) is considered to decide which key, among the keys with equal ranks, shall be tested first.

Both algorithms use a top-down approach to construct a BST. First, they select all the keys with the smallest rank in the current input list. Furthermore, every contiguous sublist of nonselected keys is condensed into a single node. After that, both algorithms construct an auxiliary strictly BST T_D, where each internal node corresponds to a selected key and each leaf corresponds to a (possibly empty) condensed sublist. The only point where ACT and WCT differ is the way that T_D is constructed. Assume that we have already solved the subproblem associated to each sublist represented by a condensed leaf. Then, both ACT and WCT obtain the final BST by replacing each condensed leaf of T_D by the BST constructed for the associated subproblem. In fact, the construction of each BST that will replace each corresponding condensed leaf is performed by a recursive call. Later in this section, we explain the construction of T_D.

Now, we illustrate ACT with an example. Let us consider a list of keys $L = [a_1, \ldots, a_9]$ with corresponding costs [0.1, 0.1, **0.05**, **0.03**, 0.3, 0.1, 0.08, 0.2, **0.04**], where the bold printed costs correspond to the keys with the smallest rank. Figure 1 illustrates the steps performed by ACT when L is the input list. ACT splits L into seven sublists: $L_1 = [a_1, a_2]$, $L_2 = [a_3]$, $L_3 = []$, $L_4 = [a_4]$, $L_5 = [a_5, \ldots, a_8]$, $L_6 = [a_9]$ and $L_7 = []$. Each of the sublists with even index (L_2, L_4, and L_6) contains exactly one key. These keys are associated to the internal nodes of the auxiliary BST T_D represented by Figure 1(a). On the other hand, the sublists with odd indices (L_1, L_3, L_5, and L_7) correspond to the condensed leaves of T_D. Figures 1(b) and 1(c) represent the BSTs constructed for L_1 and L_5, respectively. At the end of the execution, these BSTs replace their corresponding leaves in T_D. Moreover, since both

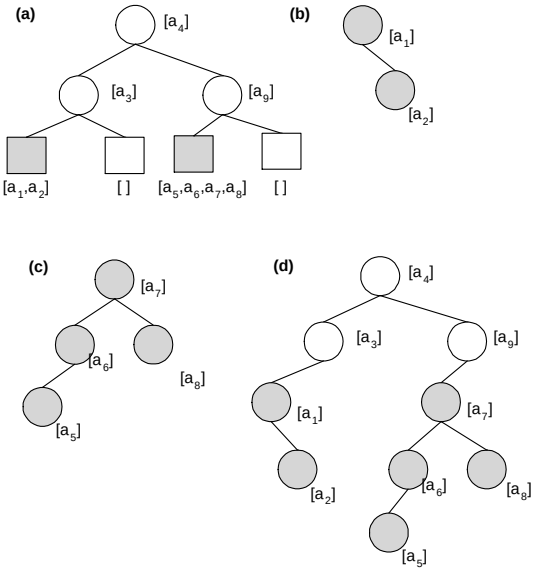

FIG. 1. (a) *The auxiliary strictly BST T_D with a_3, a_4, and a_9 corresponding to internal nodes.* (b) *The BST constructed by ACT for the subproblem ACP(L_1), where $L_1 = [a_1, a_2]$.* (c) *The BST constructed by ACT for the subproblem ACP(L_5), where $L_5 = [a_5, a_6, a_7, a_8]$.* (d) *The final BST T_L.*

the sublists L_3 and L_7 are empty, their corresponding leaves are removed from T_D. The resulting BST T_L is represented by Figure 1(d).

Now, let us formalize the notion of ranks. Let t be a positive integer number and let α be a real scaling constant greater than one. In the approximation analysis, we set the appropriate values for α and t. Assume that the real interval $[0, 1)$ is partitioned into $t + 1$ subintervals, where the first subinterval is given by $[0, 1/\alpha^t)$ and the ith interval, for $i = 2, \ldots, t+1$, is given by $[1/\alpha^{t-i+2}, 1/\alpha^{t-i+1})$. We define the rank of a key a_j as the index of the subinterval that contains $c(a_j)$. Furthermore, the rank of a sublist L is defined as the rank of the key with smallest rank in L. We use $r(L)$ to denote the rank of L.

Observe that, for the example of Figure 1, we may have $t = 4$ and $\alpha = 2$. In this case, since the first subinterval is $[0, 1/16)$, only the keys a_3, a_4, and a_9 have rank one.

A unique pseudocode for both algorithms is presented in Figure 2. The only difference between them is the construction of the auxiliary strictly BST T_D, which is performed by the CONSACT procedure for ACT and by the CONSWCT procedure for WCT. Observe that each parameter of CONSACT gives the number of keys that correspond to a node (leaf or internal node) in the auxiliary tree. On the other hand, CONSWCT receives as parameter the cost of each BST that will replace each leaf of T_D. Procedure BUILD returns a BST for L and its worst case cost $w(T_L)$. The latter returned value is not used if the problem is an ACP.

In order to improve the approximation ratio of both algorithms, BUILD constructs an optimal BST for every list L such that $|L| \leq K$ for a fixed integer parameter K. The optimal tree is constructed through the cubic time dynamic programming algorithm proposed in [3].

2.1. The CONSACT procedure. Let us recall the well-known *weighted path length problem*. Given a list of weights $[w_1, \ldots, w_{2n+1}]$, the weighted path length of a

Function BUILD(L : list of keys)

If $|L| \leq K$
  $T_L \leftarrow$ optimal BST for L constructed through dynamic programming
  return T_L and its worst case cost $w(T_L)$;
Let $a_{i_1}, a_{i_2}, \ldots, a_{i_k}$ be the keys of L with rank $r(L)$;
Let also $i_0 = 0$ and $i_{k+1} = |L| + 1$;
For $j = 1, \ldots, k$ **do**
  Create L_{2j} as the one element list $[a_{i_j}]$;
For $j = 0, \ldots, k$ **do**
  Create L_{2j+1} as the list $[a_{i_j+1}, a_{i_j+2}, \ldots, a_{i_{j+1}-1}]$;
For $j = 0, \ldots, k$ **do**
  $(T_{L_{2j+1}}, w(T_{L_{2j+1}})) \leftarrow$ BUILD(L_{2j+1}) ;
If THE PROBLEM IS ACP, **then**
  $T_D \leftarrow$ CONSACT$(|L_1|, |L_2|, \ldots, |L_{2k+1}|)$
Else
  $T_D \leftarrow$ CONSWCT$(w(T_{L_1}), w(T_{L_3}), \ldots, w(T_{L_{2k+1}}))$
For $j = 1, \ldots, k$ **do**
  Associate a_{i_j} to the jth internal node visited in an in-order traversal of T_D
For $j = 0, \ldots, k$ **do**
  Replace the $(j+1)$th leaf of T_D, from left to right, by $T_{L_{2j+1}}$;
Let T_L be the resulting tree;
Return T_L and $w(T_L)$;

FIG. 2. *Pseudocode for both ACT and WCT.*

strictly binary tree T with $2n+1$ nodes is defined by

$$\sum_{i=0}^{n} w_{2i+1} l_{2i+1} + \sum_{i=1}^{n} w_{2i}(l_{2i} + 1),$$

where l_i is the level of the ith visited node during an in-order traversal of T. Observe that the leaf levels are associated to the odd indices, while the internal nodes levels are associated to the even indices. The weighted path length problem consists of finding a strictly binary tree that minimizes the weighted path length for a given list of weights. There are several algorithms to address this problem [4, 6, 2]. CONSACT uses the linear time approximate algorithm proposed in [2] to construct a strictly binary tree T_D for the list of weights defined by the cardinality of each list L_i, that is, the list of weights $[|L_1|, |L_2|, \ldots, |L_{2k+1}|]$. In our example, CONSACT gets the parameters $[2, 1, 0, 1, 4, 1, 0]$ and constructs the tree presented in Figure 1(a).

2.2. The CONSWCT procedure. In [8], Sebö and Waksman proposed an algorithm to solve the following problem: Given a list of numbers $w = [w_1, w_2, \ldots, w_q]$, find a binary tree T, with q leaves, that minimizes

$$f(T, w) = \max_{i=1,\ldots,q} \{l_i + w_i\},$$

where l_i is the level of the ith leaf in T from left to right. Their algorithm runs in $O(q)$ time.

Let T_D be the tree that solves this problem for the list of numbers

$$[w(L_1)\alpha^{t-r(L)+1}, w(L_3)\alpha^{t-r(L)+1}, \ldots, w(L_{2k+1})\alpha^{t-r(L)+1}].$$

The procedure CONSWCT receives as parameters $w(L_1)$, $w(L_3), \ldots, w(L_{2k+1})$ and returns the tree T_D, which is constructed by Sebö's algorithm.

We must note that T_D also solves the following problem: Find a tree T that minimizes

$$w'(T) = \max_{i=0,\ldots,k} \{l_{2i+1}/\alpha^{t-r(L)+1} + w(L_{2i+1})\}, \tag{4}$$

where l_{2i+1} is the level of the ith leaf, from left to right, in T. This is true because we have multiplied only the objective function of the first problem by $1/\alpha^{t-r(L)+1}$.

3. Partitioning. Now, let us introduce a technique that provides lower bounds on both the ACP and WCP.

Let $L = [a_1, \ldots, a_m]$ be a list of keys and let T be a BST for L. Now, we consider a generic partition of L into k nonempty contiguous sublists $[a_1, \ldots, a_{i_1}]$, $[a_{i_1+1}, \ldots, a_{i_2}], \ldots, [a_{i_{k-1}+1}, \ldots, a_m]$. We use L_j to denote the jth sublist

$$[a_{i_{j-1}+1}, \ldots, a_{i_j}],$$

where $i_0 = 0$ and $i_k = m$. We show how to obtain a lower bound on the average (worst case) search cost of an optimal BST for L as a function of the average (worst case) search cost of the optimal BSTs for $L_1, \ldots, L_k$. We start with a simple lemma.

LEMMA 3.1. *For all i, with $1 \le i \le k$, there is a key in L_i that is an ancestor in T of all other keys of L_i.*

Proof. If $|L_i| = 1$, the result is obvious. Hence, we assume that $|L_i| > 1$. In this case, let a be the key of L_i with maximum number of descendants in T. If all the keys of L_i are descendants of a, we are done. Hence, we assume that there is a key b in L_i that is not a descendant of a. We have two cases. If b is an ancestor of a, we contradict the assumption that a has the maximum number of descendants among the keys of L_i. On the other hand, if b is not an ancestor of a, then let c be the lowest common ancestor of both a and b. Since T is a BST and L_i is a contiguous sublist of L, then we have that c also belongs to L_i. Hence, c has more descendants than a, which contradicts our assumption that a has the maximum number of descendants in L_i. As a result, there is a key in L_i that is an ancestor of all other keys of L_i in T. □

If a key a of L_i is an ancestor of all other keys of L_i in T, then we say that a is the *pivot* of L_i in T. Given a key $a \in L_i$, if a is not the pivot of L_i in T, let $close(a)$ be the closest strict ancestor of a in T that also belongs to L_i. Otherwise, let $close(a) = a$. We construct a tree T_i for the keys of the sublist L_i by using the following procedure.

PROCEDURE **CONSTRUCT** (T, L_i)**.**
For all $a \in L_i$, with $close(a) \neq a$, **do**
    If a is in the left subtree rooted at $close(a)$ in T, **then**
        turn a into a left child of $close(a)$ in T_i
    else turn a into a right child of $close(a)$ in T_i.

As an example, let $L = [a_1, \ldots, a_{11}]$, $L_1 = [a_1, a_2, a_3]$, $L_2 = [a_4, a_5, a_6, a_7, a_8]$, and $L_3 = [a_9, a_{10}, a_{11}]$. A BST T for L is shown in Figure 3(a). The trees T_1, T_2, and T_3 are shown in Figure 3(b). The number inside each node represents the index of the corresponding key. In addition, the nodes of L_2 are shaded in Figure 3. The pivots of the sublists L_1, L_2, and L_3 in T are a_2, a_8, and a_{10}, respectively.

We claim that, for any cost structure, the sum of the search costs of the trees T_1, T_2 and T_3 in Figure 3(b) is not greater than the search cost of T. This is true because every ancestor of a key in T_i is also an ancestor of this key in T.

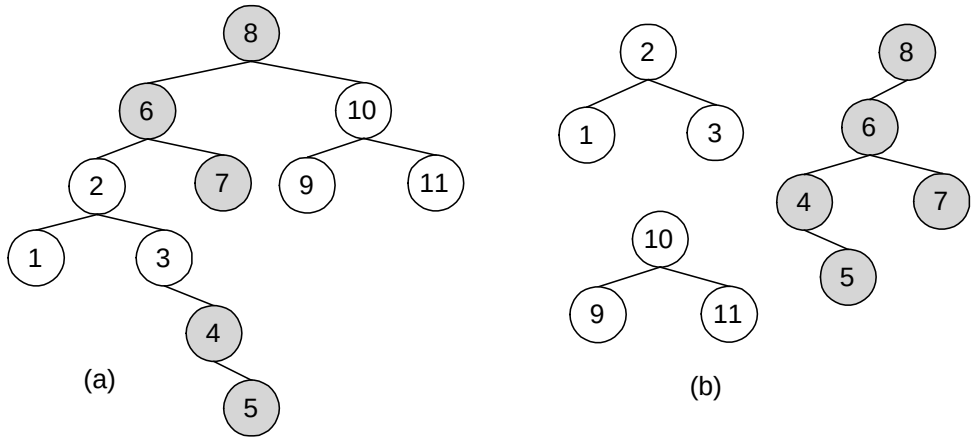

FIG. 3. (a) *BST T for the list $[a_1, \ldots, a_{11}]$.* (b) *BST's T_1, T_2 and T_3 for the lists $L_1 = [a_1, a_2, a_3]$, $L_2 = [a_4, \ldots, a_8]$ and $L_3 = [a_9, a_{10}, a_{11}]$, respectively.*

Now, let us state another simple result.

LEMMA 3.2. *Given a list L, let T be a BST for L and let L_i be a contiguous sublist of L. Furthermore, let T_i be the tree constructed by CONSTRUCT(T, L_i). Then, T_i is a binary search tree.*

Proof. The proof is in Appendix A. □

This partition technique can be used to obtain lower bounds for both the ACP and WCP. As an example, let us assume that the BST T presented in Figure 3(a) solves ACP(L). Since T_i is a feasible solution for ACP(L_i), for $i = 1, 2, 3$, then the search cost of T_i is bounded below by $c^*(L_i)$. Hence, we can conclude that

$$c^*(L) \geq c^*(L_1) + c^*(L_2) + c^*(L_3). \tag{5}$$

In the same fashion, one can conclude that

$$w^*(L) \geq \max\{w^*(L_1), w^*(L_2), w^*(L_3)\}.$$

These observations yield the following lemma.

LEMMA 3.3. *Let us assume that L is partitioned into k nonempty contiguous sublists $L_1, L_2, \ldots, L_k$. Then,*

$$c^*(L) \geq \sum_{i=1}^{k} c^*(L_i)$$

and

$$w^*(L) \geq \max_{i=1,\ldots,k} \{w^*(L_i)\}.$$

Nevertheless, this kind of lower bound is not enough to assure a constant approximation factor for both WCT and ACT. In the next sections, we show how to sharpen these lower bounds.

3.1. Lower bounds. Now, we develop specific lower bounds using the partitions suggested by both the ACT and the WCT algorithms. For that, let us assume that L is partitioned by BUILD into the sublists $L_1, L_2, \ldots, L_{2k+1}$ (lines 5–8 of the pseudocode presented in Figure 2). The reader should observe that we are not considering the subpartitioning of L due to the recursive calls to BUILD. Moreover, let us define

$$I(L) = \{i| \ |L_i| > 0 \text{ and } r(L_i) > r(L)\}$$

and

$$I'(L) = \{2, 4, \ldots, 2k\}.$$

3.1.1. The partitioning lower bound for the ACP. Here, we construct a parametric lower bound on the cost of the tree that solves ACP(L).

First, let us define a parametric problem ACP(L,d). Given a real number d, with $d \leq \min_{a\in L}\{c(a)\}$ and an input list L, the problem ACP(L, d) is to find a BST that minimizes

$$c_d(T) = \sum_{a_i \in L} \sum_{x \in N(a_i,T)} (c(x) - d)$$

in the set of all BSTs for the list L.

The key idea to improve the lower bound given by Lemma 3.3 is to decompose the cost $c(a)$ of each key $a \in L$ into two components d and $c(a) - d$ and then obtain a lower bound on $c^*(L)$ as the sum of two distinct lower bounds: a lower bound on a particular instance of ACP(L), where every key in L has the same cost d, and a lower bound on ACP(L, d). The next theorem formalizes this idea. First, we need some definitions. We use $T^*_L(d)$ to denote the tree that solves the ACP(L, d). For the sake of simplicity, we use $c^*(L, d)$, and not $c_d(T^*_L(d))$, to denote the cost of the optimal tree for ACP(L, d). When $d = 0$, we drop d, that is, $c^*(L) = c^*(L, 0)$. Now, we generalize (improve) the lower bound on $c^*(L)$ given by Lemma 3.3.

THEOREM 3.4. *Let d_1 and d_2 be two nonnegative numbers such that $d_1 + d_2 \leq \min_{a\in L}\{c(a)\}$. Then,*

$$c^*(L, d_1) \geq d_2 \times |L|(\log |L| - 1) + \sum_{i \in I(L)\cup I'(L)} c^*(L_i, d_1 + d_2).$$

Proof. Let us consider a key a that belongs to a list L_i. We use $l(a)$ to denote the level of a in $T^*_L(d_1)$ and $N_L(a)$ to denote the set of ancestors of a in $T^*_L(d_1)$. Hence, we have that

$$c^*(L, d_1) = \sum_{a\in L} \sum_{x\in N_L(a)} d_2 + \sum_{a\in L} \sum_{x\in N_L(a)} (c(x) - d_1 - d_2)$$

$$\geq \sum_{a\in L} d_2(l(a) + 1) + c^*(L, d_1 + d_2), \tag{6}$$

where the last inequality holds since $T^*_L(d_1)$ is a feasible solution for ACP($L, d_1 + d_2$).

Moreover, it follows from Lemma 3.3 that

$$c^*(L, d_1 + d_2) \geq \sum_{i \in I(L)\cup I'(L)} c^*(L_i, d_1 + d_2). \tag{7}$$

On the other hand, since $\sum_{a\in L}(l(a)+1)$ is the internal path length of a binary tree, we have that $d_2\sum_{a\in L}(l(a)+1) \geq d_2|L|(\log|L|-1)$. Hence, from (6) and (7), we can conclude that

$$c^*(L,d_1) \geq d_2|L|(\log|L|-1) + \sum_{i\in I(L)\cup I'(L)} c^*(L_i, d_1+d_2). \qquad \square$$

For example, if we apply the previous theorem for the partition of Figure 3, we obtain that

$$c^*(L,d_1) \geq 27d_2 + c^*(L_1,d_1+d_2) + c^*(L_2,d_1+d_2) + c^*(L_3,d_1+d_2).$$

In particular, for $d_1 = d_2 = 0$, we get the lower bound given by (5).

The main lower bound for the ACP, stated later in Theorem 4.1, is obtained by recursively using the previous result for every sublist of A generated by procedure BUILD. The values of d_1 and d_2 are adequately set in that theorem.

In the next theorem, we present a technical result that relates $c^*(L)$ to $c^*(L,d_1)$. This result is used only in the proof of Theorem 4.5, the constant approximation theorem.

THEOREM 3.5. *Let* $0 \leq d_1 < d_2 \leq \min_{a\in L}\{c(a)\}$. *Then*

$$\frac{c^*(L)}{c^*(L,d_1)} \leq \frac{d_2}{d_2-d_1}.$$

Proof. Let $T_L^*(d_1)$ be the tree that solves ACP(L,d_1). Also let $N_L(a)$ be the set of all ancestors of the key a in $T_L^*(d_1)$. By definition, we have that

$$c^*(L,d_1) = \sum_{a\in L}\sum_{x\in N_L(a)} (c(x)-d_1).$$

In addition, we have

$$c^*(L) \leq \sum_{a\in L}\sum_{x\in N_L(a)} c(x),$$

since $c^*(L)$ is the optimum cost of ACP(L) and $T_L^*(d_1)$ is a feasible solution for this problem. Hence,

$$\frac{c^*(L)}{c^*(L,d_1)} \leq \frac{\displaystyle\sum_{a\in L}\sum_{x\in N_L(a)} c(x)}{\displaystyle\sum_{a\in L}\sum_{x\in N_L(a)} (c(x)-d_1)} \leq \max_{a\in L}\left\{\frac{c(a)}{c(a)-d_1}\right\} = \frac{c(a^*)}{c(a^*)-d_1},$$

where $a^* = argmin_{a\in L}\{c(a)\}$.

Since $d_2 \leq c(a^*)$, it follows that

$$\frac{c^*(L)}{c^*(L,d_1)} \leq \frac{c(a^*)}{c(a^*)-d_1} \leq \frac{d_2}{d_2-d_1}. \qquad \square$$

3.1.2. The partitioning lower bound for the WCP. In this section, we improve the lower bound on $w^*(L)$ given by Lemma 3.3. For that, we take into account the level of the pivots in $T^*_W(L)$, the BST that solves WCP(L). As an example, in Figure 3, the worst case search cost of the BST T_1 corresponding to L_1 is a lower bound on the worst case search cost of the BST T for the list L. Let d be a real number with $d \leq \min_{a\in L}\{c(a)\}$. If we take into account the fact that the pivot of L_1 in T, the node with label 2, is on level 2 in T, then we can conclude that the worst case cost of T_1 added to $2d$ is also a lower bound on the worst case search cost of T. The next lemma formalizes this idea.

For $j \in I(L) \cup I'(L)$, let y_j be the pivot of the sublist L_j in the tree $T^*_W(L)$. Furthermore, let l_j^W be the level of y_j in $T^*_W(L)$. We can state the following result.

LEMMA 3.6. *Let d be a real number such that $0 \leq d \leq \min_{a\in L}\{c(a)\}$. Then,*

$$w^*(L) \geq \max_{i\in I(L)\cup I'(L)}\{d \times l_i^W + w^*(L_i)\}. \tag{8}$$

Proof. Let us consider the key a of L_i. The key a has two kinds of ancestors in $T^*_W(L)$: the ones that belong to L_i and the ones that do not belong to L_i. Since the strict ancestors of y_i in $T^*_W(L)$ do not belong to L_i, then we can conclude that the cost of searching a in $T^*_W(L)$ is at least

$$d \times l_i^W + \sum_{x\in(N_L(a)\cap L_i)} c(x),$$

where $N_L(a)$ denotes the set of all ancestors of the key a in $T^*_W(L)$. Hence, the cost of searching the key of L_i with worst case access cost in $T^*_W(L)$ is bounded below by

$$d \times l_i^W + \max_{a\in L_i}\left\{\sum_{x\in(N_L(a)\cap L_i)} c(x)\right\}. \tag{9}$$

Observe that the second term of (9) is exactly the worst case access cost of the BST T_i constructed by CONSTRUCT($T^*_W(L), L_i$). Since T_i is a feasible solution for WCP(L_i), it follows that its worst case access cost is bounded below by $w^*(L_i)$. Hence, the cost of searching the key of L_i with worst case access cost in $T^*_W(L)$ is bounded below by

$$d \times l_i^W + w^*(L_i).$$

The result is established by taking the maximum lower bound among all sublists $\{L_i | i \in I(L) \cup I'(L)\}$. ∎

Later, in the analysis of WCT, we relate d to the rank of the list L. More precisely, we set $d = 1/\alpha^{t-r(L)+2}$ when $r(L) > 1$ and $d = 0$, otherwise. The reader should observe that, for these settings, $d \leq \min_{a\in L}\{c(a)\}$.

4. Analysis of ACT. In this section, we analyze the approximation ratio of ACT. For that, we need to introduce some ideas and definitions.

Let Z be the set of all nonempty sublists of A that are passed as a parameter in some call to function BUILD. In addition, let Z_K be the set of all sublists of Z with cardinality greater than K. Recall that, for every list L, with $|L| \leq K$, BUILD constructs an optimal search tree. The main lower bound for the ACP, stated later in Theorem 4.1, is basically a function of the rank and the cardinality of the lists in Z.

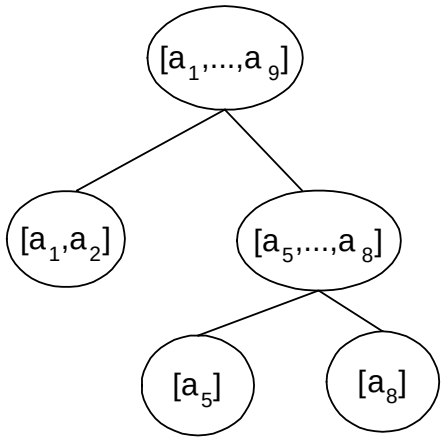

FIG. 4. *A tree T(Build).*

Similarly, the main upper bound on the search cost of the BST constructed by ACT (Theorem 4.4) is a function of the rank and the cardinality of the lists in Z.

The lists of Z can be arranged in a tree $T(Build)$ in the following way. Each node of $T(Build)$ corresponds to a sublist that belongs to Z. The root is the input list A. Given a sublist $L \in Z$, the children of L in $T(Build)$ correspond to the sublists $\{L_i | i \in I(L)\}$. Note that the sublists $L_2, L_4, \ldots, L_{2k}$ are not passed as a parameter of function BUILD, and, as a consequence, they do not appear in $T(Build)$.

Observe that Theorem 3.4 gives a lower bound on $c^*(L)$ as a function of L and its children in $T(Build)$. On the other hand, an upper bound on $c(L)$ presented later in this section (Corollary 4.3) is also a function of L and its children in $T(Build)$. As a result, by recursively evaluating these upper (lower) bounds, we can express an upper (lower) bound on $c(A)$ ($c^*(A)$) as a function of all the lists corresponding to the nodes of $T(Build)$. That is exactly the approach used in the proofs of Theorems 4.4 and 4.1.

As an example of $T(Build)$, consider the input list $A = [a_1, \ldots, a_9]$ with corresponding costs $[0.1, 0.1, 0.05, 0.03, 0.3, 0.1, 0.08, 0.2, 0.04]$. Moreover, assume that $\alpha = 2$, $t = 4$, and $K = 2$. Figure 4 shows a tree $T(Build)$ for this example. In this case, we have that $Z_2 = \{[a_1, \ldots, a_9], [a_5, \ldots, a_8]\}$ and $Z - Z_2 = \{[a_1, a_2], [a_5], [a_8]\}$.

We use $g(L)$ to denote the rank of the parent of L in $T(Build)$; that is, if L is a child of L' in $T(Build)$, then $g(L) = r(L')$. For the input list A, we define $g(A) = -\infty$. Finally, we use T_L to denote the tree constructed by ACT for the list L.

4.1. Lower bounds. In this section, we obtain a lower bound on the cost of the optimal BST for the input list A. For that, we apply the partition technique developed in section 3. We define

$$R(L) = \begin{cases} 0 \text{ if } r(L) = 1, \\ 1/\alpha^{t-r(L)+2} \text{ if } r(L) > 1. \end{cases}$$

Observe that $R(L)$ is a lower bound on the cost of the keys of L, that is, $R(L) \leq \min_{a \in L}\{c(a)\}$. If L' is the parent of L in $T(Build)$, then we define $G(L) = R(L')$. For the input list A, $G(A) = 0$.

The following theorem gives a lower bound on the cost of the tree that solves the ACP for an input list A.

THEOREM 4.1.

$$c^*(A) \geq \max\left\{1, \sum_{L\in Z_K} (R(L) - G(L))\,|L|(\log|L| - 1) + \sum_{L\in(Z-Z_K)} c^*(L, G(L))\right\}.$$

Proof. Basically, the proof is obtained by applying Theorem 3.4, recursively, starting with the input list A. For a complete proof, see Appendix B. □

4.2. Upper bounds. In this section, we obtain an upper bound on the cost $c(A)$ of the tree T_A constructed by the ACT algorithm for the input list A. The main upper bound stated in Theorem 4.4 is a function of both the cardinality and the rank of the lists in Z.

Let L be a list that belongs to Z. We consider two cases separately: (i) $|L| \leq K$ and (ii) $|L| > K$.

In case (i), we have that

$$c(L) \leq c^*(L), \tag{10}$$

since ACT constructs an optimal BST for L when $|L| \leq K$.

Now, we consider case (ii). The next theorem gives an upper bound on $c(L)$ as a function of the levels of nodes of the BST constructed by CONSACT.

THEOREM 4.2. *For $j \in I(L) \cup I'(L)$, let l_j be the level of the node associated to the sublist L_j in the tree T_D constructed by CONSACT for the input parameters $|L_1|, |L_2|, \ldots, |L_{2k+1}|$. Then,*

$$c(L) \leq \frac{1}{\alpha^{t-r(L)+1}}\left(\sum_{j\in I(L)} |L_j| l_j + \sum_{j\in I'(L)} (l_j + 1)\right) + \sum_{j\in I(L)} c(L_j).$$

Proof. Let us consider a key a that belongs to a sublist L_j with $j \in I'(L) \cup I(L)$. The key a has two kinds of ancestors in T_L: the ones that belong to L_j and the ones that do not belong to L_j. The construction of T_D implies that every ancestor of a that does not belong to L_j is an internal node in T_D with rank equal to $r(L)$. Moreover, the number of ancestors of a that do not belong to L_j is l_j. Hence, the cost of searching a in T_L is bounded above by

$$\frac{l_j}{\alpha^{t-r(L)+1}} + \sum_{x\in(N_L(a)\cap L_j)} c(x),$$

where $N_L(a)$ denotes the set of all ancestors of the key a in T_L.

Adding the previous upper bound for all the keys of L_j, we obtain the following upper bound on the cost of searching the keys of L_j in T_L:

$$\sum_{a\in L_j}\left(\frac{l_j}{\alpha^{t-r(L)+1}} + \sum_{x\in(N_L(a)\cap L_j)} c(x)\right) = \frac{|L_j| l_j}{\alpha^{t-r(L)+1}} + c(L_j).$$

Hence, by adding the previous upper bound for all sublists L_j, with $j \in I(L) \cup I'(L)$, we obtain that

$$c(L) \leq \frac{1}{\alpha^{t-r(L)+1}}\left(\sum_{j\in I(L)} |L_j| l_j + \sum_{j\in I'(L)} l_j\right) + \sum_{j\in I'(L)} c(L_j) + \sum_{j\in I(L)} c(L_j).$$

The result is established by observing that $c(L_j) \leq 1/\alpha^{t-r(L)+1}$ for $j \in I'(L)$. ∎

Now, we refine the previous result obtaining an upper bound on $c(L)$ as a function of both the cardinality and the rank of the lists that are children of L in $T(Build)$. For that, we take into account the fact that CONSACT uses the algorithm presented in [2] to construct a BST. We remark that the following result also holds if CONSACT uses the algorithm proposed in [6] instead of the one presented in [2].

COROLLARY 4.3.

$$c(L) \leq \frac{1}{\alpha^{t-r(L)+1}} \left(|L| \log |L| + 2|L| - \sum_{i \in I(L)} |L_i| \log |L_i| \right) + \sum_{i \in I(L)} c(L_i).$$

Proof. In [2], an approximation algorithm, say DPDS, is presented to solve the weighted path length problem. In particular, Theorem 7 of [2] states that if $h_1, \ldots, h_{2n+1}$ are the levels of the nodes of the BST constructed by DPDS for the list of weights $w_1, \ldots, w_{2n+1}$, then

$$\sum_{i=0}^{n} w_{2i+1} h_{2i+1} + \sum_{i=1}^{n} w_{2i} h_{2i} \leq \left(\sum_{i=1}^{2n+1} w_i \right) \log \left(\sum_{i=1}^{2n+1} w_i \right) - \sum_{i=1}^{2n+1} w_i \log w_i$$

$$+ w_{\max} - w_1 - w_{2n+1} + \sum_{i=1}^{2n+1} w_i,$$

where $w_{\max} = \max_{i=0,\ldots,n}\{w_{2i+1}\}$. We point out that the previous inequality is stated in [2] as a function of probabilities $p_1, \ldots, p_{2n+1}$, where $p_i = w_i / \sum_{i=1}^{2n+1} w_i$.

Here, we need the weaker upper bound

$$\sum_{i=0}^{n} w_{2i+1} h_{2i+1} + \sum_{i=1}^{n} w_{2i} h_{2i} \leq \left(\sum_{i=1}^{2n+1} w_i \right) \log \left(\sum_{i=1}^{2n+1} w_i \right) - \sum_{i=1}^{2n+1} w_i \log w_i + 2 \sum_{i=1}^{2n+1} w_i.$$

Since $l_1, \ldots, l_{2k+1}$ are the levels of the nodes of the BST T_D, constructed by CONSACT for the list of weights $[|L_1|, \ldots, |L_{2k+1}|]$, it follows from the discussion above that

$$\sum_{j \in I(L)} |L_j| l_j + \sum_{j \in I'(L)} (l_j + 1) \leq |L| \log |L| + 2|L| - \sum_{j \in I(L)} |L_j| \log |L_j|.$$

Hence, it follows from the previous inequality and from Theorem 4.2 that

$$c(L) \leq \frac{1}{\alpha^{t-r(L)+1}} \left(|L| \log |L| + 2|L| - \sum_{i \in I(L)} |L_i| \log |L_i| \right) + \sum_{i \in I(L)} c(L_i). \quad ∎$$

Now, we can state the main upper bound on the cost of the BST constructed by ACT for the input list A.

THEOREM 4.4.

$$c(A) \leq \sum_{L \in Z_K} \left(\frac{|L| \log |L|}{\alpha^{t-r(L)+1}} - \frac{|L| \log |L|}{\alpha^{t-g(L)+1}} + \frac{2|L|}{\alpha^{t-r(L)+1}} \right)$$

$$+\sum_{L\in(Z-Z_K)}\left(c^*(L)-\frac{|L|\log|L|}{\alpha^{t-g(L)+1}}\right).$$

Proof. This result can be proved by induction on the level of $T(Build)$ as we did in Theorem 4.1. For a complete proof we refer to Appendix C. □

4.3. Approximation. In this section, we prove that ACT obtains a $(2+\epsilon+o(1))$-approximated solution for the ACP. For that, we basically compare the lower bound given by Theorem 4.1 with the upper bound given by Theorem 4.4. Let us assume that $K \geq 2$.

THEOREM 4.5.

$$\frac{c(A)}{c^*(A)} \leq \frac{n\log n+2n}{\alpha^t}+\max\left\{\frac{\alpha}{\alpha-1},\frac{\alpha(\alpha-1)\log(K+1)+2\alpha^2}{(\alpha-1)(\log(K+1)-1)}\right\}.$$

Proof. If $|A| \leq K$, ACT generates the optimal BST. Hence, we assume that $|A| > K$. We divide our analysis into two cases:

(i) $r(A) = 1$;

(ii) $r(A) > 1$.

First, we analyze case (i). It follows from Theorem 4.4 that

$$c(A) \leq \frac{|A|(\log|A|+2)}{\alpha^t} \tag{11}$$

$$+\sum_{L\in(Z_K-\{A\})}\left(\frac{|L|\log|L|}{\alpha^{t-r(L)+1}}-\frac{|L|\log|L|}{\alpha^{t-g(L)+1}}+\frac{2|L|}{\alpha^{t-r(L)+1}}\right)+\sum_{L\in(Z-Z_K)}c^*(L).$$

On the other hand, Theorem 4.1 assures that

$$c^*(A)\geq\max\left\{1,\sum_{L\in Z_K}(R(L)-G(L))\,|L|(\log|L|-1)+\sum_{L\in(Z-Z_K)}c^*(L,G(L))\right\}.$$

Dividing (11) by the previous inequality, and using the facts that $1/\alpha^{t-r(L)+1} = \alpha R(L)$ and $\alpha G(L) \leq 1/\alpha^{t-g(L)+1}$, for $L \in Z_K - \{A\}$, we obtain that

$$\frac{c(A)}{c^*(A)} \leq \frac{|A|\log|A|+2|A|}{\alpha^t}$$

$$+\frac{\displaystyle\sum_{L\in(Z_K-A)}\alpha(R(L)-G(L))|L|\log|L|+2\alpha R(L)|L|+\sum_{L\in(Z-Z_K)}c^*(L)}{\displaystyle\sum_{L\in Z_K}(R(L)-G(L))\,|L|(\log|L|-1)+\sum_{L\in(Z-Z_K)}c^*(L,G(L))}.$$

Now, let

$$P=\max_{L\in(Z-Z_K)}\left\{\frac{c^*(L)}{c^*(L,G(L))}\right\}$$

and

$$Q = \max_{L \in (Z_K - A)} \left\{ \frac{\alpha(R(L) - G(L)) \log |L| + 2\alpha R(L)}{(R(L) - G(L))(\log |L| - 1)} \right\}.$$

Hence, we have that

$$\frac{c(A)}{c^*(A)} \leq \frac{|A| \log |A| + 2|A|}{\alpha^t} + \max\{P, Q\}. \tag{12}$$

Now, let us analyze P. Observe that $0 \leq G(L) < R(L) \leq \min_{a \in L}\{c(a)\}$ for all $L \in (Z - Z_K)$. Hence, it follows from Theorem 3.5 that

$$P = \max_{L \in (Z - Z_K)} \left\{ \frac{c^*(L)}{c^*(L, G(L))} \right\} \leq \max_{L \in (Z - Z_K)} \left\{ \frac{R(L)}{R(L) - G(L)} \right\}. \tag{13}$$

Since $G(L) \leq R(L)/\alpha$, then

$$P \leq \max_{L \in (Z - Z_K)} \left\{ \frac{R(L)}{R(L) - G(L)} \right\} \leq \frac{\alpha}{\alpha - 1}. \tag{14}$$

Now, let us analyze Q. Since $G(L) \leq R(L)/\alpha$ and $|L| > K$, for all $L \in (Z_K - A)$, we have that

$$Q \leq \frac{\alpha \log(K+1)}{\log(K+1) - 1} + \frac{2\alpha^2}{(\alpha - 1)(\log(K+1) - 1)}. \tag{15}$$

Let $|A| = n$. It follows from (12), (14), and (15) that

$$\frac{c(A)}{c^*(A)} \leq \frac{n \log n + 2n}{\alpha^t} + \max\left\{ \frac{\alpha}{\alpha - 1}, \frac{\alpha(\alpha - 1)\log(K+1) + 2\alpha^2}{(\alpha - 1)(\log(K+1) - 1)} \right\}. \tag{16}$$

Case (ii), where $r(A) > 1$, is similar. The only difference is that we do not need to consider the list A separately. Hence, the term $(n \log n + 2n)/\alpha^t$ does not appear in the right-hand side of (16). ∎

COROLLARY 4.6. *The ACT algorithm is* $(2 + \epsilon + o(1))$*-approximated for any* $\epsilon > 0$.

Proof. Let $\epsilon > 0$. Then, set $\alpha = 2$, $t = 2 \log n$, and $K = 2^{1+10/\epsilon} - 1$. It follows from Theorem 4.5 that

$$\frac{c(A)}{c^*(A)} \leq \frac{n \log n + 2n}{n^2} + 2 + \epsilon. \qquad \blacksquare$$

5. WCT analysis. Here, we prove a constant approximation ratio for WCT. Recall that we have defined $T^*_W(L)$ as the optimal tree for WCP(L). We define $T_{pv}(L)$ as the tree that connects the pivots of the sublists $\{L_i | i \in I'(L) \cup I(L)\}$ in $T^*_W(L)$. More precisely, given a pivot y_i, let *close*(y_i) be the closest strict ancestor of y_i in $T^*_W(L)$ that also belongs to $\{y_i | i \in I'(L) \cup I(L)\}$. $T_{pv}(L)$ is constructed by the following procedure:

For all $y \in \{y_i | i \in I'(L) \cup I(L)\}$ **do**
  If y is in the left subtree rooted at $close(y)$ in $T^*_W(L)$, **then**
    turn y into a left child of $close(y)$ in $T_{pv}(L)$
  else turn y into a right child of $close(y)$ in $T_{pv}(L)$

Figure 5(b) shows an example of a tree $T_{pv}(L)$ for the case where $L = [a_1, \ldots, a_9]$, $L_1 = [a_1, a_2]$, $L_2 = [a_3]$, $L_3 = []$, $L_4 = [a_4]$, $L_5 = [a_5, \ldots, a_8]$, $L_6 = [a_9]$, $L_7 = []$ and $T^*_W(L)$ is the tree of Figure 5(a).

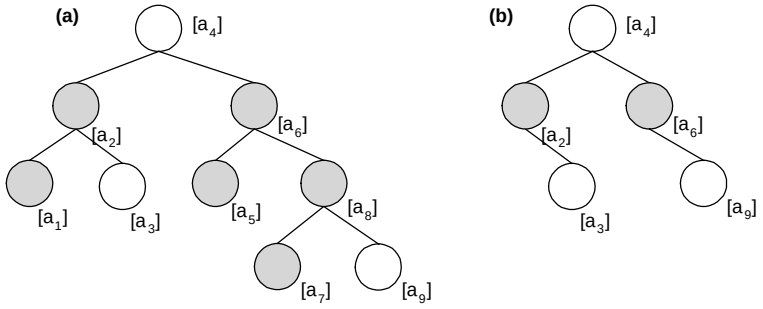

FIG. 5. (a) *An optimal tree* $T^*_W(L)$ *for* $L = [a_1, \ldots, a_9]$. (b) *The corresponding tree* $T_{pv}(L)$ *for* $L_1 = [a_1, a_2]$, $L_2 = [a_3]$, $L_3 = []$, $L_4 = [a_4]$, $L_5 = [a_5, \ldots, a_8]$, $L_6 = [a_9]$, *and* $L_7 = []$.

PROPOSITION 5.1. *$T_{pv}(L)$ is a BST.*

Proof. We omit this proof, since it is similar to that of Lemma 3.2. □

Our strategy to prove the constant approximation ratio for WCT is to obtain a lower bound on $w^*(L)$ as a function of the levels of the nodes in $T_{pv}(L)$ and to obtain an upper bound on $w(L)$ as a function of these same levels.

Now, we state a combinatorial lemma that will be used later to relate the levels of leaves in the tree T_D constructed by CONSWCT with the levels of the nodes in $T_{pv}(L)$.

LEMMA 5.2. *For $i \in I(L) \cup I'(L)$, let l_i be the level of y_i in $T_{pv}(L)$. Then, there is a BST T' formed by the pivots $\{y_i : i \in I(L) \cup I'(L)\}$ such that*

(i) *if $i \in I(L)$, then y_i is a leaf in T', where its level is at most $2l_i + 2$;*
(ii) *if $i \in I'(L)$, then y_i is a node (leaf or internal node) in T', where its level is at most $2l_i$.*

Proof. The proof is in Appendix D. □

5.1. Lower bounds. In this section, we present lower bounds on $w^*(L)$. The main lower bound, stated in the next lemma, follows from a direct application of Lemma 3.6.

LEMMA 5.3. *Let l_i be the level of y_i in $T_{pv}(L)$. If $r(L) = 1$, then*

$$w^*(L) \geq \max_{i \in I(L) \cup I'(L)} \{w^*(L_i)\}. \tag{17}$$

On the other hand, if $r(L) > 1$, then

$$w^*(L) \geq \max_{i \in I(L) \cup I'(L)} \{l_i/\alpha^{t-r(L)+2} + w^*(L_i)\}. \tag{18}$$

Proof. Clearly, if l_i^W is the level of y_i in $T_W^*(L)$, then we have $l_i \leq l_i^W$ for all $i \in I(L) \cup I'(L)$. Hence, we establish the lower bounds given by (17) and (18) applying Lemma 3.6 with $d = 0$ and with $d = 1/(\alpha^{t-r(L)+2})$, respectively. ∎

Next, we prove a simple lower bound on $w^*(L)$ that is exclusively used in the approximation analysis for the case where $L \leq K$. The reader should observe that the lower bound given by Lemma 5.3 cannot be applied for such a list since it is not partitioned by procedure BUILD, that is, $I(L) \cup I'(L) = \emptyset$.

PROPOSITION 5.4. *Let L be a sublist of A with $r(L) > 1$. Then,*

$$w^*(L) \geq \frac{\log(|L|+1)}{\alpha^{t-r(L)+2}}.$$

Proof. Observe that $w^*(L)$ is bounded below by the cost of an optimal tree T^* for a list of $|L|$ keys with costs equal to $1/\alpha^{t-r(L)+2}$. Furthermore, observe that T^* is a balanced tree, and its worst case access cost is not smaller than $\log(|L|+1)/\alpha^{t-r(L)+2}$, which establishes the proposition. ∎

5.2. Upper bounds. In this section, we obtain upper bounds on $w(L)$. We start with a simple lemma that gives an upper bound as a function of the leaf levels of the tree constructed by CONSWCT.

LEMMA 5.5. *Let T_D be the tree constructed by CONSWCT for the input parameters $w(L_1), w(L_3), \ldots, w(L_{2k+1})$. Then,*

$$w(L) \leq w'(T_D) = \max_{i=0,\ldots,k} \left\{ l_{2i+1}^D/\alpha^{t-r(L)+1} + w(L_{2i+1}) \right\},$$

where $l_1^D, l_3^D, \ldots, l_{2k+1}^D$ are the leaf levels of T_D.

Proof. Let a be the key with maximum search cost in T_L and let $N_L(a)$ be the set of ancestors of a in T_L. Moreover, assume that $a \in L_i$, where $i \in I(L) \cup I'(L)$.

If $i \in I(L)$, then

$$w(L) = \sum_{x \in N_L(a) \cap L_i} c(x) + \sum_{x \in N_L(a) - L_i} c(x) = w(L_i) + \sum_{x \in N_L(a) - L_i} c(x),$$

where the last inequality follows from the fact that a is also the key with maximum search cost in T_{L_i}. Moreover, since the cost of every internal node of T_D is bounded above by $1/\alpha^{t-r(L)+1}$, we obtain that

$$w(L) = \; w(L_i) + \sum_{x \in N_L(a) - L_i} c(x) \leq w(L_i) + l_i^D/\alpha^{t-r(L)+1} \leq w'(T_D).$$

On the other hand, if $i \in I'(L)$, then

$$w(L) = \sum_{x \in N_L(a)} c(x) \leq \max\{l_{i-1}^D, l_{i+1}^D\}/\alpha^{t-r(L)+1} \leq w'(T_D). \qquad ∎$$

Now, we prove the main upper bound, which is a function of the node levels of the tree $T_{pv}(L)$. Roughly speaking, this upper bound is a factor of 2α larger than the lower bound given by Lemma 5.3. The key idea in the proof of the main upper bound is to show that $w'(T_D) \leq w'(T'')$, where T'' is a BST obtained by adding some particular leaves to the BST T' given by Lemma 5.2.

LEMMA 5.6. *Let l_i be the level of y_i in $T_{pv}(L)$. Then,*

$$w(L) \leq \max_{i \in I(L) \cup I'(L)} \left\{ \frac{2l_i + 2}{\alpha^{t-r(L)+1}} + w(L_i) \right\}. \tag{19}$$

Proof. For the sake of simplicity, let $\gamma(L) = 1/\alpha^{t-r(L)+1}$. Let T' be the BST given by Lemma 5.2 and let l'_i be the level of y_i in T' for $i \in I(L) \cup I'(L)$. For $i \in \{1, 3, \ldots, 2k+1\} - I(L)$, define

$$l'_i = \begin{cases} l'_2 + 1 \text{ if } i = 1, \\ \max\{l'_{i-1}, l'_{i+1}\} + 1 \text{ if } 1 < i < 2k+1, \\ l'_{2k} + 1 \text{ if } i = 2k+1. \end{cases}$$

This last definition gives the levels of the leaves corresponding to the empty sublists $\{L_i | i \in \{1, 3, \ldots, 2k+1\} - I(L)\}$ in a BST T'' obtained from T' by adding such leaves. Moreover, we have that

$$w'(T'') = \max_{i=1,3,\ldots,2k+1} \{l'_i \gamma(L) + w(L_i)\}. \tag{20}$$

Now, let i^* be the index that maximizes the right-hand side of (20). If $i^* \in I(L)$, it follows from Lemma 5.2 that $l'_{i^*} \leq 2l_{i^*} + 2$. Hence, if $i^* \in I(L)$, we have that $l'_{i^*}\gamma(L) + w(L_{i^*}) \leq (2l_{i^*} + 2)\gamma(L) + w(L_{i^*})$. On the other hand, if $i^* \in \{1, 3, \ldots, 2k+1\} - I(L)$, we have that $l'_{i^*} = l'_j + 1$ for some $j \in I'(L)$. Then, it follows from Lemma 5.2 that $l'_{i^*} \leq 2l_j + 1$, and, as a consequence, $l'_{i^*}\gamma(L) + w(L_{i^*}) = l'_{i^*}\gamma(L) \leq (2l_j + 2)\gamma(L) + w(L_j)$. This analysis allows us to conclude that

$$w'(T'') \leq \max_{i \in I(L) \cup I'(L)} \{(2l_i + 2)\gamma(L) + w(L_i)\}. \tag{21}$$

Since T'' is a feasible solution for the problem defined at the end of section 2.2 and T_D is an optimal solution for this same problem, we have that $w'(T_D) \leq w'(T'')$. Hence, it follows from inequality (21) and from Lemma 5.5 that

$$w(L) \leq w'(T_D) \leq w'(T'') \leq \max_{i \in I(L) \cup I'(L)} \{(2l_i + 2)\gamma(L) + w(L_i)\}. \qquad \square$$

5.3. Approximation. Here, we prove a constant approximation for WCT. The next lemma shows how to relate $w(A)$ and $w^*(A)$ when $r(A) = 1$, while Lemma 5.8 shows how to relate $w(L)$ and $w^*(L)$ when $r(L) > 1$. The constant approximation ratio stated later in Theorem 5.9 is obtained by recursively applying Lemmas 5.7 and 5.8.

LEMMA 5.7. *Let us assume that the input list A is partitioned by BUILD into the sublists $A_1, A_2, \ldots, A_{2k+1}$. Moreover, let us assume that $r(A) = 1$ and that $A_m = argmax\{w(A_i) | i \in \{1, 2, \ldots, 2k+1\}\}$. Then,*

$$\frac{w(A)}{w^*(A)} \leq \frac{n \log n + n}{\alpha^t} + \frac{w(A_m)}{w^*(A_m)}.$$

Proof. For the sake of simplicity, we assume that CONSWCT builds a balanced tree when $r(A) = 1$. Hence, we have that $w(A) \leq (\log n + 1)/\alpha^t + w(A_m)$. The lemma is established by using the facts that $w^*(A) \geq w^*(A_m) > 0$ and $w^*(A) \geq 1/n$. $\square$

Now, we show how to compare the upper bound given by Lemma 5.6 with the lower bounds given by Lemma 5.3 and by Proposition 5.4.

LEMMA 5.8. *Let us assume that BUILD is called with parameter L such that $r(L) > 1$ and $|L| > K$. Furthermore, let p be the index that maximizes the right-hand side of* (19). *If $|L_p| > K$, then*

$$\frac{w(L)}{w^*(L)} \leq \max\left\{2\alpha, \frac{2/\alpha^{t-r(L)+1} + w(L_p)}{w^*(L_p)}\right\}. \tag{22}$$

Otherwise, if $|L_p| \leq K$, then

$$\frac{w(L)}{w^*(L)} \leq \frac{2\alpha}{\log(K+1)} + 2\alpha. \tag{23}$$

Proof. First, let us consider that case where $|L_p| > K$. By Lemma 5.6, we have that $w(L) \leq (2l_p + 2)/\alpha^{t-r(L)+1} + w(L_p)$. Moreover, it follows from Lemma 5.3 that $w^*(L) \geq l_p/\alpha^{t-r(L)+2} + w^*(L_p)$. Dividing the upper bound on $w(L)$ by the lower bound on $w^*(L)$, we obtain that

$$\frac{w(L)}{w^*(L)} \leq \frac{2l_p/\alpha^{t-r(L)+1} + 2/\alpha^{t-r(L)+1} + w(L_p)}{l_p/\alpha^{t-r(L)+2} + w^*(L_p)},$$

which yields to (22). Next, let us consider that case where $|L_p| \leq K$. In this case, we have that $w(L) \leq (2l_p + 2)/\alpha^{t-r(L)+1} + w^*(L_p)$, since BUILD constructs an optimal BST for L_p. Hence, we have that

$$\frac{w(L)}{w^*(L)} \leq \frac{2/\alpha^{t-r(L)+1}}{w^*(L)} + \frac{2l_p/\alpha^{t-r(L)+1} + w^*(L_p)}{l_p/\alpha^{t-r(L)+2} + w^*(L_p)} \leq \frac{2/\alpha^{t-r(L)+1}}{w^*(L)} + 2\alpha. \tag{24}$$

Nevertheless, it follows from Proposition 5.4 that $w^*(L) \geq \log(K+1)/\alpha^{t-r(L)+2}$. The result is established replacing this lower bound in the right-hand side of (24). ∎

The following theorem provides an approximation factor for WCT.

THEOREM 5.9.

$$\frac{w(A)}{w^*(A)} \leq \frac{n\log n + n}{\alpha^t} + \frac{2\alpha^2}{(\alpha-1)\log(K+1)} + 2\alpha.$$

Proof. If $|A| \leq K$, then $w(A)/w^*(A) = 1$. Hence, we assume that $|A| > K$. An upper bound on the ratio $w(A)/w^*(A)$ can be constructively obtained as follows.

Step 1. Obtain an initial upper bound on the ratio $w(A)/w^*(A)$ by applying either Lemma 5.7 or Lemma 5.8, depending whether or not $r(A) = 1$.

Step 2. While the current upper bound depends on the ratio $w(L)/w^*(L)$ for a sublist L of A, replace the ratio $w(L)/w^*(L)$ by the upper bound on this ratio given by Lemma 5.8.

First, let us assume that $r(A) = 1$. It follows from Lemma 5.7 that

$$\frac{w(A)}{w^*(A)} \leq \frac{n\log n + n}{\alpha^t} + \frac{w(A_m)}{w^*(A_m)}.$$

Let $L^0 = A_m$. Given L^i, define L^{i+1} as the sublist of L^i that is used by Lemma 5.8 to provide an upper bound on $w(L^i)/w^*(L^i)$. Let g be the largest integer such that $|L^g| > K$. By applying Step 2 g times, we obtain that

$$\frac{w(A)}{w^*(A)} \leq \frac{n\log n + n}{\alpha^t} + \sum_{i=1}^{g} \frac{2/\alpha^{t-r(L^{i-1})+1}}{w^*(L^i)} + \frac{w(L^g)}{w^*(L^g)}. \tag{25}$$

Moreover, we have that

$$\sum_{i=1}^{g}\left(\frac{2}{\alpha^{t-r(L^{i-1})+1}}\right) \le \frac{2}{\alpha^{t-r(L^{g-1})+1}}\sum_{i=0}^{\infty}\left(\frac{1}{\alpha^{i}}\right) \le \frac{2/\alpha^{t-r(L^{g})+1}}{\alpha-1} \tag{26}$$

and that

$$\frac{\log(K+1)}{\alpha^{t-r(L^{g})+2}} \le w^*(L^g) \le w^*(L^i) \tag{27}$$

for $i = 0, \ldots, g-1$. By combining (25), (26), and (27), we obtain that

$$\frac{w(A)}{w^*(A)} \le \frac{n\log n + n}{\alpha^t} + \frac{2\alpha}{\log(K+1)(\alpha-1)} + \frac{w(L^g)}{w^*(L^g)}.$$

Since $|L^{g+1}| \le K$, it follows from Lemma 5.8 that

$$\frac{w(A)}{w^*(A)} \le \frac{n\log n + n}{\alpha^t} + \frac{2\alpha^2}{\log(K+1)(\alpha-1)} + 2\alpha.$$

If $r(A) > 1$, then the term $(n\log n + n)/\alpha^t$ is removed from the approximation ratio. □

COROLLARY 5.10. *The WCT algorithm is* $(2+\epsilon+o(1))$*-approximated for any* $\epsilon > 0$.

Proof. For any $\epsilon > 0$, we can set $\alpha = 1+\epsilon/4$, $t = \lceil 2\log_\alpha n\rceil$ and $K = 2^{16\alpha^2/\epsilon^2} - 1$. In this case, it follows from Theorem 5.9 that

$$\frac{w(A)}{w^*(A)} \le \frac{n\log n + n}{n^2} + \epsilon/2 + (2+\epsilon/2). \qquad \square$$

6. Implementation. In this section, we describe how to implement both algorithms in $O(n)$ time. For that, we initially set $\alpha = 2$ and $t = \lceil \log n^2\rceil$.

Let $r(a_i)$ be the rank of the key a_i. We can calculate the ranks of all keys in $O(n)$ time by constructing a table T with $2n$ entries, where the value of the jth entry $T[j]$ is equal to $\lceil\log(j+1)\rceil + 1$ for $j = 0, \ldots, 2n-1$. Observe that this table can be computed in $O(n)$ time because the expression $\lceil\log(j+1)\rceil + 1$ has only $O(\log n)$ distinct values. In order to calculate the rank of a_i, we check if $c(a_i) < 2^{\lceil\log n\rceil - t}$. In the affirmative case, the rank of a_i is $T[\lfloor c(a_i)\times 2^t\rfloor]$. Otherwise, if $c(a_i) < 1$, then the rank of a_i is given by $T[\lfloor c(a_i)\times 2^{t-\lceil\log n\rceil}\rfloor] + \lceil\log n\rceil$. Finally, if $c(a_i) = 1$, then we set $r(a_i) = 1$. In Appendix E, we show how to compute the ranks for $\alpha = 2^{1/p}$, where p is a given integer larger than 1.

Let us assume that BUILD is called with the input parameter L. If $|L| \le K$, then the optimal tree is constructed through a dynamic programming algorithm, which takes $O(|L|^3)$ time. Now, we assume that $|L| > K$. If BUILD traverses the list L to obtain the keys with rank $r(L)$, then it spends $O(|L|)$ time. Let $k(L)$ be the number of keys in L with rank $r(L)$. The other operations performed by BUILD, including the call to CONSACT (CONSWCT), spend $O(k(L))$. Hence, the time complexity of both algorithms can be calculated by adding the time effort due to every call to BUILD. We get the following time complexity:

$$O\left(\sum_{L\in Z_K} k(L) + \sum_{L\in Z_K}|L| + \sum_{L\in(Z-Z_K)}|L|^3\right),$$

where both Z and Z_K are defined at the beginning of section 4.

Since two different lists in $(Z - Z_K)$ do not overlap, then

$$\sum_{L \in (Z - Z_K)} |L|^3 = O(nK^2),$$

which is linear in n for a fixed K. Moreover,

$$\sum_{L \in Z_K} k(L) = O(n).$$

Unfortunately, for some bad instances, $\sum_{L \in Z_K} |L|$ is $\Theta(n \log n)$. Hence, a direct implementation takes $O(n \log n)$ time.

In order to reduce the time complexity, we shall avoid traversing the entire list L to find the keys with rank $r(L)$. If we find these keys in $O(k(L))$ time, then the overall time complexity is reduced to $O(n)$. For that, we do some preprocessing.

6.1. Preprocessing. First, we spend $O(n)$ time to create $t + 1$ doubly linked lists $R_1, \ldots, R_{t+1}$. The list R_i contains the keys of A with rank i ordered by their indices.

Afterwards, we solve the *range minimum query* (RMQ) problem for the rank vector $[r(a_1), r(a_2), \ldots, r(a_n)]$. Given a vector of numbers $[x_1, x_2, \ldots, x_n]$ and $i < j$, the RMQ problem is to find the index of a minimum element in the range $[x_i, x_{i+1}, \ldots, x_j]$. Bender and Farach-Colton showed that every query can be responded in $O(1)$ time after preprocessing the input vector $[x_1, x_2, \ldots, x_n]$ in linear time [1]. Therefore, for every list L, one can obtain the keys of L with rank $r(L)$ in $O(k(L))$ time as follows:

1. Find a key with minimum rank in L in $O(1)$ time using the Bender's algorithm.
2. Traverse the $k(L)$ keys of L with rank $r(L)$ using the double linked list $R_{r(L)}$.

7. Conclusions. In this paper, we proposed two linear time algorithms with constant approximation ratios for binary searching with nonuniform costs. We have considered both the worst case and the average case problems. For the average case, we have assumed uniform probabilities. It would be interesting to devise a fast algorithm with a good approximation ratio for the general case where the probabilities are also nonuniform. Another interesting question is to determine whether there exists a unique approximate algorithm for both criteria: the worst case cost and the average cost.

Appendix A. Proof of Lemma 3.2. We can prove by induction on the size of L_i that T_i is a BST rooted by the pivot of L_i. If $|L_i| = 1$, the result holds since a unique node is a BST. Let us assume that the result holds for every sublist with less than k keys and let us consider the case where $|L_i| = k$. Let a be the pivot of L_i and let L_i^1 and L_i^2 be the sublist of L containing the keys smaller than a and the sublist of L containing the keys greater than a, respectively. Let T_i^1 (T_i^2) be the tree constructed by CONSTRUCT(T, L_i^1) (CONSTRUCT(T, L_i^2)). By induction, both T_i^1 and T_i^2 are BSTs rooted by the pivots of L_i^1 and L_i^2, respectively. Moreover, only the pivot of L_i^1 (L_i^2) is a left (right) child of a in T_i because for all other nodes of L_i^1 (L_i^2), the pivot of L_i^1 (L_i^2) is closer than a in T. As a result T_i is a BST. ∎

Appendix B. Proof of Theorem 4.1. Since $\sum_{i=1}^{n} c_i = 1$, then $c^*(A)$ cannot be smaller than 1.

We define Z^i and Z^i_K, respectively, by

$$Z^i = \{L | L \in Z \text{ and } L \text{ is at level at most } i \text{ in } T(Build)\}$$

and

$$Z^i_K = \{L | L \in Z^i \text{ and } |L| > K\}.$$

Now, let l be a nonnegative integer number. In order to establish the theorem, we prove that

$$c^*(A) \geq \sum_{L \in Z^l_K} (R(L) - G(L))\,|L|(\log|L| - 1) + \sum_{L \in (Z^{l+1} - Z^l_K)} c^*(L, G(L)). \tag{28}$$

Observe that (28) implies on the correctness of the theorem, since if we set l equal to the height of $T(Build)$, then we obtain that $Z^l_K = Z_K$ and $Z^{l+1} = Z$.

Now, we prove the correctness of (28) by induction on l. The basis is $l = 0$. If $|A| \leq K$, then the result follows from the fact that $Z^1 = \{A\}$, $Z^0_K = \emptyset$, and $G(A) = 0$. Hence, we assume that $|A| > K$. First, we observe that $Z^0_K = \{A\}$ and that $Z^1 - Z^0_K = \{A_i | i \in I(A)\}$. Hence, we must prove that

$$c^*(A) \geq R(A) \times |A|(\log|A| - 1) + \sum_{i \in I(A)} c^*(A_i, G(A_i)).$$

Since $G(A) = 0$, it follows that $R(A) + G(A) \leq \min_{a \in A}\{c(a)\}$. By applying Theorem 3.4 for the input list A with $d_1 = G(A) = 0$ and $d_2 = R(A)$, we obtain that

$$\begin{aligned} c^*(A) &\geq R(A)|A|(\log|A| - 1) + \sum_{i \in I'(A)} c^*(A_i, R(A)) + \sum_{i \in I(A)} c^*(A_i, R(A)) \\ &\geq R(A)|A|(\log|A| - 1) + \sum_{i \in I(A)} c^*(A_i, G(A_i)). \end{aligned}$$

Hence, (28) holds for $l = 0$. Now, we assume that the result holds for $l = p$ and we prove that it also holds for $l = p + 1$. Applying the inductive hypothesis for $l = p$, we obtain that

$$c^*(A) \geq \sum_{L \in Z^p_K} (R(L) - G(L))\,|L|(\log|L| - 1) + \sum_{L \in (Z^{p+1} - Z^p_K)} c^*(L, G(L)).$$

Since the set $Z^{p+1} - Z^p_K$ can be rewritten as the union of two disjoint sets $Z^{p+1} - Z^{p+1}_K$ and $Z^{p+1}_K - Z^p_K$, it follows that

$$\begin{aligned} c^*(A) \geq \sum_{L \in Z^p_K} (R(L) - G(L))\,|L|(\log|L| - 1) + \sum_{L \in (Z^{p+1} - Z^{p+1}_K)} c^*(L, G(L)) \\ + \sum_{L \in (Z^{p+1}_K - Z^p_K)} c^*(L, G(L)). \end{aligned} \tag{29}$$

Let $L \in (Z^{p+1}_K - Z^p_K)$. Since $R(L) \leq \min_{a_i \in L}\{c(a_i)\}$, it follows that $G(L) + R(L) - G(L) \leq \min_{a_i \in L}\{c(a_i)\}$. By applying Theorem 3.4 for the input list L, with

$d_1 = G(L)$ and $d_2 = R(L) - G(L)$, we obtain that

$$\begin{aligned} c^*(L, G(L)) &\geq (R(L) - G(L))|L|(\log|L| - 1) + \sum_{i \in I'(L)} c^*(L_i, R(L)) + \sum_{i \in I(L)} c^*(L_i, R(L)) \\ &\geq (R(L) - G(L))|L|(\log|L| - 1) + \sum_{i \in I(L)} c^*(L_i, G(L_i)). \end{aligned}$$

By adding the previous inequality for all sublists that belong to $(Z_K^{p+1} - Z_K^p)$, we obtain that

$$\begin{aligned} \sum_{L \in (Z_K^{p+1} - Z_K^p)} c^*(L, G(L)) \geq & \sum_{L \in (Z_K^{p+1} - Z_K^p)} (R(L) - G(L))|L|(\log|L| - 1) \\ & + \sum_{L \in (Z^{p+2} - Z^{p+1})} c^*(L, G(L)). \end{aligned} \tag{30}$$

Replacing the rightmost operand of (29) by the right-hand side of (30) and using the fact that the two sets $Z^{p+2} - Z^{p+1}$ and $Z^{p+1} - Z_K^{p+1}$ form a partition for $Z^{p+2} - Z_K^{p+1}$, we obtain that

$$c^*(A) \geq \sum_{L \in Z_K^{p+1}} (R(L) - G(L))\,|L|(\log|L| - 1) + \sum_{L \in (Z^{p+2} - Z_K^{p+1})} c^*(L, G(L)),$$

which completes the induction, and, as a consequence, establishes the result. ∎

Appendix C. Proof of Theorem 4.4. This result can be proved by induction on the level of $T(Build)$ as we did in Theorem 4.1.

In fact, let l be an integer; we must prove that

$$\begin{aligned} c(A) \leq & \sum_{L \in Z_K^l} \left(\frac{|L|\log|L|}{\alpha^{t-r(L)+1}} - \frac{|L|\log|L|}{\alpha^{t-g(L)+1}} + \frac{2|L|}{\alpha^{t-r(L)+1}} \right) \\ & + \sum_{L \in (Z^{l+1} - Z_K^l)} \left(c(L) - \frac{|L|\log|L|}{\alpha^{t-g(L)+1}} \right), \end{aligned} \tag{31}$$

where Z^l and Z_K^l are the sets defined at the beginning of the proof of Theorem 4.1. Observe that (31) implies the correctness of the theorem, since if we set l equal to the height of $T(Build)$, we obtain that $Z_K^l = Z_K$ and $Z^{l+1} = Z$. Furthermore, for every L, with $L \in Z - Z_K$, we have $c(L) = c^*(L)$.

Now, we prove the correctness of (31) by induction on l. The basis is $l = 0$. If $|A| \leq K$, then the result follows from the fact that $Z^1 = \{A\}$, $Z_K^0 = \emptyset$ and $g(A) = -\infty$. Hence, we assume that $|A| > K$. First, we observe that $Z_K^0 = \{A\}$ and that $Z^1 - Z_K^0 = \{A_i | i \in I(A)\}$. Hence, we must prove that

$$c(A) \leq \frac{1}{\alpha^{t-r(A)+1}} \left(|A|\log|A| + 2|A| - \sum_{i \in I(A)} |A_i|\log|A_i| \right) + \sum_{i \in I(A)} c(A_i).$$

This result follows by Corollary 4.3 when $L = A$.

Hence, (31) holds for $l = 0$. Now, we assume that the result holds for $l = p$, and we prove that it also holds for $l = p + 1$. Applying the inductive hypothesis for $l = p$, we obtain that

$$c(A) \leq \sum_{L \in Z_K^p} \left(\frac{|L| \log |L|}{\alpha^{t-r(L)+1}} - \frac{|L| \log |L|}{\alpha^{t-g(L)+1}} + \frac{2|L|}{\alpha^{t-r(L)+1}} \right) + \sum_{L \in (Z^{p+1} - Z_K^p)} \left(c(L) - \frac{|L| \log |L|}{\alpha^{t-g(L)+1}} \right). \tag{32}$$

Since the set $Z^{p+1} - Z_K^p$ can be rewritten as the union of two disjoint sets $Z^{p+1} - Z_K^{p+1}$ and $Z_K^{p+1} - Z_K^p$, it follows that

$$c(A) \leq \sum_{L \in Z_K^p} \left(\frac{|L| \log |L|}{\alpha^{t-r(L)+1}} - \frac{|L| \log |L|}{\alpha^{t-g(L)+1}} + \frac{2|L|}{\alpha^{t-r(L)+1}} \right) + \sum_{L \in (Z^{p+1} - Z_K^{p+1})} \left(c(L) - \frac{|L| \log |L|}{\alpha^{t-g(L)+1}} \right) + \sum_{L \in (Z_K^{p+1} - Z_K^p)} \left(c(L) - \frac{|L| \log |L|}{\alpha^{t-g(L)+1}} \right). \tag{33}$$

Let $L \in (Z_K^{p+1} - Z_K^p)$. Applying Corollary 4.3 we obtain that

$$c(L) \leq \frac{1}{\alpha^{t-r(L)+1}} \left(|L| \log |L| + 2|L| - \sum_{i \in I(L)} |L_i| \log |L_i| \right) + \sum_{i \in I(L)} c(L_i).$$

By adding the previous inequality for all sublists that belong to $(Z_K^{p+1} - Z_K^p)$, we obtain that

$$\sum_{L \in (Z_K^{p+1} - Z_K^p)} c(L) \leq \sum_{L \in (Z_K^{p+1} - Z_K^p)} \frac{|L| \log |L| + 2|L|}{\alpha^{t-r(L)+1}} - \sum_{L \in (Z^{p+2} - Z^{p+1})} \frac{|L| \log |L|}{\alpha^{t-g(L)+1}} + \sum_{L \in (Z^{p+2} - Z^{p+1})} c(L). \tag{34}$$

Replacing the rightmost operand of (33) by the right-hand side of (34) and using the fact that $(Z^{p+2} - Z^{p+1})$ and $(Z^{p+1} - Z_K^{p+1})$ form a partition of $Z^{p+2} - Z_K^{p+1}$, we conclude that the result also holds for $l = p + 1$, which completes the induction, and, as a consequence, establishes the result. □

Appendix D. Proof of Lemma 5.2. The proof is by induction on the number of nodes of $T_{pv}(L)$. Clearly, the result holds if $|T_{pv}(L)| = 1$. Now, assume that the result holds for all trees $T_{pv}(L)$ with $|T_{pv}(L)| < m$. We shall prove that the result also holds for all trees $T_{pv}(L)$ with $|T_{pv}(L)| = m$. Let y_r be the root of $T_{pv}(L)$. Then, we have two cases:

(a) $r \in I'(L)$;
(b) $r \in I(L)$.

Let T^ℓ and T^r be the left and the right subtrees of y_r in $T_{pv}(L)$, respectively. Moreover, let $\hat{T}^\ell$ and $\hat{T}^r$ be the two trees obtained by using the inductive hypothesis on T^ℓ and T^r, respectively. We observe that the level of y_i, for $i \neq r$, in T^ℓ (T^r) is $l_i - 1$.

In case (a), the tree T' is constructed as follows: y_r becomes the root of T'; $\hat{T}^\ell$ and $\hat{T}^r$ become, respectively, the left and the right subtrees of y_r. By construction, the level of y_i in T', for all $i \in I(L)$, is at most $2(l_i - 1) + 2 + 1 < 2l_i + 2$, which satisfies condition (i). Moreover, the level of y_i in T', for all $i \in (I'(L) - \{r\})$, is at most $2(l_i - 1) + 1 < 2l_i$, which satisfies condition (ii).

In case (b), let us initially assume that $2 < r < 2k$. We use two artificial nodes, say y and y'. The tree T' is constructed as follows: y becomes the root of T'; y' becomes the left child of y and y_r becomes the right child of y'; $\hat{T}^\ell$ becomes the left subtree of y' and $\hat{T}^r$ becomes the right subtree of y. Figure 6 illustrates this construction. The trees $T_{pv}(L)$ and T' for this case are represented by Figures 6(a) and 6(b), respectively. We observe that the node y_r is a leaf at level 2 in T'. Moreover, if y_i is a node of T', with $i \in I(L) - \{r\}$, then its level is at most $2(l_i - 1) + 2 + 2 = 2l_i + 2$. Furthermore, if y_i is a node of T', with $i \in I'(L)$, then its level is at most $2(l_i - 1) + 2 = 2l_i$. Hence, the conditions concerning the levels are respected. Now, we must choose two convenient pivots of $T_{pv}(L)$ to replace both the artificial nodes y and y'. The nodes y' and y are respectively replaced by the rightmost node y_{r-1} of $\hat{T}^\ell$ and by the leftmost node y_{r+1} of $\hat{T}^r$. Since both $r - 1$ and $r + 1$ belong to $I'(L)$ and the levels of y_{r-1} and y_{r+1} do not increase due to the replacement, then both conditions (i) and (ii) still hold.

If we have $r = 1$ ($r = 2k+1$), then the construction of T' is analogous. We remark that the artificial node y' (y) is not used in this case because T^ℓ (T^r) is empty. □

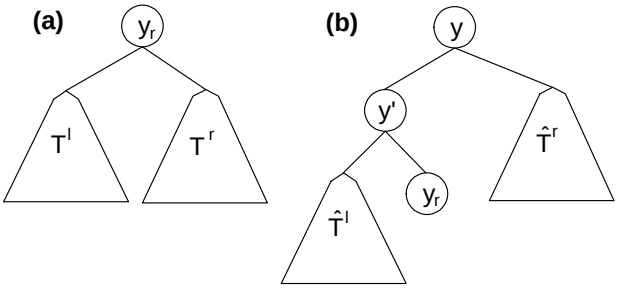

FIG. 6. (a) *A tree $T_{pv}(L)$ of pivots, where $r \in I(L)$.* (b) *The tree T' obtained from $T_{pv}(L)$, satisfying the conditions of Lemma* 5.2.

Appendix E. Calculating the ranks for fractional α. Now, let p be a fixed positive integer greater than 1. We show how to compute the key ranks for $\alpha = 2^{1/p}$ and $t = p\lceil \log n^2 \rceil + p - 1$ in $O(n)$ time. This can be useful for the WCT algorithm since better approximations are attained making α close to 1.

Let $r'(a_i)$ be the rank of a_i when the scaling parameter is equal to 2 and the total number of ranges is $t' = \lceil \log n^2 \rceil$. These auxiliary ranks can be computed in $O(n)$ time as described in the implementation section. Now, consider the following proposition.

PROPOSITION E.1. *For every $a_i \in A$, we have that $r'(a_i) = \lceil \frac{r(a_i)}{p} \rceil$.*

Proof. We have three cases:

(i) $r(a_i) = 1$;

(ii) $2 \leq r(a_i) \leq p-1$;

(iii) $r(a_i) \geq p$.

For case (iii), it is easy to check that $c(a_i) \in [1/\alpha^{t-r(a_i)+2}, 1/\alpha^{t-r(a_i)+1}) \subset [1/2^{t'-r'(a_i)+2}, 1/2^{t'-r'(a_i)+1})$. The proofs for the remaining two cases are similar. □

By the previous proposition, if the value of $r'(a_i)$ is given, then a_i has only p possible ranks: $pr'(a_i) - p + 1, pr'(a_i) - p + 2, \ldots, pr'(a_i)$. In order to compute $r(a_i)$, we construct two additional tables U and U' at the preprocessing step. We set $U[l] = \alpha^l$ for $l = 0, \ldots, p-1$, and $U'[j] = 1/2^{t'-j+1}$, for $j = 1, \ldots, t'$. Let l be the greatest index such that $c(a_i) < U'[r'(a_i)]/U[l]$. Then, $r(a_i)$ is given by $pr'(a_i) - l$, which can be computed in $O(1)$ time for a fixed value of p.

THE EFFICIENCY OF RESOLUTION AND DAVIS–PUTNAM PROCEDURES*

PAUL BEAME†, RICHARD KARP‡, TONIANN PITASSI§, AND MICHAEL SAKS¶

Abstract. We consider several problems related to the use of resolution-based methods for determining whether a given boolean formula in conjunctive normal form is satisfiable. First, building on the work of Clegg, Edmonds, and Impagliazzo in [*Proceedings of the Twenty-Eighth Annual ACM Symposium on Theory of Computing*, Philadelphia, PA, 1996, ACM, New York, 1996, pp. 174–183], we give an algorithm for unsatisfiability that when given an unsatisfiable formula of F finds a resolution proof of F. The runtime of our algorithm is subexponential in the size of the shortest resolution proof of F. Next, we investigate a class of backtrack search algorithms for producing resolution refutations of unsatisfiability, commonly known as Davis–Putnam procedures, and provide the first asymptotically tight average-case complexity analysis for their behavior on random formulas. In particular, for a simple algorithm in this class, called *ordered DLL*, we prove that the running time of the algorithm on a randomly generated k-CNF formula with n variables and m clauses is $2^{\Theta(n(n/m)^{1/(k-2)})}$ with probability $1 - o(1)$. Finally, we give new lower bounds on $\mathrm{res}(F)$, the size of the smallest resolution refutation of F, for a class of formulas representing the pigeonhole principle and for randomly generated formulas. For random formulas, Chvátal and Szemerédi [*J. ACM*, 35 (1988), pp. 759–768] had shown that random 3-CNF formulas with a linear number of clauses require exponential size resolution proofs, and Fu [*On the Complexity of Proof Systems*, Ph.D. thesis, University of Toronto, Toronto, ON, Canada, 1995] extended their results to k-CNF formulas. These proofs apply only when the number of clauses is $\Omega(n \log n)$. We show that a lower bound of the form 2^{n^γ} holds with high probability even when the number of clauses is $n^{(k+2)/4-\epsilon}$.

1. Introduction.

The satisfiability problem for boolean formulas in conjunctive normal form (*CNF formulas*) plays a central role in computer science. Historically, it was the "first" NP-complete problem. It is the natural setting in which to formulate a wide variety of constraint satisfaction problems. Its companion problem, finding a proof of unsatisfiability of a given unsatisfiable formula, plays an important role in artificial intelligence, where it is referred to as *propositional theorem proving*, and also in circuit testing.

In the last three decades, a tremendous amount of research has been directed towards understanding the mathematical structure of the satisfiability problem and developing algorithms for satisfiability testing and propositional theorem proving. Much of this research has centered around the method of *resolution*. The *resolution principle* says that if C and D are clauses and x is a variable, then any assignment that satisfies both of the clauses $C \vee x$ and $D \vee \neg\, x$ also satisfies $C \vee D$. The clause $C \vee D$ is said to be a *resolvent* of the clauses $C \vee x$ and $D \vee \neg\, x$ *on the variable* x. A *resolution refutation* for a CNF formula F consists of a sequence of clauses $C_1, C_2, \ldots, C_s$ where (i) each clause C_i is either a clause of F, or is a resolvent of two previous clauses, and (ii) C_s is the empty clause, denoted by Λ. We can represent the proof as an acyclic directed graph on vertices $C_1, \ldots, C_s$ where each clause of F has in-degree 0, and any other clause has in-degree 2 with its two in-arcs from the two clauses that produced it. It is well known that resolution is a *sound* and *complete* propositional proof system; i.e., a formula F is unsatisfiable if and only if there is a resolution refutation for F. Resolution is the most widely studied approach to propositional theorem proving, and there is a large body of research exploring *resolution algorithms*, i.e., algorithms that on input an unsatisfiable formula F, output a resolution refutation of F.

Any resolution algorithm can be used trivially to test satisfiability of an arbitrary (satisfiable or unsatisfiable) formula F, since F is satisfiable if and only if the algorithm finds no refutation. Nearly all satisfiability testers that have been studied in the literature can be derived in this way from resolution algorithms, and we say that such satisfiability testers are *resolution-based*.

One fundamental approach to satisfiability testing is to use backtrack search to look for a satisfying assignment. Algorithms that use this approach are commonly called Davis–Putnam procedures, but we will refer to them as *DLL algorithms* after Davis, Logemann, and Loveland, who first considered them [DLL62]. A DLL algorithm can be described recursively as follows. First check whether F is *trivially satisfiable* (has no clauses) or is *trivially unsatisfiable* (contains an empty clause) and if so, stop. Otherwise, select a literal l_i (a variable or the complement of a variable) and apply the search algorithm recursively to search for a satisfying assignment for the formula $F\lceil_{l_i=0}$ obtained by setting $l_i = 0$ in F. If the search succeeds, then we have an assignment for F. Otherwise, repeat the search with the formula $F\lceil_{l_i=1}$. If neither of these searches finds a satisfying assignment, then F is not satisfiable.

A particular DLL algorithm is specified by a *splitting rule*, which is a subroutine that for each recursively constructed formula determines the next splitter (literal to recurse on) and the assignment to try first. In general, the splitting rule may depend on the details of the structure of the original formula and on the results of the computation in other recursive calls. For a particular formula F, different splitting rules may result in vastly different running times.

If the splitter for some given formula F is a literal l such that l is contained in a *unit clause* (a clause C of size one), then the $l = 0$ branch falsifies C and thus terminates immediately. Effectively, the algorithm fixes $l = 1$. A splitting rule is said to use *unit propagation* if, for any formula F that has a *unit clause* (clause of size one), the splitter is chosen to be a literal in such a clause. Virtually all splitting rules considered in the literature use unit propagation, and it can be shown that any splitting rule can be modified so that it uses unit propagation at the cost of a factor of at most $O(n)$ in the running time of the algorithm, where n is the number of underlying variables. We will consider only algorithms that use unit propagation.

The simplest such splitting rule is as follows: fix an ordering of the variables $x_1, \ldots, x_n$. For a subformula F' obtained by fixing some variables, if there is a unit

clause, the splitter is the first literal belonging to such a clause. Otherwise, select the first unfixed variable. The algorithm obtained from this splitting rule is called *ordered DLL*.

The execution of a DLL algorithm A on formula F can be represented by a labeled rooted binary tree, denoted $T_A(F)$, in the usual way. Each node corresponds to a recursive call. Each internal node is labeled by its splitter, and the two out-edges correspond to the possible assignments. For any node, the path from the root to that node defines a partial assignment (*restriction*) of the variables, and the recursive call at that node is applied to the subformula obtained by applying the restriction to the original formula. Each leaf is either a *success leaf*, i.e., all of the original clauses are satisfied by the associated restriction, or a *failure leaf*, i.e., at least one original clause is falsified by the restriction. Each failure leaf is labeled by one of the original clauses that if falsifies. F is unsatisfiable if and only if all leaves are failure leaves, in which case the tree as labeled above (with internal nodes labeled by splitters and leaves labeled by falsified clauses) is called a *DLL refutation* of F. The size of the refutation is defined to be the number of nodes of the tree. It is easy to see that a formula F has a DLL refutation if and only if it is unsatisfiable. Thus DLL refutations form a complete and soundproof system.

Given a DLL refutation, it is not hard to show by induction that if we start from the clauses labeling the leaves, and work towards the root, we can label each internal node by a clause which is a resolvent of the clauses labeling its two children, and the root will be labeled by the empty clause. This tree is now the directed graph representation of a resolution refutation, and thus the DLL proof system can be viewed naturally as a restricted version of resolution.

This paper focuses on some problems concerning resolution refutations, DLL refutations, and algorithms for satisfiability. Of central importance are two parameters defined for any unsatisfiable formula F:

(i) $\mathrm{res}(F)$, the size of the smallest resolution refutation of F,
(ii) $\mathrm{DLL}(F)$, the size of the smallest DLL refutation of F.

We define $\mathrm{res}(F) = \mathrm{DLL}(F) = \infty$ for satisfiable formulas. It follows from the above discussion that $\mathrm{DLL}(F) \geq \mathrm{res}(F)$ for all formulas F. Furthermore, for any DLL-procedure for satisfiability, $\mathrm{DLL}(F)$ is a lower bound for its running time on F.

Our results fall into three groups. The first group of results shows that the resolution and DLL proof systems are, to some extent, *automatizable* in the sense that for each of these systems, there is an algorithm that on input an unsatisfiable formula F, finds a refutation of F within the proof system in time that can be upper bounded nontrivially in terms of the size of the optimal refutation within that system. In particular, we show that for any formula F in n variables and m clauses that has a DLL refutation of size at most S, there is an algorithm running in $n^{O(\log S)}m$ time that *finds* a DLL refutation of F. The analogous algorithm for resolution uses $2^{O(\sqrt{n \log S} \log n)}m$ time to find a resolution refutation for a formula F possessing one of size S. Clegg, Edmonds, and Impagliazzo [CEI96] have given algorithms to determine unsatisfiability within these time bounds, but they do not produce resolution or DLL refutations.

The second group of results concerns lower bounds for general resolution proofs. We develop simpler methods for obtaining resolution lower bounds than previously used. We illustrate this by first showing a very simple lower bound on the resolution proof complexity of the pigeonhole principle which also significantly improves on the best previous lower bounds for this problem. Our main object of study for

resolution, however, is that of randomly chosen k-CNF formulas, and we use our technique to obtain much stronger lower bounds on the resolution proof complexity of such formulas.

Our third group of results analyzes the complexity of proving unsatisfiability for random formulas (above the threshold) using DLL algorithms, the algorithms that are used most commonly in practice for satisfiability testing. We obtain the first nontrivial upper bound for resolution proofs of unsatisfiability of random formulas by showing that one of the simplest of all DLL algorithms, ordered DLL, has a running time that is qualitatively similar to the size of the best possible resolution proofs. There is still a gap between our upper bounds for DLL and the lower bounds for resolution, but we show that our analysis for ordered DLL is tight. We also make progress towards showing that our upper bound is tight for all DLL algorithms by extending our lower bound for ordered DLL to a broader class of DLL algorithms.

Our techniques result in significant simplifications and improvements of previous algorithms and lower bounds. A preliminary version of this work [BP96] pointed out that further simplification could be obtained by finding a direct relationship between $\mathrm{res}(F)$ and the minimum b for which F has a proof with all clauses at most b. Recently, Ben-Sasson and Wigderson [BSW99] have developed such a characterization of $\mathrm{res}(F)$ and $\mathrm{DLL}(F)$. Using this characterization, one can derive some of our general resolution bounds more simply. We conclude our paper with a discussion of this improvement and other directions for further research.

Because our bounds for random formulas for both DLL and general resolution are our most significant results, but are necessarily spread over several sections of the paper, we discuss them now in more detail.

Random k-CNF formulas. We consider the usual random k-CNF model, which is defined in terms of three integer parameters n, k, and m. A formula is generated by selecting m clauses of size k independently and uniformly from the set of all clauses of size k on n variables. We denote this distribution by $\mathcal{F}_m^{k,n}$ and write $F \sim \mathcal{F}_m^{k,n}$ to mean that F is selected from this distribution. The ratio $\Delta = m/n$ is referred to as the *clause density*.

The random k-CNF model has been widely studied for several good reasons. First, it is an intrinsically natural model, analogous to the random graph model, that sheds light on fundamental structural properties of the satisfiability problem. Second, for appropriate choice of parameters, randomly chosen formulas are empirically difficult for satisfiability and are a commonly used benchmark for testing satisfiability algorithms. (See, for example, the encyclopedic survey of the SAT problem in [GPFW97].) Last, it is a useful model for evaluating the effectiveness of a particular propositional proof system: strong lower bounds on proof size for random k-CNF formulas attest to the fact that the proof system in question is ineffective on average.

A fundamental conjecture about the random k-CNF formula model (see [CS88, BFU93, CF90, CR92, FS96, KKKS98]) says that there is a constant θ_k, the *satisfiability threshold*, such that a random k-CNF formula of clause density Δ is almost certainly satisfiable for Δ bounded below θ_k (as n gets large) and almost certainly unsatisfiable if Δ is bounded above θ_k. There is considerable empirical and analytic evidence for this. Recently, Friedgut [Fri99] showed that for each n and k there is a threshold $\theta_k(n)$ such that for any $\epsilon > 0$, random k-CNF formulas with clause density $\Delta \leq \theta_k(n) - \epsilon$ are almost certainly satisfiable and those with clause density $\Delta \geq \theta_k(n) + \epsilon$ are almost certainly unsatisfiable. However, he does not rule out the possibility that $\theta_k(n)$ fails to converge to a constant. It is known that $\theta_2 = 1$ is

independent of n [CR92, Goe96] and that for each k, $\theta_k(n)$ is bounded between two constants, b_k and d_k, that are independent of n; e.g., $3.26 \leq \theta_3(n) \leq 4.596$ [AS00, JSV00].

The threshold indicates three distinct ranges of clause density for investigating complexity. For Δ at the threshold, an effective algorithm must be able to distinguish between unsatisfiable and satisfiable instances. Below the threshold, a random formula is almost certainly satisfiable, and the problem of interest is to find a satisfying assignment quickly.

Above the threshold, the formula is almost certainly unsatisfiable, and we have the two closely related questions, (i) What is the typical size of the smallest unsatisfiability proof? and (ii) How quickly can an algorithm find a proof?

Several empirical studies of DLL procedures on random k-CNF formulas have been done, e.g., by Selman, Mitchell, and Levesque [SML96] and Crawford and Auton [CA96]. The former applies ordered DLL (defined earlier) to random k-CNF formulas for various values of Δ. The curves in [SML96, CA96] show very low complexity for Δ below the threshold, a precipitous increase in complexity at the threshold, and a speedy decline to low complexity above the threshold.

Much has been made of the analogy with statistical physics [KS94], and there has been a suggestion that the computational complexity at the threshold is evidence of a critical phenomenon in complex systems and based on underlying edge-of-chaos behavior present only near the threshold. The empirical observation that satisfiability is easy below the threshold is supported by analytical work. The proofs of the aforementioned lower bounds on θ_k were obtained by analyzing some DLL algorithm and showing that it almost certainly finds a satisfying assignment in linear time, provided that Δ is below some specified constant.

In their seminal paper, Chvátal and Szemerédi [CS88] showed that for any fixed Δ above the threshold there is a constant $\kappa_\Delta > 0$ such that $\text{res}(F) \geq 2^{\kappa_\Delta n}$ almost certainly if F is a random k-CNF formula of clause density Δ. (This result substantially improved the previous work of Franco and Paull [FP83] which showed subexponential time lower bounds for refuting the same class of formulas using particular DLL algorithms.) On the other hand, Fu [Fu95] showed that $\text{res}(F)$ is almost certainly polynomial in n for $m = \Omega(n^{k-1})$. These results together with the empirical work motivate the problem of determining the best constant κ_Δ for which $\text{res}(F) \geq 2^{\kappa_\Delta n}$ with prob $1 - o(1)$ for random k-CNF formulas F of density Δ. The lower bound in [CS88] as presented does not give bounds on the dependence of κ_Δ on Δ, but rough estimates show that for 3-CNF formulas the bound decreases as $1/\Delta^{\Omega(\Delta^4)}$. This implies that the lower bound declines extremely quickly and becomes trivial when the number of clauses grows above $n \log^{1/4} n$. For larger clause size k Fu [Fu95] obtained better bounds but with a similar exponential drop-off. Is there really such a sharp decline in complexity for random formulas above the threshold?

Our new lower bounds show that the drop-off in κ_Δ is at most polynomial in Δ. We show that for any constant $\epsilon > 0$ there is a constant $a_\epsilon > 0$ such that for random 3-CNF formulas the complexity of resolution proofs is almost certainly at least $2^{a_\epsilon(n/\Delta^{4+\epsilon})}$ and obtain similar results for random k-CNF formulas having larger values of k. In particular, our results imply that even random formulas with moderately large clause densities require proofs of weakly exponential size. More precisely, for any $k \geq 3$ and $\epsilon > 0$, we show that there is a $\gamma > 0$ such that almost all k-CNF formulas in n variables with at most $n^{(k+2)/4-\epsilon}$ clauses require resolution

refutations of size at least 2^{n^γ}. For example, a random 3-CNF formula with $n^{5/4-\epsilon}$ clauses requires exponentially large resolution proofs.

Although these resolution bounds show that the decline in κ_Δ is at most inverse polynomial in Δ, it is not immediately clear that even a polynomial decline with Δ is achievable. There seem to be no previously known nontrivial upper bounds on the running time of algorithms on random instances above the threshold. We prove the first such nontrivial upper bound by showing that for $F \sim \mathcal{F}_m^{k,n}$, the size of the DLL refutation of F produced by ordered DLL is $2^{O(n/\Delta^{1/(k-2)})}n^{O(1)}$. Thus κ_Δ does indeed decline as a fixed power of Δ.

At the upper end, our result shows that when $m = \Omega(n^{k-1}/\log^{k-2} n)$, the algorithm runs in polynomial time, improving on Fu's $\Omega(n^{k-1})$ bound on the number of clauses needed for polynomial-size resolution proofs but also giving an algorithm to find such proofs.

There is a gap between the exponents on Δ given by our lower bounds for general resolution and our upper bound for ordered DLL. What is the optimal exponent for general resolution or for DLL, which is more interesting since such bounds would have implications for practical satisfiability testing? We show that our upper bound for ordered DLL is indeed tight in that ordered DLL requires proofs of $2^{\Omega(n/\Delta^{1/(k-2)})}$ size.

Can a different splitting rule achieve a better exponent than ordered DLL on random formulas? We expand our understanding of DLL algorithms by showing that in the case $k = 3$, for $m = \Omega(n^{3/2}\log^\epsilon n)$, the lower bound for ordered DLL extends to a larger class of algorithms, whose splitting rule (aside from unit propagation) is independent of the formula. The key step in proving this lower bound is Lemma 6.7, which applies to *any* DLL splitting rule and therefore may be of independent interest. It shows that with high probability, along every path of a DLL tree that is "not too long," the number of unit clauses generated cannot be very large. While Lemma 6.7 is general, the remainder of the proof of the lower bound unfortunately depends heavily on the independence of the splitting rule from the formula.

Overall, our results show that for $F \sim \mathcal{F}_{\Delta n}^{k,n}$, $\log_2 \mathrm{res}(F)$ decays as a fixed power of Δ, suggesting that there is not an isolated point of complexity at the threshold but rather a slow and gradual decline in complexity as Δ increases.

2. Preliminary definitions. Let $X = \{x_1, \ldots, x_n\}$ be a set of boolean variables. Following usual parlance, an assignment ρ of 0-1 values to some subset of the variables is called a *restriction*. We will abuse notation and identify ρ with the set of literals set to 1 by ρ. We write $v(\rho)$ for the set of variables that are assigned values by ρ.

Similarly, a clause C over the variables X can be viewed as a set of literals, and we write $v(C)$ for the underlying set of variables. If $\mathcal{C}$ is a set of clauses, or F is a CNF formula, we write $v(\mathcal{C})$ or $v(F)$ for the underlying sets of variables.

If C is a clause and ρ is a restriction, then ρ satisfies C if it sets some literal of C to 1. If ρ does not satisfy C, we define $C\lceil_\rho$, the *restriction of* C *by* ρ, to be the clause obtained from C by deleting all literals set to 0 by ρ. For a formula F the *restriction of* F *by* ρ, $F\lceil_\rho$, is the formula obtained by removing all clauses satisfied by ρ and replacing any other clause C of F by $C\lceil_\rho$.

If $\mathcal{P} = (C_1, \ldots, C_r)$ is a resolution refutation of a formula F and ρ is a restriction we can construct a refutation of $F\lceil_\rho$, denoted $\mathcal{P}\lceil_\rho = (D_1, \ldots, D_r)$, as follows. For ease of description, we allow the proof to contain clauses that are identically 1. For $i \in [r]$ having defined $D_1, \ldots, D_{i-1}$, if ρ satisfies C_i, then let D_i be the identically 1 clause. Otherwise, (i) if C_i is a clause of F, let $D_i = C_i\lceil_\rho$, and (ii) if C_i is the resolvent of C_j

and C_k on variable x, then if either D_j or D_k is 1, then let D_i equal the other one, and otherwise let D_i be the resolvent of D_j and D_k on x. It is not hard to show that after deleting the 1-clauses, the result is a resolution proof of $F\lceil_\rho$.

A resolution refutation $\mathcal{P}$ is said to be *b-bounded* if all of the clauses appearing in it have size at most b.

For the purpose of generating test formulas, the most natural model of a random k-CNF formula on n variables with clause density Δ is to choose $m = \Delta n$ clauses independently with replacement. This distribution, which we denote $\mathcal{F}_m^{k,n}$, is the one analyzed in [CS88]. Another model, which is used in [Fri99], is to choose each of the possible clauses independently with probability $p = m/\binom{n}{k}2^k$; call this $\mathcal{F}^{k,n}(p)$. An easy argument shows that when considering properties of formulas that are monotone (or antimonotone) with respect to sets of clauses, the almost certain properties under both distributions are the same up to a change from m to $m \pm o(m)$. This is just a natural extension of the similar (and more precise) equivalences for the random graph model as shown, for example, in [AV79]. We generally assume the distribution $\mathcal{F}_m^{k,n}$. We write $F \sim \mathcal{F}$ to mean F is a random formula selected according to distribution $\mathcal{F}$.

We make frequent use of two well-known tail bounds for the binomial distribution (see [ASE92, Appendix A]).

PROPOSITION 2.1. *If Y is a random variable distributed according to the binomial distribution $B(n,p)$, then*

1. $Pr[Y < np/4] \leq 2^{-(np)/2}$,
2. $Pr[Y > Cnp] \leq (\frac{e}{C})^{-Cnp}$.

3. Automatizability of DLL and resolution. The quantity $\mathrm{res}(F)$ (resp., $\mathrm{DLL}(F)$) tells us the size of the smallest resolution refutation (resp., DLL refutation) of F. A fundamental problem is to find effective algorithms for constructing resolution refutations and DLL refutations whose size is "close" to optimal. This is the *automatizibility problem* for proof systems, which was formalized in [BPR97].

DEFINITION 3.1. *Let $\mathcal{S}$ be an arbitrary propositional proof system.*[1] *For the unsatisfiable formula F, let $s(F)$ denote the size of the smallest refutation of F in $\mathcal{S}$. Then $\mathcal{S}$ is said to be automatizable if there exists a deterministic algorithm that takes as input an unsatisfiable formula F on n variables and m clauses, and outputs an $\mathcal{S}$-refutation of f in time polynomial in $s(F)$ and n and m. More generally $\mathcal{S}$ is $q(s,n,m)$-automatizable if there exists a deterministic algorithm that runs in time $q(s(F),n,m)$ and outputs an $\mathcal{S}$-refutation of F (whose size is necessarily also bounded by $q(s(F),n,m)$).*

THEOREM 3.2.

1. *The DLL proof system is $q(s,n,m)$-automatizable for $q(s,n,m) = n^{O(\log s)}m$.*
2. *The resolution proof system is $q(s,n,m)$-automatizable for $q(s,n,m) = 2^{O(\sqrt{n \log s}\log n)}m$.*

These results, especially the second, fall short of the desired polynomial automatizability. Nevertheless, even the second is strong enough that if $\mathrm{res}(F)$ is subexponential, $2^{o(n)}$, then our algorithm finds a subexponential size resolution refutation in subexponential time. The results are closely related to, and motivated by, previous results of Clegg, Edmonds, and Impagliazzo. Their results concern the polynomial calculus proof system (called Groebner in [CEI96]), which is more general than the

[1] We will not provide a general definition of propositional proof system, since we are focusing exclusively on the two concrete systems, resolution and DLL, that we have defined above. The interested reader can readily formulate a general definition or consult [CR77].

resolution system. In their paper, they proposed and analyzed satisfiability testing algorithms based on the Groebner basis algorithm from commutative algebra. When run on an unsatisfiable formula F, their algorithm produces a refutation in the polynomial calculus proof system (but not necessarily a resolution refutation). They give two algorithms for this, the first of which finds a refutation in time bounded above by $O((\mathrm{DLL}(F))^{\log n})$, and the second finds a refutation in time bounded above by $O(2^{\sqrt{n\mathrm{res}(F)}\log n})$. In other words, provided that F has a short DLL refutation (resp., resolution refutation), their first (resp., second) algorithm finds a refutation that is "not too big" but in the stronger polynomial calculus proof system. Our two algorithms, which closely parallel theirs, achieve comparable running times, but produce, respectively, a DLL refutation and a resolution refutation.

Proof of Theorem 3.2. The theorem asserts the existence of two algorithms, which on input an unsatisfiable formula F, find, respectively, a DLL refutation and a resolution refutation within a specified time bound. The two algorithms are most easily described together.

First, we need a subroutine, called **Bounded-search**, which takes as input F and an integer parameter b and finds a b-bounded resolution refutation of F if one exists. It is not hard to implement this subroutine in time $T_0(n, m, b) = n^{O(b)+O(m)poly(n)}$, e.g., by listing the b-bounded clauses of F and, for each clause on the list, resolve it with each clause preceding it (if possible) and add the resolvent to the end of the list, if it is of size at most b and does not duplicate anything on the list. If the algorithm constructs the empty clause, we have the desired refutation; otherwise, there is no such refutation.

The main algorithm called **Resolution-search** also takes as input F and an auxiliary parameter b. First we use **Bounded-search**(F, b) to find a b-bounded resolution refutation for F if it exists. If not, then for each of the $2v(F)$ literals l, apply **Resolution-search** to the formula $F\lceil_{l=1}$ in order to identify the literal l for which **Resolution-search**$(F\lceil_{l=1})$ terminates fastest. These $2n$ calls to **Resolution-search** are executed in a sequence of parallel rounds; in round i the ith step of each of the $2n$ calls is performed. As soon as the first of the calls terminates, say for literal l^*, all of the other calls are aborted, except the call corresponding to $\neg\, l^*$, which is run to completion. The output of **Resolution-search**(F, b) consists of the derivation of the singleton clause l^*, followed by the derivation of the singleton clause $\neg\, l^*$ followed by $\emptyset$. (Note that the parallel search for the literal l^* described above can be replaced by a more space efficient "doubling search" which in iteration i runs each of the recursive calls one by one from the beginning for 2^i steps, stopping the first time that one of the calls terminates. The time analysis below can be modified to apply to this variant.)

The analysis of the algorithm will rely on the following technical fact, which is easily proved by induction.

PROPOSITION 3.3. *Suppose that $T(n, s)$ is a function defined for nonnegative integers n and $s > 0$ that satisfies, for some positive increasing function $h(n)$, positive constant C and $\lambda > 1$:*

$$\begin{array}{lcll} T(0,s) & \leq & h(0), & \\ T(n,s) & \leq & h(n) & \text{if } s \leq 1, \\ T(n,s) & \leq & h(n) + CnT(n-1, \frac{s}{\lambda}) + T(n-1,s) & \text{if } n \geq 1 \text{ and } s > 1. \end{array}$$

Then $T(n, s) \leq h(n)(1 + C^{\log_\lambda s} n^{2\log_\lambda s})$.

We now prove the first part of the automatization theorem. Here we use the above algorithm with $b = 0$. It is not hard to see that in this case, the output by **Resolution-**

search can be viewed as a DLL refutation, since the DAG associated to the proof is a tree. We upper bound the running time of the algorithm in terms of DLL(F). Let $T_1(n, s; m)$ denote the maximum running time of **Resolution-search**$(F, 0)$ over all formulas F with at most n variables and m clauses and for which DLL(F) $\leq s$. Consider a DLL refutation of size at most s and let x_i be the splitting variable at the root. The left and right branches of the tree give refutations for $F\lceil_{x_i}$ and $F\lceil_{\neg x_i}$, and the smaller of these is of size at most $s/2$. Hence at least one of the recursive calls terminates after at most $T_1(n-1, s/2; m)$ steps, and so the literal l^* is found after at most that number of rounds. The time for each round can be bounded above by Cn for some constant C. Once l^* is found, it takes at most $T_1(n-1, s; m)$ steps to complete the call to **Resolution-search**$(F\lceil_{\neg\, l^*})$. Thus, we conclude that for fixed m, $T_1(n, s; m)$ satisfies the recurrence of the above proposition with $h(n) = T_0(n, m, b)$ and $\lambda = 2$. We conclude that $T_1(n, s; m) = n^{O(\log s)}O(m)$ as required to prove the first automatization result.

For the second result, first define, for a set $\mathcal{P}$ of clauses, $\mathcal{P}[b]$ to be the subset of clauses of size greater than b. For a formula F, let res(F, b) denote the minimum of $|\mathcal{P}[b]|$ over all resolution refutations of F (so that for $b < 0$, res(F) = res(F, b)). Let $T_2(n, s; m, b)$ denote the maximum time needed by **Resolution-search**(F, b) on (n, m)-formulas F satisfying res$(F, b) \leq s$. Note that $T_2(n, s; m, b) \leq T_0(n, b)$ if $s < 1$ and $T_2(0, s; m, b) = O(1)$. Suppose n and s are both at least 1. Let F be an (n, m)-formula and let $\mathcal{P}$ be a resolution refutation of F with $|\mathcal{P}[b]| \leq s$. For a literal l, let $c(b, l)$ be the number of clauses of $\mathcal{P}[b]$ containing l. The average of $c(b, l)$ over literals is greater than $|\mathcal{P}[b]|b/2n$, and hence there exists a literal l with $c(b, l) > b|\mathcal{P}[b]|/2n$. Note that the refutation $\mathcal{P}\lceil_{l=1}$ of $F\lceil_{l=1}$ has at most $|\mathcal{P}[b]|(1 - \frac{b}{2n})$ clauses, and hence $T_2(n, s; m, b)$ satisfies the recurrence for T in the proposition with $\lambda = \frac{2n}{2n-b}$ and $h(n) = T_0(n, b)$. Applying the proposition, we conclude that $T_2(n, b) \leq T_0(n, b)n^{O(\frac{n}{b}\log s)}$. Choosing $b = \sqrt{n \log s}$ yields an upper bound of $2^{O(\sqrt{n \log s}\log n)}O(m)$ to complete the proof of the theorem. □

Remark. The result of Ben-Sasson and Wigderson mentioned in the introduction implies that the **Bounded-search** routine is sufficient to automatize resolution. More specifically, they show that for any formula F, if DLL(F) $\leq s$, then **Bounded-search** with $b = O(\log s)$ finds a resolution refutation of F, and if res$(F) \leq s$, then **Bounded-search** with $b = O(\sqrt{n \log s})$ finds a resolution refutation of F.

4. Lower bounding resolution proof complexity. For any unsatisfiable formula on n variables, res$(F) \leq$ DLL$(F) \leq 2^n + 1$, since a DLL proof of an n-variable formula is a binary tree of maximum depth n. Unless $coNP = NP$ one would expect that there are formulas where res(F) is superpolynomial in $|F|$, but it is not obvious how to prove such lower bounds. In a breakthrough paper, Haken [Hak85] proved the first exponential lower bounds in general resolution for a class of formulas related to the pigeonhole principle. Haken obtained his bounds using an elegant new technique called "bottleneck counting." The technique was developed further in [Urq87] to give more general bounds on resolution refutations. Building on Haken's and Urquhart's arguments, Chvátal and Szemerédi [CS88] used the bottleneck counting method to show that for a sufficiently large constant c, almost certainly a random 3-CNF formula with cn clauses requires an exponential length resolution refutation. Fu [Fu95] recently extended this bound to apply when the number of clauses is larger, but for 3-CNF formulas it gives no improvement on [CS88].

All of these proofs have the same general structure. To prove a lower bound on res(F) for all F belonging to some specified class of formulas $\mathcal{F}$, the first step

is to prove a result of the following type: for some larger class $\mathcal{F}'$ of formulas, any resolution refutation of $G \in \mathcal{F}'$ must have a "large" clause.

In the second step, which is typically the more involved part, an arbitrary resolution refutation of F is considered. Each clause in the proof is viewed as allowing certain truth assignments to flow through it, namely those that it falsifies. Using the result of the first step, one shows that every truth assignment must flow through some "complex" or "large" clause that permits only a small number of truth assignments to pass (thus the term "bottleneck counting"). Therefore, the number of clauses in the refutation must be large. The complications in the argument come in making the association between complex clauses and truth assignments.

Our method uses something very much like the first step but replaces the second step by an argument that leads to stronger results with simpler arguments. We assume for contradiction that $F \in \mathcal{F}$ has a small proof. We use this assumption to show that F can be modified to a formula $F' \in \mathcal{F}'$ that has a proof with no large clauses, contradicting the first step.

We consider two methods for modifying the formula F to get F'. The first is to apply a restriction, i.e., fix a small set of variables. The second is to *augment* F, i.e., add some additional clauses to F. The restriction method is equivalent to the special case of the augmentation method where the clauses that are added are all unit clauses.

4.1. Lower bounds for the pigeonhole principle. We illustrate our approach to lower bounds for general resolution proofs by giving a very simple proof of the exponential lower bounds for the class $\{\neg\ PHP_n^m : m > n\}$ of pigeonhole principle formulas considered by Haken. The variables of the formula $\neg\ PHP_n^m$ correspond to the entries $P_{i,j}$ of an $m \times n$ boolean matrix. (We think of the rows as corresponding to"pigeons" and the columns as corresponding to "holes".) Its clauses are (1) $P_{i,1} \vee P_{i,2} \vee \cdots \vee P_{i,n}$ for each $i \leq m$ (each row has at least one 1, or every pigeon goes into a hole) and (2) $\neg P_{i,k} \vee \neg P_{j,k}$ for each $i, j \leq m$, $k \leq n$, $i \neq j$ (each column has at most one 1, or every hole gets at most one pigeon). Since $m > n$, this is trivially unsatisfiable. Note that the number of clauses in $\neg\ PHP_n^m$ is $m + \binom{m}{2} n \leq m^3$. We prove the following theorem.

THEOREM 4.1. *For $n \geq 2$, any resolution refutation of $\neg PHP_{n-1}^n$ has size at least $2^{n/20}$.*

Proof. As in the lower bound proof of Haken [Hak85], a truth assignment to the underlying variables $P_{i,j}$ is *critical* if it defines a one-to-one, onto map from $n-1$ rows (pigeons) to $n-1$ columns (pigeonholes), with the remaining pigeon not mapped to any hole. A critical assignment where i is the pigeon left out is called *i-critical*. In what follows we will be interested only in critical truth assignments.

Let C be a clause. The monotone clause $M(C)$ associated to C is obtained by replacing each occurrence of a negative literal $\neg\ P_{i,k}$ by the set of literals $\{P_{l,k} \mid l \neq i\}$. It is easy to check that C and $M(C)$ are satisfied by precisely the same set of critical assignments.

We will be interested in restrictions corresponding to partial matchings that one obtains by repeatedly choosing an i, j, and setting $P_{i,j} = 1$, $P_{i,j'} = 0$ for $j' \neq j$, and $P_{i',j} = 0$ for $i' \neq i$. Observe that if one begins with a resolution refutation of $\neg PHP_{n-1}^n$ and one chooses such a partial matching restriction that sets t variables to 1, then the result is resolution refutation of $\neg PHP_{n-t-1}^{n-t}$. Furthermore, the restriction applied to the monotone conversion of each clause results in the same clause as doing the monotone conversion of the clause first and then applying the restriction.

(The transformation to monotone clauses, due to Buss, is not essential, but it will make our argument slightly cleaner.)

So let $C_1, \ldots, C_S$ be a resolution refutation of $\neg PHP^n_{n-1}$ and $M_1 = M(C_1), \ldots, M_S = M(C_S)$ be its monotone conversion. Say that a clause M_t is *large* if it has at least $n^2/10$ (positive) literals, i.e., at least one-tenth of all the variables. To show that $S \geq 2^{n/20}$, we will show that the number L of large clauses is at least $2^{n/20}$. Assume for contradiction that $L < 2^{n/20}$. Let $d_{i,j}$ denote the number of large clauses containing $P_{i,j}$. By averaging, there is an i, j with $d_{i,j} \geq L/10$. Choose such an i, j, and apply the restriction $P_{i,j} = 1$, $P_{i,j'} = 0$ for $j' \neq j$, and $P_{i',j} = 0$ for $i' \neq i$. Applying this restriction we obtain a monotone conversion of a refutation of $\neg PHP^{n-1}_{n-2}$ with at most $9L/10$ large clauses. Applying this argument iteratively $\log_{10/9} L$ many times, we are guaranteed to have knocked out all large clauses. Thus, we are left with a refutation of $\neg PHP^{n'}_{n'-1}$, where

$$n' \geq n - \log_{10/9} L = (1 - (\log_{10/9} 2)/20)n > 0.671n$$

and where no clause in the refutation is large. However, this contradicts the following lemma (originally due to Haken [Hak85]) which states that such a refutation must have a clause whose monotone conversion has size at least $2(n')^2/9 > n^2/10$. □

LEMMA 4.2. *Any resolution refutation of $\neg PHP^n_{n-1}$ must contain a clause C such that $M(C)$ has at least $2n^2/9$ literals.*

Proof. Given a clause C, let

$$\mathit{badpigeons}(C) = \{i \mid \text{there is some } i\text{-critical assignment } \alpha \text{ falsifying } C\}.$$

Define the complexity $\mathrm{comp}(C) = |\mathit{badpigeons}(C)|$.

Let $\mathcal{P}$ be a resolution refutation of $\neg PHP^n_{n-1}$ and consider the complexity of the clauses that appear in $\mathcal{P}$. The complexity of each initial clause is at most 1, and the complexity of the final false clause is n.

Note that if we use the resolution rule to derive a clause C from two previous clauses C' and C'', we have that $\mathrm{comp}(C) \leq \mathrm{comp}(C') + \mathrm{comp}(C'')$, since any assignment falsifying C must also falsify at least one of C' or C''. If C is the first clause in the proof with $\mathrm{comp}(C) > n/3$, we must have $n/3 < \mathrm{comp}(C) \leq 2n/3$. We will show that $M(C)$ contains a large number of variables.

For $\mathit{comp}(C) = t$ will now show that $M(C)$ has at least $(n-t)t \geq 2n^2/9$ distinct literals mentioned. Fix some $i \in \mathit{badpigeons}(C)$ and let α be an i-critical truth assignment falsifying C. For each $j \notin \mathit{badpigeons}(C)$, consider the j-critical assignment, α', obtained from α by replacing i by j, that is, by mapping i to the place that j was mapped to in α. This assignment satisfies C and differs from α only in one place: if α mapped j to l, then α' maps i to l. Since C and $M(C)$ agree on all critical assignments and $M(C)$ is monotone, it must contain the variable $P_{i,l}$.

Running over all $n - t$ j's not in $\mathit{badpigeons}(C)$ (using the same α), it follows that $M(C)$ must contain at least $n - t$ distinct variables $P_{i,l}$, $l \leq n$. Repeating the argument for all $i \in \mathit{badpigeons}(C)$ shows that C contains at least $(n-t)t$ positive literals. □

We note that Theorem 4.1 improves somewhat upon Haken's bound of $2^{n/577}$, although our major interest is in its simpler proof rather than in the better size bound. Buss and Turán [BT88] extend Haken's argument to show that $\neg PHP^m_n$ requires superpolynomial size resolution lower bounds as long as $m < n^2/\log n$. Our argument can be extended to rederive their result.

5. Resolution lower bounds for random formulas. The previous section gave a simple proof that res(F) is large for a specific class of formulas. Abstractly, we can summarize the approach as follows. We assume for contradiction that F has a small proof. In particular, F has a proof with a small number of large clauses. We then modify F (in the above case, restrict some variables) to obtain another formula F' having a proof with no large clauses. We then obtain a contradiction by showing that any proof of F' contains a large clause.

In this section we show how the same idea can be used to obtain simple and improved lower bounds on res(F) that hold with high probability when F is a randomly chosen formula of a given clause density.

5.1. Resolution refutations usually require big clauses. The first main ingredient is a result (essentially from [CS88]) that provides a set of parameterized conditions on a formula F that imply that any resolution refutation of F has at least one large clause. We then show that when F is a random formula of clause density Δ, these conditions hold for certain values of the parameters. We need some definitions.

DEFINITION 5.1. *For a real number σ, a set of clauses $\mathcal{C}$ is* σ-sparse *if $|\mathcal{C}| \leq \sigma|v(\mathcal{C})|$, where $v(\mathcal{C})$ is the set of variables appearing in $\mathcal{C}$.*

DEFINITION 5.2. *If $\mathcal{C}$ is a set of clauses and l is a literal, we say that l is* pure *in $\mathcal{C}$ if some clause of $\mathcal{C}$ contains l and no clause of $\mathcal{C}$ contains $\neg\, l$.*

DEFINITION 5.3. *For $s \geq 1$ and $\epsilon \in (0,1)$, the following properties are defined for formulas F:*

Property $A(s)$: Every set of $r \leq s$ clauses of F is 1-sparse.

Property $B_\epsilon(s)$: For r satisfying $s/2 < r \leq s$, every subset of r clauses of F has at least ϵr pure literals.

The following result is essentially due to Chvátal and Szemerédi (and is closely related to Haken's argument in Lemma 4.2).

PROPOSITION 5.4. *Let $s > 0$ be an integer and F be a CNF formula. If properties $A(s)$ and $B_\epsilon(s)$ both hold for F, then F has no $\epsilon s/2$-bounded proof.*

Proof. The result holds trivially if F is satisfiable, so assume that F is unsatisfiable. We say that a set S of clauses implies a clause C if every assignment that satisfies all of the clauses in S satisfies C. Since F is unsatisfiable, F implies any clause C. The complexity of a clause C with respect to F, comp(C) is the minimum size of a set of clauses that implies C.

Let $\mathcal{P}$ be a resolution refutation of F.

Claim. If F satisfies $A(s)$, then there is a clause $C \in \mathcal{P}$ for which $s/2 < \text{comp}(C) \leq s$.

It is easy to see that if S is a minimal set of clauses that implies C and the literal l is pure in S, then l is in C. Hence for the C given by the above claim, property $B_\epsilon(F)$ implies that $|C| \geq \epsilon\text{comp}(C) \geq \epsilon s/2$.

So it suffices to prove the claim. We first note that if $\mathcal{C}$ is a set of clauses such that any subset is 1-sparse, then it is satisfiable. Indeed, the sparsity condition is equivalent to the hypothesis of the Hall theorem on systems of distinct representatives, and the conclusion of the theorem is that there is a one-to-one mapping sending each clause $C \in \mathcal{C}$ to a variable $v_C \in C$. We can thus satisfy each clause C by appropriately fixing v_C.

Now if S implies Λ, then S is unsatisfiable, so $A(s)$ implies comp(Λ) $> s$. Choose C to be the first clause in $\mathcal{P}$ with comp(C) $\geq s/2$. Since C is the resolvent of two previous clauses C_h, C_j and comp(C) $\leq$ comp(C_h) + comp(C_j) we conclude that comp(C) $< s$. ∎

LEMMA 5.5. *For each integer $k \geq 3$ and $\epsilon > 0$, there are constants $C(k), c_\epsilon(k) > 0$ such that the following holds. Let m, n be integers with $m = \Delta n$ for some $\Delta \geq 1$. Let $F \sim \mathcal{F}_m^{k,n}$.*

1. *If $s \leq C(k)n/\Delta^{1/(k-2)}$, then F satisfies $A(s)$ probability $1 - o(1)$ in s.*
2. *If $s \leq c_\epsilon(k)n/\Delta^{2/(k-2-\epsilon)}$, then F satisfies $B_\epsilon(s)$ with probability $1-o(1)$ in s.*

This lemma is proved by elementary combinatorial probability. We defer the proof until section 5.3 where we state and prove a generalization (Lemma 5.11).

5.2. The formula augmentation method. Armed with these results we give a very simple proof that a random k-CNF F of density Δ satisfies $res(F) \geq 2^{n/\Delta^{O(1)}}$ with probability $1 - o(1)$. An *augmentation* of a formula F is a formula obtained by adding additional clauses to F. As we now describe, augmentations can simplify proofs.

We say that a clause C *subsumes* a clause D if $C \subset D$. Suppose that $\mathcal{P}$ is a proof of F and let G be a CNF formula. We can obtain a proof of the augmented formula $F \wedge G$, denoted $\mathcal{P}\lceil_G$, as follows: For each clause $D \in \mathcal{P}$, if there is a clause C in G such that C subsumes D replace D by C and propagate this simplification forward through the rest of the proof by (possibly) shortening clauses that were produced using D.

Observe that in the case that G consists of clauses of size 1, G corresponds naturally to a restriction ρ, and there is a close correspondence between the proofs $\mathcal{P}\lceil_G$ and $\mathcal{P}\lceil_\rho$.

Following our general approach, suppose we want to prove that $res(F)$ is big. Assuming for contradiction that F has a small proof $\mathcal{P}$, we show that for some integer s and $\epsilon > 0$, there is a G such that (i) G subsumes all clauses of size $\epsilon s/2$ of $\mathcal{P}$ and such that (ii) $F \wedge G$ satisfies $A(s)$ and $B_\epsilon(s)$. This is a contradiction since (i) implies that $\mathcal{P}\lceil_G$ is an $\epsilon s/2$ bounded refutation of $F \wedge G$, while (ii) and Proposition 5.4 imply that no such refutation is possible.

We will realize this approach by considering G chosen at random from some distribution $\mathcal{G}$. We say that the distribution $\mathcal{G}$ satisfies property $g(b, M)$, for $b, M > 0$ if for any clause C of size at least b, if $G \sim \mathcal{G}$, then $\Pr[G \text{ does not subsume } C] \leq 1/M$.

PROPOSITION 5.6. *Let F be a formula. Let $s, M \geq 1$ and $\epsilon > 0$, and let $\mathcal{G}$ be a distribution over formulas that satisfies $g(\epsilon s/2, M)$. Then*

$$res(F) \geq M \times Pr_{G \sim \mathcal{G}}[F \wedge G \text{ satisfies both } A(s) \text{ and } B_\epsilon(s)].$$

Proof. The conclusion follows immediately from the chain of inequalities:

$$\begin{aligned} \mathrm{res}(F)/M &\geq \Pr_{G \sim \mathcal{G}}[\mathcal{P}\lceil_G \text{ is not } \epsilon s/2 \text{ bounded}] \\ &\geq \Pr_{G \sim \mathcal{G}}[F \wedge G \text{ satisfies both } A(s) \text{ and } B_\epsilon(s)]. \end{aligned}$$

The second inequality is immediate from Proposition 5.4. For the first inequality, if $\mathcal{P}$ is a proof of F of size $\mathrm{res}(F)$, it has at most $\mathrm{res}(F)$ clauses of size at least $\epsilon s/2$, and by property $g(\epsilon s/2, M)$ the probability that there is a clause not subsumed by G is at most $\mathrm{res}(F)/M$. □

The above is stated for a fixed formula F. For distributions over formulae we have the following theorem.

THEOREM 5.7. *Let $\mathcal{F}$ be a distribution over formulas. Let $s, M \geq 1$ and $\epsilon > 0$ and suppose that $\mathcal{G}$ is a distribution over formulas that satisfies $g(\epsilon s/2, M)$. Then*

$$\begin{aligned} Pr_{F \sim \mathcal{F}}[res(F) < M/2] \leq 2(&Pr_{F \sim \mathcal{F}, G \sim \mathcal{G}}[F \wedge G \text{ does not satisfy } A(s)] \\ &+ Pr_{F \sim \mathcal{F}, G \sim \mathcal{G}}[F \wedge G \text{ does not satisfy } B_\epsilon(s)]). \end{aligned}$$

Proof. For a formula F, let

$$p(F) = Pr_{G\sim\mathcal{G}}[F \wedge G \text{ does not satisfy } A(s)] + Pr_{\rho}[F\lceil_{\rho} \text{ does not satisfy } B_{\epsilon}(s)].$$

By Proposition 5.6, $\text{res}(F) > (1 - p(F))M$. Thus

$$\text{Pr}_{F\sim\mathcal{F}}[\text{res}(F) < M/2] \leq \text{Pr}_{F}[p(F) > 1/2] < 2E_F[p(F)],$$

where $E[\cdot]$ denotes expectation. This last quantity is equal to the right-hand side of the claimed inequality. □

We now use a form of self-reduction to obtain the following theorem.

THEOREM 5.8. *For each $\mu > 0$, there exists a constant $a_\mu > 0$ such that if $F \sim \mathcal{F}_m^{k,n}$ for $m = \Delta n$ with $\Delta > 1$, then res$(F) \geq 2^{a_\mu n/\Delta^{1+4/(k-2)+\mu}}$ with probability $1 - o(1)$ in n. In particular, when $k = 3$ this reduces to res$(F) \geq 2^{a_\mu n/\Delta^{5+\mu}}$.*

Proof. We apply Theorem 5.7 to the case $\mathcal{F} = \mathcal{F}_m^{k,n}$ by choosing $\mathcal{G} = \mathcal{F}$. Note that $F \wedge G$ has the distribution $\mathcal{F}_{2m}^{k,n}$, so Lemma 5.5 implies that for any $\epsilon > 0$ and for some constant $c_\epsilon(k) > 0$, if $s \leq c_\epsilon(k)n/(2\Delta)^{2/(k-2-\epsilon)}$, then $F \wedge G$ satisfies $A(s)$ and $B_\epsilon(s)$ with probability $1 - o(1)$. (Note that the requirement on s for $B_\epsilon(s)$ is more stringent than that for $A(s)$.) Next, we choose M as large as possible so that $\mathcal{G}$ satisfies $g(\epsilon s/2, M)$. For a clause C of size at least $\epsilon s/2$, the probability that a single randomly chosen clause subsumes C is $\binom{\epsilon s/2}{k}/(2^k\binom{n}{k})$. If $G \sim \mathcal{G}$, then the probability that none of its m clauses subsume C is at most $(1-\binom{\epsilon s/2}{k}/(2^k\binom{n}{k})))^m \leq 2^{-d_\epsilon m s^k \Delta/n^{k-1}}$ for some constant d_ϵ. Substituting $s = c_\epsilon n/\Delta^{2/(k-2-\epsilon)}$, we have that, for sufficiently small ϵ, $\mathcal{G}$ satisfies $g(\epsilon s/2, 2^{e_\epsilon n\Delta^{1+4/(k-2)+O(\epsilon)}})$ for some constant e_ϵ. Hence with probability $1 - o(1)$, $\text{res}(F) \geq 2^{\Omega(n/\Delta^{1+4/(k-2)+\alpha})}$ for any $\alpha > 0$. □

COROLLARY 5.9. *For any $k \geq 3$ and $\epsilon > 0$, there is a constant γ such that almost all k-CNF formulas in n variables with at most $n^{2k/(k+2)-\epsilon}$ clauses require resolution proofs of size at least 2^{n^γ}.*

These results provide strong lower bounds on res(F) for random formulas. However, note that as k gets large, the exponent in the lower bound of res(F) tends to n/Δ, while in the upper bound obtained by using ordered DLL, the exponent is $n/\Delta^{1/(k-2)}$. We'd like to close this gap.

Observe that for property $A(s)$, Lemma 5.5 requires $s = O(n/\Delta^{1/(k-2)})$ while for property $B_\epsilon(s)$ it requires $s \leq O(n/\Delta^{2/(k-2-\epsilon)})$. It turns out that one way to significantly close the above gap would be to show that the second part of Lemma 5.5 holds if we weaken the bound on s.

Problem. Is it true that if $F \sim \mathcal{F}_m^{k,n}$, then F satisfies $B_\epsilon(s)$ with probability near 1 for $s \leq n\Delta^{1/(k-2-\epsilon)+o(1)}$?

If this were true, then the argument used in the above theorem would be improved substantially to the following: for $F \sim \mathcal{F}_m^{k,n}$, with probability near 1, res$(F) \geq 2^{n/\Delta^{2/(k-2-\epsilon)}}$, which is very comparable to the upper bound. The corollary is improved so that m can be as large as $n^{(k-\epsilon)/2}$. We discuss this problem further in section 7.

Lacking an affirmative answer to the above problem, we look for other ways to improve our result. In section 5.3, we will see that we can narrow the gap substantially using random restrictions instead of augmentations.

5.3. The random restriction method. We now apply an approach analogous to the above, using restrictions instead of augmentations. As mentioned above, applying a restriction can be viewed as applying an augmentation consisting of clauses of size one, but we use the language of restrictions because it is more familiar and natural.

Specializing Theorem 5.7 to the case of restrictions yields the following. If $\mathcal{R}$ is a probability distribution over the set of restrictions, we say that $\mathcal{R}$ has *property* $R(b, M)$ if for $b, M > 0$ for any clause C on X of size at least b, $\Pr[\rho \text{ does not satisfy } C] \leq 1/M$. Then we have the following theorem.

THEOREM 5.10. *Let $\mathcal{F}$ be a distribution over k-bounded formulae. Let s, $M \geq 1$ and $\epsilon > 0$ and suppose that $\mathcal{R}$ is a distribution over restrictions that satisfies $R(\epsilon s/2, M)$. Then*

$$Pr_{F\sim\mathcal{F}}[res(F) < M/2] \leq 2(Pr_{F\sim\mathcal{F},\rho\sim\mathcal{R}}[F\lceil_\rho \text{ does not satisfy } A(s)] + Pr_{F\sim\mathcal{F},\rho\sim\mathcal{R}}[F\lceil_\rho \text{ does not satisfy } B_\epsilon(s)]).$$

We will use this result to get a lower bound on $\mathrm{res}(F)$ for random k-CNF formulas, using the distribution $\mathcal{R}_t$ over restrictions where we first choose $v(\rho) \subseteq X$ by selecting each variable independently with probability t/n and then set the selected variables uniformly at random.

Lemma 5.5 needs to be generalized to formulas obtained from a random k-CNF by applying a random restriction.

LEMMA 5.11. *For each integer $k \geq 3$ and $\epsilon > 0$ there are constants $C(k), c_\epsilon(k) > 0$ such that the following holds. Let m, n, s, t be integers with $m = \Delta n$ for some $\Delta \geq 1$. Let $F \sim \mathcal{F}_m^{k,n}$ and $\rho \sim \mathcal{R}_t$.*

1. *If $t \leq C(k)n/m^{1/k}$ and $s \leq C(k)n/\Delta^{1/(k-2)}$, then $F\lceil_\rho$ satisfies $A(s)$ probability $1 - o(1)$ in s.*
2. *If $s, t \leq c_\epsilon(k)n/\Delta^{2/(k-2-\epsilon)}$, then $F\lceil_\rho$ satisfies $B_\epsilon(s)$ with probability $1 - o(1)$ in s.*

The proofs of these lemmas require a preliminary result. Let F and ρ be as in the statements of the lemmas. Let M denote the event that $F\lceil_\rho$ contains an empty clause. For $r, q > 0$, let $Q(r, q)$ denote the event that there exists a set R of at most r variables such that $v(C) \subseteq R$ for at least q nonempty clauses C of $F\lceil_\rho$.

PROPOSITION 5.12. *Let $m \geq n \geq t \geq k \geq 3$ be positive integers.*

1. *If $t \leq n/m^{1/(k-1)}$, then $Pr[M] \leq m^{-1/(k-1)}$.*
2. *Assume $n \geq 2k^2$. For $r, q \geq 1$, $Pr[Q(r, q)] \leq \left(\frac{ne}{r}\right)^r \left(\frac{2ekmr(t+r)^{k-1}}{qn^k}\right)^q$.*

Proof. For the first part, if C is a fixed k-clause, then $C\lceil_\rho$ is empty if and only if ρ sets all literals in C to 0. Thus $\Pr_C[C\lceil_\rho \text{ is empty}] = (t/2n)^k$. Therefore, $\Pr[M]$ is upper bounded by the expected number of empty clauses of $\mathcal{F}\lceil_\rho$ which is $m(\frac{t}{2n})^k \leq m^{-1/(k-1)}$.

For the second part, let $R \subseteq X$ with $|R| = r \geq 1$. Let C denote a randomly chosen clause and $I = v(C) \cap R$. Let $W(C)$ denote the event that $C\lceil_\rho$ is nonempty and its variables are contained in R. Then $\Pr[W(C)] = \sum_{i=1}^k \Pr[|I| = i]\Pr[v(C) - I \subseteq v(\rho) : |I| = i]$. Now $\Pr[v(C) - I \subseteq v(\rho) : |I| = i] = (t/n)^{k-i}$, while $\Pr[|I| = i] = \binom{r}{i}\binom{n-r}{k-i}/\binom{n}{k} \leq \binom{r}{i}\frac{k!}{(k-i)!}(n-k)^i \leq \binom{k}{i}(\frac{r}{n-k})^i \leq 2\binom{k}{i}(\frac{r}{n})^i$, where the last inequality holds since we assume $n \geq 2k^2$. Thus

$$\begin{aligned}\Pr[W(C)] &\leq 2\sum_{i=1}^{k}\binom{k}{i}\left(\frac{r}{n}\right)^i\left(\frac{t}{n}\right)^{k-i} \\ &\leq \frac{2kr}{n}\sum_{j=0}^{k-1}\binom{k-1}{j}\left(\frac{r}{n}\right)^j\left(\frac{t}{n}\right)^{k-1-j} \\ &= \frac{2kr}{n}\left(\frac{r+t}{n}\right)^{k-1}.\end{aligned}$$

Calling this latter probability p, if F is a random formula, the number of clauses of F for which $W(C)$ holds has the binomial distribution, $B(m,p)$. The probability that at least q clauses of F are contained in S after ρ is applied is bounded above by

$$\Pr[B(m,p) \geq q] \leq \binom{m}{q} p^q \leq \left(\frac{2ekmr(r+t)^{k-1}}{qn^k}\right)^q. \tag{5.1}$$

Summing this over the $\binom{n}{r} \leq (en/r)^r$ subsets of X of size r we obtain the desired upper bound on $\Pr[Q(r,q)]$. □

Proof of Lemma 5.11. We begin with the first part. The probability that $A(s)$ fails is at most $\sum_{r=1}^{s} \Pr[Q(r,r+1)] + \Pr[M]$. By the first part of Proposition 5.12, $\Pr[m] = o(1)$ in m and hence also in s. For $r \leq s$ we have

$$Q(r,r+1) \leq \left(\frac{ne}{r}\right)^r \left(\frac{2ekmr(r+t)^{k-1}}{(r+1)n^k}\right)^{r+1} \tag{5.2}$$

$$\leq \frac{r}{en}\left(\frac{2ekm(r+t)^{k-1}}{(r+1)n^{k-1}}\right)^{r+1}. \tag{5.3}$$

For $t \leq r \leq s$, and for some constant $C_1(k) > 0$, if $s \leq C_1(k)n/\Delta^{1/(k-2)}$, the quantity (5.3) is at most $\frac{r}{2^r n}$. Similarly, for $1 \leq r < t$, the quantity (5.3) is at most $\frac{r}{n}(C_2(k)m(\frac{t}{n})^{k-1})^{r+1}$ which is at most $\frac{r}{2^r n}$ for $t \leq C_3(k)n/m^{1/(k-1)}$ for some positive constants $C_2(k), C_3(k)$. Thus the $\sum_{r=1}^{s} Q(r,r+1)$ is at most $\frac{1}{n}\sum_{r=1}^{s}\frac{r}{2^r} < 2/n$ which is $o(1)$ in n and hence in s.

Finally, in the hypothesis of the lemma, we take $C(k) = \min(C_1(k), C_2(k))$.

Now for the second part of the lemma. We first observe

$$\Pr[\neg\, B_\epsilon(s)] \leq \sum_{\lfloor s/2\sigma \rceil \leq r \leq s/\sigma} \Pr[Q(r,\sigma r)] + \Pr[M],$$

where $\sigma = 2/(k+\epsilon)$. To see this, suppose that $B_\epsilon(s)$ fails. We want to show that either M holds or $Q(r,\sigma r)$ holds for some r in the given range. Assume M does not hold. Since $B_\epsilon(s)$ fails, there is a collection $\mathcal{C}$ of w clauses that has at most ϵw pure literals with $s/2 \leq w \leq s$. We upper bound $|v(\mathcal{C})|$. The sum of the clause sizes is wk and if u is the number of pure literals, the impure variables contribute at most $wk-u$ to this sum. Each impure variable appears in at least two clauses, so the number of impure variables is at most $\frac{wk-u}{2}$ and thus $|v(\mathcal{C})| \leq \frac{wk-u}{2} + u = \frac{wk+u}{2} \leq \frac{w(k+\epsilon)}{2}$. Extend the set $v(\mathcal{C})$ to a set R of size $r = \lfloor \frac{w(k+\epsilon)}{2} \rfloor$ so that $\lfloor \frac{s}{2\sigma} \rfloor \leq r \leq \frac{s}{\sigma}$ and R contains at least σr clauses. Thus $Q(r,\sigma r)$ holds.

So it suffices to upper bound the sum of $Q(r,\sigma r)$ for $\lfloor \frac{s}{2\sigma} \rfloor \leq r \leq \frac{s}{\sigma}$. We have

$$\begin{aligned} Q(r,\sigma r) &\leq \left(\frac{ne}{r}\right)^r \left(\frac{2ekm(r+t)^{k-1}}{\sigma n^k}\right)^{\sigma r} \\ &= \left(\frac{(ne)^{1/\sigma} C_1 m(r+t)^{k-1}}{\sigma r^{1/\sigma} n^k}\right)^{\sigma r} \\ &\leq \left(\frac{C_4 m r^{-1/\sigma}(r+t)^{k-1}}{n^{k-1/\sigma}}\right)^{\sigma r} \;<\; 2^{-\sigma r} \end{aligned}$$

for appropriate constant $C_4(k)$, provided that

$$\frac{C_4 m r^{-1/\sigma}(r+t)^{k-1}}{n^{k-1/\sigma}} \leq \frac{1}{2}.$$

For $\sigma = 2/(k+\epsilon)$, this last condition is satisfied if both s and t are at most $c_\epsilon(k)n \cdot (\frac{n}{m})^{2/(k-2-\epsilon)}$ for some constant $c_\epsilon(k) \geq 0$. Now the total failure probability for property $B_\epsilon(s)$ is at most $\sum_{r=\lfloor \frac{s}{2\sigma} \rfloor}^{s} 2^{-\sigma r} + \Pr[M]$ which is clearly $o(1)$ in s and part 2 is proved. □

Next, in order to apply Theorem 5.10, we determine as large an M as possible such that the distribution $\mathcal{R}_t$ satisfies $R(\epsilon s/2, M)$, where s and t are the largest numbers satisfying the hypotheses of both parts of the previous lemma.

LEMMA 5.13. *$\mathcal{R}_t$ satisfies $R(\epsilon s/2, e^{\epsilon s t/4n})$.*

Proof. For a fixed clause C and for $\rho \sim \mathcal{R}_t$, a variable x that is in C is fixed by ρ to satisfy C with probability $t/2n$, so the probability that ρ does not satisfy a given clause C is at most $(1-t/2n)^{|C|} \leq e^{-|C|t/2n}$. □

Applying Theorem 5.10 using Lemmas 5.11 and 5.13 yields the following theorem.

THEOREM 5.14. *For any integer $k \geq 3$ and $\epsilon > 0$ there is a constant $c'_\epsilon > 0$ such that the following holds. Let $F \sim \mathcal{F}_m^{k,n}$, where $m = \Delta n$ with Δ at least the satisfiability threshold θ_k.*

(i) *If $m \leq c'_\epsilon n^{2(k-1)/(k+\epsilon)}$, then res$(F) \geq 2^{\Omega(n^{1-1/(k-1)}/\Delta^{1/(k-1)+2/(k-2-\epsilon)})}$ with probability $1-o(1)$ in n.*

(ii) *If $m \geq c'_\epsilon n^{2(k-1)/(k+\epsilon)}$, then res$(F) \geq 2^{\Omega(n/\Delta^{4/(k-2-\epsilon)})}$ with probability $1-o(1)$ in n.*

Proof. Let $C(k)$ and $c_\epsilon(k)$ be the constants from Lemma 5.11. Let $s = c_\epsilon(k)n/\Delta^{2/(k-2-\epsilon)}$. The two cases of the theorem correspond to the two constraints on t in Lemma 5.11. The constraint $t \leq C(k)n/m^{1/(k-1)}$ is the more stringent constraint if and only if $m^{1/(k-1)} \geq (c_\epsilon(k)/C(k))(m/n)^{2/(k-2-\epsilon)}$. This holds if and only if $n \geq c''(k)m^{1-(k-2-\epsilon)/(2k-2)} = c''(k)m^{(k+\epsilon)/(2k-2)}$ for some constant $c''(k) > 0$, i.e., if $m \leq c'_\epsilon n^{(2k-2)/(k+\epsilon)}$ for some constant $c'_\epsilon > 0$. In this case, applying Lemma 5.13 yields the first bound. In the case that $m > c'_\epsilon n^{(2k-2)/(k+\epsilon)}$, the constraint $t \leq c_\epsilon n(n/m)^{2/(k-2-\epsilon)}$ is the more stringent and Lemmas 5.13 and 5.11 yield the second bound. □

When $k = 3$, the maximal possible value of m which still yields a lower bound of the form 2^{n^γ} is $n^{6/5-\epsilon}$, which matches the result obtained for $k = 3$ in Corollary 5.9. For $k \geq 4$ we obtain the following corollary.

COROLLARY 5.15. *For $k \geq 4$, and $\epsilon > 0$, there is a constant $\gamma > 0$ such that almost all k-CNF formulas with at most $n^{(k+2)/4-\epsilon}$ clauses require resolution proofs of size at least 2^{n^γ}.*

Proof. To see this, assume that $m = n^{(k+2)/4-\epsilon}$. Since $k \geq 4$ if we take $\epsilon' = 4\epsilon$, then $(k+2)/4-\epsilon = 1+(k-2-\epsilon')/4 > 1+(k-2-\epsilon')/(k+\epsilon') = (2k-2)/(k+\epsilon')$. Thus we can apply the second bound of Theorem 5.14 to derive that k-CNF formulas with at most m clauses almost certainly require resolution proofs of size $2^{\Omega(n/\Delta^{4/(k-2+\epsilon')})}$ which is $2^{\Omega(n^{2\epsilon'/(k-2+\epsilon')})}$. □

5.4. The deletion argument. In this subsection we sketch a variant of the restriction approach, which, in a preliminary version of this work [BKPS98], was shown to yield the following theorem.

THEOREM 5.16. *For each $\gamma > 0$, there exists a constant a_γ such that for all $m \geq n$, if F is a 3-CNF formula chosen according to $\mathcal{F}_m^{3,n}$, then with probability $1-o(1)$, res$(F) \geq 2^{a_\gamma(n/\Delta^{4+\gamma})}$.*

Observing that this bound is nontrivial for $m = o(n^{5/(4+\gamma)})$ and combining with Corollary 5.15 we obtain the following corollary.

COROLLARY 5.17. *For $k \geq 3$, and $\epsilon > 0$, there is a constant $\gamma > 0$ such that almost all k-CNF formulas with at most $n^{(k+2)/4-\epsilon}$ clauses require resolution proofs of size at least 2^{n^γ}.*

The proof of Theorem 5.16 in [BKPS98] is rather technical. The recent work of Ben-Sasson and Wigderson [BSW99] referred to earlier shows how one can derive the same bound in a substantially simpler way given Proposition 5.4 and Lemma 5.5. Therefore, we do not include our entire proof but instead give a short sketch.

The major bottleneck in the argument of section 5.1 is the upper bound on t needed for Lemma 5.11. Indeed, for t much larger than $n/\sqrt{m}$, there is a substantial probability that $A(s)$ does not hold for $F\lceil_\rho$. In particular, the bound computed in the proof of Lemma 5.11 on the probability that a clause of a random F becomes empty is nearly tight; an easy computation shows that the probability that no clause of a random F becomes empty when ρ is applied is $e^{-\Theta(mt^3/n^3)}$ and so, since the presence of an empty clause in $F\lceil_\rho$ violates $A(s)$, we have that $t = o(n/m^{1/3})$. (The creation of unit clauses under the restriction placed an even stronger limitation on t.)

To overcome this limitation, we want to avoid the creation of clauses of size 0 or 1 in $F\lceil_\rho$. To do this we modify the distribution on restrictions so that ρ may depend on F. The general idea is to first choose a random restriction and then delete any assignment that sets more than one variable in any clause of F. For technical reasons one must also delete assignments to variables that share some clause with too many other variables. By careful arguments one can show appropriate analogues of Theorem 5.10 and Lemma 5.11, allowing the condition $t \le cn/\sqrt{m}$ on the size of the restriction to be eliminated.

6. The behavior of DLL on random formulas. We now analyze particular DLL algorithms when applied to random formulas and show that we can obtain quite good upper bounds using a very simple splitting rule and that even certain generalizations of this splitting rule require much larger proofs than our current lower bound for general resolution shows.

6.1. Ordered DLL on random formulas.

THEOREM 6.1. *Let $k \ge 3$ and let $m = \Delta n$, where Δ is greater than the threshold $\theta_k(n)$ and $m = \Delta n$. Suppose that $F \sim \mathcal{F}_m^{k,n}$. Then with probability $1 - o(1)$ in n, the size of the refutation of F produced by ordered DLL is $2^{\Theta(n/\Delta^{1/(k-2)})}n^{\pm\Theta(1)}$. In particular, when $k = 3$, the refutation has size $2^{\Theta(n/\Delta)}n^{\pm\Theta(1)}$.*

The proof of this result has two parts, the upper bound, and lower bound, which we prove separately. To analyze the upper bound, we first consider a variant of ordered DLL that is easier to analyze.

Upper bound for ordered DLL. We first consider a variant of ordered DLL which is bit more complicated to state but easier to analyze.

Algorithm A. Set $t = 6k\lceil n(n/m)^{1/(k-2)}\rceil$; in particular, when $k = 3$ this is $18\lceil n^2/m\rceil$. Run ordered DLL, as long as the variables $x_1, \ldots, x_t$ are not all assigned. When reaching a partial assignment ρ in which $x_1, \ldots, x_t$ are all assigned (and possibly other variables by unit propagation), run the (polynomial-time) algorithm for 2-SAT on the subset $C_2(F, \rho)$ consisting of clauses of size at most 2 in the induced subformula $F\lceil_\rho$. The algorithm succeeds (finds a resolution refutation of F) provided that for each such ρ reached in the algorithm the subformula $C_2(F, \rho)$ is unsatisfiable.

To analyze Algorithm A we need the following lemma.

LEMMA 6.2. *Let F be a random 2-CNF formula chosen from $\mathcal{F}_{2n'}^{2,n'}$. Then the probability that F is satisfiable is $o(2^{-n'/9})$.*

Proof. Observe that the expected number of satisfying assignments for a 2-CNF formula with m' clauses and n' variables is $2^{n'}(3/4)^{m'}$ which is $o(2^{-n'/9})$

for $m' > 2.678n'$. (This bound can be reduced below 2 by using the techniques of [KKKS98].) □

THEOREM 6.3. *Let Δ be greater than the satisfiability threshold $\theta_k(n)$ and $m = \Delta n$. If $F \sim \mathcal{F}_m^{k,n}$, then, with probability $1 - o(1)$ in n, Algorithm A produces a resolution refutation in time $2^{O(n/\Delta^{1/(k-2)})}n^{O(1)}$; in particular, if $k = 3$ Algorithm A produces a resolution refutation in time $2^{O(n/\Delta)}n^{O(1)}$.*

Proof. Let $t = 6k\lceil n(n/m)^{1/(k-2)}\rceil$ and assume without loss of generality that $t < n/10$. Algorithm A clearly runs in time $2^{O(n/\Delta^{1/(k-2)})}n^{O(1)}$. To show that Algorithm A finds a refutation of F with probability $1 - o(1)$, it suffices to show that with probability $1 - o(1)$, $C_2(F, \rho)$ is unsatisfiable for all assignments ρ to $\{x_1, \ldots, x_t\}$. (Note that the restrictions occurring in the algorithm may have additional variables fixed by unit propagation, but this can only increase our probability of success.)

Fix ρ. Consider the set $\hat{C}_2(F, \rho)$ of clauses of size exactly 2. This size is a binomial random variable $B(m, q)$, where q is equal to the probability, for a random k-clause C, that $C\lceil_\rho$ is a 2-clause:

$$\begin{aligned}
\Pr[C\lceil_\rho \text{ is a 2-clause}] &= \frac{1}{2^{k-2}} \cdot \Pr[|\{x_1, \ldots, x_t\} \cap v(C)| = k-2] \\
&= \frac{1}{2^{k-2}} \cdot \left(\frac{\binom{n-t}{2}\binom{t}{k-2}}{\binom{n}{k}} \right) \\
&= \frac{1}{2^{k-2}} \cdot \left(\binom{k}{2} \frac{n-t}{n} \frac{n-t-1}{n-1} \frac{t}{n-2} \frac{t-1}{n-3} \cdots \frac{t-k+3}{n-k+1} \right) \\
&> \frac{1}{2^{k-2}} \binom{k}{2}^2 \frac{4}{5} \left(\frac{t}{2n} \right)^{k-2} \\
&> \binom{k}{2} \frac{4}{5} \left(\frac{3k}{2} \right)^{k-2} \frac{n}{m} \\
&> 8n/m.
\end{aligned}$$

Using the binomial tail bound of Proposition 2.1 (1), it follows that $\Pr[|\hat{C}_2(F, \rho)| \leq 2n] \leq 2^{-4n}$. By Lemma 6.2 and the fact that the clauses in $\hat{C}_2(F, \rho)$ are distributed uniformly at random on the remaining $n' = n - t$ variables,

$$\Pr[\hat{C}_2(F, \rho) \text{ is satisfiable} : |\hat{C}_2(F, \rho)| > 2n] = o(2^{-n'/9}).$$

Since there are 2^t choices for ρ, the total failure probability is $2^t \cdot (o(2^{-(n-t)/9}) + 2^{-n})$, which is $o(1)$ since $(n - t)/9 \geq t$ for $t \leq n/10$. □

Next we consider ordered DLL and prove the upper bound of Theorem 6.1. At a point in the execution of DLL, say that a variable is *critical* if setting that variable either to 0 or 1 and then applying unit propagation creates the empty clause. Thus, if the splitting rule chooses that variable the current branch will terminate simply by unit propagation.

A point in the execution of DLL corresponds to some restriction ρ. We give a sufficient condition for a variable to be critical in terms of the set $\hat{C}_2(F, \rho)$ of induced 2-clauses on the remaining set of n' variables. Define the standard directed graph $G(F, \rho)$ on $2n'$ vertices, one for each literal, that has directed edges $(\neg x, y)$, and $(\neg y, x)$ corresponding to each 2-clause $(x \vee y)$ in $\hat{C}_2(F, \rho)$. It is easy to see that a sufficient condition for the variable x_i to be critical is that there be directed paths from x_i to $\neg x_i$ and from $\neg x_i$ to x_i, i.e., that x_i and $\neg x_i$ lie in the same strongly connected component.

LEMMA 6.4. *For any $k \geq 3$, there exists a constant c such that if $F \sim \mathcal{F}_m^{k,n}$ and ρ is a fixed restriction of t variables with $n/2 \geq t \geq c\lceil n(n/m)^{1/(k-2)}\rceil$, then with probability at least $1-2^{-n}$, for at least half of the $n' = n-t$ unrestricted variables, x_i and $\neg x_i$ belong to the same strongly connected component of $G(F,\rho)$.*

Proof. Clearly, it suffices to show that with probability at least $1-2^{-n}$, $G(F,\rho)$ has a strongly connected component of size at least $3n'/2$. Let $C_1, C_2, \ldots, C_d$ be the strongly connected components ordered so that all edges between components go from lower to higher numbered components and consider the first j such that $|C_1 \cup \cdots \cup C_j| \geq n'/4$. We will show that the probability that $|C_j| < 3n'/2$ is at most 2^{-n}. If $|C_j| < 3n'/2$, then the set $S = C_1 \cup \cdots \cup C_j$ satisfies $n'/4 \leq |S| \leq 7n'/4$, and there is no edge from $\bar{S}$ to S.

So to upper bound the probability that $|C_j| < 3n'/2$ it suffices to upper bound the probability that there is a set S with $n'/4 \leq |S| \leq 7n'/4$ which is *bad* in the sense that there is no edge from $\bar{S}$ to S. Fix S of size s, with $n'/4 \leq s \leq 7n'/4$. The probability that a randomly chosen k-clause C, when restricted by ρ, gives an edge from $\bar{S}$ to S is at least $s(n'-s-1)\binom{t}{k-2}/2^k\binom{n}{k} \geq \beta'(t/n)^{k-2} \geq \beta\lceil n/m\rceil$ for some constants $\beta, \beta' > 0$ depending only on k. Hence the probability that none of the m clauses of F gives such an edge is at most $(1-\beta n/m)^m \leq e^{-\beta cn} \leq 2^{-3n}$ for c chosen greater than $3/\beta$. There are at most $2^{2n'}$ such sets S, so the probability that there is a bad set S of size between $n'/4$ and $7n'/4$ is at most 2^{-n}. □

Proof of the upper bound of Theorem 6.1. Without loss of generality we may assume that $m \geq (4c)^{k-2}n$ where c is the constant of the previous lemma, and let $t = cn(n/m)^{1/(k-2)}$ so that $t \leq n/4$.

Fix a restriction ρ of the first t variables. We claim that the probability that there is a branch of the DLL tree consistent with ρ that is still active (not terminated) after the first $4t$ variables are set and the resulting unit propagations are processed is at most 2^{-2t}. Since there are 2^t choices for ρ, this will imply that with probability $1-2^{-t}$, every branch of ordered DLL is completed after at most the first $4t$ variables are fixed and all resulting unit propagations are done, and so the tree has at most $n2^{4t}$ nodes (including nodes from unit propagation).

To prove the claim, condition on the size r of the set of critical variables for $F\lceil_\rho$. By Lemma 6.4, the probability that $r < n'/2$ is at most $2^{-n} \leq 2^{-4t}$, so we assume $r \geq n'/2$. The set of critical variables is equally likely to be any r-subset of the $n' = n-t$ unset variables, and so the probability that none of the next $3t$ variables in order are critical is at most $\binom{n'-3t}{r}/\binom{n'}{r} \leq (1-3t/n')^r \leq e^{-3t/2}$. Hence the probability that some branch consistent with ρ is unfinished after fixing the next $3t$ variables is at most $2^{-4t} + e^{-3t/2} \leq 2^{-2t}$.

Note that in order to obtain the claimed upper bound with probability $1-o(1)$ in n, we can assume without loss of generality that t is at least $\log n$. (If m, the number of clauses, is large enough so that t is less than $\log n$, we can carry out the analysis with fewer clauses since the complexity of ordered DLL decreases monotonically with the number of clauses.) □

Lower bound for ordered DLL. We now complete the proof of Theorem 6.1 by proving the lower bound.

Proof of the lower bound for Theorem 6.1. Fix $t < n(\frac{1}{4k\Delta})^{1/(k-2)}$ and let S be the first t variables with respect to the given ordering and $L(S)$ be the associated set of $2t$ literals. Let F' denote the set of all clauses of F that contain at least $k-1$ literals from $L(S)$.

Claim. With probability $1-o(1)$ in t, there is a partial assignment τ to $t/2$ of the variables of S that satisfies all clauses in F'.

Assuming the claim, we finish the proof by noting that for each of the at least $2^{t/2}$ restrictions ρ to S that are compatible with τ, all clauses of $F\lceil_\rho$ will have size at least 2. This implies that when applying ordered DLL along the path specified by ρ, no variables outside of S are fixed by unit propagation, and so there is a unique node corresponding to ρ, and hence there are at least $2^{t/2}$ nodes in the tree. Without loss of generality, we can assume that t is at least $\log n$; since $t < \log n$, our claimed lower bound is just 1.

So we prove the claim. For each $C \in F$, the probability q that it is in F' is at most $k(\frac{t}{n})^{k-1} \leq t\frac{k}{n}(\frac{t}{n})^{k-2} \leq \frac{t}{4m}$. Construct a 2-CNF F'' of size $|F'|$ by replacing each clause C' of F' by a clause C'' obtained by selecting two literals of $C' \cap L(S)$ uniformly at random. It is easy to see that F'' is a randomly chosen 2-CNF whose number of clauses is binomially distributed according to $B(m, q)$. The tail bound of Proposition 2.1 (2) implies that $|F''| < t/2$ with probability $1 - o(1)$. Conditioned on $|F''| < t/2$, the probability that F'' (and hence F') is satisfiable is $1 - o(1)$ because a random 2-CNF formula with $(1 - \epsilon)t$ variables on a set of size t is satisfiable with probability $1-o(1)$ [Goe96, CR92]. If F'' is satisfiable, there is a setting τ of at most $|F''| < t/2$ variables of S that satisfies it. This completes the proof of the claim and the theorem. □

6.2. Lower bounds for more general DLL procedures. Having analyzed ordered DLL, we next turn to the problem of proving lower bounds for a wider class of DLL procedures. In the following discussion it will be useful to introduce some additional terminology. Let A be a DLL algorithm and F be a formula, and let $T_A(F)$ denote the DLL tree associated to the execution of A on F. We classify the nodes of $T_A(F)$ into two types: *unit propagation nodes* (those corresponding to a variable in a unit clause) and *branching nodes*.

We will prove a lower bound for a class of algorithms called *oblivious DLL* algorithms. Let B_n denote the full binary tree of depth n and let λ be a labeling of the internal nodes by literals with the property that along each root-leaf path each variable occurs in exactly one literal. The labeling λ specifies an algorithm $A = A_\lambda$ as follows. On input F, A_λ recursively traverses B_n starting from the root. When arriving at node v it has a formula G which is a restriction of F, and it performs a procedure Test(G, v) defined as follows. While G has at least one unit clause but no empty clause, choose a unit clause and fix its literal to true, simplifying G accordingly. If the empty clause is produced, stop; the formula is unsatisfiable. If G ever has no clauses, then stop; the formula is satisfiable. Otherwise, when G has no empty or unit clauses, let v_0 and v_1 denote the left and right children of v. If the literal $\lambda(v)$ is already assigned a value $i \in \{0, 1\}$, move to v_i and run Test(v_i, G). Otherwise, run Test$(v_0, G\lceil_{\lambda(v)=0})$ and Test$(v_1, F\lceil_{\lambda(v)=1})$ and return unsatisfiable if both return unsatisfiable, and satisfiable if at least one of them returns satisfiable.

In the special case that B_n is labeled so that each node of distance i from the root is labeled x_i the above algorithm is ordered DLL. Another case of interest is that of *random DLL* in which the labeling of B_n is chosen at random. In general, we call such algorithms *oblivious* because (except for unit propagation) the choice of splitter does not depend on the function F.

It is worth emphasizing the distinction between the labeled tree (B_n, λ) (which is independent of F) and the DLL tree $T_{A_\lambda}(F)$ associated to an execution of the algorithm on F.

It is not hard to show that if $F \sim \mathcal{F}_m^{k,n}$, then the expected running time of any oblivious algorithm is the same. However, this does not rule out the possibility that

some oblivious algorithm may run much faster than ordered DLL on *most* instances by concentrating the bad behavior on a small set of instances. Here we show that provided that m is big enough, no oblivious algorithm can do much better than ordered DLL on most instances (see Theorem 6.8 below).

In the lower bound on ordered DLL, we showed that during the first t steps, with high probability unit propagation plays no role. We will prove something like this for oblivious algorithms. The key step is a lemma that implies that for any DLL procedure (oblivious or not) on a random formula, the number of variables fixed by unit propagation along any path in the DLL tree is not much more than the number of branching nodes along the path. For technical reasons, it is easier to consider a generalization of unit propagation that ignores the sign of variables.

The general idea is as follows. Let F be a formula and T a set of variables that have been set so far. We want to describe a natural algorithm that defines a set $\hat{T}$, where $\hat{T}$ will contain T plus the set of additional variables that are set by unit propagation. The algorithm is as follows. Initially $\hat{T} = T$. Given F, let S be the corresponding set system, where each k-clause of F corresponds to a k-set in S (over a universe of size n.) Given F (and hence S), and T, define $S' \subseteq S$ to be those clauses that intersect $\hat{T}$ in exactly $k-1$ elements. Add the elements occurring in S' that are not already in $\hat{T}$ to $\hat{T}$ and continue recursively until S' is empty. Note that the set $\hat{T}$ produced by this algorithm is a minimal set of variables that will be set by setting the variables in T, plus the additional variables set by unit-clause propagation, assuming that we ignore early termination as a result of the formula being set to 0 or 1. The intuition behind the proof of Theorem 6.8 is that with high probability, the size of $\hat{T}$ will be not much larger than the size of T. The proof of this fact will be a compression argument showing that for each fixed T, if F has the property that $\hat{T}$ is large, then F can be encoded succinctly. Intuitively, if there are a lot of variables that become unit clauses, then these clauses are not random with respect to T and therefore can be described succinctly.

We need some definitions. Given a k-CNF formula F, a set T of variables is *closed* with respect to F if no clause contains exactly $k-1$ variables of T (either positively or negatively). It is easy to see that the intersection of closed sets is closed, and hence for any set T of variables the set $\hat{T}$ obtained by intersecting all closed sets containing T yields the unique minimal closed set containing T. We call this the *closure of* T *(with respect to* F*)*. A clause is said to be *threatened* by (F, T) if it is contained in $\hat{T}$. Note that $\hat{T} = T \cup \cup_D v(D)$, where D ranges over all clauses of F threatened by (F, T). The following fact relates these notions to unit propagation.

PROPOSITION 6.5. *Let A be any DLL algorithm and F be a k-CNF formula. Suppose v is a node in the DLL tree of $T_A(F)$. Let T be the variables that appear at the branching nodes on the path to v. Then*

1. *the variables at the unit propagation nodes on the path to v are contained in $\hat{T}$;*
2. *the only clauses that can be empty upon reaching v are the clauses threatened by (F, T).*

Proof. For the first part, let $v_0, \ldots, v_j = v$ be the nodes on the path to v and let x_i be the variable whose literal l_i appears at v_i. Applying induction on i, we assume that $\{x_0, \ldots, x_{i-1}\} \subseteq \hat{T}$. Then if v_i is a branching node, then $x_i \in T$ and otherwise, if ρ is the restriction defined by the literals $l_0, \ldots, l_{i-1}$, there is a clause C of F such

that $C\lceil_\rho$ is the unit clause l_i. If $\hat{T}$ does not contain x_i, then C contains exactly $k-1$ variables of $\hat{T}$, which contradicts that $\hat{T}$ is closed.

For the second part, a clause that becomes empty must have all its literals set to 0, which means that all of its variables are in $\hat{T}$. □

We next present an algorithm for constructing $\hat{T}$ from T; the details of this algorithm are needed in what follows. Fix an ordering $x_1, \ldots, x_n$ of the variables. The algorithm $Close(F, T)$ takes as input a formula F (viewed as a list $C_1, \ldots, C_m$ of clauses) and subset T of variables with $t = |T|$, and outputs the following:

(i) A sequence $D_1, \ldots, D_u$ of distinct clauses of F, consisting of the set of clauses threatened by (F, T).

(ii) A sequence $z_1, \ldots, z_{t+u}$ of variables consisting of the variables of $\hat{T}$ (possibly with repetition). Furthermore, $T = \{z_1, \ldots, z_t\}$, listed according to the global variable ordering, and for $i \in [u]$, $z_{t+i} \in v(D_i) \subseteq \{z_1, \ldots, z_{t+i}\}$.

(iii) A sequence $j_1 \leq \cdots \leq j_u$ of integers in the range 1 to $t+u$, where j_i is the least index such that $|\{z_1, \ldots, z_{t+u}\} \cup D_i| = k-1$.

We will build these three lists in a series of iterations, which we divide into two phases. The initialization phase consists of the first t iterations, where we place the variables of T on the list, constructing $z_1, \ldots, z_t$. During the second (main) phase, in iteration $t+i$, we determine z_{t+i}, D_i, and j_i. During both phases, we maintain a list of *eligible clauses* of F. Each item on the list is a triple $(D, j(D), y(D))$, where D is a clause that contains at least $k-1$ variables on the list so far, $j(D)$ is the least index for which $|v(D) \cap \{z_1, \ldots, z_{j(D)}\}| = k-1$, and $y(D)$ is the unique variable of $v(D) - \{z_1, \ldots, z_{j(D)}\}$. At iteration j, after adding a variable z_j, the eligible list is updated by identifying all clauses C_s of F that contain z_j and that contain exactly $k-2$ distinct variables from $z_1, \ldots, z_{j-1}$. For each such clause, let $j(C_s) = j$ and let $y(C_s)$ be the unique variable of C_s that does not appear in the list. Order the set of all such triples $(C_s, j, y(C_s))$ according to the index s and append this to the list of eligible clauses.

In the initialization phase, during iteration i, we choose z_i to be the ith variable of T according to the global variable ordering, and then we update the eligible list. During iteration $t+i$ of the main phase, if there are no eligible clauses, then the algorithm terminates. Otherwise, remove the first triple (D, j, y) from the eligible list and set $z_{t+i} = y$, $D_i = D$ and $j_i = j$ and update the eligible list.

It is easy to show by induction on i that $\{z_1, \ldots, z_{t+i}\} \subseteq \hat{T}$ and that at termination the list $\{z_1, \ldots, z_{t+u}\}$ is closed and hence is $\hat{T}$. The other properties of the output asserted above are similarly obvious.

We are now ready to state and prove the key lemma.

LEMMA 6.6. *For $k \geq 3$ there is a constant $c(k)$ such that the following holds. Let n, m, t, w be positive integers and let $\Delta = m/n > 1$. Suppose that $t \leq w \leq c(k)n/\Delta^{1/(k-2)}$. Let T be a set of variables of size t. Then for $F \sim \mathcal{F}_m^{k,n}$, the probability that (F, T) threatens at least w clauses is at most 2^{-w}.*

Proof. Fix n, m, w, t and T as in the hypothesis of the lemma. We view an arbitrary formula $F \sim \mathcal{F}_m^{k,n}$ as an ordered sequence $C_1, \ldots, C_m$ of clauses. Thus F is uniformly chosen from $(2^k\binom{n}{k})^m$ possible formulas. Say that F is *bad* if (F, T) threatens at least w clauses. We will upper bound the probability that F is bad by showing that each bad F can be uniquely "encoded" in such a way that the number of encodings is a 2^{-w} fraction of the number of formulas.

Now suppose that F is bad, and thus the number u of threatened clauses is at least w. In this case, will show how to encode F efficiently. Our encoding will first

give enough information in order to recover the first w clauses, $D_1, \ldots, D_w$, output by the above algorithm, and then we will code more directly the remaining clauses of F. The encoding of $D_1, \ldots, D_w$ refers to some of the output of the above algorithm on F and will include the following:

(i) The list $z_{t+1}, \ldots, z_{t+w}$.

(ii) The list $j_1, j_2, \ldots, j_w$.

(iii) For $i \in [w]$, the sequence $d_i(1) < \cdots < d_i(k-2)$, where $d_i(j)$ is the least index such that in $|v(D_i) \cap \{z_1, \ldots, z_{d_i(j)}\}| = j$.

(iv) For each $i \in [w]$, the vector $\alpha_i \in \{+,-\}^k$, where $\alpha_i(j)$ is the sign of the appearance of $z_{d_i(j)}$ in D_i.

It is clear that this information is enough to reconstruct $D_1, \ldots, D_w$. To reconstruct the remaining clauses of F, $C_1, \ldots, C_m$, along with their ordering, we need two more things:

(i) The list $h_1, h_2, \ldots, h_w$ of indices such that $D_i = C_{h_i}$.

(ii) The ordered list of clauses $(C_i : i \notin \{h_1, \ldots, h_w\})$.

Let us count the number of such encodings. There are at most m^w ways to choose $h_1, \ldots, h_w$. There are $(2^k\binom{n}{k})^{m-w}$ ways to choose the sequence of clauses that are not among the D_i. There are at most n^w ways to choose $z_{t+1}, \ldots, z_{t+w}$. Since the list $j_1, \ldots, j_w$ satisfies $j_1 \le \cdots \le j_w$, the number of ways to choose this sequence is at most $\binom{t+2w-1}{w} \le 2^{t+2w}$. For each i the number of ways to choose $d_i(1), \ldots, d_i(k-2)$ is at most $(t+w)^{k-2}$, and the number of ways to choose α_i is at most 2^k. Multiplying these together and dividing by $(2^k\binom{n}{k})^m$ we get that the probability that (F,T) threatens at least w clauses is at most

$$\frac{m^w n^w 2^{t+2w+kw}(t+w)^{(k-2)w}}{(2^k\binom{n}{k})^w} \le \frac{m^w k^w 2^{t+2w}(t+w)^{(k-2)w}}{n^{(k-1)w}} \le \left(\frac{8km(2w)^{k-2}}{n^{k-1}}\right)^w.$$

For some constant $c(k) > 0$, if $w \le c(k)n(n/m)^{1/(k-2)}$ the above expression is at most 2^{-w}. □

Before we use this to prove the theorem, we derive an immediate corollary which we hope will be useful in analyzing other DLL algorithms. It says that for almost all formulas F every path in any DLL tree for F contains not many more unit propagation nodes than it does branching nodes.

LEMMA 6.7. *For $k \ge 3$ there is a constant $c(k)$ such that the following holds. Let n, m, t be positive integers, $\epsilon > 0$ $w = \lceil (1+\epsilon)\max(t, \log_2\binom{n}{t})\rceil$, and let $\Delta = m/n > 1$. Suppose that $t \le w \le c(k)n/\Delta^{1/(k-2)}$. Then for $F \sim \mathcal{F}_m^{k,n}$, the probability that there is a partial assignment of size t that generates at least w unit clauses is $o(1)$ in t.*

Proof. There are only $\binom{n}{t}$ sets of variables T of size t that can be the underlying set of variables of the partial assignment. Furthermore, any unit clause generated by such a partial assignment must be a clause threatened by (F,T). By Lemma 6.6, any single set T threatens w clauses with probability only 2^{-w}. Summing over all possible sets T yields the desired result. □

THEOREM 6.8. *Let $k \ge 3$ and let n, m be integers and $\Delta = m/n$. Let A be any oblivious DLL algorithm for k-CNF formulas on n variables and suppose $F \sim \mathcal{F}_m^{k,n}$. If $m = \omega(n^{k/2})$, then with probability $1 - o(1)$ in n, the running time of A on F is $2^{\Omega(n/\Delta^{1/(k-2)})}$.*

Proof. Fix k and let n, m satisfy the hypotheses of the theorem. There are two cases to consider, when F is satisfiable and when F is not satisfiable. Since

$m = \omega(n^{k/2})$, the probability that F is satisfiable is exponentially small in n. Thus, we can assume without loss of generality that F is unsatisfiable in what follows, and, in particular, every leaf node in any DLL tree for F is labeled by 0. Observe that the conclusion of the theorem is trivial if $m = \Omega(n^{k-1})$, so we may assume that $m = o(n^{k-1})$. Fix an oblivious DLL algorithm and let λ be the associated labeling of B_n. Let $t = c(k)n/\Delta^{1/(k-2)}$, where $c(k)$ is as in Lemma 6.6. The hypothesis and the assumption $m = o(n^{k-1})$ imply $t = o(\sqrt{n})$ and $t = \omega(1)$.

For a formula F, let $R = R(F)$ be the set of vertices at level t in B_n that are visited by the traversal of B_n in the execution $A_\lambda(F)$. Note that $v \in R$ means that no clause of F becomes empty along the path to v. We will show that the probability that $|R| \leq 2^{t-1}$ is $o(1)$, and since $|R|$ is a lower bound on the running time of $A_\lambda(F)$ this will prove the theorem.

First, for a fixed vertex v at level t in B_n we upper bound $\Pr[v \notin R]$. Let T be the set of variables labeling the nodes in B_n on the path to v. By the definition of the algorithm and by Proposition 6.5 the variables set by unit propagation along the path to v must be in $\hat{T}$, and any empty clause must be a clause threatened by (F, T). Consider the output $D_1, \ldots, D_u$ and $z_1, \ldots, z_{t+u}$ of the algorithm $Close(F, T)$. We claim that if the variables $z_1, \ldots, z_{t+u}$ are all distinct, then no clause of F becomes empty along the path to v, and since F is unsatisfiable, this implies that $A_\lambda(F)$ reaches v. For this, it suffices to show that for $i \in [u]$, if the variable z_{t+i} is set by unit propagation, then it can only be set because D_i becomes a unit clause. So assume for contradiction that z_{t+i} is set because some clause D_j with $j \neq i$ becomes a unit clause and that this is the first time that this happens. However, then since $z_{t+j} \in v(D_j)$, it must have been set before D_j became a unit clause, which contradicts the choice of z_{t+i}.

Thus we have

$$\begin{aligned}\Pr[v \notin R] &\leq \Pr[z_1, \ldots, z_{t+u} \text{ are not distinct}] \\ &\leq \Pr[u > t] + \Pr[z_1, \ldots, z_{t+u} \text{ are not distinct} : u \leq t].\end{aligned}$$

Now $\Pr[u > t] \leq 2^{-t}$ by Lemma 6.6. We claim that the second term is bounded above by $3t^2/2n$. To see this, note that by the definition of the algorithm *Close* the triple (D_i, j_i, z_{t+i}) is the ith item placed on the eligible clause list. Think of this triple as a random variable (which depends on the random formula F). The key observation is that at the time that we add (D_i, j_i, z_{t+i}) to the eligible list (at the end of iteration j_i) the conditional distribution of z_{t+i} is given by the uniform distribution over the set $\{x_1, \ldots, x_n\} - \{z_1, \ldots, z_{j_i}\}$. Thus the probability that $z_{t+i} \notin \{z_1, \ldots, z_{t+i-1}\}$ is $1 - (t + i - 1 - j_i)/(n - j_i) \geq 1 - (t + i - 1)/n$, and the probability that there is some $i \in [t]$ for which $z_{t+i} \in \{z_1, \ldots, z_{t+i-1}\}$ is at most $\sum_{i=1}^{t}(t + i - 1)/n \leq \frac{3t^2}{2n}$, as claimed.

We conclude that $\Pr[v \notin R] \leq 2^{-t} + \frac{3t^2}{n}$, which is $o(1)$ in n since $t = o(\sqrt{n})$ and $t = \omega(1)$. Therefore, the expected number of vertices $v \notin R$ is at most $o(2^t)$, which under the assumption on t is $o(2^t)$. Thus, by Markov's inequality, the probability that more than 2^{t-1} vertices are not in R is $o(1)$ and thus $|R| \geq 2^{t-1}$ with probability $1 - o(1)$, as required to complete the proof. □

7. Related work and further research. The question of whether or not resolution is automatizable is still open. In particular, what is the fastest deterministic or probabilistic search algorithm for resolution? The best that is known is presented in section 3 which is essentially due to Clegg, Edmonds, and Impagliazzo. It can be

shown that this is the best algorithm in the tree-like case, but we know of no negative results of this kind for the general case.

A problem pertinent to our results in section 4 is to prove exponential lower bounds for the weak pigeonhole principle, $\neg PHP_n^m$, where the number of pigeons, m, is large (say n^3). Buss and Pitassi [BP97] showed that there exists a resolution refutation of $\neg PHP_n^m$ when $m \geq 2^{\sqrt{n}\log n}$ of size $2^{\sqrt{n}\log n}$. It has been conjectured that when m is polynomial in n, any resolution refutation of $\neg PHP_n^m$ requires superpolynomial size. Razborov has shown that such a lower bound would imply that proving superpolynomial circuit lower bounds for an explicit function in NP is independent of certain systems of bounded arithmetic.[2]

In a preliminary version of this paper ([BP96]) we asked:

> Can one show that for any 3-CNF formula f, if f has a polynomial-size resolution refutation, then f also has a resolution refutation with maximum clause size $\sqrt{n}$? Such a result would justify the simple and natural deterministic simulation of resolution whereby we exhaustively search for proofs of maximum clause length i, for increasing i.

Based on the Clegg–Edmonds–Impagliazzo algorithm, a version of this clause-width conjecture has recently been proven by Ben-Sasson and Wigderson [BSW99]—in particular that size S resolution refutations can be made $O(\sqrt{n \log S})$-bounded and size S DLL proofs can be converted to $O(\log S)$-bounded resolution refutations. As stated above, this simplifies the algorithm in section 3 and can be used to show that random k-CNF formulas with n variables with clause density $\Delta \geq \theta_k(n)$ require resolution proofs of size $2^{\Omega(n/\Delta^{4/(k-2)+\epsilon})}$ and DLL proofs of size $2^{\Omega(n/\Delta^{2/(k-2)+\epsilon})}$. This size lower bound for general resolution refutations provides a simpler smooth tradeoff between Δ and proof size than our results, but it does not improve the largest densities for which exponential lower bounds for resolution are known to hold almost certainly. The size lower bound for DLL proofs is not as large as our lower bounds in section 6.1 but applies to all DLL procedures, not just oblivious ones.

The problem posed at the end of section 5.2 is whether the hypothesis on s in Lemma 5.5 needed for property $B_\epsilon(s)$ can be weakened. As mentioned, such a weakening would strengthen the lower bounds on $\mathrm{res}(F)$ for random formulas. Furthermore, when combined with the Ben-Sasson–Wigderson approach for lower bounding DLL refutation size, this improvement would yield a *tight* $2^{\Omega(n/\Delta^{1/(k-2)+o(1)})}$ lower bound on $\mathrm{DLL}(F)$ for F a random formula.[3]

Examining the proof of Lemma 5.11 we see that a critical place to look for improvement is in the last step of the proof of Proposition 5.12, where we obtain an upper bound on $\Pr[Q(r,q)]$ by multiplying $\Pr[B(m,p) \geq q]$ by $\binom{n}{r}$, which corresponds to upper bounding the probability of the union of $\binom{n}{r}$ events by their sum. Can this union bound be refined by a more careful analysis?

The essence of the question is captured by a natural question about random hypergraphs. Given a collection $\mathcal{H}$ of subsets of $[n]$, say that a subset A of $[n]$ is γ-crowded by $\mathcal{H}$ if A contains at least γn members of $\mathcal{H}$. Let $s(\mathcal{H},\gamma)$ be the largest s for which there is no set of size s that is γ-crowded by $\mathcal{H}$. The question is, If $\mathcal{H}$ is a

[2] Following a proof of subexponential lower bounds for a restricted version of resolution [PR01], such lower bounds have indeed been proved for general resolution by Raz [Raz01a] and simplified and strengthened by Razborov [Raz01b].

[3] Ben-Sasson and Galesi [BSG01] have recently shown just such a lower bound by replacing the property $B_\epsilon(s)$ with a weaker expansion property of such formulas.

random collection consisting of Δn subsets of $[n]$ each of size k what is the best lower bound on $s(\mathcal{H}, \gamma)$ that holds with probability $1 - o(1)$? A calculation analogous to that in Lemma 5.11 (using the union bound) shows that $s(\mathcal{H}, \gamma) \geq \Omega(n/\Delta^{1/(k-2-\frac{1}{\gamma})})$, while it is also not hard to show that $s(\mathcal{H}, \gamma) \leq O(n/\Delta^{1/(k-2)})$. An argument that the upper bound is tight could almost certainly be adapted to give an affirmative answer to the problem at the end of section 5.2.

A final open problem is to produce a better algorithm for finding unsatisfiability proofs for random formulas. In particular, is there a polynomial-time algorithm that succeeds in finding a proof of unsatisfiability with high probability for random formulas with cn clauses for some $c > 0$? We are not aware of *any* algorithm that provably beats the very simple ones we analyzed in section 6, even if we consider more powerful search methods that are not resolution-based.[4]

A DECISION PROCEDURE FOR UNITARY LINEAR QUANTUM CELLULAR AUTOMATA*

CHRISTOPH DÜRR† AND MIKLOS SANTHA‡

Abstract. Linear quantum cellular automata were introduced recently as one of the models of quantum computing. A basic postulate of quantum mechanics imposes a strong constraint on any quantum machine: it has to be *unitary*; that is, its time evolution operator has to be a unitary transformation. In this paper we give an efficient algorithm to decide if a linear quantum cellular automaton is unitary. The complexity of the algorithm is $O(n^{(3r-1)/(r+1)}) = O(n^3)$ in the algebraic computational model if the automaton has a continuous neighborhood of size r, where n is the size of the input.

Key words. quantum computation, reversible cellular automata

1. Introduction.

The classical models of computation, such as Turing machines, random access machines, circuits, or cellular automata, are all universal in the sense that they can simulate each other with only polynomial overhead. These models are based on classical physics, whereas physicists believe that the universe is better described by quantum mechanics.

Feynman [8, 9] pointed out first that there might be a substantial gap between computational models based on classical physics and those based on quantum mechanics. The *quantum Turing machine* (QTM), the first model of quantum computation, was introduced by Benioff [1, 2]. Deutsch in [5] described a universal simulator for QTMs with exponential overhead. Bernstein and Vazirani [3] were able to construct a universal QTM with only polynomial overhead.

Other quantum computational models were also studied recently. Deutsch [6] has defined the model of *quantum circuits*, and later Yao [19] has shown that QTMs working in polynomial time can be simulated by polynomial size quantum circuits. Physicists were also interested in *quantum cellular automata*: Biafore [4] considered the problem of synchronization, Margolus [14] described space-periodic quantum cellular automata, and Lloyd [12, 13] discussed the possibility of realizing a special type of quantum cellular automaton. *Linear quantum cellular automata* (LQCAs) were formally defined by Watrous [18] and by Dürr, LêThanh, and Santha [7]. In the former paper it was shown that a subclass of LQCAs, *partitioned linear quantum cellular automata* (PLQCAs), can be simulated by QTMs with linear slowdown. Van Dam [17] defined space-periodic LQCAs and gave a universal instance of this model.

We should make clear at this point that most of these models are only theoretically motivated. *Real life* quantum computers as built today in laboratories are essentially small quantum circuits or partitioned cellular automata.

A quantum computational device is at any moment of its computation in a *superposition of configurations*, where each configuration has an associated complex amplitude. A superposition is *valid* if it has unit norm. If the device is *observed*, then a configuration will be chosen at random, where the probability of a configuration to be chosen is equal to the squared magnitude of its amplitude. Therefore it is essential that valid superpositions be transformed into valid superpositions, or, equivalently, that the *time evolution operator* of the device preserves the norm. This property is called *well-formedness*, and thus it is a natural problem to decide if a given quantum machine is well-formed. In the case of QTMs and PLQCAs there exist easily checkable constraints on the finite local transition function of the machine which are equivalent to its well-formedness. Such constraints were identified, respectively, by Bernstein and Vazirani [3] and by Watrous [18]. In the case of LQCAs no such local constraints are known, still Dürr, LêThanh, and Santha [7] gave a polynomial time algorithm to decide if an LQCA is well-formed. Part of this algorithm was improved by Høyer [10] using a different approach.

However, one of the basic postulates of quantum mechanics imposes an even stronger constraint than norm-preserving on the time evolution operator. It actually requires that this operator—as any other quantum operator—be a unitary transformation. We will call a machine which satisfies this constraint *unitary*. In [3] and [18] it was proven that norm-preserving already implies unitarity in the case of QTMs and PLQCAs. It is also trivially true for machines with finite configuration sets such as quantum circuits. However, this is not true for LQCAs; it is quite simple to construct a well-formed LQCA which is not unitary.[1]

In this paper we give an efficient algorithm to decide if an LQCA is unitary. The complexity of our algorithm is cubic if the input LQCA has continuous neighborhood. (Most papers in the literature about classical linear cellular automata deal only with such cases.) Our algorithm will use the procedure of [7] which in quadratic time decides if the LQCA is well-formed. The present paper actually gives an algorithm which decides if a well-formed LQCA is also unitary.

Well-formedness is equivalent to the orthonormality of the column vectors of the time evolution operator; unitarity also requires orthonormality from the row vectors. Deciding unitarity is much harder than deciding well-formedness. One way of seeing this is that whereas the column vectors have finite support, the row vectors can have an infinite number of nonzero components.

2. The computational model. Let us fix for the paper the following notation. If u and v are vectors in some inner-product space over the complex or the real numbers, then $\langle u|v\rangle$ will denote the inner product of u and v, and $\|u\|$ the norm of u. If M is a matrix in such a space, then M^* denotes its conjugate transpose.

We recall here the definition of an LQCA which is the quantum generalization of the classical one-dimensional cellular automaton. A more detailed description of this model can be found in [18] and in [7].

An LQCA is a 4-tuple $A = (\Sigma, q, N, \delta)$. The *cells* of the automaton are organized in a line and are indexed by the elements of $\mathbb{Z}$. The finite, nonempty set Σ is the set of *(cell-)states*, and $q \in \Sigma$ is a distinguished *quiescent state*. The *neighborhood* $N = (a_1, \ldots, a_r)$ is a strictly increasing sequence of integers, for some $r \geq 1$, giving the addresses of the neighbors relative to each cell. This means that the neighbors of

[1] A well-known example is the classical LCA XOR= $(\{0,1\}, 0, (0,1), \delta)$, where $\delta(x,y) = (x + y) \bmod 2$. This cellular automaton is injective for finite configurations but not surjective; thus the associated LQCA is well-formed but not unitary.

cell i are indexed by $i+a_1, \ldots, i+a_r$. An automaton is *simple* if its neighborhood is an interval of integers, that is $a_r = a_1 + r - 1$. In this paper we deal only with simple automata, and we will explain only briefly in the conclusion how our results apply to the general case.

The states of the cells are changing simultaneously at every time step according to the *local transition function*. This is the mapping $\delta : \Sigma^{|N|} \to \mathbb{C}^\Sigma$, which satisfies that, for every $(x_1, \ldots, x_r) \in \Sigma^r$, there exists $y \in \Sigma$ such that $[\delta(x_1 \ldots x_r)](y) \neq 0$. If at some time step the neighbors of a cell are in states $x_1, \ldots, x_r$, then at the next step the cell will change into state y with amplitude $[\delta(x_1 \ldots x_r)](y)$ which is denoted by $\langle \delta(x_1 \ldots x_r)|y\rangle$. The quiescent state q satisfies that

$$\langle \delta(q^r)|y\rangle = \begin{cases} 1 & \text{if } y = q, \\ 0 & \text{if } y \neq q. \end{cases}$$

The set of *configurations* is $\Sigma^{\mathbb{Z}}$, where for every configuration c, and for every integer i, the state of the cell indexed by i is c_i. A configuration c is *finite* if its *support* $\{i : c_i \neq q\}$ is finite. We are dealing only with LQCAs which evolve on finite configurations. We will denote the set of finite configurations by $\mathcal{C}_A$, and from now on we use the word *configuration* to mean a *finite configuration*. For a configuration c, let $\mathrm{idom}(c)$ be the *interval domain* of c, which is the smallest integer interval containing the support of c. For the sake of definiteness, we define the empty interval as $[0, -1]$ which is the interval domain of the everywhere quiescent configuration.

The local transition function induces the *time evolution operator* which we write in matrix form $U_A : \mathcal{C}_A \times \mathcal{C}_A \to \mathbb{C}$, where $U_A(d, c)$ is the transition amplitude of changing configuration c to configuration d in one step. It is defined by

$$U_A(d, c) = \prod_{i \in \mathbb{Z}} \langle \delta(c_{i+N})|d_i\rangle,$$

where $\delta(c_{i+N})$ is a short notation for $\delta(c_{i+a_1}, \ldots, c_{i+a_r})$. This product is well-defined since c has finite support.

The automaton evolves on *superpositions of configurations* which are elements of the Hilbert space $\ell_2(\mathcal{C}_A)$. If at some time step the automaton is in the superposition $u \in \mathbb{C}^{\mathcal{C}_A}$, then at the next time step it will be in the superposition $U_A u$. Therefore U_A is also an operator on $\ell_2(\mathcal{C}_A)$. A is *well-formed* if U_A is norm-preserving, and we say that it is *unitary* if U_A is a unitary transformation.

We will work in the algebraic computational model where complex numbers take unit space and arithmetic and logical operations take unit time. The description size of an automaton is clearly dominated by the local transition table δ. Therefore we define the *size* of the automaton to be $n = |\Sigma^{r+1}|$.

For the rest of the paper we will fix a well-formed simple LQCA $A = (\Sigma, q, N, \delta)$. Without loss of generality we assume $N = (0, 1, \ldots, r-1)$. Indeed, let $A' = (\Sigma, q, N', \delta)$ be the well-formed simple LQCA with the general neighborhood $N' = (j, \ldots, j + r - 1)$ for some integer j. We claim that A is unitary if and only if A' is unitary. Let $A'' = (\Sigma, q, (j), \delta')$ be the *shift cellular automaton*, where δ' is the identity. A'' is unitary since δ' is unitary. Moreover, $U_A = U_{A''} U_{A'}$ which proves the claim.

2.1. Example. The figures in this paper will illustrate our algorithm with the following LQCA: QFLIP= $(\{a, b\}, a, (0, 1), \delta)$ with $\langle \delta(x, y)|z\rangle$ defined for all $x, y, z \in$

$\{a, b\}$ by the following table:

$xy\backslash z$	a	b
aa	1	0
ba	0	1
ab	$1/\sqrt{2}$	$1/\sqrt{2}$
bb	$1/\sqrt{2}$	$-1/\sqrt{2}$

Using the algorithm in [7] it can be shown that QFLIP is well-formed, and in this article we show that its evolution operator U_{QFLIP} is even unitary. This LQCA has an interesting property. For $n \geq 0$, let c^n be the configuration which is b in all cells of index $i \in [-n, -1]$ and is a elsewhere. Then we have for all $n \geq 1$, $U_{\text{QFLIP}}(c^1, c^n) = (1/\sqrt{2})^n$. Thus an infinite number of configurations lead with nonzero amplitude to the single configuration c^1.

For the all quiescent configuration c^0, we have $U_{\text{QFLIP}}(c^0, c^0) = 1$; thus there is a unique configuration leading to it. Therefore when the LQCA QFLIP runs backwards in time, every cell with index $i \leq -1$ depends on cell -1. From this we conclude that there cannot be a LQCA with finite neighborhood whose evolution operator is exactly U^*_{QFLIP}.

This makes the model of LQCAs different from QTMs, since for every well-formed QTM M, there exists a QTM which runs M backward in time with a constant time overhead. It explains a bit why it seems difficult to simulate any LQCA by a QTM.

3. The main result. The main result of the paper is the following theorem.

THEOREM 1. *There exists an algorithm which takes a simple LQCA as input and decides in time* $O(n^{\frac{3r-1}{r+1}}) = O(n^3)$ *if it is unitary.*

Since in [7] a $O(n^2)$ algorithm is given to decide if an LQCA is well-formed, we will give only an algorithm which decides if a well-formed LQCA is unitary. The following lemma states that we have to verify only that the rows of the time evolution operator are of unit norm.

LEMMA 2. *Let* $U \in \mathbb{C}^{\mathcal{C}_A \times \mathcal{C}_A}$ *be a linear operator. If* U *is norm-preserving, then its rows have norm at most* 1. *If all the rows are of unit norm, then* U *is unitary.*

Proof. Let c be a configuration, and let $\mathbf{c}$ be the superposition which has amplitude 1 for c and 0 elsewhere. Then the norm of the row indexed by c in U is $\|U^*\mathbf{c}\|$. Since U is norm-preserving $\|U^*\mathbf{c}\| = \|UU^*\mathbf{c}\|$ and the projection of $UU^*\mathbf{c}$ on $\mathbf{c}$ has norm

$$|\langle \mathbf{c}|UU^*\mathbf{c}\rangle| = |\langle U^*\mathbf{c}|U^*\mathbf{c}\rangle| = \|U^*\mathbf{c}\|^2.$$

However, the projection of $UU^*\mathbf{c}$ on a unit vector has norm at most $\|U^*\mathbf{c}\|$, and therefore $\|U^*\mathbf{c}\| \leq 1$.

For the second part of the lemma observe that the projection of $UU^*\mathbf{c}$ on $\mathbf{c}$ has norm 1. Since U is norm-preserving the projection on any other basis vector $\mathbf{c}'$ must be 0. Thus $\langle \mathbf{c}'|UU^*\mathbf{c}\rangle$ is 1 if $c = c'$ and 0 otherwise, or in other words $UU^* = I$, which concludes the proof. □

The outline of the proof is the following. First we give a sequence of reduction steps in section 4 to a graph theoretical problem and to another one from linear algebra. We then give an algorithm to solve the problem. The different steps of the algorithm are presented in sections 5, 6, and 7. The proof of the main theorem is then summarized in section 8.

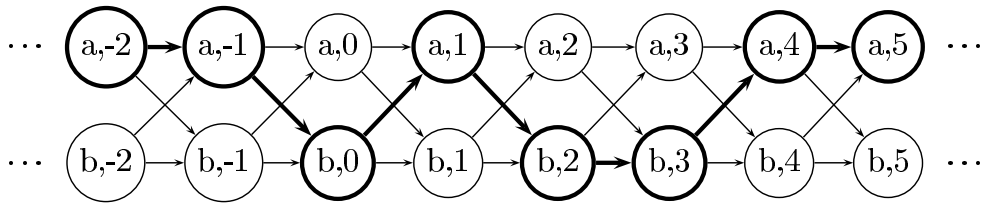

FIG. 1. *The configuration graph of the LQCA* QFLIP. *The bold path corresponds to the configuration* $\dots aababbaa \dots$.

4. The reduction. The different reduction steps are illustrated in Figures 1–3.

Our problem is the following. We have to decide if all row vectors of the evolution operator associated to a given LQCA have unit norm, under the assumption that the operator is norm-preserving. The naive method fails because one would have to compute the norm for an infinite number of rows. Moreover, for every row there can be an infinite number of nonzero entries and every entry is defined by a product on an unbounded number of terms. The purpose of this section is to reduce our problem to a finite one.

The *configuration graph* is the infinite directed graph $G_\infty(V, E)$ defined by $V = \Sigma^{r-1} \times \mathbb{Z}$ and $E = \{((xt, i), (ty, i+1)) : x, y \in \Sigma, t \in \Sigma^{r-2}, i \in \mathbb{Z}\}$. To our knowledge this type of graph was first used by Sutner and Maas [16] to show that a particular robot motion planning problem in the presence of moving obstacles is PSPACE-hard. It was used again by Sutner [15] to prove that the predecessor of every recursive configuration is also recursive.

A nonempty sequence (possibly infinite to the left, to the right, or in both directions) of vertices $(\dots, (w_i, i), \dots)$ in G_∞ is a *path* if and only if for at most a finite number of indices i we have $w_i \neq q^{r-1}$ and there is an edge between every two immediate vertices. Note that a sequence with a single vertex is already a path. We denote by F, L, R, and P, respectively, the set of paths which are finite, infinite to the left, infinite to the right, and infinite to both directions. Figure 1 illustrates a path of P.

We say that two paths p_1 and p_2 are *compatible* if the last vertex of p_1 and the first vertex of p_2 exist and they are the same. In that case the *composition* $p_1 \otimes p_2$ is the concatenation of the two sequences after identifying the extreme vertices. If P_1 and P_2 are sets of paths, then

$$P_1 \otimes P_2 = \left\{ p_1 \otimes p_2 : \begin{array}{l} p_1 \in P_1, p_2 \in P_2, \\ p_1 \text{ and } p_2 \text{ are compatible} \end{array} \right\}.$$

Let d be an arbitrary configuration. It induces a *weight* function g_d for the edges of G_∞, where $g_d((xt, i), (ty, i+1)) = |\langle \delta(xty) | d_i \rangle|^2$. We extend the weight function g_d to paths and to sets of paths. The weight of a path is the product of the respective edge weights, and the weight of a path set is the sum of the respective path weights. The weight of a path consisting of a single vertex is 1, and the weight of the empty path set is 0. We denote this *weighted configuration graph* by G_∞^d which is illustrated in Figure 2.

Although the weight of an infinite path is an infinite product, it is well-defined since all but a finite number of edges have weight 1. The following lemma establishes

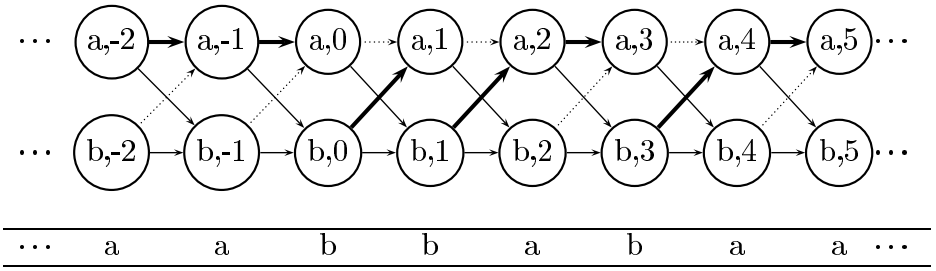

FIG. 2. *The configuration graph of the LQCA* QFLIP *weighted by the configuration* $d = \ldots aabbabaa \ldots$. *The bold edges have weight* 1, *the normal edges have weight* 1/2, *and the dotted-line edges have weight* 0.

a strong relationship between the weight of an infinite path in G^d_∞ and the entries of the time evolution matrix.

LEMMA 3. *For any configuration* d *the row indexed by* d *in* U_A *has norm* $\sqrt{g_d(P)}$.

Proof. We will show that there is a bijection h between the set of configurations $\mathcal{C}_A$ and the set of infinite paths P in G^d_∞ such that for every configuration c and d

$$g_d(h(c)) = |U_A(d,c)|^2.$$

Summing up over all configurations c will immediately conclude the lemma.

Let $h : \mathcal{C}_A \to P$ be defined for all configuration c by

$$h(c) = (\ldots, (c_i \ldots c_{i+r-2}, i), \ldots).$$

Then it is a bijection, and the following equalities conclude the proof:

$$\begin{aligned} g_d(h(c)) &= \prod_{i\in\mathbb{Z}} g_d((c_i \ldots c_{i+r-2}, i), (c_{i+1} \ldots c_{i+r-1}, i+1)) \\ &= \prod_{i\in\mathbb{Z}} |[\delta(c_{i+N})](d_i)|^2 \\ &= \left| \prod_{i\in\mathbb{Z}} [\delta(c_{i+N})](d_i) \right|^2 \\ &= |U_A(d,c)|^2. \qquad \square \end{aligned}$$

With Lemma 2 we got the following reduction of our problem.

COROLLARY 4. *In a well-formed LQCA, for every configuration* d, *we have* $g_d(P) \le 1$. *Moreover, the automaton is unitary if and only if for every* d, $g_d(P) = 1$.

Let us fix an interval $[j,k]$ and a configuration d with $\mathrm{idom}(d) \subseteq [j,k]$. This interval induces a subset of the path sets L, F, and R. For every $w, w' \in \Sigma^{r-1}$ we set

$$\begin{aligned} L^j_w &= \{p \in L : \text{the last vertex of } p \text{ is } (w,j)\}, \\ F^{j,k}_{w,w'} &= \left\{ p \in F : \begin{array}{l} \text{first vertex of } p \text{ is } (w,j), \\ \text{last vertex of } p \text{ is } (w',k+1) \end{array} \right\}, \\ R^k_{w'} &= \{p \in R : \text{the first vertex of } p \text{ is } (w',k+1)\}. \end{aligned}$$

Since the set of infinite paths can be decomposed as

$$P = \bigcup_{w,w' \in \Sigma^{r-1}} L_w^j \otimes F_{w,w'}^{j,k} \otimes R_{w'}^k,$$

we have

$$g_d(P) = \sum_{w,w' \in \Sigma^{r-1}} g_d(L_w^j) \cdot g_d(F_{w,w'}^{j,k}) \cdot g_d(R_{w'}^k).$$

The following lemma shows that $g_d(L_w^j)$ and $g_d(R_w^k)$ are independent from j, k, and d.

LEMMA 5. *For any intervals $[j,k]$, $[j',k']$ and configurations d, d' such that* $\mathrm{idom}(d) \subseteq [j,k]$, $\mathrm{idom}(d') \subseteq [j',k']$ *and for every $w \in \Sigma^{r-1}$, we have*

$$g_d(L_w^j) = g_{d'}(L_w^{j'}) \quad \text{and} \quad g_d(R_w^k) = g_{d'}(R_w^{k'}).$$

Proof. We prove only the first equation; the proof for the second one is analogous. Let $m = j' - j$. We define a bijection from L_w^j to $L_w^{j'}$ which preserves the weight. If $p = (\dots, (w_i, i), \dots, (w_j, j))$ is a path in L_w^j, then we define its image as $p' = (\dots, (w_i, i+m), \dots, (w_j, j+m))$. This is clearly a bijection and we also have $g_d(p) = g_{d'}(p')$ since $d_i = q$ for $i < j$ and $d'_i = q$ for $i < j'$. ∎

We define the *left* and *right border vectors*, respectively, $\vec{l} = (l_w)_{w \in \Sigma^{r-1}}$ and $\vec{r} = (r_w)_{w \in \Sigma^{r-1}}$ as follows: for $w \in \Sigma^{r-1}$, $l_w = g_d(L_w^j)$ and $r_w = g_d(R_w^k)$, where $[j,k]$ is an arbitrary interval and d is an arbitrary configuration satisfying $\mathrm{idom}(d) \subseteq [j,k]$. The next lemma states that $\vec{l}$ and $\vec{r}$ are in $\mathbb{R}^{\Sigma^{r-1}}$.

LEMMA 6. *For all $w \in \Sigma^{r-1}$, l_w and r_w are finite.*

Proof. Suppose there is a w such that $l_w = \infty$. (The case $r_w = \infty$ is symmetric.) We will prove that this implies the existence of a configuration such that the associated line vector has infinite norm, thus contradicting by Corollary 4 the hypothesis that A is well-formed.

Let w' be such that $r_{w'} > 0$. There exists such a w', since, for example, $r_{q^{r-1}} \geq 1$. Let $x_1, x_2, \dots, x_{2r-1} \in \Sigma$ such that $w = x_1 \dots x_{r-1}$ and $w' = x_r \dots x_{2r-2}$. We set $w_i = x_i x_{i+1} \dots x_{i+r-2}$ for $i = 1, \dots, r$ and $v_i = x_i x_{i+1} \dots x_{i+r-1}$ for $i = 1, \dots, r-1$. Note that $w_1 = w$ and $w_r = w'$. For $i = 1, \dots, r-1$ let $y_i \in \Sigma$ be such that $\langle \delta(v_i) | y_i \rangle \neq 0$. Let j be an arbitrary integer and set $k = j + r - 2$. We define the configuration d to be the quiescent state outside the interval $[j,k]$ and $d_{j+i-1} = y_i$ for $i = 1, \dots, r-1$. Then in G_∞^d the set of paths going through the vertices $(w_1, j), \dots, (w_r, k+1)$ already has infinite weight. Since each path has nonnegative weight, P also has infinite weight. ∎

The first part of our algorithm will be the computation of the border vectors $\vec{l}$ and $\vec{r}$. For the second part, we reduce now our problem to a question in linear algebra.

For every $a \in \Sigma$, let $M_a \in \mathbb{R}^{\Sigma^{r-1} \times \Sigma^{r-1}}$ be the linear operator whose matrix is defined for all $w, w' \in \Sigma^{r-1}$ as

$$M_a(w', w) = \begin{cases} |\langle \delta(xty) | a \rangle|^2 & \text{if } w = xt, w' = ty \text{ for some } x, y \in \Sigma \text{ and } t \in \Sigma^{r-2}, \\ 0 & \text{otherwise.} \end{cases}$$

We extend this definition to finite sequences over Σ. If ϵ denotes the empty word, then M_ϵ is the identity operator. Let $s > 1$ be an integer, and let $b = b_1 \dots b_s$ be an element of Σ^s. We define

$$M_b = M_{b_s} \cdots M_{b_1}.$$

LEMMA 7. *Let d be a configuration with* $\mathrm{idom}(d) = [j, k]$. *Then*

$$g_d(P) = \langle M_{d_j \dots d_k} \vec{l} | \vec{r} \rangle.$$

Proof. We have

$$\begin{aligned} g_d(P) &= \sum_{w,w' \in \Sigma^{r-1}} g_d(L^j_w) \cdot g_d(F^{j,k}_{w,w'}) \cdot g_d(R^k_{w'}) \\ &= \sum_{w,w'} l_w \cdot g_d(F^{j,k}_{w,w'}) \cdot r_{w'} \\ &= \sum_{w,w'} l_w \cdot M_{d_j \dots d_k}(w', w) \cdot r_{w'} \\ &= \sum_{w'} \left(\sum_{w} l_w \cdot M_{d_j \dots d_k}(w', w) \right) \cdot r_{w'} \\ &= \sum_{w'} (M_{d_j \dots d_k} \vec{l})(w') \cdot r_{w'} \\ &= \langle M_{d_j \dots d_k} \vec{l} | \vec{r} \rangle. \qquad \square \end{aligned}$$

Since for every $b \in \Sigma^*$ there exists a configuration d whose nonquiescent part is b, Corollary 4 and Lemma 7 imply the following reduction.

COROLLARY 8. *A well-formed LQCA is unitary if and only if for every $b \in \Sigma^*$ we have $\langle M_b \vec{l} | \vec{r} \rangle = 1$.*

We also have the following property, which simplifies our next reduction step.

LEMMA 9. *For every well-formed LQCA A we have $\langle \vec{l} | \vec{r} \rangle = 1$.*

Proof. Let d be the all quiescent configuration. Then in U_A the column indexed by d has the entry 1 at row d and 0 elsewhere. Since the column vectors of U_A are pairwise orthogonal, Lemma 2 implies that the row indexed by d has only zero entries besides column d. Therefore this row has norm 1, and the claim follows from Lemmas 3 and 7. $\square$

Let $m = |\Sigma^{r-1}|$. The border vectors can be seen as elements of $\mathbb{R}^m$, and the elements of the set $\mathcal{M} = \{M_a : a \in \Sigma\}$ can also be seen as linear transformations in $\mathbb{R}^m$. Let us fix a few notations for the inner-product space $\mathbb{R}^m$. Let $S \subseteq \mathbb{R}^m$ be a finite set of vectors. The *linear subspace* and the *affine subspace* generated by S, denoted here, respectively, by $\langle S \rangle$ and $[S]$, are defined as

$$\begin{aligned} \langle S \rangle &= \{\lambda_1 \vec{s}_1 + \cdots + \lambda_t \vec{s}_t | \; t \geq 0; \vec{s}_1, \dots, \vec{s}_t \in S; \lambda_1, \dots, \lambda_t \in \mathbb{R}\}, \\ [S] &= \{\lambda_1 \vec{s}_1 + \cdots + \lambda_t \vec{s}_t | \; t \geq 0; \vec{s}_1, \dots, \vec{s}_t \in S; \lambda_1, \dots, \lambda_t \in \mathbb{R}; \lambda_1 + \cdots + \lambda_t = 1\}. \end{aligned}$$

B is said to be a basis of $\langle S \rangle$ (respectively, of $[S]$) if $\langle B \rangle = \langle S \rangle$ (respectively, $[B] = [S]$) and has minimal cardinality for this property.

Let $\vec{u} \in \mathbb{R}^m$ be a vector and $\mathcal{F} \subseteq \mathbb{R}^{m \times m}$ be a finite family of linear transformations. We set $S + \vec{u} = \{\vec{v} + \vec{u} : \vec{v} \in S\}$, and $\mathcal{F}(S) = \{f(\vec{v}) : \vec{v} \in S, f \in \mathcal{F}\}$. Let $H_{\vec{u}}$ denote the linear subspace whose normal vector is $\vec{u}$, that is, $H_{\vec{u}} = \{\vec{v} : \langle \vec{v} | \vec{u} \rangle = 0\}$.

We define by induction on i, for $i \geq 0$, the sets $\mathcal{F}^i(S)$. Let $\mathcal{F}^0(S) = S$, and $\mathcal{F}^{i+1}(S) = \mathcal{F}^i(S) \cup \mathcal{F}(\mathcal{F}^i(S))$. We say that S is *closed* for $\vec{v}$ under $\mathcal{F}$ if $\bigcup_{i=0}^{\infty} \mathcal{F}^i(\{\vec{v}\}) \subseteq S$.

From Lemma 9, $H_{\vec{r}} + \vec{l}$ is the set of vectors which have unit inner product with $\vec{r}$, that is,

$$H_{\vec{r}} + \vec{l} = \{\vec{u} : \langle \vec{u} | \vec{r} \rangle = 1\}.$$

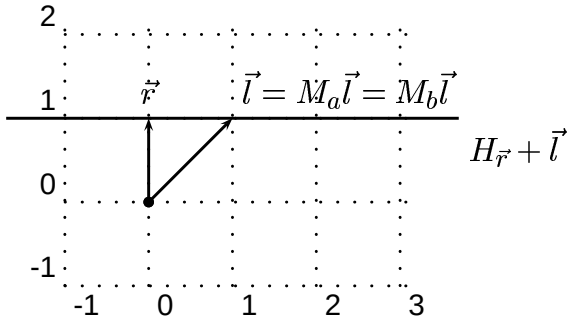

FIG. 3. *For the LQCA* QFLIP*, the border vectors* $\vec{l}$ *and* $\vec{r}$ *and the affine subspace* $H_{\vec{r}} + \vec{l}$*. In this example* $\vec{l}$ *is a fixpoint for the operators* M_a *and* M_b*, which shows that* U_{QFLIP} *is unitary.*

It is an affine subspace since $H_{\vec{r}} + \vec{l} = [H_{\vec{r}} + \vec{l}]$. Clearly for every $b \in \Sigma^*$, $\langle M_b\vec{l}|\vec{r}\rangle = 1$ if and only if $H_{\vec{r}} + \vec{l}$ is closed for $\vec{l}$ under $\mathcal{M}$. Therefore by Corollary 8 our reduction steps lead to the following theorem.

THEOREM 10. *A well-formed LQCA is unitary if and only if* $H_{\vec{r}} + \vec{l}$ *is closed for* $\vec{l}$ *under* $\mathcal{M}$*.*

This characterization is illustrated in Figure 3.

5. Computing the border vectors. In this section we will give an algorithm for computing the border vectors. By symmetry, it will be sufficient to give it only for the left vector. The main tool in the computation will be the weighted border graph. Its underlying graph can be seen as a slight modification of the finite version of the configuration graph. This graph was also used in [7] for checking that all the columns of U_A had unit norms. However, there the weights were defined as the norms of the transition state superpositions, whereas here they will be the squared magnitudes of the amplitude of the quiescent state in those superpositions.

The *(left) border graph* is the finite, directed, weighted graph $G_l = (V, E, g)$. The vertex set is $V = \Sigma^{r-1}$ and the edge set is

$$E = \{(xt, ty) : x, y \in \Sigma, t \in \Sigma^{r-2}\}.$$

The weight function is defined as

$$g((xt, ty)) = |\langle \delta(xty)|q\rangle|^2.$$

A *path* in G_l is a finite, nonempty sequence of at least two vertices such that there is an edge between every two consecutive vertices. Observe that a single vertex alone here does not form a path. As usual, the weight of a path is the product of the edge weights, and the weight of a set of paths is the sum of the individual path weights. The weight of the empty path set is 0.

For every $w \in \Sigma^{r-1}$, we define P_w as the set of paths in G_l whose first vertex is q^{r-1}, whose second vertex is different from q^{r-1}, and whose last vertex is w.

LEMMA 11. *For every* $w \in \Sigma^{r-1}$*, we have*

$$l_w = \begin{cases} g(P_w) & \text{if } w \neq q^{r-1}, \\ g(P_w) + 1 & \text{if } w = q^{r-1}. \end{cases}$$

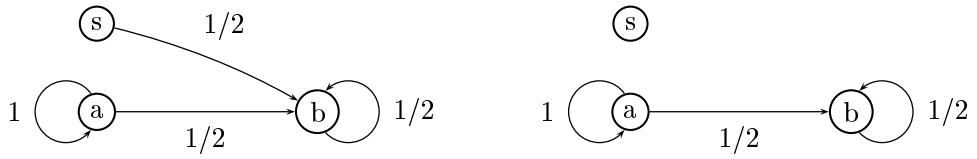

FIG. 4. *The graphs G'_l (left-hand) and G'_r (right-hand) associated to the LQCA* QFLIP. *From these graphs we can compute $\vec{l} = \binom{1}{1}$ and $\vec{r} = \binom{1}{0}$.*

Proof. Let d be a configuration with interval domain $[j, k]$, and let

$$p_q = (\dots, (q^{r-1}, i), \dots, (q^{r-1}, j)).$$

We set $L'_w = L^j_w - \{p_q\}$. We will give a weight-preserving bijection from L'_w to P_w which maps p to p'. Let $p = (\dots, (w_i, i), \dots, (w_j, j))$ be an element of L'_w, where $w_j = w$. Let $h \leq j$ be the greatest integer such that for every $i \leq h$ we have $w_i = q^{r-1}$. Then we set $p' = (q^{r-1}, w_{h+1}, \dots, w_j)$. This is clearly an injective mapping, and it is also surjective since by the choice of h, $w_{h+1} \neq q^{r-1}$. It is also weight-preserving since the edges in p until the vertex (w_h, h) all have weight 1. Since $g_d(p_q) = 1$ the lemma follows. ∎

THEOREM 12. *There exists an algorithm which computes the border vectors in time $O(n^{\frac{3(r-1)}{r+1}})$.*

Proof. According to Lemma 11 it is sufficient to compute $g(P_w)$ for $w \in \Sigma^{r-1}$. The main difficulty in this computation is that the paths of P_w are defined by a constraint which forces the second vertex to be different from q^{r-1}. The solution we propose codes this constraint directly in the graph, which we will augment by one vertex for this purpose. Then we compute the total path weight from i to j for all vertices i, j. To do this, we will adapt a standard algorithm which constructs the regular expression associated to a finite state automaton.

Let $G'_l = (V', E', g')$, where $V' = V \cup \{sq^{r-2}\}$ for a letter $s \notin \Sigma$,

$$E' = E \cup \{(sq^{r-2}, q^{r-2}y) : y \in \Sigma \backslash \{q\}\},$$

and $g'(e) = g(e)$ for all edges $e \in E$ and $g'((sq^{r-2}, q^{r-2}y)) = g((q^{r-1}, q^{r-2}y))$. This graph is illustrated in Figure 4. For every $w \in \Sigma^{r-1}$, let P'_w be the set of all paths in G'_l from sq^{r-2} to w. Clearly there is a weight-preserving bijection between P'_w and P_w.

The border vectors have only finite components; nevertheless, for their computation we have to extend the nonnegative real numbers with ∞. Let $\mathbb{R}^*$ be this set. We define the following computation rules with respect to ∞:

$$\infty + c = c + \infty = \infty,$$

for every $c \in \mathbb{R}^*$,

$$\infty \cdot c = c \cdot \infty = \infty \cdot \infty = \infty,$$

for every real number $c > 0$,

$$\infty \cdot 0 = \infty \cdot 0 = 0,$$

and $\infty^0 = 1$. We also define c^* for every $c \in \mathbb{R}^*$ as $\sum_{e'=0}^{\infty} c^{e'}$, that is,

$$c^* = \begin{cases} 1/(1-c) & \text{if } 0 \le c < 1, \\ \infty & \text{otherwise.} \end{cases}$$

Let $\{v_1, v_2, \ldots, v_{|V'|}\}$ be an arbitrary enumeration of the vertices of G'_l. For $1 \le i, j \le |V'|$ and for $0 \le k \le |V'|$, we define the path sets $P_k(i,j)$ as the set of paths which start in v_i, end in v_j, and all the other vertices in the path have indices less than or equal to k. Let $W_k(i,j)$ denote $g(P_k(i,j))$. Then we claim that $W_k(i,j)$ satisfies the following recursion for $1 \le i, j \le |V'|$ and $1 \le k \le |V'|$:

$$W_0(i,j) = \begin{cases} g'((v_i, v_j)) & \text{if } (v_i, v_j) \in E', \\ 0 & \text{otherwise,} \end{cases}$$
$$W_k(i,j) = W_{k-1}(i,j) + W_{k-1}(i,k) \cdot (W_{k-1}(k,k))^* \cdot W_{k-1}(k,j).$$

We prove our claim by induction on k. In $P_0(i,j)$ the only path is the edge between v_i and v_j if this edge exists.

Assume that this equation is true for $k-1$. We note that for every path of $P_k(i,j)$ there exists a unique integer e such that vertex v_k appears exactly e times the path. Thus we can write

$$P_k(i,j) = P_{k-1}(i,j) \cup \bigcup_{e=1}^{\infty} P_{k-1}(i,k) \otimes \underbrace{P_{k-1}(k,k) \otimes \cdots \otimes P_{k-1}(k,k)}_{e-1} \otimes P_{k-1}(k,j),$$

where the unions are disjoint and $\otimes$ is the path composition operator defined in section 4. By induction hypothesis we have

$$W_k(i,j) = W_{k-1}(i,j) + \sum_{e'=0}^{\infty} \left(W_{k-1}(i,k) \cdot (W_{k-1}(k,k))^{e'} \cdot W_{k-1}(k,j) \right),$$

which concludes the induction.

This proves the correction of the following algorithm: Let $m = |V'| = |\Sigma|^{r-1}$. Initialize W_0. For $k = 1, \ldots, m$ compute W_k using W_{k-1}. Finally, output the border vector $\vec{l}$ defined by $\vec{l}(w) = W_m(sq^{r-2}, w)$ for $w \neq q^{r-1}$ and $\vec{l}(q^{r-1}) = W_m(sq^{r-2}, q^{r-1})+1$. Proceed in similar fashion for $\vec{r}$. The complexity of the algorithm is $O(|\Sigma|^{3(r-1)}) = O(n^{\frac{3(r-1)}{r+1}})$. □

6. Closed affine subspace. In this section we will give a polynomial algorithm for the following problem.

CLOSED AFFINE SUBSPACE

Input: Two vectors $\vec{l}, \vec{r} \in \mathbb{R}^m$ such that $\langle \vec{l} | \vec{r} \rangle = 1$ and a set of linear transformations $\mathcal{M} = \{M_a : a \in \Sigma\}$ in $\mathbb{R}^m$, where $m = |\Sigma|^{r-1}$.

Question: Is $H_{\vec{r}} + \vec{l}$ closed for $\vec{l}$ under $\mathcal{M}$, i.e., for all $b \in \Sigma^*$ do we have $M_b \vec{l} \in H_{\vec{r}} + \vec{l}$?

We set $t = |\Sigma|$. For the simplicity of notation, let $H = H_{\vec{r}} + \vec{l}$ and let $E_i = \mathcal{M}^i(\{\vec{l}\})$. Since $H = [H]$, we have $E_i \subseteq H$ if and only if $[E_i] \subseteq H$. Therefore we have to decide if $[\bigcup_{i=0}^{\infty} E_i] \subseteq H$. Dimension arguments imply the existence of a fixpoint, a set E_j, such that $[E_j] = [\bigcup_{i=0}^{\infty} E_i]$. Moreover, we need only to keep track of a basis of $[E_i]$, that is, a set B_i of linearly independent vectors, with $[B_i] = [E_i]$.

THEOREM 13. *There exists an algorithm which decides if H is closed for $\vec{l}$ under $\mathcal{M}$ in time $O(n^{\frac{3r-2}{r+1}})$.*

Proof. We claim that this is realized by the following algorithm:

$B_0 := \{\vec{l}\}$
$i \quad := 1$
while $[B_i] \neq [B_i \cup \mathcal{M}(B_i)]$
$\quad B_{i+1} :=$ a basis of $[B_i \cup \mathcal{M}(B_i)]$
$\quad i := i + 1$
$B := B_i$
if $B \subseteq H$ accept
else reject

At every iteration $\dim([B_i])$ increases, and therefore the algorithm terminates in at most $m - 1$ iterations. We prove that it is correct.

We show $[B_i] = [E_i]$ for every $i \geq 0$ by induction. The statement holds by definition for $i = 0$. Suppose $[E_i] = [B_i]$ for some i. Since $\mathcal{M}$ contains only linear operators, we have for any set S, $[\mathcal{M}(S)] = [\mathcal{M}([S])]$. Therefore $[\mathcal{M}(E_i)] = [\mathcal{M}(B_i)]$ which implies $[E_{i+1}] = [B_{i+1}]$.

Since B is a fixpoint, that is, $[B] = [B \cup \mathcal{M}(B)]$, this implies that $[B] = [\bigcup_{i=0}^{\infty} E_i]$ and the correctness follows.

We now turn to the analysis of the complexity. We will build inductively the basis so that for all i, $B_i \subseteq B_{i+1}$. At the ith iteration, to build B_{i+1}, initially we set $B_{i+1} = B_i$. Then we compute every vector in $\mathcal{M}(B_i \backslash B_{i-1})$ and add it to B_{i+1} if it is not in the affine subspace generated by B_{i+1}. At the end of the algorithm, these steps were applied to all vectors $M\vec{b}$ for $M \in \mathcal{M}$ and $\vec{b} \in B$, thus at most $|\mathcal{M}| \cdot |B| = O(tm)$ times. Computing $M\vec{b}$ takes $O(m^2)$ with standard matrix multiplication, and checking affine independence also takes $O(m^2)$ with the algorithm described in the next section. Thus the overall complexity is $O(tm^3)$. The theorem follows since $t = n^{\frac{1}{r+1}}$ and $m = n^{\frac{r-1}{r+1}}$. ∎

7. Maintaining a basis. In this section we give a dynamic algorithm for the following problem. We want to maintain a basis B of a d-dimensional linear subspace in R^m such that the following requests for a given vector $\vec{u} \in \mathbb{R}^m$ can be treated efficiently:

Membership query: "Is $\vec{u} \in \langle B \rangle$?"

Add to basis: Replace B by $B \cup \{\vec{u}\}$.

We can define the problem for affine subspaces as well. Fortunately, the latter can easily be reduced to the former: Let $f : \mathbb{R}^m \to \mathbb{R}^{m+1}$ be the function which maps a vector $\vec{u}$ to $\vec{u}'$ with $u'_i = u_i$ for $i = 1, \ldots, m$ and $u'_{m+1} = 1$. Then every vector $\vec{v}$ satisfies $\vec{v} \in [B]$ if and only if $f(\vec{v}) \in \langle f(B) \rangle$.

A solution to this problem requires a tricky data structure to encode the basis. The naive way would be to represent B by a matrix such that its column vectors are exactly those of B and to apply the Gaussian elimination algorithm (see, for example, [11]) to check whether $\vec{u} \in \langle B \rangle$. This would require $O(md^2)$ time steps.

Transforming the matrix in an upper triangular form is the bottleneck of this approach. The representation we choose for B will improve this complexity.

THEOREM 14. *There is a dynamic algorithm for maintaining a basis of a d-dimensional subspace in $\mathbb{R}^m$ which treats each request in time $O(m(m-d))$.*

Proof. We represent a nonempty basis B by the couple (T, B), where $T \in \mathbb{R}^{m \times m}$ is an orthogonal matrix and $\langle T(B) \rangle = \mathbb{R}^d \times \{0\}^{m-d}$. The empty basis is represented by $(I, \emptyset)$, where I is the identity matrix.

Since $T(\langle B \rangle) = \langle T(B) \rangle$, $\vec{u} \in \langle B \rangle$ if and only if $T\vec{u} \in \mathbb{R}^d \times \{0\}^{m-d}$. Thus verifying $\vec{u} \in \langle B \rangle$ is reduced to checking if the last $m - d$ components of $T\vec{u}$ are all 0 which can

be done in time $O(m(m-d))$.

Suppose $\vec{u} \notin \langle B \rangle$. We will show that there is an orthogonal matrix M affecting only components from $d+1$ to m which satisfies $(MT\vec{u})_{d+1} \neq 0$ and $(MT\vec{u})_i = 0$ for $i = d+2, \ldots, m$. Thus $\langle MT(B) \rangle = \langle T(B) \rangle$ and $\langle MT(B \cup \{\vec{u}\}) \rangle = \mathbb{R}^{d+1} \times \{0\}^{m-(d+1)}$. Therefore $(MT, B \cup \{\vec{u}\})$ represents $B \cup \{\vec{u}\}$.

We define M as the composition of two operators M_1 and M_2 we describe now. By hypothesis $\vec{u} \notin \langle B \rangle$; therefore there exists an index $k \in \{d+1, \ldots, m\}$ such that $(T\vec{u})_k \neq 0$. Define M_1 to be the permutation matrix which exchanges k and $d+1$.

Let $\vec{u}' = M_1 T \vec{u}$. Note that $\vec{u}'_{d+1} \neq 0$. Then for an arbitrary vector $\vec{v}$ we define $(M_2\vec{v})_i = \vec{v}_i$ for $i = 1, \ldots, d+1$ and $(M_2\vec{v})_i = \vec{v}_i - \vec{v}_{d+1}\vec{u}'_i/\vec{u}'_{d+1}$ for $i = d+2, \ldots, m$. Clearly M_1 and M_2 are orthogonal linear operators, and since

$$M_2\vec{u}' = (u'_1, u'_2, \ldots, u'_{d+1}, 0, \ldots, 0)$$

M satisfies the required property. We can compute $M_2 M_1 T$ in time $O(m(m-d))$, which concludes the proof. □

8. Putting it all together. We are now able to prove Theorem 1, that is, to give an algorithm to decide if a given LQCA is unitary. Using Theorem 10 to solve this problem we have to compute the associated border vectors and decide the corresponding Closed Affine Subspace problem. According to Theorem 12 the border vectors can be computed in time $O(n^{\frac{3(r-1)}{r+1}})$, and due to Theorem 13 the last problem can be solved in time $O(n^{\frac{3r-2}{r+1}})$, which concludes the proof.

9. Conclusion. A not necessarily simple LQCA can be transformed into a simple one with the same time evolution operator. Let the original neighborhood be $N = (a_1, \ldots, a_r)$. The size of the new neighborhood will be $s = a_r - a_1 + 1$. If we define the *expansion factor* of an LQCA as $e = (s+1)/(r+1)$, then the algorithm works in the general case in time $O(n^{e\frac{3r-1}{r+1}}) = O(n^{3e})$.

In the case of space-periodic configurations, van Dam [17] has shown that LQCAs can be efficiently simulated by QTMs. Watrous [18] gave an equivalent result for partitioned LQCAs. This question still remains open for the model of this paper.

Acknowledgments. We are thankful to Laurent Rosaz, Huong LêThanh, and Umesh Vazirani for several helpful conversations. We also wish to thank the anonymous referees for helpful comments and, in particular, for simplifying section 6.

A POLYLOGARITHMIC APPROXIMATION OF THE MINIMUM BISECTION*

URIEL FEIGE† AND ROBERT KRAUTHGAMER†‡

Abstract. A bisection of a graph with n vertices is a partition of its vertices into two sets, each of size $n/2$. The bisection cost is the number of edges connecting the two sets. It is known that finding a bisection of minimum cost is NP-hard. We present an algorithm that finds a bisection whose cost is within ratio of $O(\log^2 n)$ from the minimum. For graphs excluding any fixed graph as a minor (e.g., planar graphs) we obtain an improved approximation ratio of $O(\log n)$. The previously known approximation ratio for bisection was roughly $\sqrt{n}$.

1. Introduction.

Let $G(V, E)$ be an undirected graph with n vertices and m edges, where n is even. For a subset S of the vertices (with $S \neq \emptyset, V$), the *cut* $(S, V \setminus S)$ is the set of all edges in G with one endpoint in S and one endpoint in $V \setminus S$; these edges are said to be cut by $(S, V \setminus S)$. The *cost* of a cut is the number of edges in it.

A cut $(S, V \setminus S)$ is called a *bisection* of G if its two sides, S and $V \setminus S$, are each of size $n/2$. We denote the minimum cost of a bisection of G by b. *Minimum bisection* is the problem of computing b for an input graph G. This problem is NP-hard (see [7]), and we address the problem of approximating it.

An algorithm is said to approximate a minimization problem within ratio $f \geq 1$ if it runs in polynomial time and outputs a solution whose cost is at most f times the cost of the optimal solution. The problem is said to have a polynomial time approximation scheme (PTAS) if for every fixed $f > 1$ there is an algorithm with approximation ratio f.

1.1. Previous work.

Leighton and Rao [10, 11] showed how to approximate within ratio $O(\log n)$ *minimum-quotient cuts*, which we shall call *min-ratio cuts*. In these cuts, one wishes to minimize the *cut ratio* (also called *edge expansion* or *flux*) $c/|S|$, where c is the number of edges cut and $|S|$ is the cardinality of the smaller of the two vertex sets.

A *β-balanced cut* is a cut that partitions the graph into two parts, each of size at most βn. Leighton and Rao [10] used the approximate min-ratio cuts to find a 2/3-balanced cut (also called *edge separator*) with at most $O(b \log n)$ edges; see also [11, 14]. Note that such a 2/3-balanced cut does not provide an $O(\log n)$ approximation for

the value of b. For example, when the graph consists of three disjoint cliques of equal size, an optimal 2/3-balanced cut has no edges, whereas $b = \Omega(n^2)$.

A straightforward approach for obtaining an exact bisection is to first find an almost balanced cut (e.g., using approximate min-ratio cuts) and then move a few low degree vertices from one side to the other. Using this approach one can approximate bisection within a ratio of $\tilde{O}(\sqrt{m/b})$ (we use $\tilde{O}(f)$ to denote $O(f \cdot \text{polylog } n)$); see, e.g., [11, Footnote 10] and [6]. This is a dramatic improvement over the naive ratio of $O(m/b)$ (achieved by arbitrarily picking $n/2$ vertices) but might still be larger than n.

In terms of n, the best approximation ratio previously known is $\tilde{O}(\sqrt{n})$, due to [6]. Their approach follows, in part, a divide and conquer paradigm. Two of their main tools are (i) approximate min-ratio cuts, which are used to recursively break the graph, and (ii) dynamic programming, which is used to combine certain possible parts into an exact bisection. The current work also uses a divide and conquer approach but in a more sophisticated way.

Additional related work includes the following. In [13], Saran and Vazirani give an algorithm that approximates bisection within a ratio of $n/2$. In [1], Arora, Karger, and Karpinski show that bisection has a PTAS for everywhere-dense graphs, i.e., graphs with minimum degree $\Omega(n)$. In [8], Garg, Saran, and Vazirani give an approximation ratio of 2 for the problem of finding a 2/3-balanced cut of minimum cost in a planar graph. Their result extends to a β-balanced cut, for any $\beta \geq 2/3$, but does not extend to a bisection, which is a 1/2-balanced cut. In [4], Bui and Jones show that for any fixed $\epsilon > 0$, it is NP-hard to approximate the minimum bisection within an *additive* term of $n^{2-\epsilon}$. In terms of approximation ratio, however, there is no known hardness of approximation result which excludes the possibility that bisection has a PTAS.

1.2. Our results. Our main result is an algorithm for approximating the minimum bisection within a polylogarithmic ratio.

THEOREM 1.1. *A bisection of cost within ratio of $O(\log^2 n)$ of the minimum can be computed in polynomial time.*

In section 2 we give an overview of the algorithm. On a high level, the algorithm follows a divide and conquer approach. The input graph is recursively divided into parts, using a new cut notion which we call an *amortized cut*, and then the parts are combined into a bisection using dynamic programming.

In section 4 we describe our algorithm for approximating bisection, based on a subroutine for finding an amortized cut. If the subroutine is guaranteed to find a ρ-amortized cut in a graph, the algorithm computes a bisection whose cost is within a ratio of $1 + O(\rho \log n)$ of the minimum.

In section 3 we devise an algorithm for finding an $O(\log n)$-amortized cut in a general graph. By using this algorithm as a subroutine in the $1 + O(\rho \log n)$ approximation algorithm for bisection, we are guaranteed that $\rho = O(\log n)$, proving Theorem 1.1. The subroutine uses a τ-approximate min-ratio cut in order to find an $O(\tau)$-amortized cut. The best known approximation algorithms for min-ratio cut in general graphs, due to Leighton and Rao [10, 11] and due to [2, 12], have approximation ratio $\tau = O(\log n)$.

In certain graph families, there is a better approximation ratio τ for the min-ratio cut problem. If these graph families are closed under taking induced subgraphs, then we can approximate bisection within an improved ratio of $O(\tau \log n)$. For example, it is shown in [9] that in graphs excluding any fixed graph as a minor (e.g., bounded-genus graphs) min-ratio cut can be approximated within a constant ratio, i.e., $\tau = O(1)$.

THEOREM 1.2. *In graphs excluding any fixed graph as a minor (e.g., planar graphs), a bisection of cost within a ratio of $O(\log n)$ of the minimum can be computed in polynomial time.*

In section 5 we show that our results extend to several natural generalizations of the bisection problem. These extensions include, for example, bisection of graphs with arbitrary nonnegative edge costs and graph partitioning into three parts of equal size.

1.3. Conventions and notation. We will often denote the two sides of a (not necessarily optimal) bisection as *white* W and *black* B. A graph may have several different bisections of minimum cost. For the analysis, let us fix one of them (arbitrarily) and call it *the fixed optimal bisection* (W^*, B^*).

For V_1, V_2, two disjoint subsets of vertices in a graph, let $e(V_1, V_2)$ denote the number of edges with one endpoint in V_1 and the other endpoint in V_2. Subsets $V_1, V_2 \subset V$ are called a *partition* of V if they are nonempty, disjoint, and their union is equal to V. In our context, V is the vertex set of a graph, and then a partition $V = V_1 \cup V_2$ is equivalent to the cut (V_1, V_2).

A subset of vertices $S \subset V$ with $0 < |S| < |V|$ corresponds to a cut $(S, \overline{S})$ in the graph, where $\overline{S} = V \setminus S$. We denote by $r(S)$ the ratio of this cut, i.e., $r(S) = \frac{e(S,\overline{S})}{\min\{|S|,|\overline{S}|\}}$, and by $r'(S)$ the ratio of this cut towards S, i.e., $r'(S) = \frac{e(S,\overline{S})}{|S|}$. We call S a *part* of the graph, referring either to the set of vertices S or to the subgraph induced on S, depending on the context.

2. Overview and techniques. Our approximation algorithm for minimum bisection has three stages, as outlined below.

Stage 1: Decomposition. This stage consists of a sequence of *divide steps*. The input to a divide step is a *part* of the input graph G, i.e., a vertex set and the subgraph induced on it, and the output is a partition of the vertex set into two nonempty subsets, giving two new parts of the graph. These divide steps are applied on the input graph G recursively until it is decomposed into individual vertices.

The output of the whole decomposition stage is a binary tree T that we call the *decomposition tree*. Each node i of the tree contains a part V_i obtained in a divide step, as follows. The root of the tree contains the input graph G, the leaves of the tree contain individual vertices of G, and the two direct descendants of a node i are the two subparts obtained in the divide step of its part V_i.

To complete the description of the decomposition stage, we need to explain how a divide step is performed. This is done using a new notion called an *amortized cut*, which we define later in this section. We devise an algorithm for finding amortized cuts in section 3. The decomposition stage is described in more detail in section 4.1.

Stage 2: Labeling. Consider a *labeling* of the decomposition tree T, which labels each (nonleaf) tree node as either white or black. Fixing a parameter $1/2 < \alpha < 1$, we say that a labeling is α-*consistent* with respect to a white-black bisection (W, B) of the input graph if every part V_i (at a tree node i) satisfies that $|W \cap V_i| \leq \alpha|V_i|$ if the label of node i is white and that $|B \cap V_i| \leq \alpha|V_i|$ if the label of node i is black.

The desired outcome of the labeling stage is a labeling which is α-consistent with the fixed optimal bisection (W^*, B^*), called in short an *opt-consistent labeling*. However, an optimal bisection is not known to the algorithm; so instead of finding an opt-consistent labeling, this stage produces a family of labelings such that at least one member of the family is opt-consistent. The description of how this is done is

deferred to section 4.2. For the purpose of this overview, it will be convenient to think of the labeling stage as if it produces only one labeling, which is opt-consistent.

Stage 3*: Combining.* Given a decomposition tree T and an arbitrary (not necessarily opt-consistent) labeling of it, the combining stage assigns to each vertex v of the input graph G a *white charge* and a *black charge*. The two charges are simple to compute based on the labels along the path from the root of T to the leaf that contains the vertex v.

The *charge of a bisection* (W, B) of the input graph G (with respect to the labeling) is defined as the sum of the white charges of the vertices of W and the black charges of the vertices of B. The functions white charge and black charge have the property that for every bisection, charge is an upper bound on cost (regardless of the labeling).

If the charge is defined with respect to an opt-consistent labeling of T, then our notion of amortized cut used in the decomposition stage guarantees, in addition, that the charge of the fixed optimal bisection is within a polylogarithmic factor of its cost b. Hence, using the opt-consistent labeling produced by the labeling stage ensures that the input graph G contains a bisection whose charge is within polylogarithmic ratio of b.

Finding a bisection of minimum charge in G is relatively straightforward. Associate with each vertex a *net-charge*, which is its white charge minus its black charge, and pick the $n/2$ vertices with smallest net-charge to form one side, W, leaving the remaining $n/2$ vertices in another side, B. The bisection (W, B) that we find has minimum charge, and its cost is thus within a polylogarithmic factor of b, the cost of the minimum bisection.

It is interesting to note that finding a minimum cost bisection is an optimization problem with a quadratic objective function (minimizing the number of edges, where edges are pairs of vertices). Finding a minimum charge bisection (given the decomposition tree and an opt-consistent labeling) is an optimization problem with a linear objective function (sum of net-charges over individual vertices). Hence, in a sense, our algorithm performs a linearization of a quadratic function and loses a polylogarithmic factor in the process.

The above presentation of the combining stage was oversimplified. The output of the labeling stage is not one labeling that is opt-consistent, but rather a large family of labelings, such that at least one of them is opt-consistent. Moreover, this family has exponential cardinality; so we cannot try the above net-charge approach on each labeling separately. Instead, we exploit the structure of this family of labelings and use dynamic programming to compute a labeling from the family and a bisection such that the charge of this bisection with respect to this labeling is minimum over all labeling-bisection pairs. Details appear in section 4.4.

In the rest of the overview we shall introduce and discuss the notion of *amortized cut*, which is of central importance in bounding the ratio between the charge and the cost of the fixed optimal bisection. To motivate this new notion we present our algorithm as a divide and conquer algorithm. We then suggest a kind of cut that is desirable for the algorithm's divide step and call this cut notion an amortized cut.

Divide and conquer approach. A possible divide and conquer approach for a graph problem is to divide the input graph G into two parts (using a cut), solve a subproblem for each part, and then combine the solutions of the two subproblems into a solution for G. This approach can be applied recursively, and then the input graph G is recursively divided into smaller and smaller parts, where each part is associated

with a subproblem. Note that the divide step cut is a tool of this approach and is not intended to be a solution to the subproblem.

In our context, the graph problem is minimum bisection, and we apply this divide and conquer approach for the more general problem of cutting away an arbitrary number of vertices that is given as part of the input. (Bisection is the special case where the given number is $n/2$.) Similarly, the subproblem of each part requires to cut away (from that part) an arbitrary number of vertices that is given in the subproblem. Note that minimum bisection is a cut problem, and therefore in addition to the *divide step cuts* we have here also *solution cuts* (later called *combined cuts*). Note that the solution cut of a part need not be the same as the divide step cut of this part.

Our three stage algorithm outlined above follows this divide and conquer approach. The task of breaking the input graph into smaller and smaller parts is performed by the decomposition stage, whose decomposition tree T represents the recursive structure of the divide steps.

For such a divide and conquer approach to be successful, it is desirable that (i) each of the two subproblems can be solved separately and (ii) the solutions of the two subproblems can be combined while incurring a relatively small additional cost. Below we provide an overview of how our algorithms handle these issues.

Consider the problem of cutting away k vertices from a part $U \subseteq V$ of the input graph. The corresponding divide step uses a cut (U_1, U_2) of U to break this problem into the two subproblems of cutting away k_1 vertices from U_1 and of cutting away k_2 vertices from U_2, with $k = k_1 + k_2$. (For the sake of exposition assume that k_1, k_2 can be guessed.) Let us assume that the subproblem associated with each subpart U_i is solved separately (by recursion) and the solution obtained for it is a cut (C_i, F_i) with $|C_i| = k_i$ (see also Figure 2.1). The two solution cuts are then combined into a cut of U that separates $k = k_1 + k_2$ vertices, namely $(C_1 \cup C_2, F_1 \cup F_2)$. Let $Cut(U', k')$ denote the cost of the cut of U' that separates k' vertices and is found by the algorithm. Then the cost of the combined cut is given by

$$Cut(U,k) = Cut(U_1,k_1) + Cut(U_2,k_2) + e(C_1,F_2) + e(C_2,F_1). \tag{2.1}$$

Previous accounting method. The approach of [6] is based on a straightforward upper bound on the cost (2.1) of the combined cut. The additional cost incurred by the divide step, i.e., $e(C_1, F_2) + e(C_2, F_1)$, is at most the cost of all the edges cut by the divide step, i.e., $e(U_1, U_2)$, yielding the upper bound

$$Cut(U,k) \le Cut(U_1,k_1) + Cut(U_2,k_2) + e(U_1,U_2). \tag{2.2}$$

We remark that a bound similar to (2.2) is used in divide and conquer algorithms for many other graph problems, such as minimum cut linear arrangement (a.k.a. cutwidth); see, e.g., [11].

The divide steps of [6] use an approximate min-ratio cut to break each part U. This cut appears to be suitable for the bound (2.2) because it minimizes the cost of the cut (U_1, U_2), and at the same time tries to cut the part U into parts of roughly equal size, so as to minimize the depth of the recursion.

It is particularly instructive to evaluate the quality of our upper bound in the case where the computed cut $(C_1 \cup C_2, F_1 \cup F_2)$ is just the cut induced on U by the optimal bisection (W^*, B^*). Intuitively, we analyze the case where the algorithm happens to find the optimal bisection. In fact, we will later use dynamic programming to find a bisection for which the upper bound is minimized; so such an analysis bounds from above the cost of the output bisection.

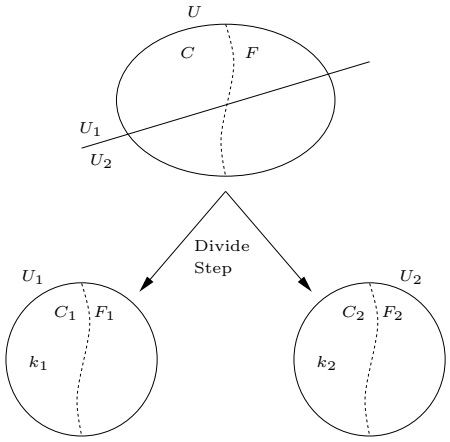

FIG. 2.1. *The divide and conquer paradigm.*

There are cases where the upper bound (2.2) is tight (i.e., holds with equality). Indeed, the cuts within each U_i are computed independently of each other, and so it might happen that all the edges between the two parts U_1, U_2 end up in the combined cut. However, this bound is insensitive to cases where only a few of the edges that are cut in the divide step end up in the combined cut, leading to a relatively poor approximation ratio.

New accounting method. We introduce a more sophisticated way of bounding the cost of the combined cut. Since $F_1 \subseteq U_1$ and $F_2 \subseteq U_2$ we can bound the cost of the combined cut by

$$Cut(U,k) \leq Cut(U_1,k_1) + Cut(U_2,k_2) + e(C_1,U_2) + e(C_2,U_1). \tag{2.3}$$

Unlike the actual cost (2.1), the upper bound (2.3) can be used in a divide and conquer approach, as follows. Let us call $e(C_1,U_2)+e(C_2,U_1)$ the *charge of the divide step* of U. This charge can be distributed into a charge $e(C_1,U_2)$ of the part U_1 and a charge $e(C_2,U_1)$ of the part U_2. The charge of a part U_i consists of the edges going from C_i to the other part U_{3-i} and thus depends on the cut (C_i,F_i) chosen in the part U_i but not on the cut chosen in the other part U_{3-i}. We obtain two separate subproblems (as in each part U_i we want to find a cut (C_i,F_i) for which the sum of the cost of this cut and the charge to this part is minimal), enabling a recursive divide and conquer approach. In contrast, the terms $e(C_1,F_2)$ and $e(C_2,F_1)$ of the actual cost of the combined cut depend on the cuts chosen in both parts and do not allow us to break the problem into two separate subproblems.

The new accounting method makes a distinction between the two sides C and F of the combined cut. Unlike, e.g., in (2.2), these two sides have different roles in the upper bound (2.3), and we will choose in a certain way which side is referred to as C (and which as F). Since we wish to minimize the charge, it makes sense to choose the smaller of the two sides to be C. In our analysis we have a somewhat relaxed condition, requiring that $|C| \leq \alpha|U|$, for a fixed $1/2 < \alpha < 1$. The task of identifying a side C as required above in each divide step (i.e., each node of the decomposition tree) is performed by the labeling stage, as explained in section 4.2.

The *charge of a bisection* is the upper bound that is obtained by applying the upper bound (2.3) recursively; i.e., it is the sum of the charges of all the divide steps.

In section 4.3 we discuss this notion in more detail, and in section 4.4 we show that its current formulation is equivalent to the one from Stage 3 of the algorithm outline (where the identification of a side C at each divide step corresponds to labeling of the decomposition tree T). From the current formulation it is straightforward that the charge of a bisection is always an upper bound on its cost (regardless of the identification of C at each divide step, i.e., the tree labeling).

We call the vertices of $C = C_1 \cup C_2$ *charged* and the vertices of $F = F_1 \cup F_2$ *free*. The edges in the part U can then be classified as charged-charged, charged-free, or free-free, according to their two endpoints.

Desired divide step. Rather than find a bisection of minimum cost, our approximation algorithm looks for a bisection of minimum charge. Our desired divide step is therefore one that guarantees that for the fixed optimal bisection, charge can be used to approximate cost. By the labeling stage, it suffices to refer here to charge with respect to an opt-consistent labeling; so from now on we assume that $|C| \leq \alpha|U|$ at each divide step.

Consider the charge of the fixed optimal bisection and recall that it is the sum of the charges of all the divide steps. The charge of a divide step of a part U is $e(C_1, U_2) + e(C_2, U_1)$ and can be written also as $e(C_1, F_2) + e(C_2, F_1) + 2e(C_1, C_2)$, i.e., the cost of the charged-free edges that the divide step cuts and twice the cost of the charged-charged edges that it cuts. Observe that a charged-free edge is always an edge of the fixed optimal bisection (and vice versa) and that each edge is cut exactly once in the decomposition stage. Hence, all the charged-free edges cut in all the divide steps are exactly all the edges of the fixed optimal bisection. So for the fixed optimal bisection, the difference between charge and cost is twice the cost of all the charged-charged edges cut in all the divide steps.

It is therefore desired that the divide step cuts relatively few charged-charged edges, where relative here is, with respect to b, the cost of the fixed optimal bisection. Since b is the total cost of the charged-free edges that are cut in all the divide steps, we seek an *amortization scheme* that amortizes the total cost of all charged-charged edges cut against the total cost of all charged-free edges cut. The partition of vertices to charged and free is not known to the divide step, and we therefore require that the amortization scheme holds for every possible partition of vertices to charged and free.

A simple amortization scheme can consider each divide step separately and amortize the cost of the charged-charged edges cut in a divide step against the cost of the charged-free edges cut in the same divide step. Suppose that in every divide step the amortized cost in this method is at most ρ; i.e., at every part U we have that $e(C_1, C_2) \leq \rho[e(C_1, F_2) + e(C_2, F_1)]$. Then the total cost of charged-charged edges cut in all divide steps is clearly at most ρb, and the charge of the fixed optimal bisection is at most $(1 + 2\rho)b$.

The problem with this simple amortization scheme is that in order to guarantee that the scheme holds for all possible partitions of vertices to charged and free, ρ might be required to be at least n, a value that is too high for our intended application. For example, consider a graph that consists of two cliques of size $n/2$ connected by an edge e. If the divide step breaks any of the cliques, then letting this clique be C and the other clique be F, the amortization cost will be at least n. Otherwise, the divide step consists of the edge e and then, letting C consist of the two endpoints of e, the amortization cost will be infinite.

We employ a more complicated amortization scheme that allows a small amortization cost ρ but introduces an additional logarithmic factor. The reason for the

logarithmic factor is that this scheme amortizes against the same edge more than once (but, in a sense, not too many times). Another complication is that this scheme actually has two amortization methods, and it uses at each divide step the one that is better (for that divide step).

Amortized cut. We amortize the cost of the charged-charged edges cut in a divide step against the cost of the charged-free edges *in the part being divided*, i.e. in the divide step of a part U we amortize $e(C_1, C_2)$ against $e(C, F)$. The edges that we amortize against are not cut in this divide step, and hence an edge may receive an amortized cost in many divide steps. However, our amortization scheme described below will guarantee that the total cost amortized against a single edge is at most $O(\rho \cdot \log n)$ for a suitable ρ. Since the edges that we amortize against are charged-free edges and hence edges of the fixed optimal bisection, it would follow that the total cost of the charged-charged edges cut in all the divide steps is at most $O(\rho \log n) \cdot b$, and so the charge of the fixed optimal bisection is $(1 + O(\rho \log n)) \cdot b$.

For motivation, consider the case where the divide steps recursion has depth $O(\log n)$, e.g., when all the divide steps are roughly balanced. In this case, an edge can receive an amortized cost in at most $O(\log n)$ divide steps. Suppose that in every divide step the amortized cost is at most ρ; i.e., in every part U we have that $e(C_1, C_2) \leq \rho \cdot e(C, F)$. Then the total cost amortized against a single edge is at most $O(\rho \log n)$.

We do not require that the divide steps are balanced but rather scale the amortization cost at a part U according to the imbalance of its divide step. Out of the several possible scaling factors we will use only the following two, where we assume, without loss of generality, that $|U_1| \leq |U_2|$. The first scaling factor is $e(C_1, F_1)/e(C, F)$, and its corresponding amortization method requires that

$$e(C_1, C_2) \leq \rho \cdot \frac{e(C_1, F_1)}{e(C, F)} \cdot e(C, F). \tag{2.4}$$

The second scaling factor is $|C_1|/|C|$, and its corresponding amortization method requires that

$$e(C_1, C_2) \leq \rho \cdot \frac{|C_1|}{|C|} \cdot e(C, F). \tag{2.5}$$

Alternative formulations. The first amortization method (2.4) can also be written as $e(C_1, C_2) \leq \rho \cdot e(C_1, F_1)$. A convenient interpretation of this formulation is that we amortize against the charged-free edges inside U_1, the smaller side of the divide step cut (rather than inside U, the part being divided), and the amortized cost is required to be at most ρ.

The second amortization method (2.5) can be written also as $e(C_1, C_2) \leq \rho \cdot r'(C) \cdot |C_1|$, where $r'(C) = e(C, F)/|C|$. (See section 1.3 for the difference between $r'(C)$ and $r(C)$.) A convenient interpretation of this formulation is that we amortize against the vertices in C_1, the charged vertices inside the smaller side of the divide step cut, and the amortized cost is required to be at most $\rho \cdot r'(C)$.

Total amortized cost. The total cost amortized in the first method (2.4) is at most $O(\rho \log n) \cdot b$. Indeed, let us use the alternative formulation in which the amortization is only against edges inside U_1, the smaller side of the divide step cut. An edge can be inside U_1 in at most $\log n$ divide steps (since the size of the part it is contained in reduces at each such divide step by a factor of 2). Hence the total cost amortized in

this method against a single edge (of the fixed optimal bisection) is at most $O(\rho \log n)$, and the claim follows.

The total cost amortized in the second method (2.5) is also at most $O(\rho \log n) \cdot b$. Indeed, we show in section 4.3 that the total cost amortized in this method against a single edge (of the fixed optimal bisection) is at most $O(\rho \log n)$ (essentially by careful summation of the relevant terms of the form $|C_1|/|C|$), and the claim follows.

Our amortization scheme. Our amortization scheme chooses at each divide step the scaling factor that is better for this divide step, and so it suffices to have that at each part U at least one of (2.4) and (2.5) holds. It follows from the above discussion (see section 4.3 for a full proof) that the total cost amortized in both methods together is at most $O(\rho \log n) \cdot b$.

We can now formally define our desired divide step according to the (alternative formulations of) the two amortization methods described above. We call this cut an amortized cut.

DEFINITION. *Let (U_1, U_2) be a cut with $|U_1| \le |U_2|$ in a graph $G'(U, E')$, and let $U = C \cup F$ be a partition of the graph vertices U to charged vertices C and free vertices F. Let us denote $C_i = U_i \cap C$ and $F_i = U_i \cap C$ for $i = 1, 2$, as in Figure* 2.1. *Let*

$$\rho_e = \frac{e(C_1, C_2)}{e(C_1, F_1)} \qquad \text{and} \qquad \rho_v = \frac{e(C_1, C_2)}{|C_1| \cdot r'(C)}, \tag{2.6}$$

where $r'(C) = e(C, F)/|C|$. We call ρ_e the amortized cost for the edges*, and ρ_v the* amortized cost for the vertices*. (Note that ρ_e, ρ_v depend on C, F.)*

The amortized cost of the cut (U_1, U_2) *is the maximum of* $\min\{\rho_e, \rho_v\}$*, where the maximum is taken over all partitions $U = C \cup F$ with $0 < |C| \le \alpha|U|$ for a fixed $\frac{1}{2} \le \alpha < 1$. We say that the cut (U_1, U_2) is* ρ-amortized *if its amortized cost is at most ρ.*

In order for us to correctly handle cases where there is no cost to amortize against, we use the convention that $\frac{0}{0}$ is defined to be 0 and that $\frac{t}{0}$ for $t > 0$ is defined to be ∞. In particular, we may extend (2.6) to the case where $C = \emptyset$ and then ρ_e, ρ_v are defined to be 0.

Convenient characterizations. A convenient characterization of an amortized cut is given in the following proposition, whose proof is straightforward. (We will use this characterization in section 4.)

PROPOSITION 2.1. *A cut (U_1, U_2) with $|U_1| \le |U_2|$ is ρ-amortized if and only if for every $C \subset U$ with $|C| \le \alpha|U|$ and $F = U \setminus C$,*

$$e(C_1, C_2) \le \rho \cdot \max\left\{ e(C_1, F_1),\ \tfrac{|C_1|}{|C|} \cdot e(C, F) \right\},$$

where $C_i = U_i \cap C$ and $F_i = U_i \cap C$ for $i = 1, 2$.

The restriction $|C| \le \alpha|U|$ implies that the two terms $r(C) = \frac{e(C,F)}{\min\{|C|,|F|\}}$ and $r'(C) = \frac{e(C,F)}{|C|}$ differ by no more than a constant factor. Indeed, $\min\{|C|, |F|\} = \Theta(|C|)$ and hence $r(C) = \frac{e(C,F)}{\min\{|C|,|F|\}} = \frac{e(C,F)}{\Theta(|C|)} = \Theta(r'(C))$.

We can therefore characterize the amortized cost of a cut (up to constant factors) in terms of $r(C)$ rather than $r'(C)$. (We will use this characterization in section 3.)

PROPOSITION 2.2. *A cut (U_1, U_2) with $|U_1| \leq |U_2|$ is $O(\rho)$-amortized if for every partition $U = C \cup F$ with $0 < |C| \leq \alpha|U|$,*

$$\min\left\{\frac{e(C_1,C_2)}{e(C_1,F_1)}\ ,\ \frac{e(C_1,C_2)}{|C_1|\cdot r(C)}\right\} \leq \rho, \tag{2.7}$$

where $C_i = U_i \cap C$ and $F_i = U_i \cap C$ for $i = 1, 2$.

Remarks. Observe that without the restriction $|C| \leq \alpha|U|$, the amortized cost ρ might be required to be $\Omega(|U|)$, a value that is too high for our intended application. For example, consider a clique on n vertices and a cut (U_1, U_2) in it with $|U_1| \leq |U_2|$. Let one vertex of U_2 be the only free vertex and the rest of the vertices be charged. The number of charged-charged edges cut is $|U_1| \cdot \Theta(n)$. There are no charged-free edges in U_1; so the amortized cost for the edges is $\rho_e = \infty$. The number of charged vertices in the smaller side is $|U_1|$ and $r'(C) = \frac{n-1}{n-1} = 1$; so the amortized cost for the vertices is $\rho_v = \frac{|U_1|\Theta(n)}{|U_1|\cdot 1} = \Theta(n)$. Therefore, the amortized cost of any cut would be $\rho = \Omega(n)$.

In contrast, we show that the restriction $|C| \leq \alpha|U|$ allows us to obtain relatively small values of ρ. Namely, there always exists a cut whose amortized cost is $\rho = O(1)$, and a cut whose amortized cost is $O(\log|U|)$ can be computed efficiently. We remark that our constructions are stronger than those required by Proposition 2.2, as they satisfy (2.7) with no restriction on $|C|$. (The point is that we use $r(C)$ rather than $r'(C)$, which makes a significant difference when $|C| \gg |F|$, as in the above clique example.)

Note that the amortized cost ρ is not an approximation ratio. On the one hand, it is not clear from the definition that every graph has an $O(1)$-amortized cut. On the other hand, the amortized cost of a cut may be smaller than 1, as demonstrated by a graph that consists of two cliques of size $n/2$ connected by an edge. The cut that separates the two cliques can be seen to have amortized cost $O(1/n)$.

3. Finding an amortized cut. In this section we devise an algorithm for finding $O(\log n)$-amortized cuts in general graphs and $O(1)$-amortized cuts in graphs excluding any fixed minor (e.g., planar graphs). The input graph for this algorithm is denoted by G (though it may be just a part of the input graph for bisection). We assume that G is connected, as otherwise we can separate a connected component while cutting no edges at all.

Section 3.1 shows that every optimal min-ratio cut is an $O(1)$-amortized cut. It follows that in every graph there exists an $O(1)$-amortized cut. An optimal min-ratio cut is NP-hard to find in general graphs, and we thus consider approximate min-ratio cuts.

Section 3.2 demonstrates an approximate min-ratio cut which would be a poor divide step for our accounting method. In particular, its amortized cost is high, showing that the arguments of section 3.1 do not immediately extend from optimal min-ratio cuts to approximate ones.

Section 3.3 presents an algorithm that uses a τ-approximate min-ratio cut in order to find an $O(\tau)$-amortized cut. Known algorithms for the min-ratio cut problem in general graphs [11, 2, 12] have approximation ratio $\tau = O(\log n)$, and we can thus find an $O(\log n)$-amortized cut. For certain graph families a better approximation ratio is possible. For example, in graphs excluding any fixed minor, a ratio of $\tau = O(1)$ is known due to [9], and we can thus find an $O(1)$-amortized cut.

3.1. Min-ratio cuts are $O(1)$-amortized. We give an $O(1)$ upper bound on the amortized cost of optimal min-ratio cuts. The proof is based on the characterization given in Proposition 2.2 for an amortized cut. We remark that our proof satisfies (2.7) with no restriction on $|C|$.

LEMMA 3.1. *An optimal min-ratio cut in a graph is $O(1)$-amortized.*

Proof. Let (V_1, V_2) be an optimal min-ratio cut in a graph G and assume, without loss of generality, that $|V_1| \le |V_2|$. Let $V = C \cup F$ be an arbitrary partition of the graph vertices to charged vertices C and free vertices F, with $0 < |C| < |V|$, and denote $C_i = V_i \cap C$ and $F_i = V_i \cap F$ for $i = 1, 2$ (see also Figure 3.1). We show below that

$$\min\left\{\frac{e(C_1,C_2)}{e(C_1,F_1)},\ \frac{e(C_1,C_2)}{|C_1|\cdot r(C)}\right\} \le 2, \tag{3.1}$$

and then by Proposition 2.2 we will have that (V_1, V_2) is $O(1)$-amortized, which proves the lemma. Note that we can assume that $|C_1| > 0$, as otherwise there is nothing to prove.

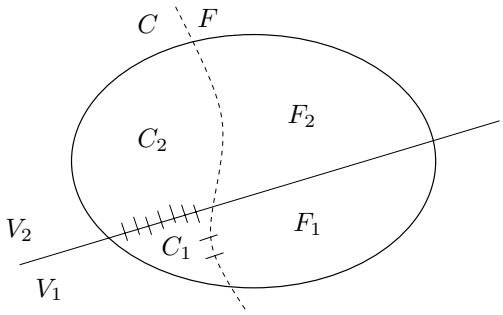

FIG. 3.1. *The amortized cost of an optimal min-ratio cut* (V_1, V_2).

One easy case is when $\frac{e(C_1,C_2)}{e(C_1,F_1)}$ (i.e., the amortized cost for the edges ρ_e) is at most 2, which clearly implies (3.1).

Another easy case is when $\frac{e(C_1,C_2)}{|C_1|} \le 2r(V_1)$. Since (V_1, V_2) is an optimal min-ratio cut, we also have that $r(V_1) \le r(C)$. We obtain that $\frac{e(C_1,C_2)}{|C_1|\cdot r(C)} \le 2\frac{r(V_1)}{r(C)} \le 2$, and therefore (3.1) holds.

We next prove that one of the two easy cases above must hold, as otherwise we must have that $r(F_1) < r(V_1)$, in contradiction with (V_1, V_2) being an optimal min-ratio cut. Indeed, assume that $e(C_1, C_2)/e(C_1, F_1) > 2$ and $\frac{e(C_1,C_2)}{|C_1|} > 2r(V_1)$. Since $r(V_1) = \frac{e(V_1,V_2)}{|V_1|}$ is the average degree from V_1 to V_2, it can be represented as the following convex combination of the average degree from C_1 to V_2 and the average degree from F_1 to V_2, namely

$$r(V_1) = \frac{|F_1|}{|V_1|}\cdot\frac{e(F_1,V_2)}{|F_1|} + \frac{|C_1|}{|V_1|}\cdot\frac{e(C_1,V_2)}{|C_1|}.$$

Since $r(F_1) = \frac{e(F_1,V_2)+e(F_1,C_1)}{|F_1|}$ (note that $|F_1| \le |V_1| \le \frac{1}{2}|V|$), we can represent $r(V_1)$ also as

$$r(V_1) = \frac{|F_1|}{|V_1|}\cdot r(F_1) + \frac{|C_1|}{|V_1|}\cdot\left[\frac{e(C_1,V_2)-e(F_1,C_1)}{|C_1|}\right].$$

By the above two assumptions (that exclude the easy cases) we have that

$$\frac{e(C_1,V_2)-e(F_1,C_1)}{|C_1|} \geq \frac{e(C_1,C_2)-e(F_1,C_1)}{|C_1|} \geq \frac{\frac{1}{2}e(C_1,C_2)}{|C_1|} > r(V_1).$$

The last two inequalities imply that

$$r(V_1) > \frac{|F_1|}{|V_1|}\cdot r(F_1) + \frac{|C_1|}{|V_1|}\cdot r(V_1).$$

We obtained that some convex combination of $r(F_1)$ and $r(V_1)$ is smaller than $r(V_1)$, and we can therefore conclude that $r(F_1) < r(V_1)$. This contradicts the fact that (V_1, V_2) is an optimal min-ratio cut and completes the proof of Lemma 3.1. ∎

The converse of Lemma 3.1 is not true, and an $O(1)$-amortized cut can be an $\Omega(n)$-approximate min-ratio cut, as follows from the next proposition with $t = O(1)$.

PROPOSITION 3.2. *Fix a constant $1/2 < \alpha < 1$ for the definition of an amortized cut. Then for every $t = o(n)$, there is an $O(1/t)$-amortized cut which is an $\Omega(n/t)$-approximate min-ratio cut.*

Proof. Consider a graph on n vertices, for a sufficiently large n, that consists of three cliques as follows. V_1 is a clique on t vertices, V_2 is a clique on αn vertices, and V_3 is a clique on the remaining $\Omega(n)$ vertices. In addition, the graph contains one edge connecting V_1 to V_2 and one edge connecting V_2 to V_3.

The cut $(V_1, V_2 \cup V_3)$ has amortized cost $O(1/t)$. Indeed, let $C \cup F$ be a partition of the vertices with $|C| \leq \alpha n$. We may assume that C contains both endpoints of the edge between V_1 and V_2, as otherwise the cut contains no charged-charged edges and its amortized cost is 0. So we have that the cost of the charged-charged edges cut is 1 and that both V_1 and V_2 contain at least one charged vertex. If V_1 contains also at least one free vertex, then the number of charged-free edges in V_1 is at least $t-1$ and hence $\rho_e = \frac{e(C_1,C_2)}{e(C_1,F_1)} \leq 1/(t-1)$. Otherwise, we have $C_1 = V_1$; since there are at most αn charged vertices, and at least one of them is in V_1, we have that V_2 contains also free vertices and thus $e(C,F) \geq \Omega(n)$; it follows that $\rho_v = \frac{e(C_1,C_2)}{e(C,F)} \cdot \frac{|C|}{|C_1|} \leq O(1/t)$.

The cut $(V_1, V_2 \cup V_3)$ is an $\Omega(n/t)$-approximate min-ratio cut. Indeed, the ratio of this cut is $r(V_1) = 1/t$, while the cut $(V_3, V_1 \cup V_2)$ is an optimal min-ratio cut and has ratio $r(V_3) = O(1/n)$. ∎

The next corollary follows from Lemma 3.1.

COROLLARY 3.3. *In every graph there exists an $O(1)$-amortized cut.*

Corollary 3.3 is optimal up to constant factors, and there are graphs for which any cut has amortized cost $\Omega(1)$. For example, consider a clique on n vertices. Given a cut (V_1, V_2) with $|V_1| \leq |V_2|$, let α be the constant in the amortized cut definition and take $(\alpha - 1/2)n$ vertices of V_2 and all of V_1 to be the charged vertices. It can be seen that $\rho_e = \infty$ and $\rho_v = \Theta(1)$, and so the amortized cost of the cut (V_1, V_2) is $\Omega(1)$, as claimed.

3.2. Approximate min-ratio cuts might be poor amortized cuts. We demonstrate that an approximate min-ratio cut of a graph might be a poor divide step and, in particular, a poor amortized cut. Consider, for example, the following graph G on $2n + 2\sqrt{\epsilon n}$ vertices for a fixed $0 < \epsilon < 1$ (see also Figure 3.2). The vertex set of the graph is $F_1 \cup F_2 \cup C_1 \cup C_2$, where each of F_1, F_2 are of size n, each of C_1, C_2 are of size $\sqrt{\epsilon n}$, and each of the four subsets forms a clique. These four cliques are connected as follows. Between F_1 and F_2 there are n edges that form a matching (i.e., have no common endpoint). Between C_1 and C_2 there are all possible ϵn edges; thus

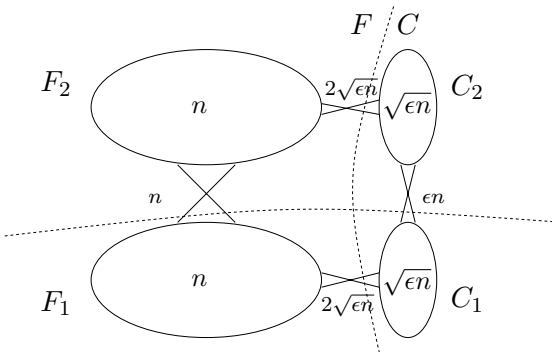

FIG. 3.2. *A poor divide step by an approximate min-ratio cut.*

$C_1 \cup C_2$ forms a clique. There are also $2\sqrt{\epsilon n}$ edges between F_i and C_i (for $i = 1, 2$) so that their endpoints at F_i are distinct and each vertex of C_i is an endpoint of exactly two of these edges.

Let $C = C_1 \cup C_2$ be the charged vertices and $F = F_1 \cup F_2$ the free vertices. Such a partition to charged and free may reflect the "right" cut of $2\sqrt{\epsilon n}$ vertices from the graph G (if, e.g., the input graph for bisection consists of this graph G and a clique on $2n - 2\sqrt{\epsilon n}$ vertices).

Consider a divide step based on the cut $(F_1 \cup C_1, F_2 \cup C_2)$, whose ratio is nearly optimal. Indeed, an optimal min-ratio cut in this graph is $(F_1, C_1 \cup F_2 \cup C_2)$ and its ratio is $1 + 2\sqrt{\epsilon}/\sqrt{n}$. The cut $(F_1 \cup C_1, F_2 \cup C_2)$ has a slightly higher ratio of $(1 + \epsilon)(1 - o(1))$, and so it is a $1 + \epsilon$ approximate min-ratio cut.

Observe that the cut $(F_1 \cup C_1, F_2 \cup C_2)$ is a poor divide step. It cuts ϵn charged-charged edges while the total number of charged-free edges in G (and the bisection cost in the input graph) is only $4\sqrt{\epsilon n}$. According to the new accounting method, such a divide step does not give an approximation ratio better than $\Omega(\sqrt{\epsilon n})$.

The observation that the cut $(F_1 \cup C_1, F_2 \cup C_2)$ is a poor divide step is supported by its high amortized cost. The amortized cost for the edges is $\rho_e = \epsilon n / 2\sqrt{\epsilon n} = \sqrt{\epsilon n}/2$. The ratio of the cut (C, F) is $r(C) = r'(C) = 2$; so the amortized cost for the vertices is $\rho_v = \epsilon n / (\sqrt{\epsilon n} r'(C)) = \sqrt{\epsilon n}/2$. We conclude that a $1 + o(1)$ approximate min-ratio cut might have amortized cost $\rho \geq \min\{\rho_e, \rho_v\} = \sqrt{\epsilon n}/2$.

3.3. Finding $O(\tau)$-amortized cut. We present an algorithm that finds an $O(\tau)$-amortized cut, given a subroutine for computing a τ-approximate min-ratio cut. The algorithm is motivated by the $O(1)$ upper bound on the amortized cost of a min-ratio cut shown in section 3.1. In particular, we examine what additional properties are required in order to extend the analysis of Lemma 3.1 from optimal min-ratio cuts to approximate ones.

The proof of Lemma 3.1 uses *twice* the fact that (V_1, V_2) is an optimal min-ratio cut. In the first usage we had that $\frac{e(C_1,C_2)}{|C_1| \cdot r(C)} \leq 2\frac{r(V_1)}{r(C)} \leq 2$, which extends to the case where (V_1, V_2) is an approximate min-ratio cut with the approximation ratio carried over to the amortized cost; i.e., if (V_1, V_2) is a τ-approximate min-ratio cut, then we have $\frac{e(C_1,C_2)}{|C_1| \cdot r(C)} \leq 2\frac{r(V_1)}{r(C)} \leq 2\tau$.

The second time we used the fact that (V_1, V_2) is an optimal min-ratio cut was to say that $r(F_1) < r(V_1)$ cannot hold and gives a contradiction. In general, this usage does not extend to an approximate min-ratio cut, as demonstrated by the example

in section 3.2. However, the proof does extend to an approximate min-ratio cut if we have the additional property that the ratio of V_1 is minimal over all its subsets F_1; i.e., $r(V_1) \leq r(F_1)$ for all $F_1 \subset V_1$. We therefore obtain that the proof of Lemma 3.1 extends to approximate min-ratio cuts as follows.

LEMMA 3.4. *Let (V_1, V_2) be a τ-approximate min-ratio cut in a graph, with $|V_1| \leq |V_2|$. If $r(V_1) \leq r(F_1)$ for every $F_1 \subset V_1$, then (V_1, V_2) is an $O(\tau)$-amortized cut.*

Note that the proof of Lemma 3.4 is not symmetric with respect to the two amortization methods. It guarantees that either $e(C_1, C_2)/e(C_1, F_1) \leq 2$ (i.e., the amortized cost for the edges ρ_e is at most 2) or $\frac{e(C_1,C_2)}{|C_1| \cdot r(C)} \leq 2\tau$ (i.e., the amortized cost for the vertices ρ_v is $O(\tau)$). In contrast, in the proof of Lemma 3.1 for optimal min-ratio both amortization costs are $O(1)$.

The amortized cut algorithm. We use Lemma 3.4 to devise an algorithm that finds an $O(\tau)$-amortized cut based on a τ-approximate min-ratio cut. The algorithm, described in Figure 3.3, starts with a τ-approximate min-ratio cut (V_1, V_2) and then "fixes" it so that it would also be "minimal" with respect to containment, as required by Lemma 3.4. It then follows that the output cut is $O(\tau)$-amortized.

In order to "fix" the cut (V_1, V_2), the algorithm uses minimum (s, t)-cuts in a related graph G', which is defined in step 2. The related graph G' contains edges of the input graph G, as well as new edges. The edges from G have unit capacity, while the capacity of the new edges is some parameter $p > 0$. Step 3 then finds the optimal value of p with respect to the minimum (s, t)-cut. Before discussing implementation issues of step 3, let us analyze the algorithm's correctness.

Algorithm FINDAMORTIZED**.**

1. Find in the input graph $G = (V, E)$ a τ approximate min-ratio cut (V_1, V_2) with $|V_1| \leq |V_2|$.
2. Create a related graph G':
   – Merge all vertices of V_2 into a single vertex t, removing self-loops at t, and keeping all edges to V_1, including parallel edges.
   – Add a new vertex s which is connected to each vertex of V_1 by an edge whose capacity (weight) is a parameter $p > 0$.
3. Let S denote the vertices of V_1 which are on the same side with s in a minimum (s, t)-cut of G'.
   – Find (e.g., by binary search) the minimum $p > 0$ for which $S \neq \emptyset$. (Possibly, $S = V_1$).
4. Output the cut $(S, V \setminus S)$ of the input graph.

FIG. 3.3. *Algorithm for amortized cuts.*

LEMMA 3.5. *The cut $(S, V \setminus S)$ output by algorithm* FINDAMORTIZED *is a τ-approximate min-ratio cut. In addition, every nonempty subset of V_1 has ratio at least as large as S, i.e., $r(S) = \min\{r(S') : \emptyset \neq S' \subseteq V_1\}$.*

Proof. Consider an arbitrary value p and an arbitrary (s, t)-cut in the related graph G' with the corresponding set $S \subset V_1$ (see Figure 3.4). The cut consists of (i) edges between s and $V_1 \setminus S$ (each of capacity p), (ii) edges between S and $V_1 \setminus S$ (these are edges from the input graph G), and (iii) edges between S and t (these are the edges between S and V_2 in the input graph G). The capacity of this (s, t)-cut is thus

$$\text{cap}(S) = p \cdot |V_1 \setminus S| + e(S, V \setminus S),$$

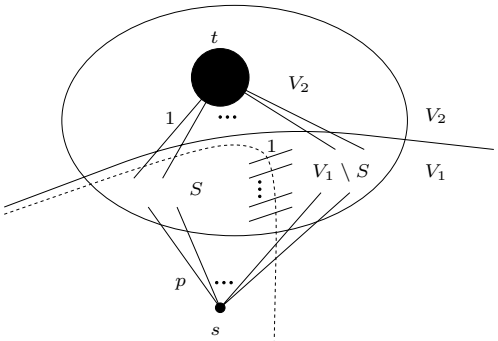

FIG. 3.4. *An (s,t)-cut in the related graph G'.*

where, as usual, $e(\cdot,\cdot)$ denotes the number of corresponding edges in the input graph G. In the special case of the empty set $S = \emptyset$, the capacity of the (s,t)-cut is

$$\mathrm{cap}(\emptyset) = p \cdot |V_1|.$$

Fixing the value of p, let us compare the capacity of the cut defined by the empty set $\emptyset$ with that of an arbitrary set $S \neq \emptyset$, i.e., $\mathrm{cap}(\emptyset)$ vs. $\mathrm{cap}(S)$. The empty set $\emptyset$ yields a smaller capacity whenever

$$\begin{aligned} p \cdot |V_1| &< p \cdot |V_1 \setminus S| + e(S, V \setminus S) \\ &\Updownarrow \\ p &< \frac{e(S, V \setminus S)}{|S|} = r(S), \end{aligned}$$

where $r(S)$ is the ratio of the cut $(S, V \setminus S)$ in the input graph G. (Note that $|S| \leq |V_1| \leq \frac{1}{2}|V|$ and that $r(S) > 0$ if G is connected.)

We claim that the value of p found at step 3 is essentially $p^* = \min\{r(S) : \emptyset \neq S \subseteq V_1\}$. Indeed, when $p < p^*$, a minimum (s,t)-cut in G' corresponds to $S = \emptyset$, and, when $p > p^*$, a minimum (s,t)-cut yields a set $S \neq \emptyset$. When $p = p^*$, a minimum (s,t)-cut can be obtained either by $S = \emptyset$ or by (one or more) $S \neq \emptyset$ with $r(S) = p^*$.

When $p = p^* + \epsilon$ for a very small $\epsilon > 0$, only the sets $S \neq \emptyset$ with $r(S) = p^*$ give smaller capacity than the empty set, and thus a minimum (s,t)-cut is obtained by one of these sets S. By the definition of p^*, this set $\emptyset \neq S \subset V_1$ has minimal ratio $r(S)$ over all nonempty subsets of V_1, i.e., $r(S) = \min\{r(S') : \emptyset \neq S' \subseteq V_1\}$, as claimed. Furthermore, since $S = V_1$ is included in this range, we get that $r(S) \leq r(V_1)$ and hence $(S, V \setminus S)$ is a τ-approximate min-ratio cut, finishing the proof. We remark that a slightly modified algorithm can guarantee in addition that $r(S) < r(S')$ for every $S' \subset S$ with $S' \neq \emptyset, S$. Details are omitted. □

THEOREM 3.6. *Given a subroutine for computing a τ-approximate min-ratio cut, algorithm* FINDAMORTIZED *finds an $O(\tau)$-amortized cut.*

Proof. Lemma 3.5 guarantees that the cut found by the algorithm satisfies the requirements of Lemma 3.4, from which it follows that the cut is $O(\tau)$-amortized. □

We now address the issue of implementing step 3. Observe that p^* is the maximum value p for which the empty set $\emptyset$ gives a minimum (s,t)-cut. Since, by definition, p^* is the ratio $r(S)$ of a set S, it has only n^3 possible values, which can be exhaustively

searched. Alternatively, p^* can be found in $O(\log n)$ iterations of binary search, since as an exact multiple of $1/|S|$ it is bounded between 0 and n, and the difference between any two of its possible values is more than $1/n^2$.

Once we find p^*, we need to find a set $S \neq \emptyset$ that gives a minimum (s,t)-cut for p^*. We can either guess a vertex of V_1 and merge it with s before computing the minimum (s,t)-cut for p^* or, alternatively, compute a minimum (s,t)-cut for $p = p^* + \epsilon$ with, e.g., $\epsilon = 1/n^2$.

4. The bisection algorithm. In this section we describe our approximation algorithm for bisection and prove the following theorem. (See section 2 for the definition of an amortized cut.)

THEOREM 4.1. *Given a subroutine that finds a ρ-amortized cut, a bisection within a ratio of $1 + O(\rho \log n)$ of the minimum can be found in polynomial time.*

4.1. Decomposition stage. The decomposition stage recursively divides the input graph $G = (V, E)$ into smaller and smaller parts using a ρ-amortized cut subroutine (e.g., the one devised in section 3). Each part is further divided unless it consists of a single vertex.

The decomposition stage builds a rooted binary tree T, called the *decomposition tree*, which corresponds to the recursive decomposition of the input graph G in a natural way, as follows. (Throughout, we call the vertices of T *nodes* to avoid confusion with the vertices of the input graph G.) Each tree node i contains a part $V_i \subseteq V$ that was found during the recursive decomposition. The root node of T contains V, i.e., the whole input graph G. Let us denote the two children of a nonleaf node i by $L(i)$ and $R(i)$. Then their two parts $V_{L(i)}, V_{R(i)}$ are the result of dividing V_i; i.e., the ρ-amortized cut found in V_i is $(V_{L(i)}, V_{R(i)})$. A leaf of the tree T contains a part that consists of a single vertex of G. Therefore T contains exactly n leaves and $n-1$ nonleaf nodes.

4.2. Labeling stage. Recall the following definitions from section 2. A *labeling* of the decomposition tree T labels each nonleaf node of the tree as either white or black. Fixing a parameter $1/2 < \alpha < 1$, we say that a labeling is α-*consistent* with respect to a white-black bisection (W, B) of G if every tree node i satisfies the following: If the label of node i is white, then $|W \cap V_i| \leq \alpha |V_i|$, and if the label of node i is black, then $|B \cap V_i| \leq \alpha |V_i|$ (where V_i is the part contained in node i). A labeling is called *opt-consistent* if it is α-consistent with the fixed optimal bisection (W^*, B^*).

The labeling stage produces a family $\mathcal{F}$ of labelings. The cardinality of $\mathcal{F}$ is exponential in n; so rather than listing its members explicitly, the labeling stage produces an implicit representation of $\mathcal{F}$. The actual work of the labeling stage is to *mark* certain nodes of T, and these nodes implicitly define the family $\mathcal{F}$, as described below.

The labeling stage marks some of the nodes of T in a process that goes from the root of T towards its leaves, as follows. The root of T is always marked, and any other node i in the tree is marked in this process if its closest marked ancestor j satisfies $|V_i| \leq \frac{1}{2\alpha}|V_j|$. (As before, V_i and V_j are the parts contained in the nodes i and j, respectively.) Note that the constant α is chosen so that $\frac{1}{2} < \alpha < 1$, implying $\frac{1}{2} < \frac{1}{2\alpha} < 1$.

A labeling of T is said to be *derived* from the marked nodes if the label of every unmarked node is the same as the label of its closest marked ancestor. (There is no

restriction on the labels of the marked nodes.) Note that in this case the labels of the marked nodes uniquely define the labels of all the internal tree nodes.

The family $\mathcal{F}$ produced by the labeling stage consists of all the labelings that can be derived from the marked nodes. Since each of the $\Omega(n)$ marked nodes can be labeled arbitrarily by one of two colors, the resulting family of labelings has exponentially large cardinality, and we cannot explicitly list all the family members. Instead, the algorithm implicitly represents this family $\mathcal{F}$ by identifying which are the marked nodes.

LEMMA 4.2. *The family of labelings $\mathcal{F}$ contains at least one opt-consistent labeling.*

Proof. Let the white-black cut (W, B) be the fixed optimal bisection. Consider the labeling that is derived from the marked nodes, with the label of each marked node i being the color in minority among the vertices of V_i.

This labeling is clearly in the family $\mathcal{F}$, and we claim that it is also opt-consistent. Indeed, the label of a marked node i is by definition the minority color in V_i. The label of an unmarked node i is the same as the label of its closest marked ancestor j. Suppose, without loss of generality, that this label (of i and j) is white. Then at most half the vertices of V_j are white, i.e., $|W \cap V_j| \leq \frac{1}{2}|V_j|$. Observe that $V_i \subset V_j$ and $|V_i| > \frac{1}{2\alpha}|V_j|$ and hence $|W \cap V_i| \leq |W \cap V_j| \leq \frac{1}{2}|V_j| < \alpha|V_i|$. Hence, this labeling of $\mathcal{F}$ is opt-consistent. ∎

4.3. The charge of a bisection. We now formally define the *charge of a bisection* (W, B) with respect to the decomposition tree T and a labeling of it. The reference to T will later be omitted, as we always refer to the tree computed in the decomposition stage.

DEFINITION. *Let (W, B) be a bisection of the input graph and assume we are given a decomposition tree T and a labeling of it. For each (nonleaf) node i of T, if i is labeled white, then we let (see Figure 4.1) $C_i = W \cap V_i$ and $F_i = B \cap V_i$, and if i is labeled black, then we let $C_i = B \cap V_i$ and $F_i = W \cap V_i$. We obtain a cut (C_i, F_i) of the part V_i, and say that C_i is* charged *and F_i is* free. *The* charge of the divide step *of a (nonleaf) node i is defined as*

$$e(C_i \cap V_{L(i)}, V_{R(i)}) + e(C_i \cap V_{R(i)}, V_{L(i)}).$$

The charge of the bisection (W, B) *is defined as the sum of all the divide steps charges, i.e.,*

$$\sum_{i \in T} e(C_i \cap V_{L(i)}, V_{R(i)}) + e(C_i \cap V_{R(i)}, V_{L(i)}).$$

(These charges are defined with respect to T and a labeling of it.)

Bisection charge vs. cost. In certain conditions, a bisection charge can approximate its cost. As shown below, the charge of a bisection upper bounds its cost, and the gap between them is not too large if the charge is taken with respect to an α-consistent labeling (as in the case of the fixed optimal bisection and an opt-consistent labeling).

LEMMA 4.3. *The charge of a bisection (W, B) with respect to any labeling is at least as large as its cost.*

Proof. As we have seen in section 2, the true cost of the (W, B) edges cut in a divide step i is $e(C_i \cap V_{L(i)}, F_i \cap V_{R(i)}) + e(C_i \cap V_{R(i)}, F_i \cap V_{L(i)})$ and is therefore not larger than the charge of this step. The proof follows by summing over all divide steps,

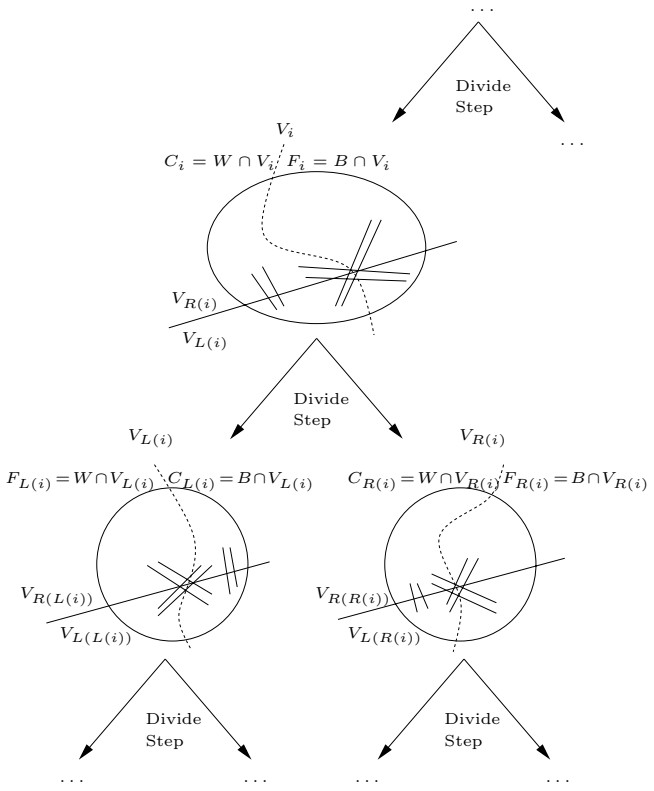

FIG. 4.1. *The charge of a bisection* (W, B) *throughout the decomposition tree.*

since the decomposition stage eventually divides the graph into individual vertices, and so every edge of the bisection (W, B) is cut at some divide step. ∎

LEMMA 4.4. *The charge of a bisection* (W, B) *with respect to a labeling that is* α*-consistent with it is at most* $e(W, B) \cdot (1 + O(\rho \log n))$.

Proof. Consider a bisection (W, B) and a labeling of T that is α-consistent with it. As we have seen in section 2 and in Lemma 4.3 the charge of a divide step is larger than the true cost of the (W, B) edges cut in that step by the cost of the charged-charged edges cut in that divide step. Summing over the divide steps we get that the charge of (W, B), the fixed optimal bisection, is larger than its cost by $2\sum_i e(C_i \cap V_{L(i)}, C_i \cap V_{R(i)})$, where i ranges over all (nonleaf) nodes i in T. We use the shorter notation $C_L = C_i \cap V_{L(i)}$ and $C_R = C_i \cap V_{R(i)}$, where i is clear from the context.

To upper bound $2\sum_i e(C_L, C_R)$, observe that each part V_i is divided using a ρ-amortized cut and that the α-consistent labeling guarantees that $|C_i| \leq \alpha |V_i|$ for all nodes i; so we can use the amortization scheme of section 2. Namely, let us assume, without loss of generality, that the decomposition stage places in the left child of a node i the smaller of the two subparts of V_i; i.e., $|V_{L(i)}| \leq |V_{R(i)}|$ for every nonleaf node i. Then by Proposition 2.1 we can upper bound

$$e(C_L, C_R) \leq \rho \cdot \max\left\{ e(C_L, F_L) \ , \ \frac{|C_L|}{|C_i|} \cdot e(C_i, F_i) \right\}$$

and obtain

$$2\sum_i e(C_L, C_R) \le 2\rho \cdot \left\{ \sum_i e(C_L, F_L) + \sum_i \tfrac{|C_L|}{|C_i|} \cdot e(C_i, F_i) \right\}. \tag{4.1}$$

Therefore, to complete the proof of Lemma 4.4 it suffices to upper bound the sums in the curly brackets (i.e., the total cost amortized in each of the two methods) by $e(W,B) \cdot O(\log n)$.

Consider first $\sum_i e(C_L, F_L)$. The edges that contribute to this sum are charged-free edges and hence edges of the bisection (W,B). An edge in the cut (C_L, F_L) must be inside $V_{L(i)}$, the smaller side of the cut of V_i, and any single edge can be inside $V_{L(i)}$ in at most $\log n$ divide steps i throughout the tree T. Hence, $\sum_i e(C_L, F_L)$ consists of at most $\log n$ times the cost of every edge of the bisection (W,B), and therefore this sum is at most $e(W,B) \cdot \log n$.

Next consider $\sum_i \frac{|C_L|}{|C_i|} \cdot e(C_i, F_i)$ and recall our convention that $\frac{0}{0}$ is defined to be 0. The edges of $e(C_i, F_i)$ contribute to the sum their cost scaled by a factor of $\frac{|C_L|}{|C_i|}$. Each edge of $e(C_i, F_i)$ is a charged-free edge and hence an edge of the bisection (W,B). However, an edge of the bisection (W,B) belongs to $e(C_i, F_i)$ if and only if this edge is inside V_i. The nodes i for which this edge is inside V_i are all on a path from the root to a leaf of the decomposition tree T, and therefore the total contribution of this edge is at most its cost scaled by the sum of $\frac{|C_L|}{|C_i|}$ over that path in T.

We claim that the sum of $\frac{|C_L|}{|C_i|}$ over any path from the root to a leaf is bounded by $O(\log n)$. It follows from this claim that $\sum_i \frac{|C_L|}{|C_i|} \cdot e(C_i, F_i)$ can be described as the cost of every edge of the bisection (W,B) scaled by at most $O(\log n)$, and therefore this sum is at most $e(W,B) \cdot O(\log n)$.

To prove the claim, consider an arbitrary path from the root to a leaf and denote the path nodes by $1, 2, \ldots, p+1$. At each node i the charged side (i.e., C_i) may be either W or B, depending on the label of the node; so denoting $w_j = |W \cap V_j|$ and $b_j = |B \cap V_j|$, we have that $\frac{|C_L|}{|C_i|}$ is either $\frac{w_{L(i)}}{w_i}$ or $\frac{b_{L(i)}}{b_i}$ and clearly at most their sum. Hence,

$$\sum_{i=1}^{p} \frac{|C_L|}{|C_i|} \le \sum_{i=1}^{p} \frac{w_{L(i)}}{w_i} + \sum_{i=1}^{p} \frac{b_{L(i)}}{b_i}.$$

First consider $\sum_1^p \frac{w_{L(i)}}{w_i}$, and observe that w_i is a nonincreasing sequence, since, in the tree, node i is a parent of node $i+1$. If node $i+1$ is a left child (of its parent node i), then $w_{L(i)} = w_{i+1}$ and hence $\frac{w_{L(i)}}{w_i} = \frac{w_{i+1}}{w_i} \le 1$. The number of such nodes i is at most $\log n$, since the path from the root to a leaf can contain at most $\log n$ left children i. (Recall that $|V_{L(i)}| \le |V_{R(i)}|$.) The contribution of all such nodes i to $\sum_1^p \frac{w_{L(i)}}{w_i}$ is therefore at most $\log n$.

If node $i+1$ is a right child (of its parent i), then $w_{L(i)} = w_i - w_{i+1}$, and the contribution of all such nodes i is at most $\sum_1^p \frac{w_i - w_{i+1}}{w_i}$. Clearly, $\frac{w_i - w_{i+1}}{w_i} \le \frac{1}{w_i} + \cdots + \frac{1}{w_{i+1}+1}$ and hence the contribution of all such nodes i to $\sum_1^p \frac{w_{L(i)}}{w_i}$ is at most $\sum_1^p \frac{w_i - w_{i+1}}{w_i} \le \frac{1}{w_1} + \cdots + \frac{1}{2} + 1 = H(w_1) \le H(n)$, where $H(k) = \sum_1^k \frac{1}{j}$ is the kth harmonic number.

We conclude that $\sum_1^p \frac{w_{L(i)}}{w_i} \le \log n + H(n) \le O(\log n)$. Similarly, $\sum_1^p \frac{b_{L(i)}}{b_i} = O(\log n)$, and together we get that $\sum_1^p \frac{|C_L|}{|C_i|} \le O(\log n)$, proving the claim and the lemma. ∎

COROLLARY 4.5. *The charge of the fixed optimal bisection* (W^*, B^*) *with respect to an opt-consistent labeling is at most* $b(1 + O(\rho \log n))$.

Distributing charge to vertices. It will be convenient (algorithmically) to distribute the charge of a bisection (W, B) (with respect to T and a labeling) to the vertices of the input graph, as follows. For each vertex $v \in V_i$ let the *cross-degree* of v at node i, denoted $cross_i(v)$, be the cost of the edges that are incident at v and are cut in divide step i. We define the *charge of a vertex* $v \in V$ as the sum of the cross-degree of v at all nodes i for which v belongs to the charged side, i.e., $\sum_{i:v \in C_i} cross_i(v)$. The next lemma proves that distributing the charge of a bisection to the graph vertices is indeed correct.

LEMMA 4.6. *The charge of a bisection* (W, B) *is the sum of the charges of all vertices in* G.

Proof. The charge of a divide step of node i is equal to the sum of the cross-degrees at node i of all vertices $v \in V_i$, i.e.,

$$e(C_i \cap V_{L(i)}, V_{R(i)}) + e(C_i \cap V_{R(i)}, V_{L(i)}) = \sum_{v \in C_i} cross_i(v) \ .$$

Summing over all nodes i in the tree T, the left-hand side is, by definition, the bisection charge, and the right-hand side is the sum of the charges of all vertices in G. The proof follows. ∎

Distributing the charge to the vertices of G is important algorithmically. The charge of a vertex depends on (and can be easily computed from) the side of this vertex in the bisection (W, B), the decomposition tree T, and the labeling of T, but it does not depend on the side of the cut (W, B) that other vertices of the graph belong to. It follows that the charge of a bisection (W, B), with respect to a given decomposition tree T and a labeling of it, depends *linearly* on the placement of vertices into W and B. This formulation of charge will be exploited by (the dynamic programming in) the combining stage.

4.4. Combining stage. The combining stage computes a bisection of the input graph G and a labeling of the decomposition tree T such that the bisection charge with respect to the labeling is at most $b \cdot (1 + O(\rho \log n))$. It then follows from Lemma 4.3 that the cost of the computed bisection is at most $b \cdot (1 + O(\rho \log n))$, as desired.

First consider the case where an opt-consistent labeling is known. Then it suffices to compute a bisection of G whose charge with respect to this opt-consistent labeling is minimal because Corollary 4.5 guarantees that the charge of the computed bisection is at most $b \cdot (1 + O(\rho \log n))$. Below we describe a simple procedure for finding a bisection of G with minimal charge with respect to a given labeling.

However, we do not know how to efficiently find an opt-consistent labeling, and therefore we go over all the labelings in the family $\mathcal{F}$. Specifically, using a more complicated procedure described below the combining stage finds a bisection of G and a labeling from $\mathcal{F}$ such that the charge of the bisection with respect to the labeling is minimal over all such bisection-labeling pairs. Lemma 4.2 guarantees that at least one of these labelings is opt-consistent, in which case Corollary 4.5 applies. Hence, the bisection-labeling pair computed by this procedure satisfies that the charge of the bisection with respect to the labeling is indeed at most $b \cdot (1 + O(\rho \log n))$.

Minimizing charge over a given labeling. Finding a bisection of minimum charge with respect to a given labeling is relatively straightforward. By Lemma 4.6, the charge of a bisection (W, B) is the sum of the vertex charges. Since the decomposition tree T and the labeling are fixed, the charge of a vertex depends only on its side

in the bisection (W, B). We can therefore compute for each vertex v what its charge is when it belongs to W, called the *white charge* of v, and what its charge is when it belongs to B, called the *black charge* of v. (Note that summing the white charge and the black charge of a vertex gives the degree of that vertex in G.)

The charge of a bisection (W, B) is then the sum of the white charges of W and the black charges of B. To find a bisection (W, B) with minimum charge with respect to the given labeling, we can thus compute for each vertex its net-charge (white charge minus black charge) and take W to be the $n/2$ vertices with smallest net-charge. (This algorithm for the case where a labeling is given was used in the algorithm outline in section 2, where we assumed that the labeling stage produces an opt-consistent labeling.)

Minimizing charge over the family $\mathcal{F}$. The combining stage uses dynamic programming to find a bisection and a labeling from the family $\mathcal{F}$ so that the charge of the bisection with respect to this labeling is minimum over all such bisection-labeling pairs.

The dynamic programming table Q has entries of the form $Q(i, k, g)$, where i is a node of the decomposition tree T, k is an integer between 0 and $|V_i|$, and g is a *guess list* that contains the labels of the marked ancestors of node i. Throughout, i is considered an ancestor of itself.

An entry $Q(i, k, g)$ in the table contains the optimal solution to the following problem: Choose k vertices of V_i and a labeling from $\mathcal{F}$ that agrees with g so that when these k vertices are placed in the side W and the remaining vertices of V_i are placed in the side B, the sum of the charges of all the vertices of V_i with respect to the chosen labeling is minimal over all such choices. Note that when we consider only labelings from the family $\mathcal{F}$ that agree with g, the labels of all the ancestors of i are uniquely defined from g, while the marked descendants of i can have arbitrary labels.

For a leaf node i, the table entry $Q(i, k, g)$ can be computed directly, as follows. Since i is a leaf node, the part V_i consists of a single vertex, say v, and k can be either 0 or 1. If $k = 0$, then v is necessarily in B, and if $k = 1$, then v is necessarily in W. The guess list g gives the labels of all the nodes on the path from the leaf i to the root and hence all the labels that can possibly affect the charge of v. Since k and g uniquely define all the data that the charge of v depends on, $Q(i, k, g)$ is just the charge of v and can be computed directly as $\sum_j cross_j(v)$, where j ranges over all ancestors of i whose label (according to g) agrees with the side of v (as follows from k).

For a nonleaf node i, the table entry $Q(i, k, g)$ can be efficiently computed from table entries of its children nodes $L(i), R(i)$. Indeed, choosing k vertices from V_i is equivalent to choosing j vertices from one child part $V_{L(i)}$ and $k - j$ vertices from the other child part $V_{R(i)}$; so we need to add up two entries, each corresponding to one child node. The optimal value of j is not known, but it can be exhaustively searched. The guess list g can be extended into lists g_L, g_R for the children nodes in possibly more than one way. Therefore,

$$Q(i, k, g) = \min_{0 \le j \le k} \min_{g_L, g_R} \{Q(L(i), j, g_L) + Q(R(i), k - j, g_R)\},$$

where g_L, g_R range over all possible extensions of g, as described below. If a child node $L(i)$ is a marked node, then there are two possible ways to extend the list g into a list g_L (by adding a label for $V_{L(i)}$), and the optimum $Q(i, k, g)$ is achieved by taking the one which is better. If a child node $L(i)$ is not a marked node, then the only extension is $g_L = g$ because i and $L(i)$ have the same marked ancestors. The

possible extensions of the child node $R(i)$ are similar. It follows that each table entry of a nonleaf node i can be computed from table entries of its children $L(i), R(i)$ in time $O(|V_i|) = O(n)$.

To fill all the table entries, start from the entries that correspond to leaf nodes i and go upwards on the decomposition tree T. In particular, the entries $Q(i_{root}, n/2, g)$ will be computed for the root node i_{root}. At the root node, the guess list g contains the label of the root and thus has only two possible values. (In fact, the two entries must be the same due to symmetry.) The combining stage outputs $\min_g Q(i_{root}, n/2, g)$, which, by definition, is the minimum charge of all bisections of the input graph with respect to any labelings from $\mathcal{F}$, as desired. A bisection that achieves this minimum charge can also be computed. Simply go over the table entries in the reverse order of computation and recover at each entry the values of j, g_L, g_R that gave the optimum. Alternatively, associate with each entry $Q(i, k, g)$ a set of k vertices of V_i which is optimal for it and its corresponding labels.

LEMMA 4.7. *The combining stage finds in polynomial time a bisection of the input graph G and a labeling from the family $\mathcal{F}$ so that the charge of the bisection with respect to the labeling is minimal over all such bisection-labeling pairs.*

Proof. The above discussion shows that the algorithm correctly computes every entry $Q(i, k, g)$, and a bisection-labeling pair as desired.

The size of the table Q is polynomial in n. Indeed, there are only $O(n)$ tree nodes i. For each tree node i, the range of k contains $O(|V_i|) = O(n)$ possible values. In addition, at each tree node i the guess list g contains labels of at most $O(\log n)$ ancestor nodes, and thus g assumes polynomially many values. The polynomial bound on the size of the table Q follows.

An entry for a leaf node i is computed efficiently. An entry for a nonleaf node is efficiently computed from previously computed entries. By the upper bound on the table size we conclude that all the table entries are computed in polynomial time, and in particular $Q(i_{root}, n/2, g)$. ∎

COROLLARY 4.8. *The combining stage finds bisection of the input graph (and a labeling of T) such that bisection charge (with respect to the labeling) is at most $b(1 + O(\rho \log n))$.*

Proof. By Lemma 4.7 and Corollary 4.5 there exists a bisection of G and a labeling of $\mathcal{F}$ such that the bisection charge with respect to the labeling is at most $b(1 + O(\rho \log n))$. The proof then follows by applying Lemma 4.2. ∎

This corollary completes the proof of Theorem 4.1, since by Lemma 4.3 the charge of a bisection is an upper bound on its actual cost.

5. Extensions. Our results extend to several variants (and generalizations) of the minimum bisection problem, including the case of edges with arbitrary nonnegative costs (section 5.1), the case of vertices with polynomially bounded nonnegative integer weights (section 5.2), the variant that requires, in addition, to separate a given pair of vertices s and t (section 5.3), the case of cutting away from the graph an arbitrary number of vertices (instead of $n/2$) that is given as part of the input (section 5.4), the case of cutting the input graph into a fixed number of equal-size parts (section 5.5), and the case of finding a 2/3-balanced cut whose cost is small relative to the minimum bisection cost b (section 5.6).

In what follows, the *basic bisection problem* refers to the minimum bisection problem that was defined in section 1. In contrast, the *extended bisection problems* refer to the variants of the problem specified above. We discuss each extended problem separately, but it is straightforward to combine together several extensions (e.g., to

allow both edge costs and vertex weights as described above and require that the total weight of the vertices cut away is a number k that is given in the input).

We consider two approaches for extending our approximation algorithm from the basic bisection problem to an extended problem. One approach is to *reduce* the extended problem to the basic one. Another approach is to *modify the algorithm* that we devised for the basic bisection problem so that it handles also the extended variant. As we discuss below, each approach has its own advantages and so it is valuable to show both approaches for each extended problem. We indeed show that for almost all the extended problems specified above both approaches can be applied, although for a few problems we provide only a modified algorithm.

A major advantage of the reduction approach is that it is self contained and not restricted to the particular algorithm that we devise; so future improvement in the approximation ratio for the basic problem may lead to an immediate improvement also for the extended problem. Most of our reductions transform an approximation ratio $f(n)$ for the basic problem into an approximation ratio $f(n^{O(1)})$ for the extended problem (because they increase the number of vertices n by a polynomial), and so for the current approximation ratio $f(n)$, which is polylogarithmic, these reductions increase the approximation ratio by at most a constant factor. The techniques used in our reductions are similar to those devised in [4, 3] for the (different) purpose of proving NP-hardness results.

The advantages of the algorithm modification approach are that it preserves aspects that are specific to our algorithm, such as an improved $O(\log n)$ approximation ratio for planar graphs, and that it is usually more efficient (and therefore practical) than the reduction approach. A drawback of the algorithm modification approach is that it requires going again through the algorithm's analysis. In particular, we might be required to verify that the approximate min-ratio cut algorithm (that we use as a black-box) can be extended accordingly. However, the necessary changes in the algorithm and its proof are usually straightforward.

5.1. Edge costs. Suppose that the edges of the input graph G have arbitrary nonnegative costs, and that the cost of a bisection is the total cost (i.e., sum of the costs) of its edges, and we wish to find a bisection of G of (approximately) minimum cost.

Reduction. We reduce the extended problem of bisection with edge costs (described above) to the basic bisection problem, as follows. Given a graph G with edge costs as an input, we first guess the most costly edge in a minimum cost bisection of G, by exhaustively trying all $O(n^2)$ edges in the input graph. By scaling all edge costs, we can assume, without loss of generality, that the cost of the guessed edge is n^2. It follows that the cost b of the optimum bisection is at least n^2 but smaller than n^4. We then round down all edge costs to their closest integer, which can decrease the cost of any bisection by at most $\binom{n}{2} \le b/2$ and therefore by a factor of at most 2. We next change to n^5 every edge cost that is larger than n^5, which does not affect the cost of nearly optimal bisections (i.e., whose original cost was within a ratio of roughly n from the minimum). Finally, we replace each vertex of the graph by a clique of size n^5 and each edge (u, v) of cost t by t unit cost edges placed arbitrarily between the clique of u and the clique of v. (Since $t < n^{10}$ we can do that with no parallel edges.)

The bisection of minimum cost b in G corresponds to a bisection of cost $\Theta(b)$ in the resulting graph. Hence, applying our algorithm for the basic problem on the resulting graph (which has n^6 vertices) yields a bisection whose cost is $O(b(\log n^6)^2) = O(b \log^2 n)$. This bisection cannot split any of the cliques that we created, as otherwise

its cost will be at least $n^5 - 1 \gg b \log^2 n$, and it therefore must correspond to a bisection of G, whose cost is roughly the same, namely $O(b \log^2 n)$, as required.

Modified algorithm. We modify our algorithm for the basic bisection problem so that it handles the extended problem with edge costs, as follows. Rather than considering the number of edges we always consider their cost; e.g., $e(V_1, V_2)$ denotes the sum of the costs of the edges with one endpoint in V_1 and one endpoint in V_2. The corresponding changes in our algorithm and analysis are straightforward. Note that the amortized cut algorithm (see Figure 3.3) requires (in step 1) a subroutine that computes an approximate min-ratio cut with respect to the edge costs, but known algorithms (e.g., due to [11]) provide this subroutine. Note also this algorithm's binary search (step 3) takes $O(M \log n)$ iterations, where M is the number of bits used to represent an edge cost, and so the running time is polynomial in the input size. The resulting approximation ratio is the same as for the basic problem, i.e., $O(\log^2 n)$.

5.2. Polynomial vertex weights. Suppose that the vertices of the input graph G have nonnegative integer weights that are bounded by a polynomial n^c (where n is the number of vertices in G), and let a bisection be a cut that separates half of the total weight (i.e., the sum of the weights) of the vertices of V. We wish to find a bisection of G of (approximately) minimum cost. Note that if the weights are allowed to be exponential in n, finding any bisection of the graph is equivalent to the partition (or subset-sum) problem and therefore NP-hard.

Reduction. We reduce the extended problem of bisection with vertex weights (described above) to the basic bisection problem, as follows. Given a graph G with vertex weights as an input, we replace each vertex of cost w in G by a clique of $\max\{1, w \cdot n^3\}$ unit weight vertices and replace each edge (u, v) in G by one edge placed arbitrarily between the clique of u and the clique of v. In addition, for each vertex of weight 0 in G we place in the graph a new isolated vertex of unit weight.

A bisection of minimum cost b in G corresponds to a bisection of the same cost b in the resulting graph. Hence, applying our algorithm for the basic problem on the resulting graph (which has at most n^{c+4} vertices) yields a bisection whose cost is $O(b(c+4)^2 \log^2 n)$. This bisection cannot split any of the cliques that we created, as otherwise its cost will be at least $n^3 - 1 \gg b \cdot (c+4)^2 \log^2 n$. Furthermore, the vertices of the created cliques of size at least n^3 must be partitioned evenly by this bisection, as otherwise their partition deviates from an even one by at least n^3 (these clique sizes are multiples of n^3) which is much more than the total number of remaining vertices, $2n^2$. (Recall that we added isolated vertices for vertices of weight 0 in G.) The computed bisection of the resulting graph therefore corresponds to a bisection of G, whose cost is the same, namely $O(b(c+3)^2 \log^2 n)$, as required.

Modified algorithm. We modify our algorithm for the basic bisection problem so that it handles the extended problem with vertex weights, as follows. Rather than considering the number of vertices in a part we always consider their total weight; e.g., $r(S)$ denotes the cost of the cut $(S, V \setminus S)$ divided by the minimum between the weight of S and the weight of $V \setminus S$. The corresponding changes in our algorithm and analysis are straightforward. Note that the amortized cut algorithm (see Figure 3.3) requires (in step 1) a subroutine that computes an approximate min-ratio cut with respect to the vertex weights, but known algorithms (e.g., due to [11]) provide this subroutine. Note also that in this algorithm's related graph G' (step 2) the capacity of an edge between a vertex $v \in V_1$ and the new vertex s is p times the weight of v_1. The resulting approximation ratio is the same as for the basic problem, i.e., $O(\log^2 n)$.

5.3. Separating two vertices from each other ($s-t$ cut). Suppose that the input graph G contains two special vertices, s and t, and we wish to find a bisection that separates s from t and has minimum cost. (Note that the converse restriction, namely that s, t will not be separated, is equivalent to merging them into one vertex of weight 2 and therefore follows from section 5.2.)

Reduction. We reduce the extended problem of a bisection that separates s from t to the extended problem of bisection with vertex weights (described in section 5.2), as follows. Given an input graph G with special vertices s, t as above, we let the vertices s, t have weights n and let all other vertices of G have weight 1. The total weight of s and t together is $2n$, while the total weight of all other vertices is $n-2$ (and thus smaller); so every bisection of the resulting graph must separate s from t. It follows that every bisection of the resulting graph corresponds to a bisection of G that separates s from t and has the same cost, and vice versa. We can therefore find a bisection of G that separates s from t and its cost is within $O(\log^2 n)$ from the minimum.

Modified algorithm. We modify our algorithm for the basic bisection problem so that it handles the extended problem of a bisection that separates s from t, as follows. We change the dynamic programming table Q of the combining stage so that every entry $Q(i,k,g)$ contains two solutions (if they exist); one solution with the k chosen vertices containing s but not t and the other solution with the k chosen vertices not containing any of s and t. Computing the table entries is straightforward, and the output of the algorithm is $\min_g Q(i_{root}, n/2, g)$, where the minimum is taken only over solutions that contain s and not t. The necessary changes in our analysis are straightforward. The resulting approximation ratio is the same as for the basic problem, i.e., $O(\log^2 n)$.

5.4. Cutting an arbitrary given number of vertices. Suppose that the input consists of a graph G and a number k, and we wish to find a minimum cost cut that separates exactly k vertices.

Reduction. We reduce the problem of cutting away a given number k of vertices to the problem of bisection with vertex weights (described in section 5.2), as follows. Given an input graph G and a number k (assume, without loss of generality, that $k \le n/2$), we let the vertices of G have weight 1 and add to the graph an isolated vertex of weight $n-2k$. It is clear that every bisection of the resulting graph corresponds to a cut of G that separates k vertices and has the same cost, and vice versa. We can therefore find a cut of G that separates k vertices and its cost is within $O(\log^2 n)$ from the minimum.

Modified algorithm. We modify our algorithm for the basic bisection problem so that it handles the extended problem of cutting a given number of vertices, as follows. The only change in the algorithm is in the combining stage, that now outputs $\min_g Q(i_{root}, k, g)$, where Q is the dynamic programming table (see section 4.4). The necessary changes in our analysis are straightforward. The resulting approximation ratio is the same as for the basic problem, i.e., $O(\log^2 n)$.

5.5. Cutting into a fixed number of parts. Suppose that we wish to find a cut that separates the input graph G into a fixed number p of parts of equal size.

We do not know of a reduction from this extended problem to the basic bisection problem. A recursive bisection approach has a poor performance in general, although it may be useful in some special cases and if some requirements are relaxed; see [15] and the references therein.

Modified algorithm. We modify our algorithm for the basic bisection problem so that it handles the problem of cutting the graph into p parts of equal size, as follows. The cost of a cut that partitions V into p parts $V^1, \ldots, V^p$ is

$$\sum_{j<l} e(V^j, V^l) = \frac{1}{2} \sum_j e(V^j, V \setminus V^j).$$

Therefore, by scaling the value of every possible solution by a factor of 2 (which clearly does not affect any approximation ratio issues), we obtain that the objective function of the extended problem has the convenient form $\sum_j e(V^j, V \setminus V^j)$. Observe that each cut $(V^j, V \setminus V^j)$ corresponds to separating V^j from the other parts, which are grouped into one part $V \setminus V^j$. Thus, each summand $e(V^j, V \setminus V^j)$ in the objective function is similar to the basic bisection problem (with the minor exception that the two sides are not of the equal sizes). Below we describe the modifications to the three stages of the algorithm, which works simultaneously on all p cuts $(V^j, V \setminus V^j)$. Its analysis is based on applying the new accounting method of section 2 separately to each of these p cuts.

The decomposition stage computes a decomposition tree T exactly as in the algorithm for the basic problem (see section 4.1). Observe that the amortized cut notion does not depend on the cut that we seek, and so the obtained decomposition (and its tree T) can be used for all cuts $(V^j, V \setminus V^j)$.

We extend the notion of a labeling of the decomposition tree, as follows. An extended labeling of T assigns to every tree node a vector of p "basic" labels, one label for each cut $(V^j, V \setminus V^j)$. An extended labeling corresponds to deciding at each tree node i and for each j, which of V^j and $V \setminus V^j$ is considered charged (and which is considered free) in the part V_i. Note that an extended labeling can be viewed as a vector, whose coordinate j forms a basic labeling for $(V^j, V \setminus V^j)$.

The labeling stage marks some nodes of the tree T exactly as in the algorithm for the basic problem (see section 4.2). This stage implicitly defines a family $\overline{\mathcal{F}}$ that consists of all extended labelings in which every unmarked node has the same label as its closest marked ancestor. (There is no restriction on the labels of the marked nodes.) It is straightforward that $\overline{\mathcal{F}}$ contains at least one extended labeling for which every coordinate j (forms a basic labeling that) is α-consistent with the cut $(V^j, V \setminus V^j)$. We can restrict the number of possible labels at the marked (and hence also unmarked) nodes from 2^p to $p+1$ values, as follows. Similar to the proof of Lemma 4.2 it is sufficient for our purposes that $\overline{\mathcal{F}}$ contains the labeling where V^j is considered free at a marked node i if more than half the vertices of the part V_i are from V^j. At any part V_i, the latter can happen for at most one value of j, and so it suffices to consider only labelings where at most one V^j is free.

We extend the notion of a charge of a vertex, as follows. The extended charge of a vertex v with respect to an extended labeling is the sum of the basic charges of v with respect to each of the p coordinates of this extended labeling.

The combining stage uses dynamic programming on a table $\overline{Q}$, whose entries are of the form $\overline{Q}(i, \overline{k}, \overline{g})$, as follows. i is a tree node. $\overline{k} = (k_1, \ldots, k_p)$, where k_j is the desired size of the jth part and $\sum_j k_j = |V_i|$. $\overline{g} = (g_1, \ldots, g_p)$, where g_j is a guess list that contains the jth label of every marked ancestor of i. An entry $\overline{Q}(i, \overline{k}, \overline{g})$ contains the optimal solution to the following problem: Choose a partition of V_i into subsets with sizes according to $\overline{k}$, and choose a labeling from $\overline{\mathcal{F}}$ that agrees with g so that the sum of the extended charges of all the vertices of V_i with respect to the chosen labeling is minimal over all such choices. Note that this problem requires

some correlation between p cuts, and therefore $\overline{Q}(i,\overline{k},\overline{g})$ is generally not equal to $\sum_j Q(i,k_j,g_j)$ (where Q is the basic table).

The rules for computing the entries of the table $\overline{Q}$ are a straightforward extension of those for the table Q (see section 4.4). The algorithm computes all the table entries and then outputs $\min_{\overline{g}} \overline{Q}(i_{root},\overline{k},\overline{g})$, where $\overline{k}=(n/p,\ldots,n/p)$.

The running time of this modified algorithm is polynomial in n (for fixed p). Indeed, the decomposition stage and the labeling stage are exactly as in the algorithm for the basic bisection problem; so let us consider the dynamic programming table $\overline{Q}$ of the combining stage. The number of tree nodes i is $O(n)$, and the range of $\overline{k}$ contains at most n^p possible values. The vector $\overline{g}$ contains one of $p+1$ possible values for each of the $O(\log n)$ marked ancestors (of the relevant tree node i); so $\overline{g}$ assumes one of $n^{O(\log p)}$ values. It follows that the size of the table $\overline{Q}$ is $n^{p+O(\log p)}$. Each table entry is computed efficiently from previously computed entries, and hence the combining stage takes polynomial time.

To analyze the approximation ratio, let $V^1,\ldots,V^p$ be the optimal partition of the input graph into p parts of equal size. Recall that the extended charge of a vertex is the sum of its basic charges with respect to each cut $(V^j, V\setminus V^j)$, and we can therefore apply the analysis of the basic algorithm for each cut $(V^j, V\setminus V^j)$ separately. It follows that the output value is guaranteed to be at most $O(\log^2 n)\cdot\sum_j e(V^j, V\setminus V^j)$. Furthermore, one can obtain from the table $\overline{Q}$ a cut (into p parts of equal size) whose cost is at most (half) this value, i.e., within a ratio of $O(\log^2 n)$ from the minimum.

5.6. Bicriteria approximation and balanced cuts. Suppose that we wish to find a 2/3-balanced cut (recall that a cut is called β-balanced if it partitions the graph into two parts, each of size at most βn) whose cost is guaranteed to be small relative to the minimum cost b of a bisection (i.e., a 1/2-balanced cut). Here, the minimum bisection problem is relaxed in two respects, as the solution cut is allowed to have cost larger than b and also to deviate from the cardinality constraints (for its two sides). Algorithms for such problems are sometimes referred to as bicriteria approximation and sometimes as pseudoapproximation.

Known bicriteria approximation algorithms find a 2/3-balanced cut whose cost is at most $O(b\log n)$. Leighton and Rao [10, 11] show how an algorithm that finds a τ approximate min-ratio cut can be used to find a 2/3-balanced cut of cost $O(b\tau)$; the approximation ratio $\tau=O(\log n)$ that they achieve is the best currently known; see also [14]. Even et al. [5] devise a different algorithm that also finds a 2/3-balanced cut of cost $O(b\log n)$.

We show below that amortized cuts can be used to obtain also bicriteria approximation algorithms (in addition to approximation algorithms) for minimum bisection. In fact, our algorithm is similar to the one of [10, 11], except that we use amortized cuts instead of approximate min-ratio cuts.

LEMMA 5.1. *An algorithm that finds a ρ-amortized cut can be used to find a 2/3-balanced cut of cost $b(1+O(\rho))$.*

Proof. Given an input graph $G(V,E)$ on n vertices, use the algorithm that finds a ρ-amortized cut, as follows. Repeatedly find (in the graph) a ρ-amortized cut and remove (from the graph) the smaller of its two sides until the graph contains no more than $2n/3$ vertices. Denoting by S the set of vertices that remain in the graph after the last iteration, output the cut $(S, V\setminus S)$.

It is straightforward to see that $n/3<|S|\le 2n/3$, and hence the output cut $(S,V\setminus S)$ is a 2/3-balanced cut. We prove below that the total cost of all edges cut

by the amortized cuts (throughout the iterations) is at most $b(1 + O(\rho))$. It would then follow immediately that $e(S, V \setminus S) \leq b(1 + O(\rho))$, as required.

We now upper bound the total cost of all edges cut in the amortized cuts. Let (W, B) be a fixed optimal bisection of cost b and call the vertices of W white and the vertices of B black. The total cost of white-black edges cut is clearly at most b. We show below that the total cost of all white-white edges cut is $O(b\rho)$. By the symmetry between W and B, we will then have a similar upper bound on the total cost of the black-black edges cut and obtain the desired upper bound of $b(1 + O(\rho))$ on the total cost of all edges cut.

To show that the total cost of white-white edges cut in the amortized cuts is $O(b\rho)$, we consider the white vertices W as charged in all the amortized cuts, and then white-white edges are charged-charged edges. The algorithm applies a ρ-amortized cut in parts of G that contain at least $2n/3$ vertices. At least $n/2 - n/3 = n/6$ of the vertices in such a part are black, while at most $n/2$ of them are white, and hence at most $3/4$ of the vertices in this part are considered charged. Taking a constant $\alpha \geq 3/4$ in the definition of an amortized cut, we have that the cost of the charged-charged edges cut can be amortized in one of two amortization methods (see section 2).

In one amortization method the cost of the charged-charged edges cut is amortized against charged-free edges in the smaller side of the cut, with amortized cost at most ρ. Observe that an edge can be in the smaller side of the amortized cut (the side that is removed) in at most one iteration; so the total cost amortized in this method (in all the iterations) against one charged-free edge is at most ρ. Hence, the total cost amortized in this method (in all the iterations) is at most $b\rho$.

In the other amortization method the cost of the charged-charged edges cut is amortized against charged-free edges in the part being divided, with amortized cost at most $\rho|C_1|/|C|$, where C denotes the charged vertices in the part being divided and C_1 denotes the charged vertices in the smaller side of the cut. The total cost amortized in this method (in all the iterations) against one charged-free edge is then upper bounded by ρ times the sum of $|C_1|/|C|$ over all iterations. Recall that the charged vertices are the white vertices, and so $|C| \geq n/6$ in all amortized cuts (i.e., iterations). Furthermore, each vertex is in the smaller side of the cut (the side that is removed) in at most one iteration, and so the sum of $|C_1|$ over all iterations is at most $n/2$. It follows that the total cost amortized in this method (in all the iterations) against one charged-free edge is at most 3ρ, and hence the total cost amortized in this method is at most $b \cdot 3\rho$.

We conclude that the total cost of all charged-charged (i.e., white-white) edges cut in all the iterations is at most $b \cdot 4\rho$. As described above, this proves that the total cost of all edges cut in all the iterations is at most $b(1 + 8\rho) = b(1 + O(\rho))$, and the lemma follows. □

We remark that a 2/3-balanced cut of cost $b(1 + O(\rho))$ can be found also by modifying the algorithm we devised for the basic bisection problem so that its combining stage outputs $\min_{g, n/3 \leq k \leq n/2} Q(i_{root}, k, g)$ (and its corresponding cut). Indeed, the proof of Lemma 5.1 shows a 2/3-balanced cut whose charge (with respect to a certain labeling in $\mathcal{F}$) is at most $b(1 + O(\rho))$. Details are omitted.

Concluding remarks. Designing an algorithm that finds a cut of amortized cost better than $O(\log n)$ remains an important open question. An efficient algorithm that accomplishes that will not only improve the approximation ratio for minimum bisection (by Theorem 4.1), but also the bicriteria approximation ratio for minimum bisection (by Lemma 5.1), which will lead, in turn, to improved approximation ratios

for many other problems; see [11, section 3].

Finding a cut whose amortized cost is better than $O(\log n)$ is, in a sense, no harder (and possibly easier) than approximating min-ratio cuts within a ratio better than $O(\log n)$, as the former problem is reducible (by Theorem 3.6) to the latter. Furthermore, an $O(1)$-amortized cut always exists (by Corollary 3.3), and we know of no hardness result for the problem of finding such a cut.

Acknowledgments. We thank Kobbi Nissim for his part in bootstrapping this research and the anonymous referees for comments that improved the presentation.

LATTICE EMBEDDINGS FOR ABSTRACT BOUNDED REDUCIBILITIES*

WOLFGANG MERKLE†

Abstract. We give an abstract account of resource-bounded reducibilities as exemplified by the polynomially time- or logarithmically space-bounded reducibilities of Turing, truth-table, and many-one type. We introduce a small set of axioms that are satisfied for most of the specific resource-bounded reducibilities appearing in the literature. Some of the axioms are of a more algebraic nature, such as the requirement that the reducibility under consideration is a reflexive relation, while others are formulated in terms of recursion theory and, for example, are related to delayed computations of arbitrary recursive sets.

The main technical result shown is that for any reducibility that satisfies these axioms, every countable distributive lattice can be embedded into any proper interval of the structure induced on the recursive sets. This extends a corresponding result for polynomially time-bounded reducibilities due to Ambos-Spies [*Inform. and Control*, 65 (1985), pp. 63–84], as well as a result on embeddings of partial orderings for axiomatically described reducibilities due to Mehlhorn [*J. Comput. System Sci.*, 12 (1976), pp. 147–178].

Key words. resource-bounded reducibilities, embeddings of partial orderings, embeddings of distributive lattices, abstract reducibilities, axiomatization of reducibilities

1. Introduction.

1.1. Overview and related work. Resource-bounded reducibilities such as the standard time- or space-bounded reducibilities are usually defined as appropriate restrictions of Turing reducibility; i.e., a set A is reducible to a set B iff there is some index e with $A = \Phi_e(B)$ such that e and B satisfy certain conditions. (Here Φ_e denotes the partial recursive functional computed by the eth oracle Turing machine M_e.) Standard examples for such conditions are given by restrictions on the way M_e might access its oracle, such as for reducibilities of many-one type, and by bounds on the amount of time, space, or other resources M_e might use. In most cases such restrictions can be conveniently expressed by specifying a set E of admissible indices as in Definition 1.

DEFINITION 1. *A binary relation $\leq_r$ on 2^ω is a* BOUNDED REDUCIBILITY *iff there is a recursive set E that contains only indices of total recursive functionals such that for all sets A and B*

$$A \leq_r B \quad \textit{iff} \quad \exists e \in E\ A = \Phi_e(B). \tag{1}$$

The concept of bounded reducibility indeed comprises most of the resource-bounded reducibilities that can be found in the literature, including the usual time- or space-bounded reducibilities. The notation bounded reducibility apparently has been introduced by Book, Lutz, and Wagner [8], while the concept has been used before by several authors.

When investigating the structures induced on the class REC of recursive sets by the various bounded reducibilities [2, 25], one typically asks whether such a structure is dense or whether it contains minimal pairs. Recall that the structure is dense iff every proper interval contains a set different from the interval's endpoints and, assuming that $\leq_r$ is a partial preordering with least element, that the structure $(\mathrm{REC}, \leq_r)$ contains a minimal pair if there are two incomparable recursive sets such that every set that is reducible to both sets is a least set.

Early results obtained for the structures $(\mathrm{REC}, \leq_{\mathrm{T}}^{\mathcal{P}})$ and $(\mathrm{REC}, \leq_{\mathrm{m}}^{\mathcal{P}})$ evolving from the polynomially time-bounded Turing and many-one reducibility,[1] respectively, are the density of the structures and the existence of minimal pairs, both due to Ladner [13]. Subsequently, Machtey [16] constructed a minimal pair of sets computable in exponential time, and Landweber, Lipton, and Robertson [15] further improved on this: actually any recursive set strictly above $\emptyset$ bounds a minimal pair. In what follows these results were extended, and the presentation of their proofs was substantially improved by several authors, including Mehlhorn [17, 18], Chew and Machtey [11], Balcázar and Díaz [3], and Schöning [30, 31]. Then Ambos-Spies [1] showed a general embedding theorem that comprises several preceding results as special cases: if $\leq_r$ is equal to $\leq_{\mathrm{T}}^{\mathcal{P}}$, to $\leq_{\mathrm{m}}^{\mathcal{P}}$, or to one of several variants of polynomially time-bounded truth table reducibility $\leq_{\mathrm{tt}}^{\mathcal{P}}$, then

(2)

> every countable distributive lattice can be embedded (as a lattice) into any proper interval of $(\mathrm{REC}, \leq_r)$ with least or greatest element preserved.

From (2) we obtain, for example, Ladner's density result by embedding the three-element total ordering into a given proper interval, and the existence of minimal pairs below a recursive set B that is strictly above $\emptyset$ follows by embedding the four-element Boolean algebra below B with least element preserved.

Ladner [13] already pointed out that his results go through for rather general types of time- or space-bounded reducibilities. Subsequently, also the stronger results mentioned were transferred to bounded reducibilities that are not defined in terms of deterministic polynomial time.

(i) Serna [32] proves that $(\mathrm{REC}, \leq_{\mathrm{NC}_1})$ is dense and possesses minimal pairs below any set strictly above $\emptyset$.

(ii) Copestake [12] demonstrates for polynomially time-bounded nondeterministic reducibility of Turing type that the corresponding structure induced on the recursive sets is dense and possesses minimal pairs.

(iii) Vollmer [34] extends the results on lattice embeddings due to Ambos-Spies to the reducibility $\leq_{\mathrm{m}}^{\log}$.

The fact that several bounded reducibilities bear similar structural properties and, what is more, that the same proof techniques apply in the different cases suggest that to some extent nontrivial structural properties of bounded reducibilities might be developed within an abstract or axiomatic approach to bounded reducibilities. In general, however, even for a reflexive and transitive bounded reducibility the structure induced on the recursive sets will not be dense; see Example 7 below. This indicates that there is no hope for deriving interesting structural results about bounded reducibilities without adding further conditions or axioms that, for example, provide,

[1] We introduce the specific reducibilities used as examples by informal descriptions. Full definitions can be found in the textbooks by Balcázar, Díaz, and Gabarró [4, 5] and by Odifreddi [24, 25].

intuitively speaking, a minimal amount of computational power that can be used in reducing one set to another.

We will pursue an abstract approach to resource-bounded reducibilities that is based on the concept of standard reducibility introduced in Definition 17 below. As the main technical result we show in section 4 that the mentioned result on lattice embedding extends to all standard reducibilities.

Archetypal examples of standard reducibilities on 2^ω are polynomially time-bounded Turing reducibility $\leq_{\mathrm{T}}^{\mathcal{P}}$ and logarithmically space-bounded many-one reducibility $\leq_{\mathrm{m}}^{\log}$. On the other hand, some bounded reducibilities that arise from more restricted models of computations are not standard reducibilities. For examples of such reducibilities see the discussion subsequent to the introduction of the concept of standard reducibility in Definition 17.

Axiomatic approaches to structural properties of bounded reducibilities have been presented previously by, among others, Basu [6], Mehlhorn [17, 18], Mueller [23], and Schmidt [29]. Our generalized approach is closely related to the work of the latter three authors, while Basu's axiom system is designed to be used in connection with reducibilities between functions and is too general if applied to reducibilities between sets. In particular, the work of Mehlhorn has been most influential to our approach via his concept of delayed simulation. Mehlhorn proves from a set of axioms, which apparently in several respects is more restrictive than ours, that the recursive sets form a dense structure, and he states that in fact every countable partial ordering can be embedded into every proper interval of the recursive sets.

Within the axiomatic approach based on the concept of standard reducibility, one cannot derive only the result on lattice embeddings shown below but also results on minimal and exact pairs or on distributivity and decidability of the structure induced on the recursive sets [19, 20]. In the context of separations by random oracles, almost classes, and bounded error probabilistic classes, results can be derived from assumptions that are more general than the ones used to define standard reducibilities; see Book, Lutz, and Wagner [8], Book, Vollmer, and Wagner [9], Merkle and Wang [22], and Regan and Royer [27].

1.2. Notation. The notation introduced in the following is mostly standard. For notation not explained here or below in the text, see Balcázar, Díaz, and Gabarró [4, 5], Odifreddi [24, 25], and Soare [33].

Natural numbers and strings. We identify the set $\omega = \{0, 1, \dots\}$ of natural numbers and the set $\{\lambda, 0, 1, 00, 01, \dots\}$ of (finite, binary) strings via the unique order isomorphism that takes the standard ordering on ω to the length-lexicographical ordering on strings, and we denote both orderings by the symbol $\leq$. We extend the identification in the canonical way to the powerset 2^ω of ω and the powerset of the set of all strings. Recall that resource-bounded reducibilities are usually defined in terms of Turing machine models where strings are used as inputs and for querying the oracle, and consequently these reducibilities are binary relations between sets of strings; by the above identification, we will view such reducibilities as binary relations on 2^ω. We refer to subsets of ω and 2^ω by the terms SETS and CLASSES, respectively. We denote sets by uppercase letters $A, B, \dots$, and classes by uppercase calligraphic letters $\mathcal{A}, \mathcal{B}, \dots$.

Functions and functionals are meant to be total, if not explicitly attributed as being partial. We denote the class of functions from ω to ω by ω^ω. We identify subsets of ω with their characteristic functions; i.e., we view 2^ω as a subclass of ω^ω.

Reducibilities. The symbol $\leq_r$ denotes any binary relation between sets of natural numbers, which is meant as reducibility. We will define the usual concepts arising in connection with reducibilities such as the LOWER and UPPER $\boldsymbol{\leq_r}$-CONE,

$$\leq_r (A) := \{X : X \leq_r A\} \quad \text{and} \quad \geq_r(A) := \{X : A \leq_r X\},$$

respectively, of a set A. Frequently, we will use the term r-cone in place of $\leq_r$-cone, and we will proceed similarly for other terms and reducibilities.

Two sets A and B are $\boldsymbol{r}$-EQUIVALENT, $A \equiv_r B$ for short, iff their upper and lower r-cones coincide, respectively. Hence two sets are r-equivalent iff, intuitively speaking, they can be substituted for each other *salva veritate* in all contexts involving only the relation $\leq_r$. Two sets A and B are $\boldsymbol{r}$-INTERREDUCIBLE, $A =_r B$ for short, iff A is reducible to B and vice versa. For a reflexive relation $\leq_r$, any pair of equivalent sets is also interreducible, and, likewise, for a transitive relation, interreducibility implies equivalence. As a consequence, interreducibility and equivalence coincide for partial preorderings, i.e., for relations that are reflexive and transitive.

Partial recursive functions and functionals. Unless we explicitly refer to some other domain, say, to ω^ω, functionals are functions from 2^ω to 2^ω. We denote functionals by uppercase Greek letters $\Gamma, \Delta, \ldots$. We identify a functional Γ with a function from $2^\omega \otimes \omega$ to $\{0,1\}$ via the equation

$$\Gamma(X, x) \;=\; (\Gamma(X))(x).$$

We use the notation M_i in order to refer to the ith Turing machine in the standard enumeration of all Turing machines of some given type, and we assume that it is always understood from the context which type of Turing machine is meant, that is, for example, whether we consider Turing machines with or without oracle access. We refer to the partial recursive function or functional computed by Turing machine M_i by

φ_i in the case of $\{0,1\}$-valued Turing machines without oracle access,
ϕ_i in the case of ω-valued Turing machines without oracle access,
Φ_i in the case of $\{0,1\}$-valued oracle Turing machines.

We refer to the class of recursive sets and functions by REC and FREC, respectively. We assume that there is some recursive function s that translates indices with respect to the enumeration $\varphi_0, \varphi_1, \ldots$ into indices with respect to the enumeration $\phi_0, \phi_1, \ldots$, that is, such that for all e in ω holds $\varphi_e = \phi_{s(e)}$.

Partial characteristic functions. Lowercase Greek letters $\alpha, \beta, \gamma, \ldots$ denote PARTIAL CHARACTERISTIC FUNCTIONS, i.e., (total) functions from some subset I of ω to $\{0,1\}$. The DOMAIN of a partial characteristic function α is denoted by $\mathrm{dom}(\alpha)$; i.e., for example, $\mathrm{dom}(\alpha)$ is equal to ω iff α is a set. A partial characteristic function is FINITE iff its domain is finite. The partial characteristic functions are partially ordered by the relation $\sqsubseteq$ where $\alpha \sqsubseteq \beta$ iff the graph of α is contained in the graph of β (i.e., iff the domain of α is contained in the domain of β and α agrees there with β).

For a partial characteristic function α and a set I, we denote by $\alpha | I$ the RESTRICTION OF $\boldsymbol{\alpha}$ TO $\boldsymbol{I}$, that is, the uniquely determined partial characteristic function $\gamma \sqsubseteq \alpha$ with domain $I \cap \mathrm{dom}(\alpha)$. In particular, $A|I$ is the partial characteristic function with domain I that agrees there with the set A.

Definition by cases and patching. For partial characteristic functions α, β, and for a set M, we let

$$\langle \alpha, \beta \rangle^M(x) \;:=\; \begin{cases} \alpha(x), & x \in M, \\ \beta(x), & x \notin M; \end{cases} \tag{3}$$

that is, the partial characteristic function $\langle \alpha, \beta \rangle^M$ agrees with α on $\mathrm{dom}(\alpha) \cap M$, with β on $\mathrm{dom}(\beta) \cap \overline{M}$, and is undefined otherwise. We denote the partial characteristic function

$$\langle \alpha, \beta \rangle \ := \ \langle \alpha, \beta \rangle^{\omega \setminus \mathrm{dom}(\beta)}$$

as $\boldsymbol{\beta}$-PATCH of α; i.e., for example, $\langle A, \beta \rangle$ is the unique set that agrees with β for all arguments in $\mathrm{dom}(\beta)$ and with A otherwise.

Joins. We define the join of two sets A and B by

$$A \oplus B(x) := \begin{cases} 0 & \text{if } x = \lambda, \\ A(y) & \text{if } x = 0y, \\ B(y) & \text{if } x = 1y. \end{cases}$$

Lattices. A partial ordering (p.o.) is a pair of a set U and a binary relation $\leq$ on U that is reflexive, transitive, and antisymmetric. A p.o. $(U, \leq)$ is a LATTICE iff for every pair a and b of elements in U there exists a least upper bound (l.u.b.) and a greatest lower bound (g.l.b.) of a and b in U. A lattice L is distributive iff for all a, b, and c in L we have $a \wedge (b \vee c) = (a \wedge b) \vee (a \wedge c)$.

Closure under finite variation. A set A is a FINITE VARIATION of a set B, $A =^* B$ for short, iff A and B differ at most at finitely many places. A subclass $\mathcal{A}$ of 2^ω is CLOSED UNDER FINITE VARIATION (C.F.V.) iff for every set A in $\mathcal{A}$, all finite variations of A are in $\mathcal{A}$, too. A binary relation $\leq_r$ on 2^ω is c.f.v. iff for all sets A, the lower and the upper r-cone of A are both c.f.v.

We let $\langle .,. \rangle : \omega^2 \to \omega$ be the standard effective and effectively invertible pairing function from $\omega \otimes \omega$ onto ω [33]. A subclass $\mathcal{A}$ of 2^ω is RECURSIVELY PRESENTABLE iff either $\mathcal{A}$ is empty or there is a recursive set E such that $\mathcal{A}$ coincides with the "rows" of E; i.e., $\mathcal{A} = \{A_0, A_1, \dots\}$ where $A_i = \{x : \langle x, i \rangle \text{ in } E\}$.

2. Standard reducibilities.

2.1. Faithful relations. In order to be able to mimic the usual proof techniques employed in connection with resource-bounded reducibilities, we will require that standard reducibilities are bounded reducibilities that are sort of "faithful" to the information contained in their set arguments and, intuitively speaking, can use a nontrivial amount of computational power in reducing one set to another. In the remainder of this section, we introduce notation related to the concept of faithfulness, and in the following sections we develop concepts related to computational power.

In the case of a transitive relation $\leq_r$, the concept of faithfulness is equivalent to the natural conditions that $\leq_r$ is reflexive, that $\emptyset$ and ω are r-reducible to all sets, and that the join of two sets is a l.u.b. for them (see Proposition 4). However, as we want to comprise reducibilities that are not necessarily transitive, we use a more involved definition of faithfulness stated in Definition 3.

DEFINITION 2. *Let $\leq_r$ be a binary relation on 2^ω, let A and B be sets, and let $\mathcal{A}$ be a subclass of 2^ω.*

(i) *The relation $\leq_r$ is* LOCALLY TRANSITIVE *at A and B iff A is not r-reducible to B or we have for all sets X and Y*

$$X \leq_r A \ \textit{implies} \ X \leq_r B, \tag{4}$$

$$B \leq_r Y \ \textit{implies} \ A \leq_r Y. \tag{5}$$

(ii) *A set U is a* LOCALLY TRANSITIVE UPPER BOUND *for (the elements of) $\mathcal{A}$ iff U is an upper bound for $\mathcal{A}$ and for all sets A in $\mathcal{A}$, the relation $\leq_r$ is locally transitive at A and U. Likewise, U is a* LOCALLY TRANSITIVE L.U.B. *for $\mathcal{A}$ iff U is a l.u.b. for $\mathcal{A}$ and for all sets A in $\mathcal{A}$ the relation $\leq_r$ is locally transitive at A and U.*

A transitive relation is locally transitive at every pair of sets; hence for a transitive relation the standard and the locally transitive variant of the concept of upper bound coincide, and a similar remark holds for l.u.b.'s.

DEFINITION 3. *A binary relation $\leq_r$ on 2^ω is* FAITHFUL *iff for all sets A, B, and X, first, the set $A \oplus B$ is a locally transitive l.u.b. for A and B in $(2^\omega, \leq_r)$ and, second,*

$$X \leq_r A \oplus B \text{ implies } X \leq_r B \oplus A, \tag{6}$$

$$X \leq_r A \oplus \emptyset \text{ implies } X \leq_r A, \tag{7}$$

$$X \leq_r A \oplus \omega \text{ implies } X \leq_r A. \tag{8}$$

Most resource-bounded reducibilities that can be found in the literature are faithful. There are nontransitive faithful reducibilities such as $\leq_{k-\mathrm{tt}}$ for every fixed $k \geq 2$. The following proposition shows that faithful relations are reflexive and for them $\emptyset$ and ω are reducible to all other sets.

PROPOSITION 4. *Let $\leq_r$ be a faithful relation on 2^ω.*

(i) *For all sets A, the sets $\emptyset$, ω, and A are r-reducible to A.*

(ii) *For all sets A and B, the set $A \oplus B$ is a l.u.b. for A and B in $(2^\omega, \leq_r)$.*

Conversely, if the relation $\leq_r$ is transitive and satisfies both of these conditions, then $\leq_r$ is faithful.

Proof. For a faithful relation $\leq_r$, condition (i) is immediate; so it remains to show (ii). Now, given a set A, then the sets A and $\emptyset$ are both r-reducible to $A \oplus \emptyset$; hence by (7) both sets are also r-reducible to A. Likewise, by (8) we obtain $\omega \leq_r A$. Conversely, assume that the relation $\leq_r$ is transitive and satisfies (i) and (ii) . By transitivity and (ii) it is immediate that the join operator provides locally transitive l.u.b.'s for every pair of sets. Furthermore, we obtain (6), (7), and (8) by transitivity of $\leq_r$ and because by assumption on the join operator we have

$$A \oplus B \leq_r B \oplus A, \qquad A \oplus \emptyset \leq_r A, \qquad \text{and} \qquad A \oplus \omega \leq_r A. \qquad \square$$

PROPOSITION 5. *Let $\leq_r$ be a faithful relation on 2^ω and let A and B be sets.*

(i) $\geq_r(A \oplus B) = \geq_r(A) \cap \geq_r(B)$.

(ii) $A \oplus B \equiv_r B \oplus A$.

(iii) $A \equiv_r A \oplus \emptyset \equiv_r A \oplus \omega$.

Proof. For a faithful relation $\leq_r$, the join of two sets is a locally transitive l.u.b. for the sets joined. Thus, concerning (i), the inclusion from left to right is immediate from the definition of locally transitive upper bound, and the reverse inclusion follows by definition of l.u.b. Using (i), we then infer that the two sets denoted by the join expressions on both sides of the equation in (ii) have identical upper cones, while for the lower cones this is immediate from (6). Concerning (iii), it is sufficient to show that the lower (respectively, upper) cones of A, $A \oplus \emptyset$, and $A \oplus \omega$ are identical. We show this for the first two sets and omit the almost identical considerations for the third set. By (i), the upper cone of $A \oplus \emptyset$ is equal to the intersection of the upper cones of A and $\emptyset$; hence it is equal to the upper cone of A. On the other hand, by (7) the lower cone of $A \oplus \emptyset$ is contained in $\leq_r (A)$, and the reverse containment holds because $A \oplus \emptyset$ is a locally transitive upper bound for A. $\square$

REMARK 6. *Fix an arbitrary faithful relation $\leq_r$. Then the fact $A \leq_r B$ implies that B and $A \oplus B$ are r-interreducible but in general does not imply that these two sets are r-equivalent. In fact, the second implication holds iff $\leq_r$ is transitive.*

For a proof, observe that B is always reducible to $A \oplus B$, while in case $A \leq_r B$, the l.u.b. $A \oplus B$ of A and B must be reducible to their upper bound B. Thus the sets B and $A \oplus B$ are interreducible and, by the discussion in section 1.2, *are thus in fact equivalent in case $\leq_r$ is indeed transitive. Conversely, assume that B and $A \oplus B$ are always equivalent if A is reducible to B. Then for given sets A, B, and Y such that $A \leq_r B \leq_r Y$, we infer that $A \oplus B$ is reducible to Y and hence, because the former set is a locally transitive upper bound for A, A is also reducible to Y. As a consequence, the relation $\leq_r$ is transitive.*

In Example 7, we construct a faithful bounded reducibility that is in addition transitive and c.f.v. but where the corresponding structure induced on the recursive sets is not dense. The example shows that in order to be able to derive the density of the recursive sets within our axiomatic framework, we have to add further assumptions on the reducibilities under consideration.

EXAMPLE 7. *Given a set A and a string w, for the scope of this example let $A^{<w>}$ be equal to the set $\{x : wx \in A\}$ and call a set A β-reducible to a set B, for short, $A \leq_\beta B$ iff for some n in ω there is a mapping*

$$r : \{0,1\}^n \to \{0,1\}^* \tag{9}$$

such that for all strings w of length n,

$$A^{<w>} \text{ is a finite variation of } \emptyset,\ \omega,\ B^{<r(w)>},\ \text{or } \overline{B^{<r(w)>}}. \tag{10}$$

So β-reducibility is of a rather restricted one-question truth-table type. For each string w of length n and for almost all places wx that extend w, the same one-place evaluation function (constant 0 *or* 1, *identity, or negation) is applied to the answer received on querying the oracle at place $r(w)x$. We omit the routine proof that β-reducibility is a faithful bounded reducibility that is transitive and c.f.v. Next we argue that the set*

$$T := \{1^k : k \in \omega\}$$

is minimal in $(2^\omega, \leq_\beta)$; hence, in particular, the structure $(\mathrm{REC}, \leq_\beta)$ is not dense.

By definition, the set T is minimal if it is not a least set, and every set A that is β-reducible to T either is a least set or T is β-reducible to A. First, the set T is not β-reducible to $\emptyset$. Given a function r that witnesses that some set X is β-reducible to $\emptyset$ where r is defined on strings of length n, then the set X contains either almost all or only finitely many strings of the form $1^n y$. Second, assume $A \leq_\beta T$ for a set A, and let this fact be witnessed by a function r as in (9) *that is defined on strings of length n. If there is some string w of length n where $r(w)$ is in T and the evaluation function is nonconstant, then, by choice of T, $A^{<w>}$ is some finite variation of either the set T or of its complement, depending on the evaluation function being identity or negation. So in this case, T is β-reducible to A. On the other hand, if for all strings w of length n the evaluation function is constant or $r(w)$ is not in T, then A is β-reducible to $\emptyset$. Hence for every set A that is β-reducible to T, we have either $T \leq_\beta A$ or $A \leq_\beta \emptyset$.*

2.2. Delayed simulations and delayed patching. In this section, we describe an abstract account of the ability of resource-bounded oracle Turing machines to overwrite or "patch" their oracle according to the results of resource-bounded subcomputations. This account is based on the concept of *delayed patching*. By patching a functional we refer to evaluating the functional not with respect to its set argument B but with respect to a patched version $\langle B, \sigma \rangle$ of B. Furthermore, the attribute delayed refers to the fact that the patching is done with respect to arbitrary effective enumerations $\alpha_0, \alpha_1, \ldots$ of finite partial characteristic functions where, however, in general the ith partial characteristic function will not be used while computing the value $\Gamma(B, i)$, but delayed, that is, for number arguments larger than i. Note again that this kind of delayed access to effectively given information is common in connection with resource-bounded oracle Turing machines. Given an effective enumeration $\alpha_0, \alpha_1, \ldots$ as above, a resource-bounded oracle Turing machine can eventually compute and access α_i for arbitrarily large values of i; however, intuitively speaking, the Turing machine has to wait until its number input and hence its resource-bounds become large enough. The ability to perform such delayed computations is modelled by the concepts delayed simulation and simulation class introduced in Definition 8.

DEFINITION 8. *Let h, s, and l be (not necessarily recursive) functions from ω to ω.*

(i) *The function s is* MANY-ONE REDUCIBLE *to h via l iff for all x in ω, we have $s(x) = h(l(x))$.*

(ii) *The function s is a* DELAYED SIMULATION *of the function h iff s is many-one reducible to h via some nondecreasing function l with range ω.*

(iii) *A subclass $\mathcal{F}$ of ω^ω is a* FUNCTIONAL SIMULATION CLASS *iff there is a recursive function* sim *from ω to ω where for all e in ω*

- *$\phi_{\mathrm{sim}(e)}$ is a function in $\mathcal{F}$;*
- *if ϕ_e is total and $\phi_e(0)$ is equal to 0, then $\phi_{\mathrm{sim}(e)}$ is a delayed simulation of ϕ_e.*

(iv) *A subclass $\mathcal{S}$ of 2^ω is a* SIMULATION CLASS *iff there is a recursive function* sim *such that $\varphi_{\mathrm{sim}(e)}$ is a set in $\mathcal{S}$ for all e in ω and in addition $\varphi_{\mathrm{sim}(e)}$ is a delayed simulation of φ_e whenever φ_e is a set that does not contain* 0.

(That is, $\mathcal{S}$ is a simulation class if it satisfies the definition of functional simulation class with ω^ω and $\phi_0, \phi_1, \ldots$ replaced by 2^ω and $\varphi_0, \varphi_1, \ldots$.)

The concept delayed simulation was introduced by Mehlhorn [18, Axiom 6]. The relation between Mehlhorn's axiomatic approach and our own one in terms of standard reducibilities is discussed in Remark 20 below.

In the definition of the concept simulation class (and likewise for functional simulation classes) it is indeed reasonable to require that the function sim yields delayed simulations only in case $\varphi_e(0) = 0$. Remark 9 shows that there cannot be a recursive function sim where $\varphi_{\mathrm{sim}(e)}$ is total for all e in ω and is a delayed simulation of φ_e for *all* sets φ_e.

REMARK 9. *Recall from recursion theory that the sets A_0 and A_1 defined by*

$$A_i := \{e \in \omega : \varphi_e(e) = i\}, \qquad i = 0, 1,$$

are recursively inseparable; that is, there is no recursive set D such that A_0 is contained in D and A_1 is contained in $\overline{D}$. For a proof, it suffices to observe that any such set D must differ from every recursive set φ_e at place e. Now, by the smn-theorem, there is a recursive function g such that for all e, x, and y in ω we have

$$\varphi_{g(e,x)}(y) = \varphi_e(x).$$

However, if we assume that there is a recursive function sim *such that* $\varphi_{\mathrm{sim}(e)}$ *is a set for all* e *in* ω *and is a delayed simulation of* φ_e *for* all *sets* φ_e*, then we obtain a contradiction because the set*

$$D := \{e \in \omega : \varphi_{\mathrm{sim}(g(e,e))}(0) = 0\}$$

is recursive and separates A_0 *from* A_1 *by definition of* g*.*

Example 10 shows that the class of functions computable in polynomial time is a functional simulation class.

EXAMPLE 10. *For every* e *in* ω*, there is some Turing machine* $M_{\mathrm{sim}(e)}$ *that operates as follows.*

> *Given an input of length* n*, the Turing machine* $M_{\mathrm{sim}(e)}$ *tries to compute successively the values* $\phi_e(0), \phi_e(1), \ldots$ *by simulating the corresponding computations of* M_e*. The simulating machine* $M_{\mathrm{sim}(e)}$ *runs for a total of* n *steps and then outputs the last successfully computed value or, if even* $\phi_e(0)$ *could not be computed, the value* 0*.*

By definition of $\mathrm{sim}(e)$*, it should be clear that the function* sim *can be chosen to be recursive and that for every* e *in* ω*,*

> *the Turing machine* $M_{\mathrm{sim}(e)}$ *is total and runs in polynomial time and* $\phi_{\mathrm{sim}(e)}$ *is a delayed simulation of* ϕ_e *whenever* ϕ_e *is total and* $\phi_e(0)$ *is equal to* 0*.*

In connection with the latter property, we can safely assume that the simulation of M_e *for a single number argument requires at least one step and that consequently the simulating computation cannot skip function values of* φ_e *in the sense that, for example, the function* ϕ_e *has value* 1 *at some place* x *and has value* 0 *everywhere else, but* $\phi_{\mathrm{sim}(e)}$ *is the constant function with value* 0*.*

REMARK 11. *The concept of simulation class introduced in Definition* 8 *is robust under various changes of its definition. For example, we obtain the same concept if we do not require* $\varphi_{\mathrm{sim}(e)}$ *to be a delayed simulation of* φ_e *for all* e *where* φ_e *is a set that does not contain* 0*, but just for all such* e *where* φ_e *is finite or cofinite. Likewise, we can equivalently define the concept of simulation classes if we replace in its definition the concept of delayed simulations by a variant where the range of the witnessing reduction* l *as in Definition* 8 *need not be equal to* ω*, i.e., where the range of* l *is unbounded but might have gaps. For proofs and for further discussion we refer to Merkle* [20, section 3.6]*.*

Let $\sigma_0, \sigma_1, \ldots$ be an appropriate effective enumeration of all partial characteristic functions where by convention we let σ_0 be equal to the empty string. Recall from the introduction that $\langle A, \alpha\rangle$, the α-patch of A, is the set that agrees with α on $\mathrm{dom}(\alpha)$ and agrees with A otherwise.

DEFINITION 12.

(i) *Given a functional* Γ *and a function* $g : \omega \to \omega$*, the* $\boldsymbol{g}$-PATCH OF $\boldsymbol{\Gamma}$ *is the functional* $\Gamma \otimes g$ *defined by*

$$(\Gamma \otimes g)(A, x) := \Gamma(\langle A, \sigma_{g(x)}\rangle, x).$$

(ii) *Let* $\mathcal{R}$ *be a class of functionals and let* $\mathcal{F}$ *be a subclass of* ω^ω*. Then the* CLASS OF $\boldsymbol{\mathcal{F}}$-PATCHES OF $\boldsymbol{\mathcal{R}}$ *is*

$$\mathcal{R} \otimes \mathcal{F} := \{\Gamma \otimes g : \Gamma \in \mathcal{R} \text{ and } g \in \mathcal{F}\}.$$

(iii) *A class* $\mathcal{R}$ *of functionals is closed under* DELAYED PATCHING *iff there is a functional simulation class* $\mathcal{F}$ *where* $\mathcal{R} \otimes \mathcal{F}$ *is contained in* $\mathcal{R}$*.*

Proposition 13, which has some interest in its own, is used in Example 14 in order to show that the standard enumeration of polynomially time-bounded oracle Turing machines yields a reduction cover for the reducibility $\leq_{\mathrm{T}}^{\mathcal{P}}$ that is closed under delayed patching.

PROPOSITION 13. *Let the recursive function b from ω to ω be nondecreasing and unbounded and let $\mathcal{F}$ be a functional simulation class. Then the class*

$$\{f \in \mathcal{F} : f(x) \leq b(x) \text{ for all } x \in \omega\} \tag{11}$$

is again a functional simulation class.

Proof. The idea of the proof is quite simple. Given some recursive function h in class $\mathcal{F}$, we construct a recursive delayed simulation g of h where $g(x) \leq b(x)$ holds for all x in ω. Then for any delayed simulation f of g, where this fact is witnessed by some nondecreasing function l with range ω, we have for all x in ω

$$f(x) \;=\; g(l(x)) \;\leq\; b(l(x)) \;\leq\; b(x).$$

The relations hold, from left to right, by choice of l, because g is bounded by b, and finally because b is nondecreasing and by $l(x) \leq x$. Thus in order to show that the class defined in (11) is a functional simulation class, we map a recursive function not just to a delayed simulation h in $\mathcal{F}$, but in addition we construct a recursive delayed simulation g of h that is bounded by b, and then we pick a delayed simulation f of g in $\mathcal{F}$. An index for such a function g can be obtained effectively from an index for h; i.e., there is a recursive function r that maps any index for a function h in $\mathcal{F}$ to an index of a delayed simulation g of h as above. Then, given a function sim that witnesses that $\mathcal{F}$ is a functional simulation class, by the preceding discussion the function

$$\mathrm{sim}' := \mathrm{sim} \circ r \circ \mathrm{sim}$$

witnesses that the class defined in (11) is a functional simulation class.

Formally, given some function h in $\mathcal{F}$, we define a corresponding function g as above by $g(x) := h(l(x))$ where $l(0)$ is equal to 0 and for all x we let

$$l(x+1) := \begin{cases} l(x)+1 & \text{in case } h(l(x)+1) \leq b(x+1), \\ l(x) & \text{otherwise.} \end{cases}$$

□

EXAMPLE 14. *We fix an effective enumeration of polynomially time-bounded oracle Turing machines where machine $\langle e, j\rangle$ in the enumeration corresponds to Turing machine M_e in the standard enumeration of Turing machines with an additional restriction on the running time that is given by polynomial j in some appropriate enumeration of all polynomials. Then the class $\mathcal{R}_{\mathrm{T}}^{\mathcal{P}}$ of all functionals computed by some oracle Turing machine in this enumeration is an effective reduction cover for $\leq_{\mathrm{T}}^{\mathcal{P}}$. Now, first, adding polynomially time-bounded subcomputations to a polynomially time-bounded oracle Turing machine will not put us outside of the class $\mathcal{R}_{\mathrm{T}}^{\mathcal{P}}$, and, second, the class $\mathcal{FP}$ of functions computable in polynomial is a functional simulation class according to Example* 10. *However, this does not imply directly that the standard reduction cover $\mathcal{R}_{\mathrm{T}}^{\mathcal{P}}$ is closed under delayed patching because given some function g that is computable in polynomial time, the corresponding function values might be so large that for more reasonable effective enumerations of the finite partial characteristic functions it will be impossible to access the values of the partial characteristic*

function $\sigma_{g(x)}$ in time polynomially bounded in the length of x. Thus if we patch a functional Γ in $\mathcal{R}^{\mathcal{P}}_{\mathrm{T}}$ by some function g computable in polynomial time, then in general the new functional $\Gamma \otimes g$ will not be computable in polynomial time unless we choose an effective enumeration $\sigma_0, \sigma_1, \ldots$ of the finite partial characteristic functions where the coding is rather inefficient.

In order to handle this problem, let b be a nondecreasing and unbounded recursive function that grows so slowly that for all x and for all $j \leq b(x)$, we can in time $|x|$ answer all relevant questions about the domain and the values of σ_j. Then by Example 10 *and Proposition* 13, *the class*

$$\mathcal{FP}_{\leq b} := \{g \in \mathcal{FP} : g(x) \leq b(x) \text{ for all } x \in \omega\}$$

is a functional simulation class. Furthermore, by our choice of b, the reduction cover $\mathcal{R}^{\mathcal{P}}_{\mathrm{T}}$ is closed under patching with functions in $\mathcal{FP}_{\leq b}$. More precisely, for any functional Γ computed by a polynomially time-bounded oracle Turing machine M and for any function g in $\mathcal{FP}_{\leq b}$, the following oracle Turing machine M' computes $\Gamma \otimes g$.

> *M' works essentially as M but every query state of M is replaced by a sequence of new states corresponding to a subcomputation that takes care of the g-patching. In the subcomputation, first, the value of $g(x)$ for the current number input x is computed and, second, it is checked whether the value y written currently on the oracle tape is in the domain of $\sigma_{g(x)}$. This check can be done in polynomial time by definition of b and by choice of g in $\mathcal{FP}_{\leq b}$. After this subcomputation, the execution of M' resumes as follows. In case y is not in the domain of $\sigma_{g(x)}$, then the next state is determined in exactly the same way as for M by the value of the oracle at place y while, otherwise, the value $\sigma_{g(x)}(y)$ is used in place of the actual value of the oracle in order to determine the next state.*

In connection with the description of the oracle Turing machine M' recall that once an oracle Turing machine enters a query state, the next state is determined by the value of the oracle for the number currently written on the oracle tape. Observe further that for Turing machine models with write-only access to the oracle tape, we have to keep a copy of the current oracle question on some work tape in order to be able to check whether the current query is in the domain of the patch we want to apply.

2.3. Definition by Oracle-dependent cases and effective reduction covers.

DEFINITION 15.

(i) *A* TT-CONDITION *is a subclass $\mathcal{T}$ of 2^ω such that for some finite set I and for all sets A, membership of A in $\mathcal{T}$ depends only on the restriction of A to I.*

(ii) *Let $\mathcal{T}$ be a tt-condition and let Γ_0 and Γ_1 be functionals. The $\boldsymbol{\mathcal{T}}$-*MIX *of Γ_0 and Γ_1 is the functional $\langle \Gamma_0, \Gamma_1 \rangle^{\mathcal{T}}$ defined by*

$$\langle \Gamma_0, \Gamma_1 \rangle^{\mathcal{T}}(A) := \begin{cases} \Gamma_0(A) & \text{if } A \in \mathcal{T}, \\ \Gamma_1(A) & \text{if } A \notin \mathcal{T}. \end{cases} \tag{12}$$

(iii) *For a tt-condition $\mathcal{T}$, we denote the transition from two functionals to their $\mathcal{T}$-mix as* DEFINITION BY ORACLE-DEPENDENT CASES *with respect to $\mathcal{T}$.*

(iv) *A class $\mathcal{R}$ of functionals is* CLOSED UNDER DEFINITION BY ORACLE-DEPENDENT CASES *iff for every tt-condition $\mathcal{T}$ the $\mathcal{T}$-mix of two functionals in $\mathcal{R}$ is again in $\mathcal{R}$.*

DEFINITION 16. *A list $\Delta_0, \Delta_1, \dots$ of functionals is an* EFFECTIVE ENUMERATION *of a set $\mathcal{R}$ of functionals iff there is a recursive function e such that $\Delta_i = \Phi_{e(i)}$ for all i and the set $\mathcal{R}$ coincides with $\{\Delta_0, \Delta_1, \dots\}$.*

A set $\mathcal{R}$ of functionals is an EFFECTIVE REDUCTION COVER *for a binary relation $\leq_r$ on 2^ω iff $\mathcal{R}$ has some effective enumeration and for all sets A and B, $A \leq_r B$ iff $A = \Gamma(B)$ for some functional Γ in $\mathcal{R}$.*

For any class $\mathcal{R}$ that has an effective enumeration, by the padding lemma this fact is always witnessed by a function e that is strictly monotonous and hence has recursive range. Using the latter observation, it is immediate from Definitions 1 and 16 that a binary relation on 2^ω is a bounded reducibility iff it has some effective reduction cover. For standard reducibilities as introduced in Definition 17, we require in addition that there is an effective reduction cover that satisfies certain closure properties.

DEFINITION 17. *A binary relation $\leq_r$ on 2^ω is a* STANDARD REDUCIBILITY *iff*

(i) *the relation $\leq_r$ is faithful and c.f.v.;*

(ii) *there is some effective reduction cover for $\leq_r$ that is closed under delayed patching and under definition by oracle-dependent cases.*

In the definition of standard reducibilities we can drop the condition that the relation is c.f.v. because this follows already from the remaining requirements. We omit the simple but lengthy proof and refer to Merkle [20, Proposition 35].

EXAMPLE 18. *Standard reducibilities comprise not only the usual polynomially time- or logarithmically space-bounded reducibilities of many-one and Turing type but also less common reducibilities such as the honest variant $\leq^{\mathcal{P}}_{\text{h-T}}$ of $\leq^{\mathcal{P}}_{\text{T}}$, the reducibility $\leq_{\text{NC}_1}$ defined in terms of circuits, as well as the nontransitive relations $\leq^{\mathcal{P}}_{k-\text{tt}}$ for any fixed $k \geq 2$* [20].

Examples of bounded reducibilities that are not standard reducibilities are given by Turing reducibility confined to constant space or by the reducibility $\leq^{\mathcal{P}}_1$, i.e., the variant of polynomially time-bounded many-one reducibility where the reduction functions are required to be one-to-one. For a proof, recall that the latter reducibility is not c.f.v. and observe that for the former reducibility the class of admissible cases is not a simulation class.

REMARK 19. *Given an effective reduction cover $\mathcal{R}$ for a bounded reducibility $\leq_r$, the closure of $\mathcal{R}$ under definition by oracle-dependent cases is again an effective reduction cover for $\leq_r$. This follows from the simple observation that for each tt-condition $\mathcal{T}$, the $\mathcal{T}$-mix $\langle \Gamma_0, \Gamma_1 \rangle^{\mathcal{T}}$ of two functionals in $\mathcal{R}$ is again a recursive functional and maps every set B to $\Gamma_0(B)$ or to $\Gamma_1(B)$, i.e., to a set that by assumption is reducible to B.*

As a consequence, a bounded reducibility always has an effective reduction cover that is closed under definition by oracle-dependent cases. The point in requiring the existence of such a reduction cover in the definition of standard reducibility is that this reduction cover at the same time is required to be closed under delayed patching. When working with such reduction covers, we are able to mimic switching between functionals according to oracle-independent subcomputations, as is done with the gap language technique. *If we first put two functionals together via a definition by cases with respect to some tt-condition, then afterwards, by finitely patching the set argument of the new compound functional at all the places the selecting tt-condition depends on, we can alternate between the two initial functionals; for details of this construction see the proof of Proposition* 39.

In Remark 20, we briefly discuss the relation of Mehlhorn's axiomatic approach to our own one in terms of the concept of standard reducibility. For a more detailed

account we refer to Merkle [20, section 3.7].

REMARK 20. *Mehlhorn's axiom system* [18] *apparently is meant to be applied to bounded reducibilities of Turing type. In accordance with this intended range of application, his axioms do not just involve delayed simulations of recursive sets but of all sets that can be computed relative to the given oracle. Furthermore, every lower cone is required to be closed under definition by number-dependent cases with respect to all sets in this lower cone. As a consequence, Mehlhorn's axiom system is satisfied for the usual reducibilities of Turing type but not for standard reducibilities such as many-one or bounded truth-table reducibility restricted to polynomial time* [20].

On the other hand, the definition of standard reducibility involves a condition on delayed patching, which has no counterpart in Mehlhorn's axiom system. The rationale for adding such a condition is that we aim at embedding distributive lattices, not just partial orderings. In connection with embeddings of lattices, the condition on delayed patching is then used for constructing pairs of sets with a specific g.l.b. Embeddings of partial orderings can indeed be obtained from assumptions that are more general than the concept of standard reducibility; see Corollary 53 *below.*

3. Three lemmas on standard reducibilities.

3.1. Gap languages and generalized use. In this section we will show three lemmas that will then be used in section 4 in the proof of our main result about lattice embeddings for standard reducibilities. Embeddings of partial orderings and of lattices have been constructed before for several specific bounded reducibilities and in corresponding proofs the use of gap languages has become a standard technique [1, 4, 30, 31].

DEFINITION 21. *A set is a* GAP LANGUAGE *iff the set and its complement are both infinite.*

A gap language A can be conceived as a partition of ω into infinitely many finite *blocks*, where each block corresponds to a maximal set of consecutive natural numbers that either all are in A or all are in the complement of A. Indeed we will use gap languages almost exclusively as a convenient tool to specify such partitions. We will number the blocks of a gap language G in the natural way, and we will assign to each x in ω the number of its block with respect to G. These concepts are formally introduced in Definition 22. For further use, however, they are defined for arbitrary partial characteristic functions and not just for gap languages. Intuitively speaking, given a partial characteristic function α where x is the least place such that $\alpha(x)$ is undefined, then the blocks of α are defined in the natural way up to but not including x, and these are all blocks of α.

DEFINITION 22. *Let $\alpha : \omega \to \{0,1\}$ be a partial characteristic function. For all x in ω such that $\alpha(y)$ is defined for all $y \leq x$, we let*

$$\mathrm{bn}(\alpha, x) \;:=\; |\{y \in \omega : y < x \;\&\; \alpha(y) \neq \alpha(y+1)\}|\,,$$

and we let $\mathrm{bn}(\alpha, x)$ be undefined for all other x. We call $\mathrm{bn}(\alpha, x)$ the BLOCK NUMBER *of x with respect to α.*

For all j in ω, we let BLOCK $\boldsymbol{j}$ OF $\boldsymbol{\alpha}$ *be equal to the set $\{x \in \omega : \mathrm{bn}(\alpha, x) = j\}$, and we say block j of α* EXISTS *iff block j of α is nonempty.*

The blocks of a partial characteristic function α are "numbered" by the function $\mathrm{bn}(\alpha, .)$, starting with block 0. Obviously, the function $\mathrm{bn}(\alpha, .)$ is total iff α is total, and α has infinitely many blocks iff α is a gap language.

DEFINITION 23. *Let A and B be gap languages. Then B is a* GAP COVER *for A iff every block of B contains some block of A.*

It is immediate from Definition 23 that the gap cover relation is transitive; that is, if B is a gap cover for A and so is C for B, then C is also a gap cover for A.

The values of a recursive functional Γ can be computed by an oracle Turing machine that on input x and oracle A can read only a finite part of A before it outputs $\Gamma(A,x)$. Consequently, there is a finite set I such that $\Gamma(A,x)$ is equal to $\Gamma(B,x)$ for all B that agree with A on I. By the theorem of Trakhtenbrot and Nerode [24, Proposition III.3.2], the set I can in fact be chosen independently of A; i.e., for all x there is a finite set I such that

$$X|I = Y|I \quad \text{implies} \quad \Gamma(X,x) = \Gamma(Y,x) \qquad \text{for all sets } X,Y. \tag{13}$$

The class of sets I that satisfy (13) are closed under intersection and thus in particular there is a least such set, which obviously is uniquely determined and finite [20, 22].

DEFINITION 24. *Let Γ be a recursive functional. For every natural number x, we call the least set I that satisfies* (13) *the* GENERALIZED USE *of Γ at x, and we denote this set by* $\mathrm{u}(\Gamma,x)$.

REMARK 25. *There is an effective procedure that on inputs x and e eventually outputs* $\mathrm{u}(\Phi_e,x)$ *whenever $\Phi_e(X,x)$ is defined for all oracles X (and that otherwise might fail to terminate). The proof of the theorem of Trakhtenbrot and Nerode shows that in the given situation a finite set I as in* (13) *can be obtained effectively. In order to determine* $\mathrm{u}(\Phi_e,x)$ *it then suffices to search through all subsets of I.*

In principle, all the material presented in what follows could be formulated in terms of the standard concept of use for oracle Turing machines, where for given oracle Turing machine, input, and oracle the use contains exactly the numbers at which the oracle Turing machine queries its oracle. However, we consider it to be convenient to work with the generalized use because the latter is determined just by the functional and does not require to specify a specific oracle Turing machine computing the functional. In fact, the concept of generalized use extends canonically to arbitrary continuous, not necessarily recursive functionals [20, 22].

3.2. The diagonalization lemma. Suppose that we are given an effective reduction cover $\{\Delta_0,\Delta_1,\dots\}$ for a bounded reducibility $\leq_r$. Then a set E is r-reducible to a set F iff there is *some* functional Δ_j where E is equal to $\Delta_j(F)$. As a consequence, we can construct sets E and F where E is not reducible to F by *diagonalizing* against all functionals Δ_j; that is, it is sufficient to ensure that for all j in ω there is some x_j in ω such that we have

$$E(x_j) \neq \Delta_j(F,x_j). \tag{14}$$

Now the generalized use of the functionals Δ_j is always finite and thus for any given j we can enforce (14) by specifying $E(x_j)$ and a finite part of F; that is, we are led to a finite extension construction. Before we employ such a construction in the proof of Lemma 28, we introduce some notation.

DEFINITION 26. *Let G be a gap language and let $k \geq 1$ be a natural number. Then two n-tuples $(X_1,\dots,X_k)$ and $(Y_1\dots,Y_k)$ of sets are* $\boldsymbol{G}$-SIMILAR, *written*

$$(X_1,\dots,X_k) \simeq^G (Y_1,\dots,Y_k)$$

iff there are infinitely many blocks I of G such that for all $i=1,\dots,k$, the sets X_i and Y_i agree on I. Two sets are G-similar iff the corresponding 1-tuples are G-similar.

For further use, we state the following easy fact, which is immediate from the definitions of the concepts involved.

REMARK 27. *If two tuples of sets are G-similar for some gap language G, then they are also H-similar for every gap cover H of G.*

LEMMA 28 (diagonalization lemma). *Let $\leq_r$ be a bounded reducibility such that $\leq_r$ is c.f.v. and let E and F be recursive sets where $E \not\leq_r F$. Then there is a recursive gap language G such that we have for all sets E' and F'*

$$(E, F) \simeq^G (E', F') \quad \textit{implies} \quad E' \not\leq_r F'.$$

The diagonalization lemma and its proof are similar to Schöning's uniform diagonalization theorem [4, 30]. We will use the diagonalization lemma in connection with results about partial order embeddings in order to ensure that the constructed embeddings preserve nonorder. More precisely, given sets E and F where E is not reducible to F, then by the diagonalization lemma in order to construct a set E' that is not reducible to F' it is sufficient to ensure that E' and F' agree with E and F, respectively, on some set that contains infinitely many blocks of the gap language G obtained from the diagonalization lemma.

Proof of Lemma 28. We construct in stages a gap language G as required in the lemma. We write I_s for block s of G and during stage s we specify which numbers are in I_s. This then determines G by letting $G(0)$ be equal to 0.

Let $\Delta_0, \Delta_1, \ldots$ be an effective enumeration of an effective reduction cover for $\leq_r$. At stage 0, we let $I_0 = \{0\}$. At stage $s > 0$, for all $j \leq s$ and for all pairs α and β of finite partial characteristic functions with domain equal to the union of the blocks $I_0, \ldots, I_{s-1}$, we let $z_{\alpha,\beta,j}$ be the least number that satisfies

$$\langle E, \alpha\rangle(z_{\alpha,\beta,j}) \neq \Delta_j(\langle F, \beta\rangle, z_{\alpha,\beta,j}). \tag{15}$$

There is indeed such a number as $\langle E, \alpha\rangle = \Delta_j(\langle F, \beta\rangle)$ would imply $E \leq_r F$ by $\leq_r$ being c.f.v. Furthermore, the least such number can be found effectively in α, β, and j because the Δ_j are uniformly recursive. Next we choose I_s so large that for all such α, β, and j we have

$$\{z_{\alpha,\beta,j}\} \cup \mathrm{u}(\Delta_j, z_{\alpha,\beta,j}) \subseteq I_0 \cup \cdots \cup I_s. \tag{16}$$

In order to show that the gap language G has the required properties, assume for a proof by contradiction that there are sets E' and F' where, first, (E', F') and (E, F) are G-similar, and, second, the set E' is r-reducible to F', say via functional Δ_k. Choose some $s \geq k$ where E' and F' agree with E and F, respectively, on block s of G. Let α and β be the restrictions of E' and F', respectively, to the union of the blocks $I_0, \ldots, I_{s-1}$. Now the witness $z_{\alpha,\beta,k}$ for $\langle E, \alpha\rangle \neq \Delta_k(\langle F, \beta\rangle)$ we found during stage s of the construction of G witnesses $E' \neq \Delta_k(F')$ due to (16) and because by assumption $\langle E, \alpha\rangle$ and $\langle F, \beta\rangle$ agree with E' and F', respectively, on the union of $I_0, \ldots, I_s$. □

3.3. The window lemma. We show now that for standard reducibilities every reduction to a recursive set is witnessed by a functional that on increasing number inputs ignores larger and larger initial parts of its set argument. In the corresponding proof we exploit that standard reducibilities possess reduction covers that are closed under delayed patching, and we apply a special form of delayed patching where we do not patch according to an arbitrary effective sequence of finite partial characteristic

functions but with increasingly long initial segments of the characteristic function of some *fixed* recursive set.

DEFINITION 29. *A function $m : \omega^2 \to \omega$ is a* MODULUS OF ORACLE SIMULATION *iff m is recursive and for all e in ω the sequence $\sigma_{m(e,0)}, \sigma_{m(e,1)}, \dots$ converges monotonously to φ_e (i.e., $\sigma_{m(e,i)} \sqsubseteq \sigma_{m(e,i+1)}$ for all i and the domain of φ_e is equal to the union of the domains of $\sigma_{m(e,0)}, \sigma_{m(e,1)}, \dots$).*

A reduction cover is CLOSED UNDER ORACLE SIMULATION *iff there is a modulus of oracle simulation m such that $\mathcal{R}$ is closed under patching with the functions $m(e,.)$ (i.e., for all Γ in $\mathcal{R}$ and all e in ω, the functional $\Gamma \otimes m(e,.)$ is in $\mathcal{R}$).*

EXAMPLE 30. *For all e and i in ω, let $m(e,i)$ be the least index such that $\sigma_{m(e,i)}$ is equal to the restriction of φ_e to the set $\{j < i : \varphi_{e,|i|}(j)\downarrow\}$, where $\varphi_{e,s}(i)$ denotes the s-step approximation to $\varphi_e(i)$. We leave it to the reader to show that the function m is recursive and is indeed a modulus of oracle simulation.*

LEMMA 31. *Let $\mathcal{F}$ be a functional simulation class. Then there is a modulus of oracle simulation m such that for all e in ω the function $m(e,.)$ is in $\mathcal{F}$.*

Proof. Let the function sim witness that $\mathcal{F}$ is a functional simulation class and fix an arbitrary modulus of oracle simulation m (for example, the one defined in Example 30). We can assume $m(e,0) = 0$ because by our convention σ_0 is the empty partial characteristic function λ; hence, for all e, the condition on the convergence of the sequence $\sigma_{m(e,0)}, \sigma_{m(e,1)}, \dots$ in Definition 29 remains valid if we change $m(e,0)$ into 0.

By the *smn*-theorem, fix a recursive function g such that for all e and x, $\phi_{g(e)}(x)$ is equal to $m(e,x)$. Then the function m' defined by

$$m'(e,x) = \phi_{\mathrm{sim}(g(e))}(x)$$

is recursive, and m' is in fact a modulus of oracle simulation because for each e the function $m'(e,.)$ is a delayed simulation of $m(e,.)$. Intuitively speaking, m' yields a simulation of φ_e that is basically the same but might be "slower" than the one provided by m. □

PROPOSITION 32. *If a reduction cover is closed under delayed patching, then it is also closed under oracle simulation. In particular, every standard reducibility has an effective reduction cover that is closed under oracle simulation.*

Proof. The first assertion follows easily from Lemma 31 and the definition of the two closure conditions involved. The second assertion is then immediate because by definition every standard reducibility has an effective reduction cover that is closed under delayed patching. □

Given a class $\mathcal{C}$ and an effective reduction cover $\mathcal{R}$ for a bounded reducibility, we will use the expression "every reduction to a set in $\mathcal{C}$ is witnessed by some functional in $\mathcal{R}$ such that ... " to express that for every C in $\mathcal{C}$ and every set X that is reducible to C, there is a functional Δ in $\mathcal{R}$ that has the properties under consideration such that X is equal to $\Delta(C)$. Furthermore, given a gap language G and some x in ω we let

$$\mathrm{Nb}(x,G) := \{y \in \omega : \mathrm{bn}(G,x) - 1 \leq \mathrm{bn}(G,y) \leq \mathrm{bn}(G,x) + 1\};$$

that is, $\mathrm{Nb}(x,G)$ consists of the block of x with respect to G and of the adjacent block to the left and to the right, respectively.

LEMMA 33 (window lemma). *Let $\mathcal{R}$ be an effective reduction cover for some bounded reducibility such that $\mathcal{R}$ is closed under delayed patching. Let the class $\mathcal{C}$ be recursively presentable.*

Then there is a recursive gap language G such that every reduction to a set in $\mathcal{C}$ is witnessed by a functional Δ in $\mathcal{R}$ such that for all but finitely many x in ω,

$$\mathrm{u}(\Delta, x) \subseteq \mathrm{Nb}(x, G).$$

Proof. We fix some effective enumeration $\Delta_0, \Delta_1, \ldots$ of $\mathcal{R}$.

Claim 1. *There is a recursive function h such that for all i and for almost all places x we have*

$$\max \mathrm{u}(\Delta_i, x) \leq h(x).$$

Proof. The set $\mathrm{u}(\Delta_i, x)$ is always finite and can be computed from i and x; hence it is sufficient to let $h(x)$ be equal to the maximal number in the union of the sets $\mathrm{u}(\Delta_0, x), \mathrm{u}(\Delta_1, x), \ldots, \mathrm{u}(\Delta_x, x)$. □

Claim 2. *There is an recursive function b that is nondecreasing and unbounded such that every reduction to a set C in $\mathcal{C}$ is witnessed by some Δ in $\mathcal{R}$ where the generalized use of Δ is almost everywhere bounded from below by b; i.e., we have for almost all x,*

$$b(x) \leq \min \mathrm{u}(\Delta, x).$$

Proof. Let r be a recursive function such that $\mathcal{C}$ is equal to $\{\varphi_{r(i)} : i \in \omega\}$. By Proposition 32, we can fix a modulus of oracle simulation m that witnesses that $\mathcal{R}$ is closed under oracle simulation. Then we let for all i and x in ω,

$$v(i, x) := \max_{y \leq x} \left[\{0, \ldots, y\} \subseteq \mathrm{dom}(\sigma_{m(r(i),x)})\right].$$

The function v is recursive because m and r are recursive. Furthermore, for every fixed i, the function $v(i, .)$ is nondecreasing and unbounded because $\varphi_{r(i)}$ is total; hence the domains of the partial characteristic functions $\sigma_{m(r(i),x)}$ converge nondecreasingly to ω as x goes to infinity. Next, we let

$$b(x+1) := \begin{cases} b(x)+1 & \text{in case } b(x)+1 \leq v(i,x) \text{ for all } i \leq b(x), \\ b(x) & \text{otherwise.} \end{cases}$$

The function b is by definition nondecreasing, and it is unbounded because the functions $v(i, .)$ are unbounded. Then given a set $C = \varphi_{r(i)}$ in $\mathcal{C}$ and a set that is reducible to C, we fix a witnessing functional Δ in $\mathcal{R}$. The functional

$$\Delta' := \Delta \otimes m(r(i), .),$$

i.e., the $m(r(i), .)$-patch of Δ, is in $\mathcal{R}$ by choice of the modulus m. The functionals Δ and Δ' agree on the set C because the patches $\sigma_{m(r(i),x)}$ agree with C on their entire domain; i.e., we have for all x

$$\Delta'(C, x) = [\Delta \otimes m(r(i), .)](C, x) = \Delta(\langle C, \sigma_{m(r(i),x)}\rangle, x) = \Delta(C, x).$$

Furthermore, by definition of b, for almost all x the numbers less than or equal to $b(x)$ are all contained in the domain of $\sigma_{m(r(i),x)}$ and hence are not in the generalized use $\mathrm{u}(\Delta', x)$. □

By Claims 1 and 2, we obtain recursive functions h and b, where b is nondecreasing and unbounded and such that every reduction to some set in $\mathcal{C}$ is witnessed by some

functional Δ in $\mathcal{R}$ where for almost all places x the generalized use $\mathrm{u}(\Delta, x)$ is a subset of the possibly empty interval between $b(x)$ and $h(x)$. Thus it is sufficient to construct a gap language G such that for all x the interval between $b(x)$ and $h(x)$ is contained in $\mathrm{Nb}(x, G)$. The blocks of G are defined inductively, where block 0 of G is equal to $\{0\}$. In the induction step, let U_s be the union of the previously defined blocks 0 through s of G and let m_s be the least number not contained in U_s such that

$$\max U_s < b(m_s) \quad \text{and} \quad \max\{h(y) : y \text{ in } U_s\} \leq m_s.$$

Then let block $s+1$ of G be equal to $\{0, \ldots, m_s\} - U_s$. □

REMARK 34. *In the conclusion of Lemma* 33 *we can replace G by any gap cover of G. This is true simply because for any gap cover M of G and for any x the set* $\mathrm{Nb}(x, G)$ *is contained in* $\mathrm{Nb}(x, M)$.

For a proof, fix x and assume that x is in block i of G and in block j of M. Then block $j-1$ of M cannot contain block i of G because the latter contains x, which is in block j of M. Thus, by M being a gap cover for G, block $j-1$ of M must contain some block k of G where $k \leq i-1$. But then, obviously, the union of the consecutive blocks $j-1$ and j of M contains block $i-1$ of G. The assertion now follows by a symmetric argument that shows that blocks j and $j+1$ of M contain block $i+1$ of G.

3.4. Admissible cases and the coding lemma. Recall from the introduction that a functional can alternatively be described as a unary function from 2^ω to 2^ω or as a binary function from $2^\omega \otimes \omega$ to $\{0,1\}$. The latter characterization suggests two ways of how two functionals might be combined into a new functional via a definition by cases. The case condition can depend on the set argument or on the number argument. In Definition 15, we have introduced a notion of DEFINITION BY ORACLE-DEPENDENT CASES, where two functionals are mixed according to a tt-condition on their set argument. We introduce now a notion of DEFINITION BY NUMBER-DEPENDENT CASES where the case condition depends on the number argument. Given two functionals Δ_0 and Δ_1 and a set M, the functional Δ obtained via definition by number-dependent cases according to M is defined by

$$\Delta(X) := \langle \Delta_0(X), \Delta_1(X) \rangle^M; \tag{17}$$

i.e., $\Delta(X, x)$ is equal to the set $\Delta_0(X, x)$ if x is in M and is equal to the set $\Delta_1(X, x)$ otherwise. We will be interested in the class of all sets M such that when applying definition by number-dependent cases according to M to a given effective reduction cover, then using the functionals obtained this way we can just reduce the same pairs of sets as before. Remark 35 gives equivalent characterizations of this class.

REMARK 35. *Let $\leq_r$ be a binary relation on 2^ω. For the moment, call a functional Γ an r-reduction iff for all sets X the set $\Gamma(X)$ is r-reducible to X. Then for any set M, the following conditions are equivalent.*

(i) *All lower r-cones are closed under definition by number-dependent cases with respect to M (i.e., if the sets A and B are both reducible to X, then so is the set $\langle A, B \rangle^M$).*

(ii) *For any r-reductions Δ_0 and Δ_1, the functional Δ defined in* (17) *is again an r-reduction.*

(iii) *For any functionals Δ_0 and Δ_1 in some fixed effective reduction cover for $\leq_r$, the functional Δ defined in* (17) *is again an r-reduction.*

First, we show that (i) *implies* (ii). *Fix any set M that satisfies* (i), *let Δ_0 and Δ_1 be arbitrary r-reductions and let Δ be defined as in* (17). *By assumption, for any set X*

the sets $\Delta_0(X)$ and $\Delta_1(X)$ are r-reducible to X; hence so is $\Delta(X)$. Now the set X has been chosen arbitrarily; thus Δ is an r-reduction. The implication from (ii) *to* (iii) *is immediate because all functionals in an effective reduction cover for $\leq_r$ must be r-reductions. It remains to show that* (iii) *implies* (i). *Fix any set M such that* (iii) *is satisfied for some reduction cover for $\leq_r$. Given sets A and B that are both reducible to some set X, choose witnessing functionals Δ_0 and Δ_1 from this reduction cover. Then the functional Δ defined in* (17) *is an r-reduction. By construction, $\Delta(X)$ is equal to $\langle A, B\rangle^M$; hence the latter set is reducible to X. As a consequence, M satisfies* (i).

DEFINITION 36. *For a binary relation on 2^ω, $\mathcal{L}_r$ denotes the* CLASS OF LEAST SETS, *i.e, $\mathcal{L}_r = \{A : A \leq_r B$ for all sets $B\}$, and $\mathcal{M}_r$ denotes the* CLASS OF ADMISSIBLE CASES, *which is defined by*

$$\mathcal{M}_r \quad := \quad \{M : \text{ for all sets } A, B, X, \\ [A \leq_r X \text{ and } B \leq_r X \text{ implies } \langle A, B\rangle^M \leq_r X]\}.$$

For the bounded reducibility $\leq_{\mathrm{T}}^{\mathcal{P}}$ it is easy to see that the class of least sets $\mathcal{L}_{\mathrm{T}}^{\mathcal{P}}$ and the class of admissible cases $\mathcal{M}_{\mathrm{T}}^{\mathcal{P}}$ are both equal to $\mathcal{P}$; hence, in particular, for the relation $\leq_{\mathrm{T}}^{\mathcal{P}}$ the class of admissible cases is closed under the set theoretical operations union, intersection, and complement. Proposition 37 shows that the latter assertion holds for all standard reducibilities and that $\mathcal{M}_r$ is always included in $\mathcal{L}_r$. Example 38 shows that this inclusion is strict for faithful relations in general.

PROPOSITION 37. *Let $\leq_r$ be a faithful relation on 2^ω.*

(i) *$\mathcal{M}_r$ is a subset of $\mathcal{L}_r$.*

(ii) *$\mathcal{M}_r$ contains $\emptyset$ and is closed under the set theoretical operations union, intersection, and complement. Equivalently, $(\mathcal{M}_r, \subseteq)$ is a subalgebra of $(2^\omega, \subseteq)$.*

Proof. For a proof of the first assertion, recall that for a faithful relation $\leq_r$ the sets $\emptyset$ and ω are reducible to all other sets; hence by definition of $\mathcal{M}_r$ we have for all sets A and for all sets M in $\mathcal{M}_r$

$$M = \langle \omega, \emptyset\rangle^M \leq_r A.$$

The second assertion follows from the definition of $\mathcal{M}_r$ and because we have for all sets A, B, M, M_0, and M_1

$$\langle A, B\rangle^{\emptyset} = B, \quad \langle A, B\rangle^{\overline{M}} = \langle B, A\rangle^M, \quad \langle A, B\rangle^{M_0 \cap M_1} = \langle \langle A, B\rangle^{M_0}, B\rangle^{M_1},$$

where the equations, from left to right, show that $\mathcal{M}_r$ contains $\emptyset$ and is closed under complement and intersection. Closure under union then follows by De Morgan's laws. □

EXAMPLE 38. *A set is called* NON-SELF-DUAL *iff it is not $\leq_{\mathrm{m}}^{\mathcal{P}}$-reducible to its complement. Ladner, Lynch, and Selman* [14] *have shown that there are recursive non-self-dual sets. Choose such a set N and let*

$$A \leq_\nu B \;:\Leftrightarrow\; A \leq_{\mathrm{m}}^{\mathcal{P}} (B \oplus \overline{N}), \tag{18}$$

where $\overline{N}$ denotes the complement of N. Then the relation $\leq_\nu$ is faithful and the class of least sets $\mathcal{L}_\nu$ is exactly the lower $\leq_{\mathrm{m}}^{\mathcal{P}}$-cone of $\overline{N}$. Hence, in particular, $\mathcal{L}_\nu$ is not closed under complement, because it contains $\overline{N}$, but cannot contain the set N due to N being non-self-dual. Consequently, by Proposition 37, *$\mathcal{M}_\nu$ is strictly contained in $\mathcal{L}_\nu$.*

PROPOSITION 39. *For a standard reducibility $\leq_r$, the class $\mathcal{M}_r$ is a simulation class.*

Proof. We choose an effective reduction cover $\mathcal{R}$ for the standard reducibility $\leq_r$ that is closed under definition by oracle-dependent cases and under delayed patching. Let the latter closure property be witnessed by some functional simulation class $\mathcal{F}$; that is, $\mathcal{R} \otimes \mathcal{F}$ is contained in $\mathcal{R}$. Furthermore, we pick i and j such that the finite partial characteristic functions σ_i and σ_j are incompatible; that is, there is some y in ω where σ_i and σ_j are both defined and disagree. In particular, by our convention that σ_0 is the empty string, i and j differ from 0. For every set L, we let

$$f_L(x) := \begin{cases} 0 & \text{if } x = 0, \\ i & \text{if } x \neq 0 \text{ and } L(x) = 0, \\ j & \text{otherwise;} \end{cases}$$

that is, basically we replace in the characteristic function of L all values 0 with i and all values 1 with j. Furthermore, we let $f_L(0)$ be equal to 0 in order to ensure that for recursive L we can effectively obtain a delayed simulation s_L of f_L in $\mathcal{F}$. We let

$$M_L \;=\; \{y \in \omega : s_L(y) = j\}.$$

We leave it to the reader to check that, first, the set M_L thus defined is a delayed simulation of L for all sets L where $L(0) = 0$ holds and that, second, the definition of M_L can be made effective in the sense that there is a recursive function sim where for all sets $L = \varphi_e$ the set M_L is equal to $\varphi_{\mathrm{sim}(e)}$. Then, in order to show that $\mathcal{M}_r$ is a simulation class, it is sufficient to show that for every recursive set L, the set M_L is in fact in $\mathcal{M}_r$. We assume that A_0, A_1, and B are sets where A_0 and A_1 are both r-reducible to B. The standard reducibility $\leq_r$ is c.f.v. and consequently A_0 and A_1 are reducible to $\langle B, \sigma_i\rangle$ and $\langle B, \sigma_j\rangle$, respectively. Let the two latter facts be witnessed by functionals Γ_0 and Γ_1 in $\mathcal{R}$, respectively, and consider the functional

$$\Gamma := \langle \Gamma_0, \Gamma_1 \rangle^{\{X : \sigma_i \sqsubseteq X\}},$$

obtained from Γ_0 and Γ_1 via definition by oracle-dependent cases; i.e., in particular, Γ is again in $\mathcal{R}$. Moreover, as σ_i and σ_j have been chosen to be incompatible, Γ reduces A_0 to $\langle B, \sigma_i\rangle$ and A_1 to $\langle B, \sigma_j\rangle$. We obtain

$$\langle A_0, A_1\rangle^{M_L} \;=\; \langle \Gamma(\langle B, \sigma_i\rangle), \Gamma(\langle B, \sigma_j\rangle)\rangle^{M_L} \;=^* \; [\Gamma \otimes s_L](B) \;\leq_r \; B. \tag{19}$$

Hence, by $\leq_r$ being c.f.v., the set $\langle A_0, A_1\rangle^{M_L}$ is reducible to B; and it follows that M_L is in $\mathcal{M}_r$. The relations in (19) hold by definition of Γ and of M_L and because $\Gamma \otimes s_L$ is an r-reduction due to the closure properties of $\mathcal{R}$. Note that in (19) we cannot replace equality up to finite variation by equality because in general the delayed simulation s_L of f_L yields the value $f_L(0) = 0$ on a finite initial segment of the natural numbers. ∎

By Propositions 37 and 39, for every standard reducibility the corresponding class of admissible cases satisfies the conditions on $\mathcal{M}$ in the assumption of Lemma 40.

LEMMA 40 (coding lemma). *Let $\mathcal{M}$ be a simulation class that contains all finite sets and where the structure $(\mathcal{M}, \subseteq)$ is a subalgebra of $(2^\omega, \subseteq)$. Let $A_0, A_1, \ldots$ be a sequence of uniformly recursive sets and let G be a gap language. Then there are sets $R_0, R_1, \ldots$ in $\mathcal{M}$ and a gap language M in $\mathcal{M}$ where*

- *the set M is a gap cover for G;*

- *for all i and s in ω and for all x in block s of M we have $R_i(x) = A_i(s)$.*

We postpone the proof of the coding lemma to section 5. The point of the coding lemma is that it yields delayed simulations R_i of the sets A_i that are "synchronized" via the gap language M; that is, for all i and s the set R_i is constant on block s of M and has the value $A_i(s)$ there. The sets R_i in the coding lemma are uniformly recursive because the sets A_i are uniformly recursive and due to the second condition in the conclusion of the coding lemma.

4. Lattice embeddings.

4.1. The countable atomless Boolean algebra. In the proof of our main result on lattice embeddings we exploit a property of the countable atomless Boolean algebra stated in Fact 42. The corresponding technique was used before in connection with lattice embeddings for polynomially time-bounded reducibilities by Ambos-Spies [1]; see there for references to results about Boolean algebras.

DEFINITION 41. *An element of a Boolean algebra is an atom iff there is exactly one element (i.e., the least element 0) strictly below it. A Boolean algebra is atomless iff it does not contain atoms.*

The theory of the atomless Boolean algebra is ω-categorical; i.e., all countable atomless Boolean algebras are the same up to isomorphism and accordingly in what follows we will speak of *the* countable atomless Boolean algebra.

FACT 42. *Every countable distributive lattice can be embedded (as a lattice) into the countable atomless Boolean algebra with least and greatest element preserved.*

By Fact 42 and because lattice embeddings compose, it suffices to embed the countable atomless Boolean algebra into a structure in order to show that indeed every countable distributive lattices can be so embedded. When constructing such embeddings we will exploit Fact 44, which gives a representation of the countable atomless Boolean algebra by the equivalence classes induced by the finite variation relation on the class $\mathcal{P}$ of sets computable in polynomial time.

DEFINITION 43. *For every subclass $\mathcal{C}$ of 2^ω, let $\mathcal{C}^*:=\{[A] : A \text{ in } \mathcal{C}\}$, where $[A]$ denotes the equivalence class $\{X : X =^* A\}$ of A in 2^ω with respect to the finite variation relation. Furthermore, let $\leq^*$ denote the p.o. induced by the relation $\subseteq^*$; i.e., $[A] \leq^* [B]$ iff $A \subseteq^* B$.*

FACT 44. *The structure $(\mathcal{P}^*, \leq^*)$ is the atomless Boolean algebra.*

Fact 44 has been shown by Ambos-Spies [1], using Breidbart's splitting theorem [10]. Fact 44 can be generalized to the assertion that for the class $\mathcal{M}_r$ of admissible cases of a standard reducibility, the structure $({\mathcal{M}_r}^*, \leq^*)$ is always the countable atomless Boolean algebra [20].

4.2. Lattice embeddings. Theorem 45 states our main technical result on lattice embeddings for standard reducibilities. Recall that the concept of standard reducibility comprises not just the reducibilities listed in Example 18 but also many other resource-bounded reducibilities that appear in the literature and observe that Theorem 45 and its corollaries can be applied to all such reducibilities.

THEOREM 45. *Let $\leq_r$ be a standard reducibility and let A and B be recursive sets where $A <_r B$. Then any countable distributive lattice can be embedded (as a lattice) into the interval between A and B of $(\mathrm{REC}, \leq_r)$ with least or greatest element preserved.*

In addition, given recursively presentable classes $\mathcal{E}_0$ and $\mathcal{E}_1$ that are both c.f.v. and where $\mathcal{E}_0$ does not contain $A \oplus \emptyset$ and $\mathcal{E}_1$ does not contain $A \oplus B$, then the range of the embedding can be chosen to be disjoint from the union of $\mathcal{E}_0$ and $\mathcal{E}_1$, except that in

case we want to preserve the least element, the latter might be mapped to an element of $\mathcal{E}_1$, and likewise for the greatest element and $\mathcal{E}_0$.

The proof of Theorem 45 follows the lines of the corresponding result for polynomially time-bounded reducibilities due to Ambos-Spies [1]. Similarly to the case of polynomially time-bounded reducibilities, we obtain as special cases of Theorem 45 several structural properties of standard reducibilities. We briefly discuss these results before proving the theorem. Another result, which can be derived from the proof of the theorem, is stated below as Corollary 53.

COROLLARY 46. *Let $\leq_r$ be a transitive standard reducibility.*

(i) *Every recursive set is the g.l.b. of a pair of recursive sets.*

(ii) *Every recursive set not in $\mathcal{L}_r$ is the l.u.b. of a pair of recursive sets.*

(iii) *Every recursive set not in $\mathcal{L}_r$ bounds a minimal pair (i.e., there are two sets that are both reducible to the given set and such that the intersection of their lower cones coincides with the class $\mathcal{L}_r$ of least sets).*

(iv) *Let A and B be recursive sets where $A<_r B$. Then every recursively presentable antichain in the open interval between A and B is not maximal with this property.*

Proof. The first assertion is immediate by embedding the diamond (i.e., the four-element Boolean algebra) above the given set with least element preserved. Likewise, the second and third assertion follow by embedding the diamond into the interval between $\emptyset$ and the given set with greatest and least element preserved, respectively. In connection with the third assertion observe that for a transitive relation $\leq_r$, first, the lower cone of a greatest lower bound of two sets is equal to the intersection of the lower cones of these two sets and, second, the lower cone of a least set is just the class of least sets.

In order to show the last assertion, let $\{C_0, C_1, \ldots\}$ be a recursively representable antichain where $A<_r C_i<_r B$ for all i in ω. In order to extend the antichain by a single set in the open interval between A and B, it suffices to embed the three-element chain between A and B according to Theorem 45 while avoiding the recursively presentable classes

$$\mathcal{E}_0 := \bigcup_{i\in\omega}\{X : C_i \leq_r X \leq_r B\} \text{ and } \mathcal{E}_1 := \bigcup_{i\in\omega}\{X : X \leq_r C_i\}. \qquad \square$$

Proof of Theorem 45. We first construct an embedding into the given interval that preserves the least element and then indicate the minor changes necessary in the symmetric case where we want to preserve the greatest element. By the discussion following Fact 42, it suffices to embed the countable atomless Boolean algebra as required. In order to do so, we specify a partial order embedding of the structure $(\mathcal{P}^*, \leq^*)$ that preserves least upper bounds. We can then argue that the restriction of this mapping to some appropriate sublattice $(\mathcal{D}^*, \leq^*)$ of $(\mathcal{P}^*, \leq^*)$ is in fact a lattice embedding, i.e., preserves also greatest lower bounds. This then finishes the proof because $(\mathcal{D}^*, \leq^*)$ is chosen such that it is the countable atomless Boolean algebra.

We fix effective enumerations $D_0, D_1, \ldots$ of $\mathcal{P}$ and $\Delta_0, \Delta_1, \ldots$ of an effective reduction cover $\mathcal{R}$ of $\leq_r$ that witnesses that $\leq_r$ is a standard reducibility. While defining the embedding, we first construct sets $R_0, R_1, \ldots$ in $\mathcal{M}_r$ and define a mapping

$$\Pi : D_i \mapsto H(R_i) \text{ where } H(X) := \langle A \oplus B, A \oplus \emptyset\rangle^X. \tag{20}$$

Then we let Π' be a function from $\mathcal{P}^*$ to $\mathcal{P}$ such that $\Pi'([D_i])$ is always a set in $[D_i]$

and we let

$$\Pi'' \;:=\; \Pi \circ \Pi'.$$

The function Π'' works by first mapping an equivalence class in $\mathcal{P}^*$ to one of its elements and then applying the function Π; hence, in particular, Π'' is well defined. Moreover, Claim 1 shows that the range of Π and thus also the range of Π'' is indeed contained in the interval between A and B.

CLAIM 1. *For every set R in $\mathcal{M}_r$, we have $A \leq_r H(R) \leq_r B$.*

Proof. By Proposition 5, the set $A \oplus \emptyset$ is r-equivalent to A and is hence reducible to B. Moreover, by faithfulness of $\leq_r$, the set $A \oplus B$ is a l.u.b. for A and B and is hence reducible to the upper bound B of these sets. As a consequence and by definition of $\mathcal{M}_r$, $H(R)$ is reducible to B for every set R in $\mathcal{M}_r$. Furthermore, by definition of the join operator, any set of the form $H(X)$ can be written in the form $A \oplus Z$ for an appropriate set Z; hence A is reducible to $H(X)$ by faithfulness of $\leq_r$. □

CLAIM 2. *The set $A \oplus B$ is not r-reducible to $A \oplus \emptyset$.*

Proof. Assuming otherwise, $A \oplus B$ was reducible to A by Proposition 5. But then contrary to assumption, B was also reducible to A because $A \oplus B$ is a locally transitive l.u.b. for B due to faithfulness of $\leq_r$. □

In order to define the sets R_i that we have used while defining Π, we construct three recursive gap languages, G_1 through G_3. First, we apply the diagonalization lemma to the sets $A \oplus \emptyset$ and $A \oplus B$ in order to obtain a gap language G_1 such that for all sets X and Y

$$(X, Y) \simeq^{G_1} (A \oplus B, A \oplus \emptyset) \quad \text{implies} \quad X \not\leq_r Y. \tag{21}$$

Second, we apply the window lemma to the recursively presentable class

$$\mathcal{C} \quad := \quad \{H(X) : X \leq_r \emptyset\} \tag{22}$$

in order to obtain a gap a gap language G_2 such that every reduction to a set in $\mathcal{C}$ is witnessed by a functional Δ in $\mathcal{R}$ where for all x,

$$\mathrm{u}(\Delta, x) \subseteq \mathrm{Nb}(x, G_2); \tag{23}$$

i.e., the generalized use of Δ at x is always contained in the neighborhood $\mathrm{Nb}(x, G_2)$ of x.

Third, we choose a recursive gap language G_3 such that, first, every set that is G_3-similar to $A \oplus \emptyset$ is not contained in $\mathcal{E}_0$ and, second, every set that is G_3-similar to $A \oplus B$ is not contained in $\mathcal{E}_1$. In order to do so, we choose block k of G_3 so large that both $A \oplus \emptyset$ and $A \oplus B$ disagree on this block with the first k sets in $\mathcal{E}_0$ and $\mathcal{E}_1$, respectively.

By the discussion preceding the coding lemma, the class $\mathcal{M}_r$ of admissible cases of the standard reducibility $\leq_r$ satisfies the conditions on the class $\mathcal{M}$ in the assumption of the coding lemma. By applying the coding lemma to $\mathcal{M}_r$, to the enumeration $D_0, D_1, \ldots$ of the class $\mathcal{P}$, and to a recursive gap cover G of G_1 through G_3, we obtain sets $R_0, R_1, \ldots$ in $\mathcal{M}_r$ and a set M in $\mathcal{M}_r$ that is a gap cover of G and hence also of G_1 through G_3.

CLAIM 3. *For all i and j, $D_i \subseteq^* D_j$ iff $R_i \subseteq^* R_j$.*

Proof. Claim 3 is immediate by choice of the sets $R_1, R_2, \ldots$ and by the second condition in the conclusion of Lemma 40. □

CLAIM 4. *For all i, the set $\Pi(D_i)$ is a finite variation of $\Pi''([D_i])$ and thus, in particular, the two sets are r-equivalent.*

Proof. Let j be the index such that D_j is equal to $\Pi'([D_i])$. Then, in particular, D_j is a finite variation of D_i and, by Claim 3, R_j is a finite variation of R_i. Now Claim 4 follows by the definitions of Π and Π''. □

In the following claims, the sets in the image of Π'' figure in such a way that the truth values of the assertions under consideration are not changed by replacing these sets with r-equivalent sets. Thus by Claim 3 in the corresponding proofs we can replace the images under Π'' with the corresponding images under Π.

CLAIM 5. *The function Π'' respects ordering.*

Proof. Assume $[D_i] \leq^* [D_j]$, i.e., $D_i \subseteq^* D_j$ and, by Claim 3, $R_i \subseteq^* R_j$. By the definition of Π, the set $\Pi(D_j)$ agrees with $A \oplus B$ on all places x in R_j and hence for almost all places x in R_i. We obtain

$$\Pi(D_i) = \langle A \oplus B, A \oplus \emptyset \rangle^{R_i} =^* \langle \Pi(D_j), A \oplus \emptyset \rangle^{R_i} \leq_r \Pi(D_j), \tag{24}$$

where the relations hold, from left to right, by definition of Π, by the preceding discussion, and finally because R_i is in $\mathcal{M}_r$ and because by Claim 1 the set A and hence by Proposition 5 also the set $A \oplus \emptyset$ is reducible to $\Pi(D_j)$. Due to $\leq_r$ being c.f.v., it is immediate from (24) that $\Pi(D_i)$ is reducible to $\Pi(D_j)$. □

CLAIM 6. *The function Π'' respects nonordering.*

Proof. Assume $[D_i] \not\leq^* [D_j]$, i.e., $D_i \not\subseteq^* D_j$ and, by Claim 3, $R_i \not\subseteq^* R_j$. Then there are infinitely many numbers and—because by construction the sets R_i and R_j are constant on the blocks of M—in fact there are infinitely many blocks of M where R_i is equal to 1, while R_j is equal to 0. By definition of Π, on each such block of M, $\Pi(D_i)$ agrees with $A \oplus B$ and $\Pi(D_j)$ agrees with $A \oplus \emptyset$; hence we have

$$(A \oplus B, A \oplus \emptyset) \simeq^M (\Pi(D_i), \Pi(D_j)). \tag{25}$$

By construction, M is a gap cover for the gap language G_1 obtained from applying the diagonalization lemma. Thus, by Remark 27, assertion (25) remains valid with M replaced by G_1 and $\Pi(D_i)$ is not reducible to $\Pi(D_j)$ because of (21). □

CLAIM 7. *The function Π'' respects l.u.b.'s.*

Proof. The l.u.b. of $[D_i]$ and $[D_j]$ in $(\mathcal{D}^*, \leq^*)$ is $[D_i \cup D_j]$. By Claim 5, the set $\Pi(D_i \cup D_j)$ is an upper bound for $\Pi(D_i)$ and $\Pi(D_j)$. So it remains to show that if the two latter sets are both reducible to some set Y, then so is $\Pi(D_i \cup D_j)$. The latter follows from

$$\begin{array}{rclcl} \Pi(D_i \cup D_j) & = & \langle A \oplus B, A \oplus \emptyset \rangle^{R_i \cup R_j} & = & \langle A \oplus B, \langle A \oplus B, A \oplus \emptyset \rangle^{R_j} \rangle^{R_i} \\ & = & \langle A \oplus B, \Pi(D_j) \rangle^{R_i} & = & \langle \Pi(D_i), \Pi(D_j) \rangle^{R_i} \leq_r Y, \end{array}$$

where the relations hold by the definition of Π and the choice of the sets R_k, by the properties of definition by number-dependent cases, by definition of $\Pi(D_j)$, because $\Pi(D_i)$ agrees with $A \oplus B$ on all numbers in R_i, and finally by assumption on Y and because R_i is in $\mathcal{M}_r$. □

Up until now we have seen that Π'' is a partial order embedding that preserves l.u.b.'s. We will now show that the restriction of Π'' to the class

$$\mathcal{D} := \{\{3 \cdot x : x \in D\} : D \in \mathcal{P}\}$$

also preserves g.l.b's. It is easy to see that $\mathcal{D}$ is a recursively presentable subclass of $\mathcal{P}$ and that $(\mathcal{D}^*, \leq^*)$ is isomorphic to $(\mathcal{P}^*, \leq^*)$. By the latter assertion and Fact 44, $(\mathcal{D}^*, \leq^*)$ is the countable atomless Boolean algebra.

CLAIM 8. *The restriction of the function Π'' to the subclass $\mathcal{D}^*$ of $\mathcal{P}^*$ respects g.l.b.'s (with respect to the structure $(\mathcal{D}^*, \leq^*)$).*

Proof. We fix sets D_i and D_j in $\mathcal{D}$. The g.l.b. of $[D_i]$ and $[D_j]$ in $(\mathcal{D}^*, \leq^*)$ is $[D_i \cap D_j]$ and so we have to show that $\Pi(D_i \cap D_j)$ is the g.l.b. of $\Pi(D_i)$ and $\Pi(D_j)$. By Claim 5, $\Pi(D_i \cap D_j)$ is a lower bound for the two latter sets. So it remains to show that if a set X is reducible to both of $\Pi(D_i)$ and $\Pi(D_j)$, then X is also reducible to $\Pi(D_i \cap D_j)$.

By Proposition 37, $\mathcal{M}_r$ is contained in the class $\mathcal{L}_r$ of least sets, which in turn is contained in the lower cone of $\emptyset$. Thus for every R in $\mathcal{M}_r$, the set $H(R)$ is in the class $\mathcal{C}$ defined in (22); i.e., in particular, the range of Π is contained in $\mathcal{C}$. Now G_2 has been obtained by applying the window lemma to the class $\mathcal{C}$ and $\mathcal{R}$; i.e., every reduction to a set in the range of Π is witnessed by a functional in $\mathcal{R}$ such that its generalized use at place x is always contained in $\mathrm{Nb}(x, G_2)$ and hence, by Remark 34, is always contained in $\mathrm{Nb}(x, M)$. As a consequence, the assumed reductions from X imply that there are functionals Δ_k and Δ_l in $\mathcal{R}$ with

$$X \;=\; \Delta_k(\Pi(D_i)) \;=\; \Delta_l(\Pi(D_j))$$

such that for all places x we have

$$\mathrm{u}(\Delta_k, x) \subseteq \mathrm{Nb}(x, M) \qquad \text{and} \qquad \mathrm{u}(\Delta_l, x) \subseteq \mathrm{Nb}(x, M). \tag{26}$$

For every m in ω, let $N(m)$ be equal to the set $\{m-1, m, m+1\} \setminus \{-1\}$ and let

$$\begin{aligned} I &:= \{m \in \omega : D_i \text{ and } D_i \cap D_j \text{ agree on } N(m)\}, \\ L &:= \{x \in \omega : x \text{ is in block } m \text{ of } M \text{ for some } m \text{ in } I\}. \end{aligned}$$

Then given x in L, we infer from the definition of Π that the sets $\Pi(D_i)$ and $\Pi(D_i \cap D_j)$ agree on $\mathrm{Nb}(x, M)$; hence by assumption on Δ_k we obtain that

$$x \in L \quad \text{implies} \quad \Delta_k(\Pi(D_i \cap D_j), x) \;=\; \Delta_k(\Pi(D_i), x) \;=\; X(x). \tag{27}$$

On the other hand, given x not in L, where we assume that x is in block m of M, then D_i and $D_i \cap D_j$ differ on $N(m)$; i.e., there must be some number in $N(m)$ that is in D_i but is not in D_j. However, the two latter sets contain only multiples of three, while for any m the set $N(m)$ contains exactly one multiple of three; hence the intersection of $N(m)$ with D_j is empty. Thus, the sets $\Pi(D_j)$ and $\Pi(D_i \cap D_j)$ have an empty intersection with $\mathrm{Nb}(x, M)$ and similar to (27) we infer

$$x \notin L \quad \text{implies} \quad \Delta_l(\Pi(D_i \cap D_j), x) \;=\; \Delta_l(\Pi(D_j), x) \;=\; X(x). \tag{28}$$

From (27) and (28) we then obtain

$$X \;=\; \langle \Delta_k(\Pi(D_i \cap D_j)), \Delta_l(\Pi(D_i \cap D_j)) \rangle^L \;.$$

This finishes the proof of Claim 8 because by definition I is in $\mathcal{P}$; i.e., I is equal to some set D_t; hence the set L is equal to R_t and is in $\mathcal{M}_r$. □

It remains to show the assertions on avoiding the classes $\mathcal{E}_0$ and $\mathcal{E}_1$ and on preserving the least or the greatest element. The former assertion follows easily from the definition of Π because G has been chosen as a gap cover of G_3 and because all equivalence classes in $\mathcal{D}^*$ that are strictly above the least equivalence class contain only sets that are infinite and coinfinite. Furthermore, the embedding Π preserves

the least element because it maps the least equivalence class in $\mathcal{D}^*$, which contains all finite sets, to a set that is r-equivalent to $A \oplus \emptyset$, where by Proposition 5 the latter set is r-equivalent to A, which is a least set of the interval between A and B. On the other hand, if we want to construct an embedding that preserves the greatest element, it suffices to replace in the construction the class $\mathcal{D}$ with the class

$$\{\{3 \cdot x : x \in D\} \cup \{3 \cdot x + 1 : x \in \omega\} \cup \{3 \cdot x + 2 : x \in \omega\} : D \in \mathcal{P}\},$$

i.e., to arrange that, intuitively speaking, the noncoding gaps of the sets in the image of the constructed embedding are filled with $A \oplus B$ instead of $A \oplus \emptyset$. Then the greatest equivalence class, which contains exactly the cofinite sets, is mapped to a set that is r-equivalent to $A \oplus B$. However, $A \oplus B$ is a locally transitive upper bound for B and thus any set that is reducible to B is also reducible to $A \oplus B$; hence the latter set is a greatest set in the interval bounded by A and B. □

4.3. Lattice embeddings for bounded reducibilities on ω^ω. The concept of standard reducibility extends canonically to binary relations on ω^ω. However, the concepts used in the definition of standard reducibilities have to be adjusted as follows.

(i) Effective reduction covers are defined with respect to the standard enumeration of partial recursive functionals from ω^ω to ω^ω.

(ii) In the definition of faithfulness, we consider arbitrary constant functions instead of just $\emptyset$ and ω; that is, for example, we require that for all functions f and for all constant functions g the lower cone of $f \oplus g$ is contained in the lower cone of f.

(iii) A tt-condition can again be defined to be a subclass of ω^ω where membership in the class depends only on the function values at a fixed finite set of places. However, when defining the concept of closure under definition by oracle-dependent cases, we consider only tt-conditions that can be generated from classes of the form $\{g : g(i) = j\}$ with i and j in ω by finitely many applications of union, intersection, and complement. Observe that it is not reasonable to require that closure under definition by oracle-dependent cases holds with respect to all tt-conditions because for any set X the class of all functions g where $g(0)$ is in X is a tt-condition.

(iv) In the definition of delayed patching the enumeration of finite partial characteristic functions is replaced by an appropriate effective enumeration of all partial functions from ω to ω with finite domain.

Using these adjusted concepts, the concept STANDARD REDUCIBILITY ON $\boldsymbol{\omega^\omega}$ can be introduced by literally the same formulation as in Definition 17; i.e., we require that the relation under consideration is faithful and c.f.v. and has an effective reduction cover that is closed under delayed patching and under definition by oracle-dependent cases. An example for a standard reducibility on ω^ω is given by the reducibility introduced by Mehlhorn [18] via his class of basic feasible functionals.

Theorem 45 on lattice embeddings for standard reducibilities on 2^ω extends to standard reducibilities on ω^ω.

THEOREM 47. *Let $\leq_r$ be a standard reducibility on ω^ω and let f and g be recursive functions where $f <_r g$. Then any countable distributive lattice can be embedded (as a lattice) into the interval between f and g of $(\mathrm{REC}, \leq_r)$ with least or greatest element preserved.*

In addition, given recursively presentable subclasses $\mathcal{E}_0$ and $\mathcal{E}_1$ of ω^ω that are c.f.v. and where $\mathcal{E}_0$ does not contain $f \oplus \emptyset$ and $\mathcal{E}_1$ does not contain $f \oplus g$, the range of the embedding can be chosen to be disjoint from the union of $\mathcal{E}_0$ and $\mathcal{E}_1$, except that in

case we want to preserve the minimum, the minimal element might be mapped to an element of $\mathcal{E}_1$, and likewise for the maximum and $\mathcal{E}_0$.

We omit the proof of Theorem 47, which is essentially the same as for Theorem 45 except that we have to take into account that in general the "use" of a recursive functional on ω^ω is unbounded. (Consider, for example, the functional Γ defined by $\Gamma(f,x) := f(f(x))$.) In order to handle this problem, we relativize the concept of generalized use to an appropriate effectively compact subclass of ω^ω, i.e., to a class $\mathcal{C}$ that can be written in the form

$$\mathcal{C} \quad = \quad \bigotimes_{i \text{ in } \omega} C_i, \tag{29}$$

where each set C_i is finite and a list of its elements can be computed from i. Defining the generalized use $\mathrm{u}^{\mathcal{C}}(\Delta, x)$ with respect to such an effectively given class $\mathcal{C}$ similarly as before, we obtain in particular that for every f in $\mathcal{C}$, the value $\Gamma(f,x)$ is determined by the restriction of f to the finite set $\mathrm{u}^{\mathcal{C}}(\Gamma, x)$. Furthermore, the following variants of the diagonalization lemma and the window lemma that are relativized to some effectively compact subclass of ω^ω can be shown as before.

LEMMA 48 (diagonalization lemma for reducibilities on $\boldsymbol{\omega^\omega}$). *Let $\leq_r$ be a bounded reducibility on ω^ω that is c.f.v., let e and f be recursive functions where $e \not\leq_r f$, and let $\mathcal{C}$ be some effectively compact subclass of ω^ω. Then there is a recursive gap language G such that we have for all functions e' and f' in $\mathcal{C}$*

$$(e,f) \simeq^G (e',f') \text{ implies } e' \not\leq_r f'.$$

LEMMA 49 (window lemma for reducibilities on $\boldsymbol{\omega^\omega}$). *Let $\mathcal{R}$ be a reduction cover for a reducibility on ω^ω and let the class $\mathcal{C}_0$ be recursively presentable such that $\mathcal{C}_0$ is contained in some effectively compact class $\mathcal{C}$. Then there is a recursive gap language G such that every reduction to a function in $\mathcal{C}_0$ is witnessed by a reduction $\Delta \in \mathcal{R}$, where $\mathrm{u}^{\mathcal{C}}(\Delta, x)$ is always contained in $\mathrm{Nb}(x, G)$.*

Lemmas 48 and 49 can be shown in exactly the same way as the original claims. The remainder of the proof of Theorem 45 then goes through by applying the adapted lemmas to the effectively compact class

$$\mathcal{C} := \bigotimes_{i \in \omega} \{[f \oplus \emptyset](i), [f \oplus g](i)\},$$

where f and g are the functions that bound the given interval. The class $\mathcal{C}$ contains all functions obtained from $f \oplus \emptyset$ and $f \oplus g$ via definition by cases with sets in $\mathcal{M}_r$, and thus $\mathcal{C}$ contains all functions in the range of the embedding Π.

4.4. Embeddings of partial orderings and decidability. In the following, we consider results on bounded reducibilities that are related to Theorem 45 on lattice embeddings for standard reducibilities but can be derived from more general assumptions. The first result of this type is Theorem 50, which amounts to an extension of Schöning's uniform diagonalization theorem [30] from a setting of polynomial time-bounds to arbitrary simulation classes. The content of Theorem 50 is roughly the same as Schmidt's Theorem 3.1 [29]; however, we formulate the result in our terms and consider only lower cones instead of arbitrary classes (see also Remark 54 below). In connection with Theorem 50, recall that a nonempty class $\mathcal{C}$ is recursively presentable if there is a recursive set E such that $\mathcal{C} = \{C_0, C_1, \dots, \}$ where $C_j = \{x : \langle x, j\rangle \text{ in } E\}$.

THEOREM 50 (Schmidt [29]). *Let $\leq_r$ be a bounded reducibility such that $\mathcal{M}_r$ is a simulation class. Then for any set A the lower r-cone of A cannot be the disjoint union of two nonempty recursively presentable classes that are c.f.v.*

Proof. Fix any set A and for a proof by contradiction assume that its lower r-cone is the disjoint union of two nonempty recursively presentable classes $\mathcal{C}_0$ and $\mathcal{C}_1$ that are c.f.v. For $i = 0, 1$, let the recursive set E_i witness that $\mathcal{C}_i$ is recursively presentable; i.e., $\mathcal{C}_i = \{C_0^i, C_1^i, \dots, \}$ where $C_j^i = \{x : \langle x, j\rangle \text{ in } E_i\}$. By assumption, we can choose sets D_0 and D_1 in the lower r-cone of A such that D_i is in $\mathcal{C}_{1-i}$ but not in $\mathcal{C}_i$.

We construct a recursive gap language G in stages $s = 0, 1, \dots$, where during stage s block s of G is defined. This then determines G by letting $G(0)$ be equal to 0. The first block I_0 just contains 0. Then, given the first s blocks $I_0, \dots, I_{s-1}$, the finite block I_s is chosen so large that every set that agrees on I_s with D_0 disagrees on I_s with C_0^0 through C_s^0 and, likewise, every set that agrees on I_s with D_1 disagrees there with C_0^1 through C_s^1. Such a block I_s exists (and can indeed be found effectively) because $\mathcal{C}_0$ and $\mathcal{C}_1$ are c.f.v.; hence D_i differs from each set in $\mathcal{C}_i$ at infinitely many places. We omit the details of the argument, which is similar to the one used in the proof of Lemma 28. Next, according to Lemma 59, we choose in the simulation class $\mathcal{M}_r$ a gap cover M for G. Then by construction and contrary to our assumption, the set

$$\langle D_0, D_1\rangle^M$$

is in the lower r-cone of A but is neither contained in $\mathcal{C}_0$ nor in $\mathcal{C}_1$. □

COROLLARY 51. *Let $\leq_r$ be a bounded reducibility that is faithful and c.f.v. and where the class $\mathcal{M}_r$ of admissible cases is a simulation class. Then the structure $(\mathrm{REC}, \leq_r)$ is dense.*

Proof. Fix recursive sets A and B where $A <_r B$ and consider the classes

$$\mathcal{C}_0 := \{X : X \leq_r A\} \qquad \mathcal{C}_1 := \{X : X \leq_r B \text{ and } B \leq_r X \oplus A\}.$$

By definition, the two classes are contained in the lower r-cone of B and by assumption on $\leq_r$ they are c.f.v. and recursively presentable. Thus by Theorem 50, the union of the two classes is strictly contained in the lower r-cone of B. However, for any set X that is r-reducible to B but is not in $\mathcal{C}_0$ or $\mathcal{C}_1$, the set $X \oplus A$ is contained in the open interval bounded by A and B. □

REMARK 52. *Let $\leq_r$ be a bounded reducibility that satisfies the assumption of Theorem 50 and let $\{\Delta_0, \Delta_1, \dots\}$ be an effective reduction cover for $\leq_r$. Consider two recursive sets A and B where A is r-reducible to B, but not vice versa, and let $\mathcal{D}$ be the nonempty class of all sets that are r-reducible to B but not to A. Then the class $\mathcal{D}$ cannot be recursively presentable. Otherwise, $\mathcal{D}$ and the lower r-cone of A were both recursively presentable and c.f.v., while the lower r-cone of B is the disjoint union of these two classes; i.e., we would obtain a contradiction to Theorem 50.*

By standard methods that involve the arithmetization of the computation of a Turing machine, we can construct an arithmetical formula δ in one free variable such that $\delta(e)$ is true in the standard model of the natural numbers iff $\Delta_e(B)$ is in $\mathcal{D}$. Then there cannot be an effective formal system in which we can derive the formula $\delta(e)$ exactly for the indices e such that $\delta(e)$ is true in the standard model. For a proof, observe that if there were such a formal system, then the set D of all such indices would be recursively enumerable and as a consequence, the class $\mathcal{D}$, which is equal to $\{\Delta_e(B) : e \in D\}$, would be recursively presentable. In a context of bounded reducibilities, results of this type have been obtained, among others, by Schöning [30]

and Regan [26]. *In a context of $\mathcal{NP}$ optimization problems similar results are given by Merkle* [21] *(unfortunately without mentioning the closely related and much earlier results of Schöning, Regan, and others, while just referring to the related work of Schmidt* [29]*).*

A strengthening of Corollary 51 to embeddings of partial orderings into intervals of the recursive sets can be obtained as a corollary to the proof of Theorem 45. A corresponding assertion has been stated by Mehlhorn [18] for reducibilities that satisfy his set of axioms.

COROLLARY 53. *Let $\leq_r$ be a faithful bounded reducibility that is c.f.v. and such that $\mathcal{M}_r$ is a simulation class. Then every countable partial ordering can be embedded into every proper interval of the structure* $(\mathrm{REC}, \leq_r)$.

Proof. It is known that every countable partial ordering can be embedded (as a partial ordering) into the countable atomless Boolean algebra. Furthermore, the proof of Theorem 45 shows that the assumption of Corollary 53 is sufficient for constructing partial order embeddings of the countable atomless Boolean algebra (indeed, of any countable distributive lattice) into any proper interval bounded by two recursive sets. So we are done because embeddings of partial orderings compose. □

REMARK 54. *The axiomatic approach of Schmidt* [29] *is based on the concept recursive gap closure, where a subclass $\mathcal{M}$ of 2^ω is* RECURSIVELY GAP CLOSED *iff for every recursive gap language G there is a set M in $\mathcal{M}$ such that the set M, as well as its complement, contain infinitely many blocks of G. (This formulation slightly deviates from the original definition, where only gap languages are considered for which strings of the same length are always in the same block.)*

Every simulation class $\mathcal{S}$ is recursively gap closed. For a proof, observe that given a recursive gap language G, then by Lemma 59 *there is some gap cover M for G in $\mathcal{S}$, and in particular M and its complement contain infinitely many blocks of G. On the other hand, there are recursively gap closed classes that are not simulation classes and that in fact do not even contain delayed simulations of all gap languages. For example, consider the subclass $\mathcal{D}$ of the recursive sets where for each set in the class there are infinitely many x where x is in the set, but $x-1$ and $x+1$ are not. Then for every set in $\mathcal{D}$, its characteristic function contains infinitely often the "pattern"* 010*. Hence the class $\mathcal{D}$, for example, contains neither a delayed simulation of the empty set nor of the recursive gap language that has the characteristic sequence* 011011011 ....

Schmidt demonstrates for several complexity classes that they are gap closed. From her proofs it is immediate that these classes are in fact simulation classes. In particular, we obtain that the class of sets simultaneously computable in linear time and logarithmic space is a simulation class. Note in this connection that Regan [26] *shows that even slightly more restrictive resource-bounds are sufficient for performing Ladner-style delayed diagonalization constructions.*

REMARK 55. *Regan and Vollmer* [28] *show results on partial order embeddings for various reducibilities of many-one type that run in logarithmic time. Typically, for given reduction function f and input x, within this time-bound just a single bit of $f(x)$ has to be computed. Hence in general for any unbounded function l, no matter how slow l grows, it will take more than logarithmic time to compute the complete value $f(x)$ even for inputs x with $f(x) \leq l(x)$. This indicates that such reducibilities will not allow patching of the oracle as required with standard reducibilities and that accordingly Theorem* 45 *on embeddings of countable distributive lattices does not apply. Yet, depending on the details of its definition, a reducibility restricted to logarithmic time will usually satisfy the assumption used to derive the results of this section.*

5. Proving the coding lemma. In this section we give the still missing proof of the coding lemma, which we have stated as Lemma 40. In its proof we use the recursion theorem in a form described in Remark 56.

REMARK 56. *If we specify a procedure that computes uniformly effectively in a given index e a partial function γ_e, then, by the smn-theorem, there is a recursive function g where $\varphi_{g(e)}$ is equal to γ_e for all e in ω. According to the recursion theorem, there is some index e_0, referred to as fixed point of g, where*

$$\varphi_{e_0} \;=\; \varphi_{g(e_0)} = \gamma_{e_0}.$$

In case we can ensure certain properties of the constructed partial function γ_e under the assumption that the given index e is an index for γ_e, we succeed in constructing a partial function with these properties because for the fixed point e_0 our assumption will be true.

In recursion theory, the following, more convenient form of this technique is widely used. Instead of viewing the index e as an argument, we assume that already during the definition of some partial recursive function γ we can use an index for γ, i.e., an index e with $\gamma = \varphi_e$. As Soare [33, p. 38] *points out, in the definition of γ we must not rely on any specific assumptions on e; i.e., while we are just interested in the cases where the number e used in our construction is indeed an index for the function under construction, in order to render the construction valid we have to ensure that the constructed partial function γ is in fact partial recursive in e.*

Subsequently, we will apply this technique by giving an effective procedure that enumerates the graph of a partial function γ, while using in the construction an index for γ. In order to address the problem mentioned in the last paragraph, we apply the following convention.

> *In case the partial function γ is eventually defined during the construction at a place x, then $\gamma(x)$ is equal to the value that is assigned first; otherwise, $\gamma(x)$ is undefined.*

It should be clear that by this convention there is always some recursive function g such that for all e, $\varphi_{g(e)}$ is equal to the function γ that we specify under the possibly wrong assumption that e is an index for the function under construction. For example, we can choose a function g that assigns to e, intuitively speaking, a Turing machine $M_{g(e)}$ that computes $\gamma(x)$ by simulating the construction of γ on the given index e until x enters the domain of γ. Then, if for some specific index e, the construction of γ "gets stuck", this simply means that the domain of $\gamma = \varphi_{g(e)}$ is finite and contains only the places that have been assigned values so far.

Remark 58 shows that in a simulation class we are not only able to find effectively delayed simulations of recursive sets but in fact we can find so—appropriately defined—delayed simulations of arbitrary partial recursive functions from ω to $\{0,1\}$.

DEFINITION 57. *A set S is a* delayed simulation *of a partial characteristic function α iff there is a nondecreasing function l from ω to ω where for all x in ω we have $S(x) = \alpha(l(x))$ and where the range of l is $\{z \in \omega : \alpha(y)$ is defined for all $y \leq z\}$.*

REMARK 58. *For every simulation class $\mathcal{S}$ there is a recursive function* sim *from ω to ω such that for all e in ω, first, $\varphi_{\mathrm{sim}(e)}$ is in $\mathcal{S}$ and, second, $\varphi_{\mathrm{sim}(e)}$ is a delayed simulation of φ_e in case $\varphi_e(0)$ is equal to 0. In fact, this is essentially the definition of simulation class except that now we require the second condition on delayed simulations for all e and not just for e where φ_e is a set.*

For a proof, recall from Example 10 *that the class of functions computable in polynomial time is a functional simulation class. Thus the class $\mathcal{P}$ of sets computable in*

polynomial time is a simulation class. Let sim_0 *be a witnessing function for the latter fact that corresponds to the type of simulation described in Example* 10. *Then* sim_0 *witnesses that the assertion we want to prove holds for* $\mathcal{S} = \mathcal{P}$. *As a consequence, if* sim_1 *witnesses that* $\mathcal{S}$ *is a simulation class, then the function* $\mathrm{sim}{:=}\mathrm{sim}_1 \circ \mathrm{sim}_0$ *has the required properties. More precisely, given some index* e *in* ω, *then* $\varphi_{\mathrm{sim}_1(\mathrm{sim}_0(e))}$ *is obviously in* $\mathcal{S}$. *Furthermore, if function* l_0 *witnesses that* $\varphi_{\mathrm{sim}_0(e)}$ *is a delayed simulation of* φ_e, *and* l_1 *witnesses that* $\varphi_{\mathrm{sim}_1(\mathrm{sim}_0(e))}$ *is a delayed simulation of* $\varphi_{\mathrm{sim}_0(e)}$, *then* $l_0 \circ l_1$ *witnesses that* $\varphi_{\mathrm{sim}(e)}$ *is a delayed simulation of* φ_e.

Before we prove the coding lemma, we consider the simpler assertion stated in Lemma 59 in order to demonstrate the techniques used. The notation and the subroutines used in the proof of Lemma 59 then are partially reused in the more involved proof of the coding lemma.

LEMMA 59. *Let* $\mathcal{S}$ *be a simulation class and let* G *be a recursive gap language. Then* $\mathcal{S}$ *contains a gap cover of* G.

Proof. Figure 1 shows an effective procedure that enumerates the graph of some partial characteristic function γ. By Remark 56, we can assume that an index e for the function under construction is already available during the construction; that is, we have $\gamma = \varphi_e$, and the specification of γ might depend on e.

Now $\mathcal{S}$ is a simulation class; hence we can choose a recursive function sim according to Remark 58; i.e., in particular, for all e in ω with $\varphi_e(0) = 0$, $\varphi_{\mathrm{sim}(e)}$ is a delayed simulation of φ_e in $\mathcal{S}$. Therefore, by letting $\gamma(0) = 0$, during the construction of γ we do not only have available some index e for γ but also the delayed simulation $M{:=}\varphi_{\mathrm{sim}(e)}$ of γ in $\mathcal{S}$. In the verification of the construction we then show that the set M in fact is a gap cover for G.

We first give an outline of the construction and sketch the ideas on which its verification is based. The course of values of γ is rather simple. If γ is defined at all at some place s, then it is equal to $\omega \oplus \emptyset$; that is, $\gamma(s)$ is 0 in case s is even, and $\gamma(s)$ is 1, otherwise. The actual load of the construction is to decide successively for $s = 1, 2, \ldots$ whether $\gamma(s)$ is to be defined or not. Thus, during the construction γ can always be written as

$$\gamma{:=}(\omega \oplus \emptyset)|\{0, \ldots, s\}, \tag{30}$$

where $s{:=}\max \mathrm{dom}(\gamma)$ is in block s of γ. (Recall that we start counting blocks with number zero.) In a situation where (30) holds, informally we denote block s of M as the open block of the construction. Now, by choice of sim and by definition of M, the set $M = \varphi_{\mathrm{sim}(e)}$ is a delayed simulation of $\gamma = \varphi_e$, and consequently at any point of the construction we have the following properties of the open block

(i) The open block exists because if γ has at least s blocks, then so does its delayed simulation M.

(ii) The open block is finite iff φ_e is defined at place $s + 1$.

The construction is based on the following idea: in the situation of (30) we refrain from defining γ at place $s + 1$ unless we can verify that the open block contains some block of G. As a consequence the open block indeed contains some block of G. In case γ indeed remained undefined at place $s+1$, then the open block would be infinite but would not contain a block of the gap language G, which is a plain contradiction. So, intuitively speaking, if we add block $s + 1$ of γ only after verifying that block s of M is large enough, then block s of M indeed is large enough. Next we give a formal proof of Lemma 59 by proving a series of claims.

CLAIM 1. *On entering stage s of the construction we have $\gamma{:=}(\omega \oplus \emptyset)|\{0,\dots,s\}$.*

Proof. Recall that the course of values of $\omega \oplus \emptyset$ is $01010\dots$. Claim 1 now follows by an easy induction argument that exploits the definitions of the construction and of the procedure *close_the_open_block*. □

CLAIM 2. *If the procedure* cover_some_block_of_G *is called during stage s of the construction, then the procedure terminates and block s of M contains some block of G.*

Proof. Let the procedure be called during some stage s of the construction. By Claim 1, on entering the procedure we have $s = \max \operatorname{dom}(\gamma)$ and γ has exactly s blocks. Thus the delayed simulation M has at least s blocks, and on start of the procedure z and y are set equal to the minimal element of block s of M, and the while loop is entered. During the iterations of the while loop, the set $\{z,\dots,y\}$ is always contained in block s of M, and consequently, by the condition in the head of the while loop, if the while loop is eventually left, then block s of M must contain some block of G. Now, assume for a contradiction that the while loop is never left and that consequently γ will remain undefined at place $s+1$ for the rest of the construction. Then the delayed simulation M of γ has exactly s blocks, and $M(y) = M(y+1)$ holds for all places y that are greater than the minimal element z in block s of M. So y goes to infinity, and the condition in the head of the while loop eventually becomes false because all blocks of the gap language G are finite. Hence the while loop is eventually left, contrary to our assumption. □

CLAIM 3. *M is a gap cover for G.*

Proof. By inspection of the construction and from Claim 2 we infer that the construction passes through all stages $s = 0, 1, \dots$. Thus Claim 1 shows that the delayed simulation M of γ has infinitely many blocks, and Claim 2 implies that each block of M contains some block of G; that is, M is a gap cover for G. □

Next we give the proof of the coding lemma, which has been already stated as Lemma 40. The proof of the coding lemma relies on the same idea as the proof of Lemma 59 but is combinatorially more involved.

LEMMA 60 (coding lemma). *Let $A_0, A_1, \dots$ be a sequence of uniformly recursive sets and let G be a recursive gap language. Let $\mathcal{M}$ be a simulation class that contains all finite sets and where the structure $(\mathcal{M}, \subseteq)$ is a subalgebra of $(2^\omega, \subseteq)$. Then there are sets $R_0, R_1, \dots$ in $\mathcal{M}$ and a gap language M in $\mathcal{M}$ such that*

- *the set M is a gap cover for G;*
- *for all i and s in ω and for all x in block s of M, it holds $R_i(x) = A_i(s)$.*

Proof. For a given gap language M, we call the blocks with numbers $0, 2, 4, \dots$ even blocks of M and, likewise, the remaining blocks of M are called odd. It is sufficient to show that given $\mathcal{M}$, G, and $A_0, A_1, \dots$ as in the assumption of the coding lemma, there is a gap language M in $\mathcal{M}$ and sets $S_1, S_2, \dots$ in $\mathcal{M}$ where, first, M is a gap cover for G and, second,

(i) for all x in an odd block s of M and for all i in ω, we have $S_{2i+1}(x) = A_i(s)$;

(ii) for all x in an even block s of M and for all i in ω, we have $S_{2i+2}(x) = A_i(s)$;

that is, for every i, the set S_{2i+2} is constant on each even block of M and attains on these blocks the values $A_i(0), A_i(2), A_i(4), \dots$, respectively, and a similar remark holds for the sets S_{2i+1} and the odd blocks of M. Given sets M and $S_1, S_2, \dots$ as above, we let

$$R_i := (S_{2i+1} \cap M) \cup (S_{2i+2} \cap \overline{M}),$$

where, due to $\mathcal{M}$ being closed under complement, we can assume $M(0) = 0$; i.e., M is the union of its odd blocks. By choice of the sets S_k, the sets R_i satisfy the

second condition required in the coding lemma. Furthermore, the sets R_i are in $\mathcal{M}$, because M and the set S_k are, and because $\mathcal{M}$ is a subalgebra of $(2^\omega,\subseteq)$. Note that it is actually sufficient to show that there are sets S_k that satisfy condition (i) and (ii) for almost all x because by assumption the subalgebra $\mathcal{M}$ contains all finite sets and is hence c.f.v.

We denote by γ^j row j of a partial characteristic function γ; that is, γ^j denotes the partial characteristic function that maps x to $\gamma(\langle x,j\rangle)$. We let r be a recursive function such that for all e the number $r(e,j)$ is an index for row j of φ_e, and we assume that $\mathcal{M}$ is a simulation class via a function sim; i.e., $\varphi_{\mathrm{sim}(e)}$ is a delayed simulation of φ_e whenever $\varphi_e(0)$ is equal to 0.

Similar to the proof of the cover lemma, we give an effective enumeration of the graph of a partial characteristic function γ where according to Remark 56 we can use an index e with $\gamma=\varphi_e$ during the specification of γ. In the construction of this enumeration, we will refer by γ to the finite partial characteristic function of which the graph has already been enumerated, and likewise we will refer by γ^j to row j of this intermediate partial characteristic function. For the index e given to the construction, we let

$$S_k \;:=\; \varphi_{\mathrm{sim}(r(e,k))} \qquad \text{and} \qquad M \;:=\; S_0 \;=\; \varphi_{\mathrm{sim}(r(e,0))};$$

that is, for all $k\geq 0$ the set S_k, which we informally denote as row k, is a delayed simulation of row k of φ_e. Note that thus for any given index e the meaning of M and S_k is fixed ahead of the construction. In the verification of the construction we

can then assume that the index e used in the construction is indeed an index for the function γ constructed in order to show that the sets M and $S_1, S_2, \dots$ have the required properties.

The construction is shown in Figures 2 and 3. Before we formally verify the construction, we give an informal description of stage s of the construction. Like in the verification of Lemma 59, at any stage of the construction, denote block $\max \operatorname{dom}(\gamma^k)$ as the open block of S_k. We assume that s is even, while the considerations for the symmetric case where s is odd are essentially the same. During stage s, first row s is initialized, and then we consider all rows $k \leq s$ where k is odd. We have to ensure that for all such k the sets S_k do not have a block-change in an odd block of M. Furthermore, if we let i be equal to k div 2, then in case $A_i(s-1)$ differs from $A_i(s+1)$, the set S_k must have exactly one block-change within block s of M, while in case $A_i(s-1)$ is equal to $A_i(s+1)$, the set S_k must not have a block-change within block s of M. In the latter case, we leave γ^k untouched, and otherwise we enforce the necessary block change by first forcing the open block of S_k to extend beyond the minimum of the open block of M, then closing the open block of S_k, and then extending the open block of M beyond the minimum of the (new) open block of S_k. These extensions are handled by the procedure *compare*, where by an invocation *compare(k,l)* we force the open block of S_l to contain an element that is greater or equal to the least element in the open block of S_k. Finally, we ensure that the open block of M contains some block of G and close the open block of M.

CLAIM 1. *Every call to close_the_open_block and to cover_some_block_of_G during the construction results in a terminating computation.*

Proof. The assertion is immediate in the case of the former procedure, while in the case of *cover_some_block_of_G* the argument is basically the same as for the corresponding claim in the proof of Lemma 59. □

In the remainder of the proof, we will use the following notation: a set I extends beyond the minimum of a set J iff we have $\min J \leq x$ for some x in I.

CLAIM 2. *Assume that on a call compare(k,l) during the construction we have*

$$m_k := \max \operatorname{dom}(\gamma^k) \quad \textit{and} \quad m_l := \max \operatorname{dom}(\gamma^l).$$

Some subroutines

⋆ The following two routines are the same as in Figure 1
⋆ with γ replaced by γ^j and γ^0, respectively

close_the_open_block(j)
$m{:=}\max\mathrm{dom}(\gamma^j)$
$\gamma^j(m+1){:=}1-\gamma^j(m)$

cover_some_block_of_G
$z{:=}\min\{i\in\omega:\mathrm{bn}(M,i)=\max\mathrm{dom}(\gamma^0)\}$
$y{:=}z$
while $\{z,\dots,y\}$ *does not contain some block of* G
if $M(y)=M(y+1)$, *then* $y{:=}y+1$

initialize_row(k)
$\gamma^k(0){:=}0$
if $A_{[k\ div\ 2]}(s)=1$, *then* $\gamma^k(1){:=}1$
compare(k,0)

compare(k,l)
$y{:=}\min\{i\in\omega:\mathrm{bn}(S_l,i)=\max\mathrm{dom}(\gamma^l)\}$
$z{:=}\min\{i\in\omega:\mathrm{bn}(S_k,i)=\max\mathrm{dom}(\gamma^k)\}$
while $y\not\leq z$
if $S_l(y)=S_l(y+1)$, *then* $y{:=}y+1$

FIG. 3. *Some subroutines used in the construction of the sets* M *and* S_i.

Then this call results in a terminating computation, and block m_l *of* S_l *extends beyond the minimum of block* m_k *of* S_k.

Proof. Similar to the case of the procedure *cover_some_block_of_G* we obtain that on entering *compare*, y and z are indeed set to the minimal elements in the open blocks of row k and l, respectively. Obviously, if the while loop is eventually left, then block m_l of S_l extends beyond the minimum of block m_k of S_k. Now, assuming that the while loop is never left, we infer that γ and a fortiori row l of γ will never be altered afterwards, and, consequently, the open block of row l is infinite and y goes to infinity; that is, the while loop is eventually left, contrary to our assumption. □

CLAIM 3. *The construction passes through infinitely many stages.*

Proof. The proof is immediate by the construction and Claims 1 and 2. □

CLAIM 4. *The set* M *is a gap cover for* G.

Proof. Similar to the proof of Claim 3 in the proof of Lemma 59 where γ is replaced with γ^0. □

We say that block-change n of a set C occurs within some set I iff the set C has at least $n+1$ blocks and the maximum of block n of C and the minimum of block $n+1$ are both in I.

CLAIM 5. *Let* C *and* D *be sets and let* I *be some block of* D. *If block* n *of* C *extends beyond the minimum of* I *and* I *in turn extends beyond the minimum of block* $n+1$ *of* C, *then block-change* n *of* C *occurs within* I.

Proof. The claim is immediate by the definition of the concepts involved. □

CLAIM 6. *For all k, s, and n in ω where $0 < k \leq s$, the number $n+1$ enters the domain of γ^k during stage s iff block-change n of S_k occurs in block s of M.*

Proof. We show first that if $n+1$ enters the domain of γ^k during stage $s \geq k$, then block-change n of S_k occurs in block s of M. In case $n+1$ enters the domain of γ^k during stage s, this is due to a call *close_the_open_block(k)* in the body of the *if* statement. So this call is preceded by a call *compare(0,k)*, and is followed by a call *compare(k,0)* where on both calls $\max \operatorname{dom}(\gamma^0)$ is equal to s, and $\max \operatorname{dom}(\gamma^k)$ is equal to n and $n+1$ on the first and on the second call, respectively. Then, if we let I be equal to block s of M, we obtain by Claim 4 that block n of S_k extends beyond the minimum of I and that in turn I extends beyond the minimum of block $n+1$ of S_k. Hence by Claim 5, the block-change n of S_k occurs in I. Conversely, if $n+1$ does not enter the domain of γ^k, then for S_k block-change n does not exist, and if $n+1$ enters the domain of γ^k during some stage s_0 different from s, then by the above argument block-change n of S_k occurs in block s_0 of M and not in block s. □

CLAIM 7. *For every k, each block of M contains at most one block-change of S_k.*

Proof. The proof is immediate from Claim 5 and the construction because at each stage at most one element enters the domain of any γ^k. □

CLAIM 8. *For all k, s in ω where $k \leq s$ and for $i := k \operatorname{div} 2$, the set S_k has a block-change in block s of M iff exactly one of k and s is odd and $A_i(s-1)$ differs from $A_i(s+1)$.*

Proof. It is obvious from the construction that any element enters the domain of γ^k during stage $s \geq k$ iff exactly one of k and s is odd and $A_i(s-1)$ differs from $A_i(s+1)$. So the assertion follows by Claim 6. □

CLAIM 9. *For every i in ω,*

for almost all x in an odd block s of M we have $S_{2i+1}(x) = A_i(s)$;
for almost all x in an even block s of M we have $S_{2i+2}(x) = A_i(s)$.

Proof. We show the assertion for the odd blocks and leave the similar proof for the even blocks to the reader. Let $k = 2i+1$ for some $i \geq 0$ and consider stage k of the construction. During the procedure *initialize_row*, row k of γ is changed such that $\gamma^k(\max \operatorname{dom}(\gamma^k))$ is equal to $A_i(s)$, and due to the call of the procedure *compare* and Claim 2 it follows that block s of M extends beyond the minimum of the open block of S_k. Now, the assertion follows by an easy induction argument because for each odd block $s = 2j+1 > k$ we have by Claim 8 that either $A_i(s-1)$ is equal to $A_i(s+1)$ and there occurs no block-change of S_k within the blocks $s-1$, s, and $s+1$ of M, or $A_i(s-1)$ and $A_i(s+1)$ differ and there occurs exactly one block-change of S_k within block s of M, but none within the blocks $s-1$ and $s+1$. □

DECIDABILITY OF TERMINATION OF GRID STRING REWRITING RULES*

ALFONS GESER†

Abstract. Termination of string rewriting is known undecidable. Termination of string rewriting with only one rule is neither known decidable nor known undecidable. This paper presents a decision procedure for rules $u \to v$ such that some letter b from u occurs as often or less often in v. We call such rules "grid" rules. By far most rules are grid rules. Grid rules cover all rules which terminate by a total division order. Thus total division orders are shown to be irrelevant for the termination problem of one-rule string rewriting.

Key words. semi-Thue system, string rewriting system, one-rule, termination, grid rule, total division order

1. Introduction and related work. String rewriting systems (SRSs) are a widely used model for computation and reasoning in finitely generated monoids. SRSs can simulate Turing machines, so many interesting properties such as confluence, local confluence, termination, and decidability of the word problem are undecidable. An intriguing question is which restricted classes of SRSs still have Turing power and which do not.

SRSs that comprise of only *one rule* have decidable local confluence and confluence problems [7, 16]. We are interested in the open problem of whether termination, too, is decidable for one-rule SRSs. It is reasonable to expect that the study of this problem will have a major impact on termination of arbitrary SRSs.

The slightly more extended class of one-rule left-linear, nonoverlapping term rewriting systems has an undecidable termination problem [2]. String rewriting with three rules also suffices for an undecidable termination problem [10]. In contrast one-rule string rewriting looks too simple. As McNaughton [12] put it, "We seem to be able to decide whether any such system is uniformly terminating."

Kurth [7] started a systematic exploration of the termination problem for one-rule SRSs. He gave a number of criteria for termination and for the existence of looping reductions of lengths 1 or 2 (and of length 3 in [8]), and implemented a sieve that, from a lexicographic enumeration of all canonical representatives of one-rule SRSs, passes only those that satisfy none of his criteria.

Kurth arrived at a characterization of termination for all (100207 representatives of) length increasing SRSs $u \to v$, $|v| \leq 6$. He had to solve by hand 32 systems that passed his sieve. By the variety and difficulty of the proofs he was led to conjecture that termination is undecidable for one-rule SRSs.

Shikishima-Tsuji, Katsura, and Kobayashi [15] reduce the termination problem of confluent one-rule SRSs to the termination problem of nonoverlapping one-rule SRSs.

McNaughton [11] conjectures that nonoverlapping one-rule SRSs have a decidable termination problem.

McNaughton [11] gives a powerful decidable property, called "left barren," that entails termination of nonoverlapping SRSs. McNaughton [12], moreover, proves that "well-behaved" SRSs have a decidable termination problem, not only in the one-rule case. This class contains terminating SRSs as well as looping ones. Kobayashi, Katsura, and Shikishima-Tsuji [6] introduce a wider class of "gentle" rules but do not offer a decidability result for this class.

Zantema and Geser [17, 18] characterized termination for systems of the form $0^p1^q \to 1^r0^s$. Sénizergues [14] showed that termination is decidable for the class $\{0^p1^q \to v \mid p, q \geq 1, v \in \{0,1\}^*\}$. For the same class, Kobayashi, Katsura, and Shikishima-Tsuji [6] added a complete characterization.

In this paper we contribute a decidability result for a wide class of rules.

DEFINITION 1.1. *A string rewriting rule $u \to v$ is called a* grid *rule if some letter b from u occurs in v as often or less often.*

The case "less often" is trivial; "as often" is the interesting case. We obtain as the main result of this paper the following characterization.

THEOREM 1.2. *Every nonterminating grid rule has a loop of length* 1 *or* 2.

By Kurth's characterizations (see Theorems 4.2 and 4.3), the existence of a loop of length 1 or 2 is decidable, whence termination of grid rules is decidable. It can even be shown that there is a linear-time decision procedure. Moreover, it is possible to extract an exponential upper bound on reduction lengths from the proof of Theorem 1.2. The interested reader may find proofs of these two claims in the technical report [3].

The class of grid rules is indeed a wide class, not only for its trivial part. It contains all rules that terminate by a total division order (Theorem 6.3). Total division orders are a widely used method for termination proofs in string rewriting. For instance, the recursive path order on strings [9] or the Knuth–Bendix order on strings [5] are total division orders. In spite of an enormous research effort, the space of total division orders is largely unexplored. Our results show that total division orders are irrelevant for the termination problem of one-rule SRSs.

The main part of the paper provides a proof of Theorem 1.2. After the preliminaries (section 2) we derive termination criteria of ascending strength. In section 3 we show that $u \to v$ terminates unless u and v have certain shapes. Particularly, we identify two strings, x_0 and x_n, on which the termination behavior crucially depends. In section 4 we give proofs for the remaining hard cases and finish the proof of Theorem 1.2. Section 5 gives an impression of the distribution of grid rules for the case $|v| = 7$. In section 6 we state and prove Theorem 6.3.

2. Preliminaries. A string is a sequence of letters from a given alphabet. Variables ranging over letters will be denoted by a, b, c, d; variables ranging over strings by z, y, x, etc., and indexed variants thereof.

We denote the empty string by ε; the concatenation of strings s and t by st; the length of a string s by $|s|$; the number of occurrences of a letter b in s by $\#_b(s)$.

Let $u \to v$ be a one-rule SRS over alphabet Σ. The induced reduction relation $\to$ is defined by the following: $u' \to v'$ if there are strings s, t such that $u' = sut$ and $v' = svt$.

s is called a *factor* of t if $t = xsy$ for some strings x, y; a *prefix* if $t = sy$ for some string y; a *suffix* if $t = xs$ for some string x. A prefix or suffix s of t is called *proper* if $s \neq t$. A string s is said to have the self-overlap t if $t \neq \varepsilon$, $s \neq t$, and there are strings x, y such that $s = xt = ty$.

Let $\to^*$ denote the reflexive-transitive closure of $\to$; i.e., $s \to^* t$ denotes that there is a reduction from s to t. Then $u \to v$ is called *confluent* if for every forking pair of reductions, $w_0 \to^* w_1$ and $w_0 \to^* w_2$, there is a joining pair of reductions, $w_1 \to^* w_3$ and $w_2 \to^* w_3$. By a result of Wrathall [16], confluence of length increasing one-rule SRSs is characterized by the property that all self-overlaps of u are also self-overlaps of v. This is the case, particularly, if $u \to v$ is *nonoverlapping*; i.e., u has no self-overlap.

The SRS $u \to v$ is called *terminating* if there is no infinite reduction sequence $u_1 \to u_2 \to \cdots$. Conveniently, termination is proven by giving a well-founded order $>$ on strings such that $sut > svt$ holds for all strings s, t.

An order $>$ on Σ induces a lexicographic order $>_{lex}$ on Σ^* by the following: $s = a_0a_1 \cdots a_n >_{lex} b_0b_1 \cdots b_n = t$ if (i) t is a proper prefix of s or (ii) there is $0 \le i \le \min\{m, n\}$ such that $a_i > b_i$ and $a_j = b_j$ for all $0 \le j < i$. It is known that for a well-founded order $>$ its lexicographic order $>_{lex}$ is well founded on strings of bounded length.

Every string s admits a unique *decomposition*, $s = s_0bs_1b \ldots bs_n$, where b does not occur in s_i, $0 \le i \le n$. The *tuple representation*, $T(s)$, of a string s is the sequence of strings $(s_0, s_1, \ldots, s_n)$ if $s = s_0bs_1b \ldots bs_n$ is the decomposition of s. For f, a function from strings to a set $\mathcal{D}$, the tuple representation *through* f is the sequence $T_f(s) = (f(s_0), f(s_1), \ldots, f(s_n))$ of elements of $\mathcal{D}$.

Our class of SRSs is particularly amenable to tuple representations (through any f) for proving termination by a lexicographic order because the tuples $T_f(sut)$ and $T_f(svt)$ have the same length.

3. The simple cases. Throughout the paper let $u \to v$ be a string rewriting rule, and let Σ denote the least alphabet containing all letters of uv. Let $b \in \Sigma$ be a letter such that $\#_b(u) > 0$ and $\#_b(u) \ge \#_b(v)$; i.e., $u \to v$ is a grid rule. If $\#_b(u) > \#_b(v)$, then $u \to v$ terminates (see, e.g., [7, Kriterium A]). This is the trivial case. Henceforth let $\#_b(u) = \#_b(v) = n$ for some $n > 0$. Then u and v are uniquely decomposed as

$$u = u_0bu_1 \cdots bu_n,$$
$$v = v_0bv_1 \cdots bv_n$$

for some $u_i, v_i \in (\Sigma \setminus \{b\})^*$, $0 \le i \le n$. In this section we are going to show that $u \to v$ terminates unless the u_i and v_i have a particular shape.

LEMMA 3.1. *If u_0 is not a suffix of v_0, then $u \to v$ terminates.*

By duality w.r.t. reversal of strings, one obtains at once the following: If u_n is not a prefix of v_n, then $u \to v$ terminates.

$acba \to accbac$ terminates by Lemma 3.1 because ac is not a suffix of acc. Likewise, $acbcbcbac \to acabacbcbac$ terminates by Lemma 3.1 because ac is not a suffix of aca. Note that in these examples the left-hand side of the rule is a subsequence of the right-hand side of the rule. This shows that termination cannot be proven by a division order (see also section 6).

Proof. Let $sut \to svt$ be an arbitrary reduction step by the rule $u \to v$. Let s' be the longest suffix of s that does not contain the letter b, and let t' be the longest prefix of t that does not contain the letter b. Distinguish cases whether $|u_0| > |v_0|$ or not.

Case $|u_0| > |v_0|$. Form the b-tuple representation through $f(w) = |w|$. Since $|s'u_0| > |s'v_0|$, one gets

$$\begin{aligned} T_f(sut) &= (\dots, |s'u_0|, |u_1|, \dots, |u_{n-1}|, |u_n t'|, \dots) \\ &> {}_{lex}(\dots, |s'v_0|, |v_1|, \dots, |v_{n-1}|, |v_n t'|, \dots) = T_f(svt), \end{aligned}$$

where the leftmost and the rightmost dots indicate the same left and right contexts.

Case $|u_0| \le |v_0|$. Form the b-tuple representation through

$$f(w) = \begin{cases} 1 & \text{if } w \text{ has suffix } u_0, \\ 0 & \text{else.} \end{cases}$$

By premise, then $f(s'u_0) = 1$ and $f(s'v_0) = 0$. Now

$$\begin{aligned} T_f(sut) &= (\dots, 1, f(u_1), \dots, f(u_{n-1}), f(u_n t'), \dots) \\ &> {}_{lex}(\dots, 0, f(v_1), \dots, f(v_{n-1}), f(v_n t'), \dots) = T_f(svt). \end{aligned}$$ □

Henceforth let us exclude the case where Lemma 3.1 or its dual apply. In other words we will assume that $v_0 = x_0 u_0$ and $v_n = u_n x_n$ for some strings x_0, x_n. That is,

$$u = \quad u_0 b u_1 \dots b u_{n-1} b u_n, \tag{3.1}$$

$$v = x_0 u_0 b v_1 \dots b v_{n-1} b u_n x_n \tag{3.2}$$

for some $x_0, x_n, u_0, \dots, u_n, v_1, \dots, v_{n-1} \in (\Sigma \setminus \{b\})^*$.

Now if $u_i = v_i$ for all $1 \le i \le n-1$, then u is a factor of v. Particularly for $n = 1$ one gets $v = x_0 u_0 b u_1 x_1$ which contains $u = u_0 b u_1$ as a factor; this already proves the case $n = 1$ of Theorem 1.2. If u is not a factor of v, then $n \ge 2$.

In the following lemma we use the regular expression $y x_0^* u_0$ to denote the set of strings $\{y x_0^p u_0 \mid p \ge 0\}$.

LEMMA 3.2. *If for some $1 \le i \le n-1$ there is no string y such that $u_i \ne v_i$ and $u_i, v_i \in y x_0^* u_0$, then $u \to v$ terminates.*

In *abba* $\to$ *aabaabaa* the factor $u_1 = \varepsilon$ has not the suffix $u_0 = a$ and $v_1 = aa \ne u_1$. In *bab* $\to$ *aabaaba*, one gets $u_0 = \varepsilon$, and so $u_1 = a = y u_0$ with $y = a$. Here $v_1 = aa \notin a(aa)^* \varepsilon = y x_0^* u_0$. Both SRSs are instances of Lemma 3.2, one per case of the proof below.

Again, by duality one gets termination if, for some $1 \le i \le n-1$, there is no string z such that one has $u_i \ne v_i$ and $u_i, v_i \in u_n x_n^* z$.

Proof. Let i be minimal. We distinguish cases whether or not u_i has suffix u_0.

Case 1. u_i has no suffix u_0. Then form the b-tuple representation through

$$f(w) = \begin{cases} 1 & \text{if } w = u_i, \\ 0 & \text{else.} \end{cases}$$

Note that $f(w) = 0$ holds for all strings w that have suffix u_0. Particularly, $f(s'u_0) = 0 = f(s'x_0u_0)$. By minimality of i one gets $f(u_j) = f(v_j)$ for all $1 \le j \le i-1$, either because $u_j = v_j$ or because both u_j and v_j have suffix u_0. So

$$\begin{aligned} T_f(sut) &= (\dots, 0, f(u_1), \dots, f(u_{i-1}), 1, f(u_{i+1}), \dots, f(u_n t'), \dots) \\ &> {}_{lex}(\dots, 0, f(v_1), \dots, f(v_{i-1}), 0, f(v_{i+1}), \dots, f(u_n x_n t'), \dots) = T_f(svt). \end{aligned}$$

Case 2. If u_i has suffix u_0, then there is y such that $u_i \in yx_0^*u_0$. Let y be shortest: y has no suffix x_0. By premise, now $v_i \notin yx_0^*u_0$. Form a b-tuple representation through

$$f(w) = \begin{cases} 1 & \text{if } w \in yx_0^*u_0, \\ 0 & \text{else.} \end{cases}$$

Let s' denote the longest suffix of s that does not contain b, and let t' denote the longest prefix of t that does not contain b. If $s' \in yx_0^*$, then $f(s'u_0) = 1 = f(s'x_0u_0)$, or else $f(s'u_0) = 0 = f(s'x_0u_0)$. By minimality of i, for all $1 \le j \le i-1$ either $u_j = v_j$, and so $f(u_j) = f(v_j)$, or there is a string y' that has no suffix x_0 such that $u_j, v_j \in y'x_0^*u_0$. If $y' = y$, then $f(u_j) = 1 = f(v_j)$, or else $f(u_j) = 0 = f(v_j)$. Then

$$\begin{aligned} &T_f(sut) \\ &\quad = (\dots, \quad f(s'u_0), f(u_1), \dots, f(u_{i-1}), 1, f(u_{i+1}), \dots, f(u_{n-1}), f(u_nt'), \dots) \\ &\quad >_{lex} (\dots, f(s'x_0u_0), f(v_1), \dots, f(v_{i-1}), 0, f(v_{i+1}), \dots, f(v_{n-1}), f(u_nx_nt'), \dots) \\ &\quad = T_f(svt). \qquad \square \end{aligned}$$

One can draw a few consequences of Lemma 3.2 that are useful during section 4.

LEMMA 3.3. *If $x_0 = \varepsilon$ and u is not a factor of v, then $u \to v$ terminates.*
