A POLYNOMIAL TIME APPROXIMATION SCHEME FOR GENERAL MULTIPROCESSOR JOB SCHEDULING*

JIANER CHEN† AND ANTONIO MIRANDA‡

Abstract. Recently, there have been considerable interests in the multiprocessor job scheduling problem, in which a job can be processed in parallel on one of several alternative subsets of processors. In this paper, a polynomial time approximation scheme is presented for the problem in which the number of processors in the system is a fixed constant. This result is the best possible because of the strong NP-hardness of the problem and is a significant improvement over the past results: the best previous result was an approximation algorithm of ratio $7/6 + \epsilon$ for 3-processor systems based on Goemans's algorithm for a restricted version of the problem.

Key words. job scheduling, approximation algorithm, polynomial time approximation scheme, multiprocessor processing

1. Introduction.

One of the assumptions made in classical scheduling theory is that a job is always executed by one processor at a time. With advances in parallel algorithms, this assumption may no longer be valid for job systems. For example, in semiconductor circuit design workforce planning, a design project is to be processed by a group of people. The project contains n jobs, and each job can be worked on by one of a set of alternatives, where each alternative consists of one or more persons in the group working simultaneously on the particular job. The processing time of each job depends on the subgroup of people being assigned to handle the job. Note that the same person may belong to several different subgroups. Now the question is how we can schedule the jobs so that the project can be finished as early as possible. Other applications include (i) the berth allocation problem [23], where a large vessel may occupy several berths for loading and unloading, (ii) diagnosable microprocessor systems [22], where a job must be performed on parallel processors in order to detect faults, (iii) manufacturing, where a job may need machines, tools, and people simultaneously (this gives an example for a system in which processors may have different types), and (iv) scheduling a sequence of meetings where each meeting requires a certain group of people [11]. In the scheduling literature [17], these kinds of problems are called *multiprocessor job scheduling* problems.

Among the others, two types of multiprocessor job scheduling problems have been extensively studied [7, 24]. The first type is the $P_m|fix|C_{\max}$ problem, in which the subset of processors and the processing time for parallel processing each job are fixed. The second type is a more general version, the $P_m|set|C_{\max}$ problem, in which each job may have a number of alternative processing modes and each processing

mode specifies a subset of processors and the job processing time on that particular processor subset. The objective for both problems is to construct a scheduling of minimum makespan on the m-processor system for a given list of jobs. The jobs are supposed to be nonpreemptive.

Approximability of the multiprocessor job scheduling problems has been studied. The $P_2|set|C_{\max}$ problem is a generalized version of the classical job scheduling problem on a 2-processor system [13]; thus it is NP-hard. Hoogeveen, van de Velde, and Veltman [18] showed that the $P_3|fix|C_{\max}$ problem (thus also the $P_3|set|C_{\max}$ problem) is NP-hard in the strong sense; thus it does not have a fully polynomial time approximation scheme unless P = NP (see also [4, 5]). Blazewicz et al. [4] developed a polynomial time approximation algorithm of ratio 4/3 for the problem $P_3|fix|C_{\max}$, which was improved later by Dell'Olmo, Speranza, and Tuza [10], who gave a polynomial time approximation algorithm of ratio 5/4 for the same problem. Both algorithms are based on the study of a special type of schedulings called *normal schedulings*. Goemans [14] further improved the algorithms by giving a polynomial time approximation algorithm of ratio 7/6 for the $P_3|fix|C_{\max}$ problem. More recently, Amoura et al. [1] developed a polynomial time approximation scheme for the problem $P_m|fix|C_{\max}$ for every fixed integer m.

Approximation algorithms for the $P_m|set|C_{\max}$ problem were not as successful as that for the $P_m|fix|C_{\max}$ problem. Bianco et al. [3] presented a polynomial time approximation algorithm for the $P_m|set|C_{\max}$ problem whose approximation ratio is bounded by m. Chen and Lee [8] improved their algorithm by giving a polynomial time approximation algorithm for the $P_m|set|C_{\max}$ problem with an approximation ratio $m/2 + \epsilon$. Miranda [25] showed that the problem $P_3|set|C_{\max}$ can be approximated in polynomial time with a ratio $7/6 + \epsilon$. Before the present paper, it was unknown whether there is a polynomial time approximation algorithm with ratio c for the problem $P_m|set|C_{\max}$, where c is a constant independent of the number m of processors in the system.

In this paper, we present a polynomial time approximation scheme for the problem $P_m|set|C_{\max}$. Our algorithm combines the techniques developed by Amoura et al. [1], who split jobs into large jobs and small jobs, and the techniques developed by Dell'Olmo, Speranza, and Tuza [10] and Goemans [14] on normal schedulings, plus the standard dynamic programming and scaling techniques. More precisely, based on a classification of large jobs and small jobs, we introduce the concept of (m, ϵ)-*canonical schedulings*, which can be regarded as a generalization of the normal schedulings. We show that for any job list, there is an (m, ϵ)-canonical scheduling whose makespan is very close to the optimal makespan. Then we show how this (m, ϵ)-canonical scheduling can be approximated. Combining these two steps gives us a polynomial time approximation scheme for the $P_m|set|C_{\max}$ problem.

Our result is the best possible in the following sense: because the problem $P_m|set|C_{\max}$ is NP-hard in the strong sense, it is unlikely that our algorithm can be further improved to a fully polynomial time approximation scheme [13]. Moreover, the polynomial time approximation scheme cannot be extended to the more general problem $P|set|C_{\max}$, in which the number m of processors in the system is given as a parameter in the input: it can be shown that there is a constant $\delta > 0$ such that the problem $P|set|C_{\max}$ has no polynomial time approximation algorithms whose approximation ratio is bounded by n^δ [25].

The paper is organized as follows. Section 2 gives necessary background and preliminaries for the problem. In section 3 we introduce (m, ϵ)-canonical schedulings

and study their properties. Section 4 presents the polynomial time approximation scheme for the problem $P_m|set|C_{\max}$ and section 5 concludes with some remarks and further research directions.

2. Preliminaries. We assume readers' familiarity with the basic concepts in approximation theory [13], such as approximation algorithms, approximation ratios, polynomial time approximation schemes, and fully polynomial time approximation schemes.

The $P_m|set|C_{\max}$ problem is a scheduling problem minimizing the makespan for a set of jobs, each of which may have several alternative processing modes. More formally, an instance $\mathcal{J}$ of the problem $P_m|set|C_{\max}$ is a list of jobs: $\{J_1, J_2, \ldots, J_n\}$, where each job J_i is associated with a list of alternative *processing modes*: $J_i = [M_{i1}, \ldots, M_{ip_i}]$. Each processing mode (or simply *mode*) M_{ij} is specified by a pair (Q_{ij}, t_{ij}), where Q_{ij} is a subset of processors in the m-processor system and t_{ij} is an integer indicating the parallel processing time of the job J_i on the processor set Q_{ij}. In case there is no ambiguity, we also say that the processor set Q_{ij} is a mode for the job J_i. For each job $J_i = [M_{i1}, \ldots, M_{ip_i}]$, where $M_{ij} = (Q_{ij}, t_{ij})$, we let $\min_i$ be the minimum t_{ij} over all j, $1 \le j \le p_i$. The value $\min_i$ will be called the *minimum parallel processing time* for the job J_i.

Given a list $\mathcal{J} = \{J_1, \ldots, J_n\}$ of jobs, a *scheduling* $\Gamma(\mathcal{J})$ of $\mathcal{J}$ on the m-processor system consists of two parts: (1) determination of a processing mode for each job J_i in $\mathcal{J}$ and (2) determination of the starting execution time for each job under the assigned mode so that at any moment, each processor in the system is used for (maybe parallel) processing at most one job (assuming that the system starts at time $\tau = 0$). The *makespan* of the scheduling $\Gamma(\mathcal{J})$ is the latest finishing time of a job in $\mathcal{J}$ under the scheduling $\Gamma(\mathcal{J})$. Let $Opt(\mathcal{J})$ denote the minimum makespan over all schedulings for $\mathcal{J}$. The $P_m|set|C_{\max}$ problem is for a given instance $\mathcal{J}$ to construct a scheduling of makespan $Opt(\mathcal{J})$ for $\mathcal{J}$.

Let P_m be the set of the m processors in the m-processor system. A collection $\{P'_1, \ldots, P'_k\}$ of k nonempty subsets of P_m is a *k-partition* of P_m if $P_m = \bigcup_{i=1}^{k} P'_i$ and $P'_i \cap P'_j = \emptyset$ for all $i \ne j$. A collection of subsets of P_m is a *partition* of P_m if it is a k-partition for some integer $k \ge 1$. The total number B_m of different partitions of the set P_m is called the mth *Bell number* [16]. It can be proved easily by induction that $B_m \le m!$.

Another combinatorial fact we need for analysis of our scheduling algorithm is the "cut-index" in a nonincreasing sequence of integers.

LEMMA 2.1. *Let $\mathcal{T} = \{t_1, t_2, \ldots, t_n\}$ be a nonincreasing sequence of integers, let $m \ge 2$ be a fixed integer, and let $\epsilon > 0$ be an arbitrary real number. Then there is an index j_0 (with respect to m and ϵ) such that*

(1) *$j_0 = (3mB_m + 1)^k$, where $k \le \lfloor m/\epsilon \rfloor$ is an integer and*
(2) *for any subset $\mathcal{T}'$ of at most $3j_0mB_m$ integers t_q in $\mathcal{T}$ with $q > j_0$, we have*

$$\sum_{t_q \in \mathcal{T}'} t_q \le (\epsilon/m) \sum_{i=1}^{n} t_i.$$

Proof. To simplify expressions, let $b_m = 3mB_m + 1$. Decompose the sum $t_1 + t_2 + \cdots + t_n$ into subsums

$$A_1 = t_1 + \cdots + t_{b_m},$$
$$A_2 = t_{b_m+1} + \cdots + t_{b_m^2},$$

$$\begin{aligned}
&\cdots\cdots\\
A_j &= t_{b_m^{j-1}+1} + \cdots + t_{b_m^j},\\
&\cdots\cdots\\
A_h &= t_{b_m^{h-1}+1} + \cdots + t_n,
\end{aligned}$$

where $h = \lceil \log n / \log b_m \rceil$.

Since $\sum_{j=1}^{h} A_j = \sum_{i=1}^{n} t_i$, there are at most $\lfloor m/\epsilon \rfloor$ subsums A_j larger than $(\epsilon/m)\sum_{i=1}^{n} t_i$. Let A_{k+1} be the first subsum such that $A_{k+1} \le (\epsilon/m)\sum_{i=1}^{n} t_i$; then $k \le \lfloor m/\epsilon \rfloor$.

Let $j_0 = b_m^k = (3mB_m + 1)^k$. Since the sum of the first $b_m^{k+1} - b_m^k = 3j_0 mB_m$ integers t_q in $\mathcal{T}$ with $q > j_0 = b_m^k$ is bounded by $(\epsilon/m)\sum_{i=1}^{n} t_i$,

$$A_{k+1} = t_{b_m^k+1} + \cdots + t_{b_m^{k+1}} \le (\epsilon/m)\sum_{i=1}^{n} t_i,$$

and the sequence $\mathcal{T} = \{t_1, t_2, \ldots, t_n\}$ is nonincreasing, we conclude that for any subset $\mathcal{T}'$ of $\mathcal{T}$ of at most $3j_0 mB_m$ integers t_q with $q > j_0$, we must have

$$\sum_{t_q \in \mathcal{T}'} t_q \le (\epsilon/m)\sum_{i=1}^{n} t_i.$$

This completes the proof. □

For the nonincreasing sequence $\mathcal{T}$ of integers, we will denote by $j_{m,\epsilon}$ the smallest index that satisfies conditions (1) and (2) in Lemma 2.1. The index $j_{m,\epsilon}$ will be called the *cut-index* for the sequence $\mathcal{T}$.

3. On (m, ϵ)-canonical schedulings. In this section, we first assume that the mode assignment for each job in the instance $\mathcal{J}$ is decided and discuss how we schedule the jobs in $\mathcal{J}$ under the mode assignment to the processor set P_m. By this assumption, the job list $\mathcal{J}$ is actually an instance for the $P_m|fix|C_{\max}$ problem (recall that the $P_m|fix|C_{\max}$ problem is the problem $P_m|set|C_{\max}$ with the restriction that every job in an instance has only one processing mode).

Let $\mathcal{J} = \{J_1, \ldots, J_n\}$ be an instance for the $P_m|fix|C_{\max}$ problem, where each job J_i requires a fixed set Q_i of processors for parallel execution with processing time t_i for $i = 1, 2, \ldots, n$. Without loss of generality, assume that the processing time sequence $\mathcal{T} = \{t_1, t_2, \ldots, t_n\}$ is nonincreasing.

For the fixed number m of processors in the system and for an arbitrarily given real number $\epsilon > 0$, let $j_{m,\epsilon}$ be the cut-index for the sequence $\mathcal{T}$ as defined in Lemma 2.1. That is, $j_{m,\epsilon} = (3mB_m + 1)^k$, where k is an integer bounded by $\lfloor m/\epsilon \rfloor$, and for any subset $\mathcal{T}'$ of at most $3j_{m,\epsilon} mB_m$ integers t_q in $\mathcal{T}$ with $q > j_{m,\epsilon}$, we have $\sum_{t_q \in \mathcal{T}'} t_q \le (\epsilon/m)\sum_{i=1}^{n} t_i$. We split the job set $\mathcal{J}$ into two subsets

$$\mathcal{J}_L = \{J_i \mid i \le j_{m,\epsilon}\}, \qquad \mathcal{J}_S = \{J_i \mid i > j_{m,\epsilon}\}. \tag{3.1}$$

The jobs in $\mathcal{J}_L$ will be called *large jobs* and the jobs in $\mathcal{J}_S$ will be called *small jobs*.

Let $\Gamma(\mathcal{J})$ be a scheduling for the job set $\mathcal{J}$. Consider the nondecreasing sequence $\{\tau_1, \tau_2, \ldots, \tau_h\}$ of integers, where $\tau_1 = 0$, $\tau_h = +\infty$, $h = 2j_{m,\epsilon} + 2$, and τ_i, $1 < i < h$, are the starting or finishing times of the $j_{m,\epsilon}$ large jobs in $\Gamma(\mathcal{J})$. A *small job block* χ in $\Gamma(\mathcal{J})$ consists of a subset $P' \subseteq P_m$ of processors and a time interval $[\tau_p, \tau_{p+1}]$,

$1 \le p \le h-1$, such that the subset $P_m - P'$ of processors are exactly those that are executing large jobs in the time interval $[\tau_p, \tau_{p+1}]$. The value $\tau_{p+1} - \tau_p$ will be called the *height* and the processor set P' will be called the *type* of the small job block χ.

Therefore, the subset P' of processors associated with the small job block χ are those processors that are either idle or used for executing small jobs in the time interval $[\tau_p, \tau_{p+1}]$. Note that the small job block χ can be of height 0 when $\tau_p = \tau_{p+1}$. The small job block of time interval $[\tau_{h-1}, +\infty]$, where τ_{h-1} is the latest finish time of a large job, will be called the "last small job block." Note that the last small job block has type P_m.

Let χ be a small job block associated with a processor set P' and a time interval $[\tau_p, \tau_{p+1}]$. The small job block at any time moment τ in the time interval $[\tau_p, \tau_{p+1}]$ can be characterized uniquely as a collection $[Q_1, \ldots, Q_s]$ of pairwise disjoint subsets of the processor set P' such that at the time τ, for $i = 1, \ldots, s$, all processors in the subset Q_i are used for parallel execution on the same small job (thus, the subset $P' - \bigcup_{i=1}^{s} Q_i$ is the subset of idle processors at time τ). The collection $[Q_1, \ldots, Q_s]$ will be called the *type* of the time moment τ. A *layer* in the small job block χ is a maximal time interval $[\tau', \tau'']$ in $[\tau_p, \tau_{p+1}]$ such that all time moments τ between τ' and τ'' are of the same type. The *type* of the layer is equal to the type of any time moment in the layer and the *height* of the layer is $\tau'' - \tau'$.

Let L_1 and L_2 be two layers in the small job block χ of types $[Q_1, \ldots, Q_s]$ and $[R_1, \ldots, R_t]$, respectively. We say that layer L_1 *covers* layer L_2 if $\{R_1, \ldots, R_t\} \subseteq \{Q_1, \ldots, Q_s\}$. In particular, if L_1 and L_2 are two consecutive layers in the small job block χ such that layer L_2 starts right after layer L_1 finishes and L_1 covers L_2, then layer L_2 is actually a continuation of the layer L_1 with some of the small jobs finished.

DEFINITION 3.1. *A* floor σ *in the small job block* χ *is a sequence* $\{L_1, L_2, \ldots, L_z\}$ *of consecutive layers such that* (1) *for* $i = 2, \ldots, z$, *layer* L_i *starts right after layer* L_{i-1} *finishes, and layer* L_{i-1} *covers layer* L_i*; and* (2) *all small jobs interlacing layer* L_1 *start in layer* L_1 *and all small jobs interlacing layer* L_z *finish in layer* L_z.

An example of a floor is given in Figure 3.1(a). Note that a small job block may not have any nonempty floor at all, as shown in Figure 3.1(b).

Remark 1. There are a few important properties of floors in a small job block. Suppose that the layer L_1 starts at time τ' while layer L_z finishes at time τ''. Then by property (2) in the definition, no small jobs cross the floor boundaries τ' and τ''. Therefore, the floor σ can be regarded as a single job that uses the processor set P', starts at time τ', and finishes at time τ''. The *height* of the floor σ is defined to be $\tau'' - \tau'$, which is equal to the sum of the heights of the layers L_1, ..., L_z. Second, since all floors in the small job block χ are for the same processor subset P' and there are no small jobs crossing the starting and finishing times of any floors, the floors in the same small job block χ can be rearranged in any order but can still fit into the small job block without exceeding the height of the small job block. Finally, property (1) in the definition ensures that no matter how the small jobs in a floor are rearranged, a simple greedy algorithm is sufficient to refit the small jobs into the floor without exceeding the floor height. The greedy algorithm is based on the idea of the well-known Graham's list scheduling algorithm for the classical job scheduling problem [15].

DEFINITION 3.2. *Let* $\mathcal{J}$ *be an instance of the problem* $P_m|fix|C_{\max}$ *and let* π *be any permutation of the jobs in* $\mathcal{J}$. *The* list scheduling algorithm *based on the ordering* π *is to schedule each job* J_i *of mode* Q_i *in* $\mathcal{J}$, *following the ordering of* π, *at the earliest time when the processor subset* Q_i *becomes available.*

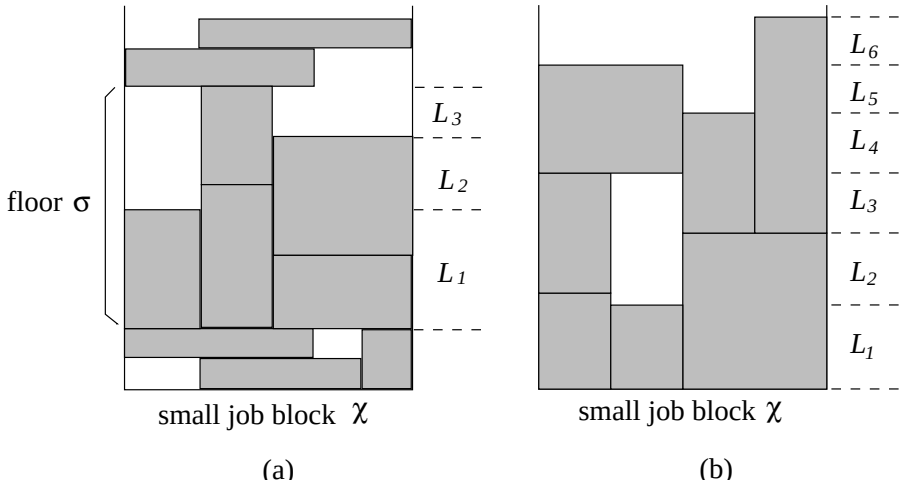

FIG. 3.1. (a) *a floor* $\{L_1, L_2, L_3\}$; (b) *a small job block with no floor.*

.

LEMMA 3.3. *Let $\mathcal{J}_\sigma$ be the set of small jobs in the floor σ. The list scheduling algorithm based on any ordering π of the jobs in $\mathcal{J}_\sigma$ will always reconstruct the floor σ.*

Proof. Suppose that the first layer in the floor σ is of type $[Q_1, \ldots, Q_s]$. Every job in $\mathcal{J}_\sigma$ must have a mode Q_i for some i, and no processor subset Q_i can become idle before its final completion time. The jobs of each mode Q_i in $\mathcal{J}_\sigma$ can be executed by the processor subset Q_i in any order without changing the completion time of Q_i. Since the list scheduling algorithm starts each job at its earliest possible time (thus no subset Q_i can become idle before its final completion time), the completion time for each subset Q_i will not be changed. Therefore, the list scheduling algorithm will construct a floor with exactly the same layers. □

DEFINITION 3.4. *Let $[Q_1, \ldots, Q_s]$ be a partition of the processor subset P'. We say that* we can assign the type $[Q_1, \ldots, Q_s]$ *to a floor $\sigma = \{L_1, \ldots, L_z\}$ if the type of the layer L_1 is a subcollection of $\{Q_1, \ldots, Q_s\}$.*

It is possible that several different types can be assigned to the same floor as long as the type of the floor is a subcollection of the assigned floor types. For example, let $[Q_1, \ldots, Q_s]$ be a partition of the processor subset P'. If the first layer L_1 in a floor σ is of type $[Q_3, \ldots, Q_s]$, then we can assign either type $[Q_1, Q_2, Q_3, \ldots, Q_s]$ or type $[Q_1 \cup Q_2, Q_3, \ldots, Q_s]$ to the floor σ.

DEFINITION 3.5. *A small job block χ is a* tower *if it is constituted by a sequence of floors such that we can assign types to the floors so that no two floors in the tower χ are of the same type.*

Note that since each floor type is a partition of the processor subset P', a tower contains at most B_m floors, where $B_m \leq m!$, the mth Bell number, is the number of different partitions of a set of m elements.

In our discussion, we will be concentrating on schedulings of a special form in the following sense.

DEFINITION 3.6. *Let $\mathcal{J}$ be an instance of the problem $P_m|fix|C_{\max}$, which is divided into large job set $\mathcal{J}_L$ and small job set $\mathcal{J}_S$ as given in* (3.1) *for a fixed integer $m > 2$ and a fixed constant $\epsilon > 0$. A scheduling $\Gamma(\mathcal{J})$ of $\mathcal{J}$ is* (m, ϵ)-canonical *if every*

small job block in $\Gamma(\mathcal{J})$ *is a tower.*

Remark 2. Note that in an (m, ϵ)-canonical scheduling, no small jobs cross the boundary of a tower. Therefore, a tower of height t and associated with a processor set Q can be simply regarded as a job of mode (Q, t).

We first show that an (m, ϵ)-canonical scheduling $\Gamma(\mathcal{J})$ of $\mathcal{J}$ can be constructed by the list scheduling algorithm when large jobs and towers in $\Gamma(\mathcal{J})$ are given in a proper order.

LEMMA 3.7. *Let* $\Gamma(\mathcal{J})$ *be an* (m, ϵ)*-canonical scheduling for the job set* $\mathcal{J}$*. Let* π *be the sequence of the large jobs and towers in* $\Gamma(\mathcal{J})$*, ordered in terms of their starting times in* $\Gamma(\mathcal{J})$*. Then the list scheduling algorithm based on the ordering* π*, which regards each tower as a single job, constructs a scheduling of* $\mathcal{J}$ *with makespan not larger than that of* $\Gamma(\mathcal{J})$*.*

Proof. Let $\mathcal{J}_i = \{J_1, \ldots, J_i\}$ be any prefix of the ordered sequence π, where each J_j is either a large job or a tower. Let $\Gamma(\mathcal{J}_i)$ be the scheduling of $\mathcal{J}_i$ obtained from $\Gamma(\mathcal{J})$ by removing all large jobs and towers that are not in $\mathcal{J}_i$ and let $\Gamma'(\mathcal{J}_i)$ be the scheduling by the list scheduling algorithm on the jobs in $\mathcal{J}_i$. By induction, it is not difficult to prove that the completion time of *each* processor in $\Gamma'(\mathcal{J}_i)$ is not larger than the completion time of the same processor in $\Gamma(\mathcal{J}_i)$. For $\mathcal{J}_i = \mathcal{J}$, this implies that the makespan of the scheduling constructed by the list scheduling algorithm based on the ordering π is not larger than the makespan of the (m, ϵ)-canonical scheduling $\Gamma(\mathcal{J})$. □

Thus, once the ordering of large jobs and towers is decided, it is easy to construct a scheduling that is not worse than the given (m, ϵ)-canonical scheduling. In the following, we will prove that for any instance $\mathcal{J}$ for the problem $P_m|fix|C_{\max}$, there is an (m, ϵ)-canonical scheduling whose makespan is very close to the optimal makespan.

THEOREM 3.8. *Let* $\mathcal{J}$ *be an instance for the problem* $P_m|fix|C_{\max}$*. Then for any* $\epsilon > 0$*, there is an* (m, ϵ)*-canonical scheduling* $\Gamma(\mathcal{J})$ *of* $\mathcal{J}$ *such that the makespan of* $\Gamma(\mathcal{J})$ *is bounded by* $(1 + \epsilon)Opt(\mathcal{J})$*.*

Proof. Let $\Gamma_1(\mathcal{J})$ be an optimal scheduling of makespan $Opt(\mathcal{J})$ for $\mathcal{J}$. We construct an (m, ϵ)-canonical scheduling for $\mathcal{J}$ based on the optimal scheduling $\Gamma_1(\mathcal{J})$. Let $\mathcal{J}_L$ and $\mathcal{J}_S$ be the set of large jobs and the set of small jobs in $\mathcal{J}$, respectively, according to the definition in (3.1). Consider a small job block χ in the scheduling $\Gamma_1(\mathcal{J})$.

Assume that the small job block χ is associated with a processor set P' of r processors, $r \leq m$, and a time interval $[\tau_p, \tau_{p+1}]$. Let $[T_1, \ldots, T_y]$ be the list of all partitions of the processor set P', where $y = B_r \leq B_m$. We divide the layers in the small job block χ into groups, each corresponding to a partition of P', as follows. A layer of type T' is put in the group corresponding to a partition T_j if T' is a subcollection of T_j. Note that a layer type T' may be a subcollection of more than one partition of P'. In this case, we put the layer arbitrarily into one and only one of the groups to ensure that each layer belongs to only one group.

For each partition T_j of P', we construct a *floor frame* σ_j whose type is T_j and height is equal to the sum of heights of all layers belonging to the group corresponding to the partition T_j. Note that so far we have not yet actually assigned any small jobs to any floor frames σ_1, …, σ_y. Moreover, since each layer belongs to exactly one of the groups, it is easy to see that the sum $\sum_{j=1}^{y} height(\sigma_j)$ of the heights of the floor frames σ_1, …, σ_y is equal to the sum of the heights of all layers in the small job block χ, which is equal to the height of the small job block χ.

The construction for the floor frames for the last small job block in $\Gamma_1(\mathcal{J})$ is

slightly different: we group layers only in which not all processors are idle. Thus, the sum of the heights of all floor frames in the last small job block is equal to $Opt(\mathcal{J})-\tau_0$, where τ_0 is the latest finish time for some large job in the scheduling $\Gamma_1(\mathcal{J})$.

After the construction of the floor frames for each small job block in the scheduling $\Gamma_1(\mathcal{J})$, we assign the small jobs in $\mathcal{J}_S$ to the floor frames using the following greedy method. For each small job J that requires a parallel processing by a processor subset Q, we assign J to an arbitrary floor frame σ in a small job block as long as the floor frame σ satisfies the following conditions: (1) the type of the floor frame σ contains the subset Q and (2) adding the job J to σ does not exceed the height of the floor frame σ (if there are more than one floor frames satisfying these conditions, arbitrarily pick one of them). Note that we assign a job to a floor frame only when the mode of the job is contained in the type of the floor frame. Therefore, this assignment will never leave a "gap" between two jobs in the same floor frame.

The above assignment of small jobs in $\mathcal{J}_S$ to floor frames stops when none of the small jobs left in $\mathcal{J}_S$ can be assigned to any of the floor frames according to the above rules. Now each floor frame becomes a floor.

For each small job block χ in $\Gamma_1(\mathcal{J})$, let S_χ be the set of floor frames in χ. Since the height of a resulting floor is not larger than the height of the corresponding floor frame, the sum of the heights of the floors resulting from the floor frames in S_χ is not larger than the height of the small job block χ. Therefore, we can put all these floors into the small job block χ (in an arbitrary order) to make χ a tower. Doing this for all small job blocks in $\Gamma_1(\mathcal{J})$ gives an (m,ϵ)-canonical scheduling $\Gamma_2(\mathcal{J}_L \cup \mathcal{J}'_S)$ for the job set $\mathcal{J}_L \cup \mathcal{J}'_S$, where $\mathcal{J}'_S$ is the set of small jobs that have been assigned to the floor frames in the above procedure. The makespan of the scheduling $\Gamma_2(\mathcal{J}_L \cup \mathcal{J}'_S)$ is bounded by $Opt(\mathcal{J})$. Now the only thing left is that we still need to schedule the small jobs that have not been assigned to any floor frames. Let $\mathcal{J}''_S = \mathcal{J}_S - \mathcal{J}'_S$ be the set of small jobs that are not assigned to any floor frames by the above procedure. We want to demonstrate that there are not many jobs in the set $\mathcal{J}''_S$.

By the definition, the number of small job blocks in the scheduling $\Gamma_1(\mathcal{J})$ is $2j_{m,\epsilon}+1 \le 3j_{m,\epsilon}$. Since each small job block is associated with at most m processors, the number of floor frames constructed in each small job block is bounded by B_m. Therefore, the total number of floor frames we constructed from the scheduling $\Gamma_1(\mathcal{J})$ is bounded by $3B_m j_{m,\epsilon}$. Moreover, each floor type is a collection of at most m processor subsets.

If the set $\mathcal{J}''_S$ contains more than $3mB_m j_{m,\epsilon}$ small jobs, then there must be a subset Q of processors such that the number of small jobs of mode Q in $\mathcal{J}''_S$ is larger than the number of the constructed floor frames whose type contains the subset Q. Let $\{\sigma_1, \ldots, \sigma_d\}$ be the set of floor frames whose type contains the subset Q.

By our assignment rules, assigning any job of mode Q in $\mathcal{J}''_S$ to a floor frame in $\{\sigma_1, \ldots, \sigma_d\}$ would exceed the height of the corresponding floor frame. Since there are more than d small jobs of mode Q in $\mathcal{J}''_S$, the sum of processing times of all small jobs of mode Q in $\mathcal{J}_S$ is larger than $\sum_{i=1}^{d} height(\sigma_i)$. On the other hand, by our construction of the floor frames in each small job block χ, the sum of the heights of the floor frames in χ whose type contains Q should not be smaller than the sum of the heights of the layers in χ whose type contains Q. Summarizing this over all small job blocks, we conclude that the sum $\sum_{i=1}^{d} height(\sigma_i)$ is not smaller than the sum of processing times of all small jobs of mode Q in $\mathcal{J}_S$ (since each small job of mode Q must be contained in consecutive layers whose type contains Q). This derives a contradiction. The contradiction shows that there are at most $3mB_m j_{m,\epsilon}$ small jobs

in the set $\mathcal{J}''_S$.

Now we assign the small jobs in $\mathcal{J}''_S$ to the floor frames in the last small job block in the scheduling $\Gamma_2(\mathcal{J}_L \cup \mathcal{J}'_S)$. For each small job J of mode Q in $\mathcal{J}''_S$, we arbitrarily assign J to a floor frame whose type contains Q in the last small job block, even if this assignment exceeds the height of the floor frame. Note that the last small job block is associated with the whole processor set P_m, so for any mode Q, there must be a floor frame in the last small job block whose type contains the processor subset Q. This procedure stops with all small jobs in $\mathcal{J}''_S$ assigned to floor frames in the last small job block. It is easy to see that the resulting scheduling is an (m, ϵ)-canonical scheduling $\Gamma(\mathcal{J})$ of the original job set $\mathcal{J}$. Moreover, since the makespan of the scheduling $\Gamma_2(\mathcal{J}_L \cup \mathcal{J}'_S)$ is bounded by $Opt(\mathcal{J})$, the makespan of the (m, ϵ)-canonical scheduling $\Gamma(\mathcal{J})$ is bounded by

$$Opt(\mathcal{J}) + \sum_{J \in \mathcal{J}''_S} t(J),$$

where $t(J)$ is the parallel processing time of the small job J. Since there are at most $3mB_m j_{m,\epsilon}$ small jobs in the set $\mathcal{J}''_S$, by Lemma 2.1,

$$\sum_{J \in \mathcal{J}''_S} t(J) \le (\epsilon/m) \sum_{i=1}^{n} t_i.$$

It is easy to see that $Opt(\mathcal{J}) \ge (\sum_{i=1}^{n} t_i)/m$. Therefore, the makespan of the (m, ϵ)-canonical scheduling $\Gamma(\mathcal{J})$ is bounded by $(1+\epsilon)Opt(\mathcal{J})$. This completes the proof of the theorem. □

Before we close this section, we introduce one more definition.

DEFINITION 3.9. *Let σ be a floor of type $[Q_1, \ldots, Q_s]$ and height l, where Q_1, ..., Q_s are pairwise disjoint subsets of processors in the processor set P_m. Then each subset Q_i plus the height l is called a* room of type Q_i *in the floor σ.*

4. The approximation scheme. Now we come back to the original problem $P_m|set|C_{\max}$. Recall that an instance $\mathcal{J}$ of the problem $P_m|set|C_{\max}$ is a set of jobs $\{J_1, J_2, \ldots, J_n\}$, where each job J_i is given by a list of alternative processing modes $[M_{i,1}, \ldots, M_{i,p_i}]$ in which each processing mode $M_{i,j} = (Q_{i,j}, t_{i,j})$ specifies the parallel processing time $t_{i,j}$ of the job J_i on the subset $Q_{i,j}$ of processors in the m-processor system.

In order to describe our polynomial time approximation scheme for the problem, let us first discuss why this problem is more difficult than the classical job scheduling problem.

In the classical job scheduling problem, each job is executed by one processor in the system. Therefore, the order of executions of jobs in each processor is not crucial: the running time of the processor is simply equal to the sum of the processing times of the jobs assigned to the processor. Therefore, the decision of which job should be assigned to which processor, in any order, will uniquely determine the makespan of the resulting scheduling. This makes it possible to use a dynamic programming approach that extends a scheduling for a subset of jobs to that for a larger subset.

The situation in the general multiprocessor job scheduling problem $P_m|set|C_{\max}$, on the other hand, is more complicated. In particular, the makespan of a scheduling depends not only on the assignment of processing modes to jobs but also on the *order* in which the jobs are executed. Therefore, the techniques of extending a scheduling

for a subset of jobs in the classical job scheduling problem are not directly applicable here.

Theorem 3.8 shows that there is an (m, ϵ)-canonical scheduling whose makespan is very close to the optimal makespan. Therefore, constructing a scheduling whose makespan is not larger than the makespan of a good (m, ϵ)-canonical scheduling will give a good approximation to the optimal schedulings.

Nice properties of an (m, ϵ)-canonical scheduling are that within the same tower, the order of the floors does not affect the height of the tower and that within the same floor, the order of the small jobs does not affect the height of the floor (see Remarks 1 and 2 in the previous section). Therefore, the only factor that affects the heights of towers and floors is the assignments of jobs to towers and floors. This makes it become possible, at least for small jobs, to apply the techniques in classical job scheduling problems to our current problem. This is described as follows.

First, suppose that we can somehow divide the job set $\mathcal{J}$ into large job set $\mathcal{J}_L$ and small job set $\mathcal{J}_S$. Let us start with an (m, ϵ)-canonical scheduling $\Gamma(\mathcal{J})$ of the job set $\mathcal{J}$. The scheduling $\Gamma(\mathcal{J})$ gives a nondecreasing sequence $\{\tau_0, \tau_1, \ldots, \tau_{p+1}\}$ of integers, where $\tau_0 = 0$, $\tau_{p+1} = +\infty$, $p = 2j_{m,\epsilon}$, and τ_i, $0 < i < p + 1$, are the starting or finishing times of the $j_{m,\epsilon}$ large jobs in $\mathcal{J}_L$. Let the $p + 1$ corresponding towers be $\{\chi_0, \chi_1, \ldots, \chi_p\}$, where the tower χ_j consists of a subset P'_j of processors and the time interval $[\tau_j, \tau_{j+1}]$.

We suppose that the subset P'_j of processors associated with each tower χ_j is known and that the large jobs and towers of the scheduling $\Gamma(\mathcal{J})$ are ordered into a sequence π in terms of their starting times. However, we assume that the assignment of small jobs to the rooms of the scheduling $\Gamma(\mathcal{J})$ is unknown. We show how this information can be recovered.

For each tower χ_j associated with the processor set P'_j, the number of floors in the tower χ_j is $q_j = B_r \leq B_m$, where r is the number of processors in the set P'_j. Let $\sigma_{j,1}$, ..., σ_{j,q_j} be the floors of all possible different types in the tower χ_j. For each floor $\sigma_{j,q}$, let $\gamma_{j,q,1}$, ..., $\gamma_{j,q,r_{jq}}$ be the rooms in the floor $\sigma_{j,q}$, where $r_{jq} \leq m$. Therefore, the configuration of the small jobs in the (m, ϵ)-canonical scheduling $\Gamma(\mathcal{J})$ can be specified by a $((2j_{m,\epsilon} + 1)B_m m)$-tuple

$$[t_{0,1,1}, \ldots, t_{j,q,r}, \ldots, t_{2j_{m,\epsilon},B_m,m}],$$

where $t_{j,q,r}$ specifies the running time of the room $\gamma_{j,q,r}$ (for index $\{j, q, r\}$ for which the corresponding room $\gamma_{j,q,r}$ does not exist, we can simply set $t_{j,q,r} = -1$).

Suppose that an upper bound T_0 for the running time of rooms is derived; then we can use a Boolean array D of $(2j_{m,\epsilon} + 1)B_m m + 1$ dimensions to describe the configuration of a subset of small jobs in a scheduling

$$D[0..n_S;\ \underbrace{0..T_0,\ \ldots\ldots,\ 0..T_0}_{(2j_{m,\epsilon}+1)B_m m}],$$

where $n_S = n - j_{m,\epsilon}$ is the number of small jobs in $\mathcal{J}$ such that

$$D[i; t_{0,1,1}, \ldots, t_{j,q,r}, \ldots, t_{2j_{m,\epsilon},B_m,m}] = \textsc{True}$$

if and only if there is a scheduling on the first i small jobs to the floors in $\Gamma(\mathcal{J})$ such that the running time of the room $\gamma_{j,q,r}$ is $t_{j,q,r}$ (recall that the running time of a room is dependent only on the assignment of small jobs to the room and independent

of the order in which the small jobs are executed in the room). Initially, all array elements in the array $D[\cdots\cdots]$ have value FALSE.

Suppose that a configuration of a scheduling for the first $i-1$ small jobs is given:

$$D[i-1; t_{0,1,1}, \ldots, t_{j,q,r}, \ldots, t_{2j_{m,\epsilon},B_m,m}] = \text{TRUE}. \tag{4.1}$$

We say that the ith small job J_i' under mode Q_i is *addable* to a room $\gamma_{j,q,r}$ in the configuration in (4.1) if the room $\gamma_{j,q,r}$ is of type Q_i and adding the job J_i' to the room does not exceed the upper bound T_0 of the running time of the room $\gamma_{j,q,r}$.

Now we are ready to present our dynamic programming algorithm for scheduling small jobs into the rooms in the (m,ϵ)-canonical scheduling $\Gamma(\mathcal{J})$. The algorithm is given in Figure 4.1.

Note that the algorithm SCHEDULE-SMALL may not return an (m,ϵ)-canonical scheduling for the job set $\mathcal{J}$. In fact, there is no guarantee that the height of the towers constructed in the algorithm does not exceed the height of the corresponding towers in the original (m,ϵ)-canonical scheduling $\Gamma(\mathcal{J})$. We first show below that the scheduling constructed by the algorithm SCHEDULE-SMALL has its makespan bounded by the makespan of the original (m,ϵ)-canonical scheduling $\Gamma(\mathcal{J})$.

The following lemma can be proved by induction on the index i.

LEMMA 4.1. *For all i, $0 \le i \le n_S$, the array element $D[i; \ldots, t_{j,q,r}, \ldots] =$ TRUE if and only if there is a way to assign modes to the first i small jobs and arrange them into the rooms such that the room $\gamma_{j,q,r}$ has running time $t_{j,q,r}$ for all $\{j,q,r\}$.*

Lemma 4.1 gives us directly the following corollary.

COROLLARY 4.2. *If the sequence π of large jobs and towers is ordered in terms of their starting times in the (m,ϵ)-canonical scheduling $\Gamma(\mathcal{J})$, then the algorithm* SCHEDULE-SMALL *constructs a scheduling for the job set $\mathcal{J}$ with makespan bounded by the makespan of the (m,ϵ)-canonical scheduling $\Gamma(\mathcal{J})$.*

Proof. Note that the (m,ϵ)-canonical scheduling $\Gamma(\mathcal{J})$ gives a way to assign and arrange all small jobs in $\mathcal{J}_S$ into the rooms. According to Lemma 4.1, the corresponding array element in the array D must have value TRUE:

$$D[n_S; \ldots, t_{j,q,r}, \ldots] = \text{TRUE}.$$

For this array element, step 3 of the algorithm will construct the towers that have exactly the same types and heights as their corresponding towers in the (m,ϵ)-canonical scheduling $\Gamma(\mathcal{J})$. (This may not give exactly the same assignment of small jobs to rooms. However, the running times of the corresponding rooms must be exactly the same.) Now since the sequence π is given in the order sorted by the starting times of the large jobs and towers in the (m,ϵ)-canonical scheduling $\Gamma(\mathcal{J})$, by Lemma 3.7, the call in step 3 to the list scheduling algorithm based on the order π and this configuration will construct a scheduling whose makespan is not larger than the makespan of the (m,ϵ)-canonical scheduling $\Gamma(\mathcal{J})$.

Finally, since step 4 of the algorithm returns the scheduling of the minimum makespan constructed in step 3, we conclude that the algorithm returns a scheduling whose makespan is not larger than the makespan of $\Gamma(\mathcal{J})$. □

We analyze the algorithm SCHEDULE-SMALL.

LEMMA 4.3. *Let T_0 be the upper bound used by the algorithm* SCHEDULE-SMALL *on the running time of the rooms. Then the running time of the algorithm* SCHEDULE-SMALL *is bounded by $O(n2^m\lambda_{m,\epsilon}T_0^{\lambda_{m,\epsilon}})$, where $\lambda_{m,\epsilon} = (2j_{m,\epsilon}+1)B_m m$.*

Proof. The number n_S of small jobs in $\mathcal{J}_S$ is bounded by the total number n of jobs in $\mathcal{J}$; each small job may have at most $2^m - 1 \le 2^m$ different modes. Also, as we

Algorithm. SCHEDULE-SMALL
Input: The set $\mathcal{J}_S$ of small jobs and an order π of the large jobs and towers in $\Gamma(\mathcal{J})$.
Output: A scheduling for the job set $\mathcal{J}$.
1. $D[0;0,\ldots,0] = \text{TRUE}$;
2. **for** $i = 1$ **to** n_S **do**
   for each mode Q_{ij} of the small job J'_i with processing time t_{ij}
   for each $D[i-1;\ldots,t_{j,q,r},\ldots] = \text{TRUE}$ such that the job J'_i under mode Q_{ij} is addable to the room $\gamma_{j,q,r}$
   $D[i;\ldots,t_{j,q,r}+t_{ij},\ldots] = \text{TRUE}$;
3. **for** each $D[n_S;\ldots,t_{j,q,r},\ldots] = \text{TRUE}$
   call the list scheduling algorithm based on the order π to construct a scheduling for $\mathcal{J}$ in which the room $\gamma_{j,q,r}$ has running time $t_{j,q,r}$ for all $t_{j,q,r} \geq 0$;
4. return the scheduling constructed in step 3 with the minimum makespan.

FIG. 4.1. *Scheduling small jobs in floors.*

indicated before, the number of rooms is bounded by $\lambda_{m,\epsilon} = (2j_{m,\epsilon}+1)B_m m$. Since the running time for each room is bounded by T_0, for each fixed i, there cannot be more than $T_0^{\lambda_{m,\epsilon}}$ elements $D[i-1;*,\ldots,*]$. Finally, for each $D[i-1;\ldots,t_{j,q,r},\ldots] = \text{TRUE}$, we can check each of the $\lambda_{m,\epsilon}$ component values $t_{j,q,r}$ to decide if the job J'_i under mode Q_{ij} is addable to the room $\gamma_{j,q,r}$. In conclusion, the running time of step 2 in the algorithm SCHEDULE-SMALL is bounded by

$$O(n \cdot 2^m \cdot T_0^{\lambda_{m,\epsilon}} \cdot \lambda_{m,\epsilon}).$$

We will also attach the mode assignment and room assignment of the job J'_i to each element $D[i;\ldots,t_{j,q,r},\ldots] = \text{TRUE}$. With this information, from a given configuration $D[n_S;\cdots,t_{j,q,r},\cdots] = \text{TRUE}$, a corresponding scheduling for the small jobs in the rooms can be easily constructed by backtracking the dynamic programming procedure and its makespan can be computed in time $\lambda_{m,\epsilon}$. Therefore, step 3 of the algorithm takes time

$$O(n \cdot T_0^{\lambda_{m,\epsilon}} \cdot \lambda_{m,\epsilon}).$$

In conclusion, the running time of the algorithm SCHEDULE-SMALL is bounded by $O(n2^m\lambda_{m,\epsilon}T_0^{\lambda_{m,\epsilon}})$, where $\lambda_{m,\epsilon} = (2j_{m,\epsilon}+1)B_m m$. □

We now discuss how an upper bound T_0 for the running time of rooms can be derived. Given an instance $\mathcal{J} = \{J_1, J_2, \ldots, J_n\}$ of the problem $P_m|set|C_{\max}$ and a positive real number $\epsilon > 0$, where each job J_i is specified by a list of alternative processing modes, $J_i = [M_{i1}, \ldots, M_{ip_i}]$ and $M_{ij} = (Q_{ij}, t_{ij})$. Recall that $\min_i = \min\{t_{ij} \mid 1 \leq j \leq p_i\}$. Then the sum $T_0 = \sum_{i=1}^{n} \min_i$ is obviously an upper bound on the makespan of the (m,ϵ)-canonical schedulings for $\mathcal{J}$. (T_0 is the makespan of a straightforward scheduling that assigns each job J_i the mode corresponding to $\min_i$, then starts each job J_i when the previous job J_{i-1} finishes. Therefore, if no (m,ϵ)-canonical scheduling has makespan better than T_0, we simply return this straightforward scheduling.) In particular, the value T_0 is an upper bound for the running time for all rooms. Moreover, since the job set $\mathcal{J}$ takes at least T_0 amount of "work" (the *work* taken by a job is equal to the parallel processing time multiplied by the number of processors involved in this processing) and the system has m processors,

the value T_0 also provides a lower bound for the optimal makespan $Opt(\mathcal{J})$:

$$Opt(\mathcal{J}) \geq T_0/m.$$

In order to apply algorithm SCHEDULE-SMALL, we first need to decide how the set $\mathcal{J}$ is split into large job set $\mathcal{J}_L$ and small job set $\mathcal{J}_S$, what are the modes for the large jobs, what are the types for the towers, and what is the ordering π for the large jobs and towers on which the list scheduling algorithm can be applied. According to Lemma 2.1, the number of large jobs is of form $j_{m,\epsilon} = (3mB_m + 1)^k$ for some integer $k \leq \lfloor m/\epsilon \rfloor$ and by the definition, the number of towers is $2j_{m,\epsilon} + 1$. When m and ϵ are fixed, the number of large jobs and the number of towers are both bounded by a constant. Therefore, we can use any brute force method to exhaustively try all possible cases.

To achieve a polynomial time approximation scheme for the problem $P_m|set|C_{\max}$, we combine the standard scaling techniques [20] with the concept of (m, ϵ)-canonical schedulings as follows.

Let $\mathcal{J} = \{J_1, \ldots, J_n\}$ be an instance of the $P_m|set|C_{\max}$ problem, where $J_i = [M_{i1}, \ldots, M_{ip_i}]$ and $M_{ij} = (Q_{ij}, t_{ij})$. We let $K = \epsilon \cdot T_0/(nm)$ and construct another instance $\mathcal{J}' = \{J'_1, \ldots, J'_n\}$ for the problem, where $J'_i = [M'_{i1}, \ldots, M'_{ip_i}]$ and $M'_{ij} = (Q_{ij}, \lfloor t_{ij}/K \rfloor)$. In other words, the jobs in $\mathcal{J}'$ are identical to those in $\mathcal{J}$ except that all processing times t_{ij} are replaced by $\lfloor t_{ij}/K \rfloor$. We say that the job set $\mathcal{J}'$ is obtained from the job set $\mathcal{J}$ by *scaling the processing times by* K. We apply the algorithm described above to the instance $\mathcal{J}'$ to construct a scheduling for $\mathcal{J}'$ from which a scheduling for $\mathcal{J}$ is induced. The formal algorithm is presented in Figure 4.2.

We explain how step 5 converts the scheduling $\Gamma_0(\mathcal{J}')$ for the job set $\mathcal{J}'$ into a scheduling $\Gamma_0(\mathcal{J})$ for the job set $\mathcal{J}$. We first multiply the processing time and the starting time of each job J'_i in the scheduling $\Gamma_0(\mathcal{J}')$ by K (but keeping the processing mode). That is, for the job J'_i of mode Q_{ij} and processing time $\lfloor t_{ij}/K \rfloor$ that starts at time τ_i in $\Gamma_0(\mathcal{J}')$, we replace it by a job J''_i of mode Q_{ij} and processing time $K \cdot \lfloor t_{ij}/K \rfloor$ and let it start at time $K\tau_i$. This is equivalent to proportionally "expanding" the scheduling $\Gamma_0(\mathcal{J}')$ by a factor K. Now on this expansion of the scheduling $\Gamma_0(\mathcal{J}')$, following the order in terms of their finish times, we do "correction" on processing times by increasing the processing time of each job J''_i from $K \cdot \lfloor t_{ij}/K \rfloor$ to t_{ij}. (Note that this increase in processing time may cause many jobs in the scheduling to delay their starting time by $(t_{ij} - K \cdot \lfloor t_{ij}/K \rfloor)$ units. In particular, this increase may cause the makespan of the scheduling to increase by $(t_{ij} - K \cdot \lfloor t_{ij}/K \rfloor)$ units.) After the corrections on the processing time for all jobs in $\mathcal{J}$, we obtain a scheduling $\Gamma_0(\mathcal{J})$ for the job set $\mathcal{J}$.

LEMMA 4.4. *For fixed $m \geq 2$ and $\delta > 0$, the running time of the algorithm* APPROX-SCHEME *for the problem $P_m|set|C_{\max}$ is bounded by $O(n^{\lambda_{m,\epsilon}+j_{m,\epsilon}+1})$, where $\epsilon = \delta/2$, $j_{m,\epsilon} \leq (3mB_m + 1)^{\lfloor m/\epsilon \rfloor}$ and $\lambda_{m,\epsilon} = (2j_{m,\epsilon} + 1)B_m m$.*

Proof. Since the integer k is bounded by $\lfloor m/\epsilon \rfloor$, the number j_0 of large jobs in $\mathcal{J}'_L$ is bounded by $j_{m,\epsilon} \leq (3mB_m+1)^{\lfloor m/\epsilon \rfloor}$. Therefore, there are at most $\binom{n}{j_{m,\epsilon}} = O(n^{j_{m,\epsilon}})$ ways to choose the large job set $\mathcal{J}'_L$. Since each job may have up to $2^m - 1 < 2^m$ alternative mode assignments, the total number of mode assignments to each large job set $\mathcal{J}'_L$ is bounded by $(2^m)^{j_{m,\epsilon}} = 2^{mj_{m,\epsilon}}$. Each tower is associated with a subset of the processor set P_m of m processors. Thus, each tower may be associated with $2^m - 1 \leq 2^m$ different subsets of P_m. Therefore, the number of different sequences of up to $2j_{m,\epsilon}+1$ towers is bounded by $(2^m)^{2j_{m,\epsilon}+1} = 2^{2mj_{m,\epsilon}+m}$. Finally, the number of permutations of the j_0 large jobs and $2j_0+1$ towers is $(3j_0+1)!$. Summarizing all these

Algorithm. APPROX-SCHEME
Input: An instance $\mathcal{J}$ for the problem $P_m|set|C_{\max}$ and $\delta > 0$.
Output: A scheduling of $\mathcal{J}$.
1. $\epsilon = \delta/2$; $T_0 = \sum_{i=1}^{n} \min_i$; $K = \epsilon \cdot T_0/(nm)$;
2. let $\mathcal{J}'$ be the job set obtained by scaling the job set $\mathcal{J}$ by K;
3. **for** $k = 0$ **to** $\lfloor m/\epsilon \rfloor$ **do**
   $j_0 = (3mB_m + 1)^k$;
3.1. **for** each subset $\mathcal{J}'_L$ of j_0 jobs in $\mathcal{J}'$
3.2. **for** each mode assignment A to the jobs in $\mathcal{J}'_L$
3.3. **for** each possible sequence of $2j_0 + 1$ towers
3.4. **for** each ordering π of the j_0 jobs in $\mathcal{J}'_L$ and the $2j_0 + 1$ towers
$\mathcal{J}'_S = \mathcal{J}' - \mathcal{J}'_L$;
call SCHEDULE-SMALL on small job set $\mathcal{J}'_S$ and the ordering π to construct a scheduling for the job set $\mathcal{J}'$ (use $T'_0 = \lceil T_0/K \rceil$ as the upper bound for the running time of rooms);
4. let $\Gamma_0(\mathcal{J}')$ be the scheduling constructed in step 3 with the minimum makespan;
5. replace each job J'_i in $\Gamma_0(\mathcal{J}')$ by the corresponding job J_i to obtain a scheduling $\Gamma_0(\mathcal{J})$ for the job set $\mathcal{J}$;
6. return the job scheduling $\Gamma_0(\mathcal{J})$.

FIG. 4.2. *The approximation scheme.*

together, we conclude that the number of times that the algorithm SCHEDULE-SMALL is called is bounded by

$$O(\lfloor m/\epsilon \rfloor \cdot n^{j_{m,\epsilon}} \cdot 2^{mj_{m,\epsilon}} \cdot 2^{2mj_{m,\epsilon}+m} \cdot (3j_{m,\epsilon} + 1)!). \tag{4.2}$$

When the algorithm SCHEDULE-SMALL is applied to the job set $\mathcal{J}'_S$, the upper bound on the running time of the rooms is

$$T'_0 = \lceil T_0/K \rceil = \lceil (nm)/\epsilon \rceil \leq (nm)/\epsilon + 1.$$

According to Lemma 4.3, each call to the algorithm SCHEDULE-SMALL takes time

$$O(n2^m \lambda_{m,\epsilon}(T'_0)^{\lambda_{m,\epsilon}}) = O(n2^m \lambda_{m,\epsilon}((nm)/\epsilon + 1)^{\lambda_{m,\epsilon}}), \tag{4.3}$$

where $\lambda_{m,\epsilon} = (2j_{m,\epsilon} + 1)B_m m$.

Combining (4.2) and (4.3) and noting that m and δ thus ϵ are fixed constants, we conclude that the running time of the algorithm APPROX-SCHEME is bounded by $O(n^{\lambda_{m,\epsilon}+j_{m,\epsilon}+1})$. □

Now we are ready to present our main theorem.

THEOREM 4.5. *The algorithm* APPROX-SCHEME *is a polynomial time approximation scheme for the problem* $P_m|set|C_{\max}$.

Proof. As proved in Lemma 4.4, the algorithm APPROX-SCHEME runs in polynomial time when m and δ are fixed constants. Therefore, we need only to show that the makespan of the scheduling $\Gamma_0(\mathcal{J})$ constructed by the algorithm APPROX-SCHEME for an instance $\mathcal{J}$ of the problem $P_m|set|C_{\max}$ is at most $(1 + \delta)$ times the optimal makespan $Opt(\mathcal{J})$ for the instance $\mathcal{J}$. Again let $\epsilon = \delta/2$.

Let $\Gamma(\mathcal{J})$ be an optimal scheduling of makespan $Opt(\mathcal{J})$. Under the scheduling $\Gamma(\mathcal{J})$, the mode assignments of the jobs are fixed. Thus, this particular mode assignment makes us able to split the job set $\mathcal{J}$ into large job set $\mathcal{J}_L$ and small job set $\mathcal{J}_S$ in terms of job processing time. According to Theorem 3.8, there is an (m, ϵ)-canonical

scheduling $\Gamma_1(\mathcal{J})$ for the instance $\mathcal{J}$, under the same mode assignments, such that the makespan of $\Gamma_1(\mathcal{J})$ is bounded by $(1+\epsilon)Opt(\mathcal{J})$.

Consider a room $\gamma_{j,q,r}$ in the (m,ϵ)-canonical scheduling $\Gamma_1(\mathcal{J})$. Suppose that J_{p_1}, ..., J_{p_q} are the small jobs assigned to the room $\gamma_{j,q,r}$ by the scheduling $\Gamma_1(\mathcal{J})$. Then $\sum_{i=1}^{q} t_{p_i} \leq T_0$, where t_{p_i} is the processing time for the job J_{p_i} under $\Gamma_1(\mathcal{J})$, which is the same as under $\Gamma(\mathcal{J})$. Thus we must have

$$\sum_{i=1}^{q} \lfloor t_{p_i}/K \rfloor \leq \sum_{i=1}^{q} t_{p_i}/K \leq T_0/K \leq T_0'.$$

Therefore, under the same mode assignments (with processing time t_{ij} replaced by $\lfloor t_{ij}/K \rfloor$) and the same room assignments, the corresponding scheduling $\Gamma_1(\mathcal{J}')$ for the job set $\mathcal{J}'$ has no rooms with running time exceeding T_0'. Thus, by Lemma 4.1, when step 3 of the algorithm Approx-Scheme loops to the stage in which the large job set and their mode assignments, the tower types, and the ordering of the large jobs and the towers all match that in the scheduling $\Gamma_1(\mathcal{J}')$, the array element $D[n_S; \ldots, t_{j,q,r}, \ldots]$ corresponding to the room configurations of the scheduling $\Gamma_1(\mathcal{J}')$ must have value True. Thus, a scheduling $\Gamma_1'(\mathcal{J}')$ based on this configuration is constructed and its makespan is calculated. Note that the scheduling $\Gamma_1'(\mathcal{J}')$ may not be exactly the scheduling $\Gamma_1(\mathcal{J}')$. However, they must have exactly the same makespan.

Since step 4 of the algorithm Approx-Scheme picks the scheduling $\Gamma_0(\mathcal{J}')$ that has the smallest makespan over all schedulings for $\mathcal{J}'$ constructed in step 3, we conclude that the makespan of the scheduling $\Gamma_0(\mathcal{J}')$ is not larger than the makespan of the scheduling $\Gamma_1'(\mathcal{J}')$, thus not larger than the makespan of the scheduling $\Gamma_1(\mathcal{J}')$.

As we described in the paragraph before Lemma 4.4, to obtain the corresponding scheduling $\Gamma_0(\mathcal{J})$ for the job set $\mathcal{J}$, we first expand the scheduling $\Gamma_0(\mathcal{J}')$ by K (i.e., multiplying the job processing times and starting times in $\Gamma_0(\mathcal{J}')$ by K). Let the resulting scheduling be $\Gamma_0(\mathcal{J}'')$. Similarly we expand the scheduling $\Gamma_1(\mathcal{J}')$ by K to obtain a scheduling $\Gamma_1(\mathcal{J}'')$. The makespan of the scheduling $\Gamma_0(\mathcal{J}'')$ is not larger than the makespan of the scheduling $\Gamma_1(\mathcal{J}'')$ since they are obtained by proportionally expanding the schedulings $\Gamma_0(\mathcal{J}')$ and $\Gamma_1(\mathcal{J}')$, respectively, by the same factor K.

Moreover, the makespan of $\Gamma_1(\mathcal{J}'')$ is not larger than the makespan of the (m,ϵ)-canonical scheduling $\Gamma_1(\mathcal{J})$. To see this, observe that these two schedulings use the same large job set under the same mode assignment, the same small job set under the same mode assignment and room assignment, and the same order of large jobs and towers. The only difference is that the processing time t_{ij} of each job J_i in $\Gamma_1(\mathcal{J})$ is replaced by a possibly smaller processing time $K \cdot \lfloor t_{ij}/K \rfloor$ of the corresponding job J_i'' in $\Gamma_1(\mathcal{J}'')$. In consequence, we conclude that the makespan of the scheduling $\Gamma_0(\mathcal{J}'')$ is not larger than the makespan of the (m,ϵ)-canonical scheduling $\Gamma_1(\mathcal{J})$, which is bounded by $(1+\epsilon)Opt(\mathcal{J})$.

Finally, to obtain the scheduling $\Gamma_0(\mathcal{J})$ for the job set $\mathcal{J}$, we make corrections on the processing times of the jobs in the scheduling $\Gamma_0(\mathcal{J}'')$. More precisely, we replace the processing time $K \cdot \lfloor t_{ij}/K \rfloor$ for job J_i'' by t_{ij}, which is the processing time of the job J_i in the job set $\mathcal{J}$. Correcting the processing time for each job J_i'' in $\Gamma_0(\mathcal{J}'')$ may make the makespan of the scheduling increase by

$$t_{ij} - K \cdot \lfloor t_{ij}/K \rfloor < K.$$

Therefore, after the corrections of processing times for all jobs in $\mathcal{J}''$, the makespan of the finally resulting scheduling $\Gamma_0(\mathcal{J})$ for the job set $\mathcal{J}$, constructed by the algorithm

Approx-Scheme, is bounded by

$$\begin{aligned}\text{the makespan of } \Gamma_1(\mathcal{J}) + n \cdot K &\leq (1+\epsilon)Opt(\mathcal{J}) + \epsilon T_0/m \\ &\leq (1+2\epsilon)Opt(\mathcal{J}) \\ &= (1+\delta)Opt(\mathcal{J}).\end{aligned}$$

Here we have used the fact that $Opt(\mathcal{J}) \geq T_0/m$.

This completes the proof of the theorem. □

5. Conclusion and remarks. In this paper, we have developed a polynomial time approximation scheme for the $P_m|set|C_{\max}$ problem for any fixed constant m. The result is achieved by combinations of the recent techniques developed in the area of multiprocessor job schedulings plus the classical dynamic programming and scaling techniques. This result is a significant improvement over the previous results on the problem: no previous approximation algorithms for the problem $P_m|set|C_{\max}$ have their approximation ratio bounded by a constant that is independent of the number m of processors in the system. Our result also confirms a conjecture made by Amoura et al. [1]. In the following we make a few remarks on further work on the problem.

The multiprocessor job scheduling problem seems an intrinsically difficult problem. For example, if the number m of processors in the system is given as a variable in the input, then the problem becomes highly nonapproximable: there is a constant δ such that no polynomial time approximation algorithm for the problem can have an approximation ratio smaller than n^δ unless P = NP [25]. Observing this plus the difficulties in developing good approximation algorithms for the problem, people had suspected whether the $P_m|set|C_{\max}$ problem for some fixed m should be MAX-NP hard [8]. The present paper completely eliminates this possibility [2].

Our study shows that there are very "normalized" schedulings whose makespan is close to the optimal ones and that these "good" normalized schedulings can be constructed systematically. We are interested in investigating the tradeoff between the degree of this kind of normalization and the time complexity of approximation algorithms.

The current form of our polynomial time approximation scheme may not be practically useful, yet. Even for a small integer m and a reasonably small constant ϵ, the time complexity of our algorithm is bounded by a polynomial of very high degree. More recently, Jansen and Porkolab [21] use the approach of Amoura et al. [1] and are able to develop a linear time approximation scheme for the $P_m|set|C_{\max}$ problem, which still does not seem practical because of the huge constant factor in the complexity of the algorithm.

We are especially interested in developing more practical polynomial time approximation algorithms for systems with small number of processors, such as $P_4|set|C_{\max}$. In particular, we would like to develop practical approximation algorithms for the $P_m|set|C_{\max}$ problem with approximation ratio better than $m/2$, which is still the best known bound for the problem [8]. Some progress has recently been made toward this direction for systems of four processors [19].

A DECOMPOSITION THEOREM FOR MAXIMUM WEIGHT BIPARTITE MATCHINGS*

MING-YANG KAO†, TAK-WAH LAM‡, WING-KIN SUNG‡, AND HING-FUNG TING‡

Abstract. Let G be a bipartite graph with positive integer weights on the edges and without isolated nodes. Let n, N, and W be the node count, the largest edge weight, and the total weight of G. Let $k(x, y)$ be $\log x/\log(x^2/y)$. We present a new decomposition theorem for maximum weight bipartite matchings and use it to design an $O(\sqrt{n}W/k(n, W/N))$-time algorithm for computing a maximum weight matching of G. This algorithm bridges a long-standing gap between the best known time complexity of computing a maximum weight matching and that of computing a maximum cardinality matching. Given G and a maximum weight matching of G, we can further compute the weight of a maximum weight matching of $G - \{u\}$ for all nodes u in $O(W)$ time.

Key words. all-cavity matchings, maximum weight matchings, minimum weight covers, graph algorithms, unfolded graphs

1. Introduction.

Let $G = (X, Y, E)$ be a bipartite graph with positive integer weights on the edges. A *matching* of G is a subset of node-disjoint edges of G. Let $\mathrm{mwm}(G)$ (respectively, $\mathrm{mm}(G)$) denote the maximum weight (respectively, cardinality) of any matching of G. A *maximum weight* matching is one whose weight is $\mathrm{mwm}(G)$. Let N be the largest weight of any edge. Let W be the total weight of G. Let n and m be the numbers of nodes and edges of G; to avoid triviality, we maintain $m = \Omega(n)$ throughout the paper.

The problem of finding a maximum weight matching of a given G has a rich history. The first known polynomial-time algorithm is the $O(n^3)$-time Hungarian method [15]. Fredman and Tarjan [5] used Fibonacci heaps to improve the time to $O(n(m + n\log n))$. Gabow [6] introduced scaling to solve the problem in $O(n^{3/4}m\log N)$ time by taking advantage of the integrality of edge weights. Gabow and Tarjan [7] improved the scaling method to further reduce the time to $O(\sqrt{n}m\log(nN))$. For the case where the edges all have weight 1, i.e., $N = 1$ (and $W = m$), Hopcroft and Karp [11] gave an $O(\sqrt{n}W)$-time algorithm, and Feder and Motwani [4] improved the time complexity to $O(\sqrt{n}W/k(n, m))$, where $k(x, y) = \log x/\log(x^2/y)$. It has remained open whether the gap between the running times of the Gabow–Tarjan algorithm and the latter two algorithms can be closed for the case where $W = o(m\log(nN))$.

We resolve this open problem in the affirmative by giving an $O(\sqrt{n}W/k(n, W/N))$-time algorithm for general W. Note that $W/N = m$ when all the edges have the same weight. The algorithm does not use scaling but instead employs a novel decomposition theorem for weighted bipartite matchings (Theorem 2.2). We also use the theorem to

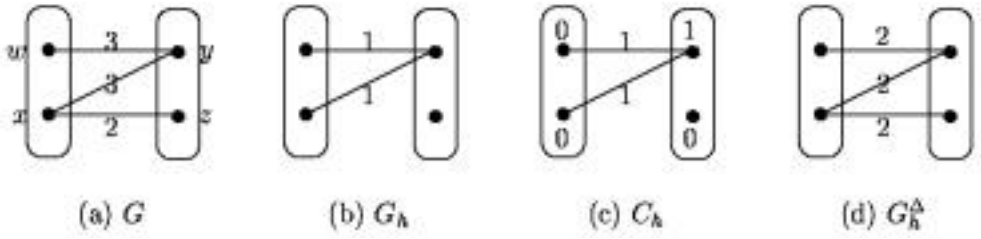

FIG. 1. *Consider $h = 1$. G is decomposed into G_h and G_h^Δ; C_h is a minimum weight cover of G_h.*

solve the *all-cavity maximum weight matching* problem which, given G and a maximum weight matching of G, asks for $\text{mwm}(G-\{u\})$ for all nodes u in G. This problem has applications to tree comparisons [2, 14]. The case where $N = 1$ has been studied by Chung [2]. Recently, Kao, Lam, Sung, and Ting [12] gave an $O(\sqrt{n}m \log N)$-time algorithm for general N. This paper presents a new algorithm that runs in $O(W)$ time.

Section 2 presents the decomposition theorem and uses it to compute the weight of a maximum weight matching. Section 3 gives an algorithm to construct a maximum weight matching. Section 4 solves the all-cavity matching problem.

2. The decomposition theorem. In section 2.1, we state the decomposition theorem and use the theorem to design an algorithm to compute the weight $\text{mwm}(G)$ in $O(\sqrt{n}W/k(n, W/N))$ time. In section 2.2, we prove the decomposition theorem. In section 3, we further construct a maximum weight matching itself within the same time bound.

2.1. An algorithm for computing mwm(G). Let $V(G)$ be the node set of G, i.e., $X \cup Y$. Let $w(u, v)$ denote the weight of an edge $uv \in G$; if u is not adjacent to v, let $w(u, v) = 0$. A *cover* of G is a function $C : X \cup Y \to \{0, 1, 2, \ldots\}$ such that $C(x) + C(y) \geq w(x, y)$ for all $x \in X$ and $y \in Y$. Let $w(C) = \sum_{z \in X \cup Y} C(z)$ be the weight of C. C is a *minimum weight* cover if $w(C)$ is the smallest possible. Let $\text{mwc}(G)$ denote the weight of a minimum weight cover of G. A minimum weight cover is a dual of a maximum weight matching as stated in the next fact.

FACT 2.1 (see [1]). *Let C be a cover and M be a matching of G. The following statements are equivalent.*

1. *C is a minimum weight cover and M is a maximum weight matching of G.*
2. *$\sum_{uv \in M} w(u, v) = \sum_{u \in X \cup Y} C(u)$.*
3. *Every node in $\{u \mid C(u) > 0\}$ is matched by some edge in M, and $C(u) + C(v) = w(u, v)$ for all $uv \in M$.*

For an integer $h \in [1, N]$, we divide G into two lighter bipartite graphs G_h and G_h^Δ as follows:

- G_h is formed by the edges uv of G with $w(u, v) \in [N - h + 1, N]$. Each edge uv in G_h has weight $w(u, v) - (N - h)$. For example, G_1 is formed by the heaviest edges of G, and the weight of each edge is exactly one.
- Let C_h be a minimum weight cover of G_h. G_h^Δ is formed by the edges uv of G with $w(u, v) - C_h(u) - C_h(v) > 0$. The weight of uv is $w(u, v) - C_h(u) - C_h(v)$.

An example is depicted in Figure 1. Note that the total weight of G_h and G_h^Δ is at most W.

The next theorem is the decomposition theorem.

THEOREM 2.2. $\mathrm{mwm}(G) = \mathrm{mwm}(G_h) + \mathrm{mwm}(G_h^{\Delta})$; *in particular,* $\mathrm{mwm}(G) = \mathrm{mm}(G_1) + \mathrm{mwm}(G_1^{\Delta})$.

Proof. See section 2.2. □

Theorem 2.2 suggests the following recursive algorithm to compute $\mathrm{mwm}(G)$.

PROCEDURE Compute-MWM(G).

1. Construct G_1 from G.
2. Compute $\mathrm{mm}(G_1)$ and find a minimum weight cover C_1 of G_1.
3. Construct G_1^{Δ} from G and C_1.
4. If G_1^{Δ} is empty, then return $\mathrm{mm}(G_1)$; otherwise, return $\mathrm{mm}(G_1)$+Compute-MWM(G_1^{Δ}).

THEOREM 2.3. Compute-MWM(G) *finds* $\mathrm{mwm}(G)$ *in* $O(\sqrt{n}W/k(n, W/N))$ *time.*

Proof. The correctness of Compute-MWM follows from Theorem 2.2. Below, we analyze the running time. We initialize a maximum heap [3] in $O(m)$ time to store the edges of G according to their weights. Let $T(n, W, N)$ be the running time of Compute-MWM excluding this initialization. Let L be the set of the heaviest edges in G. Then Step 1 takes $O(|L| \log m)$ time. In Step 2, we can compute $\mathrm{mm}(G_1)$ in $O(\sqrt{n}|L|/k(n, |L|))$ time [4]. From this matching, C_1 can be found in $O(|L|)$ time [1]. Let L_1 be the set of the edges of G adjacent to some node u with $C_1(u) > 0$; i.e., L_1 consists of the edges of G whose weights are reduced in G_1^{Δ}. Let $\ell_1 = |L_1|$. Step 3 updates every edge of L_1 in the heap in $O(\ell_1 \log m)$ time. As $L \subseteq L_1$, Steps 1 to 3 altogether use $O(\sqrt{n}\ell_1/k(n, \ell_1))$ time. Since the total weight of G_1^{Δ} is at most $W - \ell_1$, Step 4 uses at most $T(n, W - \ell_1, N')$ time, where $N' < N$ is the maximum edge weight of G_1^{Δ}. In summary, for some positive integer $\ell_1 \le W$,

$$T(n, W, N) = O(\sqrt{n}\ell_1/k(n, \ell_1)) + T(n, W - \ell_1, N'),$$

where $T(n, 0, N') = 0$. By recursion, for some positive integers $\ell_1, \ell_2, \ldots, \ell_p$ with $p \le N$ and $\sum_{1 \le i \le p} \ell_i = W$,

$$\begin{aligned} T(n, W, N) &= O\left(\sqrt{n}\left(\frac{\ell_1}{k(n, \ell_1)} + \frac{\ell_2}{k(n, \ell_2)} + \cdots + \frac{\ell_p}{k(n, \ell_p)}\right)\right) \\ &= O\left(\frac{\sqrt{n}}{\log n}\left(\left(\sum_{1 \le i \le p} \ell_i\right)\log n^2 - \sum_{1 \le i \le p} \ell_i \log \ell_i\right)\right). \end{aligned}$$

Since $x \log x$ is convex, by Jensen's inequality [10],

$$\sum_{1 \le i \le p} \ell_i \log \ell_i \ge \left(\sum_{1 \le i \le p} \ell_i\right) \log \frac{\sum_{1 \le i \le p} \ell_i}{p} \ge W \log \frac{W}{N}.$$

Therefore,

$$\begin{aligned} T(n, W, N) &= O\left(\frac{\sqrt{n}}{\log n}\left(W \log n^2 - W \log \frac{W}{N}\right)\right) \\ &= O\left(\frac{\sqrt{n}W}{\log n / \log(n^2/\frac{W}{N})}\right) = O\big(\sqrt{n}W/k(n, W/N)\big). \end{aligned}$$

□

2.2. Proof of Theorem 2.2. This section proves the statement that $\text{mwm}(G) = \text{mwm}(G_h)+\text{mwm}(G_h^\Delta)$, where G_h^Δ is defined according to an arbitrary minimum weight cover C_h of G_h. By Fact 2.1, it suffices to prove $\text{mwc}(G) = w(C_h) + \text{mwc}(G_h^\Delta)$.

To show the direction $\text{mwc}(G) \leq w(C_h) + \text{mwc}(G_h^\Delta)$, note that any cover D of G_h^Δ augmented with C_h gives a cover C of G, where $C(u) = C_h(u) + D(u)$ for each node u of G. Then $C(u) + C(v) \geq w(u, v)$ for all edges uv of G. Thus, $\text{mwc}(G) \leq w(C_h) + \text{mwc}(G_h^\Delta)$.

To show the direction $w(C_h) + \text{mwc}(G_h^\Delta) \leq \text{mwc}(C)$, let C be a minimum weight cover of G. A node u of G is called *bad* if $C(u) < C_h(u)$. Lemma 2.4 below shows that G must have a minimum weight cover C allowing no bad node. Then we can construct a cover D of G_h^Δ as follows. For each node u of G, define $D(u) = C(u) - C_h(u)$, which must be at least 0. D is a cover of G_h^Δ because for any edge uv of G_h^Δ, $D(u) + D(v) = C(u) + C(v) - C_h(u) - C_h(v) \geq w(u, v) - C_h(u) - C_h(v)$. Note that $w(D) = w(C) - w(C_h)$. Thus, $\text{mwc}(G_h^\Delta) \leq w(C) - w(C_h)$, or equivalently, $\text{mwc}(G_h^\Delta) + w(C_h) \leq \text{mwc}(G)$.

The next lemma concludes the proof of Theorem 2.2.

LEMMA 2.4. *There exists a minimum weight cover of G such that no node of G is bad.*

Proof. Suppose, for the sake of contradiction, that every minimum weight cover allows some bad node. Then we can obtain a contradiction by constructing another minimum weight cover with no bad node.

Let C be a minimum weight cover of G with u as a bad node, i.e., $C(u) < C_h(u)$. Recall that C_h is a minimum weight cover of G_h. Consider a maximum weight matching M of G_h. By Fact 2.1, since $C_h(u) > C(u) \geq 0$, u is matched by an edge in M, say, to a node v, and $C_h(u) + C_h(v) = w(u, v) - (N - h)$. We call v the *mate* of u. Note that v cannot be a bad node; otherwise, $C(u)+C(v) < w(u, v)-(N-h) \leq w(u, v)$ and a contradiction occurs.

Since C is a cover of G, $C(u) + C(v) \geq w(u, v)$. Thus, $C(v) \geq w(u, v) - C(u) \geq N - h + C_h(u) + C_h(v) - C(u)$. Define another cover C' of G as follows. For each bad node defined by C, let v be the mate of u, define $C'(u) = C_h(u)$ and $C'(v) = C(v) - (C_h(u) - C(v))$. Note that u is not a bad node with respect to C', and neither is v since $C'(v) \geq N - h + C_h(v) \geq C_h(v)$. For all other nodes x, $C'(x)$ is the same as $C(x)$. Therefore, if C' is a cover of G, C' allows no bad node. Also, $w(C') = w(C)$.

It remains to prove that C' is a cover of G. By the definition of C', $C'(v) < C(v)$ if and only if v is the mate of a bad node with respect to C. Suppose C' is not a cover of G. Then there exists an edge vt such that $C'(v) + C'(t) \leq w(v, t)$ and v is the mate of a bad node. Recall that the latter implies that $C'(v) \geq N - h + C_h(v)$. In other words,

$$C'(t) < w(v, t) - C'(v) \leq w(v, t) - (N - h) - C_h(v).$$

We can derive a contradiction as follows.

Case 1: $w(v, t) \leq N - h$. Then $C'(t) < -C_h(v) \leq 0$, which contradicts that $C'(t) \geq C_h(t) \geq 0$.

Case 2: $w(v, t) > N - h$. Then G_h contains the edge vt and $C_h(v) + C_h(t) \geq w(v, t) - (N - h)$. Thus, $C'(t) < w(v, t) - (N - h) - C_h(v) \leq C_h(t)$, which contradicts the fact that C' allows no bad node.

In conclusion, C' is a cover of G. Together with the fact that $w(C) = w(C')$, we obtain the desired contradiction that C' is a minimum weight cover of G with no bad node. Lemma 2.4 follows. ∎

3. Construct a maximum weight matching. The algorithm in section 2.1 only computes the value of mwm(G). To report the edges involved, we show below how to first construct a minimum weight cover of G in $O(\sqrt{n}W/k(n, W/N))$ time and then use this cover to construct a maximum weight matching in $O(\sqrt{n}m/k(n, m))$ time. Thus, the time required to construct a maximum weight matching is $O(\sqrt{n}W/k(n, W/N))$.

LEMMA 3.1. *Assume that h, G_h, C_h, and G_h^Δ are defined as in section 2. Let C_h^Δ be any minimum weight cover of G_h^Δ. If D is a function on $V(G)$ such that for every $u \in V(G)$, $D(u) = C_h(u) + C_h^\Delta(u)$, then D is a minimum weight cover of G.*

Proof. Consider any edge uv of G. If uv is not in G_h^Δ, then $w(u, v) \le C_h(u) + C_h(v) \le D(u) + D(v)$. Assume that uv is in G_h^Δ. Note that its weight in G_h^Δ is $w(u, v) - C_h(u) - C_h(v)$. Since C_h^Δ is a cover, $C_h^\Delta(u) + C_h^\Delta(v) \ge w(u, v) - C_h(u) - C_h(v)$. Thus, $D(u) + D(v) = C_h(u) + C_h^\Delta(u) + C_h(v) + C_h^\Delta(v) \ge w(u, v)$. It follows that D is a cover of G. To show that D is a minimum weight one, we observe that

$$\begin{array}{lcll} \sum_{u\in V(G)} D(u) & = & \sum_{u\in V(G)} C_h(u) + C_h^\Delta(u) & \\ & = & \sum_{u\in V(G)} C_h(u) + \sum_{u\in V(G)} C_h^\Delta(u) & \\ & = & \mathrm{mwm}(G_h) + \mathrm{mwm}(G_h^\Delta) & \text{by Fact 2.1} \\ & = & \mathrm{mwm}(G) & \text{by Theorem 2.2.} \end{array}$$

By Fact 2.1, D is minimum. ∎

By Lemma 3.1, a minimum weight cover of G can be computed using a recursive procedure similar to Compute-MWM as follows.

PROCEDURE Compute-Min-Cover(G).

1. Construct G_1 from G.
2. Find a minimum weight cover C_1 of G_1.
3. Construct G_1^Δ from G and C_1.
4. If G_1^Δ is empty, then return C_1; otherwise, let C_1^Δ = Compute-Min-Cover(G_1^Δ) and return D, where for all nodes u in G, $D(u) = C_1(u) + C_1^\Delta(u)$.

THEOREM 3.2. Compute-Min-Cover(G) *correctly computes a minimum weight cover of G in $O(\sqrt{n}W/k(n, W/N))$ time.*

Proof. The correctness of Compute-Min-Cover(G) follows from Lemma 3.1. For the time complexity, the analysis is similar to that of Theorem 2.3. ∎

Now, we show how to recover a maximum weight matching of G from a minimum weight cover D of G.

PROCEDURE Recover-Max-Matching(G, D).

1. Let H be the subgraph of G that contains all edges uv with $w(u, v) = D(u) + D(v)$.
2. Make two copies of H. Call them H^a and H^b. For each node u of H, let u^a and u^b denote the corresponding nodes in H^a and H^b, respectively.
3. Union H^a and H^b to form H^{ab}, and add to H^{ab} the set of edges $\{u^a u^b \mid u \in V(H),\ D(u) = 0\}$.
4. Find a maximum cardinality matching K of H^{ab} and return the matching $K^a = \{uv \mid u^a v^a \in K\}$.

THEOREM 3.3. Recover-Max-Matching(G, D) *correctly computes a maximum weight matching of G in $O(\sqrt{n}m/k(n, m))$ time.*

Proof. The running time of Recover-Max-Matching(G, D) is dominated by the construction of K. Since H^{ab} has at most $2n$ nodes and at most $3m$ edges, K can be constructed in $O(\sqrt{n}m/k(n, m))$ time using the Feder–Motwani algorithm [4].

It remains to show that K^a is a maximum weight matching of G. First, we argue that H^{ab} has a perfect matching. Let M be a maximum weight matching of G. By

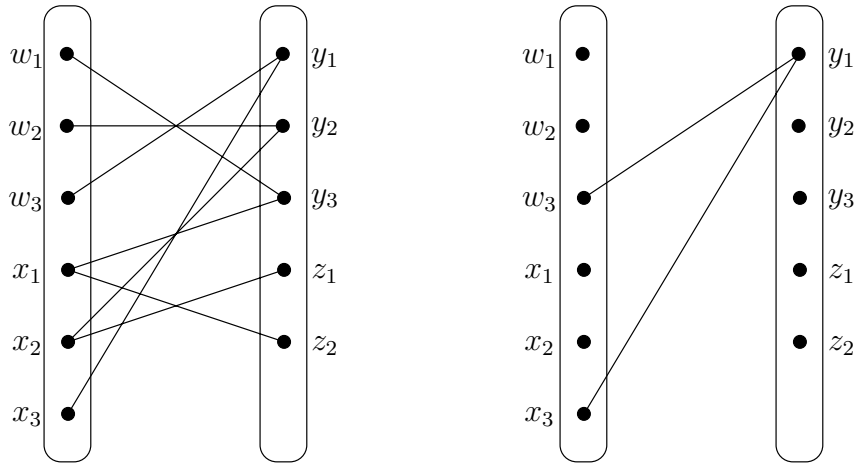

FIG. 2. (a) *The unfolded graph $\phi(G)$ of the bipartite graph given in Figure* 1(a). (b) *With respect to the cover C_h defined in Figure* 1(c)*, the node y_1 in $\phi(G)$ is the only node satisfying the condition that $1 \leq C_h(y)$. Thus, $\phi(G)|C_h$ comprises only the edges incident to y_1.*

Fact 2.1, $D(u) + D(v) = w(u, v)$ for every edge $uv \in M$. Therefore, M is also a matching of H. Let U be the set of nodes in H unmatched by M. By Fact 2.1, $D(u) = 0$ for all $u \in U$. Let Q be $\{u^a u^b \mid u \in U\}$. Let $M^a = \{u^a v^a \mid uv \in M\}$ and $M^b = \{u^b v^b \mid uv \in M\}$. Note that $Q \cup M^a \cup M^b$ forms a matching in H^{ab} and every node in H^{ab} is matched by either Q, M^a, or M^b. Thus, H^{ab} has a perfect matching.

Since K is a maximum cardinality matching of H^{ab}, K must be a perfect matching. For every node u with $D(u) > 0$, u^a must be matched by K. Since there is no edge between u^a and any x^b in H^{ab}, there exists some v^a with $u^a v^a \in K$. Thus, every node u with $D(u) > 0$ must be matched by some edge in K^a. Therefore, $\sum_{uv \in K^a} w(u, v) = \sum_{u \in X \cup Y, D(u) > 0} D(u) = \sum_{u \in X \cup Y} D(u) = \mathrm{mwm}(G)$, and K^a is a maximum weight matching of G. ∎

4. All-cavity maximum weight matchings. In section 4.1, we introduce the notion of an *unfolded graph*. In section 4.2, we use this notion to design an algorithm which, given a weighted bipartite graph G and a maximum weight matching of G, computes $\mathrm{mwm}(G - \{u\})$ for all nodes u in G using $O(W)$ time.

4.1. Unfolded graphs. The *unfolded graph* $\phi(G)$ of G is defined as follows.

- For each node u of G, $\phi(G)$ has α copies of u, denoted as $u^1, u^2, \ldots, u^\alpha$, where α is the weight of the heaviest edge incident to u.
- For each edge uv of G, $\phi(G)$ has the edges $u^1 v^\beta, u^2 v^{\beta-1}, \ldots, u^\beta v^1$, where $\beta = w(u, v)$.

See Figure 2(a) for an example. Let M be a matching of G. Consider M as a weighted bipartite graph; then, by definition, $\phi(M) = \bigcup_{uv \in M} \{u^1 v^\beta, \ldots, u^\beta v^1 \mid \beta = w(u, v)\}$ is a matching of $\phi(G)$. The number of edges in $\phi(M)$ is equal to the total weight of the edges in M, i.e., $|\phi(M)| = \sum_{uv \in M} w(u, v)$. The next lemma relates G and $\phi(G)$.

LEMMA 4.1. *Assume that M is a maximum weight matching of G.*

1. $\mathrm{mwm}(G) = \mathrm{mm}(\phi(G))$.
2. *The set $\phi(M)$ is a maximum cardinality matching of $\phi(G)$.*

Proof. Statement 4.1 follows from Statement 4.1. Statement 4.1 is proved as follows. Since M is a maximum weight matching of G, $\text{mwm}(G) = \sum_{uv \in M} w(u,v) = |\phi(M)| \leq \text{mm}(\phi(G))$. By Fact 2.1, $\text{mwm}(G) \geq \text{mm}(\phi(G))$ if and only if $\text{mwc}(G) \geq \text{mwc}(\phi(G))$. We prove the latter as follows. Given a minimum weight cover C of G, we can obtain a cover C' of $\phi(G)$ as follows. For any node u of G, $C'(u^i) = 1$ if $C(u) > 0$ and $i \leq C(u)$; otherwise, $C'(u^i) = 0$. Note that $w(C') = w(C) = \text{mwc}(G)$. Therefore, $\text{mwc}(G) \geq \text{mwc}(\phi(G))$ and $\text{mwm}(G) \geq \text{mm}(\phi(G))$. □

4.2. An algorithm for all-cavity maximum weight matchings. Let M be a given maximum weight matching of G.

By Lemma 4.1(2), $\phi(M)$ is a maximum cardinality matching of $\phi(G)$. In light of this maximality, we say that a path in $\phi(G)$ is *alternating* for $\phi(M)$ if (1) its edges alternate between being in $\phi(M)$ and being not in $\phi(M)$ and (2) in the case the first (respectively, last) node is matched by $\phi(M)$, the path contains the matched edge of u as the first (respectively, last) edge. The length of an alternating path is its number of edges. An alternating path may have zero length; in this case, the path contains exactly one unmatched node. An alternating path P can modify $\phi(M)$ to another matching, i.e., $(\phi(M) \cup P) - (\phi(M) \cap P)$. If P is of even length, the resulting matching has the same size as $\phi(M)$. If P is of odd length, P modifies M to a strictly smaller or bigger matching; yet the latter is impossible because $\phi(M)$ is maximum. Intuitively, we would like to maximize the size of the resultant matching and even-length alternating paths are preferred.

Our new algorithm for computing $\text{mwm}(G - \{u\})$ is based on the observation that $\text{mwm}(G - \{u\})$ can be determined by detecting the smallest i such that u^i has an even-length alternating path for $\phi(M)$. Details are as follows.

Definition. For each u^i in $\phi(G)$, let $\rho(u^i) = 0$ if there is an even-length alternating path for $\phi(M)$ starting from u^i; otherwise, let $\rho(u^i) = 1$.

The following lemma states a monotone property of $\rho(u^i)$ over different i's.

LEMMA 4.2. *Consider any node u in G. Let $u^1, u^2, \ldots, u^\beta$ be its corresponding nodes in $\phi(G)$. If $\rho(u^i) = 0$, then $\rho(u^j) = 0$ for all $j \in [i, \beta]$. Furthermore, there exist $\beta - i + 1$ node-disjoint even-length alternating paths $P_i, P_{i+1}, \ldots, P_\beta$ for $\phi(M)$, where each P_j starts from u^j.*

Proof. As $\rho(u^i) = 0$, let $P_i = u_0^{a_0}, v_0^{b_0}, u_1^{a_1}, v_1^{b_1}, \ldots, u_{p-1}^{a_{p-1}}, v_{p-1}^{b_{p-1}}, u_p^{a_p}$ be a shortest even-length alternating path for $\phi(M)$, where $u_0^{a_0} = u^i$.

Based on P_i, we can construct an even-length alternating path P_{i+1} for $\phi(M)$ starting from u^{i+1} as follows. If u^{i+1} is not matched by $\phi(M)$, P_{i+1} is simply a path of zero length. From now on, we assume that u^{i+1} is matched by $\phi(M)$. As P is of even length, $u_p^{a_p}$ is not matched by $\phi(M)$. Then, by the definition of $\phi(M)$, $u_p^{a_p+1}$ is also not matched by $\phi(M)$. Let h be the smallest integer in $[1, p]$ such that $u_h^{a_h+1}$ is not matched by $\phi(M)$. Notice that, for all $\ell < h$, $u_\ell^{a_\ell+1}$ is matched to $v_\ell^{b_\ell-1}$; furthermore, $\phi(G)$ contains an edge between $v_\ell^{b_\ell-1}$ and $u_{\ell+1}^{a_{\ell+1}+1}$. Thus, $P_{i+1} = u^{i+1}, v_0^{b_0-1}, u_1^{a_1+1}, v_1^{b_1-1}, \ldots, u_h^{a_h+1}$ is an even-length alternating path for $\phi(M)$. Similarly, for $j = i+2, \ldots, \beta$, we can use P_i to define an even-length alternating path P_j for $\phi(M)$ starting from u^j. By construction, $P_i, P_{i+1}, \ldots, P_\beta$ are node-disjoint. □

The next lemma is the basis of our cavity matching algorithm. It shows that given $\text{mwm}(G)$ (i.e., the weight of M), we can compute $\text{mwm}(G - \{u\})$ from the values $\rho(u^i)$, and all the $\rho(u^i)$'s can be found in $O(W)$ time.

LEMMA 4.3.

1. $\sum_{1\le i\le\beta}\rho(u^i) = \mathrm{mwm}(G) - \mathrm{mwm}(G-\{u\})$.
2. *For all* $u^i \in \phi(G)$, $\rho(u^i)$ *can be computed in* $O(W)$ *time in total.*

Proof. The two statements are proved as follows.

Statement 1. Let k be the largest integer such that $\rho(u^k) = 1$. By Lemma 4.2, $\rho(u^i) = 1$ for all $1 \le i \le k$, and 0 otherwise. Note that if $\rho(u^i) = 1$, u^i must be matched by $\phi(M)$. Thus, $\sum_{1\le i\le\beta}\rho(u^i) = k$. Below, we prove the following two equalities:

(1) $\mathrm{mm}(\phi(G) - \{u^1,\ldots,u^k\}) = \mathrm{mm}(\phi(G)) - k$.
(2) $\mathrm{mm}(\phi(G) - \{u^1,\ldots,u^\beta\}) = \mathrm{mm}(\phi(G) - \{u^1,\ldots,u^k\})$.

Then, by Lemma 4.1, $\mathrm{mwm}(G) = \mathrm{mm}(\phi(G))$ and $\mathrm{mwm}(G-\{u\}) = \mathrm{mm}(\phi(G) - \{u^1,\ldots,u^\beta\})$. Thus, $\mathrm{mwm}(G) - \mathrm{mwm}(G-\{u\}) = k$ and Statement 1 follows.

To show equality (1), let H be the set of edges of $\phi(M)$ incident to u^i with $1 \le i \le k$. Let $M' = \phi(M) - H$. Then, $|M'| = |\phi(M)| - k$. We claim that M' is a maximum cardinality matching of $\phi(G) - \{u^1,\ldots,u^k\}$. Hence, $\mathrm{mwm}(\phi(G) - \{u^1,\ldots,u^k\}) = |\phi(M)| - k$, and equality (1) follows. We prove the claim by contradiction. Suppose M' is not a maximum cardinality matching of $\phi(G) - \{u^1,\ldots,u^k\}$. Then, there exists an alternating path P that can modify M' to a larger matching of $\phi(G) - \{u^1,\ldots,u^k\}$ [8, 9]; in particular, the length of P must be odd and both of its endpoints are not matched by M'. P must start from some node v^j with $u^iv^j \in \phi(M)$ and $i < k$; otherwise, P is alternating for $\phi(M)$ in G and $\phi(M)$ cannot be a maximum cardinality matching of $\phi(G)$. Let Q be a path formed by joining u^iv^j with P. Q is an even-length alternating path for $\phi(M)$ starting from u^i in $\phi(G)$. This contradicts the fact that there is no even-length alternating path for $\phi(M)$ starting from u^i for $i < k$.

To show equality (2), we first note that $\mathrm{mm}(\phi(G) - \{u^1,\ldots,u^\beta\}) \le \mathrm{mm}(\phi(G) - \{u^1,\ldots,u^k\})$. It remains to prove the other direction. By Lemma 4.2, we can find $\beta - k$ node-disjoint even-length alternating paths $P_{k+1},\ldots,P_\beta$ for $\phi(M)$, which start from $u^{k+1},\ldots,u^\beta$. P_j starts at u^j. Let $M'' = (\phi(M) \cup (P_{j+1} \cup \cdots \cup P_\beta)) - (\phi(M) \cap (P_{j+1} \cup \cdots \cup P_\beta))$. Note that $|M''| = |\phi(M)|$ and there are no edges in M'' incident to any of $u^{k+1},\ldots,u^\beta$. M'' is a matching of $\phi(G) - \{u^{k+1},\ldots,u^\beta\}$ and $M'' - H$ of $\phi(G) - \{u^1,\ldots,u^\beta\}$. $|M'' - H| \ge |M''| - k = |\phi(M)| - k$. Since $\mathrm{mm}(\phi(G) - \{u^1,\ldots,u^k\}) = |\phi(M)| - k$ by equality (1), it follows that $\mathrm{mm}(\phi(G) - \{u^1,\ldots,u^\beta\}) \ge |M'' - H| \ge \mathrm{mm}(\phi(G) - \{u^1,\ldots,u^k\})$. Therefore, equality (2) holds.

Statement 2. We want to determine whether $\rho(u^i) = 0$ for all nodes $u^i \in \phi(G)$ in $O(W)$ time. By definition, $\rho(u^i) = 0$ if and only if there is an even-length alternating path for $\phi(M)$ starting from u^i. Let us partition the nodes of $\phi(G)$ into two parts: $\phi(X) = \{u^i \in \phi(G) \mid u \in X\}$ and $\phi(Y) = \{u^i \in \phi(G) \mid u \in Y\}$. Below, we give the details of computing $\rho(u^i)$ for all $u^i \in \phi(X)$. The case where $u^i \in \phi(Y)$ is symmetric.

Let D be a directed graph over the node set $\phi(X)$. D contains an edge u^iv^j if there exists a node $w^k \in \phi(Y)$ such that $u^iw^k \in \phi(G) - \phi(M)$ and $w^kv^j \in \phi(M)$. Consider any node v^j of D that is unmatched by $\phi(M)$. A directed path in D from v^j to a node u^i corresponds to a path in $\phi(G)$, which is indeed an even-length alternating path for $\phi(M)$ starting from u^i. Therefore, for any $u^i \in \phi(X)$, $\rho(u^i) = 0$ if and only if u^i is reachable from some node in D that is unmatched by $\phi(M)$. We can identify all such u^i by using a depth-first search on D starting with all the nodes unmatched by M. The time required is $O(|D|)$. As $|D| \le |\phi(G)| = W$, the lemma follows. ∎

The following procedure computes $\mathrm{mwm}(G-\{u\})$ for all nodes u of G. Let M be a maximum weight matching of G.

PROCEDURE Compute-All-Cavity(G, M).

1. Construct $\phi(G)$ and $\phi(M)$.
2. For every $j \in [0, n/2]$, determine A_j from $\phi(M)$.
3. For every node u^i of $\phi(G)$, if $u^i \in \bigcup_j A_j$ then $\rho(u^i) = 0$; otherwise $\rho(u^i) = 1$.
4. For every node u of G, compute $\text{mwm}(G - \{u\}) = \text{mwm}(G) - \sum_{1 \le i \le \beta} \rho(u^i)$, where u^1, u^2, ..., u^β are the nodes corresponding to u in $\phi(G)$.

THEOREM 4.4. Compute-All-Cavity(G, M) *correctly computes* $\text{mwm}(G - \{u\})$ *for all* u *of* G *in* $O(W)$ *time.*

Proof. The proof follows from Lemma 4.3 □

Acknowledgments. The authors wish to thank the anonymous referee for extremely helpful comments, which significantly improved the presentation of the paper. In particular, Theorem 2.2 was originally proved using unfolded graphs (see the conference version of this paper [13]); the new proof is based on a suggestion by the referee.

TRAVELING SALESMAN-BASED CURVE RECONSTRUCTION IN POLYNOMIAL TIME*

ERNST ALTHAUS† AND KURT MEHLHORN†

Abstract. An instance of the curve reconstruction problem is a finite sample set V of an unknown collection of curves γ. The task is to connect the points in V in the order in which they lie on γ. Giesen [*Proceedings of the 15th Annual ACM Symposium on Computational Geometry (SCG '99)*, 1999, pp. 207–216] showed recently that the traveling salesman tour of V solves the reconstruction problem for single closed curves under otherwise weak assumptions on γ and V; γ must be a single closed curve. We extend his result along several directions:

- we weaken the assumptions on the sample;
- we show that traveling salesman-based reconstruction also works for single open curves (with and without specified endpoints) and for collections of closed curves;
- we give alternative proofs; and
- we show that in the context of curve reconstruction, the traveling salesman tour can be constructed in polynomial time.

Key words. traveling salesman, polynomial time, curve reconstruction

1. Introduction.

An instance of the curve reconstruction problem is a finite sample set V of an unknown collection of curves γ. The task is to construct a graph G on V so that two points in V are connected by an edge of G iff the points are adjacent on γ. The curve reconstruction problem and the related surface reconstruction problem have received a lot of attention in the graphics and the computational geometry community. We are interested in *reconstruction algorithms with guaranteed performance*, i.e., algorithms which provably solve the reconstruction problem under certain assumptions on γ and V. Figure 1.1 illustrates the curve reconstruction problem.

Many curve reconstruction algorithms have been proposed in the past; we restrict our discussion to algorithms that provably solve the reconstruction problem for a certain class of curves and under certain assumptions on the sample set. The algorithms differ with respect to the following aspects:

- whether a collection of curves or just a single curve can be handled;
- whether (collections of) open and closed curves can be handled or only (collections of) closed curves;
- whether the sampling must be uniform or not. Uniform sampling with density ϵ requires that the sample set V contains at least one point from every curve segment of length ϵ. In nonuniform sampling, the sampling frequency may depend on local properties of the curve, e.g., can be lower in parts of low curvature;
- whether nonsmooth curves can be handled or not. A smooth curve has a

tangent everywhere. Figure 2.1 shows nonsmooth curves.

For uniformly sampled collections of closed, smooth curves several methods are known to work ranging over minimum spanning trees [12], α-shapes [5, 11], β-skeletons [16], and r-regular shapes [4]. A survey of these techniques appears in [10]. The case of nonuniformly sampled collections of closed smooth curves was first treated successfully by Amenta, Bern, and Eppstein [3], and subsequently improved algorithms such as [8, 15] appeared. Nonuniformly sampled collections of open and closed smooth curves were treated in [9]. All papers mentioned so far require the curves to be smooth.

Giesen [14] recently obtained the first result for nonsmooth curves. He considered the class of *benign semiregular curves*. An (open or closed) curve is *semiregular* if a left and a right tangent exists in every point of the curve; the two tangents may, however, be different. A semiregular curve is *benign* if the turning angle at every point of the curve is less than π; see Figure 2.1. Giesen showed that the traveling salesman tour of the sample set V solves the curve reconstruction problem for uniformly sampled benign closed semiregular curves. More precisely, he showed that for every benign semiregular closed curve γ there exists a positive ϵ such that the optimal traveling salesman tour of V is a polygonal reconstruction of γ provided that for every $x \in \gamma$ there is a $p \in V$ with $\|xp\| \leq \epsilon$, where $\|xy\|$ is the Euclidean distance of the two points x and y. Giesen's result is an existence result; he did not quantify ϵ in terms of properties of the curve γ. We extend Giesen's result in several directions:

- We relate ϵ to local properties of the curve γ and show that the optimal traveling salesman tour solves the reconstruction problem even if sampling is nonuniform. For smooth curves our sampling condition is similar to the one used in [3, 8, 15, 9].
- We show that the traveling salesman path is able to reconstruct open curves for a suitable sampling condition. We treat the case of paths with and without specified endpoints.
- We show that the optimal traveling salesman tour (path) can be constructed in polynomial time if our sampling condition is satisfied.
- We give a simplified proof that the traveling salesman tour (path) solves the curve reconstruction problem.
- We show that an extension of the traveling salesman tour algorithm is able to reconstruct nonuniformly sampled collections of closed nonsmooth curves.

We have implemented a number of curve reconstruction algorithms. The JAVA-Applet `http://review.mpi-sb.mpg.de:81/Curve-Reconstruction/` makes our implemen-

tations available. Our experiments show that the traveling salesman-based curve reconstruction is able to solve the reconstruction problem for surprisingly small sampling density and that its speed is comparable to Delaunay diagram-based reconstruction algorithms. The details are given in the companion paper [2].

A preliminary version of the present paper appeared in SODA 2000. It contained the result for open curves with specified endpoints and for closed curves. It did not contain the result for open curves without specified endpoints and for collections of closed curves. Also the proof of polynomiality was incomplete.

Since the publication of the conference version of this paper, Funke and Ramos [13] have presented an algorithm that works for collections of nonsmooth curves. The algorithm is based on filtering the Delaunay diagram and can handle collections of open and closed curves; our algorithm can only handle collections of closed curves.

This paper is structured as follows. In section 2 we give definitions and state our main results. In sections 3, 4, and 5 we prove our main theorem for open curves with and without specified endpoints and for closed curves, respectively, assuming real arithmetic. The result is extended to finite precision arithmetic in section 6. In section 7 we discuss collections of closed curves. For computational purposes it is desirable to restrict the search for the reconstruction to a sparse graph defined on the sample set. In section 8, we show that the edges of the polygonal reconstruction are in the Delaunay diagram for a slightly strengthened sampling condition. In section 10 we relate our sampling condition to the sampling conditions used by other papers, and in Section 11 we relate our result to so-called necklace tours. Necklace tours are a polynomially solvable case of the traveling salesman problem. Curve reconstruction problems are allowed to "invent" curves if the input does not satisfy the required sampling condition. This issue is discussed in section 9. Finally, in section 12 we offer conclusions and state open problems.

2. Definitions and statements of results. An open *curve* is given by an *embedding* $\gamma : [0,1] \to \mathbb{R}^2$ and a closed curve is given by an embedding $\gamma : S^2 \to \mathbb{R}^2$, where S^2 is the unit circle.

DEFINITION 2.1 (see [14]). *Let*

$$T = \{\, (t_1, t_2) \ ; \ t_1 < t_2, t_1, t_2 \in [0,1] \,\}$$

and

$$\tau : T \to S^2, (t_1, t_2) \mapsto \frac{\gamma(t_2) - \gamma(t_1)}{|\, \gamma(t_2) - \gamma(t_1) \,|}.$$

The curve γ is called left (right) regular at $\gamma(t_0)$ with left (right) tangent $\mathrm{t}_l(\gamma(t_0))$ ($\mathrm{t}_r(\gamma(t_0))$) if for every sequence (ξ_n) in T which converges to (t_0, t_0) from the left (right) in the closure of T the sequence $\tau(\xi_n)$ converges to $\mathrm{t}(\gamma(t_0))$. We call γ semiregular if it is left and right regular in all points $\gamma(t)$, $t \in [0,1]$. We call γ regular if it is semiregular and the left and right tangent coincide in every point of the curve.

Figure 2.1 shows two semiregular curves. Tangents are unit vectors. The angle between two vectors with the same source is the smaller of the two angles between the vectors. The angle is zero if the two vectors point to the same direction and the angle is π if the vectors point to opposite directions. The angle between the left and right tangent at a point $p \in \gamma$ is called the *turning angle* at p. If the curve has a tangent at p, the turning angle at p is zero. If the turning angle at p is nonzero, we call p a *singularity* of the curve. A semiregular curve is *benign* if the turning angle is less than π at every point of the curve.

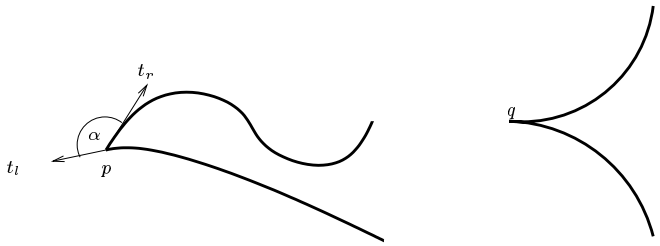

FIG. 2.1. *Two semiregular curves, one benign and one not. In the left curve, the two tangents t_l and t_r at a point p of the curve are shown. The turning angle at p is α. In the curve on the right the turning angle at q is π as the left and right tangents at q point to opposite directions.*

A traveling salesman path (tour) for a set V of points is a path (cycle) passing through all points in V. An optimal traveling salesman path (tour) is a traveling salesman path (tour) of shortest length. An optimal traveling salesman path with specified endpoints a and b, where $a \in V$ and $b \in V$ is a shortest traveling salesman path among the paths with endpoints a and b. We can now state Giesen's result.

THEOREM 2.2 (see [14]). *For every benign semiregular closed curve γ there exists an $\epsilon > 0$ with the following property: If V is a finite sample set of γ so that for every $x \in \gamma$ there is a $p \in V$ with $\|pv\| \leq \epsilon$, the optimal traveling salesman tour is a polygonal reconstruction of γ.*

The construction of optimal traveling salesman paths or tours is an NP-hard problem. A successful method for solving the Traveling Salesman problem is to formulate the problem as an integer linear program (ILP) and to use a branch-and-cut algorithm based on the LP-relaxation of the problem. We give the formulation for traveling salesman paths with specified endpoints a and b. We introduce a variable x_{uv} for every edge uv between two sample points and describe the set of all paths with endpoints a and b in the following way:

$$\sum_{v \in V} x_{uv} = 2 \text{ for all } u \in V \setminus \{a, b\},$$

$$\sum_{v \in V} x_{uv} = 1 \text{ for } u \in \{a, b\},$$

$$\sum_{u \in V', v \in V'} x_{uv} \leq |\, V' \,| - 1 \text{ for } V' \subset V,\ V' \neq \emptyset,$$

$$x_{uv} \in \{0, 1\} \text{ for all } u, v \in V.$$

We refer to this program as the *subtour-ILP for the traveling salesman path problem with specified endpoints*. Slight variations of this ILP characterize paths with unspecified endpoints (see section 4) and tours (see section 5). The equality constraints in the subtour-ILP are called *degree constraints*, the inequality constraints are called *subtour elimination constraints*, and the constraints $x_{uv} \in \{0, 1\}$ are called the *integrality constraints*. Relaxing the integrality constraints to $0 \leq x_{uv} \leq 1$ gives the *subtour-LP for the traveling salesman problem with specified endpoints*. The objective function for both programs is $\sum_{uv} \|uv\| x_{uv}$, i.e., the total Euclidean length of the edges selected.

In general, the optimal solution of the subtour-LP is fractional. Our main result states the optimal solution of the subtour-LP is integral, whenever V is a sufficiently dense sample of a benign semiregular curve. The reader might be interested to know

that we discovered this fact in our experiments on curve reconstruction. We had implemented a branch-and-cut algorithm based on the subtour-LP (the algorithm solved the subtour-LP and was then supposed to branch on a fractional variable) and observed that the algorithm never branched. After seeing this behavior in a large number of examples, we formulated it as a conjecture and set out to prove it.

THEOREM 2.3 (main theorem). *Let γ be an closed benign semiregular curve; let V be a finite set of samples of γ. If V satisfies the sampling condition given below, then*

- *the optimal traveling salesman tour of V is a polygonal reconstruction of γ;*
- *the subtour-LP for traveling salesman tours has an optimal integral solution and this solution is unique.*

In the case of an open curve let a and b be the first and last sample points, respectively (in the order on γ). The statements above hold true for the optimal traveling salesman path with endpoints a and b and the subtour-LP for traveling salesman paths with specified endpoints and also for the traveling salesman path with unspecified endpoints and for the subtour-LP for traveling salesman paths with unspecified endpoints. The latter result required a strengthened sampling condition.

We will prove our Main Theorem for open curves with specified and unspecified endpoints in sections 3 and 4, respectively. The proof for closed curves follows in section 5.

Our main theorem suggests a reconstruction algorithm for benign semiregular curves: *Solve the subtour-LP. If the optimal solution is integral, output it.* We briefly discuss two strategies for solving the subtour-LP.

A potentially exponential, but practically very efficient algorithm uses the simplex method and the cutting plane framework. One starts with the LP consisting only of the degree constraints and then solves a sequence of LPs. In each iteration one checks whether the solution X^* to the current LP satisfies all subtour elimination constraints and, if not, one adds a violated subtour elimination constraint to the LP. The check for a violated subtour elimination constraint is tantamount to a min-cut problem. One assigns capacity x_e^* to edge e for every edge e and computes a minimum (a, b)-cut. If the cut has value less than two, a violated inequality has been found. If the cut has value two, all cut constraints are satisfied. We use the simplex-based strategy in our in our experiments on curve reconstruction.

The ellipsoid method (see [18]) solves the subtour-LP in time polynomial in the size of the bit representations of the coefficients of the cost function. Distance values are, in general, nonrational numbers and hence the ellipsoid method is not directly applicable in our setting. In section 6, we extend our results to the situation where the position of the points and the distances between points are only approximately known and show how to obtain a polynomial time algorithm.

3. Open curves. We assume that our open curve is oriented and write $p < q$ if p precedes q on γ. We use $B(p, r)$ and $B^0(p, r)$ to denote the closed and open ball with center p and radius r, respectively.

3.1. The Held–Karp bound. Our proof of Theorem 2.3 exploits the connection between the subtour-LP and what is known as the Held–Karp bound. The purpose of this section is to review the relevant facts about the Held–Karp bound.

Let $G = (V, E)$ be an undirected graph, let a and b be two designated vertices of G, and let c be an arbitrary cost function on the edges of G. A function $\mu : V \to \mathbb{R}$ is called a *potential function*. It gives rise to a modified distance function c_μ via $c_\mu(u, v) = c(u, v) - \mu(u) - \mu(v)$. Now consider any traveling salesman path

T with endpoints a and b. Its costs under c and c_μ are related by $c_\mu(T) = c(T) - 2\sum_{v\in V}\mu(v) + \mu(a) + \mu(b)$ since the path uses two edges incident to every vertex except for a and b. Observe that $c_\mu(T) - c(T)$ does not depend on T and hence the optimal traveling salesman path for endpoints a and b is the same under both cost functions. Let T_0 be an optimal traveling salesman path for endpoints a and b.

Let MST_μ be a minimum spanning tree with respect to the cost function c_μ and let $C_\mu = c_\mu(\mathrm{MST}_\mu)$ be its cost. Then $C_\mu \le c_\mu(T_0)$, since a traveling salesman path is a spanning tree.

FACT 1. *Let μ be any potential function. If MST_μ is a traveling salesman path with endpoints a and b, it is an optimal Traveling Salesman path for endpoints a and b.*

Proof. From $C_\mu \le c_\mu(T_0)$, we conclude that MST_μ is an optimal traveling salesman path with respect to c_μ. Since the ranking of paths is the same under both cost functions, it is also optimal with respect to c. □

The inequality $C_\mu \le c_\mu(T_0) = c(T_0) - 2\sum_{v\in V}\mu(v) + \mu(a) + \mu(b)$ is valid for every potential function and hence

$$\max_\mu C_\mu + 2\sum_{v\in V}\mu(v) - \mu(a) - \mu(b) \le c(T_0)\ .$$

The quantity on the left is called the Held–Karp bound.[1] The following fact is crucial for our proof.

FACT 2. *The Held–Karp bound is equal to the optimal objective value of the subtour-LP.*

Proof. The fact follows by relaxing the degree constraints of the subtour-LP in a Lagrangian fashion. For a short introduction to Lagrangian relaxation, see [7, p. 259]. □

We remark (but will not use) that an optimal choice of μ in the Held–Karp bound is given by the optimal solution of the linear programming dual of the subtour-LP; μ corresponds to the dual variables for the degree constraints. We next draw a simple consequence from the two facts above, which forms the basis for our proof.

LEMMA 3.1. *Let μ be any potential function. If MST_μ is the unique minimum spanning tree with respect to c_μ and moreover is a traveling salesman path with endpoints a and b, the subtour-LP has a unique optimal solution and this solution is integral.*

Proof. If MST_μ is a traveling salesman path, it is optimal (Fact 1) and hence $c(\mathrm{MST}_\mu) = c(T_0)$. The Held–Karp bound is therefore equal to $c(T_0)$ and the same holds true for the optimal objective value of the subtour-LP (Fact 2). The incidence vector of MST_μ is a feasible solution of the subtour-LP of cost $c(\mathrm{MST}_\mu)$ and hence is *an* optimal solution of the subtour-LP. We will next argue that it is the unique optimal solution. Assume that there is an optimal solution of the subtour-LP with $x_e > 0$ for some $e \notin \mathrm{MST}_\mu$. Since MST_μ is unique there is a $\eta > 0$ so that decreasing the cost of e by η will not change the minimum spanning tree and hence will not change the

[1] A simple iterative algorithm can be used to approximate the Held–Karp bound. Let α_t, $t = 0, 1, \ldots$, be positive reals with $\alpha_t \to 0$ as $t \to \infty$ and $\sum_t \alpha_t = \infty$. Start with $\mu(v) = 0$ for all $v \in V$ and compute MST_μ. As long as MST_μ is not a path with endpoints a and b, update μ as follows: $\mu(v) = \mu(v) + \alpha_t \cdot (d(v) - deg_\mu(v))$, where $d(a) = d(b) = 1$ and $d(v) = 2$ for all other nodes, t is the index of the iteration, and $deg_\mu(v)$ is the degree of v in MST_μ. The cost of MST_μ converges to the Held–Karp bound. We found in our experiments that the convergence is rather slow and that the cutting plane approach to solving the subtour-LP is faster.

value of the Held–Karp bound. However, the objective value of the subtour-LP will decrease. This is a contradiction to the equality of the two bounds. □

We can now describe our proof strategy for open curves. We define a potential function μ such that MST_μ is the unique minimum spanning tree in the complete network $G = (V, V \times V, c)$, where c is the Euclidean distance function, and moreover MST_μ coincides with the polygonal reconstruction (and hence is a traveling salesman path with endpoints a and b, where a and b are the first and last sample point, respectively). Then MST_μ and hence the polygonal reconstruction is the unique optimal solution of the subtour-LP. We want to stress that the definition of μ is only needed for the proof of our main theorem. The reconstruction algorithm simply solves the subtour-LP.

3.2. Intuition. When will the minimum spanning tree of the sample set be the correct reconstruction? Let $V = \{v_1, v_2, \ldots, v_n\}$, where we assume the points to be numbered according to their order on the curve. Kruskal's algorithm considers the edges $v_i v_j$ in increasing order of length and adds an edge to the spanning tree if it does not close a cycle. Kruskal's algorithm will therefore construct the path v_1–v_2–$\cdots$–v_n if the potential function μ is such that

$$c_\mu(v_i, v_{i+1}) < c_\mu(v_h, v_j) \quad \text{whenever} \quad h \le i < j, j - h \ge 2\ . \tag{3.1}$$

Let us consider two special situations: γ is essentially straight (any two left or right tangents to γ form an angle of less than $\pi/3$) or γ consists of a sharp corner (a point in which γ turns by at least $7\pi/24$) and two incident straight line segments. See Figure 3.1. We will show in section 3.3 that any curve γ can be decomposed into subcurves which are either essentially straight or which consist of a sharp corner with two incident essentially straight legs.

For an essentially straight curve the minimum spanning tree will reconstruct for a large choice of potential functions. It will work without a potential function, i.e., $\mu(p) = 0$ for all p, and, more generally, it will work for any potential function that does not change too fast as a function of the position of its argument. For a point p which belongs to an essentially straight part of γ, we will essentially[2] define $\mu(p) = d(p)/3$, where $d(p)$ is maximal such that $B^0(p, d(p)) \cap \gamma$ is connected and essentially straight and $B^0(p, r)$ denotes the open ball with center p and radius r. This choice guarantees that $\mu(p)$ changes slowly with the position of its argument (with at most one third of the change in argument) and that $\mu(p)$ depends on local properties of the curve and is large in parts of γ that are intuitively simple to reconstruct. For sharp corners, the definition above leads to a potential value of zero.

Corners with a turning angle of more than $\pi/2$ will confuse the minimum spanning tree when used without a potential function as Figure 3.1 shows. One of our insights is that a simple potential function can be used to make the minimum spanning trees work. Assume that our curve consists of the two line segments $y = \pm m \cdot x$ for $0 \le x \le 1$ and let V be a finite set of samples. We define the potential as a function of the x-coordinates of the sample points. Fix $\pi(O)$ arbitrarily, let $p(x) = (x, mx)$ and $q(x) = (x, -mx)$ and define $\pi(p(x)) = \pi(q(x)) = \pi(O) - x$. Then $c_\pi(p(x), p(x_0)) = \sqrt{1 + m^2}\,|\,x - x_0\,| - 2\pi(O) + x_0 + x$ and $c_\pi(q(x), p(x_0)) = \sqrt{(x - x_0)^2 + (mx + mx_0)^2} - 2\pi(O) + x_0 + x$. It is an easy exercise in calculus to show that $c_\pi(p(x), p(x_0))$ is an increasing function of $|\,x - x_0\,|$ and that $c_\pi(q(x), p(x_0))$ is an increasing function of x. We conclude that the minimum spanning tree for the modified distance function

[2]The precise definition given in section 3.4 is somewhat more involved.

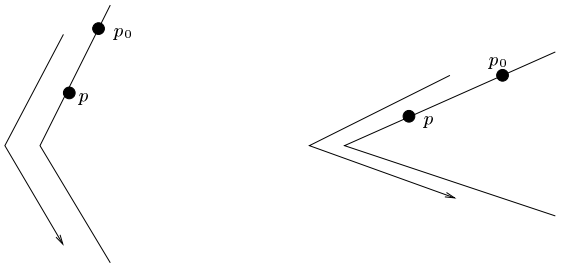

FIG. 3.1. *In the figure on the left, the Euclidean distance between p and p_0 grows as p moves away from p_0 along γ. In the figure on the right, the distance first grows and then shrinks again as p moves around the corner. The minimum spanning tree with $\mu(p) = 0$ for all p will reconstruct the curve on the left, but may fail on the curve on the right.*

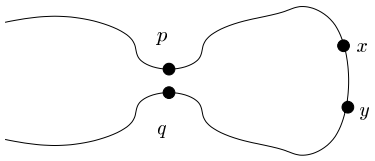

FIG. 3.2. *The edge pq does not belong to the polygonal reconstruction. Our definition of the potential function ensures that $c_\mu(p,q) > 0$. Our sampling condition is that any edge in the polygonal reconstruction has non-positive reduced cost.*

reconstructs. In the argument above the choice of $\pi(O)$ is arbitrary. The actual choice of $\pi(O)$ will depend on local properties of the curve. For every sharp corner s we will consider the largest open disk $B^0(s, c_s)$ such that $\gamma \cap B^0(s, c_s)$ is connected and is essentially a sharp corner with two incident straight legs. We set $\pi(O) = c_s$.

We can now sketch our definition of μ. For every point $p \in \gamma$, the first definition $\mu(p) = d(p)/3$ is applicable. It assigns potential zero to sharp corners. Near sharp corners we use the second definition, namely, $\mu(p) = c_s - \|sp_s\|$, where p is near the sharp corner s and p_s is the projection of p onto the angular bisector of the two tangents at s; see Figure 3.6.

The analysis above suggests that with this definition of μ, the minimum spanning tree solves the reconstruction task locally, i.e., if given the points in $V \cap \gamma'$, where γ' is a subcurve of γ that is either essentially straight or a sharp corner with two incident straight legs. In other words, inequality (3.1) holds if v_h,v_i, and v_j belong to the same γ'.

Does it also hold globally? Consider the situation shown in Figure 3.2. We have two points p and q that belong to distinct essentially straight parts of γ. We have $\max(d(p), d(q)) \leq \|pq\|$ and hence $c_\mu(p,q) > 0$. More generally, we will show in section 3.3 that any edge pq, where p and q do not belong to an either essentially straight subcurve or to a sharp corner with its incident legs, has positive modified cost.

The previous paragraph suggests our sampling condition. We require that any edge of the polygonal reconstruction has nonpositive reduced cost. Then (3.1) holds certainly when $c_\mu(v_j, v_j) > 0$. When $c_\mu(v_h, v_j) \leq 0$, v_h and v_j are guaranteed to lie in a common essentially straight subcurve or near a common sharp corner, and the local analysis applies.

This ends the informal description of our proof.

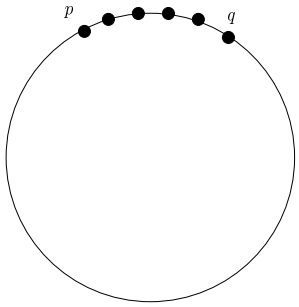

FIG. 3.3. *p and q are adjacent sample points and $c_\mu(p,q) \leq 0$ if p and q are sufficiently close. However, the sample set contradicts our intuition of what constitutes a dense sample set. Condition* (b) *excludes the case.*

3.3. The sampling condition and the global reasoning for open curves. We will give the detailed definition of our potential function in section 3.4; it assigns a positive real $\mu(x)$ to every point x of γ. Define the turning angle of a subcurve γ' of γ as the opening angle of the smallest double-cone that contains all (left and right) tangents to points $p \in \gamma'$. We require the following.

Sampling condition.

(a) For any two adjacent (on γ) samples u and v: $c_\mu(u,v) \leq 0$.

(b) For any two adjacent samples u and v: $\gamma[u,v]$ turns by less than π. For two adjacent points p, q on the curve, $\gamma[p,q]$ denotes the subcurve of γ with endpoints p and q not containing an other sample point. (In the case of closed curves we always have at least 3 sample points.)

Condition (a) implies condition (b) in the case of open curves as we will see below. For closed curves, condition (a) does not suffice as the example in Figure 3.3 indicates. Condition (a) states that adjacent sample points must be sufficiently close in a metric sense and condition (b) states that the curve must not turn too much between adjacent sample points.

The sampling condition is easily satisfied. Let $\epsilon = \inf_{x\in\gamma} \mu(x)$. Then $\epsilon > 0$ since γ is compact and hence a sample set in which γ turns by less than π between adjacent samples and in which there is at least one sample point in every curve segment of length $\epsilon/2$ satisfies the sampling condition. We want to stress that the sampling condition can also be satisfied with nonuniform sampling. In regions of γ where μ is large, the sampling may be less dense than in regions where μ is small. In section 10 we will relate our sampling condition to the conditions used in other papers on curve reconstruction.

In order to show that MST_μ is the polygonal reconstruction of γ from V, we define a family Γ of (overlapping) subcurves γ' of γ so that

(P1) each subcurve γ' is connected and the minimum spanning tree (with respect to cost function c_μ) of the points in $V \cap \gamma'$ is unique and coincides with the polygonal reconstruction of γ';

(P2) for every edge e with $c_\mu(e) \leq 0$ there is a subcurve $\gamma' \in \Gamma$ containing both endpoints of e.

We show that these conditions imply that MST_μ is the polygonal reconstruction of γ.

LEMMA 3.2. *Conditions* (P1) *and* (P2) *imply that MST_μ is the polygonal reconstruction of γ.*

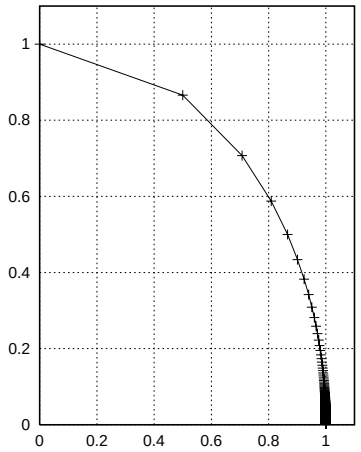

FIG. 3.4. *A semiregular curve with an infinite number of corners.*

Proof. Let MST_μ be any minimum spanning tree in (V, E, c_μ) and let $e = uv$ be any edge which does not belong to the polygonal reconstruction. We show that $e \notin \mathrm{MST}_\mu$. Observe first that any edge in the minimum spanning tree has nonpositive modified cost since there is a spanning tree, namely, the polygonal reconstruction, in which every edge has nonpositive cost. This follows from the cycle rule for minimum spanning trees. So assume $c_\mu(e) \le 0$. Then there is a subcurve $\gamma' \in \Gamma$ containing both endpoints of e by (P2). We even have $\gamma[u, v] \subseteq \gamma'$ since γ' is connected by (P1). Moreover, the minimum spanning tree of $V \cap \gamma'$ is unique and coincides with the polygonal reconstruction of γ'. Thus $c_\mu(e') < c_\mu(e)$ for every edge e' on the part of the polygonal reconstruction between u and v. We conclude that $e \notin \mathrm{MST}_\mu$. □

3.4. The definition of the potential function. In this section, we give the precise definition of our potential function. The definition depends on the parameters $\theta_{max\_sharp}, \theta_{turn}, f_{scale}, f_{wriggle}, \theta_{wriggle}$, and f_{shrink} whose choice is somewhat arbitrary but not completely independent. In section 3.6 we summarize the conditions.

Singularities cause difficulties for most curve reconstruction algorithms; the difficulties grow with the turning angle. We call a singularity p a *sharp corner* if the turning angle at p is at least $\theta_{max\_sharp} = 7\pi/24 = 52.5°$.

A semiregular curve may have an infinite number of singularities. For example, the convex hull of the points $(\cos(\pi/n), \sin(\pi/n))$, $n \ge 2$, has an infinite number of singularities; see Figure 3.4. However, a semiregular curve can have only a finite number of sharp corners. Assume otherwise. Then the sharp corners have an articulation point p. Let $p_1, p_2, \ldots$ be a increasing sequence of sharp corners converging to p. For any sharp corner p_i we can choose two points q_i and r_i in the vicinity of the corner so that the tangents at q_i and r_i form an angle of at least $\pi/6$ and so that the sequence $q_1, r_1, q_2, r_2, \ldots$ increases and converges to p. The sequence shows that γ has no left tangent at p.

We use S to denote the set of sharp corners of γ.

We are now ready to define our potential function. The definition consists of two parts dealing with the neighborhoods of sharp corners and curve parts "far away" from all sharp corners, respectively. We start with the latter parts.

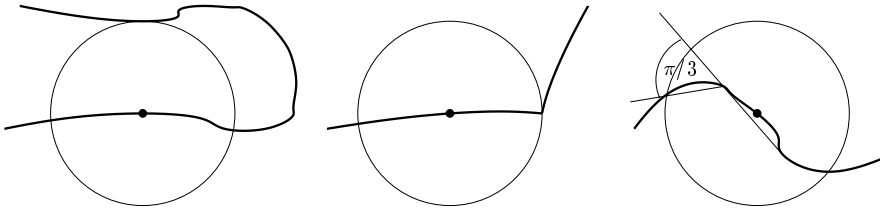

FIG. 3.5. *The closed ball intersects γ in more than one part or has a singularity on its boundary, or γ turns by $\pi/3$ in the ball.*

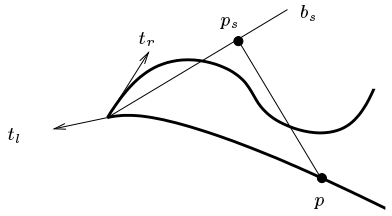

FIG. 3.6. *Illustration of the definition of b_s and p_s.*

For every point $p \in \gamma$ let $d(p)$ be maximal such that the open ball $B^0(p, d(p))$ has the following properties:

- $B^0(p, d(p)) \cap S = \emptyset$.
- $B^0(p, r) \cap \gamma$ is connected for all r with $r \leq d(p)$.
- $B^0(p, d(p)) \cap \gamma$ turns by less than $\theta_{turn} = \pi/3$.

We will define our potential in parts that are far away from sharp corners as $f_{scale} d(p)$ and choose $f_{scale} = 1/3$. We define later what we mean exactly with far away.

Observe that the closed ball $B(p, d(p))$ has one of the following properties: it has a point in S on its boundary or it intersects γ in more than one component or γ turns by $\pi/3$ in the ball (see Figure 3.5). For sharp corners $s \in S$ we have $d(s) = 0$ and for points $p \in \gamma \setminus S$ we have $d(p) > 0$. The function $p \mapsto d(p)$ is continuous. Thus $d(p)$ will be an increasing function of p as p moves away from a sharp corner for a neighborhood of any sharp corner. In section 10 we will relate $d(p)$ to the distance of p to the medial axis of γ.

For sharp corners we define a quantity δ_s. For a sharp corner $s \in S$ let b_s be the bisector of the angle between the right tangent and the reversal of the left tangent, let α_s be the turning angle at s (we have $\alpha_s \geq 7\pi/24$).

For an angle α, let $\bar{\alpha} = \pi - \alpha$. For a point $p \in \gamma$, let p_s be the orthogonal projection of p onto b_s. See Figure 3.6 for an illustration of these definitions. For every $s \in S$ let δ_s be maximal so that

- $\gamma \cap B^0(s, \delta_s)$ is connected. We call the two components of $(\gamma \setminus s) \cap B^0(s, \delta_s)$ the two legs of γ incident to s.
- The angle between any segment with both endpoints on one leg and the tangent in s of the same leg is less than $\min\{f_{wriggle} \bar{\alpha}_s, \theta_{wriggle}\}$. We choose $f_{wriggle} = 1/4$ and $\theta_{wriggle} = \pi/9$. The second bound guarantees that the angle between any segment and the perpendicular bisector is less than $\pi/2$.
- For either of the two legs $d(p)$ increases as p moves away from s.
- $B^0(s, 2\delta_s)$ contains no sharp corner different from s.

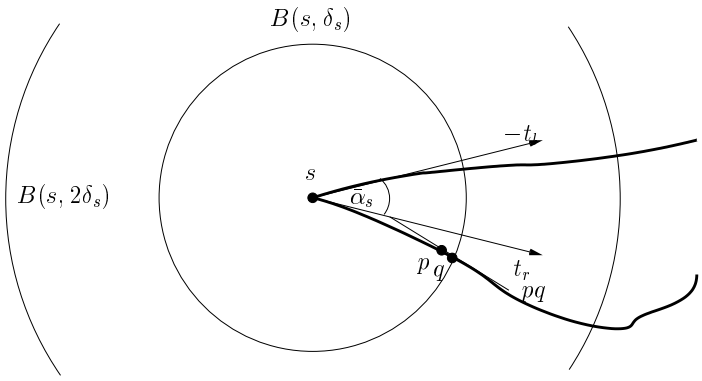

FIG. 3.7. *By the definition of δ_s, we know that γ is connected in $B^0(s,\delta_s)$, there is no sharp corner in $B^0(s,2\delta_s)$, the angle between a segment through two points of a leg in $B^0(s,\delta_s)$, say, pq, and the tangent of this leg, say, t_r, is less than* $\min(\alpha_s/4,\pi/9)$*, and the d values are increasing in $B(s,\delta_s)$.*

The last condition ensures that the balls $B^0(s,\delta_s)$, $s \in S$, are pairwise disjoint. For an illustration of the definition see Figure 3.7. Clearly, $\delta_s > 0$ for all $s \in S$.

Recall from section 3.2 that we want to define the potential near a sharp corner as $c_s - \|sp_s\|$. The change form the potential for sharp corners and smooth areas is made by choosing the maximum of the two possibilities. We use the constant c_s to specify the exact point where we change from one definition to the other. We choose c_s maximal under the restriction that all points outside the $B(s,\delta_s f_{shrink})$ ball ($f_{shrink} = 1/5$) have potential $d(p)/3$. Thus let q^1 and q^2 be the points where the two legs intersect the boundary of the circle $B(s,\delta_s/5)$ and let

$$c_s = \min\left\{ d(q^i)/3 + \|sq_s^i\| \;;\; i = 1,2 \right\}.$$

Then $c_s \le 2\delta_s/5$ since $d(q^i) \le \|sq^i\| = \delta_s/5$ and $\|q_s^i\| \le \|sq_i\| = \delta_s/5$.

Remark. In the proofs of section 3.5 we will use only the fact that $0 < c_s \le 2\delta_s/5$; the exact value of c_s does not matter. This will become important in section 5.

We are now ready to define our potential-function μ:

$$\mu(p) = \begin{cases} d(p)/3 & \text{if } p \text{ is in no } B(s,\delta_s), \\ \max\{c_s - \|sp_s\|, d(p)/3\} & \text{if } p \in B(s,\delta_s). \end{cases}$$

Observe that this definition "combines" the two cases discussed in section 3.2. We use T to denote the set of points $p \in \gamma$ with $\mu(p) = d(p)/3$, i.e., the points that are not affected by the singularities. Then $q^i \in T$ since $c_s \le d(q^i)/3 + \|sq_s^i\|$ and hence $c_s - \|sq_s^i\| \le d(q^i)/3$. Also since $d(p)$ and $\|sp_s\|$ increase as p moves away from s (at least as long as $p \in B^0(s,\delta_s)$), we have $p \in T$ for any curve point p that is not contained in $\cup_{s\in S} B^0(s,\delta_s/5)$. This also implies that μ is a continuous function. For a point $p \in B(s,\delta_s/5)$ we have $d(p) \le \delta_s/5$ and hence $\mu(p) \le c_s$.

We will frequently use the following simple observation.

LEMMA 3.3. *Let $u \in T \cap B(s,\delta_s)$ for some $s \in S$ and let v be a point on the other leg of s. Then $d(u) \le \|uv\|$.*

Proof. Assume otherwise, i.e., $\|uv\| < d(u)$. We have $d(u) \le \|us\|$ and hence $B^0(u,d(u)) \cap \gamma$ consists of at least two components, one containing u and one containing v. □

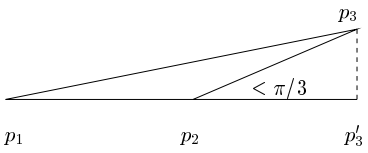

FIG. 3.8. *The situation in the proof of Lemma* 3.8. *We have* $\|p_1p_3\| \geq \|p_1p_3'\| > \|p_1p_2\| + \|p_2p_3\| \cos \pi/3$.

3.5. Local reasoning. We consider the following family Γ of subcurves:

1. $B^0(p, d(p)) \cap T \cap \gamma$ for all $p \in T$.
2. $B^0(s, \delta_s) \cap \gamma$ for all $s \in S$.

We call the subcurves of the first kind regular subcurves and the subcurves of the second kind singular subcurves.

LEMMA 3.4. *The subcurves* $\gamma' \in \Gamma$ *are connected.*

Proof. This is obvious for singular subcurves. So consider a subcurve $\gamma' = B^0(p, d(p)) \cap T \cap \gamma$ for some $p \in T$. The subcurve $B^0(p, d(p)) \cap \gamma$ is connected by definition. If γ' were not connected, $B^0(p, d(p)) \cap \gamma$ decomposes into three nontrivial segments γ_1, γ_2, and γ_3 with $\gamma_1 \cap T \neq \emptyset$, $\gamma_2 \cap T = \emptyset$, and $\gamma_3 \cap T \neq \emptyset$. This implies that γ_2 passes through a sharp corner, a contradiction to the definition of $d(p)$. ∎

LEMMA 3.5. *Let* u *and* v *be adjacent sample points and let* $\gamma' \in \Gamma$. *If* γ' *contains* u *and* v, *then* $\gamma[u, v] \subseteq \gamma'$.

Proof. γ' is connected and hence either $\gamma[u, v] \subseteq \gamma'$ or $\gamma \setminus \gamma[u, v] \subseteq \gamma'$. The latter case is impossible since $\gamma \setminus \gamma[u, v]$ is not connected in the case of an open curve and turns by more than π according to our second sampling condition in the case of a closed curve. However, γ' turns by less than π according to the definition of Γ. ∎

For open curves Lemma 3.5 holds true without the second sampling condition. Since curves $\gamma' \in \Gamma$ turn by less than π, the second sampling condition is implied by the first for open curves. We will next verify the properties (P1) and (P2).

LEMMA 3.6 (property (P2)). *Let* $e = pq$ *be an edge with nonpositive modified cost. Then there is a subcurve* $\gamma' \in \Gamma$ *containing* p *and* q.

Proof. We have $\|pq\| \leq \mu(p) + \mu(q)$ by assumption. If $p \in T$ and $q \in T$, $\mu(p) = d(p)/3$ and $\mu(q) = d(q)/3$ and hence $\|pq\| \leq (d(p) + d(q))/3 \leq 2 \max(d(p), d(q))/3$. Thus $\{p, q\} \subseteq B^0(x, d(x))$ for one of the endpoints x of e.

If one of the endpoints does not belong to T, say, $p \notin T$, then $p \in B^0(s, \delta_s/5)$ for some sharp corner. If $q \in B^0(s, \delta_s)$ we are done. Therefore, assume otherwise. We have $\mu(p) \leq 2\delta_s/5$ and $\|pq\| \geq 4\delta_s/5$. If $q \in T$, then $\mu(q) = d(q)/3 \leq \|sq\|/3 \leq (\|pq\| + \delta_s/5)/3$ and hence $\|pq\| \leq (\|pq\| + \delta_s/5)/3 + 2\delta_s/5$ or $2\|pq\|/3 \leq 7\delta_s/15$ or $\|pq\| \leq 21\delta_s/30$, a contradiction to $\|pq\| \geq 4\delta_s/5$. If $q \notin T$, then $q \in B^0(t, \delta_t/5)$ for some sharp corner t different from s and hence $\|pq\| > 4(\delta_s + \delta_t)/5$. But $\mu(p) \leq 2\delta_s/5$ and $\mu(q) \leq 2\delta_t/5$, a contradiction. ∎

In order to show that the MST_μ coincides with the polygonal reconstruction, we show that the modified distance between two points p and r is either nonnegative, or the modified distance from p to r is greater than the modified distance from p to any point q between p and r. Since we also want to use these lemmas if we treat the problem with finite precision arithmetic, we quantify the change of the modified distance in the distance of q and r.

LEMMA 3.7. *Let* p, q, *and* r *be sample points on a regular subcurve with* $p < q < r$. *If* $\{p, q, r\} \in B(t, d(t))$ *for some point* $t \in \gamma$, *then* $c_\mu(p, r) - c_\mu(p, q) \geq \|qr\|/6$.

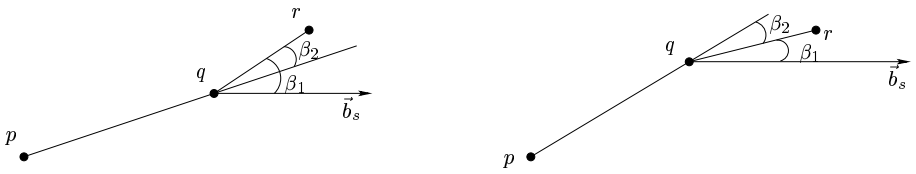

FIG. 3.9. *Illustration of the definition of β_1 and β_2, if p, q, and r are on the same leg.*

Proof. Let $t \in \gamma$ and $p < q < r \in B(t, d(t))$. Since the points are contained in a regular subcurve, we have (see Figure 3.8) $\angle(\vec{pq}, \vec{qr}) < \pi/3$ and hence $\|pr\| > \|pq\| + \|qr\| \cos \pi/3 = \|pq\| + \|qr\|/2$. Furthermore observe that $d(r) \leq d(q) + \|qr\|$. Thus

$$\begin{aligned} c_\mu(p,r) - c_\mu(p,q) &= \|pr\| - \mu(p) - \mu(r) - \|pq\| + \mu(p) + \mu(r) \\ &\geq \|qr\|/2 - \|qr\|/3 = \|qr\|/6. \qquad \square \end{aligned}$$

LEMMA 3.8 (property (P1) for regular regions). *MST_μ coincides with the polygonal reconstruction for regular subcurves.*

Proof. The lemma above for both possible orientations of the curve implies directly that Prim's minimum spanning tree algorithm finds the polygonal reconstruction. $\square$

LEMMA 3.9. *Let p, q, and r be sample points of γ with $p < q < r$. If $\{p, q, r\} \in B(s, \delta_s)$ for some sharp corner $s \in \gamma$, then $c_\mu(p,r) \geq 0$ or $c_\mu(p,r) - c_\mu(p,q) \geq \|qr\|(\sin \bar{\alpha}_s/4)^2/3$.*

Proof. We first argue that it suffices to prove the claim for the situations where either q and r both belong to T or neither of them does. Assume for the moment that those two cases have been dealt with. If exactly one of q and r belongs to T, there is a point u between q and r that belongs to the boundary of T. For this point, we have $d(u)/3 = c_s - \|su_s\|$ and hence u can be considered to be in T or outside T. The triples (p, q, u) and (p, u, r) are both in one of the special situations and hence we have $c_\mu(p,u) \geq 0$ or $c_\mu(p,u) - c_\mu(p,q) \geq \|qu\|(\sin \bar{\alpha}_s/4)^2/3$ and $c_\mu(p,r) \geq 0$ or $c_\mu(p,r) - c_\mu(p,u) \geq \|ur\|(\sin \bar{\alpha}_s/4)^2/3$. If $c_\mu(p,r) \geq 0$, we are done. Otherwise $c_\mu(p,r) < 0$ and hence $c_\mu(p,u) < 0$. Thus $c_\mu(p,r) - c_\mu(p,q) = c_\mu(p,r) - c_\mu(p,u) + c_\mu(p,u) - c_\mu(p,q) \geq (\|qu\| + \|ur\|)(\sin \bar{\alpha}_s/4)^2/3 \geq \|qr\|(\sin \bar{\alpha}_s/4)^2/3$, where the last inequality follows from the triangle inequality. We may from now on assume that q and r either both belong to T or neither of them does.

We need some further case distinctions. The first distinction is according to the sign of $c_\mu(p,q)$. The case $c_\mu(p,q) > 0$ is dealt with in the last paragraph of the proof.

We start with the assumption $c_\mu(p,q) \leq 0$. We make a further case distinction according to the position of s in the sequence $p < q < r$. In all four cases we employ a common strategy. We have $c_\mu(p,r) - c_\mu(p,q) = (\|pr\| - \|pq\|) - (\mu(r) - \mu(q))$. We bound $\|pr\| - \|pq\|$ from below and $\mu(r) - \mu(q)$ from above and estimate the difference of the bounds. In all cases we also use the estimates $\bar{\alpha}_s \leq 17\pi/24$, $\sin \bar{\alpha}_s/4 \leq 0.5281$, $(\sin \bar{\alpha}_s/4)^2/3 \leq 0.1$, and $\cos 2\pi/9 \geq 2/3$.

$s \leq p < q < r$: If $\{q, r\} \cap T = \emptyset$, $\mu(r) \leq \mu(q)$, and if $\{q, r\} \subseteq T$, $\mu(r) \leq \mu(q) + \|qr\|/3$. In either case[3], $\mu(r) \leq \mu(q) + \|qr\|/2$.

[3]In section 5.2 we will consider a modified potential function for which we know only $\mu(r) \leq \mu(q) + \|qr\|/2$. We want to reuse the proof there.

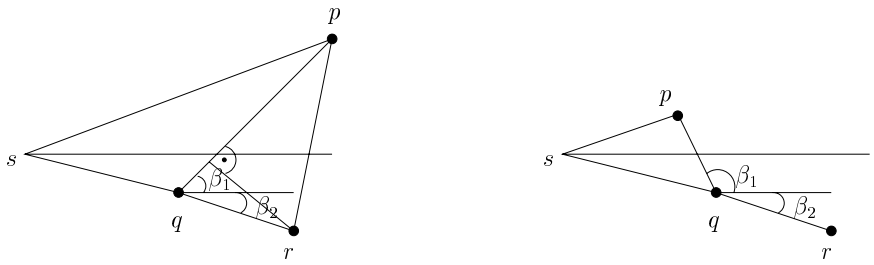

FIG. 3.10. *The case $p < s \leq q < r$: In the left part q_s is closer to s than p_s and in the right part the converse is true. In both situations the definitions of β_1 and β_2 are illustrated.*

Let β_2 be the angle between the vectors $\vec{pq}$ and $\vec{qr}$. Then $\|pr\| - \|pq\| \geq \|qr\| \cos \beta_2$. By the sampling condition, we have $\beta_2 \leq 2\pi/9$, since the angle between pr, respectively, qr, and the left tangent at s is at most $\pi/9$. Thus

$$c_\mu(p,r) - c_\mu(p,q) \geq \|qr\|(\cos(\beta_2) - 1/2) \geq \|qr\|/6 \geq \|qr\| \sin(\bar{\alpha}_s/4)^2/3 \ .$$

$p < q < r \leq s$: If $\{qr\} \subseteq T$, $\mu(r) \leq \mu(q) \leq \mu(q) + \|qr\|/2$. Let β_2 be the angle between the vectors $\vec{pq}$ and $\vec{qr}$. Then $\|pr\| - \|pq\| \geq \|qr\| \cos \beta_2$ and $\beta_2 \leq 2\pi/9$ and hence the argument used in the case $s \leq p < q < r$ applies.

Assume next that $\{q,r\} \cap T = \emptyset$. Let β_1 be the angle between the vectors $\vec{qr}$ and $\vec{b}_s$. Then $\mu(r) - \mu(q) = \|qr\| \cos \beta_1$. By the sampling condition, we have $\beta_1 \geq 3/4\bar{\alpha}_s$. Thus $\mu(r) - \mu(q) = \|qr\| \cos 3/4\bar{\alpha}_s$. Let β_2 as above be the angle between the vectors $\vec{pq}$ and $\vec{qr}$; see Figure 3.9 for an illustration. Then $\beta_2 \leq \bar{\alpha}_s/2$ (since the angle between pq, respectively, qr, and the right tangent at s is at most $\bar{\alpha}_s/4$) and $\|pr\| - \|pq\| \geq \|qr\| \cos \beta_2 \geq \|qr\| \cos \bar{\alpha}_s/2$.

Combining bounds we obtain

$$\begin{aligned} c_\mu(p,r) - c_\mu(p,q) &\geq \|qr\|(\cos(\bar{\alpha}_s/2) - \cos(\bar{\alpha}_s/2 + \bar{\alpha}_s/4)) \\ &\geq \|qr\|(\cos(\bar{\alpha}_s/2) - \cos(\bar{\alpha}_s/2)\cos(\bar{\alpha}_s/4) + \sin(\bar{\alpha}_s/2)\sin(\bar{\alpha}_s/4)) \\ &\geq \|qr\| \sin(\bar{\alpha}_s/4)^2. \end{aligned}$$

$p < s \leq q < r$: Assume first that $\{q,r\} \cap T = \emptyset$. If q_s is as least as far from s as p_s, we have $\|pr\| - \|pq\| \geq 0$ and $\mu(q) - \mu(r) \geq \|qr\| \cos(17\pi/48 + \pi/9) = \|qr\| \cos(\pi/2 - 5\pi/144) = \|qr\| \sin(5\pi/144) > 0.1 \cdot \|qr\| \geq \|qr\|(\sin \bar{\alpha}_s/4)^2/3$. The claim follows.

If q_s is closer to s than p_s, let β_1 be the angle between the vectors $\vec{qp}$ and $\vec{b}_s$ and β_2 be the angle between the vectors $\vec{qr}$ and $\vec{b}_s$; see the left part of Figure 3.10 for an illustration. We have $\mu(q) - \mu(r) = \|qr\| \cos \beta_2$ and $\|pq\| - \|pr\| \leq \|qr\| \cos(\beta_1 + \beta_2)$. By the sampling condition, we have $\beta_2 \geq \bar{\alpha}_s/4$ and $\beta_1 \geq \angle(\vec{sp}, \vec{b}_s) \geq \bar{\alpha}_s/4$, since $\angle(\vec{qp}, \vec{b}_s) \geq \angle(\vec{sp}, \vec{b}_s)$ (moving along the line $\vec{sq}$ increases the angle). Combining bounds we obtain

$$\begin{aligned} c_\mu(p,r) - c_\mu(p,q) &\geq \|qr\|(\cos \beta_2 - \cos(\beta_1 + \beta_2)) \\ &= \|qr\|(\cos \beta_2 - \cos \beta_1 \cos \beta_2 + \sin \beta_1 \sin \beta_2) \\ &\geq \|qr\| \sin(\bar{\alpha}_s/4)^2. \end{aligned}$$

We come to the case that $\{q,r\} \subseteq T$: If $p \in T$, we have $c_\mu(p,r) = \|pr\| - d(p)/3 - d(r)/3 > 0$, since $d(p) \leq \|pr\|$ and $d(r) \leq \|pr\|$.

So assume $p \notin T$. Since $q \in T$, we have $d(q)/3 \geq c_s - \|sq_s\|$ and hence $c_s \leq d(q)/3 + \|sq_s\|$. Thus[4] $0 \geq c_\mu(p,q) = \|pq\| - (c_s - \|sp_s\|) - d(q)/3 \geq \|pq\| - (\|sq_s\| - \|sp_s\|) - 2d(q)/3 \geq \|pq\|/3 - (\|sq_s\| - \|sp_s\|)$ and hence $\|sq_s\| - \|sp_s\| \geq \|pq\|/3$. In particular, q_s lies further away from s than p_s.

Let β_1 be the angle between the vectors $\vec{qp}$ and $\vec{b}_s$ and β_2 be the angle between the vectors $\vec{qr}$ and $\vec{b}_s$; see the right part of Figure 3.10 for an illustration. Then $\cos\bar{\beta}_1 \geq 1/3$, $\beta_2 \geq \bar{\alpha}_s/4$, and $\|pr\| - \|pq\| \geq \|qr\|\cos(\pi - \beta_1 - \beta_2)$.

Combining bounds we obtain $c_\mu(p,r) - c_\mu(p,q) \geq \|qr\|(\cos(\bar{\beta}_1 - \beta_2) - 1/3)$. If $\cos(\bar{\beta}_1 - \beta_2) - 1/3 \geq 4/27$, we are done since $4/27 \geq (\sin\bar{\alpha}_s/4)^2/3$. So assume $\cos(\bar{\beta}_1 - \beta_2) \leq 1/3 + 4/27 = 13/27 \leq 1/2$. Then $\bar{\beta}_1 - \beta_2 \geq \pi/3$ and hence $\bar{\beta}_1 \geq \pi/3$ and hence $(1 - \cos\bar{\beta}_1)/\bar{\beta}_1 \geq 1/2$. Since $\cos(\bar{\beta}_1 - x)$ is convex in $[0, \bar{\beta}_1]$ and hence is above the line through the points $(0,1)$ and $(\bar{\beta}_1, \cos\bar{\beta}_1)$, we have

$$\cos(\bar{\beta}_1 - \beta_2) - 1/3 \geq \cos\bar{\beta}_1 + (1 - \cos\bar{\beta}_1)(\beta_2/\bar{\beta}_1) - 1/3 \geq \beta_2/2 \geq (\sin\bar{\alpha}_s/4)^2/3.$$

$p < q < s < r$: We have $\|qr\| \leq \|qs\| + \|sr\|$. One of the previous cases applies to the triples (p,q,s) and (p,s,r) and hence $c_\mu(p,r) - c_\mu(p,q) = c_\mu(p,r) - c_\mu(p,s) + c_\mu(p,s) - c_\mu(p,q) \geq (\|qs\| + \|sr\|)(\sin\bar{\alpha}_s/4)^2/3 \geq \|qr\|(\sin\bar{\alpha}_s/4)^2/3$.

The discussion of the case $c_\mu(p,q) \leq 0$ is now completed. So let us assume $c_\mu(p,q) > 0$. If $c_\mu(p,r) < 0$ there is a point q' between q and r with $c_\mu(p,q') = 0$. The first case applies to the triple (p,q',r) and hence $c_\mu(p,r) > c_\mu(p,q')$, a contradiction. Thus $c_\mu(p,r) \geq 0$. □

LEMMA 3.10 (property (P1) for singular regions). *MST_μ coincides with the polygonal reconstruction for singular subcurves.*

Proof. The lemma above for both possible orientations of the curve implies directly that Prim's minimum spanning tree algorithm finds the polygonal reconstruction. □

3.6. Conditions on the thresholds. In the preceding sections we showed that properties (P1) and (P2) hold if one chooses the thresholds as in section 3.4. There are other possible choices for the thresholds that make the arguments work. We now collect the conditions on the thresholds. Note that the subtour-LP has an unique integral solution if there is a choice of the thresholds that make the MST_μ unique and equal to the polygonal reconstruction.

We introduced six thresholds:

θ_{max_sharp}: The minimum turning angle of a singularity, which we call sharp. We have chosen $\theta_{max\_sharp} = 7\pi/24$.

θ_{turn}: The maximal turning angle in a $B(p, d(p))$ ball. We have chosen $\theta_{turn} = \pi/3$.

f_{scale}: The factor by which we scaled the $d(p)$ value for the potential. We have chosen $f_{scale} = 1/3$.

$f_{wriggle}$: The factor by which we scaled the $\bar{\alpha}_s$ as maximal angle between a tangent and a segment in a sharp corner. We have chosen $f_{wriggle} = 1/4$.

$\theta_{wriggle}$: The maximal angle between a tangent and a segment in a sharp corner. We have chosen $\theta_{wriggle} = \pi/9$.

f_{shrink}: The factor by which we shrunk the δ_s ball to define the area where we use the potential function for sharp corners. We have chosen $f_{shrink} = 1/5$.

[4]Recall that we work under the assumption $c_\mu(p,q) \leq 0$.

First of all, we must guarantee that $\mu > 0$, which is equivalent to

$$\boxed{\theta_{turn} < \theta_{max\_sharp}.}$$

We start our investigations by looking at property (P2), i.e., to guarantee that all edges which are not contained in a region have positive modified cost. Look at any edge pq with negative reduced cost. If p and q are in T, we have to show that there is a point x with $\|px\| \leq d(x)$ and $\|qx\| \leq d(x)$. For simplicity we have assumed that x is either p or q. This is reasonable, since the conditions we get are weaker than the conditions we need later. Thus we require $\max(d(p), d(q)) \geq \|pq\|$. Since $\|pq\| \leq f_{scale}(d(p) + d(q))$ it suffices that

$$\boxed{f_{scale} < 1/2.}$$

If exactly one of p, q is not in T, we require that $2f_{shrink}\delta_s + f_{scale}\|sq\| \leq \|pq\|$. (The first summand is an upper bound for the potential of p, the second for the potential of q.) Using that $\|pq\| \geq 1 - f_{shrink}$ for all points outside the $B(s, \delta_s)$ ball, we conclude that it suffices that

$$\boxed{3f_{shrink} + f_{scale} < 1.}$$

Assume next that p and q are not in T. Then $p \in B(s_1, f_{shrink}\delta_{s_1})$ and $q \in B(s_2, f_{shrink}\delta_{s_2})$ for different sharp corners s_1 and s_2. Let without loss of generality (w.l.o.g.) $\delta_{s_1} \geq \delta_{s_2}$. It suffices that

$$\boxed{f_{shrink} < 1/3.}$$

Let us now turn to property (P1). In regular regions we require that "potential changes slower than the distance." Thus we need

$$\boxed{\cos(\theta_{turn}) > f_{scale}.}$$

For singular regions, we have to go through all cases of Lemma 3.9. If $s \leq p < q < r$ we need similarly to the case of regular cures

$$\boxed{\cos(\theta_{wriggle}) > f_{scale}.}$$

The same suffices in the case $p < q < r < s$ and q and r are in T.

If $p < q < r < s$ and q and r are not in T, we require that $\cos(1 - f_{wriggle}) < \cos(2f_{wriggle})$, which is equivalent to

$$\boxed{f_{wriggle} < 1/3.}$$

If $p < s \leq q < r$ and $q, r \notin T$, we additionally require that

$$\boxed{\theta_{max\_sharp}/2 + \theta_{wriggle} < \pi/2.}$$

If $q, r \in T$ we compute that $\cos(\bar{\beta}_1) \geq 1 - 2f_{scale}$ and require that $\cos(\bar{\beta}_1 - f_{wriggle}\alpha_s) > 1/3$. This is equivalent to

$$\boxed{f_{scale} \leq 1/3.}$$

Note that the last requirement is the only one where the condition can also be satisfied with equality, since we subtract a positive number in the derivation. This ends our discussion.

4. Open curves with unspecified endpoints. In the preceding sections we assumed that the first and last sample point (= endpoints of the traveling salesman path) are specified as part of the input. In this section we show that the subtour-LP can also reconstruct when the endpoints are not specified. Of course, the requirements on the sample will be stronger. The argument used in this section is a variant of the argument used in section 3.

We use the following formulation of the subtour-ILP. The goal is to select a total of $n-1$ edges such that at most two of them are incident to any node and such that no subset V' with $V' \neq \emptyset$ is "over-full."

$$\begin{aligned}
\min \quad & \sum_{u,v \in V} c_{uv} x_{uv} \\
\text{subject to (s.t.)} \quad & \sum_{v \in V} x_{uv} \leq 2 && \text{for all } u \in V, \\
& \sum_{u,v \in V'} x_{uv} \leq |V'| - 1 && \text{for } V' \subset V,\ V' \neq \emptyset, \\
& \sum_{u,v \in V'} x_{uv} = n-1, \\
& x_{uv} \in \{0,1\} && \text{for all } u, v \in V.
\end{aligned}$$

Selecting a total of $n-1$ edges such that at most two of them are incident to any node amounts to selecting a path and a set of cycles covering all nodes. The constraint that no set can be over-full implies that no cycles can be used and hence any solution must be a traveling salesman path. The subtour-LP is obtained by replacing the integrality constraints $x_{uv} \in \{0,1\}$ by the linear constraints $0 \leq x_{uv} \leq 1$.

As in the case of open curves with specified endpoints, we have to show that the separation problem can be solved in polynomial time. The separation algorithm works as follows. Let x^* be the optimal solution. We assign a capacity of x^*_e to edge e for every edge e. Furthermore we introduce a artificial vertex s and edges us with capacity $2 - \sum_{e \in \delta(u)} x^*_e$ for every node u of the graph. We compute a minimal cut in this graph and take as subset for the subtour elimination constraint the side of the cut that does not contain the artificial node s.

To see the correctness of this separation algorithm, we show that the subtour elimination constraint for S is violated iff the size of the cut is less than 2. Let $S \subset V$ be a subset of the nodes. First notice that the sum of the capacities of edges adjacent to a node is exactly 2 for every node in the above graph. Thus $2\sum_{e \in \gamma(S)} x^*_e + \sum_{e \in \delta(s)} x^*_e = 2\ S$. (For every node $u \in S$, we sum the capacities of the adjacent edges.) We conclude that $\sum_{e \in \delta(s)} x^*_e < 2$ iff $\sum_{e \in \gamma(S)} x^*_e >\ S\ - 1$.

We consider only nonpositive potential functions $\mu \leq 0$ in this section. Let a and b be fixed vertices and consider any traveling salesman path T with endpoints a and b. Its costs under c and c_μ are related by $c_\mu(T) = c(T) - 2\sum_{v \in V} \mu(v) + \mu(a) + \mu(b)$ since the path uses two edges incident to every vertex except for a and b. Observe that $c_\mu(T) - c(T)$ does not depend on T and hence the optimal traveling salesman path

for endpoints a and b is the same under both cost functions. However, the relative order of traveling salesman path with distinct endpoints is changed.

Let MST_μ be a minimum spanning tree with respect to the cost function c_μ and let $C_\mu = c_\mu(\mathrm{MST}_\mu)$ be its cost. Then $C_\mu \le c_\mu(T)$ for any traveling salesman path T.

FACT 3. *Let $\mu \le 0$ be any potential function. If MST_μ is a traveling salesman path and $\mu(a) = \mu(b) = 0$ for the endpoints of this path, it is an optimal traveling salesman path.*

Proof. Let T_0 be an optimal traveling salesman path, say, with endpoints u and v. Then $C_\mu \le c_\mu(T_0)$, since T_0 is a spanning tree, $c(\mathrm{MST}_\mu) = c_\mu(\mathrm{MST}_\mu) + 2\sum_{v\in V}\mu(v) - \mu(a) - \mu(b) = c_\mu(\mathrm{MST}_\mu) + 2\sum_{v\in V}\mu(v)$, since MST_μ is a path with endpoints a and b and a and b have potential zero, and $c(T_0) = c_\mu(T_0) + 2\sum_{v\in V}\mu(v) - \mu(u) - \mu(v) \ge c_\mu(T_0) + 2\sum_{v\in V}\mu(v)$, since T_0 is a path with endpoints u and v, and since the potentials of u and v are nonpositive. Thus

$$c(T_0) \ge c_\mu(T_0) + 2\sum_{v\in V}\mu(v) \ge c_\mu(\mathrm{MST}_\mu) + 2\sum_{v\in V}\mu(v) = c(\mathrm{MST}_\mu). \qquad \square$$

The inequality $C_\mu \le c_\mu(T_0) = c(T_0) - 2\sum_{v\in V}\mu(v) + \mu(u) + \mu(v) \le c(T_0) - 2\sum_{v\in V}\mu(v)$ is valid for every nonpositive potential function (the last inequality uses nonpositivity) and hence

$$\max_{\mu\le 0}\left(C_\mu + 2\sum_{v\in V}\mu(v)\right) \le c(T_0)\ .$$

The quantity on the left is called the Held–Karp bound. The following fact is crucial for our proof.

FACT 4. *The Held–Karp bound is equal to the optimal objective value of the subtour-LP.*

Proof. The proof follows from [7, p. 259]. Relaxing the degree constraints $\sum_{v\in V} x_{uv} \le 2$ in a Langrangian fashion, we obtain the problem

$$\begin{aligned}
\max_{\mu\le 0}\min_{x\ge 0} \quad & \sum_{u,v\in V} c(uv)x_{uv} + \sum_u \mu(u)\left(2 - \sum_{v\in V} x_{uv}\right) \\
\text{s.t.} \quad & \sum_{u,v\in V'} x_{uv} \le |V'| - 1 \quad \text{for } V' \subset V,\ V' \ne \emptyset, \\
& \sum_{u,v\in V} x_{uv} = n - 1, \\
& x_{uv} \le 1 \qquad \text{for all } u, v \in V.
\end{aligned}$$

Observe that we are only maximizing over nonpositive potential functions μ. This stems from the fact that in contrast to section 3, the degree constraints are now inequalities instead of equalities. The reformulation has the same objective value. The objective function of the LP can be reformulated as $\sum_{u,v\in V}(c(uv) - \mu(u) - \mu(v))x_{uv} + 2\mu(V)$. We conclude that the LP is simply a minimum spanning tree problem for the cost function c_μ. $\square$

We remark (but will not use) that the optimal choice of μ in the Held–Karp bound is given by the optimal solution of the linear programming dual of the subtour-LP; μ

corresponds to the dual variables for the degree constraints. We next draw a simple consequence from the two facts above.

LEMMA 4.1. *Let $\mu \leq 0$ be any potential function. If MST_μ is the unique minimum spanning tree with respect to c_μ, is a traveling salesman path, and $\mu(a) = \mu(b) = 0$ for its endpoints a and b, the subtour-LP has a unique optimal solution and this solution is integral.*

Proof. If MST_μ is a traveling salesman path, it is optimal (Fact 1) and hence $c(\mathrm{MST}_\mu) = c(T_0)$. The Held–Karp bound is therefore equal to $c(T_0)$ and the same holds true for the optimal objective value of the subtour-LP (Fact 2). The incidence vector of MST_μ is a feasible solution of the subtour-LP of cost $c(\mathrm{MST}_\mu)$ and hence is *an* optimal solution of the subtour-LP. We will next argue that it is the unique optimal solution. Assume that there is an optimal solution of the subtour-LP with $x_e > 0$ for some $e \notin \mathrm{MST}_\mu$. Since MST_μ is unique there is a $\eta > 0$ so that decreasing the cost of e by η will not change the minimum spanning tree and hence will not change the value of the Held–Karp bound. However, the objective value of the subtour-LP will decrease. This is a contradiction to the equality of the two bounds. □

It remains to define the appropriate potential function. We obtain it as a modification of the potential function defined in the preceding section. We use $\bar{\mu}$ to denote it. Let V be a set of sample points and let a and b be the first and the last sample point.

Let $m = \min(\bar{\mu}(a), \bar{\mu}(b))$ and set $c_s = \min(c_s, m)$ for all sharp corners. This changes $\bar{\mu}$. (It makes $\bar{\mu}$ smaller for some points near sharp corners.) Define new potential functions $\tilde{\mu}$ and μ by

$$\tilde{\mu}(p) = \min(\bar{\mu}(p), m) \quad \text{and} \quad \mu(p) = \tilde{\mu}(p) - m$$

for all $p \in \gamma$, i.e., first all potential values are capped at m and then m is subtracted. Then $\tilde{\mu}(p) \geq \mu(p)$ for all p and $\mu(p) \leq 0$ for all p. Also $\mu(a) = \mu(b) = 0$.

We strengthen the sampling condition and require $c_{\tilde{\mu}}(pq) = \|pq\| - \tilde{\mu}(p) - \tilde{\mu}(q) \leq 0$ for all edges in the reconstruction.

Since $c_s \leq m$ for all sharp corners, we have $\tilde{\mu}(p) = \bar{\mu}(p)$ for all $p \notin T$. Here $\bar{\mu}$ denotes the original potential function, but with the capped c-values.

Suppose that V satisfies the strengthened sampling condition. Then the minimum spanning tree with respect to $c_{\tilde{\mu}}$ is equal to the polygonal reconstruction. This requires us to check that Lemmas 3.6 to 3.10 stay true; we leave the straightforward but tedious check to the reader. The minimum spanning tree with respect to μ is the same as the minimum spanning tree with respect to $\tilde{\mu}$, since μ and $\tilde{\mu}$ differ only by a constant. We conclude that the minimum spanning tree with respect to μ is equal to the polygonal reconstruction and moreover unique. We finally observe that μ is nonpositive and that $\mu(a) = \mu(b) = 0$. Thus MST_μ is the unique optimal solution of the subtour-LP by Lemma 3.2.

5. Closed curves. We extend the result to closed curves in two steps.

- In section 5.2 we alter the potential function to μ' so that the two longest edges of the polygonal reconstruction have the same modified cost and so that the minimum spanning trees with respect to the new modified cost are precisely the polygonal reconstruction minus one of the edges of maximal modified cost.
- In section 5.1 we show that the preceding sentence implies our main theorem for closed curves.

Observe that, in our write-up, the second step is dealt with first.

Readers familiar with the Held–Karp bound for traveling salesman tours may wonder why we are not arguing about 1-trees. We tried but could not get the argument to work. A 1-tree is defined as follows. An arbitrary node $v \in V$ is fixed. A 1-tree consists of the two cheapest edges incident to v plus a minimum spanning tree of $V \setminus v$. We were unable to construct a potential function for which the optimal 1-tree coincides with the polygonal reconstruction. We were able to construct a potential function where the two cheapest edges incident to v were indeed the edges to the two neighbors in the polygonal reconstruction and were able to construct a potential function where the minimum spanning tree on $V \setminus v$ coincided with the polygonal reconstruction minus the two edges incident to v. We were unable to satisfy both conditions simultaneously.

5.1. The subtour-LP and the global reasoning. Assume that the potential function μ' has been constructed. The subtour-LP for the traveling salesman problem can be formulated as follows:

$$\begin{aligned}
\min \quad & \sum_{u,v \in V} c_{uv} x_{uv} \\
\text{s.t.} \quad & \sum_{v \in V} x_{uv} = 2 && \text{for } u \in V, \\
& \sum_{u \in V', v \in V'} x_{uv} \leq |V'| - 1 && \text{for } V' \subseteq V, \emptyset \neq V' \neq V, \\
& \sum_{u,v \in V} x_{uv} = |V|, \\
& 0 \leq x_{uv} \leq 1.
\end{aligned}$$

The last equality is redundant but helpful for our Lagrangian-relaxation. The length of the polygonal reconstruction is an upper bound for the objective value of the subtour-LP. We relax the set of degree equalities to the objective function and obtain the following problem with the same objective value [7, pp. 258–260]:

$$\begin{aligned}
\max \quad & 2 \sum_{u \in V} \mu(u) + \min \sum_{u,v \in V} c_\mu(uv) x_{uv} \\
\text{s.t.} \quad & \sum_{u \in V', v \in V'} x_{uv} \leq |V'| - 1 && \text{for } V' \subseteq V, \emptyset \neq V' \neq V, \\
& \sum_{u,v \in V} x_{uv} = |V|, \\
& 0 \leq x_{uv} \leq 1.
\end{aligned}$$

In this formulation the maximization is over all choices of μ. For fixed μ the inner minimization is over the choices for the x_{uv}. We will show that for $\mu = \mu'$ the polygonal reconstruction is the unique optimal solution for the minimization problem and hence the objective value of the maximization problem is at least the length of the polygonal reconstruction. It cannot be larger and hence the objective value of the maximization problem is equal to the length of the reconstruction. This proves that the polygonal reconstruction is an optimal solution to the subtour-LP. We still need to argue uniqueness. Assume that there is another optimal solution for the subtour-LP. Since the solution satisfies the degree constraints, it will give the same value to the

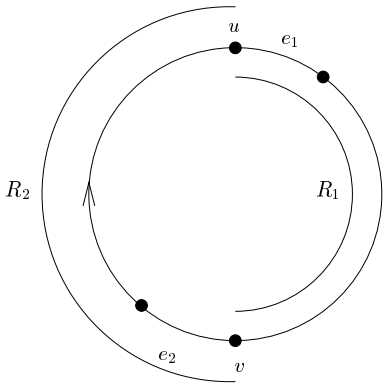

FIG. 5.1. *The notation used in the reformulations of the subtour-LP. We have* $e_i \in E_i$.

inner minimization problem as the polygonal reconstruction and hence the polygonal reconstruction is not the unique optimal solution to the inner minimization problem.

It remains to prove that for $\mu = \mu'$, the polygonal reconstruction is the unique optimal solution for the inner minimization problem. Orient γ arbitrarily, let e_1 and e_2 be edges in the polygonal reconstruction which have maximal modified cost, and let u and v be the starting nodes of e_1 and e_2, respectively, and let R_1 and R_2 be the sample points from u to v (both inclusive), respectively, from v to u (both inclusive) with respect to the order of the points along the curve; see Figure 5.1. Then $R_1 \cup R_2 = V$ and $R_1 \cap R_2 = 2$. Let E_i, $i = 1, 2$, be the set of edges having both endpoints in R_i and let C be the remaining set of edges. Then $e_i \in E_i$ and any edge $e \in C$ has a modified cost larger than e_1 (and hence e_2). Otherwise there would be a minimum spanning tree that is not contained in the polygonal reconstruction. In an optimal solution to the inner LP, the total weight of the edges in E_i is $|R_i| - 1 - o_i$ for some $o_i \geq 0$, $i = 1, 2$, and the total weight of the edges in C is $o_1 + o_2$. Thus the inner LP is relaxed by

$$
\begin{aligned}
\min_{o_1,o_2\geq 0} \min \quad & \sum_{u,v\in V} c_{\mu'}(uv)x_{uv} & & \\
\text{s.t.} \quad & \sum_{u\in R_1', v\in R_1'} x_{uv} \leq |R_1'| - 1 & & \text{for all } R_1' \subseteq R_1, \text{ with } R_1' \neq \emptyset, \\
& \sum_{u,v\in R_1} x_{uv} = |R_1'| - 1 - o_1, & & \\
& \sum_{u\in R_2', v\in R_2'} x_{uv} \leq |R_2'| - 1 & & \text{for all } R_2' \subseteq R_2, \text{ with } R_2' \neq \emptyset, \\
& \sum_{u,v\in R_2} x_{uv} = |R_2| - 1 - o_2, & & \\
& \sum_{uv\in C} x_{uv} = o_1 + o_2, & & \\
& 0 \leq x_{uv} \leq 1. & &
\end{aligned}
$$

Observe that we dropped some of the subtour elimination constraints.

Consider the inner minimization problem for fixed values of o_1 and o_2. The first two lines describe a partial minimum spanning tree for R_1 and the next two lines a

partial minimum spanning tree for R_2. More precisely, the system is minimized if one chooses the $\lfloor\ R_1\ -1-o_1\rfloor$ shortest edges of the minimum spanning tree and fills the fractional part with the next edge.[5] The same is true for R_2. The LP takes its minimum for $o_1 = o_2 = 0$ since any edge in C has higher cost than any edge in the minimum spanning tree. For $o_1 = o_2 = 0$, the system describes the minimum spanning trees for R_1 and R_2. Thus the polygonal reconstruction is the unique optimal solution of the inner minimization problem and hence of the subtour-LP.

5.2. The modified potential function and the local reasoning. We show how to alter the potential so that the two longest edges of the polygonal reconstruction have the same modified cost and so that all minimum spanning trees for V remain part of the polygonal reconstruction. Note that the new potential is defined according to a given sample set, whereas the original potential depends only on the curve.

Let e_{max} be the edge of the polygonal reconstruction with highest modified cost. We claim that one of the following cases arises:

(1) There is a sharp corner so that both endpoints of e_{max} are outside the ball $B(s, \delta_s/5)$.

(2) There is a point $v \in \gamma$ so that $\|vu\|/2 \geq \mu(u)$ for both endpoints u of e_{max} and so that v does not lie in the $B^0(s, \delta_s)$ ball of any sharp corner s.

The first case certainly arises when there are at least three sharp corners. Assume that the first case does not hold. We make a further case distinction: Either both endpoints of e_{max} lie in T (this will certainly be the case when there is no sharp corner) or some endpoint of e_{max} lies in $B(s, \delta_s/5) \setminus T$ for some sharp corner s. In the former case the curve must leave the union of the $B(u, d(u))$ balls of the two endpoints u of e_{max} (because the curve can turn by at most $2\pi/3$ within the union of these balls) and any curve point v outside the two balls (since $\|uv\| \geq d(u) = 3\mu(u)$ for any of the endpoints) and outside $\cup_{s\in S} B^0(s, \delta_s)$ will work; v exists since the regions $(B^0(s, \delta_s))_{s\in S}$ are pairwise disjoint and since γ turns by less than π in any such region. So assume that some endpoint of e_{max} lies in $B(s, \delta_s/5) \setminus T$ of some sharp corner s.

[5] For $o_1 = 0$ this is the characterization of minimum spanning trees by a linear program; see [7, Theorem 2.8]. The proof extends to nonzero values of o_1. We sketch the proof for the sake of completeness. The dual linear program has an unconstrained variable y_{R_1} and a nonpositive variable $y_{R'}$ for every proper subset of R_1. It reads $\max(|\,R_1\,|-1)y_{R_1} + \sum_{R';\emptyset\neq R'\neq R_1}(|\,R'\,|-1)y_{R'}$ subject to $y_{R_1} + \sum_{R';e\in\gamma(R')} y_{R'} \leq c_e$ for every edge e and $y_{R'} \leq 0$ for every R', $\emptyset \neq R' \neq R_1$. In this footnote we use $\gamma(R)$ to denote all edges having both endpoints in R. We use Kruskal's algorithm to construct a primal and dual solution simultaneously. The dual solution will always be feasible; the primal solution will always satisfy $x(\gamma(R')) \leq |\,R'\,| - 1$ for all nonempty R' (but will satisfy $x(\gamma(R_1)) = n - 1 - o_1$ only in the last step); and we will always have complementary slackness.

We start with the empty spanning forest, i.e., $x_e = 0$ for all e, and all dual variables equal to zero. We declare all singleton sets R' active. We then increase y_{R_1} and decrease $y_{R'}$ for all active R' at the same rate until the first constraint $y_{R_1} + \sum_{e;e\in\gamma(R)} y_R \leq c_e$ becomes tight. This will be for the minimum cost edge (let us assume for simplicity that all costs are distinct); observe that the $y_{R'}$ for singletons sets R' are irrelevant. We add e to the spanning forest, i.e., we change x_e to one. Observe that this preserves complementary slackness. The addition of e to the spanning forest combines two active sets R'_1 and R'_2 into a set R'. We declare R'_1 and R'_2 inactive and R' active. Observe that R' corresponds to a subtree of the spanning tree and hence the primal constraint $x(\gamma(R')) = |\,R'\,| - 1$ is tight. Thus $y_{R'}$ is a dual variable which complementary slackness allows to become nonzero. We proceed, i.e., we increase y_{R_1} and decrease $y_{R'}$ for every active set R' at the same rate. Observe what happens. For every edge f contained in an active set R' the left-hand side of $y_{R_1} + \sum_{e;e\in\gamma(R)} y_R \leq c_f$ will not change, because the increase of y_{R_1} is balanced by the decrease of $y_{R'}$. For any edge f connecting two active sets the left-hand side will increase. When the next edge becomes tight, we add it to the spanning tree, ... We finish when adding a partial edge makes the constraint $x(\gamma(R_1)) = n - 1 - o_1$ tight.

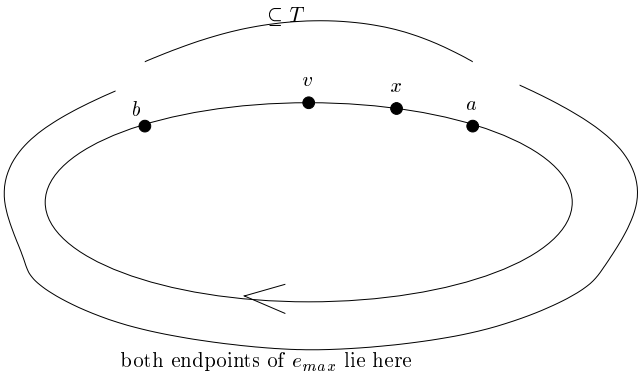

FIG. 5.2. *The construction of the potential function μ'.*

Consider the leg of s that does not contain the other endpoint of e_{max}. It contains no endpoint of e_{max} that lies in T. Let v be the point on this leg of s with distance δ_s from s and let u be an endpoint of e_{max}. If $u \in B(s, \delta_s/5)$, then $\|uv\| \geq 4\delta_s/5$ and $\mu(u) \leq \max(c_s, d(u)/3) \leq 2\delta_s/5$ and if $u \notin B(s, \delta_s/5)$, then $u \in T$ and hence u does not lie on the same leg as v does. Then $d(u) \leq \|uv\|$ by Lemma 3.3 and we are done. In either case we have shown that one of items above holds. We also need the following lemma.

LEMMA 5.1. *Let s be a sharp corner and let x and y be adjacent sample points so that $s \in \gamma[x, y]$. Then $x, y \in B(s, 3\delta_s/5)$ and either x or y lies in $B(s, \delta_s/5) \setminus T$.*

Proof. Since the regions $B^0(p, d(p)) \cap T$ do not contain any sharp corner and since the regions $(B^0(t, \delta_t))_{t \in S}$ are pairwise disjoint, we have $x, y \in B^0(s, \delta_s)$ by Lemmas 3.5 and 3.6. Assume $x \notin B(s, 3\delta_s/5)$. Then

$$c_\mu(x, y) \geq c_\mu(s, x) \geq \|sx\| - 2\delta_s/5 - \|sx\|/3 \geq 2\|sx\|/3 - 2\delta_s/5 > 2\delta_s/5 - 2\delta_s/5 = 0,$$

where the first inequality follows from the third claim in the proof of Lemma 3.10. Assume next that $x, y \in T$. Lemma 3.3 implies $d(x), d(y) \leq \|xy\|$ and hence $c_\mu(x, y) \geq \|xy\|/3 > 0$. □

We now turn to the definition of the modified potential function and the proof that all minimum spanning trees for V with respect to the modified potential function are subsets of the polygonal reconstruction.

Assume first that there is a sharp corner s so that both endpoints of e_{max} lie outside the $B(s, \delta_s/5)$ ball. We decrease c_s continuously down to zero. For $c_s = 0$, we have $\mu(x) = d(p)/3$ for all $x \in B(s, \delta_s)$ and hence the edge xy in the reconstruction that connects the two legs of s (it exists by Lemma 5.1) has positive modified cost: $c_{\mu'}(x, y) = \|xy\| - \mu'(x) - \mu'(y) \geq \|xy\| - \|xy\|/3 - \|xy\|/3 > 0$ since $d(x), d(y) \leq \|xy\|$ and hence $c_\mu(x, y) \geq \|xy\|/3 > 0$ by Lemma 3.3. The modified cost of the edge e_{max} is not affected by the change of c_s. Thus there must be a value of c_s for which the two largest modified costs in the reconstruction are the same. All edges in the reconstruction still have nonpositive modified cost (because e_{max} has) and the minimum spanning tree with respect to $c_{\mu'}$ remains the polygonal reconstruction by the remark in section 3.4 that only the fact that $0 < c_s \leq 2\delta_s/5$ is used in our proofs. This completes the discussion of the first case.

We come to the case that there is a point $v \in \gamma$ so that $\mu(u) \leq \|vu\|/2$ for both endpoints u of e_{max} and so that v lies outside the $B^0(s, \delta_s)$ balls of all sharp corners.

We split the curve at v and orient the resulting open curve arbitrarily. For any $l \in \mathbb{R}$, $0 \leq l \leq \mu(v)$, we define a as the first point with $\mu(a) = \|va\|/2 + l$ and b as the last point with $\mu(b) = \|vb\|/2 + l$ and define a potential μ' by

$$\mu'(p) = \begin{cases} \mu(p) & \text{if } a \leq p \leq b, \\ \|vp\|/2 + l & \text{otherwise.} \end{cases}$$

Observe that a, b, and μ' depend on l. For simplicity of notation we do not make this dependence explicit in the notation. Figure 5.2 illustrates the definition of μ'.

We need to argue that a and b exist for all choices of l, that the cost of e_{max} does not depend on l, that there is a choice of l for which the two largest modified costs are the same, and that every minimum spanning tree with respect to $c_{\mu'}$ uses only edges of the polygonal reconstruction.

We first show the existence of a and b for all choices of l. For $l = \mu(v)$ we have $a = b = v$. For $0 \leq l < \mu(v)$ we have $\mu(v) > l + \|vv\|/2$ and $\mu(u) \leq \|uv\|/2 \leq l + \|uv\|/2$ for either endpoint of e_{max}. From the continuity of μ we conclude that there is a point a between v and u for which $\mu(a) = \|va\|/2 + l$ and a point b between u and v for which $\mu(b) = \|vb\|/2 + l$. We have shown that a and b exist and that e_{max} does not depend on l. Furthermore we know that $\mu'(p) \leq \mu(p)$ for all p by the definition of a and b.

We next show that $a \leq r$, where r is the first point on γ with $\|sr\| = 3\delta_s/5$ for some sharp corner s, and hence $a \in T$. We have $\|rv\| \geq 2\delta_s/5$ and $\mu(r) = d(r)/3 \leq \|sr\|/3 = \delta_s/5 \leq \|rv\|/2 \leq \|rv\|/2 + l$. Continuity of μ implies that a lies between v and r. Similarly, b lies in T and after the last point r on γ with $\|sr\| = 3\delta_s/5$ for some sharp corner.

We next argue that there is a choice of l for which the two largest modified costs in the reconstruction are the same. From $a \leq u \leq b$ for any endpoint u of e_{max} we conclude that the modified cost of e_{max} does not depend on l. For $l = \mu(v)$, we have $a = b = v$ and hence $\mu = \mu'$. Thus e_{max} has the maximal modified cost $c_{\mu'}$ among all edges in the reconstruction. For $l = 0$, we consider the reconstruction edge between the last and the first sample points x and y, respectively, and show that it has positive modified cost $c_{\mu'}(xy)$. There must be a subcurve γ' containing $\gamma[x, y]$ and hence v. Since $v \notin B(s, \delta_s)$ for any sharp corner, γ' is a regular subcurve and hence $\gamma[x, y] \subseteq T$. We first show that $a < x$ and $y < b$ is impossible. Assume otherwise. Then $\mu(x) \leq \mu(a) + \|ax\|/3 = \|va\|/2 + \|ax\|/3$ and $\mu(y) \leq \mu(b) + \|by\|/3 = \|vb\|/2 + \|by\|/3$ and $\|xy\| > \|xa\|/2 + \|ab\| + \|by\|/2$ since γ' turns by less than $\pi/3$. Thus $c_\mu(x, y) > 0$, a contradiction to our sampling condition. Thus either $v \leq x \leq a$ or $b \leq y \leq v$ or both. We may assume w.l.o.g. that $v \leq x \leq a$. If $y < b$, we have $\mu(y) \leq \mu(b) + \|by\|/3 = \|vb\|/2 + \|by\|/3$, $\|xy\| > \|xv\|/2 + \|vb\| + \|by\|/2$, and $\mu'(x) = \|vx\|/2$ and hence $c_{\mu'}(x, y) > 0$. If $b \leq y$, we have $\|xy\| > \|xv\|/2 + \|vy\|/2$, $\mu'(y) = \|vy\|/2$ and $\mu'(x) = \|vx\|/2$ and hence $c_{\mu'}(x, y) > 0$. In either case we have shown that for $l = 0$ there is an edge in the reconstruction with positive modified cost. Continuity implies that there is a value of l for which the two largest modified costs in the reconstruction are the same. This completes the definition of the modified potential function in the second case.

In order to verify that all minimum spanning trees are subsets of the polygonal reconstruction is suffices to show that Lemma 3.6 holds for the new potential function and that $c_{\mu'}(p, r) > c_{\mu'}(p, q)$ for any three points with $p < q < r$ and $\{p, q, r\} \subseteq \gamma'$ for some $\gamma' \in \Gamma$.

From $\mu'(x) \leq \mu(x)$ for all x, we conclude $c_{\mu'}(pq) \leq c_\mu(pq)$ for all edges pq. Thus

Lemma 3.6 stays true.

If $\{p,q,r\} \subseteq B(u,d(u)) \cap T$ for some $r \in \gamma$, we have $\angle(\vec{pq},\vec{qr}) < \pi/3$ and hence $\|pr\| - \|pq\| > \|qr\|/2$ and $\mu'(r) \leq \mu'(q) + \|qr\|/2$. Thus $c_{\mu'}(p,r) > c_{\mu'}(p,q)$.

Assume next that $\{p,q,r\} \subseteq B(s,\delta_s)$ for some sharp corner s. If $c_{\mu'}(p,r) \geq 0$ we are done. Otherwise $c_\mu(p,r) < 0$, since the modified distance with respect to μ is at most the modified distance with respect to μ'. We make the same case distinction as in the proof of Lemma 3.9. In this proof we bounded $\|pr\| - \|pq\|$ from below and $\mu(r) - \mu(q)$ from above. We now need to bound $\mu'(r) - \mu'(q)$. Since $\mu'(x) = \mu(x)$ for $x \notin T$, we need only to reconsider the case that r and q are in T. We have $\mu'(r) \leq \mu'(q) + \|qr\|/2$ and hence the arguments used in the cases $p < q < r \leq s$, $s \leq p < q < r$, and $p < q < s < r$ stay valid. We need only to reconsider the case $p < s \leq q < r$.

If $\mu(p) \neq \mu'(p)$, we have $\mu(q) = \mu'(q)$ and $\mu(r) = \mu'(r)$ and are done. So assume $\mu(p) = \mu'(p)$. If $\mu(q) = \mu'(q)$ we have $c_{\mu'}(p,r) - c_{\mu'}(p,q) \geq c_\mu(p,r) - c_\mu(p,q) \geq 0$, since $\mu'(r) \leq \mu(r)$. Otherwise $\mu'(r) - \mu'(q) \leq 0 \leq \mu(r) - \mu(q)$, since r is closer to v than q and both q and r are in $T \cap B(s,\delta_s)$. Thus $c_{\mu'}(p,r) - c_{\mu'}(p,q) \geq c_\mu(p,r) - c_\mu(p,q) \geq 0$.

6. Solving the subtour-LP. The subtour-LP has an exponential number of constraints. The ellipsoid method [18] allows one to solve LPs with an exponential number of constraints in time polynomial in the number of variables if the following conditions are satisfied:

- The coefficients of the variables in the constraints are polynomially bounded. This is the case for the subtour-LP.
- The separation problem can be solved in polynomial time, i.e., given a vector x^*_{uv} of polynomially bounded values for the variables, one can decide in polynomial time whether the vector satisfies all constraints and, if not, exhibit a violated constraint. This is the case. It is trivial to check the degree constraints and the constraint that all values lie between zero and one. In order to check the subtour elimination constraints, we discuss the case of tours, having already discussed the case of path in sections 3 and 4. Consider the complete network on V and assign capacity x^*_{uv} to edge uv. Consider any subset V' of V with $\emptyset \neq V' \neq V$ and observe that $2|\,V'\,| = \sum_{u\in V'}\sum_{v\in V} x^*_{uv} = 2\sum_{u\in V', v\in V'} x^*_{uv} + \sum_{u\in V'}\sum_{v\notin V'} x^*_{uv}$. We conclude that the subtour elimination constraint for V' is satisfied iff the capacity of the cut $(V', V \setminus V')$ is at least two. Some subtour elimination constraint is satisfied if the minimum cut is less than two. A minimum cut can be computed in polynomial time.
- The coefficients in the objective function are polynomially bounded. This is not the case since the bit-representation of an Euclidean length is in principal infinite. Furthermore there are curves where the bit-representation of any point is infinite.

We show that it suffices to know the sample points and their Euclidean distances only approximately. More precisely, we show the following: Let S be a set of points. Let m be the minimal distance between any two points in S and for a point $p \in S$. Let p^* be a closest point of γ. If

1. $\|pp^*\| \leq \rho m/10$ for all $p \in S$, where ρ is a constant depending on γ, and
2. the set $S^* = \{p^* \mid p \in S\}$ satisfies a strengthened sampling condition,

then the subtour-LP has a unique optimal integral solution even when the distances between sample points are only known up to an error of $m\rho/10$. Moreover, the subtour-LP can be solved in polynomial time and the optimal solution is a tour connecting the points in S in the order in which the points S^* lie on γ. We also show

how to estimate ρ from the sample set and without knowledge of γ.

Now we make precisely what we mean by an approximate sample set of a curve γ. Recall that for an angle α we have defined $\bar{\alpha}$ by $\bar{\alpha} = \pi - \alpha$. Let $\alpha_0 = \max_{s \in S} \alpha_s$. We define $\bar{\alpha}_0 = 17\pi/24$, if there is no sharp corner.

DEFINITION 6.1. *Let γ be a benign semiregular curve. We call a set S of points $p \in \mathbb{Q}^2$ an* approximate sample set *of a curve γ, if for all $p \in S$*

$$\|p\gamma\| \leq (\sin \bar{\alpha}_0/4)^2 m/30.$$

For the following let $\rho = (\sin \bar{\alpha}_0/4)^2 m/3$. Then $m > 7\rho$ (since $\bar{\alpha}_0 < 17\pi/24$) and $\|pp^*\| \leq \rho/10$ for the points in an approximate sample. We need the following sampling condition.

Sampling condition for approximate sample sets.

(a) For any two adjacent (on γ) samples u^* and v^*: $\|u^*v^*\| \leq 9/10(\mu(u^*)+\mu(v^*))$.

(b) For any two adjacent samples u^* and v^*: $\gamma[u^*, v^*]$ turns by less than π. For two adjacent points p, q on the curve, $\gamma[p, q]$ denotes the subcurve of γ with endpoints p and q not containing another sample point.

Let γ be a benign semiregular curve and S an approximate sample set satisfying the sampling condition. For any two sample points p and q let $\|pq\|_{\approx}$ be a rational number, so that $\|pq\| - \|pq\|_{\approx} \leq \rho/10$. Then $\|p^*q^*\| - \|pq\|_{\approx} \leq 3\rho/10$. Note that for all $p, q \in S$ there exists a choice of $\|pq\|_{\approx}$ which has a bit representation of polynomial size in m and $\bar{\alpha}_0$. We consider the approximate subtour-LP of the approximate sample set S.

THEOREM 6.2. *Let γ be an open (closed) benign semiregular curve and S be an approximate sample set of γ satisfying the sampling condition above.*

- *The approximate subtour-LP for S has an unique optimal integral solution.*
- *The approximate subtour-LP can be solved in polynomial time.*

Proof. We define the potential function of an approximate sample point p as $\mu(p) := \mu(p^*)$. We call the new modified cost function $c_\mu^{\approx}$. We show that

1. if p and q are adjacent sample points, then $c_\mu^{\approx}(p, q) < -3\rho/10$ and hence there is a minimum spanning tree in which each edge has length less than $-3\rho/10$;
2. if p and q are sample points which are not contained in some $\gamma' \in \Gamma$, then $c_\mu^{\approx}(p, q) \geq -3\rho/10$ and hence no such edge belongs to a minimum spanning tree;
3. if $p < q < r$ are three sample points contained in some $\gamma' \in \Gamma$ and $c_\mu^{\approx}(p, r) < -3\rho/10$, then $c_\mu^{\approx}(p, r) > c_\mu^{\approx}(pq)$, and hence the minimum spanning tree reconstructs locally.

We turn to the first item. Let p and q be adjacent sample points. We have $6\rho < m - \rho \leq \|pq\| - \rho \leq \|p^*q^*\| + 2\rho/10 - \rho \leq \|p^*q^*\| \leq \mu(p^*) + \mu(q^*)$. Thus

$$\begin{aligned} c_\mu^{\approx}(p, q) &= \|pq\|_{\approx} - \mu(p) - \mu(q) \\ &\leq \|p^*q^*\| + 3\rho/10 - 1/10(\mu(p^*) + \mu(q^*)) - 9/10(\mu(p^*) + \mu(q^*)) \\ &< \|p^*q^*\| - 3\rho/10 - 9/10(\mu(p^*) + \mu(q^*)) \\ &\leq -3\rho/10. \end{aligned}$$

For the second item, consider points p and q that are not contained in any common subcurve $\gamma' \in \Gamma$. We have

$$\begin{aligned} c_\mu^{\approx}(p, q) &\geq \|p^*q^*\| - 3\rho/10 - \mu(p^*) - \mu(q^*) \\ &= c_\mu(p^*, q^*) - 3\rho/10 \\ &\geq -3\rho/10. \end{aligned}$$

We come to the third item. Consider three sample points $p < q < r$ that are contained in some $\gamma' \in \Gamma$ and for which $c^{\approx}_{\mu}(pr) < -3\rho/10$. Then $c_\mu(p^*, r^*) < 0$ and hence (using Lemmas 3.7 and 3.9 and the fact that $(\sin\bar{\alpha_0}/4)^2/3 \leq 1/6$)

$$\begin{aligned} c^{\approx}_{\mu}(p,r) - c^{\approx}_{\mu}(p,q) &\geq c_\mu(p^*, r^*) - c_\mu(p^*, q^*) - 6\rho/10 \\ &\geq \|qr\|(\sin\bar{\alpha}_0/4)^2/3 - 6\rho/10 \\ &\geq \rho - 6\rho/10 > 0. \qquad \square \end{aligned}$$

What have we achieved at this point? We have shown that the subtour-LP reconstructs provided our sample set S satisfies the sampling condition for approximate sample sets *and* we are given approximate distances of polynomial size that differ by at most $\rho/10$ from the true distances. We could compute approximate distances with the required property, if we were given ρ or alternatively α_0 as an additional input. We now show how to compute a lower bound on α_0, which leads to a polynomial precision in the input size, without any additional knowledge of the curve.

LEMMA 6.3. *Let m and M be the minimal, respectively maximal, distance between two sample points. Then $sin(\bar{\alpha}_0/4) \geq m/(15M)$.*

Proof. If γ has no sharp corners, $\alpha_0 = 17\pi/24$ and there is nothing to show. So assume otherwise and let s be any sharp corner. We prove that there is a sample point p in $B(s, \delta_s) \cap T$ on each leg of the sharp corner and then use this fact to bound $\bar{\alpha}_s$ from below.

We look at an arbitrary order of the two orders obtained by splitting the curve at s and prove that there is a sample point behind s in $B(s, \delta_s) \cap T$. Assume otherwise. Let x be the first sample point behind s outside $B(s, \delta_s)$ and let y be the sample point preceding x. Since every edge of the polygonal reconstruction must lie in at least one subcurve $\gamma' \in \Gamma$, y must lie behind s. By assumption y does not lie in T. Assume first that $x \in T$. Then $\|xy\| \geq 4\delta_s/5$ and $\mu(y) \leq 2\delta_s/5$. Thus $c_\mu(x, y) = \|xy\| - \mu(x) - \mu(y) \geq \|xy\| - 2\delta_s/5 - \|xy\|/3 \geq 2\|xy\|/3 - 2\delta_s/5 \leq 8\delta_s/15 - 2\delta_s/5 > 0$, a contradiction. Assume now $x \notin T$. Let s' be the corner so that $x \in B(s', \delta_{s'})$ and assume w.l.o.g. $\delta_s \geq \delta_{s'}$. Then $\mu(x) \leq 2\delta_s/5$, $\mu(y) \leq 2\delta_s/5$ and $\|xy\| \geq 2\delta_s - \delta_s/5 - \delta_{s'}/5 \geq \delta_s$. Thus $c_\mu(x, y) > 0$, a contradiction.

Let p be the first sample point behind s in $B(s, \delta_s) \cap T$ and let q be the adjacent sample point behind p. Then $q \in T$; if $q \notin T$, then $q \in B(s', \delta_{s'})$ for some sharp corner s' and hence s' would have no sample point in $B(s', \delta_{s'}) \cap T$. The distance between p and q is at least m. Also $\|pq\| \leq d(p)/3 + d(q)/3 \leq d(p)/3 + (d(p) + \|pq\|)/3$ and so $d(p) \geq \|pq\| \geq m$. Consider the intersections of the two legs of s with the boundary of the δ_s-ball centered at s. The intersections have distance at least m (since d-values grow along each leg) and s sees the intersections under an angle of at least $\bar{\alpha}_0/2$. Thus $\sin\bar{\alpha}_0/4 \geq m/(2\delta_s)$. Since there is at least one sample outside the ball $B(s, \delta_s)$ and at least one sample inside the ball $B(s, \delta_s/5)$, we have $M \geq 4\delta_s/5$. Thus $\sin\bar{\alpha}_0/4 \geq 4m/(10M)$. $\square$

7. Collections of closed curves. In the preceding sections we showed that the subtour-LP formulation of the traveling salesman problem is able to reconstruct *single* closed and open curves. In this section we extend the algorithm so that is can handle collections of closed curves. We do not know how to handle collections of open and closed curves. Please note that the algorithms [9, 13] can handle open and closed curves.

The algorithm works in rounds. The first round constructs an initial partition of the sample points and subsequent rounds merge blocks of the partition. The construction of the initial partition and the merging is done conservatively, i.e., all points

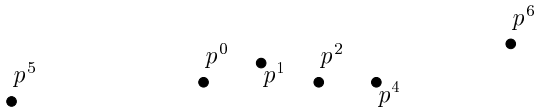

FIG. 7.1. *The points p^1 up to p^5 are joined with p^0, but p^6 is not joined.*

in the same block provably belong to the same curve. In the first round, every point is joined to points close to it; section 7.1 gives the details. In later rounds (see section 7.2), we solve the subtour-LP for each block and then analyze the solution. If the subtour-LP fails on a block or if curves constructed for different blocks interfere, some blocks are merged.

Throughout this section we assume our set of sample points to satisfy a somewhat strengthened sampling condition. The strengthened sampling condition leads to denser sampling near sharp corners. We change μ to μ' by decreasing the δ- and c-values of sharp corners. We set $\delta'_s \le \delta_s$ such that for any two points p and q in $B(s, \delta'_s/7)$ the angle between the segment pq and the corresponding tangent in s is at most $\pi/40$. Furthermore we decrease the value c_s to c'_s such that $c'_s - \|sp_s\| \le d(p)/3$ for every $p \notin B(s, \delta'_s/60)$. This enlarges the region where the potential is defined by $d(p)/3$ from T to T'. Recall that the choice of c_s guaranteed only that the points outside $B(s, \delta_s/5)$ belonged to T, whereas T' contains all points outside the balls $B(s, \delta'_s/60)$.

7.1. The initial partition. We define a graph on our set of sample points. The connected components of this graph form the initial partition. For a sample point $p = p^0$ let p^1, p^2, ... be the other sample points in order of increasing distance (ties are broken arbitrarily). We always join p^0 with p^1 and p^2. We join p^0 and p^i, $i \ge 3$, if $\angle\overrightarrow{p^{k-1}p^{k-2}}, \overrightarrow{p^{k-1}p^k} \ge 2\pi/3$ for all k with $2 \le k \le i-1$. Observe that the decision whether p^i is joined to p^0 depends only on the points p^0 up to p^{i-1}, but not on the point p^i itself. This is essential for making connections between the points on different legs of a sharp corner but also hinders the extension to open curves. Figure 7.1 illustrates the definition.

LEMMA 7.1. *If p and its two adjacent sample points are in T', then p is only joined with points in $B(p, d(p))$ and is joined with both adjacent sample points.*

Proof. Since p is in T', $\gamma \cap B(p, d(p))$ consists of a single component and turns by less than $\pi/3$. Also the two sample points q, r adjacent to p on γ lie in $B(p, d(p))$. We show this for q. We have $d(q) \le d(p) + \|pq\|$, $\mu(q) = d(q)/3$ since $q \in T'$, and, by our sample condition, $\|pq\| \le d(p)/3 + d(q)/3$. Thus $\|pq\| \le d(p)/3 + (d(p) + \|pq\|)/3$ and hence $\|pq\| \le d(p)$.

Assume w.l.o.g. that q is considered before $r = p^i$. Orient $\gamma \cap B(p, d(p))$ such that $r < p < q$. Then $q = p^1$ and $p^1 < p^2 < \cdots < p^{i-1}$. Since $\gamma \cap B(p, d(p))$ turns by less than $\pi/3$, we have $\angle\overrightarrow{p^{k-1}p^{k-2}}, \overrightarrow{p^{k-1}p^k} \ge 2\pi/3$ for all k with $2 \le k \le i-1$ and $\angle\overrightarrow{p^{i-1}p^{i-2}}, \overrightarrow{p^{i-1}p^i} \le \pi/3$. Thus p is joined with p^1 up to p^i, but not with p^{i+1}. ∎

We turn to the nonsmooth parts of the curve. We first show that our sampling condition implies that each leg of a sharp corner must contain several sample points.

LEMMA 7.2. (a) *Let p be a sample point in $B(s, \delta'_s) \setminus B(s, 2\delta'_s/60)$. Then both adjacent sample points lie on the same leg as p, the one closer to s has distance at most $\|ps\|/2$ from p, and the one further from s has distance at most $\|ps\|$ from p.*

(b) *For every leg ℓ of a sharp corner s we have at least one sample point in $B(s, 2 \cdot 2^j \delta'_s/60) \setminus B(s, 2^j \delta'_s/60)$ for $j = 1, 2, 3, 4$.*

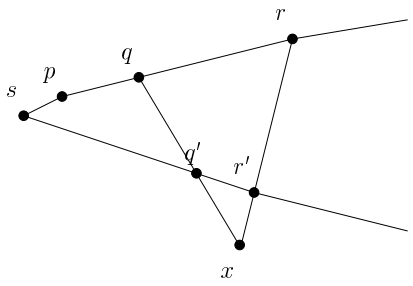

FIG. 7.2. *The angle between $q'q$ and $r'r$ must be large that the region is grown further. This contradicts the fact that the distance between q and r is short.*

Proof. (a) We have $\mu'(p) \leq \|sp\|/3$. The point q on the same leg as p with distance exactly $\|sp\|/2$ to s lies in T' and hence $\mu'(q) \leq \|sp\|/6$. Thus $c_{\mu'}(p,q) \geq \|sp\|/2 - \|sp\|/6 - \|sp\|/3 = 0$. Lemma 3.9 implies that $c_{\mu'}(p,x) \geq 0$ for any point x between s and q and for any point x on the other leg. Thus there must be a sample point between p and q. We conclude that both adjacent sample points lie on the same leg as p and that the one closer to s satisfies the distance constraint stated. For the one further from p we consider the point q on the same leg as p, further away from s than p, and having distance $\|sp\|$ from p. Then $\mu'(q) \leq 2\|sp\|/3$ and hence $c_{\mu'}(p,q) \geq \|sp\| - 2\|sp\|/3 - \|sp\|/3 = 0$. We now argue as above.

We turn to part (b). Part (a) implies that if one of the annuli contains a point, the adjacent annuli do also and hence all annuli do. We conclude that either all annuli contain a sample point or none does. Assume the latter and let p be the first sample point on ℓ outside $B(s,\delta'_s)$. The sample point q preceding p must lie in $B(s,2\delta'_s/60)$. Thus $\|pq\| \geq \|ps\| - 2\delta'_s/60$, $\mu'(p) \leq \|ps\|/3$, $\|ps\| \geq \delta'_s$, and $\mu'(q) \leq \max(2\delta'_s/60, c_s) \leq 2\delta'_s/5$, a contradiction. □

LEMMA 7.3. *A sample point p is joined only with points of the same curve.*

Proof. Consider a sample point p. If p and both adjacent sample points of p are in T', the claim follows from Lemma 7.1.

Otherwise $p \in B(s,2\delta'_s/60)$ by Lemma 7.2, part (a). Let $p = p^0, p^1, \ldots, p^j$ be the sample points in $B(s,\delta'_s)$ ordered according to their distance from p. Since both legs of the sharp corner contain sample points in the annuli $B(s,2\cdot 2^j\delta'_s/60) \setminus B(s,2^j\delta'_s/60)$ for $j = 2,3,4$, we must have a subsequence of length at least three such that the first and the last element of the subsequence, call them q and r, respectively, lie on the same leg as p and further away from s than p, and the points in between (there is at least one) lie on the other leg. Figure 7.2 illustrates the situation. We show that no point after r is joined to p. Assume otherwise. Let q' be the point added directly after q and r' be the point added directly before r.

We want to bound the angle between the segments $q'q$ and $r'r$. If q' is equal to r' this angle is at least $2\pi/3$. Otherwise the angle between $q'q$ and the segment between q' an the sample q'' added after q' is at least $2\pi/3$ and the angle between $r'r$ and the segment between r' an the sample r'' added before r' is at least $2\pi/3$ (since r is not the last point joined to p). Also q', q'', r'', and r' all lie on the same leg and hence the angle between $q'q$ and $r'r$ is at least $\pi/3 - 4\pi/40$. Here we use the strengthened sampling condition.

Let x be the intersection between the lines supporting qq' and rr'. We have $d(q) < d(r) \leq d(q) + \|qr\|$, $\|rr'\| \geq d(r)$, and $\|qq'\| \geq d(q)$ by Lemma 3.3, $\|qr\| \leq$

$(d(q) + d(r))/3$ by our sampling condition, and hence $\|rx\| \geq \|rr'\| \geq d(r) \geq (d(r) + d(q))/2 \geq 3\|qr\|/2$ and $\|qx\| \geq \|qq'\| \geq d(q) \geq (d(q) + d(r) - \|pq\|)/2 \geq \|qr\|$. Application of the "theorem of cosines[6]" with $D = \|qr\|$ yields $\cos(\angle(q'q, r'r)) \geq [(3D/2)^2 + D^2 - D^2]/(2 \cdot D \cdot 3D/2) = 3/4$ and hence $\angle(q'q, r'r) < \pi/3 - \pi/10$, a contradiction. □

LEMMA 7.4. *For any curve γ_j all sample points in $T' \cap \gamma_j$ belong to the same component.*

Proof. Breaking γ_j at its sharp corners gives us a collection of subcurves γ_{jk}. Consider any subcurve γ_{jk}. The sample points on γ_{jk} come in three groups: first a group of points outside T', then a group of points in T', and finally a group of points outside T'. Lemma 7.1 implies that all sample points in $\gamma_{jk} \cap T'$ belong to a single component. Consider now two adjacent subcurves incident to a sharp corner s. In both subcurves all points in T' belong to the same component. Let p and q be the points in the components containing the points T' which are closest to s and do not connect to both neighbors. We claim that p and q are connected to points on the other leg. Assume otherwise; say p is not connected to a point on the other leg. Since p is not connected to both neighbors we have $p \in B(s, \delta'_s/60)$. Let $p = p^0, p^1, \ldots, p^i$ be the sample points connected to p and ordered according to their distance from p. Then $s < p < p^1 < \cdots < p^i$ since p is not connected to both neighbors and since p is not connected to a sample point on the other side. Also we have shown in the proof of Lemma 7.3 that $p^i \in B(s, \delta'_s)$. Thus $\angle(p^{i-1}p^{i-2}, p^{i-1}p^i) \geq 2\pi/3$, a contradiction to the fact that p^i is the last point joined with p.

Thus p connects to a point u on the other leg and q connects to a point v on the other leg. If either u or v belong to the component containing the points in T' we are done. So assume otherwise. Then u is closer to s than q, and v is closer to s than p, and hence $pvuq$ builds a convex quadrangle. The two segments pu and qv are crossing. Thus either $\|pv\| < \|pu\|$ or $\|qu\| < \|qv\|$ since $\|pv\| + \|qu\| < \|pu\| + \|qv\|$ and hence either p or q will be joined with a sample closer to s, a contradiction. □

We call the component containing all sample points in $\gamma_j \cap T'$ the main component of γ_j.

LEMMA 7.5. *The subtour-LP applied to the main component of γ_j reconstructs γ_j.*

Proof. We show that the sample points in $\gamma_j \cap T'$ satisfy our original sampling condition. Consider two points p and q in $\gamma_j \cap T'$ that are adjacent along γ_j. If they are also adjacent in the full sample, we are done. Assume otherwise. Then $\{p, q\} \subseteq B(s, 2\delta'_s/60)$ for some sharp corner s. Let t be the point such $c_s = d(t)/3 + \|st_s\|$; see Figure 7.3. We have $\|pq\| \leq 2 \cdot (2\delta'_s/60) \cdot \sin 3\overline{\alpha}_s/4 + \|sp_s\| - \|sq_s\|$, since $\angle(sp, sp_s) \leq 3\overline{\alpha}_s/4$ and similarly for q, $d(t) \geq \delta'_s/5 \sin \overline{\alpha}_s/2$, since the ball around t with radius $\delta_s/5 \sin \overline{\alpha}_s/2$ does not intersect the other leg, $\mu(p) \geq c_s - \|sp_s\| = d(t)/3 + \|st_s\| - \|sp_s\| = d(t)/3 + \|t_sp_s\| \geq \frac{\delta'_s}{15} \sin \overline{\alpha}_s/2 + \|t_sp_s\|$ and, by the same argument, $\mu(q) \geq \frac{\delta'_s}{15} \sin \overline{\alpha}_s/2 + \|t_sq_s\|$. Thus $c_\mu(p, q) \leq \frac{4\delta'_s}{60} \sin 3\overline{\alpha}_s/4 + \|sp_s\| - \|sq_s\| - 2\frac{\delta'_s}{15}\frac{2}{3} \sin 3\overline{\alpha}_s/4 - \|t_sp_s\| - \|t_sq_s\| \leq 0$. □

7.2. Merging components. The initial partition may contain too many components. For every curve γ_j, there is a main component which contains all sample points in $\gamma_j \cap T'$ and maybe other components. We call them minor components. Each minor component is contained in $B(s, 2\delta'_s/60)$ for some sharp corner s. The

[6] $\|qr\|^2 = \|qx\|^2 + \|rx\|^2 - 2\|qx\| \cdot \|rx\| \cdot \cos(\angle(q'q, r'r))$.

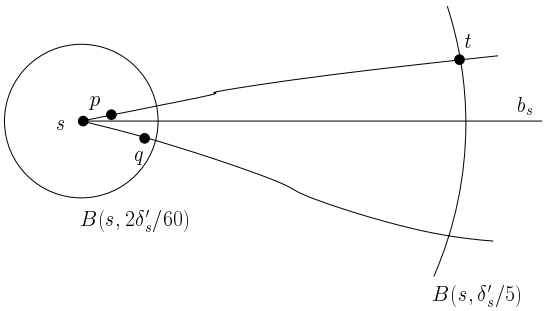

FIG. 7.3. *The definition of t.*

reconstruction based on the subtour-LP is guaranteed to succeed for the main component of every curve. For the minor components it may or may not produce a tour. In this section we describe a strategy for merging components.

We define a region R_{pq} for every edge pq of the computed reconstruction. If the region R_{pq} for an edge pq of the computed reconstruction contains a sample point from another component, we join the component containing p and q with the component of the point closest to pq and lying in another component. We continue until the components stabilize.

Before we define the regions R_{pq} we draw an important consequence of the merging rule. For an edge in a minor component the point closest to it and in another component is guaranteed to lie on the same curve. This follows from the fact that a minor component is contained in $B(s, 2\delta'_s/60)$ for some sharp corner, that the corresponding major component has a point in $B(s, 4\delta'_s/60)$, and that any point within $B(s, \delta'_s)$ belongs to the same curve.

In the arguments to follow we can therefore concentrate on edges in the reconstruction of the main component. In particular, we can use the fact that the subtour-LP correctly reconstructs the main component. We come to the definition of the regions R_{pq}. We define R_{pq} as the union of a region R'_{pq} and the circumcircle of the segment pq. For every sample point p we define β_p to be the angle between the two segments incident to p. The following paragraph motivates our definition of the region R'_{pq}.

Assume pq is the segment in the main component connecting the two legs of a sharp corner s (we say that the edge straddles the sharp corner) and let $\bar{\alpha}_s$ be the angle between the two tangents at s. Let s_p be a segment defined by two adjacent sample points on the leg of p; let s_q be a segment defined by two adjacent sample points on the leg of q, both lying in $B(s, \delta'_s/7)$. Let θ_s be the angle formed by the segments. Since either segment forms an angle less than $\bar{\alpha}_s/4$ with the corresponding tangent at s, we have $\bar{\alpha}_s/2 \leq \theta_s \leq 3\bar{\alpha}_s/2$ or $2\theta_s/3 \leq \bar{\alpha}_s \leq 2\theta_s$, i.e., θ_s is a good estimator for $\bar{\alpha}_s$. Since again the angle between any tangent on a leg and the appropriate tangent in the corner is at most $\alpha_s/4$, we know that the angle between the corner point and the points p and q is between $\bar{\alpha}_s/2$ and $3\bar{\alpha}_s/2$, thus between $\theta_s/3$ and $3\theta_s$.

We come to the definition of R'_{pq}. For an edge pq let p^+ and q^+ be the other neighbors of p and q, respectively, and let θ_s be the angle between the segments pp^+ and qq^+, i.e., $\theta_s = \beta_p + \beta_q - \pi$. We define R'_{pq} as the set of all points r with

- $\angle(\overrightarrow{rp}, \overrightarrow{rq}) \geq \theta_s/3$,
- $\angle(\overrightarrow{pr}, \overrightarrow{pq}) \leq \pi - \beta_p + \min(\pi/20, \theta_s)$ and r lies on the opposite halfspace with respect to the line pq as p^+, and

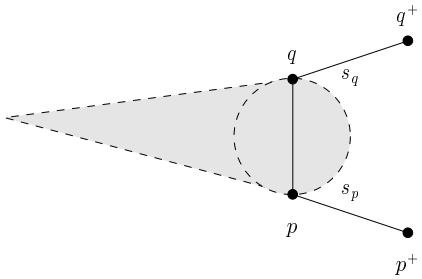

FIG. 7.4. *The definition of R_{pq}.*

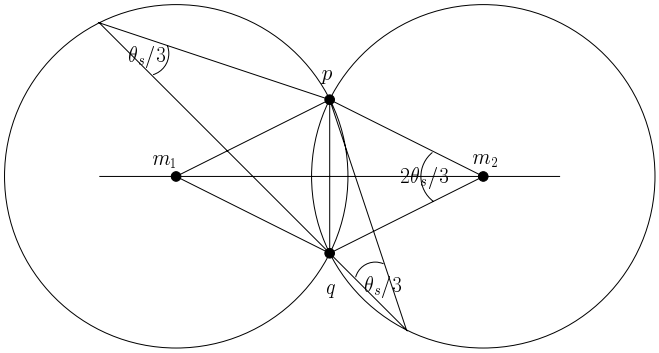

FIG. 7.5. *The inscribed angle theorem: The central angle is equal to twice the inscribed angle.*

- $\angle(\overrightarrow{qr}, \overrightarrow{pq}) \geq \pi - \beta_q + \min(\pi/20, \theta_s)$ and r lies on the opposite halfspace with respect to the line qp as q^+.

For an illustration of this definition see Figure 7.4. Note that $\pi - \beta_q + \min(\pi/20, \theta_s) \leq \pi - \beta_q + \theta_s = \beta_p \leq \pi$.

LEMMA 7.6. *If the main component of a curve does not yet contain all sample points from the curve, it will grow.*

Proof. The main component contains all points in T'. Consider a sample point on γ_j which does not belong to the main component and let p and q be its adjacent sample points in the main component. Then $\{p, q\} \subseteq B(s, 2\delta'_s/60)$ for some sharp corner. If p and q lie on the same leg of s the centerball of pq contains the subcurve between p and q and if pq straddles the sharp corner, the region R'_{pq} contains the subcurve. ∎

To prove that we do not merge components that do not belong to the same curve, we need the following three lemmas.

LEMMA 7.7. *Every point r in R'_{pq} has distance at most $\|pq\|/\sin(\theta_s/3)$ from p and q.*

Proof. Let m_1 and m_2 be the points on the perpendicular bisector of pq with distance $\|pq\|/(2\sin(\theta_s/3))$ from p and q (see Figure 7.5).

By the inscribed angle theorem, every point which sees pq under an angle of at least $\theta_s/3$ lies inside the union of the the balls with center m_1 or m_2 through p and q. Thus at any point in the region R_{pq} that distance is at most $\|pq\|/\sin(\theta_s/3)$ from p and q. ∎

LEMMA 7.8. $\theta_s \geq \alpha_s/2$.

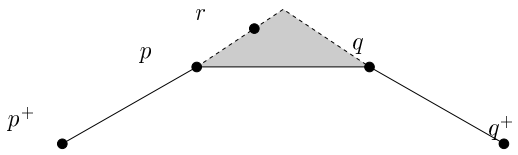

FIG. 7.6. *The segments rp and rq form a small angle with the segment pq. Thus $\|pr\|$ cannot be much larger than $\|pq\|$.*

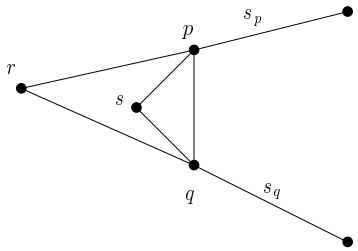

FIG. 7.7. *The two triangles pqr and pqs.*

Proof. If the segment pq straddles the corner, $\theta_s \geq \alpha_s/2$, since pp^+ lies completely on one leg and qq^+ lies completely on the other leg. If p^+ and q^+ are on the same leg, this follows directly from the sampling condition. If the segment pp^+ straddles the corner, the angle formed by the segments pp^+ and qq^+ is smaller than the angle formed by the segments sp^+ and qq^+, which is at least $\alpha_s/2$. □

LEMMA 7.9. *Let pq be a segment of the polygonal reconstruction, with $p, q \in T$ and $d(p) \geq d(q)$. Then $d(p) \geq 3\|pq\|/2$.*

Proof. Assume otherwise. Than $c_\mu(p,q) = \|pq\| - d(p)/3 - d(q)/3 \geq \|pq\| - 2d(p)/3 > \|pq\| + \|pq\| \geq 0$. □

We now turn to the proof that we do not merge a curve with points from another component.

LEMMA 7.10. *The region R_{pq} of an edge pq in the polygonal reconstruction of the main component contains no sample point of another component.*

Proof. This is obvious for the center ball of pq. We turn to the region R'_{pq}.

Assume first p and q are in T' and w.l.o.g. $d(p) \geq d(q)$. Assume there is a point r outside the the $B(p, d(p))$ ball in R'_{pq}. Then $\|pr\| \geq d(p) \geq 3\|pq\|/2$ by Lemma 7.9.

We know $\angle(\overrightarrow{pq}, \overrightarrow{pp^+}) \geq 2\pi/3$ and $\angle(\overrightarrow{pp^+}, \overrightarrow{pr}) \geq 19\pi/20$. Hence $\angle(\overrightarrow{pq}, \overrightarrow{pr}) \leq (\pi - 2\pi/3) + (\pi - 19\pi/20) = 23\pi/60$; see Figure 7.6. Analogously $\angle(\overrightarrow{qp}, \overrightarrow{qr}) \leq 23\pi/60$, thus $\angle(\overrightarrow{rp}, \overrightarrow{rq}) \geq 7\pi/30$. So[7] $\|pr\| \leq \sin(23\pi/60)/\sin(7\pi/3)\|pq\| < 3\|pq\|/2$.

Next assume that one of p and q does not belong to T'.

We will show that $R'_{pq} \subseteq B(s, \delta'_s)$. Let r be any point in R'_{pq} and let θ be the angle under which r sees the segment pq. Then $\theta \geq \theta_s/3$ by the definition of R'_{pq}.

First assume $\theta_s \geq \pi/6$. We know $\|pr\| \leq \|pq\|/\sin(\theta_s/3) \leq 6\|pq\|$. Thus $\|sr\| \leq 6(8\delta'_s/60) + 2\delta'_s/60 < \delta'_s$.

Now assume $\theta_s < \pi/6$. Look at the triangle $\triangle pqr$ and assume w. l. o. g. $\pi - \beta_p > \pi/2$ (see Figure 7.7). We show that the corner point s is almost as far away from p as r. The angle at r is at least $\theta_s/3$; the angle at p is at most $\pi + \theta_s - \beta_p$. Thus

[7] In this proof we make frequent use of the fact that $a/\sin\alpha = b/\sin\beta = c/\sin\gamma$ for a triangle with sides a, b, c and corresponding angles α, β, and γ.

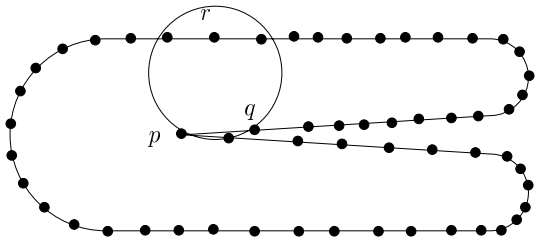

FIG. 8.1. *The edge pq does not belong to the Delaunay triangulation; p is a sharp corner with* $\delta_p = \|pr\|/2$. *Also* $c_p \approx 2\delta_p/5 = \|pr\|/5$. *If* $\|pq\| < \|pr\|/5$, *the edge pq has negative reduced cost. Thus our sampling condition is satisfied.*

$\|pr\| \leq \|pq\| \sin(\pi + \theta_s - \beta_p)/\sin(\theta_s/3)$.

The sharp corner s forms an angle of at most $3\theta_s$ with points p and q, since $\bar{\alpha}_s \leq 2\theta_s$ by Lemma 7.8. The angle at p of the triangle $\triangle pqs$ is between $\pi + \theta_s - \beta_p$ and $\pi - \theta_s + \beta_p$.

We have to distinguish two cases according to β_p. First assume $\beta_p > \pi - 2\theta_s$. We conclude $\|rs\| \leq \|ps\| + \|pr\| \leq 2\delta'_s/60 + \|pq\| \sin(\pi + \theta_s - \beta_p)/\sin(\theta_s/3) \leq 2\delta'_s/60 + \|pq\| \sin(3\theta_s)/\sin(\theta_s/3) \leq 2\delta'_s/60 + 10\|pq\| \leq 2\delta'_s/60 + 40\delta'_s/60 \leq \delta'_s$.

Now assume $\beta_p < \pi - 2\theta$. We conclude $\|rs\| \leq \|ps\| + \|pr\| \leq 2\delta'_s/60 + \|pq\| \sin(\pi + \theta_s - \beta_p)/\sin(\theta_s/3) \leq 2\delta'_s/60 + \|ps\|(\sin(3\theta)/\sin(\pi - \theta_s + \beta_p))(\sin(\pi + \theta_s - \beta_p)/\sin(\theta_s/3)) \leq 2\delta'_s/60 + \|ps\|(\sin(3\theta_s)/\sin(\theta_s))(\sin(3\theta_s)/\sin(\theta_s/3)) \leq 2\delta'_s/60 + 27\|ps\| \leq 2\delta'_s/60 + 52\delta'_s/60 < \delta'_s$. □

8. Curve reconstruction and the Delaunay diagram. Most previous curve reconstruction algorithms use sampling conditions that guarantee that the polygonal reconstruction is a subset of the Delaunay diagram. Our sampling condition does not imply that the traveling salesman tour is a subgraph of the Delaunay triangulation; see Figure 8.1. This fact can be interpreted positively and negatively: positively, as an indication of the strength of the traveling salesman-based reconstruction, and negatively, since the optimal traveling salesman tour must be searched for in the complete graph on the sample set. In this section we show that a slight strengthening of our sample condition implies that the polygonal reconstruction is contained in the Delaunay diagram.

Additional condition on the sample set. An edge pq of the polygonal reconstruction with an endpoint not in T has length at most $4\delta_s \sin(\alpha_s/2)/5$, where s is the sharp corner with $\{p, q\} \subseteq B(s, \delta_s)$.

LEMMA 8.1. *If the sample set V satisfies the strengthened sampling condition, the polygonal reconstruction is contained in the Delaunay diagram of V.*

Proof. Let pq be an edge of the polygonal reconstruction. We construct a Delaunay ball B for it.

First assume that $\{p, q\} \subseteq T$. The center ball of pq is contained in $B(p, d(p))$ and hence empty of sample points; otherwise, γ would either intersect the ball in more than one component or turn by more than $\pi/3$ within the ball.

Next assume that one of the endpoints of the edge, say, p, does not lie in T. Let s be the sharp corner with $p \in B(s, \delta_s)$. We distinguish the cases whether p and q are on the same leg of s or not.

First assume that p and q lie on different legs; see Figure 8.2. We put the center m of B into the halfspace containing s and having p and q in its boundary and set

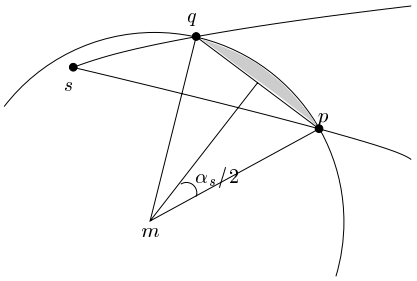

FIG. 8.2. *The sample x must lie on the upper leg behind q and in the shaded lune.*

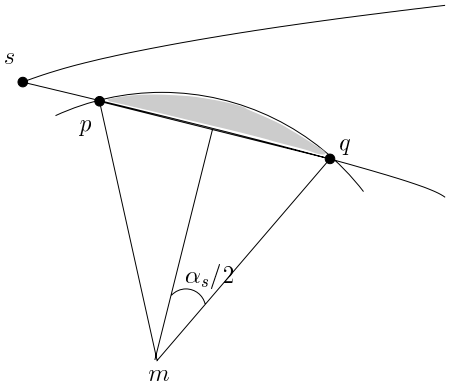

FIG. 8.3. *The sample x must lie on the upper leg and in the shaded lune.*

the radius r of B to $(\|pq\|/2)/\sin(\bar{\alpha}_s/2) \leq 2\delta_s/5$; the upper bound on the radius follows from the strengthened sampling condition. Since one of p or q is contained in $B(s, \delta_s/5)$, we conclude $B(m, r) \subseteq B(s, \delta_s)$.

Now assume that there is a sample point $x \in B(m, r)$. We discuss the case that x lies on the same leg as q and leave the other case to the reader. Since p and q are adjacent samples, x cannot lie on the segment sq and hence $\angle(\vec{sp}, \vec{qx}) = \angle(\vec{sp}, \vec{sq}) + \angle(\vec{sq}, \vec{qx}) \leq \angle(\vec{qp}, \vec{sq}) + \angle(\vec{sq}, \vec{qx}) = \angle(\vec{qp}, \vec{qx})$. (We have $\angle(\vec{sp}, \vec{sq}) < \angle(\vec{qp}, \vec{sq})$, since moving along the segment $\vec{sq}$ increase the angle.) Since x lies in the lune of $B(m, r)$ defined by pq, we have $\angle(\vec{qx}, \vec{qp}) \leq \bar{\alpha}_s/2$. Thus $\angle(\vec{sp}, \vec{qx}) \leq \bar{\alpha}_s/2$. On the other hand, the angle between the two tangents at s is $\bar{\alpha}_s$ and hence $\angle(\vec{sp}, \vec{qx}) > \bar{\alpha}_s - 2\bar{\alpha}_s/4 = \bar{\alpha}_s/2$, a contradiction.

Next assume that p and q lie on the same leg; see Figure 8.3. The center m of B lies on the same side of the angular bisector of the cone defined by the tangents $\mathrm{t}_r(s), -\mathrm{t}_l(s)$ as p and q and sees the segment pq under an angle of $\bar{\alpha}_s$. As above, we conclude that $B(m, r) \subseteq B(s, \delta_s)$. Then x must be contained in the lune of $B(m, r)$ defined by the segment pq. Since p and q are adjacent sample points, x must lie on the other leg. Assume w.l.o.g. that p is closer to s than q. We have $\angle(\vec{pq}, \vec{px}) \leq \bar{\alpha}_s/2$ and hence $\bar{\alpha}_s = \angle(\mathrm{t}_r(s), -\mathrm{t}_l(s)) < \angle(\vec{ps}, \vec{px}) + 2(\bar{\alpha}_s/4) \leq \bar{\alpha}_s$, a contradiction. □

9. Monotonicity. Intuitively, a larger sample set makes the reconstruction task simpler. We discuss how various sampling conditions and reconstruction algorithms behave with respect to larger sample sets.

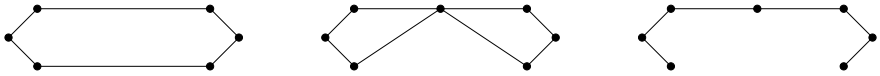

FIG. 9.1. *For the sample set in the left figure, the algorithms in* [3, 8, 15] *produce the hexagon, as shown. If one adds a sample point in the middle of one of the long segments, the algorithm in* [8] *produces the output of the middle figure, and the algorithms in* [3, 15] *produce the output of the right figure. Thus none of these algorithms is self-consistent.*

A sampling condition is called *monotone*[8] if any superset of a set satisfying the sampling condition also satisfies the sampling condition.

For closed curves and open curves with specified endpoints, our sampling condition is monotone. For open curves with unspecified endpoints the superset must satisfy the additional constraint that the additional points must lie in $\gamma[a, b]$, where a and b are the extreme sample points in the old sample. The sampling conditions used in the papers [3, 8, 15, 9] are also monotone; again the additional constraint is needed for open curves. The conditions in [13] are not monotone.

All algorithms mentioned in the present paper come with a guarantee: if the curve γ is from a certain class of curves and the sample set V is sufficiently dense, the algorithm will reconstruct γ. It is not specified what the algorithm does, if the hypothesis of the theorem is not satisfied. The algorithm may either fail, i.e., indicate that it could not find a curve, or "invent" a curve. From a practical point of view this situation is unsatisfactory as a user has in general no way of distinguishing reconstruction from invention. The situation is aggravated by the fact that the sampling densities required by the theorems are quite high and that the algorithms tend to work for smaller densities and hence are likely to be used in situations not covered by the theorems. *It would be nice to have algorithms that never invent curves.*

A reconstruction algorithm is called *self-consistent* if it has the following property. On an input V it either outputs `FAILURE` or `SUCCESS`. In the latter case it also outputs a curve Γ passing through V such that for any sample V' from Γ with $V \subseteq V'$, it will also output Γ. A reconstruction algorithm that is not self-consistent can change its mind if given additional sample points that seem to confirm the output of the algorithm.

THEOREM 9.1. *The algorithm in* [9] *and the traveling salesman-based algorithm are self-consistent; the algorithms in* [3, 8, 15, 13] *are not self-consistent.*

Proof. The algorithm in [9] is constructed to be self-consistent. For the algorithms in [3, 8, 15, 13] it is easy to come up with examples that show non-self-consistency (see Figure 9.1).

It remains to show self-consistency for the traveling salesman-based algorithm. We show that if the solution for the subtour-LP for a set V is unique and integral, then the same is true for the subtour-LP for $V \cup \{z\}$ for any z on an edge of the integral solution of the subtour-LP of V (and different from all points in V).

The claim is a simple consequence of the so-called splitting-off lemma (see [17, Problem 6.53]). Consider an optimal solution of the subtour-LP for $V \cup \{z\}$. The value C of this solution is at most the length C_0 of the optimal tour of V (since the tour for V is also a tour for $V \cup \{z\}$). The splitting-off lemma allows us to construct a solution for the subtour-LP for V from the solution for $V \cup \{z\}$. It implies the existence of a set of triples (e, f, r), where e and f are edges incident to z and r is a nonnegative real, such that

[8] Be aware, this choice of name reflects a bias on behalf of the authors.

- for each edge e incident to z the sum of the third components of all triples containing e is equal to x_e (the value of the edge e in the subtour-LP for $V \cup \{z\}$) and
- a solution for the subtour-LP for V can be obtained by modifying the solution for the subtour-LP for $V \cup \{z\}$ as follows: for each edge uv with $u \neq z$ and $v \neq z$ increase x_{uv} by the sum of the third components of all triples (uz, zv, r). Delete all edges incident to z.

For any edge $e = uv$ let y_e be the increase of x_e in this construction. The cost of the obtained solution is $C + \sum_{uv} y_{uv}(c_{uv} - c_{uz} - c_{zv})$. This cost is at most C (and hence at most C_0) since $c_{uv} \leq c_{uz} + c_{zv}$ by the triangle inequality. Since the solution for the subtour-LP for V is unique and is equal to the tour for V, the cost of the solution cannot be smaller than C_0 and hence for any edge $e = uv$ with $y_{uv} > 0$ we must have $c_{uv} = c_{uz} + c_{zv}$, i.e., z lies on the line segment $\overline{uv}$. Moreover, $y_e + x_e$ must be integral for every edge $e = uv$.

In the tour for V there is only one edge passing through z (since optimal tours are non-self-intersecting) and hence there can be only one edge uv with $y_{uv} > 0$. Thus our set of triples consists of a single triple (uz, zv, r) and since the degree constraint at z must be satisfied for the optimal solution of the subtour-LP for $V \cup \{z\}$ we conclude that $r = 1$. We conclude that the optimal solution of the subtour-LP for $V \cup \{z\}$ is unique and integral. □

10. Our sample condition and the local feature size. The papers [3, 8, 15, 9] investigated the reconstruction problem for smooth curves. A curve is smooth if it is twice-differentiable. They expressed the sampling condition in terms of the so-called *local feature size*. The local feature size $f(p)$ at a curve point p is the distance of p from the medial axis of γ. The *medial axis* of a curve is the closure of the set of points in the plane which have at least two nearest (with respect to the Euclidean metric) points on the curve. They required a sampling condition of the form: For any $p \in \gamma$ there must be a sample point $v \in V$ with $\|pv\| \leq \epsilon \cdot f(p)$; here ϵ is a parameter which depends on the algorithm. All algorithms require $\epsilon \leq 1/2$.

The experimental results in [2] suggest that the traveling salesman-based algorithms works for sparser sample sets than the algorithms mentioned above. We do not know whether this observation is a fact and can prove only a much weaker result.

LEMMA 10.1. *Let γ be a smooth curve and $\epsilon < 1/10$. If for any $p \in \gamma$ there is a sample point $v \in V$ with $\|pv\| \leq \epsilon \cdot f(p)$, then V satisfies our sampling condition.*

Before we prove Lemma 10.1, we show the following lemma.

LEMMA 10.2.

$$f(p) < 3d(p).$$

Proof. The following fact was shown in [3].

FACT 5. *Let r be a point of a smooth curve γ. Furthermore let q and s be points on γ with distance less than $f(r)$ from r with $q < r < s$. Then $\angle(\vec{rq}, \vec{rs}) > \pi/3$.*

By the definition of $d(p)$, either $B(p, d(p)) \cap \gamma$ is not connected or $B(p, d(p))$ contains three points turning by $\pi/3$.

In the first case, there is a medial axis point in $B(p, d(p))$ by Lemma 1 of [3] and hence $f(p) \leq d(p)$.

FIG. 11.1. *The underlying part of the curve is a line segment. Hence, there is no condition on the sample set. In a necklace tour the disks centered at a and b have radius at most* $2x$. *Thus the two disks will not intersect.*

We turn to the second case. Let $q < r < s \in B(p, d(p)) \cap \gamma$ forming an angle of $\pi/3$. By Fact 5 we conclude $f(r) \leq \max(\|qr\|, \|rs\|)$. Thus $f(p) \leq \|pr\| + \max(\|qr\|, \|rs\|) < 3d(p)$. □

Proof of Lemma 10.1. We have to show that for an ϵ-sampled curve, with $\epsilon < 1/10$, the modified cost of the edge between two adjacent sample points is less then 0.

Let p and q be adjacent sample points. Let w.l.o.g. $d(p) \leq d(q)$. Lemma 3.4 of [8] states $\|pq\| \leq 2\epsilon f(p)/(1-\epsilon) = 1/5 f(p)/(1-1/10)$. Thus $c_\mu(p,q) = \|pq\| - d(p)/3 - d(q)/3 < 1/5 f(p)/(1-1/10) - f(p)/9 - f(p)/9 \leq 0$. □

Our sample condition depends on several parameters and we have set these parameters to particular values in section 3. In section 3.6 we discussed the dependency between the parameters. For smooth curves we can set f_{scale} to $1/2$ and then the argument above works for $\epsilon = 1/7$.

11. Necklace tours. We have shown that curve reconstruction gives rise to a polynomially solvable case of the Euclidean traveling salesman problem. In this section we relate our results to a known solvable case, the so-called *necklace tours*. Let V be a set of points in the plane and assume that there is a set of disks centered at the points in V so that each disk intersects with exactly two other disks and so that the intersection graph of the disks is connected. The intersection graph of the disks defines a tour on V; the two neighbors of a point v correspond to the two disks that intersect the disk associated with v. The tour is called a necklace tour and is known to be an optimal traveling salesman tour of V; see [6].

We cannot claim that necklace tours are a special case of our result, since there is no curve underlying a necklace tour. The optimality proof for necklace tours is a special case of our argument. We simply define the potential of any point v as the radius of the disk associated with v. Then exactly the edges in the tour have nonpositive cost. Any tour which uses an edge outside the necklace tour must include edges of positive cost and can include only a subset of the edges in the necklace tour. This implies that the necklace tour is optimal.

Figure 11.1 shows an example of a traveling salesman problem which is covered by Theorem 2.3 and whose solution is not a necklace tour.

12. Conclusions. We have shown that traveling salesman-based curve reconstruction permits a polynomial time algorithm. In the companion paper [2] we show that traveling salesman-based curve reconstruction is reasonably efficient and works for smaller sampling density than other reconstruction algorithms. We have also shown how to extend traveling salesman-based reconstruction to collections of closed curves. The generalization to collections of open and closed curves stays open.

Surface reconstruction is the three-dimensional analogue of curve reconstruction. There are no surface reconstruction algorithms that can handle nonsmooth surfaces. Whether global minimization can also be applied to surface reconstruction remains an open question. A first step in this direction was recently taken by [1].

TREE SEARCH ON AN ATOMIC MODEL FOR MESSAGE PASSING*

PANGFENG LIU†, WILLIAM AIELLO‡, AND SANDEEP BHATT§

Abstract. This paper presents a simple atomic model of message-passing multicomputers. Within one synchronous time step each processor can receive one atomic message, perform local computation, and send one message. When several messages are destined to the same processor, then one is transmitted and the rest are blocked. Blocked messages cannot be retrieved by their sending processors; each processor must wait for its blocked message to clear before sending more messages into the network. Depending on the traffic pattern, messages can remain blocked for arbitrarily long periods.

The model is conservative when compared with existing message-passing systems. Nonetheless, we prove linear message throughput when destinations are chosen at random; this rigorously justifies an instance of folklore. Based on this result we also prove linear speedup for backtrack and branch-and-bound searches using simple randomized algorithms.

1. Introduction.

The message-passing style of programming is widely used on almost all parallel computers. The primitives to *send* and *receive* messages hide low-level architectural details and are ideal for programming many large applications. While message-passing systems have been in use for over a decade, relatively few results concerning the complexity of message-passing protocols are available. One reason for this discrepancy is the lack of theoretical models that appropriately capture issues related to communication; as stated in [5], most theoretical models "encourage exploitation of formal loopholes, rather than rewarding development of techniques that yield performance across a range of current and future parallel machines."

We propose an atomic model [18] to study the performance of message-passing programs. The model is simple and much more restricted in its capabilities in comparison with existing systems. Nevertheless, we show that it allows simple and efficient solutions (linear speedup) for message scattering and backtrack and branch-and-bound searches.

1.1. Message-passing systems.

Message-passing instructions appear in two varieties: *blocking* and *nonblocking*. Blocking instructions require synchronization between the sender and receiver: a send instruction terminates only when the corresponding receive is executed by a remote process. One advantage of blocking instructions is that no system buffering is required. However, the delay in waiting for a send

instruction to complete means that computation and communication cannot overlap; this can reduce overall performance significantly. Another disadvantage is that the programmer must carefully arrange send/receive instruction pairs to avoid deadlock.

Nonblocking instructions allow a process to execute multiple send instructions before any of the corresponding receive instructions is executed. This allows for the possibility of increased efficiency since communication and computation can overlap. However, more system resources, buffering and bandwidth, for example, are required for a nonblocking scheme; otherwise *pending* messages (those sent but not yet received) will be excessively delayed or potentially lost. Moreover, since system resources are finite, the programmer must ensure that the number of pending messages is bounded at all times.

Underneath the message-passing abstractions, a message goes through several phases before it is absorbed at its destination. During each phase it requires some critical system resource to continue its journey. For example, a memory buffer is required to compose a message. When a message buffer is sent, it goes through the network interface connecting the processor to the network. Before the message arrives at the destination, it travels in the network and occupies network buffers. On reaching its destination the message occupies a buffer at the network interface before it is removed and processed. Whenever a message cannot get the critical resource it needs, it must wait. When messages wait a long time, there is the danger that communication delays can cause processor idling, thereby reducing overall performance greatly.

In many applications it is also common practice to reduce communication costs (primarily due to system overheads) by aggregating data into fewer, but longer, atomic messages [3].[1] First, the sender notifies the receiver of the message length. Upon receipt of this notification, the receiver allocates sufficient buffer space and sends back an acknowledgment. This establishes a link between the sender and the receiver and the message is transmitted in the third step. Once again, there is ample opportunity for delay from the time the protocol is initiated until the time the data is actually transferred.

Given the limited resources of multicomputer systems, it is natural to ask whether the efficiency gained by using nonblocking instructions is lost if the number of pending messages is limited. Nevertheless, we show that nonblocking communication can still achieve high performance, even with very limited communication resources.

We investigate this question formally within the atomic model which permits only one pending message per processor. In brief, each processor is given one send buffer and one receive buffer, each capable of holding one atomic message. The system alternates between message transmission and computation cycles. During a computation cycle a processor retrieves a message from its receive buffer, performs a computation, enqueues newly generated messages into a message queue, and writes the first message in the queue into the send buffer if the send buffer is empty. During the transmission cycle, the network attempts to transmit every message in each send buffer to the receive buffer of the destination. If more than one message is destined for the same processor, exactly one is successfully transmitted. The rest remain in their send buffers. The one which is transmitted is chosen by a *network arbiter*. The *worst-case* arbiter makes choices to maximize the running time. The first in first out (FIFO) arbiter gives priority to messages with smaller time-stamps; messages with the same time-stamp can be delivered in arbitrary order.

[1] Atomic messages travel through a critical resource as a single entity; different messages do not coexist inside the critical section.

The atomic model is motivated by the desire to analyze the performance of message-passing programs in an architecture-independent manner. For this reason, we have chosen to abstract the network as an arbiter which takes one unit of time to transfer messages from send buffers to receive buffers at the destination. We believe this is reasonable in applications that involve the atomic transfer of large data sets. Unit-delay assumptions are also made in the literature on PRAMs and complete networks [13, 14]. Unlike these models, however, we explicitly account for message contention and do not allow multiple messages to be received in one step by a processor. The issue of contention at the receiving module is also addressed in models for optical communication [8] and module parallel computers [12, 20]. A key feature which distinguishes the atomic model is that once a message has been sent it cannot be retrieved; the sending processor must wait for the network to clear the send buffer after the message has been copied into the receive buffer at the destination. Finally, the atomic model can be viewed as the limiting version of the LogP model [5]; with long messages of equal length, the latency, overhead, and gap parameters of the LogP model can be lumped into a single unit time delay.

Communication contention is an important issue in modeling parallel computations. Valiant's bulk synchronous parallel (BSP) model [24] divides the parallel computation into supersteps in which processors perform local computation and exchange data. All the outstanding communication requests will be serviced before the next superstep starts. The memory contention is characterized by the length of the time interval a processor must wait before sending the next message. To model the fact that many shared memory machines now have a large number of memory banks in order to serve relatively much faster processors, Blelloch et al. [4] extended BSP into (d, x)-BSP by adding two parameters—the memory bank delay (the minimum interval length a memory bank can serve memory requests) and the ratio of the number of memory banks to processors. The QSM model [9] also characterizes the contention problem by a bandwidth parameter g so that a processor can issue memory requests only once every g steps. All these models characterize the contention by limiting the communication capability on a *per processor* basis. In contrast, the QSM(m) model by Adler et al. [1] added another parameter to describe the limitation on the communication capability for the *entire* system.

Besides characterizing the memory contention by a memory bandwidth parameter, it is also possible to model the contention by allowing atomic access to a shared resource. Dwork, Herlihy, and Waarts [6] proposed a model for shared memory access in which simultaneous accesses to a single memory location are serialized and only one will succeed at a time. However, a process may have multiple pending operations due to trying to access different memory locations. Gibbons, Matias, and Ramachandran [11] proposed a queue-read, queue-write (QRQW) model that allows concurrent reading and writing to the same memory location to be queued. Similar to BSP, the computation is divided into supersteps and all the queued memory requests in one superstep will be served before the next one. The asynchronous variant of QRQW (AQRQW) [10] relaxes the bulk synchronous requirement of QRQW and BSP and more accurately captures the memory contention phenomenon in modern shared-memory parallel computers [10]. The atomic model we propose differs from all the previous *message-passing* models in that it allows only one pending outstanding "request" *per processor.*[2]

[2]The SIMD-QRQW model in [11] also allows only one pending request per processor in shared memory.

Despite the restriction on the rate at which the network can deliver messages to a destination, as well as the adversarial nature of the arbiter, we show that simple randomized algorithms can attain linear speedup for branch-and-bound and backtrack tree searching. Furthermore, all-to-some message passing can finish within a constant factor of the optimal time with high probability if the destinations are uniformly distributed among the processors.

2. The atomic message-passing model. We model a message-passing multicomputer as a collection of p nodes connected via an interconnection network [23]. For convenience of analysis we require that the system be synchronous and operate in discrete time steps.[3] Each time step is divided between one communication step and one node computation step.

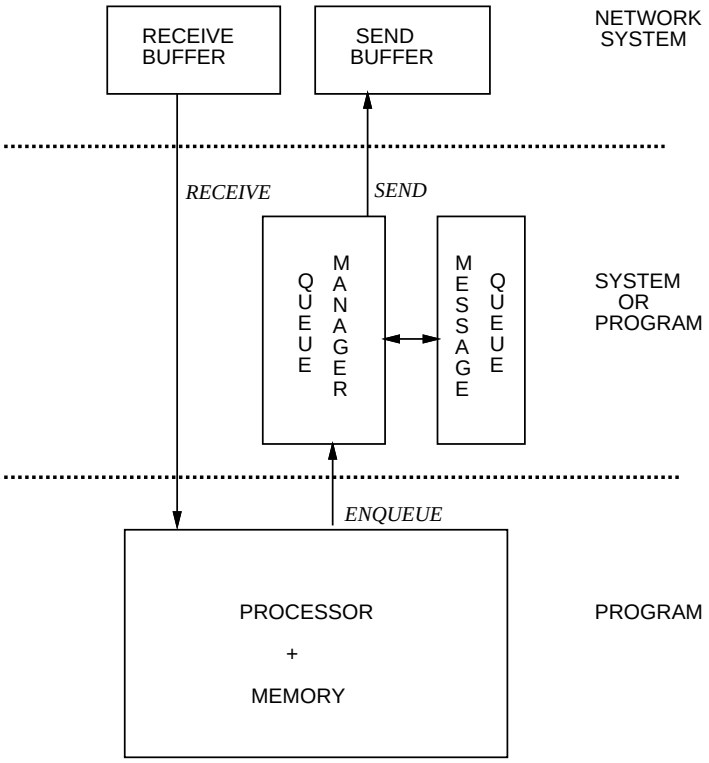

FIG. 1. *The structure of a node.*

Each node consists of a receive buffer, a processor, local memory, a queue manager, a message queue, and a send buffer (Figure 1). Each buffer can hold one atomic message. Every node can perform local computation using its processor and local memory. It can also receive a message using the receive buffer and enqueue messages into the message queue. The message queue is maintained by a queue manager which may be under the control of the processor or the system. A message from the message queue is injected into the network by placing it into the send buffer. For our purposes, it is convenient to model the actions at a node as repeated executions of the following *reactive cycle* which occurs during one synchronous time step. Notice that we consider

[3]This assumption is not required for termination but simplifies the analysis of throughput.

the communication as a sequence of time steps, and the timing of an event is expressed as the time step number at which the event occurs, not a particular point in the absolute time line. Similarly, a time interval refers to a contiguous set of time steps, not an interval in terms of wallclock time.

1. *The send phase* (performed by the processor).
   Transfer the message at the head of the queue into the send buffer if it is empty.
2. *The transmission phase* (performed by the network system).
   Take messages from send buffers to receive buffers according to message destinations. If more than one message is destined for the same receive buffer, the one which succeeds is selected by the network arbitration policy.
3. *The receive phase* (performed by the processor).
   Probe the receive buffer to receive an incoming message, if any, into local memory.
4. *The local computation phase* (performed by the processor).
   - COMPUTE. Perform local computation, possibly on the newly received message, and generate new messages.
   - ENQUEUE. Pass the newly generated messages to the queue manager, which will place it into an appropriate place in the message queue.

Observe that there are two ways a message can be delayed. First, a message may have to wait in the message queue until it is selected to be placed in the send buffer. Second, once a message is in the send buffer, it may be delayed in the network. We call the second kind a *receive-delay*.

When more than one message, occupying send buffers of different nodes, are simultaneously destined for the same node, the network must deliver one message. Since every node executes a RECEIVE instruction during its reactive cycle, this requirement of the network satisfies the network contract of the CM-5 [17]: "The data network promises to eventually accept and deliver all messages injected into the network by the processors as long as the processors promise to eventually eject all messages from the network when they are delivered to the processors." With the reactive cycle and the network contract we are assured that deadlocks cannot occur.

We wish to make as few assumptions as necessary on the message queue. Our results for backtrack search are independent of queue maintenance. Our result for branch-and-bound depends on maintaining the message queue as a priority queue.

We also wish to make as few assumptions as necessary about the network arbitration policy when multiple messages are destined for the same node. We will consider two different network arbitration policies. The *worst-case* policy selects the message which maximizes the overall time to complete the task at hand. The FIFO policy dictates that, for any pair of messages with the same destination, they will be accepted in the order of earliest occupancy of their respective send buffers. In other words, if the messages reach their send buffers at different time steps, then the earlier one will be delivered first. If two messages reach their send buffers at the same time, then the order of delivery is arbitrary. Optimal speedup for backtrack search can be achieved even with worst-case arbitration, whereas we require FIFO arbitration to prove optimal speedup for branch and bound search.

3. Overview of results. We will study three problems under the atomic message setting: all-to-some message scattering, backtrack search, and branch-and-bound search. For each of these problems we analyze the case when all messages are destined for independently chosen random nodes. Our intuition is that when messages

are headed for random destinations, the number of conflicting messages is unlikely to become too large. However, when the size of the computation is much larger than the number of processors, this is not always true and one has to prove that the effects of the conflicts do not add up significantly.

The message scattering problem is informally stated as follows: suppose that each node has a list of m messages to send (in order) to remote nodes. How much time does it take, under the worst-case (adversarial) arbitration policy, until all messages are received at their destinations? This problem arises naturally in several applications. In fact, the message scattering problem and the atomic message model are motivated by the "all-to-some" communication in our parallel N-body implementation [19].

In the backtrack search problem, each internal vertex of a search tree, $\mathcal{T}$, corresponds to a partial solution to a problem while each leaf represents a solution with a certain cost. The goal of backtrack search is to find the minimum cost leaf in the search tree. The search tree is not given in advance; it is instead spawned on-line as the search proceeds. The search begins with the root of the tree in a given node; when each internal vertex is expanded, two (or any bounded number of) children are spawned and must each be examined. When a leaf is examined, the cost is calculated and no further expansion along that branch is possible. If the total number of vertices in the search tree is n, and the maximum depth of any leaf is h, it is easy to see that the time to examine all leaves is at least $\Omega(n/p + h)$, where p denotes the number of processors.

Branch-and-bound search is similar to backtrack search, except that only a subtree of the search tree must necessarily be explored. Following Karp and Zhang [13, 14], we model a branch-and-bound tree as a binary search tree, each of whose vertices has an associated cost. The cost of each vertex is strictly less than the cost of each of its children (for simplicity we assume that all vertex costs are distinct). The problem is to find the leaf with minimum cost in the tree. Clearly, every tree vertex whose cost is less than the minimum cost leaf must be expanded because one of its children could potentially be the minimum cost leaf. These vertices form a critical subtree; call it $\mathcal{T}$ of the overall search tree.

As before, the time to complete the search is $\Omega(n/p + h)$, where n is the number of vertices in the *critical* subtree and h is the height of the critical subtree. Noncritical vertices can, in principle, be pruned by the search process and need not be explored.

Tight upper bounds for branch-and-bound, and hence for backtrack search, were given by Karp and Zhang [13] on the complete network which allows multiple messages to be simultaneously received at each node and on the concurrent PRAM which essentially allows unsuccessful writes to be detected. The basic idea was to send each node to a random processor for further exploration. Ranade [21] gave an elegant alternative proof of the Karp–Zhang result. By extending Ranade's techniques we show that the random destination strategy yields linear speedup for backtrack search in the atomic model.

THEOREM 3.1. *Using random destinations, the probability that a binary backtrack search tree of size n and depth h takes time more than $k(n/p + h)$ in the atomic transmission model with worst-case arbiter is polynomially small in n for k sufficiently large.*

Achieving linear speedup for branch-and-bound search in the atomic model is a little harder. The subtle distinction is that pending noncritical vertices can delay pending critical vertices. In the Karp–Zhang model this can never happen. Since we have no control over the number of noncritical vertices, and we do not know the

shape of the critical subtree, it is conceivable that the delays can become arbitrarily large under the worst-case arbiter which consistently favors noncritical vertices over critical vertices. However, under a FIFO arbiter we establish the following result.

THEOREM 3.2. *Let the critical subtree, $\mathcal{T}$, of a branch-and-bound search tree have size n and depth h. Using randomized destinations, the probability that the time, in the atomic model with FIFO arbiter, exceeds $k(n/p + h)$ is polynomially small in n when $n > p^2 \log p$ and k is sufficiently large.*

We present the proof of Theorems 3.1 and 3.2 in sections 6 and 7.

4. Message scattering. The off-line version of the message scattering problem in which the lists can be reordered is easily solved using standard bipartite graph edge-coloring techniques [2, 7]. If r and m are the maximum numbers of messages received and sent by any node, respectively, then $\max\{r, m\}$ steps are necessary and sufficient.

However, the distributed version of the problem, without reordering, is not as simple. We show that with each of p nodes sending m messages (m can be arbitrarily larger than p) the worst-case time is $\Omega(mp)$. In other words, the average throughput of the system is $O(1)$ messages received per time step, independent of the size of the system.

On a positive note, we show that when each of the messages is destined for a randomly chosen node (all destinations independent and uniformly drawn), then, with high probability, the time to completion is $O(m)$. As a result the average throughput is $\Omega(p)$ messages received per time step, asymptotically the maximum possible.

4.1. Lower bounds. Suppose every processor sends n messages to every processor in ascending processor index order. We show that a simple FIFO network arbiter increases the communication time to $\Omega(np^2)$ so that on average only a constant number of messages are received in one time step. The network arbiter ensures that the messages are received in FIFO order; the message sent first is received first. The messages sent at the same time are received in increasing processor index order.

Figure 2 shows the history of four processors sending two messages to each destination in ascending processor index order. A square in the intersection of row i and column j indicates that processor p_i successfully sends a message at time step j. The numbers in the squares are the processor index of the destination. Notice that two successful sends to the same destination are p time steps apart because the messages are received in FIFO order. The total number of time steps is therefore $((n-1)p+1)p + (p-1) = \Omega(np^2)$.

4.2. Randomized scattering. Formally, we establish the following theorem.

THEOREM 4.1. *Suppose that each node sends m messages and that for each message all destinations are equally likely and independent of choices of all other messages. The probability that the time until all messages have been received exceeds km is bounded by $O(e^{-m})$ for sufficiently large k and $m > \log p$.*

Proof. We adapt Ranade's proof [21] of the result of Karp and Zhang [13].

Let T be the completion time of the protocol, the last time step at which a message is received. Let message $\mathcal{M}_m$ be a message received at time step T and let S be the node which was the source of message $\mathcal{M}_m$. Let $\mathcal{M}_i$ denote the ith message sent by node S and let T_i denote the time step at which $\mathcal{M}_i$ was received at its destination Q_i.

DEFINITION. *Suppose that message $\mathcal{M}$ is selected for transmission, i.e., $\mathcal{M}$ enters the send buffer at time step τ and is destined for node q. Then we say that $\mathcal{M}$ became*

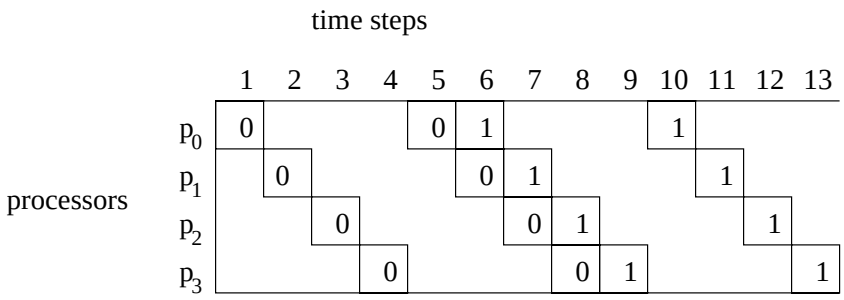

FIG. 2. *The situation when the messages are sent in ascending processor address order.*

ready for q at time step τ.

LEMMA 4.2. *There exists a partition $\Pi = \Pi_1, \ldots, \Pi_m$ of the interval $[1, T]$ and a set R of $T - m$ messages (not including those sent by S) each of which satisfies the following property: if the message became ready during Π_i its destination node is Q_i.*

Proof. Message $\mathcal{M}_i$ is received at Q_i at time step T_i. Let $T_i^{nr} < T_i$ be the maximum time step at which Q_i does not receive a message. At each time step of the interval $\Delta_i = [T_i^{nr} + 1, T_i]$, Q_i receives a message. Each of these messages became ready during the same interval Δ_i.

Observe that message $\mathcal{M}_{i-1}$ was received at time step T_{i-1} and message $\mathcal{M}_i$ became ready at time step $T_{i-1} + 1$. Therefore, $T_i^{nr} \leq T_{i-1}$. As a result there is no gap between any pair of consecutive intervals Δ_i, Δ_{i+1}. Given the intervals $\Delta_1, \ldots, \Delta_m$, we construct a partition Π as follows:

$$\begin{aligned} \Pi_m &= \Delta_m \\ \Pi_i &= \Delta_i - \bigcup_{j>i} \Pi_j, \quad 1 \leq i < m. \end{aligned}$$

By construction, it follows that every message received by Q_i during Π_i became ready during Π_i and at least $T - m$ messages received by Q_i's during Π_i's were not sent by S. This establishes the lemma. ∎

To complete the proof of the theorem, we sum, over all possible partitions, choice of source S, and choice of $T - m$ messages, the probability that these $T - m$ messages chose their destinations in accordance with the partition.

The probability that a message which becomes ready during Π_i chooses Q_i as its destination equals $\frac{1}{p}$. The probability that each of $T - m$ messages makes the right choice is $p^{-(T-m)}$. The number of choices for S, the partitions, and the $T - m$ messages equals $p\binom{T+m}{m}\binom{(p-1)m}{T-m}$. The probability that $T \geq km$ is at most

$$\begin{aligned} & p\binom{T+m}{m}\binom{(p-1)m}{T-m}p^{-(T-m)} \\ & \leq 2^{T+2m}\binom{(p-1)m}{(k-1)m}p^{-((k-1)m)} \\ & \leq 2^{(k+2)m}\left(\frac{e}{k-1}\right)^{(k-1)m} \\ & \leq \left(2^{k+2}\left(\frac{e}{k-1}\right)^{k-1}\right)^{m}. \end{aligned}$$

The first two inequalities follow from the assumption that $m > \log p$ and the fact that $\binom{x}{y} < (xe/y)^y$ (the proof can be found in [16, p. 165]). For k sufficiently large, this quantity is smaller than $O(e^{-m})$. □

5. Techniques for tree searches.

5.1. Algorithmic issues. This section outlines the algorithmic and proof strategies for backtrack and branch-and-bound searches in the atomic message model. The branch-and-bound strategy is essentially that of Karp and Zhang [13]; their model allows any number of messages to be received at a node in one time step. Our technical contribution is to extend their result to the atomic transmission model. The proofs of both results extend the techniques of the previous section.

While the goal of both search procedures is to find the minimum cost leaf, there is an essential difference. Backtrack search examines *every* vertex of the search tree. In branch-and-bound search the cost associated with each vertex increases monotonically with the distance from the root, so that only the *critical subtree*, consisting of vertices with cost no greater than the minimum cost leaf, need be examined. We call such vertices *critical vertices*. For efficient branch-and-bound search, the time devoted to examining noncritical vertices must not dominate that for examining the critical subtree.

Within each synchronous reactive cycle, each processor (1) receives a tree vertex, if any, from its receive buffer, (2) examines and expands the vertex, and (3) puts the children onto the message queue, headed for an independently chosen random destination. For backtrack search we place no requirements on the message queue discipline. However, for branch-and-bound search we require that the message queue be a priority queue, so that the tree vertex selected for transmission is the one with minimum cost.

Using priority message queues for branch-and-bound search means that noncritical vertices cannot be selected for transmission when there is at least one critical vertex inside the message queue. However, a critical vertex can arrive inside the message queue while a noncritical vertex occupies the send buffer. In this case, the critical vertex will have to wait for selection, but it is easy to see that a critical vertex can be delayed by a noncritical vertex in this manner at most once.

Once a message has been selected for transmission, it is still subject to receive-delays. Receive-delays depend on the network policy and are beyond the control of the programmer, so we would like to make as few assumptions as necessary. For backtrack search we are able to carry out the analysis without making any assumptions on network arbitration. For branch-and-bound search, however, our analysis requires that the network observes a FIFO arbitration policy.

In conclusion, our analysis for branch-and-bound search makes stronger assumptions on both the message queue discipline and the network arbitration policy. The first assumption is required to guarantee that progress is made on the critical subtree and is reasonable from an algorithmic viewpoint. The second assumption, concerning network arbitration, is required for technical reasons: we bound the running time as a function of the size of the critical subtree, not the entire search tree which can be arbitrarily larger. Currently we do not know if the FIFO assumption can be weakened, and it is conceivable that it can.

5.2. Proof techniques. In this section we describe some of the ideas and terminology common to the analysis for both backtrack and branch-and-bound searches.

In both problems our goal is to analyze the time to expand a critical tree[4] of size n and depth h on a p-node system. For branch-and-bound search the quantities n and h can each be much smaller than the size and depth of the complete search tree.

In the analysis of the running time we proceed as follows. At time $t = 1$ the root is assumed to be in the send buffer of some node and is received at its destination within that time step. Suppose that the running time is T, i.e., the last time step at which a critical vertex is received. Pick one of the critical vertices received at time T—it must be a leaf in the critical subtree. Call the path $s_1, s_2, \ldots, s_h$ from the root (s_1) to this critical leaf (s_h) the *special path* and the vertices along this path the *special vertices*. Let Q_i denote the destination queue of special vertex s_i.

The first step of the proof is similar to the proof of Lemma 4.2. For a fixed run of the algorithm we construct a partition, $\Pi = \{\Pi_1, \ldots, \Pi_h\}$, of the time interval $[1, T]$. Next, we construct a *signature set* R of nonspecial, critical vertices each of which became ready for some Q_i during the corresponding time interval Π_i. Roughly speaking, the signature set, R, is constructed such that the receive delay periods of its children are disjoint and the sum of these receive-delays is large, i.e., close to T.

There are two cases to consider: the signature set R is either large or small, compared with the threshold αT, where α is some suitably chosen constant. We first show that it is unlikely that R is large when T is large. The proof closely follows the proof of Theorem 4.1.

LEMMA 5.1. *For suitable constants k, α, the probability that $T > k(\frac{n}{p} + h)$ and $|R| \geq \alpha T$ is polynomially small in n.*

Proof. We estimate $Pr(|R| \geq \alpha T)$ by summing the probability of the event $|R| \geq \alpha T$ under all possible combinations of partition Π and queue sequence Q. Given Π and Q each critical vertex appears in R with probability $1/p$, independent of other vertices. The probability that $|R| \geq \alpha T$ and all the special nodes go to destinated Q_i is therefore bounded by $\binom{n}{\alpha T} p^{-(h+\alpha T)}$.

The number of choices for Π, Q and the special path S is no more than $\binom{T+h}{h} p^h n$. Thus, the probability that $|R| \geq \alpha T$ is bounded by

$$
\begin{aligned}
&\binom{n}{\alpha T} p^{-\alpha T} \binom{T+h}{h} n \\
&< \left(\frac{ne}{\alpha T p}\right)^{\alpha T} ((1 + T/h)e)^h n \\
&< \left(\frac{e}{\alpha k}\right)^{\alpha k(\frac{n}{p}+h)} \left(\left(k\left(\frac{n}{ph} + 1\right) + 1\right) e\right)^h n, \quad \text{when } T > k(\tfrac{n}{p} + h) \\
&< \left[\left(\frac{e}{\alpha k}\right)^{\alpha k(\frac{n}{ph}+1)} \left(\left(k\left(\frac{n}{ph} + 1\right) + 1\right) e\right)\right]^h n \\
&< \left[\left(\frac{e}{\alpha k}\right)^{\alpha k} ((2k + 1)e)\right]^h n
\end{aligned}
$$

which, for appropriately chosen k, is polynomially small in n, the size of the critical subtree since the height of the tree h is at least $\log n$. ∎

The second part of the proof argues that it is unlikely that R is small when T is large. The intuition is that the expected receive-delay of any vertex is a small constant; therefore, it would seem unlikely for the children of a small number of

[4]Every vertex in backtrack search is critical.

signature vertices to suffer a large total receive-delay. Unfortunately, the delays of the children of the signature vertices are not independent random variables, so that Chernoff bounds cannot immediately be invoked.

Briefly, in analyzing backtrack search we track the destinations of the children of the signature vertices to construct a new set of queues, a new partition of time, and a new signature set. The new signature set is guaranteed to be large; consequently, the remainder of the proof follows the proof of Lemma 5.1. The analysis of branch-and-bound search is based on the observation that, under FIFO arbitration, the delays of the children of the signature set can essentially be treated as a martingale, thereby allowing us to use Chernoff bounds.

6. Analysis of backtrack search. In this section we demonstrate that when each vertex chooses its destination randomly and independently, then with high probability the completion time of backtrack search is optimal within a constant factor.

Following the outline of the previous section, we proceed in two stages. In the first stage we identify the required signature set R; the second stage establishes the unlikelihood of the event that T is large while R is small.

6.1. Signature set. We begin with some terminology and definitions. As before, let $S = \{s_1, \ldots, s_h\}$ denote the special vertices along the special root-to-leaf path and Q_i be the destination queue which receives special vertex s_i at time T_i.

DEFINITION. *A node Q is* empty at time t *if neither the send buffer nor the message queue of Q contains a vertex* right after the send phase of time step t. *By definition a node cannot be empty at time t if it receives an internal vertex at time $t-1$. However, it is possible that a node which is empty at t receives a leaf at time $t-1$. Note that any node which is nonempty throughout an interval I attempts to inject a vertex into the network at every time step of I.*

DEFINITION. *Suppose that node Q receives a vertex at each time step during time interval W. We call the interval W an* arrival window *for node Q. Recall that a receive-delay is the time interval during which a message waits in the send buffer due to destination congestion. Note that if time interval W is the receive-delay of vertex v, then W is an arrival window for the destination queue of v.*

DEFINITION. *For $1 \le i < h$, let T_i^e denote the maximum time $t < T_{i+1}$ such that Q_i is empty at t, and T_i^{nr} denote the maximum time $t \le T_i^e$ at which Q_i does not receive a message. Finally, let N_i denote the interval $[T_i^e+1, T_{i+1}]$, $A_i = [T_i^{nr}+1, T_i^e]$ and $\Delta_i = A_i \cup N_i$.*

The following lemma summarizes three properties which are a straightforward consequence of the definitions above.

LEMMA 6.1.

1. *Q_i receives an internal vertex at time T_i^e,*
2. *Q_i is nonempty throughout N_i and Q_i attempts to inject a vertex at every step of N_i, and*
3. *A_i is an arrival window for Q_i.*

Let c_i denote the set of vertices that are injected into the network from Q_i during N_i. We obtain the following lemma.

LEMMA 6.2.

1. *The parent of every vertex in c_i becomes ready for Q_i during Δ_i,*
2. *Δ_i can be partitioned into a set of arrival windows (not necessarily for all Q_i), and*
3. *the interval Δ_i contains $[T_i, T_{i+1}]$, and $\bigcup_{i=1}^{h-1} \Delta_i = [1, T]$.*

Proof. Let w be the parent of a vertex $v \in c_i$. In contradiction to (1), suppose w is ready at or before T_i^{nr}. Two cases follow: either w is received before T_i^{nr} or after T_i^{nr}.

In the first case, if w is received before T_i^{nr}, then v will stay in the message queue of Q_i until it becomes ready. However, from the definition, v cannot become ready until $T_i^e + 1$ or later. This contradicts the fact that Q_i is empty at T_i^e.

In the second case, if w is received after T_i^{nr}, then the receive-delay of w is an arrival window for Q_i. This contradicts the fact that Q_i does not receive a vertex at T_i^{nr}. As a result w must be ready after T_i^{nr}.

From part 2 of Lemma 6.1 N_i can be partitioned into arrival windows for the destinations of c_i. Therefore, Δ_i can be partitioned into arrival window A_i for Q_i and a set of arrival windows in N_i for the destinations of c_i.

Finally, for part 3 we observe that $s_{i+1} \in c_i$, so s_i must be ready after T_i^{nr} (from part 1 of this lemma) and is received at $T_i > T_i^{nr}$. Therefore Δ_i contains $[T_i, T_{i+1}]$ and part 3 follows. □

From part 3 of Lemma 6.2 the union of all Δ_i covers the time interval $[1, T]$; consequently we can define a partition $\Pi = \{\Pi_1, \ldots, \Pi_{h-1}\}$ of the interval $[1, T]$ as follows:

$$\Pi_{h-1} = \Delta_{h-1},$$
$$\Pi_i = \Delta_i - \bigcup_{j>i} \Pi_j, \quad 1 \le i < h-1.$$

DEFINITION. *Let R_i be the set of critical vertices which are not special ($v \notin S$) but are ready for Q_i during the interval Π_i. Also, let $R = \cup_{i<h} R_i$. We call the set R the* signature set.

Having identified the signature set, it remains to estimate the probability that the signature set is small when T is large.[5] This estimation is completed in the following section.

6.2. A refined partition. As mentioned in section 5, our strategy will be to find a new partition of the interval $[1, T]$ and a corresponding signature set which is guaranteed to be large.

In this section we identify $O(|R| + h)$ arrival windows which cover the interval $[1, T]$. We will find arrival windows to cover each Π_i $(1 \le i < h)$ and argue that the sum of the number of windows in each Π_i is $O(|R| + h)$. The next section will identify the new partition and signature set.

DEFINITION. *Let C_i denote those k_i children of $R_i \cup s_i$ that are ready within $N_i \cap \Pi_i$. We sort C_i into a list $v_{i,1}, \ldots, v_{i,k_i}$ according to the time they become ready. Also let $Q_{i,j}$ denote the destination of vertex $v_{i,j}$ and $W_{i,j}$ denote the receive-delay of $v_{i,j}$.*

Each Π_i is the union of two disjoint intervals $N_i \cap \Pi_i$ and $A_i \cap \Pi_i$. The interval $N_i \cap \Pi_i$ is an initial segment of N_i which, from part 2 of Lemma 6.2, can be partitioned into arrival windows. Each such arrival window W is the receive-delay of a vertex v which is enqueued after T_i^e and becomes ready in Q_i at the beginning of W. From part 1 of Lemma 6.2 the parent of v must be ready for Q_i after T_i^{nr}. In other words, the parent of v must be ready during Π_i and consequently $v \in C_i$. As a result the

[5] The case when R and T are both large is covered by Lemma 5.1.

interval $N_i \cap \Pi_i$ can be partitioned into the receive-delays of the k_i vertices in C_i.[6] Each such receive-delay is an arrival window $W_{i,j}$ for $Q_{i,j}$ $(1 \le j \le k_i)$.

From part 3 of Lemma 6.1 $A_i \cap \Pi_i$ is an arrival window for Q_i. Let $W_{i,0} = A_i \cap \Pi_i$ and $Q_{i,0} = Q_i$, so that the interval Π_i can be partitioned into arrival windows $W_{i,j}$ for $Q_{i,j}$ $(0 \le j \le k_i)$. Finally we consider Π_i for all i and it follows that $\bigcup_{1\le i<h} \bigcup_{0\le j\le k_i} W_{i,j} = [1, T]$.

From the discussion above, the receive-delays, $W_{i,j}$, of the k_i vertices $v_{i,j} \in C_i$, and $W_{i,0}$ cover Π_i. Moreover, the parent of every vertex in $C = \bigcup_{1\le i<h} C_i$ is in either R or S; consequently, the number of arrival windows is at most $h + |C| \le h + 2(|S| + |R|) = 3h + 2|R|$ since we assume a binary search tree.

We need one more definition to derive the refined partition Π^* and queue sequence Q^*, where we can find T vertices that become ready for Q^* according to Π^*.

DEFINITION. *For the arrival window $W_{i,j} = [t_1, t_2]$ for $Q_{i,j}$, let $t \le t_1$ be the maximum time step at which $Q_{i,j}$ does not receive a message. Define $W^*_{i,j} = [t+1, t_2]$ so that $(W^*_{i,j}, Q_{i,j})$ is the* maximal backward extension *of the arrival window.*

Let Q^* be the sequence of all the queues $Q_{i,j}$, $1 \le i < h$, $1 \le j \le k_i$. Notice that every message received by $Q_{i,j}$ during the interval $W^*_{i,j} = [t+1, t_2]$ necessarily becomes ready for $Q_{i,j}$ during the same interval. Otherwise $Q_{i,j}$ would have received a message at time t, a contradiction.

From the extended windows $W^*_{i,j}$, $1 \le i < h$, $0 \le j \le k_i$, we next obtain the partition Π^* as follows:

$$\Pi^*_{h-1,k_{h-1}} = W^*_{h-1,k_{h-1}},$$
$$\Pi^*_{i,j} = W^*_{i,j} - \bigcup_{l>i \vee (l=i \wedge m>j)} \Pi^*_{l,m}.$$

Now we can find T vertices that become ready for Q^* according to Π^* since every vertex received by Q^* must be ready in the corresponding Π^* interval and the union of Π^* is $[1, T]$. Let $X_{i,j}$ denote the set of vertices v such that $v \notin C \cup R \cup S$ and v is received by $Q_{i,j}$ during $\Pi^*_{i,j}$. From the discussion above every vertex in $X_{i,j}$ must become ready for $Q_{i,j}$ during $\Pi^*_{i,j}$. Finally, let $X = \cup X_{i,j}$ and $V = C \cup R \cup S$. Since the arrival windows cover the interval $[1, T]$, it follows that $|X| \ge T - |V|$.

6.3. Execution templates. Our goal in this section is to estimate the probability of the event that T is large and R is small. We proceed in two stages; first we characterize the completion time in terms of an *execution template*. Then we show that execution templates corresponding to large completion times are unlikely. This follows the delay-sequence arguments used in the literature [21, 22].

DEFINITION. *An execution template $\mathcal{E}$ is an octuple $(S, R, C, \Pi, \Pi^*, X, Q, Q^*)$ whose elements are defined as follows:*

- *$S = \{s_1, \ldots, s_h\}$ denotes the set of vertices along a path from the root to a leaf;*
- *R_i, $1 \le i < h$, are disjoint sets of nonspecial critical vertices that become ready for Q_i during Π_i, and $R = \cup_{i=1}^{h-1} R_i$ is the signature set;*
- *C_i, $1 \le i < h$, are disjoint sets of tree vertices that are children of $s_i \cup R_i$ and become ready within $N_i \cap \Pi_i$; $|C_i| = k_i$ and $C = \cup C_i$;*
- *$\Pi = \{\Pi_1, \ldots, \Pi_{h-1}\}$ is a partition of $[1, T]$;*

[6] The receive-delay of the last vertex v_{i,k_i} may not fall entirely within $N_i \cap \Pi_i$, in which case we truncate it accordingly.

- $\Pi^* = \{\Pi_{1,1}, \ldots, \Pi_{1,k_1}, \ldots, \Pi_{h-1,1}, \ldots, \Pi_{h-1\ k_{h-1}}\}$ *is a partition of* $[1, T]$*;*
- $X_{i,j}$*,* $1 \le i < h$*,* $0 \le j \le k_i$*, are sets of tree vertices that are disjoint from* $V = C \cup R \cup S$ *and ready for* $Q^*_{i,j}$ *during* $\Pi^*_{i,j}$*,* $X = \cup X_{i,j}$ *and* $|X| \ge T - |V|$*;*
- $Q = \{Q_1, \ldots, Q_h\}$ *is a set of queues such that for every* $1 \le i < h$*,* Q_i *is the destination queue of* s_i *and also of every vertex in* R_i *and* $X_{i,0}$*, and* Q_h *is the destination of* s_h*;*
- $Q^* = \{Q^*_{1,1}, \ldots, Q^*_{1,k_1}, \ldots, Q^*_{h-1,1}, \ldots, Q^*_{h-1,k_{h-1}}\}$ *is a set of queues such that for every* $1 \le i < h, 1 \le j \le k_i$*,* $Q^*_{i,j}$ *is the destination for the* j*th element in* C_i *and every vertex in* $X_{i,j}$*.*

From the earlier discussion, when the backtrack search takes T time steps to complete, there exists an execution template where the destination of vertices in S, R, C, and X satisfy the following conditions (let $D(v)$ be the random destination of vertex v):

1. $D(s_i) = Q_i$, $1 \le i \le h$.
2. For all $v \in R_i$, $D(v) = Q_i$, $1 \le i < h$.
3. Let $v_{i,j}$ be the jth element in C_i, $D(v_{i,j}) = Q^*_{i,j}$, $1 \le i < h, 1 \le j \le k_i$.
4. For all $v \in X_{i,j}$, $D(v) = Q^*_{i,j}$, $1 \le i < h, 1 \le j \le k_i$.
5. For all $v \in X_{i,0}$, $D(v) = Q_i$, $1 \le i < h$.

6.4. Estimating the probability of execution templates. Let $\mathcal{L}$ be the event $T > k(\frac{n}{p} + h)$ and $|R| < \alpha T$. We bound the probability of event $\mathcal{L}$ by summing the probabilities of event $\mathcal{L}$ under all possible execution templates. For a fixed execution template the probability that all vertices in S, R, C, and X choose the right queue according to $\mathcal{E}$ is at most

$$p^{-|S\cup R\cup C|} p^{-(T-|S\cup R\cup C|)} = p^{-h} p^{-|R|} p^{-|C-(S\cup R)|} p^{-(T-|S\cup R\cup C|)}.$$

Next, we count the number of different execution templates. The number of possible S is n since there are at most n leaves in the tree. After S and R are specified, there are at most $\binom{2(|S|+|R|)}{|C|}\binom{n}{T-|V|}$ ways to choose C and X. The destinations of vertices from S and R are specified by Q, so the number of unspecified queues in Q^* is $|C - (S \cup R)|$ and the number of ways to choose Q and Q^* is $p^h p^{|C-(S\cup R)|}$. Finally, there are $\binom{T+|C|+h}{|C|+h}\binom{T+h}{h}$ ways to choose Π^* and Π, so the total number of execution templates is at most

$$n\binom{n}{|R|}\binom{2(|S|+|R|)}{|C|}\binom{n}{T-|V|} p^h p^{|C-(S\cup R)|}\binom{T+|C|+h}{|C|+h}\binom{T+h}{h}.$$

LEMMA 6.3. *For suitable constants* $k > 1, 0 < \alpha < 1/3$*, the probability that* $T > k(\frac{n}{p} + h)$ *and* $|R| < \alpha T$ *is polynomially small in* n*.*

Proof. The probability of $\mathcal{L}$ is no more than the product of the number of different execution templates and the probability that every vertex in S, R, C, and X will actually choose the destination according to $\mathcal{E}$ when $T > k(\frac{n}{p} + h)$ and $|R| < \alpha T$.

$$
\begin{aligned}
& n\binom{n}{|R|}\binom{2(|S|+|R|)}{|C|}p^{-|R|}\binom{n}{T-|V|}p^{-(T-|V|)}\binom{T+|C|+h}{|C|+h}\binom{T+h}{h} \\
\le\ & 2^{\log n}2^{2(|S|+|R|)}\binom{n}{\lceil\frac{n-p}{p+1}\rceil}p^{-\lceil\frac{n-p}{p+1}\rceil}\left(\frac{ne}{(T-|V|)p}\right)^{(T-|V|)}2^{T+|C|+h}2^{T+h} \\
\le\ & 2^{(2\alpha+2)T+5h+|C|}\left(\frac{ne}{\lceil\frac{n-p}{p+1}\rceil p}\right)^{\lceil\frac{n-p}{p+1}\rceil}\left(\frac{ne}{(T-|V|)p}\right)^{T-|V|} \\
\le\ & 2^{(2\alpha+2)T+5h+2h+2\alpha T}\left(\frac{ne}{\frac{n}{2p}p}\right)^{\frac{n}{p}}\left(\frac{ne}{(T-3\alpha T-3h)p}\right)^{T-3\alpha T-3h} \quad \text{since } |V|\le 3(\alpha T+h) \\
\le\ & 2^{7h+(4\alpha+2)k(\frac{n}{p}+h)}(2e)^{\frac{n}{p}}\left(\frac{ne}{((1-3\alpha)k-3)(\frac{n}{p}+h)p}\right)^{((1-3\alpha)k-3)(\frac{n}{p}+h)} \\
\le\ & 2^{((4\alpha+2)k+7)(\frac{n}{p}+h)}(2e)^{\frac{n}{p}}\left(\frac{e}{((1-3\alpha)k-3)}\right)^{((1-3\alpha)k-3)(\frac{n}{p}+h)} \\
\le\ & \left[2^{(4\alpha+2)k+7}(2e)\left(\frac{e}{((1-3\alpha)k-3)}\right)^{((1-3\alpha)k-3)}\right]^{(\frac{n}{p}+h)} \\
\le\ & 2^{-(\frac{n}{p}+h)} \text{ for suitably chosen constants } k,\alpha.
\end{aligned}
$$

The first inequality follows from the observation that $\binom{n}{x}p^{-x}$ is maximized when $x = \lceil\frac{n-p}{p+1}\rceil$. The second inequality follows from the fact that $\log n < h$, $|S| = h$ and the assumption that $R \le \alpha T$. The probability in the fourth inequality is roughly $2^{k_1 T}k_2^{n/p}k_3^{k_4 T} < (2^{k_1}k_2k_3^{k_4})^T$. As long as we keep $(2^{k_1}k_2k_3^{k_4}) < 1$ (by choosing sufficiently large k) the probability will diminish when n (and T) is sufficiently large. Therefore, when n is sufficiently large, we replace T with $k(n/p+h)$. Finally, since $h \ge \log n$, the bound in the last step is polynomially small in n. □

From Lemmas 5.1 and 6.3 we have the following theorem.

THEOREM 6.4. *Let $\mathcal{T}$ be any binary backtrack search tree of size n and depth h. Let T be the total time for the random destination backtrack search algorithm to expand $\mathcal{T}$ in a p-node network. The probability that T exceeds $k(\frac{n}{p}+h)$, where k is suitably chosen, is polynomially small in n.*

7. Analysis of branch-and-bound search. The proof for backtrack search does not apply in the branch-and-bound search case because an adversarial network arbiter can delay a critical node by favoring noncritical nodes. In the backtrack case, every tree node has to be expanded. Therefore, no matter which tree node the arbiter chooses to be received, some progress is made. In the branch-and-bound case, although a critical node cannot be delayed by a noncritical node in the competition for the send buffer, it can be delayed by noncritical nodes in the competition for the same destination. An adversarial arbiter can work against the critical nodes so that they suffer long receive-delays.

Our analysis of branch-and-bound search is based on the assumption that the network obeys the FIFO scheduling policy. Under FIFO scheduling incoming vertices are received in time-stamp order; a vertex that is ready cannot be delayed by a vertex that becomes ready at a later time-step; vertices that become ready at the same time can be received in arbitrary order.

We prove linear speedup in two steps. First, we prove that the aggregate delay

of m nonoverlapping receive delays is bounded by $O(m)$ with high probability under FIFO scheduling. Next, we show that for every execution there exists a signature set R and a set of $O(|R|+h)$ nonoverlapping receive-delays with aggregate delay $\Omega(T)$. As a result, it is very unlikely for T to be large and $|R|$ to be small. The other case, that of large T and large $|R|$, is already covered by Lemma 5.1.

7.1. Martingales.

LEMMA 7.1. *Let $X_1, \ldots, X_m$ be m random variables each in the range $[0, p-1]$ and let $X = \sum_{i=1}^{m} X_i$. Suppose that the conditional expectation $E(X_i \mid X_1 = x_1, \ldots, X_{i-1} = x_{i-1}) \leq 1$, for all $1 \leq i \leq m$, and $0 \leq x_1, \ldots, x_{i-1}, \leq p-1$. Then, $Pr(X \geq \alpha m) \leq (\frac{1}{2})^{\alpha \frac{m}{p-1}}$ when $\alpha \geq 2e$.*

Proof. The analysis is similar to the generalized Chernoff bound given by Leighton et al. [15]. We first estimate the expectation of e^{tX}:

$$\begin{aligned} E(e^{tX}) &= E(e^{tX_1} e^{tX_2} \cdots e^{tX_m}) \\ &= \sum_{x=0}^{p-1} e^{tx} E(e^{tX_2} \cdots e^{tX_m} | X_1 = x) Pr(X_1 = x). \end{aligned}$$

We then choose a value x_1^* for X_1 so that $E(e^{tX_2} \cdots e^{tX_m} | X_1)$ is maximized:

$$\begin{aligned} E(e^{tX}) &\leq \sum_{x=0}^{p-1} e^{tx} E(e^{tX_2} \cdots e^{tX_m} | X_1 = x_1^*) Pr(X_1 = x) \\ &\leq \left(\sum_{x=0}^{p-1} e^{tx} Pr(X_1 = x) \right) E(e^{tX_2} \cdots e^{tX_m} | X_1 = x_1^*) \\ &\leq E(e^{tX_1}) E(e^{tX_2} \cdots e^{tX_m} | X_1 = x_1^*) \\ &= E(e^{tX_1}) \sum_{x=0}^{p-1} e^{x} E(e^{tX_3} \cdots e^{X_m} | X_1 = x_1^*, X_2 = x) Pr(X_2 = x | X_1 = x_1^*) \\ &= E(e^{tX_1}) E(e^{tX_2} | X_1 = x_1^*) E(e^{tX_3} \cdots e^{tX_m} | X_1 = x_1^*, X_2 = x_2^*) \\ &\vdots \\ &\leq E(e^{tX_1}) E(e^{tX_2} | X_1 = x_1^*) \cdots E(e^{tX_m} | X_1 = x_1^*, \ldots, X_{m-1} = x_{m-1}^*). \end{aligned}$$

Each of these expectations is maximized when the probability is nonzero only at 0 and $p-1$, the endpoints of the range of X_i. From Markov's inequality we can bound $E(e^{tX_i} | X_1 = x_1^*, \ldots, X_{i-1} = x_{i-1}^*)$ by $Pr(X_i = 0 | X_1 = x_1^*, \ldots, X_{i-1} = x_{i-1}^*) + Pr(X_i = p-1 | X_1 = x_1^*, \ldots, X_{i-1} = x_{i-1}^*) e^{t(p-1)} \leq (1 - \frac{1}{p-1}) + \frac{1}{p-1} e^{t(p-1)}$ since $E(X_i | X_1 = x_1^*, \ldots, X_{i-1} = x_{i-1}^*)$ is bounded by 1 from the assumptions. As a result we choose t so that $e^{t(p-1)}$ is larger than 1 and $E(e^{tX_i} | X_1 = x_1^*, \ldots, X_{i-1} = x_{i-1}^*)$ is maximized when $Pr(X_i = p-1 | X_1 = x_1^*, \ldots, X_{i-1} = x_{i-1}^*)$ is maximized.

$$\begin{aligned} E(e^{tX} | X_1 = x_1^*, \ldots, X_{i-1} = x_{i-1}^*) &\leq \left(\left(1 - \frac{1}{p-1} \right) + \frac{1}{p-1} e^{t(p-1)} \right)^m \\ &= \left(1 + \frac{e^{t(p-1)} - 1}{p-1} \right)^m \\ &\leq e^{(\frac{e^{t(p-1)}-1}{p-1})m}, \qquad (1 + y < e^y). \end{aligned}$$

Then we again use Markov's inequality to bound the probability that X is greater than αm:

$$\begin{aligned} Pr(X \geq \alpha m) &= Pr(e^{tX} \geq e^{t\alpha m}) \\ &\leq \frac{e^{(\frac{e^{t(p-1)}-1}{p-1})m}}{e^{t\alpha m}} \\ &= e^{-\frac{(\alpha \ln \alpha - \alpha + 1)m}{p-1}} \qquad \text{(when } t = \tfrac{\ln \alpha}{p-1}\text{)} \\ &\leq 2^{-\frac{\alpha m}{p-1}} \qquad \text{(when } \alpha \geq 2e\text{).} \qquad \square \end{aligned}$$

LEMMA 7.2. *Let $V = \{v_1, \ldots, v_m\}$ be m vertices with nonoverlapping delays. The probability that their aggregate delay exceeds βm is smaller than $(\frac{1}{2})^{\frac{(\beta-1)m}{p-1}}$ when $\beta \geq 2e + 1$.*

Proof. Let Q_i be the destination of v_i and X_i be the number of vertices that will be received by Q_i before v_i when v_i becomes ready. The receive-delay of v_i is $X_i + 1$ and the aggregate receive-delay of V is $m + \sum_{i=1}^{m} X_i$.

Every vertex chooses its destination independently and uniformly; therefore, given $X_1, \ldots, X_{i-1}$, v_i is equally likely to pick any destination. We will argue that, given $X_1, \ldots, X_{i-1}$, the expected value of X_i is no more than 1. When v_i makes its random choice there are at most $p - 1$ other ready vertices in the system whose choices are independent of v_i's choice. Therefore, the conditional expectation of X_i is less than one.

For the aggregate delay to exceed βm, the sum of all X_i must exceed $(\beta - 1)m$. The bound on the probability of this event follows from Lemma 7.1. $\square$

7.2. The signature set. As before we consider the special vertices $S = \{s_1, \ldots, s_h\}$. Let s_i be received by Q_i at time T_i for $1 \leq i \leq h$. For every $1 \leq i < h$ we seek a set of receive-delays which together cover the interval $[T_i, T_{i+1}]$.

Let T_i^{ns} be the largest time step smaller than T_{i+1} at which the send buffer of Q_i is not occupied by a critical vertex, $(1 \leq i < h)$. Note that at each time step during the interval $\Gamma_i = [T_i^{ns} + 1, T_{i+1}]$ the send buffer of Q_i is occupied by a critical vertex. Let c_i be the critical vertices that are injected into the network from Q_i during Γ_i. As a result, Γ_i can be partitioned into receive-delays of vertices in c_i.

Among all the parents of vertices in c_i let f_i be the one that becomes ready at the earliest time step, say, T_i^f. Since $s_{i+1} \in c_i$ it follows that s_i is received no earlier than T_i^f.

It is possible for a gap to exist between the receive-delays of f_i and vertices in c_i. In this case, the send buffer of Q_i must be occupied by a noncritical vertex, call it g_i, which is received at its destination at time T_i^{ns}. Observe that g_i cannot be received at its destination any earlier, for otherwise the send buffer of Q_i would have to be occupied by a critical vertex (the message queue contains at least one critical vertex, the child of f_i, and a critical vertex gets priority over noncritical vertices to enter the send buffer). However, this contradicts the definition of T_i^{ns}.

Let T_i^g be the time step at which the parent of g_i becomes ready and let $\Delta_i = [\min(T_i^f, T_i^g), T_{i+1}]$. The following lemma summarizes our observations.

LEMMA 7.3.

1. *The parent of each vertex in c_i becomes ready for Q_i during Δ_i,*
2. *Δ_i is the union of receive-delays of vertices f_i, c_i, and g_i (if it exists), and*
3. $\bigcup_{i=1}^{h-1} \Delta_i = [1, T]$.

Proof. The parent of each vertex v in c_i must become ready before v; furthermore, it cannot become ready before f_i. For part 2, if there is a gap between the receive-delay of f_i and c_i, then this gap will be covered by the receive-delay of g_i from the discussion above. Finally s_i must be ready at or after T_i^f from the definition of f_i so it cannot be received before T_i^f; thus the interval Δ_i contains $[T_i, T_{i+1}]$, and part 3 follows. □

From part 3 of Lemma 7.3 the union of all Δ_i cover the interval $[1, T]$. We can therefore define a partition Π of $[1, T]$ as follows:

$$\Pi_{h-1} = \Delta_{h-1},$$
$$\Pi_i = \Delta_i - \bigcup_{j>i} \Pi_j, \quad 1 \le i < h-1.$$

DEFINITION. *As before, a critical vertex v is in the* signature set *R if v is not a special vertex ($v \notin S$) and v becomes ready for Q_i during Π_i.*

There are three kinds of receive-delays in Π_i: the earliest ready parent f_i, the noncritical vertex g_i, and those vertices in c_i that become ready during $\Gamma_i \cap \Pi_i$. We use F, G, and C to denote the sets of these three kinds of vertices from all Π_i. From part 1 of Lemma 7.3 and the definition of R, the parent of every vertex in C is either in R or S. As a result the number of receive-delays in $F \cup G \cup C$ is at most $2h + 2(|S| + |R|) = 4h + 2|R|$.

The receive-delays identified thus far cover the interval $[1, T]$ and there are no more than $4h + 2|R|$ in number. They are not necessarily nonoverlapping, however. Using a straightforward greedy procedure it is possible to produce a subset of no more than $2h + |R|$ intervals which are disjoint and whose union includes at least $T/2$ time steps. With this observation, we have the following theorem.

THEOREM 7.4. *Let $\mathcal{T}$ be the critical branch-and-bound subtree of size n and depth h. Let T be the total time for the random destination algorithm to expand $\mathcal{T}$ in a p-node network under FIFO scheduling strategy. The probability that T exceeds $k(\frac{n}{p} + h)$ is polynomially small, for suitably chosen k, when $n > p^2 \log p$.*

Proof. The probability that the signature set R exceeds αT in size is polynomially small by Lemma 5.1. From the above discussion we can identify a set of $2h + \alpha T$ nonoverlapping receive-delays whose aggregate delay is at least $T/2$. From the result of Lemma 7.2 this probability is bounded by $(\frac{1}{2})^{\frac{cT}{p}}$ for a suitable constant c. This quantity is polynomially small in n for $n > p^2 \log p$ and a suitably chosen k. □

8. Conclusions. In this paper we have developed a simple model which captures some aspects of message-passing systems. The model can be extended in several ways to include, for example, nonuniformity of routing times and more system buffering capacity.

We believe that the model is simple enough to carry out further algorithmic analysis which we expect will shed light on the limitations of bounded resources in parallel systems.

Acknowledgments. We thank Marina Chen, Charles Leiserson, Abhiram Ranade, Chuck Seitz, and Peter Winkler for helpful discussions. We are grateful to Lennart Johnsson and Thinking Machines Corporation for their support.

ON-LINE RANDOMIZED CALL CONTROL REVISITED*

STEFANO LEONARDI†, ALBERTO MARCHETTI-SPACCAMELA†,
ALESSIO PRESCIUTTI†, AND ADI ROSÉN‡

Abstract. We consider the problem of on-line call admission and routing on trees and meshes. Previous work gave randomized on-line algorithms for these problems and proved that they have optimal (up to constant factors) *competitive ratios*. However, these algorithms can obtain very low profit with high probability. We investigate the question of devising for these problems on-line competitive algorithms that also guarantee a "good" solution with "good" probability.

We give a new family of randomized algorithms with asymptotically optimal competitive ratios and "good" probability to get a profit close to the expectation. We complement these results by providing bounds on the probability of any optimally competitive randomized on-line algorithm for the problems we consider to get a profit close to the expectation. To the best of our knowledge, this is the first study of the relationship between the tail distribution and the competitive ratio of randomized on-line benefit algorithms.

Key words. on-line algorithms, competitive analysis, randomized algorithms, call admission control

1. Introduction.

The area of communication networks gives rise to a large number of on-line problems. One of the most extensively studied problems in this area is the problem of on-line assignment of virtual circuits in networks: a sequence of requests for calls is given on-line to an algorithm which has to select a virtual circuit between the communicating parties (or reject the request), obeying the network constraints (such as link capacities). Two kinds of decisions are involved: *admission control*, i.e., the choice of whether to accept the call or not, and *route selection*, i.e., the decision on the route of an accepted call. Each call is processed before any future call is known, while the algorithm has to make both decisions. The basic form of this problem (when link capacities are 1, and each call requests bandwidth 1) is an on-line version of the well-known problem of maximizing the number of edge-disjoint paths.

The off-line version of the maximum edge-disjoint path problem is known to be NP-hard on general networks [13]. The problem is solvable in polynomial time on tree networks [11] while it is still NP-hard on mesh networks [17]. Kleinberg and Tardos [16] give an $O(1)$ approximation algorithm for meshes and densely embedded nearly Eulerian graphs. For general graphs an $O(\sqrt{m})$ approximation is given in [14], where m is the number of edges in the graph. Recently, an $\Omega(n^{1/2-\epsilon})$ inapproximability lower bound for the maximum edge-disjoint path problem on general graphs was proved in [12] (where n is the number of nodes in the graph).

Algorithms for on-line maximization problems are usually analyzed in terms of their *competitive ratio* [20], i.e., the worst case, over all input sequences, of the ratio between the benefit obtainable by an off-line optimal algorithm (that knows the whole sequence in advance), and the benefit obtained by the on-line algorithm. It is easy to see that greedy strategies for the problems we consider here are noncompetitive; hence more sophisticated strategies are necessary. Awerbuch, Azar, and Plotkin [2] gave a deterministic on-line algorithm (denoted by AAP in this paper) for the case in which the bandwidth request of each call is small when compared with the link capacities of the network. Their algorithm works for any network topology and achieves a benefit that is at least a logarithmic fraction (in the size of the network) of the optimal solution. No deterministic algorithm can have an asymptotically better competitive ratio [2]. However, if calls may request the full bandwidth of links in the network, Awerbuch, Azar, and Plotkin [2] prove a lower bound of $\Omega(n)$ for deterministic on-line algorithms for a line network, where n is the number of vertices. (Deterministic algorithms with good competitive ratios are still possible for the maximum edge-disjoint paths problem on some particular networks like expander graphs [15].)

Therefore randomized on-line algorithms have been considered for these problems. A randomized on-line algorithm, $\mathcal{A}$, is said to be c-competitive (against an oblivious adversary [7]) if for *any* sequence of requests σ, $E[\mathcal{A}(\sigma)] \geq \frac{1}{c} \cdot OPT(\sigma)$, where $\mathcal{A}(\sigma)$ and $OPT(\sigma)$ denote the algorithm's and the optimal benefit over sequence σ, and the expectation is taken over the random choices of $\mathcal{A}$. Awerbuch et al. [3] proposed an algorithm with an $O(\log n)$-competitive ratio for trees of n vertices. This result has been improved to $O(\log D)$, where D is the diameter of the tree, by Awerbuch et al. [4]. Kleinberg and Tardos [16] presented an algorithm with an $O(\log n)$-competitive ratio for meshes and a class of planar graphs. For all these topologies, matching (up to constant factors) randomized lower bounds have also been proved. On the other hand, Bartal, Fiat, and Leonardi [5] proved an $\Omega(n^{\epsilon})$ lower bound for randomized on-line algorithms on a specific network.

However, all the aforementioned algorithms have only the property that their *competitive ratio* is "good." They have not been analyzed with respect to their probability to get a "good" solution, and they only guarantee that for any sequence of requests the *expected* benefit is "close" (usually a logarithmic fraction) to the optimum. However, it may happen that, with high probability, a very poor benefit is achieved (and the main contribution to the average is given by a high benefit, obtained with low probability).[1] Indeed, algorithms of this kind have been criticized on this basis as not giving an appropriate solution for the problems they attempt to solve. For instance, the $O(\log n)$-competitive algorithm of [3] for the maximum edge-disjoint path problem on trees obtains for some sequences σ, even with $OPT(\sigma) = \Omega(n)$, a benefit of 0 with probability $1 - \frac{1}{\log n}$. The $O(\log D)$-competitive algorithm for trees [4] behaves somewhat better; still *unless* $OPT(\sigma) = \Omega(D^{\epsilon})$, the probability of getting any constant fraction of the expectation remains $o(1)$ (as a function of D). As to meshes, the algorithm of [16] decides with probability 1/2 to accept only "short" calls and with probability 1/2 to accept only "long" calls. On sequences of calls that are composed of only one kind of call, the algorithm would obtain benefit 0 with probability at least 1/2.

[1] Note that using the Markov inequality it is possible to obtain bounds on the probability of deviating from the expectation for algorithms for on-line minimization (cost) problems as a direct consequence of the analysis of the competitive ratio. This is not the case for maximization (benefit) problems.

In this paper we investigate the question of whether it is possible to obtain competitive randomized on-line algorithms (for the problems at hand) which also guarantee a "good" solution with "good" probability. Obviously, the probability of achieving a benefit close to the expectation is related to the quality of the expectation: the expectation of deterministic algorithms is obtained with probability 1; however, these algorithms have very poor competitive ratios for the problems we consider.

We formulate the following questions. Our results give answers to most of them in the context of the on-line maximum edge-disjoint paths problem.

1. Can a randomized on-line algorithm with optimal (up to a constant factor) competitive ratio guarantee a benefit of a constant fraction of the expectation with constant probability?

2. Can a randomized on-line algorithm with optimal competitive ratio (up to a constant factor) achieve a constant fraction of the expected benefit with probability that tends to 1 (say, as the size of the optimal solution grows)? What is the possible rate of convergence?

3. What is the interplay between the competitive ratio of a randomized algorithm, and the concentration of the benefit around its expectation?

1.1. Results of the paper. We address the above questions for the call admission problem in the basic case of infinite duration, requested bandwidth and link capacities 1, on the topologies of trees and meshes. Pairs of nodes are given on-line to an algorithm, which has to accept or reject every call immediately when it is received. An accepted call has to be assigned a route which is edge-disjoint with respect to all previously assigned routes. The aim is that of maximizing the number of accepted calls. This problem is equivalent to the on-line version of the maximum edge-disjoint paths problem for the above topologies. We present new randomized algorithms for trees and meshes with asymptotically optimal competitive ratios *and* good concentration of the benefit around its expectation.

Our work contains the following results for trees:

1. We present a family of randomized algorithms, parameterized by $k \geq 12$, with competitive ratios of $2k\lceil \log 2D \rceil$, and with the property that the probability to get any fixed constant fraction of the expected benefit tends to a constant, as $OPT/\log D$ tends to infinity. In addition, these algorithms have the property that their probability to obtain a $1-\delta$ fraction of the expectation, $\delta \in (0,1]$, is at least some constant value $1-\mathcal{P}(k,\delta)$ when $\frac{OPT}{\log D}$ is a large enough constant. The value of $1-\mathcal{P}(k,\delta)$ is such that it can be made as close to 1 as desired at the expense of a larger k, i.e., a larger constant in the competitive ratio.

We also present an $O(\log D)$-competitive algorithm that for *any* sequence of calls guarantees some constant fraction of the expected benefit with probability $\Omega(1)$ (equivalently, this algorithm guarantees an $O(\log D)$ fraction of the *optimal* solution with probability $\Omega(1)$).

2. We show that no optimally competitive algorithm can guarantee a constant fraction of the expected benefit with "very high" probability, unless the optimal solution is "very high." (For a formal statement see section 3.)

3. We also show that other algorithms from the family of algorithms with a slightly worse competitive ratio of $O(\log^{1+\epsilon} D)$, for arbitrary $\epsilon > 0$, have the property to achieve any fixed constant fraction of the expectation with probability that tends

to $1 - 1/\Omega(\log^{\epsilon} D)$, as $\frac{OPT}{\log^{1+3\epsilon} D}$ tends to infinity.

4. Our family of algorithms for trees is based on a new and simple scheme. We are also able to derive an algorithm with the best known competitive ratio for the problem, $6\lceil \log 4D \rceil$, as opposed to the previously known ratio of $48 \log 2D$ [4]. Finally we point out that our algorithms, and in fact *any* algorithm for link capacities 1, can be made to apply to trees with arbitrary uniform capacities.

5. We also study the problem on meshes and we present an asymptotically optimal $O(\log n)$-competitive algorithm for meshes that obtains any constant fraction of the expected benefit with probability that tends to 1, as $\frac{OPT}{\log^4 n}$ tends to infinity. This algorithm is based on some of the ideas of [16] and [6] and on new ideas presented here.

2. The algorithms for trees. The design of our family of algorithms is based on a new approach. They are composed of two conceptual steps. In the first step we apply an on-line *deterministic filter* to the input sequence. Those calls that are *not* filtered out are called *candidate calls* and may be accepted. The set of the candidate calls has two important properties: first, its cardinality is a constant fraction of the cardinality of the largest (optimal) set of calls that can be accepted (by an off-line adversary). Second, although this set cannot be fully accepted (as some of the calls intersect), the intersections between the calls of this set exhibit "nice" properties. When a call passes the deterministic filter and becomes a candidate it is presented to an on-line *randomized selection procedure* that determines if the call is actually accepted. The randomized selection procedures that we use are very simple, and the various algorithms are distinguished by the randomized selection procedure used.

Before we describe the algorithms, we give some notations: we denote by $\sigma = (s_1, t_1), (s_2, t_2), \ldots$ the sequence of requests. We denote by $OPT(\sigma)$ and $\mathcal{A}(\sigma)$ the set of calls accepted by an optimal (off-line) algorithm and by an on-line algorithm $\mathcal{A}$, respectively, out of the sequence σ. We denote by $\mathcal{C}(\sigma)$ the set of candidate calls passed on by the deterministic filtering procedure to the randomized selection procedure. By D we indicate the diameter of the tree. We abuse notation and denote by $OPT(\sigma)$, $\mathcal{A}(\sigma)$, and $\mathcal{C}(\sigma)$ also the cardinality of the corresponding sets. We start now by describing the properties of the deterministic filter that we use.

THEOREM 2.1. *There exists a deterministic on-line filtering procedure for trees of diameter D such that for any sequence σ the following properties hold:*

- $\mathcal{C}(\sigma) \geq OPT(\sigma)/6$.
- *The number of pairs of calls in $\mathcal{C}(\sigma)$ that intersect is at most $\mathcal{C}(\sigma) \cdot \lceil \log 2D \rceil$.*

We prove this theorem in section 2.2. We also show in section 2.3 an alternative filtering procedure which makes use of the AAP algorithm but achieves somewhat worse performances.

The different algorithms of the family of algorithms are distinguished by the randomized selection procedure used. We use a single procedure parameterized by a parameter p ($p \leq \frac{1}{2\lceil \log 2D \rceil}$). Algorithm $\mathcal{A}_p$ presents the candidate calls selected by the deterministic filter, one by one as they are selected to the on-line randomized selection procedure $\mathbf{RS}_p$ defined below.

$\mathbf{RS}_p$. Any candidate call $(s, t) \in \mathcal{C}$ becomes a *considered* call with probability p and is rejected with probability $1 - p$. A considered call is accepted if it does not

intersect any previous *considered* call.[2]

2.1. Analysis of the algorithms.

THEOREM 2.2. *Algorithm $\mathcal{A}_p$ is a $\frac{6}{p(1-p\lceil \log 2D\rceil\ )}$-competitive randomized on-line algorithm for call admission on trees of diameter D. For any $\delta \in (0,1]$, and any sequence σ, $Pr[\mathcal{A}_p(\sigma) < (1-\delta)E[\mathcal{A}_p(\sigma)]] \leq \exp(-\frac{OPT(\sigma)p}{48}(\delta(1-p\lceil \log 2D\rceil\ ))^2) + \frac{1}{1+\frac{1}{2}\delta\left(\frac{1}{p\lceil \log 2D\rceil}-1\right)}$.*

Before proving the theorem we explain its consequences and give some corollaries. The proof of the first corollary follows from simple calculations.

COROLLARY 2.3. *For any fixed constant $k \geq 12$, algorithm $\mathcal{A}_p$ with $p = \frac{6}{k\lceil \log 2D\rceil}$ is a $2k\lceil \log 2D\rceil$-competitive randomized algorithm for on-line call admission on trees of diameter D. Let $P(k,\delta,\sigma) = 1 - Pr[\mathcal{A}_p(\sigma) < (1-\delta)E[\mathcal{A}_p(\sigma)]]$. Then for fixed $k \geq 12$ and fixed $\delta > 0$, $P(k,\delta,\sigma) \to (1-\mathcal{P}(k,\delta))$, for $= \mathcal{P}(k,\delta) = \frac{1}{1+\frac{1}{2}\delta(\frac{k}{6}-1)}$, as $\frac{OPT(\sigma)}{\log D} \to \infty$. Furthermore, when $OPT(\sigma) \geq \beta_k \log D$, for some constant β_k, then $P(k,\delta,\sigma) \geq 1-c$ for some fixed constant $c < 1$.[3] Note that $1-\mathcal{P}(k,\delta)$ is a constant bounded away from 0, if $k \geq 12$, and that it can be made as close to 1 as desired, at the expense of a larger constant k, i.e., a larger constant in the competitive ratio.*

Based on the above corollary we also define a slightly different algorithm, $\mathcal{B}_p$, that guarantees for *any* sequence a constant fraction of the expected benefit with probability $\Omega(1)$. This algorithm, with probability 1/2 accepts the first call (and stops); with probability 1/2 it runs algorithm $\mathcal{A}_p$ on σ.[4] Although $\mathcal{B}_p$ may have benefit only 1 with probability 1/2, it has the desirable property that it achieves an $O(\log D)$ fraction of the *optimal* solution with constant probability: if $OPT(\sigma) = O(\log D)$, then $\mathcal{B}_p$ will have an $O(\log D)$ fraction of the optimal benefit with probability 1/2 (if it takes the first call). If $OPT = \Omega(\log D)$, then with probability 1/2, $\mathcal{B}_p$ runs $\mathcal{A}_p$, which, for such sequences, achieves an $O(\log D)$ fraction of the optimum with constant probability by Corollary 2.3.

COROLLARY 2.4. *There exists an $O(\log D)$-competitive algorithm for call admission on trees of diameter D such that for any sequence of calls the benefit obtained is within some constant fraction of the expectation with constant probability.*

We now give another corollary, relative to a family of algorithms that obtain any fixed constant fraction of the expectation with probability that tends asymptotically to 1 (as $OPT(\sigma)$ and D grow) at the expense of a competitive ratio slightly higher than the optimum.

COROLLARY 2.5. *Algorithm $\mathcal{A}_p$, with $p = \Theta(\frac{1}{\log^{1+\epsilon} D})$, $\epsilon > 0$, is an $O(\log^{1+\epsilon} D)$-competitive randomized algorithm for on-line call admission on trees of diameter D.*

[2]The more natural algorithm that immediately rejects a candidate call if it intersects a previous *accepted* call, and otherwise accepts the candidate with probability p, performs at least as well. We leave the description as above for simplicity of the proof. To see that, note that for any given sequence of random choices, one for each candidate, any candidate accepted by $\mathbf{RS}_p$ is also accepted by the more natural algorithm. Since the call is accepted by $\mathbf{RS}_p$ its corresponding random choice is "positive," and it does not intersect any previous considered call (i.e., it does not intersect any previous candidate with a "positive" random choice). In the more natural algorithm this call cannot intersect any previously accepted call (as no previous candidate that intersects it had a "positive" random choice), and its own random choice is "positive." Hence it is accepted.

[3]To see that, note that $p = \Theta(1/(2\log 2D))$, and thus, for $OPT(\sigma) \geq \beta_k \log D$, and large enough β_k, the absolute value of the expression in the exponent of the first summand is at least a constant, and the second summand is bounded from above by a constant.

[4]A more natural algorithm would continue to run $\mathcal{A}_p$ after taking the first call in the first case. However, in the worst case its behavior is no better than the above algorithm.

For any constant $\delta \in (0,1]$, $Pr[\mathcal{A}_p(\sigma) < (1-\delta)E[\mathcal{A}_p(\sigma)]] < \exp(-\delta^2 \frac{OPT(\sigma)}{\Theta(\log^{1+3\epsilon} D)}) + \frac{1}{\Omega(\delta \log^{\epsilon} D)}$.

Proof of Theorem 2.2. We prove that the expected number of calls accepted by $\mathcal{A}_p$ on a sequence σ is at least $\mathcal{C}(\sigma) \cdot p(1 - p\lceil \log 2D \rceil)$, where $\mathcal{C}(\sigma)$ is the set of candidate calls picked from σ. By Theorem 2.1, $\mathcal{C}(\sigma) \geq OPT(\sigma)/6$, and the competitive ratio follows.

We number the *candidate* calls by the order that they arrive from 1 to $\ell = C(\sigma)$. If calls i and j intersect we denote this by $i \cap j$. Let c_i, $i \geq 1$, be an indicator random variable which is 1 if and only if the ith candidate is *considered*. Let $C = \sum_i c_i$. Let $y_{i,j}$, for $i < j$ and $i \cap j$, be an indicator random variable which is 1 if and only if both calls i and j are considered, and let $Y = \sum_{i<j, i \cap j} y_{i,j}$. Let r_j be an indicator random variable which is 1 if and only if there is an index $i < j$, $i \cap j$, such that $y_{i,j} = 1$. Let $R = \sum_j r_j$. Note that $R \leq Y$.

A candidate is accepted if it was considered, but none of its (previously presented) intersecting candidates was considered. Thus, if candidate j is considered but not accepted into the on-line solution, then there is a candidate $i < j$, $i \cap j$, that was considered. That is, $c_j = 1$, and $r_j = 1$. Therefore $\mathcal{A}_p(\sigma) = C - R \geq C - Y$, and we get $E[\mathcal{A}_p(\sigma)] \geq E[C] - E[Y]$.

Clearly $E[C] = \mathcal{C}(\sigma) \cdot p$ since each candidate is considered with probability p. For any pair $i < j$, $i \cap j$, $Pr[y_{i,j} = 1] = p^2$ since the event occurs if and only if call i and call j are considered. By Theorem 2.1 there are at most $\mathcal{C}(\sigma) \cdot \lceil \log 2D \rceil$ pairs $i < j$ such that $i \cap j$. Therefore $E[Y] \leq \mathcal{C}(\sigma)\lceil \log 2D \rceil \cdot p^2$. We get that $E[\mathcal{A}_p(\sigma)] \geq E[C] - E[Y] \geq \mathcal{C}(\sigma)(p - \lceil \log 2D \rceil \cdot p^2) = \mathcal{C}(\sigma) \cdot p(1 - p\lceil \log 2D \rceil)$.

We now turn to prove the second part of the claim. For $\delta \in (0,1]$, since $E[C] \geq \frac{E[Y]}{p\lceil \log 2D \rceil} \geq \frac{E[R]}{p\lceil \log 2D \rceil}$, we have

$$
\begin{aligned}
&Pr[\mathcal{A}_p(\sigma) < (1-\delta)E[\mathcal{A}_p(\sigma)]] \\
&= Pr[(C - R) < (1-\delta)E[C - R]] \\
&\leq Pr\left[C < E[C] - \frac{1}{2}\delta E[C - R]\right] \\
&\quad + Pr\left[R > E(R) + \frac{1}{2}\delta E[C - R]\right] \\
&\leq Pr\left[C < E[C] - \frac{1}{2}\delta(1 - p\lceil \log 2D \rceil)E[C]\right] \\
&\quad + Pr\left[R > E[R] + \frac{1}{2}\delta\left(\frac{1}{p\lceil \log 2D \rceil} - 1\right)E[R]\right] \\
&= Pr\left[C < \left(1 - \frac{1}{2}\delta(1 - p\lceil \log 2D \rceil)\right) \cdot E[C]\right] \\
&\quad + Pr\left[R > \left(1 + \frac{1}{2}\delta\left(\frac{1}{p\lceil \log 2D \rceil} - 1\right)\right) \cdot E[R]\right] .
\end{aligned}
$$

The variable $C = \sum_{j=1}^{l} c_j$ is the sum of $\ell = \mathcal{C}(\sigma)$ random variables $c_j \in \{0,1\}$, set by independent Bernoulli trials to 1 with equal probability p and to 0 with equal probability $1-p$. We use the following version of Chernoff's bound (cf. [19]) to bound the first summand: let $\mu = E[C] = p\mathcal{C}(\sigma)$ be the expected value of variable C; then

for every $\gamma \in (0,1]$,

$$Pr[C < (1-\gamma)\mu] < e^{(-\mu\gamma^2/2)}.$$

The variable R is the sum of dependent random variables, as for all pairs $i, j, i < j$, $y_{i,j}$ depends on the random choice for candidate i. We use the Markov inequality for the second summand.

Using $E[C] \geq \frac{OPT(\sigma)p}{6}$, we have

$$\begin{aligned}
&Pr[\mathcal{A}_p(\sigma) < (1-\delta)E[\mathcal{A}_p(\sigma)]] \\
&< \exp\left(-\frac{E[C]}{2}\left(\frac{1}{2}\delta(1-p\lceil\log 2D\rceil)\right)^2\right) \\
&\quad + \frac{1}{1+\frac{1}{2}\delta\left(\frac{1}{p\lceil\log 2D\rceil}-1\right)} \\
&= \exp\left(-\frac{\mathcal{C}(\sigma)p}{2}\left(\frac{1}{2}\delta(1-p\lceil\log 2D\rceil)\right)^2\right) + \frac{1}{1+\frac{1}{2}\delta\left(\frac{1}{p\lceil\log 2D\rceil}-1\right)} \\
&\leq \exp\left(-\frac{OPT(\sigma)p}{12}\left(\frac{1}{2}\delta(1-p\lceil\log 2D\rceil)\right)^2\right) \\
&\quad + \frac{1}{1+\frac{1}{2}\delta\left(\frac{1}{p\lceil\log 2D\rceil}-1\right)}\,. \qquad \square
\end{aligned}$$

2.2. The deterministic filter. When call (s,t) is presented to the algorithm, it is first passed through the deterministic filter, where it is discarded or becomes a candidate. We describe in the following a deterministic filter appropriately designed for trees.

First we designate an arbitrary internal vertex as the root of the tree and denote it by r. Without loss of generality we can restrict our attention to calls between two leaves of the tree. This is shown by constructing a new instance of the problem where all the calls are between leaf vertices of the tree, such that any solution to the new instance can be transformed back to a solution of the original instance, with the same size. The tree network of the new instance is obtained by adding to the original tree, for every internal vertex v and every edge e adjacent to v, a new leaf vertex v_e connected to v. For a call (s,t) of sequence σ, let e_s, e_t be the first and the last edges of the path connecting s to t. A new sequence σ' is obtained by transforming every call (s,t) into a call (s_{e_s}, t_{e_t}). It is easy to show that any subset of calls of σ can be accepted as a solution in the original tree if and only if the corresponding subset of calls of σ' can be accepted as a solution in the new tree. We note that this construction does not change the diameter of the tree.

We denote by $lca(s,t)$ the *least common ancestor* of vertices s and t in the tree rooted at r and by $p(u)$ the parent of vertex u in that tree. Path $path(s,t)$ is the *set* of edges in the path connecting s to t. Finally, $\mathcal{T}$ is the set of all edges of the tree.

Calls will be discarded on the basis of two tests. To perform the first test we block two edges when a call becomes a candidate: for any candidate (s',t') the two edges on $path(s',t')$ adjacent to $lca(s',t')$ are blocked. The edges are said to be *blocked edges.*

For the purpose of the second test we associate a weight function $w(e)$ to each edge of the tree. The value $w(e)$ is determined as follows:

1. Initially, assign $w(e) = 1$ for all edges $e \in \mathcal{T}$.

2. Double $w(e)$ whenever edge e is included in a $path(s', t')$ for a call (s', t') that becomes a candidate.

On the basis of the value of the weight function we give the following definition.

DEFINITION. *For two vertices u and v, $path(u, v)$ is a* segment *at a certain time in the run of the algorithm if at this time, for some nonempty subset of the current candidates, denoted by $\mathcal{C}'$, $path(u, v)$ is the maximal path contained in $\bigcap_{(s,t)\in\mathcal{C}'} path(s, t)$ such that no edge of the path is included in a candidate call not in $\mathcal{C}'$. We denote a segment, and its set of edges, by $seg(u, v)$.*

Note that for two vertices u and v, $path(u, v)$ may at times be a segment but later cease to be a segment. Further note that the edges of a segment may increase their weight over time, but when they form a segment they have equal weight. We thus sometimes refer to the weight of the segment being the weight of each of its edges. In what follows we will count the number of segments (of weight $w > 2$) ever created during the run of the algorithm. We identify a segment by its two endpoints. Thus, the first time that $path(u, v)$ becomes a segment, it is counted as one. If the weights of its edges increase, and it continues to be a segment, we do not count it again.

As an example, the set of segments defined by a set of candidate calls is shown in Figure 2.1.

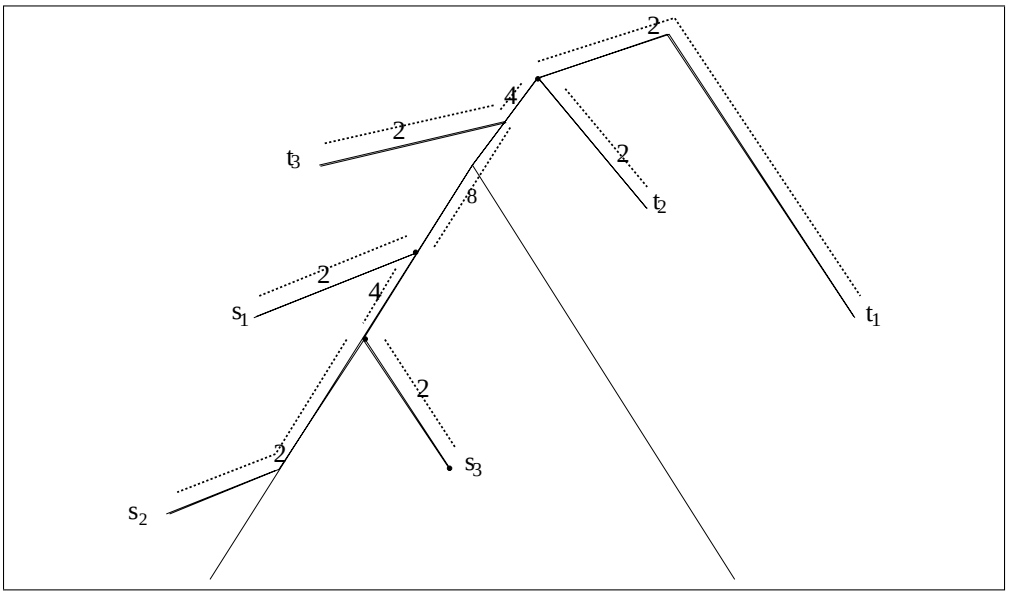

FIG. 2.1. *The segments created by the three candidate calls (s_1, t_1), (s_2, t_2), (s_3, t_3) are marked with dashed lines. The weight of each segment is indicated next to the dashed line.*

As mentioned above the filter is based on two tests:

Test 1. Discard call (s, t) if $path(s, t)$ contains a blocked edge.

If call (s, t) is not discarded by the first test, then it is submitted to the second test.

Test 2. Discard a call (s, t) if at the time the call is presented, there exists a segment $seg(u, v)$ of weight w such that $|path(lca(s, t), s) \cap seg(u, v)| \geq \frac{2D}{w}$ or $|path(lca(s, t), t) \cap seg(u, v)| \geq \frac{2D}{w}$.

A call that is not discarded by any of these test becomes a *candidate*.

DEFINITION. *For a sequence of calls σ, denote by $\mathcal{C}(\sigma)$ the set of candidates produced by the deterministic filter out of sequence σ. Denote by $\mathcal{C}_1(\sigma)$ those calls that are discarded by Test 1 and by $\mathcal{C}_2(\sigma)$ those calls that are discarded by Test 2. When the sequence σ is clear from the context, we sometimes use the notations $\mathcal{C}, \mathcal{C}_1, \mathcal{C}_2$. We also sometimes abuse notation and use $\mathcal{C}, \mathcal{C}_1, \mathcal{C}_2$ for the cardinality of the corresponding sets.*

We prove below that the number of candidates $\mathcal{C}(\sigma)$, i.e., those calls that are not discarded by any of the two tests, is at least $OPT(\sigma)/6$. In the following we will often say that edge e is included in a call (s,t) if $e \in path(s,t)$. We give some claims and lemmas as intermediate steps.

CLAIM 2.6. *A call (s,t) in $\mathcal{C} \cup \mathcal{C}_2$ intersects a previous candidate (s',t') only if (s',t') includes edge $(lca(s,t), p(lca(s,t)))$.*

Proof. If there is a previous candidate (s',t') that does not include edge $(lca(s,t), p(lca(s,t)))$ but intersects call (s,t), then $lca(s',t')$ is in the subtree rooted at $(lca(s,t))$. Then (s,t) intersects (s',t') in one of the two blocked edges of (s',t'), a contradiction to Test 1. □

CLAIM 2.7. *If the edges of a segment $seg(u,v)$ have weight $w > 2$, then either u is an ancestor of v or v is an ancestor of u.*

Proof. If $w > 2$, then the edges of the segment are included in more than one candidate call. Let (s,t) be the first such candidate call. If neither u is an ancestor of v nor v is an ancestor of u, then $lca(s,t)$ is internal to $seg(u,v)$. Two edges of $seg(u,v)$ would have been blocked when (s,t) became a candidate. The two blocked edges would also be part of any later call (s',t') that contains $seg(u,v)$, and (s',t') would not become a candidate, a contradiction. □

LEMMA 2.8. *Let (s,t) be a call in $\mathcal{C} \cup \mathcal{C}_2$ (i.e., a call that passes Test 1). Consider the intersection of $path(lca(s,t),s)$ (resp., $path(lca(s,t),t)$) with the set of calls that are candidate calls prior to the presentation of (s,t) and assume that this intersection is not empty. Then, there exists a sequence of nodes $v_0, \ldots, v_\ell$, $\ell \geq 1$, such that the following hold:*

1. *$v_0 = lca(s,t)$; v_ℓ is either equal to s (resp., t) or on $path(lca(s,t),s)$ (resp., $path(lca(s,t),t)$); and the intersection of $path(lca(s,t),s)$ (resp., $path(lca(s,t),t)$) with the set of previous candidate calls is $path(v_0, v_\ell)$.*
2. *For $0 \leq i \leq \ell - 1$, all edges between v_i and v_{i+1} have the same weight, which we denote W_i.*
3. *For $0 < i \leq \ell - 1$, $W_i < W_{i-1}$.*
4. *For $0 \leq i \leq \ell - 1$, there is a set of candidates $\mathcal{C}_i$ such that for any edge e in $path(v_i, v_{i+1})$, the set of calls that use e is exactly $\mathcal{C}_i$.*
5. *For $0 < i < \ell - 1$, $path(v_i, v_{i+1})$ is a segment.*

Proof. We prove the claim for the path from $lca(s,t)$ to s. An analogous proof holds for the path from $lca(s,t)$ to t.

Consider the time when call (s,t) is presented before it becomes a candidate. First consider an edge e on $path(lca(s,t),s)$. If there is a previous candidate call that uses this edge, then this candidate call also uses edge $(lca(s,t), p(lca(s,t))$ by Claim 2.6. It follows that for any edge e on $path(lca(s,t),s)$, if edge e is used by a previous candidate, then all edges between e and $lca(s,t)$ are used by this candidate. Let e be the edge on $path(lca(s,t),s)$ which is furthest away from $lca(s,t)$ and is included in a previous candidate call. Let the node adjacent to e and further away from $lca(s,t)$ be node v_ℓ, and let v_0 be $lca(s,t)$. This proves point 1.

Since for any edge e, any previous candidate that uses edge e also uses all edges

between edge e and $lca(s,t)$ (by Claim 2.6), it follows that going from $lca(s,t)$ to s, the weight of the edges is nonincreasing. If there is a decrease in the weight of the edges, we assign the point of decrease as one of the nodes v_i. We thus get a sequence of nodes v_i that satisfy points 2 and 3.

For $0 \leq i \leq \ell - 1$, now consider $path(v_i, v_{i+1})$. We claim that there is a set of candidates $\mathcal{C}_i$ such that all edges on $path(v_i, v_{i+1})$ are used by exactly the calls in $\mathcal{C}_i$. Consider two edges e and e' on this path, where e' is further away from $lca(s,t)$ than e. Any candidate that uses e' also uses e, following Claim 2.6. On the other hand, if there were a candidate that uses e, but not e', then the weights of e and e' would have been different. We thus establish point 4.

We further claim that for $0 < i < \ell - 1$, $path(v_i, v_{i+1})$ is the maximal path of edges that are used by exactly the calls in $\mathcal{C}_i$. For edges on $path(lca(s,t), s)$, any edge which is not on $path(v_i, v_{i+1})$ has weight not equal to W_i and thus cannot be used by exactly the calls in $\mathcal{C}_i$. Furthermore, observe that there is at least one call in $\mathcal{C}_i$ that uses also the edge leading from v_{i+1} towards s and must also reach $lca(s,t)$ (by Claim 2.6). Thus no edge outside of $path(lca(s,t), s)$ can possibly be used by the calls in $\mathcal{C}_i$. It follows from the definition of a segment that $path(v_i, v_{i+1})$ is a segment satisfying point 5. □

The number of calls that are discarded by Test 2, while accepted in the optimal solution, will be proved to be related to the number of segments of weight bigger than 2 ever created. We prove the following upper bound on the number of such segments.

LEMMA 2.9. *Consider a run of the algorithm on a sequence of calls σ. The number of segments ever created, and which at some point in time have weight bigger than 2, is at most $4\mathcal{C}(\sigma)$.*

Proof. Note that when a call is presented but does not become a candidate, there is no change in the segments in the tree. Therefore, we consider events when a new call becomes a candidate. To prove the lemma we give an upper bound on the number of segments that at such event either are created with weight bigger than 2 or reach a weight bigger than 2 (without changing their endpoints). We show that the number of such segments is at most 4 per such event.

Let (s,t) be a call that becomes a candidate. If it does not intersect any previous candidate, then no new segments of weight bigger than 2 are created. We therefore assume that call (s,t) intersects at least one previous candidate. We distinguish between two cases. The first one is when all the intersections of (s,t) with previous candidates are either on $path(lca(s,t), s)$ or on $path(lca(s,t), t)$. The second case is when there are such intersections on both $path(lca(s,t), s)$ and $path(lca(s,t), t)$.

We now consider the first case (without loss of generality assume that all intersections are on $path(lca(s,t), s)$). We use the sequence of nodes v_i, $0 \leq i \leq \ell$, guaranteed by Lemma 2.8. A new segment of weight bigger than 2 can be created either by the augmentation of the weight of edges of weight 2, or by the augmentation of the weight of edges of weight already bigger than 2, but while creating new endpoints for the segments (this may create more than one new segment).

If prior to (s,t) becoming a candidate there is a segment of weight bigger than 2 that includes $(lca(s,t), p(lca(s,t))$ and the edge e that leads from $lca(s,t)$ towards s, then two new segments of weight bigger than 2 are created with a new endpoint at $lca(s,t)$. One of these two segments is $path(v_0, v_1)$. See Figure 2.2.

Further distinguish the case where v_ℓ is inside a segment from the case where v_ℓ is not inside a segment.

If v_ℓ is inside a segment (see Figure 2.3), two new segments are created, both

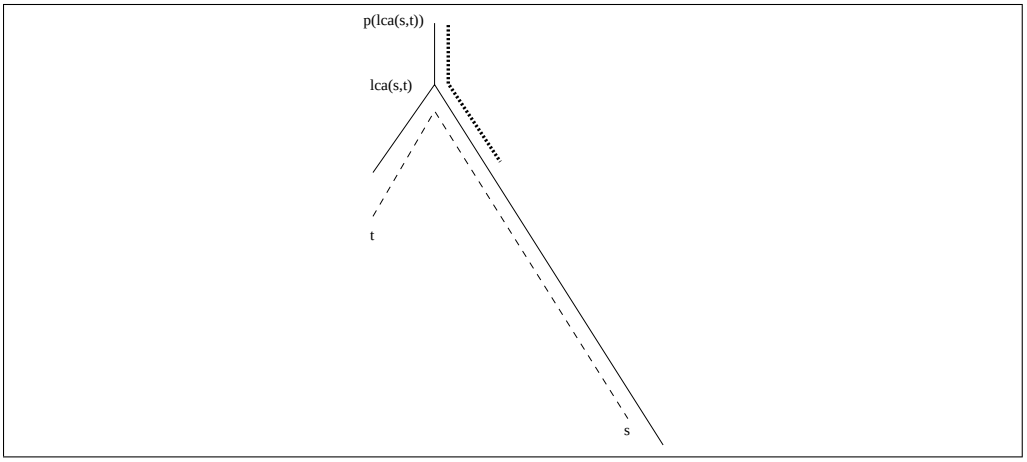

FIG. 2.2. *Two new segments are created with endpoint* $lca(s,t)$.

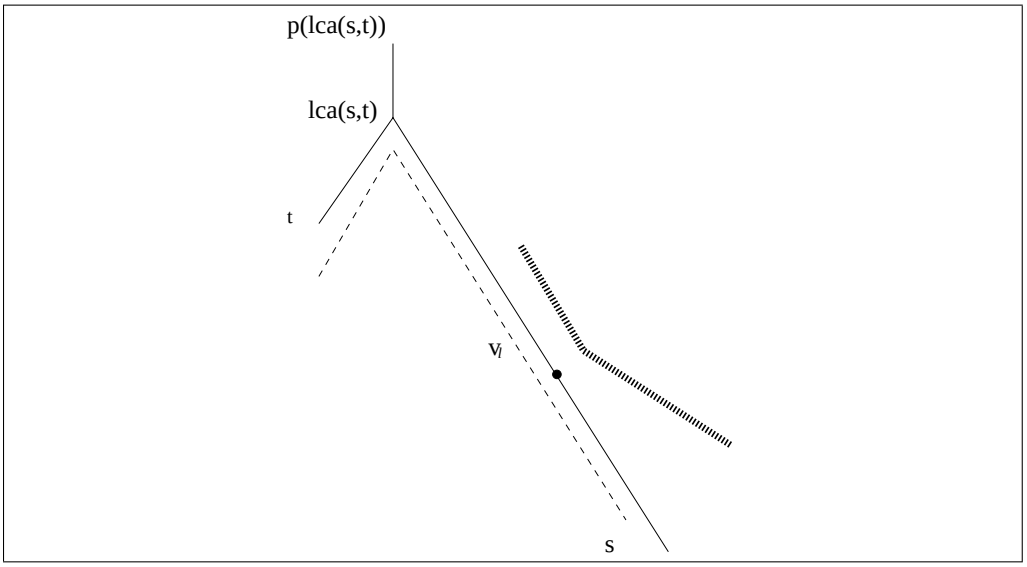

FIG. 2.3. *Vertex* v_ℓ *is inside a segment.*

with an endpoint at v_ℓ. If the weight of the segment was already bigger than 2, then two new segments of weight bigger than 2 are created. In this case all the segments $seg(v_{j-1}, v_j)$, $1 < j < \ell$, are already of weight bigger than 2; their weight will increase, but since their endpoints do not change there are no new segments here. If the weight of the segment was 2, then only one segment of weight bigger than 2 is created (while the other one is a segment of weight 2 with new endpoints). Whatever the weight of this segment was, all the segments $seg(v_{j-1}, v_j)$, $1 < j < \ell$, have weight bigger than 2 (by Lemma 2.8); their weight will increase, but since their endpoints do not change no new segments of weight bigger than 2 are created here. Altogether we get at most four new segments of weight bigger than 2.

For the case where v_ℓ is not inside a segment (see Figure 2.4), observe that the weights of the edges on $path(v_{\ell-1}, v_\ell)$ are doubled, thus possibly creating one new

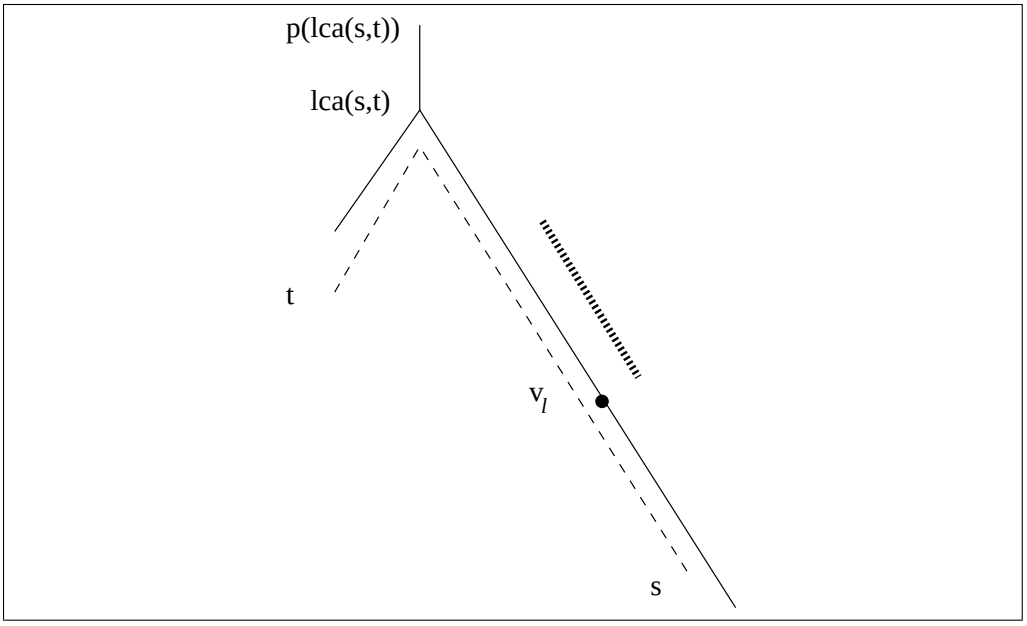

FIG. 2.4. *Vertex v_ℓ is not inside a segment.*

segment of weight bigger than 2 (which is $seg(v_{\ell-1}, v_\ell)$), if the weight of this segment was not bigger than 2 beforehand. Altogether we get for this case at most three new segments of weight bigger than 2.

We note that a new segment of weight 2 may be created as $seg(v_\ell, s)$ if $v_\ell \neq s$.

Now consider the second case where (s,t) intersects previous candidates on both $path(lca(s,t), s)$ and $path(lca(s,t), t)$. Consider the two edges e_1, and e_2, adjacent to $lca(s,t)$ and leading to s and t, respectively. Since by Claim 2.6 any previous candidate call that intersects (s,t) also uses the edge between $lca(s,t)$ and $p(lca(s,t))$, it follows that there are two candidate calls p_1 and p_2 such that p_1 uses e_1 and $(lca(s,t), p(lca(s,t))$, and p_2 uses e_2 and $(lca(s,t), p(lca(s,t))$. It follows that prior to (s,t) becoming a candidate, $(lca(s,t), p(lca(s,t))$ and e_1 (resp., e_2) cannot be in the same segment. We now use the sequence of nodes v_i guaranteed by Lemma 2.8 for each of $path(lca(s,t), s)$ and $path(lca(s,t), t)$. From the above argument it follows that the two paths $path(v_0, v_1)$ (on the two paths $path(lca(s,t), s)$ and $path(lca(s,t), t)$) are segments. No new segment will be created with a low endpoint at $lca(s,t)$ when (s,t) becomes a candidate. We therefore now consider separately $path(lca(s,t), s)$ and $path(lca(s,t), t)$. We consider in what follows $path(lca(s,t), s)$. Analogous arguments hold for $path(lca(s,t), t)$.

As argued above, prior to (s,t) becoming a candidate, $path(v_0, v_1)$ is a segment, $seg(v_0, v_1)$. When (s,t) becomes a candidate, the weight of this segment doubles.

If prior to (s,t) becoming a candidate the weight of $seg(v_0, v_1)$ was already bigger than 2, then there is no new segment at the top of $path(lca(s,t), s)$. Using the same arguments as in the case where all intersections are on $path(lca(s,t), s)$ (and not also on $path(lca(s,t), t)$) it follows that there are at most 1 or at most 2 new segments of weight bigger than 2 on $path(lca(s,t), s)$, depending on whether or not v_ℓ equals s.

If prior to (s,t) becoming a candidate the weight of $seg(v_0, v_1)$ was 2, then when the (s,t) becomes a candidate this segment becomes a new segment with weight bigger

than 2. However, it also follows that v_1 must equal v_ℓ, as there is only one previous candidate on $path(lca(s,t),s)$. No additional new segment of weight bigger than 2 will be created on $path(lca(s,t),s)$. (Note that a new segment of weight 2 may be created if $v_\ell \neq s$.)

We can conclude that on any of $path(lca(s,t),s)$ and $path(lca(s,t),t)$ at most two new segments of weight bigger than 2 can be created. Altogether at most four new segments of weight bigger than 2 are created when (s,t) becomes a candidate. □

We now prove that the number of calls not discarded (i.e., the number of calls that become candidates) is a good fraction of size of the optimal solution.

LEMMA 2.10. *For any sequence of calls σ, the number of candidate calls $\mathcal{C}(\sigma)$ has the property that $\mathcal{C}(\sigma) \geq \frac{OPT(\sigma)}{6}$.*

Proof. Since $\sigma = \mathcal{C} \cup \mathcal{C}_1 \cup \mathcal{C}_2$, we prove that the optimal solution accepts at most $2\mathcal{C}$ calls from $\mathcal{C} \cup \mathcal{C}_1$ and at most $4\mathcal{C}$ calls from $\mathcal{C}_2$.

First consider the calls from $\mathcal{C} \cup \mathcal{C}_1$ accepted in the optimal solution. Any call of $\mathcal{C} \cup \mathcal{C}_1$ includes at least one blocked edge. Since there are at most $2\mathcal{C}$ blocked edges in the tree, any solution can accept at most $2\mathcal{C}$ calls from $\mathcal{C} \cup \mathcal{C}_1$.

We now consider the calls from $\mathcal{C}_2$ accepted in the optimal solution. Consider a call $(s,t) \in \mathcal{C}_2$. It includes, when presented, at least $\frac{2D}{w}$ edges of some segment $seg(u',v')$ of weight $w > 2$ either on $path(lca(s,t),s)$ or on $path(lca(s,t),t)$. (Observe that no call is discarded because of a segment of weight 2 since $path(lca(s,t),s)$ and $path(lca(s,t),t))$ are of size at most $D-1$.) For the sake of analysis, we assign call (s,t) to a single such segment, $seg(u',v')$.

We now show that the length of $seg(u',v')$ is less than $\frac{4D}{w}$. By definition, the edges of segment $seg(u',v')$ are included in the intersection of a set $\mathcal{C}'$ of candidate calls. Let (s',t') be the call of $\mathcal{C}'$ presented last, and let $\mathcal{C}'' = \mathcal{C}' \setminus \{(s',t')\}$. Set $\mathcal{C}''$ defines a segment $seg(u'',v'')$ at the time call (s',t') is presented, and this segment includes segment $seg(u',v')$. To see that, observe that $path(u',v')$ is included in the intersection of the calls in $\mathcal{C}''$ and that at the above time no other candidate includes any edge of $path(u',v')$. We know that the weight of this segment at the time call (s',t') is presented is $\frac{w}{2}$ (since when (s',t') becomes a candidate it doubles the weights to w). Since call (s',t') becomes a candidate it passes Test 2, and we can conclude that its intersection with $seg(u'',v'')$, on either $path(lca(s',t'),s')$ or $path(lca(s',t'),t')$, is of length less than $\frac{4D}{w}$. However, by Claim 2.7, either u' is an ancestor of v' or vice versa, as $w > 2$, and $path(u',v')$ is included in call (s',t'), as $seg(u',v')$ is defined by $\mathcal{C}'$. Therefore all of $path(u',v')$ is included in this intersection. If follows that the length of segment $seg(u',v')$ is less than $\frac{4D}{w}$.

It now follows that if we consider the calls of the optimal solution, at most one call can be assigned to each segment of weight bigger than 2 in the way we described. This is because any assigned call uses more than half the edges of the segment it is assigned to, and thus any two would intersect. By Lemma 2.9, at most $4\mathcal{C}$ segments of weight bigger than 2 are ever created while the algorithm processes the sequence. We conclude that at most $4\mathcal{C}$ calls of $\mathcal{C}_2$ can be in the optimal solution. □

LEMMA 2.11. *Every candidate call intersects at most $\lceil \log 2D \rceil$ previous candidates.*

Proof. By Claim 2.6, for any candidate (s,t), all the previous intersecting candidates include edge $(lca(s,t), p(lca(s,t)))$. Their number is at most $\lceil \log 2D \rceil$, since once an edge is included in $\lceil \log 2D \rceil$ candidates, it has weight of at least $2D$. No call can become a candidate if it includes an edge of weight $2D$, as it will fail Test 2. □

Proof of Theorem 2.1. The first part of the theorem is proved in Lemma 2.10. For the second part, by Lemma 2.11 every candidate call of $\mathcal{C}(\sigma)$ intersects at most $\lceil \log 2D \rceil$ previous candidates. The number of intersecting pairs is thus at most $\mathcal{C}(\sigma) \cdot \lceil \log 2D \rceil$. □

2.3. An alternative deterministic filter. In this section we describe an alternative design of the deterministic filter at the cost of having a somewhat worse performance. This filter uses the AAP (deterministic) call control algorithm [2], originally designed for general networks of high capacity. The test runs the AAP algorithm on the tree, assuming link capacities of $\log 4D$. A call that is accepted by the AAP algorithm becomes a candidate, while a call that is rejected by AAP is also rejected by the filter. This filter relies on the following property: if the capacity is increased in that way, then the set of calls accepted by AAP is a constant fraction of the optimal set accepted by an adversary that has only capacity 1. (A similar result is also derived in [18] if the capacity is increased by a factor of $\Omega(\log n)$.) On the other hand, since the capacity of each link is bounded, the number of intersections between the candidate calls is small.

In Appendix A we give for completeness the AAP algorithm for this specific setting and prove the following claim.

THEOREM 2.12. *If for every $e \in E$ the AAP algorithm has capacity $u(e) = \log 4D$ while the adversary has capacity $u(e) = 1$, then the AAP algorithm has competitive ratio* 5.

Based on the above theorem we can now give the properties of the filter.

LEMMA 2.13. *The above filter based on the AAP algorithm, applied to trees of diameter D, achieves the following for any sequence σ:* (1) $\mathcal{C}(\sigma) \geq OPT(\sigma)/5$; (2) *The number of pairs of calls in $\mathcal{C}(\sigma)$ that intersect is at most $\mathcal{C}(\sigma) \cdot 2\lceil \log 2D \rceil$.*

Proof. The first part of the claim follows from Theorem 2.12. For the second part of the claim we consider an intersection graph of paths on a tree.[5] Our claim follows from the fact that if each edge in the tree is included in at most g of these paths, then the intersection graph is a $(2(g-1))$-inductive graph (see [6]).[6] Since the capacity used by the AAP algorithm is $\log 4D$, any edge is used by at most $\log 4D$ calls. Therefore the intersection graph of the candidate calls is a $2(\log 4D - 1)$-inductive graph, which implies that the total number of edges in this graph is at most $\mathcal{C}(\sigma) \cdot 2(\log 4D - 1) = \mathcal{C}(\sigma) \cdot 2 \log 2D$. This is a bound on the number of pairs of candidates that intersect. □

The randomized selection procedure used in conjunction with this filter is the same as for our first filter. The results stated in Theorem 2.2 are proved in a similar way with necessary modifications in the constants.

3. A bound on the probability to achieve a "good" solution. We have presented $O(\log D)$-competitive algorithms for call admission on trees that for any sequence σ, with $OPT(\sigma) = \Omega(\log D)$, achieve any constant fraction of the expected benefit with at least constant probability. The probability tends to some constant as $OPT(\sigma)$ tends to infinity. The obvious question is then if the rate of convergence and the limit probability can be improved for $O(\log D)$-competitive algorithms and in particular if the limit can be 1.

[5] The intersection graph has a node for each one of the paths. There is an edge between two nodes in the intersection graph if and only if the corresponding two paths intersect.

[6] A d-inductive graph is a graph $G = (V, E)$ for which there is an ordering of the vertices such that for any i, $|\{j : i < j, (i, j) \in E\}| \leq d$.

In this section we give a partial answer to this question. We show that for any algorithm with an $O(\log D)$-competitive ratio, there is a sequence σ with $OPT(\sigma) = \Theta(D^{1-c})$, for any $0 < c < 1/2$, for which with probability $\Omega(c)$, the on-line benefit is $o(OPT(\sigma)/\log D)$ (in fact the on-line benefit is only a $n^{-\epsilon}$ fraction of the expectation for some constant $\epsilon > 0$).

We give our lower bound on a line network of $n+1$ vertices, with $n = 2^s$, for some s. Observe that on such a line network we have $D = n$. Given a randomized $k \log n$-competitive algorithm for the line, we present a sequence of requests formed by $l = \lfloor \alpha \cdot \log n \rfloor + 1$ ($\alpha < 1/2$) phases, plus a final extra phase. At phase i, $0 \le i \le l$, 2^i pairwise disjoint calls of size $\frac{n}{2^i}$ are presented. These are calls $((j-1)\frac{n}{2^i}+1, j\frac{n}{2^i}+1)$, $1 \le j \le 2^i$. Thus, during phase l, 2^l calls of size $n/2^l$ are presented. We will prove that for any $k \log n$-competitive algorithm, at least one of these calls has the property that with probability at least $\frac{\alpha}{4k}$ all its edges are occupied by the time phase l ends. Then, we present $n/2^l$ disjoint calls of length 1 on these edges. The optimal solution is of size $n/2^l \ge n/2^{\alpha \log n} = n^{1-\alpha}$, while with probability at least $\frac{\alpha}{4k}$ the on-line algorithm can achieve a benefit of at most $2^l \le 2^{\alpha \log n} = n^\alpha$. We get that the algorithm cannot be close (by any constant fraction) to its expectation with probability $1 - o(1)$ (as a function of D), even when the size of the optimal solution is $\Omega(n^{1-c})$.

We now turn to prove our claim. Let p_m^i be the absolute probability that the mth call of phase i is accepted. We denote by P_m^l the sum of the absolute probabilities of acceptance of all the calls that include call m of level l, plus the probability that this call itself is accepted. We will show that for any $k \log n$-competitive randomized algorithm, $\sum_{m=1}^{2^l} P_m^l \ge 2^l \cdot \frac{\alpha}{4k}$. Therefore, there is at least one call m' such that $P_{m'}^l \ge \frac{\alpha}{4k}$, from which our claim follows.

We have

$$\begin{aligned}
\sum_{m=1}^{2^l} P_m^l &= \sum_{i=0}^{l} 2^{l-i} \left(\sum_{m=1}^{2^i} p_m^i \right) \\
&\ge \sum_{i=0}^{l} 2^l \frac{1}{2} \sum_{j=i}^{l} 2^{-j} \left(\sum_{m=1}^{2^i} p_m^i \right) \\
&= 2^{l-1} \sum_{j=0}^{l} 2^{-j} \sum_{i=0}^{j} \left(\sum_{m=1}^{2^i} p_m^i \right).
\end{aligned}$$

The first equation follows since the absolute probability p_m^i of accepting call m of phase i is summed up for the 2^{l-i} included calls of level l. Now, observe that $\sum_{i=0}^{j}(\sum_{m=1}^{2^i} p_m^i)$ is the algorithm's expected benefit after the calls of phase j have been presented.

We continue with $2^{-j}\sum_{i=0}^{j}(\sum_{m=1}^{2^i} p_m^i) \ge \frac{1}{k \log n}$, since the algorithm is $k \log n$-competitive, and the optimal solution can accept 2^j calls after phase j. We get

$$\sum_{m=1}^{2^l} P_m^l \ge 2^{l-1} \frac{l+1}{k \log n} > 2^l \cdot \frac{\alpha}{4k}$$

(for large enough n), which proves our claim. We can conclude the following theorem.

THEOREM 3.1. *For any $k \log n$-competitive algorithm for call admission on the line of n nodes, and any constant probability p ($p < \frac{1}{8k}$), there is a sequence σ with*

$OPT(\sigma) = n^{1-O(p)}$ *such that with probability at least* p*, the algorithm* does not *achieve any constant fraction of the expected benefit.*

4. Further extensions for trees. In this section we show that a better competitive ratio can be obtained at the expense of a larger deviation. We obtain a competitive ratio of $6\lceil \log 4D \rceil$ which improves upon the previously known bound of $48 \log 2D$ [4]. We also consider extensions of our algorithms to trees with edges of any uniform capacity and point out that *any* algorithm for call admission on trees can be converted to apply to uniform-capacity trees with almost the same competitive ratio.

First, we give an algorithm with a competitive ratio of $6\lceil \log 4D \rceil$. This is done at the expense of a larger deviation from the expectation. To obtain the improved competitive ratio we use our general framework, with the first version of the deterministic filter (section 2.2), but a different randomized selection procedure. We now use a variation of the "classify and randomly select" technique [3]: we use a set of $\lceil \log 4D \rceil$ colors and define an arbitrary order on them. We first choose uniformly at random one color among these colors, and we denote it A. When a new candidate call is presented to the randomized selection procedure, we assign to it the first color (according to the defined order) that was not assigned to any of the previous candidates that intersect the present one (i.e., we color the candidate calls with a proper coloring in their intersection graph). By Lemma 2.11, $\lceil \log 4D \rceil$ colors are sufficient, since each candidate intersects at most $\lceil \log 2D \rceil$ previous candidates. The algorithm will now accept those candidates that are assigned the color A. Since the above coloring procedure classifies the candidate calls into $\lceil \log 4D \rceil$ disjoint classes, each class fully acceptable, we obtain the following theorem.

THEOREM 4.1. *There exists a* $6\lceil \log 4D \rceil$*-competitive randomized algorithm for call admission on trees of diameter* D*.*

Proof. We partition $\mathcal{C}$ into a set of $\lceil \log 4D \rceil$ disjoint classes. Class $\mathcal{C}_i$, $i = 1, \ldots, \lceil \log 4D \rceil$, contains all the candidates which are assigned color i. All the candidates of a class can be accepted together in a solution since they are nonintersecting. The algorithm accepts a set of calls $\mathcal{A}$ that corresponds to the randomly selected class. The expected size of the on-line solution is $E(\mathcal{A}) \geq \frac{1}{\lceil \log 4D \rceil} \sum_{i=1} \mathcal{C}_i = \frac{1}{\lceil \log 4D \rceil} \mathcal{C} \geq \frac{OPT}{6\lceil \log 4D \rceil}$, since, by Lemma 2.10, $\mathcal{C} \geq \frac{OPT}{6}$. □

We also point out that our algorithms also apply to trees with any uniform capacity. In fact, *any* c-competitive algorithm for call admission on trees of capacity 1 can be converted into a $2\frac{e^{1/c}}{e^{1/c}-1} \leq (2(c+1))$-competitive algorithm for call admission on trees with arbitrary uniform capacity. Given any c-competitive algorithm for the capacity-1 case, we run a "first fit"-based technique [1] that uses k copies of the original algorithm on k copies of the tree but each with capacity 1. If the call is accepted by any of the algorithms we accept it into the actual k-capacity tree. Using [1, 9] we get for this case that we have a $\frac{e^{1/c}}{e^{1/c}-1}$ -competitive algorithm with respect to an adversary that uses k distinct, capacity-1 trees. Since this adversary is only a $1/2$ fraction away from the original adversary that has a single tree of uniform capacity k (cf. [4]), we obtain a $2\frac{e^{1/c}}{e^{1/c}-1} \leq (2(c+1))$-competitive algorithm for the problem.

5. Routing on meshes with high probability. In this section we propose a randomized algorithm for the on-line maximum edge-disjoint paths problem on meshes that has a logarithmic competitive ratio. The algorithm achieves the best possible competitive ratio up to a constant multiplicative factor *and* a benefit close to the expectation with high probability on any sequence of a large class of input instances.

Kleinberg and Tardos [16] presented the first $O(\log n)$-competitive algorithm (denoted KT in the following) for the on-line maximum edge-disjoint paths problem on meshes. They partition the input sequence into two classes: *short calls* and *long calls*. Define the distance between two vertices of the mesh as the number of edges on a shortest path connecting the two vertices. According to the partitioning of KT, every call with endpoints at distance bigger than a given value $d = \Theta(\log n)$ is a long call. KT decides with equal probability to accept only long calls or only short calls. KT has thus the drawback of obtaining benefit 0 with probability at least 1/2 on any input sequence containing only calls with endpoints at distance bigger than d (or only calls with endpoints at distance at most d).

We propose an algorithm with a logarithmic competitive ratio that achieves a constant fraction of its expected benefit with probability tending to 1 as the size of the optimal solution grows. Our algorithm for meshes is composed of a randomized stage followed by a deterministic stage. The first stage of the algorithm is a *randomized filter* that selects a subset $\mathcal{C}$ of *candidate calls* out of the input sequence σ. Calls of $\sigma \setminus \mathcal{C}$ are discarded to make space for the routing of candidate calls. The calls in $\mathcal{C}$ form a new input sequence for the second stage of the algorithm, which is a completely deterministic procedure. The subset of $\mathcal{C}$ accepted by the second stage is the set of calls finally accepted by the algorithm. Our algorithm uses a routing strategy different from that of KT. Some of its ideas are borrowed from the algorithm of Bartal and Leonardi [6] for on-line path coloring on meshes [6] .

Let us denote by $ON(\mathcal{T})$ and $OPT(\mathcal{T})$ the subsets, of some sequence $\mathcal{T}$, that are accepted (out of $\mathcal{T}$) by our on-line algorithm and by the optimal solution, respectively, and their cardinalities.

We prove (see Lemma 5.2) that $E(OPT(\mathcal{C}))$ is at least a constant fraction of $OPT(\sigma)$ and that $OPT(\mathcal{C})$ is within a constant fraction of $E(OPT(\mathcal{C}))$ with probability tending to 1 as the optimal solution grows. We present the deterministic procedure in section 5.2. We denote by $ON_D(\mathcal{T})$ the set of calls accepted by the deterministic procedure, out of some sequence $\mathcal{T}$, and its cardinality. We prove (see Lemma 5.8) that for any sequence of candidates $\mathcal{C}$, $OPT(\mathcal{C}) = O(\log n)ON_D(\mathcal{C})$. Combining the two statements (for the randomized filter and for the deterministic procedure), we conclude with the following theorem.

THEOREM 5.1. *There exists an $O(\log n)$-competitive algorithm for call control on the $n \times n$ mesh such that for any $\delta \in (0, 1]$ and any sequence σ, $Pr[ON(\sigma) \geq (1-\delta)E(ON(\sigma))] \geq 1 - 2\exp(-\frac{\delta^2 OPT(\sigma)}{O(\log^4 n)})$.*

Our algorithm thus has asymptotically optimal $O(\log n)$-competitive ratio and it is close to the expectation with probability tending to 1 as $\frac{OPT(\sigma)}{\log^4 n}$ tends to infinity.

5.1. The randomized filter. The $n \times n$ two dimensional mesh G is partitioned into a set of disjoint squares. Let $B = \lfloor \log n \rfloor$. We assume n large enough such that $B \geq 16$. Let $L = \lfloor \gamma \log n \rfloor$ for $\gamma = 13$. Let $s = \lfloor \frac{n}{L} \rfloor$, and let $s_1 = n \bmod L = n - s \cdot L$. We partition the mesh into $s \times s$ submeshes of logarithmic size. The partition of the mesh is obtained by segmenting each of its sides into $s - s_1$ contiguous segments of size L and then s_1 segments of size $L+1$. Note that with the above assumption on B this segmentation is always attainable, and that s_1 can be 0, in which case each side is segmented into s segments of size L. Every submesh is called a *square*, even if the size of its two sides differs by 1.

The first *ring* in a square S consists of all nodes of S that either are incident to a node outside of S or are on the border of the mesh. Recursively, the *ith ring* of S

for $i > 1$ consists of all nodes of S that are incident to a node of ring $i-1$ of S. Each ring, except the innermost, forms a rectangle of nodes. The first ring of a square is also called the *border* of the square. Denote by S_v the square containing vertex v.

In any square S we define three *regions* S^1, S^2, and S^3. Region S^1 consists of rings 1 to $2B$, region S^2 consists of rings $2B+1$ to $4B$, and region S^3 is formed by rings $4B+1$ to $6B$. The remaining part of S is called the *central region* of S (see Figure 5.1). The central region is a rectangle with sides of size at least B.

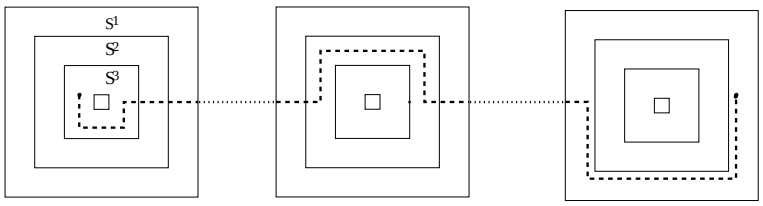

FIG. 5.1. *The routing of a long call.*

The randomized filter makes the following random choice before starting the processing of the sequence.

For every square S choose one of the regions S^1, S^2, S^3 with equal probability.

The region that has been chosen for square S is called the *selected region* of S.

Every call $(s,t) \in \sigma$, when presented, is submitted to the following test:

Add call (s,t) to $\mathcal{C}$ if s is not in the selected region of S_s *and* t is not in the selected region of S_t, otherwise discard (s,t).

As a result of this filtering procedure, no call (s,t) of $\mathcal{C}$ has an endpoint in the selected region of a square. The selected region will be used later to route calls through the square without blocking calls with endpoints inside the square.

LEMMA 5.2. *For any input sequence σ, $E(OPT(\mathcal{C})) \geq \frac{1}{3}OPT(\sigma)$. For any constant $\delta \in (0,1]$, for any sequence σ, $Pr[OPT(\mathcal{C}) \geq (1-\delta)E(OPT(\mathcal{C}))] \geq 1 - 2\exp(-\frac{OPT(\sigma)\delta^2}{82(\lfloor \gamma \log n \rfloor)^4})$.*

Proof. For the first part of the lemma we prove that every call (s,t) of $OPT(\sigma)$ is part of set $\mathcal{C}$ with probability at least $1/3$. A call (s,t) becomes a candidate if both s and t are not in the selected region of S_s and S_t. We distinguish between (i) calls with both endpoints in the same square and (ii) calls with endpoints in different squares.

(i) $S_s = S_t$. If s and t are in the same region of S_s, then this region is not selected with probability $2/3$. If s and t are in different regions, the probability that the region not containing s and t is selected is $1/3$. The claim then follows.

(ii) $S_s \neq S_t$. Vertex s (resp., t) is outside the selected region of S_s (resp., S_t) with probability $2/3$. The probability that both s and t are outside a selected region is then at least $4/9$. The first part of the claim is thus proved.

For the second part of the claim we use the "independent bounded differences inequality" in the formulation proposed by Maurey.

LEMMA 5.3 (see [10]). *Let $X_1, \ldots, X_m$ be independent random variables with X_k taking values in a set A_k for each k. Suppose that the (measurable) function $f : \prod_{k=1}^m A_k \to \Re$ satisfies $|f(\underline{x}) - f(\underline{x}')| \leq c_k$, whenever the vectors $\underline{x}$ and $\underline{x}'$ differ only in the kth coordinate, for some constant c_k. Let Y be the random variable $f(X_1, \ldots, X_m)$. Then, for any $t > 0$,*

$$Pr[|Y - E(Y)| \geq t] \leq 2\exp\left(\frac{-2t^2}{\sum_k c_k^2}\right).$$

In our problem we consider $m = s^2 = (\lfloor \frac{n}{L} \rfloor)^2$ independent random variables $X_1, \ldots, X_m$ to indicate the selected region for every square. Every random variable assumes one of three values with equal probability. For the function $f(\underline{x})$, we will use the function $|OPT(\sigma) \cap \mathcal{C}(\underline{x})|$, where $\underline{x}$ ranges over all the possible assignments of $\underline{x} = (X_1, \ldots, X_m)$. Note that $|OPT(\mathcal{C}(\underline{x}))| \geq |OPT(\sigma) \cap \mathcal{C}(\underline{x})|$. A different assignment of variable X_k results in a maximum absolute variation c_k for $f(\underline{x})$, where c_k is equal to the number of calls of $OPT(\sigma)$ with an endpoint in the kth square. For a square that does not contain any endpoint of a call of the optimal solution, we have $c_k = 0$.

Let K be the set of squares that contain the endpoint of at least one call of the optimal solution. We also denote by K the cardinality of the set K. Every square contains at most $2(L+1)^2$ edges. This is clearly a bound on the number of calls with both endpoints in the same square that can be accepted in a solution. The number of calls with only one endpoint in a square that can be accepted in a solution is bounded by the the number of edges that have one endpoint in the square and one endpoint outside of it, i.e., $4(L+1)$. Altogether, $c_k \leq 3(L+1)^2$ (using that L is large enough) for any square $k \in K$.

We have $\mu = E_{\underline{x}}(OPT(\sigma) \cap \mathcal{C}(\underline{x})) \geq \frac{1}{3} OPT(\sigma)$, and clearly $OPT(\sigma) \geq K/2$. From the bounded differences inequality of Lemma 5.3 it follows that

$$
\begin{aligned}
&Pr[|OPT(\sigma) \cap \mathcal{C}(\underline{x})| < \delta\mu] < 2\exp\left(\frac{-2(\delta\mu)^2}{\sum_k c_k^2}\right) \\
&\leq 2\exp\left(\frac{-2(\delta\frac{OPT(\sigma)}{3})^2}{K \cdot 9(L+1)^4}\right) \leq 2\exp\left(\frac{-\delta^2 OPT(\sigma)}{81(L+1)^4}\right) \\
&\leq 2\exp\left(\frac{-\delta^2 OPT(\sigma)}{82L^4}\right) \leq 2\exp\left(\frac{-\delta^2 OPT(\sigma)}{82(\lfloor \gamma \log n \rfloor)^4}\right),
\end{aligned}
$$

from which the claim follows. □

5.2. The deterministic procedure for meshes. The deterministic procedure receives as input the set of candidate calls $\mathcal{C}$ accepted by the randomized filter in the order they appear in the input sequence σ.

We follow KT and partition the set of calls into the set of *long* and the set of *short* calls. A call (s,t) is a short call if both s and t are in the same square and a long call if s and t are in different squares. Set $\mathcal{C}$ is partitioned into the set of long calls $\mathcal{L} = \{(s,t) \in \mathcal{C} : S_s \neq S_t\}$ and the set of short calls $\mathcal{S} = \{(s,t) \in \mathcal{C} : S_s = S_t\}$. Long and short calls are dealt with differently by the algorithm. However, as opposed to KT, we will accept both long calls and short calls at the same time.

The selected region of every square is dedicated to the routing of long calls through the square. For every square S, we number the columns from left to right and the rows from top to bottom. The routes assigned to long calls will traverse the border between two adjacent squares only on columns or rows in the interval $6B+1, \ldots, 7B$. A *crossbar* row (column) of square S is defined as a path on a row (column) in the interval $6B+1, \ldots, 7B$ connecting the central region of S to the closest vertex of the border of S. For every square S and two rings a and b, with ring a of index higher than ring b, define a *straight-line extension* of ring a as a path from a corner of ring a to ring b that does not include edges of a. Observe that the straight-line extensions starting from two distinct rings of a square are edge-disjoint.

We say that a ring, a crossbar row or column, or a straight-line extension is assigned to an accepted call if they contain at least one edge of the path assigned to

the accepted call.

We first describe the algorithm for long calls and then the algorithm for short calls.

Long calls.

Every call (s,t) of $\mathcal{L}$ is first submitted to the following test:

1. If a short or a long call with endpoint in S_s or S_t has been previously accepted, then discard (s,t). Otherwise add (s,t) to set $\mathcal{L}'$.

Calls of $\mathcal{L}'$ are dealt with using the idea of KT to build a simulated network G', with links of higher capacity, and run AAP on this network. A vertex of G' is associated with every square of the original mesh. Two vertices of G' are connected by an edge if and only if there is at least one edge in the original mesh that connects two nodes, each on the border of one of the corresponding squares (i.e., the two squares are adjacent in the mesh).

Every call (s,t) of $\mathcal{L}'$ is transformed into a call between the two vertices of G' associated with S_s and S_t and then submitted to the AAP algorithm. If AAP accepts (s,t), then (s,t) is added to $ON_D(\mathcal{C})$, the set of calls accepted by the algorithm. Calls not accepted by AAP are discarded.

We use the AAP algorithm with the parameter $\epsilon = 6/7$. Observe that one can use AAP with this value of ϵ, since the capacity B of the edges in the simulated network is high enough. To see that, recall that we assumed $B = \lfloor \log n \rfloor \geq 16$. Thus (see also Appendix A)

$$\epsilon \log D + 1 + \epsilon \leq \frac{6}{7}\log n + 1 + \frac{6}{7} \leq \frac{6}{7}\log n + 2 \leq \frac{6}{7}(B+1) + \frac{1}{8}B \leq B \ .$$

If AAP accepts call (s,t) it also returns a route in G' that has a straightforward interpretation as a sequence of squares $S_1, \ldots, S_p$ in the original mesh with $S_1 = S_s$ and $S_p = S_t$. Our algorithm will assign call (s,t) to a path (i) from s to the border between S_1 and S_2, (ii) from the border between S_{i-1} and S_i to the border between S_i and S_{i+1}, $i = 2, \ldots, p-1$, and (iii) from the border between S_{p-1} and S_p to t. In the following description we give the details of this route assignment.

(i) From s to the border between S_1 and S_2.
Without loss of generality assume that the border between S_1 and S_2 is on a column. We consider two cases: (a) s is outside the central area; (b) s is inside the central area.

(a) The call is routed from s through the ring containing s until it meets an unassigned crossbar row leading to the border between S_1 and S_2; this crossbar row is followed until the border between S_1 and S_2.

(b) The call is routed from s through the ring containing s until a corner of the ring is reached, where a straight-line extension is followed until ring $6B$. From there the path continues as in point (a).

(ii) From the border between S_{i-1} and S_i to the border between S_i and S_{i+1}.
Without loss of generality, assume that the border between S_{i-1} and S_i and the border between S_i and S_{i+1} are on columns of G. The path enters the border between S_{i-1} and S_i on a crossbar row that is followed until an unassigned ring of the selected region. The path is routed through the ring of the selected region until an unassigned crossbar row leading to the border between S_i and S_{i+1} is met. This crossbar row is followed until the border between S_i and S_{i+1}.

(iii) From the border between S_{p-1} and S_p to t. This case is equal to case (i).

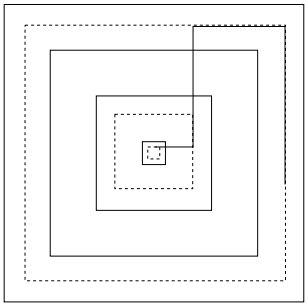

FIG. 5.2. *The routing of short calls.*

Figure 5.1 shows the routing of a long call with an endpoint in the first region and an endpoint in the third region.

Short calls.

A short call (s, t) is accepted on the basis of the following test:

1. If the ring containing s or the ring containing t has been previously assigned, then discard (s, t).
2. If either s or t, but not both, is in the central area, the other vertex is in region S^1 or S^2, but all rings in the range from $4B + 1$ to $6B$ are already assigned, then discard (s, t).
3. Otherwise, add (s, t) to $ON_D(\mathcal{C})$.

In the following we describe the route assigned to an accepted call (s, t).

If s and t are on the same ring, we route (s, t) on a path contained in the ring of s and t. Otherwise, we assume without loss of generality that the ring of s is internal to the ring of t and distinguish between two cases:

1. Both s and t are inside or are both outside the central area. We route (s, t) through the ring of s until a corner of the ring. There, we continue on a straight-line extension until the ring of t, which is then followed until t itself.
2. Either s or t, but not both, is in the central area. One of the rings from $4B + 1$ to $6B$ must be unassigned and will be assigned to (s, t) (possibly the ring containing t). A straight-line extension from a corner of the ring of s to an unassigned ring of S^3 not intersecting the crossbar row or column assigned to the single long call with endpoint in S_s is assigned to (s, t). The path follows the ring of s until the corner of the selected straight-line extension that is followed until the assigned ring of S^3. There, if t is in S^3, we follow the ring until t, otherwise we continue as at point 1.

Figure 5.2 shows the routing of short calls.

Proof of correctness. We prove that the algorithm described above routes accepted calls on edge-disjoint paths. To that end, we prove the following lemmas.

LEMMA 5.4. *The maximum number of calls routed between two adjacent squares is B.*

Proof. Each edge in the simulated network has capacity B and AAP does not violate the capacity constraints. □

LEMMA 5.5. *Let S be a square. There are at most $2B$ calls routed through square S.*

Proof. Every call routed through a square consumes two units of bandwidth on the edges incident to the vertex of G' associated with the square. The overall

bandwidth on the edges incident to a vertex of G' is $4B$; thus at most $2B$ calls are routed through a square. □

LEMMA 5.6. *The following claims hold at any time during the execution of the algorithm:*

1. *Every crossbar row or column is assigned to at most a single call.*
2. *Every ring is assigned to at most a single call.*
3. *Every straight-line extension is assigned to at most a single call.*

Proof. Clearly the claims hold before any call is accepted. We now assume that the claims hold before call (s,t) is accepted and prove that they still hold after call (s,t) is accepted.

1. Assume (s,t) is accepted on a path crossing the border between S and S'. Without loss of generality assume that the border is on a column. By Lemma 5.4 at most $B-1$ (long) calls have been previously routed between S and S'. We conclude that there is an unassigned crossbar row of S and an unassigned crossbar row of S' leading to the border between S and S', both contained in the same row, that can be assigned to (s,t).
2. Two cases: (i) (s,t) is a long call; (ii) (s,t) is a short call. (i) We prove that the rings assigned to call (s,t) are not assigned to any other call. Call (s,t) is accepted by AAP on a path crossing a sequence of squares $S_1,\ldots,S_p$, with $S_1 = S_s$ and $S_p = S_t$. A ring for every square S_i is assigned to (s,t). We first consider squares S_s and S_t. By step 1 of the algorithm for long calls, no long or short call is previously accepted in S_s and in S_t. Since vertices s and t are outside the selected regions of S_s and of S_t, the rings containing s and t are unassigned when (s,t) is accepted. Call (s,t) is also assigned to a ring of the selected region in every square S_i, $i = 2,\ldots,p-1$. By Lemma 5.5, at most $2B-1$ rings of the selected region of a square S_i are previously assigned when (s,t) is accepted. A ring of the selected region of S_i is then still available to be assigned to (s,t). (ii) By steps 1 and 2 of the routing algorithm for short calls, if (s,t) is accepted, it is assigned to at most three rings which were not previously assigned to any other call.
3. All the straight-line extensions in a square are edge-disjoint. A straight-line extension is assigned to a call if it starts from a ring that is also assigned to that call. By point 2 of the claim, every ring is assigned to at most a single call. Therefore, every straight-line extension is assigned to at most a single call. □

We can now prove the main lemma.

LEMMA 5.7. *Every pair of accepted calls is routed on two edge-disjoint paths.*

Proof. By Lemma 5.6, every crossbar row or column, ring, and straight-line extension is assigned to at most a single call. Rings and straight-line extensions are edge-disjoint, as are rings and crossbar rows and columns. Only straight-line extensions from the central region of a square may intersect crossbar rows or columns. We prove that the edges common to a straight-line extension from a ring of the central region and to a crossbar row or column are not assigned to more than one call.

Consider square S. We first exclude intersections between calls with an endpoint in S and calls that are routed through S. By point (i)b of the routing algorithm for long calls and by step 2 of the routing algorithm for short calls, a straight-line extension from a ring of the central region is followed by the route of a call at most until a ring of S^3. In this case the selected region in S is either S^1 or S^2. Therefore, by point (ii) of the routing algorithm for long calls, a call routed through S includes

only edges of S^1 and S^2 that belong to a crossbar row or column. Therefore, there is no intersection with calls routed through S.

We now consider a long call (s,t) with an endpoint, say, s, in S and a call (s',t') assigned to a straight-line extension from a ring of the central region. By step 1 of the algorithm for long calls, (s',t') must be a short call accepted after (s,t), (s,t) being the single long call with endpoint in S that is accepted. There could be a potential intersection only if (s',t') is in the central region, and (s,t) has an endpoint in S^3. There are four possible straight-line extensions that connect the ring of s' with a ring of S^3. By step 2 of the algorithm for short calls, (s',t') is assigned to a straight-line extension that does not overlap with the crossbar row or column assigned to (s,t). No edge of S^3 on the chosen straight-line extension is thus assigned to more than one call. □

The analysis. We conclude the proof that the algorithm is $O(\log n)$-competitive by showing the following lemma.

LEMMA 5.8. *For any set of candidate calls $\mathcal{C}$, $OPT(\mathcal{C}) = O(\log n) ON_D(\mathcal{C})$.*

Proof. We will prove the following lemmas:

1. $OPT(\mathcal{L} \setminus \mathcal{L}') = O(\log n)\ ON_D(\mathcal{C})$ (Lemma 5.9).
2. $OPT(\mathcal{L}') = O(\log n)\ ON_D(\mathcal{L}')$ (Lemma 5.10).
3. $OPT(\mathcal{S}) = O(\log n)\ ON_D(\mathcal{C})$ (Lemma 5.11).

The proof then easily follows:

$$\begin{aligned} OPT(\mathcal{C}) = OPT(\mathcal{L} \cup \mathcal{S}) &\leq OPT(\mathcal{L} \setminus \mathcal{L}') + OPT(\mathcal{L}') + OPT(\mathcal{S}) \\ &= O(\log n)\ ON_D(\mathcal{C})\ . \end{aligned}$$ □

LEMMA 5.9. $OPT(\mathcal{L} \setminus \mathcal{L}') = O(\log n)\ ON_D(\mathcal{C})$.

Proof. A call (s,t) of $\mathcal{L}$ is discarded if a long or a short call with an endpoint in S_s or in S_t has been previously added to $ON_D(\mathcal{C})$. At most $4(L+1)$ long calls with an endpoint in a given square can be accepted by the optimal solution, since the border of S is formed by at most $4(L+1)$ vertices (and edges). Then, for every call accepted in $ON_D(\mathcal{C})$, at most $8(L+1)$ calls of $\mathcal{L} \setminus \mathcal{L}'$ are accepted by the optimal solution. As $L = \lfloor \gamma \log n \rfloor$ the claim follows. □

LEMMA 5.10. $OPT(\mathcal{L}') = O(\log n)\ ON_D(\mathcal{L}')$.

Proof. Every call of $\mathcal{L}'$ is submitted to the AAP algorithm on G' with edges of bandwidth $B = \lfloor \log n \rfloor$. Note that this capacity is large enough to allow AAP to work correctly if we use the AAP algorithm with $\epsilon = 6/7$ (and using the assumption that $B \geq 16$). The benefit $OPT(\mathcal{L}')$, obtained by an optimal solution on the set $\mathcal{L}'$, is bounded by the benefit obtained by an optimal algorithm on G' with edges of bandwidth $L+1$, which is the maximum number of calls that can be routed between two adjacent squares. The AAP algorithm is still $O(\log n)$-competitive even if the bandwidth used by the on-line algorithm (AAP) on the edges is smaller by a constant multiplicative factor than the bandwidth used by the off-line algorithm (see [2, 16]; for completeness this is also proved in the appendix). In our case this constant factor is at most 14. The claim then follows. □

LEMMA 5.11. $OPT(\mathcal{S}) = O(\log n)\ ON_D(\mathcal{C})$.

Proof. Let us restrict our attention to a single square. Let $\mathcal{S}_1$ and $\mathcal{S}_2$ be the set of calls discarded at steps 1 and 2 of the algorithm for short calls. We have $OPT(\mathcal{S}) \leq OPT(\mathcal{S}_1) + OPT(\mathcal{S}_2) + ON_D(S)$. The proof of the lemma derives from the two following statements: (i) $OPT(\mathcal{S}_1) = O(\log n)\ ON_D(\mathcal{C})$; (ii) $OPT(\mathcal{S}_2) \leq 8\ ON_D(\mathcal{C})$.

(i) For every accepted call, at most three rings of a square are assigned by the algorithm to that call. The number of edges incident to a ring is at most $4(L+1)$. This

is a bound on the number of calls with an endpoint on a ring that can be accepted in an optimal solution. Therefore, the number of calls of $OPT(\mathcal{S})$ that are discarded at step 1 of the algorithm for short calls, per each call in $ON_D(\mathcal{C})$, is at most $12(L+1)$. As $L = \lfloor \gamma \log n \rfloor$, this proves the first statement.

(ii) Short calls with an endpoint in the central region and an endpoint outside the central region are discarded at step 2 of the algorithm if all the rings of S^3 outside the central region are assigned. At most two rings of S^3 are assigned to an accepted call. If a short call is discarded at step 2, we thus have the evidence that B calls with an endpoint in S have already been accepted. For the sake of the proof we charge, for every accepted long call, the value of $1/2$ to S and the value of $1/2$ to the square containing its other endpoint. A square is therefore already charged with at least the value of $B/2$ if a short call of the square is discarded at step 2. The number of short calls of $OPT(\mathcal{S}_2)$ with endpoints in S is bounded by $4B$, as this is the number of vertices on the border of the central region. The ratio between the number of calls of $\mathcal{S}_2$ with endpoints in S that belong to $OPT(\mathcal{S}_2)$, and the number of calls of $ON_D(\mathcal{C})$ charged to S, is thus at most 8. This proves the second statement. ∎

Appendix A. The AAP algorithm. For completeness we describe a restricted version of the AAP algorithm. We consider the case where all calls are of infinite duration, request bandwidth of 1, and are of uniform benefit that without loss of generality we assume equals to D, the length of the longest simple path in the network. Let $u(e)$, for $e \in E$, be the capacity of edge e and assume that for all $e \in E$,

$$u(e) \geq \epsilon \log D + 1 + \epsilon \quad \text{for some } 0 < \epsilon \leq 1. \tag{A.1}$$

Let $b_j(e)$ be the number of calls routed trough edge e by AAP among the first j presented calls. Define the relative load of edge e, just after call j has been processed, to be $\lambda_j(e) = \frac{b_j(e)}{u(e)}$. Define the cost of edge e just after call j has been processed to be $c_j(e) = u(e)[\mu^{\lambda_j(e)} - 1]$, where $\mu = 2^{1+1/\epsilon}D$. A request (s_j, t_j) is accepted to path P_j if $\sum_{e \in P_j)} \frac{1}{u(e)} \cdot c_{j-1}(e) \leq D$.

The above algorithm has competitive ratio $O(2^{1/\epsilon}/\epsilon + 2^{1/\epsilon} \log D)$. We give below a sketch of the proof. The proof follows the proof that appears in [8].

THEOREM A.1. *The above AAP algorithm has competitive ratio* $2^{1+1/\epsilon} \log \mu + 1$.

Proof. Let $\sigma = \sigma_1, \sigma_2, \ldots, \sigma_n$, be the sequence of requests. Let A be the set of indices of requests that are accepted by AAP and let A' be the set of indices of requests that are rejected by AAP but are accepted by the adversary. Let $C = \sum_{e \in E} c_n(e)$. Let $\mathcal{Q}(\sigma)$ denote the benefit obtained by algorithm AAP on sequence σ. We prove the following two claims that yield the desired result.

1. $C \leq (2^{1+1/\epsilon} \log \mu) \cdot |A| \cdot D$.
2. $|A'| \cdot D \leq C$.

The result follows from the above two inequalities since $\mathcal{Q}(\sigma) = |A| \cdot D$, and $OPT(\sigma) \leq \mathcal{Q}(\sigma) + |A'| \cdot D$.

The proof of inequality 1 can be found in [8]. We repeat here the proof of inequality 2 since we slightly modify it below to give the corollaries we need.

For a call σ_j that is accepted by the off-line algorithm let P_j^* be the path that is used by the off-line algorithm to accept this call. For any $j \in A'$

$$D < \min_{P_j} \sum_{e \in P_j} \frac{1}{u(e)} c_{j-1}(e) \leq \sum_{e \in P_j^*} \frac{1}{u(e)} c_{j-1}(e) \ .$$

We get

$$\begin{aligned}
|A'| \cdot D &< \sum_{j \in A'} \sum_{e \in P_j^*} \frac{1}{u(e)} c_{j-1}(e) \\
&\leq \sum_{j \in A'} \sum_{e \in P_j^*} \frac{1}{u(e)} c_n(e) \\
&= \sum_e c_n(e) \sum_{j \in A' : e \in P_j^*} \frac{1}{u(e)} \\
&\leq \sum_e c_n(e) \\
&= C.
\end{aligned}$$

The last inequality follows since the capacity of the adversary on any edge e is $u(e)$, that is, it can route at most $u(e)$ calls though edge e. □

We now give two corollaries of the above theorem.

COROLLARY A.2. *If for all $e \in E$, $u(e)$ satisfied condition* A.1, *and the off-line algorithm has capacity $c \cdot u(e)$ for each edge e, for some constant c, then AAP is $(1 + c(2^{1+1/\epsilon} \log \mu))$-competitive.*

Proof. We slightly modify the above proof for inequality 2. Since for each $e \in E$ the capacity available to the off-line algorithm is $c \cdot u(e)$, then the last inequality in the proof would yield

$$|A'| \cdot D < \sum_e c_n(e) \cdot c = C \cdot c \ .$$

Thus we get $(|A'| \cdot D)/c \leq (2^{1+1/\epsilon} \log \mu) \cdot |A| \cdot D$. And we get

$$\begin{aligned}
OPT(\sigma) &\leq \mathcal{Q}(\sigma) + |A'| \cdot D \leq \mathcal{Q}(\sigma) + c(2^{1+1/\epsilon} \log \mu) \cdot |A| \cdot D \\
&= (1 + c(2^{1+1/\epsilon} \log \mu)) \cdot \mathcal{Q}(\sigma). \qquad \square
\end{aligned}$$

COROLLARY A.3. *If AAP, with $\epsilon = 1$, has for each $e \in E$ capacity $u(e) = \log 4D$, while the off-line algorithm has for all e capacity* 1, *then the competitive ratio is* 5.

Proof. We use $\epsilon = 1$ and slightly modify the above proof of inequality 2. We again modify the last inequality of the the proof. Since the off-line algorithm has for each e only capacity $u(e)/\log 4D$, we get

$$|A'| \cdot D < \sum_e c_n(e)/\log 4D \ ,$$

i.e.,

$$|A'| \cdot D < C/\log 4D \ .$$

We get

$$\begin{aligned} OPT(\sigma) &\le \mathcal{Q}(\sigma) + |A'| \cdot D \\ &\le \mathcal{Q}(\sigma) + C/\log 4D \\ &\le \mathcal{Q}(\sigma) + ((2^{1+1/\epsilon}\log\mu)\cdot|A|\cdot D)/\log 4D \\ &= \mathcal{Q}(\sigma) + ((2^{1+1/\epsilon}\log\mu)\cdot|A|\cdot D)/\log\mu \\ &= \mathcal{Q}(\sigma) + 4\cdot|A|\cdot D = 5\cdot\mathcal{Q}(\sigma)\ . \qquad \square \end{aligned}$$

Acknowledgments. Special thanks are due to Amos Fiat for suggesting to us to look into the relationship between the competitive ratio and the deviation of the result from its expectation in randomized benefit on-line algorithms. We thank Dimitri Achlioptas and Hannah Bast for useful discussions and suggestions. We also thank an anonymous referee for very useful comments.

FIXED-PARAMETER TRACTABILITY, DEFINABILITY, AND MODEL-CHECKING*

JÖRG FLUM† AND MARTIN GROHE‡

Abstract. In this article, we study parameterized complexity theory from the perspective of logic, or more specifically, descriptive complexity theory.

We propose to consider parameterized *model-checking* problems for various fragments of first-order logic as generic parameterized problems and show how this approach can be useful in studying both fixed-parameter tractability and intractability. For example, we establish the equivalence between the model-checking for existential first-order logic, the homomorphism problem for relational structures, and the substructure isomorphism problem. Our main tractability result shows that model-checking for first-order formulas is fixed-parameter tractable when restricted to a class of input structures with an excluded minor. On the intractability side, for every $t \geq 0$ we prove an equivalence between model-checking for first-order formulas with t quantifier alternations and the parameterized halting problem for alternating Turing machines with t alternations. We discuss the close connection between this *alternation hierarchy* and Downey and Fellows' W-hierarchy.

On a more abstract level, we consider two forms of definability, called *Fagin definability* and *slicewise definability*, that are appropriate for describing parameterized problems. We give a characterization of the class FPT of all fixed-parameter tractable problems in terms of slicewise definability in finite variable least fixed-point logic, which is reminiscent of the Immerman–Vardi theorem characterizing the class PTIME in terms of definability in least fixed-point logic.

Key words. parameterized complexity, model-checking, descriptive complexity

1. Introduction.

Parameterized complexity is a branch of complexity theory which has matured in the last 10 years, as witnessed in the culminating monograph [10]. It gives a framework for a refined complexity analysis of hard algorithmic problems. The basic idea can best be explained by an example: Consider the problem of evaluating a query in a relational database. This problem usually has a high complexity (depending on the query language, of course, but the problem is NP-complete even for the very basic conjunctive queries [5]). The main factor contributing to this complexity is the length of the query. In practice, however, queries are usually short, certainly much shorter than the size of the database. Thus when analyzing the complexity of the problem we should put much more emphasis on the size of the database than on the length of the query. An algorithm evaluating a query of length k in a database of size m in time $O(2^k \cdot m)$ is therefore much better than one performing the same task in time $O(m^{k/2})$, although both are exponential.

Parameterized complexity theory studies problems whose instances are *parameterized* by some function of the input, such as the length of the query in our example. The idea is to choose the parameterization in such a way that it can be assumed to take small values for the instances one is interested in. Then the complexity of an algorithm is measured not only in the size of the input but also in terms of the param-

eter. A parameterized problem is *fixed-parameter tractable* if there is an algorithm solving it in time $f(k) \cdot n^c$, where n denotes the size of the input, k the parameter, and $f : \mathbb{N} \to \mathbb{N}$ is a computable function and $c > 0$ a constant.

Parameterized complexity theory provides methods for proving problems to be fixed-parameter tractable but also gives a framework for dealing with apparently intractable problems in a similar way that the theory of NP-completeness does in classical complexity theory.

The purpose of this article is to establish a very fruitful connection between parameterized complexity theory and logic. Our approach is that of descriptive complexity theory. We study the definability of parameterized problems and try to obtain information about the parameterized complexity of the problems through the syntactical structure of the defining sentences. On the one hand, we use this approach to prove that certain problems are tractable because they can be defined by syntactically simple formulas. On the other hand, we characterize classes of intractable problems by syntactical means.

Central to our approach are *parameterized model-checking* problems of the following form. For a class Φ of formulas, we let $MC(\Phi)$ be the problem

$MC(\Phi)$		
	Input:	A finite structure $\mathcal{A}$.
	Parameter:	A sentence $\varphi \in \Phi$.
	Question:	Does $\mathcal{A}$ satisfy φ?

In most cases, Φ will be a fragment of first-order logic.

After a preliminary section, we discuss some basic facts about parameterized model-checking problems in section 3. In section 4 we introduce two notions of definability of parameterized problems, which we call slicewise definability and Fagin definability, and relate them to model-checking. We then show how Fagin definability can be used to establish the fixed-parameter tractability of various problems.

In section 5 we study the parameterized complexity of the model-checking problem for Σ_1-formulas (that is, existential first-order formulas in prenex normal form). We associate a graph with each such formula and use it to establish a surprisingly close connection between this model-checking problem, the homomorphism problem, and the subgraph isomorphism problem. As an application of our result we show that for Σ_1-sentences whose graph has bounded tree-width, the model-checking problem is fixed-parameter tractable, even if inequalities are disregarded in the graph of the formula. Model-checking for formulas with a tree-like graph or hypergraph has recently received much attention (see [6, 24, 18, 16]).

So far we have looked only for tractable cases of the model-checking problem $MC(\Phi)$ that are obtained by restricting the class of formulas Φ. A different approach is to restrict the class of structures where the input structure $\mathcal{A}$ is taken from (see, for example, [7, 29, 17]). We prove a far reaching result: For any class C of graphs with an excluded minor, the model-checking problem for first-order logic is fixed-parameter tractable if the inputs are taken from C. This implies, for example, that parameterized versions of the dominating set problem or the (induced) subgraph isomorphism problem are fixed-parameter tractable when restricted to such classes of graphs.

Our last result on fixed-parameter tractability is a descriptive characterization of the complexity class FPT of all fixed-parameter tractable problems in terms of slicewise definability in finite variable fragments of least-fixed point logic. This simple result can be seen as a parameterized analogue of the well-known Immerman–Vardi

theorem [21, 30] characterizing the class PTIME in terms of definability in least-fixed-point logic.

The final section is devoted to fixed-parameter intractability. We define a hierarchy A[t] of parameterized complexity classes in terms of alternating Turing machine acceptance (t is the number of alternations). This hierarchy can be seen as a parameterized analogue of the polynomial hierarchy. We prove that for all $t \geq 1$, the model-checking problem for Σ_t-formulas is complete for the tth level of this hierarchy. Then we study the relation between our A-hierarchy and Downey and Fellows' W-hierarchy. It is known that the first levels of the respective hierarchies, A[1] and W[1], coincide [4]. We slightly improve a result of Downey, Fellows, and Regan [11] relating W[t], the tth level of the W-hierarchy, to the model-checking problems for a certain fragment of Σ_t. However, the question whether A[t] and W[t] coincide for $t \geq 2$ remains open.

2. Preliminaries.

2.1. Logic. We assume that the reader is familiar with first-order logic; we recall only a few basic notions to fix our notation (compare with [13] for a more detailed introduction of these notions).

In this article, a vocabulary *is a finite set of relation symbols.* Associated with every relation symbol is a natural number, its *arity*. The *arity* of a vocabulary is the maximal arity of the relation symbols it contains. Usually, vocabularies are also permitted to contain function and constant symbols. All results of this article, with the single exception of Theorem 8.4, would remain true if function and constant symbols were allowed, but adding them would not give us any new insights. Therefore, for convenience, we restrict our attention to relational vocabularies. In the following, τ always denotes a vocabulary.

A *τ-structure* $\mathcal{A}$ consists of a set A, called the *universe* of $\mathcal{A}$, and a relation $R^{\mathcal{A}} \subseteq A^r$ for each r-ary relation symbol $R \in \tau$. We synonymously write $\bar{a} \in R^{\mathcal{A}}$ or $R^{\mathcal{A}}\bar{a}$ to denote that the tuple $\bar{a} \in A^r$ belongs to the relation $R^{\mathcal{A}}$. For $\tau \subseteq \tau'$, a τ-structure $\mathcal{A}$ is the *τ-reduct* of a τ'-structure $\mathcal{A}'$ if $A = A'$ and $R^{\mathcal{A}} = R^{\mathcal{A}'}$ for all $R \in \tau$. A τ'-structure $\mathcal{A}'$ is a *τ'-expansion* of a τ-structure $\mathcal{A}$ if $\mathcal{A}$ is the *τ-reduct* of $\mathcal{A}'$.

We consider only finite structures. When we consider classes of structures, they are always assumed to be closed under isomorphism. *STR* denotes the class of all (finite) structures. If C is a class of structures, $C[\tau]$ denotes the subclass of all τ-structures in C. Furthermore, $C[s]$ denotes the class of all structures in C whose vocabulary is at most s-ary. We consider graphs as $\{E\}$-structures $\mathcal{G} = (G, E^{\mathcal{G}})$, where $E^{\mathcal{G}}$ is an irreflexive and symmetric binary relation (i.e., graphs are loop-free and undirected). *GRAPH* denotes the class of all graphs.

The class of all first-order formulas is denoted by FO. Recall that *atomic formulas* are formulas of the form $x = y$ or $Rx_1 \dots x_r$, where $x, y, x_1, \dots, x_r$ are variables and R is an r-ary relation symbol. *Literals* are atomic or negated atomic formulas. A first-order formula φ is in *negation normal form* if negation symbols occur only directly in front of atomic subformulas. φ is *existential* (*universal*) if it is in negation normal form and contains no universal quantifiers (no existential quantifiers, respectively). φ is in *prenex normal form* if it is of the form $Q_1 x_1 \dots Q_k x_k \theta$, where $Q_1, \dots, Q_k \in \{\exists, \forall\}$ and θ is quantifier-free.

EFO (AFO) denotes the class of all existential (respectively, universal) first-order

formulas. For $t \geq 1$, Σ_t denotes the class of all FO-formulas of the form

$$\exists x_{11} \ldots \exists x_{1k_1} \forall x_{21} \ldots \forall x_{2k_2} \ \ldots \ Q x_{t1} \ldots Q x_{tk_t} \ \theta,$$

where $Q = \forall$ if t is even and $Q = \exists$ otherwise and θ is quantifier-free. Π_t-formulas are defined analogously starting with a block of universal quantifiers.

If Φ is a class of formulas of some logic, then $\Phi[\tau]$ denotes the class of all formulas of vocabulary τ in L, and $\Phi[s]$ denotes the class of all formulas in Φ whose vocabulary is at most s-ary. We write $\mathcal{A} \models \varphi$ if, for some τ, $\mathcal{A}$ is a τ-structure, φ is in $\mathrm{L}[\tau]$, and $\mathcal{A}$ is a model of φ.

2.2. Coding issues. We use random access machines (RAMs) with the uniform cost measure as our underlying model of computation (cf. [1]).

Very often, the objects of our computations are structures. Therefore, we have to fix a way of representing structures on a RAM. The two most common ways of doing this are the *array representation* and the *list representation*. For both representations we assume that the universes of our structures are initial segments of the natural numbers; of course this is no real restriction because every structure is isomorphic to one with such a universe.

Both representations start with an encoding of the vocabulary and a natural number representing the size of the universe of the structure. The difference between the two representations is in how relations are stored. In the array representation, a k-ary relation is stored as a k-dimensional array with $0,1$-entries. For graphs, this is just the adjacency matrix. The advantage of this representation is that for each tuple it can be checked in constant time whether it belongs to the relation or not. However, for sparse relations this representation wastes a lot of space.

In the more concise list representation, a relation is represented as a list of all tuples it contains. Clearly, the list representation of a structure can be computed from the array representation in linear time but not vice versa. For graphs $\mathcal{G}$, it is easy to construct the common adjacency list representation from the list representation (in time linear in $|G| +$ (size of the representation), where $|G|$ denotes the number of elements in G). In this article, we always assume that structures are given in the list representation, but all results also hold for the array representation. The *size* of a structure $\mathcal{A}$, denoted by $||\mathcal{A}||$, is defined to be $|A| +$ (size of the list representation of $\mathcal{A}$). The complexity of algorithms on structures is measured in this size. Remark 3.3 shows that this can be relevant.

2.3. Parameterized problems. We recall only those notions of the theory needed in this article. For a comprehensive treatment we refer the reader to Downey and Fellows' recent monograph [10]. A *parameterized problem* is a set $P \subseteq \Sigma^* \times \Pi^*$, where Σ and Π are finite alphabets. Following [10], we usually represent a parameterized problem P in the following form:

P		
	Input:	$x \in \Sigma^*$.
	Parameter:	$y \in \Pi^*$.
	Question:	Is $(x, y) \in P$?

In most cases, we have $\Pi = \{0,1\}$ and consider the parameters $y \in \Pi^*$ as natural numbers (in binary). A natural example is the parameterized version of the well-known *VERTEX COVER* problem:

VC		
	Input:	Graph $\mathcal{G}$.
	Parameter:	$k \in \mathbb{N}$.
	Question:	Does $\mathcal{G}$ have a vertex cover of size k?

Recall that a *vertex cover* of a graph is a set X of vertices such that every edge is incident to one of the vertices in X. Similarly, we can define parameterized versions of *DOMINATING SET (DS)* and *CLIQUE*. (A *dominating set* of a graph is a set X of vertices such that every vertex not contained in X is adjacent to a vertex in X. A *clique* is a set of pairwise adjacent vertices.)

An example where the set of parameters is not $\mathbb{N}$, but the class *GRAPH* of all finite graphs, is the following parameterized *SUBGRAPH ISOMORPHISM (SI)* problem:

SI		
	Input:	Graph $\mathcal{G}$.
	Parameter:	Graph $\mathcal{H}$.
	Question:	Is $\mathcal{H}$ isomorphic to a subgraph of $\mathcal{G}$?

Similarly, we can define parameterized versions of the *INDUCED SUBGRAPH ISOMORPHISM* problem and the *GRAPH HOMOMORPHISM* problem.

DEFINITION 2.1. *A parameterized problem $P \subseteq \Sigma^* \times \Pi^*$ is* fixed-parameter tractable[1] *if there is a computable function $f : \Pi^* \to \mathbb{N}$, a constant $c \in \mathbb{N}$, and an algorithm that, given a pair $(x, y) \in \Sigma^* \times \Pi^*$, decides if $(x, y) \in P$ in time $f(y) \cdot |x|^c$.*

We denote the class of all fixed-parameter tractable problems by FPT.

Of course we can always consider parameterized problems as classical problems and determine their complexity in the classical sense. Clearly, every parameterized problem in PTIME is also in FPT.

The best currently known algorithm for vertex cover *VC* has running time $O(k \cdot n + \max\{1.255^k \cdot k^2, 1.291^k \cdot k\})$ [15], where n denotes the size of the input graph. Thus $VC \in$ FPT.

2.4. Reductions between parameterized problems. It is conjectured that none of the problems *DS*, *CLIQUE*, *SI* is in FPT. As it is often the case in complexity theory, we cannot actually prove this but prove only that the problems are hard for certain complexity classes that are conjectured to contain FPT strictly. To do this we need a suitable concept of reduction. We actually introduce three different types of reduction.

DEFINITION 2.2. *Let $P \subseteq \Sigma^* \times \Pi^*$ and $P' \subseteq (\Sigma')^* \times (\Pi')^*$ be parameterized problems.*

(1) *A* parameterized T-reduction *from P to P' is an algorithm with an oracle for P' that solves any instance (x, y) of P in time $f(|y|) \cdot |x|^c$ in such a way that for all questions $(x', y') \in P'$? to the oracle we have $|y'| \leq g(|y|)$ (for computable functions $f, g : \mathbb{N} \to \mathbb{N}$ and a constant $c \in \mathbb{N}$).*

P is fixed-parameter T-reducible *to P' (we write $P \leq_{\mathrm{T}}^{\mathrm{fp}} P'$) if there is a parameterized T-reduction from P to P'.*

[1] This is what Downey and Fellows call *strongly uniformly fixed-parameter tractable*. For variants of this definition, and also of Definition 2.2 and the definition of the W-hierarchy, the reader should consult [10].

(2) *A* parameterized m-reduction *from P to P' is an algorithm that computes for every instance (x, y) of P an instance (x', y') of P' in time $f(|y|) \cdot |x|^c$ such that $|y'| \leq g(|y|)$ and*

$$(x, y) \in P \iff (x', y') \in P'$$

(for computable functions $f, g : \mathbb{N} \to \mathbb{N}$ and a constant $c \in \mathbb{N}$).
P is fixed-parameter m-reducible *to P' (we write $P \leq_{\mathrm{m}}^{\mathrm{fp}} P'$) if there is a parameterized m-reduction from P to P'.*

Whereas every parameterized problem that is in PTIME (when considered as a classical problem) is in FPT, it is not the case that every PTIME many-one reduction between two parameterized problems is also a parameterized m-reduction. To capture both concepts we occasionally use the following third kind of reduction.

DEFINITION 2.3. *Let $P \subseteq \Sigma^* \times \Pi^*$ and $P' \subseteq (\Sigma')^* \times (\Pi')^*$ be parameterized problems.*

A pp m-reduction *from P to P' is a parameterized m-reduction from P to P' that is also a polynomial time many-one reduction from P to P' in the classical sense, i.e., the function f in Definition* 2.2(2) *is a polynomial.*

P is pp m-reducible *to P' (we write $P \leq_{\mathrm{m}}^{\mathrm{fpp}} P'$) if there is a pp m-reduction from P to P'.*

For example, *CLIQUE* $\leq_{\mathrm{m}}^{\mathrm{fp}}$ *SI* by the simple parameterized m-reduction that reduces the instance $(\mathcal{G}, k)$ of *CLIQUE* to the instance $(\mathcal{G}, \mathcal{K}_k)$ of *SI*. Here $\mathcal{K}_k$ denotes the complete graph with k vertices. Note that if we represent integers in binary, this reduction is not a pp m-reduction.

Observe that $\leq_{\mathrm{T}}^{\mathrm{fp}}$, $\leq_{\mathrm{m}}^{\mathrm{fp}}$, and $\leq_{\mathrm{m}}^{\mathrm{fpp}}$ are transitive and that for all P, P' we have

$$P \leq_{\mathrm{m}}^{\mathrm{fpp}} P' \implies P \leq_{\mathrm{m}}^{\mathrm{fp}} P' \quad \text{and} \quad P \leq_{\mathrm{m}}^{\mathrm{fp}} P' \implies P \leq_{\mathrm{T}}^{\mathrm{fp}} P'.$$

Furthermore, if $P \leq_{\mathrm{T}}^{\mathrm{fp}} P'$ and $P' \in \mathrm{FPT}$, then $P \in \mathrm{FPT}$. For any of the reductions $\leq_{\mathrm{T}}^{\mathrm{fp}}, \leq_{\mathrm{m}}^{\mathrm{fp}}, \leq_{\mathrm{m}}^{\mathrm{fpp}}$ we let $\equiv_{\dots}^{\dots}$ denote the corresponding equivalence relation.

We define *hardness* and *completeness* of parameterized problems for a parameterized complexity class (under parameterized m- or T-reductions) in the usual way. For a parameterized problem P, we let $[P]_{\mathrm{m}}^{\mathrm{fp}} := \{P' \mid P' \leq_{\mathrm{m}}^{\mathrm{fp}} P\}$, and for a class P of parameterized problems $[\mathrm{P}]_{\mathrm{m}}^{\mathrm{fp}} := \bigcup_{P \in \mathrm{P}} [P]_{\mathrm{m}}^{\mathrm{fp}}$.

Remark 2.4. Very often, it is natural to think of a parameterized problem P as derived from a (classical) problem $L \subseteq \Sigma^*$ by a *parameterization* $p : \Sigma^* \to \mathbb{N}$ in such a way that $P = \{(x, k) \mid x \in L, k = p(x)\}$.

Slightly abusing notation, we represent such a P in the following form:

P		
	Input:	$x \in \Sigma^*$.
	Parameter:	$p(x)$.
	Question:	Decide if $x \in L$?

As an example, let us reconsider the subgraph isomorphism problem. Instead of taking graph $\mathcal{H}$ as the parameter, we may also consider pairs of graphs $(\mathcal{G}, \mathcal{H})$ as inputs and parameterize the problem by the size of $\mathcal{H}$. In our new notation, this would be the problem:

SI′		
	Input:	Graphs $\mathcal{G}$, $\mathcal{H}$.
	Parameter:	$\|\|\mathcal{H}\|\|$.
	Question:	Is $\mathcal{H}$ isomorphic to a subgraph of $\mathcal{G}$?

It is easy to see, however, that $SI \equiv_{\mathrm{m}}^{\mathrm{fp}} SI'$.

2.5. Parameterized intractability. Some combinatorial problems are provably not fixed-parameter tractable, and others, such as *GRAPH COLORABILITY*, are not fixed-parameter tractable unless PTIME = NP. However, many interesting problems, such as the parameterized *CLIQUE* problem, do not seem to be fixed-parameter tractable, although there is no known way to prove this or reduce it to classical complexity theoretic questions such as PTIME $\stackrel{?}{=}$ NP. To classify such problems, Downey and Fellows (cf. [10]) introduced a hierarchy

$$\mathrm{W}[1] \subseteq \mathrm{W}[2] \subseteq \cdots$$

of classes above FPT. These classes can best be defined in terms of the satisfiability problem for formulas of propositional logic. Formulas of propositional logic are built up from *propositional variables* $X_1, X_2, \ldots$ by taking conjunctions, disjunctions, and negations. The negation of a formula φ is denoted by $\neg\varphi$. We distinguish between *small conjunctions*, denoted by $\wedge$, which are conjunctions of two formulas, and *big conjunctions*, denoted by $\bigwedge$, which are conjunctions over arbitrary finite sets of formulas. Analogously, we distinguish between *small disjunctions*, denoted by $\vee$, and *big disjunctions*, denoted by $\bigvee$.

Every formula φ corresponds to a labeled tree $\mathcal{T}_\varphi$ in a natural way. The *size* of φ is defined to be the number of vertices of $\mathcal{T}_\varphi$. The *depth* of φ is defined to be the maximum number of nodes labeled $\wedge, \bigwedge, \vee, \bigvee$ on a path from the root to a leaf of $\mathcal{T}_\varphi$. Thus when computing the depth, we do not count negations.

A formula is *small* if it contains only small conjunctions and small disjunction. We define $C_0 = D_0$ to be the class of all small formulas. For an $i \geq 1$, we define C_i to be the class of all big conjunctions of formulas in D_{i-1}, and we define D_i to be the class of all big disjunctions of formulas in C_{i-1}. Note that these definitions are purely syntactical; every formula in a C_i or D_i is equivalent to a formula in C_0. Of course the translation from a formula in C_i to an equivalent formula in C_0 usually increases the depth of a formula. For all $i, d \geq 0$ we let $C_{i,d}$ denote the class of all formulas in C_i whose small subformulas have depth at most d (equivalently, we may say that the whole formula has depth at most $d + i$). We define $D_{i,d}$ analogously.

The *weight* of an assignment α for the variables of a propositional formula is the number of variables set to TRUE by α. For any class P of propositional formulas, let *weighted satisfiability for* P be the following parameterized problem:

WSAT(P)		
	Input:	$\varphi \in P$.
	Parameter:	$k \in \mathbb{N}$.
	Question:	Does φ have a satisfying assignment of weight k?

Now we are ready to define the *W-hierarchy*: For every $t \geq 1$, we let

$$\mathrm{W}[t] := \bigcup_{d \geq 0} [\, \mathit{WSAT}(C_{t,d})]_{\mathrm{m}}^{\mathrm{fp}}.$$

In other words, a parameterized problem is in W[t] if there is a $d \geq 0$ such that the problem is fixed-parameter m-reducible to the weighted satisfiability problem for $C_{t,d}$. It is an immediate consequence of the definition of parameterized m-reductions that FPT $\subseteq$ W[1]. Actually, it is conjectured that this inclusion is strict and that W[t] is strictly contained in W[$t+1$] for every $t \geq 1$.

Example 2.5. The parameterized *CLIQUE*-problem is in W[1]. To see this, for every graph $\mathcal{G}$ we describe a propositional formula $\varphi := \varphi(\mathcal{G}) \in C_{1,1}$ such that $\mathcal{G}$ has a clique of size k if and only if φ has a satisfying assignment of weight k. It will be obvious from the construction that φ can be computed from $\mathcal{G}$ in polynomial time.

So let $\mathcal{G}$ be a graph. For all $a \in G$ let X_a be a propositional variable. Let

$$\varphi := \bigwedge_{\substack{a,b \in G, a \neq b \\ ab \notin E^G}} (\neg X_a \vee \neg X_b).$$

Then every satisfying assignment of φ corresponds to a clique of $\mathcal{G}$.

Actually, Downey and Fellows proved the following nontrivial result.

THEOREM 2.6 (Downey and Fellows [8, 9]).

(1) *CLIQUE is* W[1]*-complete under parameterized m-reductions.*

(2) *DS is* W[2]*-complete under parameterized m-reductions.*

Remark 2.7. Downey and Fellows phrase their definition of the W-hierarchy in terms of Boolean circuits rather than propositional formulas. However, since the classes of the hierarchy involve only circuits/formulas of bounded depth, this does not really make a difference (cf. [10]). In their definition of W[t], Downey and Fellows admit more complicated formulas than those in C_t. However, they prove that our definition is equivalent. A surprising by-product of their results is that for every $t \geq 1$ and every $d \geq 0$, the problem $WSAT[D_{t+1,d}]$ is contained in W[t]. It is not hard to prove this result directly, and even easier to prove that $WSAT[D_{1,d}]$ is in FPT. (This explains why we defined only a hierarchy using the C_ts.)

There is another, more serious source of confusion in the various definitions of the W-hierarchy: Downey and Fellows are never really clear about what kind of reductions they are using to define the classes. We decided, more or less in accordance with [10], that parameterized m-reductions are most natural.

We will further discuss the W-hierarchy and other seemingly intractable classes in section 8.

3. Model-checking. In this article we are mainly concerned with the complexity of various *parameterized model-checking problems*. For a set Φ of formulas, we let

$$MC(\Phi) := \big\{(\mathcal{A}, \varphi) \;\big|\; \mathcal{A} \in STR, \varphi \text{ sentence in } \Phi, \mathcal{A} \models \varphi\big\},$$

or more intuitively,

$MC(\Phi)$		
	Input:	$\mathcal{A} \in STR$.
	Parameter:	$\varphi \in \Phi$.
	Question:	Does $\mathcal{A} \models \varphi$?

In this section we collect a few basic facts about parameterized model-checking problems. For every Φ we consider, we assume that we have fixed an encoding $\gamma : \Phi \to \{0,1\}^*$, and we let $||\varphi||$ be the length of $\gamma(\varphi)$.

Taking sentences as parameters seems a little unusual. The following parameterization of the model-checking problem looks more natural:

$MC'(\Phi)$		
	Input:	$\mathcal{A} \in STR$, $\varphi \in \Phi$.
	Parameter:	$\|\|\varphi\|\|$.
	Question:	Does $\mathcal{A} \models \varphi$?

However, it is easy to see that $MC(\Phi) \equiv^{\text{fp}}_{\text{m}} MC'(\Phi)$.

It is well known that various problems of model theory or complexity theory can be reduced from structures to graphs. The following two lemmas contain such reductions. Although their proofs use only standard techniques, they are subtle and require some care. Therefore we decided to give the proofs in some detail. We will apply these lemmas several times later.

LEMMA 3.1. *There are polynomial time transformations that associate with every structure $\mathcal{A} \in STR$ a graph $\mathcal{H}(\mathcal{A})$ and with every sentence $\varphi \in$ FO a sentence $\varphi_{GRAPH} \in$ FO, respectively, such that*

$$\mathcal{A} \models \varphi \iff \mathcal{H}(\mathcal{A}) \models \varphi_{GRAPH}.$$

Furthermore for every $t \geq 1$, if $\varphi \in \Sigma_t$ then $\varphi_{GRAPH} \in \Sigma_{t+1}$ and if $\varphi \in \Pi_t$ then $\varphi_{GRAPH} \in \Pi_{t+1}$.

Proof. Let $\mathcal{A} \in STR[\tau]$ and $\varphi \in \text{FO}[\tau]$. Without loss of generality we can assume that φ is in prenex and in negation normal form.

Step 1. In the first step we translate $\mathcal{A}$ to a structure $\mathcal{B}(\mathcal{A})$ of a vocabulary $\beta(\tau)$ that consists only of unary and binary relation symbols. φ is translated to a corresponding sentence φ_B of vocabulary $\beta(\tau)$.

$\beta(\tau)$ contains unary relation symbols U and U_R for each symbol $R \in \tau$ and binary relation symbols $E_1, \ldots, E_s$, where s is the arity of τ.

The universe of $\mathcal{B}(\mathcal{A})$ is

$$B(\mathcal{A}) := A \cup \{b(R, \bar{a}) \mid R \in \tau, \bar{a} \in R^{\mathcal{A}}\}.$$

We assume that the elements $b(R, \bar{a})$ are all pairwise distinct and distinct from those in A. Note that the cardinality of $B(\mathcal{A})$ is essentially $||\mathcal{A}||$, up to an additive term depending on τ. The unary relations are defined in the obvious way: We let $U^{\mathcal{B}(\mathcal{A})} := A$ and $U_R^{\mathcal{B}(\mathcal{A})} := \{b(R, \bar{a}) \mid \bar{a} \in R^{\mathcal{A}}\}$ for every $R \in \tau$. The binary relations $E_1, \ldots, E_s$ are defined by

$$E_i^{\mathcal{B}(\mathcal{A})} := \{(a_i, b(R, \bar{a})), (b(R, \bar{a}), a_i) \mid R \in \tau, \bar{a} = (a_1, \ldots, a_r) \in R^{\mathcal{A}}, 1 \leq i \leq r\}.$$

Note that $E_i^{\mathcal{B}(\mathcal{A})}$ is symmetric; this will be useful later.

To define φ_B, we first relativize all quantifiers to U, i.e., we inductively replace all subformulas $\exists x\psi$ by $\exists x(Ux \wedge \psi)$ and all subformulas $\forall x\psi$ by $\forall x(Ux \to \psi)$. We obtain a formula φ'.

φ_B is obtained from φ' by replacing every atomic subformula $R\bar{x}$, for r-ary $R \in \tau$, by

$$\exists z \left(U_R z \wedge \bigwedge_{i=1}^{r} E_i x_i z \right), \tag{3.1}$$

where z is a new variable. Then we have

$$\mathcal{A} \models \varphi \iff \mathcal{B}(\mathcal{A}) \models \varphi_B. \tag{3.2}$$

Furthermore, $\mathcal{B}(\mathcal{A})$ can be computed from $\mathcal{A}$ in time $O(||\tau|| \cdot ||\mathcal{A}||)$, where $||\tau||$ denotes the length of the encoding of τ, and φ_B can be computed from φ in linear time.

Step 2. In this step we replace the binary relations $E_1, \dots, E_s$ by a single new binary relation E. We let

$$\gamma(\tau) := (\beta(\tau) \setminus \{E_1, \dots, E_s\}) \cup \{E, P_1, \dots, P_s\},$$

where $P_1, \dots, P_s$ are new unary relation symbols.

We transform $\mathcal{B}(\mathcal{A})$ to a $\gamma(\tau)$-structure $\mathcal{C}(\mathcal{A})$ as follows: For $1 \leq i \leq s$ and for all $a, b \in B(\mathcal{A})$ such that $E_i^{\mathcal{B}(\mathcal{A})}ab$ we introduce a new element $c(i,a,b)$, add the pairs $(a, c(i,a,b))$, $(c(i,a,b), a)$, $(c(i,a,b), b)$, $(b, c(i,a,b))$ to $E^{\mathcal{C}(\mathcal{A})}$, and add $c(i,a,b)$ to $P_i^{\mathcal{C}(\mathcal{A})}$.

We define a sentence φ_C by replacing each subformula of φ_B of the form $E_i xy$ by $\exists z(Exz \wedge Ezy \wedge P_i z)$. Then we have the analogue of (3.2) and the subsequent remarks for $\mathcal{C}(\mathcal{A}), \varphi_C$ instead of $\mathcal{B}(\mathcal{A}), \varphi_B$.

Step 3. The restriction of $\mathcal{C}(\mathcal{A})$ to E is already a graph, i.e., $E^{\mathcal{C}(\mathcal{A})}$ is symmetric and irreflexive. Therefore all we have to do is to eliminate the unary relations $U, (U_R)_{R\in\tau}, (P_i)_{1\leq i\leq s}$. Say, $Q_1, \dots, Q_l$ is an enumeration of all these relations. Note that every $a \in C(\mathcal{A})$ is either isolated or of valence two or adjacent to a vertex of valence two. We use this to define certain trees $\mathcal{T}_1, \dots, \mathcal{T}_l$ and corresponding existential first-order formulas $\xi_1(x), \dots, \xi_l(x)$ and attach a copy of $\mathcal{T}_i$ to each vertex in $Q_i^{\mathcal{C}(\mathcal{A})}$ in such a way that in the resulting graph $\mathcal{H}(\mathcal{A})$ we have for all vertices a

$$\mathcal{H}(\mathcal{A}) \models \xi_i(a) \iff a \in Q_i^{\mathcal{C}(\mathcal{A})}.$$

Furthermore, the $\mathcal{T}_i$ and thus the ξ_i can be chosen of size polynomial in l. We omit the details.

Then we let φ_{GRAPH} be the formula obtained from φ_C by replacing every subformula of the form $Q_i x$ by $\xi_i(x)$, for $1 \leq i \leq l$, and transforming the resulting formula into prenex normal form in the usual manner.

Clearly the transformations $\mathcal{A} \mapsto \mathcal{H}(\mathcal{A})$ and $\varphi \mapsto \varphi_{GRAPH}$ are polynomial, and we have

$$\mathcal{A} \models \varphi \iff \mathcal{H}(\mathcal{A}) \models \varphi_{GRAPH}.$$

It remains to prove that if $\varphi \in \Sigma_t$ ($\varphi \in \Pi_t$), then $\varphi_{GRAPH} \in \Sigma_{t+1}$ ($\varphi_{GRAPH} \in \Pi_{t+1}$, respectively). This follows easily from the way we defined the sentences φ_B, φ_C, and φ_{GRAPH} in Steps 1–3, noting that each positive (negative) occurrence of a relation symbol $R \in \tau$ gives rise only to positive (respectively, negative) occurrences of U_R, the E_i, and the P_i. Thus for the positive occurrences of the $R \in \tau$ we get a new block of existential quantifiers and for the negative occurrences a new block of universal quantifiers. This increases the alternation depth by at most one. □

Recall that for a class C of structures and an $s \geq 0$, by $C[s]$ we denote the class of all structures in C whose vocabulary is at most s-ary. Similarly, for a class Φ of formulas, by $\Phi[s]$ we denote the class of all formulas in Φ whose vocabulary is at most s-ary.

LEMMA 3.2. *Let $s \geq 1$. There is a polynomial time transformation that associates with every structure $\mathcal{A} \in STR[s]$ a graph $\mathcal{H}'(\mathcal{A})$ and a linear time function that associates with every sentence $\varphi \in \mathrm{FO}$ a sentence $\varphi'_{GRAPH} \in \mathrm{FO}$ such that*

$$\mathcal{A} \models \varphi \iff \mathcal{H}'(\mathcal{A}) \models \varphi'_{GRAPH}.$$

Furthermore, for all $t \geq 1$, if $\varphi \in \Sigma_t$, then $\varphi'_{GRAPH} \in \Sigma_t$ and if $\varphi \in \Pi_t$, then $\varphi'_{GRAPH} \in \Pi_t$.

Proof. Let us first look back at the proof of the last lemma and note that if all relation symbols occur only positively in φ, then the transformation $\varphi \mapsto \varphi_{GRAPH}$ generates only a new block of existential quantifiers. If all relation symbols occur only negatively, then we get only a new block of universal quantifiers. Thus if $\varphi \in \Sigma_{2t-1}$ ($\varphi \in \Pi_{2t}$) and all relation symbols occur only positively in φ, then also $\varphi_{GRAPH} \in \Sigma_{2t-1}$ (respectively, $\varphi_{GRAPH} \in \Pi_{2t}$). Similarly, if $\varphi \in \Sigma_{2t}$ ($\varphi \in \Pi_{2t-1}$) and all relation symbols occur only negatively in φ, then also $\varphi_{GRAPH} \in \Sigma_{2t}$ (respectively, $\varphi_{GRAPH} \in \Pi_{2t-1}$).

We first transform $\mathcal{A}$ to an $\mathcal{A}'$ and φ to a φ' in the same prefix class such that

$$\mathcal{A} \models \varphi \iff \mathcal{A}' \models \varphi',$$

and either all relation symbols in φ' occur positively or negatively, whichever we need to apply the previous remark. For this purpose, let τ be an at most s-ary vocabulary. We let $\tau' := \tau \cup \{\overline{R} \mid R \in \tau\}$, where $\overline{R}$ is a new relation symbol that has the same arity as R. For every $\mathcal{A} \in STR[\tau]$, we let $\mathcal{A}'$ be the τ'-expansion of $\mathcal{A}$ with $\overline{R}^{\mathcal{A}'} = A^r \setminus R^{\mathcal{A}}$ for r-ary $R \in \tau$. Note that $\mathcal{A}'$ can be computed from $\mathcal{A}$ in time $O(||\mathcal{A}||^s)$. To define φ' we either replace each negative literal $\neg R\bar{x}$ by $\overline{R}\bar{x}$ or each positive literal $R\bar{x}$ by $\neg\overline{R}\bar{x}$. □

Remark 3.3. Note that if we represent structures by the array representation, then the transformation of Lemma 3.2 is actually polynomial even if we do not fix the arity of the vocabulary in advance. This follows from the fact that the array representation of the structure $\mathcal{A}'$ (in the proof of the lemma) can be computed from the array representation of $\mathcal{A}$ in linear time, uniformly over all vocabularies.

For a parameterized problem $P \subseteq STR \times \Pi^*$ and a class C of structures we let $P|_C$ denote the *restriction* of P to C. In particular,

$$MC(\Phi)|_{GRAPH} = \{(\mathcal{G}, \varphi) \mid \mathcal{G} \in GRAPH, \varphi \in \Phi, \mathcal{G} \models \varphi\}.$$

Note that for every class Φ of formulas and vocabulary τ the two problems $MC(\Phi[\tau])$ and $MC(\Phi)|_{STR[\tau]}$, though formally different, are essentially the same. Therefore we do not distinguish between them.

COROLLARY 3.4.

(1) $MC(\mathrm{FO}) \equiv^{\mathrm{fpp}}_{\mathrm{m}} MC(\mathrm{FO})|_{GRAPH}$.

(2) *For all $t \geq 1$ we have*

$$MC(\Sigma_t) \leq^{\mathrm{fpp}}_{\mathrm{m}} MC(\Sigma_{t+1})|_{GRAPH} \quad \text{and} \quad MC(\Pi_t) \leq^{\mathrm{fpp}}_{\mathrm{m}} MC(\Pi_{t+1})|_{GRAPH}.$$

(3) *For all $s \geq 2$, $t \geq 1$ we have*

$$MC(\Sigma_t[s]) \equiv^{\mathrm{fpp}}_{\mathrm{m}} MC(\Sigma_t)|_{GRAPH} \quad \text{and} \quad MC(\Pi_t[s]) \equiv^{\mathrm{fpp}}_{\mathrm{m}} MC(\Pi_t)|_{GRAPH}.$$

We do not know if $MC(\Sigma_t) \leq^{\mathrm{fp}}_{\mathrm{m}} MC(\Sigma_t)|_{GRAPH}$ or $MC(\Pi_t) \leq^{\mathrm{fp}}_{\mathrm{m}} MC(\Pi_t)|_{GRAPH}$ for any $t \geq 1$.

4. Defining parameterized problems. Definability is the connection between arbitrary parameterized problems and our logical analysis that focuses on model-checking problems. In [11], Downey, Fellows, and Regan consider two forms of definability: Their exposition motivates two general notions of definability, which we call *slicewise definability* and *Fagin definability*.

For a parameterized problem $P \subseteq \Sigma^* \times \Pi^*$ and $y \in \Pi^*$, we call $P \cap (\Sigma^* \times \{y\})$ the yth *slice* of P.

DEFINITION 4.1. *Let $P \subseteq STR \times \Pi^*$ be a parameterized problem and Φ a class of formulas. P is* slicewise Φ-definable *if there is a computable function $\delta : \Pi^* \to \Phi$ such that for all $\mathcal{A} \in STR$ and $y \in \Pi^*$ we have $(\mathcal{A}, y) \in P \iff \mathcal{A} \models \delta(y)$.*

For example, the parameterized subgraph isomorphism problem SI is slicewise Σ_1-definable via the function $\delta : GRAPH \to \Sigma_1$ defined as follows: For a graph $\mathcal{H}$ with vertex set $H = \{h_1, \dots, h_n\}$ of cardinality n, $\delta(\mathcal{H})$ is the sentence

$$\exists x_1 \dots \exists x_n \left(\bigwedge_{1 \le i < j \le n} x_i \neq x_j \wedge \bigwedge_{\substack{1 \le i,j \le n \\ E^{\mathcal{H}} h_i h_j}} E x_i x_j \right).$$

Slicewise Φ-definability is closely related to the model-checking problem for Φ: If $P \subseteq STR \times \Pi^*$ is slicewise Φ-definable, then $P \le^{\mathrm{fp}}_{\mathrm{m}} MC(\Phi)$. On the other hand, if Φ is a decidable set of formulas, then the problem $MC(\Phi)$ is slicewise Φ-definable for trivial reasons.

DEFINITION 4.2. *Let τ be a vocabulary, $P \subseteq STR[\tau] \times \mathbb{N}$ a parameterized problem, and Φ a class of formulas. P is* Φ-Fagin-definable *if there is a relation symbol $X \notin \tau$ (say, r-ary) and a sentence $\varphi \in \Phi[\tau \cup \{X\}]$ such that for all $\mathcal{A} \in STR[\tau]$ and $k \in \mathbb{N}$ we have $(\mathcal{A}, k) \in P$ if and only if there is a $B \subseteq A^r$ such that $|B| = k$ and $(\mathcal{A}, B) \models \varphi$. (Here $(\mathcal{A}, B)$ denotes the $\tau \cup \{X\}$-expansion of $\mathcal{A}$ that interprets X by B.) Then φ* Fagin-defines *P.*

We often consider X as a relation *variable* and thus write $\varphi(X) \in \Phi[\tau]$ instead of $\varphi \in \Phi[\tau \cup \{X\}]$ and $\mathcal{A} \models \varphi(B)$ instead of $(\mathcal{A}, B) \models \varphi$.

For example, parameterized vertex cover VC is Fagin-defined by the formula

$$\varphi_{VC} := \forall y \forall z \big(Eyz \to (Xy \vee Xz) \big).$$

It is easy to see that every problem that is FO-Fagin-definable is also FO-slicewise definable. Indeed, if $P \subseteq STR[\tau] \times \mathbb{N}$ is Fagin-defined by a formula $\varphi(X) \in \mathrm{FO}[\tau]$, where X is r-ary, then it is slicewise FO-defined via the function $\delta : \mathbb{N} \to \mathrm{FO}[\tau]$ with $\delta(k) = \exists \bar{x}_1 \dots \exists \bar{x}_k (\bigwedge_{1 \le i < j \le k} \bar{x}_i \neq \bar{x}_j \wedge \varphi_k)$, where $\bar{x}_1, \dots, \bar{x}_k$ are r-tuples of distinct variables not occurring in φ, and φ_k is the sentence obtained from φ by replacing each subformula of the form $X\bar{y}$ by $\bigvee_{i=1}^k \bar{x}_i = \bar{y}$. Fagin definability implies slicewise definability also for other reasonable classes Φ of formulas, e.g., for the class Σ^1_1 of formulas of second-order logic of the form $\exists X_1 \cdots \exists X_l \psi$, where $X_1, \dots X_l$ are relation variables and ψ is first-order.

The converse is certainly not true, not even for problems of the specific form $P \subseteq STR[\tau] \times \mathbb{N}$: It is obvious that there are slicewise FO-definable problems of arbitrarily high classical complexity (choose δ in Definition 4.1 arbitrarily complex). On the other hand, we have the following characterization of Σ^1_1-Fagin-definable problems.

PROPOSITION 4.3. *Let $P \subseteq STR[\tau] \times \mathbb{N}$. Then,* (1) *and* (2) *are equivalent, where*

(1) *P is Σ^1_1-Fagin-definable;*

(2) *P is in* NP *(when considered as a classical problem) and for some $r \geq 1$, $(\mathcal{A}, k) \in P$ implies $k \leq |A|^r$.*

Proof. The implication of (1) $\Rightarrow$ (2) being clear, we turn to a proof of (2) $\Rightarrow$ (1). Choose r according to (2). Then,

$$\{(\mathcal{A}, B) \mid B \subseteq A^r \text{ and } (\mathcal{A}, |B|) \in P\}$$

is a class of $\tau \cup \{X\}$-structures in NP, where X is r-ary. By Fagin's theorem [14], there is a Σ^1_1-formula $\varphi(X)$ of vocabulary $\tau \cup \{X\}$ axiomatizing this class. Then, $\varphi(X)$ Σ^1_1-Fagin-defines P. □

Thus, slicewise definability is the more general notion. Nevertheless, Fagin definability can be very useful. We illustrate this by the following generalization of a result due to Cai and Chen, namely, Theorem 3.5 of [3], which is based on a result due to Kolaitis and Thakur [23] that syntactically characterizes certain minimization problems. It is motivated by comparing the formula φ_{VC} defining the fixed-parameter tractable problem *VC* with the following formulas φ_{DS} and φ_{CLIQUE} defining the W[1]-hard problems *DS* and *CLIQUE*, respectively:

$$\varphi_{DS} := \forall y \exists x (Xx \wedge (x = y \vee Exy)\big),$$
$$\varphi_{CLIQUE} := \forall y \forall z \big((Xy \wedge Xz) \rightarrow (y = z \vee Eyz)\big).$$

Observe that in φ_{DS} the relation variable X is in the scope of an existential quantifier and in φ_{CLIQUE} it occurs negatively.

THEOREM 4.4. *Let τ be a vocabulary and $P \subseteq STR[\tau] \times \mathbb{N}$ a parameterized problem that is Fagin-defined by a* FO$[\tau]$*-formula $\varphi(X)$ in which X does not occur in the scope of an existential quantifier or negation symbol. Then P is in* FPT.

Proof. For simplicity, let us assume that X is unary. Without loss of generality we can assume that

$$\varphi = \forall y_1 \ldots \forall y_l \bigvee_{i=1}^{m} \bigwedge_{j=1}^{p} \psi_{ij},$$

where each ψ_{ij} is either Xy_q for some $q \in \{1, \ldots, l\}$ or a first-order formula with free variables in $\{y_1, \ldots, y_l\}$ in which X does not occur. In a preprocessing phase we replace the latter ones by atomic formulas: For each such ψ_{ij} we introduce a new relation symbol R_{ij} whose arity matches the number of free variables of ψ_{ij} and let τ^* be the set of all these relation symbols. We let φ^* be the formula obtained from φ by replacing each subformula $\psi_{ij}(\bar{z})$ by $R_{ij}\bar{z}$. Then $\varphi^* = \forall y_1 \ldots \forall y_l \bigvee_{i=1}^{m} \chi_i$, where each χ_i is a conjunction of atomic formulas.

For a structure $\mathcal{A} \in STR[\tau]$ we let $\mathcal{A}^*$ be the τ^*-structure with universe A and with

$$R_{ij}^{\mathcal{A}^*} := \{\bar{a} \mid \mathcal{A} \models \psi_{ij}(\bar{a})\}.$$

Then we have for $B \subseteq A$,

$$\mathcal{A} \models \varphi(B) \iff \mathcal{A}^* \models \varphi^*(B).$$

Given $\mathcal{A}$, each $R_{ij}^{\mathcal{A}^*}$ can be computed in time $O(|A|^{||\psi_{ij}||})$; thus $\mathcal{A}^*$ can certainly be computed in time $O(|A|^{||\varphi||})$.

```
CHECK-φ(A ∈ STR[τ], k ∈ ℕ)
 1  compute A*
 2  initialize set S ⊆ Pow(A) by S := {∅}
 3  for all ā ∈ A^l do
 4      for all B ∈ S do
 5          if A* ⊭ ⋁_{i=1}^{m} χ_i(B, ā) then
 6              S := S \ {B}
 7              for i = 1 to m do
 8                  compute B' := β(B, ā, i)
 9                  if |B'| ≤ k and A* ⊨ χ_i(B', ā)
10                      then S := S ∪ {B'}
11  if S ≠ ∅
12      then accept
13      else reject.
```

Algorithm 1.

For $1 \leq i \leq m$, $\bar{a} = a_1 \dots a_l \in A^l$, and $B \subseteq A$ we let

$$\beta(B, \bar{a}, i) := B \cup \{a_j \mid Xy_j \text{ is a conjunct of } \chi_i\}.$$

Since $\chi_i(X, \bar{y})$ is positive in X, the following two statements are equivalent for every B' with $B \subseteq B' \subseteq A$:

- $\mathcal{A}^* \models \chi_i(B', \bar{a})$.
- $\beta(B, \bar{a}, i) \subseteq B'$ and $\mathcal{A}^* \models \chi_i(\beta(B, \bar{a}, i), \bar{a})$.

This equivalence is used by Algorithm 1 to decide P.

Recall that, given a τ-structure $\mathcal{A}$ and a parameter $k \in \mathbb{N}$, the algorithm is supposed to decide whether there is a $B \subseteq A$ with $|B| = k$ such that for all $\bar{a} \in A^l$ there is an i such that $\mathcal{A}^* \models \chi_i(B, \bar{a})$.

The crucial observation to see that the algorithm is correct is that whenever the main loop in lines 3–10 is entered, $\mathcal{S}$ is a set of subsets $B \subseteq A$ such that $|B| \leq k$ and for all $\bar{a}$ considered so far (in earlier runs through the loop) we have $\mathcal{A}^* \models \bigvee_{i=1}^{m} \chi_i(B, \bar{a})$.

To get a bound on the running time, we note that whenever a new set is added to $\mathcal{S}$ (in line 10), then it is an extension of a strictly smaller set that has been removed from $\mathcal{S}$ (in line 6). Furthermore, for each set removed (in line 6) at most m such extensions can be added. Thus an upper bound for the number of sets that can be in $\mathcal{S}$ at any time is m^k. The main loop (in lines 3–10) is called n^l times, where $n := |A|$. This gives an overall bound on the running time of $O(m^k \cdot n^l)$ plus the time needed to compute $\mathcal{A}^*$.

Since l does not depend on the instance, but only on the formula φ, this yields the fixed-parameter tractability of P. □

Besides *VC*, many other parameterized problems can be shown to be fixed-parameter tractable by a simple application of this theorem. Let us consider one example in detail: The *valence* of a graph is the maximal number of neighbors a vertex in the graph has. For an $l \geq 1$, we consider the restriction of *DOMINATING SET* to graphs of valence at most l, i.e., the following problem:

VC_l		
	Input:	Graph $\mathcal{G}$.
	Parameter:	$k \in \mathbb{N}$.
	Question:	Is the valence of $\mathcal{G}$ at most l and does $\mathcal{G}$ have a dominating set of size at most k?

This problem is Fagin-defined by the following first-order formula:

$$\forall x \exists^{\leq l} z\, Exz \wedge \forall y_0 \forall y_1 \ldots \forall y_l \left(\forall z \left(Ey_0 z \rightarrow \bigvee_{i=1}^{l} z = y_i \right) \rightarrow \bigvee_{i=0}^{l} Xy_i \right).$$

($\exists^{\leq m} x \psi(x)$ abbreviates $\exists y_1 \ldots \exists y_m \forall x (\psi(x) \rightarrow \bigvee_{i=1}^{m} x = y_i)$.)

Other examples of problems that can be shown to be in FPT by Theorem 4.4 are *HITTING SET FOR SIZE THREE SETS*, *MATRIX DOMINATION*, or *SHORT 3DIMENSIONAL MATCHING*. These problems are also considered in [10].

5. Homomorphisms, embeddings, and model-checking. In this section we analyze the close relationship between the homomorphism problem, the embedding problem, and model-checking problems for Σ_1-formulas from the point of view of parameterized complexity (compare with [24] for a further analysis of this relationship).

A *homomorphism* from a τ-structure $\mathcal{B}$ into a τ-structure $\mathcal{A}$ is a mapping $h : B \rightarrow A$ such that for all $R \in \tau$ and tuples $\bar{b} \in R^{\mathcal{B}}$ we have $h(\bar{b}) \in R^{\mathcal{A}}$. The parameterized *HOMOMORPHISM PROBLEM (HOM)* is defined as follows:

HOM		
	Input:	$\mathcal{A} \in STR$.
	Parameter:	$\mathcal{B} \in STR$.
	Question:	Is there a homomorphism from $\mathcal{B}$ to $\mathcal{A}$?

A *(weak) embedding* of $\mathcal{B}$ into $\mathcal{A}$ is an injective homomorphism from $\mathcal{B}$ to $\mathcal{A}$. Note that a graph $\mathcal{H}$ is isomorphic to a subgraph of a graph $\mathcal{G}$ in the usual graph theoretic sense if there is an embedding of $\mathcal{H}$ into $\mathcal{G}$. Thus the following parameterized *EMBEDDING PROBLEM (EMB)* is a generalization of the *SI* problem:

EMB		
	Input:	$\mathcal{A} \in STR$.
	Parameter:	$\mathcal{B} \in STR$.
	Question:	Is there an embedding of $\mathcal{B}$ into $\mathcal{A}$?

The *Gaifman graph* of a τ-structure $\mathcal{A}$ is the graph $\mathcal{G}(\mathcal{A})$ with universe A in which two elements $a \neq b$ are adjacent if there is an $R \in \tau$ and a tuple $\bar{a} \in R^{\mathcal{A}}$ such that both a and b occur in the tuple $\bar{a}$. For a class C of graphs we let $STR[C]$ denote the class of all structures whose Gaifman graph is in C. Note that $STR[GRAPH] = STR$. Furthermore, we let $STR[\tau, C] := STR[\tau] \cap STR[C]$ for every vocabulary τ and $STR[s, C] := STR[s] \cap STR[C]$ for every $s \geq 1$. We define restrictions $HOM[\ldots]$ and $EMB[\ldots]$ of the respective problems, where for every possible restriction "..." in the square brackets we require the *parameter* $\mathcal{B}$ to belong to the class $STR[\ldots]$. For example, we let

$$EMB[s, C] := EMB \cap (STR \times STR[s, C]).$$

LEMMA 5.1. *For all classes C of graphs and $s \geq 1$ we have $HOM[C] \leq_{\mathrm{m}}^{\mathrm{fpp}} EMB[C]$ and $HOM[s,C] \leq_{\mathrm{m}}^{\mathrm{fpp}} EMB[s,C]$.*

Proof. Suppose we are given an instance $(\mathcal{A},\mathcal{B})$ of $HOM[C]$. Let τ be the vocabulary of $\mathcal{A}$. Let $\mathcal{A}_B$ be the τ-structure which for every element of $\mathcal{A}$ contains $|B|$ duplicates, i.e., $A_B := A \times B$ and, for every r-ary $R \in \tau$,

$$R^{\mathcal{A}_B} := \big\{((a_1,b_1),\dots,(a_r,b_r)) \;\big|\; R^{\mathcal{A}} a_1 \dots a_r\big\}.$$

Then, every homomorphism $h : \mathcal{B} \to \mathcal{A}$ gives rise to an embedding $f : \mathcal{B} \to \mathcal{A}_B$ defined by $f(b) = (h(b), b)$ and every embedding $f : \mathcal{B} \to \mathcal{A}_B$ induces a homomorphism $h : \mathcal{B} \to \mathcal{A}$ defined by letting $h(b)$ be the projection on the first component of $f(b)$. □

Note that, unless PTIME = NP, there is no polynomial time reduction from $EMB[C]$ to $HOM[C]$ for the class C of all paths because $HOM[C]$ can easily be seen to be in PTIME by a dynamic programming algorithm, whereas $EMB[2,C]$ is NP-complete by a reduction from *HAMILTONIAN PATH*. Thus $EMB[s,C] \leq_{\mathrm{m}}^{\mathrm{fpp}} HOM[s,C]$ does not hold for any $s \geq 2$. However, we will see that for all $s \geq 2$ and C we actually have $HOM[s,C] \equiv_{\mathrm{T}}^{\mathrm{fp}} EMB[s,C]$.

Before we show this, we introduce two related model-checking problems. With each first-order formula φ we associate a graph $\mathcal{G}(\varphi)$. Its universe is $\mathrm{var}(\varphi)$, the set of all variables in φ, and there is an edge between distinct $x, y \in \mathrm{var}(\varphi)$ in $\mathcal{G}(\varphi)$ if φ has an atomic subformula in which both x, y occur.

Let $\varphi^{\neq}$ be the formula obtained from φ by deleting all inequalities, i.e., all atomic subformulas of the form $x = y$ that occur in the scope of an odd number of negation symbols. We are also interested in $\mathcal{G}(\varphi^{\neq})$. Let us see an example:

$$\varphi := \exists x_1 \dots \exists x_k \left(\bigwedge_{1 \leq i < j \leq k} \neg x_i = x_j \wedge \bigwedge_{i=1}^{k-1} E x_i x_{i+1} \right).$$

$\mathcal{G}(\varphi)$ is the complete graph with vertex set $\{x_1,\dots,x_k\}$, whereas $\mathcal{G}(\varphi^{\neq})$ is the path $x_1 \dots x_k$. Note that φ says that a graph has a subgraph isomorphic to a path of length k, whereas $\varphi^{\neq}$ says that a graph contains a homomorphic image of a path of length k. This generalizes to the following simple lemma, whose proof we omit.

LEMMA 5.2. *For every structure $\mathcal{B} \in STR$ there is a Σ_1-sentence $\varphi_{\mathcal{B}}$ (whose quantifier-free part is a conjunction of literals) such that $\mathcal{G}(\varphi_{\mathcal{B}}^{\neq}) = \mathcal{G}(\mathcal{B})$ and for every structure $\mathcal{A}$ we have*

$$\mathcal{A} \models \varphi_{\mathcal{B}} \iff \text{there is an embedding of } \mathcal{B} \text{ into } \mathcal{A},$$
$$\mathcal{A} \models \varphi_{\mathcal{B}}^{\neq} \iff \text{there is a homomorphism from } \mathcal{B} \text{ to } \mathcal{A}.$$

Furthermore, the mapping $\mathcal{B} \mapsto \varphi_{\mathcal{B}}$ is computable in linear time.

For $s \in \mathbb{N}$ and a class C of graphs we let

$$\Sigma_1[s,C] := \big\{\varphi \in \Sigma_1[\tau] \;\big|\; \tau \text{ } s\text{-ary vocabulary}, \mathcal{G}(\varphi) \in C\big\},$$
$$\Sigma_1^{\neq}[s,C] := \big\{\varphi \in \Sigma_1[\tau] \;\big|\; \tau \text{ } s\text{-ary vocabulary}, \mathcal{G}(\varphi^{\neq}) \in C\big\}.$$

Furthermore, we let $\Sigma_1[C] := \bigcup_{s \geq 1} \Sigma_1[s,C]$ and $\Sigma_1^{\neq}[C] := \bigcup_{s \geq 1} \Sigma_1^{\neq}[s,C]$.

Lemma 5.2 implies that for every $s \geq 1$ and for every class C of graphs we have $HOM[s,C] \leq_{\mathrm{m}}^{\mathrm{fpp}} MC(\Sigma_1[s,C])$ and $EMB[s,C] \leq_{\mathrm{m}}^{\mathrm{fpp}} MC(\Sigma_1^{\neq}[s,C])$. Unless PTIME =

NP, the converse of these statements is wrong. To see this, let C be the class of all graphs that consist only of isolated vertices, i.e., all graphs $\mathcal{G}$ with $E^{\mathcal{G}} = \emptyset$. Then clearly $HOM[C]$ and $EMB[C]$ are in PTIME, but we can reduce the satisfiability problem for propositional formulas to $MC(\Sigma_1[1, C])$ and $MC(\Sigma_1^{\neq}[1, C])$.

THEOREM 5.3. *Let C be a class of graphs and $s \geq 2$. Then*

$$HOM[s, C] \equiv_{\mathrm{T}}^{\mathrm{fp}} EMB[s, C] \equiv_{\mathrm{T}}^{\mathrm{fp}} MC(\Sigma_1^{\neq}[s, C]) \equiv_{\mathrm{T}}^{\mathrm{fp}} MC(\Sigma_1[s, C]).$$

Proof. We have already seen that $HOM[s, C] \leq_{\mathrm{T}}^{\mathrm{fp}} EMB[s, C]$ (Lemma 5.1) and that $EMB[s, C] \leq_{\mathrm{T}}^{\mathrm{fp}} MC(\Sigma_1^{\neq}[s, C])$ (Lemma 5.2). To complete the cycle we shall prove that $MC(\Sigma_1^{\neq}[s, C]) \leq_{\mathrm{T}}^{\mathrm{fp}} MC(\Sigma_1[s, C])$ and that $MC(\Sigma_1[s, C]) \leq_{\mathrm{T}}^{\mathrm{fp}} HOM[s, C]$.

We first prove that $MC(\Sigma_1[s, C]) \leq_{\mathrm{T}}^{\mathrm{fp}} HOM[s, C]$. Let $\varphi \in \Sigma_1[s, C]$, say, of vocabulary τ, and let $\mathcal{A}$ be a τ-structure. We shall describe an algorithm that decides whether $\mathcal{A} \models \varphi$ using $HOM[s, C]$ as an oracle.

Let S be a binary relation symbol not contained in τ and $\tau' := \tau \cup \{S\}$. Furthermore, let $\mathcal{A}'$ be the τ'-expansion of $\mathcal{A}$ with $S^{\mathcal{A}'} = \emptyset$. Our algorithm first computes a sentence $\varphi' := \bigvee_{i=1}^{m} \exists \bar{x}_i \psi_i$ of vocabulary τ' such that

(1) $\mathcal{A} \models \varphi$ if and only if $\mathcal{A}' \models \varphi'$;
(2) for $1 \leq i \leq m$, the formula ψ_i is a conjunction of literals, and we have $\mathcal{G}(\psi_i) = \mathcal{G}(\varphi)$.

This can be achieved by first translating φ to a sentence whose quantifier-free part is in disjunctive normal form, then swapping existential quantifiers and the disjunction, and then adding dummy literals of the form $\neg Sxy$ until $\mathcal{G}(\psi_i) = \mathcal{G}(\varphi)$.

Let $\tau'' := \tau' \cup \{\overline{R} \mid R \in \tau'\} \cup \{E, \overline{E}\}$, where for all $R \in \tau'$ the symbol $\overline{R}$ is a new relation symbol of the same arity as R, and $E, \overline{E}$ are new binary relation symbols. Let $\mathcal{A}''$ be the τ'' expansion of $\mathcal{A}'$ in which $\overline{R}$ is interpreted as the complement of $R^{\mathcal{A}''}$ and $E, \overline{E}$ are interpreted as equality and inequality, respectively. For $1 \leq i \leq m$, we define a τ''-structure $\mathcal{B}_i$ with $\mathcal{G}(\mathcal{B}_i) = \mathcal{G}(\varphi)$ such that $\mathcal{A}' \models \exists \bar{x}_i \psi_i$ if and only if there is a homomorphism from $\mathcal{B}_i$ into $\mathcal{A}''$. We let $\mathcal{B}_i$ be the τ''-structure with universe $\mathrm{var}(\psi_i)$ and

$$\begin{aligned}
R^{\mathcal{B}_i} &:= \{\overline{y} \mid R\overline{y} \text{ is a literal of } \psi_i\} \qquad (\text{for } R \in \tau'),\\
\overline{R}^{\mathcal{B}_i} &:= \{\overline{y} \mid \neg R\overline{y} \text{ is a literal of } \psi_i\} \qquad (\text{for } R \in \tau'),\\
E^{\mathcal{B}_i} &:= \{yz \mid y = z \text{ is a literal of } \psi_i\},\\
\overline{E}^{\mathcal{B}_i} &:= \{yz \mid \neg y = z \text{ is a literal of } \psi_i\}.
\end{aligned}$$

It is obvious that $\mathcal{B}_i$ does indeed have the desired property. Altogether, our construction yields a parameterized T-reduction.

It remains to prove that $MC(\Sigma_1^{\neq}[s, C]) \leq_{\mathrm{T}}^{\mathrm{fp}} MC(\Sigma_1[s, C])$. We use the so-called *color coding* technique of Alon, Yuster, and Zwick [2].

Let $l \geq 1$ and let X be a set. An *l-perfect family of hash functions on X* is a family F of functions $f : X \to \{1, \ldots, l\}$ such that for all subsets $Y \subseteq X$ of size l there is an $f \in F$ such that $f(Y) = \{1, \ldots, l\}$ (i.e., on Y, f is one-to-one). Alon, Yuster, and Zwick [2] show that given $n, l \geq 1$, an l-perfect family of hash functions on $\{1, \ldots, n\}$ of size $2^{O(l)} \cdot \log n$ can be computed in time $2^{O(l)} \cdot n \cdot \log n$.

For a similar reason as outlined above, without loss of generality we can restrict our attention to sentences $\varphi \in MC(\Sigma_1^{\neq}[s, C])$ whose quantifier-free part is a conjunction of literals. Given such a sentence $\varphi = \exists x_1 \ldots \exists x_k \psi$, say, of vocabulary τ and

a τ-structure $\mathcal{A}$, we define a family of sentences $\varphi_\gamma \in MC(\Sigma_1[s,C])$ and a family of structures $\mathcal{A}_f$ such that $\mathcal{A} \models \varphi$ if and only if there is a γ and f such that $\mathcal{A}_f \models \varphi_\gamma$.

A *coloring of* φ is a function $\gamma : \{1,\dots,k\} \to \{1,\dots,k\}$ such that $\gamma(i) \neq \gamma(j)$ if $\neg x_i = x_j$ occurs in φ. For a coloring γ we let ψ_γ be the formula obtained from ψ by replacing all literals $\neg x_i = x_j$ by $C_{\gamma(i)}x_i \wedge C_{\gamma(j)}x_j$ (here, $C_1,\dots,C_k$ are new unary "color" relation symbols) and let $\varphi_\gamma := \exists x_1 \dots \exists x_k \psi_\gamma$. Note that $\mathcal{G}(\varphi_\gamma) = \mathcal{G}(\varphi^{\neq})$. Thus $\varphi_\gamma \in MC(\Sigma_1[s,C])$.

With every $f : A \to \{1,\dots,k\}$, which we call a *coloring of* $\mathcal{A}$, we let $\mathcal{A}_f$ be the $\tau \cup \{C_1,\dots,C_k\}$-expansion of $\mathcal{A}$ with $C_i^{\mathcal{A}_f} := f^{-1}(i)$ for $1 \leq i \leq k$.

Observe that

$$\mathcal{A} \models \varphi \iff \text{there is a coloring } \gamma \text{ of } \varphi \text{ and a coloring } f \text{ of } \mathcal{A} \text{ such that } \mathcal{A}_f \models \varphi_\gamma. \tag{5.1}$$

The problem is that there are $k^{|A|}$ colorings of $\mathcal{A}$, so (5.1) does not yet give rise to a parameterized reduction. The crucial trick is that to achieve this equivalence we do not have to consider all possible colorings f of $\mathcal{A}$. For $1 \leq l \leq k$, let F_l be an l-perfect family of hash-function on A and $F := \bigcup_{l=1}^{k} F_l$. We claim that

$$\mathcal{A} \models \varphi \iff \text{there is a coloring } \gamma \text{ of } \varphi \text{ and an } f \in F \text{ such that } \mathcal{A}_f \models \varphi_\gamma. \tag{5.2}$$

The backward direction follows immediately from (5.1). For the forward direction, suppose that $\mathcal{A} \models \varphi$. Let $\bar{a} \in A^k$ such that $\mathcal{A} \models \psi(\bar{a})$. There is a function $f \in F$ whose restriction to $\{a_1,\dots,a_k\}$ is one-to-one. Define γ by $\gamma(i) := f(a_i)$. Then, γ is a coloring of φ, $\mathcal{A}_f \models \psi_\gamma(\bar{a})$, and hence $\mathcal{A}_f \models \varphi_\gamma$.

Since the family F can be chosen sufficiently small and computed sufficiently fast, the equivalence (5.2) gives rise to a parameterized reduction. □

Remark 5.4. We do not know if the parameterized T-reductions in Theorem 5.3 can be replaced by parameterized m-reductions. However, for many interesting classes C they can be replaced. One such example is the class of all graphs. Similar techniques work for all classes C of graphs for which there exists an algorithm that, given a graph $\mathcal{H} \in C$, computes a connected $\mathcal{H}' \in C$ such that $\mathcal{H}$ is a subgraph of $\mathcal{H}'$. For all such classes C we can show that

$$HOM[s,C] \equiv_{\mathrm{m}}^{\mathrm{fp}} EMB[s,C] \equiv_{\mathrm{m}}^{\mathrm{fp}} MC(\Sigma_1^{\neq}[s,C]) \equiv_{\mathrm{m}}^{\mathrm{fp}} MC(\Sigma_1[s,C])$$

(for all $s \geq 1$).

5.1. Sentences of bounded tree-width. Our main application of Theorem 5.3 is to sentences whose underlying graphs have bounded tree-width. In the time since we submitted this article, considerable progress has been made in this area. For an extensive discussion of model-checking algorithms based on tree-decompositions of the sentences, we refer the reader to [16].

We think of a *tree* $\mathcal{T}$ as directed from its root, which we denote by $r^{\mathcal{T}}$, to the leaves and thus can speak of a *child* and of the *parent* of a vertex.

A *tree-decomposition* of a τ-structure $\mathcal{A}$ is a pair $(\mathcal{T}, (A_t)_{t\in T})$, where $\mathcal{T}$ is a tree and $(A_t)_{t\in T}$ a family of subsets of A such that

(1) for every $a \in A$, the set $\{t \in T \mid a \in A_t\}$ is nonempty and induces a subtree of $\mathcal{T}$ (that is, is connected);
(2) for every k-ary relation symbol $R \in \tau$ and all $a_1,\dots,a_k \in A$ such that $R^{\mathcal{A}}a_1,\dots,a_k$ there exists a $t \in T$ such that $a_1,\dots,a_k \in A_t$.

The *width* of a tree-decomposition $(\mathcal{T}, (A_t)_{t\in T})$ is $\max\{|A_t| \mid t \in T\} - 1$. The *tree-width* $\mathrm{tw}(\mathcal{A})$ of $\mathcal{A}$ is the minimal width of a tree-decomposition of $\mathcal{A}$.

For $s \geq 1$, let W_s denote the class of all structures of tree-width at most s and $GW_s := GRAPH \cap W_s$. Note that $W_s \subseteq STR[s+1]$ because a graph of tree-width s has clique number at most $s+1$.[2] (The clique number of a graph $\mathcal{G}$ is the maximal cardinality of a set of pairwise adjacent vertices of $\mathcal{G}$.)

Plehn and Voigt [27] were the first to realize that tree-width is a relevant parameter for the problems considered in the previous section. They proved that the parameterized embedding problem restricted to (parameter) graphs of bounded tree-width is fixed-parameter tractable. Chekuri and Rajaraman [6] proved that for every $s \geq 1$ the problem $HOM[GW_s]$ is in PTIME (when considered as an unparameterized problem) and therefore fixed-parameter tractable. They phrased their result in terms of the equivalent *conjunctive query containment* problem (see also [24]).

Thus as a corollary of Theorem 5.3 we obtain the following corollary.

COROLLARY 5.5. *Let $s \geq 1$. Then the problems $EMB[GW_s]$, $MC(\Sigma_1[GW_s])$, and $MC(\Sigma_1^{\neq}[GW_s])$ are in* FPT.

Papadimitriou and Yannakakis [26] proved the model-checking results of this corollary for the related case of acyclic conjunctive queries.

Unfortunately, it turns out that Corollary 5.5 is the only real application of Theorem 5.3. Very recently, Grohe, Schwentick, and Segoufin [20] have proved that for every class C of graphs of unbounded tree-width and every $s \geq 2$, the problem $HOM[C, s]$ is W[1]-complete under parameterized T-reductions.

6. FO-model-checking on graphs with excluded minors. The fixed-parameter tractability results of the previous section were obtained by putting syntactical restrictions on the sentences, i.e., the *parameter* of the model-checking problem. In this section we put restrictions on the structures, i.e., the *input* of the model-checking problem.

Recall the definition of the parameterized problem $MC(\Phi)|_D$ for a class Φ of formulas and a class D of structures:

$MC(\Phi)\|_D$		
	Input:	$\mathcal{A} \in STR$.
	Parameter:	$\varphi \in \Phi$.
	Question:	Is $\mathcal{A} \in D$ and $\mathcal{A} \models \varphi$?

Our starting point is the following theorem due to Courcelle [7]. Remember that *monadic second-order logic* is the extension of first-order logic where one is allowed to quantify not only over individual elements of a structure but also over sets of elements. MSO denotes the class of all formulas of monadic second-order logic. Remember that W_s denotes the class of all structures of tree-width at most s (for $s \geq 0$).

THEOREM 6.1 (see [7]). *Let $s \geq 0$. Then $MC(\mathrm{MSO})|_{W_s}$ is in* FPT.

A graph $\mathcal{H}$ is a *minor* of a graph $\mathcal{G}$ (we write $\mathcal{H} \preceq \mathcal{G}$) if $\mathcal{H}$ can be obtained from a subgraph of $\mathcal{G}$ by contracting edges. $\mathcal{H}$ is an *excluded minor* for a class D if $\mathcal{H}$ is not a minor of any graph in D. Note that a class D of graphs has an excluded minor if and only if there is an $n \in \mathbb{N}$ such that $\mathcal{K}_n$ is an excluded minor for D.

[2] This is slightly imprecise because a structure $\mathcal{A} \in W_s$ might have a vocabulary of arbitrarily high arity, as long as no tuple contained in a relation of $\mathcal{A}$ consists of more than $s+1$ distinct elements. However, since any structure with this property can easily be transformed to an $(s+1)$-ary structure that is essentially the same, we decided to accept this imprecision in exchange for a simpler notation.

Examples of classes of graphs with an excluded minor are classes of graphs of bounded tree-width or classes of graphs embeddable in a fixed surface.

Recall that for a class D of graphs, $STR[D]$ denotes the class of all structures whose Gaifman graph is in C.

THEOREM 6.2. *Let D be a* PTIME*-decidable class of graphs with an excluded minor. Then $MC(\mathrm{FO})|_{STR[D]}$ is in* FPT.

The rest of this section is devoted to the proof of this theorem, which needs some preparation.

A class D of graphs is called *minor closed* if for all $\mathcal{G} \in D$ and $\mathcal{H} \preceq \mathcal{G}$ we have $\mathcal{H} \in D$. Robertson and Seymour proved the following theorem.

THEOREM 6.3 (see [28]). *Every minor-closed class of graphs is* PTIME*-decidable.*

This, together with Theorem 6.2, immediately yields the following corollary.

COROLLARY 6.4. *Let $D \subsetneq GRAPH$ be minor closed. Then $MC(\mathrm{FO})|_{STR[D]}$ is in* FPT.

Recall the definition of the Gaifman graph $\mathcal{G}(\mathcal{A})$ of a structure $\mathcal{A}$ (cf. p. 127). The distance $d^{\mathcal{A}}(a,b)$ between $a, b \in A$ is the length of the shortest path from a to b in $\mathcal{G}(\mathcal{A})$. For $r \in \mathbb{N}$ and $a \in A$, the *r-ball* around a is the set $B_r^{\mathcal{A}}(a) := \{b \in A \mid d^{\mathcal{A}}(a,b) \leq r\}$. For an $X \subseteq A$, $\langle X \rangle^{\mathcal{A}}$ denotes the substructure induced by $\mathcal{A}$ on X, i.e., the structure with universe X and $R^{\langle X \rangle^{\mathcal{A}}} = R^{\mathcal{A}} \cap X^r$ for all r-ary relation symbols R in the vocabulary of $\mathcal{A}$. Furthermore, we let $\mathcal{A} \setminus X := \langle A \setminus X \rangle^{\mathcal{A}}$.

The *local tree-width* of $\mathcal{A}$ is the function $\mathrm{ltw}(\mathcal{A}) : \mathbb{N} \to \mathbb{N}$ defined by

$$\mathrm{ltw}(\mathcal{A})(r) := \max\big\{\mathrm{tw}(\langle B_r^{\mathcal{A}}(a)\rangle^{\mathcal{A}}) \;\big|\; a \in A\big\}.$$

For functions $f, g : \mathbb{N} \to \mathbb{N}$ we write $f \leq g$ if $f(n) \leq g(n)$ for all $n \in \mathbb{N}$. A class D of structures has *bounded local tree-width* if there is a function $\lambda : \mathbb{N} \to \mathbb{N}$ such that for all $\mathcal{A} \in D$ we have $\mathrm{ltw}(\mathcal{A}) \leq \lambda$.

The "local" character of first-order formulas allows us to generalize Theorem 6.1 for first-order logic from classes of structures of bounded tree-width to classes of structures of bounded local tree-width.

THEOREM 6.5 (see [17]). *Let D be a* PTIME*-decidable class of structures of bounded local tree-width. Then $MC(\mathrm{FO})|_D$ is in* FPT.

For $\lambda : \mathbb{N} \to \mathbb{N}$ we let

$$GL(\lambda) := \big\{\mathcal{G} \in GRAPH \;\big|\; \forall \mathcal{H} \preceq \mathcal{G} :\ \mathrm{ltw}(\mathcal{H}) \leq \lambda\big\},$$

and, for $\mu \in \mathbb{N}$,

$$B(\lambda,\mu) := \big\{\mathcal{A} \in STR \;\big|\; \exists X \subseteq A\ (|X| \leq \mu \wedge \mathcal{G}(\mathcal{A} \setminus X) \in GL(\lambda))\big\}.$$

Note that the clique-number of a graph in $GL(\lambda)$ is at most $\lambda(1)+1$; thus the clique-number of a graph in $B(\lambda,\mu)$ is at most $\mu + \lambda(1) + 1$. This implies that $B(\lambda,\mu) \subseteq STR[\mu + \lambda(1) + 1]$.[3]

LEMMA 6.6. *Let $\lambda : \mathbb{N} \to \mathbb{N}$ and $\mu \in \mathbb{N}$. Then $MC(\mathrm{FO})|_{B(\lambda,\mu)}$ is in* FPT.

Proof. The class $GL(\lambda)$ of graphs is minor closed and hence PTIME-decidable by Theorem 6.3. This implies that $B(\lambda,\mu)$ is PTIME-decidable.

Then for $\mu = 0$ the statement follows from Theorem 6.5. The case $\mu > 0$ can be reduced to the case $\mu = 0$ as follows: For every $\mathcal{A} \in \mathcal{B}(\lambda,\mu)$ and sentence $\varphi \in \mathrm{FO}$, we define a structure $\mathcal{A}^* \in B(\lambda,0)$ and a sentence $\varphi^* \in \mathrm{FO}$ in such a way that $A \models \varphi$

[3] Cf. footnote 2.

if and only if $\mathcal{A}^* \models \varphi^*$, and the mappings $\mathcal{A} \mapsto \mathcal{A}^*$ and $\varphi \mapsto \varphi^*$ are computable in polynomial time.

Therefore, suppose we are given $\mathcal{A} \in \mathcal{B}(\lambda, \mu)$ and $\varphi \in$ FO. For simplicity, we assume that their vocabulary consists of a single binary relation symbol E.

Let $X \subseteq A$ such that $|X| \leq \mu$ and $\mathcal{A} \setminus X \in B(\lambda, 0)$. Such an X can be computed in polynomial time because the class $B(\lambda, 0)$ is PTIME-decidable. Say, $X = \{a_1, \ldots, a_\mu\}$.

Let $\tau := \{E, P_1, \ldots, P_\mu, Q_1, \ldots, Q_\mu, R_1, \ldots, R_\mu\}$, where the P_i, Q_i, and R_i are unary. We let $A^* := A$, $E^{\mathcal{A}^*} := E^{\mathcal{A}} \cap (A \setminus X)^2$, and, for $1 \leq i \leq \mu$,

$$\begin{aligned} P_i^{\mathcal{A}^*} &:= \{a_i\}, \\ Q_i^{\mathcal{A}^*} &:= \{b \in A \mid E^{\mathcal{A}} a_i b\}, \\ R_i^{\mathcal{A}^*} &:= \{b \in A \mid E^{\mathcal{A}} b a_i\}. \end{aligned}$$

Furthermore, we let φ^* be the sentence obtained from φ by replacing each subformula Exy by

$$Exy \vee \bigvee_{i=1}^{\mu} ((P_i x \wedge Q_i y) \vee (P_i y \wedge R_i x)).$$

Clearly, these definitions lead to the desired result. □

To complete the proof of Theorem 6.2 we use a decomposition theorem for non-trivial minor-closed classes of graphs that roughly says that all graphs in such a class are built up in a tree-like manner from graphs in a $B(\lambda, \mu)$. It is based on Robertson and Seymour's deep structure theory for graphs without $\mathcal{K}_n$-minors. The precise statement requires some new notation. Let $(\mathcal{T}, (A_t)_{t \in T})$ be a tree-decomposition of a structure $\mathcal{A}$. The *torso* of this decomposition at $t \in \mathcal{T}$, denoted by $[A_t]$, is the graph with universe A_t and an edge between two distinct vertices $a, b \in A_t$ if either there is an edge between a and b in the Gaifman graph $\mathcal{G}(\mathcal{A})$ or there exists an $s \in T \setminus \{t\}$ such that $a, b \in A_s$. $(\mathcal{T}, (A_t)_{t \in T})$ is a tree-decomposition *over* a class D of graphs if all its torsos belong to D.

THEOREM 6.7 (see [19]). *Let D be a class of graphs with an excluded minor. Then there exist $\lambda : \mathbb{N} \to \mathbb{N}$ and $\mu \in \mathbb{N}$ such that every $\mathcal{G} \in D$ has a tree-decomposition over $B(\lambda, \mu)$.*

Furthermore, given $\mathcal{G}$, such a decomposition can be computed in PTIME.

Clearly, this theorem implies the analogous statement for all structures in $STR[D]$.

The *adhesion* of a tree-decomposition $(\mathcal{T}, (A_t)_{t \in T})$ is $\max\{|A_s \cap A_t| \mid E^{\mathcal{T}} st\}$. The *clique number* of a class of structures is the maximum of the clique numbers of the Gaifman graphs of structures in D, if this maximum exists, or ∞ otherwise. Note that if $(\mathcal{T}, (A_t)_{t \in T})$ is a decomposition over a class D, then the clique-number of D is an upper bound for the adhesion of $(\mathcal{T}, (A_t)_{t \in T})$. Remembering that the clique-number of $B(\lambda, \mu)$ is $\lambda(1) + \mu + 1$, we see that the adhesion of a tree-decomposition over $B(\lambda, \mu)$ is at most $\lambda(1) + \mu + 1$.

Proof of Theorem 6.2. Let D be a PTIME-decidable class of graphs with an excluded minor and λ, μ such that every $\mathcal{G} \in D$ has a tree-decomposition over $B(\lambda, \mu)$. Let $\nu := \lambda(1) + \mu + 1$.

We shall describe an algorithm that, given $\mathcal{A} \in STR[D]$ and $\varphi \in$ FO, decides if $A \models \varphi$.

Therefore let $\mathcal{A} \in STR[D]$, say, of vocabulary τ and $\varphi \in \mathrm{FO}[\tau]$. Our algorithm starts by computing a tree-decomposition $(\mathcal{T}, (A_t)_{t \in T})$ of $\mathcal{A}$ over $B(\lambda, \mu)$. For $t \in T$

we let $A_{\geq t} := \bigcup_{u \geq t} A_u$ ($u \geq t$ if there is a path from t to u in the (directed) tree $\mathcal{T}$). In particular, $A_{\geq r} = A$ for the root $r := r^{\mathcal{T}}$ of $\mathcal{T}$.

Furthermore, we let $B_r := \emptyset$ and $B_t := A_t \cap A_s$ for $t \in T \setminus \{r\}$ with parent s. Recall that the adhesion of $(\mathcal{T}, (A_t)_{t \in T})$ is at most ν. Thus $|B_t| \leq \nu$ for $t \in T$.

The *quantifier rank* of a first-order formula is the maximal depth of nested quantifiers in this formula. Let q be the quantifier rank of φ. Simple techniques from logic show that there is an algorithm that, given a vocabulary τ and $q, m \in \mathbb{N}$, computes a finite set $\Phi_{\tau,q,m}$ of first-order formulas of vocabulary τ of quantifier rank $\leq q$ with free variables among $v_1, \dots, v_m$ such that every such formula is equivalent to a formula in $\Phi_{\tau,q,m}$. Without loss of generality we can assume that $\varphi \in \Phi_{\tau,q,m}$ (otherwise we can compute a $\varphi' \in \Phi_{\tau,q,m}$ equivalent to φ and work with φ').

A (τ, q, m)-*type* is a subset of $\Phi_{\tau,q,m}$. Given a τ-structure $\mathcal{A}'$ and a set $B = \{b_1, \dots, b_m\} \subseteq A'$ let $\operatorname{tp}_q^{\mathcal{A}'}(B)$—more precisely, $\operatorname{tp}_q^{\mathcal{A}'}(b_1, \dots, b_m)$—be the (τ, q, m)-type

$$\operatorname{tp}_q^{\mathcal{A}'}(B) := \{\psi(v_1, \dots, v_m) \in \Phi_{\tau,q,m} \mid \mathcal{A}' \models \psi(b_1, \dots, b_m)\}.$$

We come back to our structure $\mathcal{A}$ and the tree-decomposition $(\mathcal{T}, (A_t)_{t \in T})$. By induction from the leaves to the root, for every $t \in T$ we compute $\operatorname{tp}_q^{\langle A_{\geq t} \rangle^{\mathcal{A}}}(B_t)$, which for brevity we denote by $\operatorname{tp}_q^{\geq t}(B_t)$. Since $B_r = \emptyset$, $\operatorname{tp}_q^{\geq r}(B_r)$ is a set of sentences, and we have $\mathcal{A} \models \varphi$ if and only if $\varphi \in \operatorname{tp}_q^{\geq r}(B_r)$.

Therefore let t be a vertex of $\mathcal{T}$ and assume that we have already computed $\operatorname{tp}_q^{\geq u}(B_u)$ for all children u of t (if there are any). (Actually, the case that t has no children is much simpler than the following general case because it is a direct application of Lemma 6.6.)

For every (τ, q, m)-type Φ we introduce a new $(m+1)$-ary relation symbol R_Φ. Furthermore, we let $P_1, \dots, P_\nu$ be new unary relation symbols and $\tau' := \tau \cup \{R_\Phi \mid m \leq \nu, \Phi \text{ a } (\tau, q, m)\text{-type}\} \cup \{P_1, \dots, P_\nu\}$. In four steps, we define a τ'-structure $\widetilde{\mathcal{A}}_t$ that contains all the relevant information to compute $\operatorname{tp}_q^{\geq t}(B_t)$. In the first three steps we define "intermediate" structures $\mathcal{A}_t^1$, $\mathcal{A}_t^2$, $\mathcal{A}_t^3$.

(1) $\mathcal{A}_t^1$ is the induced substructure of $\mathcal{A}$ with universe A_t.

(2) Suppose that $B_t = \{b_1, \dots, b_m\}$ for an $m \leq \nu$. Then $\mathcal{A}_t^2$ is the $\tau \cup \{P_1, \dots, P_\nu\}$-expansion of $\mathcal{A}_t^1$ with $P_i^{\mathcal{A}_t^2} := \{b_i\}$ for $1 \leq i \leq m$ and $P_i^{\mathcal{A}_t^2} := \emptyset$ for $m+1 \leq i \leq \nu$.

(3) $\mathcal{A}_t^3$ is obtained from $\mathcal{A}_t^2$ by adding a new vertex c_u for every child u of t and edges from c_u to all vertices of B_u.

(4) $\widetilde{\mathcal{A}}_t$ is the τ'-expansion of $\widetilde{\mathcal{A}}_t^3$ with

$$R_\Phi^{\widetilde{\mathcal{A}}_t} := \big\{(d_1, \dots, d_{m_u}, c_u) \;\big|\; u \text{ child of } t, \; B_u = \{d_1, \dots, d_{m_u}\}, \operatorname{tp}_q^{\geq u}(B_u) = \Phi\big\}.$$

Standard Ehrenfeucht–Fraïssé-type methods show that there is a computable function that associates with every formula $\psi \in \Phi_{\tau,q,m}$ a sentence $\widetilde{\psi} \in \mathrm{FO}[\tau']$ such that $\psi \in \operatorname{tp}_q^{\geq t}(B_t)$ if and only if $\widetilde{\mathcal{A}}_t \models \widetilde{\psi}$.

We claim that $\widetilde{\mathcal{A}}_t \in B(\lambda + 1, \mu)$. To see this, observe that the Gaifman graph $\mathcal{G}(\widetilde{\mathcal{A}}_t)$ is the graph obtained from the torso $[A_t]$ by adding the vertices c_u and edges between c_u and every element of B_u. Recall that, by the definition of the torso, each B_u is a clique in $[A_t]$. It is easy to see that adding vertices and connecting them with cliques can increase the tree-width of a graph by at most one. This implies the claim.

ModelCheck$_D$($\mathcal{A} \in STR$, $\varphi \in$ FO)

1 **if** $\mathcal{G}(\mathcal{A}) \notin D$ **then** reject
2 compute tree-decomposition $(\mathcal{T}, (A_t)_{t\in T})$ of $\mathcal{A}$ over $B(\lambda, \mu)$
3 $q := \mathrm{qr}(\varphi)$, $\tau :=$ vocabulary of φ
4 **for** $m = 0$ **to** ν
5 compute $\Phi_{\tau,q,m}$
6 **for all** $t \in T$ (from the leaves to the root)
7 compute $\widetilde{\mathcal{A}}_t$
8 $\mathrm{tp}_q^{\geq t}(B_t) := \emptyset$
9 $m := |B_t|$
10 **for all** $\psi \in \Phi_{\tau,q,m}$
11 compute $\widetilde{\psi}$
12 **if** $\widetilde{\mathcal{A}}_t \models \widetilde{\psi}$
13 **then** $\mathrm{tp}_q^{\geq t}(B_t) := \mathrm{tp}_q^{\geq t}(B_t) \cup \{\psi\}$
14 **if** $\varphi \in \mathrm{tp}_q^{\geq r}(B_r)$
15 **then** accept
16 **else** reject.

Algorithm 2.

Now we can put everything together and obtain an algorithm for $MC(\mathrm{FO})_{STR[D]}$, a high-level description of which is given as Algorithm 2. Its correctness is straightforward. Let us have a look at the running time: Let n be the size of the input structure. Then lines 1 and 2 require time polynomial in n (independently of φ). The time required in lines 3–5 only depends on φ. The main loop in lines 6–13 is called $|T|$ times, which is polynomial in n. Computing $\widetilde{\mathcal{A}}_t$ is polynomial in $|A_t|$ and the number of children of t since we have already computed $\mathrm{tp}_q^{\geq u}(B_u)$ for all children u of t (with constants heavily depending on $||\varphi||$). The main task is to decide whether $\widetilde{\mathcal{A}}_t \models \widetilde{\psi}$ in line 12; by Lemma 6.6 this is fixed-parameter tractable because $\widetilde{\mathcal{A}}_t \in B(\lambda + 1, \mu)$. The time required in lines 14–16 again depends only on φ. □

A consequence of our results is that slicewise first-order definable parameterized problems are fixed-parameter tractable when restricted to classes of structures whose underlying class of graphs has an excluded minor.

Corollary 6.8. *Let D be a* PTIME*-decidable class of graphs with an excluded minor and $P \subseteq STR \times \Pi^*$ a parameterized problem that is slicewise* FO*-definable. Then $P|_{STR[D]}$ is in* FPT.

7. A logical characterization of fixed-parameter tractability. In this section we give a characterization of FPT in the spirit of descriptive complexity theory.

We briefly review some facts from this area (see [13, 22] for details). It is common in descriptive complexity theory to identify decision problems, usually modeled by languages $L \subseteq \Sigma^*$ for a finite alphabet Σ, with classes of finite structures. More precisely, one identifies problems with classes of *ordered finite structures*. An *ordered structure* is a structure whose vocabulary contains the binary relation symbol $\leq$, and this symbol is interpreted as a linear order of the universe. *ORD* denotes the class of all ordered structures. In this section, τ always denotes a vocabulary that contains $\leq$.

One of the most important results in descriptive complexity theory is the Immer-

man–Vardi theorem [21, 30] saying that a class of ordered structures is in PTIME if and only if it is definable in least-fixed point logic FO(LFP). More concisely,

$$\text{PTIME} = \text{FO(LFP)}.$$

We prove a similar result characterizing the class FPT in terms of the finite variable least fixed-point logics LFP^s, for $s \geq 1$, which were introduced by Kolaitis and Vardi [25]. Analogously to the classical setting we model parameterized problems by subsets of $ORD[\tau] \times \mathbb{N}$ for some τ.

THEOREM 7.1. *A parameterized problem $P \subseteq ORD[\tau] \times \mathbb{N}$ is in* FPT *if and only if there is an $s \geq 1$ such that P is slicewise* LFP^s*-definable. More concisely, we may write*

$$\text{FPT} = \bigcup_{s \geq 1} \text{slicewise-LFP}^s.$$

In the proof of this result we assume that the reader is familiar with descriptive complexity theory, in particular with least fixed-point logic and the proof of the Immerman–Vardi theorem. Those who are not may safely skip the rest of this section.

We first recall the definition of LFP^s: In the terminology of [13, p. 174], LFP^s-sentences are FO(LFP)-sentences in the form

$$\exists \bar{y}[\text{S–LFP}_{\bar{x}_1, X_1, \ldots, \bar{x}_m, X_m} \varphi_1, \ldots, \varphi_m]\bar{y},$$

where $\varphi_1, \ldots, \varphi_m$ are first-order formulas with at most s individual variables. (That is, LFP^s-sentences are existential closures of simultaneous fixed-points over FO^s-formulas.)

We use the following two facts, the first implicit in [31] and the second in the proof of the Immerman–Vardi theorem (cf. [13]). Fix τ and $s \in \mathbb{N}$ and let n always denote the size of the input structure.

(1) There is a computable function that associates an $O(n^{2s})$-algorithm $\mathbb{A}_\varphi$ with each $\varphi \in \text{LFP}^s[\tau]$ such that $\mathbb{A}_\varphi$ accepts a structure $\mathcal{A} \in ORD[\tau]$ if and only if $\mathcal{A}$ satisfies φ.

(2) There is a $t \in \mathbb{N}$ and a computable function that associates with every $O(n^s)$-algorithm $\mathbb{A}$ accepting a class $C \subseteq ORD[\tau]$ a sentence $\varphi_\mathbb{A} \in \text{LFP}^t[\tau]$ such that a τ-structure $\mathcal{A}$ satisfies $\varphi_\mathbb{A}$ if and only if $\mathcal{A} \in C$.

There is a slight twist in (2). When proving it, one usually assumes that all structures are sufficiently large, in particular larger than the constant hidden in $O(n^s)$. This way it can be assumed that the algorithm is actually an n^{s+1}-algorithm (without any hidden constants). Then one argues that small structures are no problem because they can be described up to isomorphism in first-order logic. When restricting the number of variables, one has to be careful with such an argument. Luckily, we are safe here because we consider only ordered structures, and there is a $t \in \mathbb{N}$ (depending on τ) such that every structure $\mathcal{A} \in ORD[\tau]$ can be characterized up to isomorphism by an FO^t-sentence.

Proof of Theorem 7.1. For the backward direction, suppose that $P \subseteq ORD[\tau] \times \mathbb{N}$ is slicewise LFP^s-definable via $\delta : \mathbb{N} \to \text{LFP}^s$. Then Algorithm 3 shows that P is in FPT. The crucial fact is that lines 1 and 2 do not depend on the input structure $\mathcal{A}$ and line 3 requires time $O(n^{2s})$.

For the forward direction, suppose that $P \subseteq ORD[\tau] \times \mathbb{N}$ is in FPT. Choose $f : \mathbb{N} \to \mathbb{N}$, $c \in \mathbb{N}$ and an algorithm $\mathbb{A}$ deciding P in time $f(k) \cdot n^c$. The algorithm

```
DECIDE-P(𝒜 ∈ ORD, k ∈ ℕ)
1  compute δ(k) ∈ LFP^s
2  compute 𝔸_δ(k) (cf. (1))
3  simulate 𝔸_δ(k) on input 𝒜
4  if 𝔸_δ(k) accepts 𝒜
5      then accept
6      else reject.
```

Algorithm 3.

$\mathbb{A}$ gives rise to a sequence $\mathbb{A}_k$ ($k \geq 1$) of algorithms, where $\mathbb{A}_k$ decides the class $\{\mathcal{A} \mid (\mathcal{A}, k) \in P\} \subseteq ORD[\tau]$ in time $O(n^c)$. Then (2) yields the desired slicewise definition of P. □

8. Beyond FPT. In this last section we discuss how logical definability is related to the classes of the W-hierarchy. We introduce another hierarchy of parameterized problems, which we call the A-hierarchy, in terms of model-checking problems for first-order logic and show that the A-hierarchy can be seen as a parametric analogue of the polynomial hierarchy. We then discuss the relation between the A-hierarchy and the W-hierarchy.

Our treatment is motivated by the following two results. They relate the class W[1] to model-checking and computations of nondeterministic Turing machines, respectively. Recall that $MC(\Sigma_1[s])$ denotes the parameterized model-checking problem for existential formulas in prenex normal form whose vocabulary contains at most s-ary relation symbols.

THEOREM 8.1 (Downey, Fellows, and Regan [11]). *$MC(\Sigma_1)|_{GRAPH}$ is* W[1]*-complete under parameterized m-reductions.*

Proof. We prove that $CLIQUE \equiv^{\mathrm{fp}}_{\mathrm{m}} MC(\Sigma_1)|_{GRAPH}$.

$CLIQUE \leq^{\mathrm{fp}}_{\mathrm{m}} MC(\Sigma_1)|_{GRAPH}$ follows from the fact that *CLIQUE* is slicewise Σ_1-definable, so we only have to prove the converse.

An *atomic k-type* (in the theory of graphs) is a sentence $\theta(x_1, \dots, x_k)$ of the form $\bigwedge_{1 \leq i < j \leq k} \alpha_{ij}(x_i, x_j)$, where $\alpha_{ij}(x_i, x_j)$ is either $x_i = x_j$ or Ex_ix_j or $(\neg Ex_ix_j \wedge \neg x_i = x_j)$ (for $1 \leq i < j \leq k$).

It is easy to see that there is a computable mapping f that associates with every EFO-sentence φ a sentence $\tilde{\varphi}$ of the form

$$\bigvee_{i=1}^{l} \exists x_1 \dots \exists x_k \theta_i(x_1, \dots, x_k), \tag{8.1}$$

where each θ_i is an atomic k-type, such that for all graphs $\mathcal{G}$ we have $\mathcal{G} \models \varphi \iff \mathcal{G} \models \tilde{\varphi}$.

For each graph $\mathcal{G}$ and each atomic k-type $\theta(\bar{x}) = \bigwedge_{1 \leq i < j \leq k} \alpha_{ij}(x_i, x_j)$ we define a graph $h(\mathcal{G}, \theta)$ as follows:

- The universe of $h(\mathcal{G}, \theta)$ is $\{1, \dots, k\} \times G$.
- There is an edge between (i, v) and (j, w), for $1 \leq i < j \leq k$ and $v, w \in G$, if $\mathcal{G} \models \alpha_{ij}(v, w)$.

Then $h(\mathcal{G}, \theta)$ contains a k-clique if and only if $\mathcal{G} \models \exists \bar{x} \theta(\bar{x})$. Now we are ready to define the reduction from $MC(\Sigma_1)|_{GRAPH}$ to *CLIQUE*. Given an instance $(\mathcal{G}, \varphi)$ of

$MC(\Sigma_1)|_{GRAPH}$, we first compute the sentence

$$\tilde{\varphi} = \bigvee_{i=1}^{l} \exists x_1 \dots \exists x_k \theta_i.$$

We let $\mathcal{G}'$ be the disjoint union of the graphs $h(\mathcal{G}, \theta_i)$ for $1 \leq i \leq l$. Then $\mathcal{G}'$ has a k-clique if and only if $\mathcal{G} \models \varphi$. □

THEOREM 8.2 (Cai et al. [4]). *The following parameterized problem SHORT TURING MACHINE ACCEPTANCE (NM)*[4] *is* W[1]*-complete:*

NM	*Input:*	A nondeterministic Turing machine M.
	Parameter:	$k \in \mathbb{N}$.
	Question:	Does M accept the empty word in at most k steps?

Downey and Fellows call Theorem 8.2 a parameterized "analogue of Cook's theorem." In our notation, we may write $[NM]^{\mathrm{fp}}_{\mathrm{m}} = \mathrm{W}[1]$. It is now very natural to define the following "parameterized analogue of the polynomial hierarchy," which we call the A*-hierarchy*, by letting $\mathrm{A}[t] := [AM_t]^{\mathrm{fp}}_{\mathrm{m}}$ for all $t \geq 1$:

AM_t	*Input:*	An alternating Turing machine M whose initial state is existential.
	Parameter:	$k \in \mathbb{N}$.
	Question:	Does M accept the empty word in at most k steps with at most t alternations?

Note that $NM = AM_1$; thus $\mathrm{W}[1] = \mathrm{A}[1]$. Our following theorem can be seen as a natural generalization of Theorem 8.1.

THEOREM 8.3. *For all $t \geq 1$, the problem $MC(\Sigma_t)|_{GRAPH}$ is* A$[t]$*-complete under parameterized m-reductions. Thus*

$$\mathrm{A}[t] = [MC(\Sigma_t)|_{GRAPH}]^{\mathrm{fp}}_{\mathrm{m}} = \bigcup_{s \geq 1} [MC(\Sigma_t[s])]^{\mathrm{fp}}_{\mathrm{m}}.$$

Proof. The second equality follows from Corollary 3.4(3).

To prove that $MC(\Sigma_t)|_{GRAPH} \leq^{\mathrm{fp}}_{\mathrm{m}} AM_t$, we first observe that, for every graph $\mathcal{G}$ and every quantifier-free formula $\theta(x_1, \dots, x_m)$, in time $p(||\theta||) \cdot |G|^2$, for a suitable polynomial p, we can construct a deterministic Turing machine $M(\mathcal{G}, \theta)$ with input alphabet G that accepts an input word $a_1 \dots a_m$ over G if and only if $\mathcal{G} \models \theta(a_1, \dots, a_m)$ and that performs at most $f(||\theta||)$ steps for some computable function $f : \mathbb{N} \to \mathbb{N}$. Only to give an example, to check whether $Ex_k x_l$ holds, say, with $k < l$, we need states $s(i)$ for $1 \leq i \leq k$ and $s(i, a)$ for $k < i \leq l, a \in G$. The machine starts in state $s(1)$ with head in position 1 in state $s(1)$. It moves its head right until it reaches position k in state $s(k)$, reads a_k, and goes to position $(k+1)$ in state $s(k+1, a_k)$. Then it moves right again until it reaches position l in state $s(l, a_k)$. From this state it can reach an accepting state if and only if $E^{\mathcal{G}} a_k a_l$.

[4] *NM* stands for nondeterministic Turing machine. This notation should be seen in connection with the AM_t below, which refers to alternating Turing machines.

Now suppose we are given an instance of $MC(\Sigma_t)|_{GRAPH}$, i.e., a graph $\mathcal{G}$ and a sentence

$$\varphi = \exists x_{11} \dots \exists x_{1k_1} \forall x_{21} \dots \forall x_{2k_2} \ \dots \ Q x_{t1} \dots Q x_{tk_t} \ \theta,$$

where θ is quantifier-free. Then the following alternating Turing machine $M(\mathcal{G}, \varphi)$ accepts the empty word if and only if $\mathcal{G} \models \varphi$: It first writes a sequence of elements of $\mathcal{G}$ on the tape using existential and universal states appropriately and then simulates $M(\mathcal{G}, \theta)$ on this input. Again $g(||\theta||)$, for some computable function g, is an upper bound for the number of steps $M(\mathcal{G}, \varphi)$ has to perform.

To finish the proof, by Corollary 3.4(3) it suffices to show that $\mathrm{AM}_t \leq^{\mathrm{fp}}_{\mathrm{m}} MC(\Sigma_t[\tau])$ for a suitable vocabulary τ. To illustrate the idea, we first consider the case $t = 1$. Suppose we are given a nondeterministic Turing machine M with alphabet Σ, set Q of states, initial state q_0, accepting state q_{acc}, and transition relation δ. Let $\Sigma_H := \{a_H \mid a \in \Sigma\}$, a_H coding the information that the head of M scans a cell containing a. Let $\tau := \{ST, AL, H, IN, ACC, R, L, S\}$ with unary ST, AL, H, IN, ACC and 4-ary R, L, S and let $\mathcal{A}_M$ be the τ-structure given by

$$\begin{aligned}
&A_M := Q \dot\cup \Sigma \dot\cup \Sigma_H,\\
&ST^{\mathcal{A}_M} := Q, \qquad AL^{\mathcal{A}_M} := \Sigma, \qquad H^{\mathcal{A}_M} := \Sigma_H,\\
&IN^{\mathcal{A}_M} := \{q_0\}, \quad ACC^{\mathcal{A}_M} := \{q_{\mathrm{acc}}\},\\
&R^{\mathcal{A}_M} := \{(q, a_H, b, q') \mid (q, a, 1, b, q') \in \delta\},\\
&L^{\mathcal{A}_M} := \{(q, a_H, b, q') \mid (q, a, -1, b, q') \in \delta\},\\
&S^{\mathcal{A}_M} := \{(q, a_H, b_H, q') \mid (q, a, 0, b, q') \in \delta\} \cup \{(q_{\mathrm{acc}}, a_H, a_H, q_{\mathrm{acc}}) \mid a \in \Sigma\},
\end{aligned}$$

where $(q, a, h, b, q') \in \delta$ means that if M is in state q and its head scans $a \in \Sigma$, then M replaces a by b, moves its head one cell to the right ($h = 1$), moves to the left ($h = -1$), or does not move its head ($h = 0$); finally, it changes to state q'.

Let k be given as parameter for AM_1. In k steps, M scans at most the first k cells. The quantifier-free formula (note that the following formulas depend only on k and not on M)

$$\varphi_{\mathrm{config}}(x, y_1, \dots, y_k) := STx \wedge \bigvee_{i=1}^{k} \left(Hy_i \wedge \bigwedge_{j \neq i} ALy_j \right)$$

states that $(x, y_1, \dots, y_k)$ is a configuration with state x, with the head facing y_i, and with y_j being the content of the jth cell ($j \neq i$). Let $\varphi_{\mathrm{start}}(x, y_1, \dots, y_k)$ be a quantifier-free formula stating that $(x, y_1, \dots, y_k)$ is the starting configuration. Similarly, we define a quantifier-free formula $\varphi_{\mathrm{step}}(x, y_1, \dots, y_k, x', y'_1, \dots, y'_k)$ stating that the configuration $(x', y'_1, \dots, y'_k)$ is the successor configuration of $(x, y_1, \dots, y_k)$ (we agree that each accepting configuration is its own successor).

Now, the equivalence

$$M \text{ stops in } \leq k \text{ steps} \iff \mathcal{A}_M \models \varphi_k$$

holds for the following existential sentence φ_k:

$$\begin{aligned}
&\exists x_1 \exists y_{11} \dots \exists y_{1k} \ \dots \ \exists x_k \exists y_{k1} \dots \exists y_{kk} (\varphi_{\mathrm{start}}(x, y_{11}, \dots, y_{1k})\\
&\quad \wedge \textstyle\bigwedge_{i=1}^{k-1} \varphi_{\mathrm{step}}(x_i, y_{i1}, \dots, y_{ik}, x_{i+1}, y_{i+11}, \dots, y_{i+1k}) \wedge ACCx_k).
\end{aligned}$$

For $t \geq 1$, we can proceed similarly with the addition that universal quantifiers are needed to take care of universal states of the input machine. Now, τ also contains two

further unary symbols F (for the existential states) and U (for the universal states) which get the corresponding interpretations in $\mathcal{A}_M$. For example, for $t = 2$, we can take a Σ_t-sentence equivalent to

$$\begin{aligned}
&\bigvee_{l\le k} \exists x_1\, \exists y_{11} \ldots \exists y_{1k} \;\ldots\; \exists x_k \exists y_{l1} \ldots \exists y_{lk} \\
&\quad \Big(\varphi_{\text{start}}(x, y_{11}, \ldots, y_{1k}) \\
&\wedge \textstyle\bigwedge_{i=1}^{l-1} \varphi_{\text{step}}(x_i, y_{i1}, \ldots, y_{ik}, x_{i+1}, y_{i+1\,1}, \ldots, y_{i+1\,k}) \\
&\wedge Fx_1 \wedge \ldots \wedge Fx_{l-1} \wedge Ux_l \\
&\wedge \forall x_{l+1} \forall y_{l+1\,1} \ldots \forall y_{l+1\,k} \;\ldots\; \forall x_k \forall y_{k1} \ldots \forall y_{kk} \\
&\qquad \big(\big(Ux_{l+1} \wedge \ldots \wedge Ux_{k-1} \\
&\qquad \wedge \textstyle\bigwedge_{i=l}^{k-1} \varphi_{\text{step}}(x_i, y_{i1}, \ldots, y_{ik}, x_{i+1}, y_{i+1\,1}, \ldots, y_{i+1\,k}) \big) \to ACCx_k \big) \Big).
\end{aligned}$$

(Without loss of generality we assume that the accepting state is both existential and universal and that at least one transition is always possible in a universal state.) □

The following result due to Downey, Fellows, and Regan [11] allows us to compare the W- and the A-hierarchy. Let $t, u \ge 1$. A formula φ is $\Sigma_{t,u}$ if it is Σ_t and all quantifier blocks after the leading existential block have length $\le u$.

THEOREM 8.4 (see [11]). *For all $t \ge 1$,*

$$\mathrm{W}[t] = \bigcup_{\substack{\tau \text{ vocabulary} \\ u \ge 1}} [MC(\Sigma_{t,u}[\tau])]^{\mathrm{fp}}_{\mathrm{m}} = \bigcup_{u \ge 1} [MC(\Sigma_{t,u})|_{GRAPH}]^{\mathrm{fp}}_{\mathrm{m}}.$$

Note that for $t = 1$, this is Theorem 8.1. The crucial step in proving the theorem for $t \ge 2$ is to establish the W[t]-completeness of the problems *WEIGHTED MONOTONE t-NORMALIZED SATISFIABILITY* (for even t) and *WEIGHTED ANTIMONOTONE t-NORMALIZED SATISFIABILITY* (for odd $t \ge 3$). We refer the reader to [10] for the (difficult) proofs of these results. Once these basic completeness results are established, it is relatively easy to derive Theorem 8.4 (cf. also our proof of Theorem 8.7). We encourage the reader to give a purely "logical" proof of the second equality in the theorem.

Since $\Sigma_{1,u} = \Sigma_1$, we get

$$\mathrm{W}[1] = \bigcup_{\tau \text{ vocabulary}} [MC(\Sigma_1[\tau])]^{\mathrm{fp}}_{\mathrm{m}} = [MC(\Sigma_1)|_{GRAPH}]^{\mathrm{fp}}_{\mathrm{m}} = \mathrm{A}[1].$$

By Theorem 8.3, W[t] $\subseteq$ A[t] for all $t \ge 2$. The question whether W[t] = A[t] for all t remains open; in view of Theorem 8.3 this question is equivalent to W[t] = $[MC(\Sigma_t)|_{GRAPH}]^{\mathrm{fp}}_{\mathrm{m}}$ for all $t \ge 1$. In this form it is stated as an open problem in [11]. Consider, for example, the following parameterized problem:

P_0		
	Input:	Graph $\mathcal{G}$.
	Parameter:	$(k, l) \in \mathbb{N}^2$.
	Question:	Are there $a_1, \ldots, a_k \in G$ such that every clique of size l contains an a_i?

Since P_0 is slicewise Σ_2-definable, we have $P_0 \in \mathrm{A}[2]$. However, is P_0 in $\mathrm{W}[2]$?

In the definition of the W-hierarchy we can restrict the length of the nonleading quantifier-blocks to one.

PROPOSITION 8.5. *For all $t \geq 1$,*

$$\mathrm{W}[t] = \bigcup_{\tau \text{ vocabulary}} [MC(\Sigma_{t,1}[\tau])]^{\mathrm{fp}}_{\mathrm{m}}.$$

Proof. The inclusion $\supseteq$ being trivial we turn to a proof of $\subseteq$: Fix τ and $u \geq 1$. We show that $MC(\Sigma_{t,u}[\tau]) \leq^{\mathrm{fp}}_{\mathrm{m}} MC(\Sigma_{t,1}[\tau'])$ for suitable τ'. The idea is to replace the blocks of at most u quantifiers by a single quantifier ranging over the set of u-tuples of a structure. To explain this idea we first use a vocabulary containing function symbols (and sketch afterwards how one can do without). Let $\tau' := \tau \cup \{T, p_1, \dots, p_u\}$, where T is a unary relation symbol (for ordered u-tuples) and $p_1, \dots, p_u$ are unary function symbols (the projection functions). Given a τ-structure $\mathcal{A}$ let $\mathcal{A}'$ be a τ'-structure with

$$A' := A \dot\cup A^u, \;\; T^{\mathcal{A}'} := A^u,$$

where for $(a_1, \dots, a_u) \in A^u$, $p_i(a_1, \dots, a_u) = a_i$ and where the relation symbols of τ are interpreted as in $\mathcal{A}$. Now, for example, for

$$\varphi = \exists x_1 \dots \exists x_k \forall y_1 \dots \forall y_u \psi(\bar{x}, \bar{y})$$

with quantifier-free ψ, let

$$\varphi' = \exists x_1 \dots \exists x_k \forall y (\neg T x_1 \wedge \dots \wedge \neg T x_k \wedge (Ty \to \psi(\bar{x}, p_1(y) \dots p_u(y)))).$$

Then,

$$\mathcal{A} \models \varphi \iff \mathcal{A}' \models \varphi',$$

which gives the desired parameterized m-reduction.

Let us explain, for the case $t = 2$, how to proceed to avoid function symbols. One has to add to τ, besides T as above, for every relation symbol $R \in \tau$, say, r-ary, every subset $M \subseteq \{1, \dots, r\}$, and every function $\rho : M \to \{1, \dots, u\}$ a new relation symbol $R_{M,\rho}$; e.g., if $M = \{s, \dots, r\}$, then $R^{\mathcal{A}'}_{M,\rho} a_1 \dots a_{s-1} b$ if and only if $a_1 \dots a_{s-1} \in A$, $b = (b_1, \dots, b_u) \in A^u$, and $R^{\mathcal{A}} a_1 \dots a_{s-1} b_{\rho(s)} \dots b_{\rho(r)}$; and a subformula $R x_{i_1} \dots x_{i_{s-1}} y_{\rho(s)} \dots y_{\rho(r)}$ of φ is replaced by $R_{M,\rho} x_{i_1} \dots x_{i_{s-1}} y$. □

Downey, Fellows, and Regan [11] also gave a (much simpler) characterization of the W-hierarchy in terms of Fagin definability. We find it worthwhile to sketch a short proof of this result. For a class Φ of formulas we let $\mathrm{FD}(\Phi)$ be the class of all problems that are Φ-Fagin-definable. Let $\Pi_t[s]$ denote the class of all Π_t-formulas whose vocabulary is at most s-ary.

THEOREM 8.6 (see [11]). *For all $t \geq 1$ we have* $\mathrm{W}[t] = [\mathrm{FD}(\Pi_t[2])]^{\mathrm{fp}}_{\mathrm{m}} = [\mathrm{FD}(\Pi_t)]^{\mathrm{fp}}_{\mathrm{m}}$.

Proof. Recall that $\mathrm{W}[t] = \bigcup_{d \geq 1} [WSAT(C_{t,d})]^{\mathrm{fp}}_{\mathrm{m}}$, where $C_{t,d}$ is the class of all propositional formulas of the form

$$\bigwedge_{i_1} \bigvee_{i_2} \cdots \Big(\bigwedge_{i_t} / \bigvee_{i_t} \Big) \varphi_{i_1 \dots i_t}, \tag{8.2}$$

where the $\varphi_{i_1\dots i_t}$ are small formulas of depth at most d.

To prove that $\mathrm{W}[t] \subseteq [\mathrm{FD}(\Pi_t[2])]^{\mathrm{fp}}_{\mathrm{m}}$, we first transform a propositional formula φ of the form (8.2) into a propositional formula φ' of essentially the same form, but with all the $\varphi_{i_1\dots i_t}$ being disjunctions (if t is odd) or conjunctions (if t is even) of exactly d' literals, for some constant d' depending only on d. This can be done by first transforming the small formulas into equivalent formulas in conjunctive normal form or disjunctive normal form, respectively, and then repeatedly replacing disjunctions (respectively, conjunctions) γ with less than the maximum number of literals by the two clauses $\gamma \vee X$ and $\gamma \vee \neg X$ ($\gamma \wedge X$ and $\gamma \wedge \neg X$, respectively) for some variable X not appearing in γ.

We associate with φ' an $\{E, P, N, T, L\}$-structure $\mathcal{C}$ which is obtained from the tree corresponding to φ' as follows: We first remove the root. Then we identify all leaves corresponding to the same propositional variable. To indicate whether a variable occurs positively or negatively in a clause, we use the binary relations P and N. The unary relation T contains all the top level nodes, and the unary relation L contains all the (former) leaves. It is easy to write a Π_t-formula $\psi'(X)$ such that φ' has a satisfying assignment of weight k if and only if there exists a k-element subset $B \subseteq C$ such that $\mathcal{C} \models \psi'(B)$.

This can best be illustrated with a simple example: Let

$$\varphi' := (X \vee Y \vee Z) \wedge (X \vee \neg Y \vee Z) \wedge (X \vee \neg Y \vee \neg Z) \wedge (\neg X \vee Y \vee \neg Z).$$

The corresponding structure $\mathcal{C}$ is displayed in Figure 8.1.

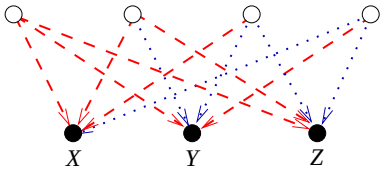

FIG. 8.1.

We let

$$\psi'(U) := \forall x(Ux \to Lx) \wedge \forall x \forall y_1 \forall y_2 \forall y_3 \Bigg(\Bigg(Tx \wedge \bigwedge_{i=1}^{3} Exy_i \wedge \bigwedge_{1 \le i < j \le 3} y_i \neq y_j \Bigg) \longrightarrow \bigvee_{i=1}^{3} \big((Pxy_i \wedge Uy_i) \vee (Nxy_i \wedge \neg Uy_i) \big) \Bigg).$$

To prove $[\mathrm{FD}(\Pi_t)]^{\mathrm{fp}}_{\mathrm{m}} \subseteq \mathrm{W}[t]$, we note only that for every formula $\psi(X) \in \Pi_t$ and every structure $\mathcal{A}$, there is a $C_{t,d}$-formula φ with the property that every assignment α for φ corresponds to a set B, whose size is the weight of the assignment, such that α satisfies φ if and only if $\mathcal{A} \models \psi(B)$. Here d is a constant that depends only on ψ. Furthermore, the transformation $(\mathcal{A}, \psi) \mapsto \varphi$ is computable in time polynomial in $\mathcal{A}$. □

We do not know of any simple proof of the equivalence between the two characterizations of the W-hierarchy in terms of slicewise $\Sigma_{t,u}$-definability (cf. Theorem 8.4) and Π_t-Fagin definability. While the proof of the previous theorem shows that Π_t-Fagin definability is actually quite close to the definition of $\mathrm{W}[t]$ in terms of the

weighted satisfiability problem for C_t-formulas, it seems that it is a significant step to get from there to slicewise $\Sigma_{t,u}$-definability.

Our last result is another characterization of the W-hierarchy in terms of Fagin definability that is much closer to the slicewise characterization. A first-order formula $\varphi(X)$ is *bounded to* the r-ary relation variable X if in $\varphi(X)$ quantifiers appear only in the form $\exists x_1 \dots \exists x_r(Xx_1 \dots x_r \wedge \psi)$ or $\forall x_1 \dots \forall x_r(Xx_1 \dots x_r \rightarrow \psi)$, which we abbreviate by $\exists \bar{x} \in X\ \psi$ and $\forall \bar{x} \in X\ \psi$, respectively. For $t \geq 1$ we let Π^b_t be the class of all formulas $\varphi(X)$ of the form

$$\forall \bar{x}_1 \exists \bar{x}_2 \dots Q\bar{x}_t \theta,$$

where $Q = \forall$ if t is odd and $Q = \exists$ otherwise and where θ is bounded to X.

For example, *CLIQUE* is Fagin-defined by the Π^b_0-formula

$$\forall x \in X \forall y \in X(x \neq y \rightarrow Exy)$$

and *DOMINATING SET* by the Π^b_1-formula

$$\forall x \exists y \in X(x = y \vee Exy).$$

THEOREM 8.7. *For $t \geq 1$, $\mathrm{W}[t] = [\mathrm{FD}(\Pi^b_{t-1})]^{\mathrm{fp}}_{\mathrm{m}}$.*

Proof. First, assume that the problem $P \subseteq STR[\tau] \times \mathbb{N}$ is Fagin-defined by $\varphi(X) \in \Pi^b_{t-1}$, say,

$$\varphi(X) := \forall \bar{y}_1 \exists \bar{y}_2 \forall \bar{y}_3 \dots Q\bar{y}_{t-1}\psi,$$

where ψ contains only bounded quantifiers. Let l be the maximum of the lengths of the tuples $\bar{y}_i$ for $1 \leq i \leq t$. For simplicity, let us assume that X is unary. Since Xy is equivalent to $\exists z \in X\, z = y$, we can assume that in ψ, the variable X occurs only in quantifier bounds. We show that $P \in \mathrm{W}[t]$. Given a parameter k set (with new variables $x_1, \dots, x_k$)

$$\varphi^k := \exists x_1 \dots \exists x_k \forall \bar{y}_1 \exists \bar{y}_2 \forall \bar{y}_3 \dots Q\bar{y}_{t-1} \left(\bigwedge_{1 \leq i < j \leq k} x_i \neq x_j \wedge \psi^* \right),$$

where ψ^* is obtained from ψ by inductively replacing $\forall u \in X \chi(u)$ and $\exists u \in X\, \chi(u)$ by $\bigwedge_{i=1}^k \chi(x_i)$ and $\bigvee_{i=1}^k \chi(x_i)$, respectively. Note that φ^k is a $\Sigma_{t,l}$-formula and that for every structure $\mathcal{A}$,

$$(\mathcal{A}, k) \in P \iff \mathcal{A} \models \varphi^k.$$

Thus, P is slicewise $\Sigma_{t,l}$-definable and hence in $\mathrm{W}[t]$.

For the converse direction, we prove that for all $t, u \geq 1$ we have

$$MC(\Sigma_{t,u})|_{GRAPH} \subseteq \mathrm{FD}(\Pi^b_{t-1}).$$

The idea is to associate with every graph $\mathcal{G}$ and $\Sigma_{t,u}$-formula $\exists x_1 \dots \exists x_k \varphi$ a structure $\mathcal{C}$ which essentially is a Boolean circuit whose satisfying assignments of size k correspond to assignments to the variables $x_1, \dots, x_k$ such that $\mathcal{G}$ satisfies φ. We can Fagin-define the weighted satisfiability problem for this circuit by a Π^b_{t-1}-formula. We leave the details to the reader.

For readers familiar with [10] (Theorem 12.6 on p. 299 is the relevant result), we state another proof. For $t = 1$, the result follows from the fact the W[1]-complete problem *CLIQUE* is Π_0^b-Fagin-definable. For odd $t \geq 2$, the problem *WEIGHTED ANTIMONOTONE t-NORMALIZED SATISFIABILITY* is W[t]-complete. It is parameterized m-reducible to the problem Fagin-defined by the Π_{t-1}^b-formula

$$\varphi(X) := \forall y_0 \forall y_1 \exists y_2 \forall y_3 \dots \exists y_{t-1} \\ ((Ey_0y_1 \wedge Ey_1y_2 \wedge \dots \wedge Ey_{t-2}y_{t-1}) \rightarrow \forall x \in X \neg Ey_{t-1}x).$$

For even t we use the completeness of *WEIGHTED MONOTONE t-NORMALIZED SATISFIABILITY* and argue similarly. □

Remark 8.8. Downey, Fellows, and Taylor [12] proved that the parameterized model-checking problem for full first-order logic is complete for the class AW[$*$], a parameterized complexity class above the W-hierarchy that is defined in terms of the satisfiability problem for quantified Boolean formulas.

APPROXIMATION TECHNIQUES FOR AVERAGE COMPLETION TIME SCHEDULING*

C. CHEKURI†, R. MOTWANI‡, B. NATARAJAN§, AND C. STEIN¶

Abstract. We consider the problem of nonpreemptive scheduling to minimize average (weighted) completion time, allowing for release dates, parallel machines, and precedence constraints. Recent work has led to constant-factor approximations for this problem based on solving a preemptive or linear programming relaxation and then using the solution to get an ordering on the jobs. We introduce several new techniques which generalize this basic paradigm. We use these ideas to obtain improved approximation algorithms for one-machine scheduling to minimize average completion time with release dates. In the process, we obtain an optimal randomized on-line algorithm for the same problem that beats a lower bound for deterministic on-line algorithms. We consider extensions to the case of parallel machine scheduling, and for this we introduce two new ideas: first, we show that a preemptive one-machine relaxation is a powerful tool for designing parallel machine scheduling algorithms that simultaneously produce good approximations and have small running times; second, we show that a nongreedy "rounding" of the relaxation yields better approximations than a greedy one. We also prove a general theorem relating the value of one-machine relaxations to that of the schedules obtained for the original m-machine problems. This theorem applies even when there are precedence constraints on the jobs. We apply this result to obtain improved approximation ratios for precedence graphs such as in-trees, out-trees, and series-parallel graphs.

Key words. approximation algorithms, scheduling, parallel machine scheduling, release dates, precedence constraints

1. Introduction.

We present new approximation techniques and results for *nonpreemptive* scheduling to minimize *average (weighted) completion time* (equivalently, sum of (weighted) completion times). In this problem, we are given n jobs $J_1, \ldots, J_n$, where job J_j has processing time p_j, release date r_j, and a positive weight w_j. A feasible schedule S assigns jobs nonpreemptively[1] to m machines such that each job starts after its release date. Let C_j^S denote the completion time of job J_j in schedule S. The

[1] In a nonpreemptive schedule, each job runs uninterrupted on one machine from start to finish; in a preemptive schedule, a job may be interrupted or may switch machines at any time.

objective is to minimize the *weighted* completion time $\sum_j w_j C_j^S$; if all w_j are $1/n$, the objective becomes the *average* completion time. For the single machine case, if the release dates are 0 for all jobs, then the weighted completion time problem can be solved optimally in polynomial time [30]. We are interested in a more general setting with release dates and precedence constraints and multiple machines, any of which makes the problem $\mathcal{NP}$-hard [23]. Thus we will consider approximation algorithms, or, in an on-line setting, competitive ratios.

An important motivation for studying scheduling to minimize sum of weighted completion times, aside from its intrinsic theoretical interest, comes from application to compiler optimizations. Compile-time instruction scheduling is essential for effectively exploiting the fine-grained parallelism offered in pipelined, superscalar, and very-long instruction word architectures (see, for example, [17, 35]). Current research is addressing the issue of profile-based compiler optimization. In a recent paper, Chekuri et al. [4] show that weighted completion time is the measure of interest in profile-driven code optimization; some of our results are related to the heuristics described and empirically tested therein.

Recent work has led to constant-factor approximations for weighted completion time for a variety of these $\mathcal{NP}$-hard scheduling problems [25, 16, 3, 12, 7, 28]. Most of these algorithms work by first constructing a relaxed solution, either a preemptive schedule or a linear programming relaxation. These relaxations are used to obtain an ordering of the jobs, and then the jobs are list scheduled as per this ordering.

We introduce new techniques that generalize this basic paradigm. We use these to obtain improved approximation algorithms for one-machine scheduling to minimize average completion time with release dates. Our main result here is a $\frac{e}{e-1} \approx 1.58$-approximation algorithm. This algorithm can be turned into a randomized on-line algorithm with the same bound, where an algorithm is on-line if before time r_j it is unaware of J_j, but at time r_j it learns all the parameters of J_j. This randomized on-line algorithm is particularly interesting as it beats a lower bound for deterministic on-line algorithms [21] and matches a recent lower bound for randomized on-line algorithms [33].

We then consider extensions to parallel machine scheduling and introduce two new ideas: first, we show that a preemptive one-machine relaxation is a powerful tool for designing parallel machine scheduling algorithms that simultaneously produce good approximations and have small running times; second, we show that a nongreedy "rounding" of the relaxation produces better approximations than simple list scheduling. In fact, we prove a general theorem relating the value of one-machine relaxations to that of the schedules obtained for the original m-machine problems. This theorem applies even when there are precedence constraints yielding better approximations for precedence graphs such as in-trees, out-trees, and series-parallel graphs, which are of interest in compiler applications that partly motivated our work.

The bounds in this paper derive from proving bounds on the ratio between solutions to a nonpreemptive scheduling problem and a relaxed version of this problem. The bounds on this ratio all hold when both the original and relaxed problems have weights; however, the relaxed problem with weights is typically not solvable exactly in polynomial time. Because of this, the performance ratios of our algorithms, in some cases, are not as good as those obtained directly through other techniques. However, given future improvement in state of the art for one-machine preemptive scheduling with release dates and/or precedence constraints, our results would also imply better

bounds for weighted completion time. We begin with a more detailed discussion of our results and their relation to earlier work.

One-machine scheduling with release dates. The first constant-factor approximation algorithm for an average completion time problem was the following 2-approximation algorithm of Phillips, Stein, and Wein [25] for minimizing the average completion time on one machine with release dates. First, an optimal preemptive schedule P is found using the shortest remaining processing time (SRPT) algorithm [23] which at any time runs an available job that has the least processing time left; note that this is an on-line algorithm. Given P, the jobs are ordered by increasing completion times, C_j^P, and are scheduled according to that ordering, introducing idle time as necessary to account for release dates. A simple proof shows that each job J_j completes at time no later than $2C_j^P$, implying a 2-approximation. Other 2-approximation algorithms have been discovered subsequently [21, 32, 12], and it is also known that no deterministic on-line algorithm has approximation ratio better than 2 [21, 32]. This approximation technique has been generalized to many other scheduling problems, and hence finding better approximations for this basic problem is believed to be an important step toward improved approximations for more general problems.

Our main result here is a deterministic off-line algorithm for the basic problem that gives an $\frac{e}{e-1}$-approximation ($\frac{e}{e-1} \approx 1.58$). We also obtain an *optimal* randomized on-line algorithm (in the *oblivious* adversary model) with expected competitive ratio $\frac{e}{e-1}$. This beats the deterministic on-line lower bound. Our approach is based on what we call α-*schedules* (this notion was also used by [25] and [15] in a somewhat different manner). Given a preemptive schedule P and $\alpha \in (0, 1]$, we define $C_j^P(\alpha)$ to be the time at which αp_j, an α-fraction of J_j, is completed. An α-schedule is a nonpreemptive schedule obtained by list scheduling jobs in order of increasing $C_j^P(\alpha)$, possibly introducing idle time to account for release dates. Clearly, an α-scheduler is an on-line algorithm; moreover, for $\alpha = 1$, the α-scheduler is exactly the algorithm of Phillips, Stein, and Wein [25] and hence a 2-approximation. We show that for arbitrary α, an α-scheduler has a *tight* approximation ratio of $1 + 1/\alpha$. Given that $1 + 1/\alpha \geq 2$ for $\alpha \in (0, 1]$, it may appear that this notion of α-schedulers is useless for obtaining ratios better than 2.

A key observation is that a worst-case instance that induces a performance ratio $1+1/\alpha$ for one value of α is not a worst-case instance for many other values of α. This suggests that a randomized algorithm which picks α at random, and then behaves like an α-scheduler, may lead to an approximation better than 2. Unfortunately, we show that choosing α uniformly at random gives an expected approximation ratio of 2 and that this is tight. However, this leaves open the possibility that for any given instance I, there exists a choice $\alpha(I)$ for which the $\alpha(I)$-schedule yields an approximation better than 2. We refer to the resulting deterministic off-line algorithm which, given I, chooses α to minimize $\alpha(I)$, as BEST-α.

It turns out, however, that the randomized on-line algorithm which chooses α to be 1 with probability 3/5 and 1/2 with probability 2/5 has competitive ratio 1.8; consequently, for any input I, either the 1-schedule or the $\frac{1}{2}$-schedule is no worse than an 1.8-approximation. More significantly, the nonuniform choice in the randomized version suggests the possibility of defining randomized choices of α that may perform better than 1.8 while being easy to analyze. In fact, our main result here is that it is possible to define a distribution for α that yields a randomized on-line $\frac{e}{e-1}$-approximation algorithm implying that BEST-α is an $\frac{e}{e-1}$-approximation algo-

rithm. It should be noted that BEST-α can be implemented in $O(n^2)$ time and all our other algorithms can be implemented in either $O(n)$ or $O(n \log n)$ time. Torng and Uthaisombut [34] recently showed that our analysis of BEST-α is tight by giving instances on which the approximation ratio achieved by BEST-α is arbitrarily close to $e/(e-1)$.

Our bounds are actually job-by-job, i.e., we produce a schedule N in which $E[C_j^N] \leq \frac{e}{e-1} C_j^P$ for all j where $E[C_j^N]$ is the expected completion time of J_j in the nonpreemptive schedule. Thus our conversion results generalize to weighted completion time. However, since for the weighted case even the preemptive scheduling problem is $\mathcal{NP}$-hard (given release dates), we must use an approximation for the relaxation. The current best approximation algorithm for the preemptive case [26] has a ratio of 4/3, which yields a 2.12-approximation for the nonpreemptive case. However, this does not improve earlier results.

Independently, Goemans [12] has used similar ideas to design a 2-approximation algorithm for the problem of nonpreemptive scheduling on one machine so as to minimize the average weighted completion time. His algorithm is also a BEST-α algorithm and works off a preemptive schedule that is optimal for a certain linear programming relaxation of the problem and the analysis is based on the linear programming formulation. Interestingly, Goemans proves the performance of his algorithm by choosing α uniformly at random in the interval $(0, 1]$. Further work [26, 13] based on the idea of using independent random α points for each job has resulted in an improved approximation ratio of 1.6853.

Scheduling parallel machines with release dates. We consider generalizations of the single machine problems to the case of m identical parallel machines. We first consider the problem of minimizing average completion time with release dates and no precedence constraints. Extending the techniques to the m-machine problem gives rise to two complications: the problem of computing an optimal m-machine preemptive schedule is $\mathcal{NP}$-hard [9], and the best known approximation ratio is 2 [25]; further, the conversion bounds from preemptive to nonpreemptive schedules are not as good. Chakrabarti et al. [3] obtain a bound of 7/3 on the conversion from the preemptive to the nonpreemptive case yielding a 14/3-approximation for scheduling on m machines with release dates. Several other algorithms do not use the preemptive schedule but use a linear programming relaxation. Phillips, Stein, and Wein [25] gave the first such algorithm, a 24-approximation algorithm. This has been greatly improved to $4 + \epsilon$ [15], $4 - \frac{1}{m}$ [16], and 3.5 [3]. Using a general on-line framework [3], one can obtain an algorithm with an approximation ratio of $2.89 + \epsilon$. Unfortunately, the algorithm with the best approximation is inefficient, as it uses the polynomial approximation scheme for makespan due to Hochbaum and Shmoys [20].

We give a new algorithm for this problem. First we introduce a different relaxation—a *preemptive one-machine relaxation*. More precisely, we maintain the original release dates and allow preemptions but divide all the processing times by m. We then compute a one-machine schedule. The resulting completion time ordering is then used to generate a nonpreemptive m-machine schedule that is a 3-approximation. Our algorithm has a running time of $O(n \log n)$ and in addition is also on-line. We then show that the approximation ratio can be improved to 2.83 using a general conversion algorithm that we develop. This improves on the approximation bounds of previous algorithms and gives a much smaller running time of $O(n \log n)$. Subsequent to our work, Schulz and Skutella [28] using some of our ideas have obtained an approximation ratio of 2 for the more general case of sum of weighted completion times.

Scheduling with precedence constraints. We now consider the weighted completion time problem with precedence constraints. For one-machine scheduling, minimizing the weighted completion time is $\mathcal{NP}$-hard for arbitrary precedence constraints even without release dates [11, 22]. A 2-approximation for the case of no release dates [16] and an $e \simeq 2.718$-approximation [29] with release dates are known. For arbitrary m, the problem is $\mathcal{NP}$-hard even without precedence constraints and release dates if weights are not required to be identical; on the other hand, the problem is strongly $\mathcal{NP}$-hard even when all weights are identical and the precedence graph is a union of chains [10]. An expected approximation ratio of $5.33 + \epsilon$ is achievable with release dates and precedence constraints [3]. This has been recently improved to 4 in [24].

A general conversion algorithm. We obtain a fairly general algorithm for m-machine problems with precedence constraints, release dates, and job weights. To do so, we first solve a one-machine preemptive relaxation and apply an algorithm we call Delay List to get an m-machine nonpreemptive schedule. Since, in general, the one-machine preemptive relaxation is also $\mathcal{NP}$-hard, we would have to settle for a ρ-approximation for it; then our algorithm would give a $(2\rho + 2)$-approximation for the m-machine case. In fact, we give an algorithm that gives a $(1 + \beta)\rho + (1 + 1/\beta)$-approximation for any $\beta > 0$ which when optimized for ρ yields a $(\rho + 2\sqrt{\rho} + 1)$-approximation. In the absence of release dates an optimal one-machine schedule can be computed in polynomial time when the precedence graph is a forest [19] or a series-parallel graph [22, 1]. Applying our conversion algorithm for these cases results in improved approximation results. Although the algorithm fails to obtain improved results for the most general problem, we feel that it is of independent interest and likely to find applications in the future. Further, our conversion algorithm has the advantage of being simple and combinatorial. In applications such as compilers [4], speed and simplicity are sometimes more important than getting the best possible ratio. Finally, our algorithm has a surprising property: it gives schedules that are good for both makespan and average completion time (Chakrabarti et al. [3] and Stein and Wein [31] also have shown the existence of such schedules).

2. One-machine scheduling with release dates. In this section, we present our results for one-machine scheduling with release dates to minimize average completion time. Let P be a preemptive schedule, and let C_i^P and C_i^α denote the completion time of J_i in P and in the nonpreemptive α-schedule derived from P, respectively. We begin by analyzing simple α-schedules. Techniques from [25, 16] are easily generalized to yield the following.

Theorem 2.1. *Given an instance of one-machine scheduling with release dates, for any $\alpha \in (0, 1]$, an α-schedule has $\sum_j C_j^\alpha \le (1 + 1/\alpha) \sum_j C_j^P$. Further, there are instances where the inequality is asymptotically tight.*

Proof. Index the jobs by the order of their α-points in the preemptive schedule P. Let $r_j^{\max} = \max_{1 \le k \le j} r_k$ be the latest release date among jobs with α points no greater than j's. By time $r_j^{\max}$, jobs 1 through j have all been released, and hence

$$C_j^\alpha \le r_j^{\max} + \sum_{k=1}^{j} p_k. \tag{2.1}$$

We know that $C_j^P \ge r_j^{\max}$, since only an α fraction j has finished by $r_j^{\max}$. We also know that $C_j^P \ge \alpha \sum_{k=1}^{j} p_k$, since the α fractions of jobs $1, \ldots, j$ must run before time C_j^P. Plugging these last two inequalities into (2.1) yields $C_j^\alpha \le (1 + \frac{1}{\alpha}) C_j^P$. Summing

over all j yields the lemma.

To see that this is tight, consider the following class of instances. Let ϵ be a small positive number. We will also allow jobs with processing time 0, although the proof can be modified even if these are not allowed. At time 0, we release a job with processing time 1. At time $\alpha - \epsilon$, we release a job with processing time ϵ and at time $\alpha + \epsilon$, we release x jobs of processing time 0. The optimal preemptive completion time is $\alpha + x(\alpha + \epsilon) + 1 + \epsilon$, while the completion time of the nonpreemptive α-schedule is $\alpha + (\alpha + 1) + x(1 + \alpha)$. As x gets large and ϵ goes to 0, the ratio between the two goes to $1 + \frac{1}{\alpha}$. □

This theorem, in and of itself, always yields approximation bounds that are worse than 2.

We thus introduce a new fact that ultimately yields better algorithms. We will show that the makespan of an α-schedule is within a $(1 + \alpha)$-factor of the makespan of the corresponding preemptive schedule; in fact, we will prove a stronger result in Lemma 2.3 below. Thus the idle time introduced in the nonpreemptive schedules decreases as α is reduced from 1 to 0. On the other hand, the (worst-case) bound on the completion time of any specific job increases as α goes from 1 to 0. It is the balancing of these two effects that leads to better approximations. In the following discussion we do not assume that the preemptive schedule is the optimal preemptive schedule found using SRPT. In fact, our results on converting preemptive schedules to nonpreemptive schedules apply in general, but when we want to prove upper bounds on the performance ratio for total completion time, we assume that the preemptive schedule is an optimal preemptive schedule whose value is a lower bound on the value of any optimal nonpreemptive schedule.

Let $S_i^P(\beta)$ denote the set of jobs which complete exactly β fraction of their processing time before C_i^P in the schedule P (note that J_i is included in $S_i^P(1)$). We overload notation by using $S_i^P(\beta)$ to also denote the sum of processing times of all jobs in the set $S_i^P(\beta)$; the meaning should be clear from the context. Let T_i be the total idle time in P before J_i completes.

The preemptive completion time of J_i can be written as the sum of the idle time and fractional processing times of jobs that ran before C_i^P. This yields the following lemma.

LEMMA 2.2. $C_i^P = T_i + \sum_{0<\beta\leq 1} \beta S_i^P(\beta)$.

We next upper bound the completion time of a job J_i in the α-schedule.

LEMMA 2.3.

$$C_i^\alpha \leq T_i + (1 + \alpha) \sum_{\beta \geq \alpha} S_i^P(\beta) + \sum_{\beta < \alpha} \beta S_i^P(\beta).$$

Proof. Let $J_1, \ldots, J_{i-1}$ be the jobs that run before J_i in the α-schedule. We will give a procedure which converts the preemptive schedule into a schedule in which

(C1) jobs $J_1, \ldots, J_i$ run nonpreemptively in that order,

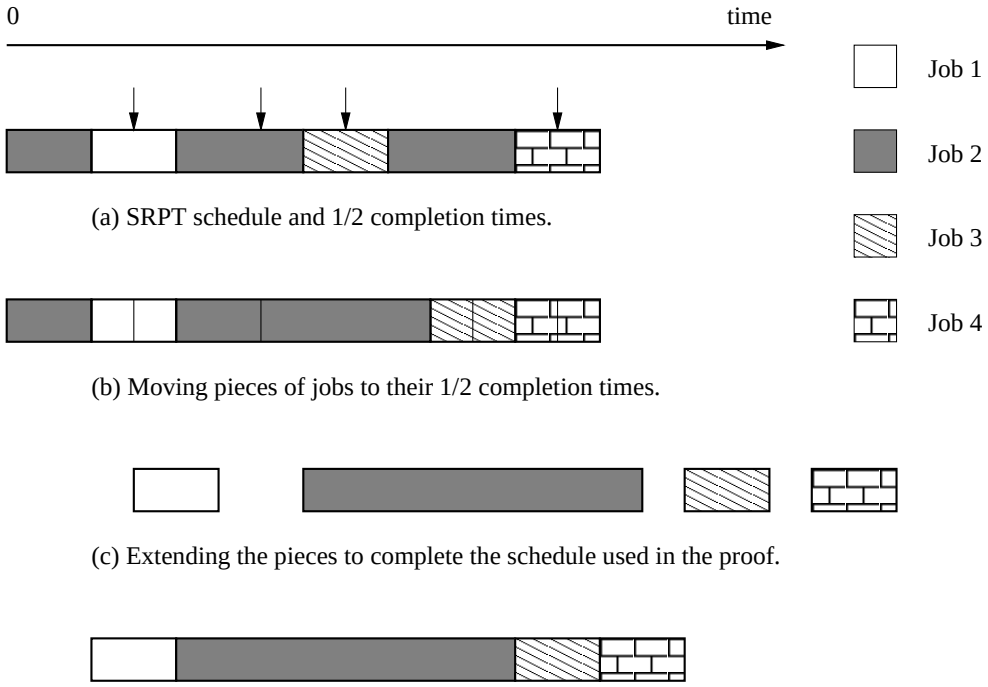
(C2) the remaining jobs run preemptively, and

(C3) the completion time of J_i obeys the bound given in the lemma.

Since the actual C_i^α is no greater than the completion time of J_i in this schedule, the lemma will be proven.

Splitting up the second term in the bound from Lemma 2.2, we get the following equation:

$$C_i^P = T_i + \sum_{\beta < \alpha} \beta S_i^P(\beta) + \sum_{\beta \geq \alpha} \alpha S_i^P(\beta) + \sum_{\beta \geq \alpha} (\beta - \alpha) S_i^P(\beta).$$



(a) SRPT schedule and 1/2 completion times.

(b) Moving pieces of jobs to their 1/2 completion times.

(c) Extending the pieces to complete the schedule used in the proof.

(d) The true 1/2-schedule.

FIG. 2.1. *Illustration of proof of Lemma* 2.3 *with* $\alpha = 1/2$ *and* $i = 4$.

Let $J^B = \bigcup_{\beta \geq \alpha} S_i^P(\beta)$ and $J^A = J - J^B$. We can interpret the four terms in the above equation as (1) the idle time in the preemptive schedule before C_i^P, (2) the pieces of jobs in J^A that ran before C_i^P, (3) for each job $J_j \in J^B$, the pieces of J_j that ran before $C_j^P(\alpha)$, and (4) for each job $J_j \in J^B$, the pieces of J_j that ran between $C_j^P(\alpha)$ and C_i^P. Let x_j be the β for which $J_j \in S_i^P(\beta)$, that is, the fraction of J_j that was completed before C_i^P. Then $\sum_{\beta \geq \alpha}(\beta - \alpha)S_i^P(\beta)$ can be rewritten as $\sum_{J_j \in J^B}(x_j - \alpha)p_j$. Observe that $(x_j - \alpha)p_j$ is the fraction of job J_j that ran between $C_j^P(\alpha)$ and C_i^P.

Let $J^C = \{J_1, \ldots, J_i\}$. Clearly J^C is a subset of J^B. Now think of schedule P as an ordered list of pieces of jobs (with sizes). For each $J_j \in J^C$ modify the list by (1) removing all pieces of jobs that run between $C_j^P(\alpha)$ and C_i^P and (2) inserting a piece of size $(x_j - \alpha)p_j$ at the point corresponding to $C_j^P(\alpha)$. In this list, we have pieces of size $(x_j - \alpha)p_j$ of jobs $J_1, \ldots, J_i$ in the correct order (plus other pieces of jobs). Now convert this ordered list back into a schedule by scheduling the pieces in the order of the list, respecting release dates. We claim that job i still completes at time C_i^P. To see this observe that the total processing time before C_i^P remains unchanged and that other than the pieces of size $(x_j - \alpha)p_j$, we moved pieces only later in time, so no additional idle time need be introduced.

Now, for each job $J_j \in J^C$, extend the piece of size $(x_j - \alpha)p_j$ to one of size p_j by adding $p_j - (x_j - \alpha)p_j$ units of processing and replace the pieces of J_j that occur earlier, of total size αp_j, by idle time. Figure 2.1 illustrates this transformation. We now have a schedule in which $J_1, \ldots, J_i$ are each scheduled nonpreemptively for p_j

units of time and in which the completion time of J_i is

$$\begin{aligned} C_i^P + \sum_{J_j \in J^C} (p_j - (x_j - \alpha)p_j) &\le C_i^P + \sum_{J_j \in J^B} (p_j - (x_j - \alpha)p_j) \\ &= C_i^P + \sum_{\beta \ge \alpha} (1 - \beta + \alpha) S_i^P(\beta) \\ &= T_i + (1 + \alpha) \sum_{\beta \ge \alpha} S_i^P(\beta) + \sum_{\beta < \alpha} \beta S_i^P(\beta), \end{aligned}$$

where the second equality just comes from reindexing terms by β instead of j, and the third comes from plugging in the value of C_i^P from Lemma 2.2. To complete the proof, we observe that the remaining pieces in the schedule are all from jobs in $J - J^C$, and we have thus met the conditions (C1), (C2), and (C3) above. □

Although we will not use it directly, applying Lemma 2.3 to the last job to complete in the α-schedule yields the following corollary.

COROLLARY 2.4. *The makespan of the α-schedule is at most $(1 + \alpha)$ times the makespan of the corresponding preemptive schedule, and there are instances for which this bound is tight.*

Having analyzed completion times as in Lemma 2.3, we see that the approximation ratio is going to depend on the distribution of the different sets $S_i^P(\beta)$. To avoid the worst-case α, we choose α randomly according to some probability distribution. We now give a general bound on this algorithm, which we call RANDOM-α.

LEMMA 2.5. *Suppose α is chosen from a probability distribution over $(0, 1]$ with a density function f. Then for each job J_i, $E[C_i^\alpha] \le (1 + \delta)C_i^P$, where*

$$\delta = \max_{0 < \beta \le 1} \int_0^\beta \frac{1 + \alpha - \beta}{\beta} f(\alpha) \mathrm{d}\alpha.$$

It follows that $E[\sum_i C_i^\alpha] \le (1 + \delta) \sum_i C_i^P$.

Proof. We will show that the expected completion time of any job J_i is within $(1 + \delta)$ of its preemptive completion time. From Lemma 2.3 it follows that for any given α,

$$C_i^\alpha \le T_i + (1 + \alpha) \sum_{\beta \ge \alpha} S_i^P(\beta) + \sum_{\beta < \alpha} \beta S_i^P(\beta).$$

Therefore, when α is chosen according to f, the expected completion time of J_i, $E[C_i^\alpha] = \int_0^1 f(\alpha) C_i^\alpha \mathrm{d}\alpha$, is bounded by

$$T_i + \int_0^1 f(\alpha) \left((1 + \alpha) \sum_{\beta \ge \alpha} S_i^P(\beta) + \sum_{\beta < \alpha} \beta S_i^P(\beta) \right) \mathrm{d}\alpha$$

since T_i is independent of α. We now bound the second term in the above expression:

$$\begin{aligned}
&\int_0^1 f(\alpha)\Big((1+\alpha)\sum_{\beta\geq\alpha} S_i^P(\beta) + \sum_{\beta<\alpha}\beta S_i^P(\beta)\Big)\mathrm{d}\alpha \\
&= \sum_{0<\beta\leq 1} S_i^P(\beta)\left(\int_0^\beta (1+\alpha)f(\alpha)\mathrm{d}\alpha + \int_\beta^1 \beta f(\alpha)\mathrm{d}\alpha\right) \\
&= \sum_{0<\beta\leq 1} \beta S_i^P(\beta)\left(1+\int_0^\beta \frac{1+\alpha-\beta}{\beta} f(\alpha)\mathrm{d}\alpha\right) \\
&\leq \left(1+\max_{0<\beta\leq 1}\int_0^\beta \frac{1+\alpha-\beta}{\beta} f(\alpha)d\alpha\right)\sum_{0<\beta\leq 1}\beta S_i^P(\beta) \\
&\leq (1+\delta)\sum_{0<\beta\leq 1}\beta S_i^P(\beta).
\end{aligned}$$

It follows that

$$E[C_i^\alpha] \leq T_i + (1+\delta)\sum_{0<\beta\leq 1}\beta S_i^P(\beta) \leq (1+\delta)C_i^P.$$

Using linearity of expectations, it is easy to show that the expected total completion time of the schedule is within $(1+\delta)$ of the preemptive schedule's total completion time. □

With Lemma 2.5 in place, we can simply choose different PDFs to establish different bounds.

THEOREM 2.6. *For the problem of scheduling to minimize weighted completion time with release dates,* RANDOM-α *performs as follows:*

1. *If α is chosen uniformly in $(0,1]$, the expected approximation ratio is at most 2.*
2. *If α is chosen to be 1 with probability $3/5$ and $1/2$ with probability $2/5$, the expected approximation ratio is at most 1.8.*
3. *If α is chosen from $(0,1]$ according to the density function $f(\alpha) = \frac{e^\alpha}{e-1}$, the expected approximation ratio is at most $\frac{e}{e-1} \approx 1.58$.*

Proof.

1. Choosing α uniformly corresponds to the PDF $f(\alpha) = 1$. Plugging into the bound from Lemma 2.5, we get an approximation ratio of

$$\begin{aligned}
1+\max_{0<\beta\leq 1}\int_0^\beta \frac{1+\alpha-\beta}{\beta}\mathrm{d}\alpha &= 1+\max_{0<\beta\leq 1}\frac{1}{\beta}\left((1-\beta)\beta+\frac{\beta^2}{2}\right) \\
&= 1+\max_{0<\beta\leq 1}\left(1-\frac{\beta}{2}\right) \\
&\leq 2.
\end{aligned}$$

2. Omitted.
3. If $f(\alpha) = \frac{e^\alpha}{e-1}$, then

$$\begin{aligned}
\max_{0<\beta\leq 1}\int_0^\beta \left(\frac{1+\alpha-\beta}{\beta}\right)\left(\frac{e^\alpha}{e-1}\right)\mathrm{d}\alpha &= \max_{0<\beta\leq 1}\frac{1}{\beta(e-1)}\Big(((1-\beta)+(\beta-1))e^\beta \\
&\qquad - ((1-\beta)-1)\Big) \\
&= \max_{0<\beta\leq 1}\frac{1}{e-1}
\end{aligned}$$

$$= \frac{1}{e-1}.$$

Therefore

$$1 + \max_{0<\beta\le 1} \int_0^\beta \left(\frac{1+\alpha-\beta}{\beta}\right)\left(\frac{e^\alpha}{e-1}\right) \mathrm{d}\alpha \le \frac{e}{e-1}. \qquad \square$$

It can be shown that the density function $\frac{e^\alpha}{e-1}$ minimizes the expression $\max_{0<\beta\le 1} \int_0^\beta \frac{1+\alpha-\beta}{\beta} f(\alpha)\mathrm{d}\alpha$ over all choices of $f(\alpha)$. In the off-line setting, rather than choosing α randomly, we can try different values of α and choose the one that yields the best schedule. We call the algorithm which computes the schedule of value $\min_\alpha \sum_j C_j^\alpha$, BEST-$\alpha$.

COROLLARY 2.7. *Algorithm* BEST-α *is an* $e/(e-1)$*-approximation algorithm for nonpreemptive scheduling to minimize average completion time on one machine with release dates. It runs in* $O(n^2)$ *time.*

Proof. The approximation bound follows from Theorem 2.6. For the running time, we observe that given a preemptive SRPT schedule we can efficiently determine the best possible choice of α. The SRPT schedule preempts only at release dates. Thus it has at most $n-1$ preemptions and there are at most n "combinatorially distinct" values of α for a given preemptive schedule. The SRPT schedule can be computed in $O(n \log n)$ time using a simple priority queue and given that schedule and an α, the corresponding α-schedule can be computed in linear time by a simple scan. $\square$

In the on-line setting, we cannot implement BEST-α. However, if we choose α randomly we get the following theorem.

THEOREM 2.8. *There is a polynomial-time randomized on-line algorithm with an expected competitive ratio* $e/(e-1)$ *for the problem of minimizing total completion time in the presence of release dates.*

Proof. The randomized on-line algorithm is the following. The algorithm picks an $\alpha \in (0,1]$ at random according to the density function $f(x) = \frac{e^x}{e-1}$ before receiving any input (this is the only randomness used in the algorithm). The algorithm simulates the on-line preemptive SRPT schedule. At the exact time when a job finishes α fraction of its processing time in the simulated SRPT schedule, it is added to the queue of jobs to be executed nonpreemptively. The nonpreemptive schedule is obtained by executing jobs in the strict order of their insertion into the queue while respecting the insertion times into the queue. Observe that this rule leads to a valid on-line nonpreemptive schedule and that in fact the order of the jobs scheduled is exactly the same as in the α-schedule. The schedule respects the insertion times; therefore no job is executed in the nonpreemptive schedule before its α point in the SRPT schedule. To show the bound on the expected competitive ratio, we claim that the bounds in Lemma 2.3 (and hence Theorem 2.6 also) hold for the nonpreemptive schedule created by the on-line algorithm. The main observation is that the proof of Lemma 2.3 does not use the true α-schedule but a weaker one in which for every job J_i the first α fraction of its processing time in the SRPT schedule is left as idle time. A careful examination of the proof of Lemma 2.3 with Figure 2.1 as an illustration makes this clear. $\square$

We also give some negative results for the various algorithms.

THEOREM 2.9. *For the problem of scheduling to minimize weighted completion time with release dates,* RANDOM-α *performs as follows:*

1. *If* α *is chosen uniformly, the expected approximation ratio is at least* 2.
2. *For the* BEST-α *algorithm, the approximation ratio is at least* 4/3.

Proof. We will use a set of parameterized instances to show all the above bounds. We define an instance $I(\delta, n)$ as follows. At time 0 a job of size 1 is released and at time $\delta < 1$, n jobs of size 0 are released (we use zero length jobs for ease of exposition). The optimal preemptive schedule for this instance has a total completion time of $1+n\delta$. The optimal nonpreemptive schedule for this instance can be obtained by first completing all the small jobs and running the large job after them for a total completion time of $1+\delta+n\delta$. It is easy to see that there are only two combinatorially distinct schedules corresponding to the values of $\alpha \leq \delta$ and $\alpha > \delta$ and we can restrict our attention to those two schedules and the probability with which they are chosen. Let $S1$ and $S2$ be the two schedules and $C1$ and $C2$ be their total completion times, respectively. It is easy to see that $C1 = 1 + n$ and $C2 = 1 + \delta + n\delta$.

1. If α is chosen uniformly at random, $S1$ is chosen with probability δ and $S2$ is chosen with probability $(1 - \delta)$ and a simple calculation shows that if we choose $n \gg 1$ and $1 \gg \delta$, the expected approximation ratio approaches 2.
2. Consider an instance I in which in addition to the jobs of $I(1/2, n)$ we release n more jobs of size 0 at time 1. The optimal preemptive schedule for I consists of the preemptive schedule for $I(1/2, \epsilon, n)$ followed by the additional n small jobs. The completion time of the optimal preemptive schedule is term $1+3n/2$. An optimal nonpreemptive schedule schedules the large job after all the small jobs and has a total completion time $2+3n/2$. It is easy to see that there are only two combinatorially distinct α-schedules, one corresponding to $\alpha \leq 1/2$ and the other corresponding to $\alpha > 1/2$. In both cases it is easy to verify that the completion time of the schedule is $1 + 2n$. Thus the approximation ratio of the BEST-α cannot be better than 4/3. □

After learning of our results, Stougie and Vestjens [33] improved the lower bound for randomized on-line algorithms to $e/(e-1)$. This implies that our randomized on-line algorithm is optimal. Torng and Uthaisombut [34] have shown that there are instances on which the approximation ratio of BEST-α can be made arbitrarily close to $\frac{e}{e-1}$. This improves our lower bound of 4/3 on BEST-α's performance and also implies that our upper bound analysis is tight.

3. Parallel machine scheduling with release dates. We now turn to the problem of minimizing average completion time on parallel machines in the presence of release dates. In this section, we give a simple 3-approximation algorithm for the problem that is also an on-line algorithm. Our algorithm does not use linear programming or slow dynamic programming. It introduces the notion of a one-machine preemptive relaxation. In the next section, we will show how to improve this to a 2.83-approximation algorithm using more involved techniques.

Given an instance I for nonpreemptive scheduling on m machines, we define a one-machine preemptive relaxation $I1$ as follows. $I1$ has the same set of jobs as those of I and has one machine. The processing time of J_j in $I1$ is $p'_j = p_j/m$ and release date is $r'_j = r_j$.

LEMMA 3.1. *The value of an optimal solution to $I1$ is a lower bound on the value of an optimal solution to I.*

Proof. We show how to convert a feasible schedule N, for input I, to a feasible schedule $P1$, for input $I1$, without increasing the average completion time. Take any schedule N and consider a particular time unit t that is sufficiently small. Let the $k \leq m$ jobs that are running during that time be $J_1, \ldots, J_k$. In $P1$, at time t, run $1/m$ units of each of jobs $J_1, \ldots, J_k$, in arbitrary order. The completion time of job J_j in $P1$, C_j^{P1} is clearly no greater than C_j^N, the completion time of J_j in N. □

Given an optimal preemptive schedule $P1$ for $I1$, we form a list schedule N by ordering jobs by C_j^{P1} and then scheduling them nonpreemptively in that order, respecting release dates. Let C_j^* be the completion time of J_j in an optimal schedule for I. $I1$ may be a bad relaxation in the sense that $\sum_j C_j^{P1}$ may be much less than $\sum_j C_j^*$. However, we can still use this relaxation to obtain a good nonpreemptive schedule.

LEMMA 3.2. *The nonpreemptive list schedule N satisfies $\sum_j C_j^N \le (3-\frac{1}{m})\sum_j C_j^*$.*

Proof. We focus on a particular job J_j. For convenience, we assume that the jobs are ordered according to their completion times in $P1$. Thus J_j is the jth job to complete in $P1$. We now derive three lower bounds on C_j^{P1}. First, we have the trivial bound $C_j^{P1} \ge r'_j + p'_j$. Further, C_j^{P1} is at least as big as the processing times of the jobs that precede it. Therefore

$$C_j^{P1} \ge \sum_{k=1}^{j} p'_k = \sum_{k=1}^{j} \frac{p_k}{m}. \tag{3.1}$$

Let $r_j^{\max} = \max_{1\le k\le j} r'_k$ be the latest release date among jobs that complete before j; then $C_j^{P1} \ge r_j^{\max}$.

Now consider the list schedule N. Clearly by time $r_j^{\max}$ all jobs $J_1, \ldots, J_j$ have been released. Even if no job starts before time $r_j^{\max}$, by standard makespan arguments J_j will complete by

$$\begin{aligned} C_j^N &\le r_j^{\max} + \sum_{k=1}^{j-1} \frac{p_k}{m} + p_j \\ &\le C_j^{P1} + C_j^{P1} + p_j\left(1 - \frac{1}{m}\right), \end{aligned} \tag{3.2}$$

where the second inequality follows from (3.1) and $C_j^{P1} \ge r_j^{\max}$ above. Summing (3.2) over all jobs, we get a total completion time of

$$\sum_j C_j^N \le 2\sum_j C_j^{P1} + \left(1 - \frac{1}{m}\right)\sum_j p_j. \tag{3.3}$$

By Lemma 3.1, $\sum_j C_j^{P1} \le \sum_j C_j^*$, and trivially the optimal solution to I must have total completion time $\sum_j C_j^* \ge \sum p_j$; therefore this algorithm is a $(3 - \frac{1}{m})$-approximation. ∎

The running time is just the time to run SRPT on the one-machine relaxation and the time to list schedule for a total of $O(n \log n)$. This algorithm can be made on-line by simulating the preemptive schedule and adding a job to the list when it completes in the preemptive schedule.

4. A general conversion algorithm. In this section we develop a technique to obtain parallel machine schedules from one-machine schedules that works even when jobs have precedence constraints and release dates. Given an average weighted completion time scheduling problem, we show that if we can approximate the one-machine preemptive variant, then we can also approximate the m-machine nonpreemptive variant with a slight degradation in the quality of approximation.

Precedence constraints will be represented in the usual way by a directed acyclic graph (DAG) whose vertices correspond to jobs and whose edges represent precedence constraints.

In this section, we use a slightly different one-machine relaxation from the previous section; namely, we do not divide the processing times by m. We use the superscript m to denote the number of machines; thus S^m denotes a schedule for m machines, C^m denotes the sum of weighted completion time of S^m, and C^m_j denotes the completion time of job J_j under schedule S^m. The subscript OPT refers to an optimal schedule; thus an optimal schedule is denoted by S^m_{OPT}, and its weighted completion time is denoted by C^m_{OPT}. For a set of jobs A, $p(A)$ denotes the sum of processing times of jobs in A.

DEFINITION 4.1. *For any vertex j, recursively define the quantity κ_j as follows. For a vertex j with no predecessors $\kappa_j = p_j + r_j$. Otherwise define $\kappa_j = p_j + \max\{\max_{i \prec j} \kappa_i, r_j\}$. Any path P_{ij} from i to j where $p(P_{ij}) = \kappa_j$ is referred to as a* critical path *to j.*

4.1. Conversion algorithm DELAY LIST. We now describe the DELAY LIST algorithm. Given a one-machine schedule which is a ρ-approximation, DELAY LIST produces a schedule for $m \geq 2$ machines whose value is within a factor $(k_1\rho + k_2)$ of the optimal m-machine schedule, where k_1 and k_2 are small constants. We will describe a variant of this scheduling algorithm which yields $k_1 = (1 + \beta)$ and $k_2 = (1 + 1/\beta)$ for any $\beta > 0$. Therefore, for cases where we can find optimal one-machine schedules (trees and series-parallel without release dates), we obtain a 4-approximation for m machines by setting $\beta = 1$. To our knowledge, these are the best results for these special cases.

The main idea is as follows. The one-machine schedule taken as a list (jobs in order of their completion times in the schedule) provides some priority information on which jobs to schedule earlier.[2] Unlike with makespan, the completion time of every job is important for weighted completion time. When trying to convert the one-machine schedule into an m-machine one, precedence constraints prevent complete parallelization. Thus we may have to execute jobs out-of-order from the list to benefit from parallelism. If all p_i are identical (say 1), we can afford to use naive list scheduling.[3] If there is an idle machine and we schedule some available job on it, it is not going to delay jobs which become available soon, since it completes in one time unit. On the other hand, if not all p_i's are the same, a job could keep a machine busy, delaying more profitable jobs that become available soon. At the same time, we cannot afford to keep machines idle. We strike a balance between the two extremes: schedule a job out-of-order only if there has been enough idle time already to justify scheduling it. To measure whether there has been enough idle time, we introduce a charging scheme.

Assume, for ease of exposition, that all processing times are integers and that time is discrete. This restriction can be removed without much difficulty and we use it only in the interests of clarity and intuition. A job is *ready* if it has been released and all its predecessors are done.

DEFINITION 4.2. *The time at which job J_i is ready in a schedule S is denoted by q^S_i and the time at which it starts is denoted by s^S_i.*

We use S^m to denote the m-machine schedule that our algorithm constructs and for ease of notation the superscript m will be used in place of S^m to refer to quantities

[2] In the rest of the paper we assume without loss of generality that a *list* obeys the precedence constraints; that is, if $i \prec j$, then i comes earlier in the list than j.

[3] In this section, by *list scheduling* we mean the algorithm which schedules the first available job in the list if a machine is free. This is in contrast to another variant considered in earlier sections in which jobs are scheduled strictly in the order of the list.

of interest in this schedule. Let $\beta > 0$ be some constant. At each discrete time step t, the algorithm applies one of the following three cases:

1. *There is an idle machine M and the first job J_j on the list is ready at time t*—schedule J_j on M and charge all uncharged idle time in the interval (q_j^m, s_j^m) to J_j.
2. *There is an idle machine and the first job J_j in the list is not ready at t, but there is another ready job on the list*—focusing on the job J_k which is the first in the list among the ready jobs, schedule it if there is at least βp_k *uncharged* idle time among all machines and charge βp_k idle time to J_k.
3. *There is no idle time or the above two cases do not apply*—do not schedule any job; merely increment t.

DEFINITION 4.3. *A job is said to be scheduled* in order *if it is scheduled when it is at the head of the list. Otherwise it is said to be scheduled* out of order. *The set of jobs which are scheduled before a job J_i but which come later in the list than J_i is denoted by O_i. The set of jobs which come after J_i in the list is denoted by A_i and those which come before J_i by B_i (includes J_i).*

DEFINITION 4.4. *For each job J_i, define a path $P_i' = J_{j_1}, J_{j_2}, \ldots, J_{j_\ell}$, with $J_{j_\ell} = J_i$ with respect to the schedule S^m as follows. The job J_{j_k} is the predecessor of $J_{j_{k+1}}$ with the largest completion time (in S^m) among all the predecessors of $J_{j_{k+1}}$ such that $C_{j_k}^m \geq r_{j_{k+1}}$; ties are broken arbitrarily. J_{j_1} is the job where this process terminates when there are no predecessors which satisfy the above condition. The jobs in P_i' define a disjoint set of time intervals $(0, r_{j_1}], (s_{j_1}^m, C_{j_1}^m], \ldots, (s_{j_\ell}^m, C_{j_\ell}^m]$ in the schedule. Let κ_i' denote the sum of the lengths of the intervals.*

FACT 4.5. $\kappa_i' \leq \kappa_i$.

FACT 4.6. *The idle time charged to each job J_i is less than or equal to βp_i.*

Proof. The fact is clear if idle time is charged to J_i according to case 2 in the description of our algorithm. Suppose case 1 applies to J_i. Since J_i was ready at q_i^m and was not scheduled according to case 2 earlier, the idle time in the interval (q_i^m, s_i^m) that is charged to J_i is less than βp_i. We remark that the algorithm with discrete time units might charge more idle time due to integrality of the time unit. However, that is easily fixed in the continuous case where we schedule J_i at the first time instant when at least βp_i units of uncharged idle time have accumulated. ∎

A crucial feature of the algorithm is that when it schedules jobs, it considers only the first job in the list that is ready, even if there is enough idle time for other ready jobs that are later in the list. The proof of the following lemma makes use of this feature.

LEMMA 4.7. *For every job J_i, there is no uncharged idle time in the time interval (q_i^m, s_i^m), and furthermore all the idle time is charged only to jobs in B_i.*

Proof. By the preceding remarks, it is clear that no job in A_i is started in the time interval (q_i^m, s_i^m) since J_i was ready at q_i^m. From this we can conclude that there is no idle time charged to jobs in A_i in that time interval. Since J_i is ready at q_i^m and was not scheduled before s_i^m, from cases 1 and 2 in the description of our algorithm there cannot be any uncharged idle time. ∎

The following lemma shows that for any job J_i, the algorithm does not schedule too many jobs from A_i before scheduling J_i itself.

LEMMA 4.8. *For every job J_i, the total idle time charged to jobs in A_i, in the interval $(0, s_i^m)$, is bounded by $m(\kappa_i' - p_i)$. It follows that $p(O_i) \leq m(\kappa_i' - p_i)/\beta \leq m(\kappa_i - p_i)/\beta$.*

Proof. Consider a job J_{j_k} in P_i'. The job $J_{j_{k+1}}$ is ready to be scheduled at the

completion of J_{j_k}, that is, $q^m_{j_{k+1}} = C^m_{j_k}$. From Lemma 4.7, it follows that in the time interval between $(C^m_{j_k}, s^m_{j_{k+1}})$ there is no idle time charged to jobs in $A_{j_{k+1}}$. Since $A_{j_{k+1}} \supset A_i$ it follows that all the idle time for jobs in A_i has to be accumulated in the intersection between $(0, s^m_i)$ and the time intervals defined by P'_i. This quantity is clearly bounded by $m(\kappa'_i - p_i)$. The second part follows since the total processing time of the jobs in O_i is bounded by $1/\beta$ times the total idle time that can be charged to jobs in A_i (recall that $O_i \subseteq A_i$). □

THEOREM 4.9. *Let S^m be the schedule produced by the algorithm* DELAY LIST *using a list S^1. Then for each job J_i, $C^m_i \le (1+\beta)p(B_i)/m + (1+1/\beta)\kappa'_i - p_i/\beta$.*

Proof. Consider a job J_i. We can split the time interval $(0, C^m_i)$ into two disjoint sets of time intervals T_1 and T_2 as follows. The set T_1 consists of all the disjoint time intervals defined by P'_i. The set T_2 consists of the time intervals obtained by removing the intervals in T_1 from $(0, C^m_i)$. Let t_1 and t_2 be the sum of the times of the intervals in T_1 and T_2, respectively. From the definition of T_1, it follows that $t_1 = \kappa'_i \le \kappa_i$. From Lemma 4.7, in the time intervals of T_2, all the idle time is either charged to jobs in B_i, and the only jobs which run are from $B_i \cup O_i$. From Fact 4.6, the idle time charged to jobs in B_i is bounded by $\beta p(B_i)$. Therefore the time t_2 is bounded by $(\beta p(B_i) + p(B_i) + p(O_i))/m$. Using Lemma 4.8 we see that $t_1 + t_2$ is bounded by $(1+\beta)p(B_i)/m + (1+1/\beta)\kappa'_i - p_i/\beta$. □

4.2. One-machine relaxation. In order to use DELAY LIST, we will need to start with a one-machine schedule. The following two lemmas provide lower bounds on the optimal m-machine schedule in terms of the optimal one-machine schedule. This one-machine schedule can be either preemptive or nonpreemptive; the bounds hold in either case.

LEMMA 4.10. $C^m_{\mathrm{OPT}} \ge C^1_{\mathrm{OPT}}/m$.

Proof. Given a schedule S^m on m machines with total weighted completion time C^m, we will construct a one-machine schedule S^1 with total weighted completion time at most mC^m as follows. Order the jobs according to their completion times in S^m with the jobs completing early coming earlier in the ordering. This ordering is our schedule S^1. Note that there could be idle time in the schedule due to release dates. If $i \prec j$, then $C^m_i \le s^m_j \le C^m_j$ which implies that there will be no precedence violations in S^1. We claim that $C^1_i \le mC^m_i$ for every job J_i. Let P be the sum of the processing times of all the jobs which finish before J_i (including J_i) in S^m. Let I be the total idle time in the schedule S^m before C^m_i. It is easy to see that $mC^m_i \ge P + I$. We claim that $C^1_i \le P + I$. The idle time in the schedule S^1 can be charged to idle time in the schedule S^m and P is the sum of all jobs which come before J_i in S^1. This implies the desired result. □

LEMMA 4.11. $C^m_{\mathrm{OPT}} \ge \sum_i w_i\kappa_i = C^\infty_{\mathrm{OPT}}$.

Proof. The length of the critical path κ_i is an obvious lower bound on the completion time C^m_i of job J_i. Summing up over all jobs gives the first inequality. It is also easy to see that if the number of machines is unbounded, every job J_i can be scheduled at the earliest time it is available and will finish by κ_i yielding the equality. □

4.3. Obtaining generic *m*-machine schedules. In this section we derive our main theorem relating m-machine schedules to one-machine schedules.

We begin with a corollary to Theorem 4.9.

COROLLARY 4.12. *Let S^m be the schedule produced by the algorithm* DELAY LIST *using a one-machine schedule S^1 as the list. Then for each job J_i, $C^m_i \le$*

$(1+\beta)C_i^1/m + (1+1/\beta)\kappa_i$.

Proof. Since all jobs in B_i come before J_i in the one-machine schedule, it follows that $p(B_i) \leq C_i^1$. Plugging this and Fact 4.5 into the bound in Theorem 4.9, we conclude that $C_i^m \leq (1+\beta)C_i^1/m + (1+1/\beta)\kappa_i$. ∎

THEOREM 4.13. *Given an instance I of scheduling to minimize sum of weighted completion times and a one-machine schedule for I that is within a factor ρ of an optimal one-machine schedule,* DELAY LIST *gives an m-machine schedule for I that is within a factor $(1+\beta)\rho + (1+1/\beta)$ of an optimal m-machine schedule.*

Proof. Let S^1 be a schedule which is within a factor ρ of the optimal one-machine schedule. Then $C^1 = \sum_i w_i C_i^1 \leq \rho C_{\mathrm{OPT}}^1$. By Corollary 4.12, the schedule created by the algorithm DELAY LIST satisfies

$$\begin{aligned} C^m &= \sum_i w_i C_i^m \\ &\leq \sum_i w_i \left((1+\beta)\frac{C_i^1}{m} + \left(1+\frac{1}{\beta}\right)\kappa_i \right) \\ &= \frac{1+\beta}{m} \sum_i w_i C_i^1 + \left(1+\frac{1}{\beta}\right) \sum_i w_i \kappa_i. \end{aligned}$$

From Lemmas 4.10 and 4.11 it follows that

$$\begin{aligned} C^m &\leq \frac{(1+\beta)\rho C_{\mathrm{OPT}}^1}{m} + \left(1+\frac{1}{\beta}\right) C_{\mathrm{OPT}}^{\infty} \\ &\leq \left((1+\beta)\rho + \left(1+\frac{1}{\beta}\right) \right) C_{\mathrm{OPT}}^m. \end{aligned}$$ ∎

COROLLARY 4.14. *There is an $O(n \log n)$ time 4-approximation algorithm for weighted completion time on parallel machines when the precedence graphs are restricted to be series-parallel graphs.*

Proof. The optimal single machine schedule with release dates ignored can be computed in $O(n \log n)$ time for series-parallel graphs [1]. Applying the DELAY LIST algorithm with $\beta = 1$ to this schedule gives the desired result. ∎

REMARK 4.15. *Since the bounds in our conversion algorithm are job-by-job, the algorithm is applicable to a more general class of metrics as well.*

There is an interesting property of the conversion algorithm that is useful in its applications and worth pointing out explicitly. We explain it via an example. Suppose we want to compute an m-machine schedule with release dates and precedence constraints. From Theorem 4.13 it would appear that we need to compute a one-machine schedule for the problem that has both precedence constraints and release dates. However, we can completely ignore the release dates in computing the one-machine schedule S^1! This follows from a careful examination of the upper bound proved in Theorem 4.9 and the proof of Theorem 4.13. This is useful since the approximation ratio for the problem $1|prec|\sum_j w_j C_j$ is 2 [16] while it is 3 for $1\,|\,prec, r_j\,|\,\sum_j w_j C_j$ [16]. In another example, the problem $1\,||\,\sum_j w_j C_j$ has a very simple polynomial-time algorithm using Smith's ratio rule while $1\,|\,r_j\,|\,\sum_j w_j C_j$ is $\mathcal{NP}$-hard. Thus release dates play a role only in the conversion algorithm and not in the single machine schedule. A similar claim can be made when there are delays between jobs. In this setting a positive delay d_{ij} between jobs i and j indicates that i is a predecessor of j and that j cannot start until d_{ij} time units after i completes. We can generalize our conversion algorithm and its analysis to handle delays

and obtain the same results as those in Theorems 4.9 and 4.13. The only change required is in the definition of ready time of a job which now depends also on the delay after a predecessor finishes. As with release dates we can ignore the delay values (not the precedence constraints implied by them though) in computing the single machine schedule. Munier, Queyranne, and Schulz [24] use linear programming ideas to generalize results for problems with precedence constraints to those with delay constraints.

4.4. Applying conversion to in-tree precedence. We obtain stronger results for in-tree precedence *without* release dates. The problem is strongly $\mathcal{NP}$-hard even for this case. We analyze the standard list scheduling algorithm which starts with an ordering on the jobs (the list) and greedily schedules each successive job in the list at the earliest possible time. We use the optimal one-machine schedule for trees as the list. We show that this algorithm gives a 2-approximation for in-trees. Recall that s_i^m is the start time of J_i in the schedule S^m.

LEMMA 4.16. *If S^m is the list schedule using a one-machine schedule S^1 as the list, then for any job J_i, $C_i^m \leq \kappa_i + C_i^1/m$.*

Proof. Since there are no release dates, we can assume that the schedule S^1 has no idle time. Without loss of generality assume that $J_1, \ldots, J_n$ is the ordering of the jobs ordered according to their *start* times s_i^m in S^m (we break ties arbitrarily). We will prove the lemma by induction on i. We strengthen the hypothesis by adding the following invariant. If $C_i^m > C_j^m + p_i$, where J_j is the last predecessor of J_i to finish in S^m, then all the jobs scheduled before s_i^m in S^m are ahead of J_i in the list S^1 and there is no idle time in the schedule before time s_i^m. In this case it follows that $C_i^m \leq p_i + C_i^1/m$. The base case is trivial since $\kappa_1 = p_1$ and the first job finishes at time p_1. Suppose that the hypothesis holds for all jobs J_k, $k < i$; we will prove it holds for J_i. If J_i has no predecessor it is easily seen that there is no idle time before J_i is scheduled and that $C_i^m \leq p_i + C_i^1/m$. Among the predecessors of i, let J_j, $j < i$ be the last to finish in the schedule S^m (ties are broken arbitrarily). We consider two cases.

1. $C_i^m = C_j^m + p_i$. By the hypothesis, $C_j^m \leq \kappa_j + C_j^1/m$. It follows that $C_i^m \leq \kappa_i + C_i^1/m$ since $\kappa_i \geq \kappa_j + p_i$ and $C_j^1 < C_i^1$.
2. $C_i^m > C_j^m + p_i$. Let $t = C_j^m$. Let P be the set of jobs which finish exactly at time t and P' be the set of jobs which had their last predecessor running until time t. Note that $J_i \in P'$, $J_j \in P$, and all the jobs in P' are ready to be run at time t. In an in-tree a node has at most one immediate successor; therefore $|P'| \leq |P|$. Therefore the number of jobs that are ready at t but were not ready at t^- is at most $|P|$. If J_i was not scheduled at t there must exist a job $J_l \notin P'$ which is scheduled at t. This implies that J_l occurs before J_i in the list S^1. Since no immediate predecessor of J_l finished at t, by the induction hypothesis we conclude that there was no idle time and no job which comes later than J_l in S^1 is scheduled before time t. Since J_i was ready at time t, it follows that there is no idle time and no job later than J_i in S^1 is scheduled between time t and the s_i^m. From these observations it follows that $C_i^m \leq p_i + C_i^1/m \leq \kappa_i + C_i^1/m$.

In both cases we see that the induction hypothesis is established for J_i and this finishes the proof. □

THEOREM 4.17. *There is an $O(n \log n)$-time algorithm with approximation ratio 2 for minimizing weighted completion time on m machines for in-tree precedence without release dates.*

Proof. The proof is similar to that of Theorem 4.13 except that we use the stronger bounds from Lemma 4.16. The running time is dominated by the time to compute the optimal one-machine schedule which can be done in $O(n \log n)$ time [1]. ∎

4.5. A 2.83-approximation for scheduling without precedence constraints. We now improve the approximation bound for parallel machine scheduling with release dates to 2.83 which improves the earlier ratio of $2.89 + \epsilon$ [3]. We combine ideas of the one-machine relaxation developed in section 3 and the idea of using delay based list scheduling to derive an alternate algorithm which has worse ratio than the algorithm in section 3. However, we observe that the bounds we get from the analysis of these two algorithms can be combined to get an improved lower bound on the optimal which leads to the improvement.

Recall from section 3 that $I1$ is the one-machine relaxation for a given instance I and $P1$ is an optimal preemptive schedule for $I1$.

LEMMA 4.18. *If we apply* DELAY LIST *to* $P1$ *with parameter* β*, the resulting schedule* D *has total completion time*

$$\sum C_j^D \leq (2+\beta)C_j^* + \frac{1}{\beta}\sum_j r_j.$$

Proof. We focus on a particular job J_j. From Theorem 4.9 and Fact 4.5 we conclude that $C_j^D \leq (1+\beta)p(B_j)/m + (1+1/\beta)\kappa_j - p_j/\beta$. Since we do not have precedence constraints on the jobs, $\kappa_j = r_j + p_j$. From the definition of B_j and the fact that the list is the order in which jobs finish in $P1$, it follows that $p(B_j)/m \leq C_j^{P1}$. We therefore conclude that $C_j^D \leq (1+\beta)C_j^{P1} + p_j + r_j/\beta$. Summing this over all jobs we obtain

$$\sum_j C_j^D \leq (1+\beta)\sum_j C_j^{P1} + \sum_j p_j + \frac{1}{\beta}\sum_j r_j.$$

Since both $\sum_j C_j^{P1}$ and $\sum_j p_j$ are lower bounds on the optimal schedule value, it follows that

$$\sum_j C_j^D \leq (2+\beta)\sum_j C_j^* + \frac{1}{\beta}\sum_j r_j. \qquad \blacksquare$$

We now balance the two algorithms, list scheduling and DELAY LIST, to achieve an approximation ratio of 2.83.

LEMMA 4.19. *For any input* I*, either list scheduling from* $P1$ *or using* DELAY LIST *on* $P1$ *for an appropriate choice of* β *produces a schedule with* $\sum_j C_j \leq 2.83\sum_j C_j^*$ *and runs in* $O(n \log n)$ *time.*

Proof. By (3.3), we know that

$$\sum_j C_j^N \leq 2\sum_j C_j^{P1} + \sum_j p_j. \tag{4.1}$$

If, for some α, we know that $\sum_j p_j \leq \alpha \sum_j C_j^*$, then the list scheduling algorithm is a $(2+\alpha)$-approximation algorithm.

Now consider the case when $\sum_j p_j > \alpha \sum_j C_j^*$. If we combine this equation with the simple bound that $\sum_j C_j^* \geq \sum_j (p_j + r_j)$, we get

$$\sum_j r_j \leq (1-\alpha)\sum_j C_j^*. \tag{4.2}$$

We can now plug (4.2) into the upper bound on C_j^D from Lemma 4.18 to get

$$\sum_j C_j^D \leq \left(2 + \beta + \frac{1-\alpha}{\beta}\right) \sum_j C_j^*.$$

We do not know the value of α, but for each possible α we can choose the β that minimizes the two terms. Simple algebra and calculus show that given α, we can choose β to be $\sqrt{(1-\alpha)}$. The expression $\min\{2+\alpha, 2+2\sqrt{1-\alpha}\}$ is minimized when $\alpha = 2\sqrt{2} - 2$ thus yielding a ratio of $2\sqrt{2} \simeq 2.83$.

To obtain the guaranteed approximation the algorithm runs both the list scheduling algorithm and the DELAY LIST algorithm with $\beta = \sqrt{3 - 2\sqrt{2}}$ and chooses the better of the two schedules. The schedules can be computed in $O(n \log n)$ time each. □

5. Conclusions. As mentioned earlier, many variants of the problem of minimizing average weighted completion time were shown to have constant factor approximations. Hoogeveen, Schuurman, and Woeginger [18] investigated the hardness of approximation of average completion time scheduling and in particular showed that the problems $P|prec, p_j = 1|\sum_j C_j$ and $R|r_j|\sum_j C_j$ are APX-hard; in other words, they do not admit a polynomial-time approximation scheme (PTAS) unless $P = NP$. Recently, much progress was made in obtained improved upper bounds as well. Several groups of authors obtained efficient PTASs for problems involving only release dates. A preliminary version describing these results is [2]. The maximal cases that were shown to have a PTAS are $P|r_j|\sum_j w_j C_j$, $Rm|r_j|\sum_j w_j C_j$, and their preemptive versions. An interesting open problem is the complexity of $1|prec|\sum_j w_j C_j$. A 2-approximation for this problem is known but no APX-hardness has been established. Subsequent to the linear programming based methods [16], simple combinatorial algorithms [6, 8] were developed for this problem matching the approximation ratio of 2. By coupling these algorithms with the DELAY LIST algorithm in this paper we obtain the first efficient and combinatorial approximation algorithms even with precedence constraints and delays. The ratio achieved for $P|r_j, prec|\sum_j w_j C_j$ is 5.83 and is worse than the currently best known ratio of 4 [24]. However, the algorithm in [24] is based on solving a linear program via the ellipsoid method.

MARKOV CHAIN ALGORITHMS FOR PLANAR LATTICE STRUCTURES*

MICHAEL LUBY†, DANA RANDALL‡, AND ALISTAIR SINCLAIR§

Abstract. Consider the following Markov chain, whose states are all domino tilings of a $2n \times 2n$ chessboard: starting from some arbitrary tiling, pick a 2×2 window uniformly at random. If the four squares appearing in this window are covered by two parallel dominoes, rotate the dominoes 90^o in place. Repeat many times. This process is used in practice to generate a random tiling and is a widely used tool in the study of the combinatorics of tilings and the behavior of dimer systems in statistical physics. Analogous Markov chains are used to randomly generate other structures on various two-dimensional lattices. This paper presents techniques which prove for the first time that, in many interesting cases, a small number of random moves suffice to obtain a uniform distribution.

Key words. Markov chains, rapid mixing, dimer systems, domino tilings, Eulerian orientations

1. Introduction.

This paper is concerned with algorithmic problems of the following type: given a simply connected region S of the two-dimensional Cartesian lattice (e.g., an $n \times n$ chessboard), generate uniformly at random a tiling of S with nonoverlapping dominoes, each of which covers two adjacent squares of the lattice. This problem arises in statistical physics, where the tilings correspond to configurations of a *dimer system* on S (see, e.g., [8]). Various physical properties of the system are related to the expected value, over the uniform distribution, of some function defined over configurations, such as the number of horizontal dominoes or the correlation between the orientation of dominoes at two given squares. An algorithm for randomly generating configurations allows such expectations to be estimated to any desired accuracy. It also enables one to formulate and test more detailed properties of a "typical" configuration, such as the Arctic Circle theorem [10], which began as a conjecture based on observations of random configurations.

A host of other problems of physical and combinatorial interest center around the properties of random structures of various kinds on a two-dimensional lattice. Further examples that we shall consider in this paper are lozenge tilings of a triangular lattice (corresponding to a dimer system with a different underlying geometry), and Eulerian orientations of a Cartesian lattice, also known in the statistical mechanics community as the six-point ice model. In all cases, algorithms that randomly generate

configurations are the major experimental tool available to researchers interested in the properties of such systems.

Returning to our first example, here is the algorithm that is most widely used in practice to generate a random domino tiling of a region S. Starting from an arbitrary tiling, pick a 2×2 window uniformly at random. If the four squares in this window are covered by two parallel dominoes, rotate the dominoes in place (see Figure 1). Repeat this operation a large number of times. The resulting tiling should then be (almost) random.

FIG. 1. *Domino rotations.*

The fact that this process (a Markov chain on the set of tilings) is connected (i.e., that every tiling is reachable from every other one by a sequence of moves of the above kind) follows from a beautiful result of Thurston [17]. However, no nontrivial upper bound is known on the number of moves needed to achieve a random tiling. In practice, this number is decided by appealing to combinatorial intuition, or experimentally by some ad hoc stopping rule. What is lacking is an analysis of the rate of convergence of the Markov chain to the uniform distribution, which would supply an a priori bound on the number of moves. Similar Markov chains, based on analogous local moves, are used to generate other two-dimensional lattice structures in the same way. Like the dominoes chain, they have so far resisted analysis.

In this paper, we develop a combinatorial framework that allows several Markov chains of this kind to be analyzed for the first time. There are two essential ingredients. The first, which we believe to be of independent combinatorial interest, is to establish a one-to-one correspondence between the configurations on a lattice region S and objects which we call *routings* on a related lattice. Informally, a routing is a collection of vertex-disjoint (or edge-disjoint) paths crossing S from left to right. (See section 2 for precise definitions and examples.) These correspondences were already known, at least implicitly, but here they play an essential role in the analysis of the associated Markov chains.

The second ingredient is to interpret natural Markov chains like the one above on domino tilings in terms of the associated routings. As we shall see, elementary moves on configurations correspond to natural local perturbations of the routings (such as displacing one vertex along a path). The crucial feature of this translation is that, when viewed in the routings world, the rate of convergence of the Markov chain turns out to be amenable to a simple and elegant analysis using a coupling argument. In fact, this analysis leads us to generalize slightly the class of random moves allowed for routings; these in turn map back to natural nonlocal moves for the configurations themselves. As a result, we obtain new, nonlocal versions of the Markov chains which are provably "rapidly mixing" (i.e., they converge quickly to the uniform distribution).

The upshot of all this is low-degree polynomial bounds on the convergence time of these Markov chains for all three of the examples mentioned above. We therefore

provide the first rigorous justification for experiments that use short simulations of the chains in order to generate random configurations.

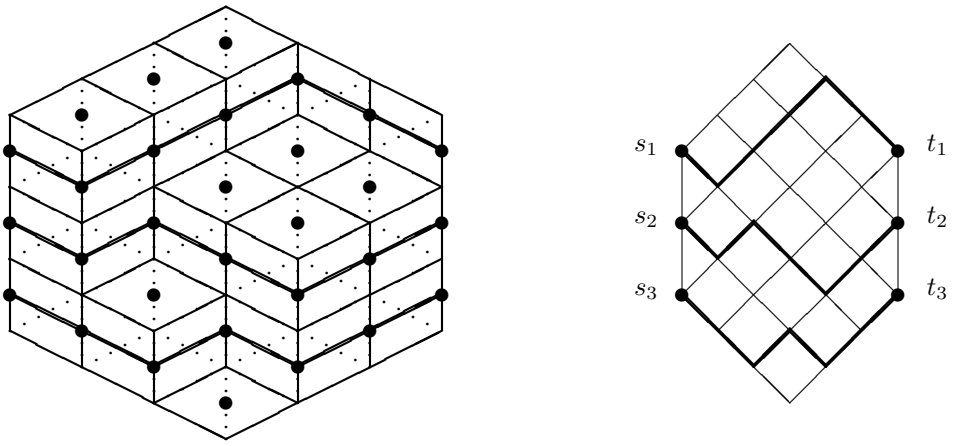
We should mention that these problems can be solved by alternative approaches. A combinatorial trick known as the Gessel–Viennot method [7] allows one to count lattice routings by evaluating a suitable determinant. In conjunction with self-reducibility properties, this allows one to generate configurations uniformly at random (see, e.g., [16]). Other Markov chain algorithms which can be applied to these structures in arbitrary graphs are given in [9, 12] (for tilings) and [13] (for Eulerian orientations). However, in the important special case of planar lattices, the algorithms in this paper have better time bounds than these other methods and are simpler, more natural, and quite widely used in practice. Moreover, our bounds are in fact quite pessimistic (our main concern is to introduce the methodology rather than to tune the bounds) and can be improved with a more detailed analysis (see the subsequent paper by Wilson [18]). We also point out that there is a simple experiment one can perform which provides a reliable estimate of the true convergence rate: this can be used to dramatically reduce the number of simulation steps required in practice, as discussed in [14].

The remainder of the paper is organized as follows. In section 2 we illustrate the correspondence between lattice configurations, routings, and height functions for each of our examples: lozenge tilings, domino tilings, and Eulerian orientations. In section 3, we show how to analyze the rate of convergence of the natural Markov chain on lozenge tilings by applying a coupling argument to the corresponding chain on routings. In the process, we will enrich the chain with nonlocal moves. In sections 4 and 5 we show how to apply the same technology to analogous Markov chains for domino tilings and Eulerian orientations.

2. Lattice routings and height functions. In this section, we consider several important examples of lattice structures and illustrate the correspondence between them and collections of paths which we call *routings*. Routings are the key for analyzing the convergence rate, or running time, of our Markov chain algorithms. As we shall see, the routings are closely related to a third representation of the lattice structures known as *height functions*, which arise from the tiling groups of Conway and Lagarias [4] and Thurston [17]. For each of our three examples we briefly outline the bijections between lattice structures, routings, and height functions. As we shall see later, this framework will make the analytical tools we develop rather generally applicable.

2.1. Lozenge tilings. The first structures we consider are lozenge tilings of a finite region of the triangular lattice: we discuss these first because the correspondence with routings is most direct here. A *lozenge* is the analogue of a domino in the Cartesian lattice: each lozenge covers two adjacent triangles in the lattice and has three possible orientations. Lozenge tilings are configurations of a dimer system on this lattice. As explained in the introduction, we are interested in the problem of generating a random lozenge tiling of the given region.

The routings corresponding to lozenge tilings are defined on an associated Cartesian lattice. Given a finite, simply connected region S of the triangular lattice, we define an associated region $\hat{S}$ of the Cartesian lattice as follows. The vertices of $\hat{S}$ correspond to the midpoints of the vertical edges in S, and two vertices in $\hat{S}$ are connected if the corresponding points in S lie on adjacent triangles. This mapping is demonstrated in Figure 2.



A lozenge tiling on S The corresponding routing on $\hat{S}$

FIG. 2. *Lozenge tilings and routings.*

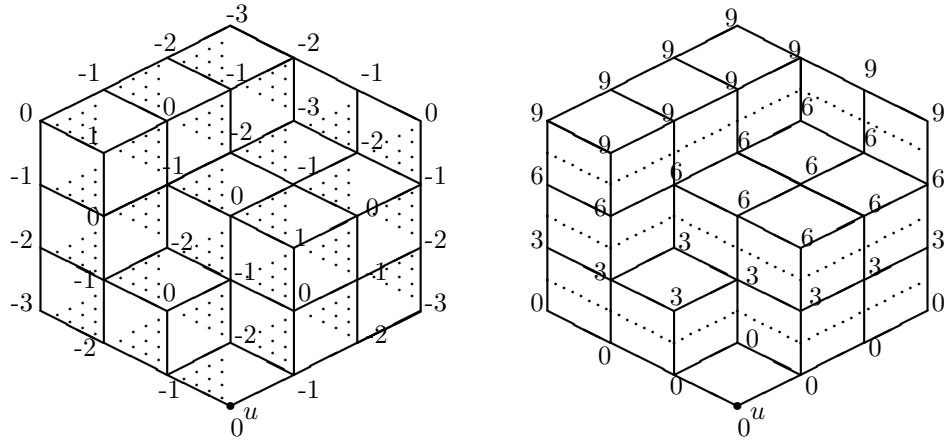
The vertices of $\hat{S}$ that correspond to edges on the boundary of S are called *sources* and *sinks*: a vertex v is a source if the interior of $\hat{S}$ lies to the right of v and a sink if the interior of $\hat{S}$ lies to its left. It is not hard to check that, if a lozenge tiling of S exists, then the numbers of sources and sinks are necessarily equal. Label the sources $s_1, \ldots, s_k$ and the sinks $t_1, \ldots, t_k$.

A *lozenge routing* of $\hat{S}$ is a set of k nonintersecting (i.e., vertex-disjoint) shortest paths on the Cartesian lattice within $\hat{S}$ from $\{s_1, \ldots, s_k\}$ to $\{t_1, \ldots, t_k\}$. It is not difficult to see that there is a bijection between lozenge tilings and lozenge routings of corresponding regions. Figure 2 provides a pictorial illustration of this correspondence for a typical region S. An easy way to see this is to "mark" the tiles containing two vertical edges with a stripe connecting the centers of these edges. Now notice that if a tile is placed next to any vertical edge of S, then it must have two vertical edges whose midpoints correspond to adjacent vertices in $\hat{S}$. Furthermore, if the vertical edge of a tile lies in the interior of S, then it must be adjacent to another tile having two vertical edges (so the markings line up). Following such a sequence of tiles, starting from each vertical edge on the boundary of S, defines a set of nonintersecting source-sink paths in $\hat{S}$, i.e., a routing. Conversely, given a routing we may invert the above construction to create a partial tiling using only marked (i.e., nonhorizontal) tiles. All vertical edges of these tiles are adjacent to another tile or to the boundary of S. The untiled portion of S therefore consists of regions bounded only by nonvertical edges. It is not hard to see that these can be tiled in only one way, using only horizontal tiles. Hence there is a bijection between the set of tilings and routings of S. Moreover, we can order the sinks so that the path from s_i always ends at t_i, for all i, and the path from s_i to t_i will have the same length in every routing.

This correspondence has been formalized by Sachs et al.

THEOREM 2.1 (see [1, 11]). *The set of lozenge tilings of S corresponds bijectively with the set of lozenge routings of $\hat{S}$.* □

The bijection between tilings and routings is closely related to the *height functions* defined by Thurston [17]. Although we don't require it for our analysis, we briefly describe this connection here because it sheds further light on the above correspondence.



The height function h_{loz} The adjusted height function $\hat{h}_{loz}$

FIG. 3. *Lozenge tilings and height functions.*

In this representation, the *height* of each vertex in the region S is determined by an underlying algebraic structure known as the tiling group, introduced by Conway and Lagarias [4]. The height function can be extended to all points within the region by a piecewise linear function, thereby defining a three-dimensional surface associated with each tiling. It turns out that, by viewing each surface from a certain orientation, the paths of a routing can be interpreted as the level sets of this surface. This is a common feature of all the structures we discuss in this paper; in the case of lozenges the surfaces are immediately apparent and are just the set of three-dimensional boxes that seem to "jump out" of the two-dimensional lozenge tiling, as in the left-hand picture in Figure 2.

The heights of the vertices of any tiling can be determined by the following simple rule. First choose a vertex u on the boundary of the region and fix its height $h_{loz}(u) = 0$. To determine the heights of all other vertices we rely on the bipartite structure of the dual lattice, which allows us to color all the triangles pointing to the right white and all those pointing to the left black. Starting at u, walk around the boundaries of tiles until an edge is traversed from a vertex v with known height $h_{loz}(v)$ to a vertex w whose height has not yet been determined. If the triangle to the left of this edge (w.r.t. the direction of traversal) is black, set $h_{loz}(w) = h_{loz}(v) + 1$; if the triangle to the left is white, set $h_{loz}(w) = h_{loz}(v) - 1$. Repeat this process until all of the vertices have been visited. For any tiling of a simply connected region, the heights are always unique and well-defined (up to translation). As an example, Figure 3 shows the height function for the tiling of Figure 2 with u being the bottom vertex. A simple consequence of the above definition is that the heights along the boundary of any tiling are determined by the region alone and are identical for all tilings of the region.

The connection between height functions and routings in the case of lozenge tilings is quite straightforward. We create an *adjusted* height function $\hat{h}_{loz}$ by letting v_y be the vertical coordinate of vertex v (i.e., the row of the lattice that it lies in) and defining $\hat{h}_{loz}(v) = h_{loz}(v) + v_y$. It is a simple exercise to verify that, for any vertex v, the adjusted height function satisfies $\hat{h}_{loz}(v) = \hat{h}_{loz}(u) + 3k$, where k is the number of paths in the routing which lie between v and u (with k being negative if these

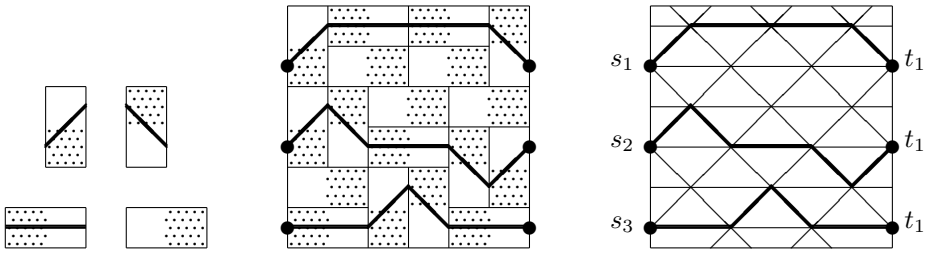


FIG. 4. *Domino tilings and routings.*

paths lie above v and positive if they lie below v); see Figure 3. This can be proved using the observation that on every lozenge the heights of the two vertices where the angle is acute must be equal. This implies that horizontal lozenges, where the two vertices with acute angles lie in the same row, will have the same adjusted height at all four corners, while on the other two types of lozenges the lower two vertices will have strictly smaller height than the upper two vertices.

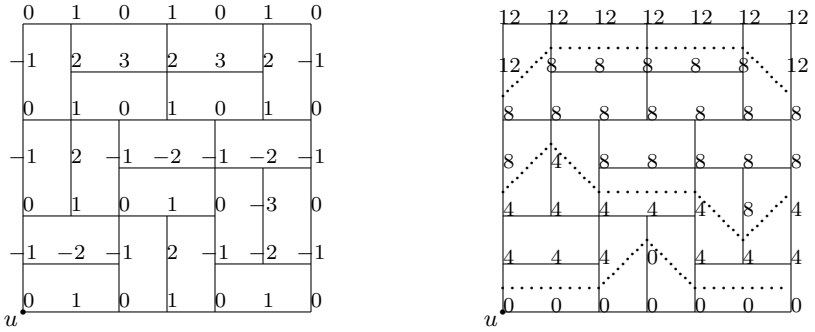
2.2. Domino tilings. A *domino tiling* is a covering of a finite region of the Cartesian lattice with dominoes, where each domino covers two adjacent squares of the region. Domino tilings are configurations of dimer systems on this lattice. As in the case of lozenge tilings, there is a family of routings which correspond bijectively to the set of domino tilings. Again, the routings are defined on an associated lattice, which in this case is triangular.

Given a finite, simply connected tileable region S in the Cartesian lattice, we define a related region $\hat{S}$ (which lies on a triangular lattice). First color the squares of the Cartesian lattice black and white as on a chessboard. The vertices of the triangular lattice can be defined as the centers of all of the vertical edges of the Cartesian lattice which have a black square to their right, where edges are defined by connecting each vertex (x, y) to $(x + 1, y + 1)$, $(x + 1, y - 1)$, and $(x + 2, y)$. The region $\hat{S}$ is the part of this triangular lattice which is defined by vertices and edges contained completely within the original region S. Sources and sinks of $\hat{S}$ are defined in similar fashion to the lozenge case: sources are boundary vertices with the interior of $\hat{S}$ to their right, and sinks are those with the interior to their left. Once again, we pair up sources $\{s_1, \ldots, s_k\}$ and sinks $\{t_1, \ldots, t_k\}$ in the obvious way. A *domino routing* of $\hat{S}$ is then a collection of nonintersecting shortest paths on the triangular lattice within $\hat{S}$ from s_i to t_i for each i.

The correspondence between domino tilings and routings is illustrated by means of an example in Figure 4: each tiling defines a unique routing using the three permitted paths through the dominoes as shown. This correspondence is formalized in the next theorem.

THEOREM 2.2. *There is a bijection between domino tilings of S and domino routings of $\hat{S}$.*

Proof. Figure 4 indicates how to use paths through dominoes to map tilings to routings as follows. Start at a source vertex s_i. By definition, there must be a black square in the interior (of the original Cartesian lattice region S) to the right of s_i. The domino occupying this square determines the first step of our path: we connect s_i to the unique point on the right boundary of the domino which is a vertex of $\hat{S}$ in the underlying triangular lattice. We now find ourselves at a new point with a



The height function h_{dom} The adjusted height function $\hat{h}_{dom}$

FIG. 5. *Domino tilings and height functions.*

black square to our right, and we can repeat this process. Since we migrate to the right in each step, we eventually hit a point on the right boundary of $\hat{S}$ which has a black square to its right and thus must be a sink. The paths must be nonintersecting because the tiles cannot overlap.

To see that the above map is bijective, we construct the inverse map from routings to tilings as follows. Each path starts at a source s_i (which has a black square to its right) and follows lattice edges to a sink t_i. As we follow the path from left to right, we tile each of the black squares to the right of the lattice points on the path (except the sink t_i). There are three possible positionings for each tile corresponding to the three possible types of edges the path can pass through. Since the paths are nonintersecting, our tiles cannot overlap and we are left with a partial tiling of S. Now there is a unique way to tile the remaining parts of the region, namely, using only horizontal tiles (whose left half covers a white square). To see this, consider any untiled black square. The white square to its left must be untiled, for if it were tiled there would be a path exiting its right boundary, and then the black square would be tiled. Therefore every black square can be tiled with the right half of a horizontal domino. This completes the tiling since there must be an equal number of black and white squares in S. The uniqueness comes from the fact that the leftmost square in each row of each untiled subregion is white, so we cannot complete the tiling if we use any vertical tiles. □

Once again, the routings defined above can be viewed as level sets of a height function. The height function which arises from the tiling group for dominoes can be summarized using a rule based on the bipartition underlying the dual lattice (i.e., the black and white squares of the chessboard). To define the height function h_{dom}, start with some point u on the boundary and assign $h_{dom}(u) = 0$. Now, walking along edges bounding the tiles starting at u, if the square to the left of an edge is black (respectively, white), increase (respectively, decrease) the height by one. An example is illustrated in Figure 5 with u being the bottom left vertex.

The connection between height functions and routings is analogous to that for lozenge tilings. For any point $v = (v_x, v_y)$, let v_y be the y coordinate of v (i.e., the row of the lattice). Let $\mathrm{par}(v) = 1$ if v is the lower left corner of a white square, and let $\mathrm{par}(v) = 0$ if v is the lower left corner of a black square. Now define the adjusted height function by $\hat{h}_{dom}(v) = -h_{dom}(v) + 2v_y + \mathrm{par}(v)$. It is easy to verify that

$\hat{h}_{dom}(v)$ is equal to $\hat{h}_{dom}(u) + 4k$, where k is the number of paths which lie between u and v in the routing (k being negative if these paths lie below u). Figure 5 illustrates this relationship.

2.3. Eulerian orientations. A third important set of structures which can be identified with lattice routings are the Eulerian orientations of a region of the Cartesian lattice with specified boundary conditions. An *Eulerian orientation* of an undirected graph is an orientation of its edges so that the in-degree of every vertex is equal to its out-degree. In this problem, the input is a finite simply connected region S of the two-dimensional Cartesian lattice, together with a fixed orientation for each of the edges that connects the boundary of S with the interior: these orientations are the *boundary conditions*. Our task is to generate uniformly at random an orientation of the edges in the interior such that all interior vertices have equal in-degree and out-degree. This is the "six-point model" in statistical mechanics, also known as the "ice model."

The correspondence between Eulerian orientations and a suitable class of routings is well known in the physics community (see, e.g., [3]) and is sketched in Figure 6. The sources and sinks in this case are defined by the boundary conditions as shown. Sources are the vertices on the boundary which are connected to the interior of the region by edges directed towards the interior and which point up or to the right; sinks are the boundary vertices which are connected to the interior by edges directed away from the interior (i.e., towards the boundary) and which also point up or to the right. A necessary condition for the existence of an Eulerian orientation is, of course, that the number of sources and sinks are equal.

An *Eulerian routing* of S is a set of shortest paths in S from sources $\{s_1, \ldots, s_k\}$ to sinks $\{t_1, \ldots, t_k\}$ on the boundary. The paths are permitted to intersect at a vertex but *not* along an edge. As illustrated in Figure 6, to get the Eulerian routing corresponding to a given Eulerian orientation, we construct the paths only from edges that are oriented up and those that are oriented to the right. It is straightforward to establish that there is a bijection between the set of Eulerian orientations of a region S and the set of Eulerian routings of S.

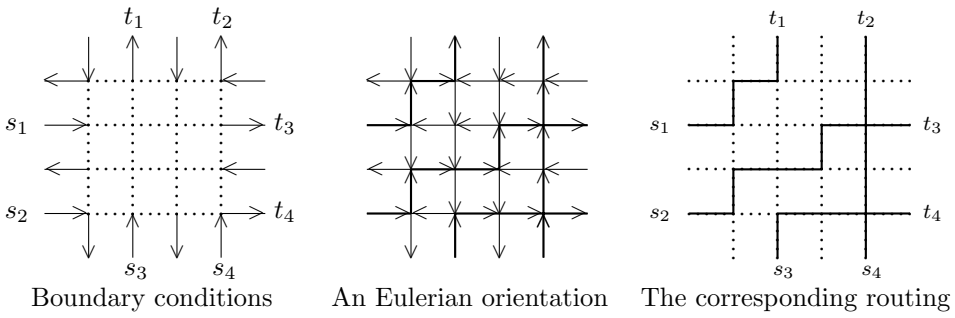


FIG. 6. *Eulerian orientations and routings.*

The height function associated with Eulerian orientations is an assignment of integers to the center of each face within a region such that neighboring faces differ in height by one. In the statistical physics community, this is known as a "solid-on-solid surface." To define the heights, start with a face adjacent to the boundary and assign to its center u the height $h_{eul}(u) = 0$. To define the heights of the other faces, walk along edges in the dual lattice. When traversing a dual edge (v, w), where the

height of v is already defined, let $h_{eul}(w) = h_{eul}(v) + 1$ if the edge of the Eulerian orientation which was crossed points to the right (relative to the path from v to w) and let $h_{eul}(w) = h_{eul}(v) - 1$ if the edge points to the left. Again this height function is unique (up to translation) and well-defined. If we define an adjusted height function $\hat{h}_{eul}(v) = h_{eul}(v) - v_x + v_y$, where v_x and v_y are the Cartesian coordinates of v, then $\hat{h}_{eul}(v) = \hat{h}_{eul}(u) + 2k$, where k is the number of paths of the routing which lie between u and v. See Figure 7 for an illustrative example.

FIG. 7. *The height function representation of an Eulerian orientation.*

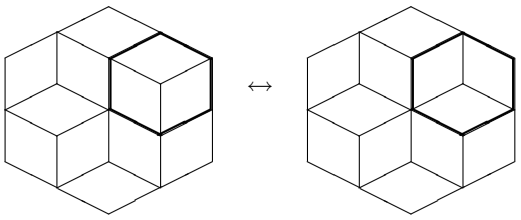
Remark 1. The solid-on-solid height function demonstrates the well-known connection between Eulerian orientations and three-colorings of a lattice region, since taking the values of the heights mod 3 always gives a valid three-coloring of the region (see, e.g., [3]). If we fix the colors of all the dual vertices on the boundary of the region (and hence the boundary conditions), then there is a bijection between three-colorings and Eulerian orientations.

3. Generating lozenge tilings. This section is devoted to an analysis of a natural Markov chain algorithm for generating random lozenge tilings. The analysis will exploit in a crucial way the correspondence with routings established in section 2.1. We present this example first because it is the most straightforward to deal with. Analogous Markov chains for generating the other structures discussed in section 2 can be analyzed by more refined applications of the same techniques, as we will demonstrate in section 4.

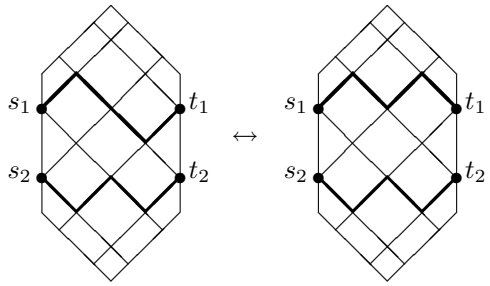
3.1. The Markov chain. In the introduction, we discussed a Markov chain on domino tilings based on a local move that rotates a pair of adjacent dominoes. The analogous Markov chain for lozenge tilings has as its local move a rotation of three neighboring lozenges (see Figure 8(a)). As in the domino case, this chain can also be shown to be connected and to converge to the uniform distribution over tilings (see section 3.2).

Let us now interpret this Markov chain in the world of routings. It is clear that a lozenge rotation induces a natural local move on the corresponding routing, in which a "peak" or a "valley" is inverted by switching two edges (see Figure 8(b)). Therefore we can think of the chain as picking a point uniformly at random on the routing and inverting it if possible.[1] It turns out that the Markov chain in the routings world

[1]Strictly speaking, this chain differs slightly from the original one in that it does not attempt to make rotations at points that are not on the current paths, which will always be rejected. This merely reduces the self-loop probabilities of the chain, and hence speeds up the mixing time by a factor that is bounded by the area of the region.



(a) Tiling rotation



(b) Routing rotation

FIG. 8. *Lozenge rotations.*

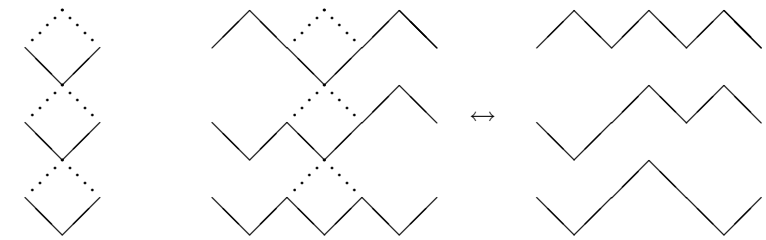
becomes considerably easier to analyze if *every* peak and valley can give rise to a rotation: note that this is not the case for the above chain, since sometimes when we try to invert a point the move will be blocked by the presence of another path. (Recall that the paths in a routing are not allowed to intersect. See, e.g., the second valley on the lower path in the left-hand routing of Figure 8(b).) This motivates the introduction of a more general set of moves in which a *tower* is rotated. The original moves will simply correspond to the special case of rotating a tower of height 1.

In the routings lattice, define the *cell at* (x, y) to be the edges connecting $(x, y), (x+1, y+1), (x, y+2)$, and $(x-1, y+1)$. A *tower of height* h is a connected set of cells at the points $(x, y), (x, y+2), \ldots, (x, y+2h-2)$, where either the points $(x, y), (x, y+2), \ldots, (x, y+2h-2)$ are all valleys and the point $(x, y+2h)$ does not lie on the routing, or the points $(x, y+2h), (x, y+2h-2), \ldots, (x, y+2)$ are all peaks and the point (x, y) does not lie on the routing. We call the points (x, y) and $(x, y+2h)$ the *bottom* and *top* of the tower, respectively (see Figure 9(a)). Provided both the top and bottom of a tower lie in the region, its peaks (respectively, valleys) can be inverted by switching pairs of edges in each of its cells. Such an operation is called a *rotation* of the tower. Figure 9(b) illustrates a rotation of a tower of height 3, and Figure 9(c) shows that tower rotations have a natural counterpart in the original tilings world.

Let R_1 and R_2 be lozenge routings of the region $\hat{S}$. We define a Markov chain $\mathcal{M}_{loz}$ in which there is a move from R_1 to R_2 iff R_1 and R_2 differ by a single tower rotation. The transition probabilities $P(\cdot, \cdot)$ of $\mathcal{M}_{loz}$ are defined by

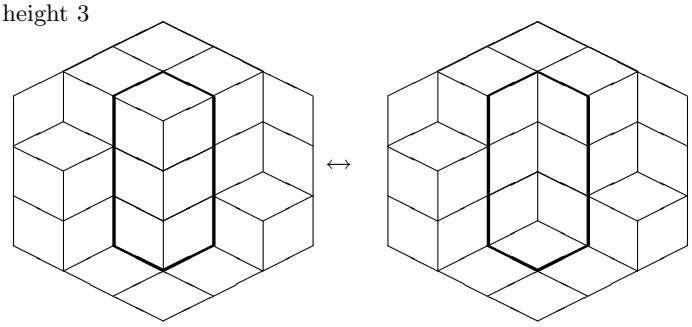
$$P(R_1, R_2) = \begin{cases} 1/2Nh & \text{if } R_1, R_2 \text{ differ by rotation of a tower of height } h; \\ 1 - \sum_{R \neq R_1} P(R_1, R) & \text{if } R_2 = R_1, \end{cases}$$

where N is the total number of internal vertices along all the paths in any routing.



(a) Tower of height 3

(b) Tower rotation in a routing



(c) Tower rotation in a tiling

FIG. 9. *A move in the Markov chain $\mathcal{M}_{loz}$ for lozenge routings (and tilings).*

Notice that we may implement a move of $\mathcal{M}_{loz}$ as follows. Given a routing R, choose an internal point p on one of the paths in R and a number $r \in [0,1]$ uniformly at random. Assume first that $r \leq 1/2$. If p is a valley, then it is the bottom of a unique tower (say, of height h); in this case, if $r \leq 1/2h$, then rotate the tower if possible (i.e., if the top of the tower lies in the region). On the other hand, if $r > 1/2$ check whether p is a peak (and hence the top of a unique tower), and if possible rotate this tower if $r \geq 1 - 1/2h$, where h is the height of the tower. In all other cases do nothing. This slightly unusual implementation is a technical device that will prove useful later when we define a coupling for the Markov chain.

As we shall see in section 3.2, this Markov chain is ergodic and converges to the uniform distribution over all lozenge routings. Therefore, we can generate a random tiling by simulating $\mathcal{M}_{loz}$ for sufficiently many steps, starting from an arbitrary routing and outputting the tiling corresponding to the final routing. The efficiency of this algorithm depends on the number of simulation steps necessary to ensure an (almost) uniform distribution, or, equivalently, on the *rate of convergence* of the Markov chain. We shall see in section 3.4 that a small number of steps suffice, or in other words that the Markov chain is "rapidly mixing." In preparation for this we will introduce some general technology in section 3.3.

3.2. Ergodicity of $\mathcal{M}_{loz}$. The fact that $\mathcal{M}_{loz}$ converges to the uniform distribution over tilings follows almost immediately from the fact that the chain is connected, i.e., every state is reachable from every other. It is actually quite straightforward to show that the Markov chain based on *simple* rotations connects the state space of all lozenge tilings. This is sufficient to show the connectedness of the Markov chain based on towers since it includes all the simple moves. Here we sketch a proof whose machinery will be useful to us in other ways.

LEMMA 3.1. *The state space of the Markov chain $\mathcal{M}_{loz}$ is connected.*

Proof. It is conceptually easier to work in the routings world. Note that there is a natural partial order on the set of all lozenge routings of a given region $\hat{S}$, defined as follows. Let R_1, R_2 be two routings, and let P_1, P_2 be a pair of corresponding paths (i.e., having the same source and sink) in R_1, R_2, respectively. We say that $P_1 \succeq P_2$ iff the ith point of P_1 lies on or above the ith point of P_2 for all i. We say that $R_1 \succeq R_2$ iff the relation $P_1 \succeq P_2$ holds for all pairs of corresponding paths P_1, P_2. Since all routings of a region $\hat{S}$ have the same number of paths, this relation is well-defined. If $R_1 \succeq R_2$, we define the distance between them to be the total area enclosed between all pairs of corresponding paths. Now it is not too hard to see that, for any finite, simply connected region $\hat{S}$, there is a unique minimum routing $R_\perp$, such that $R \succeq R_\perp$ for all routings R of $\hat{S}$.[2] We will show that every routing is connected to $R_\perp$ by a sequence of simple rotations (i.e., of towers of height 1) each of which decreases the distance to $R_\perp$ by one.

Let $R \neq R_\perp$ be an arbitrary routing. Starting with the lowest pair of corresponding paths in $R, R_\perp$ and working upwards, scan left to right along the paths until the first point x at which $R, R_\perp$ deviate from one another. Now continue to follow these two paths (say, P and $P_\perp$) until the first point y where they meet again (this must happen, at the latest, at their common sink). Notice that the union of the segments of P and $P_\perp$ that lie between x and y form a circuit whose interior is entirely contained within the interior of $\hat{S}$, since $\hat{S}$ is simply connected. In addition, since $R_\perp$ is minimal, P must lie strictly above $P_\perp$ along the segment delimited by these two points. Therefore, P must have at least one peak along this segment; let v be the leftmost such peak. It follows that v must be the top of a (rotatable) tower of height 1 in R, since v lies strictly above the corresponding point in $R_\perp$ and R coincides with $R_\perp$ on all lower paths. Therefore, if we rotate the tower at v we decrease the distance from $R_\perp$ by one unit. Applying this argument repeatedly, we arrive at $R_\perp$. □

THEOREM 3.2. *The Markov chain $\mathcal{M}_{loz}$ is ergodic and converges to the uniform distribution over lozenge tilings.*

Proof. The Markov chain is clearly aperiodic since it has a holding probability of at least $1/2$ in every state. Together with Lemma 3.1, this implies that the chain is ergodic, i.e., converges to a unique stationary distribution. That this stationary distribution is uniform follows from the fact that the transition probabilities are symmetric: for any pair of adjacent routings R_1, R_2, we have $P(R_1, R_2) = P(R_2, R_1) = 1/2Nh$, where h is the height of the tower by which R_1 and R_2 differ. □

3.3. Coupling and the convergence rate. In this subsection, we establish some general machinery for bounding the rate of convergence of Markov chains, which we shall use repeatedly in the remainder of the paper. Consider an ergodic Markov chain $\mathcal{M}$ with finite state space Ω, transition matrix P, and stationary distribution π. Following standard practice, for any given initial state x, we shall measure the deviation of the distribution $P^t(x, \cdot)$ at time t from π by the *variation distance*

$$\Delta_x(t) = \tfrac{1}{2} \sum_{y \in \Omega} |P^t(x, y) - \pi(y)|.$$

The *mixing time* of the Markov chain is defined by the function

$$\tau(\epsilon) = \max_x \min\{t : \Delta_x(t') \leq \epsilon \text{ for all } t' \geq t\}.$$

[2] A careful proof of the existence of a unique highest tiling (in the height function representation) was given by Thurston [17]; this corresponds precisely to the minimum routing defined here.

Our strategy for bounding $\tau(\epsilon)$ is to construct a *coupling* for the Markov chain, i.e., a stochastic process $(X_t, Y_t)_{t=0}^{\infty}$ on $\Omega \times \Omega$ with the following properties:

1. Each of the processes X_t and Y_t is a faithful copy of $\mathcal{M}$ (given initial states $X_0 = x$ and $Y_0 = y$).
2. If $X_t = Y_t$, then $X_{t+1} = Y_{t+1}$.

The idea here is the following. Although each of X_t, Y_t, viewed in isolation, behaves exactly like $\mathcal{M}$, they need not be independent; on the contrary, we will construct a joint distribution for the two processes in such a way that they tend to move closer together. By the second condition above, once they have met they must remain together at all future times.

The expected time taken for the processes to meet provides a good bound on the mixing time of $\mathcal{M}$. To state this formally, for initial states x, y set

$$T^{x,y} = \min\{t : X_t = Y_t \mid X_0 = x,\, Y_0 = y\}$$

and define the *coupling time* to be $T = \max_{x,y} \mathrm{E}T^{x,y}$. The following result relating the mixing time to the coupling time is standard (see, e.g., [2]).

THEOREM 3.3. $\tau(\epsilon) \le T\mathrm{e}\lceil \ln \epsilon^{-1} \rceil$. □

Next, we introduce some machinery that will help us to bound the coupling time. Suppose we have a distance function ϕ defined on $\Omega \times \Omega$ such that ϕ takes integer values in the range $[0, B]$, and $\phi(x, y) = 0$ iff $x = y$. In our examples, where the states of the Markov chain are lattice routings, ϕ will be a natural measure of the "area" between a pair of routings. We will measure the distance between a pair of processes (X_t, Y_t) using the stochastic process $\Phi(t) = \phi(X_t, Y_t)$. Our strategy will be to show that, under a suitably defined coupling, the expected change $\Delta\Phi$ in Φ is always nonpositive; intuitively, this should enable us to conclude that the coupling time is small. The following lemma makes this intuition precise.

LEMMA 3.4. *With the above notation, suppose the coupling satisfies* $\mathrm{E}\big[\Delta\Phi(t)|X_t, Y_t\big] \le 0$ *and, whenever* $\Phi(t) > 0$, $\mathrm{E}\big[(\Delta\Phi(t))^2|X_t, Y_t\big] \ge V$. *Then the expected coupling time from initial states* x, y *satisfies* $\mathrm{E}T^{x,y} \le \Phi(0)\big(2B - \Phi(0)\big)/V$.

Proof. Define the stochastic process $Z(t) = \Phi(t)^2 - 2B\Phi(t) - VT(t)$, where $T(t) = t$ if $\Phi(t) > 0$, and $T(t) = \min\{t' : \Phi(t') = 0\}$ if $\Phi(t) = 0$. Then $Z(t+1) - Z(t) = 0$ whenever $\Phi(t) = 0$, and when $\Phi(t) > 0$ we have

$$\begin{aligned}
&\mathrm{E}\big[Z(t+1)|X_t, Y_t\big] - Z(t) \\
&\quad = 2\big(\Phi(t) - B\big)\mathrm{E}\big[\Delta\Phi(t)|X_t, Y_t\big] + \big(\mathrm{E}[(\Delta\Phi(t))^2|X_t, Y_t] - V\big) \\
&\quad \ge 0.
\end{aligned}$$

Hence $Z(t)$ is a submartingale with respect to the sequence $\{(X_t, Y_t)\}_{t\ge 0}$. Moreover, the random time $T^{x,y} = \min\{t : \Phi(t) = 0\}$ (where $X_0 = x$, $Y_0 = y$) is a stopping time for $Z(t)$ with finite expectation, and the differences $|Z(t+1) - Z(t)|$ are bounded. This allows us to apply the optional stopping theorem for submartingales (see, e.g., [6, Chapter 4, Theorem 7.5] and conclude that $\mathrm{E}Z(T^{x,y}) \ge \mathrm{E}Z(0)$. From the definition of $Z(t)$, this implies that

$$-V\,\mathrm{E}T^{x,y} \ge \Phi(0)^2 - 2B\Phi(0),$$

which gives the desired upper bound on $\mathrm{E}T^{x,y}$. □

3.4. $\mathcal{M}_{loz}$ is rapidly mixing. We first consider the simplified case of routings consisting of a single path P with source s and sink t. Notice that in this case all towers have height 1.

We define a coupling as follows. Consider two copies of the Markov chain, whose states are the paths P_1 and P_2, each containing N internal points. Then in one move we choose $(i, r) \in \{1, \ldots, N\} \times [0, 1]$ uniformly at random and simultaneously move the ith points of each of P_1 and P_2 as specified by the random number r. It should be clear that this is a valid coupling. Notice that, because we are using the same value of r for both processes, the two paths will never move in opposite directions. This was the reason we implemented the Markov chain in this fashion in section 3.1.

We now proceed to bound the expected time it takes the coupled process to cause any two initial routings to agree. To simplify the analysis, we use an observation due to Propp and Wilson [14]: if the state space of a Markov chain is endowed with a partial order with unique maximum and minimum elements, and if the coupling preserves the partial order (in a sense made precise below), then the coupling time is bounded above by the expected coupling time starting from the maximum and minimum states. Recall the partial order defined in the proof of Lemma 3.1: $P_1 \succeq P_2$ iff the ith point of P_1 lies on or above the ith point of P_2 for all i. Recall also that this partial order has a unique minimum (and similarly also a unique maximum) element. To make precise the notion of preserving the partial order, we first extend the above coupling to a random function f on the entire state space; namely, pick (i, r) as above and, for any path P, let $f(P)$ be the path obtained by moving the ith point of P as specified by r. We say that the coupling is *monotone* with respect to the partial order if $P_1 \succeq P_2$ implies $f(P_1) \succeq f(P_2)$. The next lemma verifies that this condition holds for our coupling.

LEMMA 3.5. *The above coupling is monotone with respect to the partial order* $\succeq$.

Proof. Suppose $P_1 \succeq P_2$, and consider a random move defined by a pair (i, r); let $P_1' = f(P_1)$ and $P_2' = f(P_2)$ be the images of P_1, P_2, respectively. Assume that $r \geq 1/2$ (the case $r < 1/2$ is symmetric). It is straightforward to verify that if i is a peak in P_1, then either the ith point of P_1 is sufficiently far above the ith point of P_2 to ensure that $P_1' \succeq P_2$ (and therefore $P_1' \succeq P_2'$), or i is also a peak in P_2, in which case the peak is rotated in both paths. In either case we can deduce that $P_1' \succeq P_2'$. □

We now need to bound the time taken for the two extremal paths to meet. To do this, we introduce a distance function as in Lemma 3.4. For a pair of paths P_1, P_2, define the distance $\phi(P_1, P_2)$ to be the area (i.e., number of Cartesian lattice squares) of the region between P_1 and P_2. The crucial observation is that the distance $\Phi(t) = \phi(X_t, Y_t)$ will tend not to increase under our coupling, as the next lemma shows. By Lemma 3.5, we may restrict attention to the case $X_t \succeq Y_t$.

LEMMA 3.6. *Let P_1 and P_2 be any two paths such that $P_1 \succeq P_2$. Then* $\mathrm{E}[\Delta\Phi | P_1, P_2] \leq 0$.

Proof. Consider an arbitrary pair of paths $P_1 \succeq P_2$. The typical situation is as depicted in Figure 10 with path P_1 drawn as a solid line and path P_2 as a dotted line. We can partition the paths into segments $C_1, \ldots, C_\ell$ on which the two paths coincide, and segments $D_1, \ldots, D_m$ whose endpoints coincide, but for which P_1 is strictly above P_2 at all intermediate points.

First consider a segment C_i. It is clear that, if the point chosen by the coupling lies in this segment, then the point will move with the same probability on both paths, so the paths will still coincide and there will be no change in area.

Now consider a segment D_i, in which points on P_1 are strictly above the corresponding points on P_2 (except at the endpoints). On the upper path P_1, label the peaks "good" (G) and the valleys "bad" (B) and vice versa for the lower path P_2. Thus a point is good if a rotation at that point would cause the area between the paths to decrease and bad if a rotation would case the area to increase. (The boundary of the region might in fact prohibit some of these bad rotations.) It is easy to see that, on each path, the labeled points in the interior of the segment D_i are alternately good and bad with a net excess of one good point. Moreover, each endpoint of D_i contributes at most one bad point (unless D_i and D_{i+1} meet at a point, in which case there might be two bad points, but we can assign one to each segment).

Summing over all segments of the path, we see that the total number of good points is greater than or equal to the total number of bad points. Since each good or bad point is equally likely to be chosen in the coupling, the expected change in area is at most zero. □

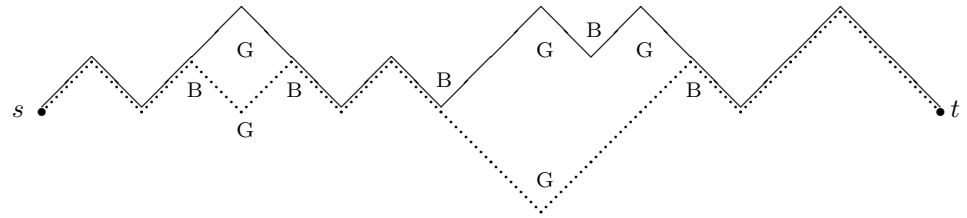


FIG. 10. *Proof of Lemma* 3.6.

THEOREM 3.7. *Let S be a region in the triangular lattice such that the corresponding region $\hat{S}$ has one source s and one sink t. Then the mixing time of the Markov chain $\mathcal{M}_{loz}$ on lozenge routings of $\hat{S}$ satisfies $\tau(\epsilon) \leq 2en^3\lceil \ln \epsilon^{-1} \rceil$, where n is the area of $\hat{S}$.*

Proof. By Theorem 3.3, it suffices to show that the coupling time T satisfies $T \leq 2n^3$. To bound T we appeal to Lemma 3.4, restricting our attention to extremal initial states following Lemma 3.5. Our distance function ϕ clearly takes integer values in the interval $[0, n]$. Moreover, we have seen in Lemma 3.6 that $\mathrm{E}[\Delta\Phi] \leq 0$. (Note that the monotonicity of the coupling ensures that any pair (P_1, P_2) that is reachable under the coupling satisfies $P_1 \succeq P_2$.) It remains only to bound $\mathrm{E}[(\Delta\Phi)^2]$, assuming that the area between the pair of paths is nonzero. In this case, there must be a segment on which the solid path is strictly above the dotted path (using the terminology in the proof of Lemma 3.6). Scanning this segment from left to right, there is a first point where at least one of the paths is good and neither is bad. If this point is chosen at the next time step, then there will be a decrease in area with probability at least $\frac{1}{2}$. Hence Φ decreases strictly with probability at least $1/2n$, so $\mathrm{E}[(\Delta\Phi)^2] \geq 1/2n$. (Clearly the number of points on a path cannot exceed n.) Plugging all of these quantities into Lemma 3.4 yields $T \leq 2n^3$. □

We now extend the above argument to the case of lozenge routings with multiple paths. The coupling we use is the following obvious generalization of our earlier one. Given a pair of routings, choose the same random point p on both, say the ith point of the jth path, and the same random bit $r \in [0, 1]$. Then update each routing by rotating at point p with the appropriate probability as determined by the random number r.

As in the single-path case, we can argue that it is sufficient to bound the expected coupling time for a pair of extremal routings. Recall the partial order defined in the proof of Lemma 3.1, in which routings R_1, R_2 satisfy $R_1 \succeq R_2$ iff the ith path of R_1 lies on or above the ith path of R_2 for all i. As before, there are unique maximum and minimum elements under $\succeq$. And once again it is not hard to check that our coupling is monotone with respect to this partial order.

LEMMA 3.8. *The above coupling for routings is monotone with respect to the partial order* $\succeq$.

Proof. Suppose $R_1 \succeq R_2$ and consider a random move defined by the pair $(p, r) \in [1, \ldots, N] \times \{0, 1\}$. Assume without loss of generality that $r \geq 1/2$. If p is the top of a rotatable tower in R_1, then either R_2 is sufficiently far away from R_1 so that rotating the tower in R_1 does not disturb the order, or p is also the top of a tower in R_2. Because $R_1 \succeq R_2$, it must be the case that the tower defined by p in R_1 has height at least as large as the tower defined by p in R_2. Thus the probability of performing a rotation in R_1 cannot exceed that of performing a rotation in R_2. Therefore, depending on the value of r, we rotate either in both routings, only in R_2, or in neither routing. In each of these cases it is clear that the partial order is preserved. □

For a pair of routings R_1, R_2, we define the distance $\phi(R_1, R_2)$ to be the sum of the areas between corresponding paths in R_1 and R_2. The next lemma, a generalization of Lemma 3.6, proves that the distance tends not to increase under the coupling. Again, in light of Lemma 3.8 we restrict our attention to the case where $R_1 \succeq R_2$.

LEMMA 3.9. *Let* R_1 *and* R_2 *be any two lozenge routings such that* $R_1 \succeq R_2$. *Then* $\mathrm{E}[\Delta\Phi | R_1, R_2] \leq 0$.

Proof. Consider a pair of routings, the upper one solid and the lower one dotted. Adopting the same terminology as in the proof of Lemma 3.6, give a point the label G_i if it defines a tower of height i and is a good point (i.e., choosing it could reduce the area between the two routings). Similarly, label a point B_i if it defines a bad tower of height i (see Figure 11). We can calculate the expected change in area by first considering the expected change if we make a move on the upper (solid) routing only and then adding to this the expected change in area from a move on the lower (dotted) routing only. Each point labeled G_i has probability $1/2Ni$ of rotating, and such a rotation decreases the area between the two routings on *each* of the i paths altered by the rotation, a total decrease of i. Summing the expected changes in area over all good and bad points, we have

$$\begin{aligned}\mathrm{E}[\Delta\Phi | R_1, R_2] &= \sum_i \sum_{B_i} \frac{i}{2Ni} - \sum_j \sum_{G_j} \frac{j}{2Nj} \\ &= \frac{1}{2N}\Big(\sum_i \#B_i - \sum_j \#G_j\Big) \leq 0,\end{aligned}$$

where $\#B_i$ is the number of points labeled B_i. The final inequality follows from the fact that on each path the number of good points is at least as large as the number of bad points, as argued in lemma 3.6. □

It is now a short step to the main theorem of this section, which confirms that simulating the Markov chain $\mathcal{M}_{loz}$ for a small number of steps suffices to generate a random lozenge tiling.

THEOREM 3.10. *Let* S *be a region of the triangular lattice. The mixing time of the Markov chain* $\mathcal{M}_{loz}$ *on lozenge routings of* $\hat{S}$ *satisfies* $\tau(\epsilon) \leq 8en^4\lceil \ln \epsilon^{-1} \rceil$, *where* n *is the area of* $\hat{S}$.

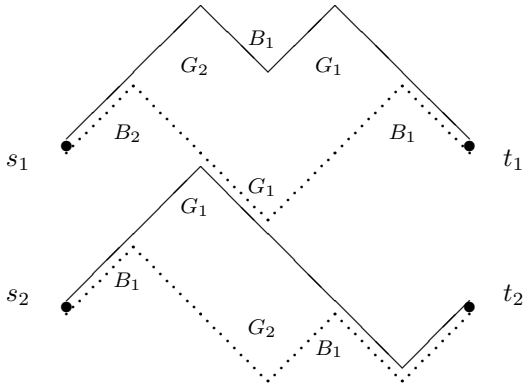

FIG. 11. *Proof of Lemma* 3.9.

Proof. By Theorem 3.3, it suffices to show that the coupling time satisfies $T \leq 8n^4$; and by Lemma 3.8 we need only consider the coupling time for the two extremal initial states. We first bound the distance between these extremal configurations.

Recall two properties of the height function h. First, the heights of all points around the boundary are fixed for all routings of a region. Second, the heights of neighboring vertices differ by at most two. For any internal point v, let k_v be the side length of the largest hexagon centered at v and fully contained within the region. This largest hexagon must share at least one vertex with the boundary of the region, and hence in any tiling the height of v can take on at most $4k_v + 1$ consecutive integer values. Finally, recall that we can walk from the lowest to the highest routing by a sequence of rotations each of which increases the height of one vertex by three (and leaves all other heights unchanged). As we perform this walk, there can be at most $\lceil \frac{4k_v+1}{3} \rceil < 2k_v$ rotations which alter the height of v. If the region being tiled has area n, then $k_v < \sqrt{n}$ for every vertex v. Therefore, summing over all internal vertices, we find that the total distance between the highest and lowest routings is at most $\sum_v 2\sqrt{n} = 2n^{3/2}$.

Lemma 3.9 confirms that $\mathrm{E}[\Delta\Phi] \leq 0$ for all pairs of states reachable under the coupling. To get a bound on $\mathrm{E}[(\Delta\Phi)^2]$, consider a pair of routings with nonzero area between them. Then there must be a pair of corresponding paths, one solid and one dotted, and a segment in which the solid path is strictly above the dotted path. Scanning this segment from left to right, call the first good point we reach on either path p. There is a $1/N$ chance of choosing the point p, and we perform the rotation at p with probability $1/2h$, where h is the height of the tower defined by p. Rotating this tower causes a decrease of h in the total area, one unit for each path included in the tower. Hence we can conclude that $\mathrm{E}[(\Delta\Phi)^2] \geq h^2/2Nh \geq 1/2n$. Putting all this together and appealing to Lemma 3.4, we see that the coupling time satisfies $T \leq 8n^4$. The result now follows from Theorem 3.3. □

Remarks. (a) We have made no attempt here to optimize the upper bound on the mixing time in Theorem 3.10; our concern has been to establish that the chain is *rapidly mixing*, in the sense that the mixing grows only *polynomially* with the area n. (Note in contrast that the size of the state space, i.e., the number of lozenge tilings, is in general *exponential* in n.) Using a more detailed analysis of our coupling, Wilson [18] has derived sharper bounds on the mixing time.

(b) The monotonicity property of our coupling allows one to determine bounds on the coupling time experimentally, simply by simulating the coupled process starting at the two extremal states. In practice, this has been found to yield significantly tighter

bounds than that of Theorem 3.10. This idea can be further extended using the technique of "coupling from the past" due to Propp and Wilson [14] to obtain a stopping rule for the simulation that eliminates all bias from the samples. Theorem 3.10 can be viewed as an a priori bound on the running time of such experiments.

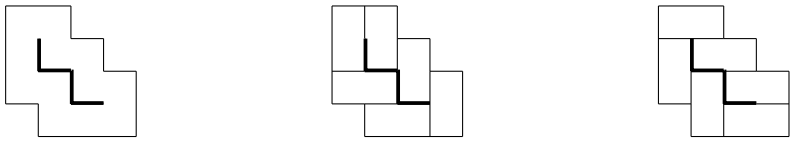
(c) Randall and Tetali [15] recently demonstrated that the comparison technique of Diaconis and Saloff-Coste [5] can be used to relate the mixing time of $\mathcal{M}_{loz}$ to that of the original Markov chain whose only moves are *simple* rotations. Their results, together with Theorem 3.10, imply that the original Markov chain is rapidly mixing as well.

4. Sampling domino tilings. The machinery presented in the last section provides a general framework which can be applied to the random generation of other lattice structures, including domino tilings and Eulerian orientations (and presumably others). In each case, the development of a provably efficient algorithm follows the same outline: we start with natural local moves connecting the space of configurations. We then interpret these moves in terms of the appropriate routings, enrich them with a small set of nonlocal moves (involving towers), and use a coupling argument to argue that the resulting Markov chain is rapidly mixing: in all these cases, the mixing time is bounded by a low-degree polynomial in the area of the region. The definition of towers is sensitive to the type of routing, and the proofs use slightly more sophisticated arguments. It is interesting that, in each case, as for lozenge tilings, the choice of towers is quite natural in the original setting as well.

Our task in this section is to construct a random domino tiling of a given region S of the Cartesian lattice. This we achieve using a Markov chain on the space of domino tilings, whose moves correspond to rotations of suitably defined towers. As before, towers are constructed so as to allow, in a single move, a series of domino rotations which enable a rotation at a particular point which would otherwise be disallowed. Consider, for example, a 2×2 block centered at a point $p = (x, y)$ which has one vertical domino to its right but a horizontal domino covering the square to its lower-left. Then we can either perform a domino rotation at the point $(x-1, y)$, which would then allow a domino rotation at p, or the square to the upper-left of p is covered by a vertical domino. Continuing in a zigzag fashion to the upper-left, we will eventually find a point $q = (x - k, y - k)$ or $q = (x - k - 1, y - k)$ where we can perform a rotation (assuming that we do not hit the boundary). Rotating dominoes along the zigzag, starting at q, we can eventually perform a rotation at p. See Figure 12. As we shall see, allowing these types of tower moves along just one of the two diagonal directions turns out to be sufficient, so we restrict our attention to those running in the NW-SE direction.

To formalize the above, a domino tower is defined by a *spine*, which is a zigzag path (staircase of unit steps along domino boundaries) in the NW-SE direction of a tiling, and the tower includes all the cells that are incident to a vertex on the spine. The endpoints of the spine are the *top* and *bottom* of the tower. Provided that all the vertices along the spine lie in the interior of the region, there are exactly two ways in which the tower can be tiled so that one of the two endpoints of the spine is the center of a 2×2 block tiled with two parallel dominoes. A *rotation* of the tower is an operation that replaces one of these two tilings with the other. There are four distinct types of domino towers, depending on whether the first and last edges of the spine are horizontal or vertical. The *height* of a tower is the number of vertices on the spine.

For the analysis it is more useful to redefine towers in terms of the corresponding routings. Recall that in Theorem 2.2 we showed that generating a random tiling



A spine defining a tower The two tilings of the tower

FIG. 12. *Towers moves for domino tilings.*

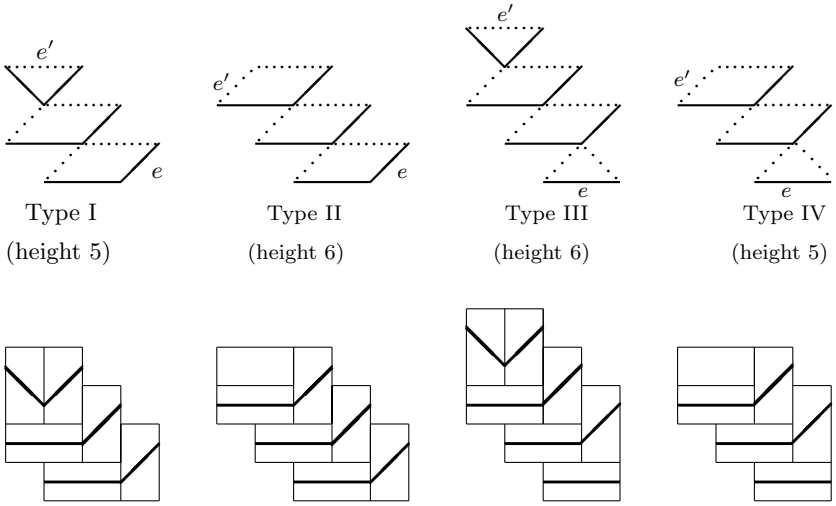


FIG. 13. *The four types of domino towers.*

is equivalent to constructing a random domino routing of a region of the triangular lattice with sources $\{s_1, \ldots, s_k\}$ and sinks $\{t_1, \ldots, t_k\}$. The four types of towers can easily be interpreted in terms of routings, as shown in Figure 13. A move of the Markov chain consists of identifying a tower and then moving between the solid and dotted local structures shown. In the routings representation, the height is just the number of unit triangles in the tower. The edges marked e in the diagram indicate the bottoms of the corresponding towers in the northwest direction, while the edges marked e' are the tops of towers in the southeast direction. (To relate this definition to tilings, if e is a diagonal edge, then it corresponds to a vertical domino such that the center of the left edge is the bottom of the spine defining the tower in the tiling; if e is horizontal, then it corresponds to a horizontal tile such that the center of the top edge is the bottom of the spine. For edges e', the center of the left or bottom edge of the corresponding domino is the top of the spine.) We refer to any of the edges e or e' as the "start" of a tower; notice that a tower can be uniquely specified by its start edge and its direction. The type of the tower merely reflects whether the top and bottom edges are horizontal or diagonal. For example, the original Markov chain based on rotating two neighboring domino tiles consists of all Type I and Type IV tower rotations of height 1.

Let N be the number of edges in any domino routing of $\hat{S}$. The transition prob-

abilities $P(\cdot,\cdot)$ of $\mathcal{M}_{dom}$ are

$$P(R_1,R_2)=\begin{cases} 1/2Nh & \text{if } R_1,R_2 \text{ differ by rotation of a tower of height } h;\\ 1-\displaystyle\sum_{R\neq R_1} P(R_1,R) & \text{if } R_2=R_1. \end{cases}$$

To implement one step of this Markov chain, starting at a routing R, choose $(e,r)\in\{1,\ldots,N\}\times[0,1]$ uniformly at random, where e is a random *edge* of R. First suppose $r\le 1/2$. If the edge e is a diagonal directed up and to the right, check whether there is a tower starting at e and extending in the northwest direction. Notice that this must be a tower of Type I or Type II and is unique. If, on the other hand, e is horizontal, check whether there is a tower of Type III or Type IV starting at e and extending northwest (again this is unique). In either case, determine the height h of the tower, and if $r\le 1/2h$ rotate the tower if possible (i.e., if the tower lies entirely within the region). The case when $r>1/2$ is similar: check whether there is a tower in the southeast direction starting at e. If e is a diagonal pointing up and to the right this would be a tower of Type II or Type IV; if e is horizontal it would be a tower of Type I or Type III. In either case rotate the tower (if possible) if $r>1-1/2h$, where h is the height of the tower.

The Markov chain $\mathcal{M}_{dom}$ can be analyzed using arguments similar to those used in the previous section for $\mathcal{M}_{loz}$. As before, we first need to show that the chain is ergodic.

THEOREM 4.1. *The Markov chain $\mathcal{M}_{dom}$ is ergodic and converges to the uniform distribution over domino tilings.*

Proof. It is easy to check that the Markov chain is symmetric and aperiodic. Therefore, it suffices to show that the Markov chain connects the state space of domino tilings of a region. We will show that the state space is connected even if we restrict the set of allowable transitions to simple domino rotations.

We start by defining a partial order on the set of all domino routings of $\hat{S}$ as follows. Let R_1,R_2 be two routings and let P_1,P_2 be a pair of corresponding paths (with the same source and sink). We say that $P_1\succeq P_2$ iff each vertical line intersecting the paths intersects P_1 at a point at least as high as the intersection with P_2. (Since the paths are piecewise linear, it suffices to check this condition at vertical lines which pass through vertices of the underlying lattice.) As before, we say $R_1\succeq R_2$ iff the relation $P_1\succeq P_2$ holds for all pairs of corresponding paths and define the distance between two routings to be the union of the area between corresponding paths.

Using an argument analogous to that in the proof of Lemma 3.1, it can be verified that there is a unique minimum routing $R_\perp$, and that for any routing $R\neq R_\perp$ we can find a tower of height 1 whose rotation will reduce the distance between R and $R_\perp$. This moves R closer to $R_\perp$ and inductively guarantees the connectedness, and thus the ergodicity, of $\mathcal{M}_{dom}$. □

It remains for us to show that the Markov chain converges rapidly to stationarity. We can define a coupling in exactly analogous fashion to that for lozenge routings in section 3.4; namely, pick a random pair (e,r) and make the appropriate move in both routings simultaneously. Once again it is not hard to check that this coupling is monotone with respect to the partial order on domino routings defined in the proof of Theorem 4.1, so when analyzing the coupling time we need consider only the two extremal routings. The key fact is the following analogue of Lemma 3.9, which says that the area $\Phi(t)$ between routings (defined in the obvious way) is nonincreasing in expectation.

LEMMA 4.2. *Let R_1 and R_2 be two domino routings such that $R_1 \succeq R_2$. Then* $\mathrm{E}[\Delta\Phi | R_1, R_2] \leq 0$.

Proof. First consider the case when R_1 and R_2 each consist of only a single path. Then, following the ideas from Lemmas 3.6 and 3.9, we can consider segments $C_1, \ldots, C_\ell$ on which the two paths coincide, and segments $D_1, \ldots, D_m$ on which the two paths coincide at the endpoints, and on which R_1 is strictly above R_2 at all intermediate points. As before, it is clear that choosing an edge on any of the C_j will not change the area between the paths.

Now consider a region D_j. Give an edge the label G_i if, when that edge is chosen by the coupling, the area between the routings could decrease by exactly i. Similarly, label an edge B_i if one of the directions could cause the area to increase. When the routings consist of a single path, i is either 1 or 2. Certain edges will receive two labels. See Figure 14.

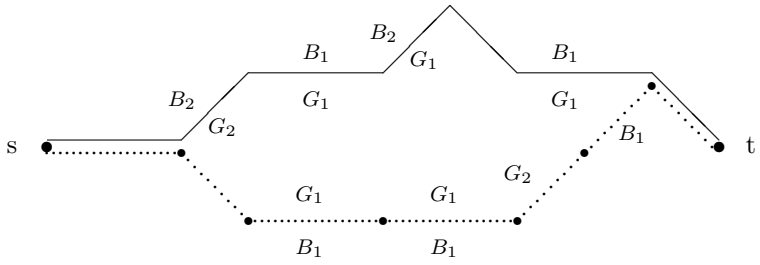

FIG. 14. *Proof of Lemma* 4.2*—single path case.*

We can match each bad edge to a unique good edge as follows. Each horizontal edge with a bad label also has a good label, so we can pair them off. Any diagonal segment which has a bad label at one end must have a good label at the other end, so we can pair these. (The moves of $\mathcal{M}_{dom}$ are defined so that we can rotate only the routing at the two extremal edges of a diagonal segment.) This tells us that the number of bad edges is less than or equal to the number of good edges. As in Lemma 3.9, the probability of rotating at a given edge is inversely proportional to the change in area caused by such a rotation. This ensures that the expected change in area is always nonpositive.

To handle multiple paths, we need to modify the above labeling slightly. It is possible that edges which would be labeled good or bad when a path is viewed in isolation might no longer be places where we can perform a rotation. In particular, if horizontal edges from adjacent paths get too close, one will not be able to rotate in the northwest direction, and the other will not be able to rotate in the southeast direction. This will have the net effect of eliminating a good and a bad label. To see this, label an edge $\hat{G}$ if it is a horizontal edge which cannot move in the good direction because of interference with another path and label it $\hat{B}$ if it cannot move in the bad direction because of interference with another path. These labels are shown in Figure 15 for the solid paths only. The crucial point is that every edge labeled $\hat{G}$ must be paired with a distinct edge labeled $\hat{B}$ and vice-versa; these are unit distance apart in the NE-SW direction. Hence $\#\hat{G} = \#\hat{B}$.

Generalizing the argument from the single path case, we have that

$$\#\hat{B} + \sum_i \#B_i \leq \#\hat{G} + \sum_j \#G_j,$$

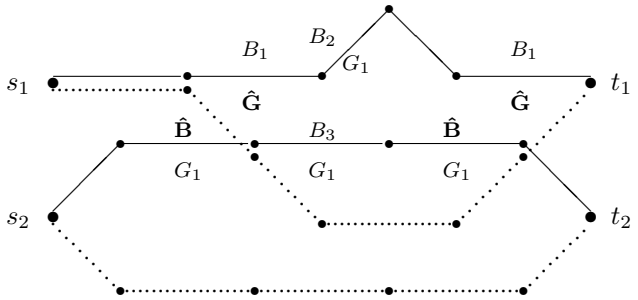

FIG. 15. *Proof of Lemma* 4.2*—multiple path case.*

whence

$$\sum_i \#B_i \le \sum_j \#G_j.$$

From this we can conclude as before that the expected change in area is always nonpositive. □

As a final ingredient, we need to bound the distance between the two extremal routings. For a fixed region with area n, the distance between the highest and lowest routings is at most $2n^{3/2}$. To see this, recall that the difference between the heights of neighboring vertices in a domino routing is at most ± 3. If k_v is the side length of the largest square centered at v which lies within the region, then the height of v is an integer value in $[h(u) - 2k_v, h(u) + 2k_v]$, where u is a vertex which lies on both the square and the boundary of the region. Each step in a walk from the lowest to the highest routing increases the height of some vertex by four, so the total number of steps is at most $\sum_v \frac{6k_v+1}{4} \le \sum_v 2\sqrt{n} = 2n^{3/2}$.

In analogous fashion to the proof of Theorem 3.10, Lemma 4.2, together with Lemma 3.4 and monotonicity of the coupling, implies that the Markov chain $\mathcal{M}_{dom}$ is rapidly mixing.

THEOREM 4.3. *Let S be a region of the Cartesian lattice, and let $\hat{S}$ be the corresponding region containing domino routings. Then the mixing time of the Markov chain $\mathcal{M}_{dom}$ on routings of $\hat{S}$ satisfies $\tau(\epsilon) \le 8en^4\lceil \ln \epsilon^{-1} \rceil$, where n is the area of S.* □

5. Sampling Eulerian orientations. Let S be a region with specified boundary conditions for Eulerian orientations: recall that these determine the sources and sinks in the routings representation. To generate a random Eulerian orientation of S, we construct a Markov chain $\mathcal{M}_{eul}$ whose state space is the set of all Eulerian routings on S with these sources and sinks. In similar fashion to the case of lozenge routings, moves will be defined in terms of "peaks" and "valleys," where in this case a valley is a vertex which is the right endpoint of a horizontal edge and the bottom endpoint of a vertical edge of the routing; a peak is a vertex which is the left endpoint of a horizontal edge and the top endpoint of a vertical edge. Note that a vertex may be both a peak and a valley at the same time. The operation of flipping a peak into a valley (or vice versa) where possible defines a simple Markov chain which we argue in Theorem 5.1 connects the state space.

For our analysis we augment this Markov chain by allowing a move between two routings if they differ by a structure which is either a vertical or horizontal tower as

depicted in Figure 16. More precisely, let the *cell at* (x, y) be the four edges of the unit square of the lattice whose lower-right corner is at (x, y). Define a *horizontal tower of height* h to be a set of cells at points $(x, y), (x-1, y), \ldots, (x-h+1, y)$, where either $(x, y), (x-1, y), \ldots, (x-h+1, y)$ are all valleys and $(x, y+1), (x-h, y)$ are not valleys, or $(x-h, y+1), \ldots, (x-1, y+1)$ are all peaks and $(x-h, y), (x, y+1)$ are not peaks. The point (x, y) is the *bottom* of the tower and $(x-h, y+1)$ is the *top* of the tower. Similarly, define a *vertical tower of height* h to be a set of cells at points $(x, y), (x, y+1), \ldots, (x, y+h-1)$, where either $(x, y), \ldots, (x, y+h-1)$ are all valleys and $(x-1, y), (x, y+h)$ are not valleys, or $(x-1, y+h), \ldots, (x-1, y+1)$ are all peaks and $(x, y+h), (x-1, y)$ are not peaks. In this case (x, y) is the bottom of the tower and $(x-1, y+h)$ is the top (see Figure 16). Note that vertical and horizontal towers of height 1 are identical and that any vertex can be the top (respectively, bottom) of at most one tower. The reader should be able to verify that any tower can be inverted in the obvious way to produce a valid routing provided all of its cells are contained within the region. As usual, we call such an operation a *rotation* of the tower.

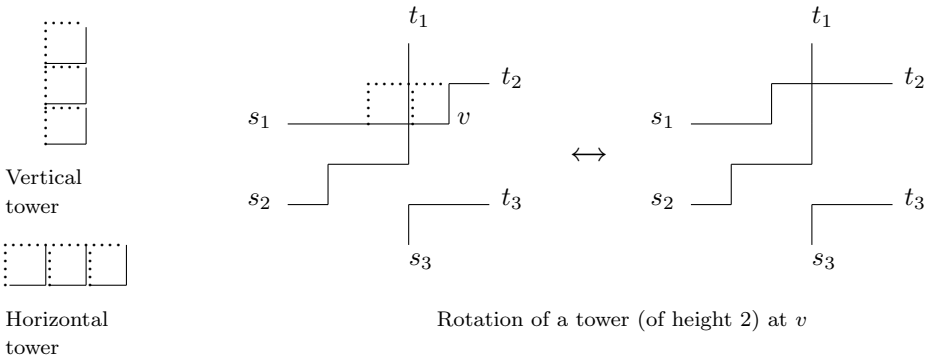

FIG. 16. *Markov chain for Eulerian orientations.*

The transition probabilities $P(\cdot\,, \cdot)$ of $\mathcal{M}_{eul}$ are defined as follows:

$$P(R_1, R_2) = \begin{cases} 1/2Nh & \text{if } R_1, R_2 \text{ differ by rotation of a tower of height } h; \\ 1 - \displaystyle\sum_{R \neq R_1} P(R_1, R) & \text{if } R_2 = R_1, \end{cases}$$

where N is the number of vertices on any routing.

To implement one step of $\mathcal{M}_{eul}$, starting at a routing R, choose $(p, r) \in \{1, \ldots, N\} \times [0, 1]$ uniformly at random, where p denotes a point on the routing. If $r \leq 1/2$, check whether p is the bottom of a tower of height h and rotate this tower if possible if $r < 1/2h$. Similarly, if $r > 1/2$ check whether p is the top of a tower of height h and rotate this tower if possible if $r > 1 - 1/2h$.

Tower rotations have a simple interpretation in terms of Eulerian orientations. A tower of height h corresponds to a directed cycle in the Eulerian orientation which is a $1 \times h$ or $h \times 1$ rectangle (with its internal edges aligned). The rotation corresponds to reversing all the orientations around this cycle, which of course produces a new Eulerian orientation.

THEOREM 5.1. *The Markov chain $\mathcal{M}_{eul}$ is ergodic and converges to the uniform distribution over Eulerian orientations.*

Proof. Since the Markov chain is symmetric and aperiodic, it is again sufficient to show that it is connected. As in the case of domino and lozenge tilings, the key to proving this fact is to define a suitable partial order on routings. For corresponding paths P_1, P_2 on two routings R_1, R_2, we say that $P_1 \succeq P_2$ if each diagonal line in the NW-SE direction intersects P_1 at a point at least as far left as P_2. We say $R_1 \succeq R_2$ iff $P_1 \succeq P_2$ holds for each pair of corresponding paths P_1, P_2. Under this partial order there will always be a unique minimum routing. An argument analogous to that in the proof of Lemma 3.1 demonstrates that, for any routing R which is not minimum, we can find a point which is the top of a rotatable tower whose rotation reduces the distance between R and the minimum routing (where again distance is defined as the sum of the area between corresponding paths). This guarantees, inductively, that the state space is connected. □

We now turn to the mixing time of the Markov chain. Note that when the boundary conditions define a set of routings consisting of a single path, the Markov chain is equivalent to the lozenge routing chain $\mathcal{M}_{loz}$ of section 3. Theorem 3.7 guarantees that this chain is rapidly mixing. We now extend this result to Eulerian routings that consist of an arbitrary number of paths. As in the previous examples, we will construct a coupling that chooses a random point p and a random number r and makes the appropriate move in both routings simultaneously. Again as before, this coupling is easily seen to be monotone with respect to the partial order defined in the proof of Theorem 5.1, so we need analyze only the coupling time starting from the two extremal routings. As usual the following lemma, which says that the area $\Phi(t)$ between routings is nonincreasing in expectation, is the key to the proof.

LEMMA 5.2. *Let R_1 and R_2 be any two Eulerian routings such that $R_1 \succeq R_2$. Then* $\mathrm{E}[\Delta\Phi | R_1, R_2] \leq 0$.

Proof. We assign labels G and B to peaks and valleys in similar fashion to the lozenge case (see Figure 17). On the lower routing, label G any corner which is the lower-right of a tower and label B any corner which is the upper-left of a tower; on the upper routing, interchange the roles of G and B. Finally we will label all the corners which do not define a tower because of interference with another path. On the lower routing, label $\hat{G}$ any unlabeled corner which goes to the right and then up if the two edges which complete the unit square are part of another path on the routing. Likewise, label $\hat{B}$ any unlabeled corner which goes up and then to the right but which is not part of a tower because the two edges completing the square are part of anther path on the routing. On the upper routing, interchange the roles of $\hat{G}$ and $\hat{B}$. Generalizing from the single path case as in Lemma 3.9, we know that $\#B + \#\hat{B} \leq \#G + \#\hat{G}$.

Next observe that each point labeled $\hat{G}$ is paired with a distinct point labeled $\hat{B}$. A point p is labeled $\hat{G}$ if the two edges which complete the unit square defined by the peak or valley at p belong to an adjacent path on the same routing. The point defining the opposite corner of the square must be labeled $\hat{B}$, and we can pair this bad point (on the same routing) with p. This pairing implies that $\#\hat{B} = \#\hat{G}$, and hence that $\#B \leq \#G$.

Finally, observe that the weights of the moves are chosen so that each bad and each good point contributes equally to the expected change in area. Hence, if N is the total number of points on the routing, we have $\mathrm{E}[\Delta\Phi] = (\#B - \#G)/2N \leq 0$. □

A simple calculation based on the height function representation reveals that the distance between extremal Eulerian routings of a region with area n is at most $n^{3/2}$.

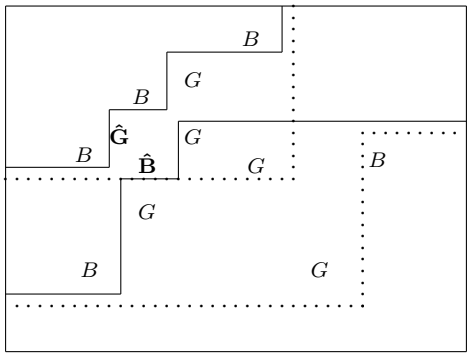

FIG. 17. *Proof of Lemma* 5.2.

Combining Lemmas 5.2 and 3.4 and the fact that the coupling is monotone, we can deduce in by now familiar fashion that the Markov chain $\mathcal{M}_{eul}$ is rapidly mixing.

THEOREM 5.3. *Let S be a region of the Cartesian lattice with specified boundary conditions. Then the mixing time of the Markov chain $\mathcal{M}_{eul}$ on Eulerian routings of S satisfies $\tau(\epsilon) \leq 2en^4\lceil \ln \epsilon^{-1} \rceil$, where n is the area of S.* □

Acknowledgment. We would like to thank James Akao for useful discussions and for implementing the Eulerian orientations algorithm.

THERE ARE NO SPARSE NP_W-HARD SETS*

FELIPE CUCKER† AND DIMA GRIGORIEV‡

Abstract. In this paper we prove that, in the context of weak machines over $\mathbb{R}$, there are no sparse NP-hard sets.

Key words. structural complexity, real number computations

AMS subject classifications. 68Q15, 68Q17, 03D15

1. Introduction. In [2] Berman and Hartmanis conjectured that all NP-complete sets are polynomially isomorphic. That is, that for all NP-complete sets A and B, there exists a bijection $\varphi : \Sigma^* \to \Sigma^*$ such that $x \in A$ if and only if $\varphi(x) \in B$. In addition, both φ and its inverse are computable in polynomial time. Here Σ denotes the set $\{0,1\}$ and Σ^* the set of all finite sequences of elements in Σ.

Should this conjecture be proved, we would have as a consequence that no "small" NP-complete set exists in a precise sense of the word "small." A set $S \subseteq \Sigma^*$ is said to be *sparse* when there is a polynomial p such that for all $n \in \mathbb{N}$, the subset S_n of all elements in S having size n has cardinality at most $p(n)$. If the Berman–Hartmanis conjecture is true, then there are no sparse NP-complete sets.

In 1982 Mahaney [11] proved this weaker conjecture by showing that there exist sparse NP-hard sets if and only if P = NP. After this, a whole stream of research developed around the issue of reductions to "small" sets (see [1]).

In a different line of research, Blum, Shub, and Smale (BSS) introduced in [4] a theory of computability and complexity over the real numbers with the aim of modelling the kind of computations performed in numerical analysis. The computational model defined in that paper deals with real numbers as basic entities and performs arithmetic operations on them as well as sign tests. Inputs and outputs are vectors in $\mathbb{R}^n$ and decision problems are subsets of $\mathbb{R}^\infty$, the disjoint union of $\mathbb{R}^n$ for all $n \geq 1$. The classes $\mathrm{P}_\mathbb{R}$ and $\mathrm{NP}_\mathbb{R}$—which are analogous to the well-known classes P and NP—are then defined, and one of the main results in [4] is the existence of natural $\mathrm{NP}_\mathbb{R}$-complete problems.

Clearly, the sparseness notion defined above for sets over $\{0,1\}$ will not define any meaningful class over $\mathbb{R}$ since now the set of inputs of size n is $\mathbb{R}^n$, and this is an infinite set. A notion of sparseness over $\mathbb{R}$ capturing the main features of the discrete one (independence of any kind of computability notion and capture of a notion of "smallness"), however, was proposed in [6]. Let $S \subseteq \mathbb{R}^\infty$. We say that S is *sparse* if, for all $n \geq 1$, the set

$$S_n = \{x \in S \mid x \in \mathbb{R}^n\}$$

has dimension at most $\log^q n$ for some fixed q. Here dimension is the dimension, in the sense of algebraic geometry, of the Zariski closure of S_n. Note that this notion of sparseness parallels the discrete one in a very precise way. For a subset $S_n \subseteq \{0,1\}^n$ its cardinality gives a measure of its size, and a sparse set is one for which, for all n, this cardinality is polylogarithmic in the largest possible (i.e., 2^n the cardinality of $\{0,1\}^n$). For a subset $S_n \subseteq \mathbb{R}^n$, we take the dimension to measure the size of S_n and again define sparseness by the property of having this measure be polylogarithmic in the largest possible (which is now n, the dimension of $\mathbb{R}^n$).

Using this definition of sparseness for subsets of $\mathbb{R}^\infty$, the main result of [6] proves that there are no sparse NP-complete sets in the context of machines over $\mathbb{R}$ which do not perform multiplications or divisions and branch only on equality tests. Note that this result is not conditioned to the inequality $\mathrm{P} \neq \mathrm{NP}$ since this inequality is known to be true in this setting (cf. [12]).

A variation on the BSS model attempting to get closer to the Turing machine (in the sense that iterated multiplication is somehow penalized) was introduced by Koiran in [10]. This model, which Koiran called *weak*, takes inputs from $\mathbb{R}^\infty$ but no longer measures the cost of the computation as the number of arithmetic operations performed by the machine. Instead, the cost of each individual operation $x \circ y$ depends on the sequences of operations which lead to the terms x and y from the input data and the machine constants.

In this paper we extend Mahaney's theorem to machines over $\mathbb{R}$ endowed with the weak cost. Again, this is not a conditional result since it is known that $\mathrm{P} \neq \mathrm{NP}$ in this context too (cf. [7]). If NP_W denotes the class of sets decided in nondeterministic polynomial cost, our main result is the following.

THEOREM 1.1. *There are no sparse* NP_W*-hard sets.*

2. The weak cost. Let M be a machine over $\mathbb{R}$, let $\alpha_1, \ldots, \alpha_s$ be its constants, and let $a = (\alpha_1, \ldots, \alpha_s) \in \mathbb{R}^s$. Let $x = (x_1, \ldots, x_n) \in \mathbb{R}^\infty$. At any step ν of the computation of M with input x, the intermediate value $z \in \mathbb{R}$ produced in this step can be written as a rational function of a and x, $z = \varphi(a, x)$. This rational function depends only on the computation path followed by M up to ν (i.e., on the sequence steps previously performed by M) and is actually a coordinate of the composition of the arithmetic operations performed along this path (see [3] for details). Let $\varphi = \frac{g_\nu}{h_\nu}$ be the representation of φ obtained by retaining numerators and denominators in this composition. For example, the representation of the product $\frac{g}{h} \cdot \frac{r}{s}$ is always $\frac{gr}{hs}$, and the representation of the addition $\frac{g}{h} + \frac{r}{s}$ is always $\frac{gs+hr}{hs}$. We will now use g_ν and h_ν to define weak cost.

DEFINITION 2.1. *The* weak cost *of any step ν is defined to be the maximum of* $\deg(g_\nu)$, $\deg(h_\nu)$, *and the maximum bit size of the coefficients of g_ν and h_ν. For any $x \in \mathbb{R}^\infty$ the* weak cost of M on x *is defined to be the sum of the costs of the steps performed by M with input x.*

The class P_W of sets decided within *weak polynomial cost* is now defined by requiring that for each input of size n the weak cost of its computation is bounded by a polynomial in n. A set S is decided in *weak nondeterministic polynomial cost* (we write $S \in \mathrm{NP}_W$) if there is a machine M working within weak polynomial cost satisfying the following: for each $x \in \mathbb{R}^\infty$, $x \in S$ if and only if there is $y \in \mathbb{R}^\infty$ with size polynomial in n such that M accepts the pair (x, y).

REMARK 1. *The definitions above do not fully coincide with those given in* [10] *since this reference requires the representation of the rational functions φ above to be relatively prime. The definitions we give here, which are taken from* [3]*, are essentially*

equivalent. For if a set is in P_W *with the definition above, it is clearly in* P_W *with Koiran's. The converse is more involved to prove. Roughly speaking, any machine can be simulated by another which keeps "programs" instead of performing the arithmetic operations at the computation nodes. When the computation reaches a branch node, the program for the register whose value is tested for positivity is evaluated at the pair* (a, x) *to decide such positivity. Now note that one can use algorithms of symbolic computation to make the numerator and denominator of the rational function computed by the program relatively prime* before *evaluating.*

3. Proof of the main result. Let $n \geq 1$. Consider the polynomial

$$f_n = x_1^{2^n} + \cdots + x_n^{2^n} - 1$$

and let $C_n = \{x \in \mathbb{R}^n \mid f_n(x) = 0\}$. The polynomial f_n is irreducible and the dimension of C_n is $n-1$. Let $C \subset \mathbb{R}^\infty$ be given by $C = \cup C_n$. We know (cf. [7]) that $C \in \mathrm{NP}_W$ but $C \notin \mathrm{P}_W$.

Let $S \subset \mathbb{R}^\infty$ be a NP$_W$-hard set. Then C reduces to S. That is, there exists a function $\varphi : \mathbb{R}^\infty \to \mathbb{R}^\infty$ computable with polynomial cost such that, for all $x \in \mathbb{R}^\infty$, $x \in C \iff \varphi(x) \in S$. For each $n \geq 1$, the restriction of φ to $\mathbb{R}^n$ is a piecewise rational function. Our first result, Proposition 3.2, gives some properties of this function. It uses the following simple fact in real algebraic geometry whose proof can be found in Chapter 19 of [3].

PROPOSITION 3.1. *Let* $f \in \mathbb{R}[x_1, \ldots, x_n]$ *be an irreducible polynomial such that the dimension of its zero set* $\mathcal{Z}(f) \subseteq \mathbb{R}^n$ *is* $n-1$. *Then, for any polynomial* $g \in \mathbb{R}[x_1, \ldots, x_n]$, g *vanishes on* $\mathcal{Z}(f)$ *if and only if* g *is a multiple of* f. □

PROPOSITION 3.2. *Let* n *be sufficiently large. There exist* $x \in C_n$ *and* $U \subset \mathbb{R}^n$, *an open ball centered at* x *such that the restriction of* φ *to* U *is a rational map* $h : U \to \mathbb{R}^m$ *for some* m *bounded by a polynomial in* n. *In addition, if* $h_1, \ldots, h_m$ *are the coordinates of* h, *then the degrees of the numerator and denominator of* h_i *are also bounded by a polynomial in* n *for* $i = 1, \ldots, m$.

Proof. Let M be a machine computing φ within weak polynomial cost. By unwinding the computation of M in a standard manner we obtain an algebraic computation tree of depth polynomial in n. To each branch η in this tree, one associates a set $D_\eta \subseteq \mathbb{R}^n$ such that the D_η partition $\mathbb{R}^n$ (i.e., $\cup D_\eta = \mathbb{R}^n$ and $D_\eta \cap D_\gamma = \emptyset$ for $\eta \neq \gamma$). In addition, each branch η computes a rational map h_η and $\varphi_{|D_\eta} = h_\eta$. The set D_η is the set of points in $\mathbb{R}^n$ satisfying a system

$$\bigwedge_{i=1}^{s_\eta} q_i(x_1, \ldots, x_n) \geq 0 \wedge \bigwedge_{i=s_\eta+1}^{t_\eta} q_i(x_1, \ldots, x_n) < 0, \tag{3.1}$$

where the $q_i(X_1, \ldots, X_n)$ are the rational functions tested along the branch. Since M works within weak cost, the numerators and denominators of the q_i, as well as those of h_η, have degrees bounded by a polynomial in n.

Everything we need to see now is that for some branch η, D_η contains an open neighborhood of a point $x \in C_n$.

To do so, first notice that, by replacing each q_i by the product of its numerator and denominator, we can assume that the q_i are polynomials. Also, by writing $q_i \geq 0$ as $q_i = 0 \vee q_i > 0$ and distributing the disjunctions in (3.1), we can express D_η as a finite union of sets satisfying a system

$$\bigwedge_{i=1}^{s} q_i(x_1, \ldots, x_n) = 0 \wedge \bigwedge_{i=s+1}^{t} q_i(x_1, \ldots, x_n) < 0. \tag{3.2}$$

We have thus described $\mathbb{R}^n$ as a union of sets which are solutions of systems like (3.2). Since this union is finite there exists one such set D containing a subset H of C_n of dimension $n-1$. Let D be the solution of a system like (3.2). We claim that there are no equalities in such a system. Assume the contrary. Then there is a polynomial q such that $H \subset \mathcal{Z}(q)$. Since $\dim H = n-1$ and C_n is irreducible, this implies that $q(C_n) = 0$ and, by Proposition 3.1, that q is a multiple of f_n. Since $\deg f_n = 2^n$, this is not possible for sufficiently large n.

The above implies that D is an open set from which the statement follows. □

For the next result we keep the notation of the statement of Proposition 3.2.

PROPOSITION 3.3. *Let $k = \dim h(U)$.*

(i) *There exist indices $i_1, \ldots, i_k \in \{1, \ldots, m\}$, a polynomial $g \in \mathbb{R}[y_1, \ldots, y_k]$, and a rational function $q \in \mathbb{R}(x_1, \ldots, x_n)$ with both numerator and denominator relatively prime with f_n such that*

$$g(h_{i_1}, \ldots, h_{i_k}) = f_n^\ell q$$

for some $\ell > 0$.

(ii) *Let n be sufficiently large. Then $k \geq n$.*

Proof. For part (i), first notice that since $\dim(h(U)) = k$, there exist $i_1, \ldots, i_k \in \{1, \ldots, m\}$ such that the functions $h_{i_1}, \ldots, h_{i_k}$ are algebraically independent. We want to show that $\dim(U \cap C_n) < k$. To do so let $X = h(U), Y = h(U - C_n)$, and $Z = h(U \cap C_n)$. We have that all X, Y, and Z are semialgebraic subsets of $\mathbb{R}^m$. In addition, Z is contained in the closure of Y with respect to the Euclidean topology relative to X since h is continuous, and $Y \cap Z = \emptyset$ since h is the restriction of φ to U and φ is a reduction.

From here it follows that Z is included in the boundary of Y relative to X. Hence, $\dim Z < \dim Y = \dim X$ (see, e.g., Proposition 2.8.12 of [5]).

The above shows that $\dim h(U \cap C_n) < k$. Therefore, there exists $g \in \mathbb{R}[y_1, \ldots, y_k]$ such that, for all $x \in U \cap C_n$, $g(h_{i_1}(x), \ldots, h_{i_k}(x)) = 0$. Write this as a rational function $g(h) = a/b$ with $a, b \in \mathbb{R}[x_1, \ldots, x_n]$ relatively prime. Then $a(C_n) = 0$ and $a \neq 0$ (since $h_{i_1}, \ldots, h_{i_k}$ are algebraically independent). By Proposition 3.1 this implies that there exists $r \in \mathbb{R}[x_1, \ldots, x_n]$ such that $a = r f_n$. If ℓ is the largest power of f_n dividing a, then the result follows by taking $q = \frac{r'}{b}$, where r' is the quotient of r divided by $f_n^{\ell-1}$.

We now proceed to part (ii). To simplify notation, assume that $i_j = j$ for $j = 1, \ldots, k$. Also, let d be a bound for the degrees of the numerators and denominators of the h_j. Recall from Proposition 3.2 that d is bounded by a polynomial in n.

By part (i) there exists $q \in \mathbb{R}(x_1, \ldots, x_n)$ relatively prime with f_n such that

$$f_n^\ell q = g(h_1, \ldots, h_k)$$

for a certain $\ell \geq 1$. Taking derivatives on both sides we obtain that, for all $x \in \mathbb{R}^n$,

$$\nabla(f_n^\ell q)(x) = \nabla(g)(h(x)) \circ Dh(x), \tag{3.3}$$

where ∇ denotes the gradient and $Dh(x)$ is the Jacobian matrix of h at x.

Assume that $k < n$. Transposing (3.3) one sees that $\nabla(f^\ell q)(x)$ is the image of a vector of dimension k. Thus, there exists a linear dependency among the first $k+1$ coordinates of $\nabla(f^\ell q)(x)$,

$$\sum_{i=1}^{k+1} \lambda_i \frac{\partial f_n^\ell q}{\partial x_i} = 0, \tag{3.4}$$

and the coefficients λ_i of this linear dependency are the determinants of some minors of $Dh(x)$. Thus, for $i = 1, \ldots, k+1$, λ_i is a rational function of x whose numerator and denominator have degrees bounded by kd. Since the submatrix of $Dh(x)$ obtained by keeping its first $k+1$ rows contains at most $k(k+1)$ different denominators, multiplying (3.4) by the product of all of them allows one to assume that the λ_i are polynomials with degree at most $kd(k+1)$.

By the product rule we get

$$\sum_{i=1}^{k+1} \lambda_i \left(\ell f_n^{\ell-1} q \frac{\partial f_n}{\partial x_i} + f_n^{\ell} \frac{\partial q}{\partial x_i} \right) = 0,$$

i.e.,

$$\ell f_n^{\ell-1} q \sum_{i=1}^{k+1} \lambda_i \frac{\partial f_n}{\partial x_i} + f_n^{\ell} \sum_{i=1}^{k+1} \lambda_i \frac{\partial q}{\partial x_i} = 0.$$

Since f_n^{ℓ} divides the second term above, it must also divide the first from which, using that f_n and q are relatively prime, it follows that f_n divides $\sum_{i=1}^{k+1} \lambda_i \frac{\partial f_n}{\partial x_i}$. That is, there exists a polynomial p such that

$$f_n p = \sum_{i=1}^{k+1} \lambda_i \frac{\partial f_n}{\partial x_i},$$

i.e.,

$$p \left(\sum_{i=1}^{n} x_i^{2^n} - 1 \right) = 2^n \sum_{i=1}^{k+1} \lambda_i x_i^{2^n - 1}.$$

Now, for n large enough, the degrees of the λ_i are smaller than $2^n - 1$ since $kd(k+1)$ is polynomial in n. This implies that the degree of p must also be bounded by $kd(k+1)$. Then, however, for each $i \leq k+1$, $px_i^{2^n} = \lambda_i x_i^{2^n - 1}$, i.e., $px_i = \lambda_i$. And from here it follows that $-p = 0$, a contradiction. □

Theorem 1.1 now readily follows. For all $n \in \mathbb{N}$, Proposition 3.2 ensures the existence of an open ball $U \subset \mathbb{R}^n$ whose image by the reduction φ is included in $\mathbb{R}^m$ with m polynomially bounded on n. However, for all n sufficiently large, this image, by Proposition 3.3(ii), has dimension at least n and therefore it cannot be polylogarithmic on m.

REMARK 2. *The result of Theorem* 1.1*, together with that in* [6]*, supports the conjecture that there are no sparse* NP*-hard sets over the reals unless* P = NP*. There are two main settings where this remains to be proved. On the one hand, there are machines which do not multiply nor divide but which branch over sign tests. On the other hand, there is the unrestricted case in which the machine can multiply or divide (and branch over sign tests) with unit cost. In these two cases, the result seems harder since there is no proof that* P ≠ NP*. In the first case, we would like to remark that if many-one reductions are replaced by Turing reductions and we assume that* P ≠ NP*, then Mahaney's conjecture is false. This is due to a result of Fournier and Koiran* [9] *proving that any* NP*-complete set in the Boolean setting (i.e., over* $\{0,1\}$*) is* NP*-complete over the reals with addition and order for Turing reductions. Since the subsets of elements of size n of any such set S have dimension* 0*, the sparseness of S is immediate. For more on this see* [8].

RANDOMNESS AND RECURSIVE ENUMERABILITY*

ANTONÍN KUČERA† AND THEODORE A. SLAMAN‡

Abstract. One recursively enumerable real α dominates another one β if there are nondecreasing recursive sequences of rational numbers $(a[n] : n \in \omega)$ approximating α and $(b[n] : n \in \omega)$ approximating β and a positive constant C such that for all n, $C(\alpha - a[n]) \geq (\beta - b[n])$. See [R. M. Solovay, *Draft of a Paper (or Series of Papers) on Chaitin's Work,* manuscript, IBM Thomas J. Watson Research Center, Yorktown Heights, NY, 1974, p. 215] and [G. J. Chaitin, *IBM J. Res. Develop.*, 21 (1977), pp. 350–359]. We show that every recursively enumerable random real dominates all other recursively enumerable reals. We conclude that the recursively enumerable random reals are exactly the Ω-numbers [G. J. Chaitin, *IBM J. Res. Develop.*, 21 (1977), pp. 350–359]. Second, we show that the sets in a universal Martin-Löf test for randomness have random measure, and every recursively enumerable random number is the sum of the measures represented in a universal Martin-Löf test.

1. Introduction.

When is a real number effectively random? To a large extent, this question was answered by the collective efforts of Chaitin [4], Kolmogorov [11], Martin-Löf [14], Schnorr [15], Solomonoff [16], [17], and Solovay [18], among others. We present a brief historical account, based in the most part on [19]. One could also consult [1] or [13].

1.1. Characterizations of effective randomness.

To fix some notation, Σ^* denotes the set of finite binary sequences. For $a \in \Sigma^*$, $|a|$ denotes the length of a and $\langle a \rangle$ denotes the rational number with binary expansion $0.a$. We order Σ^* lexicographically.

Σ^ω denotes the set of all infinite binary sequences. As above, $\langle \alpha \rangle$ denotes the real number with binary expansion $0.\alpha$. We extend the lexicographic ordering of Σ^* to that on Σ^ω.

For $A \subseteq \Sigma^*$, $A\Sigma^\omega$ denotes the open subset of Σ^ω whose elements have an initial segment in A, and $\mu(A\Sigma^\omega)$ denotes the measure of $A\Sigma^\omega$.

We have chosen to work with Σ^* and Σ^ω, as that seemed to work best notationally. We could have worked with $\mathbb{Q}$ and $\mathbb{R}$ just as well and come to the same conclusions. We will refer to elements of $\mathbb{R}$ and to elements of Σ^ω as real numbers.

Characterization by measure. Our first characterizations of effective randomness are based on the hypothesis that an effectively random real should avoid every effectively presented set of measure 0.

DEFINITION 1.1 (Martin-Löf [14]).

1. *A* Martin-Löf randomness test *is a uniformly recursively enumerable sequence* $(A_n : n \geq 1)$ *of subsets of* Σ^* *such that for each* n, $\mu(A_n\Sigma^\omega) \leq 1/2^n$.

2. *An x in Σ^ω is* Martin-Löf-random *if for every Martin-Löf test $(A_n : n \geq 1)$, $x \notin \bigcap_{n\geq 1} A_n\Sigma^\omega$.*
3. *A Martin-Löf test $(U_n : n \geq 1)$ is* universal *if for every $x \in \Sigma^\omega$, if $x \notin \bigcap_{n\geq 1} U_n\Sigma^\omega$, then x is Martin-Löf-random.*

Note that when we speak of Martin-Löf tests, we will always be referring to tests which are applied to infinite binary sequences. Such tests are also known as sequential Martin-Löf tests to distinguish them from tests applied to finite strings.

A second measure theoretic criterion was proposed by Solovay.

DEFINITION 1.2 (Solovay [18]).

1. *A* Solovay randomness test *is a uniformly recursively enumerable sequence $(A_n : n \geq 1)$ such that the sum $\sum_{n\geq 1} \mu(A_n\Sigma^\omega)$ is convergent.*
2. *An x in Σ^ω is* Solovay-random *if and only if for every Solovay randomness test $(A_n : n \geq 1)$, $\{n : x \in A_n\Sigma^\omega\}$ is finite.*

It is immediate that every Solovay-random real is Martin-Löf-random, and Solovay proved the converse.

THEOREM 1.3 (Solovay [18]). *Every x in Σ^ω which is Martin-Löf-random is also Solovay-random.*

Characterization by algorithmic complexity.. Our second characterization of effective randomness is based on the hypothesis that an effectively random sequence should be unpredictable.

Suppose that f is a partial recursive function from Σ^* to Σ^*. We say that f is *self-delimiting* if for all a and b in Σ^*, if f is defined on a and on b, then a and b are incompatible; that is to say that they are not equal and neither string extends the other.

DEFINITION 1.4 (Levin [12], Chaitin [4]). *Suppose that f is a self-delimiting recursive function. We write $f(a)\downarrow$ to indicate that f is defined on argument a.*

1. *The* halting probability *of f is $\sum_{f(a)\downarrow} 1/2^{|a|}$.*
2. *If b is in the range of f, then the* f-complexity *of b is the least length of a string a such that $f(a) = b$. If b is not in the range of f, then the f-complexity of b is ∞. Let $H_f(b)$ denote the f-complexity of b.*

Note the halting probability of a self-delimiting function is a real number between 0 and 1. Consequently, we can use its binary expansion to identify it with an element of Σ^ω. This identification is unique for irrational reals.

CONVENTION 1.5. *In the following, we will make implicit use of the identification between $\mathbb{R}$ and Σ^ω whenever we say that a real number has a property defined only on Σ^ω.*

DEFINITION 1.6 (Chaitin [4]). *A recursive function u is* Chaitin-universal *if and only if the following conditions hold:*

1. *u is self-delimiting.*
2. *For any self-delimiting recursive function f, there is a constant C such that for all a, $H_u(a)$ is less than or equal to $H_f(a) + C$.*

PROPOSITION 1.7 (Chaitin [4]). *There is a recursive function which is Chaitin-universal.*

DEFINITION 1.8 (Chaitin [4]). *An $x \in \Sigma^\omega$ is* Chaitin-random *if there is a recursive function u which is Chaitin-universal and a constant C such that for all n, $H_u(x \upharpoonright n) > n - C$. (Here $x \upharpoonright n$ is the sequence given by the first n values of x.)*

It is straightforward to check that every Martin-Löf-random real is Chaitin-random. Schnorr proved the converse; see [3].

THEOREM 1.9 (Schnorr [15]). *For every $x \in \Sigma^\omega$, if x is Chaitin-random, then x is Martin-Löf-random.*

Since all of the preceding notions of effective randomness coincide, except for historical references, we will drop the prefixes and speak of a real's being random.

Natural examples. Chaitin provided a natural class of random reals.

DEFINITION 1.10 (Chaitin [4]). *A* Chaitin Ω-number *is the halting probability of a universal function u as above.*

THEOREM 1.11.

1. (Chaitin [4]). *Every Ω-number is Chaitin-random.*
2. (Solovay [18]). *Every Ω-number is Solovay-random.*

Consequently, every Ω-number is random.

1.2. Recursive enumerability.

DEFINITION 1.12. *An α in Σ^ω is* recursively enumerable *if there is a nondecreasing sequence $(a[n] : n \in \omega)$ from Σ^* such that $\lim_{n\to\infty} a[n] = \alpha$.*

The Ω-numbers provide natural examples of recursively enumerable reals.

Solovay formulated the following notion for recursive increasing sequences of rational numbers converging to real numbers. We take the liberty of presenting his definition in terms of recursive increasing sequences from Σ^* converging to elements of Σ^ω.

DEFINITION 1.13 (Solovay [18]). *Let $(a[n] : n \in \omega)$ and $(b[n] : n \in \omega)$ be recursive monotonically (lexicographically) increasing sequences from Σ^* which converge to α and β, respectively.*

1. *$(a[n] : n \in \omega)$* dominates *$(b[n] : n \in \omega)$ if there is a positive constant C such that for all n in ω, $C(\langle\alpha\rangle - \langle a[n]\rangle) \geq (\langle\beta\rangle - \langle b[n]\rangle)$.*
2. *$(a[n] : n \in \omega)$ is* universal *if it dominates every recursive monotonically increasing sequence from Σ^*.*
3. *α is Ω-like if it is the limit of a universal monotonically increasing recursive sequence from Σ^*.*

Solovay showed that every Ω-number is Ω-like. Additionally, Solovay's proof that every Ω-number is Solovay-random generalizes to Ω-like reals.

THEOREM 1.14 (Solovay [18]). *If α is Ω-like, then α is random.*

Calude et al. [2] sharpened Theorem 1.14 as follows.

THEOREM 1.15 (Calude et al. [2]). *If α is Ω-like, then α is an Ω-number.*

Thus, every Ω-like number is an Ω-number.

Calude et al. [2] posed the natural question, "Is every recursively enumerable random real an Ω-number?" In Theorem 2.1, we show that every recursively enumerable random real is Ω-like and conclude from Theorem 1.15 that the answer to this question is yes.

A second natural class of random reals. Chaitin's Ω-numbers come from universal objects in the complexity theoretic formulation of randomness. Calude et al. [2] raised the question whether the universal objects in the measure theoretic formulation of randomness are also random. They asked, "If $(U_n : n \geq 1)$ is a universal Martin-Löf test, then is $\sum_{n\geq 1} \mu(U_n\Sigma^\omega)$ random?" In Theorem 3.1, we show that the answer is yes. As we discuss below, an equivalent form of this fact was known in the context of recursive analysis.

A dual statement is also true. Theorem 3.3 states that every random recursively enumerable real number is the sum of the measures in a some universal Martin-Löf test.

This paper represents work conducted independently by the authors. Where appropriate, we have indicated places where they came to their solutions to these problems differently.

2. Random recursive enumerability implies Ω-like.

THEOREM 2.1. *Suppose that α is a random recursively enumerable element of Σ^ω. Then α is Ω-like.*

Proof. Let $(a[n] : n \in \mathbb{N})$ be a recursive nondecreasing sequence from Σ^* which converges to α. Let β be recursively enumerable, and let $(b[n] : n \in \mathbb{N})$ be a recursive lexicographically nondecreasing sequence from Σ^* which converges to β.

We show that one of the following two conditions must hold:

1. There is a uniformly recursively enumerable sequence of sets $(A_n : n \in \mathbb{N})$ such that for each n, $A_n \subseteq \Sigma^*$, $\mu(A_n\Sigma^\omega) \leq 1/2^n$, and $\alpha \in A_n\Sigma^\omega$.
2. There is a C such that for all i, $C(\langle\alpha\rangle - \langle a[i]\rangle) \geq (\langle\beta\rangle - \langle b[i]\rangle)$.

Theorem 2.1 follows. If the first condition holds, then α is not random and Theorem 2.1 is verified. Otherwise, the second condition holds and the pair β and $(b[n] : n \in \mathbb{N})$ is not a counterexample to α's being Ω-like. Since β and $(b[n] : n \in \mathbb{N})$ were arbitrary, Theorem 2.1 is verified.

We enumerate A_n by recursion on stages s. Let $A_n[s]$ be the finite set of strings that have been enumerated into A_n during earlier stages than s. Let $s^-[s]$ be the last stage during which we enumerated an element into A_n, or equal to 0, if there was no such earlier stage. If $a[s]$ has an initial segment in $A_n[s]$ or $b[s] = b[s^-[s]]$, then we let $A_n[s+1] = A_n[s]$. Otherwise, let $a[s] + (b[s] - b[s^-[s]])/2^n$ denote the string c such that $\langle c\rangle$ is equal to $\langle a[s]\rangle + (\langle b[s]\rangle - \langle b[s^-[s]]\rangle)/2^n$. We choose a finite antichain $d_1, \ldots, d_k$ from Σ^* such that for every d in $[a[s], a[s] + (b[s] - b[s^-[s]])/2^n]$, there is an i such that d is compatible with d_i . We enumerate $d_1, \ldots, d_k$ into A_n. In other words, we add the interval from $a[s]$ to $a[s] + (b[s] + b[s^-[s]])/2^n$ to $A_n\Sigma^\omega$. Our intention is that if the approximation to β changed by ϵ, then either α will belong to $A_n\Sigma^\omega$ or the approximation to α must change by an additional amount greater than or equal to $\epsilon/2^n$.

First, we calculate that $\mu(A_n\Sigma^\omega) \leq (\langle\beta\rangle - \langle b[0]\rangle)/2^n$: $A_n\Sigma^\omega$ is a union of a disjoint set of intervals, and the measure of $A_n\Sigma^\omega$ is the sum of the lengths of those intervals. That sum has the form

$$(\langle b[t_1]\rangle - \langle b[0]\rangle)/2^n + (\langle b[t_2]\rangle - \langle b[t_1]\rangle)/2^n + (\langle b[t_3]\rangle - \langle b[t_2]\rangle)/2^n + \ldots,$$

where $t_1, t_2, \ldots$ is the sequence of stages during which we enumerate intervals into $A_n\Sigma^\omega$. This is a collapsing sum with limit less than or equal to $(\langle\beta\rangle - \langle b[0]\rangle)/2^n$. The inequality could be strict when there are only finitely many terms in the sum. In any event, $\mu(A_n\Sigma^\omega) \leq 1/2^n$.

If α belongs to each $A_n\Sigma^\omega$, then we have condition 1.

Therefore, suppose that n is fixed so that α is not in $A_n\Sigma^\omega$. By our construction, if we enumerate the interval $[a[s], a[s] + (b[s] - b[s^-[s]])/2^n]$ into $A_n\Sigma^\omega$ during stage s, then there is a stage t greater than s such that $\langle a[t]\rangle$ is greater than $\langle a[s]\rangle + (\langle b[s]\rangle - \langle b[s^-[s]]\rangle)/2^n)$.

We claim that for all s, $2^n(\langle\alpha\rangle - \langle a[s]\rangle) \geq (\langle\beta\rangle - \langle b[s]\rangle)$. Fix s and let t_0 be the greatest stage t less than s such that we enumerate something into A_n during stage t or be 0 if there is no such stage. Let $t_0, t_1, \ldots$ be the sequence of stages, beginning with stage t_0, during which we enumerate intervals into A_n. Then t_1 is greater than or equal to s and $\langle\alpha\rangle - \langle a[t_1]\rangle$ is greater than the sum $\Sigma_{k=1}^{\infty}(\langle b[t_k]\rangle - \langle b[t_{k-1}]\rangle)/2^n$. This is

another collapsing sum and is equal to $(\langle\beta\rangle - \langle b[t_0]\rangle)/2^n$. Consequently, $\langle\alpha\rangle - \langle a[s]\rangle \geq \langle\alpha\rangle - \langle a[t_1]\rangle \geq (\langle\beta\rangle - \langle b[t_0]\rangle)/2^n \geq (\langle\beta\rangle - \langle b[s]\rangle)/2^n$, as required. □

3. Universal Martin-Löf tests have random measure. Subsequent to our having proven Theorem 3.1, the first author observed that a version of it appears in [6], set in the context of recursive analysis. See Remark 3.5.

THEOREM 3.1. *Let $(U_n : n \geq 1)$ be a universal Martin-Löf test. Then, for each $n \geq 1$, $\mu(U_n\Sigma^\omega)$ is random.*

Proof. We show that for each n, $\mu(U_n\Sigma^\omega)$ is Ω-like and therefore random.

Let U be one of the elements of $(U_n : n \geq 1)$. We note that $\mu(U\Sigma^\omega)$ is less than or equal to $1/2$. Let $U[s]$ denote the set consisting of the first s elements in the enumeration of U. Let $\beta \in \Sigma^\omega$ be recursively enumerable, and let $(b[s] : s \geq 1)$ be a recursive increasing sequence from Σ^* which converges to β.

We will construct a Martin-Löf test $(A_n : n \geq 1)$ so that for all n, $A_{n+1}\Sigma^\omega \subseteq A_n\Sigma^\omega$ and so that one of the following conditions holds:

1. For each n, A_n is finite and $\mu(A_n\Sigma^\omega \setminus U\Sigma^\omega) > 0$.
2. There is a C such that for each s, $C(\mu(U\Sigma^\omega) - \mu(U[s]\Sigma^\omega)) > (\langle\beta\rangle - \langle b[s]\rangle)$.

In the first case, we will obtain a contradiction by showing that $(U_n : n \geq 1)$ is not universal. In the second case, we will show that $(\mu(U[s]\Sigma^\omega) : s \geq 1)$ dominates $(b[s] : s \geq 1)$. Since β and $(b[s] : s \geq 1)$ were arbitrary, $\mu(U\Sigma^\omega)$ is Ω-like, as required.

We construct the sets A_n and several auxiliary functions by recursion on stages s. Our continuing convention is to use the suffix $[s]$ to denote the values of these objects during stage s. For example, $A_n[s]$ denotes the finite subset of Σ^* whose elements were enumerated into A_n before stage s.

In our recursion, if the recursion variable i goes to infinity, then we verify the first disjunct above. If i does not go to infinity in the limit, then its limit infimum i^* is the least index for an infinite element of $(A_n : n \geq 1)$. In this case, U must cover a nonzero fraction of the measure of A_{i^*}. We add measure to each A_n so that we can verify the second disjunct above (where C depends on i^*; see below).

We begin the construction with each A_n empty. During stage 0, we define $m_0[0] = 1/2$, define $A_0 = \{\,()\,\}$, the set whose only element is the null sequence, and say that 0 is active during stage 0. During stage s greater than 0, we begin in step 1 and follow the instructions below until reaching one which requires the end of stage s. Upon the end of stage s, we begin stage $s + 1$.

1. Let $m_0[s] = 1/2$, let $A_0[s] = \{\,()\,\}$, and let $i = 1$. Go to step 2.
2. (a) If i has not been active during any previous stage or if all of its previous actions have been canceled, then let $s_i^-[s]$ equal 0.
   (b) Otherwise, let $s_i^-[s]$ be the most recent stage during which i was active.
   Go to step 3.
3. (a) If $s_i^-[s] = 0$ or if $\mu(A_i[s]\Sigma^\omega \setminus U[s]\Sigma^\omega)$ is less than or equal to $d_i[s_i^-[s]]m_{i-1}[s]/2$, then take the following actions.
      i. Set $d_i[s] = (\langle b[s]\rangle - \langle b[s_i^-[s]]\rangle)$ and $m_i[s] = d_i[s]m_{i-1}[s]/2$.

ii. Choose a finite set of strings $F_i[s]$ so that $\mu(F_i[s]\Sigma^\omega)$ is equal to $d_i[s]m_{i-1}[s]$, $F_i[s]\Sigma^\omega$ is a subset of $A_{i-1}[s]\Sigma^\omega$, and $F_i[s]\Sigma^\omega$ is disjoint from $U[s]\Sigma^\omega$. Enumerate the elements of $F_i[s]$ into A_i.

iii. Say that i is active during stage s. For each $j > i$, cancel all of the previous actions for the sake of j.

iv. End the stage s of the recursion.

(b) Otherwise, let $d_i[s] = d_i[s_i^-[s]]$ and $m_i[s] = d_i[s]m_{i-1}[s]/2$. Go to step 4.

4. (a) If i is less than s, then increase the value of i by 1, and go to step 2.

(b) Otherwise, end stage s of the recursion.

Suppose that we reach step 3(a) with $i = n$. If n is equal to 1, then we are required to find a set $F_1[s]$ such that $F_1[s]\Sigma^\omega \subset (\Sigma^\omega \setminus U[s]\Sigma^\omega)$ and $\mu(F_1[s]\Sigma^\omega) = d_1[s]m_0[s]$. Of course, $m_0[s] = 1/2$ and $d_1[s]$ is less than 1. Therefore we must find a set of measure less than $1/2$ in $\Sigma^\omega \setminus U[s]\Sigma^\omega$. Since U belongs to a Martin-Löf test, $\mu(U\Sigma^\omega) \leq 1/2$ and it is possible to find the set $F_1[s]$. If n is greater than 1, then at an earlier point in stage s, we noted that $\mu(A_{n-1}[s]\Sigma^\omega \setminus U[s]\Sigma^\omega)$ is greater than $d_{n-1}[s_{n-1}^-[s]]m_{n-2}[s]/2$. We defined $d_{n-1}[s] = d_{n-1}[s_{n-1}^-[s]]$ and defined $m_{n-1}[s] = d_{n-1}[s]m_{n-2}[s]/2$. Then $d_n[s]m_{n-1}[s] = d_n[s](d_{n-1}[s]m_{n-2}[s]/2)$. Since $d_n[s]$ is less than or equal to 1, this quantity is less than $d_{n-1}[s_{n-1}^-[s]]m_{n-2}[s]/2$, and again it is possible to find the set $F_n[s]$.

We say that n is *injured* during stage s if we cancel all of the previous actions for the sake of n during stage s. Note that 1 is never injured.

Let M_n be the set of stages during which n is active. M_n is naturally divided into intervals by injury to n. If M_n is not empty, then start by letting $\{q_j : j \in Q_n\}$ be an increasing enumeration of the stages s in M_n such that $s_n^-[s]$ is equal to 0. Note that Q_n may be finite or may be all of $\mathbb{N}$. In the case that Q_n is finite with greatest element j, we let q_{j+1} denote infinity and use it to refer to the semi-infinite interval of stages coming after the final injury to n.

To calculate a bound on the measures of the sets $A_n\Sigma^\omega$, we now compute $\sum_{s\in M_n} d_n[s]m_{n-1}[s]$, when n is greater than or equal to 1.

Divide M_n into intervals.

$$\sum_{s\in M_n} d_n[s]m_{n-1}[s] = \sum_{j\in Q_n} \sum_{s\in M_n\cap[q_j,q_{j+1})} d_n[s]m_{n-1}[s].$$

Note that $m_{n-1}[s]$ is constant between q_j and q_{j+1}.

$$= \sum_{j\in Q_n} \left(m_{n-1}[q_j] \sum_{s\in M_n\cap[q_j,q_{j+1})} d_n[s] \right).$$

Identify the collapsing sum.

$$\begin{aligned}
&= \sum_{j \in Q_n} \left(m_{n-1}[q_j] \sum_{s \in M_n \cap [q_j, q_{j+1})} (\langle b[s] \rangle - \langle b[s_n^-[s]] \rangle) \right) \\
&\leq \sum_{j \in Q_n} m_{n-1}[q_j](\langle \beta \rangle - \langle b[0] \rangle) \\
&\leq \sum_{j \in Q_n} m_{n-1}[q_j].
\end{aligned}$$

Note that $m_{n-1}[q_j]$ equal to $m_{n-1}[s]$, where s is the greatest stage less than q_j during which $n-1$ was active.

$$\leq \sum_{s \in M_{n-1}} m_{n-1}[s].$$

The last inequality could be strict, as there may be stages during which $n-1$ is active which are followed by an injury to $n-1$ before the next stage during which n is active.

We now check by induction that $\sum_{s \in M_n} m_n[s]$ is less than or equal to $1/2^{n+1}$.

Consider the case when n is equal to 0. Then, M_0 is equal to $\{0\}$ and $m_0[0]$ is equal to $1/2$. Consequently, $\sum_{s \in M_0} m_0[s] = 1/2$, as required.

Now, suppose that n is greater than 0. Then, $\sum_{s \in M_n} m_n[s]$ is given by the following:

$$\sum_{s \in M_n} m_n[s] = \sum_{s \in M_n} d_n[s] m_{n-1}[s]/2.$$

Move the factor $1/2$ out of the sum, and apply the previous calculation.

$$\leq \frac{1}{2} \sum_{s \in M_{n-1}} m_{n-1}[s].$$

Apply induction.

$$\begin{aligned}
&\leq \frac{1}{2}(1/2^n) \\
&= 1/2^{n+1}.
\end{aligned}$$

We have the required inequality.

Now, $\mu(A_n \Sigma^\omega)$ is less than or equal to the sum of the measures of the sets $F_n[s]\Sigma^\omega$ for $s \in M_n$. Each $F_n[s]\Sigma^\omega$ has measure $d_n[s] m_{n-1}[s]$. Therefore, $\mu(A_n \Sigma^\omega)$ is less than or equal to $\sum_{s \in M_n} d_n[s] m_{n-1}[s]$, which is less than or equal to $\sum_{s \in M_{n-1}} m_{n-1}[s]$, and hence less than or equal to $1/2^n$, as above.

Thus, $(A_n : n \geq 1)$ is a Martin-Löf test.

Suppose that for each n, n is active only finitely often. Then for each n, there is a stage s during which we execute step 3(a) for $i = n$ for the final time. Therefore, for each n, A_n is finite and $A_n \Sigma^\omega \setminus U \Sigma^\omega$ is a closed set of positive measure. Further,

for each n, $A_{n+1}\Sigma^\omega \subseteq A_n\Sigma^\omega$. Since Σ^ω is compact, $\bigcap_{n\geq 1} A_n\Sigma^\omega \setminus U\Sigma^\omega$ is not empty. Thus, $\bigcap_{n\geq 1} A_n\Sigma^\omega$ is not a subset of U, contradicting the universality of $(U_n : n \geq 1)$.

Consequently, there are numbers which are active infinitely often, and we let i^* be the least such number.

The first possibility is that i^* is equal to 1. Consider the action during a stage $s \in M_1$. We add strings to A_1 so that the measure of $A_1\Sigma^\omega \setminus U[s]\Sigma^\omega$ is greater than or equal to $d_1[s]m_0[s]$, where $d_1[s]$ is the amount that the approximation to β has increased since the most recent stage $s_1^-[s]$ during which 1 was active. At the next stage $s_1^+[s]$ in M_1 after s, the measure of $A_1[s_1^+]\Sigma^\omega \setminus U[s]\Sigma^\omega$ is less than $d_1[s]m_0[s]/2 = d_1[s]m_0[0]/2$. Thus, for s in M_1, if the approximation to β increases by $d_1[s]$ during the interval $[s_1^-[s], s)$, then the measure of $U[s_1^+]\Sigma^\omega \setminus U[s]\Sigma^\omega$ is greater than or equal to $d_1[s]m_0[s]/2$. It follows that for every s, $(\langle\beta\rangle - \langle b[s]\rangle) \leq (2/m_0[0])(\mu(U\Sigma^\omega) - \mu(U[s]\Sigma^\omega))$. Thus, every increase in the approximation to β is followed by a proportional increase in the approximation to the measure of U, and so $\mu(U[s]\Sigma^\omega : s \geq 1)$ dominates $(b[s] : s \geq 1)$.

Second, i^* may be larger than 1, but the analysis is completely parallel to that of the previous case. We start from the first stage $s[0]$ in M_{i^*} after i^* is injured for the last time, we add strings to A_{i^*} so that the measure of $A_{i^*}\Sigma^\omega \setminus U[s]\Sigma^\omega$ is greater than or equal to $d_{i^*}[s]m_{i^*-1}[s] = d_{i^*}[s]m_{i^*-1}[s_0]$, and we observe that the measure of $U\Sigma^\omega$ increases by at least half that much during the interval from s to the next stage in M_n. It follows that for every m, $(\langle\beta\rangle - \langle b[m]\rangle) \leq (2/m_{i^*-1}[s_0])(\mu(U\Sigma^\omega) - \mu(U[m]\Sigma^\omega))$.

In either case, U is Ω-like and therefore random. □

The following corollary follows easily.

COROLLARY 3.2. *Let $(U_n : n \geq 1)$ be a universal Martin-Löf test. Then $\sum_{n\geq 1} \mu(U_n\Sigma^\omega)$ is random.*

THEOREM 3.3. *For each recursively enumerable random r in Σ^ω there is a universal Martin-Löf test $(U_n : n \geq 1)$ such that $\langle r\rangle$ is equal to $\sum_{n\geq 1} \mu(U_n\Sigma^\omega)$.*

Proof. We fix a universal Martin-Löf test $(A_n : n \geq 1)$, and construct another $(U_n : n \geq 1)$ based on it so that $\langle r\rangle = \sum_{n\geq 1} \mu(U_n\Sigma^\omega)$. Let $A_n[s]$ denote the finite set of sequences which enter A_n during the first s steps of its enumeration. We may assume that for all n and s, if $s < n$, then $A_n[s]$ is empty. With analogous notation, we will make use of a universal Martin-Löf test $(V_n : n \geq 1)$ and a nondecreasing recursive sequence $(r[s] : s \geq 1)$ with limit r such that for all s, $\sum_{n\geq 1} \mu(V_n\Sigma^\omega) - \sum_{n\geq 1} \mu(V_n[s]\Sigma^\omega)$ is less than $\langle r\rangle - \langle r[s]\rangle$. We first argue that there are such sequences.

For s greater than or equal to 1, let $b[s]$ be the binary string such that the following condition holds:

$$\langle b[s]\rangle = \sum_{s\geq i\geq 1} 2^i \sum_{s\geq j\geq 1} \mu(A_{2i+j+1}[s]\Sigma^\omega).$$

Note that

$$\begin{aligned}
\sum_{s\geq i\geq 1} 2^i \sum_{s\geq j\geq 1} \mu(A_{2i+j+1}[s]\Sigma^\omega) &\leq \sum_{i\geq 1} 2^i \sum_{j\geq 1} \mu(A_{2i+j+1}\Sigma^\omega) \\
&\leq \sum_{i\geq 1} 2^i \sum_{j\geq 1} (1/2^{2i+j+1}) \\
&\leq \sum_{i\geq 1} 1/2^{i+1} \\
&\leq 1/2,
\end{aligned}$$

and so there is such a $b[s]$. Let β be $\lim_{s\to\infty} b[s]$. Since r is random, Theorem 2.1 applies and we may let $(r[s] : s \geq 1)$ be a recursive nondecreasing sequence from Σ^* with limit r and let C be constant such that for all s, $\langle\beta\rangle - \langle b[s]\rangle$ is less than $C(\langle r\rangle - \langle r[s]\rangle)$. Now let k be fixed so that 2^k is greater than C. Then for all s,

$$\begin{aligned} 2^k(\langle r\rangle - \langle r[s]\rangle) &> C(\langle r\rangle - \langle r[s]\rangle) \\ &\geq \langle\beta\rangle - \langle b[s]\rangle \\ &= \sum_{i\geq 1} 2^i \sum_{j\geq 1} \mu(A_{2i+j+1}\Sigma^\omega) - \sum_{s\geq i\geq 1} 2^i \sum_{s\geq j\geq 1} \mu(A_{2i+j+1}[s]\Sigma^\omega) \\ &\geq 2^k \sum_{j\geq 1} \mu(A_{2k+j+1}\Sigma^\omega) - 2^k \sum_{s\geq j\geq 1} \mu(A_{2k+j+1}[s]\Sigma^\omega). \end{aligned}$$

Consequently, for each s,

$$(\langle r\rangle - \langle r[s]\rangle) > \sum_{j\geq 1} \mu(A_{2k+j+1}\Sigma^\omega) - \sum_{s\geq j\geq 1} \mu(A_{2k+j+1}[s]\Sigma^\omega).$$

Then, $(A_{2k+j+1} : j \geq 1)$ is a universal Martin-Löf test such that for all s, $\sum_{j\geq 1} \mu(A_{2k+j+1}\Sigma^\omega) - \sum_{s\geq j\geq 1} \mu(A_{2k+j+1}[s]\Sigma^\omega)$ is less than $\langle r\rangle - \langle r[s]\rangle$.

We first handle the case in which $\langle r\rangle$ is less than $1/2$. Choose m so that

$$\langle r\rangle + \mu(A_{2k+m+1}\Sigma^\omega) < 1/2$$

and so that

$$\langle r\rangle > \sum_{j\geq 1} \mu(A_{2k+m+j+1}\Sigma^\omega).$$

For $n \geq 1$, let $V_n = A_{2k+m+n+1}$. For s greater than or equal to 1, let $v[s]$ be $\sum_{s\geq n\geq 1} \mu(V_n[s]\Sigma^\omega)$, and let v be $\sum_{n\geq 1} \mu(V_n\Sigma^\omega)$. By the estimates given above, for each s, $v - v[s]$ is less than or equal to $\langle r\rangle - \langle r[s]\rangle$.

We now construct our Martin-Löf test $(U_n : n \geq 1)$ so that $V_1 \subseteq U_1$ and for all n greater than 1, $V_n = U_n$.

Assuming that we establish $\sum_{n\geq 1} \mu(U_n\Sigma^\omega) = \langle r\rangle$, then since $\mu(U_1\Sigma^\omega)$ is less than or equal to $\langle r\rangle$ and $\langle r\rangle$ is less than or equal to $1/2$, $(U_n : n \geq 1)$ is a Martin-Löf test. Further, $\cap_{n\geq 1} A_n$ is a subset of $\cap_{n\geq 1} U_n$ and so $(U_n : n \geq 1)$ is universal.

We enumerate U_1 by recursion on stages s. Let $U_1[s]$ be set of strings enumerated into U_1 during stages less than s. Let $u[s]$ be $\mu(U_1[s]\Sigma^\omega) + \sum_{n>1} \mu(V_n[s]\Sigma^\omega)$, and let u be the limit of $u[s]$, as s goes to infinity.

During stage s, if $u[s]$ is less than $\langle r[s]\rangle$, then we enumerate a finite set of strings $F[s]$ into U_1 so that $F[s]\Sigma^\omega \cap U_1[s]\Sigma^\omega = \emptyset$ and $\mu(F[s]\Sigma^\omega)$ is equal to $\langle r[s]\rangle - u[s]$. (Not to ignore a fine point, since $\langle r[s]\rangle$ and $u[s]$ have finite binary expansions, there is such a finite set.) We then enumerate all of the strings that enter V_1 during stage s into U_1.

It remains to check that $u = \sum_{n\geq 1} \mu(U_n\Sigma^\omega)$ is equal to $\langle r\rangle$.

By the construction, for every s, $u[s+1]$ is greater than or equal to $\langle r[s]\rangle$. Consequently, $u \geq \langle r\rangle$.

Since $\sum_{n\geq 1} \mu(V_n\Sigma^\omega) < \langle r\rangle$, there must be a stage s such that $\langle r[s]\rangle \geq v(s)$. At the first such stage, $\langle r[s]\rangle \geq u(s)$ as well. If there are infinitely many stages s during which $\langle r[s]\rangle \geq u[s]$, then $u = \langle r\rangle$, as required. Otherwise, there are only finitely many

such stages. We argue that $\langle r\rangle \geq u$ as follows. Let s_0 be the greatest stage s during which $\langle r[s]\rangle \geq u[s]$. At the beginning of stage s_0+1, we add a finite set of elements $F[s_0+1]$ to U_1 so that the measure of $U_1\Sigma^\omega$ is momentarily equal to $\langle r[s_0]\rangle$. Since $u[s] \geq \langle r[s]\rangle$ during every stage s after s_0, we do not add any further elements to U_1 other than those in V_1. Consequently U_1 is equal to $U_1[s_0] \cup F[s_0+1] \cup V_1$. Further, u, which is equal to $\sum_{n\geq 1} \mu(U_n\Sigma^\omega)$, can be written as

$$u = \mu\left((U_1[s_0] \cup F[s_0+1])\,\Sigma^\omega\right) + \sum_{n>1} \mu(V_n[s_0]\Sigma^\omega) + \mu(V_1\Sigma^\omega \setminus (U_1[s_0] \cup F[s_0+1])\Sigma^\omega) + \sum_{n>1} \mu(V_n\Sigma^\omega \setminus V_n[s_0]\Sigma^\omega).$$

By the choice of $F[s_0+1]$,

$$\mu((U_1[s_0] \cup F[s_0+1])\Sigma^\omega) + \sum_{n>1} \mu(V_n[s_0]\Sigma^\omega) = \langle r[s_0]\rangle.$$

Further, $V_1[s_0] \subseteq U_1[s_0]$ so

$$\begin{aligned}
&\mu(V_1\Sigma^\omega \setminus (U_1[s_0] \cup F[s_0+1])\Sigma^\omega) + \sum_{n>1} \mu(V_n\Sigma^\omega \setminus V_n[s_0]\Sigma^\omega) \\
&\quad\leq \mu(V_1\Sigma^\omega \setminus V_1[s_0]\Sigma^\omega) + \sum_{n>1} \mu(V_n\Sigma^\omega \setminus V_n[s_0]\Sigma^\omega) \\
&\quad\leq \sum_{n\geq 1} \mu(V_n\Sigma^\omega) - \sum_{n\geq 1} \mu(V_n[s_0]\Sigma^\omega) \\
&\quad\leq (v - v[s_0]).
\end{aligned}$$

Then, however, $u \leq \langle r[s_0]\rangle + (v - v[s_0])$. By the above, $(v - v[s_0])$ is less than or equal to $(\langle r\rangle - \langle r[s_0]\rangle)$. We conclude that u is less than or equal to $\langle r[s_0]\rangle + (\langle r\rangle - \langle r[s_0]\rangle)$; that is, $u \leq \langle r\rangle$, as required.

Next we consider the case when $\langle r\rangle$ is greater than $1/2$. Again, let $(A_n : n \geq 1)$ be a universal Martin-Löf test. Choose $m > 1$ so that $1/2 + \sum_{n>m} \mu(A_n\Sigma^\omega)$ is less than $\langle r\rangle$. Let 0^n denote the sequence with n many 0's. For $n \geq 1$, let V_n be a subset of Σ^* such that $A_{m+n}\Sigma^\omega \cup \{0^{n+1}\}\Sigma^\omega$ is equal to $V_n\Sigma^\omega \cup \{0^{n+1}\}\Sigma^\omega$, and each element of V_n is incompatible with 0^{n+1}. For each n, $\mu(A_{m+n}\Sigma^\omega \cup \{0^{n+1}\}\Sigma^\omega)$ is less than or equal to $\mu(A_{m+n}\Sigma^\omega) + 1/2^{n+1}$, which is less than or equal to $1/2^n$. Now we use the method in the previous construction to find $(U_n : n \geq 1)$ such that the following conditions hold: $\sum_{n\geq 1} \mu(U_n\Sigma^\omega) = \langle r\rangle - 1/2$; for each n, $V_n \subseteq U_n$; and every element of U_n is incompatible with 0^{n+1}.

The last constraint is only relevant to the construction of U_1. In the notation of the previous construction, we may be asked during step $s+1$ to find a set of finite sequences $F[s+1]$ such that the measure of $F[s+1]\Sigma^\omega$ is equal to $(\langle r[s]\rangle - 1/2) - u[s]$ and $F[s+1]\Sigma^\omega \cap U_1[s]\Sigma^\omega = \emptyset$. For $n = 1$, the complement of $\{0^{n+1}\}\Sigma^\omega$ has measure $3/4$, so the measure available for the choice of $F[s+1]$ is greater than or equal to $3/4 - u[s]$. Thus it is always possible to find the set $F[s]$ as required.

Finally, we let U_n^* be $U_n \cup \{0^{n+1}\}$.

Then, $\sum_{n\geq 1} \mu(U_n^*\Sigma^\omega)$ is evaluated as follows:

$$\sum_{n\geq 1} \mu(U_n^*\Sigma^\omega) = \sum_{n\geq 1} \mu(U_n\Sigma^\omega \cup \{0^{n+1}\}\Sigma^\omega).$$

Note that $U_n\Sigma^\omega \cap \{0^{n+1}\}\Sigma^\omega$ is empty.

$$\begin{aligned}
&= \sum_{n\geq 1} \mu(U_n\Sigma^\omega) + \sum_{n\geq 1} \mu(\{0^{n+1}\}\Sigma^\omega) \\
&= \sum_{n\geq 1} \mu(U_n\Sigma^\omega) + 1/2 \\
&= (\langle r\rangle - 1/2) + 1/2 \\
&= \langle r\rangle. \qquad \square
\end{aligned}$$

Remark 3.4. Theorem 3.1 can also be proved by using the following idea. We first observe that approximating $\mu(U_n\Sigma^\omega)$ by an open set with measure less than ϵ is at least as difficult as approximating $\langle L\rangle$, where L is the least element in Σ^ω which is not in $U_n\Sigma^\omega$. More precisely, let $\langle\alpha\rangle$ denote $\mu(U_n\Sigma^\omega)$. If we were given a Martin-Löf test $(A_n : n \geq 1)$ such that α belongs to $\bigcap_{n\geq 1} A_n\Sigma^\omega$, then we could construct another Martin-Löf test $(B_n : n \geq 1)$ such that L belongs to $\bigcap_{n\geq 1} B_n\Sigma^\omega$. By virtue of L's passing the universal Martin-Löf test $(U_n : n \geq 1)$, L is random, a contradiction. Theorem 3.1 follows.

We sketch the enumeration of $(B_n : n \geq 1)$. For any σ and s, if s is the least such that

$$\sigma \in A_n[s] \text{ and } \langle\sigma\rangle \leq \mu(U_n[s]\Sigma^\omega) < \langle\sigma\rangle + 2^{-|\sigma|},$$

take the following actions. Choose a finite set of strings $G_n[s]$ such that $G_n[s]\Sigma^\omega$ is disjoint from $U_n[s]\Sigma^\omega$, $\mu(G_n[s]\Sigma^\omega) = \langle\sigma\rangle + 2^{-|\sigma|} - \mu(U_n[s]\Sigma^\omega)$; if β is the least element in Σ^ω which is not in $U_n[s]\Sigma^\omega \cup G_n[s]\Sigma^\omega$, then

$$\langle\beta\rangle = \mu(U_n[s]\Sigma^\omega \cap \{\gamma : \gamma < \beta\}) + \mu(G_n[s]\Sigma^\omega).$$

(Observe that such set $G_n[s]$ exists.) Enumerate $G_n[s]$ into B_n.

Roughly speaking, enumerate into B_n a finite set of strings $G_n[s]$ such that $G_n[s]\Sigma^\omega$ presents the leftmost part of the complement of $U_n[s]\Sigma^\omega$ (not necessarily connected) of a total length $\langle\sigma\rangle + 2^{-|\sigma|} - \mu(U_n[s]\Sigma^\omega)$.

Remark 3.5. As we mentioned above, a recursive-analysis version of Theorem 3.1 was proven by [6]. Demuth worked in the Markov/Russian style of constructive mathematical analysis. He studied a behavior of everywhere defined constructive functions of a real variable and, among others, questions of differentiation of such functions. Since random reals from the closed unit interval

1. form a set of measure one,
2. arise by avoiding sets of measure zero from a special class, and
3. can be viewed as "generic,"

one could expect that they would be important in recursive analysis. This is the case and Demuth devoted a considerable amount of effort toward understanding their role there. He started with a rather finitistic approach, and he used a more standard terminology only in his last papers. We briefly survey Demuth's work here, taking the liberty to reformulate his definitions and results into a contemporary terminology.

Demuth [6] studied reals recursive in $\emptyset'$ and defined π_1 and π_2 numbers in that context. According to Demuth, a real x recursive in $\emptyset'$ is a π_1 number if and only if for some (equivalently, for any) recursive sequence of rational numbers $(a[n] : n \in \omega)$ converging to x there is a recursive sequence of finite recursive sets $(C_m : m \in \omega)$

such that $\mu(\bigcup_{s \notin C_m} (\min(a[s], a[s+1]), \max(a[s], a[s+1])))$ is less than 2^{-m}. Dually, x recursive in $\emptyset'$ is a π_2-number if x is not a π_1-number.

In his own terminology, Demuth constructed a universal Martin-Löf test [6, Theorem 2] and showed [6, Theorem 5] that for all x recursive in $\emptyset'$, x is a π_2 number if and only if x is random in the sense of Martin-Löf. We are omitting some details here. Later, Demuth [7] worked with arithmetical reals and defined $\mathcal{A}_1$ and $\mathcal{A}_2$ numbers as natural extensions of π_1 and π_2 numbers. Demuth was not aware that Martin-Löf had formulated these notions earlier.

Finally, Demuth [9] extended these notions to all reals under a different terminology (still not using "randomness"). In [6], he proved, among other things, the following.

(Demuth [6, Lemma 3]). If $r = \sum_{n \in \omega} r_n$, for nonnegative rationals r_n, is a π_1-number (i.e., nonrandom), then $\sum_{n \in C} r_n$ for any recursively enumerable set C is again a π_1-number (no proof was given).

(Demuth [6, Corollary]). Let Q be a recursively enumerable set of strings. If $\mu(Q\Sigma^\omega)$ is a π_1-number and $\mu(Q[s]\Sigma^\omega)$ is less than 1 for all s, then there is a π_1-number x with $0 \leq x \leq 1$ such that $x \notin Q\Sigma^\omega$ (no proof was given).

In other words, if $\mu(Q\Sigma^\omega)$ is not random, then there is a nonrandom real not in $Q\Sigma^\omega$. It follows that if U_n appears as one of the sets in a universal Martin-Löf test, then $\mu(U_n\Sigma^\omega)$ is random.

For more on the massive work of Demuth on recursive analysis one could also consult [10], [8], or [9]. Finally, we note that Demuth also proved several interesting results from a more recursion theoretic point of view in his last papers; see [8], [9], [10]. He also studied various modifications of randomness, again motivated by problems arising in recursive analysis.

TREEWIDTH AND MINIMUM FILL-IN: GROUPING THE MINIMAL SEPARATORS*

VINCENT BOUCHITTÉ† AND IOAN TODINCA†

Abstract. We use the notion of potential maximal clique to characterize the maximal cliques appearing in minimal triangulations of a graph. We show that if these objects can be listed in polynomial time for a class of graphs, the treewidth and the minimum fill-in are polynomially tractable for these graphs. We prove that for all classes of graphs for which polynomial algorithms computing the treewidth and the minimum fill-in exist, we can list their potential maximal cliques in polynomial time. Our approach unifies these algorithms. Finally we show how to compute in polynomial time the potential maximal cliques of weakly triangulated graphs for which the treewidth and the minimum fill-in problems were open.

Key words. graph algorithms, treewidth, minimum fill-in, weakly triangulated graphs

1. Introduction.

The notion of *treewidth* was introduced by Robertson and Seymour in [28]. It plays a major role in graph algorithm design. Indeed, it has been shown that many classical NP-hard problems become polynomial and even linear when restricted to graphs with small treewidth. These algorithms often use a tree decomposition or a *triangulation* of the input graph, which is a chordal supergraph, i.e., all the cycles with at least four vertices of the supergraph have a chord. Computing the treewidth consists of finding a triangulation of minimum cliquesize. A related problem is the *minimum fill-in* problem, which consists of finding a triangulation of a graph such that the number of added edges is minimum. This parameter is used in sparse matrix factorization.

Both the treewidth and the minimum fill-in problems are NP-complete. Nevertheless, these parameters can be computed in polynomial time for several classes of graphs such as chordal bipartite graphs [20, 9], circle and circular-arc graphs [16, 32, 24], and AT-free graphs with a polynomial number of separators [23]. Most of these algorithms use the fact that these classes of graphs have a polynomial number of *minimal separators*. It was conjectured in [18, 19] that the treewidth and the minimum fill-in should be tractable in polynomial time for all the graphs having a polynomial number of minimal separators. The conjecture is still open.

A potential maximal clique of a graph is a set of vertices which induces a maximal clique in some minimal triangulation of the graph. Although this seems a purely combinatorial definition, a potential maximal clique corresponds to a local grouping of some minimal separators of the graph. This will lead to a local characterization of a potential maximal clique, and in particular to a polynomial algorithm that, given a graph G and a set of vertices K, decides if K is a potential maximal clique of G. We also show in this paper that if one can list in polynomial time all the potential

maximal cliques of some class of graphs, then the treewidth and the minimum fill-in of those graphs can be computed in polynomial time.

We prove that the potential maximal cliques can be enumerated in polynomial time for all the classes of graphs previously mentioned, unifying in this way the cited algorithms.

The class of *weakly triangulated graphs*, introduced in [13], is a class of graphs with a polynomial number of separators, probably the only one for which the treewidth and minimum fill-in problems were still open. We give an algorithm computing the potential maximal cliques of these graphs. Consequently, the treewidth and the minimum fill-in of weakly triangulated graphs are computable in polynomial time.

2. Chordal graphs and minimal separators. Throughout this paper we consider connected, simple, finite, undirected graphs.

A graph H is *chordal* (or *triangulated*) if every cycle of length at least four has a chord, i.e., an edge between two nonconsecutive vertices of the cycle. A *triangulation* of a graph $G = (V, E)$ is a chordal graph $H = (V, E')$ such that $E \subseteq E'$. H is a *minimal triangulation* if for any intermediate set E'' with $E \subseteq E'' \subset E'$, the graph (V, E'') is not triangulated. For example, the graph of Figure 2.1(b) is a minimal triangulation of the graph of Figure 2.1(a).

Another characterization of minimal triangulations is provided in [29].

LEMMA 2.1. *Let H be a triangulation of a graph G. Then H is a minimal triangulation of G if and only if, for any edge e of $E(H) - E(G)$, the graph $H - e$ is not triangulated.*

Now let us define the treewidth and the minimum fill-in of a graph.

DEFINITION 2.2. *Let G be a graph. The* treewidth *of G, denoted by* $\mathrm{tw}(G)$*, is the minimum, over all triangulations H of G, of $\omega(H) - 1$, where $\omega(H)$ is the maximum cliquesize of H.*

DEFINITION 2.3. *The* minimum fill-in *of a graph G, denoted by* $\mathrm{mfi}(G)$*, is the smallest value of $|E(H) - E(G)|$, where the minimum is taken over all triangulations H of G.*

In other words, computing the treewidth of G means finding a triangulation with the smallest cliquesize, while computing the minimum fill-in consists in finding a triangulation with the smallest number of edges. In both cases we can restrict our work to minimal triangulations.

Now let a and b be two nonadjacent vertices of a graph G. A set of vertices $S \subseteq V$ is an *a, b-separator* if the removal of S from the graph separates a and b in different connected components. S is a *minimal a, b-separator* if no proper subset of S separates a and b. We say that S is a *minimal separator* of G if there are two vertices a and b such that S is a minimal a, b-separator. Notice that a minimal separator can be strictly included in another one. We denote by Δ_G the set of all minimal separators of G.

Let us recall some known results about the minimal separators of a chordal graph. We will use the representation of chordal graphs provided by *clique trees*. For an extensive survey of these notions, see [2, 12]. A *clique* is a complete subgraph of G. Now consider the set $\mathcal{K}_G = \{\Omega_1, \ldots, \Omega_p\}$ of maximal cliques of G. Let $\mathcal{T}$ be a tree on $\mathcal{K}_G$, i.e., every maximal clique $\Omega \in \mathcal{K}_G$ corresponds to exactly one node of $\mathcal{T}$. We also say that the nodes of $\mathcal{T}$ are *labeled* by the cliques of $\mathcal{K}_G$ and we will simply denote by Ω the node of the tree labeled by a maximal clique Ω. We say that $\mathcal{T}$ is a *clique tree* of G if it satisfies the *clique-intersection property*: for every pair of distinct cliques $\Omega, \Omega' \in \mathcal{K}$, the set $\Omega \cap \Omega'$ is contained in every clique on the unique path connecting Ω

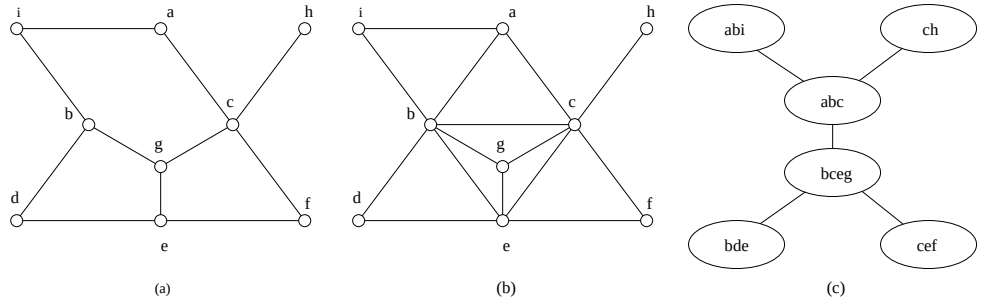

FIG. 2.1. *Minimal triangulation and clique tree.*

and Ω' in the tree $\mathcal{T}$. It is well known (see [2] for a proof) that a graph G is chordal if and only if it has a clique tree.

Figure 2.1(c) presents a clique tree of the chordal graph of Figure 2.1(b).

The following crucial property is proved in [2].

PROPOSITION 2.4. *Let H be a chordal graph and $\mathcal{T}$ be any clique tree of H. A set of vertices S is a minimal separator of H if and only if $S = \Omega \cap \Omega'$ for some maximal cliques Ω and Ω' of H adjacent in the clique tree $\mathcal{T}$.*

In particular, all minimal separators of a chordal graph are cliques. Actually, Dirac [10] has shown that a graph is chordal if and only if all its minimal separators are cliques.

The following proposition (see [2]) gives another relation between a minimal separator and a clique tree of H.

PROPOSITION 2.5. *Let $\mathcal{T}$ be any clique tree of a chordal graph H and let Ω, Ω' be two maximal cliques of H, adjacent in $\mathcal{T}$. Consider the two subtrees of $\mathcal{T}$ obtained by removing the edge between the nodes Ω and Ω'. Let $\mathcal{T}_\Omega$ be the subtree containing Ω and $\mathcal{T}_{\Omega'}$ the subtree containing Ω'. We denote by V_Ω and $V_{\Omega'}$ the union of the labels of $\mathcal{T}_\Omega$ (respectively, $\mathcal{T}_{\Omega'}$). Then the minimal separator $S = \Omega \cap \Omega'$ separates in H every vertex of $V_\Omega - S$ from every vertex of $V_{\Omega'} - S$.*

Consider, for example, the chordal graph H of Figure 2.1(b) and its clique tree of Figure 2.1(c). If we take the adjacent cliques $\{a, b, c\}$ and $\{b, c, e, g\}$, then the minimal separator $\{b, c\}$ separates in H every vertex of $\{a, h, i\}$ from every vertex of $\{d, e, f, g\}$.

Let G be a graph and S a minimal separator of G. We note $\mathcal{C}_G(S)$ to be the set of connected components of $G - S$. A component $C \in \mathcal{C}_G(S)$ is a *full* component associated with S if every vertex of S is adjacent to some vertex of C. We denote by $\mathcal{C}^*_G(S)$ the set of all full components associated with S. For the following lemma, we refer to [12].

LEMMA 2.6. *A set S of vertices of G is a minimal a, b-separator if and only if a and b are in different full components associated with S.*

If $C \in \mathcal{C}(S)$, we say that $(S, C) = S \cup C$ is a *block* associated with S. A block (S, C) is called *full* if C is a full component associated with S.

DEFINITION 2.7. *Two separators S and T* cross*, denoted by $S \sharp T$, if T intersects at least two distinct components of $G - S$. If S and T do not cross, they are called* parallel*, denoted by $S \| T$.*

It is easy to prove that these relations are symmetric (see [26]). Remark that two minimal separators S and T are parallel if and only if T is contained in some block (S, C) associated with S.

Using the fact that a separator cannot separate two adjacent vertices we deduce the following lemma.

LEMMA 2.8. *Let G be a graph, S a minimal separator, and Ω a clique of G. Then Ω is included in some block associated with S. In particular, the minimal separators of a chordal graph are pairwise parallel.*

Let $S \in \Delta_G$ be a minimal separator. We denote by G_S the graph obtained from G by completing S, i.e., by adding an edge between every pair of nonadjacent vertices of S. If $\Gamma \subseteq \Delta_G$ is a set of separators of G, G_Γ is the graph obtained by completing all the separators of Γ. The results of [22], concluded in [27], establish a strong relation between the minimal triangulations of a graph and its minimal separators.

THEOREM 2.9. *Let $\Gamma \subseteq \Delta_G$ be a maximal set of pairwise parallel separators of G. Then $H = G_\Gamma$ is a minimal triangulation of G and $\Delta_H = \Gamma$.*

Conversely, let H be a minimal triangulation of a graph G. Then Δ_H is a maximal set of pairwise parallel separators of G and $H = G_{\Delta_H}$.

In other terms, every minimal triangulation of a graph G is obtained by considering a maximal set Γ of pairwise parallel separators of G and completing the separators of Γ. The minimal separators of the triangulation are exactly the elements of Γ. For example, if G is the graph of Figure 2.1(a) and H is the graph of Figure 2.1(b), then $\Gamma = \{\{a,b\},\{b,c\},\{c\},\{b,e\},\{c,e\}\}$.

It is important to know that the elements of Γ, which become the minimal separators of H, have strictly the same behavior in H as in G. Indeed, the connected components of $H - S$ are exactly the same in $G - S$ for every $S \in \Gamma$. Moreover, the full components are the same in the two graph: $\mathcal{C}^*_H(S) = \mathcal{C}^*_G(S)$.

3. Potential maximal cliques. The previous theorem gives a characterization of the minimal triangulations of a graph by means of minimal separators, but it gives no algorithmic information about how we should construct a minimal triangulation in order to minimize its cliquesize or the fill-in. We will prove that the *potential maximal cliques* of a graph suffice to compute its treewidth and its minimum fill-in.

DEFINITION 3.1. *A set of vertices Ω of a graph G is called a* potential maximal clique *if there is a minimal triangulation H of G such that Ω is a maximal clique of H.*

In this section, we give several characterizations of the potential maximal cliques of a graph, which will allow us to recognize a potential maximal clique in polynomial time and also to enumerate these objects for several classes of graphs.

3.1. Potential maximal cliques and minimal separators. If K is a set of vertices of G, we denote by $\Delta_G(K)$ the minimal separators of G included in K. Our aim is to give a strong relation between a potential maximal clique Ω and the minimal separators of $\Delta_G(\Omega)$.

DEFINITION 3.2. *Let G be a graph and $\mathcal{S} \subseteq \Delta_G$ a set of pairwise parallel separators such that for any $S \in \mathcal{S}$, there is a block $(S, C(S))$ containing all the separators of $\mathcal{S}$. Suppose that $\mathcal{S}$ ordered by inclusion has no greatest element. We define the* piece between *the elements of $\mathcal{S}$ by*

$$P(\mathcal{S}) = \bigcap_{S \in \mathcal{S}} (S, C(S)).$$

Notice that for any $S \in \mathcal{S}$ the block $(S, C(S))$ containing all the separators of $\mathcal{S}$ is unique: if $T \in \mathcal{S}$ is not included in S, there is a unique connected component of S containing $T - S$.

LEMMA 3.3. *Let H be a chordal graph and let Ω be a maximal clique of H. Then either $\Delta_H(\Omega)$ has a greatest element, or $P(\Delta_H(\Omega))$ exists and contains Ω.*

Proof. According to Lemma 2.8, for any minimal separator $S \in \Delta_H(\Omega)$, the clique Ω is contained in some block $(S, C(S))$ of S. It follows that if $\Delta_H(\Omega)$ has no greatest element, then Ω is contained in $P(\Delta_H(\Omega))$, by definition of the piece between. □

THEOREM 3.4. *Let Ω be a maximal clique of a chordal graph H. If all the separators of $\Delta_H(\Omega)$ are contained in some $S \in \Delta_H(\Omega)$, then Ω is a block (S, C) associated with S. Otherwise, $\Omega = P(\Delta_H(\Omega))$.*

Proof. Suppose that $\bigcup_{T \in \Delta_H(\Omega)} T = S$ with $S \in \Delta_H(\Omega)$. Ω is included in some block (S, C) of S. If $x \in C$ is not in Ω, we take in a clique tree of H a path $\Omega, \Omega', \ldots, \Omega^{(i)}$ of adjacent cliques such that $x \in \Omega^{(i)}$. Then $T = \Omega \cap \Omega'$ is a minimal separator of H included in Ω, so it must be an element of $\Delta_H(\Omega)$. In particular, T is included in S. According to Proposition 2.5, T separates x and any vertex of $\Omega - T$. Since $T \subseteq S$, S clearly separates x and any vertex of $\Omega - S$, contradicting the fact that x and Ω are in the same block associated with S. It follows that $(S, C) = \Omega$.

Now suppose that no separator $S \in \Delta_H(\Omega)$ contains all the others. According to the Lemma 3.3, $P(\Delta_H(\Omega))$ exists. On the one hand, $\Omega \subseteq P(\Delta_H(\Omega))$ by Lemma 3.3. On the other hand, consider $y \in P(\Delta_H(\Omega)) - \Omega$. In a clique tree of H, we consider a path $\Omega, \Omega', \ldots, \Omega^{(i)}$ of adjacent cliques such that $y \in \Omega^{(i)}$. Then $S = \Omega \cap \Omega'$ is a minimal separator that belongs to $\Delta_H(\Omega)$ and S separates y from every vertex of $\Omega - S$ by Proposition 2.5. Let T be a separator of $\Delta_H(\Omega)$ not included in S. Then S separates y and a vertex of $T - S$, so y is not in the block $(S, C(S))$ containing Ω, contradicting our choice. It follows that $\Omega = P(\Delta_H(\Omega))$. □

Theorem 3.4 gives a relation between a maximal clique of a chordal graph and the minimal separators contained in the clique. We extend this result to the potential maximal cliques of a graph. We also establish the reverse of Theorem 3.4, which will allow us to recognize a potential maximal clique. For this we need some easy lemmas.

LEMMA 3.5. *Let H be a minimal triangulation of a graph G and T be a minimal separator of G such that $H[T]$ is a clique. Then T is also a minimal separator of H.*

Proof. We know that $H = G_\Gamma$ for a maximal set of pairwise parallel separators $\Gamma \subseteq \Delta_G$ and $\Delta_H = \Gamma$ (Theorem 2.9). Let $S \in \Gamma$ be any minimal separator of H and G. By Lemma 2.8, the clique T will be in some block (S, C) of H. Since the blocks associated with S in G are the same as in H (Theorem 2.9 and the related remarks) we deduce that S and T are parallel in G. Since Γ is a *maximal* set of pairwise parallel separators, T must be in $\Gamma = \Delta_H$. □

COROLLARY 3.6. *In particular, if T is a minimal separator of G contained in S with $S \in \Delta_H$, then $T \in \Delta_H$.*

Consider a graph G and a minimal triangulation H of G. An important consequence of Lemma 3.5 is that if Ω is a clique of H, then the minimal separators of H contained in Ω are the same as in G.

PROPOSITION 3.7. *Let G be a graph and H be a minimal triangulation of G. Then for any clique Ω of H, we have $\Delta_H(\Omega) = \Delta_G(\Omega)$.*

Proof. By Theorem 2.9, every minimal separator of H is also a minimal separator of G, so $\Delta_H(\Omega) \subseteq \Delta_G(\Omega)$. According to Lemma 3.5, since every minimal separator $S \in \Delta_G(\Omega)$ of S induces a clique in H, S is also a minimal separator of H. □

The next step is to prove that if Ω is a maximal clique of a minimal triangulation H of G, then Ω is also a clique in the graph $G_{\Delta_G(\Omega)}$, obtained by completing in G the minimal separators included in Ω.

LEMMA 3.8. *Let H be a chordal graph, Ω a maximal clique, and S a minimal*

separator of H intersecting Ω. Then $S \cap \Omega$ is contained in some minimal separator T with $T \subset \Omega$.

Proof. Consider a clique tree $\mathcal{T}$ of H. We can write $S = \Omega_1 \cap \Omega_2$ for some maximal cliques Ω_1, Ω_2 of H, adjacent in $\mathcal{T}$ (Proposition 2.4). Let us suppose that Ω_1 is closer to Ω in the clique tree than Ω_2. Let Ω' be the clique next to Ω on the path from Ω to Ω_2 in $\mathcal{T}$, i.e., the path is $\Omega, \Omega', \ldots, \Omega_1, \Omega_2$.

Then $\Omega_1 \cap \Omega \subset \Omega'$ and $\Omega_2 \cap \Omega \subset \Omega'$ by definition of a clique tree. Since $S = \Omega_1 \cap \Omega_2$, we deduce that $S \cap \Omega \subset \Omega'$ and, in particular, $S \cap \Omega$ is contained in $\Omega \cap \Omega'$, which is a minimal separator by Proposition 2.4. □

PROPOSITION 3.9. *Let Ω be a potential maximal clique of G. Then Ω is a clique in the graph $G_{\Delta_G(\Omega)}$.*

Proof. Let H be a minimal triangulation of G such that Ω is a maximal clique of H. Notice that H exists by definition of a potential maximal clique. By Theorem 2.9, $H = G_{\Delta_H}$, so for any edge $\{x, y\} \in E(H) - E(G)$, there is a minimal separator of H containing both x and y. Now let $\{x, y\}$ be an edge of $H[\Omega]$; we want to prove that $\{x, y\}$ is also an edge of $G_{\Delta_G(\Omega)}[\Omega]$. If $\{x, y\} \in E(G)$, the assertion is clearly true. Otherwise, let S be a minimal separator of H such that $x, y \in S$. By Lemma 3.8, there is a minimal separator T of H contained in Ω and containing x and y. We deduce that $\{x, y\}$ is also an edge of $G_{\Delta_G(\Omega)}$. □

We can give now a characterization of the potential maximal cliques Ω of a graph using the minimal separators of $\Delta_G(\Omega)$.

THEOREM 3.10. *Let Ω be a set of vertices of G and suppose that $\Delta_G(\Omega)$ has a maximum element S, i.e., every T in $\Delta_G(\Omega)$ is included in S. Then Ω is a potential maximal clique if and only if Ω is some block (S, C) and $G_{\Delta_G(\Omega)}[\Omega]$ is a clique.*

Proof. "⇒." Let H be a minimal triangulation of G such that Ω is a maximal clique of H. By Proposition 3.7, $\Delta_H(\Omega) = \Delta_G(\Omega)$, so S is an element of $\Delta_H(\Omega)$, maximum by inclusion. According to Theorem 3.4, Ω is a block (S, C) of S in H. Since the blocks of S are the same in H and in G, (S, C) is also a block in the graph G.

By Proposition 3.9, Ω is a clique in the graph $G_{\Delta_G(\Omega)}$. Notice that $G_{\Delta_G(\Omega)}$ is identical to G_S.

"⇐." Notice that the separators of $\Delta_G(\Omega)$ are pairwise parallel. Indeed, let H be a minimal triangulation of G such that $S \in \Delta_H$. Then each $T \in \Delta_G(\Omega)$ is a clique in H because $T \subseteq S$. Consequently $\Delta_G(\Omega) \subseteq \Delta_H$, so by Theorem 2.9, the elements of $\Delta_G(\Omega)$ are pairwise parallel in G.

We prove that $S \cup C$ is a maximal clique of H. Let Ω' be a clique of H including $S \cup C$; Ω' must be in some block associated with S in H (Lemma 2.8), and the only choice is $\Omega \subseteq (S, C)$. We conclude that Ω is a maximal clique of the minimal triangulation H of G, and therefore Ω is a potential maximal clique of G. □

THEOREM 3.11. *Let Ω be a set of vertices of G and suppose that $\Delta_G(\Omega)$ ordered by inclusion has no greatest element. Then Ω is a potential maximal clique if and only if $\Omega = P(\Delta_G(\Omega))$ and $G_{\Delta_G(\Omega)}[\Omega]$ is a clique.*

Proof. The proof is very similar to the one of the previous theorem.

"⇒." We consider a minimal triangulation H of G such that Ω is a maximal clique of H. According to Theorem 3.4, $\Omega = P(\Delta_H(\Omega))$ in H. By Proposition 3.7, $\Delta_H(\Omega) = \Delta_G(\Omega)$ and the minimal separators of $\Delta_H(\Omega)$ induce the same connected components in G and in H. Consequently, $P(\Delta_H(\Omega))$ is the same as $P(\Delta_G(\Omega))$ in G, so $\Omega = P(\Delta_G(\Omega))$ in the graph G.

By Proposition 3.9, Ω is a clique in $G_{\Delta_G(\Omega)}$.

"⇐." Since $P(\Delta_G(\Omega))$ exists, the minimal separators of $\Delta_G(\Omega)$ are pairwise parallel in G. As in the previous theorem, we prove that Ω is a maximal clique in any minimal triangulation $H = G_\Gamma$ of G with $\Delta_G(\Omega) \subseteq \Gamma$.

Since Ω is a clique in $G_{\Delta_G(\Omega)}$, Ω is also a clique in H. Consider a maximal clique Ω' of H containing Ω. Let x be a vertex of Ω'. For any $S \in \Delta_H(\Omega)$, x must be in the block $(S, C_\Omega(S))$ of H containing Ω. Therefore $x \in P(\Delta_H(\Omega))$ in the graph H. However, $\Delta_H(\Omega) = \Delta_G(\Omega)$ by Proposition 3.7, and the piece between these separators is the same in H and in G. It follows that $x \in P(\Delta_G(\Omega)) = \Omega$, so Ω is a maximal clique of H. □

Notice that Theorems 3.10 and 3.11 lead to an algorithm that, given a graph G, its minimal separators Δ_G, and a set of vertices K, verifies in polynomial time if K is a potential maximal clique of G.

3.2. A simpler characterization of potential maximal cliques. We are going to give a strong characterization of potential maximal cliques here, which does not use minimal separators. We start with some easy observations, following directly from the previous results.

COROLLARY 3.12. *Let Ω be a potential maximal clique of G and let $S \in \Delta_G(\Omega)$. Then S is strictly contained in Ω and $\Omega - S$ is in a full connected component associated with S.*

Proof. Consider a minimal triangulation H of G such that Ω is a maximal clique of H. By Lemma 3.5, S is a minimal separator of H. S is an intersection of two distinct maximal cliques of H by Proposition 2.4, so S cannot be a maximal clique of H. It follows that S is strictly contained in Ω.

Now let us prove that $\Omega - S$ is in a full connected component associated with S in G. Clearly $\Omega - S$ is in a full component associated with S in H. Since the full components associated with S in G are the same as in H, we conclude that $\Omega - S$ is in a full component associated with S in G. □

COROLLARY 3.13. *Let Ω be a potential maximal clique of a graph G and let a be any vertex of $V - \Omega$. There is a minimal separator $S \subset \Omega$ that separates a and $\Omega - S$.*

Proof. If we are in the case of Theorem 3.10, $\Delta_G(\Omega)$ has a greatest element S and $\Omega = (S, C)$. Then clearly S separates any vertex $a \in V - (S, C)$ from any vertex of $C = \Omega - S$. Now suppose that we are under the conditions of Theorem 3.11, so $\Delta_G(\Omega)$ has no greatest element and $\Omega = P(\Delta_G(\Omega))$. By definition of $P(\Delta_G(\Omega))$, since $a \notin P(\Delta_G(\Omega))$, we deduce that there is some $S \in \Delta_G(\Omega)$ separating a from $P(\Delta_G(\Omega)) - S$. □

Now let K be a set of vertices of a graph G. We denote by $C_1(K), \ldots, C_p(K)$ the connected components of $G - K$. We denote by $S_i(K)$ the vertices of K adjacent to at least one vertex of $C_i(K)$. When no confusion is possible we will simply speak of C_i and S_i. If $S_i(K) = K$, we say that $C_i(K)$ is a *full component* associated with K.

LEMMA 3.14. *Let Ω be a potential maximal clique of a graph G and let $\Delta_G(\Omega)$ be the set of all minimal separators contained in Ω. Then the elements of $\Delta_G(\Omega)$ are exactly the sets $S_i(\Omega)$.*

Proof. We prove that for any i, $1 \leq i \leq p$, S_i is a minimal a, b-separator for some $a \in C_i$ and $b \in \Omega - S_i$. Corollary 3.13 tells us that there is some minimal separator $S \in \Delta_G(\Omega)$ that separates a from $\Omega - S$; recall that $\Omega - S$ is not empty. Since every vertex in S_i has a neighbor in C_i, if S does not contain a vertex $x \in S_i$, S cannot separate $x \in \Omega - S$ from a, so we get $S_i \subseteq S$. By Corollary 3.12, $\Omega - S$ is in a full component associated with S and therefore of S_i. Let b be a vertex of $\Omega - S$.

Then a and b are in different full components associated with S_i, so S_i is a minimal a,b-separator by Lemma 2.6.

We now have to prove that for any minimal separator $S \subseteq \Omega$, there is some $i, 1 \leq i \leq p$, such that $S = S_i$. We have that $\Omega - S \neq \emptyset$ and $\Omega - S$ is in some full component associated with S. Let C be another full component associated with S. Then C is a connected component of $G - \Omega$, let us say C_i. It follows that $S \subseteq S_i$. Suppose there exists a vertex $x \in S_i - S$. Then x has a neighbor in C_i, so x must be in the connected component C of $G - S$, contradicting $C = C_i$. It remains that $S = S_i$. We conclude that the separators of G included in Ω are exactly the sets S_i. □

Remark 1. Actually, each minimal separator S_i separates any vertex of C_i from any vertex of $G - (S_i, C_i)$.

We also give a "sufficient condition" to characterize the potential maximal cliques, which is somehow the dual of Lemma 3.14.

THEOREM 3.15. *Let $K \subseteq V$ be a set of vertices. We denote by $\mathcal{S}$ the set of all $S_i(K)$. K is a potential maximal clique if and only if*

1. *$G - K$ has no full components associated to K;*
2. *$G_{\mathcal{S}}[K]$ is a clique.*

Proof. We prove the "only if" part. Suppose that K is a potential maximal clique of G. By Lemma 3.14, $\mathcal{S} = \Delta_G(K)$. By Theorems 3.10 and 3.11, K is a clique in the graph $G_{\mathcal{S}}$. It remains to show that $G - K$ has no full components associated with K. Let C_i be any connected component of $G - K$. Then S_i is the neighborhood of C_i in K. Since K is a potential maximal clique and S_i is a separator contained in K, we have that S_i is strictly contained in K by Corollary 3.12. Therefore, C_i is not a full component associated with K.

We now prove the "if" part. Let us show at first that for any $i, 1 \leq i \leq p$, S_i is a minimal separator. S_i is clearly a separator and C_i is a full component associated with S_i. Let x be a vertex of $K - S_i$. We show that x belongs to a full component associated with S_i and different from C_i. We denote by C_x the connected component of $G - S_i$ containing x. For any $y \in S_i$, y must have a neighbor in C_x. This is true if x and y are adjacent in G. If x and y are not adjacent, by the second condition of the theorem, x and y belong to a same S_j. C_j being a full component associated with S_j, there is a path in G connecting x to y entirely contained in C_j except from x and y. We deduce that $C_j \subseteq C_x$. It follows that y has a neighbor in C_x since it has a neighbor in C_j. S_i is a minimal separator of G according to Lemma 2.6.

Now, given two distinct separators S_i and S_j, we have to show that they are parallel. We prove that $K - S_i$ is in a connected component of $G - S_i$. Let $x, y \in K - S_i$. If x and y are adjacent they are clearly in the same component of $G - S_i$. Otherwise, since $G_{\mathcal{S}}[K]$ is a clique, they are in a same S_k, so they are connected via C_k. Therefore S_j intersects only the component of $G - S_i$ containing $K - S_i$ and consequently $S_i \| S_j$. Therefore $\mathcal{S}$ is a set of pairwise parallel minimal separators.

We have to show that any separator of G included in K is an element of $\mathcal{S}$. Consider a minimal triangulation H of G such that all the elements of $\mathcal{S}$ are minimal separators of H. We know that K is a clique in H. Now let $U \subseteq K$ be any minimal separator of G. Notice that U must be strictly included in K, otherwise $G - K$ would have two full components associated with K in G, contradicting our choice of K. Clearly U is a clique in H, so by Lemma 3.5, it is a minimal separator of H. Since K is a clique in H, it must be included in some full block associated with U. Let (U, C) be another full block associated with U in H and consequently in G. We have that C

is a connected component of $G-U$ and U separates C and $K-U$. We deduce that C is also a connected component of $G-K$, let us say C_i. By definition of S_i, we have $U \subseteq S_i$. Suppose there exists a vertex $x \in S_i - U$; since x has a neighbor in C, the connected component C of $G-U$ would contain x contradicting $C = C_i$. Therefore we have $U = S_i$ and $U \in \mathcal{S}$.

We want to prove that K and $\mathcal{S} = \Delta_G(K)$ satisfy the conditions of Theorems 3.10 or 3.11. Remark that for any $y \in V - K$, y is in some connected component C_i of $G-K$, and the separator $S_i \in \mathcal{S}$ separates y from $K - S_i$. Now suppose that $\mathcal{S}$ has an element S, maximum by inclusion. Let (S, C) be the block associated with S containing K. By the previous remark, for any $y \in V - K$, S separates y and $K - S$, so $y \notin (S, C)$. It follows that $(S, C) = K$, so K satisfies all the conditions of Theorem 3.10. Now if $\mathcal{S}$ does not have an element maximum by inclusion, K is clearly contained in the piece between the separators of $\mathcal{S}$ in G. By the previous remark, $P_G(\mathcal{S})$ does not contain any $y \in V - K$, so $K = P_G(\mathcal{S})$ and therefore we are under the conditions of Theorem 3.11. It follows that K is a potential maximal clique of G. □

COROLLARY 3.16. *There is an algorithm that, given a graph $G = (V, E)$ and a set of vertices $K \subseteq V$, verifies if K is a potential maximal clique of G. The time complexity of the algorithm is $\mathcal{O}(n^3)$, where n is the number of vertices of G.*

Proof. The algorithm computes the connected components C_i of $G-K$ and their neighborhoods S_i. It then checks the two conditions of Theorem 3.15. Remark that computing the sets C_i, S_i and verifying that $G-K$ has no full components associated with K can be done in linear time. We can complete each set S_i in $\mathcal{O}(n^2)$ steps, and therefore computing the graph $G_{\mathcal{S}}[K]$ takes $\mathcal{O}(n^3)$ time. □

4. Triangulating blocks. In this section we prove that the potential maximal cliques of a graph are sufficient to compute its treewidth and its minimum fill-in.

Let $B = (S, C)$ be a block of the graph G. The graph $R(S, C) = G_S[S \cup C]$ is called the *realization* of the block B. The following lemma, proved in [23], gives a relation between minimal triangulation of a graph and minimal triangulations of some block realizations.

LEMMA 4.1. *Let $S \in \Delta_G$ and let $C_1, C_2, \ldots, C_p$ be the connected components of $G - S$. Suppose that H_i is a minimal triangulation of $R(S, C_i)$ for any $i, 1 \leq i \leq p$. Then the graph $H = (V, E(H))$ with $E(H) = \bigcup_{i=1}^{p} E(H_i)$ is a minimal triangulation of G.*

Conversely, let H be a minimal triangulation of G with $S \in \Delta_H$. Then $H[S \cup C]$ is a minimal triangulation of the realization $R(S, C)$ for each component C of $G - S$.

This gives an equation for computing the treewidth and the minimum fill-in of a graph (see [23] for a proof).

COROLLARY 4.2. *Let G be a noncomplete graph. Then*

$$\mathrm{tw}(G) = \min_{S \in \Delta_G} \max_{C \in \mathcal{C}(S)} \mathrm{tw}(R(S, C)),$$

$$\mathrm{mfi}(G) = \min_{S \in \Delta_G} (\mathrm{fill}(S) + \sum_{C \in \mathcal{C}(S)} \mathrm{mfi}(R(S, C))),$$

where $\mathrm{fill}(S)$ *is the number of nonedges of S.*

We give a version of Lemma 4.1 using potential maximal cliques instead of minimal separators. If Ω is a potential maximal clique of a graph G, we denote as usual

by $C_i, 1 \leq i \leq p$, the connected components of $G - \Omega$ and by $S_i, 1 \leq i \leq p$, the neighborhood of each C_i. We say that the blocks (S_i, C_i) are the *blocks associated with* Ω in G.

THEOREM 4.3. *Let H be a minimal triangulation of G and let Ω be a maximal clique of H. Then for each block (S_i, C_i) associated with Ω in G, the graph $H_i = H[S_i \cup C_i]$ is a minimal triangulation of the realization $R(S_i, C_i)$.*

Conversely, let Ω be a potential maximal clique of G. For each block (S_i, C_i) associated with Ω in G, let H_i be a minimal triangulation of $R(S_i, C_i)$. Then $H = (V, E(H))$ with $E(H) = \bigcup_{i=1}^{p} E(H_i) \cup \{\{x, y\} | x, y \in \Omega\}$ is a minimal triangulation of G.

Proof. For proving the first part, notice that by Theorem 3.15, (S_i, C_i) are blocks of G and of H. Then by Lemma 4.1, $H[S_i \cup C_i]$ are minimal triangulations of $R(S_i, C_i)$.

We now prove the second part. Let us prove that H is a triangulated graph. Suppose that H has a chordless cycle of length at least four. Since Ω is a clique, the cycle is not contained in Ω, so it has a vertex a in some component C_i. Since $H[S_i \cup C_i]$ is chordal, the cycle is not contained in (S_i, C_i). Then at least two nonconsecutive points of the cycle, say, b and c, are in S_i. Therefore the cycle has a chord, namely, the edge $\{b, c\}$.

Now let us prove that H is a minimal triangulation of G. Let $e = \{x, y\}$ be an edge of $H - G$. Suppose at first that x and y are not both contained in Ω. Then x and y are in some H_i. Since e is not in Ω, e is not in S_i. It remains that e is an edge of $H_i - R(S_i, C_i)$. By Lemma 2.1, $H_i - e$ is not chordal, so $H - e$ is not chordal. Now suppose that $x, y \in \Omega$. Then x, y must be in some S_i, since $H[\Omega] = G_{\Delta_G(\Omega)}[\Omega]$ and $e \in H - G$. Consider two full components of $H - S_i$ associated with S_i and a shortest path from x to y in each of them. The two paths form a cycle of length at least four, which is a chordless cycle of $H - e$.

By Lemma 2.1, H is a minimal triangulation of G. □

We want to give a characterization of the minimal triangulations of a realization $R(S, C)$ using the potential maximal cliques Ω with $S \subset \Omega$ and $\Omega \subseteq (S, C)$ and the minimal triangulations of the realizations of some blocks (S_i, C_i), strictly included in (S, C). This will express the treewidth and the minimum fill-in of a realization from the treewidth (respectively, the minimum fill-in) of realizations of smaller blocks, and we will compute the two parameters by dynamic programming on blocks.

The minimal triangulations of the realizations of nonfull blocks are easily reducible to the case of full blocks. For the following lemma, see, for example, [8].

LEMMA 4.4. *Let (S, C) be a nonfull block of G and let S^* be the set of vertices of S having some neighbor in C. Then (S^*, C) is a full block of G and a super graph H of $R(S, C)$ is a minimal triangulation of $R(S, C)$ if and only if $H[S^* \cup C]$ is a minimal triangulation of $R(S^*, C)$.*

We conclude in the following corollary.

COROLLARY 4.5. *Let (S, C) be a nonfull block of G and let S^* be the vertices of S adjacent in G to at least one vertex of C. Then*

$$\mathrm{tw}(R(S, C)) = \max(|S| - 1, \mathrm{tw}(R(S^*, C))),$$

$$\mathrm{mfi}(R(S, C)) = \mathrm{mfi}(R(S^*, C)).$$

It remains to express the treewidth and the minimum fill-in of realizations of full blocks from realizations of smaller blocks.

LEMMA 4.6. *Let $R(S,C)$ be the realization of some full block (S,C) and let $H(S,C)$ be a minimal triangulation of $R(S,C)$. Then there is a maximal clique Ω of $H(S,C)$ such that $S \subset \Omega$ and Ω is a potential maximal clique of G.*

Proof. S clearly is a clique in $H(S,C)$. Consider a maximal clique Ω of $H(S,C)$ containing S. Let us show that S is strictly contained in Ω. C is a full component associated with S in G, so also in $H(S,C)$. If $S = \Omega$, then C is a full component associated with Ω in $H(S,C)$. However, Ω is also a potential maximal clique of the chordal graph $H(S,C)$, so by Theorem 3.15, $H(S,C) - \Omega$ cannot have full components associated with Ω, which leads to a contradiction. It remains to show that Ω is a potential maximal clique of G. By Lemma 4.1, there is a minimal triangulation H of G such that $H[S \cup C] = H(S,C)$. The components associated with S in H are the same as in G. Since S separates C from $V - (C \cup S)$, Ω is a maximal clique of H, so by definition it is a potential maximal clique of G. □

Notice that we have proved that any maximal clique of $H(S,C)$ is a potential maximal clique of G and, moreover, it is a maximal clique of any minimal triangulation H with $H[S \cup C] = H(S,C)$.

By Theorem 4.3 and Lemma 4.6 we have proved the following theorem.

THEOREM 4.7. *Let (S,C) be a full block of a graph G. Then $H(S,C)$ is a minimal triangulation of $R(S,C)$ if and only if there is a potential maximal clique $\Omega \subseteq (S,C)$ of G such that $S \subset \Omega$ and $H(S,C) = (S \cup C, E(H))$ with $E(H) = \bigcup_{i=1}^{p} E(H_i) \cup \{\{x,y\} | x,y \in \Omega\}$, where (S_i, C_i) are the blocks associated with Ω in $H(S,C)$ and H_i are minimal triangulations of $R(S_i, C_i)$.*

COROLLARY 4.8. *Let (S,C) be a full block of G. Then*

$$\mathrm{tw}(R(S,C)) = \min_{S \subset \Omega \subseteq (S,C)} \max(|\Omega| - 1, \mathrm{tw}(R(S_i, C_i))),$$

$$\mathrm{mfi}(R(S,C)) = \min_{S \subset \Omega \subseteq (S,C)} \left(\mathrm{fill}(\Omega) - \mathrm{fill}(S) + \sum \mathrm{mfi}(R(S_i, C_i)) \right),$$

where (S_i, C_i) are the blocks associated with Ω in $R(S,C)$.

We give in Table 4.1 a sketch of the algorithm that, given a graph and the list of all its potential maximal cliques, computes, by standard dynamic programming techniques, the treewidth and the minimum fill-in of the graph. The first part of the algorithm computes the treewidth and the minimum fill-in of the realization of each block (S,C) of G. For computing the treewidth and the minimum fill-in of a realization $R(S,C)$, all we need are the potential maximal cliques Ω such that $S \subset \Omega \subseteq (S,C)$ and the treewidth and the minimum fill-in of the realizations of some blocks strictly contained in (S,C) (see Corollaries 4.5 and 4.8). The treewidth and the minimum fill-in of the input graph is computed, as in Corollary 4.2, using the treewidth and the minimum fill-in of the realizations of its blocks.

THEOREM 4.9. *Given a graph $G = (V,E)$ and the set Π_G of all its potential maximal cliques, we can compute the treewidth and the minimum fill-in of G in $\mathcal{O}(n^2 |\Delta_G| \times |\Pi_G|)$ time.*

Proof. The whole algorithm can be implemented in $\mathcal{O}(bpn + re)$ time, where n and e are the number of vertices, respectively, of edges of G and r, b, and p are the number of minimal separators (respectively, blocks and potential maximal cliques) of G. We make some observations on the relations between r, p, and b. Each minimal separator S induces in $G - S$ at most n connected components, so the number b of blocks is at most rn. The minimal separators contained in a potential maximal

clique Ω correspond to the neighborhoods of the connected components of $G - \Omega$, so Ω contains at most n minimal separators. Thus, $r \leq pn$. The algorithm is clearly polynomial in the size of the input, i.e., in n and p. □

5. Application to some classes of graphs. Several classes of graphs have "few" minimal separators, in the sense that the number of minimal separators of such graphs is polynomially bounded in the size of the graph. Moreover, an algorithm given in [21] computes all the minimal separators of these graphs.

For some of these classes of graphs we also have algorithms computing the treewidth and the minimum fill-in in polynomial time, using the minimal separators (cf. [20, 9, 3, 32, 24, 15, 26]). Different proofs have been given for each of these algorithms. We have remarked that, for computing the treewidth or the minimum fill-in of a graph, all these algorithms compute, in an implicit manner, all the potential maximal cliques of the input graph. Therefore, our approach unifies the cited algorithms (see also [4]).

We will also show how to compute in polynomial time the potential maximal cliques for a new class of graphs, namely, the weakly triangulated graphs (see also [5]).

5.1. AT-free graphs. We say that three vertices (x, y, z) of a graph form an *asteroidal triple* of a graph G if they are pairwise nonadjacent and between every two of them there exists a path avoiding the neighborhood of the third. A graph is *AT-free*

if it has no asteroidal triple. The notion of the asteroidal triple was introduced by Lekkerkerker and Boland [25] in relation to interval graphs.

Notice that the treewidth and the minimum fill-in problems are NP-complete even restricted to the class of cobipartite graphs [1, 34], which is contained in the class of AT-free graphs. It was shown in [23, 26] that the treewidth and the minimum fill-in are tractable in polynomial time for AT-free graphs with a polynomial number of minimal separators. Among the AT-free graphs with few minimal separators, we find the *cocomparability graphs* of bounded dimension and in particular the *permutation graphs* or the *d-trapezoid graphs*, which have a polynomial number of separators for any fixed d.

The following proposition gives an easy way to compute the potential maximal cliques of an AT-free graph G in a time which is polynomial in the size of G and in the number of its minimal separators.

PROPOSITION 5.1. *Let Ω be a potential maximal clique of an AT-free graph G. Then $\Delta_G(\Omega)$ has at most two elements maximal by inclusion.*

Proof. Recall that we denote by $C_1, C_2, \dots C_p$ the connected components of $G - \Omega$ and by S_i the neighborhood of C_i in Ω. By Theorem 3.15, the elements of $\Delta_G(\Omega)$ are exactly the sets of vertices $S_1, \dots, S_p$. Suppose that $\Delta_G(\Omega)$ has three elements maximal by inclusion, say, S_1, S_2, S_3. Let x_1, x_2, and x_3 be three vertices of C_1, C_2, and C_3, respectively. We show that (x_1, x_2, x_3) is an asteroidal triple. Let y be a vertex of $S_2 - S_1$. There is a path from y to x_2 that avoids S_1, so y and x_2 are in the same connected component of $G - S_1$. Since Ω is contained in a block $(S_1, C(S_1))$ associated with S_1, we deduce that y and x_2 are in the connected component $C(S_1)$ of $G - S_1$. For the same reasons, x_3 is in the same connected component $C(S_1)$ of $G - S_1$. Therefore, there is a path from x_2 to x_3 in $C(S_1)$, which clearly avoids the neighborhood of x_1. By symmetry, x_1, x_2, and x_3 form an asteroidal triple. □

COROLLARY 5.2. *An AT-free graph G has $\mathcal{O}(|\Delta_G|^2 + n|\Delta_G|)$ potential maximal cliques, computable in a time polynomial in the number n of vertices of G and the number $|\Delta_G|$ of its minimal separators.*

Proof. In an AT-free graph, we have two types of potential maximal cliques: the potential maximal cliques Ω such that $\Delta_G(\Omega)$ has two distinct elements maximal by inclusion, and the potential maximal cliques such that $\Delta_G(\Omega)$ has one element maximum by inclusion.

Let us prove that if Ω is a potential maximal clique of G and S_1, S_2 are two distinct elements maximal by inclusion in $\Delta_G(\Omega)$, then $\Omega = P(S_1, S_2)$. For any $T \in \Delta_G(\Omega)$, let $(T, C(T))$ be the unique block of T containing Ω. If $T \subseteq S_1$, then $(T, C(T))$ contains the block $(S_1, C(S_1))$. It follows that $\cap_{T \in \Delta_G(\Omega)}(T, C(T) = (S_1, C(S_1)) \cap (S_2, C(S_2))$, so $P(\Delta_G(\Omega)) = P(S_1, S_2)$. Thus, we have $\mathcal{O}(|\Delta_G|^2)$ potential maximal cliques Ω with two maximal elements in $\Delta_G(\Omega)$. Clearly, all these potential maximal cliques can be computed in polynomial time.

If Ω is a potential maximal clique and S is the unique element maximum by inclusion in $\Delta_G(\Omega)$, then by Theorem 3.10 we have $\Omega = (S, C)$, where (S, C) is a full block associated with S. Consequently, we have at most $n|\Delta_G|$ potential maximal cliques of this type, computable in polynomial time. □

Remark 2. One can prove that an AT-free graph has at most $\mathcal{O}(n^2|\Delta_G|)$ potential maximal cliques. This result follows directly from [26].

The notion of asteroidal triple can be extended to more than three vertices. We say that a set of vertices A is an *asteroidal set* if for any $a \in A$, $A - \{a\}$ is contained in a same connected component of $G - N(a)$, where $N(a)$ is the neighborhood of a

in G. In particular, an asteroidal triple is an asteroidal set of cardinality 3. The *asteroidal number* of a graph is $\mathrm{na}(G) = \max\{|A|,\ A \text{ is an asteroidal set of } G\}$. In [7] it is proved that the treewidth and the minimum fill-in are polynomially tractable for graphs with a bounded asteroidal number and with few minimal separators. As for the AT-free graphs, a potential maximal clique of G has at most $\mathrm{na}(G)$ maximal elements, so a graph has at most $\mathcal{O}(|\Delta_G|^{\mathrm{na}(G)} + n|\Delta_G|)$ potential maximal cliques. We deduce as in Corollary 5.2 that if $\mathrm{na}(G)$ is bounded by a constant c and if G has few minimal separators, then all the potential maximal cliques of G can be listed in polynomial time.

5.2. Circle and circular arc graphs. *Circle* and *circular arc graphs* are obtained from an intersection model. A graph $G = (V, E)$ is a *circle graph* if and only if we can associate each vertex of the graph with a chord of a circle such that two vertices are adjacent in the graph if and only if the corresponding chords cross. The circle and its chords are the *circle model* $D(G)$ of the graph. In the same manner, a graph G is a *circular arc graph* if each vertex can be associated with an arc of a circle and two vertices are adjacent if and only if the corresponding arcs overlap. The circle and its circular arcs are said to be the *circular arc model* $D(G)$ of the graph.

Without loss of generality, we can assume that no two chords of the circle model (respectively, no two arcs of the circular arc model) share an endpoint. For both circle and circular arc graphs, there are recognition algorithms working in $\mathcal{O}(n^2)$ time, which also compute the circle (respectively, the circular arc model of a graph) (see [30, 11]). Therefore, we will assume that an intersection model (i.e., a circle (respectively, a circular-arc model)) of the input graph is always given.

The treewidth and the minimum fill-in problems have been solved for the circle and the circular arc graphs in $\mathcal{O}(n^3)$ time [16, 32, 24]. We show here that all the potential maximal cliques of a circle or a circular arc graph can be listed in polynomial time. We will use the results of [24] in order to prove this assertion. Actually, the cited algorithms compute, in an implicit manner, all the potential maximal cliques of the input graph.

We will present here in detail only the circle graphs. The results can be extended to circular arc graphs using the same techniques.

For these "geometrical" classes of graphs, the minimal separators can be modeled by *scanlines*. In the circle model of a circle graph, we add a *scanpoint* between every two consecutive endpoints of the chords. The scanlines are the straight line segments between two scanpoints.

Let G be a circle graph and $D(G)$ be a circle model of G. For each scanline s, we denote by $S(s)$ the set of all vertices of G corresponding to the chords of $D(G)$ that intersect s.

Kloks [16] proved the following proposition.

PROPOSITION 5.3. *Let G be a circle graph and let $D(G)$ be a circle model of G. For any minimal separator S of G, there is a scanline s in $D(G)$ such that $S = S(s)$.*

Since the circle model has n chords, we have $2n$ scanpoints and consequently $n(2n-1)$ scanlines. Therefore, a circle graph has $\mathcal{O}(n^2)$ minimal separators.

Kloks, Kratsch, and Wong [24] gave a characterization of minimal triangulations of a circle graph G using scanlines of the circle model. The scanpoints of $D(G)$ form a convex polygon P. A *planar triangulation* of P is a set T of noncrossing diagonals of P dividing the interior of P in triangles. Notice that if P has n vertices, then T has $n-3$ diagonals dividing the interior of P in $n-2$ triangles.

If T is a planar triangulation of P, the graph $H(T)$ is defined as the graph with

the same vertex set as G, and two vertices x and y are adjacent in $H(T)$ if and only if the chords corresponding to x and y in $D(G)$ intersect a same triangle of T. Clearly, $H(T)$ is a supergraph of G. Moreover, it is proved in [24] that $H(T)$ is a triangulation of G. However, we will use only the following theorem of [24].

THEOREM 5.4. *Let G be a circle graph, $D(G)$ a circle model of G, and P its polygon of scanpoints. Then for any minimal triangulation H of G, there is a planar triangulation T of P such that $H = H(T)$.*

All we have to do is to notice how maximal cliques are formed in $H(T)$. Let Q be a triangle of a planar triangulation T of P. We denote by $S(Q)$ the set of all vertices of G for which the corresponding chords intersect Q.

PROPOSITION 5.5. *Let G be a circle graph, $D(G)$ a circle model of G, and T a planar triangulation of its polygon P of scanpoints. Then for any maximal clique Ω of $H(T)$, there is a triangle Q of T such that $\Omega = S(Q)$.*

Proof. Clearly, for any triangle Q of T, the set of vertices $S(Q)$ induces a clique in $H(T)$.

We want to prove that all the chords corresponding to vertices of Ω intersect a same triangle Q. Let s be any diagonal of T and let x, y be two adjacent vertices of $H(T)$. The scanline s induces two regions $\mathcal{R}_1$ and $\mathcal{R}_2$ in the polygon P. Since x and y are adjacent in $H(T)$, the chords of $D(G)$ corresponding to x (respectively, y) cannot be in different regions induced by s. Consequently, all the chords corresponding to vertices of Ω intersect a same region induced by s, say, $\mathcal{R}_1$. If $\mathcal{R}_1$ is a triangle, we have found our triangle Q. Otherwise, let s' be a diagonal of T contained in $\mathcal{R}_1$. Then s' divides $\mathcal{R}_1$ in two smaller regions $\mathcal{R}'_1$ and $\mathcal{R}'_2$. For the same reasons as previously, the chords corresponding to vertices of Ω intersect a same subregion, say, $\mathcal{R}'_1$. We can iterate the process until finding a triangle Q such that $\Omega \subseteq S(Q)$.

We have that $\Omega \subseteq S(Q)$, $S(Q)$ is a clique in $H(T)$, and Q is a maximal clique of $H(T)$. It follows that $\Omega = S(Q)$. □

COROLLARY 5.6. *A circle graph has $\mathcal{O}(n^3)$ potential maximal cliques computable in polynomial time.*

Proof. Let Ω be a potential maximal clique of G and H a minimal triangulation of G such that Ω is a maximal clique of H. By Theorem 5.4, there is a planar triangulation T of the polygon of scanpoints such that $H = H(T)$. By Proposition 5.5, there is a triangle Q of scanlines such that $\Omega = S(Q)$.

Consequently, for any potential maximal clique Ω there is a triangle of scanpoints Q such that $\Omega = S(Q)$. Since we have at most $\mathcal{O}(n^3)$ triangle of scanpoints, G has at most $\mathcal{O}(n^3)$ potential maximal cliques.

For listing all the potential maximal cliques of G, it is sufficient to list all the triangles of scanpoints Q, to compute $S(Q)$, and to check if $S(Q)$ is a potential maximal clique of G. This enumeration can be done in polynomial time. □

Therefore for circle graphs, all the potential maximal cliques can be listed in polynomial time. Notice that the algorithms of [16, 24] that compute the treewidth and the minimum fill-in of circle graphs are looking for triangulations of type $H(T)$ of G. In particular, all the minimal triangulations of G are of this type. Moreover, these algorithms compute all the sets $S(Q)$ for all the triangles of scanlines. Therefore they implicitly use all the potential maximal cliques of the input graph. The fact that they are using triangulations of type $H(T)$ of G instead of using only minimal triangulations leads to an efficient algorithm in time $\mathcal{O}(n^3)$.

For characterizing the potential maximal cliques of a circle graph, we have used the global characterization of its minimal triangulations given by Theorem 5.4. One

proves directly that, under certain conditions, two minimal separators of a circle graph are parallel if and only if the corresponding scanlines do not cross (they may have a common endpoint). Using Theorem 3.15 and the same arguments as for the proof of Proposition 5.5, we can prove that, if Ω is a potential maximal clique of G, then the scanlines corresponding to the minimal separators of $\Delta_G(\Omega)$ determine a region $\mathcal{R}$ such that $\Omega = S(\mathcal{R})$ (the chords corresponding to vertices of Ω are exactly the chords intersecting $\mathcal{R}$). One can deduce directly the Proposition 5.5 (see [33]).

For the class of circular arc graphs, the results are very similar. Let G be a circular arc graph and $D(G)$ be a circular arc model of G. For a point p of the circle, we denote by $S(p)$ the vertices of G for which the corresponding arcs contain p. We place a point p between every two consecutive endpoints u and v of the arcs of $D(G)$. We say that p is a scanpoint if $|S(p)| < \min(|S(u)|, |S(v)|)$. Once again, a straight line s between two scanpoints is called a scanline. If p_1 and p_2 are the scanpoints determining the scanline s, we define $S(s) = S(p_1) \cup S(p_2)$, i.e., the vertices of G such that the corresponding arcs contain a point of the scanline. If Q is a triangle of scanpoints of vertices p_1, p_2, p_3, then we put $S(Q) = S(p_1) \cup S(p_2) \cup S(p_3)$. We can also define a triangulation T of the polygon P of scanpoints and the supergraph graph $H(T)$ of G in which two vertices x and y are adjacent if they are adjacent in G or if there is a scanline $s \in T$ with $x, y \in S(s)$.

Kloks, Kratsch, and Wong [24] proved the following results.

THEOREM 5.7. *Let G be a circular arc graph, $D(G)$ a circular arc model of G, and P its polygon of scanpoints. Then for any minimal triangulation H of G there is a planar triangulation T of P such that $H = H(T)$.*

We can give the same characterization of the potential maximal cliques as in the case of circle graph. The proof is almost the same as for Proposition 5.5, so we omit it.

PROPOSITION 5.8. *Let G be a circular arc graph, $D(G)$ a circular arc model of G, and T a planar triangulation of its polygon of scanpoints P. Then for any maximal clique Ω of $H(T)$, there is a triangle of scanpoints Q of T such that $\Omega = S(Q)$.*

Clearly, circular arc graphs have a polynomial number of potential maximal cliques and we can list these potential maximal cliques in polynomial time.

COROLLARY 5.9. *A circular arc graph has $\mathcal{O}(n^3)$ potential maximal cliques computable in polynomial time.*

Once again, the algorithms of [32, 24] compute all the sets of type $S(Q)$, so in particular they use the potential maximal cliques of the input graph.

5.3. Weakly triangulated graphs. We now consider two nonadjacent vertices x, y of an arbitrary graph G. Let G' be the graph obtained from G by adding the edge $\{x, y\}$. We will show in this section that the potential maximal cliques of G can be computed from the minimal separators of G and the potential maximal cliques of G'. We will use this technique to compute all the potential maximal cliques of any weakly triangulated graph.

Let Ω once again be a potential maximal clique of G. Let $C_1, \ldots, C_p$ be the connected components of $G - \Omega$ and let S_i be the set of vertices of Ω having at least a neighbor in C_i. We want to describe the behavior of Ω and $\mathcal{S}$ in the graph G'. We deduce the following lemma directly from Theorem 3.15.

LEMMA 5.10.

1. *If $x, y \in \Omega$ or there is an $i, 1 \leq i \leq p$, such that $x, y \in C_i$ or $x \in S_i$ and $y \in C_i$, then Ω is a potential maximal clique of G' and the elements of $\Delta_{G'}(\Omega)$ are $S_1, S_2, \ldots, S_p$.*

2. *If $y \in C_1$, $x \in \Omega - S_1$, and $\Omega \neq S_1 \cup \{x\}$, then Ω is a potential maximal clique of G' and the elements of $\Delta_{G'}(\Omega)$ are $S_1 \cup \{x\}, S_2, \ldots, S_p$.*
3. *If $x \in C_1$, $y \in C_2$, and $\Omega \neq S_1 \cup S_2$, then Ω is a potential maximal clique of G' and the elements of $\Delta_{G'}(\Omega)$ are $S_1 \cup S_2, S_3, \ldots, S_p$.*

Proof. By Theorem 3.15, $G - \Omega$ has no full components associated with Ω and $G_{\Delta_G(\Omega)}[\Omega]$ is a clique. Notice that, by Lemma 3.14, the elements of $\Delta_G(\Omega) = \mathcal{S}(\Omega)$ are exactly the sets $S_1, \ldots, S_p$.

If we are in the first case of the lemma, then the connected components of $G' - \Omega$ are exactly the same in $G - \Omega$, and their neighborhoods in G' are also the same. If we denote by $\mathcal{S}'(\Omega)$ the neighborhoods of the connected components of $G' - \Omega$, then $\mathcal{S}'(\Omega)$ consists of $S_1, S_2, \ldots, S_p$. Clearly, $G' - \Omega$ has no full components associated with Ω and $G_{\mathcal{S}'(\Omega)}[\Omega]$ is a clique. By Theorem 3.15, Ω is a potential maximal clique of G'.

If we are in the second case, the connected components of $G' - \Omega$ are $C_1, C_2 \ldots, C_p$ and their neighborhoods in G' are $S_1 \cup \{x\}, S_2, \ldots, S_p$. If $\Omega \neq S_1 \cup \{x\}$, then $G' - \Omega$ has no full components associated with Ω, and once again Ω is a potential maximal clique of G', by Theorem 3.15.

In the third case, the connected components of $G' - \Omega$ are $C_1 \cup C_2, C_3, \ldots, C_p$, and their neighborhoods are $S_1 \cup S_2, S_3, \ldots, S_p$, respectively. The fact that $\Omega \neq S_1 \cup S_2$ ensures that $G' - \Omega$ has no full components associated with Ω. Clearly $G_{\mathcal{S}'(\Omega)}[\Omega]$ is a clique, so by Theorem 3.15, Ω is a potential maximal clique of G'. □

The following theorem follows directly.

THEOREM 5.11. *Let Ω be a potential maximal clique of G. Let x, y be two nonadjacent vertices of G and let $G' = G \cup \{x, y\}$. Two cases are possible.*

1. *Ω can be written as $S_1 \cup \{x\}$, $S_1 \cup \{y\}$ or $S_1 \cup S_2$, where S_1, S_2 are minimal x, y-separators of G.*
2. *Ω is a potential maximal clique of G'.*

The weakly triangulated graphs were introduced in [13]. A graph G is called *weakly triangulated* if neither G nor its complement $\overline{G}$ have an induced cycle with strictly more than four vertices. This class contains the chordal graphs, the chordal bipartite graphs, and the distance hereditary graphs.

We denote by $N(x)$ the neighbors of the vertex x. We say that two vertices x, y of a graph G form a *two-pair* if their common neighbors $N(x) \cap N(y)$ form an x, y-separator. The following theorem was proved in [14].

THEOREM 5.12. *If G is a weakly triangulated graph, then every induced subgraph of G that is not a clique contains a two-pair.*

Spinrad and Sritharan give in [31] an algorithm recognizing the weakly triangulated graphs based on the following theorem.

THEOREM 5.13. *Let $G = (V, E)$ be a graph and let $\{x, y\}$ be a two-pair of G. Let $G' = (V, E')$ be the graph obtained from G by adding the edge $\{x, y\}$. Then G is weakly triangulated if and only if G' is weakly triangulated.*

Notice that a clique is a weakly triangulated graph. The recognition algorithm considers an input graph G and, while G has a two-pair $\{x, y\}$, it adds the edge between x and y to G. At the end of the loop, either G becomes a clique, in which case the initial graph is weakly triangulated by Theorem 5.13, or G is not a clique and it has no two-pair, in which case the input graph cannot be weakly triangulated by Theorems 5.12 and 5.13.

We denote by $\overline{e}$ the number of edges of $\overline{G}$. Now let $G = (V, E)$ be a weakly triangulated graph and let $f_1 = \{x_1, y_1\}, \ldots, f_{\overline{e}} = \{x_{\overline{e}}, y_{\overline{e}}\}$ be the edges added to

G by the recognition algorithm in this order. In particular, $(V, E \cup \{f_1, \ldots, f_{\overline{e}}\})$ is a clique. We denote by G_i the graph $(V, E \cup \{f_1, f_2, \ldots, f_i\})$ with $0 \leq i \leq \overline{e}$ (so $G_0 = G$ and $G_{\overline{e}}$ is a clique). We will describe the minimal separators (respectively, the potential maximal cliques of G_i) using the minimal separators (respectively, the potential maximal cliques of G_{i+1}) for any $i < \overline{e}$.

It is known that a weakly triangulated graph has at most $\overline{e}$ minimal separators (Kloks [17]). We give here the proof of this result because we will reuse the same technique for counting and listing the potential maximal cliques of a weakly triangulated graph.

THEOREM 5.14. *Let G be a noncomplete weakly triangulated graph and let $\{x, y\}$ be a two-pair of G. Let S_{xy} be the set $N(x) \cap N(y)$. Consider the graph G' obtained from G by adding the edge $\{x, y\}$. Then $\Delta_G \subseteq \Delta_{G'} \cup \{S_{xy}\}$.*

Proof. Notice that S_{xy} is a minimal x, y-separator of G by definition of a two-pair.

Let S be any minimal separator of G.

Suppose at first that S separates x and y, and let C_x, C_y be the connected components of $G - S$ containing x (respectively, y). If both C_x and C_y are full components associated with S, then S is a minimal x, y-separator by Lemma 2.6. Notice that $N(x) \subset C_x \cup S$ and $N(y) \subset C_y \cup S$. We deduce that $N(x) \cap N(y) \subseteq S$, and since $N(x) \cap N(y) = S_{xy}$ is a x, y-separator in G by definition of a two-pair, it follows that $S = S_{xy}$. Now suppose that C_x and C_y are not both full components of S in G. The connected components of $G' - S$ are the same as in $G - S$, except for C_x and C_y which form a unique component $C_x \cup C_y$ in $G' - S$. If $G - S$ has two full components D and E associated with S, both different from C_x and C_y, then D and E are full components associated with S in G', so S is a minimal separator of G' by Lemma 2.6. Otherwise, $G - S$ has a unique full component D associated with S and different from C_x and C_y, so at least one of C_x, C_y must be a full component associated with S in G. Therefore, D and $C_x \cup C_y$ are full components associated with S in G', so S is a minimal separator of G' by Lemma 2.6.

If S does not separate x and y, the connected components of $G' - S$ are the same as in $G - S$, so $G' - S$ has two full components associated with S. Consequently, S is a minimal separator of G'. □

Therefore for any $i < \overline{e}$, the graph G_i has at most one more minimal separator than G_{i+1}. We deduce the following corollary.

COROLLARY 5.15. *A weakly triangulated graph G has at most $\overline{e}$ minimal separators, where $\overline{e}$ is the number of edges of $\overline{G}$.*

We can conclude directly from Theorem 5.11 and Lemma 5.15 that all the potential maximal cliques of a weakly triangulated graph can be computed in polynomial time. However, we can refine the results of the third case of Lemma 5.10.

LEMMA 5.16. *Let G be a graph, let x, y be a two-pair of G, and let Ω be a potential maximal clique of G such that x and y are in different connected components of $G - \Omega$. Then Ω is a potential maximal clique of $G' = G \cup \{x, y\}$.*

Proof. We use the fact that if x, y is a two-pair of a graph G, then $S_{xy} = N(x) \cap N(y)$ is the only x, y-minimal separator of G. Let C_1 and C_2 be the connected components of $G - \Omega$ containing x (respectively, y). As before, let S_1 and S_2 be the sets of vertices of Ω having a neighbor in C_1 (respectively, C_2). We want to prove that both S_1 and S_2 contain S_{xy} and at least one of them is equal to S_{xy}. By Remark 1, S_1 separates x and y, so it must contain $N(x) \cap N(y) = S_{xy}$. The same holds for S_2. Suppose that there is some vertex $a \in S_1 - S_{xy}$ and some vertex $b \in S_2 - S_{xy}$. Since a has a neighbor in C_1, a is in the connected component $G - S_{xy}$ containing x. b is

also in the connected component of $G - S_{xy}$ containing y. Then Ω intersects different connected components of $G - S_{xy}$, which is, by Corollary 3.12, a contradiction to the fact that $S_{xy} \subset \Omega$. It remains that $S_1 = S_{xy}$ or $S_2 = S_{xy}$. Therefore, $S_1 \cup S_2$ is equal to S_1 or S_2, and consequently $\Omega \neq S_1 \cup S_2$ by Corollary 3.12. By the third part of Lemma 5.10, Ω will be a potential maximal clique of G'. □

We deduce from Theorem 5.11 and Lemma 5.16 the following corollary.

COROLLARY 5.17. *Let Ω be a potential maximal clique of G. Let x, y be a two-pair of G and let $G' = G \cup \{xy\}$. Let $S_{xy} = N(x) \cap N(y)$. Two cases are possible.*

1. *Ω can be written as $S_{xy} \cup \{x\}$ or $S_{xy} \cup \{y\}$.*
2. *Ω is a potential maximal clique of G'.*

COROLLARY 5.18. *A weakly triangulated graph G has at most $2\overline{e} + 1$ potential maximal cliques.*

Proof. We consider the sequence of graphs $G_0 = G, G_1, \ldots, G_{\overline{e}}$ previously defined. Since G_{i+1} is obtained from G_i by adding an edge between a two-pair, by Corollary 5.17 the graph G_i has at most two more potential maximal cliques than G_{i+1}. Clearly $G_{\overline{e}}$, which is a clique, has a unique potential maximal clique. □

COROLLARY 5.19. *The treewidth and the minimum fill-in of weakly triangulated graphs can be computed in polynomial time.*

The complexity of computing all the potential maximal cliques is $\mathcal{O}(n^3\overline{e})$. It is sufficient to use the weakly triangulated graphs recognition algorithm of [31] to generate the two-pairs $\{x_i, y_i\}$ and the sets $S_{x_i y_i}$. This takes $\mathcal{O}(n^2\overline{e})$ time. One can check in $\mathcal{O}(n^3)$ time if a set is a potential maximal clique by Corollary 3.16. Therefore the list of all potential maximal cliques is computable in $\mathcal{O}(n^3\overline{e})$ time.

For weakly triangulated graphs, the number of minimal separators is $r = \mathcal{O}(\overline{e})$, the number of blocks is $b = \mathcal{O}(n\overline{e})$, and the number of potential maximal cliques is $p = \mathcal{O}(\overline{e})$. According to the complexity of the algorithm of Corollary 3.16, the treewidth and the minimum fill-in are computable in $\mathcal{O}(n^2\overline{e}^2 + n^3\overline{e})$ time.

6. Conclusion. The main result of this paper is that, given a graph G and the list Π_G of all its potential maximal cliques, the treewidth and the minimum fill-in of G can be determined in polynomial time in the size of G and the number $|\Pi_G|$ of its potential maximal cliques.

We did not say whether there is a connection between the number of potential maximal cliques and the number of minimal separators in a graph. We have recently proved (see [6]) that, for any graph, $|\Pi_G| = \mathcal{O}(n|\Delta_G|^2)$ and the potential maximal cliques can be computed in polynomial time in the size of the graph and the number of its minimal separators. Thus, the treewidth and the minimum fill-in are tractable in polynomial time in the size of the graph and the number of its minimal separators.

THE ACCOMMODATING FUNCTION: A GENERALIZATION OF THE COMPETITIVE RATIO*

JOAN BOYAR†, KIM S. LARSEN†, AND MORTEN N. NIELSEN†

Abstract. A new measure, the *accommodating function*, for the quality of on-line algorithms is presented. The accommodating function, which is a generalization of both the competitive ratio and the competitive ratio on accommodating sequences, measures the quality of an on-line algorithm as a function of the resources that would be sufficient for an optimal off-line algorithm to fully grant all requests. More precisely, if we have some amount of resources n, the function value at α is the usual ratio (still on some fixed amount of resources n), except that input sequences are restricted to those where the optimal off-line algorithm will not obtain a better result by having more than the amount αn of resources.

The accommodating functions for three specific on-line problems are investigated: a variant of bin packing in which the goal is to maximize the number of items put in n bins, the seat reservation problem, and the problem of optimizing total flow time when preemption is allowed.

We also show that when trying to distinguish between two algorithms, the decision as to which one performs better cannot necessarily be made from the competitive ratio or the competitive ratio on accommodating sequences alone. For the variant of bin-packing considered, we show that Worst-Fit has a strictly better competitive ratio than First-Fit, while First-Fit has a strictly better competitive ratio on accommodating sequences than Worst-Fit.

Key words. on-line algorithms, performance measures, competitive analysis, restricted adversaries, bin packing, seat reservations, flow time

1. Introduction.

The competitive ratio [17, 29, 23], as a measure for the quality of on-line algorithms, has been criticized for giving bounds that are unrealistically pessimistic [5, 7, 18, 22, 25] and for not being able to distinguish between algorithms with very different behavior in practical applications [7, 18, 25, 28]. Though this criticism also applies to standard worst-case analysis, it is often more disturbing in the on-line scenario [18].

The basic problem is that the adversary is too powerful compared with the on-line algorithm. For instance, it would often be more interesting to compare an on-line algorithm to other on-line alternatives than to an all-powerful off-line algorithm. A number of papers have addressed this problem [16] by making the on-line algorithm more powerful, by providing the on-line algorithm with more information, or by restricting the set of legal input sequences.

With regard to providing the on-line algorithm with more information, most progress has been made on paging problems. It has been observed [7] that programs exhibit "locality of reference." By supplying an "access graph" as part of the input to the algorithms, this behavior can be modeled. In [7, 19], a number of classes of

access graphs have been studied. In [11], it is shown that LRU is never worse than FIFO on any access graph.

The "loose competitive ratio" from [31] represents another attempt at improving the ratio. When determining the loose competitive ratio c, the following steps are taken. First, from an infinite set of input sequences, a set of sequences, asymptotically smaller than the whole set, may be disregarded. The remaining sequences should then either be c-competitive or have small cost. The assumption is that sequences of small cost are relatively unimportant.

With regard to making the on-line algorithm more powerful, this has been achieved through so-called "extra-resource analysis" of scheduling problems. In [22] and [28], processor speed is a resource which to some degree compensates for the on-line algorithm's lack of knowledge of the future compared with the (optimal) off-line algorithm. In [28], reduced job arrival rate is also considered as an extra resource the on-line algorithms could be allowed. Another possibility for an extra resource in scheduling problems is extra machines. Graham in [17] compares two arbitrary algorithms, allowing different numbers of processors for the two algorithms. This work was done before the competitive ratio was formally defined, but if one of these two algorithms is the optimal off-line algorithm, this result can be viewed as allowing the on-line algorithm extra machines. In [30, 31], the competitive ratio is improved by allowing some limited look-ahead.

In [25], unrealistic sequences can be removed by specifying a collection of possible distributions. The off-line adversary will choose the distribution which maximizes the ratio of the expected performance of the on-line algorithm to the expected performance of the adversary.

In this paper, we obtain new and stronger results by restricting the adversary. This can be done various ways; we move in the direction of restricting the set of input sequences the adversary can supply. However, instead of a "fixed" restriction, we consider a function of the restriction, the *accommodating function*. Informally, in on-line problems, where requests are made for parts of some resource, we measure the quality of an on-line algorithm as a function of the resources that would be sufficient for an optimal off-line algorithm. More precisely, if we have some amount of resources n, the function value at α is the usual ratio (still on some fixed amount of resources n), except that input sequences are restricted to those where the optimal off-line algorithm will not obtain a better result by having more than the amount αn of resources.

In the limit, as α tends towards infinity, there is no restriction on the input sequence, so this is the competitive ratio. However, when α is very large, the allowed sequences cannot necessarily be handled very well by the optimal off-line algorithm and can, depending on the application, be quite unrealistic. To avoid comparing an on-line algorithm to the optimal off-line algorithm on problematic sequences of this type, we consider smaller values of α and restrict the adversary so that it can supply only sequences which the optimal off-line algorithm could handle optimally with only αn resources. In the case where increasing the amount of resources available will not improve the optimal off-line algorithm's result, the sequences are called *accommodating sequences* [9].[1] Thus, when $\alpha = 1$, the function value is the competitive ratio on accommodating sequences. Consequently, the accommodating function is a true gen-

[1] In that paper and a preliminary version of the current paper [10], this competitive ratio on accommodating sequences was called the accommodating ratio. The change is made here for consistency with common practice in the field.

eralization of the competitive ratio as well as the competitive ratio on accommodating sequences.

In addition to giving rise to new interesting algorithmic and analytical problems, which we have only begun investigating, this function, compared to just one ratio, contains more information about the on-line algorithms. For some problems, this information gives a more realistic impression of the algorithm than the competitive ratio does. Additionally, this information can be exploited in new ways. The shape of the function, for instance, can be used to warn against critical scenarios, where the performance of the on-line algorithm compared to the off-line can suddenly drop rapidly when more sequences are allowed.

In the next section, we formally define the accommodating function. In the following sections, the accommodating functions for three specific on-line problems are investigated: a variant of bin-packing in which the goal is to maximize the number of items put in n bins, the seat reservation problem, and the problem of optimizing total flow time when preemption is allowed.

In section 3, where we consider the variant of bin-packing, we consider two specific algorithms, First-Fit and Worst-Fit. We show that although First-Fit performs worse than Worst-Fit with respect to the competitive ratio, it performs better with respect to the competitive ratio on accommodating sequences. Thus, the choice as to which algorithm to use depends on which ratio is more relevant in a specific situation. This would depend on the actual distribution of request sequences and on the accommodating functions for the algorithms.

2. The accommodating function. Consider an on-line problem with a fixed amount of resources n. For a *maximization problem*, $\mathbb{A}(I)$ is the *value* of running the on-line algorithm $\mathbb{A}$ on I, and $\mathrm{OPT}(I)$ is the *maximum value* that can be achieved on I by an optimal off-line algorithm, OPT.

For a *minimization* problem, $\mathbb{A}(I)$ is a *cost* and $\mathrm{OPT}(I)$ is the *minimum cost* which can be achieved.

$\mathbb{A}$ and OPT use the same amount of resources, n. For a problem with some limited resource, $\mathrm{OPT}_m(\mathbb{A}_m)$ denotes the value/cost of an optimal off-line algorithm (the on-line algorithm) when the amount m of the limited resource is available.

DEFINITION 2.1. *Let P be an on-line problem with a fixed amount n of resources. For any $\alpha > 0$, an input sequence I to the problem P is said to be an* α-sequence *if $OPT_{\alpha n}(I) = OPT_{n'}(I)$ for all $n' \geq \alpha n$. 1-sequences are also called* accommodating sequences.

If an input sequence is an α-sequence, then an optimal off-line algorithm does not benefit from having more than the amount αn of resources. For maximization problems, this will often mean that the optimal off-line algorithm could have fully granted all requests with the amount αn of resources. If an input sequence is an accommodating sequence, then an optimal off-line algorithm does not benefit from having more resources than the amount already available.

For a maximization problem, the algorithm $\mathbb{A}$ is *c-competitive on α-sequences* if $c \leq 1$, and for every n and every α-sequence I, $\mathbb{A}_n(I) \geq c \cdot \mathrm{OPT}_n(I) - b$, where b is a fixed constant for the given problem, and, thus, independent of I.

Let $\mathcal{C}^{\alpha}_{\mathbb{A}} = \{c \mid \mathbb{A} \text{ is } c\text{-competitive on } \alpha\text{-sequences}\}$. The *accommodating function* $\mathcal{A}$ is defined as $\mathcal{A}_{\mathbb{A}}(\alpha) = \sup \mathcal{C}^{\alpha}_{\mathbb{A}}$.

For a minimization problem, $\mathbb{A}$ is c-competitive on α-sequences if $c \geq 1$ and for every n and every α-sequence I, $\mathbb{A}_n(I) \leq c \cdot \mathrm{OPT}_n(I) + b$, and the accommodating function is defined as $\mathcal{A}_{\mathbb{A}}(\alpha) = \inf \mathcal{C}^{\alpha}_{\mathbb{A}}$.

With this definition, the competitive ratio on accommodating sequences from [9] is $\mathcal{A}(1)$ and the competitive ratio is $\lim_{\alpha\to\infty}\mathcal{A}(\alpha)$. In this paper, we consider only $\alpha \geq 1$. In Figure 2.1, these relationships are depicted using a hypothetical example for a maximization problem.

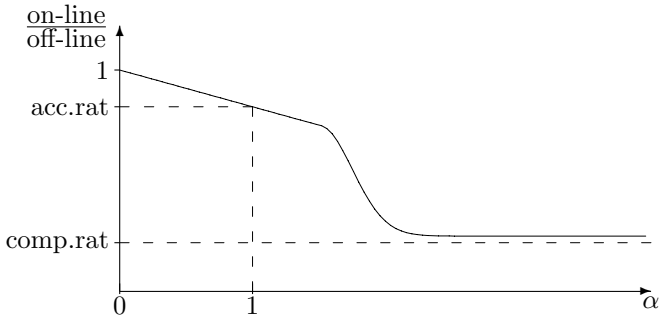

FIG. 2.1. *A typical accommodating function for a maximization problem.*

The extra information contained in the accommodating function compared with the competitive ratio can be used in different ways. If the user knows that estimates of required resources cannot be off by more than a factor three, for instance, then $\mathcal{A}(3)$ is a bound for the problem and thereby a better guarantee than the bound given by the competitive ratio. The shape of the function is also of interest. Intervals where the function is very steep are critical, since there earnings, compared to the optimal earnings, drop rapidly. Thus, the user misses out on business. Therefore, the function can warn against algorithms with unfortunate behavior, and, if such an algorithm must be used, the function can be used to locate resource critical areas.

3. Fair bin packing. Consider the following bin packing problem: Let n be the number of bins, all of size k. Given a sequence of integer-sized items of size at most k, the objective is to maximize the total number of items in these bins. This problem has been studied in the off-line setting, starting in [14], and its applicability to processor and storage allocation is discussed in [13]. (For surveys on Bin Packing, see [12, 15].) The problem we are considering is on-line, so the requests occur in a definite order. We require the packing to be *fair*; that is, an item can be rejected only if it cannot fit in any bin at the time when it is given. We refer to the problem as *Fair Bin Packing*.[2] Notice that the fairness criterion is a part of the problem specification. Thus, even though the optimal off-line algorithm knows the whole sequence of requests in advance, it must process the requests in the same order as the on-line algorithm and do so fairly.

In this problem, for a given α, we consider only sequences which could be packed in αn bins by an optimal off-line algorithm.

3.1. Summary of results. The following six theorems summarize our results for deterministic algorithms for Fair Bin Packing. Note that since this is a maximization problem, lower bounds are obtained by proving a bound on the worst-case behavior of algorithms, and upper bounds are obtained by giving adversary arguments.

[2] In [10], where a preliminary version of some of these results was presented, the same problem was referred to as Unit Price Bin Packing.

THEOREM 3.1. *For any Fair Bin Packing algorithm, the accommodating function is at most*

$$\mathcal{A}(\alpha) \leq \begin{cases} \frac{6}{7} & : \quad \alpha = 1, \\ \frac{2}{2+(\alpha-1)(k-2)} & : \quad 1 < \alpha \leq \frac{5}{4}, \\ \frac{8}{6+k} & : \quad \alpha > \frac{5}{4} \end{cases}$$

for $k \geq 3$.

THEOREM 3.2. *For any Fair Bin Packing algorithm, the accommodating function is at least*

$$\mathcal{A}(\alpha) \geq \begin{cases} \frac{1}{2} & : \quad \alpha = 1, \\ \frac{\alpha}{\max\{1+(\alpha-1)k, 2+(\alpha-1)\frac{k}{2}\}} & : \quad 1 < \alpha < 2, \\ \frac{2-\frac{1}{k}}{k} & : \quad \alpha \geq 2 \end{cases}$$

for $k \geq 3$.

The bounds presented in the previous two theorems are depicted in Figure 3.1.

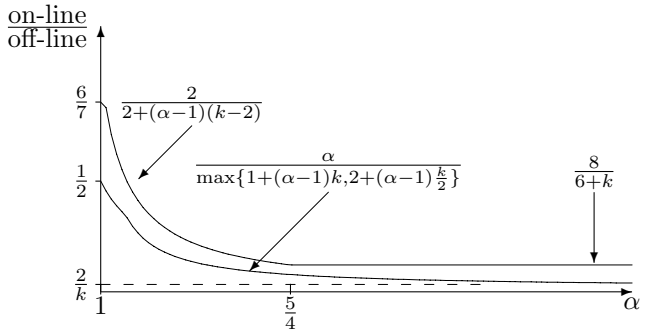

FIG. 3.1. *General upper and lower bounds on the accommodating function for Fair Bin Packing, drawn for* $k = 60$.

The specific algorithms we consider are First-Fit and Worst-Fit. First-Fit places an item in the lowest numbered bin in which it fits, while Worst-Fit places an item in one of the bins which are least full.

THEOREM 3.3. *An upper bound on the accommodating function for First-Fit is*

$$\mathcal{A}_{FF}(\alpha) \leq \begin{cases} \frac{7}{11} & : \quad \alpha = 1, \\ \frac{\alpha}{1+(\alpha-1)(k-1)} & : \quad 1 < \alpha < 2, \\ \frac{2-\frac{1}{k}}{k} & : \quad \alpha \geq 2. \end{cases}$$

The general lower bounds from Theorem 3.2 apply to all algorithms, including First-Fit. A better lower bound on the competitive ratio on accommodating sequences can be shown.

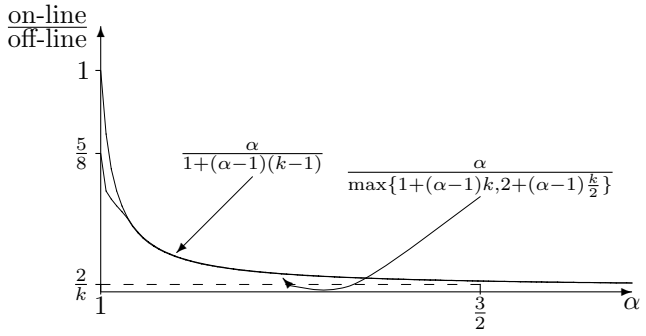

FIG. 3.2. *Upper and lower bounds on the accommodating function for First-Fit, drawn for* $k = 60$.

THEOREM 3.4. *For First-Fit, the competitive ratio on accommodating sequences is at least*

$$\mathcal{A}_{FF}(1) \geq \frac{5}{8}.$$

The bounds on First-Fit presented in the previous three theorems are depicted in Figure 3.2.

THEOREM 3.5. *An upper bound on the accommodating function for Worst-Fit is*

$$\mathcal{A}_{WF}(\alpha) \leq \begin{cases} \frac{1}{2-\frac{1}{k}} & : \quad \alpha = 1, \\ \frac{3-\frac{1}{n}}{2-\frac{1}{n}+(\alpha-1)k} & : \quad 1 < \alpha < 1 + \frac{1}{n}\left\lceil \frac{(n-1)(k-n)+(n-1)}{k} \right\rceil, \\ \frac{3+\frac{1}{n-1}}{3+\frac{1}{n-1}+(1-\frac{1}{\beta})k} & : \quad \alpha \geq 1 + \frac{1}{n}\left\lceil \frac{(n-1)(k-n)+(n-1)}{k} \right\rceil,\ k \geq \beta n,\ \beta \geq 1. \end{cases}$$

The general lower bounds from Theorem 3.2 apply to all algorithms, including Worst-Fit. A better lower bound on the competitive ratio can be shown.

THEOREM 3.6. *The competitive ratio of Worst-Fit is at least* $\frac{3}{2+k}$.

3.2. Upper bounds for all deterministic algorithms. Here we prove bounds which apply to all deterministic algorithms for Fair Bin Packing, beginning with an upper bound on the accommodating function. All of the results in this subsection also hold if one relaxes the restriction that all items must be integer-sized to a restriction that the bins have unit size and the smallest item has size $1/k$.

THEOREM 3.7. *For any Fair Bin Packing algorithm, if* $\alpha \leq \frac{5}{4}$ *and* $k \geq 3$, *then* $\mathcal{A}(\alpha) \leq \frac{2}{2+(\alpha-1)(k-2)}$.

Proof. Consider an arbitrary fair on-line algorithm $\mathbb{A}$. An adversary can give $\mathbb{A}$ the following request sequence, divided into three phases. Phase 1 consists of n small items of unit size. Phase 2 consists of items, one for each bin which $\mathbb{A}$ did not fill completely with size equal to the empty space in that bin, sorted in decreasing order. After these are given, $\mathbb{A}$ has filled all bins completely and so must reject the items in phase 3, which consists of $(\alpha n - n)k$ items of unit size. Let q denote the number of empty bins in $\mathbb{A}$'s configuration after the first phase.

In the case where $q < \frac{n}{4}$, we know that $\mathbb{A}$ has at least $n - 2q \geq 2(\alpha n - n)$ bins with exactly one item after phase 1. OPT can arrange the items from phase 1 such that half of the bins contain two items and half contain no items. In the second request phase, there are at least $2(\alpha n - n)$ items of size $k - 1$. OPT rejects at least $\alpha n - n$,

leaving room for at least $(\alpha n - n)(k-1)$ of the unit size items from phase 3. This gives a total gain of at least $(k-2)(\alpha n - n)$, and the performance ratio is at most $\frac{2n}{2n+(\alpha n-n)(k-2)} = \frac{2}{2+(\alpha-1)(k-2)}$.

In the case where $q \geq \frac{n}{4}$, we know that $\mathbb{A}$ has at least $\alpha n - n$ empty bins after phase 1. OPT places each of the items from phase 1 in a different bin. This gives a performance ratio of at most $\frac{2n}{2n+(\alpha n-n)(k-1)} = \frac{2}{2+(\alpha-1)(k-1)}$, since OPT rejects $\alpha n - n$ items of size k. □

Using the value $\alpha = \frac{5}{4}$ in the above theorem gives an upper bound on the competitive ratio.

COROLLARY 3.8. *If $k \geq 3$, no Fair Bin Packing algorithm is more than $\frac{8}{6+k}$-competitive.*

The next theorem improves the bound on the accommodating function for $\alpha = 1$.

THEOREM 3.9. *For $k \geq 7$, any Fair Bin Packing algorithm has a competitive ratio on accommodating sequences of at most $\frac{6}{7}$.*

Proof. Consider an arbitrary fair on-line algorithm $\mathbb{A}$ and assume n is even. An adversary first gives n items of size $\lceil \frac{k}{2} \rceil - 1$. Since $k \geq 7$, $\mathbb{A}$ has packed at most two items per bin. Let q denote the number of empty bins in $\mathbb{A}$'s packing. In the case where $q < \frac{2n}{7}$, the off-line algorithm can pack these n requests in the first $\frac{n}{2}$ bins. Now the adversary can give $\frac{n}{2}$ long requests of size k. The performance ratio is then $\frac{n+q}{n+\frac{n}{2}} = \frac{2n+2q}{3n} < \frac{6}{7}$.

In the case where $q \geq \frac{2n}{7}$, observe that $\mathbb{A}$ has q bins with exactly two items. Let the off-line algorithm place one item in each bin. In this case, the adversary can now give n requests of size $\lfloor \frac{k}{2} \rfloor + 1$. The performance ratio is then $\frac{2n-q}{2n} \leq \frac{6}{7}$. □

3.3. Lower bounds for all deterministic algorithms. Now we prove lower bounds which apply to all deterministic algorithms for Fair Bin Packing. The first lower bound is on the competitive ratio. Fix an on-line algorithm $\mathbb{A}$ and consider the configuration of $\mathbb{A}$ after a given sequence I has been packed. Let e denote the maximal empty space in any bin. Since all items are integer-sized, if the bins are not all full, $e \geq 1$.

LEMMA 3.10. *If $e \geq 1$, the performance ratio of $\mathbb{A}$ is at least $\frac{3}{2+k}$, for $k \geq 3$.*

Proof. Let V denote the volume of the first n requests, all of which must be accepted by $\mathbb{A}$. Note that $n \leq V \leq nk$. All items of size at most e have been accepted by $\mathbb{A}$ due to the fairness criterion. Let M count the number of such small items which arrive after the first n requests.

In the case where $e = 1$, M counts the number of unit size items. As argued above, $\mathbb{A}$ must accept the first n items, plus the M unit size items, and together they have volume $V + M$. Since $\mathbb{A}$ fills every bin with volume at least $k - 1$, these items account for all of what $\mathbb{A}$ places in at most $\lfloor \frac{V+M}{k-1} \rfloor$ bins. Thus, it must accept at least $n - \lfloor \frac{V+M}{k-1} \rfloor$ additional items. The optimal off-line algorithm OPT must also accept the first n items and the M unit size items. For other items, it has $nk - V - M$ space remaining. All other items in the request sequence have size at least 2, so OPT accepts at most $\frac{nk-V-M}{2}$ additional items. Hence, the performance ratio is at least

$$\frac{n + M + n - \lfloor \frac{V+M}{k-1} \rfloor}{n + M + \frac{nk-V-M}{2}} \geq \frac{n + M + n - \frac{V+M}{k-1}}{n + M + \frac{nk-V-M}{2}},$$

defined for $n \leq V \leq nk$ and $0 \leq M \leq nk - V$. By finding the minimum with respect

to M, it can be shown that the following is a lower bound for the performance ratio:

$$\frac{2n - \frac{V}{k-1}}{n + \frac{nk-V}{2}} \geq \frac{2n - \frac{n}{k-1}}{n + \frac{nk-n}{2}} = \frac{4k-6}{k^2-1}.$$

The last inequality is obtained by finding the minimum with respect to V.

In the case where $e \geq 2$, the performance ratio is at least

$$\begin{aligned}\frac{n + M + (n - \lfloor \frac{V+M}{k-e} \rfloor)}{n + M + \frac{nk-V-M}{e+1}} &\geq \frac{n+M}{n + M + \frac{nk-n-M}{e+1}} \\ &= \frac{(e+1)(M+n)}{en + eM + nk} \\ &\geq \frac{(e+1)n}{en+nk} \geq \frac{3}{2+k}.\end{aligned}$$

For $k \geq 3$, the case $e \geq 2$ gives the smallest value. □

THEOREM 3.11. *The competitive ratio for any Fair Bin Packing algorithm is at least* $\frac{2-\frac{1}{k}}{k}$ *when* $k \geq 3$.

Proof. Consider an algorithm $\mathbb{A}$ for Fair Bin Packing. When $k \geq 3$, the ratio $\frac{3}{2+k}$ from Lemma 3.10 is larger than $\frac{2-\frac{1}{k}}{k}$. Thus, it suffices to consider the case where $e = 0$. Again, let V denote the volume of the first n requests, all of which must be accepted by $\mathbb{A}$, since it is fair. Since $e = 0$, every bin has been filled up by the on-line algorithm, but the first n requests filled at most $\lfloor \frac{V}{k} \rfloor$ bins. Thus, $\mathbb{A}$ accepted at least $n + (n - \lfloor \frac{V}{k} \rfloor)$ items. Since all items have size at least 1, OPT accepts at most $n + (nk - V)$ items, giving a performance ratio of at least $\frac{2n - \lfloor \frac{V}{k} \rfloor}{n+nk-V} \geq \frac{2n-\frac{V}{k}}{n+nk-V} \geq \frac{2n-\frac{n}{k}}{nk} = \frac{2-\frac{1}{k}}{k}$. □

Next we give a lower bound on the competitive ratio on accommodating sequences, $\mathcal{A}(1)$. Note that the result does not depend on the items being integer-sized.

THEOREM 3.12. *Let I be an input sequence which can be accommodated within n bins. The performance ratio is greater than $\frac{1}{2}$ for any Fair Bin Packing algorithm.*

Proof. Let A denote the set of items accepted by the on-line algorithm, and let R denote the set of items rejected. The set R could be empty, but then the on-line algorithm would have accommodated every request, giving a performance ratio of 1. If R is nonempty, at least n items are accepted. Since the performance ratio is $\frac{|A|}{|A|+|R|}$, it is enough to show that $|R| < n$. Let e denote the maximal empty space in any bin. Every item in R has size greater than e. If $|R| \geq n$, then the volume of R is greater than ne. However, this contradicts the fact that the total empty space is at most ne, and the entire sequence can be packed in n bins. □

The final general lower bound is on the accommodating function.

THEOREM 3.13. *For any Fair Bin Packing algorithm, the accommodating function can be bounded by* $\mathcal{A}(\alpha) \geq \frac{\alpha}{\max\{1+(\alpha-1)k, 2+(\alpha-1)\frac{k}{2}\}}$ *for* $1 < \alpha < 2$ *and* $k \geq 4$.

Proof. Consider a worst-case sequence I for an on-line algorithm $\mathbb{A}$. We may assume that I contains no item which is rejected by both $\mathbb{A}$ and OPT, since such an item has no influence on the ratio.

Again, let A denote the set of items accepted by the on-line algorithm $\mathbb{A}$, and let R denote the set of items rejected. Let $\rho(I)$ denote the least number of bins in which the sequence can be packed and define $l = \rho(I) - n$. If $l = 0$, we can use the result from Theorem 3.12. Assume that $l \geq 1$ and note that l is a lower bound on the

number of items rejected by OPT. The first n items are accepted by both algorithms. Since, by assumption, the on-line algorithm accepts all those items OPT rejects, it must accept at least $n + l$ items. Thus, $|A| \geq n + l$. Again, let e denote the size of the maximal empty space in any bin. The proof is divided into two cases depending on e.

If $e = 0$, all n bins have been filled by the on-line algorithm, so the number of rejected items is at most lk.

In the case where $e \geq 1$, an upper bound on the number of items rejected is $|R| \leq \frac{1}{e+1}(en + lk)$ using the same arguments as in the previous theorem. We can now bound the accommodating function: $\mathcal{A}(\alpha) \geq \frac{|A|}{|A|+|R|-l} \geq \frac{n+l}{n+l+\max\{lk, \frac{en}{e+1}+l\frac{k}{e+1}\}-l}$ $\geq \frac{n+(\alpha n-n)}{n+\max\{(\alpha n-n)k, n+(\alpha n-n)\frac{k}{2}\}} = \frac{\alpha}{1+\max\{(\alpha-1)k, 1+(\alpha-1)\frac{k}{2}\}}$, for $1 < \alpha < 2$. □

3.4. Separation of First-Fit and Worst-Fit using the accommodating function. In this section, we prove that the accommodating function provides extra information by showing that the best choice between two different algorithms for the same natural problem (Fair Bin Packing) cannot be made based on either the competitive ratio or the competitive ratio on accommodating sequences alone.

The two specific algorithms that we consider are First-Fit and Worst-Fit. First-Fit places an item in the lowest numbered bin in which it fits, while Worst-Fit places an item in a bin which is least full. We show that Worst-Fit has a better competitive ratio ($r_{\mathrm{WF}} \geq \frac{3}{2+k}$) than First-Fit ($r_{\mathrm{FF}} \leq \frac{2-\frac{1}{k}}{k}$), while First-Fit has a better competitive ratio on accommodating sequences ($\mathcal{A}_{\mathrm{FF}}(1) \geq \frac{5}{8}$) than Worst-Fit ($\mathcal{A}_{\mathrm{WF}}(1) \leq \frac{1}{2-\frac{1}{k}}$). All of the results proven in this section for First-Fit also hold for Best-Fit. Best-Fit is the algorithm which places an item in the most full among the bins where it fits. If the "most full" is not unique, then Best-Fit chooses the first among those "most full" bins.

Worst-Fit's competitive ratio on accommodating sequences. First, we prove an upper bound on Worst-Fit's competitive ratio on accommodating sequences.

THEOREM 3.14. *Worst-Fit has a competitive ratio on accommodating sequences of at most* $\frac{1}{2-\frac{1}{k}}$ *for all* k.

Proof. Assume that n is divisible by k. An adversary can give the following request sequence:

1. n items of unit size;
2. $n - \frac{n}{k}$ items of size k.

Worst-Fit places one small item in each bin and must reject all the following items. The optimal algorithm behaves like First-Fit and accepts all items giving the following performance ratio: $\frac{n}{n+n-\frac{n}{k}} = \frac{1}{2-\frac{1}{k}}$. □

First-Fit's and Best-Fit's competitive ratios on accommodating sequences. Now we show that First-Fit's and Best-Fit's competitive ratios on accommodating sequences are at least $\frac{5}{8}$, which is strictly greater than Worst-Fit's competitive ratio on accommodating sequences, when $k > 2$. Thus, according to this performance measure, First-Fit and Best-Fit are better algorithms than Worst-Fit. The proof which shows this lower bound on Best-Fit's competitive ratio on accommodating sequences is essentially the same as the one for First-Fit, after the following two lemmas are proven giving lower bounds on the sizes of the first items Best-Fit places in a new bin. We let $A(\mathbb{A}, I)$ denote the set of items accepted by an on-line algorithm $\mathbb{A}$, and we let $R(\mathbb{A}, I)$ denote the set of items it rejects. The first lemma

shows that if Best-Fit packs items so that some bin is no more than half full, then the performance ratio is at least $2/3 > 5/8$, so we can safely ignore such sequences. In fact, this result holds for First-Fit, too, but we need only to apply it for Best-Fit.

LEMMA 3.15. *Suppose that OPT accepts all items in some request sequence I. Suppose further that in Best-Fit's packing of the sequence I, there is some bin which is no more than half full. Then Best-Fit accepts at least $2/3$ of the items in I.*

Proof. If Best-Fit leaves some bin b no more than half full, then every item in $R(\mathrm{BF}, I)$ must have size strictly greater than $k/2$. Suppose that among the items which Best-Fit accepts, there are x not in b which it places in bins alone. All of these x items must be larger than the empty space in bin b. Otherwise, they would have been placed in bin b or some of the contents in bin b would have been placed on top of them. Thus, these x items also have size strictly greater than $k/2$. We consider two cases:

Case 1. Bin b contains more than one item.

Case 2. Bin b contains exactly one item.

In the first case, since OPT accepts all of the items in I, there cannot be more than n items of size strictly greater than $k/2$, so $x + |R(\mathrm{BF}, I)| \leq n$. If Best-Fit rejects any items at all, it has at least two items in all except x bins, so the number of items accepted by Best-Fit, $A(\mathrm{BF}, I) \geq 2n - x$, and the total number of items in I is $A(\mathrm{BF}, I) + R(\mathrm{BF}, I)$. Thus, Best-Fit's performance ratio is at least $\frac{A(\mathrm{BF},I)}{A(\mathrm{BF},I)+R(\mathrm{BF},I)} \geq \frac{2n-x}{2n-x+R(\mathrm{BF},I)} \geq \frac{2n-x}{3n-2x} \geq \frac{2}{3}$.

The second case is argued similarly. Since b has only one item, it cannot fit with any of the x items which are placed alone or with any of the rejected items, so $1 + x + |R(\mathrm{BF}, I)| \leq n$. Another difference is that there is now an additional bin, b, which Best-Fit does not give at least two items. In this case, $A(\mathrm{BF}, I) \geq 2n - x - 1$. Thus, Best-Fit's performance ratio is at least $\frac{A(\mathrm{BF},I)}{A(\mathrm{BF},I)+R(\mathrm{BF},I)} \geq \frac{2n-x-1}{2n-x-1+R(\mathrm{BF},I)} \geq \frac{2n-x-1}{3n-2x-2} \geq \frac{2}{3}$. □

When considering Best-Fit in the following, we look only at sequences which Best-Fit packs such that all bins are more than half full. The next lemma shows that if Best-Fit packs more than one item in some bin, b, then either at least one of them has size greater than $k/2$ or at least two of them have size greater than the final empty space in any bin which was first used before bin b. We call a bin which was first used before that bin an "earlier" bin. This lemma can be seen to follow from Claim 2.2.2 in [21], but a direct proof is included below for completeness.

LEMMA 3.16. *Suppose that OPT accepts all items in some request sequence I, and that in Best-Fit's packing of the sequence I, all bins are more than half full. Then every bin contains either an item of size greater than $k/2$ or at least two items of size greater than the empty space in any earlier bin.*

Proof. Best-Fit places an item in an empty bin only when it will not fit in any earlier bin. Suppose that Best-Fit puts the first item in bin b at time t. This first item must be larger than the empty space in any earlier bin at time t and thus larger than the final empty space in any earlier bin. Suppose that this first item has size no more than $k/2$. Then, by the assumption that all bins are eventually more than half full, Best-Fit must put some other item x in bin b. In addition, all of the earlier bins must have been more than half full at time t. Thus, when this second item x is put in bin b, all earlier bins were more full than b, so this x was too large to fit in them. Thus, if the first item in a bin has size no more than $k/2$, the first two both have size larger than the final empty space in any earlier bin. □

Given a request sequence $I = \langle s_1, s_2, \ldots, s_t \rangle$, where s_i is the size of item i, we can

represent the final configuration of an algorithm $\mathbb{A}$ by $\mathit{conf}(\mathbb{A}, I) = \langle S_1, S_2, \ldots, S_n \rangle$, a list of n multisets, where the multiset S_j contains the sizes of the items in bin j. In order to prove a lower bound on First-Fit's or Best-Fit's competitive ratio on accommodating sequences, we compare $\mathit{conf}(\mathrm{FF}, I)$ or $\mathit{conf}(\mathrm{BF}, I)$ to $\mathit{conf}(\mathrm{OPT}, I)$. In the following, we write only First-Fit or FF, but everything applies to Best-Fit as well. The sizes which appear in $\mathit{conf}(\mathrm{FF}, I)$ will correspond to items in $A(\mathrm{FF}, I)$, but since we are assuming that OPT can accommodate all t items from I, there will be t items in $\mathit{conf}(\mathrm{OPT}, I)$. Consider rearranging the items in $\mathit{conf}(\mathrm{FF}, I)$ so that the items from $A(\mathrm{FF}, I)$ are placed in exactly the same bins as they are in $\mathit{conf}(\mathrm{OPT}, I)$, creating a new configuration $\mathit{good}(I) = \langle S'_1, S'_2, \ldots, S'_n \rangle$, which also contains exactly those items in $A(\mathrm{FF}, I)$.

First, we prove a lemma which relates the number of moves necessary for changing from $\mathit{conf}(\mathrm{FF}, I)$ to $\mathit{good}(I)$ to the number of items from I which First-Fit rejects. In fact, this lemma holds for any algorithm for Fair Bin Packing, not just for First-Fit and Best-Fit.

LEMMA 3.17. *For any request sequence I which could be accommodated by OPT, the minimal number of items which have to be moved, in order to change from $\mathit{conf}(\mathbb{A}, I)$ to $\mathit{good}(I)$, is an upper bound on the number of items from I which the algorithm $\mathbb{A}$ rejects.*

Proof. Consider any request sequence I and any algorithm $\mathbb{A}$ for Fair Bin Packing. The process of changing from $\mathit{conf}(\mathbb{A}, I)$ to $\mathit{good}(I)$ involves moving items out of some bins and into others. Those bins that become less full after this rearrangement may have space for one or more items from $R(\mathbb{A}, I)$. Let s denote the size of the smallest item in $R(\mathbb{A}, I)$ and write the size of item i as $s_i = q_i s + r_i$, where $0 \le r_i \le s - 1$, and the amount of empty space in bin j as $e_j = k - \sum_{s_i \in S_j} s_i$. The new empty space in bin j is $e'_j = e_j + \sum_{s_i \in S_j \setminus S'_j} s_i - \sum_{s_i \in S'_j \setminus S_j} s_i$. When item i moves from bin j to bin j', the value $s_i = q_i s + r_i$ is added to the empty space in bin j and subtracted from the empty space in bin j'. Therefore if we sum, over all bins in the configuration $\mathit{good}(I)$, the number of items of size s which could fit in their empty space, the value q_i is added to bin j and subtracted from bin j', giving a net gain of zero. Thus, the only real contribution comes from the original empty space, e_j, and the values r_i. Let $g(j)$ denote the net gain attributed to bin j. Then

$$\begin{aligned} g(j) &\le \lfloor \tfrac{1}{s}(e_j + \textstyle\sum_{s_i \in S_j \setminus S'_j} r_i) \rfloor \\ &\le \lfloor \tfrac{1}{s}(s - 1 + |S_j \setminus S'_j|(s-1)) \rfloor \\ &= \lfloor \tfrac{s-1}{s}(|S_j \setminus S'_j| + 1) \rfloor \\ &\le |S_j \setminus S'_j|, \end{aligned}$$

which is the number of items moved out of bin j. Since all of the items from $R(\mathbb{A}, I)$ fit in the empty space available in $\mathit{good}(I)$, the total number of items in $R(\mathbb{A}, I)$ is at most the total net gain after rearranging. This net gain is $\sum_{j=1}^{n} g(j) \le \sum_{j=1}^{n} |S_j \setminus S'_j|$, which is the total number of items moved from one bin to another to get from $\mathit{conf}(\mathbb{A}, I)$ to $\mathit{good}(I)$. ∎

Note that the ordering of the sets in $\mathit{conf}(\mathrm{OPT}, I)$ is irrelevant, so we may order them in any way. The above result holds for the minimum number of moves over all of these arrangements.

In order to prove a lower bound on the competitive ratio on accommodating sequences for First-Fit, we prove a lower bound on $|A(\mathrm{FF}, I)|$, which holds for all I. This is done by proving a lower bound on the number of items which do not move

when changing from *conf*(FF, I) to *good*(I). First, we prove a general result which applies to all algorithms for Fair Bin Packing, and then we use this result and the special properties of First-Fit and Best-Fit to prove the lower bound of 5/8.

Define $B(\mathbb{A}, I)$ to be the set of items in I of size greater than $k/2$ which $\mathbb{A}$ accepts. Some of the items moved, in changing from *conf*($\mathbb{A}, I$) to *good*(I), will be moved to be in the same bins as the items in $B(\mathbb{A}, I)$ or moved out of some bin containing an item from $B(\mathbb{A}, I)$. Suppose that these moves are done first. Let $O(\mathbb{A}, I)$ denote the items in $A(\mathbb{A}, I) \setminus B(\mathbb{A}, I)$ which have not moved yet. We use Vol[$\cdot$] to denote the volume of a collection of items; e.g., Vol[$O(\mathbb{A}, I)$] is the total volume of all items in $O(\mathbb{A}, I)$.

LEMMA 3.18. *There must be an ordering of the sets in conf*(OPT, I) *in which at least* $\frac{Vol[O(\mathbb{A},I)]}{k}$ *of the items in* $A(\mathbb{A}, I) \setminus B(\mathbb{A}, I)$ *are not moved.*

Proof. Consider the bipartite graph $G = ((X, Y), E)$ defined as follows:

1. For each bin b, there are two vertices $x_b \in X$ and $y_b \in Y$.
2. For each item in $O(\mathbb{A}, I)$, there is one edge. If the item is in bin i in *conf*(A, I) and in bin j in *good*(I), the corresponding edge is (x_i, y_j).

A matching in this graph G corresponds to a partial renumbering of the bins, and the edges in the matching correspond to items which have not been moved. A well-known result due to König [26] (see [6] for instance) states that the size of a maximum matching in a bipartite graph is equal to the size of a minimum vertex cover. However, a vertex cover of G corresponds to a set of bins (possibly with some from *conf*(A, I) and some from *good*(I)), which contain all of the items in $O(\mathbb{A}, I)$. Thus, the number of items which have not been moved is at least the minimum number of bins needed to contain all the items in $O(\mathbb{A}, I)$. The value $\frac{\text{Vol}[O(\mathbb{A},I)]}{k}$ is a lower bound on this number of bins. □

THEOREM 3.19. *The competitive ratios on accommodating sequences for First-Fit and Best-Fit are at least* $\frac{5}{8}$.

Proof. Within this proof, First-Fit and Best-Fit are the only on-line algorithms considered, and the sequence I will be fixed, but arbitrary, subject to the restriction that all requests would have been accepted by OPT (and for Best-Fit subject to the further restriction that, given I, Best-Fit packs all bins to more than half full). We use the following short hand notation for legibility: A is used for A(FF, I) or A(BF, I), B is used for B(FF, I) or B(BF, I), R is used for R(FF, I) or R(BF, I), and V is used for Vol[O(FF, I)] or Vol[O(BF, I)].

No two items from B can be placed in one bin, since they all have size greater than $k/2$. Therefore when counting moves as in Lemma 3.17, the items from B can be assumed not to have moved, since the bins can be reordered such that these items stay in their original bins.

According to Lemma 3.17, in order to get from *conf*(BF, I) to *good*(I), at least one item must move for each item in R. All of these items must be in A, along with the items which are not moved. Lemma 3.18 shows that at least $\frac{V}{k}$ of these items in $A \setminus B$ are not moved, so $|A| \geq |R| + |B| + \frac{V}{k}$.

We consider two cases based on the value of s, the size of the smallest item in R. In each case, we first prove a lower bound on V and then use that to prove a lower bound on the performance ratio.

Case $s > \frac{k}{3}$. Let T denote those bins which do not contain items of size greater than $k/2$, and let e_i denote the size of the empty space in the ith bin in T. For First-Fit, it is clear that, for $2 \leq i \leq n - |B|$, there are at least two items in bin i in T which have size greater than e_{i-1}. For Best-Fit, since we assume that $e_i < k/2$ for all bins i in T, this follows from Lemma 3.16. The empty space in those bins containing

items from B is at most $s-1$, since no items from R could fit in them. Thus, the total volume of those items which are moved to be in the same bins as the items in B is no more than $|B|(s-1)$. The first bin in T has volume $k-e_1$. Hence, the volume $V > (k-e_1)+2(\sum_{i=1}^{n-|B|-1} e_i)-|B|(s-1)$. The empty space above the first $n-|B|-1$ bins in T, plus the empty space above the other bins, must be large enough to contain all of the rejected items. Thus, $\sum_{i=1}^{n-|B|-1} e_i \geq |R|s-(|B|+1)(s-1)$. Hence,

$$\begin{aligned} V &> (k-e_1)+2(\textstyle\sum_{i=1}^{n-|B|-1} e_i)-|B|(s-1) \\ &\geq k-(s-1)+2|R|s-2(|B|+1)(s-1)-|B|(s-1) \\ &= k-3s+3+2|R|s-3|B|s+3|B| \\ &\geq k-3s+2|R|s-3|B|s. \end{aligned}$$

Note that either the performance ratio is greater than $\frac{5}{8}$ or $\frac{5}{8} \geq \frac{|A|}{|A|+|R|} \geq \frac{|R|+|B|}{2|R|+|B|}$, so $2|R| \geq 3|B|$. Thus, for $s \geq \frac{k}{3}$, this lower bound for V is at least the value at $s=\frac{k}{3}$. Hence, $V \geq \frac{2|R|k}{3}-|B|k$. This volume V requires at least $\frac{V}{k} \geq \frac{2}{3}|R|-|B|$ bins.

The performance ratio is then $\frac{|A|}{|A|+|R|} \geq \frac{\frac{5}{3}|R|}{\frac{8}{3}|R|} = \frac{5}{8}$.

Case $s \leq \frac{k}{3}$. Each of the bins must contain items with size adding up to at least $k-s+1$, or neither First-Fit nor Best-Fit would have rejected an item of size s. As in the previous case, the total volume of those items which are moved to be in the same bins as the items in B is no more than $|B|(s-1)$. Thus, the volume $V \geq (n-|B|)(k-s+1)-|B|(s-1) = nk-ns+n-|B|k$, and $\frac{V}{k} \geq n-\frac{ns}{k}-|B|$. For $s \leq \frac{k}{3}$, this is minimized when $s=\frac{k}{3}$, giving $\frac{V}{k} \geq \frac{2n}{3}-|B|$. In the proof of Theorem 3.12, it was shown that $|R| < n$, so the performance ratio is at least $\frac{|A|}{|A|+|R|} \geq \frac{|R|+\frac{2n}{3}}{2|R|+\frac{2n}{3}} \geq \frac{\frac{5n}{3}}{\frac{8n}{3}} = \frac{5}{8}$.

Therefore, the competitive ratios on accommodating sequences for First-Fit and Best-Fit are at least $\frac{5}{8}$. □

We now show an upper bound which applies to both First-Fit's and Best-Fit's competitive ratios on accommodating sequences.

THEOREM 3.20. *For Fair Bin Packing, First-Fit's and Best-Fit's competitive ratios on accommodating sequences are at most* $\frac{7}{11}$.

Proof. Assume that n is divisible by 13 and that k is greater than 72 and divisible by 3. An adversary can give the following request sequence, divided into four phases:

1. $\frac{3n}{13}$ of size $\frac{k}{3}-6$;
2. $\frac{6n}{13}$ pairs, one of size $\frac{k}{3}-1$ followed by one of size $\frac{k}{3}+3$;
3. $\frac{6n}{13}$ of size $\frac{2k}{3}+1$;
4. $\frac{12n}{13}$ of size $\frac{k}{3}$.

First-Fit and Best-Fit will pack phase 1 in $\frac{n}{13}$ bins, with three items in each bin. The assumption that $k > 72$ ensures that four items from this phase cannot be packed together. From phase 2, First-Fit and Best-Fit will pack one pair in each bin using $\frac{6n}{13}$ bins. In phase 3, each item will be placed in its own bin, using the last $\frac{6n}{13}$ bins. There will be no space for items from phase 4.

OPT can pack one item from phase 1 with two of the items of size $\frac{k}{3}+3$ from phase 2, using a total of $\frac{3n}{13}$ bins for this. Then, it can place one item of size $\frac{k}{3}-1$ from phase 2 together with one item from phase 3, using a total of $\frac{6n}{13}$ for this. There are now $\frac{4n}{13}$ empty bins which can each hold three items from phase 4. The ratio is thus $\frac{3+12+6}{3+12+6+12} = \frac{7}{11}$. □

This bound has been improved later to $\frac{5}{8}$ [1], showing that the lower bound from Theorem 3.19 is tight.

First-Fit's competitive ratio. Turning to the competitive ratio, we show that according to this measure, Worst-Fit is the better algorithm. First, we prove an upper bound on First-Fit's competitive ratio. Note that this result also applies to Best-Fit.

THEOREM 3.21. *For Fair Bin Packing, First-Fit has a competitive ratio which is no more than* $\frac{2-\frac{1}{k}}{k}$*, when* k *divides* n*.*

Proof. An adversary gives the following request sequence, divided into three phases:

1. n items of unit size;
2. $n - \frac{n}{k}$ items of size k;
3. $n(k-1)$ items of unit size.

First-Fit accepts the first two phases of requests. The optimal algorithm places each of the first n items in a separate bin and accepts all requests in phases 1 and 3, giving the following performance ratio: $\frac{n+n-\frac{n}{k}}{nk} = \frac{2-\frac{1}{k}}{k}$. □

For arbitrary n and k, a very similar request sequence gives an upper bound on the competitive ratio for First-Fit of $\frac{2-\frac{1}{k}+\frac{1}{n}}{k}$. By Theorem 3.11, this result is tight.

Worst-Fit's competitive ratio. Finally, we prove a lower bound on Worst-Fit's competitive ratio, but first we prove a tight upper bound, since it can provide some intuition for the lower bound $r_{\mathrm{WF}} \geq \frac{3}{2+k}$. The request sequence used to prove this upper bound involves items with sizes dependent on n, the number of bins. However, it is relatively easy to prove an upper bound of $\frac{4}{k+2}$ using a sequence where the sizes only depend on k, rather than also on n.

THEOREM 3.22. *For* $k \geq \beta n$ *and* $\beta \geq 1$*, the competitive ratio for Worst-Fit is no more than* $\frac{3+\frac{1}{n-1}}{3+\frac{1}{n-1}+(1-\frac{1}{\beta})k}$.

Proof. An adversary can give the following request sequence with four phases:

1. $n-1$ items of size $n-1$;
2. $n-1$ items of size 1;
3. n items of size $k-(n-1)$;
4. $(n-1)(k-n)+(n-1)$ items of size 1.

After phase 2, Worst-Fit has free space of size $k-(n-1)$ in every bin, and all items from phase 3 must be accepted. OPT places items from phase 1 in separate bins, and each item from phase 2 on top of an item from phase 1. OPT will then accept only one item from phase 3, making space for all the unit size items from phase 4. The performance ratio is then

$$\begin{aligned}
&\frac{(n-1)+(n-1)+n}{(n-1)+(n-1)+1+(n-1)(k-n)+(n-1)} \\
&= \frac{3n-2}{3n-2+(n-1)(k-n)} \\
&= \frac{3n-3+1}{3n-3+1+(n-1)(k-n)} \\
&= \frac{3+\frac{1}{n-1}}{3+\frac{1}{n-1}+k-n} \\
&\leq \frac{3+\frac{1}{n-1}}{3+\frac{1}{n-1}+(1-\frac{1}{\beta})k}.
\end{aligned}$$

□

In order to compare this ratio to the lower bound of $\frac{3}{2+k}$, note that it can be made arbitrarily close to $\frac{3}{3+k}$ if n and β are made large enough.

We now move on to the lower bound. Consider any request sequence I for Fair Bin Packing. Throughout this section, we assume that there are no items in I which both Worst-Fit and OPT reject. This cannot affect the results since any such item could simply be removed from the request sequence without affecting the competitive ratio.

The upper bound can give some intuition for the lower bound. In order to allow OPT to accept many more items than Worst-Fit, the adversary must give some large items which Worst-Fit will accept but OPT will reject. In a worst case example, Worst-Fit packs none of these large items alone. Since OPT is fair, OPT must pack two items in some bins such that these bins have more contents than the Worst-Fit bins just before the large items are accepted. The second small item OPT packs in each bin cannot be large enough to cause a rejection alone. Thus for each large item accepted by Worst-Fit it will accept additionally two items, while OPT will accept at most k small items. Unfortunately, there are many possibilities for sequences, so it is necessary to argue that it is possible to make certain assumptions about them.

We define the following sets:

X is the set of items which both Worst-Fit and OPT accept.
Y is the set of items which Worst-Fit accepts, but OPT rejects.
Z is the set of items which Worst-Fit rejects, but OPT accepts.

Let $y_{last} \in Y$ be the last item from Y in the request sequence I, and let i be the bin where Worst-Fit places it.

We define the following additional sets:

$X^f \subseteq X$ are those items from X which appear before y_{last} in I.
$Z^f \subseteq Z$ are those items from Z which appear before y_{last} in I.

For any item $z \in Z^f$, define the following two sets:

$Y(z)$ contains those items from Y which appear after z in I.
$Z^f(z)$ contains the item z and all z' from Z^f appearing after z in I.

If necessary, when more than one sequence is involved, we subscript these sets with the name of the sequence (Z^f_I, for instance).

Let e denote the maximal empty space in any of Worst-Fit's bins, after processing the request sequence I. The case $e \geq 1$ was considered in Lemma 3.10. We now turn to the case $e = 0$, beginning with some lemmas which allow us to make assumptions about the request sequences which give the worst performance ratio for Worst-Fit.

LEMMA 3.23. *If, for some sequence I, Worst-Fit places two items from Y_I in the same bin, then there exists another sequence I' on which Worst-Fit places all items from $Y_{I'}$ in separate bins and on which the performance ratio of Worst-Fit is smaller.*

Proof. First we show that if, for some sequence I, Worst-Fit places some item $x \in X_I$ on top of some item $y \in Y_I$ (call this an inversion), then there is another sequence I', containing exactly the same items as I, for which Worst-Fit and OPT accept exactly the same items as when given I, but Worst-Fit never places an item from $X_{I'}$ on top of an item from $Y_{I'}$.

We modify I to obtain I', correcting one of these inversions at a time. Suppose that Worst-Fit places $x \in X_I$ directly on top of $y \in Y_I$ in bin j. Clearly, y occurs before x in I. Due to fairness, y must also be larger than x since OPT accepts x but not y. Let I' be identical to I up until the point where y appears. Replace y by x. Then x will still be placed in bin j. Let the next items from I' be the same as the next items from I up to the point where Worst-Fit would put something on top of x in bin j. Assuming there was room for it, insert the item y at this point, and let the rest of I' be the same as I. Since x is smaller than y, the item y will appear in

I' no later than where x appeared in I. Thus, Worst-Fit will place the items from I' in exactly the same bins as the items from I, the only difference being that one item from X will be placed below an item from Y which it had been placed on top of when I was given. OPT will accept exactly the same items as before and place them exactly as before, since the only difference is that it receives an item it would accept anyway earlier and an item it would reject anyway later. Thus the performance ratio is unchanged. This process can be repeated until there are no inversions.

Suppose that for some sequence I, Worst-Fit places more than one item from Y_I in some bin. From the above, we may assume without loss of generality that Worst-Fit never places an item from X_I on top of an item from Y_I. Modify I to obtain I' as follows: Consider each bin which receives more than one item from Y_I, one at a time. Among the items from Y_I in the bin, choose the item O which occurs first in the request sequence I. Replace O in the sequence by a single item of size exactly equal to the sum of the sizes of all of the items from Y_I in that bin. Remove all of those other items from the request sequence. Note that all of the items which are merged had originally been placed directly on top of each other.

By induction, carrying out this modification for one bin at a time, it follows that Worst-Fit places a new item in the same bin as all of the old items from Y_I that it replaced and gives the same placement to all other items.

In addition, OPT cannot improve its ratio by accepting some of these new items, since then it could also have done it on the sequence I by accepting some of the items from Y_I. Thus, it accepts exactly the same items as from the sequence I. Hence, Worst-Fit accepts fewer items from I', while OPT accepts the same number, so the performance ratio becomes smaller. □

The following proposition is used in the next lemma and in the proof of the theorem.

PROPOSITION 3.24. *Given a request sequence I and a $z \in Z^f$ and suppose that for all $w \in Z^f(z)$ it is the case that $|Z^f(w)| \leq |Y(w)|$, then there exists a 1–1 mapping $g : Z^f(z) \to Y(z)$ such that for all $w \in Z^f(z)$, $g(w)$ occurs after w in I.*

Proof. Enumerating the items in $Y(z)$ and $Z^f(z)$ separately, starting from y_{last} and working in the direction of the beginning of the sequence I, g could be defined as the mapping which takes an item from $Z^f(z)$ numbered j to the item in $Y(z)$ numbered j. □

It would be tempting to move items accepted by OPT to the end of the sequence and then convert these to unit size items. Since OPT must be fair, there is no guarantee that it would accept exactly the same items. In fact, it might be forced to accept some items from Y, which could use up more volume than the moved elements from Z. However, under some circumstances, it is possible to perform these moves which will be used in the next lemma. It shows that an additional assumption can be made on worst-case request sequences, in those cases where Worst-Fit packs all bins so that they are completely full.

LEMMA 3.25. *If, for some sequence I for which $e = 0$, there exists an item $z \in Z_I^f$ such that $|Z_I^f(z)| \geq |Y_I(z)|$, then there exists another sequence I', where for all items $z \in Z_{I'}^f$, $|Z_{I'}^f(z)| < |Y_{I'}(z)|$, and on which the performance ratio of Worst-Fit is no larger.*

Proof. Let I be a sequence such that there exists a $z \in Z_I^f$ with $|Z_I^f(z)| \geq |Y_I(z)|$. Let z be the last item such that $|Z_I^f(z)| \geq |Y_I(z)|$. It must be the case that $|Z_I^f(z)| = |Y_I(z)|$, and $|Z_I^f(w)| < |Y_I(w)|$ for all $w \in Z_I^f$ which occur after z. From Proposition 3.24, we know that there must exist a 1–1 mapping $g : Z_I^f(z) \to Y_I$ such

that for all $w \in Z_I^f(z)$, $g(w)$ occurs after w in I. Since Worst-Fit is fair and rejects w while accepting $g(w)$, $g(w)$ must be smaller than w. This means that the total volume of all items in $Z_I^f(z)$ must be greater than the total volume in $Y_I(z)$.

Modify I to obtain I' by removing all items from $Z_I^f(z)$ and adding that many items of size 1 right after the last item accepted by Worst-Fit. This will not affect which items Worst-Fit accepts, since, by assumption, $e = 0$, which means that all bins are full at that point. On the other hand, from the new sequence I', OPT will accept some items from $Y_I(z)$, and since every moved item has size 1, it can accept at least one additional item for each item from $Y_I(z)$ which it rejects.

Since $|Z_I^f(z)| = |Y_I(z)|$, OPT accepts at least as many items from I' as from I, so the performance ratio of Worst-Fit is no larger. □

There is no problem in assuming the forms implied by Lemmas 3.23 and 3.25 simultaneously.

COROLLARY 3.26. *Given k and n, there exists a request sequence I such that the following hold:*

1. *There is no request sequence I' which Worst-Fit packs so that $e = 0$, for which we have that $\frac{WF(I')}{OPT(I')} < \frac{WF(I)}{OPT(I)}$.*
2. *Worst-Fit places all items from Y_I in separate bins.*
3. *If Worst-Fit packs I so that $e = 0$, then for all items $z \in Z_I^f$, $|Z_I^f(z)| < |Y_I(z)|$.*

Proof. Since one can assume that not both Worst-Fit and OPT reject the same item from I, there are only a finite number of sequences to be considered; one of them must give the worst performance ratio. Begin with that request sequence. The construction from Lemma 3.23 can be applied to ensure that the second condition holds. If $e = 0$ now, the construction from Lemma 3.25 can be applied, without changing Worst-Fit's behavior, so the last two properties can hold simultaneously. □

Now we are ready to prove a lower bound on the competitive ratio of Worst-Fit.

THEOREM 3.27. *For Fair Bin Packing, the competitive ratio of Worst-Fit is at least $\frac{3}{2+k}$.*

Proof. If for some sequence I, the largest empty space, e, remaining in Worst-Fit is greater than zero, then by Lemma 3.10, the performance ratio r is at least $\frac{3}{2+k}$. Therefore we assume that $e = 0$.

By Corollary 3.26, we can assume that Worst-Fit places no two items from Y in the same bin. Let B_{WF} be the set of bins which receive items from Y, and let $b = |B_{\mathrm{WF}}| = |Y|$. We first show that $|X| \geq 2(b - |Z^f|)$.

Let $U \subseteq X$ be those items from X which are placed in bins belonging to B_{WF}. For any item $x \in U$, OPT must place it with another item from X or from Z^f, or it would be unable to reject the item from Y, which Worst-Fit placed with x. Therefore if we let B_{OPT} be those bins which receive items from $U \cup Z^f$ from OPT, then every bin in B_{OPT} receives either at least two items from X or at least one from Z^f.

Consider those bins which are not in B_{OPT}. When the last item $y_{last} \in Y$ is given to OPT, such bins contain only items from $X^f \setminus U$. Recall that i is the bin where Worst-Fit placed the last item $y_{last} \in Y$. Let V be the total volume of all items from U placed in bin i by Worst-Fit. If j is a bin, not in B_{WF}, Worst-Fit placed at least one item from X^f there. If it received more than one item from X^f, only the last one could have size greater than V. Otherwise, by its strategy, Worst-Fit would have placed the next item (after the one of size greater than V) from bin j in bin i.

Thus, only this last item could be placed by OPT in a bin which has no other items from $X \cup Z^f$. The reason for this is that, since the other items have size at most V, a bin with such an item alone would have to accept the item y_{last}.

This means that only $n - b$ of OPT's bins could have no more than one item from X and no items from Z^f, so at least b bins have either at least two items from X or at least one from Z^f. Hence, even if all those from Z^f are in separate bins, $|X| \geq 2(b - |Z^f|)$.

Now Worst-Fit places the first n items, all of which must be in X, in different bins, so no item in Y can be larger than $k - 1$. By Corollary 3.26, Proposition 3.24, and fairness, items in Z^f must be larger than corresponding items in Y, so since $e = 0$, $|Z \setminus Z^f| \leq (k-1)(|Y| - |Z^f|)$, which implies that $|Z| \leq |Z^f| + (k-1)(b - |Z^f|)$.

Thus, the ratio r is bounded by
$\frac{|X|+|Y|}{|X|+|Z|} \geq \frac{|X|+b}{|X|+|Z^f|+(k-1)(b-|Z^f|)} \geq \frac{1}{\frac{|X|+|Z^f|}{|X|+b}+\frac{(k-1)(b-|Z^f|)}{3b-2|Z^f|}} \geq \frac{1}{1+\frac{k-1}{3}} = \frac{3}{2+k}$. □

3.5. The accommodating functions for First-Fit and Worst-Fit. Finally, we prove upper bounds on the accommodating functions for First-Fit and Worst-Fit. All of the results in this subsection also hold if one relaxes the restriction that all items must be integer-sized to a restriction that the bins have unit size and the smallest item has size $1/k$. The upper bound for First-Fit is close to the general lower bound of Theorem 3.13, so it is almost tight.

THEOREM 3.28. *For Fair Bin Packing, First-Fit has an accommodating function of at most* $\frac{\alpha}{1+(\alpha-1)(k-1)}$ *for* $1 < \alpha < 2$.

Proof. The adversary's request sequence is divided into four phases. First, give $\alpha n - n$ items of unit size, and second, give one item of size $k - (\alpha n - n) \bmod k$. If k divides $\alpha n - n$, this item has size 0 and is not given. Third, give $n - \lceil \frac{\alpha n - n}{k} \rceil$ items of size k. Fourth, give $(\alpha n - n)(k-1)$ items of unit size.

First-Fit accepts those items in the first three phases. The off-line algorithm places the first n items in separate bins, rejects the remaining long items, and accepts all items from phase 4. The performance ratio is at most $\frac{(\alpha n-n)+(n-\lfloor \frac{\alpha n-n}{k} \rfloor)}{n+(\alpha n-n)(k-1)} \leq \frac{\alpha n}{n+(\alpha n-n)(k-1)} = \frac{\alpha}{1+(\alpha-1)(k-1)}$. □

The proof of Theorem 3.22, giving an upper bound on Worst-Fit's competitive ratio, can be extended to prove an upper bound on Worst-Fit's accommodating function.

THEOREM 3.29. *For Worst-Fit, if* $1 \leq \alpha \leq 1 + \frac{1}{n}\lceil \frac{(n-1)(k-n)+(n-1)}{k} \rceil$ *and* $k \geq n$, *then* $\mathcal{A}_{WF}(\alpha) \leq \frac{3-\frac{2}{n}}{3-\frac{3}{n}+(\alpha-1)k(1-\frac{1}{k-n+1})}$.

Proof. In the proof of Theorem 3.22, since all of the items in the first three phases of the request sequence fit in n bins, to determine how many bins would be necessary for an optimal off-line algorithm one needs only to compute how many bins are necessary for phase 4. Thus, $\alpha = 1 + \frac{1}{n}\lceil \frac{(n-1)(k-n)+(n-1)}{k} \rceil$. Hence, for any value of α less than this, replacing phase 4 by $(\alpha-1)kn$ items of size 1 gives an α-sequence for which Worst-Fit will accept exactly those requests in the first three phases, while OPT can accept all items, except some of the items from phase 3. The number of items from phase 3 which OPT can accept is $\lfloor \frac{kn-((n-1)(n-1)+n-1+(\alpha-1)kn)}{k-(n-1)} \rfloor = \lfloor \frac{n(k-n+1)-(\alpha-1)kn}{k-n+1} \rfloor$. Thus, the accommodating function is

$$\begin{aligned} \mathcal{A}_{\mathrm{WF}}(\alpha) &\leq \frac{3n-2}{2n-2+(\alpha-1)kn+n-\lfloor \frac{(\alpha-1)kn}{k-n+1} \rfloor} \\ &\leq \frac{3-\frac{2}{n}}{3-\frac{3}{n}+(\alpha-1)k(1-\frac{1}{k-n+1})}. \end{aligned}$$ □

4. The unit price seat reservation problem. The competitive ratio on accommodating sequences was introduced in [9][3] in connection with the seat reservation problem, which was originally motivated by some ticketing systems for trains in Europe. The setup is as follows: A train with n seats travels from a start station to an end station, stopping at $k \geq 2$ stations, including the first and last. Reservations can be made for any trip from a station s to a station t. The passenger is given a single seat number when the ticket is purchased, which can be any time before departure. The algorithms (ticket agents) attempt to maximize income; i.e., the sum of the prices of the tickets sold. For political reasons, the problem must be solved in a *fair* manner, i.e., the ticket agent may not refuse a passenger if it is possible to accommodate him when he attempts to make his reservation. In this paper, we consider only the pricing policy in which all tickets have the same price, the *unit price problem*; for the proportional price problem, where the price of the ticket is proportional to the distance traveled, there does not appear to be any significant difference between the competitive ratio and the competitive ratio on accommodating sequences. We define the accommodating function $\mathcal{A}(\alpha)$ for the seat reservation problem to be the ratio of how well an on-line algorithm can do compared to the optimal off-line algorithm, OPT, when an optimal off-line algorithm could have accommodated all requests if it would have had $\alpha n \geq n$ seats. The accommodating function could help the management in determining how much benefit could be gained by adding an extra car to the train, given their current distribution of request sequences. Notice that the fairness criterion is a part of the problem specification. Thus, even though the optimal off-line algorithm knows the entire sequence in advance, it too must process the sequence in the given order and do so fairly.

The seat reservation problem is similar to the problem of coloring an interval graph on-line, which has been well studied because of applications to dynamic storage allocation. The difference is that with graph coloring, all vertices must be given a color and the goal is to minimize the number of colors. With the seat reservation problem, there is a fixed number of colors, and the goal is to maximize the number of vertices that get colors. We use, however, an interesting result from interval graph theory: Interval graphs are *perfect* [20], so the size of the largest clique is exactly the number of colors needed. Thus, when there is no pair of stations $(s, s+1)$ such that the number of people who want to be on the train between stations s and $s+1$ is greater than n, the optimal off-line algorithm will be able to accommodate all requests. The contrapositive is also clearly true; if there is a pair of stations such that the number of people who want to be on the train between those stations is greater than n, the optimal off-line algorithm will be unable to accommodate all requests. We will refer to the number of people who want to be on the train between two stations as the *density* between those stations.

4.1. Bounds on the accommodating function. In [9], the following lower bounds for the competitive ratio and the competitive ratio on accommodating sequences were proven: Any algorithm for the unit price seat reservation problem is $\frac{2}{k}$-competitive, and any algorithm for the unit price seat reservation problem is $\frac{1}{2}$-competitive on accommodating sequences. The key idea for the proof of the theorem bounding the competitive ratio on accommodating sequences is also used to prove a lower bound on the accommodating function, and the result generalizes the one for the competitive ratio on accommodating sequences.

[3] It was called the accommodating ratio there.

THEOREM 4.1. *$\mathcal{A}(\alpha) \geq \frac{1}{2+(k-2)(1-\frac{1}{\alpha})}$ is a lower bound for the unit price seat reservation problem.*

Proof. Consider any algorithm $\mathbb{A}$ for the unit price seat reservation problem and any request sequence, I, which an optimal off-line algorithm could have accommodated with $\rho(I) \geq n$ seats. Let $l = \rho(I) - n$, and suppose that $\mathbb{A}$ accepts h intervals. We first show that $\mathbb{A}$ rejects at most $h + l(k-1)$ intervals.

Let S denote the seating assignment found by the on-line algorithm, and let U be the set of unseated intervals. First, some of the intervals in U will be assigned to distinct intervals in S. Let S' be a seating assignment which is initialized to be the same as S, but which will be altered by the following process. Note that the only changes will be to increase the lengths of some intervals in S'.

First order the intervals in U by increasing left endpoint (starting station), breaking ties arbitrarily. Now process these intervals, one by one, in increasing order.

For a given interval $I \in U$, if there is no seat which is empty in S' from the point where the passenger wants to get on until at least the next station, leave I in U. Otherwise, find such a seat. Since $\mathbb{A}$ is fair and the interval I was rejected, the interval I could not be placed on that seat, so there must be a first (leftmost) interval J assigned to that seat in S' which overlaps the interval I. Assign the interval I to the interval J. Now remove I from U and replace J on this seat in S' by an interval K, which is as much of $I \cup J$ as will currently fit on that seat. Clearly, all of the intervals which are now seated in S' and all of the unseated intervals currently in U could be seated by an optimal algorithm on αn seats, since this operation cannot increase the density anywhere. This process can be repeated. The order of processing ensures that each interval $I \in U$ which gets assigned to an interval in S gets assigned to a distinct interval in S. Thus, after all of U has been processed, at most h intervals have been removed from it. For every interval I' remaining in U, the leftmost unit segment (the point where the passenger wants to get on until the next station) has density n in S', so there is now density at most l for that unit segment in U. The number of possible distinct leftmost segments in U is at most $k-1$, so the total number of leftmost segments remaining in U, and thus the total number of intervals in U, is at most $l(k-1)$. We have now shown that $\mathbb{A}$ rejects at most $h + l(k-1)$ intervals.

To compute a lower bound on the ratio of what $\mathbb{A}$ accepts to what OPT accepts, we need to have a lower bound on the number of intervals $\mathbb{A}$ accepts and an upper bound on the number of intervals OPT accepts. We may assume that there are no intervals in the request sequence which both $\mathbb{A}$ and OPT reject, since removing them from the sequence changes nothing. Since an optimal off-line algorithm could not have accommodated all of the requests with fewer than $\rho(I)$ seats, but OPT has only n seats, OPT must reject at least l intervals, and all of these must have been accepted by $\mathbb{A}$. Clearly, the first n intervals in the request sequence must have been accepted by both $\mathbb{A}$ and OPT. Thus, $\mathbb{A}$ accepts $h \geq n + l = \rho(n)$ intervals. Of the h intervals which $\mathbb{A}$ accepts, OPT rejects at least l of them. Additionally, there are at most $h + l(k-1)$ intervals which OPT accepts, but $\mathbb{A}$ does not. Thus, a lower bound on the accommodating function is $\mathcal{A}(\alpha) \geq \frac{h}{2h+l(k-1)-l} = \frac{1}{2+(k-2)\frac{l}{h}} \geq \frac{1}{2+(k-2)\frac{\rho(n)-n}{\rho(n)}} \geq \frac{1}{2+(k-2)(1-\frac{1}{\alpha})}$. ∎

In [9], the following upper bounds for the competitive ratio and the competitive ratio on accommodating sequences were proven: No deterministic algorithm for the unit price seat reservation problem is more than $\frac{8}{k+5}$-competitive, and no deterministic algorithm for the unit price seat reservation problem is more than $\frac{8k-9}{10k-15}$-competitive

on accommodating sequences, when k is divisible by 3. The proof proving an upper bound on the accommodating function for any algorithm for Unit Price Bin Packing, is very similar to the proof of the theorem in [9] giving the upper bound on the competitive ratio. The result obtained is very close to that for the competitive ratio when $\alpha > \frac{5}{4}$.

THEOREM 4.2. $\mathcal{A}(\alpha) \leq \frac{4}{3+2(k-2)\min\{\frac{1}{4},\alpha-1\}}$ *is an upper bound for the unit price seat reservation problem.*

Proof. The following is an adversary argument, so the request sequence depends on the on-line algorithm $\mathbb{A}$'s behavior. Assume that n is divisible by 2. The adversary begins with $\frac{n}{2}$ pairs of requests for $[1,2]$ and $[k-1,k]$ intervals. Suppose that the algorithm $\mathbb{A}$ places them such that after these requests there are exactly q seats which contain two intervals. Then $n-2q$ of the seats have exactly one short interval scheduled. Next, the adversary will give q requests for $[1,k]$ intervals, followed by $\frac{n-2q}{2}$ requests for $[1,k-1]$ intervals, $\frac{n-2q}{2}$ requests for $[2,k]$ intervals, and q requests for $[2,k-1]$ intervals, all of which can be accommodated by $\mathbb{A}$. Now the train is full. One of two cases will occur:

Case 1. $q \geq \frac{n}{4}$.

Case 2. $q < \frac{n}{4}$.

If Case 1 occurs, the adversary will give $\min\{q, \alpha n - n\}$ requests for each of the intervals $[1,2]$, $[2,3]$, $[3,4]$, $\ldots$, $[k-1,k]$, none of which can be accommodated by $\mathbb{A}$. On the other hand, OPT could put each of the short intervals on a separate seat, so that it would be unable to accommodate the q $[1,k]$ intervals, but all of the other intervals would fit. The on-line algorithm $\mathbb{A}$ is able to accommodate $2n$ requests, while OPT can accommodate $2n - q + \min\{q, \alpha n - n\}(k-1)$ requests. Since $\frac{n}{4} \leq q \leq \frac{n}{2}$, this ratio is less than $\frac{2n}{2n-\frac{n}{2}+\min\{\frac{n}{4},\alpha n-n\}(k-1)} = \frac{4}{3+2(k-1)\min\{\frac{1}{4},\frac{\alpha n-n}{n}\}}$.

If Case 2 occurs, the adversary will give $\min\{\frac{n-2q}{2}, \alpha n - n\}$ requests for each of the intervals $[2,3]$, $[3,4]$, $\ldots$, $[k-1,k]$, none of which can be accommodated by $\mathbb{A}$. On the other hand, OPT could pair up the short intervals, putting two per seat, so that it would be unable to accommodate the $\frac{n-2q}{2}$ $[2,k]$ intervals, but all of the other intervals would fit. The on-line algorithm $\mathbb{A}$ is able to accommodate $2n$ requests, while OPT can accommodate $2n - \frac{n-2q}{2} + (k-2)\min\{\frac{n-2q}{2}, \alpha n - n\}$ requests. Since $q < n/4$, this ratio is less than $\frac{2n}{2n-\frac{n}{4}+(k-2)\min\{\frac{n}{4},\alpha n-n\}} = \frac{8}{7+4(k-2)\min\{\frac{1}{4},\frac{\alpha n-n}{n}\}}$.

This argument assumes that $k \geq 4$, but the result also clearly holds for $k = 2$ and $k = 3$. □

As an example of a specific on-line algorithm, one might consider First-Fit, which always processes a new request by placing it on the first seat which is unoccupied for the length of that journey. The lower bound from Theorem 4.1, on the accommodating function for any algorithm, clearly applies to this specific algorithm. It also applies to Best-Fit, which always processes a new request by placing it on a seat so it leaves as little total free space as possible on that seat immediately before and after that passenger's trip. The following result, giving an upper bound on the accommodating function for these two specific algorithms, should be compared with the results in [9], which give upper bounds for the competitive ratio and the competitive ratio on accommodating sequences for First-Fit and Best-Fit: First-Fit and Best-Fit have competitive ratios which are no better than $\frac{2-\frac{1}{k-1}}{k-1}$ and competitive ratios on accommodating sequences no better than $\frac{k}{2k-6}$ for the unit price seat reservation problem. The proof is very similar to the proof of the theorem in [9] which gives the upper bound on the competitive ratios for First-Fit and Best-Fit.

THEOREM 4.3. *For the unit price seat reservation problem, First-Fit and Best-Fit have* $\mathcal{A}(\alpha) \leq \max\{\frac{2-\frac{1}{k-1}}{k-1}, \frac{2-\frac{1}{k-1}}{1+(k-1)(\alpha-1)}\}$.

Proof. We will state everything in terms of the First-Fit algorithm, but Best-Fit would behave exactly the same. We will assume that n is divisible by $k-1$. The request sequence will start with $\frac{n}{k-1}$ requests for each of the intervals $[1,2],[2,3],[3,4],\ldots,[k-1,k]$ which First-Fit will put in the first $\frac{n}{k-1}$ seats. Then there will be $n-\frac{n}{k-1}$ requests for $[1,k]$ intervals, which First-Fit will put in the remaining seats. At this point, the train will be full, but there will now be $\min\{n-\frac{n}{k-1}, \alpha n - n\}$ requests for each of the intervals $[1,2],[2,3],[3,4],\ldots,[k-1,k]$, all of which First-Fit will be unable to accommodate. It will accommodate a total of $2n-\frac{n}{k-1}$ requests. OPT will put each of the original first intervals on a different seat, thus arranging that it can reject the longest intervals. Then, it will be able to accommodate all of the additional short intervals. Thus, it will accommodate n of the original short intervals, plus $\min\{n-\frac{n}{k-1}, \alpha n - n\}(k-1)$ of the later short intervals. This gives a ratio of $\max\{\frac{2-\frac{1}{k-1}}{k-1}, \frac{2-\frac{1}{k-1}}{1+\frac{\alpha n-n}{n}(k-1)}\}$. This argument assumes that $k \geq 3$, but the result trivially holds for $k = 2$ too. □

5. Other problems. It is natural to ask if the accommodating function can be defined for any on-line problem. This is equivalent to asking if α-sequences can be defined for every on-line problem. The answer is clearly "yes" if there is no requirement that a relevant resource be considered; then the accommodating function is constant, and its value is the competitive ratio. This answer is not particularly interesting. It seems, however, that for most on-line problems, there is some relevant resource which can be used to define α-sequences and therefore also the accommodating function. For paging, the obvious resource is the number of pages in fast memory; for scheduling, it is the number of machines available; and for server problems, it is the number of servers.

Unfortunately, for some on-line problems, using the accommodating function with the obvious resource choice and $\alpha \geq 1$ fails to result in additional insight compared with what is already known from the competitive ratio. For example, one of the best known on-line problems is paging. The well-known lower bound results, which show that any deterministic on-line algorithm has a competitive ratio of at least k, where k is the number of pages in main memory, holds even if there are only $k+1$ pages in all. Thus, nothing further is said about how much it helps to have extra memory, unless one actually has enough extra memory to hold all of a program and its data. In fact, however, it was shown later [8] that the accommodating function for the paging problem becomes more interesting when $\alpha < 1$.

The situation is similar when considering the accommodating function for problems which generalize the paging problem, such as the k-server problem and metrical task systems.

5.1. Minimizing flow times on *m* identical machines. As an example of a very different type of problem where the accommodating function can be applied, we have considered a scheduling problem: the problem of minimizing flow time in a situation where there are m identical machines and preemption is allowed. Let J be the sequence of jobs. A job $j \in J$ arrives at its release time r_j, and its processing time p_j is known. The total flow time is $\sum_{j\in J}(C_j - r_j)$, where C_j denotes the completion time of job j. There are some very nice results in [27] showing that shortest remaining processing time (SRPT) has a competitive ratio of $O(\log P)$ for this problem, where

P is the ratio between the processing time for the longest job and the shortest job. They also show that any randomized algorithm for the problem has a competitive ratio of $\Omega(\log P)$.

The concept of an accommodating function can be applied to this problem, even though it is a minimization problem and no rejections are allowed. Given a request sequence J, there is an absolute minimum flow time—the sum s of the processing times for all jobs in J. Thus, one can define the competitive ratio on accommodating sequences by restricting the request sequences to those which OPT could schedule with total flow time s. This means that all jobs can be scheduled immediately when they arrive. Thus, any on-line algorithm which assigns an incoming job to some free processor, when such a processor exists, will also schedule that sequence with total flow time s, giving a competitive ratio on accommodating sequences of 1, which is significantly different from the competitive ratio. The accommodating function $\mathcal{A}(\alpha)$ can be defined by restricting the request sequences to those in which an optimal off-line algorithm could have begun each job immediately upon arrival if it had $\alpha m \geq m$ machines available.

Using the techniques from the result in [27], proving a lower bound on the competitive ratio for SRPT, and lengthening the adversary's sequence appropriately gives a lower bound of $\Omega(\log_m P)$ on the performance ratio of SRPT, even when OPT could have handled the request sequence with only $m+1$ processors. Thus, SRPT's behavior is similar to that of all paging algorithms; restricting to sequences which OPT could accommodate with only one extra unit of the resource gives essentially the same result as allowing any sequence whatsoever. It is also possible to show that all other algorithms for this problem also have a sudden change from the competitive ratio on accommodating sequences to the competitive ratio.

Although some of the ideas from the $\Omega(\log P)$ lower bound on the competitive ratio in [27] are used in the proof here, their adversary uses sequences with $\alpha = \frac{3}{2}$, while our adversary only needs $\alpha m = m + 1$.

THEOREM 5.1. *For $\alpha m = m + 1$ and $m > 4$, the performance ratio of any deterministic on-line algorithm is $\Omega(\log_m P)$.*

Proof. Consider a deterministic on-line algorithm $\mathbb{A}$ and assume P is a power of m. An adversary can give a request sequence consisting of $L = \lfloor \log_m P - 1 - \log_m 4 - 2\log_m \log_m P \rfloor$ phases. For phase $i = 0, \ldots, L-1$, let $p_i = \frac{P}{m^i}$, and $r_i = m * \sum_{j=0}^{i-1} p_j$. The adversary will repeat the same set of jobs m times. Let j denote the repetition number, and let $r_{ij} = r_i + j * p_i, j = 0, \ldots, m-1$. The following jobs are given:

1. One job of size p_i at time r_{ij};
2. m unit size jobs at each of the times $r_{ij} + k, k = 0, \ldots, p_i(1 - \frac{1}{m}) - 1$.

Let S_{ij} denote the set of all unit size jobs given in phase i and repetition j, and let U_{ij} count the number of jobs from S_{ij} that are not finished by $\mathbb{A}$ before time $w_{ij} = r_{ij} + p_i(1 - \frac{1}{m})$.

There are two cases depending on the U_{ij}.

Case 1. There exist i, j, such that $U_{ij} \geq m \log_m P$.

Case 2. For all $i, j, U_{ij} < m \log_m P$.

If Case 1 occurs for i_0, j_0, the above release pattern is stopped at time $w_{i_0 j_0}$. Instead, the adversary gives m unit size jobs at each of the next P^3 time units.

An off-line algorithm OPT could finish all jobs from one repetition before the next starts by processing the long job on one machine and the unit size jobs on the other machines. Beginning with phase i_0 and repetition j_0, OPT should process all unit size jobs, including the unit size jobs given after $w_{i_0 j_0}$, immediately when they

are released. Then OPT has only one long unfinished job at time $w_{i_0 j_0}$, which will be delayed for time P^3.

The total flow time for OPT is then at most $m^2P^2 \log P + (m+1)P^3 + P$, since from the first part there are less than $m^2 P \log P$ jobs, which will be delayed for at most P time.

Since Case 1 has occurred, the on-line algorithm has at least $m \log_m P$ jobs delayed at every time unit for P^3 time steps. The total flow time for the on-line algorithm is then more than $mP^3 \log_m P$.

In Case 1, the performance ratio is then more than $\frac{mP^3 \log_m P}{m^2P^2 \log P + (m+1)P^3 + P}$.

If Case 2 occurs, an off-line algorithm, OPT, can follow a pattern similar to Case 1 and finish every job from phase i before phase $i+1$ starts. Call the time just after the last phase ends r_L. Starting at time r_L, the adversary gives m unit size jobs at each of the next P^3 time units. OPT can process them immediately upon arrival.

In this case, OPT has a total flow time of less than $m^2P^2 \log P + mP^3$.

The on-line algorithm $\mathbb{A}$ will have many long jobs hanging at time r_L. Fixing a phase i, we want to calculate the possible processing time for long jobs in this and the following phases. In phase i, the long jobs appear one at a time, so in repetition j there are $j+1$ available. After time w_{ij} there are $\frac{P}{m^{i+1}}$ time units remaining in repetition j, and since this is Case 2, there is a total of less than $m \log_m P$ time units available on all the processors together before time w_{ij}. Thus, the maximum amount of time the m long jobs from phase i can be processed within phase i is in total bounded by $\sum_{j=1}^{m}(j\frac{P}{m^{i+1}} + m \log_m P)$. For the following phases the total time available for processing these m jobs from phase i is bounded by $\sum_{j=i+1}^{L-1}(m\frac{P}{m^{(j+1)}} + m^2 \log_m P)$. This adds up to at most $2m^2 \log_m^2 P + \frac{p_i}{m}\frac{m(m+1)}{2} + p_i \leq p_i \frac{m+2}{2} + p_i$, since by the definition of L, $2m^2 \log_m^2 P \leq \frac{p_i}{2}$ for all i. It follows that for a fixed phase i, at most $\lfloor \frac{m+4}{2} \rfloor$ of the long jobs could be run to completion. Since we have L phases, at least $\lceil \frac{m-4}{2} L \rceil$ long jobs are unfinished at time r_L. This gives a flow time of at least $\frac{m-4}{2} P^3 \log_m P$.

In Case 2, the performance ratio is at least $\frac{\frac{m-4}{2} P^3 \log_m P}{m^2P^2 \log P + mP^3}$. □

The difference between this lower bound and the lower bound on the competitive ratio from [27] is quite small: $\Omega(\log_m P)$ versus $\Omega(\log_2 P)$, i.e., for any fixed m, the bounds are the same.

6. Concluding remarks. It is now clear that in comparing on-line algorithms, the competitive ratio on accommodating sequences can give different information than the competitive ratio. This is true for Fair Bin Packing and two algorithms investigated in this paper, but these results also indicate that the competitive ratio on accommodating sequences and the accommodating function could be very useful measures generally.

With respect to Fair Bin Packing, the choice as to which algorithm to use depends on which ratio is more relevant in a specific situation. This, in turn, would depend on the actual distribution of request sequences. However, one might guess that the competitive ratio on accommodating sequences actually gives the more useful answer in most cases, since the sequences which cause First-Fit to perform so poorly with respect to the competitive ratio are in some sense rather artificial. The sequences are designed so that OPT can arrange to reject certain "difficult" requests but continue to be "fair." This may simply be a blatant example of how some unusual request sequences can cause the competitive ratio to be excessively pessimistic.

We believe that there is a broad range of on-line problems for which analysis using the competitive ratio on accommodating sequences and the accommodating function will give interesting insights. More of these problems should be investigated. In particular, an open problem left here is finding a minimization problem which has a more gradual change from the competitive ratio on accommodating sequences to the competitive ratio.

In this paper, the accommodating function was only investigated for $\alpha \geq 1$. It was natural to use this restriction, since it spans from the competitive ratio on accommodating sequences to the standard competitive ratio, the two known interesting points. It has later been discovered [8] that the accommodating function is also interesting for $\alpha < 1$. There appear to be more problems which have interesting accommodating functions if one considers $\alpha < 1$, further distinctions can be made between known algorithms, and new interesting algorithms can be developed.

Two of the upper bounds proven in this paper have since been improved. The upper bound on First-Fit's competitive ratio on accommodating sequences for Fair Bin Packing has been improved to $\frac{5}{8}$ [1]. Thus, we can conclude that the competitive ratio of First-Fit on accommodating sequences is exactly $\frac{5}{8}$. In addition, it has been shown [3] that for any deterministic algorithm for the fair unit price seat reservation problem with three seats, the competitive ratio on accommodating sequences is at most $\frac{1}{2} + \frac{3}{k+5}$, where $k \geq 7$ and $k \equiv 1 \pmod 6$. This gives an upper bound of $\frac{1}{2} + \frac{3n-3}{2k+6n-(8+2c)}$ for n seats with the same restrictions on k.

Recently, the restriction of input sequences has proven useful in another context, congestion control on the Internet [24], where the competitive ratio is a function of this restriction. It does not appear that the functions in [24] can be viewed as accommodating functions.

Acknowledgments. We would like to thank the referees for their careful reading of the paper and their helpful suggestions for improvements.

GENERATING BRACELETS IN CONSTANT AMORTIZED TIME*

JOE SAWADA†

Abstract. A bracelet is the lexicographically smallest element in an equivalence class of strings under string rotation and reversal. We present a fast, simple, recursive algorithm for generating (i.e., listing) k-ary bracelets. Using simple bounding techniques, we prove that the algorithm is optimal in the sense that the running time is proportional to the number of bracelets produced. This is an improvement by a factor of n (where n is the length of the bracelets being generated) over the fastest, previously known algorithm to generate bracelets.

1. Introduction.

The rapid growth in the fields of combinatorial chemistry and computational biology is resulting in an increased demand for efficient algorithms which produce exhaustive lists of combinatorial objects [1]. Dan Gusfield (see [9, p. xv]) claims that "significant contributions to computational biology might be made by extending or adapting [string] algorithms from computer science, even when the original algorithm has no clear utility in biology." In particular, correspondences between DNA sequences and restricted classes of circular strings are described in [3].

Within the mathematical sciences, researchers are constantly trying to find patterns hidden in the structure of combinatorial objects. The growing trend of using computers and algorithms to produce lists of such objects is allowing researchers to obtain more information about the objects themselves. Often, this will lead to a more thorough understanding of an object which may lead to new and interesting discoveries. In some cases, algorithms which produce exhaustive lists can be used to prove the existence of a related object [12].

An important consideration for any algorithm is its running time. For generation algorithms, the ultimate performance goal is an algorithm with computation proportional to the number of objects generated (where the computation reflects the total amount of change to the data structures, and not the time required to print out the object). Such algorithms are said to be CAT, for constant amortized time.

Strings with equivalence under rotation is one of the most fundamental types of combinatorial objects. Such objects, more commonly known as necklaces, arise naturally in many areas including knot theory, color printing, DNA sequencing, and the theory of free Lie algebras. Algorithms for generating necklaces and Lyndon words (aperiodic necklaces) were first developed by Fredricksen and Kessler [6] and Fredricksen and Maiorana [7]. These algorithms were proven to be CAT by Ruskey, Savage, and Wang [11].

Many applications, however, do not require all necklaces, but instead only those satisfying a particular restriction. A recursive necklace generation algorithm outlined in [2] has led to several algorithms which efficiently generate restricted classes of

necklaces including binary unlabeled necklaces [2], fixed density necklaces [12], and necklaces with forbidden substrings [13].

Another restricted class of necklaces are bracelets. More specifically, bracelets are necklaces with equivalence under string reversal. Lists of bracelets are shown to have application in the calibration of color printers by Emmel [5]. However, the problem of efficiently generating these lists has remained open for some time. Previously, the fastest known algorithm to generate bracelets was a modification of Savage and Wang's necklace algorithm [11] by Lisonek [10]. This algorithm has running time $O(n \cdot B_k(n))$ (where $B_k(n)$ denotes the number of k-ary bracelets of length n), which is the same as the second algorithm outlined in the beginning of section 3.

The problem of efficiently generating bracelets is answered in this paper with the development of a bracelet generation algorithm that runs in constant amortized time. We begin with some background and definitions of the relevant objects in section 2. In section 3, we outline our bracelet generation algorithm. In section 4, we discuss strings with no 0^i substring (forbidden substrings). These strings are then used when we analyze our bracelet generation algorithm in section 5.

2. Background. We define a *necklace* to be the lexicographically smallest element of an equivalence class of k-ary strings under rotation. The set of all necklaces of length n is denoted $\mathbf{N}_k(n)$. The cardinality of $\mathbf{N}_k(n)$ is denoted $N_k(n)$. An aperiodic necklace is called a *Lyndon word*. The set of all k-ary Lyndon words of length n is denoted $\mathbf{L}_k(n)$ and has cardinality $L_k(n)$. A word α is called a *prenecklace* if it is the prefix of some necklace. The set of all k-ary prenecklaces of length n is denoted $\mathbf{P}_k(n)$. The cardinality of $\mathbf{P}_k(n)$ is denoted $P_k(n)$.

A *bracelet* is the lexicographically smallest element of an equivalence class of k-ary strings under string rotation and reversal (or a necklace that is also lexicographically minimal among the circular rotations of its reversal). The set of all k-ary bracelets is denoted $\mathbf{B}_k(n)$ and has cardinality $B_k(n)$. In each equivalence class associated with a given bracelet, there exists at most two necklaces: the bracelet itself and the necklace corresponding to the reversal of the bracelet. (In some cases, the two may be the same.) For example, the equivalence class that contains the bracelet 00112012 also contains the necklace 00210211.

Necklaces, Lyndon words, and prenecklaces can all be generated using the recursive necklace generation algorithm GenNecklaces(t, p) shown in Figure 2.1. It is important to have a solid understanding of this algorithm because it will be the basis for the bracelet generation algorithm developed in the following section. The basic idea behind the algorithm is to generate all length n prenecklaces, and then perform an appropriate test in the function PrintIt(p) to obtain the desired object. If necklaces are required, then the prenecklace is printed only if p divides n; if Lyndon words are required, then the prenecklace is printed if $n = p$. If $\alpha = a_1 \cdots a_{t-1}$ is a prenecklace with its longest Lyndon prefix having length p, then a length t prenecklace can be obtained by appending any value greater than or equal to a_{t-p} to α. The initial call is GenNecklaces(1,1) and a_0 is initialized to 0.

The following theorem provides enumeration formulas for necklaces, Lyndon words, prenecklaces, and bracelets.

THEOREM 2.1. *The following formulas are valid for all $n \geq 1$, $k \geq 1$:*

$$L_k(n) = \frac{1}{n} \sum_{d|n} \mu(d) k^{n/d}, \tag{2.1}$$

```
procedure GenNecklaces ( t, p : integer );
local j : integer;
begin
    if t > n then PrintIt( p )
    else begin
        a_t := a_{t-p};
        GenNecklaces( t + 1, p );
        for j ∈ {a_{t-p} + 1, ..., k - 2, k - 1} do begin
            a_t := j;
            GenNecklaces( t + 1, t );
end; end; end;
```

FIG. 2.1. *The recursive necklace algorithm.*

$$N_k(n) = \frac{1}{n}\sum_{d|n}\phi(d)k^{n/d}, \tag{2.2}$$

$$P_k(n) = \sum_{i=1}^{n} L_k(i), \tag{2.3}$$

$$B_k(n) = \begin{cases} \frac{1}{2}(N_k(n) + \frac{k+1}{2}k^{n/2}), & n \text{ even,} \\ \\ \frac{1}{2}(N_k(n) + k^{(n+1)/2}), & n \text{ odd.} \end{cases} \tag{2.4}$$

Proof. The equations for $L_k(n)$, $N_k(n)$, and $B_k(n)$ are proved by Gilbert and Riordan in [8]. The equation for $P_k(n)$ is proved in [2]. □

In the analysis of our bracelet algorithm it will be useful to look at another way to count prenecklaces. Let $P_k^0(n)$ count all k-ary prenecklaces of length n that begin with 0. Notice that the number of k-ary prenecklaces of length n beginning with 1 is equal to $P_{k-1}^0(n)$. Similarly the number of k-ary prenecklaces of length n beginning with 2 is $P_{k-2}^0(n)$. This observation leads to the following equation:

$$P_k(n) = \sum_{j=1}^{k} P_j^0(n). \tag{2.5}$$

3. Generating bracelets. In this section we outline a fast algorithm to generate bracelets. Since when $k = 1$, the only bracelet is 0^n, we assume $k \geq 2$. One algorithm for generating bracelets is to generate all k-ary necklaces of length n and then test each necklace against all rotations of its reversal. If no reversed rotation is less than the generated necklace, then the necklace is a bracelet. Since there are n rotations and each test takes $O(n)$ time, this naïve approach will give us an overall running time of $O(n^2 \cdot B_k(n))$ to generate all k-ary bracelets of length n.

A more sophisticated approach will use a necklace finding algorithm, which determines the necklace of a length n string in $O(n)$ time. Such an algorithm is easily derived from Duval's algorithm for factoring a string into Lyndon words [4] or from Theorem 2.1 in [2]. Using this technique, we need only compare the generated necklace with the necklace of its reversal. This approach yields a much better running time of $O(n \cdot B_k(n))$ to generate bracelets; however, it is still far from being CAT.

In the quest to find a faster algorithm to generate bracelets, we return to the original idea of comparing a generated necklace to every rotation of it reversal. We

start by making a simple observation.

OBSERVATION 1. *If a necklace α is of the form $a^i a_{i+1} \cdots a_n$ for some character $a \neq a_{i+1}$, then we need only test the reversed rotations that also begin with a^i.*

Taking this observation into account, we are making a large improvement on the number of reversed rotations we must check. For example, for the necklace 0010023003 we need only check the three reversed rotations that begin with 00: 0030032001, 0010030032, and 0032001003. To test each reversal we could wait until the entire necklace has been generated, but this will take $O(n)$ time per reversal and we will see no improvement over the naïve algorithms. Instead, if a character is generated in position j that satisfies the condition stated in Observation 1, we immediately compare the prenecklace $a_1 \cdots a_j$ with its reversal $a_j \cdots a_1$. This comparison will yield one of three outcomes. If $a_1 \cdots a_j > a_j \cdots a_1$, then we terminate the generation from this node since appending characters to the end of these strings will not affect their relative ordering. If $a_1 \cdots a_j < a_j \cdots a_1$, then no additional testing is required for this reversal. However, if $a_1 \cdots a_j = a_j \cdots a_1$, then more testing must be done on the tail of the strings which has yet to be generated.

Following the above approach, we still need to perform additional testing for the reversals starting at position j where $a_1 \cdots a_j = a_j \cdots a_1$. The number of such reversals could be as many as $n/2$. The following theorem addresses this issue.

THEOREM 3.1. *If $a_1 \cdots a_n$ is a necklace where $a_1 \cdots a_q = a_q \cdots a_1$ and there exists an r in $\{q+1, \ldots, n\}$ such that $a_1 \cdots a_r = a_r \cdots a_1$ and $a_{r+1} \cdots a_n \leq a_n \cdots a_{r+1}$, then $a_{q+1} \cdots a_n \leq a_n \cdots a_{q+1}$.*

Proof. Let $P_q = a_1 \cdots a_q$, $P_r = a_1 \cdots a_r$, $x = a_{q+1} \cdots a_r$, and $y = a_{r+1} \cdots a_n$. Let $\hat{x}$ and $\hat{y}$ denote the reversals of x and y, respectively. Since P_r and P_q are palindromes $P_r = P_q x = \hat{x} P_q$. Thus, $\alpha = P_q xy = \hat{x} P_q y$. But since α is a necklace, $\alpha = \hat{x} P_q y \leq P_q y \hat{x}$. Thus, since $y \leq \hat{y}$, $xy \leq y\hat{x} \leq \hat{y}\hat{x}$ as required. □

This theorem implies that we need only perform extra testing on the reversal starting at the largest position r such that $a_1 \cdots a_r = a_r \cdots a_1$. This extra testing is the comparison of $a_{r+1} \cdots a_n$ to $a_n \cdots a_{r+1}$. If $a_{r+1} \cdots a_n > a_n \cdots a_{r+1}$, then the generated string is *not* a bracelet. This test can be performed in constant time per character for each character generated after position $(n-r)/2 + r$.

Finally, we note that if $a_1 = a_n$, then the only strings that are bracelets (or necklaces) must be of the form a^n for some character a.

The following is a summary of the modifications required to transform GenNecklaces(t, p) into an algorithm which generates bracelets. Notice that each modification requires only a constant amount of computation per character generated except the addition of the function CheckRev(t, i).

- Add the parameter u to maintain the value of i from Observation 1: the number of consecutive equivalent characters at the start of the prenecklace (i.e., the prenecklace starts with a^u).
- Add the parameter v to maintain the number of consecutive a's at the end of the prenecklace, where $a = a_1$.
- Add the function CheckRev(t, i) to compare the prenecklace to its reversal (when $u = v$). If the prenecklace is greater than its reversal, it returns -1; if the prenecklace is less than its reversal, it returns 0; otherwise, the prenecklace is the same as its reversal and 1 is returned.
- Add the parameter r to maintain the length of the longest prenecklace equal to its reversal (i.e., the largest value r for which $a_1 \cdots a_r = a_r \cdots a_1$).
- Add a test to each character in a position greater than $(n-r)/2 + r$ which

```
function CheckRev( t, i: integer ) returns integer;
local j: integer;
begin
    for j from i + 1 to (t + 1)/2 do begin
        if a_j < a_{t-j+1} then return 0;
        if a_j > a_{t-j+1} then return -1;
    end;
    return 1;
end;

procedure GenBracelets( t, p, r, u, v: integer; RS: boolean );
local rev, i: integer;
begin
    if t − 1 > (n − r)/2 + r then begin
        if a_{t-1} > a_{n-t+2+r} then RS := FALSE;
        else if a_{t-1} < a_{n-t+2+r} then RS := TRUE;
    end;
    if t > n then begin
        if RS = FALSE and n mod p = 0 then PrintIt();
    end
    else begin
        a_t := a_{t-p};
        if a_t = a_1 then v := v + 1;
        else v := 0;
        if u = t − 1 and a_{t-1} = a_1 then  u := u + 1;
        if t = n and u ≠ n and a_n = a_1 then begin end;
        else if u = v then begin
            rev := CheckRev( t, u );
            if rev = 0 then GenBracelets( t + 1, p, r, u, v, RS );
            if rev = 1 then GenBracelets( t + 1, p, t, u, v, FALSE );
        end;
        else GenBracelets(t + 1, p, r, u, v, RS );
        if u = t then u := u − 1;
        for j ∈ {a_{t-p} + 1, . . . , k − 1} do begin
            a_t := j;
            if t = 1 then GenBracelets( t + 1, t, r, 1, 1, RS )
            else GenBracelets( t + 1, t, r, u, 0, RS );
end; end; end;
```

FIG. 3.1. *Bracelet generation algorithm.*

will determine whether or not $a_r \cdots a_n$ is greater than its reversal. This will involve the additional parameter RS to hold intermediate boolean values indicating whether or not the reversal is smaller (RS).

- Reject the string if $a_1 = a_n$ and the string is not equal to a^n (i.e., $t = n$ and $u \neq n$).

The resulting algorithm GenBracelets(t, p, r, u, v, RS) is shown in Figure 3.1. The initial call is GenBracelets(1,1,0,0,0,FALSE). To illustrate this algorithm we trace the parameters as the string 0010023003 gets generated:

α	-	0	0	1	0	0	2	3	0	0	3
t	1	2	3	4	5	6	7	8	9	10	11
p	1	1	1	3	3	3	6	7	7	7	10
r	0	1	2	2	2	5	5	5	5	5	5
u	0	1	2	2	2	2	2	2	2	2	2
v	0	1	2	0	1	2	0	0	1	2	0
RS	F	F	F	F	F	F	F	F	F	F	T

In the following section we give several counting results for strings with no 0^i substring. These results will then be applied when we analyze the algorithm, showing that it runs in constant amortized time.

4. Forbidden substrings. We denote the set of all k-ary strings of length n with no 0^i substring by $\mathbf{I}_k(n,i)$. The cardinality of this set, denoted $I_k(n,i)$, is given by the following recurrence relation:

$$I_k(n,i) = \begin{cases} k^n & \text{if } 0 \leq n < i, \\ (k-1)\sum_{j=1}^{i} I_k(n-j,i) & \text{if } n \geq i\ . \end{cases}$$

It is easy to verify the correctness of this formula. If $n < i$, then the set $\mathbf{I}_k(n,i)$ will contain all k-ary strings. Otherwise, we categorize the strings in $\mathbf{I}_k(n,i)$ by the number of consecutive 0's found at the tail of each string. Since there are $k-1$ choices for the character appearing before this string of 0's, we arrive at the given recurrence relation.

We obtain another recurrence relation by considering a string $\alpha = a_1 \cdots a_{n-1}$ in the set $\mathbf{I}_k(n-1,i)$. If we append a character a_n to α, then the string $a_1 \cdots a_n$ is in $\mathbf{I}_k(n,i)$ as long as $a_{n-i+1} \cdots a_n \neq 0^i$. The number of strings where $a_{n-i+1} \cdots a_n = 0^i$ is exactly equal to $I_k(n-i,i)$. Thus we arrive at a second recurrence relation:

$$I_k(n,i) = \begin{cases} k^n & \text{if } 0 \leq n < i, \\ kI_k(n-1,i) - (k-1)I_k(n-i-1,i) & \text{if } n \geq i\ . \end{cases}$$

LEMMA 4.1. *If $k, i \geq 2$, then*

$$I_k(n,i) \geq \sum_{j=1}^{n-2} I_k(j,i).$$

Proof. The base cases when $n \leq i$ are trivial. If $n > i$, then we induct on n:

$$\begin{aligned} I_k(n,i) &\geq I_k(n-1,i) + I_k(n-2,i) \\ &\geq \sum_{j=1}^{n-3} I_k(j,i) + I_k(n-2,i) \\ &= \sum_{j=1}^{n-2} I_k(j,i). \end{aligned}$$ □

LEMMA 4.2. *If $n > 2$ and $k, i \geq 2$, then*

$$\frac{I_k(n,i)}{n} \geq \frac{I_k(n-1,i)}{n-1}.$$

Proof.

$$\begin{aligned}(n-1)I_k(n,i) &= k(n-1)I_k(n-1,i) - (k-1)(n-1)I_k(n-i-1,i)\\ &\geq nI_k(n-1,i) + (kn-n-k)I_k(n-1,i) - (k-1)(n-1)I_k(n-3,i)\\ &\geq nI_k(n-1,i) + 2(kn-n-k)I_k(n-3,i) - (kn-n-k+1)I_k(n-3,i)\\ &= nI_k(n-1,i) + (kn-n-k-1)I_k(n-3,i)\\ &\geq nI_k(n-1,i). \qquad \square\end{aligned}$$

We now prove a theorem that will be used in the analysis of our bracelet generation algorithm. The proof of the theorem uses the previous two lemmas.

THEOREM 4.3. *If $n > 2$ and $k, i \geq 2$, then*

$$\sum_{j=1}^{n} \frac{1}{j} I_k(j,i) \leq \frac{8}{n} I_k(n,i).$$

Proof.

$$\begin{aligned}\sum_{j=1}^{n} \frac{1}{j} I_k(j,i) &\leq 2 \sum_{j=\lceil n/2 \rceil}^{n} \frac{1}{j} I_k(j,i)\\ &\leq \frac{2}{n} I_k(n,i) + \frac{2}{n-1} I_k(n-1,i) + 2 \sum_{j=\lceil n/2 \rceil}^{n-2} \frac{1}{j} I_k(j,i)\\ &\leq \frac{4}{n} I_k(n,i) + \frac{4}{n} \sum_{j=\lceil n/2 \rceil}^{n-2} I_k(j,i)\\ &\leq \frac{8}{n} I_k(n,i). \qquad \square\end{aligned}$$

5. Analysis of the algorithm. In this section we show that the algorithm GenBracelets for generating bracelets is CAT. We analyze the algorithm by looking at the computation tree and determining the amount of computation done at each node. To get a bound on the size of the bracelet computation tree, we observe the following bounds obtained from (2.1) and (2.2) along with Lemma 4.4 from [12]:

$$L_k(n) \leq \frac{k^n}{n} \leq N_k(n) \leq 2\frac{k^n}{n}.$$

Now using (2.4) we get the following bounds on the number of bracelets:

$$\frac{k^n}{2n} \leq B_k(n) \leq 2\frac{k^n}{n}. \tag{5.1}$$

Since the necklace algorithm GenNecklaces is CAT [2], the size of its computation tree is less than ck^n/n for some constant c. This bound is also true for GenBracelets since its computation tree is smaller than that of GenNecklaces. However, unlike the necklace computation tree, the bracelet computation tree has some nodes that require more than a constant amount of computation. From our algorithm, these nodes are the ones that make a call to CheckRev. Thus, to prove the bracelet generation algorithm GenBracelets is CAT, we must show that the computation performed by all calls to CheckRev is bounded by some constant times the total number of bracelets generated. The task of analyzing this extra computation is divided into the following four subsections.

5.1. Identifying the prenecklaces. From the algorithm, each node that makes a call to CheckRev is a prenecklace of the form a^i or $a^i\gamma a^i$ where the nonempty string γ begins and ends with a character lexicographically greater than a. Note that the length of such prenecklaces is at most $n-1$. Each call to CheckRev results in computation proportional to $(t-2i)/2$, where t is the length of the prenecklace. Since any prenecklace of the form a^i requires only constant computation in CheckRev (because $t=i$), we can restrict our attention to prenecklaces of the form $a^i\gamma a^i$. To simplify this task we consider only the prenecklaces beginning with 0, later using (2.5) to account for the remaining prenecklaces. We also ignore the fact that many of these prenecklaces are never generated by the algorithm (i.e., the prenecklace 002100300 is never generated since the prenecklace 002100 is terminal).

The next series of observations are crucial to the success of the analysis. Notice that the number of prenecklaces of the form $0^i\gamma 0^i$ is less than or equal to the number of prenecklaces of the form $0^i\gamma$. We now group these prenecklaces together according to length. Such strings will have length of at least 2, but not greater than $n-2$. Define the set of all k-ary prenecklaces of length n beginning with 0, ending with a nonzero character, and with no 0^i substring to be $\mathbf{P}'_k(n,i)$. Equivalently, the set $\mathbf{P}'_k(n,i)$ contains all prenecklaces with length n of the form $0^j\gamma$ for $1 \le j < i$. The cardinality of this set is denoted as $P'_k(n,i)$. If we let $E_k(n)$ denote the extra computation that results from all calls made to CheckRev by prenecklaces beginning with 0 (while generating $\mathbf{B}_k(n)$), then we obtain the following bound:

$$E_k(n) \le \sum_{i=2}^{n-2} \frac{n-i}{2} P'_k(n-i,i). \tag{5.2}$$

5.2. Bounding the restricted prenecklaces. In this subsection we find an upper bound for $P'_k(n,i)$ first using restricted Lyndon words, and then in terms of strings with forbidden substrings. Because every prenecklace is obtained as a prefix of a β^* where β is some Lyndon word, we arrive at the formula given in (2.3):

$$P_k(n) = \sum_{j=1}^{n} L_k(j).$$

If we let $L_k(j,i)$ denote the number of Lyndon words of length j with no 0^i substring, then we obtain the following upper bound for $P'_k(n,i)$:

$$P'_k(n,i) \le \sum_{j=1}^{n} L_k(j,i). \tag{5.3}$$

Recall that the number of k-ary strings of length n with no 0^i substring is denoted by $I_k(n,i)$. Using these strings we obtain an upper bound for $L_k(n,i)$.

LEMMA 5.1. *If $n \ge 1$ and $i \ge 1$, then*

$$L_k(n,i) \le \frac{1}{n} I_k(n,i).$$

Proof. Each string counted by $L_k(n,i)$ is a representative of an equivalence class of strings each with n elements. If we add up the elements from each equivalence class we get $nL_k(n,i)$ unique strings each of length n with no 0^i substring. The expression $I_k(n,i)$ counts the total number of strings with length n and no 0^i substring. Therefore $L_k(n,i) \le \frac{1}{n} I_k(n,i)$. ∎

Using the previous lemma and Theorem 4.3 ($n > 2$) we can simplify the upper bound in (5.3). Note that the latter bound is also satisfied when $n = 2$.

$$\begin{aligned} P'_k(n,i) &\le \sum_{j=1}^{n} \frac{1}{j} I_k(j,i) \\ &\le \frac{8}{n} I_k(n,i). \end{aligned}$$

5.3. Converting back to prenecklaces. Using the bound discovered in the previous subsection, we can now substitute back into (5.2) and simplify:

$$\begin{aligned} E_k(n) &\le \sum_{i=2}^{n-2} \frac{n-i}{2} P'_k(n-i,i) \\ &\le 4 \sum_{i=2}^{n-2} I_k(n-i,i). \end{aligned}$$

We now use a clever trick to bound this sum in terms of prenecklaces. Observe that we can insert 0^i1 at the front of each string in $\mathbf{I}_k(n-i,i)$ to obtain a new a set of strings of length $n+1$. Notice that each new string is a unique prenecklace regardless of the parameter i. Thus the number of strings in the union of the sets $\mathbf{I}_k(n-i,i)$ for $i = 2, \ldots, n-1$ is less than $P_k(n+1)$. We can divide this total by $k-1$, since we could have arbitrarily chosen any of $k-1$ characters to insert after 0^i. Thus

$$\begin{aligned} E_k(n) &\le \frac{4}{k-1} P_k(n+1) \\ &\le \frac{4k}{k-1} P_k(n) \\ &\le 8 \sum_{j=1}^{n} L_k(j) \\ &\le 8 \sum_{j=1}^{n} \frac{k^j}{j} \\ &\le 24 \frac{k^n}{n}. \end{aligned} \tag{5.4}$$

The simplification found in (5.4) is valid for $k \ge 2$ and can easily be proved by induction.

5.4. Accounting for all prenecklaces. Because the bound on $E_k(n)$ is only for prenecklaces beginning with 0, we use (2.5) to get an upper bound on the extra computation performed by all prenecklaces. Note that $E_1(n) = 0$.

$$\begin{aligned} ExtraWork &\le \sum_{j=2}^{k} E_j(n) \\ &\le \frac{24}{n} \sum_{j=2}^{k} j^n \\ &\le 48 \frac{k^n}{n}. \end{aligned}$$

From (5.1), the total number of bracelets generated is bounded below by $k^n/2n$. Thus, the running time of the algorithm GenBracelets is proportional to the number of bracelets generated, which proves the following theorem.

THEOREM 5.2. *The k-ary bracelet generation algorithm GenBracelets is CAT.*

Experimentally, the constant is less than 8 where we compare the number of calls to GenBracelets plus the number of iterations of the for loop in CheckRev to the number of bracelets generated.

Acknowledgments. The author would like to thank Frank Ruskey for many helpful discussions in all aspects of this paper, as well as the anonymous referee who suggested a simpler proof for Theorem 3.1.

DISJUNCTIONS OF HORN THEORIES AND THEIR CORES*

THOMAS EITER†, TOSHIHIDE IBARAKI‡, AND KAZUHISA MAKINO§

Abstract. In this paper, we study issues on disjunctions of propositional Horn theories. In particular, we consider the problems of deciding whether a disjunction of Horn theories is Horn, and, if not, computing a Horn core (i.e., a maximal Horn theory included in this disjunction) and the Horn envelope (i.e., the minimum Horn theory including the disjunction), where a Horn core and the Horn envelope are important approximations of the original theory in artificial intelligence. The problems are investigated for two different representations of Horn theories, namely, for Horn conjunctive normal forms (CNFs) and characteristic models. While the problems are shown to be intractable in general, in the case of bounded disjunctions, we present polynomial time algorithms for testing the Horn property in both representations and for computing a Horn core in the CNF representation. Even in the case of bounded disjunction, no polynomial algorithm exists (unless P=NP) for computing a Horn core in the characteristic model representation. Computing the Horn envelope is polynomial in the characteristic model representation, while it is exponential in the CNF representation, even for bounded disjunction.

1. Introduction.

Since deduction from a set of propositional clauses is a well-known co-NP-complete problem, different approximation methods for reasoning from a clausal theory Σ have been investigated (e.g., [21, 22, 19, 20, 4, 5, 1]). One of these approaches [21, 22] uses a *greatest Horn lower bound* (also called *Horn core* [15]), which is a maximal Horn theory $\Sigma_c \subseteq \Sigma$, if we view theories as sets of models, and the *least Horn upper bound* (*Horn envelope* [15]), which is the minimal Horn theory $\Sigma_e \supseteq \Sigma$ such that Σ logically implies Σ_e. Note that, in general, different Horn cores may exist, while it is known that the Horn envelope is always unique (e.g., [21, 22, 15]).

Computing Horn envelopes and Horn cores has been investigated in [21, 22, 15, 2, 3, 4, 5, 10, 7, 1]. It has been shown that a Horn core of a theory Σ, represented by a given conjunctive normal form (CNF) φ, is computable in polynomial time with an oracle for NP [2, 3], and that all Horn cores can be generated with polynomial delay (i.e., the time between consecutive outputs is bounded by a polynomial in the input size, and the first (resp., last) output also occurs in polynomial time after (resp., before) the start (resp., halt) of the algorithm) if the theory Σ is given by the set of

its models. However, in the latter setting, computing a maximum (in terms of the numbers of models) Horn core is co-NP-hard [15].

In this paper, we consider the issue of computing Horn cores of the disjunction $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$ of Horn theories Σ_i represented either by Horn CNFs or by their *characteristic models* [13]. Characteristic models have been proposed as a model-based alternative to the formula-based theory representation. These two approaches are orthogonal with respect to space requirements, in the sense that one approach sometimes allows for an exponentially smaller representation than the other; see [14, 17]. Observe that a disjunction Σ of Horn theories is in general not Horn. Hence, in particular, it is of interest to know whether Σ is Horn, since in this case the Horn core and the Horn envelope coincide with Σ.

Disjunctions of Horn theories may be encountered in different applications. For example, suppose that two groups have, respectively, formed logical hypotheses about an application domain (the "world"), e.g., relationships between medical tests and diseases, and they believe that the relationships amount to a Horn theory. The hypotheses Σ_1 and Σ_2 of two groups (which are the sets of models) may be obtained from actual and conjectured cases, respectively, i.e., concrete measurement data (obtained by experiments) and data which are believed to be true. Suppose that the hypotheses Σ_1 and Σ_2 are merged. Then, at the logic level, the disjunction, i.e., union $\Sigma = \Sigma_1 \cup \Sigma_2$ describes the merged hypotheses. It is of particular interest to know whether Σ is Horn; if so, then the original hypotheses are compatible in the sense that no further cases have to be adopted in order to preserve the Horn property, which may indicate that the individual hypotheses are sound. However, if Σ is not Horn, then either further cases have to be added to maintain the Horn property (which corresponds to the logical consequence of the new case knowledge), or some of the adopted hypothetical cases have to be abandoned. Applying Occam's razor, it is natural to add or to abandon a minimal set of cases. In the former case, this amounts to finding the Horn envelope of Σ, and in the latter case, to finding a Horn core Π of Σ. In finding a Horn core Π, it may also be asked to add such a constraint because Π includes all actual cases Σ_1. That is, computing a Horn core Π satisfying $\Sigma_1 \subseteq \Pi \subseteq \Sigma$ can be seen as one of the important problems.

Another application concerns inference from knowledge bases. Suppose that Horn theories $\Sigma_1, \Sigma_2, \ldots, \Sigma_l$ represent knowledge bases which are located at different sites $s_1, s_2, \ldots, s_l$, respectively. A formula φ is a logical consequence of all Σ_i, for $i = 1, 2, \ldots, l$, only if φ is a logical consequence of the disjunction $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$. Thus, in order to test whether φ is a consequence in all Σ_i, it is equivalent to test whether φ is a consequence of Σ. This may be profitably used if the on-line access to the theories Σ_i at the individual sites is for instance, costly or unreliable. If Σ is stored at a distinguished site s^*, then by accessing this single site the query φ to all knowledge bases can be answered. In the case where Σ is Horn, we can store a Horn CNF (resp., the characteristic set) of Σ, which can be more compact than simply mirroring the disjunction of Horn CNFs (resp., the characteristic sets) of the individual Horn theories Σ_i at s^*, since redundancies can be avoided. For example, if each Σ_i is represented by a Horn CNF $\varphi_i = \psi \wedge (x \vee \overline{y}_i)$, for $i = 1, 2, \ldots, l$, then the Horn CNF $\varphi = \psi \wedge (x \vee \overline{y}_1 \vee \overline{y}_2 \vee \cdots \vee \overline{y}_l)$ represents the disjunction $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$. Note that, in this case, storing the individual φ_i requires more than l times space compared to φ.

In this paper, we first address the problem of checking if a disjunction $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$ of Horn theories Σ_i, represented either by Horn CNFs or by their characteristic models, is a Horn theory. We show that the problem is in general co-NP-complete for both

representations but is polynomially solvable if l is bounded by a constant. These results indicate that computing a Horn core is difficult in general. The polynomiality follows from syntactical and semantical characterizations of a disjunction of Horn theories.

We next deal with the problem of computing a Horn core Π of Σ satisfying $\Sigma_1 \subseteq \Pi \subseteq \Sigma$. We show that, if l is bounded by some constant, then the problem is polynomially solvable for Horn CNFs, while it is co-NP-hard for the representation by characteristic models, even if $l = 2$. For the formula-based representations, we first present a polynomial time algorithm CORE to compute a Horn core of the disjunction of two Horn theories Σ_1 and Σ_2. Since the algorithm CORE cannot be generalized directly to the case $l\,(\geq 3)$, we develop an algorithm CORE* which computes a Horn core of the disjunction of $l\,(\geq 3)$ Horn theories by making use of algorithm CORE repeatedly. It turns out that algorithm CORE* runs in polynomial time if l is bounded by some constant. On the other hand, we show that computing a Horn core in polynomial time is not possible for the representation by characteristic models, by exhibiting a family of theories Σ_1 and Σ_2 having small characteristic sets, while every Horn core of $\Sigma_1 \cup \Sigma_2$ is exponentially large. We also give structural characterizations of Horn cores of a disjunction of Horn theories.

As for the Horn envelope, we show that it can be computed for the representation by characteristic models in polynomial time but cannot be efficiently computed for Horn CNFs, even if $l = 2$. The negative result follows from the fact that there exist Horn theories Σ_1 and Σ_2 such that their Horn CNFs are small, but the CNF representing the Horn envelope of $\Sigma = \Sigma_1 \cup \Sigma_2$ is exponentially large.

The rest of this paper is organized as follows. In the next section, we recall some basic concepts and introduce notations. In sections 3 and 4, we consider Horn cores for formula-based and model-based representations, respectively. Section 5 considers the Horn envelope. Finally, section 6 discusses related work and concludes the paper. The complexity results of all the above problems are summarized in Table 1 of section 6.

2. Preliminaries. We assume a supply of propositional variables (atoms) x_1, $x_2, \ldots, x_n$, where each x_i evaluates to either 1 (true) or 0 (false). Negated variables are denoted by $\overline{x}_i$. These x_i and $\overline{x}_i$ are called literals. A clause is a disjunction $c = L_1 \vee \cdots \vee L_k$ of literals, while a term is a conjunction $t = L_1 \wedge \cdots \wedge L_h$ of literals. By $P(c)$ and $N(c)$ (resp., $P(t)$ and $N(t)$), we denote the sets of variables occurring positively and negatively in c (resp., t). By $\bot$ (resp.,$\top$) we denote the empty clause (resp., empty term) representing falsity (resp., truth). A formula is composed of literals and the following operators: or ($\vee$), and ($\wedge$), negation ($^-$). In particular, a conjunction of clauses $\varphi = \bigwedge_i c_i$ (resp., a disjunction of terms $\varphi = \bigvee_i t_i$) is called *conjunctive normal form* (CNF) (resp., *disjunctive normal form* (DNF)).

A *model* is a vector $v \in \{0,1\}^n$, whose ith component is denoted by v_i, and a *theory* is any set $\Sigma \subseteq \{0,1\}^n$ of models. We denote by $v \leq w$ the usual componentwise ordering of models, i.e., $v_i \leq w_i$ for all $i = 1, 2, \ldots, n$, where $0 < 1$. By $\min(\Sigma)$ and $\max(\Sigma)$ we denote the sets of minimal and maximal models in Σ under $<$, respectively, where $v \in \Sigma$ is a *maximal* (resp., *minimal*) model in Σ, if there is no $w \in \Sigma$ such that $w > v$ (resp., $w < v$). For $B \subseteq \{1, 2, \ldots, n\}$, we denote by x^B the model v such that $v_i = 1$ for $i \in B$ and $v_i = 0$ for $i \notin B$.

For any formula φ, let $T(\varphi) = \{v \in \{0,1\}^n \mid \varphi(v) = 1\}$ denote the set of models of φ. We say that a formula φ represents a theory Σ if $T(\varphi) = \Sigma$. We sometimes do not distinguish a formula from the theory it represents if no confusion arises. For any formulas φ and ψ, we write $\varphi \leq \psi$ (also $\varphi \models \psi$) if $T(\varphi) \subseteq T(\psi)$ holds. A clause c is

called an *implicate* of a theory Σ if $c(v) = 1$ for all $v \in \Sigma$ (i.e., $T(c) \supseteq \Sigma$); it is *prime* if no proper subclause is an implicate of Σ. Similarly, a term t is called an *implicant* of a theory Σ if $t(v) = 0$ for all $v \notin \Sigma$ (i.e., $T(t) \subseteq \Sigma$)); it is *prime* if no proper subterm is an implicant of Σ.

A theory Σ is *Horn* if $\Sigma = Cl_\wedge(\Sigma)$ holds, where $Cl_\wedge(S)$ is the closure of a theory $S \subseteq \{0,1\}^n$ under componentwise AND (i.e., intersection) of models v, w, denoted by $v \bigwedge w$. Observe that any Horn theory Σ has the least (unique smallest) model, denoted $lm(\Sigma)$, which is given by $\bigwedge_{v\in\Sigma} v$.

A clause c is *Horn* if $|P(c)| \leq 1$, and a CNF φ is *Horn* if it contains only Horn clauses. It is well known that a theory Σ is Horn if and only if it is represented by some Horn CNF (e.g., [18]) and that all prime implicates of a Horn theory are Horn (e.g., [11]). If φ is a Horn CNF and c is any clause, then it is known that $\varphi \leq c$ can be checked in linear time (cf. [6]).

A Horn theory Σ_c is a *Horn core* of a theory Σ if $\Sigma_c \subseteq \Sigma$ holds and no Horn theory Σ' exists such that $\Sigma_c \subset \Sigma' \subseteq \Sigma$. Observe that, in general, Σ has more than one Horn core; e.g., $\Sigma = \{(110), (101)\}$ has two Horn cores $\Sigma_c^1 = \{(110)\}$ and $\Sigma_c^2 = \{(101)\}$. The *Horn envelope* of Σ is the Horn theory $\Sigma_e \supseteq \Sigma$ for which no Horn theory Σ' satisfies $\Sigma_e \supset \Sigma' \supseteq \Sigma$. For the above Σ, we have $\Sigma_e = \{(110), (101), (100)\}$. As is easily seen, the Horn envelope is always unique (cf., e.g., [21, 22, 15]). Let φ be a formula representing a theory Σ, and let φ_c and φ_e be formulas representing a Horn core and the Horn envelope of Σ, respectively. Then φ_c and φ_e are also called a *Horn core* and the *Horn envelope* of φ, respectively.

3. CNF representations. In this section, we deal with the case in which each Horn theory is represented by a Horn CNF.

3.1. Horn property of a disjunction of Horn theories. Our first result deals with the Horn property for a disjunction of Horn CNFs.

THEOREM 3.1. *Given Horn CNFs $\varphi_1, \varphi_2, \ldots, \varphi_l$, deciding whether $\varphi = \bigvee_{i=1}^{l} \varphi_i$ is Horn is* co-NP*-complete.*

Proof. The problem is in co-NP, since we can guess and verify models v and w of φ such that $v \bigwedge w$ is not a model of φ in polynomial time.

For the hardness part, we reduce the problem of checking whether a DNF $\psi = \bigvee_{i=1}^{m} t_i$ is a tautology (which is known to be co-NP-complete) to our problem. Note that each t_i can be seen as a Horn CNF φ_i. Let x_{n+1} and x_{n+2} be two fresh variables, and let $t_{m+1} = x_{n+1}$ and $t_{m+2} = x_{n+2}$. Then we claim that $\varphi = \psi \vee t_{m+1} \vee t_{m+2}$ $(= \bigvee_{i=1}^{m+2} t_i)$ is Horn if and only if $\psi \equiv \top$ (and hence $\varphi \equiv \top$). The if-direction is obvious.

For the only-if-direction, suppose $\psi \not\equiv \top$. Then there exists a (nontautological) prime implicate c of ψ. It is then easy to see that $c' = c \vee x_{n+1} \vee x_{n+2}$ is a prime implicate of φ. Since c' is not Horn and all prime implicates of a Horn theory are Horn, it follows that no Horn CNF is equivalent to φ. This proves the result. □

Observe that the reduction proof of the above theorem makes use of an unbounded number of Horn theories. For the case in which l is bounded by some constant k, we have a positive result.

Let

$$\varphi_i = \bigwedge_{j=1}^{m_i} c_{i,j}, \quad i = 1, 2, \ldots, l,$$

where $c_{i,j}$ are Horn clauses. Then it can be easily seen that $\varphi = \bigvee_{i=1}^{l} \varphi_i$ is equivalent

to the CNF

$$\varphi' = \bigwedge_{i_1=1}^{m_1} \bigwedge_{i_2=1}^{m_2} \cdots \bigwedge_{i_l=1}^{m_l} (c_{1,i_1} \vee c_{2,i_2} \vee \cdots \vee c_{l,i_l}). \tag{3.1}$$

We now introduce the following set.

$HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$: the set of all Horn clauses c defined by $N(c) = \bigcup_{i=1}^{l} N(c_{i,j_i})$ and $P(c) = P(c_{i,j_i})$ for some i, where all the choices of $j_i \in \{1, 2, \ldots, m_i\}$ for $i = 1, 2, \ldots, l$ are considered under the constraint that the disjunction $c_{1,j_1} \vee c_{2,j_2} \vee \cdots \vee c_{l,j_l}$ of the selected clauses is not a tautology.

Namely, any Horn clause c in $HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$ can be constructed by choosing one clause c_{i,j_i} from each φ_i and then by disjuncting all negative literals in $c' = (c_{1,i_1} \vee c_{2,i_2} \vee \cdots \vee c_{l,i_l})$ and a positive literal in c' (more precisely, if some c_{i,j_i} contains no positive literal, then c might have no positive literal). Note that $HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$ contains all maximal Horn clauses c with $c \leq c'$ for each nontautological clause $c' = (c_{1,i_1} \vee c_{2,i_2} \vee \cdots \vee c_{l,i_l})$ in φ' of (3.1).

Example 3.2. Let

$$\varphi_1 = (\overline{x}_1 \vee \overline{x}_3 \vee x_4)(\overline{x}_2 \vee \overline{x}_5 \vee x_6),$$
$$\varphi_2 = (\overline{x}_1 \vee \overline{x}_2 \vee x_3)(\overline{x}_1 \vee \overline{x}_3 \vee x_6).$$

Then

$$\varphi' = (\overline{x}_1 \vee \overline{x}_3 \vee x_4 \vee x_6)(\overline{x}_1 \vee \overline{x}_2 \vee x_3 \vee \overline{x}_5 \vee x_6)(\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee \overline{x}_5 \vee x_6),$$

where tautological clauses are eliminated. The set HC is given as follows:

$$HC(\varphi_1, \varphi_2) = \{(\overline{x}_1 \vee \overline{x}_3 \vee x_4), (\overline{x}_1 \vee \overline{x}_3 \vee x_6), (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_5 \vee x_6),$$
$$(\overline{x}_1 \vee \overline{x}_2 \vee x_3 \vee \overline{x}_5), (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee \overline{x}_5 \vee x_6)\}.$$

The following lemma relates a disjunction of Horn CNFs with clauses from $HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$.

LEMMA 3.3. *Let $\varphi_1, \varphi_2, \ldots, \varphi_l$ be Horn CNFs, and let $\varphi = \bigvee_{i=1}^{l} \varphi_i$. Then φ represents a Horn theory if and only if there exists an $S \subseteq HC(\varphi_1, \varphi_2, \ldots.\varphi_l)$ such that $\varphi \equiv \bigwedge_{c \in S} c$.*

Proof. The if-part is obvious because all clauses $c \in HC(\varphi_1, \varphi_2, \ldots.\varphi_l)$ are Horn. For the only-if-part, let φ represent a Horn theory Σ. Recall that φ is equivalent to the CNF φ' of (3.1). Since this φ' also represents the Horn theory Σ and all prime implicates of a Horn theory are Horn, for each nontautological clause $c' = (c_{1,i_1} \vee c_{2,i_2} \vee \cdots \vee c_{l,i_l})$ in φ', there exists a Horn prime implicate c of Σ satisfying $\varphi' \leq c \leq c'$. Since $HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$ contains all maximal Horn clauses c^* with $c^* \leq c'$, some clause c^* in $HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$ satisfies

$$\varphi' (\equiv \varphi) \ \leq \ c \ \leq c^* \ \leq \ c'.$$

Thus, replacing each c' in φ' by such a c^* again produces Σ, which implies the only-if-part. □

THEOREM 3.4. *If l is bounded by a constant k, the problem in Theorem* 3.1 *can be solved in polynomial time.*

Proof. By Lemma 3.3, for each clause c' in φ' of (3.1), we find only a clause c^* in $HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$ such that $\varphi \leq c^* \leq c'$. If every c' has such a c^*, we can conclude that φ is Horn; otherwise, we can conclude that φ is not Horn.

As for the time complexity, since $\varphi \leq c^*$ is equivalent to the condition that $\varphi_i \leq c^*$ holds for all i, and since each φ_i is Horn, $\varphi \leq c^*$ can be checked in polynomial time. Furthermore, if l is bounded by a constant, we have at most a polynomial number of c' and c^*. Thus, the overall time is polynomial. □

3.2. Horn cores of a disjunction of Horn theories. Let us now consider the problem of computing a Horn core. The following proposition, together with Theorem 3.1, implies that this is a difficult problem if l is not bounded by some constant k. In particular, a polynomial time computation of some Horn core is infeasible, as well as the enumeration of Horn cores. As for enumeration problems, we measure their complexity in the combined size of input and output. An algorithm is called of *polynomial total time* (also called *output polynomial*) [12] if its running time is polynomial in the length of input and output.

COROLLARY 3.5. *Unless* P=NP*, there is no polynomial total time algorithm which, given Horn CNFs $\varphi_1, \varphi_2, \ldots, \varphi_l$, computes all Horn cores, or any given number $k \geq 1$ of Horn cores, of $\varphi = \bigvee_{i=1}^{l} \varphi_i$.*

Proof. Let us assume that there is a polynomial total time algorithm A for generating all Horn cores (resp., k Horn cores) of φ with polynomial running time $p(I, O)$, where I is the input length and O is the output length. Now in order to solve the tautology problem in polynomial time, we apply this algorithm A to the instance which is used to prove Theorem 3.1. Recall that, in this case, φ is Horn if and only if $\psi \equiv \varphi \equiv \top$. Let us execute A until either (i) it halts or (ii) time $p(I, 1)$ is reached, where the length of $\top$ is considered to be 1, and if A computes k Horn cores the number k is set to 1. In the case of (i), if A outputs exactly one Horn CNF $\top$, then output "Yes"; otherwise, "No." In the case of (ii), output "No," since it implies that the output length is more than 1. Therefore, the tautology problem can be solved in polynomial time, implying P=NP. □

PROPOSITION 3.6. *A theory Σ has a unique Horn core if and only if Σ is Horn.*

Proof. The if-direction is trivial. For the only-if-direction, let Π be an arbitrary Horn core of Σ, and let $v \in \Sigma \setminus \Pi$. Since theory $\{v\}$ is Horn, there exists a Horn core Π' such that $v \in \Pi'$, for which $\Pi' \neq \Pi$ holds. □

COROLLARY 3.7. *Given Horn CNFs φ_1, φ_2, ..., φ_l, deciding whether $\varphi = \bigvee_{i=1}^{l} \varphi_i$ has a unique Horn core is* co-NP*-complete.*

These are rather negative results. However, the proofs do not apply in the case of the disjunction of a small (bounded by a constant) number of Horn theories, as will be seen in the next subsection.

3.2.1. Horn cores of a disjunction of two Horn theories. In this subsection, we describe a polynomial time algorithm which computes a Horn core of the disjunction of two Horn theories. We start with the following lemma showing that any Horn core of a disjunction of Horn CNFs can be represented by a Horn CNF consisting of some clauses from $HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$. This is a generalization of the only-if-part of Lemma 3.3.

LEMMA 3.8. *Let $\varphi_1, \varphi_2, \ldots, \varphi_l$ be Horn CNFs, and let ψ be any Horn core of $\varphi = \bigvee_{i=1}^{l} \varphi_i$. Then $\psi \equiv \bigwedge_{c \in S} c$ holds for some subset $S \subseteq HC(\varphi_1, \varphi_2, \ldots . \varphi_l)$.*

Proof. Recall that φ is equivalent to the CNF φ' of (3.1) (which may not be Horn). Since ψ is a Horn core of φ, each nontautological clause c' in φ' is subsumed by some prime Horn implicate c of ψ (i.e., $c \leq c'$). Recall that $HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$ is

the set of all the maximal Horn clauses subsuming at least one of the clauses in φ'. From the maximality of the clauses in $HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$, therefore, we have a clause $c^* \in HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$ such that $c \le c^* \le c'$. Let ψ^* be the CNF obtained from φ' by replacing each c' by such a c^*. Then $\psi \le \psi^* \le \varphi' (\equiv \varphi)$ holds. Since ψ is a Horn core of φ, it then follows that $\psi \equiv \psi^*$. □

Note that the converse is not true in general; that is, not all Horn CNFs $\psi = \bigwedge_{c \in S} c$, where $S \subseteq HC(\varphi_1, \varphi_2, \ldots.\varphi_l)$, represent Horn cores of φ, even if ψ is a CNF obtained from φ' by replacing each nontautological clause c' in φ' by a clause $c^* \in HC(\varphi_1, \varphi_2, \ldots, \varphi_l)$ with $c^* \le c'$. The following example gives such an instance.

Example 3.9. Let φ_1 and φ_2 be given in Example 3.2. Then φ' of (3.1) is written as

$$\varphi' = (\overline{x}_1 \vee \overline{x}_3 \vee x_4 \vee x_6)(\overline{x}_1 \vee \overline{x}_2 \vee x_3 \vee \overline{x}_5 \vee x_6)(\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee \overline{x}_5 \vee x_6),$$

where we exclude the tautological clauses from φ'. Let us consider a Horn CNF

$$\psi = (\overline{x}_1 \vee \overline{x}_3 \vee x_4)(\overline{x}_1 \vee \overline{x}_2 \vee x_3 \vee \overline{x}_5)(\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee \overline{x}_5 \vee x_6).$$

Note that all clauses in ψ are contained in $HC(\varphi_1, \varphi_2)$ (see Example 3.2), and that this ψ is obtained from φ' in the desired way, because $(\overline{x}_1 \vee \overline{x}_3 \vee x_4) \le (\overline{x}_1 \vee \overline{x}_3 \vee x_4 \vee x_6)$, $(\overline{x}_1 \vee \overline{x}_2 \vee x_3 \vee \overline{x}_5) \le (\overline{x}_1 \vee \overline{x}_2 \vee x_3 \vee \overline{x}_5 \vee x_6)$, and $(\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee \overline{x}_5 \vee x_6) \le (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee \overline{x}_5 \vee x_6)$. However, this ψ is not a Horn core of $\varphi = \varphi_1 \vee \varphi_2$, since

$$\psi' = (\overline{x}_1 \vee \overline{x}_3 \vee x_4)(\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_5 \vee x_6)(\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee \overline{x}_5 \vee x_6) \tag{3.2}$$

satisfies $\psi < \psi' \le \varphi' (\equiv \varphi)$. In fact, $\psi \le \psi'$ follows from $\psi \le (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_5 \vee x_6)$, and this combined with $\psi(110111) = 0$ and $\psi'(110111) = 1$ implies $\psi < \psi'$. As will be shown later, ψ' of (3.2) is a Horn core of φ.

Now we give an algorithm that obtains a Horn core of the disjunction of two Horn theories.

ALGORITHM CORE
Input: Horn CNFs $\varphi_1 = \bigwedge_{i=1}^{m_1} c_{1,i}$ and $\varphi_2 = \bigwedge_{j=1}^{m_2} c_{2,j}$.
Output: A Horn core ψ of $\varphi = \varphi_1 \vee \varphi_2$.

Step 1. Set $S := \{c^*_{i,j} = c_{1,i} \vee c_{2,j} \mid c^*_{i,j} \not\equiv \top,\ i = 1, 2, \ldots, m_1,\ j = 1, 2, \ldots, m_2\}$ and

$S_2 := \{c \in S \mid |P(c)| = 2\}$.

For each $c^*_{i,j} \in S$, let $c^1_{i,j}$ (resp., $c^2_{i,j}$) denote the Horn clause c such that

$N(c) = N(c^*_{i,j})$ and $P(c) = P(c_{1,i})$ (resp., $P(c) = P(c_{2,j})$).

(Observe that $HC(\varphi_1, \varphi_2)$ is the set of all clauses $c^1_{i,j}$ and $c^2_{i,j}$.)

Step 2. $S_a := S \setminus S_2$; $S_b := S_2$;

for each $c^*_{i,j} \in S_2$ **do**

if $\varphi_1 \le c^1_{i,j}$ and $\varphi_2 \le c^1_{i,j}$ **then**

begin $S_a := S_a \cup \{c^1_{i,j}\}$; $S_b := S_b \setminus \{c^*_{i,j}\}$ **end**

elseif $\varphi_1 \le c^2_{i,j}$ and $\varphi_2 \le c^2_{i,j}$ **then**

begin $S_a := S_a \cup \{c^2_{i,j}\}$; $S_b := S_b \setminus \{c^*_{i,j}\}$ **end**;

Step 3. Output $\psi := \bigwedge_{c \in S_a} c \wedge \bigwedge_{c^*_{i,j} \in S_b} c^1_{i,j}$.

Example 3.10. Let us apply algorithm CORE to Horn CNFs φ_1 and φ_2 given in Example 3.2. In Step 1, we have $S = \{(\overline{x}_1 \vee \overline{x}_3 \vee x_4 \vee x_6), (\overline{x}_1 \vee \overline{x}_2 \vee x_3 \vee \overline{x}_5 \vee x_6), (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee \overline{x}_5 \vee x_6)\}$ and $S_2 = \{(\overline{x}_1 \vee \overline{x}_3 \vee x_4 \vee x_6), (\overline{x}_1 \vee \overline{x}_2 \vee x_3 \vee \overline{x}_5 \vee x_6)\}$. A clause

$c^*_{2,1} = (\overline{x}_1 \vee \overline{x}_2 \vee x_3 \vee \overline{x}_5 \vee x_6)$ satisfies the if-statement of Step 2 (i.e., $\varphi_1 \leq c^1_{2,1}$ and $\varphi_2 \leq c^1_{2,1}$ holds for $c^1_{2,1} = (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_5 \vee x_6)$); any other clause in S_2 satisfies neither the if- nor the elseif-statement. Thus, Step 3 outputs the Horn CNF of (3.2).

This algorithm runs in polynomial time. Indeed, both implication tests in Step 2 are done in linear time since φ_1 and φ_2 are Horn (cf. [6]), and all other steps are clearly polynomial.

THEOREM 3.11. *Let φ_1 and φ_2 be Horn CNFs. Then, algorithm* CORE *computes a Horn core ψ of $\varphi = \varphi_1 \vee \varphi_2$ in polynomial time. Moreover, $\varphi_1 \leq \psi$ holds.*

Proof. Observe that

$$\varphi_1 \leq \psi \leq \varphi_1 \vee \varphi_2 \tag{3.3}$$

obviously holds. Indeed, each clause c in S_a of Step 3 is an implicate of φ_1, and each clause $c^1_{i,j} \in S_b$ is subsumed by some clause of φ_1; hence, the first implication holds. The second holds since $\varphi_1 \vee \varphi_2 \equiv \bigwedge_{c^*_{i,j} \in S} c^*_{ij}$ holds by definition, and each clause $c = c^*_{i,j}$ in $\varphi_1 \vee \varphi_2$ is subsumed by some clause in ψ.

We claim that this ψ is a Horn core. Towards a contradiction, suppose that there exists a Horn core ψ^* such that $\psi^* > \psi$. Then, $\psi^* \equiv \bigwedge_{c \in S_a} c \wedge \bigwedge_{c^*_{i,j} \in S_b} c^{h(i,j)}_{i,j}$ must hold for some $h(i,j) \in \{1,2\}$, where S_a and S_b are the ones in Step 3. (The proof is similar to that of Lemma 3.8.) Since $\psi < \psi^*$, it follows that $\psi \leq c^2_{i,j}$ must hold for some $c^*_{i,j} \in S_b$, and hence $\varphi_1 \leq c^2_{i,j}$ by (3.3). On the other hand, since $c^2_{i,j}$ is subsumed by some clause in φ_2, $\varphi_2 \leq c^2_{i,j}$ also holds. However, this means that the clause $c^*_{i,j}$ is removed from S_b in Step 2 and hence $c^*_{i,j} \notin S_b$ in Step 3, which is a contradiction. Consequently, ψ is maximal. □

An analysis of the algorithm CORE reveals that it bears no nondeterminism in computing a Horn core ψ that satisfies $\varphi_1 \leq \psi \leq \varphi_1 \vee \varphi_2$. This may indicate that a Horn core including φ_1 is unique. This is in fact the case.

PROPOSITION 3.12. *Let Σ_1 and Σ_2 be Horn theories, and let $\Sigma = \Sigma_1 \cup \Sigma_2$. Then, there exists a unique Horn core Π that satisfies $\Sigma_1 \subseteq \Pi \subseteq \Sigma$.*

Proof. We show that for any Horn theories Π_1 and Π_2 such that $\Sigma_1 \subseteq \Pi_1 \subseteq \Sigma$ and $\Sigma_1 \subseteq \Pi_2 \subseteq \Sigma$, it holds that $\Pi' = Cl_\wedge(\Pi_1 \cup \Pi_2)$ is Horn and satisfies $\Pi_1, \Pi_2 \subseteq \Pi' \subseteq \Sigma$; the uniqueness follows from this. Indeed, if Π_1 and Π_2 were different Horn cores of Σ such that $\Sigma_1 \subseteq \Pi_1 \subseteq \Sigma$ and $\Sigma_1 \subseteq \Pi_2 \subseteq \Sigma$, then $\Pi' = Cl_\wedge(\Pi_1 \cup \Pi_2)$ would be a Horn theory such that $\Pi_1, \Pi_2 \subset \Pi' \subseteq \Sigma$. This, however, contradicts that Π_1 and Π_2 are Horn cores of Σ.

Let $w \in \Pi' \setminus (\Pi_1 \cup \Pi_2)$, and we show that $w \in \Sigma$. Note that w is of the form $w = \bigwedge_{u \in S_1} u \wedge \bigwedge_{v \in S_2} v$, where $S_1 \subseteq \Pi_1$ and $S_2 \subseteq \Pi_2$. Since Π_1 and Π_2 are Horn, $u' = \bigwedge_{u \in S_1} u \in \Pi_1$, $v' = \bigwedge_{v \in S_2} v \in \Pi_2$, and $w = u' \bigwedge v'$. Since $\Pi_1, \Pi_2 \subseteq \Sigma_1 \cup \Sigma_2$, the following four cases may occur: (1) $u', v' \in \Sigma_1$, (2) $u', v' \in \Sigma_2$, (3) $u' \in \Sigma_1$, $v' \in \Sigma_2$, and (4) $u' \in \Sigma_2$, $v' \in \Sigma_1$. Clearly, $w = u' \wedge v' \in \Sigma$ holds for case (1) or (2). As for case (3), $u' \in \Pi_2$ holds by $\Sigma_1 \subseteq \Pi_2$. This implies that $u', v' \in \Pi_2$, and hence $w \in \Pi_2 \subseteq \Sigma$ holds. Case (4) is similar to (3). □

From Proposition 3.12, we call the two Horn cores Π_1 and Π_2 satisfying $\Sigma_1 \subseteq \Pi_1 \subseteq \Sigma_1 \cup \Sigma_2$ and $\Sigma_2 \subseteq \Pi_2 \subseteq \Sigma_1 \cup \Sigma_2$, respectively, the *canonical Horn cores* of Σ_1 and Σ_2 with respect to $\Sigma = \Sigma_1 \cup \Sigma_2$ and denote them by $can(\Sigma_1, \Sigma)$ and $can(\Sigma_2, \Sigma)$, respectively.

Observe that the generalization of Proposition 3.12 to a disjunction of k (≥ 3) Horn theories does not hold. To see this, consider $\Sigma = \Sigma_1 \cup \Sigma_2 \cup \Sigma_3$ and assume that $\Sigma_1 = \emptyset$ holds. Then, if Σ_1 had the unique Horn core Π such that $\Sigma_1 \subseteq \Pi \subseteq \Sigma$ (=

$\Sigma_2 \cup \Sigma_3$), then this Π would be the unique Horn core of $\Sigma_2 \cup \Sigma_3$. Clearly, this conflicts with Proposition 3.6.

Finally, we have the following structural result.

PROPOSITION 3.13. *Let $\Sigma_1, \Sigma_2, \ldots, \Sigma_l$ be Horn theories. Then $\Delta = \bigcap_{i=1}^{l} \Sigma_i$ is contained in every Horn core of $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$.*

Proof. Let Π be any Horn core of Σ. We show that $\Omega = Cl_\wedge(\Pi \cup \Delta)$ is contained in Σ; this completes the proof, since the maximality of Π then implies $\Delta \subseteq \Pi = \Omega$.

Take any model $w \in \Omega$. Since Π and Δ are Horn, we need only to consider the case of $w = u \bigwedge v$ for some $u \in \Pi$ and $v \in \Delta$. (The same reasoning is used in the proof of Proposition 3.12.) Now, $u \in \Sigma_i$ holds for some i. Since $v \in \Delta$ is also contained in this Σ_i and Σ_i is Horn, it holds that $w \in \Sigma_i$. Hence, $w \in \Sigma$ holds, implying $\Omega \subseteq \Sigma$. □

3.2.2. Horn cores of a disjunction of more than two Horn theories. In this subsection we develop an algorithm to compute a Horn core of a general disjunction of $\varphi = \varphi_0 \vee \varphi_1 \vee \varphi_2 \vee \cdots \vee \varphi_l$ of Horn CNFs φ_i. Let us first show that the direct generalization of algorithm CORE does not produce a Horn core for the case $l \geq 2$.

Example 3.14. Let

$$\begin{aligned}
\varphi_0 &= (\overline{x}_1 \vee \overline{x}_2 \vee x_4)(\overline{x}_2 \vee x_7)(\overline{x}_3 \vee x_5 \vee \overline{x}_7),\\
\varphi_1 &= (\overline{x}_3 \vee x_5),\\
\varphi_2 &= (\overline{x}_1 \vee \overline{x}_3 \vee x_6),
\end{aligned}$$

and let $\varphi = \varphi_0 \vee \varphi_1 \vee \varphi_2$. Then φ is equivalent to the CNF

$$\begin{aligned}
\varphi' = {} & (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee x_4 \vee x_5 \vee x_6)(\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee x_5 \vee x_6 \vee x_7)\\
& (\overline{x}_1 \vee \overline{x}_3 \vee x_5 \vee x_6 \vee \overline{x}_7).
\end{aligned} \tag{3.4}$$

Since no clause c^* in φ' satisfies $|P(c^*)| = 1$ in this case, the S_b in the beginning of Step 2 of the generalized algorithm CORE becomes the set of all clauses in φ' of (3.4). Thus, in Step 3, we have

$$\psi = (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee x_4)(\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee x_7)(\overline{x}_1 \vee \overline{x}_3 \vee x_5 \vee \overline{x}_7).$$

However, this ψ is not a Horn core of φ, since

$$\psi' = (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee x_5)(\overline{x}_1 \vee \overline{x}_3 \vee x_5 \vee \overline{x}_7)$$

satisfies $\psi < \psi' \leq \varphi' (\equiv \varphi)$. We will show in Example 3.16 that this ψ' is in fact a Horn core of φ.

However, by using algorithm CORE repeatedly, we can get an algorithm to compute a Horn core of $\varphi = \vee_{i=0}^{l} \varphi_i$. This algorithm is polynomial if l is bounded by a constant k. Informally, it constructs a sequence of nondecreasing Horn theories $\psi_0 \leq \psi_1 \leq \psi_2 \leq \cdots$ which is contained in φ. The sequence converges to ψ^*, which is a Horn core of φ.

Let $\varphi_0, \varphi_1, \ldots, \varphi_l$ be Horn CNFs, and let CORE(μ_1, μ_2) denote a Horn CNF of the canonical Horn core $can(\mu_1, \mu_1 \vee \mu_2)$. We now define the following sequence ψ_k, $k \geq 0$:

$$
\begin{aligned}
\psi_0 &= \varphi_0;\\
\psi_1 &= \mathrm{CORE}(\psi_0, \varphi_1);\\
\psi_2 &= \mathrm{CORE}(\psi_1, \varphi_2);\\
&\vdots \quad \vdots\\
\psi_l &= \mathrm{CORE}(\psi_{l-1}, \varphi_l);\\
&\vdots \quad \vdots\\
\psi_{i\cdot l+j} &= \mathrm{CORE}(\psi_{i\cdot l+j-1}, \varphi_j) \qquad (i \geq 0,\ 1 \leq j \leq l);\\
&\vdots \quad \vdots
\end{aligned}
$$

This sequence ψ_k is monotonically nondecreasing from φ_0 to

$$\psi^* = \lim_{k\to\infty} \psi_k, \tag{3.5}$$

by first trying to increase it in φ_1, then in φ_2 and so on. However, note that ψ_l is not necessarily a Horn core of φ. The reason is that in building ψ_1 from ψ_0, say, some models of φ_1 may have been excluded which now can be added to the ψ_l such that the Horn property is still preserved. To catch this aspect, the algorithm cycles over φ_1, φ_2, ..., φ_l, until no further change is possible. Observe that $\psi^* = \psi_k$ holds for some finite $k \geq 0$ since there exist only finite models. Now we have the next lemma.

LEMMA 3.15. *Given Horn CNFs $\varphi_0, \varphi_1, \ldots, \varphi_l$, the CNF ψ^* as defined in* (3.5) *is a Horn core of $\varphi = \vee_{i=0}^{l} \varphi_i$.*

Proof. By an inductive argument, it is easy to show that every ψ_k is a Horn CNF satisfying $\psi_k \leq \varphi$. Hence, ψ^* is a Horn CNF satisfying $\psi^* \leq \varphi$. Now assuming that ψ^* is not a Horn core of φ, we derive a contradiction.

In this case, by Lemma 4.5 (to be shown later), there exists a model $v \in \Sigma \setminus \Pi^*$ such that $\Pi^* \cup \{v\}$ is Horn, where Π^* and Σ are the theories represented by ψ^* and φ, respectively. This model v satisfies $v \in \Sigma_i$ for some i, where Σ_i is the Horn theory represented by φ_i. Let k^* be the index such that $\psi_{k^*} = \psi^*$. Since ψ^* is the limit, $\psi_{k'} = \psi^*$ holds for all $k' > k^*$. Consider the smallest index $k' > k^*$ such that $\psi_{k'} = \mathrm{CORE}(\psi_{k'-1}, \varphi_i)$. Since $\psi_{k'-1} = \psi^*$ holds and $\Pi^* \cup \{v\}$ is Horn, this implies that ψ^* is not a Horn core of $\psi^* \vee \varphi_i$, a contradiction. □

Based on this lemma, we get the following algorithm.

ALGORITHM CORE*

Input: Horn CNFs $\varphi_i = \bigwedge_{j=1}^{m_i} c_{i,j}$, for $i = 0, 1, \ldots, l$.

Output: A Horn core ψ^* of $\varphi = \varphi_0 \vee \varphi_1 \vee \cdots \vee \varphi_l$.

Step 1. Set $\psi := \varphi_0$; $i := 0$; changes := 0;

Step 2. **while** changes $< l$ **do begin**
  if $i < l$ **then** $i := i + 1$ **else** $i := 1$;
  $\psi_{new} := \mathrm{CORE}(\psi, \varphi_i)$;
  if $\psi < \psi_{new}$ **then**
  begin $\psi := \bigwedge_{c \in HC(\varphi_0, \varphi_1, \ldots, \varphi_l) \text{ s.t. } \psi_{new} \leq c} c$;
    changes := 0;
  end
  else changes := changes + 1;
end{while};

Step 3. Output the Horn CNF $\psi^* = \psi$.

Note that, whenever $\psi_{new} = \mathrm{CORE}(\psi, \varphi_i)$ increases from ψ during the iteration of Step 2, the algorithm replaces it by

$$\psi = \bigwedge_{c \in HC(\varphi_0, \varphi_1, \ldots, \varphi_l) \text{ s.t. } \psi_{new} \leq c} c. \tag{3.6}$$

By Lemma 3.8, this replacement does not affect the correctness of the algorithm. The algorithm halts if no change within l consecutive calls is detected, i.e., $\mathrm{CORE}(\psi, \varphi_i) = \mathrm{CORE}(\psi, \varphi_{i+1}) = \cdots = \mathrm{CORE}(\psi, \varphi_{i-1})$ holds, where $i \geq 1$ and we interpret $i - 1 = l$ if $i = 1$ (arithmetically, the last index in the sequence is $(l + i - 2 \bmod l) + 1$).

Example 3.16. Let us apply the algorithm CORE* to the disjunction $\varphi = \varphi_0 \vee \varphi_1 \vee \varphi_2$, where φ_0, φ_1 and φ_2 are given in Example 3.14.

In the first iteration of Step 2, by calling algorithm CORE described in subsection 3.2.1, we have

$$\psi_{new} = \mathrm{CORE}(\varphi_0, \varphi_1) = (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee x_5)(\overline{x}_2 \vee \overline{x}_3 \vee x_5)(\overline{x}_3 \vee x_5 \vee \overline{x}_7).$$

Based on

$$\begin{aligned} HC(\varphi_0, \varphi_1, \varphi_2) = \{&(\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee x_4)(\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee x_5), (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee x_6), \\ &(\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee x_7), (\overline{x}_1 \vee \overline{x}_3 \vee x_5 \vee \overline{x}_7), (\overline{x}_1 \vee \overline{x}_3 \vee x_6 \vee \overline{x}_7)\}, \end{aligned}$$

we have

$$\psi_1 = (\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee x_5)(\overline{x}_1 \vee \overline{x}_3 \vee x_5 \vee \overline{x}_7).$$

In the second iteration, we have $\psi_{new} = \mathrm{CORE}(\psi_1, \varphi_2) = \psi_1$, and hence $\psi_2 = \psi_1$ holds. Since $l\,(= 2)$ consecutive members ψ_1 and ψ_2 satisfy $\psi_1 = \psi_2$, the algorithm outputs ψ_1 and halts.

THEOREM 3.17. *Algorithm* CORE* *outputs a Horn core* ψ *of* $\varphi = \varphi_0 \vee \varphi_1 \vee \cdots \vee \varphi_l$ *satisfying* $\varphi_0 \leq \psi \leq \varphi$. *Moreover, it runs in polynomial time if* l *is bounded by some constant.*

Proof. The correctness of the algorithm is established by Lemma 3.15. Notice that in the algorithm, each $\psi_{new} = \mathrm{CORE}(\psi, \varphi_i)$ is replaced by the increased Horn theory ψ of (3.6) for which $\psi_{new} \leq \psi \leq \varphi$ holds. The sequence ψ also converges to ψ^* of (3.5).

It thus remains to show that the algorithm is polynomial in l. Observe that each CNF ψ (except for the initial φ_0) contains only clauses from $HC(\varphi_0, \varphi_1, \ldots, \varphi_l)$. There are at most $l \cdot \Pi_{i=0}^{l} m_i$ clauses in $HC(\varphi_0, \varphi_1, \ldots, \varphi_l)$, where m_i is the number of clauses in φ_i. Clearly, for a constant l, this number is polynomial in the input size of $\varphi_0, \varphi_1, \ldots, \varphi_l$. Moreover, since $T(\psi)$ (i.e., its set of models) strictly increases in every l iterations, the set of clauses $HC(\varphi_0, \varphi_1, \ldots, \varphi_l)$ which are logically entailed by ψ monotonically decreases if ψ changes. Thus, the number of iterations is bounded by $l \cdot |HC(\varphi_0, \varphi_1, \ldots, \varphi_l)|$, which is polynomial if l is bounded by a constant. Since a call to $\mathrm{CORE}(\psi, \varphi_i)$ is done in polynomial time by Theorem 3.11, this implies that CORE* requires polynomial time. □

Remarks. (1) To keep ψ of (3.6) small, we may further replace it by a prime CNF or an irredundant prime CNF, where a CNF ψ is called *prime* if it contains only prime implicates of the function it represents and *irredundant* if no clause can be removed from ψ while preserving logical equivalence. Note that an (irredundant) prime CNF for any Horn CNF ψ is computable in quadratic time [11].

(2) We can use CORE* as a reasonable "any time algorithm" for computing an approximation of some Horn core. In fact, we can interrupt the algorithm at any step, and the contents of ψ is a Horn theory that implies φ. The approximation improves with iterations and eventually yields a Horn core.

4. Characteristic models. For a Horn theory Σ, a model $v \in \Sigma$ is called *characteristic* [13] if $v \notin Cl_\wedge(\Sigma \setminus \{v\})$ holds. The set of all characteristic models of Σ, the *characteristic set of* Σ, is denoted by $C^*(\Sigma)$. Note that every Horn theory Σ has the unique characteristic set $C^*(\Sigma)$ and that $\max(\Sigma) \subseteq C^*(\Sigma)$. For example, a Horn theory $\Sigma = \{(0101), (1001), (1000), (0001), (0000)\}$ has $C^*(\Sigma) = \{(0101), (1001), (1000)\}$ and $\max(\Sigma) = \{(0101), (1001)\}$. Given the characteristic set $C^*(\Sigma)$ of a Horn theory Σ, and an arbitrary vector v, it can be checked in polynomial time whether $v \in \Sigma$ holds or not [13].

In the rest of this section, we reconsider the problems in the previous section, assuming that Horn theories are now represented by their characteristic models.

4.1. Horn property of a disjunction of Horn theories. Like in the case of CNFs, deciding whether a disjunction of Horn theories is Horn is intractable in general.

THEOREM 4.1. *Given characteristic sets $C^*(\Sigma_1)$, $C^*(\Sigma_2)$, ..., $C^*(\Sigma_l)$ of Horn theories Σ_1, Σ_2, ..., Σ_l, respectively, deciding whether $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$ is Horn is* co-NP*-complete.*

Proof. The membership part of co-NP is similar to the proof of Theorem 3.1.

The hardness part is also similar to the proof in Theorem 3.1. Observe that in this reduction, each Horn theory Σ_i is represented by a single term t_i, and hence it has a small number of characteristic models.

For a term t, let $\Sigma(t)$ denote the theory represented by t, i.e., $\Sigma(t) = T(t)$. Then the characteristic set of $\Sigma(t)$ is represented by

$$C^*(\Sigma(t)) = \{x^{V \setminus A} \mid N \subseteq A \subseteq V \setminus P, |A \setminus N| \leq 1\},$$

where a term t has positive (resp., negative) literals whose indices are from $P \subseteq V = \{1, 2, \ldots, n\}$ (resp., $N \subseteq V$); recall that x^B is the model v such that $v_i = 1$ for $i \in B$ and $v_i = 0$ for $i \notin B$. Informally, $C^*(\Sigma(t))$ contains all models of t in which at most one of the variables not occurring in t is set to 0 and all other such variables are set to 1. Clearly, $C^*(\Sigma(t))$ is constructible from t in polynomial time. Hence, the DNFs in the proof of Theorem 3.1 can be transformed in polynomial time into equivalent theories Σ_i, $i = 1, 2, \ldots, l$, and $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$, which are given by $C^*(\Sigma_i)$ and $C^*(\Sigma)$, respectively. Thus the argument in the proof of Theorem 3.1 proves the result. ∎

The next result follows from Theorem 4.1, where its proof is similar to that of Corollary 3.5.

COROLLARY 4.2. *Unless P=NP, there is no polynomial total time algorithm which, given a positive integer k and characteristic sets $C^*(\Sigma_1)$, $C^*(\Sigma_2)$, ..., $C^*(\Sigma_l)$ of Horn theories Σ_1, Σ_2, ...,$\Sigma_l \subseteq \{0,1\}^n$, computes k Horn cores of $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$.*

The next result gives a precise semantical characterization of the Horn property of a disjunction.

LEMMA 4.3. *Let $M_i \subseteq \{0,1\}^n$, $i = 1, 2, \ldots, l$, be sets of models. Then $\Sigma = \bigcup_{i=1}^{l} Cl_\wedge(M_i)$ is Horn if and only if*

$$\bigwedge_{v \in S} v \in \Sigma \quad \textit{holds for every } S \subseteq \bigcup_{i=1}^{l} M_i \textit{ such that } 1 \leq |S| \leq l. \tag{4.1}$$

Proof. Since a Horn theory is closed under intersection, the only-if-part is obvious. For the if-part, we show by induction on $k \geq l$ that (4.1) implies

$$\bigwedge_{v \in S} v \in \Sigma \text{ holds for every } S \subseteq \bigcup_{i=1}^{l} M_i \text{ such that } 1 \leq |S| \leq k, \tag{4.2}$$

which clearly implies that $\Sigma = \bigcup_{i=1}^{l} Cl_\wedge(M_i)$ is Horn. For the base $k = l$, the statement holds by (4.1). For the induction step, assume that (4.2) holds for some $k \geq l$ and consider the case $k+1$.

Take a set $S \subseteq \bigcup_{i=1}^{l} M_i$ such that $|S| = k+1$ arbitrarily and consider the model $w = \bigwedge_{v \in S} v$. For each $S_j \subseteq S$ such that $|S_j| = |S| - 1$, we denote $u^{(j)} = \bigwedge_{v \in S_j} v$. All $u^{(j)}$ belong to Σ by the induction hypothesis, and there are $k+1$ such S_j. If these contain different S_{j_1} and S_{j_2} such that $u^{(j_1)} = u^{(j_2)}$, then $w = u^{(j_1)} \wedge u^{(j_2)} = u^{(j_1)}$ holds, and $w \in \Sigma$ follows from the induction hypothesis. Otherwise, there are $k+1 \geq l+1$ different models $u^{(1)}, u^{(2)}, \ldots, , u^{(k+1)}$. Hence, by the pigeonhole principle, $u^{(1)}$ and $u^{(2)}$, say, are both contained in $Cl_\wedge(M_{i^*})$ for some i^*. Since $w = u^{(1)} \bigwedge u^{(2)} \in Cl_\wedge(M_{i^*})$ by definition, we have $w \in \Sigma$ from the induction hypothesis. □

As an immediate consequence, we obtain the following result.

THEOREM 4.4. *If l is bounded by a constant, the problem in Theorem* 4.1 *can be solved in polynomial time.*

In fact, the proof shows this result not only for sets of characteristic models but for any sets of models representing Horn theories as in Lemma 4.3.

Theorems 4.1 and 4.4, respectively, are the characteristic model versions of Theorems 3.1 and 3.4.

4.2. Computing Horn cores of a disjunction of Horn theories. Assuming Horn CNF representations, we have presented in section 3 a polynomial time algorithm for computing a Horn core ψ satisfying $\varphi_1 \leq \psi \leq \varphi_1 \vee \varphi_2$. For characteristic models, a similar algorithm is hard to find. This is suggested by the following theorem (proved after Lemma 4.5), which implies that recognizing a Horn core is intractable, even for the case of two Horn theories.

LEMMA 4.5. *Let Σ_1 be a Horn theory and Σ_2 an arbitrary theory. Then, Σ_1 is not a Horn core of $\Sigma = \Sigma_1 \cup \Sigma_2$ if and only if there exists some model $v \in \Sigma_2 \setminus \Sigma_1$ such that $v \bigwedge w \in \Sigma_1 \cup \{v\}$ holds for all $w \in C^*(\Sigma_1)$.*

Proof. Suppose Σ_1 is not a Horn core, but Π is a Horn core such that $\Sigma_1 \subset \Pi \subseteq \Sigma_1 \cup \Sigma_2$. Let v be any minimal model in $\Pi \setminus \Sigma_1$. Then $v \bigwedge w \in \Pi$ holds for all $w \in C^*(\Sigma_1)$. By the minimality, however, this implies $v \bigwedge w \in \Sigma_1 \cup \{v\}$. Conversely, if there is a model v satisfying $v \bigwedge w \in \Sigma_1 \cup \{v\}$ for all $w \in C^*(\Sigma_1)$, then $v \bigwedge w \in \Sigma_1 \cup \{v\}$ holds for all $w \in \Sigma_1$, since each $w \in \Sigma_1$ can be represented by $w = \bigwedge_{u \in S} u$ for some $S \subseteq C^*(\Sigma_1)$ and $v \bigwedge u \in \Sigma_1$ for all $u \in S$. Hence, $\Sigma_1 \cup \{v\}$ is Horn by Lemma 4.3, which means that Σ_1 is not a Horn core. □

THEOREM 4.6. *Given characteristic sets $C^*(\Sigma_1)$ and $C^*(\Sigma_2)$ of Horn theories $\Sigma_1, \Sigma_2 \subseteq \{0,1\}^n$, respectively, deciding whether Σ_1 is a Horn core of $\Sigma = \Sigma_1 \cup \Sigma_2$ is co-NP-complete.*

Proof. By Lemma 4.5, Σ_1 is not a Horn core if and only if some $v \in \Sigma_2 \setminus \Sigma_1$ exists such that $v \bigwedge w \in \Sigma_1 \cup \{v\}$ holds for every $w \in C^*(\Sigma_1)$. Such a v can be guessed and verified in polynomial time; hence the problem is in co-NP.

We then prove the co-NP-hardness by a reduction from 3SAT [9]. For a given 3-CNF formula $\varphi = \bigwedge_{i=1}^{m} c_i$ on n variables $x_1, x_2, \ldots, x_n$, we now define polynomially computable sets M_1 and M_2 of models in $\{0,1\}^{2n+m+1}$ such that $M_1 = C^*(\Sigma_1)$,

$M_2 = C^*(\Sigma_2)$ for Horn theories Σ_1 and Σ_2, and Σ_1 is not a Horn core of $\Sigma = \Sigma_1 \cup \Sigma_2$ if and only if φ is satisfiable.

Without loss of generality, we assume that all literals in $L = \{x_j, \overline{x}_j \mid 1 \leq j \leq n\}$ appear in φ. Obviously, this restriction on φ does not affect the NP-completeness of 3SAT. Define $V = V_L \cup V_C \cup V_T$, where

$$\begin{aligned} V_L &= \{1, 2, \ldots, n, \overline{1}, \overline{2}, \ldots, \overline{n}\}, \\ V_C &= \{n+1, n+2, \ldots, n+m\}, \\ V_T &= \{n+m+1\}. \end{aligned}$$

Intuitively, the elements in V_L correspond to the literals in L, the elements i in V_C to the clauses c_i in φ, and $n+m+1$ in V_T is a special tag column. Now we define the instance of our problem as follows: $M_1 = M_{1,1} \cup M_{1,2} \cup M_{1,3}$, where

$$\begin{aligned} M_{1,1} &= \{x^{(V_C \setminus \{n+i\}) \cup (V_L \setminus \{q\})} \mid n+i \in V_C,\, q \in c_i\}, \\ M_{1,2} &= \{x^{(V_L \setminus \{j, \overline{j}\}) \cup V_T} \mid 1 \leq j \leq n\}, \\ M_{1,3} &= \{x^{(V_L \setminus \{j, \overline{j}, q\}) \cup V_T} \mid 1 \leq j \leq n,\, q \in V_L \setminus \{j, \overline{j}\}\}, \end{aligned}$$

and $M_2 = M_{2,1} \cup M_{2,2}$, where

$$\begin{aligned} M_{2,1} &= \{x^{(V_L \setminus \{q\}) \cup V_T} \mid q \in V_L\}, \\ M_{2,2} &= \{x^{V_L \setminus \{j, \overline{j}\}} \mid 1 \leq j \leq n\}. \end{aligned}$$

Intuitively, each model in $M_{1,1}$ corresponds to the selection of a literal q from a clause c_i. The intersection of such models after choosing at least one model for each clause c_i corresponds to a choice of one literal from each clause. The models in $M_{1,2}$ and $M_{1,3}$ serve to cover all choices in which two opposite literals are chosen for at least one j. The models in $M_{2,1}$ similarly correspond to the choice of a single literal, but the special component $n+m+1$ is set to 1. The models in $M_{2,2}$ have a similar role as those in $M_{1,2}$.

First, it is not hard to see that $M_i = C^*(M_i)$ holds, for $i = 1, 2$, and hence M_i is indeed the characteristic set of $\Sigma_i = Cl_\wedge(M_i)$. The sets M_1 and M_2 are constructible in polynomial time from φ.

We claim that Σ_1 is not a Horn core of Σ if and only if φ is satisfiable.

Let us first show the only-if-part. Suppose that Σ_1 is not a Horn core of Σ. By Lemma 4.5, there exists some $v \in \Sigma_2 \setminus \Sigma_1$ such that $v \bigwedge w \in \Sigma_1 \cup \{v\}$ holds for all $w \in M_1$. Consider the following two cases.

Case 1. The component v_{n+m+1} is 0. Then, $v = \bigwedge_{w \in S} w$ for some $S \subseteq M_2$ such that $S \cap M_{2,2} \neq \emptyset$. Hence, for some $j \in \{1, 2, \ldots, n\}$, it holds that components j and $\overline{j}$ of v are both 0. Thus, the model v can be generated in Σ_1 by taking the intersection of a model in $M_{1,2}$ and models from $M_{1,1}$ (recall that every literal occurs in some clause). This means $v \in \Sigma_1$, which is a contradiction.

Case 2. The component v_{n+m+1} is 1. Then, v must be the intersection of some models in $M_{2,1}$. Moreover, for each $j = 1, 2, \ldots, n$, at least one of v_j and $v_{\overline{j}}$ is 1; indeed, any model $v \in \Sigma_2$ with $v_{n+m+1} = 1$ and $v_j = v_{\overline{j}} = 0$ for some j can be generated by intersections of models in $M_{1,2} \cup M_{1,3}$, which would again imply $v \in \Sigma_1$, a contradiction. Now, by assumption, $v \bigwedge w \in \Sigma_1 \cup \{v\}$ holds for all $w \in M_1$. By choosing a model $w \in M_{1,1}$ suitably, we obtain the vector $u = v \bigwedge w$ which coincides with v on V_L and has all other components (including $n+m+1$) being 0. This implies

$u \in \Sigma_1$, and hence u can be generated in Σ_1 only by the intersection of at least m models from $M_{1,1}$ including $v^{(1)}, v^{(2)}, \ldots, v^{(m)}$ such that $v^{(i)}_{n+i} = 0$ holds for all i. By the definition of $M_{1,1}$, this corresponds to a choice of one literal from each clause c_i such that no opposite literals are chosen. It then follows that φ is satisfiable.

For the if-part, suppose that φ is satisfiable. Then, there exists a choice of one literal q_i from each clause c_i, $i = 1, \ldots, m$, such that no opposite literals are chosen. We claim that the model $v = x^B$, where $B = (V_L \setminus \{q_i \mid i = 1, \ldots, m\}) \cup V_T$, satisfies $v \in \Sigma_2 \setminus \Sigma_1$ and $v \bigwedge w \in \Sigma_1$ for all $w \in \Sigma_1$. Hence, by Lemma 4.5, it follows that Σ_1 is not a Horn core of Σ.

Clearly, such a v satisfies $v \in \Sigma_2$ (i.e., by the intersection of models in $M_{2,1}$) and $v \notin \Sigma_1$. Observe that the model v' which results from v by switching component $n + m + 1$ to 0 is in Σ_1 (by the intersection of models in $M_{1,1}$). Hence, if $w \in M_{1,1}$, then $v \bigwedge w = v' \bigwedge w \in \Sigma_1$. On the other hand, if $w \in M_{1,2} \cup M_{1,3}$, then $v \bigwedge w$ (whose component $n + m + 1$ takes value 1) is obtainable as the intersection of models in $M_{1,2} \cup M_{1,3}$; hence, $v \bigwedge w \in \Sigma_1$ also holds. □

Thus, computing a canonical Horn core is presumably difficult in general. We next point out that the difficulty can be avoided if Σ_2 is restricted in the following sense. Call a Horn theory Σ *sparse* if $|\Sigma| \leq p(|C^*(\Sigma)|)$ holds for some polynomial p. Then, based on the next lemma proved in [7], we have the following theorem.

LEMMA 4.7. *Given the characteristic set $C^*(\Sigma)$ of a Horn theory $\Sigma \subseteq \{0,1\}^n$, the models of Σ can be enumerated with $O(n^2|C^*(\Sigma)|)$ time delay.*

THEOREM 4.8. *Given characteristic sets $C^*(\Sigma_1)$ and $C^*(\Sigma_2)$ of Horn theories $\Sigma_1, \Sigma_2 \subseteq \{0,1\}^n$, respectively, computing $C^*(\Pi_1)$ for $\Pi_1 = can(\Sigma_1, \Sigma_1 \cup \Sigma_2)$ is polynomial if Σ_2 is known to be sparse.*

Proof. We can compute $C^*(\Pi_1)$ for $\Pi_1 = can(\Sigma_1, \Sigma_1 \cup \Sigma_2)$ as follows.

(1) Using the algorithm in [7], construct Σ_2 from $C^*(\Sigma_2)$. Set $\Pi := C^*(\Sigma_1)$. (Here $Cl_\wedge(\Pi)$ will eventually become Π_1.)
(2) Using Lemma 4.5, check whether some model $v \in \Sigma_2 \setminus Cl_\wedge(\Pi)$ exists such that $Cl_\wedge(\Pi) \cup \{v\}$ is Horn.
(3) If such a model v is found, then set $\Pi := \Pi \cup \{v\}$ and return to (2).
(4) Compute $C^*(\Pi)$ and output it as the result.

Step (1) can be done in polynomial time by Lemma 4.7, since Σ_2 is sparse. In step (2), $Cl_\wedge(\Pi) \cup \{v\}$ is Horn if and only if $v \bigwedge w \in Cl_\wedge(\Pi) \cup \{v\}$ holds for all $w \in \Pi$ by Lemma 4.3 (with $l = 2$), which can be checked in polynomial time; this avoids the recomputation of $C^*(\Pi)$ in each iteration. Overall, this procedure is polynomial since Σ_2 is sparse. □

Observe that the Horn theory Σ_2 in the proof of Theorem 4.6 is not sparse, and hence the above algorithm requires exponential time.

4.3. Exponential sizes of Horn cores. The intractability of recognizing a Horn core as well as that of computing a canonical Horn core does not immediately rule out the possibility of computing one of the Horn cores in polynomial time. However, our next result implies that a polynomial time algorithm (in the input length) for this task is not possible.

THEOREM 4.9. *For every $n \geq 1$, there exist Horn theories $\Sigma_1, \Sigma_2 \subseteq \{0,1\}^{4n+1}$ such that $|C^*(\Sigma_1)| = |C^*(\Sigma_2)| = 2n$, but every Horn core Π of $\Sigma = \Sigma_1 \cup \Sigma_2$ has size $|C^*(\Pi)|$ not bounded by a polynomial in n.*

Proof. Given a fixed $n\,(\geq 1)$, define two sets of models $S_1, S_2 \subseteq \{0,1\}^{4n+1}$ as follows. Let $V_k = \{(k-1)n + j \mid j = 1, 2, \ldots, n\}$ for $k = 1, 2, 3, 4$, and $V = \cup_{k=1}^4 V_k \cup \{4n+1\} = \{1, 2, \ldots, 4n+1\}$. Observe that $V_1 = \{1, 2, \ldots, n\}$ contains the

first n components, V_2 the next n components, and so on. Then,

$$S_1 = \{x^{V\setminus(V_3\cup\{i,3n+i\})}, x^{V\setminus(V_3\cup\{n+i,3n+i\})} \mid 1 \le i \le n\},$$
$$S_2 = \{x^{V\setminus(V_4\cup\{i,2n+i,4n+1\})}, x^{V\setminus(V_4\cup\{n+i,2n+i,4n+1\})} \mid 1 \le i \le n\}.$$

Informally, each model v in $S_1 \cup S_2$ consists of four blocks $b_1(v), \ldots, b_4(v)$, each of which has n bits (addressed by $V_1, \ldots, V_4$), plus an extra bit v_{4n+1}. The set S_1 contains all models v such that (1) exactly $n+2$ bits are 0, (2) $b_4(v)_i = 0$ (i.e., the ith bit in $b_4(v)$ is 0) and either $b_1(v)_i = 0$ or $b_2(v)_i = 0$ for some $i \in \{1, 2, \ldots, n\}$, and (3) $b_3(v)$ is the zero vector (0,0, …,0) (for short, $\mathbf{0}$). Similarly, S_2 contains all models v such that (1) exactly $n+3$ bits are 0, (2) $b_3(v)_i = 0$ and either $b_1(v)_i = 0$ or $b_2(v)_i = 0$ for some $i \in \{1, 2, \ldots, n\}$, and (3) $b_4(v)$ is $\mathbf{0}$ and $v_{4n+1} = 0$. Intuitively, each $v \in S_1$ represents a choice from two alternatives (either $b_1(v)$ or $b_2(v)$) for assigning 0 to a position i. This is similar for each $v \in S_2$.

Clearly, $|S_1| = |S_2| = 2n$, and $S_l = C^*(S_l)$ holds for $l = 1, 2$, since all the models in S_l are incomparable. Hence S_l is the characteristic set of $\Sigma_l = Cl_\wedge(S_l)$. Note that $\Sigma_1 \cap \Sigma_2 = \emptyset$ holds.

Let

$$H_0 = H_{0,1} \cup H_{0,2}, \tag{4.3}$$

where

$$H_{0,1} = \{x^{I_1\cup I_2} \mid I_1 \subseteq V_1, I_2 \subseteq V_2, I_1 \cap \{j - n \mid j \in I_2\} = \emptyset\},$$
$$H_{0,2} = \{x^{I_1\cup I_2\cup\{4n+1\}} \mid I_1 \subseteq V_1, I_2 \subseteq V_2, I_1 \cap \{j - n \mid j \in I_2\} = \emptyset\},$$

i.e., the set of all models v which have (1) $b_1(v)_i = 0$ or $b_2(v)_i = 0$ for all $i = 1, 2, \ldots, n$, (2) $b_3(v) = b_4(v) = \mathbf{0}$, and (3) v_{4n+1} is set arbitrarily.

Fact 1. Every Horn core Π of $\Sigma = \Sigma_1 \cup \Sigma_2$ satisfies $\Pi \supseteq H_0$.

To prove this fact, we note that $H_0 \subseteq \Sigma$, and, for each $v \in H_0$ and $w \in \Sigma$, it holds that $v \bigwedge w \in H_0$. Let Π be a Horn core of Σ. Then $\Pi \cup H_0 \subseteq \Sigma$ holds, and moreover, by Lemma 4.3 (with $l = 1$), $\Pi \cup H_0$ is Horn. Hence, the maximality of a Horn core implies $H_0 \subseteq \Pi$.

Let us first consider the canonical Horn cores $\Pi_l = can(\Sigma_l, \Sigma)$ for $l = 1, 2$. It follows from Fact 1 that $H_{0,l} \subseteq \Pi_l$ holds. Denote, for any model v,

$$\chi(v) = \{j \in \{1, 2, \ldots, n\} \mid b_1(v)_j = 1 \text{ or } b_2(v)_j = 1\},$$

i.e., $\chi(v)$ contains the positions of 1 in $b_1(v)$ or $b_2(v)$. Then we obtain

$$H_{0,l} = \{v \mid \chi(v) = \{1, 2, \ldots, n\},\ b_3(v) = b_4(v) = \mathbf{0},\ \text{ and }\ v_{4n+1} = l - 1\};$$

hence, $|\max(H_{0,l})|$ (i.e., the number of maximal models in $H_{0,l}$) is obviously exponential in n. We now claim that

$$\max(H_{0,l}) \subseteq C^*(\Pi_l) \quad \text{for } l = 1, 2, \tag{4.4}$$

which implies that $|C^*(\Pi_l)|$ is exponential in n.

We consider only the case of $l = 1$, since the case of $l = 2$ is similar. Assume that some $v \in \max(H_{0,1})$ is not contained in $C^*(\Pi_1)$. Note that $v_{4n+1} = 0$, and furthermore $w_{4n+1} = 1$ holds for every $w \in \Sigma_1$. Hence $C^*(\Pi_1)$ must contain at least one model $u \in \Sigma_2$ such that $u > v$. Since $u \in \Sigma_2$, there exists an index j such

that either $b_1(u)_j = 0$ or $b_2(u)_j = 0$. Let $w \in S_1(\subseteq \Sigma_1)$ be the vector that satisfies $b_1(w)_j = 0$ if $b_1(u)_j = 0$ (resp., $b_2(w)_j = 0$ if $b_2(u)_j = 0$). Then, for $x = u \wedge w$, we have $b_1(x) = b_1(u)$, $b_2(x) = b_2(u)$, $b_3(x) = b_4(x) = \mathbf{0}$, and $x_{4n+1} = 0$. Since $x \in \Sigma$ must hold, it follows that $x \in \Sigma_2$. Thus, $x = \bigwedge_{y \in S} y$ for some $S \subseteq S_2$. Since $b_3(x) = \mathbf{0}$, it follows that either $b_1(x)_j = b_1(u)_j = 0$ or $b_2(x)_j = b_2(u)_j = 0$ holds for all $j = 1, \ldots, n$. However, this implies $u \in H_{0,1}$, which is a contradiction to $v \in \max(H_{0,1})$. Hence (4.4) holds.

As is easily seen, besides Π_1 and Π_2, further Horn cores exist. Proposition 3.12 and Fact 1 imply that for any such Horn core Π, the sets $H_1 = (\Sigma_1 \cap \Pi) \setminus H_0$ and $H_2 = (\Sigma_2 \cap \Pi) \setminus H_0$ are both nonempty. Indeed, if $H_1 = \emptyset$ were true, then $\Sigma_1 \cap \Pi \subseteq H_0$ would hold and Fact 1 would imply $\Pi = H_0 \cup (\Sigma_2 \cap \Pi)$; thus, by Proposition 3.12, $\Pi \subseteq \Pi_2$, which is a contradiction. For $H_2 = \emptyset$, the argument is analogous. Moreover, Π has the following property.

Fact 2. For all $v^{(1)} \in H_1$ and $v^{(2)} \in H_2$, it holds that $v^{(1)} \bigwedge v^{(2)} \in H_0$.

To see this, let $w = v^{(1)} \bigwedge v^{(2)}$. Then $b_3(w) = b_4(w) = \mathbf{0}$ holds, since $v^{(1)} \in \Sigma_1$ and $v^{(2)} \in \Sigma_2$. This together with $w \in \Pi \subseteq \Sigma_1 \cup \Sigma_2$ implies $b_1(w)_j = 0$ or $b_2(w)_j = 0$ for all j, and hence $w \in H_0$.

By Fact 2, $w = v^{(1)} \bigwedge v^{(2)}$ satisfies either $b_1(w)_j = 0$ or $b_2(w)_j = 0$ (or both) for all j. Thus the models $v^{(1)}$ and $v^{(2)}$ satisfy $\chi(v^{(1)}) \cup \chi(v^{(2)}) = \{1, 2, \ldots, n\}$. Since this holds for all such $v^{(1)}$ and $v^{(2)}$, every set $\chi(v^{(1)})$ must include $\{1, 2, \ldots, n\} \setminus \bigcap_{v^{(2)} \in H_2} \chi(v^{(2)})$, and by symmetry every $\chi(v^{(2)})$ must include $\{1, 2, \ldots, n\} \setminus \bigcap_{v^{(1)} \in H_1} \chi(v^{(1)})$. This implies the following fact.

Fact 3. There exists a set $I \subset \{1, 2, \ldots, n\}$ of size $|I| \geq n/2$ such that either (1) $I \subseteq \chi(v^{(1)})$ holds for every $v^{(1)} \in H_1$, or (2) $I \subseteq \chi(v^{(2)})$ holds for every $v^{(2)} \in H_2$.

To see this, let $J = \bigcap_{v^{(1)} \in H_1} \chi(v^{(1)})$. If $|J| \geq n/2$, then (1) clearly holds for $I = J$. On the other hand, if $|J| < n/2$, then we have (2) for $I = \{1, 2, \ldots, n\} \setminus J$, since $\chi(v^{(2)})$ must include I.

Assume that (1) of Fact 3 holds; the case of (2) is similar. Choose $v^{(1)} \in \max(H_1)$ arbitrarily. Then, the maximality of Horn core Π implies that every model $w \in \Sigma_1 \setminus H_0$ such that $\chi(w) = \chi(v^{(1)})$ and w coincides with $v^{(1)}$ on the remaining part (i.e., on $V_3 \cup V_4 \cup \{4n+1\}$) is contained in Π (cf. Facts 1 and 2). There exist $2^{|\chi(v^{(1)})|}$ maximal such models w, each of which chooses 0 either in block $b_1(w)$ or in $b_2(w)$, but not in both, for the positions in $\chi(v^{(1)})$. Since $I \subseteq \chi(v^{(1)})$, at least $2^{|I|}$ models from $\Sigma_1 \setminus H_0$ are contained in Π. Note that these models are maximal in Π. Since $\max(\Pi) \subseteq C^*(\Pi)$, it follows that $|C^*(\Pi)| \geq 2^{|I|} \geq 2^{n/2}$. Thus, the size of $C^*(\Pi)$ is not bounded by a polynomial in n. This proves the theorem statement. □

COROLLARY 4.10. *There is no polynomial time algorithm for computing $C^*(\Pi)$ of any Horn core Π for $\Sigma_1 \cup \Sigma_2$, from the characteristic sets $C^*(\Sigma_1)$, $C^*(\Sigma_2)$ of Horn theories $\Sigma_1, \Sigma_2 \subseteq \{0,1\}^n$, respectively.*

Let us remark that Theorem 4.9 and Corollary 4.10 do not rule out the existence of a polynomial total time algorithm for this problem.

5. Horn envelope of a disjunction of Horn theories. In this section, we briefly discuss the Horn envelope of a disjunction $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$ of Horn theories Σ_i, $i = 1, 2, \ldots, l$. For model-based representation, we can compute the Horn envelope in polynomial time. Indeed, the characteristic set of Σ is given by $C^*(M)$, where $M = \bigcup_{i=1}^{l} C^*(\Sigma_i)$. Clearly, $C^*(M)$ is computable from M in polynomial time by removing all models v which are represented by the intersection of other models in M. Thus we have the following theorem.

TABLE 6.1
Complexity results for disjunction $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$.

	Horn		*Core*		*Envelope*	
	CNF	C^*	CNF	C^*	CNF	C^*
l is constant	P	P	P	EXP	EXP	P
l is general	co-NPC	co-NPC	co-NPH	EXP	EXP	P

P: polynomial time, co-NPH: co-NP-hard
EXP: exponential time, co-NPC: co-NP-complete

THEOREM 5.1. *Given characteristic sets* $C^*(\Sigma_1)$, $C^*(\Sigma_2)$, ..., $C^*(\Sigma_l)$ *of Horn theories* Σ_1, Σ_2, ..., Σ_l, *respectively, the characteristic set of the Horn envelope of* $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$ *can be computed in polynomial time.*

As for the CNF representation, computing the Horn envelope requires, in general, exponential time (and space). This is because any Horn CNF that represents the envelope of Σ may be exponential in the size of Horn CNFs $\varphi_1, \varphi_2, \ldots, \varphi_l$ of Σ_1,Σ_2,..., Σ_l, even if $l = 2$. Note that for CNFs representing non-Horn theories, any Horn CNF for the Horn envelope may be exponential even if $l = 1$ (cf., e.g., [22]).

For example, let $\varphi_1 = x_0$ and $\varphi_2 = (\overline{x}_1 \vee \overline{x}_2 \ldots \vee \overline{x}_m) \wedge \bigwedge_{j=1}^{m} (x_j \vee \overline{y}_j)$. Then $\varphi = \varphi_1 \vee \varphi_2$ is equivalent to the CNF $(x_0 \vee \overline{x}_1 \vee \overline{x}_2 \ldots \vee \overline{x}_m) \wedge \bigwedge_{j=1}^{m} (x_0 \vee x_j \vee \overline{y}_j)$. Thus the envelope of φ can be represented by

$$\psi = \bigwedge_{z_1 \in \{x_1, y_1\}} \bigwedge_{z_2 \in \{x_2, y_2\}} \cdots \bigwedge_{z_m \in \{x_m, y_m\}} \left(x_0 \vee \bigvee_{j=1}^{m} \overline{z}_j \right).$$

This CNF has 2^m clauses. Since all clauses in ψ are prime and removing some clause in ψ does not produce the envelope, we have the following theorem.

THEOREM 5.2. *There exist Horn CNFs* φ_i, $i = 1, 2, \ldots, l$, *such that any Horn CNF for the Horn envelope of* $\varphi = \bigvee_{i=1}^{l} \varphi_i$ *has size exponential in the size of* φ_i, $i = 1, 2, \ldots, l$, *even if* $l = 2$. *Hence, the Horn envelope of* φ *cannot be computed in polynomial time.*

6. Related work and conclusion. In this paper, we have considered the problems with disjunction $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$ of Horn theories Σ_i. The results for the three problems, i.e., recognition of the Horn property, computation of cores, and computation of envelope, are shown in Table 6.1, where the results are categorized by the representations of theories (i.e., CNFs and characteristic sets) and the values of l (i.e., constant and general).

The computation of a Horn core of a propositional theory Σ has been considered by several authors, and different algorithms have been proposed for different representations; see, e.g., [21, 22, 2, 3, 1, 15]. The papers [21, 22, 2, 3, 1] present algorithms for theories represented by CNFs, which require exponential time in the worst case. It should be noted that these algorithms are not immediately applicable if Σ is given by the disjunction of two Horn CNF formulas φ_1 and φ_2. This is because these algorithms require a CNF formula φ ($\equiv \varphi_1 \vee \varphi_2$) for input, but, since a smallest CNF φ may be exponential in the sizes of φ_1 and φ_2, the resulting procedure requires exponential time (and space) in general.

Concerning the model based representation, our intractability result on computing a Horn core for a disjunction $\Sigma = \bigcup_{i=1}^{l} \Sigma_i$ of Horn theories Σ_i represented by their

characteristic sets $C^*(\Sigma_i)$ contrasts with a positive result in [15] that all Horn cores of Σ can be enumerated with polynomial delay if all models of Σ are given for input. Intuitively, this is explained by the fact that $C^*(\Sigma)$ can be a succinct representation of Σ, and eliciting all models from it, as needed by the algorithm in [15], is not feasible in polynomial time in the input size of $C^*(\Sigma)$.

Algorithms for computing the Horn envelope for certain classes of formula representations of a theory Σ are contained in [4, 5, 15, 16, 21, 22]. In particular, [22, 4, 5] explicitly consider formula representations, while [15, 16] implicitly cover formula representations of theories in terms of disjunctions of minterms (i.e., terms such that every variable occurs either positively or negatively in them). The papers [21, 22] suggested a general framework for knowledge compilation, in which the concept of Horn envelope is generalized to the envelope (i.e., least upper bound) of the knowledge base, which is given in a source language, in a target language for compilation.

This approach was also pursued in the papers [4, 5], which made several contributions: [4] presented improvements to [21] and preliminary versions of [22], gave conditions on target clausal languages under which the algorithm in [22] for computing the envelope is correct, by which new classes of theories could be handled, and presented a modified procedure which works for all clausal propositional target languages. The paper [5] presented a new algorithm for computing theory envelopes, which works for a broad subclass of the target languages handled by the algorithm in [21] and can have an exponential increase in efficiency in some cases. Furthermore, it was shown in [5] that the algorithms in [21, 5] for envelope computation in the propositional case can be lifted to the first-order case under certain conditions.

As for the case of computing a Horn CNF for the Horn envelope of a theory represented by a CNF, the algorithms in [21, 22, 4, 5] are either known to be exponential in the worst case (in particular, as shown in [4] the algorithm in [21] uses exponential space) or not polynomial unless P=co-NP. Indeed, a given CNF φ representing a theory Σ is unsatisfiable if and only if any Horn CNF ψ for the Horn envelope of Σ is unsatisfiable, which given ψ can be decided in polynomial time. Moreover, we can also conclude from this that a polynomial total time (output-polynomial) algorithm, i.e., polynomial in the size of the input and the output of any irredundant prime CNF for the envelope, does not exist unless P=co-NP.

We have shown that the characteristic set of the Horn envelope of a disjunction of Horn theories $\Sigma_1, \ldots, \Sigma_l$ can be computed from their characteristic sets $C^*(\Sigma_1)$, $\ldots$, $C^*(\Sigma_l)$ in polynomial time. On the other hand, a Horn CNF for the Horn envelope cannot be computed from Horn CNFs $\varphi_1, \ldots, \varphi_l$ representing $\Sigma_1, \ldots, \Sigma_l$ in polynomial time in general, even if $l = 2$, since it may have exponential size. As for a possible polynomial total time algorithm, we observe that results in [15, 16] imply that such an algorithm—if one exists—is hard to find, even if each Horn theory Σ_i has a single model (which is computable from a Horn CNF φ_i for Σ_i in polynomial time). More precisely, if each φ_i is a minterm, then the problem is easily seen to be polynomially equivalent to the problem SID in [16], which is computing an irredundant prime CNF for the Horn envelope of a theory Horn Σ, given the set $C^*(\Sigma)$ of its characteristic models. By Theorem 1 in [15] and Theorem 9 in [16], this problem is at least as hard computing the transversal hypergraph of a given hypergraph for which no polynomial total time algorithm is known; see [16] for details.

Some problems remain for further work. One issue is on Horn cores when l is bounded by some constant; construct an efficient algorithm for generating all Horn cores for both representations and construct an output-efficient computation of a Horn

core (under a suitable notion) for the characteristic set representation. Another issue is a polynomial total time algorithm for computing the Horn envelope from Horn CNFs.

A FULLY DYNAMIC ALGORITHM FOR RECOGNIZING AND REPRESENTING PROPER INTERVAL GRAPHS*

PAVOL HELL†, RON SHAMIR‡, AND RODED SHARAN‡

Abstract. In this paper we study the problem of recognizing and representing dynamically changing proper interval graphs. The input to the problem consists of a series of modifications to be performed on a graph, where a modification can be a deletion or an addition of a vertex or an edge. The objective is to maintain a representation of the graph as long as it remains a proper interval graph, and to detect when it ceases to be so. The representation should enable one to efficiently construct a realization of the graph by an inclusion-free family of intervals. This problem has important applications in physical mapping of DNA.

We give a near-optimal fully dynamic algorithm for this problem. It operates in $O(\log n)$ worst-case time per edge insertion or deletion. We prove a close lower bound of $\Omega(\log n/(\log\log n + \log b))$ amortized time per operation in the cell probe model with word-size b. We also construct optimal incremental and decremental algorithms for the problem, which handle each edge operation in $O(1)$ time. As a byproduct of our algorithm, we solve in $O(\log n)$ worst-case time the problem of maintaining connectivity in a dynamically changing proper interval graph.

1. Introduction.

A graph G is called an *interval graph* if its vertices can be assigned to intervals on the real line so that two vertices are adjacent in G if and only if their assigned intervals intersect. The set of intervals assigned to the vertices of G is called a *realization* of G. If the set of intervals can be chosen to be inclusion-free, then G is called a *proper interval graph*. Proper interval graphs have been studied extensively in the literature (cf. [7, 16]), and several linear-time algorithms are known for their recognition and realization [3, 4].

This paper deals with the problem of recognizing and representing dynamically changing proper interval graphs. The input is a series of operations to be performed on a graph, where an operation is any of the following: adding a vertex (along with the edges incident to it), deleting a vertex (and the edges incident to it), adding an edge and deleting an edge. The objective is to maintain a representation of the dynamic graph as long as it is a proper interval graph, and to detect when it ceases to be so. The representation should enable one to efficiently construct a realization of the graph. In the *incremental* version of the problem, only addition operations are permitted, i.e., the set of operations includes only the addition of a vertex and the addition of an edge. In the *decremental* version of the problem only deletion operations are allowed.

The research of the third author was supported by an Eshkol fellowship from the Ministry of Science, Israel.

The motivation for this problem comes from its application to *physical mapping* of DNA [1]. Physical mapping is the process of reconstructing the relative position of DNA fragments, called *clones*, along the target DNA molecule, prior to their sequencing, based on information about their pairwise overlaps. In some biological frameworks the set of clones is virtually inclusion-free—for example, when all clones have similar lengths. (This is the case for instance for cosmid clones.) In this case, the physical mapping problem can be modeled using proper interval graphs as follows. A graph G is built according to the biological data. Each clone is represented by a vertex and two vertices are adjacent if and only if their corresponding clones overlap. The physical mapping problem then translates to the problem of finding a realization of G, or determining that none exists.

Had the overlap information been accurate, the two problems would have been equivalent. However, some biological techniques may occasionally lead to an incorrect conclusion about whether two clones intersect, and additional experiments may change the status of an intersection between two clones. The resulting changes to the corresponding graph are the deletion of an edge, or the addition of an edge. The set of clones is also subject to changes, such as adding new clones or deleting "bad" clones (such as chimerics [18]). These translate into addition or deletion of vertices in the corresponding graph. Thus, we would like to be able to dynamically change our graph, so as to reflect the changes in the biological data, as long as they allow us to construct a map, i.e., as long as the graph remains a proper interval graph.

Several authors have studied the problem of dynamically recognizing and representing various graph families. Hsu [11] has given an $O(m+n\log n)$-time incremental algorithm for recognizing interval graphs. (Throughout, we denote the number of vertices and edges in a graph by n and m, respectively.) Deng, Hell, and Huang [4] have given a linear-time incremental algorithm for recognizing and representing connected proper interval graphs. This algorithm requires that the graph will remain connected throughout the modifications. In both algorithms [11, 4] only vertex additions are handled. Recently, Ibarra [12] devised a fully dynamic algorithm for recognizing chordal graphs which handles each edge operation in $O(n)$ time. He also gave an optimal fully dynamic algorithm for recognizing split graphs, which handles each edge operation in $O(1)$ time.

Our results are as follows: For the general problem of recognizing and representing proper interval graphs we give a fully dynamic algorithm which handles each operation in time $O(d+\log n)$, where d denotes the number of edges involved in the operation. Thus, in case a vertex is added or deleted, d equals its degree, and in case an edge is added or deleted, $d = 1$. Our algorithm builds on the representation of proper interval graphs given in [4]. We prove a close lower bound of $\Omega(\log n/(\log\log n + \log b))$ amortized time per edge operation in the cell probe model of computation with word-size b [20]. It follows that our algorithm is nearly optimal (up to a factor of $O(\log\log n)$). We also give a fast $O(n)$ time algorithm for computing a realization of a proper interval graph given its representation, improving the $O(m+n)$ bound of [4].

For the incremental version of the problem we give an optimal algorithm (up to a constant factor) which handles each operation in time $O(d)$. This generalizes the result of [4] to arbitrary instances. The same bound is achieved for the decremental problem.

As a part of our general algorithm we give a fully dynamic procedure for maintaining connectivity in proper interval graphs. The procedure receives as input a

sequence of operations each of which is a vertex addition or deletion, an edge addition or deletion, or a query whether two vertices are in the same connected component. It is assumed that the graph remains proper interval throughout the modifications, since otherwise our main algorithm detects that the graph is no longer a proper interval graph and halts. We show how to implement this procedure in $O(d + \log n)$ worst-case time per operation involving d edges. In comparison, the best known algorithms for fully dynamic connectivity in general graphs require $O(\log n(\log\log n)^3)$ expected amortized time per edge operation [17], or $O(\log^2 n)$ amortized time per edge operation [10], or $O(\sqrt{n})$ worst-case time per edge operation [5]. Furthermore, we show that the lower bound of Fredman and Henzinger [9] of $\Omega(\log n/(\log\log n + \log b))$ amortized time per edge operation (in the cell probe model with word-size b) for fully dynamic connectivity in general graphs applies also to the problem of maintaining connectivity in proper interval graphs.

The paper is organized as follows: In section 2 we give the basic background and describe our representation of proper interval graphs and the realization it defines. In sections 3 and 4 we present the incremental algorithm. In section 5 we extend the incremental algorithm to a fully dynamic algorithm for proper interval graph recognition and representation. We also derive an optimal decremental algorithm. In section 6 we give a fully dynamic algorithm for maintaining connectivity in proper interval graphs. Finally, in section 7 we prove lower bounds on the amortized time per edge operation of fully dynamic algorithms for recognizing proper interval graphs and for maintaining connectivity in proper interval graphs.

2. Preliminaries. Let $G = (V, E)$ be a graph. We denote its set of vertices also by $V(G)$ and its set of edges also by $E(G)$. For a vertex $v \in V$ we define $N(v) \equiv \{u \in V : (u, v) \in E\}$ and $N[v] \equiv N(v) \cup \{v\}$. Similarly, for a set $S \subseteq V$ we define $N(S) \equiv \cup_{v \in S} N(v)$ and $N[S] = N(S) \cup S$. Let R be an equivalence relation on V defined by uRv if and only if $N[u] = N[v]$. Each equivalence class of R is called a *block* of G. Note that every block of G is a complete subgraph of G. The *size* of a block is the number of vertices in it. Two blocks A and B are *adjacent*, or *neighbors*, in G if some (and hence all) vertices $a \in A, b \in B$, are adjacent in G. A *straight enumeration* of G is a linear ordering Φ of the blocks in G, such that for every block, the block and its neighboring blocks are consecutive in Φ.

Let $\Phi = B_1 < \cdots < B_l$ be a linear ordering of the blocks of G. For any $1 \leq i < j \leq l$, we say that B_i is ordered *to the left of* B_j and that B_j is ordered *to the right of* B_i in Φ. The *out-degree* of a block B with respect to Φ, denoted by $o(B)$, is the number of neighbors of B which are ordered to its right in Φ. A *chordless cycle* is an induced cycle of length greater than 3. A *claw* is an induced $K_{1,3}$ (a 3-degree vertex connected to three 1-degree vertices). A graph is called *claw-free* if it contains no induced claw. For other definitions in graph theory see, e.g., [7].

We now quote some well-known properties of proper interval graphs that will be used in what follows.

THEOREM 2.1 (see [13]). *An interval graph (and in particular a proper interval graph) contains no chordless cycle.*

THEOREM 2.2 (see [19]). *A graph is a proper interval graph if and only if it is an interval graph and is claw-free.*

THEOREM 2.3 (see [4]). *A graph is a proper interval graph if and only if it has a straight enumeration.*

LEMMA 2.4 ("the umbrella property" [14]). *Let Φ be a straight enumeration of a connected proper interval graph G. If A, B, and C are blocks of G, such that*

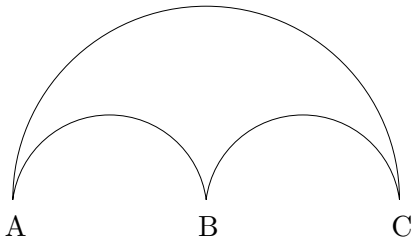

FIG. 2.1. *The umbrella property.*

$A < B < C$ in Φ and A is adjacent to C, then B is adjacent to A and to C (see Figure 2.1*).*

It is shown in [4] that a connected proper interval graph has a unique straight enumeration up to reversal. This motivates our representation of proper interval graphs: For each connected component of the dynamic graph we maintain a straight enumeration. (In fact, for technical reasons we shall maintain both the enumeration and its reversal.) The details of the data structure containing this information will be described in section 3.1.

This information implicitly defines a realization of the dynamic graph (cf. [4]) as follows: Assign to each vertex in block B_i the interval $[i, i + o(B_i) + 1 - \frac{1}{i}]$. We show in section 3.1 how to compute a realization of the dynamic graph from our data structure in time $O(n)$.

3. An incremental algorithm for vertex addition. In the following two sections we describe an optimal incremental algorithm for recognizing and representing proper interval graphs. The algorithm receives as input a series of addition operations to be performed on a graph. Upon each operation the algorithm updates its representation of the graph and halts if the current graph is no longer a proper interval graph. The algorithm handles each operation in time $O(d)$, where d denotes the number of edges involved in the operation. (Thus, $d = 1$ in case of an edge addition, and d is the degree in case of a vertex addition.) It is assumed that initially the graph is empty, or alternatively, that the representation of the initial graph is known. We also show how to compute in $O(n)$ time a realization of a graph given its representation.

A *contig* of a connected proper interval graph G is a straight enumeration of G. The first and the last blocks of a contig are called *end-blocks*, and their vertices are called *end-vertices*. The rest of the blocks are called *inner-blocks*.

As mentioned above, each connected component of the dynamic graph has exactly two contigs (which are reversals of each other) and both are maintained by the algorithm. Each operation involves updating the representation. In the following we concentrate on describing only one of the two contigs for each component. The second contig is updated in a similar way.

3.1. The data structure. We now describe the details of how we keep our representation. The following data is kept and updated by the algorithm:

1. For each vertex we keep the name of the block to which it belongs.
2. For each block we keep the following:
   (a) The *size* of the block.
   (b) Left and right *near pointers*, pointing to nearest neighbor blocks on the left and on the right, respectively.

(c) Left and right *far pointers*, pointing to farthest neighbor blocks on the left and on the right, respectively.
(d) Left and right *self pointers*, pointing to the block itself.
(e) An *end pointer* which is null if the block is not an end-block of its contig, and otherwise, points to the other end-block of that contig.

In the following we shall omit details about the obvious updates to the names of the blocks containing each of the vertices (item 1) and to the block sizes (item 2a).

We introduce self pointers due to the possible need in the course of the algorithm to update many far pointers pointing to a certain block, so that they point to another block. In order to be able to do that in $O(1)$ time we use the technique of *nested pointers*: We make the far pointers point to a *location* whose content is the address of the block to which the far pointers should point. The role of this special location will be served by our self-pointers. The value of the left and right self-pointers of a block B is always the address of B. When we say that a certain left (right) far pointer points to B we mean that it points to a left (right) self-pointer of B. Let A and B be blocks. In order to change all left (right) far pointers pointing to A so that they point to B, we require that no left (right) far pointer points to B. If this is the case, we simply *exchange* the left (right) self-pointer of A with the left (right) self-pointer of B. This means that (1) the previous left (right) self-pointer of A is made to point to B, and the algorithm records it as the new left (right) self-pointer of B; and (2) the previous left (right) self-pointer of B is made to point to A, and the algorithm records it as the new left (right) self-pointer of A.

We shall use the following notation: For a block B we denote its address in the memory by $\&B$. $\&\emptyset$ denotes the null pointer. When we set a far pointer to point to a left or to a right self-pointer of B we shall abbreviate and set it to $\&B$. We denote the left and right near pointers of B by $N_l(B)$ and $N_r(B)$, respectively. We denote the left and right far pointers of B by $F_l(B)$ and $F_r(B)$, respectively. We denote its end pointer by $E(B)$. In the rest of this paper we often refer to blocks by their addresses. For example, if A and B are blocks and $N_r(A) = \&B$, we sometimes refer to B by $N_r(A)$. We define $N_r(\emptyset) = N_l(\emptyset) = F_r(\emptyset) = F_l(\emptyset) = \&\emptyset$. When it is clear from the context, we also use a name of a block to denote any vertex in that block. Given a contig Φ we denote its reversal by Φ^R. In general when performing an operation, we denote the graph before the operation is carried out by G, and the graph after the operation is carried out by G'.

Given this data structure we can compute a realization of a contig C of G as follows: We first rank the blocks of C, starting with the leftmost block. This is done by choosing an arbitrary block of C, and marching up the enumeration of blocks of C using left near pointers, until we reach an end-block. We then set the rank of this block to 1, and march down the enumeration of blocks using right near pointers, until we reach the other end-block. We rank all the blocks of C along the way. Let us denote by $r(B)$ the rank of a block B. Then the out-degree of B is simply $o(B) = r(F_r(B)) - r(B)$, and the interval that we assign to the vertices of B is $[r(B), r(F_r(B)) + 1 - 1/r(B)]$. We conclude with the following theorem.

THEOREM 3.1. *A realization of a proper interval graph, which is represented using the data structure described above, can be computed in time $O(n)$.*

3.2. The impact of a new vertex. In the following we describe the changes made to the representation of the graph in case G' is formed from G by the addition of a new vertex v of degree d. We also give some necessary and some sufficient conditions for deciding whether G' is a proper interval graph.

Let B be a block of G. We say that v is *adjacent* to B if v is adjacent to some vertex in B. We say that v is *fully adjacent* to B if v is adjacent to *every* vertex in B. We say that v is *partially adjacent* to B if v is adjacent to B but not fully adjacent to B.

The following lemmas characterize the adjacencies of the new vertex, assuming that G' is a proper interval graph.

LEMMA 3.2. *If G' is a proper interval graph then v can have neighbors in at most two connected components of G.*

Proof. Suppose to the contrary that x, y, and z are neighbors of v in three distinct components of G. Then v, x, y, and z induce a claw in G', a contradiction. □

LEMMA 3.3 (see [4]). *Let C be a connected component of G containing neighbors of v. Let $B_1 < \cdots < B_k$ be a contig of C. Suppose that G' is a proper interval graph and let $1 \le a < b < c \le k$. Then the following properties are satisfied:*

1. *If v is adjacent to B_a and to B_c, then v is fully adjacent to B_b.*
2. *If v is adjacent to B_b and not fully adjacent to B_a and to B_c, then B_a is not adjacent to B_c.*
3. *If $b = a+1, c = b+1$, and v is adjacent to B_b, then v is fully adjacent to B_a or to B_c.*

One can view a contig Φ of a connected proper interval graph C as a weak linear order $<_\Phi$ on the vertices of C, where $x <_\Phi y$ if and only if the block containing x is ordered in Φ to the left of the block containing y. We say that Φ' is a *refinement* of Φ if either, for every $x, y \in V(C)$, $x <_\Phi y$ implies $x <_{\Phi'} y$ or, for every $x, y \in V(C)$, $x >_\Phi y$ implies $x <_{\Phi'} y$.

LEMMA 3.4. *If H is a connected induced subgraph of a proper interval graph H', Φ is a contig of H, and Φ' is a straight enumeration of H', then Φ' is a refinement of Φ.*

Proof. By induction on the number of additional vertices in H': If $H' = H$ then the claim is obvious. Let $k = |V(H') \setminus V(H)|$. By the induction hypothesis, for a proper interval graph H'' which contains H (as an induced subgraph) and is contained in H', and for which $|V(H'') \setminus V(H)| = k-1$, every straight enumeration is a refinement of Φ. Let C be a connected component of H'' for which $V(C) \supseteq V(H)$, and let Φ''_C be a contig of C. Let C' be a connected component of H' for which $V(C') \supseteq V(H)$ (and therefore $V(C') \supseteq V(C)$), and let Φ'_C be a contig of C'. In [4] it is constructively shown how Φ'_C is obtained as a refinement of Φ''_C (see also section 3.3). Since Φ''_C is a refinement of Φ, the claim follows. □

Note that whenever v is partially adjacent to a block B in G, then the addition of v will cause B to split into two blocks of G', namely, $B \setminus N(v)$ and $B \cap N(v)$. Otherwise, if B is a block of G to which v is either fully adjacent or nonadjacent, then one of B or $B \cup \{v\}$ is a block of G'.

COROLLARY 3.5. *If B is a block of G to which v is partially adjacent, then $B \setminus N(v)$ and $B \cap N(v)$ occur consecutively in a straight enumeration of G'.*

LEMMA 3.6. *Let C be a connected component of G containing neighbors of v. Let $\{B_1, \ldots, B_k\}$ denote the set of blocks in C which are adjacent to v, such that in a contig of C, $B_1 < \cdots < B_k$. If G' is a proper interval graph, then the following properties are satisfied:*

1. *$B_1, \ldots, B_k$ are consecutive in a contig of C.*
2. *If $k \ge 3$ then v is fully adjacent to $B_2, \ldots, B_{k-1}$.*
3. *If v is adjacent to a single block B_1 in C, then B_1 is an end-block.*
4. *If v is adjacent to more than one block in C and has neighbors in another*

component, then B_1 is adjacent to B_k, and one of B_1 or B_k is an end-block to which v is fully adjacent, while the other is an inner-block.

Proof. Claims 1 and 2 follow directly from part 1 of Lemma 3.3. Claim 3 follows from part 3 of Lemma 3.3. To prove the last part of the lemma let us denote the other component containing neighbors of v by D. Examine the induced connected subgraph H of G' whose set of vertices is $V(H) = \{v\} \cup V(C) \cup V(D)$. H is a proper interval graph since it is an induced subgraph of G'. It is composed of three types of blocks: blocks whose vertices are from $V(C)$, which we will henceforth call C-blocks; blocks whose vertices are from $V(D)$, which we will henceforth call D-blocks; and $\{v\}$, which is a block of H, since $H \setminus \{v\}$ is not connected. All blocks of C remain intact in H, except B_1 and B_k, each of which may split into $B_j \setminus N(v)$ and $B_j \cap N(v)$, $j = 1, k$.

Surely, in a contig of H all C-blocks must be ordered completely before or completely after all D-blocks. Let Φ denote a contig of H, in which C-blocks are ordered before D-blocks. Let X denote the rightmost C-block in Φ. By the umbrella property, $X < \{v\}$, and moreover, X is adjacent to v. By Lemma 3.4, Φ is a refinement of a contig of C. Hence, $X \subseteq B_1$ or $X \subseteq B_k$ (more precisely, $X = B_1 \cap N(v)$ or $X = B_k \cap N(v)$). Therefore, one of B_1 or B_k is an end-block.

Without loss of generality, $X \subseteq B_k$. Suppose to the contrary that v is not fully adjacent to B_k. Then by Lemma 3.4 we have $B_{k-1} \cap N(v) < B_k \setminus N(v) < \{v\}$ in Φ (note that these blocks are not consecutive), contradicting the umbrella property. We conclude that v is fully adjacent to B_k. Furthermore, B_1 must be adjacent to B_k, or else G' contains a claw consisting of v and one vertex from each of B_1, B_k, and $V(D) \cap N(v)$. It remains to show that B_1 is an inner-block in C. Suppose it is an end-block. Since B_1 and B_k are adjacent, C consists of a single block, a contradiction. Thus, claim 4 is proved. ∎

3.3. The DHH algorithm. In our algorithm we rely on the incremental algorithm of Deng, Hell, and Huang (DHH) [4]. This algorithm handles the insertion of a new vertex into a connected proper interval graph in $O(d)$ time, changing its straight enumeration appropriately or determining that the new graph is not a proper interval graph. We describe it briefly below. For simplicity, we assume throughout that the modified graph is a proper interval graph.

Let H be a connected proper interval graph, and let v be a vertex to be added, which is adjacent to d vertices in H. Let $\Phi = B_1 < \cdots < B_p$ denote a contig of H. By Lemma 3.6, the blocks to which v is fully adjacent occur consecutively in Φ. Assume that v is fully adjacent to $B_l, \ldots, B_r$, and for clarity we shall consider only the case where $1 < l < r < p$. Let $a = l - 1$ and $c = r + 1$. By Lemma 3.3(2), B_a and B_c are nonadjacent. Let $b > a$ be the largest index such that B_b is adjacent to B_a, and let $d < c$ be the smallest integer such that B_d is adjacent to B_c. It is shown in [4] that $a < b < d < c$.

In order to construct a straight enumeration of the new graph we have to distinguish between two cases:

1. If v is adjacent either to B_a or to B_c, then a straight enumeration of the new graph can be obtained as follows: If v is adjacent to B_a, we split B_a into $B_a \setminus N(v), B_a \cap N(v)$, list them in this order, and add $\{v\}$ as a block just after B_b. If v is adjacent to B_c, we split B_c into $B_c \cap N(v), B_c \setminus N(v)$ in this order, and add $\{v\}$ as a block just before B_d. In case v is adjacent to both B_a and B_c then these two instructions coincide, as shown in [4].
2. If v is adjacent neither to B_a nor to B_c then there are two possibilities: If there exists a block B_j, $b < j < d$, such that B_j is adjacent to both B_l and

B_r, then a straight enumeration is obtained by adding v to B_j. Otherwise, let u be the least integer greater than b such that B_u is adjacent to B_r. Then a straight enumeration is obtained by inserting a new block $\{v\}$ just before B_u.

In section 3.4 we show how to find the sequence of blocks $B_l, \ldots, B_r$ from our data structure in $O(d)$ time. Using near and far pointers we can find, in $O(1)$ time, $B_a = N_l(B_l), B_c = N_r(B_r), B_b = F_r(B_a)$, and $B_d = F_l(B_c)$. If v is adjacent to B_a or to B_c then updating the straight enumeration can be done in $O(1)$ time. Otherwise, finding B_j (if such exists) can be done in $O(d)$ time, and alternatively, finding $B_u = F_l(B_r)$ can be done in $O(1)$ time. Again in this case we can update the straight enumeration in $O(1)$ time. Hence, our data structure supports the insertion of a vertex of degree d in $O(d)$ time, when all its neighbors are in the same connected component.

3.4. Our algorithm. We perform the following upon a request for adding a new vertex v: We make two passes over the neighbors of v. In the first pass we discover all blocks adjacent to v, and for each such block we allocate a *counter* and initialize it to zero. In the second pass, for each neighbor u of v we add one to the counter of the block containing u. We call a block *full* if its counter equals its size, *empty* if its counter equals zero, and *partial* otherwise. In order to find a set of consecutive blocks which contain neighbors of v, we pick arbitrarily a neighbor of v and march up the enumeration of blocks to the left using the left near pointers. We continue till we hit an empty block or till we reach the end of the contig. We do the same to the right and this way we discover a maximal sequence of nonempty blocks in that component which contain neighbors of v. We call this maximal sequence a *segment*. Only the two extreme blocks of the segment are allowed to be partial, or else we fail (by Lemma 3.6(2)).

If the segment we found contains all the neighbors of v then we can use the DHH algorithm in order to insert v into G, updating our internal data structure accordingly. Otherwise, by Lemmas 3.2 and 3.6(1) there could be only one more segment which contains neighbors of v. In that case, exactly one extreme block in each segment is an end-block to which v is fully adjacent (if the segment contains more than one block), and the two extreme blocks in each segment are adjacent, or else we fail (by Lemma 3.6(3, 4)).

We proceed as above to find a second segment containing neighbors of v. We can make sure that the two segments are from two different contigs by checking that their end-blocks do not point to each other. We also check that conditions 3 and 4 in Lemma 3.6 are satisfied for both segments. If the two segments do not cover all neighbors of v, we fail.

If v is adjacent to vertices in two distinct components C and D, then we should merge their contigs. Let $\Phi = B_1 < \cdots < B_k$ and Φ^R be the two contigs of C. Let $\Psi = B'_1 < \cdots < B'_l$ and Ψ^R be the two contigs of D. The way the merge is performed depends on the identity of the end-blocks to which v is adjacent in each segment. If v is adjacent to B_k and B'_1, then by the umbrella property the two new contigs (up to refinements described below) are $\Phi < \{v\} < \Psi$ and $\Psi^R < \{v\} < \Phi^R$. In the following we describe the necessary changes to our internal data structure in case these are the new contigs. The three other cases (e.g., v is adjacent to B_1 and B'_1, etc.) are handled similarly.

- Block enumeration: We merge the two enumerations of blocks and put a new block $\{v\}$ in-between the two contigs. Let the leftmost block which is adjacent to v in the new ordering $\Phi < \{v\} < \Psi$ be B_i, and let the rightmost block

adjacent to v be B'_j. If B_i is partial we split it into two blocks $\hat{B}_i = B_i \setminus N(v)$ and $B_i = B_i \cap N(v)$ in this order. If B'_j is partial we split it into two blocks $B'_j = B'_j \cap N(v)$ and $\hat{B}'_j = B'_j \setminus N(v)$ in this order.

- End pointers: We set $E(B_1) = E(B'_1)$ and $E(B'_l) = E(B_k)$. We then nullify the end pointers of B_k and B'_1.
- Near pointers: We update $N_l(\{v\}) = \&B_k, N_r(\{v\}) = \&B'_1, N_r(B_k) = \&\{v\}$, and $N_l(B'_1) = \&\{v\}$. Let $B_0 = \emptyset$. If B_i was split we set $N_r(\hat{B}_i) = \&B_i, N_l(B_i) = \&\hat{B}_i, N_l(\hat{B}_i) = \&B_{i-1}$, and $N_r(B_{i-1}) = \&\hat{B}_i$. Analogous updates are made to the near pointers of $B'_j, \hat{B}'_j$, and B'_{j+1}, in case B'_j was split.
- Far pointers: If B_i was split we set $F_l(\hat{B}_i) = F_l(B_i), F_r(\hat{B}_i) = \&B_k$, and exchange the left self-pointer of B_i with the left self-pointer of $\hat{B}_i$. If B'_j was split we set $F_r(\hat{B}'_j) = F_r(B'_j), F_l(\hat{B}'_j) = \&B'_1$ and exchange the right self-pointer of B'_j with the right self-pointer of $\hat{B}'_j$. In addition, we set all right far pointers of $B_i, B_{i+1}, \ldots, B_k$ and all left far pointers of $B'_1, \ldots, B'_{j-1}, B'_j$ to $\&\{v\}$ (in $O(d)$ time). Finally, we set $F_l(\{v\}) = \&B_i$ and $F_r(\{v\}) = \&B'_j$.

The algorithm is summarized in Figure 3.1.

Input: A representation of the current graph G and a list of neighbors in G of a new vertex v.
Output: A representation of $G \cup \{v\}$ or a *False* value indicating that $G \cup \{v\}$ is not a proper interval graph.

1. Find the number s of segments of blocks which are adjacent to v.
2. If $s \geq 3$ then return *False*.
3. If $s = 1$ then apply the DHH algorithm.
4. Otherwise, proceed as follows ($s = 2$):
   (a) Check that exactly one extreme block in each segment is an end-block to which v is fully adjacent, and that the two extreme blocks in each segment are adjacent. Otherwise, return *False*.
   (b) Check that the two segments are in distinct contigs. Otherwise, return *False*.
   (c) Update the representation of the graph as described above.

FIG. 3.1. *An incremental algorithm for vertex addition.*

4. An incremental algorithm for edge addition. In this section we show how to handle the addition of a new edge (u, v) in $O(1)$ time. We characterize the cases for which $G' = G \cup \{(u, v)\}$ is a proper interval graph and show how to efficiently detect them and how to update our representation of the graph.

LEMMA 4.1. *If u and v are in distinct connected components in G, then G' is a proper interval graph if and only if u and v are end-vertices in a straight enumeration of G.*

Proof. To prove the "only if" part let us examine the graph $H = G' \setminus \{u\} = G \setminus \{u\}$. H is a proper interval graph as it is an induced subgraph of G. If G' is also a proper interval graph, then by Lemma 3.6(3) v must be an end-vertex in a straight enumeration of G, since u is not adjacent to any other vertex in the component containing v. The same argument applies to u.

To prove the "if" part we give a straight enumeration of the new connected component containing u and v in G'. Denote by C and D the components containing

u and v, respectively.

Let $B_1 < \cdots < B_k$ be a contig of C, such that $u \in B_k$. Let $B'_1 < \cdots < B'_l$ be a contig of D, such that $v \in B'_1$. Then $B_1 < \cdots < B_k \setminus \{u\} < \{u\} < \{v\} < B'_1 \setminus \{v\} < \ldots < B'_l$ is the required straight enumeration. □

By the previous lemma if u and v are in distinct components in G, and G' is a proper interval graph, then they must reside in end-blocks of distinct contigs. We can check that in $O(1)$ time. In case u and v are end-vertices of two distinct contigs, we update our internal data structure as follows:

- Block enumeration: Given in the proof of Lemma 4.1.
- End pointers: We set $E(B_1) = E(B'_1)$ and $E(B'_l) = E(B_k)$. We then nullify the end-pointers of B_k and B'_1.
- Notation: Let $B_0 = \emptyset$ and $B'_{l+1} = \emptyset$. Let $B_k = B_k \setminus \{u\}$ and $B'_1 = B'_1 \setminus \{v\}$. If $B_k \neq \emptyset$, let $x = k$, and otherwise, let $x = k - 1$. If $B'_1 \neq \emptyset$ let $y = 1$, and otherwise, let $y = 2$.
- Near pointers: We set $N_r(\{u\}) = \&\{v\}, N_l(\{u\}) = \&B_x, N_l(\{v\}) = \&\{u\}$, and $N_r(\{v\}) = \&B'_y$. We also update $N_r(B_x) = \&\{u\}$ and $N_l(B'_y) = \&\{v\}$.
- Far pointers: We set $F_l(\{u\}) = F_l(B_k)$ and $F_r(\{v\}) = F_r(B'_1)$. We exchange the right self-pointer of B_k with the right self-pointer of $\{u\}$, and the left self-pointer of B'_1 with the left self-pointer of $\{v\}$. Finally, we set $F_r(\{u\}) = \&\{v\}$ and $F_l(\{v\}) = \&\{u\}$.

It remains to handle the case where u and v are in the same connected component C in G. If $N(u) = N(v)$, then by the umbrella property it follows that C contains only three blocks which are merged into a single block in G'. In this case G' is a proper interval graph and updates to the internal data structure are trivial. The remaining case is analyzed in the following lemma.

LEMMA 4.2. *Let $B_1 < \cdots < B_k$ be a contig of C, such that $u \in B_i$ and $v \in B_j$ for some $1 \leq i < j \leq k$. Assume that $N(u) \neq N(v)$. Then G' is a proper interval graph if and only if $F_r(B_i) = B_{j-1}$ and $F_l(B_j) = B_{i+1}$ in G.*

Proof. Let G' be a proper interval graph. Since B_i and B_j are nonadjacent, $F_r(B_i) \leq B_{j-1}$ and $F_l(B_j) \geq B_{i+1}$. Suppose to the contrary that $F_r(B_i) < B_{j-1}$. Let $z \in B_{j-1}$. If in addition $F_l(B_j) = B_{i+1}$, then by the umbrella property $N[v] \supset N[z]$. (This is a strict containment.) As v and z are in distinct blocks, there exists a vertex $b \in N[v] \setminus N[z]$. But then v, b, z, and u induce a claw in G', a contradiction. Hence, $F_l(B_j) > B_{i+1}$ and therefore $F_r(B_{i+1}) < B_j$. Let $x \in B_{i+1}$ and let $y \in F_r(B_{i+1})$. As u and x are in distinct blocks, we have either $(u, y) \notin E(G)$ or there exists a vertex $a \in N[u] \setminus N[x]$ (or both). In the first case, v, u, x, y, and the vertices on a shortest path from y to v induce a chordless cycle in G'. In the second case u, a, x, and v induce a claw in G'. Hence, in both cases we arrive at a contradiction. By a symmetric argument we deduce that $F_l(B_j) = B_{i+1}$.

To prove the "if" part we provide a straight enumeration of $C \cup \{(u, v)\}$. If $B_i = \{u\}$, $F_r(B_{j-1}) = F_r(B_j)$, and $F_l(B_{j-1}) = B_i$ (i.e., $N[v] = N[B_{j-1}]$ in G'), we move v from B_j to B_{j-1}. Similarly, if B_j contained only v, $F_l(B_{i+1}) = F_l(B_i)$ and $F_r(B_{i+1}) = B_j$ (i.e., $N[u] = N[B_{i+1}]$ in G'), we move u from B_i to B_{i+1}. If u was not moved and B_i contained vertices other than u, we split B_i into $B_i = B_i \setminus \{u\}, \{u\}$ in this order. If v was not moved and B_j contained vertices other than v, we split B_j into $\{v\}, B_j = B_j \setminus \{v\}$ in this order. It is easy to see that the result is a straight enumeration of $C \cup \{(u, v)\}$. □

If u and v are neither end-vertices of distinct contigs nor end-vertices of a three-block contig, then, assuming that G' is a proper interval graph, the condition of

Lemma 4.2 must hold. We can check that in time $O(1)$, and if it is the case, change our data structure so as to reflect the new straight enumeration of blocks given in the proof of Lemma 4.2. We describe below the changes to our data structure.

- Block enumeration: Given in the proof of Lemma 4.2.
- Near pointers: Let $B_{k+1} = \emptyset$. If u was moved into B_{i+1}, then no change is necessary with respect to u. If $B_i \supset \{u\}$, u forms a new block and we set $N_l(\{u\}) = \&B_i, N_r(B_i) = \&\{u\}, N_r(\{u\}) = \&B_{i+1}$, and $N_l(B_{i+1}) = \&\{u\}$. Analogous updates are made with respect to v.
- Far pointers: If u was moved into B_{i+1}, then no change is necessary with respect to u. If $B_i \supset \{u\}$, we exchange the right self-pointer of B_i with the right self-pointer of (the new block) $\{u\}$. Let B denote the block containing v in G'. We also set $F_l(\{u\}) = F_l(B_i)$ and $F_r(\{u\}) = \&B$. Analogous updates are made with respect to v.

The following theorem summarizes the results of sections 3 and 4.

THEOREM 4.3. *The incremental proper interval graph representation problem is solvable in $O(1)$ time per added edge.*

5. The fully dynamic algorithm. In this section we give a fully dynamic algorithm for recognizing and representing proper interval graphs. The algorithm performs an operation involving d edges in $O(d + \log n)$ time. It supports four types of operations: adding a vertex, adding an edge, deleting a vertex, and deleting an edge. It is based on the incremental algorithm. The main difficulty in extending the incremental algorithm to handle all types of operations is updating the end pointers of blocks when both insertions and deletions are allowed. To bypass this problem we (implicitly) keep the identity of each block as an end/inner-block but do not keep end pointers at all. Instead, we maintain the connected components of G and use this information in our algorithm. In the next section we provide a fully dynamic algorithm for maintaining the connected components of a proper interval graph. This algorithm handles a modification request involving d edges in $O(d + \log n)$ time and determines whether two blocks are in the same connected component in $O(\log n)$ time. We describe below how each operation is handled by the fully dynamic proper interval graph representation algorithm.

5.1. The addition of a vertex. This operation is handled in essentially the same way as done by the incremental algorithm. However, in order to check if the end-blocks of two distinct segments are in distinct components, we query our data structure of connected components (in $O(\log n)$ time), rather than checking if the end pointers of these blocks do not point to each other.

5.2. The addition of an edge. Again, handling this operation is similar to its handling by the incremental algorithm, with the exception that in order to check if the endpoints of an edge are in distinct components, we query our data structure of connected components (in $O(\log n)$ time).

5.3. The deletion of a vertex. We show next how to update the contigs of G after deleting a vertex v of degree d. Note, that in this case G' is an induced subgraph of G, and hence, also a proper interval graph.

Denote by X the block containing v. If X contains vertices other than v then the data structure is simply updated by deleting v. Hence, we concentrate on the case that $X = \{v\}$. In time $O(d)$ we can find the segment of blocks which includes X and all its neighbors. Let the contig containing X be $B_1 < \cdots < B_k$, and let the blocks

of the segment be $B_i < \cdots < B_j$, where $X = B_l$ for some $1 \le i \le l \le j \le k$. The following updates should be performed:

- Block enumeration: If $1 < i < l$, we check whether B_i can be merged with B_{i-1}. If $F_l(B_i) = F_l(B_{i-1})$, $F_r(B_i) = B_l$, and $F_r(B_{i-1}) = B_{l-1}$, we merge these blocks by moving all vertices from B_i to B_{i-1} (in $O(d)$ time) and deleting B_i. If $l < j < k$ we deal similarly with B_j and B_{j+1}.
  Finally, we delete B_l. If $1 < l < k$ and B_{l-1}, B_{l+1} are nonadjacent, then by the umbrella property they are no longer in the same connected component, and the contig should be split into two contigs, one ending at B_{l-1} and the other beginning at B_{l+1}.
- Near pointers: Let $B_0 = \emptyset, B_{k+1} = \emptyset$. If B_i and B_{i-1} were merged, we update $N_r(B_{i-1}) = \&B_{i+1}$ and $N_l(B_{i+1}) = \&B_{i-1}$. Similar updates are made with respect to B_{j-1} and B_{j+1} in case B_j and B_{j+1} were merged. If the contig is split, we nullify $N_r(B_{l-1})$ and $N_l(B_{l+1})$. Otherwise, we update $N_r(B_{l-1}) = \&B_{l+1}$ and $N_l(B_{l+1}) = \&B_{l-1}$.
- Far pointers: If B_i and B_{i-1} were merged, we exchange the right self-pointer of B_i with the right self-pointer of B_{i-1}. Similar changes should be made with respect to B_j and B_{j+1}. We also set all right far pointers, previously pointing to B_l, to $\&B_{l-1}$ and all left far pointers, previously pointing to B_l, to $\&B_{l+1}$ (in $O(d)$ time).

Note that these updates take $O(d)$ time and require no knowledge about the connected components of G.

5.4. The deletion of an edge. Let (u, v) be an edge of G to be deleted. Let C be the connected component of G containing u and v. Let B_i and B_j be the blocks containing u and v, respectively, in a contig $B_1 < \cdots < B_k$ of C. If $i = j = k = 1$, then B_1 is split into $\{u\}, B_1 \setminus \{u, v\}$, and $\{v\}$, in this order, resulting in a straight enumeration of G'. Updates are trivial in this case. Henceforth we assume that $k > 1$. We first observe that $i \ne j$, i.e., $N[u] \ne N[v]$.

LEMMA 5.1. *If $N[u] = N[v]$ then G' is a proper interval graph if and only if C is a clique.*

Proof. To prove the "only if" part, we first show that every vertex $x \in C \setminus \{u, v\}$ is adjacent to both u and v. Suppose to the contrary that there exists a vertex $x \in C \setminus \{u, v\}$ which is not adjacent to u. Let $x = x_1, \ldots, x_k = u$ be a path in C from x to u. Let x_i be the first vertex on the path which is adjacent to u (and therefore also to v). Then $\{x_i, x_{i-1}, u, v\}$ induce a claw in G', a contradiction. Finally, if a and b are two nonadjacent vertices in $C \setminus \{u, v\}$, then $\{a, u, b, v\}$ induce a chordless cycle in G', a contradiction.

To prove the "if" part, notice that since C is a clique, it is a block in G, and therefore, $\{u\}, C \setminus \{u, v\}, \{v\}$ is a straight enumeration of $C \setminus \{(u, v)\}$. □

Since by our assumptions $k > 1$, we conclude that $N[u] \ne N[v]$, and therefore, $N(u) \ne N(v)$. Without loss of generality, $i < j$. The updates to the straight enumeration of $C \setminus \{(u, v)\}$ are derived from the following lemma.

LEMMA 5.2. *Let $B_1 < \cdots < B_k$ be a contig of C, such that $u \in B_i$ and $v \in B_j$ for some $1 \le i < j \le k$. Then G' is a proper interval graph if and only if $F_r(B_i) = B_j$ and $F_l(B_j) = B_i$ in G.*

Proof. Suppose that G' is a proper interval graph. We prove that $F_r(B_i) = B_j$. A symmetric argument shows that $F_l(B_j) = B_i$. Since B_i and B_j are adjacent in G, $F_r(B_i) \ge B_j$. Suppose to the contrary that $F_r(B_i) > B_j$. Let $x \in F_r(B_i)$. By the umbrella property $(x, v) \in E(G)$. Since x and v are in distinct blocks in G, either

there exists a vertex $a \in N[v] \setminus N[x]$ or there exists a vertex $b \in N[x] \setminus N[v]$ (or both). In the first case, by the umbrella property $(a, u) \in E(G)$. Therefore, u, x, v, and a induce a chordless cycle in G'. In the second case, x, b, u, and v induce a claw in G'. Hence in both cases we arrive at a contradiction.

To prove the converse implication we give a straight enumeration of $C \setminus \{(u, v)\}$. If $B_i = \{u\}$, $B_j = \{v\}$, and $j = i+1$, we have to split the contig into two contigs, one ending at B_i and the other beginning at B_j. If $B_j = \{v\}$, $F_l(B_{i-1}) = F_l(B_i)$, and $F_r(B_{i-1}) = B_{j-1}$ (i.e., $N[u] = N[B_{i-1}]$ in G'), we move u into B_{i-1}. If B_i contained only u, $F_r(B_{j+1}) = F_r(B_j)$ and $F_l(B_{j+1}) = B_{i+1}$ (i.e., $N[v] = N[B_{j+1}]$ in G'), we move v into B_{j+1}. If u was not moved and B_i contains vertices other than u, then B_i is split into $\{u\}, B_i = B_i \setminus \{u\}$ in this order. If v was not moved and B_j contains vertices other than v, then B_j is split into $B_j = B_j \setminus \{v\}, \{v\}$ in this order. The result is a straight enumeration of $C \setminus \{(u, v)\}$. □

If the conditions of Lemma 5.2 are fulfilled, then the following updates should be made:

- Block enumeration: Given in the proof of Lemma 5.2.
- Near pointers: Let $B_0 = \emptyset, B_{k+1} = \emptyset$. If $B_i = \{u\}$, $B_j = \{v\}$, and $j = i + 1$, we nullify $N_r(u)$. If B_i was split, we set $N_r(\{u\}) = \&B_i$, $N_l(B_i) = \&\{u\}$, $N_l(\{u\}) = \&B_{i-1}$ and $N_r(B_{i-1}) = \&\{u\}$. If B_i contained only u, and u was moved into B_{i-1}, we update $N_r(B_{i-1}) = \&B_{i+1}$ and $N_l(B_{i+1}) = \&B_{i-1}$. Analogous updates are made with respect to v.
- Far pointers: If $B_i = \{u\}$, $B_j = \{v\}$, and $j = i + 1$, we nullify $F_r(u)$. If B_i was split, we exchange the left self-pointer of B_i with the left self-pointer of $\{u\}$. We also set $F_l(\{u\}) = F_l(B_i)$ and $F_r(\{u\}) = \&B_y$, where $y = j$ in case v is no longer in B_j (that is, v was moved into B_{j+1} or B_j was split), and otherwise, $y = j - 1$. If B_i contained only u, and u was moved into B_{i-1}, we exchange the right self-pointer of B_i with the right self-pointers of B_{i-1}, and delete B_i. Analogous updates are made with respect to v.

Note that these updates take $O(1)$ time and require no knowledge about the connected components of G. Hence, from sections 5.3 and 5.4 there follows an optimal algorithm for the decremental proper interval graph representation problem. The following theorem summarizes this result.

THEOREM 5.3. *The decremental proper interval graph representation problem is solvable in $O(1)$ time per removed edge.*

6. Maintaining the connected components. In this section we describe a fully dynamic algorithm for maintaining connectivity in a proper interval graph G in $O(d + \log n)$ time per operation involving d edges. In section 7 we shall establish a lower bound of $\Omega(\log n/(\log\log n + \log b))$ amortized time per edge operation (in the cell probe model of computation with word-size b) for this problem.

The algorithm receives as input a series of operations to be performed on a graph, which can be any of the following: Adding a vertex, adding an edge, deleting a vertex, deleting an edge, or querying if two vertices are in the same connected component. It operates on the blocks of the graph rather than on its vertices. The algorithm depends on a data structure which includes the blocks and the contigs of the graph. It hence interacts with the proper interval graph representation algorithm. In response to an update request, changes are made to the representation of the graph based on the structure of its connected components prior to the update. Only then are the connected components of the graph updated. We provide a data structure of connected components which performs each operation in $O(\log n)$ time.

Let us denote by $B(G)$ the *block graph* of G, that is, a graph in which each vertex corresponds to a block of G and two vertices are adjacent if and only if their corresponding blocks are adjacent in G. The algorithm maintains a spanning forest F of $B(G)$. When a modification in the graph occurs, the spanning forest is updated accordingly. In order to decide if two blocks are in the same connected component, the algorithm checks if they belong to the same tree in F.

The key idea is to design F so that it can be efficiently updated upon a modification in G. We define the edges of F as follows: For every two vertices u and v in $B(G)$, $(u, v) \in E(F)$ if and only if their corresponding blocks are consecutive in a contig of G (or equivalently, if the near pointers of these blocks point to each other in our representation). Consequently, each tree in F is a path representing a contig. The crucial observation about F is that an addition or a deletion of a vertex or an edge in G induces $O(1)$ modifications to the vertices and edges of F. This can be seen by noting that each modification of G induces $O(1)$ updates to near pointers in our representation of G.

It remains to show a data structure for storing F that allows us to query for each vertex to which path it belongs, and that enables splitting a path upon a deletion of an edge in F, and linking two paths upon an addition of an edge to F. If we store the vertices of each path of F in a balanced binary tree, then each of these operations can be supported in $O(\log n)$ time (cf. [2]).

We are now ready to state our main result.

THEOREM 6.1. *The fully dynamic proper interval graph representation problem is solvable in $O(d + \log n)$ time per modification involving d edges.*

We note, that the performance of our representation algorithm depends on the performance of a data structure of connected components of a graph, which is a union of disjoint paths, that supports the following operations: linking two paths, splitting a path, and querying if two vertices belong to the same path. Given such a data structure which supports each operation in $O(f(n))$ time, for some function f, our representation algorithm can be implemented to run in $O(d + f(n))$ time per modification involving d edges.

7. The lower bounds. In this section we prove a lower bound of $\Omega(\log n/(\log\log n + \log b))$ amortized time per edge operation for fully dynamic proper interval graph recognition in the cell probe model of computation with word-size b (see [20] for details about the model). Furthermore, we prove the same lower bound also for the problem of fully dynamic connectivity maintenance of a proper interval graph.

Fredman and Henzinger [9] have shown a lower bound of $\Omega(\log n/(\log\log n + \log b))$ amortized time per operation (in the cell probe model of computation with word-size b) for fully dynamic connectivity, by reduction from the *helpful parity prefix sum* (HPPS) problem, which is defined below. We use similar constructions in our lower bound proofs.

The HPPS problem is a modified *parity prefix sum* problem (see [6] for definition of the latter problem). Its lower bound of $\Omega(\log n/(\log\log n + \log b))$ amortized time per operation follows from the work of Fredman and Saks [6]. It is defined as follows: Given an array $A[0], \ldots, A[n+1]$ of zeros and ones such that initially all $A[i]$ are 0, except $A[0]$ and $A[n+1]$ which are 1, execute an arbitrary sequence of the following operations:

Add(t, i, j): If $0 \le i < t < j \le n+1, A[i] > 0, A[j] > 0$, and $A[k] = 0$ for all $i < k < j$, then $A[t] = A[t] + 1$. Otherwise, do nothing.

Sum(t): Return $(\sum_{i=1}^{t} A[i]) \bmod 2$.

THEOREM 7.1. *Fully dynamic proper interval graph recognition takes amortized time* $\Omega(\log n/(\log\log n + \log b))$ *per edge operation in the cell probe model of computation with word-size* b.

Proof. Given an instance of the HPPS problem (i.e., a sequence of Add and Sum operations) we construct an instance of the dynamic proper interval graph recognition problem, such that each Add operation corresponds to $O(1)$ edge modifications in the dynamic proper interval graph instance, and each Sum operation corresponds to $O(1)$ temporary modifications in the dynamic graph: Depending on whether the modifications generate a proper interval graph we answer the Sum query and then reverse the modification. Thus, the lower bound for the HPPS problem shows that there exists a sequence of m operations for the dynamic proper interval recognition problem that takes $\Omega(m \log n/(\log\log n + \log b))$ time in the cell probe model of computation with word-size b.

Let $S_{-1} = 0$ and let $S_0 = 1$. Given an instance of the HPPS problem, define $S_t \equiv (\sum_{i=1}^{t} A[i]) \bmod 2$ for $1 \le t \le n$. The reduction is as follows: We construct a graph $G = (V, E)$ with $n + 2$ vertices labeled $-1, 0, 1, \ldots, n$, where each vertex v represents S_v. If $S_t = i$ for $i = 0, 1$, and $t' < t$ is the largest index such that $S_{t'} = i$, then G contains the edge (t', t). In other words, vertices t for which $S_t = 1$ are connected in a chain, which we henceforth call the *odd chain*, and all other vertices are connected in a chain, which we henceforth call the *even chain*. Note that the vertex labeled -1 lies on the even chain, and the vertex labeled 0 lies on the odd chain.

To answer a Sum(t) query ($1 \le t \le n$) we do the following:

1. If $(0, t) \in E$ or $(0, t'), (t', t) \in E$ for some vertex $t' \in V$, we output 1.
2. Otherwise, let t' be a vertex such that $t' > t$ and $(t, t') \in E$. If such a vertex exists, define $H \equiv G \setminus \{(t, t')\} \cup \{(0, t)\}$. Otherwise, let $H \equiv G \cup \{(0, t)\}$. If t is on the odd chain then this modification forms a chordless cycle. If t is on the even chain then the new graph is a single path or a union of two disjoint paths. Hence, H is a proper interval graph if and only if Sum(t) = 0. Thus, if H is a proper interval graph we output 0, and otherwise, we output 1. Note, that G is not modified in this case.

To perform an Add(t, i, j) operation we do the following:

1. Let i_{odd} (i_{even}) be the largest vertex on the odd (even) chain with $i_{odd} < t$ ($i_{even} < t$). Let j_{odd} (j_{even}) be the smallest vertex on the odd (even) chain with $j_{odd} \ge t$ ($j_{even} \ge t$), if such a vertex exists.
2. Delete from G the edges (i_{odd}, j_{odd}) and (i_{even}, j_{even}).
3. Add to G the edges (i_{odd}, j_{even}) and (i_{even}, j_{odd}).

By [9, Lemma 3.1] $i_{odd}, j_{odd}, i_{even}$, and j_{even} can be found by querying Sum(t) as follows: If Sum(t) = 1, then $i_{odd} = t - 1$, $j_{odd} = t$, $i_{even} = i - 1$ if $i > 1$, or $i_{even} = -1$ otherwise; and $j_{even} = j$ if $j <= n$, or j_{even} is undefined otherwise. If Sum(t) = 0, then $i_{odd} = i - 1$ if $i > 0$, or $i_{odd} = 0$ otherwise; $j_{odd} = j$ if $j \le n$, or j_{odd} is undefined otherwise; $i_{even} = t - 1$ if $t > 1$, or $i_{even} = -1$ otherwise; and $j_{even} = t$. This completes the reduction. □

Note, that since the key to the reduction above is the ability to detect cycles, similar arguments can be used to show that the same lower bound applies also to other problems, e.g., fully dynamic interval graph recognition and fully dynamic chordal graph recognition.

THEOREM 7.2. *There is a lower bound of* $\Omega(\log n/(\log\log n + \log b))$ *amortized time per edge operation in the cell probe model of computation with word-size* b *for*

fully dynamic connectivity maintenance of a proper interval graph.

Proof. We use the same reduction as in the proof of Theorem 7.1, with the exception that in order to answer a $Sum(t)$ query we check whether vertices 0 and t are connected. If the answer is positive we output 1, and otherwise we output 0. The reduction is valid, since the graph G, which is constructed in the reduction, is a union of two disjoint paths and therefore is a proper interval graph. □

Note added in proof. After the submission of the manuscript, we found out that a simpler reduction was given from the parity prefix sum problem to fully dynamic connectivity by Miltersen et al. [15]. This reduction allows the repeated modification of $A[t]$ for the same argument t and leads to alternative proofs of Theorems 7.1 and 7.2.

PROVABLY FAST AND ACCURATE RECOVERY OF EVOLUTIONARY TREES THROUGH HARMONIC GREEDY TRIPLETS*

MIKLÓS CSŰRÖS† AND MING-YANG KAO†

Abstract. We give a greedy learning algorithm for reconstructing an evolutionary tree based on a certain harmonic average on triplets of terminal taxa. After the pairwise distances between terminal taxa are estimated from sequence data, the algorithm runs in $\mathcal{O}(n^2)$ time using $\mathcal{O}(n)$ work space, where n is the number of terminal taxa. These time and space complexities are optimal in the sense that the size of an input distance matrix is n^2 and the size of an output tree is n. Moreover, in the Jukes–Cantor model of evolution, the algorithm recovers the correct tree topology with high probability using sample sequences of length polynomial in (1) n, (2) the logarithm of the error probability, and (3) the inverses of two small parameters.

Key words. evolutionary trees, the Jukes–Cantor model of evolution, computational learning, harmonic greedy triplets

1. Introduction.

Algorithms for reconstructing evolutionary trees are useful tools in biology [16, 22]. These algorithms usually compare aligned character sequences for the terminal taxa in question to infer their evolutionary relationships. In the past, such characters were often categorical variables of morphological features; newer studies have taken advantage of available biomolecular sequences. This paper focuses on datasets of the latter type.

We present a new learning algorithm, called *fast harmonic greedy triplets* (Fast-HGT), using a greedy strategy based on a certain harmonic average on triplets of terminal taxa. After the pairwise distances between terminal taxa are estimated from their observed sequences, Fast-HGT runs in $\mathcal{O}(n^2)$ time using $\mathcal{O}(n)$ work space, where n is the number of terminal taxa. These time and space complexities are optimal in the sense that n^2 is the size of an input distance matrix and n is the size of an output tree. An earlier variant of Fast-HGT takes $\mathcal{O}(n^5)$ time [5]. In the Jukes–Cantor model of sequence evolution generalized for an arbitrary alphabet [22], Fast-HGT is proven to recover the correct topology with high probability while requiring sample sequences of length ℓ polynomial in (1) n, (2) the logarithm of the error probability, and (3) the inverses of two small parameters (Theorem 3.8). In subsequent work [6], Fast-HGT and its variants are shown to have similar theoretical performance in more general Markov models of evolution.

Among the related work, there are four other algorithms which have essentially the same guarantee on the length ℓ of sample sequences. These are the dyadic closure method (DCM) [10] and the witness-antiwitness method (WAM) [11] of Erdős et al., the algorithm of Cryan, Goldberg, and Goldberg (CGG) [4], and the DCM-Buneman algorithm of Huson, Nettles, and Warnow [18]. Not all of these results

analyzed the space complexity. In terms of time complexity, DCM-Buneman is not a polynomial-time algorithm. CGG runs in polynomial time, whose degree has not been explicitly determined but which appears to be higher than n^2. DCM takes $\mathcal{O}(n^5 \log n)$ time to assemble $\mathcal{O}(n^4)$ quartets using $\mathcal{O}(n^4)$ space. The two versions of WAM take $\mathcal{O}(n^6 \log n)$ and $\mathcal{O}(n^4 \log n \log \ell)$ time, respectively. In the uniform and Yule–Harding models of randomly generating trees, with high probability, these two latter running times are reduced to $\mathcal{O}(n^3 \operatorname{polylog} n)$ and $\mathcal{O}(n^2 \operatorname{polylog} n)$, respectively. Under these two tree distributions, Erdős et al. [10] further showed that with high probability, the required sample size of DCM is polylogarithmic in n; this bound also applies to WAM, CGG, DCM-Buneman, and Fast-HGT.

Among the algorithms with no known comparbale guarantees on ℓ, the neighbor joining method of Saitou and Nei [22] runs in $\mathcal{O}(n^3)$ time and reconstructs many trees highly accurately in practice, although the best known upper bound on its required sample size is exponential in n [3]. Maximum likelihood methods [15, 14] are not known to achieve the optimal required sample size as such methods are usually expected to [20]; moreover, all their known implementations take exponential time to find local optima, and none can find provably global optima. Parsimony methods aim to compute a tree that minimizes the number of mutations leading to the observed sequences [13]; in general, such optimization is NP-hard [8]. Some algorithms strive to find an evolutionary tree among all possible trees to fit the observed distances the best according to some metric [1]; such optimization is NP-hard for L_1 and L_2 norms [7] and for L_∞ [1].

A common goal of the above algorithms is to construct a tree with the same topology as that of the true tree. In contrast, the work on PAC-learning the true tree in the j-state general Markov model [21] aims to construct a tree which is close to the true tree in terms of the leaf distribution in the sense of Kearns et al. [19] but which need not be the same as the true tree. Farach and Kannan [12] gave an $\mathcal{O}(n^2\ell)$-time algorithm (FK) for the symmetric case of the 2-state model provided that all pairs of leaves have a sufficiently high probability of being the same. Ambainis et al. [2] gave a nearly tight lower bound on ℓ for achieving a given variational distance between the true tree and the reconstructed tree. As for obtaining the true tree, the best known upper bound on ℓ required by FK is exponential in n. CGG [4] also improves upon FK to PAC-learn in the general 2-state model without the symmetry and leaf similarity constraints.

The remainder of the paper is organized as follows. Section 2 reviews the generalized Jukes–Cantor model of sequence evolution and discusses distance-based probabilistic techniques. Section 3 gives Fast-HGT. Section 4 concludes the paper with some directions for further research.

2. Model and techniques.

Section 2.1 defines the model of evolution used in the paper. Section 2.2 defines our problem of recovering evolutionary trees from biological sequences. Sections 2.3 through 2.5 develop basic techniques for the problem.

2.1. A model of sequence evolution.

This paper employs the generalized Jukes–Cantor model [22] of sequence evolution defined as follows. Let $m \geq 2$ and $n \geq 3$ be two integers. Let $\mathcal{A} = \{a_1, \ldots, a_m\}$ be a finite alphabet. An *evolutionary tree* T for $\mathcal{A}$ is a rooted binary tree of n leaves with an *edge mutation probability* p_e for each tree edge e. The edge mutation probabilities are bounded away from 0 and $1 - \frac{1}{m}$, i.e., there exist f and g such that for every edge e of T, $0 < f \leq p_e \leq g < 1 - \frac{1}{m}$. Given a sequence $s_1 \cdots s_\ell \in \mathcal{A}^\ell$ associated with the root of T, a set of n *mutated sequences* in $\mathcal{A}^\ell$ is generated by ℓ random labelings of the tree at the nodes. These ℓ labelings are

mutually independent. The labelings at the jth leaf give the jth *mutated sequence* $s_1^{(j)} \cdots s_\ell^{(j)}$, where the ith labeling of the tree gives the ith symbols $s_i^{(1)}, \ldots, s_i^{(n)}$. The ith labeling is carried out from the root towards the leaves along the edges. The root is labeled by s_i. On edge e, the child's label is the same as the parent's with probability $1 - p_e$ or is different with probability $\frac{p_e}{m-1}$ for each different symbol. Such *mutations* of symbols along the edges are mutually independent.

2.2. Problem formulation. The *topology* $\Psi(T)$ of T is the unrooted tree obtained from T by omitting the edge mutation probability and by replacing the two edges e_1 and e_2 between the root and its children with a single edge e_0. Note that the leaves of $\Psi(T)$ are labeled with the same sequences as in T, but $\Psi(T)$ need not be labeled otherwise. The *weighted topology* $\Psi_{\mathrm{w}}(T)$ of T is $\Psi(T)$ where each edge $e \neq e_0$ of $\Psi(T)$ is further weighted by its edge mutation probability p_e in T and for technical reasons, the edge e_0 is weighted by $1 - (1 - p_{e_1})(1 - p_{e_2})$.

For technical convenience, the weight of each edge XY in $\Psi_{\mathrm{w}}(T)$ is often replaced by a certain edge length, such as Δ_{XY} in (2.5), from which the weight of XY can be efficiently determined.

The *weighted evolutionary topology* problem is that of taking n mutated sequences as input and recovering $\Psi_{\mathrm{w}}(T)$ with high accuracy and high probability. Fast-HGT is a learning algorithm for this problem.

Remark. The special treatment for e_1 and e_2 is due to the fact that the root sequence may be entirely arbitrary and thus, in general, no algorithm can place the root accurately. This is consistent with the fact that the root sequence is not directly observable in practice, and locating the root requires considerations beyond those of general modeling [22]. If the root sequence is also given as input, Fast-HGT can be modified to locate the root and the weights of e_1 and e_2 in a straightforward manner.

2.3. Probabilistic closeness. Fast-HGT is based on a notion of probabilistic closeness between nodes. For the ith random labeling of T, we identify each node of T with the random variable X_i that gives the labeling at the node. Note that since $s_1 \cdots s_\ell$ may be arbitrary, the random variables X_i for different i are not necessarily identically distributed. For brevity, we often omit the index i of X_i in a statement if the statement is independent of i.

For nodes X and $Y \in T$, let $p_{XY} = \Pr\{\, X \neq Y \,\}$. The *closeness* of X and Y is

$$\sigma_{XY} = \Pr\{\, X = Y \,\} - \frac{1}{m-1}\Pr\{\, X \neq Y \,\} = 1 - \alpha p_{XY}, \text{where } \alpha = \frac{m}{m-1}. \tag{2.1}$$

LEMMA 2.1 (folklore). *If node Y is on the path between two nodes X and Z in T, then $\sigma_{XZ} = \sigma_{XY}\sigma_{YZ}$.*

If X and Y are leaves, their closeness is estimated from sample sequences as

$$\hat{\sigma}_{XY} = \frac{1}{\ell}\sum_{i=1}^{\ell} I_{\hat{X}_i \hat{Y}_i}, \tag{2.2}$$

where $\hat{X}_1, \ldots, \hat{X}_\ell$ and $\hat{Y}_1, \ldots, \hat{Y}_\ell$ are the symbols at positions $1, \ldots, \ell$ of the observed sample sequences for the two leaves, and

$$I_{xy} = \begin{cases} \frac{-1}{m-1} & \text{if } x \neq y; \\ 1 & \text{if } x = y. \end{cases}$$

The next lemma is useful for analyzing the estimation given by (2.2).

LEMMA 2.2. *For $\epsilon > 0$,*

$$\Pr\left\{ \frac{\hat{\sigma}_{XY}}{\sigma_{XY}} \le 1-\epsilon \right\} \le \exp\left(-\frac{2}{\alpha^2}\ell\sigma_{XY}^2\epsilon^2\right); \tag{2.3}$$

$$\Pr\left\{ \frac{\hat{\sigma}_{XY}}{\sigma_{XY}} \ge 1+\epsilon \right\} \le \exp\left(-\frac{2}{\alpha^2}\ell\sigma_{XY}^2\epsilon^2\right). \tag{2.4}$$

Proof. By (2.2),

$$\Pr\left\{ \frac{\hat{\sigma}_{XY}}{\sigma_{XY}} \le 1-\epsilon \right\} = \Pr\left\{ \sum_{i=1}^{\ell} (I_{X_iY_i} - \sigma_{XY}) \le -\ell\sigma_{XY}\epsilon \right\};$$

$$\Pr\left\{ \frac{\hat{\sigma}_{XY}}{\sigma_{XY}} \ge 1+\epsilon \right\} = \Pr\left\{ \sum_{i=1}^{\ell} (I_{X_iY_i} - \sigma_{XY}) \ge \ell\sigma_{XY}\epsilon \right\}.$$

Since $\frac{-1}{m-1} \le I_{X_iY_i} \le 1$ and $\mathbb{E}[\, I_{X_iY_i} - \sigma_{XY}\,] = 0$, we use Hoeffding's inequality [17] on sums of independent bounded random variables to have (2.3) and (2.4). ∎

2.4. Distance and harmonic mean. The *distance* of nodes X and $Y \in T$ is

$$\Delta_{XY} = -\ln \sigma_{XY}. \tag{2.5}$$

For an edge XY in T, Δ_{XY} is called the *edge length* of XY.

Fast-HGT uses Statement 2.3 of the next corollary to locate internal nodes of T.

COROLLARY 2.3. *Let X, Y, and Z be nodes in T.*

1. *If $X \neq Y$, then $\Delta_{XY} = \Delta_{YX} > 0$. Also, $\Delta_{XX} = 0$.*
2. *If Y is on the path between X and Z in T, then $\Delta_{XZ} = \Delta_{XY} + \Delta_{YZ}$.*
3. *For any σ with $\sigma_{XY} \le \sigma < 1$, there is a node P on the path between X and Y in T such that $\sigma(1-\alpha g)^{1/2} \le \sigma_{XP} \le \sigma(1-\alpha g)^{-1/2}$. Furthermore, if $\sigma_{XY}(1-\alpha g)^{1/2} < \sigma < (1-\alpha g)^{-1/2}$, then P is distinct from X and Y.*

Proof. Statements 1 and 2 follow from (2.1) and Lemma 2.1. Statement 3 becomes straightforward when restated in terms of distance as follows. For any Δ with $\Delta_{XY} \ge \Delta > 0$, there is a node P on the path between X and Y in T such that $\Delta + \frac{-\ln(1-\alpha g)}{2} \ge \Delta_{XP} \ge \Delta - \frac{-\ln(1-\alpha g)}{2}$. Furthermore, if $\Delta_{XY} - \frac{-\ln(1-\alpha g)}{2} > \Delta > \frac{-\ln(1-\alpha g)}{2}$, then P is distinct from X and Y. ∎

If X and Y are leaves, their distance is estimated from sample sequences as

$$\hat{\Delta}_{XY} = \begin{cases} -\ln \hat{\sigma}_{XY} & \text{if } \hat{\sigma}_{XY} > 0; \\ \infty & \text{otherwise.} \end{cases} \tag{2.6}$$

A *triplet* XYZ consists of three distinct leaves X, Y, and Z of T. There is an internal node P in T at which the pairwise paths between the leaves in XYZ intersect; see Figure 2.1. P is the *center* of XYZ, and XYZ *defines* P. Note that a star is formed by the edges on the paths between P and the three leaves in XYZ.

By Corollary 2.3(2), the distance between P and a leaf in XYZ, say, X, can be obtained as $\Delta_{XP} = \frac{\Delta_{XY}+\Delta_{XZ}-\Delta_{YZ}}{2}$, which is estimated by

$$\hat{\Delta}_{XP} = \frac{\hat{\Delta}_{XY} + \hat{\Delta}_{XZ} - \hat{\Delta}_{YZ}}{2}. \tag{2.7}$$

The *closeness* of XYZ is $\sigma_{XYZ} = \frac{3}{\frac{1}{\sigma_{XY}}+\frac{1}{\sigma_{XZ}}+\frac{1}{\sigma_{YZ}}}$, which is estimated by $\hat{\sigma}_{XYZ} = \frac{3}{\frac{1}{\hat{\sigma}_{XY}}+\frac{1}{\hat{\sigma}_{XZ}}+\frac{1}{\hat{\sigma}_{YZ}}}$. XYZ is called *positive* if $\hat{\sigma}_{XY}$, $\hat{\sigma}_{XZ}$, and $\hat{\sigma}_{YZ}$ are all positive.

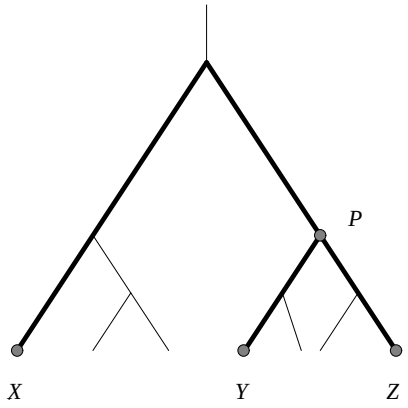

FIG. 2.1. *P is the center of triplet XYZ.*

The next corollary relates σ_{XYZ} and the pairwise closenesses of X, Y, and Z.

COROLLARY 2.4. *If $\sigma_{XP} \leq \sigma_{YP} \leq \sigma_{ZP}$, then $\sigma_{XY} \leq \sigma_{XZ} \leq \sigma_{YZ}$, $\sigma_{XZ} \geq \frac{2}{3}\sigma_{XYZ}$, and $\sigma_{YP}^2 \geq \frac{1}{3}\sigma_{XYZ}$.*

Proof. This corollary follows from Lemma 2.1 and simple algebra. □

The next lemma relates σ_{XYZ} to the probability of overestimating the distance between P and a leaf in XYZ using (2.7).

LEMMA 2.5. *For $0 < \epsilon < 1$,*

$$\Pr\left\{ \hat{\Delta}_{XP} - \Delta_{XP} \geq \frac{-\ln(1-\epsilon)}{2} \right\} \leq 3\exp\left(-\frac{2}{9\alpha^2}\ell\sigma_{XYZ}^2\epsilon^2\right).$$

Proof. See section A.1. □

2.5. Basis of a greedy strategy. Let d_{XY} denote the number of edges in the path between two leaves X and Y in T. By Lemma 2.1, σ_{XY} can be as small as $(1-\alpha g)^{d_{XY}}$. Thus, the larger d_{XY} is, the more difficult it is to estimate σ_{XY} and Δ_{XY}. This intuition leads to a natural greedy strategy outlined below that favors leaf pairs with small d_{XY} and large σ_{XY}.

The *g-depth* of a node in a rooted tree T' is the smallest number of edges in a path from the node to a leaf. Let e be an edge between nodes u_1 and u_2. Let T_1' and T_2' be the subtrees of T' obtained by cutting e which contain u_1 and u_2, respectively. The *g-depth* of e in T' is the larger of the g-depth of u_1 in T_1' and that of u_2 in T_2'. The *g-depth* of a rooted tree is the largest possible g-depth of an edge in the tree. (The prefix g emphasizes that this usage of depth is nonstandard in graph theory.)

Let d be the g-depth of T. Variants of the next lemma have proven very useful and insightful; see, e.g., [9, 11, 10].

LEMMA 2.6.

1. $d \leq 1 + \lfloor \log_2(n-1) \rfloor$.
2. *Every internal node P of T except the root has a defining triplet XYZ such that d_{XP}, d_{YP}, and d_{ZP} are all at most $d+1$ and thus, $\sigma_{XYZ} \geq (1-\alpha g)^{2(d+1)}$. Every leaf of T is in such a triplet.*

Proof. The proof is straightforward. Note that the more unbalanced T is, the smaller its g-depth is. □

In T, the star formed by a defining triplet of an internal node contains the three edges incident to the internal node. Thus, $\Psi(T)$ can be reconstructed from triplets

described in Lemma 2.6(2) or those with similarly large closenesses. This observation motivates the following definitions. Let

$$\sigma_{\mathrm{lg}} = \frac{3\sqrt{2}}{2}\left(\frac{\sqrt{2}-1}{\sqrt{2}+1}\right)^2 (1-\alpha g)^{2d+4};\quad \sigma_{\mathrm{sm}} = \frac{\sigma_{\mathrm{lg}}}{\sqrt{2}};\quad \sigma_{\mathrm{md}} = \frac{\sigma_{\mathrm{lg}}+\sigma_{\mathrm{sm}}}{2}.$$

Remark. The choice of σ_{lg} is obtained by solving (3.2), (3.3), and (3.4).

A triplet XYZ is *large* if $\sigma_{XYZ} \geq \sigma_{\mathrm{lg}}$; it is *small* if $\sigma_{XYZ} \leq \sigma_{\mathrm{sm}}$. Note that by Lemma 2.6(2), each nonroot internal node of T has at least one large defining triplet.

LEMMA 2.7. *The first inequality below holds for all large triplets XYZ, and the second holds for all small triplets.*

$$\Pr\{\,\hat{\sigma}_{XYZ} \leq \sigma_{\mathrm{md}}\,\} \leq \exp\left(-\frac{\left(\sqrt{2}-1\right)^2}{36\alpha^2}\ell\sigma_{\mathrm{lg}}^2\right); \tag{2.8}$$

$$\Pr\{\,\hat{\sigma}_{XYZ} \geq \sigma_{\mathrm{md}}\,\} \leq \exp\left(-\frac{\left(\sqrt{2}-1\right)^2}{36\alpha^2}\ell\sigma_{\mathrm{lg}}^2\right). \tag{2.9}$$

Proof. See section A.2. □

A nonroot internal node of T may have more than one large defining triplet. Consequently, since distance estimates contain errors, we may obtain an erroneous estimate of $\Psi(T)$ by reconstructing the same internal node more than once from its different large defining triplets. To address this issue, Fast-HGT adopts a threshold $0 < \Delta_{\min} < \frac{-\ln(1-\alpha f)}{2}$ based on the fact that the distance between two distinct nodes is at least $-\ln(1-\alpha f)$; also let $c = \frac{\Delta_{\min}}{-\ln(1-\alpha f)}$. Fast-HGT considers the center P of a triplet XYZ and the center Q of another triplet XUV to be separate if and only if

$$|\hat{\Delta}_{XP} - \hat{\Delta}_{XQ}| \geq \Delta_{\min}, \tag{2.10}$$

where $\hat{\Delta}_{XP} = (\hat{\Delta}_{XY} + \hat{\Delta}_{XZ} - \hat{\Delta}_{YZ})/2$ and $\hat{\Delta}_{XQ} = (\hat{\Delta}_{XU} + \hat{\Delta}_{XV} - \hat{\Delta}_{XV})/2$. Notice that two triplet centers can be compared in this manner only if the triplets share at least one leaf. The next lemma shows that a large triplet's center is estimated within a small error with high probability.

LEMMA 2.8. *Let P be the center of a triplet XYZ. If XYZ is not small, then*

$$\Pr\left\{\left|\hat{\Delta}_{XP} - \Delta_{XP}\right| \geq \frac{\Delta_{\min}}{2}\right\} \leq 7\exp\left(-\frac{c^2}{81}\ell\sigma_{\mathrm{lg}}^2 f^2\right). \tag{2.11}$$

Proof. See section A.3. □

We next define and analyze two key events $\mathcal{E}_{\mathrm{c}}$ and $\mathcal{E}_{\mathrm{g}}$ as follows. The subscripts c and g denote the words greedy and center, respectively.

- $\mathcal{E}_{\mathrm{c}}$ is the event that for every triplet XYZ that is not small, $\left|\hat{\Delta}_{XP} - \Delta_{XP}\right| < \frac{\Delta_{\min}}{2}$, $\left|\hat{\Delta}_{YP} - \Delta_{YP}\right| < \frac{\Delta_{\min}}{2}$, and $\left|\hat{\Delta}_{ZP} - \Delta_{ZP}\right| < \frac{\Delta_{\min}}{2}$, where P is the center of XYZ.
- $\mathcal{E}_{\mathrm{g}}$ is the event that $\hat{\sigma}_{XYZ} > \hat{\sigma}_{X'Y'Z'}$ for every large triplet XYZ and every small triplet $X'Y'Z'$.

LEMMA 2.9.

$$\Pr\{\,\overline{\mathcal{E}}_{\mathrm{c}}\,\} \leq 21\binom{n}{3}\exp\left(-\frac{c^2}{81}\ell\sigma_{\mathrm{lg}}^2 f^2\right);\ \Pr\{\,\overline{\mathcal{E}}_{\mathrm{g}}\,\} \leq \binom{n}{3}\exp\left(-\frac{\left(\sqrt{2}-1\right)^2}{36\alpha^2}\ell\sigma_{\mathrm{lg}}^2\right).$$

Proof. The inequalities follow from (2.11) and Lemma 2.7, respectively. ∎

3. Fast-HGT. Section 3.1 details Fast-HGT. Section 3.2 analyzes its running time and work space. Section 3.3 proves technical lemmas for bounding the algorithm's required sample size. Section 3.4 analyzes this sample size.

Algorithm Fast Harmonic Greedy Triplets
Input:
- $\Delta_{\min}$;
- $\hat{\Delta}_{XY}$ for all leaves X and Y of T which are computed via (2.2) and (2.6) from n mutated length-ℓ sequences generated by T.

Output: $\Psi_{\mathrm{w}}(T)$.

F1 Select an arbitrary leaf A and find a triplet ABC with the maximum $\hat{\sigma}_{ABC}$.
F2 **if** ABC is not positive **then** let T^* be the empty tree, **fail**, and **stop**.
F3 Let T^* be the star with three edges formed by ABC and its center D.
F4 Use (2.7) to set $\Delta^*_{AD} \leftarrow \hat{\Delta}_{AD}$, $\Delta^*_{BD} \leftarrow \hat{\Delta}_{BD}$, $\Delta^*_{CD} \leftarrow \hat{\Delta}_{CD}$.
F5 Set $\mathrm{def}(D) \leftarrow \{A, B, C\}$.
F6 First set all $\mathcal{S}[M]$ to null; then for $Q_1Q_2 \in \{AD, BD, CD\}$, Update-$\mathcal{S}(Q_1Q_2)$.
F7 **repeat**
F8 **if** $\mathcal{S}[M] =$ null for all leaves $M \in T$ **then fail** and **stop**.
F9 Find $\mathcal{S}[N] = \langle P_1P_2, NXY, P, \Delta^*_{P_1P}, \Delta^*_{P_2P}, \Delta^*_{NP}\rangle$ with the maximum $\hat{\sigma}_{NXY}$.
F10 Split P_1P_2 into two edges P_1P and P_2P in T^* with lengths $\Delta^*_{P_1P}$ and $\Delta^*_{P_2P}$.
F11 Add to T^* a leaf N and an edge NP with length Δ^*_{NP}.
F12 Set $\mathrm{def}(P) \leftarrow \{N, X, Y\}$.
F13 For every M with $\mathcal{S}[M]$ containing the edge P_1P_2, set $\mathcal{S}[M] \leftarrow$ null.
F14 For each $Q_1Q_2 \in \{P_1P, P_2P, NP\}$, Update-$\mathcal{S}(Q_1Q_2)$.
F15 **until** all leaves of T are inserted to T^*; i.e., this loop has iterated $n-3$ times.
F16 Output T^*.

FIG. 3.1. *The* Fast-HGT *algorithm.*

Algorithm Update-$\mathcal{S}$
Input: an edge $Q_1Q_2 \in T^*$
U1 Find all splitting tuples for $Q_1Q_2 \in T^*$.
U2 For each $\langle Q_1Q_2, MUV, Q, \Delta^*_{Q_1Q}, \Delta^*_{Q_2Q}, \Delta^*_{MQ}\rangle$ at line U1, assign it to $\mathcal{S}[M]$ if $\hat{\sigma}_{MUV}$ is greater than that of $\mathcal{S}[M]$.

FIG. 3.2. *The Update-*$\mathcal{S}$ *subroutine.*

3.1. The description of Fast-HGT. Fast-HGT and its subroutines Update-$\mathcal{S}$ and Split-Edge are detailed in Figures 3.1, 3.2, and 3.3, respectively.

Given $\Delta_{\min}$ and n mutated sequences as input, the task of Fast-HGT is to recover $\Psi_{\mathrm{w}}(T)$. The algorithm first constructs a star T^* formed by a large triplet at lines F1 through F3. It then inserts into T^* a leaf of T and a corresponding internal node per iteration of the repeat at line F7 until T^* has a leaf for each input sequence. The T^* at line F16 is our reconstruction of $\Psi_{\mathrm{w}}(T)$. For $k = 3, \ldots, n$, let T^*_k be the version of T^* with k leaves constructed during a run of Fast-HGT; i.e., T^*_3 is constructed at line F3, and T^*_k with $k \geq 4$ is constructed at line F11 during the $(k-3)$th iteration of the repeat. Note that T^*_n is output at line F16.

Algorithm Split-Edge
Input: an edge P_1P_2 in T^* and a relevant triplet NXY with center P.
Output: If P is strictly between P_1 and P_2 in T and thus can be inserted on P_1P_2, then we return the message "split" and the edge lengths $\Delta^*_{P_1P}$, $\Delta^*_{P_2P}$, and Δ^*_{NP}. Otherwise, we return a reason why P cannot be inserted.

S1 Use (2.7) to compute $\hat{\Delta}_{XP}$, $\hat{\Delta}_{YP}$, $\hat{\Delta}_{NP}$ for NXY.
S2 Let $X_1 \in \{X, Y\} \cap \mathrm{def}(P_1)$ and $X_2 \in \{X, Y\} \cap \mathrm{def}(P_2)$.
S3 For each $i = 1$ or 2, **if** P_i is an internal node of T^*
S4 **then** use (2.7) to compute $\hat{\Delta}_{X_iP_i}$ for the triplet formed by $\mathrm{def}(P_i)$
S5 **else** set $\hat{\Delta}_{X_iP_i} \leftarrow 0$.
S6 Set $\Delta_1 \leftarrow \hat{\Delta}_{X_1P} - \hat{\Delta}_{X_1P_1}$ and $\Delta_2 \leftarrow \hat{\Delta}_{X_2P} - \hat{\Delta}_{X_2P_2}$.
S7 **if** $|\Delta_1| < \Delta_{\min}$ or $|\Delta_2| < \Delta_{\min}$
S8 **then return** "too close"
S9 **else begin**
S10 **if** P_2 (respectively, P_1) is on the path between P_1 and X_1 (P_2 and X_2) in T^*
S11 **then** set $\Delta'_1 \leftarrow -\Delta_1$ ($\Delta'_2 \leftarrow -\Delta_2$)
S12 **else** set $\Delta'_1 \leftarrow \Delta_1$ ($\Delta'_2 \leftarrow \Delta_2$).
(*Remark.* Since X_1 may equal X_2, the tests for P_1 and P_2 are both needed.)
S13 Set $\Delta''_1 \leftarrow (\Delta'_1 + \Delta^*_{P_1P_2} - \Delta'_2)/2$ and $\Delta''_2 \leftarrow (\Delta'_2 + \Delta^*_{P_1P_2} - \Delta'_1)/2$.
(*Remark.* $\Delta''_1 + \Delta''_2 = \Delta^*_{P_1P_2}$, Δ''_1 estimates Δ_{P_1P}, and Δ''_2 estimates Δ_{P_2P}.)
S14 **if** $\Delta''_1 \geq \Delta^*_{P_1P_2}$ or $\Delta''_2 \geq \Delta^*_{P_1P_2}$
S15 **then return** "outside this edge"
S16 **else return** "split", Δ''_1, Δ''_2, $\hat{\Delta}_{NP}$.
S17 **end.**

FIG. 3.3. *The Split-Edge subroutine.*

A node Q is *strictly between* nodes Q_1 and Q_2 in T if Q is on the path between Q_1 and Q_2 in T but $Q \neq Q_1$, $Q \neq Q_2$, and Q is not the root of T. At each iteration of the repeat, Fast-HGT finds an edge P_1P_2 in T^* and a triplet NXY where $X, Y \in T^*$, $N \notin T^*$, and the center P of NXY is strictly between on P_1 and P_2 in T^*. Such P_1P_2 and NXY can be used to insert N and P into T^*. We record an insertion by letting $\mathrm{def}(P) = \{N, X, Y\}$; for notational uniformity, let $\mathrm{def}(X) = \{X\}$ for all leaves X.

At line F6, $\mathcal{S}$ is an array indexed by the leaves M of T^*. At the beginning of each iteration of the repeat, $\mathcal{S}[N]$ stores the most suitable P_1P_2 and NXY for inserting N into T^*. $\mathcal{S}$ is initialized at line F6; it is updated at lines F13 and F14 after a new leaf and a new internal node are inserted into T^*. The precise content of $\mathcal{S}$ is described in Lemma 3.6.

To further specify $\mathcal{S}[N]$, we call NXY *relevant* for $P_1P_2 \in T^*_k$ if it is positive, $N \notin T^*_k$, $X \in \mathrm{def}(P_1)$, $Y \in \mathrm{def}(P_2)$, and P_1P_2 is on the path between X and Y in T^*_k. We use Split-Edge to determine whether the center P of a relevant NXY is strictly between P_1 and P_2 in T. We also use Split-Edge to calculate an estimation $\Delta^*_{P'P''}$ of $\Delta_{P'P''}$ for each edge $P'P'' \in T^*_k$, which is called the *length* of $P'P''$ in T^*_k. Split-Edge has three possible outcomes:

1. At line S8, P is too close to P_1 or P_2 to be a different internal node.
2. At line S15, P is outside the path between P_1 and P_2 in T and thus should not be inserted into T^*_k on P_1P_2.
3. At line S16, P is strictly between P_1 and P_2 in T. Thus, P can be inserted between P_1 and P_2 in T^*_k, and the lengths $\Delta^*_{P_1P}, \Delta^*_{P_2P}, \Delta^*_{NP}$ of the possible

new edges P_1P, P_2P, and NP are returned.

In the case of the third outcome, NXY is called a *splitting triplet* for P_1P_2 in T_k^*, and $\langle P_1P_2, NXY, P, \Delta^*_{P_1P}, \Delta^*_{P_2P}, \Delta^*_{NP}\rangle$ is a *splitting tuple*. Each $\mathcal{S}[N]$ is either a single splitting tuple or null. In the latter case, the estimated closeness of the triplet in $\mathcal{S}[N]$ is regarded as 0 for technical uniformity.

Fast-HGT ensures the accuracy of T^* in several ways. The algorithm uses only positive triplets to recover internal nodes of T at lines F1 and F9. These two lines together form the greedy strategy of Fast-HGT. The maximality of the triplet chosen at these two lines favors large triplets over small ones based on Lemmas 2.6 and 2.7. With a relevant triplet as input, Split-Edge compares P to P_1 and P_2 using the rule of (2.10) and can estimate the distance between P and P_1 or P_2 from the same leaf to avoid accumulating estimation errors in edge lengths.

The next lemma enables Fast-HGT to grow T^* by always using relevant triplets.

LEMMA 3.1. *For each $k = 3, \ldots, n-1$, at the start of the $(k-2)$th iteration of the repeat at line* F7, $\operatorname{def}(P_1) \cap \operatorname{def}(P_2) \neq \emptyset$ *for every edge $P_1P_2 \in T_k^*$.*

Proof. The proof is by induction on k. The base case follows from the fact that the statement holds for T_3^* at line F3. The induction step follows from the use of a relevant triplet at line F9. ∎

Remark. A subsequence work [6] shows that Fast-HGT can run with the same time, space, and sample complexities without knowing f and $\Delta_{\min}$; this is achieved by slightly modifying some parts of Split-Edge.

3.2. The running time and work space of Fast-HGT. Before proving the desired time and space complexities of Fast-HGT in Theorem 3.2 below, we note the following three key techniques used by Fast-HGT to save time and space.

1. At line F1, ABC is selected for a fixed arbitrary A. This limits the number of triplets considered at line F1 to $\mathcal{O}(n^2)$. This technique is supported by the fact that each leaf in T is contained in a large triplet.
2. At lines F6 and F14, $\mathcal{S}$ keeps only splitting tuples. This limits the number of triplets considered for each involved edge to $\mathcal{O}(n)$. This technique is feasible since by Lemma 3.5, $\Psi(T)$ can be recovered using only relevant triplets.
3. At line F14, $\mathcal{S}$ includes no new splitting tuples for the edges Q_1Q_2 that already exist in T^* before N is inserted. This technique is feasible because the insertion of N results in no new relevant triplets for such Q_1Q_2 at all.

THEOREM 3.2. Fast-HGT *runs in $\mathcal{O}(n^2)$ time using $\mathcal{O}(n)$ work space.*

Proof. We analyze the time and space complexities separately as follows.

Time complexity. Line F1 takes $\mathcal{O}(n^2)$ time. Line F6 takes $\mathcal{O}(n)$ total time to examine $2(n-3)$ triplets for each Q_1Q_2. As for the repeat at line F7, lines F8, F9, and F13 take $\mathcal{O}(n)$ time to search through $\mathcal{S}$. For the $(k-3)$th iteration of the repeat where $k = 4, \ldots, n-1$, line F14 takes $\mathcal{O}(n)$ total time to examine at most $9(n-k-1)$ triplets for each of P_1P, P_2P, and NP. Thus, each iteration of the repeat takes $\mathcal{O}(n)$ time. Since the repeat iterates at most $n-3$ times, the time complexity of Fast-HGT is as stated.

Space complexity. T^* and the sets $\operatorname{def}(G)$ for all nodes G in T^* take $\mathcal{O}(n)$ work space. $\mathcal{S}$ takes $\mathcal{O}(n)$ space. Lines F1, F6, and F14 in Fast-HGT and lines U1 and U2 in Update-$\mathcal{S}$ can be implemented to use $\mathcal{O}(1)$ space. The other variables needed by Fast-HGT take $\mathcal{O}(1)$ space. Thus, the space complexity of Fast-HGT is as stated. ∎

3.3. Technical lemmas for bounding the sample size. Let L_k be the set of the leaves of $\Psi(T)$ that are in T_k^*. Let Ψ_k be the subtree of $\Psi(T)$ formed by the edges

on paths between leaves in L_k. A *branchless* path in Ψ_k is one whose internal nodes are all of degree 2 in Ψ_k. We say that T_k^* *matches* T if T_k^* without the edge lengths can be obtained from Ψ_k by replacing every maximal branchless path with an edge between its two endpoints.

For $k = 3, \ldots, n$, we define the following conditions:

- $\mathcal{A}_k$: T_k^* matches T.
- $\mathcal{B}_k$: For every internal node $Q \in T_k^*$, the triplet formed by $\mathrm{def}(Q)$ is not small.
- $\mathcal{C}_k$: For every edge $Q_1Q_2 \in T_k^*$, $|\Delta^*_{Q_1Q_2} - \Delta_{Q_1Q_2}| < 2\Delta_{\min}$.

In this section, Lemmas 3.3, 3.4, and 3.5 analyze under what conditions Split-Edge can help correctly insert a new leaf and a new internal node to T_k^*. Later in section 3.4, we use these lemmas to show by induction in Lemma 3.7 that the events $\mathcal{E}_{\mathrm{g}}$ and $\mathcal{E}_{\mathrm{c}}$, which are defined before Lemma 2.9, imply that $\mathcal{A}_k$, $\mathcal{B}_k$, and $\mathcal{C}_k$ hold for all k. This leads to Theorem 3.8, stating that Fast-HGT solves the weighted evolutionary topology problem with a polynomial-sized sample.

Lemmas 3.3, 3.4, and 3.5 make the following assumptions for some $k < n$:

- The $(k-3)$th iteration of the repeat at line F7 has been completed.
- T_k^* has been constructed, and $\mathcal{A}_k$, $\mathcal{B}_k$, and $\mathcal{C}_k$ hold.
- Fast-HGT is currently in the $(k-2)$th iteration of the repeat.

LEMMA 3.3. *Assume that $\mathcal{E}_{\mathrm{c}}$ holds and the triplet NXY input to Split-Edge is not small. Then, the test of line* S7 *fails if and only if $P \neq P_1$ and $P \neq P_2$ in T.*

Proof. There are two directions, both using the following equation. By line S6,

$$\Delta_1 = (\hat{\Delta}_{X_1P} - \Delta_{X_1P}) - (\hat{\Delta}_{X_1P_1} - \Delta_{X_1P_1}) + (\Delta_{X_1P} - \Delta_{X_1P_1}). \tag{3.1}$$

($\Longrightarrow$) To prove by contradiction, assume $P = P_1$ or $P = P_2$ in T. If $P = P_1$, then $\Delta_{X_1P} = \Delta_{X_1P_1}$, and by $\mathcal{A}_k$, P_1 is an internal node in T_k^*. By $\mathcal{B}_k$, the triplet formed by $\mathrm{def}(P_1)$ is not small. Thus, by $\mathcal{E}_{\mathrm{c}}$ and (3.1), $|\Delta_1| < \Delta_{\min}$. By symmetry, if $P = P_2$, then $|\Delta_2| < \Delta_{\min}$. In either case, the test of line S7 passes.

($\Longleftarrow$) Since $P \neq P_1$, $\Delta_{X_1P} - \Delta_{X_1P_1} \geq -\ln(1-\alpha f) \geq 2\Delta_{\min}$. If P_1 is a leaf in T_k^*, then by $\mathcal{A}_k$, P_1 is leaf X_1 in T, and $\hat{\Delta}_{X_1P_1} = \Delta_{X_1P_1} = 0$. By $\mathcal{E}_{\mathrm{c}}$ and (3.1), $|\Delta_1| > 1.5\Delta_{\min}$. If P_1 is an internal node in T_k^*, then by $\mathcal{B}_k$, $\mathcal{E}_{\mathrm{c}}$, and (3.1), we have $|\Delta_1| > \Delta_{\min}$. In either case, $|\Delta_1| > \Delta_{\min}$. By symmetry, since $P \neq P_2$, $|\Delta_2| > \Delta_{\min}$. Thus, the test of line S7 fails. ∎

LEMMA 3.4. *In addition to the assumption in Lemma* 3.3*, also assume that $P \neq P_1$ and $P \neq P_2$ in T, i.e., the test of line* S7 *has failed. Then, the test of line* S14 *fails if and only if P is on the path between P_1 and P_2 in T.*

Proof. There are two directions.

($\Longleftarrow$) From lines S6, S10, and Corollary 2.3(2),

$$\begin{aligned}(\Delta_1' - \Delta_2') - (\Delta_{P_1P} - \Delta_{P_2P}) = &\pm \left((\hat{\Delta}_{X_1P} - \Delta_{X_1P}) - (\hat{\Delta}_{X_1P_1} - \Delta_{X_1P_1})\right) \\ &\pm \left((\hat{\Delta}_{X_2P} - \Delta_{X_2P}) - (\hat{\Delta}_{X_2P_2} - \Delta_{X_2P_2})\right).\end{aligned}$$

Thus, whether P_1 and P_2 are leaves or internal nodes in T_k^*, by $\mathcal{A}_k$, $\mathcal{B}_k$, and $\mathcal{E}_{\mathrm{c}}$, $|(\Delta_1' - \Delta_2') - (\Delta_{P_1P} - \Delta_{P_2P})| < 2\Delta_{\min}$. By line S13 and Corollary 2.3(2),

$$\begin{aligned}\Delta_1'' &< \frac{2\Delta_{\min} + (\Delta_{P_1P} - \Delta_{P_2P}) + \Delta^*_{P_1P_2}}{2} \\ &= \frac{2(2\Delta_{\min} - \Delta_{P_2P}) + (-2\Delta_{\min} + \Delta_{P_1P_2}) + \Delta^*_{P_1P_2}}{2}.\end{aligned}$$

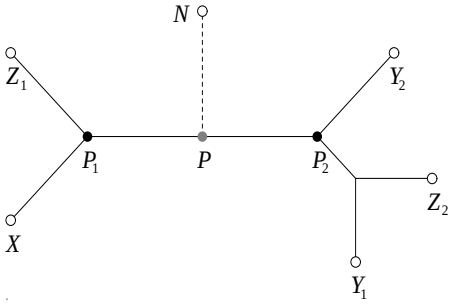

FIG. 3.4. *This subgraph of T fixes some notation used in the proof of Case* 1 *of Lemma* 3.5. *The location of Y_1 relative to Y_2 and Z_2 is nonessential; for instance, Y_1 can even be the same as Y_2. In T_k^*, $\mathrm{def}(P_1) = \{X, Y_1, Z_1\}$ and $\mathrm{def}(P_2) = \{X, Y_2, Z_2\}$. Neither XY_1Z_1 nor XY_2Z_2 is small, and $\Delta_{P_2Y_2} \le \Delta_{P_2Z_2}$. We aim to prove that there is a leaf $N \notin T_k^*$ such that NXY_2 or NZ_1Y_2 is large and defines a node P strictly between P_1 and P_2 in T.*

Then, since $P \neq P_2$ and thus $\Delta_{P_2P} \ge 2\Delta_{\min}$, by $\mathcal{C}_k$, we have $\Delta_1'' < \Delta^*_{P_1P_2}$. By symmetry, $\Delta_2'' < \Delta^*_{P_1P_2}$. Thus, the test of line S14 fails.

($\Longrightarrow$) To prove by contradiction, assume that P is not on the path between P_1 and P_2. By similar arguments, if $\Delta_{P_1P} > \Delta_{P_1P_2}$ (respectively, $\Delta_{P_2P} > \Delta_{P_1P_2}$), then $\Delta_1'' > \Delta^*_{P_1P_2}$ (respectively, $\Delta_2'' > \Delta^*_{P_1P_2}$). Thus, the test of line S14 passes. ∎

LEMMA 3.5. *Assume that P_1P_2 is an edge in T_k^* and some node is strictly between P_1 and P_2 in T. Then there is a large triplet NQ_1Q_2 with center P such that $N \notin T_k^*$, $Q_1 \in \mathrm{def}(P_1)$, $Q_2 \in \mathrm{def}(P_2)$, and P is strictly between P_1 and P_2 in T.*

Proof. By Lemma 2.6(2), for every node P strictly between P_1 and P_2 in T, there exists a leaf $N \notin T_k^*$ with $\sigma_{PN} \ge (1-\alpha g)^{d+1}$. To choose P, there are two cases: (1) both P_1 and P_2 are internal nodes in T_k^*, and (2) P_1 or P_2 is a leaf in T_k^*.

Case 1: By Lemma 3.1, let $\mathrm{def}(P_1) = \{X, Y_1, Z_1\}$ and $\mathrm{def}(P_2) = \{X, Y_2, Z_2\}$. By $\mathcal{B}_k$, neither XY_2Z_2 nor XY_1Z_1 is small. To fix the notation for $\mathrm{def}(P_1)$ and $\mathrm{def}(P_2)$ with respect to their topological layout, we assume without loss of generality that Figure 3.4 or equivalently the following statements hold:

- In T_k^* and thus in T by $\mathcal{A}_k$, P_2 is on the paths between P_1 and Y_2, between P_1 and Z_2, and between P_1 and Y_1, respectively.
- Similarly, P_1 is on the paths between P_2 and Z_1 and between P_2 and X.
- $\Delta_{P_2Y_2} \le \Delta_{P_2Z_2}$.

Both NXY_2 and NZ_1Y_2 define P, and the target triplet is one of these two for some suitable P. To choose P, we further divide Case 1 into three subcases.

Case 1a: $\sigma_{XP_2} < \sigma_{Y_2P_2}(1-\alpha g)$ and $\sigma_{Y_2P_1} < \sigma_{XP_1}(1-\alpha g)$. The target triplet is NXY_2. Since $\sigma_{XY_2} \le \sqrt{\sigma_{XY_2}}$, by Corollary 2.3(3), let P be a node on the path between X and Y_2 in T with $\sqrt{\sigma_{XY_2}(1-\alpha g)} \le \sigma_{XP} \le \sqrt{\sigma_{XY_2}(1-\alpha g)^{-1}}$ and thus by Lemma 2.1 $\sqrt{\sigma_{XY_2}(1-\alpha g)} \le \sigma_{Y_2P} \le \sqrt{\sigma_{XY_2}(1-\alpha g)^{-1}}$. By the condition of Case 1a and Lemma 2.1, P is strictly between P_1 and P_2 in T. Also, by Corollary 2.4, $\sigma_{XY_2} \ge \frac{2}{3}\sigma_{XY_2Z_2}$. Thus, by Lemma 2.1, since XY_2Z_2 is not small,

$$\sigma_{NXY_2} = \frac{3}{\frac{1}{\sigma_{XP}\sigma_{PN}} + \frac{1}{\sigma_{Y_2P}\sigma_{PN}} + \frac{1}{\sigma_{XY_2}}} \ge \frac{1}{\sqrt{\frac{2}{3}}\sigma_{XY_2Z_2}^{-1/2}(1-\alpha g)^{-d-3/2} + \frac{1}{2}\sigma_{XY_2Z_2}^{-1}} > \sigma_{\mathrm{lg}}. \tag{3.2}$$

So NXY_2 is as desired for Case 1a.

Case 1b: $\sigma_{XP_2} \geq \sigma_{Y_2P_2}(1-\alpha g)$. The target triplet is NXY_2. Let P be the first node after P_2 on the path from P_2 toward P_1 in T. Then, $\sigma_{Y_2P} \geq \sigma_{Y_2P_2}(1-\alpha g)$. By Corollary 2.4, $\sigma^2_{Y_2P} \geq \sigma_{XY_2Z_2}(1-\alpha g)^2/3$. Next, since $\sigma_{XY_2} \geq \sigma_{XZ_2}$ and $\sigma_{P_2Y_2} \geq \sigma_{P_2Z_2}$,

$$\sigma_{XY_2Z_2} \leq \frac{3}{2\sigma^{-1}_{XY_2} + \sigma^{-1}_{Y_2P_2}\sigma^{-1}_{P_2Z_2}} \leq \frac{3}{2\sigma^{-1}_{XP_2}\sigma^{-1}_{Y_2P_2} + \sigma^{-2}_{Y_2P_2}} \leq \frac{3\sigma^2_{XP_2}}{2(1-\alpha g)+(1-\alpha g)^2}.$$

So $\sigma^2_{XP} > \sigma^2_{XP_2} > \sigma_{XY_2Z_2}(1-\alpha g)^2$. Since $\sigma_{XY_2} \geq \frac{2}{3}\sigma_{XY_2Z_2}$ and XY_2Z_2 is not small,

$$\sigma_{NXY_2} = \frac{3}{\frac{1}{\sigma_{XP}\sigma_{PN}} + \frac{1}{\sigma_{Y_2P}\sigma_{PN}} + \frac{1}{\sigma_{XY_2}}} > \frac{1}{\left(\frac{1+\sqrt{3}}{3}\right)\sigma^{-1/2}_{XY_2Z_2}(1-\alpha g)^{-d-2} + \frac{1}{2}\sigma^{-1}_{XY_2Z_2}} > \sigma_{\lg}. \tag{3.3}$$

So NXY_2 is as desired for Case 1b.

Case 1c: $\sigma_{Y_2P_1} \geq \sigma_{XP_1}(1-\alpha g)$. If $\sigma_{Z_1P_1} > \sigma_{XP_1}$, the target triplet is NZ_1Y_2; otherwise, it is NXY_2. The two cases are symmetric, and we assume $\sigma_{XP_1} \geq \sigma_{Z_1P_1}$. Let P be the first node after P_1 on the path from P_1 toward P_2 in T. Then, $\sigma_{XP} \geq \sigma_{XP_1}(1-\alpha g)$. By Corollary 2.4, $\sigma^2_{XP} \geq \sigma^2_{XP_1}(1-\alpha g)^2 \geq \sigma_{XY_1Z_1}(1-\alpha g)^2/3$. Since $\sigma_{XY_2} \geq \sigma_{XZ_2}$ and $\sigma_{Y_2Z_2} > 0$,

$$\sigma_{XY_2Z_2} \;<\; \frac{3}{2\sigma^{-1}_{XY_2}} \;\leq\; \frac{3}{2\sigma^{-1}_{Y_2P_1}\sigma^{-1}_{XP_1}} \;\leq\; \frac{3\sigma^2_{Y_2P_1}}{2(1-\alpha g)}.$$

Hence $\sigma^2_{Y_2P} > \sigma^2_{Y_2P_1} > 2\sigma_{XY_2Z_2}(1-\alpha g)/3$. Then, since neither XY_2Z_2 nor XY_1Z_1 is small and $\sigma_{XY_2} \geq \frac{2}{3}\sigma_{XY_2Z_2}$,

$$\sigma_{NXY_2} = \frac{3}{\frac{1}{\sigma_{XP}\sigma_{PN}} + \frac{1}{\sigma_{Y_2P}\sigma_{PN}} + \frac{1}{\sigma_{XY_2}}} > \frac{1}{\frac{1}{\sqrt{3}}\sigma^{-1/2}_{XY_1Z_1}(1-\alpha g)^{-d-2} + \frac{1}{\sqrt{6}}\sigma^{-1/2}_{XY_2Z_2}(1-\alpha g)^{-d-3/2} + \frac{1}{2}\sigma^{-1}_{XY_2Z_2}} > \sigma_{\lg}. \tag{3.4}$$

So NXY_2 is as desired for Case 1c with $\sigma_{XP_1} \geq \sigma_{Z_1P_1}$.

Case 2: By symmetry, assume that $P_2 = X$ is a leaf in T^*_k. Since $k \geq 3$, P_1 is an internal node in T^*_k. Let $\mathrm{def}(P_1) = \{X, Y, Z\}$. By symmetry, further assume $\sigma_{YP_1} \geq \sigma_{ZP_1}$. There are two subcases. If $\sigma_{XP_1} < \sigma_{YP_1}(1-\alpha g)$, the proof is similar to that of Case 1a and the desired P is in the middle of the path between X and Y in T. Otherwise, the proof is similar to that of Case 1b and P is the first node after P_1 on the path from P_1 toward X in T. In both cases, the desired triplet is NXY. ∎

3.4. The sample size required by Fast-HGT. The next lemma analyzes $\mathcal{S}$. For $k = 3, \ldots, n-1$ and each leaf $M \in T$, let $\mathcal{S}_k[M]$ be the version of $\mathcal{S}[M]$ at the start of the $(k-2)$th iteration of the repeat at line F7.

LEMMA 3.6. *Assume that for a given $k \leq n-1$, $\mathcal{E}_{\mathrm{g}}$, $\mathcal{E}_{\mathrm{c}}$, $\mathcal{A}_{k'}$, $\mathcal{B}_{k'}$, and $\mathcal{C}_{k'}$ hold for all $k' \leq k$.*

1. *If $\mathcal{S}_k[M]$ is not null, then it is a splitting tuple for some edge in T^*_k.*

2. *If an edge $Q_1Q_2 \in T_k^*$ and a triplet MR_1R_2 with $M \notin T_k^*$ satisfy Lemma* 3.5*, then $\mathcal{S}_k[M]$ is a splitting tuple for Q_1Q_2 in T_k^* that contains a triplet $MR_1'R_2'$ with $\hat{\sigma}_{MR_1'R_2'} \geq \hat{\sigma}_{MR_1R_2}$.*

Proof. The two statements are proved as follows.

Statement 1. This statement follows directly from the initialization of $\mathcal{S}$ at line F6, the deletions from $\mathcal{S}$ at line F13, and the insertions into $\mathcal{S}$ at lines F6 and F14.

Statement 2. The proof is by induction on k.

Base case: $k = 3$. By $\mathcal{E}_{\mathrm{c}}$, $\mathcal{A}_3$, $\mathcal{B}_3$, $\mathcal{C}_3$, and Lemmas 3.3 and 3.4, MR_1R_2 is a splitting triplet for Q_1Q_2 in T_3^*. By the maximization in Update-$\mathcal{S}$ at line F6, $\mathcal{S}[M]$ is a splitting tuple for some edge $Q_1'Q_2' \in T_3^*$ that contains a triplet $MR_1'R_2'$ with $\hat{\sigma}_{MR_1'R_2'} \geq \hat{\sigma}_{MR_1R_2}$. By $\mathcal{E}_{\mathrm{g}}$, $MR_1'R_2'$ is not small. By Lemmas 3.3 and 3.4, $Q_1'Q_2'$ is Q_1Q_2.

Induction hypothesis. Statement 2 holds for $k < n - 1$.

Induction step. We consider how $\mathcal{S}_{k+1}$ is obtained from $\mathcal{S}_k$ during the $(k-2)$th iteration of the repeat at line F7. There are two cases.

Case 1: Q_1Q_2 also exists in T_k^*. By $\mathcal{A}_k$, Q_1Q_2 and MR_1R_2 also satisfy Lemmas 3.3 and 3.4 for T_k^*. By the induction hypothesis, $\mathcal{S}_k[M]$ is a splitting tuple for Q_1Q_2 in T_k^* that contains a triplet $MR_1'R_2'$ with $\hat{\sigma}_{MR_1'R_2'} \geq \hat{\sigma}_{MR_1R_2}$. Then, since $Q_1Q_2 \neq P_1P_2$ and $M \neq N$ at line F13, $\mathcal{S}_k[M]$ is not reset to null. Thus, it can be changed only through replacement at line F14 by a splitting tuple for some edge $Q_1'Q_2'$ in T_{k+1}^* that contains a triplet $MR_1''R_2''$ with $\hat{\sigma}_{MR_1''R_2''} \geq \hat{\sigma}_{MR_1'R_2'}$. By $\mathcal{E}_{\mathrm{g}}$, $MR_1''R_2''$ is not small. Thus, by $\mathcal{E}_{\mathrm{c}}$, $\mathcal{A}_{k+1}$, $\mathcal{B}_{k+1}$, $\mathcal{C}_{k+1}$, and Lemmas 3.3 and 3.4, $Q_1'Q_2'$ is Q_1Q_2.

Case 2: $Q_1Q_2 \notin T_k^*$. This case is similar to the base case but uses the maximization in Update-$\mathcal{S}$ at line F14. □

LEMMA 3.7. *$\mathcal{E}_{\mathrm{g}}$ and $\mathcal{E}_{\mathrm{c}}$ imply that $\mathcal{A}_k$, $\mathcal{B}_k$, and $\mathcal{C}_k$ hold for all $k = 3, \ldots, n$.*

Proof. The proof is by induction on k.

Base case: $k = 3$. By Lemma 2.6(2), $\mathcal{E}_{\mathrm{c}}$, and the greedy selection of line F1, line F3 constructs T_3^* without edge lengths. Then, $\mathcal{A}_3$ holds trivially. $\mathcal{B}_3$ follows from $\mathcal{E}_{\mathrm{c}}$, $\mathcal{E}_{\mathrm{g}}$, and line F1. $\mathcal{C}_3$ follows from $\mathcal{B}_3$, $\mathcal{E}_{\mathrm{c}}$ and the use of (2.7) at line F4.

Induction hypothesis. $\mathcal{A}_k$, $\mathcal{B}_k$, and $\mathcal{C}_k$ hold for some $k < n$.

Induction step. The induction step is concerned with the $(k-2)$th iteration of the repeat at line F7. Right before this iteration, by the induction hypothesis, since $k < n$, some $N'Q_1Q_2$ satisfies Lemma 3.5. Therefore, during this iteration, by $\mathcal{E}_{\mathrm{c}}$ and Lemmas 3.3, 3.4, and 3.6, $\mathcal{S}$ at line F8 has a splitting tuple for T_k^* that contains a triplet NXY with $\hat{\sigma}_{NXY} \geq \hat{\sigma}_{N'Q_1Q_2}$. Furthermore, line F9 finds such a tuple. By $\mathcal{E}_{\mathrm{g}}$, NXY is not small. Lines F10 and F11 create T_{k+1}^* using this triplet. Thus, $\mathcal{B}_{k+1}$ follows from $\mathcal{B}_k$. By Lemmas 3.3 and 3.4, $\mathcal{A}_{k+1}$ follows from $\mathcal{A}_k$. $\mathcal{C}_{k+1}$ follows from $\mathcal{C}_k$ since the triplets involved at line S13 are not small. □

THEOREM 3.8. *For any $0 < \delta < 1$, using sequence length*

$$\ell = \mathcal{O}\left(\frac{\log\frac{1}{\delta} + \log n}{(1-\alpha g)^{4d+8} f^2 c^2}\right),$$

Fast-HGT *outputs T^* with the properties below with probability at least $1 - \delta$:*

1. *Disregarding the edge lengths, $T^* = \Psi_{\mathrm{w}}(T)$.*
2. *For each edge Q_1Q_2 in T^*, $|\Delta^*_{Q_1Q_2} - \Delta_{Q_1Q_2}| < 2\Delta_{\min}$.*

Proof. By Lemma 2.9, $\Pr\{\,\overline{\mathcal{E}}_{\mathrm{g}}\,\} \leq \frac{\delta}{2}$ if

$$\ell \;\geq\; \ell_{\mathrm{g}} \;\stackrel{\mathrm{def}}{=}\; 210\alpha^2 \frac{3\ln n + \ln\frac{3}{\delta}}{\sigma^2_{\mathrm{lg}}}.$$

Similarly, by Lemma 2.9, $\Pr\{\,\overline{\mathcal{E}}_{\rm c}\,\} \le \frac{\delta}{2}$ if

$$\ell \;\ge\; \ell_{\rm c} \;\stackrel{\rm def}{=}\; 81\frac{3\ln n + \ln\frac{7}{\delta}}{\sigma_{\rm lg}^2 f^2 c^2}.$$

We choose $\ell = \lceil \max\{\ell_{\rm g}, \ell_{\rm c}\}\rceil$. Consequently, $\Pr\{\,\mathcal{E}_{\rm g} \text{ and } \mathcal{E}_{\rm c}\,\} \ge 1-\delta$. By Lemma 3.7, with probability at least $1-\delta$, Fast-HGT outputs T_n^*, and $\mathcal{A}_n$ and $\mathcal{C}_n$ hold, which correspond to the two statements of the theorem. □

4. Further research. We have shown that theoretically, Fast-HGT has the optimal time and space complexity as well as a polynomial sample complexity. It would be important to determine the practical performance of the algorithm by testing it extensively on empirical and simulated trees and sequences. Furthermore, as conjectured by one of the referees and some other researchers, there might be a trade-off between the time complexity and the practical performance. If this is indeed true empirically, it would be significant to quantify the trade-off analytically.

Appendix. Proofs of technical lemmas.

A.1. Proof of Lemma 2.5. Let $h_{XY} = \frac{\hat\sigma_{XY}}{\sigma_{XY}}$; $h_{XZ} = \frac{\hat\sigma_{XZ}}{\sigma_{XZ}}$; $h_{YZ} = \frac{\hat\sigma_{YZ}}{\sigma_{YZ}}$. By (2.6) and (2.7), and by conditioning on the events $\{h_{XZ} \le 1-r\}$ and $\{h_{YZ} \ge 1+s\}$ for some $r, s > 0$,

$$\Pr\left\{\,\hat\Delta_{XP} - \Delta_{XP} \ge \frac{-\ln(1-\epsilon)}{2}\,\right\} = \Pr\{\,h_{XY}h_{XZ} \le h_{YZ}(1-\epsilon)\,\}$$
$$\le \Pr\{\,h_{XZ} \le 1-r\,\} + \Pr\{\,h_{YZ} \ge 1+s\,\} + \Pr\left\{\,h_{XY} \le (1-\epsilon)\frac{1+s}{1-r}\,\right\}.$$

Setting $\frac{1-r}{1+s} > 1-\epsilon$, by (2.3) and (2.4),

$$\Pr\left\{\,\hat\Delta_{XP} - \Delta_{XP} \ge \frac{-\ln(1-\epsilon)}{2}\,\right\} \le$$
$$\exp\left(-\frac{2}{\alpha^2}\ell\sigma_{XZ}^2 r^2\right) + \exp\left(-\frac{2}{\alpha^2}\ell\sigma_{YZ}^2 s^2\right) + \exp\left(-\frac{2}{\alpha^2}\ell\sigma_{XY}^2\left(1-(1-\epsilon)\frac{1+s}{1-r}\right)^2\right).$$

Equating these exponential terms yields equations for r and s. The solution for r is

$$r = \frac{t-\sqrt{t^2-u}}{2\sigma_{XZ}\sigma_{YZ}};\; t = \sigma_{XY}\sigma_{YZ} + \sigma_{XZ}\sigma_{YZ} + (1-\epsilon)\sigma_{XY}\sigma_{XZ};\; u = 4\sigma_{XY}\sigma_{YZ}^2\sigma_{XZ}\epsilon.$$

Using Taylor's expansion, for $u > 0$, $(t-\sqrt{t^2-u})^2 > \frac{u^2}{4t^2}$. Thus,

$$r^2 > \frac{\epsilon^2}{\left(\frac{1}{\sigma_{XZ}} + \frac{1-\epsilon}{\sigma_{YZ}} + \frac{1}{\sigma_{XY}}\right)^2\sigma_{XZ}^2} > \frac{\epsilon^2\sigma_{XYZ}^2}{9\sigma_{XZ}^2}.$$

So $\Pr\left\{\,\hat\Delta_{XP} - \Delta_{XP} \ge \frac{-\ln(1-\epsilon)}{2}\,\right\} \le 3\exp\left(-\frac{2}{\alpha^2}\ell\sigma_{XZ}^2 r^2\right) < 3\exp\left(-\frac{2}{9\alpha^2}\ell\sigma_{XYZ}^2\epsilon^2\right)$.

A.2. Proof of Lemma 2.7. We use the following basic inequalities.

$$\min\left\{\frac{\hat\sigma_{XY}}{\sigma_{XY}}, \frac{\hat\sigma_{XZ}}{\sigma_{XZ}}, \frac{\hat\sigma_{YZ}}{\sigma_{YZ}}\right\} \le \frac{\hat\sigma_{XYZ}}{\sigma_{XYZ}} \le \max\left\{\frac{\hat\sigma_{XY}}{\sigma_{XY}}, \frac{\hat\sigma_{XZ}}{\sigma_{XZ}}, \frac{\hat\sigma_{YZ}}{\sigma_{YZ}}\right\}; \tag{A.1}$$

$$\frac{\sigma_{XYZ}}{3} \leq \min\{\sigma_{XY}, \sigma_{XZ}, \sigma_{YZ}\}. \tag{A.2}$$

The proof of (2.9) is symmetric to that of (2.8). So we only prove the latter. Pick $\lambda \geq 1$ with $\sigma_{XYZ} = \sigma_{\mathrm{lg}}\lambda$. Without loss of generality, we assume $\min\{\frac{\hat{\sigma}_{XY}}{\sigma_{XY}}, \frac{\hat{\sigma}_{XZ}}{\sigma_{XZ}}, \frac{\hat{\sigma}_{YZ}}{\sigma_{YZ}}\} = \frac{\hat{\sigma}_{XY}}{\sigma_{XY}}$. By (2.3), (A.1), and (A.2),

$$\begin{aligned}
&\Pr\{\,\hat{\sigma}_{XYZ} \leq \sigma_{\mathrm{md}}\,\} = \Pr\left\{\,\frac{\hat{\sigma}_{XYZ}}{\sigma_{XYZ}} \leq \frac{\sigma_{\mathrm{md}}}{\sigma_{\mathrm{lg}}\lambda}\,\right\} \leq \Pr\left\{\,\frac{\hat{\sigma}_{XY}}{\sigma_{XY}} \leq \frac{\sigma_{\mathrm{md}}}{\sigma_{\mathrm{lg}}\lambda}\,\right\} \\
&\leq \exp\left(-\frac{2}{\alpha^2}\ell\left(1-\frac{\sigma_{\mathrm{md}}}{\sigma_{\mathrm{lg}}\lambda}\right)^2\sigma_{XY}^2\right) \leq \exp\left(-\frac{2\left(1-\frac{\sigma_{\mathrm{md}}}{\sigma_{\mathrm{lg}}}\right)^2}{9\alpha^2}\ell\sigma_{\mathrm{lg}}^2\right).
\end{aligned}$$

Then, (2.8) follows from the fact that by the choice of σ_{md},

$$\frac{2\left(1-\frac{\sigma_{\mathrm{md}}}{\sigma_{\mathrm{lg}}}\right)^2}{9\alpha^2} = \frac{(\sqrt{2}-1)^2}{36\alpha^2}.$$

A.3. Proof of Lemma 2.8. Since Lemma 2.5 can help establish only one half of the desired inequality, we split the probability on the left-hand side of (2.11):

$$\begin{aligned}
&\Pr\left\{\,\left|\hat{\Delta}_{XP} - \Delta_{XP}\right| \geq \frac{\Delta_{\min}}{2}\,\right\} \\
&\leq \Pr\left\{\,\hat{\Delta}_{XP} - \Delta_{XP} \geq \frac{\Delta_{\min}}{6}\,\right\} + \Pr\left\{\,\hat{\Delta}_{YP} - \Delta_{YP} \geq \frac{\Delta_{\min}}{6}\,\right\} \\
&\quad + \Pr\left\{\,\hat{\Delta}_{XP} - \Delta_{XP} \leq -\frac{\Delta_{\min}}{2} \;\middle|\; \hat{\Delta}_{YP} - \Delta_{YP} < \frac{\Delta_{\min}}{6}\,\right\}.
\end{aligned}$$

Then, since $\hat{\Delta}_{XY} - \Delta_{XY} = (\hat{\Delta}_{XP} - \Delta_{XP}) + (\hat{\Delta}_{YP} - \Delta_{YP})$, we have

$$\begin{aligned}
&\Pr\left\{\,\hat{\Delta}_{XP} - \Delta_{XP} \leq -\frac{\Delta_{\min}}{2} \;\middle|\; \hat{\Delta}_{YP} - \Delta_{YP} < \frac{\Delta_{\min}}{6}\,\right\} \\
&\leq \Pr\left\{\,\hat{\Delta}_{XY} - \Delta_{XY} \leq -\frac{\Delta_{\min}}{3}\,\right\}.
\end{aligned}$$

Consequently,

$$\begin{aligned}
\Pr\left\{\,\left|\hat{\Delta}_{XP} - \Delta_{XP}\right| \geq \frac{\Delta_{\min}}{2}\,\right\} &\leq \Pr\left\{\,\hat{\Delta}_{XP} - \Delta_{XP} \geq \frac{\Delta_{\min}}{6}\,\right\} \\
&\quad + \Pr\left\{\,\hat{\Delta}_{YP} - \Delta_{YP} \geq \frac{\Delta_{\min}}{6}\,\right\} \\
&\quad + \Pr\left\{\,\hat{\Delta}_{XY} - \Delta_{XY} \leq -\frac{\Delta_{\min}}{3}\,\right\}.
\end{aligned} \tag{A.3}$$

By Lemma 2.5,

$$\Pr\left\{\,\hat{\Delta}_{XP} - \Delta_{XP} \geq \frac{\Delta_{\min}}{6}\,\right\} \leq 3\exp\left(-\frac{2}{9\alpha^2}\ell\sigma_{XYZ}^2\left(1-e^{-\frac{\Delta_{\min}}{3}}\right)^2\right).$$

By Taylor's expansion, $(1-e^{-\frac{\Delta_{\min}}{3}})^2 \geq \left(1-(1-\alpha f)^{\frac{c}{3}}\right)^2 > \frac{c^2}{9}\alpha^2 f^2$, and thus

$$\Pr\left\{ \hat{\Delta}_{XP} - \Delta_{XP} \geq \frac{\Delta_{\min}}{6} \right\} \leq 3\exp\left(-\frac{c^2}{81}\ell\sigma_{\lg}^2 f^2\right). \tag{A.4}$$

By symmetry,

$$\Pr\left\{ \hat{\Delta}_{YP} - \Delta_{YP} \geq \frac{\Delta_{\min}}{6} \right\} \leq 3\exp\left(-\frac{c^2}{81}\ell\sigma_{\lg}^2 f^2\right). \tag{A.5}$$

By (2.4), $\Pr\{\hat{\Delta}_{XY} - \Delta_{XY} \leq -\frac{\Delta_{\min}}{3}\} \leq \exp(-\frac{2}{\alpha^2}\ell\sigma_{XY}^2(e^{\frac{\Delta_{\min}}{3}} - 1)^2)$. From (A.2), $\sigma_{XY} \geq \frac{(1-\alpha g)^{2d+2}}{3\sqrt{2}}$. By Taylor's expansion, $(e^{\frac{\Delta_{\min}}{3}} - 1)^2 \geq ((1-\alpha f)^{-\frac{c}{3}} - 1)^2 > \frac{c^2}{9}\alpha^2 f^2$. Therefore,

$$\Pr\left\{ \hat{\Delta}_{XY} - \Delta_{XY} \leq -\frac{\Delta_{\min}}{3} \right\} \leq \exp\left(-\frac{c^2}{81}\ell\sigma_{\lg}^2 f^2\right). \tag{A.6}$$

Lemma 2.8 follows from the fact that putting (A.3) through (A.6) together, we have $\Pr\{|\hat{\Delta}_{XY} - \Delta_{XY}| \geq \frac{\Delta_{\min}}{2}\} \leq 7\exp(-\frac{c^2}{81}\ell\sigma_{\lg}^2 f^2)$.

PROPORTION EXTEND SORT*

JING-CHAO CHEN†

Abstract. PROPORTION EXTEND SORT is a new sorting algorithm, the basic principle of which is similar to PROPORTION SPLIT SORT. This algorithm sorts a sequence by constructing three subproblems, using a QuickSort-like pivot technique and solving recursively each subproblem. The original problem and three subproblems all are of such a structure: a sorted subsequence followed by an unsorted subsequence. The size of the original problem always equals the size of the third subproblem, but in general, the sorted subsequence of the third subproblem is $p+1$ times as much as the sorted subsequence of the original, where p is a fixed positive constant. The worst case number of comparisons required by this algorithm is less than $1/\log(1+1/(2p^2+2p-1))n\log n$ for $p \geq 1$. Empirical results show that the average number of comparisons is close to $n\log n - O(n)$ for some p. From our experiments for sorting integers, when $p = 16$, this algorithm is yet faster, on average, than PROPORTION SPLIT SORT which is faster than CLEVER QUICKSORT.

1. Introduction.

It has been studied for a long time whether there exists a simple, practical, and efficient sorting algorithm that sorts n elements using constant extra space and making $O(n\log n)$ comparisons in the worst case, and has an expected number of comparisons approaching $\log(n!) = n\log n - 1.442695n$. (All logarithms throughout the paper are base two.) Notice, $\log(n!)$ is the lower bound on the worst and average case number of comparisons for comparison based sequential sorting algorithms.

MERGESORT, BINARY INSERTION SORT, and WEAK-HEAP SORT [6], etc. are sorting algorithms approaching this lower bound in terms of the number of comparisons. MERGESORT requires $n\log n - 1.2645n$ comparisons [1], [2] on average, but uses extra storage of length n. BINARY INSERTION SORT is not efficient in practice, primarily because of its $O(n^2)$ data movements. WEAK-HEAP SORT introduced by Dutton(1993) is the fastest variant of HEAPSORT [3], [5], and the average number is conjectured to be approximately $(n-0.5)\log n - 0.413n$. Unfortunately, WEAK-HEAP SORT uses n extra bits, and by the empirical results of [8], the comparison plus exchange total required exceeds that required by the best-of-three version of QUICKSORT called CLEVER QUICKSORT.

Most versions of QUICKSORT [4] require $O(n^2)$ comparisons in the worst case but $O(n\log n)$ comparisons in the average case. CLEVER QUICKSORT is a practical version of QUICKSORT and runs in approximately $1.188(n+1)\log(n-1) - 2.255n + 2.507$ (see [7]) comparisons on average.

PROPORTION SPLIT SORT introduced by Chen [8] splits a sequence into two blocks in the ratio of $1 : p-1$, then divides them into four blocks in a QuickSort-

like pivot step, finally, sorts recursively the left two blocks and the right two blocks separately. The worst case number of comparisons of PROPORTION SPLIT SORT is bounded by $1/\log(2p/(2p-1))n\log n$ for $p > 1$ [8]. The simulation results of [8] revealed that for some p (e.g., $p = 16$), the average number of comparisons and exchanges required by PROPORTION SPLIT SORT is fewer than that required by CLEVER QUICKSORT.

This paper introduces a new algorithm called PROPORTION EXTEND SORT. The basic principle of this algorithm is similar to PROPORTION SPLIT SORT. PROPORTION EXTEND SORT assumes that a sequence to be sorted has such a structure: a sorted subsequence followed by an unsorted subsequence, then constructs three subproblems which have the same structure as the original, and solves recursively each subproblems. In general, the sorted subsequence of the third subproblem is $p+1$ times as much as the sorted subsequence of the original, where p is a positive constant given. The worst case number of comparisons of this algorithm is bounded by $1/\log(1+1/(2p^2+2p-1))n\log n$ for $p \geq 1$. By experimental results, the performance of PROPORTION EXTEND SORT is better than that of PROPORTION SPLIT SORT.

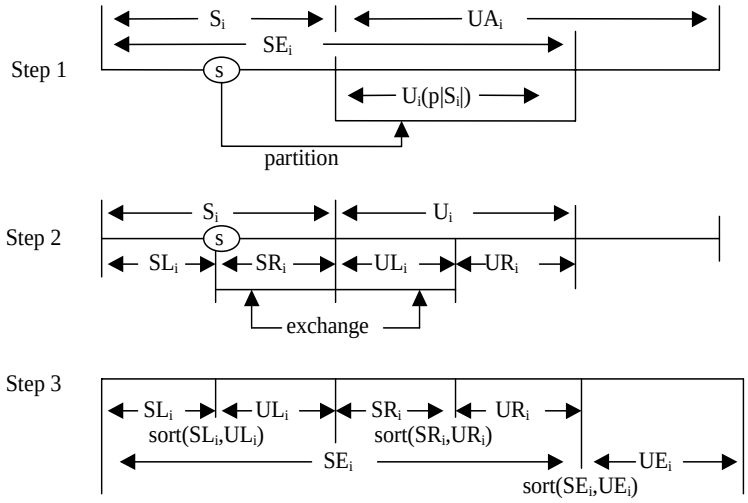

FIG. 2.1. *The basic principle of the sorting algorithm.*

2. The algorithm. The algorithm assumes that an initial array of arbitrary values $A[1..n]$ is given; it then sorts the array A in ascending order. We will design and analyze the algorithm by the following subarrays: $S_i = A[s1..s2]$, $SE_i = A[se1..se2]$, $U_i = A[u1..u2]$, $UA_i = A[ua1..ua2]$, $UL_i = A[ul1..ul2]$, $UR_i = A[ur1..ur2]$, $SL_i = A[sl1..sl2]$, $SR_i = A[sr1..sr2]$, and $UE_i = A[ue1..ue2]$. $|S_i|$ will denote the length of S_i. `Swap`(i, j), which appears below, is a procedure that interchanges the values in $A[i]$ and $A[j]$. The basic idea of PROPORTION EXTEND SORT is to regard the array A as a sequence which has such a structure: a sorted subsequence S_i followed by an unsorted subsequence UA_i, create three subproblems: (SL_i, UL_i), (SR_i, UR_i), and (SE_i, UE_i), using a QuickSort-like pivot technique, and solve recursively each subproblem. The basic idea of the algorithm is shown in Figure 2.1.

Step 1. Suppose that the first $|S_i|$ elements are sorted, and we want to extend that to $|SE_i|(=(1+p)|S_i|)$ elements, where p is a positive constant. That is, $se1 := s1$, $se2 := s1+(1+p)|S_i|-1$. Let the median of S_i be s and the unsorted subsequence in the SE_i be U_i. Use s to partition U_i into two subsequences UL_i and UR_i in a QuickSort-like pivot step, such that $\max(UL_i) \le s \le \min(UR_i)$.

Step 2. Refer to the subsequences to the left and right of s as SL_i and SR_i, respectively. Exchange the subsequences SR_i and UL_i by shifting $A[sr2]$, $A[sr2-1]$,..., $A[sr1]$ to $A[ul2], A[ul2-1], \ldots, A[ul2-(sr2-sr1)]$. This step means the following code:
for $i := 0$ **to** $sr2 - sr1$ **do** `Swap` $(sr2-i, ul2-i)$.

Step 3. After Step 2 is done, the two subproblems (SL_i, UL_i) and (SR_i, UR_i) have the same structure as the original(a sorted subsequence followed by an unsorted subsequence). Let the right subsequence contiguous to SE_i be UE_i. After the two subproblems are solved, the subproblem (SE_i, UE_i) has also the same structure as the original. Hence, the algorithm is called recursively to sort $(SL_i, UL_i), (SR_i, UR_i)$, and (SE_i, UE_i).

We implement the algorithm by way of a recursive routine. It is easy to replace this recursive routine by way of an iterative routine. Next we describe the main algorithm ProportionExtendSort with Pascal-like procedures.

ProportionExtendSort(S_i, UA_i) denotes that it sorts the two contiguous subsequences S_i and UA_i by using the parameters $s1, s2$, and $ua2$ in S_i and UA_i, where S_i is a sorted subsequence and UA_i is an unsorted subsequence. Notice, in this procedure, the parameter $ua1$ in UA_i is not used, since $ua1 = s2+1$. Initially $S_i = A[1..1]$, $UA_i = A[2..n]$.

```
ProportionExtendSort(S_i, UA_i)
      if s2 < s1 then s2 := s1                          { S_i = A[s1..s2] is sorted }
      if UA_i =empty then return                        { UA_i = A[ua1..ua2] is unsorted }
      se2 := s1 + (1 + p)|S_i| - 1                      { Extend S_i to SE_i = A[se1..se2] }
(2.1) if (1 + p)p|S_i| > |S_i| + |UA_i| then  se2 := ua2
      mid := ⌊(s1 + s2)/2⌋
      u1 := s2 + 1, u2 := se2                           { U_i = A[u1..u2] }
      ur1 := Partition(mid, U_i)                        { Split U_i into UL_i and UR_i }
(2.2) for i = 0 to s2 - mid do                          { shift A[s2..mid] to A[ur1-1...] }
            Swap (s2 - i, ur1 - 1 - i)
      sr1 := ur1 - (s2 - mid), sr2 := ur1 - 1           { SR_i = A[sr1..sr2] is sorted }
      ur2 := u2                                         { UR_i = A[ur1..ur2] is unsorted }
      sl1 := s1, sl2 := mid - 1                         { SL_i = A[sl1..sl2] is sorted }
      ul2 := sr1 - 2                                    { UL_i = A[ul1..ul2] is unsorted }
(2.3) ProportionExtendSort(SL_i, UL_i)
(2.4) ProportionExtendSort(SR_i, UR_i)
      se1 := s1
      ue2 := ua2                                        { UE_i = A[ue1..ue2] is unsorted }
      ProportionExtendSort (SE_i, UE_i)
end ProportionExtendSort
```

The routine Partition divides U_i into two subsequences and returns their boundary. The first subsequence consists of all $A[i] \le A[mid]$, and the second subsequence

consists of all $A[j] \geq A[mid]$. Partition is described as follows.

```
Partition (mid, U_i)
    { Suppose U_i = A[u1..u2] }
    i := u1, j := u2
    while i ≤ j do begin
      while i ≤ j and A[i] ≤ A[mid] do i := i + 1
      while i < j and A[j] ≥ A[mid] do j := j − 1
      if  i ≥ j then return i
      Swap(i, j)
      i := i + 1, j := j − 1
    end while
    return i
end Partition
```

The routine Partition first searches from left to right (by increasing i) until the element $> A[mid]$ is found, then searches from right to left (by decreasing j) until the element $< A[mid]$ is found. When both searches have paused, if $i < j$, then we exchange $A[i]$ and $A[j]$ and resume the process, otherwise, the algorithm terminates and returns i.

p in the algorithm is a fixed positive constant. Depending on p, we obtain various algorithms with different complexities.

Different algorithms can be obtained from this algorithm by replacing line (2.1). QUICKSORT is obtained by $se2 := ua2$, and BINARY INSERTIONSORT by $se2 := s2 + 1$. That is, QUICKSORT and BINARY INSERTIONSORT are two extreme cases of this algorithm.

ProportionExtendSort requires space for a pushdown stack which stores the arguments of pending recursive calls. We infer easily that maximal stack depth is $O(n)$. Maximal stack depth can be kept to $2 \log n$ if we make a slight modification of ProportionExtendSort: always solve the smaller subproblem first, i.e., replace lines (2.3) and (2.4) with

```
if  |UL_i| < |UR_i|
then ProportionExtendSort(SL_i, UL_i)
     ProportionExtendSort(SR_i, UR_i)
else ProportionExtendSort(SR_i, UR_i)
     ProportionExtendSort(SL_i, UL_i)
end if
```

3. Analysis and simulation results.

THEOREM 3.1. *Let $W(n)$ denote the worst case number of comparisons required by the algorithm for sorting n elements, then*

$$W(n) \leq 1/\log(1 + 1/(2p^2 + 2p - 1))n \log n, \text{for } p \geq 1.$$

Proof. In PROPORTION EXTEND SORT, comparisons occur only in the routine Partition. Partition(median of S_i, U_i) takes exactly $|U_i|$ comparisons to split U_i, where S_i and U_i denote the sorted set and the unsorted set upon entering the Partition for the ith time, respectively.

Let q denote the total number of the call to Partition, then we have

$$W(n) = \sum_{i=1}^{q} |U_i| = \sum_{i=1}^{q}\sum_{j=1}^{n} b(A[j] \in U_i) = \sum_{j=1}^{n}\sum_{i=1}^{q} b(A[j] \in U_i)$$
$$\leq n \times \max_{j=1}^{n}\left(\sum_{i=1}^{q} b(A[j] \in U_i)\right),$$

where $b(A[j] \in U_i)$ is one when $A[j]$ is in U_i, and zero otherwise.

Suppose $\max_{j=1}^{n}(\sum_{i=1}^{q} b(A[j] \in U_i)) = \sum_{i=1}^{q} b(y \in U_i) = k$. For the sake of simplicity, it will be assumed that y is in U_i for $1 \leq i \leq k$, and is not in U_t for $t > k$. By lines (2.1) in the algorithm, we have

$$|U_i| = \begin{cases} |UA_i| & \text{when } (p+1)p|S_i| > |S_i| + |UA_i|, \\ p|S_i| & \text{otherwise.} \end{cases} \tag{3.1}$$

$(p+1)p|S_i| > |S_i| + |UA_i|$ implies

$$|UA_i| < (p^2 + p - 1)|S_i| \qquad \text{for } p \geq 1. \tag{3.2}$$

By (3.1) and (3.2), we can imply

$$|U_i| \leq (p^2 + p - 1)|S_i| \qquad \text{for } p \geq 1.$$

Thus, we have

$$|U_i| + (p^2 + p - 1)|U_i| \leq (p^2 + p - 1)(|S_i| + |U_i|) \quad \text{for } p \geq 1.$$

That is,

$$|U_i| \leq \frac{(p^2 + p - 1)}{p^2 + p}(|S_i| + |U_i|) \qquad \text{for } p \geq 1. \tag{3.3}$$

By the relation of UA_{i+1} and U_{i+1}, we have

$$|U_{i+1}| \leq |UA_{i+1}|. \tag{3.4}$$

From lines (2.3) and (2.4) in the algorithm, we have

$$\begin{array}{l} S_{i+1} = SL_i \quad \text{and} \quad UA_{i+1} = UL_i, \text{ or} \\ S_{i+1} = SR_i \quad \text{and} \quad UA_{i+1} = UR_i. \end{array} \tag{3.5}$$

By the relation of UL_i, UR_i, and U_i, clearly

$$|UL_i| \leq |U_i| \quad \text{and} \quad |UR_i| \leq |U_i|. \tag{3.6}$$

Since SL_i and SR_i are the left and right half of S_i, we infer easily

$$|SL_i| \leq \frac{|S_i|}{2} \quad \text{and} \quad |SR_i| \leq \frac{|S_i|}{2}. \tag{3.7}$$

By (3.4)−(3.7) and (3.3), we obtain

$$\begin{aligned}
|S_{i+1}| + |U_{i+1}| &\le |S_{i+1}| + |UA_{i+1}| \\
&\le \max(|SL_i| + |UL_i|, |SR_i| + |UR_i|) \\
&\le \frac{|S_i|}{2} + |U_i| \\
&\le \frac{|S_i| + |U_i|}{2} + \frac{|U_i|}{2} \\
&\le \frac{|S_i| + |U_i|}{2} + \frac{(p^2+p-1)}{2(p^2+p)}(|S_i| + |U_i|) \\
&\le \frac{(2p^2+2p-1)}{2(p^2+p)}(|S_i| + |U_i|). \qquad (3.8)
\end{aligned}$$

Clearly, we have

$$|S_1| + |U_1| \le n \quad \text{and} \quad 2 \le |S_k| + |U_k|. \qquad (3.9)$$

by (3.8) and (3.9), we have

$$\begin{aligned}
2 &\le |S_k| + |U_k| \\
&\le \frac{(2p^2+2p-1)}{2(p^2+p)}(|S_{k-1}| + |U_{k-1}|) \\
&\le (\frac{(2p^2+2p-1)}{2(p^2+p)})^{k-1}(|S_1| + |U_1|) \\
&\le (\frac{(2p^2+2p-1)}{2(p^2+p)})^{k-1} \times n \qquad \text{for } p \ge 1.
\end{aligned}$$

We solve this inequality to obtain

$$k \le \frac{\log n}{\log(1 + 1/(2p^2+2p-1))}.$$

Hence,

$$W(n) \le k \times n \le \frac{n \log n}{\log(1 + 1/(2p^2+2p-1))} \quad \text{for } p \ge 1. \qquad \square$$

The worst case behavior of PROPORTION EXTEND SORT seems to occur on the completely sorted sequence as QUICKSORT. Even so, it takes only $O(n \log n)$ comparisons, and by empirical results, the actual number of comparisons required is far fewer than the formula given in the above theorem.

Since the "*ripple swap*"[8] technique can reduce the overall number of moves, the experimental results given below for PROPORTION EXTEND SORT are obtained by replacing line (2.2) with "*ripple swap*."

Table 3.1 summarizes experimental results on the average case performance we observed. For each input size n, we provided 20 distinct sets, each of which consists of randomly generated distinct values. The columns Compares and Moves reflect the average number of compares and exchanges for each instance, respectively. Columns EXSORT($p = 2$) and EXSORT($p = 6$) are the results of PROPORTION EXTEND SORT with $p = 2$ and $p = 6$, respectively. Columns SPSORT and QSORT are

the results reported for PROPORTION SPLIT SORT with $p = 16$ and CLEVER QUICKSORT, respectively, from [8].

Among the four algorithms given in Table 3.1, the average number of compares observed for EXSORT($p = 2$) is the smallest, and is less than the values of $n \log n - n$ consistently. SPSORT($p = 16$) is one of the best results of PROPORTION SPLIT SORT. Nevertheless, the average number of compares observed for EXSORT($p = 6$) is fewer than that observed for SPSORT($p = 16$); furthermore, when $n \geq 1000$, EXSORT($p = 6$) used fewer moves than SPSORT($p = 16$). For Table 3.1, exclusive of the number of compares with $n = 50$ and $n = 100$, data observed for EXSORT($p = 6$) are all lower than those observed for QSORT.

To compare PROPORTION EXTEND SORT with PROPORTION SPLIT SORT in further details, we present empirical results of these two sorting algorithms for some p in Tables 3.2 and 3.3, respectively. For each p, we employed 20 distinct sets, each of which consists of randomly generated distinct values as the simulation above. In Tables 3.2 and 3.3, Columns COMPARES and MOVES are the average number of comparisons and exchanges required to sort 50000 elements, respectively. Table 3.2 shows the results reported from [8].

As can be seen from Tables 3.2 and 3.3, the performance of PROPORTION EXTEND SORT is better than the performance of PROPORTION SPLIT SORT, since in the case of the same number of comparisons, in general, PROPORTION EXTEND SORT uses fewer moves than PROPORTION SPLIT SORT. Like PROPORTION SPLIT SORT, one can choose also the best version of PROPORTION EXTEND SORT by comparing the practical overall cost of comparisons and movements for each p based on the property of the input sequence given.

Table 3.4 shows the average execution time required by the algorithms running on Pentium II/350. All the algorithms are written in C and run under the MS-DOS operating system. Both QsortN and QsortR are the best-of-three versions of Quicksort, but when selecting three values to decide a pivot, QsortR adopts a random strategy while QsortN does not. SPSORT($p = 24$) and EXSORT($p = 16$) are the fastest

TABLE 3.3

50000	674	703	794	658

versions of PROPORTION SPLIT SORT and PROPORTION EXTEND SORT, respectively, for sorting integers. From the empirical results given in Table 3.4, our algorithm is the fastest.

4. Comments. PROPORTION EXTEND SORT is a simple, competitive, and efficient sorting algorithm that sorts n elements, using $O(\log n)$ extra space and making $O(n \log n)$ comparisons in the worst case. Since an average case theoretic analysis seems to be quite sophisticated, it is left as an open problem. However, in our simulation, this sorting algorithm is better than PROPORTION SPLIT SORT, and used fewer data moves and fewer comparisons, and its number of comparisons is close to $\log(n!)$. Therefore, we believe that it is possible to replace CLEVER QUICKSORT by PROPORTION EXTEND SORT.

APPROXIMATING THE THROUGHPUT OF MULTIPLE MACHINES IN REAL-TIME SCHEDULING*

AMOTZ BAR-NOY†, SUDIPTO GUHA†, JOSEPH (SEFFI) NAOR‡, AND BARUCH SCHIEBER§

Abstract. We consider the following fundamental scheduling problem. The input to the problem consists of n jobs and k machines. Each of the jobs is associated with a release time, a deadline, a weight, and a processing time on each of the machines. The goal is to find a nonpreemptive schedule that maximizes the weight of jobs that meet their respective deadlines. We give constant factor approximation algorithms for four variants of the problem, depending on the type of the machines (identical vs. unrelated) and the weight of the jobs (identical vs. arbitrary). All these variants are known to be NP-hard, and the two variants involving unrelated machines are also MAX-SNP hard. The specific results obtained are as follows:

- For identical job weights and unrelated machines: a greedy 2-approximation algorithm.
- For identical job weights and k identical machines: the same greedy algorithm achieves a tight $\frac{(1+1/k)^k}{(1+1/k)^k-1}$ approximation factor.
- For arbitrary job weights and a single machine: an LP formulation achieves a 2-approximation for polynomially bounded integral input and a 3-approximation for arbitrary input. For unrelated machines, the factors are 3 and 4, respectively.
- For arbitrary job weights and k identical machines: the LP-based algorithm applied repeatedly achieves a $\frac{(1+1/k)^k}{(1+1/k)^k-1}$ approximation factor for polynomially bounded integral input and a $\frac{(1+1/2k)^k}{(1+1/2k)^k-1}$ approximation factor for arbitrary input.
- For arbitrary job weights and unrelated machines: a combinatorial $(3+2\sqrt{2} \approx 5.828)$-approximation algorithm.

1. Introduction.

We consider the following fundamental scheduling problem. The input to the problem consists of n jobs and k machines. Each of the jobs is associated with a release time, a deadline, a weight, and a processing time on each of the machines. The goal is to find a nonpreemptive schedule that maximizes the weight of the jobs that meet their deadline. Such scheduling problems are frequently referred

to as *real-time* scheduling problems, and the objective of maximizing the value of completed jobs is frequently referred to as *throughput*. We consider four variants of the problem depending on the type of the machines (identical vs. unrelated) and the weight of the jobs (identical vs. arbitrary). In the standard notation for scheduling problems, the four problems we consider are $P|r_i|\sum(1-U_i)$, $P|r_i|\sum w_i(1-U_i)$, $R|r_i|\sum(1-U_i)$, and $R|r_i|\sum w_i(1-U_i)$.

Garey and Johnson [17] (see also [18]) show that the simplest decision problem corresponding to this problem is already NP-hard in the strong sense. In this decision problem the input consists of a set of n jobs with release time, deadline, and processing time. The goal is to decide whether all the jobs can be scheduled on a single machine, each within its time window. We show that the two variants involving unrelated machines are also MAX-SNP hard.

In this paper we give constant factor approximation algorithms for all four variants of the problem. To the best of our knowledge, this is the first paper that gives approximation algorithms with guaranteed performance (approximation factor) for these problems. We say that an algorithm has an approximation factor ρ for a maximization problem if the weight of its solution is at least $1/\rho \cdot \mathsf{OPT}$, where OPT is the weight of an optimal solution. (Note that we defined the approximation factor so that it would always be at least 1.)

The specific results obtained are listed below and summarized in Table 1.1.

- For identical job weights and unrelated machines, we give a greedy 2-approximation algorithm.
- For identical job weights and k identical machines, we show that the same greedy algorithm achieves a tight $\frac{(1+1/k)^k}{(1+1/k)^k-1}$ approximation factor.
- For arbitrary job weights, we round a fractional solution obtained from a linear programming relaxation of the problem. We distinguish between the case where the release times, deadlines, and processing times are integral and polynomially bounded, and the case where they are arbitrary. In the former case, we achieve a 2-approximation factor for a single machine and a 3-approximation factor for unrelated machines. In the latter case, we get a 3-approximation factor for a single machine and a 4-approximation factor for unrelated machines.
- For arbitrary job weights and k identical machines, we achieve a $\frac{(1+1/k)^k}{(1+1/k)^k-1}$ approximation factor for polynomially bounded integral input and a $\frac{(1+1/2k)^k}{(1+1/2k)^k-1}$ approximation factor for arbitrary input. Note that as k tends to infinity these factors tend to $\frac{e}{e-1} \approx 1.58198$ and $\frac{\sqrt{e}}{\sqrt{e}-1} \approx 2.54149$, respectively.
- For arbitrary job weights and unrelated machines we also present a *combinatorial* $(3+2\sqrt{2})$-approximation factor $(3+2\sqrt{2} \approx 5.828)$.

The computational difficulty of the problems considered here is due to the "slack time" available for scheduling the jobs. In general, the time window in which a job can be scheduled may be (much) larger than its processing time. Interestingly, the special case where there is no slack time can be solved optimally in polynomial time even for multiple machines [3] using dynamic programming. Moreover, the problem can be solved optimally on a single machine with the execution window strictly less than twice the length of the job, since it reduces to the case of no slack time.

Another special case that was considered earlier in the literature is the case in which all jobs are released at the same time (or equivalently, the case in which all deadlines are the same). This special case remains NP-hard even for a single machine.

TABLE 1.1

Each entry contains the approximation factors as a function of the number of machines (k) in the form $(1, 2, 3, \ldots, k, \ldots, k \to \infty)$.

Weight function	Identical machines	Unrelated machines
Identical job weights	$\left(2, 1.8, 1.73, \ldots, \frac{(1+1/k)^k}{(1+1/k)^k-1}, \ldots, 1.58\right)$	$(2, 2, 2, \ldots, 2)$
Arbitrary job weights Integral, poly-size, input	$\left(2, 1.8, 1.73, \ldots, \frac{(1+1/k)^k}{(1+1/k)^k-1}, \ldots, 1.58\right)$	$(2, 3, 3, \ldots, 3)$
Arbitrary job weights Arbitrary input	$\left(3, 2.78, 2.7, \ldots, \frac{(1+1/2k)^k}{(1+1/2k)^k-1}, \ldots, 2.54\right)$	$(3, 4, 4, \ldots, 4)$

However, Sahni [30] gave a fully polynomial approximation scheme for this special case.

The problems considered here have several applications. Hall and Magazine [21] considered the single machine version of our problem in the context of maximizing the scientific, military, or commercial value of a space mission. This means selecting and scheduling in advance a set of projects to be undertaken during the space mission, where an individual project is typically executable during only part of the mission. It is indicated in [21] that up to 25% of the budget of a space mission may be spent in making these decisions. Hall and Magazine [21] present eight heuristic procedures for finding a near optimal solution together with computational experiments. However, they do not provide any approximation guarantees on the solutions produced by their heuristics. They also mention the applicability of such problems to patient scheduling in hospitals. For more applications and related work in the scheduling literature see [11, 15] and the survey of [27].

The preemptive version of our problem for a single machine was studied by Lawler [26]. For identical job weights, Lawler showed how to apply dynamic programming techniques to solve the problem in polynomial time. He used the same techniques to obtain a pseudopolynomial algorithm for the NP-hard variant $1|r_i, pmtn|\sum w_i(1-U_i)$ in which the weights are arbitrary [26]. Lawler [25] also obtained polynomial time algorithms that solve the problem in two special cases: (i) the time windows in which jobs can be scheduled are nested, and (ii) the weights and processing times are in opposite order. Kise, Ibaraki, and Mine [23] showed how to solve the special case where the release times and deadlines are similarly ordered. For multiple machines, we note that $P|r_i, pmtn|\sum w_i(1-U_i)$ is NP-hard [27], yet there is a pseudopolynomial algorithm for this problem [26]. (However, it does not imply a fully polynomial approximation scheme [32].)

A closely related problem is considered by Adler et al. [1] in the context of communication in linear networks. In this problem, messages with release times and deadlines have to be transmitted over a bus that has a unit bandwidth, and the goal is to maximize the number of messages delivered within their deadline. It turns out that our approximation algorithms for the case of arbitrary weights can be applied to the weighted version of the unbuffered case considered in [1], yielding a constant factor approximation algorithm. No approximation algorithm is given in [1] for this version.

Spieksma [31] considered the *interval scheduling* problem on a single machine. In this problem, the possible instances of a job are given explicitly as a set of time intervals. The goal is to pick a set of maximum cardinality (or weight) of nonintersecting time intervals such that at most one interval from each set of job instances is picked. This problem can be viewed as the discrete version of our problem. Spieksma [31] considered the unweighted version of the interval scheduling problem. He proved that it is MAX-SNP hard, gave a 2-approximation algorithm which is similar to our greedy algorithm, and showed that the integrality gap of a linear programming formulation for this problem approaches 2 as well. We note that our results imply a 2-approximation algorithm for the weighted interval scheduling problem.

In the on-line version of our problems, the jobs appear one by one, and are not known in advance. Lipton and Tomkins [28] considered the nonpreemptive version of the on-line problem, while Koren and Shasha [24] and Baruah et al. [8] considered the preemptive version. The special cases where the weight of a job is proportional to the processing time were considered in the on-line setting in several papers [5, 14, 16, 19, 20, 7]. Our combinatorial algorithm for arbitrary weights borrows some of the techniques used in the on-line case.

Some of our algorithms are based on rounding a fractional solution obtained from a linear programming (LP) relaxation of the problem. In the LP formulation for a single machine we have a variable for every feasible schedule of each of the jobs, a constraint for each job, and a constraint for each time point. A naive implementation of this approach would require an unbounded number of variables and constraints. To overcome this difficulty, we first assume that all release times, deadlines, and processing times are (polynomially bounded) integers. This yields a polynomial number of variables and constraints, allowing for the LP to be solved in polynomial time. For the case of arbitrary input, we show that we need not consider more than $O(n^2)$ variables and constraints for each of the n jobs. This yields a strongly polynomial running time at the expense of a minor degradation in the approximation factor. The rounding of the fractional solution obtained from the LP relaxation is done by decomposing it into a convex sum of integral solutions, and then choosing the best one among them. We show that the bounds obtained by rounding a fractional solution are the best possible bounds that can be obtained, since they match the integrality gap of the LP relaxation.

We extend our algorithms from a single machine to multiple machines by applying a single machine algorithm repeatedly, machine-by-machine, and provide a rather general analysis for such a paradigm. Interestingly, it turns out that the approximation factor for the case of identical machines is superior to the approximation factor of the single machine algorithm which served as our starting point. A similar phenomenon (in a different context) has been observed by Cornuejols, Fisher, and Nemhauser [12]. In the unrelated machines case, our analysis is similar to the one described (in a different context) by Awerbuch et al. [4]. It is also similar to the $O(1)$-reduction described by Kalyasundaram and Pruhs [22] (in the preemptive case) from $P|r_i, pmtn| \sum w_i(1 - U_i)$ to $1|r_i, pmtn| \sum w_i(1 - U_i)$. Unlike the identical machines case, in the unrelated machines case the extension to multiple machines degrades the performance relative to a single machine.

2. Definitions and notations. Let the job system contain n jobs $\mathcal{J} = \langle J_1, \ldots, J_n \rangle$ and k machines $\mathcal{M} = \langle M_1, \ldots, M_k \rangle$. Each job J_i is characterized by the quadruple (r_i, d_i, L_i, w_i), where $L_i = \{\ell_{i,1}, \ldots, \ell_{i,k}\}$. The interpretation is that job J_i is available at time r_i, the *release time*; it must be executed by time

d_i, the *deadline*; its *processing time* on machine M_j is $\ell_{i,j}$; and w_i is the *weight* (or *profit*) associated with the job. We note that our techniques can also be extended to the more general case where the release time, deadline, and weight of each job differ on different machines. However, for simplicity, we consider only the case where the release time, deadline, and weight of each job are the same on all machines. The hardness results are also proved under the same assumption.

We refer to the case in which all job weights are the same as the *unweighted* model, and the case in which job weights are arbitrary as the *weighted* model. (In the unweighted case our goal is to maximize the cardinality of the set of scheduled jobs.) We refer to the case in which the processing times of the jobs on all the machines are the same as the *identical machines* model, and the case in which processing times differ as the *unrelated machines* model. In the identical machines model with unweighted jobs, job J_i is characterized by a triplet (r_i, d_i, ℓ_i) where $d_i \geq r_i + \ell_i$. Without loss of generality, we assume that the earliest release time is at time $t = 0$.

A feasible scheduling of job J_i on machine M_j at time t, $r_i \leq t \leq d_i - \ell_{i,j}$, is referred to as a *job instance*, denoted by $J_{i,j}(t)$. A job instance can also be represented by an *interval* on the time line $[0, \infty)$. We say that the interval $J_{i,j}(t) = [t, t + \ell_{i,j})$ *belongs* to job J_i. In general, many intervals may belong to a job. A set of job instances $J_{1,j}(t_1), \ldots, J_{h,j}(t_h)$ is a feasible schedule on machine M_j, if the corresponding intervals are independent, i.e., they do not overlap, and they belong to distinct jobs. The *weight* of a schedule is the sum of the weights of the jobs to which the intervals (job instances) belong. In the case of multiple machines, we need to find a feasible schedule of distinct jobs on each of the machines. The objective is to maximize the sum of the weights of all schedules.

We distinguish between the case where the release times, processing times, and deadlines are integers bounded by a polynomial in the number of jobs, and between the case of arbitrary inputs. The former case is referred to as *polynomially bounded integral* input and the latter case is referred to as *arbitrary* input.

3. Unweighted jobs. In this section we consider the unweighted model. We define a greedy algorithm and analyze its performance in both the unrelated and identical models. In the former model, we show that it is a 2-approximation algorithm, and in the latter model, we show that it is a $\rho(k)$-approximation algorithm, where

$$\rho(k) = \frac{(k+1)^k}{(k+1)^k - k^k} = \frac{(1+1/k)^k}{(1+1/k)^k - 1} \ .$$

For $k = 1, 2$ we get $\rho(1) = 2$ and $\rho(2) = 9/5$, and for $k \longrightarrow \infty$ we have $\rho(k) \longrightarrow e/(e-1) \approx 1.58198$.

3.1. The greedy algorithm. The greedy strategy for a single machine is as follows. At each time step t (starting at $t = 0$), the algorithm schedules the job instance that finishes first among all jobs that can be scheduled at t or later. Note that the greedy algorithm does not take into consideration the deadlines of the jobs, except for determining whether jobs are eligible for scheduling. The greedy algorithm for multiple machines executes the greedy algorithm (for a single machine) machine by machine, updating the set of jobs to be scheduled on each machine to include only jobs that have not been scheduled on previous machines.

We now give a more formal definition of our strategy and introduce some notations. Define the procedure $\mathsf{NEXT}(t, j, \mathcal{J})$. The procedure determines the job instance $J_{i,j}(t')$, $t' \geq t$, such that $t' + \ell_{i,j}$ is the earliest among all instances of jobs in $\mathcal{J}$ that

start at time t or later on machine M_j. If no such interval exists, the procedure returns *null*.

Algorithm 1-GREEDY$(j, \mathcal{J})$ finds a feasible schedule on machine M_j among the jobs in $\mathcal{J}$ by calling procedure NEXT$(t, j, \mathcal{J})$, repeatedly.

1. The first call is for $J_{i_1,j}(t_1) = \mathsf{NEXT}(0, j, \mathcal{J})$.
2. Assume the algorithm has already computed $J_{i_1,j}(t_1), \ldots, J_{i_h,j}(t_h)$. Let the current time be $t = t_h + \ell_{i_h,j}$ and let the current set of jobs be $\mathcal{J} := \mathcal{J} \setminus \{J_{i_1,j}, \ldots, J_{i_h,j}\}$.
3. The algorithm calls NEXT$(t, j, \mathcal{J})$ that returns either $J_{i_{h+1},j}(t_{h+1})$ or *null*.
4. The algorithm terminates in round $r+1$ when procedure NEXT returns *null*. It returns the set $\{J_{i_1,j}(t_1), \ldots, J_{i_r,j}(t_r)\}$.

Algorithm k-GREEDY$(\mathcal{J})$ finds k schedules such that a job appears at most once in the schedules. It calls Algorithm 1-GREEDY machine by machine, each time updating the set $\mathcal{J}$ of jobs to be scheduled. Assume that the output of 1-GREEDY$(j, \mathcal{J})$ in the first $i-1$ calls is $G_1, \ldots, G_{i-1}$, where G_j is a feasible schedule on machine M_j, for $1 \le j \le i-1$. Then, the algorithm calls 1-GREEDY$(i, \mathcal{J} \setminus \cup_{j=1,\ldots,i-1} G_j)$ to get schedule G_i.

The following property of Algorithm 1-GREEDY is used in the analysis of the approximation factors of our algorithms.

PROPOSITION 3.1. *Let the set of jobs found by* 1-GREEDY$(j, \mathcal{J})$ *for a job system* $\mathcal{J}$ *be* G. *Let* H *be any feasible schedule on machine* M_j *among the jobs in* $\mathcal{J} \setminus G$. *Then,* $|H| \le |G|$.

Proof. For each interval (job instance) in H there exists an interval in G that overlaps with it and terminates earlier. Otherwise, 1-GREEDY would have chosen this interval. The proposition follows from the feasibility of H, since at most one interval in H can overlap with the endpoint of any interval in G. ∎

3.2. Unrelated machines. Based on Proposition 3.1, the following theorem states the performance of the k-GREEDY algorithm in the unweighted jobs and unrelated machines model.

THEOREM 3.2. *Algorithm* k-GREEDY *achieves an approximation factor of* 2 *in the unweighted jobs and unrelated machines model.*

Proof. Let $G(k) = G_1 \cup \cdots \cup G_k$ be the output of k-GREEDY and let $OPT(k) = O_1 \cup \cdots \cup O_k$ be the sets of intervals scheduled on the k machines by an optimal solution OPT. (We note that these sets will be considered as jobs and job instances interchangeably.) Let $H_j = O_j \setminus G(k)$ be the set of all jobs scheduled by OPT on machine M_j that k-GREEDY did not schedule on any machine, and let $H = H_1 \cup \cdots \cup H_k$. Let $OG = OPT(k) \cap G(k)$ be the set of jobs taken by both k-GREEDY and OPT. It follows that $OPT(k) = OG \cup H$.

Proposition 3.1 implies that $|H_j| \le |G_j|$. This is true since H_j is a feasible schedule on machine M_j among the jobs that were not picked by k-GREEDY while constructing the schedule for machine M_j. Since the sets H_j are mutually disjoint and the same holds for the sets G_j, $|H| \le |G(k)|$. Since $|OG| \le |G(k)|$, we get that $|OPT(k)| \le 2|G(k)|$ and the theorem follows. ∎

3.3. Identical machines. In this section we analyze the k-GREEDY algorithm for the unweighted jobs and identical machines model. We show that the approximation factor in this case is

$$\rho(k) = \frac{(k+1)^k}{(k+1)^k - k^k} \ .$$

Recall that for $k \longrightarrow \infty$ we have $\rho(k) \longrightarrow e/(e-1) \approx 1.58198$.

The analysis below is quite general and it only uses the fact that the algorithm is applied sequentially, machine by machine, and that the machines are identical (and that no job migration is allowed). Let $OPT(k)$ be an optimal schedule for k identical machines. Let $\mathcal{A}$ be any algorithm for one machine. Define by $\alpha_{\mathcal{A}}(k)$ (or by $\alpha(k)$ when $\mathcal{A}$ is known) the approximation factor of $\mathcal{A}$ compared with $OPT(k)$. That is, if A is the set of jobs chosen by $\mathcal{A}$, then $|A| \geq (1/\alpha(k))|OPT(k)|$. Note that the comparison is done between an algorithm that uses one machine and an optimal schedule that uses k machines.

Let $\mathcal{A}(k)$ be the algorithm that applies algorithm $\mathcal{A}$, machine by machine, k times. In the next theorem we bound the performance of $\mathcal{A}(k)$ using $\alpha(k)$.

THEOREM 3.3. *Algorithm $\mathcal{A}(k)$ achieves an $\frac{\alpha(k)^k}{\alpha(k)^k-(\alpha(k)-1)^k}$ approximation factor for k identical machines.*

Proof. Let A_i be the set of jobs chosen by $\mathcal{A}(k)$ for the ith machine. Suppose that the algorithm has already determined $A_1, \ldots, A_{i-1}$. Consider the schedule given by removing from $OPT(k)$ all the jobs in $A_1, \ldots, A_{i-1}$. Clearly, this is still a feasible schedule of cardinality at least $|OPT(k)| - \sum_{j=1}^{i-1} |A_j|$. Therefore, by the definition of $\alpha(k)$, the set A_i satisfies $|A_i| \geq (1/\alpha(k))(|OPT(k)| - \sum_{j=1}^{i-1} |A_j|)$. Adding $\sum_{j=1}^{i-1} |A_j|$ to both sides gives us

$$\sum_{j=1}^{i} |A_j| \geq \frac{|OPT(k)|}{\alpha(k)} + \frac{\alpha(k)-1}{\alpha(k)} \sum_{j=1}^{i-1} |A_j| \ . \tag{3.1}$$

We prove by induction on i that

$$\sum_{j=1}^{i} |A_j| \geq \frac{\alpha(k)^i - (\alpha(k)-1)^i}{\alpha(k)^i} |OPT(k)| \ .$$

When $i = 1$, by definition, $|A_1| \geq \frac{|OPT(k)|}{\alpha(k)}$. Assume the claim holds for $i-1$. Applying the induction hypothesis to (3.1) we get

$$\sum_{j=1}^{i} |A_j| \geq \frac{|OPT(k)|}{\alpha(k)} + \frac{\alpha(k)-1}{\alpha(k)} \cdot \frac{\alpha(k)^{i-1} - (\alpha(k)-1)^{i-1}}{\alpha(k)^{i-1}} |OPT(k)| \ .$$

Rearranging terms yields the inductive claim. Setting $i = k$ proves the theorem, namely,

$$\sum_{j=1}^{k} |A_j| \geq \frac{\alpha(k)^k - (\alpha(k)-1)^k}{\alpha(k)^k} |OPT(k)| \ . \qquad \square$$

We now apply the above theorem to Algorithm k-GREEDY. We compute the value of $\alpha(k)$ for Algorithm 1-GREEDY, and observe that Algorithm k-GREEDY indeed applies Algorithm 1-GREEDY k times, as assumed by Theorem 3.3.

THEOREM 3.4. *The approximation factor of k-GREEDY is $\rho(k) = \frac{(k+1)^k}{(k+1)^k-k^k}$ in the unweighted jobs and identical machines model.*

Proof. Recall that Algorithm 1-GREEDY scans all the intervals ordered by their endpoints and picks the first possible interval belonging to a job that was not picked before. Let G be the set picked by the greedy algorithm, and consider the schedule

of $H = OPT(k) - G$ on machines $M_1, \ldots, M_k$. Similar to the arguments of Proposition 3.1, in each of the machines, if a particular job of H was not chosen, then there must be a job in progress in G. Also this job must finish before the particular job in H finishes. Thus, the number of jobs in H executed on any single machine by the optimal schedule has to be at most $|G|$. Since the jobs executed by the optimal schedule on different machines are disjoint, we get $|H| \leq k|G|$. Consequently, $|OPT(k)| \leq (k+1)|G|$ and $\alpha(k) = k+1$. The theorem follows by setting this value for $\alpha(k)$ in Theorem 3.3. □

Remark. It is not difficult to see that $\alpha(k) \leq k\alpha(1)$; that is, if the approximation factor of $\mathcal{A}$ compared with $OPT(1)$ is $\alpha(1)$, then the approximation factor of $\mathcal{A}$ compared with $OPT(k)$ is no more than $k\alpha(1)$. However, applying Theorem 3.3 using this bound for $\alpha(k)$ would yield an approximation factor for k identical machines which is inferior to the $\alpha(1)$ bound on this approximation ratio that can be achieved directly. We note that for this reason Theorem 3.3 cannot be applied to improve the result in [22].

3.4. Tight bounds for GREEDY. In this subsection we construct instances for which our bounds in the unweighted model for algorithm GREEDY are tight. We first show that for one machine (where the unrelated and identical models coincide), the 2-approximation is tight. Next, we generalize this construction for the unrelated model and prove the tight bound of 2 for $k > 1$ machines. Finally, we generalize the construction for one machine to $k > 1$ identical machines and prove the tight bound of $\rho(k)$.

Recall that in the unweighted model each job is characterized by a triplet (r_i, d_i, ℓ_i) in the identical machines model and by a triplet (r_i, d_i, L_i), where $L_i = \{\ell_{i,1}, \ldots, \ell_{i,k}\}$, in the unrelated machines model.

3.4.1. A single machine. For a single machine the system contains two jobs: $G_1 = (0, 3, 1)$ and $H_1 = (0, 2, 2)$. Algorithm 1-GREEDY schedules the instance $G_1(0)$ of job G_1 and cannot schedule any instance of H_1. An optimal solution schedules the instances $H_1(0)$ and $G_1(2)$. Clearly, the ratio is 2. We could repeat this pattern on the time axis to obtain this ratio for any number of jobs.

This construction demonstrates the limitation of the approach of Algorithm 1-GREEDY. This approach ignores the deadlines and therefore does not capitalize on the urgency in scheduling job H_1 in order not to miss its deadline. We generalize this idea further for k machines.

Note that an algorithm that does not consider job lengths and schedules solely according to deadlines may produce even worse results. Consider the following $n+1$ jobs: n jobs $H_i = (0, 2n+1, 2)$, $1 \leq i \leq n$, and one job $G_1 = (0, 2n, 2n)$. An optimal solution schedules all the H-type jobs whereas an algorithm that schedules jobs with earliest deadline first schedules the G-type job first and then is unable to schedule any of the H-type jobs.

3.4.2. Unrelated machines. For $k \geq 1$ machines the job system contains $2k$ jobs: $G_1, \ldots, G_k$ and $H_1, \ldots, H_k$. The release time of all jobs is 0. The deadline of all the G-type jobs is 3 and the deadline of all the H-type jobs is 2. The length of job G_i on machine M_i is 1 and it is 4 on all other machines. The length of job H_i on machine M_i is 2 and it is 3 on all other machines.

Note that only jobs G_i and H_i can be scheduled on machine M_i, since all other jobs are too long to meet their deadline. Hence, Algorithm k-GREEDY considers only these two jobs while constructing the schedule for machine M_i. As a result,

k-GREEDY selects the instance $G_i(0)$ of job G_i to be scheduled on machine M_i and cannot schedule any of the H-type jobs. On the other hand, an optimal solution schedules the instances $H_i(0)$ and $G_i(2)$ on machine M_i.

Overall, Algorithm k-GREEDY schedules k jobs while an optimal algorithm schedules all $2k$ jobs. This yields a tight approximation factor of 2 in the unweighted jobs and unrelated machines model.

3.4.3. Identical machines. We define job systems $\mathcal{J}(k)$ for any given $k \geq 1$. We show that on $\mathcal{J}(k)$ the performance of k-GREEDY$(\mathcal{J}(k))$ is no more than $(1/\rho(k)) \cdot \mathsf{OPT}(\mathcal{J}(k))$. The $\mathcal{J}(1)$ system is the one defined in subsection 3.4.1. The $\mathcal{J}(2)$ job system contains $2 \cdot 3^2 = 18$ jobs: $2 \cdot 3 = 6$ jobs of type $G_1 = (0, d_1, \ell)$, $2^2 = 4$ jobs of type $G_2 = (0, d_2, \ell + 1)$, and $2^3 = 8$ jobs of type $H = (0, d, \ell + 2)$. If we set $\ell = 10$, $d_1 = 100$, $d_2 = 70$, and $d = 48$, we force Algorithm 2-GREEDY to make the following selections:

- On the first machine, 2-GREEDY schedules all the 6 jobs of type G_1. This is true since the length of these jobs is less than the lengths of the jobs of type G_2 and the jobs of type H. The last G_1-type interval terminates at time 60. Hence, there is no room for a G_2-type (H-type) interval, the deadline of which is 70 (48), and the length of which is 11 (12).
- On the second machine, 2-GREEDY schedules all 4 jobs of type G_2 since they are shorter than the jobs of type H. The last G_2-type job terminates at time 44 which leaves no room for another job of type H.

Overall, 2-GREEDY schedules only 10 jobs. We show now an optimal solution that schedules all 18 jobs. It schedules 9 jobs on each machine as follows:

$$H(0), H(12), H(24), H(36), G_2(48), G_2(59), G_1(70), G_1(80), G_1(90) \ .$$

Note that all the instances terminate before their deadlines. As a result we get a ratio $\rho(2) = (2 \cdot 3^2)/(2 \cdot 3^2 - 2^3) = 9/5$.

We are ready to define $\mathcal{J}(k)$ for any $k \geq 1$. The job system contains $k(k+1)^k$ jobs. Algorithm k-GREEDY is able to schedule only $k(k+1)^k - k^{k+1}$ out of them and there exists an optimal solution that schedules all of them. As a result we get the ratio

$$\frac{k(k+1)^k}{k(k+1)^k - k^{k+1}} = \rho(k) \ .$$

The $\mathcal{J}(k)$ system is composed of $k+1$ types of jobs: $G_1, G_2, \ldots, G_k$ and H. There are $k^i(k+1)^{k-i}$ jobs $(0, d_i, \ell + i - 1)$ in G_i and k^{k+1} jobs $(0, d, \ell + k)$ in H. Indeed, $k^{k+1} + \sum_{i=1}^{k} k^i(k+1)^{k-i} = k(k+1)^k$. (To see this, divide the equation by k^{k+1} to get $1 + (1/k) \cdot \sum_{i=0}^{k-1}(1+1/k)^i = (1+1/k)^k$.) Note also that the length of the G_i-type jobs is monotonically increasing in i and that the H-type jobs are the longest.

We show how by fixing $d_1, \ldots, d_k$ and d and by setting ℓ as a large enough number, we force Algorithm k-GREEDY to select for machine i all the jobs of type G_i but no other jobs. Thus, k-GREEDY does not schedule any of the H-type jobs. On the other hand, an optimal solution is able to construct the same schedule for all the k machines. It starts by scheduling $1/k$ of the H-type jobs on each machine, and then it schedules in turn $1/k$ of the jobs from $G_k, G_{k-1}, \ldots, G_1$ in this order.

We fix the values of $d, d_k, \ldots, d_1$ to allow for such an optimal schedule. The optimal solution starts by scheduling on each machine $(1/k) \cdot k^{k+1} = k^k$ of the H-type jobs each of length $\ell + k$. Thus, we set $d = k^k \cdot (\ell + k) = k^k\ell + k^{k+1}$. Next,

$(1/k) \cdot k^k = k^{k-1}$ of the G_k-type jobs each of length $\ell + k - 1$ are scheduled. Thus, we set $d_k = d + k^{k-1} \cdot (\ell + k - 1)$. Similarly, for $i = k-1, \ldots, 1$,

$$\begin{aligned} d_i &= d_{i+1} + (1/k) \cdot k^i (1+k)^{k-i} \cdot (\ell + i - 1) \\ &= d_{i+1} + k^{i-1}(1+k)^{k-i} \cdot (\ell + i - 1) \\ &= d_{i+1} + k^{i-1}(1+k)^{k-i} \cdot \ell + k^{i-1}(1+k)^{k-i} \cdot (i-1) \ . \end{aligned}$$

Observe that $d < d_k < \cdots < d_1$.

We now have to show that with the values fixed above Algorithm k-GREEDY schedules all the jobs of type G_i but no other jobs on machine i. Note that we have not set yet the value of ℓ; we set it to be large enough to force such a behavior of k-GREEDY. First, we find the general solution to the recurrence for $d_{(k+1)-i}$, $1 \le i \le k$. The coefficient of ℓ in $d_{(k+1)-i}$ is

$$\sum_{j=1}^{i} k^{k-j}(k+1)^{j-1} + k^k = k^{k-i}(k+1)^i \ .$$

It follows that

$$d_{k+1-i} = k^{k-i}(k+1)^i \ell + k^{k+1} + \sum_{j=1}^{i} k^{k-j}(k+1)^{j-1}(k-j) \ .$$

For the analysis below we need to break the expression for d_i into two components: one is the term that depends (linearly) on ℓ, and the other that depends only on i and k. For convenience denote $d_{k+1} = d$. It follows that for $1 \le i \le k+1$,

$$d_i = k^{i-1}(k+1)^{k-i+1}\ell + f(i,k)$$

for some function $f(i,k)$ independent of ℓ.

Algorithm k-GREEDY starts by scheduling all the jobs of type G_1 on machine 1, since these are the shortest length jobs. The time taken is $k(k+1)^{k-1}\ell$. Since our goal is not to have any other jobs scheduled on machine 1, we must make the deadline of the other jobs early enough so that they cannot be scheduled after this time. In particular, to prevent scheduling G_2-type jobs on machine 1 we must have $k(k+1)^{k-1}\ell + (\ell + 1) > d_2$. Note that since the deadlines d_i are monotonically decreasing and the lengths of the G_i-type jobs are monotonically increasing, if a job of type G_i cannot be scheduled, then a job of type G_{i+1} cannot be scheduled as well. The same is true for jobs of type H. It follows that if $k(k+1)^{k-1}\ell + (\ell + 1) > d_2$, then after all the jobs of type G_1 are scheduled on machine 1, no other jobs can be scheduled on machine 1.

In general, assume that Algorithm k-GREEDY starts the scheduling on machine i after all jobs of type $G_1, \ldots, G_{i-1}$ have already been scheduled on machines $1, \ldots, i-1$, respectively. In this case Algorithm k-GREEDY schedules all the jobs of type G_i on machine i, since these are the shortest length jobs that have not been scheduled yet. The time taken is $k^i(k+1)^{k-i}(\ell + i - 1)$. Thus, if

$$k^i(k+1)^{k-i}(\ell + i - 1) + (\ell + i) > d_{i+1},$$

then the jobs of type G_{i+1} cannot be scheduled on machine i. This implies that also

all jobs of types $G_{i+2}, \ldots, G_k$ and H cannot be scheduled at this point on machine i.

We conclude that in order to force the desired behavior of Algorithm k-GREEDY we must have for all $1 \leq i \leq k$

$$k^i(k+1)^{k-i}(\ell+i-1)+(\ell+i) > d_{i+1} \ .$$

By the recurrence relation for d_{i+1} it follows that the above inequality holds if and only if the following holds:

$$k^i(k+1)^{k-i}(\ell+i-1)+(\ell+i) > k^i(k+1)^{k-i}\ell + f(i+1,k) \ .$$

This is equivalent to

$$\ell > f(i+1,k) - i - (i-1)k^i(k+1)^{k-i} \ .$$

Since $f(i+1,k)$ does not depend on ℓ, it follows that the above inequality holds for a sufficiently large ℓ. This provides a tight bound for the k-GREEDY schedule.

4. Weighted jobs. In this section we present approximation algorithms for weighted jobs. We first present algorithms for a single machine and for unrelated machines that are based on rounding an LP relaxation of the problem. Then, we reapply the analysis of Theorem 3.3 to get better approximation factors for the identical machines model. We conclude with a combinatorial algorithm for unrelated machines which is efficient and easy to implement. However, it achieves a weaker approximation guarantee than the bound obtained by rounding a fractional solution obtained from the LP relaxation.

4.1. Approximation via linear programming. In this subsection we describe an LP based approximation algorithm. We first describe the algorithm for the case of a single machine, and then generalize it to the case of multiple machines. Our LP formulation is based on discretizing time. Suppose that the time axis is divided into N time slots. The complexity of our algorithms depends on N. However, we assume for now that N is part of the input, and that the discretization of time is fine enough so as to represent any feasible schedule, up to small shifts that do not change the value of the objective function. Later, we show how to get rid of these assumptions at the expense of a slight increase in the approximation factor.

4.1.1. A single machine. In this subsection we describe our linear program assuming that the number of slots N is part of the input.

The linear program relaxes the scheduling problem in the following way. A fractional feasible solution is one which distributes the processing of a job among the job instances or intervals belonging to it with the restriction that at any given point of time t, the sum of the fractions assigned to all the intervals at t (belonging to all jobs) does not exceed 1. To this end, for each job $J_i \in \mathcal{J}$, define a variable x_{it} for each interval $[t, t+\ell_i)$ belonging to it, i.e., for which $t \geq r_i$ and $t+\ell_i \leq d_i$. It would be convenient to assume that $x_{it} = 0$ for any other value of t between 1 and N. The linear program is as follows.

$$\text{maximize} \quad \sum_{i=1}^{n} \sum_{t=r_i}^{d_i-\ell_i} w_i \cdot x_{it}$$

subject to

$$\begin{aligned}
&\text{for each time slot } t,\ 1 \le t \le N, && \sum_{i=1}^{n} \sum_{t'=t-\ell_i+1}^{t} x_{it'} \le 1,\\
&\text{for each job } i,\ 1 \le i \le n, && \sum_{t=r_i}^{d_i-\ell_i} x_{it} \le 1,\\
&\text{for all } 1 \le i \le n \text{ and } 1 \le t \le N, && 0 \le x_{it} \le 1.
\end{aligned}$$

It is easy to see that any feasible schedule defines a feasible integral solution to the linear program and vice versa. Therefore, the value of an optimal (fractional) solution to the linear program is an upper bound on the value of an optimal integral solution.

We compute an optimal solution to the linear program and denote the value of variable x_{it} in this solution by q_{it}. Denote the value of the objective function in an optimal solution by OPT. We now show how to round an optimal solution to the linear program to an integral solution.

We define the following coloring of intervals. The collection of all intervals belonging to a set of jobs $\mathcal{J}$ can be regarded as an interval representation of an interval graph $\mathcal{I}$. We define a set of intervals in $\mathcal{I}$ to be *independent* if (i) no two intervals in the set overlap and (ii) no two intervals in the set belong to the same job. (Note that this definition is more restrictive than the regular independence relation in interval graphs.) Clearly, an independent set of intervals defines a feasible schedule. The weight of an independent set P, $w(P)$, is defined to be the sum of the weights of the jobs to which the intervals belong.

Our goal is to color intervals in $\mathcal{I}$ such that each color class induces an independent set. We note that not all intervals are required to be colored and that an interval may receive more than one color. Suppose that a collection of color classes (independent sets) $P_1, \ldots, P_m$ with nonnegative coefficients $\alpha_1, \ldots, \alpha_m$ satisfies (i) $\sum_{i=1}^{m} \alpha_i \le 2$ and (ii) $\sum_{i=1}^{m} w(P_i) \cdot \alpha_i \ge \mathsf{OPT}$. By convexity, there exists a color class P_i, $1 \le i \le m$, for which $w(P_i) \ge \mathsf{OPT}/2$. This color class is defined to be our approximate solution, and the approximation factor is 2. It remains to show how to obtain the desired coloring.

We now take a short detour and define the *group constrained interval coloring problem*. Let $Q = \langle Q_1, \ldots, Q_p \rangle$ be an interval representation in which the maximum number of mutually overlapping intervals is t_1. Suppose that the intervals are partitioned into disjoint groups $g_1, \ldots, g_r$, where a group contains at most t_2 intervals. A legal group constrained coloring of the intervals in Q is a coloring in which (i) overlapping intervals are not allowed to get the same color and (ii) intervals belonging to the same group are not allowed to get the same color.

THEOREM 4.1. *There exists a legal group constrained coloring of the intervals in Q that uses at most $t_1 + t_2 - 1$ colors.*

Proof. We use a greedy algorithm to obtain a legal coloring using at most t_1+t_2-1 colors. Sort the intervals in Q by their left endpoint and color the intervals from left to right with respect to this ordering. When an interval is considered by the algorithm it is colored by any one of the free colors available at that time. We show by induction that when the algorithm considers an interval, there is always a free color.

This is true initially. When the algorithm considers interval Q_i, the colors that cannot be used for Q_i are occupied either by intervals that overlap with Q_i or by intervals that belong to the same group as Q_i. Since we are considering the intervals sorted by their left endpoint, all intervals overlapping with Q_i also overlap with each other, and hence there are at most $t_1 - 1$ such intervals. There can be at most $t_2 - 1$ intervals that belong to the same group as Q_i. Since the number of available colors is $t_1 + t_2 - 1$, there is always a free color. □

We are now back to the problem of coloring the intervals in $\mathcal{I}$. Let $N' = N^2 \cdot n^2$. We can round down each fraction q_{it} in the optimal solution to the closest fraction of the form a/N', where $1 \leq a \leq N'$. Each q_{it} decreases by at most $1/(N^2n^2)$ by this rounding, and hence the rounding decreases the objective function by at most $\max_i w_i/(Nn)$. Since the optimal solution value is at least $\max_i w_i$, it follows that the rounding incurs a negligible error (of at most $1/(Nn)$ factor) in the value of the objective function. We now generate an interval graph $\mathcal{I}'$ from $\mathcal{I}$ by replacing each interval $J_i(t) \in \mathcal{I}$ by $q_{it} \cdot N'$ "parallel" intervals. Define a group constrained coloring problem on $\mathcal{I}'$, where group g_i, $1 \leq i \leq n$, contains all instances of job J_i. Note that in $\mathcal{I}'$, the maximum number of mutually overlapping intervals is bounded by N', and the maximum number of intervals belonging to a group is also N'.

By Theorem 4.1, there exists a group constrained coloring of $\mathcal{I}'$ that uses at most $2N' - 1$ colors. Attach a coefficient of $1/N'$ to each color class. Clearly, the sum of the coefficients is less than 2. Also, by our construction, the sum of the weights of the intervals in all the color classes, multiplied by the coefficient $1/N'$, is at least OPT (up to a factor of $1 - 1/(Nn)$, due to the rounding). We conclude with the following theorem.

THEOREM 4.2. *The approximation factor of the algorithm that rounds an optimal fractional solution is* 2.

We note that the technique of rounding a fractional solution by decomposing it into a convex combination of integral solutions was used in [2, 10].

The 2-approximation factor obtained by the rounding algorithm is the best possible bound that can be obtained through our linear programming relaxation. The following example shows that the integrality gap between the fractional LP solution and the integral solution can approach 2. There are two jobs: $G_1 = (0, d, 1)$ and $H_1 = (0, d, d)$, both of unit weight. Any integral solution can process only a single job. A fractional solution may assign a fraction of $1 - 1/d$ to job H_1, and then assign a fraction of $1/d$ to all job instances of G_1 of the form $[i, i+1)$, $0 \leq i \leq d-1$. Thus, the integrality gap is $2 - 1/d$. Note that the integrality gap depends on the discretization of time and it approaches 2 as d goes to infinity.

4.1.2. A strongly polynomial bound for a single machine. The difficulty with the linear programming formulation and the rounding algorithm is that the complexity of the algorithm depends on N, the number of time slots. We now show how we choose N to be a polynomial in the number of jobs, n, at the expense of losing an additive term of one in the approximation factor.

First, we note that in case the release times, deadlines, and processing times are integral, we may assume without loss of generality that each job is scheduled at an integral point of time. If, in addition, they are restricted to integers of polynomial size, then the number of variables and constraints is bounded by a polynomial.

We now turn our attention to the case of arbitrary inputs. Partition the jobs in $\mathcal{J}$ into two classes:

- big slack jobs: $J_i \in \mathcal{J}$ for which $d_i - r_i \geq n^2 \cdot \ell_i$,

- small slack jobs: $J_i \in \mathcal{J}$ for which $d_i - r_i < n^2 \cdot \ell_i$.

We obtain a fractional solution separately for the big slack jobs and small slack jobs. We first explain how to obtain a fractional solution for the big slack jobs. For each big slack job $J_i \in \mathcal{J}$, find n^2 nonoverlapping job instances and assign a value of $1/n^2$ to each such interval. Note that this many nonoverlapping intervals can be found since $d_i - r_i$ is large enough. We claim that this assignment can be ignored when computing the solution (via LP) for the small slack jobs. This is true because at any point of time t, the sum of the fractions assigned to intervals at t belonging to big slack jobs can be at most $1/n$, and thus their effect on any fractional solution is negligible. (In the worst case, scale down all fractions corresponding to small slack jobs by a factor of $(1-1/n)$.) Nevertheless, a big slack job contributes all of its weight to the fractional objective function because it has n^2 nonoverlapping copies.

We now restrict our attention to the set of small slack jobs and explain how to compute a fractional solution for them. To bound the number of variables and constraints in the LP we partition the time axis into at most $n \cdot (n^2 + 1)$ time slots. Instead of having a variable for each job instance we consider at most $n^2 \cdot (n^2 + 1)$ variables, where for each job $J_i \in \mathcal{J}$, there are at most $n \cdot (n^2 + 1)$ variables, and the jth variable "represents" all the job instances of J_i that start during the jth time slot. Similarly, we consider at most $n \cdot (n^2 + 1)$ constraints, where the jth constraint "covers" the jth time slot. For each small slack job $J_i \in \mathcal{J}$, define $n^2 + 1$ "dividers" along the time axis at points $r_i + j\frac{d_i - r_i}{n^2}$ for $j = 0, \ldots, n^2$. After defining all the $n \cdot (n^2+1)$ dividers, the time slots are determined by the adjacent dividers. The main observation is that for each small slack job J_i, no interval can be fully contained in a time slot, i.e., between two consecutive dividers.

The LP formulation for the modified variables and constraints is slightly different from the original formulation. To see why, consider a feasible schedule. As mentioned above, a job instance cannot be fully contained in a time slot t. However, the schedule we are considering may consist of two instances of jobs such that one terminates within time slot t and the other starts within t. If we keep the constraints that stipulate that the sum of the variables corresponding to intervals that intersect a time slot is bounded by 1, then we would not be able to represent such a schedule in our formulation. To overcome this problem, we relax the linear program and allow that at every time slot t, the sum of the fractions assigned to the intervals that intersect t can be at most 2. The relaxed linear program is the following.

$$\text{maximize} \quad \sum_{i=1}^{n} \sum_{r_i \le t \le d_i - \ell_i} w_i \cdot x_{it}$$

subject to

$$\begin{aligned}
&\text{for each time slot } t, && \sum_{i=1}^{n} \sum_{t - \ell_i + 1 \le t' \le t} x_{it'} \le 2,\\
&\text{for each job } i,\ 1 \le i \le n, && \sum_{r_i \le t \le d_i - \ell_i} x_{it} \le 1,\\
&\text{for all } i \text{ and } t, && 0 \le x_{it} \le 1.
\end{aligned}$$

It is easy to see that our relaxation guarantees that the value of the objective function in the above linear program is at least as big as the value of an optimal

schedule. We round an optimal fractional solution in the same way as in the previous section. Since we relaxed our constraints, we note that when we run the group constrained interval coloring algorithm, the number of mutually overlapping intervals can be at most twice the number of intervals in each group. Therefore, when we generate the color classes $P_1, \ldots, P_m$ with coefficients $\alpha_1, \ldots, \alpha_m$, we can guarantee only that (i) $\sum_{i=1}^{m} \alpha_i < 3$ and (ii) $\sum_{i=1}^{m} w(P_i) \cdot \alpha_i = \mathsf{OPT}$, yielding an approximation factor of 3. We conclude the following.

THEOREM 4.3. *The approximation factor of the strongly polynomial algorithm that rounds a fractional solution is* 3.

4.1.3. Unrelated machines. In this section we consider the case of k unrelated machines. We first present an LP formulation. For clarity, we give the LP formulation for polynomially bounded integral inputs. However, the construction given in the previous section that achieves a strongly polynomial algorithm for arbitrary inputs can be applied here as well. Assume that there are N time slots. For each job $J_i \in \mathcal{J}$ and for each machine $M_j \in \mathcal{M}$, define a variable x_{itj} for each instance $[t, t + \ell_{i,j}]$ of J_i.

$$\text{maximize} \quad \sum_{j=1}^{k} \sum_{i=1}^{n} \sum_{t=r_i}^{d_i - \ell_{i,j}} w_i \cdot x_{itj}$$

subject to

$$\begin{aligned}
&\text{for each time slot } t,\ 1 \le t \le N,\\
&\quad \text{and machine } j,\ 1 \le j \le k, && \sum_{i=1}^{n} \sum_{t'=t-\ell_{i,j}+1}^{t} x_{it'j} \le 1,\\
&\text{for each job } i,\ 1 \le i \le n, && \sum_{j=1}^{k} \sum_{t=r_i}^{d_i-\ell_{i,j}} x_{itj} \le 1,\\
&\text{for all } 1 \le i \le n,\ 1 \le j \le k,\\
&\quad \text{and } 1 \le t \le N, && 0 \le x_{itj} \le 1.
\end{aligned}$$

The algorithm rounds the fractional solution machine by machine. Let $S = \{S_1, \ldots, S_k\}$ denote the rounded solution. When rounding machine i, we first discard from its fractional solution all intervals belonging to jobs assigned to $S_1, \ldots, S_{i-1}$. Let c denote the approximation factor that can be achieved when rounding a single machine. Namely, $c = 2$ for integral polynomial size inputs and $c = 3$ for arbitrary inputs.

THEOREM 4.4. *The approximation factor of the algorithm that rounds a k-machine solution is $(c + 1)$.*

Proof. Let F_j, $1 \le j \le k$, denote the fractional solution of machine j, and let $w(F_j)$ denote its value. Denote by F'_j the fractional solution of machine j after discarding all intervals belonging to jobs chosen to $S_1, \ldots, S_{j-1}$.

We know that for all j, $1 \le j \le k$,

$$w(S_j) \ge \frac{1}{c} \cdot w(F'_j) \ .$$

Adding up all the inequalities, since the sets S_j (F'_j) are mutually disjoint, we get that

$$w(S) \geq \frac{1}{c} \cdot \sum_{j=1}^{k} w(F'_j).$$

Recall that for each job i, the sum of the values of the fractional solution assigned to the intervals belonging to it in all the machines does not exceed 1. Therefore,

$$\sum_{j=1}^{k} w(F'_j) \geq \sum_{j=1}^{k} w(F_j) - w(S) \ .$$

Yielding that

$$w(S) \geq \frac{\sum_{j=1}^{k} w(F_j)}{c+1}. \qquad \square$$

4.1.4. Identical machines. In this subsection we apply Theorem 3.3 for the case of weighted jobs and identical machines. We distinguish between the cases of polynomially bounded integral input and arbitrary input.

THEOREM 4.5. *There exists an algorithm for the weighted jobs and identical machines case that achieves an approximation factor of* $\rho(k) = \frac{(k+1)^k}{(k+1)^k - k^k}$ *for polynomially bounded integral input and* $\rho'(k) = \frac{(2k+1)^k}{(2k+1)^k - (2k)^k}$ *for arbitrary input.*

Proof. As shown above, a linear program can be formulated such that the value of its optimal solution is at least as big as the value of an optimal schedule. Let N' be chosen in the same way as in the discussion preceding Theorem 4.2. We claim that using our rounding scheme, this feasible solution defines an interval graph that can be colored by $(k+1)N' - 1$ colors for integral polynomial size inputs and by $(2k+1)N' - 1$ colors for arbitrary inputs.

Consider first the case of integral polynomial size input. In the interval graph that is induced by the solution of the LP, there are at most N' intervals (that correspond to the same job) in the same group, and at most kN' intervals mutually overlap at any point of time. Applying our group constrained interval coloring, we get a valid coloring with $(k+1)N' - 1$ colors. Similarly, for arbitrary inputs, in the interval graph which is induced by the solution of the LP, there are at most N' intervals (that correspond to the same job) in the same group, and at most $2kN'$ intervals mutually overlap. Applying our group constrained interval coloring, we get a valid coloring with $(2k+1)N' - 1$ colors.

This implies that $\alpha(k) = k+1$ for integral polynomial size input and $\alpha(k) = 2k+1$ for arbitrary input. In other words, this is the approximation factor that can be achieved with a single machine when compared to an optimal algorithm that uses k identical machines. Setting these values of $\alpha(k)$ in our paradigm for transforming an algorithm for a single machine to an algorithm for k identical machines yields the claimed approximation factors. $\square$

Remark. Note that as k tends to infinity, the approximation factor is $\frac{e}{e-1} \approx 1.58192$ for both unweighted jobs and for weighted jobs with integral polynomial size inputs. For arbitrary input, the approximation factor is $\frac{\sqrt{e}}{\sqrt{e}-1} \approx 2.54149$. Setting $k = 1$ we get that these bounds coincide with the bounds for a single machine. For every $k \geq 2$ and for both cases these bounds improve upon the bounds for unrelated machines (of 3 and 4).

4.2. A combinatorial algorithm. In this section we present a combinatorial algorithm for the weighted jobs model. We first present an algorithm for the single-machine version and then we show how to extend it to the case where there are $k > 1$ machines, even in the unrelated machines model.

4.2.1. A single machine. The algorithm is inspired by on-line call admission algorithms (see [16, 8]). We scan the job instances (or intervals) one by one. For each job instance, we either accept it or reject it. We note that rejection is an irrevocable decision, where as acceptance can be temporary, i.e., an accepted job may still be rejected at a later point of time. We remark that in the case of nonpreemptive on-line call admission, a constant competitive factor cannot be achieved by such an algorithm. The reason is that due to the on-line nature of the problem jobs must be considered in the order of their release time. Our algorithm has the freedom to order the jobs in a different way, yielding a constant approximation factor.

We now outline the algorithm. All feasible intervals of all jobs are scanned from left to right (on the time axis) sorted by their endpoints. The algorithm maintains a set $\mathcal{A}$ of currently accepted intervals. When a new interval, I, is considered according to the sorted order, it is immediately rejected if it belongs to a job that already has an instance in $\mathcal{A}$, and immediately accepted if it does not overlap with any other interval in $\mathcal{A}$. In case of acceptance, interval I is added to $\mathcal{A}$. If I overlaps with one or more intervals in $\mathcal{A}$, it is accepted only if its weight is more than β ($\beta > 1$, to be determined later) times the sum of the weights of all overlapping intervals. In this case, we say that I "preempts" these overlapping intervals. We add I to $\mathcal{A}$ and discard all the overlapping intervals from $\mathcal{A}$. The process ends when there are no more intervals to scan.

A more formal description of our algorithm, called Algorithm ADMISSION, is given in Figure 4.1.

Algorithm ADMISSION**:**

1. Let $\mathcal{A}$ be the set of accepted job instances.
   Initially, $\mathcal{A} = \emptyset$.
2. Let $\mathcal{I}$ be the set of the yet unprocessed job instances.
   Initially, $\mathcal{I}$ is the set of all feasible job instances.
3. While $\mathcal{I}$ is not empty repeat the following procedure:
   Let $I \in J_i$ be the job instance that terminates earliest among all instances in $\mathcal{I}$ and let w be its weight.
   Let W be the sum of the weights of all instances $I_1, \ldots, I_h$ in $\mathcal{A}$ that overlap I.
   (a) $\mathcal{I} := \mathcal{I} \setminus \{I\}$.
   (b) If $J_i \cap \mathcal{A} \neq \emptyset$ then **reject** I.
   (c) Else if $W = 0$ then **accept** I;
   $\mathcal{A} := \mathcal{A} \cup \{I\}$.
   (d) Else if $\frac{w}{W} > \beta$ then **accept** I and **preempt** $I_1, \ldots, I_h$;
   $\mathcal{A} := \mathcal{A} \cup \{I\} \setminus \{I_1, \ldots, I_h\}$.
   (e) Otherwise (i.e., $\frac{w}{W} \leq \beta$) then **reject** I.

end ADMISSION

FIG. 4.1. *Algorithm* ADMISSION.

We relegate the details of implementing the above algorithm (keeping track of intervals) after we show the approximation guarantee.

We say that an interval I "caused" the rejection or preemption of another interval J, either if interval I directly rejected or preempted interval J or if, for some $h \geq 2$, there exists a sequence of intervals $I = I_0, I_1, \ldots, I_h = J$ such that I_i preempted I_{i+1} for $0 \leq i \leq h-2$ and I_{h-1} directly rejected or preempted interval I_h. Fix an interval I that was accepted by the algorithm, and consider all the intervals chosen by the optimal solution, the rejection, or the preemption of which was caused by interval I. We prove that the total weight of these intervals is at most $f(\beta)$ times the weight of the accepted interval I, for some function f. Optimizing β, we get the $3+2\sqrt{2} \approx 5.828$ bound.

THEOREM 4.6. *The approximation factor of Algorithm* ADMISSION *is* $3 + 2\sqrt{2}$.

Proof. Let $\mathcal{O}$ be the set of intervals chosen by an optimal algorithm OPT. Let the set of intervals accepted by Algorithm ADMISSION be denoted by $\mathcal{A}$. For each interval $I \in \mathcal{A}$ we define a set $R(I)$ of all the intervals in $\mathcal{O}$ that are "accounted for" by I. This set consists of I in case $I \in \mathcal{O}$, and of all the intervals in $\mathcal{O}$ the rejection or preemption of which was caused by I. More formally, we have the following.

- Assume I is accepted by rule 3(c). Then, the set $R(I)$ is initialized to be I in case $I \in \mathcal{O}$ and the empty set $\emptyset$, otherwise.
- Assume I is accepted by rule 3(d). Then $R(I)$ is initialized to contain all those intervals from $\mathcal{O}$ that were directly preempted by I and the union of the sets $R(I')$ of all the intervals I' that were preempted by I. In addition, $R(I)$ contains I in case $I \in \mathcal{O}$.
- Assume $J \in \mathcal{O}$ is rejected by rule 3(b). Let $I \in \mathcal{A}$ be the interval that caused the rejection of J. Note that both I and J belong to the same job. In this case add J to $R(I)$.
- Assume $J \in \mathcal{O}$ was rejected by rule 3(e) and let $I_1, \ldots, I_h$ be the intervals in $\mathcal{A}$ that overlapped with J at the time of rejection. Let w be the weight of J and let w_j be the weight of I_j for $1 \leq j \leq h$. We view J as h imaginary intervals $J_1, \ldots, J_h$, where the weight of J_j is $\frac{w_j \cdot w}{\sum_{i=1}^{h} w_i}$ for $1 \leq j \leq h$. Set $R(I_j) := R(I_j) \cup \{J_j\}$. Note that due to the rejection rule it follows that the weight of J_j is no more than β times the weight of I_j.

It is not hard to see that each interval from $\mathcal{O}$, or a portion of it if we use rule 3(e), belongs exactly to one set $R(I)$ for some $I \in \mathcal{A}$. Thus, the union of all sets $R(I)$ for $I \in \mathcal{A}$ covers $\mathcal{O}$.

We now fix an interval $I \in \mathcal{A}$. Let w be the weight of I and let W be the sum of weights of all intervals in $R(I)$. Define $\rho = \frac{W}{w}$. Our goal is to bound ρ from above.

Interval I may directly reject at most one interval from $\mathcal{O}$. Let w_r be the weight of (the portion of) the interval $I_r \in \mathcal{O} \cap R(I)$ that was directly rejected by I, if such exists. Otherwise, let $w_r = 0$. Observe that $w_r \leq \beta w$, since, otherwise, I_r would not have been rejected. Let $I' \in \mathcal{O}$ be the interval that belongs to the same job as the one to which I belongs (it may be I itself), if such exists. By definition, the weight of I' is w. Let $W' \geq W - w - w_r$ be the sum of the weights of the rest of the intervals in $R(I)$. Define $\alpha = \frac{W'}{w}$. It follows that $\rho \leq \alpha + \beta + 1$.

We now assume inductively that the ρ bound is valid for intervals with earlier endpoint than the endpoint of I. Since the overall weight of the jobs that I directly preempted is at most w/β, we get that $\frac{w}{\beta} \cdot \rho \geq \alpha \cdot w$. This implies that $\frac{\alpha+\beta+1}{\beta} \geq \alpha$. Or equivalently, $\alpha \leq \frac{\beta+1}{\beta-1} = 1 + \frac{2}{\beta-1}$. Therefore, $\rho \leq 2 + \beta + \frac{2}{\beta-1}$. This equation is minimized for $\beta = 1 + \sqrt{2}$ which implies that $\rho \leq 3 + 2\sqrt{2}$. Finally, since the ρ bound holds for all the intervals in $\mathcal{A}$ and since the union of all $R(I)$ sets covers all the intervals taken by OPT, we get that the value of OPT is at most ρ times the value

of $\mathcal{A}$. Hence, the approximation factor is $3 + 2\sqrt{2}$. □

Implementation. Observe that step 3 of the algorithm has to be invoked only when there is a "status" change, i.e., either a new job becomes available (n times) or a job in the schedule ends (n times). Each time step 3 is invoked the total number of jobs instances that have to be examined is at most n (at most one for each job). To implement the algorithm we employ a priority queue that holds intervals according to their endpoint. At any point of time it is enough to hold at most one job instance for each job in the priority queue. It turns out that the total number of operations for retrieving the next instance is $O(n \log n)$, totaling to $O(n^2 \log n)$ operations.

4.2.2. Unrelated machines. If the number of unrelated machines is $k > 1$, we call Algorithm ADMISSION k times, machine by machine, in an arbitrary order, where the set of jobs considered in the ith call does not contain the jobs already scheduled on machines $M_1, \ldots, M_{i-1}$. The analysis that shows how the $3 + 2\sqrt{2} \approx 5.828$ bound carries over to the case of unrelated machines is very similar to the analysis presented in the proof of Theorem 4.6. The main difference is in the definition of $R(I)$. For each interval $I \in \mathcal{A}$ that was executed on machine M_i, we define the set $R(I)$ to consist of I in case $I \in \mathcal{O}$, and of all the intervals that (i) were executed on machine M_i in the optimal schedule, and (ii) the rejection or preemption of these jobs was caused by I.

5. The MAX-SNP hardness. We show that the problem of scheduling unweighted jobs on unrelated machines is MAX-SNP hard. This is done by reducing a variant of Max-2SAT, in which each variable occurs at most three times, to this problem. In this variant of Max-2SAT, we are given a collection of clauses, each consisting of two (Boolean) variables, with the additional constraint that each variable occurs at most three times, and the goal is to find an assignment of values to these variables that would maximize the number of clauses that are satisfied (i.e., contain at least one literal that has a "true" value). This problem is known to be MAX-SNP hard (cf. [33]).

Given an instance of the Max-2SAT problem we show how to construct an instance of the problem of unweighted jobs, unrelated machines, such that the value of the Max-2SAT problem is equal to the value of the scheduling problem. Each variable x_i is associated with a machine M_i. Each clause C_j is associated with a job. The release time and deadline of every job is 0 and 3, respectively. A job can be executed only on the two machines corresponding to the variables the clause C_j contains. (The processing time of this job in the rest of the machines is set to be infinite.)

Suppose that clause C_j contains a variable x_i as a positive (negative) literal. The processing time of the job corresponding to C_j on machine M_i is $3/k$, where $k \in \{1, 2, 3\}$ is the number of occurrences of variable x_i as a positive (negative) literal. Note that in case variable x_i occurs in both positive and negative forms, it occurs exactly once in one of the forms, since a variable x_i occurs at most three times overall. It follows that in any feasible schedule, machine M_i cannot execute both a job that corresponds to a positive literal occurrence and a job that corresponds to a negative literal occurrence.

We conclude that if m jobs can be scheduled, then m clauses can be satisfied. In the other direction, it is not hard to verify that if m clauses can be satisfied, then m jobs can be scheduled. Since Max-2SAT with the restriction that each variable occurs at most three times is MAX-SNP hard, the unweighted jobs and unrelated machines case is MAX-SNP hard as well.

6. Discussion and open problems. In this paper we considered the problem of finding a schedule that maximizes the weight of jobs completed before their deadline on either a single machine or multiple machines. We presented constant approximation algorithms for four variants of the problem depending on the type of the machines (identical vs. unrelated) and the weight of the jobs (identical vs. arbitrary). Most of our algorithms are based on LP rounding. We also presented a combinatorial algorithm for arbitrary job weights and unrelated machines.

Many open problems remain. In what follows we discuss some of them.

- The computational difficulty of the problems considered here is due to the "slack time" available for scheduling the jobs. Interestingly, we do not know if the simple case in which the slack equals the length of the job is as hard as the general case, or is as easy as the case with less slack.
- We showed that the problem of scheduling unweighted jobs on unrelated machines is MAX-SNP hard. We do not know whether this holds in the case of identical machines.
- We did not consider the preemptive version of our problems. Lawler [25, 26] presented some results for the preemptive case (see discussion in the introduction), yet open problems remain. In particular, the migration issue is still open. We note that it does not seem that our LP-based rounding algorithms are of use in the preemptive case.
- Several recent papers [29, 6, 9] addressed the following generalization of our problems. A job has a width that could be an integral number (i.e., the job requires more than one machine) or a real fraction (as is the case in bandwidth allocation). Constant factor approximation algorithms for this problem were obtained by [29] by generalizing our LP rounding technique, and by [6, 9] using the local ratio technique (and deriving combinatorial algorithms as well).
- Phillips, Uma, and Wein [29] used our LP-based algorithms to achieve approximation algorithms for other scheduling problems. For example, consider a problem in which an estimate of the completion time of the jobs can be computed by solving a fractional relaxation of the problem. Then, using these estimated completion times as deadlines, our algorithms can be applied so as to get a schedule where a constant fraction of the jobs indeed finish by these completion times. This observation yields new approximation algorithms for various problems, among them the minimum flow-time problem.
- Erlebach and Jansen [13] generalized our LP rounding technique and developed a general procedure for converting a coloring algorithm into an (approximate) maximum weight independent set algorithm. Using this, they obtain improved approximation factors for several problems.

Acknowledgments. We are indebted to Joel Wein for many helpful discussions, and especially for his suggestion to consider the general case of maximizing the throughput of jobs with release times and deadlines. We thank David Shmoys for helpful comments.

LOW REDUNDANCY IN STATIC DICTIONARIES WITH CONSTANT QUERY TIME*

RASMUS PAGH†

Abstract. A *static dictionary* is a data structure storing subsets of a finite universe U, answering membership queries. We show that on a unit cost RAM with word size $\Theta(\log |U|)$, a static dictionary for n-element sets with constant worst case query time can be obtained using $B+O(\log\log|U|)+o(n)$ bits of storage, where $B = \lceil \log_2 \binom{|U|}{n} \rceil$ is the minimum number of bits needed to represent all n-element subsets of U.

1. Introduction.

Consider the problem of storing a subset S of a finite set U, such that membership queries, "$u \in S$?", can be answered in worst case constant time on a unit cost RAM. We are interested only in membership queries, so we assume that $U = \{0, \ldots, m-1\}$. Also, we restrict attention to the case where the RAM has word size $\Theta(\log m)$. In particular, elements of U can be represented within a constant number of machine words, and the usual RAM operations (including multiplication) on numbers of size $m^{O(1)}$ can be done in constant time.

Our goal will be to solve this, the *static dictionary problem*, using little memory, measured in consecutive bits. We express the complexity in terms of $m = |U|$ and $n = |S|$, and often consider the asymptotics when n is a function of m. Since the queries can distinguish any two subsets of U, we need at least $\binom{m}{n}$ different memory configurations, that is, at least $B = \lceil \log \binom{m}{n} \rceil$ bits. (Log is base 2 throughout this paper.) We will focus on the case $n \le m/2$ and leave the symmetry implications to the reader. Using Stirling's approximation to the factorial function, one can derive the following (where $e = 2.718\ldots$ denotes the base of the natural logarithm):

$$B = n\log(e\,m/n) - \Theta(n^2/m) - O(\log n). \tag{1.1}$$

It should be noted that using space very close to B is only possible if elements of S are stored *implicitly*, since explicitly representing all elements requires $n\log m = B + \Omega(n\log n)$ bits.

Previous work. The static dictionary is a very fundamental data structure and has been much studied. We focus on the development in space consumption for schemes with worst case constant query time. A bit vector is the simplest possible solution to the problem, but the space complexity of m bits is poor compared to B unless $n \approx m/2$. By the late 1970s, known dictionaries with a space complexity of $O(n)$ words (i.e., $O(n\log m)$ bits) either had nonconstant query time or worked only for restricted universe sizes [4, 16, 17].

The breakthrough paper of Fredman, Komlós, and Szemerédi [7] described a general constant time hashing scheme, from now on referred to as the FKS dictionary, using $O(n)$ words. A refined solution in the paper uses $B+O(n\log n+\log\log m)$ bits, which is $O(B)$ when $n=m^{1-\Omega(1)}$. Brodnik and Munro [2] constructed the first static dictionary using $O(B)$ bits with no restrictions on m and n. They later improved the bound to $B+O(B/\log\log\log m)$ bits [3].

No nontrivial space lower bound is known in a general model of computation. However, various restrictions on the data structure and the query algorithm have been successfully studied. Yao [17] showed that if words of the data structure must contain elements of S, the number of words necessary for $o(\log n)$ time queries cannot be bounded by a function of n. Fich and Miltersen [6] studied a RAM with standard unit cost arithmetic operations but *without division and bit operations*, and showed that query time $o(\log n)$ requires $\Omega(m/n^\epsilon)$ words of memory for any $\epsilon>0$. Miltersen [11] showed that on a RAM with bit operations but *without multiplication*, one needs m^ϵ words, for some $\epsilon>0$, when $n=m^{o(1)}$.

This paper. In this paper we show that it is possible to achieve space usage very close to the information theoretical minimum of B bits. The additional term of the space complexity, which we will call the *redundancy*, will be $o(n)+O(\log\log m)$ bits. More precisely we show the following.

THEOREM 1.1. *The static dictionary problem with worst case constant query time can be solved using $B+O(n\,(\log\log n)^2/\log n+\log\log m)$ bits of storage.*

Theorem 1.1 improves the redundancy of $\Omega(\min(n\log\log m, m/(\log n)^{o(1)}))$ obtained by Brodnik and Munro [3] by a factor of $\Omega(\min(n, \log\log m\,(\log n)^{1-o(1)}))$. For example, when $n=\Omega(m)$ we obtain space $B+B/(\log B)^{1-o(1)}$ as compared to $B+B/(\log B)^{o(1)}$. For $n=\Theta(\log m)$ our space usage is $B+n/(\log n)^{1-o(1)}$ rather than $B+\Omega(n\log n)$.

We will also show how to associate *satellite data* from a finite domain to each element of S, with nearly the same redundancy as above.

Our main observation is that one can save space by "compressing" the hash table part of data structures based on (perfect) hashing, storing in each cell not an element of S but only a *quotient* — information that distinguishes the element from the part of U that hashes to the cell.[1] This technique, referred to as quotienting, is presented in section 2, where a $B+O(n+\log\log m)$ bit dictionary is exhibited. Section 3 outlines how to improve the dependency on n to that of theorem 1.1. The construction uses a dictionary supporting *rank* and *predecessor* queries, described in section 4. Section 5 gives the details of the construction and an analysis of the redundancy. The sizes of the data structures described are not computed explicitly. Rather, indirect means are employed to determine the number of redundant bits. While direct summation and comparison with (1.1) would be possible, it is believed that the proofs given here contain more information about the "nature" of the redundancy.

Without loss of generality, we will assume that n is greater than some sufficiently large constant. This is to avoid worrying about special cases for small values of n.

2. First solution. This section presents a static dictionary with a space consumption of $B+O(n+\log\log m)$ bits. Consider a *minimal perfect hash function* for S, i.e., $h_{\text{perfect}}: U\to\{0,\ldots,n-1\}$ which is 1-1 on S. Defining an n-cell *hash table* T

[1] The term "quotient" is inspired by the use of modulo functions for hashing, in which case the integer quotient is exactly what we want in the cell.

such that $T[i] = s_i$ for the unique $s_i \in S$ with $h_{\text{perfect}}(s_i) = i$, the following program implements membership queries for S:

function lookup(x)
  return ($T[h_{\text{perfect}}(x)] = x$);
end.

A more compact data structure results from the observation that $T[i]$ does not need to contain s_i itself ($\lceil \log m \rceil$ bits), but only enough information to identify s_i within $U_i = \{u \in U \mid h_{\text{perfect}}(u) = i\}$ ($\lceil \log |U_i| \rceil$ bits). We will be slightly less ambitious, though, and not necessarily go for the minimal number of bits in each hash table cell. In particular, to allow efficient indexing we want the number of bits to be the same for each table cell. Note that $\log(m/n)$ bits is a lower bound on the size of a cell, since the average size of the U_i is m/n.

To compute the information needed in the hash table, we define a *quotient function* (for h_{perfect}) as a function $q : U \to \{0, \ldots, r-1\}$, $r \in \mathbf{N}$, which is 1-1 on each set U_i. Given such a function, let $T'[i] = q(T[i])$, and the following program is equivalent to the above:

function lookup'(x)
  return ($T'[h_{\text{perfect}}(x)] = q(x)$);
end.

Thus it suffices to use the hash table T' of $\lceil \log r \rceil$-bit entries. By the above discussion, we ideally have that r is close to m/n.

Although the FKS dictionary [7] is not precisely of the form "minimal perfect hash function + hash table," it is easy to modify it to be of this type. We will thus speak of the FKS minimal perfect hash function, h_{FKS}. It has a quotient function which is evaluable in constant time, and costs no extra space in that its parameters k, p, and a are part of the data structure already:

$$q : u \mapsto (u \operatorname{div} p)\, \lceil p/a \rceil + (k\, u \bmod p) \operatorname{div} a. \tag{2.1}$$

Intuitively, this function gives the information that is thrown away by the modulo applications of the scheme's top-level hash function:

$$h : u \mapsto (k\, u \bmod p) \bmod a, \tag{2.2}$$

where k and a are positive integers and $p > a$ is prime. We will not give a full proof that q is a quotient function of h_{FKS}, since our final result does not depend on this. However, the main part of the proof is a lemma that will be used later, showing that q is a quotient function for h.

LEMMA 2.1. *For $U_i = \{u \in U \mid h(u) = i\}$ where $i \in \{0, \ldots, a-1\}$, q is* 1-1 *on U_i. Further, $q[U] \subseteq \{0, \ldots, r-1\}$, where $r = \lceil m/p \rceil \lceil p/a \rceil$.*

Proof. Let $u_1, u_2 \in U_i$. If $q(u_1) = q(u_2)$ we have that $u_1 \operatorname{div} p = u_2 \operatorname{div} p$ and $(k\, u_1 \bmod p) \operatorname{div} a = (k\, u_2 \bmod p) \operatorname{div} a$. From the latter equation and $h(u_1) = h(u_2)$, it follows that $k\, u_1 \bmod p = k\, u_2 \bmod p$. Since p is prime and $k \neq 0$ this implies $u_1 \bmod p = u_2 \bmod p$. Since also $u_1 \operatorname{div} p = u_2 \operatorname{div} p$ it must be the case that $u_1 = u_2$, so q is indeed 1-1 on U_i. The bound on the range of q is straightforward. □

In the FKS scheme, $p = \Theta(m)$ and $a = n$, so the range of q has size $O(m/n)$ and $\log(m/n) + O(1)$ bits suffice to store each hash table element. The space needed to store h_{FKS}, as described in [7], is not good enough to show the result claimed at the beginning of this section. However, Schmidt and Siegel [15] have shown how to implement (essentially) h_{FKS} using $O(n + \log\log m)$ bits of storage (which is optimal up to a constant factor; see, e.g., [10, Theorem III.2.3.6]). The time needed to evaluate the hash function remains constant. Their top-level hash function is not of the form (2.2), but the composition of two functions of this kind, h_1 and h_2. Call the corresponding quotient functions q_1 and q_2. A quotient function for $h_2 \circ h_1$ is $u \mapsto (q_1(u), q_2(h_1(u)))$, which has a range of size $O(m/n)$. One can thus get a space usage of $n\log(m/n) + O(n)$ bits for the hash table, and $O(n + \log\log m)$ bits for the hash function, so by (1.1) we have the following proposition.

PROPOSITION 2.2. *The static dictionary problem with worst case constant query time can be solved using $B + O(n + \log\log m)$ bits of storage.*

As a by-product we get the following corollary.

COROLLARY 2.3. *When $n > c \log\log m/\log\log\log m$, for a suitable constant $c > 0$, the static dictionary problem with worst case constant query time can be solved using n words of $\lceil \log m \rceil$ bits.*

Proof. The dictionary of Proposition 2.2 uses $n\log m - n\log n + O(n + \log\log m)$ bits. For suitable constants c and N, the $O(n + \log\log m)$ term is less than $n\log n$ when $n > N$. If $n \le N$ we can simply list the elements of S. □

The previously best result of this kind needed $n \ge (\log m)^c$ for some constant $c > 0$ [5]. (An interesting feature of this nonconstructive scheme is that it is *implicit*, i.e., the n words contain a permutation of the elements in S.) The question whether n words suffice in all cases was posed in [6].

3. Overview of final construction. This section describes the ideas which allow us to improve the $O(n)$ term of Proposition 2.2 to $o(n)$. There are two redundancy bottlenecks in the construction of the previous section:

- The Schmidt–Siegel hash function is $\Omega(n)$ bit redundant.
- The hash table is $\Omega(n)$ bit redundant.

The first bottleneck seems inherent to the Schmidt–Siegel scheme: it appears there is no easy way of improving the space usage to $1 + o(1)$ times the minimum, at least if constant evaluation time is to be preserved. The second bottleneck is due to the fact that m/n may not be close to a power of two, and hence the space consumption of $n\lceil \log r \rceil$ bits, where $r \ge m/n$, may be $\Omega(n)$ bits larger than the ideal of $n\log(m/n)$ bits. Our way around these bottlenecks starts with the following observations:

- We need only to solve the dictionary problem for some "large" subset $S_1 \subseteq S$.
- We can look at some universe $U_1 \subseteq U$, where $S_1 \subseteq U_1$ and $|U_1|/|S_1|$ is "close to" a power of 2.

The first observation helps by allowing "less than perfect" hash functions which occupy much less memory. The remaining elements, $S_2 = S \backslash S_1$, can be put in a more redundant dictionary, namely the refined FKS dictionary [7]. The second observation gives a way of minimizing redundancy in the hash table.

We will use a hash function of the form (2.2). The following result from [7] shows that (unless a is not much larger than n) it is possible to choose k such that h is 1-1 on a "large" set S_1.

LEMMA 3.1. *If $u \mapsto u \bmod p$ is 1-1 on S, then for at least half the values of $k \in \{1, \ldots, p-1\}$, there exists a set $S_1 \subseteq S$ of size $|S_1| \ge (1 - O(n/a))\,|S|$, on which h is 1-1.*

Without loss of generality we will assume that $|S_1| = n_1$, where n_1 only depends on n and a, and $n_2 = n - n_1 = O(n/a)$. The hash function h is not immediately useful, since it has a range of size $a \gg n_1$. To obtain a minimal perfect hash function for S_1, we compose with a function $g : \{0, \ldots, a-1\} \to \{0, \ldots, n_1 - 1\} \cup \{\perp\}$ which has $g[h[S_1]] = \{0, \ldots, n_1 - 1\}$. (In particular, it is 1-1 on $h[S_1]$.) The extra value of g allows us to look at $U_1 = \{u \in U \mid g(h(u)) \neq \perp\}$, which clearly contains S_1. We require that $g(v) = \perp$ when $v \notin h[S_1]$, since this makes q a quotient function for $g \circ h$ (restricted to inputs in U_1).

The implementation of the function g has the form of a dictionary for $h[S_1]$ within $\{0, \ldots, a-1\}$, which apart from membership queries answers *rank queries*. (The result of a rank query on input v is $|\{w \in h[S_1] \mid w < v\}|$.) So we may take g as the function that returns $\perp$ if its input v is not in the set, and otherwise returns the rank of v. The details on how to implement the required dictionary are given in section 4.

The dictionary of section 4 will also be our dictionary of choice when $m \leq n \log^3 n$ (the "dense" case). Only when $m > n \log^3 n$ do we use the scheme described in this section. This allows us to choose suitable values of hash function parameters p and a (where $p = O(n^2 \log m)$ and $a = \Theta(n (\log n)^2) \leq m$), such that the range of the quotient function, $r = \lceil m/p \rceil \lceil p/a \rceil$, is close to m/a. The details of this, along with an analysis of the redundancy of the resulting dictionary, can be found in section 5.

4. Dictionaries for dense subsets. In this section we describe a dictionary which has the redundancy stated in Theorem 1.1 when $m = n (\log n)^{O(1)}$. Apart from membership queries, it will support queries on the ranks of elements (the rank of u is $|\{v \in S | v < u\}|$), as well as queries on predecessors (the predecessor of u is $\max\{v \in S \mid v < u\}$).

As a first step, we describe a dictionary which has redundancy dependent on m, namely $O(m \log\log m / \log m)$ bits. The final dictionary uses the first one as a substructure.

4.1. Block compression. The initial idea is to split the universe into blocks $U_i = \{b\,i, \ldots, b\,(i+1) - 1\}$ of size $b = \lceil \frac{1}{2} \log m \rceil$, and store each block in a compressed form. (This is similar to the ideas of range reduction and "a table of small ranges" used in [3].) To simplify things we may assume that b divides m (otherwise consider a universe at most $b - 1$ elements larger, increasing the space usage by $O(b)$ bits). If a block contains j elements from S, the compressed representation is the number j ($\lfloor \log\log m \rfloor$ bits) followed by a number in $\{1, \ldots, \binom{b}{j}\}$ corresponding to the particular subset with i elements ($\lceil \log \binom{b}{j} \rceil$ bits). Extraction of information from a compressed block is easy, since any function of the block representations can be computed by table lookup. (The crucial thing being that, since representations have size at most $\frac{1}{2} \log m + \log\log m$ bits, the number of entries in such a table makes its space consumption negligible compared to $O(m \log\log m / \log m)$ bits.)[2]

Let $n_i = |S \cap U_i|$ and $B_i = \lceil \log \binom{b}{n_i} \rceil$. The overall space consumption of the above encoding is $\sum_i B_i + O(m \log\log m / \log m)$. Let s denote the number of blocks, $s = O(m / \log m)$. A lemma from [2] bounds the above sum by $B + s$.

LEMMA 4.1 (Brodnik–Munro). *Let $m_0, \ldots, m_{s-1}$ and $n_0, \ldots, n_{s-1}$ be nonnegative integers. The following inequality holds:*

$$\sum_{i=0}^{s-1} \lceil \log \tbinom{m_i}{n_i} \rceil < \log \binom{\sum_{i=0}^{s-1} m_i}{\sum_{i=0}^{s-1} n_i} + s.$$

[2] Alternatively, assume that the RAM has instructions to extract the desired information.

Proof. We have $\sum_{i=0}^{s-1}\lceil\log\binom{m_i}{n_i}\rceil < \sum_{i=0}^{s-1}\log\binom{m_i}{n_i} + s \le \log\binom{\sum_{i=0}^{s-1} m_i}{\sum_{i=0}^{s-1} n_i} + s$. The latter inequality follows from the fact that there are at least $\prod_{i=0}^{s-1}\binom{m_i}{n_i}$ ways of picking $\sum_{i=0}^{s-1} n_i$ elements out of $\sum_{i=0}^{s-1} m_i$ elements (namely, by picking n_1 among the m_1 first, n_2 among the m_2 next, etc.). □

We need an efficient mechanism for extracting rank and predecessor information from the compressed representation. In particular we need a way of finding the start of the compressed representation of the ith block. The following result, generalizing a construction in [16], is used.

PROPOSITION 4.2 (Tarjan–Yao). *A sequence of integers $z_1, \ldots, z_k$, where for all $1 < i \le k$ we have $|z_i| = n^{O(1)}$ and $\max(|z_i|, |z_i - z_{i-1}|) = (\log n)^{O(1)}$, can be stored in a data structure allowing constant time random access, using $O(k \log\log n)$ bits of memory.*

Proof. Every $\lceil\log n\rceil$th integer is stored "verbatim," using a total of $O(k)$ bits. All other integers are stored as either an offset relative to the previous of these values, or as an absolute value. (One of these has size $(\log n)^{O(1)}$.) This uses $O(k \log\log n)$ bits in total. □

Placing the compressed blocks consecutively in numerical order, the sequence of pointers to the compressed blocks can be stored by this method. Also, the rank of the first element in each block can be stored like this. Finally, we may store the distance to the predecessor of the first element in each block (from which the predecessor is simple to compute). All of these data structures use $O(m \log\log m/\log m)$ bits. Ranks and predecessors of elements within a block can be found by table lookup, as sketched above. So we have the following proposition.

PROPOSITION 4.3. *A static dictionary with worst case constant query time, supporting rank and predecessor queries, can be stored in $B + O(m \log\log m/\log m)$ bits.*

4.2. Interval compression. The dictionary of section 4.1 has the drawback that the number of compressed blocks, and hence the redundancy, grows almost linearly with m. For $m \le n(\log n)^c$, where c is any integer constant, the number of "compressed units" can be reduced to $O(n \log\log n/\log n)$ by instead compressing *intervals* of varying length. We make sure that the compressed representations have length $(1 - \Omega(1))\log n$ (so that information can be extracted by lookup in a table of negligible size) by using intervals of size $O((\log n)^{c+1})$ with at most $\log n/(2c \log\log n)$ elements. We must be able to retrieve the interval number and position within the interval for any element of U in constant time. The block compression scheme of section 4.1 is then trivially modified to work with intervals, and the space for auxiliary data structures becomes $O(n(\log\log n)^2/\log n)$ bits.

We now proceed to describe the way in which intervals are formed and represented. Let $d = \lfloor\sqrt{\log n}\rfloor$, and suppose without loss of generality that d^{2c} divides m. (Considering a universe at most d^{2c} elements larger costs $O(d^{2c})$ bits, which is negligible.) Our first step is to partition U into "small blocks" U_i, satisfying $|S \cap U_i| \le \log n/(2c \log\log n)$. These will later be clustered to form the intervals. The main tool is the dictionary of Proposition 4.3, which is used to locate areas with a high concentration of elements from S. More specifically, split U into at most n blocks of size d^{2c} and store the indices of blocks that are *not* small, i.e., contain more than $\log n/(2c \log\log n)$ elements from S. Since at most $2cn \log\log n/\log n$ blocks are not small, the memory for this data structure is $O(n(\log\log n)^2/\log n)$ bits. The part of the universe contained in nonsmall blocks has size at most $2cm \log\log n/\log n \le n\, d^{2c-1}$. A rank query can be used to map the elements of nonsmall blocks injectively

and in an order preserving way to a subuniverse of this size. The splitting is repeated recursively on this subuniverse, now with at most n blocks of size d^{2c-1}. Again, the auxiliary data structure uses $O(n\,(\log\log n)^2/\log n)$ bits. At the bottom of the recursion we arrive at a universe of size at most nd, and every block of size d is small. This defines our partition of U into $O(n)$ small blocks, which we number $0, 1, 2, \ldots$ in order of increasing elements. Note that the small block number of any element in U can be computed by a rank query and a predecessor query at each level.

As every small block has size at most $(\log n)^c$, intervals can be formed by up to $\log n$ consecutive small blocks, together containing at most $\log n/(2c\log\log n)$ elements of S. The "greedy" way of choosing such compressible intervals from left to right results in $O(n\log\log n/\log n)$ intervals, as no two adjacent intervals can both contain less than $\log n/(4c\log\log n)$ elements and be shorter than $(\log n)^{c+1}$. To map the $O(n)$ block numbers to interval numbers, we use the dictionary of Proposition 4.3 to store the number of the first small block in each interval, using $O(n\,(\log\log n)^2/\log n)$ bits. A rank query on a small block number then determines the interval number. Finally, the first element of each interval is stored using Proposition 4.2, allowing positions within intervals to be computed, once again using $O(n\,(\log\log n)^2/\log n)$ bits.

THEOREM 4.4. *For $m = n\,(\log n)^{O(1)}$, a static dictionary with worst case constant query time, supporting rank and predecessor queries, can be stored in $B + O(n\,(\log\log n)^2/\log n)$ bits.*

5. Dictionary for sparse subsets. In this section we fill out the remaining details of the construction described in section 3, and provide an analysis of the redundancy obtained. By section 4 we need only consider the case $m > n\,(\log n)^c$ for some constant c. (It will turn out that $c = 3$ suffices.)

5.1. Choice of parameters. We need to specify how hash function parameters a and p are chosen. (A choice of k then follows by Lemma 3.1.) Parameter a will depend on p, but is bounded from above by $A(n)$ and from below by $A(n)/3$, where A is a function we specify later. For now, let us just say that $A(n) = n\,(\log n)^{\Theta(1)}$. (Our construction requires $A(n) = n\,(\log n)^{O(1)}$, and we want $A(n)$ large in order to make $S\backslash S_1$ small.) Parameter p will have size $O(n^2\log m)$, so it can be stored using $O(\log n + \log\log m)$ bits. It is chosen such that $u \mapsto u \bmod p$ is 1-1 on S, and such that $r = \lceil m/p\rceil\,\lceil p/a\rceil$ is not much larger than m/a.

LEMMA 5.1. *For m larger than some constant, there exists a prime p in each of the following ranges, such that $u \mapsto u \bmod p$ is 1-1 on S:*

1. $n^2\ln m \le p \le 3\,n^2\ln m$.
2. $m \le p \le m + m^{2/3}$.

Proof. The existence of a suitable prime between $n^2\ln m$ and $3\,n^2\ln m$ is guaranteed by the prime number theorem (in fact, at least half of the primes in the interval will work). See [7, Lemma 2] for details. By [9] the number of primes between m and $m + m^\theta$ is $\Omega(m^\theta/\log m)$ for any $\theta > 11/20$. Take $\theta = 2/3$ and let p be such a prime; naturally the map is then 1-1. □

A prime in the first range will be our choice for p when $m > A(n)\,n^2\ln m$; otherwise we choose a prime in the second range. In the first case, $r < (m/p+1)(p/a+1) = (1 + a/p + p/m + a/m)\,m/a$. In the second case, $r = \lceil p/a\rceil < (m + m^{2/3})/a + 1 \le (1 + a/m + m^{-1/3})\,m/a$. Since we can assume $m > a\log n$, we have in both cases that $r = (1 + O(1/\log n))\,m/a$. We make r close to a power of 2 by suitable choice of parameter a.

LEMMA 5.2. *For any $x, y \in \mathbf{R}_+$ and $z \in \mathbf{N}$, with $x/z \geq 3$, there exists $z' \in \{z+1, \ldots, 3z\}$, such that $\lceil \log \lceil x/z' \rceil + y \rceil \leq \log(x/z') + y + O(z/x + 1/z)$.*

Proof. Since $x/z \geq 3$, it follows that $\log\lceil x/z \rceil + y$ and $\log\lceil x/3z \rceil + y$ have different integer parts. So there exists z', $z < z' \leq 3z$, such that $\lceil \log \lceil x/z' \rceil + y \rceil \leq \log\lceil x/(z'-1) \rceil + y$. A simple calculation gives $\log\lceil x/(z'-1) \rceil + y = \log(x/(z'-1)) + y + O(z/x) = \log(x/z') + \log(z'/(z'-1)) + y + O(z/x) = \log(x/z') + y + O(z/x + 1/z)$, and the conclusion follows. □

Since $\log r = \log\lceil p/a \rceil + \log\lceil m/p \rceil$ and $p/A(n) \geq 3$ (for n large enough), the lemma gives an a satisfying $A(n)/3 \leq a \leq A(n)$, such that $\lceil \log r \rceil = \log r + O(a/p + 1/a) = \log((1 + O(1/\log n))\, m/a)$.

To conclude, we can choose p and a such that the number of bit patterns in each hash table cell, $2^{\lceil \log r \rceil}$, is $(1 + O(1/\log n))\, m/a$.

5.2. Storing parameters. A slightly technical point remains, concerning the storage of parameters in the data structure. If the universe size m is supposed to be implicitly known, there is no problem storing the parameters using $O(\log n + \log\log m)$ bits (say, using $O(\log\log m)$ bits to specify the number of bits for each parameter). However, if m is considered a parameter unknown to the query algorithm, it is not clear how to deal with, e.g., queries for numbers larger than m, without actually using $O(\log m)$ extra bits to store m. Our solution is to look at a slightly larger universe U', whose size is specified using $O(\log n + \log\log m)$ bits. Using $O(\log n + \log\log m)$ bits we may store $\lceil \log m \rceil$ (by assumption we know the number of bits needed to store this number within an additive constant) and the $\lceil \log n \rceil$ most significant bits of m. This defines $m' = (1 + O(1/n))\, m$, the universe size of U'. We need to estimate the information theoretical minimum of the new problem, $B' = \lceil \binom{m'}{n} \rceil$.

LEMMA 5.3. *For $n < m_1 < m_2$ we have $\log \binom{m_2}{n} - \log \binom{m_1}{n} < n \log(\frac{m_2 - n}{m_1 - n})$.*

Proof. We have $\binom{m_2}{n} / \binom{m_1}{n} = \frac{m_2\,(m_2-1)\ldots(m_2-n+1)}{m_1\,(m_1-1)\ldots(m_1-n+1)} < (\frac{m_2-n}{m_1-n})^n$. □

Thus, since $n \leq m/2$, $B' = B + O(n \log(m'/m)) = B + O(n/\log n)$. So our slight expansion of the universe is done without affecting the redundancy of Theorem 1.1.

5.3. Redundancy analysis. First note that we can assume all parts of the data structure to have size depending only on m and n (that is, not on the particular set stored). Hence, the entire data structure is a bit pattern of size $B + f(n, m)$, for some function f. To show the bound $f(n, m) = O(n\,(\log\log n)^2/\log n + \log\log m)$, we construct a function ϕ, mapping n-element subsets of U to subsets of $\{0,1\}^{B+f(n,m)}$, such that

- $\log|\phi(S)| = O(n\,(\log\log n)^2/\log n + \log\log m)$.
- $\bigcup_S \phi(S) = \{0,1\}^{B+f(n,m)}$.

This implies $B + f(n, m) \leq \log(\sum_S |\phi(S)|) = B + O(n\,(\log\log n)^2/\log n + \log\log m)$, as desired. Recall that the data structure consists of

- hash function parameters and pointers ($b_1 = O(\log n + \log\log m)$ bits);
- a dictionary supporting rank, representing the function g via a set of n_1 elements in $\{0, \ldots, a-1\}$ ($b_2 = \log \binom{a}{n_1} + O(n\,(\log\log n)^2/\log n)$ bits);
- a hash table ($b_3 = n_1 \lceil \log r \rceil$ bits);
- a dictionary representing a set of size n_2 in U ($b_4 = \log \binom{m}{n_2} + O(n_2 \log n_2 + \log\log m)$ bits).

Since the dictionary supporting rank has redundancy $O(n\,(\log\log n)^2/\log n)$, there exists a function ϕ' from the n_1-element subsets of $\{0, \ldots, a-1\}$ to $\{0,1\}^{b_2}$, such that $\cup_{\tilde{S}_1} \phi'(\tilde{S}_1) = \{0,1\}^{b_2}$ and $\log|\phi'(\tilde{S}_1)| = O(n\,(\log\log n)^2/\log n)$. Similarly, there exists a function ϕ'' from the n_2-element subsets of U to $\{0,1\}^{b_4}$, such that $\cup_{\tilde{S}_2} \phi''(\tilde{S}_2) =$

$\{0,1\}^{b_4}$ and $\log|\phi''(\tilde{S}_2)| = O(n_2 \log n_2 + \log\log m)$. Choosing $A(n) = n \log^2 n$ we have $n_2 = O(n/\log^2 n)$, and hence $\log|\phi''(\tilde{S}_2)| = O(n/\log n + \log\log m)$.

Let h_1 denote the hash function $u \mapsto (u \bmod p) \bmod a$. (Any hash function of the form (2.2) would do; we pick this one for simplicity.) By Lemma 5.3 we can assume that p divides m, since either $m \le p \le m+m^{2/3}$, in which case expanding the universe to $\{0,\ldots,p-1\}$ increases the information theoretical minimum by $O(n/m^{1/3})$, or $p = O(m/n)$, in which case the increase by rounding m to the nearest higher multiple of p is $O(1)$.

When p divides m, the number of elements hashed to a cell by h_1 is at least $\lfloor m/a \rfloor$. Hence for any function g, there is a set $T(g)$ of at least $(m/a-1)^{n_1}$ possible bit patterns in the hash table. The total number of bit patterns is $2^{\lceil \log r \rceil\, n_1} = ((1+O(1/\log n))\, m/a)^{n_1}$, so the ratio between this and the $|T(g)|$ patterns used is

$$\left(\tfrac{1+O(1/\log n)}{1-a/m}\right)^{n_1} = (1+O(1/\log n))^{n_1} = 2^{O(n/\log n)}.$$

Thus, there exists a function ϕ_g from $T(g)$ onto $\{0,1\}^{b_3}$, such that $\log|\phi_g(z)| = O(n/\log n)$. For notational convenience we will from now on denote bit patterns in the hash table simply by the corresponding set of universe elements.

We will take $\phi(S)$ as the union of sets $\phi(\tilde{S}_1, \tilde{S}_2)$, over all $\tilde{S}_1, \tilde{S}_2 \subseteq S$ with $|\tilde{S}_1| = n_1$ and $|\tilde{S}_2| = n_2$. If $|h_1[\tilde{S}_1]| \ne n_1$, we set $\phi(\tilde{S}_1, \tilde{S}_2) = \emptyset$. Otherwise $h_1[\tilde{S}_1]$ defines the function g, and we set

$$\phi(\tilde{S}_1, \tilde{S}_2) = \{s_1\, s_2\, s_3\, s_4 \mid s_1 \in \{0,1\}^{b_1},\ s_2 \in \phi'(h_1[\tilde{S}_1]),\ s_3 \in \phi_g(\tilde{S}_1),\ s_4 \in \phi''(\tilde{S}_2)\}\ .$$

By our bounds on the sizes of $\phi'(h_1[\tilde{S}_1])$, $\phi_{h_1,g}(\tilde{S}_1)$, and $\phi''(\tilde{S}_2)$, we conclude that $\log|\phi(\tilde{S}_1, \tilde{S}_2)| = O(n\,(\log\log n)^2/\log n + \log\log m)$. Since $\phi(S)$ is the union of the $2^{O(n/\log n)}$ sets of the form $\phi(\tilde{S}_1, \tilde{S}_2)$, it follows that the requirement on $|\phi(S)|$ holds.

To see that $\bigcup_S \phi(S) = \{0,1\}^{B+f(n,m)}$, take any $x \in \{0,1\}^{B+f(n,m)}$. Let $x = s_1\, s_2\, s_3\, s_4$, where $s_i \in \{0,1\}^{b_i}$. By definition of ϕ' and ϕ'', there is some set $T \subseteq \{0,\ldots,a-1\}$, $|T| = n_1$, such that $s_2 \in \phi'(T)$, and a set $\tilde{S}_2 \subseteq U$, $|\tilde{S}_2| = n_2$, such that $s_4 \in \phi''(S_2)$. The set T corresponds to a function g. From the way we defined ϕ_g, there exists a bit pattern $z \in T(g)$, such that $s_3 \in \phi_g(z)$. Let $\tilde{S}_1$ be the set of size n_1 corresponding to h_1, g, and z. We then have that $x \in \phi(\tilde{S}_1, \tilde{S}_2)$, so if we take $S \supseteq \tilde{S}_1 \cup \tilde{S}_2$, we get $x \in \phi(S)$ as desired.

6. Satellite information. We now discuss how to associate information with dictionary elements. More specifically, we consider the setting where each element of S has an associated piece of satellite information from some set $V = \{0,\ldots,s-1\}$, where $s = m^{O(1)}$. The information theoretical minimum for this problem is $B_s = \lceil \log \binom{m}{n} + n \log s \rceil$.

The quotienting technique generalizes to this setting. We simply extend the quotient function to take an extra parameter from V as follows: $q'(u,v) = q(u) + r\,v$. Note that from $q'(u,v)$ it is easy to compute $q(u)$ and v and that the range of q' has size $r\,s$. With this new quotient function, the remaining parts of the construction for $m > n\,(\log n)^3$ are unchanged.

In the dense range, the rank dictionary can be used to index into a table of V-values, but in general $\Omega(n)$ bits will be wasted in the table since $|V|$ need not be a power of 2. Thus we have the following theorem.

THEOREM 6.1. *The static dictionary problem with satellite data and worst case constant query time can be solved with storage:*

- $B_s + O(n\,(\log\log n)^2/\log n + \log\log m)$ *bits, for* $m > n\,(\log n)^3$.
- $B_s + O(n)$ *bits, otherwise.*

Using the data structure for the sparse case, it is in fact possible to achieve redundancy $o(n)$ when $n = o(m)$. The dictionary of Proposition 2.2 is then used to store S_2, and parameter a is chosen around $\sqrt{nm}$.

7. Construction. We now sketch how to construct the static dictionaries in expected time $O(n + (\log\log m)^{O(1)})$. The dictionaries of section 4 can in fact be constructed in time $O(n)$ when $m = n^{O(1)}$. The construction algorithm is quite straightforward, so we do not describe it here. As for the dictionary described in sections 3 and 5, the hardest part is finding appropriate parameters for the hash function. Once this is done, the dictionary for $h[S_1]$, the hash table, and the dictionary for S_2 can all be constructed in expected time $O(n)$ (see [7] for the latter construction algorithm).

The prime p is found by randomly choosing numbers from the appropriate interval of Lemma 5.1. Each number chosen is checked for primality (using a probabilistic check which uses expected time polylogarithmic in the number checked [1], that is, time $(\log n + \log\log m)^{O(1)}$). When a prime is found, it is checked whether $u \mapsto u \bmod p$ is 1-1 on S (the element distinctness problem on the residues, taking expected $O(n)$ time using universal hashing). The process is repeated until this is the case. Inspecting the proof of Lemma 5.1 it can be seen that the expected number of iterations is $O(1)$, so the expected total time is $O(n + (\log\log m)^{O(1)})$.

Parameter a is simple to compute according to Lemma 5.2, for example by binary search on the interval in which it is wanted.

Parameter k is tentatively chosen at random and checked in time $O(n)$ for the inequality of Lemma 3.1, with some constant c in the big-oh. For sufficiently large c, the expected number of attempts made before finding a suitable k is constant, and thus the expected time for the choice is $O(n)$.

THEOREM 7.1. *The data structure of Theorem* 1.1 *can be constructed in expected time* $O(n + (\log\log m)^{O(1)})$.

8. Conclusion and final remarks. We have seen that for the static dictionary problem it is possible to come very close to using storage at the information theoretic minimum, while retaining constant query time. From a data compression point of view this means that a sequence of bits can be coded in a number of bits close to the first-order entropy, in a way that allows efficient random access to the original bits.

The important ingredient in the solution is the concept of quotienting. Quotienting was recently applied in a space efficient dictionary supporting rank [14]. In general, quotienting can be used to save around $n \log n$ bits in hash tables. Thus, the existence of an efficiently evaluable quotient function is a desirable property for a hash function. For the quotient function to have a small range, it is necessary that the hash function used hashes U quite evenly to the entire range.

Quotienting works equally well in a dynamic setting, where it can be used directly to obtain an $O(B)$ bit scheme, equaling the result of Brodnik and Munro [2]. However, lower bounds on the time for maintaining ranks under insertions and deletions (see [8]) show that our construction involving the dictionary supporting rank will not dynamize well.

It would be interesting to determine the exact redundancy necessary to allow constant time queries. In particular, it is remarkable that no lower bound is known in the *cell probe* model (where only the number of memory cells accessed is considered). As for upper bounds, a less redundant implementation of the function g would

immediately improve the asymptotic redundancy of our scheme. There seems to be no hope of getting rid of the $O(\log \log m)$ term using our basic approach, since any hash function family ensuring that some function is 1-1 on a "large" subset of S has size $\Omega(\log m)$ [13].

Acknowledgments. The author would like to thank Peter Bro Miltersen for encouragement and advice. Thanks also to Jakob Pagter and Theis Rauhe for feedback on a previous version of this paper [12] and to Kunihiko Sadakane for pointing out an error in a draft of this paper.

MAINTAINING MINIMUM SPANNING FORESTS IN DYNAMIC GRAPHS*

MONIKA R. HENZINGER† AND VALERIE KING‡

Abstract. We present the first fully dynamic algorithm for maintaining a minimum spanning forest in time $o(\sqrt{n})$ per operation. To be precise, the algorithm uses $O(n^{1/3}\log n)$ amortized time per update operation. The algorithm is fairly simple and deterministic. An immediate consequence is the first fully dynamic deterministic algorithm for maintaining connectivity and bipartiteness in amortized time $O(n^{1/3}\log n)$ per update, with $O(1)$ worst case time per query.

1. Introduction.

We consider the problem of maintaining a minimum spanning forest during an arbitrary sequence of edge insertions and deletions. Given an n-vertex graph G with edge weights, the *fully dynamic minimum spanning forest problem* is to maintain a minimum spanning forest F under an arbitrary sequence of the following update operations:

insert(u,v). Add the edge $\{u,v\}$ to G. Add $\{u,v\}$ to F if it connects two previously unconnected trees of F or if it reduces the cost of F. If the latter, return the edge of F that has been replaced.

delete(u,v). Remove the edge $\{u,v\}$ from G. If $\{u,v\} \in F$, then (a) remove $\{u,v\}$ from F and (b) return the minimum-cost edge e of $G \setminus F$ that reconnects F if e exists or return *null* if e does not exist.

In addition, the data structure permits the following type of query:

connected(u,v). Determine if vertices u and v are connected.

In 1985 [7], Fredrickson introduced a data structure known as *topology trees* for the fully dynamic minimum spanning forest problem with a worst-case cost of $O(\sqrt{m})$ per update His data structure permitted connectivity queries to be answered in $O(1)$ time. In 1992, Eppstein, Galil, and Italiano [3] and Eppstein et al. [4] improved the update time to $O(\sqrt{n})$ using the *sparsification technique*. If only edge insertions are allowed, the Sleator–Tarjan dynamic tree data structure [13] can be used to maintain the minimum spanning forest in time $O(\log n)$ per insertion or query. If only edge deletions are allowed ("deletions-only"), then no algorithm faster than the $\Omega(\sqrt{n})$ fully dynamic algorithm is known.

Using randomization, it was recently shown that the fully dynamic connectivity problem, i.e., the restricted problem where all edge costs are the same, can be solved in amortized time $O(\log^2 n)$ per update and $O(\log n)$ per connectivity query [9, 10]. However, this approach could not be extended to arbitrary edge weights, leaving the question open as to whether the fully dynamic minimum spanning forest problem can be solved in time $o(\sqrt{n})$.

In this paper we give a positive answer to this question: We present a fully dynamic minimum spanning forest data structure that uses $O(n^{1/3}\log n)$ amortized time per update and $O(1)$ worst case time per query when update time is averaged over any sequence of $\Omega(m_{in})$ updates for m_{in} the initial size of the graph. Our technique is very different from [7].

The result is achieved in two steps: First, we give a deletions-only minimum spanning forest algorithm that uses $O(m'^{1/3}\log n + n^{\epsilon})$ amortized time per update and $O(1)$ worst case time per query when the update time is averaged over any sequence of $\Omega(m_{in})$ updates. Here ϵ is any constant such that $0 < \epsilon < 1/3$, and m' is the number of *nontree* edges at the time of the update.

Then we present a general technique which, given a deletions-only minimum spanning forest data structure with a certain property, generates a fully dynamic data structure with the same running time as the deletions-only data structure. Let $f(m', n)$ be the amortized time per deletion in the deletions-only data structure with m' nontree edges and n vertices. The property required is that, upon inserting into the graph no more than m' edges at the same time (a "batch insertion"), the deletions-only data structure can be modified to reflect these insertions and up to m' subsequent deletions can be performed in a total of $O(m'f(m', n))$ time.

Using this technique, we develop a fully dynamic minimum spanning forest algorithm with *amortized* time per update of $O(m^{1/3}\log n)$ for a sequence of updates of length $\Omega(m_{in})$, where m is the size of G at the time of the update. In other words, letting $m_{(i)}$ denote the size of G (vertices and edges) after update i, the total amount of work for processing a sequence of updates of length l is $O(\sum_{i=0}^{l} {m_{(i)}}^{1/3}\log n)$. We then apply sparsification [3, 4] to reduce the running time for the sequence to $O(ln^{1/3}\log n)$.

Our result immediately gives faster *deterministic* fully dynamic algorithms for the following problems: connectivity, bipartiteness, k-edge witness, maximal spanning forest decomposition, and Euclidean minimum spanning tree. See [9] for all but the last reduction; see Eppstein [2] for the last reduction. For these problems, the new algorithm achieves an $O(n^{1/6}/\log n)$ factor improvement over the previously best *deterministic* running time. If randomization is allowed, however, much faster times are achievable [9, 10].

Additionally, improvements can be achieved in the following static problems (see [4, 3]): randomly sampling spanning forests of a given graph [6] and finding a color-constrained minimum spanning tree [8].

The paper is structured as follows: In section 2 we give a deletions-only minimum spanning forest algorithm. In section 3, we show how to use a sequence of deletions-only data structures to create a fully dynamic data structure.

2. Maintaining a minimum spanning forest—Deletions-only. In this section, we give an algorithm which maintains a minimum spanning forest while edges are being deleted. The amortized update time is $O(m^{1/3}\log n)$ and the query time is $O(1)$ for queries of the form "Are vertices i and j connected?". Let $G = (V, E)$ be an undirected graph with edge weights. Without loss of generality, we assume that edge weights are distinct.

Initially, we compute the minimum spanning forest F of G. Let m'_{in} be the number of nontree edges in G initially and $k = {m'}_{in}^{1/3}\log n$. We sort the nontree edges by weight and partition them into ${m'}_{in}/k$ levels of size k so that the k lightest are in level 0, the next k lightest are in level 1 and so on. The set of edges in a level i is denoted by E_i. In addition, all tree edges of the initial minimum spanning forest F

are placed in level 0. (We omit floors and ceilings to simplify notation; either can be used without affecting the asympotic analysis.)

Throughout the algorithm, the level of an edge remains unchanged, and F denotes the minimum spanning forest. For $i = 0, 1, \ldots, (m'_{in}/k) - 1$, let F_i denote the minimum spanning forest of the graph with vertex set V and edgeset $\cup_{j \le i} E_j$. (Initially, all $F_i = F$, but in later stages, an edge from any level may become a tree edge. Thus, $F_0 \subseteq F_1 \subseteq \ldots \subseteq F_{(m'_0/k)-1} = F$.) Let $T_i(x)$ denote the tree in F_i which contains x and let $T(x)$ without the subscript denote the tree in F containing x.

The main idea is the following. If a nontree edge is deleted, then the minimum spanning forest F is unchanged. Suppose a tree edge $\{u, v\}$ in level i is deleted. Then for each F_j, $j \ge i$, the deletion splits the tree in F_j containing u and v into $T_j(u)$ and $T_j(v)$. We search for the minimum weight nontree edge e (called the "replacement edge") that connects $T(u)$ and $T(v)$ by gathering and then testing a set S of candidate edges on level i. If none is found, we repeat the procedure on level $i + 1$, etc., until one is found or all levels are exhausted.

We now describe the update operations.

delete(u, v). Delete edge $\{u, v\}$ from any data structures in which it occurs. If a tree edge $\{u, v\}$ from level i is deleted, then remove $\{u, v\}$ from F and search for a replacement by calling **Replace**(i, u, v). We refer to i as the level of the call to **Replace**.

In the algorithm below, the subroutine **Search** when applied to a tree in F_i finds all nontree edges in level i which are incident to the tree. A phase consists of the examination of a single edge. (Its exact definition and the details of **Search** are given in section 2.2 below.)

Replace(i, u, v).

1. Alternating in lockstep, one phase at a time, **Search**$(T_i(u))$ and **Search**$(T_i(v))$ until $k/\log n$ phases are executed (Case A) or one of the searches has stopped (Case B).
   - Case A: Let S be the set of all nontree edges in level i.
   - Case B: Let S be the set of (nontree) edges produced by the **Search** that stopped.
2. Test every edge in S to see if it connects $T(u)$ and $T(v)$.
   - If a connecting edge is found, insert the minimum weight connecting edge into F and the data structures representing the F_j, $j \ge i$.
   - Else if i is not the last level, call **Replace**$(i + 1, u, v)$.

2.1. Data structures. The idea here is to use the ET-tree data structure developed in [9]: (1) to represent and update each tree in F, so that in constant time, we can quickly test if a given edge joins two trees; and (2) to represent each tree in an F_i in such a way that we can quickly retrieve nontree edges in E_i which are incident to the tree. To avoid excessive cost, we explicitly maintain only those F_i where i is a multiple of $m'^{1/3}_{in}/\log n$. An undesirable consequence of this is that when retrieving nontree edges in E_i, other nontree edges are also retrieved.

Below, we refer to input graph vertices as "vertices" and use "node" to mean nodes of the B-tree in which we store the "ET-sequences."

ET-trees. An *ET-sequence* is a sequence generated from a tree by listing each vertex each time it is encountered ("an occurrence of the vertex") as a tree is searched depth-first. Each ET-sequence is stored in a B-tree of degree d. This allows us to implement the deletion or insertion of an edge in the forest as follows: we split a tree by deleting an edge or join two trees by inserting an edge in time $O(d \log_d n)$, using

a constant number of splits and joins on the corresponding B-trees. Also we can test two vertices of the forest to determine whether they are in the same tree in time $O(\log_d n)$, by searching up to the roots and testing for equality. See, for example, [1, 11] for operations on B-trees. If $d = n^\alpha$, for α a positive constant, then the join and split operations take time $O(d)$ and the test operation takes time $O(1)$. We refer to the B-trees used to store ET-sequences as ET-trees.

This data structure allows us to keep information about a vertex so that the cumulative information about all vertices in a tree can be maintained. To do so, we make one arbitrary occurrence of each vertex a "designated" occurrence and, in each internal node of the ET-tree, we keep cumulative information about the designated occurrences in the subtree of the ET-tree rooted at that node. Here, for example, we want to know if there is at least one nontree edge incident to a vertex in a tree. We mark the vertex's designated occurrence in the ET-tree if there is a nontree edge in the graph incident to that vertex. We mark each internal node of the ET-tree if some node in its subtree is marked. We can find the endpoint of a nontree edge by starting at the root of the ET-tree and following a path of marked nodes down to a marked designated occurrence. In a degree d ET-tree, each split or join operation or each change to the number associated with an occurrence requires the adjustment of $O(\log_d n)$ internal nodes with each adjustment taking $O(d)$ timesteps. For other applications of ET-trees, see [9].

We maintain the following data structures.

- Each edge is labelled by its level and a bit which indicates if it is a tree edge.
- Let $d_F = \max\{{m'_{in}}^{1/3} \log n, n^\epsilon\}$, for any constant $0 < \epsilon \leq 1/3$. Each tree in F is represented as an ET-sequence which is stored in a degree d_F B-tree. Note that these B-trees have a constant number of levels, so that two vertices can be tested to determine if they lie in the same tree of F in $O(1)$ time.
- Let $c = {m'_{in}}^{1/3} / \log n$. We partition consecutive levels into classes of size c. Each class is represented by the smallest level in the class, i.e., the level j such that $c|j$ ("c divides j"). That is, level i is mapped to the class $f(i) = c\lfloor i/c \rfloor$. For each representative level j,
  - we represent each tree in F_j as an ET-sequence which is stored in a binary B-tree;
  - for each vertex v, we create a list $L_j(v)$ which contains
    (i) all nontree edges incident to v which are in any level $i \in f^{-1}(j)$ and
    (ii) all tree edges incident to v which are in any level $i > j, i \in f^{-1}(j)$;
  - we mark each designated occurrence of a vertex v whose list $L_j(v)$ is nonempty. Each internal node of the ET-tree is marked if its subtree contains a marked occurrence.

2.2. The Search routine. **Search**$(T_i(u))$ returns all nontree edges in level i incident to $T_i(u)$. It begins by searching $T_{f(i)}(u)$ which is a subtree of $T_i(u)$. It proceeds by examining all edges in $L_{f(i)}(v)$ for all vertices v in the tree being searched. Nontree edges in level i are picked out and tree edges in levels $i', f(i) < i' \leq i$, are followed to other trees of $F_{f(i)}$ which are then searched in turn. Note that all such tree edges lead to other trees of $F_{f(i)}$ which are subtrees of $T_i(u)$; and all subtrees of $T_i(u)$ will be found by this procedure. A *phase* of the algorithm consists of the examination of one edge e in a list L.

Search$(T_i(u))$.

1. $S' \leftarrow \emptyset$;
2. $treelist \leftarrow T_{f(i)}(u)$;

3. Repeat until *treelist* is empty:
   - Remove an ET-tree from the *treelist*.
   - For each marked vertex x in the ET-tree and for each edge $\{x, y\}$ in each $L_{f(i)}(x)$,
     - if $\{x, y\}$ is a nontree edge on level i, add it to the set S' of edges to return;
     - else if $\{x, y\}$ is a tree edge on level l such that $l \leq i$, then add $T_{f(i)}(y)$ to *treelist*.

2.3. Analysis. *Initialization.* We compute the minimum spanning forest F, create the ET-trees for F_j, for each j such that $c|j$, and partition the nontree edges by weight. Recall that m'_{in} is the number of nontree edges in the initial graph. Let t be the number of edges in the initial minimum spanning forest. The creation of all the lists L takes time proportional to the number of nontree edges m'_{in}. The building of ET-trees for F and all F_j such that $c|j$ and the marking of internal nodes takes time proportional to the size of each forest or $O(((m'_{in}/k)/c)t + m'_{in}) = O(m'^{1/3}_{in}t + m'_{in})$.

Deletions of nontree edges. Deleting a nontree edge on any level may require unmarking a designated occurrence of a vertex in some ET-tree, which may require unmarking internal nodes on the path to the root in $O(\log n)$ time.

Deletions and insertions of tree edges. Deleting a tree edge takes worst-case time $O(d_F)$ to delete it from the ET-tree of F and worst-case time $O(\log n)$ to delete it from the ET-tree of each F_j such that $c|j$, for a total of $O(d_F + ((m'_{in}/k)/c)\log n)$ time per edge. Inserting a replacement edge takes the same time.

Finding a replacement edge. We first analyze the cost of **Search**. Let the *weight* $w(T)$ *of a tree* T *of some* F_i be $\sum |L_{f(i)}(v)|$ summed over all vertices v in T. It costs $O(\log n)$ to move down the path from the root to a leaf in an ET-tree to find a marked occurrence of a vertex, or to move up a tree from an occurrence to the root. Thus, the cost of **Search**$(T_i(x))$ is $O(\log n)$ times the number of edges examined, or $O(w(T_i(x))\log n)$, if **Search** is carried out until it ends, and $O(k)$, if it is run for $k/\log n$ phases.

In **Replace**(u, v, i), if $w(T_i(u)) \leq w(T_i(v))$, then we refer to $T_i(u)$ as the *smaller component* T_1; otherwise, T_1 is $T_i(v)$. The cost of a call to **Replace**(u, v, i) is the cost of the **Search** plus the cost of testing each edge in S. The number of edges in S is $O(\min\{k, w(T_1)\})$. We can use the d_F-degree ET-tree representation for F to test each edge at cost $O(1)$. Thus the cost of a call to **Replace** is $O(\min\{k, w(T_1)\log n\})$.

To pay for these costs, If a replacement edge is found on level i then we charge the cost of **Replace**(u, v, i) to the deletion. In addition, we charge the cost of modifying F to the deletion so the total cost charged to the deletion is $O(\min\{k, w(T_1)\log n\} + ((m'_{in}/k)/c)\log n + d_F) = O(((m'_{in}/k)/c)\log n + d_F)$.

If no replacement edge is found on level i then a tree of F_i which was split by the deletion remains split. We use the following.

Claim 2.1. $O(\sum w(T_1))$ *summed over all smaller components* T_1 *which split from a tree* T *on any given level during all* **Replace** *operations is* $O(w(T)\log n)$.

The proof of the claim follows [5]. The first time a smaller component T_1 of a tree T is searched, it can have weight no greater than $w(T)/2$. Between two successive times that $|L_{f(i)}(v)|$ contributes to the weight of a smaller component T_1 and that component splits off, the weight of a smaller component T_1 containing v is no more than half its weight the previous time. Hence $|L_{f(i)}(v)|$ contributes to the weight of any T_1 no more than $\log_2 w(T) = O(\log n)$ times. That is, $O(\sum w(T_1)) = O(\sum_{v\in T} |L_{f(i)}(v)|)\log n) = O(w(T)\log n)$.

There are at most k edges per level (except for level 0, which has at most k nontree edges). Each $L_j(v)$ consists of edges from c levels. Since level 0 tree edges do not belong to any list $L_j(v)$, the maximum weight of a tree $w(T)$ is ck. Thus the total cost charged to a level is $O(ck \log^2 n)$. Summing over all levels we have $O((m'_{in}/k)(ck \log^2 n) = O(m'_{in} c \log^2 n)$, or an amortized cost per deletion of $O(c \log^2 n) = O(m'^{1/3}_{in} \log n)$, if $\Omega(m'_{in})$ edges are deleted.

The cost charged to each deletion is $O((m'_{in}/ck)(\log n) + d_F)$. For $d_F = max\{m'^{1/3}_{in} \log n, n^\epsilon\}$ and $c = m'^{1/3}_{in}/\log n$, this is $O(m'^{1/3}_{in} \log n + n^\epsilon)$.

To summarize the cost of initialization when amortized over $\Omega(m_{in})$ operations is $O(m'^{1/3}_{in})$ and the cost per deletion of an edge and finding replacement edges, when amortized over $\Omega(m'_{in})$ operations is $O(m'^{1/3}_{in} \log n + n^\epsilon)$. Thus for a sequence of $\Omega(m_{in})$ operations, the amortized time per update is $O(m'^{1/3}_{in} \log n + n^\epsilon)$.

Finally, we note that the query of the form "Are vertices i and j connected?" can be answered using the ET-tree data structure for F in $O(1)$ time.

3. From deletions-only to fully dynamic. In this section, we show a general technique to develop a fully dynamic data structure using several deletions-only data structures with an added operation. (We call these "extended" deletions-only data structures.) As before, we assume the edge weights are distinct.

First, we define the following operation on a deletions-only data structure A.

batch_add(G, E', F'): Given a graph $G = (V, E)$ with minimum spanning forest F, insert all edges of E' into G, if they are not already there. The resulting spanning forest F' is given.

We refer to the period of time which occurs between two consecutive calls to *batch_add* on a graph G, or between the start of the algorithm and the first *batch_add* on G as a *period of* G. Alternatively, a period may be terminated prematurely (see below).

We prove the following theorem.

THEOREM 3.1. *Suppose for any value of* n *and* m'_{in}*, there is an extended deletions-only data structure for any dynamic graph* $G = (V, E)$ *with* $|V| = n$ *and the number of nontree edges in the edgeset* E *is initially* m'_{in}*, such that* $(n + m'_{in})f^0(m'_{in}, n)$ *is the worst case time needed to initialize* A*, and* $(y + m'_{in})f(m'_{in}, n)$ *is an upper bound on the time to process* y *deletions.*

Suppose we can process a batch_add(H, E', F')*, following any period in which* y *edges were deleted from* G*, in time* $O((y + m'_{in} + |F' \setminus F|)f^B(m'_{in}, n))$*, where* m'_{in} *is an upper bound on the total number of nontree edges in* G *after the batch_add.*

We also assume that f^0*,* f*,* f^B *are monotone nondecreasing functions.*

For any value d *there is a fully dynamic minimum spanning forest data structure that runs in amortized cost per edge deletion or insertion of* $O(d \log_d n + \sum_{i=0}^{s}(s - i + 1)[f^0(2^i, n) + f(2^i, n) + f^B(2^i, n)])$ *where* $s \leq 3 + \lg m$ *and* m *is the size (vertices plus edges) of the dynamic graph at the time of the update. Here, costs are amortized over a sequence of* m_{in} *update operations, where* m_{in} *is the size of the initial graph.*

In section 3.4, we show that the following corollary holds by choosing $d = n^\epsilon$ for any constant $1/3 \geq \epsilon > 0$ and using the data structure of the previous section.

COROLLARY 3.2. *A minimum spanning forest can be maintained in a fully dynamic graph with amortized cost per update of* $O(m^{1/3} \log n)$*, where* m *is the size of the graph at the time of the update, for a sequence of* $\Omega(m_{in})$ *operations.*

Noting that the function $f(m, n) = O(m^{1/3} \log n)$ is "well behaved" in the sense of Theorem 3.3.2 of [4] gives the main result of the paper.

COROLLARY 3.3. *A minimum spanning forest can be maintained in a fully dynamic graph with amortized cost per update of* $O(n^{1/3} \log n)$*, where* n *is the number of vertices in the graph at the time of the update, for a sequence of* $\Omega(m_{in})$ *operations.*

We prove our theorem by constructing a fully dynamic data structure from extended deletions-only data structures.

Definitions. We refer to the current minimum spanning forest of G as the (global) MSF. Let m' be the number of nontree edges in the current graph, m'_{in} denote the number of nontree edges in the initial graph, and m denote the current size (vertices and edges) of G.

During the course of the algorithm, we simultaneously maintain up to $s \leq \max\{\lg n, \lg(4m')\}$ extended deletions-only data structures $A_0, A_1, \ldots, A_s$, where each A_i is an extended deletions-only minimum spanning forest data structure for a subgraph $G^i + (V, E^i)$ of the global graph $G = (V, E)$. We call this the *composite data structure.* We maintain each tree of the MSF as a Sleator–Tarjan dynamic tree [13] and also as an ET-tree of degree d.

The minimum spanning forest of G^i as maintained by A_i is referred to as a *local spanning forest* and denoted F^i. A *local nontree edge* of A_i is an edge of G^i which is not in A_i's local spanning forest or the MSF. We maintain x_i to be the number of local nontree edges in $\cup_{j \leq i} A_j$.

When m' falls below $2^s/4$ and $s > \lg n$, s is *reset* and the composite data structure is reinitialized. Between two consecutive resets, we define the period of time which occurs between two consecutive calls to *batch_add* on a graph G, or between the initialization or reinitialization of the composite data structure and the first *batch_add* on G as a *period of* G. A reset terminates all periods.

The *size* of a graph refers to the number of vertices plus edges.

We maintain the following invariants.

Invariant. (1) Every edge in the local forest of some A_i is (a) in the MSF or (b) is a local nontree edge in some $A_j, j \neq i$.

(2) $E = (\cup E^i) \cup MSF$.

We now describe the algorithm.

To initialize, Let the initial value of $s = \lceil \lg m'_{in} \rceil$. We initialize A_s as an extended deletions-only data structure for $G^s = G$ with $F^s = MSF$ and the set of local nontree edges being all nontree edges of G.

To perform an insertion operation, **insert**(u, v) is called, where (u, v) is an edge to be inserted into G.

insert(e):

1. Use the dynamic tree to determine if e should be added to the MSF:
   Determine if there is a path between e's endpoints in the MSF. If so, set f to the maximum weight edge on the path.
2. If e is lighter than f, remove f from the MSF.
   If there is no path between e's endpoints, either because f has been removed or there was none previously, call **insert_nontree**(f), and add e to the MSF.
3. Else call **insert_nontree**(e).

The following subroutine inserts a nontree edge e into the composite data structure.

insert_nontree(e). Let $i = \min_{\{} j \mid x_j < 2^j\}$. Let E' be the set of local nontree edges in $\cup_{j<i} E^j \cup \{e\}$.

1. Delete the edges of E' from $A_j, j < i$.
   Set $x_j = 0$.

2. If A_i is not initialized, initialize A_i on the empty graph G^i consisting of n vertices and no edges.
3. Call $batch\_add(G^i, E' \cup MSF, MSF)$.
   Adjust x_i accordingly.

After the procedure, the local nontree edges of G^i are the nontree edges previously contained in $\cup_{j \le i} A_j$. Its local forest $F^i = MSF$. Note that at the beginning of a period of G^i, $x_j = 0$ for $j < i$.

To delete an edge e from G:

delete(e):

1. Delete e from all data structures in which it appears, including all G^i, and update corresponding A_i accordingly. Thus for each local spanning forest F^i which contained e, the local replacement edge e' is determined, if there is one.
2. If e was in the MSF, use the ET-tree representation of the tree containing e in the MSF to determine which of those local replacement edges reconnect the two subtrees which result from the deletion of e. Insert the lightest connecting edge into the MSF.
3. All other local replacement edges are reinserted into the composite data structure using the procedure *insert_nontree*.
4. If $n < x_s \le 2^{s-2}$, reinitialize the composite data structure. That is, set $s = \lceil \lg x_s \rceil$; initialize A_s as an extended deletions-only data structure for $G^s = G$ with $F^s = MSF$ and the set of local nontree edges being all nontree edges of G.

3.1. Proof of correctness. It is easy to see that the invariants are maintained, by induction on the number of operations. Initially, the invariants hold since $G^s = G$. Invariant (2) is preserved after each insertion, since each edge when added to G is either added to the MSF or some G^i. Each edge, when deleted from G, is deleted from all data structures in which it appears. Invariant (1) holds for A_i when A_i is initialized or a *batch_add* is executed since the local forest $F_i = MSF$. The local forest of A_i changes only when an edge is deleted and is replaced by some edge e. Edge e is then either put into the MSF or reinserted into the composite data structure. In that case, it is added to some A_j by a *batch_add* operation. If e is not in the MSF, then e becomes a local nontree edge of A_j. In either case, invariant (1) is preserved.

The correctness of the algorithm follows easily from the invariants. We use the well-known fact that an edge is in the minimum spanning tree iff it is not the heaviest edge in any cycle ("red rule" [14]). We also note that every edge in the composite data structure is an edge in G.

Let e be an edge of the MSF which is deleted. Let e' be the correct replacement edge. Consider the state of the composite data structures right before the deletion of e. By the invariant, since e' was not in the MSF, it was a local nontree edge in some A_i.

Suppose e' is a local nontree edge in A_i. Since e' is the correct replacement edge for e in the MSF, then after e's deletion, e' is not the heaviest edge in any cycle of G and therefore is not the heaviest edge of any cycle of G^i. Hence, after e's deletion, e' becomes a local forest edge, i.e., e' is a local replacement edge for e in G^i. Recall that e' is the minimum weight edge which connects the two subtrees of the MSF resulting from the deletion of e. Thus, e' is the lightest connecting edge from the set of local replacement edges and is chosen in Step 2 of the **delete** algorithm.

3.2. Analysis. We first prove the following claims.

CLAIM 3.4. *During any full period of G^i, there were at least $2^{i-1}/(s-i+1)$ updates to G.*

Proof. For $i > 0$, immediately before *batch_add* is executed on G^i, $x_{i-1} \geq 2^{i-1}$. Immediately afterwards, $x_{i-1} = 0$.

We examine the types of insertions into the composite data structure to see how they affect x_i: (a) when a nontree edge is inserted into G, (b) when an edge is replaced in the MSF after an insertion, and (c) when an edge is deleted in G and it is replaced in up to s local spanning forests. The first two cases cause x_i to increase by no more than one. The third case may cause up to s insertions. However, the s insertions do not affect all A_i the same. Each insertion in this case results from a local nontree edge e becoming a local forest edge. Hence if this occurs in some $A_j, j \leq i$, the increase of x_i resulting from the insertion of a copy of e into the composite data structure is offset by the decrease of x_i caused by the change in status of e from a local nontree edge to a local tree edge. Thus x_s is unchanged by a case-(c) insertion into the composite data structure, x_{s-1} is increased by at most 1, and in general, x_i is increased by at most $s-i$.

Hence, at least $2^{i-1}/(s-i+1)$ insertions or deletions occurred during any full period of G^i. This concludes the proof of the claim.

We are now ready to analyze the costs of the algorithm.

Initialization. Since each A_i is initialized once, the cost for initialization during the algorithm is $(n+2^i)f^0(2^i,n)$. Note that A_i is initialized only if the number of nontree edges exceed 2^{i-1}.

We amortize the initialization costs of the first data structure A_s and all A_i for $i < \lg n$ by requiring there to be $\Omega(m_{in})$ operations, where m_{in} is the size (vertices and edges) of the initial graph. We note that for at least half these operations, the current size of the graph $m \geq m_{in}/2$.

We amortize the cost of initializing A_i, $i \geq \lg n$ over the operations of the preceding period when at least $2^{i-1}/(s-i+1)$ operations occurred.

The cost of *reinitialization* of the composite data structure can be charged to the $2^s/2$ deletions which must have occurred since the previous reset. Note that a reset only occurs when $2^s > n$, so that the initialization cost of $(n+2^{s-2})f^0(2^{s-2},n)$ results in a charge of $f^0(2^{s-2},n)$ per operation.

Execution of batch_add. By assumption, $(y+2^i+|MSF \setminus F^i|)f^B(2^i,n)$ is an upper bound on the time to perform *batch_add*$(G^i, E' \cup MSF \setminus F^i, MSF)$, where y is the number of deletions performed on G^i in the preceding period.

We can charge the cost of $yf^B(2^i,n)$ to the y deletions for a cost of $f^B(2^i,n)$ each.

To charge the $2^i f^B(2^i,n)$, by the claim, *batch_add* is called on G^i after at least $2^{i-1}/(s-i+1)$ insertions and deletions occurred in the preceding period. Charging the $2^i f^B(2^i,n)$ to those updates gives a cost per update of $(s-i+1)f^B(2^i,n)$.

To charge the $|MSF \setminus F^i| f^B(2^i,n)$, we note that at the start of the period, $F^i = MSF$, and for each i, each insertion or deletion in G can cause at most one edge to be added to and/or one edge to be deleted from F^i. Thus we can charge the $|MSF \setminus F^i| f^B(2^i,n)$ to the operations in the preceding period, for a cost of $O(f^B(2^i,n))$ each.

Performing deletions during a period of G^i. The cost of maintaining A_i during a period containing y deletions of edges in G^i is, by assumption, bounded above by $(y+2^i)f(2^i,n)$. These costs can be charged in the same way as the costs for *batch_add*

were charged to the operations of the preceding period.

In the unique case of the initial A_s, where $s = \lceil \lg m'_{in} \rceil$ when there was no preceding period, costs are amortized over the initial sequence of $\Omega(m_{in})$ deletions and insertions, as in the analysis of the initialization costs.

After a reset of s, the cost of performing deletions in A_s, after A_s is reinitialized, is charged to the deletions which resulted in the reset, as in the analysis of the reinitialization costs.

Summary. For each i, the cost per operation is therefore $O((s-i+1)[f^0(2^i,n) + f(2^i,n) + f^B(2^i,n)])$.

Except for the initialization and reinitialization of A_s, we have charged operations of the preceding period for all costs incurred in the following period. Since the preceding periods occur in between resets of the value of s, we know that for the indices of the A_i, $i \leq s \leq max\{\lg 4m', \lg n\}$. Hence $s \leq 2 + \lg m$, m being the size of the graph at the time of the operation.

For the initialization and reinitialization of A_s, we charge operations which occurred when s may have been smaller by 1. Hence $s \leq 3 + \lg m$, m is the size of the graph at the time of the operation.

Each operation requires a constant number of updates in the dynamic tree data structure and the degree-d ET-tree data structure storing the MSF. This takes time $O(d \log_d n)$.

Summing over i, we have of $O(d \log_d n + \sum_{i=0}^{s}(s-i+1)[f^0(2^i,n) + f(2^i,n) + f^B(2^i,n)]$, where m is the current size of G at the time of the operation, when amortized over a sequence of m_{in} update operations and m_{in} is the size of the initial graph.

3.3. Implementing *batch_add*. In this section, we show how a deletions-only data structure A in section 2 for a graph G which initially had m'_{in} nontree edges can be extended so that the operation *batch_add* which occurs after a sequence σ of y edge deletions can be implemented in time $O((y + m'_{in} + |F' \setminus F|)({m'_{in}}^{1/3} \log n))$.

We begin by restoring the ET-trees of A to MSF_{old}, the minimum spanning forest of G before the start of the sequence σ of deletions. The cost of joining two ET-trees is asympotically the same as splitting them; thus the calculations of section 2 apply. For each deletion, the cost of restoration is $O(({m'}_{in}^{1/3}) \log n + n^{\epsilon})$.

We next transform MSF_{old} to MSF by again modifying the ET-trees. We remove every edge in $MSF_{old} \setminus MSF$ and insert every edge in $MSF \setminus MSF_{old}$ for a cost of $O({m'}_{in}^{1/3} \log n + n^{\epsilon})$.

To determine the transformations required, we keep a list of sorted changes which occurred since the last *batch_add*.

We remove all nontree edges which are stored in A and sort the nontree edges of $E \cup E'$, assign them to levels, and store them with the appropriate list L. The cost per edge of removing, sorting, and then storing is $O(\log n)$ per edge for the unique (binary) ET-tree in which the edge is stored.

Let $f'(m,n) = m^{1/3} \log n + n^{\epsilon}$. We have shown an extended deletions-only data structure such that $O((n + m'_{in})f'(m_{in},n))$ is an upper bound on the worst case time needed to initialize A, and $O((y + m'_{in})f'(m_{in},n))$ is an upper bound on the time to process y deletions.

We can process a *batch_add*(G, E', F'), following any period in which y edges were deleted from G, in time $O((y + m'_{in} + |F' \setminus F|)f'(m'_{in},n))$, where m'_{in} is an upper bound on the total number of nontree edges in G after the *batch_add*.

3.4. Proof of corollary. Choose $d = n^\epsilon$ for any constant ϵ with $0 < \epsilon \leq 1/3$. Substituting f' for f^B, f, and f^0, we conclude that there is a fully dynamic minimum spanning forest data structure that runs in amortized cost per edge deletion or insertion of $O(\sum_{i=0}^{s}(s-i+1)f'(2^i,n))$, where $s \leq 3 + \lg m$.

Substituting for f' and 2^i, we have $O(\sum_{i=0}^{s}(i+1)(2^{s-i})^{1/3}\log n + n^\epsilon) = O((2^s)^{1/3}\log n + n^\epsilon \log n) = O(m^{1/3}\log n + n^{\epsilon'})$ for ϵ' any constant.

EVOLUTIONARY TREES CAN BE LEARNED IN POLYNOMIAL TIME IN THE TWO-STATE GENERAL MARKOV MODEL*

MARY CRYAN†, LESLIE ANN GOLDBERG‡, AND PAUL W. GOLDBERG‡

Abstract. The j-state general Markov model of evolution (due to Steel) is a stochastic model concerned with the evolution of strings over an alphabet of size j. In particular, the two-state general Markov model of evolution generalizes the well-known Cavender–Farris–Neyman model of evolution by removing the *symmetry* restriction (which requires that the probability that a "0" turns into a "1" along an edge is the same as the probability that a "1" turns into a "0" along the edge). Farach and Kannan showed how to probably approximately correct (PAC)-learn Markov evolutionary trees in the Cavender–Farris–Neyman model provided that the target tree satisfies the additional restriction that all pairs of leaves have a sufficiently high probability of being the same. We show how to remove both restrictions and thereby obtain the first polynomial-time PAC-learning algorithm (in the sense of Kearns et al. [*Proceedings of the 26th Annual ACM Symposium on the Theory of Computing*, 1994, pp. 273–282]) for the general class of two-state Markov evolutionary trees.

1. Introduction.

The j-state general Markov model of evolution was proposed by Steel in 1994 [14]. The model is concerned with the evolution of strings (such as DNA strings) over an alphabet of size j. The model can be described as follows. A *j-state Markov evolutionary tree* consists of a *topology* (a rooted tree, with edges directed away from the root), together with the following parameters. The root of the tree is associated with j probabilities $\rho_0, \ldots, \rho_{j-1}$ which sum to 1, and each edge of the tree is associated with a stochastic transition matrix whose state space is the alphabet. A probabilistic experiment can be performed using the Markov evolutionary tree as follows: The root is assigned a letter from the alphabet according to the probabilities $\rho_0, \ldots, \rho_{j-1}$. (Letter i is chosen with probability ρ_i.) Then the letter propagates down the edges of the tree. As the letter passes through each edge, it undergoes a probabilistic transition according to the transition matrix associated with the edge. The result is a string of length n which is the concatenation of the letters obtained at the n leaves of the tree. A j-state Markov evolutionary tree thus defines a probability distribution on length-n strings over an alphabet of size j. (The probabilistic experiment described above produces a single sample from the distribution.[1])

[1]Biologists would view the n leaves as being existing species, and the internal nodes as being hypothetical ancestral species. Under the model, a single experiment as described above would produce a single bit position of (for example) DNA for all of the n species.

To avoid getting bogged down in detail, we work with a binary alphabet. Thus, we will consider *two-state* Markov evolutionary trees.

Following Farach and Kannan [9], Erdös et al. [7, 8], and Ambainis et al. [2], we are interested in the problem of learning a Markov evolutionary tree, given samples from its output distribution. Following Farach and Kannan and Ambainis et al., we consider the problem of using polynomially many samples from a Markov evolutionary tree M to "learn" a Markov evolutionary tree M' whose distribution is close to that of M. We use the *variation distance* metric to measure the distance between two distributions, $\mathcal{D}$ and $\mathcal{D}'$, on strings of length n. The variation distance between $\mathcal{D}$ and $\mathcal{D}'$ is $\sum_{s\in\{0,1\}^n} |\mathcal{D}(s) - \mathcal{D}'(s)|$. If M and M' are n-leaf Markov evolutionary trees, we use the notation $\mathrm{var}(M, M')$ to denote the variation distance between the distribution of M and the distribution of M'.

We use the probably approximately correct (PAC) distribution learning model of Kearns et al. [11]. Our main result is the first polynomial-time PAC-learning algorithm for the class of two-state Markov evolutionary trees (which we will refer to as METs).

THEOREM 1. *Let δ and ϵ be any positive constants. If our algorithm is given* $\mathrm{poly}(n, 1/\epsilon, 1/\delta)$ *samples from any MET M with any n-leaf topology T, then with probability at least $1-\delta$, the MET M' constructed by the algorithm satisfies* $\mathrm{var}(M, M') \leq \epsilon$.

Interesting PAC-learning algorithms for biologically important restricted classes of METs have been given by Farach and Kannan in [9] and by Ambainis et al. in [2]. These algorithms (and their relation to our algorithm) will be discussed more fully in section 1.1. At this point, we simply note that these algorithms only apply to METs which satisfy the following restrictions.

Restriction 1. All transition matrices are symmetric (the probability of a "1" turning into a "0" along an edge is the same as the probability of a "0" turning into a "1").

Restriction 2. For some positive constant α, every pair of leaves (x, y) satisfies $\Pr(x \neq y) \leq 1/2 - \alpha$.

We will explain in section 1.1 why the restrictions significantly simplify the problem of learning Markov evolutionary trees (though they certainly do not make it easy!). The main contribution of our paper is to remove the restrictions.

While we have used variation distance (L_1 distance) to measure the distance between the target distribution $\mathcal{D}$ and our hypothesis distribution $\mathcal{D}'$, Kearns et al. formulated the problem of learning probability distributions in terms of the Kullback–Leibler (KL) divergence distance from the target distribution to the hypothesis distribution (see [6]). This distance is defined as the sum over all length-n strings s of $\mathcal{D}(s)\log(\mathcal{D}(s)/\mathcal{D}'(s))$. Kearns et al. point out that the KL distance gives an upper bound on variation distance, in the sense that the KL distance from $\mathcal{D}$ to $\mathcal{D}'$ is $\Omega(\mathrm{var}(\mathcal{D}, \mathcal{D}')^2)$. Hence if a class of distributions can be PAC-learned using KL distance, it can be PAC-learned using variation distance. We justify our use of the variation distance metric by showing that the reverse is true. In particular, we prove the following lemma in the appendix.

LEMMA 2. *A class of probability distributions over the domain $\{0,1\}^n$ that is PAC-learnable under the variation distance metric is PAC-learnable under the KL-distance measure.*

The lemma is proved using a method related to the ϵ-Bayesian shift of Abe and Warmuth [3]. Note that the result requires a discrete domain of support for the target distribution, such as the domain $\{0,1\}^n$ which we use here.

The rest of this section is organized as follows: Subsection 1.1 discusses previous work related to the general Markov model of evolution, and the relationship between this work and our work. Subsection 1.2 gives a brief synopsis of our algorithm for PAC-learning Markov evolutionary trees. Subsection 1.3 discusses an interesting connection between the problem of learning Markov evolutionary trees and the problem of learning mixtures of Hamming balls, which was studied by Kearns et al. [11].

1.1. Previous work and its relation to our work. The two-state general Markov model [14] which we study in this paper is a generalization of the Cavender–Farris–Neyman model of evolution [5, 10, 13]. Before defining the Cavender–Farris–Neyman Model, let us return to the two-state general Markov model. We will fix attention on the particular two-state alphabet $\{0, 1\}$. Thus, the stochastic transition matrix associated with edge e is simply the matrix

$$\begin{pmatrix} 1 - e_0 & e_0 \\ e_1 & 1 - e_1 \end{pmatrix},$$

where e_0 denotes the probability that a "0" turns into a "1" along edge e and e_1 denotes the probability that a "1" turns into a "0" along edge e. The Cavender–Farris–Neyman model is simply the special case of the two-state general Markov model in which the transition matrices are required to be symmetric. That is, it is the special case of the two-state general Markov model in which Restriction 1 holds (so $e_0 = e_1$ for every edge e).

We now describe past work on learning Markov evolutionary trees in the general Markov model and in the Cavender–Farris–Neyman model. Throughout the paper, we will define the *weight* $w(e)$ of an edge e to be $|1 - e_0 - e_1|$.

Steel [14] showed that if a j-state Markov evolutionary tree M satisfies (i) $\rho_i > 0$ for all i, and (ii) the determinant of every transition matrix is outside of $\{-1, 0, 1\}$, then the distribution of M uniquely determines its topology. In this case, he showed how to recover the topology, given the joint distribution of every pair of leaves. In the two-state case, it suffices to know the exact value of the covariances of every pair of leaves. In this case, he defined the weight $\Lambda(e)$ of an edge e from node v to node w to be

$$\Lambda(e) = \begin{cases} w(e)\sqrt{\Pr(v=0)\Pr(v=1)} & \text{if } w \text{ is a leaf, and} \\ w(e)\sqrt{\frac{\Pr(v=0)\Pr(v=1)}{\Pr(w=0)\Pr(w=1)}} & \text{otherwise.} \end{cases} \tag{1}$$

Steel observed that these distances are multiplicative along a path and that the distance between two *leaves* is equal to their covariance. Since the distances are multiplicative along a path, their logarithms are additive. Therefore, methods for constructing trees from additive distances such as the method of Bandelt and Dress [4] can be used to reconstruct the topology. Steel's method does not show how to recover the *parameters* of a Markov evolutionary tree, even when the exact distribution is known and $j = 2$. In particular, the quantity that he obtains for each edge e is a one-dimensional distance rather than a *two*-dimensional vector giving the two transition probabilities e_0 and e_1. Our method shows how to recover the parameters exactly, given the exact distribution, and how to recover the parameters approximately (well enough to approximate the distribution), given polynomially-many samples from M.

Farach and Kannan [9] and Ambainis et al. [2] worked primarily in the special case of the two-state general Markov model satisfying the two restrictions on page 2. Farach and Kannan's paper was a breakthrough, because prior to their paper nothing

was known about the feasibility of reconstructing Markov evolutionary trees from samples. For any given positive constant α, they showed how to PAC-learn the class of METs which satisfy the two restrictions. However, the number of samples required is a function of $1/\alpha$, which is taken to be a constant. Ambainis et al. improved the bounds given by Farach and Kannan to achieve asymptotically tight upper and lower bounds on the number of samples needed to achieve a given variation distance. These results are elegant and important. Nevertheless, the restrictions that they place on the model do significantly simplify the problem of learning Markov evolutionary trees. In order to explain why this is true, we explain the approach of Farach et al.: Their algorithm uses samples from an MET M, which satisfies the restrictions above, to estimate the "distance" between any two leaves. (The distance is related to the covariance between the leaves.) The authors then relate the distance between two leaves to the amount of evolutionary time that elapses between them. The distances are thus turned into times. Then the algorithm of [1] is used to approximate the inter-leaf evolutionary times with times which are close, but form an additive metric, which can be fitted onto a tree. Finally, the times are turned back into transition probabilities. The symmetry assumption is essential to this approach because it is *symmetry* that relates a one-dimensional quantity (evolutionary time) to an otherwise two-dimensional quantity (the probability of going from a "0" to a "1" and the probability of going from a "1" to a "0"). The second restriction is also essential: If the probability that x differs from y were allowed to approach $1/2$, then the evolutionary time from x to y would tend to ∞. This would mean that in order to approximate the inter-leaf times accurately, the algorithm would have to get the distance estimates *very* accurately, which would require many samples. Ambainis et al. [2] generalized their results to a symmetric version of the j-state evolutionary model, subject to the two restrictions above.

Erdös et al. [7, 8] also considered the reconstruction of Markov evolutionary trees from samples. Like Steel [14] and unlike our paper or the papers of Farach and Kannan [9] and Ambainis et al. [2], Erdös et al. were interested in reconstructing only the *topology* of an MET (rather than its parameters or distribution), and they were interested in using as few samples as possible to reconstruct the topology. They showed how to reconstruct topologies in the j-state general Markov model when the Markov evolutionary trees satisfy the following: (i) every root probability is bounded above 0, (ii) every transition probability is bounded above 0 and below $1/2$, and (iii) for positive quantities λ and λ', the determinant of the transition matrix along each edge is between λ and $1 - \lambda'$. The number of samples required is polynomial in the worst case, but is only polylogarithmic in certain cases including the case in which the MET is drawn uniformly at random from one of several (specified) natural distributions. Note that restriction (iii) of Erdös et al. is weaker than Farach and Kannan's Restriction 2. However, Erdös et al. show only how to reconstruct the topology (thus they work in a restricted case in which the topology can be uniquely constructed using samples). They do not show how to reconstruct the parameters of the Markov evolutionary tree or how to approximate its distribution.

1.2. A synopsis of our method. In this paper, we provide the first polynomial-time PAC-learning algorithm for the class of METs. Our algorithm works as follows: First, using samples from the target MET, the algorithm estimates all of the pairwise covariances between leaves of the MET. Second, using the covariances, the leaves of the MET are partitioned into "related sets" of leaves. Essentially, leaves in different related sets have such small covariances between them that it is not always possible to use polynomially many samples to discover how the related sets are connected

in the target topology. Nevertheless, we show that we can closely approximate the *distribution* of the target MET by approximating the distribution of each related set closely, and then joining the related sets by "cut edges." The first step, for each related set, is to discover an approximation to the correct topology. Since we do not restrict the class of METs which we consider, we cannot guarantee to construct the *exact* induced topology (in the target MET). Nevertheless we guarantee to construct a good enough approximation. The topology is constructed by looking at triples of leaves. We show how to ensure that each triple that we consider has large inter-leaf covariances. We derive quadratic equations which allow us to approximately recover the parameters of the triple, using estimates of inter-leaf covariances and estimates of probabilities of particular outputs. We compare the outcomes for different triples and use the comparisons to construct the topology. Once we have the topology, we again use our quadratic equations to discover the parameters of the tree. As we show in section 2.4, we are able to prevent the error in our estimates from accumulating, so we are able to guarantee that each estimated parameter is within a small additive error of the "real" parameter in a (normalized) target MET. From this, we can show that the variation distance between our hypothesis and the target is small.

1.3. Markov evolutionary trees and mixtures of Hamming balls. A *Hamming ball distribution* [11] over binary strings of length n is defined by a *center* (a string c of length n) and a *corruption probability* p. To generate an output from the distribution, one starts with the center, and then flips each bit (or not) according to an independent Bernoulli experiment with probability p. A *linear mixture* of j Hamming balls is a distribution defined by j Hamming ball distributions, together with j probabilities $\rho_1, \ldots, \rho_j$ which sum to 1 and determine from which Hamming ball distribution a particular sample should be taken. For any fixed j, Kearns et al. give a polynomial-time PAC-learning algorithm for a mixture of j Hamming balls, *provided all j Hamming balls have the same corruption probability.*[2]

A *pure* distribution over binary strings of length n is defined by n probabilities, $\lambda_1, \ldots, \lambda_n$. To generate an output from the distribution, the ith bit is set to "0" independently with probability λ_i, and to "1" otherwise. A pure distribution is a natural generalization of a Hamming ball distribution. Clearly, every linear mixture of j pure distributions can be realized by a j-state MET with a star-shaped topology. Thus, the algorithm given in this paper shows how to learn a linear mixture of any two pure distributions. Furthermore, a generalization of our result to a j-ary alphabet would show how to learn any linear mixture of any j pure distributions.

2. The algorithm. Our description of our PAC-learning algorithm and its analysis requires the following definitions. For positive constants δ and ϵ, the input to the algorithm consists of $\text{poly}(n, 1/\epsilon, 1/\delta)$ samples from an MET M with an n-leaf topology T. We will let $\epsilon_1 = \epsilon/(20n^2)$, $\epsilon_2 = \epsilon_1/(4n^3)$, $\epsilon_3 = \epsilon_2^4/2^6$, $\epsilon_4 = \epsilon_1/(4n)$, $\epsilon_5 = \epsilon_2\epsilon_4/2^{10}$, and $\epsilon_6 = \epsilon_5\epsilon_2^3/2^7$. We have made no effort to optimize these constants. However, we state them explicitly so that the reader can verify below that the constants can be defined consistently. We define an ϵ_4-*contraction* of an MET with topology T' to be a tree formed from T' by contracting some internal edges e

[2]The kind of PAC-learning that we consider in this paper is *generation.* Kearns et al. also show how to do *evaluation* for the special case of the mixture of j Hamming balls described above. Using the observation that the output distributions of the subtrees below a node of an MET are independent, provided the bit at that node is fixed, we can also solve the evaluation problem for METs. In particular, we can calculate (in polynomial time) the probability that a given string is output by the hypothesis MET.

for which $\Lambda(e) > 1 - \epsilon_4$, where $\Lambda(e)$ is the edge-distance of e as defined by Steel [14] (see (1)). If x and y are leaves of the topology T then we use the notation $\mathrm{cov}(x, y)$ to denote the covariance of the indicator variables for the events "the bit at x is 1" and "the bit at y is 1." Thus,

$$\mathrm{cov}(x, y) = \Pr(xy = 11) - \Pr(x = 1)\Pr(y = 1). \tag{2}$$

We will use the following observations.

Observation 3. If MET M' has topology T' and e is an internal edge of T' from the root r to node v and T'' is a topology that is the same as T' except that v is the root (so e goes from v to r) then we can construct an MET with topology T'' which has the same distribution as M'. To do this, we simply set $\Pr(v = 1)$ appropriately (from the distribution of M'). If $\Pr(v = 1) = 0$ we set e_0 to be $\Pr(r = 1)$ (from the distribution of M'). If $\Pr(v = 1) = 1$ we set e_1 to be $\Pr(r = 0)$ (from the distribution of M'). Otherwise, we set $e_0 = \Pr(r = 1)(\text{old } e_1)/\Pr(v = 0)$ and $e_1 = \Pr(r = 0)(\text{old } e_0)/\Pr(v = 1)$.

Observation 4. If MET M' has topology T' and v is a degree-2 node in T' with edge e leading into v and edge f leading out of v and T'' is a topology which is the same as T' except that e and f have been contracted to form edge g then there is an MET with topology T'' which has the same distribution as M'. To construct it, we simply set $g_0 = e_0(1 - f_1) + (1 - e_0)f_0$ and $g_1 = e_1(1 - f_0) + (1 - e_1)f_1$.

Observation 5. If MET M' has topology T' then there is an MET M'' with topology T' which has the same distribution on its leaves as M' and has every internal edge e satisfy $e_0 + e_1 \leq 1$.

Proof of Observation 5. We will say that an edge e is "good" if $e_0 + e_1 \leq 1$. Starting from the root we can make all edges along a path to a leaf good, except perhaps the last edge in the path. If edge e from u to v is the first nongood edge in the path we simply set e_0 to $1 - (\text{old } e_0)$ and e_1 to $1 - (\text{old } e_1)$. This makes the edge good but it has the side effect of interchanging the meaning of 0 and 1 at node v. As long as we interchange 0 and 1 an even number of times along every path we will preserve the distribution at the leaves. Thus, we can make all edges good except possibly the last one, which we use to get the parity of the number of interchanges correct. □

We will now describe the algorithm. In subsection 2.6, we will prove that with probability at least $1 - \delta$, the MET M' that it constructs satisfies $\mathrm{var}(M, M') \leq \epsilon$. Thus, we will prove Theorem 1.

2.1. Step 1: Estimate the covariances of pairs of leaves. For each pair (x, y) of leaves, obtain an "observed" covariance $\widehat{\mathrm{cov}}(x, y)$ such that, with probability at least $1 - \delta/3$, all observed covariances satisfy

$$\widehat{\mathrm{cov}}(x, y) \in [\mathrm{cov}(x, y) - \epsilon_3, \mathrm{cov}(x, y) + \epsilon_3].$$

LEMMA 6. *Step* 1 *requires only* $\mathrm{poly}(n, 1/\epsilon, 1/\delta)$ *samples from* M.

Proof. Consider leaves x and y and let p denote $\Pr(xy = 11)$. By a Chernoff bound (see [12]), after k samples the observed proportion of outputs with $xy = 11$ is within $\pm\epsilon_3/4$ of p, with probability at least $1 - 2\exp(-k\epsilon_3^2/2^3)$. For each pair (x, y) of leaves, we estimate $\Pr(xy = 11)$, $\Pr(x = 1)$, and $\Pr(y = 1)$ within $\pm\epsilon_3/4$. From these estimates, we can calculate $\widehat{\mathrm{cov}}(x, y)$ within $\pm\epsilon_3$ using (2). □

2.2. Step 2: Partition the leaves of M into related sets. Consider the following *leaf connectivity graph* whose nodes are the leaves of M. Nodes x and y are connected by a "positive" edge if $\widehat{\mathrm{cov}}(x,y) \geq (3/4)\epsilon_2$ and are connected by a "negative" edge if $\widehat{\mathrm{cov}}(x,y) \leq -(3/4)\epsilon_2$. Each connected component in this graph (ignoring the signs of edges) forms a set of "related" leaves. For each set S of related leaves, let $s(S)$ denote the leaf in S with smallest index. METs have the property that for leaves x, y, and z, $\mathrm{cov}(y,z)$ is positive iff $\mathrm{cov}(x,y)$ and $\mathrm{cov}(y,z)$ have the same sign. To see this, use the following equation, which can be proved by algebraic manipulation from (2):

$$\mathrm{cov}(x,y) = \Pr(v=1)\Pr(v=0)(1-\alpha_0-\alpha_1)(1-\beta_0-\beta_1), \tag{3}$$

where v is taken to be the least common ancestor of x and y and α_0 and α_1 are the transition probabilities along the path from v to x and β_0 and β_1 are the transition probabilities along the path from v to y. Therefore, as long as the observed covariances are as accurate as stated in Step 1, the signs on the edges of the leaf connectivity graph partition the leaves of S into two sets S_1 and S_2 in such a way that $s(S) \in S_1$, all covariances between pairs of leaves in S_1 are positive, all covariances between pairs of leaves in S_2 are positive, and all covariances between a leaf in S_1 and a leaf in S_2 are negative.

For each set S of related leaves, let $T(S)$ denote the subtree formed from T by deleting all leaves which are not in S, contracting all degree-2 nodes, and then rooting at the neighbour of $s(S)$. Let $M(S)$ be an MET with topology $T(S)$ which has the same distribution as M on its leaves and satisfies the following:

(4)
- Every internal edge e of $M(S)$ has $e_0 + e_1 \leq 1$.
- Every edge e to a node in S_1 has $e_0 + e_1 \leq 1$.
- Every edge e to a node in S_2 has $e_0 + e_1 \geq 1$.

Observations 3, 4, and 5 guarantee that $M(S)$ exists.

Observation 7. As long as the observed covariances are as accurate as stated in Step 1 (which happens with probability at least $1-\delta/3$), then for any related set S and any leaf $x \in S$ there is a leaf $y \in S$ such that $|\mathrm{cov}(x,y)| \geq \epsilon_2/2$.

Observation 8. As long as the observed covariances are as accurate as stated in Step 1 (which happens with probability at least $1-\delta/3$), then for any related set S and any edge e of $T(S)$ there are leaves a and b which are connected through e and have $|\mathrm{cov}(a,b)| \geq \epsilon_2/2$.

Observation 9. As long as the observed covariances are as accurate as stated in Step 1 (which happens with probability at least $1-\delta/3$), then for any related set S, every internal node v of $M(S)$ has $\Pr(v=0) \in [\epsilon_2/2, 1-\epsilon_2/2]$.

Proof of Observation 9. Suppose to the contrary that v is an internal node of $M(S)$ with $\Pr(v=0) \in [0,\epsilon_2/2) \cup (1-\epsilon_2/2, 1]$. Using Observation 3, we can re-root $M(S)$ at v without changing the distribution. Let w be a child of v. By (3), every pair of leaves a and b which are connected through (v,w) satisfy $|\mathrm{cov}(a,b)| \leq \Pr(v=0)\Pr(v=1) < \epsilon_2/2$. The observation now follows from Observation 8. □

Observation 10. As long as the observed covariances are as accurate as stated in Step 1 (which happens with probability at least $1-\delta/3$), then for any related set S, every edge e of $M(S)$ has $w(e) \geq \epsilon_2/2$.

Proof of Observation 10. This follows from Observation 8 using (3). (Recall that $w(e) = |1-e_0-e_1|$.) □

2.3. Step 3: For each related set S, find an ϵ_4-contraction $T'(S)$ of $T(S)$. In this section, we will assume that the observed covariances are as accurate as stated in Step 1. (This happens with probability at least $1-\delta/3$.) Let S be a related set. With probability at least $1-\delta/(3n)$ we will find an ϵ_4-contraction $T'(S)$ of $T(S)$. Since there are at most n related sets, all ϵ_4-contractions will be constructed with probability at least $1-\delta/3$. Recall that an ϵ_4-contraction of $M(S)$ is a tree formed from $T(S)$ by contracting some internal edges e for which $\Lambda(e) > 1-\epsilon_4$. We start with the following observation, which will allow us to redirect edges for convenience.

Observation 11. If e is an internal edge of $T(S)$ then $\Lambda(e)$ remains unchanged if e is redirected as in Observation 3.

Proof. The observation can be proved by algebraic manipulation from (1) and Observation 3. Note (from Observation 9) that every endpoint v of e satisfies $\Pr(v = 0) \in (0,1)$. Thus, the redirection in Observation 3 is not degenerate and $\Lambda(e)$ is defined. □

We now describe the algorithm for constructing an ϵ_4-contraction $T'(S)$ of $T(S)$. We will build up $T'(S)$ inductively, adding leaves from S one by one. That is, when we have an ϵ_4-contraction $T'(S')$ of a subset S' of S, we will consider a leaf $x \in S-S'$ and build an ϵ_4-contraction $T'(S'\cup\{x\})$ of $T(S'\cup\{x\})$. Initially, $S' = \emptyset$. The precise order in which the leaves are added does not matter, but we will not add a new leaf x unless S' contains a leaf y such that $|\widehat{\mathrm{cov}}(x,y)| \geq (3/4)\epsilon_2$. When we add a new leaf x we will proceed as follows. First, we will consider $T'(S')$, and for every edge $e' = (u', v')$ of $T'(S')$, we will use the method in the following section (section 2.3.1) to estimate $\Lambda(e')$. More specifically, we will let u and v be nodes which are adjacent in $T(S')$ and have $u \in u'$ and $v \in v'$ in the ϵ_4-contraction $T'(S')$. We will show how to estimate $\Lambda(e)$. Afterwards (in section 2.3.2), we will show how to insert x.

2.3.1. Estimating $\Lambda(e)$. In this section, we suppose that we have an MET $M(S')$ on a set S' of leaves, all of which form a single related set. $T(S')$ is the topology of $M(S')$ and $T'(S')$ is an ϵ_4-contraction of $T(S')$. The edge $e' = (u', v')$ is an edge of $T'(S')$. $e = (u, v)$ is the edge of $T(S')$ for which $u \in u'$ and $v \in v'$. We wish to estimate $\Lambda(e)$ within $\pm\epsilon_4/16$. We will ensure that the overall probability that the estimates are not in this range is at most $\delta/(6n)$.

The proof of the following equations is straightforward. We will typically apply them in situations in which z is the error of an approximation:

$$\frac{x+z}{y-z} = \frac{x}{y} + \left(\frac{z}{y-z}\right)\left(1+\frac{x}{y}\right), \tag{5}$$

$$\frac{1+z}{1-z} \leq 1+4z \quad \text{if } z \leq 1/2, \tag{6}$$

$$\frac{1-z}{1+z} \geq 1-2z \quad \text{if } z \geq 0. \tag{7}$$

Case 1*: e' is an internal edge.* We first estimate e_0, e_1, $\Pr(u=0)$, and $\Pr(v=0)$ within $\pm\epsilon_5$ of the correct values. By Observation 9, $\Pr(u=0)$ and $\Pr(v=0)$ are in $[\epsilon_2/2, 1-\epsilon_2/2]$. Thus, our estimate of $\Pr(u=0)$ is within a factor of $(1\pm 2\epsilon_5/\epsilon_2) = (1\pm\epsilon_4 2^{-9})$ of the correct value. Similarly, our estimates of $\Pr(u=1)$, $\Pr(v=0)$, and $\Pr(v=1)$ are within a factor of $(1\pm\epsilon_4 2^{-9})$ of the correct values. Now using (1) we can estimate $\Lambda(e)$ within $\pm\epsilon_4/16$. In particular, our estimate of $\Lambda(e)$ is at most

$$\begin{aligned}
&(w(e)+2\epsilon_5)\sqrt{\frac{\Pr(v=0)\Pr(v=1)}{\Pr(w=0)\Pr(w=1)}}\frac{(1+\epsilon_4 2^{-9})}{(1-\epsilon_4 2^{-9})}\\
&\le (w(e)+2\epsilon_5)\sqrt{\frac{\Pr(v=0)\Pr(v=1)}{\Pr(w=0)\Pr(w=1)}}(1+\epsilon_4 2^{-7})\\
&\le \Lambda(e)+\epsilon_4/16.
\end{aligned}$$

In the inequalities, we used (6) and the fact that $\Lambda(e) \le 1$. Similarly, by (7), our estimate of $\Lambda(e)$ is at least

$$\begin{aligned}
&(w(e)-2\epsilon_5)\sqrt{\frac{\Pr(v=0)\Pr(v=1)}{\Pr(w=0)\Pr(w=1)}}\frac{(1-\epsilon_4 2^{-9})}{(1+\epsilon_4 2^{-9})}\\
&\ge (w(e)-2\epsilon_5)\sqrt{\frac{\Pr(v=0)\Pr(v=1)}{\Pr(w=0)\Pr(w=1)}}(1-\epsilon_4 2^{-8})\\
&\ge \Lambda(e)-\epsilon_4/16.
\end{aligned}$$

We now show how to estimate e_0, e_1, $\Pr(u=0)$, and $\Pr(v=0)$ within $\pm\epsilon_5$. We say that a path from node α to node β in an MET is *strong* if $|\mathrm{cov}(\alpha,\beta)| \ge \epsilon_2/2$. It follows from (3) that if node γ is on this path, then

$$|\mathrm{cov}(\gamma,\beta)| \ge |\mathrm{cov}(\alpha,\beta)|, \tag{8}$$

$$|\mathrm{cov}(\alpha,\beta)| \ge |\mathrm{cov}(\alpha,\gamma)|\,|\mathrm{cov}(\gamma,\beta)|, \tag{9}$$

We say that a quartet $(c,b \mid a,d)$ of leaves a, b, c, and d is a *good estimator* of the edge $e=(u,v)$ if e is an edge of $T(S')$ and the following hold in $T(S')$ (see Figure 1):

1. a is a descendent of v.
2. The undirected path from c to a is strong and passes through u then v.
3. The path from u to its descendent b is strong and only intersects the (undirected) path from c to a at node u.
4. The path from v to its descendent d is strong and only intersects the path from v to a at node v.

We say that $(c,b \mid a,d)$ is an *apparently good estimator* of e' if the following hold in the ϵ_4-contraction $T'(S')$:

1. a is a descendent of v'.
2. The undirected path from c to a is strong and passes through u' then v'.
3. The path from u' to its descendent b is strong and only intersects the (undirected) path from c to a at node u'.
4. The path from v' to its descendent d is strong and only intersects the path from v' to a at node v'.

Observation 12. If e is an edge of $T(S')$ and $(c,b \mid a,d)$ is a good estimator of e, then any leaves $x,y \in \{a,b,c,d\}$ have $|\mathrm{cov}(x,y)| \ge (\epsilon_2/2)^3$.

Proof. The observation follows from (8) and (9) and from the definition of a good estimator. ∎

LEMMA 13. *If $(c,b \mid a,d)$ is a good estimator of e, then it can be used (along with $\mathrm{poly}(n,1/\epsilon,1/\delta)$ samples from $M(S')$) to estimate e_0, e_1, $\Pr(u=0)$, and $\Pr(v=0)$ within $\pm\epsilon_5$. (If we use sufficiently many samples, then the probability that any of the estimates is not within $\pm\epsilon_5$ of the correct value is at most $\delta/(12n^7)$).*

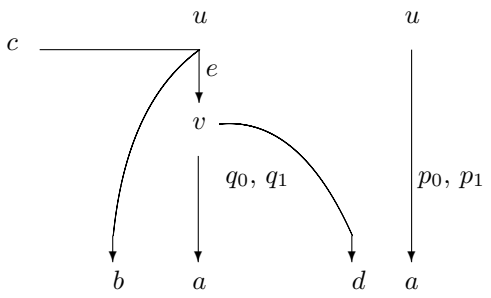

FIG. 1. *Finding* $\Pr(u=1)$, e_0, *and* e_1.

Proof. Let q_0 and q_1 denote the transition probabilities from v to a (see Figure 1) and let p_0 and p_1 denote the transition probabilities from u to a. We will first show how to estimate p_0, p_1, and $\Pr(u=1)$ within $\pm\epsilon_6$. Without loss of generality (by Observation 3) we can assume that c is a descendant of u. (Otherwise we can re-root $T(S')$ at u without changing the distribution on the nodes or p_0 or p_1.) Let β be the path from u to b and let γ be the path from u to c. We now define

$$\begin{aligned}\text{(10)}\qquad \operatorname{cov}(b,c,0) &= \Pr(abc=011)\Pr(a=0)-\Pr(ab=01)\Pr(ac=01),\\ \operatorname{cov}(b,c,1) &= \Pr(abc=111)\Pr(a=1)-\Pr(ab=11)\Pr(ac=11).\end{aligned}$$

(These do not quite correspond to the conditional covariances of b and c, but they are related to these.) We also define

$$\begin{aligned}F &= \frac{1}{2}\left(\frac{\operatorname{cov}(b,c)+\operatorname{cov}(b,c,0)-\operatorname{cov}(b,c,1)}{\operatorname{cov}(b,c)}\right), \text{ and}\\ D &= F^2-\operatorname{cov}(b,c,0)/\operatorname{cov}(b,c).\end{aligned}$$

The following equations can be proved by algebraic manipulation from (10), (2), and the definitions of F and D.

$$\begin{aligned}\text{(11)}\qquad \operatorname{cov}(b,c,0) &= \Pr(u=1)\Pr(u=0)(1-\beta_0-\beta_1)(1-\gamma_0-\gamma_1)p_1(1-p_0),\\ \operatorname{cov}(b,c,1) &= \Pr(u=1)\Pr(u=0)(1-\beta_0-\beta_1)(1-\gamma_0-\gamma_1)p_0(1-p_1),\end{aligned}$$

$$\text{(12)}\qquad F=\frac{1+p_1-p_0}{2},$$

$$\text{(13)}\qquad D=\frac{(1-p_0-p_1)^2}{4}.$$

Case 1a*:* $a\in S_1$. In this case, by (4) and by Observation 10, we have $1-p_0-p_1>0$. Thus, by (13), we have

$$\text{(14)}\qquad \sqrt{D}=\frac{1-p_0-p_1}{2}.$$

Equations (12) and (14) imply

$$\text{(15)}\qquad p_1=F-\sqrt{D},$$

$$\text{(16)}\qquad p_0=1-F-\sqrt{D}.$$

Also, since $\Pr(a=0) = \Pr(u=1)p_1 + (1-\Pr(u=1))(1-p_0)$, we have

$$\Pr(u=1) = \frac{1}{2} + \frac{F - \Pr(a=0)}{2\sqrt{D}}. \tag{17}$$

From these equations, it is clear that we could find p_0, p_1, and $\Pr(u=1)$ if we knew $\Pr(a=0)$, $\mathrm{cov}(b,c)$, $\mathrm{cov}(b,c,0)$, and $\mathrm{cov}(b,c,1)$ exactly. We now show that with polynomially many samples, we can approximate the values of $\Pr(a=0)$, $\mathrm{cov}(b,c)$, $\mathrm{cov}(b,c,0)$, and $\mathrm{cov}(b,c,1)$ sufficiently accurately so that using our approximations and the above equations, we obtain approximations for p_0, p_1, and $\Pr(u=1)$ which are within $\pm\epsilon_6$. As in the proof of Lemma 6, we can use (2) and (10) to estimate $\Pr(a=0)$, $\mathrm{cov}(b,c)$, $\mathrm{cov}(b,c,0)$, and $\mathrm{cov}(b,c,1)$ within $\pm\epsilon'$ for any ϵ' whose inverse is at most a polynomial in n and $1/\epsilon$. Note that our estimate of $\mathrm{cov}(b,c)$ will be nonzero by Observation 12 (as long as $\epsilon' \le (\epsilon_2/2)^3$), so we will be able to use it to estimate F from its definition. Now, using the definition of F and (5), our estimate of $2F$ is at most

$$2F + \frac{3\epsilon'}{\mathrm{cov}(b,c) - 3\epsilon'}(1+2F).$$

By Observation 12, this is at most

$$2F + \frac{3\epsilon'}{(\epsilon_2/2)^3 - 3\epsilon'}(1+2). \tag{18}$$

The error is at most ϵ'' for any ϵ'' whose is inverse is at most polynomial in n and $1/\epsilon$. (This is accomplished by making ϵ' small enough with respect to ϵ_2 according to (18).) We can similarly bound the amount that we underestimate F. Now we use the definition of D to estimate D. Our estimate is at most

$$(F+\epsilon'')^2 - \frac{\mathrm{cov}(b,c,0) - \epsilon'}{\mathrm{cov}(b,c) + \epsilon'}.$$

Using (5), this is at most

$$D + 2\epsilon'' F + \epsilon''^2 + \frac{\epsilon'}{\mathrm{cov}(b,c)+\epsilon'}\left(1 + \frac{\mathrm{cov}(b,c,0)}{\mathrm{cov}(b,c)}\right).$$

Once again, by Observation 12, the error can be made within $\pm\epsilon'''$ for any ϵ''' whose inverse is polynomial in n and $1/\epsilon$ (by making ϵ' and ϵ'' sufficiently small). It follows that our estimate of $\sqrt{D}$ is at most $\sqrt{D}(1+\epsilon'''/(2D))$ and (since Observation 12 gives us an upper bound on the value of D as a function of ϵ_2), we can estimate $\sqrt{D}$ within $\pm\epsilon''''$ for any ϵ'''' whose inverse is polynomial in n and $1/\epsilon$. This implies that we can estimate p_0 and p_1 within $\pm\epsilon_6$. Observation 12 and (3) imply that $w(p) \ge (\epsilon_2/2)^3$. Thus, the estimate for $\sqrt{D}$ is nonzero. This implies that we can similarly estimate $\Pr(u=1)$ within $\pm\epsilon_6$ using (17).

Now that we have estimates for p_0, p_1, and $\Pr(u=1)$ which are within $\pm\epsilon_6$ of the correct values, we can repeat the trick to find estimates for q_0 and q_1 which are also within $\pm\epsilon_6$. We use leaf d for this. Observation 4 implies that

$$e_0 = \frac{p_0 - q_0}{1 - q_0 - q_1} \text{ and } e_1 = \frac{p_1 - q_1}{1 - q_0 - q_1}.$$

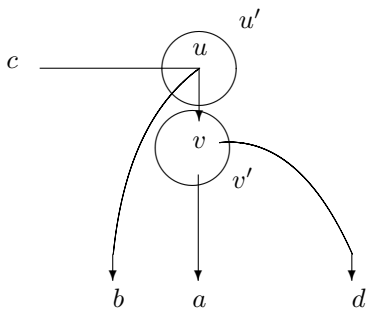

FIG. 2. $(c, b \mid a, d)$ *is a good estimator of* $e = (u, v)$ *and an apparently good estimator of* $e' = (u', v')$.

Using these equations, our estimate of e_0 is at most

$$\frac{p_0 - q_0 + 2\epsilon_6}{1 - q_0 - q_1 - 2\epsilon_6}.$$

Equation (5) and our observation above that $w(p) \geq (\epsilon_2/2)^3$ imply that the error is at most

$$\frac{2\epsilon_6}{(\epsilon_2/2)^3 - 2\epsilon_6}\left(1 + \frac{p_0 - q_0}{1 - q_0 - q_1}\right),$$

which is at most $2^7\epsilon_6/\epsilon_2^3 = \epsilon_5$. Similarly, the estimate for e_0 is at least $e_0 - \epsilon_5$ and the estimate for e_1 is within $\pm\epsilon_5$ of e_1. We have now estimated e_0, e_1, and $\Pr(u = 0)$ within $\pm\epsilon_5$. As we explained in the beginning of this section, we can use these estimates to estimate $\Lambda(e)$ within $\pm\epsilon_4/16$.

Case 1b*:* $a \in S_2$. In this case, by (4) and by Observation 10, we have $1 - p_0 - p_1 < 0$. Thus, by (13), we have

$$\sqrt{D} = -\left(\frac{1 - p_0 - p_1}{2}\right). \tag{19}$$

Equations (12) and (19) imply

$$p_1 = F + \sqrt{D}, \tag{20}$$

$$p_0 = 1 - F + \sqrt{D}. \tag{21}$$

Equation (17) remains unchanged. The process of estimating p_0, p_1, and $\Pr(u = 1)$ (from the new equations) is the same as for Case 1a. This concludes the proof of Lemma 13. □

Observation 14. Suppose that e' is an edge from u' to v' in $T'(S')$ and that $e = (u, v)$ is the edge in $T(S')$ such that $u \in u'$ and $v \in v'$. There is a good estimator $(c, b \mid a, d)$ of e. Furthermore, every good estimator of e is an apparently good estimator of e'. (Refer to Figure 2.)

Proof. Leaves c and a can be found to satisfy the first two criteria in the definition of a good estimator by Observation 8. Leaf b can be found to satisfy the third criterion by Observation 8 and (8) and by the fact that the degree of u is at least 3 (see the

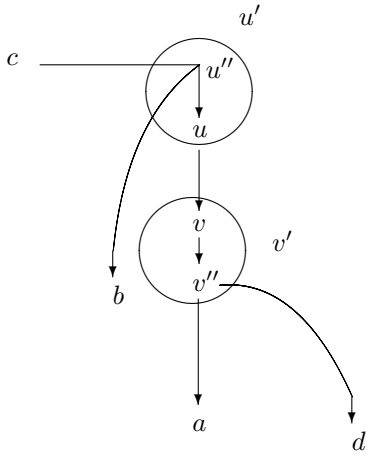

FIG. 3. $(c, b \mid a, d)$ *is an apparently good estimator of* $e' = (u', v')$ *and a good estimator of* $p = (u'', v'')$. $\Lambda(p) \leq \Lambda(u, v)$.

text just before (4)). Similarly, leaf d can be found to satisfy the fourth criterion. $(c, b \mid a, d)$ is an apparently good estimator of e' because only internal edges of $T(S')$ can be contracted in the ϵ_4-contraction $T'(S')$. □

Observation 15. Suppose that e' is an edge from u' to v' in $T'(S')$ and that $e = (u, v)$ is an edge in $T(S')$ such that $u \in u'$ and $v \in v'$. Suppose that $(c, b \mid a, d)$ is an apparently good estimator of e'. Let u'' be the meeting point of c, b, and a in $T(S')$. Let v'' be the meeting point of c, a, and d in $T(S')$. (Refer to Figure 3.) Then $(c, b \mid a, d)$ is a good estimator of the path p from u'' to v'' in $T(S')$. Also, $\Lambda(p) \leq \Lambda(e)$.

Proof. The fact that $(c, b \mid a, d)$ is a good estimator of p follows from the definition of good estimator. The fact that $\Lambda(p) \leq \Lambda(e)$ follows from the fact that the distances Λ are multiplicative along a path, and bounded above by 1. □

Observations 14 and 15 imply that in order to estimate $\Lambda(e)$ within $\pm\epsilon_4/16$, we need only estimate $\Lambda(e)$ using each apparently good estimator of e' and then take the maximum. By Lemma 13, the failure probability for any given estimator is at most $\delta/(12n^7)$, so with probability at least $1 - \delta/(12n^3)$, all estimators give estimates within $\pm\epsilon_4/16$ of the correct values. Since there are at most $2n$ edges e' in $T'(S')$, and we add a new leaf x to S' at most n times, all estimates are within $\pm\epsilon_4/16$ with probability at least $1 - \delta/(6n)$.

Case 2*: e' is not an internal edge.* In this case $v = v'$ since v' is a leaf of $T(S')$. We say that a pair of leaves (b, c) is a good estimator of e if the following holds in $T(S')$: The paths from leaves v, b, and c meet at u and $|\mathrm{cov}(v, b)|$, $|\mathrm{cov}(v, c)|$, and $|\mathrm{cov}(b, c)|$ are all at least $(\epsilon_2/2)^2$. We say that (b, c) is an apparently good estimator of e' if the following holds in $T'(S')$: The paths from leaves v, b, and c meet at u' and $|\mathrm{cov}(v, b)|$, $|\mathrm{cov}(v, c)|$, and $|\mathrm{cov}(b, c)|$ are all at least $(\epsilon_2/2)^2$. As in the previous case, the result follows from the following observations.

Observation 16. If (b, c) is a good estimator of e then it can be used (along with $\mathrm{poly}(n, 1/\epsilon, 1/\delta)$ samples from $M(S')$) to estimate e_0, e_1, and $\Pr(u = 0)$ within $\pm\epsilon_5$.

(The probability that any of the estimates is not within $\pm\epsilon_5$ of the correct value is at most $\delta/(12n^3)$.)

Proof. This follows from the proof of Lemma 13. □

Observation 17. Suppose that e' is an edge from u' to leaf v in $T'(S')$ and that $e = (u, v)$ is an edge in $T(S')$ such that $u \in u'$. There is a good estimator (b, c) of e. Furthermore, every good estimator of e is an apparently good estimator of e'.

Proof. This follows from the proof of Observation 14 and from (9). □

Observation 18. Suppose that e' is an edge from u' to leaf v in $T'(S')$ and that $e = (u, v)$ is an edge in $T(S')$ such that $u \in u'$. Suppose that (b, c) is an apparently good estimator of e'. Let u'' be the meeting point of b, v, and c in $T(S')$. Then (b, c) is a good estimator of the path p from u'' to v in $T(S')$. Also, $\Lambda(p) \leq \Lambda(e)$.

Proof. This follows from the proof of Observation 15. □

2.3.2. Using the estimates of $\Lambda(e)$. We now return to the problem of showing how to add a new leaf x to $T'(S')$. As we indicated above, for every internal edge $e' = (u', v')$ of $T'(S')$, we use the method in section 2.3.1 to estimate $\Lambda(e)$ where $e = (u, v)$ is the edge of $T(S')$ such that $u \in u'$ and $v \in v'$. If the observed value of $\Lambda(e)$ exceeds $1 - 15\epsilon_4/16$, then we will contract e. The accuracy of our estimates will guarantee that we will not contract e if $\Lambda(e) \leq 1 - \epsilon_4$, and that we definitely contract e if $\Lambda(e) > 1 - 7\epsilon_4/8$. We will then add the new leaf x to $T'(S')$ as follows. We will insert a new edge (x, x') into $T'(S')$. We will do this by either (i) identifying x' with a node already in $T'(S')$, or (ii) splicing x' into the middle of some edge of $T'(S')$.

We will now show how to decide where to attach x' in $T'(S')$. We start with the following definitions. Let S'' be the subset of S' such that for every $y \in S''$ we have $|\mathrm{cov}(x, y)| \geq (\epsilon_2/2)^4$. Let T'' be the subtree of $T'(S')$ induced by the leaves in S''. Let S''' be the subset of S' such that for every $y \in S'''$ we have $|\widehat{\mathrm{cov}}(x, y)| \geq (\epsilon_2/2)^4 - \epsilon_3$. Let T''' be the subtree of $T'(S')$ induced by the leaves in S'''.

Observation 19. If $T(S' \cup \{x\})$ has x' attached to an edge $e = (u, v)$ of $T(S')$ and e' is the edge corresponding to e in $T'(S')$ (that is, $e' = (u', v')$, where $u \in u'$ and $v \in v'$), then e' is an edge of T''.

Proof. By Observation 14 there is a good estimator $(c, b \mid a, d)$ for e. Since x is being added to S' (using (8)), $|\mathrm{cov}(x, x')| \geq \epsilon_2/2$. Thus, by Observation 12 and (9), every leaf $y \in \{a, b, c, d\}$ has $|\mathrm{cov}(x, y)| \geq (\epsilon_2/2)^4$. Thus, a, b, c, and d are all in S'' so e' is in T''. □

Observation 20. If $T(S' \cup \{x\})$ has x' attached to an edge $e = (u, v)$ of $T(S')$ and u and v are both contained in node u' of $T'(S')$ then u' is a node of T''.

Proof. Since u is an internal node of $T(S')$, it has degree at least 3. By Observation 8 and (8), there are three leaves a_1, a_2, and a_3 meeting at u with $|\mathrm{cov}(u, a_i)| \geq \epsilon_2/2$. Similarly, $|\mathrm{cov}(u, v)| \geq \epsilon_2/2$. Thus, for each a_i, $|\mathrm{cov}(x, a_i)| \geq (\epsilon_2/2)^3$ so a_1, a_2, and a_3 are in S''. □

Observation 21. $S'' \subseteq S'''$.

Proof. This follows from the accuracy of the covariance estimates in Step 1. □

We will use the following algorithm to decide where to attach x' in T'''. In the algorithm, we will use the following tool. For any triple (a, b, c) of leaves in $S' \cup \{x\}$, let u denote the meeting point of the paths from leaves a, b, and c in $T(S' \cup \{x\})$. Let M^u be the MET which has the same distribution as $M(S' \cup \{x\})$, but is rooted at u. (M^u exists, by Observation 3.) Let $\Lambda_c(a, b, c)$ denote the weight of the path from u to c in M^u. By observation 11, $\Lambda_c(a, b, c)$ is equal to the weight of the path from u to c in $M(S' \cup \{x\})$. (This follows from the fact that re-rooting at u only redirects

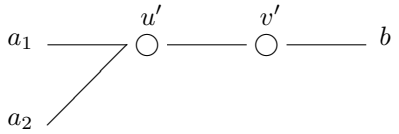

FIG. 4. *The setting for Test* $1(u', v', a_1, a_2, b)$ *and Test* $2(u', v', a_1, a_2, b)$ *when* v' *is an internal node of* T'''. *(If* v' *is a leaf, we perform the same tests with* $v' = b$.*)*

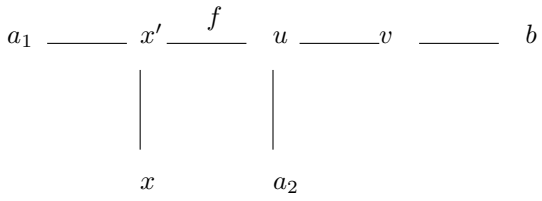

FIG. 5. *Either Test* $1(u', v', a_1, a_2, b)$ *fails or Test* $2(u', v', a_1, a_2, b)$ *fails.*

internal edges.) It follows from the definition of Λ (as in (1)) and from (3) that

$$\Lambda_c(a, b, c) = \sqrt{\frac{\mathrm{cov}(a, c)\mathrm{cov}(b, c)}{\mathrm{cov}(a, b)}}. \tag{22}$$

If a, b, and c are in $S''' \cup \{x\}$, then by the accuracy of the covariance estimates and (8) and (9), the absolute value of the pairwise covariance of any pair of them is at least $\epsilon_2^8/2^{10}$. As in section 2.3.1, we can estimate $\mathrm{cov}(a, c)$, $\mathrm{cov}(b, c)$, and $\mathrm{cov}(a, b)$ within a factor of $(1 \pm \epsilon')$ of the correct values for any ϵ' whose inverse is at most a polynomial in n, and $1/\epsilon$. Thus, we can estimate $\Lambda_c(a, b, c)$ within a factor of $(1 \pm \epsilon_4/16)$ of the correct value. We will take sufficiently many samples to ensure that the probability that any of the estimates is outside of the required range is at most $\delta/(6n^2)$. Thus, the probability that any estimate is outside of the range for any x is at most $\delta/(6n)$.

We will now determine where in T''' to attach x'. Choose an arbitrary internal root u' of T'''. We will first see where x' should be placed with respect to u'. For each neighbor v' of u' in T''', each pair of leaves (a_1, a_2) on the "u'" side of (u', v'), and each leaf b on the "v'" side of (u', v') (see Figure 4), perform the following two tests.

- *Test* $1(u', v', a_1, a_2, b)$: The test succeeds if the observed value of $\Lambda_x(a_1, x, b)/\Lambda_x(a_2, x, b)$ is at least $1 - \epsilon_4/4$.
- *Test* $2(u', v', a_1, a_2, b)$: The test succeeds if the observed value of $\Lambda_b(a_1, a_2, b)/\Lambda_b(a_1, x, b)$ is at most $1 - 3\epsilon_4/4$.

We now make the following observations.

Observation 22. If x is on the "u side" of (u, v) in $T(S''' \cup \{x\})$ and u is in u' in T''' and v is in $v' \neq u'$ in T''' then some test fails.

Proof. Since u' is an internal node of T''', it has degree at least 3. Thus, we can construct a test such as the one depicted in Figure 5. (If $x' = u$ then the figure is still correct; that would just mean that $\Lambda(f) = 1$. Similarly, if v' is a leaf, we simply have $\Lambda(f') = 1$ where f' is the edge from v to b.) Now we have

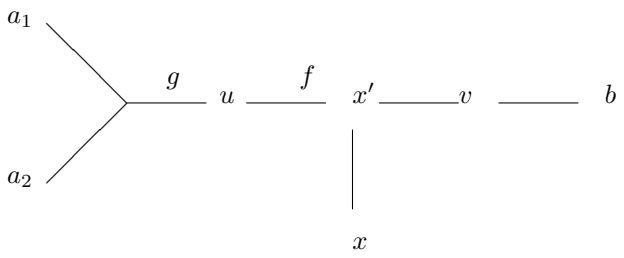

FIG. 6. *Test* $1(u', v', a_1, a_2, b)$ *and Test* $2(u', v', a_1, a_2, b)$ *succeed for all choices of* a_1, a_2, *and* b.

$$\frac{1}{\Lambda(f)} = \frac{\Lambda_x(a_1, x, b)}{\Lambda_x(a_2, x, b)} = \frac{\Lambda_b(a_1, a_2, b)}{\Lambda_b(a_1, x, b)}.$$

However, Test $1(u', v', a_1, a_2, b)$ will succeed only if the left hand fraction is at least $1 - \epsilon_4/4$. Furthermore, Test $2(u', v', a_1, a_2, b)$ will only succeed if the right hand fraction is at most $1 - 3\epsilon_4/4$. Since our estimates are accurate to within a factor of $(1 \pm \epsilon_4/16)$, at least one of the two tests will fail. □

Observation 23. If x is between u and v in $T(S''' \cup \{x\})$ and the edge f from u to x' has $\Lambda(f) \leq 1 - 7\epsilon_4/8$ then Test $1(u', v', a_1, a_2, b)$ and Test $2(u', v', a_1, a_2, b)$ succeed for all choices of a_1, a_2, and b.

Proof. Every such test has the form depicted in Figure 6, where again g might be degenerate, in which case $\Lambda(g) = 1$. Observe that $\Lambda_x(a_1, x, b)/\Lambda_x(a_2, x, b) = 1$, so its estimate is at least $1 - \epsilon_4/4$ and Test 1 succeeds. Furthermore,

$$\frac{\Lambda_b(a_1, a_2, b)}{\Lambda_b(a_1, x, b)} = \Lambda(f)\Lambda(g) \leq \Lambda(f) \leq 1 - 7\epsilon_4/8,$$

so the estimate is at most $1 - 3\epsilon_4/4$ and Test 2 succeeds. □

Observation 24. If x is on the "v side" of (u, v) in $T(S''' \cup \{x\})$ and $\Lambda(e) \leq 1 - 7\epsilon_4/8$ (recall from the beginning of section 2.3.2 that $\Lambda(e)$ *is* at most $1 - 7\epsilon_4/8$ if u and v are in different nodes of T'''), then Test $1(u', v', a_1, a_2, b)$ and Test $2(u', v', a_1, a_2, b)$ succeed for all choices of a_1, a_2, and b.

Proof. Note that this case only applies if v is an internal node of $T(S''')$. Thus, every such test has one of the forms depicted in Figure 7, where some edges may be degenerate. Observe that in both cases $\Lambda_x(a_1, x, b)/\Lambda_x(a_2, x, b) = 1$, so its estimate is at least $1 - \epsilon_4/4$ and Test 1 succeeds. Also in both cases

$$\frac{\Lambda_b(a_1, a_2, b)}{\Lambda_b(a_1, x, b)} = \Lambda(e)\Lambda(f)\Lambda(g) \leq \Lambda(e) \leq 1 - 7\epsilon_4/8,$$

so the estimate is at most $1 - 3\epsilon_4/4$ and Test 2 succeeds. □

Now note (using Observation 22) that node u' has at most one neighbor v' for which all tests succeed. Furthermore, if there is no such v', Observations 23 and 24 imply that x' can be merged with u'. The only case that we have not dealt with is the case in which there is exactly one v' for which all tests succeed. In this case, if v' is a leaf, we insert x' in the middle of edge (u', v'). Otherwise, we will either insert x' in the middle of edge (u', v'), or we will insert it in the subtree rooted at v'. In order to decide which, we perform similar tests from node v', and we check whether Test $1(v', u', a_1, a_2, b)$ and Test $2(v', u', a_1, a_2, b)$ both succeed for all choices of a_1, a_2, and b. If so, we put x' in the middle of edge (u', v'). Otherwise, we recursively place x' in the subtree rooted at v'.

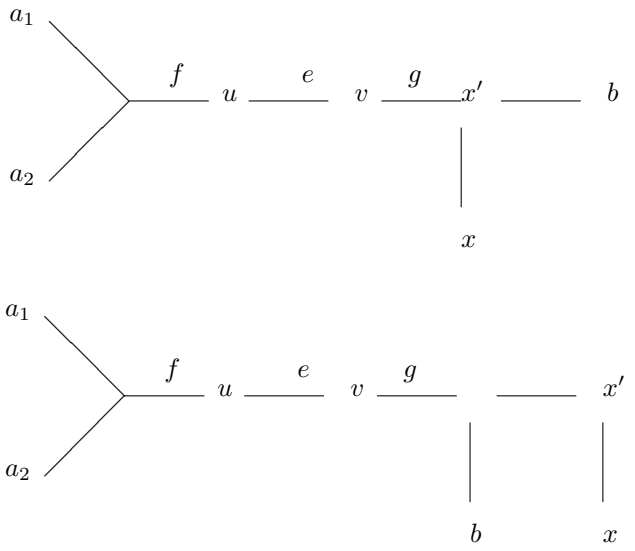

FIG. 7. *Test* $1(u', v', a_1, a_2, b)$ *and Test* $2(u', v', a_1, a_2, b)$ *succeed for all choices of* a_1, a_2, *and* b.

2.4. Step 4: For each related set S, construct an MET $M'(S)$ which is close to $M(S)$. For each set S of related leaves we will construct an MET $M'(S)$ with leaf-set S such that each edge parameter of $M'(S)$ is within $\pm\epsilon_1$ of the corresponding parameter of $M(S)$. The topology of $M'(S)$ will be $T'(S)$. We will assume without loss of generality that $T(S)$ has the same root as $T'(S)$. The failure probability for S will be at most $\delta/(3n)$, so the overall failure will be at most $\delta/3$.

We start by observing that the problem is easy if S has only one or two leaves.

Observation 25. If $|S| < 3$ then we can construct an MET $M'(S)$ such that each edge parameter of $M'(S)$ is within $\pm\epsilon_1$ of the corresponding parameter of $M(S)$.

We now consider the case in which S has at least three leaves. Any edge of $T(S)$ which is contracted in $T'(S)$ can be regarded as having e_0 and e_1 set to 0. The fact that these are within $\pm\epsilon_1$ of their true values follows from the following lemma.

LEMMA 26. *If e is an internal edge of $M(S)$ from v to w with $\Lambda(e) > 1 - \epsilon_4$ then* $e_0 + e_1 < 2\epsilon_4 = \epsilon_1/(2n)$.

Proof. First observe from Observation 9 that $\Pr(w = 0) \notin \{0, 1\}$ and from Observation 10 that $e_0 + e_1 \neq 1$. Using algebraic manipulation, one can see that

$$\Pr(v = 1) = \frac{\Pr(w = 1) - e_0}{1 - e_0 - e_1},$$
$$\Pr(v = 0) = \frac{\Pr(w = 0) - e_1}{1 - e_0 - e_1}.$$

Thus, by (1),

$$\Lambda(e)^2 = \left(1 - \frac{e_0}{\Pr(w = 1)}\right)\left(1 - \frac{e_1}{\Pr(w = 0)}\right).$$

Since $\Lambda(e)^2 \geq 1 - 2\epsilon_4$, we have $e_0 \leq 2\epsilon_4 \Pr(w = 1)$ and $e_1 \leq 2\epsilon_4 \Pr(w = 0)$, which proves the observation. □

Thus, we need only show how to label the remaining parameters within $\pm\epsilon_1$. Note that we have already shown how to do this in section 2.3.1. Here the total failure

probability is at most $\delta/(3n)$ because there is a failure probability of at most $\delta/(6n^2)$ associated with each of the $2n$ edges.

2.5. Step 5: Form M' from the METs $M'(S)$. Make a new root r for M' and set $\Pr(r=1)=1$. For each related set S of leaves, let u denote the root of $M'(S)$, and let $\overline{p}$ denote the probability that u is 0 in the distribution of $M'(S)$. Make an edge e from r to u with $e_1=\overline{p}$.

2.6. Proof of Theorem 1. Let M'' be an MET which is formed from M as follows.

- Related sets are formed as in Step 2.
- For each related set S, a copy $M''(S)$ of $M(S)$ is made.
- The METs $M''(S)$ are combined as in Step 5.

Theorem 1 follows from the following lemmas.

LEMMA 27. *Suppose that for every set S of related leaves, every parameter of $M'(S)$ is within $\pm\epsilon_1$ of the corresponding parameter in $M(S)$. Then* $\mathrm{var}(M'',M')\le\epsilon/2$.

Proof. First, we observe (using a crude estimate) that there are at most $5n^2$ parameters in M'. (Each of the (at most n) METs $M'(S)$ has one root parameter and at most $4n$ edge parameters.) We will now show that changing a single parameter of a MET by at most $\pm\epsilon_1$ yields at MET whose variation distance from the original is at most $2\epsilon_1$. This implies that $\mathrm{var}(M'',M')\le 10n^2\epsilon_1=\epsilon/2$. Suppose that e is an edge from u to v and e_0 is changed. The probability that the output has string s on the leaves below v and string s' on the remaining leaves is

$$\begin{aligned}&\Pr(u=0)\Pr(s'\mid u=0)(e_0\Pr(s\mid v=1)+(1-e_0)\Pr(s\mid v=0))\\ &+\Pr(u=1)\Pr(s'\mid u=1)(e_1\Pr(s\mid v=0)+(1-e_1)\Pr(s\mid v=1)).\end{aligned}$$

Thus, the variation distance between M'' and an MET obtained by changing the value of e_0 (within $\pm\epsilon_1$) is at most

$$\begin{aligned}&\epsilon_1\sum_s\sum_{s'}\Pr(u=0)\Pr(s'\mid u=0)(\Pr(s\mid v=1)+\Pr(s\mid v=0))\\ &\le\epsilon_1\Pr(u=0)\left(\sum_{s'}\Pr(s'\mid u=0)\right)\left(\left(\sum_s\Pr(s\mid v=1)\right)+\left(\sum_s\Pr(s\mid v=0)\right)\right)\\ &\le 2\epsilon_1.\end{aligned}$$

Similarly, if ρ_1 is the root parameter of an MET then the probability of having output s is

$$\rho_1\Pr(s\mid r=1)+(1-\rho_1)\Pr(s\mid r=0).$$

So the variation distance between the original MET and one in which ρ_1 is changed within $\pm\epsilon_1$ is at most

$$\sum_s\epsilon_1(\Pr(s\mid r=1)+\Pr(s\mid r=0))\le 2\epsilon_1. \qquad \square$$

LEMMA 28. $\mathrm{var}(M'',M)\le\epsilon/2$.

Before we prove Lemma 28, we provide some background material. Recall that the *weight* $w(e)$ of an edge e of an MET is $|1-e_0-e_1|$ and define the weight $w(\ell)$ of

a leaf ℓ to be the product of the weights of the edges on the path from the root to ℓ. We will use the following lemma.

LEMMA 29. *In any MET with root r, the variation distance between the distribution on the leaves conditioned on $r = 1$ and the distribution on the leaves conditioned on $r = 0$ is at most $2\sum_\ell w(\ell)$, where the sum is over all leaves ℓ.*

Proof. We proceed by induction on the number of edges in the MET. In the base case there are no edges so r is a leaf, and the result holds. For the inductive step, let e be an edge from r to node x. For any string s_1 on the leaves below x and any string s_2 on the other leaves,

$$\Pr(s_1 s_2 \mid r = 0) = \Pr(s_2 \mid r = 0)(e_0 \Pr(s_1 \mid x = 1) + (1 - e_0)\Pr(s_1 \mid x = 0)).$$

Algebraic manipulation of this formula shows that $\Pr(s_1 s_2 \mid r = 1) - \Pr(s_1 s_2 \mid r = 0)$ is

$$\begin{aligned}&(1 - e_0 - e_1)\Pr(s_2 \mid r = 1)\,(\Pr(s_1 \mid x = 1) - \Pr(s_1 \mid x = 0))\\ &+ \Pr(s_1 \mid r = 0)\,(\Pr(s_2 \mid r = 1) - \Pr(s_2 \mid r = 0)).\end{aligned} \tag{23}$$

It follows that the variation distance is at most the sum over all $s_1 s_2$ of the absolute value of the quantity in (23), which is at most

$$\begin{aligned}&|1 - e_0 - e_1| \left(\sum_{s_2} \Pr(s_2 \mid r = 1)\right)\left(\sum_{s_1} |\Pr(s_1 \mid x = 1) - \Pr(s_1 \mid x = 0)|\right)\\ &+ \left(\sum_{s_1} \Pr(s_1 \mid r = 0)\right)\left(\sum_{s_2} |\Pr(s_2 \mid r = 1) - \Pr(s_2 \mid r = 0)|\right).\end{aligned}$$

The result follows by induction. □

LEMMA 30. *Suppose that m is an MET with n leaves and that e is an edge from node u to node v. Let m' be the MET derived from m by replacing e_0 with $\Pr(v = 1)$ and e_1 with $\Pr(v = 0)$. Then $\mathrm{var}(m, m') \le n^2 z$, where z is the maximum over all pairs (x, y) of leaves which are connected via e in m of $|\mathrm{cov}(x, y)|$.*

Proof. By Observation 3, we can assume without loss of generality that u is the root of m. For any string s_1 on the leaves below v and any string s_2 on the remaining leaves, we find (via a little algebraic manipulation) that the difference between the probability that m outputs $s_1 s_2$ and the probability that m' does is

$$\begin{aligned}&\Pr(u = 1)\Pr(u = 0)(1 - e_0 - e_1)(\Pr(s_2 \mid u = 1)\\ &-\ \Pr(s_2 \mid u = 0))(\Pr(s_1 \mid v = 1) - \Pr(s_1 \mid v = 0)).\end{aligned}$$

Thus, the variation distance between m and m' is $\Pr(u = 1)\Pr(u = 0)(1 - e_0 - e_1)$ times the product of the variation distance between the distribution on the leaves below v conditioned on $v = 1$ and the distribution on the leaves below v conditioned on $v = 0$ and the variation distance between the distribution on the remaining leaves conditioned on $u = 1$ and the distribution on the remaining leaves conditioned on $u = 0$. By Lemma 29, this is at most

$$\Pr(u = 0)\Pr(u = 1)\left(2\sum_{\ell \text{ below } v} w(\ell)\right)\left(2\sum_{\text{other } \ell} w(\ell)\right),$$

which by (3) is

$$4 \sum_{(x,y) \text{ connected via } e} |\mathrm{cov}(x,y)|,$$

which is at most $4(n/2)^2 z = n^2 z$. □

LEMMA 31. *If, for two different related sets, S and S', an edge e from u to v is in $M(S)$ and in $M'(S)$, then $e_0 + e_1 \leq n^2\epsilon_2/(n+1)$.*

Proof. By the definition of the leaf connectivity graph in Step 2, there are leaves $a, a' \in S$ and $b, b' \in S'$ such that the path from a' to a and the path from b' to b both go through $e = u \to v$ and

$$|\widehat{\mathrm{cov}}(a,a')| \geq (3/4)\epsilon_2 \quad \text{and} \quad |\widehat{\mathrm{cov}}(b,b')| \geq (3/4)\epsilon_2,$$

and the remaining covariance estimates amongst leaves a, a', b, and b' are less than $(3/4)\epsilon_2$. Without loss of generality (using Observation 3), assume that u is the root of the MET. Let $p_{u,a'}$ denote the path from u to a' and use similar notation for the other leaves. By (3) and the accuracy of the estimates in Step 1,

$$\begin{aligned}
\Pr(u=0)^2 \Pr(u=1)^2 w(e)^2 w(p_{u,a'}) w(p_{v,a}) w(p_{u,b'}) w(p_{v,b}) &\geq ((3/4)\epsilon_2 - \epsilon_3)^2, \\
\Pr(u=0)\Pr(u=1) w(p_{u,a'}) w(p_{u,b'}) &< (3/4)\epsilon_2 + \epsilon_3, \\
\Pr(v=0)\Pr(v=1) w(p_{v,a}) w(p_{v,b}) &< (3/4)\epsilon_2 + \epsilon_3.
\end{aligned}$$

Thus,

$$w(e) \geq \left(1 - \frac{2\epsilon_3}{(3/4)\epsilon_2 + \epsilon_3}\right) \sqrt{\frac{\Pr(v=1)\Pr(v=0)}{\Pr(u=1)\Pr(u=0)}}.$$

By (1),

$$\Lambda(e) \geq 1 - \frac{2\epsilon_3}{(3/4)\epsilon_2 + \epsilon_3}.$$

The result now follows from the proof of Lemma 26. (Clearly, the bound in the statement of Lemma 31 is weaker than we can prove, but it is all that we will need.) □

Proof of Lemma 28. Let M^* be the MET which is the same as M except that every edge e which is contained in $M(S)$ and $M(S')$ for two different related sets S and S' is contracted. Similarly, let M''^* be the MET which is the same as M'' except that every such edge has *all* of its copies contracted in M''^*. Clearly, $\mathrm{var}(M, M'') \leq \mathrm{var}(M, M^*) + \mathrm{var}(M^*, M''^*) + \mathrm{var}(M''^*, M'')$. Lemma 31 then implies that $\mathrm{var}(M, M^*) + \mathrm{var}(M''^*, M'') \leq \ell n^2 \epsilon_2$, where ℓ is the number of edges in M that are contracted. We now wish to bound $\mathrm{var}(M^*, M''^*)$. By construction, $M^*(S)$ and $M^*(S')$ do not intersect in an edge (for any related sets S and S'). Now suppose that $M^*(S)$ and $M^*(S')$ both contain node u. We can modify M^* *without changing the distribution* in a way that avoids this overlap. To do this, we just replace node u with two copies of u, and we connect the two copies by an edge e with $e_0 = e_1 = 0$. Note that this change will not affect the operation of the algorithm. Thus, without loss of generality, we can assume that for any related sets S and S', $M^*(S)$ and $M^*(S')$ do not intersect. Thus, M^* and M''^* are identical, except on edges which go between the

sub-METs $M^*(S)$. Now, any edge e going between two sub-METs has the property that for any pair of leaves, x and y connected via e, $|\mathrm{cov}(x,y)| \le \epsilon_2$. (This follows from the accuracy of our covariance estimates in Step 1.) Thus, by Lemma 30, changing such an edge according to Step 5 adds at most $n^2\epsilon_2$ to the variation distance. Thus, $\mathrm{var}(M^*, M''^*) \le \ell' n^2 \epsilon_2$, where ℓ' is the number of edges that are modified according to Step 5. We conclude that $\mathrm{var}(M, M'') \le (2n)n^2\epsilon_2 = \epsilon_1/2 \le \epsilon/2$. □

3. Appendix.

3.1. Proof of Lemma 2.

LEMMA 2. *A class of probability distributions over the domain $\{0,1\}^n$ that is PAC-learnable under the variation distance metric is PAC-learnable under the KL-distance measure.*

Proof. Let K be a polynomial in three inputs and let A be an algorithm which takes as input $K(n, 1/\epsilon, 1/\delta)$ samples from a distribution $\mathcal{D}$ from the class of distributions and, with probability at least $1-\delta$, returns a distribution $\mathcal{D}'$ such that $\mathrm{var}(\mathcal{D}, \mathcal{D}') \le \epsilon$. Without loss of generality, we can assume that ϵ is sufficiently small. For example, it will suffice to have $\epsilon \le 2/15$.

Define algorithm A' as follows. Let $\xi = \epsilon^2/(12n)$. Run A with sample size $K(n, 1/\xi, 1/\delta)$. (Note that the sample size is polynomial in n, $1/\epsilon$, and $1/\delta$.) Let $\mathcal{D}'$ be the distribution returned by A. Let $\mathcal{U}$ denote the uniform distribution on $\{0,1\}^n$ and let $\mathcal{D}''$ be the distribution defined by

$$\mathcal{D}''(s) = (1 - (\xi))\mathcal{D}'(s) + \xi\,\mathcal{U}(s).$$

With probability at least $1-\delta$, $\mathrm{var}(\mathcal{D}, \mathcal{D}') \le \xi$. By definition of $\mathcal{D}''$, $\mathrm{var}(\mathcal{D}', \mathcal{D}'') \le 2\xi$. Thus, with probability at least $1-\delta$, $\mathrm{var}(\mathcal{D}, \mathcal{D}'') < 3\xi$. Note that for all s, $\mathcal{D}''(s) \ge \xi\, 2^{-n}$. Let S be the set of all output strings s satisfying $\mathcal{D}''(s) < \mathcal{D}(s)$. S contains all the strings which contribute positively to the KL-distance from $\mathcal{D}$ to $\mathcal{D}''$. Thus,

$$\begin{aligned}\mathrm{KL}(\mathcal{D}, \mathcal{D}'') &\le \sum_{s\in S} \mathcal{D}(s)(\log \mathcal{D}(s) - \log \mathcal{D}''(s)) \\ &= \sum_{s\in S} (\mathcal{D}(s) - \mathcal{D}''(s))(\log \mathcal{D}(s) - \log \mathcal{D}''(s)) + \sum_{s\in S} \mathcal{D}''(s)(\log \mathcal{D}(s) - \log \mathcal{D}''(s)).\end{aligned}$$

We have seen that $\mathrm{var}(\mathcal{D}, \mathcal{D}'') \le 3\xi$. Thus, $\sum_{s\in S}(\mathcal{D}(s) - \mathcal{D}''(s)) \le 3\xi$. So, the first term is at most

$$\begin{aligned}&\max_{s\in S}(\log \mathcal{D}(s) - \log \mathcal{D}''(s)) \sum_{s\in S}(\mathcal{D}(s) - \mathcal{D}''(s)) \\ &\le 3\xi \max_{s\in S}(\log \mathcal{D}(s) - \log \mathcal{D}''(s)) \\ &\le 3\xi \max_{s\in S}(-\log \mathcal{D}''(s)) \\ &\le 3\xi(-\log(\xi\, 2^{-n})) \\ &= 3\xi(n - \log(\xi)).\end{aligned}$$

Furthermore, the second term is at most

$$\sum_{s\in S} \mathcal{D}''(s)(\log \mathcal{D}(s) - \log \mathcal{D}''(s))$$
$$= \sum_{s\in S} \mathcal{D}''(s)(\log(\mathcal{D}''(s) + h_s) - \log \mathcal{D}''(s)),$$

where $h_s = \mathcal{D}(s) - \mathcal{D}''(s)$, which is a positive quantity for $s \in S$. By concavity of the logarithm function, the above quantity is at most

$$\sum_{s\in S} \mathcal{D}''(s) h_s \Big[\frac{d}{dx}(\log(x))\Big]_{x=\mathcal{D}''(s)} = \sum_{s\in S} h_s \le 3\xi.$$

Thus, $\mathrm{KL}(\mathcal{D}, \mathcal{D}'') \le 3\xi(1 + n - \log \xi)$. This quantity is at most ϵ for all $n \ge 1$ by the definition of ξ. □

The method in the proof of Lemma 2 converts a hypothesis distribution which is close (in variation distance) to the target distribution to a hypothesis distribution which is close (in KL-distance) to the target distribution. However, if the original hypothesis is given as a two-state MET, then the modified hypothesis would require a three-state MET to realize it. We conclude the paper by explaining how to perform a similar trick using only two-state METs. The distribution obtained is not quite the same as the one used in the proof of Lemma 2, but it has the properties needed to show that small KL-distance is achieved.

Let M be the target Markov evolutionary tree. We run the PAC learning algorithm with accuracy parameter $\xi = \epsilon^2/(12n^3)$ to obtain MET M'. Now we construct a new hypothesis M'' by adjusting some of the parameters of M' as follows:

For each edge $e = (u, l)$ of M' where l is a leaf, let e_0 and e_1 be its parameters. If $e_0 < \xi$ then we set $e_0 = \xi$ and if $e_0 > 1 - \xi$ then set $e_0 = 1 - \xi$. We make the same change to e_1. By the proof of Lemma 27, $\mathrm{var}(M', M'') \le 4n\xi$, since $2n$ parameters have each been changed by at most ξ. Hence, with probability at least $1 - \delta$, $\mathrm{var}(M, M'') \le (1 + 4n)\xi$.

For each string $s \in \{0, 1\}^n$, $M''(s) \ge \xi^n$ (where $M''(s)$ denotes the probability that M'' outputs s). Using a similar argument to the proof of Lemma 2,

$$\mathrm{KL}(M, M'') \le (1 + 4n)\xi(1 - \log(\xi^n)) = (1 + 4n)\xi(1 - n\log \xi)$$

$$= (1 + 4n)\frac{\epsilon^2}{12n^3}(1 - n(2\log \epsilon - 3\log n - \log 12))$$

which as before is at most ϵ for all $n \ge 1$.

Acknowledgment. We thank Mike Paterson for useful ideas and discussions.

THE COMPLEXITY OF COUNTING IN SPARSE, REGULAR, AND PLANAR GRAPHS*

SALIL P. VADHAN†

Abstract. We show that a number of graph-theoretic counting problems remain $\mathcal{NP}$-hard, indeed $\#\mathcal{P}$-complete, in very restricted classes of graphs. In particular, we prove that the problems of counting matchings, vertex covers, independent sets, and extremal variants of these all remain hard when restricted to planar bipartite graphs of bounded degree or regular graphs of constant degree. We obtain corollaries about counting cliques in restricted classes of graphs and counting satisfying assignments to restricted classes of monotone 2-CNF formulae. To achieve these results, a new interpolation-based reduction technique which preserves properties such as constant degree is introduced.

Key words. $\#\mathcal{P}$, completeness, matchings, vertex covers, independent sets, Fibonacci numbers, polynomial interpolation

1. Introduction.

From the time that Valiant [48, 49] introduced the class $\#\mathcal{P}$ of counting problems and gave a complexity-theoretic explanation for the apparent difficulty of enumeration, counting has held an important place in theoretical computer science. Although many researchers have continued Valiant's work by adding to the list of $\#\mathcal{P}$-complete problems, our understanding of the complexity of counting still pales in comparison to our understanding of decision problems.

This is unfortunate because, aside from being mathematically interesting, counting is closely related to important practical problems. For instance, reliability problems are often equivalent to counting problems. Computing the probability that a graph remains connected given a probability of failure on each edge is essentially equivalent to counting the number of ways that the edges could fail without losing connectivity. Counting problems also arise naturally in artificial intelligence research [33, 36, 40]. As explained by Roth [40], various methods used in reasoning, such as computing "degree of belief" and "Bayesian belief networks" are computationally equivalent to counting the number of satisfying assignments to a propositional formula. Thus, understanding the types of propositional formulae for which counting satisfying assignments is feasible tells us the extent to which these reasoning techniques might be useful. Graph-theoretic counting problems such as the ones we consider also appear often in statistical physics (cf. [15, 22, 19, 29]).

Perhaps the most significant deficiency in our understanding of counting is that, in many cases, we do not know whether hard counting problems remain hard when additional restrictions are placed on the problem instances. A quick glance at Garey and Johnson's famous catalogue of $\mathcal{NP}$-complete problems [13] reveals that the restricted-case complexity of most difficult decision problems is understood in detail. This in-

†Division of Engineering and Applied Sciences, Harvard University, Cambridge, MA 02138 (salil@deas.harvard.edu, http://deas.harvard.edu/~salil). Much of this work originally appeared in the author's undergraduate thesis [45], done at Harvard University under the supervision of Leslie Valiant, and some of it was done while the author was at MIT, supported by a DOD NDSEG graduate fellowship.

formation is useful, because a complexity-theoretic hardness result often leads us to ask whether the instances we are interested in possess special properties which make the problem tractable. Restricted-case complexity results tell us when such special properties do not make a problem any easier, closing the gap between what we can do and what we know we cannot.

While researchers have managed to prove a number of restricted-case hardness results for counting problems, the techniques have been somewhat ad hoc, requiring new ideas for each problem. One reason for this is that many of the known reductions between counting problems employ "blow-up" techniques, which destroy special properties of the original problem instance. This makes it difficult to deduce additional restricted-case results from known restricted-case results. For example, although Dagum and Luby [8] have shown that counting perfect matchings remains $\#\mathcal{P}$-complete when restricted to 3-regular bipartite graphs, the standard reduction from counting perfect matchings to counting matchings in [49] blows up the degree of the graph and does not enable us to conclude that counting matchings remains difficult in either regular or bounded-degree graphs.

Our results. In this paper, we introduce a new reduction technique that yields restricted-case complexity results for many problems of interest. In particular, we show in Theorem 4.1 that counting matchings, vertex covers, independent sets, and variants of these structures remains difficult in planar bipartite graphs of bounded degree and in regular graphs of constant degree. As immediate corollaries, we deduce hardness results for counting cliques and satisfying assignments in restricted classes of graphs and formulae. Our main reduction technique, like some of those in [49], is based on polynomial interpolation. However, in contrast to the reductions in most earlier papers on the complexity of counting, our reductions preserve graph properties such as regularity and degree-boundedness. Moreover, the technique is quite general, and it can be applied to different problems in an almost mechanical manner.

A summary of our results, together with previous work, is given in Tables 1.1 and 1.2. Precise definitions of the problems we consider can be found in sections 3 and 4 and a more detailed summary of related work is given in section 2. We note that our results for vertex covers, independent sets, monotone 2-CNF satisfying assignments, and cliques are essentially restatements of each other via well-known equivalences (cf. Propositions 3.1 and 3.2), but we list them separately on Tables 1.1 and 1.2 for clarity and comparison to previous work.

Several of our results answer open problems explicitly stated in previous work: counting maximal matchings in unrestricted graphs [49], counting satisfying assignments to monotone 2-CNF formulae in which every variable appears a bounded number of times [40], and counting satisfying assignments to planar 2-CNF formulae [17].

When counting remains hard even in restricted cases, the natural alternative is to seek *approximate* counting algorithms. However, restricted-case complexity results for approximate counting are even harder to come by than ones for exact counting. In Proposition 4.3, we obtain such a result, as we show that counting minimum cardinality vertex covers is $\mathcal{NP}$-hard even in graphs of maximal degree 3. Perhaps this could be used as a starting point for achieving other such results.

Techniques. Our main technique is best illustrated with an example: reducing #Perfect Matchings to #Matchings while preserving the sparsity of the input graph. Suppose we are given an oracle which counts all matchings in a graph, and we want to use this oracle to count the number of perfect matchings in a graph G. Let $v_1, \ldots, v_n$ be the vertices of G. For $s = 0, \ldots, n$, consider the graph G_s obtained by adding disjoint chains $v_i - v_{i,1} - v_{i,2} - \cdots - v_{i,s}$ to each vertex v_i of G.

TABLE 1.1 *$\#\mathcal{P}$-completeness results for counting problems in restricted classes of graphs.*

Problem	Polynomial-time solvable	Previous results	This paper
#PERFECT MATCHINGS	• planar [12, 27, 43] • $\Delta \leq 2$	• k-regular bipartite, any $k \geq 3$ [8] • $(n-k)$-regular bipartite, any $k \geq 3$ [8]	
#MATCHINGS	• $\Delta = 2$	• bipartite [49] • planar [19]	• bipartite, $\Delta = 4$ • planar bipartite, $\Delta = 6$ • k-regular, any $k \geq 5$
#MAXIMAL MATCHINGS	• $\Delta = 2$		• bipartite, $\Delta = 5$ • planar bipartite, $\Delta = 7$
#VERTEX COVERS #INDEPENDENT SETS	• $\Delta = 2$ • $n - \delta$ constant	• bipartite [38]	• planar bipartite, $\Delta = 4$ • k-regular, any $k \geq 5$[1]
#MIN CARDINALITY VERTEX COVERS #MAX CARDINALITY INDEPENDENT SETS	• $\Delta = 2$ • $n - \delta$ constant	• bipartite [38] • planar [17]	• planar bipartite, $\Delta = 3$ • k-regular, any $k \geq 4$
#MINIMAL VERTEX COVERS #MAXIMAL INDEPENDENT SETS	• $\Delta = 2$ • $n - \delta$ constant	• bipartite [38][2]	• planar bipartite, $\Delta = 5$ • regular
#CLIQUES, #MAXIMAL CLIQUES #MAXCARDINALITY CLIQUES[3]	• $\delta = n - 2$ • Δ constant • planar • bipartite	• unrestricted [49][2]	• regular • $\delta = n - 5$
#BIPARTITE CLIQUES, #MAXIMAL BIPARTITE CLIQUES #MAX CARDINALITY BIPARTITE CLIQUES[3]	• $\delta = n - 2$ • Δ constant • planar	• bipartite [38][2]	• bipartite • $\delta = n - 5$

Remarks.
• Δ (resp., δ) denotes an upper (resp., lower) bound on the maximum (resp., minimum) vertex degree.
• k is always a constant.
• n denotes the number of vertices, except when referring explicitly to bipartite graphs, in which case it refers to the number of vertices on each side.
[1] Greenhill [14] has improved this to $k = 3$.
[2] These results are not stated explicitly in [49, 38], but follow readily from the results and reductions in those papers.
[3] In general, any result for independent sets also holds for cliques *in the complement graph*, and conversely (cf. Proposition 3.1). An analogous relationship holds between independent sets in bipartite graphs and bipartite cliques in the bipartite complement graph (cf. Proposition 3.2). For brevity, we do not enumerate all the results we obtain in this way.

TABLE 1.2 *$\#\mathcal{P}$-completeness results for counting satisfying assignments in restricted classes of formulae.*

Problem	Polynomial-time solvable	Previous results	This paper
#SAT	• monotone 2-CNF, each variable appears at most twice [40] • monotone 2-CNF, each variable fails to appear in a clause with only a constant number of other variables • acyclic monotone 2-CNF [40] • acyclic Horn 2-CNF [40] • Horn 2-CNF, each variable appears at most twice [40]	• planar 3-CNF [17][1] • bipartite monotone 2-CNF [38] • Horn 2-CNF, each variable appears at most 3 times [40] • CNF, each literal appears exactly once [5] • monotone CNF, each variable appears at most twice [5]	• planar bipartite monotone 2-CNF, each variable appears at most 4 times • monotone 2-CNF, each variable appears exactly k times, any $k \geq 5$[2]
#MINTERMS	• monotone 2-CNF, each variable appears at most twice • monotone 2-CNF, each variable fails to appear in a clause with only a constant number of other variables	• bipartite monotone 2-CNF [49, 38][3]	• planar bipartite monotone 2-CNF, each variable appears at most 5 times • monotone 2-CNF, each variable appears the same number of times
#MIN WEIGHT SAT	• monotone 2-CNF, each variable appears at most twice • monotone 2-CNF, each variable fails to appear in a clause with only a constant number of other variable	• bipartite monotone 2-CNF [49, 38][3] • planar monotone 2-CNF [17][3]	• planar bipartite monotone 2-CNF, each variable appears at most 3 times • monotone 2-CNF, each variable appears exactly k times, and $k \geq 4$

Remarks.
• Terms such as planar, acyclic, etc., refer to properties of the graph obtained from a CNF formula by having a vertex for each variable and connecting two vertices if they appear in the same clause.
• k is always a constant.
[1] In [17], the graph associated to a CNF formula is the bipartite graph on variables and clauses in which a clause is connected to the variables it contains. For 2-CNF, the planarity of this graph is equivalent to the planarity of the graphs we consider.
[2] Greenhill [14] has improved this to $k = 3$.
[3] These results are not stated explicitly in [49, 38, 17], but follow readily from the results and reductions in those papers.

We will describe the number of matchings in G_s in terms of matchings in G. Consider any matching M in G, and let us count the number of ways M can be extended to a matching in G_s. For each vertex v_i of G which is matched by M, the edge $(v_i, v_{i,1})$ cannot be added to the matching, but we can choose an arbitrary matching for the chain $v_{i,1} - \cdots - v_{i,s}$. For each vertex v_i which is not matched by M, we can add an arbitrary matching of the chain $v_i - v_{i,1} - \cdots - v_{i,s}$ to M. Thus the number of ways to extend M to a matching in G_s is exactly $x_s^j x_{s+1}^{n-j}$, where j is the number of vertices matched by M and x_t denotes the number of matchings in a chain of t nodes. Therefore, if we let A_j denote the number matchings in G in which exactly j nodes are matched, then G_s has exactly $\sum_{j=0}^{n} A_j x_s^j x_{s+1}^{n-j}$ matchings. We can obtain these values for $s = 0, \ldots, n$ with $n+1$ oracle calls. Dividing by x_{s+1}^n, we obtain the evaluation of the polynomial $f(x) = \sum_{j=0}^{n} A_j x^j$ at the points (x_s/x_{s+1}) for $s = 0, \ldots, n$. Now, we would like to use polynomial interpolation to recover the coefficients of f, and in particular, the leading coefficient A_n which is the number of perfect matchings in G. We can do this provided we can compute the values x_s and the evaluation points x_s/x_{s+1} are distinct.

Luckily, it is not hard to get a handle on x_s, the number of matchings in a chain of s nodes. It turns out that x_s is simply the sth Fibonacci number! One can use the Fibonacci recurrence to compute the values x_s, and the well-known closed form for the Fibonacci numbers (cf. [44, section 7.3]) can be used to show that their consecutive ratios x_s/x_{s+1} never repeat. (We formally prove all this in Lemma 6.3.)

In contrast to the previously known reduction from #Perfect Matchings to #Matchings [49], the above reduction only increases the maximum vertex degree by one. It also preserves other graph properties, such as bipartiteness and planarity. Moreover, this technique generalizes quite easily to other problems and graph properties (such as regularity). We used only a few properties of chains and matchings in the reduction:

1. The number of matchings in the graphs G_s is related to matchings in the original graph G via polynomial evaluation.
2. The evaluation points can be expressed in terms of the number of matchings in a chain of length s (and the number in which one end vertex is not matched).
3. The evaluation points can be computed efficiently.
4. The evaluation points do not repeat.

We will see by inspection that analogues of the first two conditions still hold when we replace matchings with a variety of other problems, and when chains are replaced with other gadgets. For the last two conditions, we will use gadgets possessing a repetitive structure, so that the evaluation points satisfy simple linear recurrence relations. These recurrences will certainly allow the evaluation points to be computed efficiently, but we are left with proving that they do not repeat. To this end, in section 6 we prove the following lemma, which gives general conditions under which (ratios of) sequences defined by 2×2 linear recurrences do not repeat.

Lemma 6.2. *Let A, B, C, D, x_0, and y_0 be rational numbers. Define the sequences $\{x_n\}$ and $\{y_n\}$ recursively by $x_{n+1} = Ax_n + By_n$ and $y_{n+1} = Cx_n + Dy_n$. Then the sequence $\{z_n = x_n/y_n\}$ never repeats as long as all of the following conditions hold:*

$$AD - BC \neq 0, \tag{1}$$

$$D^2 - 2AD + A^2 + 4BC \neq 0, \tag{2}$$

$$D + A \neq 0, \tag{3}$$

$$D^2 + A^2 + 2BC \neq 0, \tag{4}$$

$$D^2 + AD + A^2 + BC \neq 0, \tag{5}$$

$$D^2 - AD + A^2 + 3BC \neq 0, \tag{6}$$

$$By_0^2 - Cx_0^2 - (A - D)x_0y_0 \neq 0. \tag{7}$$

Greenhill [14] has observed that when the coefficients A,B,C,D are all positive, Conditions (2)–(6) are guaranteed to hold, so only the first and last must be checked.

This lemma, with the approach outlined above, gives an almost mechanical way to find reductions that preserve properties such as sparsity and regularity. We will refer to this method as the *Fibonacci technique*, in reference to its simplest incarnation described above. The reductions we obtain from the Fibonacci technique have some interesting features not present in many previous interpolation-based reductions, such as those in [49]. First, our interpolation points are typically rapidly converging sequences of rational numbers (e.g., the consecutive ratios of Fibonacci numbers converge to the golden ratio), whereas previous methods often interpolated at distinct integer points, which seems difficult to do without losing special properties of the original graph. Second, we do not know how to reduce the number of oracle calls in these reductions to a constant. This is in contrast to the reductions done in [49]. There, Valiant asserts that all the reductions can be done with a single oracle call, because the arithmetic can be simulated by operations on the graph or formula in question. Here that does not appear to work, because the graph operations used by Valiant blow up the degree.

Of course, it is not enough to have reductions that preserve properties such as sparsity and regularity; we need initial hardness results for restricted classes of graphs from which to reduce. For this, we rely heavily on results and techniques from previous work, such as [8, 38, 19, 49, 40]. In particular, to obtain results about planar graphs, we use the Fibonacci technique to refine the reduction of Jerrum [19] so that properties such as sparsity and bipartiteness are preserved, and also extend his approach to problems involving vertex covers.

2. Related work. Our results for counting in sparse bipartite graphs first appeared in the author's undergraduate thesis [45], and the first version of this paper [47] added our results for planar and regular graphs. Some of the related work, namely that of Luby and Vigoda [28] and Bubley and Dyer [5, 6], was done subsequent to [45], but independently of [47]. We describe those works, together with more recent developments, under the heading "subsequent work." Throughout this section, we discuss only works that address the same counting problems as we do. The reader is referred to [50, 34, 45, 20] for more general surveys on the complexity of counting, and [41, 25, 31, 46, 23] for approximate counting.

Previous work. In his seminal paper [48], Valiant introduced the class $\#\mathcal{P}$ of counting problems and proved that counting perfect matchings in bipartite graphs is $\#\mathcal{P}$-complete. In [49], he showed that a number of other counting and reliability problems are $\#\mathcal{P}$-complete, including the unrestricted versions of most of the problems we study in this paper. Some of these problems, such as #Vertex Covers, were shown to remain hard in bipartite graphs by Provan and Ball [38], who also proved hardness results for reliability problems. Provan [37] obtained restricted-case results (acyclic planar graphs of maximum degree 3) for some reliability problems, but not the problems that we investigate. Jerrum [19] showed that counting matchings in planar graphs is $\#\mathcal{P}$-complete, in striking contrast to perfect matchings which can efficiently counted in planar graphs via algorithms due to Fisher, Kasteleyn, and Temperley [12, 27, 43]. Broder [4] proved that counting perfect matchings in bipartite

graphs of minimum vertex degree at least $n/2$ is $\#\mathcal{P}$-complete. Dagum and Luby [8] obtained even stronger results, showing that counting perfect matchings remains hard even in k-regular and $(n-k)$-regular bipartite graphs, for any constant $k \geq 3$.

From the start, the $\#\mathcal{P}$-completeness of counting satisfying assignments to a propositional formula was seen to follow immediately from parsimonious versions of Cook's reduction [48]. Valiant [49] proved that the problem remained just as hard in the dramatically restricted case of monotone 2-CNF, which was restricted further to bipartite monotone 2-CNF by Provan and Ball [38]. Roth [40] showed that counting satisfying assignments is $\#\mathcal{P}$-complete even in 2-CNF Horn formulae in which each variable appears at most 3 times, along with giving a number of polynomial-time algorithms to count satisfying assignments in other restricted types of 2-CNF formulae. Hunt et al. [17] showed that counting satisfying assignments to planar 3-CNF formulae is $\#\mathcal{P}$-complete, and gave a number of other counting problems that are hard in planar graphs, including counting minimum cardinality vertex covers.

The general theory of approximate counting was developed in the works of Stockmeyer [42], Karp and Luby [26], and Jerrum, Valiant, and Vazirani [24]. The first positive result for approximate counting that relates to our work is due to Karp and Luby [26], who gave a polynomial-time algorithm for approximately counting satisfying assignments to a DNF formula. After that, most of the positive results on approximate counting have come via the theory of "rapidly mixing Markov chains." In the first dramatic application of this approach to approximating a $\#\mathcal{P}$-complete counting problem, Jerrum and Sinclair [21] analyzed a Markov chain proposed by Broder [4] and thereby showed that it is possible to approximately count the number of perfect matchings in a graph of minimum vertex degree at least $n/2$ in polynomial time. They also gave an algorithm for approximately counting all matchings in an arbitrary graph. Their perfect matching algorithm was simplified by Dagum and Luby [8], who thereby obtained algorithms for approximately counting perfect matchings in αn-regular bipartite graphs for any constant α (and in fact a more general class of graphs).

For the counting problems we consider, the only previous inapproximability results involved approximately counting independent sets (equivalently, vertex covers or cliques) in general graphs [41, 51]. Specifically, Sinclair [41] used the "blow-up" technique introduced in [24] to show that it is $\mathcal{NP}$-hard to approximate the number of independent sets in a graph, even up to an approximation factor of $2^{n^{1-\varepsilon}}$, for any constant $\varepsilon > 0$. This result directly translates to the $\mathcal{NP}$-hardness of approximately counting the number of satisfying assignments to a monotone 2-CNF formula to within a factor of $2^{n^{1-\varepsilon}}$ [40] (cf. Proposition 3.1). Zuckerman [51], using techniques from the theory of probabilistically checkable proofs (PCP) [11, 2, 1], showed that it is hard to approximate arbitrarily iterated logarithms of the number of independent sets in a graph unless $\mathcal{NP}$ has slightly superpolynomial-time randomized algorithms.

Subsequent work. Since this work was done, there has been a substantial improvement in our understanding of counting independent sets (equivalently, vertex covers) in sparse graphs. With respect to exact counting, our results left a gap between the easy and hard cases; specifically, we showed that counting independent sets in graphs of maximal degree 4 is $\#\mathcal{P}$-complete, whereas the problem is polynomial-time solvable in graphs of maximal degree 2. For regular graphs, our hardness result only held for degrees ≥ 5. Greenhill [14] has closed these gaps, showing that counting independent sets in 3-regular graphs is $\#\mathcal{P}$-complete. We note that her hardness result uses ours as a starting point and also makes use of (generalizations of) our Fibonacci technique.

For approximately counting independent sets in sparse graphs, almost nothing was known at the time of this work. There were no polynomial-time approximation algorithms and no inapproximability results other than Sinclair's [41] and Zuckerman's [51] results for unrestricted graphs and our result about counting maximum cardinality independent sets. Luby and Vigoda [28] have remedied this situation in both respects. First, using the Markov chain approach, they have given a polynomial-time algorithm to approximately count independent sets in graphs of maximal degree at most 4. (Extensions and improvements can be found in [10, 29, 39].) Second, combining a blow-up technique of [41] with PCP-based inapproximability results [35, 2, 1], they proved that for some (large) constant Δ, approximately counting independent sets in graphs of maximal degree Δ is $\mathcal{NP}$-hard. Using a more sophisticated reduction and results in [16], Dyer, Frieze, and Jerrum [9] reduce the degree for this inapproximability result to $\Delta = 25$, and give evidence that the Markov chain approach is unlikely to work for any $\Delta \geq 6$. These results suggest that the PCP theorem, which has yielded many inapproximability results for optimization problems, may also be the right starting point for proving hardness of approximate counting.

Bubley and Dyer [6] have considered the problem of counting independent sets of a given size s in a graph of maximal degree Δ. Our results on counting maximum cardinality independent sets imply that the exact (resp., approximate) version of this problem is $\#\mathcal{P}$-complete (resp., $\mathcal{NP}$-hard) even when $\Delta = 3$, if there is no restriction on s. They show that in fact the approximate counting problem can be solved in polynomial time for $s < n/2(\Delta+1)+1$, whereas the exact counting problem remains $\#\mathcal{P}$-complete under this restriction.

In another work, Bubley and Dyer [5] have proven some new results about counting satisfying assignments in restricted classes of formulae. Instead of looking at 2-CNF formulae (as we do, and as happens when translating results about independent sets), they do not restrict the number of variables per clause, but only allow each variable to appear at most twice. They have shown that it is possible to efficiently approximate the number of satisfying assignments to such formulae. On the other hand, they show that exactly counting satisfying assignments remains $\#\mathcal{P}$-complete in CNF formula in which each literal appears exactly once, and monotone CNF formulae in which each variable appears at most twice. They also relate these versions of #Sat to counting "sink-free orientations" in directed graphs.

3. Preliminaries. Nearly all of the counting problems we will be considering are in Valiant's class $\#\mathcal{P}$, and the remainder are closely related to $\#\mathcal{P}$. Below, we informally review some basic definitions. For a more detailed discussion of $\#\mathcal{P}$, the reader is referred to any of [50, 45, 20, 34].

Following [24], $\#\mathcal{P}$ can be defined in terms of p-relations. Let Σ be a finite alphabet. A relation $R \subset \Sigma^* \times \Sigma^*$ is said to be a *p-relation* iff it is polynomially-balanced, i.e., there exists a polynomial p such that $\langle x, y\rangle \in R \Rightarrow |y| \leq p(|x|)$; and it can be "checked quickly," i.e., the language $L = \{\langle x, y\rangle \in R\}$ can be decided in polynomial time. The *counting problem* $\#R$ associated with R is the following: Given $x \in \Sigma^*$, output $|R(x)| = |\{y \in \Sigma^* : \langle x, y\rangle \in R\}|$. $\#\mathcal{P}$ is the class of all such counting problems.

In the above definition, x should be thought of as an instance of a problem, such as a boolean formula F, and $R(x)$ as the set of solutions associated with x, such as the satisfying assignments to F. It is easy to see that $\mathcal{NP}$ consists exactly of problems of the following form: Given x, decide whether $R(x)$ is nonempty. Thus $\#\mathcal{P}$ is the set of counting problems naturally associated with $\mathcal{NP}$ languages.

In contrast to $\mathcal{NP}$, it turns out that standard Karp reductions (i.e., polynomial-time many-one reductions) are not sufficient to describe the relative difficulty of counting problems. It is easy to construct counting problems which are obviously equivalent in difficulty, but for which there can be no one-to-one correspondence between solution sets. Hence, following [48], we consider a problem Π to be as hard as a problem Γ iff Γ can be solved by a polynomial-time algorithm with an oracle for Π, and we denote this by $\Gamma \propto \Pi$. Such a reduction is known as a *Cook reduction* (or *polynomial-time Turing reduction*), and this is the only form of reduction we will refer to in this paper. A problem Π is said to be *$\#\mathcal{P}$-hard* iff all problems in $\#\mathcal{P}$ reduce to it; if, in addition, $\Pi \in \#\mathcal{P}$ it is called *$\#\mathcal{P}$-complete*. Last, a problem is said to be *$\#\mathcal{P}$-easy* if it can be reduced to some problem in $\#\mathcal{P}$. Occasionally, we will be able to reduce one problem to another via a polynomial-time mapping of problem instances that preserves the number of solutions. Such a reduction is called a *parsimonious* reduction and these are important because they preserve inapproximability.

Having defined all the complexity-theoretic notions we will need, we proceed to define the combinatorial objects we will be studying. Let $G = (V, E)$ be an undirected graph. The *(maximum) degree* of G is the maximum number of edges incident to any vertex, and the *minimum degree* of G is defined similarly. A *vertex cover* in G is a subset S of V such that every edge in E has at least one endpoint in S. An *independent set* in G is a subset S of V such that no two vertices in S are connected by an edge in E. A *clique* in G is a subset S of V such that every two vertices in S are connected by an edge in E. It is well known that cliques, vertex covers, and independent sets are intimately related objects. Their relationship is formalized by the following proposition.

PROPOSITION 3.1. *Let $G = (V, E)$ be an undirected graph and let $\overline{G} = (V, \overline{E})$ be its (edge-)complement. Let F be the monotone 2-CNF formula on variables V given by $F = \bigwedge_{(u,v)\in E}(u \vee v)$. For $S \subset V$, let $\chi_S : V \to \{0, 1\}$ be the assignment which maps $v \in V$ to 1 iff $v \in S$. Then the correspondence $S \leftrightarrow (V - S) \leftrightarrow (V - S) \leftrightarrow \chi_S$ establishes bijections between the vertex covers in G, the independent sets in G, the cliques in $\overline{G}$, and the satisfying assignments of F.*

Proof. The proof is by definition. □

We will also be examining the complexity of these problems in bipartite graphs. However, the study of cliques in bipartite graphs is not very interesting, as the only cliques are edges. So, for a bipartite graph $G = (V, E)$, we will instead look at *bipartite cliques*, which are subsets $S \subset V$ of vertices which can be partitioned $S = S_1 \cup S_2$ so that $S_1 \times S_2 \subset E$. To obtain an analogue of Proposition 3.1, we say that bipartite graphs $G = (V, E)$ and $H = (V, F)$ are *bipartite complements* if V can be partitioned $V = V_1 \cup V_2$ such that $E \subset V_1 \times V_2$ and $F = V_1 \times V_2 \setminus E$. Note that a bipartite complement of a graph can be found in polynomial time, and is unique if the graph is connected. Proposition 3.1 has the following bipartite analogue.

PROPOSITION 3.2. *Let bipartite graphs $G = (V, E)$ and $H = (V, F)$ be bipartite complements. Then $S \subset V$ is an independent set in G iff it is a bipartite clique in H.*

Proof. The proof is by definition. □

The above propositions will enable us to immediately deduce hardness results for all of the above problems given a hardness result for one of them. Therefore, we will concentrate primarily on the vertex cover problem.

We will also study extremal variants of all of the above problems. A vertex cover S is said to be *minimal* iff no proper subset of S is a vertex cover. It is said to be of *minimum cardinality* iff there is no vertex cover with fewer vertices. Similarly, we

speak of maximal and maximum cardinality independent sets or cliques.

By Proposition 3.1, it is easy to see that minimal vertex covers correspond to *minterms* of a monotone 2-CNF formula — that is, satisfying assignments for which changing any variable from true to false would no longer satisfy the formula. It is clear that the smallest DNF form for a monotone formula F is simply the disjunction of all minterms, writing an individual minterm M as the conjunction of the variables in M. Hence, restricted-case hardness results for counting minimal vertex covers immediately imply that determining the size of the minimal DNF form is hard even for restricted classes of CNF formulae.

It is clear that if the decision problem associated with a p-relation is $\mathcal{NP}$-complete, then the associated counting problem is also $\mathcal{NP}$-hard. Thus, complexity of counting results are only interesting when the related decision problem is easy. The first nontrivial result of this form, due to Valiant, involved another type of graph-theoretic structure, known as a perfect matching. A *matching* in an undirected graph $G = (V, E)$ is a set $M \subset E$ of edges, no two of which share an endpoint. A *perfect matching* is a matching M in which every vertex in V is the endpoint of an edge in M. Valiant's theorem [48] states that counting perfect matchings in bipartite graphs is $\#\mathcal{P}$-complete. Matchings can be related to the other structures we mentioned via the following construction.

Let $G = (V, E)$ be an undirected graph. The *line graph of* G is the undirected graph $L(G) = (E, H)$, where $(e_1, e_2) \in H$ iff e_1 and e_2 share an endpoint in G.

LEMMA 3.3. *Let $G = (V, E)$ be an undirected graph. Then $M \leftrightarrow E - M$ establishes a bijective correspondence between matchings in G and vertex covers in the line graph of G.*

Proof. Notice that $M \subset E$ is a matching in G iff M is an independent set in $L(G)$. The relationship with vertex covers follows from Proposition 3.1. □

One of the restricted classes of graphs that we will examine is the class of planar graphs. A graph is said to be *planar* iff there exists an embedding of the graph in the plane (where the vertices are points and the edges are curves connecting the points) in which no two edges intersect. The bijection of Proposition 3.1 suggests how to define planarity for CNF formulae. If F is a formula in conjunctive normal form, we define $G(F)$ to be the graph whose vertices are the variables of F, where two vertices are connected if they lie in a common clause. We call F *planar* iff $G(F)$ is planar.

There are several reasons for studying the problems described above. One is that many $\mathcal{NP}$-completeness results have come via reduction from decision versions of these problems, so it reasonable to guess that many restricted-case $\#\mathcal{P}$-completeness results could come via reduction from restricted versions of these counting problems. Another reason is that these problems are closely related to important problems in other areas. As discussed in the introduction, several problems in artificial intelligence are equivalent to counting satisfying assignments to a propositional formula [33, 36, 40]. In addition, the counting problems we consider arise naturally in statistical physics; specifically, counting matchings amounts to counting arrangements of monomer-dimer systems, and counting independent sets is tantamount to computing the partition function in the hard-core model of a gas (cf. [15, 19, 29]).

For their simplicity, their relationships to other important problems, and their potential to serve as starting points for further results, the problems of counting matchings, vertex covers, and independent sets are important ones to consider. So motivated, we now proceed to classify the cases in which these problems are and are not tractable.

4. Formal statement of results. Before stating our negative results, we explain the entries in the "Polynomial-time solvable" columns of Tables 1.1 and 1.2 for which no reference is given. The tractability of problems such as counting matchings, vertex covers, and their variants in graphs of maximal degree at most 2 follows from the simple structure of these graphs: The connected components of such graphs are cycles and chains, and objects such as matchings and vertex covers multiply across connected components, so it suffices to count them in cycles and chains. It is not hard to write down closed forms or recurrences which can be used to count these structures in chains and cycles. This is done explicitly in [45]. The polynomial-time solvability of counting cliques in graphs of maximal degree at most Δ follows from the fact that the largest clique in such a graph is of size at most Δ. Thus, one can exhaustively check the $\leq n^{\Delta}$ possibilities in polynomial time. Similarly, a planar graph cannot contain any clique of size ≥ 5, nor any bipartite clique involving at least 3 vertices on both sides of the partition, as these structures are nonplanar (cf. [44, section 1.4]). Finally, as noted earlier, the only cliques in a bipartite graph are singletons and pairs. All the other entries follow from the above observations via Propositions 3.1 and 3.2.

We now state our negative results. Below, the counting problems are named as follows: the beginning of the name indicates any restrictions on the input graph or formula, and the end of the name contains the structures to be counted. A prefix of $k\Delta$ indicates that the maximum degree of the graph is at most k. An example of a problem denoted this way is the following.

#7Δ-Planar Bipartite Maximal Matchings.

Input: A planar bipartite graph G of degree ≤ 7.

Output: The number of maximal matchings in G.

Theorem 4.1. *The following problems are #$\mathcal{P}$-complete (except for Problem* 8*, which is #$\mathcal{P}$-hard*[1]*):*

1. #4Δ-Bipartite Matchings,
2. #6Δ-Planar Bipartite Matchings,
3. #k-Regular Matchings, *any fixed* $k \geq 5$,
4. #5Δ-Bipartite Maximal Matchings,
5. #7Δ-Planar Bipartite Maximal Matchings,
6. #Planar Bipartite Vertex Covers,
7. #3Δ-Planar Bipartite Minimum Cardinality Vertex Covers,
8. #k-Regular Minimum Cardinality Vertex Covers, *any fixed* $k \geq 4$,
9. #4Δ-Planar Bipartite Vertex Covers,
10. #k-Regular Vertex Covers, *any fixed* $k \geq 5$,
11. #5Δ-Planar Bipartite Minimal Vertex Covers,
12. #Regular Minimal Vertex Covers.

In the following corollary, we use the same naming conventions as above, with some additional ones. When Bipartite Cliques appears, it refers to counting bipartite cliques in bipartite graphs. A prefix of $k\delta$ means that the minimum vertex degree is at least k. n refers to the number of vertices in the graph, except when the input is restricted to be bipartite, in which case n is the number of vertices on each side of the bipartition.

[1]Problem 8 is not likely to be in #$\mathcal{P}$, because testing whether a vertex cover is of minimum cardinality is $\mathcal{NP}$-hard [13, Theorem 3.3]. But we will reduce it to a #$\mathcal{P}$ problem, proving that it is #$\mathcal{P}$-easy. The failure of #$\mathcal{P}$ to be closed under reductions and even simpler operations is discussed in [32].

In contrast, Problem 7 is in #$\mathcal{P}$ because in *bipartite graphs*, the size of the minimum cardinality vertex cover equals the size of the maximum cardinality matching. The latter quantity can be found using any of the standard maximum cardinality matching algorithms. See [34, Problem 9.5.25].

For problems involving satisfying assignments, 2SAT denotes the problem of counting the satisfying assignments of the input formula F, MINTERMS the problem of counting the minterms of F (i.e., the number of clauses in the smallest DNF formula equivalent to F), and MIN WEIGHT 2SAT the problem of counting satisfying assignments with the fewest variables set to true. A prefix of $k\Delta$ (resp., k-REGULAR) indicates that each variable appears at most (resp., exactly) k times. A *bipartite* 2-CNF formula is one in which the variables can be partitioned into two sets such that no clause contains two variables from the same set. For example, we have the following.

#3Δ-PLANAR BIPARTITE MONOTONE MIN WEIGHT 2SAT.

Input: A planar monotone formula $F = (c_{1,1} \vee c_{1,2}) \wedge \cdots \wedge (c_{r,1} \vee c_{r,2})$ on variables $X \cup Y$, where $X \cap Y = \emptyset$; $c_{i,1} \in X$, $c_{i,2} \in Y$ for each i; and each variable appears at most 3 times.

Output: The number of satisfying assignments to F with the fewest variables set to "true."

COROLLARY 4.2. *The following problems are #$\mathcal{P}$-complete (except for Problems* 2, 9, *and* 17, *which are #$\mathcal{P}$-hard):*

1. #3Δ-PLANAR BIPARTITE MAXIMUM CARDINALITY INDEPENDENT SETS,
2. #k-REGULAR MAXIMUM CARDINALITY INDEPENDENT SETS, *any fixed* $k \geq 4$,
3. #4Δ-PLANAR BIPARTITE INDEPENDENT SETS,
4. #k-REGULAR INDEPENDENT SETS, *any fixed* $k \geq 5$,
5. #5Δ-PLANAR BIPARTITE MAXIMAL INDEPENDENT SETS,
6. #REGULAR MAXIMAL INDEPENDENT SETS,
7. #$(n-3)\delta$-MAXIMUM CARDINALITY CLIQUES,
8. #$(n-3)\delta$-MAXIMUM CARDINALITY BIPARTITE CLIQUES,
9. #$(n-k)$-REGULAR MAXIMUM CARDINALITY CLIQUES, *any fixed* $k \geq 4$,
10. #$(n-4)\delta$-CLIQUES,
11. #$(n-4)\delta$-BIPARTITE CLIQUES,
12. #$(n-k)$-REGULAR CLIQUES, *any fixed* $k \geq 5$,
13. #$(n-5)\delta$-MAXIMAL CLIQUES,
14. #$(n-5)\delta$-MAXIMAL BIPARTITE CLIQUES,
15. #REGULAR MAXIMAL CLIQUES,
16. #3Δ-PLANAR BIPARTITE MONOTONE MIN WEIGHT 2SAT,
17. #k-REGULAR MONOTONE MIN WEIGHT 2SAT, *any fixed* $k \geq 5$,
18. #4Δ-PLANAR BIPARTITE MONOTONE 2SAT,
19. #k-REGULAR MONOTONE 2SAT, *any fixed* $k \geq 5$,
20. #5Δ-PLANAR BIPARTITE MINTERMS,
21. #REGULAR MINTERMS.

The following proposition contains our inapproximability result. The prefix of f-APPROX indicates the problem of solving the given counting problem within a multiplicative approximation factor of f. Though we have adopted Cook reductions as our notion of reducibility, the following results are actually proved via Karp reductions to "gap promise problems" (cf. [3]).

PROPOSITION 4.3. *The following problems are $\mathcal{NP}$-hard for every* $\epsilon > 0$*:*

1. $2^{n^{1-\epsilon}}$-APPROX #3Δ-MINIMUM CARDINALITY VERTEX COVERS,
2. $2^{n^{1-\epsilon}}$-APPROX #3Δ-MAXIMUM CARDINALITY INDEPENDENT SETS,
3. $2^{n^{1-\epsilon}}$-APPROX #$(n-3)\delta$-MAXIMUM CARDINALITY CLIQUES,
4. $2^{n^{1-\epsilon}}$-APPROX #3Δ-MIN WEIGHT MONOTONE 2SAT.

5. The reductions. We state three facts about polynomial interpolation here that we will use repeatedly in our reductions. Let K be a finite extension of $\mathbb{Q}$. For any $z \in K$, let $\|z\|$ denote the number of bits needed to represent z. (If K is a degree d extension, elements of K are represented by polynomials of degree $\leq d-1$ with rational coefficients, and arithmetic is done modulo some irreducible polynomial defining K.) For a polynomial f in several variables over K, let $\|f\|$ be the number of bits needed to represent f, which is the sum of $\|a\|$ for the coefficients a of f. We use a *dense* representation of polynomials, which means that if some monomial $x_1^{d_1} \cdot x_2^{d_2} \cdots x_n^{d_n}$ has a nonzero coefficient in f, then the coefficients of all smaller monomials (i.e., any $x_1^{e_1} \cdots x_n^{e_n}$ such that $e_i \leq d_i$ for all i) must be included when computing $\|f\|$. (Zero coefficients count as one bit). For a rational function $q = f/g$, let $\|q\| = \|f\| + \|g\|$.

FACT 5.1. *Let $F = K(y_1, y_2, \ldots, y_k)$ be the field of rational functions over K in k variables for some constant k. Let $f(x) = \sum_{i=0}^{d} a_i x^i$ be a polynomial with coefficients in F. If $(\alpha_0, \beta_0), \ldots, (\alpha_d, \beta_d)$ such that $f(\alpha_i) = \beta_i$ are known for distinct $\alpha_i \in F$, then the coefficients of f can be recovered in time polynomial in $\max_i \|\alpha_i\|$, $\max_i \|\beta_i\|$, and d.*

FACT 5.2. *Let $f(x, y) = \sum_{i+j \leq n} a_{ij} x^i y^j$ be a polynomial in two variables with coefficients in K. If for each of $n+1$ distinct $x_i \in K$, $n+1$ distinct $y_{ij} \in K$ along with the values $z_{ij} = f(x_i, y_{ij})$ are known, then the coefficients of f can be recovered in time polynomial in $\max_{ij} \|a_{ij}\|, \max_i \|x_i\|, \max_{ij} \|y_{ij}\|$, and $\max_{ij} \|z_{ij}\|$.*

FACT 5.3. *Let $f(x) = \sum_{i=0}^{d} a_i x^i$ be a polynomial with nonnegative integer coefficients. If (α, β) is known, where $f(\alpha) = \beta$ and α is a rational number satisfying $\alpha \geq (a_i + 1)$ for each i, then the coefficients of f can be recovered in time polynomial in $\|\alpha\|$, $\|\beta\|$, and d.*

Proof of Fact 5.1. Here we just use the Lagrange interpolation formula:

$$f(x) = \sum_{i=0}^{d} \beta_i \left(\frac{(x-\alpha_1)\cdots(x-\alpha_{i-1})(x-\alpha_{i+1})\cdots(x-\alpha_d)}{(\alpha_i-\alpha_1)\cdots(\alpha_i-\alpha_{i-1})(\alpha_i-\alpha_{i+1})\cdots(\alpha_i-\alpha_d)} \right).$$

This is a polynomial which agrees with f at $d+1$ distinct points, so it must be the same polynomial. By multiplying out and collecting terms, we can obtain the coefficients of f all at once, in polynomial time. □

Proof of Fact 5.2. Define, for each $0 \leq r \leq n$, $g_r(y) = \sum_{i,j} a_{ij} x_r^i y^j$. For each r, we know the evaluation of $g_r(y)$ at the $n+1$ points $y_{r0}, \ldots, y_{rn}$, so we can recover the polynomials $g_r(y)$ by Fact 5.1. These are the evaluations of $f(x, y)$, considered as a polynomial in x with coefficients in $K(y)$, at the points $x_0, \ldots, x_n$. By Fact 5.1, we can recover the coefficients of f. □

Proof of Fact 5.3. All we need to do is write β as a number in base α and the digits are our coefficients. In more detail, note that $\sum_{i=0}^{d-1} a_i \alpha^i \leq \sum_{i=0}^{d-1} (\alpha - 1)\alpha^i = \alpha^d - 1 < \alpha^d$, so $a_d = \lfloor \beta / \alpha^d \rfloor$, which we can obtain quickly by just integer multiplication and division. Now consider $f_1(x) = f(x) - a_d x^d$. We can repeat this process for f_1, obtaining the coefficients in sequence. □

Proof of Theorem 4.1.

1. #4Δ-BIPARTITE MATCHINGS. The reduction given in the introduction reduces #PERFECT MATCHINGS to #MATCHINGS while only increasing the degree by 1 and preserving bipartiteness. Dagum and Luby [8] have proven the former to be #$\mathcal{P}$-complete in 3-regular bipartite graphs; our result follows. (The facts about matchings in chains and Fibonacci sequences needed for the reduction are given by Lemma 6.3.)

2. #6Δ-Planar Bipartite Matchings. The starting point for this proof is the work of Jerrum [19] which shows that counting matchings in planar graphs is $\#\mathcal{P}$-complete. As is, his reduction produces graphs that are neither bipartite nor of bounded degree. We show how an additional step added in the middle of his reduction can transform the graphs produced into bipartite ones. We then show how a reduction like the one in Reduction 1 can replace the final step of his reduction so that the degree does not blow up.

In the course of his reduction, Jerrum considers a weighted form of #Matchings: Let $G = (V, E)$ be a graph in which each vertex $v \in V$ is assigned a weight $w(v) \in \mathbb{C}$. If $M \subset E$ is a matching in G, then we let $C(M)$ be the set of vertices in V which are covered by M, i.e., are endpoints of edges in M. Then the *weight* of M is $w(M) = \prod_{v \notin C(M)} w(v)$, i.e., the product of the weights of all vertices *not* covered by M; for a perfect matching M, $w(M) = 1$. The *weighted matching sum* $W(G)$ of G is $\sum_M w(M)$, where this sum is taken over all matchings in G. Thus if all vertices have weight 1, $W(G)$ is simply the number of matchings in G. We say that G has k *weights* if the number of distinct values other than 1 occurring as weights in G is at most k. The #$k\lambda$-Weighted Matchings problem is the following.

#$k\lambda$-Weighted Matchings.

Input: A vertex-weighted graph G with k weights.

Output: $W(G)$.

As usual, we also consider variants of this problem for bipartite, planar, and bounded degree graphs. The prefix $d\Delta$ is used to restrict to graphs of degree at most d. Our reduction will proceed in three stages. The first will show that computing $W(G)$ is hard for planar graphs of bounded degree. The second will transform any graph into a bipartite graph without changing $W(G)$, losing planarity, or increasing the degree. The third will remove weights one by one without losing any of the graph properties, showing that counting matchings in bipartite planar graphs of bounded degree is hard.

2a. #3-Regular Perfect Matchings $\propto$ #5Δ-2λ-Planar Weighted Matchings. Jerrum [19] gives a reduction from #Perfect Matchings to #2λ-Planar Weighted Matchings. We observe that his reduction produces a graph of degree 5 when applied to a graph of degree 3.

2b. #5Δ-2λ-Planar Weighted Matchings $\propto$ #5Δ-4λ-Planar Bipartite Weighted Matchings. Consider the weighted graph H with vertex set $\{v_1, v_2, v_3, v_4\}$, edges (v_1, v_2), (v_1, v_3), (v_2, v_4), (v_3, v_4), and vertex weights $w(v_1) = w(v_4) = 1$, $w(v_2) = \zeta$, $w(v_3) = \zeta^2$, where $\zeta = e^{2\pi i/3}$ is a primitive cube root of unity. (See Figure 5.1.) Straightforward calculations show the following:

1. $W(H) = W(H \setminus \{v_1, v_4\}) = 1$,
2. $W(H \setminus \{v_1\}) = W(H \setminus \{v_4\}) = 0$.

Above, the notation $H \setminus S$ denotes the graph formed by removing from H all vertices in S and any edges incident to them.

Now let G be a planar weighted graph with 2 weights and let $e = (u, v)$ be any edge in G. Consider the graph G' obtained from G by removing edge e; adding a disjoint copy of H; and adding edges $e_1 = (u, v_1)$ and $e_2 = (v, v_4)$. (See Figure 5.2.) We will show that $W(G') = W(G)$. Let M be any matching in G' that does not contain any of the edges of H. Then observation 2 above tells us that if M contains exactly one of e_1 and e_2, the net contribution to $W(G')$ of all matchings formed by adding H-edges to M will be zero. If M contains neither e_1 nor e_2, then, since $w(H) = 1$, the net contribution of all matchings formed by adding H-edges to M will

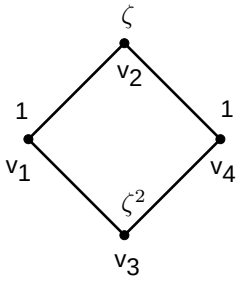

FIG. 5.1. *The graph H in Reduction 2b.*

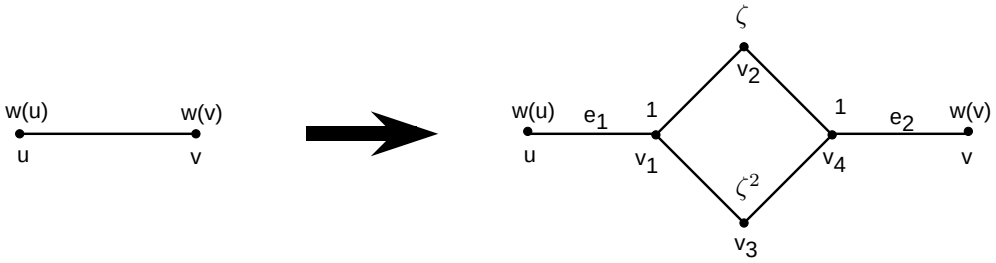

FIG. 5.2. *The transformation of Reduction 2b.*

be $\prod w(x)$ where the product is taken over all vertices $x \notin C(M) \cup \{v_1, v_2, v_3, v_4\}$. This is the same as the G-weight of M. Similarly, since $w(H \setminus \{v_1, v_4\}) = 1$, if M contains both e_1 and e_2 the net contribution will be the same as the G-weight of $(M - \{e_1, e_2\}) \cup \{e\}$. Thus, the net weight of all matchings in G' accounts exactly for the net weight of all matchings in G and $W(G') = W(G)$. Therefore, if we do this procedure to all edges in G, we will end up with a planar bipartite graph $\hat{G}$ with 4 weights (ζ and ζ^2 are the only new weights) such that $W(\hat{G}) = W(G)$. It is clear that this reduction can be carried out in polynomial time.

In the next part of the reduction, we remove weights one by one, only increasing the degree by 1. We use the prefix $k\mu$ to restrict to graphs with k weights in which all vertices with weight 1 have degree at most 6 and all other vertices have degree at most 5. In particular, an instance of #5Δ-4λ-PLANAR BIPARTITE WEIGHTED MATCHINGS satisfies this condition for $k = 4$.

2c. #$k\mu$-PLANAR BIPARTITE WEIGHTED MATCHINGS $\propto$ #$(k-1)\mu$-PLANAR BIPARTITE WEIGHTED MATCHINGS. Jerrum [19] gives a reduction which removes weights one by one, but his reduction blows up the degree. To replace his reduction, we use the Fibonacci technique.

Let G be a bipartite planar graph with k weights, in which all vertices with weight 1 have degree at most 6 and all other vertices have degree at most 5. Let $\alpha \neq 1$ be a vertex weight that occurs in G and let $v_1, \ldots, v_m$ be the vertices with weight α. For

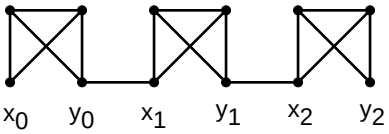

FIG. 5.3. *The graph L_2^3 in Reduction* 3.

each $s = 0, \ldots, m$, construct a graph G_s as follows: Add nodes $v_{i,j}$ to G for $1 \le i \le m$. Add edges to create disjoint chains $v_i - v_{i,1} - v_{i,2} - \cdots - v_{i,s}$ of $s+1$ nodes. Assign each of the new vertices weight 1, assign $v_1, \ldots, v_m$ weight 1, and keep all other vertex weights the same as in G. Notice that G_s is a valid instance of $\#(k-1)\mu$-PLANAR BIPARTITE WEIGHTED MATCHINGS.

Now, for every matching M in G, we can obtain matchings in G_s by adding some of the new edges to M. Suppose M covers exactly i of $v_1, \ldots, v_m$. Then the net contribution to $W(G_s)$ of the matchings formed by adding new edges to M is $x_s^i (x_{s+1}/\alpha)^{m-i} w_G(M)$, where x_t is the number of matchings in a chain of t vertices. Let $A_i = \sum w_G(M)$, where the sum is taken over all matchings in G which match exactly i of $v_1, \ldots, v_m$. Then $W(G_s) = (x_{s+1}/\alpha)^m \sum_{i=0}^m A_i (\alpha x_s / x_{s+1})^i$. As in the original application of the Fibonacci technique, we can recover the coefficients A_i with $m+1$ oracle calls and polynomial interpolation, using Lemma 6.3 to verify that the evaluation points are distinct. Then it is easy to compute $W(G) = \sum_{i=0}^m A_i$, as desired.

It may seem odd that the graphs G_s constructed in this reduction do not depend on the value of α. This is because this reduction works even if α is regarded as an indeterminate—$W(G)$ is then a polynomial in α, and we are essentially recovering this polynomial. Finally, note that $\#0\mu$-PLANAR BIPARTITE WEIGHTED MATCHINGS is exactly $\#6\Delta$-PLANAR BIPARTITE MATCHINGS.

3. $\#k$-REGULAR MATCHINGS, any fixed $k \ge 5$. We reduce from $\#(k-2)$-REGULAR BIPARTITE PERFECT MATCHINGS, which was shown to be $\#\mathcal{P}$-complete by Dagum and Luby [8]. Let H be the complete graph on $k+1$ vertices with one edge removed. Consider the graph L_s^k formed by taking $s+1$ disjoint copies of H, labelled $H_0, \ldots, H_s$, and attaching y_i to x_{i+1} for each $0 \le i < s$, where x_i and y_i are the two vertices in H_i of degree $k-1$. (See Figure 5.3.)

Now let G be any $(k-2)$-regular graph on n nodes $u_1, u_2, \ldots, u_n$. For any $0 \le s \le n$, consider the disjoint union of G with n copies of L_s^k. Let the vertices of degree $k-1$ in the ith copy of L_s^k be labelled v_i and w_i. We can form a k-regular graph G_s by connecting u_i to both v_i and w_i for each i. Let A_i be the number of matchings in G in which exactly i vertices are unmatched. Then the number of matchings in G_s is $\sum_{i=0}^n A_i (x_s + 4y_s + 3z_s)^i (x_s + 2y_s + z_s)^{n-i}$, where x_s is the number of matchings in L_s^k in which v and w—the two vertices of degree $k-1$—are both matched, y_s is the number in which v but not w is matched, and z_s is the number in which neither v nor w is matched. By Lemma 6.4, we can compute x_s, y_s, and z_s in polynomial time and the sequence $(x_s + 4y_s + 3z_s)/(x_s + 2y_s + z_s) = 1 + 2(y_s + z_s)/(x_s + 2y_s + z_s)$ never repeats. So, with $n+1$ oracle calls and interpolation, we can recover A_0, the number of perfect matchings in G.

4. $\#4\Delta$-BIPARTITE MATCHINGS$\propto$ $\#5\Delta$-BIPARTITE MAXIMAL MATCHINGS. The reduction we use is from [38], though they use it for vertex cover problems. Given a bipartite undirected graph $G = (V, E)$ of degree ≤ 4, construct $G' = (V', E')$, where $V' = V \cup \{v' : v \in V\}$ and $E' = E \cup \{(v, v') : v \in V\}$. Note that every matching W

in G yields a unique maximal matching $W' = W \cup \{(v, v') : v \text{ not matched by } W\}$ in G' and every maximal matching of G' can be obtained in this fashion.

5. #6Δ-Planar Bipartite Matchings$\propto$ #7Δ-Planar Bipartite Maximal Matchings. Notice that Reduction 4 preserves planarity, so it applies here, too.

6. #Planar Bipartite Vertex Covers. This result will come via a sequence of reductions beginning with #Vertex Covers, whose #$\mathcal{P}$-completeness follows immediately from Lemma 3.3 and the #$\mathcal{P}$-completeness of #Matchings. In the spirit of Reduction 2, the intermediate problems involve a generalization of vertex covers which we call *edge-weighted sets*. Suppose G is a graph in which each edge $e = (u, v)$ is labelled with a triple $d_e/s_e/n_e$ and S is a set of vertices in G. Then define the *weight of S with respect to e* as

$$w_e(S) = \begin{cases} d_e & \text{if } |\{u, v\} \cap S| = 2, \\ s_e & \text{if } |\{u, v\} \cap S| = 1, \\ n_e & \text{if } |\{u, v\} \cap S| = \emptyset, \end{cases}$$

so that d_e, s_e, and n_e correspond to weights if e is "doubly covered," "singly covered," or "not covered" by S, respectively. The *weight of S with respect to G* is then defined as $w_G(S) = \prod_e w_e(S)$. We now define the *edge-weighted sum* $\mathrm{EW}(G)$ to be $\sum_{S \subseteq V} w_G(S)$. Notice that if all the edges in G are labelled 1/1/0, then $\mathrm{EW}(G)$ is simply the number of vertex covers in G, so we have indeed generalized #Vertex Covers. With this in mind, we call an edge of such a labelled graph *normal* if its label is 1/1/0. For technical reasons, we will restrict to graphs with only a constant number of distinct labels. We will say a graph labelled as above has k *labels* if the number of distinct labels other than 1/1/0 is at most k.

Our first aim in reducing #Vertex Covers to planar graphs is to simplify the types of graphs we deal with. We call an embedding of a labelled graph G in the plane *simple* iff only normal edges are involved in crossings and each edge is in at most one crossing. Consider the following computational problem:

$k\lambda$-Simple Edge-Weighted Sum.

Input: A labelled graph G with k labels and a simple embedding of G in the plane.

Output: $\mathrm{EW}(G)$.

We now reduce #Vertex Covers to this problem.

6a. #Vertex Covers $\propto$ #1λ-Simple Edge-Weighted Sum. Let m be the number of edges in $G = (V, E)$. For any $s \geq 2m$ and any $t \geq 0$ consider the graph $G_{s,t} = (V_{s,t}, E_{s,t})$ formed by removing each edge $e = (u, v)$ of G and replacing it with the $s + 2$ vertices u^e, v^e, and $w_1^e, \ldots, w_s^e$. Also add the edges (u, u^e), (v, v^e), (u, w_1^e), (v, w_s^e), and (w_i^e, w_{i+1}^e) for $i = 1, \ldots, s - 1$. Furthermore, label the edges (u, u^e) and (v, v^e) with the label $(tF_{s-1}/F_s)/0/1$, where F_s is the sth Fibonacci number, as defined in Lemma 6.3. Label all other edges 1/1/0. Notice that it is easy to obtain a simple embedding of $G_{s,t}$ from any embedding of G in the plane, as we have broken each edge of G into $\geq 2m$ pieces and the edges of the form (u, u^e) clearly make no difference.

For each set of vertices S in G, let us consider the (weighted) number of ways that we may extend S to $G_{s,t}$, i.e., let us compute

$$\sum_{T : T \cap V = S} w_{G_{s,t}}(T).$$

If an edge $e = (u, v)$ of G is doubly covered by S, then there are $x_s(tF_{s-1}/F_s)^2$ (weighted) ways of adding vertices u^e, v^e, and $w_1^e, \ldots, w_s^e$ to S, where x_k is the

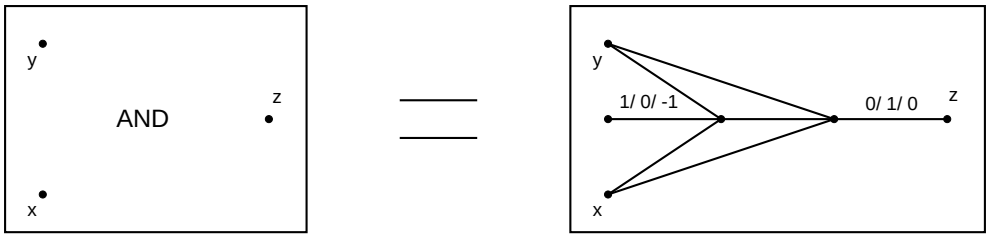

FIG. 5.4. *The AND gadget in Reduction* 6b.

number of vertex covers in a chain of k vertices. If e is singly covered by S, then there are $x_{s-1}tF_{s-1}/F_s$ ways to add these vertices. Finally, if e is not covered by S, there are x_{s-2} ways. Thus, if A_{ij} is the number of subsets of V which doubly cover i edges in G and which singly cover j edges, then

$$\mathrm{EW}(G_{s,t}) = \sum_{i,j} A_{ij}(x_s(tF_{s-1}/F_s)^2)^i(x_{s-1}tF_{s-1}/F_s)^j(x_{s-2})^{m-i-j}.$$

Writing r_k for F_k/F_{k-1} and using the fact that $x_k = F_{k+1}$ (from Lemma 6.3), we get

$$\mathrm{EW}(G_{s,t}) = \sum_{i,j} A_{ij}((F_{s+1}/F_{s-1})(t/r_s)^2)^i t^j F_{s-1}^m.$$

Using the relation $r_{s+1} = 1 + 1/r_s$, we get $F_{s+1}/F_{s-1} = r_{s+1}r_s = r_s + 1$. Substituting this above, we get

$$\mathrm{EW}(G_{s,t}) = F_{s-1}^m \sum_{i,j} A_{ij}(t^2(r_s^{-1} + r_s^{-2}))^i t^j.$$

Lemma 6.3 tells us that the sequence $\{r_s\}$ does not repeat. Since $x^{-1} + x^{-2} \neq y^{-1} + y^{-2}$ for any two distinct positive real numbers x and y, the sequence $\{r_s^{-1} + r_s^{-2}\}$ also does not repeat. Thus, by Fact 5.2, evaluating $\mathrm{EW}(G_{s,t})$ for each $t = 0, \ldots, m$ and for each $s = 2m, \ldots, 3m+1$ enables us to recover the coefficients A_{ij}. $\sum_{i+j=m} A_{ij}$ is the number of vertex covers of G.

We have reduced the problem to dealing with simple embeddings of graphs; the next step is to the problem of computing EW for planar graphs, as defined below:

$k\lambda$-PLANAR EDGE-WEIGHTED SUM.

Input: A labelled graph G with k labels and a planar embedding of G.

Output: $\mathrm{EW}(G)$.

The aim of the next reduction will be to replace crossings with planar gadgets without changing the value of $EW(G)$.

6b. $\#1\lambda$-SIMPLE EDGE-WEIGHTED SUM $\propto$ $\#5\lambda$-PLANAR EDGE-WEIGHTED SUM. First we make planar gadgets to compute elementary boolean formulae. We will write sets of vertices as functions from the set of all vertices to $\{0, 1\}$, where $S(v) = 1$ indicates that $v \in S$ and $S(v) = 0$ indicates that $v \notin S$. Consider the AND gadget in Figure 5.4.

It is easy to see that for any $a, b, c \in \{0, 1\}$,

$$\sum_{S:S(x)=a,S(y)=b,S(z)=c} w_{\mathrm{AND}}(S) = \begin{cases} 1 & \text{if } c = a \wedge b, \\ 0 & \text{otherwise.} \end{cases}$$

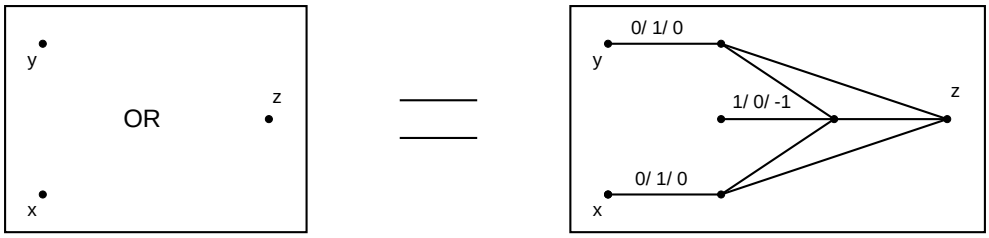

FIG. 5.5. *The OR gadget in Reduction 6b.*

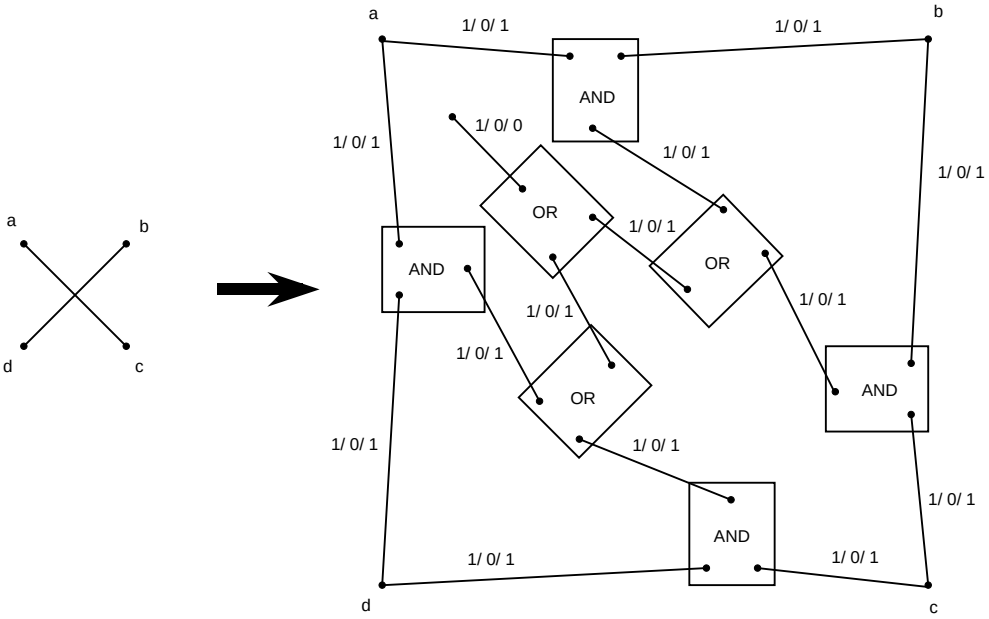

FIG. 5.6. *Replacing crossings in Reduction 6b.*

Thus, this gadget "forces" $S(z)$ to be $S(x) \wedge S(y)$. Similarly, the OR gadget of Figure 5.5 forces $S(z)$ to be $S(x) \vee S(y)$. Observe that an edge labelled 1/0/1 forces its endpoints to take on the same value and an edge labelled 1/0/0 forces both its endpoints to take on the value 1. The AND and OR gadgets constructed above along with these observations, enable us to form a complex gadget to replace crossings: Take any simple embedding of $G = (V, E)$ in the plane. Consider any two (normal) edges $e_1 = (a, c)$ and $e_2 = (b, d)$ which cross, where a, b, c, d is the order of the endpoints going clockwise around the crossing starting with a. Let G' be the graph with these edges removed. For any $S \subset V$, $w_{G'}(S) = w_G(S)$ if S contains at least one endpoint of both e_1 and e_2 and $w_G(S) = 0$ otherwise. The key observation is that S contains at least one endpoint of both e_1 and e_2 iff S contains some pair of vertices in $\{a, b, c, d\}$ which are *adjacent*, when these vertices are considered in clockwise order. Thus, if we replace the crossing with a gadget which simply forces $(S(a) \wedge S(b)) \vee (S(b) \wedge S(c)) \vee (S(c) \wedge S(d)) \vee (S(d) \wedge S(a)) = 1$, then the edge-weighted sum does not change. This can be done with the planar gadget of Figure 5.6.

If we replace all crossings of G in this manner, we obtain a planar labelled graph G' such that $\mathrm{EW}(G) = \mathrm{EW}(G')$. The gadgets only use the labels 1/0/0, 0/1/0,

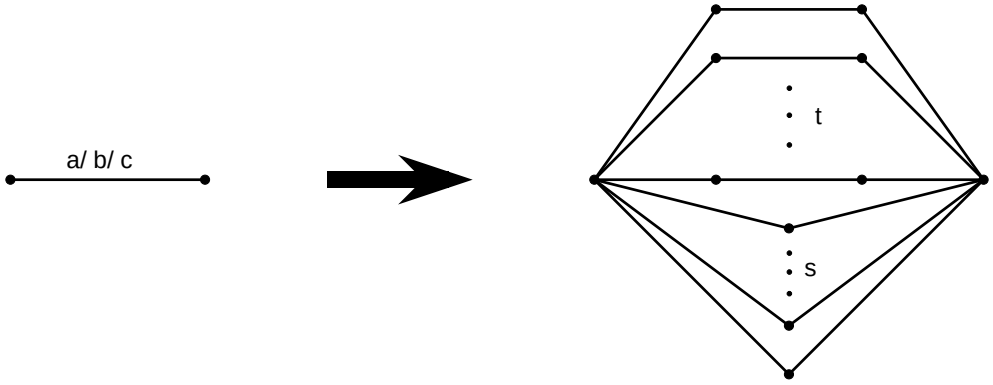

FIG. 5.7. *The transformation of Reduction* 6c.

$1/0/-1$, and $1/0/1$ in addition to the labels already present in G, so G' uses 5 labels. Finally, notice that the transformation can be performed in polynomial time.

Now we show that we can reduce the number of labels one at a time until there are none, showing that planar vertex cover is $\#\mathcal{P}$-complete.

6c. $\#k\lambda$-PLANAR EDGE-WEIGHTED SUM $\propto \#(k-1)\lambda$-PLANAR EDGE-WEIGHTED SUM. Let $G = (V, E)$ be any planar graph. Pick any label $\lambda = (a, b, c)$ used in G, let L be the set of edges with label λ and let $\ell = |L|$. Let $G_{s,t}$ be the graph formed by replacing all edges $e = (u, v)$ with label λ in the following fashion: Remove e, add vertices

$$V_e = \{w_1^e, \ldots, w_s^e, u_1^e, \ldots, u_t^e, v_1^e, \ldots, v_t^e\},$$

and add (normal) edges (u, w_i^e), (v, w_i^e), (u, u_j^e), (u_j^e, v_j^e), (v_j^e, v) for each $0 \le i \le s, 0 \le j \le t$. See Figure 5.7.

Let S be a subset of V. For each edge $e \in L$ doubly covered by S, there are $2^s 3^t$ (weighted) ways to extend S using vertices of V_e. For each edge $e \in L$ singly covered, there are 2^t ways. For each $e \in L$ not covered, there is only 1 way. Thus, if C_{ij} is the collection of subsets of V which doubly cover i edges of L and singly cover j edges of L, and

$$A_{ij} = \frac{1}{a^i b^j c^{\ell-i-j}} \sum_{S \in C_{ij}} w_G(S),$$

then

$$\mathrm{EW}(G_{s,t}) = \sum_{i,j} A_{ij} (2^s 3^t)^i (2^t)^j.$$

By Fact 5.2, if we can compute $\mathrm{EW}(G_{s,t})$ for $t = 0, \ldots, \ell$, $s = 0, \ldots, \ell$, we can recover the coefficients A_{ij} and thereby compute

$$\mathrm{EW}(G) = \sum_{i,j} A_{ij} a^i b^j c^{\ell-i-j}.$$

Notice that $\#0\lambda$-PLANAR EDGE-WEIGHTED SUM is exactly PLANAR VERTEX COVERS.

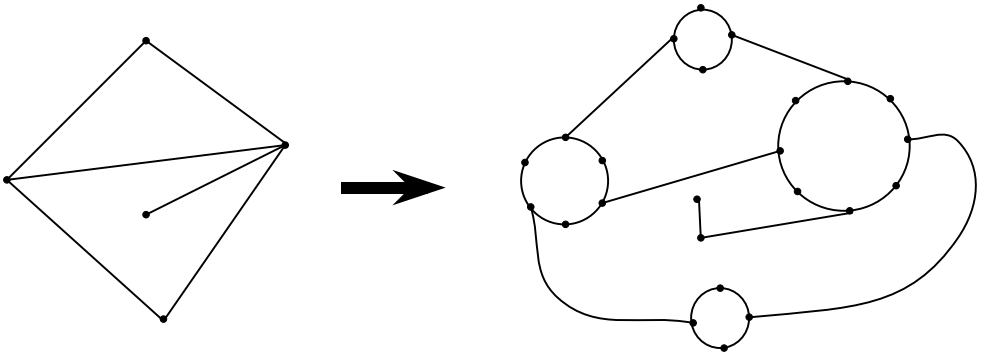

FIG. 5.8. *The transformation of Reduction* 7.

6d. #PLANAR VERTEX COVERS $\propto$ #PLANAR BIPARTITE VERTEX COVERS. Observe that the reduction of Provan and Ball [38] from #VERTEX COVERS to #BIPARTITE VERTEX COVERS preserves planarity.

7. #PLANAR BIPARTITE VERTEX COVERS $\propto$ #3Δ-PLANAR BIPARTITE MINIMUM CARDINALITY VERTEX COVERS. Let G be a bipartite planar graph. Consider the graph G' formed by taking each vertex v in G, replacing it with a cycle C_v of $2d(v)$ vertices, where $d(v)$ is the degree of v in G, and connecting the neighbors of v to alternate vertices on C_v. In order for this to preserve planarity, the neighbors must be connected with the same orientation as they have in a planar embedding of G. Let M_v be the vertices in C_v which are connected to vertices outside C_v, so $|C_v| = 2|M_v|$. See Figure 5.8 for an example.

Notice that every vertex cover in G' must be of size at least $s = \sum_{v \in V} d(v)$ to cover each cycle. Further notice that the vertex covers in G are in bijective correspondence with the covers of size s in G, under the map

$$S \mapsto \bigcup_{v \in S} M_v \cup \bigcup_{v \notin S} (C_v \setminus M_v).$$

Finally, observe that G' is bipartite (since G is), planar, and of degree at most 3.

8a. #k-REGULAR BIPARTITE PERFECT MATCHINGS $\propto$ #$(2k-2)$-REGULAR MINIMUM CARDINALITY VERTEX COVERS, any fixed $k \geq 3$. This follows immediately from Lemma 3.3, noting that the line-graph of a k-regular graph is a $(2k-2)$-regular graph.

8b. #$(k-1)$-REGULAR MINIMUM CARDINALITY VERTEX COVERS $\propto$ #k-REGULAR MINIMUM CARDINALITY VERTEX COVERS, any odd $k \geq 5$. Let H be the complete graph on $k+1$ vertices with one edge removed. Consider the sequence of graphs $\{H_n^k : n \geq 0\}$ defined as follows: H_0^k is the complete graph on $k+2$ vertices, labelled $u_1, v_1, \ldots, u_{(k-1)/2}, v_{(k-1)/2}, u, v, w$, with the edges $(u_1, v_1), \ldots, (u_{(k-1)/2}, v_{(k-1)/2}), (u, v), (v, w)$ removed. H_{n+1}^k is formed by taking the disjoint union of H_n^k and a new copy of H and and connecting one of the vertices of degree $k-1$ in H to the unique vertex in H_n^k of degree $k-1$. See Figure 5.9.

Let G be any $(k-1)$-regular graph on n nodes $u_1, u_2, \ldots, u_n$. For any $s \geq 0$, consider the disjoint union of G with n copies of H_{2s}^k. Let the vertex of degree $k-1$ in the ith copy of H_{2s}^k be labelled v_i. We can form a k-regular graph G_s by connecting u_i to v_i for each i. Lemma 6.5 tells us that there are minimum cardinality vertex covers (mcvc's) in the ith copy of H_{2s}^k both containing v_i and not containing v_i. Hence, any

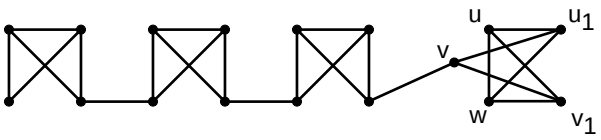

FIG. 5.9. *The graph H_3^3 in Reduction 8b.*

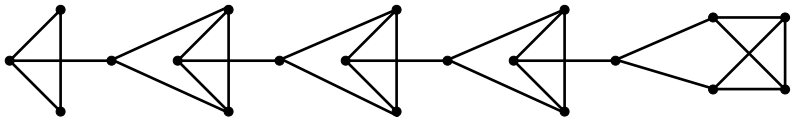

FIG. 5.10. *The graph I_4^3 in Reduction 10b.*

mcvc in G_s must be formed by taking an mcvc in G and taking mcvc's in each copy of H_{2s}^k. If G has N mcvc's and they are of size c, then G_s has $N(x_s+y_s)^c(x_s)^{n-c}$ mcvc's, where x_s is the number of mcvc's in H_{2s}^k containing the vertex of degree $k-1$ and y_s is the number not containing the vertex of degree $k-1$. With a single oracle call, we obtain the evaluation of the polynomial $f(x) = Nx^c$ at the point $z_s = 1+y_s/x_s$, which equals $1 + ((k+1)s+4)/(k-1)$ by Lemma 6.5. Notice that $f(z_0)/f(z_1) = (z_0/z_1)^c$, so with just two oracle calls we can recover c and then N. (In fact, Reduction 8a produces instances G in which we know c, so actually only one oracle call is necessary here.)

9. #3Δ-PLANAR BIPARTITE MINIMUM CARDINALITY VERTEX COVERS $\propto$ #4Δ-PLANAR BIPARTITE VERTEX COVERS. This is a standard application of the Fibonacci technique, almost identical to Reduction 1: Form G_s by attaching chains of length s to each vertex of the input graph G for $s = 0, \ldots, n$. The number of vertex covers in G_s is essentially the evaluation of a polynomial whose coefficients are the number of vertex covers in G of each size. By Lemma 6.3, these evaluation points are consecutive ratios of Fibonacci numbers, which do not repeat, so by interpolation we can recover the number of minimum cardinality vertex covers in G.

10a. #4-REGULAR MINIMUM CARDINALITY VERTEX COVERS $\propto$ #5-REGULAR VERTEX COVERS. This is another application of the Fibonacci technique. Let G be any 4-regular graph on n nodes. As in Reduction 8b, for $0 \le s \le n$, form a 5-regular graph G_s by attaching n disjoint copies of the gadget H_s^5 defined in that reduction. We recover the number of minimum cardinality vertex covers in G by polynomial interpolation, using Lemma 6.6 to guarantee that the evaluation points are distinct.

10b. #$(k-2)$-REGULAR MINIMUM CARDINALITY VERTEX COVERS $\propto$ #k-REGULAR VERTEX COVERS. This yet another application of the Fibonacci technique, with slightly different gadgets. Let H be the complete graph on $k+1$ vertices with two edges incident to some vertex v removed. Consider the sequence of graphs $\{I_n^k : n \ge 0\}$ defined as follows: I_0^k is the complete graph on $k+1$ vertices with a single edge removed. I_{n+1}^k is formed by taking the disjoint union of I_n^k and a new copy of H and connecting the vertex of degree $k-2$ in H to the two vertices of degree $k-1$ in I_n^k. See Figure 5.10. Let $(I_n^k)^+$ be the graph formed by adding to I_n^k a new vertex p and connecting p to the two vertices of degree $k-1$ in I_n^k.

Let G be any $(k-2)$-regular graph on n nodes $u_1, u_2, \ldots, u_n$. For any $0 \le s \le n$, consider the disjoint union of G with n copies of I_s^k. Let the vertices of degree $k-1$ in the ith copy of I_s^k be labelled v_i and w_i. We can form a k-regular graph

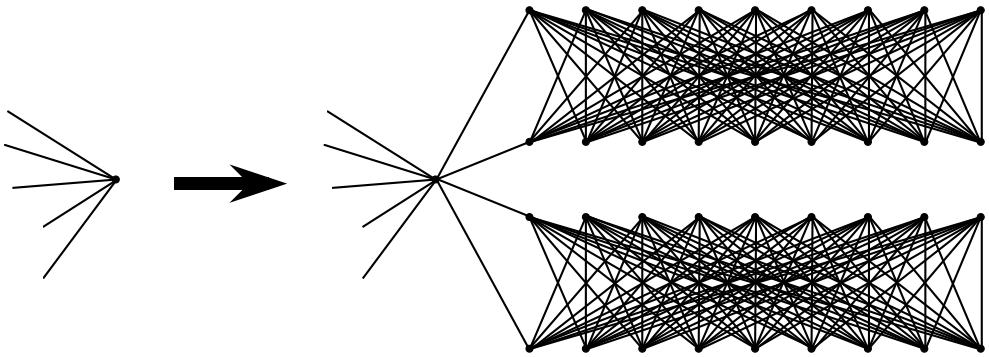

FIG. 5.11. *The transformation in Reduction* 12 *for* $r = 2$.

G_s by connecting u_i to both v_i and w_i for each i. By Lemma 6.7 and polynomial interpolation, the number of minimum cardinality vertex covers in G can be recovered from the number of vertex covers in G_s for $s = 0, \ldots, n$.

11. #4Δ-PLANAR BIPARTITE VERTEX COVERS $\propto$ #5Δ-PLANAR BIPARTITE MINIMAL VERTEX COVERS. This reduction is identical to Reduction 4.

12. #5-REGULAR VERTEX COVERS $\propto$ #REGULAR MINIMAL VERTEX COVERS. Let G be any 5-regular graph on n nodes $u_1, u_2, \ldots, u_n$. For $r \geq 0$, let J_r be the complete bipartite graph on $(5 + 2r) + (5 + 2r)$ vertices with one edge removed. Consider the disjoint union of G with nr copies of J_r, where these copies are named $H_{i,j}$ for $1 \leq i \leq n, 1 \leq j \leq r$. Let G' be the graph formed by attaching each u_i to the two vertices of degree of $4 + 2r$ in each of $H_{i,1}, H_{i,2}, \ldots, H_{i,r}$. See Figure 5.11. Notice that G' is a $(5 + 2r)$-regular graph. Notice that if G has A_i vertex covers of size i, G' has $\sum_{i=0}^{n} A_i (3^r)^i (2^r)^{n-i}$ minimal vertex covers. Dividing by 2^{rn}, we get the evaluation of $f(x) = \sum_{i=0}^{n} A_i x^i$ at $(3/2)^r$. If we choose $r = n$, we can, by Lemma 5.3, recover the coefficients of f in a single oracle call. The number of vertex covers in G is simply the sum of the coefficients. □

Proof of Corollary 4.2. These follow immediately from Theorem 4.1, Proposition 3.1, and Proposition 3.2. □

Proof of Proposition 4.3. Here we prove only that the given problems are hard to approximate within a factor $2^{n^{1/2-\epsilon}}$. Proving inapproximability within $2^{n^{1-\epsilon}}$ is more involved, and details can be found in [45] or [47].

By Proposition 3.1, we may focus on vertex covers, and the other results follow. We reduce from $2^{n^{1-\epsilon}}$-APPROX #VERTEX COVERS, which was shown to be $\mathcal{NP}$-hard by Sinclair [41] (see also Roth [40]). Note that, ignoring the planarity and bipartiteness conditions, Reduction 7 in the proof of Theorem 4.1 is a parsimonious reduction from #VERTEX COVERS to #3Δ-MINIMUM CARDINALITY VERTEX COVERS. That is, it transforms graphs G to graphs G' such that the number of minimum cardinality vertex covers in G' equals the number of vertex covers in G. Note that if G has n vertices, then the number of vertices in G' is $n' < 2n^2$, so an approximation within $2^{(n')^{1/2-\epsilon}}$ for G' gives an approximation within $2^{n^{1-\epsilon}}$ for G (for sufficiently large n). □

6. Proving that sequences do not repeat. In this section, we develop general tools for proving that sequences defined by 2×2 linear recurrences do not repeat, and apply them to deduce that the interpolation points in our reductions are distinct.

LEMMA 6.1. *Let a, b, c, d be rational numbers and let α and β be nonzero complex numbers. Let the sequence z_n be defined by*

$$z_n = \frac{a\alpha^n + b\beta^n}{c\alpha^n + d\beta^n}.$$

Then the sequence $\{z_n\}$ repeats iff $ad - bc = 0$ or α/β is a root of unity.

Proof. Cross-multiplying, we see that $z_n = z_m$ iff $(ad - bc)(\alpha^m\beta^n - \beta^m\alpha^n) = 0$ iff $ad - bc = 0$ or $(\alpha/\beta)^{n-m} = 1$. □

LEMMA 6.2. *Let A, B, C, D, x_0, and y_0 be rational numbers. Define the sequences $\{x_n\}$ and $\{y_n\}$ recursively by $x_{n+1} = Ax_n + By_n$ and $y_{n+1} = Cx_n + Dy_n$. Then the sequence $\{z_n = x_n/y_n\}$ never repeats as long as all of the following conditions hold:*

$$AD - BC \neq 0, \tag{1}$$

$$D^2 - 2AD + A^2 + 4BC \neq 0, \tag{2}$$

$$D + A \neq 0, \tag{3}$$

$$D^2 + AD + A^2 + BC \neq 0, \tag{4}$$

$$D^2 + A^2 + 2BC \neq 0, \tag{5}$$

$$D^2 - AD + A^2 + 3BC \neq 0, \tag{6}$$

$$By_0^2 - Cx_0^2 - (A - D)x_0y_0 \neq 0. \tag{7}$$

Proof. Let α and β be the eigenvalues of the matrix $\left(\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right)$. By basic linear algebra, as long as α and β are distinct, the general solution to the 2×2 system of linear recurrences describing x_n and y_n is given by $x_n = a\alpha^n + b\beta^n$ and $y_n = c\alpha^n + b\beta^n$, for some $a, b, c, d \in \mathbb{C}$. By the previous lemma, as long as $\alpha \neq \beta$ and neither α nor β is zero, $\{z_n\}$ can repeat only if $ad - bc = 0$ or α/β is a root of unity.

If α/β is a root of unity, it must be one of degree 1 or 2 over $\mathbb{Q}$, as $\alpha/\beta \in \mathbb{Q}(\alpha, \beta) = \mathbb{Q}(\alpha)$, which is a field extension of degree ≤ 2 over $\mathbb{Q}$. The degree of a primitive nth root of unity over $\mathbb{Q}$ is $\phi(n)$ (see, e.g., [18, section 13.2, Theorem 1]), where ϕ is Euler's totient function. By the formula $\phi(\prod p_i^{\alpha_i}) = \prod p_i^{\alpha_i - 1}(p_i - 1)$ for distinct primes p_i, one sees that only n for which $\phi(n) \leq 2$ are $1, 2, 3, 4$, and 6. The irreducible polynomials over $\mathbb{Q}$ for the corresponding primitive roots of unity are $x - 1$, $x + 1$, $x^2 + x + 1$, $x^2 + 1$, and $x^2 - x + 1$. So to check that α/β is not a root of unity, we need only check that α/β does not satisfy any of these polynomials. Using the quadratic formula, we can express α and β in terms of A, B, C, and D. The first 6 conditions in the lemma come from substituting these expressions into the polynomials that test whether (1) α or β is zero, (2) $\alpha = \beta$, and (3)–(6) α/β is a 2nd, 3rd, 4th, or 6th root of unity.

As long as $\alpha \neq \beta$ and neither are zero, we can solve for a, b, c, and d in terms of A, B, C, D, and the initial conditions x_0, y_0. Condition (7) amounts to testing whether $ad - bc = 0$ (given that $D^2 - 2AD + A^2 + 4BC \neq 0$, which is tested by condition (2). □

As observed by Greenhill [14], if A, B, C, and D are all positive (or if all are nonnegative and $A \neq D$), then only conditions (1) and (7) must be checked in the above lemma. We now apply this lemma to the various sequences that arise in our reductions.

LEMMA 6.3. *Let F_n denote the nth Fibonacci number. That is, $F_0 = 1$, $F_1 = 1$, and $F_{n+2} = F_{n+1} + F_n$ for all $n \geq 0$. The number of matchings (resp., vertex covers) in a chain of n vertices is F_n (resp., F_{n+1}). Moreover, $F_{n+1}/F_n \neq F_{m+1}/F_m$ for any $n \neq m$.*

Proof. Let x_n be the number of matchings in a chain of n vertices. Given a chain $C_n = v_1 - v_2 - \cdots - v_n$ with $n \geq 1$, the number of matchings in C_n in which v_1 is matched is x_{n-2} and the number in which v_1 is unmatched is x_{n-1}. Thus, $x_n = x_{n-1} + x_{n-2}$, which is the Fibonacci recurrence. Also note that $x_0 = 1$ and $x_1 = 1$. To obtain the result for vertex covers, observe that C_n is the line-graph of C_{n+1} and apply Lemma 3.3. The "moreover" part of the lemma follows from Lemma 6.1 with $A = B = C = x_0 = y_0 = 1$ and $D = 0$. □

LEMMA 6.4. *For $k \geq 4$, let L_s^k be the graph defined in Reduction 3 of the proof of Theorem 4.1. Let v and w be the vertices in L_s^k of degree $k-1$. Let x_s be the number of matchings in L_s^k in which both v and w are matched, let y_s be the number in which v is matched but w is not, and let z_s be the number in which neither v nor w is matched. Then x_s, y_s, and z_s can be computed in time polynomial in s and the sequence $\{w_s = (y_s + z_s)/(x_s + 2y_s + z_s)\}$ never repeats.*

Proof. For all m, let M_m denote the number of matchings in the complete graph on m vertices. Observe that $M_{m+1} = M_m + mM_{m-1}$. By inspection, we can verify that the sequences x_s and y_s satisfy the following recurrences:

$$\begin{aligned} x_{s+1} &= (k-1)M_{k-1}x_s + (k-1)M_{k-1}y_s + (k-1)M_{k-2}y_s \\ &= (k-1)M_{k-1}x_s + (M_k + (k-2)M_{k-1})y_s, \\ y_{s+1} &= M_k x_s + (M_k + M_{k-1})y_s. \end{aligned}$$

It is easy to see that y_s and z_s satisfy the same recurrence relations:

$$\begin{aligned} y_{s+1} &= (k-1)M_{k-1}y_s + (M_k + (k-2)M_{k-1})z_s, \\ z_{s+1} &= M_k y_s + (M_k + M_{k-1})z_s. \end{aligned}$$

The initial conditions are

$$\begin{aligned} z_0 &= M_{k-1}, \\ y_0 &= M_k - z_0 = M_k - M_{k-1}, \\ x_0 &= M_{k+1} - 2y_0 - 2x_0 = kM_{k-1} - M_k. \end{aligned}$$

We can compute x_s, y_s, and z_s in polynomial time using the above recurrences. Because we have three sequences here, we cannot apply Lemma 6.2 directly. However, the proof here is nearly identical to the one of Lemma 6.2, so we do not include the details that are worked out there. Since the two pairs of sequences satisfy the same recurrence relations, closed forms for these sequences will be of the form $x_s = a\alpha^s + b\beta^s, y_s = c\alpha^s + d\beta^s, z_s = e\alpha^s + f\beta^s$. So

$$w_s = \frac{(c+e)\alpha^s + (d+f)\beta^s}{(a+2c+e)\alpha^s + (b+2d+f)\beta^s}.$$

This sequence will not repeat as long as α/β is not a root of unity and $(c+e)(b+2d+f) - (d+f)(a+2c+e) \neq 0$. The conditions for α/β to not be a root of unity are the same as conditions (1)–(6) of Lemma 6.2; of these, conditions (2)–(6) are automatically satisfied since the recurrence coefficients are all positive. After simplification, condition (1) becomes

$$-M_k^2 - M_k M_{k-1} + (k-1)M_{k-1}^2 \neq 0.$$

Dividing by M_{k-1}^2 and applying the quadratic formula, we can reformulate this condition as

$$\frac{M_k}{M_{k-1}} \neq \frac{1 \pm \sqrt{4k-3}}{2}.$$

Moser and Wyman [30] have shown the following[2]:

$$\frac{1+\sqrt{4k-3}}{2} \leq \frac{M_k}{M_{k-1}} \leq \frac{1+\sqrt{4k+1}}{2}.$$

The proof of this fact is by straightforward induction, applying the recurrence $M_{k+1} = M_k + kM_{k-1}$. The same proof actually shows that *strict* inequality holds (on both sides) for all $k \geq 4$, as long as we use $k = 4$ as our base case. Thus condition (1) is also satisfied.

The only condition left to check is $(c+e)(b+2d+f) - (d+f)(a+2c+e) \neq 0$. Using the initial conditions to solve for these values, this reduces to

$$-2M_k^3 + (6-2k)M_{k-1}M_k^2 + (4k-6)M_{k-1}^2 M_k + (2k^2-6k+4)M_{k-1}^2 \neq 0.$$

Dividing by M_{k-1}^3, we obtain a cubic polynomial in M_k/M_{k-1} which vanishes iff

$$\frac{M_k}{M_{k-1}} \in \left\{ -k+2, \frac{1 \pm \sqrt{4k-3}}{2} \right\}.$$

The strengthened Moser–Wyman result shows that this cannot hold for any $k \geq 4$. □

LEMMA 6.5. *Fix k to be an odd integer ≥ 3. Let H_n^k be the graph defined in Reduction* 8b *of the proof of Theorem* 4.1. *Let v be the unique vertex in H_n^k of degree $k-1$. Then the number of minimum cardinality vertex covers in H_{2m}^k containing v is $(k-1)^{m+1}/2$ and the number not containing v is $(k-1)^m((k+1)m+4)/2$.*

Proof. First, let H be the complete graph on $k+1$ vertices with one edge removed. We now prove the lemma by induction on m.

$m = 0$: It is easily verified that the size of the mcvc in H_0^k is k, that there are $(k-1)/2$ such covers containing v, and that there are 2 such covers not containing v.

Induction step: Let v' be the vertex of degree $k-1$ in $H_{2(m+1)}^k$ and let v be the vertex of degree $k-1$ in H_{2m}^k. Now observe that the smallest vertex cover in H is of size $k-1$ and the only such cover omits both the vertices of degree $k-1$. The two copies of H added to H_{2m}^k to form $H_{2(m+1)}^k$ cannot both simultaneously be covered by covers of size $k-1$, for this would leave the edge between them uncovered. Hence, the smallest possible cover for $H_{2(m+1)}^k$ could only come from taking an mcvc on H_{2m}^k, a cover of size $k-1$ on one of the added copies of H and a cover of size k on the other copy of H. It is now easy to treat the problem in cases: For each mcvc of H_{2m}^k that contains v, there are $k-1$ mcvc's in $H_{2(m+1)}^k$ containing v' and $k+1$ mcvc's not containing v'. For each mcvc of H_{2m}^k not containing v, there are 0 mcvc's containing v' and $k-1$ mcvc's not containing v'. By induction hypothesis, this gives a total of $(k-1)((k-1)^{m+1}/2) = (k-1)^{m+2}/2$ mcvc's containing v' and $(k+1)((k-1)^{m+1}/2)+(k-1)[(k-1)^m((k+1)m+4)/2] = (k-1)^{m+1}((k+1)(m+1)+4)/2$ not containing v'. □

[2]Moser and Wyman discuss the number of solutions to $x^2 = 1$ in the symmetric group on k elements. It is easy to see that this quantity is exactly M_k.

LEMMA 6.6. *Fix k to be an odd integer ≥ 3. Let H_n^k be the graph defined in Reduction* 8b *of the proof of Theorem* 4.1. *Let v be the unique vertex in H_n^k of degree $k-1$. Define x_s to be the number of vertex covers in H_s^k containing v and y_s to be the number not containing v. Then x_s and y_s can be computed in time polynomial in s and the sequence $\{x_s/y_s\}$ never repeats.*

Proof. The sequences x_s and y_s satisfy the following recurrences:

$$x_{s+1} = (k+1)x_s + ky_s,$$
$$y_{s+1} = 2x_s + y_s,$$

with initial conditions $x_0 = (3k+3)/2$ and $y_0 = 3$. Conditions (1) and (7) of Lemma 6.2 are

$$-k+1 \neq 0,$$
$$(9k-9)/2 \neq 0.$$

It is clear that these hold for all odd integers $k \geq 3$. □

LEMMA 6.7. *Fix k to be an integer ≥ 3. Let $(I_n^k)^+$ be the graph defined in Reduction* 10b *of the proof of Theorem* 4.1. *Let p be the vertex in $(I_n^k)^+$ of degree* 2. *Define x_s to be the number of vertex covers in I_s^k containing v and let y_s be the number not containing v. Then x_s and y_s can be computed in time polynomial in s and the sequence $\{x_s/y_s\}$ never repeats.*

Proof. The sequences x_s and y_s satisfy the following recurrences:

$$x_{s+1} = (k+1)x_s + 3y_s,$$
$$y_{s+1} = (k-1)x_s + y_s,$$

with initial conditions $x_0 = k+3$ and $y_0 = k$. Conditions (1) and (7) of Lemma 6.2 are

$$-2k+4 \neq 0,$$
$$k^2 - 3k + 9 \neq 0.$$

It is easily verified that these hold for all integers $k \geq 3$. □

7. Conclusion. The study of counting and its computational complexity is both interesting and important. However, we have only a limited understanding of how the complexity of counting problems behaves in restricted cases. The results of this paper have improved the situation somewhat, but there are still many open problems. We believe that the tools developed here are likely to prove useful in obtaining restricted-case results for other counting problems.

Even regarding just the problems studied here, several unanswered questions stand out. For one, we have shown that a number of problems are hard in bounded-degree bipartite graphs and constant-degree regular graphs, but we do not know what happens if these conditions are imposed simultaneously. Do these problems remain hard in bipartite k-regular graphs, or even just bipartite regular graphs? In addition, we know that all the problems become tractable in degree 2, but some of our results only show hardness for degree 4 or higher. Recall that, subsequent to this work, Greenhill [14] has closed this degree gap for counting independent sets, but other gaps still remain.

For approximate counting, the gaps between positive and negative results are even larger. For instance, Luby and Vigoda [28] have given a polynomial-time algorithm for

approximately counting independent sets in graphs of degree 4, but the problem is only known to become $\mathcal{NP}$-hard at degree 25, as shown by Dyer, Frieze, and Jerrum [9]. An even larger gap in our knowledge is the long-standing open problem of approximately counting perfect matchings in general graphs. (Recall that this can be solved in polynomial time for dense graphs [21].) In the context of optimization problems, a substantial body of work has yielded numerous tight inapproximability results based on the PCP Theorem (cf. [7]). There is a need to develop analogous general techniques for the inapproximability of counting problems, perhaps by designing PCP systems that are tailored for this purpose.

Note added in proof. The open problem mentioned above, about approximately counting perfect matchings in general graphs, has been resolved in the positive by Jerrum, Sinclair, and Vigoda (to appear in STOC 2001).

Acknowledgments. I am indebted to a few people for helping me complete this work: my undergraduate advisor, Leslie Valiant, who sparked my interest in complexity theory and provided advice and inspiration throughout; Dan Roth, who suggested these problems and guided me through the initial stages of research; and Jennifer Sun, who spent many hours reading and critiquing the original version of this work.

I also thank Russ Bubley, Sergey Fomin, Michel Goemans, Catherine Greenhill, Vijay Vazirani, and the anonymous referees for numerous helpful suggestions and pointers.

MATCHINGS MEETING QUOTAS AND THEIR IMPACT ON THE BLOW-UP LEMMA*

VOJTECH RÖDL†, ANDRZEJ RUCIŃSKI‡, AND MICHELLE WAGNER§

Abstract. A bipartite graph $G = (U, V; E)$ is called ϵ-regular if the edge density of every sufficiently large induced subgraph differs from the edge density of G by no more than ϵ. If, in addition, the degree of each vertex in G is between $(d-\epsilon)n$ and $(d+\epsilon)n$, where d is the edge density of G and $|U| = |V| = n$, then G is called super (d, ϵ)-regular. In [*Combinatorica*, 19 (1999), pp. 437–452] it was shown that if $S \subset U$ and $T \subset V$ are subsets of vertices in a super-regular bipartite graph $G = (U, V; E)$, and if a perfect matching M of G is chosen randomly, then the number of edges of M that go between the sets S and T is roughly $|S||T|/n$. In this paper, we derandomize this result using the Erdős–Selfridge method of conditional probabilities. As an application, we give an alternative constructive proof of the blow-up lemma of Komlós, Sárközy, and Szemerédi (see [*Combinatorica*, 17 (1997), pp. 109–123] and [*Random Structures Algorithms*, 12 (1998), pp. 297–312]).

Key words. ϵ-regular graphs, perfect matchings, conditional probabilities, randomized algorithms, derandomization, blow-up lemma

1. A politically correct cultural revolution and its impact on the blow-up lemma.

Let X be a radical politician who, in an attempt to run a politically correct presidential election campaign, makes a promise to each minority group that it will enjoy "statistically equal" status with respect to every quality of life, such as wealth, health, or education. After winning the election, he asks his advisors how to fulfill his commitments. Fortunately, one of the advisors has a background in mathematics and she proposes a sound solution: take all citizens' social security numbers and reassign them randomly, and then let all citizens assume their new lives accordingly. Thus, with high probability every group (e.g., women, elderly, African-American, gay, etc.) will each be proportionally represented in every category of quality of life (see Proposition 1 in section 2). President X does not want to take any chances, however, and asks for a "no-risk" solution. As there are more than 250,000,000 legal citizens, searching through all posssible permutations is not an option. Hence, the mathematically inclined advisor must design an algorithm which, in reasonable time, produces a reassignment that fulfills the president's promises (see Proposition 2 in section 3).

Then another obstacle arises. One of the other advisors observes that each person can realistically be reassigned to the lives of only a subcollection of other people. As a result, the advisors produce a huge chart that illustrates all such pairs of people (a

"who can be whom" chart). Fortunately for President X, the talented female advisor notices that the chart enjoys a great deal of regularity and that each citizen can be assigned to a significant proportion of all citizens. After several years of intense research, she proves that a random reassignment, consistent with the "who can be whom" chart, is also very likely to produce a satisfiable outcome (see Theorem 2.2 in section 2). Moreover, the procedure can be "derandomized" in reasonable time to yield the required "no-risk" solution (see Theorem 4.1 in section 4).

Unfortunately, by the time the advisor proposes her solution, President X is no longer in office. So that her research does not go to waste, she searches for another real-life application and finds it in the "blow-up lemma" (see section 5).

2. The catching lemma. A permutation $\sigma : [n] \to [n]$ can be viewed as a perfect matching of the complete bipartite graph $K_{n,n}$. *A random perfect matching* of a graph is a perfect matching drawn randomly, with uniform distribution, from the set of all perfect matchings in that graph.

Suppose that two subsets S and T of $[n]$ are given. If $\sigma : [n] \to [n]$ is a random permutation of the set $[n]$, then the number $|\sigma(S) \cap T|$ of elements of S mapped onto the elements of T has a hypergeometric distribution with expectation $|S||T|/n$. Equivalently, given a random perfect matching σ of $K_{n,n}$, and a pair of sets (S, T) with S and T on opposite sides, the number of edges $|\sigma(S) \cap T|$ "caught" in between S and T is a hypergeometric random variable with expectation $|S||T|/n$. In fact, in the following proposition we shall see that using Chernoff's bound for the hypergeometric distribution, one can obtain sharp concentration results simultaneously for the number of edges caught by many pairs (S_i, T_i), $i = 1, 2, \ldots, k$.

The following statement of Chernoff's inequality is valid for every binomial or hypergeometric random variable X on n trials (see [7, pp. 28–29]): for $t \geq 0$,

$$P(|X - E(X)| \geq t) \leq 2 \exp\left(-\frac{2t^2}{n}\right). \tag{1}$$

In Proposition 1 below, as well as in other statements, the sets S_i and T_i may be repeated; in other words, it is possible that $S_i = S_j$ for some $i \neq j$. In fact, in our "real-life" application from section 1, the sets S range through all the minority groups, and, for a fixed set S_i, the sets T_j range through all categories of qualities of life. On the other hand, we shall see in section 5 that in other applications all sets S_i (and all sets T_i) may be pairwise distinct.

PROPOSITION 1 (the complete catching lemma). *Given positive integers n, k, and $0 < \lambda < 1$, let U and V, $|U| = |V| = n$, be the two vertex classes of a complete bipartite graph $K_{n,n}$, and let $S_i \subset U$, $T_i \subset V$, $i = 1, 2, \ldots, k$. If $\sigma : U \to V$ is a random perfect matching in $K_{n,n}$, then the event that the inequality*

$$|S_i||T_i|/n - \lambda n < |\sigma(S_i) \cap T_i| < |S_i||T_i|/n + \lambda n \tag{2}$$

holds for all $i = 1, \ldots, k$ occurs with probability at least $1 - 2k \exp\{-2\lambda^2 n\}$.

Proof. Set $s_i = |S_i|$, $t_i = |T_i|$, and $a_i = \lceil s_i t_i/n - \lambda n \rceil$, $b_i = \lfloor s_i t_i/n + \lambda n \rfloor$, $i = 1, \ldots, k$. Let $X_i = |\sigma(S_i) \cap T_i|$, and let A_i denote the event that $a_i \leq X_i \leq b_i$, $i = 1, 2, \ldots, k$. For every integer x, we have

$$P(X_i = x) = \frac{\binom{t_i}{x}\binom{n-t_i}{s_i-x}}{\binom{n}{s_i}}$$

and

$$P(A_i) = \sum_{x \in [a_i, b_i]} P(X_i = x).$$

By (1), it follows that

$$P(\overline{A_i}) = \sum_{x \in [a_i, b_i]} P(X_i = x) \leq 2 \exp\{-2\lambda^2 n\}.$$

Now if X counts the number of events A_i that do not occur, then the probability that (2) fails to hold for some $i = 1, 2, \ldots, k$ is

$$P(X > 0) \leq E(X) = \sum_i P(\overline{A_i}) < 2k \exp\left\{-2\lambda^2 n\right\}. \qquad \square$$

In [13], a generalization of Proposition 1 was proved. Given a bipartite graph G with bipartition (U, V) and two subsets $U' \subset U$ and $V' \subset V$, denote by $E_G(U', V')$ the set of edges of G with one endpoint in U', and the other in V', and set $e_G(U', V') = |E_G(U', V')|$. Define the *density* $d_G(U', V')$ of the pair (U', V') in G by $d_G(U', V') = \frac{e_G(U', V')}{|U'||V'|}$. The quantity $d_G(U, V)$ is also called *the density of* G.

The graph G is called *ϵ-regular* if for every pair of sets (U', V'), $U' \subset U$, $V' \subset V$, $|U'| > \epsilon|U|$, $|V'| > \epsilon|V|$, we have

$$|d_G(U', V') - d_G(U, V)| < \epsilon.$$

A bipartite graph G whose bipartition classes each have size n is referred to as a *bipartite graph with $2n$ vertices*. Let $N_G(u)$ stand for the neighborhood of vertex u in graph G, and let $deg_G(u) = |N_G(u)|$. It is easy to check that in an ϵ-regular bipartite graph G with $2n$ vertices, all but at most $3\epsilon n^2$ pairs of vertices $u_1, u_2 \in U$ satisfy

$$(d - \epsilon)n < deg(u_1), deg(u_2) < (d + \epsilon)n$$

and

$$(d - \epsilon)^2 n < |N_G(u_1) \cap N_G(u_2)| < (d + \epsilon)^2 n.$$

In fact, this implication can be reversed at the cost of enlarging ϵ slightly (see [1]).

LEMMA 2.1. *Given a positive integer n and $\epsilon > 0$, if $G = (U, V; E)$, $|U| = |V| = n$, is a bipartite graph containing at least $(1 - 5\epsilon)n^2/2$ pairs of vertices $u_1, u_2 \in U$ that satisfy*

(i) $deg(u_1), deg(u_2) > (d - \epsilon)n$,

(ii) $|N_G(u_1) \cap N_G(u_2)| < (d + \epsilon)^2 n$,

then G is $(16\epsilon)^{1/5}$-regular.

Sometimes it is desired that *all* vertices have their degrees close to the average. Given $\epsilon > 0$ and $0 < d < 1$, an ϵ-regular bipartite graph G with $2n$ vertices is called *super (d, ϵ)-regular* if the minimum degree $\delta(G)$ and the maximum degree $\Delta(G)$ of G satisfy

$$(d - \epsilon)n \leq \delta(G) \leq \Delta(G) \leq (d + \epsilon)n.$$

Using Hall's theorem, it is straighforward to show the following.

FACT 1. *Every ϵ-regular bipartite graph with $2n$ vertices and minimum degree at least ϵn contains a perfect matching.*

Moreover, in [2] it was shown that in every large super (d,ϵ)-regular bipartite graph, the number of perfect matchings is roughly the same as the number of perfect matchings expected in the random bipartite graph with edge probability d. More precisely, if $M(G)$ denotes the number of perfect matchings in G, then, for $0<\epsilon<d/2$ and n sufficiently large,

$$(d-2\epsilon)^n n! \le M(G) \le (d+2\epsilon)^n n!.$$

If G is only ϵ-regular with density d, then the upper bound still holds. This estimate was used to prove the following result (see [13]). Unlike the original statement, the probability bound is given explicitly here.

THEOREM 2.2 (catching lemma). *Given real numbers $0<d<1$, $0<\epsilon<(d/2)^4$, $\lambda>0$, and a sufficiently large integer $n_0=n_0(\epsilon)$, the following holds. Let G be a super (d,ϵ)-regular graph with bipartition (U,V), $|U|=|V|=n>n_0$, and let $S_i\subset U$, $T_i\subset V$, $i=1,2,\dots,k$. If $\sigma: U\to V$ is a random perfect matching of G, then the event that (2) holds for each $i=1,2,\dots,k$ occurs with probability at least $1-2k\exp\{4\epsilon^{1/4}n-2\lambda^2 n\}$.* □

The main goal of this paper is to show how to derandomize this probabilistic result; that is, we show how to efficiently construct a perfect matching with the property described in Theorem 2.2. For this, we use the standard Erdős–Selfridge method of conditional probabilities ([4]; cf. [3]) but in a nonstandard setting. First, we illustrate this method by proving the following lemma.

LEMMA 2.3. *Let m, n, and r be positive integers such that*

$$(r-1)(n+1)\exp\{-m^{1/3}/2\}<1,$$

and let $N_1,\dots,N_n$ be subsets of $V=\{v_1,\dots,v_m\}$. Given $0<p_j<1$, $j=1,2,\dots,r$, where $\sum_{j=1}^r p_j=1$, there exists a polynomial (in m and n) time algorithm **PARTITION** *that constructs a partition $V=R_1\cup\cdots\cup R_r$ such that for each $j=1,2,\dots,r$, $|R_j|=p_j m$, and for each $i=1,\dots,n$, $||R_j\cap N_i|-p_j|N_i||<m^{2/3}$.*

Proof. For unification, we set $N_{n+1}=V$. First notice that if a set R was constructed randomly by m independent coin flippings, each with probability p, then by (1) for the binomial distribution, the probability that for some $i=1,2,\dots,n+1$, $|R\cap N_i|-p|N_i||>\frac{1}{2}m^{2/3}$, would be at most

$$(n+1)\exp\{-m^{4/3}/2m\}=(n+1)\exp\{-m^{1/3}/2\}<1/(r-1). \tag{3}$$

We shall derandomize the above probabilistic statement simultaneuosly for all sets N_i and for all partition sets R_j. We restrict ourselves to the case $r=2$ in the proof below for clarity of exposition. The proof for arbitrary r follows along the same lines; alternatively, the general case is implied by repeated applications of the case $r=2$ (at the cost of error accumulation of at most $rm^{2/3}$).

With $r=2$, $p=p_1$, and $R=R_1$, we sequentially construct a binary sequence $\{\xi_1,\dots,\xi_m\}$, where $\xi_l=1$ if and only if $v_l\in R$. Let R^l denote $R\cap\{v_1,\dots,v_l\}$; in particular, let $R^0=\emptyset$. Let Y be a random variable that counts how many of the $n+1$ inequalities are not satisfied. By (3), we know that $E(Y)<1$.

Assuming $\xi_1,\dots,\xi_{l-1}$ have been determined, we choose $\xi_l\in\{0,1\}$ to minimize the conditional expectation $E(Y|\xi_1,\dots,\xi_l)$, which is given by

$$\sum_{i=1}^{n+1}\sum_{x\notin[a_{i,l},b_{i,l}]}\binom{n_{i,l}}{x}p^x(1-p)^{n_{i,l}-x}, \tag{4}$$

where

$$a_{i,l} = p|N_i| - m^{2/3} - |R^l \cap N_i|, \qquad b_{i,l} = p|N_i| + m^{2/3} - |R^l \cap N_i|,$$

and

$$n_{i,l} = |N_i| - |R^l \cap N_i|.$$

It is straightforward to check that

$$E(Y|\xi_1, \ldots, \xi_{l-1}) = pE(Y|\xi_1, \ldots, \xi_{l-1}, 1) + (1-p)E(Y|\xi_1, \ldots, \xi_{l-1}, 0),$$

and thus, for each $l = 1, \ldots, m$,

$$E(Y|\xi_1, \ldots, \xi_l) \le E(Y|\xi_1, \ldots, \xi_{l-1}) < 1.$$

In particular, when $l = m$, we have

$$0 < Y(\xi_1, \ldots, \xi_m) = E(Y|\xi_1, \ldots, \xi_m) < 1,$$

which implies that the integer $Y(\xi_1, \ldots, \xi_m)$ equals zero.

Hence, we have for all $i = 1, \ldots, n+1$, $||R \cap N_i| - p|N_i|| \le \frac{1}{2}m^{2/3}$. To obtain the desired set R of order pm, the values of at most $\frac{1}{2}m^{2/3}$ elements ξ_i are interchanged (from 0 to 1 or vice versa) at the cost of doubling the errors in the approximations of $|R \cap N_i|$, $i = 1, 2, \ldots, n$. □

3. Derandomizing the complete catching lemma. In this section, we warm up by derandomizing Proposition 1, the special case of Theorem 2.2 in which $G = K_{n,n}$.

PROPOSITION 2. *Let n and k be positive integers, and let $0 < \lambda < 1$ such that $2k \exp\{-2\lambda^2 n\} < 1$. There exists a deterministic polynomial (in both n and k) time algorithm which, given a complete bipartite graph $K_{n,n}$ with vertex classes U and V, and k pairs of subsets $S_i \subset U$, $T_i \subset V$, $i = 1, 2, \ldots, k$, constructs a perfect matching of $K_{n,n}$ such that inequality (2) holds for all $i = 1, 2, \ldots, k$.*

Proof. To construct the desired perfect matching, we shall apply the Erdős–Selfridge method of conditional probabilities. However, unlike Lemma 2.3, the choices of edges in the matching are not independent, and hence the underlying probability space is not binomial. In this case, the method succeeds due to a combinatorial identity enjoyed by the hypergeometric distribution (cf. Claim 1 below).

Let $s_i = |S_i|$, $t_i = |T_i|$, $a_i = \lceil s_i t_i/n - \lambda n \rceil$, and $b_i = \lfloor s_i t_i/n + \lambda n \rfloor$, and let A_i denote the event that $a_i \le |\sigma(S_i) \cap T_i| \le b_i$, $i = 1, 2, \ldots, k$. Let X count the number of events A_i that do not hold. By applying Chernoff's inequality to the hypergeometric random variable X, we have

$$E(X) = \sum_i P(\overline{A_i}) = \sum_{i=1}^{k} \sum_{x \notin [a_i, b_i]} \frac{\binom{t_i}{x}\binom{n-t_i}{s_i-x}}{\binom{n}{s_i}} < 2k \exp\left\{-2\lambda^2 n\right\} < 1.$$

We shall sequentially select edges to form a perfect matching that satisfies (2). Having chosen one edge $e_1 = uv$, $u \in U$, $v \in V$, we restrict our subsequent search to the complete bipartite graph $K_{n-1,n-1}$ obtained by removing the two endpoints of e_1. Then we update the sets S_i and T_i by setting $S_{i,1} = S_i \setminus \{u\}$ and $T_{i,1} = T_i \setminus \{v\}$. We also update the intervals $[a_i, b_i]$ by shifting them to the left one unit if e_1 is "caught"

by the pair (S_i, T_i); that is, if $u \in S_i$ and $v \in T_i$. We denote the new interval limits by $a_{i,1}$ and $b_{i,1}$. If A_i^1 is the event (in the space of all perfect matchings of $K_{n-1,n-1}$) that $a_{i,1} \le |\sigma(S_{i,1}) \cap T_{i,1}| \le b_{i,1}$, $i = 1, 2, \ldots, k$, then

$$P(\overline{A_i}|e_1) = P(\overline{A_i^1}).$$

In general, we define the following function f on the set of all matchings of $K_{n,n}$. For each $l = 0, 1, 2, \ldots, n$, let $n_l = n - l$. Given a matching $\sigma = \{e_1, \ldots, e_l\}$ we set

$$f(\sigma) = \sum_{i=1}^{k} \sum_{x \notin [a_{i,\sigma}, b_{i,\sigma}]} \frac{\binom{t_{i,\sigma}}{x}\binom{n_l - t_{i,\sigma}}{s_{i,\sigma} - x}}{\binom{n_l}{s_{i,\sigma}}}, \tag{5}$$

where

$$s_{i,\sigma} = |S_i \setminus \{e_1 \cup \cdots \cup e_l\}|, \qquad t_{i,\sigma} = |T_i \setminus \{e_1 \cup \cdots \cup e_l\}|,$$

and where

$$a_i - a_{i,\sigma} = b_i - b_{i,\sigma} = |E(S_i, T_i) \cap \{e_1 \cup \cdots \cup e_l\}|.$$

Of course, for the empty matching $\sigma = \emptyset$, we have $f(\emptyset) = E(X)$, and thus $f(\emptyset) < 2ke^{-2\lambda^2 n} < 1$.

This function can also be defined recursively. For each $l = 1, 2, \ldots, n$, and each matching $\sigma = \{e_1, \ldots, e_{l-1}\}$, set

$$f(e_1, \ldots, e_l) = \sum_{i=1}^{k} \sum_{x \notin [a_{i,l}, b_{i,l}]} \frac{\binom{t_{i,l}}{x}\binom{n_l - t_{i,l}}{s_{i,l} - x}}{\binom{n_l}{s_{i,l}}}, \tag{6}$$

where $s_{i,l-1} = s_{i,\sigma}$, $t_{i,l-1} = t_{i,\sigma}$, $a_{i,l-1} = a_{i,\sigma}$, and $b_{i,l-1} = b_{i,\sigma}$. Then for $e_l = uv$ we have

$$s_{i,l} = \begin{cases} s_{i,l-1} - 1 & \text{if } u \in S_i, \\ s_{i,l-1} & \text{if } u \notin S_i, \end{cases} \qquad t_{i,l} = \begin{cases} t_{i,l-1} - 1 & \text{if } v \in T_i, \\ t_{i,l-1} & \text{if } v \notin T_i, \end{cases} \tag{7}$$

$$a_{i,l-1} - a_{i,l} = b_{i,l-1} - b_{i,l} = \begin{cases} 1 & \text{if } u \in S_i, v \in T_i, \\ 0 & \text{otherwise,} \end{cases} \tag{8}$$

where $s_{i,0} = s_i$, $t_{i,0} = t_i$, $a_{i,0} = a_i$, $b_{i,0} = b_i$.

It is crucial that $f(e_1, \ldots, e_{l-1})$ is the average of $f(e_1, \ldots, e_l)$ over all $(n - l + 1)^2$ choices of e_l.

Claim 1. *Let E_0 be the set of all edges of $K_{n,n}$, and for each $l = 1, 2, \ldots, n$, let E_l be the set of all edges in the complete bipartite graph that remain after deleting the endpoints of the edges $e_1, \ldots, e_l$. Then*

$$\frac{1}{(n-l+1)^2} \sum_{e_l \in E_{l-1}} f(e_1, \ldots, e_l) = f(e_1, \ldots, e_{l-1}).$$

This claim shall be proved at the end of this section. Observe that as a consequence of Claim 1, there is always a choice of e_l for which

$$f(e_1, \ldots, e_l) \le f(e_1, \ldots, e_{l-1}). \tag{9}$$

Since $s_{i,l}$, $t_{i,l}$, $a_{i,l}$, and $b_{i,l}$ are updated by (7)–(8) after each edge of σ is chosen, for each $l = 1, 2, \ldots, n$ we have

$$E(X|e_1, \ldots, e_l) = \sum_i P(\overline{A_i}|e_1, \ldots, e_l) = f(e_1, \ldots, e_l).$$

In particular, when $l = n$ we may observe that $n_n = t_{i,n} = s_{i,n} = 0$, while $P(\overline{A_i}|e_1, \ldots, e_n) = 1$ if $0 \notin [a_{i,n}, b_{i,n}]$, and $P(\overline{A_i}|e_1, \ldots, e_n) = 0$ otherwise. Thus, for each event A_i that fails, there is a corresponding term in (6) that equals 1 (with $x = 0$). By (9),

$$E(X|e_1, \ldots, e_n) = f(e_1, \ldots, e_n) \leq E(X) < 1,$$

which means that $X(e_1, \ldots, e_n) = 0$. Hence, the perfect matching $\sigma = \{e_1, \ldots, e_n\}$ satisfies (2). □

Proof of Claim 1. For clarity, we shall prove only the claim for $l = 1$; that is, we shall prove that $\frac{1}{n^2} \sum_{e_1 \in E_0} f(e_1) = f(\emptyset) = E(X)$. The general case is similar. We begin by interchanging the first two summations so that

$$\frac{1}{n^2} \sum_{e_1 \in E_0} f(e_1) = \frac{1}{n^2} \sum_{i=1}^{k} \sum_{e_1 \in E_0} \Phi_i, \tag{10}$$

where

$$\Phi_i = \sum_{x \notin [a_{i,1}, b_{i,1}]} \frac{\binom{t_{i,1}}{x}\binom{n_1 - t_{i,1}}{s_{i,1} - x}}{\binom{n_1}{s_{i,1}}}.$$

Now observe that for each $i = 1, 2, \ldots, k$, the summand $\frac{\binom{t_{i,1}}{x}\binom{n_1 - t_{i,1}}{s_{i,1} - x}}{\binom{n_1}{s_{i,1}}}$ depends exclusively on which of the four positions, relative to the pair (S_i, T_i), the edge e_1 takes (see Figure 1).

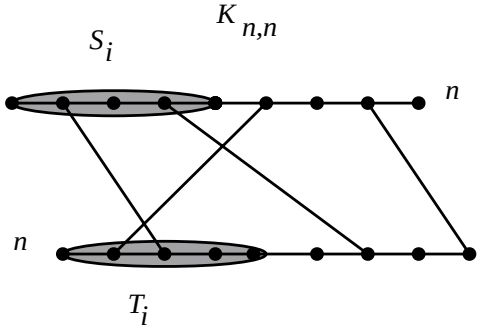

FIG. 1. *The four possible positions of* e_1.

Hence, we may write (10) as

$$\begin{aligned} \Phi_i = \frac{s_i t_i}{n^2} \sum_x p_{i,1} + \frac{s_i(n - t_i)}{n^2} \sum_x p_{i,2} \\ + \frac{(n - s_i)t_i}{n^2} \sum_x p_{i,3} + \frac{(n - s_i)(n - t_i)}{n^2} \sum_x p_{i,4}, \end{aligned} \tag{11}$$

where the four summations are taken over all $x \notin [a_{i,1}, b_{i,1}]$ and where

$$p_{i,1} = \frac{\binom{t_i-1}{x}\binom{n-t_i}{s_i-1-x}}{\binom{n-1}{s_i-1}}, \qquad p_{i,2} = \frac{\binom{t_i}{x}\binom{n-1-t_i}{s_i-1-x}}{\binom{n-1}{s_i-1}},$$

$$p_{i,3} = \frac{\binom{t_i-1}{x}\binom{n-t_i}{s_i-x}}{\binom{n-1}{s_i}}, \qquad p_{i,4} = \frac{\binom{t_i}{x}\binom{n-1-t_i}{s_i-x}}{\binom{n-1}{s_i}}.$$

Let us write $f(\emptyset) = \sum_{i=1}^{k} \Psi_i$, where

$$\Psi_i = \sum_{x \notin [a_i, b_i]} \frac{\binom{t_i}{x}\binom{n-t_i}{s_i-x}}{\binom{n}{s_i}}.$$

It can now be checked algebraically that for each $i = 1, 2, \ldots, k$, we have $\Phi_i = \Psi_i$.

Alternatively, for fixed i, imagine the following two-stage random experiment: an edge e_1 is first chosen uniformly at random; then a perfect matching is chosen randomly from the remaining subgraph $K_{n-1,n-1}$ to form a random perfect matching σ of $K_{n,n}$. Let B_j, $j = 1, 2, 3, 4$, denote the event that, relative to the pair (S_i, T_i), the edge e_1 takes a position that corresponds to the term $p_{i,j}$. Then we have $P(B_1) = \frac{s_i t_i}{n^2}$, $P(B_2) = \frac{s_i(n-t_i)}{n^2}$, $P(B_3) = \frac{(n-s_i)t_i}{n^2}$, and $P(B_4) = \frac{(n-s_i)(n-t_i)}{n^2}$. Moreover, $P(\overline{A_i}|B_j) = \sum_{x \notin [a_i, b_i]} p_{i,j}$. Hence, by the law of total probability, every term of (11) is equal to the corresponding term of the sum (6) with $l = 0$. □

Remark. One might think that it would be simpler to fix in each step an unmatched vertex u of U and choose the next edge only from among those incident with u. Unfortunately, as we shall see in section 4, this technique does not carry over to the general case of super-regular graphs since we have no control over the neighborhoods of individual vertices.

4. Derandomizing the catching lemma. Some say that super (d, ϵ)-regular graphs are like complete bipartite graphs, only sparser. In a super (d, ϵ)-regular graph, the number of edges between sets of sizes s and t is roughly dst, and the number of perfect matchings in such a graph is, very roughly, $d^n n!$. Hence, it might seem that derandomizing Theorem 2.2 involves a mere repetition of the above argument, only with the presence of a factor of d. However, we shall see that this is not so.

One difficulty we must cope with is that we can no longer enjoy the hereditary property possessed by complete bipartite graphs, namely, that every induced subgraph of a complete bipartite graph, no matter how large or how small, is itself a complete bipartite graph. This hereditary property was exploited at each step in the proof of Proposition 1 as we sequentially constructed a perfect matching of $K_{n,n}$.

By contrast, in a super (d, ϵ)-regular graph, we have no control over the regularity of subgraphs of size smaller than ϵn. Furthermore, even in large subgraphs, we cannot guarantee "high" minimum vertex degree, nor can we rule out the possibility of isolated vertices. Thus, it is possible that if edges are not chosen properly at each stage, then we may end up with a subgraph which contains no matching at all.

To circumvent this problem we shall construct the perfect matching as we did in the case of the complete graph, only now we shall rapidly change the strategy when we have but ϵn vertices left on each side. At this stage, and with no respect to the sets (S_i, T_i), we would be satisfied to find *any* perfect matching in the leftover graph.

After merging this smaller matching in the leftover subgraph with the larger matching already constructed, the error term in (2) is then enlarged only slightly.

One obstacle still remains: the leftover subgraph may have no perfect matching at all. To remedy this, we shall randomly enlarge the set of leftover unmatched vertices by selecting roughly $(\epsilon^{1/3}-\epsilon)n$ vertices from the set of matched vertices in one vertex class (along with their matched partners in the other vertex class). We shall then "unmatch" these vertices and add them to the leftover graph to form an induced subgraph. The randomness guarantees (by Chernoff's bound) that the resulting $\epsilon^{2/3}$-regular graph will have sufficiently large minimum degree, and hence will contain a perfect matching. Of course, this step must be derandomized as well, but this can easily be accomplished by applying Lemma 2.3. Once we construct a perfect matching in the enlarged leftover subgraph (using any algorithm we like), then the construction of σ is complete. The term $\epsilon^{1/3}n$ is then incorporated into the error term in (2).

THEOREM 4.1 (derandomized catching lemma). *Let $\epsilon > 0$, $1 > \gamma > 3\epsilon^{1/3}$, $\lambda > 6\epsilon^{1/4}$, and let k and n be positive integers such that*

$$2k \exp\left\{\sqrt{\epsilon}n - 2\lambda^2 n\right\} < \left(\frac{\epsilon}{e}\right)^{\epsilon n}.$$

There exists a deterministic polynomial time algorithm **CATCH** *which, given an ϵ-regular bipartite graph $G = (U, V; E)$, $|U| = |V| = n$, with minimum degree at least γn, and given k pairs of subsets $S_i \subset U$, $T_i \subset V$, $i = 1, 2, \ldots, k$, constructs a perfect matching in G such that the inequality*

$$|S_i||T_i|/n - 2\lambda n < |\sigma(S_i) \cap T_i| < |S_i||T_i|/n + 2\lambda n \tag{12}$$

holds for all $i = 1, 2, \ldots, k$.

Proof. Without loss of generality we may assume that for each $i = 1, 2, \ldots, k$, $\epsilon n < |S_i|, |T_i| < n - \epsilon n$. Otherwise the entire range of the random variable $|\sigma(S_i) \cap T_i|$ is contained in an interval of length ϵn, and since $\lambda > \epsilon$, inequality (12) would automatically be satisfied by any perfect matching σ of G. This assumption shall be used only in the proof of Claim 2 below.

Let $s_i = |S_i|$, $t_i = |T_i|$, $a_i = \lceil s_i t_i/n - \lambda n \rceil$, and $b_i = \lfloor s_i t_i/n + \lambda n \rfloor$, $i = 1, 2, \ldots, k$. First, as in the proof of Proposition 2, we shall construct a partial matching $\sigma' = \{e_1, \ldots, e_L\}$ of size $L = n - \lceil \epsilon n \rceil$, so that for all i,

$$a_i - \epsilon n \le |\sigma'(S_i) \cap T_i| \le b_i. \tag{13}$$

The obvious modification is that the next edge is chosen only from the set E_{l-1} of all edges of the subgraph of G resulting from deleting the endpoints of $e_1, \ldots, e_l$, $l = 1, \ldots, L$. By the ϵ-regularity of G, $|E_{l-1}| > (d - \epsilon)(n - l + 1)^2$, where d is the density of G.

Let $f(\sigma)$ be defined as in the proof of Proposition 2. While Claim 1 is no longer true, we shall instead prove that having chosen $e_1, \ldots, e_{l-1}$, there is always a choice of an edge e_l so that $f(e_1, \ldots, e_l) \le (1 + \sqrt{\epsilon}) f(e_1, \ldots, e_{l-1})$.

CLAIM 2. *Let E_0 be the set of all edges of G, and for each $l = 1, \ldots, L = n - \lceil \epsilon n \rceil$, let E_l be the set of all edges of the subgraph of G that remain after deleting the endpoints of $e_1, \ldots, e_l$. Then*

$$\frac{1}{|E_{l-1}|} \sum_{e_l \in E_{l-1}} f(e_1, \ldots, e_l) \le (1 + \sqrt{\epsilon}) f(e_1, \ldots, e_{l-1}).$$

We prove Claim 2 at the end of this section. As a consequence, if σ' is the partial matching of order L constructed by the algorithm described in the proof of Proposition 2 (with the obvious modification; cf. Claims 1 and 2), then

$$f(\sigma') \le (1+\sqrt{\epsilon})^L f(\emptyset) < 2k\exp\{\sqrt{\epsilon}n - 2\lambda^2 n\}. \tag{14}$$

Now we prove that (13) holds for all $i = 1, 2, \dots, k$. Let us set $\sigma_i = |\sigma'(S_i) \cap T_i|$ for convenience. Thus, $a_{i,L} = a_i - \sigma_i$ and $b_{i,L} = b_i - \sigma_i$. Suppose that for some i, (13) does not hold. If $\sigma_i > b_i$, then $b_{i,L} < 0$, and thus there exists an integer $x \notin [a_{i,L}, b_{i,L}]$ such that

$$\max\{0, s_{i,L} + t_{i,L} - \epsilon n\} \le x \le \min\{s_{i,L}, t_{i,L}\}. \tag{15}$$

Consequently, at least one term of (5) is positive, and hence

$$f(\sigma') \ge \frac{1}{\binom{\epsilon n}{s_{i,L}}} \ge 2^{-\epsilon n},$$

which contradicts (14). If, on the other hand, $\sigma_i < a_i - \epsilon n$, then $a_{i,L} > \epsilon n \ge s_{i,L} + t_{i,L} - \epsilon n$, and again there is an integer $x \notin [a_{i,L}, b_{i,L}]$ that satisfies (15). This leads to a contradiction to (14).

If we let $U' \subset U$ and $V' \subset V$ be the two sets matched by σ', then we may view σ' as a bijection $\sigma' : U' \to V'$. Let $N_1, \dots, N_n$ and $M_1, \dots, M_n$ be the neighborhoods of the vertices of U and V restricted to V' and U', respectively; that is,

$$N_j = N_G(u_j) \cap V',\ u_j \in U, \qquad M_j = N_G(v_j) \cap U',\ v_j \in V. \tag{16}$$

Now we apply algorithm **PARTITION** from Lemma 2.3 to the set V' and the input sets $N_1, \dots, N_n, \sigma'(M_1), \dots, \sigma'(M_n)$ (with $r = 2$, $m = L$, and $p = p_1 = \frac{\epsilon^{1/3} - \epsilon}{1-\epsilon}$). As a result, **PARTITION** constructs a subset R of V' of order $|R| = (\epsilon^{1/3} - \epsilon)n$ such that for all $i = 1, 2, \dots, n$,

$$|N_i \cap R| > p|N_i| - 2L^{2/3} > \frac{\epsilon^{1/3} - \epsilon}{1-\epsilon}(\gamma - \epsilon)n - 2n^{2/3} > \epsilon^{2/3} n,$$

and the same inequality holds for the sets $\sigma'(M_i)$, $i = 1, 2, \dots, n$. Thus, every vertex of G has at least $\epsilon^{2/3}n$ neighbors in R or $(\sigma')^{-1}(R)$, respectively.

Finally, consider the subgraph H of G induced by the vertex sets $R \cup (V \setminus V')$ and $(\sigma')^{-1}(R) \cup (U \setminus U')$. It is $\epsilon^{2/3}$-regular and has minimum degree at least $\epsilon^{2/3}n$. Consequently, by Fact 1, it contains a perfect matching, and we may apply, say, the Hopcroft–Karp algorithm [6] to find such a perfect matching σ'' in H. Now if σ''' is the matching obtained from σ' by removing the edges incident to the set R, then by (13), and since $\lambda > \epsilon^{1/3} + \epsilon$, the combined perfect matching $\sigma'' \cup \sigma'''$ satisfies inequality (12) for all $i = 1, 2, \dots, k$. □

Proof of Claim 2. We apply induction on l. For $l = 1$ we basically follow the proof of Claim 1, writing $e(S_i, T_i)$ instead of $s_i t_i$, and so on. However, because $\min\{s_i, t_i, n - s_i, n - t_i\} > \epsilon n$, by the ϵ-regularity of G, we obtain the bound $e(S_i, T_i) < (d + \epsilon)s_i t_i$, and so on. Thus, with the notation from the proof of Claim 1, we have

$$\frac{1}{|E_0|} \sum_{e_1 \in E_0} f(e_1) \le \frac{d+\epsilon}{d-\epsilon} \sum_{i=1}^{k} \Phi_i \le (1+\sqrt{\epsilon}) f(\emptyset),$$

where

$$\Phi_i = \frac{s_i t_i}{n^2} \sum_x p_{i,1} + \frac{s_i(n-t_i)}{n^2} \sum_x p_{i,2} + \frac{(n-s_i)t_i}{n^2} \sum_x p_{i,3} + \frac{(n-s_i)(n-t_i)}{n^2} \sum_x p_{i,4}.$$

The last inequality results from the fact that $d \geq \gamma \geq 2\sqrt{\epsilon}$. Now assume that the claim is true for all $j = 1, 2, \ldots, l-1$, and let

$$\Phi_i = \sum_{e_l \in E_{l-1}} \sum_{x \notin [a_{i,l}, b_{i,l}]} \frac{\binom{t_{i,l}}{x}\binom{n_l - t_{i,l}}{s_{i,l} - x}}{\binom{n_l}{s_{i,l}}}, \qquad \Psi_i = \sum_{x \notin [a_{i,l-1}, b_{i,l-1}]} \frac{\binom{t_{i,l-1}}{x}\binom{n_{l-1} - t_{i,l-1}}{s_{i,l-1} - x}}{\binom{n_{l-1}}{s_{i,l-1}}}.$$

In this setting we shall prove that $\Phi_i \leq (1+\sqrt{\epsilon})|E_{l-1}|\Psi_i$.

Towards this end, note that $\Psi_i = 0$ if and only if

$$a_{i,l-1} \leq \max\{0, s_{i,l-1} + t_{i,l-1} - n_{l-1}\} \leq \min\{s_{i,l-1}, t_{i,l-1}\} \leq b_{i,l-1} \ .$$

However, then for every $e_l \in E_{l-1}$, we also have

$$a_{i,l} \leq \max\{0, s_{i,l} + t_{i,l} - n_l\} \leq \min\{s_{i,l}, t_{i,l}\} \leq b_{i,l} \ ,$$

and so $\Phi_i = 0$. In other words, if at some point the above inequality is satisfied for a particular pair (S_i, T_i), then it is irrelevant with respect to that pair how the construction of σ proceeds in the future. Inequality (2) is guaranteed to hold in such a case since at any given time l the number of edges of σ that could be caught by the pair (S_i, T_i) lies between $s_{i,l} + t_{i,l} - n_l$ and $\min\{s_{i,l}, t_{i,l}\}$.

If $\Psi_i > 0$, then a straightforward calculation shows that

$$\min\{s_{i,l-1}, t_{i,l-1},\ n - s_{i,l-1}, n - t_{i,l-1}\} > \epsilon n;$$

hence, we can essentially repeat the proof of the case $l = 1$ (or Claim 1 for that matter). Indeed, there exists $x \notin [a_{i,l}, b_{i,l}]$ such that $\binom{t_{i,l-1}}{x}\binom{n_{l-1}-t_{i,l-1}}{s_{i,l-1}-x} \geq 1$. Now suppose that $s_{i,l-1} < \epsilon n$. Then

$$f(e_1, \ldots, e_{l-1}) \geq \frac{1}{\binom{n_{l-1}}{s_{i,l-1}}} \geq \frac{1}{\binom{n}{s_{i,l-1}}} > \left(\frac{\epsilon}{e}\right)^{\epsilon n}.$$

Clearly, the same inequality is obtained if $n_{l-1} - s_{i,l-1} < \epsilon n$ (by the symmetry of the binomial coefficients) and also if $t_{i,l-1} < \epsilon n$ or $n_{l-1} - t_{i,l-1} < \epsilon n$ (by the symmetry of the hypergeometric distribution). However, by the induction assumption we have

$$f(e_1, \ldots, e_{l-1}) < (1+\sqrt{\epsilon})^{l-1} f(\emptyset) < 2k \exp\{\sqrt{\epsilon} n - 2\lambda^2 n\},$$

which, by our assumption, is less than $\left(\frac{\epsilon}{e}\right)^{\epsilon n}$. This completes the proof. □

We wrap up this section with a more formal description of algorithm **CATCH**; a different version of this algorithm was outlined in [14].

Algorithm **CATCH.**
Input: An ϵ-regular bipartite graph $G = (U, V; E)$, $|U| = |V| = n$, with minimum degree at least γn and subsets $S_i \subset U$, $T_i \subset V$, $i = 1, 2, \ldots, k$, as defined in Theorem 4.1.
Output: A perfect matching $\sigma : U \to V$ such that for each $i = 1, 2, \ldots, k$, inequality (12) holds.

1. Let $\sigma' = \emptyset$, $L = n - \lceil \epsilon n \rceil$.
2. For $l = 1, 2, \ldots, L$, and given a partial matching $\sigma' = \{e_1, \ldots, e_{l-1}\}$,
   (i) choose an edge e_l so that the function $f(e_1, \ldots, e_l)$ defined in (6) is minimized;
   (ii) replace σ' by $\sigma' \cup \{e_l\}$;
   (iii) let U' and V' be the sets matched by σ'.
3. Apply **PARTITION** to the set V' and the input sets $N_1, \ldots, N_n, \sigma'(M_1), \ldots, \sigma'(M_n)$ defined in (16) and denote the output by R.
4. Apply the Hopcroft–Karp algorithm to the subgraph induced by the sets $R \cup (V \setminus V')$ and $(\sigma')^{-1}(R) \cup (U \setminus U')$ and denote the output by σ''.
5. Let $\sigma = \sigma'' \cup (\sigma' \setminus \{e : e \text{ is incident with } R\})$.

5. An algorithmic version of the blow-up lemma. In [8], Komlós, Sárközy, and Szemerédi proved a striking result called the blow-up lemma that, loosely speaking, enables one to embed any bounded degree graph H as a spanning subgraph of a large super-regular graph G. By an *embedding*, we mean a bijection $f : V(H) \to V(G)$ such that if $x_1x_2 \in E(H)$, then $f(x_1)f(x_2) \in E(G)$. Their proof was based on a probabilistic argument and, subsequently, they derandomized their approach to provide a deterministic embedding [9]. It is worth noting that the blow-up lemma has been used to affirmatively answer two well-known conjectures, the approximate form of the Pósa–Seymour conjecture on squares of Hamiltonian cycles and the Alon–Yuster conjecture on graph packings (see [10] and [11], respectively).

In [13], an alternative probabilistic proof of the blow-up lemma was presented. In this probabilistic version, first the vertex set of H is partitioned using the Hajnal–Szemerédi theorem (see [5]). Then, a corresponding partition of $V(G)$ is achieved with a random partition. Finally, a version of the catching lemma (Theorem 2.2 above) is used to embed H into G. In this section, we give a constructive proof of the blow-up lemma by derandomizing the approach just described. First, instead of using the Hajnal–Szemerédi theorem to obtain the partition of $V(H)$, we shall use the constructive Sauer–Spencer packing lemma (see [15]). Then to construct the partition of $V(G)$, we shall use a deterministic polynomial time procedure based on Lemma 2.3 (see section 2). Finally, with the derandomized catching lemma (Theorem 4.1) in hand, we shall then embed H into G by finding suitable perfect matchings in super-regular bipartite graphs. Consequently, we prove the following theorem.

THEOREM 5.1 (algorithmic blow-up lemma). *Given positive integers r and Δ, and $0 < d < 1$, let $\delta = \delta(r, \Delta, d) > 0$ be a sufficiently small real number and $n_0 = n_0(\delta)$ a sufficiently large integer. There exists an algorithm* **EMBED** *which, in time polynomial in n, does the following. Let G be an r-partite graph with partition sets $V_1, \ldots, V_r$ such that*

(i) $|V_i| = n \geq n_0$, $i = 1, \ldots, r$,
(ii) *all* $\binom{r}{2}$ *bipartite subgraphs $G[V_i, V_j]$ are super (d, δ)-regular.*

Let H be an r-partite graph with partition sets $X_1, \ldots, X_r$ such that

(iii) $|X_i| = n$, $i = 1, \ldots, r$,
(iv) $\Delta(H) \leq \Delta$.

Then **EMBED** *constructs an embedding f of H into G that maps X_i onto V_i, $i = 1, \ldots, r$.*

Algorithm **EMBED** consists of two phases, which we shall first outline here and then describe in more detail later in this section.

In the preliminary phase (Phase I), the partitions of $V(H)$ and $V(G)$ are refined, and then edges are added to H and G. For clarity, we assume that n is divisible by $2\Delta^2$; otherwise, a simple adjustment is necessary (see [13]). Then with $t = 2\Delta^2$, $m = n/t$, $s = rt$, and $\epsilon = t\delta$, Phase I results in graphs H' and G' that satisfy the following conditions. G' is an s-partite graph with partition sets $W_1, \ldots, W_s$ such that

(i′) $|W_i| = m$, $i = 1, \ldots, s$,
(ii′) all $\binom{s}{2}$ bipartite subgraphs $G'[W_i, W_j]$ are super (d, ϵ)-regular.

H' is an s-partite graph with partition sets $Y_1, \ldots, Y_s$ such that

(iii′) $|Y_i| = m$, $i = 1, \ldots, s$,
(iv′) all $\binom{s}{2}$ bipartite subgraphs $H'[Y_i, Y_j]$ are perfect matchings.

In Phase II, **EMBED** recursively constructs an embedding f of H' into G' that maps Y_i onto W_i, $i = 1, \ldots, s$, so that the edges added to G in Phase I can be only images of the edges that were added to H. Hence, f is the desired embedding.

To execute Phase I, we invoke four subroutines: **PACK**, **PARTITION** (from Lemma 2.3), **SATURATE**, and **AUGMENT**. The last two algorithms are simple and shall be described below as we go.

Procedure **PACK** is an algorithmic version of a graph packing result by Sauer and Spencer presented in [15]. Given two graphs Γ and Γ' on the same vertex set V, we say that a bijection $\pi : V \to V$ is a *packing of* Γ *and* Γ' if $E(\Gamma) \cap \pi(E(\Gamma')) = \emptyset$, where $\pi(E(\Gamma')) = \{\pi(u)\pi(v) : uv \in E(\Gamma')\}$. It is straightforward to show that Sauer and Spencer's original existence proof yields the following result (see [17] for the details).

LEMMA 5.2. *There exists a polynomial time algorithm* **PACK** *that finds a packing of two given n-vertex graphs, Γ and Γ', provided $2\Delta(\Gamma)\Delta(\Gamma') < n$.* □

In Phase I, **PACK** shall be used to pack vertex disjoint cliques onto the squares of certain graphs. Recall that given a graph F, the *square of* F, denoted by F^2, is the graph obtained from F by joining with an edge each pair of distinct vertices of F whose distance is at most two. By definition of F^2, any pair of vertices in an independent set I of F^2, are in F at distance at least three from each other. Therefore the subgraph of F induced by two such sets is a matching.

PHASE I.

Phase I takes as its input the graphs H and G which satisfy properties (i)–(iv) in Theorem 5.1. First, we use algorithm **PACK** to partition each set $X_i \subset V(H)$, $i = 1, 2, \ldots, r$, into $t = 2\Delta^2$ sets $X_{i,j}$, $j = 1, \ldots, t$, of size m, where $m = n/t$, so that each pair of distinct sets $(X_{i_1,j_1}, X_{i_2,j_2})$ induces a (possibly empty) matching in H. For a fixed set X_i, this is achieved by applying **PACK** to the graphs $\Gamma = H^2[X_i]$ and Γ', where $\Gamma = H^2[X_i]$ is the subgraph of H^2 induced by X_i and where Γ' denotes the vertex-disjoint union of t cliques of order m. Note that since $\Delta(\Gamma) \leq \Delta(\Delta - 1)$ and $\Delta(\Gamma') \leq m - 1$, the hypothesis $2\Delta(\Gamma)\Delta(\Gamma') < n$ of Lemma 5.2 indeed holds. As a result, the procedure packs Γ' onto Γ and thus splits each X_i into t subsets $X_{i,j}$, each of which has size m, and more importantly, each of which is independent in H^2. Since the vertices of an independent set in H^2 are at a distance of at least three from each

other in H, any subgraph of H induced by two such sets X_{i_1,j_1}, X_{i_2,j_2} is a (possibly empty) matching.

In the next step of Phase I, we construct a corresponding finer partition of G. For this, we use algorithm **PARTITION** from Lemma 2.3 to partition each set V_i, $i = 1, \dots, r$, into t sets $V_{i,j}$, $j = 1, 2, \dots, t$, of size $m = n/t$, and so that each pair of sets $(V_{i_1,j_1}, V_{i_2,j_2})$ with $i_1 \neq i_2$ induces a super $(d, t\delta)$-regular subgraph. More precisely, to each set V_i, we apply **PARTITION** with $p_j = t^{-1}$, $j = 1, \dots, t$, and with the sets N_v where, for each $v \notin V_i$, $N_v = N_G(v) \cap V_i$ (cf. Lemma 2.3 above). As a result, for each $i = 1, \dots, r$ we obtain a partition $V_i = \bigcup_{j=1}^{t} R_{i,j}$ with all sets $R_{i,j}$ of size m such that all induced subgraphs $G[R_{i_1,j_1}, R_{i_2,j_2}]$, $i_1 \neq i_2$, have minimum and maximum degree bounded between $(d - \delta)m - n^{2/3}$ and $(d + \delta)m + n^{2/3}$.

By the δ-regularity of G, all resulting pairs $(V_{i_1,j_1}, V_{i_2,j_2})$ with $i_1 \neq i_2$ induce in G $t\delta$-regular subgraphs. Since for large n, we have $\delta + o(1) < t\delta$, we conclude that all pairs $(V_{i_1,j_1}, V_{i_2,j_2})$ in G induce super $(d, t\delta)$-regular subgraphs.

The last two stages of Phase I involve two simple procedures called **SATURATE** and **AUGMENT**, which are performed solely to unify all steps of the recursive embedding in Phase II. For each pair $(X_{i_1,j_1}, X_{i_2,j_2})$ of sets in H that does not induce a perfect matching, procedure **SATURATE** adds edges between the pair so that a perfect matching is induced. The resulting graph is denoted by H'.

Similarly, between each pair of sets $(V_{i_1,j_1}, V_{i_2,j_2})$ in G that induces a subgraph with density 0 (i.e., for which $i_1 = i_2$), procedure **AUGMENT** inserts edges so that the pair induces a super $(d, t\delta)$-regular subgraph. For this purpose, we use the same (our favorite) super $(d, t\delta)$-regular graph on $2m$ vertices. The resulting graph is denoted by G'.

For convenience, we denote the new partition sets by $Y_1, \dots, Y_s$ and $W_1, \dots, W_s$, with $s = rt$, respectively. Hence, at the conclusion of Phase I we have two graphs H' and G', and partitions $V(H') = Y_1 \cup \cdots \cup Y_s$ and $V(G') = W_1 \cup \cdots \cup W_s$, which satisfy conditions (i′)–(iv′).

PHASE II.

This phase takes as its input the graphs H' and G' and their partitions that satisfy conditions (i′)–(iv′). In this phase, algorithm **EMBED** recursively constructs an embedding of H' into G' so that each Y_j is mapped onto the set W_j. Note that every such embedding yields the desired embedding of H into G. Indeed, every edge from $E(G') \setminus E(G)$ connects two sets $(V_{i_1,j_1}, V_{i_2,j_2})$ with $i_1 = i_2$, and thus it can only be the image of an edge from $E(H') \setminus E(H)$.

The main procedure involved in constructing the embedding is algorithm **CATCH** from Theorem 4.1; for technical reasons which shall be described later, another subroutine called **DELETE** is also used.

Before describing how the embedding is constructed, we introduce some definitions and notation. For convenience, we relabel H' and G' as H and G, respectively. For every $1 \leq j \leq s - 1$ and each vertex $x \in Y_{j+1} \cup \cdots \cup Y_s$, let $N_j(x)$ denote the set of precisely j neighbors of x which belong to $Y_1 \cup \cdots \cup Y_j$. Given a bijection f_j between $Y_1 \cup \cdots \cup Y_j$ and $W_1 \cup \cdots \cup W_j$, let $M_j(x) = f_j(N_j(x))$. Given f_j, for each $l = j+1, \dots, s$, we define a bipartite auxiliary graph A_j^l with bipartition (Y_l, W_l) and edge set

$$E(A_j^l) = \{xw : x \in Y_l, w \in W_l \text{ and } uw \in E(G) \text{ for each } u \in M_j(x)\}. \tag{17}$$

We call the graphs A_j^l *candidacy graphs* because the edges of A_j^l join a vertex $x \in Y_l$ to all vertices of W_l which, after f_j embeds $Y_1 \cup \cdots \cup Y_j$ onto $W_1 \cup \cdots \cup W_j$, are still

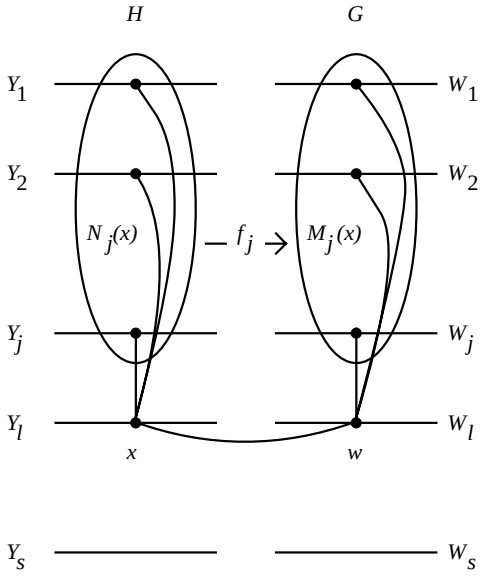

FIG. 2. $xw \in E(A_j^l)$.

good candidates for the image of x (see Figure 2).

Said another way, every neighbor w of x in A_j^l is joined in G to the images of the already embedded neighbors of x, and thus $f_l(x)$ could be set to w if the lth step (i.e., Y_l being mapped onto W_l) were next.

The construction of the embedding proceeds as follows. Let f_1 be any bijection between Y_1 and W_1. At this initial stage the graph A_1^l is isomorphic to $G[W_1, W_l]$ for all $l = 2, \ldots, s$, and thus it is super (d, ϵ)-regular. We set $\epsilon_1 = \epsilon$.

Assume that there exists an embedding f_j of $H[Y_1 \cup \cdots \cup Y_j]$ into $G[W_1 \cup \cdots \cup W_j]$ such that the candidacy graphs A_j^l, $l = j+1, \ldots, s$, are super (d^j, ϵ_j)-regular. Our goal is to extend f_j to f_{j+1} by constructing a perfect matching $\sigma_{j+1} : Y_{j+1} \to W_{j+1}$ in A_j^{j+1} such that all graphs A_{j+1}^l, $l = j+2, \ldots, s$, are super $(d^{j+1}, \epsilon_{j+1})$-regular for some ϵ_{j+1} to be fixed later. Then we shall set $f_{j+1}(x) = f_j(x)$ for $x \in Y_1 \cup \cdots \cup Y_j$ and $f_{j+1}(x) = \sigma_{j+1}(x)$ for $x \in Y_{j+1}$. The requirement that all graphs A_{j+1}^l are super $(d^{j+1}, \epsilon_{j+1})$-regular serves to carry the recursion through.

When this procedure reaches the stage $j = s-1$, then $j+2 > s$ and thus there are no candidacy graphs whose super-regularity must be maintained in the future. At this point, all that is needed is *any* perfect matching σ_s in A_{s-1}^s, and we use our favorite algorithm from [6] to find one. Then $f = f_s$ is the desired embedding of H into G.

To guarantee that there is at least one perfect matching in A_{s-1}^s, we use the fact that, by our construction, A_{s-1}^s is super $(d^{s-1}, \epsilon_{s-1})$-regular. A sufficiently small choice of δ (cf. Theorem 5.1) ensures that $d^{s-1} > 2\epsilon_{s-1}$. Thus, the minimum degree in A_{s-1}^s is at least $d^{s-1}m - \epsilon_{s-1}m > \epsilon_{s-1}m$, and by Fact 1, this last candidacy graph contains a perfect matching.

In light of the preceding discussion, it suffices to show how to extend f_j to an embedding f_{j+1} such that all graphs A_{j+1}^l, $l = j+2, \ldots, s$, will be super $(d^{j+1}, \epsilon_{j+1})$-regular. Let us fix $2 \le j < s-1$. For every $j+1 < l \le s$ let B^l be the bipartite graph

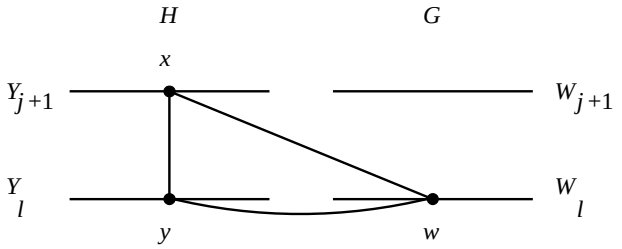

FIG. 3. $xw \in E(B^l)$.

with bipartition (Y_{j+1}, W_l) such that $xw \in E(B^l)$ if and only if $yw \in E(A_j^l)$, where y is the unique neighbor of x in Y_l (see Figure 3).
Observe that B^l is isomorphic to A_j^l. Also, set $G^l = G[W_{j+1}, W_l]$.

In preparation for finding a perfect matching in the candidacy graph A_j^{j+1} which would ensure the super-regularity of all future candidacy graphs, we apply procedure **DELETE** to remove every edge $e = xw$ of A_j^{j+1} for which the inequality

$$(d^{j+1} - 2\epsilon_j)m < |N_{B^l}(x) \cap N_{G^l}(w)| < (d^{j+1} + 2\epsilon_j)m \tag{18}$$

is violated for some $l = j+2, \ldots, s$. (We omit a formal description of this procedure.) As shown in [13], the resulting subgraph, which we denote by $\bar{A}_j^{j+1}$, is super $(d^j, 2s\sqrt{\epsilon_j})$-regular.

Note that the minimum degree in $\bar{A}_j^{j+1}$ is at least γm, where $\gamma = d^j - 2s\sqrt{\epsilon_j}$. We choose δ in Theorem 5.1 so small that $\gamma > 3(2s\sqrt{\epsilon_j})^{1/3}$, and we set $\lambda = \lambda_j - 7(2s\sqrt{\epsilon_j})^{1/4}$. These choices guarantee that the hypotheses of Theorem 4.1 are satisfied.

At this point, the stage is almost set for algorithm **CATCH** to find the desired perfect matching σ_{j+1} in $\bar{A}_j^{j+1}$.

We apply **CATCH** to the graph $\bar{A}_j^{j+1}$, where the sets S_i are the sets $N_{B^l}(w)$ and $N_{B^l}(w_1) \cap N_{B^l}(w_2)$, and the sets T_i are, respectively, the sets $N_{G^l}(w)$ and $N_{G^l}(w_1) \cap N_{G^l}(w_2)$ for all $w \in W_l$ and all pairs w_1, w_2 of vertices of W_l, $l = j+2, \ldots, s$. (Note that $k \le m + m^2$.)

As a result, a perfect matching $\sigma = \sigma_{j+1}$ of $\bar{A}_j^{j+1}$ is constructed so that for all $l = j+2, \ldots, s$, all $w \in W_l$, and all pairs w_1, w_2 of vertices of W_l,

$$\begin{aligned} |N_{B^l}(w)||N_{G^l}(w)|/m - 2\lambda m &< |\sigma(N_{B^l}(w)) \cap N_{G^l}(w)| \\ &< |N_{B^l}(w)||N_{G^l}(w)|/m + 2\lambda m \end{aligned} \tag{19}$$

and

$$\begin{aligned} &|N_{B^l}(w_1) \cap N_{B^l}(w_2)||N_{G^l}(w_1) \cap N_{G^l}(w_2)|/m - 2\lambda m \\ &< |\sigma(N_{B^l}(w_1) \cap N_{B^l}(w_2)) \cap (N_{G^l}(w_1) \cap N_{G^l}(w_2))| \\ &< |N_{B^l}(w_1) \cap N_{B^l}(w_2)||N_{G^l}(w_1) \cap N_{G^l}(w_2)|/m + 2\lambda m, \end{aligned} \tag{20}$$

where $|\sigma(S) \cap T|$ stands for the number of edges of σ that connect a vertex in S with a vertex in T.

It remains to be shown that for each $l = j+2, \ldots, s$, the graph A_{j+1}^l is super $(d^{j+1}, \epsilon_{j+1})$-regular, where $\epsilon_{j+1} = (64\lambda)^{1/5}$. Let B_σ^l be the subgraph of B_l such that $xw \in E(B_\sigma^l)$ if and only if $xw \in E(B^l)$ and $\sigma(x)w \in E(G^l)$. By definition, the graph B_σ^l is isomorphic to A_{j+1}^l (see Figure 4).

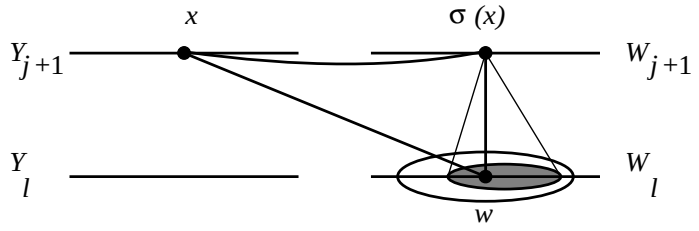

FIG. 4. $xw \in E(B^l_\sigma)$.

We now make three crucial observations.

(a) For every vertex $x \in Y_{j+1}$,

$$deg_{B^l_\sigma}(x) = |N_{G^l}(\sigma(x)) \cap N_{B^l}(x)|.$$

(b) For every vertex $w \in W_l$,

$$deg_{B^l_\sigma}(w) = |\sigma(N_{B^l}(w)) \cap N_{G^l}(w)|.$$

(c) For every pair of vertices $w_1, w_2 \in W_l$,

$$|N_{B^l_\sigma}(w_1) \cap N_{B^l_\sigma}(w_2)| = |\sigma(N_{B^l}(w_1) \cap N_{B^l}(w_2)) \cap (N_{G^l}(w_1) \cap N_{G^l}(w_2))|.$$

These observations shall be used in conjunction with Lemma 2.1 to verify the super-regularity of the graphs A^l_{j+1}.

Towards this end, inequality (18) guarantees that for every perfect matching σ of $\bar{A}^{j+1}_j$, and for each l, the degree $deg_{B^l_\sigma}(x)$ of each vertex $x \in Y_{j+1}$ satisfies

$$(d^{j+1} - 2\epsilon_j)m < deg_{B^l_\sigma}(x) < (d^{j+1} + 2\epsilon_j)m. \tag{21}$$

Also, since G^l is super (d, ϵ)-regular, the following inequality holds for all but at most ϵm^2 pairs $w_1, w_2 \in W_l$:

$$|N_{G^l}(w_1) \cap N_{G^l}(w_2)| \leq (d^2 + \epsilon)m. \tag{22}$$

Similarly, since B^l is super (d^j, ϵ_j)-regular, it follows that for all but $\epsilon_j m^2$ pairs $w_1, w_2 \in W_l$, we have

$$|N_{B^l}(w_1) \cap N_{B^l}(w_2)| \leq (d^{2j} + \epsilon_j)m. \tag{23}$$

We call a pair $w_1, w_2 \in W_l$ *good* if both (22) and (23) hold. Hence, in total there are at least $(1 - 2\epsilon_j)m^2$ good pairs in W_l.

By the super (d, ϵ)-regularity of G^l and the super (d^j, ϵ_j)-regularity of B^l, we have $|N_{G^l}(w)| > (d - \epsilon)m$ and $|N_{B^l}(w)| > (d^j - \epsilon_j)m$. Hence, conditions (b) and (19) imply that for each $w \in W_l$

$$\begin{aligned} deg_{B^l_\sigma}(w) &= |\sigma(N_{B^l}(w)) \cap N_{G^l}(w)| \\ &> |N_{B^l}(w)||N_{G^l}(w)|/m - 2\lambda m \\ &> (d^{j+1} - 4\lambda)m. \end{aligned}$$

On the other hand, by (c) and (20), for all good pairs $w_1, w_2 \in W_l$ we have

$$\begin{aligned}|N_{B^l_\sigma}(w_1) \cap N_{B^l_\sigma}(w_2)| &= |\sigma(N_{B^l}(w_1) \cap N_{B^l}(w_2)) \cap (N_{G^l}(w_1) \cap N_{G^l}(w_2))| \\ &< (d^{j+1} + 4\lambda)^2 m.\end{aligned}$$

It follows from Lemma 2.1 that for all $l = j+2, \ldots, s$, the graph B^l_σ, and thus the graph A^l_{j+1} (since they are isomorphic), is super $(d^{j+1}, (64\lambda)^{1/5})$-regular. We conclude this section with a more formal description of algorithm **EMBED**.

Algorithm **EMBED.**
Input: r-partite graphs H and G as in Theorem 5.1.
Output: An embedding f of H into G so that each X_i is mapped onto V_i, $i = 1, \ldots, r$.
Phase I:

1. Apply **PACK** to $V(H)$ and **PARTITION** to $V(G)$ and denote the output by $V(H) = Y_1 \cup \cdots \cup Y_s$ and $V(G) = W_1 \cup \cdots \cup W_s$, where $|Y_1| = |W_1| = \cdots = |Y_s| = |W_s| = m$.
2. Apply **SATURATE** to H and **AUGMENT** to G and denote the output by H' and G'.
3. Reset H and G to H' and G', respectively.

Phase II:

1. Let f_1 be any bijection from Y_1 to W_1.
2. For $j = 1, 2, \ldots, s-2$,
   (a) apply **DELETE** to A^{j+1}_j and denote the output by $\bar{A}^{j+1}_j$;
   (b) apply **CATCH** to the graph $\bar{A}^{j+1}_j$ and to the pairs $(N_{B^l}(w),\ N_{G^l}(w))$, $w \in W_l$, $l = j+2, \ldots, s$, $(N_{B^l}(w_1) \cap N_{B^l}(w_2),\ N_{G^l}(w_1) \cap N_{G^l}(w_2))$ for all good pairs $w_1, w_2 \in W_l$, $l = j+2, \ldots, s$, and denote the output by σ_{j+1};
   (c) set $f_{j+1}(x) = \begin{cases} f_j(x) & \text{if } x \in Y_1 \cup \cdots \cup Y_j, \\ \sigma_{j+1}(x) & \text{if } x \in Y_{j+1}. \end{cases}$
3. Use the Hopcroft–Karp algorithm to construct a perfect matching σ_s in A^s_{s-1} and set
   $f(x) = \begin{cases} f_{s-1}(x) & \text{if } x \in Y_1 \cup \cdots \cup Y_{s-1}, \\ \sigma_s(x) & \text{if } x \in Y_s. \end{cases}$

Acknowledgments. The authors extend thanks to Alan Frieze and an anonymous referee for their valuable comments and suggestions. The authors also thank Dwight Duffus and Michal Karoński for their generous readings of earlier versions of this manuscript.

OPTIMAL BUY-AND-HOLD STRATEGIES FOR FINANCIAL MARKETS WITH BOUNDED DAILY RETURNS*

GEN-HUEY CHEN†, MING-YANG KAO‡, YUH-DAUH LYUU†, AND HSING-KUO WONG†

Abstract. In the context of investment analysis, we formulate an abstract online computing problem called a *planning game* and develop general tools for solving such a game. We then use the tools to investigate a practical *buy-and-hold trading* problem faced by long-term investors in stocks. We obtain the unique optimal static online algorithm for the problem and determine its exact competitive ratio. We also compare this algorithm with the popular dollar averaging strategy using actual market data.

Key words. buy-and-hold trading problems, balanced strategy, dollar averaging strategy, online algorithms, competitive analysis, planning games, minimax theorem, linear programming, zero-sum two-person games

1. Introduction.

In an *online* problem, an *online* algorithm $\mathcal{B}$ is given one input at a time from a sequence of inputs. $\mathcal{B}$ takes an action on each input before seeing any remaining input. In contrast, an *offline* algorithm sees the entire input sequence before it takes any action. Each action yields a positive *accumulation*. Let E denote the set of all admissible input sequences. Let $\mathcal{C}(\vec{e})$ denote the (expected) total accumulation of an online or offline algorithm $\mathcal{C}$ on $\vec{e} \in E$. Let $\mathcal{A}$ denote the *optimal* offline algorithm, i.e., one that produces the largest total accumulation on each admissible input sequence. In competitive analysis [4, 25, 27], $\mathcal{B}$'s performance is measured by its *competitive ratio*

$$\Upsilon_{\mathcal{B}} = \sup_{\vec{e} \in E} \frac{\mathcal{A}(\vec{e})}{\mathcal{B}(\vec{e})}. \tag{1.1}$$

The *online player* seeks to minimize this ratio by choosing a suitable $\mathcal{B}$, while the *adversary* attempts to maximize it by picking $\vec{e}$ after examining $\mathcal{B}$. This paper assumes that the adversary is *oblivious*, i.e., it fixes the input sequence before $\mathcal{B}$ performs any computation such as generating random bits.

A *planning game* is an abstract online problem where the length of the input sequence is fixed and known a priori to $\mathcal{B}$. This time horizon feature captures many important online problems including those for portfolio rebalancing [7, 8, 21], asset trading [2, 5, 11, 12], secretary selection [1, 6, 13, 16], and bipartite matching [15, 17]. A planning game is *finite* if the numbers of admissible sequences of actions and inputs are both finite; otherwise, it is *infinite*. A finite planning game corresponds to a linear programming problem, where an optimal randomized online algorithm corresponds to

an optimal feasible solution. Consequently, we can show that the smallest competitive ratio of any randomized online algorithm for such a game is the reciprocal of the value of the game as a zero-sum two-person game.

In this general optimization framework, we investigate the *buy-and-hold trading problem* defined as follows. An investor starts with some capital, which is normalized to one dollar, and trades it for a certain security over n days, which is referred to as the *investment horizon*. To avoid triviality, we assume $n \geq 2$. On each day, the security has only one *exchange rate*, i.e., the number of shares of the security which one unit of capital can buy. Upon seeing the exchange rate, the investor executes one transaction for that day and may trade all or part of the remaining capital. All the capital must be traded by the nth day, and converting the acquired security back to capital is prohibited. The total *accumulation* of the investor is the number of shares of the security she accumulates at the end of the investment horizon. Note that the competitive ratio between the adversary's and the investor's accumulations is exactly the competitive ratio between the dollar values of the accumulations. This problem is faced by millions of investors who save for retirement purposes on a long-term basis; for instance, a widely popular security for today's investors would be a stock index fund.

We employ the *bounded daily return model*, in which the next day's exchange rate e' depends on the current day's exchange rate e with $e/\beta \leq e' \leq e\alpha$ for some fixed $\alpha, \beta > 1$. The values n, α, and $1/\beta$ are known a priori to the investor. We call α and $1/\beta$ the *daily return bounds*. Figure 1 gives some stock markets which enforce such ratios through circuit breakers. This model can also be regarded as an approximation to the geometric Brownian motion model used extensively in the finance community [3, 9, 14, 18, 20, 24, 26].

A *static* algorithm is an online algorithm for the buy-and-hold trading problem such that for $1 \leq i \leq n$, the (expected) amount of dollars invested by the algorithm on the ith day is the same for all exchange rate sequences. A *dynamic* algorithm refers to any online algorithm for the problem which is not necessarily static. The *static* buy-and-hold trading problem refers to the case of the problem where the investor can use only a static algorithm.

We prove that the smallest possible competitive ratio for any randomized or deterministic static algorithm is $\frac{n\alpha\beta-(n-1)(\alpha+\beta)+(n-2)}{\alpha\beta-1}$. We also obtain a deterministic static algorithm with this competitive ratio, called the *balanced strategy*, and prove that it is the only optimal deterministic static algorithm. In comparison, the popular dollar averaging strategy has a strictly greater competitive ratio and thus is not optimal. The balanced strategy is so simple that it can be executed even by those who

are not mathematically sophisticated. Starting with one dollar initially, the algorithm invests $\frac{\alpha(\beta-1)}{n\alpha\beta-(n-1)(\alpha+\beta)+(n-2)}$ dollar on the first day, $\frac{(\alpha-1)\beta}{n\alpha\beta-(n-1)(\alpha+\beta)+(n-2)}$ dollar on the last day, and $\frac{(\alpha-1)(\beta-1)}{n\alpha\beta-(n-1)(\alpha+\beta)+(n-2)}$ dollar on each of the other days.

Previously, El-Yaniv [10] and El-Yaniv et al. [11, 12] obtained optimal online algorithms for this unidirectional trading problem under the assumption that the daily exchange rates, instead of the daily returns, are between a pair of upper and lower bounds. Al-Binali [2] further studied the same setting in a framework of risk and reward [19]. Our model and that of El-Yaniv et al. [11, 12] are each formulated for real but different regulations of stock and foreign currency markets. A subtle difference between these models is that their model fixes a upper bound and a lower bound on the daily exchange rates globally for the entire investment horizon, while our model sets new bounds dynamically every day. Interestingly, although this difference might seem minor, they give rise to mathematical results of very distinct flavors using significantly different techniques.

Section 2 discusses how to compute optimal randomized online algorithms for finite planning games. Section 3 uses the general analysis in section 2 to derive the balanced strategy and compare it with the dollar averaging strategy. Section 4 concludes the paper with some open problems.

2. General analysis of finite planning games. A finite planning game G can be regarded as a finite zero-sum two-person game $\Gamma_H(m,n)$ defined as follows. For any integer $k>0$, let $Z_k=\{1,2,\ldots,k\}$. The maximizing player is the online player, whose pure strategies are the deterministic online algorithms $\mathcal{B}_i$ of G indexed with $i\in Z_m$. The minimizing player is the adversary of G, whose pure strategies are the input sequences $\vec{\sigma}_j$ of G indexed with $j\in Z_n$. The payoff matrix[1] H of $\Gamma_H(m,n)$ is defined by

$$H(i,j)=\frac{\mathcal{B}_i(\vec{\sigma}_j)}{\mathcal{A}(\vec{\sigma}_j)}>0,\quad i\in Z_m \text{ and } j\in Z_n. \tag{2.1}$$

Let $\Phi(Z_k)$ be the set of all probability density functions defined on Z_k. For $k=n$ or m, each $h\in\Phi(Z_k)$ is regarded as a point in the k-dimensional Euclidean space and represents a mixed strategy that applies the ℓth pure strategy indexed by Z_k with probability $h(\ell)$. By von Neumann's minimax theorem [22],

$$\begin{aligned}\max_{f\in\Phi(Z_m)}\min_{g\in\Phi(Z_n)}\sum_{i=1}^{m}\sum_{j=1}^{n}f(i)g(j)H(i,j) &= \min_{g\in\Phi(Z_n)}\max_{f\in\Phi(Z_m)}\sum_{i=1}^{m}\sum_{j=1}^{n}f(i)g(j)H(i,j)\\ &= \max_{f\in\Phi(Z_m)}\min_{j\in Z_n}\sum_{i=1}^{m}f(i)H(i,j)\\ &= \min_{g\in\Phi(Z_n)}\max_{i\in Z_m}\sum_{j=1}^{n}g(j)H(i,j),\end{aligned} \tag{2.2}$$

which is called the *value* v^* of $\Gamma_H(m,n)$.

[1] In (1.1), we use $\frac{\mathcal{A}(\vec{\sigma})}{\mathcal{B}(\vec{\sigma})}$ instead of $\frac{\mathcal{B}(\vec{\sigma})}{\mathcal{A}(\vec{\sigma})}$ so that the competitive ratios of different online algorithms are greater than 1 and therefore are easier to distinguish visually in Figures 6 and 9. In contrast, in (2.1), we choose $\frac{\mathcal{B}_i(\vec{\sigma}_j)}{\mathcal{A}(\vec{\sigma}_j)}$ instead of $\frac{\mathcal{A}(\vec{\sigma}_j)}{\mathcal{B}_i(\vec{\sigma}_j)}$ in order to simplify the linear algebra involved.

Let r^* be the smallest possible competitive ratio of any randomized online algorithm for G; i.e.,

$$r^* = \min_{f \in \Phi(Z_m)} \max_{j \in Z_n} \frac{\mathcal{A}(\vec{\sigma}_j)}{\sum_{i=1}^{m} f(i)\mathcal{B}_i(\vec{\sigma}_j)}.$$

A randomized online algorithm is *optimal* if its competitive ratio is r^*.

The next theorem relates G and $\Gamma_H(m,n)$.

THEOREM 2.1.

1. $r^* = \frac{1}{v^*}$.
2. *An optimal mixed strategy of the online player of* $\Gamma_H(m,n)$ *induces an optimal randomized online algorithm for* G *and vice versa.*

Proof. This theorem follows from (2.2). □

In light of Theorem 2.1, we use G and $\Gamma_H(m,n)$ interchangeably. A main purpose of this paper is to derive the exact value of r^* and an optimal randomized online algorithm for G. To do so by means of Theorem 2.1, the *primal* and *dual* problems of $\Gamma_H(m,n)$ or G are defined as follows:

Primal:		Dual:	
minimize	$x^T u_m$	maximize	$y^T u_n$
subject to	$x^T H \geq u_n^T$,	subject to	$Hy \leq u_m$,
	$x \geq 0$;		$y \geq 0$,

where u_k is the column vector of k copies of 1.

For each $j \in Z_n$, let H^j denote the jth column of H. Moreover, let X and Y be the sets of feasible solutions to the primal and dual problems of G, respectively. Let $\bar{X}$ and $\bar{Y}$ be the sets of optimal feasible solutions to these problems. Let X^* and Y^* be the sets of optimal mixed strategies of the online player and the adversary, respectively.

The next lemma is useful for computing an optimal randomized online algorithm for G and its competitive ratio via linear programming.

LEMMA 2.2.

1. *For all nonzero* $x \in X$ *and* $y \in Y$, $\frac{x}{x^T u_m}$ *and* $\frac{y}{y^T u_n}$ *are mixed strategies for the online player and the adversary, respectively.*
2. $\min_{x \in X} x^T u_m = r^* = \max_{y \in Y} y^T u_n$.
3. $X^* = \frac{1}{r^*} \cdot \bar{X} \neq \emptyset$, *and* $Y^* = \frac{1}{r^*} \cdot \bar{Y} \neq \emptyset$.
4. *For each nonzero* $x \in X$, *if* $j \in Z_n$ *satisfies* $x^T H^j = \min_{\ell \in Z_n} x^T H^\ell$, *then* $\vec{\sigma}_j$ *is a worst-case input sequence for the online player's mixed strategy* $\frac{x}{x^T u_m}$.

Proof. This lemma follows from Theorem 2.1 and the basics of linear programming [22]. □

The next fact is useful for analyzing the uniqueness of an optimal randomized online algorithm for G.

FACT 2.3 (see [23]). *For any* $x \in \bar{X}$ *and* $y \in \bar{Y}$, x *and* y *are extreme points of the convex polyhedra* $\bar{X}$ *and* $\bar{Y}$ *if and only if there is a square submatrix* $H' = (h_{ij})_{i \in I, j \in J}$ *of* H *for some* $I \subseteq Z_m$ *and* $J \subseteq Z_n$ *with the following properties:*

1. H' *is nonsingular.*
2. $\sum_{i \in I} h_{ij} x_i = 1$ *for all* $j \in J$.
3. $\sum_{j \in J} h_{ij} y_j = 1$ *for all* $i \in I$.
4. *For all* $i \notin I$, $x_i = 0$.
5. *For all* $j \notin J$, $y_j = 0$.

The next theorem combines Lemma 2.2 and Fact 2.3 for the case $m = n$.

THEOREM 2.4. *Assume that $m = n$ and H^{-1} exists. Let $x = (u_n^T H^{-1})^T$ and $y = H^{-1}u_n$. Further assume $x \geq 0$ and $y \geq 0$. Let $b = \frac{x}{x^T u_n}$.*

1. *Then, x and y are optimal feasible solutions to the primal and dual problems of G, respectively.*
2. *$\Upsilon_{\mathcal{B}} = r^* = x^T u_n$, where $\mathcal{B}$ is the randomized online algorithm corresponding to the online player's mixed strategy b; in other words, $\mathcal{B}$ is optimal for G.*
3. *For all $j = 1, \ldots, n$, $\frac{\mathcal{A}(\vec{\sigma}_j)}{\mathcal{B}(\vec{\sigma}_j)} = \Upsilon_{\mathcal{B}}$; i.e., $\mathcal{B}$ has the same performance relative to the adversary's on every input sequence.*
4. *If every component of x and y is strictly greater than 0, then x and y are the only optimal feasible solutions to the primal and dual problems of G, and, consequently, $\mathcal{B}$ is the only optimal randomized online algorithm.*

Proof.

Statement 1. By direct verification, $x \in X$ and $y \in Y$. Then, since $x^T u_n = (y^T u_n)^T = y^T u_n$, by Lemma 2.2(2) $x \in \bar{X}$ and $y \in \bar{Y}$.

Statement 2. Note that $x^T u_n = r^*$ by Statement 1 and Lemma 2.2(2). Then, by Statement 1 and Lemma 2.2(3), b is an optimal mixed strategy of the online player. Thus, this statement follows from Theorem 2.1.

Statement 3. As pointed out in Statement 2, $x^T u_n = r^*$. By direct evaluation and Statement 2 $b^T H = \frac{1}{r^*} u_n = \frac{1}{\Upsilon_{\mathcal{B}}} u_n$. Then this statement follows from the fact that by definition, the jth component of $b^T H$ equals $\frac{\mathcal{B}(\vec{\sigma}_j)}{\mathcal{A}(\vec{\sigma}_j)}$.

Statement 4. To prove the uniqueness of $\mathcal{B}$, by Theorem 2.1(2) and Lemma 2.2 (3), it suffices to show that $\bar{X}$ has a unique element. By basics of linear programming [22], $\bar{X}$ has only a finite number of extreme points, and any element in X is a finite convex combination of these extreme points. Thus, it suffices to show that x is the only extreme point of $\bar{X}$ as follows. Since H^{-1} exists, x and y are extreme points of $\bar{X}$ and $\bar{Y}$ by Fact 2.3 with $I = J = Z_n$. On the other hand, let z be any extreme point of $\bar{X}$. Since y is an extreme point of $\bar{Y}$, there is a square submatrix $H' = (h_{ij})_{i \in I, j \in J}$ of H such that z and y satisfy the five conditions in Fact 2.3. Since $y_j > 0$ for $j \in Z_n$, $J = Z_n$ by Condition 5. Since H' is square, $I = Z_n$ and $H' = H$. Then, by Condition 2, $z^T H = u_n^T$. Since $x^T H = u_n^T$, we have $z = x$ as desired. □

3. Optimal static algorithms. This section applies the general tools in section 2 to the static buy-and-hold trading problem to derive the smallest possible competitive ratio for static algorithms.

3.1. Notations. As specified in section 1, the investor in the buy-and-hold trading problem is given α, β, and n prior to an n-day investment horizon.

For $i \in Z_n$, let e_i be the given security's exchange rate on the ith day of the investment horizon. Let e_0 be the exchange rate on the 0th day, i.e., the day right before the investment horizon. Without loss of generality, we normalize e_0 to 1 to simplify the discussion. An *admissible* exchange rate sequence is any $\vec{e} = \langle e_1, e_2, \ldots, e_n \rangle$ where $e_i \in [e_{i-1}\beta^{-1}, e_{i-1}\alpha]$.

As in section 1, let E denote the set of all admissible exchange rate sequences. Let $\mathcal{A}$ denote the optimal offline trading algorithm. Let $\mathcal{B}$ be the investor's online trading algorithm. After the adversary examines $\mathcal{B}$ but before the investor starts executing $\mathcal{B}$, the adversary picks and fixes some $\vec{e} \in E$. On the ith day for $i \in Z_n$, upon seeing e_i, $\mathcal{B}$ decides the amount of remaining capital to be traded for shares of the security without knowing any future exchange rate, i.e., e_j with $j > i$. Note that $\mathcal{A}(\vec{e}) = \max_{1 \leq i \leq n} e_i$, and $\mathcal{B}(\vec{e}) = \sum_{i=1}^{n} a_i e_i$, where a_i is the (expected) amount

of dollars invested by $\mathcal{B}$ on the ith day and depends only on the current and past exchange rate $e_1, e_2, \ldots, e_i$.

For $i \in Z_n$, the algorithm $\mathcal{S}_i$ which trades the entire initial capital of one dollar on the ith day is called the *trade-once algorithm on the ith day.* Note that $\mathcal{S}_i$ is static and $\mathcal{S}_i(\vec{e}) = e_i$.

Let $\mathcal{S}$ be a randomized static algorithm. Let s_i be the expected amount of dollars invested by $\mathcal{S}$ on the ith day. Note that $s_i \geq 0$ for all i and $\sum_{i=1}^{n} s_i = 1$. Thus, let $\mathcal{S}'$ be the deterministic static algorithm that invests s_i on the ith day. Also, since the amounts $s_1, \ldots, s_n$ define a probability density function in $\Phi(Z_n)$, let $\mathcal{S}''$ be the randomized static algorithm that applies $\mathcal{S}_i$ with probability s_i.

LEMMA 3.1. *$\mathcal{S}$, $\mathcal{S}'$, and $\mathcal{S}''$ are equivalent in the sense that for all $\vec{e} \in E$, $\mathcal{S}(\vec{e}) = \mathcal{S}'(\vec{e}) = \mathcal{S}''(\vec{e})$.*

Proof. The proof is straightforward. □

By Lemma 3.1, we identify $\mathcal{S}, \mathcal{S}'$, and $\mathcal{S}''$. Also, let r_{s}^* be the smallest competitive ratio for the static algorithms; then by Lemma 3.1,

$$r_{\mathrm{s}}^* = \inf_{f \in \Phi(Z_n)} \sup_{\vec{e} \in E} \frac{\mathcal{A}(\vec{e})}{\sum_{i=1}^{n} f(i)\, \mathcal{S}_i(\vec{e})}. \tag{3.1}$$

3.2. Reduction to finite games. The static buy-and-hold trading problem is an infinite planning game because the adversary has an infinite number of pure strategies, while by Lemma 3.1 the online player has n pure strategies $\mathcal{S}_i$. In order to use the tools in section 2, we need to reduce the game to a finite one by eliminating the adversary's dominated pure strategies, i.e., non-worst-case exchange rate sequences, so that the remaining exchange rate sequences are finite in number.

For $j = 1, \ldots, n$, let

$$\vec{e}_j = \langle \overbrace{\alpha, \alpha^2, \ldots, \alpha^j}^{j}, \overbrace{\alpha^j \beta^{-1}, \alpha^j \beta^{-2}, \ldots, \alpha^j \beta^{j-n}}^{n-j} \rangle.$$

We call these n exchange rate sequences the *downturns*; see Figure 2 for an illustration.

LEMMA 3.2.

1. *Given a static algorithm $\mathcal{S}$, each $\vec{e} \in E$ is dominated by downturn $\vec{e}_j$, i.e., $\frac{\mathcal{A}(\vec{e})}{\mathcal{S}(\vec{e})} \leq \frac{\mathcal{A}(\vec{e}_j)}{\mathcal{S}(\vec{e}_j)}$, where $e_j = \max_{i=1}^{n} e_i$.*
2. *The smallest competitive ratio for the static algorithms is*

$$r_{\mathrm{s}}^* = \inf_{f \in \Phi(Z_n)} \max_{1 \leq j \leq n} \frac{\mathcal{A}(\vec{e}_j)}{\sum_{i=1}^{n} f(i)\, \mathcal{S}_i(\vec{e}_j)}.$$

3. *The static buy-and-hold trading problem can be regarded as a finite zero-sum two-person game $\Gamma_K(n, n)$ with the payoff matrix K defined by $K(i, j) = \alpha^{i-j}$ if $i \leq j$ or β^{j-i} if $i > j$, i.e.,*

$$K = \begin{pmatrix} 1 & \alpha^{-1} & \alpha^{-2} & \cdots & \alpha^{1-n} \\ \beta^{-1} & 1 & \alpha^{-1} & \cdots & \alpha^{2-n} \\ \beta^{-2} & \beta^{-1} & 1 & \cdots & \alpha^{3-n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \beta^{1-n} & \beta^{2-n} & \beta^{3-n} & \cdots & 1 \end{pmatrix}.$$

Proof. Statement 1 follows from the fact that $\frac{e_j}{e_i} \leq \alpha^{j-i}$ if $i \leq j$ and $\frac{e_j}{e_i} \leq \beta^{i-j}$ otherwise. Statement 2 follows from (3.1) and Statement 1. For Statement 3, we

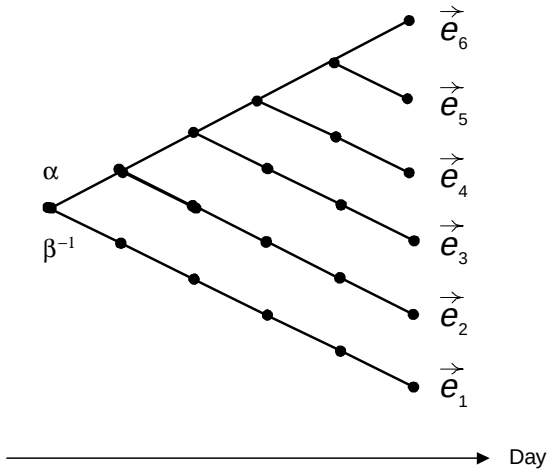

FIG. 2. *The downturns.*

let $\mathcal{S}_i$ be the online player's ith pure strategy and let $\vec{e}_j$ be the adversary's jth pure strategy. As in section 2, the payoff matrix K is defined by $K(i,j) = \frac{\mathcal{S}_i(\vec{e}_j)}{\mathcal{A}(\vec{e}_j)}$. The statement then follows from the facts that $\mathcal{A}(\vec{e}_j) = \alpha^j$ and that $\mathcal{S}_i(\vec{e}_j) = \alpha^i$ if $i \le j$ or $\alpha^j\beta^{j-i}$ otherwise. □

In light of Lemma 3.2, an optimal mixed strategy of the online player of $\Gamma_K(n,n)$ corresponds to an optimal static algorithm. Thus, we next solve $\Gamma_K(n,n)$ to derive an optimal static algorithm.

3.3. Deriving an optimal static algorithm.

LEMMA 3.3. *For $n \ge 2$, $\det(K) = (1-\alpha^{-1}\beta^{-1})^{n-1} > 0$.*

Proof. We use K_n to emphasize the dimension n of K. Let A_{ij} be the submatrix of K_n obtained by deleting row i and column j. To expand $\det(K_n)$ along the first row of K_n, observe that $A_{11} = K_{n-1}$. Furthermore, the first column of A_{12} equals β^{-1} times that of A_{11}, while the other columns of A_{12} equal the corresponding ones of A_{11}; thus $\det(A_{12}) = \beta^{-1}\det(A_{11})$. For $j = 3,\dots,n$, $\det(A_{1j}) = 0$ because in A_{1j}, the first column equals β^{-1} times the second column. Hence, $\det(K_n) = \det(A_{11}) - \alpha^{-1}\det(A_{12}) = \det(K_{n-1}) - \alpha^{-1}\beta^{-1}\det(K_{n-1}) = (1-\alpha^{-1}\beta^{-1})\det(K_{n-1})$. The lemma immediately follows by induction on n. □

Let b^* be the column vector of n components defined by

$$b_i^* = \begin{cases} \frac{\alpha(\beta-1)}{n\alpha\beta-(n-1)(\alpha+\beta)+(n-2)}, & i = 1; \\ \frac{(\alpha-1)(\beta-1)}{n\alpha\beta-(n-1)(\alpha+\beta)+(n-2)}, & 1 < i < n; \\ \frac{(\alpha-1)\beta}{n\alpha\beta-(n-1)(\alpha+\beta)+(n-2)}, & i = n. \end{cases} \tag{3.2}$$

Since $b^* > 0$ and ${b^*}^T u_n = 1$, b^* represents a mixed strategy of the online player. Therefore let BAL denote the static algorithm which applies $\mathcal{S}_i$ with probability b_i^*; note that by Lemma 3.1, BAL is equivalent to the deterministic static algorithm which invests b_i^* dollars on the ith day. Let c^* be the vector obtained by swapping the first and nth components of b^*. Similarly, $c^* > 0$ and ${c^*}^T u_n = 1$, and we intend c^* to represent a mixed strategy of the adversary.

The next theorem analyzes BAL. In light of Statement 3 of the theorem, we call BAL the *balanced strategy.*

THEOREM 3.4. *Let* $r = \frac{n\alpha\beta-(n-1)(\alpha+\beta)+(n-2)}{\alpha\beta-1}$.

1. BAL *is an optimal static algorithm, and* $\Upsilon_{\mathrm{BAL}} = r_{\mathrm{s}}^* = r$.
2. BAL *is the only optimal static algorithm subject to the equivalence stated in Lemma* 3.1.
3. *For* $j = 1, \ldots, n$, $\frac{\mathcal{A}(\vec{e}_j)}{\mathrm{BAL}(\vec{e}_j)} = \Upsilon_{\mathrm{BAL}}$*; in other words,* BAL *has the same performance relative to the adversary's on every downturn.*

Proof. Let $\bar{b} = rb^*$, and $\bar{c} = rc^*$. By Lemma 3.3, K^{-1} exists. Below we prove $\bar{b}^T = u_n^T K^{-1}$ and $\bar{c} = K^{-1}u_n$. Then, Statement 1 follows from Theorem 2.4(2) and the fact that $\bar{b} \geq 0$, $\bar{c} \geq 0$, and $\bar{b}^T u_n = r$. Statement 2 follows from Theorem 2.4(4) and the fact that every component of $\bar{b}$ and $\bar{c}$ is greater than 0. Statement 3 follows from Theorem 2.4(3)

To prove $\bar{b}^T = u_n^T K^{-1}$ and $\bar{c} = K^{-1}u_n$, observe that $\bar{c}$ can be obtained by swapping α and β in $\bar{b}$, and the jth column K^j of K can be obtained from the jth row of K by the same operation. Therefore, $\bar{b}^T K = u_n^T$ if and only if $K\bar{c} = u_n$, and we need only to establish $\bar{b}^T K = u_n^T$. Since $\bar{b}^T K^1 = 1$ if and only if $\bar{b}^T K^n = 1$, we show only $\bar{b}^T K^j = 1$ for $1 \leq j < n$ as follows:

$$\begin{aligned}
\bar{b}^T K^j &= \sum_{i=1}^{n} \bar{b}_i K(i,j) \\
&= \frac{1}{\alpha\beta-1}\left[\alpha(\beta-1)\alpha^{1-j} + \sum_{1<i\leq j}(\alpha-1)(\beta-1)\alpha^{i-j}\right. \\
&\qquad \left. + \sum_{j<i<n}(\alpha-1)(\beta-1)\beta^{j-i} + (\alpha-1)\beta\beta^{j-n}\right] \\
&= \frac{1}{\alpha\beta-1}\left[\alpha^{2-j}(\beta-1) + (\alpha-\alpha^{2-j})(\beta-1)\right. \\
&\qquad \left. +(\alpha-1)(1-\beta^{j-n+1}) + (\alpha-1)\beta^{j-n+1}\right] \\
&= \frac{1}{\alpha\beta-1}(\alpha\beta-1) \\
&= 1. \qquad \square
\end{aligned}$$

3.4. Comparison with the dollar averaging strategy. The *dollar averaging strategy* (DA) is the static algorithm which invests an equal amount of capital, i.e., $1/n$ dollars, on each trading day. Thus, by Lemma 3.1, DA is the uniformly mixed strategy for the online player in the game $\Gamma_K(n,n)$. By Theorem 3.4, DA is not an optimal static algorithm, and $\Upsilon_{\mathrm{BAL}} < \Upsilon_{\mathrm{DA}}$. The next lemma gives a closed-form formula of Υ_{DA}. Figure 3 plots the relationship between Υ_{DA} and Υ_{BAL} for $2 \leq n \leq 100$.

LEMMA 3.5. $\Upsilon_{\mathrm{DA}} = \max\{\frac{n(1-\alpha^{-1})}{1-\alpha^{-n}}, \frac{n(1-\beta^{-1})}{1-\beta^{-n}}\}$.

Proof. Let $B_j = \sum_{i=1}^{n} K(i,j)$. By Lemma 3.2, $\Upsilon_{\mathrm{DA}} = \max_{1\leq j\leq n} \frac{n}{B_j}$. By algebra, $B_{j+1} - B_j$ is a decreasing function of j. Thus, B_j is a function of j whose minimum occurs at one end of the domain $\{1, \ldots, n\}$. The lemma follows from this concavity. $\square$

We have also experimented with BAL and DA using Taiwan's market data. As shown in Figure 1, the Taipei Stock Exchange (TSE) adopts $\alpha = 1/0.93$ and $\beta = 1.07$. We select the Taiwan Semiconductor Manufacturing Company (TSMC) and Acer Computer Company (Acer) for experimental analysis. TSMC is the largest foundry of wafer manufacturing in the world and is listed on both TSE and the New York

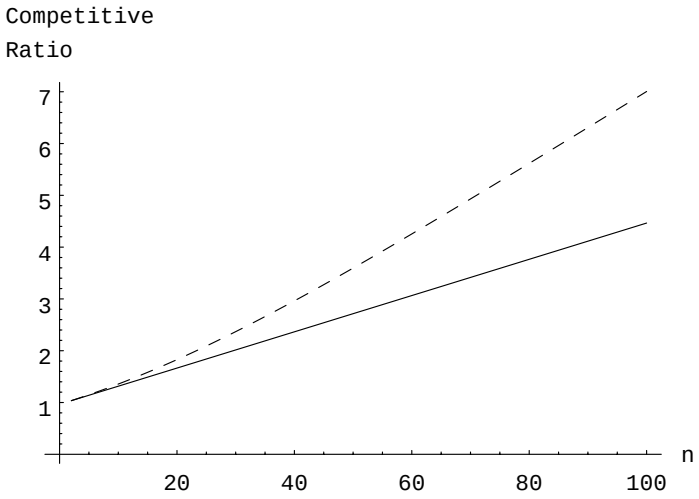

FIG. 3. *The dashed and solid dotted lines denote* Υ_{DA} *and* Υ_{BAL}*, respectively, with* $\alpha = 1/0.93$ *and* $\beta = 1.07$.

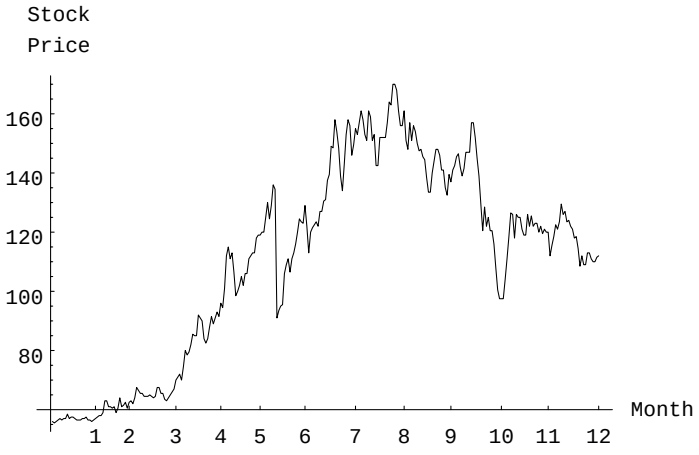

FIG. 4. *TSMC's daily closing stock prices in* 1997.

Stock Exchange (NYSE) under the symbol TSM. Acer is the world's third largest PC manufacturer as well as the fifth largest mobile PC manufacturer.

Figure 4 shows the daily closing prices of TSMC in 1997. All stock prices are quoted in the New Taiwan dollar (NT dollar). One investment plan is executed each month. Each plan buys shares of TSMC with an initial capital of one NT dollar as in section 3; however, the exchange rate of a day is the reciprocal of that day's share price without an initial normalization to one. A *monthly* accumulation is the

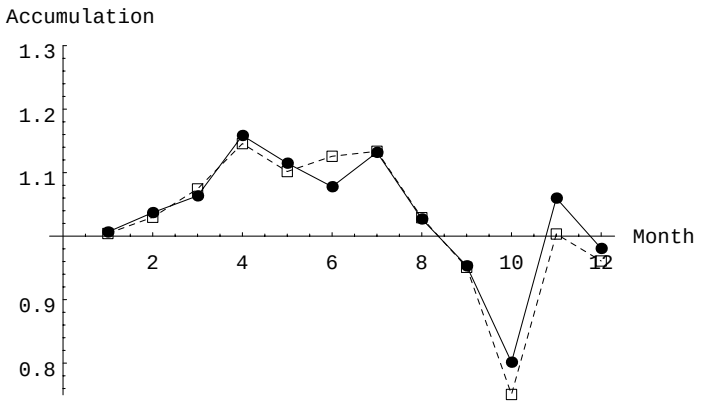

FIG. 5. *Accumulations of* BAL *and* DA *on TSMC.*

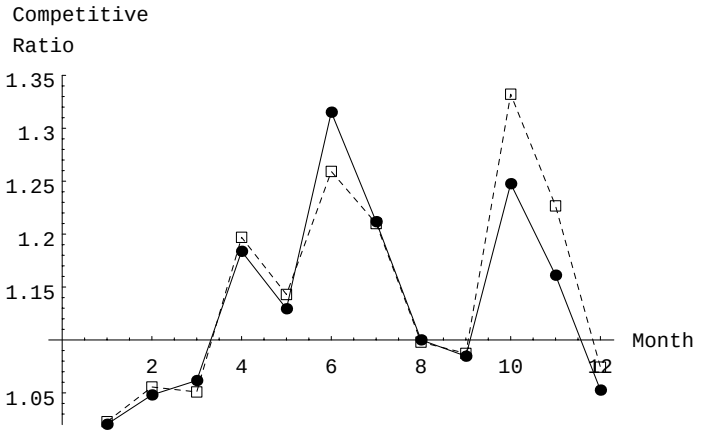

FIG. 6. *Realized competitive ratios of* BAL *and* DA *on TSMC.*

total number of shares acquired over a month. For ease of comparison, a monthly accumulation is expressed in NT dollar by converting the acquired shares into NT dollars at the price of the last trading day of each month. Figure 5 shows the monthly accumulations of BAL and DA on TSMC for each month of 1997. Notice that BAL and DA are money-making except in September, October, and December. Figure 6 shows the *realized* competitive ratios of BAL and DA, which are the performance ratios as defined in (1.1) but with $\vec{e}$ set to the actual exchange rate sequences. Note that for all 12 months, these ratios are less than 1.35. For visual clarity, we join the monthly accumulations and competitive ratios by line segments and use the solid and dotted lines to denote the graphs of BAL and DA, respectively. Observe that, overall, BAL outperforms DA.

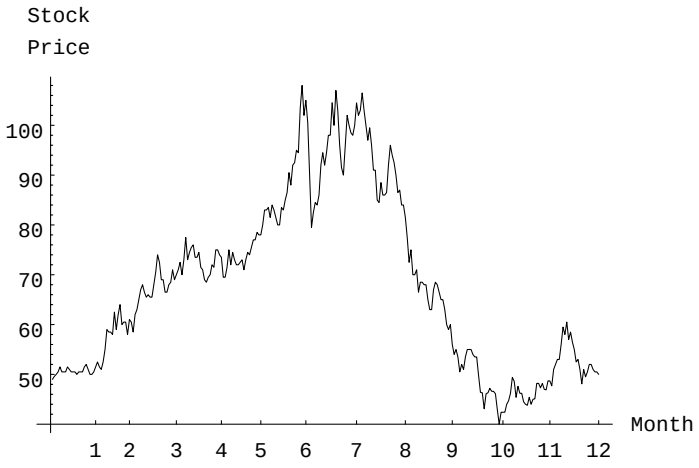

FIG. 7. *Acer's daily closing stock prices in* 1997.

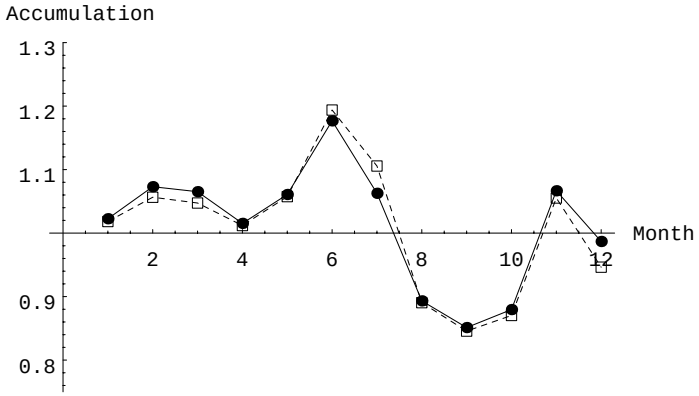

FIG. 8. *Accumulations of* BAL *and* DA *on Acer.*

Figure 7 shows the daily closing prices of Acer in 1997. Figures 8 and 9 show the monthly accumulations and realized competitive ratios of BAL and DA, respectively. The experimental results for Acer lead to similar conclusions to those for TSMC.

4. Open problems. We have presented the balanced strategy BAL and proved its unique optimality among the static algorithms. Furthermore, each of its exact competitive ratio and daily investment amounts has a closed-form expression which takes $O(1)$ time to evaluate. In light of these results, an immediate open problem is whether there are similar results for dynamic online trading algorithms. There are two orthogonal directions for further research as follows.

One direction is to change the assumption that the time horizon is fixed and

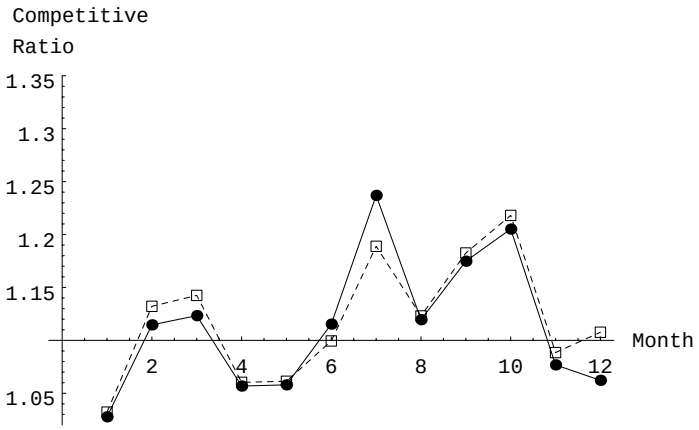

FIG. 9. *Realized competitive ratios of* BAL *and* DA *on Acer.*

known a priori to $\mathcal{B}$. For instance, it would be meaningful to consider the scenario that there is a cash stream instead of a one-time capital at the beginning of the investment horizon. For this scenario, an investor might need to guess when the cash stream will end.

The other direction is to replace α and β with a known probability distribution of the ratio $\frac{e'}{e}$. This would be an example of the standard approach in finance of considering the average-case performance under an assumed probabilistic model. While the worst-case approach in computer science is unnecessarily pessimistic, the average-case approach in finance is overly dependent on the chosen model. In general, it would be of interest to combine these two approaches to formulate more informative computational problems than either approach could.

Acknowledgment. We wish to thank the anonymous referees for very thoughtful comments. Some of the comments have resulted in open problems in section 4.

QUANTUM FORMULAS: A LOWER BOUND AND SIMULATION*

VWANI P. ROYCHOWDHURY† AND FARROKH VATAN†‡

Abstract. We show that Nechiporuk's method [I. Wegener, *The Complexity of Boolean Functions*, Teubner-Wiley, New York, 1987] for proving lower bounds for Boolean formulas can be extended to the quantum case. This leads to an $\Omega(n^2/\log^2 n)$ lower bound for quantum formulas computing an explicit function. The only known previous explicit lower bound for quantum formulas [A. Yao, *Proceedings of 34th IEEE Symposium on Foundations of Computer Science,* IEEE Computer Society Press, Los Alamitos, CA, 1993, pp. 352–361] states that the majority function does not have a linear-size quantum formula. We also show that quantum formulas can be simulated by Boolean circuits of almost the same size.

Key words. quantum formula, lower bound, mixed state, density matrix

1. Introduction.

Computational devices based on quantum physics have attracted much attention lately, and quantum algorithms that perform much faster than their classical counterparts have been developed [12, 21, 22]. To provide a systematic study of the computational power of quantum devices, models similar to those for classical computational devices have been proposed. Deutsch [9] formulated the notion of quantum Turing machine. This approach was further developed by Bernstein and Vazirani [5], and the concept of an efficient universal quantum Turing machine was introduced. As in the case of classical Boolean computation, there is also a quantum model of computation based on circuits (or networks). Yao [27] proved that the quantum circuit model, first introduced by Deutsch [10], is equivalent to the quantum Turing machine model.

Since every Boolean circuit can be simulated by a quantum circuit, with at most a polynomial factor increase in its size, any nontrivial lower bound for quantum circuits could have far-reaching consequences. In classical Boolean circuit theory, all nontrivial lower bounds are for proper subclasses of Boolean circuits such as monotone circuits, formulas, bounded-depth circuits, etc. In the quantum case it also seems that the only hope to prove nontrivial lower bounds is for proper subclasses of quantum circuits. So far the only such known lower bound has been derived by Yao [27] for quantum formulas.[1] The quantum formula is a straightforward generalization of the classical Boolean formula: in both cases, the graph of the circuit is a tree. Yao has proved that the quantum formula size of the majority function MAJ_n is not linear;[2] i.e., if $L(\mathrm{MAJ}_n)$ denotes the minimum quantum formula size of MAJ_n, then

[1] There are exponential lower bounds on the time of quantum computation for the black-box model (see, e.g., [3]), but they do not apply to the size of quantum circuits.

[2] The value of $\mathrm{MAJ}_n(x_1, \ldots, x_n)$ is 1 if at least $\lceil n/2 \rceil$ of inputs are 1.

$\lim_{n\longrightarrow\infty} L(\mathrm{MAJ}_n)/n = \infty$. This bound is derived from a bound on the quantum communication complexity of Boolean functions.

In this paper, we prove an almost quadratic lower bound for quantum formula size. The key step in the derivation of this lower bound is the extension of Nechiporuk's method to quantum formulas; for a detailed discussion of Nechiporuk's method in the Boolean setting, see [11, 26]. Nechiporuk's method has been used in several different areas of Boolean complexity (see, e.g., [11] for details). It has also been applied to models where the gates do not take on binary or discrete values, but the input/output map still corresponds to a Boolean function. For example, in [23] this method has been used to get a lower bound for arithmetic and threshold formulas. The challenging part of this method is a step that we shall refer to as "path squeezing" (see section 4 for the exact meaning of it). Although in the case of Boolean gates this part can be solved easily, in the case of analog circuits it is far from obvious (see [23]). For the quantum formulas "path squeezing" becomes even more complicated, because here we should take care of any *quantum entanglement* and interference phenomena. We show that it is still possible to squeeze a path with an arbitrary number of constant inputs to a path with a fixed number of inputs. This leads to a lower bound of $\Omega(n^2/\log^2 n)$ on the size of quantum formulas computing a class of explicit functions. For example, we get such a bound for the element distinctness function ED_n. The input of ED_n, for $n = 2\ell\log\ell$, is of the form $(z_1,\ldots,z_\ell)$, where each z_j is a string of $2\log\ell$ bits. Then $\mathrm{ED}_n(z_1,\ldots,z_\ell) = 1$ if and only if all these strings are pairwise distinct.

At the end of the paper we compare the powers of quantum formulas and Boolean *circuits*. Surprisingly, in some sense quantum formulas are not more powerful than Boolean circuits. Any quantum formula of size s and depth d can be approximated by a Boolean circuit of size $O(s\log s\log\log s)$ and depth $O(d\log\log s)$. Similar results are not known, and most probably are not true, for quantum circuits and other models which are depending on real number parameters (like arithmetic circuits [23]). The key idea for this simulation is that the computation of a quantum formula on an input (which is a pure state in the Hilbert space) can be described as performing a sequence of unitary operations on 4×4 density matrices of mixed states.

In this paper we use the notation $|\cdot|$ for two different purposes. When α is a complex number, $|\alpha|$ denotes the absolute value of α; i.e., $|\alpha| = \sqrt{\alpha\cdot\alpha^*}$. While if X is a set, then $|X|$ denotes the cardinality of X.

2. Preliminaries. A *quantum circuit* is defined as a straightforward generalization of an acyclic classical (Boolean) circuit (see [10]). For constructing a quantum circuit, we begin with a *basis* of quantum gates as elementary gates. Each elementary gate g with d inputs represents a unitary operation $U_g \in \mathbf{U}(2^d)$, where $\mathbf{U}(m)$ denotes the group of $m\times m$ unitary complex matrices. The gates are interconnected by quantum "wires." Each wire represents a quantum bit, *qubit*, which is a 2-state quantum system represented by a unit vector in $\mathbb{C}^2$. Let $\{|0\rangle, |1\rangle\}$ be the standard orthonormal basis of $\mathbb{C}^2$. The $|0\rangle$ and $|1\rangle$ values of a qubit correspond to the classical Boolean 0 and 1 values, but a qubit can also be in a superposition of the form $\alpha|0\rangle + \beta|1\rangle$, where $\alpha,\beta\in\mathbb{C}$ and $|\alpha|^2+|\beta|^2 = 1$. Note that the output of such a gate, in general, is not a tensor product of its inputs but an *entangled state,* e.g., a state like $\frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle$ which cannot be written as a tensor product.

If the circuit has m inputs, then for each d-input gate g, the unitary operation $U_g \in \mathbf{U}(2^d)$ can be considered in a natural way as an operator in $\mathbf{U}(2^m)$ by acting as the identity operator on the other $(m-d)$ qubits. Hence, a quantum circuit with m inputs computes a unitary operator in $\mathbf{U}(2^m)$, which is the product of successive

unitary operators defined by successive gates.

The *size* of a quantum circuit C, denoted by $\mathsf{size}(C)$, is the number of gates occurring in C. The *depth* of C, denoted by $\mathsf{depth}(C)$, is the length of the longest path in C from an input to an output gate.

In this paper, we consider quantum circuits that compute Boolean functions. Consider a quantum circuit C with m inputs. Suppose that C computes the unitary operator $U_C \in \mathbf{U}(2^m)$. We say C computes the Boolean function $f\colon \{0,1\}^n \longrightarrow \{0,1\}$ if the following holds. The inputs are labeled by the variables $x_1, x_2, \ldots, x_n$ or the constants $|0\rangle$ or $|1\rangle$. (Different inputs may be labeled by the same variable x_j.) We consider one of the output wires, say, the first one, as the output of the circuit. To compute the value of the circuit at $(a_1, \ldots, a_n) \in \{0,1\}^n$, let the value of each input wire with label x_j be $|a_j\rangle$. These inputs, along with the constant inputs to the circuit, define a unit vector $|\alpha\rangle$ in $\mathbb{C}^{2^m}$. In fact, this vector is a standard basis vector of the following form (up to some repetitions and a permutation):

$$|\alpha\rangle = |a_1\rangle \otimes \cdots \otimes |a_n\rangle \otimes |0\rangle \otimes \cdots \otimes |1\rangle\,.$$

The action of the circuit C on the input $|\alpha\rangle$ is the same as $U_C(|\alpha\rangle)$. Note that since U_C is unitary, $\|U_C(|\alpha\rangle)\| = 1$. We decompose the vector $U_C(|\alpha\rangle) \in \mathbb{C}^{2^m}$ with respect to the output qubit. Let the result be

$$U_C(|\alpha\rangle) = |0\rangle \otimes |A_{0,\alpha}\rangle + |1\rangle \otimes |A_{1,\alpha}\rangle\,.$$

Then we define the *probability* that C outputs 1 (on the input α) as $p_\alpha = \||A_{1,\alpha}\rangle\|^2$, i.e., the square of the length of $|A_{1,\alpha}\rangle \in \mathbb{C}^{2^{m-1}}$. Finally, we say that the quantum circuit C computes the Boolean function f if for every $\alpha \in \{0,1\}^n$, if $f(\alpha) = 1$, then $p_\alpha > 2/3$; and if $f(\alpha) = 0$, then $p_\alpha < 1/3$.

Following Yao [27], we define quantum formulas as a subclass of quantum circuits. A quantum circuit C is a *formula* if for every input there is a unique path that connects it to the output qubit. To make this definition more clear we define the *computation graph* of C, denoted by G_C. The nodes of G_C correspond to a subset of the gates of C. We start with the output gate of C, i.e., the gate which provides the output qubit, and let it be a node of G_C. Once a node v belongs to G_C, then all gates in C that provide inputs to v are considered as adjacent nodes of v in G_C. Then C is a formula if the graph G_C is a tree. Figure 2.1 provides examples of quantum circuits of both kinds, i.e., circuits that are also quantum formulas and circuits that are not formulas.

All circuits that we consider are over some fixed quantum basis. The lower bound does not depend on the basis; the only condition is that the number of inputs (and therefore the number of outputs) of each gate be bounded by some fixed constant number. (This condition is usually considered as part of the definition of a quantum basis.) For example, this basis can be the set of all 2-input 2-output quantum gates, and, as is shown in [2], this basis is universal for computation with quantum circuits.

It is well known that any Boolean circuit can be efficiently simulated by a quantum circuit over a universal basis. Indeed, for this purpose, the 3-bit *Toffoli gate* is enough (see, e.g., [4, 17]). Similarly, any Boolean formula can be efficiently simulated by a quantum formula using only a Toffoli gate or a basis universal for classical computation. In the special case, from [24] it follows that there is a polynomial-size log-depth quantum *formula* computing the majority function MAJ_n. This fact implies that for quantum formulas over reasonable bases (i.e., universal for classical computation) the threshold probability of the correct answer ($\frac{2}{3}$ in the above definition) can be efficiently boosted to a number arbitrarily close to one.

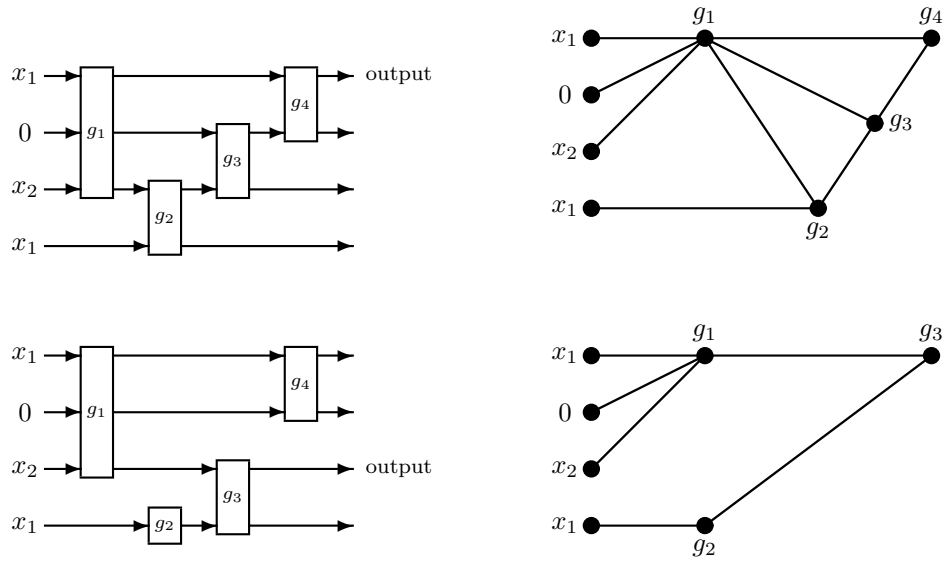

FIG. 2.1. *Quantum circuits and their computation graphs; the top circuit is not a formula, while the bottom one is a formula.*

For our proof we also need a Shannon-type result for quantum circuits. Knill [15] has proved several theorems about the quantum circuit complexity of almost all Boolean functions. We will use the following theorem.

THEOREM 2.1 (see [15]). *The number of different n-variable Boolean functions that can be computed by size N quantum circuits ($n \leq N$) with d-input d-output elementary gates is at most $2^{cN \log N}$, where c depends only on d.*

For the sake of completeness, in the appendix we have provided a proof for a slightly weaker bound. Our approach is different from that in [15], and it seems that it is shorter and simpler than the proof in [15]. Although the bound that we get is a little weaker than the bound provided by the above theorem (it is of the form $2^{O(nN)}$), our bound results in the same bound of Theorem 2.1 if $\log(N) = \Omega(n)$, which is true for almost all Boolean functions. Thus our result provides the same bound for the complexity of almost all functions and is sufficient for the bound we get in this paper.

We also need to consider general orthonormal bases in the space $\mathbb{C}^{2^n}$ other than the standard basis. In the context of quantum physics, we identify the Hilbert space $\mathbb{C}^{2^n}$ as the tensor product space $\bigotimes_{j=1}^{n} \mathbb{C}^2$, and the standard basis consists of the vectors

$$|c_1\rangle \otimes \cdots \otimes |c_n\rangle = |c_1 \cdots c_n\rangle\,,\ c_j \in \{0,1\}.$$

FACT 2.2. *Let $|A_j\rangle \in \mathbb{C}^{2^k}$ and $|B_\ell\rangle \in \mathbb{C}^{2^m}$ be unit vectors (for j and ℓ in some index sets). If $|A_j\rangle$ are pairwise orthogonal and $|B_\ell\rangle$ are pairwise orthogonal, then the family*

$$\left\{ |A_j\rangle \otimes |B_\ell\rangle \in \mathbb{C}^{2^{k+m}} : j, \ell \right\}$$

is an orthonormal set.

The following lemma, although seemingly obvious, is crucial for the "path squeezing" technique in the proof of the lower bound.

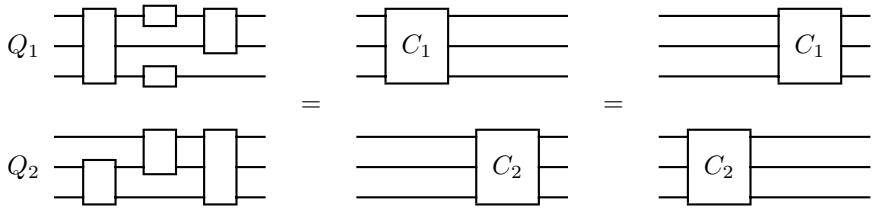

FIG. 2.2. *Decomposition of a quantum subcircuit acting on disjoint sets of qubits* (*Lemma* 2.3(a)).

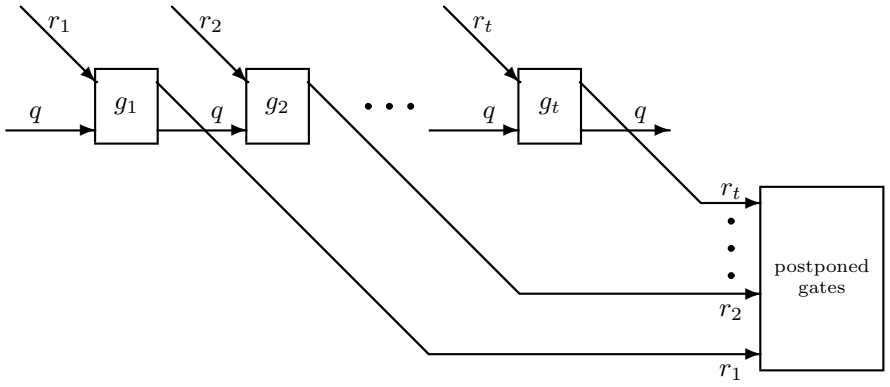

FIG. 2.3. *Postponing the gates* (*Lemma* 2.3(b)).

LEMMA 2.3. (a) *Suppose that C is a subcircuit of a quantum circuit. Let the inputs of C be divided into two disjoint sets of qubits Q_1 and Q_2. Suppose that each gate of C either acts only on qubits from Q_1 or only on qubits from Q_2. Then there are subcircuits C_1 and C_2 such that C_j acts only on qubits from Q_j, and the operation of C is the composition of operations of C_1 and C_2 no matter in which order they act; i.e., $C = C_1 \circ C_2 = C_2 \circ C_1$. Therefore the subcircuit C can be substituted by C_1 and C_2 (see Figure* 2.2*).*

(b) *Let C be a subcircuit of a quantum circuit with distinct input qubits q and $r_1, \ldots, r_t$. Suppose that only t gates $g_1, \ldots, g_t$ in C act on q. Moreover, suppose that each g_j acts on q and r_j. Then, without loss of generality (w.l.o.g.), we can assume that each qubit r_j after entering the gate g_j will not interact with any other qubit until the gate g_t is performed (see Figure* 2.3*).*

Proof. Part (a) is based on the following simple observation. If $M \in \mathbf{U}(2^m)$ and $N \in \mathbf{U}(2^n)$, then

$$\begin{aligned} M \otimes N &= (M \otimes I_n) \circ (I_m \otimes N) \\ &= (I_m \otimes N) \circ (M \otimes I_n), \end{aligned}$$

where I_t is the identity map in $\mathbf{U}(2^t)$. Note that the inputs of the subcircuit C may be in an entangled state; but to see that the equality $C = C_1 \circ C_2 = C_2 \circ C_1$ holds, it is enough to check this equality for the standard basis and extend it to the whole space by linearity.

Part (b) follows simply from part (a); as in Figure 2.4, part (a) can be applied on the subcircuit consisting of gates h_2 and h_3. Note that in this case input qubits r_j

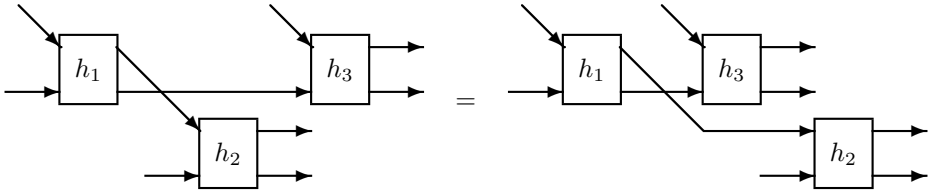

FIG. 2.4. *Changing the order of gates* (*Lemma* 2.3(b)).

of g_j's may also be in an entangled state. Again a linearity argument shows that we have to consider only the case in which r_j's are in a product state. □

The above lemma is a special case of a more general fact that operations on one part of a bipartite quantum system do not affect the result of operations on the other part (for more details see, e.g., [18]).

3. A new equivalent definition for quantum formulas. Kitaev [14] has brought to our attention that quantum formulas are equivalent to a model that is very similar to the classical formulas. In this model the inputs and the intermediate results are density matrices. Each gate is a completely positive trace-preserving super-operator, which maps density matrices of d-qubit systems to one-qubit density matrices. The underlying graph, like a classical formula, is a directed tree; i.e., from each input there is a unique path to the output gate. Thus the output of such a circuit is a density matrix of a single qubit which provides the probability of the output "0" or "1." To make the paper self-contained, we first present the definitions of the notions mentioned in this new definition.

By a *pure state* $|\alpha\rangle$ we mean a unit vector in some Hilbert space $\mathbb{C}^{2^n}$. A *mixed state* $\{\psi\}$ in $\mathbb{C}^{2^n}$ is a probability distribution on pure states in this Hilbert space. We denote such a mixed state as $\{\psi\} = \{p_k, |\psi_k\rangle\}$, where $p_k \geq 0$ and $\sum_k p_k = 1$. Then $\{\psi\}$ picks the pure state $|\psi_k\rangle$ with probability p_k.

The *density matrix* of a pure state $|\alpha\rangle$ is the matrix $\rho_{|\alpha\rangle}$ of the linear mapping $|\alpha\rangle\langle\alpha|$; i.e, the mapping $|x\rangle \longrightarrow \langle\alpha|x\rangle\,|\alpha\rangle$. Therefore, if $|0\rangle, |1\rangle, \ldots, |2^n-1\rangle$ represent the standard computational basis of $\mathbb{C}^{2^n}$ and $|\alpha\rangle = \sum_k \lambda_k |k\rangle$, then the (i,j) entry of $\rho_{|\alpha\rangle}$ is $\lambda_i \lambda_j^\star$. The importance of the density matrix is that it suffices to characterize the quantum state of the system. Specially, this matrix is enough to find the probabilities of measurements. In general, the result of each measurement can be represented by action of a projection operator $\mathcal{P}$ on the given state $|\alpha\rangle$, where $\mathcal{P}$ is a projection onto some subspace $\mathcal{E}$. Then the probability that the result of the measurement is in the subspace $\mathcal{E}$ is equal to $\mathrm{Tr}(\mathcal{P}\,\rho_{|\alpha\rangle})$.

The density matrix of a mixed state $\{\psi\} = \{p_k, |\psi_k\rangle\}$ is defined as

$$\rho_{\{\psi\}} = \sum_k p_k \rho_{|\psi_k\rangle} = \sum_k p_k\, |\psi_k\rangle\langle\psi_k|\,.$$

Like the case of pure states, the probability that the result of the measurement is in the subspace $\mathcal{E}$ is equal to $\mathrm{Tr}(\mathcal{P}\,\rho_{\{\psi\}})$.

If the (pure or mixed) state $|\psi\rangle$ can be written as the tensor product $|\phi\rangle \otimes |\chi\rangle$, then the density matrix $\rho_{|\psi\rangle}$ is equal to the tensor (Hadamard) product $\rho_{|\phi\rangle} \otimes \rho_{|\chi\rangle}$.

The next important notion is *partial trace*. Consider the Hilbert spaces $\mathcal{H}_1 = \mathbb{C}^{2^n}$ and $\mathcal{H}_1 = \mathbb{C}^{2^m}$, and $\mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2$; thus $\mathcal{H}$ is isomorphic with $\mathbb{C}^{2^{n+m}}$. Let

$$\mathcal{B}_1 = \{\, |u_i\rangle : i = 1, \ldots, 2^n \,\} \quad \text{and} \quad \mathcal{B}_2 = \{\, |v_j\rangle : j = 1, \ldots, 2^m \,\}$$

be orthonormal bases for $\mathcal{H}_1$ and $\mathcal{H}_2$, respectively. Then

$$\mathcal{B}_1 \otimes \mathcal{B}_2 = \{\, |u_i\rangle \otimes |v_j\rangle : i = 1, \ldots, 2^n,\ j = 1, \ldots, 2^m \,\}$$

is a basis for $\mathcal{H}$. Let ρ be the density matrix of a mixed state $|\psi\rangle$ in the space $\mathcal{H}$. It is possible to restrict the state $|\psi\rangle$ to the subspace $\mathcal{H}_1$. The result is a *partial trace* $\rho|_{\mathcal{H}_1} = \mathrm{Tr}_{\mathcal{H}_2}\, \rho$, which is the density matrix of some mixed state in the subspace $\mathcal{H}_1$. We also say that the subspace $\mathcal{H}_2$ is *traced out*. The partial trace $\rho|_{\mathcal{H}_1}$ enables us to calculate probabilities of the results of the measurements bearing only on the subspace $\mathcal{H}_1$. We assume that the rows and columns of the matrices ρ and $\rho|_{\mathcal{H}_1}$ are labeled by the vectors in the basis $\mathcal{B}_1 \otimes \mathcal{B}_2$ and $\mathcal{B}_1$, respectively. For example, $\rho\left(|u_{i_1}\rangle\,|v_{j_1}\rangle\,, |u_{i_2}\rangle\,|v_{j_2}\rangle\right)$ is the entry of ρ at the row labeled by $|u_{i_1}\rangle \otimes |v_{j_1}\rangle$ and the column labeled by $|u_{i_2}\rangle \otimes |v_{j_2}\rangle$. With this notation, the partial trace $\rho|_{\mathcal{H}_1}$ is defined as follows:

$$\rho|_{\mathcal{H}_1}\left(|u_{i_1}\rangle\,, |u_{i_2}\rangle\right) = \sum_{j=1}^{2^m} \rho\left(|u_{i_1}\rangle\,|v_j\rangle\,, |u_{i_2}\rangle\,|v_j\rangle\right).$$

Again let $\mathcal{E}$ be a subspace of $\mathcal{H}_1$. We can identify it with subspace $\mathcal{E} \otimes \mathcal{H}_2$ of $\mathcal{H}$. Let $\mathcal{P}\colon \mathcal{H}_1 \longrightarrow \mathcal{E}$ be the projection operator associated with $\mathcal{E}$. The operator $\mathcal{P}$ can be extended to the whole space $\mathcal{H}$ in a natural way as the operator $\mathcal{P} \otimes \mathrm{Id}_{\mathcal{H}_2}$, where $\mathrm{Id}_{\mathcal{H}_2}$ is the identity operator on $\mathcal{H}_2$. Then the probability that the result of the measurement is in the subspace $\mathcal{E}$ is equal to $\mathrm{Tr}(\mathcal{P}\,\rho|_{\mathcal{H}_1})$. (For more details on density matrices of mixed states and the partial trace, see, e.g., [8].)

Let C be a quantum circuit. For inputs of C it is possible to consider mixed states along with pure states. Toward this end, each input is substituted by its density matrix and each gate g of C by a *superoperator* $\widetilde{g}$ that maps density matrices to density matrices. In fact, if the unitary operator of the gate g is U, then the action of $\widetilde{g}$ on the density matrix ρ is as follows:

$$\widetilde{g}(\rho) = g \circ \rho = U \rho\, U^{\dagger}. \tag{3.1}$$

LEMMA 3.1 (see [1]). *If the gates g_1 and g_2 operate on disjoint sets of qubits, then for any density matrix ρ we have $g_1 \circ g_2 \circ \rho = g_2 \circ g_1 \circ \rho$.*

First we show that every quantum formula is equivalent to a circuit based on this new definition. Let $\mathcal{F}$ be a quantum formula on a basis of d-bit gates. Construct a circuit $\mathcal{C}$ from $\mathcal{F}$ by the following transformations. In each gate g, performing the unitary operation $U \in \mathbf{U}\left(2^d\right)$, keep the only output which is connected to the output and substitute the operator U by the superoperator $[g] = \mathrm{Tr}_{\mathcal{H}} \circ \widetilde{g}$, where $\mathcal{H}$ is the $(d-1)$-dimensional subspace spanned by the qubits removed from the output of this gate. The fact that the circuit $\mathcal{C}$ computes the same function as the formula $\mathcal{F}$ follows from Lemma 2.3. Thus the underlying graph of the circuit $\mathcal{C}$ is the same as the computation tree of the formula $\mathcal{F}$, where the node corresponding with the gate g computes the superoperator $[g]$.

Now let $\mathcal{C}$ be a circuit based on this new definition. We construct a quantum formula $\mathcal{F}$ from $\mathcal{C}$ by simply substituting each gate of $\mathcal{C}$, computing the superoperator T, by a $(d+2)$-input $(d+2)$-output unitary gate U; only one output of this gate is connected to the next gate and the other outputs never interact with any other qubit. Therefore $\mathcal{F}$ satisfies our original definition of quantum formula. The only thing that remains is to show how we can choose the unitary operators U such that

the formula $\mathcal{F}$ computes the same Boolean function as $\mathcal{C}$. The following theorem guarantees the existence of the correct operator U for each gate of $\mathcal{C}$. Here $\mathbf{L}(\mathcal{H})$ is the space of linear operators on the Hilbert space $\mathcal{H}$ and for unitary operator U on $\mathcal{H}$, the operator $\mathcal{O}_U \in \mathbf{L}(\mathcal{H})$ is defined as $\mathcal{O}_U(M) = U\,M\,U^\dagger$.

THEOREM 3.2 (see [7, 13, 16, 20]). *Suppose that $T : \mathbf{L}(\mathcal{H}_1) \longrightarrow \mathbf{L}(\mathcal{H}_2)$ is a trace-preserving and completely positive superoperator. Then there are Hilbert spaces $\mathcal{G}_1$ and $\mathcal{G}_2$, where $\dim(\mathcal{G}_1) = (\dim(\mathcal{H}_2))^2$ and $\dim(\mathcal{G}_2) = \dim(\mathcal{H}_1) \cdot \dim(\mathcal{H}_2)$, and there is a unitary operator $U : \mathcal{H}_1 \otimes \mathcal{G}_1 \longrightarrow \mathcal{H}_2 \otimes \mathcal{G}_2$ such that $T = \mathrm{Tr}_{\mathcal{G}_2} \circ \mathcal{O}_U$.*

We would like to mention that from now on it might be more useful to accept the new modified definition as the standard one for quantum formulas in the literature.

4. The lower bound. Let $f(x_1, \ldots, x_n)$ be a Boolean function. Let $X = \{x_1, \ldots, x_n\}$ be the set of the input variables. Consider a partition $\{S_1, \ldots, S_k\}$ of X; i.e.,

$$X = \bigcup_{j=1}^{k} S_j \quad \text{and} \quad S_{j_1} \cap S_{j_2} = \emptyset \quad \text{for} \quad j_1 \neq j_2.$$

Let $n_j = |S_j|$ for $j = 1, \ldots, k$. Let $\mathcal{F}_j$ be the set of all subfunctions of f on S_j obtained by fixing the variables outside S_j in all possible ways. We denote the cardinality of $\mathcal{F}_j$ by σ_j.

As an example, we compute the above parameters for the element distinctness function ED_n (see [6]). Let $n = 2\ell \log \ell$ (so $\ell = \Omega(n/\log n)$) and divide the n inputs of the function into ℓ strings each of $2\log\ell$ bits. Then the value of ED_n is 1 if and only if these ℓ strings are pairwise distinct. We consider the partition $(S_1, \ldots, S_\ell)$ such that each S_j contains all variables of the same string. Thus $n_j = |S_j| = 2\log\ell$. Each string in S_j represents an integer from the set $\{0, 1, \ldots, \ell^2 - 1\}$. The function ED_n is symmetric with respect to S_j's; so $|\mathcal{F}_j| = |\mathcal{F}_{j'}|$. To estimate $|\mathcal{F}_1|$, note that if the strings $(z_2, \ldots, z_\ell)$ in $S_2, \ldots, S_\ell$ represent distinct integers, then the corresponding subfunction is different from any subfunction corresponding to any other string. Therefore $\sigma_j = |\mathcal{F}_1| \geq \binom{\ell^2}{\ell-1} > \ell^{\ell-1}$.

THEOREM 4.1. *Every quantum formula computing f has size*

$$\Omega\left(\sum_{1\leq j\leq k} \frac{\log(\sigma_j)}{\log\log(\sigma_j)}\right).$$

Proof. We give a proof for any basis consisting of 2-input 2-output quantum gates. The proof for bases with more than two inputs is a simple generalization of this proof.

Let F be a formula computing f. Let Σ_j be the set of input wires of F labeled by a variable from S_j, and let $s_j = |\Sigma_j|$. Then

$$\mathsf{size}(F) = \Omega\left(\sum_{1\leq j\leq k} s_j\right). \tag{4.1}$$

We want to consider the formulas obtained from F by letting the input variables not in Σ_j to be some constant value $|0\rangle$ or $|1\rangle$. In this regard, let P_j be the set of all paths from an input wire in Σ_j to the output of F. Finally, let G_j be the set of gates of F where two paths from P_j intersect. Then $|G_j| \leq s_j$.

Let τ be an assignment of $|0\rangle$ or $|1\rangle$ to the input variable wires *not* in Σ_j. We denote the resulting formula by F_τ. Thus F_τ computes a Boolean function $f_\tau\colon \{0,1\}^{n_j} \longrightarrow \{0,1\}$ which is a subfunction of f and a member of $\mathcal{F}_j$. Consider a path

$$\pi = (g_1, g_2, \dots, g_m), \qquad m > 2, \tag{4.2}$$

in F_τ, where g_1 is an input wire or a gate in G_j, g_m is a gate in G_j or the output wire of F, and $g_\ell \notin G_j$ for $1 < \ell < m$.

To show how we can squeeze paths like (4.2) (this is the essence of the Nechiporuk's method), we introduce the following notations. We consider a natural ordering $\gamma_1, \gamma_2, \dots, \gamma_t$ on the gates of the formula F_τ, and regard F_τ as a computation in t steps, where at step ℓ the corresponding gate γ_ℓ is performed. We say two qubits q_1 and q_2 are *strong companions* of each other at step ℓ if there is a gate γ_j such that $j \le \ell$ and q_1 and q_2 are inputs of γ_j. We say qubits q_1 and q_2 are *companions* of each other at step ℓ if there exists a sequence $r_1, r_2, \dots, r_p$ of qubits such that $r_1 = q_1$, $r_p = q_2$, and r_j and r_{j+1} (for $1 \le j \le p-1$) are strong companions of each other at step ℓ (see Figure 4.1). If q_1 and q_2 are companions at step ℓ, then they are also companions at any step after ℓ. For a gate $g = \gamma_k$, we define the *set of companions* of g as the union of all companions of input qubits of g at step k.

Suppose that in the path (4.2), $g_1 = \gamma_{j_0}$, $g_m = \gamma_{j_1}$, the inputs of g_1 are q_0 and q_1, the output of γ_{j_0} from the path (4.2) is the qubit q_0, and the input of γ_{j_1} not from the path (4.2) is the qubit q_2 (see Figure 4.2). Note that q_0 is the companion of q_2 at step j_1. Let Q_π be the union of all sets of companions of $g_2, \dots, g_{m-1}$ minus q_0 and q_1 and their companions at step j_1. Let C_0 be the circuit defined by the gates $g_1, \dots, g_{m-1}$ from the path (4.2). Suppose that $|Q_\pi| = v$ and consider C_0 as an operation acting on $\mathcal{H} = \mathbb{C}^2 \otimes \mathbb{C}^2 \otimes \mathbb{C}^{2^v}$. To study the action of the subcircuit C_0, it is enough to consider the action of C_0 on the computational basis vectors of the space $\mathcal{H}$. Therefore, while the inputs of C_0 as a subcircuit of F_τ are in general entangled states, we have to study only the action of C_0 on the computational basis vectors which are product states. We label the inputs $|\alpha_0\rangle \otimes |\alpha_1\rangle \otimes |\alpha\rangle \in \mathcal{H}$ of C_0 in such a way that when C_0 acts as a subformula of F_τ, then $|\alpha_0\rangle$, $|\alpha_1\rangle$, and $|\alpha\rangle$ are replaced by q_0, q_1, and the companion qubits in Q_π, respectively. Note that because F_τ is a formula, all qubits in Q_π are constant inputs of F_τ and do not intersect any other path like (4.2). Therefore, when C_0 acts as a subformula of F_τ, the input $|\alpha\rangle$ of the subcircuit C_0 is the same for all possible inputs for $|\alpha_0\rangle$ and $|\alpha_1\rangle$. Therefore, let $\widetilde{C_0}$ be a circuit such that on input $|\alpha_0\rangle \otimes |\alpha_1\rangle \otimes |0\cdots 0\rangle \in \mathbb{C}^2 \otimes \mathbb{C}^2 \otimes \mathbb{C}^{2^v}$, it first computes $|\alpha_0\rangle \otimes |\alpha_1\rangle \otimes |\alpha\rangle$ then performs the action of C_0 on $|\alpha_0\rangle \otimes |\alpha_1\rangle \otimes |\alpha\rangle$. Then if we replace C_0 by $\widetilde{C_0}$ and assign the value $|0\rangle$ to the qubits in Q_π, the result is a circuit equivalent to F_τ. Suppose that the action of $\widetilde{C_0}$ is defined as follows:

$$|\alpha_0\rangle \otimes |\alpha_1\rangle \otimes |0\cdots 0\rangle \longrightarrow \sum_{c_0,c_1\in\{0,1\}} |c_0\rangle \otimes |c_1\rangle \otimes \left|A_{c_0,c_1}^{\alpha_0,\alpha_1}\right\rangle, \tag{4.3}$$

where $\alpha_0, \alpha_1 \in \{0,1\}$, and $\left|A_{c_0,c_1}^{\alpha_0,\alpha_1}\right\rangle \in \mathbb{C}^{2^v}$ may be not a unit vector. Let $\mathcal{A}_\pi \subseteq \mathbb{C}^{2^v}$ be the vector space spanned by $\left|A_{c_0,c_1}^{\alpha_0,\alpha_1}\right\rangle$ for $\alpha_0, \alpha_1, c_0, c_1 \in \{0,1\}$ and $d = \dim(\mathcal{A}_\pi)$. Then $1 \le d \le 16$. Let $|A_1^\pi\rangle, \dots, |A_d^\pi\rangle$ be an orthonormal basis for $\mathcal{A}_\pi$. Then we can rewrite (4.3) as follows:

$$|\alpha_0\rangle \otimes |\alpha_1\rangle \otimes |0\cdots 0\rangle \longrightarrow \sum_{c_0,c_1\in\{0,1\}} \sum_{1\le j\le d} \lambda_{j,c_0,c_1}^{\alpha_0,\alpha_1} |c_0\rangle \otimes |c_1\rangle \otimes \left|A_j^\pi\right\rangle. \tag{4.4}$$

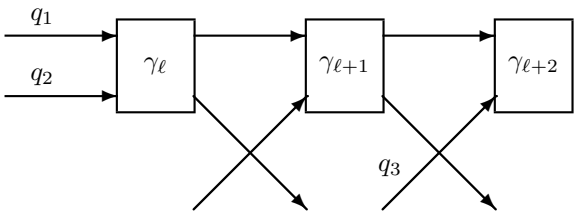

FIG. 4.1. *The qubits q_1 and q_2 are strong companions at step ℓ; the qubits q_2 and q_3 are companions at step $\ell + 2$.*

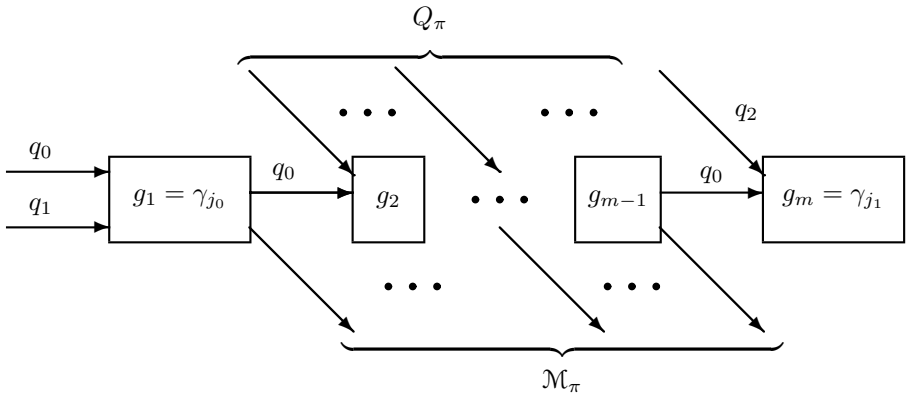

FIG. 4.2. *Squeezing a path.*

Let $\mathcal{M}_\pi$ be the set of those unitary operations that are performed after one of the gates $g_1, \ldots, g_{m-1}$ on some qubits in Q_π before the step j_1. Since qubits in Q_π do not interact with any other path of the form (4.2), by Lemma 2.3(b) we can postpone all operations in $\mathcal{M}_\pi$ after we have computed the output of g_m. Let $\pi_1, \ldots, \pi_k$ be a natural ordering on the paths like (4.2) on all paths in P_j (i.e., the last gate of π_{j+1} is not performed before the last gate of π_j). Consider the sets of postponed operations $\mathcal{M}_{\pi_1}, \ldots, \mathcal{M}_{\pi_k}$. Once again Lemma 2.3 implies that we can postpone operations in $\mathcal{M}_{\pi_1}$ after the last gate of π_2; then we can postpone operations in $\mathcal{M}_{\pi_1}$ and $\mathcal{M}_{\pi_2}$ after the last gate of π_3, and so on. Repeating this argument shows that we can postpone all operations in $\mathcal{M}_{\pi_1}, \ldots, \mathcal{M}_{\pi_k}$ after we compute the output qubit. In this way, the state of the output qubit, before the postponed operations $\mathcal{M}_{\pi_1}, \ldots, \mathcal{M}_{\pi_k}$ are applied, is of the form

$$|0\rangle \otimes |M\rangle + |1\rangle \otimes |N\rangle\,, \tag{4.5}$$

where the first qubit is the output qubit, and $|M\rangle$ and $|N\rangle$ are superpositions of tensor products of orthonormal vectors $\left|A_k^{\pi_j}\right\rangle$ used in (4.4). By Fact 2.2, these tensor products of the vectors $\left|A_k^{\pi_j}\right\rangle$ are unit vectors and pairwise orthogonal. The unitary operations in the sets $\mathcal{M}_{\pi_j}$ (for paths π_j of the form (4.2)), which are postponed to the end, do not change the lengths of $|M\rangle$ and $|N\rangle$. Thus, as far as the computation of the Boolean function f_τ is concerned, we can ignore all the postponed unitary operations. For this reason we construct the circuit $\overline{F_\tau}$ from the formula F_τ by eliminating all postponed operations in $\mathcal{M}_{\pi_j}$, substituting for each path π_j of the form (4.2) the companion qubits in Q_{π_j} by four new qubits, and the unitary operation (4.4) by the

operation defined as

$$|\alpha_0\rangle \otimes |\alpha_1\rangle \otimes |0000\rangle \longrightarrow \sum_{c_0,c_1\in\{0,1\}} \sum_{0\le j\le 15} \lambda_{j,c_0,c_1}^{\alpha_0,\alpha_1} |c_0\rangle \otimes |c_1\rangle \otimes |j\rangle\,. \tag{4.6}$$

The output of the circuit $\overline{F_\tau}$, instead of (4.5), is of the form

$$|0\rangle \otimes |M'\rangle + |1\rangle \otimes |N'\rangle\,, \tag{4.7}$$

where $\||M\rangle\| = \||M'\rangle\|$ and $\||N\rangle\| = \||N'\rangle\|$. Therefore the circuit $\overline{F_\tau}$ computes f_τ. Moreover,

$$\mathsf{size}(\overline{F_\tau}) = O(s_j),$$

and for another assignment τ', the corresponding circuit $\overline{F_{\tau'}}$ differs from $\overline{F_\tau}$ only at unitary operations defined by (4.6).

The above discussion implies that σ_j, the number of subfunctions on S_j, is at most the number of different Boolean functions computed by size $O(s_j)$ quantum circuits. Therefore, by Theorem 2.1, we get

$$\sigma_j \le 2^{O(s_j \log s_j)}.$$

Therefore $s_j = \Omega(\log(\sigma_j)/\log\log(\sigma_j))$. Now the theorem follows from (4.1). □

We would like to mention that the fact that a path like (4.2) can be squeezed to a path of constant length is a special case of the general property of the superoperators stated in Theorem 3.2.

To apply the general bound of the above theorem, we could consider any of the several explicit functions used in the case of Boolean formulas (see [11, 26]). As we mentioned in the beginning of this section, we consider the element distinctness function ED_n. For this function, $\sigma_j > \ell^{\ell-1}$, where $\ell = \Omega(n/\log n)$. Therefore, we get the lower bound $\Omega(\ell^2) = \Omega(n^2/\log^2 n)$ for the formula size.

THEOREM 4.2. *Any quantum formula computing* ED_n *has size* $\Omega(n^2/\log^2 n)$.

5. Quantum formulas vs. Boolean circuits. In this section we show that quantum formulas are not more powerful than Boolean circuits. Therefore as a model of computation, their strength lies between Boolean formulas and Boolean circuits.

Following the idea developed in section 3, we consider a quantum formula as a quantum circuit operating on *mixed states*. For the details of quantum circuits with mixed states, see [1, 13]. Before we start the proof of the main result of this section, we need to see how we can bound errors in quantum circuits with mixed states. Toward this end we need a suitable norm on superoperators. Each superoperator T which maps density matrices to density matrices is a linear mapping of the form $\mathbf{L}(\mathcal{H}_1) \longrightarrow \mathbf{L}(\mathcal{H}_2)$, where $\mathcal{H}_1$ and $\mathcal{H}_2$ are finite-dimensional Hilbert spaces and $\mathbf{L}(\mathcal{H}_j)$ is the set of linear operators on $\mathcal{H}_j$. Note that $\mathbf{L}(\mathcal{H}_j)$ itself is a linear space. Let $\mathcal{H}$ be an m-dimensional Hilbert space. There are several norms on the space $\mathbf{L}(\mathcal{H})$, of which we need the following ones. Let $A \in \mathbf{L}(\mathcal{H})$. We identify A with its $m \times m$ matrix (a_{ij}). The first norm is

$$M(A) = m \max_{i,j} |a_{ij}|.$$

The usual norm is defined as

$$\|A\| = \sup_{|x\rangle\neq 0} \frac{\|A\,|x\rangle\|}{\||x\rangle\|} = \max\left\{ \sqrt{\lambda} \colon \lambda \in \mathrm{Spec}(A^\dagger A) \right\},$$

where $\mathrm{Spec}(M)$ is the *spectrum* of the matrix M, i.e., the set of the eigenvalues of M. The other norm is the *trace norm*

$$\|A\|_{\mathrm{Tr}} = \sum_{\lambda \in \mathrm{Spec}(A^\dagger A)} \sqrt{\lambda}.$$

We need the next norm $\|\cdot\|_\star$ to define another norm: let T be a linear operator that maps matrices to matrices; i.e., $T \in \mathbf{L}(\mathbf{L}(\mathcal{H}))$; then

$$\|T\|_\star = \sup_{A \neq 0} \frac{\|TA\|_{\mathrm{Tr}}}{\|A\|_{\mathrm{Tr}}}.$$

The last norm we consider is the *diamond norm*, defined in [13] and also in [1]. To define this norm, we consider a Hilbert space $\mathcal{G}$ such that $\dim(\mathcal{G}) \geq \dim(\mathcal{H})$ and we let

$$\|T\|_\diamond = \|T \otimes I_{\mathcal{G}}\|_\star,$$

where $I_{\mathcal{G}}$ is the identity operator on $\mathcal{G}$. The following are the basic properties of these norms:

(i) $\frac{1}{m} M(A) \leq \|A\| \leq M(A)$.
(ii) $\|A\|_{\mathrm{Tr}} \leq m \|A\|$.
(iii) $\|T(\rho)\|_{\mathrm{Tr}} \leq \|T\|_\diamond \|\rho\|_{\mathrm{Tr}}$, for the density matrix ρ.
(iv) $\|TR\|_\diamond \leq \|T\|_\diamond \|R\|_\diamond$.
(v) $\|T \otimes R\|_\diamond = \|T\|_\diamond \|R\|_\diamond$.
(vi) If $T = \widetilde{g}$, for some quantum gate g, or $T = \mathrm{Tr}_{\mathcal{F}}$, then $\|T\|_\diamond = 1$.

The properties (iii)–(vi) are proved in [1, 13].

For any operator $V \in \mathbf{L}(\mathcal{H})$ we define the operator $\mathcal{O}_V \in \mathbf{L}(\mathbf{L}(\mathcal{H}))$ as

$$\mathcal{O}_V(M) = V M V^\dagger, \qquad M \in \mathbf{L}(\mathcal{H}). \tag{5.1}$$

In [1, 13] it is proved that $\|\mathcal{O}_V - \mathcal{O}_W\|_\diamond \leq 2\|V - W\|$ if $\|V\| \leq 1$ and $\|W\| \leq 1$. We need the following general form of this inequality.

LEMMA 5.1. *Let* $\dim(\mathcal{H}) = m$. *For any* $V, W \in \mathbf{L}(\mathcal{H})$ *we have*

$$\|\mathcal{O}_V - \mathcal{O}_W\|_\diamond \leq 2m \|V - W\| \min(\|V\|, \|W\|) + m\|V - W\|^2.$$

Proof. We have (for $A \in \mathbf{L}(\mathcal{H} \otimes \mathcal{H})$)

$$\begin{aligned}
\|\mathcal{O}_V - \mathcal{O}_W\|_\diamond &= \sup_{A \neq 0} \|(\mathcal{O}_V \otimes I_{\mathcal{H}})A - (\mathcal{O}_W \otimes I_{\mathcal{H}})A\|_{\mathrm{Tr}} / \|A\|_{\mathrm{Tr}} \\
&= \sup_{A \neq 0} \left\|(V \otimes I_{\mathcal{H}})\, A\, (V^\dagger \otimes I_{\mathcal{H}}) - (W \otimes I_{\mathcal{H}})\, A\, (W^\dagger \otimes I_{\mathcal{H}})\right\|_{\mathrm{Tr}} / \|A\|_{\mathrm{Tr}} \\
&= \sup_{A \neq 0} \|(V \otimes I_{\mathcal{H}})\, A\, (V^\dagger \otimes I_{\mathcal{H}}) \\
&\quad - ((V + (W - V)) \otimes I_{\mathcal{H}})\, A\, ((V^\dagger + (W^\dagger - V^\dagger)) \otimes I_{\mathcal{H}})\|_{\mathrm{Tr}} / \|A\|_{\mathrm{Tr}} \\
&\leq \sup_{A \neq 0} \left\|(V \otimes I_{\mathcal{H}})\, A\, ((W^\dagger - V^\dagger) \otimes I_{\mathcal{H}})\right\|_{\mathrm{Tr}} / \|A\|_{\mathrm{Tr}} \\
&\quad + \sup_{A \neq 0} \left\|((W - V) \otimes I_{\mathcal{H}})\, A\, (V^\dagger \otimes I_{\mathcal{H}})\right\|_{\mathrm{Tr}} / \|A\|_{\mathrm{Tr}} \qquad (5.2) \\
&\quad + \sup_{A \neq 0} \left\|((W - V) \otimes I_{\mathcal{H}})\, A\, ((W^\dagger - V^\dagger) \otimes I_{\mathcal{H}})\right\|_{\mathrm{Tr}} / \|A\|_{\mathrm{Tr}}.
\end{aligned}$$

Since $\|MN\| \leq \|M\| \cdot \|N\|$, $\|M\| \leq \|M\|_{\mathrm{Tr}} \leq m\,\|M\|$, $\|M \otimes N\| = \|M\| \cdot \|N\|$, $\left\|M^\dagger\right\| = \|M\|$, and $\|I_{\mathcal{H}}\| = 1$, it follows that

$$\begin{aligned}\left\|(V \otimes I_{\mathcal{H}})\, A\, ((W^\dagger - V^\dagger) \otimes I_{\mathcal{H}})\right\|_{\mathrm{Tr}} &\leq m \left\|(V \otimes I_{\mathcal{H}})\, A\, ((W^\dagger - V^\dagger) \otimes I_{\mathcal{H}})\right\| \\ &\leq m\,\|V \otimes I_{\mathcal{H}}\| \cdot \|A\| \cdot \left\|(W^\dagger - V^\dagger) \otimes I_{\mathcal{H}}\right\| \\ &\leq m\,\|V\| \cdot \|A\|_{\mathrm{Tr}} \cdot \|W - V\|\,.\end{aligned}$$

By applying a similar reduction to the other terms of (5.2), we derive the following inequality:

$$\|\mathcal{O}_V - \mathcal{O}_W\|_\diamond \leq 2m\,\|V - W\| \cdot \|V\| + m\,\|V - W\|^2\,.$$

We can also derive a similar inequality with $\|V\|$ substituted by $\|W\|$. This completes the proof. □

We say two $n \times m$ matrices $A = (a_{ij})$ and $B = (b_{ij})$ are *δ-close* to each other if $|a_{ij} - b_{ij}| \leq \delta$ for every $1 \leq i \leq n$ and $1 \leq j \leq m$. If the $m \times m$ matrices A and B are δ-close to each other, then

$$\|A - B\| \leq M(A - B) \leq m\,\delta. \tag{5.3}$$

The following theorem formalizes the general form of the error bound for quantum circuits when approximating the unitary operator of each gate. This theorem is actually a generalization of a weaker theorem which has appeared in several papers (see, e.g., [1, 5, 13]). We need this generalization because once we substitute any unitary gate S of the original quantum circuit by some approximated gate T, in general we do not know whether $\|T\| \leq 1$ or not. (This is the assumption of the weaker version of this theorem.)

THEOREM 5.2. *Let $S_j, T_j \in \mathbf{L}(\mathbf{L}(\mathbb{C}^{2^d}))$, $1 \leq j \leq \ell$, be defined as $S_j = \mathcal{O}_{U_j}$ and $T_j = \mathcal{O}_{V_j}$, where $U_j \in \mathbf{U}(2^d)$ is unitary and V_j is δ-close to U_j. Then*

$$\|S_\ell \cdots S_3 S_2 S_1 - T_\ell \cdots T_3 T_2 T_1\|_\diamond \leq e^{\eta(d,\delta)\ell} - 1,$$

where $\eta(d, \delta) = 2^{2d+1}\delta\left(1 + 2^d\delta\right)$.

Proof. First note that

$$\begin{aligned}\|S_j - T_j\|_\diamond &= \left\|\mathcal{O}_{U_j} - \mathcal{O}_{V_j}\right\|_\diamond \\ &\leq 2^{d+1}\,\|U_j - V_j\|\,(1 + \|U_j - V_j\|) && \text{by Lemma 5.1} \\ &\leq 2^{2d+1}\delta\left(1 + 2^d\delta\right) && \text{by (5.3)} \\ &= \eta(d, \delta);\end{aligned}$$

and, by (vi),

$$\|T_j\|_\diamond \leq \|S_j\|_\diamond + \|S_j - T_j\|_\diamond \leq 1 + \eta(d, \delta). \tag{5.4}$$

We also have the following simple inequality:

$$\begin{aligned}\|M_2 M_1 - N_2 N_1\|_\diamond &= \|M_2(M_1 - N_1) - (M_2 - N_2)N_1\|_\diamond \\ &\leq \|M_2\|_\diamond\,\|M_1 - N_1\|_\diamond + \|N_1\|_\diamond\,\|M_2 - N_2\|_\diamond\,.\end{aligned} \tag{5.5}$$

Now, by repeated applications of (5.4) and (5.5), we have

$$\begin{aligned}
\|S_\ell \cdots S_3 S_2 S_1 - T_\ell \cdots T_3 T_2 T_1\|_\diamond &\le \|S_\ell \cdots S_3 S_2\|_\diamond \|S_1 - T_1\|_\diamond \\
&\quad + \|T_1\|_\diamond \|S_\ell \cdots S_3 S_2 - T_\ell \cdots T_3 T_2\|_\diamond \\
&\le \eta(d,\delta) + (1+\eta(d,\delta)) \|S_\ell \cdots S_3 S_2 - T_\ell \cdots T_3 T_2\|_\diamond \\
&\le \eta(d,\delta) + \eta(d,\delta)(1+\eta(d,\delta)) \\
&\quad + (1+\eta(d,\delta))^2 \|S_\ell \cdots S_3 - T_\ell \cdots T_3\|_\diamond \\
&\vdots \quad \vdots \\
&\le \eta(d,\delta) \sum_{j=0}^{\ell-1} \big(1+\eta(d,\delta)\big)^j \\
&= (1+\eta(d,\delta))^\ell - 1 \\
&\le e^{\eta(d,\delta)\ell} - 1. \qquad \square
\end{aligned}$$

The following theorem is the immediate consequence of the above theorem. Note that for a gate g the superoperator $\widetilde{g}$ is defined by (3.1).

THEOREM 5.3. *Let C be a quantum circuit composed of the gates $g_1, \ldots, g_s$. Suppose that each g_j is a d-bit gate computing the unitary operator $U_j \in \mathbf{U}(2^d)$. For each $1 \le j \le s$, let $V_j \in \mathbf{L}(\mathbb{C}^{2^d})$ be a δ-close matrix to U_j. Let $T_j \in \mathbf{L}(\mathbf{L}(\mathbb{C}^{2^d}))$ be defined as $T_j = \mathcal{O}_{V_j}$. For any input density matrix ρ_0, let*

$$\psi = (\widetilde{g}_s \otimes I_{\mathcal{H}_s}) \circ \cdots \circ (\widetilde{g}_2 \otimes I_{\mathcal{H}_2}) \circ (\widetilde{g}_1 \otimes I_{\mathcal{H}_1})\, \rho_0$$

be the output of C, where $\mathcal{H}_j$ is the Hilbert space generated by the qubits not involved with the gate g_j. Also, let

$$\zeta = (T_s \otimes I_{\mathcal{H}_s}) \cdots (T_2 \otimes I_{\mathcal{H}_2})(T_1 \otimes I_{\mathcal{H}_1})\, \rho_0$$

be the approximated output of C. Then

$$\|\psi - \zeta\|_{\mathrm{Tr}} \le \left(e^{\eta(d,\delta)s} - 1\right) \|\rho_0\|_{\mathrm{Tr}},$$

where $\eta(d,\delta) = 2^{2d+1}\delta\left(1 + 2^d\delta\right)$.

THEOREM 5.4. *Let $\mathcal{B}$ be a quantum basis. Then each quantum formula of size ℓ and depth d over the basis $\mathcal{B}$ can be simulated with error at most ε by a Boolean* circuit *of size $O(\ell\,\mu\,\log\mu\log\log\mu)$ and depth $O(d\log\mu)$, where $\mu = \lceil \log\ell - \log\varepsilon \rceil$.*

Proof. The basic idea of the simulation is to look at the behavior of a quantum formula as a quantum circuit acting on density matrices of mixed states. We assume, w.l.o.g., that each gate in the basis $\mathcal{B}$ is a 2-bit gate.

Consider a quantum formula $\mathcal{F}$ over the basis $\mathcal{B}$; suppose that $\mathcal{F}$ has t inputs (constant or variable) and computes the Boolean function $f\colon \{0,1\}^n \longrightarrow \{0,1\}$. We show that there is a Boolean circuit $\mathcal{C}$ that for any input $\boldsymbol{a} = (a_1, \ldots, a_n) \in \{0,1\}^n$ simulates the action of $\mathcal{F}$ on $\boldsymbol{a}$. Let $|\alpha\rangle = |0\rangle \otimes |A_0\rangle + |1\rangle \otimes |A_1\rangle$ be the output of $\mathcal{F}$ on the input $\boldsymbol{a}$. Suppose that the first qubit is the output bit. If we *trace out* the nonoutput bits of $|\alpha\rangle$, the result is a 2×2 density matrix $\rho_{\mathrm{final}} = \rho|_{|\alpha\rangle}$. From ρ_{final} it is easy to calculate the probability of acceptance of $\mathcal{F}$. The formula structure of $\mathcal{F}$ allows us to calculate the density matrix ρ_{final} without going to the 2^t-dimensional space. The Boolean circuit $\mathcal{C}$ finds the density matrix ρ_{final} by simulating the gates of $\mathcal{F}$ step by step.

Since the trace norm of a density matrix is equal to its trace, it follows that $\|\rho_0\|_{\mathrm{Tr}} = 1$, where ρ_0 is the density matrix of the input.

Now the gates of $\mathcal{F}$ are no longer acting on pure states, but they are acting on mixed states. If the input of a gate g_j (performing the unitary operation U_j) is the 4×4 density matrix ρ, then the output is the density matrix $\rho' = U_j\, \rho\, {U_j}^\dagger$. Of the two output bits q_1 and q_2 of this gate, only one, say, q_1, is connected to the output bit of $\mathcal{F}$. Therefore we trace out the system representing q_2 and consider the new density matrix $\rho|_{q_1} = \mathrm{Tr}_{q_2}\rho'$ for q_1. By repeating this process for each gate of $\mathcal{F}$ we finally get the desired density matrix ρ_{final}. The correctness of this process follows from Lemma 3.1.

The Boolean circuit $\mathcal{C}$ can simulate the calculations of these density matrices ρ_{q_1}. The only problem for this simulation is the proper approximation of the entries of unitary matrices U_j. If we substitute each entry of U_j by its first $\mu = -\lceil \log_2 \delta \rceil$ bits, then we get a matrix that is δ-close to U_j. Let $\widetilde{\mathcal{F}}$ be the resulting formula and $\widetilde{\rho}_{\mathrm{final}}$ be the output of $\widetilde{\mathcal{F}}$. Then, by Theorem 5.3, $\|\rho_{\mathrm{final}} - \widetilde{\rho}_{\mathrm{final}}\|_{\mathrm{Tr}} \leq e^{\eta(d,\delta)\ell} - 1$. Therefore if $\delta = O\left(\frac{\varepsilon}{\ell}\right)$, i.e., $\mu = O\left(\log \ell - \log \varepsilon\right)$, then the simulation of $\mathcal{F}$ by $\widetilde{\mathcal{F}}$ has at most ε error. The theorem now follows from the fact that addition and multiplication of m bits numbers can be carried out by Boolean circuits of size $O(m \log m \log\log m)$ and depth $O(\log m)$ (see [19, 26]). □

Why does this proof not provide a Boolean *formula* instead of a Boolean circuit? The reason is that to calculate $\rho' = U_j\, \rho\, {U_j}^\dagger$, we need four copies of each entry of ρ. Thus the fan-out of the gates in the Boolean circuit obtained from the formula $\widetilde{\mathcal{F}}$ is 4. This means that the Boolean formula equivalent to this Boolean circuit, in general, has size exponential in ℓ; this size is at least $\Omega\left(\ell^3\right)$ if the graph of $\mathcal{F}$ is a full binary tree.

6. Concluding remarks. We have extended a classical technique for proving lower bound for Boolean formula size to quantum formulas. The difficult part was to effectively deal with the phenomenon of entanglement of qubits. While we have been successful in extending a classical technique to the quantum case, the challenges encountered indicate that in general the problem of extending methods of Boolean case to the quantum case may not have simple solutions. For example, even the seemingly simple issue of the exact relationship between quantum formulas and quantum circuits has not been resolved. In the Boolean case, simulation of circuits by formulas is a simple fact, but in the quantum case it is not clear whether every quantum circuit can be simulated by a quantum formula. In particular, it is not clear in the process of going from quantum circuits to formulas how we can modify the underlying entanglement of qubits while keeping the probability of reaching the final answer the same. We were also able to show that it is possible to simulate quantum formulas with Boolean circuits of almost the same size. It does not seem that Boolean formulas could efficiently simulate their quantum counterparts. Therefore evidently quantum formulas, as a model of computation, are more powerful than Boolean formulas and less powerful than Boolean circuits. A better understanding of the relations between these models remains a challenging problem.

Appendix. Counting the number of Boolean functions computed by quantum circuits of a given size.

In this appendix we prove the following upper bound.

THEOREM A.1. *The number of different n-variable Boolean functions that can be computed by size N quantum circuits ($n \leq N$) with d-input d-output elementary*

gates (for some constant d) is at most $2^{O(nN)+O(N \log N)}$.

Proof. Our proof is based on Warren's bound on the number of different sign-assignments to real polynomials [25]. We begin with some necessary notations.

Let $P_1(x_1, \ldots, x_t), \ldots, P_m(x_1, \ldots, x_t)$ be real polynomials. A *sign-assignment* to these polynomials is a system of inequalities

$$P_1(x_1, \ldots, x_t) \,\Delta_1\, 0, \ldots, \quad P_m(x_1, \ldots, x_t) \,\Delta_m\, 0, \tag{A.1}$$

where each Δ_j is either "$<$" or "$>$." The sign-assignment (A.1) is called *consistent* if this system has a solution in $\mathbb{R}^t$.

THEOREM A.2 (Warren [25]). *Let $P_1(x_1, \ldots, x_t), \ldots, P_m(x_1, \ldots, x_t)$ be real polynomials, each of degree at most d. Then there are at most $(4edm/t)^t$ consistent sign-assignments of the form* (A.1).

We consider the class of quantum circuits of size N with d-bit gates computing n-variable Boolean functions. W.l.o.g., we can assume that n', the number of input wires of such circuits, is at most $d \cdot N$. We define an equivalence relation $\bowtie$ on such circuits: we write $C_1 \bowtie C_2$ if and only if C_1 and C_2 differ only in the label of their gates; in other words, C_1 and C_2 have the same underlying graph, but the corresponding gates in these circuits may compute different unitary operations. The number of different equivalence classes is at most

$$\binom{n'}{d}^N \leq (dN)^{dN} = 2^{O(N \log N)}.$$

Now we find an upper bound for the number of different Boolean functions that can be computed by circuits in the same equivalence class. Fix an equivalence class $\mathcal{E}$. We use the variables $a_1 + ib_1, a_2 + ib_2, \ldots, a_\mu + ib_\mu$, where $\mu = d^2N$, to denote the entries of the matrices of the gates of a circuit C in $\mathcal{E}$. By substituting appropriate values to the variables $a_1, \ldots, a_\mu, b_1, \ldots, b_\mu$, we get all circuits in $\mathcal{E}$. On input $\alpha = (\alpha_1, \ldots, \alpha_n) \in \{0,1\}^n$, the probability that C outputs 1 can be represented by a *real* polynomial

$$P_\alpha(a_1, \ldots, a_\mu, b_1, \ldots, b_\mu).$$

The degree of P_α is at most $2N$. There are 2^n polynomials P_α, and the number of different Boolean functions which can be computed by C by changing the unitary operators of its gates is at most the number of different consistent sign-assignments to the following system:

$$P_\alpha(a_1, \ldots, a_\mu, b_1, \ldots, b_\mu) - \tfrac{2}{3},$$

$$P_\alpha(a_1, \ldots, a_\mu, b_1, \ldots, b_\mu) - \tfrac{1}{3},$$

for $\alpha \in \{0,1\}^n$. By Theorem A.2 this number is bounded from the above by

$$\left(\frac{4e(2N)2^{n+1}}{2\mu}\right)^{2\mu} = 2^{O(nN)+O(N \log N)}. \qquad \square$$

A 2-APPROXIMATION ALGORITHM FOR THE DIRECTED MULTIWAY CUT PROBLEM*

JOSEPH (SEFFI) NAOR† AND LEONID ZOSIN‡

Abstract. A directed multiway cut separates a set of terminals $T = \{s_1, \ldots, s_k\}$ in a directed capacitated graph $G = (V, E)$. Finding a minimum directed multiway cut is an NP-hard problem. We give a polynomial-time algorithm that achieves an approximation factor of 2 for this problem. This improves the result of Garg, Vazirani, and Yannakakis [*Proceedings of the 21st International Colloquium on Automata, Languages, and Programming*, Jerusalem, Israel, 1994, pp. 487–498], who gave an algorithm that achieves an approximation factor of $2 \log k$. Our approximation algorithm uses a novel technique for relaxing a multiway flow function in order to find a directed multiway cut. It also implies that the integrality gap of the linear program for the directed multiway cut problem is at most 2.

Key words. approximation algorithms, combinatorial optimization, multicommodity flow, multiway cut, directed graph

1. Introduction.

We consider the minimum directed multiway cut problem in this paper. Let $G = (V, E)$ be a directed graph and let c_e, for all $e \in E$, be a nonnegative capacity associated with the edge set E. Let $T = \{s_1, \ldots, s_k\} \subseteq V$ be a set of terminals. A *directed multiway cut* in G is a set of edges whose deletion disconnects all directed paths between pairs of terminals. This notion is a natural generalization of $\{s, t\}$-cuts. The capacity of a multiway cut is defined to be the sum of the capacities of the edges belonging to it. A *minimum directed multiway cut* is a directed multiway cut of minimum capacity. The minimum directed multiway cut problem was considered by Garg, Vazirani, and Yannakakis [4], who showed that it is NP-hard and MAX SNP-hard even for two terminals [4] and also gave an algorithm that achieves an approximation factor of $2 \log k$.

We present a polynomial-time approximation algorithm for the minimum directed multiway cut problem that achieves an approximation factor of 2, thus improving on the approximation factor obtained by [4]. Our factor is very close to the approximation factors known for the undirected version of the problem. Dahlhaus et al. [2] gave a $(2 - 2/k)$-approximation algorithm for the undirected *edge* multiway cut problem. This result was recently improved by [1] to $3/2 - 1/k$ and further by [6] to $1.3438 - \epsilon_k$, where $\epsilon_k > 0$. For the undirected *vertex* multiway cut problem, Garg, Vazirani, and Yannakakis [4] gave a $(2 - 2/k)$-approximation algorithm. Note that in the directed case there is no need to distinguish between the edge and vertex versions of the problem.

The minimum directed multiway cut problem can be cast as an integer linear

program. The linear relaxation of this program is an assignment of lengths to the edges such that the distance between every pair of terminals is at least 1. The dual program of the linear relaxation is a multicommodity flow function, where commodity i, $1 \leq i \leq k$, is defined to be the flow that originates in any terminal $j \neq i$, $1 \leq j \leq k$, and whose destination is terminal s_i. The goal is to maximize the net flow entering the terminals. We refer to this problem as the *multiway flow* problem. By the duality theorem, the optima of the multiway flow problem and the linear relaxation of the multiway cut problem are equal.

The main technique used by our algorithm is a novel relaxation of the multiway flow problem. A *relaxed multiway flow* function allows the total flow on an edge $e \in E$ (taken over all commodities) to go up to $2 \cdot c_e$. However, the flow on edge e belonging to the same commodity is not allowed to exceed the capacity c_e. We call the dual problem of the relaxed multiway flow problem the *relaxed multiway cut* problem. A relaxed multiway cut attaches multiple lengths to each edge that correspond to the (primal) constraints on it. The constraints are with respect to the distances between pairs of terminals.

We present an approximation algorithm that achieves a factor of 2 for the directed multiway cut problem and is based on rounding an optimal relaxed multiway cut. We show that the value of the multiway cut produced by the approximation algorithm does not exceed the value of an optimal relaxed multiway flow function. A relaxed multiway flow function can ship at most twice the amount of flow that a (standard) multiway flow function can ship. By the duality theorem, the optima of the relaxed multiway flow problem and the relaxed multiway cut problem are equal. Hence, we get that the approximation factor of our algorithm is 2. We also get that the integrality gap of the (standard) linear program for the multiway cut problem is at most 2. However, we do not see a direct way for proving this. A more intuitive explanation for this might be that a relaxed multiway flow function provides more "information" about the integral solution than a standard multiway flow function.

A relaxation similar in "spirit" of a multicommodity flow function was previously used by Even, Naor, and Zosin [3] for approximating the undirected subset feedback vertex set. However, their analysis completely differs from ours and is much more complicated. We believe that our technique for relaxing a multicommodity flow function will find more applications in the future. We note that our approximation algorithm uses complementary slackness in a way similar to the $(2 - 2/k)$-approximation algorithm of Garg, Vazirani, and Yannakakis [4] for the undirected vertex multiway cut problem.

2. Relaxed multiway flow. A multiway flow function is defined as follows. Define commodity i, $1 \leq i \leq k$, to be the flow that originates in any terminal $j \neq i$, $1 \leq j \leq k$, and whose destination is terminal s_i. Thus, each commodity is a multisource, single-sink flow function. An optimal multiway flow function maximizes the net flow entering the terminals subject to standard multicommodity flow constraints. We henceforth refer to this flow function as the *standard* multiway flow function.

We now define a *relaxed* version of the standard multiway flow function. Denote by f^i the nonnegative flow function of commodity i and denote by $f^i(e)$ the flow on edge e belonging to commodity i. Let $N^+(v)$ ($N^-(v)$) denote the set of incoming (outgoing) edges into (from) vertex v.

Objective function.

$$\text{Maximize} \qquad \sum_{i=1}^{k} \left(\sum_{e \in N^+(s_i)} f^i(e) - \sum_{e \in N^-(s_i)} f^i(e) \right).$$

Preservation. For commodity i, $1 \leq i \leq k$, for each vertex $v \in V - T$, the amount of flow of commodity i entering v is equal to the amount of flow of commodity i leaving v.

Intracommodity constraints. For each commodity i, $1 \leq i \leq k$, and for each edge $e \in E$,

$$f^i(e) \leq c_e.$$

Intercommodity constraints. For each edge $e \in E$,

$$\sum_{i=1}^{k} f^i(e) \leq 2 \cdot c_e.$$

The following lemma is immediate.

LEMMA 1. *A relaxed multiway flow function can ship at most twice the amount of flow that an optimal (standard) multiway flow function ships.*

We now define the *relaxed multiway cut* problem which is the dual problem of the relaxed multiway flow problem. Recall that the linear relaxation of the (standard) multiway cut problem assigns a length to each edge such that the distance between every pair of terminals is at least 1. In the relaxed multiway cut problem we assign to each edge $e \in E$ nonnegative length variables as follows: variable $\ell(e)$ corresponds to the intercommodity constraint on e, and variables $d^i(e)$, $1 \leq i \leq k$, correspond to the intracommodity constraints on e. Define the i-length of a path p to be $\sum_{e \in p}(d^i(e) + \ell(e))$. The linear program of the relaxed multiway cut problem is defined as follows:

$$\text{Minimize} \qquad \sum_{i=1}^{k} \sum_{e \in E} c_e \cdot d^i(e) \; + 2 \cdot \sum_{e \in E} c_e \cdot \ell(e)$$

subject to

$$\forall\, i, j \;(i \neq j),\ \forall \text{ path } p \text{ from } s_j \text{ to } s_i, \quad \sum_{e \in p} (d^i(e) + \ell(e)) \geq 1$$

$$\forall\, i, e, \quad d^i(e), \ell(e) \geq 0.$$

It is implicit that in an optimal solution, all variables are upper bounded by 1. The above linear program can be solved in polynomial time by the ellipsoid method [5]. This follows by observing that for a given solution, a shortest path computation between each pair of terminals can either determine that all constraints are satisfied or discover a violated constraint.

3. The approximation algorithm. We present in this section the approximation algorithm for the directed multiway cut problem. The algorithm derives a near-optimal multiway cut from an optimal relaxed multiway cut. The algorithm is summarized as follows.

Algorithm. DIRECTED MULTIWAY CUT

Input: A directed graph $G = (V, E)$ with special vertices $s_1, \ldots, s_k$;
Output: A multiway cut C of G;

1. Compute an optimal relaxed multiway cut.
2. For each terminal s_i, $1 \leq i \leq k$, compute a cut C_i.
3. $C \leftarrow C_1 \cup \cdots \cup C_k$.

We now elaborate on the steps of the algorithm. In the first step, an optimal relaxed multiway cut is computed. In the second step, for each terminal s_i, $1 \leq i \leq k$, define a cut C_i as follows. Let S_i be the set of vertices such that for all $v \in S_i$, there exists a path in G from s_i to v whose j-length is zero for all $1 \leq j \leq k$ and $j \neq i$. Then, $C_i = (S_i, V - S_i)$, i.e., the set of (directed) edges going from S_i to $V - S_i$ in G. The multiway cut C is defined to be the union of the cuts C_i, $1 \leq i \leq k$.

THEOREM 2. *The cut C is a multiway cut with respect to the terminals $s_1, \ldots, s_k$.*

Proof. Suppose, in contradiction, that terminal $s_j \in S_i$ for some $i \neq j$. This can happen only if there exists a path in G from s_i to s_j whose j-length is zero. This means that the solution computed in the first step of the algorithm does not satisfy the constraints of the relaxed multiway cut problem, yielding a contradiction. ∎

3.1. Analysis. We prove that the capacity of the multiway cut C computed by the algorithm is not greater than the value of an optimal relaxed multiway flow function. Lemma 1 states that the value of an optimal relaxed multiway flow function is at most twice the value of an optimal (standard) multiway flow function. By duality, the value of an optimal multiway cut is greater than or equal to the value of an optimal (standard) multiway flow function, yielding the desired approximation factor of 2.

THEOREM 3. *Let f be an optimal relaxed multiway flow function. Then, the capacity of the multiway cut C is not greater than the value of f.*

Proof. We decompose f into a set of flow paths connecting pairs of terminals. The idea of the proof is to charge the edges of C to flow paths and show that each flow path is charged at most once. By charging a flow path we mean that it "pays" the value of the flow it carries. We allow a set of flow paths to be charged by an edge e if and only if the sum of the flow they carry is at least as big as c_e. We denote by P_e the set of flow paths which edge $e \in C$ charges. We show that for any $e_1, e_2 \in C$, the intersection of P_{e_1} and P_{e_2} is empty.

The complementary slackness conditions for the relaxed multiway cut problem state that

- the length of each flow path is precisely 1;
- if, for edge e, $d^i(e) > 0$, then the corresponding intracommodity constraint with respect to commodity i is tight;
- if, for edge e, $\ell(e) > 0$, then the corresponding intercommodity constraint is tight.

We first define for each edge $e \in C$ the set of flow paths P_e to which it is charged. If e is an edge in C, then there exists a terminal s_i such that $e \in C_i$. Edge e must satisfy at least one of the following:

(1) There exists a commodity $j \neq i$ such that $d_e^j > 0$.

(2) The intercommodity constraint is tight, i.e., $\ell(e) > 0$.

Suppose that edge e satisfies (1). In this case, by complementary slackness, the intracommodity constraint for edge e with respect to commodity j is tight. We define

P_e to be the set of all flow paths that run between s_h, $1 \le h \le k$ and $h \ne j$, and s_j, and use edge e. By definition, the total amount of flow carried by the flow paths in P_e is equal to c_e. Suppose that edge e satisfies (2). In this case, by complementary slackness, the intercommodity constraint for edge e is tight. By definition,

$$\sum_j f_e^j = f^i(e) \; + \; \sum_{j \ne i} f^j(e).$$

The intracommodity constraint for edge e and commodity j implies that the first summand can be at most c_e. Therefore,

$$\sum_{j \ne i} f_e^j \ge c_e.$$

We define P_e to be the set of flow paths that contribute to the left-hand side. If edge e satisfies both (1) and (2), then we define P_e in accordance with (1).

It remains to show that for any $e_1, e_2 \in C$, the intersection of P_{e_1} and P_{e_2} is empty. Assume the contrary, that is, a flow path p that runs from s_x to s_y is charged by both $e_1 = (v_1, u_1)$ and $e_2 = (v_2, u_2)$, which appear on p in this order. Let s_{i_1} and s_{i_2} be terminals such that $e_1 \in C_{i_1}$ and $e_2 \in C_{i_2}$. (Note that i_1 and i_2 are not necessarily distinct.) The sets P_{e_1} and P_{e_2} are chosen such that $i_1 \ne y$ and $i_2 \ne y$.

By the definition of C_{i_2}, there exists a path from s_{i_2} to v_2 whose y-length is zero. By construction, either $\ell(e_1) > 0$ or $d_{e_1}^y > 0$. By complementary slackness, the y-length of p is precisely 1. Hence, there exists a path from s_{i_2} to s_y whose y-length is strictly smaller than 1, in contradiction to the requirements of a relaxed multiway cut. This completes the proof. □

4. Discussion. Our approximation algorithm derives a 2-approximate multiway cut by rounding an optimal relaxed multiway cut solution. We note that it is also possible to compute a 2-approximate multiway cut from an optimal relaxed multiway flow function. However, that would require computing an optimal relaxed multiway flow function f which has the following property. If, for edge e, some constraint is tight in f, then this constraint has to be tight in *every* optimal relaxed multiway flow function. Computing an optimal relaxed multiway flow function which has the latter property is computationally more expensive than computing an optimal relaxed multiway cut solution. Also, the analysis of a "flow-based" algorithm is slightly more complicated than the analysis of the "cut-based" algorithm. For more details regarding the flow-based algorithm, the reader is referred to [7].

A simple example shows that an approximation factor of 2 is the best factor that can be achieved by our algorithms. Garg, Vazirani, and Yannakakis [4] show that the integrality gap for the undirected multiway cut problem is 2. There exists a simple reduction from the undirected multiway cut problem to the directed multiway cut problem, which implies that the same gap holds for the directed multiway cut problem as well.

Acknowledgment. We thank Madhu Sudan for fruitful discussions.

THE GLOBAL POWER OF ADDITIONAL QUERIES TO *P*-RANDOM ORACLES*

WOLFGANG MERKLE†

Abstract. We consider separations of reducibilities by random sets. First, we show a result on polynomial time-bounded reducibilities that query their oracle nonadaptively: for every p-random set R, there is a set that is reducible to R with $k+1$ queries but is not reducible to any other p-random set with at most k queries. This result solves an open problem stated in a recent survey paper by Lutz and Mayordomo [*EATCS Bulletin*, 68 (1999), pp. 64–80]. Second, we show that the separation result above can be transferred from the setting of polynomial time-bounds to a setting of rec-random sets and recursive reducibilities. This extends the main result of Book, Lutz, and Martin [*Inform. and Comput.*, 120 (1995), pp. 49–54] who, by using different methods, showed a similar separation with respect to Martin-Löf-random sets. Moreover, in both settings we obtain similar separation results for truth-table versus bounded truth-table reducibility.

Key words. separation of reducibilities, random sets, resource-bounded measure, effective measure, resource-bounded reducibilities, effective reducibilities, bounded truth-table reducibility, truth-table reducibility

1. Introduction and related work.

We consider separations of reducibilities in the context of resource-bounded measure theory. In the following, we use the symbol $\leq$ with appropriate sub- or superscripts to denote binary relations on Cantor space, the class of all sets of natural numbers. These binary relations are meant as reducibilities and, in particular, we will consider polynomial time-bounded reducibilities of the following types: Turing (p-T), truth-table (p-tt), bounded truth-table (p-btt), and bounded truth-table restricted to at most k queries (p-btt(k)); see section 2 for more precise definitions. We say two reducibilities $\leq_r$ and $\leq_s$ are *separated by an oracle* A if the lower spans of A with respect to these reducibilities, i.e., the classes $\{X : X \leq_r A\}$ and $\{X : X \leq_s A\}$, differ. It is easy to see that two reducibilities are different (as binary relations on Cantor space) iff they are separated by some oracle. Beyond this simple observation, the question of which reducibilities are separated by what kind of oracles has been the object of intensive studies. Here, for a given pair of reducibilities, typical questions are the following. Are there separating oracles of low complexity? How comprising is the class of separating oracles? Which properties are sufficient for being a separating oracle?

Ladner, Lynch, and Selman [12] considered separations of the usual polynomial time-bounded reducibilities in the range between many-one- (p-m-) and p-T-reducibility. They showed that for every distinct pair of such reducibilities, there is a separating oracle that can be computed in exponential time. In their seminal paper [6], Bennett and Gill then obtained results about *separations by random oracles*, i.e., they showed that certain pairs of reducibilities are separated by almost all oracles in the sense that the class of separating oracles has measure 1 with respect to uniform measure on Cantor space. Subsequently, for any $k > 0$ it was shown for p-T-, p-

tt-, p-btt-, p-btt$(k+1)$-, and p-btt(k)-reducibility that the two latter reducibilities are separated by almost all tally oracles [10] and that in fact every pair of distinct reducibilities chosen from this list can be separated by random oracles [16, 21].

A separation by random oracles can be expressed equivalently by saying that the class of oracles that do not separate the reducibilities under consideration has uniform measure 0. Lutz and Mayordomo [16] could show for certain pairs of polynomial time-bounded reducibilities of truth-table type that the class of nonseparating oracles does not just have uniform measure 0 but can in fact be covered by a martingale that is computable in polynomial time. Typically, their results are derived from the assumption that for both reducibilities the number of queries is bounded by a function in the input length and that the two bounding functions are related in a specific way, say, one is growing faster than the square of the other. In the special case where the bounding functions are constant, they showed that for every natural number k, there is a martingale computable in polynomial time that covers all oracles that do not separate p-btt$(k+1)$- and p-btt(k)-reducibility; hence, in particular, these reducibilities are separated by every p-random oracle. The latter can be rephrased by saying that these reducibilities are locally separated by the class of p-random oracles. Here, formally, a nonempty class $\mathbf{C}$ *locally separates* two given reducibilities if and only if for every set A in $\mathbf{C}$, the lower spans of A with respect to these reducibilities are different.

We say a class $\mathbf{C}$ *globally separates* two given reducibilities in case for every set A in $\mathbf{C}$ there is a set B that is reducible to A with respect to one of the given reducibilities but B is not reducible to any set in $\mathbf{C}$ with respect to the other reducibility. Moreover, in case such a set B exists not for all but just for some sets A in $\mathbf{C}$, we say that $\mathbf{C}$ yields a weak global separation of the reducibilities under consideration.

The definitions of the concepts of separations given above are meant for being applied with pairs of reducibilities $\leq_r$ and $\leq_s$ where $X \leq_r Y$ implies $X \leq_s Y$. In this situation, the definitions are no more symmetric in the sense that for example sets A and B witnessing a global separation by a class $\mathbf{C}$ must satisfy $B \leq_s A$ and $B \not\leq_r Z$ for all Z in $\mathbf{C}$. In distinguishing local and global separation we follow Book, Lutz, and Martin [8], who discuss such separations for the classes of Martin-Löf-random, tally, and sparse sets.

In the sequel we will consider global separations by various classes of random sets. Such investigations can be viewed as part of a more comprising research project where one asks which types of reductions are able to transform random objects into what types of far from random objects. For results in this direction and for further discussion and references see Juedes, Lathrop, and Lutz [11] as well as Lutz and Schweizer [18].

Remark 1.1. By definition, every local or global separation by a class $\mathbf{C}$ extends trivially to every nonempty subclass of $\mathbf{C}$. This is false in general, however, for weak global separations. For example given an oracle A that separates p-btt(2)- and p-btt(1)-reducibility, the class $\{A, \emptyset\}$, but not its subclass $\{\emptyset\}$, yields a weak global separation of these two reducibilities.

Remark 1.2. By definition, global separations always imply the corresponding local separation. A similar remark for weak global separations in place of global separations, however, is false. In order to obtain a counterexample, consider the class $\mathbf{C}$ that consist of all p-random sets plus a single set A that is computable in polynomial time. Then $\mathbf{C}$ does not locally separate p-btt(1)- and p-btt(2)-reducibility because A does not separate these reducibilities. On the other hand, $\mathbf{C}$ yields a weak

global separation of these reducibilities. The latter fact follows from Theorem 4.1 and the observation that none of the sets that witness a global separation by the class of p-random sets will be p-btt(1)-reducible to A.

In Theorem 4.1, we show that the class of p-random oracles yields a global separation of p-btt$(k+1)$- and p-btt(k)-reducibility. This, together with Remark 4.3, solves Problem 7 in a recent survey article by Lutz and Mayordomo [17], where it has been asked to prove or disprove that, in our terms, the class of p-random oracles yields a weak global separation of these reducibilities. In section 5, we obtain by basically the same proof as for Theorem 4.1 that for every natural number k and any rec-random set R, there is a set that is p-btt$(k+1)$-reducible to R but is not btt(k)-reducible to any rec-random set, where btt(k)-reductions are restricted to at most k nonadaptive queries and are computed by total Turing machines that might run in arbitrary time and space. Thus in particular, the class of rec-random sets globally separates btt$(k+1)$-reducibility from btt(k)-reducibility. By an easy argument similar to the one given in Remark 1.1, this yields as a special case the main result of Book, Lutz, and Martin [8], who showed, by using different methods, a corresponding separation result with respect to the class of Martin-Löf-random sets, which is a proper subclass of the class of rec-random sets. Moreover, we will argue that in both settings, i.e., for polynomial time-bounded, as well as for recursive reductions and martingales, the corresponding random sets globally separate the corresponding notions of truth-table and bounded truth-table reducibility.

2. Notation. The notation used in the following is mostly standard, for unexplained notation refer to the surveys and textbooks cited in the bibliography [4, 7, 15]. All strings are over the alphabet $\Sigma = \{0,1\}$. We identify strings with natural numbers via the isomorphism that takes the length-lexicographical ordering on $\{\lambda, 0, 1, 00, \dots\}$ to the usual ordering on ω, the set of natural numbers. If not explicitly stated differently, the terms *set* and *class* refer to sets of natural numbers and to sets of sets of natural numbers, respectively.

A *partial characteristic function* is a (total) function from some subset of the natural numbers to $\{0,1\}$. A partial characteristic function is *finite* iff its domain is finite. The restriction of a partial characteristic function β to a set I is denoted by $\beta|I$ and thus, in particular, for any set X, the partial characteristic function $X|I$ has domain I and agrees there with X. We identify strings of length n in the natural way with a partial characteristic function with domain $\{0,\dots,n-1\}$ and hence strings can be viewed as prefixes of sets. For a partial characteristic function α with domain $\{z_0 < \cdots < z_{n-1}\}$, the *string associated with* α is the (unique) string β with domain $\{0,\dots,n-1\}$ defined by $\beta(j) = \alpha(z_j)$. For a set X and a partial characteristic function σ we write $\langle X, \sigma\rangle$ for the set that agrees with σ for all arguments in the domain of σ and agrees with X, otherwise.

We will consider the following polynomial time-bounded reducibilities: p-T, p-tt, where the queries have to be asked nonadaptively, p-btt, where for each reduction the number of queries is bounded by a constant, and, even more restrictive, *p-btt(k)-reducibility*, where for all reductions this constant is bounded by the natural number k. The relation symbol $\leq^{\mathrm{p}}_{\mathrm{btt}}$ refers to p-btt-reducibility, and relation symbols for other reducibilities are defined in a similar fashion. Expressions such as *p-T-reduction* and $\leq^{\mathrm{p}}_{\mathrm{T}}$*-reduction* will be used interchangeably. We represent p-btt-reductions by a pair of functions g and h computable in polynomial time where $g(x)$ gives the set of strings queried on input x and $h(x)$ is a truth-table of a Boolean function over k variables that specifies how the answers to the queries in the set $g(x)$ are evaluated. Here we

assume, first, via introducing dummy variables, that the cardinality of $g(x)$ is always exactly k and, second, by convention, that for $i = 1, \dots, k$, the ith argument of the Boolean function $h(x)$ is assigned the ith query in $g(x)$ where the queries are ordered by length-lexicographical ordering. All reducibilities mentioned above can be defined by specifying an appropriate sequence of total oracle Turing machines that compute the corresponding reductions. For any total oracle Turing machine M there is a corresponding functional Γ where $\Gamma(B) = A$ iff M computes the set A on oracle B. Equivalently, the functional Γ can be viewed as a binary function from pairs of sets and strings to $\{0, 1\}$ such that $\Gamma(B, x) = 1$ iff M accepts x on oracle B.

Given a reducibility r, the *lower r-span of a set A* is the class $\{X : X \leq_r A\}$ of sets that are r-reducible to A, and the *lower r-span of a class $\boldsymbol{C}$* is the class of all sets that are r-reducible to some set in $\boldsymbol{C}$.

3. Resource-bounded measure. We give a brief introduction to resource-bounded measure, which focuses on the concepts that will be used in subsequent sections. For more comprehensive accounts of resource-bounded measure theory see the recent survey papers by Ambos-Spies and Mayordomo [4] and by Lutz [15].

The theory of resource-bounded measure is usually developed in terms of *martingales*, which can be viewed as payoff functions of gambles of the following type. A player successively places bets on the individual bits of the characteristic sequence of an unknown set A or, for short, the player bets on A. The betting proceeds in rounds $i = 1, 2, \dots$, where during round i, the player receives the length $i - 1$ prefix of A and then, first, decides whether to bet on the ith bit being 0 or 1 and, second, determines the stake by specifying the fraction of the current capital that shall be bet. Formally, a player can be identified with a *betting strategy* $b : \{0, 1\}^* \to [-1, 1]$ where the bet is placed on the next bit being 0 or 1 depending on whether $b(w)$ is negative or nonnegative, respectively, and where the absolute value of the real $b(w)$ is the fraction of the current capital that shall be at stake.

The player starts with strictly positive, finite capital. At the end of each round, in case the current guess has been correct, the capital is increased by this round's stake and, otherwise, is decreased by the same amount. So given a betting strategy b, we can inductively compute the corresponding *payoff function* d by applying the equations

$$d(w0) = d(w) - b(w) \cdot d(w), \qquad d(w1) = d(w) + b(w) \cdot d(w).$$

Intuitively speaking, the payoff $d(w)$ is the capital the player accumulates till the end of round $|w|$ by betting on a set that has the string w as a prefix. Conversely, any function d from strings to nonnegative reals that for all strings w satisfies the fairness condition

$$d(w) = \frac{d(w0) + d(w1)}{2} \tag{3.1}$$

induces canonically a betting function b, where

$$b(w) = \frac{d(w1) - d(w0)}{2} \cdot \frac{1}{d(w)}$$

in case $d(w)$ differs from 0 and $b(w) = 0$ otherwise. We call a function d from strings to nonnegative reals a martingale iff $d(\lambda) > 0$ and d satisfies the fairness condition (3.1) for all strings w.

By the preceding discussion it follows for gambles as described above that for any martingale there is an equivalent betting strategy and vice versa. We will frequently

identify martingales and betting strategies via this correspondence and, if appropriate, notation introduced for martingales will be extended to the induced betting strategies.

We say a martingale d *succeeds* on a set A if d is unbounded on the prefixes of A, i.e., if

$$\limsup_{n\in\omega} d(A|\{0,\dots,n\}) = \infty,$$

and d *succeeds* on or *covers* a class iff d succeeds on every set in the class.

It is easy to see that every countable class $\boldsymbol{C} = \{C_1, C_2, \dots\}$ is covered by the following betting strategy. On input w, let i be the minimal index such that w is a prefix of C_i, then bet half of the current capital on the next bit agreeing with the corresponding bit of C_i (and abstain from betting if such an index does not exist). As a consequence, most of the classes considered in complexity and recursion theory can be covered by martingales. In order to distinguish such classes in terms of coverability, one has to restrict the class of admissible martingales. Here, in general, for a given class $\boldsymbol{C}$ we want to specify a class of admissible martingales that allows the covering of interesting subclasses of $\boldsymbol{C}$, but not of $\boldsymbol{C}$ itself. In the context of recursion theory, this led to the consideration of recursive martingales [23, 24, 25, 27], whereas in connection with complexity classes one has to impose additional resource-bounds [1, 4, 14, 15, 20]. An effective martingale d is always confined to rational values and there is a Turing machine that on input w outputs some appropriate finite representation of $d(w)$.

Recall the definition of the *uniform measure* (or *Lebesgue measure*) on Cantor space, which describes the distribution obtained by choosing the individual bits of a set by independent tosses of a fair coin. It has been shown by Ville that a class has uniform measure 0 iff the class can be covered by some martingale [4, 26]. The latter result justifies the following notation: a class has *measure* 0 with respect to a given class of martingales iff it is covered by some martingale in the class. The aim stated above can then be rephrased: for a given class $\boldsymbol{C}$, we want to specify a class of admissible martingales such that interesting subclasses of $\boldsymbol{C}$ have measure 0, but not $\boldsymbol{C}$ itself.

In connection with measure on complexity classes, most attention has been received by measure concepts for the exponential time-bounded classes

$$\mathbf{E} = \mathbf{DTIME}(2^{\mathrm{lin}}) \quad \text{and} \quad \mathbf{EXP} = \mathbf{DTIME}(2^{\mathrm{poly}}).$$

For example, in the case of the class $\mathbf{E}$, Lutz proposed to use martingales that on input w are computable in time polynomial in the length of w. Observe that the latter time-bound yields the same class of martingales as the time-bound $2^{\mathrm{O}(|x|)}$ where x is the minimal string not in the domain of w; i.e., if w is viewed as prefix of a set A, then x is the minimal string y such that $A(y)$ is not encoded in w. Lutz could show that for every constant c, the subclass $\mathbf{DTIME}(2^{c\cdot n})$ of $\mathbf{E}$ can be covered by such a martingale, but not $\mathbf{E}$ itself. The class of polynomial time-bounds used to define measure on $\mathbf{E}$ is so robust that, similar to the case of unrestricted martingales, martingales and betting strategies that can be computed in polynomial time are essentially equivalent. (However, in general, a fixed polynomial bound on the running time might not be preserved in the transition from a betting strategy to the corresponding martingale [3].) Furthermore, there is a similar correspondence between martingales and betting strategies in the case of martingales used to define measure on $\mathbf{EXP}$ [3] and in the case of recursive martingales [24].

We say a set is *p-random* if the set cannot be covered by a martingale that is computable in polynomial time, and we write p-RAND for the class of all p-random

sets. The notion *rec-random set* and the class rec-RAND of all rec-random sets are defined likewise with recursive martingales in place of martingales that are computable in polynomial time. Moreover, we will consider Martin-Löf-random sets [19]. These have been characterized in terms of martingales by Schnorr [24]. A set is *Martin-Löf-random* if and only if it cannot be covered by a subcomputable martingale. A martingale d is *subcomputable* iff there is a recursive function g in two arguments such that for all strings w, the sequence $g(w,0), g(w,1), \dots$ is nondecreasing and converges to $d(w)$.

The classes of p-random, rec-random, and Martin-Löf random sets all have uniform measure 1 because the class of sets on which a single martingale succeeds always has uniform measure 0 and, by σ-additivity, the same holds for every countable union of such classes. By definition, any rec-random set is p-random but the reverse implication is false as one can construct a recursive p-random set by diagonalizing against an appropriate weighted sum of all p-betting strategies. By the characterization of Martin-Löf-random sets stated above, it is immediate that the class of Martin-Löf-random sets is a subclass of rec-RAND. Schnorr [24] has implicitly shown that this containment is proper. For a proof, it suffices to recall that the prefixes of a Martin-Löf-random set can not be compressed by more than a constant while a corresponding statement for rec-random sets is false [13, Theorem 3.6.1 and Exercise 2.5.13].

We conclude this section by two remarks in which we describe standard techniques for the construction of martingales.

Remark 3.1. Let a finite set D be given, as well as a list $\langle D_1, \dots, D_m\rangle$ of pairwise disjoint subsets of D that all have the same cardinality $k > 0$. Then for a partial characteristic function σ with domain D and a string w of length k we might ask for the frequency

$$\alpha(\sigma, w, \langle D_1, \dots, D_m\rangle) \quad := \quad \frac{|\{j : w \text{ is the associated string of } \sigma|D_j\}|}{m}$$

with which w occurs in σ as associated string at the positions specified by the D_i. In case the sets D_i are clear from the context, we suppress mentioning them and we write $\alpha(\sigma, w)$ for short.

If we choose the bits of σ by independent tosses of a fair coin, then for every w of length k, the expected value of $\alpha(\sigma, w)$ is $1/2^k$. For large m, only for a small fraction of all partial characteristic functions with domain D will the frequency of w deviate significantly from the expected value, as can, for example, be shown by using Chernoff bounds [22, Lemma 11.9]. By using such bounds it is indeed straightforward to show that given k and a rational $\varepsilon > 0$, we can compute a natural number $m(k, \varepsilon)$ such that for all $m \geq m(k, \varepsilon)$ and for all D and $D_1, \dots, D_m$ as above we have

$$\frac{|\{\sigma : D \to \{0,1\} \ : \ \frac{1}{2}\cdot\frac{1}{2^k} < \alpha(\sigma, w, \langle D_1, \dots, D_m\rangle) < \frac{3}{2}\cdot\frac{1}{2^k}\}|}{2^{|D|}} \quad \geq \quad 1 - \varepsilon. \tag{3.2}$$

Remark 3.2. Let I be a finite set and let Θ be a subset of all partial characteristic functions with domain I. We can easily construct a martingale that by betting on places in I, increases its capital by a factor of $2^{|I|}/|\Theta|$ for all sets B where $B|I$ is in Θ. Here the martingale takes the capital available when betting on the minimal element of I and distributes it evenly among the elements of Θ, then computing values upwards according to the fairness condition for martingales.

4. Separations by p-random oracles. Lutz and Mayordomo [16] have shown that for any p-random set R, the lower p-btt(k)-span of R is strictly contained in the

lower p-btt$(k+1)$-span of R, i.e., the class p-RAND yields a local separation of these reducibilities. In Theorem 4.1, we extend this local separation to a global separation, i.e., we show that for any p-random set R there is a set that is p-btt$(k+1)$-reducible to R but is not p-btt(k)-reducible to any p-random set.

THEOREM 4.1. *Let R be a p-random set and let k be a natural number. Then the lower p-btt$(k+1)$-span of R is not contained in the lower p-btt(k)-span of* p-RAND.

Proof. In order to define a set A and a p-btt$(k+1)$-reduction (g_0, h_0) from A to R, we let $h_0(x)$ be the truth-table of the $(k+1)$-place conjunction and we let

$$g_0(x) := \{x0^1 1^{k+1}, x0^2 1^k, \ldots, x0^{k+1}1^1\}, \qquad A := \{x : g_0(x) \subseteq R\}. \tag{4.1}$$

We are done if we can show that if A is p-btt(k)-reducible to a set, then this set cannot be p-random. So let B be an arbitrary set and assume that A is reducible to B via the p-btt(k)-reduction (g, h). We will construct a martingale d that is computable in polynomial time and succeeds on B. To this end, let $m(.,.)$ be the function defined in Remark 3.1 and define a sequence $n_0, n_1, \ldots$ with

$$n_0 = 0, \qquad n_{i+1} > 2^{n_i}, \qquad \log n_{i+1} > m\left(k+1, \frac{1}{2^{i+1}}\right) \tag{4.2}$$

such that given x of length n, we can compute in time $\mathrm{O}(n^2)$ the maximal i with $n_i \leq n$. Such a sequence can be obtained by standard methods as described in the chapter on uniform diagonalization and gap languages in Balcázar, Díaz, and Gabarró [7]. For example, we can first define a sufficiently fast growing time-constructible function $r : \omega \to \omega$ and then let n_i be the value of the i-fold iteration of r applied to 0.

It is helpful to view the betting strategy of the martingale d as being performed in stages $i = 0, 1, \ldots$ where the bets of stage i depend on the g-images of the strings of length n_i. While considering the queries made for strings of length n_i with $i > 0$, we will distinguish short queries with length strictly less than

$$l_i := \left\lfloor \frac{n_i}{2k} \right\rfloor \tag{4.3}$$

and long queries, i.e., queries of length at least l_i. We call two strings x and y equivalent iff, for some i, both have identical length n_i and in addition we have

$$h(x) = h(y) \quad \text{and} \quad g(x) \cap \{z : |z| < l_i\} = g(y) \cap \{z : |z| < l_i\}\ , \tag{4.4}$$

i.e., two strings of length n_i are equivalent iff they have the same truth-table and the same set of short queries. Then for some constant c, the number of equivalence classes of strings of length n_i can be bounded from above by

$$2^{2^k} \sum_{j=0}^{k} \binom{2^{l_i} - 1}{j} \leq 2^{2^k}(k+1) \cdot 2^{l_i \cdot k} \leq c \cdot 2^{\frac{n_i}{2k} \cdot k} = c \cdot 2^{\frac{n_i}{2}}.$$

So the 2^{n_i} strings of length n_i are partitioned into at most $c \cdot 2^{\frac{n_i}{2}}$ equivalence classes, hence there is i_0 such that for all $i > i_0$, there is an equivalence class of cardinality at least $m_i := \lfloor \log n_i \rfloor$. For all such i, among all equivalence classes of strings of length n_i we choose one with maximal cardinality (breaking ties by some easily computable but

otherwise arbitrary rule), we let J_i contain the first m_i strings in this equivalence class, and we let

$$\alpha_i \quad = \quad \frac{|A \cap J_i|}{|J_i|}. \tag{4.5}$$

We show now that due to R being p-random, almost all α_i are close to $1/2^{k+1}$.

CLAIM 1. *For almost all i, α_i is contained in the open interval K defined by*

$$K \ := \ \left(\frac{1}{2} \cdot \frac{1}{2^{k+1}}, \ \frac{3}{2} \cdot \frac{1}{2^{k+1}}\right). \tag{4.6}$$

Proof. Fix any index $i > i_0$. Let $z_1 < \cdots < z_{m_i}$ be the elements of J_i, let D_j be equal to $g_0(z_j)$ for $j = \{1, \ldots, m_i\}$, and let D be the union of D_1 through D_{m_i}. Recall from Remark 3.1 the definition of the function α. For any partial characteristic function σ with domain D and any string w of length $k+1$, $\alpha(\sigma, w)$ is equal to the fraction of all indices i among $1, \ldots, m_i$ such that the string associated with $\sigma|D_i$ is equal to w. Now the truth table h_0 is just the conjunction of the queries given by g_0 and thus by construction, z_i is in A iff all strings in D_i are in R. Hence by the definitions of α_i and α, we obtain $\alpha_i = \alpha(\sigma_i, v)$ where $v = 1^{k+1}$ and σ_i is the restriction of R to places in D.

On the other hand, by choice of the m_i and by (4.2), we know that $m_i = \lfloor \log n_i \rfloor$ is larger than $m(k+1, 1/2^i)$. By definition of the function m in Remark 3.1, it is then immediate that for all but a $1/2^i$-fraction of all partial characteristic functions σ with domain D the value $\alpha(\sigma, v)$ is in K. If α_i, and hence also $\alpha(\sigma_i, v)$, is not in K, then $\sigma_i = R|D$ belongs to this exceptional fraction. Remark 3.2 shows that in this situation, by betting on the places in D, a martingale can increase its capital by a factor of 2^i when betting against the unknown set R.

Now consider the following martingale, where we leave it to the reader to show that the martingale can be computed in polynomial time. The initial capital 1 is split into infinitely many parts $c_1, c_2, \ldots$ where $c_i = 1/2^i$ is exclusively used to place bets on the strings in the set D that corresponds to the index i, i.e., the strings that are in $g_0(x)$ for some x in J_i. By the preceding discussion, the martingale can increase the capital c_i to at least 1 for all $i > i_0$ such that α_i is not in K. But if this were the case for infinitely many values of i, the martingale would succeed on R, thus contradicting the assumption that R is p-random. □

By Claim 1 for almost all i, the density of the set A on J_i is confined to the small interval K with center $1/2^{k+1}$. While constructing the martingale d that is meant to succeed on B, we will exploit that thus in particular for almost all i, this density differs from 0 and is less than

$$\rho \ = \ \frac{3}{2} \cdot \frac{1}{2^{k+1}} \ . \tag{4.7}$$

Recall from the introduction that one can view reductions as functionals and let Γ be the functional that corresponds to the btt(k)-reduction given by (g, h), hence for example A is equal to $\Gamma(B)$. For all $i \geq i_0$, let

$$H_i \quad = \quad \bigcup_{x \in J_i} \{z : z \text{ in } g(x) \text{ and } |z| \geq l_i\},$$

i.e., H_i is the set of all long queries made by strings in J_i. Then we can argue that only for a fraction of all partial characteristic functions σ with domain H_i the

set $\Gamma(\langle B, \sigma\rangle)$ has density less than ρ on J_i. Formally, for every $i > i_0$ and for every partial characteristic function σ with domain H_i, we let

$$\beta_i(\sigma) \;=\; \frac{|\Gamma(\langle B, \sigma\rangle) \cap J_i|}{|J_i|}$$

and, further,

$$\Theta_i \;=\; \{\sigma : \sigma \text{ partial characteristic function with domain } H_i \text{ and } \beta_i(\sigma) < \rho\}.$$

By Claim 1 for almost all i, the density α_i of the set $A = \Gamma(B)$ on J_i is less than ρ, hence the restriction of B to H_i must be contained in Θ_i by definition of Θ_i.

We will argue next that there is some $\delta < 1$ such that for almost all i, the set Θ_i comprises at most a δ-fraction of all partial characteristic functions with domain H_i. We will then exploit the latter fact in the construction of the martingale d by betting against the $(1 - \delta)$-fraction of partial characteristic functions outside of Θ_i, which have already been ruled out as possible restriction of B to H_i.

For the moment, let τ_x be the Boolean function obtained from $h(x)$ by hard-wiring $B(z)$ into $h(x)$ for all short queries z in $g(x)$. By definition for all x, the queries in $g(x)$ are assigned to the variables of $h(x)$ in length-lexicographical order, hence for equivalent strings x and y, the Boolean functions τ_x and τ_y are identical. Thus for every $i > i_0$, all strings in J_i are mapped to the same Boolean function, which we denote by τ_i. We call a Boolean function constant iff it evaluates to the same truth value for all assignments to its arguments (and hence in particular all 0-place Boolean functions are constant).

Claim 2. *For almost all i, τ_i is not constant.*

Proof. If τ_i is constant, then the value $A(x)$ must be the same for all x in J_i. But then α_i is either 0 or 1, while Claim 1 implies that this is the case for at most finitely many i. □

Claim 3. *There is a constant $\delta < 1$ such that for almost all i, the set Θ_i comprises at most a δ-fraction of all partial characteristic functions with domain H_i.*

Proof. For a given $i > i_0$ such that τ_i is not constant, consider the random experiment where we use independent tosses of a fair coin in order to choose the individual bits of a random partial characteristic function $\widehat{\sigma}$ with domain H_i. Then all partial characteristic functions of this type occur with the same probability; hence the fraction we want to bound is just the probability of picking an element in Θ_i.

For every string x in J_i, define a 0-1-valued random variable b_x, and define a random variable γ_i with rational values in the closed interval $[0, 1]$ by

$$b_x(\widehat{\sigma}) := \Gamma(\langle B, \widehat{\sigma}\rangle, x), \qquad\qquad \gamma_i(\widehat{\sigma}) := \frac{1}{|J_i|} \sum_{x \in J_i} b_x(\widehat{\sigma}).$$

Consider an arbitrary string x in J_i. By assumption, τ_i is not constant, hence there is at least one assignment to $\widehat{\sigma}$ such that $b_x(\widehat{\sigma})$ is 1. Moreover such an assignment occurs with probability at least $1/2^k$ because $h(x)$, and thus also τ_i, has at most k variables. Thus the expected value of b_x is at least $1/2^k$ and by linearity of expectation we obtain

$$\mathbf{E}(\gamma_i) \;=\; \frac{1}{|J_i|} \sum_{x \in J_i} \mathbf{E}(b_x) \;\geq\; \frac{1}{|J_i|} \sum_{x \in J_i} \frac{1}{2^k} \;=\; \frac{1}{2^k}. \tag{4.8}$$

If we let p be the probability of the event "$\gamma_i < \rho$," we have

$$\frac{1}{2^k} \leq \mathbf{E}(\gamma_i) \leq p \cdot \rho + (1-p) \cdot 1 \leq \rho + (1-p) = \frac{3}{4} \cdot \frac{1}{2^k} + (1-p), \tag{4.9}$$

where the relations follow, from left to right, by (4.8), by definition of p and by $\gamma_i \leq 1$, because the probability p is bounded by 1, and by the choice of ρ in (4.7). By comparing the first and last term in (4.9) we then obtain that p is bounded from above by $\delta := 1 - 1/2^{k+2}$. □

For all i, let $I_i = \{x : l_i \leq |x| < l_{i+1}\}$. The values of n_i grow sufficiently fast such that for some i_1 and for all $i > i_1$, the set H_i is contained in I_i. Moreover, by Claim 3, for some $i_2 > i_0$ and all $i > i_2$, there is a set Θ_i of partial characteristic functions with domain H_i where Θ_i contains only a δ-fraction of all such partial characteristic functions and contains the restriction of B to H_i. Let i_3 be the maximum of i_1 and i_2.

Now we are in a position to describe a betting strategy that succeeds on B. For a given input w, let x be the $(|w|+1)$th string, i.e., the string on which we might bet. We first compute the index i such that x is in I_i, together with the corresponding set H_i. In case $i \leq i_3$ or if x is not in H_i, we abstain from betting. Otherwise, we place a bet on x according to the betting strategy as described in Remark 3.2, which, while placing bets on the strings in H_i, increases the capital by a factor of at least $1/\delta$ by betting against the partial characteristic functions that are not in Θ_i. Here all necessary computations can be performed in time $2^{\mathrm{O}(n_i)}$ and hence, by $|x| \geq l_i = \lfloor n_i/2k \rfloor$, in time $2^{\mathrm{O}(|x|)}$. It follows that this betting strategy induces a martingale computable in polynomial time that on interval I_i preserves its capital in case $i \leq i_3$ and increases its capital by a factor of at least $1/\delta$ for all $i > i_3$.

This finishes the proof of Theorem 4.1. Observe that the current proof would for example also go through if we had chosen the cardinality m_i of J_i to be equal to n_i. The actual choice of the m_i emphasizes that for given k, the complexity of the martingale d covering the set B in the upper p-btt(k)-span of A is dominated by the complexity of computing the sets J_i, whereas the complexity of handling the assignments on the sets H_i can be neglected. □

Remark 4.2. The assertion of Theorem 4.1 remains valid if we simply require the set R to be n-random instead of p-random, (i.e., if we require that there is no martingale computable in time $\mathrm{O}(n)$ that succeeds on R). For a proof, note that Ambos-Spies, Terwijn, and Zheng [5] have shown that for every n^2-random set R, there is a p-random set R_0 that is p-m-reducible to R while, in fact, the latter assertion is true for n-random R. Now the relaxed version of Theorem 4.1 follows because the existence of a separating set A as required in the theorem extends directly from R_0 to R.

Remark 4.3. Theorem 4.1 states that the lower p-btt($k+1$)-span of every p-random set R contains a set A that is not in the lower p-btt(k)-span of any p-random set. As already noted by Book, Lutz, and Martin [8], for a set R that is not just p-random but is even Martin-Löf-random, such a set A cannot be recursive. This follows from the fact that every recursive sets that is p-btt($k+1$)-reducible to a Martin-Löf-random set is in fact computable in polynomial time. The latter fact is attributed to folklore by Lutz and Schweizer [18] and can be obtained as a special case of a result of Book, Lutz, and Wagner [9]. They have shown from rather general assumptions on the reducibility under consideration that every recursive set that is reducible to a Martin-Löf-random set must be contained in the corresponding almost-class, i.e., in the class of sets that have an upper span of uniform measure 1. Their assumptions are satisfied for most bounded reducibilities considered in the literature

and, in particular, their result applies to p-btt(k)-reducibility for all $k \geq 0$. Moreover, for the latter reducibilities it was shown by Ambos-Spies [2] that the corresponding almost-classes are all equal to the class of sets computable in polynomial time. As a consequence, any recursive set A in the lower p-btt($k+1$)-span of a Martin-Löf-random set is computable in polynomial time and is hence in the lower p-btt(k)-span of every Martin-Löf-random set.

From the proof of Theorem 4.1 we obtain the following corollary.

COROLLARY 4.4. *For every p-random set R, the lower p-tt-span of R is not contained in the lower p-btt span of* p-RAND.

Proof. For a given p-random set R and for every k, let the set A_{k+1} be defined in the same way as the set A has been defined in (4.1) in the proof of Theorem 4.1. Then A_{k+1} is p-btt($k+1$)-reducible to R, but is not p-btt(k)-reducible to any p-random set. Moreover, the set

$$B \quad = \quad \{x : x = 1^k 0y \text{ and } y \text{ in } A_k\}$$

is p-tt-reducible to R by construction of the sets A_k. On the other hand, if B were p-btt-reducible to some p-random set R_0, then B would be in fact p-btt(k)-reducible to R_0 for some k. Hence, in particular, A_{k+1} were p-btt(k)-reducible to R_0, thus contradicting the choice of A_{k+1}. □

5. Separations by rec-random oracles. Lutz [14] showed that recursive martingales yield a reasonable measure concept for the class of recursive sets, where in particular the class of all recursive sets cannot be covered by a recursive martingale.[1] Recall from the introduction that a set is recursively random iff it cannot be covered by a recursive martingale and that rec-RAND denotes the class of all such sets. Next we state two results on recursively random sets that correspond rather closely to Theorem 4.1 and Corollary 4.4 on p-random sets.

THEOREM 5.1. *Let the set R be in* rec-RAND *and let k be a natural number. Then the lower* p-($k+1$)-tt*-span of R is not contained in the lower btt(k)-span of* rec-RAND.

COROLLARY 5.2. *For every set R in* rec-RAND*, the lower p-tt-span of R is not contained in the lower btt-span of* rec-RAND.

In connection with Theorem 5.1 and Corollary 5.2, recall that *btt-reducibility* is defined like p-btt-reducibility, except that a btt-reduction is required to be computed by a total Turing machine that might run in arbitrary time and space and that *btt(k)-reducibility* is the restriction of btt-reducibility where the number of queries is bounded by k.

We omit the proofs of Theorem 5.1 and Corollary 5.2, which are almost literally the same as in the case of p-random sets. Besides the fact that now we consider effective martingales and reductions instead of polynomial time-bounded ones, the main difference is that for arbitrary recursive reductions from A to B we cannot compute an a priori bound on the size of the queries. Hence in order to ensure that the sets H_i are pairwise disjoint, the definition of the n_i will now depend on the given reduction (g, h). Here we choose n_{i+1} so large that all strings queried on inputs of length n_i are short queries with respect to n_{i+1}, i.e., have length strictly less than $\lfloor n_{i+1}/2k \rfloor$.

Remark 5.3. Recall from the discussion preceding Remark 3.1 that the class of Martin-Löf-random sets is a proper subclass of rec-RAND. As a consequence,

[1] For further discussion of measure concepts for the class of recursive sets see for example Schnorr [24], Terwijn [25], and Wang [27].

by an easy argument similar to the one used in Remark 1.1, from the separation by the class rec-RAND stated in Theorem 5.1 we obtain the main result of Book, Lutz, and Martin [8], who showed that for all k, the lower p-btt$(k+1)$-span of a Martin-Löf-random set is never contained in the lower btt(k)-span of the class of all Martin-Löf-random sets.

Acknowledgments. We are grateful to Elvira Mayordomo for several useful corrections and suggestions, where the latter include a significant simplification of the argument in Remark 4.2 via referring to the cited result of Ambos-Spies, Terwijn, and Zheng [5]. Furthermore, we would like to thank Klaus Ambos-Spies, Jack Lutz, and Jan Reimann for helpful discussions. Finally, we are grateful for the detailed comments of the anonymous referees of ICALP 2000 and of the *SIAM Journal on Computing*.

GEOMETRIC COMPLEXITY THEORY I: AN APPROACH TO THE *P* VS. *NP* AND RELATED PROBLEMS*

KETAN D. MULMULEY† AND MILIND SOHONI‡

Abstract. We suggest an approach based on geometric invariant theory to the fundamental lower bound problems in complexity theory concerning formula and circuit size. Specifically, we introduce the notion of a *partially stable* point in a reductive-group representation, which generalizes the notion of stability in geometric invariant theory due to Mumford [*Geometric Invariant Theory,* Springer-Verlag, Berlin, 1965]. Then we reduce fundamental lower bound problems in complexity theory to problems concerning infinitesimal neighborhoods of the orbits of partially stable points. We also suggest an approach to tackle the latter class of problems via construction of *explicit obstructions.*

1. Introduction.

It is generally agreed by now [41] that the problems in complexity theory such as P vs. NP [10, 25, 20] and the related lower bound problems for formula or arithmetic-circuit size are of fundamental importance and may have connections with deep issues in other areas of mathematics. In this article we suggest an approach based on geometric invariant theory [37, 38] to several such lower bound problems concerning formula and circuit size. We shall focus on formulae and circuits over integers or algebraically closed fields of arbitrary characteristic before addressing the ones over finite fields. Our work is based on the classical geometric invariant theory developed by Hilbert [19], Weyl [46], and others, as well as on the modern theory developed by Mumford, Fogarty, and Kirwan [37], Nagata [31], Seshadri [40], Haboush [17], Luna [27], Kempf [23], and others. Especially central in this paper is the powerful notion of stability in geometric invariant theory [19, 37, 23, 27, 40].

For a survey of earlier algebraic and geometric techniques in lower bound problems, see [5]; for a survey of earlier combinatorial techniques, see [3]. A starting point for our investigation was a result by one of the authors [33] that provided a concrete support for the $P \neq NC$ conjecture by an unconditional proof of its weaker implication in a restricted but natural and realistic *PRAM model without bit operations*, which contains virtually all known fast parallel algorithms for algebraic and weighted-combinatorial-optimization problems. In [33] it is shown that well-known network flow problems such as min-cost flow and max-flow, which can be solved efficiently without bit operations sequentially—i.e., they have the so-called strongly polynomial time algorithms [16]—cannot be solved efficiently in this model. Specifically, consider the max-flow problem. Since it is P-complete, the $P \neq NC$ conjecture implies that it cannot be solved in the usual PRAM model in $O(\text{polylog}(N))$ time using $\text{poly}(N)$

processors, where N is the total bitlength of the input. Since the PRAM model without bit operations is just a restricted version of the usual PRAM model, obtained by not allowing the bit operations in the usual model, it follows from the $P \neq NC$ conjecture that the max-flow problem cannot be solved in the PRAM model without bit operations as well in $O(\text{polylog}(N))$ time using $\text{poly}(N)$ processors. In [33], this weaker implication of the $P \neq NC$ conjecture is proved unconditionally using some algebraic geometry. (In fact, a stronger lower bound is proved.)

This was a turning point that provided a compelling argument for believing that algebraic geometry will play a crucial role in the P vs. NC and other separation problems in complexity theory. The approaches attempted earlier (cf., e.g., [3]) were combinatorial, but they had a serious natural-proof limitation as pointed out in [39]. The present approach does not have this limitation, since it is based on *explicit constructions* (cf. section 5 and Part II [34]) and the results, such as the Hilbert–Mumford–Kempf criterion [37, 23] for stability (cf. section 3), which work only for points with specific types of stabilizers. Such points are very rare because almost all points in the representations under consideration have trivial stabilizers.[1] (Loosely speaking, according to the terminology in [39], the probabilistic proof for existence of expanders would be natural because it ends up proving that a significant fraction of graphs are expanders, whereas the proof based on explicit construction [26, 29] would be unnatural because it works for only a specific graph.) A closer analysis of the limitation of the techniques in [33] in the context of the usual P vs. NC problem suggested that geometric invariant theory may help. This led us to explore the role of geometric invariant theory in the fundamental lower bound problems of complexity theory.

Geometric invariant theory is the study of the action of an algebraic reductive group on an algebraic variety. One important problem here is to understand the structure of this action in the vicinity of the orbit of any fixed point. If the variety is affine and smooth, the characteristic is zero, and the point is stable in the sense of Mumford [36] and Kempf [23], i.e., its orbit is closed, then Luna's étale slice theorem (cf. [27] and the appendix of [37]), based on the earlier work on stability of Mumford [36] and others, says that the orbit has a neighborhood which looks like a certain homogeneous fiber bundle. This gives a complete understanding of the structure of the action in the vicinity of the orbit of a stable point. The action in the vicinity of the null cone, i.e., the set of points in V on which all nonconstant homogeneous G-invariant polynomial functions on V vanish, is, however, not well understood, though there are some results concerning the structure of the null cone, e.g., the Hilbert–Mumford criterion [37] and Luna's stratification [38]. The reason is that the action in the vicinity of the orbit of an arbitrary point of the null cone may be too complex. However, the situation may be better if the point under consideration has some weaker form of stability. We define one such notion, called partial stability, that is also applicable to the points in the null cone. Then we show that an in-depth understanding of the structure of a reductive-group action in the vicinity of the orbit of a partially stable point would lead to resolution of the lower bound problems mentioned above. We also suggest an approach, which will be developed in depth in Part II [34], for studying the group action in the vicinity of the orbit of a partially stable point in the null cone. Such a study is of independent mathematical interest in geometric invariant theory.

[1] For example, the proof of Theorem 4.1 works only for points that are stabilized by the stabilizer R of the determinant. However, in the space $P(V)$ under consideration, the determinant is the only point that is stabilized by R.

We mentioned above that the max-flow problem does not have an efficient algorithm in the PRAM model without bit operations. Its dual is the problem of computing a minimum-weight s-t-mincut in a flow network. This is the weighted optimization problem associated with s-t-mincuts. The corresponding weighted counting problem is the problem of computing total weight of all s-t-mincuts in a flow network. Up to fast parallel reductions, this problem is equivalent in the PRAM model without bit operations to the problem of computing the permanent of a matrix, which is $\#P$-complete [44]. Hence it is expected to be much harder than the problem of computing a minimum-weight s-t-mincut. And yet, paradoxically, the task of proving a lower bound for this harder problem in the PRAM model without bit operations seems harder. This is so even if the model is restricted even further by allowing the running time or the number of processors to depend only on the number of input parameters and not their bitlength and, furthermore, by not allowing any branching or indirect references. The lower bound problem in this substantially restricted model is then equivalent to the one concerning formula size over integers. Valiant [45] conjectured that the permanent has no formula of polynomial size; this was posed as an algebraic analogue of the P vs. NP problem with the hope that techniques used in resolving it may shed light on the P vs. NP problem. Indeed, it is the first problem that we address in this paper.

The rest of this paper is organized as follows. In section 2 we outline our unified approach, which reduces the fundamental lower bound problems under consideration to instances of a certain orbit-closure problem in geometric invariant theory. In section 3 we review the main results in geometric invariant theory that we need. In section 4, we illustrate our approach on the lower bound problem for the formula size of the permanent. In section 5, we formulate an approach to the orbit-closure problem via *explicit obstructions*; these will be studied in depth in Part II of this paper. In sections 6, 7, and 8 we consider the P vs. NP problem with emphasis on its arithmetic implication.

2. A unified approach. Let F be an algebraically closed field. Let V be the vector space of homogeneous forms of degree m in l variables over F. Let Y denote the l-vector whose entries are these variables. Consider the reductive group $G = SL_l(F)$. It has a natural action on V. The action of any $\sigma \in SL_l(F)$ on a form $h \in V$ is given by $(\sigma h)(Y) = h(\sigma^{-1}Y)$. Let $P(V)$ denote the projective space associated with V. Then G acts on $P(V)$ as well. We shall think of a form as belonging to either V or $P(V)$ depending upon the context. Following Mumford [36], Mumford, Fogarty, and Kirwan [37], and Kempf [23], we shall say that the form $f \in P(V)$ is *stable* if the G-orbit of f in the affine space V is (Zariski) closed.

We shall reduce all lower bound problems under consideration for formulae or circuits over integers or algebraically closed fields of arbitrary characteristic to instances of the following general problem.

The orbit closure problem. Given fixed forms $g, f \in P(V)$, does f belong to the (projective) Zariski closure $\Delta[g]$ of the G-orbit of g in $P(V)$?

The explicitly given forms g and f will depend on the lower bound problem under consideration. They will be parametrized by l, the number of variables, which asymptotically goes to infinity. The orbit closure $\Delta[g]$ is a compactification of the homogeneous space G/H, where H is the stabilizer of g. The algebraic geometry of compactifications of homogeneous spaces is well understood in some special cases such as toric varieties [13], spherical embeddings [28], and compactifications of symmetric spaces [9]. In general, however, it seems very complex: a rough measure of this

complexity, proposed by Luna and Vust [28], is the difference between the dimension of the compactification and that of the orbit of a Borel subgroup. This is zero for spherical embeddings but quite high—roughly half of $\dim(G)$—in our case. This is one reason why the orbit-closure problem might well be intractable if f and g were arbitrary. The crucial result in this paper, which gives structure to this otherwise wild problem and connects complexity theory and geometric invariant theory, is that f, which arises in the context of lower bound problems in complexity theory studied here, has certain stability property, in the sense of geometric invariant theory [37], and moreover, both f and g have large nontrivial stabilizers that in a sense characterize them. We then formulate an approach to the orbit-closure problem, based on so-called *explicit obstructions*, that exploits this stability and presence of large characterizing stabilizers (section 5). This approach is developed in depth in Part II [34].

Specifically, f that arises in our context turns out to be a partially stable point in the null cone of G (Theorems 4.3 and 7.2). Partial stability (section 3) is a version of stability for points in the null cone obtained by relaxing the notion of stability due to Mumford [36], which is for points outside the nullcone. Roughly this means that (1) f is "almost" stable with respect to a reductive subgroup $L \subseteq G$ that is a Levi subgroup of a maximal parabolic subgroup $P \subseteq G$, (2) the orbit Gf is a fiber bundle over the base space G/P (whose algebraic geometry is very well understood [24]) such that each fiber is isomorphic to the L-orbit of f, and (3) the dimension of the fiber is sufficiently large in comparison to that of the orbit Gf. The precise relationship between these two dimensions will depend on the lower bound problem under consideration. Generally, the dimension of the orbit Gf will be bounded by a polynomial in the dimension of the orbit Lf, as the parameter l goes to infinity. If one could show that the answer to such an instance of the orbit-closure problem in a particular lower bound problem is negative for all large enough (or, more generally, infinitely many) l, then it would imply the desired lower bound.

Since g that arises in our context has a nontrivial reductive stabilizer that in a sense characterizes its structure, it is possible to reduce the orbit-closure problem further to a certain stabilizer problem as follows. Let D_g denote the stabilizer of g in $SL_l(F)$. First, we observe that if f lies in the closure of the $SL_l(F)$-orbit of g in $P(V)$, then, thinking of f and g as elements of the affine space V, f will lie in the closure of the $GL_l(F)$-orbit of g in V. However, the stabilizer within $SL_l(F)$ of any point in the $GL_l(F)$-orbit of g is a conjugate within $SL_l(F)$ of D_g. Hence, every (Zariski) open neighborhood of f within V will contain a point whose stabilizer in $SL_l(F)$ is a conjugate of D_g, and the same will hold for any point in the $SL_l(F)$-orbit of f in V. When this happens we will say that the group $D_g \subseteq SL_l(F)$ is present in the infinitesimal neighborhood of the $SL_l(F)$-orbit of f. The orbit-closure problem can now be reduced to the following.

The stabilizer problem. Let $D \subseteq G = SL_l(F)$ be an explicitly given reductive subgroup and $f \in V$ an explicitly given form. Can D occur as a stabilizer in the infinitesimal neighborhood of the G-orbit of f in V?

If $f \in V$ were a stable form, then Luna's étale slice theorem provides a satisfactory answer to this problem. Luna's result in our setting can be roughly stated as follows. Let H be the stabilizer of f. If f is stable, then there exists an affine variety N with an H-action such that some G-invariant affine neighborhood of the orbit of f "looks like" the homogeneous fiber bundle $G \times_H N$. This is a fiber bundle over the base space G/H with fiber N, and it is associated with the primary bundle $G \to G/H$. It easily follows from this result that if D were to occur in the infinitesimal neighborhood

of the $SL_l(F)$-orbit of f, then some conjugate of D must be contained in H. This implies, in turn, that if there exists a G-representation W that contains a trivial H-representation but not a trivial D-representation, then D cannot lie in the infinitesimal neighborhood of $SL_l(F)$-orbit of f, and hence f cannot lie in the (projective) closure of the $SL_l(F)$-orbit of a form $g \in P(V)$ with $D_g = D$. We say that such a W is an *obstruction* for the pair (f, g); i.e., its existence acts as a guarantee that f cannot lie in the projective closure of the orbit of $g \in P(V)$.

In our problem, f would be only partially stable. Therefore what we need is an extension of the preceding approach based on Luna's result from the stable to the partially stable situation. We suggest one such approach in this paper (section 5) based on explicit construction of representation-based obstructions, as above, in the partially stable situation; this serves as a starting point for our work in Part II [34]. In the context of lower bound problems in complexity theory, one can argue that obstructions ought to exist in plenty, assuming that the conjectured lower bound really holds. However, the problem is such that one has to prove their existence by constructing them more or less explicitly. Explicit construction has already been useful in complexity theory in a different context. For example, Margulis [29] and Lubotzky, Phillips, and Sarnak [26] give an explicit construction of expanders that are useful in a pseudorandom generation. The essential difference is that proving existence of expanders is easy, while proving existence of obstructions is itself a main problem.

The lower bound problem that arises in the context of the actual P vs. NP question (nonuniform boolean version) is for circuits defined over finite fields.[2] We shall reduce it (section 7) to a family of orbit-closure and stabilizer problems where f ranges over forms that are so-called F_p-equivalent to a certain base form f_b. We show that f_b is partially stable and conjecture the same for all forms F_p-equivalent to it. In any case, the lower bound problem for circuits (or formulae) over integers is a weaker version of the one over finite fields, in the sense that if g is a polynomial function with integer coefficients (e.g., the permanent) and F_p a fixed finite field, then a lower bound on the size of a circuit (or formula) over F_p for computing g, modulo F_p, implies the same lower bound on the size of a circuit (or formula) over integers for computing g. As such, it seems preferable to focus at first only on circuits or formulae over integers. In turn, the lower bound problem for circuits or formulae over integers for computing g is a weaker version of the problem over complex numbers. Hence, we shall concentrate mainly on circuits or formulae over complex numbers, or more generally, over algebraically closed fields of arbitrary characteristic.

3. Preliminaries. Geometric invariant theory is the study of actions of algebraic groups on algebraic varieties. Here reductive algebraic groups, such as the special linear group $SL_n(F)$, F algebraically closed, play a special role because they are geometrically reductive: this means that if V is a representation of a reductive group G, then there are enough polynomial functions on V which are invariant under G to distinguish disjoint closed G-invariant subsets of V. This was proved by Mumford [36] for linearly reductive groups, which include the classical simple groups over the complex field (cf. Weyl [46]), and was conjectured in general. It was eventually established by Seshadri [40] for $SL_2(F)$ and by Haboush [17] in general. What we shall really need is geometric reductivity of the special linear group $SL_n(F)$, where F is an algebraically closed field of arbitrary characteristic; for general n this was proved

[2] This finite field is usually taken to be F_2, but F_p, for any fixed prime p, will also do.

by Formanek and Procesi [12] independently of Haboush's general result.

3.1. Stability and partial stability. Consider the action of a reductive group G on an algebraic variety $\mathcal{X}$. It turns out that one cannot always put the structure of an algebraic variety on the set of all orbits of G in $\mathcal{X}$ but only on a subset chosen judiciously. For this purpose Mumford [36] introduced the notion of stability, building on the classical work of Hilbert [19], and exploited it systematically in his construction of quotients and moduli spaces. The definition of stability in the literature, though, has been anything but stable. Here we shall give a simplified definition following Kempf [23], which is somewhat different from the one in [36, 37].

Let V be a representation of a reductive group G. Then G acts on the projective space $P(V)$ of lines in V through the origin. Let y be a point in $P(V)$ and $x \in V$ any nonzero point on y. We say that y is *G-stable*, or simply *stable* if G is clear from the context, iff the orbit $G.x$ is (Zariski) closed and *properly stable* iff, in addition, the stabilizer of y in G is finite. By abuse of notation, we shall sometimes say that x is stable. We say that y is *semistable* iff the closure of the orbit $G.x$ does not contain zero. These definitions clearly do not depend on the choice of x on y. We will say that $x \in V$ is *unstable* or nilpotent if the closure of its orbit $G.x$ contains zero. The set of all nilpotent points in V is called the null cone. It can also be characterized as the set of common zeroes of all homogeneous invariants of positive degree. The concept of the null cone, important to us, was introduced by Hilbert [19].

Next, we define a weaker form of stability called partial stability, which will play a crucial role in this paper, and will be studied in depth in Part II. First assume that the characteristic is zero. Roughly, a point is partially stable if it is stable with respect to a large, nicely embedded, regular[3] reductive subgroup of G. Formally, we say that y is partial stable if there exists a maximal parabolic subgroup $P \subseteq G$ containing the stabilizer H of x in G such that

1. H contains the unipotent radical R of P—in other words, the unipotent radical fixes x;
2. y is "almost" stable with respect to a Levi subgroup $L \subseteq P$: This means the stabilizer L' of x in L is reductive (as it would be if y were stable with respect to L [32]), and y is stable with respect to a regular reductive subgroup $K \subseteq L$, whose rank is less than that of L by a small defect δ (in our case δ will be one);
3. the dimension of the orbit $Lx = L/L'$ is large enough in comparison with the dimension of the orbit Gx. The exact ratio Δ between these two dimensions will depend on the lower bound problem under consideration. Generally, the dimension of Gx will be bounded by a polynomial in the dimension of Lx.

When $P = G$, $\delta = 0$, and $\Delta = 1$, this coincides with the usual notion of stability. Therefore δ and Δ measure deviation from (complete) stability. It follows from the definition that H has a Levi decomposition of the form $L'R$, where L' is a reductive subgroup of L. It also follows that the orbit Gx is a fiber bundle over G/P such that each fiber is an affine subvariety of V isomorphic to L/L', the L-orbit of x. Moreover, the dimension of the fiber is sufficiently large in comparison with the dimension of Gx. That Gx is a fiber bundle over G/P with affine fiber has an important consequence for us: computation of the cohomology of a quasi-coherent sheaf over Gx can be reduced to a similar problem over G/P (cf. Theorem 5.4), where it is well understood [24]. Such explicit computation of cohomology will turn out to be important in our

[3]This means that the root system of the subgroup is a subsystem of the root system of G.

approach to the orbit closure problem (section 5).

If the characteristic is positive, we assume in the preceding definition of partial stability that G is a connected split reductive F-group (i.e., defined over a finite field F) and that P and H are also F-groups [42]. This is required to ensure that the Levi decomposition holds [4, 42].

3.2. Example. Let Y be a vector space of dimension $m+1$ with coordinates $y_0, \ldots, y_m$; X its subspace with coordinates $x_0, \ldots, x_n$, $n < m$, where $x_i = y_i$, $i \leq n$; and $\hat{X} \subseteq X$ the subspace with coordinates $x_1, \ldots, x_n$. We shall also think of y_i's as variables and, abusing the notation, denote by Y the variable vector with entries $y_0, \ldots, y_m$, and so on. Let $V = \mathrm{Sym}^r(Y^*)$ be the space of forms of degree r in $y_0, \ldots, y_m$, and $W = \mathrm{Sym}^s(\hat{X}^*)$, $s < r$, the space of forms of degree s in $x_1, \ldots, x_n$. We can embed W in V in a natural way using x_0 as the homogenizing variable. Formally, let ϕ be an embedding of W in V given by $(\phi h)(Y) = x_0^{r-s} h(\hat{X})$. Suppose $h \in W$ is stable with respect to the natural action of $SL_n = SL(\hat{X})$ on W with (reductive) stabilizer $K \subseteq SL(\hat{X})$.

Claim 3.1. *The embedded form $\phi h \in V$ is partially stable with respect to the action of $SL_{m+1} = SL(Y)$ on V. In other words, any stable form in the $SL(\hat{X})$-representation W becomes partially stable when embedded in the $SL(Y)$-representation V.*

Proof. First notice that the stabilizer of $\phi(h)$ in $SL(X) \subseteq SL(Y)$ is just K, assuming $r-s$ is larger than n. Although ϕh is not stable with respect to $SL(X)$—in fact, it lies in its null cone—it is stable with respect to $SL(\hat{X})$. Let $P \subseteq SL(Y)$ be the maximal parabolic subgroup that preserves the space X, i.e., consisting of matrices, acting on columns, of the form

$$\begin{bmatrix} * & * \\ 0 & * \end{bmatrix}, \tag{1}$$

where the diagonal stars denote matrices of dimension $n+1$ and $m-n-1$, respectively. This contains the stabilizer H of ϕh, as the reader can easily show. The unipotent radical R of P (i.e., the top right $*$) acts trivially on ϕh and so belongs to H. Let L be the Levi subgroup of P consisting of block diagonal matrices. The lower block of matrices in L also acts trivially on ϕh. Therefore only the action of the upper block matters. Thus the stabilizer H has a Levi decomposition $L'R$, where $L' \subseteq L$ consists of matrices of the form

$$\begin{bmatrix} \alpha & 0 & 0 \\ 0 & C & 0 \\ 0 & 0 & D \end{bmatrix}, \tag{2}$$

where α is a nonzero constant, a multiple of C belongs to K, and $D \in SL(\bar{X})$, $\bar{X}$ being the complement of X in Y. Since ϕh is stable with respect to $SL(\hat{X})$, whose rank is one less than that of $SL(X)$, it is clear that ϕh is almost stable with respect to L with defect $\delta = 1$. □

Thus each $SL(\hat{X})$-stable point in $P(W)$ gives rise to a partially stable point in $P(V)$ with respect to $SL(Y)$-action with defect one. The partially stable points in all our applications will arise from stable points in this simple fashion. Notice that the $SL(Y)$-orbit of ϕy is a fiber bundle over G/P, which is just a Grassmanian in this case. In our applications, m will be typically polynomial in n, and so is the ratio Δ between the dimension of the $SL(Y)$-orbit and the dimension of the fiber. The

dimension of the fiber will be sufficiently large, in this sense, compared to that of the $SL(Y)$-orbit; the importance of this condition will become clear in sections 4 and 6.

Also notice that explicit decomposition of V as an $SL(\hat{X})$-module can be determined by successive applications of the Pieri formula for the branching rule. The point ϕh belongs to the unique irreducible $SL(\hat{X})$-module isomorphic to $\mathrm{Sym}^s(\hat{X}^*)$ in this decomposition, and it is (completely) stable in this module with respect to the $SL(\hat{X})$-action. This is another way of looking at partially stable points that would arise in our context.

3.3. Criterion for stability. Given a point $x \in V$, how can one effectively decide if it belongs to the null cone? This is rather important, because although the ring of invariants for a reductive group action on affine varieties is finitely generated, only in rare cases can one determine an explicit set of generators for this ring. For $SL_n(C)$, Hilbert [19] proved a remarkable criterion that quite often enables one to prove instability or semistability without explicitly writing down a single invariant. This criterion was generalized to arbitrary reductive groups over any characteristic by Mumford [36]. The resulting Hilbert–Mumford criterion is a powerful tool for proving semistability. Actually, Mumford proved the following more general result, which is what we shall need.

For any closed G-invariant subset S of V, define $x \in V$ to be S-unstable if the closure of the orbit $G.x$ meets S. In the preceding classical case, i.e., when x belongs to the null cone, S contains only the zero point of V. In general, if the orbit of x is not closed, the boundary of this orbit contains a unique closed orbit of minimum dimension. We can let S be this closed orbit, and then x is S-unstable. Mumford [36] proved that if x is S-unstable, then there is a one-parameter subgroup λ of G which drives x to S; i.e., the closure of the orbit $\lambda.x$ also meets S. Kempf [23] generalized this result significantly. His result will provide us the main technical tool for proving stability of various forms that arise in the context of lower bound problems.

Kempf's criterion for stability. Assume that G has no nontrivial central one-parameter subgroup. If the stabilizer of $y \in P(V)$ in G is not contained in any proper parabolic subgroup of G, then y is stable.

Kempf's other results relevant to us may be summarized as follows. Suppose $x \in V$ is S-unstable. Then we have the following:

1. One can identify a nonempty subset $\Delta_{S,x}$ of one-parameter subgroups λ which drive x to S "most rapidly."
2. With every one-parameter subgroup λ, there is associated a parabolic subgroup $P(\lambda)$ of G consisting of those elements $g \in G$ such that $\lim_{t\to 0} \lambda(t)g\lambda^{-1}(t)$ exists in G. Then there is a parabolic subgroup $P_{S,x}$ of G such that $P(\lambda) = P_{S,x}$ for all $\lambda \in \Delta_{S,x}$.
3. Every maximal torus of $P_{S,x}$ contains a unique element of $\Delta_{S,x}$.
4. If G' is the stabilizer of x in G, then $P_{S,x}$ contains G'.
5. If, in addition, the characteristic is zero, and H is a reductive subgroup of G fixing x, then there is an element of $\Delta_{S,x}$ contained in the centralizer $Z_G(H)$ of H in G. The result also holds in positive characteristic, provided G is an F-group, F a finite field, and the Levi decomposition holds for parabolic F-subgroups of G, as it will in our case.

3.4. Slice theorem. A powerful tool in the analysis of actions of reductive groups around orbits of stable points is Luna's étale slice theorem. Let x be a stable point in a linear representation V of a reductive group. Let H be the stabilizer of x, which is reductive [32]. Then the orbit Gx of x is isomorphic to G/H. Let T

denote the tangent space of the orbit at x; it has a natural H-action. Assume that the characteristic is zero. Since H is reductive, V has an H-module decomposition $T \oplus M$, where M can be thought of as a "normal" space at x. Luna's slice theorem says that the orbit $Gx = G/H$ has a neighborhood in V that looks like (or more precisely, has a finite sheeted covering by) the induced fiber bundle $G \times_H N$ for some algebraic H-subvariety $N \subseteq M$. Formally, the following result holds.

THEOREM 3.1 (see [27, 37, 38]). *There is an excellent map ϕ from $G \times_H N$ to a G-invariant Zariski-open neighborhood U of Gx.*

The map ϕ is called excellent (or strongly étale) if the induced map $\phi/G : G \times_H N/G \to U/G$ is étale and ϕ is obtained from ϕ/G by base extension. Here $G \times_H N$ is the quotient of $G \times N$ with respect to the action of H given by

$$h(g, n) = (gh^{-1}, hn).$$

It has a natural G-action induced by the G-action (left multiplication) on $G \times N$ via the translation of the first factor.

When the base field is the field of complex numbers, the slice theorem implies that the orbit Gx has an analytic neighborhood that is actually isomorphic as a G-variety to $G \times_H N$ for some analytic (but not necessarily algebraic) H-variety $N \subseteq M$; N is called the slice at x. The slice theorem also implies that if Q occurs as a stabilizer in the infinitesimal neighborhood of the orbit Gx, then some conjugate of Q is a subgroup of H. However, determining if some conjugate of a given $Q \subseteq G$ is a subgroup of another given $H \subseteq G$ is, in general, nontrivial. This problem can be handled using explicit obstructions as in section 5.

4. Formula size. In this section we illustrate our approach by addressing a concrete lower bound problem for the formula size over an algebraically closed field. Suppose we are given a homogeneous form $g(X)$ of degree d in the n-dimensional vector variable $X = (x_1, \ldots, x_n)$ over an algebraically closed field F of arbitrary characteristic. We want to know if $g(X)$ has a formula of poly(n) (polynomial in n) size, i.e., of size $\leq n^a$, for some fixed constant a. By the formula size we mean the number of arithmetic operators in the formula. The formula size of a function is a good indicator of its parallel complexity [11, 45].

For example, suppose $n = k^2$ for some k. Think of X as a $k \times k$ matrix; so we shall denote the entries of X by x_{ij} instead of x_i. Let $g(X)$ be the permanent function

$$g(X) = \text{perm}(X) = \sum_{\sigma} \prod_{i} X_{i\sigma(i)},$$

where σ runs over all permutations of size k. This formula for the permanent has size $k \cdot k!$. However, there is a nonobvious substantially smaller formula of size $O(2^{O(k)})$ [30]. Valiant [44] conjectured that the permanent does not have a formula of size polynomial in k. No nonlinear lower bound is known so far; cf. [15] for a linear lower bound.

We shall now reduce the general lower bound problem for the formula size to an instance of the orbit-closure problem in section 2. Let Y be an $m \times m$ variable matrix, where $m > n$. Identify X with any $n \times n$-submatrix $\phi(X)$ of Y. Use some entry y of Y not in $\phi(X)$ as a *homogenizing* variable. Then any homogeneous polynomial g of degree d on X can be trivially identified with a homogeneous polynomial g^ϕ of degree m in the entries of the variable Y, where $g^\phi(Y) = y^{m-d} g(\phi(X))$.

Let V be the vector space of homogeneous forms of degree m in Y. Let $P(V)$ be the associated projective space. Let W be the vector space of homogeneous forms of

degree d in X and $P(W)$ the associated projective space. Then the function ϕ, which maps g to g^ϕ, is an embedding of W ($P(W)$) in V (resp., $P(V)$).

Let $G = SL_{m^2}(F)$. It has a natural action on V. Specifically, any $\sigma \in SL_{m^2}(F)$ acts on an $h \in V$ as $(\sigma h)(Y) = h(\sigma^{-1}Y)$, where we think of Y as an m^2-vector, by linearly ordering its entries in any way, so that the $m^2 \times m^2$-matrix σ^{-1} acts on Y in the usual way. This induces a natural action on $P(V)$ as well. The space V (and $P(V)$) contains the determinant form $\det(Y)$. Let $G(\det(Y)) \subseteq P(V)$ denote the orbit of $\det(Y)$ under this action (thinking of $\det(Y)$ as an element of $P(V)$.) Let $\Delta[\det(Y)]$ denote its Zariski closure in $P(V)$.

PROPOSITION 4.1. *If $f(X)$ has a formula of size l, then $f^\phi(Y)$ lies in the projective orbit closure $\Delta[\det(Y)]$ of the determinant, where $m = \dim(Y) = 2l$.*

Proof. We use the well-known fact that the determinant is a complete function for the class of polynomials having small formulae [11, 45]. Formally [45], if $f(X)$ had a formula of size l, there would exist a matrix M of size at most $2l$, whose each entry is either a constant or some entry x_{ij} of X such that

$$f(X) = \det(M).$$

If we identify the entries x_{ij} with the entries of the submatrix $\phi(X)$ of Y, and multiply each constant entry in M with the variable y of Y not in $\phi(X)$, we get a possibly singular matrix whose each entry is a linear combination of the entries of Y. In other words, we get a possibly singular linear transformation $A : F^{m^2} \to F^{m^2}$, where $m \leq 2l$, such that

$$f^\phi(Y) = \det(AY), \tag{3}$$

where Y is treated as an m^2-vector as above. However, $GL_{m^2}(F)$ is dense in the space of all linear transformations from F^{m^2} to itself. Therefore $f^\phi(Y)$ is in the closure of the $GL_{m^2}(F)$-orbit of $\det(Y)$ in V. The proposition follows from this. □

Thus we are led to the following instance of the orbit closure problem in section 2.

The orbit-closure problem. Can $f(Y) = \mathrm{perm}^\phi(Y)$ lie in the projective orbit closure $\Delta[\det(Y)]$ of $g(Y) = \det(Y)$ in $P(V)$?

The orbit-closure problem can in turn be reduced to an instance of the stabilizer problem in section 2. Towards that end, let us compute the stabilizer R of $\det(Y)$ in $G = SL_{m^2}(F)$. It is known to be a reductive subgroup which consists of linear transformations in G of the form (thinking of Y as an $m \times m$ matrix)

$$Y \to AY^*B^{-1}, \tag{4}$$

where Y^* is either Y or Y^T, $A, B \in GL_m(F)$. The determinant is completely characterized by its stabilizer in the following sense.

PROPOSITION 4.2. *Every form $h(Y) \in V$ stabilized by R is a multiple of* $\det(Y)$.

Proof. The proof is easy.

Now the preceding orbit-closure problem for the determinant can be reduced as in section 2 to the following.

The stabilizer problem. Can R occur as a stabilizer in the infinitesimal neighborhood of the $SL_l(F)$-orbit of $\mathrm{perm}^\phi(Y)$ in V?

We conjecture that this cannot happen if $m = \mathrm{poly}(n)$. Formally, we conjecture the following.

CONJECTURE 4.3. *If $m = n^a$, where a is any fixed constant, then $\mathrm{perm}^\phi(Y)$ cannot lie in the projective orbit closure $\Delta[\det(Y)]$. More specifically, R cannot occur*

as a stabilizer in the infinitesimal neighborhood of the $SL_l(F)$-orbit of $\text{perm}^\phi(Y)$ in V.

By Proposition 4.1, this would imply that the permanent does not have a formula of size polynomial in n. In section 5 we shall suggest an approach to this conjecture based on the construction of so-called explicit obstructions. The conjecture is not equivalent to the the original lower bound question (cf. section 4.2). However, it is "almost" equivalent in the following sense.

PROPOSITION 4.4. *Suppose F is the field of complex numbers. If Conjecture* 4.3 *were false, then $\text{perm}(X)$ can be approximated infinitesimally closely by a formula of quasi-polynomial $n^{O(\log n)}$ size (in the sense that the coefficients of the polynomial computed by this formula would be infinitesimally close to those of the permanent).*

Proof. If the conjecture were false, $\text{perm}^\phi(Y)$ lies in the closure of the SL_{m^2}-orbit of $\det(Y)$ in $P(V)$ with $m = \text{poly}(n)$. This means that, as a point in V, it lies in the closure of the GL_{m^2}-orbit of $\det(Y)$. Therefore it can be approximated infinitesimally closely by a function of the form $\det(\sigma^{-1}Y)$ for some $\sigma \in GL_{m^2}$. Let us ignore the terms in this approximation that involve variables other than y or entries of $X = \phi(X)$, which cannot occur in $\text{perm}^\phi(Y)$; i.e., think of setting these variables of Y to zero. What remains is still an approximation to $\text{perm}^\phi(Y)$. Setting y to one, we get an infinitesimally close approximation to $\text{perm}(X)$ by a function of the form $\det(W)$, where W is an $m^2 \times m^2$-matrix whose each entry is a (possibly nonhomogeneous) linear combination of the entries of X. However, such a function $\det(W)$ has a formula of size $m^{O(\log m)} = n^{O(\log n)}$ [2]. □

However, such an approximation is not expected in view of Valiant's completeness result for the permanent [44]. This provides a good support for the conjecture.

As we remarked in section 2, the general orbit-closure or the stabilizer problem seems intractable if f and g were arbitrary forms. The situation is better here because they have the following nice properties: (1) g is stable and f is partially stable (section 4.1), and (2) both have large nontrivial stabilizers that capture their structure (Propositions 4.2 and 4.5).

We have already seen that $\det(Y)$ has a large characteristic stabilizer (Proposition 4.2). Now let us turn to $\text{perm}(X)$, where the dimension of X is k. Assume that the characteristic is not equal to two. (Otherwise the permanent is equal to the determinant.) X can also be thought of as an n-vector, where $n = k^2$. Consider the natural action of $SL_n(F)$ on the projective space $P(W)$ of forms in X of degree k. Then the stabilizer K of $\text{perm}(X)$ in $SL_n(F)$ is generated [30] by linear transformations of the form (thinking of X as a $k \times k$ matrix)

$$X \to \lambda X \mu^{-1}, \tag{5}$$

where λ and μ are either diagonal or permutation matrices, and $k \geq 3$. The connected component K^0 of K is a $(2k-1)$-dimensional torus.

The following is an analogue of Proposition 4.2 that says that the permanent is completely characterized by its stabilizer.

PROPOSITION 4.5. *Every form $h(X) \in W$ stabilized by K is a multiple of $\text{perm}(X)$.*

Proof. The proof is easy.

4.1. Stability. Now we turn to the issue of stability.

THEOREM 4.1. *The point $\det(Y) \in P(V)$ is stable with respect to the action of $G = SL_{m^2}(F)$ on $P(V)$, where V is the space of homogeneous forms of degree m in Y.*

Proof. The stabilizer R of $\det(Y)$ is not contained in any parabolic subgroup of G because its representation over the space of $m \times m$ matrices given by (4) is irreducible. Therefore stability follows from Kempf's criterion [23] (cf. section 3). □

Remark. Stability of $\det(Y)$ is not needed in our approach to Conjecture 4.3 in section 5; only the stability of $\mathrm{perm}(X)$ is needed. However, stability of $\det(Y)$ is needed in other problems, where the determinant plays the role of f in the orbit-closure problem, e.g., in the NC^1 vs. NC^2 problem [11].

THEOREM 4.2. *The point* $\mathrm{perm}(X) \in P(W)$, *where* $\dim(X) = k$, *is stable with respect to the action of* $SL_n(F)$ *on* $P(W)$, *where* $n = k^2$.

Proof. The stabilizer of $\mathrm{perm}(X)$ in $SL_n(F)$ is, again, not contained in a proper parabolic subgroup because the space of $n \times n$ matrices is an irreducible representation. Therefore the assertion again follows from Kempf's criterion (section 3).

We shall also give another proof based on the property (5) of Kempf's one-parameter subgroups (cf. section 3.3) because it illustrates in a simple setting an idea that will be used later (section 8) in proving the stability of another form. This second proof ignores the discrete part of the stabilizer.

Let $\mathcal{X}$ be the vector space whose coordinates are the entries x_{ij} of X. It is a representation of K^0 as given by (5). Let E_{ij} be the one-dimensional vector space of all matrices with the only nonzero entry in the (i,j)th spot. It is easy to check that $\mathcal{X}$ decomposes as a K^0-module into $\oplus_{i,j} E_{i,j}$ and that this representation is multiplicity-free; i.e., all characters are distinct. Now assume that $\mathrm{perm}(X)$ is not stable. Let S be an $SL_n(F)$-orbit of minimum dimension in the closure of the orbit of $\mathrm{perm}(X)$ in V. It must be closed; cf. Borel [4]. In fact, since $SL_n(F)$ is reductive, and hence geometrically reductive (cf. Haboush [17]), there is a unique closed orbit S in the closure of the orbit of $\mathrm{perm}(X)$ in V.

By Kempf's result, there would be a one-parameter subgroup $\lambda : F^* \to SL_n(F)$ which drives $\mathrm{perm}(X)$ into S and which commutes with K^0. Schur's lemma forces the action of $\lambda(t)$ on $\mathcal{X}$ to be of the form

$$e_{i,j} \to t^{\alpha_{i,j}} e_{i,j},$$

where $e_{ij} \in E_{ij}$ and α_{ij} is an integer. We also have the constraint that $\sum_{i,j} \alpha_{i,j} = 0$ because $\lambda(t) \in SL_n(F)$. The effect of $\lambda(t)$ on any monomial $m_\sigma = \prod_{i=1}^m x_{i,\sigma(i)}$ in the expansion of $\mathrm{perm}(X)$ is as follows:

$$m_\sigma \to t^{\sum \alpha_{i,\sigma(i)}} m_\sigma.$$

Thus for $\lim_{t \to 0} \lambda(t)(m_\sigma)$ to exist, $\sum_{i=1}^k \alpha_{i,\sigma(i)}$ must be nonnegative for every permutation on $[k]$ (since there is no cancellation across monomials). This is possible only when each sum is actually zero, as can be seen using Hall's theorem that every regular bipartite graph is a disjoint union of perfect matchings. Thus if $\lim_{t \to 0} \lambda(t)(\mathrm{perm}(X))$ exists, then it is $\mathrm{perm}(X)$ itself. In other words, $\mathrm{perm}(X)$ cannot be S-unstable for any G-invariant closed S. □

In contrast, the point $\mathrm{perm}^\phi(Y) \in P(V)$ is not stable with respect to the action of $G = SL_{m^2}(F)$. In fact, it belongs to the null cone; this can be shown using the Hilbert–Mumford criterion [37]. However, the following result holds.

THEOREM 4.3. *The point* $\mathrm{perm}^\phi(Y) \in P(V)$ *is partially stable with respect to the action of* $G = SL_{m^2}(F)$ *with defect* $\delta = 1$.

Proof. If $h \in P(W)$ is stable, then $h^\phi \in P(V)$ is partially stable with defect $\delta = 1$, arguing exactly as in Example 3.2. Specifically, X and Y are now matrices instead of

vectors, and the homogenizing variable is y here instead of x_0. The parabolic group P consists of the linear transformations that transform the variables in Y to their linear combinations. The Levi subgroup $L \subseteq P$ consists of the linear transformations that transform the variables in Y and $X \setminus Y$ to the linear combinations of the variables in Y and $X \setminus Y$, respectively. The subgroup $L' \subseteq L$ consists of the linear transformations that transform y to its constant multiple, and the variables in Y and $X \setminus (Y \cup \{y\})$ to the linear combinations of the variables in Y and $X \setminus (Y \cup \{y\})$, respectively.

The partial stability of $\mathrm{perm}^{\phi}(Y)$ then follows from Theorem 4.2. □

The SL_{m^2}-orbit Z of $\mathrm{perm}^{\phi}(Y)$ in V is a fiber bundle over G/P, where P is similar to the one in (1), and so G/P is a Grassmanian variety. The fiber is isomorphic to the SL_{n^2}-orbit of $\mathrm{perm}(X)$ in W. The stabilizer H of $\mathrm{perm}^{\phi}(Y)$ is related to the stabilizer K of $\mathrm{perm}(X)$ just as in (2). The dimension of Z is equal to $\dim(SL_{m^2}) - \dim(H)$, and that of the fiber W is $\dim(SL_{n^2}) - \dim(K)$. In our problem, m is not too large compared to n; in fact, it is polynomial in n. Hence the dimension of the global orbit Z is also polynomial in the dimension of the fiber. The parameters δ and Δ in the definition of partial stability (section 3) that measure deviation from complete stability are not too large: we have $\delta = 1$ and $\Delta = \mathrm{poly}(n)$. Roughly, this says that although $\mathrm{perm}^{\phi}(Y)$ belongs to the null cone, it is not "too unstable."

Remark. The role of the determinant in this section can also be played by the trace: specifically, the analogues of Proposition 4.1 and Theorem 4.1 hold for $\mathrm{trace}(Y^m)$ as well.

4.2. Exterior limit points. Here we shall indicate why Conjecture 4.3 is expected to be somewhat stronger than the original lower bound question for the formula size of the permanent. It is because $\Delta[\det(Y)]$ may contain points that do not have polynomial size formulae. Let $g = \det(Y)$. We call a point in $\Delta[g]$ an *interior limit point* if it is of the form $\det(\sigma Y)$ for some *possibly singular* linear transformation σ. In other words, the set of interior points is the image of the map $\alpha : M_{m^2}(F) \to \Delta[g]$, where $M_{m^2}(F)$ is the set of $m^2 \times m^2$-matrices over F, and α maps a possibly singular matrix $\sigma \in M_{m^2}(F)$ to $\det(\sigma Y)$. This image is a constructible subset [18] of $\Delta[g]$; i.e., it is a finite disjoint union of locally closed subsets. However, it is not expected to be equal to $\Delta[g]$. The points of $\Delta[g]$ not in this image will be called *exterior limit points*. Interior limit points have formulae of quasi-polynomial size (see the proof of Proposition 4.4), whereas exterior limit points need not.

We now describe some classes of conjectured exterior limit points in $\Delta[g]$. Formally proving that a given point is an exterior limit point amounts to showing that it does not have a formula of $\Omega(\mathrm{poly}(n))$ size because the determinant is complete for the class of polynomials with small formulae; cf. the proof of Proposition 4.1. This is a lower bound problem in itself, beyond our reach at present.

If f is an interior limit point of $\Delta[g]$, then $f = \det(\sigma Y)$, where σ is possibly singular. Since diagonalizable matrices are dense in $M_{m^2}(F)$, it follows that some conjugate f' of f is of the form $\beta(g')$, β is diagonal, and g' is some conjugate of g. Let $\beta(t)$ be the one-parameter subgroup obtained by replacing the zero diagonal entries of β by t. Then $\beta = \lim_{t \to 0} \beta(t)$. We shall now give an example of a point f in $\Delta[g]$, which is of the form $\lim_{t \to 0} \det(\alpha(t)Y)$ for some one-parameter group $\alpha(t)$, but it is not expected to be of the form $\beta(g)$, where $\beta = \lim_{t \to 0} \beta(t)$ for some one-parameter group $\beta(t)$.

Let G be a nonbipartite graph on m vertices whose edges have nonnegative integer weights. Consider its skew-symmetric Tutte matrix M whose (i,j)th entry M_{ij}, $i < j$, is the variable y_{ij} if G has an edge joining vertices i and j and zero otherwise. We

have

$$\det(M) = \sum_{\pi} \operatorname{sign}(\pi)\operatorname{wt}(\pi),$$

where π ranges over all permutations of $[1, \ldots, m]$, and $\operatorname{wt}(\pi)$ is the product of the entries $M_{i\pi(i)}$. Define the cycle graph of π with nonzero weight to be the subgraph of G formed by the edges $(i, \pi(i))$. Then it is known and easy to see that

$$\det(M) = \sum_{\pi'} \operatorname{sign}(\pi')\operatorname{wt}(\pi'), \tag{6}$$

where π' ranges over only those permutations with nonzero weight whose cycle graphs contain only cycles of even length. The contributions of other permutations cancel out.

Construct a modified Tutte matrix $\tilde{M}$ by replacing every variable y_{ij}, if it indeed occurs in M, by $t^{w_{ij}} y_{ij}$, where t is an indeterminate parameter and w_{ij} is the weight of the edge joining the nodes i and j. In other words, $\tilde{M} = \beta(t)(M)$, where $\beta(t)$ is the one-parameter subgroup that maps such y_{ij} to $t^{w_{ij}} y_{ij}$. Let Y be the vector of the variables y_{ij}. Then (6) implies that

$$D(Y) = \det(\tilde{M}) = t^{2W} h(Y) + \text{higher order terms in } t,$$

where W is the weight of a minimum-weight perfect matching in G and

$$h(Y) = \sum_{\pi} \operatorname{sign}(\pi)\operatorname{wt}(\pi),$$

where π ranges over all permutations with nonzero weight whose cycle graphs can be decomposed as the union of two minimum-weight perfect matchings, not necessarily distinct. Clearly, $D(Y) = \det(\tilde{M})$ belongs to the projective orbit closure $\Delta[\det(Y)]$ for every t. Projectively, $D(Y)$ is equal to $h(Y)$ plus higher order terms in t. Since

$$h(Y) = \lim_{t \to 0} t^{-2W} D(Y),$$

in the projective space $P(V)$, we have

$$h(Y) = \lim_{t \to 0} D(Y) = \lim_{t \to 0} \det(\beta(t)M).$$

In other words, $h(Y)$ belongs to the projective closure $\Delta[\det(Y)]$; notice, however, that $\det(\beta M)$, $\beta = \lim_{t \to 0} \beta(t)$, is not well defined in the projective space $P(V)$. We conjecture that for every m there are weighted graphs G such that $h(Y)$ does not have a small polynomial size formula. This would imply that $h(Y)$ is an exterior point of $\Delta[\det(Y)]$, since the determinant is complete for the class of polynomials with small formulae.

For most weight assignments on the edges of G, there is a unique minimum-weight perfect matching (this follows from the so-called isolation lemma [35]), which means $h(Y)$ contains just one monomial, and hence surely has a small formula. What the conjecture says is that there exist pathological weighted graphs. Nonbipartiteness of G is essential here. Because if G is bipartite, then for any weight-assignment on G consider the subgraph G' formed by the union of all minimum-weight perfect matchings in G. It easily follows from Hall's theorem that the set of perfect matchings

in G' is equal to the set of minimum-weight perfect matchings in G. Therefore $h(Y)$ for G is equal to the determinant of the Tutte matrix for G' and thus has a small formula [2].

Though $h(Y)$ is an exterior limit point, it can be approximated infinitesimally closely by a formula of quasi-polynomial size (Proposition 4.4), whereas this is not expected for the permanent because of its completeness.

5. Explicit obstructions. Let V be a linear representation of a reductive group G and $P(V)$ be the associated projective space. A nonzero point $v \in V$ also corresponds to a point in $P(V)$. By abuse of notation, we denote the corresponding point in $P(V)$ by v as well. Suppose we are given two explicit points $f, g \in V$, and the goal is to show that that f is not in the closure of the G-orbit of g in the projective space $P(V)$. Conjecture 4.3 is a special case of this problem, where V is the space of homogeneous forms of degree m in the entries of an $m \times m$ variable matrix Y, $f = \text{perm}^{\phi}(Y)$, $g = \det(Y)$, and $G = SL(Y)$. Here f lies in the closure of the G-orbit of g in $P(V)$ iff it lies, considered as a point in V, in the closure of the $GL(Y)$-orbit of g in V.

We call a mathematical structure an *obstruction* for the pair (f, g) if its existence acts as a guarantee that f does not lie in the closure $\Delta[g]$ of the G-orbit of g in the projective space $P(V)$.

5.1. Polynomials as obstructions. Let Z denote the closure of the G-orbit of g in $P(V)$. Let $I(Z)$ denote the ideal of polynomial functions vanishing on Z. Any polynomial in $I(Z)$ that does not vanish at f is an obstruction for the pair (f, g) because it vanishes on the orbit of g but not on the orbit of f. We say that it *separates* the two orbits. If f does not lie in Z, then "almost every" polynomial in $I(Z)$ is an obstruction. In the setting of Conjecture 4.3, where $g = \det(Y)$ and $f = \text{perm}^{\phi}(Y)$, it is thus expected that almost every polynomial in $I(Z)$ will be an obstruction for the pair (f, g) when m is polynomial in n. To prove Conjecture 4.3 it suffices to construct an obstruction for every such m and n. Even though we know, assuming Conjecture 4.3, that such obstructions exist in plenty, the problem is such that one has to prove their existence by constructing them more or less *explicitly*.

One approach to constructing an explicit polynomial obstruction is to construct an explicit set of generators of $I(Z)$ and then isolate a generator that does not vanish at f. This problem is addressed in Part II [34], where we give a sufficiently explicit set Σ_g of generators for the ideal of the G-orbit of g in the affine space V, assuming that g is stable and has a "nice" stabilizer, and conjecture that this set actually generates $I(Z)$ for g's that arise in the context of the lower bound problems in this paper. The generators in Σ_g are quite complex and verifying that one of them does not vanish at f is a difficult task. However, they have nice representation-theoretic properties. In Part II we develop in detail an approach to the orbit-closure problem via explicit construction of obstructions based on these properties.

Here we wish only to indicate how representation theory comes into play by briefly considering explicit construction of obstructions in the context of the related stabilizer problem. The scheme for explicit construction suggested here depends on the representation-theoretic properties of the stabilizers of f and g, and serves as a starting point for the work in Part II.

Specifically, the scheme will exploit the fact that, in our context, f is partially stable (cf. Theorem 4.3) and both f and g have nontrivial reductive stabilizers that capture their structure (Propositions 4.5 and 4.2); g may or may not be stable. The

obstructions that one hopes to construct this way are not polynomials but rather representations having certain properties (cf. Theorems 5.1 and 5.2).

5.2. Representations as obstructions. In this section, we shall present our scheme when f is (completely) stable with respect to the G-action. In section 5.5 we shall suggest an extension of this scheme to the case when f is only partially stable as in Conjecture 4.3. There we shall also point out the main problems that are encountered in such an extension.

When f is stable, obstructions based on representations can be constructed using the following immediate consequence of Luna's slice theorem.

THEOREM 5.1 (characteristic zero). *Let $H \subseteq G$ be the stabilizer of $f \in V$ and $Q \subseteq G$ the stabilizer of $g \in V$. Suppose f is stable with respect to the action of G. Then a (nonzero) representation W of G is an obstruction for the pair (f, g) if W contains a trivial H-submodule but not a trivial Q-submodule. In other words, if such a W exists, then f cannot lie in the closure of the G-orbit of g in the projective space $P(V)$. More generally, W is an obstruction for (f, g) if the multiplicity of the trivial H-representation within W exceeds that of the trivial Q-representation.*

Proof. Since f is stable, by Luna's slice theorem (section 3), there is a slice N at f, a G-invariant neighborhood U of the orbit Gf, and a map $\tau : G \times_H N \to U$ that is excellent. This implies that (cf. [38]) the stabilizer of any point in U is a conjugate of a subgroup of H.

Suppose, to the contrary, that f, considered as a point in $P(V)$, lies in the closure of the G-orbit of g in $P(V)$. Then the neighborhood U must contain a point p whose some multiple p' lies in the G-orbit of g in the affine space V. The stabilizer of p is equal to the stabilizer of p', which is a conjugate of the stabilizer Q of g. Since some conjugate of the stabilizer of p is contained in H, it follows that some conjugate of Q is contained in H. Hence the multiplicity of the trivial Q-representation in any G-module must exceed that of the trivial H-representation.

Therefore if there exists a G-module W such that the multiplicity of the trivial H-representation within W exceeds that of the trivial Q-representation, then f cannot lie in the closure of the orbit of g in $P(V)$. □

Second proof. We now prove the first criterion of Theorem 5.1 (though not the second) without using Luna's slice theorem but using Peter–Weyl theorem instead; the idea in this proof will be useful later in section 5.5. We shall denote the algebraically closed base field of characteristic zero by k. Because Gf is a closed affine subvariety of V and the characteristic is zero,

$$k[V] = k[Gf] \oplus I, \tag{7}$$

as a G-module, where I is the G-invariant ideal of Gf. Thus $k[Gf] = k[G/H]$ can always be embedded equivariantly within $k[V]$. Now we shall determine an explicit G-module decomposition of the ring $k[G/H]$. First, consider $k[G]$, the ring of regular functions on G, as a $G \times G$ module by letting one copy of G act on it by left translations and the other by right translations. Then $k[G]$ has the following decomposition as a $G \times G$ module [6]:

$$k[G] = \sum_P P \otimes \bar{P}, \tag{8}$$

where P runs over all finite-dimensional G-modules, and $\bar{P}$ is its dual. This follows by applying the Peter–Weyl theorem to the Hilbert space $L_2(K)$ of L_2-functions on

a maximal compact subgroup K of G and using the fact that the K-finite vectors in $L_2(K)$ correspond to the regular polynomial functions on G; cf. [6, 22]. Since f is stable, H is reductive [32]. Then $k[G/H]$ is simply the ring of $k[G]^H$ of (right) H-invariants within $k[G]$ [37]. Therefore the decomposition in (8) implies that

$$k[Gf] = k[G/H] = \sum_P P \otimes \bar{P}^H, \tag{9}$$

where P runs over all finite-dimensional G-modules, $\bar{P}^H$ is the sum of all trivial H-submodules of $\bar{P}$, and G acts on the first factor of $P \otimes \bar{P}^H$.

Let W be an irreducible representation containing a trivial H-module but not a trivial Q-module. It can be equivariantly embedded within $k[G/H] = k[Gf]$, by (9), and hence within $k[V]$ by (7). Thus each element in W corresponds to a polynomial function on V. Now suppose to the contrary that the G-orbit of f in $P(V)$ lies in the projective closure $\Delta[g]$ of the G-orbit of g in $P(V)$. Not all functions in W can vanish on the affine cone C in V corresponding to the G-orbit of g in $P(V)$ because then they will also vanish on the affine cone in V corresponding to $\Delta[g]$, and hence on the G-orbit of f in V, since $f \in \Delta[g]$. But this is impossible since W is a nonzero submodule of $k[Gf]$. Therefore W contains at least one function ϕ which does not vanish at some point of the cone C, say, p. The stabilizer $Q_p \subseteq G$ of p is conjugate to the stabilizer Q of g. Let $W_\phi \subseteq W$ be the Q_p-submodule generated by ϕ. Consider the evaluation map from W_ϕ to k, which maps any function in W_ϕ to its value at p. Since ϕ is nonzero at p, this evaluation map is nonzero. It is also equivariant with respect to the Q_p-action. Since k is the trivial Q_p-representation, and the characteristic is zero, W_ϕ, as a Q_p-module, contains a trivial Q_p-submodule, and so does W. Since W is a G-module and Q_p is a conjugate of Q in G, it follows that W must contain a trivial Q-module; a contradiction. □

To use the obstruction criterion in this theorem effectively, one needs an explicit formula for the dimension of the trivial H (or Q) representation within a G-module W. This is an instance of the subgroup restriction problem, which will also arise later (section 5.5).

5.2.1. Example 1. Let X be the variable matrix of size d, $V = \mathrm{Sym}^d(X)$, the space of forms in X of degree d, and $G = SL(X) = SL_{d^2}(\mathbb{C})$. Let $f = \mathrm{perm}(X)$ and $g = \det(X)$ with stabilizers H and Q, respectively. We want to show that f is not in the closure of the G-orbit of g in $P(V)$.

In the present case, this can be shown by only dimension considerations. Indeed, if f were in the closure of the G-orbit of g in $P(V)$, then by Luna's slice theorem some conjugate of Q will be contained within H. However, since the dimension of Q exceeds that of H this is not possible.

However the dimension-based criterion seems too crude to be generalized to the partially stable case. Because when $(f, g) = (\mathrm{perm}^\phi(Y), \det(Y))$ as in Conjecture 4.3, the dimension of the stabilizer of f is far greater than that of g when m is only mildly larger than n. On the other hand, representations as obstructions, as in Theorem 5.1, seem suited even for the partially stable case (section 5.5). With that in mind, we construct an obstruction for the pair (f, g) using Theorem 5.1, which is applicable since $f = \mathrm{perm}(X)$ is stable with respect to the action of $G = SL(X)$ (Theorem 4.2).

Let $W = Sym^r(X)$ be the G-module of homogeneous polynomials of degree r in the entries of X, where r is a multiple ad of d for some integer $a > 1$. The multiplicity of the trivial H-representation in W exceeds one, because $\mathrm{perm}(X)^a \in W$ is fixed by

H, and so is the permanent of the matrix obtained by replacing each entry of X by its ath power. As a Q-module [7]

$$W = \sum_{\lambda} S_\lambda \otimes \bar{S}_\lambda,$$

where λ ranges over all Young diagrams of size r with at most d rows or columns, S_λ denotes the corresponding Weyl module, and $\bar{S}_\lambda$ denotes its dual. Here the elements in Q of the form (A, B), $A, B \in GL_d$, $\det(AB^{-1}) = 1$, act on $S_\lambda \otimes \bar{S}_\lambda$ in the obvious manner, and the transpositions in Q interchange the two factors. When $r = ad$, $S_\lambda \otimes \bar{S}_\lambda$ is trivial as a Q-module precisely when λ is rectangular with d rows and a columns. Hence the multiplicity of the trivial Q-module in W is precisely one. This trivial module is generated by $\det^a(X)$. By Theorem 5.1, any $\mathrm{Sym}^r(X)$, $r = ad$, $a > 1$, is an obstruction for the pair (f, g).

The preceding obstructions were constructed using the second multiplicity-based criterion of Theorem 5.1. It would be interesting to construct obstructions using the first criterion based on absence or presence of trivial representations. Specifically, it would be interesting to construct a representation W, for each d, such that W contains a trivial H-representation but not a trivial Q-representation. For this one needs to know how a given G-representation W splits when considered as a Q-module or as an H-module. Q contains a copy of $SL_d \otimes SL_d$, and H contains a copy of $S_d \times S_d$, where S_d is the symmetric group. Hence this problem is closely linked to the so-called plethysm problem of representation theory. This asks for explicit decomposition of $S_\lambda(V \otimes W)$ as a $GL(V) \times GL(W)$-module and that of $S_\lambda(S_\mu V)$ as a $GL(V)$-module, where S_λ is the Schur-functor [14].

5.3. Importance of stability. The stability of f is crucial for Theorem 5.1 to hold. Otherwise, the first proof does not apply because Luna's slice theorem may fail when f is not stable even if the stabilizer H of f is reductive (cf. Example 2 below). The second proof also fails when f is not stable because it may not be possible to extend the functions in the module $W \subseteq k[Gf] = k[G/H]$ there equivariantly to the whole of V, since Gf is not closed. It may happen that $k[V]$ contains a G-submodule W that contains a trivial H-representation but not a trivial Q-representation. That still does not guarantee that W is an obstruction because all functions in W may vanish identically on the the affine cones in V corresponding to the G-orbits of g and f in $P(V)$. In other words, an abstract representation W need not be an obstruction even if it contains a trivial H-module but no trivial Q-module. However, such a W becomes an obstruction if it has a concrete realization as a G-submodule of $k[V]$ that does not vanish when restricted to the G-orbit of f in V. When this happens (as it does when f is stable), a slight modification of the argument in the second proof of Theorem 5.1 shows that it contains a function that separates the orbits of f and g, i.e., vanishes on the orbit of g but not on the orbit of f, though such a separating function is not explicitly constructed. Thus representation-based obstructions provide an indirect way of constructing—or more precisely, guaranteeing the existence of—separating functional obstructions as in section 5.1.

5.3.1. Example 2. We give a simple example that demonstrates why stability of f is crucial for Theorem 5.1 to hold. Let V be the space of forms of total degree 3 in variables x and y, and $G = SL_2$. Let $f = x^2y$, and $g = x^3 + y^3$ [38]. Then it is easy to show that f lies in the projective closure $\Delta[g]$ of the G-orbit of g in $P(V)$. (The G-orbit of g in $P(V)$ is three-dimensional, and that of f is two-dimensional, since the

G-stabilizer of the line in V containing f and the origin is one-dimensional.) The stabilizer $H \subseteq G$ of f for the G-action on V is trivial, hence reductive, but f is not stable for the G-action. The stabilizer Q of g is equal to $\{\mathrm{diag}(\epsilon, \epsilon^{-1}) | \epsilon^3 = 1\}$. Since H is trivial, any G-representation contains a trivial H-representation. Now there are G-representations which do not contain a trivial Q-representation, e.g., the standard representation. Yet none of these is an obstruction for the pair (f, g), since we already know that f lies in $\Delta[g]$.

5.4. Positive characteristic.

THEOREM 5.2. *With the same terminology as in Theorem* 5.1*, suppose, in addition, that the orbit map is separable and that the ambient space V has an H-module decomposition in which the tangent space of the orbit Gf at f splits off as a direct summand. Then the obstruction criterion given there holds.*

Here, by multiplicity of the trivial H- or Q-representation in W, we now mean the total dimension of the sum of such trivial submodules of W. This need not be equal to the number trivial quotients in a Jordan-series filtration of W, since, in positive characteristic, W need not decompose into irreducible Q- or H-submodules.

Proof. Luna's slice theorem holds in arbitrary characteristic if the orbit map is separable and V has an H-module decomposition as above [1]. Therefore the proof of Theorem 5.1 holds. □

This points out the issues that arise in positive characteristic because of the lack of linear reductivity.

5.5. Partially stable case. In the preceding section we gave a method (Theorem 5.1 and 5.2) for constructing representation-theoretic obstructions for the pair (f, g) when f is stable. We now suggest an extension of this approach to produce obstructions when f is only partially stable. The setting in Conjecture 4.3 falls in this category. Let H denote the stabilizer of f. Let Q denote the stabilizer of g; we assume that it is reductive.

Let α denote the embedding of the orbit $Z = Gf$ in the ambient space V. Let $\mathcal{O}_V$ denote the sheaf of *analytic* functions on V. Let $\mathcal{O}_V^Z = \alpha^{-1}\mathcal{O}_V$ denote the inverse image sheaf on Z (cf. Hartshorne [18]). The stalk of $\mathcal{O}_V^Z$ at any point $z \in Z$ coincides with the stalk of $\mathcal{O}_V$ at z. The global sections, i.e., the elements of $H^0(Z, \mathcal{O}_V^Z)$, of this sheaf correspond to germs of analytic functions that are defined in some analytic open neighborhood of Z in V. The space $H^0(Z, \mathcal{O}_V^Z)$ is a G-module in a natural way.

We denote the algebraically closed base field by k in this section.

PROPOSITION 5.1. *Assume that the characteristic is zero. Let W be any finite-dimensional G-module in $H^0(Z, \mathcal{O}_V^Z)$ that does not vanish identically under the (natural) restriction to Z. Then W is an obstruction for the pair (f, g) if it does not contain a trivial Q-representation.*

Proof. Fix such a G-module W that does not vanish when restricted to Z. Since the G-action on Z is transitive, there exists a global section $\phi \in W$ that does not vanish at f when restricted to Z. Let U_ϕ be an analytic neighborhood of Z in V on which ϕ is well defined. Suppose to the contrary that the closure of the G-orbit of g in $P(V)$ contains f. Then U_ϕ contains a point p arbitrarily close to f whose multiple $\hat{p}$ lies in the G-orbit of g in the affine space V. Choose p close enough to f so that ϕ does not vanish at p. The stabilizer of p is the same as that of $\hat{p}$, which in turn is equal to the conjugate Q^α of Q for some $\alpha \in G$. Consider any $\beta \in Q^\alpha$. The function $\beta(\phi)$ is defined in the neighborhood $\beta(U_\phi)$ of Z which contains p, since it is fixed by β. Thus all functions in the Q^α-submodule $W_\phi \subseteq W$ generated by ϕ are well defined at p. Consider the evaluation map from W_ϕ to k, which maps any function

in W_ϕ to its value at p. Since ϕ is nonzero at p, this evaluation map is nonzero. It is also equivariant with respect to the Q^α-action. Since k is a trivial Q-representation, and the characteristic is zero, W_ϕ contains a trivial Q^α-module in its decomposition into irreducible Q^α-modules, and so does W. Since W is a G-module and $\alpha \in G$, its decomposition into irreducible Q-modules also contains a trivial Q-module. □

To construct an obstruction using this proposition, one needs to calculate explicitly an interesting family of finite-dimensional G-submodules within $H^0(Z, \mathcal{O}_V^Z)$. When f is stable, one gets such a family as follows.

THEOREM 5.3. *Suppose $k = \mathbb{C}$, and f is stable. Then every irreducible G-representation W that contains a trivial representation as an H-module occurs in $H^0(Z, \mathcal{O}_V^Z)$ (with multiplicity at least equal to the multiplicity of the trivial H-representation in W).*

Proof. By Luna's slice theorem (section 3), the orbit $Gf \cong G/H$ has an analytic G-invariant neighborhood of the form $G \times_H N$, where N is an analytic slice at f. This implies that any function $\phi \in k[Gf]$ can be extended canonically to a function $\bar{\phi}$ on this neighborhood so that it is constant on the slice at any point of the orbit. This extension is G-equivariant. Therefore we get a canonical G-equivariant embedding of $k[Gf] = k[G/H]$ in $H^0(Z, \mathcal{O}_V^Z)$. The Peter–Weyl theorem (cf. (9)) gives the following explicit G-module decomposition of the ring $k[G/H]$:

$$k[Gf] = k[G/H] = \sum_P P \otimes \bar{P}^H, \tag{10}$$

where P runs over all finite-dimensional G-modules, $\bar{P}^H$ is the sum of all trivial H-submodules of $\bar{P}$, and G acts on the first factor of $P \otimes \bar{P}^H$. This means every G-representation that contains a trivial representation as an H-module occurs in $k[Gf]$, and hence in $H^0(Z, \mathcal{O}_V^Z)$. □

In conjunction with Proposition 5.1, Theorem 5.3 again implies the first criterion of Theorem 5.1. The proof of Theorem 5.3 fails when f is not stable because then it may not be possible to embed $W \subseteq k[Gf] = k[G/H]$ equivariantly within $H^0(Z, \mathcal{O}_V^Z)$ since Luna's slice theorem can fail (cf. Example 2), and so Proposition 5.1 may not be applied to such a W even if it contains a trivial H-module (see also section 5.3).

To construct an obstruction using Proposition 5.1 when f is only partially stable, one needs to calculate explicitly an interesting class of finite-dimensional G-modules that occur within $H^0(Z, \mathcal{O}_V^Z)$, as we did in the stable case (Theorem 5.3). Just as in the completely stable case, we expect that partial stability of f should play a crucial role in this calculation (cf. Theorem 5.4).

When f is stable, the orbit Z is affine, and the stabilizer of f is reductive [32]. In this case, it can be shown that the higher cohomology groups $H^i(Z, \mathcal{O}_V^Z)$, $i > 0$, all vanish; we omit the proof. This statement is analogous to the Cartan–Serre–Grothendick vanishing theorem for the vanishing of higher cohomology of a (quasi-) coherent algebraic sheaf on an affine variety (or more generally on a formal scheme) [18] and the Cartan–Oka vanishing theorem for coherent analytic sheaves on Stein spaces [43]. However, it does not formally follow from the Cartan–Oka vanishing theorem because, in general, $\mathcal{O}_V^Z$ is neither coherent in the sense of Cartan and Oka nor an inverse limit of coherent sheaves.

When f is only partially stable, the higher cohomology groups need not vanish, and they can be expected to play a role in the construction of representation-theoretic obstructions. When f is stable, Theorem 5.3 and Proposition 5.1 together say that $H^0(Z, \mathcal{O}_V^Z)$ contains information in the form of finite-dimensional G-submodules that

puts fairly strong constraints on the stabilizers that can occur in the infinitesimal neighborhood of the orbit of f in V. Analogously, we expect $H^i(Z, \mathcal{O}_V^Z)$, $i \geq 0$, to contain similar information, when f is partially stable, that will constrain the (reductive) stabilizers that can occur in the infinitesimal neighborhood of the orbit of f in V. With this in mind, our approach for constructing representation-theoretic obstructions, when f is partially stable, can be formulated as follows.

1. Prove a generalization of the obstruction-based criterion in Proposition 5.1 to higher cohomology groups.
2. Explicitly calculate an interesting class of finite-dimensional G-submodules that occur within $H^0(Z, \mathcal{O}_V^Z)$, and more generally, in $H^i(Z, \mathcal{O}_V^Z)$, generalizing the method in the proof of Theorem 5.3 for the stable case.
3. Explicitly isolate a G-submodule in this class that satisfies the obstruction criterion for the pair (f, g). Thus, in the setting of Conjecture 4.3, one hopes to get an explicit obstruction this way when m is polynomial in n, thereby proving that the permanent has no polynomial size formula.

Now we elaborate on the main problems that arise in these three steps.

Generalization of the obstruction criterion. The proof of Proposition 5.1 uses evaluation of functions in $H^0(Z, \mathcal{O}_V^Z)$. As it is, this does not work for higher cohomology, since we do not have an appropriate notion of evaluation for elements of higher cohomology representations.

Explicit computation of $H^i(Z, \mathcal{O}_V^Z)$. Here partial stability is expected to be crucial, just as stability was crucial in the computation of $H^0(Z, \mathcal{O}_V^Z)$ based on Luna's slice theorem and Peter–Weyl theorem (Theorem 5.3) when f was stable. Indeed one important feature of our definition of partial stability is the following theorem.

THEOREM 5.4. *Let $\mathcal{F}$ be a coherent (algebraic or analytic) sheaf over the orbit Z. Let $\mathcal{F}^*$ be its direct image over G/P with respect to the projection of the fiber bundle $Z = Gf \to G/P$. Then $H^i(Z, \mathcal{F}) = H^i(G/P, \mathcal{F}^*)$.*

Proof. By the definition of partial stability, the fiber of the bundle $Z \to G/P$ is affine, since it is isomorphic to L/L', where L is a Levi subgroup of P and L' is a stabilizer of f within L that is reductive. Since higher cohomology of a coherent algebraic (or analytic) sheaf over an affine variety vanishes, by the Cartan–Serre theorem [18] (resp., the Cartan–Oka theorem [43]), the result follows by the Leray spectral sequence. □

This indicates why the group action in the vicinity of the orbit of a partially stable point in the null cone ought to have more structure than in the vicinity of an arbitrary point in the null cone. The sheaf $\mathcal{O}_V^Z$ is not coherent. However, the idea in the preceding proof can be pushed towards computation of some interesting families of finite-dimensional G-submodules in $H^i(Z, \mathcal{O}_V^Z)$. This will be reported elsewhere.

Construction of an explicit G-module satisfying an obstruction criterion. This step gives rise to the *subgroup restriction problem* of calculating an explicit decomposition of a G-module W when the action is restricted to a reductive subgroup of G. We have already seen this happen when f is completely stable (cf. Theorem 5.1 and the remark following its proof); the same is expected in the partially stable case. As pointed out in Example 5.2.1, the specific version of the subgroup restriction problem that arises in the context of the determinant vs. permanent problem is the plethysm problem of representation theory, which has no satisfactory solution so far. An explicit combinatorial formula for multiplicities of irreducible Weyl modules within $S_\lambda(V \otimes W)$ and $S_\lambda(S_\mu V)$, based on Weyl's character formula, is known [21].

However, this involves alternating signs, and so it is difficult to ascertain from the formula whether the specific multiplicity is zero or nonzero. What is desirable is a formula for decomposition that does not involve signs, analogous to the Littlewood–Richardson rule for the decomposition of the tensor product of two Weyl modules. Such a decomposition for the plethysm problem is so far not known.

It would be interesting to use the scheme in this section (using, say, the obstruction criterion in Proposition 5.1) on a computer to come up with explicit representation-based obstructions for the pair (f, g) in Conjecture 4.3 for small values of m and n, say, $m = 3$ and $n = 2$. Unfortunately, even for very small values, this computational problem seems quite hard. (The plethysm problem is one of the computational bottlenecks. For $m = 3$ one requires explicit decomposition of $S_\lambda(V \otimes V)$, where $\dim(V) = 9$.)

6. Circuit size. In section 5 we formulated an approach to a well-behaved instance of the orbit-closure (and the stabilizer) problem for a pair of forms (f, g) with nontrivial characteristic stabilizers, wherein f is partially stable. In section 4 we reduced the lower bound problem for the formula size of the permanent to such an instance. Next we shall do the same for certain lower bound questions concerning circuit size, which will include (section 7) the usual P vs. NP question (the stronger nonuniform[4] version) and its arithmetic analogue over an algebraically closed field.

Let $f(X)$ be again any fixed form in the variable vector X of dimension n over an algebraically closed field F. Now we wish to know if it has an arithmetic circuit over F of size l. An arithmetic circuit is a directed acyclic graph. Input variables and constants represent nodes with indegree zero. The remaining nodes are labeled as addition or multiplication nodes. All nodes function as per their labels and the result is output at the unique node with outdegree zero. The size of the circuit is the size of the graph.

The role of the determinant function in section 4 would now be played by a certain function $H(Y)$, which would be complete for the class of polynomials having small circuit size. To define it, consider a generic arithmetic circuit of depth k and width m. It consists of $k + 1$ levels of nodes, numbered 0 to k, each level containing m nodes, except the root level zero, which contains a single output node. Each node in the level $i < k$ is connected to every node in level $i + 1$. Each node u in the input level k is labeled with the variable y^u; the function computed by this node is defined to be y^u. The function $h(u)$ computed by a node u in level $i < k$ is defined to be $\sum_{v,w} y^u_{v,w} h(v)h(w)$, where v and w range over nodes in level $i + 1$ and each $y^u_{v,w}$ is an indeterminate. Let Y be the vector of the variables y^us at the input level k and the variables $y^u_{v,w}$s. Let $H(Y)$ be the function computed at the root level zero. It is a homogeneous form in Y with total degree exponential in k.

Any arithmetic circuit of size r can be obtained from the generic circuit of depth $k \le r$ and width $m \le r$ by specializing the indeterminates $y^u_{v,w}$ to some constants and the indeterminates y^us at the input level to the input parameters or constants. Hence $H(Y)$ is complete for the class of polynomials with small circuits. This can be used to prove the following analogue (Proposition 6.1) of Proposition 4.1. Let V be the space of homogeneous forms in Y with degree equal to that of $H(Y)$. Let $l = O(r^2)$ be the size of Y that corresponds to the generic circuit with depth and width r. We can define, as in section 4, the function ϕ for embedding in V the forms of lower degree

[4]In the nonuniform version, the computational circuits for various input sizes n need not be correlated, whereas in the uniform version, correlation is enforced by requiring a $\log(n)$-space machine that can recognize the circuits for all n.

in the smaller variable vector X of dimension $n < m$: specifically, identify X with some of the input variables in Y and use some remaining variable as a homogenizing parameter. Let $G = SL_l(F)$. Then the following proposition results.

PROPOSITION 6.1. *If $f(X)$ has an arithmetic circuit of size r, then $f^\phi(Y)$ lies in the (projective) Zariski closure $\Delta[H(Y)]$ of the G-orbit of $H(Y)$ in $P(V)$, where $l = O(r^2)$.*

Proof. The proof is similar to that of Proposition 4.1. The role of determinant in that proof is now played by $H(Y)$, which is complete for the class of functions with small circuits. □

The form $H(Y)$ turns out to be good like the determinant function because it has a large nontrivial stabilizer that in a sense characterizes it. Indeed, any automorphism of the generic circuit that fixes the nodes in the input level k gives rise to an element of $SL_l(F)$ that stabilizes $H(Y)$. Quite likely, the stabilizer of $H(Y)$ is precisely the discrete group Q of such automorphisms. It contains k copies of the symmetric group S_m, where k is the depth of the generic circuit and m is its width. The total degree of $H(Y)$ in the variables $y^u_{v,w}$ that occur at level i is $d_i = 2^i$, and its total degree in the input variables y_us is $d_{k+1} = 2^{k+1}$. Therefore $H(Y)$ has multidegree $(d_1, \ldots, d_{k+1})$ in these groups of variables. Let $M(Y)$ be the set of monomials over Y with total degree equal to that of $H(Y)$, i.e., with degree $d_1 + \cdots + d_{k+1}$. It has a natural Q-action induced by that on the generic circuit. Order the monomials in $M(Y)$ lexicographically. We call a monomial maximal if it is the largest monomial in its Q-orbit. Let $M_m(Y) \subseteq M(Y)$ be the subset of maximal monomials. Given any monomial α, let $\hat{\alpha}$ denote it symmetrization $\sum_{\sigma \in Q} \sigma(\alpha)$. Let V be the space of homogeneous forms in Y of total degree equal to that of $H(Y)$. The following is easy to prove.

PROPOSITION 6.2. *The set of forms $\hat{\alpha}$, $\alpha \in M_m(Y)$, is a basis of the space V^Q of Q-invariants in V.*

Unlike the determinant (cf. Proposition 4.2), $H(Y)$ is not a unique form stabilized by Q. However, all forms stabilized by Q are strongly linked to the generic circuit as in Proposition 6.2. In that sense, Q captures the structure of $H(Y)$.

Via Proposition 6.1 we can reduce our lower bound problem for the circuit size of $f(X)$ to an instance of the orbit-closure problem (section 2) with $H(Y)$ and $f^\phi(Y)$ playing the role of $g(Y)$ and $f(Y)$ there. Since $H(Y)$ has a nice stabilizer that captures its structure (Proposition 6.2), this problem in turn can be reduced to an instance of the stabilizer problem (section 2), where we let D be equal to the stabilizer of $H(Y)$. For these problems to be well behaved both $H(Y)$ and $f(X)$ should be nice functions like the determinant and permanent. We have already seen that $H(Y)$ has a nontrivial characteristic stabilizer. The form $f(X)$ should also be nice. This will indeed be the case for the form that arises in the context of the P vs. NP question, as we shall see next.

7. P vs. NP. Before turning to the $P \neq NP$ conjecture, we shall treat its arithmetic implication first. Let X be a variable vector (or matrix) of dimension n. Let $f(X)$ be a polynomial, which is defined in some uniform way for each n, such that, when reduced modulo 2, it gives an NP-complete function in the usual sense. If $P \neq NP$ (the nonuniform version), then $f(X)$, modulo 2, cannot be computed by a boolean circuit of poly(n) size. This implies that $f(X)$ cannot be computed by an integral (arithmetic) circuit of poly(n) size either; otherwise this circuit can be reduced modulo 2 to obtain a boolean circuit of poly(n) size. By arithmetic (integral) implication of the $P \neq NP$ conjecture (nonuniform version), we mean the problem

of showing that such $f(X)$ does not have an integral circuit of poly(n) size. Since it is an implication of the usual nonuniform $P \neq NP$ conjecture, and at the same time does not involve problems of positive characteristic, it is natural to address this arithmetic implication first. In turn, it suffices to consider the complex version of the $P \neq NP$ conjecture, where the problem is to show that $f(X)$ does not have a circuit of poly(n) size defined over $\mathbb{C}$. The complex version trivially implies the arithmetic one, since every integral circuit is also a complex circuit. Hence, the version of the $P \neq NP$ conjecture over $\mathbb{C}$, or more generally, over an arbitrary algebraically closed field F, should be addressed first.

More generally, we can let $f(X)$ be any integral polynomial, which when reduced modulo 2 becomes a hard function NP—this means it belongs to NP but is not expected to be in P (but it need not be NP-complete). The problem then is to show that $f(X)$ does not have a complex, and hence, an integral circuit of poly(n) size.

We begin by instantiating the form $f(X)$ in the preceding section to a certain form $E(X)$ that corresponds to a hard function in NP. Take m-dimensional vector variables $\{X_i^j | 1 \leq j \leq k,\ 1 \leq i \leq m\}$, for some fixed constant $k \geq 3$, say, $k = 3$, for simplicity. Let X be the matrix whose columns consist of these km vectors. For any function $\sigma : \{1, \ldots, m\} \to \{1, \ldots, k\}$, let $\det_\sigma(X)$ denote the determinant of the matrix whose ith column is $X_i^{\sigma(i)}$. Define $E(X) = \prod_\sigma \det_\sigma(X)$, where σ ranges over all such functions. This is well defined over any field. If the field of definition is F_2, then (the negation of) this function is almost NP-complete if $k \geq 3$; see the note at the end of this paper. When the field of definition is F_p, p a fixed prime, we let F be its algebraic closure. The problem then is to show that $E(X)$ does not have an arithmetic circuit of poly(n) size over F. Let $n = km^2$ be the total number entries in X. The stabilizer $K = \mathrm{stab}(E(X))$ of $E(X)$ in $SL_n(F)$ is nice.

PROPOSITION 7.1. *The connected component K_0 of the identity in K is of the form ST, where $S \simeq SL_m(F)$, and $T \simeq (F^*)^{km-1}$ is the $(km-1)$-dimensional algebraic torus. Each $A \in S \simeq SL_m(F)$ corresponds to a linear transformation of the form*

$$X = [\ldots, X_i^j, \ldots] \to [\ldots, AX_i^j, \ldots]. \tag{11}$$

Each element of the torus T corresponds to a linear transformation of the form

$$X = [\ldots, X_i^j, \ldots] \to [\ldots, \lambda_i^j X_i^j, \ldots]. \tag{12}$$

The discrete group K/K_0 contains the wreath product of the alternating group $\mathcal{A}_m$ and $\mathcal{S}_k$. (It acts on X by permuting its columns in the obvious way.)

Proof. That K_0 contains linear transformation of the form (11) or (12) is easy. Since $E(X) = \prod_\sigma \det_\sigma(X)$, where each $\det_\sigma(X)$ is a distinct and irreducible polynomial, each element of K must permute factors, modulo multiplications of factors by constants as in (12). Since the stabilizer of each determinantal factor is known (cf. (4)), the elements in K that fix all factors $\det_\sigma(X)$ are seen to be precisely those of the form in (11).

The elements of K/K_0 that permute the factors $\det_\sigma(X)$ are those that permute the columns of X appropriately. They form a group isomorphic to the wreath product of $\mathcal{A}_m$ and $\mathcal{S}_k$. □

Moreover, the stabilizer K characterizes $E(X)$ in the following sense. Let d denote the total degree of $E(X)$. Let $[E(X)]$ be the set of forms of deg d in the entries of X that are stabilized by K.

PROPOSITION 7.2. *Any form $h(X) \in [E(X)]$ can be expressed as a homogeneous polynomial in the maximal minors of X (which correspond to Plücker coordinates). Among such forms $E(X)$ is the simplest one, in the sense that its expansion in terms of Plücker coordinates contains only one monomial.*

Proof. Since $h(X)$ is stabilized by SL_n, which acts on X by left multiplication, the first assertion follows from classical invariant theory. In arbitrary characteristic, it follows from the result of De Concini and Procesi [8]. The second assertion then follows immediately. □

Let W be the space of forms in X with degree equal to that of $E(X)$.

THEOREM 7.1. *The point $E(X) \in P(W)$ is stable with respect to the action of $G = SL_n(F)$ on $P(W)$. We assume that the characteristic does not divide k, $k-1$, or m.*

This will be proved in section 8. Stability of $E(X)$ is a key fact that connects the P vs. NP question to geometric invariant theory.

Let V be the space of forms in Y as in section 6, where the size of Y is $l > n$. Take a suitable embedding ϕ from W $(P(W))$ to V $(P(V))$ as usual. Then Theorem 7.1 immediately implies the following analogue of Theorem 4.3.

THEOREM 7.2. *$E^\phi(Y) \in P(V)$ is partially stable with respect to the action of $SL_l = SL(Y)$ with defect $\delta = 1$. (We assume that the characteristic does not divide k, $k-1$, or m.)*

Now we make the following analogue of the first assertion in Conjecture 4.3.

CONJECTURE 7.3. *If $l = n^a$, where a is any fixed constant, then $E^\phi(Y)$ cannot lie in the (projective) Zariski closure $\Delta[H(Y)]$ of the $SL_l(F)$-orbit of $H(Y)$ in $P(V)$.*

More generally, let $[H(Y)]$ be the set of forms in the entries of Y, with the same degree as $H(Y)$, that are stabilized by the stabilizer of $H(Y)$. Let $\tilde{\Delta}[H(Y)]$ be the projective closure of $SL_l(F) \cdot [H(Y)]$. A stronger conjecture is the following one.

CONJECTURE 7.4. *If $l = n^a$, where a is any fixed constant, then $E^\phi(Y)$ cannot lie in $\tilde{\Delta}[H(Y)]$.*

By Proposition 6.1, Conjecture 7.3 would imply that $E(X)$ does not have an arithmetic circuit over F of size polynomial in n. The conjecture is not expected to be equivalent to the original lower bound question over F. However, it is "almost" equivalent to it, when F is the field of complex numbers, in the following sense.

PROPOSITION 7.5. *If Conjecture 7.3 were false, then $E(X)$ can be approximated infinitesimally closely by an arithmetic circuit of poly(n) size.*

Proof. The proof is similar to that of Proposition 4.4. □

However, such an approximation is not expected in view of the computational hardness of $E(X)$ over F_2.

Since $H(Y)$ has a nontrivial reductive stabilizer that captures its structure (Propositions 6.2), the orbit-closure problem in Conjecture 7.3 can be reduced to the stabilizer problem. Specifically, we make the following stronger conjecture, which implies Conjecture 7.3 or 7.4.

CONJECTURE 7.6. *The stabilizer of $H(Y)$ cannot occur in the infinitesimal neighborhood of the $SL_l(F)$-orbit of $E^\phi(Y)$ in the affine space V.*

Since $E(X)$ is stable, and both $H(Y)$ and $E(X)$ have nontrivial stabilizers that capture their structure, the approach based on explicit obstructions (section 5) seems appropriate for Conjecture 7.6. In the context of constructing explicit obstructions, the following problems then arise (cf. section 5.5):

1. Explicitly compute finite-dimensional G-submodules of $H^i(Z, \mathcal{O}_V^Z)$, with $E^\phi(Y)$ playing the role of f in section 5.5, and $Z = Gf$. As we mentioned there, the

fact that the orbit Gf is a fiber bundle over G/P, in conjunction with the the Leray spectral sequence, is important in this context.

2. The instances of the subgroup restriction problem that arise in the present context are the following. How does a Weyl module representation $S_\lambda(Y)$ of $SL(Y)$ decompose as a Q-module, where Q is the stabilizer of $H(Y)$? How does a Weyl module representation $S_\mu(X)$ of $SL(X)$ decompose as a K-module, where K is the stabilizer of $E(X)$?

Now, we turn to the actual P vs. NP question (the stronger nonuniform version). Here the field under consideration is no longer algebraically closed. The base field that is actually used for computation in real computers is finite, in fact, F_2, though, without of loss of generality, we can take it to be F_p for any fixed prime. We will reduce the P vs. NP question to a certain parametrized family of the general orbit-closure or stabilizer problems over F, where F is the algebraic closure of F_p.

The starting point is the following analogue of Proposition 6.1. We say that a form is an F_p-form if its coefficients are in F_p. The two forms $h_1(Y), h_2(Y) \in V$ are said to be F_p-equivalent if they are equal for all F_p-vectors Y, i.e., when we let each entry of Y range over F_p.

PROPOSITION 7.7. *If $E(X)$, considered as a function of the F_p-vector X, has an arithmetic circuit over F_p of size of r, then some F_p-form h that is F_p-equivalent to $E^\phi(Y)$ lies in the projective orbit closure $\Delta[H(Y)] \subseteq P(V)$, where the size l of Y is $O(r^2)$.*

Proof. The proof is analogous to that of Proposition 4.1. □

This leads us to the following stronger version of Conjecture 7.6, which would imply that $P \neq NP$.

CONJECTURE 7.8. *If $l = n^a$, where a is any fixed constant, then no F_p-form $h(Y)$ F_p-equivalent to $E^\phi(Y)$ can lie in the (projective) Zariski closure $\Delta[H(Y)]$ of the $SL_l(F)$-orbit of $H(Y)$ in $P(V)$. More strongly, the stabilizer of $H(Y)$ cannot occur in the infinitesimal neighborhood of the $SL_l(F)$-orbit of any such $h(Y)$ in the affine space V.*

For an approach based on explicit obstructions (section 5.5) to be applicable to this conjecture, we would want $h(Y)$ to be a good form like $E^\phi(Y)$. The latter is partially stable (Theorem 7.2), and we conjecture that, in fact, a stronger statement holds.

CONJECTURE 7.9. *Any F_p-form $h(Y)$ F_p-equivalent to $E^\phi(Y)$ is partially stable with respect to the action of $SL_l(F)$ on $P(V)$ with defect $\delta = 1$.*

One can approach other fundamental questions of complexity theory, such as NC^1 vs. NC^2, $P^{\#P}$ vs. NP in a similar fashion by reducing them to various instances of the orbit closure and the stabilizer problem.

8. Stability of $E(X)$. We prove Theorem 7.1 in this section. Let us assume that the characteristic is zero; however, essentially the same proof also works when the characteristic does not divide m, k, or $k-1$. For simplicity, we also assume that $k = 3$.

Let V be a vector space of dimension m. Let I denote the set $\{(i,j) | 1 \leq i \leq 3, 1 \leq j \leq m\}$. Let $X = \{X[i,j] | (i,j) \in I\}$ be a collection of (indeterminate) vectors of V. Let 3^m denote the collection of all functions $\sigma : \{1, \ldots, m\} \to \{1,2,3\}$. For a $\sigma \in 3^m$, let $\det_\sigma(X)$ denote the determinant of the matrix $[X[\sigma(1),1], \ldots, X[\sigma(m),m]]$. With this notation,

$$E(X) = \prod_{\sigma \in 3^m} \det_\sigma(X).$$

Clearly, the action of $SL(V)$ on V stabilizes $E(X)$. In other words, if $A \in SL(V)$ and AX denotes the collection $\{AX[i,j]|(i,j) \in I\}$, then $E(AX) = E(X)$. Let D denote the wreath-product of $\mathcal{S}_m$ with $\mathcal{S}_3$. An element of D is given by a tuple $\beta = (\mu; \alpha_1, \ldots, \alpha_m)$, where $\mu \in \mathcal{S}_m$ and each $\alpha_i \in \mathcal{S}_3$. D acts on I naturally, viz., $\beta = (\mu, (\alpha_r))(i,j) = (\alpha_j(i), \mu(j))$. This action on I extends to X naturally, viz., $\beta(X[i,j]) = X[\beta(i,j)]$, and this action stabilizes $E(X)$ up to sign.

Let $\mathcal{Y}$ be the vector space consisting of formal linear combinations of the symbols $\{y_{ij}|(i,j) \in I\}$. D acts on $\mathcal{Y}$ naturally, viz., $\beta(y_{ij}) = y_{\beta(i,j)}$. We shall examine this representation of D.

Let $e' = \sum_{(i,j)\in I} y_{ij}$ and $f'_j = y_{1j} + y_{2j} + y_{3j}$. Let $\mathcal{E}$ be the span of e' and $\mathcal{F}$ be the span of all vectors of the form $\{f'_r - f'_s|1 \leq r, s \leq m\}$. It is clear that $\mathcal{E}, \mathcal{F}$ are invariant under the action of D. We claim that $\mathcal{E}$ and $\mathcal{F}$ are, in fact, irreducible representations of D. Irreducibility of $\mathcal{E}$ is clear. For $\mathcal{F}$ note that $\mathcal{F} = \{\sum_{r=1}^m c_r f'_r | \sum_{r=1}^m c_r = 0\}$. Note that the action of D on $\mathcal{F}$ reduces to an action of $\mathcal{S}_m$ on $\mathcal{F}$ which is isomorphic to the irreducible representation of $\mathcal{S}_m$ corresponding to the partition $(m-1, 1)$. Let $\mathcal{H}$ be the following subspace of $\mathcal{Y}$:

$$\mathcal{H} = \left\{ \sum c_{ij} y_{ij} | c_{1j} + c_{2j} + c_{3j} = 0 \text{ for all } j \right\}.$$

It is easy to show that $\mathcal{H}$ is also D-irreducible. Thus we see that the D-module $\mathcal{Y}$ splits into irreducible components $\mathcal{Y} = \mathcal{E} \oplus \mathcal{F} \oplus \mathcal{H}$ as D-modules and thus $\mathcal{Y}$ is a multiplicity-free representation of D.

Let D' be the wreath-product of A_m (the alternating group) with $\mathcal{S}_3$. We note that (i) $D' \subset D$ actually stabilizes $E(X)$ and (ii) for $m > 4$ the irreducible D-modules $\mathcal{E}, \mathcal{F}$, and $\mathcal{H}$ are irreducible as D'-modules as well.

Let $h'_{1j} = 2y_{1j} - y_{2j} - y_{3j}$. Define h'_{2j} and h'_{3j} similarly and note that $h'_{ij} \in \mathcal{H}$. We may check that

$$3m.y_{ij} = e' + \sum_{r:r\neq i} (f'_i - f'_r) + m.h'_{ij}. \tag{13}$$

Next, we analyze the stability of the form $E(X)$. If $E(X)$ were unstable, then by Kempf's criteria, there is a one-parameter subgroup $\lambda : k^* \to SL(X)$ "witnessing" its instability and which commutes with the stabilizer of the form $E(X)$. In other words, there would be an $SL(X)$-invariant closed subset of S of forms on X, and a one-parameter subgroup λ commuting with D' above, driving $E(X)$ into S. Since $SL(V)$ acts on X as a diagonal action on $3m$ copies of V, by Schur's lemma, we see that the image of λ must lie in the commutator of this representation of $SL(V)$. This reduces λ to be of the form $\lambda = \gamma \otimes I(V)$, where $I(V)$ is the identity map on V and $\gamma : k^* \to SL(\mathcal{Y})$. Within $SL(\mathcal{Y})$ it must further commute with the D'-representation $\mathcal{Y}$. Since $\mathcal{Y} = \mathcal{E} \oplus \mathcal{F} \oplus \mathcal{H}$ splits as a D'-module, we conclude that D' is actually contained in a suitable parabolic subgroup of $SL(X)$, whence Kempf's first criteria, based on noncontainment of the stabilizer in a proper parabolic group, fails to apply. However, since λ commutes with D', we see that λ can be expressed as

$$\gamma(t)(3m.y_{ij}) = t^a e' + t^b \sum_{r:r\neq i} (f'_i - f'_r) + t^c.m.h'_{ij}. \tag{14}$$

Since $\dim(\mathcal{E}) = 1, \dim(\mathcal{F}) = m-1$ and $\dim(\mathcal{H}) = 2m$, and $\lambda(t) \in SL(X)$ for all t, we have the important relation

$$a + (m-1)b + 2mc = 0. \tag{15}$$

We define the "unprimed" vectors $e(X), f_j(X), h_{ij}$ (X) as the analogues of e', f'_j, and h'_{ij} by replacing the symbol y_{rs} by the vector variable $X[r,s]$. Thus $e(X) = \sum_{(i,j)\in I} X[i,j]$ and $f_j(X) = X[1,j]+X[2,j]+X[3,j]$. The vector $h_{ij}(X)$ is similarly defined. For notational convenience, we drop the argument (X) from $e(X), f_i(X)$, and $h_{ij}(X)$. In this new notation, we have the analogue of (13):

$$3m.X[i,j] = e + \sum_{r:r\neq i} (f_i - f_r) + m.h_{ij}. \tag{16}$$

Let $\chi_i = \chi_i(X)$ denote the vector $\sum_{r:r\neq i}(f_i - f_r)$. In the form $E(X)$, we may substitute the above expression for each $X[i,j]$ and using the multilinearity of the determinant expand $E(X)$ into its "constituents." These constituents may be aggregated by their weights with respect to the one-parameter subgroup λ as follows. Each constituent is a product of determinants with columns from the collection $\{e, (\chi_i), (h_{ij})\}$. If a particular determinant takes for its arguments k_1 copies of e, k_2 elements of (χ_i), and k_3 elements from the set (h_{ij}), (with $k_1 + k_2 + k_3 = m$), then the degree of that determinant may be taken as $k_1a + k_2b + k_3c$. The degree of a product of determinant factors is clearly the sum of the individual degrees. Then we have

$$\lambda(t)(E(X)) = \sum_w t^w E_w(X), \tag{17}$$

where for an integer w the term $E_w(X)$ is the form of degree w. We say that the integer w is a weight in the above expression, if $E_w(X)$ is nonzero. If $E(X)$ were unstable, then there are integers a, b, c satisfying (15) above such that

$$E_w(X) = 0 \text{ for all } w < 0. \tag{18}$$

This is precisely the condition for $\lim_{t\to 0} \lambda(t)(E(X))$ to exist. We shall show that this condition is not possible for any choice of a, b and c as above.

In the expression $E(X) = \sum_w E_w(X)$, there are many terms which vanish. First note that the vector e cannot occur twice inside any nontrivial determinant. Similarly, we have the relation $\sum_{i=1}^m \chi_i = 0$; thus not all the arguments of a nontrivial determinant can be from the set (χ_i). We also note that for any collections $\{v, (w_i)_{i=1}^m, (y_{ij})_{(i,j)\in I}\}$ of vectors in V such that $\sum_i w_i = 0$ and $y_{1j} + y_{2j} + y_{3j} = 0$ for all j, there are vectors $\overline{x} = \{x[r,s] \in V | (r,s) \in I\}$ such that $e(\overline{x}) = v, \chi_i(\overline{x}) = w_i$, and $h_{ij}(\overline{x}) = y_{ij}$.

Therefore suppose that $E(X)$ were unstable and a, b, c were as above.

Case 1. $a, b \geq c$. In this case, (15) tells us that $c \leq 0$. Thus the minimum possible weight is $w_{min} = 3^m.m.c$ coming from terms such as $\prod_{\sigma\in 3^m} \det(h_{\sigma(1),1}, \ldots, h_{\sigma(m),m})$, with a few more terms if $b = c$ or $a = c$.

It is easy to show that $E_{w_{min}} \neq 0$. Select $\overline{x} = (x[r,s])$ such that $e(\overline{x}) = \chi_i(\overline{x}) = 0$ (for all i) and $h_{1j}(\overline{x}) = h_{2j}(\overline{x}) = e_j$ and $h_{3j}(\overline{x}) = -2e_j$, where e_j is the jth "unit" basis vector. For this choice of $\overline{x}$, we see that

$$E_{w_{min}}(\overline{x}) = \prod_{\sigma\in 3^m} \det(h_{\sigma(1),1}, \ldots, h_{\sigma(m),m}) \neq 0.$$

Thus, unless $c = 0$, which in turn implies $a, b, c = 0$, there is a negative weight term, contradicting (18).

Case 2. $\boldsymbol{c \geq a, b.}$ We choose $\overline{x}$ such that $h_{ij}(\overline{x}) = 0$ for all $(i,j) \in I$. Then the minimum-weight term occurs in the expansion of

$$[\det(e(\overline{x}) + \chi_1(\overline{x}), \ldots, e(\overline{x}) + \chi_m(\overline{x}))]^{3^m}$$

(with the relation $\chi_1(\overline{x}) + \cdots + \chi_m(\overline{x}) = 0$).

Since e may occur only once and the χ_i's only $m-1$ times, the only weight possible is $w_{min} = (m-1)b + a$. We may check that $E_{w_{min}}$ is actually nonzero by choosing $\overline{x}$ such that in addition to the requirements above, we have $\chi_i(\overline{x}) = e_i$ for $i = 1, \ldots, m-1$ and $\chi_m(\overline{x}) = -(e_1 + \cdots + e_{m-1})$ and $e(\overline{x}) = e_m$. For this choice of $\overline{x}$, we see that $E_{w_{min}}(\overline{x}) \neq 0$. Since $a + (m-1)b + 2mc = 0$ (see (15)), we have that $a + (m-1)b < 0$. Thus, again, unless $a, b, c = 0$, there is a negative weight term, again contradicting (18).

Case 3. $\boldsymbol{a > c > b.}$ In this case consider the assignment $\overline{x}$ such that (i) $e = 0$, (ii) $h_{1j} = h_{2j} = e_j$, $h_{3j} = -2e_j$ for all j, and (iii) $\chi_i = e_i$ for $i = 1, \ldots, m-1$ with $\chi_m = -(e_1 + \cdots + e_{m-1})$. We see that for any $\sigma \in 3^m$, in the expression

$$\det(\chi_1 + m.h_{\sigma(1),1}, \ldots, \chi_m + m.h_{\sigma(m),m})$$

the minimum-weight term is

$$\sum_{i=1}^{m} m.\det(\chi_1, \ldots, \chi_{i-1}, s.e_i, \chi_{i+1}, \ldots, \chi_m).$$

Here the constant $s = 1$ if $\sigma(i) = 1$ or 2 and -2 otherwise. This expands exactly to either of the numbers m or $-2m$ and is thus nonzero. The weight of this term is minimum possible, which is $(m-1)b + c$. If indeed λ witnesses the instability of $E(X)$ (and therefore satisfies (18)), then $(m-1)b + c \geq 0$. If $c \geq 0$, then this implies that $(m-1)b + 2mc \geq 0$. Since $a > 0$, we have $a + (m-1)b + 2m.c > 0$ which is a contradiction to (15). On the other hand, $c \leq 0$ and $c > b$ together imply $(m-1)b + c < 0$. Thus there is a negative weight nonzero term, contradicting (18).

Case 4. $\boldsymbol{b > c > a.}$ In this case consider the assignment $\overline{x}$ such that (i) $e = e_m$, (ii) $h_{1j} = h_{2j} = e_j$, $h_{3j} = -2e_j$ for all j, and (iii) $\chi_i = 0$ for all i. With $b > c > a$, the minimum weight possible is $(m-1)c + a$. We show that this weight is indeed achieved. We analyze the expression

$$\det(e + m.h_{\sigma(1),1}, \ldots, e + m.h_{\sigma(m),m}).$$

Since $e = e_m$, the only term which survives is

$$\det(m.h_{\sigma(1),1}, \ldots, m.h_{\sigma(m-1),m-1}, e_m).$$

This is clearly nonzero. Thus there is a nonzero term of weight $(m-1)c + a$. Since (a, b, c) is a witness to the instability of $E(X)$, we must have $(m-1)c + a \geq 0$. The only way this can hold is with $c \geq 0$. This implies that $2mc + a = (m-1)c + a + (m+1)c \geq 0$. However, $b > 0$, and consequently $a + (m-1)b + 2mc > 0$, which is untenable, because of (15).

Thus we must have $(a, b, c) = (0, 0, 0)$ which proves the stability of $E(X)$. ∎

Note added in proof. The function $E(X)$ in section 7 is expected to be hard in the following sense. Consider a system of n integral polynomial equations of some constant degree $k \geq 3$ in n variables:

$$g_i(y_1, \ldots, y_n) = 0, \quad 1 \leq i \leq n, \tag{19}$$

where we assume that each g_i is a product of k linear forms. The problem of finding if this system has a nonzero solution over F_p, where $p \leq 2^{\text{poly}(n)}$, is in NP. If g_is are allowed to be nonhomogeneous, it is also NP-complete, even for $p = 2$ and $k = 3$ (reduction from 3-CNF).

Consider the special case of this problem when all g_is are homogeneous. It is expected to be hard, i.e., not expected to be in P for large enough p's; but it is not known if it is NP-complete. Take m-dimensional vector variables $\{X_i^j | 1 \leq j \leq k, 1 \leq i \leq m\}$, where, for any $i, X_i^j, 1 \leq j \leq k$, are the coefficient vectors of the k forms whose product is g_i. Let X be the matrix whose columns consist of these km vectors. Then $E(X)$, modulo F_p, is precisely the resultant of this system (19) with $m = n$.

Acknowledgments. We wish to thank Prof. Madhav Nori, Prof. C. S. Seshadri, and Prof. Burt Totaro for several illuminating discussions and help throughout the course of this research.

ON-LINE LOAD BALANCING IN A HIERARCHICAL SERVER TOPOLOGY*

AMOTZ BAR-NOY†, ARI FREUND‡, AND JOSEPH (SEFFI) NAOR‡

Abstract. In a hierarchical server environment jobs are to be assigned in an on-line fashion to a collection of servers which form a hierarchy of capability: each job requests a specific server meeting its needs, but the system is free to assign it either to that server or to any other server higher in the hierarchy. Each job carries a certain load, which it imparts to the server it is assigned to. The goal is to find a competitive assignment in which the maximum total load on a server is minimized.

We consider the linear hierarchy in which the servers are totally ordered in terms of their capabilities. We investigate several variants of the problem. In the *unweighted* (as opposed to *weighted*) problem all jobs have unit weight. In the *fractional* (as opposed to *integral*) model a job may be assigned to several servers, each receiving some fraction of its weight. Finally, *temporary* (as opposed to *permanent*) jobs may depart after being active for some finite duration of time. We show an optimal e-competitive algorithm for the unweighted integral permanent model. The same algorithm is $(e+1)$-competitive in the weighted case. Its fractional version is e-competitive even if temporary jobs are allowed. For the integral model with temporary jobs we show an algorithm which is 4-competitive in the unweighted case and 5-competitive in the weighted case. We show a lower bound of e for the unweighted case (both integral and fractional). This bound is valid even with respect to randomized algorithms. We also show a lower bound of 3 for the unweighted integral model when temporary jobs are allowed.

We generalize the problem and consider hierarchies in which the servers form a tree. In the tree hierarchy, any job assignable to a node is also assignable to the node's ancestors. We show a deterministic algorithm which is 4-competitive in the unweighted case and 5-competitive in the weighted case, where only permanent jobs are allowed. Randomizing this algorithm improves its competitiveness to e and $e+1$, respectively. We also show an $\Omega(\sqrt{n})$ lower bound when temporary jobs are allowed.

Key words. on-line algorithms, load balancing, hierarchical servers, temporary jobs, resource procurement

1. Introduction.

One of the most basic on-line load-balancing problems is the following. Jobs arrive one at a time and each must be scheduled on one of n servers. Each job has a certain load associated with it and a subset of the servers on which it may be scheduled. The goal is to assign jobs to servers so as to minimize the *cost* of the assignment, defined as the maximum load on a server.

The nature of the load-balancing problem considered here is on-line: decisions must be made without any knowledge of future jobs, and previous decisions may not be revoked. We compare the performance of an on-line algorithm to the performance of an optimal off-line scheduler—one that knows the entire sequence of jobs in advance. The efficacy parameter of an on-line scheduler is its *competitive ratio*, roughly defined

as the maximum ratio, taken over all possible sequences of jobs, between the cost incurred by the algorithm and the cost of an optimal assignment.

1.1. The hierarchical servers problem. In the *hierarchical servers* problem the servers form a hierarchy of capability; a job which may run on a given server may also run on any server higher in the hierarchy. We consider the *linear hierarchy* in which the servers are numbered 1 through n, and we imagine them to be physically ordered along a straight line running from left to right, with server 1 leftmost and server n rightmost. Leftward servers are more capable than rightward ones. We say that servers $1, \ldots, s$ are *to the left* of s, and that servers $s+1, \ldots, n$ are *to the right* of s.

The input is a sequence of jobs, each carrying a positive *weight* and *requesting* one of the servers. A job requesting server s can be assigned to any of the servers to the left of s. These servers are the job's *eligible* servers. The assignment of a job with weight w to server s increases the *load* on s by w (initially, all loads are 0). We use the terms "job" and "request" interchangeably. The *cost* of a given assignment is $COST = \max_s \{l_s\}$, where l_s is the load on server s. We use OPT for the cost of an optimal off-line assignment. An algorithm is *c-competitive* if there exists some $b > 0$, independent of the input, such that $COST \leq c \cdot OPT + b$ for all input sequences. For scalable problems (such as ours) the additive factor b may be ignored in lower bound constructions.

We consider variants, or *models*, of the problem according to three orthogonal dichotomies. In the *integral* model each job must be assigned in its entirety to a single server; in the *fractional* model a job's weight may be split among several eligible servers. In the *weighted* model jobs may have arbitrary positive weights; in the *unweighted* model all jobs have unit weight. Our results for the fractional model hold for both the unweighted and weighted cases, so we do not distinguish between the unweighted fractional model and the weighted fractional model. Finally, *permanent* jobs continue to load the servers to which they are assigned indefinitely; *temporary* jobs are *active* for a finite duration of time, after which they depart. The duration for which a temporary job is active is *not* known upon its arrival. We may allow temporary jobs or we may restrict the input to permanent jobs only. When temporary jobs are allowed, the cost of an assignment is defined as $COST = \max_t \max_s \{l_s(t)\}$, where $l_s(t)$ is the load on server s at time t. The version of the problem which we view as basic is the weighted integral model with permanent jobs only.

A natural generalization of the problem is for the servers to form a (rooted) *tree hierarchy*; a job requesting a certain server may be assigned to any of its ancestors in the tree. The various models pertain to this problem as well.

The hierarchical servers problem is an important practical paradigm. It captures many interesting applications from diverse areas such as assigning classes of service to calls in communication networks, routing queries to hierarchical databases, signing documents by ranking executives, and upgrading classes of cars by car rental companies.

From a theoretical point of view, the hierarchical servers problem is also interesting by virtue of its relation to the problem of *related machines* [3]. In this problem all servers are eligible for every job, but they may have different *speeds*; assigning a job of weight w to a server with speed v increases its load by w/v. Without loss of generality, assume $v_1 \geq v_2 \geq \cdots \geq v_n$, where v_i is the speed of server i. Consider a set of jobs to be assigned at a cost bounded by C, and let us focus on a particular job whose weight is w. To achieve $COST \leq C$ we must refrain from assigning this

job to any server i for which $w/v_i > C$. In other words, there exists a rightmost server to which we may assign the job. Thus, restricting the cost induces eligibility constraints similar to those in the hierarchical servers problem. Some of the ideas developed in the context of the hierarchical servers problems are applicable to the problem of related machines, leading to better bounds for that problem [10].

1.2. Background. Graham [16] explored the assignment problem where each job may be assigned to any of the servers. He showed that the greedy algorithm has competitive ratio $2 - \frac{1}{n}$. Later work [8, 9, 17, 2] investigated the exact competitive ratio achievable for this problem for general n and for various special cases. The best results to date for general n are a lower bound of 1.852 and an upper bound of 1.923 [2].

Over the years many other load-balancing problems were studied; see [4, 20] for surveys. The assignment problem in which arbitrary sets of eligible servers are allowed was considered by Azar, Naor, and Rom [7]. They showed upper and lower bounds of $\Theta(\log n)$ for several variants of this problem. Permanent jobs were assumed. Subsequent papers generalized the problem to allow temporary jobs; in [5] a lower bound of $\Omega(\sqrt{n})$ and an upper bound of $O(n^{2/3})$ were shown. The upper bound was later tightened to $O(\sqrt{n})$ [6].

The *related machines* problem was investigated by Aspnes et al. [3]. They showed an 8-competitive algorithm based on the doubling technique. This result was improved by Berman, Charikar, and Karpinski [12], who showed a more refined doubling algorithm that is $3 + \sqrt{8} = 5.828$-competitive. By randomizing this algorithm, they were able to improve the bound to 4.311. They also showed lower bounds of 2.438 (deterministic) and 1.837 (randomized). The randomized bound was recently improved to 2 [14]. Azar et al. [6] generalized the problem to allow temporary jobs. They showed a deterministic upper bound of 20 (which implies a randomized upper bound of $5e \approx 13.59$) and a lower bound of 3. The upper bounds were later improved to $6 + 2\sqrt{5} \approx 10.47$ (deterministic) and 9.572 (randomized) [10].

The *resource procurement* problem was defined and studied by Kleywegt et al. [18] independently of our work. In this problem jobs arrive over (discrete) time, each specifying a deadline by which it must complete, and all jobs must be executed on a single server. We can view this as a problem of assigning permanent jobs to parallel servers if we think of the time slots as servers. In fact, the problem is equivalent to the following variant of the hierarchical servers problem. The model considered is the fractional model with permanent jobs only. The input consists of precisely n jobs. The jth job to arrive specifies a server $s_j \leq n - j + 1$; the servers eligible for the job are $s_j, s_j + 1, \ldots, n - j + 1$. In addition, the on-line nature of the problem is less demanding. The scheduler need not commit to the full assignment of a job immediately on its arrival. Rather, when the jth job arrives, it must decide what fraction of each of the first j jobs to assign to server $n - j + 1$. Kleywegt et al. [18] developed a lower bound technique similar to ours and were able to establish a lower bound of 2.51 by analytic and numerical means. They also described a 3.45-competitive algorithm.

1.3. Our results. A significant portion of our work is devoted to developing a continuous framework in which we recast the problem. The continuous framework is not a mere relaxation of the problem's discrete features. Rather, it is a fully fledged model in which a new variant of the problem is defined. The advantage of the continuous model lies in the ability to employ the tools of infinitesimal calculus, making analysis much easier.

In section 2 we use the continuous model to design an optimal e-competitive algorithm. Surprisingly, this algorithm operates counterintuitively; the weight distribution of an assigned job is biased to the *left*, i.e., more weight ends up on the leftward servers. We show a general procedure for transforming an algorithm for the continuous model into an algorithm for the fractional model. We also show a general procedure for transforming an algorithm for the fractional model into an algorithm for the integral model. Thus we get an e-competitive algorithm for the fractional model and an algorithm which is, respectively, e and $(e+1)$-competitive for the unweighted integral and weighted integral models. The former algorithm admits temporary jobs; the latter does not. Our upper bound of e also applies to the resource procurement problem of Kleywegt et al. [18] by virtue of Theorem 2 in their paper. Thus we improve their best upper bound of 3.45.

In section 3 we develop a procedure for deriving lower bounds in the context of the continuous model. The construction of the continuous model is rather unconventional in its not being a generalization of the discrete model. In fact, on the surface of things, the two models seem incomparable, albeit analogous. At a deeper level, though, it turns out that the continuous model is actually a special case of the discrete model, making lower bounds obtained in the continuous model valid in the discrete setting as well. This makes the upper bound all the more intriguing, as it is developed in the continuous framework and transported back to the discrete model. The lower bounds obtained with our procedure are also valid in the discrete models (fractional as well as integral), even in the unweighted case with permanent jobs only and even with respect to randomized algorithms. Using our procedure we find that e is a tight lower bound. Since our lower bound technique is the same as the one used (independently) by Kleywegt et al. [18] in the context of the resource procurement problem, our lower bound of e applies to that problem as well, and it improves their best lower bound of 2.51. Thus our work solves this problem completely by demonstrating a tight bound of e.

In section 4 we consider temporary jobs in the integral model. We show a doubling algorithm that is 4-competitive in the unweighted case and 5-competitive in the weighted case. We also show a deterministic lower bound of 3.

Section 5 extends the problem to the tree hierarchy. We show an algorithm which is, respectively, 4-, 4-, and 5-competitive for the fractional, unweighted integral, and weighted integral models. Randomizing this algorithm improves its competitiveness to e, e, and $e+1$, respectively. We show lower bounds of $\Omega(\sqrt{n})$ for all models, both deterministic and randomized, when temporary jobs are allowed.

The effect of restricting the sets of eligible servers in several other ways is discussed in section 6. In the three cases we consider, we show a lower bound of $\Omega(\log n)$. For example, this lower bound holds in the case where the servers form a circuit (or a line) and eligible servers must be contiguous. Note that since these problems are all special cases of the problem considered in [7], an upper bound of $O(\log n)$ is immediate.

2. Upper bounds. In this section we show an algorithm whose respective versions for the fractional, unweighted integral, and weighted integral models are e, e, and $(e+1)$-competitive. The fractional version admits temporary jobs; the integral versions do not. We build up to the algorithm by introducing and studying the *semicontinuous* model and the class of *memoryless* algorithms. We begin with the optimum lemma, which characterizes OPT in terms of the input sequence.

2.1. The optimum lemma. For the fractional and unweighted integral models the lemma provides an exact formula for OPT. For the weighted integral case it gives

a 2-approximation.[1] The optimum lemma is a recurrent theme in our exposition.

For a given input sequence and a given server s, denote by W_s the total weight of jobs requesting servers to the left of s, and let $\mu_s = W_s/s$. Define $H = \max_s \{\mu_s\}$. Clearly, H is a lower bound on OPT, and in the unweighted integral model we can tighten this to $\lceil H \rceil$. In addition, the maximum weight of a job in the input sequence, denoted $w_{\max}$, is also a lower bound on OPT in the integral model.

Turning to upper bounds on OPT, let us say that a given server is *saturated* at a given moment if its load is at least H. For the integral model, consider an algorithm that assigns each job to its rightmost unsaturated eligible server. This algorithm treats the jobs in an on-line fashion but requires advance knowledge of H so it is off-line. Clearly, if an unsaturated eligible server can always be found, then $COST < H + w_{\max}$. We claim that this is indeed the case. To see this, suppose that when some job of weight w arrives, all of its eligible servers are saturated. Let s be maximal such that the servers to the left of s are all saturated. By the maximality of s, the jobs assigned to the left of s must have all requested servers to the left of s. Since their total weight is at least $s \cdot H$, we have $W_s \geq s \cdot H + w > s \cdot H$, a contradiction.

For the fractional model we modify the above algorithm as follows. When a job of weight w arrives, we assign it as follows: let s be the rightmost unsaturated eligible server and let $\delta = H - l_s$, where l_s is the current load on s. If $\delta \geq w$, we assign the job in its entirety to s. Otherwise, we split the job and assign δ units of weight to s and treat the remainder recursively as a new job to be assigned. This algorithm achieves $COST \leq H$.

The optimum lemma summarizes these results.

LEMMA 1 (optimum lemma).

- *In the fractional model,* $OPT = H$.
- *In the unweighted integral model,* $OPT = \lceil H \rceil$.
- *In the weighted integral model,* $\max\{H, w_{\max}\} \leq OPT < H + w_{\max}$.

2.2. Memoryless algorithms. A *memoryless* algorithm is an algorithm that assigns each job independently of previous jobs. Of course, memoryless algorithms are only of interest in the fractional model, which is the model we are going to consider here. We focus on a restricted type of memoryless algorithms, namely, *uniform* algorithms. Uniform memoryless algorithms are instances of the generic algorithm shown below; each instance is characterized by a function $u : \mathcal{N} \to (0, 1]$ satisfying $u(1) = 1$.

Algorithm GenericUniform

When a job of weight w requesting server s arrives, do:

1. $r \leftarrow w$; $i \leftarrow s$.
2. While $r > 0$:
   3. Assign $a = \min\{w \cdot u(i), r\}$ units of weight to server i.
   4. $r \leftarrow r - a$.
   5. $i \leftarrow i - 1$.

[1] It is unreasonable to expect an easily computable formula for OPT in the weighted integral model, for that would imply a polynomial-time solution for the NP-hard problem PARTITION

The algorithm starts with the server requested by the job and proceeds leftward as long as the job is not fully assigned. The fraction of the job's weight assigned to server i is $u(i)$, unless $w \cdot u(i)$ is more than the remainder of the job when i is reached. The condition $u(1) = 1$ ensures that the job will always be fully assigned by the algorithm.

Note that the assignment generated by a uniform memoryless algorithm is independent of both the number of servers and the order of jobs in the input. Moreover, any collection of jobs with total weight w, requesting some server s, may be replaced by a single request of weight w for s. We therefore assume that exactly one job requests each server (we allow jobs of zero weight) and that the number of servers is infinite. We denote the weight of the job requesting server s by w_s.

Consider a job of weight w requesting a server to the right of a given server s. If the requested server is close to s the job will leave $w \cdot u(s)$ units of weight on s regardless of the exact server requested. At some point, however, the job's contribution to the load on s will begin to diminish as the distance of the request from s grows. Finally, if the request is made far enough away, it will have no effect on s. We denote by p_s the point beyond which the effect on s begins to diminish and by p'_s the point at which it dies out completely:

$$p_s = \max\left\{ s' \left| \sum_{i=s}^{s'} u(i) \le 1 \right. \right\}, \qquad p'_s = \max\left\{ s' \left| \sum_{i=s+1}^{s'} u(i) < 1 \right. \right\}.$$

Note that p_s and p'_s may be undefined, in which case we take them to be infinity. We are interested only in functions u satisfying $p_s < \infty$ for all s.

The importance of p_s lies in the fact that the load on s due to jobs requesting servers in the range $s, \ldots, p_s$ is simply $u(s)$ times the total weight of these jobs. The following lemma and corollary are not difficult to prove.

LEMMA 2 (worst case lemma). *Let $\mathcal{A}$ be a uniform memoryless algorithm. The following problem,*

> *Given $K > 0$ and some server s, find an input sequence I that maximizes the load on s in $\mathcal{A}$'s assignment subject to $OPT = K$,*

is solved by $I = \langle w_1, w_2, \ldots \rangle$, where

$$w_i = \begin{cases} 0, & 1 \le i < p_s, \\ p_s K, & i = p_s, \\ K, & p_s < i \le p'_s, \\ 0, & i > p'_s \text{ (if } p'_s < \infty), \end{cases}$$

and l_s—the resultant load on s—satisfies $p_s \cdot Ku(s) \le l_s \le p'_s Ku(s)$.

COROLLARY 3. *Let $\mathcal{A}$ be a uniform memoryless algorithm, and let $C_{\mathcal{A}}$ be the competitive ratio of $\mathcal{A}$. Then $\sup_i \{p_i u(i)\} \le C_A \le \sup_i \{p'_i u(i)\}$.*

2.3. The semicontinuous model. In both the fractional and the integral versions of the problem, the servers and the jobs are discrete objects. We therefore refer to these models as the *discrete* models. In this section we introduce the *semicontinuous* model, in which the servers are made continuous. In section 3 we define the *continuous* model by making the jobs continuous as well.

The semicontinuous model is best understood through a physical metaphor. Consider the bottom of a vessel filled with some nonuniform fluid applying varying degrees of pressure at different points. The force acting at any single point is zero, but any

region of nonzero area suffers a net force equal to the integral of the pressure over the region. Similarly, in the semicontinuous model we do not talk about individual servers; rather, we have a continuum of servers, analogous to the bottom of the vessel. An arriving job is analogous to a quantity of fluid which must be added to the vessel. The notions of *load* and *weight* become divorced; *load* is analogous to pressure and *weight* is analogous to force.

Formally, the *server interval* is $[0, \infty)$, to which jobs must be assigned. Job j has weight w_j, and it requests the point $s_j > 0$ in the server interval. The assignment of job j is specified by an integrable function $g_j : [0, \infty) \to [0, \infty)$ satisfying

1. $\int_0^{s_j} g_j(x)\,dx = w_j$;
2. $x > s_j \Rightarrow g_j(x) = 0$;
3. g_j is continuous from the right at every point.

The *full assignment* is $g = \sum_j g_j$. For a given full assignment g, the *load* l_I on an interval $I = (x, x + \Delta)$, where $\Delta > 0$, is defined as $l_I = \frac{1}{\Delta} \int_x^{x+\Delta} g(z)\,dz$—the mean weight density over I. The load at a point x is defined as $l_x = \lim_{\Delta \to 0} \left\{ l_{(x,x+\Delta)} \right\} = g(x)$. (We introduce the notation l_x for consistency with previous notation.) The cost of the assignment is $COST = \sup_x \{l_x\}$.

LEMMA 4 (optimum lemma: semicontinuous model). *Let $W(x)$ be the total weight of requests made to the left of x (including x itself) and $H = \sup_{x>0} \{W(x)/x\}$. Then $OPT = H$.*

Proof. The lower bound is trivial. For the upper bound, let $x_1 \le x_2 \le \cdots$ be the points requested by the jobs and rearrange the jobs such that the jth job requests x_j. The idea is to pack the jobs (in order) in a rectangle extending from the left end of the server interval. Let $\alpha_j = \sum_{i=1}^{j-1} w_i/H$ for all j and consider the following assignment:

$$g_j(x) = \begin{cases} H, & x \in [\alpha_j, \alpha_j + w_j/H), \\ 0 & \text{otherwise.} \end{cases}$$

This assignment clearly attains $COST = H$. It follows from the definition of H that $\alpha_j + w_j/H \le x_j$ for all j, which is sufficient for the assignment's validity. ∎

We adapt the definition of uniform memoryless algorithms to the semicontinuous model. In this model a uniform algorithm is characterized by a function $u : (0, \infty) \to (0, \infty)$ as follows. For a given point $x > 0$, let $q(x)$ be the point satisfying the equation $\int_{q(x)}^{x} u(z)\,dz = 1$. Then the assignment of job j is

$$g_j(x) = \begin{cases} w_j u(x), & q(s_j) \le x < s_j, \\ 0 & \text{otherwise.} \end{cases}$$

For $q(x)$ and g_j to be defined properly we must require that $\int_0^{\epsilon} u(x)\,dx = \infty$ for all $\epsilon > 0$. (Otherwise, the algorithm may fail to fully assign jobs requesting points close to 0.) Note that the load at 0 is always zero.

For a given point $x > 0$, we define $p(x)$ as the point such that $\int_x^{p(x)} u(z)\,dz = 1$. If $p(x)$ does not exist, then the algorithm's competitive ratio is unbounded, as demonstrated by the request sequence consisting of $m \to \infty$ jobs, each of unit weight, where the jth job requests the point $s_j = j$. For this sequence, $l_x = m \cdot u(x)$, whereas $OPT = 1$. We shall therefore allow only algorithms satisfying $\int_M^{\infty} u(x)\,dx = \infty$ for all $M \ge 0$.

The semicontinuous model has the nice property that p_s and p'_s, which were disparate in the discrete model, fuse into a single entity, $p(s)$. The worst case lemma and its corollary become the following lemma.

LEMMA 5 (worst case lemma: semicontinuous model). *Let $\mathcal{A}$ be a uniform memoryless algorithm defined by $u(x)$. The following problem,*

> *Given $K > 0$ and some point $s > 0$ in the server interval, find an input sequence that maximizes the load at s in $\mathcal{A}$'s assignment, subject to $OPT = K$,*

is solved by a single job of weight $p(s)K$ requesting the point $p(s)$, and the resultant load at s is $p(s)Ku(s)$.

COROLLARY 6. *The competitive ratio of $\mathcal{A}$ is $\sup_x \{p(x)u(x)\}$.*

2.4. An e-competitive algorithm for the semicontinuous model. Consider Algorithm Harmonic, the uniform memoryless algorithm defined by $u(x) = 1/x$. Let us calculate $p(x)$:

$$1 = \int_x^{p(x)} \frac{dz}{z} = \ln \frac{p(x)}{x},$$

$$p(x) = ex.$$

Thus, the competitive ratio of Algorithm Harmonic is $\sup_x \left\{ex\frac{1}{x}\right\} = e$.

2.5. Application to the discrete models. Having devised a competitive algorithm for the semicontinuous model, we wish to import it to the discrete model. We start by showing how to transform any algorithm for the semicontinuous model into an algorithm for the (discrete) fractional model. Following that, we show how any algorithm for the fractional model may be transformed into an algorithm for the integral models.

Semicontinuous to fractional. Let I be an input sequence for the fractional model. If we treat each server as a point on $(0, \infty)$, that is, we view a request for server s as a request for the point s, then we can view I as a request sequence for the semicontinuous model as well. By the respective optimum lemmas (Lemmas 1 and 4), the value of OPT is the same for both models.

Let $\mathcal{A}$ be a c-competitive online algorithm for the semicontinuous model. Define algorithm $\mathcal{B}$ for the fractional model as follows. When job j arrives, $\mathcal{B}$ assigns $\int_{i-1}^{i} g_j(x)\,dx$ units of weight to server i, for all i, where g_j is the assignment function generated by $\mathcal{A}$ for the job. Clearly, the cost incurred by $\mathcal{B}$ is bounded by the cost incurred by $\mathcal{A}$. Thus, $\mathcal{B}$ is c-competitive.

An important observation is that if $\mathcal{A}$ is memoryless, then so is $\mathcal{B}$. Thus, even if temporary jobs are allowed, the assignment generated by $\mathcal{B}$ will be c-competitive at all times, compared to an optimal (off-line) assignment of the active jobs.

We give the algorithm thus derived from Algorithm Harmonic the name FractionalHarmonic.

PROPOSITION 7. *Algorithm FractionalHarmonic is e-competitive even when temporary jobs are allowed.*

Fractional to integral. Let $\mathcal{A}$ be an algorithm for the fractional model. Define algorithm $\mathcal{B}$ for the integral model (both weighted and unweighted) as follows. As jobs arrive, $\mathcal{B}$ keeps track of the assignments $\mathcal{A}$ would make. A server is said to be *overloaded* if its load in $\mathcal{B}$'s assignment exceeds its load in $\mathcal{A}$'s assignment. When a job arrives, $\mathcal{B}$ assigns it to the rightmost eligible server which is not overloaded (after $\mathcal{A}$ is allowed to assign the job).

PROPOSITION 8. *Whenever a job arrives at least one of its eligible servers is not overloaded.*

Proof. Denote by $l_i^A(j)$ and $l_i^B(j)$ the load on server i after job j is assigned by $\mathcal{A}$ and $\mathcal{B}$, respectively. When job j is considered for assignment by $\mathcal{B}$, server i is overloaded iff $l_i^B(j-1) > l_i^A(j)$. Define $A_i(j) = \sum_{k=1}^{i} l_k^A(j)$ and $B_i(j) = \sum_{k=1}^{i} l_k^B(j)$. We claim that for all j,

1. when job j arrives, server 1 (which is eligible) is not overloaded;
2. $A_i(j) \geq B_i(j)$ for all i.

The proof is by induction on j. The claim is clearly true for $j = 1$. Consider some job $j > 1$ whose weight is w. We have $l_1^A(j) = A_1(j) \geq A_1(j-1) \geq B_1(j-1) = l_1^B(j-1)$, where the second inequality is justified by the induction hypothesis. Thus, server 1 is not overloaded. It remains to show that for all i, $A_i(j) \geq B_i(j)$. Let a be the rightmost server to which algorithm $\mathcal{A}$ assigns part of job j, i.e., $a = \max\{s \mid A_s(j) > A_s(j-1)\}$. Let b be the server to which $\mathcal{B}$ assigns the job. By the induction hypothesis, $A_i(j-1) \geq B_i(j-1)$ for all i. Clearly, $B_i(j) \leq B_i(j-1) + w$ for all i, and $B_i(j) = B_i(j-1)$ for $i < b$. Also, $A_i(j) \geq A_i(j-1)$ for all i, and $A_i(j) = A_i(j-1) + w$ for $i \geq a$. Thus, $A_i(j) \geq B_i(j)$ for $i \geq a$ and for $i < b$.

Assuming $b < a$, we still have to prove the claim for $i \in \{b, \ldots, a-1\}$. Algorithm $\mathcal{B}$ assigns job j to server b and not to one of the servers $b+1, \ldots, a$, all of which are eligible and to the right of b. It must therefore be the case that $l_k^A(j) < l_k^B(j-1)$ for $b < k \leq a$. Thus, for $i \in \{b, \ldots, a-1\}$,

$$\begin{aligned} A_i(j) &= A_a(j) - \sum_{k=i+1}^{a} l_k^A(j) = A_a(j-1) + w - \sum_{k=i+1}^{a} l_k^A(j) \\ &> A_a(j-1) + w - \sum_{k=i+1}^{a} l_k^B(j-1) \geq B_a(j-1) + w - \sum_{k=i+1}^{a} l_k^B(j-1) \\ &= B_i(j-1) + w = B_i(j). \end{aligned}$$

The second inequality is justified by the induction hypothesis. ∎

Let $w_{\max}(j)$ be the maximum weight of a job among the first j jobs. Algorithm $\mathcal{B}$ maintains $l_i^B(j) \leq l_i^A(j) + w_{\max}(j)$ for all i and j. In the unweighted case we have $w_{\max} = 1$ and in the weighted case $w_{\max} \leq OPT$. By the optimum lemma (Lemma 1) the value of OPT in the integral model is at least as high as its value in the fractional model. Thus if $\mathcal{A}$ is c-competitive, then $\mathcal{B}$ is c-competitive in the unweighted case and $(c+1)$-competitive in the weighted case.

We give the algorithm thus derived from Algorithm FractionalHarmonic the name IntegralHarmonic.

PROPOSITION 9. *Algorithm IntegralHarmonic is e-competitive in the unweighted case and $(e+1)$-competitive in the weighted case.*

3. Lower bounds. In this section we devise a technique for proving lower bounds in the limit $n \to \infty$. The bounds obtained are valid in both the fractional and integral models, even in the unweighted case. In fact, they remain valid even in the presence of randomization with respect to oblivious adversaries. Using this technique, we obtain a tight constant lower bound of e. The success of our approach is facilitated by transporting the problem from the discrete setting into a *continuous* model, in which both jobs and servers are continuous.

3.1. A simple lower bound. We consider the fractional model, restricting our attention to *right-to-left* input sequences, defined to be sequences in which for all $i < j$, all requests for server j are made before any request for server i. We further restrict our attention to sequences in which each server is requested exactly once. (We allow jobs of zero weight.)

FIG. 1. (a) *Histogram of job weights;* $w = 12$. (b) *Histogram of* kh_i*;* k=3.

Let $\mathcal{A}$ be a k-competitive algorithm. For a given right-to-left input sequence, denote by w_s the weight of the job requesting server s and by l_s the load on server s at a given moment. Suppose the first $n-i+1$ jobs (culminating with the request for server i) have been assigned by $\mathcal{A}$. Recall the definition of H in the optimum lemma (Lemma 1); denote by h_i the value of H with respect to these jobs. Since $\mathcal{A}$ is k-competitive, the loads must obey $l_s \le kh_i$ for all s. For $j \ge i$, define $h_{i,j} = \frac{1}{j}\sum_{s=i}^{j} w_s$. Then $h_i = \max_{i \le j \le n}\{h_{i,j}\}$.

Now consider the specific input sequence defined by $w_1 = \cdots = w_n = w$ for some $w > 0$. For this sequence, $h_i = (n-i+1)w/n$ for all i. Thus, after the first job is assigned we have $l_n \le kw/n$. After the second job is handled we have $l_{n-1} \le 2kw/n$, but $l_n \le kw/n$ still holds because the new job could not be assigned to server n. In general, after the request for server s is processed, we have $l_i \le (n-i+1)kw/n$ for all $i \ge s$. Noting that the total weight of the jobs in the input equals the total load on the servers once the assignment is complete, we get

$$nw = \sum_{i=1}^{n} w_i = \sum_{i=1}^{n} l_i \le \sum_{i=1}^{n} (n-i+1)\frac{kw}{n} = \sum_{j=1}^{n} j\frac{kw}{n} = \frac{kwn(n+1)}{2n}.$$

Hence, $k \ge \lim_{n\to\infty} 2 \cdot \frac{n}{n+1} = 2$.

3.2. Discussion. Figure 1 depicts the request sequence and the resultant kh_i's in histogram-like fashion with heights of bars indicating the respective values. The bars are of equal width, so we can equivalently consider their area rather than height. To be precise, let us redraw the histograms with bars of width 1 and height equal to the numerical values they represent. Then, the total weight to be assigned is the total area of the job bars, and the total weight actually assigned is bounded from above by the total area of the kh_i bars. Now, instead of drawing a histogram of kh_i, let us draw a histogram of h_i. The lower bound is found by solving

$$\textit{total area of job bars} \le k \cdot \textit{total area of } h_i \textit{ bars},$$

$$k \ge \frac{\textit{total area of job bars}}{\textit{total area of } h_i \textit{ bars}}.$$

Note that if we multiply the weights of all jobs by some constant $c > 0$, the heights of both the job bars and the h_i bars will increase by a factor of c, leaving the area ratio intact. Similarly, we can express the scaling of job weights by scaling the width of the bars in both histograms. This, too, has no effect on the resultant ratio. Thus we can express the entire procedure in geometric terms as follows. Select an "input" histogram in which the width of each bar is $\frac{1}{n}$. Let $h_{i,j}$ be the area of bars i through j divided by j/n (the width of j bars), and let $h_i = \max_{i \le j \le n}\{h_{i,j}\}$. (We divide the area by j/n rather than j because h_i is the *height* of the bar whose *area*

equals the value of OPT for the first $n - i + 1$ jobs.) Divide the area of the input histogram by the area of the h_i histogram (drawn to the same scale) to obtain a lower bound. The scaling of the histograms allows us to keep considering finite areas as n goes to infinity. This forms the link between the discrete model and the continuous model, which we introduce next.

3.3. The continuous model. The continuous model is motivated by the observation that the analysis suggested in the previous section tends to be exceedingly difficult for all but the simplest of input histograms. We turn to the continuous model in order to avail ourselves of the machinery of infinitesimal calculus. The continuous model differs from the semicontinuous model introduced in section 2 in two ways. Instead of the infinite server interval, we use a finite interval $[0, S]$, and, more importantly, jobs in the continuous model are not discrete; rather, we have a continuous job flow arriving over time.

It is possible to define a general continuous model in which the arrival of jobs over time is described by a function of place (in the server interval) and time. Although this model is an interesting mathematical construction in its own right, we focus here on a more restricted model—one that allows only the equivalent of right-to-left sequences. Formally, the input is a *request function*, which is an integrable nonnegative real function $f(x)$ defined on the server interval $[0, S]$. The interpretation of f is by means of integration, i.e., $\int_{x_0}^{x_1} f(x)\,dx$ is the total amount of weight requesting points in the interval $[x_0, x_1]$. The underlying intuition is that the request flow is right-to-left in the sense that the infinitesimal request for point x is assumed to occur at "time" $S - x$. Assignment are continuous too; an assignment is described by an *assignment function*, which is an integrable nonnegative real function $g(x)$ on $[0, S)$ that (1) is continuous from the right at every point and (2) satisfies $\int_{x_0}^{S} g(x)\,dx \le \int_{x_0}^{S} f(x)\,dx$ for all $x_0 \in [0, S)$ with equality for $x_0 = 0$. An on-line algorithm in this model is an algorithm which, given $f(x)$, outputs $g(x)$ such that for all $x \in [0, S)$, $g(x)$ on the interval $[x, S)$ is independent of $f(x)$ outside that interval. The definition of *load* and *cost* are the same as in the semicontinuous model.

LEMMA 10 (optimum lemma: continuous model).

$$OPT = \sup_{z \in (0,S]} \left\{ \frac{1}{z} \int_0^z f(x)\,dx \right\}.$$

Proof. Let $H = \sup_{z \in (0,S]} \left\{ \frac{1}{z} \int_0^z f(x)\,dx \right\}$ and $W = \int_0^S f(x)\,dx$. Clearly, $OPT \ge H$. In addition, the assignment function

$$g(x) = \begin{cases} H, & x \le W/H, \\ 0, & x > W/H \end{cases}$$

achieves cost H. □

Let us adapt the lower bound procedure from section 3.2 to the continuous model. Consider a request function $f(x)$ and the corresponding assignment $g(x)$ generated by some k-competitive on-line algorithm. We wish to bound the value of $g(x)$ at some fixed point a. Define a new request function

$$f_a(x) = \begin{cases} f(x), & a \le x \le S, \\ 0 & \text{otherwise.} \end{cases}$$

Define, for $b > a$, $h_a(b) = \frac{1}{b} \int_a^b f(x)\,dx$. Define $h(a) = \sup_{b \in (a,S]} \{h_a(b)\}$. Then OPT with respect to f_a equals $h(a)$. (Note the analogy with $h_{i,j}$ and h_i in the discrete

model.) Define $W = \int_0^S f(x)\,dx$ and $W' = \int_0^S h(a)\,da$. The value of g in $[a, S)$ must be the same for f and f_a, as g is produced by an on-line algorithm; thus $g(a) \le kh(a)$. This is true for all a, hence,

$$W = \int_0^S f(x)\,dx = \int_0^S g(x)\,dx \le k\int_0^S h(a)\,da = kW',$$

from which the lower bound W/W' is readily obtained.

For certain request functions we can simplify the procedure. If $f(x)$ is a continuous monotonically decreasing function tending to 0 at some point $x_0 \ge S$ (where $x_0 = \infty$ is allowed), and we use f's restriction to $[0, S]$ as a request function, then we have the following shortcut to $h(a)$. Solve

$$0 = \frac{d}{db}h_a(b) = \frac{bf(b) - \int_a^b f(x)\,dx}{b^2} \iff f(b) = \frac{1}{b}\int_a^b f(x)\,dx$$

for b, and let $b(a)$ be the solution. The following is easy to justify:

$$h(a) = \frac{1}{b(a)}\int_a^{b(a)} f(x)\,dx = f(b(a)).$$

Note that if $x_0 > S$, this simplified procedure may return values for $b(a)$ outside the server interval $[0, S]$. In this case the true value of $h(a)$ is less than the value computed, leading to a less tight, but still valid, lower bound. We can therefore use the simplified method without being concerned by this issue. Also, it is sometimes more convenient to assume that the server interval, rather than being finite, is $[0, \infty)$. This too can be easily seen to make no difference, at least as far as using the simplified procedure is concerned.

Example. Let $f(x) = e^{-kx}$ with server interval $[0, \infty)$ for some $k > 0$. Then $W = \int_0^\infty e^{-kx}\,dx = \frac{1}{k}$. We find it easier to solve $e^{-kb} = \frac{1}{b}\int_a^b e^{-kx}\,dx$ for a rather than b:

$$a = b - \frac{1}{k}\ln(kb+1),$$

$$da = \left(1 - \frac{1}{kb+1}\right)db.$$

Thus, setting $z = kb + 1$,

$$\begin{aligned} W' &= \int_0^\infty h(a)\,da = \int_0^\infty f(b)\,da = \int_0^\infty e^{-kb}\left(1 - \frac{1}{kb+1}\right)db \\ &= \frac{1}{k}\int_1^\infty e^{1-z}\left(1 - \frac{1}{z}\right)dz = \frac{1}{k}\left(1 - e\int_1^\infty \frac{e^{-z}}{z}\,dz\right) = \frac{1}{k}(1 - eE_1(1)), \end{aligned}$$

where $E_n(x) = \int_1^\infty t^{-n}e^{-xt}\,dt$ is the familiar exponential integral function [1]. The lower bound obtained is therefore

$$\frac{W}{W'} = \frac{1}{1 - eE_1(1)} \approx 2.4773. \qquad \square$$

CLAIM 11. *A lower bound of e can be obtained with our method by considering the request function* $e^{-kx^{1/k}}$ *in the limit* $k \to \infty$ *with server interval* $[0, \infty)$.

Proof. For convenience we consider only integral values of k. We start by reviewing some elementary facts concerning gamma functions [1]. The gamma function is defined by $\Gamma(a) = \int_0^\infty t^{a-1}e^{-t}\,dt$, and it can be shown that for positive integer a, $\Gamma(a) = (a-1)!$. The incomplete gamma function is defined by $\Gamma(a,z) = \int_z^\infty t^{a-1}e^{-t}\,dt$. Integrating by parts we obtain the recurrence $\Gamma(a+1,z) = a\Gamma(a,z) + z^a e^{-z}$. We also need Stirling's approximation: $k! = \sqrt{2\pi k}\,(k/e)^k e^{o(1)}$, which implies $\lim_{k\to\infty}(k/e)^k/k! = 0$. Finally, consider the integral $\int_\alpha^\beta e^{-kx^{1/k}}\,dx$. Substituting $z = kx^{1/k}$ gives $\int_\alpha^\beta e^{-kx^{1/k}}\,dx = \frac{1}{k^{k-1}}\int_{k\alpha^{1/k}}^{k\beta^{1/k}} z^{k-1}e^{-z}\,dz$. Thus, for finite α and β, $\int_\alpha^\beta e^{-kx^{1/k}}\,dx = \left(\Gamma(k, k\alpha^{1/k}) - \Gamma(k, k\beta^{1/k})\right)/k^{k-1}$.

Returning to our problem,

$$W = \int_0^\infty e^{-kx^{1/k}}\,dx = \frac{1}{k^{k-1}}\int_0^\infty z^{k-1}e^{-z}\,dz = \frac{\Gamma(k)}{k^{k-1}} = \frac{(k-1)!}{k^{k-1}}.$$

The relation between a and b is given by

$$be^{-kb^{1/k}} = \int_a^b e^{-kx^{1/k}}\,dx = \frac{\Gamma(k, ka^{1/k}) - \Gamma(k, kb^{1/k})}{k^{k-1}}.$$

Let $r = ka^{1/k}, t = kb^{1/k}$. Then $da = \frac{r^{k-1}}{k^{k-1}}\,dr$. Substituting r and t in the previous equation and simplifying gives

$$k\Gamma(k,t) + t^k e^{-t} = k\Gamma(k,r).$$

Applying the recurrence to both sides of this equation and rearranging terms yields

$$\Gamma(k+1,r) - \Gamma(k+1,t) = r^k e^{-r}.$$

We also get (directly)

$$\Gamma(k,r) - \Gamma(k,t) = \left(\frac{t}{k}\right)t^{k-1}e^{-t}.$$

Let us explore the relationship between r and t. Clearly, $r \le t$. It is easy to see that the function $x^k e^{-x}$ increases in $[0,k)$ and decreases in (k,∞). Thus, referring to Figure 2(a), we see that for $r \ge k$, $\Gamma(k+1,r) - \Gamma(k+1,t) = \int_r^t x^k e^{-x}\,dx$ is the area of the region marked "X" between r and t, and $r^k e^{-r}$ is the area of the dotted rectangle between r and $r+1$. Since both areas are equal and $x^k e^{-x}$ decreases in this region, $t \ge r+1$.

Next consider $r \le k-2$. Referring to Figure 2(b) and applying the same reasoning we see that $t \le r+1 \le k-1$. Let us now consider the function $x^{k-1}e^{-x}$. Its maximum occurs at $x = k-1$. Thus, since $t \le k-1$, the function increases in the interval $[r,t]$. Referring to Figure 2(c) and appealing to $\Gamma(k,r) - \Gamma(k,t) = \left(\frac{t}{k}\right)t^{k-1}e^{-t}$, we see that $r \le t - \frac{t}{k} = t(1-\frac{1}{k})$.

To summarize,

$$r \ge k \Rightarrow\ \ t \ge r+1 \Rightarrow\ \ \ e^{-t} \le \frac{1}{e}e^{-r},$$
$$r \le k-2 \Rightarrow t \ge \frac{r}{1-1/k} \Rightarrow e^{-t} \le e^{-\frac{r}{1-1/k}}.$$

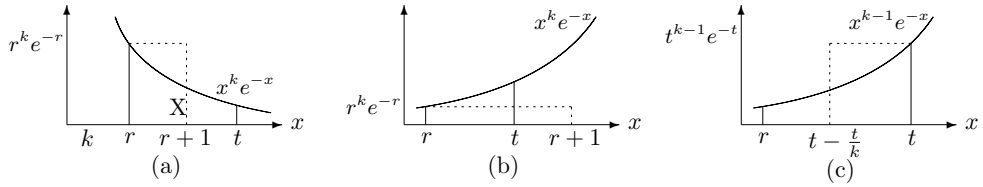

FIG. 2. *The relationship between r and t. The graphs are not drawn to the same scale.* (a) *Using $x^k e^{-x}$ to show $r \geq k \Rightarrow t \geq r+1$.* (b) *Using $x^k e^{-x}$ to show $r \leq k-2 \Rightarrow t \leq k-1$.* (c) *Using $x^{k-1}e^{-x}$ to show $t \leq k-1 \Rightarrow r \leq t - t/k$.*

By differentiating we get $\max_{x \geq 0} \left\{x^{k-1}e^{-x}\right\} = \left(\frac{k-1}{e}\right)^{k-1}$, which implies

$$\int_{k-2}^{k} r^{k-1}e^{-t}\,dr \leq \int_{k-2}^{k} r^{k-1}e^{-r}\,dr \leq 2\left(\frac{k-1}{e}\right)^{k-1}.$$

Putting all the pieces together,

$$\begin{aligned}
\frac{W'}{W} &= \frac{1}{W}\int_0^\infty e^{-kb^{1/k}}\,da = \frac{1}{W}\int_0^\infty e^{-t}\,da = \frac{k^{k-1}}{(k-1)!}\int_0^\infty e^{-t}\frac{r^{k-1}}{k^{k-1}}\,dr \\
&= \frac{1}{(k-1)!}\left(\int_0^{k-2} r^{k-1}e^{-t}\,dr + \int_{k-2}^{k} r^{k-1}e^{-t}\,dr + \int_k^\infty r^{k-1}e^{-t}\,dr\right) \\
&\leq \frac{1}{(k-1)!}\left(\int_0^{k-2} r^{k-1}e^{-\frac{r}{1-1/k}}\,dr + 2\left(\frac{k-1}{e}\right)^{k-1} + \frac{1}{e}\int_k^\infty r^{k-1}e^{-r}\,dr\right).
\end{aligned}$$

Substituting $z = \frac{r}{1-(1/k)}$ in the first integral gives

$$\int_0^{k-2} r^{k-1}e^{-\frac{r}{1-(1/k)}}\,dr = \left(1-\frac{1}{k}\right)^k \int_0^{k-\frac{1}{1-(1/k)}} z^{k-1}e^{-z}\,dz \leq \frac{1}{e}\int_0^k z^{k-1}e^{-z}\,dz.$$

Thus,

$$\frac{W'}{W} \leq \frac{1}{(k-1)!}\left(\frac{1}{e}\int_0^\infty z^{k-1}e^{-z}\,dz + 2\left(\frac{k-1}{e}\right)^{k-1}\right) = \frac{1}{e} + 2\frac{\left(\frac{k-1}{e}\right)^{k-1}}{(k-1)!}.$$

Hence, $\lim_{k\to\infty}\frac{W'}{W} \leq \frac{1}{e}$, and we obtain the lower bound $\lim_{k\to\infty}\frac{W}{W'} \geq e$. ∎

3.4. Application to the discrete models. Returning to the discrete setting, we claim that lower bounds obtained using our method in the continuous model apply in the discrete models as well. This is intuitively correct, since the continuous model may be viewed as the limiting case of the integral models with $n \to \infty$ and arbitrarily long input sequences. We omit the proofs for lack of space.

We also claim that these lower bounds are valid even against randomized algorithms. Whereas typical deterministic lower bound constructions are adversarial, that is, a different input sequence is tailored for each algorithm, our lower bound technique provides a single sequence fit for all algorithms. Consequently, the bounds we derive are also valid for randomized algorithms. This can be seen easily, either directly or via Yao's principle (see, e.g., [13]).

4. Temporary jobs. In this section we allow temporary jobs in the input. We restrict our attention to the integral model, as we have already seen (in section 2.5) an optimal e-competitive algorithm for the fractional model that admits temporary jobs. We present an algorithm that is 4-competitive in the unweighted case and 5-competitive in the weighted case. We also show a lower bound of 3 for the unweighted integral model.

Recall the definition of H in the optimum lemma (Lemma 1). Consider the jobs which are active upon job j's arrival (including job j) and denote by $H(j)$ the value of H defined with respect to these jobs. A server is *saturated* on the arrival of job j if its load is at least $kH(j)$, where k is a constant to be determined later.

Algorithm PushRight

Assign each job it to its rightmost unsaturated eligible server.

PROPOSITION 12. *If $k \geq 4$, then whenever a job arrives, at least one of its eligible servers is unsaturated. Thus, by taking $k = 4$ Algorithm PushRight becomes 4 (resp., 5)-competitive in the unweighted (resp. weighted) models.*

Proof. We begin by considering the properties of certain sequences of numbers whose role will become evident later. Consider the infinite sequence defined by the recurrence $a_{i+2} = k(a_{i+1} - a_i)$ with initial conditions $a_0 = 0$ and $a_1 = 1$. We are interested in the values of k for which this sequence increases monotonically. Solving the recurrence reveals the following.

- If $k = 4$, then $a_i = i2^{i-1}$.
- If $k > 4$, then $a_i = \frac{\lambda_1^i - \lambda_2^i}{\sqrt{k^2-4k}}$, where $\lambda_1 > \lambda_2$ are the two roots of the quadratic polynomial $\lambda^2 - k\lambda + k$.
- If $k < 4$, then $a_i = \frac{\mathrm{Im}(\lambda^i)}{\mathrm{Im}(\lambda)}$, where $\lambda = \frac{1}{2}(k + \sqrt{k^2 - 4k})$.

It is easy to see that the sequence increases monotonically in the first two cases but not in the third.

Now consider some infinite sequence $\{s_i\}$ obeying $s_0 = 0$, $s_1 > 0$, and $s_{i+2} \geq k(s_{i+1} - s_i)$ for all i. It is not difficult to show that if k is chosen such that $\{a_i\}$ increases monotonically, i.e., $k \geq 4$, then $s_{i+2} \geq k(s_{i+1} - s_i) > s_{i+1} > s_i$ for all i.

Returning to our proposition, let $k \geq 4$ and suppose that some job arrives, only to find all of its eligible servers saturated. Let j_0, be the first such job, and let s_1 be the server requested by it. We show how to construct two sequences, $\{s_i\}_{i=0}^{\infty}$ and $\{j_i\}_{i=0}^{\infty}$, with the following properties.

1. $s_0 = 0$, $s_1 > 0$, and $s_{i+2} \geq k(s_{i+1} - s_i)$ for all i.
2. For all i, although the servers $s_i + 1, \ldots, s_{i+1}$ are all eligible for job j_i, the algorithm does not assign this job to the right of s_i.
3. The jobs $\{j_i\}_{i=1}^{\infty}$ are all distinct and they arrive before j_0.

Property 3 states that job j_0 is preceded by an infinite number of jobs, yielding a contradiction.

We have already defined j_0, s_0, and s_1. Having defined $s_0, \ldots, s_{i+1}$ and $j_0, \ldots, j_i$ we define s_{i+2} and j_{i+1} as follows. Property 1 implies that $s_i < s_{i+1} < k(s_{i+1} - s_i)$. By property 2 we know that when job j_i arrives, the total weight of active jobs assigned to servers $s_i + 1$ through s_{i+1} is at least $k(s_{i+1} - s_i)H(j_i)$. By the optimum lemma (Lemma 1), at least one of these jobs must have requested a server whose number is at least $k(s_{i+1} - s_i)$. Define j_{i+1} as any one such job and s_{i+2} as the server it requests. □

4.1. A lower bound. We show a lower bound of 3 on the competitive ratio of deterministic algorithms. We use essentially the same construction as was used in [6] in the context of *related machines*. Some of the details are different, though, owing to the different nature of the two problems. For completeness, we present the construction in full detail.

We consider the unweighted model. To motivate the construction, suppose the value of OPT is known in advance and consider the algorithm that assigns each job to its rightmost eligible server whose current load is less than $k \cdot OPT$, where $k \geq 1$ is an appropriately chosen constant. We design an input sequence targeted specifically at this algorithm. As we shall see, the lower bound of 3 obtained using this input sequence is valid for *any* on-line algorithm; we use only this algorithm to motivate our construction.

Recall that a *right-to-left* input sequence is a sequence such that for all $i < j$, all requests for server j are made before any of the requests for server i. Our input sequence will be right-to-left. For now, we focus on the principles at the cost of rigor. We shall refer to either of the servers s, $s+1$, or $s-1$ simply as server s. We will also refer to server "x" without worrying about the fact that x may be noninteger. To simplify matters, we design the sequence with $OPT = 1$. (This will be changed later.) Figure 3 depicts the first few steps in the ensuing construction.

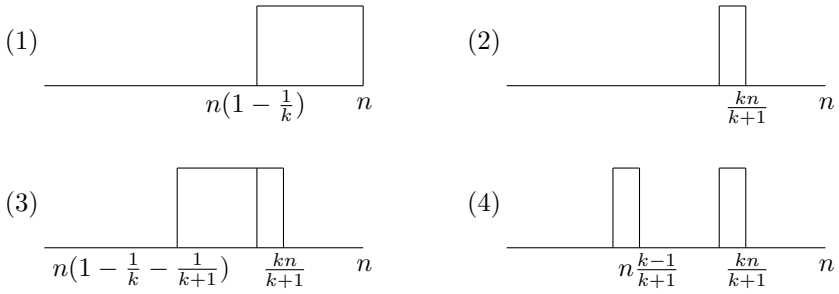

FIG. 3. *The first two rounds in the input sequence.*

We start by making requests to server n. Since OPT is already known to the algorithm, we lose nothing by making n requests, which is the maximum permitted by $OPT = 1$. The algorithm assigns these jobs to servers $n(1-\frac{1}{k}), \ldots, n$. We now remove αn jobs. (α will be determined shortly.) Naturally, the jobs we remove will be the ones assigned rightmost by the algorithm. The remaining $n(1-\alpha)$ jobs will be the ones assigned to servers $n(1-\frac{1}{k}), \ldots, n(1-\frac{1}{k}) + \frac{n(1-\alpha)}{k}$. The adversary assigns these jobs to servers $\alpha n, \ldots, n$. The value of α is determined by our desire that the remaining jobs be assigned by the algorithm strictly to the left of their assignment by the adversary. To that end, we select $\alpha = \frac{k}{k+1}$, which solves the equation $n(1-\frac{1}{k}) + \frac{n(1-\alpha)}{k} = \alpha n$.

We proceed with a second round of jobs. The logical choice is to request server $\alpha n = \frac{k}{k+1} n$. We make αn requests, again, the maximum permitted by $OPT = 1$. The algorithm assigns these jobs in the range $n(1-\frac{1}{k}-\frac{1}{k+1}), \ldots, n(1-\frac{1}{k})$. We terminate βn of these jobs, the ones assigned rightmost by the algorithm. The remaining $n(\alpha-\beta)$ jobs are assigned by the adversary in the range $\beta n, \ldots, \alpha n$ and by the algorithm in the range $n(1-\frac{1}{k}-\frac{1}{k+1}), \ldots, n(1-\frac{1}{k}) - \frac{\beta n}{k}$. To determine β we solve $n(1-\frac{1}{k}) - \frac{\beta n}{k} =$

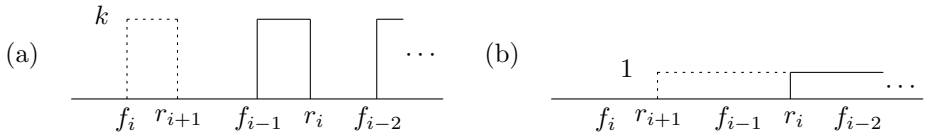

FIG. 4. *The ith round. Solid rectangles represent the assignment of the active jobs at the beginning of the round; the dotted rectangle represents the assignment of the jobs that arrive in the ith round and do not subsequently depart.* (a) *The algorithm's assignment.* (b) *The adversary's assignment.*

βn, arriving at $\beta = n\frac{k-1}{k+1}$.

To generalize the procedure, note that the number of jobs that arrive in a given round is chosen equal to the number of jobs that depart in the round preceding it. Let us introduce some notation. Denote by r_i the server to which requests are made in the ith round and by f_i the leftmost server to which any of these jobs gets assigned by the algorithm. We have already chosen $r_1 = n$ and $r_2 = \frac{k}{k+1}n$, and we have seen that $f_1 = n(1-\frac{1}{k})$ and $f_2 = n(1-\frac{1}{k}-\frac{1}{k+1})$. Define $f_0 = n$. For the ith round of jobs, suppose the following two conditions hold at the end of round $i-1$ (see Figure 4).

1. In the adversary's assignment the active jobs are all assigned in the range $r_i, \ldots, n$.

2. In the algorithm's assignment the active jobs that arrived in round $i-1$ occupy servers $f_{i-1}, \ldots, r_i$, and no jobs are assigned to the left of f_{i-1}.

In the ith round, r_i requests are made to server r_i. They are assigned by the algorithm in the range $f_i, \ldots, f_{i-1}$. Thus,

$$f_i = f_{i-1} - \frac{1}{k}r_i.$$

Next, r_{i+1} of these jobs depart, where r_{i+1} is chosen such that the $r_i - r_{i+1}$ remaining jobs occupy servers $f_i, \ldots, r_{i+1}$. Thus, $k(r_{i+1} - f_i) = r_i - r_{i+1}$, or, equivalently,

$$r_{i+1} = \frac{k}{k+1}f_{i-1}.$$

The actual lower bound construction follows. Let $\mathcal{A}$ be an on-line algorithm purporting to be k-competitive for some $k < 3$. Without loss of generality, k is a rational number arbitrarily close to 3. Consider the two sequences $\{\rho_i\}$ and $\{\varphi_i\}$ defined simultaneously below.

$$\begin{aligned} \varphi_0 &= 1, \\ \rho_1 &= 1, \\ \rho_{i+1} &= \frac{k}{k+1}\varphi_{i-1} \qquad (i = 1, 2, \ldots), \\ \varphi_{i+1} &= \varphi_i - \frac{1}{k}\rho_{i+1} \qquad (i = 0, 1, \ldots). \end{aligned}$$

By substituting $\frac{k}{k+1}\varphi_{i-1}$ for ρ_{i+1} in the second recurrence, we get

$$\varphi_{i+1} = \varphi_i - \frac{1}{k+1}\varphi_{i-1}.$$

It can be shown (see [6]) that there exists a minimal integer p such that $\varphi_p < 0$ and that ρ_i and φ_i are rational for all i. The number of servers we use is n such that $n\rho_i$ and $n\varphi_i$ are integers for $1 \le i \le p$. Define $r_i = n\rho_i$ and $f_i = n\varphi_i$. The recurrences defining $\{\varphi_i\}$ and $\{\rho_i\}$ hold for $\{f_i\}$ and $\{r_i\}$ as well. Let c be any positive integer; we construct an input sequence of unit weight jobs such that $OPT = c$.

1. cr_1 jobs request server r_1.
2. For $i = 2, \ldots, p$:
    3. Of the cr_{i-1} jobs which have requested server r_{i-1}, the cr_i jobs that were assigned rightmost by $\mathcal{A}$ depart. (Ties are broken arbitrarily.)
    4. cr_i new jobs request server r_i.

The lower bound proof proceeds as follows. (We omit the proofs for lack of space.)

For the input sequence to be well defined we must have $r_{i+1} < r_i$ for all $1 \le i < p$.

CLAIM 13. *For $1 \le i < p$, $f_p < 0 \le f_i < r_{i+1} < f_{i-1} \le r_1$ (see Figure 4).*

Denote by J_i the set of jobs requesting server r_i and by J_i' the set of the cr_{i+1} jobs in J_i that eventually depart. Let $W(s,t)$ be the number of active jobs assigned to the left of server s at time t and denote by t_i the moment in time immediately prior to the arrival of the jobs J_i.

CLAIM 14. *$OPT \le c$.*

Observe that the recurrence $f_{i+1} = f_i - \frac{1}{k} r_{i+1}$ is equivalent to $r_i = k(f_{i-1} - f_i)$.

CLAIM 15. *Suppose algorithm $\mathcal{A}$ is k-competitive. Then $W(r_i, t_i) \ge ck(r_i - f_{i-1})$ for all $1 \le i \le p$.*

COROLLARY 16. *Algorithm $\mathcal{A}$ is not k-competitive.*

5. The tree hierarchy. In this section we study a generalization of the problem in which the servers form a rooted tree. A job requesting some server t may be assigned to any of t's ancestors in the tree.

Let us introduce some terminology. A server is said to be *lower* than its proper ancestors. The *trunk* defined by a set of servers U is the set $U \cup \{\, s \mid s \text{ is an ancestor of some server in } U \,\}$. The servers eligible for a given job form a path which is also a trunk. We refer to it interchangeably as the job's *eligible path* or *eligible trunk*.

For a given input sequence, denote by W_T the total weight of jobs requesting servers in trunk T, and let $\mu_T = W_T/|T|$. Define $H = \max\{\, \mu_T \mid T \text{ is a trunk} \,\}$. Denote by $w_{\max}$ the maximum weight of a job in the sequence. Note the analogy with the linear hierarchy. The following lemma can be proved in a manner similar to the proof of the optimum lemma for the linear hierarchy (Lemma 1).

LEMMA 17 (optimum lemma: tree hierarchy).

- *In the fractional model, $OPT = H$.*
- *In the unweighted integral model, $OPT = \lceil H \rceil$.*
- *In the weighted integral model, $\max\{H, w_{\max}\} \le OPT < H + w_{\max}$.*

5.1. A doubling algorithm. The off-line algorithm used in the proof of the optimum lemma (Lemma 17) is nearly a valid on-line algorithm; its only off-line feature is the requirement that the value of H be known at the outset. Thus, employing the standard doubling technique (see, e.g., [4]) we can easily construct an on-line algorithm which is respectively 4-, 4-, and 7-competitive for the fractional, unweighted integral, and weighted integral models. The algorithm we present here is based on the more sophisticated doubling approach pioneered in [12]. It is 4-, 4-, and 5-competitive in the respective cases. The randomized version of this algorithm is, respectively, e-, e-, and $(e+1)$-competitive.

We start by describing the algorithm for the weighted integral model. The algorithm uses two variables: *GUESS* holds the current estimate of H, and *LIMIT* deter-

mines the saturation threshold; a server is *saturated* if its load is at least *LIMIT*. We say that a set of servers U is *saturated* if every server $s \in U$ is saturated. The set U is *overloaded* if the total weight assigned to servers in U is greater than $|U| \cdot LIMIT$. A newly arrived job is *dangerous* if assigning it to its lowest unsaturated eligible server will overload some trunk. In particular, if its eligible trunk is saturated, the job is dangerous. The algorithm avoids overloading any trunk by incrementing *LIMIT* whenever a dangerous job arrives. This, in turn, guarantees that whenever a job arrives, at least one of its eligible servers is unsaturated. Note that assigning the job may saturate the server to which it is assigned.

Algorithm Doubling

Initialize (upon arrival of the first job):

1. Let w be the first job's weight and T its eligible trunk.
2. $GUESS \leftarrow w/|T|$; $LIMIT \leftarrow GUESS$.

For each job:

3. While the job is dangerous:
    4. $GUESS \leftarrow 2 \cdot GUESS$.
    5. $LIMIT \leftarrow LIMIT + GUESS$.
6. Assign the job to its lowest unsaturated eligible server.

We divide the algorithm's execution into phases. A new phase begins whenever lines 4–5 are executed. (The arrival of a heavy job may trigger a succession of several empty phases.) Let p be the number of phases and denote by $GUESS_i$ and $LIMIT_i$ the respective values of *GUESS* and *LIMIT* during the ith phase. For consistency define $LIMIT_0 = 0$. Note that the initial value of *GUESS* ensures that $GUESS_1 \le H$.

PROPOSITION 18. *If $GUESS_i \ge H$ for some i, then the ith phase is the last one. Consequently, $GUESS_p < 2H$.*

Proof. Suppose $GUESS_i \ge H$ and consider the beginning of the ith phase. We claim that from this moment onward, the algorithm will not encounter any dangerous jobs. Suppose this is not true. Let us stop the algorithm when the first such dangerous job is encountered and assign the job manually to its lowest unsaturated eligible server. This overloads some trunk R. Let T be the maximal trunk containing R such that $T - R$ is saturated. Clearly, T is overloaded as well; the total weight assigned to it is greater than $|T| \cdot LIMIT_i$. On the other hand, T was not overloaded at the end of the $(i-1)$st phase, since the algorithm never overloads a trunk. Thus, the total weight of jobs assigned to T during the ith phase (including the job we have assigned manually) is greater than $|T|(LIMIT_i - LIMIT_{i-1}) = |T|GUESS_i \ge |T|H$. By T's maximality, all of these jobs must have requested servers in T. Thus, the total weight of jobs requesting servers in T is greater than $|T|H$, yielding a contradiction. □

COROLLARY 19. *$COST < 4OPT + w_{\max}$.*

Proof. The claim follows since $COST < LIMIT_p + w_{\max}$ and

$$LIMIT_p = GUESS_p \sum_{i=1}^{p} \frac{1}{2^{p-i}} < GUESS_p \sum_{i=0}^{\infty} \frac{1}{2^i} < 4H \le 4OPT. \qquad \square$$

Thus, Algorithm Doubling is 4-competitive in the unweighted integral model and 5-competitive in the weighted integral model. In the fractional model we modify the algorithm as follows. A job is called dangerous iff its eligible path is saturated. When assigning the job we may have to split it, as in the proof of the optimum lemma for

the linear hierarchy (Lemma 1). This algorithm achieves $COST \leq LIMIT_p < 4H = 4OPT$.

5.2. Randomized doubling. We consider randomization against oblivious adversaries. The randomization technique we use is fairly standard by now; a similar idea has been used several times in different contexts (see, e.g., [11, 19, 15, 12, 10]). The idea is to randomize the initial value of *GUESS* and to tweak the doubling parameter. Specifically, let r be a random variable uniformly distributed over $(0, 1]$ and select any constant $k > 1$. We replace lines 2 and 4 with

$2'$. $GUESS \leftarrow k^{r-1}w/|T|$; $LIMIT \leftarrow GUESS$;

$4'$. $GUESS \leftarrow k \cdot GUESS$.

It can be shown that $E(LIMIT_p) \leq H \cdot k/\ln k$ (see [12] or [10] for details). This expression is minimized at $e \cdot H$ by putting $k = e$. Thus, for $k = e$, the algorithm is e-competitive in the fractional and unweighted integral models and $(e+1)$-competitive in the weighted integral model.

5.3. Lower bounds for temporary jobs. In contrast to the linear hierarchy, allowing temporary jobs in the tree hierarchy has a drastic effect on the competitiveness of the solutions. For the unweighted integral model, we show deterministic and randomized lower bounds of $\sqrt{n}$ and $\frac{1}{2}(1 + \sqrt{n+1})$, respectively. These bounds are tight, up to a multiplicative constant, as demonstrated by the upper bound shown in [6] for the general problem with unrestricted eligibility constraints. Our randomized lower bound construction applies in the fractional model as well.

5.3.1. A deterministic lower bound for the integral models. Let $\mathcal{A}$ be a deterministic on-line algorithm, and let $n = k^2$ for some integer $k > 1$. We show an input sequence for which $\mathcal{A}$'s assignment satisfies $COST \geq k \cdot OPT = \sqrt{n}OPT$.

The server tree we use has a flower-like structure. It is composed of a *stem* and *petals*. The stem consists of k servers $s_1, s_2, \ldots, s_k$; s_1 is the root, and s_i is the parent of s_{i+1} for $1 \leq i < k-1$. The petals, $p_1, p_2, \ldots, p_{k^2-k}$, are all children of s_k. Server s_k is called the *calyx*.

Suppose that the competitiveness of $\mathcal{A}$ is better than k for the given n. Consider the following request sequence. Let c be an arbitrarily large integer.

1. For $i = 1, 2, \ldots, k^2 - k$:
    2. $c(k+1)$ jobs, each of unit weight, request the petal p_i.
    3. Of these jobs, ck now depart. (The rest are permanent.) The choice of which jobs depart is made so as to maximize the number of jobs assigned by $\mathcal{A}$ to p_i which depart.
4. ck jobs request the calyx.

During the first stage (lines 1–3), the adversary always assigns the permanent jobs to the petal and the temporary ones to the servers in the stem, c jobs to each server. Thus, at the beginning of the second stage, no jobs are assigned to the stem servers, and the adversary assigns c new jobs to each of them. Thus, $OPT = c$.

Consider the jobs requesting p_i. Since $\mathcal{A}$ is better than k-competitive, it assigns fewer than ck jobs to p_i. Thus, in each iteration more than c permanent jobs are assigned by $\mathcal{A}$ to servers in the stem. Hence, at the beginning of the second stage there are more than $c(k^2-k)$ jobs assigned to servers in the stem. Since the additional ck jobs must be assigned to servers in the stem, at least one server must end up with a load greater than ck, contradicting the assumption that $\mathcal{A}$ is better than k-competitive.

5.3.2. A randomized lower bound. Let us generalize the previous construction. We use a flower-like server tree with p petals and a stem of s servers ($n = s+p$). As before, the input sequence has two stages. The first consists of p iterations, where in the ith iteration, $c \cdot (s+1)$ jobs request the petal p_i and then $c \cdot s$ of them depart. In the second stage cs jobs request the calyx. The goal in the first stage is to "push" enough jobs into the stem so that the algorithm will fail in the second stage.

Consider the ith iteration. Let X_j be the random variable denoting the contribution of the jth job to the load on servers in the stem. (In the integral model this is a 0–1 variable; in the fractional model X_j may assume any value between 0 and 1.) Since the algorithm is better than k-competitive, the expected total weight assigned to p_i is less than ck, so $E(\sum_j X_j) > c(s+1-k)$. Thus, there exist c jobs $j_1, j_2, \ldots, j_c$ such that $\sum_{i=1}^{c} E(X_{j_i}) > c(s+1-k)/(s+1)$. The adversary makes these jobs permanent and terminates the rest.

Consequently, at the beginning of the second stage the expected total load on the servers in the stem is greater than $cp(s+1-k)/(s+1)$, and at the end of the second stage the expectation grows to more than $cs + cp(s+1-k)/(s+1)$. Since the algorithm is better than k-competitive, the expected maximum load on a server in the stem must be less than ck, and thus the expected total load on servers in the stem must be less than cks. To reach a contradiction we choose s and p to satisfy

$$cks = cs + \frac{cp(s+1-k)}{s+1}.$$

Solving the equation yields

$$p = \frac{s(s+1)(k-1)}{s+1-k}, \qquad n = s+p = \frac{ks^2}{s+1-k}.$$

Minimizing n (for fixed k) subject to the last equation yields $s = 2(k-1)$, $p = 2(2k-1)(k-1)$, and $n = 4k(k-1)$. Thus, $k = \frac{1}{2}(1+\sqrt{n+1})$.

6. Other eligibility restrictions. In the *hierarchical servers* problem the sets of eligible servers for a job have a restricted form. For example, in the linear hierarchy they have the following form: all servers to the left of some server s. This is a special case of the problem considered in [7], where eligible sets may be arbitrary. In this section we study various other restrictions on the eligible sets. We focus on the following three.

1. The servers form a path and the set of servers eligible for a given job must be contiguous on the path.

2. The servers form a rooted tree and each job specifies a node v, all of whose descendents (including v itself) are eligible.

3. The number of servers eligible for any given job is at most k for some fixed $2 \le k \le n$.

We show how to extend the $\Omega(\log n)$ lower bound of [7] to these three variants of the problem. This shows that the greedy algorithm, which is $O(\log n)$-competitive for the general problem, remains optimal (up to a multiplicative constant) in many restrictive scenarios.

For the first variant, consider the following input sequence. For convenience assume n is a power of 2 (otherwise consider only the first $2^{\lfloor \log n \rfloor}$ servers on the path). All jobs have unit weight, and they arrive in $\log n$ *rounds*. The ith round consists of $m_i = n/2^i$ jobs, all of which specify the same set of eligible servers S_i. The sets S_i are chosen such that $|S_i| = 2n/2^i$. In the first round all servers are eligible.

Having defined S_i, we construct S_{i+1} as follows. Suppose the total weight assigned to servers in S_i at the end of the ith round is at least $ni/2^i$ (as is certainly the case for $i = 1$). The set S_i is contiguous, i.e., its servers form a path. At least half of the total weight assigned to S_i is assigned to either the first half of this path or to its second half. We define S_{i+1} as the half to which the majority of the weight is assigned (breaking ties arbitrarily). Thus, the total weight assigned to S_{i+1} at the end of the $(i+1)$st round is at least $n/2^{i+1} + \frac{1}{2}ni/2^i = n(i+1)/2^{i+1}$. We define $S_{\log n+1}$ in the same manner and call the single server which it comprises the *leader*. The load on the leader at the end of the last round is at least $\frac{1}{2}\log n$. The adversary assigns the jobs in the ith round to the servers $S_i - S_{i+1}$, one job to each server. Thus, $OPT \leq 1$, and the lower bound follows.

For the second variant we use a very similar construction. The servers are arranged in a complete binary tree. The number of jobs in the ith round is defined by the recurrence $m_i = \frac{1}{2}(m_{i-1} - 1)$ with $m_1 = \frac{1}{2}(n-1)$. The sets of eligible servers are defined as follows. In the first round all servers are eligible. Let v_i be the root of the subtree S_i; we define S_{i+1} as the subtree rooted at the child of v_i to which more weight is assigned at the end of the ith round.

For the third variant we use a recursive construction. Partition the servers into n/k subsets of k servers each and apply the construction of the first variant to each subset. The load on the leader of each subset is now $\Omega(\log k)$. Continue recursively on the set of leaders. Each level of the recursion increases the load on the leaders in that level by $\Omega(\log k)$, and there are $\Theta(\log_k n) = \Theta(\log n/\log k)$ levels. Thus, $COST = \Omega(\log n)$. At each level of the recursion, the adversary assigns no weight to the leaders and at most one job to the other servers. Hence, $OPT \leq 1$, and the lower bound follows.

CHECKING APPROXIMATE COMPUTATIONS OF POLYNOMIALS AND FUNCTIONAL EQUATIONS*

FUNDA ERGÜN†, S. RAVI KUMAR‡, AND RONITT RUBINFELD§

Abstract. A majority of the results on self-testing and correcting deal with programs which purport to compute the correct results precisely. We relax this notion of correctness and show how to check programs that compute only a numerical approximation to the correct answer. The types of programs that we deal with are those computing polynomials and functions defined by certain types of functional equations. We present results showing how to perform approximate checking, self-testing, and self-correcting of polynomials, settling in the affirmative a question raised by [P. Gemmell et al., *Proceedings of the* 23*rd ACM Symposium on Theory of Computing,* 1991, pp. 32–42; R. Rubinfeld and M. Sudan, *Proceedings of the Third Annual ACM-SIAM Symposium on Discrete Algorithms,* Orlando, FL, 1992, pp. 23–43; R. Rubinfeld and M. Sudan, *SIAM J. Comput.,* 25 (1996), pp. 252–271]. We obtain this by first building approximate self-testers for linear and multilinear functions. We then show how to perform approximate checking, self-testing, and self-correcting for those functions that satisfy addition theorems, settling a question raised by [R. Rubinfeld, *SIAM J. Comput.,* 28 (1999), pp. 1972–1997]. In both cases, we show that the properties used to test programs for these functions are both robust (in the approximate sense) and stable. Finally, we explore the use of reductions between functional equations in the context of approximate self-testing. Our results have implications for the stability theory of functional equations.

1. Introduction.

Program checking was introduced by Blum and Kannan [7] in order to allow one to use a program safely without having to know a priori that the program is correct on all inputs. Related notions of self-testing and self-correcting were further explored in [8, 24]. These notions are seen to be powerful from a practical point of view (cf. [9]) and from a theoretical angle (cf. [5, 4]) as well. The techniques used usually consist of tests performed at run-time which compare the output of the program either to a predetermined value or to a function of outputs of the same program at different inputs. In order to apply these powerful techniques to programs computing real-valued functions, several issues dealing with *precision* need to be dealt with. The standard model, which considers an output to be wrong even if it is off by a very small margin, is too strong to make practical sense due to reasons such as the following: (i) In many cases, the algorithm is only intended to compute an approximation, e.g., Newton's method. (ii) Representational limitations

and round-off/truncation errors are inevitable in real-valued computations. (iii) The representation of some fundamental constants (e.g., $\pi = 3.14159\ldots$) is inherently imprecise.

The framework presented by [20, 3] accommodates these inherently inevitable or acceptably small losses of information by overlooking small precision errors while detecting actual "bugs," which manifest themselves with greater magnitude. Given a function f, a program P that purports to compute f, and an error bound Δ, if $|P(x) - f(x)| \leq \Delta$ (denoted $P(x) \approx_\Delta f(x)$) under some appropriate notion of norm, we say $P(x)$ is *approximately correct on input* x. *Approximate result checkers* test if P is approximately correct for a given input x. *Approximate self-testers* are programs that test if P is approximately correct for most inputs. *Approximate self-correctors* take programs that are approximately correct on most inputs and turn them into programs that are approximately correct on every input.

Domains. We work with finite subsets of fixed point arithmetic that we refer to as *finite rational domains*. For $n, s \in \mathbb{Z}^+$, $\mathcal{D}_{n,s} \stackrel{\text{def}}{=} \{\frac{i}{s} : |i| \leq n, i \in \mathbb{Z}\}$. Usually, $s = 2^l$ where l is the precision. We allow s and n to vary for generality. For a domain $\mathcal{D}$, let $\mathcal{D}^+$ and $\mathcal{D}^-$ denote the positive and negative elements in $\mathcal{D}$.

Testing using properties. There are many approaches to building self-testers. We illustrate one paradigm that has been particularly useful. In this approach, in order to test if a program P computes a function f on most inputs, we test if P satisfies certain properties of f.

As an example, consider the function $f(x) = 2x$ and the property "$f(x+1) = f(x)+2$" that f satisfies. One might pick random inputs x and verify that $P(x+1) = P(x)+2$. Clearly, if for some x, $P(x+1) \neq P(x)+2$, then P is incorrect. The program, however, might be quite incorrect and still satisfy $P(x+1) = P(x)+2$ for most choices of random inputs. In particular, there exists a P (for instance, $P(x) = 2x \bmod K$)[1] such that (i) with high probability, P satisfies the property at random x and hence will pass the test, and (ii) there is no function that satisfies the property for all x such that P agrees with this function on most inputs. Thus we see that this method, when used naively, does not yield a self-tester that works according to our specifications. Nevertheless, this approach has been used as a good heuristic to check the correctness of programs [13, 14, 35].

As an example of a property that does yield a good tester, consider the linearity property "$f(x+y) = f(x) + f(y)$," satisfied only by functions mapping $\mathcal{D}_{n,s}$ to $\mathbb{R}$ of the form $f(x) = cx, c \in \mathbb{R}$. If, by random sampling, we conclude that the program P satisfies this property for most x, y, it can be shown that P agrees with a linear function g on most inputs [8, 28]. We call the linearity property, and any property that exhibits such behavior, a *robust property*.

We now describe more formally how to build a self-tester for a *class* $\mathcal{F}$ of functions that can be characterized by a robust property. The two-step approach, which was introduced in [8], is as follows: (i) test that P satisfies the robust property (*property testing*) and (ii) check if P agrees with a *specific* member of $\mathcal{F}$ (*equality testing*). The success of this approach depends on finding robust properties which are both easy to test and lead to efficient equality tests.

A *property* is a pair $\langle \mathcal{I}, \mathcal{E}_{\tau(n,s)} \rangle$, consisting of an equation $\mathcal{I}^f(x_1, \ldots, x_k) = 0$ that relates the values of function f at various tuples of locations $\langle x_1, \ldots, x_k \rangle$, and

[1] We naturally extend the mod function to $\mathcal{D}_{n,s}$ by letting $x \bmod K$ stand for $\frac{j \bmod k}{s}$, for $x, K \in \mathcal{D}_{n,s}$, and $x = \frac{j}{s}$, $K = \frac{k}{s}$.

a distribution $\mathcal{E}_{\tau(n,s)}$ over $\mathcal{D}^k_{\tau(n,s)}$ from which the locations are picked. The property $\langle \mathcal{I}, \mathcal{E}_{\tau(n,s)} \rangle$ is said to characterize a function family $\mathcal{F}$ in the following way. A function f is a member of $\mathcal{F}$ if and only if $\mathcal{I}^f(x_1, \ldots, x_k) = 0$ for every $\langle x_1, \ldots, x_k \rangle$ that has nonzero support under $\mathcal{E}_{\tau(n,s)}$. For instance, the linearity property can be written as $\mathcal{I}^f(x_1, x_2, x_3) \equiv f(x_1) + f(x_2) - f(x_3) = 0$, and $\mathcal{E}^{\mathrm{Lin}}_{\tau(n,s)}$ is a distribution on $\langle x_1, x_2, x_1 + x_2 \rangle$, where x_1 and x_2 are chosen randomly from some distribution[2] over the domain $\mathcal{D}_{\tau(n,s)}$. In this case $\langle \mathcal{I}, \mathcal{E}^{\mathrm{Lin}}_{\tau(n,s)} \rangle$ characterizes $\mathcal{F} = \{f(x) = cx \mid c \in \mathbb{R}\}$, the set of all linear functions over $\mathcal{D}_{\tau(n,s)}$. We will adhere to this definition of a property throughout the paper; however, for simplicity of notation, when appropriate, we will talk about the distribution and the equality together. For instance, we express the linearity property as $f(x + y) = f(x) + f(y)$, giving the distributions of x, y.

We first consider robust properties in more detail. Suppose we want to infer the correctness of the program on inputs from the domain $\mathcal{D}_{n,s}$. Then we allow calls to the program on a larger domain $\mathcal{D}_{\tau(n,s)}$, where $\tau : \mathbb{Z}^2 \to \mathbb{Z}^2$ is a fixed function that depends on the structure of $\mathcal{I}$. Ideally, we would like $\tau(n, s) = (n, s)$, i.e., $\mathcal{D}_{\tau(n,s)} = \mathcal{D}_{n,s}$. However, for technical reasons, we allow $\mathcal{D}_{\tau(n,s)}$ to be a proper, but not too much larger, superset of $\mathcal{D}_{n,s}$ (in particular, the description size of an element in $\mathcal{D}_{\tau(n,s)}$ should be polynomial in the description size of an element in $\mathcal{D}_{n,s}$).[3]

To use a property in a self-tester, one must prove that the property is robust. Informally, the $(\delta, \epsilon, \mathcal{D}_{\tau(n,s)}, \mathcal{D}_{n,s})$-*robustness* of the property $\langle \mathcal{I}, \mathcal{E}_{\tau(n,s)} \rangle$ implies that if, for a program P, $\mathcal{I}^P(x_1, \ldots, x_k) = 0$ is satisfied with probability at least $1 - \epsilon$ when $\langle x_1, \ldots, x_k \rangle$ is chosen from the distribution $\mathcal{E}_{\tau(n,s)}$, then there is a function $g \in \mathcal{F}$ that agrees with P on $1 - \delta$ fraction of the inputs in $\mathcal{D}_{n,s}$. In the case of linearity, it can be shown that there is a distribution $\mathcal{E}^{\mathrm{Lin}}_{11n,s}$ on $\langle x_1, x_2, x_1 + x_2 \rangle$ where $x_1, x_2 \in \mathcal{D}_{11n,s}$ such that the property is $(2\epsilon, \epsilon, \mathcal{D}_{11n,s}, \mathcal{D}_{n,s})$-robust for all $\epsilon < 1/48$ [8, 28]. Therefore, once it is tested that P satisfies $P(x_1) + P(x_2) = P(x_1 + x_2)$ with large enough probability when the inputs are picked randomly from $\mathcal{E}^{\mathrm{Lin}}_{11n,s}$, it is possible to conclude that P agrees with some linear function on most inputs from $\mathcal{D}_{n,s}$. A somewhat involved definition of *robust* is given in [28]. Given a function τ such that for all n, s, $\mathcal{D}_{n,s}$ is a large enough subset of $\mathcal{D}_{\tau(n,s)}$, in this paper we say that a property is *robust* if for all $0 < \delta < 1$, there is an ϵ such that for all n, s the property is $(\delta, \epsilon, \mathcal{D}_{\tau(n,s)}, \mathcal{D}_{n,s})$-robust.

We now consider equality testing. Recall that once it is determined that P satisfies the robust property, then equality testing determines that P agrees on most inputs with a *specific* member of $\mathcal{F}$. For instance, in the case of linearity, to ensure that P computes the specific linear function $f(x) = x$ on most inputs, we perform the equality test which ensures that $P(x + \frac{1}{s}) = P(x) + \frac{1}{s}$ for most x. Neither the property test nor the equality test on its own is sufficient for testing the program. However, since $f(x) = x$ is the *only* function that satisfies both the linearity property and the above equality property, the combination of the property test and the equality test can be shown to be sufficient for constructing self-testers.

This combined approach yields very efficient testers (that make only $O(\epsilon^{-1} \log 1/\delta)$ calls to the program for fixed δ and ϵ) for programs computing homomorphisms (e.g., multiplication of integers and matrices, exponentiation, logarithm). This idea is further generalized in [28], where the class of functional equations called *addition theorems* is shown to be useful for self-testing. An addition theorem is a mathematical

[2] For example, choosing x_1 and x_2 uniformly from $\mathcal{D}_{\tau(n,s)}$ suffices for characterizing linearity. To prove robustness, however, [28] uses a more complicated distribution that we do not describe here.

[3] Alternatively, one could test the program over the domain $\mathcal{D}_{n,s}$ and attempt to infer the correctness of the program on most inputs from $\mathcal{D}_{n',s'}$, where $\mathcal{D}_{n',s'}$ is a large subdomain of $\mathcal{D}_{n,s}$.

TABLE 1
Some addition theorems of the form $f(x+y) = G[f(x), f(y)]$.

$G[f(x), f(y)]$	$f(x)$
$f(x) + f(y)$	Ax
$\frac{f(x)+f(y)}{1-f(x)f(y)}$	$\tan Ax$
$\frac{f(x)f(y)-1}{f(x)+f(y)}$	$\cot Ax$
$\frac{f(x)+f(y)-1}{2f(x)+2f(y)-2f(x)f(y)-1}$	$\frac{1}{1+\tan Ax}$
$\frac{f(x)+f(y)-2f(x)f(y)}{1-f(x)f(y)}$	$\frac{-Ax}{1-Ax}$
$\frac{f(x)+f(y)}{1+[f(x)f(y)]/A^2}$	$A\tanh Bx$
$\frac{f(x)f(y)}{f(x)+f(y)}$	$\frac{A}{x}$

$G[f(x), f(y)]$	$f(x)$
$f(x)f(y) - \sqrt{1-f(x)^2}\sqrt{1-f(y)^2}$	$\cos Ax$
$\frac{f(x)+f(y)-2f(x)f(y)}{1-2f(x)f(y)}$	$\frac{1}{1+\cot Ax}$
$\frac{f(x)+f(y)-2f(x)f(y)\cos a}{1-f(x)f(y)}$	$\frac{\sin Ax}{\sin Ax+a}$
$\frac{f(x)+f(y)-2f(x)f(y)\cosh a}{1-f(x)f(y)}$	$\frac{\sinh Ax}{\sinh Ax+a}$
$\frac{f(x)+f(y)+2f(x)f(y)\cosh a}{1-f(x)f(y)}$	$\frac{-\sinh Ax}{\sinh Ax+a}$
$\frac{f(x)+f(y)+2f(x)f(y)}{1-f(x)f(y)}$	$\frac{Ax}{1-Ax}$
$f(x)f(y) + \sqrt{f(x)^2-1}\sqrt{f(y)^2-1}$	$\cosh Ax$

identity of the form for all x, y, $f(x+y) = G[f(x), f(y)]$. Addition theorems characterize many useful and interesting mathematical functions [1, 11]. When G is algebraic, they can be used to characterize families of functions that are rational functions of x, e^{cx}, and doubly periodic functions (see Table 1 for examples of functional equations and the families of functions that they characterize over the reals). Polynomials of degree d can be characterized via several different robust functional equations (e.g., [6, 26, 4, 30]).

Approximate robustness and stability. When the program works with finite precision, the properties upon which the testers are built will rarely be satisfied, even by a program whose answers are correct up to the required (or hardware-wise maximal) number of digits, since they involve strict equalities. Thus, when testing, one might be willing to pass programs for which the properties are only approximately satisfied. This relaxation in the tests, however, leads to some difficulties, for in the approximate setting (i) it is harder to analyze which function families are solutions to the robust properties, and (ii) equality testing is more difficult. For instance, it is not obvious which family of functions would satisfy both $P(x_1) + P(x_2) \approx P(x_1 + x_2)$, for all $x, y \in \mathcal{D}_{\tau(n,s)}$ (approximate linearity property), and $P(x + \frac{1}{s}) \approx P(x) + \frac{1}{s}$ for all $x \in \mathcal{D}_{\tau(n,s)}$ (approximate equality property).

To construct approximate self-testers, our approach is to first investigate a notion of *approximate robustness* of the property to be used. We first require a notion of distance between two functions.

DEFINITION 1 (Chebyshev norm). *For a function f on a domain $\mathcal{D}$, $\|f\|_{\mathcal{D}} = \|f\| = \sup_{x\in\mathcal{D}}\{|f(x)|\}$.*

When the domain is obvious from the context, we drop it. Given functions f, g, the *distance* between them is $\|f-g\|$. Next, we define the *approximation* of a function by another function.

DEFINITION 2. *The function P (Δ, ϵ)-approximates f on domain $\mathcal{D}$ if $\|P-f\| \leq \Delta$ on at least $1-\epsilon$ fraction of $\mathcal{D}$.*

Approximate robustness is a natural extension of the robustness of a property. We say that a *program satisfies a property approximately* if the property is true of the program when exact equalities are replaced by approximate equalities. Once again consider the linearity property and a program P that satisfies the property approximately (i.e., $P(x_1 + x_2) \approx_\Delta P(x_1) + P(x_2)$) for all but an ϵ fraction of the choices of $\langle x_1, x_2, x_1 + x_2\rangle \in \mathcal{E}^{\text{Lin}}_{\tau(n,s)}$. The approximate robustness of linearity implies that there exists a function g and a choice of Δ', Δ'' such that $g(x+y) \approx_{\Delta'} g(x) +$

$g(y)$ for all inputs $x, y \in \mathcal{D}_{n,s}$, and g $(\Delta'', 2\epsilon)$-approximates P on $\mathcal{D}_{n,s}$ [20, 28]. In general, we would like to define approximate robustness of a property $\langle \mathcal{I}, \mathcal{E}_{\tau(n,s)} \rangle$ as the following: If a program P satisfies the equation $\mathcal{I}$ approximately on most choices of inputs according to the distribution $\mathcal{E}_{\tau(n,s)}$, then there exists a function g that (i) satisfies $\mathcal{I}$ approximately on all inputs chosen according to $\mathcal{E}_{n,s}$ and (ii) approximates P on most inputs in $\mathcal{D}_{n,s}$, the support of $\mathcal{E}_{\tau(n,s)}$. The function τ relates the distributions used for describing the behaviors of P and G and depends on $\mathcal{I}$.

We now give a formal definition of approximate robustness.

DEFINITION 3 (approximate robustness). *Let $\langle \mathcal{I}, \mathcal{E}_{\tau(n,s)} \rangle$ characterize the family of functions $\mathcal{F}$ over the domain $\mathcal{D}_{\tau(n,s)}$. Let $\mathcal{F}'$ be the family of functions satisfying $\mathcal{I}$ approximately on all inputs chosen according to $\mathcal{E}_{n,s}$. Let ϵ, δ be constants independent of n. A property $\langle \mathcal{I}, \mathcal{E}_{\tau(n,s)} \rangle$ for a function family $\mathcal{F}'$ is* $(\delta, \epsilon, \mathcal{D}_{\tau(n,s)}, \mathcal{D}_{n,s}, \Delta, \Delta', \Delta'')$-approximately robust *if for all $P, \Pr_{\langle x_1,\ldots,x_k \rangle \sim \mathcal{E}_{\tau(n,s)}}[\mathcal{I}^P(x_1, \ldots, x_k) \approx_\Delta 0] \geq 1 - \epsilon$ implies there is a $g \in \mathcal{F}'$ that (Δ'', δ)-approximates P on $\mathcal{D}_{n,s}$ and $\mathcal{I}^g(x_1, \ldots, x_k) \approx_{\Delta'} 0$ for all tuples $\langle x_1, \ldots, x_k \rangle$ with nonzero support in $\mathcal{E}_{n,s}$.*

Once we know that the property is approximately robust, the second step is to analyze the *stability* of the property, i.e., to characterize the set of functions $\mathcal{F}'$ that satisfy the property approximately and compare it to $\mathcal{F}$, the set of functions that satisfy the property exactly (*Hyers–Ulam stability* [21]). In our linearity example, the problem is the following: given g satisfying $g(x+y) \approx_\Delta g(x) + g(y)$ for all x, y in the domain, is there a homomorphism h that $(\Delta', 0)$-approximates g with Δ' depending only on Δ and *not* on the size of the domain? If the answer is affirmative, we say that the property is *stable*. In the following definition, $\mathcal{D}_{n',s'} \subseteq \mathcal{D}_{n,s}$.

DEFINITION 4 (stability). *A property $\langle \mathcal{I}, \mathcal{E}_{n,s} \rangle$ for a function family $\mathcal{F}$ is* $(\mathcal{D}_{n,s}, \mathcal{D}_{n',s'}, \Delta, \Delta')$-stable *if for all g that satisfies $\mathcal{I}^g \approx_\Delta 0$ for all tuples with nonzero support according to $\mathcal{E}_{n,s}$, there is a function h that satisfies $\mathcal{I}^h = 0$ for all tuples with nonzero support according to $\mathcal{E}_{n',s'}$ with $\|h - g\|_{\mathcal{D}_{n',s'}} \leq \Delta'$.*

If a property is both approximately robust and stable, then it can be used to determine whether P approximates some function in the desired family. Furthermore, if we have a method of doing approximate equality testing, then we can construct an approximate self-tester. Here, we assume that the distributions associated with approximate robustness and stability are samplable.

Previous work. Previously, not many of the known checkers have been extended to the approximate case. Often it is rather straightforward to extend the robustness results to show approximate robustness. However, the difficulty with extending the checkers appears to lie in showing the stability of the properties. The issue is first mentioned in [20], where approximate checkers for mod, exponentiation, and logarithm are constructed. The domain is assumed to be closed in all of these results. A domain is said to be closed under an operation if the range of the operation is a subset of the domain. For instance, a finite precision rational domain is not closed under addition. In [3] approximate checkers for sine, cosine, matrix multiplication, matrix inversion, linear system solving, and determinant are given. The domain is assumed to be closed in the results on sine and cosine. In [10] an approximate checker for floating-point division is given. In [32], a technique which uses approximation theory is presented to test univariate polynomials of degree at most 9. It is left open in [20, 3, 30, 28] whether the properties used to test polynomial, hyperbolic, and other trigonometric functions can be used in the approximate setting. For instance, showing the stability of such functional equations is not obvious; if the functional equation involves division with a large numerator and a small denominator, a small additive error in the denominator

leads to a large additive error in the output.

There has been significant work on the stability of specific functional equations. The stability of linearity and other homomorphisms is addressed in [21, 16, 18, 12]. The techniques used to prove the above results, however, cease to apply when the domain is not closed. The stronger property of stability in a nonclosed space, called *local stability*, is addressed by Skof [31], who proves that Cauchy functional equations are locally stable on a finite interval in $\mathbb{R}$. The problem of stability of univariate polynomials over continuous domains is first addressed in [2] and the problem of local stability on $\mathbb{R}$ is solved in [19]. See [17] for a survey. These results do not extend in an obvious way to finite subsets of $\mathbb{R}$ and thus cannot be used to show the correctness of self-testers. For those that can be extended, the error bounds obtained by naive extensions are not optimal. Our different approach allows us to operate on $\mathcal{D}_{n,s}$ *and* obtain tight bounds.

Results. In this paper, we answer the questions of [20, 3, 30, 28] in the affirmative by giving the first approximate versions of most of their testers. We first present an approximate tester for linear and multilinear functions with tight bounds. These results apply to several functions, including multiplication, exponentiation, and logarithm, over nonclosed domains. We next present the first approximate testers for multivariate polynomials. Finally, we show how to approximately test functions satisfying addition theorems. Our results apply to many algebraic functions of trigonometric and hyperbolic functions (e.g., sinh, cosh). All of our results apply to nonclosed discrete domains.

Since a functional equation over $\mathbb{R}$ has more constraints than the same functional equation over $\mathcal{D}_{n,s}$, it may happen that the functional equation over $\mathbb{R}$ characterizes a family of functions that is a proper subset of the functions characterized by the same functional equation over $\mathcal{D}_{n,s}$. This does not limit the ability to construct self-testers for programs for these functions, due to the equality testing performed by self-testers.

To show our results, we prove new local stability results for discrete domains. Our techniques for showing the stability of multilinearity differ from those used previously in that (i) we do not require the domain to be discrete and (ii) we do not require the range to be a complete metric space. This allows us to apply our results to multivariate polynomial characterizations. In addition to new combinatorial arguments, we employ tools from approximation theory and stability theory. Our techniques appear to be more generally applicable and cleaner to work with than those previously used.

Self-correctors are built by taking advantage of the random self-reducibility of polynomials and functional equations [8, 24] in the exact case. As in [20], we employ a similar idea for the approximate case by making several guesses at the answer and returning their median as the output. We show that if each guess is within Δ of the correct answer with high probability, then the median yields a good answer with high probability. To build an approximate checker for all of these functions, we combine the approximate self-tester and approximate self-corrector as in [8].

Subsequent to our work, our results have been extended to the case of relative error in a recent paper of [22].

Organization. Section 2 addresses the stability of the properties used to test linear and multilinear functions. Using these results, section 3 considers approximate self-testing of polynomials. Section 4 addresses the stability and robustness of functional equations. Section 5 illustrates the actual construction of approximate self-testers and self-correctors.

2. Linearity and multilinearity. In this section, we consider the stability of the robust properties used to test linearity and multilinearity over the finite rational domain $\mathcal{D}_{n,s}$. The results in this section, in addition to being useful for the testing of linear and multilinear functions, are crucial to our results in section 3.

As in [20], approximate robustness is easy to show by appropriately modifying the proof of robustness [28]. This involves replacing each exact equality by an approximate equality and keeping track of the error accrued at each step of the proof. To show stability, we use two types of bootstrapping arguments: the first shows that an error bound on a small subset of the domain implies the same error bound on a larger subset of the domain; the second shows that an error bound on the whole domain implies a tighter error bound over the same domain. These results can be applied to give the first approximate self-testers for several functions over $\mathcal{D}_{n,s}$ including multiplication, exponentiation, and logarithm (section 2.2).

2.1. Approximate linearity. The following defines formally what it means for a function to be approximately linear.

DEFINITION 5 (approximate linearity). *A function g is* Δ-approximately linear *on $\mathcal{D}_{n,s}$ if for all $x, y \in \mathcal{D}_{n,s}, g(x+y) \approx_\Delta g(x) + g(y)$.*

Hyers [21] and Skof [31] obtain a linear approximation to an approximately linear function when the domain is $\mathbb{R}$. (See Appendix A for their approach.) Their methods are not extendible to discrete domains.

Suppose we define h such that $h(\frac{1}{s}) \stackrel{\text{def}}{=} g(\frac{1}{s})$ and h is linear. In the 0-approximately linear case (exact linearity), since $g(\frac{i}{s}) = g(\frac{i-1}{s}) + h(\frac{1}{s})$ and $h(\frac{i}{s}) = h(\frac{i-1}{s}) + h(\frac{1}{s})$, by induction on the elements in $\mathcal{D}_{n,s}$, we can show that $h(x) = g(x)$ for all x. This approach is typically used to prove the sufficiency of the equality test. However, in the Δ-approximately linear case for $\Delta \neq 0$, using the same inductive argument will only yield a linear function h such that $h(\frac{i}{s}) \approx_{i\cdot\Delta} g(\frac{i}{s})$. This is quite unattractive since the error bound depends on the domain size. The problem of obtaining a linear function h whose discrepancy from g is *independent* of the size of the domain is nontrivial.

In [20], a solution is given for when the domain is a finite group. Their technique requires that the domain be closed under addition and therefore does not work for $\mathcal{D}_{n,s}$. We give a brief overview of the scheme in [20] and point out where it breaks down for nonclosed domains. The existence of a linear h that is close to g is done in [20] by arguing that if $\mathcal{D}$ is sufficiently large, then an error of at least Δ at the maximum error point x^* would imply an even bigger error at $2x^*$, contradicting the maximality assumption about error at x^*. Here, the crucial assumption is that $x \in \mathcal{D}$ implies $2x \in \mathcal{D}$. This step fails for domains which are not closed under addition.

Instead, we employ a different constructive technique to obtain a linear h on $\mathcal{D}_{n,s}$ given a Δ-approximately linear g. Our technique yields a tight bound of 2Δ on the error $e \equiv h - g$ (instead of 4Δ in [31]) and does not require that the domain be closed under addition. It is important to achieve the best (lowest) constants possible on the error because these results are used in section 3.2 where the constants affect the error in an exponential way.

The following lemma shows how to construct a linear function h that is within $2\Delta + \rho$ of a Δ-approximately linear function g in $\mathcal{D}^+_{n,s}$.

LEMMA 6. *Let g be a Δ-approximately linear function on $\mathcal{D}^+_{n,s}$, and let h be linear on $\mathcal{D}_{n,s}$. Define $e(x) = h(x) - g(x)$. If $|e(\frac{n}{s})| = \rho$, then for all $x \in \mathcal{D}^+_{n,s}, |e(x)| \leq 2\Delta + \rho$.*

Proof. We prove by contradiction that for all $x \in \mathcal{D}^+_{n,s}, e(x) \leq 2\Delta + \rho$. A symmetric argument can be made to show that $e(x) \geq -(2\Delta + \rho)$.

Recall that $\frac{n}{s}$ is the greatest positive element of the domain, and note that e is a Δ-approximately linear function. Assume that there exists a point in $\mathcal{D}^+_{n,s}$ with error greater than $2\Delta + \rho$. Let p be the maximal such element. p has to lie between $\frac{n}{2s}$ and $\frac{n}{s}$, otherwise $2p \in \mathcal{D}^+_{n,s}$ would have error greater than $2\Delta + \rho$, contradicting the maximality of p. Let $q = \frac{n}{s} - p$. Then, $e(q) + e(p) \approx_\Delta e(\frac{n}{s})$; therefore $e(q) < -\Delta$. Also, for any $x \in (p, \frac{n}{s}] \subseteq \mathcal{D}^+_{n,s}$, by definition of p, $e(x) \leq 2\Delta + \rho$. Note that any such x can be written as $x = x' + p$, where $x' \in (0, q]$. To satisfy the approximate linearity property that $e(x') + e(p) \approx_\Delta e(x)$, x' must have error strictly less than $\Delta + \rho$.

We now know that the points in the interval $(0, q]$ have error strictly less than $2\Delta + \rho$ (in fact, less than $\Delta + \rho$) and that the point q itself has error strictly less than $-\Delta$. Putting these two facts and approximate linearity together, and since any $x \in (q, 2q]$ can be written as $q + y$ where $y \in (0, q]$, we can conclude that at any point in $(q, 2q]$, the error is at most $2\Delta + \rho$. Now we can repeat the same argument by taking y from $(0, 2q]$ rather than $(0, q]$ to bound the error in the interval $(0, 3q]$ by $2\Delta + \rho$. By continuing this argument, eventually the interval contains the point p, which means that p has error at most $2\Delta + \rho$. This contradicts our initial assumption that $e(p)$ was greater than $2\Delta + \rho$. ∎

In addition, since $e(0) \approx_\Delta e(0) + e(0)$, $|e(0)| \leq \Delta$. We now generalize the error bound on $\mathcal{D}^+_{n,s}$ to $\mathcal{D}_{n,s}$.

LEMMA 7. *If a function g is Δ-approximately linear on $\mathcal{D}_{n,s}$, with h and e defined as in Lemma 6, and if $|e(\frac{n}{s})| = \rho$, then for all $x \in \mathcal{D}_{n,s}, |e(x)| \leq 2\Delta + \rho$.*

Proof. Observe that if the error $e(x)$ is upper bounded by σ when $x \in [0, \frac{n}{s}]$, then $|e(x)| \leq (\sigma + \Delta)/2$ whenever $0 \leq x \leq \frac{n}{2s}$, since $e(2x) \leq \sigma$. Also, if $|e(x)| \leq \mu$, then $|e(-x)| \leq \mu + 2\Delta$ since $e(0) \leq \Delta$. By Lemma 6, $e(x) \leq 2\Delta + \rho$ for all $x \in \mathcal{D}^+_{n,s}$. We will bound the error in $\mathcal{D}^-_{n,s}$ first by $3\Delta + \rho$ and then by $2\Delta + \rho$. From the above observations, we have $e(x) \leq 4\Delta + \rho$ for $x \in \mathcal{D}^-_{n,s}$, $e(x) \leq (3\Delta + \rho)/2$ for $x \in [0, \frac{n}{2s}]$ and $e(x) \leq (5\Delta + \rho)/2$ for $x \in [-\frac{n}{2s}, 0]$.

Assume that $\exists x \in \mathcal{D}^-_{n,s}$ such that $e(x) = 3\Delta + \rho + \epsilon > 3\Delta + \rho$. Let p be such a point with minimal absolute value. Then $p < -\frac{n}{2s}$, otherwise the error at $2p$ would exceed $3\Delta + \rho$. Let t be the point with the highest error in $\mathcal{D}^+_{n,s}$ (the maximal such one if there is a tie). We consider the possible locations for t to bound $e(t)$: (i) if $t \leq \frac{n}{2s}$, then to ensure that $e(2t) \leq e(t)$, $e(t) \leq \Delta$; (ii) if $\frac{n}{2s} < t \leq |p|$, then $t + p \in [-\frac{n}{2s}, 0]$; therefore, to satisfy the bound above on $e(t + p)$, $e(t) \leq \Delta/2 - \epsilon \leq \Delta$; (iii) if $t > |p|$, then $t + p \in (0, \frac{n}{2s}]$; therefore to satisfy the bound above, $e(t) \leq -\Delta/2 - \epsilon \leq \Delta$.

Regardless of where t lies, $e(t) \leq \Delta \leq \Delta + \rho$; hence the error in $\mathcal{D}^+_{n,s}$ is bounded by $\Delta + \rho$. However, $e(\frac{n}{s} + p) \geq 3\Delta + 2\rho + \epsilon - \Delta > 2\Delta + \rho$. Since $\frac{n}{s} + p \in \mathcal{D}^+_{n,s}$, this contradicts the bound we established before. Therefore, there cannot be a point in $\mathcal{D}^-_{n,s}$ with error greater than $3\Delta + \rho$. A symmetric argument can be used to bound negative error.

Now we reduce the error bound to $2\Delta + \rho$. Assume that p is the minimal point in $\mathcal{D}^-_{n,s}$ with error at least $2\Delta + \rho$. The proof is similar to the previous stage, using the tighter bound $e(x) \leq 2\Delta + \rho/2$ for $x \in [-\frac{n}{2s}, 0]$. Cases (i) and (iii) stay the same; for case (ii) we have $e(t + p) \leq -\epsilon \leq \Delta$. Therefore, the error cannot exceed $\Delta + \rho$ in $\mathcal{D}^+_{n,s}$. However, $e(\frac{n}{s} + p) \geq 2\Delta + \epsilon + \rho - \Delta$, which is a contradiction. ∎

The following special case proves the stability result for linearity.

COROLLARY 8. *The linearity property is $(\mathcal{D}_{n,s}, \mathcal{D}_{n,s}, \Delta, 2\Delta)$-stable.*

Proof. Suppose function g is Δ-approximately linear on $\mathcal{D}_{n,s}$. Set $h(\frac{n}{s}) = g(\frac{n}{s})$ in Lemma 7. This uniquely defines a linear h with $\rho = 0$. ∎

The intuition that drives us to set $h(\frac{n}{s}) = g(\frac{n}{s})$ in the proof of Corollary 8 is as

follows. Consider the following function of n, s: $g(\frac{n}{s}) = (\frac{n}{s} + \frac{[(n-1)/3]}{s})\Delta$ ($[x]$ denotes integer part of x). It is easy to see that $g(x+y) \approx_\Delta g(x) + g(y)$. Note that setting $h(\frac{1}{s}) = g(\frac{1}{s})$ instead of $h(\frac{n}{s}) = g(\frac{n}{s})$ does not work in general. If we set $h(\frac{1}{s}) = g(\frac{1}{s})$, then we obtain $h(\frac{n}{s}) = \frac{n}{s}\Delta$. However, $\|g-h\|$ is a growing function of n and so there is no way to bound the error at all points.

The following example shows that the error bound obtained in Corollary 8 using our technique is tight: we have shown how to construct a linear function h so that $\|h-g\| \leq 2\Delta$. We now show that there is a function g that, given our method of constructing h, asymptotically approaches this bound from below. Define g as follows: $g(n) = 0$; $g(x) = (3x/n - 1)\Delta$ for $0 \leq x \leq n-1$; $g(-x) = -g(x)$ for $0 < x \leq n$. It is easy to see that g is Δ-approximately linear: If $x+y < n$, $g(x+y) - g(x) - g(y) = \Delta$. If $x + y = n$, then $g(x+y) = 0$ and so $g(x) + g(y) = \Delta$. Our construction sets $h(n) = 0$; thus, $h \equiv 0$, the zero function. However, $\|g-h\| = |g(n-1) - h(n-1)| = (2 - 3/n)\Delta \longrightarrow 2\Delta$ for large enough n.

2.2. Approximate multilinearity. In this section we focus our attention on *multilinear functions*. A multivariate function is multilinear if it is linear in any one input when all the other inputs are fixed. A multilinear function of k variables is called a k-linear function. An example of a *bilinear* function is multiplication, and bilinearity property can be stated concisely as $f(x_1 + x_1', x_2 + x_2') = f(x_1, x_2) + f(x_1', x_2) + f(x_1, x_2') + f(x_1', x_2')$. Note that distributivity of multiplication over addition is a special case of multilinearity.

A natural extension of this class of functions is the class of approximately multilinear functions, which are formally defined below.

DEFINITION 9 (approximate multilinearity). *A k-variate function g is* Δ-approximately k-linear *on $\mathcal{D}_{n,s}^k$ if it is Δ-approximately linear on $\mathcal{D}_{n,s}$ in each variable.*

For instance, for $k = 2$, a function g is Δ-approximately bilinear if for all $x_1, x_1', x_2, x_2' \in \mathcal{D}$, $g(x_1 + x_1', x_2) \approx_\Delta g(x_1, x_2) + g(x_1', x_2)$ and $g(x_1, x_2 + x_2') \approx_\Delta g(x_1, x_2) + g(x_1, x_2')$.

Now we generalize Lemma 7 to Δ-approximately k-linear functions. Let g be a Δ-approximately k-linear function and h be the symmetric multilinear function uniquely defined by the condition $h(\frac{n}{s}, \ldots, \frac{n}{s}) = g(\frac{n}{s}, \ldots, \frac{n}{s})$. Let $e \equiv h - g$. e is a Δ-approximately k-linear function.

Since g takes k inputs from $\mathcal{D}_{n,s}$, if we consider each input to g as a coordinate, the set of all possible k-tuples of inputs of g form a $(2n+1) \times \cdots \times (2n+1)$ cube of dimension k. We show that for any point $(x_1, \ldots, x_k)$ in this cube, $|e(x_1, \ldots, x_k)|$ is bounded.

THEOREM 10. *The approximate k-linearity property is $(\mathcal{D}_{n,s}^k, \mathcal{D}_{n,s}^k, \Delta, 2k\Delta)$-stable. In other words, if a function g is Δ-approximately k-linear on $\mathcal{D}_{n,s}^k$, then there exists a k-linear h on $\mathcal{D}_{n,s}^k$ such that $\|h-g\| \leq 2k\Delta$.*

Proof. With h defined as above, $e(\frac{n}{s}, \ldots, \frac{n}{s}) = 0$. First, we argue about points that have one coordinate that is different from $\frac{n}{s}$. Fix $k-1$ of the inputs to be $\frac{n}{s}$ (hard-wire into g) and vary one (say, x_i). This operation transforms g from a Δ-approximately k-linear function of $x_1, \ldots, x_k$ to a Δ-approximately linear function of x_i. By Lemma 7, this function cannot have an error of more than 2Δ in $\mathcal{D}_{n,s}$. Therefore, $|e(\frac{n}{s}, \ldots, \frac{n}{s}, x_i, \frac{n}{s}, \ldots, \frac{n}{s})| \leq 2\Delta$, if $|x_i| < \frac{n}{s}$. Next we consider points which have two coordinates that are different from $\frac{n}{s}$. Consider without loss of generality an input $a, b, \frac{n}{s}, \ldots, \frac{n}{s}$. By the result we just argued, we know that $e(\frac{n}{s}, b, \frac{n}{s}, \ldots, \frac{n}{s}) \leq 2\Delta$. By fixing inputs 2 through k to be $b, \frac{n}{s}, \ldots, \frac{n}{s}$, and varying

the first input, by Lemma 7, we have $|e(a, b, \frac{n}{s}, \ldots, \frac{n}{s})| \leq 4\Delta$ for any $a \in \mathcal{D}_{n,s}$. Via symmetric arguments, we can bound the error by 4Δ if any two inputs are different from $\frac{n}{s}$. Continuing this way, it can be shown that for all inputs, the error is at most $2k\Delta$. □

The following theorem shows that the error can be reduced to $(1+\mu)\Delta$ for any constant $\mu > 0$ by imposing the multilinearity condition on a larger domain $\mathcal{D}'$ and fitting the multilinear function h on $\mathcal{D}$, where $|\mathcal{D}'|/|\mathcal{D}| = \lceil 2k/\mu \rceil$. Note that doubling the domain size only involves adding one more bit to the representation of a domain element.

THEOREM 11. *For any $\mu > 0$, the approximate multilinearity property is $(\mathcal{D}^k_{2kn/\mu,s}, \mathcal{D}^k_{n,s}, \Delta, (1+\mu)\Delta)$-stable.*

Proof. By Theorem 10, g is $2k\Delta$-close to a k-linear h on $\mathcal{D}_{2kn/\mu,s}$. For any $x = x_1, \ldots, x_k$, we fix all coordinates except x_i and argue in the ith coordinate as below.

For any $\mathcal{D}_{m,s}$, first we show that if $|e(x)|_{\mathcal{D}_{m,s}} \leq \rho$, then $|e(x)|_{\mathcal{D}_{m/2,s}} \leq (\rho+\Delta)/2$. To observe this, note that if $x \in \mathcal{D}_{m/2,s}$, then $2x \in \mathcal{D}_{m,s}$. Therefore the function should satisfy $e(x) + e(x) \approx_\Delta e(2x)$, which implies that $|e(x)| \leq (\rho+\Delta)/2$. Thus, in general, the maximum error in $\mathcal{D}_{m/2^i,s}$ is $\leq \rho/2^i + \Delta(1 - 1/2^i)$. Since the error in $\mathcal{D}_{2kn/\mu,s}$ is at most $2k\Delta$, the error in $\mathcal{D}_{n,s}$ is at most $(1+\mu)\Delta$ by our choice of parameters. In the multilinear case, we can make a similar argument by using points which have at least one coordinate x_i within the smaller half of the axis. □

3. Polynomials. To test programs purportedly computing polynomials, it is tempting to (i) interpolate the polynomial from randomly chosen points and then (ii) verify that the program is approximately equal to the interpolated polynomial for a large fraction of the inputs. Since a degree d k-variate polynomial can have $(d+1)^k$ terms, this leads to exponential running times. Furthermore, it is not obvious how error bounds that are *independent* of the domain size can be obtained.

Our test uses the same "evenly spaced" interpolation identity as that in [30]: f is a degree d polynomial if and only if for all $x, t \in \mathcal{D}$, $\sum_{i=0}^{d+1} (-1)^{d+1-i} \binom{d+1}{i} f(x + it) = 0$. This identity is computed by the method of successive differences which never explicitly interpolates the polynomial computed by the program, thus giving a particularly simple and efficient ($O(d^2)$ operations) test.

We can show that the interpolation identity is approximately robust by modifying the robustness theorem in [29] (section 3.3). Our proof of stability of the interpolation identity (section 3.2), however, uses a characterization of polynomials in terms of multilinear functions that previously has not been applied to program checking. This in turn allows us to use our results on the stability of multilinearity (section 2.2) and other ideas from stability theory. Section 3.4 extends these techniques to multivariate polynomials.

3.1. Preliminaries. In this section, we present the basic definitions and theorems that we will use. Define

$$\nabla_t f(x) \stackrel{\text{def}}{=} f(x+t) - f(x)$$

to be the standard *forward difference operator*. Let

$$\nabla_t^d f(x) \stackrel{\text{def}}{=} \overbrace{\nabla_t \cdots \nabla_t}^{d} f(x) = \sum_{k=0}^{d} (-1)^{d-k} \binom{d}{k} f(x + kt)$$

and $\nabla_{t_1,t_2} f(x) \stackrel{\text{def}}{=} \nabla_{t_1} \nabla_{t_2} f(x)$. The following are simple facts concerning this operator.

FACT 12. *The following are true for the difference operator* ∇*:*

1. ∇ *is linear:* $\nabla(f+g) = \nabla f + \nabla g$*;*
2. ∇ *is commutative:* $\nabla_{t_1,t_2} = \nabla_{t_2,t_1}$*; and*
3. $\nabla_{t_1+t_2} - \nabla_{t_1} - \nabla_{t_2} = \nabla_{t_1,t_2} = \nabla_{t_2,t_1}$.

Let $x^{[k]}$ denote $\overbrace{x,\ldots,x}^{k}$. For any k-ary symmetric f, let $f^*(x) = f(x^{[k]})$ denote its diagonal restriction. We use three different characterizations of polynomials [27, 15].

FACT 13. *Let* $\mathcal{D}$ *be a ring. The following are equivalent:*

1. *there exist* $a_0,\ldots,a_d \in \mathcal{D}$ *such that for all* $x \in \mathcal{D}$, $f(x) = \sum_{k=0}^{d} a_k x^k$*;*
2. *for all* $x,t \in \mathcal{D}$, $\nabla_t^{d+1} f(x) = 0$*;*
3. *there exist symmetric* k*-linear functions* F_k*,* $0 \le k \le d$*, such that for all* $x \in \mathcal{D}$, $f(x) = \sum_{k=0}^{d} F_k^*(x)$.

The above fact remains true for nonclosed domains so long as we insist that the arguments to f are from the domain.

The following definitions are motivated by the notions of using evenly and unevenly spaced points in interpolation.

DEFINITION 14 (strong approximate polynomial). *A function* g *is called* strongly Δ-approximately degree d polynomial on $\mathcal{D}$ *if for all* $x,t_1,\ldots,t_{d+1} \in \mathcal{D}$ *such that* $x + t_1 + \cdots + t_{d+1} \in \mathcal{D}$, $|\nabla_{t_1,\ldots,t_{d+1}} g(x)| \le \Delta$.

DEFINITION 15 (weak approximate polynomial). *A function* g *is called* weakly Δ-approximately degree d polynomial on $\mathcal{D}$ *if for all* $x,t \in \mathcal{D}$ *such that* $x+t(d+1) \in \mathcal{D}$, $|\nabla_t^{d+1} g(x)| \le \Delta$.

3.2. Stability for polynomials. First, we prove that if a function is strongly Δ-approximately polynomial, then there is a polynomial that $(2^{d \lg d}\Delta, 0)$-approximates it. Next, we show that if a function is weakly approximately polynomial on a domain, then there is a coarser subdomain on which the function is strongly approximately polynomial. Combining these two, we can show that if a function is weakly approximately polynomial on a domain, then there is a subdomain on which the function approximates a polynomial. By using Theorem 11, we can bring the above error arbitrarily close to Δ by assuming the hypothesis on a large enough domain. In order to pass programs that err by at most Δ', we need to set $\Delta \ge (d+1) \cdot 2^d \Delta'$.

Strongly approximate case. One must be careful in defining polynomial h that is close to g. For instance, defining h based on the values of g at some $d+1$ points will not work. We proceed by modifying techniques in [2, 19] using the following fact.

FACT 16. *If a function* f *is symmetric and* k*-linear, then* $\nabla_{t_1,\ldots,t_d} f^*(x) = k! f(t_1,\ldots,t_k)$ *if* $k = d$ *and* 0 *if* $k < d$.

The following theorem shows the stability of the strong approximate polynomial property.

THEOREM 17. *The strong approximate polynomial property is* $(\mathcal{D}_{n(d+2),s}, \mathcal{D}_{n,s}, \Delta, O(2^{d \lg d})\Delta)$*-stable. In other words, if* g *is a strongly* Δ*-approximately degree* d *polynomial on* $\mathcal{D}_{n(d+2),s}$*, then there is a degree* d *polynomial* h_d *such that* $\|g - h_d\|_{\mathcal{D}_{n,s}} \le O(2^{d \lg d})\Delta$.

Proof. Note that if $x,t_1,\ldots,t_{d+1} \in \mathcal{D}_{n,s}$, then $x + t_1 + \cdots + t_{d+1} \in \mathcal{D}_{(d+2)n,s}$. Now, the hypothesis that g is a strongly Δ-approximately degree d polynomial on $\mathcal{D}_{n(d+2),s}$ guarantees that for all $x,t_1,\ldots,t_{d+1} \in \mathcal{D}_{n,s}$, $|\nabla_{t_1,\ldots,t_{d+1}} g(x)| \le \Delta$. The rest of the proof uses this "modified hypothesis" and works with $\mathcal{D}_{n,s}$.

We induct on the degree. Let $e_d \stackrel{\text{def}}{=} |g - h_d|$. When $d = 0$, by the modified hypothesis, we have for all $x, t \in \mathcal{D}_{n,s}, |\nabla_t g(x)| \leq \Delta$, i.e., $|\nabla_t g(0)| = |g(t) - g(0)| \leq \Delta$ for all $t \in \mathcal{D}_{n,s}$. Setting $h_0 = g(0)$, a constant, we are done.

Suppose the lemma holds when the degree is strictly less than $d + 1$. Now, by the modified hypothesis, we have for all $t_1, \ldots, t_{d+1} \in \mathcal{D}_{n,s}$, $|\nabla_{t_1,\ldots,t_{d+1}} g(x)| \leq \Delta$. Using Fact 12 and then our modified hypothesis, we have $|\nabla_{t_1+t'_1,t_2,\ldots,t_d} g(x) - \nabla_{t_1,t_2,\ldots,t_d} g(x) - \nabla_{t'_1,t_2,\ldots,t_d} g(x)| = |\nabla_{t_1,t'_1,\ldots,t_d} g(x)| \leq \Delta$. By symmetry of the difference operator, we have a Δ-approximate symmetric d-linear function on $\mathcal{D}_{n,s}$, say, $G(t_1, \ldots, t_d) \stackrel{\text{def}}{=} \nabla_{t_1,\ldots,t_d} g(0)$. Theorem 10 on multilinearity guarantees a symmetric d-linear H with $\|G - H\| \leq 2d\Delta$. Let $H_d(x_1, \ldots, x_d) = H(x_1, \ldots, x_d)/d!$. Let $g'(x) = g(x) - H^*_d(x)$ for $x \in \mathcal{D}_{n,s}$.

Now, we have for all $x, t_1, \ldots, t_d \in \mathcal{D}_{n,s}$,

$$\begin{aligned}
|\nabla_{t_1,\ldots,t_d} g'(x)| &= |\nabla_{t_1,\ldots,t_d}(g(x) - H^*_d(x))| \quad \text{(definition of } g') \\
&\leq |\nabla_{t_1,\ldots,t_d} g(x) - \nabla_{t_1,\ldots,t_d} g(0)| \\
&\quad + |\nabla_{t_1,\ldots,t_d} g(0) - \nabla_{t_1,\ldots,t_d} H^*_d(x)| \quad \text{(triangle inequality)} \\
&= |\nabla_{t_1,\ldots,t_d,x} g(0)| + |\nabla_{t_1,\ldots,t_d} g(0) - \nabla_{t_1,\ldots,t_d} H^*_d(x)| \quad \text{(definition of } \nabla) \\
&= |\nabla_{t_1,\ldots,t_d,x} g(0)| + |G(t_1, \ldots, t_d) - \nabla_{t_1,\ldots,t_d} H^*_d(x)| \quad \text{(definition of } G) \\
&= |\nabla_{t_1,\ldots,t_d,x} g(0)| + |G(t_1, \ldots, t_d) - d! H_d(t_1, \ldots, t_d)| \quad \text{(Fact 16)} \\
&= |\nabla_{t_1,\ldots,t_d,x} g(0)| + |G(t_1, \ldots, t_d) - H(t_1, \ldots, t_d)| \quad \text{(definition of } H_d) \\
&\leq \Delta + |G(t_1, \ldots, t_d) - H(t_1, \ldots, t_d)| \quad \text{(modified hypothesis on } g) \\
&\leq (2d + 1)\Delta \quad \text{(since } \|G - H\| \leq 2d\Delta).
\end{aligned}$$

Now we apply the induction hypothesis. g' satisfies the hypothesis above for d and larger error $\Delta' = (2d+1)\Delta$ and so by induction, we are guaranteed the existence of a degree $d-1$ polynomial h_{d-1} such that $\|g' - h_{d-1}\| \leq e_{d-1}\Delta'$. Set $h_d = h_{d-1} + H^*_d$. By Fact 13(3) about the characterization of polynomials, h_d is a degree d polynomial. Now, $e_d = \|g - h_d\| = \|g - h_{d-1} - H^*_d\| = \|g' - h_{d-1}\| \leq e_{d-1}\Delta' = e_{d-1}(2d + 1)\Delta$.

Unwinding the recurrence, the final error $\|g - h_d\| = \Delta \prod_{i=1}^{d}(2i + 1)$. □

Weakly approximate case. We first need the following useful fact [15] which helps us to go from equally spaced points to unequally spaced points.

FACT 18. *For any $\lambda_1, \ldots, \lambda_d \in \{0, 1\}$, if $t'_{\lambda_1,\ldots,\lambda_d} = -\sum_{i=1}^{d} \lambda_i t_i/i$ and $t''_{\lambda_1,\ldots,\lambda_d} = \sum_{i=1}^{d} \lambda_i t_i$, then*

$$\nabla_{t_1,\ldots,t_d} f(x) = \sum_{\lambda_1,\ldots,\lambda_d \in \{0,1\}} (-1)^{\lambda_1+\cdots+\lambda_d} \nabla^d_{t'_{\lambda_1,\ldots,\lambda_d}} f(x + t''_{\lambda_1,\ldots,\lambda_d}).$$

Using this fact, we obtain the following theorem. Let $\mu(d) = \text{lcm}\{1, 2, \ldots, d\}$.

THEOREM 19. *If g is weakly $(\Delta/2^{d+1})$-approximately degree d polynomial on $\mathcal{D}_{n(d+1),s\mu(d+1)}$, then g is strongly Δ-approximately degree d polynomial on $\mathcal{D}_{n,s}$.*

Proof. For $t_1, \ldots, t_{d+1} \in \mathcal{D}_{n,s}$, and for any $\lambda_1, \ldots, \lambda_{d+1} \in \{0, 1\}$, we have by our choice of parameters that $t'_{\lambda_1,\ldots,\lambda_{d+1}}, t''_{\lambda_1,\ldots,\lambda_{d+1}} \in \mathcal{D}_{n(d+1),s\mu(d+1)}$. Therefore, for $x \in \mathcal{D}_{n,s}$,

$$\begin{aligned}
|\nabla_{t_1,\ldots,t_{d+1}} g(x)| &\leq \sum_{\lambda_1,\ldots,\lambda_{d+1} \in \{0,1\}} |\nabla^{d+1}_{t'_{\lambda_1,\ldots,\lambda_{d+1}}} g(x + t''_{\lambda_1,\ldots,\lambda_{d+1}})| \\
&\leq 2^{d+1}(\Delta/2^{d+1}) \leq \Delta. \quad \square
\end{aligned}$$

3.3. Approximate robustness for polynomials. This section shows that the interpolation equation for degree d polynomials is in some sense approximately robust. All the results in this subsection are modifications of the exact robustness of polynomials given in [29]. Let $\alpha_k = (-1)^{d+1-k}\binom{d+1}{k}$. To self-test P on $\mathcal{D}_{n,s}$, we use the following domains. These domains are used for technical reasons that will become apparent in the proofs of the theorems in this section.

1. $\mathcal{D}_{(d+2)n,s}$.
2. $\mathcal{T} = \mathcal{D}_{K_n,L_s}$ where $K_n = n(d+2)(n(d+1)!)^3$ and $L_s = s((d+1)!)^3$.
3. $\mathcal{T}_j = \{jx : x \in \mathcal{T}\}$ for $0 \le j \le d+1$.
4. $\mathcal{T}_{i,j} = \{ix : x \in \mathcal{T}_j\}$ for $0 \le i, j \le d+1$.

All $\mathcal{T}_j, \mathcal{T}_{i,j}$ contain $\mathcal{D}_{(d+2)n,s}$. Now, assume that P satisfies the following properties, which are similar to the low-degree test in an approximate setting and over different domains. Note that these properties can be tested by sampling. We use $\Pr_{x\in\mathcal{D}}[\cdot]$ to denote the probability of an event when x is chosen uniformly from domain $\mathcal{D}$.

1. $\displaystyle\Pr_{0\le k\le d+1, x\in\mathcal{D}_{n,s}, t\in\mathcal{T}_k}\left[\sum_{i=0}^{d+1}\alpha_i P(x+it) \approx_\Delta 0\right] \ge 1-\epsilon;$
2. for each $0 \le j \le d+1$, $\displaystyle\Pr_{0\le k,l\le d+1, x\in\mathcal{T}_{k,j}, t\in\mathcal{T}_l}\left[\sum_{i=0}^{d+1}\alpha_i P(x+it) \approx_\Delta 0\right] \ge 1-\epsilon;$ and
3. for each $0 \le i, j \le d+1$, $\displaystyle\Pr_{0\le k\le d+1, x\in\mathcal{T}_{i,j}, t\in\mathcal{T}_k}\left[\sum_{l=0}^{d+1}\alpha_l P(x+lt) \approx_\Delta 0\right] \ge 1-\epsilon.$

Define $g(x) = \text{median}_{0\le k\le d+1, t\in\mathcal{T}_k}\{\sum_{i=1}^{d+1}\alpha_i P(x+it)\}$. We obtain the following theorem that shows the approximate robustness of polynomials. Let $\mathcal{E}_{\tau(n,s)}$ be the distribution that flips a fair three-sided die and on outcome $i \in \{1,2,3\}$ chooses inputs according to distribution given in the ith property above. Let $\mathcal{D}_{\tau(n,s)}$ be the union of the domains used in the above properties.

THEOREM 20. *The interpolation equation, where inputs are picked according to the distribution $\mathcal{E}_{\tau(n,s)}$, is $(2\epsilon, \epsilon, \mathcal{D}_{\tau(n,s)}, \mathcal{D}_{n,s}, \Delta, 2^{d+3}\Delta, \Delta)$-approximately robust.*

The rest of this section is devoted to proving the above theorem.

By Markov's inequality, g's definition, and properties (1) and (3) of P, it is easy to show that P $(\Delta, 2\epsilon)$-approximates g.

THEOREM 21. *If program P satisfies the above three properties, then, for all $i, j \in \{0, \ldots, d+1\}$, $\Pr_{x\in\mathcal{T}_{i,j}}[P(x) \approx_\Delta g(x)] \ge 1-2\epsilon$ and $\Pr_{x\in\mathcal{D}_{n,s}}[P(x) \approx_\Delta g(x)] \ge 1-2\epsilon$.*

Now, we set out to prove that g is a weakly approximate polynomial. Let $\delta(p_1,p_2) = p_1$ if $p_1 = p_2$ and 0 otherwise. For two domains $\mathcal{A}, \mathcal{B}$, subsets of a universe $\mathcal{X}$, let $\delta(\mathcal{A},\mathcal{B}) = \sum_{s\in\mathcal{X}}\delta(\Pr_{x\in\mathcal{A}}[x=s], \Pr_{y\in\mathcal{B}}[y=s])$ and call the domains ϵ-*close* if $\delta(\mathcal{A},\mathcal{B})$ is at least $1-\epsilon$. Using the definitions of $\mathcal{T}, \mathcal{T}_j, \mathcal{T}_{i,j}$, the following fact can be shown.

FACT 22. *For any $x \in \mathcal{D}_{(d+2)n,s}$, the domains $\mathcal{T}_j$ and $\{x+t : t \in \mathcal{T}_j\}$ are $\epsilon_1 = O(1/n^3)$-close. For any x, the domains $\mathcal{T}_{i,j}$ and $\{x+t : t \in \mathcal{T}_{i,j}\}$ are $\epsilon_2 = O(1/n^3)$-close.*

The following lemma shows that, in some sense, g is well-defined and links it to an interpolation obtained from P.

LEMMA 23. *For all $x \in \mathcal{D}_{(d+2)n,s}$, $\Pr_{0\le k\le d+1, t\in\mathcal{T}_k}[g(x) \approx_{2^{d+2}\Delta} \sum_{j=1}^{d+1}\alpha_j P(x+jt)] \ge 1-\epsilon_3$ and for all i, $\Pr_{t\in\mathcal{T}_i}[g(x) \approx_{2^{d+2}\Delta} \sum_{j=1}^{d+1}\alpha_j P(x+jt)] \ge 1-\epsilon_4$, where $\epsilon_3 = 2(d+1)(\epsilon+\epsilon_2)$ and $\epsilon_4 = (d+1)\epsilon_3$.*

Proof. Consider $0 \le k, l \le d+1$, and $t_1 \in \mathcal{T}_k, t_2 \in \mathcal{T}_l$. For a fixed $0 \le j \le d+1$, using properties of P, and since $\mathcal{T}_{j,k}$ and $\{x + jt_1 : t_1 \in \mathcal{T}_k\}$ are ϵ_2-close (Fact 22), we get $\Pr[P(x+jt_1) \approx_\Delta \sum_{i=1}^{d+1} \alpha_i P(x+jt_1+it_2)] \ge 1-\epsilon-\epsilon_2$ and $\Pr[P(x+it_2) \approx_\Delta \sum_{j=1}^{d+1} \alpha_j P(x+jt_1+it_2)] \ge 1-\epsilon-\epsilon_2$. Summing over all $0 \le i,j \le d+1$ and noting that $\sum_{i=1}^{d+1} \alpha_j \Delta \le 2^{d+1}\Delta$, $\Pr[\sum_{j=1}^{d+1} \alpha_j P(x+jt_1) \approx_{2^{d+1}\Delta} \sum_{i=1}^{d+1} \alpha_i P(x+it_2)] \ge 1 - 2(d+1)(\epsilon+\epsilon_2) = 1-\epsilon_3$. Using Lemma 43 (see section 4.3), we can show that with a relaxation of twice the error, this probability lower bounds the probability in the first part of the lemma. The second part of the lemma follows from the first via a simple averaging argument. ∎

Now, the following theorem completes the proof that g is a weakly approximate degree d polynomial.

THEOREM 24. *For all $x \in \mathcal{D}_{(d+2)n,s}$, for all $i \in \{0,\dots,d+1\}$, $\Pr_{t\in\mathcal{T}_i}[g(x) \approx_{2^{d+3}\Delta} \sum_{j=1}^{d+1} \alpha_j g(x+jt)] \ge 1-\epsilon_5$, where $\epsilon_5 = \epsilon_4 + (d+1)(2\epsilon+\epsilon_2)$, and for all $x,t \in \mathcal{D}_{n,s}$, $\Pr_{t_1\in\mathcal{T}}[|\nabla_t^{d+1} g(x)| \le 2^{d+3}\Delta] \ge 1-(d+1)(2\epsilon_5+\epsilon_1)$.*

Proof. It is implied by Theorem 21, Lemma 23, and the closeness of the domains $\mathcal{T}_{i,j}$ and $\{x+t : t \in \mathcal{T}_{i,j}\}$ that for all $x \in \mathcal{D}_{(d+2)n,s}$, for all i, $\Pr_{t\in\mathcal{T}_i}[g(x) \approx_{2^{d+2}\Delta} \sum_{j=1}^{d+1} \alpha_j P(x+jt)] \ge 1-\epsilon_4$ and $\Pr_{t\in\mathcal{T}_i}[g(x+jt) \approx_\Delta P(x+jt)] \ge 1-2\epsilon-\epsilon_2$. Summing the latter expression and putting them together, we have the first part of the lemma. The second part follows from the first part and the fact that $\mathcal{T}_j$ and $\{t+jt_1 : t_1 \in \mathcal{T}\}$ are ϵ_1-close (Fact 22). ∎

For an appropriate choice of $\epsilon, \epsilon_1, \epsilon_2$, we have a g that is a weakly $(2^{d+3}\Delta)$-approximately degree d polynomial on $\mathcal{D}_{n,s}$ with g $(\Delta, 2\epsilon)$-approximating P on $\mathcal{D}_{n,s}$.

3.4. Multivariate polynomials. The following approach is illustrated for bivariate polynomials. We can easily generalize this to multivariate polynomials. It is easy to show that the approximate robustness holds when the interpolation equation [30] is used as in section 3.3, i.e., for any k-variate polynomial P of total degree d, the following interpolation equation is satisfied for all $\bar{x}, \bar{t} \in \mathcal{D}_{n,s}^k$:

$$\sum_{i=0}^{d+1} \alpha_i P(\bar{x} + i\bar{t}) = 0.$$

A *horizontal axis parallel line* for a fixed y is the set of points $l_{x,h} = \{(x+kh, y) : k \in \mathbb{Z}\}$. A vertical axis parallel line is defined analogously. As a consequence of approximate robustness, we have a bivariate function $g(x,y)$ that is a strongly approximately degree d polynomial along every horizontal and vertical line. We use this consequence to prove stability.

The characterization we will use is as follows: $f(x,y)$ is a bivariate polynomial (assume degree in both x and y is d) if and only if there are $d+1$ symmetric k-linear functions $F_k(y_1,\dots,y_k) : \mathcal{D}^k \to \mathcal{P}_\mathcal{D}[x]$, where the range is the space of all degree d univariate polynomials in x.

For each value of y, $g_y(x)$ is a strongly approximately degree d polynomial. Using the univariate case (Theorem 17), there is an exact degree d polynomial $P_y(x)$ such that for all x, $g(x,y) \approx_{2^{d\lg d}\Delta} P_y(x)$. Construct the function $g'(x,y) = P_y(x)$. Let $\Delta' = 2^{d\lg d}\Delta$. Now, for a fixed x (i.e., on vertical line) for any y, using $\nabla_{t_1,\dots,t_{d+1}} g(x,y) \approx_\Delta 0$, we have $\nabla_{t_1,\dots,t_{d+1}} g'(x,y) \approx_{\Delta'} 0$. Thus, $g'(x,y)$ is a bivariate function where along every horizontal line, it is an *exact* degree d polynomial and along every vertical line, it is a strongly Δ'-approximate degree d polynomial. Interpreting $g'(x,y)$ as $g'_x(y)$ and using the same idea as in univariate case, we can conclude that $\nabla(t_1,\dots,t_d)$:

$\mathcal{D}^d \to \mathcal{P}_{\mathcal{D}}[x]$ is a symmetric approximate d-linear function (here, we used the fact that $g'_x(y) \in \mathcal{P}_{\mathcal{D}}[x]$). The rest of the argument in Theorem 17 goes through because our proofs of approximate linearity (Lemma 7) and multilinearity (Theorem 10) assume that the range is a metric space (which is true for $\mathcal{P}_{\mathcal{D}}[x]$ with, say, the Chebyshev norm). The result follows from the above characterization of bivariate polynomials.

4. Functional equations. Extending the technique in Lemma 7 to addition theorems $f(x+y) = G[f(x), f(y)]$ is not straightforward, since G can be an arbitrary function. In order to prove approximate robustness (section 4.3) and stability (section 4.2), several related properties of G are required. Proving that G satisfies each individual one is tedious; however, the notion of *modulus of continuity* from approximation theory gives a general approach to this problem. We show that bounds on the modulus of continuity imply bounds on all of the quantities of G that we require. The stability of G is shown by a careful inductive technique based on a canonical generation of the elements in $\mathcal{D}_{n,s}$ (section 4.2). The scope of our techniques is not only limited to addition theorems; we also show that Jensen's equation is approximately robust and stable (section 4.2.4).

4.1. Preliminaries. For addition theorems, we can assume that G is algebraic and a symmetric function (the latter is true, in general, under some technical assumptions as in [28]). We need a notion of "smoothness" of G. The following notions are well known in approximation theory [25, 33].

DEFINITION 25 (moduli of continuity). *The* modulus of continuity *of the function $f : \mathcal{D} \to \mathbb{R}$ is the following function of $\delta \in [0, \infty)$:*

$$\omega(f; \delta) = \sup_{\substack{|x_1 - x_2| \le \delta \\ x_1, x_2 \in \mathcal{D}}} \{|f(x_1) - f(x_2)|\}.$$

The modulus of continuity *of the function $f : \mathcal{D}^2 \to \mathbb{R}$ is the following function of $\delta_x, \delta_y \in [0, \infty)^2$:*

$$\omega(f; \delta_x, \delta_y) = \sup_{\substack{|x_1 - x_2| \le \delta_x, |y_1 - y_2| \le \delta_y \\ x_1, y_1, x_2, y_2 \in \mathcal{D}}} \{|f(x_1, y_1) - f(x_2, y_2)|\}.$$

The partial moduli of continuity *of the function $f : \mathcal{D}^2 \to \mathbb{R}$ are the following functions of $\delta \in [0, \infty)$:*

$$\omega(f; \delta, 0) = \sup_{y \in \mathcal{D}} \sup_{\substack{|x_1 - x_2| \le \delta \\ x_1, x_2 \in \mathcal{D}}} \{|f(x_1, y) - f(x_2, y)|\} \text{ and}$$

$$\omega(f; 0, \delta) = \sup_{x \in \mathcal{D}} \sup_{\substack{|y_1 - y_2| \le \delta \\ y_1, y_2 \in \mathcal{D}}} \{|f(x, y_1) - f(x, y_2)|\}.$$

We now present some facts which are easily proved.

FACT 26. *The following are true of the modulus of continuity:*

1. $0 \le \omega(f; \delta) \le \omega(f; \delta')$ *if* $\delta \le \delta'$;
2. *if f', the derivative of f, exists and is bounded in $\mathcal{D}$, then $\omega(f; \delta) \le \delta \|f'\|_{\mathcal{D}}$;*
3. $\omega(f; \delta, \delta) \le \omega(f; 0, \delta) + \omega(f; \delta, 0)$, *and if $f(\cdot, \cdot)$ is symmetric, then $\omega(f; \delta, \delta) \le 2\omega(f; \delta, 0)$; and*
4. *if f'_x is the partial derivative of f with respect to x, then $\omega(f; \delta, 0) \le \delta \|f'_x\|_{\mathcal{D}}$.*

We need a notion of an "inverse" of G. If $G[x, y] = z$, denote $G_1^{-1}[z, y] = x, G_2^{-1}[x, z] = y$. Since G is symmetric, $G_1^{-1} \equiv G_2^{-1}$ and we denote $G^{-1}[z, y] = x$.

An example. Wherever necessary, we will illustrate our scheme using the functional equation $f(x+y) = \frac{f(x)f(y)}{f(x)+f(y)}$, i.e., $G[x,y] = xy/(x+y)$. The solution to this functional equation is $f(x) = C/x$ for some constant C. The following fact [34] is useful in locating the maxima of analytic functions.

FACT 27 (maximum modulus principle). *If f is analytic in a compact set $\mathcal{D}$, then f attains extremum only on the boundary of $\mathcal{D}$.*

Over a bounded rectangle $\mathcal{D} = [L,U]^2$, where $0 < L \le U$, G is analytic, and hence by Fact 27 attains its maximum on the boundary. $G \in C^1[L,U]$ in $\mathcal{D}$ (i.e., is continuously differentiable). We have $G'_x[x,y] = y^2/(x+y)^2$ which is a decreasing function of x. By Fact 27, $\|G'_x\|$ attains a maximum when $x = L$, giving $\widehat{G} = \|G'_x(\cdot,y)\| = y^2/(L+y)^2$. Therefore, using Fact 26(4), $\omega(G;\delta,0) \le \sup_{y\in[L,U]} \frac{\delta y^2}{(L+y)^2} = \frac{\delta U^2}{(L+U)^2}$.

4.2. Stability for functional equations. In this section, we prove (under some assumptions) that if a function g satisfies a functional equation approximately everywhere, then it is close to a function h that satisfies the functional equation exactly everywhere. Our functional equations are of the form $g(x+y) = G[g(x), g(y)]$, where G is a symmetric algebraic function.

Example. If g satisfies $g(x+y) \approx_\Delta \frac{g(x)g(y)}{g(x)+g(y)}$ for some $\Delta > 0$ and for all valid x, y, then there is a function h such that $h(x+y) = \frac{h(x)h(y)}{h(x)+h(y)}$ for all valid x, y, and $h(x) \approx_{\Delta'} g(x)$ for some $\Delta' > 0$ and all valid x. The domains for the valid values of x, y, as well as the relationship between Δ and Δ', will be discussed later.

In the following sections we show how to construct the function h that is close to g, satisfying a particular functional equation. Given such an h, let $e(x)$ denote $|h(x) - g(x)|$, i.e., $h(x) \approx_{e(x)} g(x)$. For simplicity, let $H_1(x) \stackrel{\text{def}}{=} G[x,x]$. Note that $H_1(h(x)) = h(2x)$. We assume that $\omega(H_1;\delta) \le c\delta$; our results thus hold for functions where the modulus of continuity is linear in δ. We will be making this assumption for our moduli of continuity when appropriate.

We consider the cases when $c < 1$, $c = 1$, and $c > 1$. We first show how to obtain h and then obtain bounds on $e(x)$. Then, we can conclude that h, which satisfies the functional equation everywhere, also approximates g; i.e., the functional equation is stable.

Call $\frac{x}{s}$ even (resp., odd) if x is even (resp., odd).

4.2.1. When $c < 1$. We begin by assuming that n is a power of 2, i.e., let $n = 2^k$ in $\mathcal{D}_{n,s}$. We first construct h by setting $h(\frac{1}{s}) = g(\frac{1}{s})$. This determines h for all values in $\mathcal{D}$ by the fact that h satisfies the functional equation.

We obtain a relationship between the error at x and $2x$ using the functional equation.

LEMMA 28. $e(2x) \le ce(x) + \Delta$.

Proof. $e(2x) = |g(2x) - h(2x)| \le \Delta + |G[g(x),g(x)] - G[h(x),h(x)]|$. However, rewriting, and using the definition of the modulus of continuity, $|H_1(g(x)) - H_1(h(x))| \le \omega(H_1; e(x)) \le ce(x)$. ∎

We explore the relationship between $e(x + \frac{1}{s})$ and $e(x)$. For simplicity, let $H_2(x) \stackrel{\text{def}}{=} G[x, g(\frac{1}{s})]$. Note that $H_2(h(x)) = h(x+1)$. We again consider functions where the modulus of continuity is bounded by a linear function in δ, i.e., $\omega(H_2;\delta) = |H'_2(\cdot, g(\frac{1}{s}))| \le d\delta$ for some constant d. Now, we introduce the following lemma.

LEMMA 29. $e(x+\frac{1}{s}) \le de(x) + \Delta$.

Proof. $e(x+\frac{1}{s}) = |g(x+\frac{1}{s}) - h(x+\frac{1}{s})| \le \Delta + |G[g(x), g(\frac{1}{s})] - G[h(x), h(\frac{1}{s})]|$. However, $|G[g(x), g(\frac{1}{s})] - G[h(x), h(\frac{1}{s})] = |H_2[g(x)] - H_2[h(x)]| \le \omega(H_2; e(x)) \le de(x)$. □

We will show a scheme to bound $e(x)$ for all x when $d < 1$. This scheme can be thought of as an enumeration scheme, where at each step of the process, certain constraint equations have to be satisfied. We construct a binary tree T_k with nodes labeled with elements from $\mathcal{D}^+_{n,s}$ where $2^k = n$. The root is labeled $\frac{1}{s}$. If x is the label of a node, then $2x$ is the label of its left child (if $2x$ is not already in the tree), and $x + \frac{1}{s}$ is the label of its right child (if $x + \frac{1}{s}$ is not already in the tree). It is easy to see that if x is even (except root), then x is a left child; if x is odd, then x is a right child.

LEMMA 30. *Let $\omega(H_1; \delta) \le c\delta, \omega(H_2; \delta) \le d\delta$ with $c, d < 1$. For all $x \in \mathcal{D}^+_{n,s}$, if x is even, then $e(x) \le \frac{1+c}{1-c}\Delta$; and if x is odd, then $e(x) \le \frac{2}{1-c}\Delta$.*

Proof. We will prove this by induction on the preorder enumeration of T_k. Let x be the next element to be enumerated. By preorder listing, its parent has already been enumerated, and hence its error is known. If $x = 2y$ is even, it is a left child and hence generated by a $2y$ operation. $e(y) \le \frac{2}{1-c}\Delta$ by the induction hypothesis. This together with Lemma 28 yields $e(x) \le ce(y) + \Delta \le c\frac{2}{1-c}\Delta + \Delta \le \frac{1+c}{1-c}\Delta$, preserving the induction hypothesis. If $x = y + \frac{1}{s}$ is odd, it is a right child, and hence generated by a $y + 1$ operation. However, y is even, so $e(y) \le \frac{1+c}{1-c}\Delta$ by the induction hypothesis. This together with Lemma 29 and $d \le 1$ yields $e(x) \le de(y) + \Delta \le e(y) + \Delta \le \frac{1+c}{1-c}\Delta + \Delta \le \frac{2}{1-c}\Delta$, preserving the induction hypothesis. □

This yields the following theorem.

THEOREM 31. *Let $\omega(H_1; \delta) \le c\delta, \omega(H_2; \delta) \le d\delta$ with $c, d < 1$ and let n be a power of 2. Then, the addition theorem is $(\mathcal{D}^+_{n,s}, \mathcal{D}^+_{n,s}, \Delta, \frac{2}{1-c}\Delta)$-stable.*

With our example, we have $H_1(x) = G[x, x] = x/2$ and so $c = 1/2$. Also, $H_2(x) = G[x, g(\frac{1}{s})]$ from which $H_2'(x) \le 1$ as $0 < L \le x, g(\frac{1}{s})$. Thus, $d \le 1$. By Theorem 31, we have $e(x) \le 4\Delta$ for all $x \in \mathcal{D}^+_{n,s}$.

When n is not a power of 2, we can argue in the following manner. From our proof, we see that we use very specific values of x, y in the approximate functional equation. Let i be such that $2^{i-1} \le n \le 2^i$ and let $\mathcal{D}' = \mathcal{D}_{2^i,s}$. We extend $\mathcal{D}^+_{n,s}$ to $\mathcal{D}'$ and define values of g at $\mathcal{D}' \backslash \mathcal{D}$: at even x $(= 2y)$ let $g(x) = H_1(g(y))$ and at odd x $(= y + 1)$ let $g(x) = H_2(g(y))$. These can be thought of as new assumptions on g which are satisfied "exactly" (i.e., without error Δ). We can use Lemma 30 to conclude that there is a linear h on $\mathcal{D}'$ that is $\frac{2}{1-c}\Delta$ close to g. Hence, h is close to g even on $\mathcal{D}^+_{n,s}$. To argue about $\mathcal{D}^-_{n,s}$, we pick a "pivot" point in $\mathcal{D}_{n,s}$ (0 for simplicity). Now, we have $h(-x) = G^{-1}[h(x), h(0)]$. Therefore, as in Theorem 31, we have $e(-x) \le \omega(G^{-1}; \frac{2c}{1-c})$.

When $d \ge 1$, the error can no longer be bounded. In this case, we have $c \le 1 < d$. Let $r = cd$. We can see from the structure of T_k that the maximum error can occur at $\frac{2^k-1}{s}$. By simple induction on the depth of the tree, the error is given by $e(\frac{2^k-1}{s}) \le \sum_{i=0}^{k-2}(d^{i+1} + d^i)c^i\Delta = (d+1)\sum_{i=0}^{k-2} r^i\Delta = (d+1)\frac{r^{k-1}-1}{r-1}\Delta$. If $r < 1$, we obtain a constant error bound of $e(x) \le (d+1)\frac{1}{1-r}\Delta$ by geometric summation. Otherwise, we obtain $e(x) = O(r^{\lg n})$.

4.2.2. When $c > 1$. In this case, we require additional assumptions. We define the quantity

$$\omega^{-1}(f;\delta) = \sup_{\substack{|f(x_1)-f(x_2)|\le\delta \\ x_1,x_2\in\mathcal{D}}} \{|x_1 - x_2|\}.$$

Note that $\omega(f;\delta) \le c\delta$ implies $\omega^{-1}(f;\delta) \ge \delta/c$. Now, we assume that $\omega^{-1}(f;\delta) \le \delta/c'$ for some $c' > 1$.

Set $h(\frac{2^k}{s}) = g(\frac{2^k}{s})$. Since h satisfies the addition theorem, this can be used to fix all of h if H_1^{-1} is well-defined. Let $e(x) = |g(x) - h(x)|$ as before.

As before, we first obtain a relationship between the error at x and at $2x$ using the addition theorem.

LEMMA 32. $e(x) \le (e(2x) + \Delta)/c'$.

Proof. We have as in Lemma 28, $|H_1(g(x)) - H_1(h(x))| \le e(2x) + \Delta$. By definition of ω^{-1} and our assumption, we get $e(x) \le \omega^{-1}(H_1; e(2x) + \Delta) \le (e(2x) + \Delta)/c'$. ∎

For simplicity, let $H_3(x) \stackrel{\text{def}}{=} G^{-1}[g(\frac{2^k}{s}), \frac{2^k}{s} - x]$. We assume that $\omega(H_3;\delta) \le d\delta$ for some constant d. The following lemma can be proved easily.

LEMMA 33. $e(x) \le de(\frac{2^k}{s} - x) + \Delta$.

$e(\frac{2^k}{s}) = 0$ by our construction. We adopt a scheme similar to the one in the previous section. Construct a binary tree T_k with nodes labeled with elements from $\mathcal{D}^+_{n,s}$. The root is labeled $\frac{2^k}{s}$. If x is the label of a node and x is even, then $x/2$ is the label of its left child (if $x/2$ is not already in the tree), and $\frac{2^k}{s} - x$ is the label of its right child (if $\frac{2^k}{s} - x$ is not already in the tree). It is easy to see that if $x \le \frac{2^{k-1}}{s}$ (except the root), then x is a left child, and if $x > \frac{2^{k-1}}{s}$, then x is a right child. We use the preorder enumeration of $\mathcal{D}^+_{n,s}$ using T_k to prove the following lemma in the spirit of the proof of Lemma 30.

LEMMA 34. *For all $x \in \mathcal{D}^+_{n,s}$, if $x \le \frac{2^{k-1}}{s}$ and $d \le 1$, then $e(x) \le \frac{2c'}{1-c'}\Delta$; and if $x > \frac{2^{k-1}}{s}$, then $e(x) \le \frac{1+c'}{1-c'}\Delta$.*

This yields (under the assumptions on $\omega^{-1}(H_1;\delta)$ and $\omega(H_3;\delta)$) the following theorem.

THEOREM 35. *Let $\omega^{-1}(H_1;\delta) \le \delta/c', \omega(H_3,\delta) \le d\delta$ with $d \le 1$ and let n be a power of 2. Then, the addition theorem is $(\mathcal{D}^+_{n,s}, \mathcal{D}^+_{n,s}, \Delta, \frac{1+c'}{1-c'}\Delta)$-stable.*

This case arises for linearity where $H_1(x) = G[x,x] = 2x$ and so $c' = 2$. Using the above theorem, we get a weaker bound of $e(x) \le 3\Delta$ (as opposed to $\le 2\Delta$ by Corollary 8). Similar techniques as in the previous section can be used to argue about $\mathcal{D}^-_{n,s}$ and when n is not a power of 2.

The case when $d > 1$ can be handled by schemes as in the previous section.

4.2.3. When $c = 1$. In this case, it means that $\omega(H_1;\delta) = \delta$ or in other words, by Fact 26(2), $\|H_1'\| = 1$. By Fact 27, the maximum occurs only at the boundary of the domain. Hence, we can test by looking at a subdomain in which the maximum is less than 1.

4.2.4. Jensen's equation. Jensen's equation is the following: for all $x, y \in \mathcal{D}_{n,s}, f(\frac{x+y}{2}) = \frac{f(x)+f(y)}{2}$. The solution to this functional equation is the set of affine linear functions, i.e., $f(x) = ax + b$ for some constants a, b. Jensen's equation can be proved approximately robust by modifying the proof of its robustness in [28]. We will show a modified version of our technique for proving its stability. As before, we have

for all $x, y \in \mathcal{D}_{n,s}, g(\frac{x+y}{2}) \approx_\Delta \frac{g(x)+g(y)}{2}$. To prove the stability of this equation, we construct an affine linear h. Note that two points are necessary and sufficient to fully determine h. We set $h(\frac{n}{s}) = g(\frac{n}{s})$ and $h(0) = g(0)$.

LEMMA 36. $e(\frac{x+y}{2}) \le e(x)/2 + e(y)/2 + \Delta$.

Proof. $e(\frac{x+y}{2}) = |g(\frac{x+y}{2}) - h(\frac{x+y}{2})| \le \Delta + |\frac{g(x)+g(y)}{2} - \frac{h(x)+h(y)}{2}|$. However, $|\frac{g(x)-h(x)}{2} + \frac{g(y)-h(y)}{2}| = e(x)/2 + e(y)/2$. ∎

The following corollary is immediate.

COROLLARY 37. $e(\frac{x}{2}) \le \Delta + e(x)/2$ *and* $e(\frac{x+\frac{n}{s}}{2}) \le \Delta + e(x)/2$.

Proof. Since for $y = 0$ and $y = \frac{n}{s}$, $e(y) = 0$ in Lemma 36. ∎

We construct a slightly different tree T_k in this case. The root of T_k is labeled by $\frac{n}{s}$ and if x is the label of a node, then $x/2$ (if integral and not already present) is label of its left child and $(\frac{n}{s} + x)/2$ (if integral and not already present) is the label of its right child.

THEOREM 38. *The Jensen equation is* $(\mathcal{D}^+_{n,s}, \mathcal{D}^+_{n,s}, \Delta, 2\Delta)$*-stable.*

Proof. The proof is by induction on an enumeration order of T_k given by, say, a breadth-first traversal. Clearly, at the root, $e(\frac{n}{s}) = 0 \le 2\Delta$. Now, if $e(x) \le 2\Delta$, then consider its children. Its left (resp., right) child (if exists) is $x/2$ (resp., $(x + \frac{n}{s})/2$). Thus, by Corollary 37, we have $e(\frac{x}{2}) \le \Delta + e(x)/2 \le 2\Delta$ (resp. $e(\frac{x+\frac{n}{s}}{2}) \le \Delta + e(x)/2 \le 2\Delta$). ∎

4.3. Approximate robustness for functional equations. As in [20, 29], we test the program on $\mathcal{D}_{2p,s}$ and make conclusions about its correctness on $\mathcal{D}_{n,s}$. The relationship between p and n will be determined later. The domain has to be such that G is analytic in it. Therefore, we consider the case when f is bounded on $\mathcal{D}_{2p,s}$, i.e., $0 < L \le f(x) \le U$. Let $\mathcal{G}$ be the family of functions f that satisfy the following conditions:

(1) $\Pr_{x \in \mathcal{D}_{2p,s}}[f(x) \ge L] \ge 1 - \epsilon$,
(2) $\Pr_{x \in \mathcal{D}_{2p,s}}[f(x) \le U] \ge 1 - \epsilon$,
(3) $\Pr_{x,y \in \mathcal{D}_{2p,s}}[G[f(x), f(y)] \ge L] \ge 1 - \epsilon$, and
(4) $\Pr_{x,y \in \mathcal{D}_{2p,s}}[G[f(x), f(y)] \le U] \ge 1 - \epsilon$.

Note that the membership in $\mathcal{G}$ is easy to determine by sampling. We can define a distribution $\mathcal{E}_{\tau(n,s)}$ such that if P satisfies the functional equation on $\mathcal{E}_{\tau(n,s)}$ with probability at least $1 - \epsilon$, then P also satisfies the following four properties:

(1) $\Pr_{x,y \in \mathcal{D}_{p,s}}[P(x + y) \approx_\Delta G[P(x), P(y)]] \ge 1 - \epsilon$,
(2) $\Pr_{x,y \in \mathcal{D}_{p,s}}[P(x) \approx_\Delta G[P(x - y), P(y)]] \ge 1 - \epsilon$,
(3) $\Pr_{x,y \in \mathcal{D}_{p,s}}[P(x) \approx_\Delta G[P(y), P(x - y)]] \ge 1 - \epsilon$, and
(4) $\Pr_{x \in \mathcal{D}_{n,s}, y \in \mathcal{D}_{p,s}}[P(x) \approx_\Delta G[P(x - y), P(y)]] \ge 1 - \epsilon$.

$\mathcal{E}_{\tau(n,s)}$ is defined by flipping a fair four-sided die and on outcome $i \in \{1, 2, 3, 4\}$ choosing inputs according to the distribution given in the ith property above. Let $\widehat{G} = \|G'_x\|_{\mathcal{D}}$. We can then show the following.

THEOREM 39. *The addition theorem with the distribution* $\mathcal{E}_{\tau(n,s)}$ *is* $(2\epsilon, \epsilon, \mathcal{D}_{2p,s}, \mathcal{D}_{n,s}, \Delta, (9\widehat{G}^2 + 5\widehat{G})\Delta, \Delta)$*-approximately robust.*

Define for $x \in \mathcal{D}_{p,s}$, $g(x) = \text{median}_{y \in \mathcal{D}_{p,s}}\{G[P(x - y), P(y)]\}$. By Markov's inequality, definition of g, and the properties of P, it is easy to show the following.

LEMMA 40. $\Pr_{x \in \mathcal{D}_{n,s}}[g(x) \approx_\Delta P(x)] > 1 - 2\epsilon$.

Proof. Consider the set of elements $x \in \mathcal{D}_{n,s}$ such that $\Pr_{y \in \mathcal{D}_{p,s}}[P(x) \approx_\Delta G[P(x - y), P(y)]] < \frac{1}{2}$. If the fraction of such elements is more than 2ϵ, then it contradicts hypothesis (4) on P that $\Pr_{x \in \mathcal{D}_{n,s}, y \in \mathcal{D}_{p,s}}[P(x) \approx_\Delta G[P(x - y), P(y)]] \ge 1 - \epsilon$. For the

rest, for at least half of the y's, $P(x) \approx_\Delta G[P(x-y), P(y)]$. By defining g to be the median (over y's in $\mathcal{D}_{p,s}$), we have for these elements $g(x) \approx_\Delta P(x)$. □

For simplicity of notation, let P_x denote $P(x)$ for any $x \in \mathcal{D}_{p,s}$ and $G_{x,y}$ denote $G[P(x), P(y)]$ for any $x, y \in \mathcal{D}_{p,s}$. Since G is fixed, we will drop G from the modulus of continuity.

A distribution U' on $\mathcal{D}$ is said to be *ϵ-uniform on $\mathcal{D}$* if $\sum_{x\in\mathcal{D}} |U'(x) - 1/|\mathcal{D}|| \le \epsilon$. Let $\gamma = n/2p$.

FACT 41. (1) *For all $x \in \mathcal{D}_{2n,s}$, the distribution of $x + y$ is γ-uniform on $\mathcal{D}_{p,s}$.*

(2) *For any event $E(x)$ and for an ϵ-uniform distribution U' on $\mathcal{D}$,* $|\Pr_{x\sim U'}[E(x)] - \Pr_{x\in\mathcal{D}}[E(x)]| \le \epsilon$.

LEMMA 42. *For $x \in \mathcal{D}_{2n,s}$,* $\Pr_{y,z\in\mathcal{D}_{p,s}}[G_{x-y,y} \approx_{2\omega(\Delta,0)} G_{x-z,z}] \ge 1 - 12\epsilon - 4\gamma$.

Proof. $\Pr_{y,z\in\mathcal{D}_{p,s}}[G_{x-y,y} \approx_{\omega(\Delta,0)} G[G_{x-z,z-y}, P_y] = G[P_{x-z}, G_{z-y,y}] \approx_{\omega(0,\Delta)} G_{x-z,z}] > 1 - 12\epsilon - 4\gamma$. The error in the first step (due to computation of P_{x-y}) is $\omega(\Delta, 0)$ and the equation holds with probability at least $1 - \epsilon - \gamma$ by property (3) and Fact 41. The bounds on $G_{x-z,z-y}$ also hold with probability at least $1 - 2\epsilon - 2\gamma$ by properties (3), (4), and Fact 41 and so the error is just $\omega(\Delta, 0)$. The next line is just rewriting. In a similar manner, the final equation holds with probability at least $1 - \epsilon - \gamma$ by property (2) and Fact 41 and the error bound is $\omega(0, \Delta)$. The bounds on random points $P_y, P_z, P_{x-z}, P_{z-y}$ hold with probability at least $1 - 8\epsilon$ by properties (1), (2) on P to make the error $\omega(0, \Delta)$. Hence, the total error is $\omega(\Delta, 0) + \omega(0, \Delta) = 2\omega(\Delta, 0)$ by Fact 26(3) and the equality holds with probability at least $1 - 12\epsilon - 4\gamma$. □

The following lemma, which helps us to bound the error, is from [23]. The proof uses the observation that the clique number of G^2 is at least as big as the maximum degree in G. Hence, for a random node x, probability that x is present in the largest clique in G^2 is more than the probability that x is connected to the maximum degree vertex (say, y) in G.

LEMMA 43 (see [23]). *If $G = \langle V, E\rangle$ is a random graph with edges inserted with probability $1 - \epsilon$, then $G^2 = \langle V, \{(x, y) : \exists z \in V, (x, z) \in E \wedge (z, y) \in E\}\rangle$ is a graph where the largest clique is of size at least $(1 - \epsilon)|V|$.*

The following shows, in some sense, that g is well-defined.

LEMMA 44. *For all $x \in \mathcal{D}_{2n,s}$,* $\Pr_{y\in\mathcal{D}_{p,s}}[g(x) \approx_{2\Delta'} G_{x-y,y}] \ge 1 - 12\epsilon - 4\gamma$, *where* $\Delta' = 2\omega(\Delta, 0)$.

Proof. We have the following: for all $x \in \mathcal{D}_{2n,s}$, $\Pr_{y,z\in\mathcal{D}_{p,s}}[G_{x-y,y} \approx_{\Delta'} G_{x-z,z}] \ge 1 - 12\epsilon - 4\gamma$. Now, we use Lemma 43. If G denotes a graph in which (y, z) is an edge if and only if $G_{x-y,y} \approx_{\Delta'} G_{x-z,z}$, then G^2 denotes the graph in which (y, z) is an edge if and only if $G_{x-y,y} \approx_{2\Delta'} G_{x-z,z}$. Now, using Lemma 43, we have that the number of elements that are $2\Delta'$ away from the largest clique is at most 2ϵ. Thus, at least $1 - 2\epsilon$ of elements are within $2\Delta'$ of each other. If $\epsilon < 1/2$ and since $g(x)$ is the median, the lemma follows. □

Now, the following theorem completes the proof that g satisfies the addition theorem approximately.

THEOREM 45. *For all $x, y \in \mathcal{D}_{n,s}$, $g(x + y) \approx_{\Delta''} G[g(x), g(y)]$ with probability at least $1 - 56\epsilon - 14\gamma$, where $\Delta'' = (9\widehat{G}^2 + 5\widehat{G})\Delta$.*

Proof.

$$\begin{aligned}
\Pr_{u,v\in\mathcal{D}_{p,s}}[G[g(x),g(y)] &\approx_{\omega(2\Delta',2\Delta')} G[G_{u,x-u},G_{v,y-v}]\\
&= && G[P_u, G[P_{x-u}, G_{v,y-v}]]\\
&= && G[P_u, G[G_{x-u,v}, P_{y-v}]]\\
&\approx_{\omega(0,\omega(\Delta,0))} && G[P_u, G_{x-u+v,y-v}]\\
&\approx_{\omega(0,\Delta)} && G_{u,x+y-u}\\
&\approx_{2\Delta'} && g(x+y)] \geq 1-56\epsilon-14\gamma.
\end{aligned}$$

By Lemma 44, the first equality holds with probability $1-24\epsilon-8\gamma$ and error $\omega(2\Delta',2\Delta')$. By property (4), the bounds on $G_{u,x-u}, G_{v,y-v}$ hold with probability at least $1-4\epsilon$ to make the error $\omega(2\Delta',2\Delta') \leq 2\omega(2\Delta',0) = 4\omega(\Delta',0) = 8\omega(\omega(\Delta,0),0)$ by Fact 26(3). The second and third equalities are always true. The fourth equality holds with probability at least $1-\epsilon-\gamma$ by property (1) and Fact 41 on P and the error accrued is $\omega(0,\omega(\Delta,0))$. The bounds on $P_u, P_{x-u}, P_v, P_{y-v}, G_{x-u,v}$ hold with probability at least $1-10\epsilon$ by properties (1)–(4) to make the error $\omega(0,\omega(\Delta,0)) = \omega(\omega(\Delta,0),0)$. The fifth equality also holds with probability at least $1-\epsilon-\gamma$ by property (1) on P and the error accrued is $\omega(0,\Delta) = \omega(\Delta,0)$, after bounds on P_u, P_{x+y-u} (with probability at least $1-4\epsilon$). The final equality holds with probability at least $1-12\epsilon-4\gamma$ by Lemma 44 and error is $2\Delta' = 4\omega(\Delta,0)$. Thus, the total error is $9\omega(\omega(\Delta,0),0) + 5\omega(\Delta,0)$. However, $\omega(\Delta,0) \leq \Delta\widehat{G}$ by Fact 26(4). Hence, $\omega(\omega(\Delta,0),0) \leq \Delta\widehat{G}^2$. □

If $\epsilon < 1/112$, $p > 14n$, we have $1-56\epsilon-14\gamma > 0$ and so the above lemma is true with probability 1. In the case of our example function, we already calculated $\widehat{G} = U^2/(L+U)^2$. Hence, $\Delta'' = \Delta(\frac{9U^4}{(L+U)^4} + \frac{5U^2}{(L+U)^2})$.

5. Approximate self-testing and self-correcting. In this section we briefly show how to apply our techniques that we developed in this paper to construct approximate self-tester and self-correctors. The approaches in this section follow [8, 20].

5.1. Definitions. The following modifications of definitions from [20] capture the idea of approximate checking, self-testing, and self-correcting in a formal manner. Let P be a program for f, $x \in \mathcal{D}_{n,s}$ an input to P, and β the confidence parameter.

DEFINITION 46. *A* $(\Delta_1,\Delta_2,\mathcal{D}_{\tau(n,s)},\mathcal{D}_{n,s})$-approximate result checker *for* f *is a probabilistic oracle program* T *that, given* P, $x \in \mathcal{D}_{n,s}$, *and* β, *satisfies the following:*

(1) P $(\Delta_1,0)$-*approximates* f *on* $\mathcal{D}_{\tau(n,s)} \Rightarrow \Pr[T^P$ *outputs "PASS"*$] \geq 1-\beta$.

(2) $P(x) \not\approx_{\Delta_2} f(x) \Rightarrow \Pr[T^P$ *outputs "FAIL"*$] \geq 1-\beta$.

DEFINITION 47. *A* $(\Delta_1,\Delta_2,\epsilon,\mathcal{D}_{\tau(n,s)},\mathcal{D}_{n,s})$-approximate self-tester *for* f *is a probabilistic oracle program* T *that, given* P *and* β, *satisfies the following:*

(1) P $(\Delta_1,0)$-*approximates* f *on* $\mathcal{D}_{\tau(n,s)} \Rightarrow \Pr[T^P$ *outputs "PASS"*$] \geq 1-\beta$.

(2) P *does not* (Δ_2,ϵ)-*approximate* f *on* $\mathcal{D}_{n,s} \Rightarrow \Pr[T^P$ *outputs "FAIL"*$] \geq 1-\beta$.

Observe that if a property is $(\delta,\epsilon,\mathcal{D}_{\tau(n,s)},\mathcal{D}_{n,s},\Delta_1,\Delta_2,\Delta_3)$-approximately robust, $(\mathcal{D}_{n,s},\mathcal{D}_{n',s'},\Delta_2,\Delta_4)$-stable, and it is possible to do equality testing for the function family satisfying the property, then it is possible to construct a $(\Delta_1,\Delta_3+\Delta_4,\epsilon,\mathcal{D}_{n,s},\mathcal{D}_{n',s'})$-approximate self-tester.

DEFINITION 48. *A* $(\Delta,\epsilon,\Delta',\mathcal{D}_{\tau(n,s)},\mathcal{D}_{n,s})$-approximate self-corrector *for* f *is a probabilistic oracle program* SC_f^P *that, given* P *that* (Δ,ϵ)-*approximates* f *on* $\mathcal{D}_{\tau(n,s)}$, $x \in \mathcal{D}_{n,s}$, *and* β, *outputs* $\mathrm{SC}_f^P(x)$ *such that* $\Pr[\mathrm{SC}_f^P(x) \approx_{\Delta'} f(x)] \geq 1-\beta$.

Note that a $(\Delta_1,\Delta_2,\epsilon,\mathcal{D}_{\tau(n,s)},\mathcal{D}_{n,s})$-approximate self-tester and $(\Delta_2,\epsilon,\Delta_3,\mathcal{D}_{\tau(n,s)},\mathcal{D}_{n,s})$-approximate self-corrector yield a $(\Delta_1,\Delta_3,\mathcal{D}_{\tau(n,s)},\mathcal{D}_{n,s})$-approximate result

checker [8].

5.2. Constructing approximate self-correctors. We illustrate how to build approximate self-correctors for functional equations. Suppose P (Δ, ϵ)-approximates f for $\epsilon < 1/8$ and $f(x+y) = G[f(x), f(y)]$. Then the self-corrector SC_f^P at input x is constructed as follows. To obtain a confidence of β,

1. choose random points $y_1, y_2, \ldots, y_N (N = O(\ln 1/\beta))$;
2. let $\mathrm{SC}_f^P(x)$ be the median of $G[P(x-y_1), P(y_1)], \ldots, G[P(x-y_N), P(y_N)]$.

By the assumption on ϵ, both the calls to P on $x - y_i$ and y_i are within Δ of f with probability greater than 3/4. In this case, the value of $G[P(x-y_i), P(y_i)]$ is $\Delta' = 2\Delta\widehat{G}$ away from $f(x)$ (see section 4.1 for $\widehat{G}$). Using Chernoff bounds, we can see that at least half of the values $G[P(x-y_i), P(y_i)]$ are at most Δ' away from $f(x)$. Thus, their median $\mathrm{SC}_f^P(x)$ is also at most Δ' away from $f(x)$.

For degree d polynomials, a similar self-corrector works with $\Delta' = O((d+1)2^d\Delta)$. In order to pass good programs, this is almost the best Δ' possible using the evenly spaced interpolation equation since the coefficients of the interpolation equation are $\Omega(2^d)$. Using interpolation equations that do not use evenly spaced points seems to require Δ' that is dependent on the size of the domain.

5.3. Constructing approximate self-testers. The following is a self-tester for any function satisfying an addition theorem $f(x+y) = G[f(x), f(y)]$ computing the function family $\mathcal{F}$ over $\mathcal{D}_{n,s}$. We use the notation from section 4.1. To obtain a confidence of β, we choose random points $x_1, y_1, \ldots, x_N, y_N (N = O(1/\epsilon \ln 1/\beta))$ and verify the assumptions on program P in the beginning of section 4.3. If P passes the test, then using Chernoff bounds, approximate robustness, and stability of the property, we are guaranteed that P approximates some function in $\mathcal{F}$. We next perform the equality test to ensure that P approximates the given $f \in \mathcal{F}$. Assume that $f(\frac{1}{s})$ when $c < 1$ (resp., $f(\frac{n}{s})$ when $c > 1$) is given. Using the proofs in section 4.2, one can show that if there is a constant Δ such that $\mathrm{SC}_f^P(\frac{1}{s}) \approx_\Delta f(\frac{1}{s})$ when $c < 1$ ($\mathrm{SC}_f^P(\frac{n}{s}) \approx_\Delta f(\frac{n}{s})$ when $c > 1$), the error between SC_f^P and f can be bounded by a constant on the rest of $\mathcal{D}_{n,s}$. Since SC_f^P approximates P, the correctness of the self-tester follows.

For polynomials, we use random sampling to verify the conditions on program P required for approximate robustness that are given in the beginning of section 3.3. If P satisfies the conditions, then using the approximate robustness and stability of the evenly spaced interpolation equation, P is guaranteed to approximate some degree d polynomial h. To perform the equality test that determines if P approximates the correct polynomial f, we assume that the tester is given the correct value of the polynomial f at $\ell = (d+1)/\epsilon$ evenly spaced points $x_1 = -\frac{n}{s}, \ldots, x_\ell = \frac{n}{s} \in \mathcal{D}_{n,s}$. Using the self-corrector SC_f^P from section 5.2, we have $\|\mathrm{SC}_f^P - h\| \le \Delta' = (d+1)2^d 2^{d \lg d}\Delta$. The equality tester now tests that for all x_i, $|f(x_i) - \mathrm{SC}_f^P(x_i)| \le (d+1)2^d\Delta$. Call an input x *bad* if $|f(x) - h(x)| > \Delta'' = \Delta' + (d+1)2^d\Delta$. If x is bad, then $|f(x) - \mathrm{SC}_f^P(x)| > (d+1)2^d\Delta$. If x is a sample point, and x is bad, then the test would have failed. Define a *bad interval* to be a sequence of consecutive bad points. If the test passes, then any bad interval in the domain can be of length at most $(2n+1)/\ell$, because any longer interval would contain at least one sample point. The two sample points immediately preceding and following the bad interval satisfy $|f(x) - h(x)| \le \Delta''$. This implies that there must be a local maximum of $f - h$ (a degree d polynomial) inside the bad interval. Since there are only d extrema of $f - h$, there can be at most d bad

intervals, and so the total number of bad points is at most $d(2n+1)/\ell$. Thus, on $1-\epsilon$ fraction of $\mathcal{D}_{n,s}$, SC_f^P's error is at most $\Delta' + \Delta''$. These arguments can be generalized to the k-variate case by partitioning the k-dimensional space into $((d+1)/\epsilon)^k$ cubes.

We have thus shown how to construct approximate self-testers and self-correctors. It is straightforward to construct approximate result-checkers using these.

5.4. Reductions between functional equations. This section explores the idea of using reductions among functions (as in [7, 3]) to obtain approximate self-testers for new functions. Consider any pair of functions f_1, f_2 that are interreducible via functional equations. Suppose we have an approximate self-tester for f_1 and let there exist continuous computable functions F, F^{-1} such that $f_2(x) = F[f_1(x)]$ and $f_1(x) = F^{-1}(f_2(x))$. Given a program P_2 computing f_2, construct program P_1 computing f_1 via F^{-1}. We can then self-test P_1. Suppose P_1 is Δ-close to f_1 on a large portion of the domain. Then for every x for which $P_1(x)$ is Δ-close to $f_1(x)$, we bound the deviation of $P_2(x)$ from $f_2(x)$ by $\Delta' = F[f_1(x) + \Delta] - f_2(x)$. Then $\Delta' = F[f_1(x) + \Delta] - F[f_1(x)] \leq \omega(F; \Delta)$. If we can bound the right-hand side by a constant (at least for a portion of the domain), we can bound the maximum deviation Δ' of P_2 from f_2. This idea can be used to give simple and alternative approximate self-testers for functions like $\sin x, \cos x, \sinh x, \cosh x$ which can be reduced to e^x.

For example, suppose we are given a $(\delta_1, \epsilon_1, \delta_2, \epsilon_2, \mathcal{D}, \mathcal{D}')$-approximate self-tester for $f_1(x) = e^x$ and we want an approximate self-tester for the function f_2 given by $f_2(x) = \cos x$. By the Euler identity, $f_1(ix) = f_2(x) + i f_2(x + 3\pi/2)$. Given a program P_2 that supposedly computes f_2, we can build a program P_1 (for e^{ix}) out of the given P_2 (for $\cos x$) and self-test P_1. $P_1(ix) = P_2(x) + iP_2(x + 3\pi/2)$.

Let the range of f_1 be equipped with the following metric: $|P_1(x) - f_1(x)| = |\Re(P_1(x) - f_1(x))| + |\Im(P_1(x) - f_1(x))|$. In other words, in our case, we have $|P_1(x) - e^{ix}| = |P_2(x) - \cos x| + |P_2(x + 3\pi/2) - \cos(x + 3\pi/2)|$. This metric ensures that P_1 is erroneous on x if and only if P_2 is erroneous on at least one of $x, x + 3\pi/2$. Alternatively, there is no "cancellation" of errors.

Suppose P_1 is (δ_1, ϵ_1)-good. Then, what can we say about P_2? For δ_1 fraction of the "bad" domain for P_1, the errors can occur in both the places where P_2 is invoked. Hence, at most $2\delta_1$ fraction of the domain for P_2 is bad. The rest of the domain for P_1 is ϵ_1-close to f_1, which by our metric implies P_2 is also ϵ_1-close to f_2. Thus, P_2 is $(2\delta_1, \epsilon_1)$-good.

Similarly, suppose P_1 is not (δ_2, ϵ_2)-good. P_1 is not good on at least δ_2 fraction of the domain, where P_1 is not ϵ_2-close to f_1. Thus, at these points in the domain, at least one of the points where P_2 is called is definitely not $\epsilon_2/2$-close to f_2. Thus, P_2 is not $(\delta_1, \epsilon_2/2)$-good.

Therefore, we have a $(2\delta_1, \epsilon_1, \delta_2, \epsilon_2/2, \mathcal{D}, \mathcal{D}')$-approximate self-tester for f_2 from a $(\delta_1, \epsilon_1, \delta_2, \epsilon_2, \mathcal{D}, \mathcal{D}')$-approximate self-tester for f_1, given by [20].

Appendix A. Proofs of some theorems for linearity.

THEOREM 49 (Hyers' theorem). *Let S be an Abelian semigroup and B be a Banach space and let $g : S \to B$ be such that for some $\Delta > 0$, g is Δ-approximately linear on S; then, for every $x \in S$, $h(x) = \lim_{n\to\infty} g(2^n x)/2^n$ exists, h is linear, and $\|g - h\| \leq \Delta$.*

Proof (see [17]). By induction on n, $|g(x)/2^n - g(x/2^n)| < \Delta(1 - 1/2^n)$. Let $q_n(x) = g(2^n x)/2^n$. Then, $q_n(x) - q_m(x) = (g(2^{m-n}2^n x) - 2^{m-n} g(2^n x))/2^m$. If $m < n$, we can obtain $|q_n(x) - q_m(x)| < \Delta(1 - 2^{m-n})/2^m$. Thus, for $x \in S$, $\{q_n(x)\}$ is a Cauchy sequence and by completeness of B, it has a limit function

$h(x) = \lim_{n\to\infty} g(2^n x)/2^n$. The properties of h are easily proved. ∎

THEOREM 50 (Skof's theorem). *Let $n > 0$ and let $g : [0, n) \to \mathbb{R}$ be such that for some $\Delta \geq 0$, $|g(x+y) - g(x) - g(y)| \leq \Delta$ for all $0 \leq x, y < n$ (such that $x + y < n$); then, there exists a linear $h : \mathbb{R} \to \mathbb{R}$ such that $\|g - h\|_{[0,n)} \leq 3\Delta$.*

Proof. For any $x \in \mathbb{R}^+$, write $x = p(n/2) + q$ where $0 \leq q < n/2$. Define $g' : \mathbb{R}^+ \to \mathbb{R}$ such that $g'(x) = pg(n/2) + g(q)$. Clearly, $\|g' - g\|_{[0,n)} \leq \Delta$. Now, the claim is $g'(x+y) \approx_{2\Delta} g'(x) + g'(y)$. As before, $x = p(n/2) + q, y = r(n/2) + s$ with $0 \leq q, s < n/2$.

If $0 \leq q + s < n/2]$, then we have $g'(x+y) = g(q+s) + (p+r)g(n/2) \approx_\Delta g(q) + g(s) + pg(n/2) + rg(n/2) = g'(x) + g'(y)$.

If $n/2 \leq q + s < n]$, then let $q + s = t + n/2$. We have $g'(x+y) = g(t) + (p + r)g(n/2) + g(n/2) \approx_{2\Delta} g(q) + g(s) + pg(n/2) + rg(n/2) = g'(x) + g'(y)$.

To extend g' to $\mathbb{R}$, define for $x < 0$, $g'(x) = -g'(-x)$. Thus, for all $x, y \in \mathbb{R}, g'(x+y) \approx_{2\Delta} g'(x) + g'(y)$. By Theorem 49, there is a linear h such that $\|g' - h\| \leq 2\Delta$. Therefore, $\|g - h\|_{[0,n)} \leq \|g - g'\|_{[0,n)} + \|g' - h\|_{[0,n)} \leq 3\Delta$. ∎

Appendix B. Proofs of some theorems for polynomials.

B.1. Stability for polynomials.

FACT 12. $(\nabla_{t_1+t_2} - \nabla_{t_1} - \nabla_{t_2})f(x) = \nabla_{t_1,t_2} = \nabla_{t_2,t_1}$.

Proof. $(\nabla_{t_1+t_2} - \nabla_{t_1} - \nabla_{t_2})f(x) = f(x+t_1+t_2) - f(x) - f(x+t_1) + f(x) - f(x+t_2) + f(x) = f(x+t_1+t_2) - f(x+t_1) - f(x+t_2) + f(x) = \nabla_{t_1} f(x+t_2) - \nabla_{t_1} f(x) = \nabla_{t_1}(f(x+t_2) - f(x)) = \nabla_{t_1,t_2} f(x) = \nabla_{t_2,t_1} f(x)$. ∎

Difference operators act on multilinear functions in a nice manner, which is captured in the following fact.

FACT 51. *If f is a k-linear function, then $\nabla_{t_1,\ldots,t_d} f^*(x) = k! f(t_1, \ldots, t_k)$ if $k = d$ and 0 if $k < d$.*

Proof. Recall that, due to multilinearity, f is also symmetric. By induction on k and chasing definitions, we have $\nabla_{t_1,\ldots,t_d} f^*(x) = \nabla_{t_1,\ldots,t_{d-1}}(f^*(x+t_d) - f^*(x)) = \nabla_{t_1,\ldots,t_{d-1}}(f((x+t_d)^{[d-1]}, x) + f((x+t_d)^{[d-1]}, t_d) - f(x^{[d]}))$, which by linearity of ∇ yields $\nabla_{t_1,\ldots,t_{d-1}} f((x+t_d)^{[d-1]}, t_d) + \nabla_{t_1,\ldots,t_{d-1}}(f((x+t_d)^{[d-1]}, x) - f(x^{[d]}))$. Observe that for any constant t, the restriction of k-linear f to any of its arguments being t (denoted f_t) results in a $(k-1)$-linear function. By induction, the first term in the above expression evaluates to $(d-1)! f_{t_d}(t_1, \ldots, t_{d-1}) = (d-1)! f(t_1, \ldots, t_d)$. Now, using the symmetry and linearity (in each variable) of f, we can write the second term as $\nabla_{t_1,\ldots,t_{d-1}}(\sum_{i=0}^{d-1} \binom{d-1}{i} f(x^{[i+1]}, {t_d}^{[d-i-1]}) - f(x^{[d]}))$ which is $(d-1)\nabla_{t_1,\ldots,t_{d-1}} f(x^{[d-1]}, t_d) + \sum_{i=0}^{d-3} \nabla_{t_1,\ldots,t_{d-1}} \binom{d-1}{i} f(x^{[i+1]}, {t_d}^{[d-i-1]})$. By induction, the first term evaluates to $(d-1)(d-1)! f_{t_d}(t_1, \ldots, t_{d-1}) = (d-1)(d-1)! f(t_1, \ldots, t_d)$, which combined with the earlier result yields $d! f(t_1, \ldots, t_d)$. The second term evaluates to 0 since each of the terms inside the sum are restrictions of f to more than 1 variable, which evaluates to 0 after applying $\nabla_{t_1,\ldots,t_{d-1}}$. ∎

FACT 13. *Let $\mathcal{D}$ be a ring. The following characterizations of polynomials, are equivalent:*

1. *for all $x \in \mathcal{D}, f(x) = \sum_{k=0}^{d} a_k x^k$;*
2. *for all $x, t \in \mathcal{D}, \nabla_t^{d+1} f(x) = 0$;*
3. *there exists symmetric k-linear functions F_k, $0 \leq k \leq d$ such that for all $x \in \mathcal{D}, f(x) = \sum_{k=0}^{d} F_k^*(x)$.*

Proof. (1) ⇔ (2) follows from Lagrangian interpolation. We first prove (1) ⇒ (3). Given (1), just set $F_k(x_1, \ldots, x_k) = a_k \prod_{i=0}^{k} x_i$. It is easy to see that F_k's are symmetric, k-linear. We now prove (3) ⇒ (2). Given (3), $\nabla_{t_1,\ldots,t_{d+1}} f(x) =$

TABLE 2
An illustration of Fact 18.

λ	t'_λ	t''_λ	Term
00	0	0	0
01	$-t_2/2$	t_2	$-[f(x) - 2f(x + t_2/2) + f(x + t_2)]$
10	$-t_1$	t_1	$-[f(x - t_1) - 2f(x) + f(x + t_1)]$
11	$-t_1 - t_2/2$	$t_1 + t_2$	$+[f(x - t_1) - 2f(x + t_2/2) + f(x + t_1 + t_2)]$

$\nabla_{t_1,\ldots,t_{d+1}} \sum_{k=0}^{d} F_k^*(x) = \sum_{k=0}^{d} \nabla_{t_1,\ldots,t_{d+1}} F_k^*(x) = 0$ by Fact 16 about difference operators. □

FACT 18. *For any* $\lambda_1, \ldots, \lambda_d \in \{0,1\}$, *if*

$$t'_{\lambda_1,\ldots,\lambda_d} = -\sum_{i=1}^{d} \lambda_i t_i / i, \qquad t''_{\lambda_1,\ldots,\lambda_d} = \sum_{i=1}^{d} \lambda_i t_i,$$

then

$$\nabla_{t_1,\ldots,t_d} f(x) = \sum_{\lambda_1,\ldots,\lambda_d \in \{0,1\}} (-1)^{\lambda_1+\cdots+\lambda_d} \nabla^d_{t'_{\lambda_1,\ldots,\lambda_d}} f(x + t''_{\lambda_1,\ldots,\lambda_d}).$$

Proof. The proof follows by a pairing argument. First, it is easy to prove that the left-hand side can be expressed as $\nabla_{h_1,\ldots,h_d} = \sum_{\lambda_1,\ldots,\lambda_d \in \{0,1\}} (-1)^{d+\lambda_1+\cdots+\lambda_d} f(x + t''_{\lambda_1,\ldots,\lambda_d})$. Now, we can expand the right-hand side as

$$\sum_{\lambda_1,\ldots,\lambda_d \in \{0,1\}} (-1)^{\lambda_1+\cdots+\lambda_d} \sum_{k=0}^{d} (-1)^{d-k} \binom{d}{k} f(x + t''_{\lambda_1,\ldots,\lambda_d} + k t'_{\lambda_1,\ldots,\lambda_d}).$$

When $k = 0$, the left-hand side is obtained. Therefore, we have to prove that for $k > 0$, the right-hand side vanishes. The terms inside $f(\cdot)$ are linear combinations of t_i's by our construction. Note that for each $k > 0$, each term inside $f(\cdot)$ on the right-hand side has exactly one t_i absent because of its cancellation between t' and t''. Therefore, for each $\lambda_1, \ldots, \lambda_d \in \{0,1\}$, construct its conjugate $\lambda'_1, \ldots, \lambda'_d \in \{0,1\}$ with $\lambda'_i = 1 - \lambda_i$ and $\lambda'_j = \lambda_j$ otherwise. It is easy to see that the terms $(-1)^{\lambda_1+\cdots+\lambda_d} f(x + t''_{\lambda_1,\ldots,\lambda_d} + k t'_{\lambda_1,\ldots,\lambda_d})$ and $(-1)^{\lambda'_1+\cdots+\lambda'_d} f(x + t''_{\lambda'_1,\ldots,\lambda'_d} + k t'_{\lambda'_1,\ldots,\lambda'_d})$ cancel. An illustration of this fact is given below. □

To illustrate with an example, consider the case when $d = 2$. Then, the left-hand side is given by $\nabla_{t_1,t_2} f(x) = f(x + t_1 + t_2) - f(x + t_1) - f(x + t_2) + f(x)$. The right-hand side is given by the sum of the entries in the last column of Table 2.

It is easy to see that appropriate cancellations take place so that the left-hand side equals the right-hand side.

THE POLYGON EXPLORATION PROBLEM*

FRANK HOFFMANN†, CHRISTIAN ICKING‡, ROLF KLEIN§, AND KLAUS KRIEGEL†

Abstract. We present an on-line strategy that enables a mobile robot with vision to explore an unknown simple polygon. We prove that the resulting tour is less than 26.5 times as long as the shortest watchman tour that could be computed off-line.

Our analysis is doubly founded on a novel geometric structure called the *angle hull*. Let D be a connected region inside a simple polygon, P. We define the *angle hull* of D, $\mathcal{AH}(D)$, to be the set of all points in P that can see two points of D at a right angle. We show that the perimeter of $\mathcal{AH}(D)$ cannot exceed in length the perimeter of D by more than a factor of 2. This upper bound is tight.

Key words. angle hull, competitive strategy, computational geometry, curve length, motion planning, navigation, on-line algorithm, optimum watchman tour, polygon, robot

1. Introduction.

In the last decade, the path planning problem of autonomous mobile systems has received a lot of attention in the communities of robotics, computational geometry, and on-line algorithms; see, e.g., Rao et al. [23], Blum, Raghavan, and Schieber [5], and the surveys by Mitchell [21] in Sack and Urrutia [25] and by Berman [4] in Fiat and Woeginger [13]. We are interested in strategies that are correct, in that the robot will accomplish its mission whenever this is possible, and in performance guarantees that allow us to relate the robot's cost to the cost of an optimal off-line solution or to other complexity measures of the scene.

In this work we are addressing a basic problem in this area. Suppose a mobile robot has to explore an unknown environment modeled by a simple polygon. The robot starts from a given point, s, on the polygon's boundary. It is equipped with a vision system that continuously provides the visibility of the robot's current position. When each point of the polygon has at least once been visible, the robot returns to s.[1]

In the on-line polygon exploration problem we ask for a *competitive* exploration strategy that guarantees that the robot's path will never exceed in length a constant *competitive factor* times the length of the optimum watchman tour through s, i. e., of the shortest tour inside the polygon that contains s and has the property that each point of the polygon is visible from some point of the tour. This approach to evaluating the performance of an on-line strategy goes back to Sleator and Tarjan [27]. A priori it is not clear whether a competitive exploration strategy exists.

[1] In the absence of holes, the robot has seen each point inside the polygon as soon as it has seen each point on its boundary.

Even the *off-line* version of the polygon exploration problem is not easy. Here we are given a simple polygon and have to compute the optimum watchman tour through a specified boundary point, s. Initially this problem has been suspected to be NP-hard. Chin and Ntafos [9] were the first to provide a polynomial time solution. They have shown how to compute the optimum watchman tour in time $O(n^4)$, where n denotes the number of vertices of the polygon. Later, their result has been improved by Tan and Hirata [28]; see also the updates in [14, 29].

Carlsson, Jonsson, and Nilsson [7] have proven that the optimum watchman tour without a specified point s can be computed in time $O(n^3)$. Furthermore, Carlsson and Jonsson [6] proposed an $O(n^6)$ algorithm for computing the shortest path inside a simple polygon from which each point of the boundary is visible when start and end points are not specified. In these papers it is always assumed that the range of the robot's visibility is unbounded. Some authors have also studied the case of limited visibility, e.g., Arkin, Fekete, and Mitchell [3] and Ntafos [22].

As to the *on-line* version of the polygon exploration problem, Deng, Kameda, and Papadimitriou [11] were the first to claim that a competitive strategy does exist. In their seminal paper they discussed a factor of 2016 for a greedy off-line approach which has to be implemented as an on-line strategy. For the rectilinear case, they gave a complete and elegant proof in [12]; here the greedy strategy can be applied that performs surprisingly well.

The first proof for the more difficult case of nonrectilinear simple polygons has been given in our conference paper [15]. There we have provided an on-line exploration strategy and sketched a proof that the tour it generates in any polygon is not longer than 133 times the length of the optimum watchman tour. One of the main difficulties with this analysis was in establishing reasonably sharp length estimates for robot paths of complex structure and in relating them to the optimum watchman tour.

The present paper contains the first complete presentation and analysis of an exploration strategy for simple polygons. As compared to the conference version [15], this full paper has been greatly simplified and describes a new analysis that is built on an interesting geometric relation between the robot's path and the optimum watchman tour. This relation is expressed in terms of the *angle hull*, a novel geometric structure. With these improvements we are able to show that an unknown polygon can be explored, from a given boundary point, s, by a tour at most 26.5 times as long as the shortest watchman tour containing s.

Of course, there is still a considerable gap between this upper bound and the lower bound of $(1+\sqrt{2})/2$ given in [11]; however, experiments with our new strategy suggest that its actual performance is much better than the bound proven here; we conjecture a number far below 10.

The organization of this paper is as follows. Section 2 contains a hierarchical description of the strategy and of its analysis. In section 2.1 we first discuss how to explore a single corner, that is, a single reflex vertex one of whose adjacent edges has not yet been visible. By *reflex vertex* we denote a vertex of the polygon whose internal angle exceeds 180°; all other vertices are called *convex*. The robot explores these corners in a sophisticated order: Of all reflex vertices that touch the visible area from the right, the robot attempts to explore the one that is clockwise first on the polygon's boundary as seen from the starting point, s. However, the vertex hereby specified may change as the robot moves. From our angle hull result we obtain a bound on the length of the resulting path in terms of the length of the shortest path that leads to the final position.

Then, in section 2.2, we use this technique for efficiently exploring groups of right reflex vertices in clockwise order. The length of the resulting local tour is shown to be bounded by the perimeter of the relative convex hull of certain *base points* times a constant. In analogy to the standard definition of convex hulls, the *relative convex hull*, $\mathcal{RCH}(D)$, of a subset D of a polygon P is the smallest subset of P that contains D and, for any two points of D, the shortest path in P connecting them.
