(iv) *Suppose $H_i = C_1 C_2 \dots C_k$ is a cycle chain. If $i < h$, then $V(H_{i+1}) \cap V(H_i) \subseteq V(C_k)$ and $V(H_{i+1}) \cap V(H_i) \ne V(C_{k-1}) \cap V(C_k)$, and if $i > 1$, then $V(H_{i-1}) \cap V(H_i) \subseteq V(C_1)$ and $V(H_{i-1}) \cap V(H_i) \ne V(C_1) \cap V(C_2)$.*

For convenience, we denote $\mathcal{H} = H_1 \dots H_h$ and view $\mathcal{H}$ as the graph $\bigcup_{i=1}^{h} H_i$. Thus $V(\mathcal{H}) := \bigcup_{i=1}^{h} V(H_i)$. Note that $\mathcal{H}$ is a multigraph, with two virtual edges between vertices in $V(H_i) \cap V(H_{i+1})$, $1 \le i \le h-1$.

In Figure 4, $\mathcal{H} = H_1 H_2 H_3$ is a block chain in G, where H_2 is the cycle chain $C_1 C_2$. In a block chain, we do not include bonds, because bonds do not contribute to the vertex count in our arguments.

3. Technical lemmas. In this section we prove several lemmas to be used in the proof of Theorem 2.1. Notice $G = G_1 \cup G_2$ in the illustration of Figure 1. If, instead, for some $k \ge 3$, $G = \bigcup_{i=1}^{k} G_i$, $E(G_i) \cap E(G_j) = \emptyset$, and $|V(G_i) \cap V(G_j)| = 3$ for $1 \le i < j \le k$, then the following lemma will enable us to conclude that if $|G_1|$ and $|G_2|$ are the largest among all $|G_i|$'s, then the cycle C produced by finding long cycles C_i in G_i (as in the first paragraph in section 2), $i = 1, 2$, will be long as well.

LEMMA 3.1. *Let $b = 3$ or $b \ge 4$ be an integer, and let m, n be positive integers with $m \ge n$. Then $m^{\log_b 2} + n^{\log_b 2} \ge (m + (b-1)n)^{\log_b 2}$.*

Proof. By dividing both sides of the above inequality by $m^{\log_b 2}$, it suffices to show that, for any s with $0 \le s \le 1$,

$$1 + s^{\log_b 2} \ge (1 + (b-1)s)^{\log_b 2}.$$

Let $f(s) = 1 + s^{\log_b 2} - (1 + (b-1)s)^{\log_b 2}$. Clearly, $f(0) = f(1) = 0$. Taking the derivative about s, we have

$$f'(s) = (\log_b 2)(s^{(\log_b 2)-1} - (b-1)(1 + (b-1)s)^{(\log_b 2)-1}).$$

A simple calculation shows that $f'(s) = 0$ has a unique solution. Therefore, since $f(0) = f(1) = 0$, either 0 is the absolute maximum of $f(s)$ over $[0, 1]$ or 0 is the absolute minimum of $f(s)$ over $[0, 1]$. That is, either $f(s) \ge 0$ for all $s \in [0, 1]$ or $f(s) \le 0$ for all $s \in [0, 1]$. Note that $0 < \frac{1}{b} < 1$ (since $b \ge 3$) and

$$\begin{aligned} f\left(\frac{1}{b}\right) &= \left(1 + \frac{1}{2}\right) - \left(1 + \frac{b-1}{b}\right)^{\log_b 2} \\ &= \frac{3}{2} - \frac{(2b-1)^{\log_b 2}}{2}. \end{aligned}$$

We claim that $f(\frac{1}{b}) > 0$. If $b = 3$, then $f(\frac{1}{b}) = \frac{1}{2}(3 - 5^{\log_3 2}) > 0$. So assume $b \geq 4$. Then $f(\frac{1}{b}) > \frac{3}{2} - \frac{(2b)^{\log_b 2}}{2} = \frac{3}{2} - 2^{\log_b 2}$. Since $b \geq 4$, $2^{\log_b 2} \leq 2^{\log_4 2} = \sqrt{2} < \frac{3}{2}$. Thus $f(\frac{1}{b}) > 0$ for $b \geq 4$.

Therefore, we have $f(s) \geq 0$ for all $s \in [0, 1]$. □

We remark that Lemma 3.1 holds for $b \geq 3$. We choose to state it for $b = 3$ and $b \geq 4$ for simplicity in calculations.

The observations in the following lemma will be convenient in the proof of Theorem 2.1.

LEMMA 3.2. *Let m be an integer, $b \geq 4$, and $d \geq 3$. If $m \geq 4$, then $m \geq m^{\log_b 2}+2$. If $m \geq 3$, then $m > (\frac{m}{2(d-1)})^{\log_b 2}+2$. If $m \geq 2$, then $m > (\frac{m}{2(d-1)})^{\log_b 2}+1$.*

Proof. Let $f(x) = x - x^{\log_b 2}$. We can show that $f'(x) > 0$ for $x \geq 4$. Hence $f(x)$ is an increasing function when $x \geq 4$. Thus, $f(x) \geq f(4) = 4 - 4^{\log_b 2} \geq 2$ (since $b \geq 4$). Thus when $m \geq 4$, we have $m \geq m^{\log_b 2} + 2$.

Next, let $f(x) = x - (\frac{x}{2(d-1)})^{\log_b 2}$. We can show that $f(x)$ is an increasing function when $x \geq 2$. The second inequality follows from $f(x) \geq f(3) > 2$, and the third inequality follows from $f(x) \geq f(2) > 1$. □

After we decompose a 2-connected graph into 3-connected components, we need to find long cycles in certain 3-connected components. This will be done by inductively applying (a), (b), or (c) of Theorem 2.1 to 3-connected components or to graphs obtained from 3-connected components by an "H-transform" or "T-transform."

Let G be a graph and let e, f be distinct edges of G. An *H-transform* of G *at* $\{e, f\}$ is an operation that subdivides e and f by vertices x and y, respectively, and then adds the edge xy. See Figure 5. Let G be a graph, let $e \in E(G)$, and let $x \in V(G)$, which is not incident with e. A *T-transform* of G *at* $\{x, e\}$ is an operation that subdivides e with a vertex y and then adds the edge xy. If there is no need to specify e, f, x, we will simply speak of an H-transform or a T-transform. The following result is easy to prove.

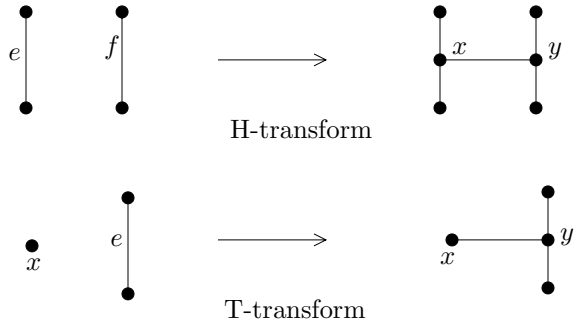

FIG. 5. *H-transform and T-transform.*

LEMMA 3.3. *Let $d \geq 3$ be an integer, and let G be a 3-connected graph with maximum degree at most d. Let G' be a graph obtained from G by an H-transform or a T-transform. Then G' is 3-connected graph, the vertex of G involved in the T-transform has degree at most $d + 1$, and all other vertices of G' have degree at most d.*

Next, we state two results from [11]. The first says that any k-connected graph contains a sparse k-connected spanning subgraph.

LEMMA 3.4. *Let G be a k-connected graph, where k is a positive integer. Then*

G contains a k-connected spanning subgraph with $O(|G|)$ edges, and such a subgraph can be found in $O(|E(G)|)$ time.

The next result is an easy consequence of a result in [11], which states that, in a 2-connected graph G, one can find, in $O(|G|)$ time, two disjoint paths between two given vertices.

LEMMA 3.5. *Let G be a 2-connected graph and let $e, f \in E(G)$. Then there is a cycle through e and f in G, and such a cycle can be found in $O(|G|)$ time.*

The final two results of this section deal with the existence of certain paths in a 3-connected graph. Since such paths need to be produced (when finding a long cycle), we also show that they can be found in linear time. The proofs of these two results are almost identical, so we omit the details of the second proof.

LEMMA 3.6. *Let G be a 3-connected graph, let $f \in E(G)$, let $ab, cd, vw \in E(G) - \{f\}$, and assume that $\{c, d\} \neq \{v, w\}$. Then there exists a path P from $\{a, b\}$ to some $z \in \{c, d\} \cup \{v, w\}$ in G such that*

(i) *$f \in E(P)$,*
(ii) *$cd \in E(P)$ or $vw \in E(P)$, and*
(iii) *if $cd \in E(P)$, then $z \in \{v, w\}$ and $vw \notin E(P)$, and if $vw \in E(P)$, then $z \in \{c, d\}$ and $cd \notin E(P)$.*

Moreover, such a path can be found in $O(|G|)$ time.

Note that in (iii) above when $vw \notin E(P)$, it is possible that $v \in V(P)$ and/or $w \in V(P)$.

Proof. First, we find a cycle C through both ab and f. This can be done in $O(|G|)$ time using Lemma 3.5. Next we distinguish three cases. Note that checking these cases can be done in $O(|G|)$ time.

Case 1. $cd, vw \in E(C)$. In this case one of the following holds: f and vw are contained in a component P of $C - \{ab, cd\}$, or f and cd are contained in a component P of $C - \{ab, vw\}$. In either case, P gives the desired path and can be found in $O(|G|)$ time.

Case 2. $cd \notin E(C)$ and $vw \in E(C)$, or $cd \in E(C)$ and $vw \notin E(C)$. By symmetry, assume that $cd \notin E(C)$ and $vw \in E(C)$. Let Q_1 and Q_2 denote the components of $C - \{ab, f\}$, and assume that $vw \in E(Q_1)$. By Lemma 3.5, we can find, in $O(|G|)$ time, disjoint paths P_1 and P_2 from c, d to some vertices c', d', respectively, of C which are also disjoint from $C - \{c', d'\}$.

If $c' \in V(Q_2)$ or $d' \in V(Q_2)$, then $(C \cup P_1 \cup P_2) - \{ab, cd\}$ contains a path P from $\{a, b\}$ to $\{c, d\}$ through f and vw. So assume that $c', d' \in V(Q_1)$.

If vw is contained in the subpath of Q_1 between c' and d', then $(C \cup P_1 \cup P_2) - \{ab, vw\}$ contains a path P from $\{a, b\}$ to $\{v, w\}$ through f and cd.

If $\{c', d'\}$ is contained in the subpath of Q_1 between vw and ab, then $(C \cup P_1 \cup P_2) - \{ab, cd\}$ contains a path P from $\{a, b\}$ to $\{c, d\}$ through f and vw.

Assume that $\{c', d'\}$ is contained in the subpath of Q_1 between vw and f. Then $(C \cup P_1 \cup P_2) - \{ab, vw\}$ contains a path P from $\{a, b\}$ to $\{v, w\}$ through f and cd.

Note that the above cases can be checked in constant time, and in each case, P can be found in $O(|G|)$ time.

Case 3. $cd \notin E(C)$ and $vw \notin E(C)$. Let Q_1 and Q_2 denote the components of $C - \{ab, f\}$. By Lemma 3.5, there are disjoint paths P_1 and P_2 in G from c, d to $c', d' \in V(C)$, respectively, which are also disjoint from $C - \{c', d'\}$ (and can be found in $O(|G|)$ time). We may assume that $\{c', d'\} \not\subseteq V(Q_i)$ for $i = 1, 2$; otherwise, $C \cup P_1 \cup P_2$ contains a cycle through ab, cd, f and, as in Cases 1 and 2, we can find the desired path in $O(|G|)$ time. Thus, by symmetry, we may assume that $c' \in V(Q_1)$

and $d' \in V(Q_2)$.

If $vw \in E(P_1 \cup P_2)$, then $(C \cup P_1 \cup P_2) - \{ab, vw\}$ contains a path P from $\{a, b\}$ to $\{v, w\}$ through f and cd, which can be found in $O(|G|)$ time. So assume that $vw \notin E(P_1 \cup P_2)$. Therefore, by Lemma 3.5, we can find, in $O(|G|)$ time, disjoint paths R_1, R_2 from v, w to $v', w' \in V(C \cup P_1 \cup P_2)$, respectively, which are also disjoint from $(C \cup P_1 \cup P_2) - \{v', w'\}$.

By similar arguments, we may assume that $\{v', w'\} \not\subseteq V(Q_i)$ (or we go back to Case 1 or Case 2) and $\{v', w'\} \not\subseteq V(P_i)$ for any $i \in \{1, 2\}$ (or we could have chosen P_1, P_2 to include vw and have gone back to the case in the previous paragraph).

Subcase 3.1. $\{v', w'\} \neq \{c', d'\}$. First assume $\{v', w'\} \subseteq V(P_1 \cup P_2)$. Then cd belongs to the subpath of $(P_1 \cup P_2) + cd$ between v' and w'. We see that there is a path P in $((C - ab) \cup P_1 \cup P_2 \cup R_1 \cup R_2) + cd \subseteq G - \{ab, vw\}$ from $\{a, b\}$ to $\{v, w\}$ through both f and cd.

Now assume $\{v', w'\} \subseteq V(Q_1 \cup Q_2)$. Then by symmetry, we may assume that $v' \in V(Q_1)$, $w' \in V(Q_2)$, and $w' \neq d'$. If f, w', d', ab occur on C in cyclic order, then there is a path P from $\{a, b\}$ to $\{v, w\}$ through f and cd in $((C - ab) \cup P_1 \cup P_2 \cup R_1 \cup R_2) + cd \subseteq G - \{ab, vw\}$. If f, d', w', ab occur on C in cyclic order, then there is a path P from $\{a, b\}$ to $\{c, d\}$ through both f and vw in $((C - ab) \cup P_1 \cup P_2 \cup R_1 \cup R_2) + vw \subseteq G - \{ab, cd\}$.

Thus we may assume by symmetry that $v' \in (V(P_1) \cup V(P_2)) - \{c', d'\}$ and $w' \in (V(Q_1) \cup V(Q_2)) - \{c', d'\}$. It is easy to see that $((C - ab) \cup P_1 \cup P_2 \cup R_1 \cup R_2) + vw \subseteq G - \{ab, cd\}$ contains a path P from $\{a, b\}$ to $\{c, d\}$ through both f and vw.

The above three cases can be checked in $O(|G|)$ time, and in all cases, P can be found in $O(|G|)$ time.

Subcase 3.2. $\{v', w'\} = \{c', d'\}$. Let S_1 and S_2 denote the paths between c' and d' in C containing f and ab, respectively. Since G is 3-connected, there is a path S from some $s \in V(R_1 \cup R_2 \cup S_2) - \{c', d'\}$ to $s' \in V(P_1 \cup P_2 \cup S_1) - \{c', d'\}$, which is also disjoint from $(C \cup P_1 \cup P_2 \cup R_1 \cup R_2) - \{s, s'\}$. Note that S can be found in $O(|G|)$ time.

If $s \in V(S_2)$, then $((C - ab) \cup P_1 \cup P_2 \cup R_1 \cup R_2 \cup S) + cd \subseteq G - \{ab, vw\}$ contains a path P from $\{a, b\}$ to $\{v, w\}$ through both f and cd. If $s' \in V(S_1)$, then $((C - ab) \cup P_1 \cup P_2 \cup R_1 \cup R_2 \cup S) + vw \subseteq G - \{ab, cd\}$ contains a path P from $\{a, b\}$ to $\{c, d\}$ through both f and vw, or $((C - ab) \cup P_1 \cup P_2 \cup R_1 \cup R_2 \cup S) + cd \subseteq G - \{ab, vw\}$ contains a path P from $\{a, b\}$ to $\{v, w\}$ through both f and cd.

Therefore, we may assume that $s \in V(R_1 \cup R_2) - \{c', d'\}$ and $s' \in V(P_1 \cup P_2) - \{v', w'\}$. Then $((C - ab) \cup P_1 \cup P_2 \cup R_1 \cup R_2 \cup S) + vw \subseteq G - \{ab, cd\}$ contains a path P from $\{a, b\}$ to $\{c, d\}$ through both f and vw.

The above three cases can be checked in constant time, and in all cases, P can be found in $O(|G|)$ time. □

LEMMA 3.7. *Let G be a 3-connected graph, let $f \in E(G)$, let $x \in V(G)$ which is not incident with f, let $cd, vw \in E(G) - \{f\}$, and assume that $\{c, d\} \neq \{v, w\}$. Then there exists a path P in G from x to some $z \in \{c, d\} \cup \{v, w\}$ such that*

(i) *$f \in E(P)$,*
(ii) *$cd \in E(P)$ or $vw \in E(P)$, and*
(iii) *if $cd \in E(P)$ then $z \in \{v, w\}$ and $vw \notin E(P)$, and if $vw \in E(P)$, then $z \in \{c, d\}$ and $cd \notin E(P)$.*

Moreover, such a path can be found in $O(|G|)$ time.

Proof. The proof is the same as for Lemma 3.6, with ab replaced by x, and when finding paths P_i, R_i, we apply Lemma 3.5 to $G - x$ (which is 2-connected). □

4. Cycles avoiding a vertex. In this section, we show how to reduce Theorem 2.1(a) to (b) and/or (c) of the same theorem in linear time. First, we state the reduction as a lemma.

LEMMA 4.1. *Let $n \geq 6$ and $d \geq 3$ be integers, let $r = \log_{2(d-1)^2+1} 2$, and assume that Theorem 2.1 holds for graphs with at most $n-1$ vertices. Let G be a 3-connected graph with n vertices, let $xy \in E(G)$ and $z \in V(G) - \{x, y\}$, and let t denote the number of neighbors of z distinct from x and y. Assume that the maximum degree of G is at most $d+1$, and every vertex of degree $d+1$ in G (if any) is incident with the edge zx or zy. Then there is a cycle C through xy in $G-z$ such that $|C| \geq (\frac{n}{2t})^r + 2$.*

Proof. We consider $G - z$. Since the vertices of G with degree $d+1$ must be incident with the edge yz or xz, the maximum degree of $G - z$ is at most d.

First, assume that $G - z$ is 3-connected. Since $n \geq 6$, $|G - z| \geq 5$, and hence Theorem 2.1 holds for $G - z$. By Theorem 2.1(c), $G - z$ contains a cycle C through xy such that

$$\begin{aligned} |C| &\geq (n-1)^r + 3 \\ &= ((n-1)^r + 1) + 2 \\ &\geq ((n-1)+1)^r + 2 \quad \text{(by Lemma 3.1)} \\ &> \left(\frac{n}{2t}\right)^r + 2. \end{aligned}$$

Therefore, we may assume that $G - z$ is not 3-connected. By Theorem 2.2, we can decompose $G - z$ into 3-connected components. Let $\mathcal{H} = H_1 \dots H_h$ be a block chain in $G - z$ such that

(i) $\{x, y\} \subseteq V(H_1)$, and $\{x, y\} \neq V(H_1) \cap V(H_2)$ when $k \neq 1$,
(ii) H_h contains an extreme 3-block of $G - z$, and
(iii) subject to (i) and (ii), $|V(\mathcal{H})|$ is maximum.

Note that $H_1 \dots H_k$ can be found in $O(|G|)$ time.

We claim that $|V(\mathcal{H})| \geq \frac{n-1}{t}$. Since G is 3-connected, each extreme 3-block of $G-z$ distinct from H_1 contains a neighbor of z that is not incident with xy. Therefore, there are at most t extreme 3-blocks of $G - z$ different from H_1. Thus there are at most t different block chains in $G-z$ starting with a 3-block or cycle chain containing $\{x, y\}$ and ending with an extreme 3-block of $G-z$ or a cycle chain in $G-z$ containing an extreme 3-block. Since all such chains cover the whole graph $G-z$, it follows from (iii) that $|V(\mathcal{H})| - 2 \geq \frac{n-3}{t}$, and thus $|V(\mathcal{H})| \geq \frac{n-1}{t}$.

Let $V(H_i) \cap V(H_{i+1}) = \{x_i, y_i\}$, $1 \leq i \leq h-1$, and assume that the notation is chosen so that H_i contains disjoint paths from x_{i-1}, y_{i-1} to x_i, y_i, respectively, where $x_0 = x$ and $y_0 = y$. See Figure 6. Next, we show how to find the desired cycle in $G - z$.

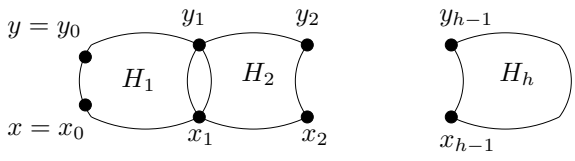

FIG. 6. *Block chain $\mathcal{H} = H_1 \dots H_h$.*

Case 1. There exists some $1 \leq i \leq h$ such that $|H_i| \geq \frac{n}{2t}$. We choose H_i so that $|H_i| \geq |H_j|$ for all $1 \leq j \leq h$. Then $|H_i| \geq \frac{n}{2t}$.

First, assume that $|H_i| = 3$. Then $3 \geq \frac{n}{2t}$. By the choice of H_i, $|H_j| = 3$ for all

$1 \le j \le h$. Since $\mathcal{H}$ does not contain two consecutive cycle chains, we have $h = 1$. Hence $G - z$ is a union of triangles which share the edge xy. Therefore, there are exactly t triangles. Because $n \ge 6$, we have $t \ge 3$, and thus $n = t + 3 \le 2t$. Hence $C := H_i$ is a cycle through xy in $G - z$, and $|C| = 3 \ge (\frac{n}{2t})^r + 2$.

We may assume that $|H_i| \ge 4$. If $H_i = K_4$ or H_i is a cycle chain in $G - z$, then, by Proposition 2.4, let C_i denote a Hamilton cycle through $x_{i-1}y_{i-1}, x_iy_i$ in H_i. By Lemma 3.2, $|C_i| = |H_i| \ge (|H_i|)^r + 2 \ge (\frac{n}{2t})^r + 2$.

Thus assume that H_i is 3-connected and $|H_i| \ge 5$. Since $|H_i| < |G|$ and the maximum degree of H_i is at most d, Theorem 2.1 holds for H_i. By Theorem 2.1 (c), there is a cycle C_i through $e_i := x_{i-1}y_{i-1}$ in H_i such that $|C_i| \ge |H_i|^r + 3 \ge (\frac{n}{2t})^r + 2$.

We can obtain a cycle C in G by replacing virtual edges contained in C_i with paths in G (in particular, replacing $x_{i-1}y_{i-1}$ by a path through xy in G). Therefore, C is a cycle through xy in G, and $|C| \ge |C_i| \ge (\frac{n}{2t})^r + 2$.

Case 2. For each $1 \le i \le h$, $|H_i| < \frac{n}{2t}$. Since $|V(\mathcal{H})| \ge \frac{n-1}{t} > \frac{n}{2t}$, we have $h \ge 2$. We will find a cycle C_i through $x_{i-1}y_{i-1}$ and x_iy_i in each H_i, where x_hy_h is an arbitrary edge of H_h.

If $H_i = K_4$ or H_i is a cycle chain in $G - z$, then, by Proposition 2.4, let C_i be a Hamilton cycle through both $x_{i-1}y_{i-1}$ and x_iy_i in H_i. By Lemma 3.2, $|C_i| = |H_i| \ge (\frac{|H_i|}{2(d-1)})^r + 2$.

Assume that $H_i \ne K_4$ and H_i is not a cycle chain in $G - z$. Then $|H_i| \ge 5$ and H_i is a 3-connected graph with maximum degree d. Since $|H_i| < n$, Theorem 2.1 holds for H_i. By Theorem 2.1 (b), there is a cycle C_i through $x_{i-1}y_{i-1}$ and x_iy_i in H_i such that $|C_i| \ge (\frac{|H_i|}{2(d-1)})^r + 3$.

Note that $C_1 - x_1y_1$, $C_h - x_{h-1}y_{h-1}$, and $C_i - \{x_{i-1}y_{i-1}, x_iy_i\}$, $2 \le i \le h-1$, are edge disjoint, and their union is a cycle C' through xy in $\mathcal{H}$. By replacing the virtual edges in C' with paths in G, we can produce a cycle C through xy in $G - z$ such that $|C| \ge |C'|$. Hence $|C| \ge (\frac{|H_1|}{2(d-1)})^r + \cdots + (\frac{|H_h|}{2(d-1)})^r + 2$.

Note that $h \ge 2$ and the vertices in $V(H_1) \cap V(H_2)$ are counted twice in $|H_1| + \cdots + |H_h|$. Hence $|H_1| + \cdots + |H_h| > \frac{n-1}{t} + 1 \ge \frac{n}{t}$. Consider the function $f(x_1, \ldots, x_h) = x_1^r + \cdots + x_h^r + 2$, with $x_1 + \cdots + x_h \ge \frac{n}{2(d-1)t}$ and $0 \le x_i \le \frac{n}{4(d-1)t}$. By the convexity of $f(x_1, \ldots, x_h)$, the minimum of $f(x_1, \cdots, x_h)$ is achieved on the boundary of its domain. In particular, the minimum is achieved when $x_1 = x_2 = \frac{n}{4(d-1)t}$ and $x_3 = \cdots = x_h = 0$. Hence

$$\begin{aligned} f(x_1, \ldots, x_h) &\ge f\left(\frac{n}{4(d-1)t}, \frac{n}{4(d-1)t}, 0, \ldots, 0\right) \\ &= 2\left(\frac{n}{4(d-1)t}\right)^r + 2 \\ &> \left(\frac{n}{2t}\right)^r + 2. \end{aligned}$$

The final inequality follows from the fact that $r = \log_{2(d-1)^2+1} 2$ and $2 = (2(d-1)^2 + 1)^r$. Therefore, $|C| \ge (\frac{n}{2t})^r + 2$. □

As we can see from the above proof, the desired cycle through xy in $G - z$ can be found either (1) directly, (2) by finding a long cycle through e_i in some H_i with $|H_i| \ge \frac{n}{2t}$, or (3) by finding long cycles through $x_{j-1}y_{j-1}$ and x_jy_j in H_j, $1 \le j \le h$. Next we show that the proof of Lemma 4.1 implies that this process can be done in $O(|E(G)|)$ time.

Algorithm Avoidvertex. Let G be a 3-connected graph, $e = xy \in E(G)$, and

$z \in V(G) - \{x, y\}$, satisfying the conditions of Lemma 4.1. The algorithm performs the following steps.

1. *Preprocessing.* Replace G by a 3-connected spanning graph of G with $O(|G|)$ edges. (This can be done in $O(|E(G)|)$ time using Lemma 3.4.)
2. Decompose $G - z$ into 3-connected components. (This can be done in $O(|G|)$ time using Lemma 2.2.)
3. If there is only one 3-block of $G - z$, then $G - z$ is 3-connected and we proceed to find a cycle D through $e = xy$ in $G - z$ such that $|D| \geq (|G|-1)^r + 3$. That is, we reduce (a) for G, xy, z to (c) for $G - z, xy$. (Clearly, this reduction can be done in constant time.)
4. If there are at least two 3-blocks of $G - z$, then $G - z$ is not 3-connected. We find a block chain $\mathcal{H} = H_1 \dots H_k$ in $G - z$ such that $\{x, y\} \subseteq V(H_1)$, $\{x, y\} \neq V(H_1) \cap V(H_2)$, and $|\mathcal{H}| \geq \frac{n-1}{t}$. Let $V(H_i) \cap V(H_{i+1}) = \{x_i, y_i\}$ for $1 \leq i \leq h-1$. (Note that $\mathcal{H}$ can be found in $O(|G|)$ time by a simple search.)
5. Either find some H_i with $|H_i| \geq \frac{n}{2t}$, or certify that $|H_i| < \frac{n}{2t}$ for all $1 \leq i \leq h$. (This can be done in $O(|G|)$ time by a simple search.)
6. Suppose there exists some $1 \leq i \leq h$ for which $|H_i| \geq \frac{n}{2t}$.
   - If $H_i = K_4$ or H_i is a cycle chain, then let C_i denote a Hamilton cycle in H_i through the edge $x_{i-1}y_{i-1}$. Let C be a cycle in G obtained from C_i by replacing virtual edges with paths in G, and make sure $e \in E(C)$. (Note that C_i can be found in $O(|H_i|)$ time using Proposition 2.4, and so C can be found in $O(|G|)$ time.)
   - If H_i is 3-connected and $H_i \neq K_4$, then to find the desired cycle in $G - z$ through e it suffices to find a cycle D in H_i through $x_{i-1}y_{i-1}$ such that $|D| \geq |H_i|^r + 3$. Hence, we reduce (a) for G, e, z to (c) for $H_i, x_{i-1}y_{i-1}$. (This can be done in constant time.)
7. Now assume that, for all $1 \leq j \leq h$, $|H_j| < \frac{n}{2t}$. Then $h \geq 2$. For each $1 \leq j \leq h$, we perform the following:
   - If $H_j = K_4$ or H_j is a cycle chain in $G - z$, let C_j denote a Hamilton cycle through both $x_{j-1}y_{j-1}$ and x_jy_j in H_j. (Note that C_j can be found in $O(|H_j|)$ time using Proposition 2.4.)
   - If H_j is 3-connected and $H_j \neq K_4$, then it suffices to find a cycle D in H_j through $x_{j-1}y_{j-1}$ and x_jy_j such that $|D| \geq (\frac{|H_j|}{2(d-1)})^r + 3$. Hence, we reduce (a) for G, xy, z to (b) for $H_j, x_{j-1}y_{j-1}, x_jy_j$, for all H_j which are not cycle chains and are not isomorphic to K_4. (Clearly, this can done in $O(|G|)$ time. Moreover, any such H_j contains a vertex that does not belong to any other H_k—this is why we want $H_j \neq K_4$, and it will be used in the final complexity analysis.)

The correctness of the algorithm follows from the proof of Lemma 4.1. To summarize, we have the following result.

PROPOSITION 4.2. *Let $G, e = xy, z, t, d, r$ be as in Theorem* 2.1(a). *Then, in $O(|E(G)|)$ time, we can either*

(1) *find a cycle C through e in $G - z$ with $|C| \geq (\frac{|G|}{2t})^r + 2$,*
(2) *reduce* (a) *of Theorem* 2.1 *for G, xy, z to* (c) *of Theorem* 2.1 *for some* 3*-block H_i of $G - z$ that is* 3*-connected and $|H_i| \geq \max\{5, \frac{|G|}{2t}\}$, or*
(3) *reduce* (a) *of Theorem* 2.1 *for G, xy, z to* (b) *of Theorem* 2.1 *for $H_j, x_{j-1}y_{j-1}$, x_jy_j for some* 3*-connected* 3*-blocks $H_j \neq K_4$.*

Moreover, in (3)*, each H_j contains a vertex that does not belong to any other H_k, $k \neq j$.*

5. Cycles through two edges. In this section, we show how to reduce (b) of Theorem 2.1 to (a) or (b) of the same theorem for smaller graphs. We will show that such a reduction can be performed in linear time.

LEMMA 5.1. *Let $n \geq 6$ and $d \geq 3$ be integers, let $r = \log_{2(d-1)^2+1} 2$, and assume that Theorem 2.1 holds for graphs with at most $n-1$ vertices. Suppose G is a 3-connected graph on n vertices and that the maximum degree of G is at most d. Then for any $\{e, f\} \subseteq E(G)$ there is a cycle C through e, f in G such that $|C| \geq (\frac{n}{2(d-1)})^r + 3$.*

Proof. First, assume that e is incident with f. Let $e = xz$ and $f = yz$, and let $G' := G + xy$. Then G' is a 3-connected graph with maximum degree at most $d+1$, and the possible vertices of degree $d+1$ in G' are x and y, which are incident with the edge zx or zy. By applying Lemma 4.1 to G', xy, z, there is a cycle C' through xy in $G' - z$ such that $|C'| \geq (\frac{n}{2t})^r + 2$, where t is the number of neighbors of z in G' distinct from x and y. Since $zx, zy \in E(G)$, $t \leq d-1$. Now let $C := C' - xy + \{e, f\}$. Then $|C| \geq (\frac{n}{2t})^r + 3 \geq (\frac{n}{2(d-1)})^r + 3$, and C gives the desired cycle.

Therefore, we may assume that e and f are not incident. Let $e = xy$, and consider $G - y$. Since y is not incident with f, $f \in E(G - y)$. Since G is 3-connected, $G - y$ is 2-connected.

Suppose that $G - y$ is 3-connected. Let $y' \neq x$ be a neighbor of y. Then $G' := (G-y)+xy'$ is a 3-connected graph with maximum degree at most d, and $5 \leq |G'| < n$. Hence Theorem 2.1 holds for G'. By Theorem 2.1(b), there is a cycle C' through xy' and f in G' such that $|C'| \geq (\frac{n-1}{2(d-1)})^r + 3$. Let $C := (C' - xy') + \{y, xy, yy'\}$. Then

$$\begin{aligned} |C| &= |C'| + 1 \\ &\geq \left(\frac{n-1}{2(d-1)}\right)^r + 3 + 1 \\ &\geq \left(\frac{n-1}{2(d-1)} + 1\right)^r + 3 \quad \text{(by Lemma 3.1)} \\ &> \left(\frac{n}{2(d-1)}\right)^r + 3. \end{aligned}$$

Assume that $G - y$ is not 3-connected. By Theorem 2.2, we can decompose $G - y$ into 3-connected components. Let $\mathcal{H} := H_1 \dots H_h$ be a block chain in $G - y$ such that $x \in V(H_h)$, $x \notin V(H_{h-1})$ when $h \geq 2$, $f \in E(H_1)$, and f is not incident with both vertices in $V(H_1) \cap V(H_2)$. See Figure 7. Define $V(H_s) \cap V(H_{s+1}) = \{a_s, b_s\}$ for $1 \leq s \leq h-1$.

For each $1 \leq s \leq h$ we define A_s, which consists of vertices of H_s to be counted when applying induction. If H_s is 3-connected, then let $A_s := V(H_s)$. If $h = 1$ and $H_s = C_1 \dots C_k$ is a cycle chain in $G - y$, then let A_s consist of the vertices incident with f and the vertices in $\bigcup_{i=1}^{k-1} V(C_i \cap C_{i+1})$. If $h > 1$ and $H_1 = C_1 \dots C_k$ is a cycle chain in $G-y$, then let A_1 consist of those vertices of $H_1 - \{a_1, b_1\}$ which are incident with f or contained in $\bigcup_{i=1}^{k-1} V(C_i \cap C_{i+1})$. If $1 < s < h$ and $H_s = C_1 \dots C_k$ is a cycle chain, then let $A_s := (\bigcup_{i=1}^{k-1} V(C_i \cap C_{i+1})) - (\{a_{s-1}, b_{s-1}\} \cup \{a_s, b_s\})$. If $1 < s = h$ and $H_s = C_1 \dots C_k$ is a cycle chain, then let $A_s := (\bigcup_{i=1}^{k-1} V(C_i \cap C_{i+1})) - \{a_{s-1}, b_{s-1}\}$.

Note that when H_h is a cycle chain, we may choose H_h so that $x \notin A_h$. Define $\sigma(\mathcal{H}) := |\bigcup_{s=1}^{h} A_s|$. Intuitively, $\sigma(\mathcal{H})$ consists of the vertices incident with f, and those vertices which are of degree at least three in $\mathcal{H}$ (when viewed as a graph).

We wish to route our cycle through two large "parts" of $G - y$. For this purpose, we consider chains $\mathcal{I}$ and $\mathcal{J}$ in $G - y$ defined below.

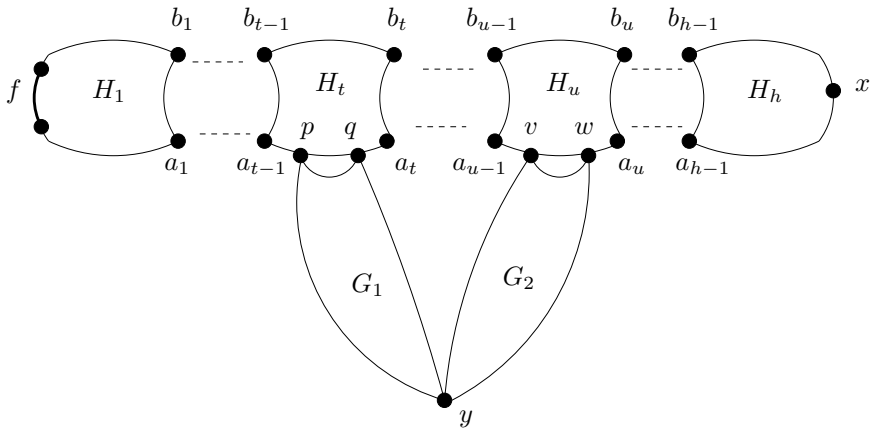

FIG. 7. *Block chains $\mathcal{H}$, $\mathcal{I}$, and $\mathcal{J}$.*

Let $\mathcal{I} := I_1 \dots I_i$ be a block chain in $G - y$ such that (i) $|V(I_1) \cap V(\mathcal{H})| = 2$, (ii) $V(\mathcal{I}) \cap V(\mathcal{H}) = V(I_1) \cap V(\mathcal{H})$, (iii) I_i is an extreme 3-block of $G - y$, and (iv) subject to (i), (ii), and (iii), $|V(\mathcal{I})|$ is maximum. We may choose the notation of e and f so that $\mathcal{I}$ is nonempty, and hence, G_1 is defined. Let $V(I_1) \cap V(\mathcal{H}) = \{p, q\}$. In this case, $\{p, q, y\}$ is a 3-cut of G, and we let G_1 denote the subgraph of G by deleting those components of $G - \{p, q, y\}$ that contain an element of $V(\mathcal{H})$. (Note that G_1 can be defined in a more direct way; however, defining it from $\mathcal{I}$ is more natural for our algorithm because we have all 3-blocks.) See Figure 7.

Since all degree two vertices in $\mathcal{H}$ are contained in some other 3-blocks of $G-y$ or are neighbors of y, $G-y$ can be covered by at most $d-1$ block chains starting from a 3-block containing f and ending with an extreme 3-block (or a cycle chain containing an extreme 3-block). Hence, we have the following.

Observation 1. $|G_1| \geq \frac{n-\sigma(\mathcal{H})}{d-1}$.

Let $\mathcal{J} := J_1 \dots J_j$ be a block chain in $G - y$ such that (i) $|V(J_1) \cap (V(\mathcal{H}) \cup V(G_1))| = 2$, (ii) $V(\mathcal{J}) \cap (V(\mathcal{H}) \cup V(G_1)) = V(J_1) \cap (V(\mathcal{H}) \cup V(G_1))$, (iii) J_j is an extreme 3-block of $G - y$, and (iv) subject to (i), (ii), and (iii), $|V(\mathcal{J})|$ is maximum. When $\mathcal{J}$ is nonempty, let $V(\mathcal{J}) \cap (V(\mathcal{H}) \cup V(G_1)) = \{v, w\}$. By the choice of G_1, $\{v, w\} \neq \{p, q\}$ and $\{v, w\} \subseteq V(\mathcal{H})$. In this case, $\{v, w, y\}$ is a 3-cut of G, and we let G_2 denote the subgraph of G by deleting those components of $G - \{v, w, y\}$ that contain an element of $V(G_1) \cup V(\mathcal{H})$. Note that $V(G_1) \cap V(G_2) \subseteq \{p, q, y\} \cap \{v, w, y\}$ and $|V(G_1) \cap V(G_2)| \leq 2$ (because $\{v, w\} \neq \{p, q\}$). See Figure 7.

By the same reasoning as for Observation 1, we have the following two observations.

Observation 2. If G_2 is defined, then $|G_2| \geq \frac{n-\sigma(\mathcal{H})-(|G_1|-1)}{d-2}$.

Observation 3. If $\sigma(\mathcal{H}) \geq |G_2|$, then $\sigma(\mathcal{H}) \geq \frac{n-|G_1|+1}{d-1}$.

Next we distinguish two cases by comparing $\sigma(\mathcal{H})$ and $|G_2|$.

Case 1. $\sigma(\mathcal{H}) \geq |G_2|$. In this case, it suffices to consider $\mathcal{H}$ and G_1. Clearly, there is some $1 \leq t \leq h$ such that $\{p, q\} \subseteq V(H_t)$, and $\{p, q\} \neq \{a_{t-1}, b_{t-1}\}$ when $t \neq 1$. Let a_0, b_0 be the vertices incident with f. We will find paths in H_s, $1 \leq s \leq h$, and a path in G_1 to form the desired cycle.

(1) If $s = 1 < t$, then there is a path P_1 from a_1 to b_1 in H_1 such that $f \in E(P_1)$ and $|E(P_1)| \geq (\frac{|A_s|}{2(d-1)})^r + 1$. If $1 < s < t$, then there exists $P_s \subseteq H_s$, consisting of

disjoint paths from $\{a_{s-1}, b_{s-1}\}$ to $\{a_s, b_s\}$, such that $|E(P_s)| \geq (\frac{|A_s|}{2(d-1)})^r + 1$.

Suppose $H_s = K_4$ or H_s is a cycle chain. By Proposition 2.4, let C_s denote a Hamilton cycle through $a_{s-1}b_{s-1}$ and a_sb_s in H_s. Since $|H_s| \geq 3$ and by Lemma 3.2,

$$|C_s| = |H_s| \geq \left(\frac{|H_s|}{2(d-1)}\right)^r + 2 \geq \left(\frac{|A_s|}{2(d-1)}\right)^r + 2.$$

If $s = 1$, then $P_1 := C_1 - a_1b_1$ gives the desired path for (1). Now assume $1 < s < t$. If $|H_s| \geq 4$, then $|C_s| = |H_s| \geq (\frac{|H_s|}{2(d-1)})^r + 3$, and if $|H_s| = 3$, then $|A_s| = 0$, and hence $|C_s| = |H_s| = (\frac{|A_s|}{2(d-1)})^r + 3$. Hence $P_s := C_s - \{a_{s-1}b_{s-1}, a_sb_s\}$ gives the desired path for (1).

Now suppose H_s is 3-connected and $H_s \neq K_4$. Then $5 \leq |H_s| < n$, and hence Theorem 2.1 holds for H_s. By Theorem 2.1(b), there is a cycle C_s through $a_{s-1}b_{s-1}$ and a_sb_s in H_s such that $|C_s| = (\frac{|H_s|}{2(d-1)})^r + 3 \geq (\frac{|A_s|}{2(d-1)})^r + 3$.

When $s \neq 1$, then $P_s := C_s - \{a_{s-1}b_{s-1}, a_sb_s\}$ is as desired, and when $s = 1$, then $P_s := C_s - a_sb_s$ gives the desired path for (1).

(2) Next we find $P_t \subseteq H_t$, and to do so, we consider three subcases.

(2a) First, assume that $1 = t = h$. We will find a path P_t from x to $\{p, q\}$ such that $f \in E(P_t)$, $pq \notin E(P_t)$ unless $pq = f$, and $|E(P_t)| \geq (\frac{\sigma(\mathcal{H})}{2(d-1)})^r + 1$.

If H_t is a cycle chain, then by Proposition 2.8, let P_t denote a path from x to $\{p, q\}$ in H_t such that $f \in E(P_t)$, $pq \notin E(P_t)$ unless $pq = f$, and $A_t \subseteq V(P_t)$. When H_t consists of only one 3-block of $G - y$, then $|E(P_t)| \geq 2 = |A_t| > (\frac{|A_t|}{2(d-1)})^r + 1 = (\frac{\sigma(\mathcal{H})}{2(d-1)})^r + 1$ (by Lemma 3.2). When H_t has at least two 3-blocks of $G - y$, then $|A_t| \geq 3$ and $|E(P_t)| \geq |A_t| - 1 \geq (\frac{|A_t|}{2(d-1)})^r + 1 = (\frac{\sigma(\mathcal{H})}{2(d-1)})^r + 1$ (by Lemma 3.2). So P_t gives the desired path for (2a).

If $H_t = K_4$, then $\sigma(\mathcal{H}) = 4$. Let P_t denote a Hamilton path from x to $\{p, q\}$ in H_t such that $f \in E(P_t)$, and $pq \notin E(P_t)$ unless $pq = f$. Then $|E(P_t)| = 3 \geq (\frac{\sigma(\mathcal{H})}{2(d-1)})^r + 2$. Hence, P_t gives the desired path for (2a).

Now assume that H_t is not a cycle chain and $H_t \neq K_4$.

If $x \in \{p, q\}$, then $f \neq pq$ since x is not incident with f. Since $5 \leq |H_t| < n$, Theorem 2.1 holds for H_t. By Theorem 2.1(b), there exists a cycle C_t in H_t such that $pq, f \in E(P_t)$ and $|C_t| \geq (\frac{|H_t|}{2(d-1)})^r + 3 = (\frac{\sigma(\mathcal{H})}{2(d-1)})^r + 3$. Hence $P_t := C_t - pq$ gives the desired path.

Assume $x \notin \{p, q\}$.

Suppose $f \neq pq$. Let H_t' be obtained from H_t by a T-transform at $\{x, pq\}$, and let x' denote the new vertex. By Lemma 3.3 and since x has degree at most $d - 1$ in H_t, H_t' is a 3-connected graph with maximum degree at most d. Since $G - y$ is not 3-connected, $|H_t| < n - 1$. Hence $5 \leq |H_t'| < n$, and Theorem 2.1 holds for H_t'. By Theorem 2.1(b), there exists a cycle C_t in H_t' such that $f, xx' \in E(C_t)$ and $|C_t| \geq (\frac{|H_t|}{2(d-1)})^r + 3 = (\frac{\sigma(\mathcal{H})}{2(d-1)})^r + 3$. Hence $P_t := C_t - x'$ gives the desired path for (2a).

Finally, assume that $f = pq$. Let $H_t' := H_t + \{px, qx\}$. Then H_t' is a 3-connected graph with maximum degree at most $d + 1$, and all vertices of degree $d + 1$ must be incident with px or pq. By Theorem 2.1(a), we can find a cycle C_t in $H_t' - p$ through xq such that $|C_t| \geq (\frac{|H_t|}{2t})^r + 2 = (\frac{\sigma(\mathcal{H})}{2t})^r + 2$, where $t \leq d - 1$ is the number of neighbors of p distinct from x and q. Hence $P_t := (C_t - qx) + \{p, pq\}$ gives the desired path for (2a).

(2b) Now assume that $1 \le t < h$. If $t = 1$, we will find a path P_t from $\{a_t, b_t\}$ to $\{p, q\}$ in H_t such that $f \in E(P_t)$, $pq \notin E(P_t)$ unless $pq = f$, and $|E(P_t)| \ge (\frac{|A_t|}{2(d-1)})^r$. If $t \ne 1$, we will find $P_t \subseteq H_t$, consisting of disjoint paths from $\{p, q\}$ and $\{a_t, b_t\}$ to $\{a_{t-1}, b_{t-1}\}$ such that $|E(P_t)| \ge (\frac{|A_t|+2}{2(d-1)})^r - 1$.

Suppose H_t is a cycle chain. If $\{a_t, b_t\} = \{p, q\}$, then by Proposition 2.4 let C_t denote a Hamilton path in H_t from a_t to b_t through $a_{t-1}b_{t-1}$. If $\{a_t, b_t\} \ne \{p, q\}$, then by Proposition 2.7, let C_t denote a path in $H_t - a_tb_t$ from $\{a_t, b_t\}$ to $\{p, q\}$ such that $a_{t-1}b_{t-1} \in E(C_t)$, $pq \notin E(C_t)$, and $A_t \subseteq V(C_t)$. From the definition of A_t and since $t < h$, $a_t \notin A_t$ and $b_t \notin A_t$. Also note that if $t \ne 1$, then $a_{t-1} \notin A_t$ or $b_{t-1} \notin A_t$. So if $t = 1$, then $|E(C_t)| \ge |A_t|$, and if $t \ne 1$, then $|E(C_t)| \ge |A_t| + 1$. Let $P_t := C_t$ if $t = 1$, and let $P_t := C_t - a_{t-1}b_{t-1}$ if $t \ne 1$. Then P_t is as desired for (2b).

If $H_t = K_4$, then let C_t denote a Hamilton path in $H_t - \{pq, a_tb_t\}$ from $\{a_t, b_t\}$ to $\{p, q\}$ through $a_{t-1}b_{t-1}$. Then $|E(C_t)| = 3 > (\frac{|A_t|}{2(d-1)})^r + 1$, and so $P_t := C_t - a_{t-1}b_{t-1}$ is as desired for (2b).

Now assume that H_t is not a cycle chain and $H_t \ne K_4$.

Suppose $\{a_t, b_t\} = \{p, q\}$. Since $5 \le |H_t| < n$, Theorem 2.1 holds for H_t. By Theorem 2.1(b), there is a cycle C_t through $a_{t-1}b_{t-1}$ and a_tb_t in H_t such that $|C_t| \ge (\frac{|H_t|}{2(d-1)})^r + 3 = (\frac{|A_t|}{2(d-1)})^r + 3$. If $t = 1$ then $P_t := C_t - a_tb_t$ gives the desired path, and if $t \ne 1$ then $P_t := C_t - \{a_{t-1}b_{t-1}, a_tb_t\}$ is as desired for (2b).

Now assume that $\{a_t, b_t\} \ne \{p, q\}$. Let H'_t be obtained from H_t by an H-transform at $\{a_tb_t, pq\}$, and let a', b' denote the new vertices. By Lemma 3.3, H'_t is a 3-connected graph with maximum degree at most d. Since $G - y$ is not 3-connected and since $\mathcal{I}$ is nonempty (when $\{p, q\}$ is defined), we have $|H_t| \le n - 3$. Hence $5 \le |H'_t| < n$. Hence Theorem 2.1 holds for H'_t. By Theorem 2.1(b), there is a cycle C_t through $a'b'$ and $a_{t-1}b_{t-1}$ in H'_t such that $|C_t| \ge (\frac{|H'_t|}{2(d-1)})^r + 3 = (\frac{|A_t|+2}{2(d-1)})^r + 3$. If $t = 1$, then $P_t := C_t - \{a, a'\}$ gives the desired path, and if $t \ne 1$ then $P_t := C_t - \{a, a', a_{t-1}b_{t-1}\}$ is as desired for (2b).

(2c) Finally, assume $1 < t = h$. We will find $P_t \subseteq H_t$, consisting of disjoint paths from x and $\{p, q\}$ to $\{a_{t-1}, b_{t-1}\}$, such that $|E(P_t)| \ge (\frac{|A_t|}{2(d-1)})^r$.

If H_t is a cycle chain, then by Proposition 2.8, let C_t denote a path in H_t from x to $\{p, q\}$ such that $a_{t-1}b_{t-1} \in E(C_t)$, $pq \notin E(P_t)$, and $A_t \subseteq V(P_t)$. Since $x, a_{t-1}, b_{t-1} \notin A_t$, $|E(C_t)| \ge |A_t| + 1 > (\frac{|A_t|}{2(d-1)})^r + 1$. Hence $P_t := C_t - a_{t-1}b_{t-1}$ is as desired for (2c).

If $H_t = K_4$, then let C_t denote a Hamilton path in $H_t - pq$ from x to $\{p, q\}$ through $a_{t-1}b_{t-1}$. Then $|E(C_t)| = 3 \ge (\frac{|H_t|}{2(d-1)})^r + 2 = (\frac{|A_t|}{2(d-1)})^r + 2$. Hence $P_t := C_t - a_{t-1}b_{t-1}$ is as desired for (2c).

Now assume that H_t is not a cycle chain and $H_t \ne K_4$.

Suppose $x \in \{p, q\}$. Since $5 \le |H_t| < n$, Theorem 2.1 holds for H_t. By Theorem 2.1(b), there is a cycle C_t through $a_{t-1}b_{t-1}$ and pq in H_t such that $|C_t| \ge (\frac{|H_t|}{2(d-1)})^r + 3 = (\frac{|A_t|}{2(d-1)})^r + 3$. Then $P_t := C_t - \{pq, a_{t-1}b_{t-1}\}$ is as desired.

Now assume that $x \notin \{p, q\}$. Recall that $\{p, q\} \ne \{a_{t-1}, b_{t-1}\}$. Let H'_t be obtained from H_t by a T-transform at $\{x, pq\}$ and let c' denote the new vertex. By Lemma 3.3, H'_t is a 3-connected graph with maximum degree at most d (because the degree of x in H_t is at most $d - 1$). Since $G - y$ is not 3-connected, $|H_t| \le n - 2$, and so, $5 \le |H'_t| < n$. Hence Theorem 2.1 holds for H'_t. By Theorem 2.1(b), there is a cycle C_t through xc' and $a_{t-1}b_{t-1}$ in H'_t such that $|C_t| \ge (\frac{|H'_t|}{2(d-1)})^r + 3 > (\frac{|A_t|}{2(d-1)})^r + 3$.

Hence $P_t := C_t - \{c', a_{t-1}b_{t-1}\}$ is as desired for (2c).

(3) For each $t+1 \le s \le h$, we will find a path $P_s \subseteq H_s$ such that $|E(P_s)| \ge (\frac{|A_s|}{2(d-1)})^r$ when $s \ne h$, $|E(P_s)| \ge (\frac{|A_s|}{2(d-1)})^r + 1$ when $s = h$, and $\bigcup_{s=t+1}^{h} P_s$ is a path from x to the end of P_t contained in $\{a_t, b_t\}$ and is otherwise disjoint from P_t.

We find P_s in the order $s = t+1, \dots, h$.

Suppose P_{s-1} is found, and the notation of $\{a_{s-1}, b_{s-1}\}$ is chosen so that a_{s-1} is an end of P_{s-1}, and assume that the notation of $\{a_s, b_s\}$ is chosen so that $a_s \notin \{a_{s-1}, b_{s-1}\}$.

First, assume that H_s is a cycle chain. If $s \ne h$, then by Proposition 2.5, let P_s denote a path in $H_s - \{a_{s-1}b_{s-1}, a_sb_s\}$ from a_{s-1} to $\{a_s, b_s\}$ such that $A_s \subseteq V(P_s)$. Since $a_{s-1}, b_{s-1}, a_s, b_s \notin A_s$, we have that $|E(P_s)| \ge |A_s|+1 \ge (\frac{|A_s|}{2(d-1)})^r+1$. If $s = h$, then by Proposition 2.6 let P_s be a path from x to a_{s-1} in $H_s - a_{s-1}b_{s-1}$ such that $A_s \subseteq V(P_s)$. Since $x, a_{s-1}, b_{s-1} \notin A_s$, we have that $|E(P_s)| \ge |A_s|+1 > (\frac{|A_s|}{2(d-1)})^r+1$.

Now assume $H_s = K_4$. If $s \ne h$, then let P_s denote a path in $H_s - \{a_{s-1}b_{s-1}, a_sb_s\}$ from a_{s-1} to a_s with $|E(P_s)| \ge 1 \ge (\frac{|A_s|}{2(d-1)})^r$. If $s = h$, then let P_s be a path in $H_s - a_{s-1}b_{s-1}$ from a_{s-1} to x with $|E(P_s)| \ge 2 > (\frac{|A_s|}{2(d-1)})^r + 1$.

Therefore, we may assume that H_s is not a cycle chain and $H_s \ne K_4$.

Suppose $s \ne h$. If $b_{s-1} = b_s$, then let $H'_s := H_s + a_{s-1}a_s$. Clearly, H'_s is 3-connected with maximum degree at most $d+1$, and the vertices of degree $d+1$ must be incident with $a_{s-1}b_{s-1}$ or a_sb_{s-1}. Thus by Theorem 2.1(a), there is a cycle C_s in $H'_s - b_{s-1}$ such that $a_{s-1}a_s \in E(C_s)$ and $|C_s| \ge (\frac{|H'_s|}{2(d-1)})^r + 2$. Let $P_s := C_s - a_{s-1}a_s$. Then $|E(P_s)| \ge (\frac{|A_s|}{2(d-1)})^r+1$. So assume $b_{s-1} \ne b_s$. Let H''_s be obtained from H_s by a T-transform at $\{b_{s-1}, a_sb_s\}$, and let a' denote the new vertex. Let $H'_s := H''_s + a_{s-1}a'$. Since $G - y$ is not 3-connected, $|H''_s| \le n-2$, and so $5 \le |H'_s| < n$. By Lemma 3.3, H''_s is a 3-connected graph with maximum degree at most $d+1$, and the vertices of degree $d+1$ must be incident with $b_{s-1}a'$ or $b_{s-1}a_{s-1}$. Thus $H'_s, a_{s-1}a', b_{s-1}$ satisfy the conditions of Theorem 2.1(a). By Theorem 2.1(a), there is a cycle C_s through $a_{s-1}a'$ in $H'_s - b_{s-1}$ such that $|C_s| \ge (\frac{|H'_s|}{2(d-1)})^r + 2$. Let $P_s := C_s - a'$. Then $|E(P_s)| \ge (\frac{|A_s|}{2(d-1)})^r$.

Now assume $s = h$. Let $H'_s := H_s + \{xb_{s-1}, xa_{s-1}\}$. Then H'_s is a 3-connected graph, the vertices x, a_{s-1}, b_{s-1} have degree at most $d+1$, and all other vertices of H'_s have degree at most d. Thus $H'_s, a_{s-1}x, b_{s-1}$ satisfy the conditions of Theorem 2.1(a). By Theorem 2.1(a), there is a cycle C'_s through $a_{s-1}x$ in $H'_s - b_{s-1}$ such that $|C'_s| \ge (\frac{|H'_s|}{2(d-1)})^r + 2$. Let $P_s := C'_s - a_{s-1}x$. Then P_s is a path from a_{s-1} to x and $|E(P_s)| \ge (\frac{|H'_s|}{2(d-1)})^r + 1 \ge (\frac{|A_s|}{2(d-1)})^r + 1$.

It is easy to see that $\bigcup_{s=t+1}^{h} P_s$ is a path from x to the end of P_t in $\{a_t, b_t\}$ and is otherwise disjoint from P_t.

(4) Let $P := \bigcup_{s=1}^{h} P_s$. We claim that P is a path from x to $\{p, q\}$, $f \in E(P)$, $pq \notin E(P)$ unless $pq = f$, and $|E(P)| \ge (\frac{\sigma(\mathcal{H})}{2(d-1)})^r + 1$.

This is obvious if $h = 1$ (by (2a)). So assume that $h \ge 2$.

Suppose $t \ne 1$. Then $|E(P_s)| \ge (\frac{|A_s|}{2(d-1)})^r + 1$ for $1 \le s \le t-1$ (by (1)), $|E(P_t)| \ge (\frac{|A_t|+2}{2(d-1)})^r - 1$ when $t \ne h$ (by (2b)), $|E(P_t)| \ge (\frac{|A_t|}{2(d-1)})^r$ when $t = h$ (by (2c)), $|E(P_s)| \ge (\frac{|A_s|}{2(d-1)})^r$ when $t+1 \le s < h$ (by (3)), and $|E(P_h)| \ge (\frac{|A_h|}{2(d-1)})^r) + 1$ when $t < h$ (by (3)). Hence we have the following:

$$\begin{aligned}|E(P)| &= \sum_{s=1}^{h} |E(P_s)| \\ &\geq \left(\sum_{s=1}^{h} \left(\frac{|A_s|}{2(d-1)}\right)^r\right) + 1 \\ &\geq \left(\frac{\sum_{s=1}^{h} |A_s|}{2(d-1)}\right)^r + 1 \quad \text{(by Lemma 3.1)} \\ &\geq \left(\frac{\sigma(\mathcal{H})}{2(d-1)}\right)^r + 1.\end{aligned}$$

Now suppose $t = 1$. Then $|E(P_t)| \geq (\frac{|A_t|}{2(d-1)})^r$ (by (2b)), $|E(P_s)| \geq (\frac{|A_s|}{2(d-1)})^r$ for $2 \leq s \leq h-1$ (by (3)), and $|E(P_h)| \geq (\frac{|A_h|}{2(d-1)})^r + 1$ (by (3)). Hence by the same argument as in the above paragraph, we have $|E(P)| \geq (\frac{\sigma(\mathcal{H})}{2(d-1)})^r + 1$. Thus, we have (4).

By (4), we may assume that the notation of $\{p, q\}$ is chosen so that P is from x to p.

(5) We claim that there is a path Q in $G_1 - q$ from p to y such that $|E(Q)| \geq (\frac{|G_1|}{2(d-1)})^r + 1$.

Note that $G_1' := G_1 + \{yp, yq, pq\}$ is a 3-connected graph.

If $G_1' = K_4$, then we can find a path Q in $G_1' - q$ from p to y such that $|E(Q)| = 2 \geq (\frac{|G_1|}{2(d-1)})^r + 1$.

Now assume that $G_1' \neq K_4$. Then Theorem 2.1 holds for G_1'. Note that all vertices of G_1' have degree at most d, except possibly y, p, q, which have degree at most $d+1$. By Theorem 2.1(a), there is a cycle C_1 through py in $G_1' - q$ such that $|C_1| \geq (\frac{|G_1|}{2(d-1)})^r + 2$. Let $Q := C_1 - py$. Then Q gives the desired path.

(6) Finally, let $C := (P \cup Q) + xy$. Then C is a cycle through e and f in G and, by (4) and (5), $|C| \geq ((\frac{\sigma(\mathcal{H})}{2(d-1)})^r + 1) + ((\frac{|G_1|}{2(d-1)})^r + 1) + 1 = (\frac{\sigma(\mathcal{H})}{2(d-1)})^r + (\frac{|G_1|}{2(d-1)})^r + 3$. Recall that $\sigma(\mathcal{H}) \geq |G_2|$ and $|G_1| \geq |G_2|$.

If $\sigma(\mathcal{H}) < |G_1|$, then

$$\begin{aligned}|C| &\geq \left(\frac{\sigma(\mathcal{H})}{2(d-1)}\right)^r + \left(\frac{|G_1|}{2(d-1)}\right)^r + 3 \\ &\geq \left((d-1)\sigma(\mathcal{H}) + \frac{|G_1|}{2(d-1)}\right)^r + 3 \quad \text{(by Lemma 3.1 and since } \sigma(\mathcal{H}) < |G_1|) \\ &\geq \left(\frac{n}{2(d-1)}\right)^r + 3 \quad \text{(by Observation 3).}\end{aligned}$$

Otherwise, $\sigma(\mathcal{H}) \geq |G_1|$. Hence,

$$\begin{aligned}|C| &\geq \left(\frac{\sigma(\mathcal{H})}{2(d-1)}\right)^r + \left(\frac{|G_1|}{2(d-1)}\right)^r + 3 \\ &\geq \left(\frac{\sigma(\mathcal{H})}{2(d-1)} + (d-1)|G_1|\right)^r + 3 \quad \text{(by Lemma 3.1 and since } \sigma(\mathcal{H}) \geq |G_1|) \\ &> \left(\frac{n}{2(d-1)}\right)^r + 3 \quad \text{(by Observation 1).}\end{aligned}$$

Case 2. $\sigma(\mathcal{H}) \le |G_2|$. In this case G_2 is defined. We will use G_1 and G_2 to find the desired cycle. Let $V(G_2) \cap V(\mathcal{H}) = \{v, w\}$. Then there exists some $1 \le u \le h$ such that $\{v, w\} \subseteq V(H_u)$, and $\{v, w\} \ne \{a_{u-1}, b_{u-1}\}$ when $u \ne 1$. Also there exists some $1 \le t \le h$ such that $\{p, q\} \subseteq V(H_t)$, and $\{p, q\} \ne \{a_{t-1}, b_{t-1}\}$ when $t \ne 1$.

(1) We claim that we can find, in $O(|V(\mathcal{H})|)$ time, a path P from x to some $z \in \{p, q\} \cup \{v, w\}$ in $\bigcup_{s=1}^{h} H_s$ for which

(i) $f \in E(P)$,

(ii) $pq \in E(P)$ or $vw \in E(P)$, and

(iii) if $pq \in E(P)$, then $z \in \{v, w\}$, and $vw \notin E(P)$ unless $vw = f$, and if $vw \in E(P)$, then $z \in \{p, q\}$, and $pq \notin E(P)$ unless $pq = f$.

To prove (1), let us assume that $t \le u$; the case $t \ge u$ can be taken care of in exactly the same way.

When $t \ne 1$, we use Lemma 3.5 to find a cycle Q' in $\bigcup_{s=1}^{t-1} H_s$ through $a_{t-1}b_{t-1}$ and f. Let $Q := Q' - a_{t-1}b_{t-1}$, which is a path from a_{t-1} to b_{t-1} through f. Let $Q = \emptyset$ when $t = 1$. We distinguish two cases.

Subcase (1a). $t < u$. By choosing the notation of $\{a_t, b_t\}$, we may assume that $(\bigcup_{s=t+1}^{h} H_s) - b_t$ contains a path X from a_t to x through vw.

If $b_t \in \{p, q\}$, then we use Lemma 3.5 to find a cycle C_t through $a_{t-1}b_{t-1}$ and a_tb_t in H_t. If $pq \notin E(C_t)$ or $b_t \in \{a_{t-1}, b_{t-1}\}$, let $P_t := C_t - \{a_{t-1}b_{t-1}, a_tb_t\}$ when $t \ne 1$, and let $P_t := C_t - a_tb_t$ when $t = 1$. Then $P := Q \cup X \cup P_t$ gives the desired path for (1) (with $z = b_t$). So assume $pq \in E(C_t)$ and $b_t \notin \{a_{t-1}, b_{t-1}\}$. Then let $P_t := C_t - \{a_{t-1}b_{t-1}, b_t\}$ when $t \ne 1$, and let $P_t := C_t - b_t$ when $t = 1$. Then $P := Q \cup X \cup P_t$ gives the desired path for (1) (with $z \in \{p, q\} - \{b_t\}$).

We may therefore assume that $b_t \notin \{p, q\}$.

Suppose H_t is not a cycle chain. Then H_t is 3-connected. Let H'_t be obtained from H_t by subdividing pq with a vertex a' and adding an edge $a'a_t$ (if not already present). Then $H'_t - b_t$ is 2-connected. By Lemma 3.5, we find a cycle C'_t through $a_{t-1}b_{t-1}$ and $a'a_t$ in $H'_t - b_t$. If $t = 1$, then let $P_t := C'_t - a'$, and if $t \ne 1$, then let $P_t := C'_t - \{a', a_{t-1}b_{t-1}\}$. Then $P := Q \cup P_t \cup X$ gives the desired path for (1).

Now assume that H_t is a cycle chain. By the structure of a cycle chain, we can, in $O(|H_t|)$ time, either find a path C_t in $H_t - a_tb_t$ from a_t to $\{p, q\}$ through $a_{t-1}b_{t-1}$, or find a path C'_t in H_t from a_t to b_t through $a_{t-1}b_{t-1}$ and pq.

If we find C_t, then let $P_t := C_t - a_{t-1}b_{t-1}$ when $t \ne 1$ and $P_t := C_t$ when $t = 1$. In this case, $P := Q \cup P_t \cup X$ gives the desired path for (1).

Assume that we find C'_t. In this case, we cannot use X. Let $P_t := C'_t$ if $t = 1$, and otherwise let $P_t := C'_t - a_{t-1}b_{t-1}$. Let $H := \bigcup_{s=t+1}^{h} H_s$. If $x \in \{v, w\}$, then find a cycle C' in H through a_tb_t and vw, and so $P := Q \cup P_t \cup (C' - \{a_tb_t, vw\})$ gives the desired path for (1). So assume that $x \notin \{v, w\}$. Let H' be obtained from H by a T-transform at $\{x, vw\}$, and let x' denote the new vertex. Then H' is a 2-connected graph. By Lemma 3.5, we find a cycle C' through a_tb_t and xx'. Now $P := Q \cup P_t \cup (C' - \{x', a_tb_t\})$ gives the desired path for (1).

Subcase (1b). $t = u$. Recall that $\{p, q\} \ne \{v, w\}$.

First, assume that $t \ne h$. We claim that there is a path Q_t in H_t from $\{a_t, b_t\}$ to some $z \in \{p, q\} \cup \{v, w\}$ such that (i) $a_{t-1}b_{t-1} \in E(Q_t)$, (ii) $pq \in E(Q_t)$ or $vw \in E(Q_t)$, and (iii) if $pq \in E(Q_t)$, then $z \in \{v, w\}$, and $vw \notin E(Q_t)$ unless $vw = a_{t-1}b_{t-1}$, and if $vw \in E(Q_t)$, then $z \in \{p, q\}$, and $pq \notin E(Q_t)$ unless $pq = a_{t-1}b_{t-1}$. This is easy to see if H_t is a cycle chain, and otherwise, it follows from Lemma 3.6. Assume without loss of generality that $a_t \in V(Q_t)$. In $(\bigcup_{s=t+1}^{h} H_s) - b_t$, we find a path R from a_t to x. Now $P := Q \cup Q_t \cup R$ gives the desired path for (1).

Now assume that $t = h$. We note that there is a path Q_t in H_t from x to $z \in \{p, q\} \cup \{v, w\}$ such that (i) $a_{t-1}b_{t-1} \in E(Q_t)$, (ii) $pq \in E(Q_t)$ or $vw \in E(Q_t)$, and (iii) if $pq \in E(Q_t)$, then $z \in \{v, w\}$, and $vw \notin E(Q_t)$ unless $vw = a_{t-1}b_{t-1}$, and if $vw \in E(Q_t)$, then $z \in \{p, q\}$, and $pq \notin E(Q_t)$ unless $pq = a_{t-1}b_{t-1}$. This is easy to see if H_t is a cycle chain, and otherwise, it follows from Lemma 3.7. Now $P := Q \cup Q_t$ gives the desired path for (1).

Assume that $vw \in E(P)$ in (1) (the case $pq \in E(P)$ is similar), and assume p is an end of P.

(2) Note that $G_1' := G_1 + \{yp, yq, pq\}$ is a 3-connected graph, vertices y, p, q have degree at most $d + 1$ in G_1', and all other vertices of G_1' have degree at most d. If $G_1' = K_4$, then we can find a path P_1 from p to y in $G_1' - q$ such that $|E(P_1)| = 2 \geq (\frac{|G_1|}{2(d-1)})^r + 1$. If $G_1' \neq K_4$, then Theorem 2.1 holds for G_1'. By Theorem 2.1(a), there is a cycle C_1 through py in $G_1' - q$ such that $|C_1| \geq (\frac{|G_1|}{2t_1})^r + 2$, where t_1 is the number of neighbors of q in G_1' distinct from p and y. Let $P_1 := C_1 - py$. Then P_1 is a path from p to y in $G_1' - q$. Since $t_1 \leq d - 1$, we have $|E(P_1)| \geq (\frac{|G_1|}{2(d-1)})^r + 1$.

(3) Note that $G_2' := G_2 + \{yv, yw, vw\}$ is a 3-connected graph, vertices y, v, w have degree at most $d + 1$ in G_2', and all other vertices of G_2' have degree at most d. If $G_2' = K_4$, then we can find a path P_2 from v to w in $G_2' - y$ such that $|E(P_2)| = 2 \geq (\frac{|G_2|}{2(d-1)})^r + 1$. If $G_2' \neq K_4$, then Theorem 2.1 holds for G_2'. By Theorem 2.1(a), there is a cycle C_2 through vw in $G_2' - y$ such that $|C_2| \geq (\frac{|G_2'|}{2t_2})^r + 2$, where t_2 is the number of neighbors of y in G_2' distinct from v and w. Let $P_2 := C_2 - vw$. Then P_2 is a path from v to w in $G_2' - y$. Since $t_2 \leq d - 1$, we have $|E(P_2)| \geq (\frac{|G_2|}{2(d-1)})^r + 1$.

Let $C := ((P - vw) \cup P_1 \cup P_2) + e$. Then C is a cycle through e and f in G and

$$\begin{aligned}
|C| &= |E(P)| + |E(P_1)| + |E(P_2)| + 1 \\
&\geq \left(\frac{|G_1|}{2(d-1)}\right)^r + \left(\frac{|G_2|}{2(d-1)}\right)^r + 3 \quad \text{(by (2) and (3))} \\
&\geq \left(\frac{|G_1|}{2(d-1)} + (d-1)|G_2|\right)^r + 3 \quad \text{(by Lemma 3.1 and since } |G_1| \geq |G_2|\text{)} \\
&\geq \left(\frac{n}{2(d-1)}\right)^r + 3,
\end{aligned}$$

where the final inequality holds because of Observation 2 and since $|G_2| \geq \sigma(\mathcal{H})$. □

Next we show that the above proof gives an $O(|E(G)|)$ algorithm which reduces Theorem 2.1(b) to (a) and (b) of the same theorem (for smaller graphs).

ALGORITHM TWOEDGE. Let n, d, r, G, e, f be as in Lemma 5.1.

1. *Preprocessing.* Replace G with a 3-connected spanning subgraph of G with $O(|G|)$ edges. (This can be done in $O(|E(G)|)$ time using Lemma 3.4.)
2. If e is adjacent to f, then let $e = xz$ and $f = yz$. It suffices to find a cycle C' through xy in $G' := (G + xy) - z$ such that $|C'| \geq (\frac{|G'|}{2t})^r + 2$, where t is the number of neighbors of z in G' distinct from x and y. That is, we reduce Theorem 2.1(b) for G, e, f to Theorem 2.1(a) for G', xy, z. We apply Algorithm Avoidvertex to G', xy, z. (By Proposition 4.2, we can, in $O(|E(G)|)$ time, either find the desired cycle C' or reduce it to (a) or (c) for smaller graphs. Moreover, each smaller graph contains a vertex that does not belong to any other smaller graph.)
3. Now assume that e is not adjacent to f, and let $e = xy$. Decompose $G - y$ into 3-connected components. (This can be done in $O(|G|)$ time using Theorem

2.2.)

4. Suppose there is only one 3-connected component of $G-y$. Then $G-y$ is 3-connected, and let y' denote a neighbor of y distinct from x. Let $G' := (G-y)+xy'$ and $e'=xy'$. To find the desired cycle through e and f in G, it suffices to find a cycle C' through e' and f in G' such that $|C'| \geq (\frac{|G'|}{2(d-1)})^r+3$. Thus we reduce Theorem 2.1(b) for G, e, f to Theorem 2.1(b) for G', e', f, with $|G'|<|G|$. (This reduction can be done in constant time.)
5. Now assume that $G-y$ has at least two 3-connected components. Find the block chain $\mathcal{H}=H_1\dots H_h$ such that $f\in E(H_1)$, $x\in V(H_h)-V(H_{h-1})$, and f is not incident with both vertices in $V(H_1)\cap V(H_2)$. Find G_1 and G_2 as in the proof of Lemma 5.1. (This can be done in $O(|G|)$ time.)
6. Suppose $\sigma(\mathcal{H})>|G_2|$.
   - Assume $1\leq s\leq t-1$. We need to find P_s as in (1) of Case 1 in the proof of Lemma 5.1. If $H_s=K_4$ or H_s is a cycle chain then we find P_s, and otherwise, we need to find a cycle C_s through $a_{s-1}b_{s-1}$ and a_sb_s in H_s such that $|C_s|\geq(\frac{|H_s|}{2(d-1)})^r+3$. So either we find P_s in $O(|H_s|)$ time or we reduce the problem of finding P_s to Theorem 2.1(b) for $H_s, a_{s-1}b_{s-1}, a_sb_s$ in constant time.
   - We need to find $P_t\subseteq H_t$ as in (2) of Case 1 in the proof of Lemma 5.1. If H_t is a cycle chain or $H_t=K_4$ then we find $P_t\subseteq H_t$ as in (2) of Case 1 in the proof of Lemma 5.1. (This can be done in $O(|H_t|)$ time.) If H_t is not a cycle chain and $H_t\neq K_4$, then we reduce the problem of finding P_t to the following: Theorem 2.1(b) for H_t, f, pq or H'_t, f, xx'; Theorem 2.1(a) for H'_t, px, q (as in (2a) of Case 1); Theorem 2.1(b) for $H_t, a_{t-1}b_{t-1}, a_tb_t$ or $H'_t, a_{t-1}b_{t-1}, a'b'$ (as in (2b) of Case 1); Theorem 2.1(b) for $H_t, a_{t-1}b_{t-1}, pq$ or $H'_t, a_{t-1}b_{t-1}, xc'$ (as in (2c) of Case 1). (This reduction can be done in constant time.)
   - Suppose $t+1\leq s\leq h$. We need to find P_s as in (3) of Case 1 in the proof of Lemma 5.1. If $H_s=K_4$ or H_s is a cycle chain, we find a path P_s. (This can be done in $O(|H_s|)$ time.) If $H_s\neq K_4$ and H_s is not a cycle chain, then we reduce the problem of finding P_s to the following: Theorem 2.1(a) for $H'_s, a_{s-1}a_s, b_{s-1}$, or $H'_s, a_{s-1}a', b_{s-1}$, or $H'_s, a_{s-1}x, b_{s-1}$. (This reduction can be done in constant time.)
   - Let $G'_1:=G_1+\{yp, yq, pq\}$. We need to find a path Q in G'_1 as in (5) of Case 1 in the proof of Lemma 5.1. If $G'_1=K_4$, we find a path Q in $O(|G_1|)$ time, and otherwise, we reduce the problem of finding Q to Theorem 2.1(a) for G'_1, py, q, in constant time.

   (The operations in step 6 can be done in $O(|G|)$ time. Also each 3-connected graph reduced from H_s's or G_1 contains a vertex which does not belong to any other 3-connected graphs reduced from H_s's or G_1.)
7. Now assume $\sigma(\mathcal{H})\leq|G_2|$.
   - First, we find H_t and H_u such that $\{p,q\}\subseteq V(H_t)$, $\{p,q\}\neq\{a_{t-1},b_{t-1}\}$ when $t\neq 1$, $\{v,w\}\subseteq V(H_u)$, and $\{v,w\}\neq\{a_{u-1},b_{u-1}\}$ when $u\neq 1$. (This can be done in $O(|G|)$ time by searching the 3-connected components of $G-y$.)
   - Assume that $t\leq u$ ($u\geq t$ can be treated similarly). Find a path P in $\bigcup_{s=1}^{t}H_s$ from x to $\{p,q\}$ (or $\{v,w\}$) through f and vw (or pq). (This can be done in $O(|G|)$ time as in (1) of Case 2 in the proof of Lemma 5.1.)

- Assume P is from x to p and through f and vw. If $G'_1 = K_4$, then we find a path P_1 in $G'_1 - q$ from p to y of length 2. If $G'_1 \neq K_4$, then we need to apply Theorem 2.1(a) to G'_1, yp, q. (This reduction can be done in constant time, as in (2) of Case 2 in the proof of Lemma 5.1.)
- If $G'_2 = K_4$, then find a path P_2 in $G'_2 - y$ from v to w of length 2. If $G'_2 \neq K_4$, then we need to apply Theorem 2.1(a) to G'_2, vw, y. (Again, this can be done in constant time, as in (3) of Case 2 in the proof of Lemma 5.1.)

To summarize, we have the following.

PROPOSITION 5.2. *Given G, e, f, n, d, r as in Lemma 5.1, we can, in $O(|E(G)|)$ time, either*

(1) *find a cycle C through e and f in G such that $|C| \geq (\frac{|G|}{2(d-1)})^r + 3$, or*
(2) *reduce Theorem 2.1(b) for G, e, f to (a) or (b) of the same theorem for smaller 3-connected graphs.*

Moreover, any smaller graph in (2) comes from a 3-connected 3-block of $G - y$ that is not K_4. Hence, any smaller graph in (2) contains a vertex that does not belong to any other smaller graph in (2).

6. Cycles through one edge. In this section, we show how to reduce Theorem 2.1(c), in linear time, to (a), (b), or (c) of the same theorem for smaller graphs. As in the previous two sections, we state the reduction as a lemma.

LEMMA 6.1. *Let $n \geq 6$ and $d \geq 3$ be integers, let $r = \log_{2(d-1)^2+1} 2$, and assume that Theorem 2.1 holds for graphs with at most $n-1$ vertices. Let G be a 3-connected graph on n vertices, and assume that the maximum degree of G is at most d. Then for any $e \in E(G)$ there is a cycle C through e in G such that $|C| \geq n^r + 3$.*

Proof. Let $e = xy \in E(G)$, and consider $G - y$.

If $G - y$ is 3-connected, then let y' be a neighbor of y other than x. Clearly, $G' := (G - y) + xy'$ is a 3-connected graph with maximum degree at most d. Since $5 \leq |G'| < n$, Theorem 2.1 holds for G'. By Theorem 2.1(c), there is a cycle C' through xy' in G' such that $|C'| \geq (n-1)^r + 3$. Now let $C := (C' - xy') + \{y, xy, yy'\}$. Then C is a cycle through xy in G and

$$\begin{aligned} |C| &= |C'| + 1 \\ &\geq (n-1)^r + 1 + 3 \\ &\geq n^r + 3 \quad \text{(by Lemma 3.1).} \end{aligned}$$

Therefore, we may assume that $G - y$ is not 3-connected. Since G is 3-connected, $G - y$ is 2-connected. By Theorem 2.2, we can decompose $G - y$ into 3-connected components.

First, let us consider the case where all 3-blocks of $G - y$ are cycles. Let $\mathcal{I} = I_1 \dots I_i$ be a block chain in $G - y$ such that (i) $x \in V(I_1) - V(I_2)$, (ii) I_i is an extreme 3-block of $G - y$, and (iii) subject to (i) and (ii), $|V(\mathcal{I})|$ is maximum. For convenience, let $B := I_1$. Then $|V(\mathcal{I})| \geq \frac{(n-1)-|B|}{t-1} + |B| = \frac{n+(t-2)|B|-1}{t-1}$, where t is the number of extreme 3-blocks of $G - y$ distinct from I_1. So $n \geq t + 4$ (since $|B| \geq 3$) and $t \leq d - 1$. It is easy to see that there is some $y' \in V(\mathcal{I}) - \{x\}$ such that $\bigcup_{s=1}^{i} I_s$ contains a Hamilton path P from x to y' and G has a path Q from y' to y disjoint from $V(\mathcal{I}) - \{y\}$. (Note that P and y' can be found in $O(|G|)$ time.) Let $C := (P \cup Q) + \{y, xy, yy'\}$. Then $|C| \geq |V(\mathcal{I})| + 1 \geq \frac{n+(t-2)|B|-1}{t-1} + 1$. Next we show that $|C| - 3 \geq n^r$. Note that $|C| - 3 \geq \frac{n+(t-2)|B|-1}{t-1} - 2 \geq \frac{n+t-5}{t-1}$ (since $|B| \geq 3$).

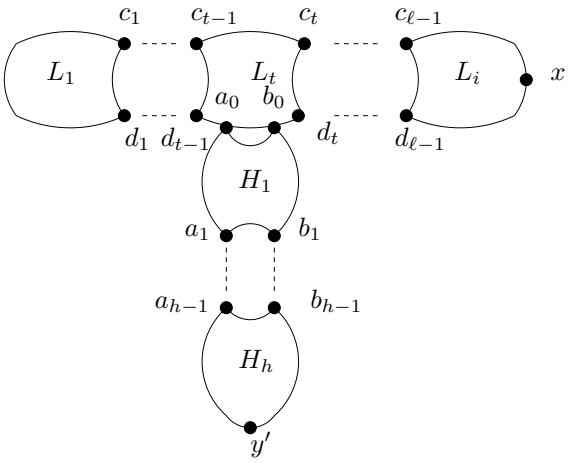

FIG. 8. *Block chains $\mathcal{L}$ and $\mathcal{H}$.*

One can prove that $\frac{x+t-5}{t-1} - x^r$ is an increasing function when $x \geq 2(d-1)^2+1$. Hence when $n \geq 2(d-1)^2+1$, $\frac{n+t-5}{t-1} \geq n^r$. Now if $t+4 \leq n \leq 2(d-1)^2$, then $\frac{n+t-5}{t-1} > 2 > n^r$. Therefore, $|C|-3 \geq n^r$, and so $|C| \geq n^r+3$.

Hence, we may assume that some 3-block of $G-y$ is 3-connected. Let L denote a 3-connected 3-block of $G-y$ with $|L|$ maximum. Then $|L| \geq 4$. Let $\mathcal{L} := L_1 \dots L_\ell$ denote a block chain in $G-y$ such that $L_1 = L$ and $x \in V(L_\ell) - V(L_{\ell-1})$, where $\ell \geq 1$. See Figure 8.

Let $V(L_i) \cap V(L_{i+1}) = \{c_i, d_i\}$ for $1 \leq i \leq \ell-1$. For each $1 \leq i \leq \ell$, we define B_i as follows: if L_i is 3-connected, then $B_i := V(L_i)$; if $i < \ell$ and $L_i = C_1 \dots C_k$ is a cycle chain, then $B_i = (\bigcup_{i=1}^{k-1} V(C_i \cap C_{i+1})) - (\{c_{i-1}, d_{i-1}\} \cup \{c_i, d_i\})$; if $L_\ell = C_1 \dots C_k$ is a cycle chain, then B_ℓ consists of x and the vertices in $(\bigcup_{i=1}^{k-1} V(C_i \cap C_{i+1})) - \{c_{\ell-1}, d_{\ell-1}\}$. Define $\sigma(\mathcal{L}) := |\bigcup_{s=1}^{\ell} B_s|$.

If $V(\mathcal{L}) = V(G) - \{y\}$, then let $\mathcal{H} = \emptyset$. Otherwise, let $\mathcal{H} := H_1 \dots H_h$ denote a block chain in $G-y$ such that (i) $|V(\mathcal{H}) \cap V(\mathcal{L})| = 2$, (ii) $V(\mathcal{H}) \cap V(\mathcal{L}) = V(H_1) \cap V(\mathcal{L}) \neq V(H_1) \cap V(H_2)$, (iii) H_h is an extreme 3-block of $G-y$. See Figure 8. Let $V(H_i) \cap V(H_{i+1}) = \{a_i, b_i\}$, $1 \leq i \leq h-1$. Let a_0, b_0 denote the vertices in $V(\mathcal{H}) \cap V(\mathcal{L})$. If $\mathcal{H} = \emptyset$, then let y' denote a neighbor of y distinct from x and let $a_0 = b_0 = y'$. If $\mathcal{H} \neq \emptyset$, then let y' be a neighbor of y in $V(H_h) - \{a_{h-1}, b_{h-1}\}$. For each $1 \leq s \leq h$, we define A_s as follows: if H_s is 3-connected, then $A_s := V(H_s)$; if $h = 1$ and $H_1 = C_1 \dots C_k$ is a cycle chain, then $A_1 := (\bigcup_{i=1}^{k-1} V(C_i \cap C_{i+1})) \cup (\{a_0, b_0\} - B_t)$; if $h > 1$ and $H_1 = C_1 \dots C_k$ is a cycle chain, then A_1 is the union of $\{a_0, b_0\} - B_t$ and $(\bigcup_{i=1}^{k-1} V(C_i \cap C_{i+1})) - \{a_1, b_1\}$; if $1 < s < h$ and $H_s = C_1 \dots C_k$ is a cycle chain, then $A_s = (\bigcup_{i=1}^{k-1} V(C_i \cap C_{i+1})) - \{a_{s-1}, b_{s-1}, a_s, b_s\}$; if $h > 1$ and $H_h = C_1 \dots C_k$ is a cycle chain, then A_h consists of y' and those vertices in $(\bigcup_{i=1}^{k-1} V(C_i \cap C_{i+1})) - \{a_{h-1}, b_{h-1}\}$. Define $\sigma(\mathcal{H}) := |\bigcup_{s=1}^{h} A_s|$.

We choose $\mathcal{H} = H_1 \dots H_h$ so that, subject to (i)–(iii), $\sigma(\mathcal{H})$ is maximum. Without loss of generality, we may assume that, for some $1 \leq t \leq \ell$, $a_0, b_0 \in V(L_t)$ and $\{a_0, b_0\} \neq \{c_{t-1}, d_{t-1}\}$ (or $y' \notin \{c_{t-1}, d_{t-1}\}$ if $a_0 = b_0 = y'$) when $t \geq 2$.

Note that each vertex in $(\bigcup_{i=1}^{\ell}(V(L_i) - B_i)) \cup (\bigcup_{s=1}^{h}(V(H_s) - A_s))$ either appears in some other block chain in $G-y$ or is adjacent to y. By the choice of $\mathcal{H}$ and

since there are at most $d-1$ extreme blocks of $G-y$ not containing x, we have $\sigma(\mathcal{H}) \geq \frac{(n-1)-\sigma(\mathcal{L})}{d-1}$. Hence we have the following.

Observation. $\sigma(\mathcal{L}) + (d-1)\sigma(\mathcal{H}) \geq n-1$.

We consider three cases.

Case 1. $\ell = 1$. In this case, $\sigma(\mathcal{L}) = |L_1|$ (because L_1 is not a cycle chain). Since $G-y$ is not 3-connected, $\mathcal{H} \neq \emptyset$.

(1) First, we find a path P in $\mathcal{L} - a_0b_0$ from x to $\{a_0, b_0\}$ such that $|E(P)| \geq (\sigma(\mathcal{L})+1)^r + 1$.

If $L_1 = K_4$, then we can find a Hamilton path P from x to $\{a_0, b_0\}$ in $L_1 - a_0b_0$. Hence by Lemma 3.2, $|E(P)| = 3 \geq |L_1|^r + 2 \geq (\sigma(\mathcal{L})+1)^r + 1$. So assume that $L_1 \neq K_4$.

If $x \in \{a_0, b_0\}$, then by Theorem 2.1(c), there is a cycle C_1 through a_0b_0 in L_1 such that $|C_1| \geq |L_1|^r + 3$. Now $P := C_1 - a_0b_0$ is a path from x to $\{a_0, b_0\}$ in $L_1 - a_0b_0$ and $|E(P)| \geq (\sigma(\mathcal{L})^r + 2(\sigma(\mathcal{L})+1)^r + 1$ (by Lemma 3.1).

Assume $x \notin \{a_0, b_0\}$. Let L_1' denote the graph obtained from L_1 by a T-transform at $\{x, a_0b_0\}$, and let x' denote the new vertex. By Lemma 3.3 and because x has degree at most $d-1$ in L_1, L_1' is a 3-connected graph with maximum degree at most d. Note that $5 \leq |L_1'| < n$. Thus Theorem 2.1 holds for L_1'. By Theorem 2.1(c), there is a cycle C_1 through xx' in L_1' such that $|C_1'| \geq |L_1'|^r + 3 = (|L_1|+1)^r + 3$. Now $P := C_1 - x'$ gives the desired path.

Without loss of generality, we may assume that the path P found in (1) is from x to a_0.

(2) For $i = 1, \ldots, h-1$, we find paths Q_i from $\{a_{i-1}, b_{i-1}\}$ to $\{a_i, b_i\} - \{a_{i-1}, b_{i-1}\}$ in H_i such that

(i) $\bigcup_{i=1}^{h-1} Q_i$ is a path from a_0 to $\{a_{h-1}, b_{h-1}\}$,

(ii) if H_i is 3-connected, then $|E(Q_i)| \geq (\frac{|A_i|}{2(d-1)})^r$,

(iii) if H_i is a cycle chain, then $|E(Q_i)| \geq |A_i| + 1$.

Suppose that, for some $1 \leq i \leq h-1$, we have found paths Q_j, $1 \leq j \leq i-1$, from $\{a_{j-1}, b_{j-1}\}$ to $\{a_j, b_j\}$ in H_j such that $\bigcup_{j=1}^{i-1} Q_j$ is a path from a_0 to $\{a_{i-1}, b_{i-1}\}$ and (ii)–(iii) above are satisfied for H_j, Q_j, A_j. For ease of presentation, we may assume that a_{i-1} is an end of $\bigcup_{j=1}^{i-1} Q_j$.

If $H_i = K_4$, then we find a path Q_i in $H_i - b_{i-1}$ from a_{i-1} to $\{a_i, b_i\}$ such that $|E(Q_i)| \geq 2$. Clearly, $|E(Q_i)| \geq 2 \geq (\frac{|A_i|}{2(d-1)})^r$.

If H_i is a cycle chain, then by Proposition 2.5 let Q_i be a path in $H_i - \{a_{i-1}b_{i-1}, a_ib_i\}$ from a_{i-1} to $\{a_i, b_i\}$ such that $A_i \subseteq V(Q_i)$. Since $(\{a_{i-1}, b_{i-1}\} \cup \{a_i, b_i\}) \cap A_i = \emptyset$, we have $|E(Q_i)| \geq |A_i| + 1$.

Now assume that H_i is not a cycle chain and $H_i \neq K_4$.

If $b_{i-1} \in \{a_i, b_i\}$, then assume $b_{i-1} = b_i$ (by choosing the notation of $\{a_i, b_i\}$), and let $H_i' := H_i + a_{i-1}a_i$. Clearly, H_i' is 3-connected with maximum degree at most $d+1$, and the possible vertices of degree $d+1$ are incident with $a_{i-1}b_{i-1}$ or a_ib_{i-1}. By Theorem 2.1(a), there is a cycle D_i through $a_{i-1}a_i$ in $H_i' - b_{i-1}$ such that $|E(D_i)| \geq (\frac{|A_i|}{2t_i})^r + 2$, where t_i is the number of neighbors of b_{i-1} in H_i' distinct from a_{i-1} and a_i. So $t_i \leq d-1$. Let $Q_i := D_i - a_{i-1}a_i$. Then $|E(Q_i)| \geq (\frac{|A_i|}{2(d-1)})^r + 1$.

Hence, assume $b_{i-1} \notin \{a_i, b_i\}$. Let H_i'' be obtained from H_i by a T-transform at $\{b_{i-1}, a_ib_i\}$, and let a denote the new vertex. By Lemma 3.3, H_i'' is a 3-connected graph. Let $H_i' := H_i'' + a_{i-1}a$. Then $5 \leq |H_i'| < n$. Also a_{i-1}, b_{i-1}, a have degrees at most $d+1$ in H_i', and all other vertices have degree at most d in H_i'. Thus by Theorem 2.1(a), there is a cycle D_i through $a_{i-1}a$ in $H_i' - b_{i-1}$ such that $|D_i| \geq (\frac{|H_i'|}{2t_i})^r + 2$,

where t_i is the number of neighbors of b_{i-1} in H_i' distinct from a and a_{i-1}. Thus $t_i \le d-1$. Let $Q_i := D_i - a$. Then Q_i is a path in $H_i - b_{i-1}$ between a_{i-1} and $\{a_i, b_i\}$ and $|E(Q_i)| \ge (\frac{|H_i|}{2(d-1)})^r$.

(3) We find a path Q_h in H_h from $\{a_{h-1}, b_{h-1}\}$ to y' such that

(i) $\bigcup_{i=1}^{h} Q_i$ is a path from a_0 to y',

(ii) if H_h is 3-connected, then $|E(Q_h)| \ge (\frac{|A_h|}{2(d-1)})^r + 1$,

(iii) if H_h is a cycle chain, then $|E(Q_h)| \ge |A_h| + 1$.

For ease of presentation, let us assume that $\bigcup_{i=1}^{h-1} Q_i$ is from a_0 to a_{h-1}.

If H_h is a cycle chain, then by Proposition 2.6, let Q_h denote a path from a_{h-1} to y' in $H_h - b_{h-1}$ such that $A_h \subseteq V(Q_h)$. Since a_{h-1}, b_{h-1}, and $y' \notin A_h$, we have (iii).

If $H_h = K_4$, then let Q_h be a Hamilton path from a_{h-1} to y' in $H_h - b_{h-1}$. Then $|E(Q_h)| = 2 \ge (\frac{|H_h|}{2(d-1)})^r + 1 = (\frac{|A_h|}{2(d-1)})^r + 1$, and (ii) holds.

Now assume that H_h is not a cycle chain and $H_h \ne K_4$. Let $H_h' := H_h + \{a_{h-1}y', b_{h-1}y'\}$. Then H_h' is 3-connected, the vertices a_{h-1}, b_{h-1}, y' have degree at most $d+1$ in H_h', and all other vertices have degree at most d in H_h'. By Theorem 2.1(a), there is a cycle D_h through $a_{h-1}y'$ in $H_h' - b_{h-1}$ such that $|D_h| \ge (\frac{|H_h|}{2(d-1)})^r + 2$. Let $Q_h := D_h - a_{h-1}y'$. Then $|E(Q_h)| \ge (\frac{|A_h|}{2(d-1)})^r + 1$, and we have (ii).

(4) Let $C := (P \cup (\bigcup_{i=1}^{h} Q_i)) + \{y, xy, yy'\}$. Now C is a cycle in G through xy and, by (1)–(3), we have

$$|C| \ge (\sigma(\mathcal{L}) + 1)^r + 1 + \left(\sum |A_i|\right) + \left(\sum \left(\frac{|A_i|}{2(d-1)}\right)^r\right) + 2,$$

where the first summation is over all cycle chains H_i and the second summation is over all 3-connected H_i. Note that each $|A_i|$ in the first summation can be written as $1^r + \cdots + 1^r$ ($|A_i|$ times), and this allows us to apply Lemma 3.1 in the following inequalities. Hence

$$\begin{aligned} |C| &\ge \left(\sigma(\mathcal{L}) + 1 + (d-1)\sum_{i=1}^{h} |A_i|\right)^r + 3 \quad \text{(by Lemma 3.1)} \\ &= (\sigma(\mathcal{L}) + 1 + (d-1)\sigma(\mathcal{H}))^r + 3 \\ &\ge n^r + 3 \quad \text{(by the observation preceding Case 1).} \end{aligned}$$

Case 2. $1 = t < \ell$. Recall that if $\mathcal{H} = \emptyset$, then $a_0 = b_0 = y'$, and $\{a_0, b_0\} = \{y'\}$.

(1) We find a path P_1 from $\{a_0, b_0\}$ to $\{c_1, d_1\}$ in $L_1 - \{a_0b_0, c_1d_1\}$ such that $|E(P_1)| \ge (|B_1| + 2)^r$. (Note that $|B_1| = |L_1|$ by definition.)

If $L_1 = K_4$, then we can find a Hamilton path P_1 from $\{a_0, b_0\}$ to $\{c_1, d_1\}$ in $L_1 - \{a_0b_0, c_1d_1\}$ (or in $L_1 - c_1d_1$ when $\mathcal{H} = \emptyset$). Thus, $|E(P_1)| = 3 \ge |L_1|^r + 1 = |B_1|^r + 1 > (|B_1| + 2)^r$ (by Lemma 3.1).

Now assume that $L_1 \ne K_4$. If $\{a_0, b_0\} \subseteq \{c_1, d_1\}$, then by Theorem 2.1(c) there is a cycle C_1 through c_1d_1 in L_1 such that $|C_1| \ge |L_1|^r + 3$. Let $P_1 := C_1 - c_1d_1$; then P_1 is a path between c_1 and $d_1 \in \{a_0, b_0\}$, and $|E(P_1)| \ge |L_1|^r + 2 = |B_1|^r + 2 > (|B_1| + 2)^r$ (by Lemma 3.1).

Assume that $\{a_0, b_0\} \not\subseteq \{c_1, d_1\}$. If $\mathcal{H} = \emptyset$, then let L_1' be obtained from L_1 by a T-transform at $\{y', c_1d_1\}$, let $a = y'$, and let c denote the new vertex. If $\mathcal{H} \ne \emptyset$, then let L_1' be obtained from L_1 by an H-transform at $\{a_0b_0, c_1d_1\}$, and let a, c denote the new vertices with a adjacent to a_0 and b_0 and c adjacent to c_1 and d_1. By Lemma

3.3, L_1' is a 3-connected graph with maximum degree at most d. Since $5 \le |L_1'| < n$, Theorem 2.1 holds for L_1'. By Theorem 2.1(c), there is a cycle C_1 in L_1' through ac such that $|C_1| \ge |L_1'|^r + 3$. If $\mathcal{H} = \emptyset$, let $P_1 := C_1 - c$; then P_1 is a path from $\{a_0, b_0\}$ to $\{c_1, d_1\}$ in L_1 and $|E(P_1)| \ge |L_1'|^r + 1 = (|L_1| + 1)^r + 1 \ge (|L_1| + 2)^r = (|B_1| + 2)^r$ (by Lemma 3.1). If $\mathcal{H} \ne \emptyset$ let $P_1 := C_1 - \{a, c\}$; then P_1 is a path from $\{a_0, b_0\}$ to $\{c_1, d_1\}$ in L_1 and $|E(P_1)| \ge |L_1'|^r = (|L_1| + 2)^r = (|B_1| + 2)^r$.

Without loss of generality, assume that the notation of $\{a_0, b_0\}$ and $\{c_1, d_1\}$ is chosen so that P_1 is between c_1 and a_0.

(2) For $i = 2, \dots, \ell - 1$, we find paths P_i from $\{c_{i-1}, d_{i-1}\}$ to $\{c_i, d_i\}$ in L_i such that

(i) $\bigcup_{i=2}^{\ell-1} P_i$ is a path from c_1 to $\{c_{\ell-1}, d_{\ell-1}\}$,

(ii) if L_i is 3-connected, then $|E(P_i)| \ge (\frac{|B_i|}{2(d-1)})^r$, and

(iii) if L_i is a cycle chain, then $|E(P_i)| \ge |B_i| + 1$.

Assume that, for some $2 \le i \le \ell - 1$, we have found paths P_j, $1 \le j \le i - 1$, from $\{c_{j-1}, d_{j-1}\}$ to $\{c_j, d_j\}$ in L_j such that $\bigcup_{j=2}^{i-1} P_j$ is a path from c_1 to $\{c_{i-1}, d_{i-1}\}$ and (ii) and (iii) are satisfied for L_j, B_j, P_j. Without loss of generality, assume that c_{i-1} is the end of $\bigcup_{j=2}^{i-1} P_j$ other than c_1.

If L_i is a cycle chain, then by Proposition 2.5 let P_i be a path from c_{i-1} to $\{c_i, d_i\}$ in $L_i - \{c_{i-1}d_{i-1}, c_i d_i\}$ such that $B_i \subseteq V(P_i)$. Then, since $c_{i-1}, d_{i-1}, c_i, d_i \notin B_i$, we see that $|E(P_i)| \ge |B_i| + 1$, and we have (iii).

Now assume that L_i is not a cycle chain.

If $c_{i-1} \in \{c_i, d_i\}$, then, by choosing the notation of $\{c_i, d_i\}$, we may assume $c_i \notin \{c_{i-1}, d_{i-1}\}$. If $L_i = K_4$, then let P_i be a path from c_{i-1} to c_i in $L_i - d_{i-1}$ such that $|E(P_i)| = 2 \ge (\frac{|B_i|}{2(d-1)})^r$. If $L_i \ne K_4$, then let $L_i' := L_i + c_i d_{i-1}$. By Theorem 2.1(a), there is a cycle C_i through $c_{i-1}c_i$ in $L_i' - d_{i-1}$ such that $|C_i| \ge (\frac{|L_i'|}{2(d-1)})^r + 2 = (\frac{|B_i|}{2(d-1)})^r + 2$. Let $P_i := C_i - c_i c_{i-1}$; then P_i is a path from c_{i-1} to c_i in $L_i - d_{i-1}$, $|E(P_i)| \ge (\frac{|B_i|}{2(d-1)})^r + 1$, and we have (ii).

Assume that $c_{i-1} \notin \{c_i, d_i\}$. Let L_i'' be obtained from L_i by a T-transform at $\{c_{i-1}, c_i d_i\}$, and let c denote the new vertex. Let $L_i' := L_i'' + d_{i-1}c$. By Lemma 3.3, L_i' is 3-connected. Note that c, c_i, d_{i-1} have degree at most $d + 1$ in L_i', and all other vertices have degree at most d in L_i'. By Theorem 2.1(a), there is a cycle C_i through $c_{i-1}c$ in $L_i' - d_{i-1}$ such that $|C_i| \ge (\frac{|L_i'|}{2(d-1)})^r + 2$. Let $P_i := C_i - c_{i-1}'$. Then P_i is a path from c_{i-1} to $\{c_i, d_i\}$ in $L_i - d_{i-1}$ and $|E(P_i)| \ge (\frac{|B_i|}{2(d-1)})^r$, and we have (iii).

(3) We find a path P_ℓ from $\{c_{\ell-1}, d_{\ell-1}\}$ to x in L_ℓ such that

(i) $\bigcup_{i=2}^{\ell} P_i$ is a path from c_1 to x,

(ii) if L_ℓ is 3-connected, then $|E(P_\ell)| \ge (\frac{|B_\ell|}{2(d-1)})^r + 1$, and

(iii) if L_ℓ is a cycle chain, then $|B_\ell| \ge 1$ and $|E(P_\ell)| \ge |B_\ell|$.

By choosing the notation of $\{c_{\ell-1}, d_{\ell-1}\}$, we may assume that $\bigcup_{i=2}^{\ell-1} P_i$ is between c_1 and $c_{\ell-1}$.

If L_ℓ is a cycle chain, then by Proposition 2.6 let P_ℓ be a path from x to $c_{\ell-1}$ in L_ℓ such that $B_\ell \subseteq V(P_\ell)$. Since $c_{\ell-1}, d_{\ell-1} \notin B_\ell$, we have $|E(P_\ell)| \ge |B_\ell|$. Note that $|B_\ell| = 1$ only if L_ℓ is a cycle and $B_\ell = \{x\}$.

If $L_\ell = K_4$, then we can find a path P_ℓ from x to $c_{\ell-1}$ in $L_\ell - d_{\ell-1}$ with $|E(P_\ell)| = 2 \ge (\frac{|L_\ell|}{2(d-1)})^r + 1 = (\frac{|B_\ell|}{2(d-1)})^r + 1$.

Now assume that L_ℓ is not a cycle chain and that $L_\ell \ne K_4$. Let $L_\ell' := L_\ell + \{xc_{\ell-1}, xd_{\ell-1}\}$. Then L_ℓ' is a 3-connected graph, the vertices $x, c_{\ell-1}, d_{\ell-1}$ have degree

at most $d+1$ in L'_ℓ, and all other vertices of L'_ℓ have degree at most d. So by Theorem 2.1(a), there is a cycle C_ℓ through $xc_{\ell-1}$ in $L'_\ell - d_{\ell-1}$ such that $|C_\ell| \geq (\frac{|L_\ell|}{2(d-1)})^r + 2$. Now $P_\ell := C_\ell - xc_{\ell-1}$ gives the desired path for (ii).

(4) Let $P := \bigcup_{i=1}^{\ell} P_i$. Clearly P is a path in $\bigcup_{i=1}^{\ell} L_i$ from x to a_0. We claim that $|E(P)| \geq (\sigma(\mathcal{L})+1)^r + 1$.

By (2), we have

$$|E(P)| \geq |E(P_1)| + \Big(\sum |B_i|\Big) + \left(\sum \left(\frac{|B_i|}{2(d-1)}\right)^r\right) + |E(P_\ell)|,$$

where the first summation is over all cycle chains L_i and the second is over all 3-connected L_i. Note that each B_i in the first summation can be written as $1^r + \cdots + 1^r$ ($|B_i|$ times), and this allows the application of Lemma 3.1 in the following argument.

If L_ℓ is 3-connected, then by (1) and (3),

$$\begin{aligned}|E(P)| &\geq (|B_1|+2)^r + \Big(\sum |B_i|\Big) + \left(\sum \left(\frac{|B_i|}{2(d-1)}\right)^r\right) + \left(\left(\frac{|B_\ell|}{2(d-1)}\right)^r + 1\right)\\ &\geq \left(2 + \sum_{i=1}^{\ell} |B_i|\right)^r + 1 \quad \text{(by Lemma 3.1)}\\ &> (\sigma(\mathcal{L})+1)^r + 1.\end{aligned}$$

If L_ℓ is a cycle chain, then by (1) and (3),

$$\begin{aligned}|E(P)| &\geq (|B_1|+2)^r + \Big(\sum |B_i|\Big) + \left(\sum \left(\frac{|B_i|}{2(d-1)}\right)^r\right) + (|B_\ell|-1) + 1\\ &\geq \left(1 + \sum_{i=1}^{\ell} |B_i|\right)^r + 1 \quad \text{(by Lemma 3.1)}\\ &= (\sigma(\mathcal{L})+1)^r + 1.\end{aligned}$$

(5) For $i = 1, \ldots, h-1$, we find paths Q_i from $\{a_{i-1}, b_{i-1}\}$ to $\{a_i, b_i\}$ in H_i, as in (2) of Case 1.

(6) We find a path Q_h in H_h as in (3) of Case 1.

(7) Let $C := (P \cup (\bigcup_{i=1}^{h} Q_i)) + \{y, xy, yy'\}$. Now C is a cycle in G through xy and

$$|C| \geq ((\sigma(\mathcal{L})+1)^r + 1) + \Big(\sum |A_i|\Big) + \left(\sum \left(\frac{|A_i|}{2(d-1)}\right)^r\right) + 2,$$

where the first summation is over all cycle chains H_i and the second is over all 3-connected H_i. Again, when we apply Lemma 3.1 in the following argument, each $|A_i|$ in the first summation may be written as $1^r + \cdots + 1^r$. Since $\sigma(\mathcal{L}) \geq |L_1| \geq |A_i|$ for all 3-connected H_i, we have

$$\begin{aligned}|C| &\geq \left(\sigma(\mathcal{L}) + 1 + (d-1)\sum_{i=1}^{h} |A_i|\right)^r + 3 \quad \text{(by Lemma 3.1)}\\ &= (\sigma(\mathcal{L}) + 1 + (d-1)\sigma(\mathcal{H}))^r + 3\\ &\geq n^r + 3 \quad \text{(by the observation preceding Case 1).}\end{aligned}$$

Case 3. $1 < t \le \ell$. Note that in this case there exist $y'' \in V(L_1) - \{c_1, d_1\}$ and a path Y in G from y to y'' disjoint from $(V(\mathcal{L}) - \{y''\}) \cup V(\mathcal{H})$. For convenience, let $S := (\bigcup_{i=2}^{t} B_i) - (B_1 \cup B_{t+1})$. We consider two subcases by comparing $\sigma(\mathcal{H})$ and $|S|$.

Subcase 3.1. $|S| < \sigma(\mathcal{H})$. Then $\mathcal{H} \neq \emptyset$ and $a_0 \neq b_0$. Since $\sum_{i=1}^{h} |A_i| \ge \sigma(\mathcal{H})$ and there are at most $d-2$ extreme 3-blocks of $G - y$ containing neither x nor y'', we have the following inequality:

$$\sigma(\mathcal{L}) - |S| + (d-1)\sum_{i=1}^{h} |A_i| \ge n - 1.$$

(1) First, we find a path P_1 from c_1 to d_1 in L_1 such that $|E(P_1)| \ge (|B_1|+1)^r + 1$.

If $L_1 = K_4$, then let P_1 be a Hamilton path from c_1 to d_1 in L_1. Hence $|E(P_1)| = 3 \ge (|L_1|+1)^r + 1 = (|B_1|+1)^r + 1$. If $L_1 \neq K_4$ then $5 \le |L_1| < n$. By Theorem 2.1(c), there is a cycle C_1 through c_1d_1 in L_1 such that $|C_1| \ge |L_1|^r + 3 = |B_1|^r + 3 > (|B_1|+1)^r + 2$. Then $P_1 := C_1 - c_1d_1$ gives the desired path.

(2) Next, we find $Q \subseteq (\bigcup_{i=2}^{t} L_i) - \{a_0b_0, c_td_t\}$ such that (1) $P_1 \cup Q$ is a path from $\{a_0, b_0\}$ to $\{c_t, d_t\}$ when $t \neq \ell$, and (2) $P_1 \cup Q$ is a path from $\{a_0, b_0\}$ to x when $t = \ell$.

Let $K := \bigcup_{i=2}^{t} L_i$. First, assume that $t \neq \ell$. If $\{a_0, b_0\} = \{c_t, d_t\}$, then by Lemma 3.5 we find a cycle D through a_0b_0 and c_1d_1 in K, and $Q := D - \{a_0b_0, c_1d_1\}$ is as desired. If $\{a_0, b_0\} \neq \{c_t, d_t\}$, then let K' be obtained from K by an H-transform at $\{a_0b_0, c_td_t\}$, and let a, c denote the new vertices. By Lemma 3.5, we find a cycle D' through ac and c_1d_1, and $Q := D' - \{a, c, c_1d_1\}$ is as desired.

Now assume that $t = \ell$. If $x \in \{a_0, b_0\}$, then by Lemma 3.5 there is a cycle D in K through a_0b_0 and c_1d_1, and $Q := D - \{a_0b_0, c_1d_1\}$ is as desired. So assume that $x \notin \{a_0, b_0\}$. Let K' be obtained from K by a T-transform at $\{x, a_0b_0\}$, and let a denote the new vertex. By Lemma 3.5, there is a cycle D in K' through xa and c_1d_1. Now $Q := D - \{a, c_1d_1\}$ is as desired.

We choose the notation of $\{a_0, b_0\}$ and $\{c_t, d_t\}$ so that $P_1 \cup Q$ is from a_0 to c_t.

(3) For each $t+1 \le i \le \ell-1$, we find a path P_i in L_i from $\{c_{i-1}, d_{i-1}\}$ to $\{c_i, d_i\}$ exactly as in (2) of Case 2 such that (i) $(\bigcup_{i=t+1}^{\ell-1} P_i) \cup P_1 \cup Q$ is a path from $\{c_{\ell-1}, d_{\ell-1}\}$ to $\{a_0, b_0\}$, (ii) $|E(P_i)| \ge (\frac{|B_i|}{2(d-1)})^r$ when L_i is 3-connected, and (iii) $|E(P_i)| \ge |B_i|+1$ when L_i is a cycle chain.

(4) If $t \neq \ell$, we find a path P_ℓ between $\{c_{\ell-1}, d_{\ell-1}\}$ and x exactly as in (3) of Case 2 such that (i) $(\bigcup_{i=t+1}^{\ell} P_i) \cup P_1 \cup Q$ is a path from $\{a_0, b_0\}$ to x, (ii) $|E(P_\ell)| \ge (\frac{|B_\ell|}{2(d-1)})^r + 1$ when L_ℓ is 3-connected, and (iii) $|E(P_\ell)| \ge |B_\ell|$ when L_ℓ is a cycle chain.

(5) For $i = 1, \ldots, h-1$, we find paths Q_i from $\{a_{i-1}, b_{i-1}\}$ to $\{a_i, b_i\}$ in $H_i - b_{i-1}$, as in (2) of Case 1, such that (i) $\bigcup_{i=1}^{h-1} Q_i$ is a path from a_0 to $\{a_{h-1}, b_{h-1}\}$, (ii) $|E(Q_i)| \ge (\frac{|A_i|}{2(d-1)})^r$ when H_i is 3-connected, and (iii) $|E(Q_i)| \ge |A_i|$ when H_i is a cycle chain.

(6) We find a path Q_h exactly as in (3) of Case 1 such that (i) $\bigcup_{i=1}^{h} Q_i$ is a path from a_0 to y', (ii) $|E(Q_h)| \ge (\frac{|A_h|}{2(d-1)})^r + 1$ when H_h is 3-connected, and (iii) $|E(Q_h)| \ge |A_h|$ when H_h is a cycle chain.

(7) Let $C := (P_1 \cup Q \cup (\bigcup_{i=t+1}^{\ell} P_i) \cup (\bigcup_{i=1}^{h} Q_i)) + \{y, xy, yy'\}$. Then C is a cycle in G through xy and, by (1)–(6), we have

$$|C| \ge (|L|+1)^r + \Big(\sum |B_i|\Big) + \Big(\sum \Big(\frac{|B_i|}{2(d-1)}\Big)^r\Big) + \Big(\sum |A_i|\Big) + \Big(\sum \Big(\frac{|A_i|}{2(d-1)}\Big)^r\Big) + 3,$$

where the first sum is taken over all cycle chains L_i for $t+1 \le i \le \ell$, the second is

over all 3-connected L_i for $t+1 \le i \le \ell$, the third is over all cycle chains H_i, and the fourth is over all 3-connected H_i. Because $|L| \ge |A_i|$ for all 3-connected H_i, and $|L| \ge |B_j|$ for all 3-connected L_j, we have

$$\begin{aligned}|C| &\ge \left(\sigma(\mathcal{L}) + 1 - |S| + (d-1)\sum_{i=1}^{h}|A_i|\right)^r + 3 \quad \text{(by Lemma 3.1)}\\ &\ge n^r + 3.\end{aligned}$$

The second inequality follows from the inequality in the first paragraph of this subcase.

Subcase 3.2. $|S| \ge \sigma(\mathcal{H})$. As in the previous subcase, we deduce the following inequality:

$$|B_1| + (d-1)\sum_{i=2}^{\ell}|B_i| \ge n-1.$$

(1) First, we find a path P_1 from y'' to $\{c_1, d_1\}$ in $L_1 - c_1d_1$ such that $|E(P_1)| \ge (|B_1|+1)^r + 1$.

Let L_1' denote the graph obtained from L_1 by a T-transform at $\{y'', c_1d_1\}$, and let y^* denote the new vertex. By Lemma 3.3 and since y'' has degree at most $d-1$ in L_1, L_1' is a 3-connected graph with maximum degree at most d. Since $5 \le |L_1'| < n$, Theorem 2.1 holds for L_1'. By Theorem 2.1(c), L_1' has a cycle C_1 through y^*y'' such that $|C_1| \ge |L_1'|^r + 3 = (|B_1|+1)^r + 3$. Then $P_1 := C_1 - y^*$ gives the desired path for (1).

We may choose the notation of $\{c_1, d_1\}$ so that P_1 is between y'' and c_1.

(2) For each $2 \le i \le \ell - 1$, we find a path P_i in L_i as in (2) of Case 2 such that (i) $\bigcup_{i=2}^{\ell-1} P_i$ is a path from c_1 to $\{a_{\ell-1}, b_{\ell-1}\}$, (ii) $|E(P_i)| \ge (\frac{|B_i|}{2(d-1)})^r$ when L_i is 3-connected, and (iii) $|E(P_i)| \ge |B_i| + 1$ when L_i is a cycle chain.

(3) We find a path P_ℓ as in (3) of Case 2 such that (i) $\bigcup_{i=2}^{\ell} P_i$ is a path from c_1 to x, (ii) $|E(P_\ell)| \ge (\frac{|B_\ell|}{2(d-1)})^r + 1$ when L_ℓ is 3-connected, and (iii) $|E(P_\ell)| \ge |B_\ell|$ when L_ℓ is a cycle chain.

(4) Let $C := (Y \cup (\bigcup_{i=1}^{\ell} P_i)) + xy$. Then C is a cycle in G through xy and

$$|C| \ge (|B_1|^r + 1) + \left(\sum |B_i|\right) + \left(\sum \left(\frac{|B_i|}{2(d-1)}\right)^r\right) + 2,$$

where the first sum is over all L_i which are cycle chains and the second is over all 3-connected L_i. Again, we may view $|B_i|$ in the first summation as $1^r + \cdots 1^r$ ($|B_i|$ times). Since $|B_1| \ge |B_i|$ for all 3-connected L_i, we have

$$\begin{aligned}|C| &\ge \left(|B_1| + 1 + (d-1)\sum_{i=2}^{\ell}|B_i|\right)^r + 3 \quad \text{(by Lemma 3.1)}\\ &\ge n^r + 3.\end{aligned}$$

The second inequality follows from the inequality in the first paragraph of this case. ∎

Next we show that the above proof gives rise to an $O(|E(G)|)$ algorithm which reduces Theorem 2.1(c) to (a), (b), and (c) of the same theorem for smaller graphs.

Algorithm Oneedge. Let n, d, r, G, e, be as in Lemma 6.1.

1. *Preprocessing.* Replace G by a 3-connected spanning subgraph of G with $O(|G|)$ edges. (This can be done in $O(|E(G)|)$ time using Lemma 3.4.)
2. Let $e = xy$. Decompose $G - y$ into 3-connected components. (This can be done in $O(|G|)$ time using Theorem 2.2.)
3. If there is only one 3-connected component of $G-y$, then $G-y$ is 3-connected. Let y' denote a neighbor of y other than x, and let $G' := (G - y) + xy'$ and $e' = xy'$. It suffices to find a cycle C' through e' in G' such that $|C'| \geq |G'|^r + 3$. So reduce Theorem 2.1(c) for G, e to Theorem 2.1(c) for G', e', with $|G'| < |G|$. (Note that this reduction takes constant time.)
4. Now assume that $G - y$ has at least two 3-connected components. If all 3-blocks of $G - y$ are cycles, find a cycle chain $\mathcal{I} = I_1 \dots I_i$ such that (i) $x \in V(I_1) - V(I_2)$, (ii) I_i is an extreme 3-block of $G - y$, and (iii) subject to (i) and (ii), $|V(\mathcal{I})|$ is maximum. (This can be done in $O(|G|)$ time by a simple search.) Then, find a neighbor $y' \in V(\mathcal{I}) - \{x\}$ of y, a Hamilton path P in $\mathcal{I}$ from x to y', and a path Q from y to y' disjoint from $V(\mathcal{I}) - \{y'\}$, so that $(P \cup Q) + \{y, xy, yy'\}$ gives the desired cycle. (These paths can be computed in $O(|G|)$ time as in the proof of Lemma 6.1.)
5. Now assume that $G - y$ has at least two 3-blocks, and at least one is 3-connected. We choose a 3-connected 3-block L of $G - y$ such that $|L|$ is maximum. Find the block chain $\mathcal{L} = L_1 \dots L_\ell$ such that $L_1 = L$ and $x \in V(L_\ell) - V(L_{\ell-1})$. Find a block chain $\mathcal{H} = H_1 \dots H_h$ in $G - y$ with $y' \in H_h$, and define a_i, b_i, A_i, c_j, d_j, B_j for $i = 1, \dots h$ and $j = 1, \dots, \ell$ as in the proof of Lemma 6.1. (All these can be done in $O(|G|)$ time by searching the 3-blocks of $G - y$.)
6. Suppose $\ell = 1$.
   - First, we need to find a path P in $\mathcal{L}$ from x to $\{a_0, b_0\}$ as in (1) of Case 1. We either find the desired P or reduce the problem of finding P to Theorem 2.1(c) for L_1, a_0b_0 or L_1', xx', both are smaller graphs. (From (1) of Case 1 in the proof of Lemma 6.1, this can be done in constant time.)
   - For each $1 \leq i \leq h - 1$, we want to find a path Q_i from $\{a_{i-1}, b_{i-1}\}$ to $\{a_i, b_i\}$ in H_i as in (2) of Case 1 in the proof of Lemma 6.1. We either find the desired Q_i or reduce the problem of finding Q_i to Theorem 2.1(a) for $H_i', a_{i-1}a_i, b_{i-1}$ or $H_i', a_{i-1}a, b_{i-1}$. (From (2) of Case 1 in the proof of Lemma 6.1, this can be done in $O(|H_i|)$ time.)
   - We need to find a path Q_h in H_h from a_{h-1} to y' as in (3) of Case 1. We either find the desired Q_h or reduce the problem of finding Q_h to Theorem 2.1(a) for $H_h', a_{h-1}y', b_{h-1}$. (From (3) of Case 1 in the proof of Lemma 6.1, this can be done in $O(|H_h|)$ time.)
   - Since $\sum_{i=1}^{h}(|H_i| - 2) = |V(\mathcal{H})| - 2$, we see that this step takes $O(|G|)$ time.
7. Suppose $1 = t < \ell$.
   - First, we need to find a path P_1 from $\{a_0, b_0\}$ to $\{c_1, d_1\}$ in L_1, as in (1) of Case 2 in the proof of Lemma 6.1. We either find the desired P_1 or reduce the problem of finding P_1 to Theorem 2.1(c) for either L_1, c_1d_1 or L_1', ac. (From (1) of Case 2 in the proof of Lemma 6.1, this can be done in constant time.)
     Assume that the notation is chosen so that P_1 is a path from a_0 to c_1.
   - For each $2 \leq i \leq \ell - 1$, we need to find a path P_i from $\{c_{i-1}, d_{i-1}\}$ to

$\{c_i, d_i\}$ in L_i as in (2) of Case 2 in the proof of Lemma 6.1. We either find the desired P_i or reduce the problem of finding P_i to Theorem 2.1(a) for either $L'_i, c_{i-1}c_i, d_{i-1}$ or $L'_i, c_{i-1}c, d_{i-1}$. (From (2) of Case 2 in the proof of Lemma 6.1, this can be done in $O(|L_i|)$ time.)

- We need to find a path P_ℓ from $\{c_{\ell-1}, d_{\ell-1}\}$ to x in L_ℓ, as in (3) of Case 2 in the proof of Lemma 6.1. We either find the desired path P_ℓ or reduce the problem of finding P_ℓ to Theorem 2.1(a) for $L'_\ell, xc_{\ell-1}, d_{\ell-1}$. (From (3) of Case 2 in the proof of Lemma 6.1, this can be done in $O(|L_\ell|)$ time.)
- Next we need to find paths Q_i, $1 \le i \le h$. This is taken care of exactly as in step 6 above.
  (Since $\sum_{i=1}^{h}(|H_i| - 2) = |V(\mathcal{H})| - 2$ and $\sum_{i=1}^{\ell}(|L_i| - 2) = |V(\mathcal{L})| - 2$, we see that all operations in this step can be done in $O(|G|)$ time.)

8. Suppose $1 < t \le \ell$. First, find a path Y from y to $y'' \in V(L_1) - V(L_2)$ such that $Y - y''$ is disjoint from $V(\mathcal{L}) \cup V(\mathcal{H})$. Define $S := (\bigcup_{i=2}^{t} B_i) - (B_1 \cup B_{t+1})$. (Note that Y and all B_i's can be found in $O(|G|)$ time, as in Case 3 in the proof of Lemma 6.1.)
9. Suppose $|S| < \sigma(\mathcal{H})$.
   - We need to find a path P_1 from c_1 to d_1 in L_1, as in (1) of Subcase 3.1 in the proof of Lemma 6.1. We either find the desired P_1 or reduce the problem of finding P_1 to Theorem 2.1(c) for L_1, c_1d_1. (From (1) of Subcase 3.1 in the proof of Lemma 6.1, this can be done in $O(|L_1|)$ time.)
   - Find $Q \subseteq (\bigcup_{i=2}^{t} L_i) - \{a_0b_0, c_td_t\}$ as in (2) of Subcase 3.1 in the proof of Lemma 6.1. (From (2) of Subcase 3.1 in the proof of Lemma 6.1, this can be done in $O(|G|)$ time.)
   - For each $t + 1 \le i \le \ell - 1$, we need to find a path P_i from $\{c_{i-1}, d_{i-1}\}$ to $\{c_i, d_i\}$, as in (3) of Subcase 3.1 in the proof of Lemma 6.1. (This can be done as in step 7 above, and hence in $O(|G|)$ time.)
   - Next, we need to find a path P_ℓ from $\{c_{\ell-1}, d_{\ell-1}\}$ to x in L_ℓ as in (4) of Subcase 3.1 in the proof of Lemma 6.1. (This can be done as in step 7 above, and hence in $O(|L_\ell|)$ time.)
   - For each $1 \le i \le h - 1$, we want to find a path Q_i as in (5) of Subcase 3.1 in the proof of Lemma 6.1. (This can be done as in step 6 above, and hence in $O(|H_i|)$ time.)
   - Finally, we find a Q_h in H_h from $\{a_{h-1}, b_{h-1}\}$ to y' as in (6) of Subcase 3.1 in the proof of Lemma 6.1. (This can be done as in step 6 above, and hence in $O(|H_h|)$ time.)
     (Since $\sum_{i=1}^{h}(|H_i| - 2) = |V(\mathcal{H})| - 2$ and $\sum_{i=1}^{\ell}(|L_i| - 2) = |V(\mathcal{L})| - 2$, we see that all operations in this step can be done in $O(|G|)$ time.)
10. Suppose $|S| \ge \sigma(\mathcal{H})$.
    - First, we need to find a path P_1 from y'' to $\{c_1, d_1\}$ in L_1, as in (1) of Subcase 3.2 in the proof of Lemma 6.1. We either find the desired P_1 or reduce the problem of finding P_1 to Theorem 2.1(c) for L'_1, y^*y''. (From (1) of Subcase 3.2 in the proof of Lemma 6.1, this can be done in $O(|L_1|)$ time.)
    - For each $2 \le i \le \ell - 1$, we need to find a P_i as in (2) of Subcase 3.2 in the proof of Lemma 6.1. (This can be done as in step 7 above for each i, and hence, in $O(|L_i|)$ time.)

- Next, we want to find a path P_ℓ from $\{c_{\ell-1}, d_{\ell-1}\}$ to x in L_ℓ as in (3) of Subcase 3.2 in the proof of Lemma 6.1. (This can be done as in step 7 above, and hence, in $O(|L_\ell|)$ time.)
  (All operations in this step can be done in $O(|G|)$ time since $\sum_{i=1}^{\ell}(|L_i|-2) = |V(\mathcal{L})| - 2$.)

We summarize the above procedure as follows.

PROPOSITION 6.2. *Given G, e, n, d, r as in Lemma 6.1, we can, in $O(|E(G)|)$ time, either*

(1) *find a cycle C through e in G such that $|C| \geq |G|^r + 3$, or*
(2) *reduce Theorem 2.1(c) for G, e to (a), (b), or (c) of the same theorem for smaller 3-connected graphs.*

Moreover, any smaller graph in (2) results from a 3-connected 3-block of $G - y$ which is not K_4. Hence, any smaller graph in (2) contains a vertex that does not belong to any other smaller graph in (2).

7. Conclusions. We now complete the proof of Theorem 2.1. Let n, d, r, G be given as in the theorem. We will prove the conclusions by applying induction on n. When $n = 5$, then G is isomorphic to one of the following three graphs: K_5, K_5 minus an edge, or the wheel on five vertices. In each case, we can verify that Theorem 2.1 holds. So assume that $n \geq 6$ and that Theorem 2.1 holds for all 3-connected graphs with at most $n-1$ vertices. Then (a) holds by Lemma 4.1, (b) holds by Lemma 5.1, and (c) holds by Lemma 6.1. This completes the proof of Theorem 2.1. □

ALGORITHM CYCLE. Let G be a 3-connected graph with maximum degree at most d, let $e = xy \in E(G)$, and assume $|G| \geq 5$. The following procedure finds a cycle C through e in G with $|C| \geq |G|^r + 3$.

1. *Preprocessing.* Replace G with a 3-connected spanning subgraph of G with $O(|G|)$ edges.
2. Apply Algorithm Oneedge to G, e. We either find the desired cycle C or we reduce the problem to Theorem 2.1(a), (b), or (c) for some 3-connected graphs G_i, for which $|G_i| < |G|$ and each G_i contains a vertex which does not belong to any other G_i.
3. Replace each G_i with a 3-connected spanning subgraph of G_i with $O(|G_i|)$ edges.
4. Apply Algorithm Avoidvertex to those G_i for which Theorem 2.1(a) needs to be applied. Apply Algorithm Twoedge to those G_i for which Theorem 2.1(b) needs to be applied. Apply Algorithm Oneedge to those G_i for which Theorem 2.1(c) needs to be applied.
5. Repeat steps 3 and 4 for new 3-connected graphs.
6. In the final output, replace all virtual edges by paths in G to complete the desired cycle C.

Note that step 1 takes $O(|E(G)|)$ time by Lemma 3.4 and step 2 takes $O(|E(G)|)$ time by Proposition 4.2.

By Lemma 3.4, step 3 spends $O(|E(G_i)|)$ time for each G_i from step 2. Note that each G_i in step 2 contains a vertex which does not belong to any other G_i. By Theorem 2.2 and since each G_i contributes at most three additional edges due to T-transform or H-transform, the total number of edges in step 2 is at most $3|E(G)| - 6 + 3|V(G)|$. Hence step 3 takes $O(|E(G)|)$ time.

From Propositions 4.2, 5.2, and 6.2, we see that step 4 spends $O(|E(G_i)|)$ time for each G_i from step 2. By Theorem 2.2 and since each G_i contributes at most three additional edges due to T-transform or H-transform, the total number of edges in step

4 is at most $\sum_i(3|E(G_i)| - 6 + 3|V(G_i)|)$. Since each G_i in step 2 contains a vertex which does not belong to any other G_i, step 4 takes $O(|G|^2)$ time.

Since there are at most $|G|$ iterations, we see that Algorithm Cycle takes $O(|G|^3)$ time.

A SWITCHING LEMMA FOR SMALL RESTRICTIONS AND LOWER BOUNDS FOR k-DNF RESOLUTION*

NATHAN SEGERLIND†, SAM BUSS‡, AND RUSSELL IMPAGLIAZZO§

Abstract. We prove a new switching lemma that works for restrictions that set only a small fraction of the variables and is applicable to formulas in disjunctive normal form (DNFs) with small terms. We use this to prove lower bounds for the Res(k) propositional proof system, an extension of resolution which works with k-DNFs instead of clauses. We also obtain an exponential separation between depth d circuits of bottom fan-in k and depth d circuits of bottom fan-in $k+1$.

Our results for Res(k) are as follows:

1. The $2n$ to n weak pigeonhole principle requires exponential size to refute in Res(k) for $k \leq \sqrt{\log n / \log\log n}$.
2. For each constant k, there exists a constant $w > k$ so that random w-CNFs require exponential size to refute in Res(k).
3. For each constant k, there are sets of clauses which have polynomial size Res($k+1$) refutations but which require exponential size Res(k) refutations.

Key words. propositional proof complexity, Boolean circuit complexity, switching lemmas, lower bounds, k-DNFs, resolution, Res(k), circuit bottom fan-in, random restriction, Sipser functions, weak pigeonhole principles, random CNFs

1. Introduction.

This paper studies the complexity of Res(k), a propositional refutation system that extends resolution by allowing k-DNFs instead of clauses [24]. The complexity of propositional proof systems has close connections to open problems in computational and circuit complexity [14, 23, 29, 6], as well as implications for the run times of satisfiability algorithms and automated theorem provers. Resolution is one of the most studied proof systems and is used as the basis for many satisfiability algorithms. Backtracking algorithms for satisfiability, such as the popular Davis–Putnam–Logeman–Loveland procedure (DPLL), that branch on a single variable provide tree-like resolution refutations on unsatisfiable formulas. General resolution proofs correspond to adding a limited form of memoization (previously refuted subproblems are saved for reuse rather than refuted again) to DPLL. Res(k) corresponds to algorithms that branch on more general conditions: the value of any function of up to k variables.

The Res(k) systems are also interesting as intermediates between previously studied proof systems. Resolution can be thought of as Res(1), and depth two Frege can be thought of as Res(n) (where n is the number of variables). The Res(k) systems provide a transition between these systems. Moreover, statements provable in the theory

$T_2^2(\alpha)$ (a fragment of Peano's arithmetic that allows induction only on Σ_2^b predicates) correspond to propositional statements with quasi-polynomial size Res(polylog(n)) refutations [24]. T_2^2 is the weakest fragment of Peano's arithmetic known to be able to use counting arguments such as the weak pigeonhole principle [25]. On the other hand, these counting tautologies are known to require exponential-size resolution refutations. Thus, there must be a critical range for k between 1 and polylog(n) where these arguments become possible in subexponential size. More generally, we can ask, When does increasing k give the Res(k) system more power? Is there a reason to want to branch on more complex functions in satisfiability algorithms? Does such branching give algorithms better performance in the average case?

We give partial answers to all of these questions. In particular we prove the following:

1. The $2n$ to n weak pigeonhole principle requires size $2^{\Omega(n^\epsilon)}$ to refute in Res(k) for all $k \leq \sqrt{\log n / \log\log n}$. So having large bottom fan-in is necessary for counting arguments.
2. For each k, there exists a constant $w > k$ so that random w-CNFs require size $2^{\Omega(n^\epsilon)}$ to refute in Res(k). Therefore, extending DPLL algorithms to branch on multiple (but a constant number of) variables will not make run times subexponential on average.
3. Res($k+1$) is exponentially more powerful than Res(k). We demonstrate sets of clauses that have polynomial size Res($k+1$) refutations but require size $2^{\Omega(n^\epsilon)}$ to refute in Res(k). Therefore, increasing the complexity of branching conditions can make proofs exponentially smaller.

Our lower bounds are proved using a new kind of switching lemma. A switching lemma provides conditions under which an OR of small ANDs can be rewritten as an AND of small ORs after the application of a random restriction [1, 18, 21, 4]. Our switching lemma differs from previous switching lemmas in that the random restriction is allowed to set a small number of the variables, even as few as $n^{1-\epsilon}$ out of n. The trade-off is that ORs of *extremely* small ANDs are transformed into ANDs of modestly small ORs. Therefore, our switching lemma cannot be iterated to prove lower bounds for proof systems of depth more than two. However, one application of our switching lemma suffices to prove lower bounds for the Res(k) proof systems, because each line in such a proof is of depth two with small bottom fan-in.

Our switching lemma also gives an exponential separation between depth d circuits with bottom fan-in k from depth d circuits with bottom fan-in $k+1$. This refines a previous result of Håstad [21], which states that for all d there exist $\epsilon > \delta > 0$ so that there are functions on n variables, computable with polynomial size, depth d circuits of bottom fan-in n^ϵ but which require exponential size to compute with depth d circuits of bottom fan-in n^δ. Our result also refines results of Cai, Chen, and Håstad [12]. They showed that for each constant d, there exist functions computable with polynomial-size, depth $d+1$, bottom fan-in 2 circuits that require exponential size to compute with depth d circuits, and that for each constant k, there exists a function of n variables computable by depth d circuits of polynomial-size and bottom fan-in $O(\log n)$ that requires exponential size to compute with depth d circuits of bottom fan-in k.

Because resolution may be viewed as Res(1), our results for Res(k) generalize known results for resolution. The weak pigeonhole principle (for any number of pigeons) is known to require an exponential number of steps to refute in resolution [35, 20, 36, 11, 5, 15, 28, 30, 31], and we generalize these lower bounds for the case

of the cn to n pigeonhole principle. Resolution refutations of randomly chosen sets of clauses are also known to require exponential size [13, 5, 8]. We extend these results to general Res(k) systems, although as k increases, so does the width of the random CNFs for which our lower bounds apply.

Our work also extends previous research on the Res(k) system. The complexity of Res(k) refutations was first studied by Krajíček [24], who was motivated by the connection between Res(polylog(n)) and the provability of combinatorial statements in the arithmetic theory $T_2^2(\alpha)$. Atserias, Bonet, and Esteban [3] gave exponential lower bounds for Res(2) refutations of the $2n$ to n weak pigeonhole principle and of random 3-CNFs. They also proved a quasi-polynomial separation between Res(2) and resolution; this separation was later strengthened to almost-exponential by Atserias and Bonet [2]. Esteban, Galesi, and Messner [17] showed that that there is an exponential separation between tree-like Res(k) and tree-like Res($k+1$), and that general (DAG-like) Res(k) requires high *space* to refute random CNFs and the weak pigeonhole principle.

The lower bounds for Res(k) refutations of the weak pigeonhole principle given by Atserias, Bonet, and Esteban [3] apply only for $k = 2$; our lower bound works for nonconstant k up to $\sqrt{\log n / \log\log n}$. On the other hand, Maciel, Pitassi, and Woods [25] gave quasi-polynomial-size refutations in Res(polylog(n)). Our results show that superconstant bottom fan-in is necessary for subexponential-size proofs of the weak pigeonhole principle. Indeed, after the preliminary version of this paper appeared [33], our techniques were extended by Alexander Razborov to prove that the weak pigeonhole principle requires exponential size to refute in Res($\epsilon \log n / \log\log n$) [32].

Our lower bounds for Res(k) refutations of random w-CNFs are the first such lower bounds for Res(k) with $k \geq 3$. Atserias, Bonet, and Esteban [3] gave exponential lower bounds for random 3-CNFs in Res(2). We extend these results to Res(k), although the width w increases with k (it is $4k^2 + 2$). At present, the Res(k) systems are the strongest fragments of bounded-depth Frege systems for which we know there are superpolynomial-size lower bounds for refutations of random sets of clauses.

The separation between Res($k+1$) from Res(k) is the first for $k \geq 2$. The earlier work of Atserias and Bonet [2] gave a $2^{\Omega(2^{\log^{\epsilon} n})}$ separation of Res(2) from Res(1), and our result improves this to $2^{\Omega(n^{\epsilon})}$.

In the time since the preliminary version of this paper appeared [33], we have extended one of our results. The original separation of Res($k+1$) from Res(k) was based on clauses of width $O(\log n)$, whereas the new separation uses clauses of constant width. We include proofs for both results.

1.1. Outline of the paper. Background material, including the basics of the Res(k) proof system, is given in section 2. In section 3 we prove the switching lemma. Section 4 applies the switching lemma to prove a separation between constant-depth circuits of bottom fan-in $k+1$ and constant-depth circuits of bottom fan-in k. In section 5 we prove that Res(k) refutations of sets of clauses whose lines are represented by short decision trees can be transformed into narrow resolution refutations. This conversion is used in combination with the switching lemma to prove lower bounds for Res(k) refutations. Lower bounds for Res(k) refutations of the weak pigeonhole principle are proved in section 6 and lower bounds for Res(k) refutations of random CNFs are proved in section 7. The separations between Res($k+1$) and Res(k) are proved in sections 8 and 9.

2. Background. A *literal* is a variable or its negation. A *term* is a constant 0 or 1 or a conjunction of literals. Our convention is that a term is specified as a set of literals, with 1 corresponding to the empty set and 0 to any literal and its negation. We say that a term T contains a literal l if $l \in T$, and that a term T contains a variable x if either $x \in T$ or $\neg x \in T$. We will often identify literals with terms of size one, and will write l instead of $\{l\}$. A *DNF* is a disjunction of terms, specified as a set of terms. A *k-DNF* is a DNF whose terms are each of size at most k. A *clause* is a 1-DNF, i.e., a disjunction of literals. The width of a clause C, written $w(C)$, is the number of literals appearing in C. The width of a set of clauses is the maximum width of any clause in the set. A *CNF* is a conjunction of clauses, specified as a set of clauses. A *k-CNF* is a CNF whose clauses are each of width at most k. Two terms t and t' are *consistent* if there is no literal l with $l \in t$ and $\neg l \in t'$.

A *restriction* ρ is a map from a set of variables to $\{0, 1, *\}$. For a formula F, *the restriction of F by ρ*, $F \restriction_\rho$ is defined as usual, simplifying only when a subexpression has become explicitly constant. For any restriction ρ, let $\mathrm{dom}(\rho)$ denote the set of variables to which ρ assigns the value 0 or 1.

Resolution is a refutation system for propositional logic. The input to a resolution refutation is a set of clauses $\mathcal{C}$; a resolution refutation consists of a derivation of the empty clause from the clauses in $\mathcal{C}$ using only the resolution inference: $\frac{A \vee x \quad \neg x \vee B}{A \vee B}$. Notice that every line in a resolution refutation is a clause. $w_R(\mathcal{C})$ denotes the minimum width of a resolution refutation of $\mathcal{C}$; if $\mathcal{C}$ is satisfiable, then there is no refutation and we use the convention that $w_R(\mathcal{C})$ is ∞.

The $\mathrm{Res}(k)$ refutation system is a generalization of resolution that can reason using k-DNFs.

DEFINITION 2.1. *Res(k) is the refutation system whose lines are k-DNFs and whose inference rules are given below (A, B are k-DNF's, $1 \leq j \leq k$, and $l, l_1, \ldots, l_j$ are literals):*

$$\textit{Subsumption:} \quad \frac{A}{A \vee l} \qquad \textit{AND-introduction:} \quad \frac{A \vee l_1 \ \cdots \ A \vee l_j}{A \vee \bigwedge_{i=1}^{j} l_i}$$

$$\textit{Cut:} \quad \frac{A \vee \bigwedge_{i=1}^{j} l_i \quad B \vee \bigvee_{i=1}^{j} \neg l_i}{A \vee B} \qquad \textit{AND-elimination:} \quad \frac{A \vee \bigwedge_{i=1}^{j} l_i}{A \vee l_i}$$

Let $\mathcal{C}$ be a set of k-DNFs. A $\mathrm{Res}(k)$ derivation from $\mathcal{C}$ *is a sequence of k-DNFs $F_1, \ldots, F_m$ so that each F_i either belongs to $\mathcal{C}$ or follows from the preceding lines by an application of one of the inference rules. For a set of k-DNFs $\mathcal{C}$, a* $\mathrm{Res}(k)$ refutation of $\mathcal{C}$ *is a derivation from $\mathcal{C}$ whose final line is the empty clause. The size of a Res(k) refutation is the number of lines it contains. $S_k(\mathcal{C})$ denotes the minimum size of a Res(k) refutation of $\mathcal{C}$. If $\mathcal{C}$ is satisfiable, then $\mathcal{C}$ has no refutation and we use the convention that $S_k(\mathcal{C})$ is ∞.*

We do not use the exact definition of the $\mathrm{Res}(k)$ system in our arguments; the main property we use is *strong soundness*: if F is inferred from $F_1, \ldots, F_j$, and $t_1, \ldots, t_j$ are mutually consistent terms of $F_1, \ldots, F_j$, respectively, then there is a term t of F implied by $\bigwedge_{i=1}^{j} t_i$. In other words, any reason why $F_1, \ldots, F_k$ are true implies a reason why F is true. This is stronger than mere soundness.

LEMMA 2.2. *Res(k) is strongly sound.*

We also use the following well-known interpolation property for resolution.

LEMMA 2.3. *Let $\mathcal{C}_1$ and $\mathcal{C}_2$ be unsatisfiable sets of clauses on disjoint sets of variables. If there is a resolution refutation Γ of $\mathcal{C}_1 \cup \mathcal{C}_2$, then there is a refutation Γ'*

of either $\mathcal{C}_1$ or $\mathcal{C}_2$. Moreover, $w(\Gamma') \leq w(\Gamma)$.

2.1. The Chernoff bounds. Throughout this paper we will repeatedly make use of a simplified form of the Chernoff bounds. These formulations come from standard references on applying such bounds in algorithmics; cf. [26, 37].

LEMMA 2.4. *Let $X_1, \ldots, X_n$ be independent random indicator variables. Let $\mu = E[\sum_{i=1}^{n} X_i]$.*

$\Pr\left[\sum_{i=1}^{n} X_i < \frac{\mu}{2}\right] \leq e^{-\mu/8}$ and $\Pr\left[\sum_{i=1}^{n} X_i > 2\mu\right] \leq e^{-\mu/4}$.

2.2. Miscellaneous notation. We will use the notation $[k] = \{i \mid 1 \leq i \leq k\}$. For graphs $G = (V, E)$ and $S \subseteq V$ we will write $G - S$ to denote the induced subgraph on $V \setminus S$.

3. The switching lemma. A switching lemma is a guarantee that after the application of a randomly chosen restriction, a disjunction of small ANDs can be represented by a conjunction of small ORs, thus "switching" an OR into an AND. We use a slightly stronger variation: after the application of a random restriction, a k-DNF can be represented by a short decision tree.

DEFINITION 3.1. *A* decision tree *is a rooted binary tree in which every internal node is labeled with a variable, the edges leaving a node correspond to whether the variable is set to 0 or 1, and the leaves are labeled with either 0 or 1. Every path from the root to a leaf may be viewed as a partial assignment. For a decision tree T and $v \in \{0, 1\}$, we write the set of paths (partial assignments) that lead from the root to a leaf labeled v as $\mathrm{Br}_v(T)$. For a partial assignment ρ, $T \restriction_\rho$ is the decision tree obtained by deleting from T every edge whose label conflicts with ρ and contracting along each edge whose label belongs to ρ. We say that a decision tree T* strongly represents *a DNF F if for every $\pi \in \mathrm{Br}_0(T)$, for all $t \in F$, $t \restriction_\pi = 0$ and for every $\pi \in \mathrm{Br}_1(T)$, there exists $t \in F$, $t \restriction_\pi = 1$. The representation height of F, $h(F)$, is the minimum height of a decision tree strongly representing F.*

Notice that the function computed by a decision tree of height h can be computed both by an h-CNF and by an h-DNF.

Our switching lemma will exploit a trade-off based on the minimum size of a set of variables that meets each term of a k-DNF. When this quantity is small, we can build a decision tree by querying these variables and recursing on the $(k-1)$-DNFs created. When this quantity is large, the DNF has many disjoint terms and is likely to be satisfied by a random restriction.

DEFINITION 3.2. *Let F be a DNF, and let S be a set of variables. If every term of F contains a variable from S, then we say that S* is a cover of F. *The* covering number of F, $c(F)$, *is the minimum cardinality of a cover of F.*

For example, the 3-DNF $xyz \vee \neg x \vee yw$ has covering number two.

The switching lemma is shown to hold for all distributions which satisfy certain properties. When we apply the switching lemma, we will show that the random restrictions used satisfy these properties.

THEOREM 3.3. *Let $k \geq 1$, let $s_0, \ldots, s_{k-1}$ and $p_1, \ldots, p_k$ be sequences of positive numbers, and let $\mathcal{D}$ be a distribution on partial assignments so that for every $i \leq k$ and every i-DNF G, if $c(G) > s_{i-1}$, then $\Pr_{\rho \in \mathcal{D}}[G \restriction_\rho \neq 1] \leq p_i$. Then for every k-DNF F,*

$$\Pr_{\rho \in \mathcal{D}}\left[h(F \restriction_\rho) > \sum_{i=0}^{k-1} s_i\right] \leq \sum_{i=1}^{k} 2^{\left(\sum_{j=i}^{k-1} s_j\right)} p_i.$$

Proof. We proceed by induction on k. First consider $k = 1$. If $c(F) \leq s_0$, then at most s_0 variables appear in F. We can construct a height $\leq s_0$ decision tree that strongly represents $F \restriction_\rho$ by querying all of the variables of $F \restriction_\rho$. On the other hand, if $c(F) > s_0$, then $\Pr_{\rho\in\mathcal{D}}[F \restriction_\rho \neq 1] \leq p_1$. Therefore, $h(F \restriction_\rho)$ is nonzero with probability at most $p_1 2^{\sum_{j=1}^{k-1} s_j} = p_1$ (because $k = 1$).

For the induction step, assume that the theorem holds for all k-DNFs, let F be a $(k+1)$-DNF, and let $s_0, \ldots, s_k$ and $p_1, \ldots, p_{k+1}$ be sequences of positive numbers satisfying the hypotheses of the theorem. If $c(F) > s_k$, then by the conditions of the lemma, $\Pr_{\rho\in\mathcal{D}}[F \restriction_\rho \neq 1] \leq p_{k+1}$. Because

$$p_{k+1} \leq \sum_{i=1}^{k+1} 2^{\sum_{j=i}^{k} s_j} p_i,$$

we have that $h(F \restriction_\rho)$ is nonzero with probability at most $\sum_{i=1}^{k+1} 2^{\sum_{j=i}^{k} s_j} p_i$.

Consider the case when $c(F) \leq s_k$. Let S be a cover of F of size at most s_k. Let π be any assignment to the variables in S. Because each term of F contains at least one variable from S, $F \restriction_\pi$ is a k-DNF. By combining the induction hypothesis with the union bound, we have that

$$\begin{aligned}\Pr_{\rho\in\mathcal{D}}\left[\exists \pi \in \{0,1\}^S \;\; h((F \restriction_\rho) \restriction_\pi) > \sum_{i=0}^{k-1} s_i\right] &\leq 2^{s_k}\left(\sum_{i=1}^{k} 2^{\left(\sum_{j=i}^{k-1} s_j\right)} p_i\right) \\ &< \sum_{i=1}^{k+1} 2^{\left(\sum_{j=i}^{k} s_j\right)} p_i.\end{aligned}$$

In the event that for all $\pi \in \{0,1\}^S$, $h((F \restriction_\rho) \restriction_\pi) \leq \sum_{i=0}^{k-1} s_i$, we construct a decision tree for $F \restriction_\rho$ as follows. First, query all variables in S unset by ρ, and then underneath each branch, β, simulate a decision tree of minimum height strongly representing $(F \restriction_\rho) \restriction_\beta$. For each such β, let $\pi = (\rho \cup \beta) \restriction_S$, and note that $h((F \restriction_\rho) \restriction_\beta) = h((F \restriction_\rho) \restriction_\pi)$. Therefore the height of the resulting decision tree is at most $s_k + \max_{\pi\in\{0,1\}^S} h((F \restriction_\rho) \restriction_\pi) \leq \sum_{i=0}^{k} s_i$.

Now we show that the decision tree constructed above strongly represents $F \restriction_\rho$. Let π be a branch of the tree. Notice that $\pi = \beta \cup \sigma$, where β is an assignment to the variables in $S \setminus \mathrm{dom}(\rho)$ and σ is a branch of a tree that strongly represents $(F \restriction_\rho) \restriction_\beta$. Consider the case that π leads to a leaf labeled 1. In this case, σ satisfies a term t' of $(F \restriction_\rho) \restriction_\beta$. We may choose a term t of F so that $t' = (t \restriction_{\rho\cup\beta})$, and $\pi = \beta \cup \sigma$ satisfies the term $t \restriction_\rho$ of $F \restriction_\rho$. Now consider the case that π leads to a leaf labeled 0. There are two cases, $(F \restriction_\rho) \restriction_\beta = 0$ and $(F \restriction_\rho) \restriction_\beta \neq 0$. If $(F \restriction_\rho) \restriction_\beta = 0$, then for every term t of $F \restriction_\rho$, t is inconsistent with β and hence with π. If $(F \restriction_\rho) \restriction_\beta \neq 0$, then because the subtree underneath β strongly represents $(F \restriction_\rho) \restriction_\beta$, for every term t of $(F \restriction_\rho) \restriction_\beta$, t is inconsistent with σ. Therefore, every term of $F \restriction_\rho$ is inconsistent with either β or σ, and thus with $\pi = \beta \cup \sigma$. □

We usually use this theorem in the following normal form for the parameters.

COROLLARY 3.4. *Let k, s, and d be positive integers, let γ and δ be real numbers from the range $(0, 1]$, and let $\mathcal{D}$ be a distribution on partial assignments so that for every k-DNF G, $\Pr_{\rho\in\mathcal{D}}[G \restriction_\rho \neq 1] \leq d2^{-\delta(c(G))^\gamma}$. For every k-DNF F,*

$$\Pr_{\rho\in\mathcal{D}}[h(F \restriction_\rho) > 2s] \leq dk2^{-\delta' s^{\gamma'}},$$

where $\delta' = 2(\delta/4)^k$ *and* $\gamma' = \gamma^k$.

Proof. Let $s_i = (\delta/4)^i(s^{\gamma^i})$ and $p_i = d2^{-4s_i}$. Note that $s_{i-1}/4 \geq (\delta/4)s_{i-1} = (\delta/4)(\delta/4)^{i-1}s^{\gamma^{i-1}} \geq (\delta/4)^i s^{\gamma^i} = s_i$. It follows that $\sum_{j=i}^{k} s_j \leq \sum_{j\geq i} s_i/4^{j-i} \leq 2s_i$. Also, for any i-DNF G, with $c(G) \geq s_{i-1}$, $\Pr_{\rho\in\mathcal{D}}[G\restriction_\rho \neq 1] \leq d2^{-\delta(c(G))^\gamma} \leq d2^{-\delta s_{i-1}^\gamma} = 2^{-\delta(\delta/4)^{i-1}(s^{\gamma^{i-1}})^\gamma} = d2^{-4s_i}$. Thus, we can apply Theorem 3.3 with parameters $p_1,\ldots,p_k,s_0,\ldots,s_{k-1}$. For every k-DNF F,

$$\Pr_{\rho\in\mathcal{D}}[h(F\restriction_\rho) > 2s] \leq \Pr_{\rho\in\mathcal{D}}\left[h(F\restriction_\rho) > \sum_{i=0}^{k-1} s_i\right] \leq \sum_{i=1}^{k} 2^{\left(\sum_{j=i}^{k-1} s_j\right)} p_i$$

$$\leq \sum_{i=1}^{k} 2^{2s_i}(d2^{-4s_i}) \leq dk2^{-2s_k} = dk2^{-\delta' s^{\gamma'}}. \qquad \square$$

3.1. Switching with small restrictions. In this subsection, we show that small, uniform restrictions meet the conditions for the switching lemma. Using Corollary 3.4, k-DNFs can then be converted into decision trees—*using restrictions that set only a polynomially small fraction of the bits*. We include it here for comparison with previous switching lemmas. Later, it will be used to prove the lower bound on Res(k) refutations of random CNFs. More complicated distributions are used for our other results.

DEFINITION 3.5. *Let* $n > 0$ *and* $p \in [0,1]$. *Define* $\mathcal{D}_p$ *to be the family of random restrictions which arises by assigning variables* $*$ *with probability* $1-p$, *and* 0, 1 *each with probability* $\frac{p}{2}$.

LEMMA 3.6. *Let* $i \geq 1$, *let* G *be an* i*-DNF, and let* ρ *be chosen from* $\mathcal{D}_p$. *Then* $\Pr[G\restriction_\rho \neq 1] \leq e^{-\frac{c(G)p^i}{i2^i}}$.

Proof. Because every covering set of G has size at least $c(G)$, there is a set of variable-disjoint terms of size at least $c(G)/i$ (such a set can be found by greedily choosing a maximal set of disjoint terms). Each of these variable-disjoint terms is satisfied with independent probability at least $(p/2)^i$. Therefore,

$$\Pr_{\rho\in\mathcal{D}_p}[G\restriction_\rho \neq 1] \leq \left(1-\left(\frac{p}{2}\right)^i\right)^{\frac{c(G)}{i}} \leq e^{-\left(\frac{p}{2}\right)^i\frac{c(G)}{i}} = e^{-\frac{c(G)p^i}{i2^i}}. \qquad \square$$

Combining this with the switching lemma shows that a k-DNF is strongly represented by a short decision tree when restricted.

COROLLARY 3.7. *Let* $k \geq 1$ *be given. There exists* $\gamma > 0$ *so that for any* k*-DNF* F, $w > 0$, $p \geq n^{-1/(2k^2)}$, $\Pr_{\rho\in\mathcal{D}_p}[h(F\restriction_\rho) > w] \leq k2^{-\gamma w n^{-1/2}}$.

Proof. In the notation of Corollary 3.4, set $p = n^{-1/2k^2}$, $d = 1$, $\gamma = 1$, $s = w/2$, and $\delta = (\log e)\frac{p^k}{k2^k} = (\log e)\frac{n^{-1/2k}}{k2^k}$. Combining Lemma 3.6 with Corollary 3.4 shows that for every k-DNF F,

$$\Pr_{\rho\in\mathcal{D}_p}[h(F\restriction_\rho) > w] \leq k2^{-2(w/2)(\delta^k/4^k)} = k2^{-w(\log e)^k n^{-1/2}/4^k k^k 2^{k^2}}.$$

Because k is fixed, we may take $\gamma = (\log e)^k/4^k k^k 2^{k^2}$. $\square$

4. An application to circuit bottom fan-in. Our first application of the switching lemma is an exponential-size separation between depth d circuits of bottom fan-in k and depth d circuits of bottom fan-in $k+1$.

Our circuits are organized into alternating layers of AND and OR gates, with connections appearing only between adjacent levels. NOT gates may have only variables as their inputs. The output gate is said to be at level one, the gates feeding into the output gate are said to be at level two, and so forth. The depth of a circuit is the maximum depth of an AND or OR gate in the circuit. The size of a circuit is the number of AND and OR gates appearing in it. The *bottom fan-in* of a depth d circuit is the maximum number of inputs of a gate at level d. For more detail on the basics of constant depth circuits, consult the survey by Boppana and Sipser [10].

4.1. The functions.

DEFINITION 4.1 (see [34, 10]). *Let integers d and $m_1, \ldots, m_d$ be given, and let there be variables $x_{i_1,\ldots,i_d}$ for $1 \leq i_j \leq m_j$.*

$$f_d^{m_1,\ldots,m_d} = \bigwedge_{i_1 \leq m_1} \bigvee_{i_2 \leq m_2} \cdots \bigodot_{i_d \leq m_d} x_{i_1,\ldots,i_d},$$

where $\bigodot = \bigvee$ if d is even, and $\bigodot = \bigwedge$ if d is odd.

The Sipser function f_d^m *is $f_d^{m_1,\ldots,m_d}$, with $m_1 = \sqrt{m/logm}$, $m_2 = \cdots = m_{d-1} = m$, and $m_d = \sqrt{dm \log m/2}$.*

The modified Sipser function $g_d^{m,k}$ *is $f_{d+1}^{m_1,\ldots,m_d,k}$, with $m_1 = \sqrt{m/logm}$, $m_2 = \cdots = m_{d-1} = m$, and $m_d = 4\sqrt{dm \log m/2}$.*

Notice that the function f_d^m depends on $m^{d-1}\sqrt{d/2}$ many variables and can be computed by a circuit of depth d and size linear in the number of variables. Furthermore, we will often identify these functions with the circuits defining them.

Our result builds upon the earlier result that it is impossible to decrease the bottom fan-in of a circuit computing a Sipser function without increasing the size or the depth. Moreover, an OR of depth d, small bottom fan-in circuits requires exponential size to compute f_d^m.

THEOREM 4.2 (see [21]). *For all $d \geq 1$, there exists $\epsilon_d > 0$ so that if a depth d, bottom fan-in k circuit with an AND gate at the output and at most S gates in levels 1 through $d-1$ computes f_d^m, then either $k \geq m^{\epsilon_d}$ or $S \geq 2^{m^{\epsilon_d}}$.*

For all $d \geq 1$, there exists $\beta_d > 0$ so that if a depth $d+1$, bottom fan-in k circuit with an OR gate at the output and at most S gates in levels 1 through d computes f_d^m, then either $S \geq 2^{m^{\beta_d}}$ or $k \geq m^{\beta_d}$.

We use the modified Sipser function $g_d^{m,k+1}$ to obtain the exponential separation between depth $d+1$, bottom fan-in $k+1$ and depth $d+1$, bottom fan-in k circuits. For each $i_1, \ldots, i_d$, we say that the variables $x_{i_1,\ldots,i_d,1}, \ldots, x_{i_1,\ldots,i_d,k}$ come from *block* $(i_1, \ldots, i_d)$. Variables in the same block occur in the same bottom-level conjunction of $g_d^{m,k}$. Notice that the function $g_d^{m,k}$ has $4m^{d-1}\sqrt{d/2}$ many blocks and $4km^{d-1}\sqrt{d/2}$ many variables. Moreover, it can be computed by a circuit of depth $d+1$, bottom fan-in k and size linear in the number of variables.

4.2. The lower bounds. We will show that depth $d+1$ circuits with bottom fan-in k require exponential size to compute $g_d^{m,k+1}$. In light of Theorem 4.2, it suffices to consider only circuits with an AND gate at the output level. Furthermore, we consider only the case when d is even. This ensures that all gates at depth d are OR gates. The case for odd d is dual and we simply invert the random restriction used. Each gate at depth d computes a k-DNF, and we will apply random restrictions which almost certainly collapse all of the k-DNFs to narrow CNFs and thus collapse the circuits to depth d circuits with small bottom fan-in. On the other hand, the

random restrictions will probably leave $g_d^{m,k+1}$ containing f_d^m as a subfunction, and thus we obtain a contradiction to Theorem 4.2.

DEFINITION 4.3. *Let m, d, and k be given. Set $m_1 = \sqrt{m/logm}$, $m_2 = \cdots = m_{d-1} = m$, and $m_d = 4\sqrt{dm \log m/2}$.*

Let $\mathcal{B}_{d,0}^{m,k+1}$ be the random distribution on partial assignments given by the following experiment: For each $i_1 \leq m_1, \ldots, i_d \leq m_d$, with independent probability $\frac{1}{2}$ either set $x_{i_1,\ldots,i_d,j} = *$, for all $j \in [k+1]$, or uniformly choose a $0/1$ assignment to $\{x_{i_1,\ldots,i_d,j} \mid j \in [k+1]\}$ which sets at least one of the variables to 0. The dual distribution, $\mathcal{B}_{d,1}^{m,k+1}$, selects a restriction according to $\mathcal{B}_{d,0}^{m,k+1}$ and then inverts the 0's and 1's.

LEMMA 4.4. *Let $k \geq 1$ be given. There exists a constant $\gamma_k > 0$ so that for every k-DNF F,*

$$\Pr_{\rho \in \mathcal{B}_{d,0}^{m,k+1}} [F \restriction_\rho \neq 1] \leq 2^{-\gamma_k c(F)}.$$

Proof. We say that two terms T and T' are *block-disjoint* if no variable of T shares a block with a variable of T'. More formally, whenever a variable $x_{i_1,\ldots,i_{d+1}}$ appears in T and a variable $x_{j_1,\ldots,j_{d+1}}$ appears in T', we have that $(i_1, \ldots, i_d) \neq (j_1, \ldots, j_d)$. Because each term involves at most k variables, there must be a set of $c(F)/k$ many variable-disjoint terms, and hence a set of $c(F)/(k(k+1))$ many block-disjoint terms.

We now show that each term is satisfied with probability at least $\frac{1}{6^k}$. Because the literals of a term come from at most k distinct blocks, the chance that every variable in the term is set to 0 or 1 is at least $\frac{1}{2^k}$. Conditioned on this event, the probability of satisfying the term is at least $\frac{1}{3^k}$. To see this, consider the chance of satisfying each literal of the term in turn, conditioned on the event of satisfying the previous literals. If a variable from that block has already been set to 0, then clearly the probability of satisfying the current literal is $\frac{1}{2}$. If not, then suppose there are l variables in the block of the current variable that have not yet been set to a value. The probability of satisfying the current literal is at least $(2^{l-1} - 1)/(2^l - 1)$. Because there are $k+1$ variables and the term has size at most k, $l \geq 2$, and thus the probability is at least $\frac{1}{3}$.

The events of satisfying block-disjoint terms are independent; therefore we have

$$\Pr_{\rho \in \mathcal{B}_{d,0}^{m,k+1}} [F \restriction_\rho \neq 1] \leq \left(1 - \frac{1}{6^k}\right)^{c(F)/(k(k+1))}.$$

Set $\gamma_k = -\log_2(1 - \frac{1}{6^k})/(k(k+1))$. □

Symmetrically, the dual result holds for k-CNFs when we apply a random restriction from $\mathcal{B}_{d,1}^{m,k+1}$.

LEMMA 4.5. *Let $k \geq 1$ be given. There exists a constant ϵ_k so that for all d, for all w sufficiently large with respect to k, and for every depth $d+1$, bottom fan-in k circuit C of size $S \leq 2^{\epsilon_k w}$, when ρ is chosen from $\mathcal{B}_{d,0}^{m,k+1}$ ($\mathcal{B}_{d,1}^{m,k+1}$), with probability at least $3/4$, $C \restriction_\rho$ is equivalent to a depth d, bottom fan-in w circuit with at most S gates in levels 1 through $d-1$.*

Proof. We will solve for the particular values of ϵ_k and w after going through the calculations.

We consider the case when d is even; the case when d is odd is handled by using the restrictions $\mathcal{B}_{d,1}^{m,k+1}$ instead of $\mathcal{B}_{d,0}^{m,k+1}$. Each gate at depth d is an OR gate and its inputs are AND gates of fan-in at most k. For each gate g at depth d, we let F_g denote the k-DNF computed by the subcircuit at g.

Suppose that there is a partial assignment $\rho \in \mathcal{B}^{m,k}_{d,0}$ so that for each depth d gate g of C, $h(F_g \restriction_\rho) < w$. For each g at depth d, let T_g be the shortest decision tree representing $F_g \restriction_\rho$. We can compute $C \restriction_\rho$ with a depth d, bottom fan-in w circuit with at most S gates in levels 1 through $d-1$ by starting with C, replacing each level d gate g with the conjunction of the negated branches of $\mathrm{Br}_0(T_g)$, and then merging these conjuncts with the AND gate at depth $d-1$ to which g sends its output.

We now show that for ρ chosen according to the distribution $\mathcal{B}^{m,k}_{d,0}$, with probability at least $\frac{3}{4}$, every depth d gate g of C has $h(F_g \restriction_\rho) < w$.

Let g be a depth d gate of the circuit. By combining Lemma 4.4 with Corollary 3.4, setting $d = 1$, $\gamma = 1$, $s = w/2$, and $\delta = \gamma_k$ shows that

$$\Pr_{\rho \in \mathcal{B}^{m,k}_{d,0}} [h(F_g) > w] \leq k 2^{-w\gamma_k^k/4^k}.$$

Because there are at most $S = 2^{\epsilon_k w}$ many gates at depth d, by the union bound, there exists a gate with $h(F_g) > w$ with probability at most $2^{w(\epsilon_k - \gamma_k^k/4^k) + \log k}$. We simply take ϵ_k sufficiently small so that this probability is less than $1/4$. □

THEOREM 4.6. *For all $k \geq 1$, $d \geq 1$, there exists $\epsilon_k, \epsilon_d > 0$ so that for every m sufficiently large, every size S, depth $d+1$, bottom fan-in k circuit for $g_d^{m,k+1}$ has $S \geq 2^{\epsilon_k m^{\epsilon_d}}$.*

Proof. We will have to take m sufficiently large to apply Theorem 4.2 and Lemma 4.5, and large enough for an application of the Chernoff bounds. Set $w = m^{\epsilon_d}$ (with ϵ_d from Theorem 4.2) and $S = 2^{\epsilon_k w}$ (with ϵ_k from Lemma 4.5). Furthermore, we consider the case when d is even; the case when d is odd is handled by using the restrictions $\mathcal{B}^{m,k+1}_{d,1}$ instead of $\mathcal{B}^{m,k+1}_{d,0}$.

Suppose, for the sake of contradiction, that C is a size S, depth d, bottom fan-in k circuit computing $g_d^{m,k+1}$.

Fix an OR gate at depth d in $g_d^{m,k+1}$. When ρ is chosen from the distribution $\mathcal{B}^{m,k+1}_{d,0}$, the expected number of blocks underneath this gate that are left unset is $2\sqrt{dm \log m/2}$. By the Chernoff bounds, with probability at most $e^{-\sqrt{dm \log m/2}/4}$ there are fewer than $\sqrt{dm \log m/2}$ blocks left unset by ρ underneath this gate.

Because there are $m^{d-3/2}/\sqrt{\log m}$ many depth d gates in $g_d^{m,k+1}$, by the union bound, the probability that there exists a depth d gate underneath which there are fewer than $\sqrt{dm \log m/2}$ many blocks unset is at most $(m^{d-3/2}/\sqrt{\log m}) e^{-\sqrt{dm \log m/2}/4}$. This tends to 0 as m tends to infinity.

On the other hand, by Lemma 4.5, with probability at least $3/4$, $C \restriction_\rho$ is equivalent to a depth d, bottom fan-in w circuit with at most S gates in levels 1 through $d-1$.

Therefore we may choose $\rho \in \mathcal{B}^{m,k+1}_{0,d}$ so that underneath each depth d gate of $g_d^{m,k+1}$ there are at least $\sqrt{dm \log m/2}$ many blocks unset by ρ, and $C \restriction_\rho$ is equivalent to a depth d, bottom fan-in w circuit with $\leq S$ gates in levels $1, \ldots, d-1$.

Because $C \restriction_\rho$ computes $g_d^{m,k+1} \restriction_\rho$, a restriction of it computes f_d^m: set some blocks to 0 and collapse the other blocks to a single variable. This gives a depth d circuit with $\leq S$ gates in levels $1, \ldots, d-1$, and bottom fan-in w that computes f_d^m, a contradiction to Theorem 4.2. □

5. Decision trees and Res(k) refutations. All of our lower bounds for Res(k) refutations use the fact that when the lines of a Res(k) refutation can be strongly represented by short decision trees, the Res(k) refutation can be converted into a narrow resolution refutation.

THEOREM 5.1. *Let $\mathcal{C}$ be a set of clauses of width $\leq h$. If $\mathcal{C}$ has a Res(k) refutation so that for each line F of the refutation, $h(F) \leq h$, then $w_R(\mathcal{C}) \leq kh$.*

Proof. We will use the short decision trees to construct a narrow refutation of $\mathcal{C}$ in resolution augmented with subsumption inferences: whenever $A \subseteq B$, infer B from A. These new inferences simplify our proof, but they may be removed from the resolution refutation without increasing the size or the width.

For a line F of the Res(k) refutation, let T_F be a decision tree of minimum height that strongly represents F. Notice that for each initial clause $C \in \mathcal{C}$, T_C is the tree that queries the (at most h) variables in C, stopping with a 1 if the clause becomes satisfied and stopping with a 0 if the clause becomes falsified.

For any partial assignment π let C_π be the clause of width $\leq h$ that contains the negation of every literal in π, i.e., the clause that says that branch π was not taken. We construct a resolution refutation of width $\leq kh$ by deriving C_π for each line F of the refutation and each $\pi \in \mathrm{Br}_0(T_F)$.

Notice that for $\pi \in \mathrm{Br}_0(T_\emptyset)$, $C_\pi = \emptyset$, and for each $C \in \mathcal{C}$, for the unique $\pi \in \mathrm{Br}_0(T_C)$, $C_\pi = C$.

Let F be a line of the refutation that is inferred from previously derived formulas $F_1, \ldots, F_j$, $j \leq k$. Assume we have derived all $C_\pi \in \mathrm{Br}_0(T_{F_i})$ for $1 \leq i \leq j$. To guide the derivation of $\{C_\pi \mid \pi \in \mathrm{Br}_0(T_F)\}$, we construct a decision tree that represents $\bigwedge_{i=1}^{j} F_i$. The tree (call it T) begins by simulating T_{F_1} and outputting 0 on any 0-branch of T_{F_1}. On any 1-branch, it then simulates T_{F_2}, etc. If all j branches are 1, T outputs 1; otherwise T outputs 0. The height of T is at most $jh \leq kh$, so the width of any such C_π, with $\pi \in \mathrm{Br}(T)$, is at most kh. The set of clauses $\{C_\sigma \mid \sigma \in \mathrm{Br}_0(T)\}$ can be derived from the previously derived clauses by subsumption inferences because every $\sigma \in \mathrm{Br}_0(T)$ contains some $\pi \in \bigcup_{i=1}^{j} \mathrm{Br}_0(T_{F_i})$.

We now show that for every $\sigma \in \mathrm{Br}_1(T)$, there exists a $t \in F$ so that σ satisfies t. Choose $\pi_1 \in \mathrm{Br}_1(T_{F_1}), \ldots, \pi_j \in \mathrm{Br}_1(T_{F_j})$ so that $\pi_1 \cup \cdots \cup \pi_j = \sigma$. Because the decision trees $T_{F_1}, \ldots, T_{F_j}$ strongly represent the k-DNFs $F_1, \ldots, F_j$, there exist terms $t_1 \in F_1, \ldots, t_j \in F_j$ so that $\bigwedge_{i=1}^{j} t_i$ is satisfied by σ. By strong soundness of Res(k), there exists $t \in F$ so that σ satisfies t.

Let $\sigma \in \mathrm{Br}_0(T_F)$ be given. Because T_F strongly represents F, σ falsifies all terms of F. By the preceding paragraph, for all $\pi \in \mathrm{Br}(T)$, if π is consistent with σ, then $\pi \in \mathrm{Br}_0(T)$ (otherwise, σ would not falsify the term of F satisfied by π). For each node v in T, let π_v be the path (viewed as a partial assignment) from the root to v. Bottom-up, from the leaves to the root, we recursively derive $C_{\pi_v} \vee C_\sigma$ for each v so that π_v is consistent with σ. When we reach the root, we will have derived C_σ. If v is a leaf, then $\pi_v \in \mathrm{Br}_0(T)$ so it has already been derived. If v is labeled with a variable that appears in σ, call it x, then there is a child u of v with $\pi_u = \pi_v \cup \{x\}$. Therefore, $C_{\pi_v} \vee C_\sigma = C_{\pi_u} \vee C_\sigma$. By induction, the clause $C_{\pi_u} \vee C_\sigma$ has already been derived. If v is labeled with a variable x that does not appear in σ, then for both of the children of v, call them v_1, v_2, the paths π_{v_1} and π_{v_2} are consistent with σ. Moreover, $C_{\pi_{v_1}} \vee C_\sigma = x \vee C_{\pi_v} \vee C_\sigma$ and $C_{\pi_{v_2}} \vee C_\sigma = \neg x \vee C_{\pi_v} \vee C_\sigma$. Resolving these two previously derived clauses gives us $C_{\pi_v} \vee C_\sigma$. ∎

We will use this theorem after we apply a random restriction which simultaneously collapses every line of a Res(k) refutation to a short decision tree. Hence, we can use a width lower bound for resolution refutations of a restricted tautology to give a size lower bound for Res(k) refutations of the original tautology.

COROLLARY 5.2. *Let $\mathcal{C}$ be a set of clauses of width $\leq h$, let Γ be a Res(k) refutation of $\mathcal{C}$, and let ρ be a partial assignment so that for every line F of Γ,*

$h(F\restriction_\rho) \leq h$. Then $w_R(\mathcal{C}\restriction_\rho) \leq kh$.

6. Lower bounds for the weak pigeonhole principle.

DEFINITION 6.1. *The m to n* pigeonhole principle, *PHP_n^m, is the following set of clauses:*

1. *For each $i \in [m]$, $\bigvee_{j\in[n]} x_{i,j}$.*
2. *For each $i, i' \in [m]$ with $i \neq i'$, $\neg x_{i,j} \vee \neg x_{i',j}$.*

THEOREM 6.2. *For every $c > 1$, there exists $\epsilon > 0$ so that for all n sufficiently large, if $k \leq \sqrt{\log n / \log\log n}$, then every Res($k$) refutation of PHP_n^{cn} has size at least 2^{n^ϵ}.*

The idea of the proof for Theorem 6.2 is as follows: Suppose there is a small Res(k) refutation of the weak pigeonhole principle. Then by applying a random restriction we obtain a low-width resolution refutation of the restricted pigeonhole principle. By the well-known lower bounds on the width of resolution refutations of the pigeonhole principle, this is impossible.

In order to make the random restriction method work, we prove lower bounds for the pigeonhole principle restricted to a low degree graph. Because these principles reduce to the pigeonhole principle by setting some variables to 0, this suffices to prove lower bounds for the pigeonhole principle. The difficulty with applying random restrictions directly to the clauses of the pigeonhole principle is that there are clauses of high width which are not satisfied with very high probability. If we were to choose a random subset of the holes and place into each hole a randomly chosen pigeon, then a clause of the form $\bigvee_{i=1}^m x_{i,j}$ would be satisfied with probability no better than the chance that hole j is in the random subset (this will be no better than a constant in our proof). At the heart of this problem is that each hole j appears in cn distinct variables, $x_{1,j}, \ldots, x_{cn,j}$, and restricting the principle to low-degree graphs solves this.

DEFINITION 6.3. *Let $G = (U \cup V, E)$ be a bipartite graph. The* pigeonhole principle of G, PHP(G), *is the following set of clauses:*

1. *For each $u \in U$*

$$\bigvee_{\substack{v\in V\\ \{u,v\}\in E}} x_{u,v}.$$

2. *For each $u, u' \in [m]$, with $u \neq u'$, and each $v \in V$ with $\{u, v\} \in E$ and $\{u', v\} \in E$,*

$$\neg x_{u,v} \vee \neg x_{u',v}.$$

DEFINITION 6.4. *Let $G = (U \cup V, E)$ be a bipartite graph. The* maximum degree of G, $\Delta(G)$, *is defined to be* $\max_{v\in V} \deg v$.

Furthermore, we assume that all Res(k) refutations have been put into a normal form in which no term of any DNF asks that two pigeons be mapped to the same hole. See, for example, [3].

DEFINITION 6.5. *Let $G = (U \cup V, E)$ be a bipartite graph. A term is said to be in* pigeon-normal-form *if it does not contain two literals $x_{u,v}$ and $x_{u',v}$ with $u \neq u'$. A DNF is said to be in pigeon-normal-form if all of its terms are in pigeon-normal-form and a Res(k) refutation is said to be in pigeon-normal-form if every line is in pigeon-normal-form.*

Every Res(k) refutation of $PHP(G)$ can be transformed into a refutation in pigeon-normal-form which at most doubles the number of lines in the proof. When

there is an AND-introduction inference that creates a line not in pigeon-normal-form, say

$$\frac{(A \vee x_{u,v}) \quad (A \vee x_{u',v}) \quad \cdots \quad (A \vee l_j)}{A \vee \left(x_{u,v} \wedge x_{u',v} \wedge \bigwedge_{i=3}^{j} l_i \right)},$$

replace the inference by a derivation that cuts $A \vee x_{u',v}$ with $\neg x_{u,v} \vee \neg x_{u',v}$ to obtain $A \vee \neg x_{u,v}$. Cut this with $A \vee x_{u,v}$ to obtain A. We may proceed through the rest of the proof with A because it subsumes $A \vee x_{u,v} \wedge x_{u',v} \wedge \bigwedge_{i=3}^{j} l_i$.

6.1. Random restrictions.

DEFINITION 6.6. *For a bipartite graph $G = (U \cup V, E)$ and a real number $p \in [0,1]$, let $\mathcal{M}_p(G)$ denote the distribution on partial assignments which arises from the following experiment:*

Independently, for each $v \in V$, with probability $1-p$ choose to match v, and with probability p leave v unmatched. If v is matched, uniformly select a neighbor u of v, set $x_{u,v}$ to 1, and for every $w \neq u$ that is a neighbor of v, set $x_{w,v}$ to 0. Moreover, for each $v' \neq v$, set $x_{u,v'} = 0$.

Let V_ρ be the set of vertices of V matched by ρ, let U_ρ be the set of vertices of U matched by ρ, and let $S_\rho = U_\rho \cup V_\rho$.

These restrictions randomly associate pigeons with holes in an injective way. While some pigeons can be associated with multiple holes, no two pigeons can be associated with the same hole. It is easy to check that for any $\rho \in \mathcal{M}_p(G)$, we have that $PHP(G) \restriction_\rho = PHP(G - S_\rho)$.

LEMMA 6.7. *Let $p \in [0,1]$, $i \in [k]$ be given. Let $G = (U \cup V, E)$ be a bipartite graph with $\Delta = \Delta(G)$. Let F be an i-DNF in pigeon-normal-form.*

$$\Pr_{\rho \in \mathcal{M}_p(G)} [F \restriction_\rho \neq 1] \leq 2^{-\frac{(\log e)(1-p)^i c(F)}{i\Delta^{i+1}}}.$$

Proof. For a term T, define the *holes of* T as $\mathrm{Holes}(T) = \{v \mid x_{u,v} \in T \text{ or } \neg x_{u,v} \in T\}$. We say that two terms T and T' are *hole-disjoint* if $\mathrm{Holes}(T) \cap \mathrm{Holes}(T') = \emptyset$.

Because F contains at least $c(F)/i$ many variable-disjoint terms, and each hole $v \in V$ appears in at most Δ many variables, F must contain at least $c(F)/i\Delta$ many hole-disjoint terms.

The events of satisfying hole-disjoint terms are independent, and for a given term, T, the probability that $T \restriction_\rho = 1$ is at least $(1-p)^i/\Delta^i$. This is because with probability $(1-p)^i$, every hole of T is matched, and with probability at least $1/\Delta^i$ the holes are matched in a way that satisfies T (here we use the fact that F is in pigeon-normal-form). Therefore, we have the following inequalities:

$$\Pr_\rho [F \restriction_\rho \neq 1] \leq \left(1 - (1-p)^i/\Delta^i\right)^{\frac{c(F)}{i\Delta}} \leq \left(e^{-(1-p)^i/\Delta^i}\right)^{\frac{c(F)}{i\Delta}} = 2^{-\frac{(\log e)(1-p)^i c(F)}{i\Delta^{i+1}}}. \qquad \square$$

6.2. Width lower bounds for resolution. For the lower bound proof to work, we need a graph G so that after the application of a random restriction ρ, with high probability, $PHP(G) \restriction_\rho$ requires high width to refute in resolution. We call such graphs *robust*, and in this subsection we probabilistically demonstrate robust, low-degree graphs.

DEFINITION 6.8. *A bipartite graph G is said to be* (p, w)-robust *if, when ρ is selected from $\mathcal{M}_p(G)$, with probability at least $\frac{1}{2}$, $w_R(PHP(G) \restriction_\rho) \geq w$.*

All we need for the size lower bound is the following lemma, which is proven probabilistically in section 6.2.1. Readers who believe that random graphs should be robust can skip to the proof of the lower bound.

LEMMA 6.9. *For all $c > 1$, there exists $d > 0$, so that for n sufficiently large, there exists a $(3/4, n/24)$-robust graph with $\Delta(G) \leq d \log n$ on the vertex sets $[cn]$ and $[n]$.*

6.2.1. Existence of robust graphs. As a starting point, we use a now standard lower bound of $w_R(PHP(G))$ in terms of the expansion of G.

DEFINITION 6.10. *For a vertex $u \in U$, let $N(u)$ be its set of neighbors. For a subset $V' \subseteq V$, let its boundary be*

$$\partial V' = \{u \in U \mid |N(u) \cap V'| = 1\}.$$

A bipartite graph G is an (m, n, r, f)-expander if $|V| = m$, $|U| = n$, and for all $V' \subseteq V$, $|V'| \leq r$, $|\partial V'| \geq f|V'|$.

THEOREM 6.11 (see [8]). *If G is a bipartite graph that is an (m, n, r, f)-expander, then $w_R(PHP(G)) \geq rf/2$.*

DEFINITION 6.12. *Let $G_{m,n,p}$ be the distribution on bipartite graphs with vertex sets $[m]$ and $[n]$ in which every edge is included with independent probability p.*

The following lemma was proven by Atserias, Bonet and Esteban [3].

LEMMA 6.13 (see [3]). *Let $m = cn$, $q = \frac{48c \ln m}{m}$, $\alpha = \frac{1}{mq}$, and $f = \frac{nq}{6}$. Let G be selected according to the distribution $G_{m,n,q}$.*

$$\Pr_G [G \text{ is an } (m, n, \alpha m, f)\text{-expander }] \geq \frac{2}{3}.$$

LEMMA 6.14. *Let $m = cn$, let $q \geq \frac{48c \ln m}{m}$, and let G be selected according to the distribution $G_{m,n,q}$.*

$$\Pr_G [w_R(PHP(G)) \geq n/12] \geq \frac{2}{3}.$$

Proof. Let $\alpha = \frac{1}{mq}$ and $f = \frac{nq}{6}$. Because $\alpha m f/2 = (1/mq)m(nq/6)/2 = n/12$, an application of Theorem 6.11 shows that when G is selected according to $G_{m,n,\frac{48c \ln m}{m}}$, with probability at least $\frac{2}{3}$, $w_R(PHP(G)) \geq n/12$.

Now consider G selected according to $G_{m,n,q}$, with $q \geq \frac{48c \ln m}{m}$. Whenever G_0 is an edge-induced subgraph of G_1, $w_R(PHP(G_1)) \geq w_R(PHP(G_0))$ because a refutation of $PHP(G_1)$ can always be transformed into a refutation of $PHP(G_0)$ by setting some variables to 0. Therefore, by increasing the probability of including an edge, the probability of having no small resolution refutation for $PHP(G)$ only increases. ∎

We now prove Lemma 6.9.

Proof. Set $m = cn$, $p = \frac{3}{4}$, and $q = \frac{192c \ln m}{m}$. Consider the joint distribution that arises by selecting G according to $G_{m,n,q}$ and ρ according to $\mathcal{M}_{3/4}(G)$. We will bound the probability that the degree is too large, that too many holes are matched, and that the restricted graph is expanding.

By the Chernoff bounds, for each $v \in [n]$ the probability that v has degree in excess of $2mq$ is at most $e^{-mq/4}$. By the union bound, the probability that there exists some $v \in [n]$ of degree in excess of $2mq$ is at most $ne^{-mq/4}$. Similarly, the probability that there exists some $v \in [m]$ of degree in excess of $2mq$ is at most $me^{-nq/4}$. Therefore, the probability that the maximum degree of G exceeds $2mq$ is bounded as follows:

$$ne^{-mq/4} + me^{-nq/4} = ne^{-m192c \ln m/m} + me^{-n192c \ln m/m} = O(n^{-191}).$$

Remember that V_ρ is the set of holes matched by the restriction ρ. By the Chernoff bounds, the probability that $|V_\rho| \geq 2n(1-p) = n/2$ is at most $e^{-\frac{n(1-p)}{4}} = e^{-n/16}$.

We now bound the probability that $G - S_\rho$ is an expander. First, up to renaming vertices, $G - S_\rho$ is distributed as $G_{m_\rho,n_\rho,q}$, with $n_\rho = n - |V_\rho|$ and $m_\rho = m - |U_\rho|$. This is because for fixed sets of vertices $V_0 \subseteq V$ and $U_0 \subseteq U$, when we condition on the event that $V_\rho = V_0$ and $U_\rho = U_0$, the edges $\{u, v\}$ with $u \in U \setminus U_0$ and $v \in V \setminus V_0$ are included in $G - S_\rho$ with independent probability q. Now, condition on the event that $|V_\rho| \leq n/2$. We have that $m_\rho = m - |U_\rho| \geq m - n/2 \geq m/2$ and thus $q = 192c \ln m/m \geq 192c \ln m_\rho/m \geq 192c \ln m_\rho/2m_\rho = 48 \cdot 2c \ln m_\rho/m_\rho$. Because $\frac{m_\rho}{n_\rho} \leq \frac{cn}{n/2} = 2c$, we can apply Lemma 6.14 and deduce that $w_R(PHP(G - S_\rho)) \geq n_\rho/12$ with probability at least $\frac{2}{3}$. Because $n_\rho \geq n/2$, with the same probability, $w_R(G - S_\rho) \geq n/24$.

Combining the three inequalities from the preceding paragraphs shows that the probability that G contains a vertex of degree in excess of $192c \ln m$, that V_ρ contains more than $n/2$ vertices, or that $w_R(PHP(G - S_\rho)) < n/24$ is at most

$$\frac{1}{3} + O(n^{-191}) + e^{-n/16}.$$

For sufficiently large n, this probability is bounded above by $\frac{1}{2}$. By averaging over the choices of the edges, there exists a bipartite graph G on vertex sets $[cn]$ and $[n]$ with $\Delta(G) \leq 2mq = 384c \ln(cn)$, so that upon selection of $\rho \in \mathcal{R}_{3/4}(G)$, $w_R(G - S_\rho) \geq n/24$ with probability at least $\frac{1}{2}$. □

6.3. Size lower bounds for Res(k). To prove the size lower bounds for Res(k) refutations of PHP_n^{cn} we first prove size lower bounds for the weak pigeonhole principle restricted to a robust graph, and then we reduce these principles to PHP_n^{cn}.

LEMMA 6.15. *For any $c > 1$ and $d > 0$, there exists $\epsilon > 0$ so that for all n sufficiently large, if $k \leq \sqrt{\log n / \log\log n}$ and G is a $(3/4, n/24)$-robust bipartite graph with vertex sets of sizes cn and n and $\Delta(G) \leq d \log n$, then $S_k(PHP(G)) \geq 2^{n^\epsilon}$.*

Proof. By Lemma 6.7, for each $i \in [k]$ and every i-DNF F,

$$\Pr_{\rho \in \mathcal{M}_{3/4}(G)} [F \restriction_\rho \neq 1] \leq 2^{-\frac{(\log e)(1-3/4)^i c(F)}{i(d \log n)^{i+1}}} = 2^{-\frac{(\log e) c(F)}{i \cdot 4^i (d \log n)^{i+1}}}.$$

In the interest of obtaining a better bound, we will not appeal to Corollary 3.4, but directly apply Theorem 3.3. We define sequences $s_0, \ldots, s_k$ and $p_1, \ldots, p_k$ for use in the switching lemma. Set $s_0 = \frac{3}{4k}(n/24 - 1)$. For each $i \in [k]$, set

$$s_i = \left(\frac{\log e}{2i4^i (d \log n)^{i+1}} \right) s_{i-1}.$$

For each $i \in [k]$ set $p_i = 2^{-2s_i}$. For any i-DNF F so that $c(F) > s_{i-1}$, we have the following inequality:

$$\Pr_{\rho \in \mathcal{M}_{3/4}(G)} [F \restriction_\rho \neq 1] < 2^{-\frac{(\log e) s_{i-1}}{i \cdot 4^i (d \log n)^{i+1}}} = 2^{-2\frac{(\log e) s_{i-1}}{2i4^i (d \log n)^{i+1}}} = 2^{-2s_i} = p_i.$$

It can be shown that there exists $\epsilon > 0$ so that for sufficiently large n, $s_k \geq n^\epsilon$. To avoid distraction, we show this in Lemma 6.17 at the end of this subsection. Suppose that Γ is a Res(k) refutation of $PHP(G)$ of size less than 2^{n^ϵ}.

By an application of Theorem 3.3 and the union bound, we have

$$\Pr_{\rho\in\mathcal{M}_{3/4}(G)}\left[\exists F\in\Gamma,\ h(F\restriction_\rho)>\sum_{i=0}^{k-1}s_i\right]\le 2^{n^\epsilon}\sum_{i=1}^{k}p_i2^{\sum_{j=i}^{k-1}s_j}$$

$$\le 2^{s_k}\sum_{i=1}^{k}p_i2^{\sum_{j=i}^{k-1}s_j}=\sum_{i=1}^{k}p_i2^{\sum_{j=i}^{k}s_j}.$$

We now bound $p_i2^{\sum_{j=i}^{k}s_j}$ for each $i>0$. For each i, $s_{i+1}<\frac{1}{4}s_i$ so $\sum_{j=i}^{k-1}s_j\le\frac{4}{3}s_i$. This gives us the following inequality:

$$p_i2^{\sum_{j=i}^{k-1}s_j}=2^{\sum_{j=i}^{k-1}s_j-2s_i}\le 2^{(4/3-2)s_i}=2^{-(2/3)s_i}\le 2^{-(2/3)s_k}\le 2^{-(2/3)n^\epsilon}.$$

Therefore,

$$\begin{aligned}&\Pr_{\rho\in\mathcal{M}_{3/4}(G)}\left[\exists F\in\Gamma,\ h(F\restriction_\rho)>(n/24-1)/k\right]\\&\le\Pr_{\rho\in\mathcal{M}_{3/4}(G)}\left[\exists F\in\Gamma,\ h(F\restriction_\rho)>\sum_{i=0}^{k-1}s_i\right]\\&\le\sum_{i=1}^{k}p_i2^{\sum_{j=i}^{k-1}s_j}\le\sum_{i=1}^{k}2^{-(2/3)n^\epsilon}\le k2^{-(2/3)n^\epsilon}=2^{\log k-(2/3)n^\epsilon}.\end{aligned}$$

For n sufficiently large, this probability is strictly less than $\frac{1}{2}$. Because G is $(3/4,n/24)$-robust, for $\rho\in\mathcal{M}_{3/4}(G)$, with probability at least $\frac{1}{2}$, $w_R(PHP(G)\restriction_\rho)\ge n/24$. Thus, there is a ρ so that $w_R(PHP(G)\restriction_\rho)\ge n/24$ and for all $F\in\Gamma$, $h(F\restriction_\rho)\le\frac{1}{k}(n/24-1)$. This is a contradiction, because by Corollary 5.2, there is a resolution refutation of $PHP(G)\restriction_\rho$ of width $\le n/24-1$. □

THEOREM 6.16. *For each $c>1$, there exists $\epsilon>0$ so that for all n sufficiently large, if $k\le\sqrt{\log n/\log\log n}$, then every Res($k$) refutation of PHP_n^{cn} has size at least 2^{n^ϵ}.*

Proof. Apply Lemma 6.9 and choose d so that for sufficiently large n, there exists a $(3/4,n/24)$-robust graph G on vertex sets cn and n, with $\Delta(G)\le d\log n$. By Lemma 6.15, there exists $\epsilon>0$ so that for $k\le\sqrt{\log n/\log\log n}$, $S_k(PHP(G))\ge 2^{n^\epsilon}$. Because $PHP(G)$ can be obtained by setting some of the variables of PHP_n^{cn} to 0, every Res(k) refutation of PHP_n^{cn} can be converted into a Res(k) refutation of $PHP(G)$ of the same or lesser size. Therefore, all Res(k) refutations of PHP_n^{cn} must have size at least 2^{n^ϵ}. □

Now we prove the lower bound on the number s_k that we used in Lemma 6.15. The constants are *not* optimized.

LEMMA 6.17. *There exists $\epsilon>0$, so that for all n sufficiently large, with $k\le\sqrt{\log n/\log\log n}$ and $s_0,\dots,s_k$ defined as in the proof of Lemma* 6.15, *$s_k\ge n^\epsilon$.*

Proof. Unwinding the recursive definition of the s_i's gives the following equality:

$$s_k=\frac{1}{2^k}(\log e)^k\frac{1}{k!}\left(\frac{1}{4}\right)^{\sum_{j=1}^{k}j}\left(\frac{1}{d\log n}\right)^{\sum_{j=2}^{k+1}j}\frac{3}{4k}(n/24-1).$$

Because $k\le\sqrt{\log n/\log\log n}$, we have that $\frac{1}{2^k}(\log e)^k\frac{1}{k!}\left(\frac{1}{4}\right)^{\sum_{j=1}^{k}j}\frac{3}{4k}=n^{-o(1)}$.

$$\begin{aligned}s_k&=n^{-o(1)}(1/d\log n)^{(k+2)(k+1)/2}(n/24-1)\\&=n^{-o(1)}2^{-(\log(d\log n))(k^2+3k+2)/2}(n/24-1).\end{aligned}$$

Because $k \leq \sqrt{\log n / \log\log n}$ and d is a constant, thus for n sufficiently large, $(\log(d \log n))(k^2 + 3k + 2)/2 = (\log n)(1 + o(1))/2$. Therefore,

$$s_k = n^{-o(1)} 2^{-(\log n)(1+o(1))/2}(n/24 - 1),$$

and there exists $\epsilon > 0$ so that for all n sufficiently large, $s_k \geq n^\epsilon$. □

7. Lower bounds for random CNFs. It is well known that, in some cases, randomly generated sets of clauses require exponentially large resolution refutations; see [13, 5, 8]. We extend these results by giving exponential lower bounds for the size of Res(k) refutations of randomly chosen sets of width $4k^2 + 2$ clauses.

DEFINITION 7.1. *Let n, Δ, and w be given. The distribution $\mathcal{F}_w^{n,\Delta}$ is defined by choosing $\Delta \cdot n$ many clauses independently, with repetitions, from the set of all $\binom{n}{w}2^w$ clauses of width w.*

Our main result for this section is the following.

THEOREM 7.2. *For any $\epsilon \in [0, \frac{1}{6})$, there exists $\delta > 0$, so that for n sufficiently large and for $\Delta = n^\epsilon$,*

$$\Pr_{F \in \mathcal{F}_{4k^2+2}^{n,\Delta}} \left[S_k(F) \leq 2^{n^\delta} \right] = o(1).$$

The reason that our proof does not give lower bounds for refutations of random 3-CNFs in Res(k) is that, on one hand, we want our random restrictions to have a good chance of satisfying a fixed k-term (so we can apply the switching lemma), but on the other hand, the restrictions should have little probability of falsifying any of the initial clauses (this would make the restricted set of clauses trivial to refute). Because satisfying a k-term is equivalent to falsifying a k-clause, we can only work with initial clauses of width larger than k.

A set of clauses that, with constant probability, requires high width to refute after random restriction is called *robust*. Recall the distribution $\mathcal{D}_p$ from Definition 3.5.

DEFINITION 7.3. *Let F be a CNF in variables $x_1, \ldots, x_n$. We say that F is (p, r)* robust *if $\Pr_{\rho \in \mathcal{D}_p}[w_R(F \restriction \rho) \geq r] \geq 1/2$.*

It turns out that for sufficiently large w, a random w-CNF is almost surely robust. We state the result below and prove it in the following subsection.

LEMMA 7.4. *There exists a constant c so that for any constants w and t, $w \geq 2t + 2$, for every n sufficiently large, and for every $\epsilon \in [0, 1/2]$, if we set $\Delta = n^\epsilon$, then the following inequality holds:*

$$\Pr_{F \in \mathcal{F}_w^{n,\Delta}} \left[F \text{ is not } \left(n^{-1/t}, cn^{\frac{1-2\epsilon}{1+2\epsilon}} \right)\text{-robust} \right] = o(1).$$

We now prove the size lower bound. We set bits with probability $n^{-1/2k^2}$ so we can collapse k-DNFs but still have that most $4k^2 + 2$ CNFs are robust. For each $k \geq 1$, let γ_k be the constant of corollary 3.7.

LEMMA 7.5. *Let n, r, w, and k be given. For sufficiently large n, if F is an $(n^{-1/2k^2}, r)$-robust w-CNF, then $S_k(F) \geq \frac{1}{4k} 2^{(\gamma_k (r-1)/k\sqrt{n})}$.*

Proof. Suppose that Γ is a Res(k) refutation of F of size at most $\frac{1}{4k} 2^{(\gamma_k (r-1)/k\sqrt{n})}$. By Corollary 3.7, with $p = n^{-1/2k^2}$ and $w = (r-1)/k$, we have that for every line F of Γ, $\Pr_{\rho \in \mathcal{D}_p}[h(F \restriction \rho) > (r-1)/k] \leq k 2^{-\gamma_k (r-1)/k\sqrt{n}}$. By the union bound we have that

$$\Pr_{\rho \in \mathcal{D}_p}[\exists F \in \Gamma \; h(F \restriction \rho) > (r-1)/k] \leq |\Gamma| \cdot k \cdot 2^{-\gamma_k (r-1)/k\sqrt{n}}$$

$$\leq \frac{1}{4k} 2^{(\gamma_k(r-1)/k\sqrt{n})} \cdot k \cdot 2^{-\gamma_k(r-1)/k\sqrt{n}} = \frac{1}{4}.$$

Because F is (p,r)-robust, with probability at least $\frac{1}{2}$ over choices of ρ, then $w_R(F \restriction_\rho) \geq r$. Therefore, we may choose $\rho \in \mathcal{D}_p$ so that $w_R(F \restriction_\rho) \geq r$ and for all $F \in \Gamma$, $h(F \restriction_\rho) \leq (r-1)/k$. This is a contradiction because by Corollary 5.2 there should be a width $r-1$ resolution refutation of $F \restriction_\rho$. □

Combining Lemmas 7.4 and 7.5 with $t = 2k^2$, $w = 4k^2 + 2$, and $r = cn^{\frac{1-2\epsilon}{1+2\epsilon}}$ shows that a random $(4k^2+2)$-CNF almost surely requires exponential size to refute in Res(k).

COROLLARY 7.6. *There exists a constant c so that for every k, for every n sufficiently large, and for $\epsilon \in [0, 1/2]$, if we set $\Delta = n^\epsilon$, then the following inequality holds:*

$$\Pr_{F \in \mathcal{F}^{n,\Delta}_{4k^2+2}} \left[S_k(F) \leq 2^{\gamma_k(cn^{\frac{1-2\epsilon}{1+2\epsilon}}-1)/k\sqrt{n}} \right] = o(1).$$

This gives an exponential lower bound only when $\frac{1-2\epsilon}{1+2\epsilon} > \frac{1}{2}$. This holds exactly for $\epsilon \in [0, \frac{1}{6})$.

THEOREM 7.7. *For any $\epsilon \in [0, \frac{1}{6})$, there exists $\delta > 0$, so that for n sufficiently large and for $\Delta = n^\epsilon$,*

$$\Pr_{F \in \mathcal{F}^{n,\Delta}_{4k^2+2}} \left[S_k(F) \leq 2^{n^\delta} \right] = o(1).$$

7.1. Robustness of random CNFs. In this section we show that for appropriate clause densities, a random w-CNF is almost surely robust.

We begin with a width bound for resolution refutations of random 3-CNFs given by Ben-Sasson and Wigderson.

THEOREM 7.8 (see [8]). *There exists a constant c, so that for all n, and for all $\epsilon \in [0, 1/2]$ with $\Delta = n^\epsilon$, the following inequality holds:*

$$\Pr_{F \in \mathcal{F}^{n,\Delta}_3} \left[w_R(F) \leq cn^{\frac{1-2\epsilon}{1+2\epsilon}} \right] = o(1).$$

LEMMA 7.9. *There exists a constant c so that for any constants w and t with $w \geq 2t+2$, for every n sufficiently large, and for $\epsilon \in [0, 1/2]$, if we set $\Delta = n^\epsilon$ and $p = n^{-1/t}$, then the following inequality holds:*

$$\Pr_{\substack{F \in \mathcal{F}^{n,\Delta}_w \\ \rho \in \mathcal{D}_p}} \left[w_R(F \restriction_\rho) \leq cn^{\frac{1-2\epsilon}{1+2\epsilon}} \right] = o(1).$$

Proof. Let w, t, n, ϵ be given as above and set $\Delta = n^\epsilon$ and $p = n^{-1/t}$.

Because the expected size of $\mathrm{dom}(\rho)$ is pn, the Chernoff bounds show that the size of $\mathrm{dom}(\rho)$ exceeds $2pn = 2n^{1-\frac{1}{t}}$ with probability at most $e^{-n^{1-1/t}/4} = o(1)$.

Let C be a fixed clause of width w that contains no opposite literals. When we choose $\rho \in \mathcal{D}_p$, the probability that the domain of ρ contains at least $w-2$ variables of C is at most $\binom{w}{2} p^{w-2}$. Because w is a constant, this probability is $O\left(n^{-(w-2)/t}\right)$. Because $w \geq 2t+2$, this probability is $O\left(n^{-2}\right)$. For any fixed w-CNF F on Δn many clauses, an application of the union bound shows that there is some clause with

$\geq w-2$ of its variables in the restriction with probability $O(\Delta n \cdot n^{-2}) = o(1)$. Because this calculation holds for every w-CNF of Δn many clauses, we have that

$$\Pr_{\substack{F \in \mathcal{F}_w^{n,\Delta} \\ \rho \in \mathcal{D}_p}} [\exists C \in F,\ |vars(C) \setminus \mathrm{dom}(\rho)| \leq 2] = o(1).$$

Fix a restriction ρ so that $\mathrm{dom}(\rho) \leq 2n^{1-\frac{1}{t}}$ and let $n' = n - |\mathrm{dom}(\rho)|$. Conditioned on the event that for all $i \in [\Delta]$, $|vars(C_i) \setminus \mathrm{dom}(\rho)| \geq 3$, $F \restriction_\rho$ is subsumed by a random 3-CNF distributed as $\mathcal{F}_3^{n',\Delta}$. (To see this, consider the distribution on 3-CNFs that chooses three literals unset by ρ from each C_i.) Choose ϵ' so that $n^\epsilon = (n')^{\epsilon'}$. Adding up the conditional probabilities and applying Theorem 7.8 shows that

$$\Pr_{\substack{F \in \mathcal{F}_w^{n,\Delta} \\ \rho \in \mathcal{D}_p}} \left[w_R(F \restriction_\rho) \leq c {n'}^{\frac{1-2\epsilon'}{1+2\epsilon'}} \right] = o(1).$$

Because $n' \geq n - 2n^{1-1/t}$, we may choose c' so that

$$\Pr_{\substack{F \in \mathcal{F}_w^{n,\Delta} \\ \rho \in \mathcal{D}_p}} \left[w_R(F \restriction_\rho) \leq c' n^{\frac{1-2\epsilon}{1+2\epsilon}} \right] = o(1). \qquad \square$$

From Lemma 7.9, an averaging argument yields the following phrasing of Lemma 7.4.

LEMMA 7.10. *There exists a constant c so that for any constants w and t, $w \geq 2t+2$, for every n sufficiently large, and for $\epsilon \in [0, 1/2]$, if we set $\Delta = n^\epsilon$ and let $p = n^{-1/t}$, then the following inequality holds:*

$$\Pr_{F \in \mathcal{F}_w^{n,\Delta}} \left[\Pr_{\rho \in \mathcal{D}_p} \left[w_R(F \restriction_\rho) \leq c n^{\frac{1-2\epsilon}{1+2\epsilon}} \right] \geq 1/2 \right] = o(1).$$

8. Separation between Res(k) and Res($k+1$). In this section we show that for each constant k, there is an $\epsilon_k > 0$ and a family of unsatisfiable CNFs which have polynomial-size Res$(k+1)$ refutations but which require size $2^{n^{\epsilon_k}}$ to refute in Res(k). The unsatisfiable clauses are a variation of the graph ordering tautologies [19, 9].

DEFINITION 8.1. *Let G be an undirected graph. For each vertex u of G, let $N(u)$ denote the set of neighbors of u in G. For each ordered pair of vertices $(u, v) \in V(G)^2$, with $u \neq v$, let there be a propositional variable $X_{u,v}$.*

The graph ordering principle for G, $GOP(G)$, *is the following set of clauses:*

(1) *The relation X is transitive: for all $u, v, w \in V(G)$, $X_{u,v} \wedge X_{v,w} \to X_{u,w}$.*
(2) *The relation X is antisymmetric: for all $u, v \in V(G)$ with $u \neq v$, $\neg X_{u,v} \vee \neg X_{v,u}$.*
(3) *There is no locally X-minimal element: for every $u \in V(G)$, $\bigvee_{v \in N(u)} X_{v,u}$.*

The k-fold graph ordering principle of G, $GOP^k(G)$, *is obtained by replacing each variable $X_{u,v}$ by a conjunction of k variables, $X^1_{u,v}, \ldots, X^k_{u,v}$, and then using the distributive rule and DeMorgan's law to express this as a set of clauses.*

Notice that for a graph G on n vertices with maximum degree d, the principle $GOP(G)$ consists of $O(n^3)$ many clauses each of width at most $\max\{3, d\}$. Therefore, for any graph G on n vertices with maximum degree d, the principle $GOP^k(G)$ has size $O(n^3 k^d)$.

It is readily shown that, for any graph G, the principle $GOP(G)$ has polynomial-size resolution refutations. Furthermore, these refutations can be transformed into Res$(k+1)$ refutations of $GOP^{k+1}(G)$, as shown in Lemma 8.4. On the other hand,

we will also prove that Res(k) refutations of $GOP^{k+1}(G)$ require exponential size for certain graphs.

THEOREM 8.2. *Let k be a positive integer. There exist constants $c > 0$, $\epsilon_k > 0$ and a family of graphs G on n vertices (for n sufficiently large) with maximum degree $c \log n$ so that Res(k) refutations of $GOP^{k+1}(G)$ require size at least $2^{\Omega(n^{\epsilon_k})}$.*

8.1. The upper bounds. We build Res(k) refutations for $GOP^k(G)$ from resolution refutations of $GOP(G)$.

The resolution refutation of $GOP(G)$ is a slight variation of the resolution refutation of GT_n [19, 9].

LEMMA 8.3. *Let G be an n vertex graph. There is a resolution refutation of $GOP(G)$ of size $O(n^3)$.*

Proof. To construct the resolution refutation of $GOP(G)$, we iteratively derive the formulas $\bigvee_{\substack{i\in[l,n]\\ i\neq j}} X_{i,j}$ for all i, j with $1 \leq l \leq j \leq n$. The clauses $\bigvee_{\substack{i\in[n]\\ i\neq j}} X_{i,j}$ are derived by weakening the hypotheses. We proceed in stages as l ranges from 1 up to n. At stage l, for $j = l$, we have $\bigvee_{i\in[l+l,n]} X_{i,l}$. For $j \neq l$, we resolve $\bigvee_{i\in[l+1,n]} X_{i,l}$ with the transitivity axioms $\neg X_{i,l} \vee \neg X_{l,j} \vee X_{i,j}$ to obtain $\neg X_{l,j} \vee X_{j,l} \bigvee_{\substack{i\in[l+1,n]\\ i\neq j}} X_{i,j}$. This clause is resolved with $\neg X_{l,j} \vee \neg X_{j,l}$ and $\bigvee_{\substack{i\in[l,n]\\ i\neq j}} X_{i,j}$ to obtain $\bigvee_{i=l+1}^{n} X_{i,j}$. At stage n, with $j = n$, we have derived the empty clause. This refutation clearly has size $O(n^3)$. □

LEMMA 8.4. *For each k, and for every G with n vertices and degree at most $d \geq 3$, $GOP^k(G)$ has a Res(k) refutation of size $O(n^3 k^d)$.*

Proof. Let τ be the operation that replaces $X_{u,v}$ by $\bigwedge_{i=1}^{k} X^i_{u,v}$ and $\neg X_{u,v}$ by $\bigvee_{i=1}^{k} \neg X^i_{u,v}$.

Let Γ be the size $O(n^3)$ resolution refutation of $GOP(G)$ given above, and remove all of its weakening inferences. If we apply the transformation τ to the refutation, we obtain a Res(k) refutation of $\tau(GOP(G))$.

From the clauses of $GOP^k(G)$ we can derive the k-DNFs of $\tau(GOP(G))$ by a sequence of $O(k^d)$ many AND-introduction inferences per formula. Thus, we have a Res(k) refutation of $GOP^k(G)$ of the claimed size. □

8.2. Random restrictions. In this subsection we define a distribution on partial assignments so that i-DNFs with high cover number are satisfied with high probability. The idea is to randomly color the graph with $4k$ many colors, and then, between vertices u and v of distinct color classes, uniformly choose an assignment to $X^1_{u,v}, \ldots, X^{k+1}_{u,v}, X^1_{v,u}, \ldots, X^{k+1}_{v,u}$ which makes both $\bigwedge_{i=1}^{k+1} X^i_{u,v}$ and $\bigwedge_{i=1}^{k+1} X^i_{v,u}$ false.

DEFINITION 8.5. *Let $k \geq 1$ be given. Let G be a graph. The distribution $\mathcal{P}_{k+1}(G)$ on partial assignments ρ to the variables of $GOP^{k+1}(G)$ is given by the following experiment.*

For each $(u, v) \in V(G)^2$, let $\sigma^{u,v}_\rho$ be chosen uniformly among $0, 1$ assignments to $X^1_{u,v}, \ldots, X^{k+1}_{u,v}$ so that for at least one $i \in [k + 1]$, $\sigma^{u,v}_\rho(X^i_{u,v}) = 0$.

Select a random coloring of $V(G)$ by $4k$ many colors, $c_\rho : V(G) \to [4k]$.

The partial assignment, ρ, is defined as

$$\rho = \bigcup_{\substack{(u,v)\in V(G)^2\\ c_\rho(u)\neq c_\rho(v)}} \sigma^{u,v}_\rho.$$

The auxiliary total assignment, σ_ρ, is defined as

$$\sigma_\rho = \bigcup_{(u,v)\in V(G)^2} \sigma_\rho^{u,v}.$$

If we let B_ρ be the set of edges which are bichromatic under the coloring c_ρ, then $GOP^{k+1}(G) \restriction_\rho$ is $GOP^{k+1}(G \setminus B_\rho)$. Moreover, we have the following lemma, which the reader can easily check.

LEMMA 8.6. *Let G be a graph. Let $\rho \in \mathcal{P}_{k+1}(G)$ be given. Let B_ρ be the set of edges of G that are bichromatic under c_ρ. Let $G_1, \ldots, G_m$ be the connected components of $G \setminus B_\rho$.*

$$GOP^{k+1}(G) \restriction_\rho = \bigcup_{j=1}^{m} GOP^{k+1}(G_j).$$

Formulas with high cover number contain many variable-disjoint terms, but the events of satisfying these terms with $\rho \in \mathcal{P}_{k+1}(G)$ are not necessarily independent. To obtain independence, we look at the pairs of vertices involved with the literals of the terms. Remember that in the definition of $GOP(G)$, there are no variables $X_{u,u}$.

DEFINITION 8.7. *Let $X^i_{u,v}$ be a variable of $GOP^{k+1}(G)$. The* underlying pair *of $X^i_{u,v}$ is the set $\{u,v\}$. The* underlying ordered pair *of $X^i_{u,v}$ is (u,v). Let T be a term. The set of* vertex pairs of T, P_T, *is defined as*

$$P_T = \{\{u,v\} \mid \ \{u,v\} \text{ is the underlying pair of a variable in } T\}.$$

The set of vertices of T, S_T, *is defined as $S_T = \bigcup P_T$.*

We use combinatorial sunflowers to obtain independence between the events of satisfying terms of an i-DNF with high cover number. To guarantee that such a system exists, we apply the Erdös–Rado lemma.

DEFINITION 8.8. *A (p,l)* sunflower *is a collection of sets $P_1, \ldots, P_p$, each of size $\leq l$, so that there exists a set C so that $P_i \cap P_j = C$ for all $i,j \in [p]$, $i \neq j$. The set C is called the* core *of the sunflower.*

THEOREM 8.9 (see [16, 22]). *Let l be given. Let $\mathcal{Z}$ be a family of M distinct sets, each with cardinality $\leq l$. $\mathcal{Z}$ contains a (p,l) sunflower where $p \geq \left(\frac{M}{l!}\right)^{\frac{1}{l}}$.*

DEFINITION 8.10. *Let $T_1, \ldots, T_t$ be terms in the variables of $GOP^{k+1}(G)$. We say that the terms are* sufficiently independent *if the following conditions hold:*

1. *For $i,j \in [t]$, if $i \neq j$, then $S_{T_i} \neq S_{T_j}$.*
2. *The family $\{S_{T_i} \mid 1 \leq i \leq t\}$ forms a sunflower with core C.*
3. *For each $i \in [t]$, each $\{u,v\} \in P_{T_i}$, $\{u,v\} \not\subseteq C$.*

LEMMA 8.11. *Let $T_1, \ldots, T_t$ be a sufficiently independent set of terms. The sets P_{T_i}, $1 \leq i \leq t$, are disjoint.*

Proof. Let i,j, $1 \leq i < j \leq t$, be given and let C denote the core of the sunflower. Suppose that $\{u,v\} \in P_{T_i} \cap P_{T_j}$. We then have that $\{u,v\} \subseteq S_{T_i} \cap S_{T_j}$, so $\{u,v\} \subseteq C$. Therefore, by the third property of sufficient independence, $\{u,v\} \notin P_{T_i}$—a contradiction. □

We begin the task of showing that a DNF with high cover number is likely to be satisfied by a random restriction. The quality of our bounds is most affected by the use of the sunflower lemma, and the particular constants we obtain at other points have limited impact. Therefore, to conserve space and readability, we will not optimize many of the probabilities involved.

LEMMA 8.12. *Let k be given. There exist constants $\beta_k > 0$ and $c_k > 0$ so that for every k-DNF F in the variables of $GOP^{k+1}(G)$, F contains a sufficiently independent set of size at least $\beta_k(c(F))^{\frac{1}{2k}} - c_k$.*

Proof. F contains a set of $s = c(F)/k$ many variable-disjoint terms, $T_1, \ldots, T_s$. It is possible that $S_{T_m} = S_{T_l}$ for some $m \neq l$. However, because all terms have size at most k, for each i, $|S_{T_i}| \leq 2k$, and a set of $\leq 2k$ many vertices can be the underlying set of fewer than $\big((k+1)4k^2\big)^k$ many different variable-disjoint terms (since a variable $X^i_{u,v}$ is determined by an ordered pair $(u,v) \in [S_T]^2$ and $i \in [k+1]$). Therefore, there is a subcollection of $\frac{s}{((k+1)4k^2)^k}$ many variable-disjoint terms whose underlying sets of vertices are distinct.

Because the underlying sets of vertices have size at most $2k$, we can apply the sunflower lemma to find $s' = \big(\frac{s}{((k+1)4k^2)^k(2k)!}\big)^{\frac{1}{2k}} = \big(\frac{c(F)}{k((k+1)4k^2)^k(2k)!}\big)^{\frac{1}{2k}}$ many terms whose sets of underlying vertices form an $(s', 2k)$ sunflower. We rename these terms $T_1, \ldots, T_{s'}$.

Let C be the core of the sunflower $S_{T_1}, \ldots, S_{T_{s'}}$. Notice that $|C| \leq 2k$. Call a variable *bad* if both of its underlying vertices belong to C. There are fewer than $2k^2$ many unordered pairs of vertices contained in C, and each is the underlying pair of exactly $2(k+1)$ many variables. Therefore, there are fewer than $2(k+1)\cdot 2k^2 = 4k^2(k+1)$ many variables whose underlying vertices are both in C. The terms $T_1, \ldots, T_{s'}$ are variable-disjoint, so each bad variable appears in at most one term, and when we remove all terms containing a bad variable, we obtain a sufficiently independent set of terms of size $s' - 4k^2(k+1) = \big(\frac{c(F)}{k(2k)!((k+1)4k^2)^k}\big)^{\frac{1}{2k}} - 4k^2(k+1)$. ∎

Before we bound the probability of satisfying a DNF with high covering number, we make a few observations.

FACT 1. *Let T be a term, and let $\rho \in \mathcal{P}_{k+1}(G)$ be given. $T \restriction_\rho = 1$ if and only if the following two events occur:* (i) *$T \restriction_{\sigma_\rho} = 1$, and* (ii) *for each $\{u,v\} \in P_T$, $c_\rho(u) \neq c_\rho(v)$.*

For each term T in a Res(k) refutation of $GOP^{k+1}(G)$, because T contains at most k literals, there is a nonzero chance that it will be satisfied by σ_ρ when ρ is a random restriction chosen according to $\mathcal{P}_{k+1}(G)$. This is made precise in the following lemma. Recall that by construction, $\bigwedge_{i=1}^{k+1} X^i_{u,v} \restriction_{\sigma_\rho} = 0$, so the lemma fails for terms of size $k+1$ (as it should, since we are separating Res($k+1$) from Res(k)). The argument is similar to that in Lemma 4.4.

LEMMA 8.13. *Let T be a term of size at most k.*

$$\Pr_{\rho \in \mathcal{P}_{k+1}(G)}\left[T \restriction_{\sigma_\rho} = 1\right] \geq \frac{1}{3^k}.$$

Proof. Order the literals of T as $l_1, \ldots, l_k$. For each j, $1 \leq j \leq k$, if we condition on the event that each $l_1, \ldots, l_{j-1}$ is satisfied, then the probability of l_j being satisfied is at least $\frac{1}{3}$. This is because in the worst case, l_j is a literal $X^{i_j}_{u,v}$ and the other literals are $X^{i_1}_{u,v}, \ldots, X^{i_{j-1}}_{u,v}$, and in this case, the probability that $X^{i_j}_{u,v}$ is satisfied by σ_ρ is at least $\frac{1}{3}$. ∎

LEMMA 8.14. *Let G be a graph and let k be a positive integer. Let F be a k-DNF which contains t sufficiently independent terms.*

$$\Pr_{\rho \in \mathcal{P}_{k+1}(G)}\left[F \restriction_\rho \neq 1\right] \leq \left(1 - \frac{1}{3^k 2^{2k}}\right)^t.$$

Proof. Let $T_1, \ldots, T_t$ be the sufficiently independent terms of F. Let C be the core

of the sunflower $S_{T_1}, \ldots, S_{T_t}$. Fix a coloring of the vertices in the core, $\chi : C \to [4k]$. Condition on the event that $c_\rho \restriction_C = \chi$.

We now lower-bound the probability that a given term T of the sufficiently independent set is satisfied. First, we bound the probability that every underlying edge of T is bichromatic. Note that by property (3) of sufficient independence, for all $\{u, v\} \in P_T$, $\{u, v\} \not\subseteq C$, so it suffices to bound the probability that the vertices in $S_T \setminus C$ receive distinct colors not in the range of χ. Therefore, the probability that every pair in P_T is bichromatic, conditioned on $c_\rho \restriction_C = \chi$, is at least $\frac{1}{2^{2k}}$. Because T contains at most k literals, the probability that $T \restriction_{\sigma_\rho} = 1$ is at least $\frac{1}{3^k}$. These two events are independent, so we have $\Pr_{\rho \in \mathcal{P}_{k+1}(G)}[T \restriction_\rho = 1 \mid c_\rho \restriction_C = \chi] \geq \frac{1}{2^{2k}} \frac{1}{3^k}$.

Now we show that (when we condition on the event that $c_\rho \restriction_C = \chi$) the events $T_i \restriction_\rho = 1$ are totally independent. Because the terms share no underlying pairs, the events $T_i \restriction_{\sigma_\rho}$ are independent of the satisfaction of other terms. The events "for each $\{u, v\} \in P_{T_i}$, $c_\rho(u) \neq c_\rho(v)$" are independent of the satisfaction of other terms. This is because once we condition on the event $c_\rho \restriction_C = \chi$, the probability that every pair of P_{T_i} is bichromatic under c_ρ depends only on the values that c_ρ takes on $S_{T_i} \setminus C$ and, for all $i \neq j$, $S_{T_i} \cap S_{T_j} = C$.

Combining the results of the previous two paragraphs shows that

$$\Pr_{\rho \in \mathcal{P}_{k+1}(G)}[F \restriction_\rho \neq 1 \mid c_\rho \restriction_C = \chi] \leq \left(1 - 1/3^k 2^{2k}\right)^t.$$

Because this holds for all colorings $\chi : C \to [4k]$, we have that

$$\Pr_{\rho \in \mathcal{P}_{k+1}(G)}[F \restriction_\rho \neq 1] \leq \left(1 - 1/3^k 2^{2k}\right)^t. \qquad \square$$

We now have the lemma relating cover number to the probability that a restriction satisfies a k-DNF.

LEMMA 8.15. *For each k there exist positive constants δ, γ, and d so that for any k-DNF F,*

$$\Pr_{\rho \in \mathcal{P}_{k+1}(G)}[F \restriction_\rho \neq 1] \leq d 2^{-\delta (c(F))^\gamma}.$$

Proof. By Lemma 8.12, F contains a sufficiently independent set of size at least $\beta_k (c(F))^{\frac{1}{2k}} - c_k$.

By Lemma 8.14,

$$\Pr_{\rho \in \mathcal{P}_{k+1}(G)}[F \restriction_\rho \neq 1] \leq \left(1 - \frac{1}{3^k 2^{2k}}\right)^{\beta_k (c(F))^{\frac{1}{2k}} - c_k}.$$

Because k is fixed, this concludes the proof with $\delta = -\beta_k \log\left(1 - \frac{1}{3^k 2^{2k}}\right)$, $\gamma = 1/2k$, and $d = \left(1 - \frac{1}{3^k 2^{2k}}\right)^{-c_k}$. $\square$

8.3. Width lower bound for resolution. In this subsection we show that for each n, if G is a graph on n vertices satisfying a certain expansion-like property, then $w_R(GOP^{k+1}(G)) = \Omega(n)$. Combining this with a probabilistic calculation will show that there exist graphs G so that for $\rho \in \mathcal{P}_{k+1}(G)$, with probability at least $\frac{1}{2}$, $w_R(GOP^{k+1}(G) \restriction_\rho) = \Omega(n)$.

The proof of the resolution width bound is similar to the one used by Bonet and Galesi for the GT_n principles [9]. They worked with complete graphs, but we do not because the principles $GOP^2(K_n)$ have sizes in excess of 2^n. Fortunately, for the

proof technique to work, G need not be complete but instead must have the following property.

DEFINITION 8.16. *Let G be an undirected graph on n-vertices. We say that G is ϵ-neighborly if, between every pair of disjoint sets of vertices, $A, B \subseteq V(G)$ with $|A|, |B| \geq \epsilon n$, there exists an edge joining A and B.*

We now show that resolution refutations of $GOP(G)$ require large width when G is a connected, neighborly graph.

LEMMA 8.17. *If G is a connected graph of n vertices that is ϵ-neighborly, then every resolution refutation of $GOP(G)$ contains a clause of width $\left(\frac{1-3\epsilon}{6}\right) n$.*

Proof. We begin by defining the "measure" of a clause. A *critical truth assignment*, or *cta*, is an assignment to the variables of $GOP(G)$ which forms a total order on $V(G)$. For each $v \in V(G)$, let $C_v := \bigvee_{u \in N(v)} X_{u,v}$, and for each $I \subseteq V(G)$, $C_I := \bigwedge_{v \in I} C_v$. Let C be a clause. The *measure of C, $\mu(C)$,* is the minimum cardinality of a set $I \subseteq V(G)$ so that for every cta α, if α satisfies C_I, then α satisfies C.

Notice that if a clause $A \vee B$ is the resolvent of $A \vee x$ and $B \vee \neg x$, then $\mu(A \vee B) \leq \mu(A \vee x) + \mu(A \vee \neg x)$. Because of this, we say that μ is *subadditive with respect to resolution.* If $A \subseteq B$, then we have that $\mu(B) \leq \mu(A)$, so μ is *decreasing with respect to subsumption.*

We now show that $\mu(\emptyset) = n$. Suppose otherwise, and let I be a subset of $V(G)$ with $|I| \leq n - 1$. Choose one vertex $v_0 \in V(G) \setminus I$ and let α be a total order which arises by taking a depth-first search of G starting with v_0. Clearly α satisfies C_I but α does not satisfy $\emptyset$.

Because every clause of $GOP(G)$ has measure either 0 or 1, the empty clause has measure n, and the measure is both subadditive with respect to resolution and decreasing with respect to subsumption, there must exist a clause C so that $\frac{n}{3} \leq \mu(C) \leq \frac{2n}{3}$. Suppose for the sake of contradiction that $w(C) < \frac{n-3\epsilon n}{6}$.

Let I be a minimal subset of $V(G)$ so that for every critical truth assignment α, if α satisfies C_I, then α satisfies C. Let $J = V(G) \setminus I$. Notice that $|I|, |J| \geq \frac{n}{3}$.

Let S be the set of vertices mentioned by variables of C. Clearly, $|S| \leq 2w(C) < 2\left(\frac{n-3\epsilon n}{6}\right) = \frac{n-3\epsilon n}{3}$. Therefore, $|I \setminus S| \geq \frac{n}{3} - \frac{n-3\epsilon n}{3} = \epsilon n$. Similarly, $|J \setminus S| \geq \epsilon n$. Because G is ϵ-neighborly, we may choose $u \in I \setminus S$ and $v \in J \setminus S$ so that $\{u, v\}$ is an edge of G.

Let α be a cta so that α satisfies $C_{I \setminus \{u\}}$, but α does not satisfy C_u and α does not satisfy C. Let β be the cta which arises by moving v to the front of the order given by α. For $w \in I$, $w \neq u$, β satisfies C_w because every predecessor of w in α is a predecessor of w in β. For u, β satisfies C_u because β satisfies $X_{v,u}$. However, β does not satisfy C because α does not satisfy C and no variable mentioning u or v appears in C. Therefore, β satisfies C_I but β does not satisfy C—a contradiction to the choice of I. □

A resolution refutation of $GOP^k(G)$, $k \geq 1$, can be transformed into a resolution refutation of $GOP(G)$ by setting the appropriate variables to 1. Applying a restriction does not increase the width of a resolution refutation, so we have the following corollary.

COROLLARY 8.18. *If G is a connected graph of n vertices that is ϵ-neighborly, then for all $k \geq 1$, $w_R(GOP^k(G)) \geq \left(\frac{1-3\epsilon}{6}\right) n$.*

8.4. Robust graphs.

DEFINITION 8.19. *We say that a graph G is r-robust if for ρ selected at random by $\mathcal{P}_{k+1}(G)$, with probability at least $\frac{3}{4}$, $w_R(GOP(G) \restriction_\rho) \geq r$.*

To guarantee that the restricted principle will require high width to refute, it suffices that the graph obtained by deleting the bichromatic edges should consist of large, neighborly connected components. Random graphs of degree $\Theta(\log n)$ have this property with high probability. This is shown in the following subsection.

LEMMA 8.20. *There exists a constant c so that for sufficiently large n, there exists an $\frac{n}{96k}$-robust graph G on n vertices with degree at most $c \log n$.*

The proof of this lemma is a standard probabilistic argument. The reader may skip its proof in section 8.4.1, and move directly to the proof of the lower bound in section 8.5.

8.4.1. Demonstration of robust graphs. An easy probabilistic argument shows that with very high probability, a random graph of expected degree $\Theta((1/\epsilon)\log n)$ is almost surely ϵ-neighborly.

LEMMA 8.21. *Let n and d be positive integers so that $d \leq n$ and let $p = d/n$. Let $G_{n,p}$ be the distribution on graphs on n vertices in which every edge is included with independent probability p. With probability $\leq e^{2\epsilon n(1+\ln(1/\epsilon))-d\epsilon^2 n}$, a graph selected according to $G_{n,p}$ is* not *ϵ-neighborly.*

Proof. There are fewer than $\binom{n}{\epsilon n}^2 \leq \left(\frac{en}{\epsilon n}\right)^{2\epsilon n} = e^{2\epsilon n(1+\ln(1/\epsilon))}$ many pairs of disjoint sets of ϵn many vertices. Each such pair has a chance of at most $(1-p)^{\epsilon^2 n^2}$ of being unconnected. However, $(1-p)^{\epsilon^2 n^2} = (1-\frac{d}{n})^{\epsilon^2 n^2} \leq e^{-d\epsilon^2 n}$, so by the union bound the probability is at most $e^{2\epsilon n(1+\ln(1/\epsilon))} e^{-d\epsilon^2 n} = e^{2\epsilon n(1+\ln(1/\epsilon))-d\epsilon^2 n}$. ∎

We now show that a random graph will probably have each component large and neighborly if we randomly partition it into vertex-induced subgraphs.

LEMMA 8.22. *For all $\epsilon > 0$ and all integers $k \geq 1$, there exists a constant c so that for sufficiently large n, there exists graph G with $\Delta(G) \leq 2c \log n$ so that upon the random partition of G into $4k$ many vertex-induced subgraphs, with probability at least $\frac{1}{2}$, each component has size at least $n/8k$ and is ϵ-neighborly.*

Proof. Let $p = \frac{c \log n}{n}$. We will solve for the value of c at the end. Consider the following experiment: Select a graph G according to the distribution $G_{n,p}$, and independently color each vertex with one of $4k$ colors. Then remove all bichromatic edges to form $4k$ vertex induced-subgraphs, $G_1, \ldots, G_{4k}$.

Let P be the probability that G has a vertex of degree $> 2c \log n$, or that one of the induced subgraphs has size $< \frac{n}{8k}$, is disconnected, or is not ϵ-neighborly. We now bound this probability.

Consider the probability that G has a vertex of degree $\geq 2c \log n$. By the Chernoff bounds, the probability of any one vertex having degree in excess of $2p(n-1)$ is no more than $e^{-p(n-1)/4} = e^{-c(\log n)(n-1)/4n}$. Therefore, the probability of there existing a vertex with degree in excess of $2p(n-1)$ is no more than $ne^{-c(\log n)(n-1)/4n}$.

The Chernoff bounds also allow us to bound the probability that any of the G_i's contain too few vertices. The probability that a given color class of the partition contains fewer than $\frac{1}{2} \cdot \frac{n}{4k} = \frac{n}{8k}$ vertices is bounded by $e^{-\frac{n}{64k}}$.

Once we condition upon all pieces of the partition containing at least $\frac{n}{8k}$ vertices, we can bound the probability that any induced subgraph is disconnected. Consider a fixed set of $s \geq \frac{n}{8k}$ many vertices, and condition upon the event that those vertices receive the same color in the partition. Each edge internal to the set is included with probability $\frac{c \log n}{n} = \frac{(cs/n)\log n}{s} \geq \frac{(c/8k)\log s}{s}$. By a standard result on the connectivity of random graphs (cf. [27]), each color class is disconnected with probability bounded by $O\left(1/n^{(c/8k)-1}\right)$.

Finally, we consider the probability that each of the components G_i is ϵ-neighborly. For a fixed set of $s \geq \frac{n}{8k}$ vertices, if we condition on the event that set forms a component after partition, each internal edge is included with probability $\frac{c \log n}{n} \geq \frac{(c/8k) \log s}{s}$. By Lemma 8.21, that means that the component is *not* ϵ-neighborly with probability at most $e^{2\epsilon s(1+\ln(1/\epsilon))-(c/8k)(\log s)\epsilon^2 s} = e^{-\Omega(n \log n)}$.

Therefore,

$$P \leq ne^{-c(\log n)(n-1)/4n} + 4ke^{-\frac{n}{64k}} + O\left(4k/n^{(c/8k)-1}\right) + e^{-\Omega(n \log n)}.$$

For a sufficiently large constant c, dependent only on k and ϵ, this is below $\frac{1}{4}$.

Therefore, by an averaging argument on the edge choices, there exists a graph G of maximum degree $\leq 2c \log n$ so that upon random partition of its vertices into $4k$ color classes, its induced subgraphs are each connected, of size $\geq \frac{n}{8k}$, and ϵ-neighborly with probability $\geq \frac{3}{4}$. ∎

We now prove Lemma 8.20.

Proof. Using Lemma 8.22, choose c so that for sufficiently large n, there exists graph G so that upon the random partition of G into $4k$ many vertex-induced subgraphs, with probability at least $\frac{3}{4}$, each component has size at least $n/8k$ and is $(\frac{1}{6})$-neighborly. Therefore we may choose $\rho \in \mathcal{P}_{k+1}(G)$ so that for each $i \in [4k]$, $w_R(GOP^{k+1}(G_i)) \geq \left(\frac{n}{8k}\right)\left(\frac{1-3\frac{1}{6}}{6}\right) = \frac{n}{96k}$ (by Corollary 8.18).

Let Γ be a resolution refutation of $GOP^{k+1}(G) \restriction_\rho$. By Lemma 8.6, $GOP^{k+1}(G) \restriction_\rho = \bigcup_{i=1}^{4k} GOP^{k+1}(G_i)$. However, for each $i, j \in [4k]$, $i \neq j$, we have that $GOP^{k+1}(G_i)$ and $GOP^{k+1}(G_j)$ are variable disjoint. Therefore, by Lemma 2.3, for some $i \in [4k]$, there exists a resolution refutation of $GOP^{k+1}(G_i)$ of width at most $w(\Gamma)$. However, by the preceding paragraph, each $GOP^{k+1}(G_i)$ requires width $\frac{n}{96k}$ to refute in resolution. Therefore $w(\Gamma) \geq \frac{n}{96k}$. ∎

8.5. The lower bound.

THEOREM 8.23. *Let k be given. There exist constants $c > 0$, $\epsilon_k > 0$ and a family of graphs G on n vertices (for n sufficiently large) with maximum degree $c \log n$ so that Res(k) refutations of $GOP^{k+1}(G)$ require size at least $2^{\Omega(n^{\epsilon_k})}$.*

Proof. Let k be given. Apply Lemma 8.20 and choose c so that for sufficiently large n, there exists a $\frac{n}{96k}$-robust graph G on n vertices with degree at most $c \log n$. By Lemma 8.15, there are positive constants d, δ, and γ so that for every k-DNF F $\Pr_{\rho \in \mathcal{P}_{k+1}(G)}[F \restriction_\rho \neq 1] \leq d2^{-\delta(c(F))^\gamma}$. By Corollary 3.4, with $s = (\frac{n}{96k} - 1)/k$, for every k-DNF F,

$$\Pr_{\rho \in \mathcal{P}_{k+1}(G)}[h(F \restriction_\rho) > (n/96k - 1)/k] \leq dk2^{-2\delta^k((n/96k-1)/k)^{\gamma^k}/4^k}.$$

Because d, γ, and δ depend only on k, there exists ϵ_k so that

$$\Pr_{\rho \in \mathcal{D}}[h(F \restriction_\rho) > (n/96k - 1)/k] \leq \frac{1}{2}2^{-n^{\epsilon_k}}.$$

Suppose for the sake of contradiction that Γ is a Res(k) refutation of $GOP^{K+1}(G)$ of size less than $2^{n^{\epsilon_k}}$. By the union bound, with probability at least $\frac{1}{2}$, every line F of Γ has $h(F \restriction_\rho) \leq (n/96k - 1)/k$. On the other hand, because G is $(n/96k)$-robust, $w_R(GOP^{k+1}(G) \restriction_\rho) \geq n/96k$ with probability at least $\frac{3}{4}$. So we may choose $\rho \in \mathcal{P}_{k+1}(G)$ so that $w_R(GOP^{k+1}(G) \restriction_\rho) \geq n/96k$, and for all lines F of Γ, $h(F \restriction_\rho) \leq (n/96k - 1)/k$. By Corollary 5.2, $GOP^{k+1}(G) \restriction_\rho$ has a resolution refutation of width at most $n/96k - 1$. This is a contradiction. ∎

9. Separating Res(k) and Res($k+1$) with constant width clauses. The separation between Res($k+1$) and Res(k) given by Theorem 8.23 uses sets of clauses whose maximum width is $\Theta(\log n)$. In this section we present a similar result which separates Res(k) and Res($k+1$) using constant width clauses.

DEFINITION 9.1. *Let $X_1, \ldots, X_k$ be propositional variables. The formula Odd $(X_1, \ldots, X_k)$ is the k-DNF expressing that the number of satisfied variables of $X_1, \ldots, X_k$ is odd. The formula Even $(X_1, \ldots, X_k)$ is the k-DNF expressing that the number of satisfied variables of $X_1, \ldots, X_k$ is even.*

The k-parity graph ordering principle of G, *$GOP^{\oplus k}(G)$, is obtained by replacing each literal $X_{u,v}$ by Odd $(X^1_{u,v}, \ldots, X^k_{u,v})$, replacing each literal $\neg X_{u,v}$ by Even $(X^1_{u,v}, \ldots, X^k_{u,v})$, and then using the distributive rule and DeMorgan's law to express this set of k-DNFs as a set of clauses.*

Because every clause of $GOP(G)$ contains at most $\max(d, 3)$ literals, every k-DNF in $GOP(G)[X_{u,v} \leftarrow \mathrm{Odd}(X^1_{u,v}, \ldots, X^k_{u,v}), \neg X_{u,v} \leftarrow \mathrm{Even}(X^1_{u,v}, \ldots, X^k_{u,v})]$ contains at most dk variables. When such a DNF is expressed as a set of clauses using the distributive rule, the set of clauses has size at most $2^{O(dk)}$ and each clause has width at most dk. Therefore, $GOP^{\oplus k}(G)$ contains at most $2^{O(dk)}n^3$ clauses, each of width at most dk.

For any graph G, the polynomial-size refutations of $GOP(G)$ can be transformed into Res($k+1$) refutations of $GOP^{\oplus(k+1)}(G)$. On the other hand, Res(k) refutations of $GOP^{\oplus(k+1)}(G)$ require exponential size for certain graphs.

THEOREM 9.2. *Let k be given. There exist constants $d > 0$, $\epsilon_k > 0$ and a family of graphs G on n vertices (for n sufficiently large) with maximum degree d so that Res(k) refutations of $GOP^{\oplus(k+1)}(G)$ require size at least $2^{\Omega(\epsilon_k n)}$.*

9.1. The upper bounds. We build Res(k) refutations for $GOP^{\oplus k}(G)$ from resolution refutations of $GOP(G)$.

DEFINITION 9.3. *Let k be a positive integer and let $X_1, \ldots, X_n$ be propositional variables. Let $X^1_1, \ldots, X^k_1, X^1_2, \ldots, X^k_n$ be new variables. Let σ be the mapping given by $\sigma(X_i) = Even(X^1_i, \ldots, X^k_i)$ and $\sigma(\neg X_i) = Odd(X^1_i, \ldots, X^k_i)$. For a clause $C = \bigvee_i l_i$, let $\sigma(C) = \bigvee_i \sigma(l_i)$.*

LEMMA 9.4. *Let k be a constant. There exists a constant c (dependent only on k) so that for all clauses $A \vee X_i$ and $B \vee \neg X_i$ in the variables $X_1, \ldots, X_n$, there is a derivation of $\sigma(A) \vee \sigma(B)$ from $\{\sigma(A) \vee \sigma(X_i), \sigma(B) \vee \sigma(\neg X_i)\}$ of size $\leq c$.*

Proof. By the completeness of Res(k), there is a Res(k) refutation of the pair of k-DNFs $\{\mathrm{Even}(X_1, \ldots, X_k), \mathrm{Odd}(X_1, \ldots, X_k)\}$. Let c be the minimum size of such a refutation. Because $\sigma(X_i) = \mathrm{Odd}(X^1_i, \ldots, X^k_i)$ and $\sigma(\neg X_i) = \mathrm{Even}(X^1_i, \ldots, X^k_i)$, there is a derivation of $\sigma(A) \vee \sigma(B)$ from $\{\sigma(A) \vee \sigma(X_i), \sigma(B) \vee \sigma(\neg X_i)\}$ of size greater than or equal to c. □

LEMMA 9.5. *For each k, there exists a constant c so that for every G with n vertices and degree at most $d \geq 3$, $GOP^{\oplus k}(G)$ has a Res(k) refutation of size $2^{O(dk)}n^3$.*

Proof. With the repeated application of AND-introduction inferences, $\sigma(GOP(G))$ can be derived from $GOP^{\oplus k}(G)$ in $2^{O(dk)}n^3$ many inferences. By Lemma 8.3, $GOP(G)$ has a refutation of size $O(n^3)$ so by Lemma 9.4, $\sigma(GOP(G))$ has a Res(k) refutation of size $O(cn^3)$. Therefore, $GOP^{\oplus k}(G)$ has a refutation of size $2^{O(dk)}n^3$. □

9.2. Random restrictions.

DEFINITION 9.6. *Let $k \geq 1$ be given, and let G be a graph. The distribution $\mathcal{P}_{k+1}(G)$ on partial assignments ρ to the variables of $GOP^{\oplus(k+1)}(G)$ is given by the*

following experiment:

For each $(u,v) \in V(G)^2$, choose $i \in \{1,\ldots,k+1\}$ uniformly and independently. For each $j \in \{1,\ldots,k\}$, $j \neq i$, set $X^j_{u,v}$ to 0 or 1, uniformly and independently.

LEMMA 9.7. *Let k be given; let F be a k-DNF in the variables of $GOP^{\oplus(k+1)}(G)$. There exist constants $\delta > 0$, dependent only on k, so that $\Pr_{\rho\in\mathcal{P}_{k+1}(G)}[F \restriction_\rho \neq 1] \leq 2^{-\delta\cdot c(F)}$*

Proof. We will say that two terms T and T' are *underlying-variable-disjoint* if whenever $X^i_{u,v} \in T$ and $X^{i'}_{u',v'} \in T'$, we have that $(u,v) \neq (u',v')$. Because F is a k-DNF, it contains at least $c(F)/k(k+1)$ many underlying-variable-disjoint terms. Each of these terms is satisfied with independent probability at least $1/4^k$ (consider setting each variable of a term in turn, the probability that a variable is set to 0 or 1 is always greater than or equal to $1/(k+1-(k-1)) = 1/2$). Therefore, $\Pr_{\rho\in\mathcal{P}_{k+1}(G)}[F \restriction_\rho \neq 1] \leq (1-1/4^k)^{c(F)/k(k+1)}$. □

When we apply a random restriction from $\mathcal{P}_{k+1}(G)$ to $GOP^{\oplus(k+1)}(G)$, we do not necessarily obtain an instance of $GOP(G)$. It is possible that some of the edge variables will become inverted. However, inverting some variables does not affect the width required for a resolution refutation, and we may apply Lemma 8.17.

COROLLARY 9.8. *If G is a connected graph that is ϵ-neighborly, then for all $k \geq 1$ and for all $\rho \in \mathcal{P}_{k+1}(G)$, $GOP^{\oplus(k+1)}(G) \restriction_\rho$ requires width $\left(\frac{1-3\epsilon}{6}\right)n$.*

9.3. The lower bound.

THEOREM 9.9. *Let k be given. There exist constants $d > 0$, $\epsilon_k > 0$ and a family of graphs G on n vertices (for n sufficiently large) with maximum degree c so that Res(k) refutations of $GOP^{\oplus(k+1)}(G)$ require size at least $2^{\Omega(\epsilon_k n)}$.*

Proof. Let k be given. Set $p = 15\ln 6/n$. Consider a random graph selected according to $G_{n,p}$; by Lemma 8.21, G is almost certainly $\frac{1}{6}$-neighborly, and by the Chernoff bounds, it has maximum degree $\leq 2pn = 26\ln 6$. Let G be a graph that is both $\frac{1}{6}$-neighborly and has maximum degree $\leq 26\ln 6$.

By Lemma 9.7, we have that for every k-DNF F, $\Pr_{\rho\in\mathcal{P}_{k+1}(G)}[F \restriction_\rho \neq 1] \leq 2^{-\delta\cdot c(F)}$. Now apply Corollary 3.4 with $s = (n/12-1)/k$, $d = 1$. For every k-DNF F,

$$\Pr_{\rho\in\mathcal{P}_{k+1}(G)}[h(F\restriction_\rho) > (n/12-1)/k] \leq k2^{-2\delta^k((n/12-1)/k)/4^k}.$$

Because k is fixed and δ depends only on k, there exists ϵ_k so that

$$\Pr_{\rho\in\mathcal{D}}[h(F\restriction_\rho) > (n/12-1)/k] < 2^{-\epsilon_k n}.$$

Suppose for the sake of contradiction that Γ is a Res(k) refutation of $GOP^{\oplus(k+1)}(G)$ of size less than $2^{\epsilon_k n}$. By the union bound, with probability greater than 0, every line F of Γ has $h(F\restriction_\rho) \leq (n/12-1)/k$. By Corollary 5.2, $GOP^{k+1}(G)\restriction_\rho$ has a resolution refutation of width at most $n/12-1$. On the other hand, because G is $\frac{1}{6}$-neighborly, $w_R(GOP(G)) \geq \left(\frac{1-3(1/6)}{6}\right)n = n/12$, and therefore $w1_R(GOP^{\oplus(k+1)}(G)\restriction_\rho) \geq w_R(GOP(G)) \geq n/12-1$. This is a contradiction. □

10. Conclusions and open problems. Switching with small restrictions seems to be a promising technique for analyzing the power of bottom fan-in in proof and circuit complexity. Our results could not have been obtained by switching with larger restrictions. For example, the lower bounds for random w-CNFs could not be proved using restrictions that set a constant fraction of the variables because some clause of the hypothesis would be falsified with high probability. Also, this method is relatively easy to apply because you do not have to re-prove the switching lemma for every lower

bound, but only check that the restrictions in question are likely to satisfy k-DNFs with high cover number.

However, switching with small restrictions still suffers from the limitations of random restriction method. In particular, it seems ineffective against random 3-CNFs and very weak pigeonhole principles. The only techniques for understanding the refutation complexity of such CNFs seem specific to resolution [8, 7, 30, 31]. Understanding the refutation complexity of these principles in Res(k) is a necessary step before understanding them in more powerful systems, and the Res(k) systems might be simple enough for the development of new techniques.

With this in mind, we suggest the following open problems as particularly relevant: (1) Do random 3-CNFs almost surely require exponential size refutations in Res(k) for all k? (2) Does there exist a family of 3-CNFs that require exponential size to refute in Res(k) but have (quasi-)polynomial-size proofs in Res($k+1$)? (3) Do Res(2) refutations of PHP_n^m require size exponential in n for all m? (4) Do there exist polynomial-size depth two Frege refutations PHP_n^{2n}? (5) Let $0 < \epsilon \leq 1/2$. Do there exist subexponential-size refutations for $PHP_n^{n+n^{1-\epsilon}}$ in Res(polylog(n))? or even in depth two Frege? (6) Does there exist a family of CNFs that require exponential-size refutations in Res(polylog(n)) but have (quasi-)polynomial-size depth two Frege refutations? (7) For given $\epsilon < \delta \leq 1$, does there exist a family of CNFs that require exponential-size refutations in Res(n^ϵ) but have (quasi-)polynomial-size Res(n^δ) refutations?

APPROXIMATE LOCAL SEARCH IN COMBINATORIAL OPTIMIZATION*

JAMES B. ORLIN†, ABRAHAM P. PUNNEN‡, AND ANDREAS S. SCHULZ§

Abstract. Local search algorithms for combinatorial optimization problems are generally of pseudopolynomial running time, and polynomial-time algorithms are not often known for finding locally optimal solutions for NP-hard optimization problems. We introduce the concept of ε-local optimality and show that, for every $\varepsilon > 0$, an ε-local optimum can be identified in time polynomial in the problem size and $1/\varepsilon$ whenever the corresponding neighborhood can be searched in polynomial time. If the neighborhood can be searched in polynomial time for a δ-local optimum, a variation of our main algorithm produces a $(\delta+\varepsilon)$-local optimum in time polynomial in the problem size and $1/\varepsilon$. As a consequence, a combinatorial optimization problem has a fully polynomial-time approximation scheme if and only if the problem of determining a better neighbor in an exact neighborhood has a fully polynomial-time approximation scheme.

1. Introduction.

A *combinatorial optimization problem* Π consists of a collection of instances $(\mathcal{F}, c)$, where the set $\mathcal{F}$ of feasible solutions is a family of subsets of a finite ground set $E = \{1, \ldots, n\}$. The objective function $c : E \to \mathbb{Q}_+$ assigns a nonnegative cost to every feasible solution $S \in \mathcal{F}$ through $c(S) := \sum_{e \in S} c_e$.[1] We assume that Π is closed under componentwise scaling of objective function coefficients; i.e., if $(\mathcal{F}, c) \in \Pi$, then $(\mathcal{F}, c') \in \Pi$ for all $c' \in \mathbb{Q}_+$. For technical reasons, let us also assume that $c(S) \neq 0$ for $S \in \mathcal{F}$. The goal is to find a globally optimal solution, i.e., a feasible solution S^* such that $c(S^*) \leq c(S)$ for all $S \in \mathcal{F}$.[2] The traveling salesperson problem (TSP) or the minimum spanning tree problem are typical examples of combinatorial optimization problems (see, e.g., Lawler (1976); Papadimitriou and Steiglitz (1982); Lawler et al. (1985); Cook et al. (1998); Korte and Vygen (2002)).

Many combinatorial optimization problems are NP-hard, and one popular practical approach for attacking them is using local search strategies, which presupposes the

[1]Formally, we should point out that we focus on *linear* combinatorial optimization problems as opposed to "general" combinatorial optimization problems, in which the cost of a feasible solution is not necessarily the sum of the cost coefficients of its elements. In other words, the class of problems we are looking at here is equivalent to that of 0/1-integer linear programming problems.

[2]Although we restrict the following discourse to minimization problems, all results extend in a natural way to the case of maximization problems.

concept of a neighborhood. A *neighborhood function* for an instance $(\mathcal{F}, c)$ of a combinatorial optimization problem Π is a mapping $N_{\mathcal{F}} : \mathcal{F} \to 2^{\mathcal{F}}$. Note that we assume that $N_{\mathcal{F}}$ does not depend on the objective function c. For convenience, we usually drop the subscript and simply write N. For a feasible solution S, $N(S)$ is called the *neighborhood* of S. We assume that $S \in N(S)$. A feasible solution $\bar{S}$ is said to be *locally optimal* with respect to N if $c(\bar{S}) \leq c(S)$ for all $S \in N(\bar{S})$. The *local search problem* is that of finding a locally optimal solution. Classic neighborhood functions include the k-opt neighborhood for the TSP (Lin (1965)), the flip neighborhood for MAX CUT and MAX 2SAT (Schäffer and Yannakakis (1991)), and the swap neighborhood for the graph partitioning problem (Kernighan and Lin (1970)). However, the class of problems that we are considering here also includes neighborhoods of exponential size, such as, for the TSP, the twisted sequences neighborhood, the pyramidal tours neighborhood, the permutation tree neighborhood, neighborhoods based on partial orders, and neighborhoods induced by polynomial-time solvable special cases. We refer the reader to Deineko and Woeginger (2000), Ahuja et al. (2002), and Gutin, Yeo, and Zverovitch (2002) for a detailed description of these neighborhood functions.

Roughly speaking, a local search algorithm sets out with an initial feasible solution and then repeatedly searches neighborhoods to find better and better solutions until it reaches a locally optimal solution. Figure 1.1 gives a generic description of the standard local search algorithm, which is sometimes also called *iterative improvement*.

Step 1: Compute a feasible starting solution $\bar{S}$;
Step 2: **while** $\bar{S}$ is not locally optimal **do**
Choose $S \in N(\bar{S})$ such that $c(S) < c(\bar{S})$;
$\bar{S} := S$;
Step 3: Output $\bar{S}$.

FIG. 1.1. *Standard local search algorithm.*

Computational studies of local search algorithms and their variations have been extensively reported in the literature for various combinatorial optimization problems (see, e.g., Johnson et al. (1989) and Johnson and McGeoch (1997) for studies of the graph partitioning problem and the TSP, respectively). Empirically, local search heuristics appear to converge rather quickly, within low-order polynomial time. Compared to this wealth of information on empirical analysis, relatively little is known about theoretical properties of this class of algorithms. Of course, if one first multiplies all cost coefficients with their smallest common denominator to make them integer, the standard local search algorithm terminates in a pseudopolynomial number of iterations since it improves the objective function value by an integral amount in each iteration.[3] However, polynomial-time algorithms for computing a local optimum are in general not known. This is especially true for the above-mentioned combinatorial optimization problems and neighborhoods. On the other hand, Lawler (1976) constructed instances of the metric TSP such that the standard local search algorithm with the 2-opt neighborhood takes an exponential number of iterations under a particular pivoting rule. Chandra, Karloff, and Tovey (1999) extended this result to k-opt for all fixed $k > 2$.

[3] Note that the scaling of rational coefficients to integers does not cause a superpolynomial blowup. We henceforth assume without loss of generality (w.l.o.g.) that all cost coefficients c_e for $e \in E$ are integers. An algorithm is pseudopolynomial if it is polynomial in the input dimension n and in $c_{\max} := \max_{e \in E} c_e$.

Input:	Objective function $c : E \to \mathbb{N}$ and feasible solution $S \in \mathcal{F}$.
Output:	"YES" if S is locally optimal with respect to c and N.
	"NO" and S' if there exists $S' \in N(S)$ with $c(S') < c(S)$.

FIG. 1.2. *Specification of the subroutine (oracle)* IMPROVE$_N$.

This discontenting situation prompted Johnson, Papadimitriou, and Yannakakis (1988) to introduce the complexity class PLS (for polynomial-time local search). A combinatorial optimization problem Π together with a given neighborhood function N belongs to PLS if (a) instances are polynomial-time recognizable and a feasible solution is efficiently computable, (b) the feasibility of a proposed solution can be checked in polynomial time, and (c) neighborhoods can be searched efficiently. That is, there is a polynomial-time algorithm that decides whether a given feasible solution is locally optimal and, if not, computes a better solution in its neighborhood; see Figure 1.2 for a detailed description of the input and output of this algorithm. Note that all common local search problems are in PLS, in particular the problems mentioned earlier. The class PLS has its own type of reduction, which gives rise to the identification of complete problems in that class. For instance, MAX CUT and MAX 2SAT with the flip neighborhood, graph partitioning with the swap neighborhood, and TSP with the Lin–Kernighan neighborhood are PLS-complete (Krentel (1990); Schäffer and Yannakakis (1991); Papadimitriou (1992)), and so is TSP with the k-opt neighborhood for some constant k (Krentel (1989)). In particular, if a local optimum can be found in polynomial time for one of these problems, then a local optimum can be computed in polynomial time for all problems in PLS. Unfortunately, it is unknown whether it is hard to find a local optimum for a PLS-complete problem (but Johnson, Papadimitriou, and Yannakakis (1988) pointed out that this would imply NP = co-NP) or whether this can be done in polynomial time.[4]

In light of this somewhat elusive situation, it is interesting to explore the possibility of identifying *approximately locally optimal* solutions in polynomial time. We therefore introduce the notion of an ε-locally optimal solution, which is to some extent related to the worst-case relative performance guarantee of an approximation algorithm. We say that a feasible solution S^ε to an instance of a combinatorial optimization problem Π with neighborhood function N is an *ε-local optimum* if

$$\frac{c(S^\varepsilon) - c(S)}{c(S)} \leq \varepsilon \qquad \text{for all } S \in N(S^\varepsilon)$$

for some $\varepsilon > 0$. Hence, while S^ε is not necessarily a local optimum, it "almost" is. A family of algorithms $(A_\varepsilon)_{\varepsilon>0}$ for Π is an *ε-local optimization scheme* if A_ε produces an ε-local optimum. If the running time of algorithm A_ε is polynomial in the input size and $1/\varepsilon$, it is called a *fully polynomial-time ε-local optimization scheme*. In this paper, we show that every combinatorial optimization problem with an efficiently searchable neighborhood has a fully polynomial-time ε-local optimization scheme. In particular, an ε-locally optimal solution can be computed in polynomial time for every problem

[4]Note that the negative results for the TSP mentioned at the end of the previous paragraph apply only to the standard local search algorithm, as described in Figure 1.1. Actually, there exist instances for every PLS-complete problem for which the standard local search algorithm takes exponential time, regardless of the tie-breaking and pivoting rules used (Yannakakis (1997), Theorem 13).

in PLS, including the PLS-complete problems and the problems with exponentially sized neighborhoods mentioned above.

Related work. Ausiello and Protasi (1995) introduced the class GLO (for guaranteed local optima) of optimization problems that have the property that the objective function value of each local optimum is guaranteed to be within a constant factor of that of a global optimum. Khanna et al. (1998) extended this notion to nonoblivious GLO problems, which allow for a modification of the objective function used to compute a local optimum. In either class, the underlying neighborhoods contain all solutions of bounded Hamming distance from the current solution; moreover, it is assumed that the number of distinct objective function values over the set of feasible solutions is polynomially bounded. Hence, the standard local search algorithm yields a locally optimal solution in polynomial time. In contrast, we do not make any assumption on the objective function values or neighborhoods considered; we show that an ε-local optimum can always be computed with a polynomial number of calls to the IMPROVE subroutine. On the other hand, while an ε-local optimum has nearly the properties of a local optimum, its objective function value is not guaranteed to be close to that of a global optimum. However, this is in general true for local optima as well. For instance, Papadimitriou and Steiglitz (1977) showed that no local optimum of an efficiently searchable neighborhood for the TSP can be within a constant factor of the optimal value unless P = NP. Yet, whenever a combinatorial optimization problem has an efficiently searchable neighborhood such that the value of each local optimum is within a constant factor $\alpha \geq 1$ of that of a global minimum, then we can compute in polynomial time an ε-local optimum of cost not worse than $\alpha + \varepsilon$ times that of a global optimum. In other words, we give an $(\alpha+\varepsilon)$-approximation algorithm for any $\varepsilon > 0$.

Klauck (1996) studied the complexity of finding a solution whose objective function value is approximately as good as that of the worst local optimum by using a restricted form of PLS-reductions. Completeness under this reduction implies that an approximation of a local optimum cannot be achieved efficiently unless P = PLS. For instance, 0/1-programming with the k-flip neighborhood and the TSP with the k-opt neighborhood for constant k are complete under this reduction.

A neighborhood function N of a combinatorial optimization problem Π is *exact* if every locally optimal solution with respect to N is also globally optimal. In this case, our fully polynomial-time ε-local optimization scheme actually is a fully polynomial-time approximation scheme (FPTAS). This remains true even if IMPROVE already outputs "YES" when the current feasible solution is a δ-local optimum (and does so in time polynomial in the input size and $1/\delta$ for any $\delta > 0$). Grötschel and Lovász (1995) and Schulz, Weismantel, and Ziegler (1995) showed that if a combinatorial optimization problem has an exact neighborhood that can be searched efficiently (and exactly), one can actually find an exact optimal solution efficiently. Schulz and Weismantel (1999, 2002) discussed extensions of this result from 0/1-integer linear programming problems (i.e., combinatorial optimization problems) to arbitrary integer programs. However, none of the employed techniques can be extended to compute a local optimum in polynomial time unless the neighborhood is exact. In fact, otherwise P = PLS.

Fischer (1995) examined a different question, which implies that our main result is best possible if one considers the class of algorithms that iteratively move from one feasible solution to a feasible solution in its neighborhood: Given a feasible solution S to an instance $(\mathcal{F}, c)$ of a combinatorial optimization problem Π and a number k

in unary, does there exist a local optimum within k neighborhood steps of S? She showed that this question is NP-complete for MAX CUT and MAX 2SAT under the flip neighborhood and for the TSP under the 2-opt neighborhood, among others.

Our results. Apart from our main result presented above and discussed in more detail in section 2 below, we offer various evidence in section 3 to show that this result is indeed the "best possible."

First, the fully polynomial-time ε-local optimization scheme produces an ε-locally optimal solution by proceeding from one feasible solution to a solution in its neighborhood, and so forth. In this sense, it is a typical local search algorithm. Fischer's result shows that one cannot hope to find a local optimum in polynomial time by proceeding in this manner. Yet, an ε-local optimum can be determined in polynomial time. The key is to modify the original objective function so as to make sufficient progress in a relatively small number of steps. It is worth mentioning that our algorithm follows a path of feasible solutions that is not necessarily monotone with respect to the original objective function. In particular, it differs from a standard local search algorithm, which always replaces the current solution with a neighboring solution of lower cost.

Second, we point out that *any* algorithm for computing a local optimum that treats the neighborhood search and the feasibility check of PLS problems as oracles must be in the worst case exponential in the input dimension. In other words, if there exists a polynomial-time algorithm to compute a local optimum for a PLS-complete problem, it must use problem-specific knowledge. In contrast, our algorithmic scheme works for any combinatorial optimization problem so long as a feasible solution can be efficiently computed; in particular, it treats the subroutine IMPROVE as a black box.

Third, we show that the existence of a family $(A_\varepsilon)_{\varepsilon>0}$ of algorithms that find ε-local optima in time polynomial in the input size and $\log 1/\varepsilon$ implies the existence of a polynomial-time algorithm for computing a local optimum, and we just argued why this is impossible in our framework. Hence, the dependence of the running time on $1/\varepsilon$ cannot be significantly improved. Furthermore, we prove that replacing the relative error in the definition of an ε-local optimum with the absolute error would also yield the existence of a polynomial-time algorithm for computing a local optimum.

Finally, in section 4 we present various extensions and variations of the main result, including more general integer linear programming problems and the new characterization for when a combinatorial optimization problem has an FPTAS, which we already described in the context of related results for exact neighborhoods. Moreover, we discuss neighborhoods of polynomial size and efficiently searchable neighborhoods with local optima guaranteed to be near-optimal.

2. A fully polynomial-time ε-local optimization scheme. In this section we develop a polynomial-time algorithm to compute an ε-local optimum for a given instance $(\mathcal{F}, c)$ with ground set E of a combinatorial optimization problem Π with neighborhood function N.[5] The algorithm starts with a feasible solution S^0. We then alter the element costs c_e for $e \in E$ according to a prescribed scaling rule to generate a modified instance. Using local search on this modified problem, we look for a solution with an objective function value (with respect to the original cost) that is half that of S^0. If no such solution is found, we are at a local optimum for the

[5] The algorithm presented here works for neighborhoods of any size, in particular exponential-sized neighborhoods. Section 4.3 features a somewhat simpler algorithm for neighborhoods of polynomial size, which are given explicitly.

Input: Objective function $c : E \to \mathbb{N}$; subroutine IMPROVE$_N$; initial feasible solution $S^0 \in \mathcal{F}$; accuracy $\varepsilon > 0$.

Output: Solution $S^\varepsilon \in \mathcal{F}$ that is an ε-local optimum with respect to N and c.

Step 1: Let $i := 0$;

Step 2: Let $K := c(S^i)$, $q := \dfrac{K\varepsilon}{2n(1+\varepsilon)}$, and $c'_e := \left\lceil \dfrac{c_e}{q} \right\rceil q$ for $e \in E$;

Step 3: Let $k := 0$ and $S^{i,k} := S^i$;

Step 4: **repeat**

Call IMPROVE$_N(S^{i,k}, c')$;

if the answer is "NO," **then**

Let $S^{i,k+1} \in N(S^{i,k})$ such that $c'(S^{i,k+1}) < c'(S^{i,k})$; set $k := k + 1$;

else $S^\varepsilon := S^{i,k}$; **stop**.

until $c(S^{i,k}) \le K/2$;

Step 5: Let $S^{i+1} := S^{i,k}$, set $i := i + 1$ and **goto** Step 2.

FIG. 2.1. *ε-local search algorithm.*

modified problem and output this solution. Otherwise we replace S^0 by the solution of cost less than half, we call the latter one S^1, and the algorithm is repeated. A formal description of the algorithm is given in Figure 2.1. Note that the modification of the cost coefficients in Step 2 merely amounts to rounding them up to the closest integer multiple of q. Let us establish correctness first.

THEOREM 2.1. *The ε-local search algorithm produces an ε-local optimum.*

Proof. The ε-local search algorithm terminates, which follows from the running time analysis following this proof. Let S^ε be the solution produced by the algorithm, and let $S \in N(S^\varepsilon)$ be an arbitrary solution in its neighborhood. Let K and q denote the corresponding values from the last execution of Step 2 of the algorithm. Note that

$$c(S^\varepsilon) = \sum_{e \in S^\varepsilon} c_e \le \sum_{e \in S^\varepsilon} \left\lceil \frac{c_e}{q} \right\rceil q \le \sum_{e \in S} \left\lceil \frac{c_e}{q} \right\rceil q \le \sum_{e \in S} q\left(\frac{c_e}{q} + 1 \right) \le \sum_{e \in S} c_e + nq = c(S) + nq,$$

where $n = |E|$. Here, the second inequality follows from the fact that S^ε is locally optimal with respect to c'. Together with $c(S^\varepsilon) \ge K/2$, this implies

$$\frac{c(S^\varepsilon) - c(S)}{c(S)} \le \frac{nq}{c(S)} \le \frac{nq}{c(S^\varepsilon) - nq} \le \frac{2nq}{K - 2nq} = \varepsilon. \qquad \square$$

Let us now analyze the running time of the ε-local search algorithm. In each improving move within the local search in Step 4 of the algorithm, the objective function value (with respect to c') is decreased by at least q units. Thus the number of calls to IMPROVE between two consecutive iterations of Step 2 is $O(n(1+\varepsilon)/\varepsilon) = O(n/\varepsilon)$. Step 2 is executed at most $\log c(S^0)$ times, where S^0 is the starting solution. Thus the total number of neighborhoods searched is $O(n\,\varepsilon^{-1} \log c(S^0))$. Therefore, if the neighborhood N can be searched in polynomial time for an improving solution, we have a fully polynomial-time ε-local optimization scheme. Note that the number of

iterations includes the factor $\log c(S^0)$, and hence the bound is not strongly polynomial. However, it is possible to prove a strongly polynomial bound on the number of iterations. For this, we make use of the following lemma, which Radzik (1993) attributed to Goemans.

LEMMA 2.2. *Let $d = (d_1, \ldots, d_n)$ be a real vector and let $y_1, \ldots, y_p$ be vectors in $\{0,1\}^n$. If, for all $i = 1, \ldots, p-1$, $0 \le d\,y_{i+1} \le \frac{1}{2}\,d\,y_i$, then $p = \mathrm{O}(n \log n)$.*

Note that the value of K at each execution of Step 2 is reduced at least by half. Further, K is a linear combination of c_e for $e \in E$ and the coefficients in this linear combination are from the set $\{0,1\}$. Lemma 2.2 implies that Step 2 of the ε-local search algorithm can be executed at most $\mathrm{O}(n \log n)$ times. Thus the total number of calls of IMPROVE in Step 4 throughout the algorithm is $\mathrm{O}(\varepsilon^{-1} n^2 \log n)$. If $\zeta(n, \log c_{\max})$ is the time needed to search the neighborhood N for an improving solution (i.e., the running time of IMPROVE) and $\xi(n)$ is the time needed to obtain a feasible starting solution, the complexity of the ε-local search algorithm is $\mathrm{O}(\xi(n) + \zeta(n, \log c_{\max}) n\,\varepsilon^{-1} \min\{n \log n, \log K^0\})$, where $K^0 := c(S^0)$ is the objective function value of the starting solution and $c_{\max}$ is the maximal value of an objective function coefficient. The following theorem summarizes the preceding discussion.

THEOREM 2.3. *The ε-local search algorithm correctly identifies an ε-locally optimal solution of an instance of a combinatorial optimization problem in $\mathrm{O}(\xi(n) + \zeta(n, \log c_{\max}) n\,\varepsilon^{-1} \min\{n \log n, \log K^0\})$ time.*

Thus if $\zeta(n, \log c_{\max})$ and $\xi(n)$ are polynomial, then the ε-local search algorithm is a fully polynomial-time ε-local optimization scheme. Note that $\zeta(n, \log c_{\max})$ and $\xi(n)$ are indeed polynomials of the input size for all problems in PLS.

COROLLARY 2.4. *Every problem in PLS has a fully polynomial-time ε-local optimization scheme.*

The running time of the ε-local search algorithm can sometimes be improved by exploiting the special structure of the underlying neighborhood. A neighborhood function N generates a so-called k-opt neighborhood if $S_1, S_2 \in N(S)$ implies $|(S_1 \setminus S_2) \cup (S_2 \setminus S_1)| \le k$, which is equivalent to bounding the Hamming distance between the incidence vectors of S_1 and S_2 by k. For the k-opt neighborhood, by choosing the parameter $q := \frac{K\varepsilon}{2k(1+\varepsilon)}$ in the ε-local search algorithm, we still get an ε-local optimum. Moreover, the number of calls of IMPROVE between two consecutive executions of Step 2 of this modified algorithm is $\mathrm{O}(\varepsilon^{-1})$ for fixed k. This brings down the total number of such calls to $\mathrm{O}(\varepsilon^{-1} \min\{n \log n, \log K^0\})$ and implies a running time of $\mathrm{O}(\xi(n) + n^k \varepsilon^{-1} \min\{n \log n, \log K^0\})$ for the ε-local search algorithm.

Similarly, if the considered combinatorial optimization problem possesses a 2-approximation algorithm, one can use this algorithm to compute the starting solution S^0. If such a solution is used as the starting solution, then the ε-local search algorithm executes Step 2 only once and hence the total number of improving moves is $\mathrm{O}(n\,\varepsilon^{-1})$. Consequently, the overall running time of the ε-local search algorithm is $\mathrm{O}(\xi(n) + \zeta(n, \log c_{\max}) n\,\varepsilon^{-1})$, where $\xi(n)$ now denotes the running time of the 2-approximation algorithm. In fact, whenever one has a feasible solution S^0 for an instance I such that $c(S^0) \le p(\langle I \rangle) c(S^*)$ for some polynomial p of the input size $\langle I \rangle$, then one can adapt the value of q to $q := (K\varepsilon)/(n\,p(\langle I \rangle)(1+\varepsilon))$ and the stopping criterion of the main loop accordingly, so that the ε-local search algorithm computes an ε-local optimum in $\mathrm{O}(n\,p(\langle I \rangle)\varepsilon^{-1})$ iterations.

Arkin and Hassin (1998) applied a similar approach to that used in the ε-local search algorithm to compute a local optimum in polynomial time in the context of the weighted k-set packing problem. They considered a neighborhood for which the value of each local optimum is within a certain factor of the value of a global optimum;

hence, this approach, which they attributed to Rubinstein, leads to a polynomial-time approximation algorithm. It has since been applied in related situations as well; see, e.g., Arkin et al. (2002).

3. Negative results. In this section we present a collection of results that underscore that neither the accuracy of the solutions produced by the ε-local search algorithm nor its running time can be significantly improved unless additional, problem-specific knowledge is used. Let us first argue that any algorithm to compute a local optimum for a problem in PLS has to have exponential running time in the worst case if the algorithms for checking feasibility and neighborhood search are oracles completely hiding both the set of feasible solutions and the neighborhood structure.

THEOREM 3.1. *If the only available information on an instance $(\mathcal{F}, c)$ of a combinatorial optimization problem Π is the objective function vector c, a feasible solution $S^0 \in \mathcal{F}$, a membership oracle, and a neighborhood search oracle* IMPROVE*, then any algorithm for computing a local optimum takes exponential time in the worst case.*

Proof. Let the ground set be $E = \{1, 2, \ldots, n\}$. The objective function coefficients are $c_i = 2^{i-1}$ for $i = 1, 2, \ldots, n$. Let the nonempty subsets of E be labeled $S^0, S^1, \ldots, S^{2^n-2}$ such that $c(S^0) > c(S^1) > \cdots > c(S^{2^n-2})$. Let A be an arbitrary algorithm that computes a local optimum. Note that A can either call IMPROVE with a feasible solution and some objective function or check whether a particular solution is feasible by asking the membership oracle. We show that A needs exponential time in the worst case by exhibiting an adverse strategy. In fact, an adversary adapts the set of feasible solutions and the neighborhood function to A's sequence of questions as follows. Whenever A asks the membership oracle whether a set S^i is feasible, the adversary answers "NO" unless S^i has been declared feasible earlier. On the other hand, whenever A calls up IMPROVE with a feasible solution S^i and an objective function vector c', IMPROVE returns S^j, where $j > i$ is the smallest index for which S^j has not been labeled infeasible. If no such j exists or $c'(S^j) \geq c'(S^i)$, then S^i is locally optimal (with respect to c'). It is not difficult to see that A has to touch every single subset before it can identify the unique minimum. □

The importance of Theorem 3.1 relates to the fact that the ε-local search algorithm requires only a subset of the information stated in the assumptions of this theorem; in particular, it does not make use of the membership oracle.

We next note that finding an ε-local optimum of *additive error* ε with respect to a given neighborhood structure is as hard as finding a local optimum with respect to the same neighborhood structure. While its proof relies on a standard argument, the result is still worth recording.

OBSERVATION 3.2. *If there is an algorithm that for every instance $(\mathcal{F}, c)$ of a combinatorial optimization problem Π with neighborhood N finds in polynomial time a feasible solution S_ε such that $c(S_\varepsilon) \leq c(S) + \varepsilon$ for all $S \in N(S_\varepsilon)$ for some fixed $\varepsilon > 0$, then there is a polynomial-time algorithm to find a local optimum.*

Proof. Let $(\mathcal{F}, c)$ be an instance of Π, where w.l.o.g. c is an integer-valued function. Create a new instance $(\mathcal{F}, c')$ by setting $c'_e := (1+\varepsilon)c_e$ for all elements e of the ground set. Apply the given algorithm to the new instance and let S' be the resulting solution. Then $c'(S') - c'(S) \leq \varepsilon$ for all $S \in N(S')$. Thus, $c(S') - c(S) \leq \varepsilon/(\varepsilon + 1) < 1$ for all $S \in N(S')$. Since c is integer-valued, it follows that S' is a local optimum for the original instance. □

The next result is somewhat similar to (Garey and Johnson (1979), Theorem 6.8) except that we are discussing it in the context of local optimality.

OBSERVATION 3.3. *If a combinatorial optimization problem Π has a fully poly-*

nomial-time ε-local optimization scheme $(A_\varepsilon)_{\varepsilon>0}$ such that the actual running time of A_ε is polynomial in the input size and $\log 1/\varepsilon$, then there is a polynomial-time algorithm that computes a local optimum.

Proof. Let $(\mathcal{F}, c)$ be an instance of Π, where w.l.o.g. c is an integer-valued function. Choose $\varepsilon := 1/(n\, c_{\max} + 1)$ and apply A_ε. Note that its running time is polynomial in the input size of the instance. If S^ε is the solution returned by this algorithm, then $c(S^\varepsilon) \le (1+\varepsilon)c(S) < c(S) + 1$ for all $S \in N(S^\varepsilon)$. Hence, S^ε is a local optimum. ∎

4. Extensions and variants. We now discuss some extensions and variations of the results of section 2 that range from approximation guarantees in the case of exact neighborhoods, over simplifications of the ε-local search algorithm for explicitly given neighborhoods of polynomial size, to replacing IMPROVE with weaker oracles and bounded integer programming problems.

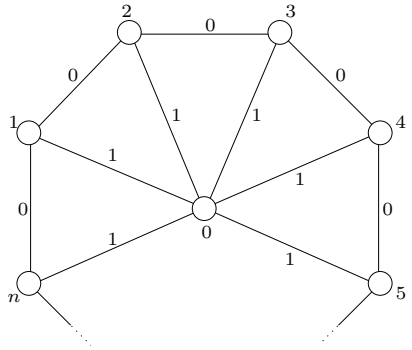

FIG. 4.1. *A wheel on $n+1$ nodes.*

4.1. Exact neighborhoods. Recall that a neighborhood function N for a combinatorial optimization problem Π is exact if every local optimum is already globally optimal. In view of this, one may be tempted to conjecture that the objective function value of an ε-local optimum with respect to an exact neighborhood is also within a factor of $(1+\varepsilon)$ of the value of a global optimum. However, this is not true as shown by the following example.

Let $G = (V, E)$ be a connected graph with edge weights c_e for $e \in E$. Let $\mathcal{F}$ be the family of all spanning trees of G. Hence, we are considering the minimum spanning tree problem. For any tree $T \in \mathcal{F}$, consider the neighborhood $N(T)$ that consists of those spanning trees obtained from T by adding an edge $e \in E \setminus T$ to T and removing an edge $f \in T$ from the induced elementary cycle. This is the 2-opt neighborhood, which is known to be exact. Now choose G as a wheel (see Figure 4.1) with node set $\{0, 1, \ldots, n\}$. For each edge $(0, i)$, $i = 1, 2, \ldots, n$, of this wheel, assign a cost of 1, and for each edge $(i, i+1)$, $i = 1, 2, \ldots, n$ (where node $n+1$ is identified with node 1), assign a cost of zero. The spanning tree T^ε, which is a star rooted at node 0, is a $1/(n-1)$-local optimum for any $n \ge 3$. However, the Hamiltonian path $T^* = (0, 1, \ldots, n)$ is a minimum spanning tree and $c(T^\varepsilon) - c(T^*) = (n-1)c(T^*)$. Thus, T^ε is not a $(1+\varepsilon)$-approximation for any $\varepsilon < n - 1$.

Still, for exact neighborhoods our fully polynomial-time ε-local optimization scheme actually is an FPTAS, as the following theorem shows.

THEOREM 4.1. *If the neighborhood N of a combinatorial optimization problem Π is exact, then the objective function value of the solution produced by the ε-local search algorithm is within a factor of $(1+\varepsilon)$ of that of a global minimum.*

Proof. Let $(\mathcal{F}, c)$ be a given instance of Π. Let S^* be an optimal solution and let S^ε be the solution produced by the algorithm. Let K, q, and c' denote the corresponding values from the last execution of Step 2 of the ε-local search algorithm. Since S^ε is locally optimal with respect to c' and the neighborhood is exact, S^ε is an optimal solution for $(\mathcal{F}, c')$. Thus,

$$c(S^\varepsilon) \le \sum_{e \in S^\varepsilon} \left\lceil \frac{c_e}{q} \right\rceil q \le \sum_{e \in S^*} \left\lceil \frac{c_e}{q} \right\rceil q \le \sum_{e \in S^*} q\left(\frac{c_e}{q} + 1\right) \le c(S^*) + nq \le c(S^*) + \frac{\varepsilon}{1+\varepsilon}\, c(S^\varepsilon),$$

where the last inequality follows from the definition of q and the fact that $c(S^\varepsilon) \ge K/2$. The result follows. □

Theorem 4.1 implies that whenever a combinatorial optimization problem has an exact neighborhood and an initial feasible solution is readily available, then the ε-local search algorithm is a $(1+\varepsilon)$-approximation algorithm that calls IMPROVE a polynomial number of times. However, Grötschel and Lovász (1995) and Schulz, Weismantel, and Ziegler (1995) showed that under these circumstances, one can actually compute an optimal solution with a polynomial number of calls of IMPROVE. Yet, one still obtains an FPTAS even if the exact neighborhood can only be searched approximately, as we are about to see next.

4.2. Approximate version of neighborhood search. Very large-scale neighborhood (VLSN) search algorithms are local search algorithms using neighborhoods of very large size; see Ahuja et al. (2002) for a survey. For many VLSNs of NP-hard combinatorial optimization problems, the problem of finding an improving solution is itself NP-hard. On the other hand, solutions produced by local search algorithms using such huge neighborhoods could be of very high quality. To keep the complexity of a VLSN algorithm manageable, approximation algorithms are often employed to search an underlying neighborhood such that if the approximation algorithm fails to find an improving move, the algorithm terminates, leaving an "approximate" local solution. More precisely, instead of IMPROVE, we may only have at our command a subroutine δ-IMPROVE, which solves the following problem:

(4.1)

Given an objective function vector c and a solution $S \in \mathcal{F}$, find $S' \in N(S)$ such that $c(S') < c(S)$, or assert that S is a δ-local optimum.

Naturally, finding a δ-local optimum efficiently, given an algorithm δ-IMPROVE, faces similar difficulties as the problem of finding a local optimum when an algorithm IMPROVE is provided. However, one can easily modify the ε-local search algorithm so that it computes a $(\delta+\varepsilon)$-local optimum in polynomial time. In fact, if one uses δ-IMPROVE in lieu of IMPROVE and selects the scaling parameter q to be $q := \frac{K\varepsilon}{2n(1+\delta)(1+\delta+\varepsilon)}$, the resulting algorithm produces a $(\delta+\varepsilon)$-local optimum in time $O(\xi(n) + \psi(n, \log c_{\max})\, n\, \varepsilon^{-1} \min\{n \log n, \log K^0\})$, where $\psi(n, \log c_{\max})$ is the running time of δ-IMPROVE. Hence, a (strongly) polynomial-time algorithm for solving (4.1) implies a (strongly) polynomial-time algorithm to compute a $(\delta+\varepsilon)$-local optimum for every $\varepsilon > 0$. In view of the results discussed in section 4.1, it is particularly interesting to note that in the case of an exact neighborhood, the existence of a polynomial-time algorithm δ-IMPROVE for all $\delta > 0$ implies that the combinatorial optimization problem possesses an FPTAS. Indeed, if we call (4.1) the *augmentation problem* if N is exact (e.g., $N(S) = \mathcal{F}$ for all $S \in \mathcal{F}$) and $\delta = 0$, and a family of algorithms δ-IMPROVE (with running time polynomial in the input size and $1/\delta$ for all

$\delta > 0$) a *fully polynomial-time approximation scheme for the augmentation problem*, we can state the following result.

THEOREM 4.2. *A combinatorial optimization problem has a fully (strongly) polynomial-time approximation scheme if and only if its corresponding augmentation problem has a fully (strongly) polynomial-time approximation scheme.*

The proof of Theorem 4.2 is similar to that of Theorem 4.1.

Sometimes the objective function value of each local optimum is within a constant factor of that of a global optimum. The class of problems with this property contains the class GLO (Ausiello and Protasi (1995)). For instance, each local optimum of the flip neighborhood for the MAX CUT problem has value at least half that of an optimal cut (Sahni and Gonzalez (1976)). The following theorem can be proved in a similar manner to Theorem 4.1 by setting $q := \frac{K\varepsilon}{2n\alpha(1+\varepsilon)}$ in the ε-local search algorithm.

THEOREM 4.3. *Let Π be a combinatorial optimization problem with efficiently searchable neighborhood function N such that every local optimum is within a constant factor $\alpha \geq 1$ of the optimal value. Then there is an algorithm that computes a feasible solution of cost at most $\alpha + \varepsilon$ times that of an optimal solution in time polynomial in the input size and $1/\varepsilon$, for any $\varepsilon > 0$.*

4.3. Polynomial-sized neighborhoods. The ε-local search algorithm is designed to work for any local search problem for which an IMPROVE (or δ-IMPROVE) oracle is available, regardless of the size or structure of the neighborhood and the implementation of IMPROVE. In particular, the ε-local search algorithm identifies for the TSP and each of the following neighborhoods an ε-local optimum in polynomial time: the twisted sequences neighborhood, the pyramidal tours neighborhood, the permutation tree neighborhood, neighborhoods based on partial orders, as well as neighborhoods induced by polynomial-time solvable special cases. While all these exponential-sized neighborhoods can be searched efficiently (i.e., they have polynomial-time improvement oracles), it is not known for any of them how to find a local optimum in polynomial time (Deineko and Woeginger (2000); Ahuja et al. (2002); Gutin, Yeo, and Zverovitch (2002)).

Input:	Objective function $c : E \to \mathbb{N}$; neighborhood function $N : \mathcal{F} \to 2^{\mathcal{F}}$; initial feasible solution $S \in \mathcal{F}$; accuracy $\varepsilon > 0$.
Output:	Solution $S^{\varepsilon} \in \mathcal{F}$ that is an ε-local optimum with respect to N and c.
Step 1:	**while** S is not ε-locally optimal **do** Choose $S' \in N(S)$ satisfying $c(S') < c(S)/(1+\varepsilon)$; $S := S'$;
Step 2:	**return** $S^{\varepsilon} := S$.

FIG. 4.2. *ε-local search algorithm for neighborhoods of polynomial size.*

Nonetheless, neighborhoods frequently are of polynomial size and explicitly given, like the k-opt neighborhood for the TSP (for fixed k), the flip neighborhood for MAX CUT and MAX 2SAT, or the swap neighborhood for the graph partitioning problem. In this case, one can give a simpler algorithm for computing an ε-local optimum; see Figure 4.2. Note that Step 1 can be realized by an exhaustive search of the neighborhood of S. Obviously, the running time of this algorithm is polynomial in the input size and $1/\varepsilon$. By using an appropriately modified version of Lemma 2.2, one can actually show that the running time depends only on the input dimension n and $1/\varepsilon$.

However, this simpler algorithm has some drawbacks compared to the general ε-local search algorithm, even if one limits this comparison to problems with explicitly given neighborhoods of polynomial size. In particular, neither Theorem 4.1 nor Theorem 4.2 can be proved with its help. In fact, for the minimum spanning tree example described in Figure 4.1, the simpler algorithm with accuracy $\varepsilon \geq 1/(n-1)$ would terminate with the initially given solution T^{ε}, although the cost of this solution is n times that of an optimal solution. In contrast, the original ε-local search algorithm would return an optimal solution in this case (and a $(1+\varepsilon)$-approximate solution in general).

4.4. Weaker version of neighborhood search. In the context of global optimization, Schulz, Weismantel, and Ziegler (1997) pointed out that the requirements on the improvement oracle can be somewhat weakened. Interestingly, this extension also works in the context of local optimization, as we will show now. For that, we replace IMPROVE with another subroutine, which we call TEST. TEST accepts the same input as IMPROVE, namely, a current feasible solution S together with an objective function vector c. It also answers "YES" or "NO" depending on whether S is locally optimal with respect to c or not, but in contrast to IMPROVE it does not provide a solution $S' \in N(S)$ of lower cost if S is not locally optimal. It just answers "YES" or "NO."

LEMMA 4.4. TEST *can emulate* IMPROVE *in polynomial time; i.e., whenever the input solution S is not locally optimal, a polynomial number of calls to* TEST *suffices to create a solution $S' \in N(S)$ of lower cost.*[6]

Proof. Let $(\mathcal{F}, c)$ be an instance and S a feasible solution that is not locally optimal with respect to c under the given neighborhood N. W.l.o.g., we may assume that $S = E$.[7] Here, $E = \{1, 2, \ldots, n\}$ is the ground set. The algorithm that we are about to explain proceeds by considering one coordinate after the other. In particular, it will call TEST n times. The first call $\text{TEST}_N(S, c^1)$ is made with the objective function

$$c_e^1 := \begin{cases} c_1 - M & \text{if } e = 1, \\ c_e & \text{otherwise} \end{cases} \qquad \text{for } e \in E,$$

where $M := n\, c_{\max} + 1$. If TEST responds with "YES," then we can infer that all solutions S' in $N(S)$ of cost lower than S with respect to c satisfy $1 \notin S'$. On the other hand, if the reply is "NO," then there is at least one solution $S' \in N(S)$ such that $c(S') < c(S)$ and $1 \in S'$.

In general, assume that we already know a subset $R \subseteq \{1, 2, \ldots, k\}$ for some $k \in \{1, 2, \ldots, n-1\}$ with the following two properties:

(i) there exists a solution $S' \in N(S)$ with $c(S') < c(S)$ such that $R = S' \cap \{1, 2, \ldots, k\}$;
(ii) if $j \notin R$ for $1 \leq j \leq k$, then all solutions $S'' \in N(S)$ with $c(S'') < c(S)$ satisfy $R \cap \{1, 2, \ldots, j\} = S'' \cap \{1, 2, \ldots, j\}$.

We then call $\text{TEST}_N(S, c^{k+1})$ with

$$c_e^{k+1} := \begin{cases} c_e - M & \text{if } e \in R, \\ c_{k+1} - M & \text{if } e = k+1, \\ c_e & \text{otherwise} \end{cases} \qquad \text{for } e \in E.$$

If the result is "YES," then we can infer that all solutions $S' \in N(S)$ with $c(S') < c(S)$ and $S' \cap \{1, 2, \ldots, k\} = R$ satisfy $k+1 \notin S'$. However, if the reply is "NO," then there

[6] In contrast to all other results presented in this paper, here we need to assume that TEST accepts arbitrary, not just nonnegative, cost coefficients. In particular, we set $c_{\max} := \max_{e \in E} |c_e|$.

[7] Otherwise one can transform the given instance into an equivalent one for which this is the case.

must be a solution $S' \in N(S)$ with $c(S') < c(S)$ and $S' \cap \{1, 2, \ldots, k\} = R$ such that $k+1 \in S'$. We leave R unchanged in the former case, and we set $R := R \cup \{k+1\}$ in the latter case.

Consequently, after n steps we have identified a set $S' = R \in N(S)$ such that $c(S') < c(S)$. □

Lemma 4.4 and Theorem 2.3 imply the following result.

COROLLARY 4.5. *An ε-local optimum of an instance $(\mathcal{F}, c)$ of a combinatorial optimization problem Π with neighborhood function N that is given via a* TEST *oracle of running time $\zeta(n, \log c_{\max})$ can be computed in time*

$$O(\xi(n) + \zeta(n, \log c_{\max}) n^2 \varepsilon^{-1} \min\{n \log n, \log K^0\}).$$

4.5. Bounded integer linear programming problems. Let us finally discuss some generalizations to the case of integer linear programs with bounded variables. In our discussions so far, we considered combinatorial optimization problems, which in fact are 0/1-integer linear programs, i.e., problems of the form $\min\{c\,x : x \in \mathcal{F}\}$ with $\mathcal{F} \subseteq \{0,1\}^n$. Interestingly, most of our results extend directly to the case of integer linear programs with bounded variables, which can be described as follows: $\min\{c\,x : x \in \mathcal{F}\}$ with $\mathcal{F} \subseteq \{0, 1, \ldots, u\}^n$ for some nonnegative integer u. In this context, a neighborhood assigns to each feasible solution $x \in \mathcal{F}$ a set of feasible points in $\{0, 1, \ldots, u\}^n$. If an initial feasible solution and an algorithm IMPROVE are available, the ε-local search algorithm can easily be modified to compute an ε-local optimum in this setting as well. In fact, by choosing the scaling parameter $q := \frac{K\varepsilon}{2n(1+\varepsilon)u}$, its number of iterations (and therefore the number of calls to IMPROVE) is $O(n\,\varepsilon^{-1} u \log K^0)$. Thus, if an initial feasible solution can be identified in polynomial time, if IMPROVE can be implemented in polynomial time, and if u is bounded by a polynomial in n and $\log c_{\max}$, then the ε-local search algorithm runs in polynomial time.

Acknowledgments. The authors are grateful to an anonymous referee for several insightful suggestions, which helped to improve the presentation of this paper. In particular, he or she brought the algorithm described in Figure 4.2 to their attention. They also thank Rafi Hassin for pointing them to the papers by Arkin and Hassin (1998) and Arkin et al. (2002) after reading an earlier version of this paper.

A NOTE ON THE HOMOTOPY TYPE OF WAIT-FREE ATOMIC SNAPSHOT PROTOCOL COMPLEXES*

JOHN HAVLICEK†

Abstract. In the atomic snapshot system model, the processes of an asynchronous distributed system communicate by atomic write and atomic snapshot read operations on a shared memory consisting of single-writer multiple-reader registers. The processes may fail by crashing. It is shown that in this model, a wait-free full-information protocol complex is homotopy equivalent to the underlying input complex. A span in the sense of Herlihy and Shavit provides the homotopy equivalence. It follows that the protocol and input complexes are indistinguishable by ordinary homology or homotopy groups.

Key words. distributed computing, wait-free protocol, atomic snapshot, topology, homotopy, simplicial complex

1. Introduction.

Consider an asynchronous distributed system of $n+1$ processes that interact via shared objects, and assume that processes may fail by crashing. Coordination problems such as consensus and its generalizations, known as *decision tasks*, are fundamental to computation in such a system. A basic question of fault-tolerant computability in the system is whether a given decision task can be solved despite failure by various numbers of the constituent processes. A protocol that solves a decision task regardless of any pattern of failures by up to f processes is called *f-resilient*. A protocol that is n-resilient for a system of $n+1$ processes is said to be *wait-free*.

In this note, we restrict our attention to wait-free computation by deterministic protocols. By using Borowsky–Gafni simulation [BG2, B, LR], the question of f-resilient solvability of a decision task can in many cases be reduced to the question of wait-free solvability of essentially the same task in a smaller system. Thus, the theory of wait-free computation is of considerable significance.

It has been well established that insight into wait-free solvability of decision tasks is gained by introducing certain simplicial complexes and using standard techniques for studying their combinatorial and topological structure. The primer [HR] provides a good introduction to this area of research. Simplicial complexes are associated with the inputs and outputs of the task, and recent work [H] shows that it is also possible to define a simplicial complex representing the task relation. If a protocol is wait-free on an input complex, then there is an associated protocol complex, which is a geometric representation of the various possible executions of the protocol. The general structure of the protocol complex depends on the system model and is especially sensitive to the kinds of shared objects that are available. The success of the entire approach hinges on the fact that the topology of the simplicial complexes is computationally significant. Indeed, the combinatorial and topological relationships between the various complexes

†Motorola, Inc., 7700 W. Parmer Lane, Austin, TX 78729 (john.havlicek@motorola.com).

convey critical information about the solvability of the task and, if solvable, about the complexity of solution.

A typical system model in this line of research has a foundation of single-writer multiple-reader shared-memory registers. More sophisticated shared objects, such as (m, k)-consensus objects, may be added, significantly increasing the computational power of the system. For this note, however, we are interested in the underlying shared-memory register system. In addition to atomic writes, the system is assumed, without loss of generality [Af+], to provide atomic snapshot reads for accessing shared memory. This basic system will be referred to as the *atomic snapshot* (AS) system model. In order to maximize computational power in the model, it is generally assumed that protocols are structured to record full information. This means that each process locally accumulates a *view* (i.e., history) of the computation and maintains a copy of this view in shared memory. When a process reads, it appends a snapshot of the entire shared memory to its local view; and when a process writes, the value written is simply the current view of the process. It is not difficult to see that any other value that one might desire the process to write can be inferred from the view.

Several variations on the AS system model have been proposed. [BG1] introduces the *immediate snapshot* (IS) system model, whose executions are a strict subset of the AS executions. In the IS model, the individual write and read operations are fused into a single *WriteRead* operation. A set of processes may execute concurrent WriteRead operations, the effect being equivalent to an AS execution in which the processes of the set perform concurrent writes and then immediately perform concurrent snapshot reads. Another alternative is the *iterated immediate snapshot* (IIS) system model [B, BG3, HoS]. For the IIS system model, shared memory is divided into disjoint regions; one region is used for each immediate snapshot of the system. When a process executes its kth WriteRead operation, it writes a value into its single-writer portion of the kth memory region, and an immediate atomic snapshot of the kth memory region (only) is returned to the process. This snapshot value is then the value to be written by the process in the $(k+1)$th WriteRead operation.

It is known [BG3] that the AS, IS, and IIS system models are all computationally equivalent for wait-free solution of decision tasks. In other words, a decision task is wait-free solvable in one of the system models if and only if it is wait-free solvable in all three. However, the protocol complexes that arise from the different models are structurally distinct.

The IIS system model is the most restrictive. As a result, the associated protocol complexes have the simplest structure. If a protocol is normalized so that each process is directed to execute the same number of WriteRead operations (i.e., there is no early stopping), then the protocol complex is an iterated standard chromatic subdivision of the complex of input values [B, BG3, HS2]. Without normalization, the protocol complex is a nonuniform chromatic subdivision of the input complex [HoS]. In either case, an IIS protocol complex is homeomorphic to (i.e., of the same topological type as) the underlying input complex.

It has been claimed [BG3, p. 197] that protocol complexes in the IS system model are also chromatic subdivisions of the underlying input complexes, from which it follows that an IS protocol complex is also homeomorphic to the underlying input complex. No published proof of the claim is known to the author.

The purpose of this note is to clarify the structure of wait-free full-information protocol complexes in the AS system model. An AS protocol complex is not generally homeomorphic to the underlying input complex. Nevertheless, an AS protocol com-

plex is equivalent to the input complex in a weaker topological sense. In this note we show that a wait-free full-information AS protocol complex is homotopy equivalent to (i.e., of the same homotopy type as) the underlying input complex. In fact, a span in the sense of Herlihy and Shavit provides the homotopy equivalence.

Loosely speaking, homotopy equivalence is equivalence up to continuous deformation. It is a common notion in algebraic topology, and important standard functors, such as the ordinary homology and homotopy group functors, do not differentiate between spaces of the same homotopy type. Thus, from the point of view of ordinary homology or homotopy groups, a wait-free AS protocol complex is indistinguishable from the underlying input complex.

The fact that a wait-free AS protocol complex is homotopy equivalent to the underlying input complex gives an intuitive explanation for why the asynchronous computability theorem [HS2, HS3] works. Roughly speaking, the protocol complex holds computational information in topological form, and all of the topological structure of the protocol complex exists, up to homotopy equivalence, in the input complex. A span makes the translation between the two. The homotopy equivalence also clarifies the basis of the obstruction method introduced in [H] for detecting impossibility of solution of decision tasks. The obstruction method relies on the fact that a span admits a left homotopy inverse, and this note shows that the left homotopy inverse can be arranged as a two-sided homotopy inverse.

2. Preliminaries and notation. It is assumed that the reader is generally familiar with the use of simplicial complexes in the study of wait-free solvability of decision tasks. See [HR] for an introduction. Standard references for algebraic topology are [Mu] and [S].

2.1. Simplexes and complexes. If $\mathcal{A}$ is an abstract simplicial complex, then $|\mathcal{A}|$ denotes its polyhedron. Strictly speaking, $\mathcal{A}$ is a combinatorial object, while $|\mathcal{A}|$ is an associated topological space. If $f\colon \mathcal{A} \to \mathcal{B}$ is a simplicial map of simplicial complexes, then $|f|\colon |\mathcal{A}| \to |\mathcal{B}|$ denotes the associated piecewise-linear map between the polyhedra. $\mathcal{A}^{(k)}$ denotes the k-skeleton of $\mathcal{A}$, which is the subcomplex consisting of simplexes of $\mathcal{A}$ of dimension $\leq k$. If $\sigma(\mathcal{A})$ is a subdivision of $\mathcal{A}$ and S is a simplex of $\sigma(\mathcal{A})$, then carrier(S) denotes the smallest simplex of $\mathcal{A}$ whose polyhedron contains $|S|$. If A is a simplex, then ∂A denotes its boundary.

Fix a set L of labels. A *coloring* of simplex S is an injective function from the vertices of S to L. A *coloring* of simplicial complex $\mathcal{A}$ is a function χ from the vertices of $\mathcal{A}$ to L such that the restriction of χ to each simplex of $\mathcal{A}$ is a coloring of that simplex. A simplex or complex together with a coloring is called *chromatic*. If $\mathcal{A}$ and $\mathcal{B}$ are chromatic complexes, then a simplicial map $f\colon \mathcal{A} \to \mathcal{B}$ is called *chromatic*, provided $\chi(f(a)) = \chi(a)$ for each vertex a of $\mathcal{A}$. The set of labels used below is the set of identifiers of the processes of the distributed system.

An *input pair* is an ordered pair (p, v), where p is a process identifier and v is an input value. If $x = (p, v)$, then we write $\mathrm{id}(x) = p$ and $\mathrm{val}(x) = v$. A nonempty set $X = \{x_0, \ldots, x_r\}$ of input pairs forms an *input simplex*, provided that $\mathrm{id}(x_0), \ldots, \mathrm{id}(x_r)$ are distinct. In this case, X is an r-dimensional chromatic simplex with coloring $x \mapsto \mathrm{id}(x)$. We write $\mathrm{ids}(X) = \{\mathrm{id}(x_0), \ldots, \mathrm{id}(x_r)\}$. A set $\mathcal{K}$ of input simplexes is an *input complex*, provided that it satisfies the usual hereditary property of simplicial complexes: if $X \in \mathcal{K}$ and X' is a nonempty subset of X, then $X' \in \mathcal{K}$.

As a protocol executes, each process accumulates its local view of the computation. We assume that the view of a process begins with its input value. Therefore, the process copies its input value to shared memory in its first write operation. The

view continues, according to full information, with the sequence of snapshots of shared memory witnessed by the process. If a process completes the protocol, then its view at halting is its *final view* in the execution. A *protocol pair* is an ordered pair $z = (p, w)$, where p is a process identifier and w is the final view accumulated by p in some execution of the protocol. We write $\mathrm{id}(z) = p$ and $\mathrm{view}(z) = w$. Also, $\mathrm{inval}(z)$ denotes the input value for p in the execution. By assumption, $\mathrm{inval}(z)$ appears at the beginning of $\mathrm{view}(z)$. A nonempty set $Z = \{z_0, \dots, z_r\}$ of protocol pairs forms a *protocol simplex*, provided that there is a single execution e of the protocol such that for each $j = 0, \dots, r$ process $\mathrm{id}(z_j)$ accumulates $\mathrm{view}(z_j)$ as its final view in e. In this case, we say that e *certifies* Z. We write $\mathrm{ids}(Z) = \{\mathrm{id}(z_0), \dots, \mathrm{id}(z_r)\}$.

If z is a protocol pair, then there may exist input pairs other than $(\mathrm{id}(z), \mathrm{inval}(z))$ that can be inferred from z. This is because the snapshots in $\mathrm{view}(z)$ may witness the input values copied by other processes into shared memory. By $\Xi(z)$ we mean the input simplex consisting of all input pairs that are determined in this fashion from z. If Z is a protocol simplex, then we let

$$\Xi(Z) = \bigcup_{z \in Z} \Xi(z).$$

There is a chromatic simplicial map $\psi\colon Z \to \Xi(Z)$ defined by $z \mapsto (\mathrm{id}(z), \mathrm{inval}(z))$.

Consider a full-information AS protocol that is wait-free on the input simplex X. By $\mathcal{P}(X)$ we mean the *protocol complex* of all protocol simplexes that can be certified by executions with X as input simplex:

$$\mathcal{P}(X) = \{Z : \Xi(Z) \subseteq X\}.$$

Note in particular that $Z \in \mathcal{P}(\Xi(Z))$. If $\mathcal{K}$ is an input complex on which the protocol is wait-free, then $\mathcal{P}(\mathcal{K})$ is the union of the complexes $\mathcal{P}(X)$ as X ranges over the various input simplexes of $\mathcal{K}$. In this case, there is a chromatic simplicial map $\psi\colon \mathcal{P}(\mathcal{K}) \to \mathcal{K}$ defined as above.

2.2. Homotopy. By *space* we mean a topological space embedded in a finite-dimensional Euclidean space. By *map* we mean a continuous function. Let X and Y be spaces, and let $f, g\colon X \to Y$ be maps. A *homotopy* from f to g is a map

$$F\colon X \times [0,1] \to Y$$

that satisfies

$$F(-,0) = f \quad \text{and} \quad F(-,1) = g.$$

In other words, when suitably identifying the ends of the cylinder $X \times [0,1]$ with X, the restriction of F to one end is the map f, and the restriction of F to the other end is the map g. Furthermore, the restriction of F to the cross section $X \times \{t\}$ is a map $F(-,t)\colon X \to Y$. Continuity of F on the cylinder ensures that as t moves from 0 to 1, $F(-,t)$ "deforms continuously" from f to g. If there is a homotopy from f to g, then f and g are said to be *homotopic*.

Example 2.2.1. Let X and Y be nonempty spaces with Y convex, and let $f, g\colon X \to Y$ be maps. Define $F\colon X \times [0,1] \to Y$ by

$$F(x,t) = (1-t)f(x) + tg(x).$$

F is into Y because $(1-t)f(x) + tg(x)$ parameterizes the line segment $[f(x), g(x)]$, which lies in Y by convexity. The continuity of f and g ensures that F is continuous.

Thus, f and g are homotopic. F is often referred to as a *straight-line homotopy* between f and g. It may be possible to form a straight-line homotopy even if Y is not globally convex. If for every $x \in X$ both $f(x)$ and $g(x)$ lie in a convex neighborhood of Y, then F is a straight-line homotopy between f and g. □

Let $f\colon X \to Y$ and $g\colon Y \to X$ be maps. If $f \circ g$ is homotopic to the identity map of Y, then g is called a *right homotopy inverse* for f, and if $g \circ f$ is homotopic to the identity map of X, then g is called a *left homotopy inverse* for f. If g is both a left and a right homotopy inverse for f, then the same is true of f for g. In this case, (1) f and g are called *homotopy inverses* of one another, (2) each of f and g is said to be a *homotopy equivalence*, and (3) the spaces X and Y are said to be *homotopy equivalent*.

A space X is *contractible* if it is homotopy equivalent to a one-point space. Any nonempty convex space is contractible, and thus the polyhedron of any simplex is contractible. A map $f\colon X \to Y$ is called *null-homotopic* if f is homotopic to a constant map. Any map from a nonempty space to a contractible space is null-homotopic. The following extension property is well known.

PROPOSITION 2.2.2. *Let X be homeomorphic to a closed disk, let ∂X be the boundary sphere of X, and let Y be a nonempty space. A map $f\colon \partial X \to Y$ can be extended to a map $X \to Y$ if and only if f is null-homotopic.* □

Note that if A is a simplex, then Proposition 2.2.2 can be applied with $X = |A|$ and $\partial X = |\partial A|$. Since $|\partial A|$ has a collar neighborhood in $|A|$, one has the following special case of the simplicial approximation theorem.

PROPOSITION 2.2.3. *Let A be a simplex, let $\sigma_0(\partial A)$ be a subdivision of its boundary, and let $\mathcal{B}$ be a simplicial complex. Suppose that there is a simplicial map $\varphi_0\colon \sigma_0(\partial A) \to \mathcal{B}$. If $|\varphi_0|$ is null-homotopic, then there is a subdivision $\sigma(A)$ and there is a simplicial map $\varphi\colon \sigma(A) \to \mathcal{B}$ such that $\sigma(\partial A) = \sigma_0(\partial A)$ and such that the restriction of φ to $\sigma(\partial A)$ equals φ_0.* □

The next result is fundamental and lies at the heart of the asynchronous computability theorem of Herlihy and Shavit. It can be proved by generalizing the critical state technique from the seminal paper [FLP] of Fischer, Lynch, and Paterson.

THEOREM 2.2.4 (contractibility theorem [HS1]). *Assume that an AS protocol records full information, and let X be an input simplex on which the protocol is wait-free. Then $|\mathcal{P}(X)|$ is contractible.* □

In [HS3], Herlihy and Shavit actually prove that $|\mathcal{P}(X)|$ has trivial fundamental group and trivial reduced homology groups in all dimensions. The theorem of Whitehead [S, p. 399] and standard homotopy theory [S, pp. 405–406] imply that these conditions are equivalent to the contractibility of $|\mathcal{P}(X)|$.

3. Wait-free AS protocol complexes. Consider a full-information AS protocol that is wait-free on the input complex $\mathcal{K}$. We show in Theorem 3.2.2 that the map

$$|\psi|\colon |\mathcal{P}(\mathcal{K})| \to |\mathcal{K}|$$

is a homotopy equivalence and that if $\varphi\colon \sigma(\mathcal{K}) \to \mathcal{P}(\mathcal{K})$ is a span in the sense of Herlihy and Shavit, then $|\varphi|$ is a homotopy inverse for $|\psi|$. The existence of spans is proved in [HS3], but the condition that φ be chromatic is not needed in order to prove the homotopy equivalence. In [HS3], most of the technical work to prove the existence of spans is concerned with arranging the chromatic condition. To avoid assuming these arguments, we review in subsection 3.1 the simple proof of the existence of

"nonchromatic" spans that appears in [HS3]. This argument also serves as a model for the proof of Theorem 3.2.2.

3.1. Nonchromatic spans. A *nonchromatic span* (for the protocol on $\mathcal{K}$) is a simplicial map φ from a subdivision $\sigma(\mathcal{K})$ of $\mathcal{K}$ to $\mathcal{P}(\mathcal{K})$ such that for any simplex S of $\sigma(\mathcal{K})$, $\varphi(S) \in \mathcal{P}(\text{carrier}(S))$. Note that if $\varphi\colon \sigma(\mathcal{K}) \to \mathcal{P}(\mathcal{K})$ is a nonchromatic span and if $\mathcal{L}$ is a subcomplex of $\mathcal{K}$, then the restriction of φ to $\sigma(\mathcal{L})$ is a nonchromatic span for the protocol on $\mathcal{L}$.

THEOREM 3.1.1 (see [HS3]). *Assume that an AS protocol records full information, and let $\mathcal{K}$ be an input complex on which the protocol is wait-free. Then there exists a nonchromatic span for the protocol on $\mathcal{K}$.*

Proof. We construct the subdivision $\sigma(\mathcal{K})$ and the map φ inductively on the skeleta of $\mathcal{K}$. The 0-skeleton of $\mathcal{K}$ admits no subdivision. Let x be a vertex of $\mathcal{K}$, and let $p = \text{id}(x)$. Since the protocol is wait-free, there is a finite execution e in which p starts with input value $\text{val}(x)$ and only p has events. Let $z = (p, w)$, where w is the final view of p in e. Then $\mathcal{P}(\{x\})$ has only the single vertex z. We must, therefore, let $\varphi(x) = z$. This defines φ as a nonchromatic span for the protocol on $\mathcal{K}^{(0)}$.

Assume now that $k > 0$, that the subdivision $\sigma(\mathcal{K}^{(k-1)})$ has been defined, and that φ has been defined as a nonchromatic span for the protocol on $\mathcal{K}^{(k-1)}$. Let X be a k-simplex of $\mathcal{K}$. The boundary ∂X is contained in $\mathcal{K}^{(k-1)}$, so φ gives a simplicial map $\sigma(\partial X) \to \mathcal{P}(X)$. According to the contractibility theorem, $|\mathcal{P}(X)|$ is contractible, and so the restriction of $|\varphi|$ to $|\partial X|$ is null-homotopic. By Proposition 2.2.3, the subdivision $\sigma(\partial X)$ can be extended to a subdivision $\sigma(X)$, and φ can be extended to a simplicial map $\sigma(X) \to \mathcal{P}(X)$. In this way, we define the subdivision $\sigma(\mathcal{K}^{(k)})$ and the map $\varphi\colon \sigma(\mathcal{K}^{(k)}) \to \mathcal{P}(\mathcal{K}^{(k)})$. Suppose that S is simplex of $\sigma(\mathcal{K}^{(k)})$. If S lies in $\sigma(\mathcal{K}^{(k-1)})$, then $\varphi(S) \in \mathcal{P}(\text{carrier}(S))$ by the inductive hypothesis. Otherwise, $\text{carrier}(S)$ is a k-simplex of $\mathcal{K}$, say X. From our construction, we see that φ maps S into $\mathcal{P}(X) = \mathcal{P}(\text{carrier}(S))$. This verifies that φ is a nonchromatic span for the protocol on $\mathcal{K}^{(k)}$ and completes the inductive step. □

3.2. The homotopy type of wait-free AS protocol complexes. In this subsection, we show that $|\mathcal{K}|$ and $|\mathcal{P}(\mathcal{K})|$ are homotopy equivalent spaces. According to Theorem 3.1.1, there is a nonchromatic span $\varphi\colon \sigma(\mathcal{K}) \to \mathcal{P}(\mathcal{K})$. We first show that $|\varphi|$ is a right homotopy inverse for $|\psi|$.

PROPOSITION 3.2.1. *$|\psi| \circ |\varphi|$ is homotopic to the identity map of $|\mathcal{K}|$.*

Proof. Without loss of generality, $|\mathcal{K}| = |\sigma(\mathcal{K})|$. For any simplex S in $\sigma(\mathcal{K})$,

$$\psi \circ \varphi(S) \subseteq \text{carrier}(S).$$

Since $|S| \subseteq |\text{carrier}(S)|$ and since $|\text{carrier}(S)|$ is convex, we can form a straight-line homotopy between $|\psi| \circ |\varphi|$ and the identity map of $|\mathcal{K}|$. □

THEOREM 3.2.2. *Assume that an AS protocol records full information. Let $\mathcal{K}$ be an input complex on which the protocol is wait-free, and let $\varphi\colon \sigma(\mathcal{K}) \to \mathcal{P}(\mathcal{K})$ be a nonchromatic span. Then $|\varphi|$ and $|\psi|$ are homotopy inverses, and so $|\mathcal{P}(\mathcal{K})|$ and $|\mathcal{K}|$ are homotopy equivalent.*

Proof. From Proposition 3.2.1 we have that $|\psi| \circ |\varphi|$ is homotopic to the identity map of $|\mathcal{K}|$. We now construct a homotopy

$$F\colon |\mathcal{P}(\mathcal{K})| \times [0, 1] \to |\mathcal{P}(\mathcal{K})|$$

from $|\varphi| \circ |\psi|$ to the identity map of $|\mathcal{P}(\mathcal{K})|$ by induction on the skeleta of $\mathcal{P}(\mathcal{K})$. F will be arranged so that for all $Z \in \mathcal{P}(\mathcal{K})$,

$$(*) \qquad F(|Z| \times [0,1]) \subseteq |\mathcal{P}(\Xi(Z))| \,.$$

Let z be a vertex of $\mathcal{P}(\mathcal{K})$. Then z is a vertex of $\mathcal{P}(\Xi(z))$. Also $\psi(z)$ is a vertex of $\Xi(z)$, and hence $\varphi \circ \psi(z)$ is a vertex of $\mathcal{P}(\Xi(z))$. Since $|\mathcal{P}(\Xi(z))|$ is contractible, there is a path in $|\mathcal{P}(\Xi(z))|$ from $|\varphi| \circ |\psi|(|z|)$ to $|z|$. This path defines F on $|z| \times [0,1]$. Combining these paths defines F on $|\mathcal{P}(\mathcal{K})^{(0)}| \times [0,1]$ in a way that satisfies $(*)$ for all vertices of $\mathcal{P}(\mathcal{K})$.

Now let $k > 0$, and assume that F has been defined on $|\mathcal{P}(\mathcal{K})^{(k-1)}| \times [0,1]$ and satisfies $(*)$ for all simplexes in $\mathcal{P}(\mathcal{K})^{(k-1)}$. Let Z be a k-simplex of $\mathcal{P}(\mathcal{K})$. Then $Z \in \mathcal{P}(\Xi(Z))$, and hence $|Z| \subseteq |\mathcal{P}(\Xi(Z))|$. Also $\psi(Z) \subseteq \Xi(Z)$, and hence $|\varphi| \circ |\psi|(|Z|) \subseteq |\mathcal{P}(\Xi(Z))|$. Let

$$\Sigma \;=\; |Z| \times \{0\} \;\cup\; |\partial Z| \times [0,1] \;\cup\; |Z| \times \{1\}.$$

Notice that Σ is the boundary of the closed $(k+1)$-disk $|Z| \times [0,1]$, and hence Σ is a k-sphere. By the inductive hypothesis, F is already defined on $|\partial Z| \times [0,1]$ and satisfies $F(|\partial Z| \times [0,1]) \subseteq |\mathcal{P}(\Xi(Z))|$. For $x \in |Z|$, let $F(x,0) = |\varphi| \circ |\psi|(x)$ and $F(x,1) = x$. These definitions of F cohere to give a map $\Sigma \to |\mathcal{P}(\Xi(Z))|$. Since $|\mathcal{P}(\Xi(Z))|$ is contractible, Proposition 2.2.2 implies that F can be extended to a map of the disk $|Z| \times [0,1] \to |\mathcal{P}(\Xi(Z))|$. Combining these extensions for the various k-simplexes of $\mathcal{P}(\mathcal{K})$ gives the extension of F to $|\mathcal{P}(\mathcal{K})^{(k)}| \times [0,1]$. By construction, $(*)$ holds for all simplexes in $\mathcal{P}(\mathcal{K})^{(k)}$. □

AVERAGE-CASE PERFORMANCE OF THE APRIORI ALGORITHM*

PAUL W. PURDOM†, DIRK VAN GUCHT†, AND DENNIS P. GROTH‡

Abstract. The failure rate of the Apriori Algorithm is studied analytically for the case of random shoppers. The time needed by the Apriori Algorithm is determined by the number of item sets that are output (successes: item sets that occur in at least k baskets) and the number of item sets that are counted but not output (failures: item sets where all subsets of the item set occur in at least k baskets but the full set occurs in less than k baskets). The number of successes is a property of the data; no algorithm that is required to output each success can avoid doing work associated with the successes. The number of failures is a property of both the algorithm and the data.

We find that under a wide range of conditions the performance of the Apriori Algorithm is almost as bad as is permitted under sophisticated worst-case analyses. In particular, there is usually a *bad level* with two properties: (1) it is the level where nearly all of the work is done, and (2) nearly all item sets counted are failures. Let l be the level with the most successes, and let the number of successes on level l be approximately $\binom{m}{l}$ for some m. Then, typically, the Apriori Algorithm has total output proportional to approximately $\binom{m}{l}$ and total work proportional to approximately $\binom{m}{l+1}$. In addition m is usually much larger than l, so the ratio of work to output is proportional to approximately $m/(l+1)$.

The analytical results for random shoppers are compared against measurements for three data sets. These data sets are more like the usual applications of the algorithm. In particular, the buying patterns of the various shoppers are highly correlated. For most thresholds, these data sets also have a bad level. Thus, under most conditions nearly all of the work done by the Apriori Algorithm consists in counting item sets that fail.

1. Introduction.

The Apriori Algorithm [2, 3, 6, 16] solves the frequent item sets problem, which is at the core of various algorithms for data mining problems. The best known such problem is the problem of finding the *association rules* that hold in a basket-items relation [2, 3, 16, 20]. Other data mining problems based on the Apriori Algorithm are discussed in [6, 14, 16, 18, 21, 22].

The Apriori Algorithm analyzes a data set of baskets, each containing a set of items, to determine which combination of items occur together frequently. Consider a store with $|I|$ items where b shoppers each have a single basket. Each shopper selects a set of items for their basket. The input to the Apriori Algorithm is a list giving the contents of each basket. For a fixed threshold k, the algorithm outputs a list of those sets of items that are *frequent*; that is, they are contained in at least k of the b baskets.

The Apriori Algorithm is a level-wise algorithm. It considers sets of items in order of their size: first sets of size one are tested to see whether they are contained in k baskets, then sets of size two, etc. On each level, the algorithm knows the result

of the previous level. The key idea of the Apriori Algorithm is that, on level l, a set is tested if and only if all its subsets of size $l-1$ are frequent. An item set satisfying this property is called a *candidate* (at level l). It is a *success* (at level l) if it is contained in at least k baskets, and it is a *failure* otherwise.

This paper considers only the Apriori Algorithm. Many of its performance characteristics come from the fact that it outputs every frequent item set. There are several interesting algorithms for the frequent item set problem that output only the maximal frequent item sets, since every subset of a frequent item set is also frequent [1, 4, 12]. Also, there is an algorithm complementary to the Apriori Algorithm that finds the infrequent item sets, starting with the set of all items and working downward in set size.

This paper considers the expected amount of work that the Apriori Algorithm does when the shoppers shop at random. Specifically, the probability that a shopper buys an item is p, independent of all other shoppers and all other items. This is the same probability model that has previously been used to estimate the probability that a set is frequent [3, 17, 21]. The main advantage of using a parameterized probability model is that we can study the performance of the algorithm under a wide range of conditions. While the later sections contain many mathematical details, the main conclusions are fairly simple. For most values of the parameters, random data result in a high success rate (essentially 1) for small values of l, with a sudden switch to a low success rate (essentially 0) for larger values of l. When l is below the level of the switch, the number of candidates is just below $\binom{|I|}{l}$ and almost all of the candidates are successes. When l is above the level of the switch, almost all candidates are failures, and the number of candidates decreases rapidly. The level for the switch depends on the parameters. When l is much less than $|I|$, nearly all the work of the algorithm is done testing candidates from the level with the most successes. The algorithm has a *bad level* where (1) most of the work is done and (2) there are a lot of candidates, but few successes. For a few thresholds, two levels in a row are bad.

The main disadvantage of using a simple probability model is that most applications of the Apriori Algorithm involve data sets with complex correlations, and such data sets are difficult to model mathematically. Therefore, we also measured the success, candidate, and failure rates of the performance of the Apriori Algorithm on three data sets: (1) synthetic data generated by the generator from the IBM Quest Research Group [13]; (2) U.S. Census data, using Public Use Microdata Samples (PUMS) (the same sample that was used by [5, 6] and processed in the same way); and (3) a Web data set [24]. In one important way, the results with these data sets were similar to that of random shoppers. For most thresholds, the experimental data show the existence of a single bad level. This bad level came just after the level with the most successes, it had a low success rate, and it consumed most of the work that the algorithm did. On the other hand, with the experimental data there are also many failures below the bad level, so that the number of candidates is much less than $\binom{|I|}{l}$.

2. The Apriori Algorithm. Let J_l be a set of $l \geq 1$ items where the items are selected from the set I. For a given J_l, define J_l^{-h} to be the set obtained from J_l by omitting element h, where h is an element of J_l. The key idea of the Apriori Algorithm is that the set J_l cannot possibly have k occurrences unless, for each h in J_l, the set J_l^{-h} has k occurrences. Since the algorithm considers possible sets in order of their size, it has already gathered the information about all the sets of size $l-1$ before it considers sets of size l.

APRIORI ALGORITHM.
Step 1. For l from 1 to $|I|$ do
Step 2. For each set J_l such that for each $h \in J_l$ the set J_l^{-h} occurs in at least k baskets do
Step 3. Examine the data to determine whether the set J_l occurs in at least k baskets. Remember those cases where the answer is "yes."

Step 2 of the algorithm generates each set J_l such that J_l^{-h} occurs at least k times (for each h in J_l). The sets that are generated are called *candidates*. For those sets that are candidates, Step 3 examines the data (basket contents) to determine which set of items occurs in at least k baskets. This counting and comparing with the threshold is called the *frequency test*. A candidate that passes the frequency test is called a *success* (or a *frequent item set*). A set that is subjected to the frequency test but fails is called a *failure*. For algorithms that verify each success by doing the frequency test, the main place for improvement is to reduce the number of failures.

For typical data sets, a careful implementation of the Apriori Algorithm will have it spending most of its time accessing the data base (counting the occurrences of the various candidates). The implementation should exit the loop in Step 1 early if there are no "yes" answers for some value of l. On level l, it should consider only those sets that are formed from sets that passed the frequency test on level $l-1$. In addition, no set of size l should be generated more than once. The sets can be generated by assigning an order to the items and extending each set S on level $l-1$ only with items that are greater than the largest item in S. *Assuming unit time for hash table look-ups* (for looking up various subsets of the extended S), the algorithm can do the work for a single candidate set on level l in time bounded by a constant times $l+1$. See [2] for further discussion of the techniques used in good implementations.

Although the Apriori Algorithm uses explicit counting to verify that an item set is frequent, this is not always logically necessary. Thus, if item A occurs in b_A baskets and item B occurs in b_B baskets, then A and B must occur together in at least $b_A + b_B - b$ baskets [11]. Similar ideas are explored in [7].

3. Best and worst cases. We use the number of candidates as a proxy for the amount of computing that the Apriori Algorithm does. Let N_S be the number of item sets that are successes. Let N_F be the number of failures (candidates that are not successes). The total work is proportional to $N_S + N_F$. The term N_S represents work that must be done by any algorithm that outputs every frequent item set, and it is a property of the data, not of the algorithm. On the other hand, N_F represents work that we might hope to avoid.

The worst-case output is exponentially larger than the input (every set might be frequent), so the worst-case time needed can be exponential in the size of the input. A closely related problem that is NP-complete is to determine whether or not there are any sets of size l that occur k times; this is NP-complete because the balanced complete bipartite subgraph problem [9] reduces to it. The appendix has the details of proofs for this and many other statements.

For algorithms that must output every frequent item set, the ratio $N_S/(N_S+N_F)$ is the natural measure of algorithm efficiency. When every item set is frequent, N_S is $2^{|I|}$ and $N_F = 0$, so the algorithm is efficient. The worst ratio of work to output occurs when no (nonempty) item set is frequent, in this case $N_S = 1$, $N_F = |I|$. (Most versions of the algorithm avoid outputting the empty set, leading to values of N_S one less than above.)

Intermediate amounts of output are more interesting. In such cases, one can have

a lot of output and also a high failure rate. In this regard, the worst-case bounds of Geerts, Goethals, and Van den Bussche [10] are interesting. For their Theorem 1, they write the number of successes on level l as a binomial coefficient with l on the bottom in which the top index is as large as possible subject to the binomial coefficient being no larger than the number of success. If the difference between the number of successes and the binomial coefficient is positive, then they repeat the process with the difference. Thus, they write the number of successes as a sum of binomial terms. They show that the result of increasing each bottom index to $l+1$ gives an upper bound on the number of candidates for level $l+1$. This bound is exact for some data sets, including one that results in no failures on level l. Experiments show that in many cases this upper bound on candidates is close to the exact value for level $l+1$. The same idea can be used to predict the number of successes on later levels, but it often works less well for those levels.

The following argument also limits the number of candidates on level $l+1$. Consider the graph where each candidate on level $l+1$ (each J_{l+1}) is connected to each of its associated frequent items sets (J_{l+1}^{-h}). Thus, there are $[N_S(l+1)+N_F(l+1)](l+1)$ arcs. Each of the $N_S(l)$ frequent item sets on level l is connected to at most $|I|-l$ candidates on level $l+1$. Indeed, if we use $|I_l|$ to be the number of items that occur among the frequent item sets of level l, there are at most $|I_l|-l$ connections from a single level l frequent item set. Thus, we have

$$[N_S(l+1)+N_F(l+1)](l+1) \le N_S(l)(|I_l|-l), \tag{1}$$

$$[N_S(l+1)+N_F(l+1)] \le \left(\frac{|I_l|-l}{l+1}\right) N_S(l). \tag{2}$$

This gives

$$\sum_{0\le l\le |I_l|-1} \left(\frac{|I_l|-l}{l+1}\right) N_S(l) \tag{3}$$

as an upper bound on the amount of work. In many cases, $N_S(l)$ increases rapidly for small l and then suddenly drops rapidly to zero. In such cases, the largest term in this sum is a good approximation to its total value.

We see that the Apriori Algorithm is rather efficient for algorithms that output every frequent item set. The total work is never more than a constant plus a factor $|I|$ times larger than N_S, the least amount of work that could possibly be done by any algorithm in the class. When most of the work is concentrated on level $l+1$, the amount of work is better than this product by a factor of $l+1$.

4. Average case. We now start an exact computation of the average-case performance of the Apriori Algorithm for the case when the baskets are filled at random. That is, each basket j has item i with probability p independent of what happens for other baskets and other items. We eventually show that for most values of the parameters, the average performance is not significantly better than that suggested by the worst-case analysis (equation (3)).

Let S_l be the probability that the set consisting of items 1 to l is a frequent item set, and let F_l be the probability that the same set is a candidate but fails to be a frequent item set. Since each basket is filled randomly, any other set of l items has

the same probability of success and failure. The expected number of successes is

$$\sum_{1\le l\le |I|} \binom{|I|}{l} S_l, \tag{4}$$

and the expected number of failures is

$$\sum_{1\le l\le |I|} \binom{|I|}{l} F_l. \tag{5}$$

The number of item sets for which the basket data is examined is

$$\sum_{1\le l\le |I|} \binom{|I|}{l} (S_l + F_l). \tag{6}$$

Under the above assumptions, the running time is bounded by a constant times

$$\sum_{1\le l\le |I|} (l+1)\binom{|I|}{l} (S_l + F_l). \tag{7}$$

Define the following conditions with respect to a single basket:

- M_0: the basket has all the items 1 to l, and
- M_h $(1 \le h \le l)$: the basket has all items from 1 to l except that it does *not* have item h.

These conditions are disjoint; each basket obeys at most one of the conditions M_h, $0 \le h \le l$.

The probability that a randomly filled basket obeys condition M_0 is

$$P(l) = p^l \tag{8}$$

(when $l \le |I|$). The probability that a randomly filled basket obeys condition M_h (for any h in the range 1 to l) is

$$Q(l) = p^{l-1}(1-p). \tag{9}$$

Note that

$$P(l-1) = P(l) + Q(l). \tag{10}$$

The probability that at least k baskets obey condition M_0 is

$$S_l = \sum_{j\ge k} \binom{b}{j} [P(l)]^j [1-P(l)]^{b-j} = 1 - \sum_{j<k} \binom{b}{j} [P(l)]^j [1-P(l)]^{b-j}. \tag{11}$$

The probability that j_0 baskets obey condition M_0, j_1 baskets obey condition M_1, $\ldots$, j_l baskets obey condition M_l, and the remaining $b - j_0 - \cdots - j_l$ baskets do not obey any of the conditions is

$$\binom{b}{j_0, \ldots, j_l, b - j_0 - \cdots - j_l} [P(l)]^{j_0} [Q(l)]^{j_1+\cdots+j_l} [1 - P(l) - lQ(l)]^{b-j_0-\cdots-j_l}, \tag{12}$$

where the multinomial coefficient is the number of ways to arrange b distinct baskets into $l+1$ sets, where set 0 has j_0 baskets, ..., set l has j_l baskets, and $b-j_0-\cdots-j_l$ baskets are not in any of the $l+1$ sets.

The item set $\{1,\ldots,l\}$ is a candidate if and only if for each h in the range $1 \le h \le l$ we have the number of baskets satisfying condition M_0 plus the number of baskets satisfying condition M_h totaling at least k. Thus, item set $\{1,\ldots,l\}$ is a candidate in just those cases where the conditions

$$j_0 + j_1 \ge k,\ j_0 + j_2 \ge k,\ \ldots,\ j_0 + j_l \ge k \tag{13}$$

are all true. Thus, the probability that the set $\{1,\ldots,l\}$ is a candidate is the above probability (12) summed over those cases that satisfy the conditions (13),

$$\begin{aligned} C_l = \sum_{\substack{j_0 \\ j_1\ge k-j_0 \\ j_2\ge k-j_0 \\ \cdots \\ j_l\ge k-j_0}} & \binom{b}{j_0,\ldots,j_l,b-j_0-\cdots-j_l} \\ & \times [P(l)]^{j_0}[Q(l)]^{j_1+\cdots+j_l}[1-P(l)-lQ(l)]^{b-j_0-\cdots-j_l}. \end{aligned} \tag{14}$$

Since the set $\{1,\ldots,l\}$ either does or does not occur in at least k baskets, the probability that the item set $\{1,\ldots,l\}$ is a candidate but not a frequent item set is

$$\begin{aligned} F_l = C_l - S_l = \sum_{\substack{j_0<k \\ j_1\ge k-j_0 \\ j_2\ge k-j_0 \\ \cdots \\ j_l\ge k-j_0}} & \binom{b}{j_0,\ldots,j_l,b-j_0-\cdots-j_l} \\ & \times [P(l)]^{j_0}[Q(l)]^{j_1+\cdots+j_l}[1-P(l)-lQ(l)]^{b-j_0-\cdots-j_l}. \end{aligned} \tag{15}$$

4.1. Efficient computation of F_l. The number of arithmetic operations needed to compute S for fixed b, l, and p (using the right part of (11)) is $O(k)$. Furthermore, the number of operations for fixed l and p and for all k is only $O(b)$.

The number of operations needed to compute F by direct application of (15) is $O(kb^l)$. However, using the recurrence equations below, F can be computed in time that is independent of k and polynomial in b and l.

Write (15) as

$$F_l = \sum_{j_0<k} \binom{b}{j_0} [P(l)]^{j_0} R_{k-j_0}(b-j_0,l,l,l), \tag{16}$$

where

$$\begin{aligned} R_k(b,l,m,n) = \sum_{\substack{j_1\ge k \\ j_2\ge k \\ \cdots \\ j_l\ge k}} & \binom{b}{j_1,\ldots,j_l,b-j_1-\cdots-j_l} \\ & \times [Q(m)]^{j_1+\cdots+j_l}[1-P(m)-nQ(m)]^{b-j_1-\cdots-j_l}. \end{aligned} \tag{17}$$

By considering the sum over j_l (represented by j in the sum below) separately, we have

$$R_k(b,l,m,n) = \sum_{j\ge k} \binom{b}{j} [Q(m)]^j R_k(b-j,l-1,m,n), \tag{18}$$

with boundary condition

$$R_k(b,0,m,n) = [1 - P(m) - nQ(m)]^b. \tag{19}$$

With these equations, a particular $R_k(b,l,m,n)$ can be computed from the various $R_k(c,l-1,m,n)$, where $k \le c \le b$, in $O(b)$ operations. To compute R by repeated application of (19), we need l levels with $O(b)$ R's per level. This leads to time $O(lb^2)$ to compute a set of R. The time to compute F_l is dominated by the time needed to compute the R's, leading to time $O(lb^2)$ to compute a particular F. For fixed p and b and for all k, F_l can also be computed in time $O(lb^2)$.

5. Approximations.

5.1. Chernoff bounds. The sums for S_l and F_l are incomplete binomial sums. They do not have closed forms (implied by [15]), but, as we show below, Chernoff techniques [8] lead to useful approximations. For

$$L(i) = \begin{cases} 1, & i \le k, \\ 0, & i > k \end{cases} \quad \text{and} \quad U(i) = \begin{cases} 0, & i < k, \\ 1, & i \ge k \end{cases} \tag{20}$$

and for some fixed k in the range $0 \le k \le n$, we have

$$\sum_{0 \le i \le k} a_i = \sum_{0 \le i \le n} a_i L(i) \quad \text{and} \quad \sum_{k \le i \le n} a_i = \sum_{0 \le i \le n} a_i U(i). \tag{21}$$

In addition, when each $a_i \ge 0$, replacing $L(i)$ (or $U(i)$) with a pointwise upper bound gives an upper bound on the sum. Chernoff [8] noticed that useful bounds for partial binomial sums result when one uses

$$L(i) = x^{-k+i} \quad \text{with } x \le 1 \quad \text{and} \quad U(i) = x^{-k+i} \quad \text{with } x \ge 1 \tag{22}$$

and then chooses the x that gives the smallest upper bound.

The Chernoff bound for S is

$$S_l \le x^{-k} \sum_j \binom{b}{j} [xP(l)]^j [1 - P(l)]^{b-j} = x^{-k}[1 + (x-1)P(l)]^b \tag{23}$$

for any $x \ge 1$.

A Chernoff bound for R is

$$R_k(b,l,m,n) \le x^{-kl} \sum_{j_1,\ldots,j_l} \binom{b}{j_1, \ldots, j_l, b - j_1 - \cdots - j_l}$$

$$\times [xQ(m)]^{j_1+\cdots+j_l} [1 - P(m) - nQ(m)]^{b-j_1-\cdots-j_l} \tag{24}$$

$$\le x^{-kl}[1 - P(m) - (n - lx)Q(m)]^b \tag{25}$$

for any $x \ge 1$.

Using this Chernoff bound for R leads to the following Chernoff bound for F:

$$F_l \le y^{-k+1} \sum_j \binom{b}{j} [yP(l)]^j x^{-(k-j)l} [1 - P(l) + l(x-1)Q(l)]^{b-j} \tag{26}$$

$$\le x^{-kl} y^{-k+1} [1 + (x^l y - 1)P(l) + l(x-1)Q(l)]^b \tag{27}$$

for any $x \ge 1$ and any $y \le 1$.

5.2. Regions and boundaries for S_l. The optimum x for (23) is either on the boundary ($x = 1$) or when the derivative with respect to x is equal to zero. Letting x_* be the x value that gives a derivative of zero, we have

$$x_* = \frac{k[1 - P(l)]}{(b-k)P(l)}. \tag{28}$$

When $x_* \geq 1$, it is the optimum x for (23). Otherwise ($x_* < 1$) the optimum x is 1. In addition, we check whether x_* is strictly within the range ($x_* > 1$). This is the case when

$$k > bP(l). \tag{29}$$

This completes the first stage of finding the Chernoff approximation to S_l. In the next two sections we determine just how small the Chernoff bound is as a function of the parameters (b, k, l, and p). We show that the bound on S_l is an exponential function of the negative of the square of the distance α_1 (with $\alpha_1 = k/b - P(l)$) inside the boundary (29). As we vary k, S_l is extremely small inside the region ($k > bP(l)$), except near the boundary ($bP(l)$). Next we show that S_l is close to 1 once we go on the other side of the boundary; the difference between S_l and 1 is an exponential function of the negative of the square of the distance α_2 ($\alpha_2 = (P(l) - k/b) + 1/b = -\alpha_1 + 1/b$) from the boundary. Thus, knowing whether the optimizing x is strictly within range or not gives us the most basic information about S_l (whether it is small ($x_* > 1$) or large ($x_* < 1$)).

5.2.1. Upper bound on S_l. We now give an upper bound on S_l when $k > bP(l)$ to show that it is near 0. In the next section we give a lower bound when $k > bP(l)$ to show that in that case it is near 1.

By plugging the x_* value from (28) into the bound from (23) we obtain

$$S_l \leq \left(\frac{P(l)}{k}\right)^k \left(\frac{1 - P(l)}{b-k}\right)^{b-k} b^b \tag{30}$$

so long as $x_* \geq 1$. By (29) the condition $x_* > 1$ is equivalent to $k > bP(l)$, so we will define α_1 by

$$k = b[P(l) + \alpha_1]. \tag{31}$$

When k is greater than $bP(l)$, S_l goes to zero rapidly. In particular

$$S_l \leq e^{-b\alpha_1^2/\{2P(l)[1-P(l)]\} + O(b\alpha_1^3[1-P(l)]^{-2})} \tag{32}$$

when $\alpha_1 > 0$.

5.2.2. Lower bound on S_l. To obtain a lower bound on S_l when it is near 1, start with the right part of (11). Shift the relation between k and α_1 by 1 so that α_2 is defined implicitly by

$$k = b[P(l) - \alpha_2] + 1. \tag{33}$$

We can now modify the derivation of (32) (with $x_* < 1$) to obtain

$$S_l \geq 1 - e^{-b\alpha_2^2/\{2P(l)[1-P(l)]\} + O(b\alpha_2^3 P(l)^{-2})} \tag{34}$$

when $\alpha_2 > 0$ (the dominant O term here is different from what it was for (32)).

5.3. Regions and boundaries for F_l. To find the optimum value for x and y in (27) we start by taking derivatives of the bound with respect to x and y, setting each result to zero, and solving for x and y. We want the x_* that satisfies

$$(b-k)P(l)x_*^l y + (b-kl)Q(l)x_* - k[1-P(l)-lQ(l)] = 0. \tag{35}$$

We want the y_* that satisfies

$$(b-k+1)P(l)x^l y_* - (k-1)[1-P(l)+lQ(l)(x-1)] = 0. \tag{36}$$

When considering whether the optimum x and y are strictly within range ($x_* > 1$, $y_* < 1$) or on the boundary, there are four cases to investigate.

Region 1. Equation (35) with $y = 1$, $x_* > 1$.

Region 2. Equation (36) with $x = 1$, $y_* < 1$.

Region 3. Equations (35) and (36), $x_* > 1$, $y_* < 1$.

Region 4. $x = 1$, $y = 1$.

In (35) and (36), x_* is associated with the effectiveness of the candidacy test (inequality (25)), and y_* is associated with the probability of a set failing the frequency test (inequality (27)).

The main regions of interest are Region 1, where we will show that F_l is small because the candidacy test fails with high probability; Region 2, where F_l is small because S_l is near 1 (F_l can never be larger than $1 - S_l$ since failure requires not only passing the candidacy test but also failing the frequency test); and Region 4, where F_l has the trivial bound of 1. In section 5.3.3 we show that the set of parameter values that satisfy the conditions for Region 3 includes the intersection of Regions 1 and 2. Also Region 3 has no values outside of the union of Regions 1 and 2.

When the optimum value for at least one of x and y is strictly within range (not equal to 1) then the bound for F_l is smaller. It will be shown in section 5.4 that the bound on F_l is an exponential function of the square of the distance (basically the difference between k/b and $P(l)$ or $P(l-1)$; see section 5.4 for details) of x_* or y_* from the boundary, so F_l rapidly becomes extremely small as x_* or y_* moves away from the boundary.

5.3.1. Region 1. When $x_* > 1$, we will show in section 5.4.1 that the candidacy test fails with high probability. To find when this occurs, notice that (35) is satisfied by $x = 1$, $y = 1$ when

$$k = b[P(l) + Q(l)] = bP(l-1). \tag{37}$$

As b decreases, x_* increases. This implies that, for $y = 1$, $x_* > 1$ when

$$k > bP(l-1). \tag{38}$$

5.3.2. Region 2. When $y_* < 1$, we will show in section 5.4.2 that the frequency test succeeds with high probability. Consequently, since F_l can be no larger than $1 - S_l$, F_l is near 0 in this case.

When $x = 1$, the solution to (36) is

$$y_* = \frac{(k-1)[1-P(l)]}{(b-k+1)P(l)}. \tag{39}$$

This results in $y_* < 1$ when

$$k < bP(l) + 1. \tag{40}$$

For most parameter values, the regions (permitted values of k) of (38) and (40) do not overlap. However, subtracting the right side of (40) from the right side of (38), we find that they do overlap when

$$bQ(l) < 1. \tag{41}$$

This happens both when p^{l-1} is small ($p^{l-1} \leq 1/b$ is small enough) and also when $1-p$ is small ($1-p \leq 1/b$ is small enough). When (41) is true for all l, the Apriori Algorithm has no bad level. In this case, S_l is small for every l. Conditions where the Apriori Algorithm does have a bad level (cases where S_l is near 1) are discussed in section 5.4.4.

5.3.3. Region 3. To find values for the parameters such that $x_* > 1$ and $y_* < 1$ we need to satisfy (35) and (36) simultaneously. This results in the values

$$x_* = \frac{1 - P(l) - lQ(l)}{(b-k-l+1)Q(l)}, \tag{42}$$

$$y_* = (k-1)\left(\frac{(b-k-l+1)Q(l)}{1-P(l)-lQ(l)}\right)^{l-1}\frac{Q(l)}{P(l)}. \tag{43}$$

We have $x_* > 1$ when

$$k+l-1 < b < k+l-1+\frac{1-P(l)-lQ(l)}{Q(l)}. \tag{44}$$

The upper and lower limits are the same when $l = 1$, so the range is empty in that case.

All solutions to (44) are in the union of Regions 1 (inequality (38)) and 2 (inequality (40)). The smallest k that satisfies (38) is k just above $bP(l-1)$. This value for k satisfies (44) when

$$b < \frac{1}{Q(l)}. \tag{45}$$

Inequality (45) is true under the same conditions that (41) is true. Thus, (44) is satisfied by k values outside of Region 1 only when Regions 1 and 2 overlap. Since Region 1 gives a lower limit on k and Region 2 gives an upper limit, when Regions 1 and 2 overlap, their union includes all k values.

For $k = 1$, (43) implies that $y = 0$, which is less than 1. For $l = 1$, (43) has no solutions. For $k \geq 2$ and $l \geq 2$, (43) implies $y_* < 1$ when

$$b < k+l-1+\frac{1-P(l)-lQ(l)}{Q(l)}\left(\frac{P(l)}{(k-1)Q(l)}\right)^{1/(l-1)}. \tag{46}$$

For parameter values to be in Region 3, both (44) and (46) must be satisfied.

The upper bound on b from (46) is greater than the lower bound from (44). The upper bound on b from (46) is less than the upper bound from (44) when

$$k > \frac{1}{1-p}. \tag{47}$$

For $p < 1/2$, this condition is the same as $k > 1$.

Since

$$\frac{1-P(l)-lQ(l)}{Q(l)}\left(\frac{P(l)}{(k-1)Q(l)}\right)^{1/(l-1)} > 0, \tag{48}$$

any $k \geq b-l+1$ always satisfies (46). For $l=2$, this rightmost term from (46) reduces to

$$\frac{1}{k-1}, \tag{49}$$

which is less than 1 for $k \geq 2$. Thus, for $l=2$, the only solution to (46) is $k \geq b-l+1$.

The leftmost term of the right side of (46) (k) increases linearly with k; the rightmost term decreases with k. The rate of decrease slows down as k increases. As a result, the bound on b decreases at first and then increases. In some cases the bound (for fixed l) holds for small k, does not hold for moderate k, and then holds again for large k. As shown above (below (48)) the bound on b (inequality (44)) is always obeyed when k is large. Numerical investigations show that sometimes the bound also holds for small k, and sometimes it does not; sometimes the small k region extends all the way to the large k region, and sometimes it does not.

5.3.4. Region 4. In this case $x_* < 1$ and $y_* > 1$. Thus by section 5.3.1, $k < bP(l-1)$ and by section 5.3.2, $k > bP(l)+1$. Thus, for such k, we have $bP(l) < k < bP(l-1)$. In such cases, the candidacy test succeeds with probability near 1, but the frequency test fails with high probability (F_l is high). Thus, the Apriori Algorithm experiences a bad level in this region. In section 5.4.4 we give bounds on F_l.

5.4. Bounds for F_l. Section 5.3 found the parameters regions relevant to F_l. In this section we will establish bounds on F_l associated with these regions.

5.4.1. Bounds on F_l in Region 1. When $k > bP(l-1)$ we are in Region 1 of section 5.3. We now give an upper bound on F_l to show that it is near 0 in this case. Thus in this region the candidacy test fails with high probability.

By (27) with $y=1$

$$F_l \leq x_*^{-kl}[1+(x_*^l-1)P(l)+l(x_*-1)Q(l)]^b. \tag{50}$$

(Note that bounds on F_l obtained with $y=1$ are also bounds on $C_l = F_l + S_l$. The definition for C_l (equation (14)) has a sum over all values of j_0, but setting $y=1$ also sums at unit weight over all values of j_0.) The optimum x_* is given by (35). Solve (35) (with $y=1$) for x_* with $x_* = 1+\delta$ and small δ. Let θ stand for a function that approaches 1 in the limit as δ approaches 0. (Just as various big O's are associated with different implied constants, different θ's are associated with different functions that approach 1 in the limit.)

$$\delta = \frac{k-bP(l)-bQ(l)}{b[lP(l-1)]-kl[P(l-1)]}\left(1+\frac{[k-bP(l)-bQ(l)](b-k)l(l-1)P(l)\theta/2}{\{b[lP(l)+Q(l)]-kl[P(l-1)]\}^2}\right)^{-1}. \tag{51}$$

Define α_3 by

$$k = b[P(l-1)+\alpha_3]. \tag{52}$$

In (50) replace k by its value in terms of α_3 and plug in the value of x implied by (51) to obtain

$$F_l \le e^{-bl\theta\alpha_3^2/(2\{P(l-1)+(l-1)P(l)-l[P(l-1)]^2\})} \tag{53}$$

when α_3 is small enough, i.e.,

$$\alpha_3 = \{lP(l) + Q(l) - l[P(l-1)]^2\}o(1). \tag{54}$$

5.4.2. Region 2. When $k < bP(l) + 1$ we are in Region 2 of section 5.3, and by (34) nearly all item sets pass the frequency test. Since an item set must first pass the candidacy test and then fail the frequency test, F_l can be no larger than $1 - S_l$, which (by (34)) gives the bound

$$F_l \le e^{-b\alpha_2^2/\{2P(l)[1-P(l)]\}+O(\alpha_2^3 bP(l)^{-2})}, \tag{55}$$

where α_2 is defined by $k = b[P(l) - \alpha_2] + 1$ (equation (33)).

5.4.3. Region 3. Since the k values for Region 3 are entirely inside the union of Regions 1 and 2, we can use results from the previous two sections to obtain upper bounds on F_l. With additional algebra, even better upper bounds could be obtained, but the previous bounds are good enough for most purposes.

5.4.4. Region 4. When $bP(l) < k < bP(l-1)$ we are in Region 4 of section 5.3. The candidacy test succeeds with high probability, but the frequency test succeeds with low probability. We now give a lower bound on F_l to show that there are cases where it is near 1.

In (17), the quantity R_k is defined by sums where each $j_i \ge k$ (for $1 \le i \le l$). Using inclusion-exclusion arguments, an alternate way to compute R_k is

$$R_k(b,l,m,n) = \sum_h (-1)^h \binom{l}{h} r_k(b,l,m,n,h), \tag{56}$$

where

$$\begin{aligned} r_k(b,l,m,n,h) = {} & \sum_{\substack{j_1<k \\ j_2<k \\ \cdots \\ j_h<k \\ j_{h+1},\ldots,j_l}} \binom{b}{j_1, j_2, \ldots, j_l, b - j_1 - \cdots - j_l} \\ & \times [Q(m)]^{j_1+\cdots+j_l}[1 - P(m) - nQ(m)]^{b-j_1-\cdots-j_l} \end{aligned} \tag{57}$$

$$\begin{aligned} = {} & \sum_{\substack{j_1<k \\ j_2<k \\ \cdots \\ j_h<k}} \binom{b}{j_1, j_2, \ldots, j_l, b - j_1 - \cdots - j_l} \\ & \times [Q(m)]^{j_1+\cdots+j_h}[1 - P(m) - (n-l+h)Q(m)]^{b-j_1-\cdots-j_h}. \end{aligned} \tag{58}$$

The $h = 0$ term of (56) is the sum over the full range for the j's. The $h = 1$ term subtracts (for each j) the part of the range that is not included in the definition of R. The $h = 2$ corrects for the overcorrection of the $h = 1$ term (regions where two j's were out of range were subtracted off twice). Each successive h corrects for the previous h. Therefore, if the sum over h is terminated at some value before l, the

result is a lower or upper limit on R depending on whether the first omitted term is negative or positive. We use the following case of this result:

$$R_k(b,l,m,n) \geq r_k(b,l,m,n,0) - lr_k(b,l,m,n,1) \tag{59}$$
$$\geq [1-P(m)-(n-l)Q(m)]^b - l \times \sum_{j<k} \binom{b}{j} [Q(m)]^j [1-P(m)-(n-l+1)Q(m)]^{b-j}. \tag{60}$$

By (16) we have

$$F_l \geq \sum_{j_0<k} \binom{b}{j_0} [P(l)]^{j_0} \times \left([1-P(l)]^{b-j_0} - l \sum_{j<k-j_0} \binom{b-j_0}{j} [Q(l)]^j [1-P(l)-Q(l)]^{b-j_0-j} \right). \tag{61}$$

A lower bound on the sum that comes from the first term in the large parentheses can be obtained by combining (32) with the right part of (11). Applying reasoning similar to that leading to (27) gives the following bound related to the second term:

$$\sum_{j_0<k} \binom{b}{j_0} [P(l)]^{j_0} \sum_{j<k-j_0} \binom{b-j_0}{j} [Q(l)]^j [1-P(l)-Q(l)]^{b-j_0-j} \leq x^{-k+1} y^{-k+1} [1+(xy-1)P(l)+(x-1)Q(l)]^b, \tag{62}$$

with the requirement $x \leq 1$, $y \leq 1$. By setting $y = 1$ the bound becomes $x^{-k+1}[1 + (x-1)P(l-1)]^b$ (using (10)). The same techniques that give the exponential term in (34) can be applied to bound this term. Combining the bounds on the two parts gives

$$F_l \geq 1 - e^{-b\alpha_1^2/\{2P(l)[1-P(l)]\}+O(b\alpha_1^3[1-P(l)]^{-2})} - le^{-b\alpha_4^2/\{2P(l-1)[1-P(l-1)]\}+O(b\alpha_4^3[P(l-1)]^{-2})}, \tag{63}$$

with α_1 and α_4 related to k by $k = b[P(l)+\alpha_1]$ and $k = b[P(l-1)-\alpha_4]-1$ when both α_1 and α_4 are positive.

This bound is good enough to show that for some values of k, the Apriori Algorithm has one bad level. Consider k equal to the integer nearest $[bP(l)+bP(l-1)-1]/2$, i.e.,

$$k = \frac{bP(l)+bP(l-1)-1}{2} + \eta, \tag{64}$$

with $|\eta| \leq 1/2$. This results in

$$\alpha_1 = \frac{bP(l-1)-P(l)+1/b}{2} + \eta, \qquad \alpha_4 = \frac{P(l-1)-P(l)+1/b}{2} - \eta. \tag{65}$$

For fixed k, p, and l and for large b, α_1 and α_4 approach constants. The bound on F_l (inequality (61)) approaches 1 when b becomes large. Thus, when b is large, there is a k value where F_l is extremely close to 1. When k is near $bP(l)$ for some l the bound from (63) is not good enough to show that F_l is close to 1. The sample calculations (in section 7), however, show that for such k values there are usually two l values that are each moderately bad (F_l above a constant), at least when b is not small. Thus, the conclusion is that the Apriori Algorithm, when it is run on random data, usually has one bad level or two half-bad levels.

6. Total work. Equation (63) shows that for random data there are many cases where the Apriori Algorithm has one bad level, i.e., a level where many item sets pass the candidacy test but few of them pass the frequency test. Equation (41) shows that there are rare cases where the Apriori Algorithm has no bad levels. The Apriori Algorithm has a reputation for being effective in practice [2, 6, 20]. In this section we show that for many parameter values, even when there is a bad level, the bad level comes before the algorithm has done much work and the algorithm is extremely good for the levels after the bad one. This leads to good overall performance. Under the assumption that accesses to the original data dominate the running time, large running times result from those terms in (6) where the binomial coefficient is large and $S_l + F_l$ is not small. No algorithm that explicitly examines the data to verify the number of occurrences for a set can be fast if a large fraction of the possible sets for large l must be processed. The merit of the Apriori Algorithm is that $S_l + F_l$ usually becomes extremely small once l increases beyond the value that results in $k > bP(l)$. This is shown by the following rough calculation. Consider the ratio of the l and $l+1$ terms from (6):

$$\binom{|I|}{l+1} \Big/ \binom{|I|}{l} = \frac{|I|-l}{l+1} \approx \frac{|I|}{l+1}, \tag{66}$$

so long as l is much less than $|I|$. Now choose l so that k is near to $bP(l-1)$. Using this value of l in (53) results in α_3 near 0 and F_l near 1. Now consider the failure rate on the next level. Using l to refer to the earlier level, for the level following l, the bound on the failure rate is given by (53) using a value of α_3 near $b[P(l-1) - P(l)]$. For this value of α_3, (53) gives the bound

$$F_{l+1} \le e^{-b^3(l+1)[P(l-1)-P(l)]^2\theta/(2\{P(l)+lP(l+1)-(l+1)[P(l)]^2\})}. \tag{67}$$

Since $P(l)$ is p^l, for small p this bound is approximately

$$e^{-b^3(l+1)p^{-2}/2}. \tag{68}$$

Since almost every possible item set needs work on level l, the ratio of the amount of work that the Apriori Algorithm performs on level $l+1$ to the amount of work on level l is approximately

$$\frac{|I|}{l} e^{-(l+1)b^3/(2p^2)}. \tag{69}$$

In most interesting cases this ratio will be much less than 1. There is further improvement as l increases. For most parameter values and for random data the amount of work that the Apriori Algorithm does drops rapidly after the bad level.

7. Sample computations. This section contains sample calculations for $b = 1024$ baskets, $1 \le l \le 5$, with thresholds in the range $1 \le k \le 1024$. Table 1 gives S_l for $p = 1/2$, $1 \le l \le 5$. Table 2 gives S_l for $p = 1/16$. Table 3 gives F_l for $p = 1/2$. Table 4 gives F_l for $p = 1/16$. Each table has results for only a few selected values of k. The selected values for k include those were F_l is maximum, where it is just above $1/2$, and where it is just below $1/2$. Figure 1 is a graph of S_l for $p = 1/2$ (solid curves). Upper and lower bounds (dashed curves) from (32) and (34) are also included. Figure 2 is a graph of F_l (solid curve) for $p = 1/2$ along with the bounds from (53), (55), and (63) (dashed). For all bounds plotted in the figures, big O terms

were ignored and θ was set to 1. The $p = 1/16$ cases do not lead to clear graphs, so none are given. For this case, one can best see what is happening by examining the tables.

When deciding which results to report, we had to balance the interest in large values for b (up to 100,000 in [2]) with the need to keep the computing time reasonable. Also, we had to balance the interest in small values for p with the need for results to show the various characteristics of the algorithm. And it is difficult to compute $(1-p)^j$ accurately when p is near zero and j is large. We used code where the number of multiplications increased only as fast as $\ln j$. The values of S were computed exactly using Maple and then converted to floating point. The Maple program was too slow to compute F in this way, so F was computed only with floating point arithmetic. For S, the results from exact arithmetic were not significantly different from those for floating point arithmetic, but the floating point calculations sometimes gave zero for values below 10^{-70}. Also, it was difficult to tell just how close to 1 a floating point value was once it went above $1 - 10^{-12}$.

From Table 1 and also from Figure 1, we see that, for fixed, moderate-sized values of k, S_l is extremely close to 1 for small values of l and that S_l is extremely small for large values of l. The transition from near 1 to small is quite sharp with increasing l. The transition value of l increases as k decreases. For large k, even S_1 is small. For small k one must go to large l values (not shown) before S_l becomes small. In Figure 1, the red curves (rightmost group) refer to $l = 1$. The upper dotted one is the upper

bound from (32). The solid one is the actual value from (11). The lower dashed one is the lower bound from (34). Proceeding to the left, we have corresponding groups for $l = 2$, 3, 4, and 5. For $l = 3$, 4, and 5, one can notice that the plotted "upper bound" goes below the actual value. This is because the big O term was omitted, and it is significant in these cases. Nonetheless, even without the big O term the upper bound gives the general idea for how the actual function behaves (it becomes extremely small). Table 2 shows that the $p = 1/16$ is similar to the $p = 1/2$ case. Notice that S with $p = 1/2$ and $l = 4$ has approximately the same value that S does for $p = 1/16$ and $l = 1$, particularly when k is small.

Table 3 and also Figure 2 show the values of F_l (solid) for $p = 1/2$ from (16), (17), and (19). Figure 3 also shows the upper (dotted) and lower (dashed) bounds computed from (53), (55), and (63). The red group of curves (rightmost) is for $l = 1$. The next rightmost group (orange) is for $l = 2$; the leftmost group is for $l = 5$ (blue). For any fixed k, there is one or sometimes two values of l for which F_l is not small. For most large values of k, there is just one l value where F_l is large, and for that one l value the resulting F_l is extremely close to 1, but for some large k values, there are two l values for which F_l is moderately large. As k becomes smaller, the l value that results in F_l being near 1 decreases. Also, F_l no longer becomes quite so close to 1. Table 4 shows F_l for $p = 1/16$. Notice that, for small k, F with $p = 1/2$ and $l = 4$ has approximately the same value as F does for $p = 1/16$ and $l = 1$. Table 5 shows the extend of the various regions when $b = 1024$, $p = 1/2$, and $1 \le l \le 5$. Table 6 shows information for the $p = 1/16$ case.

8. Experimental results. In this section we report the results of running the Apriori Algorithm on data that are more like those used in practice. We used three data sets: (1) synthetic data produced by the generator from the IBM Quest Research

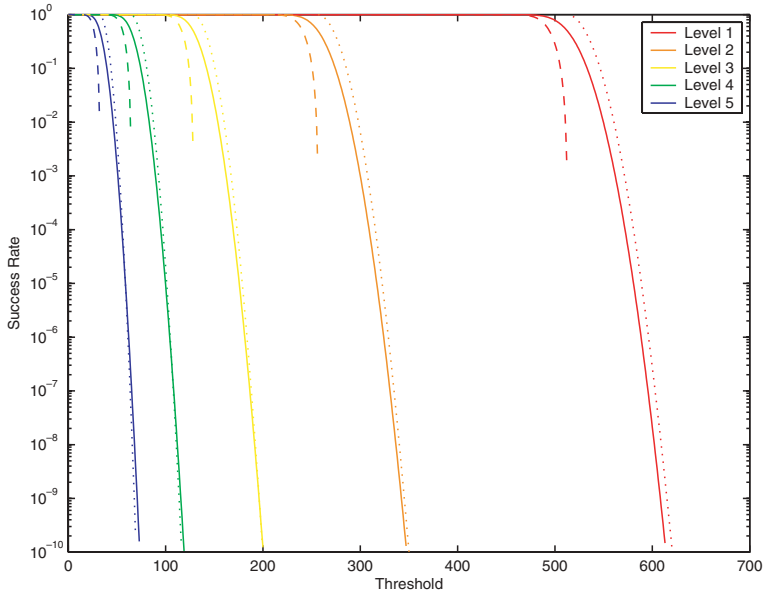

FIG. 1. *The value of S_l and approximations to S_l for $p = 1/2$ and $1 \leq l \leq 5$. The red curves are for S_1. The upper red dotted curve is the upper bound on S_1 ((32) with the big O term omitted). The solid red curve is the actual value of S_1. The lower red dashed curve is the lower bound on S_1 ((34) with the big O term omitted). The bounds are plotted only for the range where they are valid. Proceeding to the left, each group of three curves shows similar information on S_l for $l = 2$, 3, 4, and 5.*

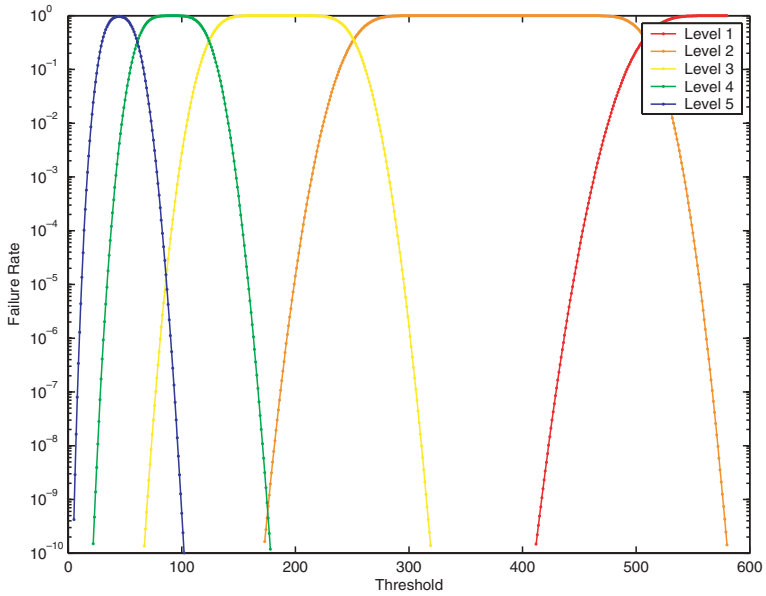

FIG. 2. *The value of F_l for $p = 1/2$ and $1 \leq l \leq 5$. The leftmost hump is the curve for $l = 5$, the next leftmost hump is for $l = 4$, etc.*

Group [13]; (2) real data based on the U.S. Census [23]; and (3) real Web data [24]. These data sets have two major differences from the sets analyzed in the previous sections: (1) the probability of an item being in a basket is not the same for every item, but varies greatly from item to item (this effect is particularly strong in the census and Web data sets), and (2) the items are correlated [5].

Given the major differences between the data used in the analytical study and the data used for the experimental study, it is not surprising that many of the results from the experiments differ from those of the analysis. However, the experiments did verify one important conclusion of the analysis: work done by the Apriori Algorithm is dominated by the failure rate and the total failure rate is almost as high as it possibly can be. To be more precise, for most thresholds, there is a single level where most of

the work is done, and on this level almost every candidate fails to be a success.

In the random model, there is a fixed number of items, $|I|$, each occurring in a basket with probability p. For level l, when the threshold, k, is such that $k < bp^l$, almost every item set with l items ($\binom{|I|}{l}$ item sets) is frequent. Once l is large enough that $k > bp^l$, then almost no item set with l items is frequent. When p is small, the value of bp^l changes rapidly with l.

One can obtain an informal understanding of the experimental data presented below by permitting $|I|$, b, and p to vary (both with the threshold, k, and the level, l). In the random model, level l will have approximately $\binom{|I|}{l}$ successful item sets so long as k is much less than bp^l, and it will have a lot less if k is much larger than bp^l. Also, when p is small, the value of bp^l changes rapidly with l. The ratio of the number of item sets on level l to level $l-1$ is $\binom{|I|}{l}/\binom{|I|}{l-1}$, which is approximately $|I|/l$ if $|I|$ is much larger than l. Thus, we would expect the number of item sets to increase rapidly with l until the level where bp^l becomes larger than k. Even when the effective $|I|$ decreases with l and the effective p increases, one is likely to get behavior that is qualitatively the same. The number of item sets will increase rapidly at first, and then it will suddenly decrease. The cause of the decrease will be the high failure rate on the level just before the decrease. This will be the level where most of the work is done, because it is the level with the most candidates.

Now, consider some actual data sets. These data sets were run through a version of the Apriori Algorithm that computes frequent item sets for all values of the threshold with a lower limit being imposed on the threshold as needed to avoid running out of computer memory. Figures 4–9 show the results for three data sets. In each figure, the bottom axis shows the threshold. Each color curve refers to one level of the Apriori Algorithm: level 1, red; level 2, orange; level 3, yellow; level 4, green; level 5, blue. Figures 4, 6, and 8 show, for each of the data sets, the number of candidates as a solid curve, the upper bound from [10] as a dotted curve, and the number of failures as a dashed curve. For a given level, the upper bound is highest, the number of candidates is in the middle, and the number of failures is lowest. Often the dotted and/or dashed curves are so close to the solid curve that they don't show up. Figures 5, 7, and 9 show, for each of the data sets, the ratio of failures to candidates (for each level).

8.1. Synthetic data. The first data set was generated using the synthetic data set generator from the IBM Quest Research Group [13] to create data sets in the same fashion as [3]. We tested several synthetic data sets, each of which had 1000 items. We report the results for the T5.I2.D100K (average transaction size, 5; size of the average maximal frequent item set, 2; number of transactions, 100,000), as they are representative of the experimental results for the other synthetic data sets.

The solid curves in Figure 4 show the number of candidates on each level (which is proportional to the work done on the level). Notice that for high thresholds (above 849) the most work is done on level 1; for intermediate thresholds (between 16 and 849) the most work is done on level 2; and for low thresholds (between 1 and 15) the most work is done on level 3. Notice that for the highest solid curve (which one is highest depends on the threshold) the number of failures is almost equal to the number of candidates. In Figure 4 this shows up by the dashed curve falling on top of the solid curve (or almost on top). Figure 5 shows the ratio of failures to candidates. This ratio is close to 1 for the curve that is uppermost in Figure 4.

For each threshold, the uppermost curve represents the bad level, the level where most of the work is done and where almost every candidate is a failure. For levels past the bad level, one may want to use a version of the Apriori Algorithm that counts

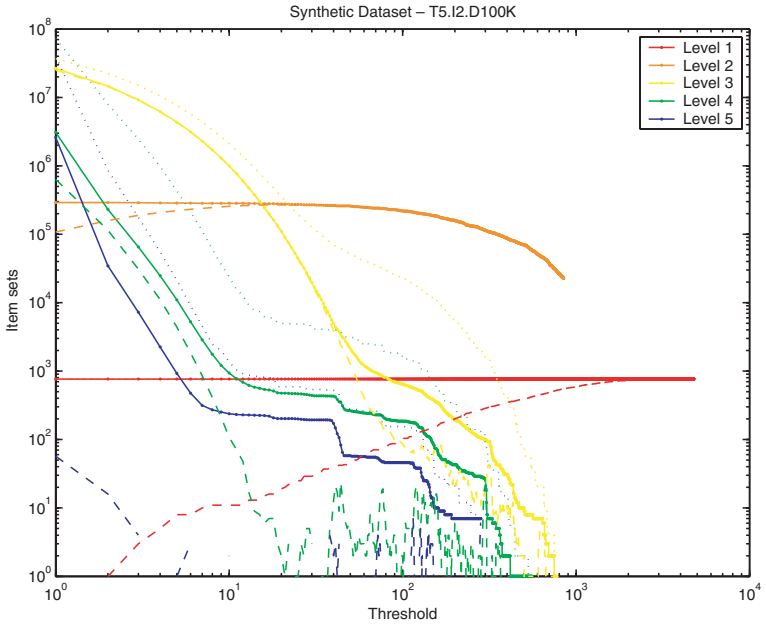

FIG. 4. *Behavior of the algorithm on synthetic data. The dotted lines show the upper bounds, the solid lines show the actual number of candidates considered, and the dashed lines show the number of candidates that fail for each level.*

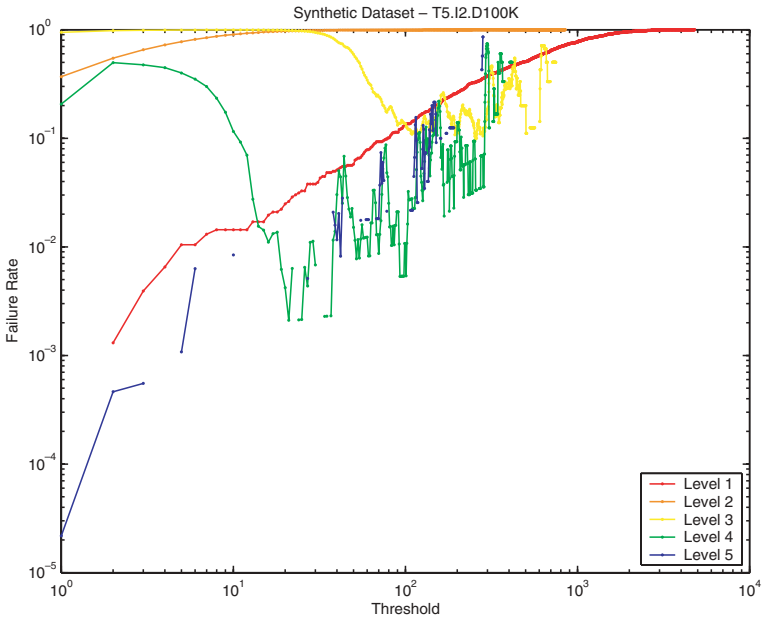

FIG. 5. *The failure rate for the synthetic data set.*

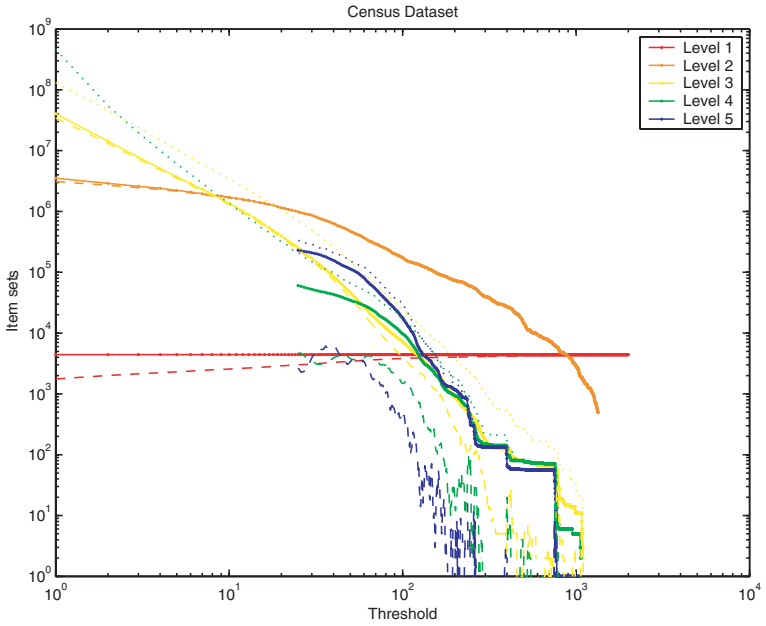

FIG. 6. *Behavior of the algorithm on census data. The dotted lines show the upper bounds, the solid lines show the actual number of candidates considered, and the dashed lines show the number of candidates that fail for each level.*

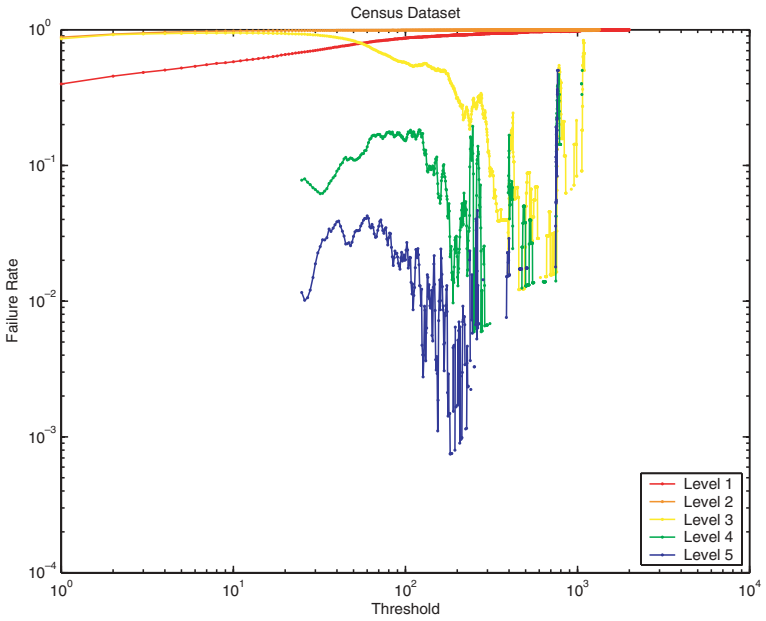

FIG. 7. *The failure rate for the census data set.*

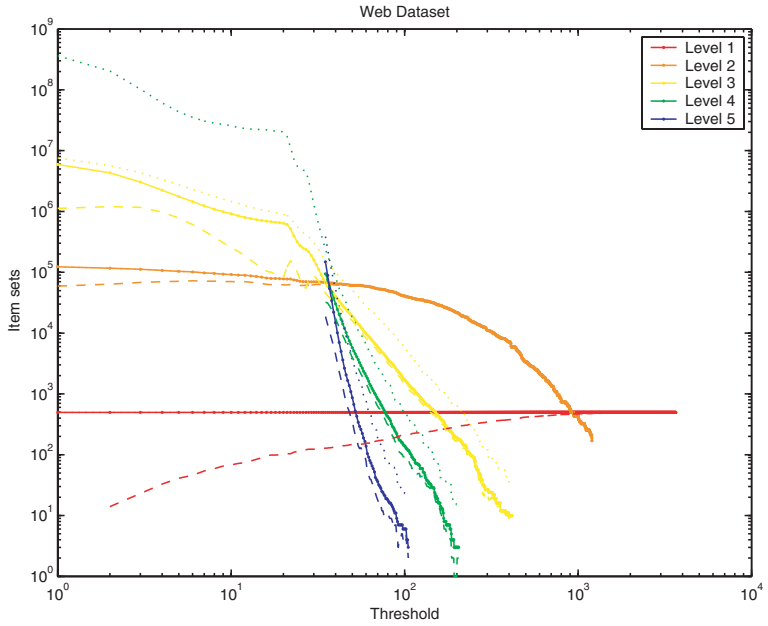

FIG. 8. *Behavior of the algorithm on Web data. The dotted lines show the upper bounds, the solid lines show the actual number of candidates considered, and the dashed lines show the number of candidates that fail for each level.*

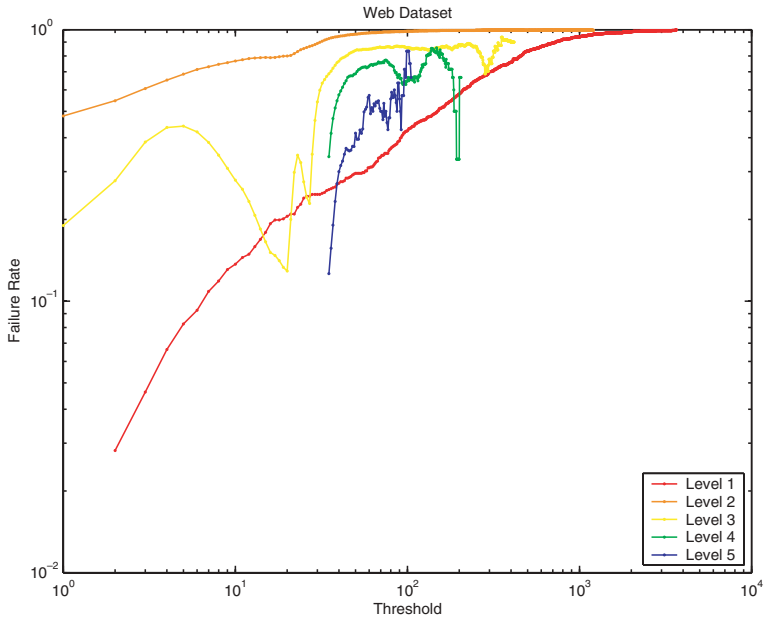

FIG. 9. *The failure rate for the Web data set. Note that each of the first three levels is "bad" for certain ranges of the threshold value.*

item sets for all remaining levels in one pass. (This was one of the main motivations for [10].)

8.2. Census data. The second data set was U.S. Census data, using Public Use Microdata Samples (PUMS) [23]. We chose the same sample that was used by [5, 6]. The data represents a 5% sample of the 1990 U.S. Census data for Washington, D.C. It contains 30,370 entries with 122 attributes.

Following [5, 6, 11], we modified the data in the following ways. For monetary values, we took the ceiling of the logarithm of the value. Then we assigned a unique integer to each possible value in the data. In total, the converted PUMS data was 16.6 MB, with 7523 unique items. In addition, we pruned the highly frequent items, which yield an intractable number of frequent item sets.

Due to the high number of correlated items in this type of data our computing resources did not permit us to compute levels 4 and 5 for thresholds less than 25.

The solid curves in Figure 6 show the number of candidates on each level. Notice that for high thresholds (above 872) the most work is done on level 1 and for intermediate thresholds (between 25 and 872) the most work is done on level 2. We are missing data for low thresholds. Figures 6 and 7 show that for the level where most of the work is done, the ratio of failures to candidates is almost 1.

8.3. Web data. The third data set was the BMS-WebView-1 data set described in [24]. This data contains click stream data from a Web-based merchandising company. There are 59,602 transaction and 497 distinct items in the Web data.

Figure 8 shows the results for the Web data. Resources did not permit thresholds below 35 for levels 4 and above.

Level 3, however, has a large enough number of successes to suggest that levels 4 and 5 are the truly "bad" levels for this data. The slope of these two levels is extremely steep, with level 5 being nearly vertical. Figure 9 shows the ratio of failures to candidates for the Web data.

9. Discussion. For random shopper and for most values of the parameters, the amount of work that the Apriori Algorithm does increases rapidly with the level until a bad level is reached. Until the bad level, almost every item set is frequent; level l will have almost $\binom{|I|}{l}$ successes. At the bad level and beyond almost every item set fails to be frequent. Almost all of the work done by the algorithm consists of processing the failures on the bad level. Which level is bad depends on the threshold (and the other parameters). For special values of the threshold two neighboring level will each be halfway bad.

The experimental data in the paper came from shoppers that were far from random. For most thresholds, there still was a bad level where almost all the work for the whole algorithm consisted of processing failures on the bad level. The fraction of failures on the early levels was not large, but it was large enough that the number of successes on level l was much less than $\binom{|I|}{l}$.

Our assumptions on random shoppers and the assumptions that realize the worst-case bounds of [10, Theorem 1] (highly correlated shopping) appear quite different, but in some ways they are quite similar. Consider the case where the number of successes on level l is $\binom{m}{l}$ for some integer m. Then the upper bound limit on the number of candidates for level $l+1$ is $\binom{m}{l+1}$, the same as for the random shopper case when $p = 1$ and $|I| = m$. Indeed the random shopper model gives essentially the same prediction for the number of candidates for any value of p large enough that $k < bp^l$. From this point of view, the key insight of their Theorem 1 is that the

binomial coefficient leads to a useful estimate of how many items are still important when the Apriori Algorithm gets to level l.

We believe that comparing properties that are observed for the random shopper with the properties that are observed with worst-case shoppers can give some insight as to how the Apriori Algorithm will behave with typical data sets.

Appendix. This section gives proofs and the derivations of equations.

Proof. A subpart of the Apriori Algorithm is NP-complete. Determining whether some set of size l occurs k times is in NP because one can guess the set and then verify the number of occurrence by counting the occurrences. The proof that the problem is NP-hard uses reduction from the balanced complete bipartite subgraph problem: given a positive integer K and a bipartite graph with vertices V and edges E, determine whether there are two disjoint sets of edges (V_1 and V_2) such that $|V_1| = K$, $|V_2| = K$, and such that there is an edge in E between each vertex in V_1 and each vertex in V_2. Since any such subgraph must be in a single connected component of the original graph, we can process each connected component of the graph separately. In a single connected component, the vertices of a bipartite graph naturally fall into two groups where all the edges in a group are connected by paths of even length. To map the given single component bipartite graph to baskets and items, associate (in a one-to-one manner) each vertex of one part with an item, and associate (in a one-to-one manner) each vertex of the other part with a basket. Have item i in basket b if and only if the vertex associated with i has an edge connecting to the vertex associated with b. If there is solution to the given instance of the balanced complete bipartite subgraph problem, then that solution directly gives an item set of size K that occurs in K baskets. Also if there is an item set of size K that occurs in K baskets, then the corresponding subgraph is a solution to the given instance. □

Equation (11). We have j ($j \geq k$) baskets that contain the set and $b - j$ baskets that do not contain the set, so

$$S_l = \sum_{j \geq k} \binom{b}{j} [P(l)]^j [1 - P(l)]^{b-j}. \tag{11a}$$

From the binomial theorem we have

$$\sum_{j} \binom{b}{j} [P(l)]^j [1 - P(l)]^{b-j} = 1, \tag{A1}$$

so

$$\sum_{j \geq k} \binom{b}{j} [P(l)]^j [1 - P(l)]^{b-j} = 1 - \sum_{j < k} \binom{b}{j} [P(l)]^j [1 - P(l)]^{b-j}. \tag{11b}$$

Equation (12). The factor $[P(l)]^{j_0}$ is the probability that the first j_0 baskets obey condition M_0, $[Q(l)]^{j_1}$ is the probability that the next j_1 baskets obey condition M_1, ..., $[Q(l)]^{j_l}$ is the probability that the next j_l baskets obey condition M_l, and $[1 - P(l) - lQ(l)]^{b-j_0-\cdots-j_l}$ is the probability that the remaining baskets obey none of the conditions $M_0, \ldots, M_l$. (Notice that each basket obeys at most one of the conditions M_h ($0 \leq h \leq l$).) However, the various baskets can come in any order, and the multinomial coefficient allows for this. Thus the probability that j_h baskets obey condition M_h ($0 \leq h \leq l$) and that the remaining $b - j_0 - \cdots - j_l$ baskets do not obey

any of the conditions is

$$\binom{b}{j_0,\ldots,j_l,b-j_0-\cdots-j_l}[P(l)]^{j_0}[Q(l)]^{j_1+\cdots+j_l}[1-P(l)-lQ(l)]^{b-j_0-\cdots-j_l}. \tag{12}$$

Equation (18).

$$\begin{aligned} R_k(b,l,m,n) &= \sum_{\substack{j_1\ge k\\ j_2\ge k\\ \cdots\\ j_l\ge k}} \binom{b}{j_1,\ldots,j_l,b-j_1-\cdots-j_l} \\ &\quad\times [Q(m)]^{j_1+\cdots+j_l}[1-P(m)-nQ(m)]^{b-j_1-\cdots-j_l} \qquad (17)\\ &= \sum_{j_1\ge k}\binom{b}{j_1}[Q(m)]^{j_1}\sum_{\substack{j_2\ge k\\ j_3\ge k\\ \cdots\\ j_l\ge k}}\binom{b-j_1}{j_2,\ldots,j_l,b-j_1-\cdots-j_l} \\ &\quad\times [Q(m)]^{j_2+\cdots+j_l}[1-P(m)-nQ(m)]^{(b-j_1)-j_2-\cdots-j_l} \qquad (A2)\\ &= \sum_{j\ge k}\binom{b}{j}[Q(m)]^{j}R_k(b-j,l-1,m,n). \qquad (18) \end{aligned}$$

Equation (19). The boundary condition is just (17) with l replaced with 0.

Equation (27). Using the binomial theorem on the j_l sum in (25), we have

$$\begin{aligned} &x^{-kl}\sum_{j_1,\ldots,j_l}\binom{b}{j_1,\ldots,j_l,b-j_1-\cdots-j_l} \\ &\qquad\times [xQ(m)]^{j_1+\cdots+j_l}[1-P(m)-nQ(m)]^{b-j_1-\cdots-j_l} \\ &= x^{-kl}\sum_{j_1,\ldots,j_{l-1}}\binom{b}{j_1,\ldots,j_{l-1},b-j_1-\cdots-j_{l-1}} \\ &\qquad\times [xQ(m)]^{j_1+\cdots+j_{l-1}}[1-P(m)-nQ(m)]^{b-j_1-\cdots-j_{l-1}}. \qquad (A3) \end{aligned}$$

The remaining $l-1$ sums can be done the same way to obtain

$$\begin{aligned} R_k(b,l,m,n) &\le x^{-kl}\sum_{j_1,\ldots,j_l}\binom{b}{j_1,\ldots,j_l,b-j_1-\cdots-j_l} \\ &\qquad\times [xQ(m)]^{j_1+\cdots+j_l}[1-P(m)-nQ(m)]^{b-j_1-\cdots-j_l} \\ &\le x^{-kl}[1-P(m)-(n-lx)Q(m)]^b. \qquad (25) \end{aligned}$$

Equation (28). Less algebra is needed to minimize the logarithm of the bound, and it leads to the same result. Start with the derivative of the logarithm of (23):

$$\frac{d\{-k\ln x+b\ln[1+(x-1)P(l)]\}}{dx} = \frac{-k}{x}+\frac{bP(l)}{1+P(l)(x-1)}. \tag{A4}$$

Now set the logarithm to zero and replace x (the free variable) with x_* (the value

that results in the derivative being zero):

$$\frac{-k}{x_*} + \frac{bP(l)}{1 + P(l)(x_* - 1)} = 0, \tag{A5}$$

$$-kP(l)(x_* - 1) - k + bP(l)x_* = 0, \tag{A6}$$

$$x_* = \frac{k[1 - P(l)]}{(b - k)P(l)}. \tag{28}$$

Equation (29).

$$\frac{k[1 - P(l)]}{(b - k)P(l)} > 1, \tag{A7}$$

$$k[1 - P(l)] > (b - k)P(l) \tag{A8}$$

(since $b > k$), so

$$k > bP(l). \tag{29}$$

Equation (30). Plugging (28) into (23) gives

$$S_l \le \left(\frac{k[1 - P(l)]}{(b - k)P(l)}\right)^{-k} \left[1 + \left(\frac{k[1 - P(l)]}{(b - k)P(l)} - 1\right) P(l)\right]^b, \tag{A9}$$

$$S_l \le \{k[1 - P(l)]\}^{-k}[P(l)]^k(b - k)^{-b+k}(b - k + \{k[1 - P(l)] - (b - k)P(l)\})^b,$$

$$S_l \le \left(\frac{P(l)}{k}\right)^k \left(\frac{1 - P(l)}{b - k}\right)^{b-k} b^b. \tag{30}$$

Equation (32). Replace k in (30) with its value in terms of α_1 (equation (31)):

$$S_l \le \left(\frac{P(l)}{b[P(l) + \alpha_1]}\right)^{b[P(l)+\alpha_1]} \left(\frac{1 - P(l)}{b - b[P(l) + \alpha_1]}\right)^{b-b[P(l)+\alpha_1]} b^b, \tag{A10}$$

$$S_l \le \left(\frac{P(l)}{b[P(l) + \alpha_1]}\right)^{b[P(l)+\alpha_1]} \left(\frac{1 - P(l)}{b[1 - P(l) - \alpha_1]}\right)^{b[1-P(l)-\alpha_1]} b^b, \tag{A11}$$

$$S_l \le \left(\frac{1}{b[1 + \alpha_1/P(l)]}\right)^{b[P(l)+\alpha_1]} \left(\frac{1}{b\{1 - \alpha_1/[1 - P(l)]\}}\right)^{b[1-P(l)-\alpha_1]} b^b, \tag{A12}$$

$$S_l \le \left(\frac{1}{1 + \alpha_1/P(l)}\right)^{b[P(l)+\alpha_1]} \left(\frac{1}{1 - \alpha_1/[1 - P(l)]}\right)^{b[1-P(l)-\alpha_1]}. \tag{A13}$$

To further simplify this, we will write it as $S_l \le e^X$ with

$$X = \ln\left[\left(\frac{1}{1 + \alpha_1/P(l)}\right)^{b[P(l)+\alpha_1]} \left(\frac{1}{1 - \alpha_1/[1 - P(l)]}\right)^{b[1-P(l)-\alpha_1]}\right] \tag{A14}$$

$$= -b[P(l) + \alpha_1] \ln\left(1 + \frac{\alpha_1}{P(l)}\right) - b[1 - P(l) - \alpha_1] \ln\left(1 - \frac{\alpha_1}{[1 - P(l)]}\right). \tag{A15}$$

Dividing by b, we have

$$\frac{X}{b} = -[P(l)+\alpha_1]\ln\left(1+\frac{\alpha_1}{P(l)}\right) - [1-P(l)-\alpha_1]\ln\left(1-\frac{\alpha_1}{[1-P(l)]}\right) \tag{A16}$$

$$= -[P(l)+\alpha_1]\left[\left(\frac{\alpha_1}{P(l)}\right) - \frac{1}{2}\left(\frac{\alpha_1}{P(l)}\right)^2 + O\left(\left(\frac{\alpha_1}{P(l)}\right)^3\right)\right] \tag{A17}$$

$$+ [1-P(l)-\alpha_1]\left[\left(\frac{\alpha_1}{1-P(l)}\right) + \frac{1}{2}\left(\frac{\alpha_1}{1-P(l)}\right)^2 + O\left(\left(\frac{\alpha_1}{1-P(l)}\right)^3\right)\right] \tag{A18}$$

$$= -\alpha_1 + \frac{\alpha_1^2}{2P(l)} - O\left(\frac{\alpha_1^3}{P(l)^2}\right) - \frac{\alpha_1^2}{P(l)} + \frac{\alpha_1^3}{2P(l)^2} - O\left(\frac{\alpha_1^4}{P(l)^3}\right)$$

$$+ \alpha_1 + \frac{\alpha_1^2}{2[1-P(l)]} + O\left(\frac{\alpha_1^3}{[1-P(l)]^2}\right) - \frac{\alpha_1^2}{1-P(l)} - \frac{\alpha_1^3}{2[1-P(l)]^2}$$

$$- O\left(\frac{\alpha_1^4}{[1-P(l)]^3}\right) \tag{A19}$$

$$= -\frac{\alpha_1^2}{2P(l)} - \frac{\alpha_1^2}{2[1-P(l)]} + O\left(\frac{\alpha_1^3}{[1-P(l)]^2}\right) - O\left(\frac{\alpha_1^3}{P(l)^2}\right). \tag{A20}$$

The big O is with respect to α_1. We assume that $0 < p < 1$. Since negative big O terms can be dropped in an upper limit,

$$S_l \le e^{-b\alpha_1^2/\{2P(l)[1-P(l)]\}+O(b\alpha_1^3[1-P(l)]^{-2})}. \tag{32}$$

Equation (35). The derivative of the logarithm of the bound on F (inequality (27)) with respect to x is

$$\frac{d\,[-kl\ln x - (k-1)\ln y + b\ln[1+(x^l y-1)P(l)+l(x-1)Q(l)]}{dx}$$

$$= \frac{-kl}{x} + \frac{b[lx^{l-1}yP(l)+lQ(l)]}{1+(x^l y-1)P(l)+l(x-1)Q(l)}. \tag{A21}$$

Setting this to zero gives

$$-kl[1+(x_*^l y-1)P(l)+l(x_*-1)Q(l)] + bx_*[lx_*^{l-1}yP(l)+lQ(l)] = 0, \tag{A22}$$

$$-kl - klP(l)x_*^l y + klP(l) + kl^2Q(l) - kl^2Q(l)x_* + blP(l)x_*^l y + blQ(l)x_* = 0, \tag{A23}$$

$$(b-k)P(l)x_*^l y + (b-kl)Q(l)x_* - k[1-P(l)-lQ(l)] = 0. \tag{35}$$

Equation (36). The derivative of the logarithm bound (inequality (27)) with respect to y gives

$$\frac{d\,[-kl\ln x - (k-1)\ln y + b\ln[1+(x^l y-1)P(l)+l(x-1)Q(l)]}{dy} \tag{A24}$$

$$= -\frac{k-1}{y} + \frac{bx^lP(l)}{1+(x^l y-1)P(l)+l(x-1)Q(l)}. \tag{A25}$$

Setting this to zero gives

$$-(k-1)[1+(x^l y_*-1)P(l)+l(x-1)Q(l)]+bx^l y_* P(l)=0, \tag{A26}$$

$$(b-k+1)P(l)x^l y_*-(k-1)[1-P(l)+lQ(l)(x-1)]=0. \tag{36}$$

Equation (37). Equation (35) with $x_*=1$, $y=1$ is

$$(b-k)P(l)+(b-kl)Q(l)-k[1-P(l)-lQ(l)]=0, \tag{A27}$$

$$k=b[P(l)+Q(l)]=bP(l-1). \tag{37}$$

Equation (38). By implicit differentiation of (35) (with $y=1$) we have

$$\frac{d\{(b-k)P(l)x_*^l+(b-kl)Q(l)x_*-k[1-P(l)-lQ(l)]\}}{db}=0, \tag{A28}$$

$$P(l)x_*^l+Q(l)x_*+[(b-k)lP(l)x_*^{l-1}+(b-kl)Q(l)]\frac{d\,x_*}{db}=0, \tag{A29}$$

$$\frac{d\,x_*}{db}=-\frac{P(l)x_*^l+Q(l)x_*}{(b-k)lP(l)x_*^{l-1}+(b-kl)Q(l)}. \tag{A30}$$

Since x_* solves (35) (with $y=1$) we have

$$(b-k)P(l)x_*^l+(b-kl)Q(l)x_*=k[1-P(l)-lQ(l)], \tag{A31}$$

which is positive. Thus

$$\begin{aligned}(b-k)P(l)lx_*^{l-1}+(b-kl)Q(l)=&\frac{(b-k)P(l)x_*^l+(b-kl)Q(l)x_*}{x_*}\\&+(l-1)(b-k)P(l)x_*^{l-1}\end{aligned} \tag{A32}$$

is also positive (because $x_*>0$, $b-k>0$, and $l\geq 1$). Thus, $d\,x_*/db$ is negative. If we start at the b value that results in $x_*=1$, and decrease b, then x_* increases. Thus, it becomes larger than 1 and stays larger than 1.

Equation (39). Equation (36) with $x=1$ is

$$(b-k+1)P(l)y_*-(k-1)[1-P(l)]=0, \tag{A33}$$

$$y_*=\frac{(k-1)[1-P(l)]}{(b-k+1)P(l)}. \tag{39}$$

Equation (40).

$$\frac{(k-1)[1-P(l)]}{(b-k+1)P(l)}<1, \tag{A34}$$

$$(k-1)[1-P(l)]<(b-k+1)P(l), \tag{A35}$$

$$k-1<bP(l), \tag{A36}$$

$$k<bP(l)+1. \tag{40}$$

Equation (42). From (35)

$$P(l)x_*^l y = \frac{k[1-P(l)-lQ(l)]-(b-kl)Q(l)x_*}{b-k}. \tag{A37}$$

From (36)

$$P(l)x^l y_* = \frac{(k-1)[1-P(l)+l(x-1)Q(l)]}{b-k+1}. \tag{A38}$$

Setting x to x_*, y to y_*, the two right sides equal, and clearing fractions gives

$$\begin{aligned} &k(b-k+1)[1-P(l)-lQ(l)]-(b-kl)(b-k+1)Q(l)x \\ &\quad = (k-1)(b-k)[1-P(l)+lQ(l)x-lQ(l)], \end{aligned} \tag{A39}$$

$$\begin{aligned} &(b^2-bk+b-bkl+k^2l-kl)Q(l)x = (bk-k^2+k)[1-P(l)-lQ(l)] \\ &\quad -(bk-k^2-b+k)[1-P(l)+lQ(l)x-lQ(l)], \end{aligned} \tag{A40}$$

$$\begin{aligned} &(b^2-bk+b-bkl+k^2l-kl+bkl-k^2l-bl+kl)Q(l)x \\ &\quad = (bk-k^2+k-bk+k^2+b-k)[1-P(l)-lQ(l)], \end{aligned} \tag{A41}$$

$$(b^2-bk+b-bl)Q(l)x = b[1-P(l)-lQ(l)], \tag{A42}$$

$$x = \frac{1-P(l)-lQ(l)}{(b-k-l+1)Q(l)}. \tag{42}$$

Equation (43). Plugging the value of x from (42) into (35) gives

$$\begin{aligned} &(b-k)\left(\frac{1-P(l)-lQ(l)}{(b-k-l+1)Q(l)}\right)^l P(l)y \\ &\quad + \frac{(b-kl)[1-P(l)-lQ(l)]}{b-k-l+1} - k[1-P(l)-lQ(l)] = 0, \end{aligned} \tag{A43}$$

$$y = \frac{k[1-P(l)-lQ(l)] - \frac{(b-kl)[1-P(l)-lQ(l)]}{b-k-l+1}}{(b-k)\left(\frac{1-P(l)-lQ(l)}{(b-k-l+1)Q(l)}\right)^l P(l)}, \tag{A44}$$

(A45)

$$y = \frac{(b-k-l+1)^{l-1}Q(l)^l\{k(b-k-l+1)[1-P(l)-lQ(l)]-(b-kl)[1-P(l)-lQ(l)]\}}{(b-k)[1-P(l)-lQ(l)]^l P(l)},$$

$$y = \frac{(b-k-l+1)^{l-1}Q(l)^l(bk-k^2-kl+k-b+kl)[1-P(l)-lQ(l)]}{(b-k)[1-P(l)-lQ(l)]^l P(l)}, \tag{A46}$$

$$y = \frac{(b-k-l+1)^{l-1}Q(l)^l(k-1)[1-P(l)-lQ(l)]}{[1-P(l)-lQ(l)]^l P(l)}, \tag{A47}$$

$$y = (k-1)\left(\frac{(b-k-l+1)Q(l)}{1-P(l)-lQ(l)}\right)^{l-1}\frac{Q(l)}{P(l)}. \tag{43}$$

Equation (44). To have $x > 1$ we need

$$\frac{1 - P(l) - lQ(l)}{(b - k - l + 1)Q(l)} > 1. \tag{A48}$$

For $b > k + l - 1$ we have

$$1 - P(l) - lQ(l) > (b - k - l + 1)Q(l), \tag{A49}$$

$$1 - P(l) > (b - k + 1)Q(l), \tag{A50}$$

$$b < k - 1 + \frac{1 - P(l)}{Q(l)}. \tag{A51}$$

So that the upper and lower bounds look more similar, we rewrite the upper bound on b by adding and subtracting l:

$$k + l - 1 < b < k + l - 1 + \frac{1 - P(l) - lQ(l)}{Q(l)}. \tag{44}$$

Suppose $b < k + l - 1$. Then from (A48) we have

$$1 - P(l) - lQ(l) < (b - k - l + 1)Q(l), \tag{A52}$$

$$1 - P(l) < (b - k + 1)Q(l), \tag{A53}$$

$$b > k - 1 + \frac{1 - P(l)}{Q(l)}, \tag{A54}$$

$$k + l - 1 > b > k - 1 + \frac{1 - P(l)}{Q(l)}. \tag{A55}$$

For this range to be nonempty, we need

$$k + l - 1 > k - 1 + \frac{1 - P(l)}{Q(l)}, \tag{A56}$$

$$0 > \frac{1 - P(l)}{Q(l)} - l, \tag{A57}$$

$$0 > \frac{1 - P(l) - lQ(l)}{Q(l)}, \tag{A58}$$

but this cannot be. We have $P(l) + lQ(l) = p^l + l(1 - p)p^{l-1}$, which are some of the terms in the binomial expansion of $[p + (1 - p)]^l = 1$. Since all of the terms are nonnegative (for $0 \geq p \geq 1$) the sum of some of the terms is no more than 1, so the right side of (A58) is nonnegative. Thus, the range is always empty.

Equation (45).

$$b < bP(l - 1) + l - 1 + \frac{1 - P(l) - lQ(l)}{Q(l)}, \tag{A59}$$

$$b[1 - P(l - 1)] < \frac{1 - P(l) - Q(l)}{Q(l)}, \tag{A60}$$

$$b[1 - P(l - 1)] < \frac{1 - P(l - 1)}{Q(l)}, \tag{A61}$$

$$b < \frac{1}{Q(l)}. \tag{A62}$$

Equation (46). To have $y < 1$ we need

$$(k-1)\left(\frac{(b-k-l+1)Q(l)}{1-P(l)-lQ(l)}\right)^{l-1}\frac{Q(l)}{P(l)} < 1. \tag{A63}$$

For $l \geq 2$

$$\frac{(b-k-l+1)Q(l)}{1-P(l)-lQ(l)}\left(\frac{(k-1)Q(l)}{P(l)}\right)^{1/(l-1)} < 1, \tag{A64}$$

$$b-k-l+1 \leq \frac{1-P(l)-lQ(l)}{Q(l)\left(\frac{(k-1)Q(l)}{P(l)}\right)^{1/(l-1)}}, \tag{A65}$$

$$b < k+l-1+\frac{1-P(l)-lQ(l)}{Q(l)}\left(\frac{P(l)}{(k-1)Q(l)}\right)^{1/(l-1)}. \tag{46}$$

The upper bound on b from (46) is greater than the lower bound from (44).

$$k+l-1+\frac{1-P(l)-lQ(l)}{Q(l)}\left(\frac{P(l)}{(k-1)Q(l)}\right)^{1/(l-1)} > k+l-1, \tag{A66}$$

$$\frac{1-P(l)-lQ(l)}{Q(l)}\left(\frac{P(l)}{(k-1)Q(l)}\right)^{1/(l-1)} > 0. \tag{A67}$$

All the terms on the left are positive for $0 < p < 1$.

Equation (47). We now consider when the upper bound on b from (46) is less than the upper bound from (44):

(A68)

$$k+l-1+\frac{1-P(l)-lQ(l)}{Q(l)}\left(\frac{P(l)}{(k-1)Q(l)}\right)^{1/(l-1)} < k+l-1+\frac{1-P(l)-lQ(l)}{Q(l)},$$

$$\frac{1-P(l)-lQ(l)}{Q(l)}\left(\frac{P(l)}{(k-1)Q(l)}\right)^{1/(l-1)} < \frac{1-P(l)-lQ(l)}{Q(l)}, \tag{A69}$$

$$0 < \frac{1-P(l)-lQ(l)}{Q(l)}\left[1-\left(\frac{P(l)}{(k-1)Q(l)}\right)^{1/(l-1)}\right]. \tag{A70}$$

As shown above (below (A58)), the first factor is always positive. For the second factor to be positive we need

$$1 > \left(\frac{P(l)}{(k-1)Q(l)}\right)^{1/(l-1)}, \tag{A71}$$

$$1 > \frac{P(l)}{(k-1)Q(l)}, \tag{A72}$$

$$(k-1)(1-p)p^{l-1} > p^l, \tag{A73}$$

$$(k-1)(1-p) > p, \tag{A74}$$

$$k-kp-1+p > p, \tag{A75}$$

$$k(1-p) > 1, \tag{A76}$$

$$k > \frac{1}{1-p}. \tag{47}$$

Equation (51). Equation (35) with $y = 1$ is

$$(b-k)P(l)x^l + (b-kl)Q(l)x - k[1-P(l)-lQ(l)] = 0. \tag{A77}$$

Let $x = 1+\delta$ with small δ and expand to second order. Let θ stand for quantities that approach 1 in the limit as δ approaches 0. In other words, θ is short for $[1 + o(1)]$, where δ is the variable that is approaching zero.

(A78)
$$(b-k)P(l)\left(1 + l\delta + \frac{l(l-1)\delta^2\theta}{2}\right) + (b-kl)Q(l)(1+\delta) = k[1-P(l)-lQ(l)],$$

$$\begin{aligned}&(b-k)P(l)\left(l\delta + \frac{l(l-1)\delta^2\theta}{2}\right) + (b-kl)Q(l)\delta \\ &\quad = k[1-P(l)-lQ(l)] - (b-k)P(l) - (b-kl)Q(l),\end{aligned} \tag{A79}$$

$$\delta = \frac{k[1-P(l)-lQ(l)] - (b-k)P(l) - (b-kl)Q(l)}{l(b-k)P(l)[1+(l-1)\theta\delta/2] + (b-kl)Q(l)}, \tag{A80}$$

$$\delta = \frac{k - bP(l) - bQ(l)}{b[lP(l)+Q(l)] - kl[P(l)+Q(l)] + (b-k)l(l-1)P(l)\theta\delta/2}, \tag{A81}$$

$$\delta = \frac{k - bP(l-1)}{b[lP(l)+Q(l)] - klP(l-1) + (b-k)l(l-1)P(l)\theta\delta/2}, \tag{A82}$$

$$\delta = \frac{k - bP(l-1)}{b[lP(l)+Q(l)] - klP(l-1)}\left(1 + \frac{(b-k)l(l-1)P(l)\theta\delta/2}{b[lP(l)+Q(l)] - klP(l-1)}\right)^{-1}, \tag{A83}$$

(51)
$$\delta = \frac{k - bP(l-1)}{b[lP(l)+Q(l)] - klP(l-1)}\left(1 + \frac{[k-bP(l-1)](b-k)l(l-1)P(l)\theta/2}{\{b[lP(l)+Q(l)] - klP(l-1)\}^2}\right)^{-1}.$$

Equation (53). Write (50) as

$$F_l \le e^X, \tag{A84}$$

with

$$X = \ln\{x^{-kl}[1 + (x^l-1)P(l) + l(x-1)Q(l)]^b\} \tag{A85}$$

$$= -kl\ln x + b\ln[1 + (x^l-1)P(l) + l(x-1)Q(l)]. \tag{A86}$$

Replace x with $1+\delta$:

$$X = -kl\ln(1+\delta) + b\ln\{1 + [(1+\delta)^l - 1]P(l) + lQ(l)\delta\}. \tag{A87}$$

Expanding X in a power series to second order gives

$$X = -kl\ln(1+\delta) + b\ln\left(1 + l\delta P(l) + \frac{l(l-1)P(l)\theta\delta^2}{2} + lQ(l)\delta\right)$$

$$= -kl\delta + \frac{kl\theta\delta^2}{2} + b\left(lP(l)\delta + \frac{l(l-1)\delta^2 P(l)\theta}{2} + lQ(l)\delta\right)$$

$$- \frac{b}{2}\left(lP(l)\delta + \frac{l(l-1)P(l)\theta\delta^2}{2} + lQ(l)\delta\right)^2\theta \tag{A88}$$

$$= -l[k - bP(l) - bQ(l)]\delta + \frac{kl + bl(l-1)P(l) - bl^2[P(l)+Q(l)]^2}{2}\theta\delta^2 \tag{A89}$$

$$= -l[k - bP(l-1)]\delta + \frac{kl + bl(l-1)P(l) - bl^2[P(l-1)]^2}{2}\theta\delta^2. \tag{A90}$$

Replace k by its definition in terms of α_3 (equation (52)) to obtain

$$X = -l[k - bP(l-1)]\delta + \frac{\{kl + bl(l-1)P(l) - bl^2[P(l-1)]^2\}\theta}{2}\delta^2 \tag{A91}$$

$$= -bl\alpha_3\delta + \frac{bl\{P(l-1) + \alpha_3 + (l-1)P(l) - l[P(l-1)]^2\}\theta}{2}\delta^2 \tag{A92}$$

$$= \left(-bl\alpha_3 + \frac{bl\{P(l-1) + \alpha_3 + (l-1)P(l) - l[P(l-1)]^2\}\theta\delta}{2}\right)\delta. \tag{A93}$$

Also replace k in (51) by its value in terms of α_3 to obtain

$$\delta = \frac{\alpha_3 b}{b[lP(l)+Q(l)] - b[P(l-1)+\alpha_3]lP(l-1)}$$

$$\times\left(1 + \frac{b\alpha_3\{b - b[P(l-1)+\alpha_3]\}l(l-1)P(l)\theta/2}{\{b[lP(l)+Q(l)] - b[P(l-1)+\alpha_3]l[P(l-1)]\}^2}\right)^{-1} \tag{A94}$$

$$= \frac{\alpha_3}{lP(l)+Q(l) - l[P(l-1)+\alpha_3]P(l-1)}$$

$$\times\left(1 + \frac{\alpha_3[1 - P(l-1) - \alpha_3]l(l-1)P(l)\theta/2}{\{lP(l)+Q(l) - l[P(l-1)+\alpha_3][P(l-1)]\}^2}\right)^{-1}. \tag{A95}$$

Since δ and α_3 go to zero together, this can be written as

$$\delta = \frac{\theta\alpha_3}{lP(l)+Q(l) - l[P(l-1)]^2}. \tag{A96}$$

Plugging the value of δ into the expression for X (equation (A93)) gives

$$X = \left(-bl\alpha_3 + \frac{bl\{P(l-1)+\alpha_3+(l-1)P(l)-l[P(l-1)]^2\}\theta\delta}{2}\right)\delta \tag{A97}$$

$$= \left(-bl\alpha_3 + \frac{bl\{P(l-1)+(l-1)P(l)-l[P(l-1)]^2+\alpha_3\}\theta\alpha_3}{2\{P(l-1)+(l-1)P(l)-l[P(l-1)]^2\}}\right)$$

$$\times \frac{\theta\alpha_3}{P(l-1)+(l-1)P(l)-l[P(l-1)]^2} \tag{A98}$$

$$= \left(-bl\alpha_3 + \frac{bl\theta\alpha_3}{2} + \frac{bl\theta\alpha_3^2}{2\{P(l-1)+(l-1)P(l)-l[P(l-1)]^2\}}\right)$$

$$\times \frac{\theta\alpha_3}{P(l-1)+(l-1)P(l)-l[P(l-1)]^2} \tag{A99}$$

$$= -\frac{bl\theta\alpha_3^2}{2\{P(l-1)+(l-1)P(l)-l[P(l-1)]^2\}}. \tag{A100}$$

Thus,

$$F_l \le e^{-bl\theta\alpha_3^2/(2\{P(l-1)+(l-1)P(l)-l[P(l-1)]^2\})}. \tag{53}$$

Equation (54). The derivation of (53) requires that $\delta = o(1)$. The step from (A98) to (A99) requires that α_3 be small compared to some other terms. Both conditions imply

$$\alpha_3 = \{lP(l)+Q(l)-l[P(l-1)]^2\}o(1). \tag{54}$$

Equation (56). By inclusion-exclusion, the sum for the region that defines R_k is equal to the sum over the entire area ($r_k(b,l,m,n,0)$), minus the sums over the various regions where a single j is required to be outside of R_k's region (l copies of $r_k(b,l,m,n,1)$), plus the sums over regions where two j's are required to be outside of R_k's region, etc.

Equation (58).

$$r_k(b,l,m,n,h) = \sum_{\substack{j_1<k\\ j_2<k\\ \cdots\\ j_h<k\\ j_{h+1},\ldots,j_l}} \binom{b}{j_1,j_2,\ldots,j_l,b-j_1-\cdots-j_l}$$

$$\times [Q(m)]^{j_1+\cdots+j_l}[1-P(m)-nQ(m)]^{b-j_1-\cdots-j_l} \tag{57}$$

$$= \sum_{\substack{j_1<k\\ j_2<k\\ \cdots\\ j_h<k\\ j_{h+1},\ldots,j_{l-1}}} \binom{b}{j_1,j_2,\ldots,j_{l-1},b-j_1-\cdots-j_{l-1}}$$

$$\times [Q(m)]^{j_1+\cdots+j_{l-1}}[1-P(m)-(n-1)Q(m)]^{b-j_1-\cdots-j_{l-1}} \tag{A101}$$

$$\cdots$$

$$= \sum_{\substack{j_1<k\\ j_2<k\\ \cdots\\ j_h<k}} \binom{b}{j_1,j_2,\ldots,j_h,b-j_1-\cdots-j_h}$$

$$\times [Q(m)]^{j_1+\cdots+j_h}[1-P(m)-(n-l+h)Q(m)]^{b-j_1-\cdots-j_h}. \tag{58}$$

Bound on first term of (61). For

$$\sum_{j_0<k} \binom{b}{j_0} [P(l)]^{j_0} [1-P(l)]^{b-j_0}$$

use the Chernoff bound from (23).

Equation (62).

$$\begin{aligned}
&\sum_{j_0<k} \binom{b}{j_0} [P(l)]^{j_0} \sum_{j<k-j_0} \binom{b-j_0}{j} [Q(l)]^j [1-P(l)-Q(l)]^{b-j_0-j} \\
&\quad \le x^{-k+1} y^{-k+1} \sum_{j_0,j} \binom{b}{j_0} [xyP(l)]^{j_0} \binom{b-j_0}{j} \\
&\quad\quad \times [xQ(l)]^j [1-P(l)-Q(l)]^{b-j_0-j} \qquad \text{(A102)} \\
&\quad \le x^{-k+1} y^{-k+1} [1+(xy-1)P(l)+(x-1)Q(l)]^b. \qquad \text{(A103)}
\end{aligned}$$

In real life, the Apriori Algorithm is used to analyze data that are more complex. Presumably, no one is interested in running the algorithm on truly random data. Rather, one is interested in the way in which the data differ from random. Nonetheless, we believe that analysis with this simple probability model brings out the main features of the performance of the algorithm. In principle, the techniques in this paper can be applied to more complex probability models of shopping. The challenge is to carry out the resulting calculations so that one can understand the implications of the formulas that result when the analysis is done on more general probability models.

With our probability model we calculate two quantities:

1. *Success rate*: the probability that a set is a success (i.e., passes the frequency test) and test.
2. *Failure rate*: the probability that a set is a candidate (i.e., passes the candidacy test) but not a success (i.e., fails the frequency test).

Notice that the success rate is a property of the probability model, not the algorithm. All correct algorithms will have the same success rate. The Apriori Algorithm never believes that an item set occurs k times without verifying the fact by counting occurrences in the data base. For algorithms that use this approach, the success rate represents unavoidable work. The Apriori Algorithm is clever in trying to reduce the failure rate. The failure rate represents work that one might hope to avoid.

Also, when there is a total of b baskets, b_A baskets with item A, and b_B items with item B, the Apriori Algorithm is not aware that there must be at least $2b - b_A - b_B$ baskets that contain both items A and B [11]. Similar ideas are explored in [7].

In the best case, the test for candidacy correctly predicts the result of the test for frequency, and the amount of time spent by the Apriori Algorithm is essentially the amount of time spent verifying that all the output sets should be output. A naive upper bound comes from the fact that each candidate is based on a previous success. Each success can lead to at most $|I|$ candidates. Many previous papers have focused on the total amount of work done by the Apriori Algorithm without concern as to the amount of output generated, but such studies can be misleading in that the amount of output is the main factor that determines how much work an Apriori-like algorithm will do, and the amount of output is a feature of the problem instance rather than of the algorithm. The simple lower and upper bound analyses say that the ratio between

the number of candidates and the number of successes (i.e, the output) is between 1 and $|I|$ (so long as there is at least one success).

Stronger worst-case bounds are given by Geerts, Goethals, and Van den Bussche [10]. They start by writing the number of successes on level l as the sum of distinct binomial coefficients where the first binomial coefficient has l as its bottom index and the largest possible top index. The remaining terms (if any) have smaller bottom indices. Their Theorem 1 says that the number of candidates on level $l+1$ is bounded by the number obtained from increasing each bottom index by 1. This bound is exact for some distributions, including one that results in no failures. Experiments show that in many cases this upper bound is close to the exact value.

At first sight, the approach of Theorem 1 of [10] looks quite different from the approach in this paper. However, in those cases where the number of candidates on level l is exactly $\binom{m_{l,l}}{l}$ for some $m_{l,l}$ there are just two differences. First, [10] considers only items that might still be active during the current level of the Apriori Algorithm ($m_{l,l}$). This is their main insight. Second, the upper limit corresponds to setting our p to 1. The work in [10] shows that the number of candidates on level l can never be more than $\binom{m_{l,l}}{l+1}$. If $m_{l,l}$ is much bigger than l, the ratio of candidates on level $l+1$ to candidates on level l is approximately $m_{l,l}/(l+1)$. When the number of candidates cannot be represented as an appropriate binomial, there are additional technical differences between the approach in [10] and in this paper, but they are not significant to a qualitative understanding of the situation.

It is not logically necessary that an algorithm verify occurrences by explicit counting. One alternative algorithm uses ideas that are the complement of those used by the Apriori Algorithm. The key idea for this complementary algorithm is that if some superset of a set J occurs at least k times, then so does set J. Also, if one changes the problem so that one needs only the maximal frequent item sets instead of all frequent item sets, then the amount of output needed is greatly reduced for some problem instances.

Acknowledgments. The authors want the express their thanks to Nele Dexters for helpful discussions and careful proofreading. They would also like to acknowledge the support of Indiana University Research and Technology Services for computing support during the experiments.

FAST, DISTRIBUTED APPROXIMATION ALGORITHMS FOR POSITIVE LINEAR PROGRAMMING WITH APPLICATIONS TO FLOW CONTROL*

YAIR BARTAL†, JOHN W. BYERS‡, AND DANNY RAZ§

Abstract. We study combinatorial optimization problems in which a set of distributed agents must achieve a global objective using only local information. Papadimitriou and Yannakakis [*Proceedings of the 25th ACM Symposium on Theory of Computing*, 1993, pp. 121–129] initiated the study of such problems in a framework where distributed decision-makers must generate feasible solutions to *positive linear programs* with information only about local constraints. We extend their model by allowing these distributed decision-makers to perform local communication to acquire information over time and then explore the tradeoff between the amount of communication and the quality of the solution to the linear program that the decision-makers can obtain.

Our main result is a distributed algorithm that obtains a $(1+\epsilon)$ approximation to the optimal linear programming solution while using only a polylogarithmic number of rounds of local communication. This algorithm offers a significant improvement over the logarithmic approximation ratio previously obtained by Awerbuch and Azar [*Proceedings of the 35th Annual IEEE Symposium on Foundations of Computer Science*, 1994, pp. 240–249] for this problem while providing a comparable running time. Our results apply directly to the application of network flow control, an application in which distributed routers must quickly choose how to allocate bandwidth to connections using only local information to achieve global objectives. The sequential version of our algorithm is faster and considerably simpler than the best known approximation algorithms capable of achieving a $(1+\epsilon)$ approximation ratio for positive linear programming.

Key words. linear programming, approximation algorithm, primal-dual, flow control

1. Introduction.

Processors in a distributed environment must make decisions based only on local data; thus fast distributed algorithms must often do without global information about the system as a whole. This is exactly why computing many target functions in distributed models quickly is provably hard [15]. However, quite surprisingly, some of the most interesting global optimization problems can be very closely approximated based only on local information and a modest amount of local communication.

Our work is motivated by the application of developing flow control policies which must achieve global objective functions. Flow control is the mechanism by which routers of a network distribute the available network bandwidth across connections. In our work, routing policies determine the routes in the network that connections must use to transmit packets. Regulating the rates at which the connections may inject data along these fixed routes is the problem of flow control. This connection-oriented, or rate-based, approach to flow control is a standard for routing available bit-rate

traffic in ATM networks [9] and is expected to become widely used in packet-switched networks. In this approach, each router in the network must make regulatory decisions based only on local information, which typically consists of the current transmission rates of connections using the router. Most existing flow control policies try to satisfy local objective functions such as *max-min fairness* [13, 7, 1, 11]. However, there are many other practical scenarios in which global objective functions are the appropriate choice. For example, in a commercial intranetwork in which users are paying for use of the network bandwidth (possibly at different rates), the administrator would want to use a flow control policy which maximizes total revenue. We express such a flow control policy objective as a *positive linear program*, a linear program (LP) in which all entries of the constraint matrix are nonnegative. Complicating the issue is the problem that routers must generate feasible solutions to this LP quickly, and based only on available information.

Motivated by this application and other related applications, Papadimitriou and Yannakakis considered the problem of having distributed decision-makers assign values to a set of variables in an LP, where the agents have limited information [18]. In one scenario that they describe, each agent, acting in isolation, must set the value of a single primal variable, knowing only the constraints affecting that variable in the LP. In the context of flow control, where the objective is to maximize the total flow through the network, this corresponds to a setting in which connections only know how many other connections share each of the routers they intend to use. When all edge capacities are 1, their "safe" algorithm sets each connection's flow to the reciprocal of the maximum number of connections which share an edge with that connection. It is not hard to see that the worst-case approximation ratio achieved by the "safe" algorithm is $\Theta(\Delta)$, where Δ is the maximum number of connections that share an edge. They also prove that the "safe" algorithm achieves the best possible worst-case ratio when agents may not communicate, leaving open the possibility that much better ratios can be obtained when agents can interact.

We extend their model to allow computation to proceed in a sequence of *rounds*, in each of which agents can communicate a fixed-size message to their immediate neighbors, where agents are neighbors if and only if they share one or more constraints in the LP. Our goal is to determine the number of rounds necessary to achieve a $(1 + \epsilon)$ approximation ratio to the optimum LP solution. Although we focus on the application of flow control, this study could also be performed on a range of resource allocation problems, including those described in [18]. We note that similar models for describing the interaction between connections and routers in both theoretical and practical evaluations of flow control policies have been suggested in [3, 1, 5, 16].

Of course, a centralized administrator with complete information could solve the problem exactly using one of the well-known polynomial-time algorithms for linear programming (see, for example, [14]). Recently, however, much faster algorithms that produce approximate solutions to positive LPs to within a $(1 + \epsilon)$ factor of optimal have been designed. The sequential algorithm of Plotkin, Shmoys, and Tardos [19] repeatedly identifies a globally minimum weight path and pushes more flow along that path. More recently, faster approximation algorithms have been considered for several related flow and bin-packing problems [8, 12] using this same principle of repeatedly choosing a good flow, and incrementally increasing the rate of that flow. The technical difficulty is to balance the amount of flow increase, such that the required approximation is achieved, with the number of needed steps (i.e., running time). In all of these algorithms a global operator choosing the appropriate unsatisfied constraints is used. Moreover, the more general multicommodity flow problem cannot be formulated as

a positive LP, unless the number of dual variables or the number of constraints is exponential. In these cases one must use a separation oracle, since only polynomially many flows can be handled. For positive LPs, however, the number of constraints is polynomially bounded and thus one can increase all dual variables simultaneously. This is the approach taken by the algorithm of Luby and Nisan [17]. This algorithm, which has both a fast sequential and parallel implementation, repeatedly performs a global median selection algorithm on the values of the dual variables to choose a threshold, then increases values of dual variables above this threshold. Although these algorithms have efficient implementations, they both perform global operations, which makes them unsuitable for fast distributed implementation, since emulating those global operations requires a polynomial number of distributed rounds, and we are interested in much more time-efficient solutions.

The only previously known result for a distributed flow control algorithm with a global objective function is an algorithm of Awerbuch and Azar [3] which gives a logarithmic approximation ratio and also runs in a polylogarithmic number of rounds. Their algorithm is based on fundamental results from competitive analysis [2, 4]. The deterministic algorithm we present produces $(1+\epsilon)$ approximate solutions to positive LPs, both in general and for the flow control problem, and builds on ideas used in these other algorithms [3, 17, 19]. Our algorithm is most closely related to the algorithm of Luby and Nisan but eliminates the need for the complex global selection operations and a global normalization step upon termination, enabling fast implementation in a distributed setting. Those simplifications carry over to serial and parallel settings as well, where we have a dramatically simpler implementation which saves a $\frac{1}{\epsilon}$ factor in the running time over the Luby–Nisan algorithm. Finally, we can parameterize the algorithm to quantify a tradeoff between the number of rounds and the quality of the approximation. In practice, we can run the algorithm for any number of *phases*, with the guarantee that after a constant number of phases, we have a logarithmic factor approximation, and after a logarithmic number of phases, we have a $(1+\epsilon)$ approximation.

The rest of the paper is organized as follows. We begin with a presentation of our algorithm first as an easily understandable and implementable serial algorithm for approximately solving positive linear programming in section 2. In section 2.3, we prove that the algorithm achieves a $(1+\epsilon)$ approximation ratio, and we analyze its running time. We formulate our distributed model and give an explanation of the correspondence between flow control policies and positive LPs in section 3. Then in section 3.2, we present the distributed implementation applicable to the flow control problem and explain the modifications to the analysis for this case.

2. Sequential approximation algorithms. We consider positive LPs represented in the following standard form, which is well known to be as general as arbitrary positive linear programming.

PRIMAL	DUAL
$\max Y = \sum_{j=1}^{n} y_j$	$\min X = \sum_{i=1}^{m} x_i$
$\forall i, \sum_j a_{ij} y_j \leq 1$	$\forall j, \sum_i a_{ij} x_i \geq 1$
$\forall j,\ y_j \geq 0$	$\forall i,\ x_i \geq 0$
$\forall i, j,\ a_{ij} \geq 0$	$\forall i, j,\ a_{ij} \geq 0$

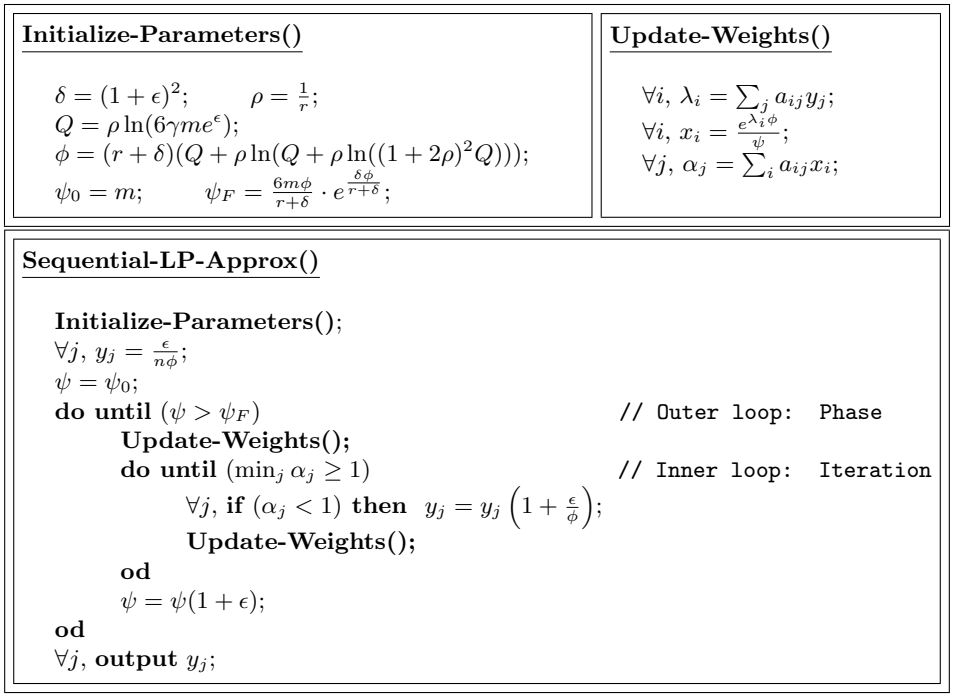

FIG. 1. *The sequential positive LP approximation algorithm.*

We will further assume that the LP is presented to the algorithm in a normalized form in which the a_{ij} are either 0 or satisfy $\frac{1}{\gamma} \leq a_{ij} \leq 1$. In the sequential case, one can convert an arbitrary LP in standard form into an LP in normalized form in linear time simply by dividing all constraints by $a_{max} = \max a_{ij}$ and setting $\gamma = \frac{a_{max}}{a_{min}}$ (where $a_{min} = \min\{a_{ij} | a_{ij} > 0\}$). We will describe how to perform this transformation efficiently in a distributed setting in section 3.

2.1. Overview of results. The parameterized algorithm for approximately solving a positive LP in normalized form is given in Figure 1. The main theorem that we will prove about the performance of this algorithm relates the quality of the approximation to the running time as follows.

THEOREM 1. *For any $0 < \epsilon \leq 1$ and $0 < r \leq \ln(\gamma m)$, the algorithm produces a feasible $(r + (1+\epsilon)^2)$ approximation to the optimum primal linear programming solution and runs in $O\left(\frac{nm \ln(\frac{\gamma m}{r})}{r\epsilon}\right)$ time.*

The following corollary clarifies the tradeoff between the running time and the quality of the approximation and follows directly from Theorem 1.

COROLLARY 2. *For any $\epsilon \leq 1$, the algorithm produces a $(1+\epsilon)$ approximation to the optimum in $O\left(\frac{nm \ln(\frac{\gamma m}{\epsilon})}{\epsilon^2}\right)$ time. For any $1 \leq r' \leq \ln(\gamma m)$, the algorithm produces a $(1+r')$ approximation to the optimum in $O\left(\frac{nm \ln^2(\gamma m)}{r'}\right)$ time.*

Proof of Corollary 2. To prove the first claim of the corollary, set $r = \epsilon$ in Theorem 1, and to prove the second, set $r = 1 + r' - (1+\epsilon)^2$ and choose ϵ so that $0 < \epsilon < \sqrt{2} - 1$, which implies $r > 0$ in Theorem 1. □

2.2. Description of the algorithm. In the sequential implementation of our algorithm presented in Figure 1, the main body of the program in the bottom panel

runs in a sequence of *phases*, the number of which ultimately depends only on the desired approximation ratio. Within a phase, values of appropriate primal variables y_j are increased monotonically until a threshold is reached. We refer to a set of increase operations across all primal variables constituting the inner loop of our main program as an *iteration* of our algorithm, noting that the number of iterations per phase may vary. We will demonstrate that at the time slot t ending each phase, the nonnegative settings for the primal variables $y_j(t)$ and the dual variables $x_i(t)$ are primal and dual feasible, respectively, satisfying the constraints below.

$$\textbf{Primal Feasibility: } \forall i, \sum_{j=1}^{n} a_{ij} y_j(t) \leq 1.$$

$$\textbf{Dual Feasibility: } \forall j, \sum_{i=1}^{m} a_{ij} x_i(t) \geq 1.$$

2.2.1. Moving between pairs of feasible solutions. Since the values of primal variables increase monotonically in our algorithm, it is crucial to carefully select the variables to increase in each phase. To this end, our algorithm uses exponential weight functions which have been employed in a variety of related contexts, including [2, 4, 17, 19, 3]. To do so, we associate each dual constraint with a measure $\alpha_j(t) = \sum_i a_{ij} x_i(t)$, and we associate each primal constraint with a measure $\lambda_i(t) = \sum_j a_{ij} y_j(t)$. Throughout the algorithm, the values of the dual variables x_i are tied to the values of "neighboring" primal variables y_j by the exponential weighting function defined in **Update-Weights()**:

$$\forall t : x_i(t) = \frac{e^{\lambda_i(t)\phi}}{\psi} = \frac{e^{\Sigma_j a_{ij} y_j(t)\phi}}{\psi},$$

where ϕ is a constant which again depends only on the desired approximation ratio, and ψ is a scaling factor which is initialized to m, then grows geometrically with the phase number until it reaches ψ_F, which is the termination condition.

By establishing this connection between primal and dual variables, when the value $\alpha_j(t)$ is less than 1, the dual constraint $\sum_i a_{ij} x_i(t) \geq 1$ is violated, but can be satisfied by a sufficient increase in y_j. This relationship suggests the following idea for an algorithm, which we employ. Start with a pair of dual and primal feasible solutions. Scale down the dual feasible solution by a multiplicative factor, making the solution dual infeasible, and causing some dual constraints to be violated. Then move back to a dual feasible solution by increasing those primal variables j for which $\alpha_j(t) < 1$, and repeat the process until a satisfactory approximation is achieved.

A hypothetical depiction of the intermediate primal and dual feasible solutions $Y(t) = \sum_j y_j(t)$ and $X = \sum_i x_i(t)$ at the end of each phase relative to the value of the optimal solution is shown in Figure 2. We maintain the invariant that the values of the intermediate primal feasible solutions are monotonically nondecreasing over time, but no such guarantee is provided for the intermediate dual feasible solutions. Linear programming feasibility ensures that values of intermediate primal feasible solutions are necessarily smaller than or equal to the value of the program, denoted by OPT, and similarly, values of intermediate dual feasible solutions are necessarily larger than or equal to the value of the program. Upon termination, we prove that the final (and maximal) primal feasible solution is within a desired (in this case, $1 + \epsilon$) factor of the minimal intermediate dual feasible solution. By linear programming duality, this

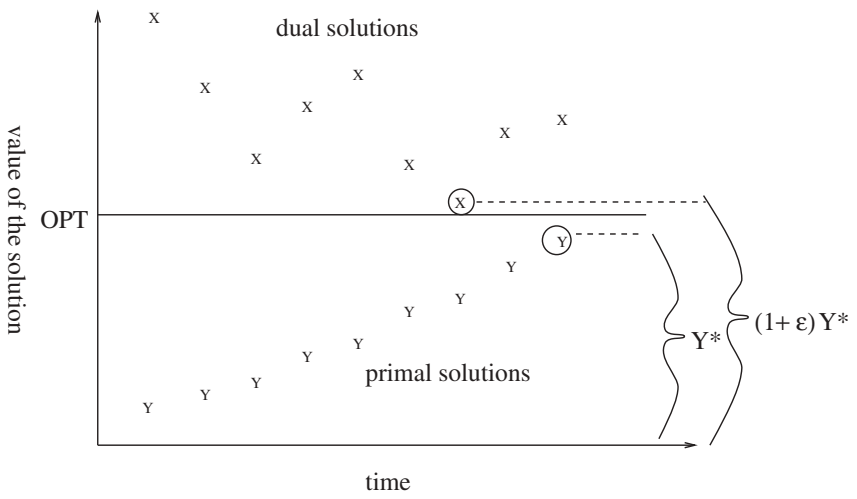

FIG. 2. *Intermediate primal and dual feasible solutions.*

implies that the final primal feasible solution gives the desired approximation to the value of the program.

In the sequential implementation presented in Figure 1, the bottleneck operation is to recompute the α_j's after each iteration, which takes $O(nm)$ time. In fact, the running time of this bottleneck operation can be more precisely written as $O(E)$, where E is the total number of nonzero entries of the constraint matrix of the LP. When multiplied by the total number of iterations, which we demonstrate to be at most polylogarithmic in section 2.3, we have the bound on the total sequential running time.

2.3. Analysis of the algorithm. In this section, we bound the approximation ratio of our approximation algorithm and present an analysis of its sequential running time. We will later extend both of these results in a straightforward way to the distributed case.

First we prove a claim we made earlier, that at the end of each phase both the primal and the dual solutions are feasible. From the definition of the algorithm, the values of primal variables increase monotonically, and therefore the values of intermediate primal solutions also increase monotonically. Thus to carry out the analysis of the approximation ratio, it will remain only to prove that the value of the final primal feasible solution and the value of the minimal dual feasible solution are at most a $(1+\epsilon)$ factor apart. In the proof we use the following three facts, which all follow from the initialization of the parameters given in **Initialize-Parameters()** in Figure 1.

FACT 3. $\phi \geq \epsilon$.

Proof. Fact 3 immediately follows from the definition of ϕ and from the fact that $\epsilon \leq 1$. □

FACT 4. $\phi = O\left(\frac{(r+\delta)\ln\left(\frac{\gamma m}{r}\right)}{r}\right)$.

Proof. By definition, $\phi = (r+\delta)(Q + \rho\ln(Q + \rho\ln((1+2\rho)^2 Q)))$ and $Q = \rho\ln(6\gamma m e^{\epsilon})$. Thus $Q \geq \rho$ and we have $\phi = O((r+\delta)(Q+\rho\ln Q))$. Since by definition

we also have $Q = O(\rho \ln(\gamma m))$ (recall that ρ is a shorthand for $1/r$), it suffices to show

$$\rho \ln(\gamma m) + \rho \ln(\rho \ln(\gamma m)) = O(\rho \ln(\rho \gamma m)).$$

Now since $r \leq \ln(\gamma m)$, we have that $\ln(\gamma m) = O(\ln(\rho \gamma m))$, and $\ln(\rho(\ln(\gamma m)) = O(\ln \rho + \ln \ln(\gamma m)) = O(\ln \rho + \ln(\gamma m)) = O(\ln(\rho \gamma m))$, and the result follows directly. ∎

FACT 5. $e^{\phi - \epsilon} \geq \gamma \psi$.

Proof. Substituting ψ_F for ψ and multiplying by e^{ϵ}, we must show

$$e^{\phi} \geq (\gamma e^{\epsilon}) \frac{6m\phi}{r+\delta} e^{\frac{\delta \phi}{r+\delta}}$$

or

$$e^{\frac{r\phi}{r+\delta}} \geq (6\gamma m e^{\epsilon}) \left(\frac{\phi}{r+\delta} \right)$$

or

$$e^{\frac{\phi}{r+\delta}} \geq \left(6\gamma m e^{\epsilon} \frac{\phi}{r+\delta} \right)^{\frac{1}{r}}.$$

Now by taking the natural logarithm of both sides above, we need to show

$$\frac{\phi}{r+\delta} \geq \frac{1}{r} \left[\ln(6\gamma m e^{\epsilon}) + \ln \left(\frac{\phi}{r+\delta} \right) \right].$$

Recall from the definitions that $\rho = \frac{1}{r}$, $Q = \rho \ln(6\gamma m e^{\epsilon})$, and $\frac{\phi}{r+\delta} = Q + \rho \ln(Q+P)$, where $P = \rho \ln((1+2\rho)^2 Q)$. Therefore, it is enough to prove the following:

$$\begin{aligned} &Q + \rho \ln(Q+P) - Q - \rho \ln(Q + \rho \ln(Q+P)) \\ &\quad = \rho \ln \left(\frac{Q+P}{Q + \rho \ln(Q+P)} \right) \geq 0. \end{aligned}$$

Since P and ρ are clearly nonnegative, and $Q \geq 1$, to show that $\rho \ln\left(\frac{Q+P}{Q+\rho \ln(Q+P)}\right)$ is nonnegative we need $P \geq \rho \ln(Q+P)$ or, substituting for P,

$$\begin{aligned} \rho \ln((1+2\rho)^2 Q) &\geq \rho \ln(Q + \rho \ln((1+2\rho)^2 Q)), \\ (1+2\rho)^2 Q &\geq Q + \rho \ln((1+2\rho)^2 Q), \\ 2Q(2\rho+2) &\geq \ln((1+2\rho)^2 Q). \end{aligned}$$

Using $2\ln((1+2\rho)Q) \geq \ln((1+2\rho)^2 Q)$, and $2Q(2\rho+2) \geq 2Q(2\rho+1)$, we have to show

$$2Q(2\rho+1) \geq 2\ln((1+2\rho)Q).$$

The final inequality follows from the fact that $x \geq \ln x$, which completes the proof. ∎

2.4. Feasibility. Recall that the algorithm maintains the invariant that dual feasibility is achieved prior to each increase in ψ.

FACT 6 (dual feasibility). *At the end of each phase, for all j, $\alpha_j \geq 1$.*

We next prove that the y_j's are primal feasible throughout the execution of the algorithm, using Claim 7 to help perform the induction. In the proof it will be convenient to treat the initial increase of y_j's from 0 to their initialized value as iteration 0.

CLAIM 7. *For all i and for every iteration, $\Delta\lambda_i \leq \frac{\epsilon}{\phi}$.*

CLAIM 8 (primal feasibility). *For all i, $\lambda_i \leq 1$ throughout the execution of the algorithm.*

We prove these two claims simultaneously by induction over iterations of the algorithm.

Proof. Let $J_i = \{j | a_{ij} > 0\}$. The first step is to prove that the claims hold for iteration 0:

$$\lambda_i = \sum_{j \in J_i} a_{ij} y_j \leq \sum_{j \in J_i} a_{ij} \frac{\epsilon}{n\phi} \leq \frac{\epsilon}{\phi}.$$

Since $\phi \geq \epsilon$ this also implies that Claim 8 holds at iteration 0.

Consider a subsequent iteration, and let Δv denote the change in variable v during that iteration. We have that for all j, $\Delta y_j \leq y_j \frac{\epsilon}{\phi}$ by the rate of increase in an iteration, so for all i,

$$\Delta\lambda_i = \sum_j a_{ij} \Delta y_j \leq \sum_j a_{ij} y_j \frac{\epsilon}{\phi} = \lambda_i \frac{\epsilon}{\phi} \leq \frac{\epsilon}{\phi},$$

where the final inequality holds by the inductive hypothesis of Claim 8. This completes the proof of Claim 7.

To complete the proof of Claim 8, we consider two cases for λ_i separately. We first consider values i for which $\lambda_i < 1 - \frac{\epsilon}{\phi}$ prior to an iteration. From the proof of Claim 7 we have that after such an iteration, $\lambda_i' \leq \lambda_i + \frac{\epsilon}{\phi} < 1$, giving the desired result.

Next we consider those i for which $\lambda_i \geq 1 - \frac{\epsilon}{\phi}$ prior to an iteration. Fix such an i and fix any $j \in J_i$. We have that

$$\alpha_j = \sum_k a_{kj} x_k \geq a_{ij} x_i = a_{ij} \frac{e^{\lambda_i \phi}}{\psi} \geq a_{ij} \frac{e^{\phi - \epsilon}}{\psi}.$$

By Fact 5, we have that by our choice of ϕ, $e^{\phi-\epsilon} \geq \gamma\psi$, and hence $\alpha_j \geq a_{ij}\gamma \geq 1$, by the definition of γ. By the increase rule in the algorithm, we never increase the value of primal variable y_j if $\alpha_j \geq 1$, so in fact no primal variable in J_i increases in this iteration. Therefore, λ_i does not increase during this iteration and remains smaller than 1 by the induction hypothesis, completing the proof. ∎

2.5. Proof of a $(1+\epsilon)$ approximation ratio. We now turn to bound the approximation ratio obtained by the algorithm stated as the first half of Theorem 1.

CLAIM 9. *For any $0 < \epsilon \leq 1$ and $0 < r \leq \ln(\gamma m)$, the algorithm produces a feasible $(r + (1+\epsilon)^2)$ approximation to the optimum primal linear programming solution.*

We use the notation $\Delta Y = \sum_j \Delta y_j$ to denote the aggregate change in the y values over the course of an iteration and similar notation for other variables. We begin with the following lemma.

LEMMA 10. *For every iteration,*

$$\frac{\Delta X}{\Delta Y} \leq \phi(1+\epsilon).$$

Proof. As $\epsilon \leq 1$, we have from Claim 7 that $\Delta\lambda_i\phi \leq \epsilon \leq 1$. It follows that

$$\begin{aligned}\Delta x_i &= x_i\left(e^{\Delta\lambda_i\phi} - 1\right)\\ &\leq x_i\Delta\lambda_i\phi(1+\Delta\lambda_i\phi)\\ &\leq x_i\Delta\lambda_i\phi(1+\epsilon),\end{aligned}$$

using the inequality $e^z - 1 \leq z(1+z)$ for $z \leq 1$.

Prior to a given iteration, let $S = \{j|\alpha_j < 1\}$. S is the set of indices of primal variables which will be active in the upcoming iteration, i.e., those variables y_j whose values will increase in the iteration. (Recall that a variable y_j may be increased several times in a phase.) The lemma follows from the following sequence of inequalities:

$$\begin{aligned}\Delta X &= \sum_i \Delta x_i \leq \sum_i x_i\Delta\lambda_i\phi(1+\epsilon)\\ &= \sum_i x_i \sum_{j\in S} a_{ij}\Delta y_j\phi(1+\epsilon)\\ &= \sum_{j\in S}\Delta y_j \sum_i a_{ij}x_i\phi(1+\epsilon)\\ &= \sum_{j\in S}\Delta y_j\alpha_j\phi(1+\epsilon)\\ &< \Delta Y\phi(1+\epsilon).\end{aligned}$$

The final inequality holds from the definition of S. □

In stating and proving the next lemma, we require a more precise description of our notation. We now consider the change in the values of the dual variables X over the course of a *phase*. In the proof, we let X' denote the sum of the x_i at the end of the current phase, and we let X denote the sum of the x_i at the end of the previous phase, i.e., before they are scaled down. We let ΔX denote the change in the sum of the x_i over the course of the current phase. We further define X^* to be the minimum over all dual feasible solutions obtained at the end of each phase and let Y_L be the primal feasible solution obtained at the end of the final phase. Fact 6 and Claim 8, respectively, imply that X^* is dual feasible and Y_L is primal feasible. In conjunction with Lemma 11 below, this implies the approximation result stated in Claim 9, by linear programming duality.

LEMMA 11.

$$Y_L \geq \frac{X^*}{r + (1+\epsilon)^2}.$$

Proof. We prove the lemma for two separate cases: the first is an easy case in which the initial primal feasible solution is a close approximation to the optimum, and in the second we repeatedly apply Lemma 9 to bound the ratio between X^* and Y_L. Let X_0 denote the value for X before the initialization of the y_j's, that is, $X_0 = \sum_i \frac{e^0}{m} = 1$, and let X_1 denote the value for X after the first phase. Similarly, let X_L denote the value of the dual solution at the end of the final phase.

Case I. $X_L \leq \frac{r+\delta}{\phi(1+\epsilon)}(X_1 - X_0)$. Letting Y_1 denote the value of the primal solution at the end of the first phase, we apply Lemma 9 to the iterations comprising the first phase, giving us

$$X_1 - X_0 \leq Y_1\phi(1+\epsilon).$$

Since the values of the primal feasible solutions increase monotonically throughout the course of the algorithm, the lemma holds by the following sequence of inequalities:

$$X^* \leq X_L \leq (r+\delta)Y_1 \leq (r+(1+\epsilon)^2)Y_L.$$

Case II. $X_L > \frac{r+\delta}{\phi(1+\epsilon)}(X_1 - X_0)$. Since the values X are scaled by a $\frac{\psi}{\psi'} = \frac{1}{1+\epsilon}$ factor just following the end of each phase, the earlier definitions imply that

$$X' = X\frac{\psi}{\psi'} + \Delta X.$$

By rewriting this expression and applying the inequality $e^z \geq 1 + z$, we have

$$X' = X\frac{\psi}{\psi'}\left(1 + \frac{\Delta X(1+\epsilon)}{X}\right) \leq X\frac{\psi}{\psi'}\left(e^{\frac{\Delta X(1+\epsilon)}{X}}\right).$$

Now, using $X^* \leq X$ and applying Lemma 10 yields

$$X' \leq X\frac{\psi}{\psi'}\left(e^{\frac{\Delta Y\phi(1+\epsilon)^2}{X^*}}\right).$$

Let ψ_1 and ψ_L to be the initial value of ψ and the value of ψ in the last phase of the algorithm, i.e., $\psi_L < \psi_F$. Using the bound above repeatedly to compare X_L with X_1 gives us

$$X_L \leq X_1\frac{\psi_1}{\psi_L}\left(e^{\frac{Y_L\phi(1+\epsilon)^2}{X^*}}\right). \tag{1}$$

Since X_L is dual feasible and the optimal solution is bounded below by 1 (by the normalized form of the program) we have that $X_L \geq 1 = X_0$. Also note that by the assumption $r \leq \ln(\gamma m)$, we have $\phi \geq (r+\delta)$. We can now use these facts in conjunction with the fact that $X_L > \frac{r+\delta}{\phi(1+\epsilon)}(X_1 - X_0)$ to obtain

$$X_1 < \frac{X_L\phi(1+\epsilon)}{r+\delta} \leq X_L\left(\frac{\phi(1+\epsilon)}{r+\delta} + 1\right) \leq X_L\frac{\phi(2+\epsilon)}{r+\delta}.$$

Using the bound above in (1) and observing that $\psi_1 = m$ and $\psi_L \geq \psi_F/(1+\epsilon)$ we get

$$e^{\frac{Y_L\phi(1+\epsilon)^2}{X^*}} \geq \frac{\psi_F}{m\frac{\phi(2+\epsilon)}{r+\delta}(1+\epsilon)} = \frac{6m\frac{\phi}{r+\delta}e^{\frac{\delta\phi}{r+\delta}}}{m(2+\epsilon)(1+\epsilon)\frac{\phi}{r+\delta}} = \frac{6e^{\frac{\delta\phi}{r+\delta}}}{(2+\epsilon)(1+\epsilon)} \geq e^{\frac{(1+\epsilon)^2\phi}{r+(1+\epsilon)^2}},$$

where the final inequality holds by substituting $\delta = (1+\epsilon)^2$ and using $\epsilon \leq 1$. We therefore get

$$\frac{Y_L}{X^*} \geq \frac{1}{r+(1+\epsilon)^2},$$

concluding the proof of the lemma for Case II. □

2.6. Running time. For the algorithm provided so far, we have the following running time bounds, which are slightly weaker than those stated in Theorem 1. These weaker bounds are presented since a natural translation of these time bounds and the preceding analysis extends directly to the distributed algorithm which we present in section 3. After proving these bounds, we provide a simple improvement which applies only in the sequential case and which is used to give the time bounds stated in Theorem 1.

CLAIM 12. *The sequential algorithm runs in* $O\left(\frac{(r+1)nm\ln^2\left(\frac{\gamma m}{r}\right)\ln\left(\frac{(r+1)\gamma n\ln m}{r\epsilon}\right)}{r^2\epsilon^2}\right)$ *time.*

Proof. We bound the number of phases by measuring the change in ψ, which increases by a $(1+\epsilon)$ factor per phase. From the definitions in Figure 1, and using Fact 4 for the final equality, we have that

$$\left\lceil \log_{1+\epsilon}\left(\frac{\psi_F}{\psi_0}\right)\right\rceil = O\left(\frac{\frac{\delta\phi}{r+\delta}+\ln\left(\frac{\phi}{r+\delta}\right)}{\epsilon}\right) = O\left(\frac{\phi}{(r+\delta)\epsilon}\right) = O\left(\frac{\ln(\frac{\gamma m}{r})}{r\epsilon}\right).$$

We now bound the number of iterations in a phase by computing the maximum number of iterations needed to increase all α_j values above 1. For a given j, we say that y_j is *large* once $y_j \geq \frac{\gamma}{\phi}\ln(\gamma\psi)$. We show that once y_j is large, $\alpha_j \geq 1$, and therefore j no longer participates in the phase. Let the set $I_j = \{i | a_{ij} > 0\}$. Therefore for all $i \in I_j$,

$$\lambda_i = \sum_k a_{ik}y_k \geq \frac{1}{\gamma}y_j \geq \frac{1}{\phi}\ln(\gamma\psi),$$

$$\alpha_j = \sum_i a_{ij}x_i = \sum_i a_{ij}\cdot\frac{e^{\lambda_i\phi}}{\psi} \geq 1.$$

Initially, $y_j = \frac{\epsilon}{n\phi}$ and at every iteration it increases by a factor of $1+\frac{\epsilon}{\phi}$. Therefore the number of iterations y_j can participate in before y_j becomes large is at most

$$\left\lceil \log_{1+\frac{\epsilon}{\phi}}\left(\frac{n\phi}{\epsilon}\cdot\frac{\gamma}{\phi}\ln(\gamma\psi)\right)\right\rceil = O\left(\frac{\phi}{\epsilon}\cdot\ln\left(\frac{\gamma n}{\epsilon}\ln(\gamma\psi)\right)\right).$$

From Fact 5 we have $\ln(\gamma\psi) = O(\phi)$. By using this fact, and by another application of Fact 4, we bound the number of iterations during a phase by

$$O\left(\frac{\phi}{\epsilon}\cdot\ln\left(\frac{\gamma n\phi}{\epsilon}\right)\right) = O\left(\frac{r+\delta}{r\epsilon}\ln\left(\frac{\gamma m}{r}\right)\ln\left(\frac{\gamma n}{\epsilon}\frac{r+\delta}{r}\ln\left(\frac{\gamma m}{r}\right)\right)\right)$$

$$= O\left(\frac{(r+1)\ln\left(\frac{\gamma m}{r}\right)\ln\left(\frac{(r+1)\gamma n\ln m}{r\epsilon}\right)}{r\epsilon}\right).$$

Note that the term $\frac{r+1}{r}$ cannot be removed since r can be any value satisfying $0 < r \leq \ln(\gamma m)$. Multiplying this by the earlier bound on the number of phases and using the fact that each iteration can be computed in $O(nm)$ time, this completes the proof of Claim 12. ∎

To prove the time bound stated in the second half of Theorem 1, we need to give a sequential algorithm which completes in $O\left(\frac{nm\ln(\frac{\gamma m}{r})}{r\epsilon}\right)$ time. This running time can be achieved by an algorithm which performs exactly one iteration per phase. In

the sequential case, we accomplish this by increasing a candidate y_j not merely by a multiplicative factor of $1 + \frac{\epsilon}{\phi}$ per iteration, but by increasing it by the amount which causes α_j to reach a value of 1 directly. (Note that this procedure is straightforward to implement in the sequential case, but not in the distributed case.) This improvement causes each phase to terminate in a single iteration; Claims 7 and 8 still hold (the other claims are unaffected); and we achieve the time bound stated in Theorem 1.

3. The distributed model. We now consider the following model in the spirit of Papadimitriou and Yannakakis [18], in which distributed agents generate approximate solutions to positive LPs in the standard form presented in section 2.

We associate a *primal agent* with each of the n primal variables y_j and a *dual agent* with each of the m dual variables x_i. Each agent is responsible for setting the value of their associated variable. For any i, j such that $a_{ij} > 0$, we say that dual agent i and primal agent j are *neighbors*. In each distributed round of computation, each agent may broadcast a fixed-size message to all of its neighbors; i.e., in one round each primal agent j may broadcast one message to its set of dual neighbors $I_j = \{i | a_{ij} > 0\}$, and each dual agent i may broadcast one message to its set of primal neighbors $J_i = \{j | a_{ij} > 0\}$.

After a fixed number of rounds, the agents must choose feasible values for their variables to minimize (in the case of the primal) the approximation ratio, $\frac{\text{OPT}}{\sum y_j}$, where OPT is the value of the optimal solution to the LP. We then study the tradeoff between the number of rounds and the quality of the approximation ratio obtained.

The application of flow control in a network with per-flow queuing motivates the following mapping to our model of primal agents and dual agents. Each of n connections transmits data along a fixed path in the network, and a connection corresponds to a primal agent. Each of the paths traverses an ordered subset of the m routers which comprise the network, and these routers correspond to dual agents. At a given time step t, each connection j transmits at a given rate into the network, thereby establishing the value $y_j(t)$ of its primal variable. Once these new flow values stabilize, each router i uses its local load to set a value for the primal variable $x_i(t)$. Based on a simple function (the sum) of the values of dual variables along its path, the source uses this control information to compute a new flow value $y_j(t+1)$. To compute this sum, each connection transmits a fixed-length control message which loops through the routers along its path and back to the source. As mentioned earlier, this simple and natural model of communication between connections and routers corresponds to models previously suggested in both practical and theoretical studies of flow control [3, 1, 5, 16].

Each router i has capacity C_i, which it may share among the connections which utilize it, while each connection accrues benefit B_j for every unit of end-to-end capacity which it receives. Therefore, the connections act as the primal agents and the routers act as the dual agents in the following positive LP:

$$\max \sum_{j=1}^{n} B_j y_j,$$

$$\forall i, \sum_j \tilde{a}_{ij} y_j \leq C_i,$$

$$\forall i, j, \tilde{a}_{ij} = 1 \text{ or } 0.$$

Clearly, this positive LP can be converted to standard form by the local operation $a_{ij} = \frac{\tilde{a}_{ij}}{B_j C_i}$. In a synchronous model, each round takes time equal to the maximum

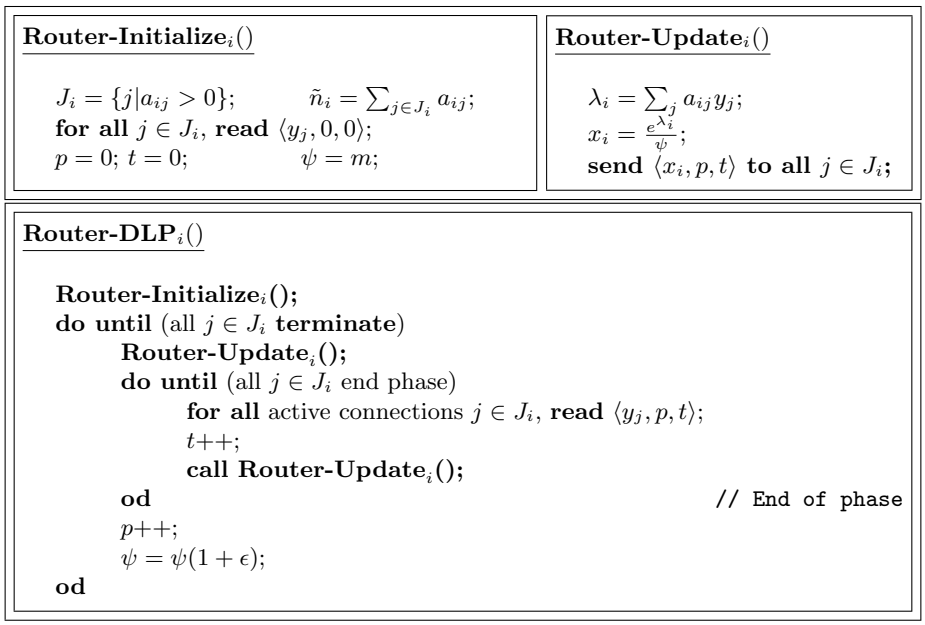

FIG. 3. *The distributed algorithm at router i.*

round-trip time experienced by a connection in the network. However, this synchronization assumption can and will subsequently be relaxed with no changes to the algorithms we propose. A final note is that the message size we use in our implementation can be bounded by a number of bits polynomial in $\log m$, $\log \gamma$, and $1/\epsilon$.

3.1. The distributed approximation algorithm. Several additional complications must be addressed in the definition and description of the distributed algorithm provided in Figures 3 and 4 for routers and connections, respectively. Since global operations cannot be performed efficiently, each connection and router must be able to independently compute the values of all of the parameters described in the serial implementation. In the case of parameters which are fixed, such as the value of m (the number of nodes in the network), and for the parameters which affect the approximation ratio, r and ϵ, we assume that these values are known in advance to all connections and routers. We do not assume that n, the number of connections, is globally known. In the sequential case, knowledge of this parameter was required to initialize the variables y_j so as to satisfy Claims 7 and 8. In the distributed setting, each connection j instead computes a local estimate of n, n_j, which it can compute in two distributed rounds, and which then used in initialization satisfies Claims 7 and 8. Finally, the parameter γ used to convert the program into normalized form may not be globally known, in which case the LP cannot be normalized efficiently. Approximately solving such programs in the distributed setting adds considerable complexity, and we defer providing techniques for doing so until section 3.2.

Connections and routers communicate using the message-passing model described in section 3. As in the serial algorithm, agents track time in terms of phases and iterations. When transmitting the value of a variable using the **send** primitive, agents timestamp the transmission with their current phase number p and iteration t. Likewise, in receiving the value of a variable using the **read** primitive, agents specify

Connection-Initialize$_j()$

$I_j = \{i | a_{ij} > 0\}$;
$n_j = \mathbf{max}_{i \in I_j} \tilde{n}_i$;
$y_j = \frac{\epsilon}{n_j \phi}$;
send$_{i \in I_j}$ $\langle y_j, 0, 0 \rangle$;

Update-$y_j()$

t++;
$y_j = y_j \left(1 + \frac{\epsilon}{\phi}\right)$;
send$_{i \in I_j}$ $\langle y_j, p, t \rangle$;

Compute-$\alpha_j()$

read$_{i \in I_j}$ $\langle x_i, p, t \rangle$;
$\alpha_j = \mathbf{sum}_{i \in I_j} a_{ij} x_i$;

Connection-DLP$_j()$

```
Initialize-Parameters();                    // As defined in Figure 1
Connection-Initialize_j();
p = 0;                                      // Phase counter
do until (ψ > ψ_F)
        t = 0;                              // Iteration counter
        Compute-α_j();
        do until (α_j ≥ 1)
                Update-y_j();
                Compute-α_j();
        od                                  // End of phase
        p++;
od
output y_j and terminate;
```

FIG. 4. *The distributed algorithm at connection j.*

their phase number p and iteration t, and they wait until they receive the appropriate value. For simplicity, we assume that these control messages reliably flow through the path, although, in practice, retransmissions would likely be necessary. Also, strict alternation between primal and dual rounds eliminates the possibility of deadlock.

In our implementation, message-passing primitives enable control to alternate between connections and routers at a local level. This is not to say that control is globally synchronized—in fact, at any instant in time, connections in separate areas of the network might not even be working on the same phase. However, it is the case that any given router is working on only a single phase at an instant in time. Therefore, all the connections through a router which is currently working on phase i are either actively working on phase i themselves or are idle and awaiting permission to proceed to phase $i+1$. Aside from message-passing, the other technical obstacle in converting the centralized algorithm to a distributed algorithm is the condition for ending a phase. In the centralized algorithm, a phase terminates when $\min_k \alpha_k \geq 1$. Since we cannot hope to track the value of this global expression in our distributed model, we instead let each connection j check whether $\alpha_j \geq 1$ locally and independently. When the condition is satisfied, connection j terminates its phase by incrementing its phase number and informing its neighboring routers.

The analysis of feasibility and the bounds on the quality of the approximation are identical to those for the centralized algorithm. This is the case because the value of any primal variable at the time that the corresponding connection completes phase i satisfies the conditions placed on primal variables after phase i in the centralized implementation. A similar statement holds with respect to the values of dual variables at the time their corresponding routers complete phase i. These statements hold for

each primal and dual variable independently, and irrespective of the fact that phase completion times may not occur uniformly across the network. As for the distributed running time, the following corollary to Claim 12 holds.

COROLLARY 13. *The distributed algorithm runs in* $O\left(\frac{(r+1)\ln^2(\frac{\gamma m}{r})\ln\left(\frac{(r+1)\gamma n \ln m}{r\epsilon}\right)}{r^2\epsilon^2}\right)$ *rounds.*

3.2. Distributed techniques to convert to special form. Recall that we can convert a program in standard form to the normalized form by dividing all constraints by a_{max}, thereby setting $\gamma = \frac{a_{max}}{a_{min}}$. If bounds on the values of a_{max} and a_{min} are known in advance, for example, if connections and routers can all bound the min and max values of the edge capacities and benefit coefficients, then γ can be estimated. But these bounds may not be globally known; moreover, the value of γ, which impacts the running time of our algorithm, depends on the values of the entries of the matrix. We now show that solving a problem in standard form can be reduced to solving problems in a *special form* (similar to a form used by Luby and Nisan in [17]), where the value of γ depends only on m and ϵ and does not affect the approximation ratio obtained, nor does it significantly affect the running time of our algorithm. Moreover, this transformation can be done distributively in a constant number of rounds, without global knowledge of a_{max} and a_{min}.

A precondition for transforming an LP Z in standard form to an LP Z' in special form is that we can generate a feasible solution for Z with value c which approximates the value of the optimal solution for Z to within a factor of τ: $c \leq \text{OPT} \leq c\tau$. If this precondition is satisfied, we can perform the following transformation, which bounds the value of the a'_{ij} in Z' by $\frac{\epsilon^2}{m\tau} \leq a'_{ij} \leq 1$ for all i and j, giving $\gamma' = \frac{m\tau}{\epsilon^2}$. Note that the value of γ now depends on the extent to which we can bound the value of the LP, but not on the relative values of the constraints (which could be very small).

Define $\nu = \frac{m}{c\epsilon}$, and perform the following transformation operation on the constraints:

$$a'_{ij} = \begin{cases} \frac{\epsilon}{\nu\tau c} & \text{if } a_{ij} < \frac{\epsilon}{c\tau}, \\ 1 & \text{if } a_{ij} > \nu, \\ \frac{a_{ij}}{\nu} & \text{otherwise.} \end{cases}$$

This transformed LP has the following properties:

1. If $\{y'_j\}$ is a primal feasible solution for Z', then

$$\left\{ y_j = \begin{cases} 0 & \text{if } \exists i \text{ such that } a'_{ij} = 1, \\ \frac{y'_j}{\nu} & \text{otherwise} \end{cases} \right\}$$

   is primal feasible for Z, and $\sum_j y_j \geq \frac{\sum_j y'_j}{\nu} - \epsilon \cdot \text{OPT}$.
2. If $\{y_j\}$ is primal feasible for Z, then $\left\{y'_j = \frac{y_j\nu}{1+\epsilon}\right\}$ is primal feasible for Z', and $\sum_j y'_j = \sum_j \frac{y_j\nu}{1+\epsilon}$.
3. $\frac{\epsilon}{\nu\tau c} \leq a'_{ij} \leq 1$ for all i and j.

Property 3 is clearly true, but the other two properties require the short proofs below.

Proof of property 1. Take a feasible solution $\{y'_j\}$ for Z' and let $\{y_j\}$ be as

specified. Then for any fixed value of i,

$$\sum_j a_{ij} y_j = \sum_{j|a'_{ij}<1} a_{ij} y_j \le \sum_{j|a'_{ij}<1} \nu a'_{ij} y_j \le \sum_{j|a'_{ij}<1} \nu a'_{ij} \frac{y'_j}{\nu} \le 1.$$

The final inequality holds by the feasibility of the solution $\{y'_j\}$, so the solution $\{y_j\}$ is feasible for Z. The value of this solution satisfies

$$\begin{aligned}\sum_j y_j &= \sum_j \frac{y'_j}{\nu} - \sum_{j|\exists i \text{ s.t. } a'_{ij}=1} \frac{y'_j}{\nu} \\ &\ge \sum_j \frac{y'_j}{\nu} - \sum_{j|\exists a'_{ij}=1} \frac{1}{\nu} \\ &\ge \sum_j \frac{y'_j}{\nu} - \frac{m}{\nu} \\ &\ge \sum_j \frac{y'_j}{\nu} - \epsilon \cdot \mathrm{OPT}.\end{aligned}$$

The first inequality holds by the fact that for any feasible $\{y'_j\}$ and for any i and j, $a'_{ij} y'_j \le 1$. The second inequality holds by the bound on the number of routers in the network, and the final inequality holds by the definition of ν. □

Proof of property 2. Take a feasible solution $\{y_j\}$ for Z and let $\{y'_j\}$ be as specified. Then for any fixed value of i,

$$\begin{aligned}\sum_j a'_{ij} y'_j &= \sum_j a'_{ij} \left(\frac{y_j \nu}{1+\epsilon}\right) \\ &= \sum_{j|a_{ij} > \frac{\epsilon}{c\tau}} a'_{ij} \left(\frac{y_j \nu}{1+\epsilon}\right) + \sum_{j|a_{ij} \le \frac{\epsilon}{c\tau}} a'_{ij} \left(\frac{y_j \nu}{1+\epsilon}\right) \\ &\le \sum_{j|a_{ij} > \frac{\epsilon}{c\tau}} \frac{a_{ij} y_j}{1+\epsilon} + \sum_{j|a_{ij} \le \frac{\epsilon}{c\tau}} \frac{\epsilon y_j}{(1+\epsilon)\tau c} \\ &\le \frac{1}{1+\epsilon} + \frac{\epsilon}{(1+\epsilon)\tau c} \sum_j y_j \\ &\le \frac{1}{1+\epsilon} + \frac{\epsilon}{(1+\epsilon)} = 1.\end{aligned}$$

The final line holds from the bound on the optimal solution for Z: $\sum_j y_j \le \mathrm{OPT} \le c\tau$, so the solution y'_j is feasible. □

Now we generate an approximate solution to Z by performing the transformation to special form and then computing a $(1+\epsilon)$ approximation $\{y'_j\}$ for Z' using our algorithm. We transform this solution to $\{y_j\}$ using the transformation described in

property 1 and get a primal feasible solution Y for our LP such that

$$Y = \sum_j y_j \geq \frac{\sum_j y'_j}{\nu} - \epsilon \cdot \mathrm{OPT} \geq \frac{\mathrm{OPT}'}{\nu(1+\epsilon)} - \epsilon \cdot \mathrm{OPT}$$
$$\geq \mathrm{OPT}\left(\frac{1}{(1+\epsilon)^2} - \epsilon\right).$$

The first inequality is from property 1, the second is based on the fact that $\{y'_j\}$ is a $(1+\epsilon)$ approximation to the value of Z' (denoted by OPT'), and the final inequality is from property 2.

Next we need to explain how to choose the parameters c and τ so as to guarantee the precondition $c \leq \mathrm{OPT} \leq c\tau$. Recall that I_j denotes the set of edges incident to connection j, $I_j = \{i | a_{ij} > 0\}$, and J_i denotes the set of connections incident to edge i, $J_i = \{j | a_{ij} > 0\}$. Now define

$$\beta_i = \min_{l \in J_i} \max_{k \in I_l} a_{kl},$$

a quantity which can be locally computed in one round for each router i. Also, let $\beta = \min_i \beta_i$, and for each connection j, define $\widehat{\beta}_j = \min_{i \in I_j} \beta_i$. It is relatively easy to show that $\frac{1}{\beta} \leq \mathrm{OPT} \leq \frac{m}{\beta}$. The first inequality holds from the primal feasibility of the solution in which the connection j used in the evaluation of the minimum β_i is assigned flow $y_j = \frac{1}{\beta}$. The second inequality holds from the dual feasibility of the solution in which each router i is assigned weight $x_i = \frac{1}{\beta_i}$.

Therefore, we can set $c = \frac{1}{\beta}$, and $\tau = m$ in the sequential implementation, giving $\gamma' = \frac{m^2}{\epsilon^2}$ and an $O\big(\frac{nm \ln(m/r\epsilon)}{r\epsilon}\big)$ running time.

3.3. Approximating β in the distributed setting. In the sequential case, knowledge of β is enough to perform the transformation to special form, but connections and routers may not know this value. We now describe a technique in which we distributively subdivide the LP into subprograms based on local estimates of β. The value of each subprogram is bounded, so we can work in special form. Then we recombine solutions in such a way as to only assign nonzero rates to connections with good estimates of β, but we prove that this only reduces the sum of the rates by a small factor.

Set $p = \lceil \frac{1}{\epsilon} \rceil$, and for $q = 0, \ldots, p-1$, define the sets

$$G_t^q = \left\{ j \;\middle|\; \left(\frac{m}{\epsilon}\right)^{p(t-1)+q} \leq \widehat{\beta}_j < \left(\frac{m}{\epsilon}\right)^{pt+q} \right\}$$

for integer t. It is clear that each connection belongs to exactly p of these sets. Independently for each value of q, each router i assigns flow only to connections which are members of $G^q_{T_{iq}}$, where T_{iq} is the minimal value of t for which $G_t^q \bigcap J_i$ is nonempty. In effect, this means that the algorithm is run on the network p successive times. From the connection's point of view, it runs p successive algorithms, using β_j as an approximation for β. In each of these p trials, it can be rejected (i.e., given no flow) by some of the routers. The final flow assigned to connection j is the average of the flows given in the p independent trials. We will prove that this procedure does not decrease the sum of the rates by more than an additional $(1-\epsilon)^2$ factor.

Now define $\mathrm{OPT}(X)$ to be the value of the modified LP when flow can *only* be assigned to connections in the set X. It is not difficult to show that $\mathrm{OPT}(G_t^q)$ is

bounded between $\left(\frac{\epsilon}{m}\right)^{p(t-1)+q}$ and $\left(\frac{\epsilon}{m}\right)^{p(t-1)+q} \cdot \left(\frac{m}{\epsilon}\right)^{1/\epsilon} \cdot m$. Thus, we have that for each set G_t^q, the special form of the modified LP for connections in G_t^q satisfies the precondition with $c = \left(\frac{\epsilon}{m}\right)^{p(t-1)+q}$ and $\tau = \left(\frac{m}{\epsilon}\right)^{1/\epsilon} \cdot m$. Therefore, for each of these LPs, we can use $\gamma = \frac{m\tau}{\epsilon^2} = \left(\frac{m}{\epsilon}\right)^{2+1/\epsilon}$.

We now turn to bound the approximation ratio. Consider a particular $q \in \{0, \ldots, p-1\}$, and let T and Q be the unique integers such that β is in the interval defined by G_T^q and $\beta > \left(\frac{m}{\epsilon}\right)^{pT+Q-1}$. For $q \neq Q$ and for the dual feasible setting $\{x_i = \frac{1}{\beta_i}\}$,

$$\begin{aligned} \mathrm{OPT}\left(\bigcup_{t>T} G_t^q\right) &\leq \sum_{i \mid i \in I_l, l \in G_t^q, t>T} x_i \\ &\leq \frac{m}{\left(\frac{m}{\epsilon}\right)^{pT+Q}} \leq \frac{\epsilon}{\beta} \leq \epsilon \cdot \mathrm{OPT}. \end{aligned}$$

This implies that $\mathrm{OPT}(G_T^q) \geq (1-\epsilon)\,\mathrm{OPT}$ for all $q \neq Q$. The quality of the solution we obtain is therefore bounded below by

$$\frac{1}{p} \sum_{q \neq Q} \mathrm{OPT}(G_T^q) \geq \frac{p-1}{p}(1-\epsilon)\,\mathrm{OPT} \geq (1-\epsilon)^2\,\mathrm{OPT}\,.$$

Putting everything together, we have a distributed algorithm that assumes global knowledge only of m and the approximation parameters r and ϵ. This algorithm finds a primal feasible $(r + (1+\epsilon)^5)$ approximation of the optimal solution, and terminates in $O\left(\frac{(r+1)\ln^2(m/r\epsilon)\ln(\frac{(r+1)mn}{r\epsilon})}{r^2\epsilon^5}\right)$ distributed rounds.

4. Discussion. We studied the problem of having distributed decision-makers with local information generate feasible solutions to positive LPs. Our results explore the tradeoff between the amount of local communication that these agents may perform and the quality of the solution they obtain, measured by the approximation ratio. While we have provided an algorithm which obtains a $(1+\epsilon)$ approximation ratio in a polylogarithmic number of distributed communication rounds, proving nontrivial lower bounds on the running time needed to obtain a $(1+\epsilon)$ approximation remains an open question, as does the challenging problem of providing fast approximation algorithms for general LPs.

Acknowledgments. We would like to thank Christos Papadimitriou for stimulating discussions and useful insights in the early stages of this work. We also thank Dick Karp, Mike Luby, Dorit Hochbaum, and the anonymous SICOMP referees for their helpful comments on earlier versions of results presented in this paper.

PREEMPTIVE WEIGHTED COMPLETION TIME SCHEDULING OF PARALLEL JOBS*

UWE SCHWIEGELSHOHN†

Abstract. We present a new algorithm for the preemptive offline scheduling of independent jobs on a system consisting of m identical machines. The jobs can be parallel; that is, they may need the concurrent availability of several machines for their execution. To this end, we introduce a machine model which is based on existing multiprocessors and accounts for the penalty of preemption. After examining the relation between makespan and total weighted completion time costs for the scheduling of parallel jobs, we show that our new algorithm achieves an approximation factor of 2.37 for total weighted completion time scheduling if no preemption penalty is considered. This compares favorably to the thus far best approximation factor of 8.53 for the nonpreemptive case. To fine-tune the algorithm with respect to different preemption penalties, we use a fairly simple numerical optimization problem. Further, we present an algorithm to transform the preemptive schedule into a nonpreemptive one. This leads to an improved approximation factor of 7.11 for the nonpreemptive weighted completion time scheduling.

1. Introduction.

We address preemptive and nonpreemptive scheduling of parallel jobs without release dates. There is a job system τ consisting of independent parallel jobs to be scheduled on m identical machines. Each job j is characterized by its fixed degree of parallelism $m_j \leq m$, its processing time $p_j \geq 1$, and a weight $w_j \geq 0$. Exactly m_j machines must be allocated to a job j at any time the job is executing and each machine can execute at most one job at a time. Note that the actual processing of job j will require the same time on any subset of m_j machines. In the preemptive version, it is possible to temporarily suspend the execution of a job j on all machines assigned to it and to resume its processing on the same subset of machines at a later time, that is, no migration of the job after a preemption is permitted. This preemption process can be repeated. Both the suspension and the resumption of the job will result in a preemption penalty of $\frac{p}{2}$. Our preemptive model and its relation to real implementations are explained in section 2 in more detail.

The completion time of job j in a schedule S is denoted as $C_j(S)$. In this paper, it is the goal of the scheduling algorithm to minimize the sum of the weighted completion times $C(S) = \sum_{j\in\tau} w_j C_j(S)$ of S, also called total weighted completion time of S. These problems are denoted as $Pm|\text{size}_j|\sum w_j C_j = Pm|m_j|\sum w_j C_j$ and $Pm|m_j, \text{prmp, no mig}|\sum w_j C_j$, respectively. In addition, we consider the makespan $C_{\max}(S) = \max_{j\in\tau} C_j(S)$ of S, that is, the problems $Pm|m_j|C_{\max}$ and $Pm|m_j, \text{prmp, no mig}|C_{\max}$. Minimizing the total weighted completion time is known to be NP-hard in the strong sense, even if all jobs are sequential; that is, $m_j = 1$ is

valid for all $j \in \tau$ [2]. This result also holds in the preemptive case [9]. Hence, we are interested in polynomial-time algorithms that provide approximate solutions. Such an algorithm is called a ρ-approximation algorithm if its result is never worse than ρ times the optimal value. Then we also say that ρ is the approximation factor. Further, we denote the optimal total weighted completion time and the optimal makespan for a job system τ on a given machine system $\mathcal{M}$ as $C^*(\tau, \mathcal{M})$ and $C^*_{\max}(\tau, \mathcal{M})$, respectively. If the context is clear, we will omit τ and/or $\mathcal{M}$.

Approximation algorithms have already been presented for several nonpreemptive variants of this problem. For sequential jobs ($m_j = 1$), Kawaguchi and Kyan [8] described a list scheduling algorithm called LRF (*largest ratio first*) with an approximation factor of $\frac{1+\sqrt{2}}{2}$. This problem is denoted as $Pm||\sum w_j C_j$. The extension of this problem to include parallel jobs ($Pm|m_j|\sum w_j C_j$) has only recently been addressed when Schwiegelshohn et al. [11] showed that the SMART (*scheduling to minimize average response time*) algorithm generates shelf-based nonpreemptive schedules with an approximation factor of 8.53. Turek et al. [14] proved that a generalization of Kawaguchi and Kyan's LRF method produces an approximation factor of 2 for parallel jobs with unique weights if the resource requirement of each job is at most 50% of the maximum number of machines. However, when allowing arbitrary jobs, this method may result in schedules which significantly deviate from the optimum.

Among other problems, Chakrabarti et al. [3] addressed the nonpreemptive scheduling of so-called malleable jobs with different release dates and proved an expected performance within 8.67 of optimal for a randomized online algorithm. We call a job malleable if it can be executed on any number of machines up to m_j with a corresponding increase or decrease of the processing time. Deng et al. [5] discussed preemptive response time scheduling for malleable jobs with unique weights and described a 2-approximation algorithm. They use an online model where the total resource consumption of a job (the sum of the execution times of this job on all machines) is invariant but becomes known only at the completion of the job. Note that Deng's model is significantly different from ours as migration is allowed and the number of machines allocated to a job may change after the preemption of the job. Based on the work from Afrati et al. [1], Fishkin, Jansen, and Porkolab [7] recently showed a PTAS (polynomial time approximation scheme) for the problem $Pm|m_j, r_j|\sum w_j C_j$ if the number of machines is constant; that is, a $1+\epsilon$ approximation is achieved with a running time of $f(\frac{1}{\epsilon}, m)O(n \log n)$. Note that the running time of this algorithm is exponential in m while m is used in our algorithm only to compare values. Finally, Phillips, Stein, and Wein [10] have demonstrated how to transform preemptive schedules of sequential jobs ($m_j = 1$) into nonpreemptive schedules with only a factor 3 increase in the average weighted completion time.

In this paper, we present a 2.37-approximation algorithm for our preemptive problem if there is no preemption penalty. This result is further used to derive a nonpreemptive algorithm with an approximation factor of 7.11. In both cases, we also give a performance guarantee for the makespan problem. This concept of bicriteria scheduling has been introduced by Stein and Wein [13] who showed that there are always schedules which approximate both the makespan and the total weighted completion time.

After presenting our model in section 2 and comparing it to some real world constraints, we discuss some aspects of bicriteria scheduling of parallel and independent jobs. Previous results with relevance to our algorithm are addressed in section 4. Next, we introduce the new preemptive algorithm in section 5 and analyze it after-

ward. We show that the total weighted completion time approximation factor of our algorithm can be minimized by solving a numerical optimization problem. Then we present a method, similar to the one published by Phillips, Stein, and Wein [10], to transform our preemptive schedule into a nonpreemptive one. Finally, our preemptive and nonpreemptive results are compared to the worst-case bounds of nonpreemptive SMART schedules.

2. The model. For a given job system τ and a machine system $\mathcal{M}$ consisting of m independent machines and a preemption penalty p, we now formally introduce a preemptive schedule with no migration being permitted.

DEFINITION 2.1 (preemptive schedule without migration).

In a preemptive schedule $S(\tau, \mathcal{M})$ without migration, each job $j \in \tau$ is assigned

1. *a nonnegative integer d_j,*
2. *a $(2d_j + 2)$-tuple of time instants $t_j(0) \le t_j(1) \le \cdots \le t_j(2d_j + 1)$, and*
3. *a set $M_j \subseteq \{1, \ldots, m\}$ with $|M_j| = m_j$.*

Again, we usually omit τ and $\mathcal{M}$. In Definition 2.1, d_j denotes the number of preemptions for job j in schedule S. The execution of job j in S is started at time $t_j(0)$, suspended at times $t_j(2\delta - 1)$, resumed at times $t_j(2\delta)$, and completed at time $t_j(2d_j+1) = C_j(S)$ with $0 < \delta \le d_j$. Finally, M_j is the set of machines on which job j is executed. Note that for a system of identical machines and either a nonpreemptive schedule or a preemptive schedule with migration, it is sufficient to consider only the number m_j of required machines, while the specification of the actual machine set M_j is necessary in a preemptive schedule without migration. In the latter case, we say that a job j is resident on M_j from $t_j(0)$ to $t_j(2d_j + 1)$.

A preemptive schedule $S(\tau, \mathcal{M})$ without migration is called valid if the following conditions are fulfilled for all $j \in \tau$:

1. $\sum_{\delta=0}^{d_j} t_j(2\delta + 1) - t_j(2\delta) = p_j + pd_j$,
2. $t_j(\mu) - t_j(\mu - 1) \ge \begin{cases} 0 & \text{for } \mu = 2\delta \text{ with } 0 < \delta \le d_j, \\ \frac{p}{2} & \text{for } (\mu = 1 \text{ or } \mu = 2d_j + 1) \text{ and } d_j \ne 0, \\ p & \text{for } \mu = 2\delta + 1 \text{ with } 0 < \delta < d_j, \end{cases}$
3. $M_j \cap M_{j'} = \emptyset$ if $j \ne j'$ and $t_j(2\delta) \le t_{j'}(2\delta') < t_j(2\delta + 1)$ for any $0 \le \delta \le d_j$ and $0 \le \delta' \le d_{j'}$

Job j executes between time $t_j(2\delta)$ and time $t_j(2\delta+1)$ while it is inactive between time $t_j(2\delta - 1)$ and time $t_j(2\delta)$. As each suspension and each resumption of a job execution produce a preemption penalty of $\frac{p}{2}$, there is a minimal time period between resumption and the next suspension of a job. This property is described in condition 2 above. Note that no preemption penalty is encountered if a job starts or terminates. The various cases of condition 2 can be seen in Figure 1. In the figures shown in this paper, all machines are arranged along a single (horizontal) line. In a nonpreemptive schedule, the execution of a job can therefore be described as several rectangles of the same height which are aligned along a horizontal line. However, for reasons of simplicity, we simply assume that the machines assigned to a job are arranged in a contiguous fashion. Hence, we represent each nonpreemptively executed job as a single rectangle. Then in a preemptive schedule without migration, the execution of a job is described as several rectangles which are aligned along a vertical line. In order to better demonstrate the preemption penalty, we assume that during the preemption penalty all involved machines remain idle; see Figure 1. Therefore, the combined area of all rectangles associated with the actual processing of a job j remains invariant and has the value $m_j p_j$. Condition 1 gives the total time a job j is active on its assigned machines including all preemption penalties. Finally, condition 3 ensures

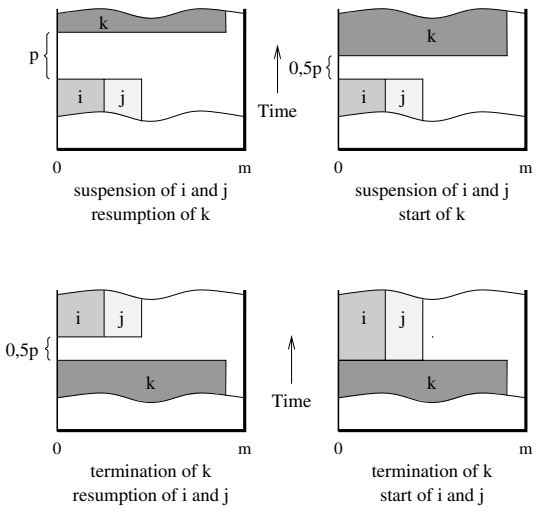

FIG. 1. *Different preemption penalty cases.*

that no machine can be assigned to more than one job at any time.

Our machine model is based on multiprocessor systems like the IBM RS/6000 SP. A typical installation consists of m nodes which use an interconnection network for communication. Each node has its own processor, main memory, and a local hard disk for swapping. Usually most of the nodes are identical. In the IBM machine, the interconnection network does not prefer specific subsets of nodes, and the nodes are assigned to jobs in an exclusive fashion. Therefore, the execution time of a job does not depend on the assigned node partition.

Some multiprocessors perform preemption by simultaneously switching the context of all nodes executing the same job. This kind of preemption is called *gang scheduling* [6]. Our model also uses gang scheduling as at any time, a job can execute only on all or on none of the machines of its machine set. In practice, the context switch is typically executed with the help of the local processor memory and/or the local hard disk. Typically during the context switch, the interconnection network is needed only to synchronize the nodes of a partition to act concurrently. However, the context switch may leave some messages in the interconnection network without target process. These messages must be temporarily saved until the target process resumes execution. Further, the context switch requires the saving and loading of a job status and may cause additional cache misses and page faults. In our model, all those delays are combined into a constant overhead, the so-called preemption penalty $\frac{p}{2}$. This preemption penalty is encountered whenever the execution of a job is interrupted or resumed. Therefore, a complete context switch produces the preemption penalty p.

3. Bicriteria scheduling. Most previous scheduling work has addressed a single scheduling goal. Algorithms that approximate more than one criterion have received little attention. Recently, Stein and Wein [13] showed that for any scheduling problem, there are always schedules with a total weighted completion time and a makespan that are both within 2 of the optimal value.

Although we focus mainly on the total weighted completion time in this paper, we also address the makespan of our schedules. While Stein and Wein were primarily

interested in the existence of schedules with bicriteria properties, we want to show that our polynomial time algorithms approximate both the total weighted completion time and the makespan, similar to Chakrabarti et al. [3].

In this section, we give a few results to show the relation between total weighted completion time and makespan scheduling for parallel jobs on identical machines. First, we present a simple example to demonstrate that there are job systems where any optimal makespan schedule $S_{\max}$ results in $C(S_{\max}) = \Theta(m)C^*$.

Example 3.1. Assume a system τ of $m+1$ jobs such that there are m identical jobs j with $m_j = 1$, $p_j = 1$, and $w_j = 1$ and a single job j' with $m_{j'} = m-1$, $p_{j'} = m$, and $w_{j'} = 1$. It is easy to see that in any optimal makespan schedule $S_{\max}$, job j' must start at time 0 on any subset of $m-1$ machines while all other jobs are executed one after another on the single remaining machine. However, in the optimal total completion time schedule S, all m small jobs start concurrently at time 0 while job j' is executed after all other jobs are completed. This yields $C_{\max}(S_{\max}) = m = C^*_{\max}$ and $C(S_{\max}) = \frac{m(m+3)}{2} = \Theta(m)(2m+1) = \Theta(m)C(S)$. Although $S_{\max}$ and S are both nonpreemptive schedules, the result is also valid in the preemptive case.

Next, we address the opposite case; that is, we determine the makespan for optimal total weighted completion time schedules. First, we consider nonpreemptive schedules.

LEMMA 3.1. *There are job systems such that any nonpreemptive optimal total weighted completion time schedule S results in $C_{\max}(S) = \Theta(m)C^*_{\max}$.*

Proof. Assume a system of $2m$ jobs such that $p_{2i-1} = m+i-1$, $m_{2i-1} = 1$, $p_{2i} = 1$, and $m_{2i} = m$ hold for $1 \le i \le m$. The weights of the jobs are defined recursively. We start with $w_{2m} = 1$. For all other jobs, there is $w_{2i-1} = w_{2i}(m+i)$ and $w_{2i} = (m+i)\sum_{k=2i+1}^{2m} w_k$.

It is easy to see that we have $C^*_{\max} = 3m-1$ as job $2m-1$ cannot be executed concurrently with any job $2i$. Therefore, an optimal makespan schedule is obtained by starting job $2i$ at time i while all jobs $2i-1$ concurrently start their execution at time m.

On the other hand, we consider a list schedule S where all jobs start in the order $1, 2, \ldots, 2m$. Then no two jobs are executed concurrently as each sequential job ($m_j = 1$) is sandwiched between two parallel jobs requiring all machines. This results in $C_{\max}(S) = 1.5(m^2+m) = \Theta(m)C^*_{\max}$. It remains to be shown that S is the only nonpreemptive schedule with optimal total weighted completion time.

Note that we need to consider only schedules with nonnegative integer starting times for all jobs as the processing time of each job is an integer. Otherwise it is possible to reduce the total weighted completion time by starting the first job j with a noninteger starting time r at time $\lfloor r \rfloor$, as this does not affect the execution of any other job.

Assume that the starting times of jobs $1, \ldots, 2k$ are identical in schedule S and in any optimal total weighted completion time schedule. Then no job $j > 2k$ can start before $C_{2k}(S) = t_{2k}(1)$ due to its processing time for odd j or its degree of parallelism for even j. Therefore, we simply disregard all jobs $1, \ldots, 2k$ and assume $t_{2k}(1) = 0$ for the rest of the proof. Let us further introduce job system $\check{\tau} = \{2k+3, \ldots, 2m\}$. There are three possible cases:

1. *Schedule S_1.* Jobs $2k+1$ and $2k+2$ start at times 0 and $p_{2k+1} = m+k$, respectively. All jobs from $\check{\tau}$ are executed in the time frame $[m+k+1, \infty)$ in an optimal fashion.

2. *Schedule S_2.* Job $2k+1$ does not start before time 1. All jobs from $\check{\tau}$ and

job $2k+2$ are executed in the time frame $[0,\infty)$ in an optimal fashion.

3. *Schedule* S_3. Job $2k+2$ does not start before time $p_{2k+1}+1$. All jobs from $\check{\tau}$ and job $2k+1$ are executed in the time frame $[0,\infty)$ in an optimal fashion.

This results in the following total weighted completion times:

$$\begin{aligned}
C(S_1) &= C^*(\check{\tau}) + \left(\sum_{j\in\check{\tau}} w_j\right)(m+k+1) + w_{2k+2}(m+k+1)(m+k)\\
&\quad + \ w_{2k+2}(m+k+1)\\
&= C^*(\check{\tau}) + \left((m+k+1)^2 + \frac{m+k+1}{m+k+2}\right) w_{2k+2},\\
C(S_2) &\geq C^*(\check{\tau}) + w_{2k+2}(m+k+1)(m+k+1) + w_{2k+2}\\
&= C^*(\check{\tau}) + ((m+k+1)^2+1)w_{2k+2},\\
C(S_3) &\geq C^*(\check{\tau}) + w_{2k+2}(m+k+1)(m+k) + w_{2k+2}(m+k+2)\\
&= C^*(\check{\tau}) + ((m+k+1)^2+1)w_{2k+2}.
\end{aligned}$$

Therefore, jobs $2k+1$ and $2k+2$ must start at times $t_{2k}(1)$ and $t_{2k}(1)+p_{2k+1}$, respectively, to obtain an optimal total weighted completion time schedule. It follows by induction that S is the only schedule with optimal total weighted completion time. □

However, if preemption with migration is allowed, the relation between total weighted completion time scheduling and makespan scheduling is different as shown by the next lemma. Contrary to the model of Definition 2.1, the model of Lemma 3.2 allows the execution of job j to resume after a preemption on any subset of m_j idle machines. This problem is denoted as $P|m_j, \text{prmp}|\sum w_jC_j$.

LEMMA 3.2. *Assume m identical machines and a system τ of independent jobs. If preemption with job migration and without preemption penalty is allowed, then any optimal total weighted completion time schedule S also guarantees $C_{\max}(S) \leq (2-\frac{1}{m})C^*_{\max}$.*

Proof. We say that a time instance t in schedule S is *open* if at most $\frac{m}{2}$ machines are used at t. If schedule S does not contain any open time instances in the interval $[0, C_{\max}(S))$, then we have

$$C^*_{\max} \geq \frac{1}{m}\sum_{j\in\tau} m_jp_j \geq \frac{m+1}{2m}C_{\max}(S) \geq \frac{m}{2m-1}C_{\max}(S).$$

Otherwise, assume that t is the last open time instance in schedule S with m_t machines being busy at t. Further, let job j execute at t. Then S has the following properties:

(i) If j does not execute in S at a time instance t' of the interval $[0, t_j(2d_j+1))$, then at least $m-m_j+1 \geq m-m_t+1$ machines are busy at t'.

(ii) If j executes at a time instance t' in S, then at least $m_t \geq m_j$ machines must be used at t' as all jobs executing at t must also execute at all previous open time instances.

(iii) At least $m-m_t+1$ machines must be used at any time instance t' in the interval $[C_j(S), C_{\max}(S))$ as t is the last open time instance and there must be at least one job that executes at t' while not executing at t if we have $C_j(S) < C_{\max}(S)$.

Therefore, a total machine-time product of at least $m_tp_j+(m-m_t+1)(C_{\max}(S)-$

$p_j) \leq mC^*_{\max}$ is required for τ. For $p_j \geq \frac{C_{\max}(S)}{2-\frac{1}{m-m_t+1}}$, this results in

$$\frac{C_{\max}(S)}{2-\frac{1}{m}} \leq \frac{C_{\max}(S)}{2-\frac{1}{m-m_t+1}} \leq p_j \leq C^*_{\max}.$$

Otherwise as $2m_t < m+1$ holds, we have

$$\begin{aligned} C^*_{\max} &\geq \frac{1}{m}((m-m_t+1)C_{\max}(S) - (m-2m_t+1)p_j) \\ &\geq \left(m-m_t+1-\frac{m-2m_t+1}{2-\frac{1}{m-m_t+1}}\right)\frac{C_{\max}(S)}{m} \\ &= \frac{1}{2-\frac{1}{m-m_t+1}}C_{\max}(S) \geq C_{\max}(S)\frac{1}{2-\frac{1}{m}}. \qquad \square \end{aligned}$$

This lemma shows that any optimal total weighted completion time schedule deviates by at most a factor $2-\frac{1}{m}$ from the optimal makespan schedule for a specific scheduling problem $(P|m_j, \text{prmp}|\sum w_jC_j)$, while Stein and Wein [13] proved a more general result with a deviation factor for the total weighted completion time. Also note that it is still an open problem to bound the makespan approximation factor for an optimal total weighted completion time schedule using our model of preemption without migration.

4. Previous results and simple extensions. We start this section by extending our comparison of preemptive and nonpreemptive schedules with respect to the total weighted completion time criterion. Then we give the total weighted completion time and the makespan approximation factors for two types of algorithms: a list scheduling algorithm based on Smith's ratio [12] and the SMART algorithm [15].

For the case that all jobs of a job system are sequential ($m_j = 1$ for all $j \in \tau$), McNaughton [9] proved that the total weighted completion time of the optimal nonpreemptive schedule cannot be reduced by introducing preemption. However, our results in the previous section already indicate that there are differences between preemptive and nonpreemptive schedules if jobs are parallel. The following simple example shows that the total weighted completion time of an optimal preemptive schedule is smaller than the corresponding value of an optimal nonpreemptive schedule for some job systems. It can also be seen that this result holds, even if all jobs have unit weight.

Example 4.1. Assume a system of three jobs with the properties $w_1 = w_2 = w_3 = 1$, $p_1 = 2$, $p_2 = 1$, $p_3 = 4$, $m_1 = m$, $m_2 = m-1$, and $m_3 = 1$. In an optimal nonpreemptive total weighted completion time schedule S_n, job 2 starts concurrently with job 3. This block and job 1 are then scheduled in any order resulting in $C(S_n) = 11$; see the left schedule of Figure 2.

In the optimal preemptive total weighted completion time schedule S_p, however, first job 2 and job 3 are started together; see the right schedule of Figure 2. Then at time $t = 1$, job 3 is interrupted and job 1 is executed to completion. Finally, the execution of job 3 is resumed at time $t = 3$. Assuming no preemption penalty ($p = 0$), we have $C(S_p) = 10$.

Next, we consider the LRF algorithm, a simple nonpreemptive list scheduling algorithm where the order of the jobs is determined by the nonincreasing ratio $s_j = \frac{w_j}{p_j m_j}$. Since the ratio $\frac{w_j}{p_j}$ is known as Smith's ratio [12], we call s_j the modified Smith ratio. The LRF algorithm always removes the first job in a list and schedules it as

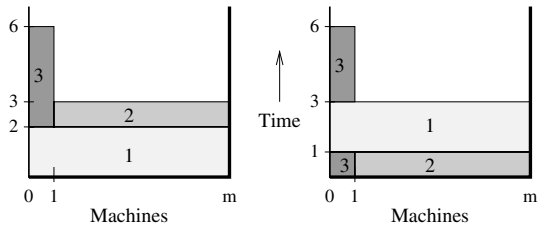

FIG. 2. *Optimal nonpreemptive schedule (left) and optimal preemptive schedule (right).*

early as possible without affecting the completion time of any previously scheduled job.

Kawaguchi and Kyan [8] have shown that the LRF algorithm guarantees $C(S) \leq \frac{\sqrt{2}+1}{2} C^*$ if all jobs are sequential ($m_j = 1$ for all $j \in \tau$).

Later, Turek et al. [14] proved that the approximation factor of the LRF algorithm is 2 if $m_j \leq \frac{m}{2}$ and $w_j = 1$ hold for each job $j \in \tau$. This proof can be easily extended to the weighted case. Before this is done, we repeat Lemma 3.2 of [11], which gives several lower bounds for nonpreemptive weighted completion time schedules.

LEMMA 4.1. *For any job system τ and a machine system that does not allow preemption, the optimal total weighted completion time solution C^* satisfies $A_\tau \leq C^*$, $\sum_{j\in\tau} w_j p_j \leq C^*$, and $A_\tau + \frac{1}{2}\sum_{j\in\tau} w_j p_j - \frac{1}{2m}\sum_{j\in\tau} w_j p_j m_j \leq C^*$.*

A_τ is called the squashed area bound and was originally introduced for the unweighted case in [15]. For this bound, each job j is transformed into a fully parallel job j' with $m_{j'} = m$, $p_{j'} = \frac{p_j m_j}{m}$, and $w_{j'} = w_j$. Therefore, the resulting scheduling problem is equivalent to a simple single machine problem, and an optimal schedule for these parallel jobs is generated by Smith's rule. For a proof of Lemma 4.1, see [11].

Next, we extend Turek's Lemma 4.1 in [14] to consider arbitrary weights as well.

LEMMA 4.2. *For any job system τ with $m_j \leq \frac{m}{2}$ for all $j \in \tau$ and a machine system that does not allow preemption, $C(S) \leq 2C^*$ holds for all LRF schedules S.*

Proof. We prove this lemma by induction. Let us assume that the jobs of τ are enumerated using the modified Smith ratio and that the following condition holds for job system $\tau' = \{1, \ldots, j-1\}$:

$$C(\tau') \leq 2A_{\tau'} + \sum_{i\in\tau'} w_i p_i - \frac{1}{m}\sum_{i\in\tau'} w_i p_i m_i \leq 2C^*(\tau').$$

Using $\tau'' = \tau' \cup \{j\}$, we need to show that

$$\begin{aligned} C(\tau'') &= C(\tau') + w_j C_j(S) \\ &\leq 2A_{\tau''} + \sum_{i\in\tau''} w_i p_i - \frac{1}{m}\sum_{i\in\tau''} w_i p_i m_i \\ &= 2A_{\tau'} + 2\frac{w_j}{m}\sum_{i\in\tau'} p_i m_i + 2\frac{w_j p_j m_j}{m} + \sum_{i\in\tau'} w_i p_i + w_j p_j - \frac{1}{m}\sum_{i\in\tau'} w_i p_i m_i \\ &\quad - \frac{w_j p_j m_j}{m}. \end{aligned}$$

Due to the induction assumption, this is true if the following inequality holds:

$$w_j(C_j(S) - p_j) \leq 2\frac{w_j}{m}\sum_{i\in\tau'} p_i m_i + \frac{w_j p_j m_j}{m}.$$

To see the validity of the inequality, note that $C_j(S) - p_j$ is the starting time of job j in any nonpreemptive schedule S. Further, at any time instance before $C_j(S) - p_j$, more than $\frac{m}{2}$ machines are used by jobs in τ' as S is a list schedule and each job needs at most $\frac{m}{2}$ machines. ∎

Next, let us consider the case where all jobs of a job system require more than 50% of the machines ($m_j > \frac{m}{2}$). Here it is easy to obtain an optimal total weighted completion time schedule as no two jobs can be executed concurrently. However, due to different machine requirements of the various jobs, scheduling the jobs in Smith order is not necessarily optimal.

COROLLARY 4.3. *Assume a job system τ with $m_j > \frac{m}{2}$ for all $j \in \tau$. Then any LRF schedule S satisfies $C(S) \leq 2C^*$.*

Proof. We construct a new job system τ' such that for each job $j \in \tau$, there is a job $j' \in \tau'$ with $w_{j'} = w_j$, $m_{j'} = m$, and $p_{j'} = \frac{p_j m_j}{m} > \frac{p_j}{2}$. Arranging the jobs of τ' in Smith order produces an optimal schedule $S' = A_{\tau'}$. Note that jobs j and j' have the same relative position in schedules S and S', respectively. This results in $C_j(S) < 2C_{j'}(S')$ and leads to

$$C(S) < 2C(S') = 2A_{\tau'} = 2A_\tau \leq 2C^*. \qquad \blacksquare$$

But if both cases in Lemma 4.2 and Corollary 4.3 are combined, meaning that jobs may be arbitrary, the approximation factor for the LRF algorithm may be as bad as m [14].

Further, many nonpreemptive schedules with small approximation factors for $C^*_{\max}$ cannot guarantee a constant approximation factor for C^*; see [15]. Here, we want to address the opposite case and discuss the approximation factors for $C^*_{\max}$ of some nonpreemptive schedules with good total weighted completion time performance. For the sake of completeness, we briefly recall the γ-SMART$_{\text{NFIW}}$ as used in [11]. The SMART algorithm generates a shelf schedule; that is, the jobs are assigned to shelves, and all jobs belonging to the same shelf start at the same time. The height of a shelf is the processing time of the longest running job assigned to it, and a shelf is placed on top of its predecessor with the first shelf starting at time 0. For γ-SMART, the job system τ is partitioned such that all jobs j with $\gamma^\mu \leq p_j < \gamma^{\mu+1}$ belong to the same height component $\mu \geq 0$. The jobs in such a height component are then ordered by increasing ratio $\frac{m_j}{w_j}$ and assigned to shelves in a next fit fashion (next fit increasing width (NFIW) to weight). Finally, the shelves are scheduled using Smith's rule, where the Smith ratio of a shelf is determined by its height and the sum of the weights of all jobs assigned to it.

COROLLARY 4.4. *For any job system τ, a γ-SMART$_{NFIW}$ schedule S satisfies $C_{\max}(S) < (1 + 2\gamma + \frac{\gamma}{\gamma-1})C^*_{\max}$.*

Proof. First, we restrict ourselves to a job system $\tau_1 \subseteq \tau$ that contains all jobs scheduled on the first shelf of each height component. We use the notation $C_{\max}(S, \tau_1)$ to denote the makespan of schedule S if we restrict ourselves to the jobs of τ_1 and remove all time intervals of S where all machines are idle. Assuming $\gamma^k \leq p_{\max} = \max_{j\in\tau} p_j < \gamma^{k+1}$, that is, at most $k+1$ height components, we obtain for the makespan $C_{\max}(S, \tau_1) \leq p_{\max} + \gamma\frac{\gamma^k - 1}{\gamma - 1}$. Therefore, we have

$$C_{\max}(S, \tau_1) < \left(1 + \frac{\gamma}{\gamma - 1}\right) p_{\max} \leq \left(1 + \frac{\gamma}{\gamma - 1}\right) C^*_{\max}(\tau).$$

Next, we consider all shelves belonging to the same height component μ. Assume that those shelves are enumerated in the order in which they are filled with jobs. As

the jobs of this height component are assigned to the shelves in a next fit fashion, the width of the first job in shelf $2i$ plus the width of all jobs in shelf $2i-1$ must exceed m. With n_μ and τ_μ denoting the number of shelves and the jobs in height component μ, respectively, we obtain

$$\sum_{j\in\tau_\mu} m_j > \left\lfloor \frac{n_\mu}{2} \right\rfloor m \geq \frac{n_\mu - 1}{2} m$$

and

$$\frac{1}{m} \sum_{j\in\tau_\mu} p_j m_j > \frac{n_\mu - 1}{2} \gamma^\mu.$$

Note that $n_\mu \gamma^{\mu+1}$ is an upper bound for the combined height of all shelves of height component μ in schedule S. Further, one shelf of each height component is already considered in the schedule for the jobs of τ_1. Finally, we have $C^*_{\max}(\tau) \geq \frac{1}{m}\sum_{j\in\tau} p_j m_j$. The combination of all those results leads to

$$\begin{aligned} C_{\max}(S) &< C_{\max}(S,\tau_1) + \sum_{\mu=0}^{k} (n_\mu - 1)\gamma^{\mu+1} < \left(1 + \frac{\gamma}{\gamma - 1}\right) C^*_{\max}(\tau) + 2\gamma \frac{1}{m} \sum_{j\in\tau} p_j m_j \\ &< \left(1 + \frac{\gamma}{\gamma - 1} + 2\gamma\right) C^*_{\max}(\tau). \qquad \square \end{aligned}$$

In the next corollary, we again address job systems where no job needs more than 50% of the machines.

COROLLARY 4.5. *Assume a job system τ with $m_j \leq \frac{m}{2}$ for all $j \in \tau$. Then an LRF schedule S satisfies $C_{\max}(S) < (3 - \frac{1}{m}) C^*_{\max}$.*

Proof. Assume job j with $C_j(S) = C_{\max}(S)$. As S is a nonpreemptive LRF schedule, there are at least $\frac{m+1}{2}$ machines busy during all time instances before time $t_j(0) = C_j(S) - p_j$. This leads to $C^*_{\max} \geq \frac{1}{m}\sum_{j\in\tau} p_j m_j > \frac{1}{m}\frac{(m+1)(C_j(S)-p_j)}{2}$.

Therefore, we have $C^*_{\max} \geq p_j$ and $C^*_{\max} > \frac{m+1}{2m}(C_{\max}(S) - p_j) \geq \frac{1}{2-\frac{1}{m}}(C_{\max}(S) - p_j)$ which results in

$$C_{\max}(S) = C_{\max}(S) - p_j + p_j < \left(3 - \frac{1}{m}\right) C^*_{\max}. \qquad \square$$

If $m_j = 1$ holds for all jobs $j \in \tau$, the LRF schedule S becomes a list schedule and therefore guarantees $C_{\max}(S) \leq (2 - \frac{1}{m}) C^*_{\max}$.

5. The algorithm. In this section, we introduce the new preemptive algorithm *PSRS* (preemptive Smith ratio scheduling), shown in Table 1.

Let us start the discussion of Algorithm PSRS by explaining the elements and components used during its execution. Q is the list of those jobs that are not yet scheduled. The order of Q is determined by the modified Smith ratio (largest ratio first). t_s is a local variable of the algorithm and gives the earliest starting time of the next job to be scheduled. Note that t_s cannot decrease during the run of the algorithm and that it is not smaller than the starting time of the job that has been scheduled last. Therefore, all jobs will start in the order given by Q. Next, $T(m')$ is a function returning the first time instance after t_s such that at least m' machines are

TABLE 1
The preemptive Algorithm PSRS.

```
Create a priority list Q for all jobs such that job i precedes job j if s_i > s_j;
t_s = 0;
while (Q ≠ ∅){
        pick the next job j and delete it from Q;
        d_j = 0;
        if (m_j > m/2 and p_j/v ≤ T(m_j) − T(m/2)) {
                t_j(0) = T(m/2) + p/2 + p_j/v;
                t_s = t_j(0) + p_j + p/2;
                for all jobs i with t_i(2d_i + 1) ≥ t_j(0) − p/2 do {
                        d_i = d_i + 1;
                        t_i(2d_i + 1) = t_i(2d_i − 1) + p_j + p;
                        t_i(2d_i − 1) = t_i(0);
                        t_i(2d_i) = t_s − p/2;
                }
        } else {
                t_j(0) = T(m_j);
                t_s = t_j(0);
        }
        t_j(1) = t_j(0) + p_j;
}
```

available in the temporary schedule at time t_s. As no job in this temporary schedule starts after time t_s, we can formally write

$$T(m') = \min \left\{ t | t \geq t_s \text{ and } m - m' \geq \sum_j m_j \text{ with } t_j(2d_j + 1) > t \right\}.$$

Note that $t_j(2d_j+1)$ is a value that may change during the further run of the algorithm and therefore may be different from the final completion time $C_j(S)$. Finally, $v \leq 1$ is a constant that is used to minimize the approximation factor of Algorithm PSRS. The value of v will be determined in the next section.

Intuitively, Algorithm PSRS removes the first job j from Q and schedules it in a nonpreemptive (LRF) fashion as long as the job needs at most 50% of all machines ($m_j \leq \frac{m}{2}$). However, if a job j requires more than $\frac{m}{2}$ machines, we determine the difference between the first time instances after t_s where $\frac{m}{2}$ and m_j machines are available, respectively. If this time difference is less than the ratio $\frac{p_j}{v}$, we schedule j in the same way as those jobs with less parallelism; that is, j starts at time $T(m_j)$ and runs to completion. Otherwise at time $T(\frac{m}{2}) + \frac{p_j}{v}$, we preempt all jobs in the temporary schedule that do not finish before that time and start job j at time $T(\frac{m}{2}) + \frac{p_j}{v} + \frac{p}{2}$ as we need to account for the preemption penalty to interrupt those other jobs. Note that we also preempt jobs that would complete at time $T(\frac{m}{2}) + \frac{p_j}{v}$. Those jobs complete immediately after their execution is resumed. This is only done for the sake of a slightly simpler analysis. After job j has been completed, the execution of those preempted jobs is resumed, thus causing another preemption penalty of $\frac{p}{2}$. The next job cannot start before the execution of the preempted jobs is resumed. This assures that the necessary machines are available to resume execution of the preempted job without migration. Therefore, any preemption-causing job will not execute concurrently with any other job. Finally, note that jobs $j \in \tau$ with $m_j > \frac{m}{2}$ are not preempted.

In further parts of this paper, we use the following notation for variables or functions that change their values during an iteration of the algorithm: $q(j)$ and $\overline{q}(j)$

denote the value of a variable or a function q at the beginning and at the end of the iteration where job j is scheduled, respectively.

Now, we discuss the validity of the schedule produced by PSRS.

LEMMA 5.1. *Consider a job system τ and a machine system $\mathcal{M}$. Then PSRS always generates a valid schedule that does not require migration.*

Proof. First note that at the beginning of any iteration, $t_j(2d_j) \leq t_s$ holds for any job j that is already scheduled ($j \in \tau \backslash Q$). Initially, PSRS assigns to each job j an integer $d_j = 0$ and time instances $t_j(0)$ and $t_j(1)$ with $t_j(1) - t_j(0) = p_j \geq 1$ and $t_s(j) \leq t_j(0) \leq \overline{t_s}(j)$. During a later iteration, job j' may cause preemption and $d_j(j')$ may become $\overline{d_j}(j') = d_j(j') + 1$ while the schedule remains unchanged in the interval $[0, 2d_j(j'))$. The validity of the scheduling conditions for $t_j(2\overline{d_j}(j') - 1)$, $t_j(2\overline{d_j}(j'))$, and $t_j(2\overline{d_j}(j') + 1)$ can easily be verified. Finally, as already mentioned above, each preempted job can be continued on the same set of machines it has used before. ∎

The time complexity of PSRS is $O(|\tau|^2)$ as in the worst case, $O(|\tau|)$ jobs may preempt $O(|\tau|)$ jobs each. Also note that the LRF schedules for sequential jobs and for jobs requiring at most $\frac{m}{2}$ machines are both included in Algorithm PSRS. Therefore, if the job system τ observes the corresponding resource restrictions, PSRS guarantees $C(S) < \frac{\sqrt{2}+1}{2} C^*$ [8] and $C(S) < 2C^*$, respectively.

6. Approximation factors. In this section, we address the approximation factors for Algorithm PSRS. First, we derive the makespan approximation factor.

THEOREM 6.1. *$C_{\max}(S) < (2 + \frac{1}{v} + p) C^*_{\max}$ holds for all PSRS schedules S.*

Proof. First, we address the average machine usage in the time interval $[0, (\overline{T(\frac{m}{2})})(i))$ with i being the job scheduled last by PSRS. Note that $C_{\max}(S) - (\overline{T(\frac{m}{2})})(i) \leq \max_{j \in \tau}\{p_j\}$ holds.

Consider the scheduling of job j. Algorithm PSRS will not introduce any additional idle time in the time interval $[0, (\overline{T(\frac{m}{2})})(j))$ during the later scheduling of any other job.

If $m_j \leq \frac{m}{2}$ holds, then more than $\frac{m}{2}$ machines are used at any time instance in $[(T(\frac{m}{2}))(j), (\overline{T(\frac{m}{2})})(j))$.

Assume job j with $m_j > \frac{m}{2}$. Then fewer than m_j machines are idle at any moment in time interval $[(T(\frac{m}{2}))(j), (T(m_j))(j))$. If j does not cause any preemption, then $(T(m_j))(j) - (T(\frac{m}{2}))(j) < \frac{p_j}{v}$ and $(\overline{T(\frac{m}{2})})(j) = (T(m_j))(j) + p_j$ hold. At least m_j machines are used in S at any time instance of the interval $[(T(m_j))(j), (\overline{T(\frac{m}{2})})(j))$. Therefore, at least the fraction $\frac{1}{\frac{1}{v}+1} \leq \frac{1}{2}$ of all machines is used on average in the time frame $[(T(\frac{m}{2}))(j), (\overline{T(\frac{m}{2})})(j))$ of schedule S.

Next, assume that job j preempts jobs $j_1, \ldots, j_k$. Therefore, we have $m_j + \sum_{\mu=1}^{k} m_{j_\mu} > m$. Execution of jobs $j_1, \ldots, j_k$ is resumed at time $t_j(1) + \frac{p}{2} = (T(\frac{m}{2}))(j) + (1 + \frac{1}{v})p_j + p = (\overline{T(\frac{m}{2})})(j)$. During the time frame $[(T(\frac{m}{2}))(j), (\overline{T(\frac{m}{2})})(j))$, the total used machine-time product is at least $\sum_{\mu=1}^{k} m_{j_\mu} \frac{1}{v} p_j + m_j p_j > m p_j$. With $(\overline{T(\frac{m}{2})})(j) - (T(\frac{m}{2}))(j) = p_j(\frac{1}{v} + 1) + p$ and $p_{j'} \geq 1$ for all jobs $j' \in \tau$, we can therefore conclude that more than the fraction $\frac{1}{\frac{1}{v}+1+p}$ of all machines is used on average in $[(T(\frac{m}{2}))(j), (\overline{T(\frac{m}{2})})(j))$ and in $[0, (\overline{T(\frac{m}{2})})(i))$ as well.

Further, we have $C^*_{\max} \geq \sum_{j \in \tau} \frac{m_j p_j}{m}$ and $C^*_{\max} \geq \max_{j \in \tau} p_j$. This results in

$$C_{\max}(S) = C_{\max}(S) - \left(\overline{T\left(\frac{m}{2}\right)}\right)(i) + \left(\overline{T\left(\frac{m}{2}\right)}\right)(i)$$

TABLE 2
Worst-case job system for makespan schedules.

$\frac{1}{v}$	1	p_j	$2m$
1	$m-1$	m_j	m
m	1	p_j	1

TABLE 3
Worst-case job system for weighted completion time schedules.

p_j	m_j	w_j	Number of jobs
$\frac{1}{v}$	1	p_j	$k(x+1)$
1	$m-x$	m_j	k
ky	1	p_j	x
1	m	0	$\lfloor kyv \rfloor$

$$< \max_{j\in\tau} p_j + \left(\frac{1}{v} + 1 + p\right) \frac{1}{m} \sum_{j\in\tau} m_j p_j$$
$$\leq C^*_{\max} + \left(\frac{1}{v} + 1 + p\right) C^*_{\max} = \left(\frac{1}{v} + 2 + p\right) C^*_{\max}. \qquad \square$$

Note that the approximation factor is a function of v and p. This factor is tight for Algorithm PSRS and large values of m. This can be seen from the job system in Table 2 for which PSRS produces $C_{\max}(S) = (2 + \frac{1}{v} + p)C^*_{\max}$ if $m \to \infty$ holds. As the modified Smith ratio is the same for all jobs, we assume that in list Q of Algorithm PSRS, two jobs of the first group are always followed by one job of the second group, while the single job of the third group is the last job of Q. This results in $C_{\max}(S) = m(\frac{1}{v} + 1 + p) + m$. In an optimal schedule, the job of the last group is scheduled first. Then all jobs of the second group are executed concurrently with this job followed by all jobs of the first group. This leads to $C^*_{\max} = m + \frac{2}{v}$.

Next, we introduce the job systems of Table 3. Those job systems consist of four different types of jobs. Later, we will prove that one of those job systems produces the maximum ratio $\frac{C(S)}{C^*}$ of any PSRS schedule S for $k \gg m \to \infty$. First, we determine $C(S)$ and C^*, respectively. The real number $y \geq \frac{1}{k}$ and the nonnegative integer $x \leq \frac{m}{2} - 1$ in Table 3 are parameters.

The modified Smith ratio is 1 for all jobs of the first three types. Therefore, any order of those jobs in list Q is possible. We assume that $x + 1$ jobs of the first type are always followed by one job of the second type. The type 2 job causes preemption of the previous $x + 1$ type 1 jobs. All jobs of the third type are put into Q after all jobs of the first two types. Note that the last type of job has a modified Smith ratio of 0. Hence, these jobs must be at the end of Q and they do not contribute to C^*. However, these jobs delay the completion of type 3 jobs and therefore indirectly increase $C(S)$ of the PSRS schedule S.

A schedule with an optimal total weighted completion time schedule for this job system is obtained by starting all type 3 jobs at time 0 (contribution of those jobs to

the total weighted completion time: xk^2y^2). All type 2 jobs are executed one after another. The whole staple of these jobs also starts at time 0 (contribution of all type 2 jobs: $(m-x)\frac{k(k+1)}{2}$). Finally, all jobs of type 1 are scheduled at the earliest time possible, that is, on top of either the type 2 jobs or the type 3 jobs. This leads to three possible cases:

1. All type 1 jobs do not complete after time k, that is, the completion time of the last type 2 job.
2. All type 1 jobs do not complete after time ky, that is, the completion time of all type 3 jobs.
3. Some type 1 jobs complete after $\max\{k, ky\}$.

By comparison of those three cases, it can be determined that the worst ratio $\frac{C(S)}{C^*}$ is obtained for case 2, that is, if $y > 1 + \frac{x+1}{v(m-x)}$ holds. Therefore, the contribution of type 1 jobs is between $\frac{k(x+1)}{v}k + \frac{m-x}{2v^2}\lfloor\frac{k(x+1)}{m-x}\rfloor(\lfloor\frac{k(x+1)}{m-x}\rfloor + 1)$ and $\frac{k(x+1)}{v}k + \frac{m-x}{2v^2}\lceil\frac{k(x+1)}{m-x}\rceil(\lceil\frac{k(x+1)}{m-x}\rceil + 1)$.

In the PSRS schedule, the first $x+1$ type 1 jobs and the first job of type 2 will contribute to the total weighted completion time with $(\frac{x+1}{v}+m-x)(\frac{1}{v}+1+p)-\frac{(m-x)p}{2}$. Therefore, the contribution of all type 1 and type 2 jobs together is $\frac{k(k+1)}{2}(\frac{x+1}{v}+m-x)(\frac{1}{v}+1+p) - k\frac{(m-x)p}{2}$. Finally, all type 3 jobs are executed after all type 1 and type 2 jobs. As already mentioned, the completion time of those jobs is increased by type 4 jobs. This results in a contribution of not more than $kxy(kyv+k)(\frac{1}{v}+1+p)$. Hence, the high order terms of $C(S)$ and C^* are given by

$$\lim_{k\gg m, m\to\infty} C^* = k^2\left(xy^2 + \frac{1}{2}(m-x)\left(\frac{x+1}{v(m-x)}+1\right)^2\right) \quad \text{and}$$

$$\lim_{k\gg m, m\to\infty} C(S) = k^2\left(xy(yv+1) + \frac{1}{2}\left(\frac{x+1}{v}+m-x\right)\right)\left(\frac{1}{v}+1+p\right).$$

The maximum ratio $\frac{C(S)}{C^*}$ of all PSRS schedules S for the job system of Table 3 with $k \gg m \to \infty$ depends on p and is denoted as $f_C(p)$. It is obtained by solving the following optimization problem:

$$f_C(p) = \lim_{k,m\to\infty} \min_{0<v\le 1}\left(\max_{y\ge 0, 0\le x<\frac{m}{2}}\left(\frac{C(S)}{C^*}\right)\right).$$

First, we discuss the reason to assume $m \to \infty$. There are $k(x+1)$ type 1 jobs in the job systems of Table 3. If we allow any value between 0 and $\frac{m}{2}$ for x in the optimization problem, then we need to consider only the contribution of the additional k type 1 jobs as their influence on the ratio of $\frac{C(S)}{C^*}$ varies with the size of m. The contribution of those jobs to C^* is at least $\frac{k^2}{v}$, while they contribute $\frac{k(k+1)}{2v}(\frac{1}{v}+1+p)$ to $C(S)$. As we have $\frac{k(k+1)}{2} \le k^2$ for $k \ge 1$, we can ignore this contribution in order to determine an upper bound of the worst case; that is, we can assume $m \to \infty$. With respect to Algorithm PSRS, this means that we allow a parallel job j to preempt jobs that together use $m - m_j$ instead of $m - m_j + 1$ machines. In particular, this includes the case where $m_j = \lceil\frac{m}{2}\rceil$ holds; see the proof of Corollary 6.5, step 4. Clearly, this modification does not reduce $C(S)$. However, note that it is used for the analysis only.

Before determining the approximation factor for the total weighted completion time, we introduce a lower bound $\tilde{C}^*$ for the optimal total weighted completion time

C^*. To obtain $\tilde{C}^*$, we simply assume that for all jobs, we have either $m_j = 1$ or $m_j > \lceil \frac{m}{2} \rceil$ in the optimal schedule. This is achieved by modifying the job system τ such that every job $j \in \tau$ with $1 < m_j \leq \lceil \frac{m}{2} \rceil$ is replaced by m_j sequential jobs $i_1, \ldots, i_{m_j}$ with $p_{i_\kappa} = p_j$, $m_{i_\kappa} = 1$, and $s_{i_\kappa} = s_j$ for $1 \leq \kappa \leq m_j$. Any valid schedule for τ is valid for the new job system as well. Therefore, $\tilde{C}^*$ is a lower bound for C^*. Note that $\tilde{C}^* = C^*$ holds for the job systems of Table 3.

If there are no jobs $j \in \tau$ with $2 \leq m_j \leq \lceil \frac{m}{2} \rceil$ and all jobs of job system τ have a modified Smith ratio of 1, then there are no intermittent idle times on any machine in the optimal schedule as no parallel jobs ($m_j > \frac{m}{2}$) can be executed concurrently. Note that the optimal schedule is nonpreemptive in this case and the total weighted completion time for each machine of the system is $\frac{1}{2}((\sum_j p_j)^2 + \sum_j p_j^2)$ with the sums being taken over all jobs $j \in \tau$ that are scheduled on this machine [12].

Under these conditions, the total weighted completion time is minimized if the makespan is the same for all machines of the system due to reasons of convexity [8]. Although the same makespan for all machines cannot be achieved for the job systems of Table 3, we will use this property for a subset of machines. In particular, we assume that in the optimal schedule, all those machines executing more than one sequential job have the same makespan. Again for the job systems of Table 3, this assumption does not result in a deviation from C^* as for $k \to \infty$, the execution time of all type 1 and type 2 jobs is small compared to the makespan of the machines assigned to them.

Further, for our analysis we increase the completion time of each preemption-causing job in a PSRS schedule by $\frac{p}{2}$; that is, the job completes at the same time when the execution of the preempted jobs is resumed. Hence for such a preemption-causing job j, we have $t_j(1) = t_s(j) = (\overline{T(\frac{m}{2})})(j)$. This modification increases the ratio $\frac{C(S)}{\tilde{C}^*}$ while $f_C(p)$ remains unchanged.

The next theorem is one of the main results of this paper and states that the approximation factor of PSRS is $f_C(p)$.

THEOREM 6.2. *$\frac{C(S)}{C^*} \leq f_C(p)$ holds for all PSRS schedules S.*

To prove Theorem 6.2, we gradually restrict the number of job systems, which must be considered in order to generate the maximum deviation of $C(S)$ from the lower bound $\tilde{C}^*$ of the optimum C^*, until we reach the job systems of Table 3. To enhance readability, the proof of Theorem 6.2 is divided into a lemma and several corollaries.

The total weighted completion times of the PSRS schedule and the optimal schedule for the job systems of Table 3 are determined only by jobs with the same modified Smith ratio. Therefore, we start our proof by showing that for the determination of the approximation factor of Algorithm PSRS, it is sufficient to consider only the completion times of the jobs with maximum modified Smith ratio in all job systems and PSRS schedules. To this end, we introduce the following notations:

$$\hat{\tau} = \left\{ i | i \in \tau \text{ and } s_i = \max_{j \in \tau}(s_j) \right\},$$
$$\hat{C}(S) = \sum_{i \in \hat{\tau}} w_i t_i (2d_i + 1).$$

$\hat{C}(S)$ is a restriction of $C(S)$ to the contribution of all jobs of the subset $\hat{\tau}$ in schedule S. As the order of all jobs $j \in \hat{\tau}$ in Q is arbitrary, there may be several different PSRS schedules S with different values of $\hat{C}(S)$ for a given job system τ.

Further, we consider $\tilde{C}^*(\hat{\tau})$, which is the lower bound of the optimal total weighted completion time for a job system consisting of only the jobs in $\hat{\tau}$.

With these notations, we can state the next lemma, which is closely related to Theorem 2 of Kawaguchi and Kyan's paper [8].

LEMMA 6.3 (Kawaguchi and Kyan). *If* $\frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})} \leq \lambda$ *holds for all job systems and PSRS schedules* S*, then* $\frac{C(S)}{\tilde{C}^*}$ *is also upper bounded by* λ.

This lemma allows us to assume that for the purpose of worst-case analysis, any job system consists only of some jobs with a modified Smith ratio of 1 while $s_j = 0$ holds for all other jobs j of the job system as s_j is only used in Algorithm PSRS to determine the order of Q. Note that this property is true for the job systems of Table 3. Although the proof can be directly derived from [8], it is restated here for the sake of completeness.

Proof. The proof is done by induction over the number k of different modified Smith ratios in a job system. The lemma clearly holds for $k = 1$.

Assume that the claim holds for all job systems with k different modified Smith ratios and that τ is a job system with $k+1$ different modified Smith ratios. We use $s_1 = \max_{j\in\tau}\{s_j\}$ and $s_2 = \max_{j\in\tau\setminus\hat{\tau}}\{s_j\}$ to denote the largest and the second largest modified Smith ratio values of τ, respectively. Further, we have $\frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})} \leq \lambda$.

We generate a job system τ' by modifying the weights of the jobs in τ as follows:

$$w_j \leftarrow \begin{cases} \frac{s_2}{s_1} w_j & \text{for } j \in \hat{\tau}, \\ w_j & \text{for } j \in \tau\setminus\hat{\tau}, \end{cases}$$

Note that any PSRS schedule $S(\tau)$ is also a PSRS schedule for τ' as any order of jobs in τ also can be applied to τ'. Based on our induction assumption, $\frac{C(S(\tau'))}{\tilde{C}^*(\tau')} \leq \lambda$ holds for such a schedule $S(\tau')$ as there are only k different modified Smith ratios in τ'.

As the difference between the total weighted completion times of schedule S for job systems τ and τ' is caused only by jobs in $\hat{\tau}$, we have

$$C(S(\tau)) - C(S(\tau')) = \left(1 - \frac{s_2}{s_1}\right)\hat{C}(S).$$

Further, note that the contribution of all jobs in $\hat{\tau}$ to $\tilde{C}^*(\tau)$ is at least $\tilde{C}^*(\hat{\tau})$. Therefore, we can state the following relationship between $\tilde{C}^*(\tau)$ and $\tilde{C}^*(\tau')$:

$$\tilde{C}^*(\tau) \geq \left(1 - \frac{s_2}{s_1}\right)\tilde{C}^*(\hat{\tau}) + \tilde{C}^*(\tau').$$

Combining those inequalities finally results in

$$\frac{C(S(\tau))}{\tilde{C}^*(\tau)} \leq \frac{C(S(\tau')) + (1 - \frac{s_2}{s_1})\hat{C}(S)}{\tilde{C}^*(\tau') + (1 - \frac{s_2}{s_1})\tilde{C}^*(\hat{\tau})} \leq \lambda \frac{\tilde{C}^*(\tau') + (1 - \frac{s_2}{s_1})\tilde{C}^*(\hat{\tau})}{\tilde{C}^*(\tau') + (1 - \frac{s_2}{s_1})\tilde{C}^*(\hat{\tau})} = \lambda. \qquad \square$$

However, jobs in $\tau\setminus\hat{\tau}$ may cause preemption and therefore indirectly affect $\hat{C}(S)$ by increasing the completion time of some jobs in $\hat{\tau}$; see, for instance, the type 4 jobs in the job systems of Table 3. As we are interested in this property only for jobs $j \in \tau\setminus\hat{\tau}$, we assume that $m_j = m$ holds for those jobs. To formally describe an upper bound for the influence of those jobs, we define the time t_b in a PSRS schedule to be

$$t_b = \min_{j\in\tau\setminus\hat{\tau}} \left\{ T\left(\frac{m}{2}\right)(j) \right\}.$$

t_b is a lower bound for the first time in a PSRS schedule at which a job $j \in \tau\backslash\hat{\tau}$ with $m_j = m$ may be scheduled. If $\tau = \hat{\tau}$ holds, then we simply add a job j with $w_j = 0$, $m_j = m$, and $p_j = 1$. This job cannot decrease $\hat{C}(S)$ while $\tilde{C}^*$ remains unchanged.

Therefore, $t_j(0) \leq t_b$ holds for all $j \in \hat{\tau}$, and any job $i \in \hat{\tau}$ with $t_i(2d_i + 1) < t_b + \frac{1}{v}$ is not preempted by any job $j \in \tau\backslash\hat{\tau}$ as we have $p_j \geq 1$. We use the set $\hat{\tau}_t = \{j \in \hat{\tau} | t_j(2d_j + 1) \geq t_b + \frac{1}{v}\}$ to describe those jobs whose completion time is delayed by jobs in $\tau\backslash\hat{\tau}$. Let $\check{p}_j$ be the remaining processing time of a job $j \in \hat{\tau}$ at time t_b in the PSRS schedule S. Then there can be at most $\lfloor v\check{p}_j \rfloor$ jobs with processing time 1 and a modified Smith ratio of 0 that preempt job j. Therefore, we have $t_j(2d_j + 1) \leq t_b + \check{p}_j(1 + v + vp)$. As we are interested only in the worst case, it is assumed from now on that $t_j(2d_j + 1) = t_b + \check{p}_j(1 + v + vp)$ holds for all jobs $j \in \hat{\tau}_t$. This allows us to ignore all jobs $j \in \tau\backslash\hat{\tau}$. Again note that the following properties hold in the job systems of Table 3:

(i) $t_b = k(\frac{1}{v} + 1 + p)$;
(ii) $\hat{\tau}_t$ consists of all type 3 jobs with $\check{p}_j = p_j$;
(iii) $t_j(2d_j + 1) = t_b + p_j(1 + v + vp)$ for all jobs $j \in \hat{\tau}_t$ and $k \to \infty$.

The rest of the proof of Theorem 6.2 is divided into three corollaries. As already mentioned, we repeatedly transform a job system τ into a new (more restricted) job system τ'. To distinguish between corresponding expressions of both systems we use the single quote character, for instance, schedule $S(\tau)$ for job system τ and another schedule $S'(\tau')$ for job system τ'.

Assume that a job system τ with $\frac{\hat{C}(S(\tau))}{\tilde{C}^*(\hat{\tau})} \geq \Delta > 0$ is transformed into a job system τ' such that $\hat{C}(S(\tau)) - \hat{C}(S'(\tau')) \leq \Delta(\tilde{C}^*(\hat{\tau}) - \tilde{C}^*(\hat{\tau}'))$ holds. Then we have

$$\frac{\hat{C}(S')}{\tilde{C}^*(\hat{\tau}')} = \frac{\hat{C}(S) - (\hat{C}(S) - \hat{C}(S'))}{\tilde{C}^*(\hat{\tau}')} \geq \frac{\hat{C}(S) - \Delta(\tilde{C}^*(\hat{\tau}) - \tilde{C}^*(\hat{\tau}'))}{\tilde{C}^*(\hat{\tau}')}$$
$$\geq \frac{\hat{C}(S) - \frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})}(\tilde{C}^*(\hat{\tau}) - \tilde{C}^*(\hat{\tau}'))}{\tilde{C}^*(\hat{\tau}')} = \frac{\hat{C}(S)\frac{\tilde{C}^*(\hat{\tau}')}{\tilde{C}^*(\hat{\tau})}}{\tilde{C}^*(\hat{\tau}')} = \frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})}.$$

For worst-case analysis, it is therefore sufficient to consider only job system τ' instead of both systems τ and τ'. We will repeatedly use this approach to restrict the number of those job systems which may generate a worst case.

In the following, we say that all jobs $j \in \tau$ with $m_j > \frac{m}{2}$ are *wide* jobs. In the first of the above mentioned three corollaries, we address those wide jobs.

COROLLARY 6.4. *Assume a job system τ with $\frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})} \geq 1 + \frac{1}{v} + p$ and a PSRS schedule $S(\tau)$. Then there is a job system τ' and a PSRS schedule $S'(\tau')$ with $\frac{\hat{C}(S'(\tau'))}{\tilde{C}^*(\hat{\tau}')} \geq \frac{\hat{C}(S(\tau))}{\tilde{C}^*(\hat{\tau})}$ such that for every job $j \in \hat{\tau}'$ with $m_j > \frac{m}{2}$*

1. *either we have $p_j = 1$ and j causes preemption in S',*
2. *or $(T(m_j))(j) = (T(\frac{m}{2}))(j)$ holds in Algorithm PSRS.*

Proof. We prove this corollary by using three different simple transformations that are described below.

1. *Time split of a wide job causing preemption.* A time split is a division of the job into several independent jobs with the same amount of parallelism. Assume a wide job $j \in \hat{\tau}$ with $p_j \geq 2$ that causes preemption in S. Then we have $t_j(1) = (T(\frac{m}{2}))(j) + (\frac{1}{v} + 1)p_j + p$. Remember that the completion time of job j has been increased by $\frac{p}{2}$.

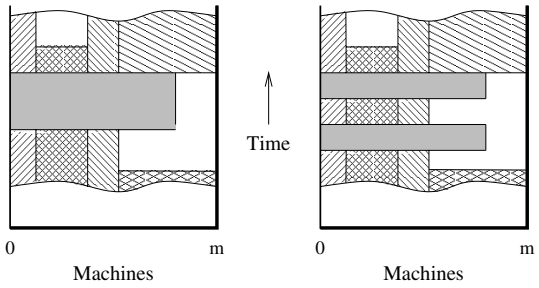

FIG. 3. *Time split of a job causing preemption ($p = 0$).*

We transform τ into τ' by replacing j in Q with two jobs j_1 and j_2 such that

$$m_{j_1} = m_{j_2} = m_j, \;\; s_{j_1} = s_{j_2} = s_j = 1, \;\; p_{j_1} = 1, \;\; \text{and} \;\; p_{j_2} = p_j - 1 \;\; \text{holds.}$$

S' is the result of applying Algorithm PSRS on job system τ' with the new list Q'. Note that S and S' are identical until time $(T(\frac{m}{2}))(j)$ and that both jobs j_1 and j_2 will cause preemption in S'. The completion times of jobs j_1 and j_2 in S' are given below:

$$t'_{j_1}(1) = \left(T'\left(\frac{m}{2}\right)\right)(j_1) + \frac{1}{v} + 1 + p = \left(T\left(\frac{m}{2}\right)\right)(j) + \frac{1}{v} + 1 + p$$

and

$$t'_{j_2}(1) = t_j(1) + p.$$

Further, no job in $\tau \cap \tau'$ can complete earlier in S' than it does in S; that is, $t_i(2d_i + 1) \le t'_i(2d'_i + 1)$ holds for all jobs $i \in \tau \cap \tau'$ (see also Figure 3). This results in

$$\begin{aligned}\hat{C}(S) - \hat{C}(S') &\le m_j p_j t_j(1) - m_{j_1} p_{j_1} t'_{j_1}(1) - m_{j_2} p_{j_2} t'_{j_2}(1) \\ &= m_j(p_j - 1)\left(\frac{1}{v} + 1 - p\right) \le m_j(p_j - 1)\left(\frac{1}{v} + 1 + p\right).\end{aligned}$$

It is easy to see that a valid schedule for τ' can be obtained from any valid schedule for τ by replacing job j with jobs j_1 and j_2. With $\check{t}_j$ denoting the completion time of job j in the optimal schedule for τ, we have

$$\tilde{C}^*(\hat{\tau}) - \tilde{C}^*(\hat{\tau'}) \ge m_j p_j \check{t}_j - m_{j_2} p_{j_2} \check{t}_j - m_{j_1} p_{j_1}(\check{t}_j - p_{j_2}) = m_j(p_j - 1).$$

Together with the remarks above, this yields

$$\frac{\hat{C}(S')}{\tilde{C}^*(\hat{\tau'})} \ge \frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})} \ge 1 + \frac{1}{v} + p.$$

2. *Scaling.* Next, a job system τ is transformed into τ'' by replacing each job $i \in \tau$ with job $j \in \tau''$ such that we have

$$m_j = m_i, \;\; p_j = a p_i, \;\; \text{and} \;\; w_j = a w_i$$

using a positive integer a. This results in $\frac{\hat{C}(S'')}{\tilde{C}^*(\hat{\tau''})} = \frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})}$ if $p = 0$ holds. Then we obtain τ' from τ'' by repeatedly applying the previous time splitting step to all jobs

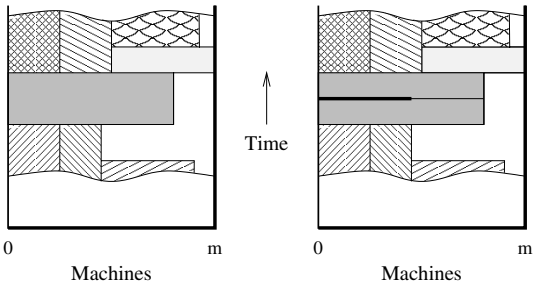

FIG. 4. *Time split of a wide job not causing preemption ($p = 0$).*

$j \in \tau''$ if those jobs cause preemption and have $p_j \geq 2$. Note that if a job $i \in \hat{\tau}$ is preempted k-times in schedule S, then the corresponding job $j \in \hat{\tau}'$ is preempted at least ak-times in S'. Also remember that $t_i(2d_i + 1) = t_b + \check{p}_i(1 + v + vp)$ holds for all jobs $i \in \hat{\tau}_t$. The same is true for all jobs $i \in \hat{\tau}'_t$. This scaling procedure will therefore result in $\hat{C}(S') \geq a\hat{C}(S)$, $\tilde{C}^*(\hat{\tau}') = a\tilde{C}^*(\hat{\tau})$, and in

$$\frac{\hat{C}(S')}{\tilde{C}^*(\hat{\tau}')} \geq \frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})} \geq 1 + \frac{1}{v} + p,$$

even if p is positive.

If all p_i are rational numbers, then a can be selected such that $p_j = 1$ holds for all jobs $j \in \hat{\tau}'$ that cause preemption in S'. As scaling will not decrease the ratio $\frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})}$, we can assume $k \to \infty$ and that $p_j = 1$ holds for every preemption-causing job j. These properties are valid for the job systems of Table 3.

3. *Time split of a wide job not causing preemption.* Assume a job $i \in \hat{\tau}$ with $m_i > \frac{m}{2}$ such that we have $(T(m_i))(i) - (T(\frac{m}{2}))(i) > 0$ and $\frac{p_i}{v} > (T(m_i))(i) - (T(\frac{m}{2}))(i)$ in Algorithm PSRS; that is, i does not cause preemption in schedule S. Now, job system τ is transformed into τ' by replacing i in Q with two jobs i_1 and i_2 such that $m_{i_1} = m_{i_2} = m_i$, $s_{i_1} = s_{i_2} = s_i = 1$, $p_{i_1} = v((T(m_i))(i) - (T(\frac{m}{2}))(i))$, and $p_{i_2} = p_i - p_{i_1}$ hold.

If we have $p_{i_1} < 1$ or $p_{i_2} < 1$, then the job system is appropriately scaled as described above. In S', job i_1 now causes preemption while $(T'(m_{i_2}))(i_2) = (T'(\frac{m}{2}))(i_2)$ holds for job i_2 in Algorithm PSRS; see Figure 4. Therefore, we have $t'_{i_2}(1) = t_i(1) + p$ and $t'_{i_1}(1) = t_i(1) - p_{i_2} + p$.

This results in

$$\begin{aligned}\hat{C}(S) - \hat{C}(S') &\leq m_i p_i t_i(1) - m_{i_1} p_{i_1} t'_{i_1}(1) - m_{i_2} p_{i_2} t'_{i_2}(1) \\ &= m_i(p_{i_1} p_{i_2} - p_{i_1} p - p_{i_2} p) \leq m_i p_{i_1} p_{i_2} \left(\frac{1}{v} + 1 + p\right) \quad \text{and} \\ \tilde{C}^*(\hat{\tau}) - \tilde{C}^*(\hat{\tau}') &\geq m_i p_{i_1} p_{i_2}. \qquad \square\end{aligned}$$

Note that Corollary 6.4 is valid for any p.

Now, we describe the properties of our next target job system. There are only wide and sequential jobs in this job system. All jobs in $\hat{\tau}_t$ start at the same time after the other jobs in $\hat{\tau}$ have completed. All other sequential jobs ($m_j = 1$) in $\hat{\tau}$ are preempted exactly once and have a remaining processing time of 0 when their execution is resumed. Finally, each wide job $j \in \hat{\tau}$ preempts $m - m_j$ sequential jobs;

that is, as many machines as possible are left idle. Again, all these properties are valid for the job systems of Table 3 if those additional k type 1 jobs are ignored in the PSRS schedule as discussed before.

COROLLARY 6.5. *Assume a job system τ with $\frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})} \geq 1 + \frac{1}{v} + p$ and a PSRS schedule S. Then there is another job system τ' and a PSRS schedule S' such that $\frac{\hat{C}(S')}{\tilde{C}^*(\hat{\tau}')} \geq \frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})}$ and the following properties hold:*

(i) *$m_i \geq \lceil \frac{m}{2} \rceil$ or $m_i = 1$ for all jobs $i \in \hat{\tau}'$;*
(ii) *$t'_i(0) = t'_b$ for all jobs $i \in \hat{\tau}'_t$ in S';*
(iii) *$p_i = \frac{1}{v}$ and $d'_i = 1$ for all jobs $i \in \hat{\tau}' \backslash \hat{\tau}'_t$ with $m_i = 1$;*
(iv) *$m - m_j$ jobs are preempted by any job $j \in \hat{\tau}'$ with $m_j \geq \lceil \frac{m}{2} \rceil$ in S.*

Proof. Again we use several simple transformations to prove this corollary.

1. *Time split after preemption.* In this part, we apply time splitting to all jobs that are preempted and have more than 0 processing time left when their execution is resumed. To this end, let $i \in \hat{\tau}$ be a job with $m_i \leq \frac{m}{2}$ and $t_i(2d_i + 1) > t_i(2d_i)$ that is preempted at least once by a job in $\hat{\tau}$ in PSRS schedule S. Then schedule S and job system τ are transformed into schedule S' and job system τ' by replacing i in S with two jobs i_1 and i_2 such that $m_{i_1} = m_{i_2} = m_i$, $s_{i_1} = s_{i_2} = s_i = 1$, $p_{i_1} = t_i(1) - t_i(0)$, $p_{i_2} = p_i - p_{i_1}$, $d'_{i_1} = 1$, $d'_{i_2} = d_i - 1$, $t'_{i_1}(\mu) = t_i(\mu)$ for $0 \leq \mu \leq 2$, $t'_{i_1}(3) = t_i(2)$, and $t'_{i_2}(\mu - 2) = t_i(\mu)$ for $2 \leq \mu \leq 2d_i + 1$ hold.

Note that job i is split in S at the time when its execution is resumed after its first preemption. A temporary violation of the minimal execution time condition for job i_2 always can be removed by use of the scaling procedure of Corollary 6.4. This is also true for other parts of this proof.

For this time splitting of job i, the condition $t'_{i_2}(2d'_{i_2} + 1) - t'_{i_2}(0) \leq p_{i_2}(1 + v + vp)$ holds, and the completion time of no other job is affected. Therefore, we have

$$\begin{aligned}
\hat{C}(S) - \hat{C}(S') &\leq m_i p_i t_i(2d_i + 1) - m_{i_2} p_{i_2} t'_{i_2}(2d'_{i_2} + 1) - m_{i_1} p_{i_1} t'_{i_1}(2d'_{i_1} + 1) \\
&= m_i p_{i_1}(t'_{i_2}(2d'_{i_2} + 1) - t'_{i_2}(0)) \\
&\leq m_i p_{i_1} p_{i_2}(1 + v + vp) \\
&\leq m_i p_{i_1} p_{i_2} \left(1 + \frac{1}{v} + p\right) \quad \text{and} \\
\tilde{C}^*(\hat{\tau}) - \tilde{C}^*(\hat{\tau}') &\geq m_i p_{i_1} p_{i_2}.
\end{aligned}$$

To generate PSRS schedule S' for τ', we simply construct Q' from Q by replacing i with i_1 and introducing i_2 just after the job j, which causes preemption of i_1 in S'. This is possible as $s_j = 1$ holds.

The repeated application of this procedure in combination with the proper scaling will assure that each job i in $\hat{\tau}' \backslash \hat{\tau}'_t$ with $m_i \leq \frac{m}{2}$ is preempted at most once and that it will complete immediately when its execution is resumed. Further, no job in $\hat{\tau}_t$ is preempted by any job in $\hat{\tau}$.

2. *Machine split after a preemption.* The division of a parallel job into several independent jobs with the same processing time and the same modified Smith ratio is called a machine split of this job.

If a job $i \in \hat{\tau}$ starts in schedule S at time 0 or at the same time that a preemption-causing job completes, we replace i with m_i identical jobs j such that $m_j = 1$, $p_j = p_i$, and $s_i = s_j = 1$ hold. Note that we have $t_s(i) = t_i(0)$. Therefore, none of the m_i newly generated sequential jobs can start before $t_i(0)$ in PSRS schedule S'. Hence, this transformation does not affect the cost of the PSRS schedule and results in $\hat{C}(S) - \hat{C}(S') = 0 \leq \tilde{C}^*(\hat{\tau}) - \tilde{C}^*(\hat{\tau}')$.

3. *Removal of sequential jobs.* Next, we transform τ into τ' by removing a sequential job $i \in \hat{\tau} \backslash \hat{\tau}_t$, if this procedure does not decrease the completion time of any other job and if there is a (preemption-causing) wide job $j \in \hat{\tau}$ with $t_i(2d_i+1) \leq t_j(1)$. Note that after the removal of job i, a combined machine-time product of at least $\frac{mt_j(1)}{1+\frac{1}{v}+p}$ is still used for the execution of all jobs in $\hat{\tau} \backslash \hat{\tau}_t$ that complete no later than $t_j(1)$ in S'; see step 1 of this proof and the proof of Theorem 6.1. As already mentioned, we assume that the makespan is the same for all machines executing more than one sequential job in the schedule producing $\tilde{C}^*(\hat{\tau}')$. Therefore, this makespan is at least $\frac{t_j(1)}{1+\frac{1}{v}+p}$. With $k \to \infty$, this results in

$$\hat{C}(S) - \hat{C}(S') \leq p_i t_j(1)$$

and

$$\tilde{C}^*(\hat{\tau}) - \tilde{C}^*(\hat{\tau}') \geq \frac{1}{2m}\left(\frac{mt_j(1)}{1+\frac{1}{v}+p} + p_i\right)^2 - \frac{1}{2}\left(\frac{t_j(1)}{1+\frac{1}{v}+p}\right)^2 \geq p_i \frac{t_j(1)}{1+\frac{1}{v}+p}.$$

If a job $j \in \hat{\tau}$ preempts n sequential jobs, then we transform τ into τ' with the help of steps 1 and 3 by removing $n + m_j - m$ of these sequential jobs. This will not affect the completion time of any other job.

4. *Increase of the preemption ratio.* Next, we address those time intervals of the schedule where preemption occurs less frequently. Intuitively, it seems obvious that these intervals cannot contribute to a worst case as there the ratio of busy machines to idle machines is not worse than in intervals with more preemption. To prove this, we consider a time interval $T = [t_a, t_e)$ that starts either at 0 or at $t_{j_1}(1) < t_b$ with $j_1 \in \hat{\tau}$ being a preemption-causing job. Let j_2 be the first job in $\hat{\tau}$ that completes after time t_a in S. We define $t_e = t_{j_2}(2d_{j_2} + 1)$ and consider those cases where job j_2 does not cause preemption and cannot be removed using step 2.

Let $i_1, \ldots, i_n$ be the jobs which start at time t_a in schedule S. As shown in step 2 of this proof, we can assume that all these jobs are sequential. Note that there are more than $\frac{m}{2}$ of those jobs and all of them do not complete before time t_e.

Now, we perform several transformations with jobs $i_1, \ldots, i_n$ in order to introduce preemption in T. Remember that we can always apply the scaling procedure to avoid any problems with the minimum processing time.

(i) Every job i_μ with $t_{i_\mu}(1) > t_e$ is split at time t_e using the previously described method. The descendant of job i_μ that starts at time t_a replaces job i_μ in Q'. Now, all jobs that are executed in T start at time t_a and complete at time t_e. Note that the resulting schedule will probably not be a PSRS schedule.

(ii) We use scaling with a factor a and time splitting to obtain b groups of $\lfloor \frac{m}{2} \rfloor$ jobs with processing time $\frac{1}{v}$ and b groups of $\lceil \frac{m}{2} \rceil$ jobs with processing time 1 such that the combined processing time of all those jobs is equivalent to $a(t_e - t_a)n$. In schedule S'', we arrange those jobs such that all jobs of a group are executed concurrently and one group with processing time $\frac{1}{v}$ is immediately followed by one group with processing time 1. For the resulting job system τ'' and schedule S'', we have $\frac{\hat{C}(S'')}{\tilde{C}^*(\hat{\tau}'')} \geq \frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})}$.

(iii) Next, we combine each group with processing time 1 into a single wide job to generate job system τ'. Note that we still have $\tilde{C}^*(\hat{\tau}') = \tilde{C}^*(\hat{\tau}'')$.

(iv) Finally, we arrange Q' such that the original jobs, executing in T, are replaced by a repeated sequence of $\lfloor \frac{m}{2} \rfloor$ sequential jobs always followed by one wide

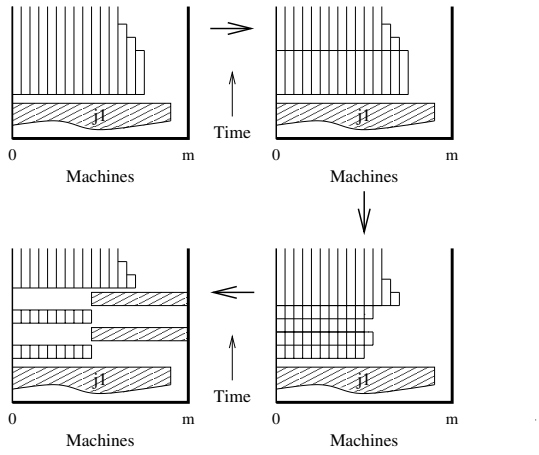

FIG. 5. *Increase of the preemption ratio.*

TABLE 4
Source (top) and target (bottom) job system for the special case.

p_i	m_i	s_i	Number of jobs
g	1	1	$\frac{m}{2}$
$b-a$	1	1	$\frac{m}{2}$
1	$\frac{m}{2}$	1	a

p_i	m_i	s_i	Number of jobs
$d-c$	1	1	m'
1	$m-m'$	1	$e-c$
1	m	1	c

job. These jobs are introduced into Q' before the other descendants of jobs $i_1, \ldots, i_n$. This produces PSRS schedule S'. The completion time of no job completing after at_e in schedule S'' is decreased. Therefore, we have $C(S') \geq C(S'')$.

These steps are also described in Figure 5. Due to this transformation, we can assume that each job $i \in \hat{\tau}_t$ starts at time t_b.

The proof of Corollary 6.5 results from the combination of those four steps. ∎

To complete the proof of Theorem 6.2, we must address the processing times of the jobs in $\hat{\tau}_t$ and the machine requirements of all preemption-causing jobs.

We start by looking at the special case described in Figure 6. There, we transform the source job system into the target system in Table 4 with m' not necessarily being an integer. Further, we assume that $g > b > a \gg 1$ holds. This can always be achieved by scaling; see Corollary 6.4. Optimal schedules for both systems are given in Figure 6. In addition, we consider separate optimal schedules for the sequential jobs only and require that the machine-time product and the total weighted completion time remain invariant for both systems; that is, we have

$$(g+b-a)\frac{m}{2} = (d-c)m' \text{ and } (g^2+(b-a)^2)\frac{m}{2} = (d-c)^2 m'.$$

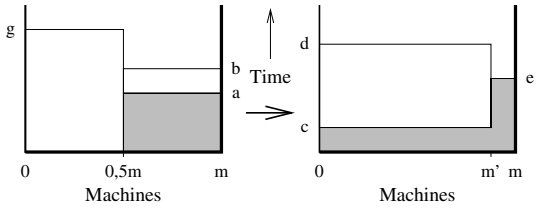

FIG. 6. *Source (left) and target (right) optimal schedules for the special case.*

The same must be valid for the parallel jobs in the schedules of Figure 6; that is,

$$a\frac{m}{2} = cm' + e(m-m') \text{ and } \frac{1}{2}a^2\frac{m}{2} = \frac{1}{2}(c^2m' + e^2(m-m')) \text{ hold.}$$

There are four equations to determine the four variables m', c, d, and e. Solving this system of equations results in

$$m' = \frac{m}{2}\frac{(g+b-a)^2}{g^2+(b-a)^2},\quad c = \frac{a(b-a)}{g+b-a},\quad d = c + \frac{g^2+(b-a)^2}{g+b-a},\quad e = \frac{ag}{g-b+a}.$$

There is no difference in the total weighted completion time of both schedules, as we have

$$a(b-a)\frac{m}{2} = c(d-c)m'.$$

Intuitively, we can therefore state that for $m \to \infty$, a job system containing m sequential jobs with two different processing times always can be transformed into a job system where all sequential jobs have the same processing time and the same total weighted completion times, and the total machine-time products of the optimal schedules remain invariant. This transformation can be applied repeatedly to handle job systems where several different processing times exist for the m sequential jobs. With this result, we are ready to prove the next corollary.

COROLLARY 6.6. *Assume a job system τ as described in Corollaries* 6.4 *and* 6.5 *with $\frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})} > 1 + \frac{1}{v} + p$ and a PSRS schedule S. Then there is another job system τ' and a PSRS schedule S' such that $\frac{\hat{C}(S')}{\tilde{C}^*(\hat{\tau}')} \geq \frac{\hat{C}(S)}{\tilde{C}^*(\hat{\tau})}$ and the following properties in addition to those of Corollaries* 6.4 *and* 6.5 *hold:*

(i) $p_i = p_j$ *for all jobs* $i, j \in \hat{\tau}'_t$;
(ii) $m_i = m - |\hat{\tau}'_t|$ *for all wide jobs* $i \in \hat{\tau}'$.

Finally, the job systems described by this corollary are the job systems of Table 3 if the additional k type 1 jobs are ignored in the PSRS schedule.

Proof. Using our lower bound approximations, the optimal schedule for job system $\hat{\tau}$ can be described by the top left schedule in Figure 7 where all jobs in $\hat{\tau}_t$ are shaded. Consider a machine with a larger makespan than the minimal makespan for all machines in this schedule. Such a machine executes a single job $j \in \hat{\tau}_t$ and possibly some parallel jobs from $\hat{\tau}$. We group all those machines such that the same number of parallel jobs is executed on each machine of a group and the sequential jobs on these machines have the same processing time.

We choose two groups and pick $\bar{m}$ machines from each group. $\bar{m}$ need not be an integer. The special case is applied to these $2\bar{m}$ machines. Note that it is not necessary

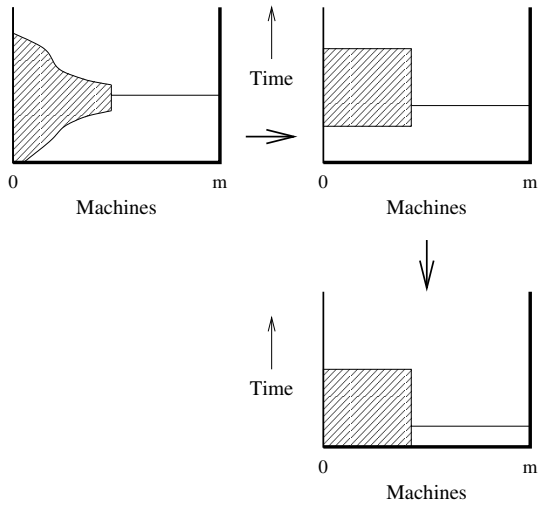

FIG. 7. *Transformation of* $\hat{\tau}'$.

to consider the parallel jobs that are executed on each of these $2\bar{m}$ machines. This procedure is applied repeatedly until we obtain the job system τ'' and the optimal schedule given by the top right schedule of Figure 7. The special case does not change the combined machine-time product of all parallel jobs together. However, as we have $e > a$ in the special case, it is necessary to combine some of the resulting jobs in order to generate parallel jobs, that is, to guarantee that in the optimal schedule, no parallel job is executed concurrently with any sequential job in $\hat{\tau}''\backslash\hat{\tau}''_t$. The processing time 1 for all parallel jobs can be achieved by using scaling and splitting; see the proof of Corollary 6.4.

Without taking into account any scaling, we have $\tilde{C}^*(\hat{\tau}) \geq \tilde{C}^*(\hat{\tau}'')$ as the number of machines not executing any job in $\hat{\tau}''_t$ is increased by the transformation, and their makespan is balanced.

The PSRS schedule S'' is obtained by ordering all parallel jobs $i, j \in \hat{\tau}''$ such that i precedes j in Q if $m_i > m_j$ holds, and arranging the sequential jobs in $\hat{\tau}''\backslash\hat{\tau}''_t$ accordingly to fit the conditions of Corollary 6.5. Therefore, S is transformed into S'' by repeatedly exchanging a sequential job $i \in \hat{\tau}\backslash\hat{\tau}_t$ of processing time $\frac{1}{v}$ with a part of a parallel job $j \in \hat{\tau}$ with processing time 1 and $t_i(3) < t_j(1)$ in S. As we have $v \leq 1$, this results in $\hat{C}(S) \leq \hat{C}(S'')$.

If there is any $j \in \hat{\tau}''$ with $m_j = m$, then we can assume that this job completes first in S''. Remember that this job will preempt a single sequential job i. However, this job i is ignored in our analysis. Next, we remove j. The repeated application of this procedure leads to job system $\hat{\tau}'$ and schedule S' as shown on the bottom of Figure 7. The removal of job j results in

$$\hat{C}(S'') - \hat{C}(S') = \left(1 + \frac{1}{v} + p\right) \sum_{i \in \hat{\tau}''} w_i$$

and

$$\tilde{C}^*(\hat{\tau}'') - \tilde{C}^*(\hat{\tau}') = \sum_{i \in \hat{\tau}''} w_i.$$

Finally, if there is any wide job i with $m_i < |\hat{\tau}_t|$, then we create a new job system τ' by enlarging i to i' with $m_{i'} = |\hat{\tau}_t|$ and by removing $|\hat{\tau}_t| - m_i$ of the sequential jobs preempted by i in S. As $v \leq 1$ holds, this procedure is similar to the removal of a sequential job; see step 3 in the proof of Corollary 6.5. Note that increasing the parallelism of any job up to $|\hat{\tau}_t|$ does not constrain the optimal schedule. □

The proof of Corollary 6.6 also concludes the proof of Theorem 6.2.

To obtain the minimal value $f_C(0) = 2.366$, we choose $v = 0.836$, $x = 0.183m$, and $y = 2$. Note that we have $f_C(0) > \frac{1}{v} + 1 = 2.196$.

7. Nonpreemptive scheduling. Preemptive schedules are sometimes used to construct nonpreemptive ones with good performance; see Phillips, Stein, and Wein [10] and Chekuri et al. [4]. As PSRS schedules have a good approximation factor compared to the best nonpreemptive methods, they are a good candidate for this approach. In addition, a PSRS schedule is a simple interleave of two nonpreemptive schedules which can easily be separated. Therefore, we address the transformation of a PSRS schedule into a nonpreemptive schedule in this section.

For the purpose of this transformation, we use the case $p = 0$. Further, $\tau_p(S)$ denotes the set of jobs that preempt at least one other job in a given PSRS schedule S. Remember that no job $i \in \tau \backslash \tau_p(S)$ is executed concurrently with any job in $\tau_p(S)$ in schedule S. Formally, we can therefore state that

$$t_i(2d_i + 1) \geq p_i + \sum_{j \in \tau_P(S) \wedge t_j(1) < t_i(2d_i+1)} p_j.$$

The transformation algorithm is given in Table 5. All schedule data used in this algorithm, like $t_i(2d_i + 1)$, refer to the PSRS schedule S. Intuitively, the algorithm generates two sequences of time frames, each of which covers the whole schedule. The time frames of each sequence increase in size with their position in the sequence. The second frame of the second sequence may be the only exception to this rule. The second sequence is related to all jobs in $\tau_p(S)$ while the first sequence covers all other jobs in τ. Finally, a nonpreemptive schedule is generated by interleaving both sequences and determining a new list of jobs. The order of this list is based on the time frame in which a job completes. For jobs completing in the same time frame, the order of the original priority list Q is used. Schedule S' depends on two parameters $\alpha > 1$ and $\Delta < 1$, which describe the rate of frame length increase and the offset between the time frames of different sequences, respectively. The algorithm further uses n as an iteration counter and the variables l_1, l_2, l_3, and l_4 to denote the bounds of the actual time frames. The transformation algorithm has the same time complexity as Algorithm PSRS.

For the construction of the nonpreemptive list schedule, it is important to remember that removing any job from the priority list in such a list schedule cannot increase the completion time of any other job in the schedule.

To evaluate the resulting nonpreemptive schedule S', we first determine the makespan of the schedule after iteration n.

COROLLARY 7.1. *After execution of iteration n of the transformation algorithm, the makespan of this part of the nonpreemptive schedule is upper bounded by*

$$\begin{aligned}\sum_{\mu=0}^{n} \sum_{\nu=0}^{\mu} \alpha^{\nu} + c_1 + c_2 - c_3 &= \sum_{\mu=0}^{n} \frac{\alpha^{\mu+1} - 1}{\alpha - 1} + c_1 + c_2 - c_3 \\ &= \frac{\alpha^{n+2} - \alpha - (n+1)(\alpha - 1)}{(\alpha - 1)^2} + c_1 + c_2 - c_3\end{aligned}$$

TABLE 5
Nonpreemptive transformation of a PSRS schedule.

```
Generate a PSRS schedule S for a job system τ and a priority list Q;
n = 0;
l_1 = 0;
l_3 = 0;
while (l_1 < max_{i∈τ} t_i(2d_i + 1)){
        l_2 = l_1 + α^n;
        list schedule all jobs i ∈ τ\τ_p(S) with l_1 < t_i(2d_i + 1) ≤ l_2 in the order given by Q;
        l_1 = l_2;
        l_4 = l_2 + Δα^{n+1};
        list schedule all jobs i ∈ τ_p(S) with l_3 < t_i(2d_i + 1) ≤ l_4 in the order given by Q;
        l_3 = l_4;
        n = n + 1;
}
```

with

(i) $c_1 = t_i(1) - l_2$ *for* $i \in \tau_p(S)$ *and* $t_i(0) < l_2 < t_i(1) \le l_4$,
(ii) $c_2 = \sum p_i$ *with* $i \in \tau_p(S)$ *and* $l_2 \le t_i(0) < t_i(1) \le l_4$, *and*
(iii) $c_3 = l_2 - t_i(0)$ *for* $i \in \tau_p(S)$ *and* $t_i(0) < l_2 < l_4 < t_i(1)$.

Note that for jobs from $\tau_p(S)$, the processing time, which falls into the time interval $[0, l_2]$, is considered in the double sum term. Therefore, the correction terms c_1 and c_2 are used for jobs from $\tau_p(S)$ that complete after l_2 but before l_4. Hence, they are scheduled in iteration n. The correction term c_3 addresses a job from $\tau_p(S)$ that starts before l_2 and finishes after l_4. Therefore, it is not yet scheduled but considered in the double sum term. Of course, if we have $c_3 \neq 0$, then $c_1 = c_2 = 0$ must hold.

Proof. The proof is done by induction over the iteration index n. The claim clearly holds for $n = 0$. Assume that it is also true for some n. In the next iteration, the first sequence will cover S up to time $l_2 = \sum_{\mu=0}^{n+1} \alpha^\mu = \frac{\alpha^{n+2}-1}{\alpha-1}$. Here l_1, l_2, l_3, and l_4 denote the bounds of the frames in this iteration $n + 1$.

For the makespan $\bar{C}_{\max}$ of a list schedule of all jobs j in $\tau_{n+1} = \{j \in \tau\backslash\tau_p(S) | l_1 < t_j(2d_j + 1) \le l_2\}$ with the order of Q, we have

$$\bar{C}_{\max} \le \max_{j \in \tau_{n+1}} \{t_j(2d_j + 1)\} - \sum_{i \in \tau_p(S) \wedge t_i(1) \le t_j(2d_j+1)} p_i$$

due to our observation above. Note that setting $\max_{j\in\tau_{n+1}}\{t_j(2d_j + 1)\} = l_2$ includes the processing time of all jobs from $\tau_p(S)$ that complete in the time interval $[0, l_2]$. Considering the jobs in $\tau_p(S)$ with $l_2 < t_i(1)$ and $t_i(0) < l_4$ completes the proof. ∎

Now, we give a bound on the completion time $t'_i(1)$ of job $i \in \tau\backslash\tau_p(S)$ in the nonpreemptive schedule S'. To this end, we assume that i is scheduled in iteration n; that is, $l_1 = \sum_{\mu=0}^{n-1} \alpha^\mu < t_i(2d_i + 1) \le \sum_{\mu=0}^{n} \alpha^\mu = l_2$ holds.

For $n = 0$, it is easy to see that we have $t'_i(1) \le t_i(2d_i + 1)$. In all other cases, there is

$$\begin{aligned}\frac{t'_i(1)}{t_i(2d_i+1)} &\le \frac{t_i(2d_i+1) + \sum_{\mu=0}^{n-1} \frac{\alpha^{\mu+1}-1}{\alpha-1} + c_1 + c_2 - c_3}{t_i(2d_i+1)} \\ &\le 1 + \frac{\sum_{\mu=0}^{n-1} \frac{\alpha^{\mu+1}-1}{\alpha-1} + \Delta\alpha^n}{\sum_{\mu=0}^{n-1} \alpha^\mu}\end{aligned}$$

$$= 1 + \frac{\alpha}{\alpha - 1} + \frac{\Delta(\alpha - 1)\alpha^n - n}{\alpha^n - 1}$$
$$\leq 1 + \frac{\alpha}{\alpha - 1} + \Delta(\alpha - 1) \quad \text{for } \Delta(\alpha - 1) \leq n.$$

Similarly, a bound on the completion time $t'_i(1)$ in S' is calculated for any job $i \in \tau_p(S)$. Again, it is assumed that i is scheduled in iteration n with $l_3 = \sum_{\mu=0}^{n-1} \alpha^\mu + \Delta\alpha^n < t_i(1) \leq \sum_{\mu=0}^{n} \alpha^\mu + \Delta\alpha^{n+1} = l_4$. Remember that for all jobs from $\tau \backslash \tau_p(S)$, the processing time, which falls into the time interval $[0, l_2]$ in schedule S, is already included in the term $\sum_{\mu=0}^{n} \frac{\alpha^{\mu+1}-1}{\alpha-1}$.

For $n = 0$, there is $\frac{t'_i(1)}{t_i(1)} \leq \frac{1+\Delta\alpha}{1+\frac{1}{v}}$. In the general case, we have

$$\begin{aligned}
\frac{t'_i(1)}{t_i(1)} &\leq \frac{\max\{0, t_i(1) - l_2\} + \sum_{\mu=0}^{n} \frac{\alpha^{\mu+1}-1}{\alpha-1}}{t_i(1)} \\
&\leq \frac{\sum_{\mu=0}^{n} \frac{\alpha^{\mu+1}-1}{\alpha-1}}{\sum_{\mu=0}^{n-1} \alpha^\mu + \Delta\alpha^n} \\
&= \frac{\alpha^{n+2} - 1 - (\alpha - 1)(n + 2)}{(\alpha - 1)(\alpha^n - 1 + \Delta\alpha^n(\alpha - 1))} \\
&\leq \frac{\alpha^2}{(\alpha - 1)(1 + \Delta(\alpha - 1))} \quad \text{for } \alpha + 1 - \Delta \leq (1 + \Delta(\alpha - 1))(n + 2).
\end{aligned}$$

Therefore, we can derive the following performance guarantee for the nonpreemptive schedule.

THEOREM 7.2. *If* $\Delta(\alpha - 1) \leq 1$, $\alpha + 1 - \Delta \leq 3(1 + \Delta(\alpha - 1))$, *and* $\frac{1+\Delta\alpha}{1+\frac{1}{v}} \leq \frac{\alpha^2}{(\alpha-1)(1+\Delta(\alpha-1))}$ *hold, then the transformation of a PSRS schedule* S *into a nonpreemptive schedule* S' *guarantees*

$$\frac{C(S')}{C^*} \leq \max\left\{1 + \frac{\alpha}{\alpha - 1} + \Delta(\alpha - 1), \frac{\alpha^2}{(\alpha - 1)(1 + \Delta(\alpha - 1))}\right\} f_c(0).$$

Proof. The proof is a direct consequence of the statements made above. ∎

For $\Delta = 0.25$ and $\alpha = 3$, we obtain $\frac{C(S')}{C^*} \leq 3 \times 2.37 = 7.11$. The validity of the additional conditions of Theorem 7.2 can easily be checked. Similarly, a makespan performance guarantee can be determined from the proof of Theorem 7.2.

8. Conclusion. First, we addressed bicriteria scheduling of parallel jobs in general and gave a few new results. Then we presented an algorithm that generates preemptive offline schedules for parallel and independent jobs with fixed resource requirements. This algorithm is obtained by combining two algorithms with good performance for restricted input sets. The schedule is based on a priority list and has small approximation factors for both total weighted completion time and makespan criteria. It does not require job migration. The method belongs to the class of list scheduling algorithms. It is carefully analyzed and a tight worst-case approximation factor is determined. Moreover, the analysis provides information about the structure of "bad cases." Also, we derived a numerical optimization problem which can be used to fine-tune the total weighted completion time approximation factor. Finally, we transformed the preemptive schedules into nonpreemptive ones with a better bound for total weighted completion time than those obtained by previously known methods.

TABLE 6
Comparison between various scheduling methods.

Schedule	Type	$\frac{C(S)}{C^*}$	$\frac{C_{\max}(S)}{C^*_{\max}}$
SMART	nonpreemptive	8.53	5.19
SMART	nonpreemptive	9	5
PSRS	nonpreemptive	7.11	9.60
PSRS	nonpreemptive	7.26	9.00
PSRS with $p = 0$	preemptive	2.37	3.20
PSRS with $p = 0$	preemptive	2.42	3
PSRS with $p = 1$	preemptive	3.41	4.31
PSRS with $p = 1$	preemptive	3.61	4

The generated schedules are based upon our machine model which is derived from existing parallel computers. To our knowledge, it is also the first time that a preemption penalty is considered in the analysis of such an algorithm. Compared with nonpreemptive SMART schedules, our approximation factors are significantly better, even if we assume that a context switch is as time consuming as the minimal completion time of a job including loading the job and storing its results, that is, if $p = 1$ holds. As shown in Table 6, PSRS and SMART schedules can be fine-tuned to minimize either $\frac{C(S)}{C^*}$ or $\frac{C_{\max}(S)}{C^*_{\max}}$.

PSRS schedules have the additional advantage that they use preemption only for jobs which require at most 50% of the nodes. Even in this case, there are at most two jobs resident on any node at the same time. Moreover, PSRS schedules only need global preemption which may be easier to implement than other forms of gang scheduling with respect to running messages in the interconnection network.

Acknowledgments. The author is grateful to Joel Wein for a helpful discussion on bicriteria scheduling. The author would also like to thank the anonymous referees for their helpful remarks.

ALGEBRAIC PROPERTIES FOR SELECTOR FUNCTIONS*

LANE A. HEMASPAANDRA†, HARALD HEMPEL‡, AND ARFST NICKELSEN§

Abstract. The *nondeterministic* advice complexity of the P-selective sets is known to be exactly linear. Regarding the *deterministic* advice complexity of the P-selective sets—i.e., the amount of Karp–Lipton advice needed for polynomial-time machines to recognize them in general—the best current upper bound is quadratic [K. Ko, *J. Comput. System Sci.*, 26 (1983), pp. 209–221] and the best current lower bound is linear [L. Hemaspaandra and L. Torenvliet, *Theoret. Comput. Sci.*, 154 (1996), pp. 367–377].

We prove that every associatively P-selective set is commutatively, associatively P-selective. Using this, we establish an algebraic sufficient condition for the P-selective sets to have a linear upper bound (which thus would match the existing lower bound) on their deterministic advice complexity: If all P-selective sets are associatively P-selective, then the deterministic advice complexity of the P-selective sets is linear. The weakest previously known sufficient condition was P = NP.

We also establish related results for algebraic properties of, and advice complexity of, the nondeterministically selective sets.

1. Introduction.

Selman [Sel79, Sel81, Sel82a, Sel82b] defined the P-selective sets about twenty years ago. In addition to being of interest in their own right, they have recently had some surprising applications. For example, selectivity is a powerful tool in the study of search versus decision problems [HNOS96a], and nondeterministic generalizations of selectivity are the key tools used to show that even NP machines cannot uniquely refine satisfying assignments unless the polynomial hierarchy collapses [HNOS96b], that even weaker refinements are also precluded unless the polynomial hierarchy collapses [Ogi96, NRRS98], and that many cardinality types of nondeterministic function classes cannot collapse unless the polynomial hierarchy collapses [HOW02].

DEFINITION 1.1 (see [Sel79]). *A set B is* P*-selective if and only if there is a (total) polynomial-time function $f : \Sigma^* \times \Sigma^* \to \Sigma^*$ such that*

1. $(\forall x, y)[f(x, y) = x \ \vee \ f(x, y) = y]$, *and*
2. $(\forall x, y)[(x \in B \ \vee \ y \in B) \implies f(x, y) \in B]$.

We call such a function f a P*-selector function for B.*

That is, a set B is P-selective if there is a polynomial-time function f that, given any two strings, always chooses one of them, and f does this in such a way that if exactly one of the strings is in B, then the P-selector function chooses that string. $f(x, y)$ is often described, very informally, as choosing one of x or y that is more likely to be in the set, though a more accurate description would be that f chooses one of x or y that is logically no less likely than the other to be in the set.

The P-selective sets have been extensively studied, and much about them is well understood (see the recent book [HT03] about selectivity theory). Though some P-selective sets are very complex—highly undecidable—the P-selective sets nonetheless have a broad range of structural simplicity properties. Most crucially in terms of the study in this paper, Ko [Ko83] showed that they have low nonuniform complexity (P-sel $\subseteq$ P/$\mathcal{O}(n^2)$). The following are a few of the many other simplicity results known to hold: Ko and Schöning [KS85] showed that all P-selective sets in NP are in the second level of the low hierarchy of Schöning [Sch83], and Allender and Hemachandra [AH92] showed that the Ko–Schöning result is the strongest lowness result for P-sel that holds with respect to all oracles; a long line of work starting with Selman [Sel79] and Toda [Tod91] (see also [Siv99] and the references therein) has shown that no P-selective set can be NP-hard under $\leq^{\mathrm{p}}_m$ or various other reductions unless P = NP; Naik and Selman [NS99] have shown that no P-selective set can be truth-table-hard for NP unless certain (intuitively unlikely) containments hold in the relationship between adaptive and nonadaptive queries to NP; and as a consequence of the work of Ko [Ko83] and Cai [Cai01] no P-selective set can be truth-table-hard for NP (or even Turing-hard for NP) unless the polynomial hierarchy collapses to S_2, where S_2 is the symmetric alternation class of Canetti [Can96] and Russell and Sundaram [RS98]. Note that $\mathrm{S}_2 \subseteq \mathrm{ZPP}^{\mathrm{NP}} \subseteq \mathrm{NP}^{\mathrm{NP}}$ [Cai01], where ZPP as usual denotes expected polynomial time, so this is a very dramatic collapse.

In this paper, we show that sets having P- or NP-selector functions with nice algebraic properties have simplicity properties far beyond those known for general P-selective or NP-selective sets. More generally, we study the class of languages one obtains from P- and NP-selector functions having certain algebraic properties, and the possibility of obtaining such algebraically nice P- or NP-selector functions.

In particular, section 4 shows that any P-selective (NP-selective) set having an associative P-selector (NP-selector) function also has a commutative, associative P-selector (NP-selector) function. Section 5 shows that sets having an associative P-selector can be accepted by deterministic advice interpreters using only a linear amount of advice. In contrast, the best upper bound on the deterministic advice complexity of the P-selective sets is the quadratic bound obtained by Ko [Ko83].

Our result provides a new sufficient condition—all P-selective sets are associatively P-selective—for all P-selective sets having linear deterministic advice; the weakest previously known sufficient condition was the quite demanding assumption that P = NP.

Section 6 shows that associatively NP-selective sets with weak census functions cannot be coNP-immune. Section 7 establishes a structural sufficient condition for all P-selective sets being associatively, commutatively P-selective, and proves that if all NPMV-selective sets have associative NPMV-selector functions, then the polynomial hierarchy collapses.

2. Definitions. Commutativity and associativity are concepts often associated with single-valued total functions. However, as we will discuss soon, these concepts can be naturally applied to multivalued and/or partial functions (see, e.g., [RS97, HR99]).

For a 2-ary multivalued function f, let *set-*$f(x, y)$ denote the set of values of f on input (x, y).[1] $f(x, y)$ is undefined if and only if *set-*$f(x, y) = \emptyset$. We extend this notation to single-valued functions in the obvious way. For a 2-ary single-valued function f let *set-*$f(x, y) = \{f(x, y)\}$ if $f(x, y)$ is defined and let *set-*$f(x, y) = \emptyset$ otherwise. For a (single- or multivalued) function f, a set A, and a string y, define *set-*$f(A, y) = \bigcup_{a \in A}$ *set-*$f(a, y)$ and *set-*$f(y, A) = \bigcup_{a \in A}$ *set-*$f(y, a)$. A 2-ary function f is called *total on a set* B if and only if $f(x, y)$ is defined for all $x, y \in B$. A function is called total if it is total on Σ^*.

A total 2-ary (single- or multivalued) function f is *associative on a set* B if and only if *set-*$f(a,$ *set-*$f(b, c)) =$ *set-*$f($*set-*$f(a, b), c)$ holds for all $a, b, c \in B$.[2] (Note that for total single-valued functions this is equivalent to saying that $f(a, f(b, c)) = f(f(a, b), c)$ holds for all $a, b, c \in B$.) We say a total function f is *associative* if f is associative on Σ^*. A total 2-ary (single- or multivalued) function f is *associative at each length* if f is associative on Σ^n for each n (where Σ^n is the set of words of length n). A 2-ary function f (partial or total, single- or multivalued) is *commutative* if and only if *set-*$f(a, b) =$ *set-*$f(b, a)$ holds for all a and b. (For total single-valued functions this is equivalent to saying that $f(a, b) = f(b, a)$ holds for all a, b.)

For partial functions the literature distinguishes two notions of associativity, namely, (strong) associativity and weak associativity [HR99, RS97]. A partial 2-ary function f is called associative (or strongly associative) if and only if *set-*$f(a,$ *set-*$f(b, c))$ $=$ *set-*$f($*set-*$f(a, b), c)$ holds for all a, b, and c. A partial 2-ary function f is called weakly associative if and only if for all a, b, and c, either (a) *set-*$f(a,$ *set-*$f(b, c)) = \emptyset$ or *set-*$f($*set-*$f(a, b), c) = \emptyset$, or (b) *set-*$f(a,$ *set-*$f(b, c)) =$ *set-*$f($*set-*$f(a, b), c)$. In other words, if any of the four applications of f are undefined, weak associativity "forgives" the equality requirement. The two approaches to associativity for functions correspond to the two notions of equality for partial functions, which date back to the work of Kleene [Kle52]. Note that both of these definitions, for total functions, exactly coincide with the associativity definition for total functions given earlier.

DEFINITION 2.1 (see [HHN+95, HNOS96b]). *For any class of (partial or total, single- or multivalued) functions $\mathcal{F}$, we say a set B is $\mathcal{F}$-selective exactly if there is a function $f \in \mathcal{F}$ such that*

1. $(\forall x, y)[$*set-*$f(x, y) \subseteq \{x, y\}]$, *and*
2. $(\forall x, y)[\{x, y\} \cap B \neq \emptyset \implies ($*set-*$f(x, y) \neq \emptyset \wedge$ *set-*$f(x, y) \subseteq B)]$.

A function f with property 1 *is called a self-contained function. A function with properties* 1 *and* 2 *is called an $\mathcal{F}$-selector function for B (when B is clear from context or unimportant, we will simply speak of an $\mathcal{F}$-selector function, and when $\mathcal{F}$ is clear from context or unimportant, we will simply speak of a selector function (for B)).*

[1] Formally, one should speak of relations rather than functions. However, the longstanding convention in computer science is to refer to such objects as "multivalued functions" (see [BLS84, BLS85, Sel96]). Similarly, the notation "*set-*$f(...)$" is also standard in the literature on multivalued functions, and we follow it. Though this notation makes equations a bit longer and less beautiful (than in the reasonable alternative, which some people prefer, of viewing f as standing for *set-*f), it does avoid some confusion. For example, suppose f is undefined when its first argument is x_0 and its second argument is y_0. Then we would say that $f(x_0, y_0)$ is undefined. In contrast, *set-*$f(x_0, y_0)$ certainly *is* defined, and in particular *set-*$f(x_0, y_0) = \emptyset$. Readers particularly interested in the history, types, and notation involving multivalued functions may wish to look at the interesting papers of Book, Long, and Selman mentioned earlier in this footnote.

[2] As it stands, the definition allows the possibility that some of the values or all of the values in *set-*$f(b, c)$, *set-*$f(a, b)$, *set-*$f(a,$ *set-*$f(b, c))$, and *set-*$f($*set-*$f(a, b), c)$ might not belong to B. However, since we will typically be applying this to total, *self-contained* functions, the four just-mentioned sets will each be nonempty subsets of B.

This definition requires a selector function for a set B to be defined whenever at least one input is in B. In other words, partial selector functions can be undefined only if both inputs are in $\overline{B}$. Observe that for any *total* self-contained function f we have that for any strings a, b, and c,

$$\textit{set-}f(a,b) \cap \textit{set-}f(a,c) \subseteq \textit{set-}f(a,\textit{set-}f(b,c)) \subseteq \textit{set-}f(a,b) \cup \textit{set-}f(a,c)$$

and

$$\textit{set-}f(a,c) \cap \textit{set-}f(b,c) \subseteq \textit{set-}f(\textit{set-}f(a,b),c) \subseteq \textit{set-}f(a,c) \cup \textit{set-}f(b,c).$$

We will use the following notational shorthand for the classes that we will study. (The ordering of "A" and "C" changes to avoid confusion with the existing class "AC," and to make clear that the "ℓ" modifies just the "A.")

DEFINITION 2.2. *For any class of (partial or total, single- or multivalued) functions $\mathcal{F}$,*

1. $\mathcal{F}\textit{-sel} = \{B \mid B \textit{ is } \mathcal{F}\textit{-selective}\}$,
2. $A\textit{-}\mathcal{F}\textit{-sel} = \{B \mid B \textit{ is } \mathcal{F}\textit{-selective via an associative } \mathcal{F}\textit{-selector function}\}$,
3. $C\textit{-}\mathcal{F}\textit{-sel} = \{B \mid B \textit{ is } \mathcal{F}\textit{-selective via a commutative } \mathcal{F}\textit{-selector function}\}$,
4. $CA\textit{-}\mathcal{F}\textit{-sel} = \{B \mid B \textit{ is } \mathcal{F}\textit{-selective via a commutative, associative } \mathcal{F}\textit{-selector function}\}$,
5. $A_\ell\textit{-}\mathcal{F}\textit{-sel} = \{B \mid B \textit{ is } \mathcal{F}\textit{-selective via an } \mathcal{F}\textit{-selector function that is associative at each length}\}$,
6. $A_\ell C\textit{-}\mathcal{F}\textit{-sel} = \{B \mid B \textit{ is } \mathcal{F}\textit{-selective via a commutative } \mathcal{F}\textit{-selector function that is associative at each length}\}$.

FP will denote the (possibly partial) polynomial-time computable functions. $\mathrm{FP_t}$ will denote those functions in FP that are total. (In the literature, some authors use the notation "FP" to denote what we in this paper denote $\mathrm{FP_t}$. To avoid confusion, we urge the reader to note carefully that throughout this paper FP (and also the function classes NPSV and NPMV to soon be defined) do not require totality except when subscripted with a "t", i.e., $\mathrm{FP_t}$, $\mathrm{NPSV_t}$, and $\mathrm{NPMV_t}$.)

For any set C, FP^C will be the class of all (possibly partial) functions that are computable in polynomial time with the help of oracle C. For any class $\mathcal{C}$, $\mathrm{FP}^{\mathcal{C}} = \{g \mid (\exists C \in \mathcal{C})[g \in \mathrm{FP}^C]\}$. ${\mathrm{FP_t}}^C$ and ${\mathrm{FP_t}}^{\mathcal{C}}$ are defined analogously.

FP and $\mathrm{FP_t}$ functions each have some fixed arity for their domain, and their codomain is of arity one and is Σ^*. That is, FP and $\mathrm{FP_t}$ are, respectively, potentially-partial and per-force-total functions, each of type $\Sigma^* \to \Sigma^*$, or of type $\Sigma^* \times \Sigma^* \to \Sigma^*$, or of type $\Sigma^* \times \Sigma^* \times \Sigma^* \to \Sigma^*$, etc. However, for selector functions, which are the main focus of this paper, the (input) arity is always two—selector functions by their nature are two-argument functions. So, throughout this paper, whenever we speak of selector-type functions (or related functions that by their nature or the way we use them are clearly 2-ary), we will simply write expressions such as "there is an $f \in \mathrm{FP}$" when in fact we mean "there is a 2-ary function $f \in \mathrm{FP}$."

We will follow the same convention regarding the nondeterministic function classes NPSV, $\mathrm{NPSV_t}$, NPMV, and $\mathrm{NPMV_t}$. These classes in general are meaningful for 1-ary functions, for 2-ary functions, etc. However, since this paper focuses on selector functions, which are always 2-ary, we will in effect silently treat the classes as if they are over 2-ary functions. So, for example, in the following paragraph, our machines have two arguments. (The case of k-ary, $k \neq 2$, functions belonging to these classes is identically defined except with k arguments.) And throughout this paper we simply

say, for our nondeterministic function classes, things such as "there is an $f \in \mathrm{NPSV}$" when in fact we mean "there is a 2-ary function $f \in \mathrm{NPSV}$."

In the literature (and in the present paper), $\mathrm{FP_t}$-sel is often denoted P-sel (note that Definition 2.2 for $\mathcal{F} = \mathrm{FP_t}$ yields the same class of P-selective sets as defined in Definition 1.1), and $\mathrm{NPSV_t}$-sel is often denoted NP-sel. (Both $\mathrm{FP_t}$-sel and $\mathrm{NPSV_t}$-sel in fact, by the convention mentioned in the previous paragraph, actually are intended to refer to functions of type $\Sigma^* \times \Sigma^* \to \Sigma^*$ from $\mathrm{FP_t}$ and $\mathrm{NPSV_t}$, respectively.)

We now define the standard nondeterministic function classes [BLS84, BLS85]. For any nondeterministic polynomial-time Turing machine (NPTM, for short) M taking two strings as its input and for any two strings x and y, let $out_M(x, y)$ denote the set of all strings that are output on some accepting path of $M(x, y)$, by which we mean M with x as its first argument and y as its second argument. Note that we view the collection of outputs as a set, not as a multiset (if one path outputs 101 and seven paths output 1100, the set of outputs is simply $\{101, 1100\}$), and note also that the functions computed by such machines may in some cases be partial functions, and may in some cases be multivalued functions. NPSV is the class of all single-valued functions f such that there exists an NPTM M such that, for all $x, y \in \Sigma^*$, $out_M(x, y) = \{f(x, y)\}$ if $f(x, y)$ is defined and $out_M(x, y) = \emptyset$ if $f(x, y)$ is undefined. NPMV is the class of all functions f such that there exists an NPTM M such that, for all $x, y \in \Sigma^*$, $out_M(x, y) = set\text{-}f(x, y)$. $\mathrm{NPSV_t}$ and $\mathrm{NPMV_t}$ denote the set of all total NPSV and NPMV functions, respectively.

As to levels of the polynomial hierarchy [MS72, Sto76] beyond NP, as is standard we will use Σ_2^p to denote the class of all languages that can be accepted by nondeterministic polynomial-time Turing machines with the help of an NP oracle, i.e., $\Sigma_2^p = \mathrm{NP}^{\mathrm{NP}}$. And as is standard we will use Σ_3^p to denote the class of all languages that can be accepted by nondeterministic polynomial-time Turing machines with the help of a Σ_2^p oracle, i.e., $\Sigma_3^p = \mathrm{NP}^{\Sigma_2^p} = \mathrm{NP}^{\mathrm{NP}^{\mathrm{NP}}}$.

Just as P-sel and NP-sel are standard notational conventions when $\mathrm{FP_t}$-sel and $\mathrm{NPSV_t}$-sel are actually meant (see [Sel79] and [HHN+95]), we similarly write A-P-sel and A-NP-sel as shorthand for A-$\mathrm{FP_t}$-sel and A-$\mathrm{NPSV_t}$-sel, respectively, and we do likewise for the other four prefixes C-, CA-, A_ℓ-, and A_ℓC-.

From the definitions,

$$\text{CA-P-sel} \subseteq \left\{\begin{array}{c}\subseteq \text{A-P-sel} \subseteq \\ \subseteq \mathrm{A}_\ell\text{C-P-sel} \subseteq\end{array}\right\} \mathrm{A}_\ell\text{-P-sel} \subseteq \text{P-sel}$$

and

$$\mathrm{A}_\ell\text{C-P-sel} \subseteq \text{C-P-sel} \subseteq \text{P-sel}.$$

Exactly the same inclusion relations hold for the various subtypes of NP-selective and of $\mathrm{NPMV_t}$-selective sets.

The following facts are well known.

FACT 2.3.

1. FP-sel = P-sel = C-P-sel.
2. NP-sel = C-NP-sel.
3. NPSV-sel = C-NPSV-sel.
4. $\mathrm{NPMV_t}$-sel = C-$\mathrm{NPMV_t}$-sel.
5. NPMV-sel = C-NPMV-sel.

Regarding the first equality of part 1 of Fact 2.3, recall that any partial selector function can only be undefined if both of its inputs are not in the selected set. Of course one can alter a deterministic polynomial-time Turing machine computing a partial selector function f for a set A in such a way that it outputs any one of the two inputs, say the lexicographically larger one, in the case that it "plans" to output nothing. The total function computed by the altered Turing machine is also a selector function for A. The other facts hold since if a set B is $\mathcal{F}$-selective via an $\mathcal{F}$-selector function f (with $\mathcal{F} \in \{\mathrm{FP_t}, \mathrm{NPSV_t}, \mathrm{NPSV}, \mathrm{NPMV_t}, \mathrm{NPMV}\}$), then the function f' defined by

$$(*) \qquad f'(x,y) = f(\min(x,y), \max(x,y))$$

is a commutative $\mathcal{F}$-selector function for B.

Advice classes capture the information content of sets with respect to some complexity class of decoder sets.

DEFINITION 2.4 (see [KL80]).

1. *For a complexity class $\mathcal{C}$ and a function $f : \mathbb{N} \to \mathbb{N}$, a set B is in $\mathcal{C}/f(n)$ if and only if there exist a set $C \in \mathcal{C}$ and a function $h : 1^* \to \Sigma^*$ such that, for all $x \in \Sigma^*$,*
   (a) $|h(1^{|x|})| = f(|x|)$, *and*
   (b) $x \in B \iff \langle x, h(1^{|x|})\rangle \in C$.
2. *For any complexity class $\mathcal{C}$ and any function class $\mathcal{F}$, $\mathcal{C}/\mathcal{F} = \bigcup_{f\in\mathcal{F}} \mathcal{C}/f(n)$.*

In this paper, we are particularly interested in the advice classes $\mathrm{P}/\mathcal{O}(n)$, $\mathrm{P}/n{+}1$, P/n, $(\mathrm{NP}\cap\mathrm{coNP})/n{+}1$, and $\mathrm{NP}/n{+}1$. Also, poly denotes the class of polynomials mapping from $\mathbb{N}$ to $\mathbb{N}$, and we will use later classes of the form $\mathcal{C}/\mathrm{poly}$.

For each set of strings A and each natural number n, let $A^{=n}$ and $A^{\leq n}$ denote all strings in A of length exactly n and of length up to and including n, respectively. Let $\mathcal{F}$ be any function class. A set B is *$\mathcal{F}$-printable* if there is a function $g \in \mathcal{F}$ such that, for all $n \in \mathbb{N}$, $g(1^n)$ outputs $B^{\leq n}$ in some fixed standard way of encoding sets as strings [HY84]. That is, there is a function from $\mathcal{F}$ that finds all elements in the set up to a given length. By tradition, P-printable denotes the $\mathrm{FP_t}$-printable sets.

Consider a relation R over the universe U, i.e., $R \subseteq U \times U$. We say that R is reflexive if and only if $(\forall a \in U)[(a,a) \in R]$. R is said to be antisymmetric if and only if $(\forall a, b \in U)[((a,b) \in R \wedge (b,a) \in R) \implies a = b]$. We say that R is a *transitive relation* if and only if $(\forall a, b, c \in U)[((a,b) \in R \wedge (b,c) \in R) \implies (a,c) \in R]$. For each $a, b \in U$, a and b are called comparable with respect to R if $(a,b) \in R \vee (b,a) \in R$. R is called a partial order on U if and only if R is reflexive, antisymmetric, and transitive. (Informally, order mirrors the relation "less than or equal to.") R is called a linear order (or total order, or, for short, we may sometimes simply write order) on U if and only if R is a partial order on U and each pair of elements from U is comparable with respect to R. Given a set U and a relation $\leq$ that is a partial order on U, (a) an element $x \in U$ is said to be maximal if and only if $(\forall y \in U)[x \leq y \implies x = y]$; (b) an element $x \in U$ is said to be minimal if and only if $(\forall y \in U)[y \leq x \implies x = y]$. If a maximal (minimal) element exists in a linear order it is unique and can be referred to as maximum (minimum). (For a review of the basics of orders see, e.g., [Cam94, Chapter 12].)

As is standard in graph theory, in a directed graph (digraph for short) $G = (V, E)$, we have that V is a finite set and $E \subseteq V \times V$. A digraph $G = (V, E)$ is called a *tournament* if and only if (a) for all $u, v \in V$ such that $u \neq v$, exactly one of the edges (u, v) and (v, u) belongs to E, and (b) for all $u \in V$, it holds that $(u, u) \notin E$. We will

in this paper slightly modify this notion by adding self-loops at each node, that is, a digraph $G = (V, E)$ is called a *self-looped tournament* (s-tournament, for short) if and only if (a) for all $u, v \in V$ such that $u \neq v$, exactly one of the edges (u, v) and (v, u) belongs to E, and (b) for all $u \in V$, it holds that $(u, u) \in E$. (If we were dealing only with tournament-type graphs, this modification would not be useful. However, in this paper we study even multivalued selector functions, and the natural graphs that these induce are of a different flavor, and in particular when they are transitive and contain cycles will have self-loops along all cycles even if we do not build self-loops into the way we induce these graphs. Thus, to allow the similarity of the relationship—which we will later see—between associativity of selector functions and transitivity of selector-induced digraphs to be as clear as possible, we use s-tournaments rather than tournaments.)

A digraph $G = (V, E)$ is called a *complete digraph* (or synonymously a *weak clique*) if and only if, for all $u, v \in V$, *at least* one of the edges (u, v) and (v, u) belongs to E. A digraph $G = (V, E)$ is called a *strong clique* if and only if, for all $u, v \in V$, the edge (u, v) belongs to E. (Note that both complete digraphs and strong cliques by these definitions must have every self-loop.) A subgraph G' of G is called a maximal strong clique if G' is a strong clique and there is no subgraph G'' in G that is a strong clique and contains G' as a proper subgraph.

As is standard, given a digraph $G = (V, E)$, a digraph $G' = (V', E')$ is said to be an *induced subgraph of* G exactly if $V' \subseteq V$ and $E' = \{(a, b) \mid a \in V' \wedge b \in V' \wedge (a, b) \in E\}$.

3. Commutative selectors and digraphs. Parts 1, 2, and 4 of Fact 2.3 establish that without loss of generality one can assume P- (NP- or $\mathrm{NPMV_t}$-) selectors to be commutative. Or, to be more precise, they make clear that restricting oneself to commutative selector functions in these contexts in no way shrinks the class of sets obtained. This observation enables one to use results from graph theory, in particular, from tournament theory, to pinpoint the advice complexity of selective sets.

Below we would like to make the link between commutative selector functions and directed graphs (in special cases, s-tournaments) more explicit and prove some results regarding this link.

Since our focus will be on self-contained associative functions, the following easy observation will be quite useful in the upcoming proofs. Note that the functions g spoken of in Proposition 3.1 may potentially be nontotal and/or multivalued.

PROPOSITION 3.1. *Let $B \subseteq \Sigma^*$ and let g be any commutative self-contained function that is total on B. Then the following are equivalent:*

1. *g is associative on B.*
2. $(\forall a, b, c \in B)[\textit{set-g}(a, \textit{set-g}(b, c)) = \textit{set-g}(b, \textit{set-g}(a, c)) = \textit{set-g}(c, \textit{set-g}(a, b))]$.
3. $(\forall a, b, c \in B : ||\{a, b, c\}|| = 3)[\textit{set-g}(a, \textit{set-g}(b, c)) = \textit{set-g}(b, \textit{set-g}(a, c)) = \textit{set-g}(c, \textit{set-g}(a, b))]$.

Proof. Let g be a commutative self-contained function that is total on B, $B \subseteq \Sigma^*$. Note that part 1 in light of g's commutativity implies part 2 and that part 2 implies part 3. We will complete the proof by showing that part 3 implies part 2 and that part 2 implies part 1.

Suppose that part 2 holds; that is, suppose $(\forall a, b, c \in B)[\textit{set-g}(a, \textit{set-g}(b, c)) = \textit{set-g}(b, \textit{set-g}(a, c)) = \textit{set-g}(c, \textit{set-g}(a, b))]$. Let $x, y, z \in B$. By our assumption we have $\textit{set-g}(x, \textit{set-g}(y, z)) = \textit{set-g}(z, \textit{set-g}(x, y))$. Since g is total on B and commutative we have $\textit{set-g}(z, \textit{set-g}(x, y)) = \textit{set-g}(\textit{set-g}(x, y), z)$ and thus $\textit{set-g}(x, \textit{set-g}(y, z)) = \textit{set-g}(\textit{set-g}(x, y), z)$. This by definition shows that g is associative.

Now suppose that part 3 holds; that is, suppose $(\forall a, b, c \in B : ||\{a, b, c\}|| = 3)[\textit{set-g}(a, \textit{set-g}(b, c)) = \textit{set-g}(b, \textit{set-g}(a, c)) = \textit{set-g}(c, \textit{set-g}(a, b))]$. Let $x, y, z \in B$. The only cases we need to consider are $||\{x, y, z\}|| = 1$ and $||\{x, y, z\}|| = 2$. If $||\{x, y, z\}|| = 1$, i.e., $x = y = z$, then $\textit{set-g}(x, \textit{set-g}(y, z)) = \textit{set-g}(y, \textit{set-g}(x, z)) = \textit{set-g}(z, \textit{set-g}(x, y)) = \{x\}$ since g is total on B and self-contained. If $||\{x, y, z\}|| = 2$, assume without loss of generality that $x = z$ and $x \neq y$. It follows that $\textit{set-g}(y, \textit{set-g}(x, z)) = \textit{set-g}(y, x)$ since g is total on B and self-contained, and $\textit{set-g}(y, x) = \textit{set-g}(x, y)$ since g is commutative. Observe that $\textit{set-g}(x, \textit{set-g}(y, z)) = \textit{set-g}(x, \textit{set-g}(y, x)) = \textit{set-g}(x, \textit{set-g}(x, y)) = \textit{set-g}(z, \textit{set-g}(x, y))$ since $x = z$ and g is commutative. It remains to show that $\textit{set-g}(z, \textit{set-g}(x, y)) = \textit{set-g}(y, \textit{set-g}(x, z))$, i.e., in the current setting, showing that $\textit{set-g}(x, \textit{set-g}(x, y)) = \textit{set-g}(x, y)$. Note that $\textit{set-g}(x, x) = \{x\}$ and $\textit{set-g}(x, y) \in \{\{x\}, \{y\}, \{x, y\}\}$ since g is total on B. If $\textit{set-g}(x, y) = \{x\}$, then $\textit{set-g}(x, \textit{set-g}(x, y)) = \textit{set-g}(x, y) = \{x\}$. If $\textit{set-g}(x, y) = \{y\}$, then $\textit{set-g}(x, \textit{set-g}(x, y)) = \textit{set-g}(x, y) = \{y\}$. If $\textit{set-g}(x, y) = \{x, y\}$, then $\textit{set-g}(x, \textit{set-g}(x, y)) = \textit{set-g}(x, y) = \{x, y\}$. We have shown that part 3 implies part 2. □

In particular note that, by Proposition 3.1, for any commutative self-contained function g that is total on some set B, g is associative on every one- or two-element set of strings from B, since item 3 of Proposition 3.1 is trivially satisfied when $||\{a, b, c\}|| < 3$.

Let f be a (single- or multivalued) commutative self-contained function, $f : B \times B \to B$ for a finite set B. Consider the digraph $G = (B, E)$, where $E = \{(x, y) \mid x, y \in B \wedge y \in \textit{set-f}(x, y)\}$. If f is total on B, then G is a complete digraph. If f is single-valued and total on B, then G is even an s-tournament. We will call G the f-induced digraph on B. If f is single-valued and total on B, then G will be called the f-induced s-tournament on B. Note that the functions f spoken of in Proposition 3.2 may be multivalued.

PROPOSITION 3.2. *Let B be a finite set and let f be a commutative self-contained function that is total on B. f is associative on B if and only if $E = \{(x, y) \mid x, y \in B \wedge y \in \textit{set-f}(x, y)\}$, the edge set of the f-induced digraph, is a transitive relation.*

Proof. Let B be a finite set and let f be a commutative self-contained function that is total on B.

We first prove the "only if" direction. So let f be associative on B, i.e., for all $x, y, z \in B$, $\textit{set-f}(x, \textit{set-f}(y, z)) = \textit{set-f}(\textit{set-f}(x, y), z)$. Suppose that E is not transitive. This means that there exist strings $a, b, c \in B$ such that $(a, b) \in E$ and $(b, c) \in E$ yet $(a, c) \notin E$. It follows that $a \neq b$ (since if $a = b$, then $(b, c) = (a, c)$), $b \neq c$ (since if $b = c$, then $(a, b) = (a, c)$), and $a \neq c$ (since if $a = c$, then $(a, a) = (a, c)$ and since f is total on B $(a, a) \in E$). So $a, b, c \in B$ are pairwise different strings such that $(a, b) \in E$, $(b, c) \in E$, and $(a, c) \notin E$. We will derive a contradiction by showing that f is not associative, i.e., $\textit{set-f}(\textit{set-f}(a, b), c) \neq \textit{set-f}(a, \textit{set-f}(b, c))$. We do so by showing $c \in \textit{set-f}(\textit{set-f}(a, b), c)$ and $c \notin \textit{set-f}(a, \textit{set-f}(b, c))$. We have $b \in \textit{set-f}(a, b)$ and $c \in \textit{set-f}(b, c)$, and thus $c \in \textit{set-f}(\textit{set-f}(a, b), c)$. On the other hand, $c \notin \textit{set-f}(a, b)$ since f is a self-contained function and $c \neq a$ and $c \neq b$. We also have $c \notin \textit{set-f}(a, c)$ since $(a, c) \notin E$. Since $\textit{set-f}(a, \textit{set-f}(b, c)) \subseteq \textit{set-f}(a, b) \cup \textit{set-f}(a, c)$ we have $c \notin \textit{set-f}(a, \textit{set-f}(b, c))$.

We now prove the "if" direction. So suppose that E is transitive. We have to show that f is associative on B, i.e., for any strings $a, b, c \in B$ we have to show $\textit{set-f}(a, \textit{set-f}(b, c)) = \textit{set-f}(\textit{set-f}(a, b), c)$. By Proposition 3.1 it suffices to show that, for all strings $a, b, c \in B$ such that $||\{a, b, c\}|| = 3$, $\textit{set-f}(a, \textit{set-f}(b, c)) =$

set-f$(b, $*set-f*$(a, c)) =$ *set-f*$(c, $*set-f*$(a, b))$. So suppose $a, b, c \in B$ are strings such that $||\{a, b, c\}|| = 3$.

We show *set-f*$(c, $*set-f*$(a, b)) \subseteq$ *set-f*$(a, $*set-f*$(b, c))$. (The proof of the other inclusions follows via variable renaming and commutativity.) Consider $w \in$ *set-f*$(c,$ *set-f*$(a, b))$. If $w = a$, we have $a \in$ *set-f*$(c, $*set-f*$(a, b))$, which implies, since $a \neq c$, $a \in$ *set-f*(a, b) and implies, since $a \notin \{b, c\}$, $a \in$ *set-f*$(c, a) =$ *set-f*(a, c). Since *set-f*$(a, b) \cap$ *set-f*$(a, c) \subseteq$ *set-f*$(a, $*set-f*$(b, c))$ it follows that $a \in$ *set-f*$(a, $*set-f*$(b, c))$. Similarly, if $w = b$, we have $b \in$ *set-f*$(c, $*set-f*$(a, b))$, which in turn implies (since $b \neq c$) $b \in$ *set-f*(a, b) and implies (since $b \notin \{a, c\}$ and $b \in$ *set-f*(a, b)) $b \in$ *set-f*$(c, b) =$ *set-f*(b, c). It follows that *set-f*$(a, b) \subseteq$ *set-f*$(a, $*set-f*$(b, c))$ and hence $b \in$ *set-f*$(a,$ *set-f*$(b, c))$. Finally suppose $w = c$, which yields $c \in$ *set-f*$(c, $*set-f*$(a, b))$. It follows (since $c \notin \{a, b\}$) that either (a) $a \in$ *set-f*(a, b) and $c \in$ *set-f*$(c, a) =$ *set-f*(a, c), or (b) $b \in$ *set-f*(a, b) and $c \in$ *set-f*$(c, b) =$ *set-f*(b, c). If (a) holds we have $(b, a) \in E$ and $(a, c) \in E$. By the transitivity of E it follows that also $(b, c) \in E$. By the definition of E this implies $c \in$ *set-f*(b, c), and thus $c \in$ *set-f*$(a, $*set-f*$(b, c))$. If (b) holds, we have $(a, b) \in E$ and $(b, c) \in E$. Hence also $(a, c) \in E$ since E is transitive. It follows that $c \in$ *set-f*(a, c), and thus $c \in$ *set-f*$(a, $*set-f*$(b, c))$. □

Tournaments such that their edge set is a transitive relation are called transitive tournaments. Transitive tournaments implicitly impose a linear order on their nodes. We will use the following result (which can be viewed as a tournament-language expression of the fact that each finite linear order has a minimal and also a maximal element).

PROPOSITION 3.3 (see [Moo68][3]). *The following statements are equivalent for s-tournaments $G = (V, E)$:*

1. *G is a transitive s-tournament.*
2. *G contains no directed cycles of length greater than* 1.
3. *Every induced (directed) subgraph $G' = (V', E')$, $V' \neq \emptyset$, of G contains a (distance-one) source node, i.e., a node $s \in V'$ such that for all $u \in V'$, $(s, u) \in E'$.*
4. *Every induced (directed) subgraph $G' = (V', E')$, $V' \neq \emptyset$, of G contains a (distance-one) target node, i.e., a node $t \in V'$ such that for all $u \in V'$, $(u, t) \in E'$.*

From Propositions 3.1, 3.2, and 3.3 we immediately obtain the following corollary.

COROLLARY 3.4. *Let f be a single-valued, commutative self-contained function that is total on $\{a, b, c\}$. f is not associative on $\{a, b, c\}$ if and only if both $||\{a, b, c\}|| = 3$ and the f-induced s-tournament on $\{a, b, c\}$ is a* 3*-cycle (plus three self-loops).*

A statement similar to that of Proposition 3.3 can also be made for complete digraphs. But in contrast to the linear order implicitly given by a transitive s-tournament, a transitive complete digraph gives a linear order on a partition of its set of nodes, while the nodes of each part of the partition are in some sense pairwise indistinguishable.

Without giving all the definitions, we mention that in graph theory textbooks (see [BJG00], for instance) one can find the fact that the strongly connected components of a general digraph form a partial order. If we consider a complete digraph, we immediately have that the strongly connected components form an order. The additional assumption of transitivity then yields that the strongly connected compo-

[3]Moon stated the result for tournaments, and so his statement lacks the "length greater than 1" condition in statement 2.

nents are actually strong cliques. However, for reasons of self-containment we state and prove that graph-theoretic result below in a way that suits our purposes best.

PROPOSITION 3.5. *The following statements are equivalent for complete digraphs* $G = (V, E)$*:*

1. E *is a transitive relation.*
2. *For every* $k \geq 1$*, if* $(a_1, a_2), (a_2, a_3), \ldots, (a_{k-1}, a_k), (a_k, a_1) \in E$*, then* $(a_i, a_j) \in E$ *for all* $1 \leq i, j \leq k$*. In other words, if* $a_1 \to a_2 \to \cdots \to a_{k-1} \to a_k \to a_1$ *is a directed cycle in* G*, then the nodes* $a_1, a_2, \ldots, a_k$ *form a strong clique.*
3. *Every induced (directed) subgraph* $G' = (V', E')$*,* $V' \neq \emptyset$*, of* G *contains a nonempty strong distance-one source-clique, i.e., an induced subgraph* $S = (V_S, E_S)$*,* $V_S \neq \emptyset$*, of* G' *having the following properties:*
   (a) S *is a maximal strong clique, i.e., for every* $v \in V' - V_S$*, the induced graph on the vertices* $V_S \cup \{v\}$ *is not a strong clique.*
   (b) *For all* $u \in V_S$ *and for all* $v \in V' - V_S$*,* $(u, v) \in E'$ *and* $(v, u) \notin E'$*.*
4. *Every induced (directed) subgraph* $G' = (V', E')$*,* $V' \neq \emptyset$*, of* G *contains a nonempty strong distance-one target-clique, i.e., an induced subgraph* $T = (V_T, E_T)$*,* $V_T \neq \emptyset$*, of* G' *having the following properties:*
   (a) T *is a maximal strong clique, i.e., for every* $v \in V' - V_T$*, the induced graph on the vertices* $V_T \cup \{v\}$ *is not a strong clique.*
   (b) *For all* $u \in V_T$ *and for all* $v \in V' - V_T$*,* $(u, v) \notin E'$ *and* $(v, u) \in E'$*.*

Proof. Let $G = (V, E)$ be a complete digraph. If $V = \emptyset$, all four conditions hold, so in this proof we henceforward assume $V \neq \emptyset$.

Statement 1 *implies statement* 2. Suppose that E is transitive. Transitivity implies that for any vertices u, v we have that the existence of a directed path from u to v implies $(u, v) \in E$. (This can easily be shown by induction on the length of the path connecting u and v.) Now consider a cycle $a_1 \to a_2 \to \cdots \to a_{k-1} \to a_k \to a_1$. Because for any vertices a_i, a_j there is a path from a_i to a_j, we have $(a_i, a_j) \in E$. Hence the nodes $a_1, a_2, \ldots, a_k$ form a strong clique.

Statement 2 *implies both statement* 3 *and statement* 4. Suppose that statement 2 holds for a complete digraph $G = (V, E)$. Let $G' = (V', E')$, $V' \neq \emptyset$, be an induced subgraph of G. There are strong cliques in G', because in a complete digraph every vertex forms a one-node strong clique. For the same reason, G' has no zero-node maximal strong cliques. We show that maximal strong cliques are disjoint. If two maximal strong cliques C and C' have a vertex in common, then there is a cycle connecting all vertices in C and C'. Then statement 2 implies that $C \cup C'$ forms a strong clique, contradicting the maximality of C and C'. Also, for two maximal strong cliques C and C' all edges between them lead from C to C', or all of them lead from C' to C, because otherwise there would be a cycle through all vertices of C and C', contradicting the maximality of C and C'. Since every vertex $v \in V'$ is in a maximal strong clique, the maximal strong cliques partition V'. Define a relation $\preceq$ on the maximal strong cliques by $C \preceq C'$ if and only if there are $a \in C$ and $a' \in C'$ with $(a, a') \in E$. Note that any two maximal strong cliques are comparable with respect to this relation, since G is a complete directed graph. Furthermore, the relation $\preceq$ is reflexive, antisymmetric, and transitive. Reflexivity and antisymmetry are obvious. Transitivity can be seen as follows: Suppose $C \preceq C'$ and $C' \preceq C''$ holds for three maximal strong cliques C, C', and C'' of G'. We have to show that then also $C \preceq C''$. If $C = C''$, then $C \preceq C''$ holds trivially since $\preceq$ is reflexive. If $C \neq C''$, then either $C \preceq C''$ or $C'' \preceq C$, but not both since $\preceq$ is antisymmetric. If $C \preceq C''$, we are done. If $C'' \preceq C$, then it indeed holds that there is a cycle through all vertices of $C \cup C' \cup C''$.

So, by statement 2, $C \cup C' \cup C''$ forms a strong clique, contradicting the maximality of C, C', and C''. Thus the transitivity of $\preceq$ is proven.

We have shown that the maximal strong cliques of G' are linearly ordered by $\preceq$. Let $C_{\min}$ be the minimum element, and let $C_{\max}$ be the maximum element in this order. ($C_{\min}$ and $C_{\max}$ do exist since G' is a (finite) graph and thus contains only a finite number of maximal strong cliques.) Then $C_{\min}$ witnesses statement 3 and $C_{\max}$ witnesses statement 4.

Statement 3 *implies statement* 1. Let $a, b, c \in V$ and suppose $(a, b) \in E$ and $(b, c) \in E$. We will show that also $(a, c) \in E$. Note that if $a = b$ or $a = c$ or $b = c$, then $(a, c) \in E$ is trivially satisfied. So let $||\{a, b, c\}|| = 3$ and consider the induced subgraph consisting of the three nodes a, b, and c—call it $G_{[a,b,c]} = (\{a, b, c\}, E_{abc})$. According to statement 3 there is a subgraph $S = (V_S, E_S)$, $V_S \subseteq \{a, b, c\}$, satisfying (a) S is a maximal strong clique and (b) for all $u \in V_S$ and for all $v \in \{a, b, c\} - V_S$, $(u, v) \in E_{abc}$ and $(v, u) \notin E_{abc}$. Hence, if $c \in V_S$, then $b \in V_S$, and if $b \in V_S$, then also $a \in V_S$. Since $V_S \neq \emptyset$, we can therefore conclude $a \in V_S$. It follows that $(a, c) \in E$.

Quite similarly to the proof that *statement* 3 *implies statement* 1, one can show that *statement* 4 *implies statement* 1. □

Combining Propositions 3.2 and 3.5 we get the following corollary.

COROLLARY 3.6. *Let f be a (potentially multivalued) commutative self-contained function that is total on $\{a, b, c\}$. f is not associative on $\{a, b, c\}$ if and only if both $||\{a, b, c\}|| = 3$ and the f-induced digraph on $\{a, b, c\}$ contains exactly one of the cycles $a \to b \to c \to a$ and $a \leftarrow b \leftarrow c \leftarrow a$.*

Proof. Let f be a multivalued, commutative self-contained function that is total on a set $\{a, b, c\}$. Let $G = (\{a, b, c\}, E)$ be the f-induced digraph on $\{a, b, c\}$.

Suppose that f is not associative on $\{a, b, c\}$. By the comment made immediately after the proof of Proposition 3.1, it follows that $||\{a, b, c\}|| = 3$. It follows from Proposition 3.2 that the edge set of the f-induced digraph is not a transitive relation and thus the f-induced digraph does not satisfy statement 2 of Proposition 3.5. It is not hard to see that this can only be the case if the f-induced digraph on $\{a, b, c\}$ contains exactly one of the cycles $a \to b \to c \to a$ and $a \leftarrow b \leftarrow c \leftarrow a$.

Now assume that $||\{a, b, c\}|| = 3$ and the f-induced digraph on $\{a, b, c\}$ contains exactly one of the cycles $a \to b \to c \to a$ and $a \leftarrow b \leftarrow c \leftarrow a$. By Proposition 3.5 we conclude that the edge set of the f-induced digraph is not transitive, which in turn, by Proposition 3.2, implies that f is not associative on $\{a, b, c\}$. □

Later in this paper, we will establish advice bounds in part by using the fact that associativity of a selector function (a restricted form of self-contained function) implies a linear structure on the underlying set.

4. Adding commutativity to associativity is free. Are all associatively P-selective sets commutatively, associatively P-selective? If they are, this will not only collapse two of our classes, but will also allow us to use results from the previous section in our study of associative selector functions. Unfortunately, Fact 2.3 (P-sel = C-P-sel) does *not* say that A-P-sel = CA-P-sel. The reason it does not guarantee this is that it is conceptually possible that the transformation denoted there by $(*)$ will, while gaining commutativity, destroy associativity. Theorem 4.1 and its proof establish that, for the case of $\mathrm{FP_t}$- and $\mathrm{NPSV_t}$-selector functions, this conceptual possibility is *not* a reality.

THEOREM 4.1.

1. A-P-sel = CA-P-sel.
2. A-NP-sel = CA-NP-sel.

Proof. As noted earlier, if B is P-selective (NP-selective) via a P-selector (NP-selector) function f, then the function $f'(x,y) = f(\min(x,y), \max(x,y))$ is a commutative P-selector (NP-selector) for B. We show that the above transformation from f to f' preserves associativity when f is a P-selector (NP-selector) function. Let $B \in$ A-P-sel ($B \in$ A-NP-sel) via an associative $\mathrm{FP_t}$-selector ($\mathrm{NPSV_t}$-selector) function f. It is clear that $f' \in \mathrm{FP_t}$ ($f' \in \mathrm{NPSV_t}$) and that f' is commutative. As mentioned above, f' is also a P-selector (NP-selector) for B. It remains to show that f' is associative.

Suppose that f' is not associative. According to Proposition 3.1 there exist three strings a, b, and c such that $||\{a,b,c\}|| = 3$ and $f'(a,f'(b,c)) = f'(b,f'(a,c)) = f'(c,f'(a,b))$ does not hold. Without loss of generality assume $a <_{\mathrm{lex}} b <_{\mathrm{lex}} c$. It follows from Corollary 3.4 that the f'-induced s-tournament on $\{a,b,c\}$ is a 3-cycle (plus three self-loops). Suppose that the cycle is directed from a to b, from b to c, and back to a. This implies that $f'(a,b) = b$, $f'(b,c) = c$, and $f'(a,c) = a$. However, due to the definition of f' this implies that $f(a,b) = f'(a,b) = b$, $f(b,c) = f'(b,c) = c$, and $f(a,c) = f'(a,c) = a$ which contradicts the associativity of f since $f(a,f(b,c)) = a$ yet $f(f(a,b),c) = c$. Similarly, if the cycle is directed from c to b, from b to a, and back to c, then $f'(a,b) = a$, $f'(b,c) = b$, and $f'(a,c) = c$. According to the definition of f' this implies $f(a,b) = f'(a,b) = a$, $f(b,c) = f'(b,c) = b$, and $f(a,c) = f'(a,c) = c$ which contradicts the associativity of f since $f(a,f(b,c)) = a$ yet $f(f(a,b),c) = c$. This shows that f' is associative. □

Similarly we have the following result.

THEOREM 4.2.

1. $\mathrm{A_\ell}$-P-sel = $\mathrm{A_\ell C}$-P-sel.
2. $\mathrm{A_\ell}$-NP-sel = $\mathrm{A_\ell C}$-NP-sel.

Proof. If a selector function f is associative at each length, then we may invoke the entire proof of Theorem 4.1, except only seeking a counterexample (to the "associativity at each length" of $f'(x,y) = f(\min(x,y), \max(x,y))$) among triples of strings all of the same length. As in that proof, if such a counterexample exists (among some three strings of the same length) it forms a 3-cycle (plus three self-loops) in the associated digraph. However, exactly as in the proof of Theorem 4.1, that contradicts the assumed associativity-at-each-length of f.[4] □

So the transformation from a selector f to a selector f' via $f'(x,y) = f(\min(x,y), \max(x,y))$ not only provides commutativity but also preserves associativity if f is total and single-valued. We mention that for this same case another standard transformation providing commutativity (namely, $f''(x,y) = \max(f(x,y), f(y,x))$) also has the associativity-preserving property.

However, the picture changes dramatically if one looks at multivalued selector

[4] Note that in the above proof, though commutativity of f' follows immediately from the definition of f', showing that f' is associative at each length relies on the fact that f is total at each length. However, the following strengthening of Theorem 4.2 clearly follows from the proof of Theorem 4.2: For every FP-selector (respectively, NPSV-selector) f for a set B that is associative at each length, f' is a commutative FP-selector (respectively, NPSV-selector) for B that is associative at each length n at which f is total.

However, we note in passing that one cannot strengthen Theorem 4.2 further to $\mathrm{A_\ell}$-FP-sel = $\mathrm{A_\ell C}$-FP-sel and $\mathrm{A_\ell}$-NPSV-sel = $\mathrm{A_\ell C}$-NPSV-sel by exploiting f'. A counterexample is the following: For strings a,b,c, $b <_{\mathrm{lex}} c <_{\mathrm{lex}} a$ all of the same length, let $\mathit{set}\text{-}f(a,b) = \mathit{set}\text{-}f(b,a) = \mathit{set}\text{-}f(a,c) = \mathit{set}\text{-}f(c,b) = \emptyset$ and $\mathit{set}\text{-}f(c,a) = \mathit{set}\text{-}f(b,c) = \{c\}$. One can easily check that f is associative on the three-element set $\{a,b,c\}$. But $f'(a,f'(b,c)) = c$ yet $f'(f'(a,b),c) = \emptyset$. Similarly to the counterexample showing that f' does not preserve associativity for multivalued functions (Proposition 4.3), one can extend the definition of f to cover all strings from Σ^*.

functions f, for instance, NPMV$_t$ selector functions. Though for the second transformation it is not even clear what is meant by $\max(f(x,y), f(y,x))$ and whether that is again a function from NPMV$_t$, it can be shown that the first transformation does *not* preserve associativity.

PROPOSITION 4.3. *There are total associative multivalued selector functions f such that the selector function f', defined by $f'(x,y) = f(\min(x,y), \max(x,y))$, is not associative.*

Proof. Set $a = \epsilon$, $b = 0$, and $c = 1$. Consider the total multivalued selector function f that has the following values on a, b, and c and thus induces the following values of f' on a, b, and c:

$$\begin{array}{lll|l} \textit{set-}f(a,b) = \{a\} & \textit{set-}f(b,a) = \{b\} & & \textit{set-}f'(a,b) = \textit{set-}f'(b,a) = \textit{set-}f(a,b) = \{a\} \\ \textit{set-}f(a,c) = \{a,c\} & \textit{set-}f(c,a) = \{c\} & & \textit{set-}f'(a,c) = \textit{set-}f'(c,a) = \textit{set-}f(a,c) = \{a,c\} \\ \textit{set-}f(b,c) = \{b,c\} & \textit{set-}f(c,b) = \{c\} & & \textit{set-}f'(b,c) = \textit{set-}f'(c,b) = \textit{set-}f(b,c) = \{b,c\} \end{array}$$

Furthermore, for each $x \in \{a,b,c\}$ and each $y \in \Sigma^* - \{a,b,c\}$, let $\textit{set-}f(x,y) = \textit{set-}f(y,x) = \{y\}$. And for $y,z \in \Sigma^* - \{a,b,c\}$ let $\textit{set-}f(y,z) = \textit{set-}f(z,y) = \{\max(y,z)\}$. Note that if $\{e,e'\} \not\subseteq \{a,b,c\}$, then we have $\textit{set-}f(e,e') = \textit{set-}f'(e,e')$.

It is not hard to verify that f is indeed associative, due to the way any non-$\{a,b,c\}$ argument "trumps" any $\{a,b,c\}$ argument, and regarding all-$\{a,b,c\}$ arguments we have

$$\begin{array}{l} \textit{set-}f(a, \textit{set-}f(b,c)) = \textit{set-}f(\textit{set-}f(a,b), c) = \{a,c\}, \\ \textit{set-}f(a, \textit{set-}f(c,b)) = \textit{set-}f(\textit{set-}f(a,c), b) = \{a,c\}, \\ \textit{set-}f(b, \textit{set-}f(a,c)) = \textit{set-}f(\textit{set-}f(b,a), c) = \{b,c\}, \\ \textit{set-}f(b, \textit{set-}f(c,a)) = \textit{set-}f(\textit{set-}f(b,c), a) = \{b,c\}, \\ \textit{set-}f(c, \textit{set-}f(a,b)) = \textit{set-}f(\textit{set-}f(c,a), b) = \{c\}, \\ \textit{set-}f(c, \textit{set-}f(b,a)) = \textit{set-}f(\textit{set-}f(c,b), a) = \{c\}. \end{array}$$

But f' is not associative since it holds that $\textit{set-}f'(a, \textit{set-}f'(c,b)) = \{a,c\}$ and $\textit{set-}f'(\textit{set-}f'(a,c), b) = \{a,b,c\}$. □

Observe that we have shown that under the mentioned transformation from f to f' gains in commutativity can lose associativity. However, for total multivalued functions there is another transformation that does preserve associativity while adding commutativity, namely, $\textit{set-}\widehat{f}(x,y) = \textit{set-}f(x,y) \cup \textit{set-}f(y,x)$ for all x and y. Theorem 4.4 establishes this.

THEOREM 4.4. A-NPMV$_t$-sel = CA-NPMV$_t$-sel.

Proof. It suffices to show A-NPMV$_t$-sel $\subseteq$ CA-NPMV$_t$-sel. Let $B \in$ A-NPMV$_t$-sel and let $f \in$ NPMV$_t$ be an associative selector for B. We will now show that $\widehat{f}$ is a commutative and associative NPMV$_t$-selector for B.

It is not hard to see that $\widehat{f}$ is commutative, that $\widehat{f} \in$ NPMV$_t$, and that indeed $\widehat{f}$ is an NPMV$_t$-selector for B. It remains to show that $\widehat{f}$ is associative. By Proposition 3.1 it suffices to show that $\widehat{f}$ is associative on every set $\{a,b,c\}$ such that $||\{a,b,c\}|| = 3$. By Corollary 3.6 it suffices to show that the $\widehat{f}$-induced graph on $\{a,b,c\}$, call it $G_{[a,b,c]} = (\{a,b,c\}, E_{abc})$, contains both the cycles $a \to b \to c \to a$ and $a \leftarrow b \leftarrow c \leftarrow a$ if it contains at least one of them.

Suppose $G_{[a,b,c]}$ contains $a \to b \to c \to a$ (the case where $G_{[a,b,c]}$ contains $a \leftarrow b \leftarrow c \leftarrow a$ is analogous under renaming so we do not separately cover it). We have to show that the other cycle is also in $G_{[a,b,c]}$, i.e., (a,c), (c,b), and (b,a) are in E_{abc}. For symmetry reasons, it suffices to show that $(a,c) \in E_{abc}$ or, equivalently, $c \in \textit{set-}\widehat{f}(a,c)$. Because $(a,b) \in E_{abc}$, we have $b \in \textit{set-}\widehat{f}(a,b)$ and thus $b \in \textit{set-}f(a,b)$

or $b \in set\text{-}f(b,a)$. Similarly, because $(b,c) \in E_{abc}$, we have $c \in set\text{-}\widehat{f}(b,c)$ and thus $c \in set\text{-}f(b,c)$ or $b \in set\text{-}f(c,b)$. We distinguish four cases.

Case 1 ($b \in set\text{-}f(a,b)$ and $c \in set\text{-}f(b,c)$):
This implies $c \in set\text{-}f(set\text{-}f(a,b),c)$. Since f is associative, we have that $c \in set\text{-}f(a, set\text{-}f(b,c))$. Since f is self-contained and thus $set\text{-}f(a, set\text{-}f(b,c)) \subseteq set\text{-}f(a,b) \cup set\text{-}f(a,c)$ we conclude $c \in set\text{-}f(b,c)$ and $c \in set\text{-}f(a,c)$. Therefore $c \in set\text{-}\widehat{f}(a,c)$.

Case 2 ($b \in set\text{-}f(a,b)$ and $c \in set\text{-}f(c,b)$):
This implies $c \in set\text{-}f(c, set\text{-}f(a,b))$. Since f is associative, we have that $c \in set\text{-}f(set\text{-}f(c,a),b)$. It follows that $c \in set\text{-}f(c,a)$ since f is self-contained. Therefore $c \in set\text{-}\widehat{f}(a,c)$.

Case 3 ($b \in set\text{-}f(b,a)$ and $c \in set\text{-}f(b,c)$):
This implies $c \in set\text{-}f(set\text{-}f(b,a),c)$. Since f is associative, we have that $c \in set\text{-}f(b, set\text{-}f(a,c))$. Again, it follows that $c \in set\text{-}f(a,c)$ since f is self-contained. Therefore $c \in set\text{-}\widehat{f}(a,c)$.

Case 4 ($b \in set\text{-}f(b,a)$ and $c \in set\text{-}f(c,b)$):
This implies $c \in set\text{-}f(c, set\text{-}f(b,a))$. Since f is associative, we have that $c \in set\text{-}f(set\text{-}f(c,b),a)$. It follows that $c \in set\text{-}f(c,b)$ since f is self-contained and thus $c \in set\text{-}f(c,a)$. Therefore $c \in set\text{-}\widehat{f}(a,c)$.

It follows that $(a,c) \in E_{abc}$. This completes the proof that $\widehat{f}$ is associative. □

We also have the following.

THEOREM 4.5. $\mathrm{A}_\ell\text{-NPMV}_\mathrm{t}\text{-sel} = \mathrm{A}_\ell\text{C-NPMV}_\mathrm{t}\text{-sel}$.

The proof of this theorem proceeds in analogy to the proof of Theorem 4.4, except that here we focus on strings of equal length.[5]

Finally we turn to partial selector functions. The definition of selector functions allows a partial selector function for a set B to be undefined only when both inputs are not contained in B. However, the additional requirement of associativity forces any selector function for a nonempty set to be outright total.

PROPOSITION 4.6.

1. *If a (single- or multivalued) selector function f for a set $B \neq \emptyset$ is associative, then f is a total function.*
2. *If a (single- or multivalued) selector function f for a set B is associative at each length, then $f(x,y)$ is defined for all x and y such that both $|x| = |y|$ and $B^{=|x|} \neq \emptyset$.*

Proof. We first prove part 1 of the proposition. Let f be an associative selector function for a set $B \neq \emptyset$. For any inputs x and y such that $\{x,y\} \cap B \neq \emptyset$, $f(x,y)$ is not undefined (equivalently, $set\text{-}f(x,y) \neq \emptyset$), due to the definition of selectivity. Assume $x, y \notin B$ and $f(x,y)$ is undefined, i.e., $set\text{-}f(x,y) = \emptyset$. Consider a third string $z \in B$. Such a string exists since $B \neq \emptyset$. Note that $set\text{-}f(x,z) = \{z\}$ and $set\text{-}f(y,z) = \{z\}$ according to the definition of a selector function. So $set\text{-}f(x, set\text{-}f(y,z)) = \{z\}$

[5]Comments similar to those of footnote 4 apply here. Namely, the following strengthening of Theorem 4.5 clearly follows from the proof of Theorem 4.5: For every NPMV-selector f for a set B that is associative at each length, $\widehat{f}$ is a commutative NPMV-selector for B that is associative at each length n at which f is total.

However, Theorem 4.5 cannot be strengthened to A_ℓ-NPMV-sel = A_ℓC-NPMV-sel using $\widehat{f}$. A counterexample is the following: For strings a, b, c all of the same length, let $set\text{-}f(a,b) = set\text{-}f(b,a) = set\text{-}f(a,c) = set\text{-}f(c,b) = \emptyset$ and $set\text{-}f(c,a) = set\text{-}f(b,c) = \{c\}$. One can easily check that f is associative on the three-element set $\{a,b,c\}$. But $set\text{-}\widehat{f}(a, set\text{-}\widehat{f}(b,c)) = \{c\}$ yet $set\text{-}\widehat{f}(set\text{-}\widehat{f}(a,b),c) = \emptyset$. Similarly to the counterexample showing that f' does not preserve associativity for multivalued functions (Proposition 4.3), one can extend the definition of f to cover all strings from Σ^*.

yet (since $\textit{set-}f(x,y) = \emptyset$) $\textit{set-}f(\textit{set-}f(x,y),z) = \emptyset$. This contradicts the associativity of f.

The proof of part 2 is very similar to the proof of part 1. □

COROLLARY 4.7.

1. A-FP-sel = A-$\mathrm{FP_t}$-sel = CA-$\mathrm{FP_t}$-sel. *(That is,* A-FP-sel = A-P-sel = CA-P-sel.*)*
2. *Every set* $B \in \mathrm{A_\ell}$-FP-sel *has a commutative* FP*-selector that is total at each length* n *for which* $B^{=n} \neq \emptyset$ *and associative at each length* n *for which* $B^{=n} \neq \emptyset$.
3. A-NPSV-sel = A-$\mathrm{NPSV_t}$-sel = CA-$\mathrm{NPSV_t}$-sel. *(That is,* A-NPSV-sel = A-NP-sel = CA-NP-sel.*)*
4. *Every set* $B \in \mathrm{A_\ell}$-NPSV-sel *has a commutative* NPSV*-selector that is total at each length* n *for which* $B^{=n} \neq \emptyset$ *and associative at each length* n *for which* $B^{=n} \neq \emptyset$.
5. A-NPMV-sel = A-$\mathrm{NPMV_t}$-sel = CA-$\mathrm{NPMV_t}$-sel.
6. *Every set* $B \in \mathrm{A_\ell}$-NPMV-sel *has a commutative* NPMV*-selector that is total at each length* n *for which* $B^{=n} \neq \emptyset$ *and associative at each length* n *for which* $B^{=n} \neq \emptyset$.

Parts 1 and 3 follow directly from Proposition 4.6 and Theorem 4.1. Note that $\emptyset$ is trivially contained in CA-P-sel. Parts 2 and 4 follow implicitly from Proposition 4.6 and the proof of Theorem 4.2 (note footnote 4). Part 5 follows directly from Proposition 4.6 and Theorem 4.4. Part 6 again follows implicitly from Proposition 4.6 and the proof of Theorem 4.5 (note footnote 5).

5. Associativity drops advice complexity to linear. Ko showed the following result.

THEOREM 5.1 (see [Ko83]). P-sel $\subseteq \mathrm{P}/\mathcal{O}(n^2)$.

That is, deterministic advice interpreters given quadratic advice accept the P-selective sets. It is also known that nondeterministic advice interpreters with linear advice accept the P-selective sets, and this is optimal.

THEOREM 5.2 (see [HT96]; see also [HNP98]). P-sel $\subseteq \mathrm{NP}/n{+}1$ *but* P-sel $\not\subseteq \mathrm{NP}/n$.

It is natural to wonder whether the "P" advice interpretation of Theorem 5.1 can be unified with the linear advice amount of Theorem 5.2 to obtain the very strong claim P-sel $\subseteq \mathrm{P}/\mathcal{O}(n)$. Currently, no proof of this claim is known, researchers studying selectivity generally doubt that it holds, and there is some very recent relativized evidence in harmony with that doubt [Tha03]. However, proving the claim false seems unlikely in the immediate future, since by Theorem 5.2 any such proof would implicitly prove P ≠ NP.

Nonetheless, the following result shows that all associatively P-selective sets *are* accepted by deterministic advice interpreters with linear advice.

THEOREM 5.3. $\mathrm{A_\ell}$-FP-sel $\subsetneq \mathrm{P}/n{+}1$.

$(\mathrm{P}/1) - \mathrm{NPMV\text{-}sel} \neq \emptyset$ (see the comments in the proof of Theorem 5.3 below regarding why this holds). In light of this inequality, Theorem 5.3 supports the following corollary.

COROLLARY 5.4.

1. A-P-sel $\subsetneq \mathrm{P}/n{+}1$.
2. $\mathrm{A_\ell}$-P-sel $\subsetneq \mathrm{P}/n{+}1$.

Proof of Theorem 5.3. Let $B \in \mathrm{A_\ell}$-FP-sel. Let f be a commutative FP-selector for B that (a) is total at each length n such that $B^{=n} \neq \emptyset$ and that (b) is associative at

each length n such that $B^{=n} \neq \emptyset$. By Corollary 4.7 we know that such a commutative FP-selector for B must exist.

Let $n \in \mathbb{N}$ such that $B^{=n} \neq \emptyset$. Consider the directed graph $G_n = (B^{=n}, E_n)$, where $E_n = \{(x, y) \mid x, y \in B^{=n} \wedge f(x, y) = y\}$. G_n is a nonempty s-tournament.

Since f is a commutative selector function that is total and associative on $B^{=n}$, it follows from Proposition 3.2 that E_n is a transitive relation. So G_n is a transitive s-tournament, which by Proposition 3.3 implies that G_n contains a source node s_n. Note that $x \in B^{=n}$ implies $f(x, s_n) = x$ and $x \in \Sigma^n - B^{=n}$ implies $f(x, s_n) = s_n$. In other words, for all $n \in \mathbb{N}$, if $B^{=n} \neq \emptyset$ then there exists a string $s_n \in B^{=n}$ such that for all $x \in \Sigma^n$,

$$x \in B \iff f(x, s_n) = x.$$

Define, for all $n \in \mathbb{N}$,

$$h(1^n) = \begin{cases} 1s_n & \text{if } B^{=n} \neq \emptyset, \\ 0^{n+1} & \text{otherwise.} \end{cases}$$

Note that h on any input 1^n outputs a string of length exactly $n + 1$. Let $L = \{\langle x, 1y\rangle \mid |x| = |y| \wedge f(x, y) = x\}$. Clearly, $L \in \mathrm{P}$. Due to the above construction we also have, for all $x \in \Sigma^*$,

$$x \in B \iff \langle x, h(1^{|x|})\rangle \in L.$$

This shows that $B \in \mathrm{P}/n{+}1$.

It remains to show that $\mathrm{P}/n{+}1 - \mathrm{A}_\ell\text{-FP-sel} \neq \emptyset$. In fact, it clearly holds even that $(\mathrm{P}/1) - \text{NPMV-sel} \neq \emptyset$. The proof of this claim consists of a diagonalization against all self-contained NPMV functions. Let $f_1, f_2, \ldots$ be an enumeration (not necessarily effective, though in fact there do exist such effective enumerations) of all self-contained NPMV functions. Set

$$\begin{aligned} B = &\left\{0^{2i-1} \mid i \in \mathbb{N} \wedge \mathit{set}\text{-}f_i(0^{2i-2}, 0^{2i-1}) = \{0^{2i-2}\}\right\} \\ &\cup \left\{0^{2i-2} \mid i \in \mathbb{N} \wedge \mathit{set}\text{-}f_i(0^{2i-2}, 0^{2i-1}) \neq \{0^{2i-2}\}\right\}. \end{aligned}$$

B is not NPMV-selective, yet $B \in \mathrm{P}/1$. □

Note that for the correctness of the proof of Theorem 5.3 it actually suffices for f to be a partial FP-selector that is weakly associative at each length. f being a selector for B ensures that G_n is an s-tournament since partial selectors for B can be undefined only if both inputs are not in B. The weak associativity at each length of f yields that E_n is transitive. And finally, the above-defined set L remains a P set even under those weaker assumptions.

We note also that, more generally than Theorem 5.3, if a set A and a (not necessarily commutative) P-selector f for it have the property that at each nonempty length m there is some string $y \in A^{=m}$ at that length—or even at some length linearly related to that length—such that $f(y, z) = z$ or $f(z, y) = z$ for each $z \in A^{=m}$, then A is in $\mathrm{P}/\mathcal{O}(n)$. However, among ways of ensuring that this condition is met, we feel that associativity is a particularly natural and well-structured property to study.

The number of advice bits in Theorem 5.3 and Corollary 5.4, $n + 1$, is optimal.

THEOREM 5.5. $\text{A-P-sel} \not\subseteq \mathrm{P}/n$.

Proof. Hemaspaandra and Torenvliet [HT96] construct a P-selective set, which we will call B, such that $B \not\subseteq \mathrm{P}/n$. We will show that their set is A-selective. (We will

not repeat their proof that $B \not\subseteq \mathrm{P}/n$, since they already proved that.) Hemaspaandra and Torenvliet do not completely specify the P-selector function for B, though they make it clear that B is P-selective. In fact, it is easy to see that there are ways of completing the specification of their P-selector function so that it is not associative. However, our task is merely to prove that there is at least one way to complete their P-selector function so as to make it associative. We now do so.

The set B constructed by Hemaspaandra and Torenvliet satisfies the following properties:

1. $B \in \mathrm{DTIME}[2^{2^n}]$.
2. For all strings x, if $x \in B$, then $|x| \in \mathcal{L}$, where $\ell_0 = 2$, $\ell_{i+1} = 2^{2^{\ell_i}}$ for all $i \geq 0$, and $\mathcal{L} = \{\ell_0, \ell_1, \ell_2, \dots\}$.
3. For all strings x and y such that $|x| = |y|$, if $x \leq_{\mathrm{lex}} y$, then $\chi_B(x) \leq \chi_B(y)$, where χ_B denotes the characteristic function of B.

Let f be the following function:

$$f(x,y) = \begin{cases} x & \text{if } |x| \in \mathcal{L} \text{ and } |y| \notin \mathcal{L}, \\ y & \text{if } |x| \notin \mathcal{L} \text{ and } |y| \in \mathcal{L}, \\ x & \text{if } |x|, |y| \in \mathcal{L},\ |x| < |y|, \text{ and } x \in B, \\ y & \text{if } |x|, |y| \in \mathcal{L},\ |x| < |y|, \text{ and } x \notin B, \\ y & \text{if } |x|, |y| \in \mathcal{L},\ |x| > |y|, \text{ and } y \in B, \\ x & \text{if } |x|, |y| \in \mathcal{L},\ |x| > |y|, \text{ and } y \notin B, \\ \max(x,y) & \text{otherwise.} \end{cases}$$

Note that the "otherwise" case is reached exactly when

$$(|x| \notin \mathcal{L} \text{ and } |y| \notin \mathcal{L}) \text{ or } |x| = |y|.$$

In light of the above properties of B it is not hard to verify that f is polynomial-time computable. The key thing to note to see this is that when $|x|, |y| \in \mathcal{L}$ and $|x| \neq |y|$, then in that case the huge gaps in $\mathcal{L}$ and the fact that $B \in \mathrm{DTIME}[2^{2^n}]$ allow us to brute-force test $\min(x,y) \in B$ in time polynomial in $|x| + |y|$. Also (the polynomial-time computable function) f is clearly a P-selector for B.

What remains to show is that f is associative. From its definition, f is clearly commutative. So by Proposition 3.1, it suffices to show that for all $x, y, z \in \Sigma^*$, $||\{x,y,z\}|| = 3$, it holds that $f(x, f(y,z)) = f(y, f(x,z)) = f(z, f(x,y))$. So let a, b, and c be three strings such that $||\{a,b,c\}|| = 3$. Assume without loss of generality that $a <_{\mathrm{lex}} b <_{\mathrm{lex}} c$. Clearly it will also hold that $|a| \leq |b| \leq |c|$.

Case 1 ($|a|, |b|, |c| \notin \mathcal{L}$):
Applying the definition of f, we see that $f(a, f(b,c)) = f(b, f(a,c)) = f(c, f(a,b)) = \max(a,b,c)$.

Case 2 (the length of exactly one string from $\{a,b,c\}$ is in $\mathcal{L}$):
Let $w \in \{a,b,c\}$ be the unique string among a, b, and c such that $|w| \in \mathcal{L}$. Let v_1 and v_2 be the two strings in $\{a,b,c\}$ such that $|v_1|, |v_2| \notin \mathcal{L}$. So $f(w, v_1) = w$, $f(w, v_2) = w$, and consequently, since f is a self-contained function, $f(w, f(v_1, v_2)) = f(v_1, f(w, v_2)) = f(v_2, f(w, v_1)) = w$. It follows that $f(a, f(b,c)) = f(b, f(a,c)) = f(c, f(a,b)) = w$.

Case 3 (the length of exactly two strings from $\{a,b,c\}$ is in $\mathcal{L}$):
Let $v \in \{a,b,c\}$ be the unique string among a, b, and c such that $|v| \notin \mathcal{L}$. Let w_1 and w_2 be the two strings in $\{a,b,c\}$ such that $|w_1|, |w_2| \in \mathcal{L}$. So $f(v, w_1) = w_1$, $f(v, w_2) = w_2$, and consequently $f(v, f(w_1, w_2)) = f(w_1, f(v, w_2)) = f(w_2, f(v, w_1)) = f(w_1, w_2)$. It follows that $f(a, f(b,c)) = f(b, f(a,c)) = f(c, f(a,b)) = f(w_1, w_2)$.

Case 4 ($|a|, |b|, |c| \in \mathcal{L}$):

Case 4.1 ($\|\{|a|, |b|, |c|\}\| = 1$):

So $|a| = |b| = |c|$ and thus, by the definition of f, we have $f(a, f(b, c)) = f(b, f(a, c)) = f(c, f(a, b)) = \max(a, b, c)$.

Case 4.2 ($\|\{|a|, |b|, |c|\}\| = 2$):

So, as $|a| \leq |b| \leq |c|$, it holds that $|a| = |b|$ or $|b| = |c|$, yet not all three strings have the same length.

Case 4.2.1 ($|a| = |b|$ and $|b| < |c|$):

Note that $f(a, b) = \max(a, b) = b$,

$$f(a,c) = \begin{cases} a & \text{if } a \in B, \\ c & \text{otherwise,} \end{cases} \qquad \text{and} \qquad f(b,c) = \begin{cases} b & \text{if } b \in B, \\ c & \text{otherwise.} \end{cases}$$

Recall that $a <_{\text{lex}} b <_{\text{lex}} c$. Due to the third property of B quoted earlier in this proof, we thus have $a \in B \implies b \in B$ or, equivalently, $b \notin B \implies a \notin B$. So

$$f(a, f(b, c)) = f(b, f(a, c)) = f(c, f(a, b)) = \begin{cases} b & \text{if } b \in B, \\ c & \text{otherwise.} \end{cases}$$

Case 4.2.2 ($|a| < |b|$ and $|b| = |c|$):

Recall that $a <_{\text{lex}} b <_{\text{lex}} c$. So $f(b, c) = \max(b, c) = c$,

$$f(a,b) = \begin{cases} a & \text{if } a \in B, \\ b & \text{otherwise,} \end{cases} \qquad \text{and} \qquad f(a,c) = \begin{cases} a & \text{if } a \in B, \\ c & \text{otherwise.} \end{cases}$$

It follows that

$$f(a, f(b, c)) = f(b, f(a, c)) = f(c, f(a, b)) = \begin{cases} a & \text{if } a \in B, \\ c & \text{otherwise.} \end{cases}$$

Case 4.3 ($\|\{|a|, |b|, |c|\}\| = 3$):

So we have $|a|, |b|, |c| \in \mathcal{L}$ and $|a| < |b| < |c|$. Thus

$$f(a,b) = \begin{cases} a & \text{if } a \in B, \\ b & \text{otherwise,} \end{cases} \qquad f(a,c) = \begin{cases} a & \text{if } a \in B, \\ c & \text{otherwise,} \end{cases}$$

$$\text{and} \qquad f(b,c) = \begin{cases} b & \text{if } b \in B, \\ c & \text{otherwise.} \end{cases}$$

It follows that

$$f(a, f(b, c)) = f(b, f(a, c)) = f(c, f(a, b)) = \begin{cases} a & \text{if } a \in B, \\ b & \text{if } a \notin B \text{ and } b \in B, \\ c & \text{otherwise.} \end{cases}$$

This completes the proof of the claim that f is associative. □

COROLLARY 5.6.

1. A_ℓ-P-sel $\not\subseteq$ P/n.
2. A_ℓ-FP-sel $\not\subseteq$ P/n.

In fact, for any recursive function g, A-P-sel $\not\subseteq$ DTIME$[g(n)]/n$. The reason for this is that we may take the P-selective set that Hemaspaandra and Torenvliet [HT96] prove is not in DTIME$[g(n)]/n$ and, just as in the proof of Theorem 5.5, may complete

its P-selector function in a manner that achieves associativity. From this observation, it follows that the linear advice bound for associatively NP-selective sets and also the linear advice bound for associatively NPMV-selective sets that will be proven as Theorem 5.9 and Corollary 5.10 are optimal.

COROLLARY 5.7.

1. A-NP-sel $\not\subseteq$ (NP $\cap$ coNP)/n.
2. A_ℓ-NP-sel $\not\subseteq$ (NP $\cap$ coNP)/n.
3. A_ℓ-NPSV-sel $\not\subseteq$ (NP $\cap$ coNP)/n.
4. A-NPMV$_t$-sel $\not\subseteq$ NP/n.
5. A_ℓ-NPMV$_t$-sel $\not\subseteq$ NP/n.
6. A_ℓ-NPMV-sel $\not\subseteq$ NP/n.

So we have established an n-bit lower bound for the advice complexity of (associatively) NP- and NPMV-selective sets. The following upper bounds on the amount of advice needed to (nondeterministically) accept NP- and NPMV-selective sets are known.

THEOREM 5.8.

1. [HHN$^+$95] NP-sel $\subseteq$ (NP $\cap$ coNP)/poly.
2. [HNOS96b] NPSV-sel $\subseteq$ NP/poly $\cap$ coNP/poly *and* NPSV-sel $\cap$ NP $\subseteq$ (NP $\cap$ coNP)/poly.
3. [HNOS96b] NPMV$_t$-sel $\subseteq$ NP/poly $\cap$ coNP/poly.
4. [HNOS96b] NPMV-sel $\subseteq$ NP/poly.

We note that the results we have stated that involve complexity classes relativize. In particular, one can relativize them by any particular NP $\cap$ coNP set, and so regarding associativity and the NP-selective sets (equivalently, the NPSV$_t$-selective sets and, equivalently, the $\mathrm{FP}_t^{\mathrm{NP}\cap\mathrm{coNP}}$-selective sets and, equivalently, the $\mathrm{FP}^{\mathrm{NP}\cap\mathrm{coNP}}$-selective sets; see [HNOS96b, HHN$^+$95] for definitions and discussion; note that $\mathrm{FP}_t^{\mathrm{NP}\cap\mathrm{coNP}}$-sel $= \mathrm{FP}^{\mathrm{NP}\cap\mathrm{coNP}}$-sel for basically the same reason that FP$_t$-sel = FP-sel), it follows from our results that all length-associatively NP-selective sets are in (NP $\cap$ coNP)/$n+1$.

THEOREM 5.9.

1. A_ℓ-NP-sel $\subsetneq$ (NP $\cap$ coNP)/n+1.
2. A_ℓ-NPMV-sel $\subsetneq$ NP/n+1 $\cap$ coNP/n+1.

Proof. Regarding the strictness ($\subsetneq$ rather than $\subseteq$) of both parts, this follows from the easy fact (noted in the proof of Theorem 5.3) that (P/1) $-$ NPMV-sel $\neq \emptyset$. The containment claims of both parts remain to be proven.

We now prove the containment part of item 1 of the theorem, i.e., that A_ℓ-NP-sel $\subseteq$ (NP $\cap$ coNP)/n+1. Let $B \in A_\ell$-NP-sel. It follows from Theorem 4.2 that there exists a commutative NPSV$_t$-selector f for B that is associative at each length.

One can now invoke the entire containment part of the proof of Theorem 5.3, i.e., the proof for the claim A_ℓ-P-sel $\subseteq$ P/n+1 (this is actually that proof weakened to the case described by part 2 of Corollary 5.4), with the obvious change from P-selector to NPSV$_t$-selector, and thus resulting in the fact that the set L defined in the proof of Theorem 5.3 is now in NP $\cap$ coNP. To see the latter, simply note that $L = \{\langle x, 1y\rangle \mid |x| = |y| \wedge f(x,y) = x\}$ can also be written as $L = \{\langle x, 1y\rangle \mid |x| = |y| \wedge (x = y \vee f(x,y) \neq y)\}$ since f is a total NPSV-selector.

We now show the containment part of item 2, i.e., that A_ℓ-NPMV-sel $\subseteq$ NP/n+1 $\cap$ coNP/n+1. Let $B \in A_\ell$-NPMV-sel. It follows from Corollary 4.7 that there exists a commutative NPMV-selector f for B that is total at each length at which B is nonempty, and that is associative at each length at which B is nonempty.

Let $n \in \mathbb{N}$ be such that $B^{=n} \neq \emptyset$. Consider the digraph $G_n = (B^{=n}, E_n)$, where $E_n = \{(x,y) \mid x, y \in B^{=n} \wedge y \in \mathit{set}\text{-}f(x,y)\}$. By the definition of NPMV-selectivity

(see Definition 2.1), f must be defined for all $x, y \in B^{=n}$. So G_n is a nonempty complete digraph. In fact, note even that, from Proposition 4.6, f is defined for all $x, y \in \Sigma^n$. Since f is a commutative selector function that is total and associative on $B^{=n}$, it follows from Proposition 3.2 that E_n is a transitive relation. So it follows from Proposition 3.5 that G_n contains a nonempty strong distance-one source-clique, i.e., an induced subgraph $S = (V_S, E_S)$, $V_S \neq \emptyset$, having the following properties:

1. S is a maximal strong clique.
2. For all $u \in V_S$ and for all $v \in B^{=n} - V_S$, $(u, v) \in E_n$ and $(v, u) \notin E_n$.

Let u_n denote the lexicographically smallest string in V_S. (This is just for specificity. Any string from V_S would function the same way.) Note that $x \in B^{=n}$ implies $x \in \mathit{set}\text{-}f(u_n, x)$, whereas $x \in \Sigma^n - B^{=n}$ implies $x \notin \mathit{set}\text{-}f(u_n, x)$. Hence, for all $n \in \mathbb{N}$ such that $B^{=n} \neq \emptyset$ there exists a string $u_n \in B^{=n}$ such that for all $x \in \Sigma^n$,

$$x \in B \iff x \in \mathit{set}\text{-}f(u_n, x).$$

Define, for all $n \in \mathbb{N}$,

$$h(1^n) = \begin{cases} 1u_n & \text{if } B^{=n} \neq \emptyset, \\ 0^{n+1} & \text{otherwise.} \end{cases}$$

Note that h on any input 1^n outputs a string of length exactly $n+1$. Let $L = \{\langle x, 1y\rangle \mid |x| = |y| \wedge x \in \mathit{set}\text{-}f(y, x)\}$. Clearly, $L \in \mathrm{NP}$. Due to the above construction we also have, for all $x \in \Sigma^*$,

$$x \in B \iff \langle x, h(1^{|x|})\rangle \in L.$$

This shows that $B \in \mathrm{NP}/n{+}1$.

To see that $B \in \mathrm{coNP}/n{+}1$ we have to repeat the argument on $\Sigma^n - B^{=n}$. Let $n \in \mathbb{N}$ such that both $B^{=n} \neq \emptyset$ and $\Sigma^n - B^{=n} \neq \emptyset$. (If $B^{=n} = \emptyset$ or $\Sigma^n - B^{=n} = \emptyset$, then we at this length easily have a $\mathrm{coNP}/n{+}1$ algorithm for that case and will signal such cases explicitly in the advice function that we will soon build.) Consider the digraph $G'_n = (\Sigma^n - B^{=n}, E'_n)$, where $E'_n = \{(x, y) \mid x, y \in \Sigma^n - B^{=n} \wedge y \in \mathit{set}\text{-}f(x, y)\}$. G'_n is a nonempty complete digraph. (G'_n is nonempty since $\Sigma^n - B^{=n} \neq \emptyset$ and G'_n is a complete digraph since f is total at length n due to $B^{=n} \neq \emptyset$ and Proposition 4.6.) Since f is a commutative selector function that is total and associative on $\Sigma^n - B^{=n}$ it follows from Proposition 3.2 that E'_n is a transitive relation. Hence it follows from Proposition 3.5 that G'_n contains a nonempty strong distance-one target-clique, i.e., an induced subgraph $T = (V_T, E_T)$, $V_T \neq \emptyset$, having the following properties:

1. T is a maximal strong clique.
2. For all $u \in V_T$ and for all $v \in (\Sigma^n - B^{=n}) - V_T$, $(u, v) \notin E'_n$ and $(v, u) \in E'_n$.

Let v_n denote the lexicographically largest string in V_T. (This is just for specificity. Any string from V_T would function the same way.) It follows that for $n \in \mathbb{N}$, if $B^{=n} \neq \emptyset$ and $\Sigma^n - B^{=n} \neq \emptyset$, then there exists a string $v_n \in \Sigma^n - B^{=n}$ such that for all $x \in \Sigma^n$,

$$x \in B \iff v_n \notin \mathit{set}\text{-}f(x, v_n).$$

Define, for all $n \in \mathbb{N}$,

$$h'(1^n) = \begin{cases} 0^{n+1} & \text{if } B^{=n} = \emptyset, \\ 01^n & \text{if } B^{=n} = \Sigma^n, \\ 1v_n & \text{if } B^{=n} \neq \emptyset \text{ and } B^{=n} \neq \Sigma^n. \end{cases}$$

Note that h' on any input 1^n outputs a string of length exactly $n+1$. Let $L' = \{\langle x, 1y\rangle \mid |x| = |y| \wedge y \notin \mathit{set}\text{-}f(x,y)\} \cup \{\langle x, 01^{|x|}\rangle \mid x \in \Sigma^*\}$. Clearly, $L' \in \mathrm{coNP}$. Due to the above construction we also have, for all $x \in \Sigma^*$,

$$x \in B \iff \langle x, h'(1^{|x|})\rangle \in L'.$$

This shows that $B \in \mathrm{coNP}/n{+}1$. □

Since, as noted earlier, $(\mathrm{P}/1) - \mathrm{NPMV\text{-}sel} \neq \emptyset$, Theorem 5.9 yields the following corollary.

COROLLARY 5.10.

1. $\mathrm{A\text{-}NP\text{-}sel} \subsetneq (\mathrm{NP} \cap \mathrm{coNP})/n{+}1$.
2. $\mathrm{A}_\ell\mathrm{\text{-}NPSV\text{-}sel} \subsetneq \mathrm{NP}/n{+}1 \cap \mathrm{coNP}/n{+}1$.
3. $\mathrm{A\text{-}NPMV}_\mathrm{t}\mathrm{\text{-}sel} \subsetneq \mathrm{NP}/n{+}1 \cap \mathrm{coNP}/n{+}1$.
4. $\mathrm{A}_\ell\mathrm{\text{-}NPMV}_\mathrm{t}\mathrm{\text{-}sel} \subsetneq \mathrm{NP}/n{+}1 \cap \mathrm{coNP}/n{+}1$.

We mention in passing that—since $\log_2((2^{n+1}-1)+1) = n+1$ and thus one can include in the advice-seeking s-tournament all lengths up to the current one—the $n+1$ advice bounds in part 1 of Corollaries 5.4 and 5.10 even hold in the "strong advice" model of Ko, Balcázar, and Schöning [Ko87, BS92] in which advice must work for all strings up to and including a given length (see also the discussion in [HT96]). The $n+1$ advice bound in the "$\mathrm{NP}/n+1$" of part 3 of Corollary 5.10 for the same reason holds also in the "strong advice" model. Since the "$\mathrm{coNP}/n+1$" part of the proof of part 2 of Theorem 5.9 had *two* special-meaning advice cases, at first it might seem that regarding the "$\mathrm{coNP}/n+1$" of part 3 of Corollary 5.10 $\lceil \log_2((2^{n+1}-1)+2)\rceil = n+2$ advice bits, rather than $n+1$ advice bits, are needed in the "strong advice" model. However, note that we can hardcode into our machine the issue of whether some one string, say ϵ, is in our $\mathrm{A\text{-}NPMV}_\mathrm{t}$-sel set, and then can leave ϵ out of all the tournaments and always handle it directly. This ensures that the size of the collection of strings that we have to worry about of length up to n is $2^{n+1}-2$, and so the advice size we need is $\lceil \log_2((2^{n+1}-2)+2)\rceil = n+1$. So $\mathrm{A\text{-}NPMV}_\mathrm{t}$-sel indeed is in $\mathrm{NP}/_{\mathrm{strong}}\, n+1 \cap \mathrm{coNP}/_{\mathrm{strong}}\, n+1$, where by $/_{\mathrm{strong}}$ we mean the strong advice model. Keeping in mind that $(\mathrm{P}/1) - \mathrm{NPMV\text{-}sel} \neq \emptyset$, we state the discussion of this paragraph as follows.

PROPOSITION 5.11.

1. $\mathrm{A\text{-}P\text{-}sel} \subsetneq \mathrm{P}/_{\mathrm{strong}}\, n+1$.
2. $\mathrm{A\text{-}NP\text{-}sel} \subsetneq (\mathrm{NP} \cap \mathrm{coNP})/_{\mathrm{strong}}\, n+1$.
3. $\mathrm{A\text{-}NPMV}_\mathrm{t}\mathrm{\text{-}sel} \subsetneq \mathrm{NP}/_{\mathrm{strong}}\, n+1 \cap \mathrm{coNP}/_{\mathrm{strong}}\, n+1$.

It is natural to wonder whether there is some natural "NPSV" analogue of part 1 of Theorem 5.9 that yields an $(\mathrm{NP}\cap\mathrm{coNP})/n{+}1$ result. In light of part 2 of Theorem 5.8, one in particular might hope that $\mathrm{A}_\ell\mathrm{\text{-}NPSV\text{-}sel} \cap \mathrm{NP} \subseteq (\mathrm{NP}\cap\mathrm{coNP})/n+1$. However, we see no way of proving this. The key obstacle is obtaining the "$\mathrm{NP}\cap\mathrm{coNP}$" of "$(\mathrm{NP}\cap\mathrm{coNP})/n+1$" when dealing with partial function classes such as NPSV. One can patch one's way around the partialness of NPSV, namely, by using the advice to give not just an appropriate (via part 3 of Proposition 3.3) string from the set but also a certificate proving that the string is in the set. However, doing so requires enough bits to encode the certificate. So what one obtains, if one modifies part 1 of Theorem 5.9 carefully via the strategy just described, is the following result, in which NP_1 denotes the class, introduced by Kintala and Fischer in 1977 ([KF77]; see also, for contrast, [KF80]), of sets that are accepted by NP machines that use at most a linear number of nondeterministic moves.

THEOREM 5.12. $\mathrm{A}_\ell\mathrm{\text{-}NPSV\text{-}sel} \cap \mathrm{NP}_1 \subseteq (\mathrm{NP}\cap\mathrm{coNP})/\mathcal{O}(n)$.

The following is crucial in seeing that Theorem 5.12 holds. When given advice asserting that our A_ℓ-NPSV-selective set, B, contains y as a "magic" (in the sense of part 3 of Proposition 3.3) string for length $|y|$, only if the advice contains a correct certificate for $y \in B$ do we go forward and run our NPSV-selector function f, i.e., $f(x, y)$, where x, $|x| = |y|$, is the string whose membership we are interested in. So we run f only on cases in which at least one of the inputs on which we run f is clearly known by us to belong to B. By the definition of NPSV-selectivity, f on such inputs will always be defined. Thus, working hand in hand with the advice and the definition of NPSV-selectivity, we have in effect locally total-ized f, and this is what creates an $\mathrm{NP} \cap \mathrm{coNP}$ set and yields the $(\mathrm{NP} \cap \mathrm{coNP})/\mathcal{O}(n)$ result.

To the best of our knowledge, Theorem 5.12 is only the second time in the literature that the direct local totalization of NPSV functions appears. The first time was in Hemaspaandra et al. [HNOS96b], though in contrast there they were in the context of a Ko-type [Ko83] advice setting, i.e., one in which (ignoring certificate space) a linear number of linear-sized strings were being provided. Here, we have given a second application of their local totalization technique, this time in the context of the (ignoring certificate space) one-string advice of the sort provided by part 3 of Proposition 3.3.

Finally, we would like to remark on results involving weak associativity. If we assume the NPSV- or NPMV-selectors to be only weakly associative, we are merely able to show containment in $\mathrm{NP}/n{+}1$.

6. Printability and nonimmunity. Associativity yields additional simplicity properties. Let us consider nonimmunity results (i.e., presence of infinite subsets). For general NPSV-selective sets and thus also for NP- and P-selective sets, Theorem 6.1 holds. In contrast, for associatively NPSV-selective sets, we have Theorem 6.2. To see how these bounds relate, note that $\mathrm{UP}^{\mathrm{NP}} \subseteq \mathrm{NP}^{\mathrm{NP}}$. Of course, $\mathrm{NP}^{\mathrm{NP}}$ is synonymous with Σ_2^p; however, so as to ensure the relationship to $\mathrm{UP}^{\mathrm{NP}}$—and the way we'll use those "NP"s in our proofs—shows clearly, throughout this section we will write $\mathrm{NP}^{\mathrm{NP}}$ rather than Σ_2^p.

THEOREM 6.1. *Every infinite* NPSV*-selective set B has an infinite* $\mathrm{FP}^{B \oplus \mathrm{NP}^{\mathrm{NP}}}$*-printable subset.*

THEOREM 6.2. *Every infinite set B that is either* A-NPSV*-selective or* A_ℓ-NP*-selective has an infinite* $\mathrm{FP}^{B \oplus \mathrm{UP}^{\mathrm{NP}}}$*-printable subset.*

COROLLARY 6.3.

1. *Every infinite* P*-selective set B has an infinite* $\mathrm{FP}^{B \oplus \mathrm{NP}^{\mathrm{NP}}}$*-printable subset.*
2. *Every infinite* NP*-selective set B has an infinite* $\mathrm{FP}^{B \oplus \mathrm{NP}^{\mathrm{NP}}}$*-printable subset.*
3. *Every infinite* A-P*-selective (or even* A_ℓ-P*-selective) set B has an infinite* $\mathrm{FP}^{B \oplus \mathrm{UP}^{\mathrm{NP}}}$*-printable subset.*
4. *Every infinite* A-NP*-selective set B has an infinite* $\mathrm{FP}^{B \oplus \mathrm{UP}^{\mathrm{NP}}}$*-printable subset.*

Proof of Theorem 6.1. Let B be an infinite NPSV-selective set. By Fact 2.3 there exists a commutative NPSV-selector f for B. Let $n \in \mathbb{N}$. Consider the f-induced digraph on $B^{=n}$ (in the sense defined in section 3) and call it $G_{B,n,f}$. Since f is always defined when at least one of its inputs is in B, it follows that $G_{B,n,f}$ is an s-tournament. By applying a standard result (stated as Theorem 3.1 in [HO02]; the theorem refers to tournaments rather than s-tournaments, but the difference does not affect this result) of Ko [Ko83] about tournament theory to $G_{B,n,f}$, we have that for each $n \in \mathbb{N}$ there exists a set $D_n \subseteq B^{=n}$ such that

1. $\|D_n\| \leq n+1$, and
2. for every string $x \in B^{=n}$, there exists a string $y \in D_n$ such that $y \in \mathit{set}\text{-}f(x,y)$.

Of course, when $B^{=n} = \emptyset$, $G_{B,n,f}$ has no nodes and $D_n = \emptyset$.

Since f is a selector for B and thus $f(u,v) = v$ for all $u \notin B$ and all $v \in B$, we can state that for each $n \in \mathbb{N}$ such that $B^{=n} \neq \emptyset$ there exists a set $D_n \subseteq B^{=n}$ such that

1. $\|D_n\| \leq n+1$, and
2. for every string $x \in \Sigma^n$, there exists a string $y \in D_n$ such that $y \in \mathit{set}\text{-}f(x,y)$.

Let *setcode* denote some standard encoding (of finite sets into strings) that is computable and invertible in polynomial time. Let $\langle \cdot, \cdot \rangle$ be a standard polynomial-time computable, polynomial-time invertible pairing function. Define

$$E = \{\langle 1^n, \mathit{setcode}(\{y_1, y_2, \ldots, y_j\})\rangle \mid 1 \leq j \leq n+1 \wedge |y_1| = \cdots = |y_j| = n \wedge (\forall x \in \Sigma^n)(\exists i : 1 \leq i \leq j)[x \notin \mathit{set}\text{-}f(x, y_i)]\}.$$

Observe that the condition $x \notin \mathit{set}\text{-}f(x,y_i)$ is equivalent to $\mathit{set}\text{-}f(x,y_i) \in \{\emptyset, \{y_i\}\}$. Clearly, $E \in \mathrm{coNP}$. For all n, let $g(1^n)$ denote the lexicographically largest string ω such that $\langle 1^n, \omega\rangle \in E$ if such a string ω exists. (Note that in light of the discussion earlier in this proof and the properties and single-valuedness of f, it holds that, for each n such that $B^{=n} \neq \emptyset$, there exists at least one string w such that $\langle 1^n, w\rangle \in E$.) Otherwise $g(1^n)$ is undefined. Given 1^n one can by applying a prefix search procedure compute $g(1^n)$ in polynomial time with the help of oracle queries to the oracle $F = \{\langle 1^n, z\rangle \mid n \in \mathbb{N} \wedge z \in \Sigma^* \wedge (\exists \omega \in \Sigma^*)[\langle 1^n, z\omega\rangle \in E]\}$. Clearly, $F \in \mathrm{NP}^{\mathrm{NP}}$ and hence $g \in \mathrm{FP}^{\mathrm{NP}^{\mathrm{NP}}}$.

We claim that, for all n, if $B^{=n} \neq \emptyset$, then for every $\langle 1^n, \mathit{setcode}(\{y_1, y_2, \ldots, y_j\})\rangle \in E$ $(1 \leq j \leq n+1)$—and so in particular for $\langle 1^n, g(1^n)\rangle$—there exists an index i, $1 \leq i \leq j$, such that $y_i \in B^{=n}$. To see this, suppose that $B^{=n} \neq \emptyset$, yet there exists some $\langle 1^n, \mathit{setcode}(\{y_1, y_2, \ldots, y_j\})\rangle \in E$ $(1 \leq j \leq n+1)$ such that, for all i, $1 \leq i \leq j$, $y_i \notin B^{=n}$. Let $x \in B^{=n}$. Due to the definition of E we have that there exists an index i, $1 \leq i \leq j$, such that either $\mathit{set}\text{-}f(x,y_i) = \{y_i\}$ or $f(x,y_i)$ is undefined, both of which are impossible since f is an NPSV-selector for B and so, when exactly one of its arguments (x in this case) is in B, it outputs that argument.

Consider the set

$$C = B \cap \bigcup_{\{i \in \mathbb{N} \mid g(1^i) \text{ is defined}\}} \mathit{setcode}^{-1}(g(1^i)).$$

Note that C is infinite if B is infinite. Also $C \subseteq B$. In order to see that C is $\mathrm{FP}^{B \oplus \mathrm{NP}^{\mathrm{NP}}}$-printable, consider the following DPTM M: On input 1^n, $M(1^n)$ computes $g(1^0), g(1^1), \ldots, g(1^n)$ with the help of the $\mathrm{NP}^{\mathrm{NP}}$ part, F, of its $B \oplus \mathrm{NP}^{\mathrm{NP}}$ oracle. It then computes the polynomial-sized set $\bigcup_{\{i \leq n \mid g(1^i) \text{ is defined}\}} \mathit{setcode}^{-1}(g(1^i))$ and then, using the B part of its oracle, finds which of these strings are in B and outputs them. □

Theorem 6.1 should be contrasted with the result of Hemaspaandra et al. [HOZZ04] that P-sel is not (weak-$\mathrm{FP}^{\mathrm{NP}^{\mathrm{NP}}}$-rankable)-immune.

Proof of Theorem 6.2. In light of part 3 of Corollary 4.7, it actually holds that A_ℓ-NP-sel $\supseteq$ A-NP-sel = A-NPSV-sel. Hence it suffices to show the claim for A_ℓ-NP-selective sets. Let B be an infinite A_ℓ-NP-selective set. By part 2 of Theorem 4.2,

A_ℓ-NP-sel = A_ℓC-NP-sel. So, let f be a commutative $NPSV_t$-selector for B that is associative at each length.

Consider the function *score* that is defined as

$$score(x) = \|\{z \in \Sigma^{|x|} \mid f(x,z) = x\}\|.$$

Note that for each $n \in \mathbb{N}$ and for each $x \in \Sigma^n$, (a) $x \notin B \implies score(x) \leq 2^n - \|B^{=n}\|$ and (b) $x \in B \implies score(x) \geq 2^n - \|B^{=n}\| + 1$. So for all $x \in B$ and all $y \notin B$ such that $|x| = |y|$, $score(y) < score(x)$. It follows from the fact that f is commutative, total, single-valued, and length-associative that for all n, $\max\{score(y) \mid |y| = n\} = 2^n$ (consider Proposition 3.3 applied to the f-induced digraph on the nodes $(\Sigma^*)^{=n}$). So for each n there exists exactly one string at length n, call it d_n, such that $score(d_n) = \max\{score(y) \mid |y| = n\} = 2^n$. Thus, the set

$$F = \{\langle 1^n, z\rangle \mid n \in \mathbb{N} \wedge z \in (\Sigma^*)^{\leq n} \wedge (\exists \omega : |\omega| = n - |z|)[score(z\omega) = 2^n]\}$$

is in UP^{NP}. (To see this, note that $score(x) = 2^{|x|}$ is in our setting equivalent to $(\forall y \in \Sigma^{|x|})[x = y \vee f(x,y) \neq y]$.) Given 1^n, computing d_n can be done in polynomial time with the help of oracle F. Let $C = B \cap \{d_i \mid i \geq 0\}$. Clearly, since B is infinite, by our choice of d_i we have that C is both infinite and $FP^{B \oplus UP^{NP}}$-printable. □

So, Theorems 6.1 and 6.2 have been proven.[6]

It follows from the proof of Theorem 6.2 that any associatively NPSV selective set for which there is an infinite set of lengths at which we know it is not empty is in fact not coNP-immune. This is a *very* weak type of partial census information.

Definition 6.4. *We say a set B is hintable if there is an infinite tally set, $T \subseteq 1^*$, such that $T \in P$ and*

$$(\forall i)[1^i \in T \implies \|B^{=i}\| \neq 0].$$

Theorem 6.5. *Any hintable* A-NPSV-*selective (or even* A_ℓ-NPSV-*selective) set has an infinite* coNP *subset (i.e., languages in* A_ℓ-NPSV-sel$\cap$Hintable *are not* coNP-*immune).*

Proof. Let B be an infinite hintable A_ℓ-NPSV-selective set. Let the tally set T be a hint set for B in the sense of Definition 6.4. Let f be a commutative NPSV-selector for B that is total at each length n such that $B^{=n} \neq \emptyset$ and associative at each length n such that $B^{=n} \neq \emptyset$. Such a selector for B exists by Corollary 4.7. Define the function *score* as in the proof of Theorem 6.2. Since B is A_ℓ-NPSV-selective, we have that, for all n, if $B^{=n} \neq \emptyset$, then there exists a unique string of length n having a score of 2^n and it is in B. (If $B^{=n} = \emptyset$, then there might be no string at length n having a score of 2^n.) The set

$$C = \{x \mid 1^{|x|} \in T \wedge score(x) = 2^n\}$$

is an infinite subset of B and is in coNP since it will hold that $C = \{x \mid 1^{|x|} \in T \wedge (\forall y : |y| = |x|)[y = x \vee y \notin set\text{-}f(x,y)]\}$. □

[6] If one cares about the number of queries to B needed in the printability claims of Theorems 6.1 and 6.2 and Corollary 6.3, the following, which was communicated to us (regarding a somewhat weaker set of results in an earlier version of this paper) by Till Tantau [Tan01], can be observed: One can limit one's queries to B to a logarithmic number by putting the queries to B into a Toda-like ordering ([Tod91]; see also [HT03]) and binary searching to find which are in and which are out. (For the nondeterministic selectivity claims, one will use the power of NP in the oracle to Toda-order the strings. Also, the partial-function cases do not present a problem, e.g., on those one can modify for the partial case the "bubblesort"-type proof given by Hemaspaandra and Torenvliet [HT03, Proof of Lemma 4.5].

7. Are all P-selective sets associatively P-selective? Many of our results give simplicity properties of A-P-sel. It is natural to wonder whether in fact A-P-sel is all of P-sel, that is, whether all P-selective sets are associatively P-selective. In this section, we prove upper bounds on the power needed to associatively select sets. One consequence, Corollary 7.3, is that if P = NP, then A-P-sel and P-sel are equal.

THEOREM 7.1.

1. *Every* $\mathrm{NPMV_t}$*-selective set has a single-valued, commutative selector function in* $\mathrm{FP_t}^{\mathrm{NP}}$ *that is associative.*
2. *Every* NPMV*-selective set* A *has a single-valued, commutative selector function in* $\mathrm{FP_t}^{\mathrm{NP}}$ *that is associative on* A*.*
3. *Every* NPMV*-selective set has a single-valued, commutative selector function in* $\mathrm{FP_t}^{\Sigma_2^p}$ *that is associative.*

Proof. We first prove part 1 of the result. Let A be an $\mathrm{NPMV_t}$-selective set. Let f be an $\mathrm{NPMV_t}$-selector for A. Without loss of generality, assume f to be commutative (see Fact 2.3). For every pair of strings x and y, ω is called a connector of x and y if and only if either (a) $\omega \in \mathit{set}\text{-}f(x,\omega)$ and $y \in \mathit{set}\text{-}f(\omega,y)$, or (b) $x \in \mathit{set}\text{-}f(x,\omega)$ and $\omega \in \mathit{set}\text{-}f(\omega,y)$. Note that for any two strings x and y, there always exist connectors of x and y, namely, x and y. Define the function g by setting, for all x and y,

$$g(x,y) = \begin{cases} y & \text{if the lexicographically smallest connector } \omega \text{ of } x \text{ and } y \text{ yields } \omega \in \mathit{set}\text{-}f(x,\omega) \wedge y \in \mathit{set}\text{-}f(\omega,y) \text{ but not } x \in \mathit{set}\text{-}f(x,\omega) \wedge \omega \in \mathit{set}\text{-}f(\omega,y), \\ x & \text{if the lexicographically smallest connector } \omega \text{ of } x \text{ and } y \text{ yields } x \in \mathit{set}\text{-}f(x,\omega) \wedge \omega \in \mathit{set}\text{-}f(\omega,y) \text{ but not } \omega \in \mathit{set}\text{-}f(x,\omega) \wedge y \in \mathit{set}\text{-}f(\omega,y), \\ \max(x,y) & \text{if the lexicographically smallest connector } \omega \text{ of } x \text{ and } y \text{ yields } \omega \in \mathit{set}\text{-}f(x,\omega) \wedge y \in \mathit{set}\text{-}f(\omega,y) \text{ and } x \in \mathit{set}\text{-}f(x,\omega) \wedge \omega \in \mathit{set}\text{-}f(\omega,y). \end{cases}$$

Note that g is a single-valued function in $\mathrm{FP_t}^{\mathrm{NP}}$. To compute $g(x,y)$ the NP oracle is first used to—via either binary search or prefix search—compute the lexicographically smallest connector of x and y, and then, via two more queries, is used to determine which of the three cases from the definition of g is applicable. Note that g is commutative and self-contained.

To see that g is even a selector for A, suppose that there are strings x and y such that $x \in A$ and $y \notin A$ yet $g(x,y) = y$. Let ω be the lexicographically smallest connector for x and y. It follows that either (a) $\omega \in \mathit{set}\text{-}f(x,\omega) \wedge y \in \mathit{set}\text{-}f(\omega,y)$ but not $x \in \mathit{set}\text{-}f(x,\omega) \wedge \omega \in \mathit{set}\text{-}f(\omega,y)$, or (b) $y = \max(x,y)$, $\omega \in \mathit{set}\text{-}f(x,\omega) \wedge y \in \mathit{set}\text{-}f(\omega,y)$, and $x \in \mathit{set}\text{-}f(x,\omega) \wedge \omega \in \mathit{set}\text{-}f(\omega,y)$. However, in both cases the properties of a selector function (in this case f) imply that if $x \in A$, so are ω and y, contradicting our assumption.

It remains to show that g is associative. Suppose that g is not associative. Let a,b,c be a counterexample to the associativity of g. Since g is a single-valued, commutative self-contained function, it follows from Corollary 3.4 that both $||\{a,b,c\}|| = 3$ and the g-induced digraph on a,b,c is a 3-cycle (plus three self-loops). Without loss of generality, suppose that $g(a,b) = b$, $g(b,c) = c$, and $g(a,c) = a$. Let ω be the lexicographically smallest connector among all connectors for a and b, for b and c, and for a and c.

Suppose that ω is a connector for a and b. Due to symmetry we can make that assumption without loss of generality. Since $g(a,b) = b$ there are two possible scenarios.

$$h(x,y) = \begin{cases} y & \text{if } x \text{ and } y \text{ have a connector } z \text{ such that } z \leq_{\text{lex}} \max(x,y) \text{ and the lexicographically smallest connector } \omega \text{ of } x \text{ and } y \text{ yields } \omega \in \textit{set-f}(x,\omega) \wedge y \in \textit{set-f}(\omega,y) \text{ but not } x \in \textit{set-f}(x,\omega) \wedge \omega \in \textit{set-f}(\omega,y), \\ x & \text{if } x \text{ and } y \text{ have a connector } z \text{ such that } z \leq_{\text{lex}} \max(x,y) \text{ and the lexicographically smallest connector } \omega \text{ of } x \text{ and } y \text{ yields } x \in \textit{set-f}(x,\omega) \wedge \omega \in \textit{set-f}(\omega,y) \text{ but not } \omega \in \textit{set-f}(x,\omega) \wedge y \in \textit{set-f}(\omega,y), \\ \max(x,y) & \text{if } x \text{ and } y \text{ have a connector } z \text{ such that } z \leq_{\text{lex}} \max(x,y) \text{ and the lexicographically smallest connector } \omega \text{ of } x \text{ and } y \text{ yields both } \omega \in \textit{set-f}(x,\omega) \wedge y \in \textit{set-f}(\omega,y) \text{ and } x \in \textit{set-f}(x,\omega) \wedge \omega \in \textit{set-f}(\omega,y), \\ \max(x,y) & \text{if } x \text{ and } y \text{ have no connector } z \text{ such that } z \leq_{\text{lex}} \max(x,y). \end{cases}$$

FIG. 7.1. *Definition of the function h used in the proof of Theorem* 7.1.

Case 1 ($\omega \in$ *set-f*$(a,\omega) \wedge b \in$ *set-f*(ω,b) but not $a \in$ *set-f*$(a,\omega) \wedge \omega \in$ *set-f*(ω,b)):
Since f is total, *set-f*$(\omega,c) \neq \emptyset$. If *set-f*$(\omega,c) = \{c\}$, then ω is also a connector for a and c contradicting, in light of the definition of g and the fact that in this case $\omega \in$ *set-f*(a,ω) and *set-f*$(\omega,c) = \{c\}$ yet $\omega \notin$ *set-f*(ω,c), $g(a,c) = a$. If *set-f*$(\omega,c) = \{\omega\}$, then ω is also a connector for b and c in such a way as to similarly contradict $g(b,c) = c$. If *set-f*$(\omega,c) = \{\omega,c\}$, there are two possibilities. The first is that *set-f*$(\omega,b) = \{b\}$. However, that implies $g(b,c) = b$, which contradicts our assumption that $g(b,c) = c$. The second possibility is that *set-f*$(\omega,b) = \{b,\omega\}$. This implies (under the rules of Case 1 and the subcase we are in) that *set-f*$(a,\omega) = \{\omega\}$. However, this implies that $g(c,a) = c$, which contradicts our assumption that $g(a,c) = a$.

Case 2 ($b = \max(a,b)$, $\omega \in$ *set-f*$(a,\omega) \wedge b \in$ *set-f*(ω,b), and $a \in$ *set-f*$(a,\omega) \wedge \omega \in$ *set-f*(ω,b)):
Since f is total, $f(\omega,c)$ is defined. If *set-f*$(\omega,c) = \{c\}$, then we have $g(a,c) = c$, contradicting our assumption that $g(a,c) = a$. If *set-f*$(\omega,c) = \{\omega\}$, then we have $g(b,c) = b$, contradicting our assumption that $g(b,c) = c$. If *set-f*$(\omega,c) = \{\omega,c\}$, then the definition of g and the assumed values of g imply that $b = \max(a,b)$, $a = \max(a,c)$, and $c = \max(b,c)$, which contradicts $||\{a,b,c\}|| = 3$.

It follows that g is associative, which completes the proof of part 1.

We next show part 2. This can be shown quite similarly, and so we will sketch only the main differences to the proof of part 1. Let A be an NPMV-selective set. Let f be an NPMV-selector for A. Without loss of generality, assume f to be commutative (Fact 2.3). Observe that $f(x,y)$ and also that one of $f(x,x)$ and $f(y,y)$ is defined whenever at least one of x and y is in A. Thus, whenever at least one of x and y is in A there exists a connector z of x and y such that $z \leq_{\text{lex}} \max(x,y)$. Define the function h, for all x and y, as shown in Figure 7.1. Note that h is a single-valued $\text{FP}_{\text{t}}^{\text{NP}}$ function that is commutative. Similarly to the proof of part 1, one can now show that h is a selector function for A that is associative on A. For the latter note that any connector z of two strings $x, y \in A$ is also in A.

Part 3 follows from the proofs of parts 1 and 2. The function h as defined in the proof of part 2 is a total, commutative, and single-valued FP^{NP} function. We can

now repeat the entire proof of part 1 but replacing f by h and NPMV$_t$ by $\mathrm{FP}_t^{\mathrm{NP}}$ in that proof. It follows that the function g as defined in the proof of part 1 is now in our modified version a total single-valued $\mathrm{FP}^{\Sigma_2^p}$-selector for A that is commutative and associative. □

COROLLARY 7.2.

1. *Every* P*-selective set, and even every* FP*-selective set, has a commutative selector function in* $\mathrm{FP}_t^{\mathrm{NP}}$ *that is associative.*
2. *Every* NP*-selective set has a commutative selector function in* $\mathrm{FP}_t^{\mathrm{NP}}$ *that is associative.*
3. *Every* NPSV*-selective set A has a commutative selector function in* $\mathrm{FP}_t^{\mathrm{NP}}$ *that is associative on A.*
4. *Every* NPSV*-selective set has a commutative selector function in* $\mathrm{FP}_t^{\Sigma_2^p}$ *that is associative.*

The above corollary is a straightforward consequence of Theorem 7.1. Regarding the "every FP-selective" in part 1, recall FP-sel = P-sel from Fact 2.3.

COROLLARY 7.3. *If* P = NP*, then* P-sel = A-P-sel*,* FP-sel = A-FP-sel*,* NP-sel = A-NP-sel*,* NPSV-sel = A-NPSV-sel*,* NPMV$_t$-sel = A-NPMV$_t$-sel*, and* NPMV-sel = A-NPMV-sel*.*

The above corollary follows directly from Theorem 7.1 and and Corollary 7.2. Regarding the NPSV-sel = A-NPSV-sel and NPMV-sel = A-NPMV-sel conclusions of the above corollary, recall that $\mathrm{P} = \mathrm{NP} \iff \mathrm{P} = \Sigma_2^p$.

Theorem 5.3 provides a sufficient condition, based on an algebraic property for selector functions, for P-sel $\subseteq \mathrm{P}/\mathcal{O}(n)$. If one were interested only in *structural complexity-class-collapse* sufficient conditions, Theorem 5.3 would be no improvement over the P = NP sufficient condition implicit in the result of Hemaspaandra and Torenvliet that P-sel $\subseteq \mathrm{NP}/\mathcal{O}(n)$ (and thus P-sel $\subseteq \mathrm{P}/\mathcal{O}(n)$ if P = NP), since in light of Corollary 7.3 the best known structural complexity-class-collapse condition sufficient to imply P-sel = A-P-sel is also the collapse P = NP. However, we feel that this is the wrong view, and that "P-sel = A-P-sel" is probably a fundamentally different type of assumption than P = NP. For example, if P-sel = A-P-sel were in fact equivalent to P = NP, then P = NP would (trivially) not just be a sufficient condition for P-sel = A-P-sel but would also be a necessary condition. In fact, not only is P = NP not known to be necessary for P-sel = A-P-sel, but in fact no structural complexity-class-collapse condition—not even very weak collapses like P = UP or P = ZPP—is known to be necessary. Our point here is that, though by Corollary 7.3 P = NP is one way to achieve P-sel = A-P-sel, we conjecture that it is unlikely that one can prove that it characterizes P-sel = A-P-sel. And thus our P-sel = A-P-sel sufficient condition for P-sel $\subseteq \mathrm{P}/\mathcal{O}(n)$ is best viewed as a new algebraic sufficient condition quite different from the known (and extremely demanding) structural complexity-class-collapse sufficient conditions.

We do have a structural complexity-class-collapse condition, namely, the collapse of the polynomial hierarchy, that follows from the assumption that every NPMV-selective set is in fact associatively NPMV-selective. (S_2 is the symmetric alternation class of Canetti [Can96] and Russell and Sundaram [RS98]. Note that a collapse to $\mathrm{S}_2^{\mathrm{NP}}$ is known to be at least as strong as a collapse to $\mathrm{ZPP}^{\Sigma_2^p}$ or to Σ_3^p, since $\mathrm{S}_2^{\mathrm{NP}} \subseteq \mathrm{ZPP}^{\Sigma_2^p} \subseteq \Sigma_3^p$ ([CCHO03]; see that paper also for the definition of $\mathrm{S}_2^{\mathrm{NP}}$).)

THEOREM 7.4. NPMV-sel = A-NPMV-sel $\implies$ PH = $\mathrm{S}_2^{\mathrm{NP}}$.

Proof. Assume that NPMV-sel = A-NPMV-sel. By Corollary 5.10 we have that A-NPMV-sel $\subseteq \mathrm{NP}/n{+}1 \cap \mathrm{coNP}/n{+}1$. So under our assumption, NPMV-sel $\subseteq$

$\mathrm{NP}/n{+}1 \cap \mathrm{coNP}/n{+}1$. However, it is well known that $\mathrm{NP} \subseteq$ NPMV-sel. Putting all the pieces together we obtain $\mathrm{NP} \subseteq \mathrm{coNP}/n{+}1$. This itself, by the recent strengthening of Yap's theorem [Yap83] by Cai et al. [CCHO03], implies that $\mathrm{PH} = \mathrm{S}_2^{\mathrm{NP}}$ (equivalently, $\mathrm{PH} = \mathrm{NP}^{\mathrm{NP}^{\mathrm{NP}}} = \mathrm{ZPP}^{\mathrm{NP}^{\mathrm{NP}}} = \mathrm{S}_2^{\mathrm{NP}}$). □

Finally, we mention two open issues. First, can one prove a complete or partial converse of other parts of Corollary 7.3? Second, one would ultimately like to know whether all P-selective sets have linear deterministic advice, i.e., whether P-sel $\subseteq \mathrm{P}/\mathcal{O}(n)$. This paper gives a new sufficient condition for that, namely, P-sel $\subseteq \mathrm{P}/\mathcal{O}(n)$ if all P-selective sets have associative (or even merely length-associative) selector functions.

Acknowledgments. We thank the COCOON 2001 and SICOMP referees for their helpful comments, and we thank Dieter Kratsch, Haiko Müller, Till Tantau, and Leen Torenvliet for helpful conversations and comments. We are deeply grateful to Klaus Wagner for his valuable suggestions.

GRAPHS WITH TINY VECTOR CHROMATIC NUMBERS AND HUGE CHROMATIC NUMBERS*

URIEL FEIGE†, MICHAEL LANGBERG‡, AND GIDEON SCHECHTMAN§

Abstract. Karger, Motwani, and Sudan [*J. ACM*, 45 (1998), pp. 246–265] introduced the notion of a vector coloring of a graph. In particular, they showed that every k-colorable graph is also vector k-colorable, and that for constant k, graphs that are vector k-colorable can be colored by roughly $\Delta^{1-2/k}$ colors. Here Δ is the maximum degree in the graph and is assumed to be of the order of n^{δ} for some $0 < \delta < 1$. Their results play a major role in the best approximation algorithms used for coloring and for maximum independent sets.

We show that for every positive integer k there are graphs that are vector k-colorable but do not have independent sets significantly larger than $n/\Delta^{1-2/k}$ (and hence cannot be colored with significantly fewer than $\Delta^{1-2/k}$ colors). For $k = O(\log n/\log\log n)$ we show vector k-colorable graphs that do not have independent sets of size $(\log n)^c$, for some constant c. This shows that the vector chromatic number does not approximate the chromatic number within factors better than $n/\text{polylog}n$.

As part of our proof, we analyze "property testing" algorithms that distinguish between graphs that have an independent set of size n/k, and graphs that are "far" from having such an independent set. Our bounds on the sample size improve previous bounds of Goldreich, Goldwasser, and Ron [*J. ACM*, 45 (1998), pp. 653–750] for this problem.

1. Introduction.

An independent set in a graph G is a set of vertices that induce a subgraph which does not contain any edges. The size of the maximum independent set in G is denoted by $\alpha(G)$. For an integer k, a k-coloring of G is a function $\sigma : V \to [1 \dots k]$ which assigns colors to the vertices of G. A valid k-coloring of G is a coloring in which each color class is an independent set. The chromatic number $\chi(G)$ of G is the smallest k for which there exists a valid k-coloring of G.

Finding $\alpha(G)$ and $\chi(G)$ are fundamental NP-hard problems, closely related by the inequality $\alpha(G)\chi(G) \geq n$. Given G, the question of estimating the value of $\alpha(G)$ ($\chi(G)$) or finding large independent sets (small colorings) in G has been studied extensively. Let G be a graph of size n. Both $\chi(G)$ and $\alpha(G)$ can be approximated within a ratio of $O(\frac{n(\log\log n)^2}{\log^3 n})$ (see [Hal93, Fei02]). It is known that unless NP = ZPP, neither $\alpha(G)$ nor $\chi(G)$ can be approximated within a ratio of $n^{1-\varepsilon}$ for any $\varepsilon > 0$ [Hås99, FK98]. Under stronger complexity assumptions, there is some $0 < \delta < 1$ such that neither problem can be approximated within a ratio of $n/2^{\log^{\delta} n}$ [Kho01].

The approximation ratios for these problems significantly improve in graphs that have very large independent sets or very small chromatic numbers. The algorithms achieving the best ratios in these cases [KMS98, AK98, BK97, HNZ01] are all based on the idea of *vector coloring*, introduced by Karger, Motwani, and Sudan [KMS98].

DEFINITION 1.1. *A vector k-coloring of a graph is an assignment of unit vectors to its vertices such that, for every edge, the inner product of the vectors assigned to its endpoints is at most (in the sense that it can only be more negative) $-1/(k-1)$.*

Every k-colorable graph is also vector k-colorable (by identifying each color class with one vertex of a perfect $(k-1)$-dimensional simplex centered at the origin). Moreover, unlike the chromatic number, a vector k-coloring (when it exists) can be found in polynomial time using semidefinite programming (up to arbitrarily small error in the inner products). Given a vector k-coloring of a graph, Karger, Motwani, and Sudan show how to color a graph with roughly $\Delta^{1-2/k}$ colors, where Δ is the maximum degree in the graph. (In comparison, the technique of inductive coloring might use $\Delta+1$ colors.) In fact, they show how to find an independent set of size roughly $n/\Delta^{1-2/k}$. Combined with other ideas, this leads to coloring algorithms and algorithms for finding independent sets with the best currently known performance guarantees. For example, there is a polynomial time algorithm that colors 3-colorable graphs with roughly $n^{3/14}$ colors [BK97]. For nonconstant values of k, it is known how to find an independent set of size $\Omega(\log n)$ in a vector $\log n$-colorable graph.

There have also been negative results regarding vector k-colorable graphs. Examples appearing in [KMS98] (and improved by Alon and Szegedy) show vector 3-colorable graphs that do not have independent sets larger than roughly $n^{0.95}$. The case of nonconstant k is addressed in [Fei97] (technically, the results there deal with the Lovász theta function, which is even a stronger notion than vector coloring), where graphs that are vector $2^{O(\sqrt{\log n})}$-colorable are shown not to have independent sets larger than $2^{O(\sqrt{\log n})}$. In all these negative examples, the vertex sets of the graphs involved can be viewed as a subset of $\{0,1\}^n$, with two vertices connected by an edge if their Hamming distance is larger than some prespecified value.

Our results. In this work we present a different family of graphs with stronger negative properties. For every constant $k>2$ and every $\varepsilon>0$, we show graphs that are vector k-colorable, with $\alpha(G) \le n/\Delta^{1-\frac{2}{k}-\varepsilon}$. This essentially matches the positive results of [KMS98]. As a function of n rather than Δ, we show vector 3-colorable graphs with $\alpha(G) < n^{0.843}$. Moreover, for $k = O(\log n/\log\log n)$, we show vector k-colorable graphs with $\alpha(G) \le (\log n)^c$, for some universal c. This shows that the vector coloring number by itself does not approximate the chromatic number within a ratio better than $n/\text{polylog}n$. Another consequence of this (that is touched upon in Remark 2.1 in section 2) is that certain semidefinite programs do not approximate the size of the maximum independent set with a ratio better than $n/\text{polylog}n$.

THEOREM 1.2.

1. *For every constant $\varepsilon>0$ and constant $k>2$, there are infinitely many graphs G that are vector k-colorable and satisfy $\alpha(G) \le n/\Delta^{1-\frac{2}{k}-\varepsilon}$, where n is the number of vertices in G, Δ is the maximum degree in G, and $\Delta > n^{\delta}$ for some constant $\delta>0$.*
2. *For some constant c, there are infinitely many graphs G that are vector $O(\frac{\log n}{\log\log n})$-colorable and satisfy $\alpha(G) \le (\log n)^c$.*
3. *There are infinitely many graphs G that are vector 3-colorable and satisfy $\alpha(G) \le n^{0.843}$.*

Observe that if Theorem 1.2(1) is proven for some graph with n vertices and

maximum degree Δ, then for every positive integer c it also holds for some graph with $c \cdot n$ vertices and the same maximum degree Δ. (Simply make c disjoint copies of the original graph.) Hence the theorem becomes stronger as Δ becomes larger in comparison to n. We guarantee that Δ can be taken at least as large as n^{δ} for some δ that depends on ϵ and k. For every fixed ϵ and k, the value of δ can be taken as a fixed constant bounded away from 0 and independent of n. We have not made an attempt to find the tightest possible relation between δ and ϵ and k.

Proof techniques. The graphs that we use are essentially the same graphs that were used in [FS02] to show integrality gaps for semidefinite programs for Max-Cut. Namely, they are obtained by placing n points at random on a d-dimensional unit sphere and connecting two points by an edge if the inner product of their respective vectors is below $-1/(k-1)$. Such graphs are necessarily vector k-colorable, as the embedding on the sphere is a vector k-coloring. So the bulk of the work is in proving that they have no large independent set. For this we use a two-phase plan. First we consider a continuous (infinite) graph, where every point on the sphere is a vertex and two vertices are connected by an edge if the inner product of their respective vectors is below $-1/(k-1)$. On this continuous graph we use certain symmetrization techniques in order to analyze its properties. Specifically, we prove certain inequalities regarding its expansion. In the second phase, we consider a (finite) random vertex induced subgraph of the continuous graph. Based on the expansion properties of the continuous graph, we show that the random sample has no large independent set.

Two remarks are in order here. One is that it is very important for our bounds that the final random graph does not contain too many vertices compared to the dimension d. A small number of vertices implies low degree, and allows for a more favorable relation between the maximum degree and the chromatic number. For this reason we cannot use the continuous graph (or a finite discrete approximation of the continuous graph) as is. Its degree is very large compared to its chromatic number. We thus consider the graph obtained by randomly sampling the vertices of the continuous graph. In section 7, we follow a suggestion of Luca Trevisan (private communication) and present an alternative proof of Theorem 1.2(1) by considering the graph obtained by randomly sampling the *edges* of the continuous graph. It appears that parts (2) and (3) of Theorem 1.2 cannot be proven using edge sampling.

The other remark is that we do not get an explicit graph as our example, but rather a random graph (or a distribution on graphs). This is to some extent unavoidable, given that there are no known efficient deterministic constructions of Ramsey graphs (graphs in which the size of the maximum independent set and maximum clique are both bounded by some polylog in n). The graphs we construct (when $k = \log n / \log\log n$) are Ramsey graphs, because it can be shown that the maximum clique size is never larger than the vector coloring number.

Property testing. The following problem in property testing is addressed by Goldreich, Goldwasser, and Ron [GGR98]. For some value of $\rho < 1$, consider a graph with the following "promise": either it has an independent set of size ρn, or it is far from any such graph, in the sense that any vertex-induced subgraph of ρn vertices induces at least εn^2 edges. One wants an algorithm that samples as few vertices as possible, looks at the subgraph induced on them, and, based on the size of the maximum independent set in that subgraph, decides correctly (with high probability) which of the two cases above hold. In [GGR98] it is shown that a sample of size proportional to ε^{-4} suffices. We are in a somewhat similar situation when we move from the continuous graph to our random sample. The continuous graph is far from having an indepen-

dent set of *measure* ρ.[1] We want to take a sample as small as possible (its size will be denoted by s) such that the induced subgraph does not contain an independent set of size ρs. Luckily in our case, we can use a stronger guarantee on the continuous graph. We know that even every set of measure $\rho/2$ induces at least the measure of ε edges.[2] In this case we show that a sample size s proportional to $1/\varepsilon$ suffices. This dramatic improvement over the [GGR98] bound is crucial to the success of our analysis. We note that this improvement is not only based on our stronger guarantee on the continuous graph G. Even in exactly the same setting of [GGR98], we show that a sample size s proportional to ε^{-3} suffices. These results are of interest in the context of property testing regardless of their applications to the vector coloring issue.

Strict vector coloring. One may strengthen the notion of vector k-coloring by requiring that, for every edge, the inner product of the unit vectors corresponding to its endpoints be exactly $-1/(k-1)$, rather than at most $-1/(k-1)$. This is called a strict vector coloring. This notion is known to be equivalent to the theta function of Lovász [Lov79, KMS98]. Every k-colorable graph is also strictly vector k-colorable. As strict vector coloring is a stronger requirement than vector coloring, then it is possible that strict vector k-colorable graphs have smaller chromatic numbers than vector k-colorable graphs. So far, there are not any algorithmic techniques that can use this observation to further improve the approximation ratios for chromatic number or for independent set. We remark, however, that the negative results in this work apply only to vector coloring and not to strict vector coloring. It is an open question whether similar negative results are true for strict vector coloring, or equivalently, whether the same gaps (such as $n/\text{polylog}n$) can be shown between the value of the theta function and the size of the maximum independent set. Note that the weaker negative results of [Fei97] and some of the negative results in [KMS98] do apply also to strict vector coloring.

The remainder of this paper is organized as follows. In section 2 we briefly review the semidefinite programs that compute the vector chromatic number and its variants. In section 3 we present the continuous graph and analyze its properties. In section 4 we prove Theorem 1.2. Our results on property testing are presented in sections 5 and 6. In section 7 we present an alternative proof of Theorem 1.2(1). In section 8 we discuss some problems that remain open. Finally, in section 9 we present the proof of several technical lemmas that appear throughout our work.

2. The vector chromatic number and its variants. There are many equivalent ways to define the vector chromatic number and its variants. We will follow the definitions suggested in [KMS98, Cha02]. Let $G = (V, E)$ be a graph of size n. For convenience we will assume that $V = [1, \ldots, n]$. The semidefinite relaxations below assign unit vectors to every vertex $i \in V$. These unit vectors are to satisfy certain constraints which will in turn determine the value of the relaxations.

$COL_1(G)$ Minimize k
subject to
$\langle v_i, v_j \rangle \leq -\frac{1}{k-1}$ $\forall (i,j) \in E$,
$\langle v_i, v_i \rangle = 1$ $\forall i \in V$;

$COL_2(G)$ Minimize k

[1] As the continuous graph is infinite, terms such as the *number* of vertices are replaced by the continuous analog *measure*. The measure we use on the unit sphere is the natural measure, which associates with each subset its relative area on the sphere.

[2] The measure we use on the edge set is the product measure induced by the standard uniform measure on S^{d-1}.

subject to

$$\langle v_i, v_j \rangle = -\tfrac{1}{k-1} \qquad \forall (i,j) \in E,$$
$$\langle v_i, v_i \rangle = 1 \qquad \forall i \in V;$$

$COL_3(G)$ Minimize k

subject to

$$\langle v_i, v_j \rangle = -\tfrac{1}{k-1} \qquad \forall (i,j) \in E,$$
$$\langle v_i, v_j \rangle \geq -\tfrac{1}{k-1} \qquad \forall i,j \in V,$$
$$\langle v_i, v_i \rangle = 1 \qquad \forall i \in V.$$

The function $COL_1(G)$ is the vector chromatic number of G as defined in [KMS98]. The function $COL_2(G)$ is the strict vector chromatic number of G and is equal to the Lovász θ function on $\bar{G}$ [Lov79, KMS98], where $\bar{G}$ is the *complement* graph of G. Finally, the function $COL_3(G)$ will be referred to as the *strong* vector chromatic number as defined in [Sze94, Cha02]. Let $\omega(G)$ denote the size of the maximum clique in G; in the following we show that

$$\omega(G) \leq COL_1(G) \leq COL_2(G) \leq COL_3(G) \leq \chi(G).$$

It is not hard to verify that $COL_1(G) \leq COL_2(G) \leq COL_3(G)$. To show the other inequalities we need the following fact. For every integer k, the k unit vectors $\{v_1, \ldots, v_k\}$ that minimize the value of $\max_{i \neq j \in [1,\ldots,k]} \langle v_i, v_j \rangle$ are the vertices of a simplex in R^{k-1} centered at the origin. For each $i, j \in [1, \ldots, k]$, these vectors satisfy $\langle v_i, v_j \rangle = -\frac{1}{k-1}$.

Now to prove the inequality $COL_3(G) \leq \chi(G)$, consider a k-coloring σ of G. The coloring σ partitions the vertex set V into k color classes $\{V_1, \ldots, V_k\}$. Assigning each color class V_i with the corresponding vector v_i above, we obtain a valid assignment for $COL_3(G)$. To show that $\omega(G) \leq COL_1(G)$, consider a graph G with maximum clique size $\omega(G)$. To obtain a valid assignment of vectors to $COL_1(G)$ of value k we require that all pairs of vectors corresponding to the vertices of the maximum clique will have inner product of value at most $-\frac{1}{k-1}$. As mentioned above, this can happen only if $\omega(G) \leq k$.

Remark 2.1. The results of our work show a large gap between $COL_1(G)$ and $\chi(G)$ (Theorem 1.2). Combining these results with certain proof techniques appearing in [Sze94], a similar gap between $\omega(G)$ and $COL_3(G)$ can also be obtained. Details are omitted.

3. The continuous graph. Let d be a large constant, and let $S^{d-1} = \{v \in R^d \mid \|v\| = 1\}$ be the d-dimensional unit sphere. Let $G_k = (V, E)$ be the continuous graph in which (a) the vertex set V consists of all the points on the unit sphere S^{d-1}, and (b) the edge set E of G_k consists of all pairs of vertices whose respective vectors (from the origin) form an angle of at least $\arccos(-1/(k-1))$. As the size of V and E is infinite (and uncountable), terms such as the *number* of vertices in V will be replaced by the continuous analogue *measure*.

In this section we analyze various properties of G_k. Specifically, we show that G_k has certain expansion properties. We then use this fact in section 4 to prove the main theorem of our work. In our analysis, we will assume that the dimension d is (at least) a very large constant (our proofs rely on such d). Additional constants that will be presented in the remainder of this section are to be viewed as independent of d.

DEFINITION 3.1 (sphere measure). *Let μ be the normalized $(d-1)$-dimensional natural measure on S^{d-1}, and let μ^2 be the induced measure on $S^{d-1} \times S^{d-1}$. For any*

two (not necessarily disjoint) subsets A and B of V, we define the measure of edges from A to B as

$$E(A,B) = \mu^2\left(\{(x,y) \mid x \in A,\ y \in B,\ (x,y) \in E\}\right).$$

DEFINITION 3.2 (sphere caps). *Let $a \in [0,1]$ and $x \in S^{d-1}$. An a-cap centered at x is defined to be the set $\mathcal{C}_a = \{u \in S^{d-1} \mid \langle u,x\rangle \geq a\}$. Denote the measure of an a-cap by $\rho(a)$.*

A few remarks are appropriate. Notice that for every $x,\ x'$, an a-cap centered at x has the same measure as an a-cap centered at x' (sphere symmetry). Furthermore, notice that *large* caps have *small* corresponding values of a and vice versa. The value of $\rho(a) = \mu(\mathcal{C}_a)$ is approximately given by the following lemma proven, for example, in [FS02].

LEMMA 3.3. *Let $\mathcal{C}_a$ be an a-cap centered at some $x \in S^{d-1}$. There exists a constant $c > 0$ (independent of a and d) s.t. (such that)*

$$\frac{c}{\sqrt{d}}\left(1-a^2\right)^{\frac{d-1}{2}} \leq \mu(\mathcal{C}_a) = \rho(a) \leq \frac{1}{2}\left(1-a^2\right)^{\frac{d-1}{2}}.$$

LEMMA 3.4. *Let $\rho(\frac{1}{k-1})$ be the measure of a $\frac{1}{(k-1)}$-cap. Every vertex v in the graph G_k has degree $\rho(\frac{1}{k-1})$.*

Proof. Each vertex v in G_k is adjacent to every vertex in the $\frac{1}{(k-1)}$-cap centered at $-v$ (here $-v$ is the vertex antipodal to v). Hence, the measure of vertices adjacent to a given vertex v in G_k is that of a $\frac{1}{(k-1)}$-cap. ∎

The main property of G_k of interest to us is the measure of edges between any two given subsets of V of a specified size. We first prove that the sets in G_k which share the least amount of edge are caps with the same center.

THEOREM 3.5. *Let $1 \geq a > 0$, and let A and B be two (not necessarily disjoint) measurable sets in V of measure $\rho(a)$. Let x be an arbitrary vertex of S^{d-1}. The minimum of $E(A,B)$ is obtained when $A = B = \mathcal{C}_a$, where $\mathcal{C}_a$ is an a-cap of measure $\rho(a)$ centered at x.*

The proof of Theorem 3.5 is based on symmetrization techniques similar to those presented in [BT76, FS02]. We prove Theorem 3.5 in section 9. We now turn to analyzing the measure of edges between caps of measure $\rho(a)$. Namely, we study the value of $E(\mathcal{C}_a,\mathcal{C}_a)$. For *large* values of a, it is not hard to see that $\mathcal{C}_a$ will not induce any edges. This follows from the fact that any two vertices u and v in $\mathcal{C}_a$ satisfy $\langle u,v\rangle \geq 2a^2-1$. Hence, in the following we consider values of a which satisfy $2a^2-1 < -\frac{1}{k-1}$. For such values of a we show that $E(\mathcal{C}_a,\mathcal{C}_a)$ is proportional to $\mu^2(E)\rho(a)^{2+\frac{2}{k-2}}$ (which we denote by $\lambda(a)$). Notice that two random subsets A and B of G_k of measure $\rho(a)$ are expected to satisfy $E(A,B) = \mu^2(E)\rho(a)^2$, which is fairly close to $\lambda(a)$. Actually, we show that $E(\mathcal{C}_a,\mathcal{C}_a)$ is in the range $[(1-c\sqrt{\log(d)/d})^{\frac{d-1}{2}}\lambda(a),\lambda(a)]$ for some large constant c. It is not hard to verify that the term $(1-c\sqrt{\log(d)/d})^{\frac{d-1}{2}}$ is negligible compared to $\lambda(a)$, once d is taken to be large enough.

THEOREM 3.6. *Let $\sqrt{\frac{k-2}{2(k-1)}} > a > 0$ and $k > 2$ be constant. Let $x \in S^{d-1}$, and let $\mathcal{C}_a$ be an a-cap centered at x. Let $\varepsilon(a)$ be the value of $E(\mathcal{C}_a,\mathcal{C}_a)$. Finally let*

$$\lambda(a) = \left(\left(1-\frac{1}{(k-1)^2}\right)\left(1-\frac{2(k-1)}{k-2}a^2\right)\right)^{\frac{d-1}{2}}.$$

Then $\varepsilon(a) \in [(1-c\sqrt{\log(d)/d})^{\frac{d-1}{2}}\lambda(a),\lambda(a)]$ for some constant $c > 0$.

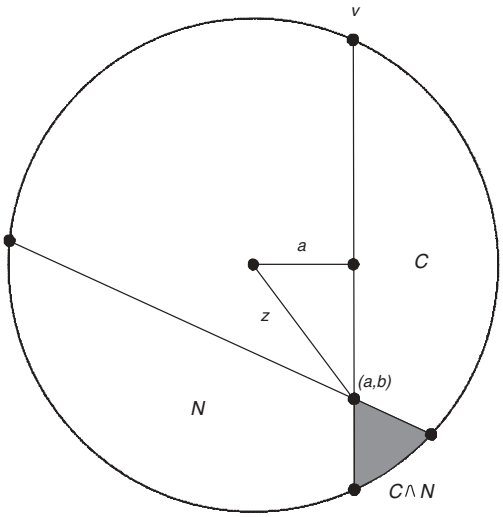

FIG. 1. *Projecting S^{d-1} onto the two-dimensional subspace $\{(r_1, r_2, 0, \ldots, 0) \mid r_1, r_2 \in R\}$ of R^d, we obtain the circle above. C is the projection of an a-cap $\mathcal{C}_a$ centered at $(1, 0, \ldots, 0)$ (where a is the distance of the cap from the origin). The vertex $v = (a, \sqrt{1-a^2}, 0, \ldots, 0) \in \mathcal{C}_a$ is on the boundary of $\mathcal{C}_a$. N is the projection on the sphere of the set of points $N(v)$ that are adjacent to v (i.e., form an angle of at least* $\arccos(-1/(k-1))$ *with v). The shaded section is $C \cap N$ (the projection of $\mathcal{C}_a \cap N(v)$). The point (a, b) is the closest point of the projection of $\mathcal{C}_a \cap N(v)$ to the origin. It is not hard to verify that $b^2 = (1/(k-1) + a^2)^2/(1-a^2)$. Finally, we denote the value of $\sqrt{a^2+b^2}$ by z. Claim 3.7 addresses the measure of $\mathcal{C}_a \cap N(v)$ and states that it is essentially the measure of a z-cap. This is done by studying the points in S^{d-1} whose projection falls* close *to (a, b). Roughly speaking, we first show that such points are in $\mathcal{C}_a \cap N(v)$; then, using Claim 9.7, we show that the measure of these points is essentially the measure of a z-cap.*

Proof. Let $x \in S^{d-1}$. Let $\mathcal{C}_a$ be an a-cap centered at x. W.l.o.g. we will assume that $x = (1, 0, \ldots, 0)$. Consider a vertex $v \in \mathcal{C}_a$ on the boundary of $\mathcal{C}_a$. Let $N(v)$ be the set of vertices adjacent to v. We start by computing the measure of vertices that are neighbors of v and are in the cap $\mathcal{C}_a$, i.e., the measure of $N(v) \cap \mathcal{C}_a = \{u = (u_1, \ldots, u_d) \in S^{d-1} \mid u_1 \geq a \text{ and } \langle v, u \rangle \leq -1/(k-1)\}$.

CLAIM 3.7. *Let a, k be as in Theorem 3.6. Let $v = (a, \sqrt{1-a^2}, 0, \ldots, 0)$ be a vertex on the boundary of $\mathcal{C}_a$.Let $N(v)$ be the set of neighbors of v. Let $z = \sqrt{a^2 + \frac{(1/(k-1)+a^2)^2}{1-a^2}}$.Finally let $\delta = c\sqrt{\frac{\log(d)}{d}}$ for a sufficiently large constant c. The measure of vertices in $N(v) \cap \mathcal{C}_a$ satisfies*

$$(1-\delta)^{\frac{d-1}{2}} \left(1-z^2\right)^{\frac{d-1}{2}} \leq \mu(N(v) \cap \mathcal{C}_a) \leq \left(1-z^2\right)^{\frac{d-1}{2}}.$$

Claim 3.7 addresses the measure of $\mathcal{C}_a \cap N(v)$, and states that it is essentially the measure of a z-cap $\left(\text{where } z = \sqrt{a^2 + \frac{(1/(k-1)+a^2)^2}{1-a^2}}\right)$. To prove Claim 3.7 we study the measure of certain restricted sets in S^{d-1}. These sets are studied in Claim 9.7 of section 9. Claims 3.7 and 9.7 are depicted in Figure 1 and proven in section 9.

To complete the proof of Theorem 3.6, let a, z, δ be as in Claim 3.7. For a vertex $v \in \mathcal{C}_a$ let $N(v) \cap \mathcal{C}_a$ be the set of vertices adjacent to v in $\mathcal{C}_a$. For the upper bound, notice that of all vertices in $\mathcal{C}_a$, the vertices v in which $\mu(N(v) \cap \mathcal{C}_a)$ is largest are the vertices on the boundary of $\mathcal{C}_a$. By Claim 3.7, for these vertices $\mu(N(v) \cap \mathcal{C}_a)$ is bounded by $(1-z^2)^{\frac{d-1}{2}}$. We thus conclude that $\varepsilon(a)$ is bounded by the measure of

vertices in $\mathcal{C}_a$ times $(1-z^2)^{\frac{d-1}{2}}$. That is,

$$\varepsilon(a) \le \rho(a)(1-z^2)^{\frac{d-1}{2}} \le (1-a^2)\left(1-\left(a^2+\frac{(1/(k-1)+a^2)^2}{1-a^2}\right)\right)^{\frac{d-1}{2}} = \lambda(a).$$

As for the lower bound, let $w=(w_1,w_2,\ldots,w_d)$ be a vertex in $\mathcal{C}_a$ with first coordinate w_1 of value $a+\delta$. Consider any vertex $v=(v_1,v_2,\ldots,v_d)\in\mathcal{C}_a$ with first coordinate v_1 of value less than $a+\delta$. It is not hard to verify that the measure of $N(v)\cap\mathcal{C}_a$ is greater than the measure of $N(w)\cap\mathcal{C}_a$. Using an analysis similar to that of Claim 3.7, we have that $\mu(N(w)\cap\mathcal{C}_a)$ is greater than or equal to

$$(1-c\delta)^{\frac{d-1}{2}}\left(1-\left(a^2+\frac{(1/(k-1)+a(a+\delta))^2}{1-(a+\delta)^2}\right)\right)^{\frac{d-1}{2}} \ge (1-c\delta)^{\frac{d-1}{2}}\left(1-z^2\right)^{\frac{d-1}{2}}$$

for a sufficiently large constant c (which changes values between both sides of the second inequality). Furthermore, for our choice of δ, the measure of vertices $v=(v_1,v_2,\ldots,v_d)$ in $\mathcal{C}_a$ with $v_1\le a+\delta$ is at least $\rho(a)/2$ (Claim 9.3). Hence, we conclude that $E(\mathcal{C}_a,\mathcal{C}_a)$ is at least $\frac{\rho(a)}{2}(1-c\delta)^{\frac{d-1}{2}}\left(1-z^2\right)^{\frac{d-1}{2}}$. Simplifying the above expression, we conclude our assertion. □

Theorem 3.6 addresses the case in which k is constant and the caps considered are both of measure $\rho(a)$ for a constant value of a. For the proof of Theorem 1.2(2) we also need to address nonconstant values of a and k which depend on d.

THEOREM 3.8. *Let $a=(\log(d)/d)^{\frac{1}{4}}$. Let k satisfy $1/(k-1)=a^2$. Let $x\in S^{d-1}$, and let $\mathcal{C}_a$ be an a-cap centered at x. Let $\varepsilon(a)$ be the value of $E(\mathcal{C}_a,\mathcal{C}_a)$. The value of $\varepsilon(a)$ is in the range*

$$\left[\frac{1}{poly(d)}\left(1-\frac{2(k-1)}{k-2}a^2\right)^{\frac{d-1}{2}},\ \left(1-\frac{2(k-1)}{k-2}a^2\right)^{\frac{d-1}{2}}\right].$$

The outline of the proof of Theorem 3.8 is similar to that of Theorem 3.6. A full proof appears in section 9.

DEFINITION 3.9. *Let $\rho<1$. A graph $G=(V,E)$ is said to be pairwise $\langle\rho,\varepsilon\rangle$-connected iff every two (not necessarily disjoint) subsets A and B of V of measure ρ satisfy $E(A,B)\ge\varepsilon$.*

Combining Theorems 3.5, 3.6, and 3.8 we obtain the following result.

COROLLARY 3.10. *Let a,k, $\varepsilon(a)$ be defined as in Theorem* 3.6 *or* 3.8. *The graph G_k is pairwise $\langle\rho(a),\varepsilon(a)\rangle$-connected.*

Roughly speaking, Corollary 3.10 addresses the expansion properties of the continuous graph G_k. In section 5, we show that these properties imply certain upper bounds on the independence number of a small random sample of G_k. Namely, we prove the following theorem.

THEOREM 3.11. *Let a,k, $\varepsilon(a)$ be defined as in Theorem* 3.6 *or* 3.8. *Let H be a random sample of s vertices of G_k (according to the uniform distribution on S^{d-1}). Let c be a sufficiently large constant. If $s\ge c\frac{\rho(a)}{\varepsilon(a)}\log^2(1/\rho(a))$, then the probability that $\alpha(H)>e^2\rho(a)s$ is at most* 1/4.

In the following section, Theorem 3.11 is used to prove the main result of this work, Theorem 1.2. The proof of Theorem 3.11 will be presented in section 5.2.

4. Proof of Theorem 1.2. Recall that we are looking for a graph H for which both the vector chromatic number and the size of the maximum independent set are

small. The graphs H that we present are random subgraphs of the graphs G_k defined in section 3. The three assertions of Theorem 1.2 are all proven similarly; the main difference among their proofs is the choice of parameters used. To avoid confusion, we restate Theorem 1.2 using a slightly different notation then that appearing in the original presentation.

THEOREM 1.2 (restated).

1. *For every constant $\gamma > 0$ and constant $k > 2$, there are infinitely many graphs H that are vector k-colorable and satisfy $\alpha(H) \le s/\Delta_H^{1-\frac{2}{k}-\gamma}$, where s is the number of vertices in H, Δ_H is the maximum degree in H, and $\Delta_H > s^\delta$ for some constant $\delta > 0$.*
2. *For some constant c, there are infinitely many graphs H of size s that are $O(\frac{\log s}{\log\log s})$ vector colorable and satisfy $\alpha(H) \le (\log s)^c$.*
3. *There are infinitely many graphs H of size s which are vector 3-colorable and satisfy $\alpha(H) \le s^{0.843}$.*

Proof of Theorem 1.2(1). Let $k > 2$ be constant. Let $\gamma > 0$ be an arbitrarily small constant. Let c be a sufficiently large constant, and let $a = \gamma/c$. Let $G = G_k = (V, E)$ be the continuous graph from section 3. (Here and in the remainder of the proof, we assume that the dimension d of the graph G_k is taken to be significantly larger than $1/\gamma$.) Finally, let $\Delta = \rho(\frac{1}{k-1})$ be the measure of vertices adjacent to any given vertex of G.

Recall (from Corollary 3.10) that G is pairwise $\langle \rho(a), \varepsilon(a)\rangle$-connected. Let $\rho = \rho(a)$ and $\varepsilon = \varepsilon(a)$. This implies (Theorem 3.11) that with probability $\ge 3/4$ a random subset H of G of size $s \ge c\frac{\rho}{\varepsilon}\log^2(1/\rho)$ satisfies $\alpha(H) \le e^2\rho s$. (Recall that c is a sufficiently large constant.) We start by simplifying the expression bounding s.

CLAIM 4.1. *A random subset H of G of size $s = 1/(\Delta\rho^{\frac{k}{k-2}+\gamma})$ satisfies $\alpha(H) \le e^2\rho s = e^2/(\Delta\rho^{\frac{2}{k-2}+\gamma})$ with probability $\ge 3/4$.*

Proof. It suffices to prove that $s = 1/(\Delta\rho^{\frac{k}{k-2}+\gamma}) \ge c\frac{\rho}{\varepsilon}\log^2(1/\rho)$. The claim follows (by basic calculations) from the fact that ε can be bounded by $\Delta\rho^{\frac{2(k-1)}{k-2}+\gamma}$. By Theorem 3.6, we have that

$$\varepsilon(a) = \left[\left(1 - c\left(\sqrt{\frac{\log(d)}{d}}\right)\right)\left(1 - \frac{1}{(k-1)^2}\right)\left(1 - \frac{2(k-1)}{k-2}a^2\right)\right]^{\frac{d-1}{2}}.$$

It is not hard to verify that $(1-c(\sqrt{\log(d)/d}))^{\frac{d-1}{2}} > \rho^{\gamma/2}$. Furthermore, by Lemma 3.3 we have that $(1 - \frac{1}{(k-1)^2})^{\frac{d-1}{2}} > \Delta$. Hence, $\varepsilon(a) \ge \rho^{\gamma/2}(1 - \frac{2(k-1)}{k-2}a^2)^{\frac{d-1}{2}}\Delta$. Recall that a was defined as γ/c for a sufficiently large constant c. This implies that

$$\gamma \ge 2\frac{a^2\left(\frac{2(k-1)}{k-2}\right)^2}{1 - a^2\frac{2(k-1)}{k-2}}$$

($k > 2$ is constant). This expression is designed to fit the requirement appearing in Claim 9.1 (of section 9). Now by Claim 9.1, it holds that $(1 - \frac{2(k-1)}{k-2}a^2)^{\frac{d-1}{2}} \ge \rho^{\frac{2(k-1)}{k-2}+\frac{\gamma}{2}}$. We conclude that $\varepsilon(a) \ge \Delta\rho^{\frac{2(k-1)}{k-2}+\gamma}$. ∎

Let H be a random subgraph of G of size $s = 1/(\Delta\rho^{\frac{k}{k-2}+\gamma})$. We will show that H satisfies the asserted conditions with probability greater than 1/2. First notice that any subgraph of G is vector k-colorable, including the subgraph H. Second, by

Claim 4.1, $\alpha(H) \leq e^2/(\Delta\rho^{\frac{2}{k-2}+\gamma})$ with probability $\geq 3/4$. It is left to analyze the maximum degree of H.

CLAIM 4.2. *With probability greater than* $3/4$*, the maximum degree* Δ_H *of the subgraph* H *is in the range* $[\frac{1}{2}\Delta s, 2\Delta s]$.

Proof. Consider a vertex $h \in H$. Let d_h be the degree of h. As every vertex in G is of degree Δ, the expected value of d_h is $\Delta(s-1)$. Thus (using standard bounds) the probability that d_h deviates from its expectation by more than a constant fraction of its expectation is at most $2^{-\Omega(\Delta s)}$. The probability that some vertex in H has degree $\notin [\frac{1}{2}\Delta s, 2\Delta s]$ is thus at most $2^{\log(s)-\Omega(\Delta s)} \leq 3/4$ for our choice of s. □

The first assertion of Theorem 1.2 now follows using basic calculations. □

Proof of Theorem 1.2(2). Let d be a large constant. Let $k-1 = \sqrt{d/\log(d)}$. Let $a^2 = \frac{1}{k-1}$. Let $G = G_k = (V, E)$ be the continuous graph from section 3.

Recall (Corollary 3.10) that G is pairwise $\langle \rho(a), \varepsilon(a)\rangle$-connected. Let $\rho = \rho(a)$ and $\varepsilon = \varepsilon(a)$. This implies (Theorem 3.11) that with probability $\geq 3/4$ a random subset H of size $s \geq c\frac{\rho}{\varepsilon}\log^2(1/\rho)$ satisfies $\alpha(H) \leq e^2\rho s$ (here c is a sufficiently large constant). As before we start by simplifying the expression bounding s.

CLAIM 4.3. *There exists a constant* γ *s.t. with probability at least* $3/4$ *a random set* H *of* G *of size* $s = \frac{d^\gamma}{\rho}\log^2(1/\rho)$ *satisfies* $\alpha(H) \leq e^2\rho s$ *with probability* $\geq 3/4$.

Proof. Recall that $k-1 = \sqrt{d/\log(d)}$, $a^2 = \frac{1}{k-1}$. As before, it suffices to bound $\varepsilon = \varepsilon(a)$. By Theorem 3.8, we have

$$\varepsilon \geq \frac{1}{poly(d)}\left(1 - a^2\frac{2(k-1)}{k-2}\right)^{\frac{d-1}{2}}.$$

Furthermore, using Claims 9.1 and 9.2 (of section 9), we obtain

$$\left(1 - a^2\frac{2(k-1)}{k-2}\right)^{\frac{d-1}{2}} = \left(1 - a^2\left(2 + \frac{2}{k-2}\right)\right)^{\frac{d-1}{2}} \geq \frac{1}{poly(d)}\left(1-a^2\right)^{d-1} \geq \frac{\rho^2}{poly(d)}.$$

We conclude that there exists a constant γ such that $\varepsilon \geq \frac{\rho^2}{d^\gamma}$. □

Let H be a random subset of vertices of G of size $s = \frac{d^\gamma}{\rho}\log^2(1/\rho)$. Notice that $\log(s) = \theta(\sqrt{d\log d})$ and $s \leq \theta(\frac{d^{\gamma+2}}{\rho})$. By definition, G is k vector colorable. This implies that any subgraph of G (including that induced by H) is $k = O\big(\frac{\log(s)}{\log(\log(s))}\big)$ vector colorable, which completes the proof of the first part of our assertion. For the second part of our assertion, by Claim 4.3 the subset H does not have an independent set of size $e^2\rho s \leq \log^\gamma(s)$ with probability at least $3/4$ (for some different constant γ). □

Proof of Theorem 1.2(3). The proof follows the line of proof appearing above. In general, we use the graph $G = G_3$, but this time the value of a is set to be $a = 0.36$. Again, G is pairwise $\langle \rho(a), \varepsilon(a)\rangle$-connected, where $\varepsilon(a)$ can be bounded by approximately $(\frac{3}{4}(1-4a^2))^{\frac{d-1}{2}}$. Let $\rho = \rho(a)$ and $\varepsilon = \varepsilon(a)$. By Theorem 3.11, a random subset H of size $s \geq c\frac{\rho}{\varepsilon}\log^2(1/\rho)$ does not have an independent set of size $e^2\rho s$ (with probability $\geq 3/4$). Computing the value of $\log_s \rho s$, we obtain our assertion. We would like to note that results of a similar nature can be obtained using the above techniques for any value of k. □

5. Random sampling. We now turn to proving Theorem 3.11 stated in section 3. This is done in two steps. In section 5.1 we prove results analogous to those presented in Theorem 3.11 when the graphs considered are finite. In section 5.2 we

show that our analysis extends to the continuous case (of section 3) as well. Finally, in section 5.3, we continue the study of finite graphs, and obtain results of independent interest in the context of property testing.

Let G be a graph of size n which does not have an independent set of size ρn (i.e., $\alpha(G) < \rho n$). Let H be a random subgraph of G of size s (i.e., H is the subgraph induced by a random subset of vertices in G of size s). In this section we study the minimal value of s for which $\alpha(H) \leq \rho s$ with high probability.

In general, if our only assumption on G is that $\alpha(G) < \rho n$, we cannot hope to set s to be smaller than n. Hence, we strengthen our assumption on G, to graphs G which not only satisfy $\alpha(G) \leq \rho n$ but are also *far* from having an independent set of size ρn. (We defer defining the exact notion of "far" until later in this discussion.) That is, given a graph G which is *far* from having an independent set of size ρn, we ask for the minimal value of s for which (with high probability) a random subgraph of size s does not have an independent set of size ρs. This question (and many other closely related ones) have been studied in [GGR98] under the title of *property testing*.

In [GGR98], a graph G of size n is said to be ε-far from having an independent set of size ρn if any set of size ρn in G has at least εn^2 induced edges. It was shown in [GGR98] that if G is ε-far from having an independent set of size ρn, then with high probability a random subgraph of size $s = \frac{c \log(1/\varepsilon)\rho}{\varepsilon^4}$, for a sufficiently large constant c, does not have an independent set of size ρs.

The results of [GGR98] do not suffice for the proof (as we present it) of Theorem 1.2. We thus turn to strengthening their results. To do so, we introduce a stronger notion of being "ε-far." Roughly speaking, we prove that, under our new notion of distance, choosing s to be of size $\frac{\rho}{\varepsilon}$ suffices. Furthermore, by applying our proof techniques on the original notion of distance presented in [GGR98], we improve the result of [GGR98] stated above and obtain a sample size proportional to $1/\varepsilon^3$. In section 6 we continue to study the original notion of ε-far from [GGR98] and present a lower bound on the sample size which is proportional to $1/\varepsilon^2$. The proof techniques used in this section are based on the techniques appearing in [GGR98] and [AK02]. (In the latter, property testing of the chromatic number is considered.) We start with the following definitions (which are finite versions of those given in section 3.)

DEFINITION 5.1. *Let A and B be (not necessarily disjoint) subsets of G. For each vertex $v \in A$ let $d_v(B)$ be the number of neighbors v has in B. Let $E(A,B) = \sum_{v \in A} d_v(B)$.*

DEFINITION 5.2. *Let $\rho < 1$. A graph $G = (V,E)$ is said to be $\langle \rho, \varepsilon \rangle$-connected iff every subset A of V of size ρn satisfies $E(A,A) \geq \varepsilon n^2$ (i.e., the number of edges in the subgraph induced by A is greater than $\frac{\varepsilon}{2} n^2$).*

Notice that $\varepsilon \leq \rho^2$. Furthermore, notice that a graph G is $\langle \rho, \varepsilon \rangle$-connected iff G is $\varepsilon/2$-far (by the definitions presented in [GGR98]) from having an independent set of size ρn.

DEFINITION 5.3. *Let $\rho < 1$. A graph $G = (V,E)$ is said to be* pairwise $\langle \rho, \varepsilon \rangle$*-connected iff every two (not necessarily disjoint) subsets A and B of V of size ρn satisfy $E(A,B) \geq \varepsilon n^2$.*

As mentioned above, for $\langle \rho, \varepsilon \rangle$-connected and pairwise $\langle \rho, \varepsilon \rangle$-connected graphs G, we study the minimal value of s for which a random subgraph H of G of size s satisfies $\alpha(H) \leq \rho s$ with high probability. Namely, we analyze the probability that a random subset H of G satisfies $\alpha(H) \leq \rho s$ (as a function of ρ, ε, and the sample size s). The main idea behind our proof is as follows. Given a sample size s, we start by bounding the probability that a random subset R of G of size $k > \rho s$ is an independent set.

Then, using the standard union bound on all subsets R of H of size greater than ρs, we bound the probability that $\alpha(H) > \rho s$.

Throughout this section we analyze the properties of random subsets H which are assumed to be *small*. Namely, we assume that the value of s and the parameters ρ, ε, and n satisfy (a) $s < c\sqrt{n}$ and (b) $s < c\rho n$ for a sufficiently small constant c. In our applications (and also in standard ones) these assumptions hold.

In section 5.1 we analyze the above proof strategy and show that it suffices to bound a condition slightly weaker than the condition $\alpha(H) > \rho s$. Namely, using this scheme, we are able to bound the probability for which $\alpha(H) > \delta\rho s$ for sufficiently large constants δ. This result is used to prove Theorem 3.11 of section 3. In section 5.3 we refine our scheme and obtain the main result of this section.

THEOREM 5.4. *Let G be a $\langle\rho,\varepsilon\rangle$-connected graph. Let H be a random sample of G of size s. For any constant $c_1 > 0$ there exists a constant $c_2 > 0$ (depending on c_1 alone) s.t.*

1. *if $s \geq c_2 \frac{\rho^4}{\varepsilon^3} \log\left(\frac{\rho}{\varepsilon}\right)$, then the probability that H has an independent set of size $> \rho s$ is at most $e^{-c_1 \frac{\rho}{\varepsilon}}$;*
2. *if G is pairwise $\langle\rho,\varepsilon\rangle$-connected, and $s \geq c_2 \frac{\rho^5}{\varepsilon^3} \log\left(\frac{\rho}{\varepsilon}\right) \log(\frac{1}{\rho})$, then the probability that H has an independent set of size $> \rho s$ is at most $e^{-c_1 \frac{\rho^2 \log(1/\rho)}{\varepsilon}}$.*

5.1. The naive scheme. Let $G = (V, E)$ be a $\langle\rho,\varepsilon\rangle$-connected graph (pairwise or not). In this section we study the probability that a random subset R of V of size k is an independent set. We then use this result to bound the probability that a random subset H of G of size s has a large independent set.

We would like to bound (from above) the probability that R induces an independent set. Let $\{r_1, \ldots, r_k\}$ be the vertices of R. Consider choosing the vertices of R one by one such that at each step the random subset chosen so far is $R_i = \{r_1, \ldots, r_i\}$. Assume that at some stage R_i is an independent set. We would like to show (with high probability) that after adding the remaining vertices of $\{r_{i+1}, \ldots, r_k\}$ to R_i, the final set R will not be an independent set.

Let $I(R_i)$ (for *independent*) be the set of vertices in V which are not adjacent to any vertices in R_i, and let $N(R_i)$ be the set of vertices that are adjacent to a vertex in R_i. Consider the next random vertex $r_{i+1} \in R$. If r_{i+1} is chosen from $N(R_i)$, then R_{i+1} is no longer an independent set (implying that neither is R), and we view this round as a success. Otherwise, r_{i+1} happens to be in $I(R_i)$, and R_{i+1} is still an independent set. But if r_{i+1} also happens to have many neighbors in $I(R_i)$, then adding it to R_i will substantially reduce the size of $I(R_{i+1})$, which works in our favor. This later case is also viewed as a successful round regarding R_i.

Motivated by the discussion above, we continue with the following definitions. As before, let $G = (V, E)$ be a $\langle\rho,\varepsilon\rangle$-connected graph (pairwise or not), let $R = \{r_1, \ldots, r_k\}$ be a set of vertices in V, and let $R_i = \{r_1, \ldots, r_i\}$. Each subset R_i of V defines the following partition (LI_i, HI_i, N_i) of V:

- Let I_i be the vertices that are not adjacent to any vertex in R_i (notice that it may be the case that $R_i \cap I_i \neq \phi$). I_i is now partitioned into two parts: vertices in I_i which have *low* degree, denoted as the set LI_i, and vertices of *high* degree, denoted as HI_i. Namely, LI_i is defined to be the ρn vertices of I_i with minimal degree (in the subgraph induced by I_i), and HI_i is defined to be the remaining vertices of I_i. Ties are broken arbitrarily or in *favor* of vertices in R_i (namely, vertices in R_i are placed in I_i before other vertices of identical degree). If it is the case that $|I_i| \leq \rho n$, then LI_i is defined to be I_i,

and HI_i is defined to be empty.

- N_i is defined to be the remaining vertices of V (namely, the vertices that share an edge with some vertex in R_i).

We define the partition corresponding to $R_0 = \phi$ as (LI_0, HI_0, NI_0), where LI_0 are ρn vertices of G of minimal degree, HI_0 are the remaining vertices of G, and $N_0 = \phi$.

Notice, using this notation, that the subset R_i is an independent set iff $R_i \cap N_i = \phi$, or equivalently, $R_i \subseteq I_i$. Moreover, in this case $R_i \subseteq LI_i$. (All vertices of R_i have degree 0 in the subgraph induced by I_i.) Furthermore, each vertex r_i in an independent set $R = R_k = \{r_1, \ldots, r_k\}$ satisfies $r_i \in I_{i-1}$.

We are now ready to bound the probability that a random subset $R = \{r_1, \ldots, r_k\}$ of G is independent. Let $R_i = \{r_1, \ldots, r_i\}$, and let (LI_i, HI_i, N_i) be the corresponding partitions of V defined by R_i. Consider the case in which R is an independent set. As mentioned above, this happens iff for every i the vertex r_i is chosen to be independent from the subset R_{i-1}, or in other words, $r_i \in I_{i-1} = LI_{i-1} \cup HI_{i-1}$. We would like to show that this happens with small probability (if k is large enough).

Initially, the subset I_0 is large (the entire vertex set V), and it gets smaller and smaller as we proceed in the choice of vertices in R. Each vertex in $r_i \in HI_{i-1}$ reduces the size of I_{i-1} substantially, while each vertex in LI_{i-1} may only slightly change the size of I_{i-1}. In the following, we show that there cannot be many vertices $r_i \in R$ that happen to fall into HI_{i-1} (as each such vertex reduces the size of I_{i-1} substantially). We thus turn to considering vertices r_i that fall in LI_{i-1}. (There are almost k such vertices.) The size of LI_i is bounded by ρn. Hence, the probability that $r_i \in LI_i$ is bounded by ρ (by our definitions $R_{i-1} \subseteq LI_{i-1}$ and the vertex r_i is random in $V \setminus R_{i-1}$). This implies that the probability that R is an independent set is roughly bounded by ρ^k. Details follow.

LEMMA 5.5. *Let G be a $\langle \rho, \varepsilon \rangle$-connected graph. Let $R = \{r_1, \ldots, r_k\}$ be a set in G. The number of vertices r_i that satisfy $r_i \in HI_{i-1}$ is bounded by $t = \frac{\rho}{\varepsilon}$. If G is pairwise $\langle \rho, \varepsilon \rangle$-connected, then the number of vertices r_i that satisfy $r_i \in HI_{i-1}$ is bounded by $t = \frac{2\rho^2 \lceil \log(1/\rho) \rceil}{\varepsilon}$.*

Proof. We start with the following claim.

CLAIM 5.6. *Let R_i be as defined above, and let (LI_i, HI_i, N_i) be its corresponding partition. Let $I_i = LI_i \cup HI_i$. If G is $\langle \rho, \varepsilon \rangle$-connected, then every vertex in HI_i has degree at least $\frac{\varepsilon}{\rho} n$ (in the subgraph induced by I_i). If G is pairwise $\langle \rho, \varepsilon \rangle$-connected, then every vertex in HI_i has degree at least $\frac{\varepsilon}{2\rho^2}|I_i|$ (in the subgraph induced by I_i).*

Proof. Assume that $|I_i| = \alpha \rho n$ for some $\alpha \geq 1$ (otherwise the set HI_i is empty, and the claim holds). Notice that this implies $|LI_i| = \rho n$. For the first part of our claim, recall by the definition of $\langle \rho, \varepsilon \rangle$-connected graphs that $E(LI_i, LI_i) \geq \varepsilon n^2$. Hence, we conclude that there exists a vertex in LI_i of degree at least $\frac{\varepsilon}{\rho} n$ (in the subgraph induced by LI_i). The set $LI_i \subseteq I_i$, and thus also, in the subgraph induced by I_i, there exists a vertex in LI_i of degree at least $\frac{\varepsilon}{\rho} n$. As LI_i are the vertices of minimal degree in I_i, we conclude the first part of our assertion.

For the second part, let $I_i = X_1 \cup X_2 \cup \cdots \cup X_\ell$, where $\{X_1, \ldots, X_\ell\}$ is a partition of I_i into ℓ sets in which the size of X_j for all $j \neq \ell$ is ρn. Notice that $\ell = \lfloor \alpha \rfloor + 1$. For each $v \in I_i$ let $d_v(I_i)$ be the degree of v in the subgraph induced by I_i.

In this case our graph G is pairwise $\langle \rho, \varepsilon \rangle$-connected. This implies that the value of $E(LI_i, X_j)$ for each j (except $j = \ell$) is at least εn^2. Hence, $\sum_{v \in LI_i} d_v(I_i)$ is at least $\lfloor \alpha \rfloor \varepsilon n^2 \geq \frac{\alpha}{2} \varepsilon n^2$. This implies that LI_i must include a vertex v with degree $d_v(I_i) \geq \alpha \frac{\varepsilon}{2\rho} n$. As LI_i are the vertices of minimal degree in I_i, we conclude our assertion. ∎

Now to prove our lemma, consider the subsets $R_i = \{r_1, \ldots, r_i\}$ and their corresponding partitions (LI_i, HI_i, N_i). Let $I_i = LI_i \cup HI_i$. Let $N(r_i)$ be the vertices adjacent to r_i in I_{i-1}. We would like to bound the number of vertices r_i that are in HI_{i-1}. We start with the case in which G is $\langle \rho, \varepsilon \rangle$-connected. Consider a vertex r_i in HI_i. By Claim 5.6, its degree in I_{i-1} is $|N(r_i)| \geq \frac{\varepsilon}{\rho} n$. Each vertex $r_i \in HI_{i-1}$ increases the size of N_{i-1} by at least $|N(r_i)|$. Initially, N_0 is empty, and after r_k is chosen, $|N_k| \leq n$. We conclude that there are at most $\frac{\rho}{\varepsilon}$ vertices r_i in R which are in HI_{i-1}. This bound can be further improved by a factor of approximately ρ to $\frac{2\rho^2 \lceil \log(1/\rho) \rceil}{\varepsilon}$ using tighter analysis when G is also pairwise $\langle \rho, \varepsilon \rangle$-connected; details follow.

Let $x \geq 0$ be an integer, and let $S_x = \{i \mid r_i \in HI_{i-1} \text{ and } |I_{i-1}| \in [\frac{n}{2^{x+1}}, \frac{n}{2^x})\}$. We would like to bound the size of S_x for all possible values of x. We start by considering values of x between 0 and $\lceil \log(1/\rho) \rceil - 1$. Consider a vertex r_i in which $i \in S_x$. That is, $r_i \in HI_{i-1}$ and $\frac{n}{2^x} \geq |I_{i-1}| > \frac{n}{2^{x+1}}$. By Claim 5.6, the degree of r_i in I_{i-1} is $|N(r_i)| \geq \frac{\varepsilon}{2\rho^2} |I_{i-1}| \geq \frac{\varepsilon}{2\rho^2} \frac{n}{2^{x+1}}$. Each vertex r_i in which $i \in S_x$ increases the size of N_{i-1} by at least $|N(r_i)|$. For such vertices, N_{i-1} is of size at least $n - \frac{n}{2^x}$ and at most $n - \frac{n}{2^{x+1}}$. We conclude that $|S_x|$ is of size at most $\frac{2\rho^2}{\varepsilon}$.

For $x \geq \lceil \log(1/\rho) \rceil$, the set S_x is a subset of $\{i \mid r_i \in HI_{i-1} \text{ and } |I_{i-1}| \leq \rho n\}$. Recall that $HI_{i-1} = \phi$ whenever $|I_{i-1}| \leq \rho n$. This implies that $S_x = \phi$ in these cases. In sum, we conclude that $\sum_x |S_x| \leq \frac{2\rho^2 \lceil \log(1/\rho) \rceil}{\varepsilon}$, which concludes our proof. ∎

THEOREM 5.7. *Let G be a $\langle \rho, \varepsilon \rangle$-connected graph (pairwise or not). Let t be as in Lemma 5.5. Let $k \geq 2t$. The probability that k random vertices of G induce an independent set is at most*

$$\rho^k \left(\frac{ek}{t\rho} \right)^t.$$

Proof. Let $R = \{r_1, \ldots, r_k\}$ be a set of k random vertices. As mentioned previously, the probability that $r_i \in LI_{i-1}$ is at most ρ. This follows from the fact that (1) the size of LI_{i-1} is at most ρn, (2) $R_{i-1} \subseteq LI_{i-1}$ (by our definitions), and (3) the vertex r_i is random in $V \setminus R_{i-1}$.

Now in order for R to be an independent set, every vertex r_i of R must be in the set I_{i-1}. Furthermore, by Lemma 5.5 all but t vertices r_i of R must satisfy $r_i \in LI_{i-1}$. Hence, the probability that R is an independent set is at most

$$\binom{k}{t} \rho^{k-t} \leq \left(\frac{ke}{t} \right)^t \rho^{k-t} = \rho^k \left(\frac{ek}{t\rho} \right)^t. \qquad \blacksquare$$

Let δ be a large constant. We now use Theorem 5.7 to bound the probability that a random subset H of G of size s has an independent set of size $> \delta \rho s$. The result is the following Corollary 5.8, which will be used in section 5.2 to prove Theorem 3.11. In section 5.3 we refine our proof techniques and *get rid* of the parameter δ. That is, we bound the probability that a random subset H of G of size s has an independent set of size $> \rho s$.

COROLLARY 5.8. *Let G be a $\langle \rho, \varepsilon \rangle$-connected graph (pairwise or not). Let t be as in Lemma 5.5. Let H be a random sample of G of size s. Let $\delta > e$, and let c be a sufficiently large constant. If $s \geq ct \frac{\log(1/\rho)}{\rho}$, then the probability that $\alpha(H) > \delta \rho s$ is at most $\left(\frac{e}{\delta}\right)^{\Omega(\delta \rho s)}$.*

Proof. Let $k = \delta \rho s$. Using Theorem 5.7 and the fact that a subset R of H is random in G, the probability that there is an independent set R in H of size k is at

most

$$\binom{s}{k}\rho^k\left(\frac{ek}{t\rho}\right)^t \le \left[\left(\frac{e}{\delta}\right)^{\frac{k}{t}}\frac{ek}{t\rho}\right]^t \le \left(\frac{e}{\delta}\right)^{\Omega(k)}.$$

In the last inequality we have used the fact that $\frac{k}{t}$ is greater than $c\log(1/\rho)$ for a sufficiently large constant c. □

5.2. Proof of Theorem 3.11. We would now like to show that the analysis presented in section 5.1 also holds for our continuous graph G_k of section 3. Namely, we would like to prove the following analogue of Corollary 5.8.

THEOREM 3.11 (restated). *Let a, k, $\varepsilon(a)$ be defined as in Theorem* 3.6 *or* 3.8. *Let H be a random sample of s vertices of G_k (according to the uniform distribution on S^{d-1}). Let c be a sufficiently large constant. If $s \ge c\frac{\rho(a)}{\varepsilon(a)}\log^2(1/\rho(a))$, then the probability that $\alpha(H) > e^2\rho(a)s$ is at most* 1/4.

Proof. Let $H = \{h_1, \ldots, h_s\}$ be s random points of the unit sphere (that is, H is a random subset of G_k of size s). Let $R_k = \{r_1, \ldots, r_k\}$ be a subset of H of size k. Finally, for $i \in \{1, \ldots, k\}$ let $R_i = \{r_1, \ldots, r_i\}$ and (LI_i, HI_i, N_i) be its corresponding partition (as defined in section 5.1). For each i the subsets LI_i, HI_i, and N_i are measurable (this follows from the fact that the neighborhood of each vertex is a cap of S^{d-1}). Hence, the proofs of Lemma 5.5 and Theorem 5.7 hold under Definitions 3.1, 3.2, and 3.9 of section 3. This suffices to conclude our assertion. □

5.3. An enhanced analysis. Let $G = (V, E)$ be a $\langle\rho, \varepsilon\rangle$-connected graph (pairwise or not), and let $H = \{h_1, \ldots, h_s\}$ be a set of random vertices of size s in V. In the previous section we presented a bound on the probability that $\alpha(H) > \delta\rho s$ for large constant values of δ. In this section we enhance our analysis and bound the probability that $\alpha(H) > \rho s$ (namely, we get rid of the additional parameter δ).

Recall our proof technique from section 5.1. We started by analyzing the probability that a subset R of H of size k is an independent set. Afterwards we bounded the probability that $\alpha(H) > \delta\rho n$ by using the standard union bound on all subsets R of H of size greater than $k = \delta\rho n$. In this section we enhance the first part of this scheme by analyzing the probability that a subset R of H of size k is a *maximum* independent set in H (rather than just an independent set of H). Then, as before, using the standard union bound on all large subsets R of H, we bound the probability that $\alpha(H) > \rho s$. We show that taking the maximality property of R into account will suffice to prove Theorem 5.4.

Let $H = \{h_1, \ldots, h_s\}$ be s random vertices in G. We would like to analyze the probability that a given subset R of H of size k is a *maximum* independent set. Recall (section 5.1) that the probability that R is an independent set is bounded by approximately ρ^k. An independent set R is a maximum independent set in H only if adding any other vertex in H to R will yield a set which is no longer independent. Let $R = R_k$ be an independent set, and let (LI_k, HI_k, N_k) be the partition (as defined in section 5.1) corresponding to R. Consider an additional random vertex h from H. The probability that $R \cup h$ is no longer an independent set is approximately $|N_k|/n$ (here we assume that $|R|$ is small compared to n). The probability that for every $h \in H \setminus R$ the subset $R \cup \{h\}$ is no longer independent is thus $\simeq (|N_k|/n)^{s-k}$. Hence, the probability that a given subset R of H of size k is a *maximum* independent set is bounded by approximately $\rho^k\,(|N_k|/n)^{s-k}$. This value is substantially smaller than ρ^k iff $|N_k|$ is substantially smaller than n. We conclude that it is in our favor to somehow ensure that $|N_k|$ is not too large. We do this in an artificial manner.

Let $R = \{r_1, \ldots, r_k\}$ be an independent set, let $R_i = \{r_1, \ldots, r_i\}$, and let (LI_i, HI_i, N_i) be the partition (as defined in section 5.1) corresponding to R_i. Roughly speaking, in section 5.1, every time a vertex r_i was chosen, the subset N_i was updated. If r_i was chosen in HI_{i-1}, then N_{i-1} grew substantially, and if r_i was chosen in LI_{i-1}, the subset N_{i-1} was only slightly changed. We would like to change the definition of the partition (LI_i, HI_i, N_i) corresponding to R_i to ensure that N_i is always substantially smaller than n. This cannot be done unless we relax the definition of N_i. In our new definition, N_i will no longer represent the entire set of vertices adjacent to R_i; rather, N_i will include only a subset of vertices adjacent to R_i (a subset which is substantially smaller than n). Namely, in our new definition of the partition (LI_i, HI_i, N_i) the set N_{i-1} is changed only if r_i was chosen in HI_{i-1}. In the case in which $r_i \in LI_{i-1} \cup N_{i-1}$, we do not change N_{i-1} at all. As we will see, such a definition will imply that $|N_i| \leq (1-\rho)s$, which will now suffice for our proof.

A new partition. Let $H = \{h_1, \ldots, h_s\}$ be a subset of V. Let $R_i = \{r_1, \ldots, r_i\}$ be a subset of H of size i. Each such subset R_i defines a partition (LI_i, HI_i, N_i) of V. As before, let $I_i = LI_i \cup HI_i$.

1. Initially $R_0 = \phi$, LI_0 is the ρn vertices in V of minimal degree (in V), $HI_0 = V \setminus LI_0$, and $N_0 = \phi$. In the above, ties are broken by an assumed ordering on the vertices in V.
2. Let (LI_i, HI_i, N_i) be the partition corresponding to R_i, and let r_{i+1} be a new random vertex. Let $R_{i+1} = R_i \cup \{r_{i+1}\}$; then we define the partition $(LI_{i+1}, HI_{i+1}, N_{i+1})$. Let $N(r_{i+1})$ be the neighbors of r_{i+1} in I_i. We consider the following cases:
   - If $r_{i+1} \in LI_i$, then the partition corresponding to R_{i+1} will be exactly the partition corresponding to R_i, namely, $LI_{i+1} = LI_i$, $HI_{i+1} = HI_i$, and $N_{i+1} = N_i$. Notice that this implies that N_{i+1} no longer represents all neighbors of R_{i+1}. There may be vertices adjacent to R_{i+1} which are in I_{i+1}.
   - If $r_{i+1} \in HI_i$, then we consider two subcases:
     - If $|N_i \cup N(r_{i+1})| \leq (1-\rho)n$, then LI_{i+1}, HI_{i+1}, and N_{i+1} are defined as in section 5.1. Namely, $N_{i+1} = N_i \cup N(r_{i+1})$. I_{i+1} is defined to be $V \setminus N_{i+1}$. LI_{i+1} is defined to be the ρn vertices of I_{i+1} with minimal degree (in the subgraph induced by I_{i+1}), and HI_{i+1} is defined to be the remaining vertices of I_{i+1}. Ties are broken by the assumed ordering on V.
     - If $|N_i \cup N(r_{i+1})| > (1-\rho)n$, then let $\hat{N}(r_{i+1})$ be the first (according to the assumed ordering on V) $(1-\rho)n - |N_i|$ vertices in $N(r_{i+1})$, and set $N_{i+1} = N_i \cup \hat{N}(r_{i+1})$. Furthermore, set LI_{i+1} to be the remaining ρn vertices of G, and HI_i to be empty. Notice that in this case, $|N_{i+1}|$ is of size exactly $(1-\rho)n$.
   - If $r_{i+1}, \in N_i$ then, once again, the partition corresponding to R_{i+1} will be exactly the partition corresponding to R_i.

A few remarks are in order. First, it is not hard to verify that the definition above implies the following claim.

CLAIM 5.9. *Let $i \in \{1, \ldots, k\}$. The partitions (LI_i, HI_i, N_i) corresponding to R_i as defined above satisfy* (a) $I_i \subseteq I_{i-1}$, (b) $N_{i-1} \subseteq N_i$, (c) $|N_i| \leq (1-\rho)n$, (d) $|LI_i| = \rho n$, (e) *that the set LI_i is the ρn vertices of minimal degree in I_i.*

Second, due to the iterative definition of our new partition, the partitions (LI_i, HI_i, N_i) corresponding to the subsets R_i depend strongly on the specific ordering of

the vertices in R_i. Namely, in contrast to the partitions used in section 5.1, a single subset R with two different orderings may yield two different partitions. For this reason, in the remainder of this section we will assume that the vertices of H are chosen one by one. This will imply an ordering on H and on any subset R of H. The partitions we will study will correspond to these orderings only.

Finally, in section 5.1, an (ordered) subset $R = \{r_1, \ldots, r_k\}$ was independent iff for all i, $r_i \in I_{i-1}$ (according to the definition of I_{i-1} appearing in section 5.1). In this section, if R is independent, then it still holds that for all i, $r_i \in I_{i-1}$. However, it may be the case that for all i, $r_i \in I_{i-1}$, but R is not an independent set. In the remainder of this section, we call ordered subsets R for which for all i, $r_i \in I_{i-1}$, *free* sets. We analyze the probability that a random ordered subset H of V of size s does not have any free sets of size larger then ρs. This implies that H does not include any independent sets of size ρs.

DEFINITION 5.10. *An ordered subset $R_i = \{r_1, \ldots, r_i\}$ is said to be free if it is the case that $r_j \in I_{j-1}$ for all $j \leq i$.*

CLAIM 5.11. *Let $H = \{h_1, \ldots, h_s\}$ be an ordered set of vertices in a (pairwise) $\langle \rho, \varepsilon \rangle$-connected graph G. If $\alpha(H) > \rho s$, then the maximum free set in H (w.r.t. the ordering implied by H) is of size $> \rho s$.*

Proof. Let I be an independent set of size $> \rho s$ in H. It is not hard to verify that I (under the ordering implied by H) is a free set. We conclude that the maximum free set R in H (ordered by the ordering implied by H) is of size $> \rho s$. ∎

Claim 5.11 implies that to prove Theorem 5.4 it suffices to analyze the maximum free set $R \subseteq H$. Moreover, the only ordered subsets R that we need to consider are those ordered by the ordering implied by H. We now turn to proving Theorem 5.4. Roughly speaking, we start by analyzing the probability that a random subset R is a free set. We then analyze the probability that a given subset R in H is a maximum free set. Finally, we use the union bound on all subsets R of H of size $> \rho s$ to obtain our results.

In the remainder of this section, we will assume that the subset H is chosen from G randomly *with repetitions*. That is, H is a random multiset of size s. Our results (with minor modifications) apply also to the case in which H is a random subset of G (and not a multiset) if the size of H is not very large (here we assume that $|H| \ll \sqrt{n}$). As in such cases, a set H of size s which is randomly chosen from V with repetitions will not include the same vertex twice (with high probability).

We start by stating the following lemmas, which are analogous to Lemma 5.5 and Theorem 5.7 from section 5.1. The main difference between the lemmas below (and their proofs) and those of the previous section is in the definition of the partition (LI_i, HI_i, N_i) and in the fact that they address free sets instead of independent sets. Proof of the lemmas is omitted.

LEMMA 5.12. *Let G be a $\langle \rho, \varepsilon \rangle$-connected graph. Let $R = \{r_1, \ldots, r_k\}$ be an ordered set in G of size k. The number of vertices r_i which satisfy $r_i \in HI_{i-1}$ is bounded by $t = \frac{\rho}{\varepsilon}$. If G is pairwise $\langle \rho, \varepsilon \rangle$-connected, then the number of vertices r_i which satisfy $r_i \in HI_{i-1}$ is bounded by $t = \frac{2\rho^2 \lceil \log(1/\rho) \rceil}{\varepsilon}$.*

LEMMA 5.13. *Let G be a $\langle \rho, \varepsilon \rangle$-connected graph (pairwise or not). Let t be as in Lemma 5.12. Let $k \geq 2t$. Let $R = \{r_1, \ldots, r_k\}$ be k random vertices of G. The probability that R induces a free set is at most*

$$\rho^k \left(\frac{ek}{t\rho} \right)^t.$$

We now address the probability that a random subset R of H is a maximum free set. We will then use the union bound on all subsets R of H of size $> \rho s$ to obtain our results.

LEMMA 5.14. *Let G be a $\langle \rho, \varepsilon \rangle$-connected graph (pairwise or not). Let t be as in Lemma 5.12. Let $k \geq 2t$. Let H be an ordered random sample of G of size $s \geq k$. The probability that a given subset R of H is a maximum free set is at most*

$$\rho^k \left(\frac{ek}{t\rho}\right)^t (1-\rho)^{s-k}.$$

Proof. Let $R = \{r_1, \ldots, r_k\}$ (ordered by the ordering induced by H). The set R is a maximum free set in H only if (a) R is free and (b) for each vertex $h \in H$ which is not in R, the ordered set $R^+ = \{r_1, \ldots, r_j, h, r_{j+1}, \ldots, r_k\}$ is not free. Here the index j is such that r_j appears before h in the ordering of H, and r_{j+1} appears after h (i.e., R^+ is ordered according to the ordering of H).

The probability that R is free has been analyzed in Lemma 5.13. It is left to analyze the probability that R^+ is not free for every vertex $h \notin R$, given that R is free. Consider a vertex $h \in H$ which is not in R, and let $R^+ = \{r_1, \ldots, r_j, h, r_{j+1}, \ldots, r_k\}$.

CLAIM 5.15. *Let $R = \{r_1, \ldots, r_k\}$ be a free set and $R^+ = \{r_1, \ldots, r_j, h, r_{j+1}, \ldots, r_k\}$. Let the partition corresponding to $R_j = \{r_1, \ldots, r_j\}$ be (LI_j, HI_j, N_j). If $h \in LI_j$, then R^+ is also a free set.*

Proof. We will use the following notation. Let $R_i = \{r_1, \ldots, r_i\}$ denote the first i vertices of R, and let (LI_i, HI_i, N_i) be its corresponding partition. For $i > j$, let $R_i^+ = \{r_1, \ldots, r_j, h, r_{j+1}, \ldots, r_i\}$ denote the first $i+1$ vertices of R^+, and let (LI_i^+, HI_i^+, N_i^+) be its corresponding partition. Finally, let R_h^+ denote the subset $\{r_1, \ldots, r_j, h\}$ and (LI_h^+, HI_h^+, N_h^+) be its corresponding partition.

We would like to prove that R^+ is free. That is, we would like to show (a) that $r_i \in I_{i-1}$ for each $i \leq j$, (b) that $h \in I_j$, (c) that $r_{j+1} \in I_h^+$, and (d) that $r_i \in I_{i-1}^+$ for $i \geq j+2$. Recall that R is free, and thus $r_i \in I_{i-1}$ for all $i \in \{1, \ldots, k\}$.

The first assertion follows from the fact that the first j vertices of R and R^+ are identical. The second follows from the assumption that $h \in LI_j$. For the third assumption, notice (as $h \in LI_j$) that the partition corresponding to $R_h^+ = \{r_1, \ldots, r_j, h\}$ is equal to the partition corresponding to $R_j = \{r_1, \ldots, r_j\}$. This follows from our definition of the partition (LI_h^+, HI_h^+, N_h^+). As $r_{j+1} \in I_j$, we conclude that $r_{j+1} \in I_h^+$.

For the final assertion, observe that for any $i \geq j+1$, the partition corresponding to R_i^+ is equal to the partition corresponding to R_i. This can be seen by induction (on i). We start with the partitions corresponding to R_{j+1} and R_{j+1}^+. The partition $(LI_{j+1}, HI_{j+1}, N_{j+1})$ is defined uniquely by the partition corresponding to R_j and the vertex r_{j+1}. Similarly, the partition $(LI_{j+1}^+, HI_{j+1}^+, N_{j+1}^+)$ is defined uniquely by the partition corresponding to R_h^+ and the vertex r_{j+1}. As the partition corresponding to R_h^+ is equal to the partition corresponding to R_j, we conclude that the same hold for the partitions corresponding to R_{j+1} and R_{j+1}^+. The inductive step is done similarly. The partition corresponding to R_i (R_i^+) is defined uniquely by the partition corresponding to R_{i-1} (R_{i-1}^+) and the vertex r_i. As the partition corresponding to R_{i-1} equals that corresponding to R_{i-1}^+, we conclude our claim. As R is free, $r_i \in I_{i-1}$ for every $i \geq j+2$. This implies also that $r_i \in I_{i-1}^+$, which proves the final assertion. ∎

Claim 5.15 implies that the probability that $R^+ = \{r_1, \ldots, r_j, h, r_{j+1}, \ldots, r_k\}$ is not free, given that R is free, is at most $(1-\rho)$ (recall that the set LI_j is of size exactly ρn). This holds independently for every vertex h in $H \setminus R$. We conclude that

the probability that R is a maximum free subset of H is at most the probability that R is free times $(1-\rho)^{s-k}$. ∎

We now turn to analyzing the probability that a random ordered subset H of G of size s has a free set of size larger than ρs. We follow the line of analysis given in section 5.1 and analyze the probability that H has a free set of size larger than $\delta\rho s$ for any $\delta > 1$. We then get rid of the factor δ to obtain our main theorem of this section.

COROLLARY 5.16. *Let G be a $\langle\rho,\varepsilon\rangle$-connected graph (pairwise or not). Let t be as in Lemma* 5.12. *Let H be a random sample of G of size s. Let $\delta > 1$, and let c be a sufficiently large constant. Let $\Gamma = \ln\delta - \frac{\delta-1}{\delta}$. If $s \geq \frac{ct}{\rho\Gamma}\left(\log(1/\rho) + \log(1+1/\Gamma)\right)$, then the probability that H has a free set of size $> \delta\rho s$ is at most*

$$s\left(\frac{1}{e^{\Gamma}}\right)^{\Omega(\delta\rho s)}.$$

Proof. Let $k = \delta\rho s$, let $\delta' > \delta$, and let $k' = \delta'\rho s > k$. Using Lemma 5.14, the probability that there is a maximum free set R in H of size k' is at most

$$\begin{aligned}
\sum_{k'>k}\binom{s}{k'}\rho^{k'}\left(\frac{ek'}{t\rho}\right)^{t}(1-\rho)^{s-k'} &\leq \sum_{k'>k}\left(\frac{ek'}{t\rho}\right)^{t}\frac{s^s(1-\rho)^{s-k'}}{{k'}^{k'}(s-k')^{s-k'}}\rho^{k'} \\
&\leq \sum_{k'>k}\left(\frac{ek'}{t\rho}\right)^{t}\frac{e^{k'\frac{\delta'-1}{\delta'}}}{{\delta'}^{k'}} \\
&= \sum_{k'>k}\left[\frac{ek'}{t\rho}\left(\frac{1}{e^{\ln\delta'-\frac{\delta'-1}{\delta'}}}\right)^{\frac{k'}{t}}\right]^{t} \\
&\leq \sum_{k'>k}\left[\frac{ek'}{t\rho}\left(\frac{1}{e^{\Gamma}}\right)^{\frac{k'}{t}}\right]^{t} \\
&\leq \sum_{k'>k}\left(\frac{1}{e^{\Gamma}}\right)^{\Omega(k')} \leq s\left(\frac{1}{e^{\Gamma}}\right)^{\Omega(k)}.
\end{aligned}$$

We use the facts that $\frac{k'}{t}$ is greater than both $c\frac{1}{\Gamma}\log(1+1/\Gamma)$ and $c\frac{1}{\Gamma}\log(1/\rho)$ for a sufficiently large constant c, and that Γ is an increasing function of δ (for $\delta > 1$). ∎

It remains to get rid of the additional parameter δ of Corollary 5.16 (namely, to analyze the probability that $\alpha(H) > \rho s$).

LEMMA 5.17. *If a given graph G is (pairwise) $\langle\rho,\varepsilon\rangle$-connected, then G is also (pairwise) $\langle\rho(1-\frac{\varepsilon}{4\rho^2}),\frac{\varepsilon}{2}\rangle$-connected.*

Proof. We present proof for the case in which G is $\langle\rho,\varepsilon\rangle$-connected; a similar proof holds for the case in which G is pairwise $\langle\rho,\varepsilon\rangle$-connected. Let A be some subset of G of size $\rho(1-\frac{\varepsilon}{4\rho^2})n$. Let A^c be any set in $V\setminus A$ of size $\frac{\varepsilon}{4\rho}n$. It is known that the number of edges induced by the set $A\cup A^c$ is at least $\frac{\varepsilon}{2}n^2$ (notice that $|A\cup A^c| = \rho n$ and $E(A\cup A^c, A\cup A^c) \geq \varepsilon n^2$). The number of edges (in $A\cup A^c$) adjacent to vertices in A^c is bounded by $\frac{\varepsilon}{4\rho}\rho n^2 = \frac{\varepsilon}{4}n^2$. Hence, the number of edges induced by vertices in A is at least $\frac{\varepsilon n^2}{4}$, implying that $E(A,A) \geq \frac{\varepsilon}{2}n^2$. ∎

THEOREM 5.4 (restated). *Let G be a $\langle\rho,\varepsilon\rangle$-connected graph (pairwise or not). Let t be as in Lemma* 5.12. *Let H be a random sample of G of size s. Let c be a*

sufficiently large constant. If $s \geq ct\frac{\rho^3}{\varepsilon^2}\log\left(\frac{\rho}{\varepsilon}\right)$, *then the probability that* H *has an independent set of size* $> \rho s$ *is at most* $e^{-\Omega(t)}$.

Proof. By Lemma 5.17, G is also $\langle \rho(1-\frac{\varepsilon}{4\rho^2}), \frac{\varepsilon}{2}\rangle$-connected (pairwise or not). Let $\rho' = \rho(1-\frac{\varepsilon}{4\rho^2})$ and $\varepsilon' = \frac{\varepsilon}{2}$. We would like to bound the probability that H does not have any independent sets of size greater than ρs. Let $\delta = 1 + \frac{\varepsilon}{4\rho^2}$. Notice that $\delta\rho' \leq \rho$. Hence, it suffices to bound the probability that $\alpha(H) > \delta\rho' s$. This probability, in turn, is at most the probability that H has a maximum free set of size greater than $k = \delta\rho' s$ (Claim 5.11).

Let $\Gamma = \ln(\delta) - \frac{\delta-1}{\delta}$. It is not hard to verify that $\Gamma = \theta((\delta-1)^2) = \theta(\frac{\varepsilon^2}{\rho^4})$ for our value of δ. By our assumption, s is greater than or equal to

$$\begin{aligned} ct\frac{\rho^3}{\varepsilon^2}\log\left(\frac{\rho}{\varepsilon}\right) &\geq \frac{c_1 t}{\rho(\delta-1)^2}\left(\log\left(\frac{1}{\rho'}\right) + \log\left(1+\frac{1}{(\delta-1)^2}\right)\right) \\ &\geq \frac{c_2 t}{\rho'\Gamma}\left(\log\left(\frac{1}{\rho'}\right) + \log\left(1+\frac{1}{\Gamma}\right)\right), \end{aligned}$$

where in the above, c_1 and c_2 are constants closely related to c. Now, by Corollary 5.16, for our choice of s, the probability that H has a maximum free set of size greater than $k = \delta\rho' s$ is at most $s\left(\frac{1}{e^\Gamma}\right)^{\Omega(\delta\rho' s)} \leq e^{-\Omega(t)}$. ∎

Roughly speaking, Theorem 5.4 states that, given a $\langle\rho,\varepsilon\rangle$-connected graph G, a random sample H of G of size s proportional to $\frac{\rho^4}{\varepsilon^3}$ (or larger) will not have an independent set of size ρs (with high probability). This improves upon the bound of $s \simeq \frac{\rho}{\varepsilon^4}$ presented in [GGR98] both in the dependence on ρ (as $\rho < 1$) and in the dependence on ε. Moreover, we present a further improvement to $s \simeq \frac{\rho^5}{\varepsilon^3}$ if our graphs are considered to be pairwise $\langle\rho,\varepsilon\rangle$-connected. In section 6 we continue to study the minimal value of s for which $\alpha(H) < \rho s$ with high probability, and present a lower bound on the size of s which is proportional to $\frac{\rho^3}{\varepsilon^2}$.

6. Lower bounds for the testing of $\alpha(G)$. In this section we present graphs G which are $\langle\rho,\varepsilon\rangle$-connected, but with some constant probability a random sample R of G of size $s \sim \rho^3/\varepsilon^2$ is likely to have an independent set of size greater than ρs.

LEMMA 6.1. *Let* ρ *be a small constant and* $\varepsilon < \rho^2$ *s.t.* $\rho^3/\varepsilon^2 \ll n$. *For* n *large enough, there exists a graph* G *on* n *vertices for which* (a) G *is* $\langle\rho,\varepsilon\rangle$*connected, and* (b) *with constant probability (independent of* ρ *and* ε*) a random set* R *of size* $s = \frac{\rho^3}{\varepsilon^2}$ *will have an independent set of size* ρs.

Proof. Consider the graph $G = (V, E)$ in which $|V| = n$, and V consists of two disjoint sets A and $V \setminus A$, where A is an independent set of size $(1-\frac{\varepsilon}{\rho^2})\rho n$, $V \setminus A$ induces a clique, and every vertex in A is adjacent to every vertex in $V \setminus A$. On one hand, every subset of size ρn in G induces a subgraph with at least $\varepsilon n^2/2$ edges (implying that G is $\langle\rho,\varepsilon\rangle$-connected). On the other hand, let R be a random subset of V obtained by picking each vertex independently with probability $\frac{\rho^3}{\varepsilon^2 n}$. The expected size of R is $s = \frac{\rho^3}{\varepsilon^2}$. In the following we assume that R is exactly of size s; minor modifications in the proof are needed if this assumption is not made. The set $R \cap A$ is an independent set in the subgraph induced by R. The expected size of $R \cap A$ is $(1-\frac{\varepsilon}{\rho^2})\rho s$. Let $N(0,1)$ denote a standard normal variable. It can be seen using the central limit theorem (for example, [Fel66]) that, for our choice of parameters, the probability that $|R \cap A|$ deviates from its expectation by more than a square root of

its expectation is at least

$$\Pr\left[|R \cap A| > \left(1 - \frac{\varepsilon}{\rho^2}\right)\rho s + \sqrt{\rho s}\right] > \Pr\left[N(0,1) > 1\right],$$

which is some constant probability independent of ε and ρ. In such a case the size of $R \cap A$ will be greater than $(1 - \frac{\varepsilon}{\rho^2})\rho s + \sqrt{\rho s} = \rho s$ for our value of s, hence implying assertion (b) of the lemma. □

7. An alternative proof of Theorem 1.2(1). In Theorem 1.2(1), we are interested in presenting a vector k-colorable graph H in which a special relationship is satisfied between its maximum degree and its maximum independent set. It is not hard to verify that the graphs G_k presented in section 3 are far from satisfying this relationship, as the maximum degree Δ of these graphs is too large. We overcome this problem in sections 4 and 5 by considering a random (vertex-induced) subgraph of G_k. We have shown that such a subgraph will suffice for proving the three parts of Theorem 1.2.

Another method for coping with the large maximum degree Δ of G_k was suggested by Luca Trevisan (private communication). Instead of sampling vertices from G_k at random in order to obtain a sparse graph, consider sampling *edges* at random. In the following section we combine the idea of edge sampling with our results from section 3 and prove the first part of Theorem 1.2. The use of edge sampling simplifies the proof of Theorem 1.2(1) (as the analysis presented in section 5 is no longer needed). It appears that the remainder of Theorem 1.2 cannot be proven using edge sampling (as we are interested in graphs in which the maximum independent set is small with respect to the number of vertices in the graph).

To construct the graph H we will follow a three-phase plan. Our starting point will be the continuous graph G_k (of section 3), which is vector k-colorable and proven to be pairwise $\langle \rho, \varepsilon \rangle$-connected. We then define and analyze a (finite) discrete version G_k^d of G_k, which will be shown to inherit many of the properties of G_k. Namely, this discrete graph will be *almost* vector k-colorable, and will be pairwise $\langle \rho, \varepsilon \rangle$-connected. Finally, we will define H to be the graph obtained by randomly removing edges from the discrete graph G_k^d.

The discrete graph G_k^d. We now define a discrete analogue G_k^d of the continuous graph G_k from section 3. Recall that the vertex set of G_k is the d-dimensional unit sphere S^{d-1}. It is shown in [FS02] that S^{d-1} can be partitioned into $n = 2^{\theta(d^2)}$ cells of equal size and of diameter at most 2^{-d} each. Let $\mathcal{P} = \{C_1, \ldots, C_n\}$ denote the cells obtained in the above partition. The graph G_k^d will be of size n, in which each vertex $v_i \in V$ corresponds to a cell $C_i \in \mathcal{P}$. The edge set of G_k^d consists of an edge (u, v) iff there is a positive measure of edges in G_k between their corresponding cells C_u, C_v.

LEMMA 7.1. *Let A and B be subsets of G_k^d, and let A_c and B_c be the corresponding subsets of G_k.* (a) *The size of A (B) is ρn iff A_c (B_c) has measure ρ.* (b) $E(A, B) \geq E(A_c, B_c)n^2$. *The definition of $E(A, B)$ is given in Definition* 5.1 *of section* 5.

Proof. For the first part of the lemma, assume that the set A has ρn vertices; thus the corresponding subset A_c consists of ρn cells each of measure n^{-1}. We conclude that the subset A_c has measure exactly ρ. On the other hand, if A_c has measure ρ and consists of the union of k cells of measure n^{-1}, then k must be ρn. For the second part, assume that $E(A, B) = \varepsilon n^2$; then, by the fact that each edge between A and B corresponds to at most the measure of n^{-2} edges between A_c and B_c, we conclude that $E(A_c, B_c)$ is at most ε. □

THEOREM 7.2. *Let a, k, $\varepsilon(a)$ be as defined in Theorem* 3.6 *or* 3.8. *The graph G_k^d is pairwise $\langle \rho(a), \varepsilon(a) \rangle$-connected.*

Proof. Let A and B be subsets (in G_k^d) of size $\rho(a)n$. The corresponding subsets A_c and B_c of G_k are also of measure $\rho(a)$ (Lemma 7.1). By Corollary 3.10, $E(A_c, B_c) \geq \varepsilon(a)$. We conclude that $E(A, B) \geq E(A_c, B_c)n^2 \geq \varepsilon(a)n^2$. □

LEMMA 7.3. *The graph G_k^d is vector $k\big(1+\frac{ck^2}{2^d}\big)$-colorable for some constant $c > 0$.*

Proof. Recall that each cell in G_k^d has diameter at most 2^{-d}. Hence, two vertices in G_k^d are connected only if their inner product is less than $-1/(k-1) + \theta(1)2^{-d} \leq -\frac{1}{k(1+\frac{\theta(k)}{2^d})-1}$. □

By definition, the continuous graph G_k is vector k-colorable. In Lemma 7.3 we showed that the finite approximation G_k^d to G_k is *almost* vector k-colorable. In general, this does not suffice for the proof of Theorem 1.2, as we are interested in graphs which are vector k-colorable (rather than "almost vector k-colorable"). This can be fixed by starting with a continuous graph with vector coloring number slightly less than k (e.g., $k/\big(1+\frac{ck^2}{2^d}\big)$). In order to simplify our presentation, we ignore this point and consider the graph G_k^d to be exactly vector k-colorable. This is possible due to the fact that the properties of G_k are *continuous* in k. Namely, choosing d large enough, it can be seen that the multiplicative error of $(1+\frac{ck^2}{2^d})$ in the value of k does not affect the analysis appearing throughout this section.

LEMMA 7.4. *Let $\rho(\frac{1}{k-1})$ be the measure of a $\frac{1}{(k-1)}$-cap. Every vertex v in the graph G_k^d has degree $d_v \in [\frac{1}{poly(d)}\rho(\frac{1}{k-1})n, poly(d)\rho(\frac{1}{k-1})n]$.*

Proof. Consider a vertex v in G_k^d and its corresponding cell C_v. The degree of v is the number of cells in G_k that share a positive measure of edges with the cell C_v. The total measure of these cells is at least the measure of a $(\frac{1}{k-1} + \theta(2^{-d}))$-cap and at most the measure of a $(\frac{1}{k-1} - \theta(2^{-d}))$-cap. Hence, by Lemma 7.1, we conclude our theorem. □

We now prove the first part of Theorem 1.2 by considering the graph H obtained by randomly sampling the edges of G_k^d.

THEOREM 7.5. *For every constant $\gamma > 0$ and constant $k > 2$, there are infinitely many graphs H that are vector k-colorable and satisfy $\alpha(H) \leq n/\Delta_H^{1-\frac{2}{k}-\gamma}$, where n is the number of vertices in H and Δ_H is the maximum degree in H.*

Proof. Let $k > 2$ be constant. Let $\gamma > 0$ be an arbitrarily small constant. Let $a = \gamma/c$ for a sufficiently large constant c. Let $G = G_k^d = (V, E)$ be the discrete graph defined above. Let n be the size of the vertex set V of G, and let Δ be the maximum degree of G. Recall that $n = 2^{\theta(d^2)}$, where d is the dimension in which the corresponding graph G_k was defined. We will assume that the dimension d is a very large constant determined after fixing a. Finally, let $\rho = \rho(a)$.

By Lemma 7.4, all vertices in G are of degree in the range $[\frac{1}{poly(d)}\Delta, \Delta]$, where $\Delta \sim poly(d)\rho(\frac{1}{k-1})n$. By Theorem 7.2 and the proof of Claim 4.1, every subset of vertices U in G of size ρn has at least $\Delta\rho^{\frac{2(k-1)}{k-2}+\gamma}n$ edges.

Let $p = 1/(\Delta\rho^{\frac{k}{k-2}+2\gamma})$. Let H be the subgraph of G obtained by deleting each edge of G independently with probability $(1-p)$.

LEMMA 7.6. *With probability $\geq 3/4$, all vertices v of H will have degree $d_v(H)$ in the range*

$$\left[\frac{1}{poly(d)}\rho^{-\frac{k}{k-2}-2\gamma}, 2\rho^{-\frac{k}{k-2}-2\gamma}\right].$$

Proof. The expected degree $d_v(H)$ of each vertex v in H satisfies

$$d_v(H) \in \left[\frac{1}{poly(d)}\rho^{-\frac{k}{k-2}-2\gamma}, \rho^{-\frac{k}{k-2}-2\gamma}\right].$$

It is not hard to verify (using standard bounds) that with probability $\geq 3/4$ it is the case that all vertices v have degree $d_v(H)$, which does not deviate from their expectation by more than a constant fraction of their expectation. □

LEMMA 7.7. *With probability* $\geq 3/4$ *the size of the maximum independent set in* H *(*$\alpha(H)$*) is at most* ρn.

Proof. It suffices to show that every subset U of H of size ρn has at least a single edge. Using Claim 9.2, it follows that for each subset U of H, the probability that all its edges were removed is at most

$$(1-p)^{\Delta\rho^{\frac{2(k-1)}{k-2}+\gamma}n} \leq e^{-\rho^{1-\gamma}n}.$$

The number of subsets U of size ρn is

$$\binom{n}{\rho n} \leq e^{\rho n \ln n} \leq \frac{1}{4}e^{\rho^{1-\gamma}n}.$$

Applying the union bound on all subsets U of H of size ρn, we conclude our assertion. □

Now with probability at least 1/2 both Lemma 7.6 and Lemma 7.7 hold, implying our theorem. □

8. Discussion. In our work we have presented *tight* bounds on the chromatic number of vector k-colorable graphs, tight in the sense that they match the upper bounds presented in [KMS98]. Many questions still remain open.

Stronger coloring relaxations. As mentioned in the introduction and section 2, there are stronger relaxations for the minimum coloring problem that also have a geometrical interpretation. For example, one such relaxation is the well known (and extensively studied) Lovász theta function [Lov79]. It is not hard to verify that these relaxations can be used *as is* in the coloring algorithm presented in [KMS98]. One may speculate that using such stronger relaxations will yield improved coloring results. At the moment this is not known to be true.

One may consider proving that even the use of such stronger relaxations in the [KMS98] algorithm cannot yield stronger coloring results. Or in other words, one may try to extend our negative results to stronger relaxations as well. A few remarks are in place. It seems as though the techniques we use in this work do not extend to the stronger coloring relaxations presented in section 2. Our graphs (continuous and random), or to be precise, their embeddings, are not valid with respect to these stronger coloring relaxations. Therefore, in order to extend our negative results, one must change these embeddings appropriately without increasing their vector chromatic number. It seems as if changing the embedding of our graphs to satisfy these stronger coloring relaxations has a large effect on their vector chromatic number. This implies that such an approach will yield weaker negative results.

Alternatively, one may consider using our proof techniques on graphs other than the ones presented. One natural candidate is the graph $G = (V, E)$ in which the vertex set V consists of the set $\{0,1\}^n$ and two vertices are connected by an edge if their Hamming distance is equal to some prespecified value. The graph G and certain

subgraphs of G have been used in the past in the context under discussion (see, e.g., [KMS98, Fei97, GK98, Cha02]). Using our proof technique on such graphs involves the analysis of certain edge isoperimetric inequalities (analogous to those presented in Theorem 3.5). Unfortunately, little is known regarding the edge isoperimetric inequalities of the above graphs G. Such inequalities have been studied in the past [Bez02, KKL88], yielding partial results. However, these results do not suffice to extend our proof techniques. A better understanding of edge isoperimetric inequalities of these graphs is of great interest, regardless of their application to the vector coloring issue.

Property testing. In sections 5 and 6 we study the property testing paradigm with respect to the independent set problem. We present improved results on the sample size needed when testing graphs which are *far* from having large independent sets. Namely, in Theorem 5.4 we prove that if a graph G of size n is $\langle \rho, \varepsilon \rangle$-connected, then with high probability a random induced subgraph of G of size $s \sim 1/\varepsilon^3$ will not have an independent set of size ρs. (This improves upon the sample size of $s \sim 1/\varepsilon^4$ presented in [GGR98].) Moreover, in Lemma 6.1 we show that the sample size s must be of size at least $\sim 1/\varepsilon^2$ if we wish the probability of failure to be nonconstant. It would be interesting if the factor ε gap between the upper and lower bounds presented above could be settled.

9. Proof of claims.

CLAIM 9.1. *For $1 \geq p \geq 0$ and $y \geq 1$, we have that $(1-p)^y \geq 1 - py \geq (1-p)^{y+\frac{py^2}{1-py}}$.*

Proof. It is well known that $e^y \geq 1 + y$ for any real y. Hence,

$$1 - py = \frac{1}{1 + py + \frac{p^2y^2}{1-py}} \geq e^{-p(y+\frac{py^2}{1-py})} \geq (1-p)^{y+\frac{py^2}{1-py}}.$$

As for the other direction, for every $y \geq 1$

$$\frac{d}{dp}((1-p)^y - 1 + py) = y(1 - (1-p)^{y-1}) \geq 0. \qquad \square$$

CLAIM 9.2. *For all $x > 1$*

$$\left(1 - \frac{1}{x}\right)\frac{1}{e} \leq \left(1 - \frac{1}{x}\right)^x \leq \frac{1}{e}.$$

Proof. It is known that for all $x > 1$

$$\left(1 - \frac{1}{x}\right)^x \leq \frac{1}{e} \leq \left(1 - \frac{1}{x}\right)^{x-1}. \qquad \square$$

CLAIM 9.3. *Let $a > \delta > 0$ such that $a\delta \geq 2\log(d)/d$; then*

$$\rho(a) - \rho(a+\delta) \geq \left(1 - \frac{1}{d}\right)\rho(a).$$

Proof. Recall that $\frac{c}{\sqrt{d}}\left(1-a^2\right)^{\frac{d-1}{2}} \leq \rho(a) \leq \left(1-a^2\right)^{\frac{d-1}{2}}$, for some constant $c > 0$. Thus,

$$\begin{aligned}\rho(a+\delta) &\leq \left(1 - a^2 - \delta^2 - 2a\delta\right)^{\frac{d-1}{2}} \leq \left((1-a^2)(1-2a\delta)\right)^{\frac{d-1}{2}} \\ &\leq \left(1-a^2\right)^{\frac{d-1}{2}} \frac{2}{d^2} \leq \frac{\rho(a)}{d}. \qquad \square\end{aligned}$$

THEOREM 3.5 (restated). *Let $1 \geq a > 0$, and let A and B be two (not necessarily disjoint) measurable sets in V of measure $\rho(a)$. Let r be an arbitrary vertex of S^{d-1}. The minimum of $E(A,B)$ is obtained when $A = B = \mathcal{C}_a$, where $\mathcal{C}_a$ is an a-cap of measure $\rho(a)$ centered at r.*

Proof. Our proof is similar to that presented in [FS02]. We start by reviewing the *two-point symmetrization* procedure introduced in [BT76]. Let $r \in S^{d-1}$ and H be the hyperplane passing through the origin with normal r. The hyperplane H partitions S^{d-1} into three sets: points *above*, *below*, and *on* the hyperplane. Define S_0 to be the set $\{u \in S^{d-1} \mid \langle u, r\rangle = 0\}$, S^+ to be $\{u \in S^{d-1} \mid \langle u, r\rangle > 0\}$, and S^- to be $\{u \in S^{d-1} \mid \langle u, r\rangle < 0\}$. For any $x \in S^{d-1}$ denote its reflection with respect to H as $\sigma(x)$. Finally, given any (measurable) subset X of S^{d-1}, we define the *symmetrization* X^* of X w.r.t. H as follows. If x is a point in $X \cap S^-$ such that $\sigma(x) \notin X$, replace x with $\sigma(x)$. All other points $x \in X$ remain in X^*, and no other new points are added to X^*. Formally

$$X^* = X \setminus \{x \mid x \in X \cap S^-,\ \sigma(x) \notin X\} \cup \{\sigma(x) \mid x \in X \cap S^-,\ \sigma(x) \notin X\}.$$

Notice that the measure of X and X^* are identical.

Now, let Λ be the set consisting of all pairs of closed subsets in S^{d-1}. Given two closed subsets A and B of measure $\rho(a)$, let $\lambda(A,B) = \lambda \subset \Lambda$ be the set of pairs $(\alpha, \beta) \in \Lambda$ that satisfy the following:

1. $\mu(A) = \mu(\alpha)$, $\mu(B) = \mu(\beta)$;
2. for all $\varepsilon > 0$, $\mu(A_\varepsilon) \geq \mu(\alpha_\varepsilon)$ $\mu(B_\varepsilon) \geq \mu(\beta_\varepsilon)$;
3. $E(A,B) \geq E(\alpha, \beta)$,

where for any set A, the set A_ε is defined as $\{x \in S^{d-1} \mid \exists y \in A \text{ s.t. } \|x - y\| \leq \varepsilon\}$.

We start by showing that λ is closed under the two-point symmetrization technique. Next we prove that λ is a closed subset of Λ (under the Hausdorff topology). Afterwards, we show that there exists a cap C of measure $\rho(a)$ such that $(C,C) \in \lambda = \lambda(A,B)$, implying that $E(A,B) \geq E(C,C)$. This concludes our proof for subsets A and B which are closed. Finally, we turn to the general case.

LEMMA 9.4. *The set λ is closed under the two-point symmetrization procedure (w.r.t. any $r \in S^{d-1}$ and the hyperplane H passing through the origin defined by r).*

Proof. Let H be some hyperplane passing through the origin. Let (α, β) be a pair in λ. Let α^* and β^* be the sets obtained after the symmetrization procedure w.r.t. H applied to the sets α and β. It suffices to show that $(\alpha^*, \beta^*) \in \lambda$. In [Ben84] it is shown that both α^* and β^* preserve the first two properties of λ. Hence, we turn to the third property. We need to show that the subsets α^* and β^* obtained after the symmetrization procedure share fewer edges than the original sets α and β (which in turn share fewer edges than A and B). Let x^+ and y^+ be two points in S^+, and let x^- and y^- be their corresponding mirror images. Let α' be the restriction of α to these four points (that is, $\alpha' = \alpha \cap \{x^+, x^-, y^+, y^-\}$). Define β', $\alpha^{*'}$, and $\beta^{*'}$ similarly. We will show that $E(\alpha', \beta') \geq E(\alpha^{*'}, \beta^{*'})$. It is not hard to verify that this implies our assertion.

Let E' be the edge set induced by the vertices $\{x^+, x^-, y^+, y^-\}$. Recall, by the definition of our continuous graph G_k, that the edge set E consists of pairs of points x and y in S^{d-1} which satisfy $\langle x, y\rangle \leq -\frac{1}{k-1}$. This implies that E' is symmetric and has the following properties:

1. $(x^+, y^+) \in E' \leftrightarrow (x^-, y^-) \in E'$.
2. $(x^+, y^-) \in E' \leftrightarrow (x^-, y^+) \in E'$.
3. $(x^+, y^+) \in E' \rightarrow (x^+, y^-) \in E'$.

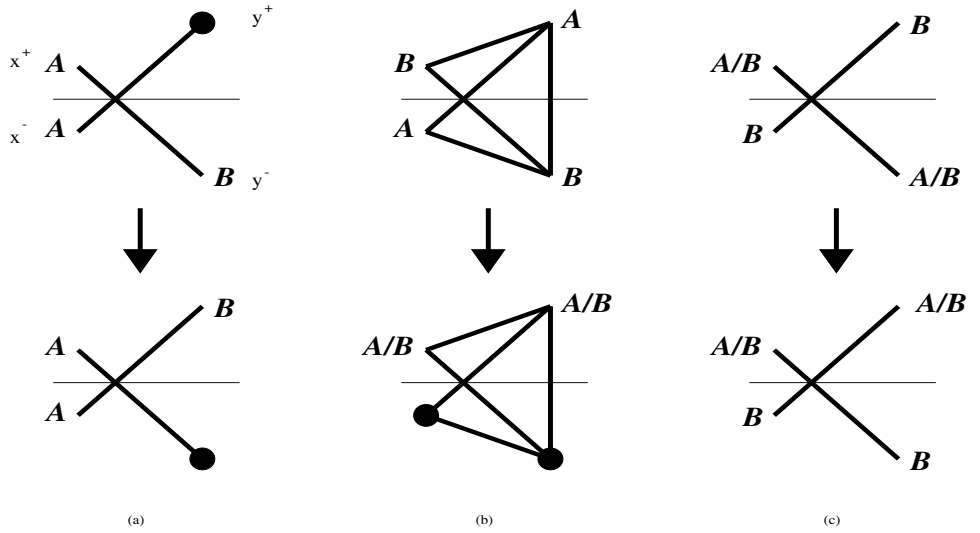

FIG. 2. *Three cases of E', α', and β' are presented. The set $\alpha' = \alpha \cap \{x^+, x^-, y^+, y^-\}$ and $\alpha^{*'}$ are presented by the letter A. The set $\beta' = \beta \cap \{x^+, x^-, y^+, y^-\}$ and $\beta^{*'}$ are presented by the letter B. A point in $\alpha' \cap \beta'$ ($\alpha^{*'} \cap \beta^{*'}$) is presented by A/B. A point in neither α nor β is represented by a solid dot. The edge set E' is depicted by solid lines. Finally, the hyperplane H is represented as a horizontal line. Each configuration is presented before (above) and after (below) the symmetrization procedure. In case* (a) *the set α' is closed under the symmetrization procedure w.r.t H and $-H$. In such cases it holds that $E(\alpha', \beta') = E(\alpha^{*'}, \beta^{*'})$. In cases* (b) *and* (c) *notice that there is a difference between the value of $E(\alpha^{*'}, \beta^{*'})$ and the number of undirected edges between the sets $\alpha^{*'}$ and $\beta^{*'}$ (for example, in case* (b)*, $E(\alpha^{*'}, \beta^{*'}) = \{(x^+, y^+), (y^+, x^+)\}$ is of size* 2*).*

Consider the case in which E' consists of the edges (x^+, y^-) and (x^-, y^+) only, the subset α' is equal to $\{x^+, x^-\}$, and the subset β' is equal to $\{y^-\}$. This case in depicted in Figure 2(a). In this specific case we have that $\alpha^{*'} = \alpha'$ and $\beta^{*'} = \{y^+\}$, implying that $E(\alpha', \beta') = E(\alpha^{*'}, \beta^{*'}) = 1$. Notice that, as α' and β' are finite sets, we measure the amount of edges between α' and β' using the discrete analogue of $E(\alpha', \beta')$ defined in Definition 5.1 of section 5 (the same goes for $\alpha^{*'}$ and $\beta^{*'}$).

There are, of course, several other cases to consider (12 edge configurations and 256 cases of different subsets α' and β'). Some of these cases are depicted in Figure 2. This large case analysis may be significantly reduced using various observations (involving the equivalence of many different cases). We have checked our assertion on the full case analysis (using a computer program). A similar proof holds when x^+ or y^+ are in S_0 (details omitted). □

LEMMA 9.5. *λ is closed in Λ.*

Proof. Let (α_n, β_n) be a sequence in λ tending to (α, β) (in the Hausdorff topology). We will show that $(\alpha, \beta) \in \lambda$. For every $\varepsilon, \delta > 0$ we have for large enough values of n that

$$\alpha_\varepsilon \subseteq (\alpha_n)_{\varepsilon+\delta}, \quad \beta_\varepsilon \subseteq (\beta_n)_{\varepsilon+\delta}; \quad \mu((\alpha_n)_{\varepsilon+\delta}) \leq \mu(A_{\varepsilon+\delta}), \quad \mu((\beta_n)_{\varepsilon+\delta}) \leq \mu(B_{\varepsilon+\delta}).$$

Sending δ to zero and using the fact that for all closed sets α, $\mu(\alpha_\varepsilon) \to \mu(\alpha)$, we conclude the second property of λ, namely that $\mu(\alpha_\varepsilon) \leq \mu(A_\varepsilon)$ and $\mu(\beta_\varepsilon) \leq \mu(B_\varepsilon)$.

For the first property, sending ε to zero, we have on one hand that $\mu(\alpha) \leq \mu(A)$ and $\mu(\beta) \leq \mu(B)$. For the other direction observe that $\mu(\alpha_\varepsilon) \geq \mu(\alpha_n) = \mu(A)$ and $\mu(\beta_\varepsilon) \geq \mu(\beta_n) = \mu(B)$ for any $\varepsilon > 0$, provided that n is large enough.

For the final property of λ, let $\theta(\varepsilon) = \mu^2(\{(x,y) \mid x \in \alpha_\varepsilon,\ y \in \beta_\varepsilon,\ (x,y) \in E\})$. Notice that $E(\alpha,\beta) \le \theta(\varepsilon)$. Let n be large enough to ensure that $\alpha_\varepsilon \subseteq (\alpha_n)_{2\varepsilon}$, $\beta_\varepsilon \subseteq (\beta_n)_{2\varepsilon}$. For such n it is the case that $\theta(\varepsilon) \le E((\alpha_n)_{2\varepsilon},(\beta_n)_{2\varepsilon})$. Furthermore, as $(\alpha_n,\beta_n) \in \lambda$ for all values of n, we have that $\mu((\alpha_n)_{2\varepsilon} \setminus \alpha_n) \le \mu(A_{2\varepsilon} \setminus A)$ and $\mu((\beta_n)_{2\varepsilon} \setminus \beta_n) \le \mu(B_{2\varepsilon} \setminus B)$. Observe that both $\mu(A_{2\varepsilon} \setminus A)$ and $\mu(B_{2\varepsilon} \setminus B)$ tend to zero as ε tends to zero. We conclude that $E((\alpha_n)_{2\varepsilon},(\beta_n)_{2\varepsilon})$ tends to $E(\alpha_n,\beta_n)$ as ε tends to zero *uniformly* in n.

Hence, given $\delta > 0$, one can find $\varepsilon > 0$ such that $E((\alpha_n)_{2\varepsilon},(\beta_n)_{2\varepsilon}) \le E(\alpha_n,\beta_n)+\delta$ for all values of n. We conclude that for n large enough

$$E(\alpha,\beta) \le \theta(\varepsilon) \le E((\alpha_n)_{2\varepsilon},(\beta_n)_{2\varepsilon}) \le E(\alpha_n,\beta_n) + \delta \le E(A,B) + \delta.$$

Since this holds for all δ, we conclude our assertion. □

LEMMA 9.6. *There exists a cap C of measure $\rho(a)$ such that $(C,C) \in \lambda$.*

Proof. Fix a point $x_0 \in S^{d-1}$, and let C be the cap centered at x_0 of measure $\rho(a)$. The function $f_1(\alpha,\beta) = \mu(C \cap \alpha)$ is upper semicontinuous on Λ.[3] Λ with the Hausdorff topology is a compact set, since λ is closed (Lemma 9.5); the function f_1 achieves its maximum over λ on some pair $(\alpha_{max},\beta_{max}) \in \lambda$. In [FS02] it is shown (using Lemma 9.4) that $\alpha_{max} = C$. This is done by showing that $f_1(\alpha^*_{max},\beta) \ge f_1(\alpha_{max},\beta)$ with equality iff $\alpha_{max} = C$, where α^*_{max} is the subset obtained by the symmetrization procedure with respect to a hyperplane H s.t. $x_0 \notin H$, and β is arbitrary.

Now consider the function $f_2(C,\beta) = \mu(C \cap \beta)$ defined on $\Lambda' = \{(C,\beta) \mid (C,\beta) \in \Lambda\}$. The function f_2 is also upper semicontinuous (this time on Λ'). Furthermore, it is shown in [FS02] that Λ' with the Hausdorff topology is a compact set and that $\lambda' = \{(C,\beta) \mid (C,\beta) \in \lambda\}$ is closed in Λ'. Therefore, the function f_2 achieves its maximum over λ' on some pair (C,β_{max}). As before, it can be seen that $\beta_{max} = C$. We conclude that $(C,C) \in \lambda$. □

As mentioned previously, Lemma 9.6 implies our theorem for subsets A and B, which are closed. The proof for general subsets A and B follows by considering any series $\{A_i\}$ and $\{B_i\}$ of closed sets that satisfy: (a) for all n, $A_n \subseteq A$ and $B_n \subseteq B$, (b) $\mu(A_n) \to \mu(A)$ and $\mu(B_n) \to \mu(B)$, and (c) for all n, $\mu(A_n) = \mu(B_n)$. Now let C, $\{C_i\}$ be caps, all centered at the same point $x \in S^{d-1}$ such that $\mu(C) = \mu(A) = \mu(B)$ and for all n, $\mu(C_n) = \mu(A_n) = \mu(B_n)$. It now holds that

$$E(A,B) \ge E(A_n,B_n) \ge E(C_n,C_n) \to E(C,C). \qquad \square$$

CLAIM 9.7. *Let a,z,δ be as in Claim 3.7. Let $b^2 = z^2 - a^2$. Let $N = \{(u_1,\ldots,u_d) \in S^{d-1} \mid u_1 = a,\ u_2 = b\}$. Let N_δ be a δ neighborhood of N (i.e., all points in S^{d-1} which are of distance less that δ from the set N). The measure of the set N_δ is at least $(1-z^2)^{\frac{d-1}{2}}$.*

Proof. Recall that $z = \sqrt{a^2+b^2}$. Let $\hat{N} = \{(u_1,\ldots,u_d) \in S^{d-1} \mid u_1 = z,\ u_2 = 0\}$ be the set obtained from N by rotating the unit sphere by an angle of $\arccos\frac{a}{z}$. Using spherical symmetry, we have that the measure of the set N_δ is equal to the measure of the δ neighborhood of the set $\hat{N}$ (which will be denoted as $\hat{N}_\delta$). Hence, in the following we will present a lower bound on the measure of $\hat{N}_\delta$. We start by computing the measure of the strip

$$S = \left\{(u_1,\ldots,u_d) \in S^{d-1} \mid u_1 \in \left[z - \frac{\delta^2}{1000}, z + \frac{\delta^2}{1000}\right]\right\}.$$

[3] $f(\alpha)$ is upper semicontinuous on Λ if for every sequence $\alpha_n \to \alpha$ in Λ it is the case that $f(\alpha)$ is at least $\limsup f(\alpha_n)$.

Using Claims 9.2 and 9.3, we conclude (for sufficiently large d) that

$$\mu(S) = \rho\left(z - \frac{\delta^2}{1000}\right) - \rho\left(z + \frac{\delta^2}{1000}\right) \geq \frac{1}{2}\rho\left(z - \frac{\delta^2}{1000}\right) \geq \frac{1}{\delta^3}\left(1 - z^2\right)^{\frac{d-1}{2}}.$$

Let γ be a constant such that $\sqrt{1-z^2} \geq |\gamma| > \delta/10$. Consider the set $R = \{(u_1, \ldots, u_d) \in S^{d-1} \mid u_1 = z,\ u_2 = \gamma\}$. Denote the $\delta^2/200$ neighborhood of R as R_γ. Using spherical symmetry, one can upper bound the measure of the set R_γ by the measure of the cap $\{(u_1, \ldots, u_d) \in S^{d-1} \mid u_1 > \sqrt{z^2 + \gamma^2} - \delta^2/200\}$, which is at most

$$\left(1 - \left(\sqrt{z^2 + \gamma^2} - \frac{\delta^2}{200}\right)^2\right)^{\frac{d-1}{2}} \leq \left(1 - z^2\right)^{\frac{d-1}{2}} \leq \delta^3 \mu(s).$$

Let $\mathcal{R}$ be the union of the sets R_γ for $|\gamma| = \delta/10, \delta/10 + \delta^2/1000, \delta/10 + 2\delta^2/1000, \ldots, \sqrt{1-z^2}$. We conclude that the measure of $\mathcal{R}$ is at most $\frac{1}{2}\mu(S)$.

Finally, each $v = (v_1, \ldots, v_d) \in S \setminus \mathcal{R}$ satisfies $v_1 \in [z - \delta^2/1000, z + \delta^2/1000]$ and $v_2 \in [-\delta/10, \delta/10]$ and thus is in $\hat{N}_\delta$. Hence $S \setminus \mathcal{R} \subseteq \hat{N}_\delta$, implying that the measure of $\hat{N}_\delta$ is at least $\frac{1}{2}\mu(S) \geq (1 - z^2)^{\frac{d-1}{2}}$. ∎

Claim 3.7 (restated). *Let a, k be as in Theorem 3.6. Let $v = (a, \sqrt{1-a^2}, 0, \ldots, 0)$ be a vertex on the boundary of $\mathcal{C}_a$. Let $N(v)$ be the set of neighbors of v. Let $z = \sqrt{a^2 + \frac{(1/(k-1)+a^2)^2}{1-a^2}}$. Finally let $\delta = c\sqrt{\frac{\log(d)}{d}}$ for a sufficiently large constant c. The measure of vertices in $N(v) \cap \mathcal{C}_a$ satisfies*

$$(1-\delta)^{\frac{d-1}{2}}(1-z^2)^{\frac{d-1}{2}} \leq \mu(N(v) \cap \mathcal{C}_a) \leq (1-z^2)^{\frac{d-1}{2}}.$$

Proof. The set $N(v) \cap \mathcal{C}_a$ is equal to

$$\left\{(u_1, \ldots, u_d) \in S^{d-1} \mid u_1 \geq a \text{ and } u_2 \leq -\frac{1/(k-1) + au_1}{\sqrt{1-a^2}}\right\}.$$

Denote $\frac{1/(k-1)+a^2}{\sqrt{1-a^2}}$ by $f(a)$. Let $z = \sqrt{a^2 + f(a)^2}$. By spherical symmetry, it can be seen that the above set is of measure at most $(1-z^2)^{\frac{d-1}{2}}$, and of measure greater or equal to the measure of $\Gamma = \{(u_1, \ldots, u_d) \in S^{d-1} \mid u_1 \geq z \text{ and } 0 \leq u_2 \leq c(u_1 - z)\}$, where $1 \geq c \geq \tan(\frac{\arccos(a)}{2})$ (for any $a \in [0, 1/2]$, c is in the range $(1/2, 1)$). Hence, it suffices to bound the measure of Γ by below.

Let $\delta = c\sqrt{\frac{\log(d)}{d}}$ for a sufficiently large constant c. The set Γ above is of measure larger than the measure of the δ neighborhood of

$$N = \left\{(u_1, \ldots, u_d) \in S^{d-1} \mid u_1 = z + \delta\left(1 + \frac{2}{c}\right) \text{ and } u_2 = \delta\right\}$$

for c as above. (The δ neighborhood of N is defined as in Claim 9.7.) We denote this set as N_δ. By Claim 9.7, the measure of N_δ is at least of value $(1 - z^2 - \theta(\delta))^{\frac{d-1}{2}}$. (Notice that $z > 1/k$, which in turn is independent of d; thus Claim 9.7 can be applied in our case.) Hence, the measure of $N(v) \cap \mathcal{C}_a$ is at least $(1 - \theta(\delta))^{\frac{d-1}{2}}(1 - z^2)^{\frac{d-1}{2}}$, which concludes our proof. ∎

THEOREM 3.8 (restated). *Let $a = (\frac{\log(d)}{d})^{\frac{1}{4}}$. Let k satisfy $\frac{1}{k-1} = a^2$. Let $r \in S^{d-1}$, and let $\mathcal{C}_a$ be an a-cap centered at r. Let $\varepsilon(a)$ be the value of $E(\mathcal{C}_a, \mathcal{C}_a)$. The value of $\varepsilon(a)$ is in the range*

$$\left[\frac{1}{poly(d)}\left(1-\frac{2(k-1)}{k-2}a^2\right)^{\frac{d-1}{2}},\ \left(1-\frac{2(k-1)}{k-2}a^2\right)^{\frac{d-1}{2}}\right].$$

Proof. We start by stating the following claim.

CLAIM 9.8. *Let $\mathcal{C}_a$ be an a-cap centered at $r = (1, 0, \ldots, 0)$. Let v be the vertex $(a, \sqrt{1-a^2}, 0, \ldots, 0)$ on the boundary of $\mathcal{C}_a$. Let $N(v)$ be the set of neighbors of v. Let $z = \sqrt{a^2 + \frac{(1/(k-1)+a^2)^2}{1-a^2}}$. If $z^4 = O(\log(d)/d)$, then the measure of vertices in $N(v)$ which are in the cap $\mathcal{C}_a$ satisfies*

$$\frac{1}{poly(d)}\left(1-z^2\right)^{\frac{d-1}{2}} \le \mu(N(v)\cap\mathcal{C}_a) \le \left(1-z^2\right)^{\frac{d-1}{2}}.$$

Proof. The set $N(v)\cap\mathcal{C}_a$ is equal to

$$\left\{(u_1,\ldots,u_d)\in S^{d-1} \mid u_1 \ge a \text{ and } u_2 \le -\frac{1/(k-1)+au_1}{\sqrt{1-a^2}}\right\}.$$

Denote $\frac{1/(k-1)+a^2}{\sqrt{1-a^2}}$ by $f(a)$. Let $z = \sqrt{a^2+f(a)^2}$. By spherical symmetry, it can be seen that the above set is of measure at most $(1-z^2)^{\frac{d-1}{2}}$, and of measure greater than or equal to the measure of $\Gamma = \{(u_1,\ldots,u_d)\in S^{d-1} \mid u_1 \ge z \text{ and } 0 \le u_2 \le c(u_1 - z)\}$, where $1 \ge c \ge \tan(\frac{\arccos(a)}{2})$. Hence, it suffices to bound the measure of Γ by below.

Let $r_1,\ldots,r_d$ be independent standard normal variables, let $s = \sqrt{\sum_{i=1}^d r_i^2}$, and let $s_3 = \sqrt{\sum_{i=3}^d r_i^2}$. Let $\phi(x)$ be the standard normal density function. The measure of Γ is given by the probability

$$\begin{aligned}
\mu(\Gamma) &= \Pr\left[\frac{r_1}{s} \ge z \text{ and } 0 \le \frac{r_2}{s} \le c\left(\frac{r_1}{s} - z\right)\right] \\
&\ge \Pr\left[r_1 \ge \sqrt{\frac{z^2(r_2^2+s_3^2)}{1-z^2}} \text{ and } 0 \le r_2 \le A\right] \\
&\ge \Pr[s_3^2 \le d]\Pr\left[r_1 \ge \sqrt{\frac{z^2(r_2^2+d)}{1-z^2}} \text{ and } 0 \le r_2 \le A_d\right] \\
&\ge \frac{1}{4}\Pr\left[r_1 \ge \sqrt{\frac{z^2 d}{1-z^2}} \text{ and } 0 \le r_2 \le \min(A_d, B)\right] \\
&\ge \frac{1}{4}\Pr\left[\sqrt{\frac{z^2 d}{1-z^2}} \le r_1 \le \sqrt{\frac{z^2(d+1)}{1-z^2}} \text{ and } 0 \le r_2 \le \min(A_d, B)\right],
\end{aligned}$$

where $A = c\frac{r_1 - z\sqrt{r_1^2(1+c^2-c^2z^2)+s_3^2(1-c^2z^2)}}{1-c^2z^2}$, $A_d = c\frac{r_1 - z\sqrt{r_1^2(1+c^2-c^2z^2)+d(1-c^2z^2)}}{1-c^2z^2}$, and B is of value $\sqrt{\frac{r_1^2(1-z^2)}{z^2} - d}$. Notice that we have used the fact that $\Pr[s_3^2 \le d] \ge 1/4$.

We proceed by evaluating $\min(A_d, B)$. Both A_d and B are functions of r_1. Furthermore, r_1^2 is in the range $[\frac{z^2 d}{1-z^2}, \frac{z^2(d+1)}{1-z^2}]$. Letting $x \in [0,1]$, we can represent A_d and B as functions of x by setting r_1 to be $\sqrt{\frac{z^2(d+x)}{1-z^2}}$. That is, $A_d =$

$z\frac{\sqrt{d+x}-\sqrt{d+xz^2(1+c^2-c^2z^2)}}{\sqrt{1-z^2}(1-c^2z^2)}$ and $B=\sqrt{x}$. It is not hard to verify that for our value of z it is the case that $\min(A_d,B)=A_d$. Thus

$$\begin{aligned}
\mu(\Gamma) &\geq \frac{1}{4}\Pr\left[\sqrt{\frac{z^2d}{1-z^2}}\leq r_1\leq\sqrt{\frac{z^2(d+1)}{1-z^2}}\text{ and }0\leq r_2\leq A_d\right]\\
&= w\int_{r_1\in R_1}\int_{r_2=0}^{A_d} e^{-\frac{r_1^2+r_2^2}{2}} \geq w\int_{r_1\in R_1}\frac{e^{-\frac{r_1^2}{2}}}{A_d}\int_{r_2=0}^{A_d} r_2e^{-\frac{r_2^2}{2}}\\
&= w\int_{r_1\in R_1}\frac{e^{-\frac{r_1^2}{2}}}{A_d}(1-e^{-\frac{A_d^2}{2}}) \geq w\int_{r_1\in R_1} A_de^{-\frac{r_1^2}{2}}\\
&\geq w\int_{x=0}^{1} A_de^{-\frac{z^2(d+x)}{2(1-z^2)}}\frac{z}{2\sqrt{1-z^2}\sqrt{d+x}}dx\\
&\geq w\frac{z^2}{d(1-z^2)(1-c^2z^2)}e^{-\frac{dz^2}{2(1-z^2)}}\int_{x=0}^{1} xe^{-\frac{z^2x}{2(1-z^2)}}\\
&\geq w\frac{z^2}{d(1-z^2)(1-c^2z^2)}e^{-\frac{dz^2}{2(1-z^2)}}\\
&\geq w\frac{z^2}{d(1-z^2)(1-c^2z^2)}\left(1-\frac{z^2}{1-z^2}\right)^{\frac{d-1}{2}}\\
&\geq w\frac{z^2}{d(1-z^2)(1-c^2z^2)}\left(1-z^2\right)^{\frac{d-1}{2}}\left(1-2z^4\right)^{\frac{d-1}{2}},
\end{aligned}$$

where R_1 is the range $[\sqrt{\frac{z^2d}{1-z^2}},\sqrt{\frac{z^2(d+1)}{1-z^2}}]$, and w is some constant independent of d (the value of w may change from line to line). Above we use the fact that $e^x>1+x$ and the fact that A_d is bounded by above by a constant independent of d. In the final inequalities we use a change of variables $r_1=\sqrt{\frac{z^2(d+x)}{1-z^2}}$ and the fact that $1+\alpha/3\leq\sqrt{1+\alpha}\leq 1+\alpha/2$ for $\alpha<3$. As $\mu(\Gamma)\geq\frac{1}{poly(d)}(1-z^2)^{\frac{d-1}{2}}$ for $z^4=O(\log(d)/d)$, we conclude our assertion. □

For the proof of Theorem 3.8, let $z=\sqrt{a^2+\frac{(1/(k-1)+a^2)^2}{1-a^2}}$ (as in Claim 9.8); thus $z^4=O(\log(d)/d)$. For the upper bound, use a bound on the measure of $\mathcal{C}_a$ and the upper bound in Claim 9.8. As for the lower bound, let $\delta=2(\frac{\log(d)}{d})^{\frac{3}{4}}$. Such a choice of δ will satisfy $a\delta\geq 2\frac{\log(d)}{d}$, and $z\delta=O(\log(d)/d)$.

Let $w=(w_1,w_2,\ldots,w_d)\in\mathcal{C}_a$ with first coordinate w_1 of value $a+\delta$. Consider a vertex $v=(v_1,v_2,\ldots,v_d)\in\mathcal{C}_a$ with first coordinate v_1 of value less than $a+\delta$. By Claim 9.8, it is not hard to verify that the measure of $N(v)\cap\mathcal{C}_a$ is greater than the measure of $N(w)\cap\mathcal{C}_a$, which is greater than $\frac{1}{poly(d)}\left(1-cz\delta\right)^{\frac{d-1}{2}}\left(1-z^2\right)^{\frac{d-1}{2}}\geq\frac{1}{poly(d)}(1-z^2)^{\frac{d-1}{2}}$ for some constant c. (We use Claim 9.2 and the fact that $z\delta=O(\log(d)/d)$.) As $a\delta\geq 2\log(d)/d$, we conclude, using Corollary 9.3, that the measure of edges in $E(\mathcal{C}_a,\mathcal{C}_a)$ is at least

$$\begin{aligned}
(\rho(a)-\rho(a+\delta))\frac{1}{poly(d)}\left(1-z^2\right)^{\frac{d-1}{2}} &\geq \frac{\rho(a)}{poly(d)}\left(1-z^2\right)^{\frac{d-1}{2}}\\
&\geq \frac{1}{poly(d)}\left(1-a^2\right)^{\frac{d-1}{2}}\left(1-z^2\right)^{\frac{d-1}{2}}.
\end{aligned}$$

Simplifying the above expression with the help of Claim 9.2, we then conclude our assertion. □

Acknowledgment. We would like to thank Luca Trevisan for his suggestion to analyze *edge* sampling.

DISJOINT NP-PAIRS*

CHRISTIAN GLASSER†, ALAN L. SELMAN‡, SAMIK SENGUPTA‡, AND LIYU ZHANG‡

Abstract. We study the question of whether the class DisjNP of disjoint pairs (A, B) of NP-sets contains a complete pair. The question relates to the question of whether optimal proof systems exist, and we relate it to the previously studied question of whether there exists a disjoint pair of NP-sets that is NP-hard. We show under reasonable hypotheses that nonsymmetric disjoint NP-pairs exist, which provides additional evidence for the existence of P-inseparable disjoint NP-pairs.

We construct an oracle relative to which the class of disjoint NP-pairs does not have a complete pair; an oracle relative to which optimal proof systems exist, and hence complete pairs exist, but no pair is NP-hard; and an oracle relative to which complete pairs exist, but optimal proof systems do not exist.

Key words. disjoint NP-pairs, promise problems, propositional proof systems, oracles, symmetry

1. Introduction.

We study the class DisjNP of disjoint pairs (A, B), where A and B are nonempty, disjoint sets belonging to NP. Such disjoint NP-pairs are interesting for at least two reasons. First, Grollmann and Selman [GS88] showed that the question of whether DisjNP contains P-inseparable disjoint NP-pairs is related to the existence of public-key cryptosystems. Second, Razborov [Raz94] and Pudlák [Pud03] demonstrated that these pairs are closely related to the theory of proof systems for propositional calculus. Specifically, Razborov showed that existence of an optimal propositional proof system implies existence of a complete pair for DisjNP. Primarily in this paper we are interested in the question raised by Razborov [Raz94] of whether DisjNP contains a complete pair. We show connections between this question and earlier work on disjoint NP-pairs, and we exhibit an oracle relative to which DisjNP does not contain any complete pair.

From a technical point of view, disjoint pairs are simply an equivalent formulation of promise problems. There are natural notions of reducibilities between promise problems [ESY84, Sel88] that disjoint pairs inherit easily [GS88]. Hence, completeness and hardness notions follow naturally. We begin in the next section with these definitions, some easy observations, and a review of the known results.

In section 3 we observe that if DisjNP does not contain a Turing-complete disjoint NP-pair, then DisjNP does not contain a disjoint NP-pair all of whose separators are Turing-hard for NP. The latter is a conjecture formulated by Even, Selman, and Yacobi [ESY84] and has several known consequences: Public-key cryptosystems that are NP-hard to crack do not exist; NP $\neq$ UP, NP $\neq$ coNP, and NPMV $\not\subseteq_c$

NPSV. Our main result in this section is an oracle X relative to which DisjNP does not contain a Turing-complete disjoint NP-pair and relative to which P $\neq$ UP. Relative to X, by Razborov's result [Raz94], optimal propositional proof systems do not exist. P-inseparable disjoint NP-pairs exist relative to X, because P $\neq$ UP [GS88]. Most researchers believe that P-inseparable disjoint NP-pairs exist, and we believe that no disjoint NP-pair has only NP-hard separators. Both of these properties hold relative to X. This is the first oracle relative to which both of these conditions hold simultaneously. Homer and Selman [HS92] obtained an oracle relative to which all disjoint NP-pairs are P-separable, so the conjecture of Even, Selman, and Yacobi holds relative to their oracle only for this trivial reason. Now let us say a few things about the construction of oracle X. Previous researchers have obtained oracles relative to which certain (promise) complexity classes do not have complete sets. However, the technique of Gurevich [Gur83], who proved that NP$\cap$coNP has Turing-complete sets if and only if it has many-one-complete sets, does not apply. Neither does the technique of Hemaspaandra, Jain, and Vereshchagin [HJV93], who demonstrated, among other results, an oracle relative to which FewP does not have a Turing-complete set.

In section 4 we show that the question of whether DisjNP contains a Turing-complete disjoint NP-pair has an equivalent natural formulation as a hypothesis about classes of single-valued partial functions. Section 5 studies *symmetric* disjoint NP-pairs. Pudlák [Pud03] defined a disjoint pair (A, B) to be symmetric if (A, B) is many-one reducible to (B, A). P-separable easily implies symmetric. We give complexity-theoretic evidence of the existence of nonsymmetric disjoint NP-pairs. As a consequence, we obtain new ways to demonstrate existence of P-inseparable sets. Also, we use symmetry to show under reasonable hypotheses that many-one and Turing reducibilities differ for disjoint NP-pairs. (All reductions in this paper are polynomial-time-bounded.) Concrete candidates for P-inseparable disjoint NP-pairs come from problems in UP or in NP $\cap$ coNP. Nevertheless, Grollmann and Selman [GS88] proved that the existence of P-inseparable disjoint NP-pairs implies the existence of P-inseparable disjoint NP-pairs, where both sets are NP-complete. Here we prove two analogous results. Existence of nonsymmetric disjoint NP-pairs implies existence of nonsymmetric disjoint NP-pairs, where both sets are NP-complete. If there exists a many-one-complete disjoint NP-pair, then there exists such a pair where both sets are NP-complete. Natural candidates for nonsymmetric or $\leq_m^{pp}$-complete disjoint NP-pairs arise either from cryptography or from proof systems [Pud03]. Our theorems show that the existence of such pairs will imply that nonsymmetric (or $\leq_m^{pp}$-complete) disjoint NP-pairs exist where both sets of the pair are $\leq_m^p$-complete for NP.

Section 6 constructs two oracles O_1 and O_2 that possess several interesting properties. First, let us mention some properties that hold relative to both of these oracles. Relative to both oracles, many-one-complete disjoint NP-pairs exist. Therefore, while we expect that complete disjoint NP-pairs do not exist, this is not provable by relativizable techniques. P-inseparable disjoint NP-pairs exist relative to these oracles, which we obtain by proving that nonsymmetric disjoint NP-pairs exist. The conjecture of Even, Selman, and Yacobi holds. Therefore, while nonexistence of Turing-complete disjoint NP-pairs is a sufficient condition for this conjecture, the converse does not hold, even in worlds in which P-inseparable pairs exist. Also, relative to these oracles, there exist P-inseparable pairs that are symmetric. Whereas nonsymmetric implies P-inseparability, again, we see that the converse does not hold.

In section 6 we discuss the properties of these oracles in detail. Relative to O_1, optimal proof systems exist, while relative to O_2, optimal proof systems do not exist. In particular, relative to O_2, the converse of Razborov's result does not hold. (That

is, relative to O_2, many-one complete pairs exist.)

The construction of O_2 involves some aspects that are unusual in complexity theory. We introduce undecidable requirements, and as a consequence, the oracle is undecidable. In particular, we need to define sets A and B, such that relative to O_2, the pair (A, B) is many-one complete. Therefore, we need to show that for every two nondeterministic, polynomial-time-bounded oracle Turing machines NM_i and NM_j, either $L(NM_i^{O_2})$ and $L(NM_j^{O_2})$ are not disjoint or there is a reduction from the disjoint pair $(L(NM_i^{O_2}), L(NM_j^{O_2}))$ to (A, B). We accomplish this as follows: Given NM_i, NM_j, and a finite initial segment X of O_2, we prove that either there is a finite extension Y of X such that for all oracles Z that extend Y,

$$L(NM_i^Z) \cap L(NM_j^Z) \neq \emptyset$$

or there is a finite extension Y of X such that for all oracles Z that extend Y,

$$L(NM_i^Z) \cap L(NM_j^Z) = \emptyset.$$

Then we select the extension Y that exists. In this manner we *force* one of these two conditions to hold.

In the latter case, to obtain a reduction from the pair $(L(NM_i^{O_2}), L(NM_j^{O_2}))$ to (A, B) requires encoding information into the oracle O_2. The other conditions that we want O_2 to satisfy require diagonalizations. In order to prove that there is room to diagonalize, we need to carefully control the number of words that must be reserved for encoding. This is a typical concern in oracle constructions, but even more so here. We manage this part of the construction by inventing a unique data structure that stores words reserved for the encoding, and then prove that we do not store too many such words.

2. Preliminaries. We fix the alphabet $\Sigma = \{0, 1\}$, and we denote the length of a word w by $|w|$. The set of all (resp., nonempty) words is denoted by Σ^* (resp., Σ^+). Let $\Sigma^{<n} \stackrel{df}{=} \{w \in \Sigma^* \mid |w| < n\}$, and define $\Sigma^{\leq n}$, $\Sigma^{\geq n}$, and $\Sigma^{>n}$ analogously. For a set of words X let $X^{<n} \stackrel{df}{=} X \cap \Sigma^{<n}$, and define $X^{\leq n}$, $X^{=n}$, $X^{\geq n}$, and $X^{>n}$ analogously. For sets of words we take the complement with respect to Σ^*. For $A, B \subseteq \Sigma^*$ let $A \oplus B \stackrel{df}{=} \{0x \mid x \in A\} \cup \{1y \mid y \in B\}$.

The set of (nonzero) natural numbers is denoted by $\mathbb{N}$ (resp., $\mathbb{N}^+$). We use polynomial-time computable and polynomial-time invertible pairing functions $\langle \cdot, \cdot \rangle : \mathbb{N}^+ \times \mathbb{N}^+ \to \mathbb{N}^+$ and $\langle \cdot, \cdot, \cdot \rangle : \mathbb{N}^+ \times \mathbb{N}^+ \times \mathbb{N}^+ \to \mathbb{N}^+$. For a function f, $\mathrm{dom}(f)$ denotes the domain of f.

Cook and Reckhow [CR79] defined a *propositional proof system* (proof system, for short) to be a function $f : \Sigma^* \to \mathrm{TAUT}$ such that f is onto and $f \in \mathrm{PF}$. (TAUT denotes the set of tautologies.) Note that f is not necessarily honest; it is possible that a formula $\phi \in \mathrm{TAUT}$ has only exponentially long proofs w, i.e., $f(w) = \phi$ and $|w| = 2^{\Omega(|\phi|)}$.

Let f and f' be two proof systems. We say that f *simulates* f' if there is a polynomial p and a function $h : \Sigma^* \to \Sigma^*$ such that for every $w \in \Sigma^*$, $f(h(w)) = f'(w)$ and $|h(w)| \leq p(|w|)$. If, additionally, $h \in \mathrm{PF}$, then we say that f *p-simulates* f'.

A proof system is *optimal* (resp., *p-optimal*) if it simulates (resp., p-simulates) every other proof system. The notion of simulation between proof systems is analogous to the notion of reducibility between problems. Using that analogy, optimal proof systems correspond to complete problems.

2.1. Disjoint pairs, separators, and a conjecture. We begin with the following definition.

DEFINITION 2.1. *A* disjoint NP-pair *(*NP*-pair, for short) is a pair of nonempty sets A and B such that $A, B \in$ NP and $A \cap B = \emptyset$. Let* DisjNP *denote the class of all disjoint* NP*-pairs.*

Given a disjoint NP-pair (A, B), a *separator* is a set S such that $A \subseteq S$ and $B \subseteq \overline{S}$; we say that S *separates* (A, B). Let $Sep(A, B)$ denote the class of all separators of (A, B). For disjoint NP-pairs (A, B), the fundamental question is whether $Sep(A, B)$ contains a set belonging to P. In that case the pair is P*-separable*; otherwise, the pair is P*-inseparable*. The following proposition summarizes the known results about P-separability.

PROPOSITION 2.2.

1. P $\neq$ NP $\cap$ coNP *implies that* NP *contains* P*-inseparable sets.*
2. P $\neq$ UP *implies that* NP *contains* P*-inseparable sets* [GS88].
3. *If* NP *contains* P*-inseparable sets, then* NP *contains* NP*-complete* P*-inseparable sets* [GS88].

While it is probably the case that NP contains P-inseparable sets, there is an oracle relative to which P $\neq$ NP and P-inseparable sets in NP do not exist [HS92]. So P $\neq$ NP probably is not a sufficiently strong hypothesis to show existence of P-inseparable sets in NP.

DEFINITION 2.3. *Let (A, B) be a disjoint* NP*-pair.*

1. $X \leq_m^{pp} (A, B)$ *if, for every separator S of (A, B), $X \leq_m^p S$.*
2. $X \leq_T^{pp} (A, B)$ *if, for every separator S of (A, B), $X \leq_T^p S$.*
3. (A, B) *is* NP-hard *if* SAT $\leq_T^{pp} (A, B)$.
4. (A, B) *is* uniformly NP-hard *if there is a deterministic polynomial-time oracle Turing machine M such that for every $S \in Sep(A, B)$,* SAT $\leq_T^p S$ *via M.*

Grollmann and Selman [GS88] showed that NP-hard implies uniformly NP-hard; i.e., both statements of the definition are equivalent. Even, Selman, and Yacobi [ESY84] conjectured that there does not exist a disjoint NP-pair (A, B) such that all separators of (A, B) are $\leq_T^p$ hard for NP.

CONJECTURE 2.4 (see [ESY84]). *There do not exist disjoint* NP*-pairs that are* NP*-hard.*

If Conjecture 2.4 holds, then no public-key cryptosystem is NP-hard to crack [ESY84]. This conjecture is a strong hypothesis with the following known consequences. In section 3 we show a sufficient condition for Conjecture 2.4 to hold.

PROPOSITION 2.5 (see [ESY84, GS88, Sel94]). *If Conjecture* 2.4 *holds, then* NP $\neq$ coNP*,* NP $\neq$ UP*, and* NPMV $\not\subseteq_c$ NPSV*.*

2.2. Reductions for disjoint pairs. We review the natural notions of reducibilities between disjoint pairs [GS88].

DEFINITION 2.6 (nonuniform reductions for pairs). *Let (A, B) and (C, D) be disjoint pairs.*

1. (A, B) *is* many-one reducible in polynomial-time *to (C, D), $(A, B) \leq_m^{pp} (C, D)$, if for every separator $T \in Sep(C, D)$ there exists a separator $S \in Sep(A, B)$ such that $S \leq_m^p T$.*
2. (A, B) *is* Turing reducible in polynomial-time *to (C, D), $(A, B) \leq_T^{pp} (C, D)$, if for every separator $T \in Sep(C, D)$ there exists a separator $S \in Sep(A, B)$ such that $S \leq_T^p T$.*

DEFINITION 2.7 (uniform reductions for pairs). *Let (A, B) and (C, D) be disjoint pairs.*

1. (A, B) *is* uniformly many-one reducible in polynomial-time *to* (C, D), $(A, B) \leq^{pp}_{um} (C, D)$, *if there exists a polynomial-time computable function* f *such that for every separator* $T \in Sep(C, D)$, *there exists a separator* $S \in Sep(A, B)$ *such that* $S \leq^{p}_{m} T$ *via* f.
2. (A, B) *is* uniformly Turing reducible in polynomial-time *to* (C, D), $(A, B) \leq^{pp}_{uT} (C, D)$, *if there exists a polynomial-time oracle Turing machine* M *such that for every separator* $T \in Sep(C, D)$, *there exists a separator* $S \in Sep(A, B)$ *such that* $S \leq^{p}_{T} T$ *via* M.

If f and M are as above, then we also say that $(A, B) \leq^{pp}_{um} (C, D)$ via f and $(A, B) \leq^{pp}_{uT} (C, D)$ via M. Observe that if $(A, B) \leq^{pp}_{m} (C, D)$ and (C, D) is P-separable, then so is (A, B) (and the same holds for $\leq^{pp}_{T}$, $\leq^{pp}_{um}$, and $\leq^{pp}_{uT}$). We retain the promise problem notation in order to distinguish from reducibilities between sets. Grollmann and Selman proved that Turing reductions and uniform Turing reductions are equivalent.

PROPOSITION 2.8 (see [GS88]). $(A, B) \leq^{pp}_{T} (C, D) \Leftrightarrow (A, B) \leq^{pp}_{uT} (C, D)$ *for all disjoint pairs* (A, B) *and* (C, D).

In order to obtain the corresponding theorem for $\leq^{pp}_{um}$, we can adapt the proof of Proposition 2.8, but a separate argument is required.

LEMMA 2.9. *Let* S *and* T *be nonempty, disjoint sets. Let* X *and* Y *be nonempty, finite, disjoint sets such that* $X \cap T = \emptyset$ *and* $Y \cap S = \emptyset$. *Then the disjoint pairs* (S, T) *and* $(S \cup X, T \cup Y)$ *are equivalent by polynomial-time uniform reductions.*

Proof. First we show that $(S \cup X, T \cup Y) \leq^{pp}_{um} (S, T)$. Choose $a \in S$ and $b \in T$. Define the polynomial-time computable function f by

$$f(x) \stackrel{df}{=} \begin{cases} a & \text{if } x \in X, \\ b & \text{if } x \in Y, \\ x & \text{otherwise.} \end{cases}$$

Let $A \in Sep(S, T)$. We need to see that $f^{-1}(A) \in Sep(S \cup X, T \cup Y)$. So we show that

1. $S \cup X \subseteq f^{-1}(A)$, and
2. $T \cup Y \subseteq \overline{f^{-1}(A)}$.

For item 1, if $x \in X$, then $f(x) = a \in S \subseteq A$. So $f(X) \subseteq A$. Hence, $X \subseteq f^{-1}(A)$. If $x \in S - X$, then $f(x) = x \in S \subseteq A$. So, $S - X \subseteq f^{-1}(A)$. For item 2, if $x \in Y$, then $f(x) = b \in T \subseteq \overline{A}$. So $f(Y) \cap A = \emptyset$. That is, $Y \subseteq \overline{f^{-1}(A)}$. If $x \in T - Y$, then $f(x) = x \in T$. So $f(T - Y) \cap A = \emptyset$. That is, $T - Y \subseteq \overline{f^{-1}(A)}$.

Every separator of $(S \cup X, T \cup Y)$ is a separator of (S, T). Therefore, the identity function provides a uniform reduction from (S, T) to $(S \cup X, T \cup Y)$. □

THEOREM 2.10. $\leq^{pp}_{m} = \leq^{pp}_{um}$.

Proof. Assume that (Q, R) is not uniformly many-one reducible to (S, T). That is, for every polynomial-time computable function f, there exists a set $A \in Sep(S, T)$ such that $f^{-1}(A) \notin Sep(Q, R)$. Then for every polynomial-time computable function f, there exists $A \in Sep(S, T)$ and a string y that witnesses the fact that $f^{-1}(A) \notin Sep(Q, R)$. Namely, either

$$y \in Q \wedge y \notin f^{-1}(A) \text{ (i.e., } f(y) \notin A) \qquad \text{or} \qquad y \in R \wedge y \in f^{-1}(A) \text{ (i.e., } f(y) \in A).$$

We will show from this assumption that (Q, R) is not many-one reducible to (S, T). We will construct a decidable separator A of (S, T) such that for every polynomial-time computable function f, $f^{-1}(A)$ is not a separator of (Q, R). Let $\{f_i\}_{i \geq 1}$ be an

effective enumeration of the polynomial-time computable functions with associated polynomial-time bounds $\{p_i\}_{i\geq 1}$.

The separator A of (S,T) will be constructed inductively to be of the form $S \cup \bigcup\{Y_i \mid i \geq 1\}$, where $\bigcup\{Y_i \mid i \geq 1\}$ is a subset of $\overline{T}$ and $Y_0 \subseteq Y_1 \subseteq \cdots$. At stage i of the construction, we will choose a finite subset Y_i of $\overline{T}$ such that $f^{-1}(S \cup Y_i)$ is not a separator of (Q,R).

Stage 0. Define $Y_0 = \{0\}$ and $n_0 = 1$.

Stage i ($i \geq 1$). By induction hypothesis, Y_{i-1} is defined, $n_{i-1} \geq 0$ is defined, and $Y_{i-1} \subseteq \overline{T} \cap \Sigma^{\leq n_{i-1}}$.

Now we state a sequence of claims.

CLAIM 2.11. *There exists a set* X, $X \subseteq \overline{T \cup \Sigma^{\leq n_{i-1}}}$, *and a witness* y_i *demonstrating that* $f_i^{-1}(S \cup Y_{i-1} \cup X)$ *is not a separator of* (Q,R). *That is,*

$$y_i \in Q \wedge y_i \notin f_i^{-1}(S \cup Y_{i-1} \cup X) \text{ (i.e., } f_i(y_i) \notin S \cup Y_{i-1} \cup X)$$

or

$$y_i \in R \wedge y_i \in f_i^{-1}(S \cup Y_{i-1} \cup X) \text{ (i.e., } f_i(y_i) \in S \cup Y_{i-1} \cup X).$$

If the claim is false, then for every $X \subseteq \overline{T \cup \Sigma^{\leq n_{i-1}}}$, $Q \subseteq f_i^{-1}(S \cup Y_{i-1} \cup X)$ and $R \subseteq \overline{f_i^{-1}(S \cup Y_{i-1} \cup X)}$. The set of all languages $S \cup Y_{i-1} \cup X$, where $X \subseteq \overline{T \cup \Sigma^{\leq n_{i-1}}}$, is exactly the set of separators of the disjoint pair

$$(S \cup Y_{i-1}, T \cup (\Sigma^{\leq n_{i-1}} - (S \cup Y_{i-1}))).$$

Thus, if the claim is false, then (Q,R) is uniformly many-one reducible to $(S \cup Y_{i-1}, T \cup (\Sigma^{\leq n_{i-1}} - Y_{i-1}))$. However, by Lemma 2.9, this contradicts the assumption that (Q,R) is not uniformly reducible to (S,T). Hence the claim is true.

CLAIM 2.12. *There exists a finite set* X, $X \subseteq \overline{T \cup \Sigma^{\leq n_{i-1}}}$, *and a witness* y_i *that satisfy the condition of Claim* 2.11.

For X and witness y_i, whose existence Claim 2.11 guarantees, $|f_i(y_i)| \leq p_i(|y_i|)$. So $X' = X \cap \Sigma^{\leq p_i(|y_i|)}$ and y_i satisfy the condition as well.

CLAIM 2.13. *There is an effective procedure that on input* (i, Y_{i-1}, n_{i-1}) *finds a finite set* $X \subseteq \overline{T \cup \Sigma^{\leq n_{i-1}}}$ *and witness* y_i *to satisfy the condition of Claim* 2.11.

This is trivial. Effectively enumerate pairs of finite sets and strings until a pair with the desired property is found.

At Stage i, apply Claim 2.13; define $Y_i = Y_{i-1} \cup X$ and define $n_i = 1 + \max(2^{n_{i-1}}, p_i(|y_i|))$.

Define $A = S \cup \bigcup\{Y_i \mid i \geq 1\}$. Since $\bigcup\{Y_i \mid i \geq 1\} \subseteq \overline{T}$, A is a separator of (S,T). It is easy to see that A is decidable. Finally, for every f_i, $i \geq 1$, $f_i^{-1}(A)$ is not a separator of (Q,R): Clearly this holds for $f_i^{-1}(S \cup Y_i)$, and the construction preserves this property. □

We obtain the following useful characterization of many-one reductions. Observe that this is the way Razborov [Raz94] defined reductions between disjoint pairs.

THEOREM 2.14. $(Q,R) \leq_m^{pp} (S,T)$ *if and only if there exists a polynomial-time computable function* f *such that* $f(Q) \subseteq S$ *and* $f(R) \subseteq T$.

Proof. By Theorem 2.10 there is a polynomial-time computable function f such for every $A \in Sep(S,T)$, $f^{-1}(A) \in Sep(Q,R)$. That is, if $A \in Sep(S,T)$, then $Q \subseteq f^{-1}(A)$ and $R \subseteq \overline{f^{-1}(A)}$, which implies that $f(Q) \subseteq A$ and $f(R) \cap A = \emptyset$. Well, $S \in Sep(S,T)$. So $f(Q) \subseteq S$. Also, $\overline{T} \in Sep(S,T)$. So $f(R) \cap \overline{T} = \emptyset$. That is, $f(R) \subseteq T$. The converse is immediate. □

3. Complete disjoint NP-pairs. Keeping with common terminology, a disjoint pair (A, B) is $\leq_m^{pp}$-complete ($\leq_T^{pp}$-complete) for the class DisjNP if $(A, B) \in$ DisjNP and for every disjoint pair $(C, D) \in$ DisjNP, $(C, D) \leq_m^{pp} (A, B)$ (resp., $(C, D) \leq_T^{pp} (A, B)$).

Consider the following assertions:

1. DisjNP does not have a $\leq_T^{pp}$-complete disjoint pair.
2. DisjNP does not have a $\leq_m^{pp}$-complete disjoint pair.
3. DisjNP does not contain a disjoint pair all of whose separators are $\leq_T^p$-hard for NP (i.e., Conjecture 2.4 holds).
4. DisjNP does not contain a disjoint pair all of whose separators are $\leq_m^p$-hard for NP.

Assertions 1 and 2 are possible answers to the question raised by Razborov [Raz94] of whether DisjNP contains complete disjoint pairs. Assertion 3 is Conjecture 2.4. Assertion 4 is the analogue of this conjecture using many-one reducibility.

We can dispense with assertion 4 immediately, for it is equivalent to NP $\neq$ coNP.

PROPOSITION 3.1. NP $\neq$ coNP *if and only if* DisjNP *does not contain a disjoint pair all of whose separators are* $\leq_m^p$*-hard for* NP.

Proof. If NP = coNP, then $(\mathrm{SAT}, \overline{\mathrm{SAT}})$ is a disjoint pair in DisjNP all of whose separators are $\leq_m^p$-hard for NP.

To show the other direction, consider the disjoint pair $(A, B) \in$ DisjNP and assume that all of its separators are $\leq_m^p$-hard for NP. Since $\overline{B}$ is a separator of (A, B), SAT $\leq_m^p \overline{B}$. Therefore, $\overline{\mathrm{SAT}} \leq_m^p B$, implying that $\overline{\mathrm{SAT}} \in$ NP. Thus, NP = coNP. □

PROPOSITION 3.2. *Assertion* 1 *implies assertions* 2 *and* 3. *Assertion* 2 *implies assertion* 4. *Assertion* 3 *implies assertion* 4.

This proposition states, in part, that assertion 1 is so strong as to imply Conjecture 2.4.

Proof. It is trivial that assertion 1 implies assertion 2, and that assertion 3 implies assertion 4.

We prove that assertion 1 implies assertion 3. Assume assertion 3 is false and let $(A, B) \in$ DisjNP such that all separators are NP-hard. We claim that (A, B) is $\leq_T^{pp}$-complete for DisjNP. Let (C, D) belong to DisjNP. Let S be an arbitrary separator of (A, B). Note that S is NP-hard and $C \in$ NP. So $C \leq_T^p S$. Since C is a separator of (C, D), this demonstrates that $(C, D) \leq_T^{pp} (A, B)$.

Similarly, we prove that assertion 2 implies assertion 4. In this case, every separator S of (A, B) is $\leq_m^p$-hard for NP. So $C \leq_m^p S$. Therefore, $(C, D) \leq_m^{pp} (A, B)$. □

Homer and Selman [HS92] constructed an oracle relative to which P $\neq$ NP and every disjoint NP-pair is P-separable. Relative to this oracle, assertion 3 holds and assertions 1 and 2 are false. To see this, let (A, B) be an arbitrary disjoint NP-pair. We show that (A, B) is both $\leq_T^{pp}$-complete and $\leq_m^{pp}$-complete. For any other pair $(C, D) \in$ DisjNP, since (C, D) is P-separable, there is a separator S of (C, D) that is in P. Therefore, for any separator L of (A, B), S trivially $\leq_m^p$-reduces and $\leq_T^p$-reduces to L. So $(C, D) \leq_m^{pp} (A, B)$ and $(C, D) \leq_T^{pp} (A, B)$.

There exists an oracle relative to which UP = NP $\neq$ coNP [GW03]. So, relative to this oracle assertion 4 holds, but assertion 3 is false. In section 6 we will construct oracles relative to which assertion 4 holds while assertions 1 and 2 fail.

In Theorem 3.8 we construct an oracle X relative to which assertion 1 is true. In Corollary 3.11 we observe that P $\neq$ UP relative to X. Therefore, by Proposition 3.2, all of the following properties hold relative to X:

1. DisjNP does not have a $\leq_T^{pp}$-complete disjoint pair.
2. Conjecture 2.4 holds; so UP $\neq$ NP, NP $\neq$ coNP, NPMV $\not\subseteq_c$ NPSV, and NP-hard public-key cryptosystems do not exist [ESY84, Sel94].
3. P $\neq$ UP; therefore P-inseparable disjoint NP-pairs exist [GS88].
4. Optimal propositional proof systems do not exist [Raz94].
5. There is a tally set $T \in \text{coNP} - \text{NP}$ and a tally set $T' \in \text{coNE} - \text{E}$ [Pud86, KP89].

The following lemma is essential to the proofs of Theorems 3.8 and 6.1. Intuitively this lemma says that, given two nondeterministic machines and some oracle, either we can force the languages accepted by these machines to be not disjoint, or we can ensure that one of the machines rejects a given string q by reserving only polynomially many strings.

LEMMA 3.3. *Let M and N be nondeterministic polynomial-time oracle Turing machines with polynomial-time bounds p_M and p_N, respectively. Let Y be an oracle and $q \in \Sigma^*$, $|q| = n$. Then, for any set T, at least one of the following holds:*

- *$\exists S \subseteq T$, $\|S\| \leq p_M(n) + p_N(n)$, such that $q \in L(M^{Y \cup S}) \cap L(N^{Y \cup S})$.*
- *$\exists S' \subseteq T$, $\|S'\| \leq p_M(n) \cdot (p_N(n) + 1)$, such that either* (i) *for any $S \subseteq T$, if $S \cap S' = \emptyset$, then $M^{Y \cup S}(q)$ rejects, or* (ii) *for any $S \subseteq T$, if $S \cap S' = \emptyset$, then $N^{Y \cup S}(q)$ rejects.*

Proof. Let us define the following languages:

- $L_M = \{\langle P, Q_y, Q_n\rangle \mid$ for some set $S_M \subseteq T$, P is an accepting path of $M^{Y \cup S_M}(q)$ and Q_y (resp., Q_n) is the set of words in S_M (resp., $T - (Y \cup S_M)$) that are queried on $P\}$.
- $L_N = \{\langle P, Q_y, Q_n\rangle \mid$ for some set $S_N \subseteq T$, P is an accepting path of $N^{Y \cup S_N}(q)$ and Q_y (resp., Q_n) is the set of words in S_N (resp., $T - (Y \cup S_N)$) that are queried on $P\}$.

We say that $\langle P, Q_y, Q_n\rangle \in L_M$ *conflicts* with $\langle P', Q'_y, Q'_n\rangle \in L_N$ if $Q_y \cap Q'_n \neq \emptyset$ or $Q'_y \cap Q_n \neq \emptyset$. In other words, there is a conflict if there exists at least one query that is in T and that is answered differently on P and P'.

Case I. There exist $\langle P, Q_y, Q_n\rangle \in L_M$ and $\langle P', Q'_y, Q'_n\rangle \in L_N$ that do not conflict.

Let $S = Q_y \cup Q'_y$. We claim in this case that $q \in L(M^{Y \cup S}) \cap L(N^{Y \cup S})$. Let S_M and S_N be the subsets of T that witness $\langle P, Q_y, Q_n\rangle \in L_M$ and $\langle P', Q'_y, Q'_n\rangle \in L_N$. So P is an accepting path of $M^{Y \cup S_M}(q)$, and P' is an accepting path of $N^{Y \cup S_N}(q)$. Assume that on P there exists a query r that is answered differently with respect to the oracles $Y \cup S_M$ and $Y \cup S$. Hence $r \notin Y$. Moreover, either $r \in S_M - S$ or $r \in S - S_M$. However, r cannot belong to $S_M - S$, since otherwise $r \in Q_y$, and therefore $r \in S$. So $r \in S - S_M$. Hence $r \notin Q_y$, and therefore $r \in Q'_y$. On the other hand, $r \in S - S_M$ implies $r \in T - (Y \cup S_M)$. Therefore, $r \in Q_n \cap Q'_y$, which contradicts the assumption in Case I. This shows that P is an accepting path of $M^{Y \cup S}(q)$. Analogously we show that P' is an accepting path of $N^{Y \cup S}(q)$. Hence $q \in L(M^{Y \cup S}) \cap L(N^{Y \cup S})$. Note that $\|S\| = \|Q_y \cup Q'_y\| \leq p_M(n) + p_N(n)$.

Case II. Every triple $\langle P, Q_y, Q_n\rangle \in L_M$ conflicts with every triple $\langle P', Q'_y, Q'_n\rangle \in L_N$.

Note that in this case we cannot have both a triple $\langle P, \emptyset, Q_n\rangle$ in L_M and a triple $\langle P', \emptyset, Q'_n\rangle$ in L_N, simply because these two triples do not conflict with each other. We use the following algorithm to create the set S' as claimed in the statement of this lemma.

$\mathtt{S'} = \emptyset$
`while` ($\mathtt{L_M} \neq \emptyset$ `and` $\mathtt{L_N} \neq \emptyset$)

```
(1)        Choose some (P*, Q*_y, Q*_n) ∈ L_M
(2)        S' = S' ∪ Q*_y ∪ Q*_n
(3)        For every t = (P, Q_y, Q_n) ∈ L_M
(4)           if Q_y ∩ (Q*_y ∪ Q*_n) ≠ ∅ then remove t
(5)        For every t' = (P', Q'_y, Q'_n) ∈ L_N
(6)           if Q'_y ∩ (Q*_y ∪ Q*_n) ≠ ∅ then remove t'
      end while
```

We claim that after k iterations of the *while* loop, for every triple $(P', Q'_y, Q'_n) \in L_N$, $\|Q'_n\| \geq k$. If this claim is true, the while loop iterates at most $p_N(n)+1$ times, since for any triple in L_N, $\|Q'_n\|$ is bounded by the running time of N on q, i.e., $p_N(n)$. On the other hand, during each iteration, S' is increased by at most $p_M(n)$ strings, since for any triple in L_M, $\|Q_y \cup Q_n\|$ is bounded by the running time of M on q, i.e., $p_M(n)$. Therefore, $\|S'\| \leq p_M(n) \cdot (p_N(n)+1)$ when this algorithm terminates.

CLAIM 3.4. *After the kth iteration of the* while *loop of the above algorithm, for every $t' = \langle P', Q'_y, Q'_n\rangle$ that remains in L_N, $\|Q'_n\| \geq k$.*

Proof. For every k, t_k denotes the triple $\langle P^k, Q^k_y, Q^k_n\rangle \in L_M$ that is chosen during the kth iteration in step (1). For every $t' = \langle P', Q'_y, Q'_n\rangle$ that is in L_N at the beginning of this iteration, t_k conflicts with t' (assumption of Case II). Therefore, there is a query in $(Q^k_n \cap Q'_y) \cup (Q^k_y \cap Q'_n)$. If this query is in $Q^k_n \cap Q'_y$, then t' will be removed from L_N in step (6). Otherwise, i.e., if $Q^k_y \cap Q'_n \neq \emptyset$, then let q' be the lexicographically smallest query in $Q^k_y \cap Q'_n$. In this case, t' will not be removed from L_N; we say that t' *survives* the kth iteration *due to query* q'. Note that t' can survive only due to a query that is in Q'_n. We will use this fact to prove that $\|Q'_n\| \geq k$ after k iterations.

We show now that any triple that is left in L_N after k iterations survives each iteration due to a different query. This will complete the proof of the claim. Assume that t' survives iteration k by query $q' \in Q^k_y \cap Q'_n$. If t' had survived an earlier iteration $l < k$ by the same query q', then q' is also in $Q^l_y \cap Q'_n$. Therefore, $Q^l_y \cap Q^k_y \neq \emptyset$. So $t_k = \langle P^k, Q^k_y, Q^k_n\rangle$ should have been removed in step (4) during iteration l, and cannot be chosen at the beginning of iteration k, as claimed. Hence, q' cannot be the query by which t' had survived iteration l. This proves Claim 3.4. □

Therefore, now we have a set $S' \subseteq T$ of the required size such that either L_M or L_N is empty. Assume that L_M is empty, and for some set $S_M \subseteq T$ it holds that $S_M \cap S' = \emptyset$ and $M^{(Y \cup S_M)}(q)$ accepts. Let P be an accepting path of $M^{(Y \cup S_M)}(q)$ and let Q_y (resp., Q_n) be the set of words in S_M (resp., $T - (Y \cup S_M)$) that are queried on P. The triple $\langle P, Q_y, Q_n\rangle$ must have been in L_M and has been removed during some iteration. This implies that during that iteration, $Q_y \cap S' \neq \emptyset$ (step (4)). Since $Q_y \subseteq S_M$, this contradicts the assumption that $S_M \cap S' = \emptyset$.

A similar argument holds for L_N. Hence either $L_M = \emptyset$ and $M^{(Y \cup S)}(q)$ rejects for any $S \subseteq T$ such that $S \cap S' = \emptyset$, or $L_N = \emptyset$ and $N^{(Y \cup S)}(q)$ rejects for any $S \subseteq T$ such that $S \cap S' = \emptyset$. This ends the proof of Lemma 3.3. □

We define the following notions for reductions relative to oracles.

DEFINITION 3.5. *For any set X, a pair of disjoint sets (A, B) is* polynomial-time Turing reducible relative to X *($\leq^{pp,X}_T$) to a pair of disjoint sets (C, D) if for any separator S that separates (C, D), there exists a polynomial-time deterministic oracle Turing machine M such that $M^{S \oplus X}$ accepts a language that separates (A, B).*

DEFINITION 3.6. *For any set X, let*

$$\text{DisjNP}^X = \{(A, B) \mid A \in \text{NP}^X,\ B \in \text{NP}^X,\ A \neq \emptyset,\ B \neq \emptyset,\ \textit{and}\ A \cap B = \emptyset\}.$$

(C, D) is $\leq^{pp,X}_T$-complete for DisjNP^X *if $(C, D) \in \text{DisjNP}^X$ and for all $(A, B) \in$*

DisjNP^X, $(A,B) \leq_T^{pp,X} (C,D)$. *Similarly,* (C,D) *is* $\leq_T^{pp}$*-complete for* DisjNP^X *if* $(C,D) \in \mathrm{DisjNP}^X$ *and for all* $(A,B) \in \mathrm{DisjNP}^X, (A,B) \leq_T^{pp} (C,D)$.

However, the following proposition shows that if there exists a disjoint pair that is Turing-complete relative to X, then there is a pair that is Turing-complete such that the reduction between the separators does not access the oracle.

PROPOSITION 3.7. *For any set* X, DisjNP^X *has a* $\leq_T^{pp,X}$*-complete pair if and only if* DisjNP^X *has a* $\leq_T^{pp}$*-complete pair.*

Proof. The *if* direction is trivial. We only show the *only if* direction. Suppose (C,D) is $\leq_T^{pp,X}$-complete for DisjNP^X. We claim that $(C \oplus X, D \oplus \overline{X})$ is $\leq_T^{pp}$-complete for DisjNP^X. Observe that $(C \oplus X, D \oplus \overline{X}) \in \mathrm{DisjNP}^X$. Consider any $(A,B) \in \mathrm{DisjNP}^X$. Let S' separate $(C \oplus X, D \oplus \overline{X})$. Define $S = \{x \mid 0x \in S'\}$. Then S separates (C,D) and $S' = S \oplus X$. Since (C,D) is $\leq_T^{pp,X}$-complete for DisjNP^X, there exists a polynomial-time oracle Turing machine M so that $L(M^{S \oplus X})$ separates (A,B). That is, $L(M^{S'})$ separates (A,B), which is what we needed to prove. □

THEOREM 3.8. *There exists an oracle* X *such that* DisjNP^X *does not have a* $\leq_T^{pp,X}$*-complete pair.*

Proof. By Proposition 3.7, it suffices to show that DisjNP^X has no $\leq_T^{pp}$-complete pair. By Proposition 2.8, it suffices to construct X such that for every $(C,D) \in \mathrm{DisjNP}^X$ there exists a disjoint pair $(A,B) \in \mathrm{DisjNP}^X$ such that $(A,B) \not\leq_{uT}^{pp} (C,D)$.

Suppose $\{M_k\}_{k \geq 1}$ (resp., $\{N_i\}_{i \geq 1}$) is an enumeration of deterministic (resp., nondeterministic) polynomial-time oracle Turing machines. Let r_k and p_i be the corresponding polynomial time bounds for M_k and N_i. For any r, s, d, let $\Sigma_{rs}^d = 0^r 10^s 1 \Sigma^d$ and $l_{rs}^d = r + s + d + 2$ (i.e., l_{rs}^d is the length of strings in Σ_{rs}^d). For $Z \subseteq \Sigma^*$, $i \geq 1$, and $j \geq 1$, define

$$A_{ij}^Z = \{0^n \mid \exists x,\ |x| = n,\ 0^i 10^j 10x \in Z\}$$

and

$$B_{ij}^Z = \{0^n \mid \exists x,\ |x| = n,\ 0^i 10^j 11x \in Z\}.$$

We construct the oracle in stages. X_m denotes the oracle before stage m. We define $X = \bigcup_{m \geq 1} X_m$. Initially, let $X = \emptyset$. In stage $m = \langle i,j,k \rangle$, we choose some number $n = n_m$ and add strings from Σ_{ij}^{n+1} to the oracle such that either $L(N_i^{X_{m+1}}) \cap L(N_j^{X_{m+1}}) \neq \emptyset$ or $(A_{ij}^{X_{m+1}}, B_{ij}^{X_{m+1}})$ is not uniformly Turing reducible to $(L(N_i^{X_{m+1}}), L(N_j^{X_{m+1}}))$ via $M_k^{X_{m+1}}$. This construction ensures that for every i and j, $(L(N_i^X), L(N_j^X))$ is not $\leq_{uT}^{pp}$-complete for DisjNP^X.

We describe the construction of X_{m+1}. We choose some large enough $n = n_m$, and we will add words from Σ_{ij}^{n+1} to the oracle. We need a sufficient number of words in Σ_{ij}^{n+1} for diagonalization. Therefore, n has to be large enough such that

$$r_k(n) p_i(r_k(n))(p_j(r_k(n)) + 1) < 2^n.$$

On the other hand, if $m \geq 2$, then we have to make sure that adding words of length l_{ij}^{n+1} does not influence diagonalizations made in former steps. Therefore, if $m \geq 2$ and $m - 1 = \langle i', j', k' \rangle$, then $n > n_{m-1}$ and n has to be large enough such that l_{ij}^{n+1} is greater than $l_{i'j'}^{n_{m-1}+1}$, $\max(p_{i'}(n_{m-1}), p_{j'}(n_{m-1}))$, and $\max(p_{i'}(r_{k'}(n_{m-1})), p_{j'}(r_{k'}(n_{m-1})))$. Since $n_{m-1} > n_{m-2} > \cdots$, these conditions not only guard against interference with step $m-1$, but guard against interference with all steps $m' < m$.

Suppose there exists an $S \subseteq \Sigma^{n+1}_{ij}$ such that $L(N_i^{X_m \cup S}) \cap L(N_j^{X_m \cup S}) \cap \Sigma^{\leq r_k(n)} \neq \emptyset$. Let $X_{m+1} = X_m \cup S$ and go to the next stage $m+1$.

Otherwise,

$$\text{for all } S \subseteq \Sigma^{n+1}_{ij}, \quad L(N_i^{X_m \cup S}) \cap L(N_j^{X_m \cup S}) \cap \Sigma^{\leq r_k(n)} = \emptyset. \tag{1}$$

In this case, we consider the computation of M_k on 0^n. We determine some $w \in \Sigma^{n+1}_{ij}$ and let $X_{m+1} = X_m \cup \{w\}$. We construct a set $Q \subseteq \overline{L(N_j^{X_{m+1}})}$. Hence $L(N_i^{X_{m+1}}) \cup Q$ is a separator of $(L(N_i^{X_{m+1}}), L(N_j^{X_{m+1}}))$. The sets X_{m+1} and Q satisfy either

$$0^n \in A_{ij}^{X_{m+1}} \quad \text{and} \quad 0^n \notin L(M_k^{L(N_i^{X_{m+1}}) \cup Q}) \tag{2}$$

or

$$0^n \in B_{ij}^{X_{m+1}} \quad \text{and} \quad 0^n \in L(M_k^{L(N_i^{X_{m+1}}) \cup Q}). \tag{3}$$

This shows that $(A_{ij}^{X_{m+1}}, B_{ij}^{X_{m+1}})$ does not $\leq^{pp}_{uT}$-reduce to $(L(N_i^{X_{m+1}}), L(N_j^{X_{m+1}}))$ via M_k.

The difficulty of finding w and Q rises mainly from the following: If we want to preserve the computation of M_k on 0^n, then we have to ensure that all oracle queries are preserved. Since the oracle is a separator of two NP languages, we have to maintain the acceptance behaviors of N_i and N_j with respect to the queries made by $M_k(0^n)$. This results in reserving too many strings. In particular, this may leave no room for the diagonalization in Σ^{n+1}_{ij}. However, by Lemma 3.3, we can do better.

Now we construct the set Q, and at the same time we reserve strings for $\overline{X_{m+1}}$. The latter makes sure that either N_i or N_j rejects on certain queries.

Initially we set $Q = \emptyset$. We run M_k on 0^n using oracle $L(N_i^{X_m}) \cup Q$, until the first string q is queried. We apply Lemma 3.3 with $M = N_i$, $N = N_j$, $Y = X_m$, and $T = \Sigma^{n+1}_{ij}$. By equation (1), the first statement of Lemma 3.3 cannot hold. Hence, there is a set $S' \subseteq \Sigma^{n+1}_{ij}$, $\|S'\| \leq p_i(r_k(n)) \cdot (p_j(r_k(n)) + 1)$, such that either

$$(\forall S,\, S \subseteq \Sigma^{n+1}_{ij},\, S \cap S' = \emptyset)[q \notin L(N_i^{X_m \cup S})] \tag{4}$$

or

$$(\forall S,\, S \subseteq \Sigma^{n+1}_{ij},\, S \cap S' = \emptyset)[q \notin L(N_j^{X_m \cup S})]. \tag{5}$$

We reserve all strings in S' for $\overline{X_{m+1}}$. If equation (4) is true, then we continue running M_k without changing Q. (Hence, answer "no" to query q.) Otherwise, let $Q = Q \cup \{q\}$ and continue running M_k with oracle $X_m \cup Q$. (Hence, answer "yes" to query q.) By the choice of q, Q remains a separator of $(L(N_i^{X_m}), L(N_j^{X_m}))$. We continue running M_k until the next string is queried and then apply Lemma 3.3 again, obtain the set S' that satisfies equation (4) or (5) for the new query, and update Q accordingly. We do this repeatedly until the end of the computation of M_k on 0^n.

The number of strings in Σ^{n+1}_{ij} that are reserved for $\overline{X_{m+1}}$ is at most

$$r_k(n) \cdot p_i(r_k(n)) \cdot (p_j(r_k(n)) + 1) < 2^n.$$

So there exist a string $0^i10^j10x \in \Sigma^{n+1}_{ij}$ and a string $0^i10^j11y \in \Sigma^{n+1}_{ij}$ such that neither string is reserved for $\overline{X_{m+1}}$. If $M_k^{L(N_i^{X_m}) \cup Q}(0^n)$ accepts, then let $w = 0^i10^j11y$.

Otherwise, let $w = 0^i 10^j 10x$. We define $X_{m+1} = X_m \cup \{w\}$. This completes stage m and we can go to the next stage $m+1$.

The following two claims prove the correctness of the construction.

CLAIM 3.9. *After every stage $m = \langle i,j,k\rangle$, either $L(N_i^{X_{m+1}}) \cap L(N_j^{X_{m+1}}) \cap \Sigma^{\leq r_k(n_m)} \neq \emptyset$ or $(A_{ij}^{X_{m+1}}, B_{ij}^{X_{m+1}})$ does not $\leq_{uT}^{pp}$-reduce to $(L(N_i^{X_{m+1}}), L(N_j^{X_{m+1}}))$ via M_k.*

Proof. If $L(N_i^{X_{m+1}}) \cap L(N_j^{X_{m+1}}) \cap \Sigma^{\leq r_k(n_m)} \neq \emptyset$, then we are done. Otherwise, it follows that equation (1) holds. In this case we constructed Q. We know that every string that was added to Q is enforced to be rejected by $N_j^{X_m}$. Since w is not reserved and $X_{m+1} = X_m \cup \{w\}$, Q is also in the complement of $L(N_j^{X_{m+1}})$. Therefore, $L(N_i^{X_{m+1}}) \cup Q$ is a separator of $(L(N_i^{X_{m+1}}), L(N_j^{X_{m+1}}))$.

All queries of $M_k(0^{n_m})$ under oracle $L(N_i^{X_{m+1}}) \cup Q$ are answered the same way as in the construction of Q. The reason is as follows: For any query q, if we reserve strings from $\Sigma_{ij}^{n_m+1}$ for $\overline{X_{m+1}}$ such that N_i always rejects q (equation (4)), then q will not be put into Q. Hence q will get the answer "no" from oracle $L(N_i^{X_{m+1}}) \cup Q$, which is the same as in the construction of Q. If we reserve strings from $\Sigma_{ij}^{n_m+1}$ for $\overline{X_{m+1}}$ such that N_j always rejects q (equation (5)), then q will be put into Q. Hence q gets the answer "yes" under oracle $L(N_i^{X_{m+1}}) \cup Q$, which is the same answer as given in the construction of Q. Therefore, by the choice of w, we obtain the following:

- If $M_k^{L(N_i^{X_{m+1}}) \cup Q}(0^{n_m})$ accepts, then $0^{n_m+1} \in B_{ij}^{L(N_i^{X_{m+1}}) \cup Q}$.
- If $M_k^{L(N_i^{X_{m+1}}) \cup Q}(0^{n_m})$ rejects, then $0^{n_m+1} \in A_{ij}^{L(N_i^{X_{m+1}}) \cup Q}$.

Hence $L(M_k^{L(N_i^{X_{m+1}}) \cup Q})$ does not separate $(A_{ij}^{X_{m+1}}, B_{ij}^{X_{m+1}})$. □

CLAIM 3.10. *For all $(C,D) \in \mathrm{DisjNP}^X$, where $C = L(N_i^X)$ and $D = L(N_j^X)$, it holds that $(A_{ij}^X, B_{ij}^X) \in \mathrm{DisjNP}^X$ and $(A_{ij}^X, B_{ij}^X) \not\leq_{uT}^{pp} (C,D)$.*

Proof. First, we claim that there is no stage $m = \langle i,j,k\rangle$ such that $L(N_i^{X_{m+1}}) \cap L(N_j^{X_{m+1}}) \cap \Sigma^{\leq r_k(n_m)} \neq \emptyset$. Otherwise, since the number n_{m+1} is chosen large enough, all strings that are added to the oracle in later stages will not change the computations of N_i and N_j on inputs of lengths $\leq r_k(n_m)$. Therefore, $L(N_i^X) \cap L(N_j^X) \neq \emptyset$, which contradicts our assumption.

From Claim 3.9 it follows that for every stage $m = \langle i,j,k\rangle$, $(A_{ij}^{X_{m+1}}, B_{ij}^{X_{m+1}})$ does not $\leq_{uT}^{pp}$-reduce to $(L(N_i^{X_{m+1}}), L(N_j^{X_{m+1}}))$ via M_k. Again, since n_{m+1} is chosen large enough, all strings added to the oracle in later stages will not change the following:

1. The membership of 0^{n_m} in $A_{ij}^{X_{m+1}}$ and $B_{ij}^{X_{m+1}}$. Strings of length $l_{ij}^{n_m+1}$ are only added to the oracle at stage m and not in any other stage.
2. The computations of N_i and N_j on inputs of lengths $\leq r_k(n_m)$ (which is the maximal length of strings that can be queried by M_k on 0^{n_m}).

Hence, (A_{ij}^X, B_{ij}^X) does not $\leq_{uT}^{pp}$-reduce to (C,D) via M_k. Since this holds for all k, we obtain $(A_{ij}^X, B_{ij}^X) \not\leq_{uT}^{pp} (C,D)$.

It remains to observe that $(A_{ij}^X, B_{ij}^X) \in \mathrm{DisjNP}^X$: For each $m = \langle i,j,k\rangle$ we added exactly one string from $\Sigma_{ij}^{n_m+1}$ to the oracle. Moreover, for any other $m' = \langle i',j',k'\rangle$ we added only words from $\Sigma_{i'j'}^{n_{m'}+1}$ to the oracle; this does not influence A_{ij}^X and B_{ij}^X. □

This completes the proof of the theorem. □

COROLLARY 3.11. *For the oracle X from Theorem 3.8 it holds that $\mathrm{P}^X \neq \mathrm{UP}^X$.*

Proof. Choose i and j such that N_i^X (resp., N_j^X) accepts X (resp., $\overline{X}$). We show that $A_{ij}^X \in \mathrm{UP}^X - \mathrm{P}^X$.

Note that $L(N_i^X) \cap L(N_j^X) = \emptyset$. By the construction in Theorem 3.11, for every length n, we add at most one string of the form $0^i 10^j 10x$, $|x| = n$, to the oracle. So $A_{ij}^X \in \mathrm{UP}^X$.

Assume $A_{ij}^X = L(M_k^X)$ for some deterministic polynomial-time oracle Turing machine M_k. Note that X is the only separator of $(L(N_i^X), L(N_j^X))$. Therefore, it follows that $(A_{ij}^X, B_{ij}^X) \leq_{uT}^{pp} (L(N_i^X), L(N_j^X))$ via M_k. This contradicts Claim 3.10. □

4. Function classes and disjoint pairs. We show that there exists a Turing-complete disjoint NP-pair if and only if NPSV contains a Turing-complete partial function. We know already that there is a connection between disjoint NP-pairs and NPSV. Namely, Selman [Sel94] proved that Conjecture 2.4 holds if and only if NPSV does not contain an NP-hard partial function, and Köbler and Messner [KM00] proved that there exists a many-one-complete disjoint NP-pair if and only if NPSV contains a many-one-complete partial function. Recall [Sel94] that NPSV is the set of all partial, single-valued functions computed by nondeterministic polynomial-time-bounded transducers.

If g is a single-valued total function, then we define $M[g]$, the single-valued partial function computed by M with oracle g, as follows: $x \in \mathrm{dom}(M[g])$ if and only if M reaches an accepting state on input x. In this case, $M[g](x)$ is the final value of M's output tape. In the case that g is a total function and $f = M[g]$, we write $f \leq_T^p g$.

The literature contains two different definitions of reductions between partial functions, because one must decide what to do in case a query is made to the oracle function when the query is not in the domain of the oracle function. Fenner et al. [FHOS97] determined that in this case the value returned should be a special symbol, $\perp$. Selman [Sel94] permits the value returned in this case to be arbitrary, which is the standard paradigm for promise problems. Here we use the promise problem definition of Selman [Sel94]. Recall that for multivalued partial functions f and g, g is *an extension* of f if $\mathrm{dom}(f) \subseteq \mathrm{dom}(g)$, and for all $x \in \mathrm{dom}(f)$ and for every y, if $g(x) \mapsto y$, then $f(x) \mapsto y$.

DEFINITION 4.1. *For polynomial-length-bounded, partial multivalued functions f and g, f is* Turing reducible to g *(as a promise problem, so we write $f \leq_T^{pp} g$) in polynomial time if for some deterministic polynomial-time-bounded oracle transducer M, for every single-valued total extension g' of g, $M[g']$ is an extension of f.*

Here, if the query q belongs to the domain of g, then the oracle returns a value of $g(q)$. We will use the result [Sel94] that $f \leq_T^{pp} g$ if and only if for every single-valued total extension g' of g, there is a single-valued total extension f' of f such that $f' \leq_T^p g'$.

A single-valued partial function g is $\leq_T^{pp}$*-complete* for NPSV if g belongs to NPSV and, for all $f \in$ NPSV, $f \leq_T^{pp} g$.

THEOREM 4.2. NPSV *contains a $\leq_T^{pp}$-complete partial function* $\Leftrightarrow$ DisjNP *contains a $\leq_T^{pp}$-complete pair.*

Proof. For any $f \in$ NPSV, define the following sets:

$$R_f = \{\langle x, y\rangle \mid x \in \mathrm{dom}(f),\ y \leq f(x)\} \tag{6}$$

and

$$S_f = \{\langle x, y\rangle \mid x \in \mathrm{dom}(f),\ y > f(x)\}. \tag{7}$$

Note that (R_f, S_f) is a disjoint NP-pair.

CLAIM 4.3. *For every separator A of (R_f, S_f), there is a single-valued total extension f' of f such that $f' \leq_T^p A$.*

Consider the following oracle transducer T that computes f' with oracle A. On input x, if $x \in \mathrm{dom}(f)$, then T determines the value of $f(x)$, using a binary search algorithm, by making repeated queries to A. Note that for $x \in \mathrm{dom}(f)$ and for any y, if $y \leq f(x)$, then $\langle x, y\rangle \in R_f$, and if $y > f(x)$, then $\langle x, y\rangle \in S_f$. Clearly, T computes some single-valued total extension of f. This proves the claim.

Let f be a $\leq_T^{pp}$-complete function for NPSV and assume that A separates R_f and S_f. By Claim 4.3, there is a single-valued total extension f' of f such that $f' \leq_T^p A$.

Let $(U, V) \in$ DisjNP. We want to show that $(U, V) \leq_T^{pp} (R_f, S_f)$. Define

$$g(x) = \begin{cases} 0 & \text{if } x \in U, \\ 1 & \text{if } x \in V, \\ \uparrow & \text{otherwise.} \end{cases}$$

Then $g \in$ NPSV, so $g \leq_T^{pp} f$. Therefore, there is a single-valued total extension g' of g such that $g' \leq_T^p f'$.

Define $L = \{x \mid g'(x) = 0\}$. It is easy to see that $L \leq_T^p g'$. Also note that $U \subseteq L$ and $V \subseteq \overline{L}$, and, therefore, L separates U and V. Then the following sequence of reductions shows that $L \leq_T^p A$:

$$L \leq_T^p g' \leq_T^p f' \leq_T^p A.$$

Thus, for every separator A of (R_f, S_f), there is a separator L of (U, V) such that $L \leq_T^p A$. Therefore, (R_f, S_f) is $\leq_T^{pp}$-complete for DisjNP.

For the other direction, assume that (U, V) is $\leq_T^{pp}$-complete for DisjNP. Define the following function:

$$f(x) = \begin{cases} 0 & \text{if } x \in U, \\ 1 & \text{if } x \in V, \\ \uparrow & \text{otherwise.} \end{cases}$$

Clearly, $f \in$ NPSV.

Let f' be a single-valued total extension of f, and let $L = \{x \mid f'(x) = 0\}$. Clearly, $L \leq_T^p f'$. Also, since $U \subseteq L$ and $V \subseteq \overline{L}$, L is a separator of (U, V).

We want to show that for any $g \in$ NPSV, $g \leq_T^{pp} f$. Consider the disjoint NP-pair (R_g, S_g) for the function g as defined in equations (6) and (7). There is a separator A of (R_g, S_g) such that $A \leq_T^p L$, since L is a separator of the $\leq_T^{pp}$-complete disjoint NP-pair (U, V). As noted in Claim 4.3, there is a single-valued total extension g' of g such that $g' \leq_T^p A$. Therefore, the following sequence of reductions shows that $g \leq_T^{pp} f$:

$$g' \leq_T^p A \leq_T^p L \leq_T^p f'.$$

Hence, f is complete for NPSV. □

COROLLARY 4.4.

1. *Let $f \in$ NPSV be $\leq_T^{pp}$-complete for* NPSV. *Then (R_f, S_f) is $\leq_T^{pp}$-complete for* DisjNP.

2. *If* (U, V) *is* $\leq_T^{pp}$*-complete for* DisjNP*, then* $f_{U,V}$ *is complete for* NPSV*, where*

$$f_{U,V}(x) = \begin{cases} 0 & \text{if } x \in U, \\ 1 & \text{if } x \in V, \\ \uparrow & \text{otherwise.} \end{cases}$$

3. *Relative to the oracle in Theorem* 3.8*,* NPSV *does not have a* $\leq_T^{pp}$*-complete partial function.*

5. Nonsymmetric pairs and separation of reducibilities. Pudlák [Pud03] defined a disjoint pair (A, B) to be *symmetric* if $(B, A) \leq_m^{pp} (A, B)$. Otherwise, (A, B) is *nonsymmetric*. For example, the canonical disjoint NP-pair for the propositional proof system Resolution is symmetric [Pud03] (see section 6.3 for the definition of canonical pairs). In this section we give complexity-theoretic evidence of the existence of nonsymmetric disjoint NP-pairs. As a consequence, we obtain new ways to demonstrate existence of P-inseparable sets and show that $\leq_m^{pp}$ and $\leq_T^{pp}$ reducibilities differ for disjoint NP-pairs.

A set L is *P-printable* if there is $k \geq 1$ such that all elements of L up to length n can be printed by a deterministic Turing machine in time $n^k + k$ [HY84, HIS85]. Every P-printable set is sparse and belongs to P. An infinite set A is *P-printable-immune* if no infinite subset of A is P-printable.

A set L is *p-selective* if there is a polynomial-time-bounded function f such that for every $x, y \in \Sigma^*$, $f(x, y) \in \{x, y\}$, and $\{x, y\} \cap L \neq \emptyset \Rightarrow f(x, y) \in L$ [Sel79].

A partial function $f \in$ PF is *almost-always one-way* [FPS01] if no polynomial-time Turing machine inverts f correctly on more than a finite subset of range(f).

Proposition 5.1.

1. (A, B) *is symmetric if and only if* (B, A) *is symmetric.*
2. *If* (A, B) *is P-separable, then* (A, B) *is symmetric.*

Proof. The proof of the first assertion is trivial. For the proof of the second assertion, let (A, B) be a P-separable disjoint NP-pair. Fix $a \in A$ and $b \in B$, and let the separator be $S \in$ P. Consider the following polynomial-time computable function f. On input x, if $x \in S$, then f outputs b; otherwise, f outputs a. Therefore, $x \in A$ implies $x \in S$, which implies $f(x) = b \in B$, and $x \in B$ implies $x \notin S$, which implies $f(x) = a \in A$. Therefore, $(A, B) \leq_m^{pp} (B, A)$, i.e., (A, B) is symmetric. □

We will show the existence of a nonsymmetric disjoint NP-pair under certain hypotheses, due to the following proposition, that will separate $\leq_m^{pp}$ and $\leq_T^{pp}$ reducibilities.

Proposition 5.2.

1. *If* (A, B) *is a nonsymmetric disjoint* NP*-pair, then* $(B, A) \not\leq_m^{pp} (A, B)$.
2. *For any disjoint* NP*-pair* (A, B), $(B, A) \leq_T^{pp} (A, B)$.

Proof. The first assertion follows from the definition of symmetric pairs. For the second assertion, observe that for any S separating A and B, $\overline{S}$ separates B and A, while for any set S, $\overline{S} \leq_T^p S$. □

We will use the following proposition in a crucial way to provide some evidence for the existence of nonsymmetric disjoint NP-pairs. In other words, we will seek to obtain a disjoint NP-pair (A, B) such that either A or B is p-selective, but (A, B) is not P-separable.

Proposition 5.3. *For any disjoint* NP*-pair* (A, B)*, if either* A *or* B *is p-selective, then* (A, B) *is symmetric if and only if* (A, B) *is P-separable.*

Proof. We know from Proposition 5.1 that if (A, B) is P-separable, then it is symmetric. Now assume that (A, B) is symmetric via some function f and assume

(without loss of generality) that A is p-selective and the p-selector function is g. The following algorithm M separates A and B. On input x, M runs g on the strings $(x, f(x))$, and accepts x if and only if g outputs x. If $x \in A$, then $f(x) \in B$, and therefore g has to output x. On the other hand, if $x \in B$, then $f(x) \in A$. So g will output $f(x)$ and M will reject x. Therefore, $A \subseteq L(M) \subseteq \overline{B}$. □

Now we give evidence for the existence of nonsymmetric disjoint NP-pairs.

THEOREM 5.4. *If* $\mathrm{E} \neq \mathrm{NE} \cap \mathrm{coNE}$*, then there is a set* $A \in \mathrm{NP} \cap \mathrm{coNP}$ *such that* $(A, \overline{A})$ *is not symmetric.*

Proof. If $\mathrm{E} \neq \mathrm{NE} \cap \mathrm{coNE}$, then there is a tally set $T \in (\mathrm{NP} \cap \mathrm{coNP}) - \mathrm{P}$. From Selman [Sel79, Theorem 5], the existence of such a tally set implies that there is a p-selective set $A \in (\mathrm{NP} \cap \mathrm{coNP}) - \mathrm{P}$. Clearly, $(A, \overline{A})$ is not P-separable. Hence, by Proposition 5.3, $(A, \overline{A})$ is nonsymmetric. □

As a corollary, if $\mathrm{E} \neq \mathrm{NE} \cap \mathrm{coNE}$, then there is a set $A \in \mathrm{NP} \cap \mathrm{coNP}$ such that $(A, \overline{A}) \not\leq_m^{pp} (\overline{A}, A)$, yet clearly $(A, \overline{A}) \leq_T^{pp} (\overline{A}, A)$.

We will show that the hypotheses in Theorem 5.5 imply the existence of a nonsymmetric disjoint NP-pair. Note that the hypotheses in this theorem are similar to those studied by Fortnow, Pavan, and Selman [FPS01] and Pavan and Selman [PS02]. However, our hypotheses are stronger than the former and weaker than the latter.

THEOREM 5.5. *The following are equivalent.*

1. *There is a* UP*-machine* N *that accepts* 0^* *and, for every polynomial-time machine* M*,* $\{n \mid M$ *on input* 0^n *outputs the accepting computation of* N *on input* $0^n\}$ *is a finite set.*
2. *There is a set* S *in* UP *accepted by a* UP*-machine* N *such that* S *has exactly one string of every length and, for every polynomial-time machine* M*, the following set is finite:* $\{n \mid M$ *on input* 0^n *outputs the accepting computation of* N *on input* $x_n\}$*, where* x_n *denotes the word of length* n *that belongs to* S*.*
3. *There is an honest one-to-one, almost-always one-way function* f *such that* $\mathrm{range}(f) = 0^*$*.*
4. *There is a language* $L \in \mathrm{P}$ *that has exactly one string of every length and* L *is P-printable-immune.*
5. *There is a language* $L \in \mathrm{UP}$ *that has exactly one string of every length and* L *is P-printable-immune.*

Proof. We show the following cycles: $1 \Rightarrow 2 \Rightarrow 3 \Rightarrow 1$ and $1 \Rightarrow 4 \Rightarrow 5 \Rightarrow 1$.

Trivially, item 1 implies item 2. To prove that item 2 implies item 3, let N be a UP-machine that satisfies the conditions of item 2 and let $S = L(N)$. For any y that encodes an accepting computation of N on some string x, define $f(y) = 0^{|x|}$. Since y also encodes x, f is polynomial-time computable. Since N runs in polynomial time, f is honest. On the other hand, if any polynomial-time computable machine can invert f on 0^n for infinitely many n, then that machine actually outputs infinitely many accepting computations of N.

We show that item 3 implies item 1. Given f as in item 3, we know that since f is honest, $\exists k > 0$ such that $|x| \leq |f(x)|^k$. We describe a UP-machine N that accepts 0^*. On input 0^n, N guesses x, $|x| \leq n^k$, and accepts 0^n if and only if $f(x) = 0^n$. Since f is one-to-one, N has exactly one accepting path for every input of the form 0^n, and since $\mathrm{range}(f) = 0^*$, $L(N) = 0^*$. If there is a polynomial-time machine M that outputs infinitely many accepting computations of N, then M also inverts f on infinitely many strings.

To prove that item 1 implies item 4, let N be the UP-machine in item 1. We can assume without loss of generality that for all but finitely many n, on input 0^n, N has

exactly one accepting computation of length n^k for some $k > 0$. Let us define the following language:

$$L' = \{x10^n10^l \mid n \geq 0,\ x \text{ is an accepting path of } N(0^n), \text{ and } 0 \leq l \leq (n+1)^k - n^k\}.$$

It is easy to see that L' is in P, and for all but finitely many n, L has exactly one string of length n. Therefore, there exists a finite variation $L \in \mathrm{P}$ such that L has exactly one string of every length. If L has an infinite P-printable subset, then so has L'. Let M' be a polynomial-time transducer that prints an infinite subset of L'. It follows that M' outputs infinitely many accepting computations of N.

Item 4 trivially implies item 5. We show that item 5 implies item 1. Let L be such a language in UP via a UP-machine N. Define a UP-machine N' to accept 0^* as follows. On input 0^n, N' guesses a string x of length n and a computation path w of N on x. N' accepts 0^n if and only if w is an accepting computation. If a polynomial-time machine can output infinitely many accepting computations of N', then essentially the same machine also outputs infinitely many strings in L, and hence L cannot be P-printable-immune. □

THEOREM 5.6. *Each of the hypotheses stated in Theorem* 5.5 *implies the existence of nonsymmetric disjoint* NP*-pairs.*

Proof. Let us define the following function:

$$dt(i) = \begin{cases} 1 & \text{if } i = 0, \\ 2^{2^{dt(i-1)}} & \text{otherwise.} \end{cases}$$

Let M be the UP-machine accepting 0^*, as in the first hypothesis in Theorem 5.5. Let a_n be the accepting computation of M on 0^n. We can assume that $|a_n| = p(n)$, where $p(\cdot)$ is some fixed polynomial. We define the following sets:

$$L_M = \{\langle 0^n, w\rangle \mid w \leq a_n,\ n = dt(i) \text{ for some } i > 0\}$$

and

$$R_M = \{\langle 0^n, w\rangle \mid w > a_n,\ n = dt(i) \text{ for some } i > 0\}.$$

Note that (L_M, R_M) is a disjoint NP-pair. We claim that L_M is p-selective. The description of a selector f for L_M follows. Assume that $\langle 0^k, w_1\rangle$ and $\langle 0^l, w_2\rangle$ are input to f. If $k = l$, then f outputs the lexicographically smaller one of w_1 and w_2. Otherwise, assume that $k < l$, and without loss of generality, both k and l are in range(dt). In that case, $l \geq 2^{2^k} > 2^{|a_k|}$, and therefore f can compute a_k, the accepting computation of M on 0^k, by checking all possible strings of length $|a_k|$. Therefore, in $O(l)$ time, f outputs $\langle 0^k, w_1\rangle$ if $w_1 \leq a_k$, and outputs $\langle 0^l, w_2\rangle$ otherwise. Similarly, we can show that R_M is p-selective.

We claim that (L_M, R_M) is a nonsymmetric disjoint NP-pair. Assume on the contrary that this pair is symmetric. Therefore, by Proposition 5.3 (L_M, R_M) is P-separable; i.e., there is $S \in \mathrm{P}$ that is a separator for (L_M, R_M). Using a standard binary search technique, a polynomial-time machine can compute the accepting computation of M on any 0^n, where $n = dt(i)$ for some $i > 0$. Since the length of the accepting computation of M on 0^n is $p(n)$, this binary search algorithm takes time $O(p(n))$ which is polynomial in n. This contradicts our hypothesis, since we assumed that no polynomial-time machine can compute infinitely many accepting computations of M. Therefore, (L_M, R_M) is a nonsymmetric disjoint NP-pair. □

If the hypotheses stated in Theorem 5.5 hold, then there exists a disjoint NP-pair (A, B) so that $(A, B) \not\leq_m^{pp} (B, A)$ while $(A, B) \leq_T^{pp} (B, A)$.

Grollmann and Selman [GS88] proved that the existence of P-inseparable disjoint NP-pairs implies the existence of P-inseparable pairs where both sets of the pair are NP-complete. The following results are in the same spirit. We note that natural candidates for nonsymmetric (or $\leq_m^{pp}$-complete) disjoint NP-pairs arise either from cryptography or from proof systems [Pud03]. However, the following theorems show that the existence of such pairs will imply that nonsymmetric (or $\leq_m^{pp}$-complete) disjoint NP-pairs exist where both sets of the pair are $\leq_m^p$-complete for NP.

THEOREM 5.7. *There exists a nonsymmetric disjoint* NP*-pair* (A, B) *if and only if there exists a nonsymmetric disjoint* NP*-pair* (C, D) *where both* C *and* D *are* $\leq_m^p$*-complete for* NP.

Proof. The *if* part is trivial. We prove the *only if* part. Let $\{NM_i\}_{i\geq 1}$ be a standard enumeration of polynomial-time-bounded nondeterministic Turing machines with associated polynomial-time bounds $\{p_i\}_{i\geq 1}$. It is known that the following set is NP-complete [BGS75]:

$$K = \{\langle i, x, 0^n\rangle \mid NM_i \text{ accepts } x \text{ within } n \text{ steps}\}.$$

Let (A, B) be a nonsymmetric disjoint NP-pair. There exists $i \geq 1$ such that $A = L(NM_i)$, and $A \leq_m^p K$ via $f(x) = \langle i, x, 0^{p_i(|x|)}\rangle$. Note that f is honest and one-to-one.

Our first goal is to show that $(K, f(B))$ is nonsymmetric. Since f is a reduction from A to K and $A \cap B = \emptyset$, $f(A) \subseteq K$ and $f(B) \subseteq \overline{K}$, and so $f(B)$ and K are disjoint sets. Observe that $f(B)$ is in NP because on any input y, we can guess x, and verify that $x \in B$ and $f(x) = y$. Therefore, $(K, f(B))$ is a disjoint NP-pair, and K is $\leq_m^p$-complete for NP.

In order to prove that this pair is nonsymmetric, assume otherwise. Then $(K, f(B)) \leq_m^{pp} (f(B), K)$ and, therefore, $\exists g \in$ PF such that $g(K) \subseteq f(B)$ and $g(f(B)) \subseteq K$. Consider the following polynomial-time computable function h. On input x, h first computes $y = g(f(x))$. If $y = \langle i, x', 0^{p_i(|x'|)}\rangle$ for some x', then h outputs x'; otherwise, it returns a fixed string $a \in A$. We claim that $h(A) \subseteq B$ and $h(B) \subseteq A$, thereby making (A, B) symmetric. For any $x \in A$, we know that $f(x) \in K$. Hence $g(f(x)) \in f(B)$, since $g(K) \subseteq f(B)$. So $g(f(x)) = \langle i, x', 0^{p_i(|x'|)}\rangle$ for some $x' \in B$, and so $h(x) = x' \in B$. For any $x \in B$, $y = g(f(x)) \in K$, since $g(f(B)) \subseteq K$. If $y = \langle i, x', 0^{p_i(|x'|)}\rangle$ for some x', then x' must be in A; else h will return $a \in A$, and so, in either case, $x \in B$ will imply that $h(x) \in A$. Therefore, $h(A) \subseteq B$ and $h(B) \subseteq A$. Thus $(A, B) \leq_m^{pp} (B, A)$, contradicting the fact that (A, B) is nonsymmetric. Hence $(K, f(B))$ is a nonsymmetric disjoint NP-pair.

To complete the proof of the theorem, apply the construction once again, this time with an honest reduction f' from $f(B)$ to K. Namely, $f'(f(B)) \subseteq K$ and $f'(K) \subseteq \overline{K}$. Similar to the above argument, it can be shown that $f'(K)$ and K are disjoint. Also, since f' is one-to-one, we claim that $f'(K)$ is $\leq_m^p$-complete for NP. Clearly, $x \in K$ implies $f'(x) \in f'(K)$. On the other hand, for some $x \notin K$, $f'(x)$ cannot be in $f'(K)$; otherwise, $f'(x) = f'(y)$ for some $y' \in K$, contradicting the fact that f' is one-to-one. Then K and $f'(K)$ are disjoint NP-complete sets, and the argument already given shows that $(f'(K), K)$ is nonsymmetric. □

THEOREM 5.8. *There exists a* $\leq_m^{pp}$*-complete disjoint* NP*-pair* (A, B) *if and only if there exists a* $\leq_m^{pp}$*-complete disjoint* NP*-pair* (C, D)*, where both* C *and* D *are* $\leq_m^p$*-complete sets for* NP.

Proof. The proof is similar to that of Theorem 5.7. Consider the one-to-one

function f defined by $f(x) = \langle i, x, 0^{p_i(|x|)} \rangle$ that many-one reduces A to the canonical NP-complete set K.

Obviously $(A, B) \leq_m^{pp} (K, f(B))$ via f, since $f(A) \subseteq K$, and $K \cap f(B) = \emptyset$, as shown in the proof of Theorem 5.7. Similar to that theorem, we apply the one-to-one function f' that many-one reduces $f(B)$ to K to obtain another disjoint pair $(f'(K), K)$ where $(K, f(B)) \leq_m^{pp} (f'(K), K)$ via f'. So $(A, B) \leq_m^{pp} (K, f(B)) \leq_m^{pp} (f'(K), K)$. Therefore $(f'(K), K)$ is also a $\leq_m^{pp}$-complete disjoint NP-pair, and both $f'(K)$ and K are $\leq_m^p$-complete sets for NP. □

6. Optimal proof systems relative to an oracle. The question of whether optimal propositional proof systems exist has been studied in detail. Pudlák [Pud86] and Krajíček and Pudlák [KP89] showed that NE = coNE implies the existence of optimal proof systems. Ben-David and Gringauze [BDG98] and Köbler, Messner, and Torán [KMT03] obtained the same conclusion under weaker assumptions. On the other hand, Messner and Torán [MT98] and Köbler, Messner, and Torán [KMT03] proved that existence of optimal proof systems results in the existence of $\leq_m^p$-complete sets for the promise class NP ∩ SPARSE. These results hold relative to all oracles. Therefore, optimal proof systems exist relative to any oracle in which NE = coNE holds. Krajíček and Pudlák [KP89], Ben-David and Gringauze [BDG98], and Buhrman et al. [BFFvM00] constructed oracles relative to which optimal proof systems do not exist. In addition, NP ∩ SPARSE does not have complete sets relative to the latter oracle.

The relationship between the existence of optimal proof systems and disjoint NP-pairs was first established by Razborov [Raz94], who showed that the existence of optimal proof systems implies the existence of many-one-complete disjoint NP-pairs. Köbler, Messner, and Torán [KMT03] proved that this holds even for a stronger form of many-one reductions. They defined *strong many-one reduction* (we denote this by $\leq_{sm}^{pp}$) between disjoint NP-pairs as follows: $(A, B) \leq_{sm}^{pp} (C, D)$ if there is $f \in$ PF such that $f(A) \subseteq C$, $f(B) \subseteq D$, and $f(\overline{A \cup B}) \subseteq \overline{C \cup D}$.[1]

In this section, we construct two oracles, O_1 and O_2. Relative to O_1, NE = coNE, and therefore [Pud86, KP89] optimal proof systems exist, implying the existence of $\leq_m^p$-complete sets for NP ∩ SPARSE [MT98] as well as the existence of $\leq_{sm}^{pp}$-complete disjoint NP-pairs [KMT03]. On the other hand, relative to this oracle, E ≠ NE∩coNE = NE, thus implying, by Theorem 5.4, that nonsymmetric (and therefore P-inseparable) pairs exist. Since nonexistence of $\leq_T^{pp}$-complete disjoint NP-pairs implies Conjecture 2.4, it is natural to ask whether the converse of this implication holds. Relative to O_1, Conjecture 2.4 holds, and so the converse is false.

Ben-David and Gringauze [BDG98] asked whether the converse to Razborov's result holds. Relative to O_2, NP ∩ SPARSE does not have a complete set, and so optimal proof systems do not exist. On the other hand, $\leq_{sm}^{pp}$-complete disjoint NP-pairs exist. This shows that the converse to Razborov's result does not hold (even for the stronger notion of many-one reduction) in a relativized setting. Relative to O_2, the existence of $\leq_{sm}^{pp}$-complete disjoint NP-pairs does not imply the existence of $\leq_m^p$-complete sets in NP∩SPARSE. In addition, relative to O_2, NE ≠ coNE [Pud86, KP89] and nonsymmetric disjoint NP-pairs exist.

Since relative to both O_1 and O_2, Conjecture 2.4 holds, $\leq_{sm}^{pp}$-complete disjoint NP-pairs exist, and nonsymmetric pairs exist, it follows that these are "independent"

[1] A forthcoming paper [GSS04] proves that there exist $\leq_{sm}^{pp}$-complete disjoint NP-pairs if and only if there exist $\leq_m^{pp}$-complete disjoint NP-pairs.

TABLE 1
Comparison of oracle properties.

	O_1	O_2
$\exists \leq_{sm}^{pp}$-complete disjoint NP-pairs	Yes	Yes
$\exists$ nonsymmetric disjoint NP-pairs	Yes	Yes
Conjecture 2.4 holds	Yes	Yes
E $\neq$ NE	Yes	Yes
NE = coNE	Yes	No
$\exists$ optimal propositional proof systems	Yes	No
NP $\cap$ SPARSE has $\leq_m^p$-complete sets	Yes	No

of the assertion that NE = coNE, the existence of optimal proof systems, and existence of $\leq_m^p$-complete sets in NP $\cap$ SPARSE. In Table 1, we summarize the properties of both oracles; "Yes" denotes that a particular property holds, while "No" means that the property does not hold.

6.1. Notation. We fix the following enumerations: $\{NM_i\}_i$ is an effective enumeration of nondeterministic, polynomial-time-bounded oracle Turing machines; $\{NE_i\}_i$ is an effective enumeration of nondeterministic, linear exponential-time-bounded oracle Turing machines; $\{M_i\}_i$ is an effective enumeration of deterministic, polynomial-time-bounded oracle Turing machines; $\{E_i\}_i$ is an effective enumeration of deterministic, linear exponential-time-bounded oracle Turing machines; and $\{T_i\}_i$ is an effective enumeration of deterministic, polynomial-time-bounded oracle Turing transducers. Moreover, NM_i, M_i, and T_i have running time $p_i = n^i$, and NE_i and E_i have running time 2^{in} independent of the choice of the oracle. For any oracle Z, let f_i^Z denote the function that T_i^Z computes.

We use the following model of nondeterministic oracle Turing machines. On some input the machine starts the first phase of its computation, during which it is allowed to make nondeterministic branches. In this phase the machine is not allowed to ask any queries. At the end of the first phase the machine has computed a list of queries $q_1, \ldots, q_n$, a list of guessed answers $g_1, \ldots, g_n$, and a character, which is either + or −. Now the machine asks in parallel all queries and gets the vector of answers $a_1, \ldots, a_n$. The machine accepts if the computed character is + and $(a_1, \ldots, a_n) = (g_1, \ldots, g_n)$; otherwise the machine rejects. An easy observation shows that for every nondeterministic polynomial-time oracle Turing machine M there exists a machine N that works in the described way such that for all oracles X, $L(M^X) = L(N^X)$.[2] The analogous statement holds for nondeterministic, linear exponential-time-bounded oracle Turing machines.

A computation path P of a nondeterministic polynomial-time oracle Turing machine N on an input x contains all nondeterministic choices, all queries, and all guessed answers. A computation path P that has the character + (resp., −) is called a positive (resp., negative) path. The set of queries that are guessed to be answered positively (resp., negatively) is denoted by P^{yes} (resp., P^{no}); the set of all queries is denoted by $P^{\text{all}} \stackrel{df}{=} P^{\text{yes}} \cup P^{\text{no}}$. The length of P (i.e., the number of computation steps) is denoted by $|P|$. Note that this description of paths makes it possible to talk about paths of computations without specifying the oracle; i.e., we can say that N on x has

[2]Note that for this property we need both: the character must be + and g_i must be guessed correctly. If the machine accepts just when the answers are guessed correctly, then we miss the machine that accepts $\emptyset$ for every oracle.

a positive path P such that P^{yes} and P^{no} satisfy certain conditions. However, when talking about accepting and rejecting paths we always have to specify the oracle. (A positive path can be accepting for certain oracles, and it can be rejecting for other oracles.)

For $X, Y \subseteq \Sigma^*$ we write $Y \supseteq_m X$ if $X \subseteq \Sigma^{\leq m}$ and $Y^{\leq m} = X$. We write $Y \subseteq_m X$ if and only if $X \supseteq_m Y$. We need to consider injective, partial functions $\mu : \mathbb{N}^+ \to \mathbb{N} \times \mathbb{N}^+$ that have a finite domain. We do not distinguish between the function and the set of all (n, i, j) such that $\mu(n) = (i, j)$. We denote both by μ. Let μ and μ' be injective, partial functions $\mathbb{N}^+ \to \mathbb{N} \times \mathbb{N}^+$ that have a finite domain. If $\mu \neq \emptyset$, then $\mu_{\max} \stackrel{df}{=} \max(\text{dom}(\mu))$. We write $\mu \preceq \mu'$ if either $\mu = \emptyset$, or $\mu \subseteq \mu'$ and $\mu_{\max} < n$ for all $n \in \text{dom}(\mu' - \mu)$. We write $\mu \prec \mu'$ if $\mu \preceq \mu'$ and $\mu \neq \mu'$.

For $j \geq 1$, SPARSE_j denotes the class of all languages L such that for all $k \geq 0$, $\|L \cap \Sigma^k\| \leq k^j + j$.

6.2. Existence of optimal proof systems. Now we develop the first of these oracles.

THEOREM 6.1. *There exists an oracle relative to which the following holds:*

(i) $\text{E} \neq \text{NE} = \text{coNE}$.

(ii) *Conjecture* 2.4 *holds.*

For a fixed set X, let us define the following set, which is complete for NE^X:

$$C^X \stackrel{df}{=} \{\langle i, x, l\rangle \mid NE_i^X \text{ accepts } x \text{ within } l \text{ steps}\}.$$

We also define the following property:

$$\text{P1:} \qquad \langle i, x, l\rangle \in C^X \Leftrightarrow (\forall y,\ |y| = 2^{2|\langle i,x,l\rangle|})[\langle i, x, l\rangle y \notin X].$$

We call a set $X \subseteq \Sigma^{\leq k}$ *k-valid* if property P1 holds for all strings $\langle i, x, l\rangle$ such that $|\langle i, x, l\rangle| + 2^{2|\langle i,x,l\rangle|} \leq k$. Note that $\emptyset$ is 0-valid and that the condition on the right-hand side of P1 only depends on words in X that have length $2^{2n} + n$ for some natural number n. We define the following sets:

$$A^X \stackrel{df}{=} \{0^n \mid (n \text{ is odd}) \wedge (\exists y,\ |y| = 2^n)[y \in X]\}$$

and

$$B^X \stackrel{df}{=} \{0^{2^n} z \mid (n \text{ is odd}) \wedge |z| = 2^n \wedge (\exists y,\ |y| = 2^n)[zy \in X]\}.$$

Clearly, $A^X \in \text{NE}^X$ and $B^X \in \text{NP}^X$. We require the following for O_1:

1. $C^{O_1} \in \text{coNE}^{O_1}$. (This implies $\text{NE}^{O_1} = \text{coNE}^{O_1}$, because C^{O_1} is complete for NE^{O_1} by a reduction that is computable in linear time.)
2. $A^{O_1} \notin \text{E}^{O_1}$ (which implies $\text{E}^{O_1} \neq \text{NE}^{O_1}$, since $A^{O_1} \in \text{NE}^{O_1}$).
3. For every i, j, and r, B^{O_1} does not $\leq_T^{pp}$-reduce to $(L(NM_i^{O_1}), L(NM_j^{O_1}))$ via M_r. This will ensure that Conjecture 2.4 holds relative to O_1.

Proof of Theorem 6.1. We will begin by stating two lemmas that will be used in this proof.

LEMMA 6.2. *For every i and every k-valid X, there exists an l-valid $Y \supseteq_k X$, where $l > k$, such that for every $Z \supseteq_l Y$, $A^Z \neq L(E_i^Z)$.*

LEMMA 6.3. *For every i, j, r and every k-valid X, there exists an l-valid $Y \supseteq_k X$, where $l > k$, such that for every $Z \supseteq_l Y$, B^Z does not $\leq_T^{pp}$-reduce to $(L(NM_i^Z), L(NM_j^Z))$ via M_r.*

We define the following list $\mathcal{T}$ of requirements. At the beginning of the construction, $\mathcal{T}$ contains $\{i\}_{i \geq 1}$ and $\{(i, j, r)\}_{i,j,r \geq 1}$. These have the following interpretations:

- $i \in \mathcal{T}$: ensure that $A^{O_1} \neq L(E_i^{O_1})$.
- $(i,j,r) \in \mathcal{T}$: ensure that B^{O_1} does not $\leq_T^{pp}$-reduce to $(L(NM_i^{O_1}), L(NM_j^{O_1}))$ via M_r.

The following algorithm is used to construct the oracle O_1.

```
1    O_1 := ∅; k := 0
2    while {true} {
3        Remove the next requirement t from T
4        if t = i then
5           apply Lemma 6.2 with X = O_1 to get Y and l
6        else  // t = (i, j, r)
7           apply Lemma 6.3 with X = O_1 to get Y and l
8        O_1 := Y; k := l
9    }
```

It is clear that the oracle constructed by this algorithm satisfies items (i) and (ii) of Theorem 6.1. It remains to prove Lemmas 6.2 and 6.3.

Proof of Lemma 6.2. Fix an i and let X be any k-valid oracle. Let n be the smallest odd length such that $k \leq 2^n - 1$, $n-1 < 2^{n-1}$, and $2^{in} < 2^{2^n}$. Note first that we can assume that $k = 2^n - 1$. Otherwise, we claim that X can be extended to some (2^n-1)-valid oracle $X' \supseteq_k X$. Assume that X is $(m-1)$-valid for $k < m \leq 2^n - 1$; we will show how X can be extended to an m-valid oracle. This can be iterated to extend X to be (2^n-1)-valid.

Assume $m = 2^{2r} + r$ and consider some $\langle j,x,l\rangle$ of length r. (If m is not of this form, then, by property P1, an $(m-1)$-valid oracle is automatically an m-valid oracle.)

Note that $|x| \leq r$ and $|l| \leq r$. Hence, $NE_j^X(x)$ can ask only queries of length $\leq 2^r < m-1$. The answers to these queries will not change during the later stages of the construction. So the result of $NE_j^X(x)$ is fixed. If $NE_j^X(x)$ rejects within l steps, then choose some y of length 2^{2r} and put $\langle j,x,l\rangle y$ in X. Otherwise, do not put any such string in X. After all strings $\langle j,x,l\rangle$ are treated, we obtain an oracle X that is m-valid. This shows that we can assume X to be (2^n-1)-valid.

Also note that any string $w = \langle j,x,l\rangle y$ cannot have length 2^n. If $|w| = 2^n$, then, since $|y| = 2^{2|\langle j,x,l\rangle|}$, $|\langle j,x,l\rangle| < n/2$. Hence, the highest length possible for $\langle j,x,l\rangle$ is $(n-1)/2$, in which case $|y| = 2^{n-1}$ and $|w| = (n-1)/2 + 2^{n-2} < 2^n$. If $|\langle j,x,l\rangle|$ is even smaller, then y is of smaller length as well, and so is $|w|$. This shows that $|w|$ can never be 2^n for any n. As a consequence, we know that at stage $k+1$ we do not have to put any strings of the form $\langle j,x,l\rangle y$ into X. Therefore, we can use this stage for diagonalization.

Now we want to show that there exists an l-valid Y, $l \geq 2^n$, such that for every $Z \supseteq_l Y$, $A^Z \neq L(E_i^Z)$. Consider the computation of E_i^X on 0^n. Since the running time of E_i is bounded above by 2^{in}, the queries made by $E_i^X(0^n)$ have length at most 2^{in}. Let N be the set of queries of length $\geq 2^n$ (these are answered "no" in this computation). Note that $\|N\| \leq 2^{in} < 2^{2^n}$. We put some $v \in \Sigma^{2^n} - N$ in X if and only if $E_i^X(0^n)$ rejects. By the above discussion, $k = 2^n \neq 2^{2r} + r$ for any r, and so v cannot be of the form $\langle j,x,l\rangle y$. Therefore, X is 2^n-valid.

Claim 6.4. *We can extend X to some 2^{in}-valid $Y \supseteq_{2^n} X$ such that $N \subseteq \overline{Y}$.*

Proof. Fix some $\langle j,x,l\rangle$ such that $2^n < |\langle j,x,l\rangle y| \leq 2^{in}$. First we show that there are at least 2^{2^n} different such y for this $\langle j,x,l\rangle$. We show this by proving that $|y| \geq 2^n$. If $|y| < 2^n$, then, since length of y can only be a power of 2, let us assume that $y = 2^{n-1}$. Then $|\langle j,x,l\rangle| = (n-1)/2$, and therefore $|\langle j,x,l\rangle y| = (n-1)/2 + 2^{n-1} < 2^n$, contradicting that $|\langle j,x,l\rangle y| > 2^n$.

Now, simulate $NE_j^X(x)$ for l steps. If the simulation $NE_j^X(x)$ accepts within l steps, then do not update X. Otherwise, i.e., if the simulation rejects, then choose y' such that $|y'| = 2^{2|\langle j,x,l\rangle|}$ and $\langle j,x,l\rangle y' \notin N$. Put $\langle j,x,l\rangle y'$ in X. Existence of such y' is ensured, since the possible number of these words is 2^{2^n}, whereas $\|N\| \le 2^{in} < 2^{2^n}$.

So, if NE_j^X accepts x within l steps, no extra string is put in X. On the other hand, if $NE_j^X(x)$ does not accept within l steps, then we put an appropriate $\langle j,x,l\rangle y' \notin N$ in X. Once this procedure is completed for all $\langle j,x,l\rangle$, the oracle we obtain is 2^{in}-valid. We call that oracle Y. This proves Claim 6.4. □

The proof of the lemma is completed by noting that $Y \supseteq_{2^n} X$ and $Y \subseteq \overline{N}$. Hence, $0^n \in A^Y \Leftrightarrow 0^n \notin L(E_i^Y)$. Let $l = 2^{in}$ (which is the l Lemma 6.2 refers to). Any $Z \supseteq_{2^{in}} Y$ differs from Y only by strings of lengths $> 2^{in}$. This does not affect the computation of $E_i(0^n)$, and therefore, by our construction, it follows that $0^n \in A^Z \Leftrightarrow 0^n \notin L(E_i^Z)$. This proves Lemma 6.2. □

Proof of Lemma 6.3. Similar to the proof of Lemma 6.2, we can assume that $k = 2^{n+1} - 1$, where n is odd. Let $c \stackrel{df}{=} (2^{n+1})^{r(i+j)}$. We choose n to be large enough so that the following hold:

- $p_r(2^{n+1})p_i(p_r(2^{n+1}))(p_j(p_r(2^{n+1})) + 1) < 2^{2^n}$;
- $2(2^{n+1})^{2r(i+j)} < 2^{2^n}$, i.e., $2c^2 < 2^{2^n}$.

CLAIM 6.5. *There exist $Y' \subseteq \Sigma^{\le c}$, $N' \subseteq \Sigma^{\le c}$ such that $\|Y'\| \le c^2$, $\|N'\| \le c^2$, and for all $X' \subseteq \Sigma^{2^{n+1}}$, if $N' \subseteq \overline{X'}$, then $X \cup Y' \cup X'$ is c-valid.*

We will prove this claim later.

Choose some z such that $|z| = 2^n$ and for all y, $|y| = 2^n$, $zy \notin Y'$, and $zy \notin N'$. (Such a z exists because both $\|Y'\|, \|N'\| \le c^2$, and $2c^2 < 2^{2^n}$.) We can assume that

$$(\forall X' \subseteq z\Sigma^{2^n})[L(NM_i^{X\cup Y'\cup X'}) \cap L(NM_j^{X\cup Y'\cup X'}) \cap \Sigma^{\le p_r(2^{n+1})} = \emptyset]. \tag{8}$$

Otherwise $Y = X \cup Y' \cup X'$ satisfies the requirement of Lemma 6.3.

We will consider the computation of M_r on $0^{2^n}z$ and construct sets Q and X' such that $L(NM_i^{X\cup Y'\cup X'}) \cup Q$ is a separator of $L(NM_i^{X\cup Y'\cup X'})$ and $L(NM_j^{X\cup Y'\cup X'})$, and either

$$0^{2^n}z \in B^{X\cup Y'\cup X'} \quad \text{and} \quad 0^{2^n}z \notin L(M_r^{L(NM_i^{X\cup Y'\cup X'})\cup Q})$$

or

$$0^{2^n}z \notin B^{X\cup Y'\cup X'} \quad \text{and} \quad 0^{2^n}z \in L(M_r^{L(NM_i^{X\cup Y'\cup X'})\cup Q}).$$

This will imply that $B^{X\cup Y'\cup X'}$ does not $\le_T^{pp}$-reduce to $(L(NM_i^{X\cup Y'\cup X'}), L(NM_j^{X\cup Y'\cup X'}))$ via M_r. The details follow.

Initially we set $Q = \emptyset$. We run M_r on $0^{2^n}z$ using oracle $L(NM_i^{X\cup Y'}) \cup Q$. Note that this oracle is a separator of $(L(NM_i^{X\cup Y'}), L(NM_j^{X\cup Y'}))$. The simulation of M_r on $0^{2^n}z$ is continued until it makes some query q. At this point, we apply Lemma 3.3 with $M = NM_i$, $N = NM_j$, $Y = X \cup Y'$, and $T = z\Sigma^{2^n}$. Note that on input $0^{2^n}z$, M_r can make queries up to length $p_r(2^{n+1})$, and we have $\|T\| = 2^{2^n} > p_i(p_r(2^{n+1}))(p_j(p_r(2^{n+1})) + 1)$. By Lemma 3.3 and equation (8), there is a set $S' \subseteq z\Sigma^{2^n}$ such that either

$$(\forall S \subseteq z\Sigma^{2^n},\ S \cap S' = \emptyset)[q \notin L(NM_i^{X\cup Y'\cup S})] \tag{9}$$

or

$$(\forall S \subseteq z\Sigma^{2^n},\ S \cap S' = \emptyset)[q \notin L(NM_j^{X\cup Y'\cup S})]. \tag{10}$$

We know that $\|S'\| \leq p_i(p_r(2^{n+1}))(p_j(p_r(2^{n+1})) + 1)$. We reserve all strings in S' for $\overline{X'}$. If equation (9) is true, then we continue simulating M_r without modifying the oracle (hence, answer "no" to query q). Otherwise, if equation (9) does not hold, we update $Q = Q \cup \{q\}$ (hence, answer "yes" to query q and add q to the oracle) and continue the simulation of M_r on $0^{2^n}z$. We continue running M_r until the next query, and then we apply Lemma 3.3 again, obtain the set S' that satisfies above equation (9) or equation (10) for the new query and update Q accordingly. We keep doing this until the end of the computation of M_r on $0^{2^n}z$. The number of strings in $z\Sigma^{2^n}$ we reserved for $\overline{X'}$ during the above process is at most $p_r(2^{n+1})p_i(p_r(2^{n+1}))(p_j(p_r(2^{n+1})) + 1) < 2^{2^n}$ since the running time of M_r on $0^{2^n}z$ is bounded by $p_r(2^{n+1})$.

Since the number of strings reserved for $\overline{X'}$ in the above process is strictly less than the number of strings of length 2^n, there exists a string zy in $z\Sigma^{2^n}$ that is not reserved for $\overline{X'}$. If M_r using oracle $L(NM_i^{X\cup Y'}) \cup Q$ accepts $0^{2^n}z$, we define $X' = \emptyset$. In this case, $0^{2^n}z \notin B^{X\cup Y'\cup X'}$. Otherwise, define $X' = \{zy\}$, in which case $0^{2^n}z \in B^{X\cup Y'\cup X'}$. Also observe that q is put in Q only when $q \notin L(NM_j^{X\cup Y'\cup X'})$. Therefore, $L(NM_i^{X\cup Y'\cup X'}) \cup Q$ remains a separator of $L(NM_i^{X\cup Y'\cup X'})$ and $L(NM_j^{X\cup Y'\cup X'})$.

Let $Y \stackrel{df}{=} X \cup Y' \cup X'$. It is clear from the discussion above that B^Y does not $\leq_T^{pp}$-reduce to $L(NM_i^Y, NM_j^Y)$ via M_r. Since $X' \subseteq \overline{N'}$, Y is $c = (2^{n+1})^{r(i+j)}$-valid. Furthermore, any string q that can be queried by M_r on $0^{2^n}z$ is of length $\leq (2^{n+1})^r$. Therefore, the strings that are queried by NM_i and NM_j on input q are of lengths at most $(2^{n+1})^{r(i+j)} = c$. This implies that for all $Z \supseteq_c Y$, B^Z does not $\leq_T^{pp}$-reduce to $(L(NM_i^Z), L(NM_j^Z))$ via M_r, since any string of length more than c will not affect the outcome of the computation. It remains to prove Claim 6.5.

Proof of Claim 6.5. We use the following algorithm to construct Y' and N'. Recall that $c = (2^{n+1})^{r(i+j)}$.

```
1.   Y' = ∅, N' = ∅
2.   Treated = ∅
3.   L = {⟨i,x,l⟩ | 2^{n+1} < |⟨i,x,l⟩y| ≤ c where |y| = 2^{2|⟨i,x,l⟩|}}
4.   while L ≠ ∅ {
5.      Remove the smallest ⟨i,x,l⟩ from L
6.      Treated = Treated ∪ {⟨i,x,l⟩}
7.      if (∃X' ⊆ Σ^{2^{n+1}} such that X' ⊆ N̄' and
                    NE_i^{X∪Y'∪X'}(x) accepts within l steps)
8.         Choose an accepting path P
9.         Y' = Y' ∪ P^yes and N' = N' ∪ P^no
        else
10.        Choose some y ∈ Σ^{2|⟨i,x,l⟩|} such that ⟨i,x,l⟩y ∉ N'
11.        Y' = Y' ∪ {⟨i,x,l⟩y}
12.  } //end while.
```

We claim that after each iteration of the *while* loop, the following invariance holds: For every $X' \subseteq \overline{N'} \cap \Sigma^{2^{n+1}}$, property P1 holds for each $\langle i, x, l\rangle$ in `Treated` with oracle $X \cup Y' \cup X'$. Initially, when `Treated` is empty, this holds trivially.

Let us assume that $\langle i, x, l\rangle$ is put in `Treated` during iteration $m \geq 1$ of the while loop. It is straightforward to see that after this iteration, the statements in the loop ensure that the invariance holds for $\langle i, x, l\rangle$, since $\langle i, x, l\rangle y$ is put into the oracle if and only if NE_i does not accept x within l steps. We have to show that the invariance also holds for every such triple that had been put into `Treated` in some iteration $m' < m$. Let $\langle j, u, t\rangle$ be such a triple. It suffices to show that for t steps, $NE_j(u)$ behaves the

same way after the mth iteration as it does after the m'th iteration. Assume that during the m'th iteration NE_j accepted u in t steps. All the queries that are made on that accepting path are already in Y' or N' accordingly. Therefore, that path remains accepting even during the mth iteration.

On the other hand, let us assume that for every X', NE_j rejected u in t steps during the m'th iteration. We will show that it will still reject u after the mth iteration. To see this, let us assume that a previously rejecting path has become an accepting path after the mth iteration. A query that was answered "yes" at that point cannot be answered "no" now, since Y' now contains strictly more strings. So assume that the queries $q_1, \ldots, q_d$ were answered "no" during the m'th iteration with $X \cup Y' \cup X'$ as the oracle and are now answered "yes." All strings that are added to Y' after iteration m' are either of lengths $\geq |\langle j, u, t\rangle y| > t$ or are from some $X' \subseteq \Sigma^{2^{n+1}}$. Hence $q_1, \ldots, q_d$ must be of length 2^{n+1}. Note that at least one of these queries must have been in N' during the m'th iteration; otherwise NE_j would accept u at that point with oracle $X \cup Y' \cup (X' \cup \{q_1, \ldots, q_d\})$. But any string that was in N' during an earlier iteration is not put in X' or Y' in later iterations. Therefore, our assumption is false, and NE_j will reject u during the mth iteration as well. This proves the invariance.

What remains to show are the bounds on the sizes of Y' and N' and the maximum length of strings in Y' and N'. For the size of Y' and N', note that if $|\langle i, x, l\rangle y| \leq c$, then, since $|y| = 2^{2|\langle i,x,l\rangle|}$, $|\langle i, x, l\rangle| \leq (\log c)/2$, and therefore $\|\mathcal{L}\| \leq 2^{(\log c)/2+1} < c$. On the other hand, during every iteration, at most l strings are added to Y' and N', and $|l| < |\langle i, x, l\rangle| \leq (\log c)/2$, and therefore $l < c$ as well. Since both Y' and N' are initially empty, they are at most c^2 in size. The maximum length of strings in Y' and N' is c since the longest string that is added to Y' or N' is $\max_{\langle i,x,l\rangle \in \mathcal{L}} |\langle i, x, l\rangle y| \leq c$.

This completes the proof of Claim 6.5. □

This finishes the proof of Lemma 6.3. □

This proves Theorem 6.1. □

COROLLARY 6.6. *The oracle O_1 of Theorem* 6.1 *has the following additional properties:*

(i) $\mathrm{UP}^{O_1} \neq \mathrm{NP}^{O_1} \neq \mathrm{coNP}^{O_1}$ *and* $\mathrm{NPMV}^{O_1} \not\subseteq_c \mathrm{NPSV}^{O_1}$.

(ii) *Relative to O_1, optimal propositional proof systems exist.*

(iii) *There exists a $\leq_{sm}^{pp,O_1}$-complete disjoint NP^{O_1}-pair (A, B) that is P^{O_1}-inseparable but symmetric.*

6.3. Nonexistence of optimal proof systems. In this section we construct an oracle relative to which there exist $\leq_{sm}^{pp}$-complete disjoint NP-pairs. For any oracle X, $(A, B) \leq_{sm}^{pp,X} (C, D)$ if there is a function $f \in \mathrm{PF}^X$ such that $f(A) \subseteq C$, $f(B) \subseteq D$, and $f(\overline{A \cup B}) \subseteq \overline{C \cup D}$.[3]

THEOREM 6.7. *There exists an oracle O_2 relative to which the following holds:*

(i) *There exist $\leq_{sm}^{pp}$-complete disjoint* NP*-pairs.*

(ii) *There exist nonsymmetric disjoint* NP*-pairs.*

(iii) $\mathrm{NP} \cap \mathrm{SPARSE}$ *does not have $\leq_m^p$-complete sets.*

(iv) *Conjecture* 2.4 *holds.*

[3] $(A, B) \leq_m^{pp,X} (C, D)$ if for every separator $T \in Sep(C, D)$, there exists a separator $S \in Sep(A, B)$ such that $S \leq_m^{p,X} T$. However, since Theorems 2.10 and 2.14 hold relative to all oracles, $(A, B) \leq_m^{pp,X} (C, D)$ if and only if there is a function $f \in \mathrm{PF}^X$ such that $f(A) \subseteq C$ and $f(B) \subseteq D$. It follows immediately that $(A, B) \leq_{sm}^{pp,X} (C, D)$ implies $(A, B) \leq_m^{pp,X} (C, D)$.

Proof. In our construction we use the following witness languages, which depend on an oracle Z:

$$A(Z) \stackrel{df}{=} \{w \mid w = 0^n 10^t 1x \text{ for } n,t \geq 1,\ x \in \Sigma^* \text{ and } (\exists y \in \Sigma^{3|w|+3})[0wy \in Z]\},$$
$$B(Z) \stackrel{df}{=} \{w \mid w = 0^n 10^t 1x \text{ for } n,t \geq 1,\ x \in \Sigma^* \text{ and } (\exists y \in \Sigma^{3|w|+3})[1wy \in Z]\},$$
$$C(Z) \stackrel{df}{=} \{0^k \mid k \equiv 1 \pmod 4,\ (\exists y \in \Sigma^{k-1})[0y \in Z]\},$$
$$D(Z) \stackrel{df}{=} \{0^k \mid k \equiv 1 \pmod 4,\ (\exists y \in \Sigma^{k-1})[1y \in Z]\},$$
$$E_i(Z) \stackrel{df}{=} \{0^i 1x \mid |0^i 1x| \equiv 1 \pmod 4 \text{ and } (\exists y \in \Sigma^*,\ |y| = |0^i 1x|)[0^i 1xy \in Z]\} \quad \text{for } i \geq 1,$$
$$F(Z) \stackrel{df}{=} \{0^k \mid k \equiv 3 \pmod 4,\ (\exists y \in \Sigma^k)[y \in Z]\}.$$

These languages are in NP^Z. By definition, $A(Z)$ and $B(Z)$ depend on oracle words of length $\equiv 0 \pmod 4$, $C(Z)$ and $D(Z)$ depend on oracle words of length $\equiv 1 \pmod 4$, all $E_i(Z)$ depend on oracle words of length $\equiv 2 \pmod 4$, and $F(Z)$ depends on oracle words of length $\equiv 3 \pmod 4$. We construct the oracle O_2 such that $A(O_2) \cap B(O_2) = C(O_2) \cap D(O_2) = \emptyset$ and the following holds:

- $(A(O_2), B(O_2))$ is $\leq^{pp}_{sm}$-complete. That is,

$$\begin{aligned}&(\forall (G,H) \in \mathrm{DisjNP}^{O_2})(\exists f \in \mathrm{PF})\\ &[f(G) \subseteq A(O_2) \wedge f(H) \subseteq B(O_2) \wedge f(\overline{G \cup H}) \subseteq \overline{A(O_2) \cup B(O_2)}].\end{aligned} \tag{11}$$

- $(C(O_2), D(O_2))$ is nonsymmetric. That is,

$$(\forall f \in \mathrm{PF}^{O_2})[f(C(O_2)) \not\subseteq D(O_2) \vee f(D(O_2)) \not\subseteq C(O_2)]. \tag{12}$$

- $\mathrm{NP}^{O_2} \cap \mathrm{SPARSE}$ does not have $\leq^{p,O_2}_m$-complete sets. That is,

$$\begin{aligned}&(\forall j,\ L(NM_j^{O_2}) \in \mathrm{SPARSE}_j)(\exists n,\ E_n(O_2) \text{ contains } \leq 2 \text{ words of every length})\\ &(\forall f \in \mathrm{PF}^{O_2})[E_n(O_2) \text{ does not } \leq^{p,O_2}_m\text{-reduce to } L(NM_j^{O_2}) \text{ via } f].\end{aligned} \tag{13}$$

- $F(O_2) \not\leq^{pp,O_2}_T (A(O_2), B(O_2))$. That is,

$$(\exists S,\ A(O_2) \subseteq S \subseteq \overline{B(O_2)})[F(O_2) \notin \mathrm{P}^S]. \tag{14}$$

In (11) and (14) we really mean $f \in \mathrm{PF}$ and $F(O_2) \notin \mathrm{P}^S$; we explain why this is equivalent to $f \in \mathrm{PF}^{O_2}$ and $F(O_2) \notin \mathrm{P}^{S,O_2}$. We have to see that expressions (11), (12), (13), and (14) imply statements (i), (ii), (iii), and (iv) of Theorem 6.7. For (11) and (12) this follows from the fact that $f \in \mathrm{PF}$ implies $f \in \mathrm{PF}^{O_2}$. Each language in NP is accepted by infinitely many machines NM_j. Therefore, if there exists a sparse language L such that L is many-one-complete for $\mathrm{NP}^{O_2} \cap \mathrm{SPARSE}$, then there exists a $j \geq 1$ such that $L = L(NM_j^{O_2})$ and $L \in \mathrm{SPARSE}_j$. This shows that expression (13) implies (iii). In (14) we actually should have $F(O_2) \notin \mathrm{P}^{S,O_2}$ since the reducing machine has access to the oracle O_2. However, since (i) holds and since $(O_2, \overline{O_2}) \in \mathrm{DisjNP}^{O_2}$, there exists an $f \in \mathrm{PF}$ with $f(O_2) \subseteq A(O_2) \subseteq S$ and $f(\overline{O_2}) \subseteq B(O_2) \subseteq \overline{S}$. Hence, $q \in O_2 \Leftrightarrow f(q) \in S$. So we can transform queries to O_2 into queries to S; i.e., it suffices to show $F(O_2) \notin \mathrm{P}^S$. By expression (14), the complete pair $(A(O_2), B(O_2))$ is not NP^{O_2}-hard; it follows that no disjoint NP^{O_2}-pair is NP^{O_2}-hard.

We define the following list $\mathcal{T}$ of requirements. At the beginning of the construction, $\mathcal{T}$ contains all pairs (i,n) with $i \in \{1,2,3,4\}$ and $n \in \mathbb{N}^+$. These pairs have the following interpretations, which correspond to statements (i)–(iv) of Theorem 6.7:

- $(1, \langle i, j\rangle)$: ensure

$$L(NM_i^{O_2}) \cap L(NM_j^{O_2}) \neq \emptyset$$

or

$$(L(NM_i^{O_2}), L(NM_j^{O_2})) \leq_{sm}^{pp} (A(O_2), B(O_2)).$$

- $(2, i)$: ensure that there exists some n such that $[0^n \in C(O_2) \wedge T_i^{O_2}(0^n) \notin D(O_2)]$ or $[0^n \in D(O_2) \wedge T_i^{O_2}(0^n) \notin C(O_2)]$.
- $(3, \langle i, j\rangle)$: ensure either $L(NM_j^{O_2}) \notin \mathrm{SPARSE}_j$ or [for some n, $E_n(O_2)$ contains ≤ 2 words of every length, and $E_n(O_2)$ does not $\leq_m^{p,O_2}$-reduce to $L(NM_j^{O_2})$ via $f_i^{O_2}$] (in the construction, n does not depend on i; i.e., $(3, \langle i, j\rangle)$ and $(3, \langle i', j\rangle)$ use the same n).
- $(4, i)$: ensure that $(A(O_2), B(O_2))$ has a separator S such that $0^n \in F(O_2) \Leftrightarrow 0^n \notin L(M_i^S)$.

Once a requirement is satisfied, we delete it from the list. Conditions of the form $(2, \cdot)$ and $(4, \cdot)$ are reachable by the construction of one counterexample. In contrast, if we cannot reach $L(NM_i^{O_2}) \cap L(NM_j^{O_2}) \neq \emptyset$ for a condition of the first type, then we have to ensure $(L(NM_i^{O_2}), L(NM_j^{O_2})) \leq_{sm}^{pp} (A(O_2), B(O_2))$. Similarly, if we cannot reach $L(NM_j^{O_2}) \notin \mathrm{SPARSE}_j$ for a condition of the third type, then, for a suitable n, we have to ensure that $E_n(O_2)$ contains ≤ 2 words of every length. But these conditions cannot be reached by a finite segment of an oracle; instead they influence the whole remaining construction of the oracle. We have to encode answers to queries of the form "does x belong to $L(NM_i^{O_2})$ or to $L(NM_j^{O_2})$" into the oracle O_2, and we have to keep an eye on the number of elements of $E_n(O_2)$. For this reason we introduce the notion of (μ, k)-valid oracles. Here k is a natural number and μ is an injective, partial function $\mathbb{N}^+ \to \mathbb{N} \times \mathbb{N}^+$ that has a finite domain. Each (μ, k)-valid oracle is a subset of $\Sigma^{\leq k}$. If a pair $(0, j)$, $j \geq 1$, is in the range of μ, then this means that $L(NM_j^{O_2}) \in \mathrm{SPARSE}_j$ is forced, and therefore we must construct O_2 so that for a suitable n, $E_n(O_2)$ contains ≤ 2 words of every length. If a pair (i, j), $i, j \geq 1$, is in the range of μ, then $L(NM_i^{O_2}) \cap L(NM_j^{O_2}) = \emptyset$ is forced, and therefore we must construct O_2 so that $(L(NM_i^{O_2}), L(NM_j^{O_2})) \leq_{sm}^{pp} (A(O_2), B(O_2))$ holds. For the latter condition we have to encode certain information into O_2, and the number k says up to which level this encoding has been done. So (μ, k)-valid oracles should be considered as finite prefixes of oracles that contain these encodings. For the moment we postpone the formal definition of (μ, k)-valid oracles (Definition 6.9); instead we mention its essential properties, which we will prove later.

(a) The oracle $\emptyset$ is $(\emptyset, 0)$-valid.
(b) If X is a finite oracle that is (μ, k)-valid, then for all $\mu' \preceq \mu$, X is (μ', k)-valid.
(c) If O_2 is an oracle such that for some μ, ${O_2}^{\leq k}$ is (μ, k)-valid for infinitely many k, then the following hold:
   - $A(O_2) \cap B(O_2) = C(O_2) \cap D(O_2) = \emptyset$.
   - For all $(i, j) \in \mathrm{range}(\mu)$, if $i > 0$, then

$$(L(NM_i^{O_2}), L(NM_j^{O_2})) \leq_{sm}^{pp} (A(O_2), B(O_2))$$

     via some $f \in \mathrm{PF}$.
   - For all $(n, 0, j) \in \mu$ it holds that $E_n(O_2)$ contains ≤ 2 words of every length and $L(NM_j^{O_2}) \in \mathrm{SPARSE}_j$.

Properties (a), (b), and (c) will be proved later in Propositions 6.10 and 6.11. Moreover, we will prove the following for all $i, j \geq 1$ and all (μ, k)-valid X. (Note that there is a correspondence between (i)–(iv) and P1–P4.)

P1: There exists an $l > k$ and a (μ', l)-valid $Y \supseteq_k X$, $\mu \preceq \mu'$ such that
- either for all $Z \supseteq_l Y$, $L(NM_i^Z) \cap L(NM_j^Z) \neq \emptyset$, or
- $(i, j) \in \text{range}(\mu')$.[4]

P2: There exists an $l > k$ and a (μ, l)-valid $Y \supseteq_k X$ such that for all $Z \supseteq_l Y$, if $C(Z) \cap D(Z) = \emptyset$, then $(C(Z), D(Z))$ does not $\leq_m^{pp,O_2}$-reduce to $(D(Z), C(Z))$ via T_i^Z.

P3: (a) There exists an $l > k$ and a (μ', l)-valid $Y \supseteq_k X$, $\mu \preceq \mu'$, such that
- either for all $Z \supseteq_l Y$, $L(NM_j^Z) \notin \text{SPARSE}_j$, or
- $(0, j) \in \text{range}(\mu')$.

(b) For every n, if $\mu(n) = (0, j)$, then there exists an $l > k$ and a (μ, l)-valid $Y \supseteq_k X$ such that for all $Z \supseteq_l Y$, $E_n(Z)$ does not $\leq_m^{p,Z}$-reduce to $L(NM_j^Z)$ via f_i^Z.

P4: There exists an $l > k$ and a (μ, l)-valid $Y \supseteq_k X$ such that for all $Z \supseteq_l Y$, if $A(Z) \cap B(Z) = \emptyset$, then there exists a separator S of $(A(Z), B(Z))$ such that $F(Z) \neq L(M_i^S)$.

We will prove properties P1, P2, P3(a), P3(b), and P4 in Propositions 6.21, 6.22, 6.23, 6.25, and 6.32, respectively.

We construct an ascending sequence of finite oracles $X_0 \subseteq_{k_0} X_1 \subseteq_{k_1} X_2 \subseteq_{k_2} \cdots$ such that each X_r is (μ_r, k_r)-valid, $k_0 < k_1 < k_2 < \cdots$, and $\mu_0 \preceq \mu_1 \preceq \mu_2 \preceq \cdots$. By definition, $O_2 = \bigcup_{r \geq 0} X_r$. By items (b) and (c), $A(O_2) \cap B(O_2) = C(O_2) \cap D(O_2) = \emptyset$ follows immediately. Note that for each $r \geq 0$ and $i \geq 1$ it holds that $X_{r+i} \supseteq_{k_r} X_r$ and $\mu_r \preceq \mu_{r+i}$.

1. $r := 0$, $k_r := 0$, $\mu_r := \emptyset$, and $X_r := \emptyset$. Then by (a), X_r is (μ_r, k_r)-valid.
2. Let e be the next requirement on $\mathcal{T}$.
   (a) If $e = (1, \langle i, j \rangle)$, then we apply property P1 to X_r. Define $k_{r+1} = l$, $\mu_{r+1} = \mu'$, and $X_{r+1} = Y$. Then $k_r < k_{r+1}$, $\mu_r \preceq \mu_{r+1}$, and $X_{r+1} \supseteq_{k_r} X_r$ is (μ_{r+1}, k_{r+1})-valid such that
   - either for all $Z \supseteq_{k_{r+1}} X_{r+1}$, $L(NM_i^Z) \cap L(NM_j^Z) \neq \emptyset$, or
   - $(i, j) \in \text{range}(\mu_{r+1})$.

   Remove e from $\mathcal{T}$ and go to step 3.

   Comment: If the former holds, then, since $O_2 \supseteq_{k_{r+1}} X_{r+1}$, it holds that $L(NM_i^{O_2}) \cap L(NM_j^{O_2}) \neq \emptyset$, and therefore $(L(NM_i^{O_2}), L(NM_j^{O_2})) \notin \text{DisjNP}^{O_2}$. Otherwise, $(i, j) \in \text{range}(\mu_{r+1})$. By (b), for all $i \geq 1$, X_{r+i} is (μ_{r+1}, k_{r+i})-valid. Therefore, by (c), $(L(NM_i^{O_2}), L(NM_j^{O_2})) \leq_{sm}^{pp} (A(O_2), B(O_2))$ via some $f \in \text{PF}$.

   (b) If $e = (2, i)$, then $\mu_{r+1} \stackrel{df}{=} \mu_r$ and apply property P2 to X_r. We define $k_{r+1} = l$ and $X_{r+1} = Y$. Then $k_{r+1} > k_r$ and $X_{r+1} \supseteq_{k_r} X_r$ is (μ_{r+1}, k_{r+1})-valid so that for all $Z \supseteq_{k_{r+1}} X_{r+1}$, if $C(Z) \cap D(Z) = \emptyset$, then $(C(Z), D(Z))$ does not $\leq_m^{pp,O_2}$-reduce to $(D(Z), C(Z))$ via T_i^Z. Remove e from $\mathcal{T}$ and go to step 3.

   Comment: Since $O_2 \supseteq_{k_{r+1}} X_{r+1}$ and $C(O_2) \cap D(O_2) = \emptyset$, this ensures that $(C(O_2), D(O_2))$ does not $\leq_m^{pp,O_2}$-reduce to $(D(O_2), C(O_2))$ via $T_i^{O_2}$.

   (c) If $e = (3, \langle i, j \rangle)$ and $(0, j) \notin \text{range}(\mu_r)$, then we apply property P3(a) to X_r. Define $k_{r+1} = l$, $\mu_{r+1} = \mu'$, and $X_{r+1} = Y$. Then $k_r < k_{r+1}$, $\mu_r \preceq \mu_{r+1}$, and $X_{r+1} \supseteq_{k_r} X_r$ is (μ_{r+1}, k_{r+1})-valid such that
   - either for all $Z \supseteq_{k_{r+1}} X_{r+1}$, $L(NM_j^Z) \notin \text{SPARSE}_j$, or

[4] Proposition 6.21 says $L(NM_i^Z) \cap L(NM_j^Z) \cap \Sigma^{\leq l} \neq \emptyset$, which is a stronger statement.

- $(0, j) \in \text{range}(\mu_{r+1})$.

If the former holds, then remove e from $\mathcal{T}$ and go to step 3. Otherwise, do not remove e from $\mathcal{T}$ (it will be removed in the next iteration) and go to step 3.

Comment: If the former of the two alternatives holds, then, since $O_2 \supseteq_{k_{r+1}} X_{r+1}$, it holds that $L(NM_j^{O_2}) \notin \text{SPARSE}_j$. Otherwise, for a suitable n, $(n, 0, j) \in \mu_{r+1}$. By (b), for all $i \geq 1$, X_{r+i} is (μ_{r+1}, k_{r+i})-valid. Therefore, by (c), it is enforced that $E_n(O_2)$ contains ≤ 2 words of every length and $L(NM_j^{O_2}) \in \text{SPARSE}_j$. From now on, all requirements of the form $(3, \langle \cdot, j \rangle)$ are treated in step 2(d). These steps will make sure that $E_n(O_2) \not\leq_m^{p,O_2} L(NM_j^{O_2})$.

(d) If $e = (3, \langle i, j \rangle)$ and $(0, j) \in \text{range}(\mu_r)$, then choose n such that $(n, 0, j) \in \mu_r$ and apply property P3(b) to X_r. Define $k_{r+1} = l$, $\mu_{r+1} = \mu_r$, and $X_{r+1} = Y$. Then $k_r < k_{r+1}$, $\mu_r \preceq \mu_{r+1}$, and $X_{r+1} \supseteq_{k_r} X_r$ is (μ_{r+1}, k_{r+1})-valid such that for all $Z \supseteq_{k_{r+1}} X_{r+1}$, $E_n(Z)$ does not $\leq_m^{p,Z}$-reduce to $L(NM_j^Z)$ via f_i^Z. Remove e from $\mathcal{T}$ and go to step 3.

Comment: In the comment of the previous step we have seen that $(0, j) \in \text{range}(\mu_r)$ implies that $E_n(O_2) \in \text{SPARSE}_{j+1}$. Since $O_2 \supseteq_{k_{r+1}} X_{r+1}$ this step ensures that $E_n(O_2)$ does not $\leq_m^{p,O_2}$-reduce to $L(NM_j^{O_2})$ via $f_i^{O_2}$.

(e) If $e = (4, i)$, then $\mu_{r+1} \stackrel{df}{=} \mu_r$ and apply property P4 to X_r. We define $k_{r+1} = l$ and $X_{r+1} = Y$. Then $k_{r+1} > k_r$ and $X_{r+1} \supseteq_{k_r} X_r$ is (μ_{r+1}, k_{r+1})-valid such that for all $Z \supseteq_{k_{r+1}} X_{r+1}$, if $A(Z) \cap B(Z) = \emptyset$, then there exists a separator S of $(A(Z), B(Z))$ such that $F(Z) \neq L(M_i^S)$. Remove e from $\mathcal{T}$ and go to step 3.

Comment: Since $O_2 \supseteq_{k_{r+1}} X_{r+1}$ and $A(O_2) \cap B(O_2) = \emptyset$, this ensures that there exists a separator S of $(A(O_2), B(O_2))$ such that $F(O_2) \neq L(M_i^S)$.

3. $r := r + 1$, go to step 2.

We see that this construction ensures (i), (ii), (iii), and (iv). This proves Theorem 6.7 except to show that we can define an appropriate notion of a (μ, k)-valid oracle that has properties (a), (b), (c) and P1, P2, P3, P4.

We want to construct our oracle such that $(A(O_2), B(O_2))$ is a $\leq_{sm}^{pp}$-complete disjoint NP^{O_2}-pair. So we have to make sure that pairs $(L(NM_i), L(NM_j))$ that are enforced to be disjoint (which means that $(i, j) \in \text{range}(\mu)$) can be $\leq_{sm}^{pp}$-reduced to $(A(O_2), B(O_2))$. Therefore, we put certain codewords into O_2 if and only if the computation $NM_i^{O_2}(x)$ (resp., $NM_j^{O_2}(x)$) accepts within t steps.

DEFINITION 6.8 (μ-codeword). *Let $\mu : \mathbb{N}^+ \to \mathbb{N} \times \mathbb{N}^+$ be an injective, partial function with a finite domain. A word w is called a* μ-codeword *if $w = 00^n10^t1xy$ or $w = 10^n10^t1xy$ such that $n, t \geq 1$, $|y| = 3|00^n10^t1x|$, and $\mu(n) = (i, j)$ such that $i, j \geq 1$. If $w = 00^n10^t1xy$, then we say that w is a μ-codeword for (i, t, x); if $w = 10^n10^t1xy$, then we say it is a μ-codeword for (j, t, x).*

Condition (i) of Theorem 6.7 opposes conditions (ii), (iii), and (iv), because for (i) we have to encode information about NP^{O_2} computations into O_2, and (ii), (iii), and (iv) say that we cannot encode too much information (e.g., enough information for $\text{UP}^{O_2} = \text{NP}^{O_2}$). For this reason we have to look at certain finite oracles that contain the needed information for (i) and that allow all diagonalization needed to reach (ii), (iii), and (iv). We call such oracles (μ, k)-valid.

DEFINITION 6.9 ((μ, k)-valid oracle). *Let $k \geq 0$ and let $\mu : \mathbb{N}^+ \to \mathbb{N} \times \mathbb{N}^+$ be an injective, partial function with a finite domain. We define a finite oracle X to be (μ, k)-valid by induction over the size of the domain of μ.*

(IB) *If $\|\mu\| = 0$, then X is (μ, k)-valid $\stackrel{df}{\iff}$ $X \subseteq \Sigma^{\leq k}$ and $A(X) \cap B(X) = C(X) \cap D(X) = \emptyset$.*

(IS) *If* $\|\mu\| > 0$, *then* $\mu = \mu_0 \cup \{(n_0, i_0, j_0)\}$, *where* $n_0 = \mu_{\max}$ *and* $\mu_0 \prec \mu$. X *is* (μ, k)*-valid* $\overset{df}{\iff}$ $k \geq n_0$, X *is* (μ_0, k)*-valid, and the following holds:*

1. *If* $i_0 > 0$, *then we demand the following:*
   (a) *For all* $t \geq 1$ *and all* $x \in \Sigma^*$, *if* $4 \cdot |00^{n_0}10^t1x| \leq k$, *then*
      (i) $(\exists y,\ |y| = 3|00^{n_0}10^t1x|)[00^{n_0}10^t1xy \in X] \Leftrightarrow NM_{i_0}^X(x)$ *accepts within* t *steps, and*
      (ii) $(\exists y,\ |y| = 3|10^{n_0}10^t1x|)[10^{n_0}10^t1xy \in X] \Leftrightarrow NM_{j_0}^X(x)$ *accepts within* t *steps.*
   (b) *For all* $l \geq n_0$ *and all* (μ_0, l)*-valid* Y, *if* $Y^{\leq n_0} = X^{\leq n_0}$, *then* $L(NM_{i_0}^Y) \cap L(NM_{j_0}^Y) \cap \Sigma^{\leq l} = \emptyset$.
2. *If* $i_0 = 0$, *then*
   (a) *for every* $r \geq 0$, $\|E_{n_0}(X) \cap \Sigma^r\| \leq 2$, *and*
   (b) *for all* $l \geq n_0$ *and all* (μ_0, l)*-valid* Y, *if* $Y^{\leq n_0} = X^{\leq n_0}$, *then* $L(NM_{j_0}^Y) \cap \Sigma^{\leq l} \in \mathrm{SPARSE}_{j_0}$.

Due to conditions 1(b) and 2(b), (μ, k)-valid oracles can be extended to (μ, k')-valid oracles with $k' > k$ (Lemma 6.17). There we really need the intersection with $\Sigma^{\leq l}$. Otherwise—for example, in 1(b)—it could be possible that for a small oracle $Y \subseteq \Sigma^{\leq l}$ both machines accept the same word w that is much longer than l, but there is no way to extend Y in a valid way to the level $|w|$ such that both machines still accept w (the reason is that the reservations (Definition 6.12) become too large).

Proposition 6.10 (basic properties of validity).

1. *The oracle* $\emptyset$ *is* $(\emptyset, 0)$*-valid (property* (a)*).*
2. *For every* (μ, k)*-valid* X *and every* $\mu' \preceq \mu$, X *is* (μ', k)*-valid (property* (b)*).*
3. *For every* (μ, k)*-valid* X *and every* $(n, 0, j) \in \mu$, *it holds that*
   (a) *for every* $r \geq 0$, $\|E_n(X) \cap \Sigma^r\| \leq 2$, *and*
   (b) $L(NM_j^X) \cap \Sigma^{\leq k} \in \mathrm{SPARSE}_j$.
4. *Let* X *be* (μ, k)*-valid and* $S \subseteq \Sigma^{k+1}$ *such that* $k + 1 \not\equiv 0 \pmod 4$, $C(S) \cap D(S) = \emptyset$, *and for all* $(n, 0, j) \in \mu$ *it holds that* $\|E_n(S)\| \leq 2$. *Then* $X \cup S$ *is* $(\mu, k+1)$*-valid.*
5. *For every* (μ, k)*-valid* X *and every* $(i, j) \in \mathrm{range}(\mu)$, $i > 0$, *it holds that* $L(NM_i^X) \cap L(NM_j^X) \cap \Sigma^{\leq k} = \emptyset$.
6. *If* X *is* (μ, k)*-valid, then for every* k', $\mu_{\max} \leq k' \leq k$ *(resp.,* $0 \leq k' \leq k$ *if* $\mu = \emptyset$*), it holds that* $X^{\leq k'}$ *is* (μ, k')*-valid.*

Proof. Statements 6.10.1 and 6.10.2 follow immediately from Definition 6.9.

Let X be (μ, k)-valid and let $(n, 0, j) \in \mu$. Let $n_0 \overset{df}{=} n$, $i_0 \overset{df}{=} 0$, $j_0 \overset{df}{=} j$, and $\mu_0 \overset{df}{=} \{(n', i', j') \in \mu \mid n' < n\}$. By 6.10.2, X is $(\mu_0 \cup \{(n_0, i_0, j_0)\}, k)$-valid and also (μ_0, k)-valid. From 6.9.2(a) it follows that 6.10.3(a) holds. From 6.9.2(b) (for $l = k$ and $Y = X$) we obtain $L(NM_{j_0}^X) \cap \Sigma^{\leq k} \in \mathrm{SPARSE}_{j_0}$. This shows 6.10.3(b).

We prove statement 6.10.4 by induction on $\|\mu\|$. First of all we see that $A(S) = B(S) = \emptyset$, since S contains no words of length $\equiv 0 \pmod 4$. If $\|\mu\| = 0$, then, by Definition 6.9, $X \cup S$ is $(\mu, k+1)$-valid. So assume $\|\mu\| > 0$ and choose μ_0, n_0, i_0, j_0 as in Definition 6.9. We assume as an induction hypothesis that if X is (μ_0, k)-valid, then $X \cup S$ is $(\mu_0, k+1)$-valid. We verify Definition 6.9 for $X \cup S$ and $k+1$. Clearly, $k + 1 > k \geq n_0$. Since X is (μ, k)-valid it is also (μ_0, k)-valid. By the induction hypothesis we obtain that $X \cup S$ is $(\mu_0, k+1)$-valid.

Assume that $i_0 > 0$; we verify item 1 of Definition 6.9. Since $k + 1 \not\equiv 0 \pmod 4$, the condition $4 \cdot |00^{n_0}10^t1x| \leq k + 1$ is equivalent to $4 \cdot |00^{n_0}10^t1x| \leq k$. Since $t < k$, the computations mentioned in 6.9.1(a) cannot ask queries longer than k. So nothing changes when these machines use oracle X instead of $X \cup S$. Moreover, at the left-

hand sides in 6.9.1(a), we can also use X instead of $X \cup S$ since we only test the membership for words of length $\equiv 0 \pmod 4$. This shows that in 6.9.1(a) we can replace every occurrence of $X \cup S$ with X and obtain an equivalent condition. This condition holds since X is (μ, k)-valid. Therefore, 6.9.1(a) holds for $X \cup S$ and $k+1$. Condition 6.9.1(b) holds for $X \cup S$ and $k+1$, since this condition does not depend on k and since $(X \cup S) \cap \Sigma^{\leq k} = X^{\leq k}$.

Assume that $i_0 = 0$; we verify item 2 of Definition 6.9. By assumption, $\|E_{n_0}(S)\| \leq 2$ and (since X is (μ, k)-valid) for all $r \geq 0$, it holds that $\|E_{n_0}(X) \cap \Sigma^r\| \leq 2$. Words in $E_{n_0}(X)$ are of length $\leq \lfloor k/2 \rfloor$. In contrast, words in $E_{n_0}(S)$ are of length $\lceil (k+1)/2 \rceil$. Hence, words in $E_{n_0}(X)$ are shorter than words in $E_{n_0}(S)$. So for all $r \geq 0$,

$$\begin{aligned}\|E_{n_0}(X \cup S) \cap \Sigma^r\| &= \|(E_{n_0}(X) \cap \Sigma^r) \cup (E_{n_0}(S) \cap \Sigma^r)\| \\ &= \|(E_{n_0}(X) \cap \Sigma^r)\| + \|(E_{n_0}(S) \cap \Sigma^r)\| \leq 2.\end{aligned}$$

This shows 6.9.2(a). Condition 6.9.2(b) holds for $X \cup S$ and $k+1$, since this condition does not depend on k, and since $(X \cup S) \cap \Sigma^{\leq k} = X^{\leq k}$. This proves statement 6.10.4.

We prove statement 5 of Proposition 6.10 as follows. Let X be (μ, k)-valid and $(i_0, j_0) \in \text{range}(\mu)$ such that $i_0 > 0$. Choose n_0 such that $(n_0, i_0, j_0) \in \mu$. Let $\mu_0 \stackrel{df}{=} \{(n', i', j') \in \mu \mid n' < n_0\}$. By 6.10.2, X is $(\mu_0 \cup \{(n_0, i_0, j_0)\}, k)$-valid and also (μ_0, k)-valid. Together with 6.9.1(b) (for $l = k$ and $Y = X$) this implies that $L(NM_{i_0}^X) \cap L(NM_{j_0}^X) \cap \Sigma^{\leq k} = \emptyset$.

We prove statement 6 of Proposition 6.10 by induction on $\|\mu\|$. If $\|\mu\| = 0$, then, by Definition 6.9, $X^{\leq k'}$ is (μ, k')-valid for $0 \leq k' \leq k$. So assume $\|\mu\| > 0$ and choose μ_0, n_0, i_0, j_0 as in Definition 6.9. We assume as an induction hypothesis that if X is (μ_0, k)-valid, then, for every k', $n_0 \leq k' \leq k$, it holds that $X^{\leq k'}$ is (μ_0, k')-valid. Choose k' such that $n_0 \leq k' \leq k$; we show that $X^{\leq k'}$ is (μ, k')-valid. Since X is (μ, k)-valid it is also (μ_0, k)-valid. By the induction hypothesis we obtain that $X^{\leq k'}$ is (μ_0, k')-valid.

Assume that $i_0 > 0$; we verify Definition 6.9.1. Note that in 6.9.1(a) we have the condition $4 \cdot |00^{n_0}10^t1x| \leq k'$. Hence, $t < k'$, and therefore the computations mentioned in 6.9.1(a) cannot ask queries longer than k'. So nothing changes when these machines use oracle X instead of $X^{\leq k'}$. Moreover, at the left-hand sides in 6.9.1(a), we can also use X instead of $X^{\leq k'}$ since we only test the membership for words of length $\leq k'$. This shows that in 6.9.1(a) we can replace every occurrence of $X^{\leq k'}$ with X and obtain an equivalent condition. This condition holds since X is (μ, k)-valid. Therefore, 6.9.1(a) holds. Condition 6.9.1(b) holds, since $X^{\leq k'} \cap \Sigma^{\leq n_0} = X^{\leq n_0}$.

Assume that $i_0 = 0$; we verify Definition 6.9.2. Condition 6.9.2(a) follows immediately, since X is (μ, k)-valid. Condition 6.9.2(b) holds, since $X^{\leq k'} \cap \Sigma^{\leq n_0} = X^{\leq n_0}$. This proves statement 6 of Proposition 6.10. □

PROPOSITION 6.11. *Let O_2 be an oracle such that for some μ there exist infinitely many k such that $O_2{}^{\leq k}$ is (μ, k)-valid (property* (c)*).*

1. $A(O_2) \cap B(O_2) = C(O_2) \cap D(O_2) = \emptyset$.
2. *For all $(i, j) \in \text{range}(\mu)$, $i > 0$, it holds that $L(NM_i^{O_2}) \cap L(NM_j^{O_2}) = \emptyset$ and there exists some $f \in \text{PF}$ such that $(L(NM_i^{O_2}), L(NM_j^{O_2})) \leq_{sm}^{pp} (A(O_2), B(O_2))$ via f.*
3. *For all $(n, 0, j) \in \mu$ it holds that $E_n(O_2)$ contains ≤ 2 words of every length, and $L(NM_j^{O_2}) \in \text{SPARSE}_j$.*

Proof. Assume that $A(O_2) \cap B(O_2) \neq \emptyset$ and let $w \in A(O_2) \cap B(O_2)$. Then, for $k = 4 \cdot (|w| + 1)$, w is already in $A(O_2{}^{\leq k}) \cap B(O_2{}^{\leq k})$. This contradicts the

assumption that there exists a $k' \geq k$ such that ${O_2}^{\leq k'}$ is (μ, k')-valid. Therefore, $A(O_2) \cap B(O_2) = \emptyset$. Analogously we see that $C(O_2) \cap D(O_2) = \emptyset$. This shows item 1 of Proposition 6.11.

Let $(i,j) \in \text{range}(\mu)$, $i > 0$, and choose n such that $(n,i,j) \in \mu$. Assume $L(NM_i^{O_2}) \cap L(NM_j^{O_2}) \neq \emptyset$, and let $w \in L(NM_i^{O_2}) \cap L(NM_j^{O_2})$. Then, for $k = |w|^{i+j}$, w is already in $L(NM_i^{O_2'}) \cap L(NM_j^{O_2'}) \cap \Sigma^{\leq k}$, where ${O_2}' \stackrel{df}{=} {O_2}^{\leq k}$. By our assumption there exists a $k' \geq k$ such that ${O_2}'' \stackrel{df}{=} {O_2}^{\leq k'}$ is (μ, k')-valid. It follows that $w \in L(NM_i^{O_2''}) \cap L(NM_j^{O_2''}) \cap \Sigma^{\leq k'}$. This contradicts Proposition 6.10.5, and therefore $L(NM_i^{O_2}) \cap L(NM_j^{O_2}) = \emptyset$.

Let $\mu_0 \stackrel{df}{=} \{(n',i',j') \in \mu \mid n' < n\}$. From our assumption and Proposition 6.10.2 it follows that for infinitely many k, ${O_2}^{\leq k}$ is $(\mu_0 \cup \{(n,i,j)\}, k)$-valid. So by Definition 6.9, for infinitely many k the following holds: For all $t \geq 1$ and all $x \in \Sigma^*$, if $4 \cdot |00^n10^t1x| \leq k$, then

- $(\exists y,\ |y| = 3|00^n10^t1x|)[00^n10^t1xy \in {O_2}^{\leq k}] \Leftrightarrow NM_i^{{O_2}^{\leq k}}(x)$ accepts within t steps, and
- $(\exists y,\ |y| = 3|10^n10^t1x|)[10^n10^t1xy \in {O_2}^{\leq k}] \Leftrightarrow NM_j^{{O_2}^{\leq k}}(x)$ accepts within t steps.

During the first t steps a machine can ask queries of length $\leq t < k$ only. Therefore, above we can replace $NM_i^{{O_2}^{\leq k}}(x)$ and $NM_j^{{O_2}^{\leq k}}(x)$ by $NM_i^{O_2}(x)$ and $NM_j^{O_2}(x)$, respectively. Moreover, since we have the condition $4 \cdot |00^n10^t1x| \leq k$, we can replace ${O_2}^{\leq k}$ with O_2 on the left-hand sides. Since the resulting condition holds for infinitely many k, the following holds for all $t \geq 1$ and $x \in \Sigma^*$:

- $(\exists y,\ |y| = 3|00^n10^t1x|)[00^n10^t1xy \in O_2] \Leftrightarrow NM_i^{O_2}(x)$ accepts within t steps.
- $(\exists y,\ |y| = 3|10^n10^t1x|)[10^n10^t1xy \in O_2] \Leftrightarrow NM_j^{O_2}(x)$ accepts within t steps.

The left-hand sides of these equivalences say $0^n10^t1x \in A(O_2)$ and $0^n10^t1x \in B(O_2)$, respectively. This shows that $(L(NM_i^{O_2}), L(NM_j^{O_2})) \leq_{sm}^{pp} (A(O_2), B(O_2))$ via some $f \in \text{PF}$.[5] Hence statement 2 of Proposition 6.11 holds.

Let $(n,0,j) \in \mu$. Assume that there exists an $r \geq 0$ such that $\|E_n(O_2) \cap \Sigma^r\| \geq 3$. Then there exists some k such that $\|E_n({O_2}') \cap \Sigma^r\| \geq 3$, where ${O_2}' \stackrel{df}{=} {O_2}^{\leq k}$. By our assumption there exists some $k' \geq k$ such that ${O_2}'' \stackrel{df}{=} {O_2}^{\leq k'}$ is (μ, k')-valid. It follows that $\|E_n({O_2}'') \cap \Sigma^r\| \geq 3$. This contradicts Proposition 6.10.3(a), and therefore $E_n(O_2)$ contains at most two words of every length.

Assume that $L(NM_j^{O_2}) \notin \text{SPARSE}_j$. Then there exists some m such that $L(NM_j^{O_2}) \cap \Sigma^m$ contains more than $m^j + j$ words. Therefore, with $k \stackrel{df}{=} m^j$ and ${O_2}' \stackrel{df}{=} {O_2}^{\leq k}$ we obtain $L(NM_j^{O_2'}) \cap \Sigma^{\leq k} \notin \text{SPARSE}_j$. By our assumption there exists some $k' \geq k$ such that ${O_2}'' \stackrel{df}{=} {O_2}^{\leq k'}$ is (μ, k')-valid. It follows that $L(NM_j^{O_2''}) \cap \Sigma^{\leq k'} \notin \text{SPARSE}_j$. This contradicts Proposition 6.10.3(b), and therefore $L(NM_j^{O_2}) \in \text{SPARSE}_j$. □

Remember that our construction consists of a coding part to obtain condition (i) of Theorem 6.7 and of separating parts to obtain conditions (ii), (iii), and (iv). In order to diagonalize, we will fix certain words that are needed for the coding part, and we will change our oracle on nonfixed positions to obtain the separation. For this we introduce the notion of a reservation for an oracle. A reservation consists of two sets Y and N, where Y contains words that are reserved for the oracle while N

[5] We can use $f(x) \stackrel{df}{=} 0^n10^{|x|^{i+j}}1x$, since $NM_i(x)$ and $NM_j(x)$ have computation times $|x|^i$ and $|x|^j$, respectively.

contains words that are reserved for the complement of the oracle. This notion has two important properties:

- Whenever an oracle X agrees with a reservation that is not too large, we can find an extension of X that agrees with the reservation (Lemma 6.14).
- If we want to fix certain words to be in the oracle, then this is possible using a reservation of small size. For this reason we can fix certain words to be in the oracle and still be able to diagonalize (Lemma 6.18).

DEFINITION 6.12 ((μ,k)-reservation). *A pair (Y,N) of finite sets is a (μ,k)-reservation for X if X is (μ,k)-valid, $Y\cap N=\emptyset$, $Y^{\leq k}\subseteq X$, $N^{\leq k}\subseteq \overline{X}$, $A(Y)\cap B(Y)=\emptyset$, all words in $Y^{>k}$ are of length $\equiv 0 \pmod 4$, and if $w\in Y^{>k}$ is a μ-codeword for (i,t,x), then $NM_i(x)$ has a positive path P such that $|P|\leq t$, $P^{\text{yes}}\subseteq Y$, and $P^{\text{no}}\subseteq N$.*

PROPOSITION 6.13 (basic properties of reservations). *The following holds for every (μ,k)-valid X:*

1. *$(\emptyset,\emptyset)$ is a (μ,k)-reservation for X.*
2. *If (Y,N) is a (μ,k)-reservation for X, then also $(Y,N\cup N')$ for every $N'\subseteq \overline{Y\cup X}$.*
3. *For every $N\subseteq\overline{X}$, $(\emptyset,N)$ is a (μ,k)-reservation for X.*
4. *Let (Y,N) be a (μ,k)-reservation for X. For each $(\mu,k+1)$-valid $Z\supseteq_k X$ such that $Y^{=k+1}\subseteq Z^{=k+1}\subseteq \overline{N}^{=k+1}$, it holds that (Y,N) is a $(\mu,k+1)$-reservation for Z.*
5. *Let (Y,N) be a (μ,k)-reservation for X. For every $m\geq 0$, $(Y\cap\Sigma^{\leq m}, N\cap\Sigma^{\leq m})$ is a (μ,k)-reservation for X.*

Proof. This follows immediately from Definition 6.12. □

Whenever a (μ,k)-reservation of some oracle X is not too large, then X has a (μ,m)-valid extension Z that agrees with the reservation.

LEMMA 6.14. *Let (Y,N) be a (μ,k)-reservation for X and let $m\stackrel{df}{=}\max(\{|w|\mid w\in Y\cup N\}\cup\{k\})$. If $\|N\|\leq 2^{k/2}$, then there exists a (μ,m)-valid $Z\supseteq_k X$ such that $Y\subseteq Z$, $N\subseteq\overline{Z}$, and $(Z-Y)\cap\Sigma^{>k}$ contains only μ-codewords.*

Proof. Assume $\|N\|\leq 2^{k/2}$. We show the lemma by induction on $n\stackrel{df}{=}m-k$. If $n=0$, then let $Z=X$ and we are done.

Now assume $n>0$. First of all we show that it suffices to find a $(\mu,k+1)$-valid $Z'\supseteq_k X$ such that $Y^{=k+1}\subseteq Z'^{=k+1}\subseteq\overline{N}^{=k+1}$ and $(Z'-Y)\cap\Sigma^{k+1}$ contains only μ-codewords. In this case, Proposition 6.13.4 implies that (Y,N) is a $(\mu,k+1)$-reservation for Z'. So we can apply the induction hypothesis to (Y,N) considered as a $(\mu,k+1)$-reservation for Z'. We obtain a (μ,m)-valid $Z\supseteq_{k+1}Z'$ such that $Y\subseteq Z$, $N\subseteq\overline{Z}$, and $(Z-Y)\cap\Sigma^{>k+1}$ contains only μ-codewords. Together this yields $Z\supseteq_k X$ and $(Z-Y)\cap\Sigma^{>k}$ contains only μ-codewords. It remains to find the mentioned Z'.

If $k+1\not\equiv 0 \pmod 4$, then $Y^{=k+1}=\emptyset$, since $Y^{=k+1}$ contains only words of length $\equiv 0 \pmod 4$. We apply Proposition 6.10.4 to $S\stackrel{df}{=}\emptyset$, and obtain that X is $(\mu,k+1)$-valid. Therefore, with $Z'\stackrel{df}{=}X$ we found the desired Z'.

If $k+1\equiv 0 \pmod 4$, then, starting with the empty set, we construct a set $S\subseteq\Sigma^{k+1}$ by doing the following for each $(n,i,j)\in\mu$, each $t\geq 1$, and each $x\in\Sigma^*$ such that $i>0$ and $4\cdot|00^n10^t1x|=k+1$:

- If $NM_i^X(x)$ accepts within t steps, then choose some $y\in\Sigma^{3|00^n10^t1x|}$ such that $00^n10^t1xy\notin N$. Add 00^n10^t1xy to S.
- If $NM_j^X(x)$ accepts within t steps, then choose some $y\in\Sigma^{3|10^n10^t1x|}$ such that $10^n10^t1xy\notin N$. Add 10^n10^t1xy to S.

Observe that the choices of words y are possible since $\|N\| \leq 2^{k/2} < 2^{3(k+1)/4} = \|\Sigma^{3|00^n10^t1x|}\|$. Moreover, S contains only μ-codewords. For $Z' \stackrel{df}{=} X \cup S \cup Y^{=k+1}$ we have $Z' \supseteq_k X$ and $Y^{=k+1} \subseteq Z'^{=k+1} \subseteq \overline{N}^{=k+1}$, since $S \subseteq \overline{N}^{=k+1}$. In addition, $(Z' - Y) \cap \Sigma^{k+1}$ contains only μ-codewords, since this set is a subset of S. It remains to show that Z' is $(\mu, k+1)$-valid.

CLAIM 6.15. $A(Z') \cap B(Z') = C(Z') \cap D(Z') = \emptyset$.

Proof. Since X is (μ, k)-valid we have $A(X) \cap B(X) = C(X) \cap D(X) = \emptyset$. When we look at the definitions of $A(X)$, $B(X)$, $C(X)$, and $D(X)$, we see that in order to show Claim 6.15, it suffices to show

$$A(Z') \cap B(Z') \cap \Sigma^{\frac{(k+1)}{4}-1} = C(Z') \cap D(Z') \cap \Sigma^{k+1} = \emptyset.$$

We immediately obtain $C(Z') \cap D(Z') \cap \Sigma^{k+1} = \emptyset$, since by definition, $C(Z')$ and $D(Z')$ contain only words of lengths $\equiv 1 \pmod 4$. Assume that $A(Z') \cap B(Z') \cap \Sigma^{(k+1)/4-1} \neq \emptyset$, and choose some $w \in A(Z') \cap B(Z') \cap \Sigma^{(k+1)/4-1}$. So there exist $n, t \geq 1$, $x \in \Sigma^*$, and $y_0, y_1 \in \Sigma^{3|w|+3}$ such that $w = 0^n10^t1x$ and $0wy_0, 1wy_1 \in Z'$. Note that $0wy_0, 1wy_1 \in S \cup Y^{=k+1}$, but both words cannot be in $Y^{=k+1}$, since otherwise we have $A(Y) \cap B(Y) \neq \emptyset$, which contradicts our assumption that (Y, N) is a (μ, k)-reservation. Therefore, either $0wy_0$ or $1wy_1$ belongs to S. Since all words in S are μ-codewords, there exist $i, j \geq 1$ such that $(n, i, j) \in \mu$. Hence $0wy_0$ and $1wy_1$ are μ-codewords. We claim that $NM_i^X(x)$ accepts within t steps, regardless of whether $0wy_0$ belongs to S or to $Y^{=k+1}$. This can be seen as follows:

- If $0wy_0 \in S$, then from the construction of S it follows that $NM_i^X(x)$ accepts within t steps.
- If $0wy_0 \in Y^{=k+1}$, then, since $0wy_0$ is a μ-codeword of length $> k$, $NM_i(x)$ has a positive path P with $|P| \leq t$, $P^{\text{yes}} \subseteq Y$, and $P^{\text{no}} \subseteq N$. Since $t \leq k$ it follows that $P^{\text{yes}} \cup P^{\text{no}} \subseteq \Sigma^{\leq k}$, and therefore $P^{\text{yes}} \subseteq X$ and $P^{\text{no}} \subseteq \Sigma^{\leq k} - X$. It follows that $NM_i^X(x)$ accepts within t steps.

Analogously we obtain that $NM_j^X(x)$ accepts within t steps. Since $|x| \leq k$ we have seen that $L(NM_i^X) \cap L(NM_j^X) \cap \Sigma^{\leq k} \neq \emptyset$ and $(i, j) \in \text{range}(\mu)$ such that $i > 0$. This contradicts Proposition 6.10.5 and finishes the proof of Claim 6.15. □

CLAIM 6.16. *Z' is $(\mu', k+1)$-valid for every $\mu' \preceq \mu$.*

Proof. We prove the claim by induction on $\|\mu'\|$. If $\|\mu'\| = 0$, then Z' is $(\mu', k+1)$-valid by Claim 6.15.

Assume now that $\|\mu'\| > 0$, and choose suitable μ_0, n_0, i_0, j_0 such that $n_0 = \mu'_{\max}$, $\mu' = \mu_0 \cup \{(n_0, i_0, j_0)\}$, and $\mu_0 \prec \mu'$. Clearly, $n_0 \leq \mu_{\max} \leq k < k+1$. As an induction hypothesis we assume that Z' is $(\mu_0, k+1)$-valid. We show that Z' is $(\mu', k+1)$-valid.

Assume $i_0 > 0$. We claim that for all $t \geq 1$ and all $x \in \Sigma^*$, if $4 \cdot |00^{n_0}10^t1x| \leq k+1$, then the equivalences in 6.9.1(a) hold for Z' instead of X. This is seen as follows:

- If $4 \cdot |00^{n_0}10^t1x| \leq k$, then they hold since X is (μ', k)-valid and $Z' \supseteq_k X$.
- If $4 \cdot |00^{n_0}10^t1x| = k+1$, then the implications "$\Leftarrow$" in statement 6.9.1(a) hold, since $NM_{i_0}^{Z'}(x)$ and $NM_{j_0}^{Z'}(x)$ run at most $t \leq k$ steps and can therefore use oracle X instead of Z', and because $S \subseteq Z'$. For the other direction, let $w = 0^{n_0}10^t1x$ and assume that there exists some $y \in \Sigma^{3|w|+3}$ such that $0wy \in Z'$. If $0wy \in S$, then we have put this word to S, because $NM_i^X(x)$ accepts within t steps. Since $t < k$, also $NM_i^{Z'}(x)$ accepts within t steps. So assume $0wy \in Y^{=k+1}$ and note that $0wy$ is a μ-codeword. Since (Y, N) is a (μ, k)-reservation for X, $NM_i(x)$ has a positive path P with $|P| \leq t$, $P^{\text{yes}} \subseteq Y$, and $P^{\text{no}} \subseteq N$. Since $t < k$, we have $P^{\text{yes}} \subseteq X$ and $P^{\text{no}} \subseteq \Sigma^{\leq k} - X$.

Hence, $NM_i^X(x)$ accepts within t steps, and therefore $NM_i^{Z'}(x)$ accepts within t steps. This shows the implication "$\Rightarrow$" in 6.9.1(a)(i). Analogously we see the implication "$\Rightarrow$" in 6.9.1(a)(ii).

Condition 6.9.1(b) holds for Z' instead of X, since X is (μ', k)-valid, $n_0 \leq k$ and therefore $Z'^{\leq n_0} = X^{\leq n_0}$.

Assume $i_0 = 0$. Since X is (μ', k)-valid, for all $r \geq 0$ it holds that $\|E_{n_0}(X) \cap \Sigma^r\| \leq 2$. Moreover, we have $E_{n_0}(Z' \cap \Sigma^{k+1}) = \emptyset$, since by definition, E_{n_0} depends only on oracle words of lengths $\equiv 2 \pmod 4$. Therefore, for all $r \geq 0$, $\|E_{n_0}(Z') \cap \Sigma^r\| \leq 2$. This shows 6.9.2(a). Condition 6.9.2(b) holds for Z' instead of X, since X is (μ', k)-valid, $n_0 \leq k$, and therefore $Z'^{\leq n_0} = X^{\leq n_0}$. This proves Claim 6.16. □

Claim 6.16 implies in particular that Z' is $(\mu, k+1)$-valid. This completes the proof of Lemma 6.14. □

One of the main consequences of Lemma 6.14 is that (μ, k)-valid oracles can be extended to (μ, k')-valid oracles for larger k'. We needed to include conditions 1(b) and 2(b) in Definition 6.9 in order to obtain this property. Otherwise it is possible that a certain way of extending the finite oracle X to some oracle X' has no extension to an infinite oracle O_2 so that $L(NM_i^{O_2}) \cap L(NM_j^{O_2}) = \emptyset$. If this happens, then by statement 6.9.1(a), for all extensions to an infinite oracle O_2, $A(O_2)$ and $B(O_2)$ would not be disjoint.

LEMMA 6.17. *If X is (μ, k)-valid, then for every $m > k$ there exists a (μ, m)-valid $Z \supseteq_k X$ such that $Z^{>k}$ contains only μ-codewords.*

Proof. It suffices to show the lemma for $m = k+1$. Let $Y = \emptyset$ and $N = \{0^{k+1}\}$. By Proposition 6.13.3, (Y, N) is a (μ, k)-reservation for X. Since $\|N\| = 1 \leq 2^{k/2}$ we can apply Lemma 6.14, and we obtain a $(\mu, k+1)$-valid $Z \supseteq_k X$ such that $Z^{>k}$ contains only μ-codewords. □

For a finite $X \subseteq \Sigma^*$, let $\ell(X) \stackrel{df}{=} \sum_{w \in X} |w|$.

LEMMA 6.18. *Let X be (μ, k)-valid and let $Z \supseteq_k X$ be (μ, m)-valid such that $m \geq k$ and $Z^{>k}$ contains only words of length $\equiv 0 \pmod 4$. For every $Y \subseteq Z$ and every $N \subseteq \overline{Z}$ there exists a (μ, k)-reservation (Y', N') for X such that $Y \subseteq Y'$, $N \subseteq N'$, $\ell(Y' \cup N') \leq 2 \cdot \ell(Y \cup N)$, $Y' \subseteq Z$, and $N' \subseteq \overline{Z}$.*

Proof. For every $Y \subseteq Z$ let

$$\mathcal{D}(Y) \stackrel{df}{=} \{q \mid Y^{>k} \text{ contains a } \mu\text{-codeword for } (i,t,x) \text{ and } q \in P^{\text{all}}_{i,t,x}\},$$

where $P_{i,t,x}$ is the lexicographically smallest path among all paths of $NM_i^Z(x)$ that are accepting and that are of length $\leq t$. Note that $\mathcal{D}(Y)$ is well-defined: If $Y^{>k} \subseteq Z$ contains a μ-codeword, then this has the form $00^{n_0}10^t1xy$ (resp., $10^{n_0}10^t1xy$), and there exist $i_0, j_0 \geq 1$ such that $(n_0, i_0, j_0) \in \mu$. Let $\mu_0 \stackrel{df}{=} \{(n', i', j') \in \mu \mid n' < n_0\}$. By statement 2 of Proposition 6.10, Z is $(\mu_0 \cup \{(n_0, i_0, j_0)\}, m)$-valid. From statement 6.9.1(a) it follows that the path $P_{i_0,t,x}$ (resp., $P_{j_0,t,x}$) exists.

If w is a μ-codeword for (i,t,x), then $|P_{i,t,x}| \leq t < |w|/4$. Therefore, when looking at the definition of $\mathcal{D}(Y)$, we see that the sum of lengths of q's that are induced by some μ-codeword w is at most $|w|/4$ (remember that we use nondeterministic machines that ask all queries in parallel). This shows the following.

CLAIM 6.19. *For all $Y \subseteq Z$, $\ell(\mathcal{D}(Y)) \leq \ell(Y)/4$, and words in $\mathcal{D}(Y)$ are not longer than the longest word in Y.*

Given Y and N, the procedure below computes the (μ, k)-reservation (Y', N').

```
1    Y_0 := Y
2    N_0 := N
3    c := 0
```

```
4    do
5        c := c + 1
6        Y_c := D(Y_{c-1}) ∩ Z
7        N_c := D(Y_{c-1}) ∩ Z̄
8    repeat until Y_c = N_c = ∅
9    Y' := Y_0 ∪ Y_1 ∪ ··· ∪ Y_c
10   N' := N_0 ∪ N_1 ∪ ··· ∪ N_c
```

Note that since all Y_c are subsets of Z, the expressions $\mathcal{D}(Y_{c-1})$ in lines 6 and 7 are defined. It is immediately clear that $Y \subseteq Y' \subseteq Z$ and $N \subseteq N' \subseteq \overline{Z}$. Therefore $Y' \cap N' = \emptyset$. From Claim 6.19 we obtain $\ell(Y_i \cup N_i) = \ell(\mathcal{D}(Y_{i-1})) \leq \ell(Y_{i-1})/4$ for $1 \leq i \leq c$. Therefore, the procedure terminates and $\ell(Y' \cup N') \leq 2 \cdot \ell(Y \cup N)$. It remains to show the following.

CLAIM 6.20. *(Y', N') is a (μ, k)-reservation for X.*

Clearly, $Y'^{\leq k} \subseteq X$ and $N'^{\leq k} \subseteq \overline{X}$. Moreover, $A(Y') \cap B(Y') = \emptyset$, since otherwise $A(Z) \cap B(Z) \neq \emptyset$, which is not possible, since Z is (μ, m)-valid. All words in $Y'^{>k}$ are of length $\equiv 0 \pmod 4$, since $Y' \subseteq Z$. Let $v \in Y'^{>k}$ be a μ-codeword for (i, t, x). More precisely, $v \in Y_{i'} \subseteq Z$ for a suitable $i' < c$. Z is (μ, m)-valid and v is a μ-codeword that belongs to Z. Therefore, as seen at the beginning of this proof, it follows that $NM_i^Z(x)$ accepts within t steps. Thus the path $P_{i,t,x}$ exists and we obtain $P^{\text{all}}_{i,t,x} \subseteq \mathcal{D}(Y_{i'})$. It follows that $P^{\text{yes}}_{i,t,x} \subseteq Y_{i'+1} \subseteq Y'$ and $P^{\text{no}}_{i,t,x} \subseteq N_{i'+1} \subseteq N'$. Therefore, $NM_i(x)$ has a positive path P with $|P| \leq t$, $P^{\text{yes}} \subseteq Y'$, and $P^{\text{no}} \subseteq N'$. This proves Claim 6.20 and finishes the proof of Lemma 6.18. □

For any (μ, k)-valid oracle either we can find a finite extension that makes the languages accepted by NM_i and NM_j not disjoint, or we can force these languages to be disjoint for all valid extensions.

PROPOSITION 6.21 (property P1). *Let $i, j \geq 1$ and let X be (μ, k)-valid. There exists an $l > k$ and a (μ', l)-valid $Y \supseteq_k X$, $\mu \preceq \mu'$ such that*

- *either for all $Z \supseteq_l Y$, $L(NM_i^Z) \cap L(NM_j^Z) \cap \Sigma^{\leq l} \neq \emptyset$, or*
- *$(i, j) \in \text{range}(\mu')$.*

This proposition tells us that if the first property does not hold, then by Definition 6.9, since Y is (μ', l)-valid, $L(NM_i^Z) \cap L(NM_j^Z) \cap \Sigma^{\leq m} = \emptyset$ for all (μ', m)-valid extensions Z of Y, where $m \geq l$.

Proof. By Lemma 6.17, we can assume that k is large enough so that $2 \cdot k^{i+j} < 2^{k/2}$. If $(i, j) \in \text{range}(\mu)$, then by Lemma 6.17, for $\mu' = \mu$ and $l = k + 1$ there exists a (μ', l)-valid $Y \supseteq_k X$. Otherwise we distinguish two cases.

Case 1. There exists an $l' > k$ and a (μ, l')-valid $Y' \supseteq_k X$ such that $L(NM_i^{Y'}) \cap L(NM_j^{Y'}) \cap \Sigma^{\leq l'} \neq \emptyset$. Choose some $x \in L(NM_i^{Y'}) \cap L(NM_j^{Y'}) \cap \Sigma^{\leq l'}$ and let P_i, P_j be accepting paths of the computations $NM_i^{Y'}(x)$, $NM_j^{Y'}(x)$, respectively. Note that $(P_i^{\text{yes}} \cup P_j^{\text{yes}}) \cap \Sigma^{>l'} = \emptyset$ and let $N \stackrel{df}{=} (P_i^{\text{no}} \cup P_j^{\text{no}}) \cap \Sigma^{>l'}$. By Proposition 6.13.3, $(\emptyset, N)$ is a (μ, l')-reservation for Y'. Since $\|N\| \leq 2 \cdot |x|^{i+j} \leq 2 \cdot l'^{i+j} < 2^{l'/2}$ we can apply Lemma 6.14. We obtain some $l \geq l' > k$ and some (μ, l)-valid $Y \supseteq_{l'} Y' \supseteq_k X$ such that $N \subseteq \Sigma^{\leq l}$ and $N \subseteq \overline{Y}$. Therefore, for every $Z \supseteq_l Y$ the computations $NM_i^Z(x)$ and $NM_j^Z(x)$ will accept at the paths P_i and P_j, respectively. Hence $L(NM_i^Z) \cap L(NM_j^Z) \cap \Sigma^{\leq l} \neq \emptyset$ for every $Z \supseteq_l Y$.

Case 2. For every $l' > k$ and every (μ, l')-valid $Y' \supseteq_k X$ it holds that $L(NM_i^{Y'}) \cap L(NM_j^{Y'}) \cap \Sigma^{\leq l'} = \emptyset$. By Lemma 6.17, there exists a (μ, l)-valid $Y \supseteq_k X$ where $l \stackrel{df}{=} k + 1$. Let $n_0 \stackrel{df}{=} l$, $i_0 \stackrel{df}{=} i$, $j_0 \stackrel{df}{=} j$, $\mu_0 \stackrel{df}{=} \mu$, and $\mu' \stackrel{df}{=} \mu_0 \cup \{(n_0, i_0, j_0)\}$. Observe that $n_0 > k \geq \mu_{\max}$, and therefore $\mu \preceq \mu'$. We show that Y is (μ', l)-valid.

We already know that $l \geq n_0$ and that Y is (μ_0, l)-valid. Since $i_0 > 0$ we only have to verify Definition 6.9.1. When looking at condition 6.9.1(a), we see that $4 \cdot |00^{n_0}10^t1x| \leq l$ is not possible, since $n_0 = l$. Therefore, condition 6.9.1(a) holds. Condition 6.9.1(b) follows from our assumption in Case 2. Therefore, Y is (μ', l)-valid. □

In order to show that $(C(O_2), D(O_2))$ is not symmetric we have to diagonalize against every possible reducing function, i.e., against every deterministic polynomial-time oracle transducer. The following proposition makes sure that this diagonalization is compatible with the notion of valid oracles.

PROPOSITION 6.22 (property P2). *Let $i \geq 1$ and let X be (μ, k)-valid. There exists an $l > k$ and a (μ, l)-valid $Y \supseteq_k X$ such that for all $Z \supseteq_l Y$, if $C(Z) \cap D(Z) = \emptyset$, then $(C(Z), D(Z))$ does not $\leq_m^{pp,O_2}$-reduce to $(D(Z), C(Z))$ via T_i^Z.*

Proof. By Lemma 6.17 we can assume that $k \equiv 0 \pmod 4$ and $(k+1)^i + 1 < 2^{(k+1)/2}$. Consider the computation $T_i^X(0^{k+1})$, let x be the output of this computation, and let N be the set of queries that are of length greater than k. If $|x| > k$, then additionally we add the word $0^{|x|}$ to N. Note that this yields an N such that $X \cap N = \emptyset$ and $\|N\| \leq (k+1)^i + 1 < 2^{(k+1)/2}$.

If $x \in C(X)$ (note that this implies $x = 0^{k'}$ for some $k' \leq k$), then choose some $y \in 0\Sigma^k - N$ and let $S \stackrel{df}{=} \{y\}$. In this case it holds that $0^{k+1} \in C(X \cup S) \wedge x \notin D(X \cup S)$. The right part of the conjunction holds, since X is (μ, k)-valid, and therefore $C(X) \cap D(X) = \emptyset$. Otherwise, if $x \notin C(X)$, then choose some $y \in 1\Sigma^k - N$ and let $S \stackrel{df}{=} \{y\}$. Here we obtain $0^{k+1} \in D(X \cup S) \wedge x \notin C(X \cup S)$. Together this means that we find some $y \in \Sigma^{k+1} - N$ such that with $S \stackrel{df}{=} \{y\}$ it holds that

$$(15) \quad [0^{k+1} \in C(X \cup S) \wedge x \notin D(X \cup S)] \ \vee \ [0^{k+1} \in D(X \cup S) \wedge x \notin C(X \cup S)].$$

Note that $S \subseteq \Sigma^{k+1}$ and $k+1 \not\equiv 0 \pmod 4$. Moreover, $C(S) \cap D(S) = \emptyset$ and for every n, $E_n(S) = \emptyset$, since by definition E_n depends only on oracle words of length $\equiv 2 \pmod 4$. From Proposition 6.10.4 it follows that $X \cup S$ is $(\mu, k+1)$-valid. So by Proposition 6.13.3, $(\emptyset, N)$ is a $(\mu, k+1)$-reservation for $X \cup S$. Since $\|N\| < 2^{(k+1)/2}$ we can apply Lemma 6.14. For $l \stackrel{df}{=} \max(\{|w| \mid w \in N\} \cup \{k+1\})$ we obtain a (μ, l)-valid $Y \supseteq_{k+1} X \cup S$ such that $N \subseteq \overline{Y}$ and $Y^{>k+1}$ contains only words of length $\equiv 0 \pmod 4$. Therefore, $T_i^Y(0^{k+1})$ computes x. Since all queries asked at this computation are of length $\leq l$, we obtain that $T_i^Z(0^{k+1})$ computes x for every $Z \supseteq_l Y$. Since $Y^{>k+1}$ does not contain words of length $\equiv 1 \pmod 4$ we have $C(Z) \cap \Sigma^{\leq l} = C(X \cup S)$ and $D(Z) \cap \Sigma^{\leq l} = D(X \cup S)$ for each $Z \supseteq_l Y$. Note that $k+1 \leq l$ and $|x| \leq l$. Therefore, by equation (15), the following holds for every $Z \supseteq_l Y$:

$$(16) \quad [0^{k+1} \in C(Z) \wedge T_i^Z(0^{k+1}) \notin D(Z)] \ \vee \ [0^{k+1} \in D(Z) \wedge T_i^Z(0^{k+1}) \notin C(Z)].$$

Hence, for every $Z \supseteq_l Y$, if $C(Z) \cap D(Z) = \emptyset$, then $(C(Z), D(Z))$ does not $\leq_m^{pp,O_2}$-reduce to $(D(Z), C(Z))$ via T_i^Z. □

For any (μ, k)-valid oracle, either we can find a finite extension that destroys NM_j's promise to be sparse, or we can force NM_j to be sparse for all valid extensions.

PROPOSITION 6.23 (property P3(a)). *Let $j \geq 1$ and let X be (μ, k)-valid. There exists an $l > k$ and a (μ', l)-valid $Y \supseteq_k X$, $\mu \preceq \mu'$, such that*

- *either for all $Z \supseteq_l Y$, $L(NM_j^Z) \notin \mathrm{SPARSE}_j$, or*
- *$(0, j) \in \mathrm{range}(\mu')$.*

This proposition tells us that if the first property does not hold, then there exists some n such that $(n, 0, j) \in \mu'$. In this case, from Definition 6.9 we obtain that for all

(μ', m)-valid extensions Z of Y it holds that $L(NM_j^Z) \cap \Sigma^{\leq m} \in \mathrm{SPARSE}_j$ and $E_n(Z)$ contains at most 2 words of every length.

Proof. By Lemma 6.17, we can assume that k is large enough so that $(k^j + j + 1) \cdot k^j < 2^{k/2}$. If $(0, j) \in \mathrm{range}(\mu)$, then by Lemma 6.17, for $\mu' = \mu$ and $l = k + 1$ there exists a (μ', l)-valid $Y \supseteq_k X$. Otherwise we distinguish two cases.

Case 1. There exists an $l' > k$ and a (μ, l')-valid $Y' \supseteq_k X$ such that $L(NM_j^{Y'}) \cap \Sigma^{\leq l'} \notin \mathrm{SPARSE}_j$. More precisely, there exists an $m \leq l'$ such that $\|L(NM_j^{Y'}) \cap \Sigma^m\| > m^j + j$. We choose $m^j + j + 1$ different words $x_0, \ldots, x_{m^j+j}$ from $L(NM_j^{Y'}) \cap \Sigma^m$. For $0 \leq i \leq m^j + j$, let P_i be an accepting path of the computation $NM_j^{Y'}(x_i)$. For all i, note that $P_i^{\mathrm{yes}} \cap \Sigma^{>l'} = \emptyset$ and let N be the union of all $P_i^{\mathrm{no}} \cap \Sigma^{>l'}$. By Proposition 6.13.3, $(\emptyset, N)$ is a (μ, l')-reservation for Y'. Since $\|N\| \leq (m^j+j+1) \cdot m^j \leq (l'^j + j + 1) \cdot l'^j < 2^{l'/2}$ we can apply Lemma 6.14. We obtain some $l \geq l' > k$ and some (μ, l)-valid $Y \supseteq_{l'} Y' \supseteq_k X$ such that $N \subseteq \Sigma^{\leq l}$ and $N \subseteq \overline{Y}$. Therefore, for every $Z \supseteq_l Y$ and every i, the computation $NM_j^Z(x_i)$ will accept at path P_i. Hence, for every $Z \supseteq_l Y$, $L(NM_j^Z) \notin \mathrm{SPARSE}_j$.

Case 2. For every $l' > k$ and every (μ, l')-valid $Y' \supseteq_k X$, it holds that $L(NM_j^{Y'}) \cap \Sigma^{\leq l'} \in \mathrm{SPARSE}_j$. By Lemma 6.17, there exists a (μ, l)-valid $Y \supseteq_k X$ with $l \stackrel{df}{=} k + 1$. Let $n_0 \stackrel{df}{=} l$, $i_0 \stackrel{df}{=} 0$, $j_0 \stackrel{df}{=} j$, $\mu_0 \stackrel{df}{=} \mu$, and $\mu' \stackrel{df}{=} \mu_0 \cup \{(n_0, i_0, j_0)\}$. Observe that $n_0 > k \geq \mu_{\max}$, and therefore $\mu_0 \preceq \mu'$. We will show that Y is (μ', l)-valid.

Since $l = \mu'_{\max}$ we have $l \geq \mu'_{\max}$. We already know $l \geq n_0$ and that Y is (μ_0, l)-valid. Since $i_0 = 0$, we only have to verify Definition 6.9.2. Since $l = n_0$ and $Y \subseteq \Sigma^{\leq l}$, we have $E_{n_0}(Y) = \emptyset$, which shows 6.9.2(a). Condition 6.9.2(b) follows from our assumption in Case 2. Therefore, Y is (μ', l)-valid. □

If NM_j is forced to be sparse for all valid extensions (Proposition 6.23), then we have to make sure that $L(NM_j)$ is not many-one-complete for NP ∩ SPARSE. We show that a certain E_n is sparse but is not many-one reducible to $L(NM_j)$. For this we have to diagonalize against every possible reducing function, i.e., against every deterministic polynomial-time oracle transducer. Proposition 6.25 makes sure that this diagonalization is possible. Before we give this proposition, we prove the following argument, which is used in the proofs for Proposition 6.25 and Lemma 6.29.

PROPOSITION 6.24. *Let X be (μ, k)-valid. Let (Y_1, N_1) be a $(\mu, k+1)$-reservation of some $(\mu, k+1)$-valid $Z_1 \supseteq_k X$, and let (Y_2, N_2) be a $(\mu, k+1)$-reservation of some $(\mu, k+1)$-valid $Z_2 \supseteq_k X$ such that ${Y_1}^{>k+1} \cup {Y_2}^{>k+1}$ contains only μ-codewords. If $\|N_1 \cup N_2\| \leq 2^{(k+1)/2}$, $Y_1 \cap N_2 = Y_2 \cap N_1 = \emptyset$, and $X' \stackrel{df}{=} X \cup {Y_1}^{=k+1} \cup {Y_2}^{=k+1}$ is $(\mu, k+1)$-valid, then $A(Y_1 \cup Y_2) \cap B(Y_1 \cup Y_2) = \emptyset$.*

Proof. In order to see that (Y_1, N_1) is a $(\mu, k+1)$-reservation for X', it suffices to show that ${Y_1}^{=k+1} \subseteq X'$ and ${N_1}^{=k+1} \subseteq \overline{X'}$. The first inclusion holds by the definition of X'. The second one holds, since otherwise either $Y_1 \cap N_1 \neq \emptyset$ (not possible since (Y_1, N_1) is a $(\mu, k+1)$-reservation) or $Y_2 \cap N_1 \neq \emptyset$ (not possible by assumption). It follows that (Y_1, N_1) is a $(\mu, k+1)$-reservation for X', and, analogously, (Y_2, N_2) is a $(\mu, k+1)$-reservation for X'.

Assume that $A(Y_1 \cup Y_2) \cap B(Y_1 \cup Y_2) \neq \emptyset$. Choose a shortest $w \in A(Y_1 \cup Y_2) \cap B(Y_1 \cup Y_2)$. Hence, there exist $y_0, y_1 \in \Sigma^{3|w|+3}$ such that $0wy_0, 1wy_1 \in Y_1 \cup Y_2$. Let $m \stackrel{df}{=} |0wy_0| - 1$. We show $m \geq k + 1$. Otherwise, if $m \leq k$, then $|0wy_0| = |1wy_1| \leq k + 1$. It follows that $0wy_0, 1wy_1 \in X'$, since (Y_1, N_1) and (Y_2, N_2) are $(\mu, k+1)$-reservations for X'. This implies $w \in A(X') \cap B(X')$, which is not possible. Therefore, $m \geq k + 1$.

By Proposition 6.13.5, $(Y_1^{\leq m}, N_1^{\leq m})$ and $(Y_2^{\leq m}, N_2^{\leq m})$ are $(\mu, k+1)$-reservations for X'. Let $Y \stackrel{df}{=} Y_1^{\leq m} \cup Y_2^{\leq m}$ and $N \stackrel{df}{=} N_1^{\leq m} \cup N_2^{\leq m}$. We show that (Y, N) is a $(\mu, k+1)$-reservation for X'. For this it suffices to verify $Y \cap N = \emptyset$ and $A(Y) \cap B(Y) = \emptyset$. The first equality holds, since otherwise either $Y_1 \cap N_2 \neq \emptyset$ or $Y_2 \cap N_1 \neq \emptyset$, which is not possible by assumption. If $A(Y) \cap B(Y) \neq \emptyset$, then there exists some $w' \in A(Y) \cap B(Y)$ such that $|w'| < |w|$. This is not possible, since $A(Y) \cap B(Y) \subseteq A(Y_1 \cup Y_2) \cap B(Y_1 \cup Y_2)$ and since w was chosen as short as possible. Therefore, (Y, N) is a $(\mu, k+1)$-reservation for X'.

Note that $\|N\| \leq 2^{(k+1)/2}$. By Lemmas 6.14 and 6.17, there exists a (μ, m)-valid $Z \supseteq_{k+1} X'$ such that $Y \subseteq Z$ and $N \subseteq \overline{Z}$. We know that $|0wy_0| > k+1$ and $0wy_0 \in Y_1 \cup Y_2$. Without loss of generality we assume $0wy_0 \in Y_1$. So by assumption, $0wy_0$ is a μ-codeword. Hence, $w = 0^n 10^t 1x$ for suitable n, t, x such that n is in the domain of μ. Let $\mu(n) = (i, j)$, where $i, j \geq 1$. From $0wy_0 \in Y_1$ it follows that $NM_i(x)$ has a positive path P such that $|P| \leq t$, $P^{\text{yes}} \subseteq Y_1$, and $P^{\text{no}} \subseteq N_1$. Since elements from P^{yes} and P^{no} are of length $\leq t \leq m$, we obtain $P^{\text{yes}} \subseteq Y \subseteq Z$, and $P^{\text{no}} \subseteq N \subseteq \overline{Z}$. It follows that $NM_i^Z(x)$ accepts. Analogously (i.e., with the help of $1wy_1$) we obtain that $NM_j^Z(x)$ accepts. This shows $x \in L(NM_i^Z) \cap L(NM_j^Z) \cap \Sigma^{\leq m}$, which contradicts Proposition 6.10.5. □

PROPOSITION 6.25 (property P3(b)). *Let $i, j \geq 1$ and let X be (μ, k)-valid such that for a suitable n, $\mu(n) = (0, j)$. There exists an $l > k$ and a (μ, l)-valid $Y \supseteq_k X$ such that for all $Z \supseteq_l Y$, $E_n(Z)$ does not $\leq_m^{p,Z}$-reduce to $L(NM_j^Z)$ via f_i^Z.*

Proof. Let $\alpha \stackrel{df}{=} (k+1)^i$, $\beta \stackrel{df}{=} (\alpha+1) \cdot (\alpha^j + j) + 1$, and $\gamma \stackrel{df}{=} \beta \cdot (2 \cdot \alpha^j + 2)$. Note that if i and j are considered as constants, then the values of α, β, and γ are polynomial in $k+1$. By Lemma 6.17, we can assume that $k \equiv 1 \pmod 4$, and that k is large enough such that $n + 2 + \log \gamma \leq (k+1)/2$ and $(2 \cdot \alpha^j + 2) \cdot \gamma < 2^{(k+1)/2}$.

Let $x_1, \ldots, x_\gamma$ be the binary representations (possibly with leading zeros) of $1, \ldots, \gamma$, respectively, such that for all r, $|0^n 1 x_r| = (k+1)/2$. For $1 \leq r \leq \gamma$, let $z_r \stackrel{df}{=} f_i^X(0^n 1 x_r)$ and note that the lengths of these words are bounded by α. We consider two cases.

Case 1. There exist a, b such that $1 \leq a < b \leq \gamma$ and $z_a = z_b$. Let N be the set of queries of length $> k$ that are asked during the computations $f_i^X(0^n 1 x_a)$ and $f_i^X(0^n 1 x_b)$. Note that these are negative queries. Observe that $\|N\| \leq 2 \cdot \alpha < 2^{(k+1)/2}$ and choose a word y_a of length $(k+1)/2$ such that $0^n 1 x_a y_a \notin N$. Let $S \stackrel{df}{=} \{0^n 1 x_a y_a\}$. It follows that $C(S) \cap D(S) = \emptyset$. Moreover, for all $n' \geq 1$, $\|E_{n'}(S)\| \leq 1$. From Proposition 6.10.4 it follows that $X' \stackrel{df}{=} X \cup S$ is $(\mu, k+1)$-valid. By Proposition 6.13.3, $(\emptyset, N)$ is a $(\mu, k+1)$-reservation for X'. By Lemma 6.14, there exists a (μ, l)-valid $Y \supseteq_{k+1} X'$ such that $N \subseteq \Sigma^{\leq l}$ and $N \subseteq \overline{Y}$. Therefore, for all $Z \supseteq_l Y$ it holds that $f_i^Z(0^n 1 x_a) = f_i^Z(0^n 1 x_b) = z_a$. Moreover, $0^n 1 x_a \in E_n(Z)$ and $0^n 1 x_b \notin E_n(Z)$. This shows that for all $Z \supseteq_l Y$, $E_n(Z)$ does not $\leq_m^{p,Z}$-reduce to $L(NM_j^Z)$ via f_i^Z.

Case 2. For $1 \leq r \leq \gamma$, all z_r are pairwise different. The remaining part of the proof deals with this case. Until the end of the proof, r will always be such that $1 \leq r \leq \gamma$. For every r, define the following set:

$$L_r \stackrel{df}{=} \{(Y_r, N_r) \mid (Y_r, N_r) \text{ is a } (\mu, k+1)\text{-reservation for some } (\mu, k+1)\text{-valid } Z \supseteq_k X \text{ such that } Z^{=k+1} \subseteq 0^n 1 \Sigma^*,\ \|Z^{=k+1}\| \leq 1,\ Y_r{}^{>k+1} \text{ contains only } \mu\text{-codewords},\ \ell(Y_r \cup N_r) \leq 2 \cdot \alpha^j,\ \text{and } NM_j(z_r) \text{ has a positive path } P_r \text{ such that } P_r^{\text{yes}} \subseteq Y_r \text{ and } P_r^{\text{no}} \subseteq N_r\}.$$

In the following we consider vectors $v = ((Y_{r_1}, N_{r_1}), (Y_{r_2}, N_{r_2}), \ldots, (Y_{r_s}, N_{r_s}))$ such that $1 \leq s \leq \beta$, all r_a are from $[1, \gamma]$ and are pairwise different, and $(Y_{r_a}, N_{r_a}) \in$

L_{r_a}. Such vectors v are called *vectors of reservations from* $L_1, \ldots, L_\gamma$. We say that v *has a conflict* if there exist a, b such that $1 \le a < b \le s$, and either $Y_{r_a} \cap N_{r_b} \neq \emptyset$ or $N_{r_a} \cap Y_{r_b} \neq \emptyset$. In this case we also say that the reservations (Y_{r_a}, N_{r_a}) and (Y_{r_b}, N_{r_b}) *conflict*. Now we are going to prove three claims. After this, with Claim 6.28 at hand, we are able to finish Case 2.

CLAIM 6.26. *Let* $(Y_a, N_a) \in L_a$ *and* $(Y_b, N_b) \in L_b$. *If* (Y_a, N_a) *and* (Y_b, N_b) *do not conflict, then* $A(Y_a \cup Y_b) \cap B(Y_a \cup Y_b) = \emptyset$.

Assume that (Y_a, N_a) and (Y_b, N_b) do not conflict. Let $S \stackrel{df}{=} {Y_a}^{=k+1} \cup {Y_b}^{=k+1}$ and $X' \stackrel{df}{=} X \cup S$. From the definition of L_a and L_b it follows that $\|S\| \le 2$. Therefore, for all $n' \ge 1$, $\|E_{n'}(S)\| \le 2$. Moreover, $C(S) = D(S) = \emptyset$, since C and D depend only on oracle words of length $\equiv 1 \pmod 4$. From Proposition 6.10.4, we obtain that X' is $(\mu, k{+}1)$-valid. Note that $\|N_a \cup N_b\| \le 2^{(k+1)/2}$, since $\|N_a \cup N_b\| \le \ell(N_a) + \ell(N_b) + 2 \le 2(2\alpha^j + 1) \le \gamma(2\alpha^j + 1)$. By assumption, $Y_a \cap N_b = Y_b \cap N_a = \emptyset$. Therefore, from Proposition 6.24 it follows that $A(Y_a \cup Y_b) \cap B(Y_a \cup Y_b) = \emptyset$. This shows Claim 6.26.

CLAIM 6.27. *Every* β*-dimensional vector of reservations has a conflict.*

Proof. Assume that there exists a vector of reservations

$$v = ((Y_{r_1}, N_{r_1}), (Y_{r_2}, N_{r_2}), \ldots, (Y_{r_\beta}, N_{r_\beta}))$$

such that v has no conflict. Let $\mu' \stackrel{df}{=} \{(n', i', j') \in \mu \mid n' < n\}$. Note that X is (μ', k)-valid and also $(\mu' \cup \{n, 0, j\}, k)$-valid (Proposition 6.10.2). Let $Y \stackrel{df}{=} \bigcup_{1 \le a \le \beta} Y_{r_a}$, $N \stackrel{df}{=} \bigcup_{1 \le a \le \beta} N_{r_a}$, and $X' \stackrel{df}{=} X \cup Y^{=k+1}$. We show that X' is $(\mu', k+1)$-valid. Since C and D depend only on oracle words of length $\equiv 1 \pmod 4$, we have $C(Y^{=k+1}) = D(Y^{=k+1}) = \emptyset$. Moreover, since n is not in the domain of μ' and since all words in $Y^{=k+1}$ have the prefix $0^n 1$, for all $(n', 0, j') \in \mu'$ it holds that $E_{n'}(Y^{=k+1}) = \emptyset$. Therefore, from Proposition 6.10.4 it follows that X' is $(\mu', k+1)$-valid.

Let us show that for $1 \le a \le \beta$, (Y_{r_a}, N_{r_a}) is a $(\mu', k+1)$-reservation for X'. By definition, (Y_{r_a}, N_{r_a}) is a $(\mu, k+1)$-reservation for some $(\mu, k+1)$-valid $Z \supseteq_k X$. Since every μ'-codeword is a μ-codeword, it suffices to verify ${Y_{r_a}}^{=k+1} \subseteq X'$ and ${N_{r_a}}^{=k+1} \subseteq \overline{X'}$. The first inclusion holds by the definition of X'. If the latter inclusion does not hold, then ${N_{r_a}}^{=k+1} \cap Y^{=k+1} \neq \emptyset$. Since $N_{r_a} \cap Y_{r_a} = \emptyset$, it follows that $N_{r_a} \cap Y_{r_b} \neq \emptyset$ for some $b \neq a$. This implies that v has a conflict, which is not possible by our assumption. This shows that for all a, if $1 \le a \le \beta$, then (Y_{r_a}, N_{r_a}) is a $(\mu', k+1)$-reservation for X'.

We show that (Y, N) is a $(\mu', k{+}1)$-reservation for X'. All (Y_{r_a}, N_{r_a}) are $(\mu', k{+}1)$-reservations that do not conflict with each other. From this we immediately obtain that $Y \cap N = \emptyset$, $Y^{\le k+1} \subseteq X'$, $N^{\le k+1} \subseteq \overline{X'}$, and all words in $Y^{>k+1}$ are of length $\equiv 0 \pmod 4$. If $A(Y) \cap B(Y) \neq \emptyset$, then there exist a, b such that $A(Y_{r_a} \cup Y_{r_b}) \cap B(Y_{r_a} \cup Y_{r_b}) \neq \emptyset$. This contradicts Claim 6.26. Therefore, $A(Y) \cap B(Y) = \emptyset$. Finally, if $w \in Y^{>k+1}$ is a μ'-codeword for (i', t', x'), then there exists some a such that $w \in {Y_{r_a}}^{>k+1}$. Since (Y_{r_a}, N_{r_a}) is a $(\mu', k+1)$-reservation, $NM_{i'}(x')$ has a positive path P such that $|P| \le t'$, $P^{\text{yes}} \subseteq Y_{r_a} \subseteq Y$, and $P^{\text{no}} \subseteq N_{r_a} \subseteq N$. This shows that (Y, N) is a $(\mu', k+1)$-reservation for X'.

By definition, for all r and all $(Y_r, N_r) \in L_r$ it holds that $\ell(Y_r \cup N_r) \le 2 \cdot \alpha^j$. Therefore, $\|N_r\| \le 2 \cdot \alpha^j + 1$ and it follows that $\|N\| \le \beta \cdot (2 \cdot \alpha^j + 1) \le 2^{(k+1)/2}$. By Lemmas 6.14 and 6.17 there exists some (μ', m)-valid $Z \supseteq_{k+1} X'$ such that $Y \cup N \subseteq \Sigma^{\le m}$, $Y \subseteq Z$, $N \subseteq \overline{Z}$, and $m \ge \alpha$. From the definition of the sets L_r it follows that for all a, if $1 \le a \le \beta$, then $NM_j^Z(z_{r_a})$ accepts. The length of all z_{r_a} is bounded by α. So there exists a length l such that $0 \le l \le \alpha$ and at least $\beta/(\alpha + 1) > (\alpha^j + j) \ge l^j + j$

of the words z_{r_a} are of length l. Hence $\|L(NM_j^Z) \cap \Sigma^l\| > l^j + j$, and therefore $L(NM_j^Z) \cap \Sigma^{\leq m} \notin \text{SPARSE}_j$.

We know that X is $(\mu' \cup \{n, 0, j\}, k)$-valid. Moreover, $m \geq k \geq n$ and Z is (μ', m)-valid such that $Z^{\leq k} = X^{\leq k}$, and therefore $Z^{\leq n} = X^{\leq n}$. From Definition 6.9.2(b) it follows that $L(NM_j^Z) \cap \Sigma^{\leq m} \in \text{SPARSE}_j$. This contradicts our observation in the last paragraph and finishes the proof of Claim 6.27. □

CLAIM 6.28. *There exist some r and an $N \subseteq \Sigma^{>k}$ such that $\|N\| \leq (2 \cdot \alpha^j + 2) \cdot \gamma$ and, for every (μ, m)-valid $Z \supseteq_k X$, if $m > k$, $N \subseteq \overline{Z} \cap \Sigma^{\leq m}$, $Z^{=k+1} \subseteq 0^n 1 \Sigma^*$, $\|Z \cap \Sigma^{k+1}\| \leq 1$, and $Z^{>k+1}$ contains only μ-codewords, then $NM_j^Z(z_r)$ rejects.*

Proof. We use the following algorithm to create the set N. Note that this algorithm modifies the sets L_r. This will decrease the number of possible vectors of reservations from $L_1, \ldots, L_\gamma$.

```
1  N(0) := ∅, R(0) := ∅, i := 0
2  while (all L_r ≠ ∅)
3     i := i + 1
4     choose the largest d such that there exists a
         d-dimensional vector v = ((Y_{r_1}, N_{r_1}), ..., (Y_{r_d}, N_{r_d})) of
         reservations from L_1, ..., L_γ such that
         v has no conflict
5     R(i) := R(i − 1) ∪ {r_1, r_2, ..., r_d}
6     N(i) := N(i − 1) ∪ Y_{r_1}^{>k} ∪ N_{r_1}^{>k} ∪ ··· ∪ Y_{r_d}^{>k} ∪ N_{r_d}^{>k}
7     for every r and every (Y_r, N_r) ∈ L_r:
         remove (Y_r, N_r) if Y_r ∩ N(i) ≠ ∅
8  end while
9  N := N(i)
```

Let $i \geq 1$ and consider the algorithm after the ith iteration of the *while* loop. We claim that for every $r \notin R(i)$ and every (Y_r, N_r) that remains in L_r, it holds that $N_r \cap (N(i) - N(i-1)) \neq \emptyset$. Otherwise, there exist r and (Y_r, N_r) such that $r \notin R(i)$, $(Y_r, N_r) \in L_r$, $N_r \cap (N(i) - N(i-1)) = \emptyset$, and (Y_r, N_r) has not been removed in step 7. Therefore, $Y_r \cap N(i) = \emptyset$, which implies $Y_r \cap (N(i) - N(i-1)) = \emptyset$. Together with our assumption, this gives us $(Y_r \cup N_r) \cap (N(i) - N(i-1)) = \emptyset$. By step 6 this means that (Y_r, N_r) does not conflict with any reservation in v. Therefore, with $((Y_r, N_r), (Y_{r_1}, N_{r_1}), \ldots, (Y_{r_d}, N_{r_d}))$ we found a $(d+1)$-dimensional vector of reservations that has no conflict. This contradicts the choice of v in step 4. Therefore, for every $r \notin R(i)$ and every (Y_r, N_r) that remains in L_r, it holds that $N_r \cap (N(i) - N(i-1)) \neq \emptyset$. It follows that after l iterations of the *while* loop, for every $r \notin R(l)$ and every (Y_r, N_r) that remains in L_r, it holds that $\|N_r\| \geq l$.

By Claim 6.27 and the choice of d in step 4 we have $d < \beta$. Therefore, after $(2 \cdot \alpha^j + 2)$ iterations, $\|R(i)\| < (2 \cdot \alpha^j + 2) \cdot \beta = \gamma$. So during the first $(2 \cdot \alpha^j + 2)$ iterations i there always exists an $r \notin R(i)$. Moreover, for every r and every $(Y_r, N_r) \in L_r$, it holds that $\ell(Y_r \cup N_r) \leq 2 \cdot \alpha^j$, and therefore $\|N_r\| \leq 2 \cdot \alpha^j + 1$. From the conclusion of the previous paragraph it follows that the *while* loop iterates at most $2 \cdot \alpha^j + 2$ times. This shows that the algorithm terminates. Since $d < \beta$, for all $i \geq 1$ it holds that $\|N(i) - N(i-1)\| < \beta \cdot (2 \cdot \alpha^j + 1) \leq \gamma$. Therefore, $\|N\| \leq (2 \cdot \alpha^j + 2) \cdot \gamma$ and $N \subseteq \Sigma^{>k}$ when the algorithm terminates.

So we have a set N of the required size and an r such that $L_r = \emptyset$. We show that N and r satisfy Claim 6.28. Assume that for some $m \geq k+1$ there exists a (μ, m)-valid $Z \supseteq_k X$ such that $N \subseteq \overline{Z} \cap \Sigma^{\leq m}$, $Z^{=k+1} \subseteq 0^n 1 \Sigma^*$, $\|Z \cap \Sigma^{k+1}\| \leq 1$, $Z^{>k+1}$ contains only μ-codewords, and $NM_j^Z(z_r)$ accepts. Let P_r be an accepting path of $NM_j^Z(z_r)$.

Let $Z' \stackrel{df}{=} Z^{\leq k+1}$. From Proposition 6.10.6 it follows that Z' is $(\mu, k+1)$-valid (since $k+1 > k \geq \mu_{\max}$). $Z^{>k+1}$ contains only words of length $\equiv 0 \pmod 4$, since it contains only μ-codewords. So we can apply Lemma 6.18 (for $X = Z'$, $Y = P_r^{\text{yes}}$, and $N = P_r^{\text{no}}$). We obtain a $(\mu, k+1)$-reservation (Y', N') for Z' such that $P_r^{\text{yes}} \subseteq Y'$, $P_r^{\text{no}} \subseteq N'$, $\ell(Y' \cup N') \leq 2 \cdot \ell(P_r^{\text{yes}} \cup P_r^{\text{no}}) \leq 2 \cdot \alpha^j$, $Y' \subseteq Z$, and $N' \subseteq \overline{Z}$. Together with $N \subseteq \overline{Z}$, this implies

$$Y' \cap N = \emptyset. \tag{17}$$

We show that at the beginning of the algorithm, (Y', N') must have been in L_r . Since $Z^{>k+1}$ contains only μ-codewords and since $Y' \subseteq Z$, then $Y'^{>k+1}$ also contains only μ-codewords. Moreover, $Z'^{=k+1} = Z^{=k+1} \subseteq 0^n 1 \Sigma^*$ and $\|Z' \cap \Sigma^{k+1}\| = \|Z \cap \Sigma^{k+1}\| \leq 1$. By our assumption, P_r is a positive path of $NM_j(z_r)$, and it holds that $P_r^{\text{yes}} \subseteq Y'$ and $P_r^{\text{no}} \subseteq N'$. It follows that (Y', N') must have been in L_r.

Since $L_r = \emptyset$ when the algorithm terminates, (Y', N') has been removed during some iteration i. This implies that during that iteration, $Y' \cap N(i) \neq \emptyset$ (by line 7). Moreover, by line 9, $N(i) \subseteq N$. This implies $Y' \cap N \neq \emptyset$, which contradicts (17). This proves Claim 6.28. □

Now we finish Case 2. Let r and N be as in Claim 6.28. Choose a word y_r of length $(k+1)/2$ such that $0^n 1 x_r y_r \notin N$. Let $S \stackrel{df}{=} \{0^n 1 x_r y_r\}$. It follows that $C(S) = D(S) = \emptyset$. Moreover, for all $n' \geq 1$, $\|E_{n'}(S)\| \leq 1$. From Proposition 6.10.4 it follows that $X' \stackrel{df}{=} X \cup S$ is $(\mu, k+1)$-valid. By Proposition 6.13.3, $(\emptyset, N)$ is a $(\mu, k+1)$-reservation for X'. Note that $\|N\| \leq (2 \cdot \alpha^j + 2) \cdot \gamma < 2^{(k+1)/2}$. Therefore, by Lemmas 6.14 and 6.17 there exists an $l \geq \alpha^j$ and a (μ, l)-valid $Y \supseteq_{k+1} X'$ such that $N \subseteq \overline{Y} \cap \Sigma^{\leq l}$ and $Y^{>k+1}$ contains only μ-codewords. From Claim 6.28 it follows that $NM_j^Y(z_r)$ rejects. The computation times of $f_i^Y(0^n 1 x_r)$ and $NM_j^Y(z_r)$ are bounded by $\alpha^j \leq l$. Therefore, for all $Z \supseteq_l Y$ it holds that $f_i^Z(0^n 1 x_r) = z_r$, $0^n 1 x_r \in E_n(Z)$, and $NM_j^Z(z_r)$ rejects. This shows that $E_n(Z)$ does not $\leq_m^{p,Z}$-reduce to $L(NM_j^Z)$ via f_i^Z. This finishes the proof of Proposition 6.25. □

Recall that we want to construct the oracle in a way such that $(A(O_2), B(O_2))$ is not $\leq_T^{pp,O_2}$-hard for NP^{O_2}. We have seen that it suffices to construct $F(O_2)$ such that it does not $\leq_T^{pp}$-reduce to $(A(O_2), B(O_2))$. We prevent $F(O_2) \leq_T^{pp} (A(O_2), B(O_2))$ via M_i as follows: We consider the computation $M_i(0^n)$, where the machine can ask queries to the pair $(A(X), B(X))$. In Lemma 6.29 we show that each query to this pair can be forced to be either in the complement of $A(X)$ or in the complement of $B(X)$. For this forcing it is enough to reserve polynomially many words for the complement of X. If we forced the query to be in the complement of $A(X)$, then the oracle can safely answer that the query belongs to $B(X)$. Otherwise it can safely answer that the query belongs to $A(X)$. After forcing all queries of the computation, we add an unreserved word to $F(X)$ if and only if the computation rejects. This will show that $F(X)$ does not $\leq_T^{pp}$-reduce to $(A(X), B(X))$ via M_i (Proposition 6.32).

LEMMA 6.29. *Let $k \equiv 2 \pmod 4$ and let X be (μ, k)-valid. For every $q \in \Sigma^*$, $|q| \leq 2^{k/2-4} - 2$, there exists an $N \subseteq \Sigma^{>k}$ such that $\|N\| \leq (8 \cdot |q| + 10)^2$ and one of the following properties holds:*

1. *For all (μ, m)-valid $Z \supseteq_k X$, if $m > k$, $N \subseteq \overline{Z}$, and $Z^{>k+1}$ contains only μ-codewords, then $q \notin A(Z)$.*
2. *For all (μ, m)-valid $Z \supseteq_k X$, if $m > k$, $N \subseteq \overline{Z}$, and $Z^{>k+1}$ contains only μ-codewords, then $q \notin B(Z)$.*

Proof. We can assume that $q = 0^n 10^t 1x$ for suitable n, t, x. Otherwise, q cannot belong to $A(Z) \cup B(Z)$ for all oracles Z, and we are done. Define the following sets:

$L_A \stackrel{df}{=} \{(Y_A, N_A) \mid (Y_A, N_A)$ is a $(\mu, k{+}1)$-reservation for some $(\mu, k{+}1)$-valid $Z \supseteq_k X$, ${Y_A}^{>k+1}$ contains only μ-codewords, $\ell(Y_A \cup N_A) \leq 8(|q|+1)$, and $(\exists y \in \Sigma^{3|q|+3})[0qy \in Y_A]\}$,

$L_B \stackrel{df}{=} \{(Y_B, N_B) \mid (Y_B, N_B)$ is a $(\mu, k{+}1)$-reservation for some $(\mu, k{+}1)$-valid $Z \supseteq_k X$, ${Y_B}^{>k+1}$ contains only μ-codewords, $\ell(Y_B \cup N_B) \leq 8(|q|+1)$, and $(\exists y \in \Sigma^{3|q|+3})[1qy \in Y_B]\}$.

We say that $(Y_A, N_A) \in L_A$ and $(Y_B, N_B) \in L_B$ *conflict* if and only if $Y_A \cap N_B \neq \emptyset$ or $N_A \cap Y_B \neq \emptyset$. Note that if (Y_A, N_A) and (Y_B, N_B) conflict, then even $Y_A \cap N_B \cap \Sigma^{>k} \neq \emptyset$ or $N_A \cap Y_B \cap \Sigma^{>k} \neq \emptyset$.

Claim 6.30. *Every $(Y_A, N_A) \in L_A$ conflicts with every $(Y_B, N_B) \in L_B$.*

Proof. Assume that there exist $(Y_A, N_A) \in L_A$ and $(Y_B, N_B) \in L_B$ that do not conflict. Let $Y' \stackrel{df}{=} Y_A \cup Y_B$, $N' \stackrel{df}{=} N_A \cup N_B$ and $S \stackrel{df}{=} {Y_A}^{=k+1} \cup {Y_B}^{=k+1}$.

We show that (Y', N') is a $(\mu, k+1)$-reservation for $X' \stackrel{df}{=} X \cup S$. Since $k \equiv 2 \pmod 4$ and $S \subseteq \Sigma^{k+1}$, it holds that $C(S) = D(S) = \emptyset$ and, for all $n' \geq 1$, $E_{n'}(S) = \emptyset$. From Proposition 6.10.4, it follows that X' is $(\mu, k+1)$-valid. Note that $\|N_A \cup N_B\| \leq 2^{(k+1)/2}$, since $\|N_A \cup N_B\| \leq \ell(N_A) + \ell(N_B) + 2 \leq 16|q| + 18 \leq 2^{k/2}$. By assumption, $Y_A \cap N_B = Y_B \cap N_A = \emptyset$. From Proposition 6.24 it follows that $A(Y_A \cup Y_B) \cap B(Y_A \cup Y_B) = \emptyset$. Therefore, it remains to verify $Y' \cap N' = \emptyset$, ${Y'}^{=k+1} \subseteq X'$, and ${N'}^{=k+1} \subseteq \overline{X'}$. The first condition holds, since (Y_A, N_A) and (Y_B, N_B) do not conflict. The second one holds by the definition of X'. Finally, ${N'}^{=k+1} \subseteq \overline{X'}$ holds, since otherwise ${N'}^{=k+1} \cap S \neq \emptyset$, and therefore $Y' \cap N' \neq \emptyset$. This shows that (Y', N') is a $(\mu, k+1)$-reservation for X'.

From the definition of L_A and L_B it follows that $\|N'\| \leq 16 \cdot |q| + 18 \leq 2^{k/2}$. By Lemma 6.14, there exist an $m \geq k+1$ and a (μ, m)-valid $Z \supseteq_{k+1} X'$ such that $Y' \subseteq Z$. Since $(Y_A, N_A) \in L_A$ and $(Y_B, N_B) \in L_B$, there exist $y_0, y_1 \in \Sigma^{3|q|+3}$ such that $0qy_0 \in Y_A \subseteq Y' \subseteq Z$ and $1qy_1 \in Y_B \subseteq Y' \subseteq Z$. Therefore, $q \in A(Z) \cap B(Z)$, which contradicts the fact that Z is (μ, m)-valid. This proves Claim 6.30. □

We use the following algorithm to create the set N as claimed in the statement of this lemma.

```
1    N := ∅
2    while (L_A ≠ ∅ and L_B ≠ ∅)
3        choose some (Y'_A, N'_A) ∈ L_A
4        N := N ∪ Y'_A^{>k} ∪ N'_A^{>k}
5        for every (Y_A, N_A) ∈ L_A
6            remove (Y_A, N_A) if Y_A ∩ (Y'_A^{>k} ∪ N'_A^{>k}) ≠ ∅
7        for every (Y_B, N_B) ∈ L_B
8            remove (Y_B, N_B) if Y_B ∩ (Y'_A^{>k} ∪ N'_A^{>k}) ≠ ∅
9    end while
```

We claim that after l iterations of the *while* loop, for every $(Y_B, N_B) \in L_B$, $\|N_B\| \geq l$. If this claim is true, the while loop iterates at most $8 \cdot |q| + 10$ times, since for any $(Y_B, N_B) \in L_B$, $\ell(N_B) \leq 8 \cdot |q| + 8$, and therefore $\|N_B\| \leq 8 \cdot |q| + 9$. On the other hand, during each iteration, N is increased by at most $8 \cdot |q| + 9$ strings. Therefore, $\|N\| \leq (8 \cdot |q| + 10)^2$ and $N \subseteq \Sigma^{>k}$ when this algorithm terminates.

Claim 6.31. *After l iterations of the* while *loop, for every (Y_B, N_B) that remains in L_B, $\|N_B\| \geq l$.*

Proof. For every l, let us denote the pair that is chosen during the lth iteration in step 3 by (Y_A^l, N_A^l). By Claim 6.30, every (Y_B, N_B) that belongs to L_B at the beginning of this iteration conflicts with (Y_A^l, N_A^l), i.e., $N_A^l \cap Y_B \cap \Sigma^{>k} \neq \emptyset$ or $Y_A^l \cap N_B \cap \Sigma^{>k} \neq \emptyset$. If $N_A^l \cap Y_B \cap \Sigma^{>k} \neq \emptyset$, then (Y_B, N_B) will be removed from L_B in step 8. Otherwise, $Y_A^l \cap N_B \cap \Sigma^{>k}$ is not empty, and therefore there exists a lexicographically smallest word w_l in this set. In this case, (Y_B, N_B) will not be removed from L_B; we say that (Y_B, N_B) *survives* the lth iteration *due to the word* w_l. Note that (Y_B, N_B) can survive only due to a word that belongs to N_B. We will use this fact to prove that $\|N_B\| \geq l$ after l iterations.

We show now that any pair (Y_B, N_B) that is left in L_B after l iterations survives each of these iterations due to a different word. Since these words all belong to N_B, this will complete the proof of the claim. Assume that there exist iterations l and l' with $l < l'$ such that $w_l = w_{l'}$. Then $w_l \in Y_A^l \cap N_B \cap \Sigma^{>k}$ and $w_{l'} \in Y_A^{l'} \cap N_B \cap \Sigma^{>k}$. Therefore, $Y_A^l \cap Y_A^{l'} \cap \Sigma^{>k} \neq \emptyset$. So the pair $(Y_A^{l'}, N_A^{l'})$ should have been removed in iteration l (step 6) and cannot be chosen at the beginning of iteration l', as claimed. Hence, $w_l \neq w_{l'}$. This proves Claim 6.31. □

Therefore, we now have a set N of the required size such that either L_A or L_B will be empty. Assume that L_A is empty; we will show that Lemma 6.29.1 holds. Analogously we show that if L_B is empty, then Lemma 6.29.2 holds. Assume that for some $m \geq k+1$ there exists a (μ, m)-valid $Z \supseteq_k X$ such that $q \in A(Z)$, $N \subseteq \overline{Z}$, and $Z^{>k+1}$ contains only μ-codewords. Hence, there exists some $y \in \Sigma^{3|q|+3}$ such that $0qy \in Z$.[6]

Let $Z' \stackrel{df}{=} Z^{\leq k+1}$. From Proposition 6.10.6 it follows that Z' is $(\mu, k+1)$-valid. Since $Z^{>k+1}$ contains only μ-codewords, we can apply Lemma 6.18 for $(\{0qy\}, \emptyset)$. We obtain a $(\mu, k+1)$-reservation (Y', N') for Z' such that $0qy \in Y'$, $\ell(Y' \cup N') \leq 2 \cdot |0qy| = 8 \cdot (|q|+1)$, and $Y' \subseteq Z \subseteq \overline{N'}$. Together with $N \subseteq \overline{Z}$, this implies

$$Y' \cap N = \emptyset. \tag{18}$$

Moreover, since $Y' \subseteq Z$, it holds that ${Y'}^{>k+1}$ contains only μ-codewords. It follows that (Y', N') must have been in L_A and has been removed during some iteration. This implies that during that iteration, $Y' \cap ({Y'_A}^{>k} \cup {N'_A}^{>k}) \neq \emptyset$ (by line 6). Moreover, by line 4, ${Y'_A}^{>k} \cup {N'_A}^{>k}$ is a subset of N when the algorithm stops. This implies $Y' \cap N \neq \emptyset$, which contradicts equation (18). This proves Lemma 6.29. □

PROPOSITION 6.32 (property P4). *Let $i \geq 1$ and let X be (μ, k)-valid. There exists an $l > k$ and a (μ, l)-valid $Y \supseteq_k X$ such that for all $Z \supseteq_l Y$, if $A(Z) \cap B(Z) = \emptyset$, then there exists a separator S of $(A(Z), B(Z))$ such that $F(Z) \neq L(M_i^S)$.*

Proof. By Lemma 6.17, we can assume that $k \equiv 2 \pmod 4$ and $64(k+10)^{3i} < 2^{k/2}$.

We describe the construction of S_A and S_B, which are sets of queries we reserve for $\overline{B(Y)}$ and $\overline{A(Y)}$, respectively. Let $S_A := A(X)$ and $S_B := B(X)$. We simulate the computation $M_i^{S_A}(0^{k+1})$ until we reach a query q_1 that belongs to neither S_A nor S_B. Note that $|q_1| \leq (k+1)^i \leq 2^{k/2-4} - 2$. From Lemma 6.29 we obtain some $N_1 \subseteq \Sigma^{>k}$ such that $\|N_1\| \leq (8 \cdot |q_1| + 10)^2$ and either property 6.29.1 or property 6.29.2 holds. If property 6.29.1 holds, then add q_1 to S_B; otherwise add q_1 to S_A. Now return the

[6] Actually, it even holds that $0qy \in Z - X$, but we do not need this explicitly in our argumentation. In order to see this, we assume that $0qy$ is in X. Then q is in $A(X)$ and $(\{0qy\}, \emptyset)$ is a (μ, k)-reservation for X. Therefore, $(\{0qy\}, \emptyset)$ is a $(\mu, k+1)$-reservation for every $(\mu, k+1)$-valid $Z \supseteq_k X$. Hence, $(\{0qy\}, \emptyset)$ is in L_A at the beginning of the algorithm. So it has been removed during the algorithm. But this is not possible since elements in L_A can only be removed in step 6, and there we remove only (Y_A, N_A) with $Y_A \cap \Sigma^{>k} \neq \emptyset$. This shows $0qy \in Z - X$.

answer of "$q_1 \in S_A$?" to the computation. We continue the simulation until we reach a query q_2 that belongs to neither S_A nor S_B. Again we apply Lemma 6.29, obtain the set N_2, and add q_2 either to S_A or to S_B. We continue the simulation until the computation stops. Let n be the number of queries that were added to S_A or S_B. Observe that $S_A \cap S_B = \emptyset$ at the end of our simulation.

Let $N \stackrel{df}{=} N_1 \cup \cdots \cup N_n \cup \{0^{4(k+1)^i+4}\}$. Then $\|N\| \leq (k+1)^i \cdot (8 \cdot (k+1)^i + 10)^2 + 1 \leq 2^{k/2}$. Hence there exists some $w \in \Sigma^{k+1} - N$. If the simulation accepts, then let $S' = \emptyset$; otherwise let $S' \stackrel{df}{=} \{w\}$. Since $S \subseteq \Sigma^{k+1}$ and $k+1 \equiv 3 \pmod 4$, we have $C(S') = D(S') = \emptyset$ and for all $n \geq 1$, $E_n(S') = \emptyset$. From Proposition 6.10.4, it follows that $Y' \stackrel{df}{=} X \cup S'$ is $(\mu, k+1)$-valid. Since $N \subseteq \Sigma^{>k}$ and $N \cap S' = \emptyset$, we have $N \subseteq \overline{Y'}$. Therefore, by Proposition 6.13.3, $(\emptyset, N)$ is a $(\mu, k+1)$-reservation for Y'. By Lemma 6.14, there exist an $l \geq 4(k+1)^i + 4$ and a (μ, l)-valid $Y \supseteq_{k+1} Y'$ such that $N \subseteq \overline{Y}$ and $Y^{>k+1}$ contains only μ-codewords. In particular, it holds that $l > k$ and $Y \supseteq_k X$.

CLAIM 6.33. *For every $Z \supseteq_l Y$ it holds that $S_A \subseteq \overline{B(Z)}$ and $S_B \subseteq \overline{A(Z)}$.*

Assume that $S_A \cap B(Z) \neq \emptyset$ for some $Z \supseteq_l Y$, and choose a $v \in S_A \cap B(Z)$. Since S_A contains only words of length $\leq (k+1)^i$, we obtain $v \in S_A \cap B(Z^{\leq 4(k+1)^i+4}) \subseteq S_A \cap B(Y)$. So v cannot belong to $A(Y)$ since $A(Y) \cap B(Y) = \emptyset$. In particular this means $v \in S_A - A(X)$; i.e., $v = q_j$ for a suitable j with $1 \leq j \leq n$. By our construction q_j was only added to S_A when property 2 of Lemma 6.29 holds. Remember that Y is (μ, l)-valid with $l > k$, $Y \supseteq_k X$, $N_j \subseteq N \subseteq \overline{Y}$, and $Y^{>k+1}$ contains only μ-codewords. Therefore, from property 6.29.2 it follows that $v = q_j \notin B(Y)$, which contradicts $v \in S_A \cap B(Y)$. This shows $S_A \subseteq \overline{B(Z)}$. By the symmetric argument we obtain $S_B \subseteq \overline{A(Z)}$. This proves Claim 6.33.

Consider any $Z \supseteq_l Y$ with $A(Z) \cap B(Z) = \emptyset$. Let $S \stackrel{df}{=} A(Z) \cup S_A$. Assume that S is not a separator of $(A(Z), B(Z))$. Since $A(Z) \subseteq S$, we must have $S \cap B(Z) \neq \emptyset$. Since $A(Z) \cap B(Z) = \emptyset$, this implies $S_A \cap B(Z) \neq \emptyset$. This contradicts Claim 6.33. So S is a separator of $(A(Z), B(Z))$. It remains to show $F(Z) \neq L(M_i^S)$.

By our construction, $0^{k+1} \in F(Y')$ if and only if $M_i^{S_A}(0^{k+1})$ rejects. Since $Z \supseteq_{k+1} Y'$, it holds that $0^{k+1} \in F(Z)$ if and only if $M_i^{S_A}(0^{k+1})$ rejects. Assume that there exists a query q that is answered differently in the computations $M_i^{S_A}(0^{k+1})$ and $M_i^S(0^{k+1})$ (take the first such query). Since $S_A \subseteq S$, we obtain $q \in S - S_A$, i.e., $q \in A(Z)$. If q is in $B(X)$, then q is in $B(Z) \subseteq \overline{S}$, which is not possible. So q is neither in S_A nor in $B(X)$, but q is asked in the computation $M_i^{S_A}(0^{k+1})$. It follows that $q = q_j$ for some j with $1 \leq j \leq n$, and during the construction we added q_j to S_B. So we have $q \in S_B \cap A(Z)$, which contradicts Claim 6.33. Therefore, $M_i^{S_A}(0^{k+1})$ accepts if and only if $M_i^S(0^{k+1})$ accepts. This shows $0^{k+1} \in F(Z)$ if and only if $M_i^S(0^{k+1})$ rejects, i.e., $F(Z) \neq L(M_i^S)$. □

This finishes the proof of Theorem 6.7. □

COROLLARY 6.34. *The oracle O_2 of Theorem 6.7 has the following additional properties:*

(i) $\mathrm{UP}^{O_2} \neq \mathrm{NP}^{O_2} \neq \mathrm{coNP}^{O_2}$ *and* $\mathrm{NPMV}^{O_2} \not\subseteq_c \mathrm{NPSV}^{O_2}$.

(ii) *Relative to O_2, no optimal propositional proof systems exist.*

(iii) *There exists a $\leq_{sm}^{pp}$-complete disjoint NP^{O_2}-pair (A, B) that is P^{O_2}-inseparable but symmetric.*

Proof. It is known that Conjecture 2.4 implies item (i) [ESY84, GS88, Sel94]. Relative to O_2, NP∩SPARSE does not have $\leq_m^{p,O_2}$-complete sets. Messner and Torán [MT98] proved that this implies that there are no optimal propositional proof systems. This shows (ii).

Since (A, B) is $\leq^{pp}_{sm}$-complete, it is symmetric. If (A, B) is P^{O_2}-separable, then every disjoint NP^{O_2}-pair is P^{O_2}-separable, and therefore symmetric. This contradicts item (ii) of Theorem 6.7. So (A, B) is P^{O_2}-inseparable. □

7. Relationship to optimal propositional proof systems. It is known that existence of optimal propositional proof systems implies existence of $\leq^{pp}_{m}$-complete disjoint NP-pairs. Messner and Torán [MT98] state that this result was communicated to them by Impagliazzo and Pitassi. Ben-David and Gringauze [BDG98] cite Razborov [Raz94] for this result. Köbler, Messner, and Torán [KMT03] cite Razborov, and they prove the stronger result that existence of optimal propositional proof systems implies existence of $\leq^{pp}_{sm}$-complete disjoint NP-pairs.[7] For the sake of completeness, we provide here a straightforward proof of the weaker result.

THEOREM 7.1. *If optimal propositional proof systems exist, then there is a* $\leq^{pp}_{m}$*-complete disjoint NP-pair.*

Proof. Let f be an optimal propositional proof system. We define the canonical pair [Raz94, Pud03] for this proof system, $(\mathrm{SAT}^*, \mathrm{REF}_f)$, where

$$\mathrm{SAT}^* = \{(x, 0^n) \mid x \in \mathrm{SAT}\}$$

and

$$\mathrm{REF}_f = \{(x, 0^n) \mid \neg x \in \mathrm{TAUT} \text{ and } \exists y[|y| \leq n \text{ and } f(y) = \neg x]\}.$$

Note that since f is polynomial-time computable, both SAT^* and REF_f are in NP. Also, for any n, if $(x, 0^n) \in \mathrm{SAT}^*$, then $x \in \mathrm{SAT}$, and if $(x, 0^n) \in \mathrm{REF}_f$, then $x \notin \mathrm{SAT}$. Therefore, these sets are disjoint, and so $(\mathrm{SAT}^*, \mathrm{REF}_f)$ is a disjoint NP-pair. We will prove that this pair is $\leq^{pp}_{m}$-complete.

Consider any other disjoint NP-pair (A, B). We will define a proof system $f_{A,B}$ using this pair. Assume that $A \leq^{p}_{m} \mathrm{SAT}$ via $g \in \mathrm{PF}$ and there is a polynomial $p(\cdot)$ and a polynomial-time predicate $R(\cdot, \cdot)$ such that $z \in B \Leftrightarrow \exists w, |w| \leq p(|z|), R(z, w)$.

$$f_{A,B}(y) = \begin{cases} \neg g(z) & \text{if } y = (z, w), \text{ where } |w| \leq p(|z|) \text{ and } R(z, w), \\ z & \text{if } y = (z, w), \text{ where } |w| > 2^{|z|} \text{ and } z \in \mathrm{TAUT}, \\ z \vee \neg z & \text{otherwise.} \end{cases} \tag{19}$$

We claim that $f_{A,B}$ is a proof system. First, note that for every $z \in \mathrm{TAUT}$, $f_{A,B}(z, w)$, for some $w, |w| > 2^{|z|}$, will output z in time polynomial in $|(z, w)|$. Also, since $A \cap B = \emptyset$ and g reduces A to SAT, $g(B) \subset \overline{\mathrm{SAT}}$. Therefore, for every $z \in B$ (i.e., for every z such that $R(z, w)$ for some $w, |w| \leq p(|z|)$), $g(z) \notin \mathrm{SAT}$. Therefore, $f_{A,B}$ outputs all possible tautologies and does not output anything that is not in TAUT. Also, since g is polynomial-time computable, so is $f_{A,B}$. It is therefore clear that $f_{A,B}$ is a proof system; since f is an optimal proof system, there is a polynomial $q(\cdot)$ such that for every tautology ϕ, and for every w such that $f_{A,B}(w) = \phi$, there is a $w', |w'| \leq q(|w|)$ and $f(w') = \phi$.

Now we define $h \in \mathrm{PF}$ such that $(A, B) \leq^{pp}_{m} (\mathrm{SAT}^*, \mathrm{REF}_f)$ via h. On input x, h outputs $(g(x), 0^{r(|x|)})$, where $r(\cdot)$ is some polynomial that we will fix later. If $x \in A$, then $g(x) \in \mathrm{SAT}$, and therefore $h(x) \in \mathrm{SAT}^*$.

On the other hand, for all $x \in B$, $g(x) \notin \mathrm{SAT}$, i.e., $\neg g(x) \in \mathrm{TAUT}$. Since $x \in B$, there exists $y = (x, w)$, where $|w| \leq p(|x|)$ such that $f_{A,B}(y) = \neg g(x)$. So,

[7] However, a forthcoming paper [GSS04] proves that there exist $\leq^{pp}_{sm}$-complete disjoint NP-pairs if and only if there exist $\leq^{pp}_{m}$-complete disjoint NP-pairs.

there is some y', $|y'| \leq q(|y|)$, such that $f(y') = \neg g(x)$. We choose r to be large enough so that $r(|x|) > |y'|$, and since q and p are polynomial, r can be chosen to be a polynomial as well. This shows that $x \in B$ implies $h(x) \in \mathrm{REF}_f$. Therefore, $(A, B) \leq_m^{pp} (\mathrm{SAT}^*, \mathrm{REF}_f)$; i.e., $(\mathrm{SAT}^*, \mathrm{REF}_f)$ is $\leq_m^{pp}$-complete. □

8. Conclusions. We partially summarize the import of the oracle results we obtained in this paper. Various implications have been known and/or are observed here for the first time. For several of these, our oracles demonstrate that the converses do not hold robustly. The following are convenient lists of these instances:

- Existence of optimal proof systems implies existence of $\leq_{sm}^{pp}$-complete NP-pairs [Raz94, KMT03]. Relative to oracle O_2, the converse is false.

Relative to both oracles O_1 and O_2, the converses of the following implications are false:

1. Nonexistence of $\leq_T^{pp}$-complete NP-pairs implies Conjecture 2.4 (observed in section 3).
2. Nonsymmetric implies P-inseparable (observed in section 5).
3. Nonexistence of $\leq_T^{pp}$-complete NP-pairs implies NP $\neq$ coNP (observed in section 3).
4. Nonexistence of $\leq_m^{pp}$-complete NP-pairs implies NP $\neq$ coNP (observed in section 3).

INCREMENTAL CLUSTERING AND DYNAMIC INFORMATION RETRIEVAL*

MOSES CHARIKAR†, CHANDRA CHEKURI‡, TOMAS FEDER§, AND RAJEEV MOTWANI¶

Abstract. Motivated by applications such as document and image classification in information retrieval, we consider the problem of clustering *dynamic* point sets in a metric space. We propose a model called *incremental clustering* which is based on a careful analysis of the requirements of the information retrieval application, and which should also be useful in other applications. The goal is to efficiently maintain clusters of small diameter as new points are inserted. We analyze several natural greedy algorithms and demonstrate that they perform poorly. We propose new deterministic and randomized incremental clustering algorithms which have a provably good performance, and which we believe should also perform well in practice. We complement our positive results with lower bounds on the performance of incremental algorithms. Finally, we consider the dual clustering problem where the clusters are of fixed diameter, and the goal is to minimize the number of clusters.

Key words. incremental clustering, dynamic information retrieval, minimum diameter clustering, agglomerative clustering, k-center, performance guarantee

1. Introduction.

We consider the following problem: as a sequence of points from a metric space is presented, efficiently maintain a clustering of the points so as to minimize the maximum cluster diameter. Such problems arise in a variety of applications, in particular in document and image classification for information retrieval. We propose a model called *incremental clustering* based primarily on the requirements for the information retrieval application, although our model should also be relevant to other applications. We begin by analyzing several natural greedy algorithms and discover that they perform rather poorly in this setting. We then identify some new deterministic and randomized algorithms with provably good performance. We complement our positive results with lower bounds on the performance of incremental algorithms. We also consider the dual clustering problem where the clusters are of fixed diameter, and the goal is to minimize the number of clusters. Before describing our results in any greater detail, we motivate and formalize our new model.

Clustering is used for data analysis and classification in a wide variety of applications [1, 20, 29, 35, 44]. It has proved to be a particularly important tool in *information retrieval* for constructing a taxonomy of a corpus of documents by forming groups of closely related documents [21, 24, 37, 44, 45, 47, 48]. For this purpose, a distance metric is imposed over documents, enabling us to view them as points in a metric space. The central role of clustering in this application is captured by the so-called *cluster hypothesis*: *documents relevant to a query tend to be more similar to each other than to irrelevant documents and hence are likely to be clustered together.* Typically, clustering is used to accelerate query processing by considering only a small number of representatives of the clusters, rather than the entire corpus. In addition, it is used for classification [19] and has been suggested as a method for facilitating browsing [16, 17].

The current information explosion, fueled by the availability of hypermedia and the World Wide Web, has led to the generation of an ever-increasing volume of data, posing a growing challenge for information retrieval systems to efficiently store and retrieve this information [50]. A major issue that document databases are now facing is the extremely high rate of update. Several practitioners have complained that existing clustering algorithms are not suitable for maintaining clusters in such a dynamic environment, and they have been struggling with the problem of updating clusters without frequently performing complete reclustering [7, 8, 9, 15, 45]. From a theoretical perspective, many different formulations are possible for this dynamic clustering problem, and it is not clear a priori which of these best addresses the concerns of the practitioners. After a careful study of the requirements, we propose the model described below.

Hierarchical agglomerative clustering. The clustering strategy employed almost universally in information retrieval is *hierarchical agglomerative clustering* (HAC); see [20, 44, 45, 47, 48, 49]. This is also popular in other applications such as biology, medicine, image processing, and geographical information systems. The basic idea is this: initially assign the n input points to n distinct clusters; repeatedly merge pairs of clusters until their number is sufficiently small. Many instantiations have been proposed and implemented, differing mainly in the rule for deciding which clusters to merge at each step. Note that HAC computes hierarchy trees of clusters (also called *dendograms*) whose leaves are individual points and whose internal nodes correspond to clusters formed by merging clusters at their children. A key advantage of these trees is that they permit refinement of responses to queries by moving down the hierarchy. Typically, the internal nodes are labeled with indexing information (sometimes called *conceptual information*) used for processing queries and in associating semantics with clusters (e.g., for browsing). Experience shows that HAC performs extremely well both in terms of efficiency and cluster quality. In the dynamic setting, it is desirable to retain the hierarchical structure while ensuring efficient update and high-quality clustering. An important goal is to avoid any major modifications in the clustering while processing updates, since any extensive recomputation of the index information will swamp the cost of clustering itself. The input size in typical applications is such that superquadratic time is impractical, and in fact it is desirable to obtain close to linear time.

A model for incremental clustering. Various measures of distance between documents have been proposed in the literature, but we will not concern ourselves with the details thereof; for our purposes, it suffices to note that these distance measures induce a metric space. Since documents are usually represented as high-dimensional vectors, we cannot make any stronger assumption than that of an arbitrary metric

space, although, as we will see, our results improve significantly in geometric spaces.

Formally, the *clustering* problem is as follows: given n points in a metric space $\mathcal{M}$, partition the points into k clusters so as to minimize the maximum cluster diameter. The *diameter* of a cluster is defined to be the maximum interpoint distance in it. Sometimes the objective function is chosen to be the maximum cluster radius. In Euclidean spaces, *radius* denotes the radius of the minimum ball enclosing all points in the cluster. To extend the notion of radius to arbitrary metric spaces, we first select a *center* point in each cluster, whereupon the radius is defined as the maximum distance from the center to any point in the cluster. We will assume the diameter measure as the default. We mention that there are several other measures of cluster quality that have been considered in the literature (e.g., sum of squares of distances to cluster centers, etc.). In this paper, we shall consider only the radius and diameter measures.

We define the *incremental clustering* problem as follows: for an update sequence of n points in $\mathcal{M}$, maintain a collection of k clusters such that as each input point is presented, either it is assigned to one of the current k clusters or it starts off a new cluster while two existing clusters are merged into one. We define the *performance ratio* of an incremental clustering algorithm as the maximum over all update sequences of the ratio of its maximum cluster diameter (or radius) to that of the optimal clustering for the input points.

Our model enforces the requirement that *at all times* an incremental algorithm should maintain a HAC for the points presented up to that time. As before, an algorithm is free to use any rule for choosing the two clusters to merge at each step. This model preserves all the desirable properties of HAC while providing a clean extension to the dynamic case. In addition, it has been observed that such incremental algorithms exhibit good paging performance when the clusters themselves are stored in secondary storage, while cluster representatives are preserved in main memory [42].

We have avoided labeling this model as the *online clustering problem* or referring to the performance ratio as a *competitive ratio* [34] for the following reasons. Recall that in an online setting, we would compare the performance of an algorithm to that of an adversary which knows the update sequence in advance but must process the points in the order of arrival. Our model has a stronger requirement for incremental algorithms, in that they are compared to adversaries which do not need to respect the input ordering, i.e., we compare our algorithms to optimal clusterings of the final point set, and no intermediate clusterings need be maintained. Also, online algorithms are permitted superpolynomial running times. In contrast, our model essentially requires polynomial-time approximation algorithms which are constrained to incrementally maintain a HAC. It may be interesting to explore the several different formulations of online clustering; for example, when the newly inserted point starts off a new cluster, we could allow the points of one old cluster to be redistributed among the remaining, rather than requiring that two clusters be merged together. The problem with such formulations is that they do not lead to HACs; moreover, they entail the recomputation of the index structures for *all clusters*, which renders the algorithms useless from the point of view of real applications. We note that since the incremental clustering model is more restrictive than the online model, our algorithms can also be viewed as online clustering algorithms; the competitive ratios are the same as the performance ratios that we prove here.

Previous work in static clustering. The closely related problems of clustering to minimize diameter and radius are also called *pairwise clustering* and the *k-center problem*, respectively [4, 30]. Both are NP-hard [25, 38], and in fact hard to approximate to within a factor of 2 for arbitrary metric spaces [4, 30]. For Euclidean spaces, clus-

tering on the line is easy [6], but in higher dimensions it is NP-hard to approximate to within factors close to 2, regardless of the metric used [22, 23, 27, 39, 40]. The *furthest point heuristic* due to Gonzalez [27] (see also Hochbaum and Shmoys [32, 33]) gives a 2-approximation in all metric spaces. This algorithm requires $O(kn)$ distance computations, and when the metric space is induced by shortest-path distances in weighted graphs, the running time is $O(n^2)$. Feder and Greene [22] gave an implementation for *Euclidean* spaces with running time $O(n \log k)$.

Clustering problems have been extensively studied in different communities from a variety of different perspectives. The optimization viewpoint of clustering formulates the problem as that of finding a solution that optimizes a certain objective function that measures cluster quality. In addition to the minimum diameter and radius measures described above, several other objective functions have also been considered in the literature. A lot of recent work has focused on the k-median objective [11, 36, 2]. Here the goal is to assign points to k centers such that the sum of distances of points to their centers is minimized. Other objectives that have been studied include the objective of minimizing the sum of all distances within each cluster [3, 18] and that of minimizing the sum of cluster diameters [14]. In addition to this, outlier formulations of clustering problems have also been studied [12]. Here the algorithm is allowed to discard a fraction of the input as outliers and is required to obtain a clustering solution that minimizes a given objective function on the remaining input points.

Overview of results. Our results for incremental clustering show that it is possible to obtain algorithms that are comparable to the best possible in the static setting, both in terms of efficiency and performance ratio. We begin in section 2 by considering natural greedy algorithms that choose clusters to merge based on some measure of the resulting cluster. We establish that greedy algorithms behave poorly by proving that a center-greedy algorithm has a tight performance ratio of $2k - 1$, and a diameter-greedy algorithm has a lower bound of $\Omega(\log k)$. It seems likely that greedy algorithms behave better in geometric spaces, and we discover some evidence in the case of the line. We show that diameter-greedy has performance ratio 2 for $k = 2$ on the line. This analysis suggests a variant of diameter-greedy, and this is shown to achieve ratio 3 for all k on the line. In section 3 we present the doubling algorithm and show that its performance ratio is 8, and that a randomized version has ratio 5.43. While the obvious implementation of these algorithms is expensive, we show that they can be implemented so as to achieve amortized time $O(k \log k)$ per update. These results for the doubling algorithm carry over to the radius measure. We also give a variant of this algorithm that is oblivious to the number of clusters k. We maintain a hierarchy from which, for any given k, at most k clusters can be obtained such that the diameter of the clusters is at most a factor of 8 times the optimal diameters for that value of k. Then, in section 4, we present the clique algorithm and show that it has performance ratio 6, and that a randomized version has ratio 4.33. While the clique algorithm may appear to dominate the doubling algorithm, this is not the case since the former requires computing clique partitions, an NP-hard problem, although it must be said in its defense that the clique partitions need only be computed in graphs with $k + 1$ vertices. While the performance ratio of the clique algorithm is 8 for the radius measure, improved bounds are possible for d-dimensional Euclidean spaces; specifically, we show that the radius performance ratio of the clique algorithm in $\Re^d$ improves to $4(1 + \sqrt{d/(2d + 2)})$, which is 6 for $d = 1$, and is asymptotic to 6.83 for large d. In section 5, we provide lower bounds for incremental clustering algorithms. We show that even for $k = 2$ and on the line, no deterministic or randomized algorithm can achieve a ratio better than 2.

TABLE 1.1

Summary of results: An asterisk indicates randomization. All algorithms have lower bounds on their performance ratios that match the upper bounds we establish.

Measure	Algorithm	Upper bound	Lower bound
Diameter			$1+\sqrt{2}$
	Center-greedy	$2k-1$	
	Diameter-greedy		$\Omega(\log k)$
	Doubling	8	
	Clique partition	6	
			$(2-\epsilon)^*$
	Doubling	5.437^*	
	Clique partition	4.33^*	
Radius			3
	Doubling	8	
	Clique partition	8	
			$(3-\epsilon)^*$
	Doubling	5.437^*	
	Clique partition	5.77^*	
Dual clust.			$\Omega(\frac{\log d}{\log\log\log d})$ in $\Re^d$
		$O(2^d d\log d)$ in $\Re^d$	$\Omega(2^d d\log d)$

We improve this lower bound to 2.414 for deterministic algorithms in general metric spaces. Finally, in section 6 we consider the dual clustering problem of minimizing the number of clusters of a fixed radius. Since it is impossible to achieve bounded ratios for general metric spaces, we focus on d-dimensional Euclidean spaces. We present an incremental algorithm that has performance ratio $O(2^d d\log d)$, and also provide a lower bound of $\Omega(\log d/\log\log\log d)$. See Table 1.1 for a summary of our results.

Many interesting directions for future research are suggested by our work. There are the obvious questions of improving our upper and lower bounds, particularly for the dual clustering problem. An important theoretical question is whether the geometric setting permits better ratios than metric spaces do. Our model can be generalized in many different ways. Depending on the exact application, we may wish to consider other measures of clustering quality, such as minimum variance in cluster diameter, and the sum of squares of the interpoint distances within a cluster. Then there is the issue of handling deletions which, though not important for our motivating application of information retrieval, may be relevant in other applications. Finally, there is the question of formulating a model for *adaptive clustering*, wherein the clustering may be modified as a result of queries and user feedback, even without any updates.

Recently, there has been considerable attention devoted to the streaming data model which was formalized and extensively studied after the appearance of the conference version of this paper. The streaming model is motivated by the goal of designing highly efficient algorithms for very large data sets. In this model, an algorithm is required to perform its computation in one pass or a few passes over the data while using very little memory. Our algorithms can be viewed as streaming algorithms for clustering problems where the goal is to minimize the maximum diameter or radius of the clusters produced. Subsequent to this work, other clustering objectives have also been studied in the streaming model, most notably the k-median objective [28, 13] and the sum of cluster diameters objective [14].

2. Greedy algorithms. We begin by examining some natural greedy algorithms. A *greedy incremental clustering algorithm* always merges clusters to minimize

some fixed measure. Our results indicate that such algorithms perform poorly.

DEFINITION 2.1. *The center-greedy algorithm associates a center for each cluster and merges the two clusters whose centers are closest. The center of the old cluster with the larger radius becomes the new center.*

It is possible to define variants of center-greedy based on how the centers of the clusters are picked, but we restrict ourselves to the above definition for reasons of simplicity and intuitiveness.

DEFINITION 2.2. *The diameter-greedy algorithm always merges those two clusters which minimize the diameter of the resulting merged cluster.*

We can establish the following lower bounds on the performance ratio of these two greedy algorithms.

THEOREM 2.3. *The center-greedy algorithm's performance ratio has a lower bound of* $2k-1$.

Proof. We first construct a graph $G=(V,E)$ which defines the metric space on which center-greedy has a performance ratio of $2k-1$. The vertex set of G is the union of $2k$ disjoint sets $S_0, S_1, \ldots, S_{2k-1}$ with a total of 2^k+k-1 vertices. The request sequence consists of the entire set of vertices $v_1, v_2, \ldots, v_{2^k+k-1}$. We use a complete binary tree $T=(V_T, E_T)$ whose leaves in a left to right order are the vertices $v_1, \ldots, v_{2^k}$ to describe our construction. Each internal node x of T has a binary *label* associated with it, denoted by $label(x)$. Let x_l and x_r be the left and right children of node x. We recursively define the labels of nodes of T as follows. The root of the tree is labeled with 0. If $label(x)=i$, we set $label(x_l)=i$ and $label(x_r)=1-i$. With each edge (x,y) of the tree we associate an integer weight of value $label(x)+label(y)-1$. Note that the weights belong to $\{-1,0,1\}$ by our labeling procedure. We now specify the sets $S_0, S_1, \ldots, S_{2k-1}$. A leaf v_i belongs to the set S_j if and only if the sum of the weights of the edges on the path from v_i to the root of T is equal to $j-k$. The vertices $v_{2^k+1}, \ldots, v_{2^k+k-1}$ belong to S_k. With each node x of T we also associate a vertex $v(x)$ of G as follows. If x is a leaf, we set $v(x)=x$; for an internal node x, we set $v(x)=v(x_r)$. For a node x of T let $po(x)=i$ if x is the ith vertex to be visited in a *post order* traversal of T, where we do not include the leaves in the traversal.

Now we specify the distances among the vertices of G. We first specify the edges present in G and then associate lengths with them. The other distances are induced by these edges. The edge set E is defined by the sets $S_0, \ldots, S_{2k-1}$ as follows:

$$\{(v_i,v_j) \mid v_i, v_j \in S_r, 0 \le r \le 2k-1\} \bigcup \{(v_i,v_j) \mid v_i \in S_r, v_j \in S_{r+1}, 0 \le r < 2k-1\}.$$

Edges between two vertices in the same set S_i are called *clique* edges. All the clique edges have length 1. The lengths of the other edges are defined as follows. We do a post order traversal of T and, as we process each internal node x of T, we set $d(v(x), v(x_l)) = 1-\epsilon_{po(x)}$ such that $1 \gg \epsilon_1 > \epsilon_2 > \cdots > \epsilon_{2^k-1} > 0$. By our placement of vertices in the sets S_i, we are guaranteed that $(v(x), v(x_l)) \in E$ for all x in T. We set to 1 any edge-length of an edge in E which is not already determined by the above process. See Figure 2.1 for an illustration of the construction.

Let C_x denote the cluster with $v(x)$ as the center and the leaves in the subtree rooted at x as the elements. Let $po^{-1}(i)$ denote the vertex x where $po(x)=i$. For $1 \le i \le 2^k-1$, let A_i be the set of clusters C_y such that y is the left child of some node on the path from $po^{-1}(i)$ to the root of T but does not itself lie on the path. We also include C_x in A_i, where $x=po^{-1}(i)$.

The lower bound is based on the following two claims.

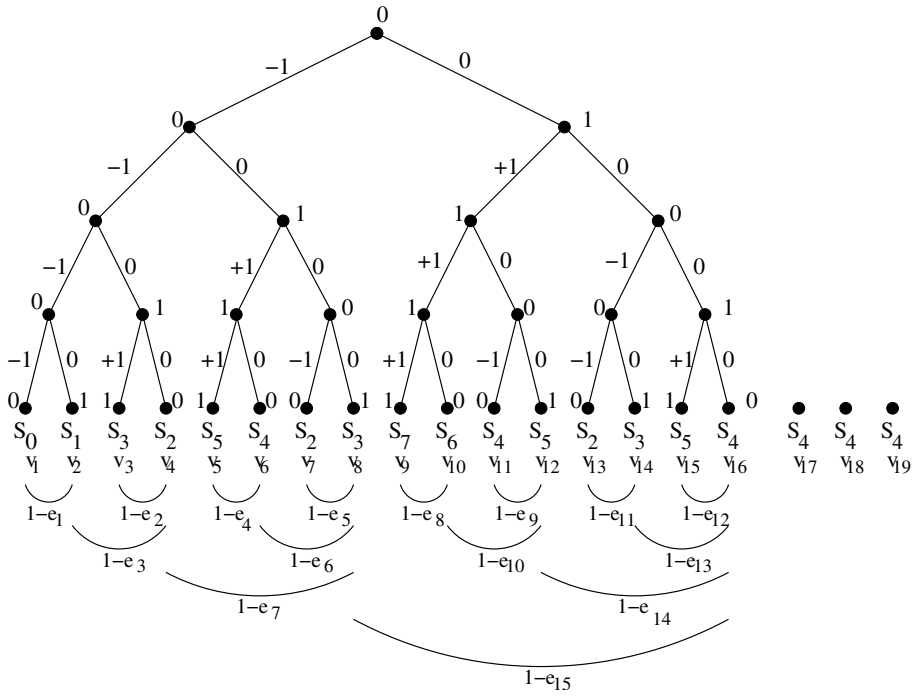

FIG. 2.1. *Illustration of the lower bound construction for center-greedy for $k = 4$. The instance consists of $2^k + k - 1 = 19$ vertices labeled $v_1, \ldots, v_{19}$. Each vertex belongs to one of the sets $S_0, \ldots, S_7$ as indicated. Vertex and edge labels defined on the tree structure are illustrated. The curved edges at the bottom of the figure indicate the additional edges added. (Note that distances within each S_i are all 1 and are not shown in the figure.) The curved edges also indicate the order in which clusters are merged by the center-greedy algorithm: cluster centers at the end points of the edge labeled $1 - \epsilon_1$ are first merged followed by centers at the end points of the edge labeled $1 - \epsilon_2$, then $1 - \epsilon_3$ and so on.*

CLAIM 2.4. *For $1 \le i \le 2k - 1$, A_i is the set of clusters of center-greedy which contain more than one vertex after the $k + i$ vertices $v_1, \ldots, v_{k+i}$ are given.*

Observe that $v_1 \in S_0$ and $v_{2^{k-1}+1} \in S_{2k-1}$, and the distance between them is at least $(2k - 1)(1 - \epsilon_1)$. From the above claim it follows that at the end of the request sequence, all the vertices $v_1, \ldots, v_{2^k}$ are in one cluster. Therefore, the diameter of this cluster is at least $(2k - 1)(1 - \epsilon_1)$.

CLAIM 2.5. *There is a k-clustering of G of diameter 1.*

The clustering which achieves the above diameter is $\{S_0 \cup S_1, \ldots, S_{2k-2} \cup S_{2k-1}\}$. This finishes the proof of the theorem. □

THEOREM 2.6. *The diameter-greedy algorithm's performance ratio is $\Omega(\log k)$, even on the line.*

Proof. We will prove a lower bound of $\Omega(\log k)$ for diameter-greedy on the real line. Let F_j be the jth Fibonacci number. Let k and r be such that $k = 2\sum_{i=1}^{r} F_i$. We will prove a lower bound of $r+1$ on diameter-greedy. To this end, we define sets of points A_{ij} for $1 \le i \le r$ and $1 \le j \le F_i$. Fix ϵ and δ such that $\epsilon < \delta \ll 1$. The set A_{ij} consists of the points p_{ij}, q_{ij}, r_{ij}, and s_{ij} sorted by their x-coordinates; the distances between them are as follows: $d(p_{ij}, q_{ij}) = 1 + \epsilon$, $d(q_{ij}, r_{ij}) = i$, and $d(r_{ij}, s_{ij}) = 1 + \delta$. Further, the distance between two distinct A_{ij}'s is set to ∞ (although any sufficiently large value will do). For $i = 1, \ldots, r$, let U_i, V_i, W_i, X_i, Y_i, and Z_i denote the following

clusters:

$$\begin{aligned}
U_i &= \cup_{j=1}^{F_i}\{\{p_{ij}, q_{ij}\}, \{r_{ij}, s_{ij}\}\},\\
V_i &= \cup_{j=1}^{F_i}\{\{q_{ij}\}, \{r_{ij}\}\},\\
W_i &= \cup_{j=1}^{F_i}\{\{p_{ij}\}, \{q_{ij}, r_{ij}\}\},\\
X_i &= \cup_{j=1}^{F_i}\{\{p_{ij}\}, \{q_{ij}, r_{ij}\}, \{s_{ij}\}\},\\
Y_i &= \cup_{j=1}^{F_i}\{\{p_{ij}, q_{ij}, r_{ij}\}, \{s_{ij}\}\},\\
Z_i &= \cup_{j=1}^{F_i}\{\{p_{ij}, q_{ij}, r_{ij}, s_{ij}\}\}.
\end{aligned}$$

Initially, the points given to diameter-greedy are the points q_{ij} and r_{ij} for each of the sets A_{ij}. Let P_i denote the sequence of requests $p_{i1}, \ldots, p_{iF_i}$ and let S_i denote the sequence $s_{i1}, \ldots, s_{iF_i}$. Define $K_i = P_1S_1P_2S_2 \ldots P_iS_i$. The request sequence is K_{r-1}. Note that $K_t = K_{t-1}P_tS_t$. We show inductively that the following invariant is maintained.

When the last element of K_t is received, diameter-greedy's $k+1$ clusters are

$$(\cup_{i=1}^{t-2} Z_i) \bigcup Y_{t-1} \bigcup X_t \bigcup (\cup_{i=t+1}^{r} V_i).$$

Since there are $k+1$ clusters, two of the clusters have to be merged and the algorithm merges two clusters in V_{t+1} to form a cluster of diameter $(t+1)$. Without loss of generality, we may assume that the clusters merged are $\{q_{(t+1)1}\}$ and $\{r_{(t+1)1}\}$.

Suppose that the situation is as described above at the end of the sequence K_t. We will show that the invariant holds at the end of the sequence K_{t+1}. Note that $K_{t+1} = K_tP_{t+1}S_{t+1}$. Observe that merging any two clusters in Y_{t-1} will increase their diameter to $(t+1+\epsilon+\delta)$. Merging any two clusters in X_t will increase their diameter to $(t+1+\epsilon)$. Because we start with the situation where there is a cluster $\{q_{(t+1)1}, r_{(t+1)1}\}$, the request $p_{(t+1)1}$ forces the formation of the cluster $\{q_{(t+1)2}, r_{(t+1)2}\}$, since any other merging results in a diameter of more than $t+1$. Thus, at the end of the sequence of requests P_{t+1}, we have $k+1$ clusters $(\cup_{i=1}^{t-2} Z_i) \bigcup Y_{t-1} \bigcup X_t \bigcup X_{t+1} \bigcup (\cup_{i=t+2}^{r} V_i)$.

Since there are $k+1$ clusters, diameter-greedy merges two clusters in X_t to form a cluster of diameter $(t+1+\epsilon)$. Thus, as we give points in S_{t+1}, it will form the clusters Y_t. Since $F_{t+1} > F_t$, after F_t requests in the sequence S_{t+1} all the clusters in X_t would have merged and diameter-greedy starts merging clusters in Y_{t-1} to form clusters Z_{t-1} of diameter $(t+1+\epsilon+\delta)$. Since $F_{t+1} = F_t + F_{t-1}$, at the end of the request sequence S_{t+1} it will have the $k+1$ clusters $(\cup_{i=1}^{t-1} Z_i) \bigcup Y_t \bigcup X_{t+1} \bigcup (\cup_{i=t+2}^{r} V_i)$. This shows that the invariant is maintained at the end of the request sequence K_{t+1}.

It is easy to verify that the invariant is true for the base case of $t = 3$. Thus, at the end of the request sequence K_{r-1}, the maximum diameter of the clusters of diameter-greedy is r. Since $k = 2\sum_{i=1}^{r} F_i = 2F_{r+2} - 2$, it follows that $r = \Omega(\log k)$. To finish the proof we observe that the optimal clusters are $\cup_{i=1}^{r-1} U_i \bigcup V_r$, and the diameter of these clusters is at most $1+\delta$. □

We now give a tight upper bound for the center-greedy algorithm. Note that for $k = 3$ it has ratio 5, but for larger k its performance is worse than that of the algorithms to be presented later.

THEOREM 2.7. *The center-greedy algorithm has performance ratio of $2k-1$ in any metric space.*

Proof. Suppose that a set P of n points is inserted. Let their optimal clustering be the partition $S = \{C_1, \ldots, C_k\}$, with d as the optimal diameter. We will show that the diameter of any cluster produced by center-greedy is at most $(2k-1)d$.

We define a graph G on the set S of the optimal clusters, where two clusters are connected by an edge if the minimum distance between them is at most d, where the distance between two clusters is the minimum distances between points in them. Consider the connected components of G. Note that two clusters in different connected components have a minimum distance strictly greater than d. We say that a cluster X intersects a connected component consisting of the optimal clusters $C_{i_1}, \ldots, C_{i_r}$ if X intersects $\cup_{j=1}^{r} C_{i_j}$.

We claim that at all times, any cluster produced by center-greedy intersects exactly one connected component of G. We prove this claim by induction over n. Suppose the claim is true before a new point p arrives. Initially, p is in a cluster of its own and center-greedy has $k+1$ clusters, each of which intersect exactly one connected component of G. Since there are $k+1$ cluster centers, two of them must be in the same optimal cluster. This implies that the distance between the two closest centers is at most d. If X_1 and X_2 are the clusters that center-greedy merges at this stage, the centers of X_1 and X_2 must be at most d apart. Hence, both clusters' centers must lie in the same connected component of G, say $\mathcal{C}$. By the inductive hypothesis, all points in X_1 and X_2 must be in $\mathcal{C}$. Hence, all points in the new cluster $X_1 \cup X_2$ must lie in $\mathcal{C}$, establishing the inductive hypothesis.

Since each cluster produced by center-greedy lies in exactly one connected component of G, the diameter is bounded by the maximum diameter of a connected component, which is at most $(2k-1)d$. ∎

For diameter-greedy in general metric spaces, we can only prove the following weak upper bound.

THEOREM 2.8. *For $k = 2$, the diameter-greedy algorithm has a performance ratio 3 in any metric space.*

Proof. Let d be the diameter in the optimal clustering. If the minimum distance between the two clusters (in the optimal clustering) is greater than d, then diameter-greedy keeps the two clusters separate and achieves the optimum. If the minimum distance between the two clusters is at most d, then all the points together form a cluster of diameter at most $3d$. ∎

In spite of the lower bounds for greedy algorithms, they may not be entirely useless since some variant may perform well in geometric spaces. We obtain some positive evidence in this regard via the following analysis for the line. The upper bounds given here should be contrasted with the lower bound of 2 for the line shown in section 5. The following definitions underlie the analysis.

DEFINITION 2.9. *Given a set S of n points in the line, a* t-partition *subdivides the interval between the first and last points of S into t subintervals whose end points are in S. The* t-diameter *of S is the minimum over all t-partitions of the maximum interval length in a t-partition of S. The* 1*-diameter is the diameter, while the* 2*-diameter is the radius of S where the center is constrained to be a point of S.*

We define the following family of algorithms based on the notion of the t-diameter.

DEFINITION 2.10. *The t-diameter-greedy algorithm merges those two clusters which minimize the t-diameter of the merged cluster. Note that* 1*-diameter-greedy is the same as diameter-greedy.*

A few preliminary results on the t-diameter-greedy algorithm can be found in the appendix.

3. The doubling algorithm. We now describe the doubling algorithm which has performance ratio 8 for incremental clustering in general metric spaces. The algorithm works in phases and uses two parameters α and β to be specified later, such that $\alpha/(\alpha-1) \leq \beta$. At the start of phase i, it has a collection of $k+1$ clusters $C_1, C_2, \ldots, C_{k+1}$ and a lower bound d_i on the optimal clustering's diameter (denoted by OPT). Each cluster C_i has a center c_i which is one of the points of the cluster. The following invariants are assumed at the start of phase i:

1. for each cluster C_j, the radius of C_j defined as $\max_{p \in C_j} d(c_j, p)$ is at most αd_i;
2. for each pair of clusters C_j and C_l, the intercenter distance $d(c_j, c_l) \geq d_i$;
3. $d_i \leq \text{OPT}$.

Each phase consists of two stages: the first is a *merging stage*, in which the algorithm reduces the number of clusters by merging certain pairs; the second is the *update stage*, in which the algorithm accepts new updates and tries to maintain at most k clusters without increasing the radius of the clusters or violating the invariants (clearly, it can always do so by making the new points into separate clusters). A phase ends when the number of clusters again exceeds k.

DEFINITION 3.1. *The* t-threshold graph *on a set of points* $P = \{p_1, p_2, \ldots, p_n\}$ *is the graph* $G = (P, E)$ *such that* $(p_i, p_j) \in E$ *if and only if* $d(p_i, p_j) \leq t$.

The merging stage works as follows. Define $d_{i+1} = \beta d_i$, and let G be the d_{i+1}-threshold graph on the $k+1$ cluster centers $c_1, c_2, \ldots, c_{k+1}$. The graph G is used to merge clusters by repeatedly performing the following steps while the graph is nonempty: pick an arbitrary cluster C_i in G and merge all its neighbors into it; make c_i the new cluster's center; and remove C_i and its neighbors from G. Let $C'_1, C'_2, \ldots, C'_m$ be the new clusters at the end of the merging stage. Note that it is possible that $m = k+1$ when the graph G has no edges, in which case the algorithm will be forced to declare the end of phase i without going through the update stage.

LEMMA 3.2. *The pairwise distance between cluster centers after the merging stage of phase* i *is at least* d_{i+1}.

LEMMA 3.3. *The radius of the clusters after the merging stage of phase* i *is at most* $d_{i+1} + \alpha d_i \leq \alpha d_{i+1}$.

Proof. Prior to the merging, the distance between two clusters which are adjacent in the threshold graph is at most d_{i+1}, and their radius is at most αd_i. Therefore, the radius of the merged clusters is at most

$$d_{i+1} + \alpha d_i \leq (1 + \alpha/\beta) d_{i+1} \leq \alpha d_{i+1},$$

where the last inequality follows from the choice that $\alpha/(\alpha-1) \leq \beta$. ∎

The update stage continues while the number of clusters is at most k. When a new point arrives, the algorithm attempts to place it in one of the current clusters without exceeding the radius bound αd_{i+1}: otherwise, a new cluster is formed with the update as the cluster center. When the number of clusters reaches $k+1$, phase i ends and the current set of $k+1$ clusters along with d_{i+1} are used as the input for the $(i+1)$st phase.

All that remains to be specified about the algorithm is the initialization. The algorithm waits until $k+1$ points have arrived and then enters phase 1 with each point as the center of a cluster containing just itself, and with d_1 set to the distance between the closest pair of points. It is easily verified that the invariants hold at the start of phase 1. The following lemma shows that the clusters at the end of the ith phase satisfy the invariants for the $(i+1)$st phase.

LEMMA 3.4. *The $k+1$ clusters at the end of the ith phase satisfy the following conditions:*

1. *The radius of the clusters is at most αd_{i+1}.*
2. *The pairwise distance between the cluster centers is at least d_{i+1}.*
3. *$d_{i+1} \leq$ OPT, where OPT is the diameter of the optimal clustering for the current set of points.*

Proof. We have $k+1$ clusters at the end of the phase since that is the terminating condition for a phase. From Lemma 3.3, the radius of the clusters after the merging stage is at most αd_{i+1}. When adding new points, the algorithm ensures that the radius bound is respected. From Lemma 3.2, the distance between the clusters centers after the merging stage is d_{i+1}, and a new cluster is created only if a request point is at least d_{i+1} away from all current cluster centers. Therefore, the cluster centers have pairwise distance at least d_{i+1}. Since at the end of the phase we have $k+1$ cluster centers that are d_{i+1} apart, the optimal clustering is forced to put at least two of them in the same cluster. It follows that OPT $\geq d_{i+1}$. □

We make the following observations. The algorithm ensures the invariant that $d_i \leq$ OPT at the start of phase i. The radius of the clusters during phase i is at most αd_{i+1}. Therefore, the performance ratio at any time during the phase is at most $2\alpha d_{i+1}/\text{OPT} \leq 2\alpha\beta d_i/\text{OPT} \leq 2\alpha\beta$. We choose $\alpha = \beta = 2$; note that this choice satisfies the condition that $\alpha/(\alpha-1) \leq \beta$. This leads to the following performance bound, which can be shown to be tight.

THEOREM 3.5. *The doubling algorithm has performance ratio 8 in any metric space.*

We give a simple example showing that our analysis of the doubling algorithm is tight. Here we assume that $k \geq 3$. The input sequence consists of $k+3$ points, $p_1, \ldots, p_{k+1}, p_{k+2}, p_{k+3}$, given in that order. The points $p_1, \ldots, p_{k+1}$ form a uniform metric space with distance 1. The points p_{k+2} and p_{k+3} are distance 4 from the points $p_1, \ldots, p_{k+1}$ and are distance 8 from each other. It is easy to ensure that both p_{k+2} and p_{k+3} will be added to the same cluster during the update stage of phase 1, and thus the diameter of the largest cluster formed by the doubling algorithm is 8. However, an optimum clustering can achieve diameter 1 by having p_{k+2} and p_{k+3} in their own clusters and the rest of the points in a single cluster of diameter 1.

An examination of the proof of the preceding theorem shows that the radius of the clusters is within a factor of 4 of the diameter of the optimal clustering, leading to the following result.

COROLLARY 3.6. *The doubling algorithm has performance ratio 8 for the radius measure.*

A simple modification of the doubling algorithm, in which we pick the new cluster centers by a simple left-to-right scan, improves the ratio to 6 for the case of the line.

While the obvious implementation of this algorithm appears to be inefficient, we can establish the following time bound, which is close to the best possible.

THEOREM 3.7. *The doubling algorithm can be implemented to run in $O(k \log k)$ amortized time per update.*

Proof. First of all, we assume that there is a black box for computing the distance between two points in the metric space in unit time. This is a reasonable assumption in most applications, and in any case even the static algorithms' analysis requires such an assumption. In the information retrieval application, the documents are represented as vectors and the black-box implementation will depend on the vector length as well as the exact definition of distance.

We now show how the doubling algorithm may be implemented so that the amortized time required for processing each new update is bounded by $O(k \log k)$. We maintain the edge lengths of the complete graph induced by the current cluster centers in a heap. Since there are at most k clusters the space requirement is $O(k^2)$. When a new point arrives, we compute the distance of this point to each of the current cluster centers, which requires $O(k)$ time. If the point is added to one of the current clusters, we are done. If, on the other hand, the new point initiates a new cluster, we insert into the heap edges labeled with the distances between this new center and the existing cluster centers. For accounting purposes in the amortized analysis, we associate $\log k$ credits with each inserted edge. We will show that it is possible to charge the cost of implementing the merging stage of the algorithm to the credits associated with the edges. This implies the desired time bound.

We can assume, without loss of generality, that the merging stage merges at least two clusters. Let t be the threshold used during the phase. The algorithm extracts all the edges from the heap which have length less than t. Let m be the number of edges deleted from the heap. The deletion from the heap costs $O(m \log k)$ time. The t-threshold graph on the cluster centers is exactly the graph induced by these m edges. It is easy to see that the procedure described to find the new cluster centers using the threshold graph takes time linear in the number of edges of the graph, assuming that the edges are given in the form of an adjacency list. Forming the adjacency list from the edges takes linear time. Therefore, the total cost of the merging phase is bounded by $O(m \log k + m) = O(m \log k)$ time. The credit of $\log k$ placed with each edge when it is inserted into the heap accounts for this cost, completing the proof. □

Finally, we describe a randomized doubling algorithm with significantly better performance ratio. The algorithm is essentially the same as before, the main change being in the value of d_1, which is the lower bound for phase 1. In the deterministic case we chose d_1 to be the minimum pairwise distance of the first $k+1$ points, say x. We now choose a random value r from $[1/e, 1]$ according to the probability density function $1/r$, set d_1 to rx, and redefine $\beta = e$ and $\alpha = e/(e-1)$. Similar randomization of doubling algorithms was used earlier in scheduling [41], and later in other applications [10, 26].

THEOREM 3.8. *The randomized doubling algorithm has expected performance ratio* $2e \approx 5.437$ *in any metric space. The same bound is also achieved for the radius measure.*

Proof. Let σ be the sequence of updates and let the optimal cluster diameter for σ be γx for some $\gamma \geq 1$; by the definition of x, the optimal value is at least x. Suppose we choose $d_1 = rx$ for some $r \in (0, 1]$. Let ρ_r be the radius of the clusters created for σ with this value of r. Using arguments similar to those in the proof of Theorem 3.5, we can show that ρ_r is at most $d_{i+1} + \alpha d_i = e^{i+1} d_1/(e-1)$, where i is the largest integer such that $d_i = e^{i-1} d_1 = e^{i-1} rx \leq \text{OPT} = \gamma x$. Let i^* be the integer such that $e^{i^*-1} \leq \gamma < e^{i^*}$ and $\delta = \gamma / e^{i^*}$. Then $\rho_r \leq \frac{re x \gamma}{(e-1)\delta}$ when $r > \delta$, and $\rho_r \leq \frac{re^2 x \gamma}{(e-1)\delta}$ when $r \leq \delta$. Let X_r^- and X_r^+ be indicator variables for the events $[r \leq \delta]$ and $[r > \delta]$, respectively. We claim that the expected value of ρ_r is bounded by

$$
\begin{aligned}
E[\rho_r] &\leq \int_{1/e}^{1} \frac{re\gamma x(eX_r^- + X_r^+)}{\delta r(e-1)} \mathrm{d}r \\
&= \text{OPT} \frac{e}{\delta(e-1)} \int_{1/e}^{1} (eX_r^- + X_r^+) \mathrm{d}r
\end{aligned}
$$

$$= \text{OPT}\frac{e\delta(e-1)}{\delta(e-1)}$$
$$= e\text{OPT}.$$

Therefore, the expected diameter is at most $2e\text{OPT}$. □

Remark 3.9. The randomized version of the doubling algorithm can be converted to a deterministic algorithm for the offline case which runs in $O(\frac{1}{\epsilon}nk^2)$ time and has a performance ratio of $4(1+\epsilon)$.

3.1. An oblivious clustering algorithm. In this section we describe an incremental hierarchical clustering algorithm that does not need an a priori bound on the number of clusters. From the hierarchy, given an integer k, we can obtain a k-clustering of the points such that the diameter of the clustering is at most a factor of 8 times the optimum diameter for the given value of k.

For convenience, assume that we have an a priori upper bound on the maximum distance between points, which we take to be 1. We maintain the current points in a tree, where every point is a vertex of the tree. For convenience, we assume that if a point is a vertex of the tree, then one of its children corresponds to the same vertex. The root, at depth 0, is a single vertex. The vertices at depth $i \geq 1$ are points within distance $1/2^{i-1}$ of their parents, and all the vertices at depth i are at a distance greater than $1/2^i$ from each other.

Initially, we have a single point at the root, which also occurs as the only child, the only child of this child, and so on; for conceptual clarity, we may assume that the depth of the tree is infinite. Suppose we have a tree representing the points at some stage, and a new point p comes in. Let i be the largest integer such that p is within $1/2^i$ of some point q at depth i. Then p is added at depth $i+1$, with q as its parent, with p as its only child, p as the only child of the child, and so on. So p is at depth $i+1$ with parent within distance $1/2^i$ as desired, and also the vertices representing p at depth $j \geq i+1$ are at a distance greater than $1/2^j$ of other points at depth j. See Figure 3.1 for an example.

It remains to indicate how we obtain the k clusters from the tree when k is given. Let i be the greatest depth containing at most k points. These are the k cluster centers. The subtrees of the vertices at depth i are the clusters. As points are added, the number of vertices at depth i increases; if it goes beyond k, then we change i to $i-1$, collapsing certain clusters; otherwise, the new point is inserted in one of the existing clusters.

THEOREM 3.10. *The algorithm that outputs the k clusters obtained from the tree construction has performance ratio 8 for the diameter measure and the radius measure.*

Proof. Suppose the optimal diameter is $1/2^{i+1} < d \leq 1/2^i$. Then points at depth i are in different clusters, so there are at most k of them. Let $j \geq i$ be the greatest depth containing at most k points. Then these are the cluster centers, and the vertices in the corresponding subtrees are at a distance of the root within $1/2^j + 1/2^{j+1} + 1/2^{j+2} + \cdots \leq 1/2^{i-1} < 4d$. Hence the radius of the clusters is at most $4d$, and thus the diameter is at most $8d$. This proof also implies that if the optimal radius is r, the radius of the clusters output is at most $8r$. □

The randomization technique used in the randomized doubling algorithm can also be applied here to get a better performance ratio (in expectation). The construction of the tree described above used distance threshold $1/2^i$ for depth i. Instead, we use distance threshold r/e^i for depth i, where r is chosen at random from the interval

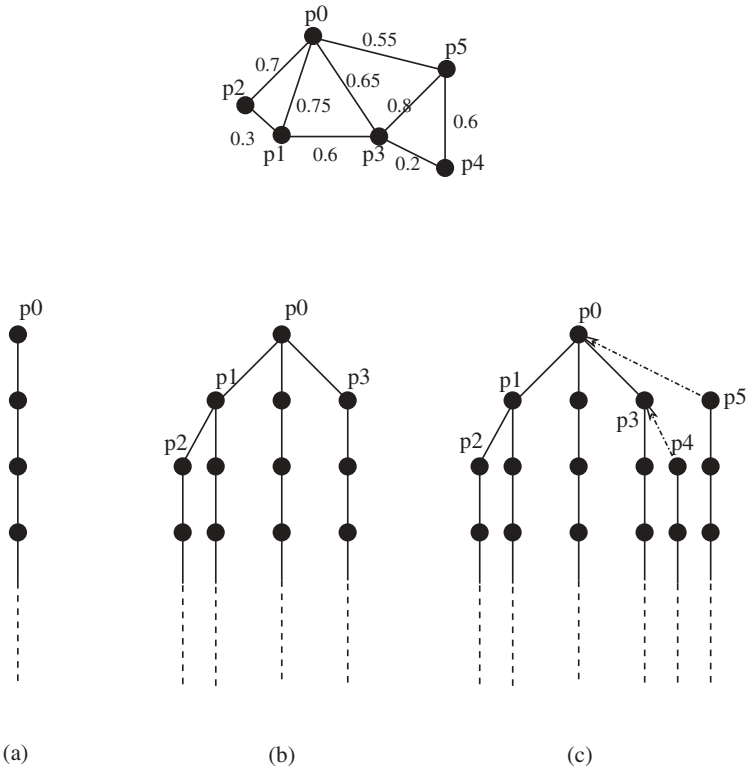

FIG. 3.1. *Illustration of the oblivious clustering algorithm. The points are numbered according to their order of arrival, and the distance between points is the minimum of* 1 *and the distance induced by the weighted graph shown.* (a) *Tree after first point* $p0$ *arrives.* (b) *Tree after four points.* (c) *Addition of* $p4$ *and* $p5$. *If* $k = 3$, *in* (b), *the clusters are centered around* $p0$, $p1$, *and* $p3$; *in* (c) *there is a single cluster around* $p0$.

$[1, e]$, according to the probability density function $1/r$. Note that the value r is chosen once at the beginning of the tree construction. By performing an analysis very similar to that for the randomized doubling algorithm, we can show that the expected diameter of the k-clustering obtained from the tree is at most $2e \approx 5.437$ times the optimal diameter. The same bound holds for the radius as well.

4. The clique partition algorithm. We now describe the clique algorithm, which has performance ratio 6. This does not totally improve upon the doubling algorithm since the new algorithm involves solving the NP-hard clique partition problem, even though it is only on a graph with $k + 1$ vertices. Finding a minimum clique partition is NP-hard even for graphs induced by points in the Euclidean plane [25], although it is in polynomial time for points on the line. Since the algorithm needs to solve the clique partition problem on graphs with $k + 1$ vertices, this may not be too inefficient for small k.

DEFINITION 4.1. *Given an undirected unweighted graph* $G = (V, E)$, *an* l*-clique partition is a partition of* V *into* $V_1, V_2, \ldots, V_l$ *such that for* $1 \leq i \leq l$, *the induced graph* $G[V_i]$ *is a clique. A* minimum clique partition *is an* l*-clique partition with the minimum possible value of* l.

The clique algorithm is similar to the doubling algorithm in that it also operates

in phases which have a merging stage followed by an update stage. The invariants maintained by the algorithm are different though. At the start of the ith phase we have $k+1$ clusters $C_1, C_2, \ldots, C_{k+1}$ and a value d_i such that

1. the radius of each cluster C_j is at most $2d_i$;
2. the diameter of each cluster C_j is at most $3d_i$;
3. $d_i \leq \text{OPT}$.

The merging works as follows. Let $d_{i+1} = 2d_i$. We form the minimum clique partition of the d_{i+1}-threshold graph G of the cluster centers. The new clusters are then formed by merging the clusters in each clique of the clique partition. We arbitrarily choose one cluster from each clique and make its center the cluster center of the new merged cluster. Let $C'_1, C'_2, \ldots, C'_{l_i}$ be the resulting clusters. In the rest of the phase we also need to know which old clusters merged to form each of the new clusters.

LEMMA 4.2. *After the merging stage, the radius of the new clusters is at most* $2d_{i+1}$ *and the diameter is at most* $3d_{i+1}$.

Proof. Let $C_{j_1}, C_{j_2}, \ldots, C_{j_{n_j}}$ be the clusters whose union is the new cluster C'_j and without loss of generality assume that the center of C_{j_1} was chosen to be the center of C'_j. Since the centers of $C_{j_1}, C_{j_2}, \ldots, C_{j_{n_j}}$ induce a clique in the d_{i+1}-threshold graph, the distance from the new center to each of the old cluster centers is at most d_{i+1}. The radius of each of $C_{j_1}, C_{j_2}, \ldots, C_{j_{n_j}}$ is at most $2d_i$. Therefore it follows that the new radius is at most $d_{i+1} + 2d_i \leq 2d_{i+1}$ and the diameter is at most $2d_i + d_{i+1} + 2d_i \leq 3d_{i+1}$. ∎

During the update phase, a new point p is handled as follows. Let the current number of clusters be m, where $l_i \leq m \leq k$. Recall that $C'_1, C'_2, \ldots, C'_{l_i}$ are the clusters formed during the merging stage. If there exists j such that $j > l_i$ and $d(p, c'_j) \leq d_{i+1}$, or if $j \leq l_i$ and $d(p, c_{j_s}) \leq d_{i+1}$ where C_{j_s} is a cluster which merged to form C'_j, add p to the cluster C'_j. If no such j exists, make a new cluster with p as the center. The phase ends when the number of clusters exceeds $k+1$, or if there are $k+1$ clusters at the end of the merging phase.

The following lemmas show that the clusters at the end of phase i satisfy the invariants for phase $i+1$.

LEMMA 4.3. *The radius of the clusters at the end of the phase* i *is at most* $2d_{i+1}$ *and the diameter of the clusters is at most* $3d_{i+1}$.

Proof. From Lemma 4.2, the radius of the clusters at the end of the merging stage of phase i is at most $2d_{i+1}$ and the diameter is at most $3d_{i+1}$. We now argue that these bounds are maintained during the update stage. If a point p is added to a cluster C_j, $j > l_i$, it satisfies the condition $d(p, c'_j) \leq d_{i+1}$; hence the radius of such a cluster is at most d_{i+1}, and hence the diameter is at most $2d_{i+1}$. If p is added to a cluster C'_j, $j \leq l_i$, then p satisfies the condition $d(p, c_{j_s}) \leq d_{i+1}$ where c_{j_s} is the center of a cluster that was merged to form the cluster C'_j. The center c'_j of C'_j is at a distance at most d_{i+1} from the centers of all the clusters that were merged to form C'_j. Therefore p is at a distance $2d_{i+1}$ from c'_j. This shows the radius bound. For the diameter bound, consider any two points p and q in the cluster C'_j. There must be cluster centers c_{j_s} and c_{j_t} of clusters that merged to form C'_j such that $d(p, c_{j_s}) \leq d_{i+1}$ and $d(q, c_{j_t}) \leq d_{i+1}$. The diameter bound follows since $d(c_{j_s}, c_{j_t}) \leq d_{i+1}$. ∎

LEMMA 4.4. *At the end of phase* i, $d_{i+1} \leq \text{OPT}$.

Proof. Suppose $d_{i+1} > \text{OPT}$. Let $S = \{c_1, c_2, \ldots, c_{k+1}\}$ be the cluster centers at the beginning of the phase i. Note that the centers $c'_1, \ldots, c'_{l_i}$ belong to S. Let $S' = \{c'_j \mid j > l_i\}$ be the set of cluster centers of the clusters which are formed

in phase i after the merging stage. Since each center c'_j in S' started a new cluster, $d(c'_j, p) > d_{i+1}$ for all $p \in S \cup S' - \{c'_j\}$. Therefore, in the optimal solution, each center in S' is in a cluster which contains no center from S. This implies that the centers in S are contained in at most $l_i - 1$ clusters of diameter d_{i+1}. This is a contradiction since l_i was the size of the minimum clique partition of the d_{i+1}-threshold graph on S. □

THEOREM 4.5. *The clique algorithm has performance ratio* 6 *in any metric space.*

Proof. The diameter of the clusters during phase i is at most $3d_{i+1}$, and we maintain the invariant that $d_i \leq \text{OPT}$ at the start of the phase. Therefore the performance ratio of the algorithm is at most $3d_{i+1}/d_i \leq 6$. □

The analysis of the clique algorithm is tight, as shown by the following example. We assume that $k \geq 4$. The sequence consists of $k+3$ points $p_1, \ldots, p_{k+1}, p_{k+2}, p_{k+3}$. The first k points form a uniform metric space with distance 1. The point p_{k+1} is at a distance 2 from p_2 and distance 1 from p_i for $2 \leq i \leq k$. The point p_{k+2} has the following properties: $d(p_{k+2}, p_1) = 2$, $d(p_{k+2}, p_i) = 3$ for $2 \leq i \leq k$, $d(p_{k+2}, p_{k+1}) = 4$, and $d(p_{k+2}, p_{k+3}) = 6$. The point p_{k+3} has the following properties: $d(p_{k+3}, p_1) = 4$, $d(p_{k+3}, p_i) = 3$ for $2 \leq i \leq k$, $d(p_{k+3}, p_{k+1}) = 2$, and $d(p_{k+3}, p_{k+2}) = 6$. After the first $k+1$ points are given the algorithm enters phase 1 with $d_1 = 1$ and $d_2 = 2$. In the merging stage the first $k+1$ points are merged into one single cluster since they form a clique in the d_2-threshold graph. It is easy to see that points p_{k+2} and p_{k+3} will be added to this cluster in the update stage, and the diameter of this cluster is seen to be 6. There is, however, an optimal clustering that achieves diameter 1 for all clusters: p_{k+2} and p_{k+3} are in their own clusters, p_1 and p_{k+1} are in different clusters, and the rest of the points can go either into the cluster containing p_1 or into the one containing p_{k+1}.

Since the radius of the clusters is within 4 of the optimal diameter, we obtain the following corollary.

COROLLARY 4.6. *The clique algorithm has performance ratio* 8 *in any metric space for the radius measure.*

As in the case of the doubling algorithm, we can use randomization to improve the bound. Let x be the minimum distance among the first $k+1$ points. The randomized algorithm sets $d_1 = rx$ in phase 1 of the deterministic algorithm, where r is chosen from $[1/2, 1]$ according to the probability density function $\frac{1}{r \ln 2}$. The analysis is similar to that of Theorem 3.8 and we omit the details.

THEOREM 4.7. *The randomized clique algorithm has performance ratio* $\frac{3}{\ln 2} \approx 4.33$ *in any metric space.*

COROLLARY 4.8. *The randomized clique algorithm has performance ratio* $\frac{4}{\ln 2} \approx 5.77$ *for the radius measure in any metric space.*

The special structure of the clusters in the clique algorithm can be used to show that the performance ratio for the radius measure is better than 8 for the geometric case. This is based on the following result in geometry, known as Jung's theorem (see [5, pp. 84–85]).

PROPOSITION 4.9. *Any convex set in* R^d *of diameter at most* 1 *can be circumscribed by a sphere of radius* $r_d = \sqrt{d/(2d+2)}$.

THEOREM 4.10. *The clique algorithm has performance ratio* $4(1 + r_d)$ *for the* radius *measure in* R^d. *This implies performance ratio* 6 *for* $d = 1$, 6.3 *for* $d = 2$, *and* 6.83 *asymptotically for large* d.

Proof. Let a_i be the maximum radius of the clusters of the algorithm in phase

i and let a_i^* be the radius achievable by an optimal clustering. We claim that $a_i \leq d_{i+1}(1+r_d) = 2d_i(1+r_d)$. Trivially, we have that $a_i^* \geq \text{OPT}_i/2$, where OPT_i is the optimal diameter achievable for points at the start of phase i. From the invariants of the algorithm we have that $d_i \leq \text{OPT}_i$, and hence we get that $a_i \leq 4a_i^*(1+r_d)$.

Now we prove the claim by induction. Assuming that the claim is true in phase $i-1$, we prove that it is true in phase i. In phase i let $C_1', C_2', \ldots, C_{l_i}'$ be clusters formed in the merging stage. It is easy to see that any new cluster formed during the update stage has radius at most d_{i+1}; hence we can focus on the clusters $C_1', C_2', \ldots, C_{l_i}'$. Without loss of generality consider C_1', which is formed by the merging of clusters $C_1, C_2, \ldots, C_j$ from the start of the phase. Let c_i be the center of C_i, $1 \leq i \leq j$. Since the clusters were merged, it follows that the diameter of the point set $\{c_1, c_2, \ldots, c_j\}$ is at most d_{i+1}. Hence their radius, by Proposition 4.9, is at most $d_{i+1}r_d$. From the invariants at the start of the phase, $d(p, c_i) \leq 2d_i = d_{i+1}$ for $p \in C_i$. Further, any new point added to the cluster C_1' is at most a distance of d_{i+1} from a point in $\{c_1, c_2, \ldots, c_j\}$. It follows that the radius of the cluster C_1' throughout the phase is at most $d_{i+1}r_d + d_{i+1}$, which proves the claim. ∎

5. Lower bounds. We present some lower bounds on the performance of incremental clustering. The lower bounds apply to both diameter and radius measures, but our proofs are given for the diameter case. The following theorem shows that even for the simplest geometric space, we cannot expect a ratio better than 2.

THEOREM 5.1. *For $k = 2$, there is a lower bound of 2 and $2 - 1/2^{k/2}$ on the performance ratio of deterministic and randomized algorithms, respectively, for incremental clustering on the line.*

Proof. Start with the three points $1, 2, 3$. Two consecutive points are necessarily merged, say 2 and 3. Add a new point at 4. Then 1 or 4 is merged with $[2, 3]$. This gives diameter 2, while the optimum is 1. In fact, this construction can be repeated to obtain n points $1, 2, \ldots, n$ clustered into 1 and $[2, n]$.

For the randomized lower bound, consider the instance in the preceding paragraph. To convert this to a randomized lower bound, the adversary places the fourth point at 0 or 4 with equal probability, and now the algorithm has probability $1/2$ of creating the wrong cluster (that is, with diameter 2). This gives a lower bound of 1.5. For general k, the algorithm makes $k/2$ copies of the above scenario far enough from each other that the above analysis applies locally. The probability that the algorithm succeeds in creating clusters of diameter 1 on all $k/2$ copies is $2^{-k/2}$. This implies a lower bound of $2 - 2^{-k/2}$. ∎

In the case of general metric spaces, we can establish a stronger lower bound.

THEOREM 5.2. *There is a lower bound of $1+\sqrt{2} \approx 2.414$ on the performance ratio of any deterministic incremental clustering algorithm for arbitrary metric spaces.*

Proof. Consider a metric space consisting of the points p_{ij}, $1 \leq i, j \leq 4$, $i \neq j$. The distances between the points are the shortest path distances in the graph with the following distances specified: $d(p_{ij}, p_{ji}) = 1$, and $d(p_{ij_1}, p_{ij_2}) = \sqrt{2}$ for $j_1 \neq j_2$. Let $B_i = \{p_{ij} \mid 1 \leq j \leq 4, i \neq j\}$. Note that the sets B_i, $1 \leq i \leq 4$, partition the metric space into 4 clusters of diameter $\sqrt{2}$. See Figure 5.1. Let A be any deterministic algorithm for the incremental clustering problem. Let $k = 6$. Consider the clusters produced by A after it is given the 12 points p_{ij} described above.

Case 1. Suppose the maximum diameter of A's clusters is 1. Then A's clusters must be the 6 sets $\{p_{ij}, p_{ji}\}$. Now the adversary gives a point q such that $d(q, p_{ij}) = 10$ for $1 \leq i, j \leq 4$. The optimal clustering is $\{q\}$ and the sets B_1, B_2, B_3, B_4. The optimal diameter is $\sqrt{2}$. We claim that the maximum diameter of A is at least $2 + \sqrt{2}$. If the

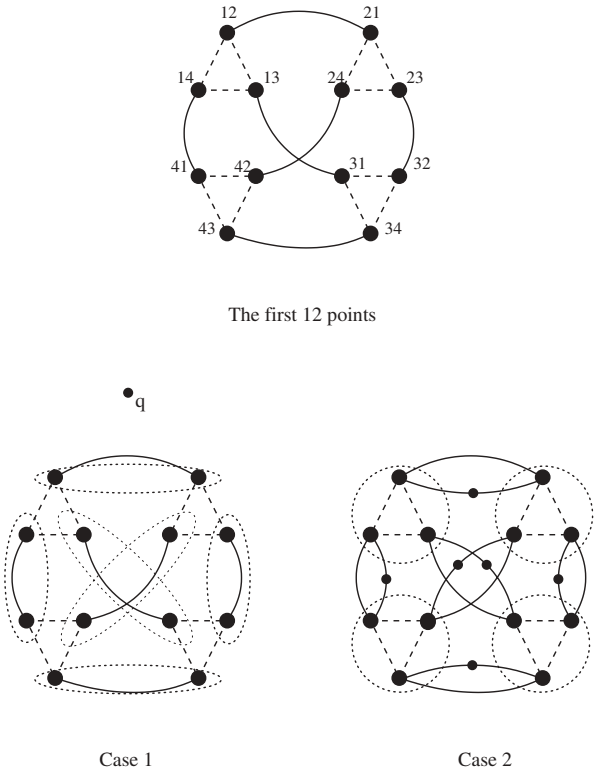

FIG. 5.1. *Lower bound instance. Solid and dashed lines show edges of length* 1 *and* $\sqrt{2}$*, respectively. Dotted ellipses show potential clusters. New points inserted after the first batch of* 12 *points are shown as smaller circles.*

cluster that contains q contains any other point, then our claim is clearly true. If on the other hand the cluster that contains q does not contain any other point, A must have merged two of its existing clusters. Then the maximum diameter of A's resulting clusters is at least $2+\sqrt{2}$. Thus the performance ratio of A is at least $1+\sqrt{2}$.

Case 2. Suppose the maximum diameter of A's clusters is greater than 1. Then some cluster of A contains 2 points which are at least distance $\sqrt{2}$ apart. Let these points be p_{wx} and p_{yz}, $(w,x) \neq (z,y)$. Now the adversary gives 6 points r_{ij}, $1 \leq i < j \leq 4$, such that $d(r_{ij}, p_{ij}) = d(r_{ij}, p_{ji}) = 1$. The optimal clustering consists of the 6 sets $\{r_{ij}, p_{ij}, p_{ji}\}$. The optimal diameter is 1. We claim that the maximum diameter of A's clusters must be at least $1+\sqrt{2}$. Note that $d(r_{i_1 j_1}, p_{i_2 j_2}) \geq 1+\sqrt{2}$ for $(i_2, j_2) \neq (i_1, j_1)$, $(i_2, j_2) \neq (j_1, i_1)$. Also $d(r_{i_1 j_1}, r_{i_2 j_2}) \geq 2+\sqrt{2}$ for $(i_1, j_1) \neq (i_2, j_2)$. If A puts any two r_{ij} in the same cluster, our claim is clearly true. If all the r_{ij} are in separate clusters, each of the 6 clusters must contain one of them. Also one of the 6 clusters, say C, must contain both the points p_{wx} and p_{yz}. Then C must have diameter at least $1+\sqrt{2}$, since the r_{ij} in C must be at a distance at least $1+\sqrt{2}$ from one of p_{wx} and p_{yz}. Hence the performance ratio of A is at least $1+\sqrt{2}$.

This proves a lower bound of $1+\sqrt{2}$ on the performance ratio of any deterministic incremental algorithm. □

Finally, we can improve the randomized lower bound slightly for the case of arbitrary metric spaces.

THEOREM 5.3. *For any $\epsilon > 0$ and $k \geq 2$, there is a lower bound of $2 - \epsilon$ on the performance ratio of any randomized incremental algorithm.*

Proof. We use Yao's technique and show a lower bound on deterministic algorithms on an appropriately chosen distribution. Let A be a deterministic algorithm for incremental clustering. The distribution on inputs is as follows. Initially, the adversary provides n points $P_1, P_2, \ldots, P_n$ such that the distance between any two of them is 1. Then the adversary partitions the n points into k disjoint sets $S_1, S_2, \ldots, S_k$ at random, such that all partitions are equally likely. Finally the adversary provides k points $Q_1, Q_2, \ldots, Q_k$, such that $d(Q_i, P_j) = 1$ if $P_j \in S_i$, $d(Q_i, P_j) = 2$ if $P_j \notin S_i$, $d(Q_i, Q_j) = 3$. Now, the diameter of the optimal solution for any input in the distribution is 1, obtained by constructing the k clusters $S_i \cup \{Q_i\}$. However, the incremental algorithm can produce a clustering with diameter 1 only if the clusters it produces after it sees points $P_1, P_2, \ldots, P_n$ are precisely the sets S_i (selected at random by the adversary). Let $X_k(n)$ be the number of ways to partition the n points into k sets. Then the probability that the incremental algorithm produces a clustering of diameter 1 is at most $p = 1/X_k(n)$. With probability at least $1 - p$, the incremental algorithm produces a clustering of diameter at least 2. Thus the expected value of the diameter of the clustering produced is at least $2 - p$. Hence the expected value of the performance ratio is at least $2 - p$. By choosing n suitably large, $X_k(n)$ can be made arbitrarily large, and hence p can be made arbitrarily small, in particular smaller than ϵ for any fixed $\epsilon > 0$. □

For the radius measure we have the following theorem.

THEOREM 5.4. *For the radius measure, no deterministic incremental clustering algorithm has a performance ratio better than 3 and no randomized algorithm has a ratio better than $3 - \epsilon$ for any fixed $\epsilon > 0$.*

Proof. We first consider the randomized case. The instances are very similar to the ones used in the proof of Theorem 5.3. The only difference is that $d(Q_i, P_j) = 0.5$ if $P_j \in S_i$ and $d(Q_i, P_j) = 1.5$ if $P_j \notin S_i$. The optimal clusters are $S_i \cup \{Q_i\}$ for $1 \leq i \leq k$ and each of them has a radius of 0.5. Any other clustering has radius at least 1.5 and the algorithm has a probability of $(1 - 1/X_k(n))$ of having such a cluster.

The instance used above can be adapted easily to show a bound of 3 for the deterministic case; we leave the details to the reader. □

6. Dual clustering. We now consider the dual clustering problem: for a sequence of points $p_1, p_2, \ldots, p_n \in \Re^d$, cover each point with a unit ball in $\Re^d$ as it arrives, so as to minimize the total number of balls used. In the static case, this problem is NP-complete and a PTAS is achievable in any fixed dimension [31]. We note that in general metric spaces, it is impossible to achieve any bounded ratio (for example, consider the uniform metric space).

Our algorithm's analysis is based on a theorem from combinatorial geometry called Roger's theorem [46] (see also [43, Theorem 7.17]), which says that R^d can be covered by any convex shape with covering density $O(d \log d)$. Since the volume of a radius 2 ball is 2^d times the volume of a unit-radius ball, the number of balls needed to cover a ball of radius 2 using balls of unit radius is $f(d) = O(2^d d \log d)$. We first describe an incremental algorithm which has performance ratio $f(d)$. We also establish an asymptotic lower bound of $\Omega(\frac{\log d}{\log \log \log d})$; for $d = 1$ and 2, our proof yields lower bounds of 2 and 4, respectively.

THEOREM 6.1. *For the dual clustering problem in $\Re^d$, there is an incremental algorithm with performance ratio $O(2^d d \log d)$.*

Proof. Our incremental algorithm maintains a set $\mathcal{C}$ of *centers* which is a subset

of the points that have arrived so far; initially, $\mathcal{C} = \emptyset$. Define the *range* $R(p)$ of a center p to be the sphere of radius 2 about p. For any two centers p_1 and p_2, we ensure that $d(p_1, p_2) > 2$. Associated with each center p is a set of points $\Gamma(p)$ called the *neighbors* of p. For convenience, we assume that $p \in \Gamma(p)$. We ensure that all neighbors of p lie in $R(p)$. When a new point x is received, if $x \in R(p)$ for some center p, we add x to $\Gamma(p)$, breaking ties arbitrarily. If no such center exists, x must be at a distance greater than 2 from all the existing centers. In this case, we make x a new center and set $\Gamma(x) = \{x\}$.

From Roger's theorem on packing density, a sphere of radius 2 in $\Re^d$ can be covered by $f(d) = O(2^d d \log d)$ spheres of radius 1. When a new center p is created, we fix a set of spheres $S_1(p), S_2(p), \ldots, S_{f(d)}(p)$ which cover $R(p)$. Whenever a point x is added to $\Gamma(p)$, if it is not already covered by some previously placed sphere, we add the sphere $S_r(p)$, where r is any value such that $x \in S_r(p)$. Note that such a sphere must exist as $x \in R(p)$ and the spheres $S_1(p), S_2(p), \ldots, S_{f(d)}(p)$ cover $R(p)$ completely.

Since no two centers can be covered by a sphere of unit radius, any solution must use a separate sphere to cover each center. Hence, the number of centers is a lower bound for the number of spheres used by the optimal offline algorithm. For each center p, the incremental algorithm uses at most $f(d)$ spheres to cover the points in $\Gamma(p)$. Hence, the performance ratio of the incremental algorithm is bounded by $f(d) = O(2^d d \log d)$. □

THEOREM 6.2. *For the dual clustering problem in $\Re^d$, any incremental algorithm must have performance ratio $\Omega(\frac{\log d}{\log \log \log d})$.*

Proof. The idea is as follows. At time t, when t points have been given by the adversary, it will be the case that the points $p_1, \ldots, p_t$ can be covered by a ball of radius $R_t < 1$. Then the adversary will find a point p_{t+1} lying outside the t unit balls laid down by the algorithm so as to minimize the radius R_{t+1} of the ball required to cover all $t + 1$ points and present that as a request. The game terminates when, at some time $k+1$, we have for the first time that $R_{k+1} > 1$. Clearly, k is a lower bound on the performance ratio since the points $p_1, \ldots, p_k$ can be covered by a ball of radius $R_k \leq 1$, and the algorithm has used k balls up to that point. It remains to analyze the worst-case growth rate of R_t as a function of t. Note that $R_1 = 0$ and $R_2 = 1/2$.

Let α_d denote the volume of a unit ball in $\Re^d$. At time t, let D_t be any ball of radius (at most) R_t that covers the points $p_1, \ldots, p_t$. For some δ_t to be specified later, define the ball D_t^* as a ball with the same center as D_t and with radius $R_t + \delta_t$. We will choose δ_t such that the volume of D_t^* is at least $t\alpha_d$, implying that the current t unit balls placed by the algorithm cannot cover the entire volume of D_t^*. This would imply that there is a choice of a point p_{t+1} inside D_t^* which is not covered by the current t balls. It is also clear that the new set of $t + 1$ points now can be covered by a ball of radius at most $R_t + \delta_t/2$, implying that

$$R_{t+1} \;=\; R_t + \frac{\delta_t}{2}.$$

Determining the value of δ_t is easy, since we have the inequality

$$\alpha_d (R_t + \delta_t)^d \;>\; t\alpha_d$$

from the requirement that the ball D_t have volume equal to that of t unit balls. Now let $R_t = 1 - \epsilon_t$. Substituting in the above equations, we obtain that $\delta_t = 2(\epsilon_t - \epsilon_{t+1})$

and hence $R_t + \delta_t = 1 + \epsilon_t - 2\epsilon_{t+1}$. Therefore

$$\alpha_d(1 + \epsilon_t - 2\epsilon_{t+1})^d \;>\; t\alpha_d,$$

which implies that

$$\ln(1 + \epsilon_t - 2\epsilon_{t+1}) \;>\; \frac{\ln t}{d}.$$

Note that $\epsilon_t - 2\epsilon_{t+1} < 1$. Using the fact that $\ln(1+x) > x/2$ for $x < 1$, we see that choosing ϵ_i such that

$$\frac{\epsilon_t - 2\epsilon_{t+1}}{2} \;=\; \frac{\ln t}{d}$$

will satisfy our requirements. Unfolding the recurrence,

$$\frac{\epsilon_1}{2^t} - \epsilon_{t+1} \;=\; \sum_{i=1}^{t} \frac{\ln i}{d2^{t-i}} \;=\; \sum_{i=1}^{t} \frac{\ln i}{d2^{t-i}} \;\le\; \sum_{i=1}^{t} \frac{\ln t}{d2^{t-i}} \;\le\; \frac{2\ln t}{d}.$$

Noting that $\epsilon_1 = 1$, we obtain that $\epsilon_{t+1} \ge 2^{-t} - 2d^{-1}\ln t$. The lower bound is the smallest value of t for which ϵ_{t+1} is negative. Let t_{max} be the largest value of t for which

$$\frac{1}{2^t} - \frac{2\ln t}{d} \;\ge\; 0.$$

This implies that $2^{t+1}\ln t \le d$ and hence

$$t_{max} \;=\; \Omega\left(\frac{\log d}{\log\log\log d}\right).$$

This gives the desired lower bound. □

Appendix. *t*-diameter-greedy algorithm. We give a few preliminary results on the t-diameter-greedy algorithm defined in section 2.

THEOREM A.1. *For $k = 3$, there is a lower bound of 3 on the performance ratio of the diameter-greedy algorithm on the line.*

Proof. We first show that diameter-greedy achieves a ratio of 3 for $k = 3$. Suppose that the optimal clustering is $[r, s], [t, u], [v, w]$ with $\max(s - r, u - t, w - v) = d$. It is sufficient to show that a merging of two out of four clusters does not create a cluster of diameter greater than $3d$. There are two cases: if $t - s, v - u > d$, then this algorithm actually produces the optimal solution; conversely, if $t - s \le d$, then either the first two out of four clusters are contained in $[r, u]$ with $u - r \le 3d$ or the last two out of four clusters are contained in $[v, w]$ with $w - v \le d$.

For the case $k = 2$, we will in fact show that diameter-greedy creates two intervals whose radius (the 2-diameter) is at most the diameter of the optimal solution. Suppose the two intervals obtained by the algorithm are $[0, a]$ and $[b, 1]$, with $a < b$. The optimum diameter is achieved when $a \le 1/2 \le b$, in which case it is $\max(a, 1 - b)$. The other case has a and b on the same side of $1/2$, say $b < 1/2$. We claim that in this case, there are no gaps greater than b between consecutive points. Consequently, the two consecutive points $x \le 1/2 \le y$ satisfy $y - x \le b$, and the optimum diameter is $d = \max(x, 1 - y)$. The interval $[0, a]$ has radius at most $a < b \le x \le d$ as needed. The interval $[b, 1]$ has radius at most $\max(y - b, 1 - y) \le \max(x, 1 - y) = d$ as needed.

It remains to verify the claim that there are no gaps greater than b. If there is such a gap, it must be inside $[b, 1]$. At some point, a merge crossing this gap was performed. That is, we had three intervals $[r, s], [t, u], [v, w]$ with $t - s > b$, and a merge producing $[r, u]$ was carried out. This can only happen if $w - u > b$. Thus, we obtain two intervals $[r, u]$ and $[v, w]$ with $b < (w - r)/2$, $v - r > b$, and $w - u > b$. We shall show that these three inequalities are preserved for the two current intervals until the end of the algorithm. However, they are false at the end for the two intervals $[0, a]$ and $[b, 1]$, a contradiction.

We show that the three inequalities are preserved. A new point z is added either between the two intervals or outside the two intervals, say after w. If z is added after w, then the resulting intervals are either $[r, u]$ and $[v, z]$, in which case the inequalities still hold, or $[r, w]$ and $[z, z]$, which can only happen if $z - w > b$ and so the inequalities still hold. If z is added between the two intervals, say $z \leq (w + r)/2$, and the two resulting intervals are $[r, z]$ and $[v, w]$, then $w - z \geq (w - r)/2 > b$, completing the proof. □

For $k = 3$, we give an example where a greedy algorithm based on diameter cannot do strictly better than 3.

THEOREM A.2. *For $k = 3$, there is a lower bound of 3 on the performance ratio of the diameter-greedy algorithm on the line.*

Proof. The adversary gives the following sequence of points: $1 + \epsilon, 2 + \epsilon, 3, 4, 6 - 2\epsilon, 4 - \epsilon, 7 - 2\epsilon$. The optimal intervals are $[1 + \epsilon, 2 + \epsilon], [3, 4], [6 - 2\epsilon, 7 - 2\epsilon]$, giving diameter 1. However, when the first four points are introduced, the interval $[2 + \epsilon, 3]$ is created by diameter-greedy; when $6 - 2\epsilon$ is added the interval $[4, 6 - 2\epsilon]$ is created; when $4 - \epsilon$ is added then the enlarged interval $[2 + \epsilon, 4 - \epsilon]$ is created; and finally when $7 - 2\epsilon$ is added either $[1 + \epsilon, 4 - \epsilon]$ or $[4, 7 - 2\epsilon]$ is created, for a factor of $[3 - 2\epsilon]$. □

The proof only gives a lower bound of 2 for the t-diameter-greedy algorithm when $t > 1$, leaving open the possibility that these algorithms may perform better than diameter-greedy. Indeed, we have the following result.

THEOREM A.3. *The 3-diameter-greedy algorithm has performance ratio 3 on the line.*

Proof. In fact, we show that it produces a clustering with 3-diameter at most the optimal diameter, and the factor of 3 follows. Assume this holds before the last two clusters are merged. Let $I_1, I_2, \ldots, I_k$ be the intervals in the optimal clustering, with maximum diameter d. Let $C_1, C_2, \ldots, C_{k+1}$ be the current clusters, each with 3-diameter at most d, of which two must be merged. If C_i starts in I_a and ends in I_b, let $x_i = b - a$; notice that $x_1 + \cdots + x_{k+1} \leq k - 1$. We assume that if C_i ends in I_b, then C_{i+1} starts in I_b; otherwise, we could replace the argument in the k intervals I_j by an argument either in the first b intervals $I_1, \ldots, I_b$ if there are at least $b + 1$ clusters C_i in this region, or in the last $k - b$ intervals $I_{b+1}, \ldots, I_k$ if there are at least $k - b + 1$ current clusters C_i in this region. Now, the bounds imply that for some i, we have $x_i + x_{i+1} < 2$. If $x_i = x_{i+1} = 0$, then the merging of C_i and C_{i+1} is contained in a single interval I_j and has a diameter at most d. If say $x_i = 0$ and $x_{i+1} = 1$, then the gap G between the two consecutive intervals I_j and I_{j+1} involved is at most d, since C_{i+1} has 3-diameter at most d, so the merger of C_i and C_{i+1} has 3-diameter at most d given by the 3-partition I_j, G, I_{j+1}. This completes the proof. □

We comment briefly on the running time of this algorithm. In the above proof, the 3-diameter of an interval may be replaced by an easily computed upper bound: at the time of creation of interval $[a, b]$, let $[x, y]$ be the gap containing $(a + b)/2$, and let the upper bound be $\max(x - a, y - x, b - y)$. Maintaining the n points sorted in a balanced tree, the running time is $O(\log n)$ for each of the n points inserted.

Acknowledgments. We thank Pankaj Agarwal and Leonidas Guibas for helpful discussions and for suggesting that we consider the dual clustering problem. We thank Bernard Chazelle for pointing out reference [5].

TIGHT BOUNDS FOR TESTING BIPARTITENESS IN GENERAL GRAPHS*

TALI KAUFMAN†, MICHAEL KRIVELEVICH‡, AND DANA RON§

Abstract. In this paper we consider the problem of testing bipartiteness of general graphs. The problem has previously been studied in two models, one most suitable for dense graphs and one most suitable for bounded-degree graphs. Roughly speaking, dense graphs can be tested for bipartiteness with constant complexity, while the complexity of testing bounded-degree graphs is $\tilde{\Theta}(\sqrt{n})$, where n is the number of vertices in the graph (and $\tilde{\Theta}(f(n))$ means $\Theta(f(n) \cdot \text{polylog}(f(n)))$). Thus there is a large gap between the complexity of testing in the two cases.

In this work we bridge the gap described above. In particular, we study the problem of testing bipartiteness in a model that is suitable for all densities. We present an algorithm whose complexity is $\tilde{O}(\min(\sqrt{n}, n^2/m))$, where m is the number of edges in the graph, and we match it with an almost tight lower bound.

Key words. property testing, bipartiteness, randomized algorithms

1. Introduction.

Property testing algorithms [21, 12] are algorithms that perform *approximate decisions*. Namely, for a predetermined property P they should decide whether a given object O has property P or is *far* from having property P. In order to perform this approximate decision they are given *query access* to the object O. Property testing problems are hence defined by the type of objects in question, the property tested, the type of queries allowed, and the notion of distance to having a property. Much of the focus of property testing has been on testing properties of graphs. In this context several models have been considered. In all models, for a fixed graph property P, the algorithm is required to accept graphs that have P and to reject graphs that are ϵ-far from having P for a given distance parameter ϵ. In all cases the algorithm is allowed a constant probability of failure. The models differ in the type of queries they allow and in the notion of distance they use (which underlies the definition of being ϵ-far from having the property). The complexity of the algorithm is measured by the number of queries that the algorithm performs.

1.1. Models for testing graph properties.

The first model, introduced in [12], is the adjacency-matrix model. In this model the algorithm may perform queries of the following form: "Is there an edge between vertices u and v in the graph?" That is, the algorithm may probe the adjacency matrix representing the graph. We refer to such queries as *vertex-pair* queries. The notion of distance is also linked to this representation: a graph is said to be ϵ-far from having property P if more

than ϵn^2 edge modifications should be performed on the graph so that it obtains the property, where n is the number of vertices in the graph. In other words, ϵ measures the fraction of entries in the adjacency matrix of the graph that should be modified. This model is most suitable for *dense* graphs in which the number of edges, denoted m, is $\Theta(n^2)$. This model was studied in [12, 3, 2, 1, 4, 16, 8].

The second model, introduced in [13], is the (bounded-degree) incidence-lists model. In this model, the algorithm may perform queries of the following form: "Who is the ith neighbor of vertex v in the graph?" That is, the algorithm may probe the incidence lists of the vertices in the graph, where it is assumed that all vertices have degree at most d for some fixed degree-bound d. We refer to these queries as *neighbor* queries. Here too the notion of distance is linked to the representation: A graph is said to be ϵ-far from having property P if more than ϵdn edge modifications should be performed on the graph so that it obtains the property. In this case ϵ measures the fraction of entries in the incidence-lists representation (among all dn entries) that should be modified. This model is most suitable for graphs with $m = \Theta(dn)$ edges, that is, whose maximum degree is of the same order as the average degree. In particular, this is true for *sparse* graphs that have *constant degree*. This model was studied in [14, 13, 7].

In [20] it was suggested to decouple the issues of representation and type of queries allowed from the definition of distance to having a property. Specifically, it was suggested to measure the distance simply with respect to the number of edges, denoted m, in the graph. Namely, a graph is said to be ϵ-far from having a property if more than ϵm edge modifications should be performed so that it obtains the property. In [20] the algorithm was allowed the same type of queries as in the bounded-degree incidence-lists model, but no fixed upper-bound was assumed on the degrees and the algorithm could query the degree of any vertex. The main advantage of this model over the bounded-degree incidence-lists model is that it is suitable for graphs whose degrees may vary significantly. To illustrate this, consider a (sparse) graph having $m = O(n)$ edges, where the maximum degree d of vertices in the graph is $\Omega(n)$. Suppose we want to determine whether the graph is bipartite or ϵ-far from being bipartite for some constant ϵ. If we worked in the bounded-degree incidence-lists model then we could trivially accept all graphs, since for $d = \Omega(n)$ and constant ϵ every graph having $O(n) = o(dn)$ edges is ϵ-close to being bipartite. However, this is no longer true when distance is measured with respect to the actual number of edges m.

The model studied in this paper. In this work we are interested in a model that may be useful for testing all types of graphs: dense, sparse, and graphs that lie in-between the two extremes. As is discussed in more detail in the next subsection, the two extremes sometimes exhibit very different behavior in terms of the complexity of testing the same property. We are interested in understanding the transformation from testing sparse (and, in particular, bounded-degree) graphs to testing dense graphs.

Recall that a model for testing graph properties is defined by the distance measure used and by the queries allowed. The model of [20] is indeed suitable for all graphs in terms of the distance measure used, since distance is measured with respect to the actual number of edges m in the graph. Thus this notion of distance adapts itself to the density of the graph, and we shall use it in our work.

The focus in [20] was on testing properties that are of interest in sparse (but not necessarily bounded-degree) graphs, and hence they allowed only neighbor queries. However, consider the case in which the graph is not sparse (but not necessarily dense).

In particular, suppose that the graph has $\omega(n^{1.5})$ edges and that we are seeking an algorithm that performs $o(\sqrt{n})$ queries. While in the case of sparse graphs, there is no use in asking vertex-pair queries (i.e., is there an edge between a particular pair of vertices), such queries may become helpful when the number of edges is sufficiently large. Hence, we allow our algorithms to perform both neighbor queries and vertex-pair queries.

1.2. Testing bipartiteness. One of the properties that has received quite a bit of attention in the context of property testing is *bipartiteness*. Recall that a graph is bipartite if it is possible to partition its vertices into two parts such that there are no edges with both endpoints in the same part. This property was first studied in [12] where it was shown that bipartiteness can be tested in the adjacency-matrix model by a simple algorithm using $\tilde{O}(1/\epsilon^3)$ queries. This was improved in [3] to $\tilde{O}(1/\epsilon^2)$ queries. The best lower bound known in this model is $\tilde{\Omega}(1/\epsilon^{1.5})$, due to [8]. Thus the complexity of this problem in the adjacency-matrix model is independent of the number of vertices n and is polynomial in $1/\epsilon$. It is interesting to note that testing bipartiteness is considered implicitly already in [9]. The result in [9] can be used to obtain a testing algorithm in the adjacency-matrix model whose query complexity does not depend on the size of the graph but whose dependence on ϵ is a tower of height polynomial in $1/\epsilon$.

The complexity of testing bipartiteness is significantly different when considering the bounded-degree incidence-lists model. In [14] a lower bound of $\Omega(\sqrt{n})$ was established in this model for constant ϵ and constant d (where d is the degree bound). An almost matching upper bound of $\tilde{O}(\sqrt{n} \cdot \mathrm{poly}(1/\epsilon))$ was shown in [13]. Thus, in the case of bipartiteness there is a large gap between the results that can be obtained for dense graphs and for constant-degree graphs.

Here we venture into the land of graphs that are neither necessarily sparse nor necessarily dense and study the complexity of testing bipartiteness. As we discuss briefly in subsection 1.5, other graph properties exhibit similar (and sometimes even larger) gaps, and hence we believe that understanding the transformation from sparse to dense graphs is of general interest.

1.3. Our results. In this work we present two complementary results for n-vertex graphs having m edges:

- We describe and analyze an algorithm for testing bipartiteness in general graphs whose query complexity and running time are $O(\min(\sqrt{n}, n^2/m) \cdot \mathrm{poly}(\log n/\epsilon))$. The algorithm has a one-sided error (i.e., it always accepts bipartite graphs). Furthermore, whenever it rejects a graph it provides *evidence* that the graph is not bipartite in the form of an odd cycle[1] of length $\mathrm{poly}(\log n/\epsilon)$.
- We present an almost matching lower bound of $\Omega(\min(\sqrt{n}, n^2/m))$ (for a constant ϵ). This bound holds for all testing algorithms (that is, for those that are allowed a two-sided error and are adaptive). Furthermore, the bound holds for regular graphs.

As seen from the above expressions, as long as $m = O(n^{1.5})$, that is, the average degree is $O(\sqrt{n})$, the complexity of testing (in terms of the dependence on n) is $\tilde{\Theta}(\sqrt{n})$. Once the number of edges goes above $n^{1.5}$, we start seeing a decrease in the query complexity, which in this case is at most $O((n^2/m) \cdot \mathrm{poly}(\log n/\epsilon))$. In terms of our algorithm, this is exactly the point where our algorithm starts exploiting its

[1] We use the term "odd cycle" as a shorthand for "odd-length cycle."

access to vertex-pair queries. Our lower bound shows that this behavior of the query complexity is not only an artifact of our algorithm but is inherent in the problem.

Notes.

1. Observe that even if the graph is sparse, we obtain a new result that does not follow from [13]. Namely, we have an algorithm with complexity $\tilde{O}(\sqrt{n} \cdot \text{poly}(1/\epsilon))$ for sparse graphs with varying degrees.
2. We note that the algorithm does not actually require to be given the number of edges, m, in the graph but can instead compute an estimate of this number. Such an estimate can be obtained without increasing the query complexity of the algorithm [11, 15], and we discuss this issue shortly in section 4.
3. We assume that $m = \Omega(n)$. Since our distance measure is with respect to the number of edges in the graph, without such an assumption it would be impossible to distinguish between the following two (families of) graphs: a graph that consists of many isolated edges and a single very small subgraph that is far from bipartite (e.g., a clique), and a graph that consists of many isolated vertices and a very small bipartite subgraph. We discuss this issue briefly in section 4 as well.

1.4. Our techniques. We present our algorithm in two stages. First we describe an algorithm that works for almost-regular graphs, that is, graphs in which the maximum degree is of the same order as the average degree. The algorithm and its analysis closely follow the algorithm and analysis in [13]. Indeed, as long as the degree d of the graph is at most $\sqrt{n}$, we execute the algorithm described in [13]. The place where we depart from [13] is in the usage of vertex-pair queries once $d > \sqrt{n}$. We refer to our first algorithm as Test-Bipartite-Reg.

In the second stage we show how to reduce the problem of testing bipartiteness of general graphs to testing bipartiteness of almost-regular graphs. Namely, we show how, for every given graph G, it is possible to define a graph G' such that (1) G' has roughly the same number of vertices and edges as G, and its maximum degree is of the same order as its average degree (which is roughly the same as the average degree in G); (2) if G is bipartite, then so is G', and if G is far from being bipartite, then so is G'. We then show how to emulate the execution of the algorithm Test-Bipartite-Reg on G' given query access to G so that we may accept G if it accepts G' and reject G if it rejects G'.

In the course of this emulation we are confronted with the following interesting problem: We would like to sample vertices in G according to their degrees (which aids us in sampling vertices uniformly in G', a basic operation that is required by Test-Bipartite-Reg). The former is equivalent to sampling *edges* uniformly in G. In order not to harm the performance of our testing algorithm, we are required to perform this task using $\tilde{O}(\min(\sqrt{n}, n^2/m))$ queries. If m is sufficiently large (once again, if $m \geq n^{1.5}$), this can be performed without increasing the complexity of our algorithm simply by sampling sufficiently many pairs of vertices in G. However, we do not know how to perform this task exactly (in an efficient manner) when the number of edges is significantly smaller than $n^{1.5}$. Nonetheless, we provide a sampling procedure that selects edges according to a distribution that approximates the desired uniform distribution on edges and is sufficient for our purposes. The approximation is such that for all but a small fraction of the m edges, the probability of selecting an edge is $\Omega(1/m)$. This procedure may be of independent interest.

We also conjecture that variants of our construction of G' (and, in particular, a simple probabilistic construction we suggest) may be useful in transforming other

results that hold for graphs whose maximum degree is similar to their average degree into results that hold for graphs with varying degrees.

We establish our lower bound by describing, for every pair n, d (n even, $d \geq 64$), two distributions over d-regular graphs. In one distribution all graphs are bipartite by construction. For the other distribution we prove that almost all graphs are far from being bipartite. We then show that every testing algorithm that can distinguish between a graph chosen randomly from the first distribution (which it should accept with probability at least 2/3) and a graph chosen randomly from the second distribution (which it should reject with probability at least 2/3) must perform $\Omega(\min(\sqrt{n}, n/d)) = \Omega(\min(\sqrt{n}, n^2/m))$ queries.

Our lower-bound proof implies the necessity of both neighbor queries and vertex-pair queries in obtaining an upper bound whose dependence on n and m is $\tilde{O}(\min(\sqrt{n}, n^2/m))$. Specifically, if only neighbor queries are allowed, then our analysis implies a lower bound of $\Omega(\sqrt{n})$ for every m, which is higher than $\tilde{O}(n^2/m)$ when $m = \omega(n^{1.5})$. If only vertex-pair queries are allowed, then our analysis implies a lower bound of $\Omega(n^2/m)$, which is above the upper bound of $\tilde{O}(\sqrt{n})$ when $m = o(n^{1.5})$.

1.5. Further research. As noted previously, there are other problems that exhibit a significant gap between the query complexity of testing dense graphs (in the adjacency-matrix model) and the complexity of testing sparse bounded-degree graphs (in the bounded-degree incidence-lists model). In particular, this is true for testing k-colorability. It is possible to test dense graphs for k-colorability using poly(k/ϵ) queries [12, 3, 10], while testing sparse graphs requires $\Omega(n)$ queries [7]. We stress that these bounds are for query complexity, where we put time complexity aside. We would like to understand this transformation from essentially constant complexity (for constant k and ϵ) to linear complexity, and we would like to know whether any intermediate results can be obtained for graphs that are neither sparse nor dense. Other problems of interest are testing whether a graph has a relatively large clique [12], testing acyclicity of directed graphs [6], and testing that a graph does not contain a certain subgraph [1, 4].

1.6. Organization of the paper. In section 2 we give some basic definitions and notation. In sections 3 and 4 we describe and analyze our testing algorithms. In section 5 we present our lower bound.

2. Preliminaries. Let $G = (V, E)$ be an undirected graph with n vertices labeled $1, \ldots, n$, and let $m = m(G) = |E(G)|$ be the total number of edges in G. Unless stated otherwise, we assume that G contains no multiple edges. For each vertex $v \in V$ let $\Gamma(v)$ denote its set of neighbors, and let $\deg(v) = |\Gamma(v)|$ denote its degree. The edges incident to v are labeled from 1 to $\deg(v)$. We make no assumption on the corresponding order of the neighbors of a vertex. Note that each edge has two possibly different labels, one with respect to each of its endpoints. We hence view edges as quadruples. That is, if there is an edge between v and u and it is the ith edge incident to v and the jth edge incident to u, then this edge is denoted by (u, v, i, j). When we want to distinguish between the quadruple (u, v, i, j) and the pair (u, v), then we refer to the latter as an *edge-pair*. We let $d_{\max} = d_{\max}(G)$ denote the maximum degree in the graph G and $d_{\text{avg}} = d_{\text{avg}}(G)$ denote the average degree in the graph (that is, $d_{\text{avg}}(G) = 2m(G)/n$).

Distance to having a property. Consider a fixed graph property $\mathcal{P}$. For a given graph G, let $e_{\mathcal{P}}(G)$ be the minimum number of edges that should be added to G or removed from G so that it obtains property $\mathcal{P}$. The distance of G to having property $\mathcal{P}$

is defined as $e_{\mathcal{P}}(G)/m(G)$. In particular, we say that graph G is ϵ-*far* from having the property $\mathcal{P}$ for a given distance parameter $0 \leq \epsilon < 1$ if $e_{\mathcal{P}}(G) > \epsilon \cdot m(G)$. Otherwise, it is ϵ-*close* to having property $\mathcal{P}$. In some cases we may define the distance to having a property with respect to an upper bound $m_{\max} \geq m(G)$ on the number of edges in the graph (that is, the distance to having property $\mathcal{P}$ is defined as $e_{\mathcal{P}}(G)/m_{\max}$). For example, if the graph is dense so that $m(G) = \Omega(n^2)$, then we set $m_{\max} = n^2$, and alternatively, if the graph has some bounded degree d, then we set $m_{\max} = d \cdot n$. (In the latter case we could set $m_{\max} = (d \cdot n)/2$, but for simplicity we set the slightly higher upper bound.) If $e_{\mathcal{P}}(G)/m_{\max} > \epsilon$, then we shall say that the graph is ϵ-far from having property $\mathcal{P}$ *with respect to* $m_{\max}$.

Testing algorithms. A testing algorithm for a graph property $\mathcal{P}$ is required to accept with probability at least 2/3 every graph that has property $\mathcal{P}$ and to reject with probability at least 2/3 every graph that is ϵ-far from having property $\mathcal{P}$, where ϵ is a given distance parameter. If the algorithm always accepts graphs that have the property, then it is a *one-sided error* algorithm. The testing algorithm is given the number of vertices in the graph, the number of edges in the graph, or an upper bound on this number,[2] and it is provided with *query access* to the graph. Specifically, we allow the algorithm the following types of queries.

- The first type of queries is *degree* queries. That is, for any vertex u of its choice, the algorithm can obtain $\deg(u)$. We assume that a degree query has cost one.
- The second type of queries is *neighbor* queries. Namely, for every vertex u and index $1 \leq i \leq \deg(u)$, the algorithm may obtain the ith neighbor of vertex u.
- The third type of queries is *vertex-pair* queries. Namely, for any pair of vertices (u, v), the algorithm can query whether there is an edge between u and v in G.

Note that degree queries can be easily implemented using neighbor queries with cost $O(\log d_{\max}) = O(\log n)$.

Bipartiteness. In this work we focus on the property of *bipartiteness*. Let (V_1, V_2) be a partition of V. We say that an edge $(u, v) \in E$ is a *violating* edge with respect to (V_1, V_2) if u and v belong to the same subset V_b (for some $b \in \{1, 2\}$). A graph is *bipartite* if there exists a partition of its vertices with respect to which there are no violating edges. By definition, a graph is ϵ-far from being bipartite if for every partition of its vertices, the number of violating edges with respect to the partition is greater than $\epsilon \cdot m$. Recall that a graph is bipartite if and only if it contains no odd cycles.

3. The algorithm for the almost-regular case. In this section we describe an algorithm that accepts every bipartite graph and that rejects with probability at least 2/3 every graph that is ϵ-far from being bipartite with respect to an upper bound $m_{\max} = d_{\max} n$ on the number of edges. Namely, this algorithm rejects (with probability at least 2/3) graphs for which the number of edges that need to be removed so that they become bipartite is greater than $\epsilon \cdot m_{\max} = \epsilon \cdot d_{\max} n$. The query complexity and running time of this algorithm are $O(\min(\sqrt{n}, n/d_{\max}) \cdot \mathrm{poly}(\log n/\epsilon))$.

In the case where the graph is almost regular, that is, the maximum degree of the graph $d_{\max}$ is of the same order as the average degree, d_{avg}, then we essentially obtain

[2] As noted in the introduction, we can remove this assumption and have the algorithm compute an estimate of the number of edges.

a tester as desired (since in such a case $\epsilon d_{\max} n = O(\epsilon m)$). However, in general, $d_{\max}$ may be much larger than d_{avg} (for example, it is possible that $d_{\max} = \Theta(n)$ while $d_{\text{avg}} = \Theta(1)$). To deal with the general case we show in the next section (section 4) how to reduce the problem in the general case to the special case of $d_{\max} = O(d_{\text{avg}})$.

Test-Bipartite-Reg($n, d_{\max}, \epsilon$)

- Repeat $T = \Theta(\frac{1}{\epsilon})$ times:
  1. Uniformly select a vertex s in V.
  2. If Odd-Cycle(s) returns found, then output reject.
- In case no call to Odd-Cycle returned found, then output accept.

Odd-Cycle(s)

1. If $d = d_{\max} \leq \sqrt{n}$, then let $K \stackrel{\text{def}}{=} \Theta\left(\frac{\sqrt{n} \cdot \log^{1/2}(n/\epsilon)}{\epsilon^3}\right)$ and $L \stackrel{\text{def}}{=} \Theta\left(\frac{\log^3(n/\epsilon)}{\epsilon^5}\right)$. Otherwise ($d > \sqrt{n}$), let $K \stackrel{\text{def}}{=} \Theta\left(\frac{\sqrt{n/d} \cdot \log^{1/2}(n/\epsilon)}{\epsilon^8}\right)$, and $L \stackrel{\text{def}}{=} \Theta\left(\frac{\log^6(n/\epsilon)}{\epsilon^8}\right)$.
2. Perform K random walks starting from s, each of length L.
3. Let A_0 (A_1) be the set of vertices that appear at the ends of the walks performed in the previous step whose paths are of even (odd) length.
4. If $d \leq \sqrt{n}$, then check whether $A_0 \cap A_1 \neq \emptyset$. If the intersection is nonempty, then return found; otherwise return not-found.
5. Else ($d > \sqrt{n}$), perform vertex-pair queries between every pair of vertices $u, v \in A_0$ ($u, v \in A_1$). If an edge is detected, then return found; otherwise return not-found.

FIG. 1. *Algorithm Test-Bipartite-Reg for testing bipartiteness with respect to the upper bound $m_{\max} = d_{\max} \cdot n$ on the number of edges, and the procedure Odd-Cycle for detecting odd cycles in the graph G.*

A high level description of the algorithm. Throughout this section let $d = d_{\max}$. Our algorithm, whose pseudocode appears in Figure 1, builds on the testing algorithm for bipartiteness described in [13]. The query complexity of that algorithm is $O(\sqrt{n} \cdot \text{poly}(\log n/\epsilon))$, and it works with respect to $m_{\max} = dn$ as well. In fact, as long as $d \leq \sqrt{n}$, our algorithm is the same as the algorithm in [13].

In particular, as in [13], our algorithm selects $\Theta(1/\epsilon)$ *starting vertices* and from each it performs several random walks (using neighbor queries), each walk of length $\text{poly}(\log n/\epsilon)$. The exact form of these random walks is described momentarily. If $d \leq \sqrt{n}$, then the number of these random walks from each starting vertex s is $O(\sqrt{n} \cdot \text{poly}(\log n/\epsilon))$, and the algorithm simply checks whether an odd cycle was detected in the course of these random walks. Specifically, the algorithm checks whether there exists some vertex v that is reached at the end of two different walks from s, where one walk corresponds to a path in the graph with even length, and one walk corresponds to a path with odd length. The existence of such a vertex v implies an odd cycle that contains s and v, and the algorithm rejects the graph in such a case.

If $d > \sqrt{n}$, then there are two important modifications as compared to the case $d \leq \sqrt{n}$ (which, as noted above, follows [13]). These modifications reduce the number of queries performed as the degree increases.

1. The number of random walks performed from each starting vertex is reduced to $O(\sqrt{n/d} \cdot \text{poly}(\log n/\epsilon))$ (as compared to $O(\sqrt{n} \cdot \text{poly}(\log n/\epsilon))$ walks for the case $d \leq \sqrt{n}$).

2. The algorithm still considers the vertices reached at the end of these walks, but now it performs an additional step. It partitions these vertices into two subsets, denoted A_0 and A_1, according to the parity of the lengths of the paths corresponding to the walks. The algorithm then performs vertex-pair queries on each pair of vertices that belong to the same subset. If any edge (u, v) is detected for $u, v \in A_0$ or $u, v \in A_1$, then the algorithm has evidence of an odd cycle that included s (the starting vertex), u, and v, and it rejects. The total number of vertex-pair queries is $O((n/d) \cdot \text{poly}(\log n/\epsilon))$.

On a very intuitive level, if a graph is far from being bipartite, then many edges (and vertices) belong to many odd cycles. The difference between the two cases described above is that if $d \leq \sqrt{n}$, then the algorithm tries to reach the same vertex twice, once via an even-length path and once via an odd-length path. To this end it performs about $\sqrt{n}$ random walks (so as to "hit" the same vertex twice). In the case $d > \sqrt{n}$, the algorithm performs far fewer walks, and so we cannot expect to reach the same vertex twice. However, since the edge-density is higher, we do expect to have an edge in the subgraph induced by the ending points of the walk. In particular, as our analysis shows, we expect to see such an edge between vertices that are reached via paths whose lengths have the same parity.

Random walks and paths in the graph. The random walks performed are defined as follows: At each step, if the degree of the current vertex v is $d' \leq d$, then the walk *remains* at v with probability $1 - \frac{d'}{2d} \geq \frac{1}{2}$, and for each $u \in \Gamma(v)$, the walk *traverses* to u with probability $\frac{1}{2d}$. The important property of the random walk is that the stationary distribution it induces over the vertices is uniform.

To every walk (or, more generally, to any sequence of steps), there corresponds a *path* in the graph. The path is determined by those steps in which an edge is traversed (while ignoring all steps in which the walk stays at the same vertex). Such a path is not necessarily simple but does not contain self-loops. Note that when referring to the length of a walk, we mean the total number of steps taken, including steps in which the walk remains at the current vertex, while the length of the corresponding path does not include these steps.

THEOREM 1. *The algorithm Test-Bipartite-Reg accepts every graph that is bipartite and rejects with probability at least* 2/3 *every graph that is* ϵ*-far from being bipartite with respect to* $m_{\max} = d_{\max} n$*. Furthermore, whenever the algorithm rejects a graph, it outputs a* certificate *to the nonbipartiteness of the graph in the form of an odd cycle of length* $\text{poly}(\log n/\epsilon)$*. The query complexity and running time of the algorithm are* $O\left(\min(\sqrt{n}, n/d_{\max}) \cdot \text{poly}(\log n/\epsilon)\right)$.

Note that the algorithm can work when G contains self-loops and multiple edges. The latter will be of importance in the next section.

As a direct corollary of Theorem 1 (using $m(G) = (n d_{\text{avg}}(G))/2$), we get the following.

COROLLARY 2. *For a given graph* G*, let* $\gamma(G) \stackrel{\text{def}}{=} d_{\max}(G)/d_{\text{avg}}(G)$*. Then* Test-Bipartite-Reg$(n, d_{\max}(G), \epsilon/(2\gamma(G)))$ *accepts every graph that is bipartite and rejects with probability at least* 2/3 *every graph that is* ϵ*-far from being bipartite (with respect to* $m(G)$*).*

The corollary below will become useful in the next section.

COROLLARY 3. *If* G *is* ϵ*-far from being bipartite with respect to* $m_{\max} = d_{\max} n$*, then* $\Omega(\epsilon)$*-fraction of its vertices* s *are such that* Odd-Cycle(s) *returns* found *with probability at least* $\frac{2}{3}$.

The completeness part of Theorem 1 (i.e., showing that the algorithm accepts bi-

partite graphs) is straightforward. We focus on proving the soundness of the algorithm (i.e., that graphs that are ϵ-far from being bipartite are rejected with probability $\frac{2}{3}$). What we eventually show (in subsection 3.6) is the contrapositive statement, namely, that if the test accepts G with probability greater than $\frac{1}{3}$, then there exists an ϵ-good partition of G.

Our analysis follows the analysis presented in [13] quite closely. In particular, whenever possible we refer the reader to proofs given in [13]. Here we present what is necessary to establish the correctness of our algorithm and in particular those proofs in which we diverge from [13]. Since the algorithm for the case $d_{\max} \leq \sqrt{n}$ is fully analyzed in [13], from this point on we assume $d_{\max} > \sqrt{n}$ and analyze the algorithm for this case.

3.1. Gaining intuition: The rapidly mixing case. To gain some intuition, consider first the following "ideal" case: From each starting vertex s in G, and for every $v \in V$, the probability that a random walk of length $L = \text{poly}((\log n)/\epsilon)$ ends at v is at least $\frac{1}{2n}$ and at most $\frac{2}{n}$, i.e., approximately the probability assigned by the stationary distribution. (Note that this ideal case occurs when G is an expander.) Let us fix a particular starting vertex s. For each vertex v, let p_v^0 be the probability that a random walk (of length L) starting from s ends at v and corresponds to an even-length path. Define p_v^1 analogously for odd paths. Then, by our assumption on G, for every v, $p_v^0 + p_v^1 \geq \frac{1}{2n}$. We consider two cases regarding the sum $\sigma(G) \stackrel{\text{def}}{=} \sum_{\substack{v,u \in V \\ (v,u) \in E}} (p_v^0 p_u^0 + p_v^1 p_u^1)$.

In case $\sigma(G)$ is (relatively) "small," we show that there exists a partition (V_0, V_1) of V that is ϵ-good, and so G is ϵ-close to being bipartite. Otherwise (i.e., when the sum is not "small"), we show that the rejection probability is bounded away from zero. This implies that in case G is accepted with probability at least $\frac{1}{3}$, then G is ϵ-close to being bipartite.

Consider first the case in which $\sigma(G) < c \cdot \frac{\epsilon d}{n}$ for some suitable constant $c < 1$. Let the partition (V_0, V_1) be defined as follows: $V_0 = \{v : p_v^0 \geq p_v^1\}$ and $V_1 = \{v : p_v^1 > p_v^0\}$. Consider a particular vertex $v \in V_0$. By definition of V_0 and our rapid-mixing assumption, $p_v^0 \geq \frac{1}{4n}$.

$$\begin{aligned}
\sigma(G) &= \sum_{\substack{v,u \in V \\ (v,u) \in E}} (p_v^0 p_u^0 + p_v^1 p_u^1) \\
&\geq \sum_{\substack{v,u \in V_0 \\ (v,u) \in E}} p_v^0 p_u^0 \quad + \quad \sum_{\substack{v,u \in V_1 \\ (v,u) \in E}} p_v^1 p_u^1 \\
&\geq \sum_{\substack{v,u \in V_0 \\ (v,u) \in E}} \frac{1}{16n^2} + \sum_{\substack{v,u \in V_1 \\ (v,u) \in E}} \frac{1}{16n^2} \\
&\geq \frac{1}{16n^2} \cdot (\text{the number of violating edges with respect to } (V_0, V_1)). \qquad (1)
\end{aligned}$$

Thus, if there are more than ϵdn violating edges with respect to (V_0, V_1), then $\sigma(G) > \frac{1}{16} \cdot \frac{\epsilon d}{n}$, which contradicts our case hypothesis concerning $\sigma(G)$ assuming $c \leq 1/16$.

We now turn to the second case, $\sigma(G) \geq c \cdot \frac{\epsilon d}{n}$. For every fixed pair $i, j \in \{1, \ldots, K\}$ (recall that $K = \Theta(\sqrt{n/d} \cdot \text{poly}(\log n/\epsilon))$ is the number of walks taken from s), consider the 0/1 random variable $\eta_{i,j}$ that is 1 if and only if both the ith

and the jth walks have path length with the same parity and if the endpoints of the paths are vertices u, v such that $(u, v) \in E$. Then for every pair i, j,

$$\text{Exp}[\eta_{i,j}] \;=\; \sum_{u,v \in V,\,(u,v)\in E} (p_v^0 p_u^0 + p_v^1 p_u^1) \;=\; \sigma(G). \tag{2}$$

Since there are $K^2 = \Theta(n/d \cdot \text{poly}(\log n/\epsilon))$ such pairs i, j, the expected value of the sum over all $\eta_{i,j}$'s is greater than some constant $c' > c$. These random variables are not pairwise independent; nonetheless we can obtain a constant bound on the probability that the sum is 0 using Chebyshev's inequality (cf. [5, sec. 4.3]).

Unfortunately, we may not assume in general that for every (or even some) starting vertex, all (or even almost all) vertices are reached with probability $\Theta(1/n)$. However, roughly speaking, we are able to show that every graph can be partitioned into parts such that within each part we can perform an analysis that builds on the ideas presented above. Furthermore, the different parts are separated by small cuts so that if each part is close to being bipartite, then so is the whole graph. An important component in the analysis is the definition of the Markov chain $\text{M}_{\ell_1}^{\ell_2}(H)$, and we turn to this definition in the next subsection.

3.2. The Markov chain $\mathbf{M}_{\boldsymbol{\ell_1}}^{\boldsymbol{\ell_2}}(\boldsymbol{H})$. Let H be an induced subgraph of G. For any given pair of lengths, ℓ_1 and ℓ_2, we define a Markov chain $\text{M}_{\ell_1}^{\ell_2}(H)$. Roughly speaking, $\text{M}_{\ell_1}^{\ell_2}(H)$ captures random walks of length at most $\ell_1 \cdot \ell_2$ in G that do not exit H for (sub)walks of length ℓ_2 or more. The states of the chain consist of the vertices of H and some additional auxiliary states. For vertices that do not have neighbors outside of H, the transition probabilities in $\text{M}_{\ell_1}^{\ell_2}(H)$ are exactly as in walks on G. However, for vertices v that have neighbors outside of H there are two modifications: (1) For each vertex u, the transition probability from v to u, denoted $q_{v,u}$, is the probability of a walk (in G) starting from v and ending at u after less than ℓ_2 steps (without passing through any other vertex in H). Thus, walks of length less than ℓ_2 out of H (and, in particular, the walk $v - u$ in case $(v, u) \in E$) are contracted into single transitions. Note that for every u and v in H we have $q_{u,v} = q_{v,u}$. (2) There is an auxiliary path of length ℓ_1 emitting from v. The transition probability from v to the first auxiliary vertex on the path equals the probability that a walk starting from v exits H and does not return in less than ℓ_2 steps. From the last vertex on the auxiliary path there are transitions to vertices in H with the corresponding conditional probabilities of reaching them after such a walk.

A more formal definition of $\text{M}_{\ell_1}^{\ell_2}(H)$ appears in the appendix, together with an illustration (see Figure 8). The following definition and lemma will be instrumental in our analysis.

DEFINITION 3.1. *We say that a vertex s is* useful *with respect to $\text{M}_{\ell_1}^{\ell_2}(H)$ if the probability that a walk in $\text{M}_{\ell_1}^{\ell_2}(H)$ starting from s enters an auxiliary path after at most ℓ_1 steps is at most $\frac{2\ell_1}{\ell_2} \cdot \frac{n}{|H|}$.*

LEMMA 1. *Let H be a subgraph of G, and let ℓ_1 and ℓ_2 be integers. Then at least half of the vertices s in H are useful with respect to $\text{M}_{\ell_1}^{\ell_2}(H)$.*

The proof of the lemma appears in [13].

3.3. Useful vertices and small cuts. The following lemma can be viewed as presenting a "contrapositive statement" of the work of Mihail [19]. While Mihail showed that high expansion leads to fast convergence of random walks to the stationary distribution, the lemma below shows that too slow of a convergence implies

small cuts that have certain additional properties. In particular, the vertices on one side of the cut can be reached with roughly the same, relatively high probability from some vertex s (where s need not necessarily be on the same side of the cut). In the special case where $H = G$ and G is rapidly mixing, the set S will be all of V, but in the general case it will be a subset of those vertices that are reached from s with probability that is not much smaller than that assigned by the stationary distribution (of $\mathrm{M}_{\ell_1}^{\ell_2}(H)$).

For states x and y in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ and an integer t, let $q_{x,y}(t)$ denote the probability that a random walk in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ that starts at x ends at y after t steps.

LEMMA 2. *Let H be a subgraph of G with at least $\frac{\epsilon}{4}n$ vertices, and let $\ell_1 = \Theta\left(\left(\frac{\log(n/\epsilon)}{\epsilon}\right)^3\right)$, $\ell_2 = \Theta\left(\frac{\ell_1}{\epsilon^2}\right)$, and $F = O\left(\frac{1}{\epsilon}\right)$. Then for every vertex s that is* useful *with respect to $\mathrm{M}_{\ell_1}^{\ell_2}(H)$, there exists a subset of vertices S in H, an integer t, $\ell_1/2 \le t \le \ell_1$, and a value $\beta = \Omega\left(\frac{\epsilon^2}{\log(n/\epsilon)}\right)$ such that the following hold:*

1. *The number of edges between S and the rest of H is at most $\frac{\epsilon}{2} \cdot d \cdot |S|$.*
2. *For every $v \in S$,*

$$\sqrt{\frac{1}{|S|} \cdot \frac{\beta}{|H|}} \le q_{s,v}(t) \le F \cdot \sqrt{\frac{1}{|S|} \cdot \frac{\beta}{|H|}}.$$

The proof of the lemma appears in [13].

3.4. Sufficient conditions for good partitions. In the next lemma we give sufficient conditions under which subsets of vertices can be partitioned without having many violating edges. For each $b \in \{0,1\}$ let $q_{s,v}^b(t)$ denote the probability in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ of a walk of length t starting from s, ending at v, and corresponding to a path whose length has parity b. What the lemma essentially requires is that for some fixed vertex s and subset of vertices S in H, there is a lower bound on the probability that each vertex in S is reached from s (in t steps), and there are not too many vertices v in the subset such that both $q_{s,v}^0(t)$ and $q_{s,v}^1(t)$ are large (with respect to this lower bound).

LEMMA 3. *Let H be a subgraph of G, s a vertex in H, S a subset of vertices in H, and ℓ_1 and ℓ_2 integers. Assume that for some $\alpha > 0$, $t < \ell_1$, the following hold in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$:*

1. *For every $v \in S$, $q_{s,v}(t) \ge \alpha$.*
2. *$\sum_{v,u \in S,\,(v,u)\in E}(q_{s,v}^0(t)q_{s,u}^0(t) + q_{s,v}^1(t)q_{s,u}^1(t)) < \frac{\epsilon}{c} \cdot d \cdot |S| \cdot \alpha^2$ for some constant c.*

Let (S_0, S_1) be a partition of S, where $S_0 = \{v : q_{s,v}^0(t) \ge q_{s,v}^1(t)\}$ and $S_1 = \{v : q_{s,v}^1(t) > q_{s,v}^0(t)\}$. Then the number of violating edges in G with respect to (S_0, S_1) is at most $\frac{\epsilon}{c} \cdot d \cdot |S|$.

Proof. Consider a vertex v and let $v \in S_b$ for $b \in \{0,1\}$. By definition of the partition (S_0, S_1), $q_{s,v}^b(t) \ge \frac{1}{2}q_{s,v}(t) \ge \frac{\alpha}{2}$.

Assume, contrary to what is claimed in the lemma, that the number of violating edges with respect to (S_0, S_1) is more than $\frac{\epsilon}{c} \cdot d \cdot |S|$. Then

$$\sum_{v,u \in S,\,(v,u)\in E} (q_{s,v}^0(t)q_{s,u}^0(t) + q_{s,v}^1(t)q_{s,u}^1(t))$$

$$\ge \sum_{v,u \in S,\,(v,u)\in E,\,u,v \in S_0} (q_{s,v}^0(t)q_{s,u}^0(t)) + \sum_{v,u \in S,\,(v,u)\in E,\,u,v \in S_1} (q_{s,v}^1(t)q_{s,u}^1(t)) \tag{3}$$

$$\ge \sum_{v,u \in S,\,(v,u)\in E,\,u,v \in S_0} \frac{\alpha^2}{4} + \sum_{v,u \in S,\,(v,u)\in E,\,u,v \in S_1} \frac{\alpha^2}{4} \tag{4}$$

$$\geq \frac{\alpha^2}{4} \cdot \frac{\epsilon}{c} \cdot d \cdot |S|. \tag{5}$$

But this contradicts the second hypothesis of the lemma. □

3.5. Sufficient conditions for detecting odd cycles. In the next lemma we describe sufficient conditions for "detecting" odd cycles when performing walks in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ starting from some vertex s. What the lemma essentially requires is that there exists a subset S of vertices such that there are both lower and upper bounds on the probability that each vertex in S is reached from s (in $t < \ell_1$ steps), and there are many vertices v in S such that both $q_{s,v}^0(t)$ and $q_{s,v}^1(t)$ are large (with respect to the lower bound). As stated later in Corollary 4, these conditions are sufficient for detecting odd cycles when performing random walks in G of length $\ell_1 \cdot \ell_2$.

LEMMA 4. *Let H be a subgraph of G, s a vertex in H, S a subset of vertices in H, and ℓ_1 and ℓ_2 integers. Assume that for some $\alpha > 0$ and $F = \Theta(\frac{1}{\epsilon})$ and $t < \ell_1$, the following hold in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$:*

1. *For every $v \in S$, $\alpha \leq q_{s,v}(t) \leq F \cdot \alpha$;*
2. *$\sum_{v,u \in S,\,(v,u)\in E}(q_{s,v}^0(t)q_{s,u}^0(t)+q_{s,v}^1(t)q_{s,u}^1(t)) \geq \frac{\epsilon}{c}\cdot d\cdot|S|\cdot\alpha^2$ for some constant c.*

Suppose we perform $O\left(\frac{F^5}{\epsilon\cdot\alpha\sqrt{d}\sqrt{|S|}}\right)$ random walks of length t starting from s in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$. Let A_0 (A_1) be the set of vertices that appear at the end of the walks whose corresponding paths have even (odd) length, and let G_0 (G_1) be the subgraph induced by A_0 (A_1). Then with probability at least 0.99 (taken over the random walks), either G_0 contains an edge or G_1 contains an edge (i.e., the algorithm detects an odd cycle).

We note that when we apply Lemma 4, we set $\alpha = \mathrm{poly}(\epsilon/(\log n))/\sqrt{|S| \cdot |H|}$ and $F = O(1/\epsilon)$ so that the number of random walks that should be performed is $O(\sqrt{n/d} \cdot \mathrm{poly}((\log n)/\epsilon))$.

Proof. Let $\gamma \stackrel{\mathrm{def}}{=} \sum_{v,u\in S,\,(v,u)\in E}(q_{s,v}^0(t)q_{s,u}^0(t)+q_{s,v}^1(t)q_{s,u}^1(t))$ so that by the second hypothesis of the lemma $\gamma \geq \frac{\epsilon}{c} \cdot d \cdot |S| \cdot \alpha^2$. Consider $m = O\left(\frac{F^5}{\epsilon\cdot\alpha\cdot\sqrt{d}\sqrt{|S|}}\right)$ random walks of length t starting from s. For $1 \leq i \neq j \leq m$, let $\eta_{i,j}$ be a 0/1 random variable that is 1 if and only if both the ith and the jth walk have path length with the same parity and if the endpoints of the paths are the vertices $u, v \in S$ such that $(u, v) \in E$.

Thus, we would like to bound the probability that $\sum_{i<j} \eta_{i,j} = 0$. The difficulty is that the $\eta_{i,j}$'s are not pairwise independent. Yet, since the sum of the covariances of the dependent $\eta_{i,j}$'s is quite small, Chebyshev's inequality is still very useful (cf. [5, sec. 4.3]). Details follow. For every $i \neq j$,

$$\mathrm{Exp}[\eta_{i,j}] \;=\; \sum_{v,u\in S,\,(v,u)\in E} (q_{s,v}^0(t)q_{s,u}^0(t) + q_{s,v}^1(t)q_{s,u}^1(t)) \;=\; \gamma.$$

By Chebyshev's inequality,

$$\Pr\left[\sum_{i<j} \eta_{i,j} = 0\right] \;\leq\; \frac{\mathrm{Var}\left[\sum_{i<j} \eta_{i,j}\right]}{\left(\mathrm{Exp}\left[\sum_{i<j} \eta_{i,j}\right]\right)^2} \;<\; \frac{\mathrm{Var}\left[\sum_{i<j} \eta_{i,j}\right]}{\left(\binom{m}{2} \cdot \gamma\right)^2}. \tag{6}$$

We now bound $\mathrm{Var}[\sum_{i<j} \eta_{i,j}]$. Since the $\eta_{i,j}$'s are not pairwise independent, some

care is needed: Let $\bar{\eta}_{i,j} \stackrel{\text{def}}{=} \eta_{i,j} - \text{Exp}[\eta_{i,j}]$.

$$\begin{aligned}
\text{Var}\left[\sum_{i<j}\eta_{i,j}\right] &= \text{Exp}\left[\left(\sum_{i<j}\bar{\eta}_{i,j}\right)^2\right] \\
&= \sum_{i<j}\sum_{k<\ell}\text{Exp}\left[\bar{\eta}_{i,j}\cdot\bar{\eta}_{k,\ell}\right] \\
&= \sum_{i<j}\text{Exp}\left[\bar{\eta}_{i,j}^2\right] + 4\sum_{i<j<k}\text{Exp}\left[\bar{\eta}_{i,j}\cdot\bar{\eta}_{j,k}\right] + 0 \\
&= \binom{m}{2}\cdot\text{Exp}[\bar{\eta}_{1,2}^2] + 4\cdot\binom{m}{3}\cdot\text{Exp}\left[\bar{\eta}_{1,2}\cdot\bar{\eta}_{2,3}\right]. \qquad (7)
\end{aligned}$$

The factor of 4 in the third equality is the number of possibilities that among the four elements i, j, k, ℓ (where $i < j$ and $k < \ell$) exactly two are equal (namely, $i = k < j < \ell$, $i < j = k < \ell$, $i < k < j = \ell$, and $k < i = \ell < j$). The 0 term is due to the fact that when i, j, k, l are all distinct,

$$\begin{aligned}
\text{Exp}\left[\bar{\eta}_{i,j}\cdot\bar{\eta}_{k,\ell}\right] &= \text{Exp}\left[\eta_{i,j}\cdot\eta_{k,\ell}\right] - \gamma^2 \\
&= \sum_{i,j,k,\ell\in S,\,(i,j),(k,\ell)\in E} q^0_{s,i}(t)q^0_{s,j}(t)q^0_{s,k}(t)q^0_{s,\ell}(t) \\
&\quad + \sum_{i,j,k,\ell\in S,\,(i,j),(k,\ell)\in E} q^0_{s,i}(t)q^0_{s,j}(t)q^1_{s,k}(t)q^1_{s,\ell}(t) \\
&\quad + \sum_{i,j,k,\ell\in S,\,(i,j),(k,\ell)\in E} q^1_{s,i}(t)q^1_{s,j}(t)q^0_{s,k}(t)q^0_{s,\ell}(t) \\
&\quad + \sum_{i,j,k,\ell\in S,\,(i,j),(k,\ell)\in E} q^1_{s,i}(t)q^1_{s,j}(t)q^1_{s,k}(t)q^1_{s,\ell}(t) - \gamma^2 \\
&= \left(\sum_{(i,j)\in E(S)} q^0_{s,i}(t)q^0_{s,j}(t) + q^1_{s,i}(t)q^1_{s,j}(t)\right)^2 - \gamma^2 = \gamma^2 - \gamma^2 = 0. \qquad (8)
\end{aligned}$$

We next bound each of the two terms in (7).

$$\text{Exp}[\bar{\eta}_{1,2}^2] \;\le\; \text{Exp}[\eta_{1,2}^2] \;=\; \text{Exp}[\eta_{1,2}] \;=\; \gamma. \qquad (9)$$

Let v_i be a random variable that represents the vertex at which the ith walk ends.

$$\begin{aligned}
\text{Exp}[\bar{\eta}_{1,2}\cdot\bar{\eta}_{2,3}] &\le \text{Exp}[\eta_{1,2}\cdot\eta_{2,3}] \\
&\le \sum_{v_1,v_2,v_3\in S,\,(v_1,v_2),(v_3,v_2)\in E} q^0_{s,v_1}(t)q^0_{s,v_2}(t)q^0_{s,v_3}(t) + q^1_{s,v_1}(t)q^1_{s,v_2}(t)q^1_{s,v_3}(t) \\
&\le (\text{number of pairs of edges in } S \text{ with a common vertex in } S) \\
&\quad \cdot 2(\max_v\{q_{s,v}(t)\})^3 \\
&\le 2\cdot\min(|S|^2 d, |S|d^2)\cdot F^3\cdot\alpha^3. \qquad (10)
\end{aligned}$$

Since by the lemma's second hypothesis $\gamma \ge \frac{\epsilon}{c}\cdot d\cdot|S|\cdot\alpha^2$, we can replace α in (10) with $\sqrt{\frac{c\cdot\gamma}{\epsilon\cdot d\cdot|S|}}$ and get

$$\text{Exp}[\bar{\eta}_{1,2}\cdot\bar{\eta}_{2,3}] \;\le\; 2\cdot\min(|S|^2 d, |S|d^2)\cdot F^3\cdot\left(\frac{c\gamma}{\epsilon d|S|}\right)^{\frac{3}{2}}. \qquad (11)$$

Combining (6)–(11), we get

$$\Pr\left[\sum_{i<j}\eta_{i,j}=0\right] = O\left(\frac{m^2\cdot\gamma + m^3\cdot\min(|S|^2 d, |S|d^2)\cdot F^3\cdot(\frac{\gamma}{\epsilon d|S|})^{\frac{3}{2}}}{m^4\cdot\gamma^2}\right)$$

$$= O\left(\frac{1}{\gamma\cdot m^2} + \frac{F^3\min\left(\sqrt{\frac{|S|}{d}}, \sqrt{\frac{d}{|S|}}\right)}{m\cdot\epsilon^{\frac{3}{2}}\cdot\sqrt{\gamma}}\right)$$

$$= O\left(\frac{\epsilon}{F^{10}} + \frac{1}{F^2\cdot\epsilon}\right) = O(\epsilon). \tag{12}$$

As observed above, by the lemma's hypothesis concerning γ, it holds that $\alpha = O(\sqrt{\gamma/(\epsilon d|S|)})$. Since $m = \Omega\left(\frac{F^5}{\epsilon\cdot\alpha\cdot\sqrt{d}\sqrt{|S|}}\right)$, we have that $m = \Omega\left(F^5\sqrt{\frac{1}{\epsilon\cdot\gamma}}\right)$, and the lemma follows. □

Based on the construction of $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ we can map walks of length $\ell_1\cdot\ell_2$ in G to walks of length ℓ_1 in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ and obtain the following corollary to Lemma 4.

COROLLARY 4. *Let H be a subgraph of G, and let S, s, ℓ_1, ℓ_2, t, α, and F be as in Lemma 4. Suppose we perform $\Theta\left(\frac{F^5}{\epsilon\cdot\alpha\cdot\sqrt{d}\sqrt{|S|}}\right)$ random walks of length $\ell_1\cdot\ell_2$ starting from s in G. Let A_0 (A_1) be the set of vertices that appear at the end of the walks whose corresponding paths have even (odd) length, and let G_0 (G_1) be the subgraph induced by A_0 (A_1). Then with probability at least 0.99, either G_0 contains an edge or G_1 contains an edge (i.e., the algorithm detects an odd cycle).*

The proof of the corollary is similar to that of an analogous corollary that appears in [13].

3.6. Proof of Theorem 1. Recall that we need to show that if the test accepts G with probability greater than $\frac{1}{3}$, then G is ϵ-close to being bipartite.

We say that a vertex s in G is *good* (for defining a partition) if the following holds. Suppose we take K random walks of length L in G starting from s. Then the probability that we reach two vertices u and v such that $(u,v)\in E$ and both u and v appear at the ends of walks whose corresponding paths have lengths with the same parity is at most 0.1. If a vertex is not good, then it is *bad*. Here K and L are set in the algorithm.

Since the test rejects G with probability less than $\frac{2}{3}$, and $T=\Theta(1/\epsilon)$, we know that, for an appropriate constant in the $\Theta(\cdot)$ notation above, the fraction of bad vertices in G is at most $\frac{\epsilon}{16}$. We now show that in such a case we can find a partition of the graph vertices that has at most ϵdn violating edges. We shall do so in steps, where in each step we partition a new set of vertices, denoted S, until we are left with at most $\frac{\epsilon}{4}n$ vertices. For each partitioned set S we show that (1) there are few (at most $\frac{\epsilon}{4}d|S|$) violating edges with respect to the partition of S; and (2) there are few (at most $\frac{\epsilon}{2}d|S|$) edges between S and the yet "unpartitioned" vertices R so that no matter how the vertices in R are partitioned, the number of violating edges between S and R is small.

At each step, let D be the set of vertices we have already partitioned, and let H be the subgraph induced by $V\setminus D$. Initially, $D=\emptyset$, and $H=G$. Let ℓ_1 and ℓ_2 be as required by Lemma 2, and let the length L of the walks we perform on G be $\ell_1\cdot\ell_2$. Since $\ell_1 = O\left(\left(\frac{\log(n/\epsilon)}{\epsilon}\right)^3\right)$, and $\ell_2 = O\left(\frac{\ell_1}{\epsilon^2}\right)$, we get that $L = O\left(\frac{\log^6(n/\epsilon)}{\epsilon^8}\right)$. Let $\mathrm{M} \stackrel{\text{def}}{=} \mathrm{M}_{\ell_1}^{\ell_2}(H)$. While $|H|\geq\frac{\epsilon}{4}n$, we do the following. We select any vertex s in H

that is both *good* and *useful* with respect to M (see Definition 3.1). By Lemma 1, at least half of the vertices in H are *useful*. Since $|H| \geq \frac{\epsilon}{4}n$ and the total number of *bad* vertices is $\frac{\epsilon}{16}n < \frac{\epsilon}{8}n$, there exist at least $\frac{\epsilon}{16}n$ vertices which are *good* and *useful*.

We next apply Lemma 2 to determine a set S and an integer t, $\ell_1/2 \leq t \leq \ell_1$, with the properties stated in the lemma. In particular, the number of edges between S and the rest of H is at most $\frac{\epsilon}{2}d|S|$, and for every $v \in S$, $\sqrt{\frac{\beta}{|S|\cdot|H|}} \leq q_{s,v}(t) \leq F \cdot \sqrt{\frac{\beta}{|S|\cdot|H|}}$, where $F = O\left(\frac{1}{\epsilon}\right)$, and $\beta = \Omega\left(\frac{\epsilon^2}{\log(n/\epsilon)}\right)$. We claim that it must be the case that $\sum_{v,u\in V,\,(v,u)\in E}(p_v^0(t)p_u^0(t) + p_v^1(t)p_u^1(t)) \leq \frac{\epsilon\cdot\beta\cdot d}{|H|}$. This claim (which we establish momentarily) implies that we can apply Lemma 3 (with $\alpha = \sqrt{\frac{\beta}{|S|\cdot|H|}}$) to show that S can be partitioned so that there are at most $\frac{\epsilon}{4}d|S|$ violating edges with respect to this partition. The claim holds since otherwise we could apply Corollary 4 and reach a contradiction. Specifically, by letting the number of walks performed from each starting vertex be

$$O\left(\frac{F^5}{\epsilon\cdot\alpha\cdot\sqrt{d}\cdot\sqrt{|S|}}\right) = O\left(\frac{\sqrt{|H|}}{\epsilon^6\cdot\sqrt{d}\cdot\sqrt{\beta}}\right) = O\left(\frac{\log^{1/2}(n/\epsilon)\cdot\sqrt{n/d}}{\epsilon^8}\right) = K$$

(where F, α, and β are as set above), we would obtain a contradiction to our assumption that s is *good*.

Thus, as long as $|H| \geq \frac{\epsilon}{4}n$, each set S contributed at most $\frac{\epsilon}{4}\cdot|S|\cdot d + \frac{\epsilon}{2}\cdot|S|\cdot d$ violating edges to the partition. Since these sets are disjoint, all these violating edges sum up to $\frac{3\epsilon}{4}\cdot d\cdot n$. The final H contributes at most $\frac{\epsilon}{4}\cdot n\cdot d$, and so G is ϵ-close to being bipartite.

Verifying that indeed $T = O(1/\epsilon)$, $K = \Theta(\sqrt{n/d}\cdot\mathrm{poly}(\log n/\epsilon))$, and $L = \mathrm{poly}((\log n)/\epsilon))$ and that the algorithm can be implemented using $O(K\cdot L + K^2) = O(n/d\cdot\mathrm{poly}(\log n/\epsilon))$ queries, the theorem follows. (Recall that if $d < \sqrt{n}$, then we obtain the bound of $O(\sqrt{n}\cdot\mathrm{poly}(\log n/\epsilon))$.)

4. The algorithm for the general case. In this section we build on the testing algorithm presented in the previous section and describe a one-sided error testing algorithm for bipartiteness that works with respect to the actual number of edges $m = m(G)$. Hence this algorithm is suitable for general graphs (for which $d_{\max}$ may vary significantly from d_{avg}). The query complexity and running time of the algorithm are of the same order of magnitude as for Test-Bipartite-Reg, that is, $O(\min(\sqrt{n}, n^2/m)\cdot\mathrm{poly}(\log n/\epsilon))$. We note that once the graph becomes very dense, that is, $m = \Omega(n^2/\log^c n)$ (where c is approximately 4), it is preferable to use the adjacency-matrix model algorithm [12, 3] with distance parameter $\epsilon/(n^2/m)$.

A high level description of the algorithm. The basic idea is to reduce the problem of testing with respect to the actual number of edges m to the problem of testing with respect to the upper bound $m_{\max} = d_{\max}\cdot n$. Specifically, for any graph G we show how to define a graph G' over $\Theta(n)$ vertices that has the following useful properties. First, the maximum degree in G' is roughly the same as the average degree, and furthermore, this degree is roughly the same as the average degree in G. In particular, this implies that the two graphs have roughly the same number of edges. Second, G' approximately preserves the distance of G to bipartiteness. More precisely, if G is bipartite, then so is G', but if G is far from being bipartite with respect to $m(G)$, then G' is far from being bipartite with respect to $m_{\max} = d_{\max}(G')n'$. Thus G' can be viewed as a kind of "regularized-degree version" of G.

If we had direct access to G', then by the above we would be done: by running the algorithm Test-Bipartite-Reg on G' we could decide whether G is bipartite or far from being bipartite. However, we have access only to G. Nonetheless, given query access to G we can efficiently "emulate" queries in G'. This would almost suffice for running Test-Bipartite-Reg on G'. One more issue is the uniform selection of starting vertices in G', required by Test-Bipartite-Reg. As we shall see, selecting a vertex uniformly from G' is (roughly) equivalent to uniformly selecting an edge in G.

While we do not know how to efficiently select a vertex in G' uniformly, we describe a different selection procedure that suffices for our purposes. Specifically, the selection procedure is such that for all but a small fraction of the n' vertices in G', the probability of selecting a vertex v is $\Omega(1/n')$. With slight abuse of terminology we shall refer to this procedure as Sample-Vertices-Almost-Uniformly-in-G'.[3] By Corollary 3, this suffices for our purposes.

Multiple edges and the relation between m and n. The analysis of the algorithm Test-Bipartite-Reg did not require any assumptions on the actual number of edges m in the graph, and it did not preclude the existence of multiple edges. Here we consider graphs that do not contain any multiple edges, and we assume that the number of edges m in G is $\Omega(n)$. To justify the assumption on the number of edges, consider a graph that consists of a clique over $k = o(\sqrt{n})$ vertices, where all remaining vertices are isolated. This graph has $m = \Theta(k^2)$ edges and is clearly far from being bipartite. However, in order to distinguish it from a graph that consists of a complete bipartite graph over $2k$ vertices (where all remaining vertices are isolated and clearly bipartite), we need $\Omega(n/k) = \omega(\sqrt{N})$ queries. (Taking this to an extreme, if $k = \Theta(1)$, then we will need $\Omega(n)$ queries.) We note that we could replace this assumption by introducing to the complexity of the algorithm a dependence on n/m. This would, however, make the analysis more cumbersome, without much benefit.

Another alternative assumption would be that the algorithm has the ability to "ignore" isolated vertices (that is, vertices that have no incident edges and are hence immaterial to the question of bipartiteness) and sample uniformly from the *nonisolated* vertices. This would effectively imply that the algorithm is executed on a subgraph induced by the $n' \leq n$ nonisolated vertices, where within this subgraph, the number of edges $m' = m$ is at least $n'/2$.

For simplicity we assume from this point on that $m \geq n$.

We also note that we can actually deal with the case where there are multiple edges, but they do not constitute more than a constant fraction of the total number of edges.[4] However, in order to deal with this case efficiently, we need to assume that there is a concise way to represent the sets of labels of multiple edges that are incident to each vertex. (In particular, this holds if the labels of multiple edges incident to each vertex are consecutive.) For simplicity we assume there are no multiple edges.

The main theorem of this subsection follows.

THEOREM 5. *For every graph G having n vertices and $m \geq n$ edges, we can define a graph G' having n' vertices and m' edges for which the following hold:*

[3]The reason we say that we abuse terminology is that the distribution on vertices in G' induced by this procedure may be very far from uniform according to any standard distance measure (e.g., statistical difference). However, it approximates the uniform distribution in the sense of assigning relatively large weight to every sufficiently large subset.

[4]If the number of multiple edges is more than a constant fraction, then it is possible to obtain a lower bound on the number of queries that depends on the ratio between the number of multiple edges and the total number of edges. Specifically, consider a graph that contains a small clique with many multiple edges, which is far from bipartite but cannot be distinguished from a bipartite graph that contains a small complete bipartite graph with many multiple edges.

1. $n \leq n' \leq 4n$, $m \leq m' \leq 8m$, *and* $d_{\max}(G') \leq 2d_{\text{avg}}(G)$.
2. *If* G *is bipartite, then* G' *is bipartite, and if* G *is* ϵ*-far from being bipartite with respect to* m*, then* G' *is* ϵ'*-far being from bipartite with respect to* $m_{\max}(G') = d_{\max}(G')n'$ *for* $\epsilon' = \Theta(\epsilon)$.
3. *Given a starting vertex* s *in* G' *it is possible to emulate random walks in* G' *starting from* s *by performing queries to* G. *The amortized cost of each random-walk step is* $O(\log^2 n)$ *(degree and neighbor) queries in* G. *By emulating these random walks it is possible to execute a slight variant of* Odd-Cycle(s) *in* G' *which we denote* Odd-Cycle$'(s)$. *This variant is such that* $\Pr[\text{Odd-Cycle}'(s) = \textsf{found}] \geq \Pr[\text{Odd-Cycle}(s) = \textsf{found}]$, *where if* Odd-Cycle$'(s)$ *returns* found, *then we can obtain an odd cycle of length* $\text{poly}(\log n/\epsilon)$ in the original graph G.
4. *There exists a procedure* Sample-Vertices-Almost-Uniformly-in-G' *that for any given parameter* $0 < \delta \leq 1$ *performs* $\tilde{O}(\min(\sqrt{n/\delta}, n^2/m))$ *queries in* G *and returns a vertex in* G' *such that the following holds: For all but at most* $\delta n'$ *of the vertices* x *in* G', *the probability that* x *is selected by the procedure is* $\Omega(1/n')$.

We note that for every graph G there is actually a *family* of graphs G' with the above properties (all defined over the same set of vertices). When we run algorithm Test-Bipartite-Gen, we construct one such (arbitrary) graph G' in the family as we go along. One difficulty that arises is that when the algorithm asks a neighbor query of the form "Who is the ith neighbor of v?", it gets a vertex name u as an answer. However, the algorithm lacks the information that v is (say) the jth neighbor of u. This lack of knowledge makes the emulation of random walks and Odd-Cycle(s) in G' more complicated. Due to that, item 3 of Theorem 5 is somewhat more involved.

As a corollary to Theorem 5 and Corollary 3 we obtain the following.

COROLLARY 6. *Algorithm Test-Bipartite-Gen (see Figure* 2*) accepts every graph* G *that is bipartite and rejects with probability at least* $2/3$ *every graph* G *that is* ϵ*-far from being bipartite (with respect to* $m(G)$*). Furthermore, whenever the algorithm rejects a graph, it outputs a* certificate *to the nonbipartiteness of the graph* G *in the form of an odd cycle of length* $\text{poly}(\log n/\epsilon)$. *The query complexity and running time of the algorithm are* $O\left(\min(\sqrt{n}, n^2/m) \cdot \text{poly}(\log n/\epsilon)\right)$.

Test-Bipartite-Gen($n, d_{\text{avg}}, \epsilon$)

- Repeat $T = \Theta(\frac{1}{\epsilon})$ times:
  1. Set $\epsilon' = \epsilon/144$.
  2. Select a vertex s in G' by calling the procedure Sample-Vertices-Almost-Uniformly-in-G' with $\delta = \epsilon'/c$ (where c is a sufficiently large constant).
  3. Apply Odd-Cycle$'(s)$.
  4. If Odd-Cycle$'(s)$ returns found, then output reject.
- In case no call to Odd-Cycle$'$ returned found, then output accept.

FIG. 2. *Algorithm Test-Bipartite-Gen for testing bipartiteness with respect to the actual number of edges* $m = m(G)$ *in the graph* G.

Note that d_{avg}, the average degree of the graph, is given as a parameter to the algorithm. Since the algorithm does not actually need the exact value of d_{avg}, it can instead estimate it. Specifically, Feige [11] shows how to obtain an estimate that is within a factor of roughly 2 of the true value by performing at most $O(\sqrt{n/d_0})$ degree queries where d_0 is an a priori lower bound on d_{avg}. Inspired by our procedure

Sample-Edges-Almost-Uniformly-in-G, Goldreich and Ron [15] suggest an alternative procedure that improves on the quality of the estimate. More importantly in our context, they observe that both in the case of their procedure and in the case of Feige's procedure, it is possible to eliminate the need of the lower bound d_0. That is, given's Feige's algorithm, it is possible to obtain a constant factor estimate by performing $O(\sqrt{n/d_{\text{avg}}}) \leq O(\min(\sqrt{n}, n^2/m))$ queries (but without any knowledge about d_{avg}).

We now turn to proving Theorem 5. We actually provide two proofs: one is based on a deterministic construction of G' and one on a probabilistic construction. We start by presenting the deterministic construction.

4.1. Defining G' and proving the first two items in Theorem 5. In all that follows, let $d = d_{\text{avg}}(G)$, and let $d' = d_{\max}(G')$. We shall assume that d is a sufficiently large constant. If $d_{\text{avg}}(G)$ is not sufficiently large, then we still set d in the construction below to be sufficiently large and run the algorithm with ϵ set to $\epsilon/(d/d_{\text{avg}}(G))$.

The idea. Recall that part of our goal is to have G' be a "regularized" version of G in the sense that in G' all vertices have degree at most $2d$ (while in G there may be vertices with degree much higher than the average degree d). To this end, every vertex of G with degree higher than d is represented in G' by a subset of vertices. Each such subset is partitioned into two equal parts: an *external* subset (consisting of *external* vertices) and an *internal* subset (consisting of *internal* vertices). The edges between external vertices in G' are determined by the edges of G. Namely, if (u, v) is an edge in G, then in G' there is an edge between one of the vertices in the external subset of u to one of the vertices in the external subset of v. In addition, for every vertex v (with degree greater than d) there is a bipartite subgraph between its internal and external vertices. All vertices in the subgraph have degree d, and the subgraph has good expansion properties.

The role of these subgraphs between external and internal vertices is to ensure that if G is far from being bipartite, then so is G'. To gain some intuition observe that for every partition (V_1, V_2) of G, there exists a corresponding partition (V_1', V_2') of G' that has the same number of violating edges. Specifically, for every vertex $v \in V_1$ ($v \in V_2$) we put in V_1' (V_2') all external vertices that correspond to v, and we put in V_2' (V_1') all internal vertices that correspond to v. By this construction, there is a one-to-one mapping between the edges in G that are violating with respect to (V_1, V_2) and the edges in G' that are violating with respect to (V_1', V_2') (where all edges in the subgraphs between external and internal vertices are nonviolating). Thus, if G is far from being bipartite, so that all partitions (V_1, V_2) of G have many violating edges, then this is also true of all partitions (V_1', V_2') as defined above. However, there are other partitions of G' that may split the external vertices that correspond to the same vertex in G into different parts and possibly have fewer violating edges. What we show is that such splits must introduce violating edges in the subgraphs between external and internal edges, where this is due to the expansion properties of the subgraphs. Roughly speaking, if a partition "avoids violations" between external vertices by splitting sets of external vertices, then it "pays" by introducing violations between external and internal vertices.

4.1.1. The construction of G'. For each vertex v in G such that $\deg(v) \leq d$, we have a single vertex in G'. For each vertex v in G such that $\deg(v) > d$, the graph G' contains a subgraph, denoted $H(v)$. It is a bipartite graph over two subsets of vertices, one denoted $X(v)$, the *external* part, and one denoted $I(v)$, the *internal*

part. Both parts consist of $\lceil \deg(v)/d \rceil$ vertices. Every vertex in $X(v)$ is assigned up to d specific neighbors of v according to some fixed *but arbitrary* partition of the neighbors of v. As we shall see below, this assignment determines the edges between pairs of external vertices in G' that correspond to different vertices in G. We refer to the vertices in the two subsets by $\{X_i(v)\}_{i=1}^{\lceil \deg(v)/d \rceil}$ and $\{I_i(v)\}_{i=1}^{\lceil \deg(v)/d \rceil}$, respectively.

The edges in $H(v)$ are determined as follows. In case $\deg(v)/d < d$ then we have $\frac{\lfloor d^2/\deg(v) \rfloor}{2}$-multiple edges between every internal vertex and every external vertex in $H(v)$. It follows that the degree of every vertex within $H(v)$ is

$$\frac{\lfloor d^2/\deg(v) \rfloor}{2} \cdot \lceil \deg(v)/d \rceil \;\leq\; \frac{d^2}{2 \cdot \deg(v)} \cdot \frac{\deg(v)+d}{d} \;\leq\; \frac{d^2}{2 \cdot \deg(v)} \cdot \frac{2\deg(v)}{d} \;=\; d.$$

In case $\deg(v)/d \geq d$, denote $s = \lceil \deg(v)/d \rceil$, and let $H(v)$ be a bipartite expander where each of its sides has s vertices ($s \geq d$). Each vertex in $H(v)$ has degree d. All eigenvalues of the adjacency matrix of H but the largest one and the smallest one (which are equal to d and $-d$, respectively) are at most $d/4$ in their absolute values. Explicit constructions of such expanders can be found, e.g., in [18, 17]. Furthermore, these constructions allow the determination of the ith neighbor of any given vertex in constant time.

For the sake of the presentation, when $\deg(v) \leq d$ so that v is represented by a single vertex, we let $H(v)$ be the subgraph that consists of this single vertex. This vertex is considered an external vertex, denoted $X_1(v)$, and it is assigned all neighbors of v.

We have described how vertices of G are transformed into vertices of G' (some of which are connected by edges). It remains to describe the relevant transformation to the edges of G. Consider an edge $(u,v) \in E(G)$, where v is the ith neighbor of u and u is the jth neighbor of v. Let $X_k(u)$ and $X_\ell(v)$ be the external vertices that are assigned the ith neighbor of u and the jth neighbor of v, respectively. Then, there is an edge $(X_k(u), X_\ell(v))$ in G'. It directly follows that every vertex in G' has degree at most $2d$ and that $n' = |V(G')| \leq \sum_{v \in G} 2\lceil \deg(v)/d \rceil \leq 4n$, and $m' = m(G') \leq 4dn = 8m$.

For an illustration of the construction of G', see Figure 3.

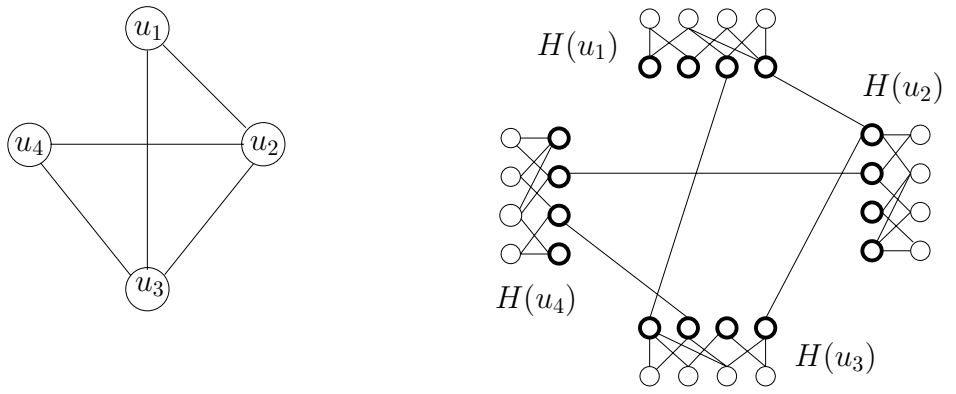

FIG. 3. *An illustration for the construction of G'. On the left are four vertices in G and their induced subgraph. On the right are the four corresponding subgraphs in G' and the edges between the external vertices in these subgraphs. (The external vertices are marked in bold, and there are additional edges that do not appear in the figure between the external vertices in the figure and external vertices of other subgraphs.)*

We have thus established the first item in Theorem 5, and we turn to the second item. From the construction of G' it is obvious that if G is bipartite, then so is G'. It remains to prove the following lemma.

LEMMA 5. *If G is ϵ-far from being bipartite (with respect to $m = (dn)/2$), then G' is ϵ'-far from being bipartite with respect to $d'n'$ for $\epsilon' = \frac{\epsilon}{144}$.*

In order to prove Lemma 5, we first prove the following proposition concerning bipartite expander graphs. For any two (disjoint) subsets of vertices, A and B, we let $e(A, B)$ denote the number of edges with one endpoint in A and another in B.

PROPOSITION 7. *Let $G = (A \cup B, E)$ be a d-regular bipartite graph with sides A and B of size s. Assume that all eigenvalues of the adjacency matrix of G, but the largest one and the smallest one, are at most λ in their absolute values. Assume further that $\lambda \leq d/4$. Then for every two partitions $A = A_1 \cup A_2$, $B = B_1 \cup B_2$, satisfying $|A_1| \geq s/2$,*

$$e(A_1, B_1) + e(A_2, B_2) \geq \frac{d|A_2|}{8}.$$

Proof. It is well known that the larger the "spectral gap" (i.e., the difference between d and λ) is, the closer the edge distribution in G approaches that of a truly random bipartite graph with sides of size s and edge probability d/s. Specifically, for every $A_0 \subseteq A$, $B_0 \subseteq B$ of sizes $|A_0| = a_0$, $|B_0| = b_0$,

$$\left| e(A_0, B_0) - \frac{da_0b_0}{s} \right| \leq \lambda\sqrt{a_0b_0} \tag{13}$$

(see, e.g., Chapter 9 of [5]).

Let $|A_1| = a_1$, $|A_2| = a_2 = s - a_1$, $|B_1| = b_1$, $|B_2| = b_2 = s - b_1$. It is given that $a_1 \geq s/2$. We may obviously assume that $b_1 \geq a_2/2$, as otherwise at least half of the edges incident to A_2 have their other endpoint outside B_1, implying $e(A_2, B_2) \geq da_2/2$.

Applying the bound in (13) twice, we get

$$e(A_1, B_1) = d|B_1| - e(A_2, B_1) \geq db_1 - \frac{da_2b_1}{s} - \lambda\sqrt{a_2b_1} = \frac{da_1b_1}{s} - \lambda\sqrt{a_2b_1}, \tag{14}$$

$$e(A_2, B_2) = d|A_2| - e(A_2, B_1) \geq da_2 - \frac{da_2b_1}{s} - \lambda\sqrt{a_2b_1} = \frac{da_2b_2}{s} - \lambda\sqrt{a_2b_1}. \tag{15}$$

Consider first the case $b_2 \leq s/2$. In this case it follows from (14) that

$$\begin{aligned} e(A_1, B_1) &\geq \frac{da_1b_1}{s} - \lambda\sqrt{a_2b_1} \geq \frac{d(s/2)(s/2)}{s} - \lambda\sqrt{(s/2)s} \\ &= \frac{ds}{4} - \frac{\lambda s}{\sqrt{2}} \geq \frac{ds}{14} \geq \frac{da_2}{7}. \end{aligned}$$

We thus assume that $b_2 > s/2$. If $da_2b_2/s \geq 2\lambda\sqrt{a_2b_1}$, we obtain from (15) that

$$e(A_2, B_2) \geq \frac{da_2b_2}{2s} \geq \frac{da_2(s/2)}{2s} = \frac{da_2}{4}.$$

Hence we may assume that $da_2b_2/s \leq 2\lambda\sqrt{a_2b_1}$. If $da_1b_1/s \geq 2\lambda\sqrt{a_2b_1}$, then it follows from (14) that

$$e(A_1, B_1) \geq \frac{da_1b_1}{2s} \geq \frac{d(s/2)(a_2/2)}{2s} = \frac{da_2}{8},$$

as required. Hence we may assume that $da_1b_1/s \leq 2\lambda\sqrt{a_2b_1}$. It remains to check that the latter assumption together with $da_2b_2/s \leq 2\lambda\sqrt{a_2b_1}$ brings us to a contradiction. Indeed, multiplying these inequalities, we get $d^2a_1a_2b_1b_2/s^2 \leq 4\lambda^2a_2b_1$ or

$d^2 a_1 b_2 \leq 4\lambda^2 s^2$. Recalling that $a_1 \geq s/2$, $b_2 > s/2$, it follows that $d < 4\lambda$, which is a contradiction to our assumption on λ. □

Proof of Lemma 5. We shall show that the number of edges that should be removed from G' so as to make it bipartite is at most a constant factor smaller than the number of edges that should be removed from G so as to make G bipartite. Since the total numbers of edges in G and in G' are of the same order, this suffices to prove the lemma. To this end we prove the contrapositive statement. Specifically, suppose G' is ϵ'-close to being bipartite with respect to $m_{\max} = d'n'$. Namely, there exists a partition $P' = (V_0', V_1')$ of the vertices in G' with respect to which there are at most $\epsilon' \cdot d'n'$ violating edges in G'. We shall show how to construct, based on P', a partition $P = (V_0, V_1)$ of the vertices in G with respect to which there are at most $\epsilon dn/2 = \epsilon m$ violating edges in G, thus proving the lemma.

Consider a particular vertex v in G and the subset of external vertices $X(v)$ in G' that correspond to v. Let $X^0(v) = X(v) \cap V_0'$, and let $X^1(v) = X(v) \cap V_1'$. We refer to the larger subset as the *majority subset* of v and to the smaller subset as the *minority subset* of v. We define $P = (V_0, V_1)$ by assigning each vertex v in G according to its majority subset. Namely, if $|X^0(v)| \geq |X^1(v)|$, then v is assigned to V_0; otherwise, it is assigned to V_1. In what follows it will be convenient to refer to 0 and 1 as *colors*.

Also, when we refer to edges in G' as violating edges, we mean with respect to P', and when we refer to edges in G as violating edges, we mean with respect to P. Note that the partition P is defined only according to the coloring of the external vertices in G', ignoring the coloring of the internal vertices. Also recall that there is a one-to-one mapping between edges in G and edges in G' whose endpoints are both external vertices.

Since each vertex v in G is assigned the color of its majority subset, the violating edges in G' between pairs of vertices that both belong to majority subsets, or between pairs of vertices that both belong to minority subsets, become violating edges in G. Similarly, nonviolating edges in G' between vertices in majority subsets, or between vertices in minority subsets, become nonviolating edges in G. It remains to deal with edges between minority and majority subsets in G'. These edges can be nonviolating in G' but may become violating in G.

We next show that the total number of vertices in G' that belong to minority subsets can be bounded as a function of the number of violating edges in G'. To this end we show that if there were many minority vertices, then there would be many violating edges in G' *between internal and external vertices*.

For each vertex v in G, consider the majority and minority subsets of (the external vertices of) v. Let the majority subset of $X(v)$ be $X^\alpha(v)$, and let the minority subset be $X^\beta(v)$ (where $\alpha, \beta \in \{0,1\}$).

Claim 1. *For every vertex v in G, the number of violating edges in G' between vertices in $X(v)$ and vertices in $I(v)$ is at least $\left|X^\beta(v)\right| \cdot (d/8)$.*

Proof. Similarly to our notation for external vertices, for the internal vertices of v let $I^0(v) \stackrel{\text{def}}{=} I(v) \cap V_0'$ and $I^1(v) \stackrel{\text{def}}{=} I(v) \cap V_1'$. Consider first the case $\frac{\deg(v)}{d} < d$. By construction of G', $|X(v)| = |I(v)| = \lceil \deg(v)/d \rceil$, and there are $\frac{\lfloor d^2/\deg(v) \rfloor}{2}$ multiple edges between every pair of vertices (x, y) such that $x \in X(v)$ and $y \in I(v)$. Hence the number of edges between $X(v)$ and $I(v)$ that are violating (with respect to P') is

$$\begin{aligned}
&\left(|X^\alpha(v)||I^\alpha(v)| + |X^\beta(v)||I^\beta(v)|\right) \cdot \frac{\lfloor d^2/\deg(v) \rfloor}{2} \\
&\geq \left(|X^\beta(v)||I^\alpha(v)| + |X^\beta(v)||I^\beta(v)|\right) \cdot \frac{d^2}{4\deg(v)} = |X^\beta(v)| \cdot \frac{d}{4}.
\end{aligned}$$

Next consider the more interesting case where $\frac{\deg(v)}{d} \geq d$. In this case Claim 1 directly follows from Proposition 7. □

Thus we can conclude that if there are w external vertices that belong to minority subsets, then they contribute at least $w \cdot d/8$ violating edges in G'. Since the number of violating edges in G' is at most $\epsilon' n' d' \leq 8\epsilon' nd$, we have that $w \leq 64\epsilon' n$. As noted previously, the total number of violating edges in G is upper bounded by the number of violating edges in G' plus the number of edges between minority and majority (external) subsets. By the above discussion and the fact that every external vertex has at most d neighbors that are external vertices, the number of violating edges in G is at most $8\epsilon' nd + 64\epsilon' nd = 72\epsilon' nd$. Since $\epsilon' = \epsilon/144$ and $m = (nd)/2$, the lemma follows. □

We have completed proving the first two items of Theorem 5, and we now turn to the third item.

4.2. Establishing item 3 in Theorem 5. Here we stress that if the neighbor and the vertex-pair queries would have returned more information, then the proof of the current item would be significantly simpler. In particular, suppose that a neighbor query (u, i) is answered with a pair (v, j) (instead of only v), which means that v is the ith neighbor of u and u is the jth neighbor of v. Suppose also that when performing a vertex-pair query (u, v), the algorithm is not only told whether (u, v) is an edge or not, but rather, in the former case, it is also provided with pair (i, j), which means that v is the ith neighbor of u and u is the jth neighbor of v. With this additional information, the structure of G' is implicitly given, and thus the emulation of random walks in the execution of the procedure Odd-Cycle on G' is straightforward. Here we need to work harder to overcome the lack of information.

Random-walk steps. We first briefly discuss the emulation of random walks. If the walk stays at the current vertex, then clearly there is no need for any emulation. Hence, we need only to consider the case in which we have to select a random neighbor. Recall that vertices in G' are either of the form $X_i(v)$ (the ith external vertex corresponding to vertex v in G) or of the form $I_i(v)$ (the ith internal vertex), where $1 \leq i \leq \lceil \deg(v)/d \rceil$. Recall that we can obtain $\deg(v)$ for any v by a single degree query and, in particular, use this to find the degree of vertices in G'. For simplicity of presentation, we assume from this point on that for every vertex v in G, the degree of every vertex $I_i(v)$ in G' is d (instead of being at most d), and the degree of every $X_i(v)$ is $2d$ (instead of being at most $2d$).

Performing a random-walk step in G' from an internal vertex $I_i(v)$ can be easily done by using the explicit structure of the graph $H(v)$ (which is either a complete bipartite graph with multiple edges or an explicitly constructible expander). In order to perform a random-walk step from an external vertex, $X_i(v)$, we first determine whether to take one of the d edges within the graph $H(v)$ or whether to take one of the d edges going from $X_i(v)$ to another external vertex. In the first case we then select an internal neighbor given the explicit structure of $H(v)$. It remains to deal with selecting an external neighbor. Note that in the special, but easy, case in which $\deg(v) \leq d$ and so $H(v)$ is a single vertex, there is only the latter option.

As noted just following the statement of Theorem 5, we actually construct G' as we go along. The important thing to note is that the definition of G' allows us to assign the vertices in $X(v)$ edges of v in an *arbitrary* manner (as long as each $X_i(v)$ is assigned (at most d) different edges). Hence, all we need to take care of is to be consistent with previous choices and to ensure the correct distribution in the choice of the random-walk step. To this end we may think of each external vertex as having

d "ports," labeled $1, \ldots, d$, which are initially unassigned. As the algorithm proceeds, it puts a "link" between, say, the tth port of $X_i(v)$ and the ℓth port of $X_j(u)$ (where $(v,u) \in E(G)$). When performing a random-walk step from $X_i(v)$ (to a vertex outside of $H(v)$), we uniformly select a port. Let us denote the index of the port selected by t. If port t of $X_i(v)$ is already linked to another port, then we simply take this link to the port (and vertex) at the other end. Otherwise, we first set the link and then take it. In order to set the link properly, we need to uniformly select a neighbor u of v among the neighbors of v *that were not yet assigned* (to any port of one of the external vertices of v). After doing so and selecting a neighbor u, we need to select a yet unassigned port of one of the external vertices of u. The above can be done, with the aid of sampling, at an amortized cost of $O(\log n)$ queries in G. Details follow.

For each external vertex $X_i(v)$, the algorithm keeps a vector of length d, $\Gamma_i(v)$. The kth entry of $\Gamma_i(v)$ contains the kth neighbor of $X_i(v)$, if it was determined, and is empty otherwise. Denote by $f_i(v)$ the number of free entries in the vector $\Gamma_i(v)$. Also denote by $A(v)$ the set of neighbors of v that were already assigned to external vertices of v, and by $NA(v)$ the vertices that were not assigned. When setting a link to a yet-unassigned port (filling in a new entry in $\Gamma_i(v)$), we distinguish between two cases.

Case 1. If less than half of the neighbors of v in G are in $A(v)$, then the algorithm repeats at most $(\log^2 n)$ times the following procedure: It chooses uniformly at random a neighbor of v in G. If that neighbor belongs to $NA(v)$, then a desired neighbor is found. By repeating the above procedure $O(\log^2 n)$ times, the probability that the algorithm did not find a desired neighbor is at most $o(1/n)$. In this case we say that the algorithm fails. Since the total number of queries that the algorithm performs is at most $o(n)$, the total failure probability of the algorithm is $o(1)$. Suppose that a desired neighbor of v with the name u is found. In that case the algorithm should move to one of the external vertices of u. The selected vertex $X_k(u)$ is chosen with probability $\frac{f_k(u)}{\sum_{1 \le j \le \lceil \deg(u)/d \rceil} f_j(u)}$. According to the chosen $X_j(u)$, the algorithm sets $\Gamma_i(v)[t] \leftarrow X_j(u)$. In addition, the algorithm chooses uniformly at random one of the $f_j(u)$ free entries in the vector $\Gamma_j(u)$. Assume that the chosen index is t', $1 \le t' \le d$; then the algorithm sets $\Gamma_j(u)[t'] \leftarrow X_i(v)$.

Case 2. If more than half of the neighbors of v in G are in $A(v)$, then the algorithm reads all the neighbors of v in G that belong to $NA(v)$ and attaches them arbitrarily to the unoccupied entries in $\Gamma_j(v)$, $1 \le j \le \lceil \deg(v)/d \rceil$. By doing this, the algorithm (at most) doubles the number of neighbor queries performed on vertex v of G. Now, suppose that in $\Gamma_i(v)[t]$ there is a name of a vertex of G, say, u. In that case, the algorithm should move to one of the external vertices $X_k(u)$, $1 \le k \le \lceil \deg(u)/d \rceil$, and this is done as in the first case.

Modifying the procedure Odd-Cycle. The procedure Odd-Cycle$'$ is the same as Odd-Cycle in terms of the performance of random walks, which are emulated as described above. The only modification is in the last stage, where the procedure performs vertex-pair queries. Let (x,y) be the pair of vertices queried in G'. We answer the query as follows. If $(x,y) = (X_i(v), I_j(v))$ for some vertex v in G, then we answer according to the explicit construction of the subgraph $H(v)$. If $(x,y) = (X_i(v), I_j(u))$ for $u \neq v$, then the answer is always negative. If $(x,y) = (X_i(u), X_j(v))$, then we query the pair (u,v) in G. If there is no edge between (u,v) in G, we answer that there is no edge between $X_i(u)$ and $X_j(v)$. Otherwise, we give a positive answer. While this answer may be inconsistent with the construction of G' (since it would correspond to having a complete bipartite subgraph in G' between the external

vertices of u and the external vertices of v), it always provides evidence to an odd cycle in the input graph G. An explanation follows.

Consider two paths in G', where both paths start at the same vertex $x \in H(s)$ and end at a pair of external vertices $X_i(v)$ and $X_j(u)$, respectively, and whose lengths have the same parity (so that $X_i(v)$ and $X_j(u)$ both belong to the same A_b, $b \in \{0,1\}$). By construction of G', such a pair of paths in G' corresponds to a pair of paths in G, which start at s, end at v and u, respectively, and have the same parity b as well. But if there is an edge in G between v and u, then there is an odd cycle in G.

4.3. Establishing item 4 in Theorem 5. In this subsection we prove the last item in Theorem 5. Recall that we are interested in a procedure for selecting a vertex in G' so that there is a sufficiently high probability of hitting any fixed sufficiently large subset of vertices in G'. In particular, if G' is far from being bipartite, then we are interested in hitting the subset of vertices s for which Odd-Cycle(s) returns found with probability at least 2/3.

Let $V_\ell(G) = \{v \in V(G) : \deg(v) \le d\}$, and let $V_h(G) = \{v \in V(G) : \deg(v) > d\}$, where "$\ell$" stands for *low*, "$h$" stands for *high*, and, as before, $d = d_{\text{avg}}(G)$ denotes the average degree of vertices in G. We also define the corresponding sets in G': $V_\ell(G') = \{x \in V(H(v)) : v \in V_\ell(G)\}$ and $V_h(G') = \{x \in V(H(v)) : v \in V_h(G)\}$. (Recall that $H(v)$ is the subgraph in G' that corresponds to v, and $V(H(v))$ is its set of vertices.) Since $V(G') = V_\ell(G') \cup V_h(G')$, it follows that selecting a vertex uniformly in $V(G')$ can be done by first deciding whether to pick a vertex from $V_\ell(G')$ or from $V_h(G')$ with probability proportional to the size of each set (relative to $n' = |V(G')|$) and then picking a vertex uniformly from the selected set.

Recall that for every $v \in V_\ell(G)$ we have $|V(H(v))| = 1$ while for every $v \in V_h(G)$, $|V(H(v))| = 2\lceil \deg(v)/d \rceil$. Therefore, picking a vertex uniformly in $V_\ell(G')$ corresponds to picking a vertex uniformly in $V_\ell(G)$, while picking a vertex uniformly in $V_h(G')$ corresponds to picking a vertex in $V_h(G)$ with probability proportional to its degree.

Since we are not required to actually select every vertex in $V(G')$ with exactly equal probability, but rather we are required to be able to select all but $\delta n'$ of the vertices in $V(G')$ with probability at least $\Omega(1/n')$, we may perform the above steps in an approximate manner. In particular, by taking a sample of $\Theta(1/\delta^2)$ vertices in G and querying their degrees, we may obtain an estimate, denoted $\hat{\mu}(G')$, of $|V_\ell(G')|/n' = |V_\ell(G)|/n'$ such that if $|V_\ell(G')|/n' \ge \delta/2$, then $(1/8)|V_\ell(G')|/n' \le \hat{\mu}(G') \le 2(|V_\ell(G')|/n')$ (recall that $n \le n' \le 4n$). In order to uniformly select a vertex in $V_\ell(G)$ (so as to obtain a uniformly selected vertex in $V_\ell(G')$), we can simply take a sample of vertices from $V(G)$, query their degrees, and pick the first vertex in the sample that belongs to $V_\ell(G)$ if such a vertex exists. If $|V_\ell(G')|/n' \ge \delta/2$, so that $|V_\ell(G)|/n \ge \delta/2$, then a sample of size $O(1/\delta)$ suffices to ensure that with high constant probability, the sample will indeed contain a vertex in $V_\ell(G)$.

The only step that is more involved is that of selecting a vertex in $V_h(G)$ with probability proportional to its degree. Observe that selecting a vertex from all of $V(G)$ with probability proportional to its degree can be performed by uniformly selecting an *edge* in $E(G)$ and then selecting one of its two endpoints with equal probability. In the next subsection we describe and analyze a procedure that performs a certain approximation to the uniform selection of an edge in $E(G)$. In subsection 4.3.2 we return to the problem of selecting a vertex in G' almost uniformly.

4.3.1. Sampling edges almost uniformly in *G*. We consider two cases: $d > \sqrt{\delta n}$ and $d \le \sqrt{\delta n}$. Recall that our goal is to use $\tilde{O}(\min(\sqrt{n/\delta}, n/d))$ queries

to G. The first case is easy since if G contains sufficiently many edges, then we simply sample $\Theta(n/d) = \Theta(n^2/m)$ pairs of vertices in order to obtain an edge.

Sample-Edges-Uniformly-in-G

Repeat $\Theta(n/d)$ times:

- Select two vertices in G uniformly and at random.
- Check if there is an edge between these two vertices (by performing a single vertex-pair query). If the answer is positive, then output this edge (and exit the repeat loop).

FIG. 4. *A procedure for sampling edges uniformly in G.*

The straightforward procedure for this case is given in Figure 4. Clearly every edge in G has equal probability of being selected by the procedure, and the query complexity of this procedure is $\Theta(n/d)$, which for $d > \sqrt{\delta n}$ is $\Theta(\min(\sqrt{n/\delta}, n/d))$ as required. (To be more precise, there is some probability that this procedure fails to output an edge. However, the probability that this occurs can be made sufficiently small so as to have a negligible effect on the success probability of our algorithm.)

In the second case, where G contains fewer edges ($d \leq \sqrt{\delta n}$), we do not have an algorithm that selects an edge uniformly from G (using relatively few queries). However, we can show the following.

LEMMA 6. *There exists a procedure* Sample-Edges-Almost-Uniformly-in-G *that uses $\tilde{O}(\sqrt{n/\delta})$ degree and neighbor queries in G and for which the following holds: For all but $(\delta/4)m$ of the edges e in G, the probability that the procedure outputs e is at least $1/(64m)$. Furthermore, there exists a subset $U_0 \subset V(G)$, $|U_0| \leq (\delta n/2)$, such that for all edges $e = (u, v)$ that are output with probability less than $1/(64m)$, we have $u, v \in U_0$.*

Sample-Edges-Almost-Uniformly-in-$G(\delta)$

1. Let $t = 2\sqrt{n/\delta} \cdot \log m$. Uniformly select a subset of vertices $S \subset V(G)$, where $|S| = t$.
2. Partition the sampled vertices into subsets according to their degree: $S_i = \{v \in S : \deg(v) \in (2^{i-1}, 2^i]\}$.
3. Choose an index i, $1 \leq i \leq \log m$, with probability $\frac{|S_i|2^i}{\sum_i |S_i|2^i}$.
4. Uniformly select a vertex $v \in S_i$.
5. Uniformly select an edge incident to v.

FIG. 5. *A procedure for selecting an edge in G so that all but at most a $(\delta/4)$-fraction of the edges are selected with probability $\Omega(1/m)$.*

The procedure referred to in Lemma 6 is described in Figure 5. Before proving Lemma 6 we provide some intuition concerning this procedure. We define the following $\log m$ "buckets": for $1 \leq i \leq \log m$,

$$B_i = \left\{v \in V(G) \ : \ \deg(v) \in (2^{i-1}, 2^i]\right\}. \tag{16}$$

Thus, in each bucket, all vertices have approximately the same degree. Suppose we had a way to pick an index i with probability proportional to $|B_i| \cdot 2^i$, which is approximately the same as picking i with probability proportional to the number of edges incident to vertices in B_i. Further assume that for each i we could uniformly

select a vertex in B_i. Then we could select an edge almost uniformly by selecting an index i as described above, uniformly selecting a vertex $v \in B_i$, and then uniformly selecting an edge incident to v.

The procedure Sample-Edges-Almost-Uniformly-in-G can be viewed as approximating this "ideal" procedure. Assume first that all buckets are relatively large (i.e., $|B_i| = \Omega(\sqrt{n})$ for every $1 \leq i \leq \log m$). Then, by taking a uniformly selected sample of $\tilde{\Theta}(\sqrt{n})$ vertices in G, we can obtain a good estimate of $|B_i|$ (and by that, of $|B_i| \cdot 2^i$), for every i, and we can uniformly select a vertex $v \in B_i$ for any given i. Unfortunately, if some buckets are small, then we might not sample from them at all.

To illustrate the seeming difficulty with such a case, suppose the graph is a star, so that there is one vertex, denoted v^* with degree $n-1$, and all other vertices have degree 1. In terms of our buckets we have $|B_0| = n-1$ so that $|B_0| \cdot 2^0 = n-1$, and $|B_{\log n}| = 1$ so that $|B_{\log n}| \cdot 2^{\log n} = n$. The "ideal" procedure would select each of the two buckets roughly with equal probability, and if it selects the bucket $B_{\log n}$, then it picks v^*. In other words, it picks v^* with probability roughly $1/2$. But if we take a sample of $\tilde{\Theta}(\sqrt{n})$ vertices, then the probability that v^* falls in the sample is extremely small. However, this turns out to be almost immaterial to the analysis since we are interested in the end result of the distribution on *edges*. In the case of the star graph, every edge incident to v^* is also incident to one of the degree-1 vertices and hence will be selected with equal probability.

In general, as we shall see in detail in the proof of Lemma 6, we can lower-bound the probability of selecting each edge that has both endpoints in sufficiently large buckets. On the other hand, we can upper-bound the total number of edges that have both endpoints in small buckets. Details follow.

Proof of Lemma 6. Let the subsets ("buckets") B_i be as defined in (16). Note that in the procedure Sample-Edges-Almost-Uniformly-in-G (Figure 5), the subsamples S_i are simply $S_i = S \cap B_i$. Next we define a set of indices I_0 that includes indices of all buckets B_i that have "few" elements. More precisely,

$$I_0 = \left\{ i \ : \ 1 \leq i \leq \log m \text{ and } |B_i| \leq \frac{\sqrt{\delta n}}{2 \log m} \right\}. \tag{17}$$

Let U_0 be the set of vertices that belong to buckets with "few" elements: $U_0 = \bigcup_{i \in I_0} B_i$.

Consider any fixed vertex $v \notin U_0$, and let $i(v)$ be the index of the bucket that v belongs to, that is, $v \in B_{i(v)}$. We denote by C_v the event that v is selected in step 4 of the sampling algorithm. Then, for a vector $(s_1, \ldots, s_{\log m})$ we can estimate

$$\Pr[C_v \ : \ |S_1| = s_1, \ldots, |S_{\log m}| = s_{\log m}] = \frac{s_{i(v)}}{|B_{i(v)}|} \cdot \frac{s_{i(v)} 2^{i(v)}}{\sum_i s_i 2^i} \cdot \frac{1}{s_{i(v)}} \tag{18}$$

(first require that v falls in $S_{i(v)}$, then choose the bucket $S_{i(v)}$, and then choose v inside $S_{i(v)}$). Thus the above conditional probability is

$$\frac{s_{i(v)}}{|B_{i(v)}|} \cdot \frac{2^{i(v)}}{\sum_i s_i 2^i} \geq \frac{s_{i(v)} \deg(v)}{|B_{i(v)}| \sum_i s_i 2^i}. \tag{19}$$

The random variable $s_{i(v)}$ is hypergeometrically distributed with parameters n, $|B_{i(v)}|$, and t. It thus has mean $t|B_{i(v)}|/n$, and using known bounds on the tails of the

hypergeometric distribution and our assumption on v ($v \notin U_0$ and therefore $B_{i(v)}$ is large), we can get

$$\Pr\left[\frac{s_{i(v)}}{|B_{i(v)}|} \geq \frac{t}{2n}\right] \geq \frac{3}{4}.$$

Consider the sum $\sum_{i=1}^{t} s_i 2^i$. We have

$$\begin{aligned}\mathrm{Exp}\left[\sum_i |S_i|2^i\right] &= \sum_i \frac{|B_i|}{n} \cdot t \cdot 2^i \\ &= \frac{t}{n} \cdot \sum_i |B_i|2^i \\ &\leq \frac{t}{n} \cdot \sum_i \sum_{v \in B_i} (2\deg(v)) \quad \leq \quad \frac{4 \cdot t \cdot m}{n}.\end{aligned}$$

By Markov's inequality, the probability that $\sum_i |S_i|2^i > \frac{16tm}{n}$ is less than $1/4$. It thus follows that

$$\Pr\left[\left(\frac{s_{i(v)}}{|B_{i(v)}|} \geq \frac{t}{2n}\right) \& \left(\sum_i s_i 2^i \leq \frac{16tm}{n}\right)\right] \geq \frac{1}{2}. \tag{20}$$

Consider only such vectors $(s_1, \ldots, s_t)$. From (19) we obtain

$$\Pr[C_v] \geq \frac{1}{2} \cdot \frac{t}{2n} \cdot \frac{\deg(v)}{\frac{16tm}{n}} = \frac{\deg(v)}{64m}. \tag{21}$$

Finally, for an edge $e \in E(G)$, let us denote by C_e the event that e is selected in the fourth step of the procedure Sample-Edges-Almost-Uniformly-in-G. Let $E(U_0)$ denote the set of edges between pairs of vertices in U_0, that is, $E(U_0) = \{(u,v) \in E(G) : u, v \in U_0\}$. By definition of U_0, $|U_0| \leq \sqrt{\delta n}/2$, and hence $|E(U_0)| \leq (\delta n)/4$. Therefore, for all but at most $(\delta n)/4 \leq \delta m/4$ of the edges in $E(G)$, at least one of their endpoints is *not* in U_0. (Note that here we have used the assumption that $m \geq n$.) For each such edge (u,v) where $u \notin U_0$ (or $v \notin U_0$), we have

$$\Pr[C_e] \geq \Pr[C_u] \cdot \frac{1}{\deg(u)} \geq \frac{\deg(u)}{64m} \cdot \frac{1}{\deg(u)} = \frac{1}{64m}. \tag{22}$$

□

4.3.2. Sampling vertices in G'. We now return to selecting vertices in G'. As discussed earlier, we can easily obtain an estimate of $|V_\ell(G')|/n' = |V_\ell(G)|/n'$, denoted $\hat{\mu} = \hat{\mu}(G')$, such that if $|V_\ell(G')|/n' \geq \delta/2$, then $(1/8)|V_\ell(G')|/n' \leq \hat{\mu}(G') \leq 2(|V_\ell(G')|/n')$, and hence we assume that we indeed have such an estimate.

Proof of item 4 *in Theorem* 5. We now show that the procedure Sample-Vertices-Almost-Uniformly-in-G' (see Figure 6) is as required in item 4 of Theorem 5. Consider first the vertices in $V_\ell(G')$. If $|V_\ell(G')|/n' \geq \delta/2$, then for each vertex $x \in V_\ell(G')$, the probability that we select x is $\hat{\mu}(G')$, times the probability that the sample contains a vertex in $V_\ell(G')$, times $1/|V_\ell(G')|$. Since $\hat{\gamma} = \Omega(|V_\ell(G')/n')$ and the sample contains a vertex from $V_\ell(G)$ with constant probability, the probability that we select x is $\Omega(1/n')$ as required. If $|V_\ell(G')|/n' < \delta/2$, then the probability that we obtain any vertex in $V_\ell(G')$ may be very small, but we are allowed to have $\delta n'$ such vertices and we shall account for these at most $(\delta/2)n'$ vertices.

Sample-Vertices-Almost-Uniformly-in-$G'(d, \delta, \hat{\mu})$

1. Flip a coin with bias $\hat{\mu}$.
2. If the outcome is "heads," then do (select a vertex in $V_\ell(G')$):
   (a) Uniformly select $\Theta(1/\delta)$ vertices in G and query their degrees.
   (b) If some vertex in the sample belongs to $V_\ell(G)$, then let v be the first such vertex and output the single vertex $x \in V(H(v))$. Otherwise, pick an arbitrary vertex v in the sample and output an arbitrary vertex $x \in V(H(v))$.
3. Else (the outcome is "tails"), do (select a vertex in $V_h(G')$):
   (a) If $d > \sqrt{\delta n}$, then sample an edge $e \in E(G)$ by running the procedure Sample-Edges-Uniformly-in-G. In case the procedure fails, pick an arbitrary edge e in $E(G)$.
   (b) Else ($d \leq \sqrt{\delta n}$), sample an edge $e \in E(G)$ by running the procedure Sample-Edges-Almost-Uniformly-in-$G(\delta/2)$.
   (c) Choose with equal probability one of the endpoints v of the edge e.
   (d) Choose uniformly at random one of the vertices x in $V(H(v))$.

FIG. 6. *A procedure for selecting a vertex in G' so that all but at most a δ-fraction of the vertices are selected with probability $\Omega(1/n')$.*

We now turn to the vertices in $V_h(G')$. For an edge $e \in E(G)$, let C_e denote the event that e is selected by Sample-Edges-Uniformly-in-G in case $d > \sqrt{\delta n}$, or by Sample-Edges-Almost-Uniformly-in-G in case $d \leq \sqrt{\delta n}$. For $v \in V(G)$ let C_v denote the event that v is selected in step 3(c) of procedure Sample-Vertices-Almost-Uniformly-in-G'. For $x \in V(G')$ let C_x denote the event that x is selected in step 3(d) of the procedure, and let $v(x)$ be such that $x \in H(v(x))$. Recall that for every $v \in V_h(G)$, we have $|V(H(v))| = 2\lceil \deg(v)/d \rceil$. Therefore, for every $x \in V_h(G')$,

$$\Pr[C_x] \geq \Pr[C_{v(x)}] \cdot \frac{1}{2\lceil \deg(v(x))/d \rceil} = \sum_{e=(u,v(x))} \frac{1}{2} \Pr[C_e] \cdot \frac{1}{2\lceil \deg(v(x))/d \rceil}. \tag{23}$$

If $d > \sqrt{\delta n}$, then $\Pr[C_e]$ is only slightly smaller than $1/m$ (since there is a probability that the procedure Sample-Edges-Uniformly-in-G fails to output an edge), implying that $\Pr[C_x] = \Omega(1/n')$. If $d \leq \sqrt{\delta n}$, then $\Pr[C_e]$ is determined by the procedure Sample-Edges-Almost-Uniformly-in-G. Let U_0 be as defined in Lemma 6, and consider first the case where $v(x) \notin U_0$. Then for every edge e that is incident to $v(x)$, we have that $\Pr[C_e] \geq 1/(64m) = 1/(32dn)$. By (23), for each such vertex x we have that

$$\Pr[C_x] \geq \frac{1}{2}\deg(v(x)) \cdot \frac{1}{32dn} \cdot \frac{1}{2\lceil \deg(v(x))/d \rceil} \geq \frac{1}{256n} \geq \frac{1}{256n'} \tag{24}$$

as required. Next consider the case that $v(x) \in U_0$ but $\deg(v(x)) \geq 2|U_0|$. In such a case for at least half of the edges e incident to $v(x)$ we have that $\Pr[C_e] \geq 1/(32dn)$, and we can deduce that $\Pr[C_x] \geq \frac{1}{512n'}$. It remains to show that the total number of vertices x such that $v(x) \in U_0$ and $\deg(v) \leq 2|U_0|$ is at most $(\delta/2)n'$. Using the fact that $|U_0| \leq \sqrt{(\delta/2)n}/2$ (recall that the procedure Sample-Edges-Almost-Uniformly-in-G is called with its input parameter set to $\delta/2$), and for every vertex $v \in V_h(G)$, $|V(H(v))| = 2\lceil \deg(v)/d \rceil \leq 2\deg(v)$, we get

$$\sum_{v \in U_0:\ \deg(v) \leq 2|U_0|} |V(H(v))| \leq 4|U_0|^2 \leq (\delta/2)n'. \tag{25}$$

The lemma follows.

4.4. A probabilistic construction of G'. In this subsection we describe an alternative, probabilistic construction of a graph G' that establishes Theorem 5. More precisely, we describe such a construction that, under certain conditions on d and ϵ, results, with very high probability, in a graph G' as required in the theorem. Here too the graph is constructed as the algorithm proceeds. In all that follows, let $d = d_{\text{avg}}(G)$, and let $d' = d_{\max}(G')$. Let n (n') be the number of vertices in G (G'), and m (m') be the number of edges in G (G'). The probabilistic construction is simpler, and it is possible that it may be applicable to other problems as well. However, in this construction we need that $d = \Omega(\log n + 1/\epsilon)$.

4.4.1. The construction. As in the deterministic construction, every vertex of G is transformed into $\lceil \deg(v)/d \rceil$ vertices. Denote by $X(v)$ the vertices in G' related to a vertex $v \in V(G)$. The vertices in $X(v)$ are denoted by $X_i(v), 1 \le i \le \lceil \deg(v)/d \rceil$. Thus, $n' = |V(G')| \le \sum_{v \in G} \lceil \frac{\deg(v)}{d} \rceil \le 2n$. The edges of G' are determined as follows: an edge $(u, v) \in E(G)$ chooses independently uniformly at random a vertex from $X(v)$ and a vertex from $X(u)$. In G' there will be an edge between these two randomly chosen vertices. Clearly, $m' = |E(G')| = |E(G)| = (nd)/2$.

LEMMA 7. *For $d = \Omega(\log n)$, the maximum degree d' of G' constructed above is $2d$ with probability $1 - o(1)$.*

Proof. Let $W_v^{i,j}$ be an indicator random variable which is 1 if the jth induced edge of $v \in V(G)$ ($1 \le j \le \deg(v)$) chooses vertex $X_i(v) \in V(G')$. Let $W_v^i \stackrel{\text{def}}{=} \sum_{1 \le j \le \deg(v)} W_v^{i,j}$. W_v^i is a sum of j independent indicator variables. $\text{Exp}[W_v^i] = \deg(v) \cdot 1/(\deg(v)/d) = d$. Let X_v^i be an indicator variable which is 1 if $W_v^i > 2\text{Exp}[W_v^i] = 2d$ and 0 otherwise.

Using standard bounds on tails of sums of bounded random variables (see, e.g., [5]) for a specific $v \in V(G)$ and $1 \le i \le \lceil \deg(v)/d \rceil$, it follows that $\Pr[X_v^i = 1] < e^{-cd}$. Using a union bound over all X_v^i's, $v \in V(G)$ and $1 \le i \le \lceil \deg(v)/d \rceil$, we get that the probability that there exist a vertex v and an index i for which $X_v^i = 1$ is at most $n' \cdot e^{-cd} = o(1)$; thus with probability $1 - o(1)$, the maximum degree of G' constructed above is $2d$. ∎

LEMMA 8. *For a graph G with $d > 512/\epsilon$ the following holds: If G is ϵ-far from being bipartite (with respect to $m = (dn)/2$), then with probability $1 - o(1)$, G' is ϵ'-far from being bipartite with respect to $d'n'$ for $\epsilon' = \frac{\epsilon}{128}$.*

Proof. Consider a fixed partition $P' = (V_0', V_1')$ of the vertices in G'. The partition P' induces a partition of $X(v)$ for every v. Let us denote by $X^\alpha(v)$ the majority subset of $X(v)$ induced by P'. Consider a partition $P = (V_0, V_1)$ of the vertices of G induced by P' in the following way. For $v \in V(G)$, if $X^\alpha(v) \subset V_0'$, then $v \in V_0$; otherwise $v \in V_1$. Since G is ϵ-far from being bipartite, at least one of the subsets V_0, V_1 contains $\frac{1}{4}\epsilon nd$ edges. Without loss of generality, assume that $|E(V_0)| \ge \frac{1}{4}\epsilon nd$. Let H' be a subgraph of G', defined as follows. The vertices of H' are

$$\bigcup_{v \in V_0} X^\alpha(v).$$

The edges of H' are the edges of G', induced by $V(H')$. Thus, $V(H') \subset V_0'$ and $E(H') \subset E(V_0')$.

CLAIM 2. $\Pr[|E(H')| \le (\epsilon/32)nd] < 2^{-c \cdot n}$, *where $c > 1$.*

Once Claim 2 is proved, by taking a union bound over all possible partitions P' of the vertices of G' we get that for *every* partition $P' = (V_0', V_1')$ of the vertices of G',

the number of violating edges in G' is at least $\epsilon/32 \cdot n \cdot d$ with probability $1 - o(1)$. Recall that $n' \leq 2n$ and $d' \leq 2d$ with probability $1 - o(1)$. Thus, for *every* partition of the vertices of G', the number of violating edges is at least $\epsilon/128 \cdot n' \cdot d'$ with probability $1 - o(1)$, as required.

Proof of Claim 2. Consider an edge $e = (u, v) \in E(G)$, and let $\phi(e) = (X_i(v), X_j(u))$ be its corresponding edge in $E(G')$. For $e \in E(V_0)$, $\Pr[\phi(e) \in E(H')] \geq 1/2 \cdot 1/2 = 1/4$. Thus,

$$\mathrm{Exp}[|E(H')|] \geq 1/4|E(V_0)|.$$

As $|E(H')|$ is a sum of $|E(V_0)|$ independent Bernoulli random variables, each with expectation at least $1/4$, it follows from standard bounds on the tails of binomial random variables (see, e.g., [5]) that

$$\Pr[X_{|E(V_0)|} < (1/32)\epsilon nd] < e^{-\epsilon nd/512}.$$

Thus, for $d \geq 512/\epsilon$ we have

$$\Pr[|E(H')| \leq \epsilon/32nd] < 2^{-cn}$$

for $c > 1$, and the lemma is proved. □

We have completed proving the first two items of Theorem 5, with regard to the probabilistic construction.

4.4.2. Proving item 3 in Theorem 5. In order to prove this item we need to explain how to emulate queries in G' by performing queries in G.

Degree queries. Here we assume that in G' the maximum degree is $2d$. It was proved before to be true with probability $1 - o(1)$. Consider the following procedure Assign-Edges(v), where v is a vertex of G: Find $\deg(v)$ by one query on G; for each edge-index $r \in \{1, \ldots, \deg(v)\}$, choose one of the vertices $X_i(v) \in X(v)$ ($1 \leq i \leq \lceil \deg(v)/d \rceil$) uniformly at random. Denote by $Q_i(v)$ a vector of $2d$ cells. This vector contains the indices of edges that are assigned to $X_i(v)$. Finally, choose an empty cell t in the vector $Q_i(v)$, and set $Q_i(v)[t] := r$. This procedure corresponds to the random construction of G'.

Neighbor queries. For each vertex $X_i(v)$, the algorithm keeps a vector (of length $2d$), $W_i(v)$ that contains an ordered list of all the vertices of G' such that the algorithm is committed to the existence of an edge between them and $X_i(v)$. That is, if $W_i(v)[t] = X_j(u)$, it means that there is an edge $(X_i(v), X_j(u))$ in G'. In this case $W_j(u)[t'] = X_i(v)$ for some t', $1 \leq t' \leq 2d$. Note that the procedure Assign-Edges(v) assigns each of the edges of v independently to one of the vertices $X_i(v)$, $1 \leq i \leq \lceil \deg(v)/d \rceil$.

Suppose that the algorithm is located in $X_i(v)$ and it wishes to perform a neighbor query. Choose uniformly at random a number k, $1 \leq k \leq 2d$. Take an empty vector $Q_i(v)$ of length $2d$ and copy into it the vector $W_i(v)$. By that the algorithm keeps its commitment about the edges which have already been exposed. Then, apply the Assign-Edges(v) procedure only for edges of v that do not appear in one of the $W_i(v)$, $1 \leq i \leq \lceil \deg(v)/d \rceil$ (i.e., to edges which were not exposed yet by the algorithm). If $Q_i(v)[k]$ is empty, then the walk remains at $X_i(v)$. If $Q_i(v)[k]$ contains a name of a vertex in G', the walk moves to that vertex; otherwise, $Q_i(v)[k]$ contains an index of a neighbor of v in G. By performing a single neighbor query on G, the algorithm determines the name of that neighbor (say) u in G. Then the walk needs to move to one of the vertices $X_j(u)$, $1 \leq j \leq \deg(u)/d$. It chooses one of the vertices $X_j(u)$

uniformly at random. For the chosen j set $W_i(v)[k] := X_j(u)$. Now choose a free cell k', $1 \le k' \le 2d$, in $W_j(v)$, and set $W_j(v)[k'] := X_i(v)$. The walk is now at $X_j(u)$.

Modifying the procedure Odd-Cycle. The procedure is modified in a similar manner to that described for the deterministic construction. In particular, random walks are emulated as described above. In the last stage, when vertex-pair queries are performed, we do the following. In order to answer a vertex-pair query $(X_i(v), X_j(u))$ in G', perform a vertex-pair query (u, v) in G. If there is no edge between (u, v) in G, answer that there is no edge between $X_i(u)$ and $X_j(v)$. Otherwise, as explained for the deterministic case, an odd cycle is detected in G.

4.4.3. Establishing item 4 in Theorem 5. In this subsection we prove the last item in Theorem 5 (for the probabilistic construction). The proof is essentially a simplified version of the proof for the deterministic case, but for the sake of completeness we include the details.

Recall that we are interested in a procedure for selecting a vertex in G' such that there is sufficiently high probability of hitting any fixed sufficiently large subset of vertices in G' (and, in particular, of hitting the subset of vertices s for which Odd-Cycle(s) returns found with probability at least 2/3 (in the case G' is far from being bipartite)).

Sample-Vertices-Almost-Uniformly-in-$G'(d, \delta)$

1. If $d > \sqrt{\delta n}$, then sample an edge $e \in E(G)$ by running the procedure Sample-Edges-Uniformly-in-G. In case the procedure fails, pick an arbitrary edge e in $E(G)$.
2. Else ($d \le \sqrt{\delta n}$), sample an edge $e \in E(G)$ by running the procedure Sample-Edges-Almost-Uniformly-in-$G(\delta/2)$.
3. Choose with equal probability one of the endpoints v of the edge e.
4. Choose uniformly at random one of the vertices x in $X(v)$.

FIG. 7. *A procedure for selecting a vertex in G' so that all but at most a δ-fraction of the vertices are selected with probability $\Omega(1/n')$.*

We now show that the procedure Sample-Vertices-Almost-Uniformly-in-G' (see Figure 7) is as required in item 4 of Theorem 5.

For an edge $e \in E(G)$, let C_e denote the event that e is selected by Sample-Edges-Uniformly-in-G in case $d > \sqrt{\delta n}$, or by Sample-Edges-Almost-Uniformly-in-G in case $d \le \sqrt{\delta n}$. For $v \in V(G)$ let C_v denote the event that v is selected in step 3 of procedure Sample-Vertices-Almost-Uniformly-in-G'. For $x \in V(G')$ let C_x denote the event that x is selected in step 4 of the procedure, and let $v(x)$ be such that $x \in X(x(v))$. Recall that $|X(v)| = \lceil \deg(v)/d \rceil$. Therefore, for every $x \in V(G')$,

$$\Pr[C_x] \;\ge\; \Pr[C_{v(x)}] \cdot \frac{1}{\lceil \deg(v(x))/d \rceil} \;=\; \sum_{e=(u,v(x))} \frac{1}{2} \Pr[C_e] \cdot \frac{1}{\lceil \deg(v(x))/d \rceil}. \tag{26}$$

If $d > \sqrt{\delta n}$, then $\Pr[C_e]$ is only slightly smaller than $1/m$ (since there is a probability that the procedure Sample-Edges-Uniformly-in-G fails to output an edge), implying that $\Pr[C_x] = \Omega(1/n')$. If $d \le \sqrt{\delta n}$, then $\Pr[C_e]$ is determined by the procedure Sample-Edges-Almost-Uniformly-in-G. Let U_0 be as defined in Lemma 6, and consider first the case where $v(x) \notin U_0$. Then for every edge e that is incident to $v(x)$, we have that $\Pr[C_e] \ge 1/(64m) = 1/(32dn)$. By (26), for each such vertex x we have that

$$\Pr[C_x] \geq \frac{1}{2}\deg(v(x)) \cdot \frac{1}{32dn} \cdot \frac{1}{\lceil \deg(v(x))/d \rceil} \geq \frac{1}{128n} \geq \frac{1}{128n'} \tag{27}$$

as required. Next consider the case that $v(x) \in U_0$ but $\deg(v(x)) \geq 2|U_0|$. In such a case for at least half of the edges e incident to $v(x)$ we have that $\Pr[C_e] \geq 1/(32dn)$, and we can deduce that $\Pr[C_x] \geq \frac{1}{256n'}$. It remains to show that the total number of vertices x such that $v(x) \in U_0$ and $\deg(v) \leq 2|U_0|$ is at most $(\delta/2)n'$. Using the fact that $|U_0| \leq \sqrt{(\delta/2)n}/2$ (recall that the procedure Sample-Edges-Almost-Uniformly-in-G is called with its input parameter set to $\delta/2$), and for every vertex $v \in V(G)$, $|X(v)| = \lceil \deg(v)/d \rceil \leq \deg(v)$, we get

$$\sum_{v \in U_0:\ \deg(v) \leq 2|U_0|} |X(v)| \ \leq \ 2|U_0|^2 \ \leq \ (\delta/2)n'. \tag{28}$$

Thus, item 4 of Theorem 5 follows.

5. A lower bound. In this section we present a lower bound on the number of queries necessary for testing bipartiteness. Similarly to the lower bound presented in [14], this lower bound holds for testing algorithms that are allowed a two-sided error, and the graphs used for the lower bound construction are regular graphs. However, the lower bound of $\Omega(\sqrt{n})$ (for constant ϵ) established in [14] holds for graphs having constant degree (e.g., degree 3), and when the algorithm is allowed only neighbor queries. Our lower bound is more general in that it allows the algorithm to perform both neighbor queries and vertex-pair queries, and it is applicable to all degrees. Indeed, the two families of graphs that we define below in our lower bound construction can be viewed as generalizing the two families presented in [14]. However, since we have to deal with any given degree d and not only with $d = 3$, and since we have to deal with both types of queries, the analysis itself does not follow as a straightforward generalization of the analysis in [14].

THEOREM 8. *Every algorithm for testing bipartiteness with distance parameter* $\epsilon \leq 2^{-4}$ *must perform* $\Omega(\min(\sqrt{n}, n^2/m))$ *queries.*

The high level structure of our proof is similar to other lower-bound proofs for testing, which can be traced back to [22]. Specifically, we present two distributions over graphs (which are defined in detail below): $\mathcal{G}(n,d)$ and $\mathcal{G}(n/2, n/2, d)$, where d is the degree of the vertices in the graphs. (For simplicity we assume that n is even.) We prove that graphs created randomly according to $\mathcal{G}(n,d)$ are ϵ-far from being bipartite with high probability, while all graphs in the support of $\mathcal{G}(n/2, n/2, d)$ are bipartite. We then show that a bipartite tester that asks $o(\min(\sqrt{n}, n^2/m))$ queries cannot distinguish with sufficiently high probability whether a graph is created according to the distribution $\mathcal{G}(n,d)$ or $\mathcal{G}(n/2, n/2, d)$. Note that by definition, in both cases $m = (nd)/2$, and so $n^2/m = 2n/d$.

The graph distribution $\mathcal{G}(n,d)$. A graph G in the support of the distribution $\mathcal{G}(n,d)$ is composed of n vertices, and it is a d-regular graph. The edges of G are determined according to the following random process. Consider a two-dimensional table of size $n \times d$, which we refer to as the *matching table*. Each cell in the matching table is denoted by $c_{u,i}$, where u denotes the row in which the cell is located (and corresponds to a vertex in the graph) and i denotes the column in which the cell is located (and corresponds to a label of an edge incident to v).

Consider a perfect matching over the cells of the table, randomly chosen over all possible perfect matchings. This randomly chosen matching defines the edges of the graph G. That is, if the cells $c_{u,i}$ and $c_{v,j}$ are matched, then this means that there is an edge (u, v, i, j) in the graph.

The graph distribution $\mathcal{G}(n/2, n/2, d)$. A graph G in the support of the distribution $\mathcal{G}(n/2, n/2, d)$ is a bipartite d-regular graph composed of n vertices, where each side of the partition is of size $n/2$. The edges of G are determined according to the following random process. First, we select a random partition of the graph vertices $\{1, \ldots, n\}$ into two parts (sides), each of size $n/2$. Second, consider two tables, each of size $n/2 \times d$, where each is attached to one of the partition sides. The rows in each table refer to the vertices that belong to the relevant side of the partition. Let us refer to the table attached to the first side of the partition as the *even table* and to the table attached to the second side of the partition as the *odd table*.

A cell in these tables is denoted by $c_{b,u,i}$, where $b \in \{1, 2\}$ denotes the relevant table, u denotes the row in which the cell is located, and i denotes the column in which the cell is located.

Now, consider a perfect matching over the cells of the two tables, randomly chosen over all possible perfect matchings that are restricted to matching cells from the odd table with cells from the even table. This randomly chosen matching defines the edges of the graph G. That is, if the cell $c_{1,u,i}$ is matched to the cell $c_{2,v,j}$, this means that there is an edge (u, v, i, j) in the graph (where u belongs to one side of the bipartite graph and v to the other side).

By definition, all graphs in the support of $\mathcal{G}(n/2, n/2, d)$ are bipartite. We can show that almost all graphs in the support of $\mathcal{G}(n, d)$ are far from being bipartite.

LEMMA 9. *With probability* $1 - o(1)$*, a graph chosen uniformly according to the distribution* $\mathcal{G}(n, d)$ *is* ϵ*-far from being bipartite for every* $\epsilon \leq 1/16$ *and* $d \geq 64$.

Proof. We shall show that for every fixed partition (V_0, V_1) of V, the probability, taken over the selection of a graph in $\mathcal{G}(n, d)$, that there are more than $\epsilon \cdot n \cdot d$ violating edges with respect to (V_0, V_1), is very close to one. The lemma will then follow by a union bound (over all partitions).

Let $P = (V_0, V_1)$ be an arbitrary fixed partition of V. Without loss of generality, let $|V_0| \geq n/2$. Consider the following process, denoted by C_P, for choosing a random d-regular graph having n vertices (i.e., a perfect matching over a matching table of size $n \times d$). Starting from $b = 0$, choose an arbitrary cell $c_{u,i}$ such that $u \in V_b$, and match $c_{u,i}$ to a randomly chosen unmatched cell $c_{v,j}$. If the number of unmatched cells that belong to vertices in V_b is smaller than the number of unmatched cells that belong to the other side of the partition, then switch sides (i.e., let $b \leftarrow 1 - b$). Finish when all the cells are matched. Thus, the number of steps in this process is $\frac{nd}{2} - 1$. (In the last step there are two unmatched cells, which are matched together.) We denote by G_P the graph chosen according to process C_P.

CLAIM 3. *For every fixed partition* P*, the distribution on graphs induced by the process* C_P *is identical to* $\mathcal{G}(n, d)$.

Proof. For each step t in the process C_P, $1 \leq t \leq \frac{nd}{2} - 1$, let e_t be the edge selected in that step. Let R_0 be the set of all graphs in the support of $\mathcal{G}(n, d)$, and denote by $R_t \subset R_0$ the set of graphs in R_0 that contain the edges $e_1, \ldots, e_t$. Using this notation, at the start of process C_P, before any edge is selected (any two cells are matched), the process can potentially select any graph in R_0. After performing t steps, it is restricted to selecting graphs from R_t.

The probability that a particular graph G in the support of $\mathcal{G}(n, d)$ is selected is

$$\Pr[G_P = G] \;=\; \Pr[G \in R_1] \cdot \Pr[G \in R_2 | G \in R_1] \cdot \;\cdots\; \cdot \Pr[G \in R_{\frac{nd}{2}-1} | G \in R_{\frac{nd}{2}-2}].$$

Consider any particular term $\Pr[G \in R_t | G \in R_{t-1}]$ in the above expression. Conditioned on G belonging to R_{t-1} (that is, the edges $e_1, \ldots, e_{t-1}$ selected by the

process C_P are all edges in G), we would like to know what the probability is that G belongs to R_t as well. Let $c_{u,i}$ be the arbitrary unmatched cell selected by C_P in step t. Let v be the ith neighbor of u in G, where u is the jth neighbor of v. Since $G \in R_{t-1}$, necessarily $c_{v,j}$ is an unmatched cell in the matching table. Hence, the probability that G belongs to R_t (conditioned on it belonging to R_{t-1}) equals the probability that $c_{u,i}$ is matched to $c_{v,j}$, which is $1/(dn - 2(t-1) - 1)$. Therefore,

$$\begin{aligned}\Pr[G_P = G] &= \frac{1}{dn-1} \cdot \frac{1}{dn-3} \cdot \cdots \cdot \frac{1}{3} \;=\; \frac{dn \cdot (dn-2) \cdot \cdots \cdot 2}{(dn)!} \\ &= \frac{(2(dn/2)) \cdot (2((dn/2)-1)) \cdot \cdots \cdot 2}{(dn)!} \;=\; \frac{2^{dn/2} \cdot (dn/2)!}{(dn)!}. \end{aligned} \tag{29}$$

It remains to show that the above expression equals $1/|R_0|$. But this is easy to verify. By definition, $|R_0|$ is the total number of possible perfect matchings between the dn cells in the matching table. Each such matching can be obtained by ordering all the cells and letting the matching be defined by successive pairs. The number of such orderings is $(dn)!$. However, different orderings may produce the same matching. In particular, we need to take into account the overcounting due to orderings within the pairs (i.e., the pairs $(c_{v,i}, c_{u,j})$ and $(c_{u,j}, c_{v,i})$ are the same) and the overcounting due to orderings between the different pairs. In other words, we need to divide $(dn)!$ by $2^{dn/2} \cdot (dn/2)!$. We have thus obtained the inverse of the expression in (29), as required. □

We have thus completed proving the claim and may view a graph G selected uniformly from $\mathcal{G}(n,d)$, as if it is created according to the process C_P, for any fixed partition P. It remains to show that with very high probability over the choice of such a graph, it has more than $\epsilon \cdot nd$ violating edges with respect to the partition P.

By definition, during the process C_P, we always try to match a cell that belongs to a side of the partition having more unmatched cells. Thus, at each step we create a violating edge with probability at least $\frac{1}{3}$ (except the last stage), independent of the past events. It follows that the expected number of violating edges in the final resulting graph G, with respect to a particular partition P, is $\mu \geq (nd/2 - 1) \cdot \frac{1}{3} > \frac{nd}{8}$. Let Y_P denote the number of violating edges with respect to P. By applying the Chernoff bound we have that for any constant $0 < \alpha < 1$,

$$\Pr[Y_P < (1-\alpha)\mu] < \exp(-(1/2)\alpha^2\mu).$$

In particular, for $\alpha = 1 - 8\epsilon$ (recall that $\epsilon \leq 1/16$) we obtain

$$\begin{aligned}\Pr[Y_P < \epsilon nd] &\leq \Pr[Y_P < 8\epsilon\mu] \\ &< \exp(-(1/2)(1-8\epsilon)^2\mu) \\ &\leq \exp(-(1-8\epsilon)^2 nd/16).\end{aligned}$$

Since the total number of partitions is 2^n, if we take a union bound over all possible partitions, then we can deduce that the probability that G has less than ϵnd violating edges with respect to *any* partition P is bounded from above by $2^n \cdot \exp(-(1-8\epsilon)^2 nd/16)$. Taking $\epsilon \leq 1/16$ and $d \geq 64$, we get that a graph constructed according to a distribution $\mathcal{G}(n,d)$ is ϵ-far from being bipartite with probability $1 - o(1)$ as required. □

Let ALG be an algorithm for testing bipartiteness using $Q = Q(n)$ queries. Namely, ALG is a (possibly probabilistic) mapping from *query-answer histories*

$\langle (q_1, a_1), \cdot, (q_t, a_t) \rangle$ to q_{t+1} for every $t < Q$, and to $\{\mathsf{accept}, \mathsf{reject}\}$ for $t = Q$. Recall that a query q_t can be of two types: a neighbor query and a vertex-pair query. A neighbor query q_t is a pair (u_t, i_t), where $u_t \in V$ and $i_t \in \{1, \ldots, \deg(u_t)\}$. Here the corresponding answer a_t is a pair (v_t, j_t), where $v_t \in V$ and $j_t \in \{1, \ldots, \deg(v_t)\}$ such that v_t is the i_tth neighbor of u_t and u_t is the j_tth neighbor of v_t. A vertex-pair query q_t is a pair (u_t, v_t), where $u_t, v_t \in V$, and the corresponding answer is of the form $a_t = (y_t, i_t, j_t)$. If there is an edge between u_t and v_t, then $y_t = 1$, and i_t and j_t are the corresponding labels of the edge. If no such edge exists, then $y_t = 0$, and i_t and j_t are set arbitrarily, say, to 1. In the former case we shall say that ALG has *detected an edge* (by a vertex-pair query). In the latter case we shall say that (u_t, v_t) is a *nonedge* (and that ALG has detected a nonedge).[5] Note that the answers to the queries of ALG contain additional indexing information that does not appear in our model. We show that even by using the extra information, ALG cannot do better than the stated lower bound.

We assume that the mapping determined by the algorithm is defined only on histories that are consistent with some n-vertex graph. Any query-answer history of length t can be used to define a *knowledge graph* G_t at time t. The vertex set of G_t contains all vertices that appear in the history (either in queries or in answers). For every neighbor query $(u_{t'}, i_{t'})$ answered by $(v_{t'}, j_{t'})$ $(t' \leq t)$, the graph G_t contains the edge $(u_{t'}, v_{t'}, i_{t'}, j_{t'})$, and similarly for every vertex-pair query $(v_{t'}, u_{t'})$ that is answered by $(1, i_{t'}, j_{t'})$. In addition, for every vertex-pair query $(v_{t'}, u_{t'})$ that is answered by $(0, 1, 1)$, the knowledge graph maintains the information that $(v_{t'}, u_{t'})$ is a nonedge. Thus G_t is a subgraph of the graph tested by ALG.

In what follows we describe two random processes, P^1 and P^2, which interact with an arbitrary algorithm ALG. The process P^1 answers ALG's queries while constructing a random graph from $\mathcal{G}(n, d)$, and the process P^2 answers ALG's queries while constructing a random graph from $\mathcal{G}(n/2, n/2, d)$. We assume without loss of generality that ALG does not ask queries whose answer can be derived from its knowledge graph, since such queries give it no new information. (For example, ALG does not ask a vertex-pair query about a pair of vertices which are already known to be connected by an edge due to a neighbor query.)

For a fixed algorithm ALG that uses Q queries, and for $b \in \{1, 2\}$, let D^b_{ALG} denote the distribution on query-answer histories (of length Q) induced by the interaction of ALG and P^b. We show that for any given ALG that uses $o(\min(\sqrt{n}, n/d))$ queries, the statistical distance between D^1_{ALG} and D^2_{ALG} is $o(1)$. Combining this with Lemma 9 (and the fact that $m = (nd)/2$), Theorem 8 follows.

Definition of P^b, $b \in 1, 2$.

- Let R^1 be the set of all graphs in the support of $\mathcal{G}(n, d)$, and let R^2 be the set of all graphs in the support of $\mathcal{G}(n/2, n/2, d)$.
  For an edge $e_k = (u, v, i, j)$, denote by $R^b_{e_k} \subset R^b$ the subset of graphs in R^b that contain e_k. We may refer to $R^b_{e_k}$ as $R^b_{(u,v,i,j)}$.
  For an edge-pair $f_k = (u, v)$, denote by $R^b_{f_k} \subset R^b$ the subset of graphs in R^b that contain an edge between the vertices u, v. Denote by $R^b_{\overline{f_k}} \subset R^b$ the subset of graphs in R^b that do not contain an edge between the vertices u, v.
- The process P^b answers queries as follows. Initialize $R^b_0 = R^b$ (in general, as is explained in more detail below, for any $t \geq 0$, the set R^b_t consists of all graphs in R^b that are consistent with the first t queries and answers).

[5] In case multiple edges are allowed, then the answer is of the form (y_t, I_t, J_t), where I_t and J_t are sets of labels.

1. If the tth query is a vertex-pair query $q_t = (u_t, v_t)$, then the answer $a_t = (y_t, i_t, j_t)$ is selected as follows. Let $y_t = 1$ with probability $|R^b_{(u_t,v_t)} \cap R^b_{t-1}|/|R^b_{t-1}|$, and let $y_t = 0$ with probability $1 - |R^b_{(u_t,v_t)} \cap R^b_{t-1}|/|R^b_{t-1}|$. In the former case, for any pair $i, j \in \{1, \ldots, d\}$, the probability that $i_t = i$ and $j_t = j$ is $|R^b_{(u_t,v_t,i,j)} \cap R^b_{t-1}|/|R^b_{t-1}|$, and we set $R^b_t = R^b_{(u_t,v_t,i,j)} \cap R^b_{t-1}$. In the latter case, the values of i_t and j_t can be selected arbitrarily (say, to 1), and we set $R^b_t = R^b_{\overline{(v_t,u_t)}} \cap R^b_{t-1}$.
2. If the tth query is a neighbor query $q_t = (u_t, i_t)$, then for each $v \in V$, $j \in \{1, \ldots, d\}$, answer $a_t = (v, j)$ with probability $|R^b_{(u_t,v,i_t,j)} \cap R^b_{t-1}|/|R^b_{t-1}|$, and set $R^b_t = R^b_{(u_t,v_t,i,j)} \cap R^b_{t-1}$.

- After all queries are answered (that is, after Q queries), uniformly choose a random graph G from R^b_Q. This is the graph constructed by P^b, $b \in 1, 2$.

LEMMA 10. *For every algorithm* ALG*, the process P^1, when interacting with* ALG*, uniformly generates graphs in $\mathcal{G}(n, d)$, and the process P^2, when interacting with* ALG*, uniformly generates graphs in $\mathcal{G}(n/2, n/2, d)$.*

Proof. Consider a specific graph $G \in R^b_0$. Recall that $R^1_0 = \mathcal{G}(n, d)$, and $R^2_0 = \mathcal{G}(n/2, n/2, d)$.

The probability that G is generated by P^b, $b \in 1, 2$, is

$$\Pr[G \in R^b_1] \cdot \Pr[G \in R^b_2 | G \in R^b_1] \cdot \cdots \cdot \Pr[G \in R^b_Q | G \in R^b_{Q-1}] \cdot \frac{1}{|R^b_Q|}$$
$$= \frac{|R^b_1|}{|R^b_0|} \cdot \frac{|R^b_2|}{|R^b_1|} \cdot \cdots \cdot \frac{|R^b_Q|}{|R^b_{Q-1}|} \cdot \frac{1}{|R^b_Q|} = \frac{1}{|R^b_0|},$$

and the lemma follows. ∎

We next want to upper-bound the probability that ALG, after performing $o(n/d)$ queries, gets a positive answer (that is, of the form $(1, *, *)$) when it performs a new vertex-pair query and interacts with either one of the two processes. We first introduce some more notation. For $b \in \{1, 2\}$ and any set of edges $B = \{e_1, \ldots, e_\ell\}$, let $R^b_B \stackrel{\text{def}}{=} R^b_{e_1} \cap \cdots \cap R^b_{e_\ell}$ (where $R^b_{e_j}$ is as defined above in the description of the processes $\{P^b\}_{b \in \{1,2\}}$). Similarly, for any set of edge-pairs $D = \{f_1, \ldots, f_h\}$, let $R^b_{\overline{D}} \stackrel{\text{def}}{=} R_{\overline{f_1}} \cap \cdots \cap R_{\overline{f_h}}$. Finally, let $R^b_{B,\overline{D}} = R^b_B \cap R^b_{\overline{D}}$. That is, $R^b_{B,\overline{D}}$ is the subset of all graphs in R^b that are consistent with a particular set of edges and a particular set of nonedges. In particular, if B and D correspond to the set of edges and nonedges, respectively, that were observed by ALG in the course of its first t queries, then $R^b_{B,\overline{D}} = R^b_t$.

LEMMA 11. *Let $B = \{e_1, \ldots, e_\ell\}$ be any set of edges, and let $D = \{f_1, \ldots, f_h\}$ be any set of edge-pairs such that no edge-pair in D appears in B and such that $|B|, |D| = o(n/d)$. Then for each $b \in \{1, 2\}$ and for every $(u, v, i, j) \notin B$ we have*

$$\frac{|R^b_{(u,v,i,j)} \cap R^b_{B,\overline{D}}|}{|R^b_{B,\overline{D}}|} \leq \frac{4}{dn}.$$

Proof. Consider first the process P^1 and recall that R^1 is the set of graphs in the support of $\mathcal{G}(n, d)$. For the sake of brevity we remove the superscript 1 for the remaining discussion (until we turn to the process P^2). For each $e_k \in B$, let $e_k = (u_k, v_k, i_k, j_k)$. For any $w \leq \ell = |B|$, the total number of possible perfect

matchings in the matching table that match c_{u_k,i_k} to c_{v_k,j_k} for $1 \le k \le w$ (that is, the number of matchings that are consistent with the edges $e_1, \ldots, e_w$) is

$$\frac{(dn-2w)!}{2^{(\frac{dn}{2}-w)}(\frac{dn}{2}-w)!}.$$

The argument required for establishing this expression is a slight extension of the one used in the proof of Lemma 9 (when determining the size of R_0). It follows that for any (u,v,i,j) such that neither $c_{u,i}$ nor $c_{v,j}$ is yet matched,

$$\frac{|R_{(u,v,i,j)} \cap R_B|}{|R_B|} = \frac{\frac{(dn-2(k+1))!}{2^{(\frac{dn}{2}-(k+1))}(\frac{dn}{2}-(k+1))!}}{\frac{(dn-2k)!}{2^{(\frac{dn}{2}-k)}(\frac{dn}{2}-k)!}} = \frac{1}{dn-2k-1}.$$

For an edge-pair (u,v) we can thus deduce that

$$\begin{aligned}\frac{|R_{(u,v)} \cap R_B|}{|R_B|} &= \frac{\left|\left(\bigcup_{1\le i,j\le d} R_{(u,v,i,j)}\right) \cap R_B\right|}{|R_B|} \\ &\le \frac{\sum_{1\le i,j\le d} |R_{(u,v,i,j)} \cap R_B|}{|R_B|} \\ &\le \frac{d^2}{dn-2k-1} = O\left(\frac{d}{n}\right). \end{aligned} \tag{30}$$

Hence we obtain that

$$\begin{aligned}\frac{|R_{B,\overline{D}}|}{|R_B|} &= \frac{\left|R_B \cap \left(\bigcap_{1\le w\le h} R_{\overline{f_w}}\right)\right|}{|R_B|} \\ &= \frac{\left|R_B \setminus \left(\bigcup_{1\le w\le h} R_{f_w}\right)\right|}{|R_B|} \\ &\ge 1 - \sum_{1\le w\le h} \frac{|R_{f_w} \cap R_B|}{|R_B|} \\ &= 1 - o\left(\frac{n}{d}\right)\cdot O\left(\frac{d}{n}\right) = 1 - o(1), \end{aligned} \tag{31}$$

and so $\frac{|R_B|}{|R_{B,\overline{D}}|} = 1 + o(1)$.

Putting the above together, we get that for every $(u,v,i,j) \notin B$

$$\begin{aligned}\frac{|R_{(u,v,i,j)} \cap R_{B,\overline{D}}|}{|R_{B,\overline{D}}|} &= \frac{|R_{(u,v,i,j)} \cap R_B|}{|R_B|} \cdot \frac{|R_{(u,v,i,j)} \cap R_{B,\overline{D}}|}{|R_{(u,v,i,j)} \cap R_B|} \cdot \frac{|R_B|}{|R_{B,\overline{D}}|} \\ &\le \frac{1}{dn-2k-1} \cdot 1 \cdot (1+o(1)) \le \frac{4}{dn}. \end{aligned} \tag{32}$$

We now turn to $P^b = P^2$ and recall that R^2 is the support of $\mathcal{G}(n/2, n/2, d)$. Also recall that in order to construct a random graph from $\mathcal{G}(n/2, n/2, d)$ we do the following: we partition the n vertices into two equal parts at random, and we use two matching tables (one named the odd table and one the even table). We then

randomly select a perfect matching between cells in the odd table and cells in the even table. Here too we remove the superscript $b = 2$ for the sake of brevity.

Let $w = o(n/d)$, and let M_w be the number of possibilities to partition n vertices into two parts of equal size so that the endpoints of the edges $e_1, \ldots, e_w$ belong to different sides of the partition. The total number of graphs in $R = R^2$ that contain the edges $e_1, \ldots, e_w \in B$ is $M_w \cdot (dn/2 - w)!$. To verify this, consider any fixed equal partition amongst the M_w possible ones (such that the endpoints of the edges $e_1, \ldots, e_w$ belong to different sides of the partition). For each such partition, consider the $dn/2 - w$ cells in the odd/even tables which are not part of the edges $e_1, \ldots, e_w$. A matching between them can be uniquely defined by an arbitrary order on the unmatched cells in the odd table and a permutation on the unmatched cells in the even table.

Note that by the definition of M_w we have that $\frac{M_{w+1}}{M_w} \leq 1$. Therefore,

$$\frac{|R_{(u,v,i,j)} \cap R_B|}{|R_B|} = \frac{M_{k+1} \cdot (dn/2 - (k+1))!}{M_k \cdot (dn/2 - k)!} \leq \frac{1}{dn/2 - k}. \tag{33}$$

As in the case of $P^b = P^1$ it follows that

$$\frac{|R_{(u,v)} \cap R_B|}{|R_B|} \leq \frac{d^2}{dn/2 - k} = O\left(\frac{d}{n}\right), \tag{34}$$

from which we can obtain that $\frac{|R_B|}{|R_{B,\overline{D}}|} = 1 + o(1)$.

By combining the above we get that

$$\begin{aligned} \frac{|R_{(u,v,i,j)} \cap R_{B,\overline{D}}|}{|R_{B,\overline{D}}|} &= \frac{|R_{(u,v,i,j)} \cap R_B|}{|R_B|} \cdot \frac{|R_{(u,v,i,j)} \cap R_{B,\overline{D}}|}{|R_{(u,v,i,j)} \cap R_B|} \cdot \frac{|R_B|}{|R_{B,\overline{D}}|} \\ &\leq \frac{1}{dn/2 - k} \cdot 1 \cdot (1 + o(1)) \leq \frac{4}{dn}. \end{aligned} \tag{35}$$

∎

The next two lemmas follow as corollaries of Lemma 11.

LEMMA 12. *Let* ALG *be an algorithm that interacts with a process P^b, $b \in 1, 2$, and performs $o(n/d)$ queries. The probability that* ALG *detects an edge by a vertex-pair query at any step is $o(1)$.*

Proof. Consider the interaction of ALG with P^b. For each $1 \leq t \leq Q$, $Q = o(n/d)$, let B_{t-1} be the set of edges in the induced knowledge graph G_{t-1}, and let D_{t-1} be the set of edge-pairs that are nonedges in the graph. By definition of the process P^b, we know that $R^b_{t-1} = R^b_{B_{t-1},\overline{D_{t-1}}}$. Suppose that the tth query of ALG is a vertex-pair query (u_t, v_t) (where, by our assumption, the pair (u_t, v_t) is neither an edge(-pair) nor a nonedge in G_{t-1}, but other than that it may be any vertex-pair). Then by Lemma 11 (and using the fact that $R^b_{t-1} = R^b_{B_{t-1},\overline{D_{t-1}}}$), for every $i, j \in \{1, \ldots, d\}$, $|R^b_{(u_t,v_t,i,j)} \cap R^b_{t-1}|/|R^b_{t-1}| \leq 4/(dn)$. Therefore,

$$\begin{aligned} \frac{\left|R^b_{(u_t,v_t)} \cap R^b_{t-1}\right|}{|R^b_{t-1}|} &= \frac{\left|\left(\bigcup_{i,j \in \{1,\ldots,d\}} R^b_{u_t,v_t,i,j}\right) \cap R^b_{t-1}\right|}{|R^b_{t-1}|} \\ &\leq \frac{\sum_{i,j=1}^{d} \left|\left(R^b_{u_t,v_t,i,j} \cap R^b_{t-1}\right)\right|}{|R^b_{t-1}|} \leq \frac{4d}{n}. \end{aligned} \tag{36}$$

It follows by the definition of P^b that the answer $a_t = (y_t, i_t, j_t)$ satisfies $y_t = 1$ with probability at most $4d/n$. Note that the above is true for every step t, for every pair

of sets B_{t-1} and D_{t-1}, and for every vertex-pair (u_t, v_t) (that does not already appear in B_{t-1} or in D_{t-1}). Hence, the probability that $y_t = 1$ in any one of the $Q = o(n/d)$ queries performed by the algorithm is $o(1)$ as required. ∎

Next we turn to neighbor queries and prove a similar claim.

LEMMA 13. *Let* ALG *be an algorithm that interacts with process P^b, $b \in 1, 2$, and performs $o(\sqrt{n})$ queries. Then the probability that* ALG*, while performing a neighbor query $q_t = (u_t, i_t)$ at any step t of the interaction, receives as an answer $a_t = (v_t, j_t)$, where v_t is a vertex that belongs to the knowledge graph G_{t-1}, is $o(1)$.*

Proof. Let $t = o(\sqrt{n})$, and let $q_t = (u_t, i_t)$ be a neighbor query. Denote by p_t the probability that following this query ALG reaches a vertex that was previously visited (i.e., p_t is the probability that in the answer $a_t = (v_t, j_t)$ we get a vertex v_t that already belongs to the knowledge graph G_{t-1}). Then by the definition of P^b (for both $b = 1$ and $b = 2$),

$$p_t = \frac{\left|\bigcup_{v \in G_{t-1},\, 1 \le j \le d} \left(R^b_{(u_t, v, i_t, j)} \cap R^b_{t-1}\right)\right|}{|R^b_{t-1}|}. \tag{37}$$

By Lemma 11 (using the same argument as the one applied in the proof of Lemma 12), we can deduce that for any specific v and j, $v \in G_{t-1}$ and $1 \le j \le d$,

$$\left|R^b_{(u_t, v, i_t, j)} \cap R^b_{t-1}\right| \;\le\; \frac{4}{dn} \cdot \left|R^b_{t-1}\right|. \tag{38}$$

Therefore,

$$\begin{aligned}\left|\bigcup_{v \in G_{t-1},\, 1 \le j \le d} \left(R^b_{(u_t, v, i_t, j)} \cap R^b_{t-1}\right)\right| &\le \sum_{v \in G_{t-1},\, 1 \le j \le d} \left|R^b_{(u_t, v, i_t, j)} \cap R^b_{t-1}\right| \\ &\le d \cdot 2t \cdot \frac{4}{dn} \cdot \left|R^b_{t-1}\right| \quad = \quad \frac{8t}{n} \cdot \left|R^b_{t-1}\right|. \end{aligned} \tag{39}$$

Since $t = o(\sqrt{n})$, we get that $p_t = o(1/\sqrt{n})$. Since this holds for every $1 \le t \le Q = o(\sqrt{n})$, the probability that for some t (in which a neighbor query is performed) the algorithm reaches a vertex in the knowledge graph is $o(1)$. ∎

In particular, we can obtain the following corollary.

COROLLARY 9. *Let* ALG *be an algorithm that interacts with process P^b and performs $Q = o(\min(\sqrt{n}, n/d))$ queries. Then* ALG *does not detect a cycle with probability $1 - o(1)$.*

Recall that D^b_{ALG}, $b \in \{1, 2\}$, denotes the distribution on query-answer histories (of length Q), induced by the interaction of ALG and P^b. We are now ready to show that the two distributions are indistinguishable if Q is sufficiently small.

LEMMA 14. *For every algorithm* ALG *that asks $Q = o(\min(\sqrt{n}, n/d))$ queries, the statistical distance between D^1_{ALG} and D^2_{ALG} is at most $o(1)$. Furthermore, with probability at least $1 - o(1)$, the knowledge graph at the time of termination of* ALG *contains no cycles.*

Proof. Recall that G_Q, the knowledge graph after Q queries, contains all the vertices that appeared in one of the queries or answers, all the edges found by queries, and all the nonedges found by queries.

Recall that we assume without loss of generality that ALG does not ask queries whose answer can be derived from the knowledge graph, since those give it no new information. Under this assumption the following hold:

1. According to Lemma 12, both in D^1_{ALG} and in D^2_{ALG} the total weight of query-answer histories in which an edge is detected by a vertex-pair query is $o(1)$. In all other histories (whose weight is $1-o(1)$ under both distributions), all answers to vertex-pair queries are of the form $(0,1,1)$.
2. According to Lemma 13, both in D^1_{ALG} and in D^2_{ALG} the total weight of query-answer histories in which any neighbor query q_t is answered with a vertex that belongs to the knowledge graph G_{t-1} is $o(1)$. In particular, this means that, with probability at least $1-o(1)$, the knowledge graph at the time of termination of ALG contains no cycles.

Let Π_1 be the set of all possible query-answer histories in which a vertex-pair query is answered by $(1,*,*)$, let Π_2 be the set of histories in which a neighbor query is answered with a vertex that appears in the current knowledge graph, and let Π_3 be the set of all remaining histories. Then the statistical distance between D^1_{ALG} and D^2_{ALG} is upper-bounded by

$$\sum_{\pi\in\Pi_1}\left|D^1_{\mathrm{ALG}}(\pi)-D^2_{\mathrm{ALG}}(\pi)\right|+\sum_{\pi\in\Pi_2}\left|D^1_{\mathrm{ALG}}(\pi)-D^2_{\mathrm{ALG}}(\pi)\right| + \sum_{\pi\in\Pi_2}\left|D^1_{\mathrm{ALG}}(\pi)-D^2_{\mathrm{ALG}}(\pi)\right|. \tag{40}$$

Observe that

$$\begin{aligned}\sum_{\pi\in\Pi_1}\left|D^1_{\mathrm{ALG}}(\pi)-D^2_{\mathrm{ALG}}(\pi)\right| &\le \sum_{\pi\in\Pi_1}D^1_{\mathrm{ALG}}(\pi)+\sum_{\pi\in\Pi_1}D^2_{\mathrm{ALG}}(\pi)\\ &= D^1_{\mathrm{ALG}}(\Pi_1)+D^2_{\mathrm{ALG}}(\Pi_2)\end{aligned}$$

(and similarly for the sum over Π_2). Hence the first two terms in (40) contribute $o(1)$.

As for the third term, first note that for every fixed history $\langle(q_1,a_1),\ldots,(q_{t-1},a_{t-1})\rangle$, the distribution on the next query q_t that ALG performs is the same no matter which process it interacts with. By definition of Π_3, if q_t is a vertex-pair query, then $a_t=(0,1,1)$ for both processes. Finally, if $q_t=(u_t,i_t)$, then again by the definition of Π_3 the answer $a_t=(v_t,j_t)$ is such that $v_t\notin G_{t-1}$. For both processes, conditioned on $v_t\notin G_{t-1}$, the vertex v_t is uniformly distributed among all vertices not in G_{t-1}, and j_t is uniformly distributed over $\{1,\ldots,d\}$. Therefore, the third term in (40) is bounded by $|D^1_{\mathrm{ALG}}(\Pi_3)-D^2_{\mathrm{ALG}}(\Pi_3)|$ which is $o(1)$ as well, and the lemma follows. □

Theorem 8 follows by combining Lemma 14 with Lemma 9.

5.1. Self-loops and multiple edges. The lower-bound proof as stated above is valid for graphs that may contain multiple edges and self-loops. In both the distribution $\mathcal{G}(n,d)$ and the distribution $\mathcal{G}(n/2,n/2,d)$ the probability of a multiple edge between vertices u and v is $O(\frac{d^2}{n^2})$, and the probability of a self-loop edge incident to vertex v is $O(\frac{d}{n})$. Thus, graphs created according to these distributions contain self-loops and multiple edges with probability close to 1. However, with probability $1-o(1)$ there are at most $O(d^2)$ loops and multiple edges in the graphs created according to these distributions.

We have shown in Lemma 9 that graphs created according to the distribution $\mathcal{G}(n,d)$ are ϵ-far from being bipartite with probability $1-o(1)$. Hence we can deduce that by removing self-loops and multiple edges from a graph G constructed according to a distribution $\mathcal{G}(n,d)$, the resulting graph is ϵ-far from being bipartite with probability $1-o(1)$.

In addition, an algorithm ALG that interacts with process P^b detects a multiple edge with probability $o(1)$ due to the following reason: ALG does not detect any edges by sampling steps with probability $1 - o(1)$. The probability to detect a multiple edge/self-loop in a neighbor query is at most the probability that such a query is answered by a vertex in the knowledge graph. This probability was shown (in Lemma 13) to be $o(1)$.

Thus, P^b in the end of the interaction with ALG can delete all the loops and multiple edges from the resulting graph so that the resulting graph contains no loops and multiple edges. In the case of P^2 the graph is bipartite as before, and in the case of P^1 the graph is (still) ϵ-far from being bipartite.

As a conclusion we get that our lower bound is valid also for graphs with no multiple edges and loops.

5.2. The necessity of both neighbor queries and vertex-pair queries. As noted in the introduction, our lower-bound proof implies the necessity of both neighbor queries and vertex-pair queries in obtaining an upper bound whose dependence on n and m is $\tilde{O}(\min(\sqrt{n}, n^2/m))$. Specifically, if only neighbor queries are allowed, then Lemma 13 implies a lower bound of $\Omega(\sqrt{n})$ for every m, which is higher than $\tilde{O}(n^2/m)$ when $m = \omega(n^{1.5})$. On the other hand, every bipartite tester that uses only vertex-pair queries has to make $\Omega(n^2/m)$ since otherwise it will not see any edge. This lower bound is above the upper bound of $\tilde{O}(\sqrt{n})$ when $m = o(n^{1.5})$.

5.3. A lower bound for testing *k*-colorability. It is possible to generalize the lower bound stated for bipartite testers to a lower bound for k-colorability. By using similar arguments we can get that a graph chosen uniformly from the distribution $\mathcal{G}(n, d)$ is ϵ-far from being k-colorable. In addition, by defining a distribution $\mathcal{G}(n/k, n/k, \ldots, n/k, d)$ in an analogous way to the definition of $\mathcal{G}(n/2, n/2, d)$ and by an analogous definition of the processes P^b, $b \in 1, 2$, we can get a lower bound for k-colorability which is $\Omega(\min(\sqrt{n}, n^2/m))$.

Appendix. A formal definition of $\mathbf{M}_{\ell_1}^{\ell_2}(H)$. For every vertex v in H we have a state v in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ (see Figure 8). For simplicity, we shall continue referring to these states as vertices. Let the *border* of H, denoted $B(H)$, be the set of vertices in H that have at least one neighbor in G that is not in H. Then, for every vertex $v \in B(H)$, we have a set $a_{v,1}, \ldots, a_{v,\ell_1}$ of *auxiliary* states. Let $p_{v,u}^H(t)$ denote the probability of a walk of length t that starts at v and ends at u without passing through any other vertex in H. Namely, it is the sum over all such walks w, of the product, taken over all steps in w, of the transition probabilities of these steps. In particular, $p_{v,v}^H(1) \geq \frac{1}{2}$ (where equality holds in case v has degree d), and for every $u \in \Gamma(v)$, $p_{v,u}^H(1) = \frac{1}{2d}$ (here we assume that we can choose a random neighbor of a vertex within time which is $O(1)$). The transition probabilities, $q_{x,y}$, in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ are defined as follows:

- For every v and u in H, $q_{v,u} = \sum_{t=1}^{\ell_2 - 1} p_{v,u}^H(t)$.
  Thus, $q_{v,u}$ is a sum of $p_{v,u}^H(1)$ and $\sum_{t=2}^{\ell_2-1} p_{v,u}^H(t)$. The first term implies that for every v in H, $q_{v,v} \geq \frac{1}{2}$ and for every pair of neighbors v and u, $q_{v,u} \geq \frac{1}{2d}$. The second term, which we refer to as the *excess* probability, is due to walks of length less than ℓ_2 (from v to u) passing through vertices outside of H and can be viewed as a *contraction* of these walks.
  Hence, for every pair of vertices v and u, $q_{v,u} = q_{u,v}$.
- For every $v \in B(H)$, $q_{v,(a_{v,1})} = \sum_{u \in H} \sum_{t \geq \ell_2} p_{v,u}^H(t)$; for every ℓ, $1 \leq \ell < \ell_1$, $q_{(a_{v,\ell}),(a_{v,\ell+1})} = 1$; and for every $u \in H$, $q_{(a_{v,\ell_1}),u} = \frac{1}{q_{v,(a_{v,1})}} \cdot \sum_{t \geq \ell_2} p_{v,u}^H(t)$.

(The parentheses added in the notation above (e.g., $q_{(a_{v,\ell}),(a_{v,\ell+1})}$) are only for the sake of readability.)

In other words, $q_{v,(a_{v,1})}$ is the probability that a random walk in G that starts from v takes at least ℓ_2 steps outside of H before returning to H, and $q_{(a_{v,\ell_1}),u}$ is the conditional probability of reaching u in such a walk. Thus, the auxiliary states form auxiliary paths in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$, where these paths correspond to walks of length at least ℓ_2 outside of H.

We shall restrict our attention to walks of length at most ℓ_1 in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$, and hence any walk that starts at a vertex of H and enters an auxiliary path never returns to vertices of H.

For any two states y, z in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ let $q_{y,z}(t)$ be the probability that a walk of length t starting from y ends at z. In particular, $q_{y,z} \equiv q_{y,z}(1)$, and for any two vertices u and v and any integer t, we have $q_{u,v}(t) = q_{v,u}(t)$. We further let the parity of the lengths of paths corresponding to walks in G be carried on to $\mathrm{M}_{\ell_1}^{\ell_2}(H)$. That is, each transition between vertices v and u that corresponds to walks outside of H consists of two transitions—one due to even-length paths corresponding to walks from v to u outside of H and one due to odd-length paths. For any two vertices in H we let $q_{v,u}^b(t)$ denote the probability in $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ of a walk of length t starting from v, ending at u, and corresponding to a path whose length has parity b.

In all that follows we assume that G is connected. Our analysis can easily be modified to deal with the case in which G is not connected, simply by treating separately each of its connected components. Under the assumption that G is connected, for every v and u in H, there exists a t such that $q_{u,v}(t) > 0$, and hence $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ is irreducible. Furthermore, because for each $v \in H$ it holds that $q_{v,v} \geq \frac{1}{2}$, $\mathrm{M}_{\ell_1}^{\ell_2}(H)$ is also aperiodic. Thus it has a unique stationary distribution.

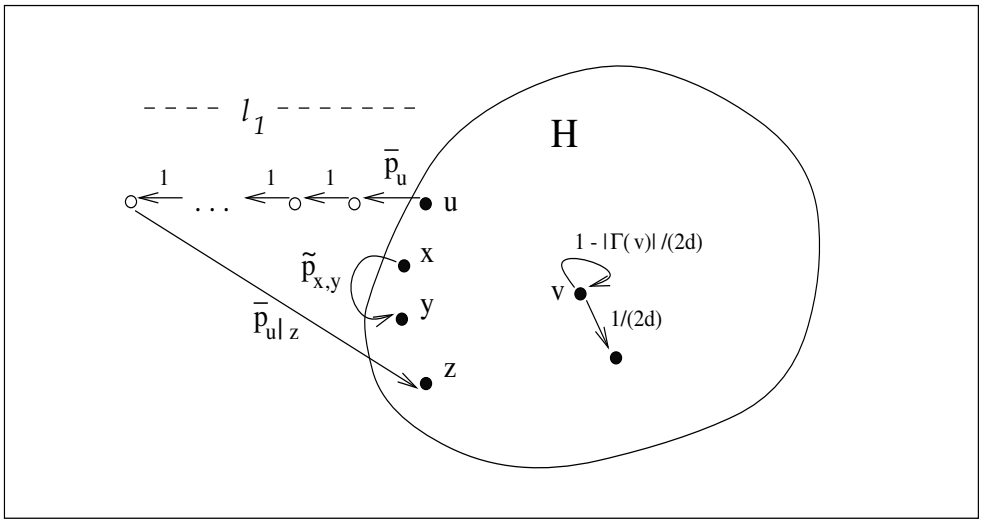

FIG. 8. *The structure of* $\mathrm{M}_{\ell_1}^{\ell_2}(H)$. *The states corresponding to vertices of* H *are depicted as black dots, and the auxiliary states are depicted as white ones. Here* $\tilde{p}_{x,y}$ *denotes the transition probability between any two vertices* $x, y \in B(H)$, *which equals* $\sum_{t=1}^{\ell_2-1} p_{x,y}^H(1)$, $\bar{p}_u$ *denotes the probability of entering an auxiliary path starting from* $u \in B(H)$, *which equals* $\sum_{z\in H}\sum_{t\geq\ell_2} p_{u,z}^H(t)$, *and* $\bar{p}_{u|z}$ *denotes the probability of returning from the last state on this auxiliary path to* $z \in B(H)$, *which equals* $\frac{1}{\bar{p}_u} \cdot \sum_{t\geq\ell_2} p_{u,z}^H(t)$.

Acknowledgment. We would like to thank the anonymous reviewers of this paper for very helpful comments.

DEPTH OPTIMAL SORTING NETWORKS RESISTANT TO k PASSIVE FAULTS*

MAREK PIOTRÓW†

Abstract. We study the problem of constructing a sorting network that is tolerant to faults and whose running time (i.e., depth) is as small as possible. We consider the scenario of worst-case comparator faults and follow the model of *passive* comparator failure proposed by Yao and Yao [*SIAM J. Comput.*, 14 (1985), pp. 120–128], in which a faulty comparator outputs its inputs directly without comparison. Our main result is the first construction of an N-input k-fault-tolerant sorting network with an asymptotically optimal depth $\theta(\log N+k)$. That improves over the result of Leighton and Ma [*Proceedings of the 5th Annual ACM Symposium on Parallel Algorithms and Architectures*, Velen, Germany, 1993, ACM, New York, pp. 30–41], whose network is of depth $O(\log N+k\log\frac{\log N}{\log k})$.

Actually, we present a fault-tolerant correction network that can be added after any N-input sorting network to correct its output in the presence of at most k faulty comparators. Since the depth of the network is $O(\log N + k)$ and the constants hidden behind the "O" notation are small, the construction can be of practical use.

Developing the techniques necessary to show the main result, we construct a fault-tolerant network for the insertion problem. As a by-product, we get an N-input $O(\log N)$-depth INSERT-network that is tolerant to random faults, thereby answering a question posed by Ma in his Ph.D. thesis [*Fault-Tolerant Sorting Network*, Department of Mathematics, Massachusetts Institute of Technology, Cambridge, MA, 1994].

The results are based on a new notion of constant delay comparator networks, that is, networks in which each register is used (compared) only in a period of time of a constant length. Copies of such networks can be pipelined with only a constant increase in the total depth per copy.

Key words. fault-tolerant sorting, sorting networks, comparators

1. Introduction.

A comparator is a simple device that takes the contents of two registers and performs a *compare-exchange* operation on them; that is, the minimum is put into the first register and the maximum into the second one. Networks built from comparators are commonly used to perform such tasks as selection, sorting, and merging. They have also proved to be very useful for a variety of applications, including circuit switching and packet routing [6]. Therefore, there has been much research in this area. The most famous constructions are those of Batcher [3], who introduced two types of sorting networks both of depth $(\log^2 N + \log N)/2$, and of Ajtai, Komlos, and Szemeredi [1], who showed that there exist sorting networks of depth $O(\log N)$.[1] None of these constructions addresses the issue of fault-tolerance.

The study of fault-tolerant sorting networks was initiated by Yao and Yao [13] in 1985. They introduced a fault type in which a *faulty* comparator does not work at all: the contents of registers remain unchanged. Later, this type of fault was called

[1] In this paper all the logarithms are taken in base 2.

passive. In [13], the authors consider the use of redundancy to enhance reliability for sorting and related networks under two alternative fault models. In the *random-fault* model, comparators fail independently with probability upper-bounded by a constant less than 1, and the goal is to construct networks which work correctly with probability at least $1 - \frac{1}{N}$ under this assumption. In the *k-fault* model (or *worst-case* model), the goal is to build k-fault-tolerant networks, that is, networks which work correctly if any set of at most k comparators is faulty.

Yao and Yao observed that any sorting network could be made random-fault-tolerant if each of the original comparators was replicated $O(\log N)$ times. This yields a fault-tolerant sorting network with $O(\log^2 N)$ depth. No improvement of this bound was obtained for several years. In 1993, Leighton and Ma (see [7]) gave a new analysis of the AKS network [1], which resulted in an improved upper bound $O(\log N \log\log N)$ on the depth of random-fault-tolerant sorting networks. Later, Ma [10] presented a new construction of such networks with optimal size $O(N \log N)$. This result resolved the old conjecture of Yao and Yao that the size of random-fault-tolerant sorting networks is $\omega(N \log N)$.

Other types of faulty comparators were also studied in [2, 7, 8] in this context. In the *reversal* fault model, a faulty comparator outputs its inputs in reversed order. In the *destructive* fault model, a faulty comparator with inputs x and y may output any of the pairs (x, y), (y, x), (x, x), or (y, y); thus it can destroy one of the inputs, replacing it with the other one. In order to tolerate such types of faulty elements, Assaf and Upfal [2] extended the model of comparator networks by allowing the use of more registers than input items and introducing *replicators* that are used to copy the contents of one register to another register. Replicators are assumed to be fault-free. In [2] they gave a general method for converting any sorting network into a reversal-fault-tolerant or destructive-fault-tolerant sorting network in the random-fault model. Applying this technique to the AKS network, they obtained fault-tolerant networks of size $O(N \log^2 N)$. For the destructive fault model the result is asymptotically optimal—the corresponding lower bound was proved by Leighton and Ma in [8]. For the reversal fault model, the upper bound was improved in [7] to $O(N \log^{\log_2 3} N)$. All the mentioned results concern the random fault model. For the worst-case model, a construction of a k-reversal-fault-tolerant sorting network of size $O(N(\log N + k \log\log_k N + k^{\log_2 3}))$ was also provided in [7].

For the worst-case passive model, Yao and Yao [13] constructed a k-fault-tolerant sorting network of the optimal size. They did not consider the depth of these networks; in fact, the increase in the depth was $O(kN)$. Schimmler and Starke [12] gave another construction of the network, where the depth of an N-input k-fault-tolerant sorting network was reduced to $O(k \log N)$. Further improvement was obtained by Leighton, Ma, and Plaxton [7], who derived a new upper bound $O(\log N + k \log \frac{\log N}{\log k})$ on the depth of the networks in question. In this construction, the constant in the "O" notation depends on the structure of a modified AKS-network and is quite big. Our main result closes the gap between this upper bound and the trivial lower bound $\Omega(\log N + k)$.

Actually, we present a fault-tolerant correction network that can be added after any N-input sorting network to correct its output in the presence of at most k faulty comparators. Since the depth of this additional network is $O(\log N + k)$ and the constants hidden behind the "O" notation are not big, the construction can be of practical use.

MAIN THEOREM. *There exists an explicit construction of N-input k-fault-tolerant sorting networks of depth $O(\log N + k)$.*

Developing the techniques necessary to show the main result, we construct a fault-tolerant network for the insertion problem. As a by-product, we get an N-input $O(\log N)$-depth INSERT-network that is tolerant to random faults, thereby answering a question posed by Ma in his Ph.D. thesis [9].

THEOREM 1.1. *There exists an explicit construction of an N-input k-fault-tolerant* INSERT*-network of depth $O(\log N + k)$.*

THEOREM 1.2. *There exists an explicit construction of an N-input random-fault-tolerant* INSERT*-network of depth $O(\log N)$.*

The results are based on a new notion of constant delay comparator networks, that is, networks in which each register is used (compared) only in a period of time of a constant length. Copies of such networks can be pipelined with only a constant increase in the total depth per copy. To look at this method more closely, consider the case of two copies A_1 and A_2 of a d-delay network A. Obviously, A_1 and A_2 have the same pattern of comparators. Therefore, to start performing comparisons from A_2 we do not have to wait until all comparisons from A_1 take place. Indeed, an initial comparator $[i : j]$ from A_2 can be applied just after all comparisons from A_1 involving registers i and j have been finished. Since a copy of $[i : j]$ is also the first comparator applied to i and j in A_1 and since registers i and j are used only in the next $d-1$ phases of A_1, $[i : j]$ can be applied again, this time as a comparator of A_2, just after d phases. The situation is quite similar to the pipelining of data items in systolic computations.

1.1. Overview of the construction. First, let us recall two well-known facts. The first one is the zero-one principle: a network sorts all sequences when it sorts all sequences built from zeroes and ones. The second one is due to Yao and Yao [13]: when any i comparators from a sorting network are faulty and we input a 0-1 sequence to the faulty network, then the Hamming distance[2] between the output and the sorted sequence is at most $2i$. Assuming that the input contains exactly j zeroes and $N-j$ ones, the second fact implies that in the output there are at most i ones inside the initial j items (we will denote them by 1^*s) and at most i zeroes inside the last $N-j$ items (we will denote them by 0^*s). We can look at this sequence as if it were created from a sorted one, $0^j 1^{N-j}$, in two phases: (1) exactly i zeroes were replaced by 1^*s, (2) exactly i ones from the last $N-i$ items were replaced by 0^*s. We would like to correct results of these phases separately. Therefore, the basic structure of our network can be presented as follows, where SORT denotes any sorting network:

Faulty comparators can appear in any part of the network, but their total number must be at most k. If i of them, $0 < i \le k$, appear in the SORT part, at most $k-i$ can appear in the CORRECT 1^*s or CORRECT 0^*s parts. Thus, an A is defined to be a *$CORRECT_k^1$ network* (*$CORRECT_k^0$ network*, respectively) if for all i, $0 < i \le k$, A is $(k-i)$-fault-tolerant and sorts any 0-1 sequence that can be obtained from a sorted one by changing exactly i zeroes to ones (i ones to zeroes, respectively). Our first observation is that parts two and three of the network are symmetric: each one can be obtained from the other by complementing every comparator (recall from [12] that the complement of a comparator $[u : v]$ is defined to be $\overline{[u : v]} = [N-1-v : N-1-u]$).

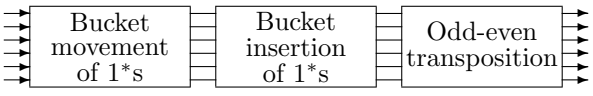
[2]The Hamming distance between two binary sequences of equal length is the number of positions at which the sequences differ.

The second important observation is that after applying both parts, the output sequence is sorted. The reasons are the following: the input to the third part starts with at least $j - i$ zeroes and contains at most i 0^*s among ones; symmetrically, we can analyze the second part as if its input ended up with $N - j$ ones and contained at most i 1^*s among zeroes. We can do that while, whenever 1^* is compared/exchanged with 0^*, the Hamming distance decreases immediately by 2. Both observations are formally proved in section 3. Thus, the only difficult part that remains is a construction of $\mathrm{CORRECT}_k^1$ networks.

We can look at the correction problem as at the problem of insertion: a certain number of "displaced" items (1^*s) should be inserted into a sorted sequence. Since the initial positions of 1^*s are unknown, we split the insertion task into two subtasks: moving 1^*s to certain "well-known" positions and inserting the items from such positions.

In the construction of Schimmler and Starke [12], we can split the whole k-correction network into a sequence of k pairs of subnetworks, where the first element of each pair does the moving subtask and the second element does the insertion. The goal of the whole sequence is to correct an output of a sorting network with i, $i \leq k$, faults and to be resistant to $k - i$ faulty comparators itself. Since the number of fault-free pairs of subnetworks is not smaller than the number of displaced items, a fault-free pair can be assigned to each such item, and the items are corrected one after another, starting from the innermost in an input. The only problem that remains is that the pairs of subnetworks cannot be pipelined well—the total depth of the network is k times the depth of each pair, which yields $O(k \log N)$. We would like to solve the problem by pipelining separately k copies of a modified "moving" subnetwork first, and then k copies of a modified "inserting" subnetwork.

As far as we know, even in the case of one "displaced" item, no fault-tolerant insertion network of the optimal depth has been given so far in the literature. We present such a network in section 4. Then we modify the construction to deal with a greater number of such items. The problem that must be solved is how to avoid, in the process of insertion, comparisons between 1^*s. The result of each such comparison is the same as if the upper 1^* met a faulty comparator, and there can be up to $k/2$ such comparisons in each stage of insertion. The solution that we use is to group each k consecutive registers into a so-called bucket, in each bucket find the minimum and the maximum, and apply the insertion process on buckets, where a comparison between buckets u and v means a comparison between the maximum of u and the minimum of v. Due to the bucket size, the compared items cannot both be 1^* and, therefore, comparisons between 1^*s can happen only inside buckets. The last thing we do after the bucket insertion is to sort items inside buckets (in fact, in one bucket) using odd-even transposition. Thus the whole structure of $\mathrm{CORRECT}_k^1$'s networks can be drawn as follows:



The first two parts are of depth $O(\log N + k)$; the last one is of depth $3k$. The details of their construction and the analysis of their correctness are given in the following sections. It should be emphasized that, in order to make our presentation simpler, we do not force the constants to be optimally small.

2. Preliminaries. Let $N \geq 2$ be an integer and $\mathcal{R}^N$ be the set of N-element vectors of reals. For every $\overline{x} \in \mathcal{R}^N$, $\overline{x}[i]$ denotes the ith term of $\overline{x}$. Let $[N]$ denote the set $\{0, 1, \ldots, N-1\}$, and for $i, j \in [N]$ the *comparator* $[i : j]$ is a mapping from $\mathcal{R}^N$ to $\mathcal{R}^N$ which transforms a vector $\overline{x}$ into vector $\overline{x}' = \overline{x}[i : j]$ defined as follows:

$$\overline{x}'[k] = \begin{cases} \overline{x}[k], & k \neq i, j, \\ \min(\overline{x}[i], \overline{x}[j]), & k = i, \\ \max(\overline{x}[i], \overline{x}[j]), & k = j. \end{cases}$$

Thus $[i : j]$ compares $\overline{x}[i]$ with $\overline{x}[j]$ and places the smaller of them in position i and the larger one in position j. We call $[i : j]$ a *standard comparator* if $i < j$. For a standard comparator $[i : j]$, let $j - i$ be its *length*, and we will sometimes say that it is an *outgoing* comparator from the register i and an *incoming* comparator to the register j.

An *N-comparator stage* S is a set of r comparators $\{[i_1 : j_1], [i_2 : j_2], \ldots, [i_r : j_r]\}$, where $i_1, j_1, \ldots, i_r, j_r \in [N]$ are pairwise different. The comparator stage S defines a *mapping* from $\mathcal{R}^N$ to $\mathcal{R}^N$, which is a composition of the mappings associated with $[i_1 : j_1], [i_2 : j_2], \ldots, [i_r : j_r]$ applied in arbitrary order. Let $\mathit{support}(S)$ denote the set $\{i_1, j_1, i_2, j_2, \ldots, i_r, j_r\}$.

An N-input *comparator network* A is a sequence $S_1, S_2, \ldots, S_d$ of N-comparator stages. The N-input network A defines the mapping from $\mathcal{R}^N$ to $\mathcal{R}^N$ by successively applying the mappings induced by $S_1, S_2, \ldots, S_d$. Let $\overline{x}A$ denote the result of applying A to $\overline{x} \in \mathcal{R}^N$. A *standard network* is a network consisting of standard comparators only. Let $\mathit{depth}(A) = d$ and $\mathit{size}(A) = \sum_{i=1}^{d} |S_i|$.

For an N-input network $A = S_1, S_2, \ldots, S_d$ and $j \in [N]$, we define the following parameters:

$$\begin{aligned} \mathit{fst}(j, A) &= \min\{1 \leq i \leq d : j \in \mathit{support}(S_i)\}, \\ \mathit{lst}(j, A) &= \max\{1 \leq i \leq d : j \in \mathit{support}(S_i)\}, \\ \mathit{delay}(A) &= \max_{j \in [N]} \{\mathit{lst}(j, A) - \mathit{fst}(j, A) + 1\}. \end{aligned}$$

We can look at a computation in a comparator network A as the process of synchronous data movement through an array of computation units (i.e., comparators), where each stage is a column of the array, and rows correspond to registers. We assume that it takes a unit of time to move data items to the next column. In this way, we can consider the whole process as systolic computation. In this context, $\mathit{fst}(j, A)$ denotes the first unit of time when the item in register j reaches a computation unit, and $\mathit{delay}(A)$ is the maximum time required to move any data item through all its computation units. At time $\mathit{fst}(j, A) + \mathit{delay}(A)$, the contents of register j is fixed after all computations and can possibly be pipelined to a next copy of A.

All comparator networks presented in this paper are standard, and whenever it is possible in the constructions we use subnetworks of a constant delay. This allows us to put copies of such a subnetwork one after another so that the total depth is small. The following definitions and Proposition 2.1 formalize this technique.

Let $A = S_1, S_2, \ldots, S_d$ and $A' = S'_1, S'_2, \ldots, S'_{d'}$ be N-input comparator networks such that for each i, $1 \leq i \leq \min(d, d')$, $\mathit{support}(S_i) \cap \mathit{support}(S'_i) = \emptyset$. Then $A \cup A'$ is defined to be $(S_1 \cup S'_1), (S_2 \cup S'_2), \ldots, (S_{\max(d,d')} \cup S'_{\max(d,d')})$, where empty stages are added at the end of the network of smaller depth. Let $A^{\Rightarrow D}$ denote the shift of A

by D stages, that is,

$$A^{\Rightarrow D} = \underbrace{\emptyset, \ldots, \emptyset}_{D \text{ times}}, S_1, S_2, \ldots, S_d.$$

PROPOSITION 2.1. *Let $A = S_1, S_2, \ldots, S_d$ be an N-input comparator network. Then the network $B \stackrel{\text{def}}{=} A \cup A^{\Rightarrow delay(A)}$ is correctly defined, and $depth(B) = depth(A) + delay(A)$.*

Proof. Let $D = delay(A)$. To prove that B is correctly defined, it suffices to check whether

$$\forall\ 0 \le j \le N-1, \quad lst(j, A) < fst(j, A^{\Rightarrow D}).$$

Since for each j, $0 \le j \le N-1$, $fst(j, A^{\Rightarrow D}) = D + fst(j, A)$ and $lst(j, A) - fst(j, A) < D$, the statement holds and, therefore, B is correctly defined. The second part of the lemma follows directly from the definition. □

Using Proposition 2.1, we can define a network $A^{(i)}$ built from i, $i > 0$, copies of the network A, where copies are put one after another, each shifted further by $delay(A)$ stages. Formally,

$$A^{(i)} \stackrel{\text{def}}{=} \bigcup_{j=0}^{i-1} A^{\Rightarrow j \cdot delay(A)}.$$

Most of our networks will be defined recursively. To make recursive definitions precise, the standard set of register indexes $\{0, 1, \ldots, N-1\}$ will sometimes be replaced by another N-element set of nonnegative integers, and comparators will be redefined to this set. We will also use a one-to-one order-preserving mapping to replace one set of indexes by another. For example, if A is a comparator network and s is a positive integer, then $A \Downarrow s$ will denote the network whose registers are indexed by $\{s, s+1, \ldots, s+N-1\}$, and each comparator $[i : j]$ in A is replaced by $[i+s : j+s]$.

An N-input network A is an *INSERT-network* if, for every $\overline{x} \in \mathcal{R}^N$, the fact that $(\overline{x}[1], \ldots, \overline{x}[N-1])$ is sorted implies that $\overline{y} = \overline{x}A$ is sorted. An N-input network A is a *MAX-network* (*MINMAX-network*) if, for every $\overline{x} \in \mathcal{R}^N$, we have $(\overline{x}A)[N-1] = \max\{\overline{x}[0], \ldots, \overline{x}[N-1]\}$ (respectively, if A is a MAX-network and $(\overline{x}A)[0] = \min\{\overline{x}[0], \ldots, \overline{x}[N-1]\}$ for every $\overline{x} \in \mathcal{R}^N$ holds).

We say that B is a j-fault subnetwork of A if B can be obtained from A by deleting exactly j comparators. By definition of a faulty comparator, instead of deleting comparators it is equivalent to say that the comparators in question fail. An N-input SORT-network (MAX-network, MINMAX-network, INSERT-network) is said to be k-fault-tolerant if every j-fault subnetwork of A, $j \le k$, is also a SORT-network (MAX-network, MINMAX-network, INSERT-network, respectively).

The following tool is very useful in the studies of comparator networks.

PROPOSITION 2.2 (zero-one principle). *If an N-input network sorts all 2^N sequences of 0's and 1's, then it is a SORT-network.*

Proof. See [4, 5.3.4, Theorem Z]. □

The zero-one principle can easily be generalized to the case of INSERT-networks, MAX-networks, and MINMAX-networks. Using the zero-one principle, we can restrict our attention to input vectors $\overline{x} \in \{0, 1\}^N$.

PROPOSITION 2.3 (insert 0-1 principle). *If a standard N-input network sorts all N sequences of the form 10^t1^{N-t-1}, $0 \le t < N$, then it is an INSERT-network.*

Proof. The proof follows the same ideas as the proof of the zero-one principle. Recall that for any nondecreasing function f, a comparator network A, and an input $\overline{x}$, $f(\overline{x})A = f(\overline{x}A)$. Let A be a standard network that sorts all N sequences of the form 10^t1^{N-t-1}, $0 \le t < N$. To obtain a contradiction, suppose that there is an input sequence $\overline{x} \subset \mathcal{R}^N$ such that $(x[1], x[2], \ldots, x[N-1])$ is sorted but $\overline{y} = \overline{x}A$ is not sorted. Let i be the index such that $y[i] > y[i+1]$, and define $f(z)$ to be 1 if $z \ge y[i]$ and 0 otherwise. Then $f(\overline{y})$ is not sorted. On the other hand, $f(\overline{x})$ is of one of the forms 10^t1^{N-t-1} or 0^t1^{N-t} for some $t \ge 0$, since f is nondecreasing. Due to the definition of A, $f(\overline{x})A$ is sorted, a contradiction. □

3. Basic results. In this section, we formally prove the basic results that were introduced in section 1, namely, the existence of efficient worst-case fault-tolerant sorting networks (main theorem) and random-fault-tolerant inserting networks (Theorem 1.2). The proofs are based on Lemma 3.1 and Theorem 1.1, which describe the most difficult parts of the whole construction. Actually, the latter theorem is a special case of the former lemma, but it will be proved separately in section 4, because it is of independent interest and because a solution to the general case will be given on the base of a solution to this special case.

LEMMA 3.1. *There is an explicit construction of a standard N-input* $\mathrm{CORRECT}_k^1$ *network of depth $O(\log N + k)$.*

This is the key lemma in our paper, and we will proceed towards its proof through the rest of the paper; thus the proof is postponed to the end of section 6. In the next lemma we prove that the complement of a standard N-input $\mathrm{CORRECT}_k^1$ network is a $\mathrm{CORRECT}_k^0$ network.

LEMMA 3.2. *There is an explicit construction of a standard N-input* $\mathrm{CORRECT}_k^0$ *network of depth $O(\log N + k)$.*

Proof. Let N and k be fixed positive integers. Let $A = S_1, S_2, \ldots, S_d$, $d = O(\log N + k)$, denote the $\mathrm{CORRECT}_k^1$ network from Lemma 3.1. We would like to prove that the complement of A is a $\mathrm{CORRECT}_k^0$ network. To this end and for the sake of completeness let us recall from [12] the definition and the basic lemma of a network complement.

Let $c(\overline{x})$ denote the complement of 0-1 sequence $\overline{x}$; that is, $c(\overline{x})[i] = 1 - \overline{x}[N-1-i]$ for each $i \in [N]$. For a comparator $[i:j]$ the complement is defined by

$$\overline{[i:j]} = [N-1-j : N-1-i].$$

Clearly, the complement of a standard comparator is standard. Finally, the complement $\overline{A} = \overline{S_1}, \overline{S_2}, \ldots, \overline{S_d}$ of the network $A = S_1, S_2, \ldots, S_d$ is defined by $\overline{S_i} = \{\overline{[i:j]} : [i:j] \in S_i\}$, $i = 1, \ldots, d$.

LEMMA 3.3 (after Schimmler and Starke [12, Lemma 4]). *For every N-input network A and every vector $\overline{x} \in \{0,1\}^N$, $c(c(\overline{x})\overline{A}) = \overline{x}A$.*

Let A be the $\mathrm{CORRECT}_k^1$ network, and let i, j denote nonnegative integers such that $i + j \le k$. In order to prove that $\overline{A}$ is a $\mathrm{CORRECT}_k^0$ network, consider j-fault subnetwork B of $\overline{A}$ and an input $\overline{x}$ obtained from a sorted 0-1 sequence by replacing exactly i zeroes with ones. Then $\overline{B}$ is a j-fault subnetwork of A, and $c(\overline{x})$ is also obtained from a sorted sequence by replacing exactly i ones with zeroes. By the definition of A, $c(\overline{x})\overline{B}$ is sorted. Observe that the complement of a sorted 0-1 sequence is also sorted. Using this and Lemma 3.3, we finally get that $\overline{x}B = c(c(\overline{x})\overline{B})$ is sorted, which completes the proof. □

Using these two lemmas, we are now able to prove our main theorem.

Proof of the main theorem. Let N and k be fixed positive integers. Let S, A, and B

respectively denote the following N-input networks: the AKS sorting network [1], the $\mathrm{CORRECT}_k^1$ network of Lemma 3.1, and the $\mathrm{CORRECT}_k^0$ network of Lemma 3.2. We claim that

$$C = S \cup A^{\Rightarrow depth(S)} \cup B^{\Rightarrow depth(S)+depth(A)}$$

is a k-fault-tolerant sorting network of depth $O(\log N + k)$. Indeed, consider a j-fault subnetwork C' of C; let S', A', and B' denote parts of C' corresponding to S, A, and B with i, j_1, and j_2 faults, respectively, where $i + j_1 + j_2 = j \le k$. If $i = 0$, then C' is a sorting network, because $S' = S$ sorts any input and the following standard networks A' and B' cannot make any change in a sorted sequence.

Now consider $i > 0$, and fix an input 0-1 sequence $\overline{x}$ with l zeroes and $N - l$ ones. Let $\overline{x}' = \overline{x}S'$, $\overline{y} = \overline{x}'A'$, and $\overline{z} = \overline{y}B'$. The proof is completed by showing that $\overline{z}$ is sorted. Due to a lemma of Yao and Yao [13], the Hamming distance between $\overline{x}'$ and $0^l 1^{N-l}$ is at most $2i$; in particular, there are at most i zeroes in the last $N - l$ positions of $\overline{x}'$. As before, denote these by 0^*s. Let $\overline{x}''$ denote the sequence $\overline{x}'$ after replacing all 0^*s with $\frac{1}{2}$, and let $\overline{y}'' = \overline{x}''A'$.

It is well known that for any nondecreasing function f, comparator network A, and input $\overline{x}$, $f(\overline{x})A = f(\overline{x}A)$. We use two such functions $f_1, f_2 : \{0, \frac{1}{2}, 1\} \mapsto \{0, 1\}$ by $f_1(0) = f_2(0) = 0$, $f_1(1) = f_2(1) = 1$, $f_1(\frac{1}{2}) = 0$, and $f_2(\frac{1}{2}) = 1$. Observe that $f_1(\overline{x}'') = \overline{x}'$, $\overline{y} = \overline{x}'A' = f_1(\overline{x}'')A' = f_1(\overline{y}'')$, and $f_2(\overline{x}'')A' = f_2(\overline{y}'')$. The sequence $f_2(\overline{x}'')$ contains only ones in the last $N - l$ positions and at most i ones in the first l positions, and thus it is an appropriate input for a $\mathrm{CORRECT}_k^1$ network. Since $i + j_1 \le k$, Lemma 3.1 implies that $f_2(\overline{y}'')$ is sorted. Furthermore, $\overline{y} = f_1(\overline{y}'')$ differs from this sorted sequence in at most i positions where it has zeroes instead of ones; hence we can apply Lemma 3.2 and finally get that $\overline{z} = \overline{y}B'$ is sorted. □

We conclude this section with a proof of Theorem 1.2. To this end we assume that Theorem 1.1 holds (it is proved in section 4).

Proof of Theorem 1.2. We consider now the case of random faults, where each comparator fails independently with probability upper-bounded by $p < 1$. A random-fault-tolerant INSERT-network should remain an INSERT-network with probability at least $1 - \frac{1}{N}$ in this context. Let us notice that the failure upper bound p can be decreased to p^t by repeating each comparator in a network t times. In this way, we can choose the value of p as small as we need. For a small enough p we prove that the k-fault-tolerant INSERT-network from Theorem 1.1 with $k = O(\log N)$ is a random-fault-tolerant INSERT-network.

Let $s > 0$ be a constant such that $s(\log N + k)$ is an upper bound on the depth of the N-input k-fault-tolerant INSERT-networks. Assuming that $p < \frac{1}{2s}$, let us set $k = \lfloor c \log N \rfloor$, where

$$c = \max\left(2, \frac{16ps}{(1-2ps)^2 \cdot \log e}\right).$$

For the constants selected and a fixed N, let $A = S_1, S_2, \ldots, S_d$, $d \le s(c+1)\log N$, be the $\lfloor c \log N \rfloor$-fault-tolerant INSERT-network. Now apply a random procedure to A, which fails each comparator in A independently with probability less than p, and let A' denote the result. We have to prove that

$$\Pr\{A' \text{ is not an INSERT-network}\} < \frac{1}{N}.$$

Using the insert 0-1 principle, we can restate this inequality as

$$\Pr\{\exists\ 0 < t < N \text{ such that } (10^t 1^{N-t-1})A' \text{ is not sorted}\} < \frac{1}{N}.$$

Hence, it suffices to prove that for any fixed t, $\Pr\{(10^t 1^{N-t-1})A' \text{ is not sorted}\} < N^{-2}$. To this end we apply the principle of deferred decisions; that is, we do not assume that the entire set of random choices is made in advance, but instead we simulate the network A' on $10^t 1^{N-t-1}$, and at the beginning of each stage of A' we fail at random the outgoing comparator of the register in which the first 1 is currently located (other comparators cannot change the contents of registers). Let X_t denote the random variable corresponding to the number of faulty comparators revealed in this procedure. The variable X_t is easily seen to be the sum of at most $s(c+1)\log N$ independent Poisson trials, where each trial has the success probability upper-bounded by p. Thus, a standard Chernoff-type argument [11, Theorem 4.1] implies that for our choice of the constant c

$$\Pr\{X_t > c\log N\} < \frac{1}{N^2}.$$

Since A is a $(c\log N)$-fault-tolerant INSERT-network, we get that the probability that $(10^t 1^{N-t-1})A'$ is not sorted is less than N^{-2}, which completes the proof. □

4. Worst-case fault-tolerant INSERT-network. In this section, we define an N-input INSERT-network that is resistant to k faults and which is of the asymptotically optimal depth $O(\log N + k)$. In this way, Theorem 1.1 will be proved.

The simplest way of inserting an item located in register 0 into a sorted sequence located in registers $1, \ldots, N-1$ is to perform compare-exchange operations on pairs of consecutive registers $[0:1], [1:2], \ldots$. This algorithm is implemented by an odd-even transposition network. The nice property of the algorithm is that it can be easily made fault-tolerant: to tolerate k faults one should add $2k$ stages. The obvious disadvantage is its depth: to move an item from register i to register j one needs $j-i+1$ stages of the network. Since we would like to have a network of a logarithmic depth, we can apply odd-even transposition only at the end of the inserting procedure, when we know that the item is within a logarithmic distance from its final position.

The quickest deterministic way to insert an item is a binary algorithm which is similar to the binary search: we always try to insert the item in the middle of its potential final positions. This algorithm is of logarithmic depth and can be implemented on comparator networks (compare [12]), but it is not easily transformable into an effective fault-tolerant network. The first problem is that we try to move an item from certain positions $\log N$ times; hence a copy of the network could not be applied before time $\log N$. To tolerate k faults we need k copies, and thus the total depth would be of $\Theta(k\log N)$. The second problem is that a simple application of copies is not enough to recover from certain faults: if an item does not move through a faulty comparator it would in the fault-free network, it will probably move through one of the following shorter ones and end up somewhere between its initial and final positions.

In the construction described below, we solve both problems as follows: (1) we apply only one step of the binary insert procedure to an item, and if it does not succeed, we move the item to the next register; (2) we add a set of correcting comparators that recover an item from its wrong positions. Functionally, the network consists of two parts. The first part is intended to do approximate insertion in the presence of at most

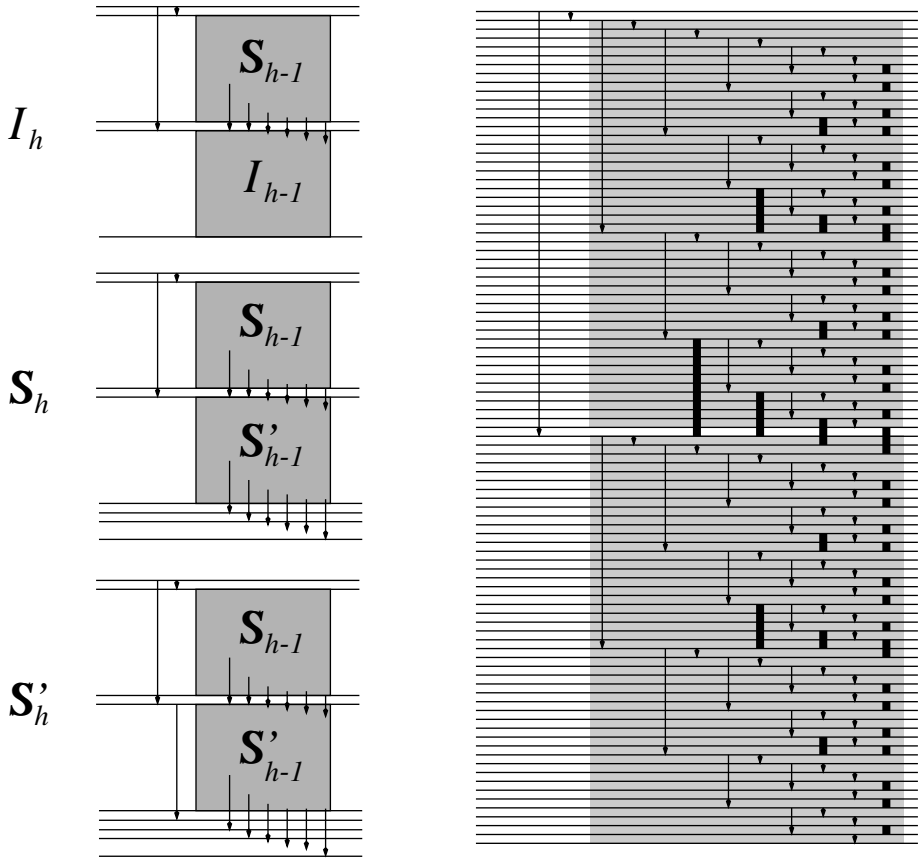


FIG. 4.1. *The recursive structure of I_h is shown on the left-hand side. All visible comparators, except those starting at the register* 0*, are correcting. The I_5 network is depicted on the right-hand side, where the S_4 and I_4 subnetworks are shadowed. All correcting comparators in I_5 are drawn with a thick line.*

k faults, where the end position of an inserted item is at a distance of at most $\log N$ from its correct one. $k+1$ copies of the network I_h (to be described below), each of depth $O(\log N)$ and of a constant delay, form this part. By Proposition 2.1, the total depth of this part is $O(\log N + k)$. The second part is simply the $O(\log N + k)$-depth odd-even transposition network, which adjusts the position of the inserted item to its correct value.

4.1. Definition of inserting networks. The network I_h, $h \geq 0$, contains $N = N_h = 3 \cdot 2^h - 1$ registers and is defined by induction on h with the help of two additional networks S_h and S'_h. In all these networks, we distinguish a certain set of comparators and call them *correcting comparators*. The correcting comparators play a special role in the analysis of the networks. (The name derives from the fact that without correcting comparators, I_h, S_h, and S'_h are all INSERT-networks but do not possess the fault-tolerance property.)

Before we formally define I_h, let us look for a moment at the sample network I_5 in Figure 4.1. It consists of 95 registers numbered $0, 1, \ldots, 94$. Assume that we put the sequence $10^{49}1^{45}$ to them and run a fault-free copy of I_5. It moves the 1 initially located in register 0 into register 49 (it is represented by the second line in the lower

shadowed area) through comparators [0 : 48] and [48 : 49]. But what would happen if [0 : 48] were faulty? Assume now that comparators [0 : 48] and [1 : 25] are faulty and that we have two additional fault-free copies of I_5 after the faulty one. In the faulty I_5, the 1 is moved into register 25 using comparators [0 : 1], [1 : 2], [2 : 14], [14 : 20], [20 : 25]. The last comparator is a correcting one (these are drawn with the thick line), and it enables the next copy of I_5 to recover from the effects of the faulty [1 : 25]. The first fault-free copy moves the 1 further to register 48 using [25 : 37] and another correcting comparator [37 : 48]. Finally, in the second fault-free copy of I_5, comparator [48 : 49] recovers from the effects of the faulty comparator [0 : 48], and we obtain the expected result.

Networks S_h and S'_h contain N_h *normal* registers and some number of *extra* registers denoted by $i_1, i_2, \ldots$. We assume that $N_h \le i_1 \le i_2 \le \cdots$ and that $i_1, i_2, \ldots$ are, in fact, parameters of the networks to be specified later, at the next levels of the recursive definition. In general, there are h extra registers in S_h and $h+1$ in S'_h. The only exception is S_0, where there is a single extra register. Therefore, we will use the notation $S_h(i_1, i_2, \ldots, i_{h'})$ and $S'_h(i_1, i_2, \ldots, i_{h+1})$, where $h' = \max(1, h)$. By $CC(X)$ we will denote the set of correcting comparators of X. The definition of the networks and their sets of correcting comparators follows[3] (see also Figure 4.1):

$$I_0 \stackrel{\text{def}}{=} \{[0:1]\}, \quad S_0(i_1) \stackrel{\text{def}}{=} S'_0(i_1) \stackrel{\text{def}}{=} \{[0:1]\}\{[1:i_1]\},$$

$$CC(I_0) \stackrel{\text{def}}{=} \emptyset, \quad CC(S_0(i_1)) \stackrel{\text{def}}{=} CC(S'_0(i_1)) \stackrel{\text{def}}{=} \{[1:i_1]\}.$$

Let $h \ge 1$, $h'' = \max(h-3, 0)$, and $N' = 3 \cdot 2^{h-1}$. Then

$$\begin{aligned}
I_h &\stackrel{\text{def}}{=} \{[0:N']\}, \{[0:1]\} \cup (I_{h-1}^{\Rightarrow 2} \Downarrow N') \\
&\quad \cup (S_{h-1}^{\Rightarrow 2}(N', N', N'+1, N'+2, \ldots, N'+h'') \Downarrow 1), \\
S_h(i_1, \ldots, i_h) &\stackrel{\text{def}}{=} \{[0:N']\}, \{[0:1]\} \cup (S'^{\Rightarrow 2}_{h-1}(i_1, \ldots, i_h) \Downarrow N') \\
&\quad \cup (S_{h-1}^{\Rightarrow 2}(N', N', N'+1, N'+2, \ldots, N'+h'') \Downarrow 1), \\
S'_h(i_1, \ldots, i_{h+1}) &\stackrel{\text{def}}{=} \{[0:N']\}, \{[0:1][N':i_1]\} \cup (S'^{\Rightarrow 2}_{h-1}(i_2, \ldots, i_{h+1}) \Downarrow N') \\
&\quad \cup (S_{h-1}^{\Rightarrow 2}(N', N', N'+1, N'+2, \ldots, N'+h'') \Downarrow 1).
\end{aligned}$$

The rule for finding correcting comparators in the networks I_h, $S_h(i_1, \ldots, i_{h'})$, and $S'_h(i_1, \ldots, i_{h+1})$ is that, whenever a comparator is defined to be correcting, it remains such at the next steps of the recursive definition. Therefore, we should only say which of the comparators introduced at the step h is the correcting one. In fact, there is only one new correcting comparator, namely $[N' : i_1]$, in the definition of $S'_h(i_1, \ldots, i_{h+1})$. Formally, the sets are defined by the following equations:

$$\begin{aligned}
CC(I_h) &\stackrel{\text{def}}{=} CC(I_{h-1}^{\Rightarrow 2} \Downarrow N') \\
&\quad \cup CC(S_{h-1}^{\Rightarrow 2}(N', N', N'+1, N'+2, \ldots, N'+h'') \Downarrow 1), \\
CC(S_h(i_1, \ldots, i_h)) &\stackrel{\text{def}}{=} CC(S'^{\Rightarrow 2}_{h-1}(i_1, \ldots, i_h) \Downarrow N') \\
&\quad \cup CC(S_{h-1}^{\Rightarrow 2}(N', N', N'+1, N'+2, \ldots, N'+h'') \Downarrow 1), \\
CC(S'_h(i_1, \ldots, i_{h+1})) &\stackrel{\text{def}}{=} \{[N' : i_1]\} \cup CC(S'^{\Rightarrow 2}_{h-1}(i_2, \ldots, i_{h+1}) \Downarrow N') \\
&\quad \cup CC(S_{h-1}^{\Rightarrow 2}(N', N', N'+1, N'+2, \ldots, N'+h'') \Downarrow 1),
\end{aligned}$$

[3] In the definition we assume that the shift down operation $\Downarrow$ is applied only to normal registers; the transformation of extra registers is given explicitly by assigning new values to parameters.

where the shift operations preserve the property of being a correcting comparator.

Notice that when we delete extra registers in a network $S(i_1, \ldots, i_{h'})$ (or in $S'_h(i_1, \ldots, i_{h+1})$) and comparators that use them, then the network becomes identical to I_h.

It is not quite clear whether the stages of the networks defined above consist of disjoint comparators only. Namely, at the stage h we assign extra registers of S_{h-1} to normal registers, and conflicts could occur between comparators that used those extra registers and comparators that used the normal registers to which they are assigned. Lemma 4.1 states that this is not the case.

LEMMA 4.1. *Let $h \geq 0$, $h' = \max(1, h)$, and X_h denote one of the networks I_h, $S_h(i_1, \ldots, i_{h'})$, or $S'_h(i_1, \ldots, i_{h+1})$. Then all comparators in any stage of X_h are pairwise disjoint and delay$(X_h) \leq 8$.*

Proof. Network X_0 is explicitly given, so assume $h \geq 1$. Register 0 is connected to two comparators at stages 1 and 2. Hence $fst(0, X_h) = 1$ and $lst(0, X_h) = 2$. Using induction on h, we shall prove the following facts about X_h, $h \geq 1$:

(a) $fst(j, X_h) \geq 2j$ and $lst(j, X_h) \leq 2j + 2$ for $1 \leq j \leq h$;
(b) $fst(i_j, S'_h) = lst(i_j, S'_h) = 2j$ for $j = 1, 2, \ldots, h + 1$;
(c) $fst(i_j, S_h) = lst(i_j, S_h) = 2j + 2$ for $j = 1, 2, \ldots, h$;
(d) $lst(j, X_h) - fst(j, X_h) \leq 7$ for $h < j < N_h$;
(e) at each stage of X_h a register j is involved in at most one comparison, $j = 0, \ldots, N_h - 1, i_1, i_2, \ldots$.

For $h = 1$ these properties could be easily checked by drawing the simple networks. Assume $h \geq 2$ and that the facts hold for $h - 1$. Let $N'_h = 3 \cdot 2^{h-1}$.

(a) Look at the layout of comparators in Figure 4.1. Register 1 is compared directly at stage 2, and it is used as register 0 by S_{h-1}; thus it is compared also at stages 3 and 4. It follows that $fst(1, X_h) = 2$ and $lst(0, X_h) = 4$. Registers $2, \ldots, h$ are used by the subnetwork $(S^{\Rightarrow 2}_{h-1}) \Downarrow 1$ only, where they correspond to registers $1, \ldots, h-1$ of S_{h-1}. By the induction hypothesis, $fst(j, S_{h-1}) \geq 2j$ and $lst(j, S_{h-1}) \leq 2j + 2$ for $1 \leq j \leq h - 1$. Stages of S_{h-1} are shifted two positions to the right in X_h, and thus $fst(j, X_h) \geq 2j$ and $lst(j, X_h) \leq 2j + 2$ for $2 \leq j \leq h$.

(b) Extra register i_1 of S'_h is used only once at stage 2. Thus $fst(i_1, S'_h) = lst(i_1, S'_h) = 2$. Extra registers $i_2, \ldots, i_{h+1}$ of S'_h are mapped to $i_1, \ldots, i_h$ of $(S'^{\Rightarrow 2}_{h-1}) \Downarrow N'_h$. By induction, $fst(i_j, S'_h) = lst(i_j, S'_h) = 2j$ for $j = 1, 2, \ldots, h$. Since all stages of S'_{h-1} are shifted two positions to the right in X_h and the index j is increased by 1, fact (b) holds also for $i_2, \ldots, i_h + 1$.

(c) Extra registers $i_1, \ldots, i_h$ of S_h are mapped to extra registers $i_1, \ldots, i_h$ of $(S'^{\Rightarrow 2}_{h-1}) \Downarrow N'_h$. Using fact (b) and inductive arguments similar to those above, we get that fact (c) is also true.

(d) Consider the set of registers $\{h + 1, \ldots, N_h - 1\}$. Only registers $N'_h, \ldots, N'_h + \max(h - 3, 0)$ are involved in new comparisons at the level h of the recursive definition of X_h. For the others the inductive hypothesis applies. Registers $N'_h + j$, $j = 0, \ldots, \max(h - 3, 0)$, are assigned to the extra registers of $(S^{\Rightarrow 2}_{h-1}) \Downarrow 1$, which are used at stages $6, 8, \ldots, 2h+2$, respectively, by fact (c). (We have taken into account the shift to the right.) On the other hand, registers $N'_h, \ldots, N'_h + \max(h-3, 0)$ correspond to the initial registers of the subnetwork I_{h-1} or S'_{h-1}, and thus, by fact (a), they are used only at stages $2j+2$, $2j+3$, $2j+4$ (with the shift). Combining these, we conclude that register N'_h is used only at stages $1, 2, 3, 4, 6, 8$ (notice that the first comparator also uses it, and it is assigned to i_1 and i_2), and register $N'_h + j$, $1 \leq j \leq \max(h-3, 0)$, is used at stages $2j + 2$, $2j + 3$, $2j + 4$, $2j + 8$. This proves the claim.

(e) It follows from the considerations in (a)–(d) and the induction hypothesis that each register is used at most once in any stage of X_h. □

COROLLARY 4.2. *If $[i:j]$ is a correcting comparator at stage l of X_h, then there does not exist $[j:i']$ for any i' at any stage later than l in X_h. Moreover, if $[i:j]$ is not a correcting comparator at stage l of X_h, then there does not exist $[j:i']$ for any i' at any stage earlier than l in X_h.*

Proof. Consider the stage h of the construction of X_h in the inductive proof above. New correcting comparators of the form $[* : j]$, where j is an index of a normal register, could appear only for $j \in \{N', N'+1, \ldots, N'+h-1\}$. But it is easy to notice that such comparators are the last ones in the sequence of comparisons in which j is involved. To prove the second part of the corollary, observe that (1) j must be greater than zero, (2) new comparators of the form $[j : *]$ are added only to the first two stages of X_h, and (3) the new comparators are outgoing comparators from registers 0 or N'. By (1) and (3), we should consider only $j = N'$, and, by (2), there is only one new comparator of the form $[j : *]$, namely $[N' : i_1]$ at stage 2. The only noncorrecting comparator $[i : N']$ for any i is added in stage 1, thus earlier than stage 2. □

We shall use the insert 0-1 principle to prove that, in the presence of at most k faulty comparators, $k+1$ copies of I_h approximately insert an item initially located in register 0 into a nondecreasing sequence of items initially located in registers $1, \ldots, N_h - 1$. Therefore, we will consider only inputs of the form 10^t1^{N-t-1}, where $1 \le t \le N-1$. To distinguish the 1 that should be inserted, we will denote it by 1^*.

For a given input 10^t1^{N-t-1} with t zeroes we will say that a comparator $[i:j]$ is *active* (with respect to t) if $j \le t$. Otherwise it is *inactive*. Thus, an inactive comparator (with respect to t) in a standard network never moves any value, when 10^t1^{N-t-1} is initially put to its registers. In the fault-free case, one copy of I_h is enough to move 1^* to register t. On the other hand, if there are faults in I_h, we need additional copies of I_h to recover from a wrong register to which 1^* could be moved. In section 4.2, based upon the structure of active comparators in I_h, we will assign weights to registers in I_h to measure the progress in the recovery procedure from the effect of faulty comparators, which 1^* has already met.

From now on, by X_h we will denote one of the networks I_h, $S_h(i_1, \ldots, i_h)$, or $S'_h(i_1, \ldots, i_{h+1})$. Consider the sequence $([i:j_0], [i:j_1], \ldots, [i:j_{m_i}])$ of all outgoing comparators from a register i, $0 \le i \le N-1$, in a network X_h, where the order of comparators is the same as the order of stages, to which the stages belong.

FACT 1. *The sequence of all outgoing comparators from a register i, $0 \le i \le N-1$, in X_h is empty or in one of the following forms:*

(a) $([i:l], [i:j_1], [i:j_2])$,
(b) $([i:l], [i:j_1])$,
(c) $([i:l])$,
(d) $([i:j_0], [i:j_1])$,
(e) $([i:j_0])$,

where $[i:l] \in CC(X_h)$, $[i:j_0]$, $[i:j_1]$, $[i:j_2] \notin CC(X_h)$, and $i < j_2 < j_1 < l$ or $i < j_1 < j_0$.

Remark. Let $10^t1^{N_h-t-1}$ be an input to I_h, and consider the sequence of active comparators (with respect to t) outgoing from a register i, $0 \le i < N_h$. It should be noticed that each such sequence also fulfills the statement of Fact 1. There are two reasons for that: (1) active comparators form an end segment of a sequence of all outgoing comparators, since they are shorter than inactive ones, and (2) sequences in the cases (a)–(e) represent also all their end segments.

4.2. Register weights. Assume that 1^* is now in a register i and that there are active comparators outgoing from i. In such a situation, 1^* will move through the first active comparator that is not faulty. The weight $c_h(i,t)$, defined formally below, is supposed to estimate the number of fault-free copies of I_h that are needed to move 1^* from the register i close to the register t. The definition depends only on the structure of I_h (fault-free). However, the definition is formulated in such a way that it will be used to bound the effects of "wrong" movements of 1^* due to faulty comparators. In other words, if we consider the sequence of faulty subnetworks of I_h, then this number will also describe the difference between the number of faulty comparators that have blocked 1^* on the way from the initial register to the register i and the number of correcting comparators through which 1^* has moved. Roughly speaking, each faulty comparator increases the weight by 1, and each correcting comparator decreases it by 1.

The outline of technical details in this subsection is as follows. In Lemma 4.3, we consider a single copy of I_h with k faults and give an upper bound on the weight difference between the output and input registers of 1^*. In Lemma 4.4, we analyze the number of copies that are required to reduce the weight of the output register to zero when k is the upper bound on the total number of faults in all copies. Next, in Fact 2 we prove that registers of weights zero are within logarithmic distance from the expected final position of 1^*. Finally, in Lemma 4.5 we estimate the weight of register 0 and the weights of all other registers for all inputs under consideration. We finish this subsection by proving Theorem 1.1.

Let $h \geq 0$ and $0 \leq t \leq N_h - 1$. Inductively, for $i = N_h - 1, N_h - 2, \ldots, 0$ we define the weight $c_h(i,t)$ of register i in I_h with respect to the goal register t. If $i > t$ or the sequence of active comparators outgoing from i is empty, then $c_h(i,t) \stackrel{\text{def}}{=} 0$. Otherwise, the sequence has to have one of the forms described in Fact 1. Using the notation from Fact 1, we define

$$c_h(i,t) \stackrel{\text{def}}{=} \max(1, c_h(l,t)+1, c_h(j_0,t), c_h(j_1,t)-1, c_h(j_2,t)-2), \tag{4.1}$$

where any terms that are undefined for a particular case should be replaced by 0.

The basic properties of weights $c_h(i,t)$ with respect to the behavior of a faulty version of I_h are summarized in the following two lemmas.

LEMMA 4.3. *Let $h \geq 0$, $N_h = 3 \cdot 2^h - 1$, and $0 \leq i < t \leq N_h - 1$. Let I'_h denote any k-fault subnetwork of I_h, and let $\overline{x_i} = 0^i 10^{t-i} 1^{N-t-1}$ be an input to I'_h. Then the output $\overline{x_i} I'_h$ has a form $\overline{x_j} = 0^j 10^{t-j} 1^{N-t-1}$, and if $c_h(j,t) \neq 0$, then*

$$c_h(j,t) - c_h(i,t) \leq k - 1.$$

Proof. The network I'_h is standard, because all comparators in I_h are standard. Therefore, the only 1 that can possibly move is the 1 initially located in the register i (referred to as 1^* in the following). Thus the output takes the form $\overline{x_j}$ for some $j \geq i$.

Since $c_h(j,t) \neq 0$ is assumed, the condition $c_h(i,t) \geq 1$ must be true (otherwise, since $i < t$ and $c_h(i,t) = 0$, there is no active comparator outgoing from i, and so $j = i$, a contradiction). Consider the sequence $i = i_0 < i_1 < \cdots < i_s = j$, $s \geq 0$, such that 1^* moves through comparators $[i_0 : i_1], [i_1 : i_2], \ldots, [i_{s-1} : i_s]$ in a given order (in the faulty network I'_h). Due to Corollary 4.2, only the last comparator could be a correcting one, and if $[i_{m-1} : i_m]$, $0 < m \leq s$, is a noncorrecting comparator at stage l_m, then all comparators outgoing from i_m are at stages later than l_m. Consider now all but the last comparators in the sequence.

By Fact 1, we know the structure of the sequence of comparators outgoing from register i_m, $0 \le m < s$. At the beginning of the sequence there could be inactive comparators, followed by zero or more faulty comparators, and then there is the comparator $[i_m : i_{m+1}]$. Let k_m denote the number of active faulty comparators outgoing from i_m before $[i_m : i_{m+1}]$. Then, by the definition of $c_h(i_m, t)$,

$$c_h(i_m, t) \ge c_h(i_{m+1}, t) - k_m. \tag{4.2}$$

For the last comparator in the sequence, we have two cases, as follows.

Case $[i_{s-1} : i_s] \in CC(I_h)$. In this case, by Fact 1, k_{s-1} must be zero, and from (4.1) we can get a stronger inequality $c_h(i_{s-1}, t) \ge c_h(i_s, t) + 1$. Summing up the inequality with (4.2) over all $m = 0, \ldots, s-2$, we get

$$c_h(i_s, t) - c_h(i_0, t) \le k_0 + k_1 + \cdots + k_{s-2} - 1 \le k - 1.$$

Case $[i_{s-1} : i_s] \notin CC(I_h)$. Because $c_h(i_s, t) > 0$, there is at least one active comparator outgoing from i_s. By Corollary 4.2, comparators outgoing from i_s must occur at stages later than that of $[i_{s-1} : i_s]$. Due to Fact 1 and our definition of i_s, all active comparators outgoing from i_s must be faulty. Therefore $k_0 + k_1 + \cdots + k_{s-1} \le k - 1$. Summing up the inequalities as in the previous case, we get the desired result. □

LEMMA 4.4. *Let* $L_h^s \stackrel{\text{def}}{=} \{i \in [N_h] : \forall\ i \le t \le N_h - 1,\ c_h(i, t) \le s\}$, *where* $h \ge 0$, $s > 0$, *and* $N_h = 3 \cdot 2^h - 1$. *Moreover, let* $k \ge k' \ge 0$ *and* A *be any* k'*-fault subnetwork of* $I_h^{(k+s)}$. *Then for an input* $\overline{x_i} = 0^i 10^{t-i} 1^{N_h - t - 1}$, $0 \le i \le t \le N_h - 1$ *and* $i \in L_h^s$, *the output* $\overline{x_i}A = 0^j 10^{t-j} 1^{N_h - t - 1}$ *has the property that* $c_h(j, t) = 0$.

Proof. Assume to the contrary that there are h, s, k, k', A, i, t described in the lemma such that $c_h(j, t) > 0$. Let $k_1, k_2, \ldots, k_{k+s}$ denote the number of faulty comparators in the first, the second, ..., the $(k+s)$th copy of I_h. Let $i = i_0 \le i_1 \le \cdots \le i_{k+s} = j$ denote the positions of the first 1 between the corresponding copies. Clearly, $c_h(i_m, t) > 0$ for $0 \le m \le k + s$. Using Lemma 4.3 for each k_m-fault subnetwork of I_h and summing up the inequalities, we get

$$c_h(i_{k+s}, t) - c_h(i_0, t) \le \left(\sum_{m=1}^{k+s} k_m \right) - (k + s).$$

Because $\sum_{m=1}^{k+s} k_m \le k' \le k$ and $c_h(i, t) \le s$, we have arrived at the contradiction $c_h(j, t) \le 0$. □

One can observe that 1^* has no chance to move when it is in a register i such that $c_h(i, t) = 0$. Fortunately, in such cases 1^* is very close to its target position t.

FACT 2. *Let* $h \ge 0$ *and* $0 \le t \le N_h - 1$. *Consider a register* i, $i < t$, *such that* $c_h(i, t) = 0$. *Then* $t - i \le h$.

Proof. By induction on h, we prove that for each register i, $0 \le i \le N_h - 2$, in X_h at least one comparator outgoing from i is of length $\le h + 1$.

Basis: $h = 0$. There is only one comparator $[0 : 1]$ outgoing from 0.

Inductive step: $h > 0$. Let $N' = 3 \cdot 2^{h-1}$. For $1 \le i \le N' - 2$ and $N' \le i \le N_h - 2$ the statement holds due to the inductive assumption about I_{h-1}, S_{h-1}, and S'_{h-1}. Therefore, we should consider only registers 0 and $N' - 1$. By construction, there is a comparator of length 1 outgoing from 0. In case of $N' - 1$, there is a correcting comparator $[N' - 1 : N' + \max(h - 3, 0)]$ in X_h of length not greater than $h + 1$, and we are done.

Assume now that $c_h(i,t) = 0$ for some $i < t$. Then each comparator $[i : j]$ is inactive, particularly those of length $\leq h+1$. Because $j \geq t+1$, $t-i \leq h$ is true and Fact 2 holds. □

To prove Theorem 1.1, we need only to estimate the weight $c_h(i,t)$ for i in particular sets of register indexes. In fact, we are interested in two sets: $\{0\}$ and $\{0,1,\ldots,N-1\}$.

LEMMA 4.5. *Let $h \geq 0$ and $0 \leq t \leq N_h - 1$. Then*

(i) $c_h(0,t) \leq 1$,

(ii) $0 \leq c_h(i,t) \leq h+1$ *for* $0 \leq i \leq t$.

We postpone the proof of Lemma 4.5 to the next subsection. Now, we can prove the main result of this section, namely, Theorem 1.1.

Proof of Theorem 1.1. We should prove that for each $N > 0$ and $k \geq 0$ there exists an explicit construction of an N-input k-fault-tolerant INSERT-network of depth $O(\log N + k)$.

Assume $N > 2$. (For $N = 2$ one takes $(k+1)$-times the comparator $[0 : 1]$.) Let $h \geq 1$ be such that $3 \cdot 2^{h-1} - 1 < N \leq 3 \cdot 2^h - 1$. Consider the network A that consists of $I_h^{(k+1)}$ followed by $h + 2k$ stages of the odd-even transposition network. A contains $N_h = 3 \cdot 2^h - 1 \geq N$ registers. To get the N-input network, we delete the last superfluous registers and comparators that use them. Let the truncated network be called B. We prove that B has the desired properties.

Since $depth(I_h) = 2h + 2$, $depth(I_h^{(k+1)}) = 2h + 2 + 8k$, with respect to Proposition 2.1 and Lemma 4.1. Accordingly, $depth(B) \leq depth(A) = 3h + 10k + 3$. Since $h = \lceil \log \frac{N+1}{3} \rceil$, the total depth of B is of $O(\log N + k)$.

To prove that B is a k-fault-tolerant INSERT-network, we will use the insert 0-1 principle. Therefore, we consider only the behavior of B on inputs of the form $\overline{y_t} \stackrel{\text{def}}{=} 10^t 1^{N-t-1}$, where $0 \leq t \leq N-1$. However, the behavior of B is the same as the behavior of the first N registers of A on the corresponding input $\overline{y'_t} \stackrel{\text{def}}{=} 10^t 1^{N_h-t-1}$, because the deleted registers contain 1's in A, and thus the deleted comparators are inactive.

By Lemma 4.5, $c_h(0,t) \leq 1$. Using Lemma 4.4 with $s = 1$ and $L_h^s \supseteq \{0\}$, we get that after $I_h^{(k+1)}$, item 1^* is in a register j such that $c_h(j,t) = 0$. According to Fact 2, $t - j \leq h$. By standard arguments, $h + 2k$ stages of an odd-even transposition will move 1^* to the register t, even in the presence of k faulty comparators. That proves that A is a k-fault-tolerant INSERT-network, and, by the arguments above, so is B. □

Remark. Due to Lemma 4.5(ii), the item to be inserted can be given in any register (i.e., not necessarily in register 0), and such a generalized INSERT-network is still of depth $O(\log N + k)$. To construct the network we should take $(h + k)$ copies of I_h, followed by $(h + k)$ copies of the symmetric version of I_h (replace each comparator $[i : j]$ in I_h by $[N - j : N - i]$), and then the odd-even transposition part. The same arguments as above prove that the network is correct.

4.3. Estimation of weights. This subsection is devoted to the proof of Lemma 4.5, that is, to an estimation of the values $c_h(i,t)$. Since the weights are defined in a sequential manner and the structure of I_h is described recursively, we need a tool that allows us to apply induction on the structure of I_h in order to get the estimation. The weights below are defined recursively based on the structure of the networks, but they possess sequential properties similar to those of the weights $c_h(i,t)$ and, in consequence, will be used as their upper bounds.

Weights $w_h(i)$ for registers in $S_h(i_1, \ldots, i_h)$ (and similar weights $w'_h(i)$ for registers in $S'_h(i_1, \ldots, i_{h+1})$) are defined recursively below. Let $h > 0$, $N_h = 3 \cdot 2^h - 1$, and $N'_h = 3 \cdot 2^{h-1}$. Then

$$w_0(j) \stackrel{\text{def}}{=} w'_0(j) \stackrel{\text{def}}{=} \begin{cases} 2, & j = 0, 1, \\ 1, & j = i_1, \end{cases}$$

$$w_h(j) \stackrel{\text{def}}{=} \begin{cases} 2, & j = 0, \\ w_{h-1}(j-1) + 1, & 0 < j < N'_h, \\ w'_{h-1}(j - N'_h), & N'_h \le j < N_h, \\ l, & j = i_l,\ l \le h, \end{cases}$$

$$w'_h(j) \stackrel{\text{def}}{=} \begin{cases} 2, & j \in \{0, N'_h\}, \\ w_{h-1}(j-1) + 1, & 0 < j < N'_h, \\ w'_{h-1}(j - N'_h) + 1, & N'_h < j < N_h, \\ l, & j = i_l,\ l \le h+1. \end{cases}$$

We will need the following properties of the weights.

FACT 3. *Let $h \ge 0$. Then $w_h(j) = w'_h(j) = j + 2$ for $j = 0, 1, \ldots, h$. Moreover, $w_h(j) \le h + 2$ and $w'_h(j) \le h + 2$ for $j = 0, 1, \ldots, N_h - 1$.*

Proof. The proof follows from an easy induction. □

FACT 4. *Let $h \ge 0$ and $0 \le i \le N_h - 1$. Consider the sequence of comparators in S_h (or S'_h) outgoing from the register i, which must be of a form described in Fact* 1. *Then, using the notation given there,*

$$w_h(i) \ge \max(w_h(l) + 1, w_h(j_0), w_h(j_1) - 1, w_h(j_2) - 2),$$

$$w'_h(i) \ge \max(w'_h(l) + 1, w'_h(j_0), w'_h(j_1) - 1, w'_h(j_2) - 2),$$

where any terms that are undefined for a particular case should be replaced by zero.

Proof. The idea of the proof is to proceed by induction and reduce the inequalities for h to the corresponding inequalities for $h - 1$. Separately, we should check only registers that have new outgoing comparators, that is, the register 0 in S_h and the registers $0, N'_h$ in S'_h. Moreover, it should be verified that, in the process of assigning extra registers from the level $h - 1$ to registers from the level h, their weights do not increase more than the recurrence allows (otherwise, we could not apply induction). We check only the register 0 in S_h, the register N'_h in S'_h, and the reassignment of extra registers in the definition of S'_h. The other cases are left to the reader.

Case 0 *in* S_h. The sequence of outgoing registers from 0 in S_h is $([0 : N'_h], [0 : 1])$. Since $w_h(0) = 2$, $w_h(N'_h) = w'_{h-1}(0) = 2$, and $w_h(1) = w_{h-1}(0) + 1 = 3$, the inequality $w_h(0) \ge \max(w_h(N'_h), w_h(1) - 1)$ holds.

Case N'_h *in* S'_h. The corresponding sequence for N'_h in S'_h is $([N'_h : i_1], [N'_h : N'_h + N'_{h-1}], [N'_h : N'_h + 1])$, where the first comparator is a correcting one and the last one is absent for $h = 1$. By induction, we know that $2 = w'_{h-1}(0) \ge \max(w'_{h-1}(N'_{h-1}), w'_{h-1}(1) - 1)$. Since $w'_h(N'_h) = 2$, $w'_h(i_1) = 1$, $w'_h(N'_h + N'_{h-1}) = w'_{h-1}(N'_{h-1}) + 1 \le 3$, and $w'_h(N'_h + 1) = w'_{h-1}(1) + 1 \le 4$, the inequality $w'_h(N'_h) \ge \max(w'_h(i_1) + 1, w'_h(N'_h + N'_{h-1}) - 1, w'_h(N'_h + 1) - 2)$ holds.

Case extra registers in S'_h. For each register j in S'_h, $N'_h < j < N_h$, we have $w'_h(j) = w'_{h-1}(j - N'_h) + 1$. Hence, the weights increase by 1 in this part of the network. We should check that the weights of extra registers in S'_{h-1} do not increase more that 1 through the reassignment in S'_h. However, a register i_l, $1 \le l \le h$, in S'_{h-1} is assigned to i_{l+1} in S'_h, and therefore, its weight increases by exactly 1.

Let $h' = \max(h-1, 1)$. Consider the subnetwork S_{h-1} in S'_h. Its extra registers $i_1, \ldots, i_{h'}$ have weights $w_{h-1}(i_1) = 1, \ldots, w_{h-1}(i_{h'}) = h'$ and are assigned to normal registers $N', N', N'+1, \ldots, N'+h'-2$. Since $w'_h(N') = 2$ and $w'_h(N'+j) = w'_{h-1}(j)+1 = j+3$ for $j = 1, \ldots, h'-2$ (the last equality being due to Fact 3), the weights of the extra registers have increased by at most 1. However, $w'_h(j)$ increases by exactly 1 with respect to $w_{h-1}(j-1)$, where $0 < j < N'_h$. Consequently, we can use induction to prove Fact 4 for all other registers in S'_h. □

Proof of Lemma 4.5. We shall prove the lemma by induction on h. To this end we extend (i) to (i′) and add a new statement (iii).

(i′) $c_h(i,t) \le i+1$ for $0 \le i \le \min(h,t)$,

(ii) $0 \le c_h(i,t) \le h+1$ for $0 \le i \le t$,

(iii) $c_h(i,t) \le w_{h-1}(i-1)$ for $h \ge 1$ and $1 \le i < 3 \cdot 2^{h-1} \le t$,

where weights $w_h(i)$ for registers in $S_h(i_1, \ldots, i_h)$ have been defined above. In the following, induction is made on h for all the three inequalities being proved.

Directly from the definition, one can check that (i′), (ii), and (iii) hold for $h = 0, 1$. Assume that $h > 1$. Let $N_h = 3 \cdot 2^h - 1$ and $N'_h = 3 \cdot 2^{h-1}$. In the proof, we will use the following observation concerning weights $c_h(i,t)$ in I_h:

$$c_h(i,t) = \begin{cases} c_{h-1}(i-1, t-1), & 1 \le i \le t < N'_h, \\ c_{h-1}(i-N'_h, t-N'_h), & N'_h \le i \le t < N_h. \end{cases}$$

The first equality is a consequence of the fact that if $1 \le t < N'_h$, then all registers assigned to extra registers of S_{h-1} contain 1's, and therefore, the subnetworks of S_{h-1} and I_{h-1} consisting of active comparators only (with respect to $t-1$) are identical. Recall that I_h and S_h are identical after deleting extra registers in S_h and the comparators that use them. The second equality follows directly from the definitions.

First, we prove (iii) for a fixed t, proceeding by induction backwards on i and using Fact 4. Assume first that $t \ge N'_h + h - 3$. Then for each register i, $1 \le i < N'_h$, all its outgoing comparators are active. Therefore, the symbols l, j_0, j_1, and j_2 in the definition of $c_h(i,t)$ and in the inequalities of Fact 4 denote the right-hand ends of the same comparators. If, by induction, (iii) holds for l, j_0, j_1, and j_2, then it holds for i too. To start the induction, we should check only whether (iii) holds for registers assigned to the extra registers of S_{h-1}. A register i_m, $1 \le m < h$, has the weight $w_{h-1}(i_m) = m$ and is assigned to the register $j_m = N'_h + \max(0, m-2)$ with weight $c_h(j_m, t) = c_{h-1}(j_m - N'_h, t - N'_h) \le \max(1, m-1) \le m$, where we use (i′) from the inductive assumption about I_{h-1}. By induction, (iii) follows.

If $N'_h \le t < N'_h + h - 3$, then there are inactive correcting comparators outgoing from registers in $\{1, \ldots, N'_h - 1\}$. It is not difficult to see that these comparators are exactly $[N'_h - 1 : N'_h + h - 3], [N'_h - N_0 : N'_h + h - 4], [N'_h - N_1 : N'_h + h - 5], \ldots, [N'_h - N_{m_t} : t+1]$, where $m_t = N'_h + h - t - 5$. Moreover, the structure of active outgoing comparators for a register i in an interval $[N'_h - N_j, N'_h - 1]$, $j \le m_t$, is the same as the structure of all comparators outgoing from i in I_j. Hence, $c_h(N'_h - N_j, t) = c_j(0, N_j - 1) \le 1$. Since $w_{h-1}(j) \ge 2$ is true for any j, the inequality (iii) holds for a register i in the set $\{N'_h - N_j : j \le m_t\}$. For a register not in the set, all its outgoing comparators are active, and the inductive arguments from the previous paragraph are valid.

(ii) Obviously, $c_h(0,0) = 0$. Assume $t > 0$. If $t < N'_h$, then $c_h(i,t) = c_{h-1}(i-1, t-1) \le h$ by induction for all i, $1 \le i \le t$. Since $[0 : N'_h]$ is inactive, $c_h(0,t) = c_h(1,t) \le h$. If $N'_h \le t < N_h$, then $c_h(i,t) = c_{h-1}(i - N'_h, t - N'_h) \le h$ for $N'_h \le i \le t$. For other values of i we use (iii) and Fact 3. Namely, if $1 \le i < N'_h$, then $c_h(i,t) \le$

$w_{h-1}(i-1) \leq h+1$. By definition and the inequalities above, $c_h(0,t)$ is also bounded by $h+1$.

(i′) By similar arguments as in (ii), one can get the inequality. □

5. Bucket fault-tolerant INSERT-network. In this section, we describe the second part of the CORRECT$_k^1$ network, namely, bucket-insertion of 1*s. The problem we will deal with is quite similar to the problem of inserting an item into a sorted sequence (discussed in the previous section), but instead of one displaced item, there are s, $s \leq k$, such items. As before, we will use a generalized insert 0-1 principle; that is, we assume that an input to our network consists of a sequence of 0's with at most k "displaced" 1*s spread inside it, followed by a sequence of 1's.

As we showed in the previous section, in case of one 1^* to be inserted, there is a well-defined path in the INSERT-network, along which the item can be moved to its destination, and only faulty comparators on the path can make the item to switch to another (wrong) path. In case there are more 1*s to be inserted, a comparison between two 1*s causes the upper one to be blocked on its path by the lower 1^*. We call such a situation a *conflict*. For the upper 1^* the effect of a conflict is the same as if it met a faulty comparator. Potentially, we can have up to $k/2$ conflicts at each stage of the INSERT-network. To avoid this, we group consecutive k registers into so-called *buckets* and organize the movement of items between buckets in such a way that conflicts occur inside buckets only.

The idea is to replace each register in the INSERT-network with a bucket of registers, and each comparator $[i : j]$ with the comparator $[l_i : u_j]$, where l_i is the lower (last) register in the ith bucket and u_j is the upper (first) register in the jth bucket. To make the construction work, subnetworks based on a MINMAX-network are put in each bucket so that the MAX-item in one bucket is compared to the MIN-item in the other bucket. Since the buckets are of size k, this will never cause a situation where 1^* in the MAX-register of a bucket is compared to 1^* in the MIN-register of another one. Thus, the conflicts outside buckets will be avoided unless there are faulty comparators.

We start by fixing some definitions. Let $k > 1$ be an integer. We say that a bucket of size k is *empty* (respectively, *full*) if it contains k zeroes (respectively, k ones). The register $l_i = i \cdot k$ and $u_i = (i+1) \cdot k - 1$ will be called the *MIN-register* and the *MAX-register*, respectively, of the ith bucket.

Constructing the networks for buckets, we would like to achieve the following three goals in the fault-free case:

1. An incoming 1 is never blocked by another 1 in the MIN-register of a bucket.
2. If a bucket is nonempty, a 1 is moved into the MAX-register before its first outgoing comparator is used.
3. If a bucket is empty and it has an incoming comparator preceding the first outgoing one, the incoming 1 is moved directly to the MAX-register before the first outgoing comparator is used.

If the network contains faulty comparators and some of the goals are not achieved, we would like to assign a distinct faulty comparator to each such a goal. (Each incoming 1 that has been blocked counts on its own.)

Recall from the previous section that the INSERT-network consists of $k+1$ copies of I_h followed by $h+2k$ stages of an odd-even transposition network (cf. the proof of Theorem 1.1 in subsection 4.2). First, we present the implementation of the odd-even transposition on buckets. Then we will deal with I_h. The bucket versions of both networks are shown in Figure 5.1. A basic component of the net-

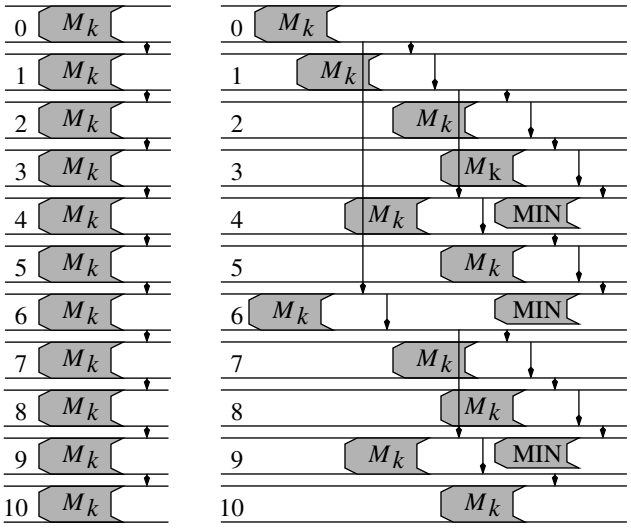

FIG. 5.1. *Examples of $T_{N,k}$ and $J_{N,k}$ networks—the bucket versions of odd-even transposition and the I_2 network.*

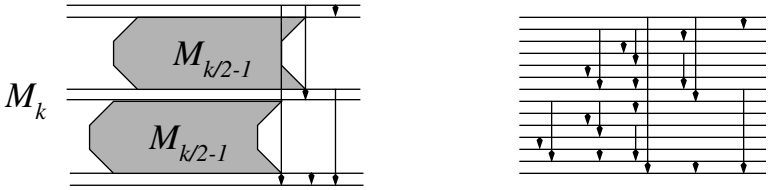

FIG. 5.2. *The recursive structure of M_k and the M_{14} network.*

works inside buckets is a MINMAX-network M_k that is described in Lemma 5.1. The next two lemmas give the correcting properties of our bucket INSERT-networks. In Lemma 5.2, we consider a single copy of the bucket version of I_h. This is an analogue of Lemma 4.3. Finally, Lemma 5.3 summarizes the properties of the whole construction.

LEMMA 5.1. *For each $k \geq 2$ there is an explicit construction of a standard k-input MINMAX-network M_k such that $depth(M_k) \leq 2 \log k$ and $delay(M_k) \leq 4$.*

Proof. The recursive construction of M_k that we give is applicable for $k \geq 6$ (see also Figure 5.2). The construction of the network for the initial values of k is straightforward: $M_2 = \{[0:1]\}$, $M_3 = \{[0:1]\}\{[0:2]\}\{[1:2]\}$, $M_4 = \{[0:3],[1:2]\}\{[0:1],[2:3]\}$, and $M_5 = \{[0:4],[1:2]\}\{[0:1],[3:4]\}\{[0:3],[2:4]\}$. Let $k \geq 6$. It is easier to give the recurrence for the reversed sequence of stages. Therefore, assume that $\mathrm{rev}(A)$ denotes a network A after reversing the sequence of stages of A; that is, $\mathrm{rev}(A) = S_d, S_{d-1}, \ldots, S_1$ if $A = S_1, \ldots, S_d$:

$$\mathrm{rev}(M_k) \stackrel{\mathrm{def}}{=} (\{[0:1],[\lceil k/2\rceil - 1 : k-1]\},\{[0:\lceil k/2\rceil],[k-2:k-1]\},\{[0:k-1]\}) \\ \cup (\mathrm{rev}(M_{\lceil k/2\rceil - 1})^{\Rightarrow 1} \Downarrow 1) \cup (\mathrm{rev}(M_{\lfloor k/2\rfloor - 1})^{\Rightarrow 2} \Downarrow \lceil k/2\rceil).$$

Note that in order to obtain $delay(M_k) \leq 4$, the upper subnetwork $M_{k/2-1}$ is shifted one position to the right compared to the lower one. The reason is that registers of the upper subnetwork are used outside it in the last stage only, while registers of

the lower one are used one stage earlier. Clearly, the network is correctly defined. Moreover, the depth of M_k is bounded by

$$\max(\mathit{depth}(M_{\lceil k/2\rceil-1})+1, \mathit{depth}(M_{\lfloor k/2\rfloor-1})+2),$$

and this is at most $2\log(k/2)+2 = 2\log k$. To see that $\mathit{delay}(M_k)$ is at most 4, notice that the external registers 0 and $k-1$ are used only in the last three stages. □

FACT 5. *For $k > 2$ and $j > 0$ let N_k denote the j-fault subnetwork of M_k. If for some input $\overline{x} \in 1\{0,1\}^{k-2}0$ the output of N_k has the property $(\overline{x}N_k)[0] = 1$ and $(\overline{x}N_k)[k-1] = 0$, then $j \geq 2$.*

Proof. Assume to the contrary that the conditions from Fact 5 hold and that $j = 1$. Then $[0 : k-1]$ is the only faulty comparator in N_k. Consider the initial contents of the register 1, which is different from registers 0 and $k-1$, when $k > 2$. If $\overline{x}[1] = 0$, then the comparator $[0:1]$ must also be faulty. If $\overline{x}[1] = 1$, then this 1 is moved to the register $\lceil k/2\rceil - 1$ (or 2 if $k = 4$), and then also the comparator $[\lceil k/2\rceil - 1 : k-1]$ ($[2:3]$, respectively) must be faulty—a contradiction. □

Informally speaking, Fact 5 says that to destroy both MIN and MAX outputs of M_k we need at least two faulty comparators if $k > 2$. For $k = 2$ we obtain the same effect when we repeat the network $M_2 = \{[0:1]\}$ twice.

To make all our notation simpler, from now on we assume that $k > 2$ and $N = pk$, that is, that the set of registers can be exactly divided into p buckets of k registers each.[4] Thus, we are dealing with the INSERT-network of p inputs. For $m = 0, 1, \ldots, p-1$, let $l_m = mk$ and $u_m = (m+1)k - 1$. Define transportation network $T_{N,k}$ (compare Figure 5.1) to be

$$T_{N,k} \stackrel{\text{def}}{=} \{[u_{m-1} : l_m] : 0 < m < p\}^{\Rightarrow \mathit{depth}(M_k)} \cup \bigcup_{m=0}^{p-1} (M_k \Downarrow l_m).$$

Note that $\mathit{depth}(T_{N,k}) \leq 2\log k + 1$ and $\mathit{delay}(T_{N,k}) \leq 4$. Since $T_{N,k}$ can transport 1^*s between adjacent buckets, to move s such items by the distance of $h+1$ buckets we need $h+1+s$ copies of $T_{N,k}$. If, in addition, j comparators can be faulty, the number of copies increases to $h+1+s+j$. Because, in the case of correction network, $s+j \leq k$, we take $h+k+1$ copies of $T_{N,k}$ with the total depth upper-bounded by $2\log k + 1 + 4(h+k) \leq 4\log N + 4k$.

Now we are going to show how I_h is transformed into the bucket version. Note that the INSERT-network that we need has exactly p inputs; therefore we choose h such that $3 \cdot 2^{h-1} \leq p \leq 3 \cdot 2^h - 1$. If there are superfluous registers in I_h, the last ones should be deleted (cf. the proof of Theorem 1.1).

To describe the transformation, we need the structure of incoming and outgoing comparators of each register in I_h. Recall that comparators involving a register i can only appear at stages $S_{\mathit{fst}(i,I_h)}, S_{\mathit{fst}(i,I_h)+1}, \ldots, S_{\mathit{lst}(i,I_h)}$. By simple induction one can check that the sequence of comparators for a register i satisfies the following properties.

FACT 6. *For each register i, $1 \leq i \leq 3 \cdot 2^h - 1$, in the network $I_h = S_1, S_2, \ldots, S_d$ the following hold:*

1. *if $[i : *] \in S_{\mathit{fst}(i,I_h)}$, then $\mathit{lst}(i, I_h) \leq \mathit{fst}(i, I_h) + 1$ and $[* : i] \notin S_{\mathit{fst}(i,I_h)+1}$;*
2. *if $[* : i] \in S_{\mathit{fst}(i,I_h)}$, then*
   - *$[* : i] \notin S_{\mathit{fst}(i,I_h)+1} \cup S_{\mathit{fst}(i,I_h)+2}$,*

[4] In the general case, we can take the first (upper) bucket smaller.

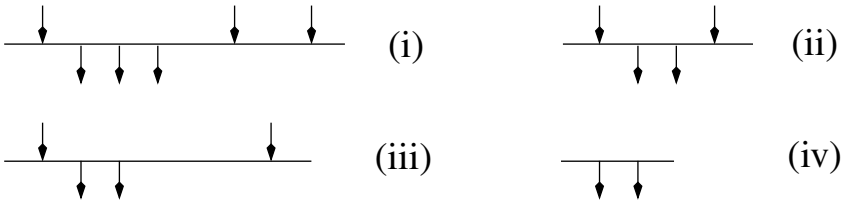

FIG. 5.3. *The four basic cases of a comparator sequence for register i in I_h.*

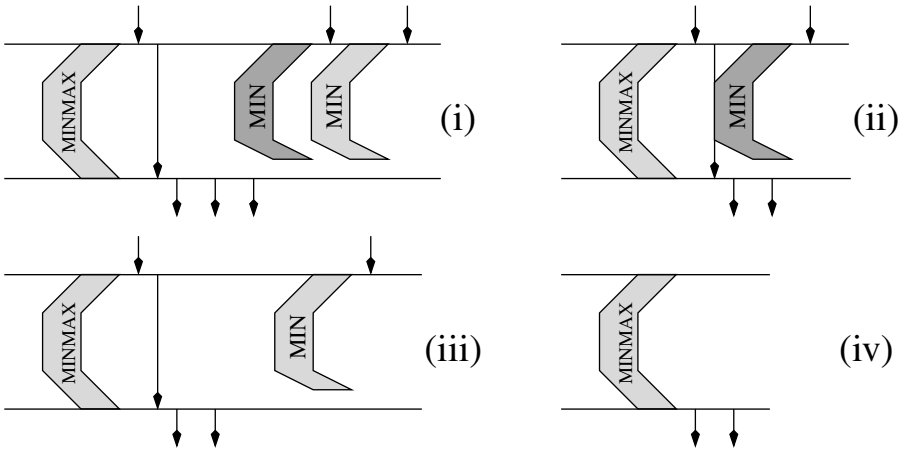

FIG. 5.4. *The structure of buckets in the bucket version of I_h.*

- $i \notin support(S_{fst(i,I_h)+4})$,
- $[i:*] \notin S_{fst(i,I_h)+5} \cup S_{fst(i,I_h)+6} \cup S_{fst(i,I_h)+7}$,
- *if* $[*:i] \in S_{fst(i,I_h)+3}$, *then* $lst(i,I_h) = fst(i,I_h)+3$,
- *if* $[*:i] \in S_{fst(i,I_h)+6}$, *then* $i \notin support(S_{fst(i,I_h)+3} \cup S_{fst(i,I_h)+5} \cup S_{fst(i,I_h)+7})$,
- *if* $[i:*] \in S_{fst(i,I_h)+3}$, *then* $i \notin support(S_{fst(i,I_h)+6})$,
- *if* $[l:i] \in S_{fst(i,I_h)+j}$ *and* $j \geq 1$, *then* $[l:j]$ *is a correcting comparator.*

These properties of the sequence of comparators for a register i are depicted in Figure 5.3. It shows that the sequence is a subsequence of one of the four basic sequences.

Our transformation consists of the following steps:

1. replace each comparator $[i:j]$ by $[u_i:l_j]$, where $u_i = i \cdot k + k - 1$ and $l_j = j \cdot k$;
2. insert an empty stage after each stage of I_h;
3. put the MINMAX-networks M_k, the MIN-networks M'_k (to be described below), and an additional comparator inside buckets, as shown in Figure 5.4.

The M'_k network is obtained from the M_k network by deleting comparators incoming to the last (MAX) register. Let $J_{N,k}$ denote the whole network after the transformation. For example, $J_{11k,k}$ is depicted in Figure 5.1.

To define $J_{N,k}$ formally, let $N = pk$ and $A_p = S_1, S_2, \ldots, S_d$ denote the network I_h, $3 \cdot 2^{h-1} \leq p \leq 3 \cdot 2^h - 1$, after deleting registers $p+1, p+2, \ldots, 3 \cdot 2^h - 1$ and all comparators that use them. Let $B_{N,k} = T_1, T_2, \ldots, T_{2d}$ denote the network after transformations 1 and 2; that means that $T_2 = T_4 = \cdots = T_{2d} = \emptyset$ and $T_{2l-1} = \{[u_i:l_j] : [i:j] \in S_l\}$, $l = 1, 2, \ldots, d$. Moreover, let $C_{k,m}$ be the network put in bucket

m, $0 \le m < p$, that is, $C_{k,m} = M_k \cup \{[0 : k-1]^{\Rightarrow depth(M_k)+1} : [* : m] \in S_{fst(m,A_p)}\} \cup \bigcup\{(M'_k)^{\Rightarrow 2j} : [* : m] \in S_{fst(m,A_p)+j} \wedge j \ge 1\}$. Finally, let

$$J_{N,k} \stackrel{\text{def}}{=} (B_{N,k})^{\Rightarrow depth(M_k)} \cup \bigcup_{m=0}^{p-1} (C_{k,m} \Downarrow l_m)^{\Rightarrow 2fst(m,A_p)-2}.$$

Due to Fact 6, the above definition is correct. One can verify that $depth(J_{N,k}) \le 4\log N + 3$ and $delay(J_{N,k}) \le 18$.

Furthermore, with respect to Fact 5, one faulty comparator inside a MINMAX-network cannot cause both MIN and MAX outputs to be faulty. If such a comparator destroys the MIN output (respectively, MAX output), the effect is as though the next incoming (respectively, outgoing) comparator had been faulty. This effect leads us, informally, to an assumption that only comparators between buckets become faulty and to an analysis of the networks as in the case of INSERT-networks. Formally, we will prove an analogue of Lemma 4.3 for the bucket version of I_h.

Consider an input $\overline{x} \in \{0,1\}^N$ that has l 1^*s among zeroes and $N-t-l$ ones at its end; that is, $\overline{x} = 0^{j_0}10^{j_1}10^{j_2}\dots10^{j_l}1^{N-t-l}$, where $0 \le l \le k$, $j_0, j_1, \dots, j_{l-1} \ge 0$, $j_l \ge 1$, and $\sum_{m=0}^{l} j_m = t$. We say that a comparator $[u_i : l_j]$ between buckets i and j is active with respect to t if $l_j \le t$. Since the structure of active comparators outgoing from a bucket i is the same as in I_h, we can use equality (4.1) to define $c_h(i,t)$, the weight of the bucket i with respect to t. Let $i_1 = \lfloor j_0/k \rfloor, i_2 = \lfloor (j_0 + j_1 + 1)/k \rfloor, \dots, i_l = \lfloor (j_0 + \dots + j_{l-1} + l - 1)/k \rfloor$ denote the indices of buckets that contain 1^*s. Then the weight of $\overline{x}$ is defined to be

$$C_h(\overline{x}, t) \stackrel{\text{def}}{=} \sum_{j=1}^{l} c_h(i_j, t).$$

LEMMA 5.2. *Let $k > 2$, $N = pk$, and h be such that $3 \cdot 2^{h-1} \le p \le 3 \cdot 2^h - 1$. Let $\overline{x} = 0^{j_0}10^{j_1}10^{j_2}\dots10^{j_l}1^{N-t-l}$, where $0 \le l \le k$, $j_0, j_1, \dots, j_{l-1} \ge 0$, $j_l \ge 1$, and $\sum_{m=0}^{l} j_m = t$. Moreover, let $J'_{N,k}$ denote any s-fault subnetwork of $J_{N,k}$ and $\overline{y} = \overline{x}J'_{N,k}$. If the weight $C_h(\overline{x}, t)$ is positive, then*

$$C_h(\overline{y}, t) - C_h(\overline{x}, t) \le s - 1.$$

Proof. Let $J_{N,k} = R_1R_2\dots R_D$ and $J'_{N,k} = R'_1R'_2\dots R'_D$, where $D = depth(J_{N,k})$ and $R'_i \subseteq R_i$, $i = 1, \dots, D$. Let $\overline{x}_i = \overline{x}R'_1R'_2\dots R'_i$, $i = 0, \dots, D$. We say that a comparator $[u_i : l_j] \in R_m$ between buckets i and j is an *exchanging* comparator with respect to $J'_{N,k}$ and $\overline{x}$ if it really exchanges 0 with 1, that is, if $[u_i : l_j] \in R'_m$ and $\overline{x}_{m-1}[u_i] = 1$ and $\overline{x}_{m-1}[l_j] = 0$ (hence $\overline{x}_m[u_i] = 0$ and $\overline{x}_m[l_j] = 1$). Only exchanging comparators move ones among buckets and, therefore, can change the weight of the sequence $\overline{x}_i$. Let $E(J'_{N,k}, \overline{x})$ denote the set of all exchanging comparators with respect to $J'_{N,k}$ and $\overline{x}$. One can easily observe that

$$C_h(\overline{y}, t) - C_h(\overline{x}, t) = \sum_{[u_i:l_j] \in E(J'_{N,k}, \overline{x})} c_h(j, t) - c_h(i, t).$$

For each i, there is at most one exchanging comparator $[u_i : *]$ outgoing from a bucket i, since all outgoing comparators are applied one after another (cf. Figure 5.4). To prove the lemma, we would like to assign to each bucket i a set of faulty comparators F_i such that $F_i = \emptyset$ if there are no exchanging comparators outgoing from i, or

else it contains enough elements to get $c_h(j,t) - c_h(i,t) \leq |F_i|$, where $[u_i : l_j]$ is the exchanging comparator. In addition, all these sets should be pairwise disjoint.

Let f_i be the number of active comparators outgoing from a bucket i that precede an exchanging comparator $[u_i : l_j]$. By the definition of c_h, $c_h(i,t) \geq c_h(j,t) - f_i$. Therefore, we have only to choose f_i faulty comparators for F_i. Since the preceding comparators do not move the 1 located in the ith MAX-register down, they have to be faulty or blocked by another 1 in their destination registers. The faulty comparators are inserted directly into F_i. In case of a blocked comparator, there is a 1 in the MIN-register of its destination bucket. The bucket cannot be full, because of our definition of active comparators. That means that there must be a faulty comparator in the subnetworks M_k or M'_k which precede the comparator in question in the destination bucket. We make it also a member of F_i. Sets F_i, $i = 0, 1, \ldots, p-1$, are pairwise disjoint, because each faulty active comparator is inserted into at most one set F_i, and the faulty comparators responsible for blocking 1's are selected from different subnetworks.

Summing up the inequalities, we would get $C_h(\overline{y},t) - C_h(\overline{x},t) \leq \sum_{i=0}^{p-1} f_i \leq s$. In order to get the stronger upper bound $s-1$, we will show that at least one of the following situations always must occur:

(i) there is an exchanging comparator that is also a correcting comparator;

(ii) there is an exchanging comparator that moves a 1 from a bucket with some positive weight to a bucket with zero weight;

(iii) there exists a faulty comparator outside $\bigcup_{i=0}^{p-1} F_i$.

In cases (i) and (ii), for at least one exchanging comparator $[u_i : l_j]$ we have a stronger upper bound $c_h(j,t) - c_h(i,t) \leq -1$. The result follows. In case (iii), obviously, $\sum_{i=0}^{p-1} f_i \leq s-1$. To finish the proof, we assume that (i) and (ii) do not hold, and we prove (iii).

Consider a bucket with the highest index i_{max} such that $c_h(i_{max},t) > 0$ and such that bucket contains at least one 1 at the moment when the sequence $\overline{y}$ is in the registers. Such a bucket must exist, because (ii) does not hold and there are buckets with positive weights at the moment when $\overline{x}$ is in registers. Since $c_h(i_{max},t) > 0$, there are active comparators outgoing from i_{max}, but none of them is an exchanging comparator, due to our assumption. This can only be caused by one of the following situations:

1. The bucket i_{max} contained 1's at the beginning, but no 1 was moved to the MAX-register due to faulty comparators in the subnetwork M_k. Due to Fact 5, we can select a faulty comparator which is not in $\bigcup_{i=0}^{p-1} F_i$.
2. The bucket i_{max} contained a 1 at the beginning that was moved to the MAX-register, but all active comparators outgoing from i_{max} were faulty or blocked. We can select at least one faulty comparator as in the case of F_i. Recall that $F_{i_{max}}$ is empty in this case.
3. The bucket i_{max} contained no 1's at the beginning. The 1 which is in the bucket at the end could only be moved there by the first incoming comparator (the second and the third one, if they exist, are correcting and could not be exchanging due to the assumption that (i) does not hold). The 1 is blocked in the bucket by the next faulty comparator $[l_{i_{max}} : u_{i_{max}}]$ or by faulty/blocked outgoing comparators, as in the previous case. □

Repeating the further arguments from section 4, we get that if an $\overline{x}$ with l 1*s is given as an input to the bucket INSERT-network and $C_h(\overline{x},t) \leq l$ holds, then k copies of $J_{N,k}$ are enough to obtain an output $\overline{y}$ with $C_h(\overline{y},t) = 0$ and to have a network resistant to $k-l$ faults. Since buckets of weight 0 are at the distance of at most $h+1$

buckets from the zero/one border, the previously described network $T_{n,k}^{(h+k+1)}$ will gather all 1^* in one "border" bucket. To end up with the sorted sequence, we must only sort the bucket. Thus, the bucket fault-tolerant INSERT-network is defined to be

$$L_{N,k} \stackrel{\text{def}}{=} J_{N,k}^{(k)} \cup (T_{n,k}^{(h+k+1)})^{\Rightarrow depth(J_{N,k}^{(k)})}.$$

The total depth of the network is bounded by $4\log N + 3 + 18(k-1) + 4\log N + 4k = O(\log N + k)$. An output of the network will be sorted by the third part of our CORRECT 1^*s network, namely, by $3k$ stages of odd-even transposition. Formally, we have the following lemma.

LEMMA 5.3. *Let $k > 2$, $N = pk$, and h be such that $3 \cdot 2^{h-1} \le p \le 3 \cdot 2^h - 1$. Let $\overline{x} = 0^{j_0}10^{j_1}10^{j_2}\ldots10^{j_l}1^{N-t-l}$, where $0 \le l \le k$, $j_0, j_1, \ldots, j_{l-1} \ge 0$, $j_l \ge 1$, and $\sum_{m=0}^{l} j_m = t$. Moreover, let $0 \le s \le k-l$, $L'_{N,k}$ denote any s-fault subnetwork of $L_{N,k}$, and $\overline{y} = \overline{x}L'_{N,k}$. If the weight $C_h(\overline{x}, t)$ is not greater than l, then the output $\overline{y}$ is sorted except for the contents of bucket $t' = \lfloor t/k \rfloor$; that is,*

$$\Big[(y[0], \ldots, y[kt'-1]) = 0^{kt'} \wedge (y[k(t'+1)], \ldots, y[N-1]) = 1^{N-k(t'+1)}\Big].$$

Proof. Let s_i, $0 < i \le k$, denote the number of faulty comparators in the ith copy of $J_{N,k}$, and let $s' = s - \sum_{i=1}^{k} s_i$. Moreover, let $\overline{x}_i$ be the contents of registers after the execution of the ith (faulty) copy of $J_{N,k}$, and let $\overline{x}_0 = \overline{x}$. First, we would like to prove that $C_h(\overline{x}_k, t)$ is zero. To this end, assume to the contrary that $C_h(\overline{x}_k, t) > 0$. Due to the definition, all weights $C_h(\overline{x}_i, t)$, $0 \le i \le k$, must be positive. By Lemma 5.2, for each i, $0 \le i \le k$, we have

$$C_h(\overline{x}_i, t) - C_h(\overline{x}_{i-1}, t) \le s_i - 1.$$

Summing up the inequalities, we get $C_h(\overline{x}_k, t) - C_h(\overline{x}_0, t) \le (\sum_{i=1}^{k} s_i) - k$. Since $C_h(\overline{x}_0, t) \le l$ and $s + l \le k$, we finally get $C_h(\overline{x}_k, t) \le 0$, which is a contradiction.

Let us define the *bucket distance* between registers i and j to be $\lfloor j/k \rfloor - \lfloor i/k \rfloor$. The *bucket length* of a comparator $[i : j]$ is the bucket distance between i and j. Obviously, the bucket length of $[u_i : l_j]$ is equal to the length of $[i : j]$. Due to Fact 2, the bucket distance between a register i such that $i < t$ and $\overline{x}_k[i] = 1$ and the register t is at most h. Since $\lfloor t/k \rfloor + 1$ is the index of the last bucket that can contain zeroes in $\overline{x}_k$, the goal of an s'-fault subnetwork of $T_{N,k}^{(h+k+1)}$ is to transport all (at most l) 1^*s by the bucket distance of at most $h+1$.

In the s'-fault subnetwork of $T_{N,k}^{(h+k+1)}$ there are at least $h + k + 1 - s' \ge h + l + 1$ fault-free copies of $T_{N,k}$. The standard analysis of odd-even transposition among consecutive buckets (cf. [6, pp. 139–144]) shows that this number of transposition levels is enough to fill up bucket $t' + 1$ and gather all other 1^*s in bucket t'. □

In the next section, we describe a network that moves 1^*s to buckets whose weights are bounded by 1 each.

6. The movement network. The aim of the movement network is to place all 1^*s in buckets with weights at most one. The idea of the movement is the same as in the construction of Schimmler and Starke [12]. It can be summarized as follows:

(i) comparators between buckets create a forest of binary trees, where the goal of each tree is to place the maximum of the numbers in its nodes in the root;

(ii) the maximum in a binary tree is sought by applying in each node the following simple procedure: compare-exchange numbers with its children and then with its parent.

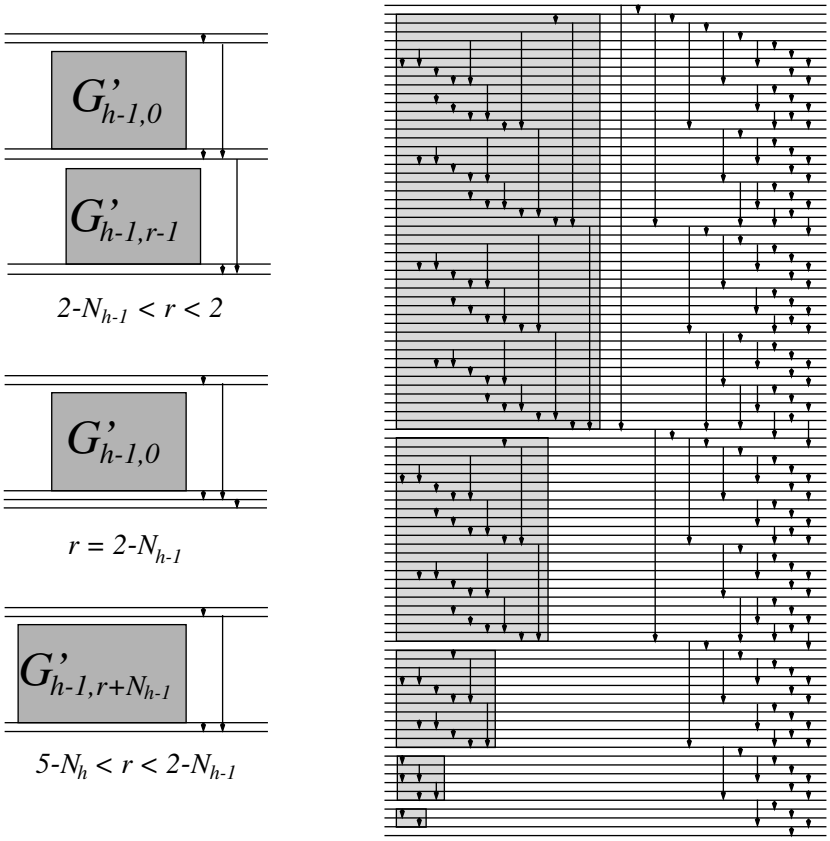

FIG. 6.1. *The recursive structure of $G_{h,r}$ and the F_5 network in front of I_5.*

In our case, the structure of binary trees should reflect the structure of I_h defined in section 4. For example, registers in I_h should be divided into the following groups: the register number 0 has always the weight at most 1; registers $1, 2, \ldots, N_{h-1}$ can have bigger weights, and therefore we should construct a binary tree on them with the root in $N_{h-1} + 1$, where the weight is again at most 1; and so on. In general, our forest is defined on $N_h = 3 \cdot 2^h - 1$ registers as

$$F_h \stackrel{\text{def}}{=} \bigcup_{i=1}^{h} G_{h-i,+1} \Downarrow (N_h - N_{h-i+1} + 1).$$

Before we formally define the subnetworks of F_h, let us look for a moment at the sample network F_5 in Figure 6.1. It consists of 95 registers numbered $0, 1, \ldots, 94$. Assume that we put an input sequence $0^i 10^{45-i} 1^{49}$, $0 \leq i < 45$, into them. To see what F_5 is doing, let us try first to answer the following question: If F_5 were not in front of I_5, what would be the values of i for which the input would be sorted by one fault-free copy of I_5?

For the inputs under consideration, active comparators of I_5 are all above the border between registers 45 and 46. Therefore, we have only one sequence of consecutive active comparators that ends at register 45, namely, the sequence $[0 : 1]$, $[1 : 25]$, $[25 : 37]$, $[37 : 43]$, $[43 : 44]$, $[44 : 45]$. Thus the answer is that i should be in the

set $\{0,1,25,37,43,44,45\}$. If i is not in this set, we need F_5 in front of I_5: the aim of F_5 is to move 1 from any input register i, $0 \le i < 45$, to the output register in the set. For example, if $1 \le i \le 25$, then the output is in register 25; if $26 \le i \le 37$, then the output is in register 37; and so on. Note that for each i in the set we have $c_5(i,45) \le 1$, where c_h is the weight function defined in section 4.

$G_{h,r}$ is a network corresponding to a binary tree and is defined on $N_h + r$ registers, where an integer $r \le 1$ can be negative; it is a MAX-network. Since it should reflect the structure of I_h and, moreover, should have a small delay, the sons of the root $N_h + r - 1$ are $N_h + r - 2$ and $N_{h-1} + 1$. In addition, 0 should be a son of 1. Formally, we will define $G_{h,r}$ with the help of another recursively defined MAX-network $G'_{h,r}$, which does not change the contents of register 0 and finds the maximum value in all other registers. Let $G'_{0,+1} \stackrel{\text{def}}{=} \{[1:2]\}$ and $G'_{0,r} \stackrel{\text{def}}{=} \emptyset$ for $r \le 0$. Then

$$G_{h,r} \stackrel{\text{def}}{=} \begin{cases} G'_{h,r} \cup \{[0:1]\}^{\Rightarrow depth(G'_{h,r})-3}, & 1 - N_{h-1} < r \le 1, \\ G'_{h,r} \cup \{[0:1]\}^{\Rightarrow depth(G'_{h,r})-2}, & 3 - N_h < r \le 1 - N_{h-1}, \\ G'_{h,r} \cup \{[0:1]\}, & r = 3 - N_h, 2 - N_h, \\ \emptyset, & r < 2 - N_h. \end{cases}$$

As in the case of MINMAX-network M_k, it would be easier to define the sequence of stages of $G'_{h,r}$ in reverse order. Let $lst_h = N_h + r - 1$, $mid_h = N_{h-1} + 1$, and

$$B_h^1 \stackrel{\text{def}}{=} \{[mid_h : lst_h]\}\{[1 : mid_h], [lst_h - 1 : lst_h]\}\{[mid_h - 1 : mid_h]\},$$
$$B_h^2 \stackrel{\text{def}}{=} \{[lst_h - 1 : lst_h]\}\{[1 : lst_h - 1]\}\{[lst_h - 2 : lst_h - 1]\},$$
$$B_h^3 \stackrel{\text{def}}{=} \{[1 : lst_h]\}\{[lst_h - 1 : lst_h]\},$$

$$\operatorname{rev}(G'_{h,r}) \stackrel{\text{def}}{=} \begin{cases} B_h^1 \cup \operatorname{rev}(G'_{h-1,r-1})^{\Rightarrow 2} \Downarrow N_{h-1} \cup \operatorname{rev}(G'_{h-1,0})^{\Rightarrow 3} \Downarrow 1, & \\ & 2 - N_{h-1} < r \le 1, \\ B_h^2 \cup \operatorname{rev}(G'_{h-1,0})^{\Rightarrow 3} \Downarrow 1, & r = 2 - N_{h-1}, \\ B_h^3 \cup \operatorname{rev}(G'_{h-1,N_{h-1}+r})^{\Rightarrow 2} \Downarrow 1, & 3 - N_h < r \le 1 - N_{h-1}, \\ \{[1:2]\}, & r = 3 - N_h, \\ \emptyset, & r < 3 - N_h. \end{cases}$$

Both networks $G_{h,r}$ and $G'_{h,r}$ have depth not greater than $3h$ since we add at most three new stages at each level of the recursive definition. The delay of the networks is at most 3, because each register has at most two incoming and one outgoing comparators at three consecutive stages. Clearly, $G_{h,r}$ is a MAX-network, and $G'_{h,r}$ is a MAX-network of registers $1, \ldots, N_h + r - 1$. The following lemma states that, whenever F_h is applied to an input with one 1^* inside t zeroes, the 1^* is output in register j such that $c_h(j,t) \le 1$.

LEMMA 6.1. *Let $h \ge 0$, $2 - 3 \cdot 2^h \le r \le 1$, and let X denote one of the networks F_h, $G_{h,+1}$, or $G'_{h,r}$. Moreover, let $t \ge 1$ be smaller than the number of registers in X. Then for each input $\overline{x} = 0^i 10^{t-i} 1^*$, $0 \le i < t$, the output $\overline{y} = \overline{x}X$ is of the form $0^j 10^{t-j} 1^*$, $0 \le j \le t$, and $c_h(j,t) \le 1$.*

Proof. The proof is by induction on h. If $h = 0$, there is at most one active comparator in X. Therefore, for each register j of X and any admissible t, we have $c_0(j,t) \le 1$ (cf. Definition 4.1).

Assume now that $h > 0$ and that the lemma holds for $h - 1$. Observe first that $F_h = G_{h-1,+1} \cup F_{h-1} \Downarrow N_{h-1}$. If $t \le N_{h-1}$, then active comparators in I_h are the same

as in I_{h-1}. Thus $c_h(j,t) = c_{h-1}(j,t)$ for any $1 \le j \le t$, and we can use an inductive hypothesis about $G_{h-1,+1}$. Otherwise, $t \ge N_{h-1}+1$, and the network $G_{h-1,+1}$ gets at most one 1 in its registers. Since $G_{h-1,+1}$ is a MAX-network, it moves the 1 to the register $N'_h = N_{h-1}+1$. Thus we should prove that in this case $c_h(N'_h,t) \le 1$. To this end we need the recursive structure of c_h observed in the proof of Lemma 4.5—$c_h(j,t) = c_{h-1}(j-N'_h, t-N'_h)$ for $N'_h \le j \le t < N_h$—and the first statement from the lemma: $c_h(0,t) \le 1$. Substituting $j = N'_h$, we get the result. If there is no 1 in the first N'_h+1 registers, the problem is reduced to the network F_{h-1} and the lemma follows from the inductive assumption.

Since quite similar arguments also work for networks $G_{h,+1}$ and $G'_{h,r}$, we leave the rest of the proof to the interested reader. □

Having the network F_h, we can create its bucket version by applying a transformation similar to that of section 5. As in the definitions there, assume that $N = pk$, where p is an integer, and choose h such that $3 \cdot 2^{h-1} \le p \le 3 \cdot 2^h - 1$. Since we now need a forest F_h with p registers only, we delete the superfluous registers $p, p+1, \ldots, 3 \cdot 2^h - 1$ and the comparators pointing to them. After that the following transformations are made to the network:

1. replace each comparator $[i:j]$ by $[u_i : l_j]$, where $u_i = i \cdot k + k - 1$ and $l_j = j \cdot k$;
2. insert an empty stage after each stage of F_h;
3. put the MINMAX-networks M_k in front of the first comparator in each bucket j and an additional comparator $[l_j : u_j]$ between incoming and outgoing comparators of the bucket. (Note that in each bucket there is at most one outgoing comparator and at most two incoming ones that precede it.)

Let $K_{N,k}$ be the network after the transformations. Its delay is still a constant, and we can use copies of $K_{N,k}$ to move all 1^*s to buckets of weight at most 1. Moreover, we have a network resistant to faulty comparators. Evidently, it is enough to take k copies, since the sum of the number of faulty comparators in $K^{(k)}_{N,k}$ and the number of 1^* in an input is not greater than k.

LEMMA 6.2. *Let $k \ge 2$, $N = pk$, and h be such that $3 \cdot 2^{h-1} \le p \le 3 \cdot 2^h - 1$. Let $\overline{x} = 0^{j_0}10^{j_1}10^{j_2}\ldots10^{j_l}1^{N-t-l}$, where $0 \le l \le k$, $j_0, j_1, \ldots, j_{l-1} \ge 0$, $j_l \ge 1$, and $\sum_{m=0}^{l} j_m = t$. Moreover, let $K'_{N,k}$ denote any s-fault subnetwork of $K^{(k)}_{N,k}$, where $s \le k - l$. Then $C_h(\overline{x}K'_{N,k}, t) \le l$.*

Proof. One can observe that there are at least l fault-free copies of $K_{N,k}$ in $K'_{N,k}$. Each fault-free copy takes a 1^* from the last nonempty bucket with weight greater than 1 and moves it to a bucket with weight less than or equal to 1, due to Lemma 6.1. From its destination bucket there is no active outgoing comparator. Therefore, faulty copies cannot move such a 1^* further. After application of all fault-free copies, all l 1^*s are in buckets with weight upper-bounded by 1. The result follows. □

Based on Lemma 6.2, we can choose $K^{(k)}_{N,k}$ as our bucket movement network. Since $delay(K_{N,k}) \le 9$ and $depth(K_{N,k}) = O(\log N)$, the total depth of the bucket movement network is $O(\log n + k)$.

We finish this section by proving Lemma 3.1.

Proof of Lemma 3.1. Our N-input CORRECT^1_k-network is a concatenation of three networks: $K_{N,k}$ described above, $L_{N,k}$ presented in the previous section, and the standard odd-even transposition network $O_{N,k}$ of depth $3k$ [6, pp. 139–144]. The required correcting and fault-tolerance properties of the first two parts follow from Lemmas 6.2 and 5.3. The aim of $O_{N,k}$ is to sort the remaining unsorted area of size k. In the fault-free model, k stages of odd-even transposition suffice to sort such an area (see [6]). In the k-fault model, there could be up to k faulty stages in

$O_{N,k}$. Nevertheless, there still remain k alternating fault-free stages of odd-even and even-odd comparators that will sort the area. □

7. Concluding remarks. We have presented a construction of N-input k-fault-tolerant sorting networks with asymptotically optimal depth $O(\log N + k)$. The main part of the construction is the fault-tolerant correcting network, which consists of two subnetworks itself: $\mathrm{CORRECT}_k^1$ and $\mathrm{CORRECT}_k^0$. Each subnetwork performs three tasks in sequence: first, it moves the inserted items into selected buckets, then it inserts them into the destination bucket, and finally, it sorts all buckets. The part performing each task has been made fault-tolerant by pipelining a certain number of copies of a constant-delay network. One can observe that instead of pipelining we can get the same result by using in cycle a network of constant depth with output recirculated back as input. Such networks are called *constant-periodic*. Thus, our correcting networks can be implemented as a sequence of constant-periodic networks. An interesting question is whether the whole network can be made constant-periodic without significant increase in correction time. For the fault-free case, efficient constant-periodic sorting networks were presented in [5].

Acknowledgments. The author thanks Yuan Ma for his helpful discussion about the first version of the construction. Many thanks also to anonymous referees and Mirosław Kutyłowski for their comments on the paper.

ARITHMETIC CIRCUITS AND POLYNOMIAL REPLACEMENT SYSTEMS*

PIERRE MCKENZIE†, HERIBERT VOLLMER‡, AND KLAUS W. WAGNER§

Abstract. This paper addresses the problems of counting proof-trees (as introduced by Venkateswaran and Tompa) and counting proof-circuits, a related but seemingly more natural question. These problems lead to a common generalization of straight-line programs which we call polynomial replacement systems PRSs. We contribute a classification of these systems and we investigate their complexity. Diverse problems falling within the scope of this study include, for example, counting proof-circuits and evaluating $\{\cup, +\}$-circuits over the natural numbers. A number of complexity results are obtained, including a proof that counting proof-circuits is #P-complete.

1. Introduction.

1.1. Motivation. When + and × replace ∨ and ∧ in Figure 1, the gate g_1 on input $x_1 = x_2 = 1$ evaluates to 9. Equivalently, the tree-like Boolean circuit T obtained from the circuit in Figure 1 has nine *proof-trees* [24], i.e., nine different minimal subcircuits witnessing that T outputs 1 (gates replicated to form T are independent). This relationship between proof-tree counting and monotone arithmetic circuits was used by Venkateswaran [23] to characterize nondeterministic time classes, including #P [22], and by Vinay [25] to characterize the counting version of LOGCFL [20]. The same relationship triggered the investigation of $\#\mathrm{NC}^1$ by Caussinus et al. [6] and that of $\#\mathrm{AC}^0$ by Agrawal, Allender, and Datta [1]. See [4, 14, 2] for further results and for motivation to study such "small" arithmetic classes.

A recent goal has been to capture small arithmetic classes by counting objects other than proof-trees, notably paths in graphs. Allender et al. [3] succeeded in identifying appropriate graphs for $\#\mathrm{AC}^0$. Given the growing importance of counting classes, our motivation for the present work was the desire to avoid unwinding circuits into trees before counting their "proofs." Define a proof-*circuit* to be a minimal subcircuit witnessing that a circuit outputs 1. More precisely, for a Boolean circuit C and an input x, a proof-circuit is an edge-induced connected subcircuit of C which evaluates to 1 on x. This subcircuit must contain the output-gate of C, as well as exactly one C-edge into each ∨-gate and all C-edges into each ∧-gate. The reader should convince herself that the circuit depicted above, which had nine proof-trees on input $x_1 = x_2 = 1$, has only seven proof-circuits on that input.

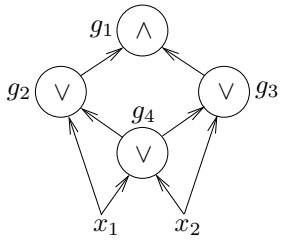

FIG. 1.

What counting classes arise from counting proof-circuits instead of trees? This question held in stock two surprises, the first of which is the following algorithm.

1. replace $\vee$ by $+$ and $\wedge$ by $\times$ in a negation-free Boolean circuit C,
2. view C as a straight-line program prescribing in the usual way a formal polynomial in the input variables $x_1, \ldots, x_n$,
3. compute the polynomial top-down, with an important proviso: at each step, knock any nontrivial exponent down to 1 in the intermediate sum-of-monomials representation.

We get the number of proof-circuits of C on an input x by evaluating the final polynomial at x! For example, the circuit depicted above had seven proof-circuits on input $x_1 = x_2 = 1$ because

$$g_1 \to g_2 g_3 \tag{1.1}$$

$$\to (x_1 + g_4) g_3 \tag{1.2}$$

$$\to (x_1 + g_4)(g_4 + x_2) \quad \to \quad x_1 g_4 + x_1 x_2 + g_4 + g_4 x_2 \tag{1.3}$$

$$\to x_1(x_1 + x_2) + x_1 x_2 + (x_1 + x_2) + (x_1 + x_2) x_2, \tag{1.4}$$

where g_4^2 became g_4 in the middle of step (1.3).

One's intuition might be that such a simple strategy could be massaged into an arithmetic circuit or at least into a sublinear parallel algorithm [21]. Our second surprise was that counting proof-circuits, even for depth-4 semiunbounded circuits, is #P-complete. Hence, not only is our strategy hard to parallelize, but it likely genuinely requires exponential time!

Our three-step algorithm above thus counts proof-*trees* in the absence of the idempotent rules $y^2 \to y$, and it counts proof-*circuits* in their presence. Moreover, whereas an arithmetic circuit computing the number of proof-*trees* of a circuit is readily available, producing such a circuit to compute proof-*circuits* seems intractable. What is special about the idempotent rules? What would the effect of multivariate rules be? Which nontrivial rules would nonetheless permit expressing the counting in the form of an arithmetic circuit? What is a general framework in which complexity questions such as these can be investigated?

1.2. Results. We view our results as forming three main contributions.

Our first contribution is to define and classify *polynomial replacement systems* (PRSs). PRSs provide the answer to the framework question. A PRS in its full generality is a start polynomial $q \in \mathbb{N}[x_1, \ldots, x_m]$ together with a set of replacement rules. A replacement rule is a pair of polynomials (p_1, p_2). Informally, (p_1, p_2) is applicable to a polynomial q if q can be written in a form in which p_1 appears. Applying (p_1, p_2) to q then consists of replacing p_1 by p_2 (see section 3 for formal definitions).

A PRS generally defines a *set* of polynomials, since the choice and sequencing of the rules, and the way in which the rules are applied, may generate different polynomials. Computational problems of interest include computing the polynomials themselves (POLY), evaluating the polynomials at specific points (EVAL), and testing membership in their ranges (RANGE). We identify four natural families of PRSs: *simple* if the rules replace only variables, *deterministic* if no two rules have the same left-hand side, *acyclic* if no nontrivial infinite sequence of rules is applicable, and *idempotent* if the rules (y^2, y) are present.

For general PRSs, we obtain canonical forms, we discuss representation, and we outline broad complexity issues. Our detailed complexity analysis involves *simple* PRSs. For instance, we exhibit simple and deterministic PRSs for which RANGE is NP-complete. When the simple and deterministic PRS is given as part of the input, POLY is P-hard and in coRP, while RANGE is NP-complete and EVAL is P-complete.

Our second contribution concerns the specific case of proof-trees and proof-circuits. We prove that, for every Boolean circuit C and input x, there is an easily computable, idempotent, simple, deterministic, and acyclic PRS S having the property that the number of proof-trees (resp., proof-circuits) of C on x is the maximum (resp., minimum) value of the EVAL problem for S on x, and vice versa (see Lemma 5.13). This offers one viewpoint on the reason why our algorithm from subsection 1.1 counts proof-circuits correctly. We also prove that computing the minimum of the EVAL problem for idempotent, simple, deterministic, and acyclic PRSs is #P-complete, or, equivalently, that counting proof-circuits is #P-complete under Turing reductions (but not under many-one reductions unless P = NP). This provides a new characterization of #P which is to be contrasted with Venkateswaran's (polydegree, polydepth) characterization [23] and with the retarded polynomials characterization of Babai and Fortnow [5]. We also prove that detecting whether a circuit has more proof-trees than proof-circuits is NP-complete.

Our third contribution concerns the specific case of a simple and acyclic PRS. We prove that the EVAL problem for such a PRS is the evaluation problem for $\{\cup, +, \times\}$-circuits. These circuits have been considered previously (under the name hierarchical descriptions) in [28, 29]. They are obtained by generalizing, from trees to general circuits, the $\{\cup, +, \times\}$-expressions (a.k.a. integer expressions), whose evaluation problem was shown to be NP-complete by Stockmeyer and Meyer [19]. From a PSPACE upper bound given in [28] we conclude that evaluation of a simple acyclic PRS has a polynomial space algorithm, and from a PSPACE-hardness result given in [30] we then conclude that the problem is PSPACE-complete.

1.3. Paper organization. Section 2 defines proof-trees and circuits, and proves complexity results about them, in a self-contained way independent from PRSs. The formal definition of a PRS, as well as their canonical forms, are found in section 3. Section 4 briefly discusses the representation of polynomials and the complexity of equivalence testing. Section 5 describes the four natural families of PRSs and relates these to straight-line programs, $\{\cup, +, \times\}$-circuits, and the proof-trees vs. proof-circuits problem. Section 6 investigates the complexity theoretic properties of simple PRSs in depth.

2. Counting circuits vs. counting trees. We assume that the reader is minimally familiar with the complexity classes TC^0, P, ZPP, RP, NP, PSPACE, EXPTIME, FP, and #P; see, for example, [9, 17, 27].

2.1. Definition of problems. By a circuit C, in this paper, we will mean a circuit over the basis $\{\wedge, \vee\}$ in the usual sense, with $2n$ inputs labeled $x_1, x_2, \ldots, x_n, \neg x_1, \neg x_2, \ldots, \neg x_n$.

Fix an input x to C. Unwind C into a tree C' by (repeatedly) duplicating gates with fan-out greater than 1. Define an *accepting subtree* as a subgraph H of C' whose gates evaluate to 1 and which additionally fulfills the following properties: Subtree H must contain the output-gate of C. For every $\wedge$-gate v in H, all the input wires of v must be in H, and for every $\vee$-gate v in H, exactly one input wire of v must be in H. Only wires and nodes obtained in this way belong to H. By $\#C(x)$ we denote the number of accepting subtrees of C.

Define an *accepting subcircuit* as a subcircuit H of C with the same properties as above (i.e., the only difference is that now we do *not* start by unwinding C into a tree). Given an input x, let $\#_c C(x)$ denote the number of accepting subcircuits of C on x.

Since an accepting subtree or subcircuit of a circuit C is some form of proof that C evaluates to 1 on the given input, we will also refer to these as *proof-trees* and *proof-circuits*, respectively. We will consider the following problems:

Problem: PT
Input: circuit C over $\{\wedge, \vee\}$, an input $x \in \{0,1\}^*$, a number k in unary
Output: $\#C(x) \bmod 2^k$

Problem: PC
Input: circuit C over $\{\wedge, \vee\}$, an input $x \in \{0,1\}^*$
Output: $\#_c C(x)$

Observe that if we unwind a circuit into a tree, there may be an exponential blowup in size, which has the consequence that the number of accepting subtrees may be doubly exponential in the size of the original circuit. This is not possible for the problem PC; the values of this function can be at most exponential in the input length. In order to achieve a fair comparison of the complexity of the problems, we therefore count proof-trees only modulo an exponential number.

2.2. Some initial reductions.

LEMMA 2.1. PT *is complete for* FP *under* $\leq_m^{\log}$.

Proof. By the well-known connection between counting accepting subtrees and the evaluation of arithmetic circuits [26, 23, 11], PT $\in$ FP since it is sufficient to evaluate such a circuit modulo an exponential number.

Let now $f \in$ FP and $x \in \{0,1\}^*$. Let f for inputs of length $|x|$ be computed by the polynomial size circuit C. Let $g_1, \ldots, g_m$ be the output-gates of C, and let $D_1, \ldots, D_m$ be those subcircuits of C whose output-gates are the gates $g_1, \ldots, g_m$. Say that C is unambiguous if for every circuit D_i there is at most one accepting subtree. We may suppose without loss of generality that C is unambiguous [13]. Now let C_i be the trivial circuit with 2^i accepting subtrees. Then $f(x)$ is equal to the number of accepting subtrees of the circuit $\bigvee_{i=1}^{m}(D_i \wedge C_i)$. □

LEMMA 2.2.

1. *The following problem is* NP*-complete under* $\leq_m^{\log}$: *Given a circuit* C*, is there an input* x *such that* $\#C(x) \neq \#_c C(x)$*?*

2. *The following problem is* P*-complete under* $\leq_m^{\log}$: *Given a circuit* C *and an input* $x \in \{0,1\}^*$*, is* $\#C(x) \neq \#_c C(x)$*?*

Proof. 1. Containment in NP is obtained by the following algorithm: On input C, guess an input x and evaluate every gate in C. Check if there is an $\vee$-gate g such

that both its inputs evaluate to 1, and there are at least 2 different paths from g to the output of C which are simultaneously contained in some accepting subtree. This latter problem is essentially the directed graph accessibility problem, since we have only to check that there are two paths from g to C's output-gate which join at some $\wedge$-gate in C, such that all gates on these paths evaluate to 1.

To prove completeness, we give a reduction from 3-SAT: Given a 3-CNF formula F, we construct an $\{\wedge, \vee\}$ circuit C_F with the same structure (that is, C_F actually is a formula). Let C' be some fixed circuit with differing numbers of accepting subtrees and subcircuits. Then the circuit $C =_{\text{def}} C_F \wedge C'$ will have $\#C(x) \neq \#_c C(x)$ for some input x if and only if F is satisfiable.

2. Observe that the algorithm given in the proof of case 1 is deterministic, once the input x is guessed. Hence the problem examined here is in P. Completeness is also shown along the lines above, this time using the P-complete circuit value problem. □

Remark 2.3. If we restrict our attention to circuits of depth d, then the problem in case 2 of the above lemma is in DSPACE(d); this is witnessed by the well-known depth-first search circuit evaluation algorithm which is used to show (uniform-)DEPTH(s) $\subseteq$ DSPACE(s).

2.3. Counting proof-circuits is #P-complete. For functions f, h, we say that $f \leq^{\log}_{1\text{-T}} h$ if there are functions g_1, g_2 computable in logarithmic space such that, for all x, $f(x) = g_1\big(x, h(g_2(x))\big)$.

THEOREM 2.4. PC *is complete for* #P *under* $\leq^{\log}_{1\text{-T}}$ *but not under* $\leq^{\text{p}}_m$ *unless* P = NP.

Proof. For a conjunctive normal form formula H with three literals per clause, define SA(H) to be the number of satisfying assignments to the variables of H. It is known (see [22]) that SA is $\leq^{\text{p}}_m$-complete for #P. We describe a $\leq^{\log}_{1\text{-T}}$-reduction from SA to PC. Let PC(C, x) denote the number of accepting subcircuits of circuit C with input x.

Let $H(x_1, \ldots, x_n) = \bigwedge_{i=1}^{m} C_i$ be a conjunctive normal form formula with three literals per clause. We define a $\{\vee, \wedge\}$-circuit C_H, all of whose inputs are set to 1, which has six levels and is stratified; i.e., the edges are only between gates of adjacent levels. The levels are as follows:

1. Level 1 consists of the input-gates v_{ikl} for $i = 1, \ldots, m$, $k = 0, \ldots, n$, and $l = 0, 1$. In the application below, all these will be set to 1.

2. Level 2 consists of the $\vee$-gates v_{ik} for $i = 1, \ldots, m$ and $k = 0, \ldots, n$. Gate v_{ik} has incoming edges from v_{ik0} and v_{ik1}.

3. Level 3 consists of the $\wedge$-gates v_i for $i = 1, \ldots, m$. Gate v_i has incoming edges from $v_{i0}, v_{i1}, \ldots, v_{in}$.

4. Level 4 consists of the $\wedge$-gates $w_1, \ldots, w_n, w'_1, \ldots, w'_n$. Gate w_j has incoming edges from all gates v_i such that x_j appears in the clause C_i. Gate w'_j has incoming edges from all gates v_i such that $\neg x_j$ appears in the clause C_i. Here, we stipulate that an $\wedge$-gate with no input wires computes the constant 1.

5. Level 5 consists of the $\vee$-gates $u_1, \ldots, u_n$. Gate u_j has incoming edges from the gates w_j and w'_j.

6. Level 6 consists of the output-gate which is an $\wedge$-gate. It has incoming edges from the gates $u_1, \ldots, u_n$.

Now let $a_1, \ldots, a_n \in \{0, 1\}$. We define the circuit $C_H^{[a_1 \cdots a_n]}$ to be that subcircuit of C_H which results from cutting the edge between w'_j and u_j if $a_j = 1$ and between w_j and u_j if $a_j = 0$ ($j = 1, \ldots, n$). The following facts are easy to see:

(i) $\mathrm{PC}(C_H, (1 \cdots 1)) = \sum_{a_1,\ldots,a_n \in \{0,1\}} \mathrm{PC}(C_H^{[a_1 \cdots a_n]}, (1 \cdots 1))$.

(ii) $(a_1, \ldots, a_n)$ satisfies exactly k clauses of H if and only if $\mathrm{PC}(C_H^{[a_1 \cdots a_n]}, (1 \cdots 1)) = 2^{k \cdot (n+1)}$.

(iii) If $(a_1, \ldots, a_n)$ satisfies H, then $\mathrm{PC}(C_H^{[a_1 \cdots a_n]}, (1 \cdots 1)) = 2^{m \cdot (n+1)}$, and if $(a_1, \ldots, a_n)$ does not satisfy H, then $\mathrm{PC}(C_H^{[a_1 \cdots a_n]}, (1 \cdots 1)) \leq 2^{(m-1) \cdot (n+1)}$.

(iv) $\mathrm{SA}(H) \cdot 2^{m \cdot (n+1)} \leq \mathrm{PC}(C_H, (1 \cdots 1)) < (\mathrm{SA}(H) + 1) \cdot 2^{m \cdot (n+1)}$.

Hence $\mathrm{SA}(H)$ can easily be computed from $\mathrm{PC}(C_H, (1 \cdots 1))$, i.e., $\mathrm{SA} \leq_{1\text{-T}}^{\log} \mathrm{PC}$.

Now, assume PC is complete for #P under $\leq_m^{\mathrm{p}}$ reductions. Let $A \in \mathrm{NP}$; then there is a function $f \in \#\mathrm{P}$ such that for all x, $x \in A \iff f(x) > 0$. Under our assumption, there is a many-one reduction g from f to PC; hence $x \in A \iff \mathrm{PC}\big(g(x)\big) > 0$. This latter condition, however, can be checked in polynomial time since the underlying Boolean circuit has a positive number of proof-circuits if and only if it evaluates to 1 (over the Boolean semiring). □

3. How to generate polynomials. A straight-line program P over variables $x_1, \ldots, x_m$ is a sequence of instructions of one of the following types: $x_i \leftarrow x_j + x_k$, $x_i \leftarrow x_j \cdot x_k$, $x_i \leftarrow 0$, $x_i \leftarrow 1$, where $j, k < i$. Every variable appears at most once on the left-hand side of the $\leftarrow$. Those variables that never appear on the left-hand side of the $\leftarrow$ are the *input variables*. The variable x_m is the *output variable*. Given values for the input variables, the values of all other variables are computed in the obvious way. The value computed by P is the value of the output variable. Let $p_P \colon \mathbb{N}^r \to \mathbb{N}$ denote the function computed in this way by P, where r is the number of input variables.

A straight-line program hence is just another way of looking at an arithmetic circuit. By the connection mentioned above between the problem of counting proof-trees and the evaluation of arithmetic circuits, we see that an obvious algorithm to determine the number of proof-trees of a circuit consists of producing the appropriate straight-line program and evaluating it in the order of its variables.

In section 1.1 we sketched an algorithm to count proof-circuits. We now give a more precise description of this algorithm: Given circuit C with input-gates $x_1, \ldots, x_n$ and inputs $a_1, \ldots, a_n \in \{0, 1\}$, let $g_1, \ldots, g_s$ be the non–input-gates of C in topological order (i.e., a total order on the gates of C which is consistent with the partial order given by the wires; hence $u < v$ whenever there is a wire from u to v).

1. Transform C into a straight-line program P as above.
2. In the following, we manipulate a polynomial p, which has variables $g_1, \ldots, g_s$, $x_1, \ldots, x_n$. Initially we set p to g_s.
3. **for** $i = s, s-1, \ldots, 1$, **do**
   1. Replace variable g_i in p by the right-hand side of that instruction in P, whose left-hand side is g_i.
   2. Transform p into the "sum-of-monomials" form.
   3. Reduce all powers of variables in p to 1; i.e., replace all z^2 by z, where z is a variable. At the end of this step, p will be a multilinear polynomial.
   4. Substitute the values of $a_1, \ldots, a_n$ for $x_1, \ldots, x_n$ and evaluate the resulting expression.

To see why this algorithm correctly counts proof-circuits, let $M(C)$ be the following nondeterministic Turing machine. On input x, $M(C)$ first evaluates all the gates of C on input x and prunes away any zero-gate. Unless the output-gate g_s of C was pruned away, $M(C)$ starts at g_s in the pruned circuit and implements a recursive procedure *evaluate*. At an $\wedge$-gate g, *evaluate* triggers consecutive recursive calls, one for each predecessor of g. At an $\vee$-gate, *evaluate* triggers a single recursive call for a

predecessor of g chosen nondeterministically. At a gate with no predecessor, *evaluate* simply accepts. It is well known that $M(C)$ has $\#C(x)$ accepting paths (see, e.g., [6]). But how can $M(C)$ be made to have $\#_c C(x)$ accepting paths instead? Simply by making sure that, whenever *evaluate* encounters a gate g a second time, g is treated as the constant gate 1: this will reflect the fact that the choice of an accepting subcircuit rooted at g was already made, on the first encounter! Let $M_c(C)$ be the machine $M(C)$ modified in this way. The algorithm of section 1.1, formalized above, precisely computes the number of accepting paths of $M_c(C)$. Encountering a gate g twice means that different paths out of g meet at an $\wedge$-gate (recall the proof of Lemma 2.2). This is equivalent, in the straight-line arithmetic program point of view, to obtaining a monomial in which g^2 appears. Replacing g^2 by g thus precisely models counting the number of accepting paths of $M_c(C)$, and thus the number of proof-circuits of C on input x.

To summarize, the algorithm to compute proof-circuits produces a polynomial (computing for argument $(x_1, \ldots, x_n)$ the number of proof-trees of circuit C on input $x_1 \cdots x_n$), which is obtained by evaluating the straight-line program given by C, but whenever possible during the computation we replace a power x^2 by x. This is only one type of a general class of *polynomial replacement systems* (PRSs), which we define below. PRSs will produce sets of polynomials from a given start polynomial, using rules replacing certain polynomials by other polynomials. This will be very similar to the way formal grammars produce sets of words from a start symbol, applying production rules.

In this paper we almost exclusively consider polynomials with nonnegative integer coefficients. This is motivated by the application to proof-trees and proof-circuits discussed above. We write $p(z_1, \ldots, z_s)$ to denote that p is such a polynomial in variables $z_1, \ldots, z_s$.

Below, the variable vector $\overline{x}$ will always be defined to consist of $\overline{x} = (x_1, \ldots, x_m)$. A variable x_i is *fictive* (or, *inessential*) in the polynomial $p(\overline{x})$ if for all $a_1, \ldots, a_m, a_i' \in \mathbb{N}$ we have $p(a_1, \ldots, a_{i-1}, a_i, a_{i+1}, \ldots, a_m) = p(a_1, \ldots, a_{i-1}, a_i', a_{i+1}, \ldots, a_m)$. This means that x_i is fictive in p if and only if p can be written as a term in which x_i does not appear.

DEFINITION 3.1. *A* polynomial replacement system (PRS) *is defined as a quadruple* $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$, *where*

(i) $\{x_1, \ldots, x_n\}$ *is the set of* terminal variables,

(ii) $\{x_{n+1}, \ldots, x_m\}$ *is the set of* nonterminal variables,

(iii) q *is a polynomial in the variables* $x_1, \ldots, x_m$, *the* start polynomial, *and*

(iv) R *is a finite set of* replacement rules, *i.e., a finite set of pairs of polynomials in the variables* $x_1, \ldots, x_m$.

How does such a system generate polynomials?

DEFINITION 3.2. *Let* $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$ *be a PRS, and let* p_1, p_2 *be polynomials in the variables* $\overline{x}$.

$$p_1 \underset{S}{\Longrightarrow} p_2 \iff_{\text{def}} \text{there exist } (p_3, p_4) \in R \text{ and a polynomial } p_5(\overline{x}, y) \text{ such that } p_1(\overline{x}) = p_5(\overline{x}, p_3(\overline{x})) \text{ and } p_2(\overline{x}) = p_5(\overline{x}, p_4(\overline{x})).$$

Let $\overset{*}{\underset{S}{\Longrightarrow}}$ *be the reflexive and transitive closure of* $\underset{S}{\Longrightarrow}$, *i.e.,* $p_1 \overset{*}{\underset{S}{\Longrightarrow}} p_2$, *if and only if there exist* $t \geq 0$ *and polynomials* $q_0(\overline{x}), q_1, (\overline{x}) \ldots, q_t(\overline{x})$ *such that* $p_1 = q_0 \underset{S}{\Longrightarrow} q_1 \underset{S}{\Longrightarrow} \cdots \underset{S}{\Longrightarrow} q_t = p_2$.

It turns out that the above form for derivations can be simplified as follows.

DEFINITION 3.3. *Let S, p_1, p_2 be as above.*

$$p_1 \underset{S}{\rightarrow} p_2 \iff_{\text{def}} \text{there exist } (p_3, p_4) \in R \text{ and polynomials } p_5(\overline{x}), p_6(\overline{x}) \text{ such that } p_1(\overline{x}) = p_5(\overline{x}) \cdot p_3(\overline{x}) + p_6(\overline{x}) \text{ and } p_2(\overline{x}) = p_5(\overline{x}) \cdot p_4(\overline{x}) + p_6(\overline{x}).$$

Let $\overset{*}{\underset{S}{\rightarrow}}$ be the reflexive and transitive closure of $\underset{S}{\rightarrow}$.

LEMMA 3.4 (normal form of replacement). *For any PRS $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$ and any polynomials $p_1(\overline{x}), p_2(\overline{x})$, we have*

$$p_1 \overset{*}{\underset{S}{\Longrightarrow}} p_2 \quad \text{if and only if} \quad p_1 \overset{*}{\underset{S}{\rightarrow}} p_2.$$

Proof. Clearly, $p_1 \underset{S}{\rightarrow} p_2$ implies $p_1 \underset{S}{\Longrightarrow} p_2$. We prove that $p_1 \underset{S}{\Longrightarrow} p_2$ implies $p_1 \overset{*}{\underset{S}{\rightarrow}} p_2$. Let $(p_3, p_4) \in R$, and let p_5 be a polynomial such that $p_1(\overline{x}) = p_5(\overline{x}, p_3(\overline{x}))$ and $p_2(\overline{x}) = p_5(\overline{x}, p_4(\overline{x}))$. We can represent p_5 as $p_5(\overline{x}, y) = \sum_{i=0}^{k} q_i(\overline{x}) \cdot y^i$ with suitable $k \geq 0$ and polynomials $q_0, q_1, \ldots, q_k$. Hence $p_1(\overline{x}) = \sum_{i=0}^{k} q_i(\overline{x}) \cdot p_3(\overline{x})^i$ and $p_2(\overline{x}) = \sum_{i=0}^{k} q_i(\overline{x}) \cdot p_4(\overline{x})^i$. Defining the polynomials

$$r_m(\overline{x}, y) =_{\text{def}} \sum_{i=0}^{m-1} q_i(\overline{x}) \cdot p_4(\overline{x})^i + \sum_{i=m}^{k} q_i(\overline{x}) \cdot p_4(\overline{x})^{m-1} \cdot p_3(\overline{x})^{i-m} \cdot y$$

for $m = 1, \ldots, k$, and

$$t_m(\overline{x}) =_{\text{def}} \sum_{i=0}^{m-1} q_i(\overline{x}) \cdot p_4(\overline{x})^i + \sum_{i=m}^{k} q_i(\overline{x}) \cdot p_4(\overline{x})^{m-1} \cdot p_3(\overline{x})^{i-m+1}$$

for $m = 1, \ldots, k+1$, we get $r_m(\overline{x}, p_3(\overline{x})) = t_m(\overline{x})$ and $r_m(\overline{x}, p_4(\overline{x})) = t_{m+1}(\overline{x})$ for $m = 1, \ldots, k$, and moreover, $t_1(\overline{x}) = p_1(\overline{x})$ and $t_{k+1}(\overline{x}) = p_2(\overline{x})$.

Consequently, $p_1 = t_1 \underset{S}{\rightarrow} t_2 \underset{S}{\rightarrow} \cdots \underset{S}{\rightarrow} t_k \underset{S}{\rightarrow} t_{k+1} = p_2$ and thus $p_1 \overset{*}{\underset{S}{\rightarrow}} p_2$. ∎

A PRS thus generates a set of polynomials; hence we have the following definition.

DEFINITION 3.5. *For a PRS $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$, let*

$$\text{POLY}(S) = \big\{ p(x_1, \ldots, x_n) \;\big|\; \text{there exists } p'(\overline{x}) \text{ such that } q \overset{*}{\underset{S}{\Longrightarrow}} p' \text{ and } p(x_1, \ldots, x_n) = p'(x_1, \ldots, x_n, a_{n+1}, \ldots, a_m) \text{ for all } a_{n+1}, \ldots, a_m \in \mathbb{N} \big\}.$$

From the set $\text{POLY}(S)$ of polynomials we derive several sets of natural numbers, whose complexities we will determine in the upcoming sections.

DEFINITION 3.6. *Let $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$ be a PRS. Define*

(i) $\text{RANGE}(S) =_{\text{def}} \big\{ p(a) \;\big|\; p \in \text{POLY}(S) \wedge a \in \mathbb{N}^n \big\}$;

(ii) $\text{EVAL}(S) =_{\text{def}} \big\{ (a, p(a)) \;\big|\; p \in \text{POLY}(S) \text{ and } a \in \mathbb{N}^n \big\}$.

Observe that if we also allow negative numbers as coefficients for our polynomials, then there are PRSs S such that $\text{RANGE}(S)$ is not decidable. This is seen as follows. By the Robinson–Matiyasevich result (see [15]), every recursively enumerable set can be represented in the form $\big\{ p(a) \;\big|\; a \in \mathbb{N}^n \big\}$, where p is a suitable n-ary polynomial with integer coefficients. Now let p be such an n-ary polynomial such that $\big\{ p(a) \;\big|\; a \in \mathbb{N}^n \big\}$ is not decidable. Defining the PRS $S_p =_{\text{def}} (\{x_1, \ldots, x_n\}, \emptyset, p, \emptyset)$, we obtain $\text{POLY}(S_p) = \{p\}$ and $\text{RANGE}(S_p) = \big\{ p(a) \;\big|\; a \in \mathbb{N}^n \big\}$.

Besides the membership problems POLY(S), RANGE(S), and EVAL(S), we also consider the corresponding *variable membership problems*.

DEFINITION 3.7.

(i) POLY$(\cdot) =_{\text{def}} \{(S,p)|\ S$ *PRS and* $p \in$ POLY$(S)\}$;
(ii) RANGE$(\cdot) =_{\text{def}} \{(S,a)|\ S$ *PRS and* $a \in$ RANGE$(S)\}$;
(iii) EVAL$(\cdot) =_{\text{def}} \{(S,a,p(a))|\ S$ *PRS*, $p \in$ POLY(S), *and* $a \in \mathbb{N}^*\}$.

4. Representations of polynomials and equivalence test. To discuss the complexity of the sets defined above we have to talk about representations of polynomials. We distinguish different kinds of representations.

DEFINITION 4.1. *Let* $p(\overline{x})$ *be a polynomial.*

1. *The* full representation *of* p *is its sum-of-monomials form. That is, we describe* p *as a sequence of vectors* $(c, e_1, \ldots, e_m)$*, each consisting of* $m+1$ *nonnegative integers, where* $c, e_1, \ldots, e_m$ *are given in unary. Such a vector stands for the monomial* $c \cdot \prod_{i=1}^{m} x_i^{e_i}$.

2. *In the* extended full representation (ef representation)*, we describe* p *as a sequence of vectors as above, but this time* c *is given in binary while all numbers* $e_1, \ldots, e_m$ *are given in unary.*

3. *In the* formula representation*,* p *is described by a formula involving the variables* $\overline{x}$*. More precisely, the set of formulas in variables* $\overline{x}$ *is defined inductively by the following rules:*

1. $x_1, \ldots, x_m, 0, 1$ *are formulas.*
2. *If* F, G *are formulas, then so are* $(F+G)$ *and* $(F \times G)$.

3. *In the* straight-line program representation (slp representation)*, we describe* p *by a straight-line program with input variables* $\overline{x}$ *that computes* p.

If Φ is a representation of a polynomial of one of the above types, then we denote the polynomial represented by Φ by p_Φ.

It is easy to see that the above definition introduces a chain of representations with increasing succinctness. For every representation of type (i) of a polynomial, equivalent representations of types (j) for $j > i$ can be computed in logarithmic space. Moreover, if p has a full or ef or formula representation of size n, then the degree of p is bounded by n, and if p has an slp representation of size n, then the degree of p is at most exponential in n.

The idea to use slp representations as a data structure for polynomials was introduced and promoted by Erich Kaltofen (see, e.g., [12]).

In the upcoming sections we will have to determine if two representations stand for the same polynomial. This gives rise to the *equivalence problem*

$$\left\{ \langle \Phi_1, \Phi_2 \rangle \;\middle|\; \Phi_1 \text{ and } \Phi_2 \text{ are representations of polynomials such that } p_{\Phi_1} = p_{\Phi_2} \right\}$$

for the various types of representations. A result similar to the next theorem was obtained in [10].

THEOREM 4.2. *The equivalence problem is*

1. *in* P *for full and ef representation;*
2. *in* coRP *for formula and slp representation.*

The proof will make instrumental use of the following well-known result [18, 31] (see also [16, p. 165f]).

PROPOSITION 4.3 (Schwartz–Zippel). *Let* $p(x_1, \ldots, x_n)$ *be a polynomial of degree* d *over some field* $\mathbb{F}$ *that is not the zero polynomial. Let* $\mathbb{S} \subseteq \mathbb{F}$ *be a finite set, and let*

$a_1, \ldots, a_n$ be chosen independently and uniformly at random from $\mathbb{S}$. Then

$$\operatorname{prob}[p(a_1, \ldots, a_n) = 0] \leq \frac{d}{|\mathbb{S}|}.$$

Proof of Theorem 4.2. Two polynomials in (extended) full representation are equivalent if and only if they have the same monomials. This can be checked in polynomial time.

Given now two formulas F_1 and F_2, we know that the degree d of the two represented polynomials is at most linear in the length of F_1 and F_2. Hence by Proposition 4.3 it suffices to evaluate F_1 and F_2 for a random input drawn from an exponential number of possible input vectors. The actual evaluation of the formulas is in P.

Finally, we are given two straight-line programs P_1 and P_2. Compared with the above, we now have to deal with the fact the degree of the represented polynomial can be exponential; hence the numbers we operate with can be double exponential in $n =_{\text{def}} |P_1| + |P_2|$. Therefore, we cannot carry out the necessary arithmetic operations in polynomial time. Instead we proceed as follows (see also [16, p. 169]).

Suppose the two numbers $a, b < 2^{2^n}$ are different; then $|a - b|$ can have at most 2^n different prime divisors. Let $\pi(m)$ denote the number of primes smaller than or equal to m. Hence for a random prime smaller than $k2^n \log(k2^n)$, the probability that $a \equiv b \pmod{p}$ is at most $\frac{2^n}{\pi(k2^n \log(k2^n))} \leq O(\frac{1}{k})$. Thus if two numbers are different, then they are different modulo most primes having a polynomial number of bits.

Hence P_1 and P_2 are not equivalent if and only if for most inputs within an exponential range we get inequality if and only if for most inputs within an exponential range we get inequivalence modulo most primes having a polynomial number of bits. Since the set of prime numbers is in ZPP, the resulting algorithm is an RP algorithm. □

5. Different types of replacement systems. The definition of PRSs we presented above is very general. Here, we introduce a number of natural restrictions. Our approach is similar to the way different restrictions of grammar types were introduced, e.g., in the definition of the classes of the Chomsky hierarchy. We will later view the problems of counting proof-trees and proof-circuits as two instances of a problem about these restricted PRS types.

5.1. Simple polynomial replacement systems.

DEFINITION 5.1. *A PRS $S = (\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R)$ is* simple *(or* context-free*), if the polynomials in the left-hand sides of the rules of R are variables from $\{x_{n+1}, \ldots, x_m\}$.*

All definitions made in the preceding section for general PRSs carry over to the special cases of simple systems. However, for a simple PRS we additionally define a particular type of replacement, where the application of a rule (z, q) results in the replacement of *all occurrences* of z with q. This latter form is denoted by $\underset{S}{\models\!\!\Rightarrow}$, in contrast to the notation $\underset{S}{\Longrightarrow}$ for the derivations defined so far. Formally, we have the following.

DEFINITION 5.2. *Let $S = (\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R)$ be a simple PRS.*

$$p_1 \underset{S}{\models\!\!\Rightarrow} p_2 \iff_{\text{def}} \text{there exist } (x_i, p_3) \in R \text{ such that } p_2(\overline{x}) = p_1(x_1, \ldots, x_{i-1}, p_3(\overline{x}), x_{i+1}, \ldots, x_m).$$

Let $\underset{S}{\overset{*}{\models\!\!\Rightarrow}}$ be the reflexive and transitive closure of $\underset{S}{\models\!\!\Rightarrow}$.

For the sets of polynomials and numbers derived from simple systems using our new derivation type, we use the same names as before but now use square brackets $[\cdots]$ instead of parentheses $(\cdots)$; formally we have the following.

DEFINITION 5.3. *For a simple PRS* $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$, *let*

$$\text{POLY}[S] = \Big\{ p(x_1, \ldots, x_n) \;\Big|\; \text{there exists } p'(\overline{x}) \text{ such that } q \overset{*}{\underset{S}{\Longrightarrow}} p' \text{ and } p(x_1, \ldots, x_n) = p'(x_1, \ldots, x_n, a_{n+1}, \ldots, a_m) \text{ for all } a_{n+1}, \ldots, a_m \in \mathbb{N} \Big\}.$$

As in the case of $\text{POLY}(S)$, we have the following definition.

DEFINITION 5.4. *Let* $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$ *be a simple PRS. Define*

(i) $\text{RANGE}[S] =_{\text{def}} \big\{\, p(a) \;\big|\; p \in \text{POLY}[S] \wedge a \in \mathbb{N}^n \,\big\}$;

(ii) $\text{EVAL}[S] =_{\text{def}} \big\{\, (a, p(a)) \;\big|\; p \in \text{POLY}[S] \text{ and } a \in \mathbb{N}^n \,\big\}$.

We also define the following variable membership problems:

(i) $\text{POLY}[\cdot] =_{\text{def}} \big\{\, (S, p) \;\big|\; S \text{ simple PRS and } p \in \text{POLY}[S] \,\big\}$;

(ii) $\text{RANGE}[\cdot] =_{\text{def}} \big\{\, (S, a) \;\big|\; S \text{ simple PRS and } a \in \text{RANGE}[S] \,\big\}$;

(iii) $\text{EVAL}[\cdot] =_{\text{def}} \big\{\, (S, a, p(a)) \;\big|\; S \text{ simple PRS}, p \in \text{POLY}[S] \text{ and } a \in \mathbb{N}^* \,\big\}$.

It is clear that for any simple PRS S, we have $\text{POLY}[S] \subseteq \text{POLY}(S)$; hence we also obtain $\text{RANGE}[S] \subseteq \text{RANGE}(S)$, $\text{EVAL}[S] \subseteq \text{EVAL}(S)$, $\text{POLY}[\cdot] \subseteq \text{POLY}(\cdot)$, $\text{RANGE}[\cdot] \subseteq \text{RANGE}(\cdot)$, and $\text{EVAL}[\cdot] \subseteq \text{EVAL}(\cdot)$.

5.2. Simple deterministic or acyclic PRSs.

DEFINITION 5.5. *A PRS* $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$ *is said to be* deterministic *if no two different rules in* R *have the same left-hand side.*

DEFINITION 5.6. *Let* $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$ *be a PRS. The* dependency graph G_S *of* S *is the directed graph* $G_S = \big(\{1, \ldots, m\}, E_S\big)$, *where* E_S *consists of all edges* (j, i) *for which there exists a rule* $(p_1, p_2) \in R$ *such that* x_i *is essential in* p_1 *and* x_j *is essential in* p_2. *The PRS* S *is said to be* acyclic *if its dependency graph* G_S *is acyclic.*

LEMMA 5.7. *For every simple and deterministic PRS* S, *there exists a simple, deterministic, and acyclic PRS* S' *such that* $\text{POLY}(S) = \text{POLY}(S')$ *and* $\text{POLY}[S] = \text{POLY}[S']$. *The system* S' *can be obtained from* S *in polynomial time.*

Proof. Let $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$ be a simple and deterministic PRS. If S is not acyclic, then there exist $k \geq 1$, $i_1, \ldots, i_k \in \{n+1, \ldots, m\}$, and polynomials $p_1(\overline{x}), \ldots, p_k(\overline{x})$ such that $(x_{i_1}, p_1), (x_{i_2}, p_2), \ldots, (x_{i_k}, p_k) \in R$ and $x_{i_{r+1}}$ is essential in p_r for $r = 1, \ldots, k$ (where we set $i_{k+1} = i_1$). Since $x_{i_1}, \ldots, x_{i_k}$ are nonterminal variables, we claim that they have to be fictive in every polynomial p such that $q \overset{*}{\underset{S}{\Longrightarrow}} p \overset{*}{\underset{S}{\Longrightarrow}} p'$ and $p' \in \text{POLY}(S)$. Indeed, S is deterministic, and hence such a replacement would necessarily run along the cycle described by the rules $(x_{i_1}, p_1), (x_{i_2}, p_2), \ldots, (x_{i_k}, p_k)$. Hence, if p has a nonfictive variable from $\{x_{i_1}, \ldots, x_{i_k}\}$, then every p' such that $p \overset{*}{\underset{S}{\Longrightarrow}} p'$ will have a nonfictive variable from $\{x_{i_1}, \ldots, x_{i_k}\}$. Thus we have $\text{POLY}(S) = \text{POLY}(S')$ and $\text{POLY}[S] = \text{POLY}[S']$, where

$$S' =_{\text{def}} \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\} \setminus \{x_{i_1}, \ldots, x_{i_k}\}, q, R'\big) \quad \text{and}$$

$$R' =_{\text{def}} R \setminus \big\{\, (x_i, p) \;\big|\; x_i \text{ or an essential variable in } p \text{ is from } \{x_{i_1}, \ldots, x_{i_k}\} \,\big\}.$$

Now we repeat this cycle removement step as long as the PRS still has cycles. Since in every step at least one nonterminal variable is removed, we get after a polynomial number of steps a PRS which is simple, deterministic, and acyclic. ∎

We also obtain the following easy properties.

LEMMA 5.8.

1. *If S is a simple and deterministic PRS, then* $\text{POLY}(S) = \text{POLY}[S]$*, and this set consists of at most one polynomial.*

2. *If S is a simple and acyclic PRS, then* $\text{POLY}(S)$ *and* $\text{POLY}[S]$ *are finite.*

Proof. If S is simple, deterministic, and without loss of generality, moreover, acyclic, then the rules replace every variable by a unique polynomial. Since S is simple, we always have to replace all occurrences of each nonterminal variable sooner or later. Hence the result of the whole derivation process is unique.

If S is acyclic, then every nonterminal variable can only be replaced in a bounded number of ways, and hence we can only obtain finitely many polynomials. □

Note that there are simple and acyclic PRSs S such that $\text{POLY}[S] \subsetneq \text{POLY}(S)$. For example take $S = (\{x\}, \{z\}, 2z, \{(z, x), (z, 2x)\})$, where $\text{POLY}[S] = \{2x, 4x\}$ and $\text{POLY}(S) = \{2x, 3x, 4x\}$. Thus, the requirement that S is deterministic is necessary in Lemma 5.8.1.

In the remainder of this subsection, we relate simple deterministic and simple acyclic PRSs to different forms of circuits operating over the natural numbers.

First, it is intuitively clear that there is some connection between simple, deterministic, and acyclic systems and straight-line programs. This is made precise in the following lemma.

LEMMA 5.9.

1. *If S is a simple, deterministic, and acyclic PRS such that* $\text{POLY}(S) \neq \emptyset$*, then there exists a straight-line program P such that* $\text{POLY}(S) = \{p_P\}$.

2. *If P is a straight-line program, then there exists a simple, deterministic, and acyclic PRS S such that* $\{p_P\} = \text{POLY}(S)$.

3. *The transformations from a simple, deterministic, and acyclic PRS to the corresponding straight-line program and vice-versa can be computed in logarithmic space.*

Proof. The program P is obtained from S by transforming every single replacement rule into a sequence of straight-line program instructions and then ordering these according to a topological order of G_S. Statement 2 is proved similarly. Statement 3 is obvious. □

Next we show that acyclic systems are strongly related to a new type of arithmetic circuit we now define. These circuits are immediate generalizations of *integer expressions*, introduced by Stockmeyer and Meyer [19]. Therefore, we call our circuits *integer circuits* (not to be confused with ordinary arithmetic circuits), or, referring to the operations allowed, $(\cup, +, \times)$-circuits.

An integer circuit with n inputs is a circuit C where the inner nodes compute one of the operations $\cup, +, \times$. Such a circuit C has a specified output-gate g_s. It computes a function $f_C \colon \mathbb{N}^n \to 2^{\mathbb{N}}$ as follows: We first define for every gate $g \in C$ the function f_g computed by g.

1. If g is an input-gate x_i, then $f_g(a_1, \ldots, a_n) = \{a_i\}$ for all $a_1, \ldots, a_n \in \mathbb{N}$.
2. If g is a $+$-gate with predecessors g_l, g_r, then $f_g(a_1, \ldots, a_n) = \{\, k + m \mid k \in f_{g_l}(a_1, \ldots, a_n), m \in f_{g_r}(a_1, \ldots, a_n) \,\}$. The function computed by a $\times$-gate is defined analogously.
3. If g is a $\cup$-gate with predecessors g_l, g_r, then $f_g(a_1, \ldots, a_n) = f_{g_l}(a_1, \ldots, a_n) \cup f_{g_r}(a_1, \ldots, a_n)$.

Finally, the function computed by C is $f_C =_{\text{def}} f_{g_s}$.

The following relation between simple, acyclic replacement systems and integer

circuits is obtained by an easy induction.

LEMMA 5.10.

1. *For every simple, acyclic PRS* $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$, *there is an integer circuit* C *with* n *inputs such that* $f_C(a) = \big\{\, b \;\big|\; (a,b) \in \text{EVAL}(S) \,\big\}$ *for all* $a \in \mathbb{N}^n$.

2. *For every integer circuit* C *with* n *inputs, there is a simple, acyclic PRS* S *such that* $\big\{\, b \;\big|\; (a,b) \in \text{EVAL}(S) \,\big\} = f_C(a)$ *for all* $a \in \mathbb{N}^n$.

3. *The transformations from a simple, acyclic PRS to the corresponding integer circuit and vice-versa can be computed in logarithmic space.*

We consider the following problems:

$$\mathbb{N}\text{-MEMBER}(\cup,+,\times) =_{\text{def}} \big\{\, (C, a_1, \ldots, a_n, b) \;\big|\; C \text{ is an integer circuit with } n \text{ inputs}, \; a_1, \ldots, a_n, b \in \mathbb{N} \text{ and } b \in f_C(a_1, \ldots, a_n) \,\big\},$$

$$\mathbb{N}\text{-RANGE}(\cup,+,\times) =_{\text{def}} \big\{\, (C, b) \;\big|\; C \text{ is an integer circuit with } n \text{ inputs}, \; b \in \mathbb{N} \text{ and } (\exists a_1, \ldots, a_n) b \in f_C(a_1, \ldots, a_n) \,\big\}.$$

Analogous notation will be used when we restrict the gate types allowed.

The following lemma is immediate from Lemma 5.10.

LEMMA 5.11. *For all representations, the following hold:*

1. $\mathbb{N}\text{-MEMBER}(\cup,+,\times) \equiv_m^{\log} \text{EVAL}(\cdot)$.
2. $\mathbb{N}\text{-RANGE}(\cup,+,\times) \equiv_m^{\log} \text{RANGE}(\cdot)$.

5.3. Idempotent polynomial replacement systems.

DEFINITION 5.12. *For a PRS* $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$, *let* $S_{\text{idem}} =_{\text{def}} \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R \cup \big\{\, (x_i^2, x_i) \;\big|\; 1 \le i \le m \,\big\}\big)$ *be the* idempotent PRS *derived from* S.

In the case that S is simple (deterministic, acyclic, respectively), we will say that S_{idem} is an idempotent simple (idempotent deterministic, idempotent acyclic, respectively) PRS. Note that if S_{idem} is idempotent simple, we mean that it is an idempotent PRS that originates from a simple PRS, not that S_{idem} itself is simple (similarly for deterministic and acyclic systems).

For a PRS $S = \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_m\}, q, R\big)$ and $a \in \mathbb{N}^n$, we use the notation $\min \text{EVAL}(S, a)$ as shorthand for $\min\big\{\, p(a) \;\big|\; p \in \text{POLY}(S) \,\big\}$ (analogously, we use $\max \text{EVAL}(S, a)$).

LEMMA 5.13.

1. *For every Boolean circuit* C, *input* x, *and* $k \in \mathbb{N}$, *there exists a simple, deterministic, and acyclic PRS* S *such that*

$$\min \text{EVAL}\big(S_{\text{idem}}, (1, \ldots, 1)\big) = \#_c C(x), \text{ and } \max \text{EVAL}\big(S_{\text{idem}}, (1, \ldots, 1)\big) = \#C(x).$$

2. *For every simple, deterministic, and acyclic PRS* S_{idem}, *there exists a Boolean circuit* C *such that*

$$\min \text{EVAL}\big(S_{\text{idem}}, (1, \ldots, 1)\big) = \#_c C(x), \text{ and } \max \text{EVAL}\big(S_{\text{idem}}, (1, \ldots, 1)\big) = \#C(x).$$

3. *The transformations from an idempotent simple, deterministic, and acyclic PRS to the corresponding circuit and vice-versa can be computed in logarithmic space.*

Proof. Arithmetic circuits and straight-line programs are only two different views of the same concept. Hence we go from circuit C to system S and vice versa exactly as in Lemma 5.9. Clearly the simple, deterministic, and acyclic system S computes $\#C(x)$ as explained in the discussion in the beginning of section 3.

Now convert S into the idempotent system S_{idem}. That the number of proof-circuits coincides with the minimal element in $\text{EVAL}\big(S_{\text{idem}}, (1, \ldots, 1)\big)$ is a consequence of the algorithm given at the beginning of section 3. The minimal element is obtained if and only if during the derivation of a polynomial all rules (x_i^2, x_i) are applied whenever possible. The maximal element is obtained if and only if we never pick such a rule, i.e., if we use only rules from S. □

6. Complexity results for simple replacement systems.

6.1. Deterministic systems. In this section, we consider the complexity of the above defined sets for simple replacement systems. Let us start with the complexity of fixed membership problems.

THEOREM 6.1. *Let S be simple and deterministic.*

1. $\text{POLY}(S), \text{POLY}[S] \in \text{P}$ *for all representations, and* $\text{POLY}(S), \text{POLY}[S]$ *are* P*-complete for the slp representation.*

2. $\text{RANGE}(S), \text{RANGE}[S] \in \text{NP}$ *for all representations. In fact, for all representations there are systems S such that the problems* $\text{RANGE}(S)$ *and* $\text{RANGE}[S]$ *are* NP*-complete.*

3. $\text{EVAL}(S), \text{EVAL}[S] \in \text{TC}^0$ *for all representations.*

Proof. First we recall that $\text{POLY}(S)$ and $\text{POLY}[S]$ consist of at most one polynomial p. In full and ef representation, p has only finitely many representations; hence the complexity of $\text{POLY}(S), \text{POLY}[S]$ is trivial. However, in formula and slp representation, p may have infinitely many representations. That is, we face the following problem: Given a straight-line program P (the case of formulas is even easier), does $p_P = p$ (where p is fixed)?

Say that P is reduced if the following holds: P has no instructions of the form $x_j \leftarrow \cdots$, where the x_j never appears on the right-hand side of any other instructions (unless x_j is the output variable). Additionally, if $x_j \leftarrow x_i + x_k$ is an instruction in P, then the polynomials computed by x_i and x_k are both not the constant zero polynomial (otherwise, the instruction is useless, for, e.g., if $x_i \equiv 0$, then $x_j \equiv x_k$, and hence we do not compute anything new; we might delete the above instruction and in further instructions we use x_k instead of x_j). Similarly, for $x_j \leftarrow x_i \cdot x_k$ we require that x_i and x_k are not constant one.

Now the following holds: Every polynomial p has only finitely many representations by reduced straight-line programs (except for an isomorphic renumbering of the variables). Moreover, a program P can be transformed into reduced form as follows: Inductively, determine the sets of variables that compute the constant zero or constant one polynomial. Then remove those instructions that do not compute a new polynomial, and change the variables in the other instructions as described above. This shows that $\text{POLY}(S), \text{POLY}[S] \in \text{P}$.

Hardness follows from a reduction from the circuit value problem as follows: Let C be a Boolean circuit. Let p be the polynomial that gives the number of proof-trees of C. Let $\text{POLY}(S) = \text{POLY}[S] = \{p'\}$; then $p + p' \in \text{POLY}(S) = \text{POLY}[S]$ iff C does not evaluate to 1 and if and only if C is not in CVP.

For statement 2 we have to decide the range of a multivariate polynomial with nonnegative coefficients. This is clearly in NP by the obvious guessing algorithm. For the hardness proof, we give a reduction from the quadratic Diophantine equations problem (problem AN8 in [7, p. 250]) as follows: This problem consists of all triples (a, b, c) such that the quadratic equation $ax^2 + by = c$ has a solution in positive integers. Define $\langle x, y, z\rangle =_{\text{def}} z + (y+z)^2 + (x+y+z)^3$. Observe that $\langle \cdots \rangle$ is one-one. Now, define the four-variable polynomial $p(u, v, x, y) =_{\text{def}} ux^2 + vy$. Then for all

$a, b, c \in \mathbb{N}$, the equation $ax^2 + by = c$ has a solution if and only if there are x, y such that $p(a, b, x, y) = c$, if and only if there are x, y such that $\langle a, b, p(a, b, x, y)\rangle = \langle a, b, c\rangle$, and if and only if there are u, v, x, y such that $\langle u, v, p(u, v, x, y)\rangle = \langle a, b, c\rangle$. Hence we see that the quadratic Diophantine equations problem reduces to the range of the polynomial $q(u, v, x, z) =_{\text{def}} \langle u, v, p(u, v, x, y)\rangle$.

For statement 3 observe that we have to evaluate a fixed polynomial; hence the result follows since addition and multiplication are in TC^0. □

Concerning variable membership problems of simple, deterministic systems, we obtain the following theorem.

THEOREM 6.2. *For simple and deterministic PRSs and for all representations,*

1. POLY$(\cdot)$ *and* POLY$[\cdot]$ *are in* coRP *and* P*-hard under* $\leq_m^{\log}$ *(in fact* P*-complete for full and ef representations)*;
2. RANGE$(\cdot)$ *and* RANGE$[\cdot]$ *are* NP*-complete under* $\leq_m^{\log}$;
3. EVAL$(\cdot)$ *and* EVAL$[\cdot]$ *are* P*-complete under* $\leq_m^{\log}$.

Proof. Containment. In all cases, given the simple and deterministic PRS S, first construct in polynomial time the slp representation of the unique polynomial p (if any) in POLY(S) = POLY$[S]$ by Lemmas 5.7 and 5.8. Statement 1 then follows by equivalence test (Theorem 4.2). For statement 2, guess suitable input values and evaluate p; for statement 3, just evaluate p (until finished or until the bounds are exceeded, as above).

Hardness: Statement 3. We give a reduction from the circuit value problem CVP as follows: Given a circuit C and an input a to C, produce the replacement system S which computes the number of proof-trees of C on input a. S is simple and deterministic (see section3), and if we "hardwire" the input a of C directly into S, the resulting polynomial has only fictive variables, i.e., is essentially a natural number. Now C accepts a if and only if this number is greater than 0; hence $(C, a) \in$ CVP if and only if $(S, a, 0) \notin$ EVAL$[\cdot]$ = EVAL$(\cdot)$. Statement 1: Proceeding as above, we obtain $(C, a) \in$ CVP if and only if the constant 0 polynomial is not in POLY(S) = POLY$[S]$. Statement 2: This follows from Theorem 6.1.2. □

6.2. Acyclic systems. Let us next deal with simple, acyclic, but not necessarily deterministic systems. For such systems S the sets POLY(S) and POLY$[S]$ are finite (by Lemma 5.8); hence we obtain the following analogous to Theorem 6.1.

THEOREM 6.3. *Let S be simple and acyclic. For all representations the following hold:*

1. POLY(S), POLY$[S] \in$ P.
2. RANGE(S), RANGE$[S] \in$ NP*, and there are systems S such that the problems* RANGE(S) *and* RANGE$[S]$ *are* NP*-complete.*
3. EVAL(S), EVAL$[S] \in \text{TC}^0$.

Again, interesting questions arise when we examine variable membership problems.

THEOREM 6.4. *For simple and acyclic PRSs and for all representations,*

1. POLY$[\cdot]$ *is contained in* MA *and is* NP*-hard under* $\leq_m^{\log}$,
2. RANGE$[\cdot]$ *and* EVAL$[\cdot]$ *are* NP*-complete under* $\leq_m^{\log}$.

Proof. The containment proofs are similar to that of Theorem 6.2, but before applying Lemma 5.7 we select nondeterministically a deterministic PRS by deleting some of the rules of the originally given PRS. The claim follows since MA $= \exists \cdot$ coRP [8].

Hardness for POLY$[\cdot]$ is proven by giving a logspace many-one reduction from the sum-of-subset problem SOS (problem SP13 in [7, p. 223]) to POLY$[\cdot]$ as follows: Let

$m, b_1, \ldots, b_m, c \in \mathbb{N} \setminus \{0\}$. Define the PRS S by

$$S =_{\text{def}} \big(\{x_1, \ldots, x_n\}, \{x_{n+1}, \ldots, x_{n+m}\}, x_{n+m}, R\big), \text{ where}$$
$$R =_{\text{def}} \big\{(x_{n+1}, 0), (x_{n+1}, b_1)\big\} \cup \bigcup_{i=2}^{m} \big\{(x_{n+i}, x_{n+i-1}), (x_{n+i}, x_{n+i-1} + b_i)\big\}.$$

Note that S is acyclic and simple, and $\text{POLY}[S]$ consists only of polynomials without essential variables. For $c \in \mathbb{N}$, define $p_c(x_1, \ldots, x_n) =_{\text{def}} c$. Now we obtain

$$(b_1, \ldots, b_m, c) \in \text{SOS} \iff p_c \in \text{POLY}[S] \iff (S, p_c) \in \text{POLY}[\cdot].$$

Since a deterministic PRS can (by Lemma 5.7) be assumed to be acyclic; hardness for $\text{RANGE}[\cdot]$ follows as in Theorem 6.2.

We next prove hardness for $\text{EVAL}[\cdot]$ by giving a logspace many-one reduction from the SOS problem: Given $m, b_1, \ldots, b_m, c > 0$, define S as in the proof of $\text{POLY}[\cdot]$ above. Then we obtain $(b_1, \ldots, b_m, c) \in \text{SOS} \iff (S, a, c) \in \text{EVAL}[\cdot]$ for any $a \in \mathbb{N}^n$. □

Next, we turn to different variable membership problems for simple, acyclic systems under "$\Longrightarrow$" derivations.

Stockmeyer and Meyer considered integer expressions (in our terminology, these are integer circuits with fan-out of non–input-gates at most 1) where the only operations allowed are $\cup$ and $+$. They proved that the membership problem in that case is NP-complete. It is easy to see that their result carries over to the case in which we also allow multiplication; i.e., the problems $\mathbb{N}$-MEMBER$(\cup, +)$ and $\mathbb{N}$-MEMBER$(\cup, +, \times)$ for expressions are NP-complete. The corresponding problems for circuits were not considered in their paper but in later papers by Wagner [28, 29] (under the name *hierarchical descriptions*). Only PSPACE as an upper bound is known from there, but recently it was shown by Ke Yang that $\mathbb{N}$-MEMBER$(\cup, +, \times)$ is PSPACE-hard [30]. (We remark that the problem $\mathbb{N}$-MEMBER$(\cup, +)$, which is not so interesting from a PRS point of view, can be shown to be NP-complete also in the circuit case.)

By Lemma 5.11 the member and range problems for these circuits are equivalent to the $\text{EVAL}(\cdot)$ and $\text{RANGE}(\cdot)$ problems for simple acyclic PRSs. Since $\text{EVAL}(\cdot)$ clearly reduces to $\text{RANGE}(\cdot)$ in this case, we conclude the following.

THEOREM 6.5. *For simple and acyclic PRSs and for all representations,*

1. $\text{POLY}(\cdot) \in$ EXPTIME*,*
2. $\text{RANGE}(\cdot), \text{EVAL}(\cdot)$ *are* PSPACE*-complete.*

6.3. Idempotent systems. Note that, if S is simple and deterministic, then $\text{POLY}(S_{\text{idem}})$ and $\text{POLY}[S_{\text{idem}}]$ are finite, and we obtain results analogous to Theorem 6.1.

THEOREM 6.6. *Let S be simple, deterministic, and acyclic. For all representations the following hold:*

1. $\text{POLY}(S_{\text{idem}}) \in$ P.
2. $\text{RANGE}(S_{\text{idem}}) \in$ NP*. In fact, there are systems S such that the problem* $\text{RANGE}(S_{\text{idem}})$ *is* NP*-complete.*
3. $\text{EVAL}(S_{\text{idem}}) \in \text{TC}^0$.

For the variable membership problems the following can be said.

THEOREM 6.7. *For idempotent, simple, deterministic, and acyclic PRSs and for all representations,* $\text{POLY}(\cdot), \text{RANGE}(\cdot), \text{EVAL}(\cdot) \in$ EXPTIME.

Proof. The proof follows by the trivial evaluation of the system. □

Lemma 5.13 shows the importance of the minimization and maximization operations in the case of idempotent systems.

THEOREM 6.8. *For idempotent, simple, deterministic, and acyclic replacement systems and for all representations,*

1. *the functions* $\min \text{EVAL}(\cdot)$ *and* $\min \text{EVAL}[\cdot]$ *are* #P*-complete under* $\leq^{\log}_{1\text{-T}}$*-reductions*;

2. *the functions* $\max \text{EVAL}(\cdot)$ *and* $\max \text{EVAL}[\cdot]$ *are* FP*-complete under* $\leq^{\text{p}}_{m}$.

Proof. The proof is an immediate consequence of Lemma 2.1, Theorem 2.4, and Lemma 5.13. □

For completeness, we note the following.

Remark 6.9. For simple deterministic and for simple acyclic PRSs and for all representations, the functions $\min \text{EVAL}(\cdot)$, $\min \text{EVAL}[\cdot]$, $\max \text{EVAL}(\cdot)$, $\max \text{EVAL}[\cdot]$ are FP-complete.

Proof. For simple deterministic S and $a \in \mathbb{N}^*$, obtain from Lemmas 5.7 and 6.1 the slp representation of the unique polynomial p in $\text{POLY}(S)$ (if there is one). Then compute $p(a)$ which hence is the minimum and maximum. This element can be computed as in Theorem 6.2, showing that the functions are in FP. Hardness follows immediately from Lemma 2.1.

For simple acyclic S, we evaluate S according to a topological order of G_S. The minimal element is obtained if for every variable x we consider only those rules with left-hand side x, whose right-hand side is minimal. Hence we essentially deal with a deterministic system, and the upper bound follows from the above. The case of maximization is treated similarly. Hardness follows from hardness of the problem in the deterministic case. □

7. Conclusion. It may be of interest to consider the complexity of the proof-circuit problem PC (see section 2) for circuits of restricted depth. The circuit constructed in the proof of Theorem 2.4 has depth 5. Simply merging the $\wedge$-gates on levels 3 and 4 makes it depth-4. Furthermore, it is easy to see that for depth $d+1$ circuits with an $\vee$ output-gate the problem is as hard as for depth-d circuits with an $\wedge$ output-gate. Next observe that the problem is easy (i.e., in FP) for depth-2 circuits with an $\wedge$ output-gate (and hence also for depth-3 circuits with an $\vee$ output-gate).

This means that the complexity of PC is not known only in the case of depth-3 circuits with an $\wedge$ output-gate (or, equivalently, for depth-4 circuits with an $\vee$ output-gate). It is not hard to see that this reduces to the case of four-level stratified circuits with

(i) level 1: 1 gate,
(ii) level 2: $\vee$ gates,
(iii) level 3: $\vee$ gates,
(iv) level 4: $\wedge$ gate (output-gate).

This problem in its turn is equivalent to the following problem: Given natural numbers $b_1, \ldots, b_m$ and the polynomial $f(x_1, \ldots, x_m) = \prod_{k=1,\ldots,n} \sum_{i=1,\ldots,m} a_{ki} \cdot x_i$ with $\text{a}_{ki} \in \{0, 1\}$, exploit distributivity to re-express this polynomial as a sum of monomials, and replace every x_i^r, $r > 1$, with x_i. Let $f^*(x_1, \ldots, x_m)$ be this new polynomial. Goal: Compute $f^*(b_1, \ldots, b_m)$. (The complexity is measured in the value—i.e., unary—of $n + b_1 + \cdots + b_m$.)

It is interesting to see that the problem of computing the permanent can be formulated in a way similar to the above problem, only substituting "replace every x_i^r, $r > 1$, with x_i" by "replace every x_i^r, $r \geq 1$, with 0." Nevertheless, it is not clear how to use this idea to reduce the problem of computing the permanent to the above problem.

Determining the complexity of the sets $\text{RANGE}(S), \text{RANGE}[S]$ for fixed S is often equivalent to determining the complexity of the range of a multivariate polynomial with nonnegative integer coefficients. While this is always in NP, we showed that

there is a four-variable polynomial of degree 6 whose range is NP-complete. Can this be improved?

From a complexity-theoretic point of view, further obvious open questions are whether the gaps between lower and upper bounds in Theorems 6.5 and 6.7 can be closed.

Many other questions about PRSs remain open. Returning to some of the problems posed in subsection 1.1, we did not study multivariate rules at all. Also, it may be worth examining if PRS families other than idempotent systems can be related to counting problems involving arithmetic or Boolean circuits.

Acknowledgments. We thank Sven Kosub (Würzburg) and Thomas Thierauf (Ulm) for helpful discussions. Also we are grateful to an anonymous referee for pointing out an oversight in Theorem 6.1 and for comments that helped to improve the presentation.
