We claim that the existence of these mappings implies the theorem as follows. For a packet $p \in Q(t)$ define the *rank* of p to be its rank in the sequence of packets in $Q(t)$ ordered in ascending values. The existence of the mappings implies that for each time step t, the value of the packet ranked i in $Q_{GH}(t)$ is at most the value of the packet ranked i in $Q_G(t)$. Since $|D_{GH}(t)| = |D_G(t)|$, and since in any greedy algorithm $D(t)$ consists of the lowest ranked packets in $Q(t)$, it follows that $v(D_{GH}(t)) \leq v(D_G(t))$.

The value served by an algorithm is $\sum_t v(S(t))$; hence we get

$$\begin{aligned}\sum_t v(S_{GH}(t)) &= \sum_t v(A(t)) - \sum_t v(D_{GH}(t)) \\ &\geq \sum_t v(A(t)) - \sum_t v(D_G(t)) \\ &= \sum_t v(S_G(t)).\end{aligned}$$

All that remains is to prove the existence of the mappings. Fix a time step t and consider $Q_G(t)$ and $Q_{GH}(t)$. To construct the mapping, we use the natural concept of "height" of a packet in a buffer: For an algorithm A and a packet $p \in Q_A(t)$, the *height* of p, denoted by $h_A(p,t)$, is 1 plus the number of packets that have to be either transmitted or dropped before p can be transmitted. In other words, $h_A(p,t)$ is the rank of p in the sequence of packets in $Q_A(t)$ ordered by arrival time. We also say that a packet $p \in Q_A(t)$ is said to be *below* (or *above*) a packet $p' \in Q_A(t)$ if $h_A(p,t) < h_A(p',t)$ (or, respectively, $h_A(p,t) > h_A(p',t)$).

We now define the mapping from $Q_{GH}(t)$ to $Q_G(t)$. Each packet in $Q_{GH}(t) \cap Q_G(t)$ is mapped to itself. To complete the mapping, consider the packets in $Q_{GH}(t) \setminus Q_G(t)$ in ascending order of height. Map each such packet p to the packet with the lowest height in $Q_G(t) \setminus Q_{GH}(t)$ that has not been mapped yet. It is not difficult to see that this mapping is indeed 1-1. We need to show that each packet in $Q_{GH}(t) \setminus Q_G(t)$ is mapped to a packet in $Q_G(t) \setminus Q_{GH}(t)$ of at least the same value. For this we prove the following two lemmas.

LEMMA 3.6. *Let $p \in Q_{GH}(t) \setminus Q_G(t)$ for some time t. Then $v(p) \leq v(q)$, for all $q \in Q_G(t)$ satisfying $h_G(q,t) \leq h_{GH}(p,t)$.*

Proof. Let t_0 be the time in which G dropped p (and hence $p \notin Q_G(t_0+1)$). We prove the lemma by induction on $t - t_0$. For the base case $t = t_0 + 1$, we have by the greedy rule that $v(p) \leq v(p')$ for any $p' \in Q_G(t)$. For the inductive step, let $t > t_0+1$. First, note that p arrived before step $t-1$, since otherwise it must have been dropped at step $t-1$, contradicting the assumption that $t > t_0 + 1$. It follows that

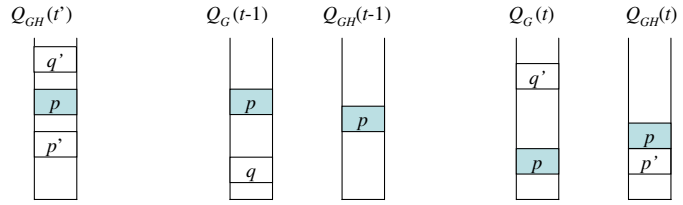

FIG. 3.2. *Scenario considered in the proof of Lemma* 3.7. $p \notin Q_G(t)$, $q' \notin Q_{GH}(t)$, *and* $q \notin D_G(t-1)$.

$h_{GH}(p, t-1)$ is well defined. Consider a packet $p' \in Q_G(t)$ with $h_G(p', t) \leq h_{GH}(p, t)$. If $h_G(p', t-1)$ is defined and $h_G(p', t-1) \leq h_{GH}(p, t-1)$, we are done by induction. If $p' \in A(t-1)$ or if $h_G(p', t-1) > h_{GH}(p, t-1)$, then it must be the case that some packet $p'' \in Q_G(t-1)$ with $h_G(p'', t-1) \leq h_{GH}(p, t-1)$ is dropped by G at time $t-1$. By the greedy rule $v(p') \geq v(p'')$. Since by induction $v(p'') \geq v(p)$, we are done in this case too. □

LEMMA 3.7. *Let t be any time step. If $p \in Q_{GH}(t) \cap Q_G(t)$, then $h_{GH}(p, t) \leq h_G(p, t)$.*

Proof. Suppose that the lemma does not hold. Let t be the first time it is violated, and let p be the packet with the minimal height such that $h_G(p, t) < h_{GH}(p, t)$. Let p' be the packet immediately below p in $Q_{GH}(t)$ (see Figure 3.2). Note that p' is well defined, since by assumption $h_{GH}(p, t) > h_G(p, t) \geq 1$. Also note that $p' \notin Q_G(t)$. This is because otherwise we would also have $h_G(p', t) < h_{GH}(p', t)$, contradicting the height minimality of p. Due to the minimality of t, $h_G(p, t-1) \geq h_{GH}(p, t-1)$. (Note that we cannot have the situation of $p \in A(t-1)$ and $h_G(p, t) < h_{GH}(p, t)$.) Thus, we must have that $D_G(t-1)$ contains at least one packet below p. Denote this packet by q. We claim that $v(q) \geq v(p')$. If $q = p'$, the claim is trivial. Otherwise, we have that $p' \notin Q_G(t-1)$ and $h_{GH}(p', t-1) \geq h_G(q, t-1)$, and hence, by Lemma 3.6, $v(p') \leq v(q)$. Since $Q_G(t)$ has more packets above p than $Q_{GH}(t)$ has, there must be a packet q' above p in $Q_G(t)$ that is not in $Q_{GH}(t)$. Since $q' \notin D_G(t-1)$ and $q \in D_G(t-1)$, it must be that $v(q') \geq v(q) \geq v(p')$. However, the packet q' is not in $Q_{GH}(t)$. Hence, it has been dropped by GH at some $t' < t$. This yields a contradiction to the head-drop rule, since $v(p') \leq v(q')$, both p' and q' are in $Q_{GH}(t')$, and $h_{GH}(q', t') > h_{GH}(p', t')$. □

We can now complete the proof of the theorem by proving the existence of the mapping. Suppose that $p \in Q_{GH}(t) \setminus Q_G(t)$ is mapped to $q \in Q_G(t) \setminus Q_{GH}(t)$. We now show that $h_{GH}(p, t) \geq h_G(q, t)$. By Lemma 3.6 this implies that $v(p) \leq v(q)$. Recall that the mapping of the packets in $Q_{GH}(t) \setminus Q_G(t)$ is done in ascending order of heights and that any such packet is mapped to the packet with the minimal height in $Q_G(t) \setminus Q_{GH}(t)$ that has not been mapped so far. To obtain a contradiction, suppose that p is the packet with the minimal height in $Q_{GH}(t) \setminus Q_G(t)$ that is mapped to $q \in Q_G(t) \setminus Q_{GH}(t)$, and $h_{GH}(p, t) < h_G(q, t)$. Consider the packet $p' \in Q_G(t)$ such that $h_G(p', t) = h_{GH}(p, t)$. It must be that $p' \in Q_G(t) \cap Q_{GH}(t)$. We must also have that the number of packets below p in $Q_{GH}(t) \setminus Q_G(t)$ is the same as the number of packets below p' in $Q_G(t) \setminus Q_{GH}(t)$. Thus, the set of packets below p in $Q_{GH}(t) \cap Q_G(t)$ is the same as the set of packets below p' in $Q_G(t) \cap Q_{GH}(t)$. It follows that $h_G(p', t) < h_{GH}(p', t)$, in contradiction to Lemma 3.7. This completes the proof of Theorem 3.5. □

The following theorem proves that GH can do much better than the greedy tail-

drop algorithm. Let GT denote the greedy tail-drop algorithm.

THEOREM 3.8. *There exist input sequences for which the value transmitted by GH is arbitrarily close to* $3/2$ *times the value transmitted by GT.*

Proof. We describe sequences for the case $W = 1$, using parameters α and B. At time 0, $B/2 + 2$ packets of value 1 arrive. At time 1, $B/2$ packets of value $\alpha \gg 1$ arrive. Thus, at time 2, the head half of the buffer is filled with cheap packets, and the tail half of the buffer is filled with expensive packets. At time 2, $B/2+1$ more 1-value packets arrive (resulting in overflow); finally, at time $2+B/2$, $B+1$ packets of value α arrive, resulting in an additional overflow. Let us now consider the performance of GT and GH. GT drops at time 2 the last $B/2$ cheap packets and transmits a cheap packet in steps $2, 3, \ldots, 1 + B/2$. At time $2 + B/2$, GT drops $B/2$ expensive packets, and the total value eventually transmitted is $\alpha(B+1)+1(\frac{B}{2}+1)$. On the other hand, GH drops at time 2 the first $B/2$ cheap packets and then drops at time $2 + B/2$ the other $B/2$ cheap packets, for a total transmitted value of $\alpha(\frac{3B}{2} + 1) + 1$. The result follows for large B and α values. □

4. Bounded delay buffers. In this section we consider the case of bounded delay buffers. General bounded delay buffers are studied in section 4.1. We prove a lower bound on the competitiveness of any on-line algorithm. The lower bound holds even in the uniform-delay model, independent of the allowed delay. We then show that for the general model, the greedy algorithm is exactly 2-competitive (the bound is refined in case there are exactly two packet values). Finally, in section 4.2 we provide a detailed analysis of the special case where the delay bound is 2.

4.1. General bounded delay buffers. In this section we consider the general case, where the slack times and values of the packets are arbitrary. We first present a lower bound on the competitiveness of all on-line algorithms and then we turn to analyze the simple greedy algorithm. We show that the greedy algorithm is exactly 2-competitive for the general delay-bounded case.

We begin with a negative result motivated by the following (false) intuition. It may seem reasonable to hope that as the delay bound grows, the competitive factor of on-line algorithms might tend to 1, since infinite delay bound seems like the off-line case. This is not true, as proved in the following theorem. The proof is similar in spirit to the proof in the FIFO case (Theorem 3.1).

THEOREM 4.1. *Let* α *be the ratio of the largest to the smallest packet value. Then for any delay bound* δ*, the competitive ratio of any on-line algorithm is at least* $1+\frac{\alpha-1}{\alpha(\alpha+1)}$*, even for uniform-delay buffers. Furthermore, if there are two packet values whose ratio is* $1 + \sqrt{2}$*, then the competitive ratio of any on-line algorithm is at least* $1 + \frac{1}{(1+\sqrt{2})^2} \approx 1.17$ *for any value of* δ*.*

Proof. Let A be any on-line algorithm, and let C_A be its competitive ratio. To bound C_A, consider the following scenario. All packets have the same slack value δ. At time $t = 0$ the buffer is empty and δ packets of value 1 arrive. During each of the following $\delta - 1$ steps ($t = 1, \ldots, \delta - 1$), a single packet of value $\alpha > 1$ arrives. Let x be the number of value 1 packets transmitted by A by time δ. We consider two possible continuations of the scenario. In the first case, no more packets arrive, and in the second case, δ packets of value α arrive at time δ. In the former case, the value served by A is at most $x + \delta\alpha$, while the optimal value is $\delta + \delta\alpha$. In the latter case, the value served by A is $x + \alpha(2\delta - x)$, while the optimal value is $2\delta\alpha$. It follows that the competitive ratio of A is at least

$$C_A \geq \max\left(\frac{\delta(1+\alpha)}{x+\delta\alpha}, \frac{2\delta\alpha}{x+\alpha(2\delta-x)}\right).$$

Consider the two possible ratios. To get the lower bound our goal is to fix α so that the maximum of the two ratios for any value of x is minimized. This is because the on-line algorithm fixes x given the value of α. For any value of α, it is not difficult to see that the best value of x that can be chosen by A is the one where the two ratios are equal. Solving for x as a function of α, we get that the maximum of the ratios is minimized when

$$x(\alpha) = \frac{2\delta\alpha}{\alpha^2+2\alpha-1},$$

in which case the competitive ratio of the algorithm is

$$C_A \geq 1 + \frac{\alpha-1}{\alpha(\alpha+1)}.$$

This proves the first part of the theorem. To prove the second part of the theorem, we find the worst case α by elementary calculus. It turns out that the competitive ratio is maximized (for $x(\alpha)$, i.e., when the algorithm makes the optimal choice) when $\alpha = 1+\sqrt{2}$. In this case we get that $C_A \geq 1 + \frac{1}{(1+\sqrt{2})^2}$, as desired. □

Next, consider the greedy algorithm for the general case where the allowed delays may be different and the link bandwidth is W. The greedy algorithm is extremely simple: at each time step t, transmit the W packets with the highest value whose deadlines have not expired yet. Ties are broken arbitrarily. Note that effectively, the greedy algorithm views each value as a priority class, in the sense that high-priority packets are always transmitted before low-priority ones. For this simplistic strategy, the following relatively strong property was already known [1, 12, 4] in slightly different models.

THEOREM 4.2. *The greedy algorithm is exactly* 2*-competitive in the bounded-delay buffer model, for any output link bandwidth.*

The lower bound for the greedy algorithm holds even if all jobs have the same weight. We note that for the unslotted model (where a packet may arrive during the transmission of another, and preemption is disallowed), [12] proves a lower bound of 2 on the competitive ratio of any deterministic algorithm, and 4/3 for the expected competitive ratio of any randomized algorithms.

In some practical cases, the values assigned to packets are not very refined. In the extreme case, there may be just "cheap" and "expensive" packets, for example, in ATM's Cell Loss Priority bit [23]. We can formalize this model by assigning only two possible values to packets: 1 for "cheap" and $\alpha > 1$ for "expensive." In the following theorem we prove that in this case, the bound guaranteed by Theorem 4.2 can be sharpened to $1 + 1/\alpha$. Notice that the competitive ratio approaches 1 when α tends to infinity.

THEOREM 4.3. *The greedy algorithm is at most* $1 + 1/\alpha$*-competitive in the bounded-delay buffer model with two packet values of* 1 *and* $\alpha > 1$*, for any output link bandwidth.*

Proof. Fix the input sequence, and let W be the output link bandwidth. Consider any optimal algorithm for the sequence. Clearly, $v(S_O^\alpha) \leq v(S_G^\alpha)$. In addition, the greedy algorithm schedules all packets from S_O^1, except the packets that were lost due to the decision of the greedy algorithm to transmit high-value packets with later deadlines. Since each high-value packet may cause loss of at most one low-value packet, we obtain that $v(S_O^1) - v(S_G^1) \leq v(S_G^\alpha)/\alpha$. The theorem follows. □

4.2. The case of $\delta = 2$. Improving on the greedy algorithm in the bounded-delay model turns out to be a challenging task. In this subsection we present a candidate algorithm. However, we are able to analyze its behavior only for the special case of $\delta = 2$, i.e., under the assumption that each packet must be sent either when it arrives or in the following time step. We also present improved lower bounds for this case.

Before we start, let us recall the following well-known fact. A schedule for a set of packets is called *earliest deadline first schedule* (or EDF for short) if the order in which packets are sent is the order of their deadlines.

LEMMA 4.4. *A set of packets with given arrival times and deadlines can be scheduled with link bandwidth W if and only if it can be scheduled by an EDF schedule.*

In addition, packets with the same deadline in a feasible schedule can be further ordered according to their values.

LEMMA 4.5. *A feasible EDF schedule may be transformed into another feasible EDF schedule in which packets with the same deadline are sent in order of nonincreasing value.*

Thus, without loss of generality, we may assume that the optimal algorithm schedules packets in order of nondecreasing deadlines, and packets with the same deadline in order of nonincreasing value. Ties are broken by the arrival order; i.e., packets arriving first are scheduled first.

We use the following algorithms, stated for general delay bound δ and link bandwidth W. The local-EDF algorithm is presented in Figure 4.1. We show in section 5 how the computation of the optimal schedule can be done efficiently. The β-EDF algorithm is defined by a parameter $0 \le \beta \le 1$ and appears in Figure 4.2.

Note that 1-EDF is the greedy algorithm, which sends the W packets with the highest value, and that 0-EDF is the local-EDF algorithm.

THEOREM 4.6. *The $1/\phi$-EDF algorithm is at most ϕ-competitive in the 2-variable bounded-delay buffer model, for any output link bandwidth W.*

Proof. Fix an arrival sequence. We compare the schedule generated by ϕ-EDF with a specific optimal schedule OPT. Specifically, by Lemmas 4.4 and 4.5, we may assume that OPT is EDF, and that if two packets with the same deadline and different values are sent at different times, then the more valuable packet is sent before the less valuable one. We now prove a series of simple properties that follow directly from the definition of the algorithms.

LEMMA 4.7. *If p is transmitted before p' by β-EDF, then p is not transmitted after p' by OPT.*

Proof. Suppose, for contradiction, that there exist packets p, p' such that $p \in S_G(t) \cap S_O(t+1)$ and $p' \in S_O(t) \cap S_G(t+1)$. Clearly both p and p' have deadline $t+1$. The lemma follows from the fact that both β-EDF and OPT send packets with the same deadline in order of nonincreasing value. ∎

LEMMA 4.8. *If $p \in S_G(t)$ performed a push-out at time t, then $v(q') \le v(p)/\phi$ for all packets q' pushed out at time t.*

Proof. It follows from the fact that at Step 3 of the β-EDF, we consider packets pushing out and packets to be pushed out in order of nonincreasing and nondecreasing value, respectively. ∎

LEMMA 4.9. *Suppose that $p, p' \in S_G(t)$ are packets with deadline $t+1$ such that p performed push-out at time t and p' did not perform a push-out at time t. Then $v(p) \le v(p')$.*

At each time step t do the following:

1. Compute the optimal schedule $\hat{S}$ for all packets not yet sent or expired (i.e., implicitly assuming no new packet will arrive).
2. Send the W packets which are sent at time t in $\hat{S}$ (we may assume, without loss of generality, that $\hat{S}$ is EDF).

FIG. 4.1. *The local-EDF algorithm.*

At each time step t do the following:

1. Compute the optimal EDF schedule $\hat{S}$ for all packets not yet sent or expired. Let S be the set of all packets scheduled in $\hat{S}$, and let S' and S'' be the sets of packets scheduled in $\hat{S}$ to be sent at times t and $t+1$, respectively.
2. Let $p \in S'$ be the packet of minimal value in S', and let $q \in S''$ be the packet of maximal value in S''.
3. If $v(p) < \beta \cdot v(q)$, then
   (a) **Push-out step:** Let $S' \leftarrow S' \cup \{q\} \setminus \{p\}$, and $S'' \leftarrow S'' \setminus \{q\}$. The packet q is said to have *pushed out* packet p.
   (b) Go to Step 2.
4. Otherwise (i.e., $v(p) \geq \beta \cdot v(q)$), terminate the algorithm and transmit S'.

FIG. 4.2. *The β-EDF algorithm.*

Proof. By definition, β-EDF sends packets with the same deadline in nondecreasing value order. □

LEMMA 4.10. *Consider the sets S' constructed at Step 1 at time t by the β-EDF algorithm. If some packet $p \in S_O(t)$ with deadline t is not included in S_G, then $(S' \cap A(t)) \subset S_O(t)$.*

Proof. Let $p' \in S' \cap A(t)$. Notice that $|S'| = W$ and $v(p') > v(p)$ because $p \notin S_G$. We argue that $p' \in S_O(t)$. First, note that $p' \in S_O$, since otherwise OPT could have been improved by swapping p and p'. Hence $p \in S_O(t) \cup S_O(t+1)$. To see that $p' \in S_O(t)$, suppose for contradiction that $p' \in S_O(t+1)$. Note that since p is not included in S_G, we must have that either S' contains no packet with deadline $t+1$, or $|S| = 2W$. In the former case, we get a contradiction to our assumption that $p' \in S'$ because the deadline of p' is $t+1$. In the latter case, we get that since $p' \in S' \cap S_O(t+1)$ and $|S| = 2W$, there exists a packet $p'' \in A(t) \cap S$ with deadline $t+1$ such that $p'' \notin S_O$. Moreover, $v(p'') > v(p)$ by construction of the β-EDF schedule. In this case, OPT can be improved by replacing p with p''. The lemma follows. □

For the remainder of the proof, we define a mapping $m : S_O \rightarrow S_G$ iteratively as follows.

1. If $p \in S_O(t) \cap (S_G(t-1) \cup S_G(t))$ for some time step t, then $m(p) = p$.
2. For each time step t, map any unmapped packet $p \in S_O(t)$ to $p' \in S_G(t)$ such that either
   (a) p' is unmapped, or
   (b) $p' \in S_O(t+1)$ and $|m^{-1}(p')| = 1$.

To prove the theorem, it suffices to show that (i) all packets in S_O are mapped, and that (ii) $v(m^{-1}(p)) \leq \phi \cdot v(p)$ for all $p \in S_G$.

LEMMA 4.11. *If at Step 2 a packet $p \in S_O(t)$ has to be mapped, then there always exists a packet $p' \in S_G$ eligible for either Step 2(a) or Step 2(b).*

Proof. Consider an unmapped packet $p \in S_O(t)$ that is processed in the course of Step 2. Since p has not been mapped at Step 1, either $p \in S_G(t+1)$ or $p \in S_O \setminus S_G$. Thus, since p is available to ϕ-EDF at time t and it is not transmitted at that time, we have that $|S_G(t)| = W$. The lemma follows by construction of the mapping. ∎

LEMMA 4.12. *If a packet $p \in S_O(t)$ is mapped to a packet p', then $v(p) \le v(p')/\phi$.*

Proof. Suppose first that p is mapped to a packet p' during Step 2(a). Then since p is available to ϕ-EDF at time t and it is not transmitted, the value of any packet that is scheduled at that time is at least $v(p) \cdot \phi$. So for the remainder of the proof, assume that p is mapped to p' during Step 2(b). In this case, since p has not been mapped at Step 1, either $p \in S_G(t+1)$ or $p \in S_O \setminus S_G$. By Lemma 4.7, $p \notin S_G(t+1)$. Also, p cannot have deadline $t+1$, since otherwise, $v(p) > v(p')$ and ϕ-EDF would have replaced p' by p. Hence $p \in (S_O \setminus S_G)$, and the deadline of p is t. It follows that it must be the case that either (1) p is pushed out at Step 3(a) of β-EDF, or (2) $p \notin S$, where S is the set computed at Step 1 of β-EDF. Let us analyze these cases.

(1) If p' performed a push-out, then we are done by Lemma 4.8. Otherwise, let q be the packet that pushed out p. According to Lemma 4.9 we have that $v(q) \le v(p')$, and consequently, $v(p) \le v(p')/\phi$.

(2) If $p \notin S$, then by Lemma 4.10 we have that $p' \notin S' \cap A(t)$ because $p' \notin S_O(t) \cap A(t)$ (recall that $p' \in S_O(t+1)$). Thus, if $p' \in S_G(t)$, then it should have pushed out some packet q such that $v(q) \le v(p)/\phi$. By construction of the optimal ϕ-EDF schedule we have that $v(q) \ge v(p)$. Hence, $v(p) \le v(p')/\phi$. ∎

Lemmas 4.11 and 4.12 conclude the proof of Theorem 4.6. ∎

Uniform delay buffers. We remark that for uniform-delay buffers with $\delta = 2$, better upper bounds can be obtained. For example, Corollary 5.5 (in conjunction with Theorem 3.4) says that a competitive ratio of 1.5 is achieved by the FIFO-greedy algorithm in this model. Moreover, careful case analysis shows that the β-EDF algorithm achieves a ratio of about 1.43 when $\beta = \frac{3+\sqrt{13}}{2} \approx 3.3$. We omit the details.

We now prove lower bounds for the case $\delta = 2$. First, we consider the case of arbitrary bandwidth.

THEOREM 4.13. *The competitive ratio of any on-line algorithm for a W-bandwidth 2-uniform bounded-delay model is at least* 10/9. *Moreover, the competitive ratio of any on-line algorithm for a W-bandwidth 2-variable bounded-delay model is at least* 1.17.

Proof. We first show the bound for the uniform model. Fix an on-line algorithm A and consider the following scenarios. Initially, the buffer is empty and $2W$ packets of value 1 arrive. At the next step W packets of value α arrive. Suppose that A drops a fraction $x \le 1$ of the 1-value packets. We consider two possible scenarios. In the first no more packets arrive. Then the competitive ratio is bounded from below by $\frac{\alpha+2}{\alpha+2-x}$ since there exists a feasible schedule of the whole sequence. In the second scenario $2W$ packets of value α arrive at the following time step. In this case the competitive ratio of A is bounded from below by $\frac{3\alpha+1}{(2+x)\alpha+2-x}$. Similar to the proof of Theorem 4.1, the "best" value of x is the one that equates the two ratios. In this case we get $x = \frac{(\alpha+2)(\alpha-1)}{\alpha^2+4\alpha-1}$. Substituting and maximizing for α we get $\alpha = 3$ and $x = 1/2$ to yield the ratio 10/9.

We now establish the bound for the variable model. Fix an on-line algorithm A and consider the following scenarios. Initially, the buffer is empty and W packets of value 1 and delay 1 arrive. At the same step, W packets of value α and delay 2 arrive. Suppose that A drops a fraction $x \le 1$ of the 1-value packets. We consider two possible scenarios. In the first no more packets arrive. Then the competitive

ratio is bounded from below by $\frac{\alpha+1}{\alpha+1-x}$ since there exists a feasible schedule of the whole sequence. In the second scenario, W packets of value α and delay 1 arrive at the next time step. In this case the competitive ratio of A is bounded from below by $\frac{2\alpha}{(1+x)\alpha+1-x}$. These are the same ratios considered in the proof of Theorem 4.1, and hence we get the same bound of $1+\frac{1}{(1+\sqrt{2})^2} \approx 1.17$. □

Slightly better results can be proved for bandwidth 1.

THEOREM 4.14. *The competitive ratio of any deterministic on-line algorithm for a* 2*-uniform and a* 2*-variable bounded-delay model with bandwidth* 1 *is at least* 1.25 *and* $\sqrt{2}$*, respectively.*

Proof. Consider the uniform model first. Fix an on-line algorithm A and consider the following scenario. At time 0, the buffer is empty and two packets of value 1 arrive, and at time 1, a packet of value $\alpha > 1$ arrives. There are two possible continuations. In one, no more packets arrive, and in the other, at time 2 two additional packets of value α arrive. Now, if A drops one of the low-value packets, then its competitive ratio is at least $\frac{\alpha+2}{\alpha+1}$ since there exists a feasible schedule of all three packets of the first continuation. Otherwise, at least one packet of value α is lost by A in the second continuation, and hence the competitive ratio of A is at least $\frac{3\alpha+1}{2\alpha+2}$. Setting $\frac{\alpha+2}{\alpha+1} = \frac{3\alpha+1}{2\alpha+2}$, we get that for $\alpha = 3$, the competitive ratio of A is at least 1.25.

The bad example for the variable delay model is even simpler. Let A be an on-line algorithm, and consider the following scenario. At time 0, the buffer is empty and a packet having value 1 and delay 1 arrives together with a packet of value $\alpha > 1$ and delay of 2. The two possible continuations are (i) no more arrivals and (ii) at time 1 an additional packet of value α with delay 1 (i.e., zero slack time) arrives. If A drops the low-value packet, then its competitive ratio for continuation (i) is $\frac{\alpha+1}{\alpha}$ since there exists a feasible schedule of both packets. If the low-value packet is scheduled, then for continuation (ii), A loses at least one high-value packet, showing that its competitive ratio is at least $\frac{2\alpha}{\alpha+1}$. Solving $\frac{\alpha+1}{\alpha} = \frac{2\alpha}{\alpha+1}$, we get that for $\alpha = 1+\sqrt{2}$, the competitive ratio of A is at least $\sqrt{2}$. □

5. The off-line case. In this section we show that the FIFO model has matroid structure in the off-line setting. As a result, optimal off-line solutions can be found in polynomial time. We also study the connection between the FIFO model and the bounded-delay model.

We first consider the FIFO model. Fix the input sequence for the remainder of this section. We also assume, without loss of generality, that all packets admitted to the buffer are later sent: since we are dealing with the off-line case, a packet that will be dropped can simply be rejected when it arrives.

Let $\mathcal{C}$ be the class of all work-conserving schedules, defined as follows. A schedule A is said to be *work conserving*, denoted by $A \in \mathcal{C}$, if

$$|S_A(t)| = \min(W,\ |Q_A(t) \cup A(t) \setminus D_A(t)|) \qquad \text{for all time steps } t,$$

where W is the link bandwidth. In words, a schedule is work-conserving if a packet may be delayed only when the full bandwidth is used by other packets. Note that work-conserving algorithms may still reject packets arbitrarily.

THEOREM 5.1. *For a FIFO schedule* A*, let* S_A *be the set of all packets served by* A*. Then* $\mathfrak{I}_{FIFO} \stackrel{\text{def}}{=} \{S_A : A \in \mathcal{C}\}$ *is a matroid.*

Proof. There are three properties to verify. The first two are trivial: $\emptyset \in \mathfrak{I}$, and for $S_A \subset S_B$ with $S_B \in \mathfrak{I}$, we clearly have that $S_A \in \mathfrak{I}$ by dropping the packets in $B \setminus A$. It remains to verify the following property: If $|S_A| > |S_B|$, then there exists $p \in S_A \setminus S_B$

such that $S_B \cup \{p\} \in \mathfrak{I}$. This can be seen as follows. Let t_0 be the first time in which $|S_A(t_0)| > |S_B(t_0)|$: t_0 exists by the assumption that $|S_A| > |S_B|$. Let $t_1 \le t_0$ be the last step before t_0 where $|D_A(t_1)| < |D_B(t_1)|$: t_1 exists by the assumption that B is work conserving. Then there exists a packet $p \in D_B(t_1) \setminus D_A(t_1)$. Moreover, since by our choice, for any $t \in [t_1, t_0]$ we have that $|S_B(t)| \ge |S_A(t)$ and $|D_B(t)| \le |D_A(t)|$, and since A is work conserving by assumption, we also have that $|Q_B(t)| < |Q_A(t)|$ for all $t \in [t_1, t_0]$. Hence the packet p can be added to S_B while keeping the schedule feasible. □

A similar result for the bounded delay case is well known [10, Theorem 17.12]. We state it here for completeness.

THEOREM 5.2. *For a bounded delay schedule A, let S_A be the set of all packets served by A. Then $\mathfrak{I}_{BD} \stackrel{\text{def}}{=} \{S_A : A \in \mathcal{C}\}$ is a matroid.*

We remark that for the FIFO model (and hence for the uniform bounded-delay model as well; see Theorem 5.4 below), an optimal solution can be found in $O(n \log B)$ time, and in $O(n^2)$ time for the variable bounded delay model, where n is the number of packets in the input sequence and B is the buffer size.

COROLLARY 5.3. *An optimal schedule for the FIFO and bounded delay models can be found in polynomial time.*

The following theorem shows a transformation from the FIFO model to the uniform bounded-delay model.

THEOREM 5.4. *For any input sequence, the optimal value served by a FIFO schedule with buffer size B is equal to the optimal value served by a uniform bounded-delay schedule with $\delta = B + 1$.*

Proof. Let OPT_F be the optimal value served by a FIFO schedule with buffer size B, and let OPT_D be the optimal value served by a uniform bounded-delay schedule with $\delta = B + 1$. First, note that any work-conserving schedule in the FIFO model is also a schedule in the bounded delay model, since no packet in the FIFO model is served more than B time units after its arrival, and hence $OPT_F \le OPT_D$. For the other direction, consider any schedule in the uniform bounded-delay model. Since in this model, a set of packets can be served if and only if the EDF schedule of this set is feasible, we may assume without loss of generality that the schedule is EDF. Also note that the number of packets in the bounded delay buffer is never more than the maximal delay bound (recall that only packets that are eventually transmitted enter the buffer). The result now follows from the fact that an EDF schedule in the uniform bounded delay model is exactly the FIFO order, and hence $OPT_D \le OPT_F$. □

A nice feature of the FIFO to bounded-delay transformation in the proof of Theorem 5.4 is that it does not require off-line information. We therefore have the following corollary.

COROLLARY 5.5. *Let $C_F(B)$ be the best competitive factor of on-line FIFO algorithms with buffer size B, and let $C_D(\delta)$ be the best competitive factor of on-line uniform bounded-delay algorithms with maximal delay δ. Then $C_D(B+1) \le C_F(B)$.*

We remark that the converse cannot be proved by our transformation, since it requires knowledge of the future.

6. Conclusion. In this work we studied competitive overflow management. We sharpened the results of [20] for the FIFO model, and initiated a study in the bounded-delay model. In particular, we have proved the following facts:

- The greedy algorithm is 2-competitive for FIFO buffers.
- Among all the greedy algorithms, head-drop is the best.
- No on-line algorithm can be optimal for the bounded-delay case.

- The greedy algorithm is $(1+\frac{1}{\alpha})$-competitive in the bounded delay model when the set of possible values is 1 and $\alpha > 1$.

Many important questions remain open:

- In the FIFO model, can one substantially improve on the 2-competitiveness of the greedy algorithm in the general case? The best known result [14] is for the case of two packet values 1 and $\alpha > 4$, with competitive ratio of $\frac{\sqrt{\alpha}+1}{\sqrt{\alpha}}$. Combining this with our results for the greedy algorithm, one can get a competitive ratio better than 2 for this case only. There is no real improvement for the general case of packet values.
- In the bounded delay model, we know very little in the general case. Even for the uniform bounded delay case, we know how to improve the greedy algorithm only for the special case of $\delta = 2$.

ON THE FRAME–STEWART CONJECTURE ABOUT THE TOWERS OF HANOI*

XIAO CHEN† AND JIAN SHEN‡

Abstract. The multipeg Towers of Hanoi problem consists of k pegs mounted on a board together with n disks of different sizes. Initially these disks are placed on one peg in the order of their size, with the largest at the bottom. The rules of the problem allow disks to be moved one at a time from one peg to another as long as a disk is never placed on top of a smaller disk. The goal of the problem is to transfer all the disks to another peg with the minimum number of moves, denoted by $H(n,k)$. An easy recursive argument shows that $H(n,3) = 2^n - 1$. However, the problem of computing the exact value of $H(n,k)$ for $k \geq 4$ has been open since 1939, and in particular, the special case of $H(n,4)$ has been open since 1907.

In 1941, Frame and Stewart each gave an algorithm to solve the Towers of Hanoi problem based on an unproved assumption. The Frame–Stewart number, denoted by $FS(n,k)$, is the number of moves needed to solve the Towers of Hanoi problem using the "presumed optimal" Frame–Stewart algorithm. Since then, proving the Frame–Stewart conjecture $FS(n,k) = H(n,k)$ has become a notorious open problem.

In this paper, we prove that $FS(n,k)$ and $H(n,k)$ both have the same order of magnitude of $2^{(1\pm o(1))(n(k-2)!)^{1/(k-2)}}$. This provides the strongest evidence so far to support the Frame–Stewart conjecture.

Key words. Towers of Hanoi problem, Frame–Stewart conjecture, optimal algorithm, Frame–Stewart algorithm

1. Introduction.

The Towers of Hanoi problem, introduced by Édouard Lucas in 1883, consists of three pegs and a set of n disks of different diameters that can be stacked on the pegs. The towers are formed initially by stacking the disks onto one peg in the order of their size, with the largest at the bottom. The rules of the problem allow disks to be moved one at a time from one peg to another as long as a disk is never placed on the top of a smaller disk. The goal of the problem is to transfer all the disks to another peg with the minimum number of moves. An easy argument using a recursive relation shows that $2^n - 1$ moves are necessary and sufficient to carry out this task.

The Towers of Hanoi problem was extended to four pegs by Dudeney [2] in 1907 and to any arbitrary $k \geq 3$ pegs by Stewart [7] in 1939. In 1941, Frame [3] and Stewart [8] independently proposed an algorithm to the Towers of Hanoi problem with $k \geq 4$ pegs:

1. Recursively transport a stack of $n - i$ smallest disks from the first peg to a temporary peg, using all k pegs;
2. Transport the remaining stack of i largest disks from the first peg to the final peg, using $k - 1$ pegs and ignoring the peg occupied by the smaller disks;

3. Recursively transport the smallest $n-i$ disks from the temporary peg to the final peg, using all k pegs.

(Indeed, Frame's algorithm is slightly different from the above proposed by Stewart. But both algorithms are essentially equivalent [4].) The Frame–Stewart number, denoted by $FS(n,k)$, is the minimum number of moves needed to solve the Towers of Hanoi problem using the above Frame–Stewart algorithm. Thus $FS(n,k)$ has the following recursive formula:

$$FS(n,k) = \begin{cases} 2^n - 1 & \text{if } k = 3, \\ \min_{1 \le i < n} \{2FS(n-i,k) + FS(i,k-1)\} & \text{if } k \ge 4. \end{cases}$$

The Frame–Stewart number $FS(n,k)$ is called the "presumed optimal" solution since no justification has ever been made that an optimal algorithm must be of this form. Let $H(n,k)$ be the minimum number of moves needed to solve the Towers of Hanoi problem. The Frame–Stewart conjecture $FS(n,k) = H(n,k)$ is still open now. (As pointed out by Klavžar, Milutinović, and Petr [4], the claimed proof of the conjecture by Majumdar [6] is indeed incorrect.) Donald Knuth commented on the conjecture, saying "I doubt if anyone will ever resolve the conjecture; it is truly difficult" (see [5]).

In the attempt to prove the Frame–Stewart conjecture, Bode and Hinz [1] verified the conjecture for four pegs with up to 17 disks. Recently, Szegedy [9] proved that

$$FS(n,k) \ge 2^{(1 \pm o(1)) c_k n^{1/(k-2)}},$$

where $c_k = \frac{1}{2}\left(\frac{12}{k(k-1)}\right)^{1/(k-2)}$.

For convenience, let $\log x$ denote the logarithmic function with base 2. In this paper, we prove that for $n \ge 1$ and $k \ge 3$,

$$\log FS(n,k) = \log H(n,k) + \Theta(k + \log n) = (n(k-2)!)^{1/(k-2)} + \Theta(k + \log n).$$

In other words, for each fixed $k \ge 3$ and for $n \gg k$,

$$FS(n,k) = 2^{(1 \pm o(1))(n(k-2)!)^{1/(k-2)}} = H(n,k).$$

This provides the strongest evidence so far to support the Frame–Stewart conjecture.

2. Lower bound on the optimal number of moves. In this section, we derive a lower bound on the optimal number $H(n,k)$ of moves for the Towers of Hanoi problem. We adopt the remarkable strategy introduced by Szegedy [9] who considered the following generalized problem: What is the minimum number of moves to move each disk at least once among all possible initial setups of disks? The advantage of this strategy is that one can use induction in the proofs.

An arrangement of k pegs and n disks is called a configuration if it obeys the "smaller disk on the top of larger disk" rule. For a configuration C, let $g(C)$ be the minimum number of moves required to have every disk moved at least once, where all moves are taken according to the rules of the Towers of Hanoi. Szegedy [9] defined

$$g(n,k) = \min_C g(C),$$

where C runs through all possible configurations of n disks and k pegs. The function $g(n,k)$ is well defined since $g(C)$ is finite for some configuration C [9, Remark 1]. By the definition of $g(n,k)$, we have $H(n,k) \ge g(n,k)$, and thus a lower bound on

$H(n,k)$ can be derived from Theorem 2. We begin with a study of the monotone properties of the function $g(n,k)$.

LEMMA 1. *Suppose $n \geq 1$ and $k \geq 3$. Then the function $g(n,k)$ is decreasing with respect to the variable k.*

THEOREM 1. *Suppose $n \geq 2$ and $k \geq 4$. Then there exists some m with $1 \leq m \leq n-1$ such that*

$$g(n,k) \geq \begin{cases} 2\max\{g(n-m,k), g(m,k-1)\} & \text{if } g(n-m,k) = g(m,k-1), \\ 2\max\{g(n-m,k), g(m,k-1)\} - 1 & \text{if } g(n-m,k) \neq g(m,k-1). \end{cases}$$

Proof. Let C be an extremal configuration of n disks and k pegs with $g(C) = g(n,k)$. Let $S = \left(s_1, s_2, \ldots, s_{g(C)}\right)$ be a sequence of $g(C)$ moves that move every disk of C at least once, where all moves are taken according to the rules of the Towers of Hanoi. Let $S = S_1 \cup S_2$ with $|S_1| = \lfloor g(C)/2 \rfloor$ and $|S_2| = \lceil g(C)/2 \rceil$; that is, S_1 and S_2 are the first half and the second half of the sequence of moves of S, respectively. For $i = 1, 2$, let

$$D_i = \{j : \text{disk } j \text{ is moved at least once by } S_i\}.$$

Then $|D_1 \cup D_2| = n$.

Claim. $D_1 - D_2 \neq \emptyset$ and $D_2 - D_1 \neq \emptyset$.

Proof of the claim. Let $s_1(C)$ be the configuration obtained by applying the first move s_1 of S to C. Suppose the move s_1 moves disk i. We observe that disk i cannot be moved more than once by S; otherwise, each disk in the configuration $s_1(C)$ can be moved at least once by the following $g(C) - 1$ $(= g(n,k) - 1)$ moves $s_2, \ldots, s_{g(C)}$, contradicting the definition of $g(n,k)$. Since disk i is moved only by $s_1 \in S_1$, we have $i \in D_1 - D_2 \neq \emptyset$. Similarly, the disk moved by the last move $s_{g(C)}$ of S cannot be moved more than once by S either. Thus $D_2 - D_1 \neq \emptyset$.

Let $D_1 - D_2 = \{r_1, \ldots, r_l\}$ and $D_2 - D_1 = \{t_1, \ldots, t_m\}$, where $1 \leq l, m \leq n-1$. We may label the disks in such a way that disk i has larger size than disk j if and only if $i > j$. Let r_1 be the smallest number in $(D_1 - D_2) \cup (D_2 - D_1)$. Since $|D_1| = |D_1 \cup D_2| - |D_2 - D_1| = n - m$, by the definition of D_1, we know that S_1 moves $n - m$ different pegs. Suppose the moves of S_1 take place in t pegs, where $t \leq k$. Then, by Lemma 1,

$$|S_1| \geq g(n-m,k). \tag{1}$$

Since $r_1 \in D_1 - D_2$, disk r_1 is not moved by S_2. Since $r_1 < t_i$ for all $1 \leq i \leq m$, all disks t_i $(1 \leq i \leq m)$ have larger sizes than disk r_1, which is idle during the whole movement of S_2. By the "smaller disk on the top of larger disk" rule, the peg occupied by disk r_1 is completely useless when each disk t_i $(1 \leq i \leq m)$ is moved by S_2. Thus the m disks $t_1, \ldots, t_m$ are moved by S_2 using at most $k-1$ pegs. (S_2 might also move disks other than disks $t_1, \ldots, t_m$. But those moves and disks can be ignored since they do not affect the moves involving disks $t_1, \ldots, t_m$. So one can focus on only the subsequence of S_2 that moves disks $t_1, \ldots, t_m$.) By Lemma 1,

$$|S_2| \geq g(m,k-1). \tag{2}$$

Note that $g(n,k) \geq 2\max\{|S_1|, |S_2|\} - 1$. If $g(n-m,k) \neq g(m,k-1)$, then Theorem 1 follows from (1) and (2). If $g(n-m,k) = g(m,k-1)$, then $g(n,k) \geq 2|S_1| \geq 2g(n-m,k) = 2\max\{g(n-m,k), g(m,k-1)\}$. ∎

LEMMA 2. *Suppose $n \geq 1$ and $k \geq 3$. Then the function $g(n,k)$ is strictly increasing with respect to the variable n.*

Proof. Let C be an extremal configuration of n disks and k pegs with $g(C) = g(n,k)$. Let $S = \left(s_1, s_2, \ldots, s_{g(C)}\right)$ be a sequence of $g(C)$ moves that move every disk of C at least once, where all moves are taken according to the rules of the Towers of Hanoi. Let $s_1(C)$ be the configuration obtained by applying the first move s_1 of S to C. Suppose the move s_1 moves disk i. In the proof of Theorem 1, it is shown that disk i cannot be moved more than once by S. Then every disk except disk i in the configuration of $s_1(C)$ is moved at least once by $S - \{s_1\}$, which consists of a sequence of $g(n,k) - 1$ moves. Let C' be the configuration obtained by removing the disk i from the configuration $s_1(C)$. Then C' has $n-1$ disks and k pegs, and $g(n-1,k) \leq g(C') = g(C) - 1 = g(n,k) - 1$. □

COROLLARY 1. *Suppose $n \geq 2$ and $k \geq 4$. Then for every m with $1 \leq m \leq n-1$,*

$$g(n,k) \geq 2\min\{g(n-m,k), g(m,k-1)\}.$$

Proof. By Lemma 2, $g(n-m,k)$ is a strictly decreasing function of m, and $g(m,k-1)$ is a strictly increasing function of m. Corollary 1 obviously follows from Theorem 1. □

As usual, the function $\binom{x}{t}$ can be extended to real x for each integer t as follows:

$$\binom{x}{t} = \begin{cases} 0 & \text{if } t < 0, \\ 1 & \text{if } t = 0, \\ x(x-1)\cdots(x-t+1)/t! & \text{if } t > 0. \end{cases}$$

In particular, $\binom{0}{0} = 1$ by the above definition. The identity $\binom{x}{t} = \binom{x-1}{t} + \binom{x-1}{t-1}$ will be used repeatedly in the proofs.

THEOREM 2. *Suppose $k \geq 3$. Then for every integer $s \geq 2$,*

$$g\left(\binom{s}{k-2} + \binom{s+k-7}{k-5}, k\right) \geq 2^{s-2}.$$

Proof. We use double-induction on k and s. First, we use induction on k. If $k = 3$, by [9, Remark 2],

$$g\left(\binom{s}{k-2} + \binom{s+k-7}{k-5}, k\right) = g(s,3) \geq 2^{s-2} + 1$$

for all $s \geq 2$. Now suppose $k \geq 4$ and suppose the theorem is true for $k-1$; that is, for every integer $s \geq 2$,

$$g\left(\binom{s}{k-3} + \binom{s+k-8}{k-6}, k-1\right) \geq 2^{s-2}.$$

Equivalently, by using $s-1$ to replace s in the above, we have

$$g\left(\binom{s-1}{k-3} + \binom{s+k-9}{k-6}, k-1\right) \geq 2^{s-3} \tag{3}$$

for all $s \geq 3$.

Second, we use induction on s. If $s = 2$, then $\binom{s}{k-2} + \binom{s+k-7}{k-5} = \binom{2}{k-2} + \binom{k-5}{k-5} = 1$ since $k \geq 4$. Thus

$$g\left(\binom{s}{k-2} + \binom{s+k-7}{k-5}, k\right) = g(1,k) = 1 = 2^{s-2};$$

that is, Theorem 2 is true for $s = 2$ and $k \geq 4$. Now suppose $s \geq 3$ and suppose the theorem is true for $s - 1$; that is, for every integer $k \geq 4$,

$$g\left(\binom{s-1}{k-2} + \binom{s+k-8}{k-5}, k\right) \geq 2^{s-3}. \tag{4}$$

Let $n = \binom{s}{k-2} + \binom{s+k-7}{k-5}$ and $m = \binom{s-1}{k-3} + \binom{s+k-8}{k-6}$. Then by Corollary 1 together with (3) and (4),

$$\begin{aligned} g(n,k) &\geq 2\min\{g(n-m,k), g(m,k-1)\} \\ &= 2\min\left\{g\left(\tbinom{s-1}{k-2} + \tbinom{s+k-8}{k-5}, k\right), g\left(\tbinom{s-1}{k-3} + \tbinom{s+k-8}{k-6}, k-1\right)\right\} \\ &\geq 2\min\left\{g\left(\tbinom{s-1}{k-2} + \tbinom{s+k-8}{k-5}, k\right), g\left(\tbinom{s-1}{k-3} + \tbinom{s+k-9}{k-6}, k-1\right)\right\} \\ &\geq 2^{s-2}; \end{aligned}$$

that is, Theorem 2 is true for s and k. The proof is complete by the principle of double-induction. □

3. Proof of main result. By the definition of $g(n,k)$ and $H(n,k)$, we have $g(n,k) \leq H(n,k) \leq FS(n,k)$. Thus, in order to obtain the order of magnitude of $H(n,k)$, one needs to have a lower bound on $g(n,k)$ and an upper bound on $FS(n,k)$ with the same order of magnitude.

LEMMA 3. *Suppose $n \geq 1$ and $k \geq 3$. Then*

$$\log FS(n,k) < (n(k-2)!)^{1/(k-2)} + \log n.$$

Proof. For any fixed k and n, there is a unique s such that $\binom{k+s-3}{k-2} < n \leq \binom{k+s-2}{k-2}$. The exact expression on $FS(n,k)$ in the first line below can be found in many papers (for example, [3]).

$$\begin{aligned} FS(n,k) &= 2^s\left(n - \tbinom{k+s-3}{k-2}\right) + \sum_{t=0}^{s-1} 2^t \tbinom{k+t-3}{k-3} \\ &\leq 2^s\left(n - \tbinom{k+s-3}{k-2}\right) + \tbinom{k+s-4}{k-3}\sum_{t=0}^{s-1} 2^t \\ &< 2^s\left(n - \tbinom{k+s-3}{k-2}\right) + \tbinom{k+s-4}{k-3}2^s \\ &= 2^s\left(n - \tbinom{k+s-3}{k-2} + \tbinom{k+s-4}{k-3}\right) \\ &= 2^s\left(n - \tbinom{k+s-4}{k-2}\right) < n2^s. \end{aligned}$$

Thus $\log FS(n,k) \leq s + \log n$. To estimate s, we have $n > \binom{k+s-3}{k-2} > s^{k-2}/(k-2)!$, which implies $s < (n(k-2)!)^{1/(k-2)}$. □

LEMMA 4. *Suppose $n \geq 1$ and $k \geq 3$. Then*

$$\log g(n,k) > (n(k-2)!)^{1/(k-2)} - k + 1.$$

Proof. Lemma 4 holds for $n = 1$ since

$$\log g(1,k) = \log 1 = 0 > ((k-2)!)^{1/(k-2)} - k + 1.$$

If $k = 3$, by [9, Remark 2], we have $g(n, 3) \geq 2^{n-2} + 1$ for all $n \geq 2$. Thus

$$\log g(n, 3) > n - 2 = (n(k-2)!)^{1/(k-2)} - k + 1.$$

Now suppose $n \geq 2$ and $k \geq 4$. Then there is a unique s such that $\binom{s}{k-2} + \binom{s+k-7}{k-5} < n \leq \binom{s+1}{k-2} + \binom{s+k-6}{k-5}$. Also it is easy to verify that $s \geq 2$. To estimate s, we have

$$\begin{aligned} n &\leq \tbinom{s+1}{k-2} + \tbinom{s+k-6}{k-5} \leq \begin{cases} \tbinom{s+1}{k-2} & \text{if } k = 4, \\ \tbinom{s+k-4}{k-2} + \tbinom{s+k-4}{k-3} & \text{if } k \geq 5 \end{cases} \\ &= \tbinom{s+k-3}{k-2} < (s+k-3)^{k-2}/(k-2)!, \end{aligned}$$

from which $s > (n(k-2)!)^{1/(k-2)} - k + 3$. By Lemma 2 and Theorem 2,

$$\log g(n, k) > \log g\left(\binom{s}{k-2} + \binom{s+k-7}{k-5}, k\right) \geq s-2 > (n(k-2)!)^{1/(k-2)} - k + 1. \qquad \square$$

Finally, we have the main theorem (Theorem 3) showing that $FS(n, k)$ and $H(n, k)$ both have the order of magnitude of $2^{(1\pm o(1))(n(k-2)!)^{1/(k-2)}}$.

THEOREM 3. *Suppose $n \geq 1$ and $k \geq 3$. Then*

$$\log FS(n, k) = \log H(n, k) + \Theta(k + \log n) = (n(k-2)!)^{1/(k-2)} + \Theta(k + \log n).$$

In other words, for each fixed k and for $n \gg k$,

$$FS(n, k) = 2^{(1\pm o(1))(n(k-2)!)^{1/(k-2)}} = H(n, k).$$

Proof. By the definition of $g(n, k)$ and $H(n, k)$, we have $g(n, k) \leq H(n, k) \leq FS(n, k)$. By Lemmas 3 and 4,

$$(n(k-2)!)^{1/(k-2)} - k + 1 < \log H(n, k) \leq \log FS(n, k) < (n(k-2)!)^{1/(k-2)} + \log n,$$

from which Theorem 3 follows. $\square$

INCOMPLETE DIRECTED PERFECT PHYLOGENY*

ITSIK PE'ER†, TAL PUPKO‡, RON SHAMIR§, AND RODED SHARAN¶

Abstract. Perfect phylogeny is one of the fundamental models for studying evolution. We investigate the following variant of the model: The input is a species-characters matrix. The characters are binary and directed; i.e., a species can only gain characters. The difference from standard perfect phylogeny is that for some species the states of some characters are unknown. The question is whether one can complete the missing states in a way that admits a perfect phylogeny. The problem arises in classical phylogenetic studies, when some states are missing or undetermined. Quite recently, studies that infer phylogenies using inserted repeat elements in DNA gave rise to the same problem. Extant solutions for it take time $O(n^2m)$ for n species and m characters. We provide a graph theoretic formulation of the problem as a graph sandwich problem, and give near-optimal $\tilde{O}(nm)$-time algorithms for the problem. We also study the problem of finding a single, general solution tree, from which any other solution can be obtained by node splitting. We provide an algorithm to construct such a tree, or determine that none exists.

Key words. perfect phylogeny, incomplete data, graph sandwich, evolution

1. Introduction.

When studying evolution, the divergence patterns leading from a single ancestor species to its contemporary descendants are usually modeled by a tree structure, called *phylogenetic tree*, or *phylogeny*. Extant species correspond to the tree leaves, while their common progenitor corresponds to the root. Internal nodes correspond to hypothetical ancestral species, which putatively split up and evolved into distinct species. Tree branches model changes through time of the hypothetical ancestor species. The common case is that one has information regarding the leaves, from which the phylogenetic tree is to be inferred. This task, called *phylogenetic reconstruction* (cf. [8]), was one of the first algorithmic challenges posed by biology, and the computational community has been dealing with problems of this flavor for over three decades (see, e.g., [13]).

The character-based approach to tree reconstruction describes extant species by their attributes or *characters*. Each character takes on one of several possible *states*. The input is represented by a matrix $\mathcal{A}$, where a_{ij} is the state of character j in

species i, and the ith row is the *character vector* of species i. The output sought is a hypothesis regarding evolution, i.e., a phylogenetic tree along with the suggested character vectors of the internal nodes. This output must satisfy properties specified by the problem variant.

One important class of phylogenetic reconstruction problems concerns finding a *perfect phylogeny*. The property required from such a phylogeny is that for each possible character state, the set of all nodes that have that state induces a connected subtree. The general perfect phylogeny problem is NP-hard [5, 21]. When considering the number of possible states per character as a parameter, the problem is fixed parameter tractable [2, 16]. For *binary characters*, having only two possible states, perfect phylogeny is linear-time solvable [12].

When no perfect phylogeny is possible, one option is to seek a largest subset of characters which admits a perfect phylogeny. Characters in such a subset are said to be *compatible*. Compatibility problems have been studied extensively (see, e.g., [18]).

Another common optimization approach to phylogenetic reconstruction is the *parsimony* criterion. It calls for a solution with the fewest state changes altogether, counting a change whenever the state of a character changes between a species and its ancestor species. This problem is known to be NP-hard [9]. A variant introduced by Camin and Sokal [6] assumes that characters are binary and *directed*, namely, only $0 \rightarrow 1$ changes may occur on any path from the root to a leaf. Denoting by 1 and 0 the presence and absence, respectively, of the character, this means that characters can only be gained throughout evolution. Another related binary variant is Dollo parsimony [7, 20], which assumes that a $0 \rightarrow 1$ change may happen only once; i.e., a character can be gained once, but it can be lost several times. Both of these variants are polynomially solvable (cf. [8]).

In this paper, we discuss a variant of binary perfect phylogeny which combines assumptions of both Camin–Sokal parsimony and Dollo parsimony. The setup is as follows: The characters are binary, directed, and can be gained only once. As in perfect phylogeny, the input is a matrix of character vectors, with the difference that some character states are missing. The question is whether one can complete the missing states in a way admitting a perfect phylogeny. We call this problem *Incomplete Directed Perfect phylogeny (IDP)*.

The problem of handling incomplete phylogenetic data arises whenever some of the data are missing. It is also encountered in the context of morphological characters, where for some species it may be impossible to reliably assign a state to a character. The problem of determining whether a set of incomplete *undirected* characters is compatible was shown to be NP-complete, even in the case of binary characters [21]. Indeed, the popular PAUP software package [22] provides an exponential solution to the problem by exhaustively searching the space of missing states.

Quite recently, a novel kind of genomic data has given rise to the same problem: Nikaido, Rooney, and Okado [19] use inserted repetitive genomic elements, particularly Short Interspersed Nuclear Elements (SINEs), as a source of evolutionary information. SINEs are short DNA sequences that were copied and randomly reinserted into various genomic loci during evolution. The distinct insertion loci are identifiable by the flanking sequences on both sides of the insertion site (see Figure 1). These insertions are assumed to be unique events in evolution, because the odds of having separate insertion events at the very same locus are negligible. Furthermore, a SINE insertion is assumed to be irreversible; i.e., once a SINE sequence has been inserted somewhere along the genome, it is practically impossible for the exact, complete SINE to leave

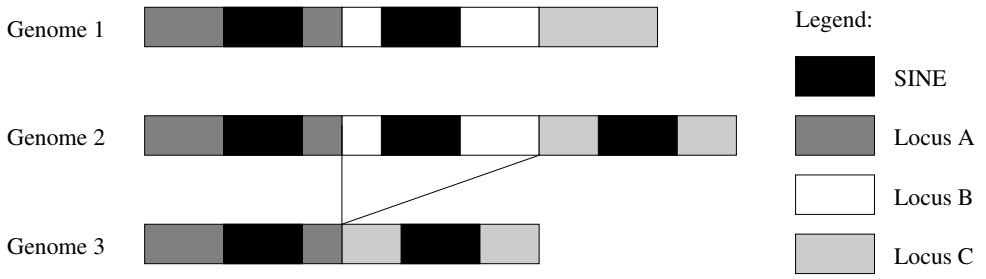

FIG. 1. *SINEs (black boxes) repeat in different loci (different shades of grey) across distinct genomes. A SINE insertion transformed Genome* 1 *into Genome* 2*. A deletion of a locus transformed Genome* 2 *into Genome* 3*. Given Genomes* 1 *and* 3*, we can identify that the SINE on locus C is not present in Genome* 1*, by its flanking sequence. However, locus B is missing in Genome* 3*.*

that specific locus. However, the inserted segment along with its flanking sequences may be lost when a large genomic region, which includes them, is deleted. In that case we do not know whether a SINE insertion had occurred in the missing site prior to its deletion. One can model such data by assigning to each locus a character, whose state is "1" if the SINE occurred in that locus, "0" if the locus is present but does not contain the SINE, and "?" if the locus is missing. The resulting reconstruction problem is precisely IDP.

The IDP problem becomes polynomial when the characters are directed: Benham et al. [4] studied the compatibility problem on generalized characters. Their work implies an $O(n^2m)$-time algorithm for IDP, where n and m denote the number of species and characters, respectively. Another problem related to IDP is the consensus tree problem [3, 14]. This problem calls for constructing a consensus tree from binary subtrees, and is solvable in polynomial time. One can reduce IDP to the latter problem, but the reduction itself takes $\Omega(n^2m)$ time.

Our approach to the IDP problem is graph theoretic. We first provide several graph and matrix characterizations for solvable instances of binary directed perfect phylogeny. We then reformulate IDP as a *graph sandwich* problem: The input data is recast as two nested graphs, and solving IDP is shown to be equivalent to finding a graph of a particular type "sandwiched" between them. This formulation allows us to devise efficient algorithms for IDP.

We provide two algorithms for IDP, which we call Algorithms A and B. Algorithm A has two possible implementations: deterministic and randomized. Its deterministic complexity is $O(nm + k\log^2(n+m))$, for an instance with k 1-entries in the species-characters matrix. The randomized version of Algorithm A takes $O(nm + k\log(l^2/k) + l(\log l)^3 \log\log l)$ expected time, where $l = n + m$. Algorithm B is deterministic and takes $O(l^2 \log l)$ time. For both algorithms, the improved complexity is obtained by using dynamic data structures for maintaining the connected components of a graph [23, 14, 15]. Since an $\Omega(nm)$ lower bound was shown by Gusfield for directed binary perfect phylogeny [12], our algorithms have near-optimal time complexity.

We also study the issue of multiple solutions for IDP. Often there is more than one phylogeny that is consistent with the data. When the input matrix is complete and has a solution, there is always a tree $\mathcal{T}^*$ that is *general*; i.e., it is a solution, and every other tree consistent with the data can be obtained from $\mathcal{T}^*$ by node splitting. In other words, $\mathcal{T}^*$ describes all the definite information in the data, and ambiguities (nodes

with three or more children) can be resolved by additional information. This is not always the case if the data matrix is incomplete: There may or may not be a general solution tree. In that case, using a particular solution and additional information, one can conclude that the data is inconsistent, even though the additional information may be consistent with another solution. It is thus desirable to know if a general solution exists and to generate such a solution if the answer is positive.

We provide answers to both questions. We prove that Algorithm A provides the general solution of a problem instance, if such exists. We also give an algorithm which determines if the solution $\mathcal{T}$ produced by Algorithm A is indeed general. The complexity of the latter algorithm is $O(nm + kd)$, where d denotes the maximum out-degree of $\mathcal{T}$.

The paper is organized as follows. In section 2 we provide some preliminaries, and formalize the IDP problem. In section 3 we characterize binary matrices admitting a directed perfect phylogeny, and provide the graph sandwich formulation for IDP. In section 4 we present algorithms for IDP. Finally in section 5 we analyze the generality of the solution produced by Algorithm A.

2. Preliminaries. We first specify some terminology and notation. We reserve the terms *nodes* and *branches* for trees, and use the terms *vertices* and *edges* for other graphs. Matrices are denoted by an upper-case letter, while their elements are denoted by the corresponding lower-case letter.

Let $G = (V, E)$ be a graph. We denote its set of vertices also by $V(G)$, and its set of edges also by $E(G)$. Let $\emptyset \neq V' \subseteq V$ be a subset of the vertices. The subgraph *induced* by V' is the graph $(V', E \cap (V' \times V'))$. We say that V' is *connected* in G, if V' is contained in some connected component of G. The *length* of a path in G is the number of edges along it.

Let $\mathcal{T}$ be a rooted tree with leaf set S, where branches are directed from the root towards the leaves. The *out-degree* of a node x in $\mathcal{T}$ is its number of children, and is denoted by $d(x)$. For a node x in $\mathcal{T}$ we denote the leaf set of the subtree rooted at x by $L(x)$. $L(x)$ is called a *clade* of $\mathcal{T}$. For consistency, we consider $\emptyset$ to be a clade of $\mathcal{T}$ as well, and call it the *empty clade*. $S, \emptyset$, and all singletons are called *trivial clades*. We denote by $triv(S)$ the collection of all trivial clades. Two sets are said to be *compatible* if they are either disjoint, or one of them contains the other.

OBSERVATION 1 (cf. [18]). *A collection $\mathcal{S}$ of subsets of a set S is the set of clades of some tree over S if and only if $\mathcal{S}$ contains $triv(S)$ and its subsets are pairwise compatible.*

A tree $\mathcal{T}$ is uniquely characterized by its set of clades. The transformation between a branch-node representation of a tree and a list of its clades is straightforward. Thus, we hereafter identify a tree with the set of its clades, and use the notation $S \in \mathcal{T}$ to indicate that S is a clade of $\mathcal{T}$. If $\hat{S}$ is a subset of the leaves of $\mathcal{T}$, then the subtree of $\mathcal{T}$ *induced* on $\hat{S}$ is the collection $\{\hat{S} \cap S' : S' \in \mathcal{T}\}$ (which defines a tree).

Throughout the paper we denote by $S = \{s_1, \ldots, s_n\}$ the set of all species and by $C = \{c_1, \ldots, c_m\}$ the set of all (binary) characters. For a graph K, we define $C(K) \equiv C \cap V(K)$ and $S(K) \equiv S \cap V(K)$. Let $\mathcal{B}_{n \times m}$ be a binary matrix whose rows correspond to species, each row being the character vector of its corresponding species. That is, $b_{ij} = 1$ if and only if the species s_i has the character c_j. A *phylogenetic tree for $\mathcal{B}$* is a rooted tree $\mathcal{T}$ with n leaves corresponding to the n species of S, such that each character is associated with a clade S' of $\mathcal{T}$, and the following properties are satisfied:

(1) If c_j is associated with S', then $s_i \in S'$ if and only if $b_{ij} = 1$.

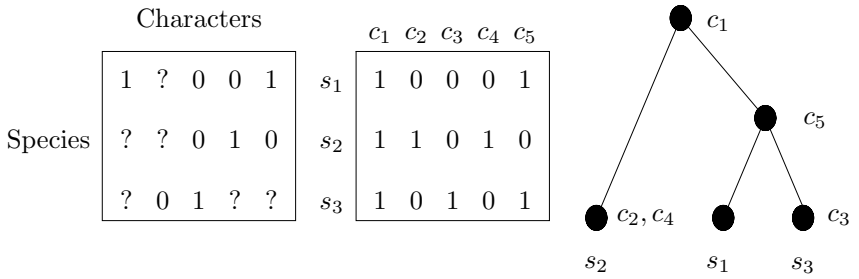

FIG. 2. *Left to right: An incomplete matrix $\mathcal{A}$, a completion $\mathcal{B}$ of $\mathcal{A}$, and a phylogenetic tree that explains $\mathcal{A}$ via $\mathcal{B}$. Each character is written to the right of its origin node.*

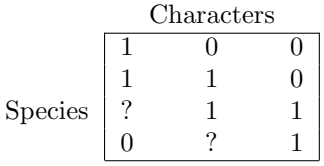

FIG. 3. *An incomplete matrix which has no phylogenetic tree although every pair of its columns has one.*

(2) Every nontrivial clade of $\mathcal{T}$ is associated with at least one character.

For a character c, the node x of $\mathcal{T}$ whose clade $L(x)$ is associated with c is called the *origin* of c with respect to $\mathcal{T}$. Characters associated with $\emptyset$ have no origin.

A $\{0, 1, ?\}$ matrix is called *incomplete*. For convenience, we consider binary matrices as incomplete. Let $\mathcal{A}_{n\times m}$ be a $\{0, 1, ?\}$ matrix in which $a_{ij} = 1$ if s_i has c_j, $a_{ij} = 0$ if s_i lacks c_j, and $a_{ij} =?$ if it is not known whether s_i has c_j. For a character c_j and a state $x \in \{0, 1, ?\}$, the *x-set* of c_j in $\mathcal{A}$ is the set of species $\{s_i \in S : a_{ij} = x\}$. c_j is called a *null character* if its 1-set is empty. For subsets $\hat{S} \subseteq S$ and $\hat{C} \subseteq C$, define $\mathcal{A}|_{\hat{S},\hat{C}}$ to be the submatrix of $\mathcal{A}$ induced on $\hat{S} \cup \hat{C}$.

A binary matrix $\mathcal{B}$ is called a *completion* of $\mathcal{A}$ if $a_{ij} \in \{b_{ij}, ?\}$ for all i, j. Thus, a completion replaces all the ?'s in $\mathcal{A}$ by zeroes and ones. If $\mathcal{B}$ has a phylogenetic tree $\mathcal{T}$, we say that $\mathcal{T}$ is a *phylogenetic tree for* $\mathcal{A}$ as well. We also say that $\mathcal{T}$ *explains* $\mathcal{A}$ *via* $\mathcal{B}$, and that $\mathcal{A}$ is *explainable*. An example of these definitions is given in Figure 2.

The following lemma, closely related to Observation 1, has been proved independently by several authors.

LEMMA 2 (cf. [18]). *A binary matrix $\mathcal{B}$ has a phylogenetic tree if and only if the* 1*-sets of every two characters are compatible.*

An analogous lemma holds for undirected characters (cf. [12]). In contrast, for incomplete matrices, even if every pair of columns has a phylogenetic tree, the full matrix might not have one. An example of such a matrix was provided in [8] for incomplete undirected characters. We provide a simpler example for incomplete *directed* characters in Figure 3. Indeed, if we consider columns 1 and 2 in the example, then the missing entry on column 1 should be completed to 1 and the one on column 2 should be completed to 0. However, in such a completion the characters on columns 2 and 3 are not compatible.

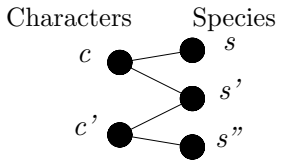

FIG. 4. *The* Σ *subgraph.*

We are now ready to state the IDP problem as follows:

Incomplete Directed Perfect Phylogeny (IDP):

Instance: An incomplete matrix $\mathcal{A}$.

Goal: Find a phylogenetic tree for $\mathcal{A}$, or determine that no such tree exists.

In section 3 we characterize complete binary matrices that admit a perfect phylogeny. In section 4 we present our algorithmic approaches for IDP.

3. Characterizations of explainable binary matrices.

3.1. Forbidden subgraph characterization. Let $\mathcal{B}$ be a species-characters binary matrix of order $n \times m$. Construct the bipartite graph $G(\mathcal{B}) = (S, C, E)$ with $E = \{(s_i, c_j) : b_{ij} = 1\}$. A Σ *subgraph* is an induced subgraph of $G(\mathcal{B})$ that includes three vertices from S, two vertices from C, and exactly four edges, forming a path of length 4 in $G(\mathcal{B})$ (see Figure 4). A bipartite graph with no induced Σ subgraph is called Σ-*free*.

The following theorem restates Lemma 2 in terms of graph theory.

THEOREM 3. *$\mathcal{B}$ has a phylogenetic tree if and only if $G(\mathcal{B})$ is Σ-free.*

COROLLARY 4. *Let $\hat{S} \subseteq S$ and $\hat{C} \subseteq C$ be subsets of the species and characters, respectively. If $\mathcal{A}$ is explainable, then so is $\mathcal{A}|_{\hat{S},\hat{C}}$.*

OBSERVATION 5. *Let $\mathcal{A}$ be a matrix explained by a tree $\mathcal{T}$ and Let $\hat{S} = L(x)$ be a clade in $\mathcal{T}$, where x is a node of $\mathcal{T}$. Then the submatrix $\mathcal{A}|_{\hat{S},C}$ is explained by the subtree of $\mathcal{T}$ rooted at x.*

For a subset $S' \subseteq S$ of species, we say that a character c is S'-*universal* in $\mathcal{B}$, if its 1-set (in $\mathcal{B}$) contains S'.

PROPOSITION 6. *If $G(\mathcal{B})$ is connected and Σ-free, then there exists a character which is S-universal in $\mathcal{B}$.*

Proof. Suppose to the contrary that $\mathcal{B}$ has no S-universal character. Consider the collection of all 1-sets of characters in $\mathcal{B}$. Let c be a character whose 1-set is maximal with respect to inclusion in this collection. Let s'' be a species which lacks c. Since $G(\mathcal{B})$ is connected, there exists a path from s'' to c in $G(\mathcal{B})$. Consider a shortest such path P. Since $G(\mathcal{B})$ is bipartite, the length of P is odd. However, P cannot be of length 1, by the choice of s''. Furthermore, if P is of length greater than 3, then its first five vertices induce a Σ subgraph, a contradiction. Thus $P = (s'', c', s', c)$ must be of length 3. By maximality of the 1-set of c, it is not contained in the 1-set of c'. Hence, there exists a species s which has the character c but lacks c'. Together with s, the vertices of P induce a Σ subgraph, as depicted in Figure 4, a contradiction. ∎

Let Ψ be a graph property. In the Ψ *sandwich problem* one is given a vertex set V and a partition of $V \times V$ into three disjoint subsets: E_0—*forbidden edges*, E_1—*mandatory edges*, and $E_?$—*optional edges*. The objective is to find a supergraph of (V, E_1) which satisfies Ψ and contains no forbidden edges. Hence, the required graph (V, F) must be "sandwiched" between (V, E_1) and $(V, E_1 \cup E_?)$. The reader is referred to articles [10, 11] for a discussion of various sandwich problems.

For the property "containing no induced Σ subgraph" (a property of bipartite graphs) the sandwich problem is defined as follows:

Σ-*free Sandwich*:

Instance: A vertex set $V = S \cup C$ with $S \cap C = \emptyset$, and a partition $E_0 \cup E_? \cup E_1$ of $S \times C$.

Goal: Find a set of edges F such that $F \supseteq E_1$, $F \cap E_0 = \emptyset$, and the graph (V, F) is Σ-free, or determine that no such set exists.

Theorem 3 motivates looking at the IDP problem with input $\mathcal{A}$ as an instance $((S, C), E_0^{\mathcal{A}}, E_?^{\mathcal{A}}, E_1^{\mathcal{A}})$ of the Σ-free sandwich problem. Here, $E_x^{\mathcal{A}} = \{(s_i, c_j) : a_{ij} = x\}$ for $x = 0, ?, 1$. In what follows, we omit the superscript $\mathcal{A}$ when it is clear from the context.

PROPOSITION 7. *The Σ-free sandwich problem is equivalent to IDP.*

Note that there is an obvious 1-1 correspondence between completions of $\mathcal{A}$ and possible solutions of the corresponding sandwich instance $((S, C), E_0, E_?, E_1)$. Hence, in what follows we refer to matrices and their corresponding sandwich instances interchangeably.

3.2. Forbidden submatrix characterizations. A binary matrix $\mathcal{B}$ is called *good* if it can be decomposed as follows:

(1) Its left $k_1 \geq 0$ columns are all ones.
(2) There exist good matrices $\mathcal{B}_1, \ldots, \mathcal{B}_l$, such that the rest (0 or more) of the columns of $\mathcal{B}$ form the block-structure illustrated in Figure 5.

A matrix $\mathcal{A}$ is *canonical* if $\mathcal{A} = [\mathcal{B}, \mathcal{C}]$, where $\mathcal{B}$ is a zero submatrix and $\mathcal{C}$ is good. We say that a matrix $\mathcal{B}$ *avoids* a matrix $\mathcal{X}$, if no submatrix of $\mathcal{B}$ is identical to $\mathcal{X}$.

THEOREM 8. *Let $\mathcal{B}$ be a binary matrix. The following are equivalent:*

1. *$\mathcal{B}$ has a phylogenetic tree.*
2. *$G(\mathcal{B})$ is Σ-free.*
3. *Every matrix obtained by permuting the rows and columns of $\mathcal{B}$ avoids the following matrix:*

$$\mathcal{Z} = \begin{bmatrix} 1 & 1 \\ 1 & 0 \\ 0 & 1 \end{bmatrix}.$$

4. *There exists an ordering of the rows and columns of $\mathcal{B}$ which yields a canonical matrix.*
5. *There exists an ordering of the rows and columns of $\mathcal{B}$ so that the resulting matrix avoids the following matrices:*

$$\mathcal{X}_1 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad \mathcal{X}_2 = \begin{bmatrix} 0 & 1 \\ 1 & 1 \end{bmatrix}, \quad \mathcal{X}_3 = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \quad \mathcal{X}_4 = \begin{bmatrix} 1 \\ 0 \\ 1 \end{bmatrix}.$$

The reader is referred to article [17] for other problems of permuting matrices to avoid forbidden submatrices.

Proof.

1⇔2 Theorem 3.

2⇔3 Trivial.

1⇒4 Suppose $\mathcal{T}$ is a tree that explains $\mathcal{B}$. Assign to each node of $\mathcal{T}$ an index which equals its position in a preorder visit of $\mathcal{T}$. Sort the characters according to the indices of their origin nodes, letting null characters come first. Sort

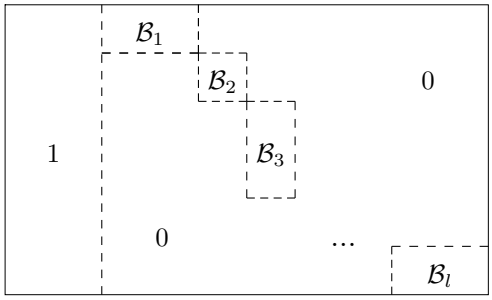

FIG. 5. *Construction of a good matrix. Each $\mathcal{B}_i$ is a good matrix. A canonical matrix is formed from it by appending columns of zeroes on the left.*

the species according to the indices of their corresponding leaves in $\mathcal{T}$. The result is a canonical matrix.

4⇒5 It is easy to verify that canonical matrices avoid $\mathcal{X}_1, \ldots, \mathcal{X}_4$.

5⇒3 Suppose to the contrary that $\mathcal{B}$ has an ordering of its rows and columns, so that rows i_1, i_2, i_3 and columns j_1, j_2 of the resulting matrix form the submatrix $\mathcal{Z}$. Consider the permutations $\theta_{row}, \theta_{col}$ of the rows and columns of $\mathcal{B}$, respectively, which yield a matrix avoiding $\mathcal{X}_1, \ldots, \mathcal{X}_4$. In this ordering, row $\theta_{row}(i_1)$ necessarily lies between rows $\theta_{row}(i_2)$ and $\theta_{row}(i_3)$ or, else, the submatrix $\mathcal{X}_4$ occurs. Suppose that $\theta_{row}(i_2) < \theta_{row}(i_3)$ and $\theta_{col}(j_1) < \theta_{col}(j_2)$; then $\mathcal{X}_3$ occurs, a contradiction. The remaining cases are similar. □

Note that a matrix which avoids $\mathcal{X}_4$ has the consecutive ones property in columns. Gusfield [12, Theorem 3] has proven that a matrix which has an *undirected* perfect phylogeny can be reordered so as to satisfy this property. In fact, for explainable binary matrices, the reordering used by Gusfield's proof essentially generates a canonical matrix. Note also that Σ-free graphs are bipartite convex as they avoid $\mathcal{X}_1$, $\mathcal{X}_2$, and $\mathcal{X}_3$ (see, e.g., [1]).

4. Algorithms for solving IDP. We now return to the problem of completing an incomplete binary matrix. Let $\mathcal{A}$ be the input matrix, and define $G(\mathcal{A}) = (S, C, E_1^{\mathcal{A}})$. For a nonempty subset $S' \subseteq S$, we say that a character is *S'-semiuniversal* in $\mathcal{A}$ if its 0-set does not intersect S'. The following lemmas motivate a divide and conquer approach to IDP, which is the basis of our algorithms for solving it.

LEMMA 9. *Let $\mathcal{A}$ be an incomplete matrix with a Σ-free completion $\mathcal{B}$. Let c be S-semiuniversal in $\mathcal{A}$. Let $\mathcal{B}'$ be the matrix obtained from $\mathcal{B}$ by setting all entries in the column of c to 1. Then $\mathcal{B}'$ is also a Σ-free completion of $\mathcal{A}$.*

Proof. Suppose to the contrary that $\{s_1, c_1, s_2, c_2, s_3\}$ induce a Σ subgraph in $G(\mathcal{B}')$. Since $G(\mathcal{B})$ is Σ-free, if follows that at least one of the Σ edges was added to $\mathcal{B}'$. But then one of c_1 and c_2 is c, a contradiction. □

LEMMA 10. *Let $\mathcal{A}$ be an incomplete matrix with a Σ-free completion $\mathcal{B}$. Let $(K_1, \ldots, K_r)$ be a partition of $S \cup C$ such that each K_i is a union of one or more connected components of $G(\mathcal{A})$. Let $\mathcal{B}'$ be the matrix obtained from $\mathcal{B}$ by setting all entries between vertices of K_i and K_j to 0, for all $i \neq j$. Then $\mathcal{B}'$ is also a Σ-free completion of $\mathcal{A}$.*

Proof. Suppose to the contrary that $\{s_1, c_1, s_2, c_2, s_3\}$ induce a Σ subgraph in $G(\mathcal{B}')$. Then one of the nonedges (s_1, c_2) or (c_1, s_3) contains one vertex from K_i and the other from K_j, for $i \neq j$. It follows that there is a path in $G(\mathcal{B}')$ between a vertex of K_i and a vertex of K_j, a contradiction. □

Alg_A$(\mathcal{A} = ((S, C), E_0, E_?, E_1))$**:**
1. **If** $|S| > 1$ then **do**:
   (a) Remove all S-semiuniversal characters and all null characters from $G(\mathcal{A})$.
   (b) If the resulting graph G' is connected, then output *False* and **halt**.
   (c) Otherwise, let $K_1, \ldots, K_r$ be the connected components of G', and let $\mathcal{A}_1, \ldots, \mathcal{A}_r$ be the corresponding submatrices of $\mathcal{A}$.
   (d) **For** $i = 1, \ldots, r$ **do**: Alg_A$(\mathcal{A}_i)$.
2. Output S.

FIG. 6. *Algorithm A for solving IDP.*

We now describe two efficient $\tilde{O}(nm)$-time algorithms for solving IDP.

4.1. Algorithm A. Algorithm A is described in Figure 6. The algorithm outputs the set of nonempty clades of a tree explaining $\mathcal{A}$, or outputs *False* if no such tree exists. The algorithm is recursive and is initially called with Alg_A$(\mathcal{A})$.

THEOREM 11. *Algorithm A correctly solves IDP.*

Proof. Suppose that the algorithm outputs *False*. Then there exists a recursive call Alg_A$(\mathcal{A}')$ in which the graph $G' = (S', C', E')$, obtained in Step 1b (see Figure 6), was found to be connected. Suppose to the contrary that $\mathcal{A}$ has a phylogenetic tree. Then by Corollary 4, there exists some edge set F^*, which solves $\mathcal{A}'$. The graph $G^* = (S', C', F^*)$ is connected and by Theorem 3, it is also Σ-free. Therefore, by Proposition 6 there exists an S'-universal character in G^*. That character must be S'-semiuniversal in $\mathcal{A}'$. By Algorithm A this vertex should have been removed at Step 1a, a contradiction.

To prove the other direction, we will show that if the algorithm outputs a collection $\mathcal{T}' = \{S_1, \ldots, S_l\}$ of sets, then $\mathcal{T} = \mathcal{T}' \cup \{\emptyset\}$ is a tree which explains $\mathcal{A}$. We first prove that the collection $\mathcal{T}$ of sets is pairwise compatible, implying by Observation 1 that $\mathcal{T}$ is a tree. Associate with each S_i the recursive call Alg_A$(\mathcal{A}_i)$ at which it was output. Observe that each such call makes recursive calls associated with disjoint subsets of S_i. By induction, it follows that $S_i \subseteq S_j$ if and only if the recursive call associated with S_i is nested within the one associated with S_j. Otherwise, $S_i \cap S_j = \emptyset$. Hence, $S_1, \ldots, S_l$ are pairwise compatible and, thus, $\mathcal{T}$ is a tree.

It remains to show that $\mathcal{T}$ is a phylogenetic tree for $\mathcal{A}$. Associate each null character with the empty clade. Each other character $\hat{c}$ is removed at Step 1a only once in the course of the algorithm, during some recursive call Alg_A$(\hat{\mathcal{A}})$. Associate $\hat{c}$ with the clade $\hat{S}$ which was output at that recursive call. Observe that each nontrivial clade $\hat{S} \in \mathcal{T}$ is associated with at least one character. Finally, define a binary matrix $\mathcal{B}_{n \times m}$ with $b_{sc} = 1$ if and only if s belongs to the clade S_c associated with c. Since $a_{sc} \neq 1$ for all $s \notin S_c$ and $a_{sc} \neq 0$ for all $s \in S_c$, $\mathcal{B}$ is a completion of $\mathcal{A}$. The claim follows. ∎

Let $h \leq \min\{m, n\}$ be the height of the reconstructed tree. Each recursive call increases the height of the output tree by at most one. The work at each level of the tree requires (1) Finding semiuniversal vertices and (2) finding connected components in disjoint graphs whose total number of edges is at most mn. Hence, the total work is $O(mn)$ per level, and a naive implementation requires $O(hmn)$ time. We give a faster implementation below.

THEOREM 12. *Algorithm A has a deterministic implementation which takes* $O(nm+|E_1|\log^2(n+m))$ *time, and a randomized implementation which takes* $O(nm+|E_1|\log(l^2/|E_1|)+l(\log l)^3\log\log l)$ *expected time, where* $l=n+m$.

Proof. For the complexity proof we give an alternative, nonrecursive implementation of Algorithm A, shown in Figure 7. This iterative version mimics the recursive one, but traverses the tree of recursive calls in a breadth first manner, rather than a depth first manner. Consequently, the implementation deals with a single graph, rather than a different graph per each recursive call. The reduction in complexity is primarily due to the use of an efficient dynamic data structure for graph connectivity. The data structure maintains the connected components of the graph while edge deletions occur.

We now analyze the running time of this implementation. Step 1 takes $O(nm)$ time. Each iteration of the "while" loop (Step 2) splits the (potential) clades added in the previous one. Thus, Algorithm A performs one iteration of this type per each level of the tree returned, and at most h iterations.

Step 2b requires explicitly computing the connected components of G. Both data structures that we use for storing the connected components of G (see below) maintain a spanning tree for each connected component of G, and allow computing the connected components in $O(n+m)$ time per iteration, or $O(h(m+n))=O(nm)$ time in total.

The loop of Step 2c is performed at most $\min\{2n-1,m\}$ times altogether, as in each (successful) iteration at least one character is removed from G (Step 2cvii), and at least one clade is added to $\mathcal{T}$. Thus, Step 2ci takes $O(\min\{n,m\})$ time altogether, and Step 2cii takes $O(nm)$ time in total. Step 2ciii takes $O(nm)$ time in total, as it considers each species-character pair only once throughout the execution of the algorithm.

In order to analyze the complexity of Step 2civ, observe that the following invariants hold in this step for each character $c\in C(K_i)$:

- $d_c^?=|\{(s,c)\in E_?|s\in S(K_i)\}|$, as guaranteed by Step 2ciii.
- $d_c^1=|\{(s,c)\in E_1|s\in S(K_i)\}|=|\{(s,c)\in E_1|s\in S\}|$, as initialized in Step 1b, since species are never removed, and each species adjacent to c must be in its connected component until c is removed.

Given $d_c^1, d_c^?$ and $|S(K_i)|$, one can check in $O(1)$ time whether c is $S(K_i)$-semiuniversal, and thus Step 2civ takes $O(|C(K_i)|)$ time, or $O(hm)$ time in total.

Since each set added to $\mathcal{T}$ in Step 2cvi corresponds to at least one character, and each character is associated with exactly one such set, updating $\mathcal{T}$ requires $O(nm)$ time in total. This also implies an $O(nm)$ bound on the size of the output produced in Step 3.

It remains to discuss the cost of the dynamic data structure, which is charged for Step 2cvii. Using the dynamic algorithm of [15], the connected components of G can be maintained during $|E_1|$ edge deletions at a total cost of $O(|E_1|\log^2(n+m))$ time spent in Step 2cvii. Alternatively, using the Las Vegas type randomized algorithm of [23] for decremental dynamic connectivity, the edge deletions can be supported in $O(|E_1|\log(l^2/|E_1|)+l(\log l)^3\log\log l)$ expected time. The complexity follows. ∎

4.2. Algorithm B. We now describe another deterministic algorithm for IDP, which is faster than Algorithm A whenever $|E_1|=\omega((n+m)^2/\log(n+m))$. Algorithm B uses the dynamic-connectivity data structure of [14], which supports deletion of batches of edges from a graph, while detecting after each batch one of the new connected components in the resulting graph (if new components were formed).

Alg_A_fast$(\mathcal{A} = ((S, C), E_0, E_?, E_1))$**:**

1. Initialize:
   (a) Set $t \leftarrow 0$, $\mathcal{K}^0 \leftarrow \{S \cup C\}$, $G \leftarrow G(\mathcal{A})$, $\mathcal{T} \leftarrow triv(S)$.
   (b) **For** each character c, and $i \in \{1, ?\}$ **do:**
   Set $d_c^i \leftarrow |\{s \in S | (s, c) \in E_i\}|$.
   (c) Remove all S-semiuniversal and all null characters from G.
   (d) Initialize a data structure for maintaining the connected components of G.
2. **While** $E(G) \neq \emptyset$ **do**:
   (a) Increment t.
   (b) Explicitly compute the set $\mathcal{K}^t$ of connected components $K_1, \ldots, K_r$ of G.
   (c) **For** each connected component $K_i \in \mathcal{K}^t$ such that $|E(K_i)| \geq 1$ **do**:
      i. Pick any character $c' \in C(K_i)$.
      ii. Compute $S' = S(K') \setminus S(K_i)$, where K' is the component in $\mathcal{K}^{t-1}$ which contains c'.
      iii. **For** each species-character pair $(s, c) \in S' \times C(K_i)$ **do**:
      If $(s, c) \in E_?$ **then** decrement $d_c^?$.
      iv. Compute the set U of all characters in K_i which are $S(K_i)$-semiuniversal in $\mathcal{A}$.
      v. **If** $U = \emptyset$, **then** output *False* and **halt**.
      vi. Set $\mathcal{T} \leftarrow \mathcal{T} \cup \{S(K_i)\}$.
      vii. Remove U from G and update the data structure of connected components accordingly.
3. Output $\mathcal{T}$.

FIG. 7. *An iterative presentation of Algorithm A.*

Algorithm B is described in Figure 8. For an instance $\mathcal{A}$ it outputs the nonempty clades of a tree explaining $\mathcal{A}$ (except possibly the root clade, if it has no matching character), or *False* if no such tree exists. It is initially called with Alg_B($\mathcal{A}$).

THEOREM 13. *Algorithm B correctly solves IDP in* $O((n + m)^2 \log(n + m))$ *deterministic time.*

Proof. Correctness. We prove correctness by induction on the problem size. If G' is connected (at Step 2c), then by Proposition 6 $\mathcal{A}$ has no phylogenetic tree, and indeed the algorithm outputs *False*. Otherwise, let $\mathcal{A}_1$ and $\mathcal{A}_2$ be the subinstances induced on K and $K' = V(G') \setminus K$, respectively, as detected in Step 2b. If $\mathcal{A}$ has a phylogenetic tree, then by Corollary 4 so do $\mathcal{A}_1$ and $\mathcal{A}_2$. On the other hand, let $\mathcal{T}_1, \mathcal{T}_2$ be phylogenetic trees for $\mathcal{A}_1, \mathcal{A}_2$, respectively. Note that by definition, $\mathcal{T}_2$ must contain the trivial clade $S(K')$, which is not necessarily a clade in a phylogenetic tree for $\mathcal{A}$ (if K' has no semiuniversal character). To remedy that, define $\mathcal{T}_2' = \mathcal{T}_2$ if the algorithm outputs $S(K')$, and $\mathcal{T}_2' = \mathcal{T}_2 \setminus \{S(K')\}$ otherwise. Then $\mathcal{T}_1 \cup \mathcal{T}_2' \cup \{S\}$ is a phylogenetic tree for $\mathcal{A}$.

Complexity. The data structure of [14] dynamically maintains a graph $H = (V, E)$ through batches of edge deletions, with each batch followed by a query for a newly created connected component in the resulting graph. If we denote by b_0 the number of batches which do not result in a new component, then as shown in [14], the total cost of answering the queries and performing the batch deletions, if eventually all edges are deleted, is $O(|V|^2 \log |V| + b_0 \min\{|V|^2, |E| \log |V|\})$.

Alg_B$(\mathcal{A} = ((S, C), E_0, E_?, E_1))$**:**

1. **If** $|S| = 1$ or $G(\mathcal{A})$ has an S-semiuniversal vertex, **then** output S.
2. **If** $|S| > 1$, **then** do:
   (a) Remove all S-semiuniversal characters and all null characters from $G(\mathcal{A})$.
   (b) **If** the resulting graph G' contains a new connected component K, **then** do:
      i. Let $\mathcal{A}_1, \mathcal{A}_2$ be the submatrices of $\mathcal{A}$ induced on $V(K)$ and $V(G') \setminus V(K)$, respectively.
      ii. **For** $i = 1, 2$ **do**: Alg_B$(\mathcal{A}_i)$.
   (c) **Else** output *False* and **halt**.

FIG. 9. *A counterexample to the greedy approach. A: The input matrix. B: A solution.*

We use this data structure to maintain $G(\mathcal{A})$ during all the recursive calls. As $b_0 = 1$ (since in case no new component is formed the algorithm outputs *False* and halts) and $|V| = n+m$, the total cost is $O((m+n)^2 \log(n+m))$ time. This expression dominates the complexity, as finding the semiuniversal vertices at each recursive call costs in total only $O(nm)$ time (see proof of Theorem 12). □

We remark that an $\Omega(nm)$-time lower bound for (undirected) binary perfect phylogeny was proved by Gusfield [12]. A closer look at Gusfield's proof reveals that it applies, as is, also to the directed case. As IDP generalizes directed binary perfect phylogeny, any algorithm for this problem would require $\Omega(nm)$ time.

4.3. Greedy approach fails. We end the section by showing that a simple greedy approach to IDP fails. Let $\mathcal{A}$ be an incomplete matrix. We say that $a_{sc} =?$ is *forced* if there exists an assignment $x \in \{0, 1\}$ such that completing a_{sc} to x results in an induced Σ in the graph $(S, C, E_1^{\mathcal{A}'} \cup E_?^{\mathcal{A}'})$ corresponding to the completed matrix $\mathcal{A}'$. $\mathcal{A}$ is called *forced* if it has some forced ?-entry.

A naive greedy algorithm for IDP is as follows: At each step complete one ?-entry in the matrix. If there are no forced entries, choose any ?-entry and complete it arbitrarily. Otherwise, try to complete a forced entry. If such completion is not possible (an induced Σ is formed), report *False*.

Figure 9(A) shows an explainable instance with no forced entries. Setting the bottom-left ?-entry to 0 results in an instance which cannot be explained. A solution matrix is shown in Figure 9(B).

5. Determining the generality of the solution. A "yes" instance of IDP may have several distinct phylogenetic trees as solutions. These trees may be related in the following way: We say that a tree $\mathcal{T}$ *generalizes* a tree $\mathcal{T}'$, and write $\mathcal{T} \subseteq \mathcal{T}'$,

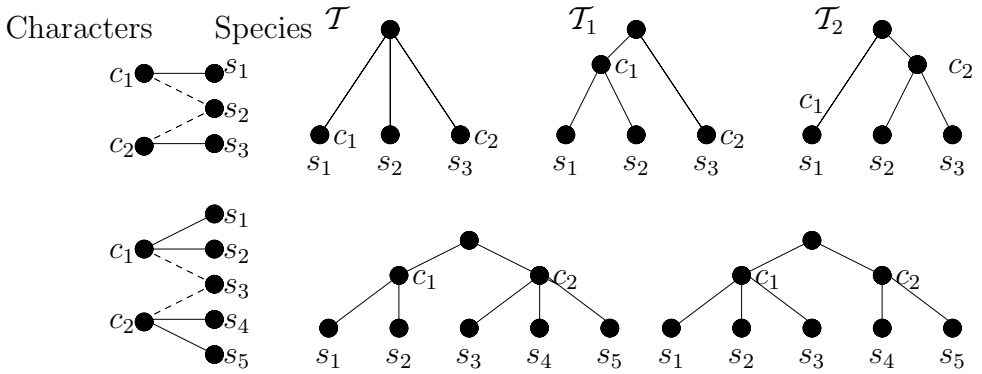

FIG. 10. *Top left: An IDP instance which has a general solution. Dashed lines denote $E_?$-edges, while solid lines denote E_1-edges. Top-right: $\mathcal{T}, \mathcal{T}_1$, and $\mathcal{T}_2$ are the possible solutions. $\mathcal{T}$ generalizes $\mathcal{T}_1$ and $\mathcal{T}_2$ (which are obtained by splitting the root node of $\mathcal{T}$), and is the general solution. Bottom left: An IDP instance which has no general solution. Bottom middle and bottom right: Two possible solutions. The only tree which generalizes both solutions is the tree composed of the trivial clades only, which is not a solution.*

if every clade of $\mathcal{T}$ is a clade of $\mathcal{T}'$; i.e., the evolutionary scenario expressed by $\mathcal{T}'$ includes all the details of the scenario expressed by $\mathcal{T}$, and possibly more. Therefore, $\mathcal{T}'$ represents a more specific scenario, and $\mathcal{T}$ represents a more general one. We say that a tree $\mathcal{T}$ is the *general solution* of an instance $\mathcal{A}$, if $\mathcal{T}$ explains $\mathcal{A}$ and generalizes every other tree which explains $\mathcal{A}$. Figure 10 demonstrates the definitions and also gives an example of an instance that has no general solution.

We give in this section a characterization of IDP instances that admit a general solution. We prove that whenever a general solution exists, Algorithm A finds it. We also provide an algorithm to determine whether the solution tree $\mathcal{T}$ returned by Algorithm A is general. The complexity of the latter algorithm is shown to be $O(mn + |E_1|d)$, where d is the maximum out-degree in $\mathcal{T}$.

This notation is used in what follows. Let $\mathcal{A}$ be an incomplete matrix and let $\hat{S} \subseteq S$. We denote by $W_{\mathcal{A}}(\hat{S})$ the set of $\hat{S}$-semiuniversal characters in $\mathcal{A}$. Note that if $\mathcal{A}$ is binary, then $W_{\mathcal{A}}(\hat{S})$ is its set of $\hat{S}$-universal characters. We now define the operator $\widetilde{\ }$ on incomplete matrices: We denote by $\widetilde{\mathcal{A}}$ the submatrix $\mathcal{A}|_{S,C\setminus W_{\mathcal{A}}(S)}$ of $\mathcal{A}$. In particular, $G(\widetilde{\mathcal{A}})$ is the graph produced from $G(\mathcal{A})$ by removing its set of S-semiuniversal characters. A species set $\emptyset \neq S' \subseteq S$ is said to be *connected* in a graph G, if S' is contained in some connected component of G.

LEMMA 14. *Let $\mathcal{T}$ be the general solution for an instance $\mathcal{A}$ of IDP. Let $S' = L(x)$ be a clade of $\mathcal{T}$, corresponding to some node x. Let $\mathcal{T}'$ be the subtree of $\mathcal{T}$ rooted at x, and let $\mathcal{A}'$ be the instance induced on $S' \cup C$. Then $\mathcal{T}'$ is the general solution for $\mathcal{A}'$.*

Proof. By Observation 5, $\mathcal{T}'$ explains $\mathcal{A}'$. Suppose that $\mathcal{T}''$ also explains $\mathcal{A}'$ and $\mathcal{T}' \not\subseteq \mathcal{T}''$. Then $\hat{\mathcal{T}} = (\mathcal{T} \setminus \mathcal{T}') \cup \mathcal{T}''$ explains $\mathcal{A}$, and $\mathcal{T} \not\subseteq \hat{\mathcal{T}}$, a contradiction. ∎

A nonempty clade of a tree is called *maximal* if the only clade that properly contains it is S.

LEMMA 15. *Let $\mathcal{T}$ be a phylogenetic tree for a binary matrix $\mathcal{B}$. A nonempty clade S' of $\mathcal{T}$ is maximal if and only if S' is the species set of some connected component of $G(\widetilde{B})$.*

Proof. Suppose that S' is a maximal clade of $\mathcal{T}$. We first claim that S' is contained in some connected component K of $G(\widetilde{B})$. If $|S'| = 1$ this trivially holds. If $|S'| > 1$,

let c be a character associated with S'. c is adjacent to all vertices in S' and to no other vertex. Hence, c is not S-universal, implying that all the edges $\{(c,s) : s \in S'\}$ are present in $G(\widetilde{B})$. This proves the claim. It remains to show that $S(K) = S'$. Suppose $S(K) \supset S'$. In particular, $|S(K)| > 1$. By Proposition 6, there exists a character c' in $G(\widetilde{B})$ whose 1-set is $S(K)$. Hence, $S(K)$ must be a clade of $\mathcal{T}$ which is associated with c', contradicting the maximality of S'.

To prove the converse, let S' be the species set of some connected component K of $G(\widetilde{B})$. We first claim that S' is a clade. If $|S'| = 1$, S' is a trivial clade. Otherwise, by Proposition 6 there exists an S'-universal character c' in $G(\widetilde{B})$. Since K is a connected component, c' has no neighbors in $S \setminus S'$. Hence, S' must be a clade in $\mathcal{T}$. Suppose to the contrary that S' is not maximal; then it is properly contained in a maximal clade S'', which by the previous direction is the species set of K, a contradiction. ∎

THEOREM 16. *Algorithm A produces the general solution for every IDP instance that has one.*

Proof. Let $\mathcal{A}$ be an instance of IDP for which there exists a general solution $\mathcal{T}^*$. Let $\mathcal{T}_{alg}$ be the solution tree produced by Algorithm A. By definition $\mathcal{T}^* \subseteq \mathcal{T}_{alg}$. Suppose to the contrary that $\mathcal{T}^* \neq \mathcal{T}_{alg}$. Let S' be the largest clade reported by Algorithm A, which is not a clade of $\mathcal{T}^*$ (S' must be nontrivial), and let S'' be the smallest clade in $\mathcal{T}_{alg}$ which properly contains S'. Let $\mathcal{A}'$ be the instance induced on $S'' \cup C$. By Observation 5, $\mathcal{A}'$ is explained by the corresponding subtrees $\mathcal{T}'_{alg}$ of $\mathcal{T}_{alg}$ and $\mathcal{T}'^*$ of $\mathcal{T}^*$. By Lemma 14, $\mathcal{T}'^*$ is the general solution of $\mathcal{A}'$. Due to the recursive nature of Algorithm A, it produces $\mathcal{T}'_{alg}$ when invoked with input $\mathcal{A}'$. Thus, without loss of generality, one can assume that $S'' = S$ and S' is a maximal clade of $\mathcal{T}_{alg}$.

Suppose that $\mathcal{T}^*$ explains $\mathcal{A}$ via a completion $\mathcal{B}^*$, and let $G^* = G(\mathcal{B}^*)$. Since S' is a maximal clade, it is reported during a second level call of Alg_A($\cdot$) (the call at the first level reports the trivial clade S). Hence, it must be the species set of some connected component K in $G(\widetilde{\mathcal{A}})$. Since every S-universal character in G^* is S-semiuniversal in $\mathcal{A}$, S' is contained in some connected component K^* of $G(\widetilde{B^*})$. Denote $S^* \equiv S(K^*)$. By Lemma 15, S^* is a maximal clade of $\mathcal{T}^*$. Since $S' \notin \mathcal{T}^*$, we have $S' \neq S^*$, and therefore, $S^* \supset S'$. But $\mathcal{T}^* \subseteq \mathcal{T}_{alg}$, implying that S^* is also a nontrivial clade of $\mathcal{T}_{alg}$, in contradiction to the maximality of S'. ∎

We now characterize IDP instances for which a general solution exists. Let $\mathcal{A}$ be a "yes" instance of IDP. Consider a recursive call Alg_A($\mathcal{A}'$) nested within Alg_A($\mathcal{A}$), where $\mathcal{A}' = \mathcal{A}|_{C',S'}$. Let $K_1, \ldots, K_r$ be the connected components of $G(\widetilde{\mathcal{A}'})$, computed in Step 1c. Observe that $S(K_1), \ldots, S(K_r)$ are clades to be reported by recursive calls launched during Alg_A($\mathcal{A}'$). A set U of characters is said to be (K_i, K_j)-*critical* if characters in U are both $S(K_i)$-semiuniversal and $S(K_j)$-semiuniversal in $\mathcal{A}'$, and removing U from $G(\widetilde{\mathcal{A}'})$ disconnects $S(K_i)$. Note that by definition of U, $U \subseteq W_{\mathcal{A}'}(S(K_i))$, and $a'_{sc} =?$ for all $c \in U, s \in S(K_j)$. A clade $S(K_i)$ is called *optional* (with respect to $\mathcal{A}'$) if $r \geq 3$ and there exists a (K_i, K_j)-critical set for some index $j \neq i$. If $S(K_i)$ is not optional we say it is *mandatory*. In the example of Figure 10 (bottom), let $K_1 = \{s_1, s_2, c_1\}$, $K_2 = \{s_3\}$, and $K_3 = \{s_4, s_5, c_2\}$. The set $U = \{c_1\}$ is (K_1, K_2)-critical, so $S(K_1) = \{s_1, s_2\}$ is optional. In contrast, in Figure 10 (top) no clade is optional.

THEOREM 17. *The tree produced by Algorithm A is the general solution if and only if all its clades are mandatory.*

Proof. ⇒ Suppose that $\mathcal{T}_{alg}$ is the general solution of an instance $\mathcal{A}$. Suppose to the contrary that it contains an optional clade. Without loss of generality, assume it is maximal; i.e., during the recursive call Alg_A($\mathcal{A}$), $G' = G(\widetilde{\mathcal{A}})$ has $r \geq 3$ connected

components, $K_1, \ldots, K_r$, and there exists a (K_i, K_j)-critical set U (for some $1 \leq i \neq j \leq r$). Let $\mathcal{A}_i, \mathcal{A}_j$ and $\mathcal{A}_{ij}$ be the subinstances induced on K_i, K_j and $K_i \cup K_j$, respectively. Consider the tree $\mathcal{T}'$ which is produced by a small modification to the execution of Alg_A($\mathcal{A}$): Instead of recursively invoking Alg_A($\mathcal{A}_i$) and Alg_A($\mathcal{A}_j$), call Alg_A($\mathcal{A}_{ij}$). Then $\mathcal{T}'$ is a phylogenetic tree which explains $\mathcal{A}$ and includes the clade $S(K_i \cup K_j)$. Since removing U from $G(\widetilde{\mathcal{A}})$ disconnects $S(K_i)$, $|S(K_i)| \geq 2$ so $S(K_i)$ is nontrivial. Moreover, $S(K_i)$ is not a clade of $\mathcal{T}'$ for the same reason. Hence, $\mathcal{T}'$ does not contain all clades of $\mathcal{T}_{alg}$, in contradiction to the generality of $\mathcal{T}_{alg}$.

$\Leftarrow$ Suppose that $\mathcal{T}_{alg}$ is not the general solution of an instance $\mathcal{A}$; i.e., there exists a solution $\mathcal{T}^*$ of $\mathcal{A}$ such that $\mathcal{T}_{alg} \not\subseteq \mathcal{T}^*$. We shall prove the existence of an optional clade in $\mathcal{T}_{alg}$. (The reader is referred to the example in Figure 13 for notation and intuition. The example follows the steps of the proof, leading to the identification of an optional clade.) Let $\mathcal{B}^*$ be a completion of $\mathcal{A}$ which is explained by $\mathcal{T}^*$, and denote $G^* = G(\mathcal{B}^*)$. Let $S' \in \mathcal{T}_{alg} \setminus \mathcal{T}^*$ be the largest clade reported by Algorithm A which is not a clade of $\mathcal{T}^*$. Without loss of generality (as argued in the proof of Theorem 16), S' is a maximal clade of $\mathcal{T}_{alg}$, and we let $S' = S(K_1)$, where $K_1, \ldots, K_r$ are the connected components of $G(\widetilde{\mathcal{A}})$.

Observe that a binary matrix has at most one phylogenetic tree. Thus, an application of Algorithm A to $\mathcal{B}^*$ necessarily outputs $\mathcal{T}^*$. Consider such an application, and let $\{S_i^*\}_{i=1}^t$ be the nested set of reported clades in $\mathcal{T}^*$ which contain S': $S = S_1^* \supset \cdots \supset S_t^* \supset S'$ (see Figure 11). For each $i = 1, \ldots, t$, let $\mathcal{B}_i^*$ be the instance invoked in the recursive call which reports S_i^*, and let H_i^* be the graph $G(\widetilde{\mathcal{B}_i^*})$, computed in Step 1a of that recursive call. Let C_i^* be the set of characters in H_i^*. Equivalently, C_i^* is the set of characters in $\mathcal{B}_i^*$ whose 1-set is nonempty and is properly contained in S_i^*. Furthermore, define H_i to be the subgraph of $G(\mathcal{A})$ induced on $S_i^* \cup C_i^*$. Observe that H_i^* is the subgraph of G^* induced on the same vertex set. Since G^* is a supergraph of $G(\mathcal{A})$, each H_i^* is a supergraph of H_i.

Claim 18. *S' is disconnected in H_t^*, and therefore also in H_t.*

Proof. Suppose to the contrary that S' is contained in some connected component K^* of H_t^*. K^* is thus computed during the tth recursive call (with argument $\mathcal{B}_t^*$), and $S(K^*)$ is reported as a clade in $\mathcal{T}^*$ by a nested recursive call. Therefore, $S_t^* \supset S(K^*) \supset S'$, where the first proper containment follows from the fact that H_t^* is disconnected, and the second from the assumption that S' is not a clade of $\mathcal{T}^*$. Hence, we arrive at a contradiction to the minimality of S_t^*. ∎

We now return to the proof of Theorem 17. Recall that S' is connected in $H_1 = G(\widetilde{A})$. Thus, the previous claim implies that $t > 1$. Let K_p be a connected component of $G(\widetilde{\mathcal{A}})$ such that $S(K_p) \subseteq S \setminus S_2^*$ (see Figure 11). Let l be the minimal index such that there exists some connected component K_i of $G(\widetilde{\mathcal{A}})$ for which $S(K_i)$ is disconnected in H_l. l is properly defined as $S(K_1) = S'$ is disconnected in H_t. $l > 1$, since otherwise some K_i is disconnected in H_1 and, therefore, also in its subgraph $G(\widetilde{\mathcal{A}})$, in contradiction to the definition of $K_1, \ldots, K_r$.

By minimality of l, $S_l^* \supseteq S(K_i)$. Also, $S_l^* \supseteq S_t^* \supset S' = S(K_1)$, so $S_l^* \neq S(K_i)$. We now claim that there exists some connected component K_j of $G(\widetilde{\mathcal{A}})$, $j \neq i$, such that $S(K_j) \subseteq S_l^*$. Indeed, if $i \neq 1$, then $j = 1$. If $i = 1$, then $l = t$ (by an argument similar to that in the proof of Claim 18), and since $S_l^* \setminus S'$ is nonempty, it intersects $S(K_j)$ for some $j \neq i$. By minimality of l, $S(K_j)$ is properly contained in $S_l^* \setminus S'$.

Define $U \equiv W_{G^*}(S_l^*)$. We now prove that U is a (K_i, K_j)-critical set. By definition all characters in U are S_l^*-universal in G^*, and are thus both K_i-semiuniversal

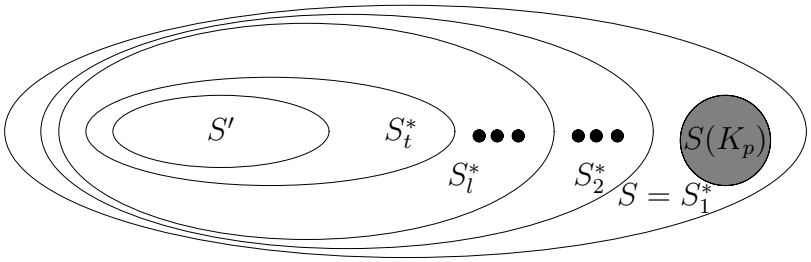

FIG. 11. *The clades* $S = S_1^* \supset S_2^* \supset \cdots \supset S_t^* \supset S'$.

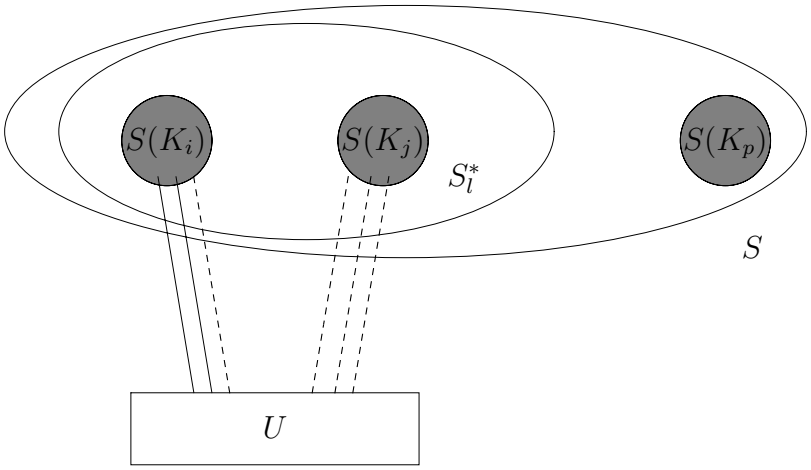

FIG. 12. $S(K_i)$, $S(K_j)$, *and* $S(K_p)$. *Note that removing* U *disconnects* $S(K_i)$.

and K_j-semiuniversal in $\mathcal{A}$. $S(K_i)$ is disconnected in $H_l = G(\mathcal{A}|_{C_l^*,S_l^*})$. Since K_i is a connected component of $G(\widetilde{\mathcal{A}})$, $S(K_i)$ is disconnected in $G(\mathcal{A}|_{C_l^*,S})$, implying that U is a (K_i, K_j)-critical set. Also, K_i, K_j, and K_p are distinct, implying that $r \geq 3$ (see Figure 12). In conclusion, U demonstrates that $S(K_i)$ is optional. □

The characterization of Theorem 17 leads to an efficient algorithm for determining whether a solution $\mathcal{T}_{alg}$ produced by Algorithm A is general.

THEOREM 19. *There is an* $O(nm + |E_1|d)$*-time algorithm to determine if a given solution* $\mathcal{T}_{alg}$ *is general, where* d *is the maximum out-degree in* $\mathcal{T}_{alg}$.

Proof. The algorithm simply traverses $\mathcal{T}_{alg}$ bottom-up, searching for optional clades. For each internal node x visited, whose children are $y_1, \ldots, y_{d(x)}$, the algorithm checks whether any of the clades $L(y_1), \ldots, L(y_{d(x)})$ is optional. If an optional clade is found the algorithm outputs *False*. Correctness follows from Theorem 17.

We show how to efficiently check whether a clade $L(y_i)$ is optional. If $d(x) = 2$, or y_i is a leaf, then certainly $L(y_i)$ is mandatory. Otherwise, let U_i be the set of characters whose origin (in $\mathcal{T}_{alg}$) is y_i. Let U_j^i denote the set of characters in U_i which are $L(y_j)$-semiuniversal, for $j \neq i$. The computation of U_j^i for all i and j takes $O(nm)$ time in total, since for each character c and species s we check at most once whether $(s, c) \in E_?^{\mathcal{A}}$, for an input instance $\mathcal{A}$.

It remains to show how to efficiently check whether for some j, U_j^i disconnects $L(y_i)$ in the appropriate subgraph encountered during the execution of Algorithm A. To this end, we define an auxiliary bipartite graph H^i whose set of vertices is $W_i \cup U_i$,

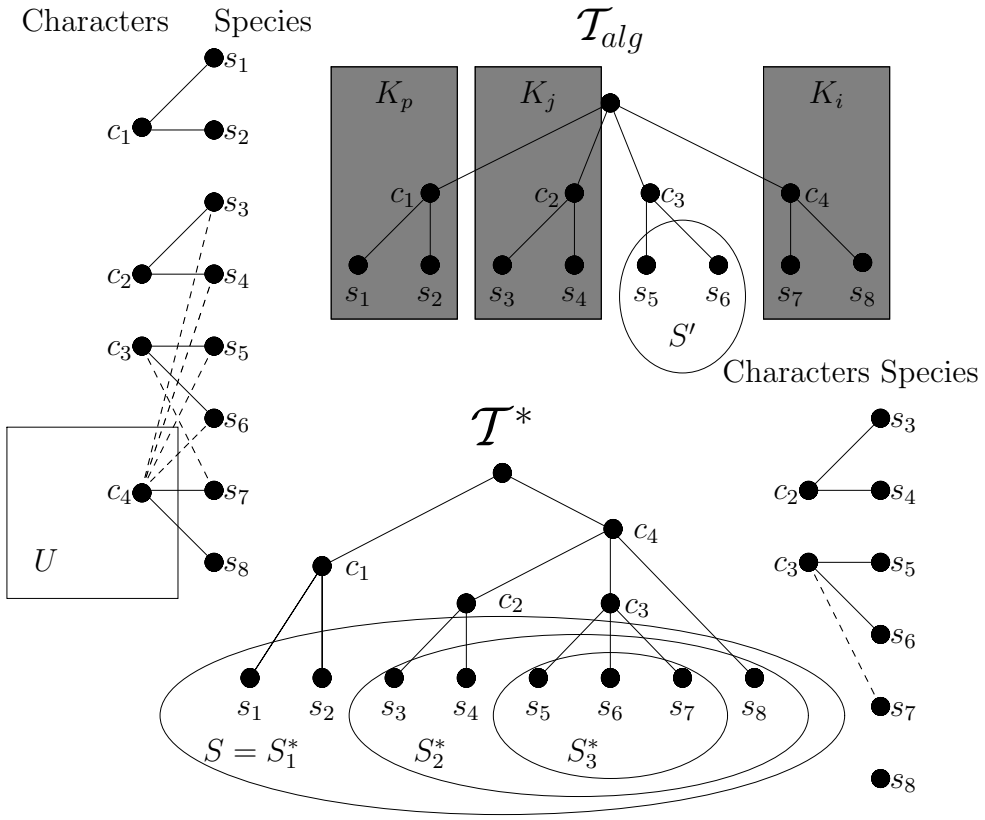

FIG. 13. *An example demonstrating the proof of the "if" part of Theorem* 17*, using the notation in the proof. Left: A graphical representation of an input instance* $\mathcal{A}$*. Dashed lines denote* $E_?$*-edges, while solid lines denote* E_1*-edges. Top right: The tree* $\mathcal{T}_{alg}$ *produced by Algorithm A. Bottom middle: A tree* $\mathcal{T}^*$ *corresponding to a completion* $\mathcal{B}^*$ *that uses all the edges in* $E_?$*. Bottom right: The graphs* H_2 *(solid edges) and* H_2^* *(solid and dashed edges).* $\mathcal{T}_{alg} \not\subseteq \mathcal{T}^*$*, and* $S' = \{s_5, s_6\}$*. There are* $t = 3$ *clades of* $\mathcal{T}^*$ *which contain* S'*:* $S_1^* = \{s_1, \ldots, s_8\}$*,* $S_2^* = \{s_3, \ldots, s_8\}$*, and* $S_3^* = \{s_5, s_6, s_7\}$*. The component* $K_p = \{c_1, s_1, s_2\}$ *has its species in* $S \setminus S_2^*$*. Since* $W_{\mathcal{A}}(S) = W_{\mathcal{B}^*}(S) = \emptyset$*,* $H_1 = G(\mathcal{A})$*. Since* $W_{\mathcal{B}^*}(S_2^*) = \{c_4\}$*, the species set of the connected component* $K_i = \{s_7, s_8, c_4\}$ *is disconnected in* H_2*, implying that* $l = 2$*. For a choice of* $K_j = \{s_3, s_4, c_2\}$*, the set* $U = \{c_4\}$ *is* (K_i, K_j)*-critical, demonstrating that* S' *is optional.*

where $W_i = \{w_1, \ldots, w_{d(y_i)}\}$ is the set of children of y_i in $\mathcal{T}_{alg}$. We include the edge (w_r, c_p) in H^i, for $w_r \in W_i, c_p \in U_i$, if $(c_p, s) \in E_1^{\mathcal{A}}$ for some species $s \in L(w_r)$. We construct for each $j \neq i$ a subgraph H_j^i of H^i induced on $W_i \cup (U_i \setminus U_j^i)$. All we need to report is whether H_j^i is connected.

For each i we construct H^i by considering all $E_1^{\mathcal{A}}$ edges connecting characters in U_i to species in $L(y_i)$. This takes $O(|E_1^{\mathcal{A}}|)$ time in total. There are $d(y_i)$ subgraphs H_j^i for every y_i. Hence, computing H_j^i for all j and determining whether each H_j^i is connected take $O\left(|E(H^i)|d(y_i)\right)$ time. Since $\sum_i |E(H^i)| \leq |E_1^{\mathcal{A}}|$, the total time complexity is $O(mn + \sum_i |E(H^i)|d(y_i)) = O(mn + |E_1^{\mathcal{A}}| \cdot \max_{v \in \mathcal{T}_{alg}} d(v))$. ∎

$(1+\epsilon,\beta)$-SPANNER CONSTRUCTIONS FOR GENERAL GRAPHS*

MICHAEL ELKIN† AND DAVID PELEG‡

Abstract. An (α,β)-*spanner* of a graph G is a subgraph H such that $dist_H(u,w) \leq \alpha \cdot distt_G(u,w)+\beta$ for every pair of vertices u,w, where $dist_{G'}(u,w)$ denotes the distance between two vertices u and v in G'. It is known that every graph G has a polynomially constructible $(2\kappa-1,0)$-spanner (also known as *multiplicative* $(2\kappa-1)$-spanner) of size $O(n^{1+1/\kappa})$ for every integer $\kappa \geq 1$, and a polynomially constructible $(1,2)$-spanner (also known as *additive* 2-spanner) of size $\tilde{O}(n^{3/2})$. This paper explores hybrid spanner constructions (involving both multiplicative and additive factors) for general graphs and shows that the multiplicative factor can be made *arbitrarily close to* 1 while keeping the spanner size arbitrarily close to $O(n)$, at the cost of allowing the additive term to be a sufficiently large constant. More formally, we show that for any constant $\epsilon,\lambda > 0$ there exists a constant $\beta = \beta(\epsilon,\lambda)$ such that for every n-vertex graph G there is an efficiently constructible $(1+\epsilon,\beta)$-spanner of size $O(n^{1+\lambda})$.

Key words. spanners, graph algorithms, graph partitions

1. Introduction.

1.1. Motivation and previous results.

Spanners for general graphs were introduced in [15] as a tool for constructing synchronizers, and were later studied in various contexts. Generally speaking, spanners appear to be the underlying graph structure in a number of constructions in distributed systems and communication networks (cf. [13]). Spanners have turned out to be relevant also in other contexts. For instance, in the area of robotics and computational geometry, spanners have been considered in the Euclidean setting, assuming that the vertices of the graph are points in space, and the edges are line segments connecting pairs of points (cf. [5, 6, 1] and the references therein).

Intuitively, spanners can be thought of as a generalization of the concept of a spanning tree, allowing the spanning subgraph to have cycles, but aiming towards maintaining the locality properties of the network. These locality properties revolve around the notion of *stretch*, namely, the (worst) multiplicative factor by which distances increase in the network as a result of using the spanner edges alone and ignoring non-spanner edges. Formally, given an unweighted graph $G=(V,E)$, we say that the subgraph $H=(V,E')$ (where $E' \subseteq E$) is an α-*spanner* of G if $dist_H(u,w) \leq \alpha \cdot dist_G(u,w)$ for every $u,w \in V$, where $dist_{G'}(u,v)$ denotes the distance between two vertices u and v in G', namely, the minimum length of a path in G' connecting them.

There exists a well-understood tradeoff between the size of a spanner (namely, the number of edges it uses) and its stretch [14, 1, 4]. Generally speaking, for an integer parameter κ, a stretch of $O(\kappa)$ can be guaranteed by a spanner using $O(n^{1+1/\kappa})$ edges. The best known bound for the stretch is $2\kappa-1$ [1]. This bound is very close to the

best possible in view of the lower bounds shown in [14, 1, 4], by which for every odd $\kappa \geq 3$ there exist (infinitely many) n-vertex graphs $G = (V, E)$ for which every $(\kappa - 2)$-spanner requires $\Omega(n^{1+4/3\kappa})$ edges. In fact, for 3-, 5-, and 9-spanners, even better lower bounds are known [16].

However, it is not clear a priori that the stretch must be expressed as a *multiplicative* factor. An alternative notion of *additive graph spanners* was introduced in [11, 12]. A subgraph H is an *additive β-spanner* of G if $dist_H(u, w) \leq dist_G(u, w) + \beta$ for every $u, w \in V$. While the results of [11, 12] concerned only special graph classes, like pyramids, hypercubes and multidimensional grids of degree bounded by 4, a result demonstrating the potential usefulness of this notion for general graphs was presented in [7], where it was shown that for every graph G there exists an additive 2-spanner with $\tilde{O}(n^{3/2})$ edges. Again, this is the best possible up to polylogarithmic factors given the aforementioned lower bounds. Unfortunately, this result has so far resisted attempts of extending it to values of κ greater than 2.

In this paper, we study the somewhat more general and unifying concept of (α, β)-*spanners*, also introduced in [11]. A subgraph H is an (α, β)-*spanner* of G if $dist_H(u, w) \leq \alpha \cdot dist_G(u, w) + \beta$ for every $u, w \in V$. Cast in this terminology, the above mentioned results imply that $O(n^{1+1/\kappa})$ edges suffice to construct a $(2\kappa - 1, 0)$-spanner, for any integer $\kappa \geq 1$, and that $\tilde{O}(n^{3/2})$ edges suffice to construct a $(1, 2)$-spanner.

However, intuitively it seems that a tighter bound on the behavior of spanners may be obtained. In particular, it seems plausible that the multiplicative factor of $2\kappa - 1$ is not entirely unavoidable, as it might stem in part due to a "hidden" additive term affecting mainly the stretching behavior of the spanner with respect to *nearby* vertex pairs.

The current paper not only confirms this intuition, but also shows that the multiplicative stretch can be made *arbitrarily close to* 1 by allowing the additive term to be a sufficiently large *constant*.

1.2. Our results. Our main construction establishes the existence and efficient constructibility of $(1 + \epsilon, \beta)$-spanners of size $O(\beta n^{1+1/\kappa})$ for every n-vertex graph G, where $\beta = \beta(\kappa, \epsilon)$ is constant whenever κ and ϵ are. We stress that in our construction, both the stretch and the size of the spanner can be made arbitrarily small *simultaneously*, where the tradeoff is between their values on the one hand and the value of the additive term on the other.

Note that the existence of spanners with properties as described above implies that for any constant $\epsilon, \lambda > 0$ and graph G, there exists a spanning subgraph H with $O(n^{1+\lambda})$ edges which behaves like a $(1 + \epsilon)$-spanner for "sufficiently distant" pairs of vertices. More formally, for any constant $\epsilon, \lambda > 0$ there exists a constant $\beta(\epsilon, \lambda)$ such that for any n-vertex graph $G = (V, E)$ there exists an efficiently constructible spanning subgraph H with $O(n^{1+\lambda})$ edges such that $dist_H(u, w) \leq (1 + \epsilon) dist_G(u, w)$ for every pair of vertices $u, w \in V$ such that $dist_G(u, w) \geq \beta(\epsilon, \lambda)$.

We remark that this result is optimal in the sense that the statement becomes false if either ϵ or λ is set to zero. Specifically, taking $\epsilon = 0$ yields a false statement since for any $0 < \lambda < 1$ there exists an infinite graph family $\mathcal{H}(\lambda)$ such that every n-vertex graph $G \in \mathcal{H}(\lambda)$ has $\Omega(n^{1+\lambda})$ edges and for any subgraph H of G there exists a pair of nodes u, w in the graph such that $d_G(u, w) = \Omega(n^{1/2-\lambda/2})$ and $d_H(u, w) > d_G(u, w)$. Analogously, setting λ to zero falsifies the statement because for any $0 < \epsilon < 1$ and $\beta(\epsilon) \geq 1$ there exists an infinite graph family $\hat{\mathcal{H}}(\epsilon, \beta)$ such that any n-vertex graph $G \in \hat{\mathcal{H}}(\epsilon, \beta)$ has $n^{1+\Omega(1/\beta(\epsilon))}$ edges (i.e., significantly more than $O(n) = O(n^{1+\lambda})$)

and for any subgraph H of G there exists a pair of nodes u, w in the graph such that $d_G(u,w) \geq \beta(\epsilon)$ and $d_H(u,w) \geq 2\beta(\epsilon)$ [3].

Furthermore, our construction enables us to obtain a multiplicative stretch that is even smaller than $1+\epsilon$ for constant $\epsilon > 0$, i.e., $1+1/\operatorname{polylog} n$ or even $1+2^{-\log n/\log^{(b)} n}$ (where $\log^{(b)}$ denotes the b-iterated log function), while still keeping the size of the spanner equal to $O(n^{1+\lambda})$ for arbitrarily small $\lambda > 0$, at the cost of increasing the additive term to $\operatorname{polylog} n$ or $\exp(O(\log n/\log^{(b)} n))$, respectively.

A straightforward implementation of our construction requires $O(|E| \cdot n)$ time, but we show that our construction can be implemented even faster, and establish a tradeoff between the time complexity of the construction algorithm and the additive term. Specifically, we show that a $(1+\epsilon, \beta')$-spanner of size $O(\beta' n^{1+1/\kappa})$ can be constructed in $\tilde{O}(n^{2+\mu})$ time for any n-vertex graph G, where the additive term $\beta' = \beta'(\kappa, \epsilon, \mu)$ is constant whenever κ, ϵ, and μ are.

The additive terms involved in our constructions are roughly $\beta(\kappa,\epsilon) = \kappa^{\log\log\kappa - \log\epsilon}$ and $\beta'(\kappa,\epsilon,\mu) = \max\{\beta(\kappa,\epsilon), \kappa^{-\log\mu}\}$. Although optimizing these additive terms is not in the focus of the current paper, we remark that β and β' are always $O((\log n)^{\log^{(3)} n})$, because $\kappa = O(\log n)$. Indeed, for $\kappa = \Omega(\log n)$ the size of the spanner becomes almost linear (i.e., $O(n \cdot (\log n)^{\log^{(3)} n})$).

Finally, analysis of our construction for specific small values of κ enables us to derive some secondary results. First, a construction of an additive 2-spanner of size $O(n^{3/2})$ can be derived. This is tight up to a constant factor due to lower bound of [16], and improves upon the construction of [7] by a logarithmic factor. However, the running time of our construction is $O(n^{5/2})$ instead of $\tilde{O}(n^2)$ of the construction of [7]. Additionally, a construction of a $(1+\epsilon, 4)$-spanner of size $O(\epsilon^{-1} n^{4/3})$ can be derived. This improves the previously known construction of a multiplicative 5-spanner of size $O(n^{4/3})$. The details of the analysis of our algorithm for small values of κ were presented in the preliminary versions of this paper [9, 10] and are omitted here.

Since the appearance of a preliminary version of this paper [10], a more time-efficient construction of $(1+\epsilon, \beta)$-spanners for general graphs was devised in [8]. Specifically, it is shown therein that $(1+\epsilon, \beta'')$-spanners of size $O(\beta'' n^{1+1/\kappa})$ can be constructed in $O(|E| n^{\mu})$ time, where the additive term $\beta'' = \beta''(\kappa, \epsilon, \mu)$ is constant whenever κ, ϵ, and μ are. The improved running time of the construction of [8] makes it possible to use $(1+\epsilon, \beta)$-spanners as a building block of the most efficient currently known algorithm for computing almost shortest paths with constant almost additive error from s, $1 \ll s \ll n$, sources. However, the additive term β'' in the construction of [8] is asymptotically greater than the additive term β' in the present construction.

2. The construction algorithm. In this section we present the polynomial time algorithm that for any constant $0 < \epsilon < 1$ and constant integer $\kappa \geq 2$, and for any n-vertex graph G, constructs a $(1+\epsilon, \beta)$-spanner with $O(\beta n^{1+1/\kappa})$ edges, where $\beta = \beta(\epsilon, \kappa)$ is a constant (independent of n and of any other parameter of the graph).

We start with some necessary definitions. We refer to the vertex and edge sets of a subgraph G' by $V(G')$ and $E(G')$, respectively. For any subgraph $G' = (V', E')$ and any integer $\ell \geq 0$ and vertex $v \in V'$, we denote the ℓ-neighborhood of v in G' by $\Gamma_\ell^{G'}(v) = \{u \mid dist_{G'}(v,u) \leq \ell\}$. For any subset of vertices $U \subseteq V'$, denote the set of neighbors of U in G' by $\Gamma^{G'}(U) = \{z \mid \exists u \in U \text{ such that } (u,z) \in E'\}$. We also denote $\Gamma_\ell(v) = \Gamma_\ell^G(v)$ and $\Gamma(U) = \Gamma^G(U)$.

Input: Graph $G=(V,E)$.
Output: Spanned partition $\mathcal{G}$, subgraph H.

1. $U \leftarrow V$; $\mathcal{G} \leftarrow \emptyset$; $\mathcal{S}' \leftarrow \emptyset$; $E(H) \leftarrow \emptyset$;
2. **While** $U \neq \emptyset$ **do:**
   (a) Pick an arbitrary vertex $v \in U$;
   (b) $S \leftarrow \{v\}$;
   (c) **While** $|S \cup \Gamma(S) \cap U| \geq n^{1/\kappa}|S|$ **do:**
   - $S \leftarrow S \cup \Gamma(S) \cap U$; /* the cluster
   (d) $\hat{S} \leftarrow S \cup \Gamma(S) \cap U$; /* the shell
   (e) Form a BFS spanning tree T for (v,S);
   (f) $\mathcal{S}' \leftarrow \mathcal{S}' \cup \{(v,\hat{S})\}$; $\mathcal{G} \leftarrow \mathcal{G} \cup \{(v,S,T)\}$; $U \leftarrow U \setminus S$;
3. **For every** $(v,\hat{S}) \in \mathcal{S}'$ **do:**
   (a) Create a BFS spanning tree T' rooted at v for $\hat{S}$ (namely, a tree spanning $\hat{S}$ and yielding shortest paths to v in the induced subgraph $G(\hat{S})$);
   (b) $E(H) \leftarrow E(H) \cup E(T')$;
4. Return$(\mathcal{G},H)$;

FIG. 1. *Procedure* DOWN_PART.

For a subset of vertices $W \subseteq V$, let $G(W)$ denote the subgraph of G induced by W. With a slight abuse of notation, for a subset $E' \subseteq E$ of edges, let $G(E')$ denote the graph $(V(E'),E')$, where $V(E') = \{v \in V \mid \exists e \in E' s.t.\ v \in e\}$. A subset of vertices $C \subseteq V$ is called a *cluster* if its induced subgraph $G(C)$ is connected. A triple (v,S,T) is called a *spanned cluster* if $v \in S$, and T is a connected spanning tree of S. (Note that S itself is not necessarily connected, and the tree T may span also some vertices that do not belong to S.) The *radius* of a spanned cluster (v,S,T) is $rad(v,S,T) = \max\{dist_{G(T)}(v,u) \mid u \in S\}$, and the *diameter* is $diam(v,S,T) = \max\{dist_{G(T)}(u,w) \mid u,w \in S\}$. Since in a spanned cluster (v,S,T), the tree T is necessarily connected, the radius and the diameter of a spanned cluster are always finite. The spanned clusters (v_i,S_i,T_i) and (v_j,S_j,T_j) are *disjoint* if $S_i \cap S_j = \emptyset$. A set of disjoint spanned clusters $\{(v_i,S_i,T_i)\}$ is called a *spanned partition*. For any pair of vertex sets $U_1,U_2 \subseteq V$ denote $dist_G(U_1,U_2) = \min\{dist_G(u_1,u_2) \mid u_1 \in U_1, u_2 \in U_2\}$. For a spanned partition $\mathcal{U}$, a cluster S, and an integer ℓ, denote

$$\Gamma^{\mathcal{U}}_{\ell}(S) \;=\; \{(v_i,S_i,T_i) \in \mathcal{U} \mid dist_G(S_i,S) \leq \ell\}\ .$$

2.1. The initial partitioning procedure. Our algorithm starts by invoking Procedure DOWN_PART, described in Figure 1. This procedure is a variant of the procedures for constructing partitions due to [14, 7]. The procedure creates a spanned partition $\mathcal{G}$, which we also call the *ground partition*, since the algorithm uses it as a basis for constructing other partitions. (This partition satisfies that $\bigcup_i S_i = V$; the partitions constructed later on may be *partial*, i.e., they will not necessarily have this property.) For each cluster that the procedure creates, it also builds a "shell" consisting of the cluster and one external layer, in a way similar to the partitioning algorithm of [2]. The procedure also creates a subgraph H, which is a subset, and in some sense a *core*, of the spanner created by the algorithm. This subgraph H consists of the union of the breadth first search (BFS) trees of all the shells created by the procedure. (Given a cluster S centered at a vertex v in the graph G, a *BFS tree* for (v,S) is a tree spanning S which yields shortest paths to v in the induced subgraph $G(S)$.)

Let us next establish some basic properties concerning the output of Procedure Down_Part. Given a spanned partition $\mathcal{S} = \{(v_j, S_j, T_j)\}$, denote by $\mathcal{A}_i(\mathcal{S})$ the subset of spanned clusters of $\mathcal{S}$ with radius i,

$$\mathcal{A}_i(\mathcal{S}) \;=\; \{(v,S,T) \in \mathcal{S} \mid rad(v,S,T) = i\}.$$

For any spanned partition $\mathcal{S}$ denote the minimum cluster size by $\check{S}(\mathcal{S}) = \min_{S\in\mathcal{S}} |S|$.

Lemma 2.1. *Let $\mathcal{G}$ be the ground partition returned by Procedure* Down_Part. *Then $\check{S}(\mathcal{A}_j(\mathcal{G})) \geq n^{j/\kappa}$ for any integer $0 \leq j \leq \kappa - 1$.*

Proof. Consider a spanned cluster $(v,S,T) \in \mathcal{A}_j(\mathcal{G})$. By definition of $\mathcal{A}_j(\mathcal{G})$, $rad(v,S,T) = j$. Each cluster constructed by Procedure Down_Part starts with radius zero, and each iteration of the internal while loop (step 2(c)) of the procedure increases the radius of the cluster by at most 1. Hence the cluster (v,S,T) was involved in the loop for at least j iterations. In each iteration its size grew by a factor of at least $n^{1/\kappa}$. The lemma follows.

Next, we argue that the subgraph H returned by Procedure Down_Part is sparse.

Lemma 2.2. $|E(H)| \;=\; O(n^{1+1/\kappa})$.

Proof. For every cluster $S \in \mathcal{S}$, the shell consists of $\hat{S} = S \cup \Gamma(S) \cap U$ at the time of insertion, so by the condition of step 2(c) for selecting the cluster, $|\hat{S}| < n^{1/\kappa} \cdot |S|$. Hence the number of edges inserted into H in step 3 of Procedure Down_Part is bounded by

$$\sum_{S\in\mathcal{S}} |S| n^{1/\kappa} \;=\; n^{1/\kappa} \sum_{S\in\mathcal{S}} |S| \;=\; O(n^{1+1/\kappa}),$$

since the clusters S are disjoint. ∎

An additional important property of the ground partition $\mathcal{G}$ and the subgraph H returned by the invocation Down_Part(G) is that for any pair of neighboring clusters of $\mathcal{G}$ and for any edge e between these clusters, there is an edge between these clusters in H that is incident to one of the endpoints of e. More specifically, we introduce the following key definition.

Definition 2.3. *A spanned partition $\mathcal{S}$ of a graph $G = (V,E)$ is said to be* adjacency-preserving *with respect to a subgraph H such that $E(H) \subseteq E$ if it satisfies the following two properties.*

(P1) *For any spanned cluster $(v,S,T) \in \mathcal{S}$, there exists a BFS spanning tree T' for (v,S) such that $E(T') \subseteq E(H)$.*

(P2) *For any pair of neighboring clusters $(v_1,S_1,T_1), (v_2,S_2,T_2) \in \mathcal{S}$ (i.e., such that $dist_G(S_1,S_2) = 1$) and for any edge $e = (u_1,u_2) \in E$ such that $u_1 \in S_1$ and $u_2 \in S_2$, there exists either a node $u_2' \in S_2$ such that $(u_1,u_2') \in E(H)$ or a node $u_1' \in S_1$ such that $(u_1',u_2) \in E(H)$. In the former (resp., latter) case, the edge e is said to be* spanned through *the cluster S_2 (resp., S_1).*

Note that in the definition above, if the edge (u_1,u_2) is spanned through the cluster S_i, for $i \in \{1,2\}$, then $dist_H(u_1,u_2) \leq diam(S_i) + 1$.

Lemma 2.4. *Let $(\mathcal{G},H)$ be the pair returned by Procedure* Down_Part(G). *Then the spanned partition $\mathcal{G}$ is adjacency-preserving with respect to H.*

Proof. To prove that the pair $(\mathcal{G},H)$ satisfies property (P1) of Definition 2.3, consider some spanned cluster (v,S,T). Note that at step 3(a) of Procedure Down_Part, the BFS spanning tree T' of its shell $\hat{S}$ rooted at v was inserted into the subgraph H. Note that such a tree is, in particular, a BFS spanning tree for S rooted at v (although not necessarily the same as T), completing the proof of property (P1).

To prove that $(\mathcal{G}, H)$ satisfies property (P2) as well, consider some pair of neighboring spanned clusters (v_1, S_1, T_1) and (v_2, S_2, T_2), and some edge $e = (u_1, u_2)$ between them, such that $u_1 \in S_1$ and $u_2 \in S_2$. Assume, without loss of generality, that the cluster S_1 was created before the cluster S_2. Consider the iteration of the main loop of Procedure Down_Part on which S_1 was created. Denote by U' the set U at the beginning of this iteration. Note that at this stage all the nodes of S_1 and S_2 were still uncovered, i.e., $S_1, S_2 \subseteq U'$, and thus in particular $u_1, u_2 \in U'$. It follows that e is in $G' = G(U')$, the subgraph of G induced by U', and hence $u_2 \in \Gamma^{G'}(S_1) \subseteq \hat{S}_1$.

Denote the radius of S_1 by $\rho = rad(v_1, S_1, T_1)$. By step 2(c) of Procedure Down_Part, $\Gamma^{G'}_{\rho}(v_1) = S_1$ and $\Gamma^{G'}_{\rho+1}(v_1) = \hat{S}_1$. Recalling that $u_2 \in \hat{S}_1 \setminus S_1$, we conclude that $dist_{G'}(v_1, u_2) = \rho + 1$.

The spanning tree T' constructed for $\hat{S}_1$ at step 3(a) of Procedure Down_Part spans $\hat{S}_1$, and thus $u_2 \in V(T')$. Since T' is a BFS spanning tree with respect to v_1 in the induced subgraph $G'(\hat{S}_1)$, and since $dist_{G'}(v_1, u_2) = \rho + 1$, it follows that the parent z_1 of u_2 in T' satisfies $dist_{G'}(v_1, z_1) = \rho$, and thus $z_1 \in \Gamma^{G'}_{\rho}(v_1) = S_1$, as required. ∎

2.2. The superclustering procedure. We next proceed to describing the *superclustering* procedure SC. The procedure receives a spanned partition $\mathcal{C}$, identifies its "dense" sets of clusters, and merges them into *superclusters*. By a dense set of clusters we mean a set containing "fairly many" clusters, which are "close enough" to each other. These qualitative notions are quantified by two additional parameters. The *size* parameter σ of Procedure SC specifies the minimum number of clusters close to a given cluster S that justifies creating a supercluster around S that will contain them, whereas the *distance* parameter δ specifies when two clusters are considered to be close. Procedure SC returns a spanned partition $\mathcal{C}'$ which contains the superclusters created and a subgraph H that will later be added into the spanner. When Procedure SC finishes creating superclusters, it remains with a collection $\mathcal{R}$ of original clusters of the input partition that were left untouched. Procedure SC then finds shortest paths between close pairs in the collection $\mathcal{R}$ and inserts these paths as well into the output subgraph H. The size parameter σ controls also the number of pairs of close $\mathcal{R}$ clusters and therefore the size of the subgraph H. The procedure is described in Figure 2.

Note that in step 2(b)ii, while augmenting the set of edges T' associated with a supercluster S' by adding the edges of the shortest path P_i, we do not insert the vertices of this path into the vertex set S' associated with this supercluster. The reason is that these vertices are clustered in other clusters of the ground partition and they may be superclustered separately. In other words, the same vertex may participate in the shortest path connecting two clusters of one supercluster, and at the same time be clustered in another supercluster. Hence T' is not necessarily contained in $E(G(S'))$.

Intuitively, the following lemma states that Procedure SC does not destroy the adjacency-preservation property.

Lemma 2.5. *Let the triple $(\mathcal{C}', H', \mathcal{R})$ be the output of the invocation* SC$(G, \mathcal{C}, \sigma, \delta)$ *for a graph $G = (V, E)$, its spanned partition $\mathcal{C}$ and some arbitrary σ and δ. Suppose that the spanned partition $\mathcal{C}$ is adjacency-preserving with respect to some subgraph H of G such that $E(H) \subseteq E$. Then the output spanned partitions $\mathcal{C}'$ and $\mathcal{R}$ are adjacency-preserving with respect to $H \cup H'$.*

Proof. Note first that the adjacency-preservation property is monotone in both parameters (i.e., if a spanned partition $\tilde{\mathcal{S}}$ is adjacency-preserving with respect to

Input: Graph $G = (V, E)$, spanned partition $\mathcal{C} = \{(v_i, S_i, T_i)\}$ of G, integers σ, $\delta \geq 1$.
Output: Spanned partition $\mathcal{C}' = \{(v'_i, S'_i, T'_i)\}$ of G, subgraph H', collection $\mathcal{R}$ of unmerged clusters.

1. $E(H') \leftarrow \emptyset$; $\mathcal{U} \leftarrow \mathcal{C}$; $\mathcal{C}' \leftarrow \emptyset$;
2. **while** there exists a spanned cluster $(v, S, T) \in \mathcal{U}$ such that $|\Gamma^{\mathcal{U}}_{\delta}(S) \cap \mathcal{U}| \geq \sigma$ **do:**
   (a) $S' \leftarrow \bigcup_{(v_i, S_i, T_i) \in \Gamma^{\mathcal{U}}_{\delta}(S)} S_i$;
   (b) i $T' \leftarrow T$;
   ii **For** every S_i such that $(v_i, S_i, T_i) \in \Gamma_{\mathcal{U}}(S)$ **do:**
   A. Compute the shortest path P_i in G between the clusters S and S_i;
   B. $E(T') \leftarrow E(T') \cup E(P_i) \cup E(T_i)$;
   (c) $\mathcal{C}' \leftarrow \mathcal{C}' \cup \{(v, S', T')\}$;
   (d) $\mathcal{U} \leftarrow \mathcal{U} \setminus \Gamma^{\mathcal{U}}_{\delta}(S)$;
   (e) $E(H') \leftarrow E(H') \cup E(T')$;
3. $\mathcal{R} \leftarrow \mathcal{U}$; /* Remaining (unmerged) clusters */
4. **For** every pair of spanned clusters $(v_i, S_i, T_i), (v_j, S_j, T_j) \in \mathcal{R}$ such that $dist_G(S_i, S_j) \leq \delta$ **do:**
   (a) Compute the shortest path P_{ij} between S_i and S_j in G;
   (b) $E(H') \leftarrow E(H') \cup E(P_{ij})$;
5. Return$(\mathcal{C}', H', \mathcal{R})$;

FIG. 2. *Procedure* SC.

some subgraph $\tilde{H}$, then this spanned partition is adjacency-preserving with respect to any subgraph $\bar{H}$ such that $E(\tilde{H}) \subseteq E(\bar{H}) \subseteq E$). Also, if $\bar{\mathcal{C}} \subseteq \tilde{\mathcal{C}}$, and $\tilde{\mathcal{C}}$ is adjacency-preserving with respect to some subgraph $\tilde{H}$, then the spanned partition $\bar{\mathcal{C}}$ is adjacency-preserving with respect to $\tilde{H}$ as well.

Now the statement of the lemma regarding the spanned partition $\mathcal{R}$ follows from the observation that $\mathcal{R} \subseteq \mathcal{C}$, and from the assumption of the lemma that $\mathcal{C}$ is adjacency-preserving with respect to H.

It remains to establish the lemma for $\mathcal{C}'$. Observe that the pair $(\mathcal{C}', H \cup H')$ satisfies property (P1) of Definition 2.3, by the same assumption of the lemma, and by step 2(e) of Procedure SC. To prove that the pair $(\mathcal{C}', H \cup H')$ satisfies property (P2) as well, consider a pair of neighboring superclusters $(v_1, S_1, T_1), (v_2, S_2, T_2) \in \mathcal{C}'$, and an edge $(u_1, u_2) \in E$ between them such that $u_1 \in S_1$ and $u_2 \in S_2$. By step 2(a) of Procedure SC, $S_1, S_2 \subseteq \bigcup_{\tilde{S}_i \in \mathcal{C}} \tilde{S}_i$. Hence there exist clusters $\tilde{S}_i, \tilde{S}_j \in \mathcal{C}$ such that (a) $\tilde{S}_i \subseteq S_1$, (b) $\tilde{S}_j \subseteq S_2$, (c) $u_1 \in \tilde{S}_i$, and (d) $u_2 \in \tilde{S}_j$. Since $\mathcal{C}$ is adjacency-preserving with respect to H, it follows from (c) and (d) that there exists either a node $u_j \in \tilde{S}_j$ such that the edge (u_1, u_j) is in $E(H)$, or a node $u_i \in \tilde{S}_i$ such that the edge (u_i, u_2) is in $E(H)$. In either case, we are done by (a) and (b). □

2.3. The main algorithm. We proceed with the description of our main algorithm, named Algorithm SP_CONS. Our construction uses parameters κ, J, and Υ, to be fixed explicitly later on. The following analysis is valid for any nonnegative integers κ, J, and Υ that satisfy $1 \leq J \leq \lceil \log \kappa \rceil$ and $\Upsilon = \Omega((\kappa/2^{J-3})^J)$. Set $t_j = (\kappa - 2^{j-1}) \,/\, (2^{j-1}\kappa)$ and $\delta_j = \delta_j(\Upsilon, J) = \Upsilon^{j/J}$ for every $1 \leq j \leq J$. Also for every $1 \leq j \leq J-1$ set $\sigma_j = n^{t_{J-j} - t_{J-j+1}} = n^{2^{j-J}}$. Denote $\tau_j = [\kappa t_{J+1-j}, \kappa t_{J-j})$ for

Input: Graph $G=(V,E)$, integers $\kappa, J, \Upsilon > 1$.
Output: Subgraph H

1. $(\mathcal{G}, H) \leftarrow$ DOWN_PART(G);
2. $\mathcal{C}' \leftarrow \emptyset$;
3. **For** $j = 1$ to $J-1$ **do:**
   (a) $\mathcal{C} \leftarrow \mathcal{C}' \cup \bigcup_{i\in\tau_j} \mathcal{A}_i(\mathcal{G})$;
   (b) $(\mathcal{C}', H', \mathcal{R}) \leftarrow \mathrm{SC}(G, \mathcal{C}, \sigma_j, 2\delta_j(\Upsilon, J))$;
   (c) $E(H) \leftarrow E(H) \cup E(H')$;
4. $\mathcal{R} \leftarrow \mathcal{C}' \cup \bigcup_{i\in\tau_J} \mathcal{A}_i(\mathcal{G})$;
5. **For** every pair of spanned clusters (v_i, S_i, T_i), $(v_j, S_j, T_j) \in \mathcal{R}$ such that $dist_G(S_i, S_j) \le 2\delta_J(\Upsilon, J)$ **do:**
   (a) Calculate the shortest path P_{ij} between S_i and S_j;
   (b) $E(H) \leftarrow E(H) \cup E(P_{ij})$.
6. Return H as the resulting spanner.

FIG. 3. *Algorithm* SP_CONS.

$1 \le j \le J-1$ and $\tau_J = [\kappa t_1, \kappa)$. Observe that for $j \le J \le \lceil \log\kappa \rceil$, t_j is nonnegative. The parameters Υ and J will be chosen in a such a way that $\Upsilon^{1/J}$ will be a rather large constant, so the parameters δ_j for $1 \le j \le J$ are just the consecutive powers of this constant. These powers will serve as distance thresholds, and will grow as the algorithm proceeds.

As already mentioned, the algorithm starts by forming the ground partition $\mathcal{G}$. The ground partition contains a subset $\mathcal{Z} = \bigcup_{i<t_J\kappa} \mathcal{A}_i(\mathcal{G})$ of *singleton* clusters, that is, clusters that contain single vertex, and therefore have radius 0 (these properties of the clusters of the set $\mathcal{Z}$ will be ensured by the appropriate choice of the parameters J and κ). After forming the ground partition $\mathcal{G}$, the algorithm invokes iteratively Procedure SC. On each iteration the procedure forms a new spanned partition with fewer clusters (each of which is larger), and also takes care of clusters that were not merged into superclusters, by interconnecting pairs of nearby clusters by paths which are added to the subgraph H. More specifically, the input spanned partition $\mathcal{C}$ of Procedure SC on iteration j, $j = 1, 2, \ldots, J-1$, is the union of the output spanned partition $\mathcal{C}'$ of the previous $(j-1)$st iteration (for $j = 0$, $\mathcal{C}' = \emptyset$), and of the appropriate subset $Q_j = \bigcup_{i\in\tau_j} \mathcal{A}_i(\mathcal{G})$. The radii and the sizes of the clusters of Q_j grow with j. Algorithm SP_CONS repeats these iterations until we are left with a sufficiently small number of large clusters. The pairs of nearby clusters among these large clusters in the final spanned partition are again interconnected by shortest paths. These shortest paths are inserted into the subgraph H. At the end of this process, H contains the spanning trees of the shells of all the clusters and superclusters created through the process, and also all the shortest paths between clusters and superclusters that were created throughout the execution. Note that the notion of a "nearby" pair of clusters changes from one iteration of the algorithm to another. Specifically, on iteration j, pairs of clusters at distance $\delta_j(\Upsilon, \kappa)$ are considered close. This change corresponds to the increase of clusters radii.

A formal description of the algorithm is given in Figure 3. Figure 4 provides a schematic illustration.

Remark. The spanned partition $\mathcal{R}$ returned by Procedure SC is not used by the main algorithm; it is output by the procedure for the convenience of the analysis only.

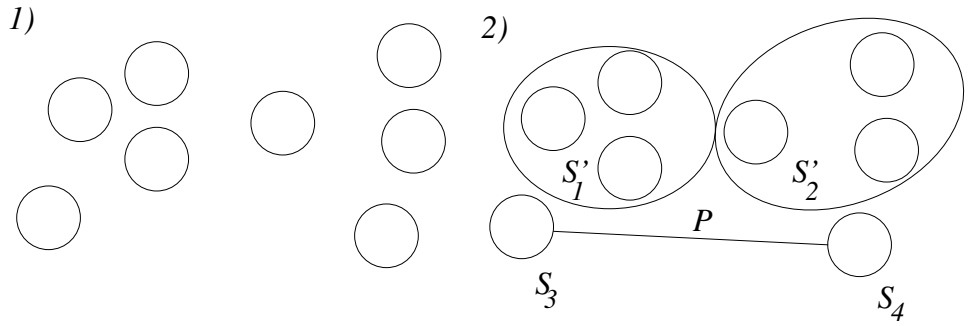

FIG. 4. 1) *The ground partition $\mathcal{G}$ is obtained by applying Procedure* DOWN_PART *to the graph G.* 2) *The two superclusters S'_1 and S'_2 were formed by an application of Procedure* SC. *The two clusters S_3 and S_4 were not merged into a supercluster. Thus, the shortest path P between them was inserted into the subgraph H.*

3. Analysis. To begin with, it is not hard to see that Algorithm SP_CONS runs in polynomial time. Indeed, each invocation of Procedure SC requires essentially at most n BFS explorations of the graph, and the same is true regarding Procedure DOWN_PART. The precise analysis of its running time is deferred to section 4.

We proceed with an analysis of the properties of the algorithm.

3.1. Bounding the cluster diameters. We first bound the diameters of the clusters and superclusters that are created in different iterations of Algorithm SP_CONS. For a spanned partition $\mathcal{C}$ denote $\hat{D}(\mathcal{C}) = \max_{(v,S,T)\in\mathcal{C}}\{diam(v,S,T)\}$ (for an empty spanned partition $\mathcal{C} = \emptyset$, let $\hat{D}(\mathcal{C}) = 0$). Since the graph G remains the same in all the invocations of Procedure SC, we henceforth omit it from its list of parameters.

LEMMA 3.1. *Let $\mathcal{C}'$ be spanned partition output by the invocation* $\mathrm{SC}(\mathcal{C},\sigma,\delta)$ *of Procedure* SC. *Then $\hat{D}(\mathcal{C}') \le 3\hat{D}(\mathcal{C}) + 2\delta$.*

Proof. Consider some supercluster $(v', S', T') \in \mathcal{C}'$. It was created at step 2(b)ii of Procedure SC. Therefore, it has the form of a star, with a cluster $(v' = v_0, S_0, T_0) \in \mathcal{C}$ in the middle, connected to some $b \ge \sigma$ clusters $(v_1, S_1, T_1), \ldots, (v_b, S_b, T_b) \in \mathcal{C}$ by shortest paths $P_1, \ldots, P_b$ of length at most δ. Consider a pair of vertices $z_i \in S_i$, $z_j \in S_j$ such that $1 \le i < j \le b$. Let $u_i \in S_i$ and $w_i \in S_0$ be the endpoints of the path P_i, and let $u_j \in S_j$ and $w_j \in S_0$ be the endpoints of the path P_j. Then

$$\begin{aligned} dist_{G(T')}(z_i,z_j) \le\ & dist_{G(T')}(z_i,u_i) + dist_{G(T')}(u_i,w_i) + dist_{G(T')}(w_i,w_j) \\ & + dist_{G(T')}(w_j,u_j) + dist_{G(T')}(u_j,z_j)\ . \end{aligned}$$

As by step 2(b)iiB of Procedure SC, $E(T_0), E(T_i), E(T_j) \subseteq E(T')$, and $z_i, u_i \in V(T_i)$, $w_i, w_j \in V(T_0)$ and $u_j, z_j \in V(T_j)$, it follows that

$$\begin{aligned} dist_{G(T')}(z_i,u_i) &\le dist_{G(T_i)}(z_i,u_i) \ \le\ diam(v_i,S_i,T_i)\ , \\ dist_{G(T')}(w_i,w_j) &\le dist_{G(T_0)}(w_i,w_j) \ \le\ diam(v_0,S_0,T_0)\ , \\ dist_{G(T')}(u_j,z_j) &\le dist_{G(T_j)}(u_j,z_j) \ \le\ diam(v_j,S_j,T_j)\ . \end{aligned}$$

Note that $diam(v_i,S_i,T_i), diam(v_0,S_0,T_0), diam(v_j,S_j,T_j) \le \hat{D}(\mathcal{C})$. Also, (by step 2(b)iiB of Procedure SC), $E(P_i), E(P_j) \subseteq E(T')$, and $u_i, w_i \in V(P_i)$, $u_j, w_j \in V(P_j)$,

implying that

$$dist_{G(T')}(u_i,w_i) \le dist_{G(P_i)}(u_i,w_i) \le \delta\ ,$$
$$dist_{G(T')}(u_j,w_j) \le dist_{G(P_j)}(u_j,w_j) \le \delta\ .$$

To conclude

$$\begin{aligned} dist_{G(T')}(z_i,z_j) &\le diam(v_i,S_i,T_i) + \delta + diam(v_0,S_0,T_0) + \delta + diam(v_j,S_j,T_j) \\ &\le 3\hat{D}(\mathcal{C}) + 2\delta. \end{aligned}$$

It is easy to see that this bound applies to the distance between any pair of vertices z_i, z_j in S'. □

For any $1 \le j \le J-1$, let $\mathcal{C}_j$ be the input partition of the jth invocation of Procedure SC and let $(\mathcal{C}'_j, H_j, \mathcal{R}_j)$ be the output returned by this invocation. The collection of clusters $\mathcal{R}_J$ is defined to be the set $\mathcal{R}$ created in step 4 of Algorithm Sp_Cons. We refer to clusters of $\mathcal{R}_j$ as the *jth level clusters* of the resulting partition. Note that these clusters are never merged again in subsequent iterations.

By steps 1 and 3 of Procedure SC, and since after step 1 of Procedure SC no cluster is inserted into the collection of uncovered spanners $\mathcal{U}$, we have that for every $1 \le j \le J-1$,

$$\mathcal{R}_j \ \subseteq\ \mathcal{C}_j. \tag{1}$$

Also, for every $1 \le j \le J-1$, since on the jth iteration of Algorithm Sp_Cons, Procedure SC is invoked with distance parameter δ_j, by Lemma 3.1

$$\hat{D}(\mathcal{C}'_j) \ \le\ 3\hat{D}(\mathcal{C}_j) + 2\delta_j. \tag{2}$$

Lemma 3.2. *For every integer $0 \le j \le J-2$,*

$$\mathcal{R}_{j+1} \subseteq \mathcal{C}_{j+1} \ =\ \mathcal{C}'_j \cup \bigcup_{i\in\tau_{j+1}} \mathcal{A}_i(\mathcal{G}).$$

Also, $\mathcal{R}_J \subseteq \mathcal{C}'_{J-1} \cup \bigcup_{i\in\tau_J} \mathcal{A}_i(\mathcal{G})$.

Proof. The first statement of the lemma follows by step 3(a) of Algorithm Sp_Cons and using (1). The second statement follows from the definition of $\mathcal{R}_J$ and step 4 of Algorithm Sp_Cons. □

Lemma 3.3. *For every integer $1 \le j \le J-1$,*

$$\text{(a)}\quad \hat{D}(\mathcal{C}'_j) \le 2\left(3^j\kappa t_{J-1} + \sum_{l=1}^{j} 3^{j-l}\Upsilon^{l/J}\right),$$
$$\text{(b)}\quad \hat{D}(\mathcal{C}_j) \le 2\left(3^{j-1}\kappa t_{J-1} + \sum_{l=1}^{j-1} 3^{j-1-l}\Upsilon^{l/J}\right).$$

Proof. By induction on j. For the induction base for $j=1$, note that the first invocation of Procedure SC is with $\mathcal{C} = \bigcup_{i\in\tau_1} \mathcal{A}_i(\mathcal{G})$. By definition of $\mathcal{A}_i(\mathcal{G})$ we have $\hat{D}(\mathcal{C}) < \hat{D}(\mathcal{A}_{t_{J-1}\kappa}(\mathcal{G})) \le 2t_{J-1}\kappa$, establishing claim (b). Claim (a) now follows by inequality (2).

For the induction step, assume the claims for j between 1 and $J-2$ and consider $j+1$. The parameter δ in the invocation of Procedure SC that formed the clusters of $\mathcal{C}'_{j+1}$ was equal to $\delta_{j+1} = \Upsilon^{(j+1)/J}$. By the induction hypothesis

$$\hat{D}(\mathcal{C}'_j) \;\leq\; 2\left(3^j \kappa t_{J-1} + \sum_{l=1}^{j} 3^{j-l}\Upsilon^{l/J}\right). \tag{3}$$

By step 3(a) of Algorithm Sp_Cons, $\mathcal{C}_{j+1} = \mathcal{C}'_j \cup \bigcup_{i\in\tau_{j+1}} \mathcal{A}_i(\mathcal{G})$. Hence

$$\hat{D}(\mathcal{C}_{j+1}) \;\leq\; \max\left\{\hat{D}(\mathcal{C}'_j), \hat{D}\left(\bigcup_{i\in\tau_{j+1}} \mathcal{A}_i(\mathcal{G})\right)\right\}. \tag{4}$$

By definition of $\mathcal{A}_i(\mathcal{G})$ and t_j

$$\hat{D}(\bigcup_{i\in\tau_{j+1}} \mathcal{A}_i(\mathcal{G})) \;\leq\; 2\kappa t_{J-(j+1)} \;\leq\; \frac{\kappa}{2^{J-j-3}}\,.$$

Recall that $\Upsilon^{1/J} = \Omega(\kappa/2^{J-3})$. Also, if Υ is set in such a way that $\Upsilon^{1/J}$ is a sufficiently large constant (e.g., $\Upsilon^{1/J} \geq 4$), then $2^j \leq \Upsilon^{(j-1)/J}$, and thus

$$\hat{D}\left(\bigcup_{i\in\tau_{j+1}} \mathcal{A}_i(\mathcal{G})\right) \;\leq\; \frac{\kappa}{2^{J-j-3}} \;\leq\; \Upsilon^{j/J} \;\leq\; \sum_{l=1}^{j} 3^{j-l}\Upsilon^{l/J}\,. \tag{5}$$

Now using inequalities (3), (4), and (5), we get

$$\hat{D}(\mathcal{C}_{j+1}) \;\leq\; 2\left(3^j \kappa t_{J-1} + \sum_{l=1}^{j} 3^{j-l}\Upsilon^{l/J}\right),$$

yielding claim (b). Also by inequality (2),

$$\begin{aligned}\hat{D}(\mathcal{C}'_{j+1}) \;&\leq\; 3\cdot 2\left(3^j \kappa t_{J-1} + \sum_{l=1}^{j} 3^{j-l}\Upsilon^{l/J}\right) + 2\Upsilon^{(j+1)/J}\\ &=\; 2\left(3^{j+1} \kappa t_{J-1} + \sum_{l=1}^{j+1} 3^{j+1-l}\Upsilon^{l/J}\right),\end{aligned}$$

yielding claim (a). □

Corollary 3.4. *For every integer $1 \leq j \leq J$,*

$$\hat{D}(\mathcal{R}_j) \;\leq\; 2\left(3^{j-1} \kappa t_{J-1} + \sum_{l=1}^{j-1} 3^{j-1-l}\Upsilon^{l/J}\right).$$

Proof. For $1 \leq j \leq J-1$ the claim follows from Lemma 3.3 by (1). For $j = J$, we get by step 4 of Algorithm Sp_Cons that

$$\hat{D}(\mathcal{R}_J) \;\leq\; \max\{\kappa, \hat{D}(\mathcal{C}'_{J-1})\} \;\leq\; 2\left(3^{J-1} \kappa t_{J-1} + \sum_{l=1}^{J-1} 3^{J-l}\Upsilon^{l/J}\right). \tag{6}$$

□

3.2. Bounding the construction size. In this section we bound the size of the subgraph returned by Algorithm Sp_Cons. First, by Lemma 2.2, the number of edges inserted into the subgraph H by Procedure Down_Part (i.e., by step 1 of Algorithm Sp_Cons) is $O(n^{1+1/\kappa})$. Next, we analyze the number of edges inserted into the subgraph H at step 3 of Algorithm Sp_Cons.

As each of the superclusters created by Procedure SC contains at least σ (disjoint) clusters of the input partition $\mathcal{C}$, we have the following.

LEMMA 3.5. *Let $\mathcal{C}'$ denote the spanned partition output by an invocation* $\mathrm{SC}(\mathcal{C},\sigma,\delta)$ *of Procedure* SC. *Then $\check{S}(\mathcal{C}') \geq \sigma \cdot \check{S}(\mathcal{C})$.*

LEMMA 3.6. *Let H denote the subgraph output by an invocation of Procedure* $\mathrm{SC}(\mathcal{C},\sigma,\delta)$. *Then $|E(H)| = O(n\sigma\delta/\check{S}(\mathcal{C}))$.*

Proof. Note that by definition of spanned partition, $\mathcal{C}$ is a collection of disjoint clusters. Hence $|\mathcal{C}| \leq n/\check{S}(\mathcal{C})$.

Consider the supergraph G' in which every vertex represents a cluster of $\mathcal{C}$ and there is an edge between two vertices if and only if the corresponding two clusters are at distance of at most δ in G. Step 2 of Procedure SC creates a forest $\mathcal{F}$ of disjoint star-like trees covering a subset of vertices of G'. It then inserts into H the spanning trees of all the clusters of $\mathcal{C}$ corresponding to the vertices of G' covered by $\mathcal{F}$ (summing up to $O(n)$ edges) and the paths in G corresponding to the edges of $\mathcal{F}$. As $\mathcal{F}$ is a forest,

$$|E(\mathcal{F})| \;\leq\; |V(\mathcal{F})| \;\leq\; |\mathcal{C}| \;\leq\; n/\check{S}(\mathcal{C})\;.$$

Also each path represented by an edge of $\mathcal{F}$ has length of at most δ. Hence step 2 of Procedure SC inserts at most $n\delta/\check{S}(\mathcal{C})$ edges into H.

Note that after removing from G' the vertices covered by $\mathcal{F}$, the removed supergraph has maximal degree of at most σ. Hence the number of remaining edges is at most $|\mathcal{C}|\sigma \leq n\sigma/\check{S}(\mathcal{C})$. Step 4 inserts into H all the paths corresponding to the edges left in G'. Hence it inserts at most $n\sigma\delta/\check{S}(\mathcal{C})$ edges.

It follows that overall, the number of edges inserted by Procedure SC is at most

$$n\sigma\delta/\check{S}(\mathcal{C}) + n\delta/\check{S}(\mathcal{C}) + n \;=\; O(n\sigma\delta/\check{S}(\mathcal{C})). \qquad \square$$

LEMMA 3.7. *For any $1 \leq j \leq J-1$, $\check{S}(\mathcal{C}_j) \geq n^{t_{J-j+1}}$.*

Proof. The proof is by induction on j. The induction base is $j=1$. Recall that $\mathcal{G}$ is the ground partition returned by Procedure Down_Part. In iteration 1,

$$\check{S}(\mathcal{C}_1) \;=\; \check{S}\left(\bigcup_{i\in\tau_1}\mathcal{A}_i(\mathcal{G})\right) \;=\; \check{S}(\mathcal{A}_{t_J\kappa}(\mathcal{G})) \geq n^{t_J}$$

by Lemma 2.1.

For the induction step, let $1 < j < J-1$, and assume (by the inductive hypothesis) that $\check{S}(\mathcal{C}_j) \geq n^{t_{J-j+1}}$. Since $\sigma_j = n^{t_{J-j}-t_{J+1-j}}$, Lemma 3.5 implies that

$$\check{S}(\mathcal{C}'_j) \;\geq\; \check{S}(\mathcal{C})\cdot\sigma_j \geq n^{t_{J+1-j}}\cdot n^{t_{J-j}-t_{J+1-j}} = n^{t_{J-j}}.$$

Also $\mathcal{C}_{j+1} = \mathcal{C}_j \cup \bigcup_{i\in\tau_{j+1}}\mathcal{A}_i(\mathcal{G})$. Hence $\check{S}(\mathcal{C}_{j+1}) \geq \min\{\check{S}(\mathcal{C}'_j), \check{S}(\bigcup_{i\in\tau_{j+1}}\mathcal{A}_i(\mathcal{G}))\}$. Since by Lemma 2.1, $\check{S}(\bigcup_{i\in\tau_{j+1}}\mathcal{A}_i(\mathcal{G})) \geq n^{t_{J-j}}$, the lemma follows. $\square$

LEMMA 3.8. *At the end of step 3 of Algorithm* Sp_Cons, *$|E(H)| = O(\Upsilon n^{1+1/\kappa})$.*

Proof. By Lemma 3.7, $|\mathcal{C}_j| \leq n/\check{S}(\mathcal{C}_j) \leq n^{1-t_{J-j+1}}$. Hence by Lemma 3.6, in the jth iteration, Procedure SC inserts into the output subgraph H_j no more than $\delta_j n^{1-t_{J-j+1}}\sigma_j$ edges. Hence

$$|E(H_j)| \leq n^{1-t_{J-j+1}} n^{t_{J-j}-t_{J-j+1}}\delta_j \;=\; n^{1+t_{J-j}-2t_{J-j+1}}\delta_j \;. \tag{7}$$

Observe that the exponent is

$$1 + t_{J-j} - 2t_{J-j+1} \;=\; 1 + \frac{\kappa - (2^{J-j-1}-1)}{2^{J-j-1}\kappa} - 2\cdot\frac{\kappa-(2^{J-j}-1)}{2^{J-j}\kappa} \;=\; \frac{\kappa+1}{\kappa}\;.$$

Thus $|E(H_j)| \;=\; O(n^{1+1/\kappa}\Upsilon^{j/J})$. Hence the size of the subgraph H generated at the end of step 3 of Algorithm Sp_Cons can be bounded by

$$|E(H)| \;\leq\; \sum_{j=1}^{J}|E(H_j)| \;=\; O(n^{1+1/\kappa})\sum_{j=1}^{J}(\Upsilon^{1/J})^j \;=\; O(\Upsilon n^{1+1/\kappa})\;. \qquad \square$$

Lemma 3.9. *Step* 5 *of Algorithm* Sp_Cons *inserts at most* $O(\Upsilon n^{2/\kappa})$ *additional edges to the subgraph* H.

Proof. By Lemma 3.2,

$$\mathcal{R}_J \;\subseteq\; \mathcal{C}'_{J-1} \cup \bigcup_{i\in\tau_J}\mathcal{A}_i(\mathcal{G})\;,$$

and thus

$$\check{S}(\mathcal{R}_J) \;\geq\; \min\left\{\check{S}(\mathcal{C}'_{J-1}), \check{S}\left(\bigcup_{i\in\tau_J}\mathcal{A}_i(\mathcal{G})\right)\right\} \;=\; \min\left\{\check{S}(\mathcal{C}'_{J-1}), \min_{i\geq\kappa t_1}\check{S}(\mathcal{A}_i(\mathcal{G}))\right\}\;.$$

By Lemma 3.5, $\check{S}(\mathcal{C}'_{J-1}) \geq n^{t_2}n^{t_1-t_2} = n^{t_1}$. By Lemma 2.1, $\min_{i\geq\kappa t_1}\{\check{S}(\mathcal{A}_i(\mathcal{G}))\} \geq n^{t_1}$. Hence $\check{S}(\mathcal{R}_J) \geq n^{t_1}$. Thus the number of pairs of such clusters is no greater than $n^{2-2t_1} = n^{2/\kappa}$. Since the path inserted into the output subgraph between each pair is of length at most $2\cdot\Upsilon$, the total number of edges inserted is at most $O(\Upsilon n^{2/\kappa})$. $\square$

Combining Lemmas 3.8 and 3.9, we have the following.

Corollary 3.10. *The size of the subgraph output by Algorithm* Sp_Cons *is* $O(\Upsilon n^{1+1/\kappa})$.

3.3. Stretch analysis. In this section we bound the stretch of the spanner H output by Algorithm Sp_Cons. This is done by considering a pair of nodes $u, w \in V$, and one of the shortest paths P between u and w in G. This path is partitioned to segments of length no longer than Υ^J. It is convenient to visualize this path as going from left to right, from u to w (see Figure 5).

Consider some segment P' and let u' (resp., w') be its left (resp., right) endpoint. For a set X of clusters, a node u (resp., a path P) is said to be *X-clustered* if $u \in C$ (resp., $V(P) \subseteq C$) for some cluster C of X. Let u_J (resp., w_J) be the leftmost (resp., rightmost) $\mathcal{R}_J$-clustered node of P', and let C_{u_J} and C_{w_J} be the clusters such that $u_J \in C_{u_J}$ and $w_J \in C_{w_J}$. Since $dist_G(C_{u_J}, C_{w_J}) \leq dist_G(u_J, w_J) \leq \Upsilon$, there is a path of length $dist_G(C_{u_J}, C_{w_J})$ between some nodes $u'' \in C_{u_J}$ and $w'' \in C_{w_J}$ in the spanner H. It follows that there is a path of length no longer than $dist_G(u_J, w_J) + diam(C_{u_J}) + diam(C_{w_J})$ between u_J and w_J in H.

Next, we consider the subpaths from u to u_J, and from w_J from w for every segment of P, and observe that these subpaths are $(\mathcal{Z} \cup \bigcup_{i=1}^{J-1}\mathcal{R}_i)$-clustered. We partition these subpaths into subsegments of length $\Upsilon^{(J-1)/J}$, on each subsegment

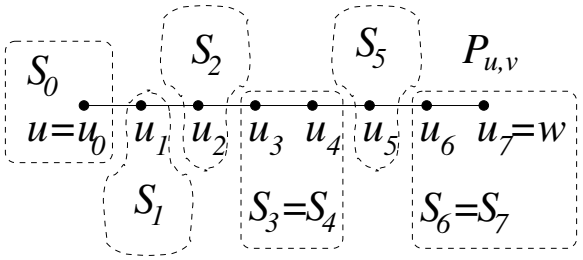

FIG. 5. *The path $P_{u,w}$ and the clusters along it.*

find the leftmost and the rightmost $\mathcal{R}_{J-1}$-clustered nodes and use the "short" paths between their clusters in the spanner. This argument is repeated recursively J times, until we are left with $\mathcal{Z}$-clustered subpaths, whose stretch can be easily bounded.

We next present a rigorous argument formalizing the above intuitive description. First, the following lemma can be proved using Lemmas 2.4 and 2.5 by a straightforward induction on the number of iterations of the algorithm.

LEMMA 3.11. *All the spanned partitions created throughout Algorithm* SP_CONS *are adjacency-preserving with respect to the resulting subgraph H returned by the algorithm.*

Next, we establish the following property of adjacency-preserving partitions that will be later used in the stretch analysis.

LEMMA 3.12. *Let $u, w \in V$ be a pair of nodes in the graph $G = (V, E)$, and let $P_{u,w} = (u = u_0, u_1, \ldots, u_x = w) \subseteq E$ be one of the shortest paths between them. Let H be a subgraph of G with $E(H) \subseteq E$, and let $\mathcal{S}$ be an adjacency-preserving spanned partition with respect to H, such that $V(P_{u,w}) \subseteq \bigcup_{(v,S,T)\in\mathcal{S}} S$. For $i = 0, 1, \ldots, x$, let $(v_i, S_i, T_i) \in \mathcal{S}$ be spanned clusters such that $u_i \in S_i$. (This is well-defined, since $V(P_{u,w}) \subseteq \bigcup_{(v,S,T)\in\mathcal{S}} S$, and the clusters of $\mathcal{S}$ are disjoint, by definition of spanned partition.) Finally, let $u'_0 \in S_0$, $u'_x \in S_x$ be some nodes. Then*

$$dist_H(u'_0, u'_x) \;\leq\; \sum_{i=0}^{x} (diam(v_i, S_i, T_i) + 1) - 1 \;.$$

Proof. The proof is by induction on x. The induction base is $x = 0$. Then $\{S_0, \ldots, S_x\} = \{S_0\}$, and $u = w \in S_0$. Let $u'_0, u'_x \in S_0$ be some arbitrary nodes in this cluster. Since $T_0 \subseteq H$, $dist_H(u'_0, u'_x) \leq diam(v_0, S_0, T_0)$, as required.

For the induction step, assume that the statement of the lemma is true for some $x \geq 0$. Consider the pair of neighboring clusters S_x, S_{x+1}. The edge (u_x, u_{x+1}) between them is spanned either through S_x or through S_{x+1}. In the former case, there exists a node $u'_x \in S_x$ such that the edge (u'_x, u_{x+1}) is in H. In the latter case, there exists a node u'_{x+1} such that the edge (u_x, u'_{x+1}) is in H.

Consider some pair of nodes $u''_0 \in S_0$, $u''_{x+1} \in S_{x+1}$. In the case when the edge (u_x, u_{x+1}) is spanned through S_x, using the induction hypothesis for the pair of nodes $u''_0 \in S_0$ and $u'_x \in S_x$, it follows that

$$\begin{aligned} dist_H(u''_0, u''_{x+1}) &\leq dist_H(u''_0, u'_x) + dist_H(u'_x, u_{x+1}) + dist_H(u_{x+1}, u''_{x+1}) \\ &\leq \left(\sum_{i=0}^{x} (diam(v_i, S_i, T_i) + 1) - 1 \right) + 1 + diam(v_{x+1}, S_{x+1}, T_{x+1}) \\ &= \sum_{i=0}^{x+1} (diam(v_i, S_i, T_i) + 1) - 1 \;. \end{aligned}$$

The case when the edge (u_x, u_{x+1}) is spanned through S_{x+1} follows symmetrically. □

We use the following notions. For $0 \leq j \leq J$, a path P in G is called a *class-j path* if it contains only $(\mathcal{Z} \cup \bigcup_{i=1}^{j} \mathcal{R}_i)$-clustered vertices (in particular, P is a class-0 path if all its vertices are $\mathcal{Z}$-clustered). A pair of vertices u, w is *j-reachable* if there is a shortest path between them that is a class-j path.

For every $1 \leq j \leq J$ denote

$$\gamma_j \;=\; \sum_{i=1}^{j} 2^i \cdot \hat{D}(\mathcal{R}_{j-i+1}).$$

For a real r, let $down(r) = \lceil r \rceil - 1$.

LEMMA 3.13. *For every integer $1 \leq j \leq J$, and for every j-reachable pair of vertices u'_j, u''_j,*

$$dist_H(u'_j, u''_j) \;\leq\; dist_G(u'_j, u''_j) \left(2 \cdot down(t_J \kappa) + 1 + \sum_{i=1}^{j} \frac{\gamma_i}{\Upsilon^{i/J}} \right) + \gamma_j \ .$$

Proof. Let P be a class-j path in G between u'_j and u''_j. It is convenient to visualize the path P as going from left to right, with the vertex u'_j at the leftmost end and the vertex u''_j the rightmost end. We prove by induction on j a claim that is slightly stronger than the statement of the lemma. Specifically, let S'_j, S''_j be the clusters such that $u'_j \in S'_j$, $u''_j \in S''_j$. Let $v'_j \in S'_j$, $v''_j \in S''_j$ be arbitrary nodes. Then

$$dist_H(v'_j, v''_j) \;\leq\; dist_G(u'_j, u''_j) \left(2 \cdot down(t_J \kappa) + 1 + \sum_{i=1}^{j} \frac{\gamma_i}{\Upsilon^{i/J}} \right) + \gamma_j \ .$$

Induction base ($j = 1$): We claim that

$$dist_H(v'_1, v''_1) \;\leq\; dist_G(u'_1, u''_1) \left(2 \cdot down(t_J \kappa) + 1 + \frac{\gamma_1}{\Upsilon^{1/J}} \right) + \gamma_1 \tag{8}$$

for a pair of 1-reachable vertices $u'_1 \in S'_1, u''_1 \in S''_1$ and any pair of nodes $v'_1 \in S'_1$, $v''_1 \in S''_1$.

We separate the discussion to two cases.

Case 1. $dist_G(u'_1, u''_1) \leq 2\Upsilon^{1/J}$.

Case 1.1. If the path P is a class-0 path, then it contains only $\mathcal{Z}$-clustered vertices. Note that $\mathcal{Z} = \bigcup_{i < t_J \kappa} \mathcal{A}_i(\mathcal{G}) = \bigcup_{i=0}^{down(t_J \kappa)} \mathcal{A}_i(\mathcal{G})$. Denote $z = down(t_J \kappa)$. By Lemmas 3.11 and 3.12,

$$\begin{aligned} dist_H(v'_1, v''_1) &\leq (dist_G(u'_1, u''_1) + 1) \left(\hat{D}(\mathcal{Z}) + 1 \right) - 1 \\ &\leq dist_G(u'_1, u''_1)(2z + 1) + 2z \ . \end{aligned}$$

Case 1.2. If the path P contains only one $\mathcal{R}_1$-clustered vertex, then by Lemmas 3.11 and 3.12,

$$dist_H(v'_1, v''_1) \;\leq\; dist_G(u'_1, u''_1)(2z + 1) + \hat{D}(\mathcal{R}_1) \ ,$$

and, again, we are done.

Case 1.3. It therefore remains to consider only the case where at least two vertices in the path P are $\mathcal{R}_1$-clustered. Let l_2 be the distance between the leftmost $\mathcal{R}_1$-clustered vertex, $w_1' \in S_1'$, and the rightmost $\mathcal{R}_1$-clustered vertex, $w_1'' \in S_1''$, of P. Hence the two subpaths, from v_1' to w_1' and from w_1'' to v_1'', are spanned with multiplicative stretch of at most $(\hat{D}(\mathcal{Z})+1)$. The distance between S_1' and S_1'' in G is at most $2\Upsilon^{1/J} = 2\delta_1(\Upsilon, J)$. Since at iteration 1 of Algorithm Sp_Cons, at step 4 of Procedure SC the shortest paths between all the pairs of clusters from $\mathcal{R}_1$ that are at distance at most $2\delta_1(\Upsilon, J)$ one from another were inserted into the subgraph H, it follows that there exist nodes $z_1' \in S_1'$, $z_1'' \in S_1''$ such that $dist_H(z_1', z_1'') = dist_G(w_1', w_1'') = l_2$. By Lemmas 3.11 and 3.12,

$$dist_H(v_1', z_1') \le dist_G(u_1', w_1')(2z+1) + \hat{D}(\mathcal{R}_1) \ ,$$
$$dist_H(z_1'', v_1'') \le dist_G(w_1'', u_1'')(2z+1) + \hat{D}(\mathcal{R}_1) \ .$$

Hence

$$\begin{aligned} dist_H(v_1', v_1'') &\le (dist_G(u_1', u_1'') - l_2)(2z+1) + 2\hat{D}(\mathcal{R}_1) + l_2 \\ &\le dist_G(u_1', u_1'')(2z+1) + 2\hat{D}(\mathcal{R}_1) \ . \end{aligned} \tag{9}$$

Case 2. $dist_G(u_1', u_1'') > 2\Upsilon^{1/J}$. By partitioning the path P into segments of length $\Upsilon^{1/J}$, we get $dist_G(u_1', u_1'') = (a-1)\Upsilon^{1/J} + \Upsilon'$, where $\Upsilon^{1/J} < \Upsilon' < 2\Upsilon^{1/J}$ and $a = \lfloor dist_G(u_1', u_1'')/\Upsilon^{1/J} \rfloor$. Applying the previous argument to each segment separately, it follows that

$$\begin{aligned} dist_H(v_1', v_1'') &\le (a-1)\left(\Upsilon^{1/J}(2z+1) + 2\hat{D}(\mathcal{R}_1)\right) + \Upsilon'(2z+1) + 2\hat{D}(\mathcal{R}_1) \\ &= dist_G(u_1', u_1'')(2z+1) + 2a \cdot \hat{D}(\mathcal{R}_1) \\ &\le dist_G(u_1', u_1'')(2z+1) + \frac{dist_G(u_1', u_1'') \cdot 2\hat{D}(\mathcal{R}_1)}{\Upsilon^{1/J}} \\ &= dist_G(u_1', u_1'')\left(2z+1+\frac{\gamma_1}{\Upsilon^{1/J}}\right) \ . \end{aligned} \tag{10}$$

As $\gamma_1 = 2\hat{D}(\mathcal{R}_1)$, the expression (8) dominates both (9) and (10), completing the proof of the induction base.

Induction step: Assume the induction hypothesis for some integer $1 < j \le J-1$. Consider a class-$(j+1)$ path P connecting u' and u'' in G. Let v' (resp., v'') be an arbitrary node in the same cluster as u' (resp., u'').

Case 1. P is of length no greater than $\Upsilon^{(j+1)/J}$.

We break the discussion into three subcases.

Case 1.1. If no $\mathcal{R}_{j+1}$-clustered vertex appears in the path P, we apply the induction hypothesis and we are done.

Case 1.2. Exactly one $\mathcal{R}_{j+1}$-clustered vertex w appears on P. Let w' be the left-hand neighbor of w and let w'' be the right-hand neighbor of w. Denote by S (resp., S'; S'') the cluster that contains w (resp., w'; w''). Let P' (resp., P'') be the path between u' and w' (resp., w'' and u''). Note that both subpaths P' and P'' are class-j paths (see Figure 6). Hence, the induction hypothesis is applicable to these subpaths.

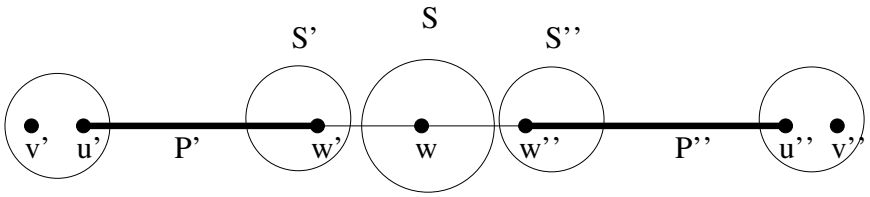

FIG. 6. *The solid lines represent class-j paths P' and P''. The cluster S is in $\mathcal{R}_{j+1}$.*

Therefore,

$$\begin{aligned} dist_H(v',v'') &\le dist_H(v',w') + dist_H(w',w'') + dist_H(w'',v'') \\ &\le (dist_G(u',u'')-2)\left(2z+1+\sum_{i=1}^{j}\frac{\gamma_i}{\Upsilon^{i/J}}\right) \\ &\quad +2\gamma_j + dist_H(w',w'') \ . \end{aligned}$$

The analysis decomposes again to three subsubcases.

Case 1.2.1. The first is that both edges (w',w) and (w,w'') are spanned through the cluster S, i.e., there exist nodes $z,y \in S$ such that the edges (w',z) and (y,w'') are in H. Then

$$\begin{aligned} dist_H(w',w'') &\le dist_H(w',z) + dist_H(z,y) + dist_H(y,w'') \\ &\le 2 + \hat{D}(\mathcal{R}_{j+1}) \ . \end{aligned}$$

Case 1.2.2. The edge (w',w) is spanned through the cluster S', and the edge (w,w'') is spanned through the cluster S''. In this situation there exist nodes $z' \in S'$, $z'' \in S''$ such that the edges (z',w) and (w,z'') are in H. Thus $dist_H(w',w'') \le dist_H(w',z') + dist_H(z',z'') + dist_H(z'',w'')$. However, we observe that the induction hypothesis is applicable to the pairs of nodes v',z' and z'',v'' as well. Note also that $dist_H(z',z'')=2$. Hence

$$\begin{aligned} dist_H(v',v'') &\le dist_H(v',z') + dist_H(z',z'') + dist_H(z'',v'') \\ &\le (dist_G(u',u'')-2)\left(2z+1+\sum_{i=1}^{j}\frac{\gamma_i}{\Upsilon^{i/J}}\right) + 2\gamma_j + 2 \ . \end{aligned}$$

Case 1.2.3. The edge (w',w) is spanned through the cluster S', and the edge (w,w'') is spanned through the cluster S (the situation when the edge (w',w) is spanned through the cluster S, and the edge (w,w'') is spanned through the cluster S'' is symmetrical to this one). In this subcase there exist nodes $z' \in S'$, $z \in S$ such that the edges (z',w) and (z,w'') are in H. Hence we may apply the induction hypothesis to the pairs v',z' and w'',v'', and get

$$\begin{aligned} dist_H(v',v'') &\le (dist_G(u',u'')-2)\left(2z+1+\sum_{i=1}^{j}\frac{\gamma_i}{\Upsilon^{i/J}}\right) \\ &\quad +2\gamma_j + 2 + \hat{D}(\mathcal{R}_{j+1}) \ . \end{aligned}$$

In all these three subsubcases,

$$dist_H(v',v'') \;\le\; dist_G(u',u'')\left(2z+1+\sum_{i=1}^{j}\frac{\gamma_i}{\Upsilon^{i/J}}\right)+2\gamma_j+\hat{D}(\mathcal{R}_{j+1})\ .$$

This expression is smaller than the bound in Lemma 3.13 with $j+1$ substituted for j, and so we are done in Case 1.2 too.

Case 1.3. There are at least two $\mathcal{R}_{j+1}$-clustered vertices in P. Let w (resp., z) be the leftmost (resp., rightmost) such vertex. Again, let w' (resp., z'') denote the left-hand (resp., right-hand) neighbor of w (resp., z). Denote by S_w, S_z, S', and S'' the clusters such that $w\in S_w$, $z\in S_z$, $w'\in S'$, and $z''\in S''$. Observe that H contains a path of length $dist_G(S_w,S_z)\le dist_G(w,z)$ between S_w and S_z. Similarly to the analysis of Case 1.2, where there was only one $\mathcal{R}_j$-clustered node in P, we decompose the analysis to subcases depending on whether the edge (w',w) is spanned through S_w or S', and on whether the edge (z,z'') is spanned through S_z or S''. Like in that situation, we apply the induction hypothesis on the subpaths between v' and w' (or some other appropriate node in S') and between z'' (or some other appropriate node in S'') and v''. Recall that $dist_G(S_w,S_z)\le 2\Upsilon^{(j+1)/J}=2\delta_{j+1}(\Upsilon,J)$. Also, at $(j+1)$st iteration of Algorithm Sp_Cons, at step 4 of Procedure SC (if $j<J-1$; if $j=J-1$ then at step 4 of Algorithm Sp_Cons) one of the shortest paths between S_w and S_z in G was inserted into H. Thus

$$\begin{aligned} dist_H(v',v'') &\le (dist_G(u',u'')-dist_G(w,z))\left(2z+1+\sum_{i=1}^{j}\frac{\gamma_i}{\Upsilon^{i/J}}\right)\\ &\quad+2\gamma_j+2\hat{D}(\mathcal{R}_{j+1})+dist_G(w,z)\\ &\le dist_G(u',u'')\left(2z+1+\sum_{i=1}^{j}\frac{\gamma_i}{\Upsilon^{i/J}}\right)+\gamma_{j+1}\ . \end{aligned}\tag{11}$$

Case 2. $dist_G(u',u'')>2\Upsilon^{(j+1)/J}$. In this situation, we partition the path into segments of length $\Upsilon^{(j+1)/J}$ each, except the last segment which may be of length between $\Upsilon^{(j+1)/J}$ and $2\Upsilon^{(j+1)/J}$. We next show that in this situation γ_{j+1} divided by $\Upsilon^{(j+1)/J}$ is introduced into the multiplicative term. Formally, $dist_G(u',u'')=(a-1)\Upsilon^{(j+1)/J}+\Upsilon'$, where $\Upsilon^{(j+1)/J}<\Upsilon'<2\Upsilon^{(j+1)/J}$ and $a=\lfloor dist_G(u_1',u_1'')/\Upsilon^{1/J}\rfloor$. Then

$$\begin{aligned} dist_H(v',v'') &\le (a-1)\left(\left(2z+1+\sum_{i=1}^{j}\frac{\gamma_i}{\Upsilon^{i/J}}\right)\Upsilon^{(j+1)/J}+\gamma_{j+1}\right)\\ &\quad+\left(2z+1+\sum_{i=1}^{j}\frac{\gamma_i}{\Upsilon^{i/J}}\right)\Upsilon'+\gamma_{j+1}\\ &=\left(2z+1+\sum_{i=1}^{j}\frac{\gamma_i}{\Upsilon^{i/J}}\right)\left((a-1)\Upsilon^{(j+1)/J}+\Upsilon'\right)+\gamma_{j+1}a\\ &\le dist_G(u',u'')\left(2z+1+\sum_{i=1}^{j}\frac{\gamma_i}{\Upsilon^{i/J}}\right)+\gamma_{j+1}\ \frac{dist_G(u',u'')}{\Upsilon^{(j+1)/J}}\\ &= dist_G(u',u'')\left(2z+1+\sum_{i=1}^{j+1}\frac{\gamma_i}{\Upsilon^{i/J}}\right)\ . \end{aligned}\tag{12}$$

In summary, for any $(j+1)$-reachable pair of vertices $u' \in S'$, $u'' \in S''$, and for any pair of nodes $v' \in S'$, $v'' \in S''$ the bound $dist_H(v', v'') \leq dist_G(u', u'')(2z+1+\sum_{i=1}^{j+1} \frac{\gamma_i}{\Upsilon^{i/J}}) + \gamma_{j+1}$ dominates both former bounds (11) and (12) on $dist_H(v', v'')$. □

Observe that any path in G is a class-J path. Hence by Lemma 3.13 we have the following corollary.

COROLLARY 3.14. *For any pair of vertices u', u'', $dist_H(u', u'') \leq \alpha \cdot dist_G(u', u'') + \beta$ for $\alpha = 2 \cdot down(t_J\kappa) + 1 + \sum_{i=1}^{J} \frac{\gamma_i}{\Upsilon^{i/J}}$ and $\beta = \gamma_J$.*

LEMMA 3.15. *For Υ and J such that $\Upsilon^{1/J} \geq 6$ and for any $1 \leq j \leq J$, $\gamma_j = O(t_{J-1}\kappa \cdot 3^j + \Upsilon^{(j-1)/J})$.*

Proof. By the definition of γ_j, $\gamma_j = \sum_{i=0}^{j-1} 2^{j-i} \hat{D}(\mathcal{R}_{i+1})$ for any $1 \leq j \leq J$. Next substitute the explicit formula for $\hat{D}(\mathcal{R}_j)$ given in Corollary 3.4 and get (dividing the expression by 4 for convenience)

$$\frac{\gamma_j}{4} \leq 2^{j-1} t_{J-1}\kappa + 2^{j-2}\left(3t_{J-1}\kappa + \Upsilon^{1/J}\right) + \cdots + 2^0\left(3^{j-1}\kappa t_{J-1} + \sum_{i=1}^{j-1} 3^{j-1-i}\Upsilon^{i/J}\right)$$

$$= t_{J-1}\kappa \sum_{i=0}^{j-1} 3^i 2^{j-1-i} + \sum_{l=1}^{j-1}\left(\Upsilon^{l/J} \sum_{i=0}^{j-l-1} 3^i 2^{j-l-1-i}\right). \tag{13}$$

Note that for any integer $p \geq 1$, $\sum_{i=0}^{p} 3^i 2^{p-i} < 3^p \frac{1}{1-2/3} = 3^{p+1}$. Since $\Upsilon^{1/J} \geq 6$,

$$\begin{aligned} \gamma_j/4 &\leq t_{J-1}\kappa 3^j + \sum_{i=1}^{j-1} \Upsilon^{i/J} 3^{j-i} \leq t_{J-1}\kappa 3^j + \Upsilon^{(j-1)/J} 3 \sum_{i=0}^{j-2}\left(\frac{3}{\Upsilon^{1/J}}\right)^i \\ &< t_{J-1}\kappa 3^j + 6\Upsilon^{(j-1)/J}. \end{aligned}$$ □

LEMMA 3.16. *For Υ and J such that $\Upsilon^{1/J} \geq 6$,*

1. *the additive term is $\beta = O(t_{J-1}\kappa \cdot 3^J + \Upsilon^{(J-1)/J})$,*
2. *the multiplicative factor is bounded by $\alpha = 1 + 2 \cdot down(t_J\kappa) + O(\frac{J + t_{J-1}\kappa}{\Upsilon^{1/J}})$.*

Proof. By Corollary 3.14 and substituting $j = J$ in Lemma 3.15, we get

$$\begin{aligned} \alpha &\leq 1 + 2 \cdot down(t_J\kappa) + \sum_{j=1}^{J} \frac{\gamma_j}{\Upsilon^{j/J}} \\ &\leq 1 + 2 \cdot down(t_J\kappa) + O\left(\frac{J}{\Upsilon^{1/J}}\right) + O\left(t_{J-1}\kappa \sum_{j=1}^{J} \frac{3^j}{\Upsilon^{j/J}}\right) \\ &\leq 1 + 2 \cdot down(t_J\kappa) + O\left(\frac{J}{\Upsilon^{1/J}}\right) + O\left(t_{J-1}\kappa \cdot \frac{1}{\Upsilon^{1/J}} \cdot \frac{1}{1 - 3/\Upsilon^{1/J}}\right) \\ &= 1 + 2 \cdot down(t_J\kappa) + O\left(\frac{J + t_{J-1}\kappa}{\Upsilon^{1/J}}\right) \end{aligned}$$

and $\beta = O(t_{J-1}\kappa 3^J + \Upsilon^{(J-1)/J})$. This completes the proof of Lemma 3.16. □

THEOREM 3.17. *For any fixed $0 < \epsilon < 1$ and fixed integer $2 \leq \kappa = O(\log n)$ there exists a fixed $\beta = \beta(\kappa, \epsilon) = \kappa^{\max\{\log\log\kappa - \log\epsilon, 3\}}$ such that for any graph G, running Algorithm* SP_CONS *on G, κ, $J = \log\kappa$ and β yields a $(1+\epsilon, \beta)$-spanner of G with $O(\beta n^{1+1/\kappa})$ edges.*

Proof. Since $t_i = (\kappa - 2^{i-1}) \,/\, (2^{i-1}\kappa)$, it is sufficient to set $J = \lceil \log \kappa \rceil$ in order to ensure $t_J \kappa \leq 1$, i.e., $down(t_J \kappa) = 0$. Therefore, substituting $J = \lceil \log \kappa \rceil$ into Lemma 3.16 implies that the multiplicative factor of the stretch is $\alpha = 1 + O(\frac{\log \kappa}{\Upsilon^{1/\log \kappa}})$ and the additive term is $\beta = O(\Upsilon^{(\log \kappa - 1)/\log \kappa} + \kappa^{\log 3})$. To get a multiplicative stretch of $1+\epsilon$ for any fixed $0 < \epsilon < 1$ and to ensure that $\Upsilon^{1/J} \geq \kappa/2^{J-3} = 8$, we set $\Upsilon^{1/\log \kappa} = \max\{\epsilon^{-1} \log \kappa, 8\}$, or $\Upsilon = \kappa^{\max\{\log\log\kappa - \log\epsilon, 3\}}$. The theorem now follows by Corollary 3.10. □

Note that for $\kappa = \Theta(\log n)$ the size of the spanner becomes $O(\beta(\kappa,\epsilon)n) = o(n^{1+\nu})$ for any $\nu > 0$, and so there is no reason to consider values of κ greater than $O(\log n)$.

COROLLARY 3.18. *For any constant $\epsilon > 0$, $\lambda > 0$ there exists a constant $\beta'(\epsilon,\lambda)$ such that for any n-vertex graph $G = (V,E)$ there exists a polynomial time constructible subgraph H, $E(H) \subseteq E$, with $O(n^{1+\lambda})$ edges, such that for every pair of vertices $u, w \in V$ with $dist_G(u,w) \geq \beta'(\epsilon,\lambda)$, $dist_H(u,w) \leq (1+\epsilon) dist_G(u,w)$.*

Proof. By Theorem 3.17 there exists a constant $\beta(\epsilon/2, \lceil 1/\lambda \rceil)$ such that there exists a polynomial time constructible $(1+\epsilon/2, \beta(\epsilon/2, \lceil 1/\lambda \rceil))$-spanner H, $E(H) \subseteq E$, with $O(n^{1+\lambda})$ edges. Set $\beta'(\epsilon,\lambda) = 2\beta(\epsilon/2, \lceil 1/\lambda \rceil) \,/\, \epsilon$ and observe that for any pair of vertices $u, w \in V$ with $dist_G(u,w) \geq \beta'(\epsilon,\lambda)$,

$$dist_H(u,w) \;\leq\; (1+\epsilon/2) dist_G(u,w) + \beta(\epsilon/2, \lceil 1/\lambda \rceil) \;\leq\; (1+\epsilon) dist_G(u,w)\,. \qquad \square$$

In order to get a multiplicative stretch factor asymptotically close to 1 we just substitute $\epsilon = 1/\log^b n$ for any constant b in Theorem 3.17.

COROLLARY 3.19. *For any fixed integer $2 \leq \kappa = O(\log n)$ and constant $b > 0$ and for any graph G, running Algorithm* SP_CONS *with G, κ, $\beta(\kappa,n) = \kappa^{\log\log\kappa} \log^{b \log \kappa} n$ and $J = \log \kappa$ yields a $(1 + 1/\log^b n, \beta(\kappa,n))$-spanner of G with $O(\beta(\kappa,n) \cdot n^{1+1/\kappa})$ edges.*

Again, for any constant $\kappa \geq 2$ this yields a $(1 + 1/\operatorname{polylog} n, \operatorname{polylog} n)$-spanner with $\tilde{O}(n^{1+1/\kappa})$ edges.

In order to get an almost linear number of edges (or formally, $o(n^{1+\nu})$ for any $\nu > 0$) we substitute $\epsilon = (\log n)^{\log^{(3)} n}$ and $\kappa = \log n$ in Theorem 3.17, and get the following.

COROLLARY 3.20. *For any graph G, running Algorithm* SP_CONS *with G, $\kappa = \log n$, $\beta(n) = (\log n)^{O(\log^{(2)} n \log^{(3)} n)}$ and $J = \log \kappa$ yields a $(1+1/(\log n)^{\log^{(3)} n}, \beta(n))$-spanner of G with $O(\beta(n)n)$ edges.*

Theorem 3.17 also enables us to decrease the multiplicative stretch to $1 + 2^{-\log n/\log^{(b)} n}$ while not significantly increasing the other parameters. Specifically, we obtain the following.

COROLLARY 3.21. *For any fixed $2 \leq \kappa = O(\log n)$, constant $b \geq 2$ and graph G, running Algorithm* SP_CONS *with G, κ, $J = \log \kappa$ and $\beta(\kappa,n) = \kappa^{\log\log\kappa} \cdot 2^{\log\kappa \log n/\log^{(b)} n}$ yields a $(1 + 2^{-\log n/\log^{(b)} n}, \beta(\kappa,n))$-spanner of G with $O(\beta(\kappa, n)n^{1+\frac{1}{\kappa}})$ edges.*

In particular, for $\kappa = \log n$ this yields a $(1 + 2^{-\log n/\log^{(b)} n}, 2^{O(\log n/\log^{(b)} n)})$-spanner with $2^{O(\log n/\log^{(b)} n)} n$ edges.

Finally, we remark that for some specific small values of κ, tighter bounds on ϵ and β parameters of the spanner that is constructed by Algorithm SP_CONS, can be obtained (see the preliminary versions of this paper [9, 10] for the details). In particular, the following statements hold.

THEOREM 3.22.

1. *Algorithm* SP_CONS*, when run with parameter* $\kappa = 2$*, yields a construction of an additive* 2*-spanner with* $O(n^{3/2})$ *edges.*
2. *Algorithm* SP_CONS*, when run with parameter* $\kappa = 3$*, yields a construction of a* $(1+\epsilon, 4)$*-spanner with* $O(\epsilon^{-1}n^{4/3})$ *edges for any* $\epsilon > 0$*.*

The first result improves by a logarithmic factor the result of [7] and it is tight up to constant factors due to an $\Omega(n^{3/2})$ lower bound of [16]. However, the running time of Algorithm SP_CONS with parameter $\kappa = 2$ is $O(n^{5/2})$, which is significantly larger than the running time of the algorithm of [7], which is $\tilde{O}(n^2)$. The second result significantly improves the previously known construction of 5-spanner with $O(n^{4/3})$ edges, due to [1].

4. Running time. In this section we analyze the running time of Algorithm SP_CONS. We then show that it can be modified to run in time $\tilde{O}(n^{2+\mu})$, for arbitrarily small $\mu > 0$, while maintaining α, β and the size of the generated spanner as before.

4.1. Time complexity of Algorithm SP_CONS. We start by analyzing the running time of Algorithm SP_CONS as described above, without modifications.

LEMMA 4.1. *The running time of Procedure* DOWN_PART *is* $O(|E|+n^{1+1/\kappa}\log n)$.

Proof. Procedure DOWN_PART starts by picking a vertex and running a depth-limited version of the unweighted BFS algorithm from this vertex. The BFS algorithm continues adding new layers until the next iteration increases the size of the cluster by a factor smaller than $n^{1/\kappa}$. Let S be some cluster of the spanned partition $\mathcal{G}$ built by the procedure. By using appropriate data structures, the operation of counting the number of vertices at the next layer that joins the cluster takes $O(|S|n^{1/\kappa}\log(|S|n^{1/\kappa}))$ time, since the total number of vertices involved in this process is $O(|S|n^{1/\kappa})$. Hence summing over all the cluster constructions, the running time invested in deciding whether to terminate the construction of the current cluster and to start the construction of the next cluster is

$$\sum_{S\in\mathcal{G}} O(|S|n^{1/\kappa}\log(|S|n^{1/\kappa})) \;=\; O\left(n^{1/\kappa}\log n\sum_{S\in\mathcal{G}}|S|\right) \;=\; O(\log n\cdot n^{1+1/\kappa})\ .$$

Note that when constructing a new cluster, Procedure DOWN_PART might touch the vertices of the shell of an already built cluster S, but it will never explore again the edges that have at least one endpoint in S. Note also that the edges connecting two vertices of the shell of S were not explored during the construction of the cluster S. Thus Procedure DOWN_PART never re-explores edges that were previously explored.

For a cluster $S_i \in \mathcal{G}$, let $E'(S_i)$ be the set of edges explored during the construction of the cluster S_i. By the above considerations, $E'(S_i)\cap E'(S_j) = \emptyset$ for any two clusters $S_i, S_j \in \mathcal{G}$. Also $\cup_{S\in\mathcal{G}}E'(S) \subseteq E$. The depth-limited unweighted BFS algorithm that explores m' edges and n' vertices requires $O(m' + n'\log n')$ time. Hence the total running time of all invocations of the depth-limited unweighted BFS algorithm by Procedure DOWN_PART is $\sum_{S\in\mathcal{G}}|E'(S)| + O(n^{1+1/\kappa}\log n) = O(|E| + n^{1+1/\kappa}\log n)$. Hence the overall running time of the procedure is $O(|E| + n^{1+1/\kappa}\log n)$. □

Note that the problem is interesting mainly when $|E|$ is greater than $O(n^{1+1/\kappa})$, since otherwise the graph itself may serve as its own sparse 1-spanner, with $O(n^{1+1/\kappa})$ edges.

LEMMA 4.2. *Procedure* SC *can be executed on an input spanned partition* $\mathcal{C}$ *in* $O(|E|n/\check{S}(\mathcal{C}))$ *time.*

Proof. It is easy to see that the most expensive parts of Procedure SC are steps 2(b)iiA and 4, which are concerned with computing the shortest paths between clusters. This task can be performed by running BFS algorithm separately from every cluster. Note that BFS algorithm enables computing all the distances from a single source, where this source need not be a single vertex but may be a subset of vertices as well. Recall that for a subset of vertices U and a vertex v, the distance between U and v is $\min\{dist_G(u,v) \mid u \in U\}$. Each invocation of BFS algorithm requires $O(|E| + n \cdot \log n) = O(|E|)$ time. The number of clusters is $O(n/\check{S}(\mathcal{C}))$. Hence the running time of the procedure is $O(|E|n/\check{S}(\mathcal{C}))$. ∎

LEMMA 4.3. *The running time of Algorithm* SP_CONS *is* $O(|E|n^{(\kappa-1)/\kappa})$.

Proof. The dominant term in the time complexity of the algorithm is the running time of the very first invocation of Procedure SC. In this invocation, $\check{S}(\mathcal{G}) \geq n^{1/\kappa}$, and so by Lemma 4.2 it requires $O(|E|n^{(\kappa-1)/\kappa})$ time. The running time of all later invocations of SC is significantly smaller, as those are applied to spanned partitions $\mathcal{C}$ with $\check{S}(\mathcal{C}) \geq n^{2/\kappa}$. The complexity of step 5 can be analyzed along the same lines as in the proof of Lemma 4.2 and shown to be at most $O(|E|n^{1/\kappa})$. The running time of Procedure DOWN_PART is at most $O(|E| + n^{1+1/\kappa}\log n)$. Thus, the overall complexity of Algorithm SP_CONS is $O(|E|n^{(\kappa-1)/\kappa})$. ∎

4.2. Speeding up algorithm SP_CONS. In this section we present a modification of Algorithm SP_CONS that has smaller time complexity, but α, β and size parameters similar to those of section 3.3.

The main idea is to save time by finding *almost* shortest paths instead of shortest ones. Specifically, the modified algorithm receives an additional parameter $t \geq 1$. It starts with invoking an *all pairs almost shortest path* algorithm $APASP_t$ due to [7]. This algorithm runs for $\tilde{O}(n^{2+1/t})$ time and for every pair of vertices $u, w \in V$ computes a path of length $dist'(u,w) \leq dist_G(u,w) + t$. Next, the algorithm sorts the obtained n^2 distances in $O(n^2 \log n)$ time and for each pair maintains the index in the sorted array (i.e., a pair of closer vertices will have a smaller index). Next, it runs Algorithm SP_CONS as is, except that whenever it needs to compute a shortest path between two clusters it uses the precomputed array. Specifically, for two clusters S_i and S_j it takes $|S_i| \cdot |S_j|$ time to find the pair of vertices $u_i \in S_i$, $u_j \in S_j$ such that $dist'(u_i,u_j) = \min\{dist'(u,w) \mid u \in S_i, w \in S_j\}$. Hence, overall, the approximate computation of all the distances between clusters of some partition $\mathcal{C}$ and all the paths between close cluster pairs (i.e., at distance bounded by $\Upsilon^{i/J}$ for some $1 \leq i \leq J$) takes time bounded by

$$O\left(\sum_{S_i,S_j\in\mathcal{C}} \Upsilon|S_i|\cdot|S_j|\right) \;\leq\; O\left(\Upsilon\left(\sum_{S_i\in\mathcal{C}}|S_i|\right)^2\right) \;=\; O(\Upsilon n^2)\ .$$

Since there are $O(J)$ iterations, the distances and paths for different partitions are computed $O(J)$ times, i.e., the total running time of computing the distances and paths is $O(J\Upsilon n^2)$. Hence, the overall running time of the modified algorithm is $\tilde{O}(n^{2+1/t} + J\Upsilon n^2)$, and setting $J = \log\kappa = O(\log\log n)$ and $\Upsilon = O(\kappa^{\log\kappa}) = O((\log n)^{\log\log n})$, the resulting time bound is $\tilde{O}(n^{2+1/t})$.

It remains to analyze the α, β and size parameters of the spanner obtained by the above modification of Algorithm SP_CONS. First, instead of Lemma 3.1 we now get

$$\hat{D}(\mathcal{C}') \;\leq\; 3\hat{D}(\mathcal{C}) + 2\delta + 2t. \tag{14}$$

Next, Lemma 3.3 is replaced by the following.

LEMMA 4.4. *For every integer* $1 \leq j \leq J-1$,

$$\text{(a)} \quad \hat{D}(\mathcal{C}'_j) \leq 2\left(3^j \kappa t_{J-1} + \sum_{l=1}^{j} 3^{j-l}\Upsilon^{l/J}\right) + t(3^j - 1) \ ,$$

$$\text{(b)} \quad \hat{D}(\mathcal{R}_j) \leq 2\left(3^{j-1} \kappa t_{J-1} + \sum_{l=1}^{j-1} 3^{j-1-l}\Upsilon^{l/J}\right) + t(3^{j-1} - 1) \ .$$

Proof. The induction base holds since $\hat{D}(\mathcal{R}_1) \leq \hat{D}(\mathcal{C}_1) \leq 2t_{J-1}\kappa + t(3^0 - 1) = 2t_{J-1}\kappa$ and $\hat{D}(\mathcal{C}_1) \leq 2(3^1 t_{J-1}\kappa + \Upsilon^{1/J}) + t(3^1 - 1)$, by Lemma 3.3 and inequality (14).

The induction hypothesis changes to

$$\hat{D}(\mathcal{C}'_j) \ \leq \ 2\left(3^j \kappa t_{J-1} + \sum_{l=1}^{j} 3^{j-l}\Upsilon^{l/J}\right) + t(3^j - 1) \ .$$

The inequalities (4) and (5) are unchanged, and hence

$$\hat{D}(\mathcal{R}_{j+1}) \ \leq \ \hat{D}(\mathcal{C}_{j+1}) \ \leq \ 2\left(3^j \kappa t_{J-1} + \sum_{l=1}^{j} 3^{j-l}\Upsilon^{l/J}\right) + t(3^j - 1) \ .$$

So by inequality (14), it follows that

$$\begin{aligned}\hat{D}(\mathcal{C}_{j+1}) &\leq 3 \cdot 2\left(3^j \kappa t_{J-1} + \sum_{l=1}^{j} 3^{j-l}\Upsilon^{l/J}\right) + 3t(3^j - 1) + 2\Upsilon^{(j+1)/J} + 2t \\ &= 2\left(3^{j+1} \kappa t_{J-1} + \sum_{l=1}^{j+1} 3^{j+1-l}\Upsilon^{l/J}\right) + t(3^{j+1} - 1) \ . \qquad \square\end{aligned}$$

Analogously to inequality (6), it follows that

$$\hat{D}(R_J) \ \leq \ 2\left(3^{J-1} \kappa t_{J-1} + \sum_{l=1}^{J-1} 3^{J-l-1}\Upsilon^{l/J}\right) + t(3^{J-1} - 1) \ .$$

Next, it is easy to see that inequality (7) becomes

$$|E(H_j)| \ = \ O(n^{1+t_{J-j}-2t_{J-j+1}}(\delta_{J+1-j} + t)) \ .$$

Hence

$$|E(H)| \ = \ \sum_{j=1}^{J-1} |E(H_j)| \ = \ O(n^{1+1/\kappa}(\Upsilon + tJ)) \ .$$

Lemmas 3.13 and 3.14 are unchanged. However, since the expression for $\hat{D}(\mathcal{R}_j)$ is modified, inequality (13) becomes

$$\begin{aligned}\gamma_j/4 &\leq 2^{j-1} t_{J-1}\kappa + 2^{j-2}\left(3t_{J-1}\kappa + \Upsilon^{1/J} + 2t\right) + \cdots \\ &\quad + 2^0\left(3^{j-1} t_{J-1}\kappa + \sum_{i=1}^{j-1} 3^{j-1-i}\Upsilon^{i/J} + t(3^{j-1} - 1)\right) \\ &= t_{J-1}\kappa \sum_{i=0}^{j-1} 3^i 2^{j-1-i} + \sum_{l=1}^{j-1}\left(\Upsilon^{l/J} \sum_{i=0}^{j-l-1} 3^i 2^{j-l-i-1}\right) + t\sum_{i=1}^{j-1} 2^{j-1-i}(3^i - 1) \\ &\leq t_{J-1}\kappa 3^j + 6\Upsilon^{(j-1)/J} + t3^j \ = \ 3^j(t_{J-1}\kappa + t) + 6\Upsilon^{(j-1)/J} \ .\end{aligned}$$

Hence the multiplicative factor is at most $1 + 2t_J\kappa + O(\frac{J + t_{J-1}\kappa + t}{\Upsilon^{1/J}})$, the additive term is

$O((t_{J-1}\kappa+t)3^J+\Upsilon^{(J-1)/J})$ and the size of the constructed spanner is $O(n^{1+1/\kappa}(\Upsilon+tJ))$, and we have the following.

THEOREM 4.5. *For any fixed $0<\epsilon<1$ and fixed integers $t\geq 1$ and $\kappa\geq 2$ there exist fixed $\bar{\beta}=\bar{\beta}(\kappa,\epsilon,t)=\kappa^{\max\{\log\log\kappa-\log\epsilon,3\}}+t\log\kappa$ and $\tilde{\beta}=\tilde{\beta}(\kappa,\epsilon,t)=\kappa^{\max\{\log\log\kappa-\log\epsilon,\log t,3\}}$ such that every n-vertex graph has a $(1+\epsilon,\tilde{\beta})$-spanner of size bounded by $O(n^{1+1/\kappa}\bar{\beta})$ that can be built in time $\tilde{O}(n^{2+1/t})$.*

In particular, setting $t=O(\log\kappa)$ we obtain results analogous to Theorem 3.17 and Corollaries 3.18–3.20 by an algorithm of time complexity $\tilde{O}(n^{2+1/\log\kappa})$. Getting a running time of $\tilde{O}(n^{2+1/\kappa})$ requires raising the additive term to $O(\kappa^{\max\{\log\kappa,-\log\epsilon\}})$, which is, nonetheless, still constant for constant κ and ϵ. This enables us to generalize Corollary 3.18 and get the following.

COROLLARY 4.6. *For any constant $\epsilon>0,\lambda>0,\mu>0$ there exists a constant $\beta''(\epsilon,\lambda,\mu)$ such that for any n-vertex graph $G=(V,E)$ there exists a subgraph H, $E(H)\subseteq E$, that satisfies the following properties*

1. *For every pair of vertices $u,w\in V$ with $dist_G(u,w)\geq\beta''(\epsilon,\lambda,\mu)$, $dist_H(u,w)\leq(1+\epsilon)dist_G(u,w)$.*
2. *$|E(H)|=O(n^{1+\lambda})$.*
3. *H can be constructed in $\tilde{O}(n^{2+\mu})$ time.*

Acknowledgments. We thank Uri Zwick for his helpful comments, corrections and suggestions of improvements, and an anonymous referee for helpful remarks.

OPT VERSUS *LOAD* IN DYNAMIC STORAGE ALLOCATION*

ADAM L. BUCHSBAUM†, HOWARD KARLOFF†, CLAIRE KENYON‡, NICK REINGOLD†, AND MIKKEL THORUP†

Abstract. Dynamic storage allocation is the problem of packing given axis-aligned rectangles into a horizontal strip of minimum height by sliding the rectangles vertically but not horizontally. Where $L = LOAD$ is the maximum sum of heights of rectangles that intersect any vertical line and OPT is the minimum height of the enclosing strip, it is obvious that $OPT \geq LOAD$; previous work showed that $OPT \leq 3 \cdot LOAD$. We continue the study of the relationship between OPT and $LOAD$, proving that $OPT = L + O((h_{\max}/L)^{1/7})L$, where $h_{\max}$ is the maximum job height. Conversely, we prove that for any $\epsilon > 0$, there exists a $c > 0$ such that for all sufficiently large integers $h_{\max}$, there is a dynamic storage allocation instance with maximum job height $h_{\max}$, maximum load at most L, and $OPT \geq L + c(h_{\max}/L)^{1/2+\epsilon}L$, for infinitely many integers L. En route, we construct several new polynomial-time approximation algorithms for dynamic storage allocation, including a $(2+\epsilon)$-approximation algorithm for the general case and polynomial-time approximation schemes for several natural special cases.

Key words. approximation algorithms, dynamic storage allocation, polynomial-time approximation schemes

1. Introduction.

We study a simple rectangle-packing problem: Given a set of n isothetic (i.e., axis-parallel) open rectangles in the x-y plane, the ith extending from x-coordinate x_i to x-coordinate y_i on the real line and having height h_i, slide each rectangle up or down *but not sideways* so that (1) each rectangle is a subset of the positive quadrant, (2) the regions of the plane they occupy are pairwise disjoint, and (3) the supremum of the y-coordinates used is minimized. Resembling off-line Tetris in which the rectangles slide vertically but not horizontally, this problem is formally known as dynamic storage allocation for the following reason. View a rectangle starting at x-coordinate x_i, ending at x-coordinate y_i, and of height h_i as a request for h_i contiguous bytes of storage starting at time x_i and ending at time y_i. Then the problem of finding a rectangle placement that minimizes the supremum of the y-coordinates used is exactly that of minimizing the number of contiguous bytes needed to satisfy all memory requests.

Formally, an instance of dynamic storage allocation is a set of some number n of *jobs*, each job i being an open interval $I_i = (x_i, y_i)$ (for rationals $x_i < y_i$), which we assume without loss of generality is a subset of $(0,1)$, and a positive rational *height* h_i. We say job i is *live at x-coordinate t* (or simply *live at t*) if $t \in I_i$. A feasible solution is an assignment of a nonnegative real $s(i)$ to each job i such that if we define $S(i)$ to be the open real interval $(s(i), s(i) + h_i)$ (the region of memory assigned to job i during time period (x_i, y_i)), then for all $t \in (0,1)$, the jobs i that are live at t have pairwise disjoint $S(i)$'s. The goal is to minimize the *makespan*: $\max_i\{s(i) + h_i\}$.

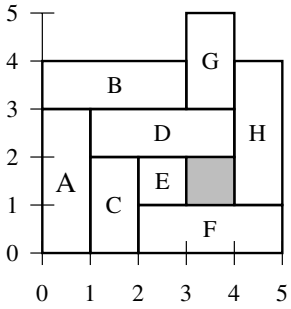

FIG. 1.1. *An optimal packing for the jobs (in the form* (x_i, y_i, h_i)*)* $A = (0, 1, 3)$, $B = (0, 3, 1)$, $C = (1, 2, 2)$, $D = (1, 4, 1)$, $E = (2, 3, 1)$, $F = (2, 5, 1)$, $G = (3, 4, 2)$, *and* $H = (4, 5, 3)$. *The shaded region is a gap. In this example,* $LOAD = 4$, *but* $OPT = 5$.

By scaling, we will assume that each h_i is integral, in which case it is easy to see that without loss of generality $s(i)$ is integral too.

Dynamic storage allocation was proven NP-complete in 1976 by Stockmeyer. (See problem SR2 in Garey and Johnson [3].) The first polynomial-time, constant-factor approximation algorithm was given by Kierstead in 1988 [6], using a reduction from dynamic storage allocation to on-line coloring of interval graphs discovered by Woodall in 1973 [8] and independently by Chrobak and Slusarek in 1988 [1]. Kierstead's algorithm is an 80-approximation algorithm. Kierstead [7] later exhibited a 6-approximation algorithm for dynamic storage allocation. The next improvements were 5- and 3-approximation algorithms by Gergov [4, 5]. Neither of Gergov's two algorithms uses the Woodall–Chrobak–Slusarek reduction.

Define OPT to be the optimal makespan for a given instance. The *load* $L(t)$ *at (x-coordinate)* t is the sum of h_i over all jobs i that are live at t. The *maximum load* $LOAD$ (also L) is the maximum over all t of the load at t. $LOAD$ is a trivial lower bound on OPT. When all heights are equal, $OPT = LOAD$, and an optimal solution can be found via interval graph coloring. In general, however, OPT need not equal $LOAD$, as exemplified by Figure 1.1.

All four of the algorithms mentioned above actually find packings of makespan at most c times $LOAD$, not just c times OPT, for the respective c (80, 6, 5, or 3). We further study the relationship between OPT and $LOAD$ in dynamic storage allocation, providing new upper and lower bounds on the gap between them; all of our upper bounds are expressed algorithmically. Recall $L = LOAD$; denote the maximum job height by $h_{\max}$ and the minimum job height by $h_{\min}$. Our main results are as follows.

1. We devise an algorithm that yields makespan $(1 + O((h_{\max}/L)^{1/7}))L$. This bound is $L + o(L)$ when $h_{\max} = o(L)$. When $h_{\max}$ is bounded by a constant, we improve the makespan bound to $(1 + O(((\lg^2 L)/L)^{1/4}))L$. Note that the case $h_{\max} = o(L)$ does not subsume that of $h_{\max}$'s being a constant, because, e.g., L might itself be bounded by a constant. No result of the form $OPT \le L + o(L)$ is possible in the general case, since one can "scale up" the heights in the example of Figure 1.1 to get $L = 4k$ and $OPT = 5k$ for any positive integer k.

2. For any $\epsilon > 0$, there exists a $c > 0$ such that for all sufficiently large constants $h_{\max}$, there is a dynamic storage allocation instance with maximum job height $h_{\max}$, maximum load at most L, and $OPT \ge (1 + c(h_{\max}/L)^{1/2+\epsilon})L$, for infinitely many integers L. This is the first nontrivial lower bound to include the case when $h_{\max}$ is bounded by a constant. This lower bound shows that our upper bounds in (1) are

optimal up to the exact powers of $h_{\max}/L$. In particular, the "1/7" in the general upper bound (and the "1/4" in the bounded-$h_{\max}$ upper bound) cannot be replaced by any real greater than 1/2.

We also contribute the following corollaries to our main results.

1. For all $\epsilon > 0$, we give polynomial-time, $(2+\epsilon)$-approximation algorithms.
2. We give polynomial-time approximation schemes (PTASs) for the following cases:
   (a) $h_{\max} = o(L)$;
   (b) $h_{\max}$ is bounded by a constant.

Finally, using straightforward dynamic programming, we give a PTAS when $h_{\min} = \Omega(L \lg\lg n / \lg n)$ and a polynomial-time, exact solution when $L = O(\lg n / \lg\lg n)$.

We begin in section 2 by introducing our main tool: boxing jobs into larger rectangles so that the total wasted space in the rectangles remains small. Along with some results for simple cases (small load and large jobs) described in section 3, we use boxing to devise our algorithms for bounded-height jobs (section 4) and finally for the remaining cases (section 5). We present the lower bound in section 6.

2. Boxing jobs. Let Y be any set of jobs and t be any x-coordinate. $L_Y(t)$ denotes the load of the jobs in Y that are live at t.

To *box* a set Y of jobs means to place the jobs into a box b of minimum x-coordinate $x_b = \min\{x_j : j \in Y\}$, maximum x-coordinate $y_b = \max\{y_j : j \in Y\}$, and height $h_b \geq \sum_{j \in Y} h_j$. A *boxing* of a set Y into a set B of boxes is a partition of Y into at most $|B|$ subsets, each of which is then boxed into a distinct box $b \in B$. The boxes can be viewed as jobs in a modified instance. Then L_B (resp., $L_B(t)$) is well defined to mean the *load of the boxes* (resp., *at* t). In particular, any unused space in a box still counts toward the load contributed by that box. All of the boxing procedures that follow run in polynomial time.

2.1. Boxing for a fixed time.

LEMMA 2.1. *Given a set Y of unit-height jobs, all live at some fixed x-coordinate t, an integer* box-height parameter *H, and a sufficiently small positive ϵ, there exist a subset Y' of Y, $|Y - Y'| \leq 2H\lceil 1/\epsilon^2 \rceil$, a set B of boxes, each of height H, and a boxing of Y' into B such that at any x-coordinate u,*

$$L_B(u) \leq L_{Y'}(u) + 4\epsilon L_Y(u).$$

Proof. It is convenient to view a job starting at x and ending at y as a point (x, y) in the plane, as depicted in Figure 2.1(a)–(b). Now partition the jobs of Y into *strips*, as exemplified by Figure 2.1(c). The first two strips are defined as follows.

1. Create a vertical strip consisting of the $H\lceil 1/\epsilon^2 \rceil$ jobs with the earliest starting x-coordinates (or fewer if there are not enough jobs).

2. If any jobs remain, create a horizontal strip consisting of the $H\lceil 1/\epsilon^2 \rceil$ jobs that remain with the latest ending x-coordinates (or fewer if not enough jobs remain).

Define Y' to be the set of all jobs in neither the first vertical nor the first horizontal strip. Obviously $|Y - Y'| \leq 2H\lceil 1/\epsilon^2 \rceil$. Now partition the jobs of Y' into strips by repeating the following as long as jobs remain.

1. Create a vertical strip consisting of the $H\lceil 1/\epsilon \rceil$ jobs that remain with the earliest starting x-coordinates (or fewer if not enough jobs remain).

2. If any jobs remain, create a horizontal strip consisting of the $H\lceil 1/\epsilon \rceil$ jobs that remain with the latest ending x-coordinates (or fewer if not enough jobs remain).

Now for every vertical strip of Y', take the jobs in order of decreasing ending x-coordinate in groups of size H (the last group of the last strip possibly smaller),

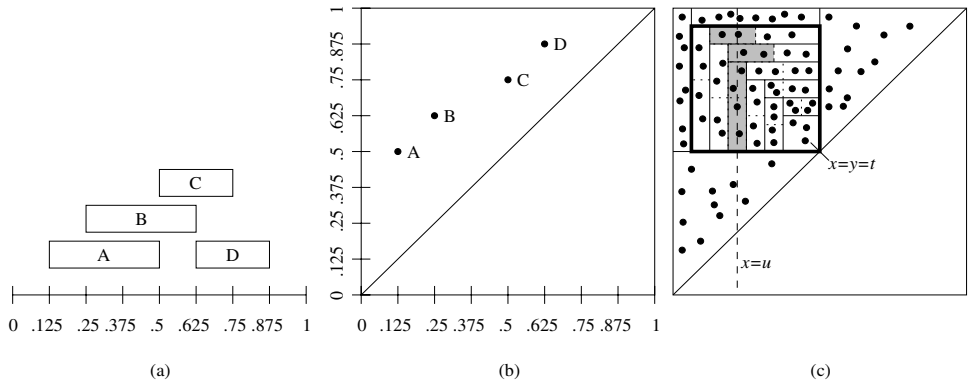

FIG. 2.1. (a) *Four jobs.* (b) *The jobs of* (a) *viewed as* (x, y) *points. Note that all jobs are above the* $x = y$ *diagonal.* (c) *Stripping a set of jobs with* $H = 2$ *and* $\epsilon = .5$. *The rectangle* R_t *defines the set* Y *of jobs. The first (leftmost) vertical and (topmost) horizontal strips each contains* $H\lceil 1/\epsilon^2 \rceil = 8$ *jobs. The remaining jobs, which comprise* Y', *are shown in the bold subrectangle.* Y' *is partitioned into strips containing* $H\lceil 1/\epsilon \rceil = 4$ *jobs each. Within each strip of* 4 *jobs in* Y', *the jobs are grouped (dotted lines) into groups of height* $H = 2$. *The groups that intersect the line* $x = u$ *are shaded.*

and box them. Similarly, for every horizontal strip of Y', take the jobs in order of increasing starting x-coordinate in groups of size H (the last group of the last strip possibly smaller), and box them.

We analyze the construction using Figure 2.1(c). For all reals u, the jobs live at u correspond to the rectangle $R_u = \{(x, y) : x < u < y\}$. The fact that the jobs in Y are all live at t means that all the corresponding vertices are inside the rectangle R_t.

A box (other than a last box) corresponds to a group of exactly H jobs. If all are live at u, then these jobs contribute exactly H to $L_{Y'}(u)$, because each job has unit height, and the box contributes exactly H to $L_B(u)$. If none of them is live at u, then they contribute 0 to $L_{Y'}(u)$, and the box contributes 0 to $L_B(u)$. The troublesome case is the one in which some but not all of the jobs are live at u, since the jobs may contribute as little as 1 to $L_{Y'}(u)$, while the box still contributes H to $L_B(u)$.

Assume without loss of generality that $u < t$. Then the troublesome case corresponds to groups of jobs whose vertices are on both sides of the line $x = u$. By construction, this can happen to at most one group in each horizontal strip of Y'. (Recall that points in a horizontal strip are grouped in order of increasing x-coordinates.) Moreover, this can happen to groups inside at most one vertical strip of Y'.

Notice that if the line $x = u$ intersects, say, k horizontal strips of Y', then the rectangle R_u entirely contains at least $k - 1$ vertical strips of Y'. (In fact, in the current case, R_u entirely contains at least k vertical strips of Y'. In the symmetric case, when $t < u$, the number is $k - 1$. We argue without loss of generality.)

If the rectangle R_u does not contain any job of Y', then the lemma trivially holds. Otherwise, R_u must contain all the jobs in the (only) vertical strip of $Y - Y'$, which number $H\lceil 1/\epsilon^2 \rceil$.

Observe that

$$L_B(u) - L_{Y'}(u) \leq kH + H\lceil 1/\epsilon \rceil + H, \tag{2.1}$$

where the first term accounts for the groups in the k horizontal strips that are intersected by $x = u$, the second term accounts for the groups in the single vertical strip

that is intersected by $x = u$, and the third term accounts for (possibly) the last group of the last strip.

But

$$L_Y(u) \geq H\lceil 1/\epsilon^2 \rceil + \max\{k-1, 0\} \cdot H\lceil 1/\epsilon \rceil, \tag{2.2}$$

where the first term accounts for the vertical strip of $Y - Y'$, and the second accounts for the $\max\{k-1, 0\}$ vertical strips of Y' that are contained in the rectangle R_u.

Now observe that

$$kH + H\lceil 1/\epsilon \rceil + H \leq (k-1)H + H/\epsilon + 3H; \tag{2.3}$$

$$H/\epsilon + 3H \leq H\epsilon(3/\epsilon + 1/\epsilon^2) \leq H\epsilon(4/\epsilon^2) \leq (4\epsilon)[H\lceil 1/\epsilon^2 \rceil]; \tag{2.4}$$

$$(k-1)H \leq \epsilon \max\{k-1, 0\} \cdot H\lceil 1/\epsilon \rceil \leq (4\epsilon)[\max\{k-1, 0\} \cdot H\lceil 1/\epsilon \rceil]. \tag{2.5}$$

Combining equations (2.1)–(2.5) yields

$$L_B(u) - L_{Y'}(u) \leq 4\epsilon L_Y(u). \qquad \square$$

We call the jobs in $Y - Y'$ *unresolved jobs*.

2.2. Boxing over all times. We bootstrap Lemma 2.1 so that we can box all the jobs (i.e., not just jobs live at a particular, fixed x-coordinate) with just a small amount of wasted space. Our main technical result is particularly interesting when $L \gg (H \lg H) \lg(1/\epsilon)/\epsilon^2$. We use this theorem in the following sections to devise approximation schemes for dynamic storage allocation.

THEOREM 2.2. *Given a set Z of jobs, each of height* 1*, an integer* box-height parameter *H, and a sufficiently small positive ϵ, there exist a set B of boxes, each of height H, and a boxing of Z into B such that for all x-coordinates t,*

$$L_B(t) \leq (1 + 4\epsilon)L_Z(t) + O\left(\frac{H \lg H}{\epsilon^2} \lg \frac{1}{\epsilon}\right).$$

To prove Theorem 2.2, we are going to apply Lemma 2.1 many times, boxing the unresolved jobs into additional boxes as we go along. Our general goal is to keep the wasted load (free space) in those additional boxes small at any x-coordinate. We use the following recursive method. Given are

1. a set X of jobs and an open *bounding interval* I, such that $\forall j \in X, I_j \subseteq I$;
2. a nonempty finite set of *critical x-coordinates* $T = \{\inf I = t_0 < t_1 < \cdots < t_q < t_{q+1} = \sup I\} \subseteq I \cup \{\inf I, \sup I\}$;
3. a set F of *free spaces*. Each free space is an open subinterval of I of height 1 *having endpoints in* T. Any free space $f \in F$ is called *spanning* if $f = I$ and *nonspanning* otherwise.

Initially, $X = Z$, $I = (0, 1)$, $T = \{0, t, 1\}$ for some arbitrary x-coordinate t at which some job from Z is live, and $F = \emptyset$. Recall that $I_j = (x_j, y_j)$ denotes the interval of job j. With the help of T, define partition

$$X = (R_1 \cup R_2 \cup \cdots \cup R_q) \cup (X_0 \cup X_1 \cup \cdots \cup X_q)$$

as follows. (See Figure 2.2.) First, define $X_i = \{j \in X : I_j \subseteq (t_i, t_{i+1})\}$ for $0 \leq i \leq q$. The X_i's contain precisely the jobs that are not live at any critical time.

Then define the R_i's recursively as in an interval tree [2]. Define $X' = X \setminus (X_0 \cup X_1 \cup \cdots \cup X_q)$, the set of jobs that are live at some (not necessarily unique) critical

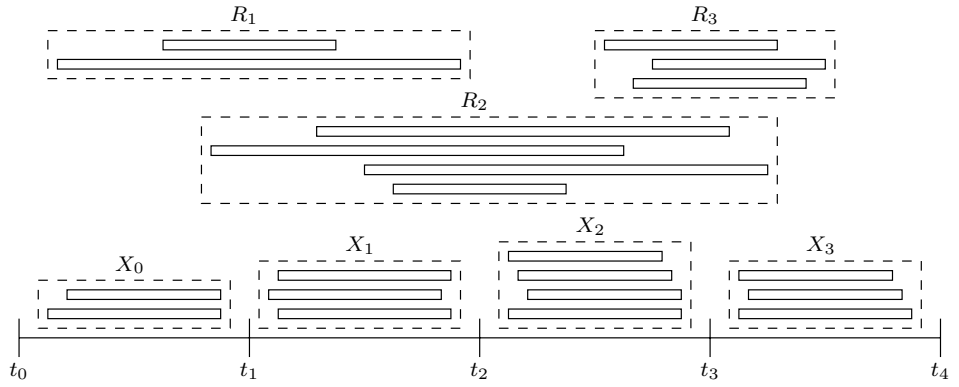

FIG. 2.2. *A set of jobs (solid rectangles) partitioned into subsets (dashed rectangles) X_i and R_j using critical x-coordinates $t_0, \ldots, t_4$.*

time. Note that $q \geq 1$. Define $R_{\lceil q/2 \rceil} = \{j \in X' : t_{\lceil q/2 \rceil} \in I_j\}$. Define P to be the set of remaining jobs j of X' with $y_j < t_{\lceil q/2 \rceil}$, and define Q to be the set of remaining jobs j of X' with $t_{\lceil q/2 \rceil} < x_j$. That is, $R_{\lceil q/2 \rceil}$ is the set of jobs that are live at $t_{\lceil q/2 \rceil}$; P is the set of jobs that are live at some critical time but end before $t_{\lceil q/2 \rceil}$; and Q is the set of jobs that are live at some critical time but start after $t_{\lceil q/2 \rceil}$. If $P \neq \emptyset$, recursively partition P using $\{t_1, t_2, \ldots, t_{\lceil q/2 \rceil - 1}\}$. Afterward, if $Q \neq \emptyset$, recursively partition Q using $\{t_{\lceil q/2 \rceil + 1}, t_{\lceil q/2 \rceil + 2}, \ldots, t_q\}$.

We will box the jobs in the R_i's, in the process establishing parallel, recursive instances of the decomposition to handle the X_i's. First, to each X_i associate a set F_i of intervals (free spaces), initially empty. As sections of free spaces in F are used to box jobs in the R_i's, the unused fragments will be deposited into the appropriate F_i's for use deeper in the recursion, to box jobs in the X_i's.

To box the jobs in the R_i's, first apply Lemma 2.1 to each R_i, $1 \leq i \leq q$, in any order; note that all jobs in R_i are live at t_i. For each i, this boxes all the jobs of R_i except for at most $2H\lceil 1/\epsilon^2 \rceil$ unresolved jobs. Now consider the set U of all the unresolved jobs from all the R_i's. Derive an optimal packing of U using interval graph coloring. (Recall that all jobs are of height one.) This packing has makespan L_U.

Let $s(F)$ denote the subset of spanning free spaces of F. If $|s(F)| < L_U$, create $\lceil (L_U - |s(F)|)/H \rceil$ boxes of height H and horizontal extent I. This yields $H\lceil (L_U - |s(F)|)/H \rceil$ new spanning free spaces; add them to F. Now there are at least as many spanning free spaces in F as rows of the packing of U.

For each $1 \leq j \leq L_U$, remove one spanning free space from F, and use it to place all the jobs in row j of the packing. This creates *gaps*, or unused portions, in the original free space, each of the form $[\alpha, \beta]$, where for some i, j: $t_i \leq \alpha < t_{i+1}$ and $t_j \leq \beta < t_{j+1}$; recall that $t_0 = \inf I$ and $t_{q+1} = \sup I$. For each such $[\alpha, \beta]$, if $i \neq j$, then split $[\alpha, \beta]$ into $(\alpha, t_{i+1}), (t_{i+1}, t_{i+2}), \ldots, (t_{j-1}, t_j), (t_j, \beta)$; and add (α, t_{i+1}) to F_i, (t_{i+1}, t_{i+2}) to F_{i+1}, ..., (t_{j-1}, t_j) to F_{j-1}, and (t_j, β) to F_j. Otherwise $(i = j)$, simply deposit (α, β) into F_i. This *fragments* the gaps.

Now all the jobs in all the R_i's are boxed. Consider the unused free spaces in F, if any. Each is of the form (t_i, t_j) for some $i \neq j$. Split each such (t_i, t_j) into $(t_i, t_{i+1}), (t_{i+1}, t_{i+2}), \ldots, (t_{j-1}, t_j)$. Add (t_i, t_{i+1}) to F_i, (t_{i+1}, t_{i+2}) to F_{i+1}, ..., and (t_{j-1}, t_j) to F_{j-1}. This *passes down* the unused free spaces to the subproblems.

In parallel for each $\ell = 0, 1, 2, \ldots, q$, if $X_\ell \neq \emptyset$, recursively apply the construction

with new $X \leftarrow X_\ell$, new free space set $F \leftarrow F_\ell$, new bounding interval $I \leftarrow (t_\ell, t_{\ell+1})$, and new critical x-coordinate set $T \leftarrow \{\text{endpoints of elements of } F_\ell\} \cup \{t_\ell, t_{\ell+1}\}$. Note that this preserves the invariant that the endpoints of intervals in F are in T for each recursive subproblem. Also note that the unused free spaces passed down span their entire respective boundary intervals, whereas the gaps that were fragmented need not do so. This completes the construction.

2.3. Analysis. Fix a real u. (Recall that to prove Theorem 2.2 we want to bound the load of the boxes at any x-coordinate u in terms of the load of the original jobs at u.) For any m, define $I_m(u)$ to be the bounding interval of the depth-m recursive call whose bounding interval contains x-coordinate u. Similarly, define $T_m(u)$ to be the set of critical x-coordinates, $p_m(u) = |T_m(u)|$, and $U_m(u)$ to be the set of unresolved jobs from all the R_i's in that same depth-m recursive call. Define $F_m(u)$ to be the set of free spaces during the same depth-m recursive call, and note that this set changes during that procedure. Figure 2.2, for example, depicts for some m a piece of the depth-m stage of the recursion; i.e., $I_m(u) = (t_0, t_4)$ for $u \in (t_0, t_4)$. The jobs in each X_i will form the set of jobs for each subproblem at depth $m+1$; i.e., $I_{m+1}(u) = (t_0, t_1)$ for $u \in (t_0, t_1)$, $I_{m+1}(u) = (t_1, t_2)$ for $u \in (t_1, t_2)$, etc.

LEMMA 2.3. *For all m, $p_{m+1}(u) \le 2H\lceil 1/\epsilon^2 \rceil \lceil \lg(p_m(u)+1) \rceil + 2$.*

Proof. Note that $p_0(u) = 3$. In the depth-m recursive call, the definition of the R_i's implies that the number of R_i's containing jobs with endpoints in $I_{m+1}(u)$ is at most $\lceil \lg(p_m(u)+1) \rceil$. (The process of repeatedly looking at the middle index resembles binary search, and the worst-case running time of binary search on a list of length p is $\lceil \lg(p+1) \rceil$.) For each such R_i, Lemma 2.1 is applied, and each application yields at most $2H\lceil 1/\epsilon^2 \rceil$ unresolved jobs. Each unresolved job contributes at most one new endpoint and hence at most one critical x-coordinate to each of two different intervals $I_{m+1}(\cdot)$. The total number of critical x-coordinates contributed to $I_{m+1}(u)$ is thus at most $2H\lceil 1/\epsilon^2 \rceil \lceil \lg(p_m(u)+1) \rceil + 2$, where the "+2" comes from the endpoints $\inf I_{m+1}(u)$ and $\sup I_{m+1}(u)$. □

COROLLARY 2.4. *For all m, $p_m(u) = O(\frac{H \lg H}{\epsilon^2} \lg \frac{1}{\epsilon})$.*

Proof sketch. If $a_{m+1} \le k \lg a_m$ for all m, and $a_0 \le 3k \lg k$, then $a_m \le 3k \lg k$ for all m, a fact that is easily proven by induction on m. □

Let P denote the upper bound of the corollary. For all m, the number of critical x-coordinates in the subproblem defined by bounding interval $I_m(u)$ is at most P. Let $f_m(u)$ denote the number of free spaces in $F_m(u)$ *at the beginning* of that recursive call, and let $f'_m(u)$ denote the number of free spaces in $F_m(u)$ *at the end* of that recursive call. Abusing notation, let $L_m(u)$ denote the load of $U_m(u)$, the set of unresolved jobs from all the R_i's in the depth-m recursive call over bounding interval $I_m(u)$.

LEMMA 2.5. *For all m, $L_m(u) \le 2H\lceil 1/\epsilon^2 \rceil \lceil \lg(P+1) \rceil$.*

Proof. As above, at most $\lceil \lg(P+1) \rceil$ R_i's include jobs that contain u' for any $u' \in I_m(u)$. By Lemma 2.1 each such R_i contributes at most $2H\lceil 1/\epsilon^2 \rceil$ unresolved jobs to $U_m(u)$. □

COROLLARY 2.6. *For all m, $f'_m(u) \le f_m(u) + 2H\lceil 1/\epsilon^2 \rceil \lceil \lg(P+1) \rceil$.*

Proof. Boxing the unresolved jobs in the depth-m recursive call requires creating at most $\lceil L_m(u)/H \rceil$ new boxes of height H, which adds at most $H\lceil L_m(u)/H \rceil$ new (spanning) free spaces to $F_m(u)$, after which free spaces are only removed from $F_m(u)$. Lemma 2.5 completes the proof. □

LEMMA 2.7. *For all m,*

1. $f_{m+1}(u) \le f_m(u) + 2H\lceil 1/\epsilon^2 \rceil \lceil \lg(P+1) \rceil$;
2. *if* $f_m(u) \ge 4H\lceil 1/\epsilon^2 \rceil \lceil \lg(P+1) \rceil$, *then* $f_{m+1}(u) \le f_m(u)$.

Proof. 1. This follows from Corollary 2.6 and the fact that the fragmented gaps from any used spanning free space of $F_m(u)$ are distributed to distinct subproblems.

2. The free spaces of $F_m(u)$ at the beginning of the depth-m recursive call come from two sources.

(i) Unused free spaces of $F_{m-1}(u)$ that were passed down; as noted above, they yield spanning free spaces of $F_m(u)$, i.e., free spaces that span the entire interval $I_m(u)$.

(ii) Fragmented free spaces obtained during the depth-$(m-1)$ recursive call by placing an unresolved job in a free space of $F_{m-1}(u)$. Lemma 2.5 implies that there are at most $2H\lceil 1/\epsilon^2\rceil\lceil \lg(P+1)\rceil$ such spaces.

Assume $f_m(u) \geq 4H\lceil 1/\epsilon^2\rceil\lceil \lg(P+1)\rceil$. The number of spanning free spaces is the total number of free spaces minus the number of nonspanning free spaces. Because there are at most $2H\lceil 1/\epsilon^2\rceil\lceil \lg(P+1)\rceil$ nonspanning free spaces, $F_m(u)$ starts with at least

$$4H\lceil 1/\epsilon^2\rceil\lceil \lg(P+1)\rceil - 2H\lceil 1/\epsilon^2\rceil\lceil \lg(P+1)\rceil = 2H\lceil 1/\epsilon^2\rceil\lceil \lg(P+1)\rceil$$

spanning free spaces. When the unresolved jobs are boxed during the depth-m recursive call, there are enough spanning free spaces to fit *all* the unresolved jobs (again by Lemma 2.5), so no new free spaces are created. Thus, $f_{m+1}(u) \leq f_m(u)$. □

COROLLARY 2.8. *For all m, $f_m(u) = O\big(\frac{H \lg H}{\epsilon^2} \lg \frac{1}{\epsilon}\big)$.*

Proof. The proof follows from Corollary 2.4 and Lemma 2.7. □

COROLLARY 2.9. *For all m, $f'_m(u) = O\big(\frac{H \lg H}{\epsilon^2} \lg \frac{1}{\epsilon}\big)$.*

Proof. The proof follows from Corollaries 2.4, 2.6, and 2.8. □

We can now finish the proof of Theorem 2.2. Consider any x-coordinate u, and let m' denote the greatest depth of the recursion for which there existed an $I_{m'}(u)$. Of the jobs in Z that are live at u, let Z_R denote those that are resolved during applications of Lemma 2.1, and let Z_U denote the rest. The load at u of the boxes used to resolve jobs in Z_R is at most $L_{Z_R}(u) + 4\epsilon L_Z(u)$, by Lemma 2.1. The load at u of the boxes used to place jobs in Z_U is $L_{Z_U}(u) + f'_{m'}(u)$, because jobs in Z_U are only placed into free spaces in the various $F_m(u)$'s, and unused free spaces containing u in $F_m(u)$ for any $0 \leq m < m'$ are inherited by $F_{m+1}(u)$. Therefore, using Corollary 2.9 and the fact that $L_Z(u) = L_{Z_R}(u) + L_{Z_U}(u)$, the total storage allocated at x-coordinate u does not exceed

$$\big[L_{Z_R}(u) + 4\epsilon L_Z(u)\big] + \big[L_{Z_U}(u) + f'_{m'}(u)\big] = (1+4\epsilon)L_Z(u) + O\left(\frac{H \lg H}{\epsilon^2} \lg \frac{1}{\epsilon}\right). \quad \square$$

3. Dynamic programming solutions. In addition to boxing, our later results use the following results based on dynamic programming to solve simple cases.

THEOREM 3.1. *The optimal makespan can be determined in $O(\mathrm{poly}(n)(3L)^{2L+1})$ time.*

Proof. First, using the fact that $OPT \leq 3L$ [5], guess the optimal makespan M^*. Build an array T with, for each x, an entry for each feasible placement C_x of jobs that cross the vertical line at x. Now define $T[C_x]$ to be 0–1, with $T[C_x] = 1$ if and only if the set of jobs that intersect $[0, x)$ can be placed using height at most M^* with a placement that respects C_x. We have $T[C_x] = 1$ if and only if there is a $C_{x-1} = 1$ such that C_{x-1} is compatible with C_x and $T[C_{x-1}] = 1$.

There are $3L$ possibilities for M^*. There are $2n$ possibilities for x. For each x, there are $(M^*)^L \leq (3L)^L$ configurations C_x. Computing $T[C_x]$ takes time at most $(3L)^L$. The overall time bound is thus

$$O((3L)(3L)^L(3L)^L\mathrm{poly}(n)),$$

which is $O(\text{poly}(n)(3L)^{2L+1})$. □

COROLLARY 3.2. *Dynamic storage allocation can be solved optimally in polynomial time when* $L = O(\lg n / \lg\lg n)$.

Proof. The proof follows immediately from Theorem 3.1. □

THEOREM 3.3. *Let* C *be a positive real and let* $\alpha = \alpha(n)$ *be a positive function of* n *such that for all sufficiently large* n, $\alpha(n) \geq \lg\lg n/(C \lg n)$. *There is a PTAS for the special case of dynamic storage allocation in which* $h_{\min}/L \geq \alpha(n)$.

Proof. Given C, α, and $\epsilon > 0$, apply the dynamic program in the proof of Theorem 3.1 to the same jobs, except with height h replaced by $\lceil h/(\epsilon\alpha(n)L)\rceil$. Let L' be the load in the new problem. If there were no ceiling in the definition of the new heights, the load in the new problem would be $L/(\epsilon\alpha(n)L) = 1/(\epsilon\alpha(n))$. Since each original height h satisfies $h/(\epsilon\alpha(n)L) \geq 1/\epsilon$, the ceiling introduces an additional factor of at most $1+\epsilon$. It follows that $L' \leq (1+\epsilon)/(\epsilon\alpha(n)) \leq (2C/\epsilon)\lg n/\lg\lg n$ if n is large enough and $\epsilon \leq 1$. The new problem can be solved exactly in polynomial time by Corollary 3.2. □

4. Algorithm for bounded-height jobs. Let X be the set of all jobs and ϵ be a sufficiently small positive real. Recall that L is a trivial lower bound to OPT. If all the jobs have the same height, then the problem reduces to interval graph coloring and can be solved optimally in a greedy fashion; furthermore, $OPT = L$. Our algorithm will be a reduction to this simple case. Let $H = h_{\max}\lceil 1/\epsilon\rceil$, and assume that the maximum height of a job, $h_{\max}$, is a constant.

ALGORITHM.

1. If $L \leq C\frac{1}{\epsilon^4}\lg^2\frac{1}{\epsilon}$, for some C to be determined later, apply Corollary 3.2 and halt.

2. For each $h = 1, 2, 3, \ldots, h_{\max}$:

(i) Let X_h denote the set of jobs of height h. Let $H_h = \lfloor H/h\rfloor h$.

(ii) Scale each job in X_h down by a factor of h, apply Theorem 2.2 with box-height parameter $\lfloor H/h\rfloor$ and the given ϵ to this new set of jobs, and then scale the jobs back up by the same factor h.

3. Enlarge the boxes so that they all have height exactly H. Call the new set of boxes B'.

4. Apply the greedy algorithm for interval graph coloring to B'.

THEOREM 4.1. *The makespan of the packing produced by the algorithm is at most* $(1+15\epsilon)OPT$. *(Recall that* $h_{\max}$ *is a constant and* ϵ *is sufficiently small.)*

Proof. Assume for now that the algorithm does not stop in step 1. We argue for all t. By Theorem 2.2, step 2 produces a boxing B_h of the jobs of X_h into boxes of height H_h such that

$$L_{B_h}(t) \leq (1+4\epsilon)L_{X_h}(t) + O\left(\frac{1}{\epsilon^2}\cdot\frac{H}{h}\left(\lg\frac{H}{h}\right)\lg\frac{1}{\epsilon}\right)h. \tag{4.1}$$

(The final h comes from the scaling back up at the end of step (2); we have applied the theorem to jobs of height 1 with box-height parameter there equal to $\lfloor H/h\rfloor = H_h/h$.) Let $B = B_1 \cup B_2 \cup \cdots \cup B_{h_{\max}}$. Adding (4.1) yields

$$L_B(t) \leq (1+4\epsilon)L_X(t) + O\left(h_{\max}\frac{H\lg H}{\epsilon^2}\lg\frac{1}{\epsilon}\right).$$

Enlarging the boxes increases them by at most a factor of $1/(1-\epsilon)$. All together,

$$\begin{aligned}\text{makespan} &= \max_t L_{B'}(t)\\ &\le \max_t \left[\frac{1}{1-\epsilon}\left((1+4\epsilon)L_X(t) + O\left(h_{\max}\frac{H\lg H}{\epsilon^2}\lg\frac{1}{\epsilon}\right)\right)\right]\\ &\le \frac{1+4\epsilon}{1-\epsilon}\max_t L_X(t) + \frac{1}{1-\epsilon}O\left(h_{\max}\frac{H\lg H}{\epsilon^2}\lg\frac{1}{\epsilon}\right).\end{aligned}$$

$$\begin{aligned}\text{Thus, makespan} &\le \frac{1+4\epsilon}{1-\epsilon}L + O\left(h_{\max}\frac{H\lg H}{\epsilon^2}\lg\frac{1}{\epsilon}\right)\\ &\le \frac{1+4\epsilon}{1-\epsilon}OPT + O\left(h_{\max}\frac{H\lg H}{\epsilon^2}\lg\frac{1}{\epsilon}\right).\end{aligned} \tag{4.2}$$

Choose C so that the error term $O\big(h_{\max}\frac{H\lg H}{\epsilon^2}\lg\frac{1}{\epsilon}\big) \le \epsilon L$, which is possible under the assumptions that $L > C\frac{1}{\epsilon^4}\lg^2\frac{1}{\epsilon}$, $h_{\max}$ is a constant, and $H = h_{\max}\lceil 1/\epsilon\rceil$. If $L \le C\frac{1}{\epsilon^4}\lg^2\frac{1}{\epsilon}$, then the algorithm stops in step (1), and Theorem 3.1 applies. Otherwise, it follows that makespan $\le (1+15\epsilon)OPT$, because $L \le OPT$. ∎

THEOREM 4.2. *The makespan produced by the packing is* $(1+O(((\lg^2 L)/L)^{1/4}))L$. *(Recall that* $h_{\max}$ *is a constant.)*

Proof. Set $\epsilon = \sqrt{\lg L}/L^{1/4}$, and run the algorithm starting in step (2). The claim follows from inequality (4.2). ∎

5. Algorithms for larger jobs. From Theorem 2.2, we can prove the following corollary.

COROLLARY 5.1. *Let* H *be a positive integer* box-height parameter, $h_{\min}$ *be a positive real, and* $\epsilon > 0$ *be a sufficiently small* error parameter. *Given a set* Z *of jobs, each of height between* $h_{\min}$ *and* ϵH, *there exist a set* B *of boxes, each of height* H, *and a boxing of* Z *into* B *such that for all* x*-coordinates* t,

$$L_B(t) \le (1+9\epsilon)L_Z(t) + O\left(\frac{H\lg^2(H/h_{\min})}{\epsilon^4}\right).$$

Proof. We construct an appropriate boxing. First, round the job heights: each height h is rounded up to $\lfloor(1+\epsilon)^i\rfloor$, where i is defined by $(1+\epsilon)^{i-1} < h \le (1+\epsilon)^i$. Let Y denote the resulting set of rounded jobs.

Now partition the jobs according to their heights. For each rounded height h, let Y_h denote the set of jobs of height h. Divide the heights of all jobs in Y_h by h; apply Theorem 2.2 with box-height parameter $\lfloor H/h\rfloor$; and then multiply all box heights by h to get a set B_h of boxes of height at most H. The output is a set $B = \bigcup_h B_h$ of boxes, which we can assume are all of height H.

Let us analyze this construction. There are approximately $\log_{(1+\epsilon)}(\epsilon H/h_{\min}) = O(\lg(H/h_{\min})/\epsilon)$ parts in the partition. Applying Theorem 2.2 to Y_h yields

$$\begin{aligned}\forall t,\quad L_{B_h}(t) &\le (1+4\epsilon)L_{Y_h}(t) + O\left(h\frac{\lfloor H/h\rfloor\lg\lfloor H/h\rfloor}{\epsilon^2}\lg\frac{1}{\epsilon}\right)\\ &\le (1+4\epsilon)L_{Y_h}(t) + O\left(\frac{H\lg(H/h_{\min})}{\epsilon^3}\right),\end{aligned}$$

because $h_{\min} \le h$ and $\lg(1/\epsilon) \le 1/\epsilon$. Summing over h, we get

$$\forall t,\quad L_B(t) \le (1+4\epsilon)L_Y(t) + O\left(\frac{H\lg^2(H/h_{\min})}{\epsilon^4}\right).$$

Since rounding increased heights by a factor of $1+\epsilon$ at most, we have $L_Y(t) \le (1+\epsilon)L_Z(t)$. Since $(1+\epsilon)(1+4\epsilon) \le 1+9\epsilon$ for $\epsilon \le 1$, the corollary follows. □

We are now ready to prove our main theorem.

THEOREM 5.2. *For any* fixed $\epsilon \in (0,1]$ *there exists a polynomial-time algorithm, which depends on* ϵ*, that takes an arbitrary set* X *of jobs as input and produces a feasible solution to dynamic storage allocation on* X *with makespan at most* $(1+c\epsilon)L + O(h_{\max}/\epsilon^6)$*, where* c *is a universal constant.*

Proof. It suffices to prove the theorem for $\epsilon \le \epsilon_0$ for some small, positive ϵ_0, for the following reason. Suppose for all $\epsilon \le \epsilon_0$ we get a makespan bound of $(1+c_0\epsilon)L + c_1(h_{\max}/\epsilon^6)$ for some constants c_0 and c_1. Then for $\epsilon \in (\epsilon_0, 1]$ we simply use $(1+c_0\epsilon_0)L + c_1 h_{\max}/\epsilon_0^6 \le (1+c_0\epsilon)L + (c_1/\epsilon_0^6)h_{\max}/\epsilon^6$. Similarly, by reducing ϵ by a factor of at most two, we may assume that $1/\epsilon \in \mathbb{Z}$.

We are going to apply Corollary 5.1 repeatedly, boxing the smallest jobs so as to increase the minimum job height $h_{\min}$ until it gets close enough to the maximum job height $h_{\max}$ that we can finish with a last application of Corollary 5.1.

We argue for all t. Let r denote the ratio $h_{\max}/h_{\min}$, and recall that $L = L_X$. Assume first that $\lg^2 r \ge 1/\epsilon$, and set $\mu = \epsilon/\lg^2 r$ and $H = \lceil \mu^5 h_{\max}/\lg^2 r \rceil$. Consider the partition $X = X_s \cup X_\ell$, where X_s denotes the jobs of height at most μH and $X_\ell = X \setminus X_s$. Now apply Corollary 5.1 to X_s with box-height parameter H and error parameter μ. This yields a set B_s of boxes of height H into which the jobs of X_s fit such that for some constants c_2 and c_3,

$$\begin{aligned} L_{B_s}(t) &\le (1+9\mu)L_{X_s}(t) + O\left(\frac{H\lg^2(H/h_{\min})}{\mu^4}\right) \\ &\le (1+9\mu)L_{X_s}(t) + c_2\mu h_{\max} \\ &\le L_{X_s}(t) + c_3\mu L(t) \\ &= L_{X_s}(t) + (c_3\epsilon/\lg^2 r)L(t). \end{aligned}$$

Now consider B_s as a set of jobs and the revised problem on $X' = B_s \cup X_\ell$. For this new problem, the load $L'(t)$ is at most $(1 + c_3\epsilon/\lg^2 r)L(t)$. Moreover, the new minimum height $h'_{\min}$ is at least μH, and the maximum height remains at most $h_{\max}$, so we get the new ratio

$$r' \le \frac{h_{\max}}{h'_{min}} \le \frac{h_{\max}}{\mu\lceil \mu^5 h_{\max}/\lg^2 r\rceil} \le \frac{h_{\max}}{\mu^6 h_{\max}/\lg^2 r} = \frac{\lg^2 r}{\mu^6} = \frac{\lg^{14} r}{\epsilon^6} \le \lg^{26} r.$$

Recall that the above construction was conditioned on $\lg^2 r \ge 1/\epsilon$. For ϵ sufficiently small, this implies $\lg^{26} r \le \sqrt{r}$ and hence that $r' \le \sqrt{r}$ and also $\lg^2 r' \le \lg^2 \sqrt{r} \le (1/4)\lg^2 r$.

Iterate the above boxing of small jobs, each time using new error parameter $\mu' = \epsilon/\lg^2 r'$, until it yields a problem X^* with minimum job height $h^*_{\min}$ for which the ratio $r^* = h_{\max}/h^*_{\min}$ is such that $\lg^2 r^* < 1/\epsilon$. Since the ratio decreases by at least a square root each time, this process terminates in polynomial time.

Let $(r_0, \ldots, r_p = r^*)$ be the sequence of ratios, and let $(L_0(t), \ldots, L_p(t) = L^*(t))$ be the sequence of loads. For $0 \le i < p$ we know that

$$L_{i+1}(t) \le (1 + c_3\epsilon/\lg^2 r_i)L_i(t); \tag{5.1}$$

$$\lg^2 r_{i+1} \le (1/4)\lg^2 r_i. \tag{5.2}$$

For some constant c_4, we therefore get

$$\begin{aligned}
L^*(t) &\le L_0(t) \prod_{i=0}^{p-1} (1 + c_3\epsilon/\lg^2 r_i) \quad \text{by (5.1)} \\
&\le L_0(t) \exp\left(\sum_{i=0}^{p-1} (c_3\epsilon/\lg^2 r_i)\right) \\
&\le L_0(t) \exp(c_4\epsilon/\lg^2 r_{p-1}) \quad \text{by (5.2)} \\
&\le L_0(t) \exp(c_4\epsilon^2) \quad \text{because } \lg^2 r_{p-1} \ge 1/\epsilon \\
&\le (1 + 2c_4\epsilon^2) L_0(t) \quad \text{for } \epsilon \text{ sufficiently small.}
\end{aligned}$$

Now apply Corollary 5.1 to all of X^* with box-height parameter $H = h_{\max}/\epsilon$ (recall that $1/\epsilon \in \mathbb{Z}$) and error parameter ϵ; this is the "last application" of Corollary 5.1 to which we alluded earlier. For some constant c, this yields a final set X^f of jobs of identical height H and with load

$$\begin{aligned}
L^f(t) &= (1 + 9\epsilon) L^*(t) + O\left(\frac{H \lg^2(H/h^*_{\min})}{\epsilon^4}\right) \\
&\le (1 + 9\epsilon)(1 + 2c_4\epsilon^2) L_0(t) + O\left(\frac{H \lg^2(H/h^*_{\min})}{\epsilon^4}\right) \\
&\le (1 + c\epsilon) L_0(t) + O\left(\frac{h_{\max} \lg^2(r^*/\epsilon)}{\epsilon^5}\right).
\end{aligned}$$

Noting that $\lg^2 r^* < 1/\epsilon$ and $\lg^2(1/\epsilon) < 1/\epsilon$ for ϵ sufficiently small, we derive $\lg^2(r^*/\epsilon) \le 4/\epsilon$. Therefore

$$L^f(t) \le (1 + c\epsilon) L_0(t) + O(h_{\max}/\epsilon^6). \qquad \square$$

COROLLARY 5.3. *There exists a polynomial-time algorithm that takes an arbitrary set X of jobs as input and produces a feasible solution to dynamic storage allocation on X with makespan at most $(1 + O((h_{\max}/L)^{1/7}))L$.*

Proof. Apply Theorem 5.2 to X with $\epsilon = (h_{\max}/L)^{1/7}$. $\square$

COROLLARY 5.4. *Fix some function $f(m) = o(m)$. Then there is a PTAS for dynamic storage allocation when $h_{\max} \le f(L)$.*

Proof. Given $\epsilon > 0$, there is an L_0 such that $f(L) \le \epsilon^7 L$ for all $L \ge L_0$. If $L < L_0$, use the dynamic program of Theorem 3.1. If $L \ge L_0$, then

$$h_{\max} \le f(L) \le \epsilon^7 L.$$

Apply the algorithm of Theorem 5.2. The error term of Theorem 5.2 is $O(h_{\max}/\epsilon^6) \le c'\epsilon L$ for some constant c'. Hence the makespan of the schedule is at most $(1 + (c + c')\epsilon)L$. $\square$

THEOREM 5.5. *For all $\epsilon > 0$, there exists a polynomial-time $(2+\epsilon)$-approximation algorithm for dynamic storage allocation.*

Proof. Consider some small positive δ to be determined later. Let $X = X_s \cup X_\ell$, where X_s is the set of jobs of height less than $\delta^7 L$ and $X_\ell = X \setminus X_s$. Use Theorem 5.2 with error parameter δ to pack the jobs in X_s, yielding a $(1 + c'\delta)$-approximation for some constant c'. Apply the $(1+\delta)$-approximation algorithm implied by Theorem 3.3 with the same δ to pack the jobs in X_ℓ, which is possible because the load divided by the minimum height is at most $1/\delta^7$, which is certainly at most $C \lg n / \lg\lg n$ for $C = 1/\delta^7$; this yields a $(1 + \delta)$-approximation. Choose δ so that $\delta(c' + 1) = \epsilon$. $\square$

6. Lower bounds for *OPT − LOAD*. Fix a positive integer d. Given a bipartite multigraph $G = (X, Y, E)$, $X = Y = \{1, 2, \ldots, n\}$, build an instance of dynamic storage allocation as follows. Start with n rectangles of height d, with $x_i = 0$, $y_i = i$ for $i = 1, 2, \ldots, n$, and then add n more rectangles of height d, with $x_i = 3n - i$, $y_i = 3n$ for $i = 1, 2, \ldots, n$. Call these $2n$ items *d-items*. For each $e = (j, k) \in E$ (with multiplicity, as E is a multiset), $1 \le j, k \le n$, add one item of height 1 having $x_i = j$, $y_i = 3n - k$. Call these jobs *1-items*. These are all the jobs. Call the instance I.

LEMMA 6.1. *If G is d-regular, then $L_I(t) \le dn$ for all $t \in (0, 3n)$.*

Proof. For any noninteger $t \in [n, 2n]$, the statement of the lemma is obvious, since the set of jobs that intersect $(n, 2n)$ is the set of all 1-items, that set has size dn, and each such job has height 1.

For any noninteger $t \in [0, n]$, let $j = \lfloor t \rfloor$. Crossing t are $n - j$ d-items (these jobs have $x_i = 0$) and dj 1-items (these have $x_i \in \{1, 2, \ldots, j\}$), because G is d-regular, and no others. Hence the load at t is $(n - j) \cdot d + (dj) \cdot 1 = dn$.

For a noninteger $t \in [2n, 3n]$, the argument is symmetric to the case of $t \in [0, n]$.

For any integer $t \in (0, 3n)$, $L_I(\cdot)$ achieves a local minimum at t. ∎

LEMMA 6.2. *For any positive integers n, d, f, and $s < \frac{n^{1/2-1/f}}{\sqrt{d}}$, there exists a d-regular bipartite multigraph (X, Y, E) with $X = Y = \{1, \ldots, n\}$ such that for any subsets X' of s consecutive vertices from X and Y' of s consecutive vertices from Y, the number of edges induced by $X' \cup Y'$ is smaller than f.*

Proof. Consider the following probability space of n-vertex-by-n-vertex d-regular bipartite multigraphs. Choose d independent permutations π of $\{1, \ldots, n\}$; for each, add edges between $i \in X$ and $\pi(i) \in Y$ for $1 \le i \le n$. We will show that the probability that a graph not of the claimed structure exists is less than 1; the claim then follows. Consider such a graph $G = (X, Y, E)$. There are some j and k such that $X' = \{j, \ldots, j + s - 1\} \subseteq X$, $Y' = \{k, \ldots, k + s - 1\} \subseteq Y$, and the subgraph induced by $X' \cup Y'$ has at least f edges. Consider any f such edges and fix an arbitrary order of them; this forms a sequence of edges $F = ((u_1, v_1), \ldots, (u_f, v_f))$, where each $u_i \in X'$ and each $v_i \in Y'$. There are no more than n^2 choices for the pair (j, k) and no more than s^{2f} possible sequences F. The probability that any particular edge exists is at most d/n. By the union bound, the probability that G exists is therefore no more than $P = n^2 s^{2f} (d/n)^f$. Simple algebra yields $P < 1$ when $s < \frac{n^{1/2-1/f}}{\sqrt{d}}$. ∎

THEOREM 6.3. *For all positive integers n and d, there is an instance of dynamic storage allocation with maximum job height d, $L(t) \le dn$ for all t, and $OPT - LOAD \ge \frac{n^{1/2-1/\lceil d/2 \rceil}}{12\sqrt{d}}$.*

Proof. Let $G = (X, Y, E)$ be a d-regular bipartite multigraph such that $|X| = |Y| = n$. Build the instance I associated with G, as above, with $2n$ d-items and dn 1-items. Lemma 6.1 shows that the load is at most dn everywhere.

Assume an optimal solution, and denote by Z the region defined by the isothetic bounding box of the d-items. Z is the rectangle $[0, 3n] \times [\min, \max]$, where min is the minimum y-coordinate of the bottoms of the $2n$ d-items and max is the maximum y-coordinate of the tops of the $2n$ d-items. Define Z' to be the set of 1-items placed outside Z. Because $\max - \min \ge dn$ and the load is at most dn everywhere, it follows that the load of Z' lower bounds $OPT - LOAD$ and that the area of the jobs in Z' lower bounds the empty space inside Z.

Now, for any positive real $s < n$, assume that fewer than $s/12$ 1-items are placed outside Z and also that $\max - \min < dn + s/12$. The area of Z is thus $(\max - \min)(3n) < (dn + s/12)(3n)$. The total area of all the jobs is $(dn)(3n)$. There-

fore, if all the jobs were placed in Z, the empty space in Z would be at most $(s/12)(3n)$. For each job placed outside Z, the empty space inside Z grows by at most $3n$. The total empty space inside Z is thus less than $2(s/12)(3n) = sn/2$.

Consider a d-item to be comprised of d unit-height *rows*, which are placed contiguously in the plane. Define the *left* (resp., *right*) *d-items* to be those whose left (resp., right) endpoints are 0 (resp., $3n$). Call region $(3n-1, 3n) \times (k, k+1)$ for any integer $k \in [\min, \max - 1]$ a *right gap* if it is unoccupied by every right d-item. Clearly $OPT - LOAD$ is at least the number of right gaps, so we may assume this number is less than $n/2$. It follows that at least $n/2$ left d-items are adjacent to no right gaps; i.e., for each such left d-item x, there is a row of some right d-item to the right of each one of x's d rows. Call these the *good left d-items.*

For any left d-item J, define its *neighbor right d-items* to be the (at most two) right d-items whose y-coordinates overlap with J, and call the actual rows of those neighbors that occupy the same y-coordinates as J its *neighbor right rows.* Because there are at least $n/2$ good left d-items and the total empty space inside Z is less than $sn/2$, there must be at least one good left d-item J with less than s empty space between it and its neighbor right rows. Because $s < n$, there is some 1-item x placed between each row of J and the corresponding neighbor right row; furthermore, the left endpoint of x is within $s-1$ of the right endpoint of J, and the right endpoint of x is within $s-1$ of the left endpoint of the corresponding neighbor right row. For one of the at most two neighbor right d-items K of J, there are at least $\lceil d/2 \rceil$ neighbor right rows of J belonging to K. In G, therefore, there are subsets of $\lfloor s \rfloor$ consecutive vertices of X (starting at vertex $j \in X$, where j is the right endpoint of J) and $\lfloor s \rfloor$ consecutive vertices of Y (starting at vertex $k - \lfloor s \rfloor + 1 \in Y$, where k is the left endpoint of K) with at least $\lceil d/2 \rceil$ edges between them, corresponding to these 1-items.

If $s < \frac{n^{1/2-1/\lceil d/2 \rceil}}{\sqrt{d}}$, Lemma 6.2 (with $f = \lceil d/2 \rceil$) shows that there is some G' without such a window of edges. By contradiction, therefore, for any such G' there must be at least $s/12$ 1-items placed outside Z, or else $\max - \min \geq s/12$; in either case, $OPT - LOAD \geq s/12$. The theorem follows by choosing $s = \frac{n^{1/2-1/\lceil d/2 \rceil}}{\sqrt{d}}$ and noting that in fact $OPT - LOAD \geq \lceil s/12 \rceil$. □

COROLLARY 6.4. *For any $\epsilon > 0$, there exist $c, d > 0$ such that for all sufficiently large integers L, there is an instance of* dynamic storage allocation *with maximum job height d, $L(t) \leq L$ for all t, and $OPT - LOAD \geq cL^{1/2-\epsilon}$.*

Proof. Fix $d = \lceil 2/\epsilon \rceil$, and choose a large $L \in \mathbb{Z}$. Define $n, r \in \mathbb{Z}$ such that $n > 0$, $0 \leq r < d$, and $L = nd + r$. Define $L' = nd$. By Theorem 6.3, there is a dynamic storage allocation instance I with maximum job height d, $L_I(t) \leq L' = dn$ for all t, and $\Delta = OPT - LOAD \geq \frac{n^{1/2-1/\lceil d/2 \rceil}}{12\sqrt{d}}$. Because $n = \frac{L-r}{d} \leq \frac{L}{d}$, it follows that $L_I(t) \leq L$ for all t; and because $n \geq \frac{L}{2d}$, it follows that

$$\Delta \geq \frac{n^{1/2-1/\lceil d/2 \rceil}}{12\sqrt{d}} \geq \frac{\left(\frac{L}{2d}\right)^{1/2-1/\lceil d/2 \rceil}}{12\sqrt{d}} = \frac{1}{12\sqrt{d}} \left(\frac{1}{2d}\right)^{1/2-1/\lceil d/2 \rceil} L^{1/2-1/\lceil d/2 \rceil}.$$

The claim follows by setting

$$c = \frac{1}{12\sqrt{d}} \left(\frac{1}{2d}\right)^{1/2-1/\lceil d/2 \rceil}$$

and noting that $1/\lceil d/2 \rceil \leq \epsilon$. □

COROLLARY 6.5. *For any $\epsilon > 0$, there exists a $c' > 0$ such that for all sufficiently large integers $h_{\max}$, there is a* dynamic storage allocation *instance with maximum job*

height $h_{\max}$, maximum load at most L, and $OPT - LOAD \geq c'(h_{\max}/L)^{1/2+\epsilon}L$, for infinitely many integers L.

Proof. Given $\epsilon > 0$, define $h = h(\epsilon)$ and $c > 0$ so that for all sufficiently large L_0, Corollary 6.4 yields a dynamic storage allocation instance with maximum job height h, maximum load at most L_0, and optimum makespan $OPT_0 \geq L_0 + cL_0^{1/2-\epsilon}$. Set $c' = c/h^{1/2+\epsilon}$. For all integers L and $h_{\max}$ such that L and $L/h_{\max}$ are sufficiently large and $h_{\max}/h$ and $L/(h_{\max}/h)$ are integral, set $L_0 = L/(h_{\max}/h)$. Now scale up the instance by $h_{\max}/h$. The new optimum makespan is $OPT = (h_{\max}/h)OPT_0$. The new load is at most $L_0 h_{\max}/h = L$, and

$$\begin{aligned} OPT &= (h_{\max}/h)OPT_0 \\ &\geq (h_{\max}/h)(L_0 + cL_0^{1/2-\epsilon}) \\ &= L + (h_{\max}/h)cL_0^{1/2-\epsilon} \\ &= L(1 + (h_{\max}/(hL))cL_0^{1/2-\epsilon}) \\ &= L(1 + (h_{\max}/(hL))c(hL/h_{\max})^{1/2-\epsilon}) \\ &= L(1 + (c/h^{1/2+\epsilon})(h_{\max}/L)^{1/2+\epsilon}) \\ &= L(1 + c'(h_{\max}/L)^{1/2+\epsilon}). \qquad \square \end{aligned}$$

Acknowledgments. We thank the anonymous referees for several helpful comments.

DISTANCES AND FINGER SEARCH IN RANDOM BINARY SEARCH TREES*

LUC DEVROYE† AND RALPH NEININGER‡

Abstract. For the random binary search tree with n nodes inserted the number of ancestors of the elements with ranks k and ℓ, $1 \le k < \ell \le n$, as well as the path distance between these elements in the tree are considered. For both quantities, central limit theorems for appropriately rescaled versions are derived. For the path distance, the condition $\ell - k \to \infty$ as $n \to \infty$ is required. We obtain tail bounds and the order of higher moments for the path distance. The path distance measures the complexity of finger search in the tree.

Key words. random binary search tree, finger search, path distance, limit law, analysis of algorithms

1. Introduction and results. In this paper we analyze the asymptotic behavior of the path distance between nodes in random binary search trees. The path distance between two nodes is the number of nodes on the shortest path connecting them in the tree. This quantity is motivated by the cost of a finger search in the tree. The finger search operation in a search tree takes as input a pointer to a node u, the current node, and either the key value of another node v or an incremental rank value Δ. The objective is to find v quickly. In the latter case, the rank of v differs from the rank of u by Δ. Finger search trees are search trees in which the finger operation takes time $O(1 + \ln \Delta)$. Various strategies are known for this. For example, Brown and Tarjan [2] recommend (2, 4) or red-black trees with level linking. Huddleston and Mehlhorn [6] show how to update these trees efficiently in an amortized sense. On pointer-based machines, Brodal [1] shows how to implement insertion in constant worst-case time in an adaptation of these trees.

In a random binary search tree or a treap, suitably augmented but without level linking, we note that both kinds of finger search operations take time proportional to the path distance between the nodes. The augmentation consists of maintaining with each node either the minimum and maximum keys in the subtree, or the size of the subtree. These parameters are easy to update. Furthermore, when searching for v, starting from u, one first proceeds by following parent pointers towards the root until the least common ancestor of u and v is found. At that point, one can find v by the standard search operation.

If the nodes are level-linked, then it is also possible to identify an ancestor of v that is either the least common ancestor of u and v, or a descendant of that least common ancestor, simply by checking the key values of the appropriate level neighbors of the ancestors of u when traveling towards the root. In this implementation, the

complexity of the finger search operation is the path distance between u and v or less. Other possible augmentations for treaps are presented by Seidel and Aragon [14].

We give an approach of the distributional analysis of the path distance between nodes in a random binary search tree whose keys have ranks that differ by Δ. The connection used between records and random permutations for the study of random binary search trees was developed in Devroye [4] and, when it applies, leads to short and intuitive proofs. While the expectation of the path distance of two nodes that hold keys with ranks differing by Δ is always $O(\ln \Delta)$ as $\Delta \to \infty$, for a refined distributional analysis the location of the ranks matters, since in particular the leading constant in the expansion of the expectation of the path distance depends upon the location of the ranks. This affects the proper scaling of the quantities to obtain distributional convergence; see Theorem 1.3 below.

For simplicity we assume that the random binary search tree is built up from the keys $1, \dots, n$ identifying the key of rank j with the key j. See, e.g., Mahmoud [8] for the definition of random binary search trees. For $1 \le k \le \ell \le n$ we denote by $A_{k\ell}$ the number of ancestors of the nodes holding the keys k and ℓ in the tree when n numbers are inserted. Note that A_{kk} is the depth of the node with rank k in the tree, $1 \le k \le n$. By $P_{k\ell}$ the path distance between the keys k and ℓ is denoted, that is, the number of nodes on the path (strictly) between k and ℓ, $1 \le k < \ell \le n$.

We denote by $\mathcal{N}(0,1)$ the standard normal distribution and by $\xrightarrow{\mathcal{L}}$ convergence in distribution. For sequences $(a_n), (b_n)$ asymptotical equivalence, $a_n/b_n \to 1$ as $n \to \infty$, is denoted by $a_n \sim b_n$. We have the following asymptotic behavior.

THEOREM 1.1. *For all $1 \le k < \ell \le n$, where k, ℓ may depend on n, we have, as $n \to \infty$,*

$$\begin{aligned} \mathbb{E}\, A_{k\ell} &= \ln(k(\ell-k)^2(n-\ell+1)) + O(1), \\ \frac{A_{k\ell} - \ln(k(\ell-k)^2(n-\ell+1))}{\sqrt{\ln(k(\ell-k)^2(n-\ell+1))}} &\xrightarrow{\mathcal{L}} \mathcal{N}(0,1). \end{aligned}$$

THEOREM 1.2. *For all $1 \le k \le n$, where k may depend on n, we have, as $n \to \infty$,*

$$\frac{A_{kk} - \ln(k(n-k+1))}{\sqrt{\ln(k(n-k+1))}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1).$$

THEOREM 1.3. *For all $1 \le k < \ell \le n$ with k, ℓ depending on n such that $\Delta := \ell - k + 1 \to \infty$ as $n \to \infty$ and $a_n := (k \wedge \Delta)\Delta^2((n-\ell+1) \wedge \Delta)$ we have, as $n \to \infty$,*

$$\frac{P_{k\ell} - \ln a_n}{\sqrt{\ln a_n}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1).$$

THEOREM 1.4. *Let P_n denote the path distance between a pair of nodes chosen uniformly at random from all possible pairs of different nodes in the tree. Then we have, as $n \to \infty$,*

$$\frac{P_n - 4\ln n}{\sqrt{4\ln n}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1).$$

THEOREM 1.5. *There exists a constant $C > 0$ such that for all $\varepsilon > 0$ and all $1 \le k < \ell \le n$ with $\Delta := \ell - k + 1 \ge \Delta_0$ we have with $a_n := (k \wedge \Delta)\Delta^2((n-\ell+1) \wedge \Delta)$:*

$$\mathbb{P}(P_{k\ell} > (1+\varepsilon)\ln a_n) \le C\Delta^{-\varepsilon^2/(2+3\varepsilon)}.$$

Here, for all $\delta > 0$, we can choose $\Delta_0 \ge 1$ uniformly for all $\varepsilon \in [\delta, \infty)$.

Moreover, if $\Delta \to \infty$ *as* $n \to \infty$, *we have, for all* $p \geq 1$,

$$\mathbb{E}\, P_{k\ell}^p \sim \ln^p a_n.$$

Note that exact expressions for $\mathbb{E}\, A_{kk}$ and $\mathbb{E}\, P_{k\ell}$ in terms of harmonic numbers are given in Seidel and Aragon [14] and, for $\mathbb{E}\, A_{k\ell}$, in Prodinger [13]. The limit law in Theorem 1.4, together with additional results for the model of uniformly chosen pairs of nodes, has been derived in Mahmoud and Neininger [9] and Panholzer and Prodinger [12], and an exact expression for $\mathbb{E}\, P_n$ has first been given in Flajolet, Ottmann, and Wood [5]. Finally, we note that the limit law for the depth of a typical node inserted in a random binary search tree was obtained by Mahmoud and Pittel [10], Louchard [7], and Devroye [4]. It can be obtained from Theorem 1.2 by replacing k with a uniform$\{1, \dots, n\}$ random variable.

2. Representation via records. In a permutation $(x_1, \dots, x_n)$ of distinct numbers we define the local ranks $R_1, \dots, R_n$, where R_j denotes the rank of x_j in $\{x_1, \dots, x_j\}$. If $R_j = j$ or $R_j = 1$, we say that x_j is an up-record or down-record in $x_1, \dots, x_n$, respectively. It is well known that if the permutation is a random permutation, i.e., all $n!$ permutations are equally likely, R_j is uniformly distributed on $\{1, \dots, j\}$ for all $j = 1, \dots, n$ and that $R_1, \dots, R_n$ are independent.

We give a representation of the number $A_{k\ell}$ of ancestors of keys k and ℓ in terms of local ranks and records, so that based on the independence properties we can apply the classical central limit theorem in the version of Lindeberg–Feller.

Let us build up the random binary search tree from the numbers $1, \dots, n$ as follows: We draw independent unif$[0,1]$ random variables $T_1, \dots, T_n$, where unif$[0,1]$ denotes the uniform distribution on the interval $[0,1]$. These we use as time stamps as T_j is associated with j and denotes the time at which number j is inserted into the tree. Inserting now the numbers in order according to their time stamps, starting with the earliest, yields a random binary search tree for the keys $1, \dots, n$.

A basic property of the binary search tree is that j is an ancestor of k in the tree if and only if it is inserted before k and also before all numbers s between j and k. Now we fix $1 \leq k < \ell \leq n$ and count the ancestors $A_{k\ell}$ of the elements k and ℓ in the tree. If, for $i < k$, element i is ancestor of ℓ, then it is ancestor of k as well and hence it contributes to $A_{k\ell}$ if and only if

$$T_i = \min\{T_i, T_{i+1}, \dots, T_k\}, \quad i < k.$$

Analogously, for $i > \ell$, we get a contribution of number i to $A_{k\ell}$ if and only if $T_i = \min\{T_\ell, T_{\ell+1}, \dots, T_i\}$, and in the case $k < i < \ell$ if $T_i = \min\{T_k, T_{k+1}, \dots, T_i\}$ or $T_i = \min\{T_i, T_{i+1}, \dots, T_\ell\}$. Passing to indicator functions we rewrite these events as

$$\begin{aligned}
\mathbf{1}_{\{T_i = \min\{T_i, T_{i+1}, \dots, T_k\}\}} &= \mathbf{1}_{\{T_i = \min\{T_i, \dots, T_{k-1}\}\}} - \mathbf{1}_{\{T_k < T_i,\, T_i = \min\{T_i, \dots, T_{k-1}\}\}} \\
&=: \mathbf{1}_{B_i} - \mathbf{1}_{C_i}, \quad i < k, \\
\mathbf{1}_{\{T_i = \min\{T_\ell, \dots, T_i\}\}} &= \mathbf{1}_{\{T_i = \min\{T_{\ell+1}, \dots, T_i\}\}} - \mathbf{1}_{\{T_\ell < T_i,\, T_i = \min\{T_{\ell+1}, \dots, T_i\}\}} \\
&=: \mathbf{1}_{B_i} - \mathbf{1}_{C_i}, \quad i > \ell,
\end{aligned}$$

and

$$\mathbf{1}_{B_i} := \mathbf{1}_{\{T_i = \min\{T_k, T_{k+1}, \dots, T_i\}\} \cup \{T_i = \min\{T_i, T_{i+1}, \dots, T_\ell\}\}}, \quad k \leq i \leq \ell.$$

Note that above $\mathbf{1}_{B_i}, \mathbf{1}_{C_i}$ are differently defined for the three ranges of the index i.

All together we obtain the representation

$$A_{k\ell} = \sum_{i=1}^{n} \mathbf{1}_{B_i} - \sum_{i=1}^{k-1} \mathbf{1}_{C_i} - \sum_{i=\ell+1}^{n} \mathbf{1}_{C_i} - 2, \tag{2.1}$$

where we subtract 2 referring to the convention that k and ℓ are not counted as ancestors of themselves. The main contribution comes from the sum over the $\mathbf{1}_{B_i}$, as the sums over the $\mathbf{1}_{C_i}$ will be asymptotically negligible.

To get the connection with records we introduce three auxiliary random binary search trees as follows. The binary search tree $\mathcal{T}_<$ is built up from the elements $1, \dots, k-1$, inserted according to their time stamps $T_1, \dots, T_{k-1}$. Analogously $\mathcal{T}_>$ is built up from the elements $\ell+1, \dots, n$, inserted according to their time stamps $T_\ell, \dots, T_n$ and $\mathcal{T}$ is built up from the elements $k, \dots, \ell$, inserted according to their time stamps $T_k, \dots, T_\ell$. Now, for $i < k$, the event B_i is equivalent for i to be an ancestor of $k-1$ in $\mathcal{T}_<$. Since $k-1$ is the largest element in $\mathcal{T}_<$, this implies that i is an up-record at the time of insertion into $\mathcal{T}_<$. Analogously, for $i > \ell$, the event B_i is equivalent for i to constitute a down-record at time of its insertion into $\mathcal{T}_>$. For $k \le i \le \ell$, event B_i is equivalent to i being up- or down-record at its time of insertion into $\mathcal{T}$.

We denote by R_j the local rank of the (in time) jth element inserted into $\mathcal{T}_<$ at the time of its insertion, $1 \le j < k$, and by R'_j, R''_j analogously the local ranks of the jth elements inserted into $\mathcal{T}$, $\mathcal{T}_>$ for $1 \le j \le \ell-k+1$ and $1 \le j \le n-\ell$, respectively. Note that $R_1, \dots, R_{k-1}, R'_1, \dots, R'_{\ell-k+1}, R''_1, \dots, R''_{n-\ell}$ are independent and R_j, R'_j, R''_j are uniform$\{1, \dots, j\}$ distributed for $j = 1, \dots, k-1$ and $j = 1, \dots, \ell-k+1$ and $j = 1, \dots, n-\ell$, respectively. We have

$$\sum_{i=1}^{n} \mathbf{1}_{B_i} = \sum_{j=1}^{k-1} \mathbf{1}_{\{R_j = j\}} + \sum_{j=1}^{\ell-k+1} \mathbf{1}_{\{R'_j \in \{1,j\}\}} + \sum_{j=1}^{n-\ell} \mathbf{1}_{\{R''_j = 1\}}. \tag{2.2}$$

For the representation of $P_{k\ell}$ we denote

$$T_A := \min\{T_k, \dots, T_\ell\}.$$

For $1 \le i \le n$, element i belongs to the path between k and ℓ if and only if it is ancestor of k or ℓ and $T_i \ge T_A$. Hence with $D_i := \{T_i \ge T_A\}$ we have

$$P_{k\ell} = \sum_{i=1}^{n} \mathbf{1}_{B_i \cap D_i} - \sum_{i=1}^{k-1} \mathbf{1}_{C_i \cap D_i} - \sum_{i=\ell+1}^{n} \mathbf{1}_{C_i \cap D_i} - 2. \tag{2.3}$$

The main contribution will come from the sum over the $\mathbf{1}_{B_i \cap D_i}$. For the corresponding representation with records we introduce

$$N_1 := |\{1 \le j < k : T_j < T_A\}|, \quad N_2 := |\{\ell < j \le n : T_j < T_A\}|$$

and obtain

$$\begin{aligned} \sum_{i=1}^{n} \mathbf{1}_{B_i \cap D_i} &= \sum_{j=N_1+1}^{k-1} \mathbf{1}_{\{R_j = j\}} + \sum_{j=1}^{\ell-k+1} \mathbf{1}_{\{R'_j \in \{1,j\}\}} + \sum_{j=N_2+1}^{n-\ell} \mathbf{1}_{\{R''_j = 1\}} \\ &=: \mathcal{P}_I + \mathcal{P}_{II} + \mathcal{P}_{III}. \end{aligned} \tag{2.4}$$

3. Proofs. Throughout this section we denote by $H_n := \sum_{i=1}^{n} 1/i = \ln n + O(1)$ the nth harmonic number for $n \geq 1$ and $H_0 := 0$.

Proof of Theorem 1.1. We derive $\mathbb{E}\, A_{k\ell}$ using the representations (2.1) and (2.2). From the distribution of the local ranks R_j, R'_j, and R''_j we obtain

$$\mathbb{E} \sum_{i=1}^{n} \mathbf{1}_{B_i} = H_{k-1} + 2H_{\ell-k+1} - 1 + H_{n-\ell} = \ln(k(\ell-k)^2(n-\ell+1)) + O(1).$$

The remaining summands in (2.1) we denote by $\Upsilon := \sum_{i=1}^{k-1} \mathbf{1}_{C_i} + \sum_{i=\ell+1}^{n} \mathbf{1}_{C_i} + 2$. For $1 \leq i < k$ we have

$$\begin{aligned}
\mathbb{E}\, \mathbf{1}_{C_i} &= \mathbb{P}\Big(T_k < T_i,\ T_i = \min\{T_i, \ldots, T_{k-1}\}\Big) \\
&\leq \mathbb{P}\Big(T_k, T_i \text{ are the smallest elements among } T_i, \ldots, T_k\Big) \\
&= \binom{k-i+1}{2}^{-1} \leq \frac{2}{(k-i)^2}.
\end{aligned}$$

This implies $\mathbb{E} \sum_{i=1}^{k-1} \mathbf{1}_{C_i} = O(1)$. Analogously we conclude to find $\mathbb{E}\, \Upsilon = O(1)$, hence we obtain $\mathbb{E}\, A_{k\ell} = \ln(k(\ell-k)^2(n-\ell+1)) + O(1)$.

For the central limit law we write

$$\begin{aligned}
\frac{A_{k\ell} - \ln(k(\ell-k)^2(n-\ell+1))}{\sqrt{\ln(k(\ell-k)^2(n-\ell+1))}} &= \frac{\sum_{i=1}^{n} \mathbf{1}_{B_i} - \ln(k(\ell-k)^2(n-\ell+1))}{\sqrt{\ln(k(\ell-k)^2(n-\ell+1))}} \\
&\quad - \frac{\Upsilon}{\sqrt{\ln(k(\ell-k)^2(n-\ell+1))}}.
\end{aligned}$$

For all choices of $1 \leq k < \ell \leq n$ we have $\ln(k(\ell-k)^2(n-\ell+1)) \to \infty$ as $n \to \infty$, and from (2.2) it follows that the Lindeberg–Feller condition (see Chow and Teicher [3, p. 291]) is satisfied for $\sum_{i=1}^{n} \mathbf{1}_{B_i}$; thus the first fraction on the right-hand side of the latter display tends in distribution to the standard normal distribution. Again since $\ln(k(\ell-k)^2(n-\ell+1)) \to \infty$ and $\mathbb{E}\,|\Upsilon| = O(1)$ we obtain from Markov's inequality that $\Upsilon / \ln(k(\ell-k)^2(n-\ell+1)) \to 0$ in probability as $n \to \infty$. The assertion follows. □

Proof of Theorem 1.2. Note that for A_{kk} we have the same representation as for $A_{k\ell}$ given, for the case $k < \ell$, in (2.1), where we have to replace the -2 there by -1 due to the fact that we now have $\mathbf{1}_{B_k} = 1$. Hence the same arguments as in the proof of Theorem 1.1 apply. □

Proof of Theorem 1.3. We have $P_{k\ell} = \mathcal{P}_I + \mathcal{P}_{II} + \mathcal{P}_{III} - \Upsilon'$, with $\Upsilon' := \sum_{i=1}^{k-1} \mathbf{1}_{C_i \cap D_i} + \sum_{i=\ell+1}^{n} \mathbf{1}_{C_i \cap D_i} + 2$ and $a_n := (k \wedge \Delta)\Delta^2((n-\ell+1) \wedge \Delta) \to \infty$ as $n \to \infty$. From $\mathbb{E}\,|\Upsilon'| = O(1)$ we obtain from Markov's inequality $\Upsilon' / \sqrt{\ln a_n} \to 0$ in probability. Thus it is sufficient to show

$$\frac{\mathcal{P}_I + \mathcal{P}_{II} + \mathcal{P}_{III} - \ln a_n}{\sqrt{\ln a_n}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1). \tag{3.1}$$

Since we want to apply the central limit theorem to the sum of indicators in (2.4) we will condition on the random indices N_1 and N_2. Note that we may assume $k \to \infty$ and $n - \ell + 1 \to \infty$ as $n \to \infty$ since otherwise $\mathcal{P}_I$ and $\mathcal{P}_{III}$ remain bounded and do not contribute respectively.

First we consider the case $k/\Delta > \ln k$ and $(n-\ell+1)/\Delta > \ln(n-\ell+1)$ for all sufficiently large n. We define, for $\varepsilon > 0$,

$$B_\varepsilon := \{N_1 \in [\alpha_1, \beta_1]\} \cap \{N_2 \in [\alpha_2, \beta_2]\},$$

with

$$\alpha_1 = \frac{\varepsilon}{2}\frac{k}{\Delta}, \quad \beta_1 = \frac{2}{\varepsilon}\frac{k}{\Delta}, \qquad \alpha_2 = \frac{\varepsilon}{2}\frac{n-\ell+1}{\Delta}, \quad \beta_2 = \frac{2}{\varepsilon}\frac{n-\ell+1}{\Delta}.$$

Note that the values of N_1 and N_2 depend on $T_k, \dots, T_\ell$. However, conditioned on N_1 and N_2 the permutations induced by $T_1, \dots, T_{k-1}$, by $T_k, \dots, T_\ell$, and by $T_{\ell+1}, \dots, T_n$ are independent and uniformly distributed. In particular, conditioning on N_1, N_2 preserves the independence and the distributions of $R_1, \dots, R_{k-1}, R'_1, \dots, R'_\Delta, R''_1, \dots, R_{n-\ell}$.

On B_ε we have the bounds $P^-_{k\ell} \le P_{k\ell} \le P^+_{k\ell}$ with

$$P^-_{k\ell} = \sum_{j=\lceil\beta_1\rceil+1}^{k-1} \mathbf{1}_{\{R_j=j\}} + \sum_{j=1}^{\Delta} \mathbf{1}_{\{R'_j\in\{1,j\}\}} + \sum_{j=\lceil\beta_2\rceil+1}^{n-\ell} \mathbf{1}_{\{R''_j=1\}},$$
$$P^+_{k\ell} = \sum_{j=\lfloor\alpha_1\rfloor}^{k-1} \mathbf{1}_{\{R_j=j\}} + \sum_{j=1}^{\Delta} \mathbf{1}_{\{R'_j\in\{1,j\}\}} + \sum_{j=\lfloor\alpha_2\rfloor}^{n-\ell} \mathbf{1}_{\{R''_j=1\}}.$$

Now, we have

$$\begin{aligned}\mathbb{E}\, P^-_{k\ell} &= \ln k - \ln\lceil\beta_1\rceil + 2\ln\Delta \\ &\quad + \ln(n-\ell+1) - \ln\lceil\beta_2\rceil + O(1) \\ &= \ln a_n + O\Big(1 + \ln\frac{1}{\varepsilon}\Big),\end{aligned} \tag{3.2}$$

where, for the last equality, we distinguish the cases $k/\Delta \le 2/\varepsilon$, $k/\Delta > 2/\varepsilon$ as well as $(n-\ell+1)/\Delta \le 2/\varepsilon$ and $(n-\ell+1)/\Delta > 2/\varepsilon$. Analogously we obtain $\operatorname{Var}(P^-_{k\ell}) = \mathbb{E}\, P^-_{k\ell} + O(1+\ln(1/\varepsilon))$. Since $\varepsilon > 0$ is fixed and $a_n \to \infty$ as $n \to \infty$ we obtain from the central limit theorem in the version of Lindeberg–Feller that

$$\frac{P^-_{k\ell} - \ln a_n}{\sqrt{\ln a_n}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1), \quad n \to \infty. \tag{3.3}$$

Similarly, we obtain $(P^+_{k\ell} - \ln a_n)/\sqrt{\ln a_n} \to \mathcal{N}(0,1)$ in distribution as $n \to \infty$. We have, for $x \in \mathbb{R}$,

$$\begin{aligned}\mathbb{P}\Big(\frac{P_{k\ell} - \ln a_n}{\sqrt{\ln a_n}} \le x\Big) &\le \mathbb{P}(B^c_\varepsilon) + \mathbb{P}\Big(\frac{P_{k\ell} - \ln a_n}{\sqrt{\ln a_n}} \le x \Big| B_\varepsilon\Big) \\ &\le \mathbb{P}(B^c_\varepsilon) + \mathbb{P}\Big(\frac{P^-_{k\ell} - \ln a_n}{\sqrt{\ln a_n}} \le x\Big).\end{aligned}$$

Hence denoting by Φ the distribution function of the standard normal distribution and $\psi(\varepsilon) := \limsup_{n\to\infty} \mathbb{P}(B^c_\varepsilon)$ we obtain

$$\limsup_{n\to\infty} \mathbb{P}\Big(\frac{P_{k\ell} - \ln a_n}{\sqrt{\ln a_n}} \le x\Big) \le \Phi(x) + \psi(\varepsilon),$$

and analogously

$$\begin{aligned}\liminf_{n\to\infty} \mathbb{P}\Big(\frac{P_{k\ell} - \ln a_n}{\sqrt{\ln a_n}} \le x\Big) &\ge \liminf_{n\to\infty} \mathbb{P}(B_\varepsilon)\mathbb{P}\Big(\frac{P^+_{k\ell} - \ln a_n}{\sqrt{\ln a_n}} \le x\Big) \\ &= (1-\psi(\varepsilon))\Phi(x).\end{aligned}$$

Hence the central limit law is established once we have shown that $\psi(\varepsilon) \to 0$ as $\varepsilon \downarrow 0$. For this it is sufficient to show that $[\limsup_{n\to\infty} \mathbb{P}(N_i \notin [\alpha_i, \beta_i])] \to 0$ as $\varepsilon \downarrow 0$ for $i = 1, 2$. By symmetry we only need to show the case $i = 1$.

We denote by $B_{n,u}$ a binomial $B(n, u)$ distributed random variable, $n \geq 0$, $u \in [0, 1]$. Since N_1 has the mixed $B(k-1, T_A)$ distribution with $T_A = \min\{T_k, \ldots, T_\ell\}$ we obtain with Chebyshev's inequality, for $k \geq 4$ and Δ sufficiently large such that $\varepsilon/\Delta \leq 1$,

$$\begin{aligned}
\mathbb{P}\Big(N_1 < \frac{\varepsilon k}{2\Delta}\Big) &\leq \mathbb{P}\Big(T_A < \frac{\varepsilon}{\Delta}\Big) + \mathbb{P}\Big(B_{k-1,\varepsilon/\Delta} \leq \frac{\varepsilon k}{2\Delta}\Big) \\
&\leq 2\varepsilon + \mathbb{P}\Big(\Big|B_{k-1,\varepsilon/\Delta} - \frac{\varepsilon(k-1)}{\Delta}\Big| \geq \frac{\varepsilon k}{4\Delta}\Big) \\
&\leq 2\varepsilon + \frac{16}{\varepsilon(k/\Delta)} \\
&\leq 2\varepsilon + \frac{16}{\varepsilon \ln k} \\
&\to 2\varepsilon
\end{aligned}$$

as $n \to \infty$. Similarly we obtain for sufficiently large Δ,

$$\begin{aligned}
\mathbb{P}\Big(N_1 > \frac{2k}{\varepsilon\Delta}\Big) &\leq \mathbb{P}\Big(T_A > \frac{1}{\varepsilon\Delta}\Big) + \mathbb{P}\Big(B_{k-1,1/(\varepsilon\Delta)} \geq \frac{2k}{\varepsilon\Delta}\Big) \\
&\leq 2e^{-1/\varepsilon} + \frac{\varepsilon}{\ln k} \\
&\to 2e^{-1/\varepsilon}
\end{aligned}$$

as $n \to \infty$. Hence we obtain $[\limsup_{n\to\infty} \mathbb{P}(N_1 \notin [\alpha_1, \beta_1])] \leq 2(\varepsilon + e^{-1/\varepsilon}) \to 0$ as $\varepsilon \downarrow 0$.

In the second case we assume that $k/\Delta \leq \ln k$ and $(n - \ell + 1)/\Delta > \ln(n - \ell + 1)$ for all n sufficiently large. Now we replace α_i, β_i with

$$\alpha_1' = 0, \quad \beta_1' = \ln^2 k, \qquad \alpha_2' = \alpha_2, \quad \beta_2' = \beta_2$$

and define $B_\varepsilon, P_{k\ell}^-, P_{k\ell}^+$ as in the first case but with the α_i, β_i replaced by α_i', β_i', $i = 1, 2$. The argument is now applied as in the first case. The only difference to be shown is that we have $\limsup_{n\to\infty} \mathbb{P}(N_1 \notin [\alpha_1', \beta_1']) = 0$: We have

$$\mathbb{P}(N_1 \notin [\alpha_1', \beta_1']) = \mathbb{P}(N_1 > \ln^2 k) \leq \frac{\mathbb{E}\, N_1}{\ln^2 k} = \frac{(k-1)/\Delta}{\ln^2 k} \leq \frac{1}{\ln k} \to 0$$

as $n \to \infty$.

The case $k/\Delta > \ln k$ and $(n - \ell + 1)/\Delta \leq \ln(n - \ell + 1)$ is covered by the previous case by symmetry. In the remaining case $k/\Delta \leq \ln k$ and $(n - \ell + 1)/\Delta \leq \ln(n - \ell + 1)$ we replace α_i, β_i with

$$\alpha_1'' = \alpha_1', \quad \beta_1'' = \beta_1', \qquad \alpha_2'' = 0, \quad \beta_2'' = \ln(n - \ell + 1)^2,$$

and define $B_\varepsilon, P_{k\ell}^-, P_{k\ell}^+$ as in the first case but with the α_i, β_i replaced by α_i'', β_i'', $i = 1, 2$. The argument is again applied as in the first case and $\limsup_{n\to\infty} \mathbb{P}(N_i \notin [\alpha_i'', \beta_i'']) = 0$ follows for $i = 1, 2$ as in the second case.

This finishes the proof of the limit law since for a given sequence $(k,\ell)=(k(n),\ell(n))$ with $\ell(n)-k(n)\to\infty$ we decompose into four subsequences according to whether $k/\Delta\le\ln k$ or $k/\Delta>\ln k$ and $(n-\ell+1)/\Delta\le\ln(n-\ell+1)$ or $(n-\ell+1)/\Delta>\ln(n-\ell+1)$. Each of the subsequences satisfies, by the previous arguments, the limit law (3.1), hence the whole sequence satisfies the limit law. □

Proof of Theorem 1.4. We denote by (K,L) the ranks of the pair of nodes chosen uniformly at random from all possible pairs of distinct nodes in the tree, where we may assume that $K<L$. We define the set

$$B:=\Big\{K<\frac{n}{\ln n}\Big\}\cup\Big\{n-L<\frac{n}{\ln n}\Big\}\cup\Big\{L-K<\frac{n}{\ln n}\Big\}$$

and note that $\mathbb{P}(B)\to 0$ as $n\to\infty$. On B^c we will condition on $(K,L)=(k,\ell)$. For these (k,ℓ) we have $\ln(k(\ell-k+1)^2(n-\ell+1))=4\ln n+O(\ln\ln n)$. Hence application of Theorem 1.3 yields $(P_{k\ell}-4\ln n)/\sqrt{4\ln n}\to\mathcal{N}(0,1)$ in distribution. Denoting by Φ the distribution function of $\mathcal{N}(0,1)$ and by σ the distribution of (K,L) we obtain, for all $x\in\mathbb{R}$,

$$\begin{aligned}&\left|\mathbb{P}\left(\frac{P_n-4\ln n}{\sqrt{4\ln n}}\le x\right)-\Phi(x)\right|\\&\le\mathbb{P}(B)+\int\left|\mathbb{P}\left(\frac{P_{k\ell}-4\ln n}{\sqrt{4\ln n}}\le x\right)-\Phi(x)\right|d\sigma(k,\ell)\\&\to 0\end{aligned}$$

by dominated convergence. The assertion follows. □

To prepare for the proof of Theorem 1.5 we provide the following tail estimate:

LEMMA 3.1. *Let Y_j, $1\le j\le n$ be independent and Y_j be Bernoulli $B(p_j)$ distributed for $0\le p_j\le 1$, and $\mu=\sum_{j=1}^n p_j$. Then we have, for all $\varepsilon>0$,*

$$\mathbb{P}\left(\sum_{j=1}^n Y_j\ge\mu+\varepsilon\right)\le\exp\Big(-\frac{\varepsilon^2}{2\mu+\varepsilon}\Big).$$

Proof. The proof relies on Chernoff's bounding technique. The details follow the proof of Theorem L1 in Devroye [4]. □

COROLLARY 3.2. *Let X_j,X_j' be Bernoulli $B(1/j)$ distributed, $j\ge 1$, $Z_1=1$ and Z_j be $B(2/j)$ distributed, $j\ge 2$, such that all random variables are independent. Then for all $1\le q\le s$, $\Delta\ge 1$, $1\le r\le t$ we have with $\alpha:=s\Delta^2t/(qr)$,*

$$\mathbb{P}\left(\sum_{j=q}^s X_j+\sum_{j=1}^{\Delta}Z_j+\sum_{j=r}^t X_j'-\ln\alpha\ge\varepsilon\right)\le\exp\left(-\frac{(\varepsilon-7)^2}{\varepsilon+6+2\ln\alpha}\right).$$

Proof. We apply Lemma 3.1 and note that from $\ln(n+1)\le H_n\le 1+\ln n$ for $n\ge 1$, we obtain

$$\ln(\alpha)-7\le H_s-H_{q-1}+2H_\Delta-1+H_t-H_{r-1}\le\ln(\alpha)+3.$$

The assertion follows. □

Proof of Theorem 1.5. First we prove the tail bound, where we distinguish several cases for the ranges of k and $n-\ell+1$. We abbreviate a_n as in Theorem 1.5. Let ε be arbitrarily given.

For $k \geq \Delta^{1+\varepsilon}$, $n-\ell+1 \geq \Delta^{1+\varepsilon}$ we have with the representations (2.3) and (2.4) and X_j, X'_j, and Z_j as in Corollary 3.2

$$\begin{aligned}
&\mathbb{P}(P_{k\ell} > (1+\varepsilon)\ln a_n)\\
&\leq \mathbb{P}(\mathcal{P}_I + \mathcal{P}_{II} + \mathcal{P}_{III} > (1+\varepsilon)\ln a_n)\\
&\leq \mathbb{P}\left(\left\{N_1 < \frac{k-1}{\Delta^{1+\varepsilon}}\right\} \cup \left\{N_2 < \frac{n-\ell}{\Delta^{1+\varepsilon}}\right\}\right)\\
&\quad + \mathbb{P}\left(\sum_{j=\lfloor (k-1)/\Delta^{1+\varepsilon}\rfloor+1}^{k-1} X_j + \sum_{j=1}^{\Delta} Z_j + \sum_{j=\lfloor (n-\ell)/\Delta^{1+\varepsilon}\rfloor+1}^{n-\ell} X'_j > (1+\varepsilon)\ln a_n\right).
\end{aligned} \tag{3.4}$$

Using that N_1 is $B(k-1, T_A)$ distributed and $T_A = \min\{T_k, \ldots, T_\ell\}$, we obtain

$$\mathbb{P}\left(N_1 < \frac{k-1}{\Delta^{1+\varepsilon}}\right) \leq \mathbb{P}\left(T_A < \Delta^{-(1+\varepsilon/2)}\right) + \mathbb{P}\left(B_{k-1,1/\Delta^{1+\varepsilon/2}} < \frac{k-1}{\Delta^{1+\varepsilon}}\right). \tag{3.5}$$

The first summand in (3.5) is bounded by

$$\mathbb{P}\left(T_A < \Delta^{-(1+\varepsilon/2)}\right) = 1 - (1-\Delta^{-(1+\varepsilon/2)})^{\Delta} \leq \Delta^{-\varepsilon/2}.$$

For the second summand in (3.5) we use Okamoto's inequality [11], which states that $\mathbb{P}(B_{n,u} \leq ny) \leq \exp(-n(u-y)^2/(2u(1-u)))$ for all $y \leq u \leq 1/2$. For $y := \Delta^{-(1+\varepsilon)}$ and $u := \Delta^{-(1+\varepsilon/2)}$ we obtain, for Δ sufficiently large,

$$\begin{aligned}
\mathbb{P}\left(B_{k-1,1/\Delta^{1+\varepsilon/2}} < \frac{k-1}{\Delta^{1+\varepsilon}}\right) &\leq \exp\left(-(k-1)\frac{\left(\Delta^{-(1+\varepsilon/2)} - \Delta^{-(1+\varepsilon)}\right)^2}{2\Delta^{-(1+\varepsilon/2)}}\right)\\
&\leq \exp\left(-\frac{k-1}{8\Delta^{1+\varepsilon/2}}\right)\\
&\leq \exp\left(-\frac{k+1}{\Delta^{1+\varepsilon}}\frac{\Delta^{\varepsilon/2}}{24}\right)\\
&\leq \exp\left(-\frac{\Delta^{\varepsilon/2}}{24}\right)\\
&\leq 24\Delta^{-\varepsilon/2},
\end{aligned}$$

where we used that $(k+1)/\Delta^{1+\varepsilon} \geq 1$. Note that for this estimate Δ can be chosen uniformly large for all $\varepsilon \in [\delta, \infty)$, $\delta > 0$. By symmetry we obtain the same bound for $\mathbb{P}(N_2 < (n-\ell)/\Delta^{1+\varepsilon})$. The second summand in (3.4) we estimate with Corollary 3.2

for Δ sufficiently large:

$$\begin{aligned}
&\mathbb{P}\left(\sum_{j=\lfloor (k-1)/\Delta^{1+\varepsilon}\rfloor+1}^{k-1} X_j + \sum_{j=1}^{\Delta} Z_j + \sum_{j=\lfloor (n-\ell)/\Delta^{1+\varepsilon}\rfloor+1}^{n-\ell} X'_j > (1+\varepsilon)\ln a_n\right)\\
&\le \mathbb{P}\left(\sum_{j=\lfloor (k-1)/\Delta^{1+\varepsilon}\rfloor+1}^{k-1} X_j + \sum_{j=1}^{\Delta} Z_j + \sum_{j=\lfloor (n-\ell)/\Delta^{1+\varepsilon}\rfloor+1}^{n-\ell} X'_j - \ln\Delta^{4+2\varepsilon} > 2\varepsilon\ln\Delta\right)\\
&\le \exp\left(-\frac{(2\varepsilon\ln\Delta-7)^2}{2\ln\Delta^{4+2\varepsilon}+6+2\varepsilon\ln\Delta}\right)\\
&\le \exp\left(\frac{28\varepsilon}{8+6\varepsilon} - \frac{4\varepsilon^2}{9+6\varepsilon}\ln\Delta\right)\\
&\le e^5\Delta^{-\varepsilon^2/(3+2\varepsilon)}. \qquad (3.6)
\end{aligned}$$

Collecting the estimates, we obtain $\mathbb{P}(P_{k\ell} \ge (1+\varepsilon)\ln a_n) \le 200\Delta^{-\varepsilon^2/(3+2\varepsilon)}$.

For the case $\Delta \le k \le \Delta^{1+\varepsilon}$ and $n-\ell+1 \ge \Delta^{1+\varepsilon}$ we estimate

$$\begin{aligned}
&\mathbb{P}(P_{k\ell} > (1+\varepsilon)\ln a_n)\\
&\le \mathbb{P}\left(N_2 < \frac{n-\ell}{\Delta^{1+\varepsilon}}\right)\\
&\quad + \mathbb{P}\left(\sum_{j=1}^{\lfloor\Delta^{1+\varepsilon}\rfloor} X_j + \sum_{j=1}^{\Delta} Z_j + \sum_{j=\lfloor (n-\ell)/\Delta^{1+\varepsilon}\rfloor+1}^{n-\ell} X'_j > (1+\varepsilon)\ln a_n\right),
\end{aligned}$$

and both summands can be estimated as in the previous case.

The same estimates apply to the cases $k \ge \Delta^{1+\varepsilon}$ and $\Delta \le n-\ell+1 \le \Delta^{1+\varepsilon}$ as well as $\Delta \le k \le \Delta^{1+\varepsilon}$ and $\Delta \le n-\ell+1 \le \Delta^{1+\varepsilon}$. The remaining cases are where either $k < \Delta$ or $n-\ell+1 < \Delta$. If $k < \Delta$ and $n-\ell+1 \ge \Delta^{1+\varepsilon}$, then

$$\begin{aligned}
&\mathbb{P}(P_{k\ell} > (1+\varepsilon)\ln a_n)\\
&\le \mathbb{P}\left(N_2 < \frac{n-\ell}{\Delta^{1+\varepsilon}}\right)\\
&\quad + \mathbb{P}\left(\sum_{j=1}^{k-1} X_j + \sum_{j=1}^{\Delta} Z_j + \sum_{j=\lfloor (n-\ell)/\Delta^{1+\varepsilon}\rfloor+1}^{n-\ell} X'_j > (1+\varepsilon)\ln a_n\right),
\end{aligned}$$

where the first summand is bounded as before and the second one has the upper bound

$$\begin{aligned}
&\mathbb{P}\left(\sum_{j=1}^{k-1} X_j + \sum_{j=1}^{\Delta} Z_j + \sum_{j=\lfloor (n-\ell)/\Delta^{1+\varepsilon}\rfloor+1}^{n-\ell} X'_j - \ln(k\Delta^{3+\varepsilon}) > 2\varepsilon\ln\Delta\right)\\
&\le \exp\left(-\frac{(2\varepsilon\ln\Delta-7)^2}{2\ln(k\Delta^{3+\varepsilon})+6+2\varepsilon\ln\Delta}\right),
\end{aligned}$$

which leads to the bound given in (3.6) since $k\Delta^{3+\varepsilon} \le \Delta^{4+2\varepsilon}$. For the case $k \le \Delta$

and $\Delta \le n-\ell+1 \le \Delta^{1+\varepsilon}$ we estimate

$$\mathbb{P}(P_{k\ell} > (1+\varepsilon)\ln a_n) \le \mathbb{P}\left(\sum_{j=1}^{k-1} X_j + \sum_{j=1}^{\Delta} Z_j + \sum_{j=1}^{\lfloor \Delta^{1+\varepsilon} \rfloor} X'_j > (1+\varepsilon)\ln a_n\right),$$

and, for the case $k \le \Delta$ and $n-\ell+1 \le \Delta$,

$$\mathbb{P}(P_{k\ell} > (1+\varepsilon)\ln a_n) \le \mathbb{P}\left(\sum_{j=1}^{k-1} X_j + \sum_{j=1}^{\Delta} Z_j + \sum_{j=1}^{n-\ell} X'_j > (1+\varepsilon)\ln a_n\right),$$

and estimate as before. The remaining cases with $n-\ell+1 \le \Delta$ are covered by symmetry.

To show the second claim of the theorem, $\mathbb{E}\,P_{k\ell}^p \sim \ln^p a_n$, we fix $p \ge 1$ and $\delta \in (0,1)$. Then, by the first part, there is a $C > 0$ with $\mathbb{P}(P_{k\ell} \ge (1+\varepsilon)\ln a_n) \le C\Delta^{-\varepsilon^2/(3+2\varepsilon)}$ for all Δ sufficiently large and all $\varepsilon \ge \delta$. We obtain

$$\begin{aligned}
\mathbb{E}\,P_{k\ell}^p &= \mathbb{E}\left[P_{k\ell}^p\left(\mathbf{1}_{\{P_{k\ell} \le (1+\delta)\ln a_n\}} + \mathbf{1}_{\{P_{k\ell} > (1+\delta)\ln a_n\}}\right)\right] \\
&\le (1+\delta)^p \ln^p a_n + \int_{(1+\delta)^p \ln^p a_n}^{\infty} \mathbb{P}(P_{k\ell}^p \ge t)\,dt \\
&\le (1+\delta)^p \ln^p a_n + C\int_{(1+\delta)^p \ln^p a_n}^{\infty} \exp\left(-\frac{\varepsilon^2}{3+2\varepsilon}\ln\Delta\right) dt,
\end{aligned}$$

with $\varepsilon = \varepsilon(t) = (t^{1/p}/\ln a_n) - 1$.

Note that for any convex function $f : [t_0, \infty) \to \mathbb{R}$, $t_0 \in \mathbb{R}$, differentiable in t_0 with $f'(t_0) > 0$, we have

$$\int_{t_0}^{\infty} \exp(-f(t))\,dt \le \frac{\exp(-f(t_0))}{f'(t_0)}.$$

This follows estimating $f(t) \ge f(t_0) + f'(t_0)(t-t_0)$ for all $t \ge t_0$ and evaluating the resulting integral.

Now, the function $f(t) = (\varepsilon^2/(3+2\varepsilon))\ln\Delta$ with $\varepsilon = \varepsilon(t)$ given above and $t_0 = (1+\delta)^p \ln^p a_n$ has the latter form. Hence an explicit calculation yields

$$\begin{aligned}
\int_{(1+\delta)^p \ln^p a_n}^{\infty} \exp\left(-\frac{\varepsilon^2}{3+2\varepsilon}\ln\Delta\right) dt &\le \frac{\exp(-f(t_0))}{f'(t_0)} \\
&= \frac{p(1+\delta)^{p-1}\ln^p a_n}{(6\delta+2\delta^2)\ln\Delta}\Delta^{-\delta^2/(3+2\delta)} \\
&= O\left(\frac{\ln^{p-1}\Delta}{\Delta^{\delta^2/(3+2\delta)}}\right),
\end{aligned}$$

which gives a vanishing contribution as $\Delta \to \infty$.

Hence we obtain

$$\limsup_{n\to\infty} \frac{\mathbb{E}\,P_{k\ell}^p}{\ln^p a_n} \le (1+\delta)^p$$

for all $\delta > 0$; hence $\limsup_{n\to\infty} \mathbb{E}\,P_{k\ell}^p/\ln^p a_n \le 1$.

For the lower bound we choose $c \in \mathbb{R}$. Then for all n sufficiently large such that $a_n > \exp(c^2)$ we have

$$\begin{aligned}\frac{\mathbb{E}\, P_{k\ell}^p}{\ln^p a_n} &\geq \frac{1}{\ln^p a_n}\, \mathbb{E}\left[\mathbf{1}_{\{(P_{k\ell}-\ln a_n)/\sqrt{\ln a_n}\geq c\}} P_{k\ell}^p\right] \\ &\geq \left(1+\frac{c}{\sqrt{\ln a_n}}\right)^p \mathbb{P}\left(\frac{P_{k\ell}-\ln a_n}{\sqrt{\ln a_n}} \geq c\right) \\ &\to 1-\Phi(c)\end{aligned}$$

as $n \to \infty$, by Theorem 1.3, where Φ denotes the distribution function of the standard normal distribution. With $c \to -\infty$ we obtain $\liminf_{n\to\infty} \mathbb{E}\, P_{k\ell}^p / \ln^p a_n \geq 1$. □

THE EFFECTS OF TEMPORARY SESSIONS ON NETWORK PERFORMANCE*

MATTHEW ANDREWS† AND LISA ZHANG†

Abstract. We consider a packet network, in which packets are injected in *sessions* along fixed paths. Packet movement is restricted by link bandwidth. In case of contention, a *contention resolution protocol* determines which packets proceed. In the *permanent session model*, a fixed set of connections is present in the network at all times. In the *temporary session model*, connections come and go over time. In this paper we compare network performance in these two models in terms of stability and end-to-end delay.

We provide the first separation of the two models in terms of stability. In particular, we show that generalized processor sharing (GPS) can be unstable with temporary sessions, whereas GPS is known to be stable and have polynomial delay bounds with permanent sessions.

We also observe that the relative performance of protocols can differ in the two models. For example, in the temporary session model the protocol farthest-to-go (FTG) is known to be stable and therefore outperforms GPS. However, in the permanent session model we show that FTG can suffer exponential delays and is therefore outperformed by GPS.

Although polynomial delay bounds are easy to obtain for permanent sessions, this is not the case when sessions can be temporary. We show that a common framework for bounding delays can only lead to superpolynomial bounds in the temporary session model. We also construct superpolynomial lower bounds on delay for a large class of deterministic, distributed protocols that includes the longest-in-system protocol.

1. Introduction.

Packet switching is a common feature of modern communication networks. In this environment, flows of small packets carry information from one location to another. The movement of packets within the network can be restricted due to limited link bandwidth. If too many packets are contending for the same link, a *contention resolution protocol* is used to determine which packets can proceed and which packets must wait.

Recently, there has been a great deal of work on the analysis of networks that are subject to worst-case traffic patterns. This work can broadly be divided into two groups. In the *session-oriented* model [2, 5, 6, 7, 9, 10, 11, 12, 13, 14, 15, 16, 18, 19, 20], a fixed set of *sessions* (i.e., connections) is present in the network. Each session claims bandwidth along a fixed session path at all times. This model is appropriate for the study of networks where connections persist for long periods. In this paper we refer to it as the *permanent session* model.

Alternatively, in the *temporary session* model sessions come and go over time. A temporary session claims its bandwidth only during its *active* period. The unused link bandwidth during its *inactive* period can be claimed by other sessions. This model is identical to the *adversarial queueing* model of [1, 4] in terms of the permitted injection patterns. However, these two papers have no notion of session rate. We choose to

perform our analysis in terms of temporary sessions, thereby allowing us to study popular protocols that are rate-based.

Our aim is to discover how the performance of networks with temporary sessions differs from the performance of networks with permanent sessions. To the best of our knowledge, this topic has not been previously studied.

Performance measures. One of the most important measures in network performance is *stability*. A network is *stable* if the total number of packets in the network is bounded by a quantity independent of time. A closely related measure is *end-to-end delay*, i.e., the time taken for a packet to traverse its path. Many interactive applications rely on low delay to function properly.

A necessary condition for stability is that the total bandwidth claimed by all sessions on any link is no more than the link bandwidth. Under this condition, there is more freedom for packet injections in the temporary session model than in the permanent session model. Hence, it is more difficult to achieve stability and small delays when temporary sessions are present.

Protocols. In this paper we focus on simple, deterministic, distributed protocols, such as *shortest-in-system* (SIS), *longest-in-system* (LIS), *farthest-to-go* (FTG), and *generalized processor sharing* (GPS). SIS (resp., LIS) gives priority to the packet that has been in the system the shortest (resp., longest) amount of time, and FTG gives priority to the packet that has the most number of links still to traverse. SIS, LIS, and FTG were all shown to be stable for temporary sessions in [1]. GPS divides the link bandwidth among sessions in proportion to their session rates. (Note that GPS is not well-defined without session rates.) Parekh and Gallager [14, 15] showed that GPS achieves low end-to-end delay in the permanent session model. This work has created a lot of interest in GPS and has often been studied in connection with the provision of quality-of-service in the Internet [17]. We also consider a large class of deterministic, distributed protocols that we call *vulnerable* protocols.

Our results. Network performance can indeed differ depending on whether or not temporary sessions are present. We show in this paper that achieving stability and low delay is strictly more difficult in the temporary session model.

- In section 3, we show that GPS can be unstable in the temporary session model. Although GPS achieves low delays for permanent sessions, our result indicates that its performance can be extremely poor if there are temporary sessions. This is the first result to show that a natural protocol can have different stability properties in the two models;[1] i.e., we have a *separation* in terms of stability.

  We also present extra conditions under which GPS is in fact stable for temporary sessions. However, this stability comes at the expense of a lower link utilization.
- In section 4 we observe that the relative performance of protocols can depend on whether or not temporary sessions are present. In the temporary session model, our previous result indicates that FTG outperforms GPS since FTG is known to be stable. In contrast, in the permanent session model we show that the delays produced by FTG can be $e^{\Omega(d)}$, whereas GPS is known to have polynomial delays. Hence, GPS outperforms FTG.
- In section 5 we give limits on the delay bounds that can be derived in the

[1] One could artificially create a protocol that behaves like the unstable protocol first-in-first-out (FIFO) in the temporary session model and behaves like the stable protocol LIS in the permanent session model. However, such unnatural protocols are not the subject of interest here.

temporary session model. In particular, we examine an open question posed in [1]. Is there a deterministic, distributed protocol that achieves polynomial delays?

We first show that one common technique for bounding delay can only lead to superpolynomial bounds of the form $e^{\Omega(\sqrt{d})}$, where d is the maximum path length of a session. We then construct a lower bound of $e^{\Omega(d)}$ on the actual delays produced by LIS. (Whether or not LIS guarantees polynomial delays was previously unknown.) Finally, we extend the analysis to give a lower bound of $e^{\Omega(\sqrt{d})}$ for a large class of deterministic, distributed protocols that we call *vulnerable* protocols.

However, for permanent sessions simple, deterministic, distributed protocols such as GPS do have polynomial delays.

2. The models. We consider a packet-switched network. Packets are injected into the network over time and are routed along predetermined paths of maximum length d. Packet movement is constrained by link bandwidth. In this paper we assume unit packet sizes and unit link bandwidth; i.e., at each time step one packet is allowed to traverse each link.

The injection of each *session* i is characterized by its injection rate ρ_i and burst size σ_i. In addition each session i is associated with a set of *active periods*, $[a_i^0, b_i^0]$, $[a_i^1, b_i^1], \ldots$, which are time intervals during which session i is allowed to inject packets. We say that a session is active during its active periods and inactive at all other times. In the *permanent sessions* model, every session has active period $[0, \infty)$. In the *temporary sessions* model some sessions can be inactive at times.

The injections into session i are (σ_i, ρ_i)-regulated [6, 7]. That is, the total size of packets injected into session i in any active interval of length t is at most $\sigma_i + \rho_i t$. We must ensure that no link is overloaded, otherwise it is impossible to provide any meaningful performance guarantees. In the permanent sessions model we require that

$$\sum_{i \in S_e} \rho_i \leq 1 \quad \text{for all links } e, \tag{1}$$

where S_e is the set of sessions passing through e. We refer to (1) as the *admissibility condition for permanent sessions*. In the temporary sessions model, we could have an analogous condition to (1) on the ρ_i, namely, $\sum_{i \in S_e(t)} \rho_i \leq 1$, where $S_e(t)$ is the set of *active* sessions passing through e. However, this is not sufficient since session i could become active for a very short instant but still inject packets of size σ_i. Instead we require that, during any time interval of length t, the total number of packets that are allowed to be injected into the network to pass through any link e be at most

$$W + (1 - \varepsilon)t \tag{2}$$

for some W and $\varepsilon \geq 0$. We refer to the above as the *admissibility condition for temporary sessions*.

Note that during its active period a session i may inject packets at a rate lower than ρ_i, or even inject no packets at all. A permanent session is active at all times no matter how few packets it injects, and it can be viewed as reserving the bandwidth of ρ_i along the links of its path at all times. On the contrary, when a temporary session is inactive, its bandwidth can be claimed by other sessions. This difference allows more freedom in admissible packet injections in the temporary session model than in the permanent session model.

We now illustrate a set of injections that are admissible in the temporary session model but not in the permanent sessions model. Consider a network of three links e_1, e_2, and e_3. For even i, during time interval $[2^i, 2^{i+1})$ session 0 injects packets at rate $2/3$ along paths e_1 and e_2; for odd i, during time interval $[2^i, 2^{i+1})$ session 1 injects packets at rate $2/3$ along paths e_1 and e_3. Note that these time intervals are disjoint and increase in length. Therefore these sessions are not (σ, ρ)-regulated for any fixed σ if $\rho < 2/3$. Since both sessions pass through link e_1 the injections do not satisfy the admissibility condition (1) for permanent sessions. However, in the temporary session model we define $[2^i, 2^{i+1})$, where i is even to be the active periods for session 0 and $[2^i, 2^{i+1})$, where i is odd to be the active periods for session 1. Then at any given time instant the total injection rate from the active sessions on server e_1 is equal to $2/3$ and so the injections are admissible in the temporary sessions model.

3. Instability of GPS with temporary sessions. GPS is a protocol designed for the *fluid model*, in which link bandwidth can be *instantaneously* shared among backlogged sessions. (A session is backlogged at a link if it has packets queueing at the link.) In particular, each session i has a specified weight Φ_i. If $B_e(t)$ represents the set of backlogged sessions at link e at time t, then e services session $i \in B_e(t)$ at rate

$$\phi_i = \frac{\Phi_i}{\sum_{j \in B_e(t)} \Phi_j};$$

i.e., e gives session i a fraction ϕ_i of its bandwidth.

In this paper, we adopt the most common method of choosing the weights by setting Φ_i to ρ_i. (This is also known as *rate proportional processor sharing*, or RPPS.) In practice, *weighted fair queueing* (WFQ), a packet-by-packet protocol, is often implemented to emulate the fluid behavior of GPS. In particular, WFQ gives priority to the packet that would finish traversing the link first under GPS. A more detailed description of these protocols can be found in [8, 14, 15].

In [14, 15], Parekh and Gallager derived polynomial delay bounds for GPS and WFQ in the permanent session model. In contrast, we show in the following that GPS and WFQ can be unstable when temporary sessions are present. This implies unbounded delays.

3.1. Instability with temporary sessions. We now show that GPS can be unstable in the temporary session model. We use the "double-ring" network from [1] on which the FIFO, last-in-first-out (LIFO), and nearest-to-go protocols were shown to be unstable. However, the injections into the network are somewhat different. There are six links in the network in total. Four of the links, e_0, f_0, e_1, and f_1, form a ring. The other two links, f_0' and f_1', are parallel to f_0 and f_1, respectively. (See Figure 1.)

THEOREM 1. *The double-ring network is unstable under GPS in the temporary session model.*

Proof. We analyze the packet movement in phases. We inductively assume that at the beginning of the current phase, s packets from some session A are waiting to traverse links e_0 and f_0. At the end of the phase there will be strictly more than s packets waiting to traverse links e_1 and f_1. By symmetry, we can repeat the process indefinitely to build up an unbounded number of packets in the network.

The injection pattern during the current phase is as follows. Let the beginning of the phase be time 0. For each session, we specify its active time period during

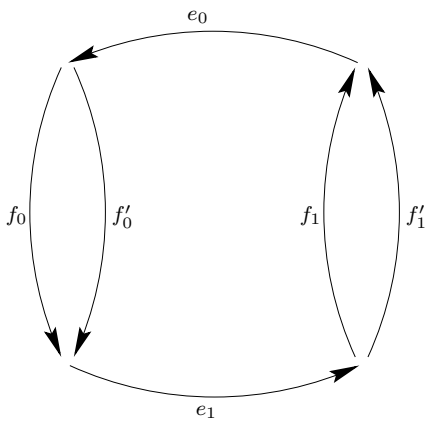

FIG. 1. *The double-ring network.*

which the session injects packets. All sessions have a common injection rate ρ. Our construction creates instability for $\rho \geq 0.973$. Note that the injection pattern satisfies the admissibility condition for temporary sessions (2). Note also that in the permanent session model, the injection is not admissible since, for example, sessions B and D share links e_1 and f_1 and have a total rate higher than 1.

1. During $[0, 2s)$, session B is active on path $e_0 f'_0 e_1 f_1$ and session C is active on path f_0.

2a. During $[2s, 4\rho s)$, session D is active on path $f_0 e_1 f_1$.

2b. During $[2s, 2\rho s + s)$, session E is active on path f'_0.

2c. During $[2\rho s + s, 4\rho s)$, session F is active on path f'_0.

3. During $[4\rho s, 4\rho s + T)$, session G is active on path $e_1 f_1$. We define the parameter T in (3).

At a qualitative level, the above injection pattern creates the following effect. During step 1, session A contends with sessions B and C and slows down their service. As a result, at time $2s$, session B has a backlog at link e_0 and session C has a backlog at link f_0. During step 2a, the backlog of session C slows down the service of session D. During step 2b, session E slows down the service of session B. During step 2c sessions E and F *both* slow down the service of B. At time $4\rho s$, sessions B and D have a total backlog of more than s packets that still have to traverse $e_1 f_1$.

The purpose of the injections in step 3 is to create one single session G with more than s packets waiting to traverse $e_1 f_1$. The state of the network at time $4\rho s + T$ is the same as the state at time 0 except that we now have more packets waiting and they have been shifted from the head of the path $e_0 f_0$ to the head of the path $e_1 f_1$. Hence we can repeat the process indefinitely to create instability.

To obtain a better understanding of the numbers, suppose that ρ is 1. Session G will then have $7s/6$ packets waiting to traverse $e_1 f_1$ at time $4\rho s + T$. For $\rho < 1$, fewer than $7s/6$ packets from session G will be waiting to traverse $e_1 f_1$. However, if we choose ρ sufficiently close to 1, then the number of packets waiting can still be strictly more than s.

Note that it is crucial that E and F are two *different* sessions during step 2c. This creates three sessions B, E, and F that are all competing for link f'_0. Session B is therefore serviced at rate $1/3$. If E and F were the same session, then B would be serviced at rate $1/2$ at f'_0 and at most s packets would be waiting to traverse $e_1 f_1$.

This is not sufficient to create instability.

We now give a more detailed description of the phase. Since all sessions have the same injection rate, under GPS each link services all backlogged sessions at the same rate.

1. During $[0, 2s)$, link e_0 services both sessions A and B at rate $1/2$; link f_0 services sessions A and C at rate $1/2$.
   At time $2s$, there are no session-A packets left in the network; session B has $2s(\rho - 1/2)$ packets queueing at link e_0; session C has $2s(\rho - 1/2)$ packets queueing at link f_0.

2a. During $[2s, 4\rho s)$, link f_0 services sessions C and D at rate $1/2$.
   At time $4\rho s$, session C has no packets left in the network; session D has $(4\rho s - 2s)(\rho - 1/2)$ packets queueing at link f_0.

2b. During $[2s, 2\rho s + s)$, link f_0' services sessions B and E at rate $1/2$; links e_1 and f_1 service sessions B and D at rate $1/2$.
   At time $2\rho s + s$, session B has $2s(\rho - 1/2) - (2\rho s - s)/2 = s(\rho - 1/2)$ packets queueing at link f_0'; session E has $(2\rho s - s)(\rho - 1/2)$ packets queueing at f_0'.

2c. During $[2\rho s + s, 4\rho s)$, *three* sessions B, E, and F are backlogged at link f_0'. Link f_0' services all these sessions at rate $1/3$. Links e_1 and f_1 service session D at rate $1/2$ and they service session B at rate $1/3$. Note that sessions B and D have no backlogs at e_1 and f_1, and hence they are served at the rate at which they arrive.
   At time $4\rho s$, session B has $s(\rho - 1/2) - (2\rho s - s)/3 = s(\rho - 1/2)/3$ packets queueing at link f_0'; sessions E and F both have packets queueing at f_0'.

3. During $[4\rho s, 4\rho s + T)$, link e_1 first services sessions B, D, and G at rate $1/3$ for the first $\rho s - s/2$ steps until session B has no packets left in the network. Link e_1 then services D and G at rate $1/2$ until time $4\rho s + T$, which we define to be the time at which session D has no packets left. The value of T is therefore

$$\begin{aligned} T &= 3 \cdot (s(\rho - 1/2)/3) + 2 \cdot ((4\rho s - 2s)(\rho - 1/2) - s(\rho - 1/2)/3) \\ &= (8\rho s - 11s/3)(\rho - 1/2). \end{aligned} \tag{3}$$

   At time $4\rho s + T$, the number of session G packets that are waiting to traverse e_1 and f_1 is

$$\begin{aligned} &T\rho - s(\rho - 1/2)/3 - (T - s(\rho - 1/2))/2 \\ &= T(\rho - 1/2) + s(\rho - 1/2)/6. \end{aligned}$$

   For $\rho \geq 0.973$, the above quantity is strictly greater than s. □

So far we have considered the GPS protocol that applies to the fluid model in which service can be allocated fractionally among different sessions. The key feature of our instability analysis is that we bound the amount of service that GPS gives to *each session over long time scales*. If we move from the fluid model of GPS to the packetized model of WFQ, we note that the amount of service given to each session by GPS or by WFQ is indistinguishable over large time scales. Therefore we have the following.

COROLLARY 2. *The double-ring network is unstable under WFQ in the temporary session model.*

3.2. Stability at reduced link utilization. By imposing extra conditions, it is possible to ensure network stability under GPS and WFQ when temporary sessions

are present. The instability in the previous section comes from the fact that a new active session can start to inject packets *before* the packets from an inactive session reach their destination. For example, sessions E and F start to inject packets before some session-B packets are at their destination. Let a session be *live* if it has packets that are not yet at their destination. We can choose to not free up the bandwidth used by a live session (even if the session is inactive). In other words, one can enforce the following condition in addition to condition (2).

$$\sum_{i \in L_e(t)} \rho_i \leq 1 - \varepsilon \quad \text{for all links } e \text{ and time } t, \tag{4}$$

where $L_e(t)$ represents the set of sessions that pass through link e and that are live at time t. With this enforcement we can show that GPS and WFQ are stable. However, the total injection rate on some link can be arbitrarily small. The link utilization therefore suffers.

THEOREM 3. *GPS and WFQ are stable in the temporary session model if condition* (4) *holds. However, the total injection rate on some link can be arbitrarily close to* 0.

Proof. If condition (4) holds, then the total injection rate over all live sessions at any link is at most $1 - \varepsilon$ at all time. This allows us to adapt the analysis of Parekh and Gallager [15] to obtain the same polynomial delay bound for GPS and WFQ as in the permanent session model.

Suppose sessions A and B share link e. Both sessions have injection rate $1 - \varepsilon$ and K links on their paths. Suppose A and B alternate between being active and inactive, and the length of their active period is α. The injection rate on link e over time is at most

$$\frac{\alpha(1-\varepsilon)}{\alpha + K},$$

since it takes at least K time steps for the packets to reach their destinations. When K/α is large, the above quantity can be arbitrarily close to 0. ∎

4. Exponential delay of FTG with permanent sessions. In the temporary session model, our result in section 3 indicates that GPS is outperformed by the FTG protocol since FTG is stable [1]. In this section we show that the relative performance of the two protocols is reversed when all sessions are permanent. Parekh and Gallager [15] derived a polynomial delay bound for GPS. We show in the following that the delays under FTG can be of the form $e^{\Omega(d)}$, where d is the maximum path length.

THEOREM 4. *Under FTG, the delays can be* $e^{\Omega(d)}$ *even if all sessions are permanent.*

Proof. We construct a network in which there exists a session A that experiences exponential delay under FTG. Suppose that session A has burst size $\sigma \geq 1$, injection rate $\rho = 0.45$, and path $e_0, e_1, \ldots, e_{d-1}$. At link e_0, A contends with session Z. The path of Z consists of e_0 and then d additional links. Suppose that session Z also has burst size σ.

At time t_0, a burst of σ session-A packets and σ session-Z packets arrives at link e_0. Under FTG, session Z has priority over A on link e_0. Hence, during the time interval $[t_0, t_0 + \sigma)$, the only packets that traverse link e_0 are the σ session-Z packets. During this interval $[t_0, t_0 + \sigma)$, session A injects additional packets at rate ρ.

Session Z injects no packets. Let $t_1 = t_0 + \sigma$. The total number of session-A packets queued at link e_0 at time t_1 is $\sigma(1+\rho)$.

At time $t_{i+1} = t_i + \sigma(1+\rho)^i$, we inductively assume that a total of $\sigma(1+\rho)^{i+1}$ session-A packets are queueing at links $e_0, e_1, \ldots, e_i$, among which at least $\sigma(1+\rho)^i$ are queueing at e_i. In addition we assume no packets from other sessions are queueing at $e_0, \ldots, e_i$ at time t_{i+1}. (As we can see from the previous paragraph, the basis of induction holds for $i = 0$.) Let Π_i be the injection process that created this state and let N_i be the network on which the injections of Π_i are made.

We now create a network N_i' that is identical to N_i except that the end of each session path in N_i' is extended by one extra link. Let session A' in N_i' correspond to session A in N_i, and let $e_0', \ldots, e_i', e_{i+1}$ be the first $i+2$ links of session A'. Networks N_i' and N_i share no common links other than e_{i+1}. (See Figure 2.) The injection process Π_i' in N_i' is identical to Π_i up to time t_{i+1}. After t_{i+1}, session A' injects no packets and session A continues to inject at rate ρ.

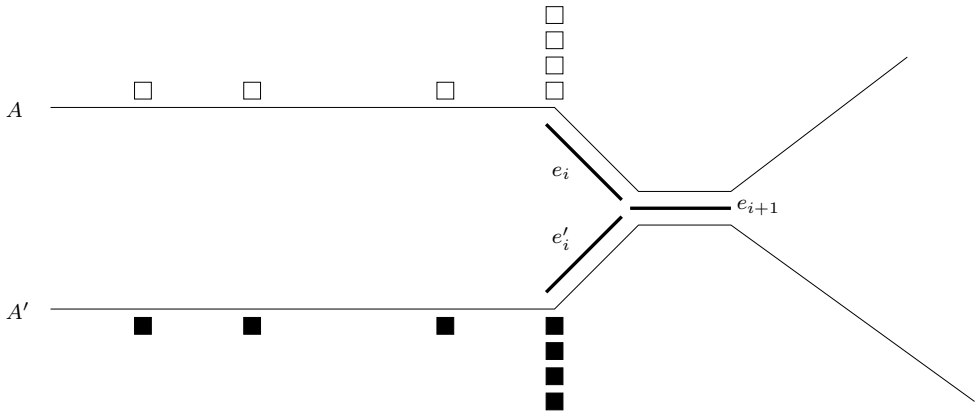

FIG. 2. *Sessions A and A' in the inductive assumption at time t_{i+1}. Other sessions are omitted in this drawing.*

With the above construction, the same inductive assumption holds for network N_i' at time t_{i+1}. Under FTG, session A' has priority over A on link e_{i+1}. During time interval $[t_{i+1}, t_{i+2})$, where $t_{i+2} = t_{i+1} + \sigma(1+\rho)^{i+1}$, $\sigma(1+\rho)^{i+1}$ session-A' packets traverse links e_i' and e_{i+1} one after another. Note that some session-A' packets may not be at e_i' at time t_{i+1}. However, since other sessions have no packets queueing at links $e_0', \ldots, e_i'$, these session-A' packets can reach e_i' by time $t_{i+1} + \sigma(1+\rho)^i$ since $\sigma(1+\rho)^i > i$ for all i when $\rho = 0.45$. By a similar argument, during time interval $[t_{i+1}, t_{i+2})$, $\sigma(1+\rho)^{i+1}$ session-A packets traverse links e_i' one after another and then queue up at e_{i+1}. Meanwhile, $\sigma(1+\rho)^{i+1}\rho$ session-A packets are injected. Thus, a total of $\sigma(1+\rho)^{i+2}$ packets are queueing up at links $e_0, \ldots, e_{i+1}$, among which at least $\sigma(1+\rho)^{i+1}$ are at e_{i+1}. In addition, during $[t_{i+1}, t_{i+2})$ no packets other than those from session A are injected along $e_0, \ldots, e_i$. Since by induction no packets from other sessions are queueing at these links at time t_{i+1}, no packets from other sessions can be queueing at links $e_0, \ldots, e_i$ at t_{i+2}. The inductive step is complete.

We note that ρ is set at 0.45 for two reasons. First, link e_{i+1} is the only link where 2 sessions merge in the inductive step. For $\rho = 0.45$ the admissibility condition of (2) holds for a fixed burst. Second, in the inductive step we need $\sigma(1+\rho)^i > i$ for all i and $\rho = 0.45$ suffices. □

5. Superpolynomial lower bounds on delay for temporary sessions. In this section we derive lower bounds on delay in the temporary session model. In section 5.1 we show that a common framework for deriving delay bounds in this model cannot give bounds that are polynomial in d, the maximum session length. We refer to this framework as the *no-early-arrival* framework. In section 5.2 we extend the result to show that a large class of *deterministic*, *distributed* protocols, including LIS, cannot give polynomial delay bounds. On the other hand protocols such as GPS can guarantee polynomial delays in the permanent session model.

Throughout this section, we focus on the injection of individual packets and do not explicitly define sessions. However, we can regard a single packet injection as a session with a burst size of 1, an arbitrarily small injection rate, and an active period of 1 time step.

5.1. Lower bound for the no-early-arrival framework. We describe the no-early-arrival framework that has been used to derive delay bounds for a number of protocols, e.g., LIS, SIS, and FTG, in [1]. In this framework, for a given protocol $\mathcal{P}$ we create a sequence $T_1, T_2, \ldots$ for which every packet traverses its ith link within T_i steps of its injection. Each T_i is calculated by assuming that each packet traverses its $(i-1)$st link *exactly* at time T_{i-1}. We bound the additional amount of time, S_i, that a packet takes to traverse its ith link. We then set $T_i = T_{i-1} + S_i$. Each S_i is bounded by some inequality expressed in terms of the T's, where this inequality explores the properties of $\mathcal{P}$. If these inequalities have a positive solution, then the delay bounds are obtained.

For example, consider the SIS protocol. Suppose a packet p is injected at time T_0 and arrives at its ith link at time $T_0 + T_{i-1}$. During the time period $[T_0 + T_i, T_0 + T_{i-1} + S_i)$, at most $\sigma + (1-\varepsilon)(T_{i-1} + S_i)$ packets can have priority over packet p at link e. If

$$\begin{aligned} S_i &\geq \frac{\sigma + (1-\varepsilon)T_{i-1}}{\varepsilon} \\ \Rightarrow S_i &\geq \sigma + (1-\varepsilon)(T_{i-1} + S_i), \end{aligned}$$

then packet p traverses its ith link e by time $T_0 + T_{i-1} + S_i$. Thus, we can set $T_i = T_{i-1} + S_i$. By induction we obtain a bound on T_d. (A variant of this proof was used to show stability of SIS in [1].)

The above approach does not take advantage of the fact that some packets may traverse their ith link *earlier* than T_i. We refer to this approach as the *no-early-arrival* framework. In [1], the delay bounds for the three stable protocols LIS, SIS, and FTG were all derived within the no-early-arrival framework. We now show that within this framework we *cannot* prove polynomial delay bounds for *any* protocol. More precisely, we have the following.

THEOREM 5. *If the no-early-arrival framework is used to bound the delay in the temporary session model, then for any protocol* $T_d = e^{\Omega(\sqrt{d})}$.

Proof. Suppose that $T_1, T_2, \ldots, T_d$ is a sequence of delay bounds that has been derived for a protocol $\mathcal{P}$ using the no-early-arrival framework. We use the following injections to obtain a lower bound for T_d. All of the packets are to traverse some common link e. The packets are divided into $d-1$ groups. Let $\tau \geq T_{d-1}$ and $T_0 = 0$. For $1 \leq i \leq d-1$, group i consists of $(1-\varepsilon)(T_i - T_{i-1})$ packets that are injected during time interval $[\tau - T_i, \tau - T_{i-1})$. These packets in group i have link e as the $(i+1)$st link on their paths. (See Figure 3.) Since the different groups inject packets at disjoint time intervals, condition (2) is satisfied. In the no-early-arrival framework,

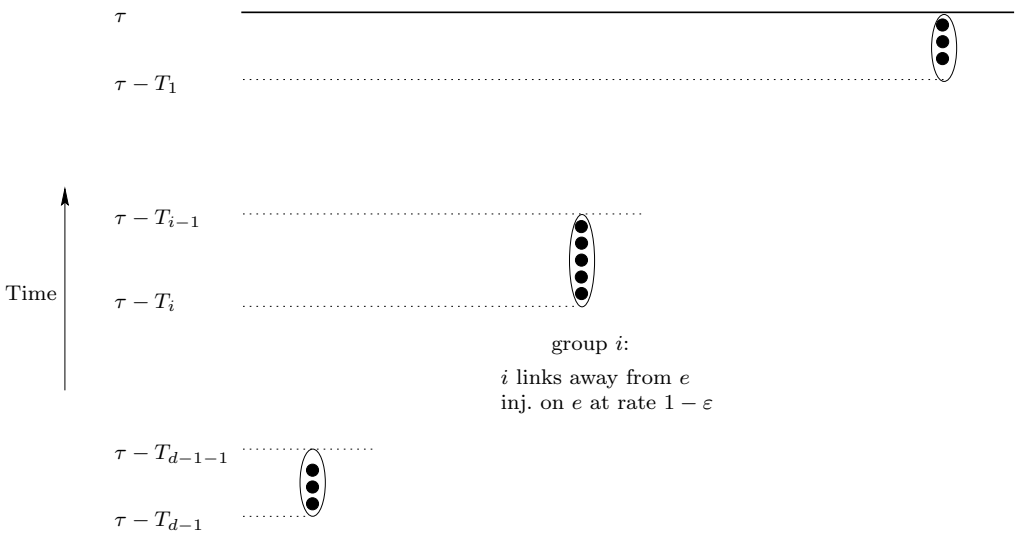

FIG. 3. *Packets arrive at e no earlier than τ in the no-early-arrival framework.*

we assume that all packets from these $d-1$ groups arrive at link e no earlier than time τ.

We order the groups by the time at which all the packets from the group have traversed link e under protocol $\mathcal{P}$. Let $\pi_1, \pi_2, \ldots, \pi_{d-1}$ be this ordering; i.e., if $i < j$, all the packets from π_i traverse link e before the last packet of π_j. Let p be the last packet from group π_i to traverse link e. Since p is in group π_i, it is injected by time $\tau - T_{\pi_i - 1}$ and therefore traverses link e by time $\tau + T_{\pi_i+1} - T_{\pi_i-1}$. By the definition of the ordering, all packets from groups $\pi_1, \ldots, \pi_i$ traverse link e before p. Since all these packets arrive at link e no earlier than τ and $(1-\varepsilon)(T_{\pi_j} - T_{\pi_j - 1})$ packets are in group π_j, we have the following recurrence:

(5)
$$T_{\pi_i+1} - T_{\pi_i-1} \geq (1-\varepsilon)[(T_{\pi_i} - T_{\pi_i-1}) + (T_{\pi_{i-1}} - T_{\pi_{i-1}-1}) + \cdots + (T_{\pi_1} - T_{\pi_1-1})].$$

We proceed to show that $T_d = e^{\Omega(\sqrt{d})}$ regardless of the ordering, π. By letting $S_i = T_i - T_{i-1}$, the recurrence (5) is equivalent to the following:

$$S_{\pi_i+1} + S_{\pi_i} \geq (1-\varepsilon)(S_{\pi_i} + S_{\pi_{i-1}} + \cdots + S_{\pi_1}). \tag{6}$$

For simplicity, we refer to each recurrence (6) by its subscript π_i. We say that a recurrence π_i is *right-big* if $S_{\pi_{i+1}} \leq S_{\pi_i}$; a recurrence is *left-big* otherwise. Note that if recurrence π_i is right-big, then $S_{\pi_i} \geq \frac{1-\varepsilon}{2}(S_{\pi_i} + S_{\pi_{i-1}} + \cdots + S_{\pi_1})$. If π_i is left-big, then $S_{\pi_i+1} \geq \frac{1-\varepsilon}{2}(S_{\pi_i} + S_{\pi_{i-1}} + \cdots + S_{\pi_1})$. We also say that recurrences π_j for $j > i$ are *above* recurrence π_i and that recurrences π_j for $j < i$ are *below* recurrence π_i.

It suffices to show that $S_i = e^{\Omega(\sqrt{d})}$ for some i, since $T_d = \sum_{1 \leq i \leq d} S_i$. We observe that S_{π_i} appears on the right-hand side (RHS) of the recurrence π_i. Also, every term on the RHS of π_i appears on the RHS of all the recurrences above π_i. These two simple observations allow us to prove lower bounds on any subset of *right-big* recurrences.

LEMMA 6. *If $\varphi_1, \ldots, \varphi_k$ are right-big recurrences such that φ_i appears above φ_{i-1} for all $1 < i \leq k$, then $\sum_{1 \leq i \leq k} S_{\varphi_i}$ is at least $\left(1 + \frac{1-\varepsilon}{2}\right)^{k-1} S_{\varphi_1}$. As a result, $S_{\varphi_k} = e^{\Omega(k)}$.*

Proof. The lemma holds trivially for $k = 1$. Inductively, we have

$$\begin{aligned} S_{\varphi_k} &\geq \frac{1-\varepsilon}{2}(S_{\varphi_k} + S_{\varphi_{k-1}} + \cdots + S_{\varphi_1}) \\ &\geq \frac{1-\varepsilon}{2}\left(1 + \frac{1-\varepsilon}{2}\right)^{k-2} S_{\varphi_1}. \end{aligned}$$

The first inequality holds since recurrence φ_k is right-big and $S_{\varphi_k}, \ldots, S_{\varphi_1}$ all appear on the RHS of recurrence φ_k by our earlier observations. The second inequality follows from the inductive hypothesis. ∎

If we have more than $\sqrt{d}$ right-big recurrences, then by Lemma 6 we are done. However, this is not always true. Our general strategy is to prove a lower bound exponential in k, where k is the length of the longest monotone subsequence of $\pi_1, \ldots, \pi_{d-1}$. It is well known that $k \geq \sqrt{d-1}$. Let $\varphi_1, \ldots, \varphi_k$ be a longest monotone subsequence.

We define a sequence of *delay lower bounds*, B_i, such that the RHS of recurrence φ_i is at least $(1-\varepsilon)B_i$. For the base case, let $B_1 = S_{\varphi_1}$. The RHS of recurrence φ_1 is at least $(1-\varepsilon)B_1$. For recurrence φ_i where $i \geq 2$, we either show that its RHS is at least $(1-\varepsilon)\left(1 + \frac{1-\varepsilon}{2}\right) B_{i-1}$ or else we find a new right-big recurrence. In the former case, we set $B_i = (1 + \frac{1-\varepsilon}{2})B_{i-1}$. In the latter case we set $B_i = B_{i-1}$. Hence, either at least $(k-1)/2$ recurrences are right-big or else $B_k \geq \left(1 + \frac{1-\varepsilon}{2}\right)^{(k-1)/2} S_{\varphi_1}$. In the former case we have $S_{\varphi_k} = e^{\Omega(k)}$ by Lemma 6. In the latter case we have $S_{\varphi_k+1} + S_{\varphi_k} \geq (1-\varepsilon)B_k = e^{\Omega(k)}$. In both cases we have

$$T_d = \sum_{1 \leq i \leq d} S_i \geq S_{\varphi_k+1} + S_{\varphi_k} = e^{\Omega(\sqrt{d})}.$$

The details of the analysis depend on whether or not the monotone subsequence is increasing or decreasing.

Case 1: *Increasing subsequence,* $\varphi_1 < \cdots < \varphi_k$. For each recurrence φ_i where $2 \leq i \leq k$ we define a *helper* as follows. If recurrence $\varphi_{i-1} + 1$ is below or the same as φ_i, then recurrence φ_{i-1} is the helper. Otherwise, there exists some j where $\varphi_{i-1} < j < \varphi_i$ such that recurrence j is above φ_i and recurrence $j+1$ is below or the same as φ_i. We define recurrence j to be the helper. Suppose recurrence j is the helper of φ_i. We observe the following.

PROPOSITION 7. *The term S_{j+1} is on the RHS of φ_i and all the recurrences above φ_i.*

PROPOSITION 8. *Recurrence j is no lower than recurrence φ_{i-1}.*

If j is left-big, we can lower bound S_{j+1} using the RHS of φ_{i-1} and then lower bound the RHS of φ_i using S_{j+1}. More precisely, let us define $W_{\varphi_i} = W_{\varphi_{i-1}} + S_{j+1}$ and $W_{\varphi_1} = S_{\varphi_1}$. Since the RHS of recurrence φ_i is at least $(1-\varepsilon)W_{\varphi_i}$ due to Proposition 7, it suffices to lower bound W_{φ_i}. Assume inductively that $W_{\varphi_{i-1}} \geq B_{i-1}$. We now consider recurrence φ_i and let j be its helper. If j is left-big, we have

$$S_{j+1} \geq \frac{1}{2} \cdot \text{RHS of recurrence } \varphi_{i-1} \geq \frac{1-\varepsilon}{2} W_{\varphi_{i-1}}.$$

The first inequality holds because j is left-big. The second inequality follows from Proposition 8. As a result,

$$\begin{aligned} W_{\varphi_i} &= S_{j+1} + W_{\varphi_{i-1}} \\ &\geq \left(1 + \frac{1-\varepsilon}{2}\right) W_{\varphi_{i-1}} \geq \left(1 + \frac{1-\varepsilon}{2}\right) B_{i-1}. \end{aligned}$$

Hence, we set $B_i = \left(1 + \frac{1-\varepsilon}{2}\right) B_{i-1}$. If recurrence j is right-big, then we have found a new right-big recurrence. Note that j is distinct from any right-big recurrence found earlier since our construction ensures that all helpers are distinct. Since φ_i is above φ_{i-1} the RHS of φ_i is at least as big as the RHS of φ_{i-1}. Hence, we set $B_i = B_{i-1}$.

At the conclusion of this process, either $B_k \geq \left(1 + \frac{1-\varepsilon}{2}\right)^{(k-1)/2} S_{\varphi_1}$ or we have at least $(k-1)/2$ distinct right-big recurrences. As described earlier, in both cases we have $T_d = e^{\Omega(\sqrt{d})}$.

Case 2: *Decreasing subsequence,* $\varphi_1 > \cdots > \varphi_k$. The analysis for a decreasing subsequence is similar. We highlight the differences here. For each recurrence φ_i where $2 \leq i \leq k$ we define its helper as follows. If $\varphi_i + 1$ is below recurrence φ_i, then φ_i is its own helper. Otherwise, there exists some j where $\varphi_i < j < \varphi_{i-1}$ such that recurrence j is above φ_i and recurrence $j+1$ is below φ_i. We define recurrence j to be the helper. As before, if j is the helper of φ_i, then it satisfies Propositions 7 and 8. If j is left-big, we lower bound S_{j+1} and this in turn lower bounds the RHS of φ_i. Otherwise, j is right-big. We handle the set of right-big recurrences using Lemma 6. □

The analysis of Theorem 5 shows that the exponent in the lower bound is determined by the length of the longest monotone sequence. The sequence $\pi_1, \ldots, \pi_{d-1}$ is increasing for protocol SIS and is decreasing for protocol LIS. Hence, we have the following.

COROLLARY 9. *If the no-early-arrival framework is used to bound the delay in the temporary session model, then* $T_d = e^{\Omega(d)}$ *for SIS and LIS.*

5.2. Lower bounds for a class of deterministic, distributed protocols. In the previous section we concentrated on a particular technique for deriving delay bounds. In this section we show that the above arguments can be used to lower bound the actual delay produced by many protocols. It was proven in [1] that the delays due to SIS and FTG can be $e^{\Omega(d)}$. However, the question of whether or not LIS has polynomial delays was previously unresolved. More generally, [1] poses the question of whether or not any deterministic, distributed protocol can guarantee polynomial delays. In the following, we construct an exponential bound $e^{\Omega(d)}$ for the actual delays produced by LIS. We then extend the argument to show a superpolynomial lower bound for a large class of deterministic, distributed protocols.

THEOREM 10. *Under LIS, there exists some network for which some packet takes* $e^{\Omega(d)}$ *steps to traverse a path of* d *links in the temporary session model.*

Proof. We construct the network in stages. At stage j we inductively obtain a set of networks $N_1^{(j)}, \ldots, N_{d-1}^{(j)}$ and a set of delay bounds $T_1^{(j)} < T_2^{(j)} < \cdots < T_{d-1}^{(j)}$ such that under some injection process $\Pi_i^{(j)}$ some packet p_i takes exactly $T_i^{(j)}$ time steps to traverse an i-link path P_i in network $N_i^{(j)}$. At stage 1 we have $T_i^{(1)} = i$ and the network $N_i^{(1)}$ is a linear array of i links. The injection process $\Pi_i^{(1)}$ injects one packet that must traverse all i links of $N_i^{(1)}$.

Given the set of networks at stage j, we now show how to construct the networks at stage $j+1$. The idea of our analysis is similar to that in Theorem 5. We create one big network N which consists of one new link e and $(1-\varepsilon)(T_i^{(j)} - T_{i-1}^{(j)})$ copies of network $N_i^{(j)}$ for $1 \leq i \leq d-1$. The link e is appended to the tail of the path P_i for every copy of $N_i^{(j)}$. (See Figure 4.) We modify the injection process $\Pi_i^{(j)}$ so that p_i is to traverse link e after traversing path P_i. It is important to observe the following.

PROPOSITION 11. *Under LIS, the packet movement within* $N_i^{(j)}$ *due to the*

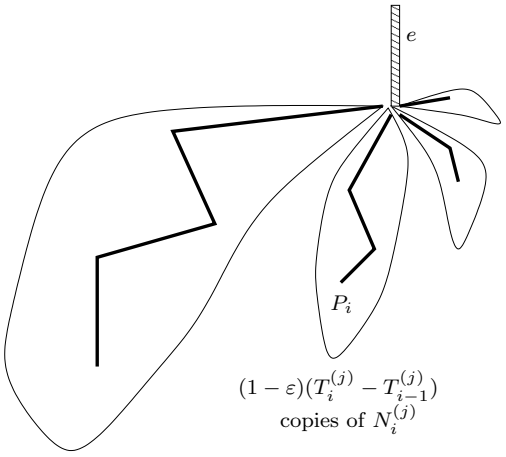

FIG. 4. *The construction of network N from $N_1^{(j)}, \ldots, N_d^{(j)}$.*

injection process $\Pi_i^{(j)}$ is unchanged by these modifications.

The injection process Π on N is as follows. Let $\tau \geq T_{d-1}^{(j)}$. We space out the starting time of the injection process $\Pi_i^{(j)}$ on each copy of $N_i^{(j)}$. In particular, the ℓth copy, where $0 \leq \ell < (1-\varepsilon)(T_i^{(j)} - T_{i-1}^{(j)})$, starts at time $\tau - T_i^{(j)} + \ell/(1-\varepsilon)$. This ensures that the p_i's are injected at the new link e at a rate $1-\varepsilon$. (These packets injected by the processes $\Pi_i^{(j)}$ are equivalent to the packets in group i in Theorem 5. See Figure 3.) We note that the injection process Π on N is admissible by (2) since the injection process $\Pi_i^{(j)}$ is admissible on each copy of $N_i^{(j)}$ and the new link e is not overloaded due to the spacing of the starting times of $\Pi_i^{(j)}$. There are two cases to consider.

Case 1. Under LIS, every packet p_i for $1 \leq i \leq d-2$ traverses link e within $T_{i+1}^{(j)}$ steps of its injection. By induction, packet p_i arrives at the head of link e exactly $T_i^{(j)}$ steps after its injection. Hence recurrences (5) hold for a decreasing sequence $\pi_1, \ldots, \pi_{d-1}$. In particular,

$$T_i^{(j)} - T_{i-2}^{(j)} \geq (1-\varepsilon)(T_{d-1}^{(j)} - T_{i-2}^{(j)}) \quad \text{for } 2 \leq i \leq d-1.$$

This inequality is equivalent to (5). By an argument similar to the proof of Theorem 5, we have $T_{d-1}^{(j)} = e^{\Omega(d)}$.

Case 2. Under LIS, some packet p_i traverses link e at a time T' steps after its injection where $T' > T_{i+1}^{(j)}$. Therefore, we can set $N_{i+1}^{(j+1)} = N$, $T_{i+1}^{(j+1)} = T'$, and $\Pi_{i+1}^{(j+1)} = \Pi$. The new path P_{i+1} is the old path P_i concatenated with link e. For $i' \neq i+1$, it is trivial to construct networks and injection processes for which we can set the $T_{i'}^{(j+1)}$ so that $T_{i'}^{(j+1)} \geq T_{i'}^{(j)}$ and $T_{i'}^{(j+1)} > T_{i'-1}^{(j+1)}$.

Note that for Case 2, one of the T_i values *strictly* increases. Hence after $j = de^{\Omega(d)}$ stages we must have $T_i^{(j)} = e^{\Omega(d)}$ for some i. □

For any protocol, if Proposition 11 holds, then we can construct a network in stages as shown in Theorem 10. More precisely, we say that protocol P is *vulnerable* if

1. protocol P is deterministic;

2. protocol P is independent of the remainder of the path that each packet still has to traverse;
3. given isomorphic networks A and B with identical injection processes, the behavior of protocol P is identical in A and B.

Note that for an arbitrary vulnerable protocol we can have an arbitrary ordering of the recurrences (5). Hence, the analysis gives a lower bound that is exponential in $\sqrt{d}$.

COROLLARY 12. *For a vulnerable protocol P, there exists some network for which some packet takes $e^{\Omega(\sqrt{d})}$ steps to traverse a path of d links in the temporary session model.*

We remark that SIS, LIS, and GPS are all vulnerable protocols. In addition, by adapting the construction of the networks N we can obtain a lower bound of $e^{\Omega(d)}$ for FTG even though it is not strictly vulnerable. (FTG is dependent on the remainder of a packet's path.) We also remark that our lower bound does not apply to randomized protocols or centralized protocols.

6. Conclusion. In this paper we have shown that the presence of temporary sessions can cause significant deterioration in network performance. There are a number of open problems. Note that for the lower bounds in sections 4 and 5.2 the network sizes are exponential in d. Although we believe that d is the correct parameter to consider when deriving delay bounds, it would be interesting to know if our arguments can be adapted to give lower bounds that are superpolynomial in network size.

For permanent sessions, protocols with near-optimal delay performance were described in [2, 13, 16]. It would be interesting to know if these ideas can be applied to temporary sessions. In particular, it is not clear how to adapt these protocols so that they are stable for the network in section 3. We note that if the link utilization is sufficiently small, the protocols of [3] provide low delay bounds in the temporary session model.

COMPLETE AXIOMATIZATIONS FOR REASONING ABOUT KNOWLEDGE AND TIME*

JOSEPH Y. HALPERN†, RON VAN DER MEYDEN‡, AND MOSHE Y. VARDI§

Abstract. Sound and complete axiomatizations are provided for a number of different logics involving modalities for knowledge and time. These logics arise from different choices for various parameters regarding the interaction of knowledge with time and regarding the language used. All the logics considered involve the discrete time linear temporal logic operators "next" and "until" and an operator for the knowledge of each of a number of agents. Both the single-agent and multiple-agent cases are studied: in some instances of the latter there is also an operator for the common knowledge of the group of all agents. Four different semantic properties of agents are considered: whether they (i) have a unique initial state, (ii) operate synchronously, (iii) have perfect recall, and (iv) learn. The property of no learning is essentially dual to perfect recall. Not all settings of these parameters lead to recursively axiomatizable logics, but sound and complete axiomatizations are presented for all the ones that do.

Key words. complete axiomatizations, knowledge, common knowledge, temporal logic, epistemic logic

1. Introduction.

It has recently been argued that knowledge is a useful tool for analyzing the behavior and interaction of agents in a distributed system (see [1] and the references therein). When analyzing a system in terms of knowledge, not only is the current state of knowledge of the agents in the system relevant, but it is also relevant how that state of knowledge changes over time. A formal propositional logic of knowledge and time was first proposed by Sato [17]; many others have since been proposed [2, 12, 11, 15, 18]. Unfortunately, while these logics often use similar or identical notation, they differ in a number of significant respects.

In [8], logics for knowledge and time were categorized along two major dimensions: the language used and the assumptions made on the underlying distributed system. The properties of knowledge in a system turn out to depend in subtle ways on these assumptions. The assumptions considered in [8] concern whether agents have *unique initial states*, operate *synchronously* or *asynchronously*, have *perfect recall*, and whether they satisfy a condition called *no learning*. There are 16 possible combinations of these assumptions on the underlying system. Together with 6 choices of language, this gives us 96 logics in all. All the logics considered in the papers

mentioned above fit into the framework. In [6, 7, 8], the computational complexity of these logics is completely characterized; the results of these papers show how the subtle interplay of the parameters can have a tremendous impact on complexity. The complexity results show that some of these logics cannot be given a recursive axiomatization, since the set of valid formulas for these logics is not recursively enumerable (r.e.). Of these 96 logics, 48 involve *linear time* and 48 involve *branching time*. (The distinction between linear and branching time essentially amounts to whether or not we can quantify over the possible executions of a program [16].) To keep this paper to manageable length, we focus here on the linear time logics, and provide axiomatic characterizations of all the linear time logics for which an axiomatization is possible at all (i.e., for those logics for which the set of valid formulas is r.e.).

The rest of this paper is organized as follows. In the next section, we provide formal definitions for the logics we consider. In section 2, we review the syntax and semantics of all the logics of knowledge and time that we consider here. In particular, we review the four assumptions on the underlying system that we axiomatize in this paper. In section 3, we state the axioms for all the systems. In section 4, we introduce the notion of *enriched systems*, which form the basis for all our completeness proofs. In section 5, we prove soundness and completeness for the axiom systems described in section 3. The definition of no learning that we use here is slightly different from that used in [1, 5], although they agree in many cases of interest. We discuss the motivation for our change in section 6. We conclude with some further discussion in section 7.

2. The formal model: Language and systems. The material in this section is largely taken from [8] and is repeated here to make this paper self-contained. The reader is encouraged to consult [8] for further details and motivation.

The logics we are considering are all propositional. Thus, we start out with primitive propositions $p, q, \ldots$ and we close the logics under negation and conjunction, so that if φ and ψ are formulas, so are $\neg\varphi$ and $\varphi \wedge \psi$. In addition, we close off under modalities for knowledge and time, as discussed below. As usual, we view *true* as an abbreviation for $\neg(p \wedge \neg p)$, $\varphi \vee \psi$ as an abbreviation for $\neg(\neg\varphi \wedge \neg\psi)$, and $\varphi \Rightarrow \psi$ as an abbreviation for $\neg\varphi \vee \psi$.

If we have m agents (in distributed systems applications, this would mean a system with m processors), we add the modalities $K_1, \ldots, K_m$. Thus, if φ is a formula, so is $K_i\varphi$ (read "agent i knows φ"). We take $L_i\varphi$ to be an abbreviation for $\neg K_i \neg\varphi$. In some cases we also want to talk about common knowledge, so we add the modalities E and C into the language; $E\varphi$ says that everyone knows φ, while $C\varphi$ says φ is common knowledge.

There are two basic linear temporal modalities (sometimes called *operators* or *connectives*): a unary operator $\bigcirc$ and a binary operator U. Thus, if φ and ψ are formulas, then so are $\bigcirc\varphi$ (read "next time φ") and $\varphi\, U\, \psi$ (read "φ until ψ"). $\Diamond\varphi$ is an abbreviation for $true\, U\, \varphi$, while $\Box\varphi$ is an abbreviation for $\neg\Diamond\neg\varphi$. Intuitively, $\bigcirc\varphi$ says that φ is true at the next point (one time unit later), $\varphi U \psi$ says that φ holds until ψ does, $\Diamond\varphi$ says that φ is eventually true (either in the present or at some point in the future), and $\Box\varphi$ says that φ is always true (in the present and at all points in the future). In [8], branching time operators are also considered, which have quantifiers over runs. For example, $\forall\bigcirc$ is a branching time operator such that $\forall\bigcirc\varphi$ is true when $\bigcirc\varphi$ is true for all possible futures. Since we do not consider branching time operators in this paper, we omit the formal definition here. We take CKL_m to be the language for m agents with all the modal operators for knowledge and linear time discussed above; KL_m is the restricted version without the E and C operators.

A *system* for m agents consists of a set $\mathcal{R}$ of runs, where each run $r \in \mathcal{R}$ is a function from $\mathbb{N}$ to $\mathbf{L}^{m+1}$, where $\mathbf{L}$ is some set of *local states*. There is a local state for each agent, together with a local state for the *environment*; intuitively, the environment keeps track of all the relevant features of the system not described by the agents' local states, such as messages in transit but not yet delivered. Thus, $r(n)$ has the form $\langle l_e, l_1, \ldots, l_m \rangle$, where l_e is the state of the environment, and l_i is the local state of agent i for $i = 1, \ldots, m$; such a tuple is called a *global state*. (Formally, we could view a system as a tuple $(\mathcal{R}, \mathbf{L}, m)$, making the $\mathbf{L}$ and m explicit. We have chosen not to do so in order to simplify notation. The $\mathbf{L}$ and m should always be clear from context.) An *interpreted system $\mathcal{I}$ for m agents* is a tuple $(\mathcal{R}, \pi)$, where $\mathcal{R}$ is a system for m agents, and π maps every point $(r, n) \in \mathcal{R} \times \mathbb{N}$ to a truth assignment $\pi(r, n)$ to the primitive propositions (so that $\pi(r, n)(p) \in \{\mathbf{true}, \mathbf{false}\}$ for each primitive proposition p).[1]

We now give semantics to CKL_m and KL_m. Given an interpreted system $\mathcal{I} = (\mathcal{R}, \pi)$, we write $(\mathcal{I}, r, n) \vDash \varphi$ if the formula φ is true at (or *satisfied by*) the point (r, n) of interpreted system $\mathcal{I}$. We define $\vDash$ inductively for formulas of CKL_m (for KL_m we just omit the clauses involving C and E). In order to give the semantics for formulas of the form $K_i\varphi$, we need to introduce one new notion. If $r(n) = \langle l_e, l_1, \ldots, l_m \rangle$, $r'(n') = \langle l'_e, l'_1, \ldots, l'_m \rangle$, and $l_i = l'_i$, then we say that $r(n)$ and $r'(n')$ are *indistinguishable to agent i* and write $(r, n) \sim_i (r', n')$. Of course, $\sim_i$ is an equivalence relation on global states (inducing an equivalence relations on points). $K_i\varphi$ is defined to be true at (r, n) exactly if φ is true at all the points whose associated global state is indistinguishable to i from that of (r, n). We proceed as follows:

- $(\mathcal{I}, r, n) \vDash p$ for a primitive proposition p iff $\pi(r, n)(p) = \mathbf{true}$.
- $(\mathcal{I}, r, n) \vDash \varphi \wedge \psi$ iff $(\mathcal{I}, r, n) \vDash \varphi$ and $(\mathcal{I}, r, n) \vDash \psi$.
- $(\mathcal{I}, r, n) \vDash \neg\varphi$ iff $(\mathcal{I}, r, n) \nvDash \varphi$.
- $(\mathcal{I}, r, n) \vDash K_i\varphi$ iff $(\mathcal{I}, r', n') \vDash \varphi$ for all (r', n') such that $(r, n) \sim_i (r', n')$.
- $(\mathcal{I}, r, n) \vDash E\varphi$ iff $(\mathcal{I}, r', n') \vDash K_i\varphi$ for $i = 1, \ldots, m$.
- $(\mathcal{I}, r, n) \vDash C\varphi$ iff $(\mathcal{I}, r', n') \vDash E^k\varphi$, for $k = 1, 2, \ldots$ (where $E^1\varphi = E\varphi$ and $E^{k+1}\varphi = EE^k\varphi$).
- $(\mathcal{I}, r, n) \vDash \bigcirc\varphi$ iff $(\mathcal{I}, r, n + 1) \vDash \varphi$.
- $(\mathcal{I}, r, n) \vDash \varphi U \psi$ iff there is some $n' \geq n$ such that $(\mathcal{I}, r, n') \vDash \psi$, and for all n'' with $n \leq n'' < n'$, we have $(\mathcal{I}, r, n'') \vDash \varphi$.

There is a graphical interpretation of the semantics of C which we shall find useful in what follows. Fix an interpreted system $\mathcal{I}$. A point (r', n') in $\mathcal{I}$ is *reachable* from a point (r, n) if there exist points $(r_0, n_0), \ldots, (r_k, n_k)$ such that $(r, n) = (r_0, n_0)$, $(r', n') = (r_k, n_k)$, and for all $j = 0, \ldots, k - 1$ there exists i such that $(r_j, n_j) \sim_i (r_{j+1}, n_{j+1})$. The following result is well known (and easy to check).

LEMMA 2.1 (see [4]). *$(\mathcal{I}, r, n) \vDash C\varphi$ iff $(\mathcal{I}, r', n') \vDash \varphi$ for all points (r', n') reachable from (r, n).*

As usual, we define a formula φ to be *valid with respect to a class $\mathcal{C}$ of interpreted systems* iff $(\mathcal{I}, r, n) \vDash \varphi$ for all interpreted systems $\mathcal{I} \in \mathcal{C}$ and points (r, n) in $\mathcal{I}$. A

[1] Note that while we are being consistent with [8] here, in [1], π is taken to be a function from global states (not points) to truth values. Essentially, this means that in [1] a more restricted class of structures is considered, where π is forced to be the same at any two points associated with the same global state. Clearly our soundness results hold in the more restricted class of structures. It is also easy to see that our completeness results hold in the more restricted class too. All our completeness proofs have (or can be easily modified to have) the property that a structure is constructed where each point is associated with a different global state, and thus is an instance of the more restrictive structures used in [1].

formula φ is *satisfiable with respect to* $\mathcal{C}$ iff for some $\mathcal{I} \in \mathcal{C}$ and some point (r, n) in $\mathcal{I}$, we have $(\mathcal{I}, r, n) \models \varphi$.

We now turn our attention to formally defining the classes of interpreted systems of interest. For some of these definitions, it will be useful to give a number of equivalent presentations.

Perfect recall means, intuitively, that an agent's local state encodes everything that has happened (from that agent's point of view) thus far in the run. To make this precise, we need to define "what has happened so far from the agent's point of view." Let *agent i's local-state sequence at the point* (r, n) be the sequence $l_0, \ldots, l_k$ of states that agent i takes on in run r up to and including time n, with consecutive repetitions omitted. For example, if from times 0 through 4 in run r agent i goes through the sequence l, l, l', l, l of states, its history at $(r, 4)$ is just l, l', l. Agent i's local-state sequence at a point (r, m) essentially describes what has happened in the run up to time m, from i's point of view. Omitting consecutive repetitions from the local-state is intended to model asynchrony; "stuttering" is ignored.

Roughly speaking, agent i has perfect recall if i's current state encodes its history, i.e., i's whole local-state sequence. More formally, we say that *agent i has perfect recall* (alternatively, *agent i does not forget*) in system $\mathcal{R}$ if at all points (r, n) and (r', n') in $\mathcal{R}$, if $(r, n) \sim_i (r', n')$, then r has the same local-state sequence at both (r, n) and (r', n').

There are a number of equivalent characterizations of perfect recall. One characterization that will prove particularly useful in the comparison with the concept of no learning, which we are about to define, is the following. Let $S = (s_0, s_1, s_2, \ldots)$ and $T = (t_0, t_1, t_2, \ldots)$ be two (finite or infinite) sequences and let $\sim$ be a relation on the elements of S and T. Then we say that S and T are $\sim$-concordant if there is some k (k may be ∞) and nonempty consecutive intervals $S_1, \ldots, S_k$ of S and $T_1, \ldots, T_k$ of T such that for all $s \in S_j$ and $t \in T_j$, we have $s \sim t$ for $j = 1, \ldots, k$.

LEMMA 2.2 (see [5, 14]). *The following are equivalent.*

(a) *Agent i has perfect recall in system $\mathcal{R}$.*

(b) *For all points $(r, n) \sim_i (r', n')$ in $\mathcal{R}$, $((r, 0), \ldots, (r, n))$ is $\sim_i$-concordant with $((r', 0), \ldots, (r', n'))$.*

(c) *For all points $(r, n) \sim_i (r', n')$ in $\mathcal{R}$, if $n > 0$, then either $(r, n-1) \sim_i (r', n')$ or there exists a number $l < n'$ such that $(r, n-1) \sim_i (r', l)$ and for all k with $l < k \leq n'$ we have $(r, n) \sim_i (r', k)$.*

(d) *For all points $(r, n) \sim_i (r', n')$ in $\mathcal{R}$, if $k \leq n$, then there exists $k' \leq n'$ such that $(r, k) \sim_i (r', k')$.*

Proof. The implications from (a) to (b), from (b) to (c), and from (c) to (d) are straightforward. The implication from (d) to (a) can be proved by a straightforward induction on $n + n'$. □

Lemma 2.2 shows that perfect recall requires an unbounded number of local states in general, since agent i may have an infinite number of distinct histories in a given system. A system where agent i has perfect recall is shown in Figure 2.1, where the vertical lines denote runs (with time 0 at the top) and all points that i cannot distinguish are enclosed in the same region.

We remark that the official definition of perfect recall given here is taken from [1]. In [5], part (d) of Lemma 2.2 was taken as the definition of perfect recall (which was called "no forgetting" in that paper).

Roughly speaking, no learning is the dual notion to perfect recall. Perfect recall says that if the agent considers run r' possible at the point (r, n), in that there is a point (r', n') that the agent cannot distinguish from (r, n), then the agent must have

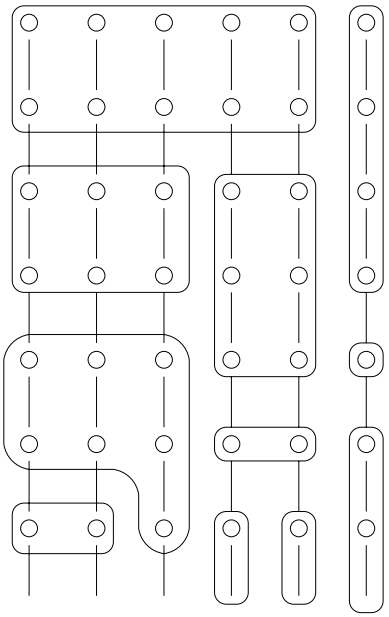

FIG. 2.1. *A system where agent i has perfect recall.*

considered r' possible at all times in the past (i.e., at all points (r, k) with $k \leq n$); it is not possible that the agent once considered r' impossible and then forgot this fact. No learning says that if the agent considers r' possible at (r, n), then the agent will consider r' possible at all times in the future; the agent will not learn anything that will allow him to distinguish r from r'. More formally, we define an agent's *future local-state sequence* at (r, n) to be the sequence of local states $l_0, l_1, \ldots$ that the agent takes on in run r, starting at (r, n), with consecutive repetitions omitted. We say agent i *does not learn* in system $\mathcal{R}$ if at all points (r, n) and (r', n') in $\mathcal{R}$, if $(r, n) \sim_i (r', n')$, then r has the same future local-state sequence at both (r, n) and (r', n').

Just as with perfect recall, there are a number of equivalent formulations of no learning.

LEMMA 2.3. *The following are equivalent.*

(a) *Agent i does not learn in system* $\mathcal{R}$.
(b) *For all points* $(r, n) \sim_i (r', n')$ *in* $\mathcal{R}$, $((r, n), (r, n+1), \ldots)$ *is* $\sim_i$*-concordant with* $((r', n'), (r', n'+1), \ldots)$.
(c) *For all points* $(r, n) \sim_i (r', n')$ *in* $\mathcal{R}$, *either* $(r, n+1) \sim_i (r', n')$ *or there exists a number* $l > n'$ *such that* $(r, n+1) \sim_i (r', l)$ *and for all* k *with* $l > k \geq n'$ *we have* $(r, n) \sim_i (r', k)$.

Notice that we have no analogue to part (d) of Lemma 2.2 in Lemma 2.3 (where $\leq$ is replaced by $\geq$). The analogue of (d) is strictly weaker than (a), (b), and (c), although they are equivalent in synchronous systems (which we are about to define formally). It was just this analogue of (d) that was used to define no learning in [5, 8]. We examine the differences between the notions carefully in section 6, where we provide more motivation for the definition chosen here.

In a *synchronous* system, we assume that every agent has access to a global clock that ticks at every instant of time, and the clock reading is part of its state. Thus,

in a synchronous system, each agent always "knows" the time. More formally, we say that a system $\mathcal{R}$ is *synchronous* if for all agents i and all points (r, n) and (r', n'), if $(r, n) \sim_i (r', n')$, then $n = n'$.[2] Observe that in a synchronous system where $(r, n) \sim_i (r', n)$, an easy induction on n shows that if i has perfect recall and $n > 0$, then $(r, n-1) \sim_i (r', n-1)$, while if i does not learn, then $(r, n+1) \sim_i (r', n+1)$.

Finally, we say that a system $\mathcal{R}$ has a *unique initial state* if for all runs $r, r' \in \mathcal{R}$, we have $r(0) = r'(0)$. Thus, if $\mathcal{R}$ is a system with a unique initial state, then we have $(r, 0) \sim_i (r', 0)$ for all runs r, r' in $\mathcal{R}$ and all agents i.

We say that $\mathcal{I} = (\mathcal{R}, \pi)$ is an interpreted system where agents have perfect recall (resp., agents do not learn, time is synchronous, there is a unique initial state) exactly if $\mathcal{R}$ is a system with that property. We use $\mathcal{C}_m$ to denote the class of all interpreted systems for m agents, and add the superscripts *nl*, *pr*, *sync*, and *uis* to denote particular subclasses of $\mathcal{C}_m$. Thus, for example, we use $\mathcal{C}_m^{nl,pr}$ to denote the set of all interpreted systems with m agents that have perfect recall and do not learn. We omit the subscript m when it is clear from context.

The results of [6, 7, 8] (some of which are based on earlier results of Ladner and Reif [11]) are summarized in Table 2.1. Each entry states a complexity class for which the corresponding problem is complete. For $\varphi \in KL_m$, we define $ad(\varphi)$ to be the greatest number of alternations of distinct K_i's along any branch in φ's parse tree. For example, $ad(K_1 \neg K_2 K_1 p) = 3$; temporal operators are not considered, so that $ad(K_1 \Box K_1 p) = 1$. (In Table 2.1, we do not consider the language CKL_1. This is because if $m = 1$, then $C\varphi$ is equivalent to $K_1\varphi$. Thus, CKL_1 is equivalent to KL_1.) We omit the definitions of complexity classes such as Π_1^1 and nonelementary time $ex(ad(\varphi) + 1, c|\varphi|)$ here; see [9] for details. (Note that c is a constant in the latter expression.) All that matters for our purposes is that for the cases where the complexity is Π_1^1 or co-r.e., there can be no recursive axiomatization; the validity problem is too hard. We provide complete axiomatizations here for the remaining cases.

TABLE 2.1

3. Axiom systems. In this section, we describe the axioms and inference rules that we need for reasoning about knowledge and time for various classes of systems,

[2] We remark that in [5], a slightly weaker definition is given: There, a system is said to be synchronous if for all runs r, if $(r, n) \sim_i (r, n')$, then $n = n'$. It is easy to show (by induction on n) that the two definitions are equivalent for systems where agents have perfect recall. In general, however, they are different. The definition given here is the one used in [1, 8].

and we state the completeness results. The proofs of these results are deferred to section 5.

For reasoning about knowledge alone, the following system, with axioms K1–K5 and rules of inference R1–R2, is well known to be sound and complete [1, 9]:

K1. All tautologies of propositional logic
K2. $K_i\varphi \wedge K_i(\varphi \Rightarrow \psi) \Rightarrow K_i\psi$, $i = 1, \ldots, m$
K3. $K_i\varphi \Rightarrow \varphi$, $i = 1, \ldots, n$
K4. $K_i\varphi \Rightarrow K_iK_i\varphi$, $i = 1, \ldots, m$
K5. $\neg K_i\varphi \Rightarrow K_i\neg K_i\varphi$, $i = 1, \ldots, m$
R1. From φ and $\varphi \Rightarrow \psi$ infer ψ
R2. From φ infer $K_i\varphi$, $i = 1, \ldots, m$

This axiom system is known as $\mathrm{S5}_m$.

For reasoning about the temporal operators individually, the following system (together with K1 and R1), is well known to be sound and complete [3]:

T1. $\bigcirc\varphi \wedge \bigcirc(\varphi \Rightarrow \psi) \Rightarrow \bigcirc\psi$
T2. $\bigcirc(\neg\varphi) \Leftrightarrow \neg\bigcirc\varphi$
T3. $\varphi\, U\, \psi \Leftrightarrow \psi \vee (\varphi \wedge \bigcirc(\varphi\, U\, \psi))$
RT1. From φ infer $\bigcirc\varphi$
RT2. From $\varphi' \Rightarrow \neg\psi \wedge \bigcirc\varphi'$ infer $\varphi' \Rightarrow \neg(\varphi\, U\, \psi)$

The system containing the above axioms and inference rules for both knowledge and time is called $\mathrm{S5}_m^U$. $\mathrm{S5}_m^U$ is easily seen to be sound for $\mathcal{C}_m$, the class of all systems for m agents. Given that there is no necessary connection between knowledge and time in $\mathcal{C}_m$, it is perhaps not surprising that $\mathrm{S5}_m^U$ should be complete with respect to $\mathcal{C}_m$ as well. Interestingly, even if we impose the requirements of synchrony or uis, $\mathrm{S5}_m^U$ remains complete; our language is not rich enough to capture these conditions.

THEOREM 3.1. *$\mathrm{S5}_m^U$ is a sound and complete axiomatization for the language KL_m with respect to $\mathcal{C}_m$, $\mathcal{C}_m^{sync}$, $\mathcal{C}_m^{uis}$, and $\mathcal{C}_m^{sync,uis}$.*

We get the same lack of interaction between knowledge in the classes $\mathcal{C}_m$, $\mathcal{C}_m^{sync}$, $\mathcal{C}_m^{uis}$, and $\mathcal{C}_m^{sync,uis}$ even when we add common knowledge. It is well known that the following two axioms and inference rule characterize common knowledge [1, 4]:

C1. $E\varphi \Leftrightarrow \bigwedge_{i=1}^{m} K_i\varphi$
C2. $C\varphi \Rightarrow E(\varphi \wedge C\varphi)$
RC1. From $\varphi \Rightarrow E(\psi \wedge \varphi)$ infer $\varphi \Rightarrow C\psi$

Let $\mathrm{S5C}_m^U$ be the result of adding C1, C2, and RC1 to $\mathrm{S5}_m^U$. We then have the following extension of Theorem 3.1.

THEOREM 3.2. *$\mathrm{S5C}_m^U$ is a sound and complete axiomatization for the language CKL_m with respect to $\mathcal{C}_m$, $\mathcal{C}_m^{sync}$, $\mathcal{C}_m^{uis}$, and $\mathcal{C}_m^{sync,uis}$.*

If we restrict our attention to systems with perfect recall or no learning, then knowledge and time do interact. We start by stating five axioms of interest and then discuss them.

KT1. $K_i\Box\varphi \Rightarrow \Box K_i\varphi$, $i = 1, \ldots, m$
KT2. $K_i\bigcirc\varphi \Rightarrow \bigcirc K_i\varphi$, $i = 1, \ldots, m$
KT3. $K_i\varphi_1 \wedge \bigcirc(K_i\varphi_2 \wedge \neg K_i\varphi_3) \Rightarrow L_i((K_i\varphi_1)\, U\, [(K_i\varphi_2)\, U\, \neg\varphi_3])$, $i = 1, \ldots, m$
KT4. $K_i\varphi_1\, U\, K_i\varphi_2 \Rightarrow K_i(K_i\varphi_1\, U\, K_i\varphi_2)$, $i = 1, \ldots, m$
KT5. $\bigcirc K_i\varphi \Rightarrow K_i\bigcirc\varphi$, $i = 1, \ldots, m$

Axiom KT1 was first discussed by Ladner and Reif [11]. Informally, this axiom states that if a proposition is known to be always true, then it is always known to be true. It is not hard to show, using Lemma 2.2, that axiom KT1 holds with perfect recall, that is, KT1 is valid in $\mathcal{C}_m^{pr}$. It was conjectured in an early draft of [1] that the

system $S5^U_m + KT1$ would be complete for $\mathcal{C}^{pr}_m$. However, it was shown in [14] that this conjecture was false. To get completeness we need a stronger axiom: KT3.

It is not hard to see that KT3 is valid in systems with perfect recall. A formal proof is provided in section 5, but we can give some intuition here. Suppose that $(\mathcal{I}, r, n) \models K_i\varphi_1 \wedge \bigcirc(K_i\varphi_2 \wedge \neg K_i\varphi_3)$. That means that $(\mathcal{I}, r, n+1) \models \neg K_i\varphi_3$, so there must be some point $(r', n') \sim_i (r, n+1)$ such that $(\mathcal{I}, r', n') \models \neg\varphi_3$. Because agent i has perfect recall, there must exist some $k' \leq n'$ such that $(r', k') \sim_i (r, n)$. It is not hard to show, using Lemma 2.2(c), that $(\mathcal{I}, r', k') \models K_i\varphi_1\, U\, (K_i\varphi_2\, U\, \neg\varphi_3)$. It follows that $(\mathcal{I}, r, n) \models L_i(K_i\varphi_1\, U\, (K_i\varphi_2\, U\, \neg\varphi_3))$.

In the presence of the other axioms, KT3 implies KT1. The following general lemma, which applies to all the proof systems we consider, is useful for the proof.

LEMMA 3.3. *Suppose that* $\vdash \varphi_1 \Leftrightarrow \varphi_2$ *and let* ψ' *be the result of replacing some of the occurrences of* φ_1 *in* ψ *by* φ_2. *Then* $\vdash \psi \Leftrightarrow \psi'$.

Proof. By induction, it suffices to assume that ψ' is the result of replacing one occurrence of φ_1 in ψ by φ_2. The proof proceeds by a straightforward induction on the structure of ψ. □

LEMMA 3.4. KT1 *is provable in* $S5^U_m + KT3$.

Proof. Note that by purely temporal reasoning, we can show $\vdash \Box\varphi \Leftrightarrow \Box\Box\varphi$. Using R2 and K2, this implies that $\vdash K_i\Box\varphi \Leftrightarrow K_i\Box\Box\varphi$. Now if $\varphi_1 = \varphi_2 = \mathit{true}$, then (using 3.3) KT3 simplifies to $\bigcirc\neg K_i\varphi_3 \Rightarrow \neg K_i\Box\varphi_3$. In particular, taking the contrapositive, substituting $\varphi_3 = \Box\varphi$, and using T2, we obtain $\vdash K_i\Box\Box\varphi \Rightarrow \bigcirc K_i\Box\varphi$, which yields $\vdash K_i\Box\varphi \Rightarrow \bigcirc K_i\Box\varphi$ by the equivalence noted above. It is also straightforward to show that $\vdash \Box\varphi \Rightarrow \varphi$, from which it follows, using K2 and R2, that $\vdash K_i\Box\varphi \Rightarrow K_i\varphi$. The axiom KT1 now follows using the rule RT2 (using the fact that $\Box\varphi$ is an abbreviation for $\neg(\mathit{true}\, U\, \neg\varphi)$). □

KT3 turns out to be strong enough to give us completeness, with or without the condition uis.

THEOREM 3.5. $S5^U_m + KT3$ *is a sound and complete axiomatization for the language* KL_m *with respect to* $\mathcal{C}^{pr}_m$ *and* $\mathcal{C}^{pr,uis}_m$.

Theorem 3.1 shows that requiring synchrony or uis does not have an impact when we consider the class of all systems—$\mathcal{C}_m$, $\mathcal{C}^{sync}_m$, $\mathcal{C}^{uis}_m$, and $\mathcal{C}^{sync,uis}_m$ are all axiomatized by $S5^U_m$—and Theorem 3.5 shows that adding uis does not have an impact in the presence of perfect recall. However, requiring synchrony does have an impact in the presence of perfect recall. It is easy to see that KT2 is valid in $\mathcal{C}^{pr,sync}_m$, and it clearly is not valid in $\mathcal{C}^{pr}_m$. Moreover, KT2 suffices for completeness in $\mathcal{C}^{pr,sync}_m$; we do not need the complications of KT3.

THEOREM 3.6. $S5^U_m + KT2$ *is a sound and complete axiomatization for the language* KL_m *with respect to* $\mathcal{C}^{pr,sync}_m$ *and* $\mathcal{C}^{pr,sync,uis}_m$.

KT4 is the axiom that characterizes no learning. More precisely, we have the following.

THEOREM 3.7. $S5^U_m + KT4$ *is a sound and complete axiomatization for the language* KL_m *with respect to* $\mathcal{C}^{nl}_m$.

Unlike previous cases, the uis assumption is not innocuous in the presence of nl. For one thing, it is not hard to check that assuming uis leads to extra properties. Indeed, as Table 2.1 shows, if $m \geq 2$, then assuming a unique initial state along with no learning results in a class of systems that do not have a recursive axiomatic characterization, since the validity problem is co-r.e.-complete. On the other hand, if there is only one agent in the picture, things simplify. No learning together with uis implies perfect recall. Thus, we get the following.

THEOREM 3.8. $S5_m^U + KT3 + KT4$ *is a sound and complete axiomatization for the language* KL_m *with respect to* $\mathcal{C}_m^{nl,pr}$. *Moreover, it is a sound and complete axiomatization for the language* KL_1 *with respect to* $\mathcal{C}_1^{nl,pr,uis}$.

In synchronous systems with no learning, things again become simpler. KT5, the converse of KT2, suffices to characterize such systems.

THEOREM 3.9. $S5_m^U + KT5$ *is a sound and complete axiomatization for the language* KL_m *with respect to* $\mathcal{C}_m^{nl,sync}$.

Of course, it follows from Theorem 3.9 that KT4 can be derived in the system $S5_m^U + KT5$ (although this result takes some work to prove directly).

Not surprisingly, if we combine perfect recall, no learning, and synchrony, then KT2 and KT5 give us a complete axiomatization.

THEOREM 3.10. $S5_m^U + KT2 + KT5$ *is a sound and complete axiomatization for the language* KL_m *with respect to* $\mathcal{C}_m^{nl,pr,sync}$.

Finally, it can be shown that when we combine no learning, synchrony, and uis, then not only do all agents consider the same worlds possible initially, but they consider the same worlds possible at all times. As a result, the axiom $K_i\varphi \Leftrightarrow K_j\varphi$ is valid in this case. This allows us to reduce to the single-agent case. Moreover, as we observed above, in the single-agent case, no learning and uis imply perfect recall. Thus, we get the following result.

THEOREM 3.11. $S5_m^U + KT2 + KT5 + \{K_i\varphi \Leftrightarrow K_1\varphi\}$ *is a sound and complete axiomatization for the language* KL_m *with respect to* $\mathcal{C}_m^{nl,sync,uis}$ *and* $\mathcal{C}_m^{nl,pr,sync,uis}$.

A glance at Table 2.1 shows that we have now provided axiomatizations for all the cases where complete axiomatizations exist. (Notice that for the language CKL_m, if $m = 1$, then common knowledge reduces to knowledge, while if $m > 1$, then complete axiomatizations can exist only for $\mathcal{C}_m$, $\mathcal{C}_m^{sync}$, $\mathcal{C}_m^{uis}$, $\mathcal{C}_m^{sync,uis}$, $\mathcal{C}_m^{nl,sync,uis}$, and $\mathcal{C}_m^{nl,pr,sync,uis}$. The first four cases were dealt with in Theorem 3.2, while in the last two, as we have observed, common knowledge reduces to the knowledge of agent 1.)

4. A framework for completeness proofs. In this section we develop a general framework for completeness proofs that reduces the work required in each of the different completeness results to a single lemma. With respect to the temporal dimension, our constructions resemble those previously used for completeness of dynamic logic [10] and temporal logics, in that we construct a model for a consistent formula ψ out of consistent subsets of a finite set of formulas, called the *closure* of ψ. However, in order to deal with the knowledge modalities, we need a number of distinct levels of closure, having a tree-like structure. At the leaves of this tree-like structure, the closure is like the usual closure for temporal logic. As we move towards the root, we add formulas to the closure that increase the level of nesting of the knowledge modalities.

A formula ψ is said to be *consistent* in a logic $\mathcal{L}$ if it is not the case that $\vdash_{\mathcal{L}} \neg\psi$. For each of the pairs $(\mathcal{L}, \mathcal{C})$ of logic $\mathcal{L}$ and class $\mathcal{C}$ of systems we consider, the proof that $\mathcal{L}$ is complete with respect to $\mathcal{C}$ proceeds by constructing, for every formula ψ consistent with respect to $\mathcal{L}$, a system in $\mathcal{C}$ containing a point at which ψ is true. All the results in this section hold for every logic containing $S5_m^U$, except for Lemma 4.8, which mentions common knowledge. This lemma holds for every logic containing $S5C_m^U$. Rather than mentioning the logic $\mathcal{L}$ explicitly in each case, we just write $\vdash$ rather than $\vdash_{\mathcal{L}}$; the intended logic(s) will be clear from context. We also fix the formula ψ, which is assumed to be consistent with respect to $\mathcal{L}$.

A finite sequence $\sigma = i_1 i_2 \ldots i_k$ of agents, possibly equal to the null sequence ϵ, is called an *index* if $i_l \neq i_{l+1}$ for all $l < k$. We write $|\sigma|$ for the length k of such a sequence; the null sequence has length equal to 0.

If S is a set, and S^* is the set of all finite sequences over S, we define the absorptive concatenation function $\#$ from $S^* \times S$ to S^* as follows. Given a sequence σ in S^* and an element x of S, we take $\sigma\#x = \sigma$ if the final element of σ is x. If the final element of σ is not equal to x, then we take $\sigma\#x$ to be σx, i.e., the result of concatenating x to σ. We write simply $x_1\#x_2\#x_3\#\ldots\#x_n$ for $(\ldots((x_1\#x_2)\#x_3)\ldots)\#x_n$. We shall have two distinct uses for this function, applying it primarily to sequences of agents, and sometimes to sequences of "instantaneous states" of agents in the context of asynchronous systems.

If $\psi \in CKL_m$, for each $k \geq 0$, we define the k-closure $cl_k(\psi)$, and for each agent i, we define the k,i-closure $cl_{k,i}(\psi)$. The definition of these sets proceeds by mutual recursion: First, we let the *basic closure* $cl_0(\psi)$ be the smallest set containing ψ that is closed under subformulas, contains $\neg\varphi$ if it contains φ and φ is not of the form $\neg\varphi'$, contains $EC\varphi$ if it contains $C\varphi$, and contains $K_1\varphi, \ldots, K_m\varphi$ if it contains $E\varphi$. (Of course, the last two clauses do not apply if ψ is in KL_m, and thus does not mention common knowledge.) If i is an agent, we take $cl_{k,i}(\psi)$ to be the union of $cl_k(\psi)$ with the set of formulas of the form $K_i(\varphi_1 \vee \cdots \vee \varphi_n)$ or $\neg K_i(\varphi_1 \vee \cdots \vee \varphi_n)$, where the φ_l are distinct formulas in $cl_k(\psi)$. (It is not necessary to close under subformulas here, since the disjunctions in these formulas are already "decided" in the sense defined below.) Finally, $cl_{k+1}(\psi)$ is defined to be $\bigcup_{i=1}^{m} cl_{k,i}(\psi)$.

If X is a finite set of formulas, we write φ_X for the conjunction of the formulas in X. A finite set X of formulas is said to be consistent if φ_X is consistent. If X is a finite set of formulas and φ is a formula, we write $X \Vdash \varphi$ when $\vdash \varphi_X \Rightarrow \varphi$.[3] A finite set Cl of formulas is said to be *negation closed* if, for all $\varphi \in Cl$, either $\neg\varphi \in Cl$ or φ is of the form $\neg\varphi'$ and $\varphi' \in Cl$. (Note that the sets $cl_k(\psi)$ and $cl_{k,i}(\psi)$ are negation closed.) We define an *atom* of Cl to be a maximal consistent subset of Cl.

The following lemma collects a number of obvious facts that we typically use without comment.

LEMMA 4.1. *Suppose that X is a finite set of formulas and Cl is a negation-closed set of formulas.*

(a) *If $X \Vdash \varphi_1$ and $\vdash \varphi_1 \Rightarrow \varphi_2$, then $X \Vdash \varphi_2$.*

(b) *If X is an atom of Cl and $\varphi \in Cl$, then either $X \Vdash \varphi$ or $X \Vdash \neg\varphi$.*

(c) *If $\vdash$ denotes provability in a proof system containing* K1 *and* R1*, then $\vdash \bigvee_{X \text{ an atom of } Cl} \varphi_X$.*

Proof. All parts of the lemma are quite easy. We remark that (c) follows from the observation that $\bigvee_{X \text{ an atom of } Cl} \varphi_X$ is equivalent to *true*, which can be easily proved using only propositional reasoning (K1 and R1). □

We begin the construction of the model of ψ by first constructing a *premodel*, which is a structure $\langle S, \rightarrow, \approx_1, \ldots, \approx_n\rangle$ consisting of a set S of states, a binary relation $\rightarrow$ on S, and for each agent i an equivalence relation $\approx_i$ on S. Recall from section 2 that for a formula $\varphi \in KL_m$, the alternation depth $ad(\varphi)$ is the number of alternations of distinct operators K_i in φ. Let $d = ad(\psi)$ if $\psi \in KL_m$; otherwise (that is, if ψ mentions the modal operator C), let $d = 0$.

The set S consists of all the pairs (σ, X) such that σ is an index, $|\sigma| \leq d$, and

1. if $\sigma = \epsilon$, then X is an atom of $cl_d(\psi)$; and
2. if $\sigma = \tau i$, then X is an atom of $cl_{k,i}(\psi)$, where $k = d - |\sigma|$.

We can partition the set S of states into sets S_σ according to the first component;

[3] Note that $X \Vdash \varphi$ is not equivalent to $X \vdash \varphi$ (under perhaps the most natural definition of $\vdash$ with sets of formulas on the left-hand side) because of generalization rules like R2 and RT1. For example, although $\varphi \vdash K_i\varphi$, it is not the case that $\vdash \varphi \Rightarrow K_i\varphi$.

that is, $S_\sigma = \{(\sigma, X) \mid (\sigma, X) \in S\}$. The indices σ put a tree-like structure on this collection. Note that as $|\sigma|$ decreases, the size of the closure from which the atoms X are drawn increases.

The relation $\rightarrow$ is defined so that $(\sigma, X) \rightarrow (\tau, Y)$ iff $\tau = \sigma$ and the formula $\varphi_X \wedge \bigcirc\varphi_Y$ is consistent. If X is an atom, we write X/K_i for the set of formulas φ such that $K_i\varphi \in X$. We say that states (σ, X) and (τ, Y) are *i-adjacent* if $\sigma\#i = \tau\#i$. The relation $\approx_i$ is defined so that $(\sigma, X) \approx_i (\tau, Y)$ iff σ and τ are i-adjacent and $X/K_i = Y/K_i$. Clearly, i-adjacency is an equivalence relation, as is the relation $\approx_i$.

A *σ-state (for ψ)* is a pair (σ, X) as above. A state (for ψ) is a σ-state for some index σ with $|\sigma| \leq d$. Thus (σ, X) is the unique σ-state with atom X. If $s = (\sigma, X)$ is a state, we define φ_s to be the formula φ_X, and write $s \Vdash \varphi$ for $\vdash \varphi_s \Rightarrow \varphi$. We say that the state s *directly decides* a formula φ if either (a) $\varphi \in X$, (b) $\neg\varphi \in X$, or (c) $\varphi = \neg\varphi'$ and $\varphi' \in X$. We say that s *decides* φ if either $s \Vdash \varphi$ or $s \Vdash \neg\varphi$. Clearly, if s directly decides φ, then s decides φ. Note that if $\sigma = \tau i$, then, by Lemma 4.1(b), each σ-state directly decides every formula in $cl_{d-|\sigma|,i}(\psi)$. Also, every ϵ-state directly decides every formula in $cl_d(\sigma)$.

LEMMA 4.2. *If s and t are i-adjacent states, then the same formulas of the form $K_i\varphi$ are directly decided by s and t.*

Proof. Suppose that s and t are i-adjacent, $s = (\sigma, X)$ and $t = (\tau, Y)$. By definition, we have that either (i) $\sigma = \tau$, (ii) $\sigma = \tau i$, or (iii) $\sigma i = \tau$. Clearly if $\sigma = \tau$, then s and t directly decide the same formulas (and, a fortiori, the same formulas of the form $K_i\varphi$) since they are both maximal consistent subsets of the same set of formulas. If $\sigma \neq \tau$, then either $\sigma = \tau i$ or $\tau = \sigma i$. By symmetry, it suffices to deal with the case $\sigma = \tau i$. By definition, s directly decides the K_i-formulas in $cl_{d-|\sigma|,i}(\psi)$, while t directly decides the K_i-formulas in $cl_{d-|\tau|,j}(\psi)$ if $\tau = \tau' j$ or $cl_d(\psi)$ if $\tau = \epsilon$. Thus, it suffices to show that, for all formulas φ and agents j, we have that $K_i\varphi \in cl_{k,i}(\psi)$ iff $K_i\varphi \in cl_{k+1,j}$ if $k < d-1$ and that $K_i\varphi \in cl_{d-1,i}(\psi)$ iff $K_i\varphi \in cl_d(\psi)$. This is immediate from the definitions. □

If s is a σ-state, we take $\Phi_{s,i}$ to be the disjunction of the formulas φ_t, where t ranges over the σ-states satisfying $s \approx_i t$, and we take $\Phi^+_{s,i}$ to be the disjunction of the formulas φ_t, where t ranges over the $(\sigma\#i)$-states satisfying $s \approx_i t$.[4] Observe that because $\approx_i$ is an equivalence relation we have that if $s \approx_i t$, then $\Phi_{s,i} = \Phi_{t,i}$ and $\Phi^+_{s,i} = \Phi^+_{t,i}$. The following result lists a number of knowledge formulas decided by states.

LEMMA 4.3.

(a) *If s is a σ-state and t is a σ-state or $(\sigma\#i)$-state such that $s \not\approx_i t$, then $s \Vdash K_i\neg\varphi_t$.*
(b) *For all σ-states s, we have $s \Vdash K_i\Phi_{s,i}$; in addition, if $|\sigma\#i| \leq d$, then $s \Vdash K_i\Phi^+_{s,i}$.*
(c) *For all σ-states s and $(\sigma\#i)$-states t with $s \approx_i t$, we have $s \Vdash L_i\varphi_t$.*
(d) *If s is a σ-state and t is a $(\sigma\#i)$-state such that $s \not\approx_i t$, then $t \Vdash \neg K_i\Phi^+_{s,i}$.*

Proof. For (a), suppose that $s \not\approx_i t$, where $s = (\sigma, X)$ and $t = (\tau, Y)$, where τ is either σ or $\sigma\#i$. Then $X/K_i \neq Y/K_i$ so either there exists a formula $K_i\varphi \in X$ such that $K_i\varphi \notin Y$ or there exists a formula $K_i\varphi \in Y$ such that $K_i\varphi \notin X$. As the states s and t are i-adjacent, by Lemma 4.2, in either case the formula $K_i\varphi$ is directly decided by both the states s and t. In the first case, since $K_i\varphi \notin Y$ and $K_i\varphi$ is directly decided by t, it follows that $\neg K_i\varphi \in Y$, and hence that $\vdash \varphi_t \Rightarrow \neg K_i\varphi$. Using R2, it

[4] It can be shown that if $|\sigma\#i| \leq d$, then $\Phi_{s,i}$ is logically equivalent to $\Phi^+_{s,i}$, but we do not need this fact here.

follows that $\vdash K_i(K_i\varphi \Rightarrow \neg\varphi_t)$. By K4 we obtain from the fact that $K_i\varphi \in X$ that $s \Vdash K_iK_i\varphi$. It now follows using K2 that $s \Vdash K_i\neg\varphi_t$. In the second case, we have that $\vdash \varphi_t \Rightarrow K_i\varphi$, and hence, using R2, that $\vdash K_i(\neg K_i\varphi \Rightarrow \neg\varphi_t)$. By K4 we obtain from the fact that $\neg K_i\varphi \in X$ that $s \Vdash K_i\neg K_i\varphi$. It now follows using K2 that $s \Vdash K_i\neg\varphi_t$.

For (b), by Lemma 4.1(c), we have that $\vdash \bigvee_{X \text{ an atom of } cl_{k,i}(\psi)} \varphi_X$. Hence, by R2 we obtain that $\vdash K_i \bigvee_{\sigma\text{-states } t} \varphi_t$. It follows from this using (a) and K2 that $s \Vdash K_i\Phi_{s,i}$. If $|\sigma\#i| \leq d$, then a similar argument shows that $s \Vdash K_i\Phi^+_{s,i}$.

For (c), suppose that $s = (\sigma, X) \approx_i (\sigma\#i, Y) = t$ and $k = d - |\sigma\#i|$. We claim first that if $W = Y \cap cl_k(\psi)$, then $s \Vdash K_i\neg\varphi_t \Leftrightarrow K_i\neg\varphi_W$. This is because the fact that Y is a subset of $cl_{k,i}(\psi)$ implies that all formulas φ in $Y \setminus W$ are of the form $K_i\varphi'$ or $\neg K_i\varphi'$, and hence $\varphi \in X$ iff $\varphi \in Y$. Also, by K4 and K5 we have that $s \Vdash K_iK_i\varphi'$ when $K_i\varphi' \in X$ and $s \Vdash K_i\neg K_i\varphi'$ when $K_i\varphi' \notin X$. It follows using K2 that $s \Vdash K_i\varphi_{Y\setminus W}$. Since φ_t is equivalent to $\varphi_W \wedge \varphi_{Y\setminus W}$, we obtain using K2 that $s \Vdash K_i\neg\varphi_t \Leftrightarrow K_i\neg\varphi_W$.

Now by K3 we have $\vdash \varphi_t \Rightarrow L_i\varphi_t$. Further, the argument of the previous paragraph also shows $t \Vdash K_i\neg\varphi_t \Leftrightarrow K_i\neg\varphi_W$, so we obtain that $t \Vdash L_i\varphi_W$. But $\neg\varphi_W$ is equivalent to the disjunction of a subset $\{\varphi_1, \ldots, \varphi_n\}$ of $cl_k(\psi)$. Let α be the formula $K_i(\varphi_1 \vee \cdots \vee \varphi_n)$, which is equivalent to $K_i\neg\varphi_W$. It follows from the definition of $cl_{k,i}(\psi)$ that α is in $cl_{k,i}(\psi)$, and hence directly decided by both t and s. Consequently, α is not in Y, since $t \Vdash \neg\alpha$. Because $X/K_i = Y/K_i$, the formula α is not in X either, so $s \Vdash \neg\alpha$. Applying the fact that α is equivalent to $K_i\neg\varphi_W$, we see that $s \Vdash L_i\varphi_W$. The equivalence of the previous paragraph now yields that $s \Vdash L_i\varphi_t$.

For (d), note that if t and v are distinct $(\sigma\#i)$-states, then $t \Vdash \neg\varphi_v$. Thus, if s is a σ-state such that $s \not\approx_i t$, then $t \Vdash \neg\Phi^+_{s,i}$, which implies, using K3, that $t \Vdash \neg K_i\Phi^+_{s,i}$. □

If T is a set of states, then we write φ_T for the disjunction of the formulas φ_t for t in T. Using RT1, T1, and T2, the following result is immediate from the fact that $s \nrightarrow t$ implies $\vdash \varphi_s \Rightarrow \neg\bigcirc\varphi_t$, together with the fact that $\vdash \bigvee_{s \text{ a } \sigma\text{-state}} \varphi_s$, which follows from Lemma 4.1(c).

LEMMA 4.4. *Let s be a state and let T be the set of states t such that $s \to t$. Then $s \Vdash \bigcirc\varphi_T$.*

The next result provides a useful way to derive formulas containing the "until" operator.

LEMMA 4.5. *For all formulas α, β, and γ, if $\vdash \alpha \Rightarrow (\neg\gamma \wedge \bigcirc(\alpha \vee (\neg\beta \wedge \neg\gamma)))$, then $\vdash \alpha \Rightarrow \neg(\beta\, U\, \gamma)$.*

Proof. Suppose that $\vdash \alpha \Rightarrow \neg\gamma \wedge \bigcirc(\alpha \vee (\neg\beta \wedge \neg\gamma))$. By T3, we obtain that $\vdash \alpha \wedge (\beta\, U\, \gamma) \Rightarrow \neg\gamma \wedge \bigcirc(\beta\, U\, \gamma) \wedge \bigcirc(\alpha \vee (\neg\beta \wedge \neg\gamma))$. Since, by T3 again, $\vdash \beta\, U\, \gamma \Rightarrow \neg(\neg\beta \wedge \neg\gamma)$, it follows using T1 and RT1 that $\vdash \alpha \wedge (\beta U \gamma) \Rightarrow \neg\gamma \wedge \bigcirc(\alpha \wedge (\beta U \gamma))$. Now using RT2 we obtain $\vdash \alpha \wedge (\beta U \gamma) \Rightarrow \neg(\beta U \gamma)$, which implies that $\vdash \alpha \Rightarrow \neg(\beta U \gamma)$. □

The following shows that the premodel has properties resembling those for the truth definitions for formulas in the basic closure. Note that every state directly decides all formulas in the basic closure. Define a *$\to$-sequence* of states to be a (finite or infinite) sequence $s_1, s_2, \ldots$ such that $s_1 \to s_2 \to \cdots$.

LEMMA 4.6. *For all σ-states s, we have the following:*

(a) *If $\bigcirc\varphi \in cl_0(\psi)$, then for all states t such that $s \to t$, we have $s \Vdash \bigcirc\varphi$ iff $t \Vdash \varphi$.*

(b) *If $K_i\varphi \in cl_0(\psi)$, then $s \Vdash \neg K_i\varphi$ iff there is some σ-state t such that $s \approx_i t$ and $t \Vdash \neg\varphi$. Moreover, if $|\sigma\#i| \leq d$, then $s \Vdash \neg K_i\varphi$ iff there is some $(\sigma\#i)$-state t such that $s \approx_i t$ and $t \Vdash \neg\varphi$.*

(c) *If $\varphi_1 U \varphi_2 \in cl_0(\psi)$, then $s \Vdash \varphi_1 U \varphi_2$ iff there exists a $\rightarrow$-sequence $s = s_0 \rightarrow s_1 \rightarrow \cdots \rightarrow s_n$, where $n \geq 0$, such that $s_n \Vdash \varphi_2$, and $s_k \Vdash \varphi_1$ for all $k < n$.*

Proof. For part (a), suppose first that $s \Vdash \bigcirc\varphi$ and $s \rightarrow t$. Since $\varphi \in cl_0(\psi)$, it follows that $t \Vdash \varphi$ or $t \Vdash \neg\varphi$. However, by T1 and T2, the latter would contradict the assumption that $\varphi_s \wedge \bigcirc\varphi_t$ is consistent. Hence we have $t \Vdash \varphi$. Conversely, suppose that $s \rightarrow t$ and $t \Vdash \varphi$. Using T1, we have $\vdash \bigcirc\varphi_t \Rightarrow \bigcirc\varphi$. Since $\bigcirc\varphi \in cl_0(\psi)$ we have either $s \Vdash \bigcirc\varphi$ or $s \Vdash \neg\bigcirc\varphi$. But the latter would contradict $s \rightarrow t$, so we obtain $s \Vdash \bigcirc\varphi$.

For the "if" direction of part (b), note that the fact that $K_i\varphi$ is in $cl_0(\psi)$ implies that if $s \approx_i t$ and $s \Vdash K_i\varphi$, then $t \Vdash K_i\varphi$, and hence $t \Vdash \varphi$ by K3. For the converse, suppose that $t \Vdash \varphi$ for all σ-states t with $s \approx_i t$. Then $\vdash \Phi_{s,i} \Rightarrow \varphi$, and hence $\vdash K_i\Phi_{s,i} \Rightarrow K_i\varphi$, using K2 and R2. By Lemma 4.3(b), we have $s \Vdash K_i\Phi_{s,i}$. It follows immediately that $s \Vdash K_i\varphi$. If $|\sigma\#i| \leq d$, a similar argument shows that if $t \Vdash \varphi$ for all $(\sigma\#i)$-states t such that $s \approx_i t$, then $s \Vdash K_i\varphi$.

For part (c), note that if $\varphi_1 U \varphi_2$ is in $cl_0(\psi)$, then every state directly decides each of the formulas φ_1, φ_2, and $\varphi_1 U \varphi_2$. We first show that if there exists a sequence of states $s = s_0 \rightarrow s_1 \rightarrow \cdots \rightarrow s_n$ such that $s_n \Vdash \varphi_2$ and $s_k \Vdash \varphi_1$ for all $k < n$, then $s \Vdash \varphi_1 U \varphi_2$. We proceed by induction on n. The case $n = 0$ is immediate from T3. For the general case, notice that it follows from the induction hypothesis that $s_1 \Vdash (\varphi_1 U \varphi_2)$. Since $s_0 \rightarrow s_1$, it follows that $\varphi_{s_0} \wedge \bigcirc(\varphi_1 U \varphi_2)$ is consistent. By assumption, we also have $s_0 \Vdash \varphi_1$. Using T3, we see that $s_0 \Vdash \neg(\varphi_1 U \varphi_2)$ would be a contradiction. Hence $s_0 \Vdash \varphi_1 U \varphi_2$.

The converse follows immediately from Lemma 4.7 below. □

LEMMA 4.7. *If $\varphi_s \wedge (\varphi_1 U \varphi_2)$ is consistent, then there exists a $\rightarrow$-sequence $s = s_0 \rightarrow s_1 \rightarrow \cdots \rightarrow s_n$, such that $\varphi_{s_n} \wedge \varphi_2$ is consistent, and $\varphi_{s_k} \wedge \varphi_1$ is consistent for all $k < n$.*

Proof. Suppose by way of contradiction that $\varphi_s \wedge (\varphi_1 U \varphi_2)$ is consistent and no appropriate $\rightarrow$-sequence exists. Let T be the smallest set S of states such that (i) $s \in S$, and (ii) if $t \in S$, $t \rightarrow u$, and $s_u \wedge \varphi_1$ is consistent, then $u \in S$. Then we have that $t \Vdash \neg\varphi_2$ for all $t \in T$, so $\vdash \varphi_T \Rightarrow \neg\varphi_2$. In addition, for each $t \in T$ and state u such that $t \rightarrow u$, we have either $u \in T$ or $u \Vdash \neg\varphi_1 \wedge \neg\varphi_2$. Thus, using Lemma 4.4, we obtain $\vdash \varphi_T \Rightarrow \bigcirc(\varphi_T \vee (\neg\varphi_1 \wedge \neg\varphi_2))$. It now follows using Lemma 4.5 that $\vdash \varphi_T \Rightarrow \neg(\varphi_1 U \varphi_2)$. In particular, since $s \in T$, we have $s \Vdash \neg(\varphi_1 U \varphi_2)$, which contradicts the assumption that $\varphi_s \wedge (\varphi_1 U \varphi_2)$ is consistent. □

For the next result, recall that when the formula ψ contains the common knowledge operator we take $d = 0$, so that all states are ϵ-states.

LEMMA 4.8. *If $C\varphi \in cl_0(\psi)$, then $s \Vdash \neg C\varphi$ iff there is a state t reachable from s through the relations $\approx_i$ such that $t \Vdash \neg\varphi$.*

Proof. The implication from right to left is a straightforward consequence of the fact that if $t \Vdash \neg\varphi$, then $t \Vdash \neg C\varphi$, by C1, C2, and K3, together with the fact that if $t \approx_i t'$, then $t \Vdash C\varphi$ iff $t' \Vdash C\varphi$. (Proof of the latter fact: If $t \Vdash C\varphi$, then $t \Vdash K_iC\varphi$ by C1 and C2. Hence, since $t \approx_i t'$ and $K_iC\varphi \in cl_0(\psi)$, we must have $t' \Vdash C\varphi$. The opposite direction follows symmetrically.) This leaves only the implication from left to right, for which we prove the contrapositive. Suppose that no state containing $\neg\varphi$ is reachable from s by means of a sequence of steps through the relations $\approx_i$. Let T be the set of states reachable from s. By Lemma 4.3(a), if t and t' are states with $t \not\approx_i t'$, then $t \Vdash K_i\neg\varphi_{t'}$. It follows from this that $t \Vdash K_i\varphi_T$ for every state $t \in T$ and agent i. Thus, because $\vdash \varphi_T \Rightarrow \varphi$ we have $\vdash \varphi_T \Rightarrow E(\varphi_T \wedge \varphi)$. By RC1 it follows that $\vdash \varphi_T \Rightarrow C\varphi$. Since $s \in T$, it is immediate that $s \Vdash C\varphi$. □

We say that an infinite $\rightarrow$-sequence of states $(s_0, s_1, \ldots)$, where $s_n = (\sigma, X_n)$ for all n, is *acceptable* if for all $n \geq 0$, if $\varphi_1 \, U \, \varphi_2 \in X_n$, then there exists an $m \geq n$ such that $s_m \Vdash \varphi_2$ and $s_k \Vdash \varphi_1$ for all k with $n \leq k < m$.

DEFINITION 4.9. *An* enriched system *for ψ is a pair $(\mathcal{R}, \Sigma)$, where $\mathcal{R}$ is a set of runs and Σ is a* partial *function mapping points in $\mathcal{R} \times \mathbb{N}$ to states for ψ such that the following hold for all runs $r \in \mathcal{R}$:*

1. *If $\Sigma(r, n)$ is defined, then $\Sigma(r, n')$ is defined for all $n' > n$, and $\Sigma(r, n)$, $\Sigma(r, n+1), \ldots$ is an acceptable $\rightarrow$-sequence.*
2. *For all points $(r, n) \sim_i (r', n')$, if $\Sigma(r, n)$ is defined, then $\Sigma(r', n')$ is defined and $\Sigma(r, n) \approx_i \Sigma(r', n')$.*
3. *If $\Sigma(r, n)$ and s are σ-states such that $\Sigma(r, n) \approx_i s$, then there exists a point (r', n') such that $(r, n) \sim_i (r', n')$ and $\Sigma(r', n') = s$.*
4. *If $C\varphi \in cl_0(\psi)$ and $\Sigma(r, n) \Vdash \neg C\varphi$, then there exists a point (r', n') reachable from (r, n) such that $\Sigma(r', n') \Vdash \neg\varphi$.*

An enriched$^+$ system *for ψ is a pair $(\mathcal{R}, \Sigma)$ satisfying conditions* 1, 2, *and the following modification of* 3*:*

3′. *If $\Sigma(r, n)$ is a σ-state and s is a $(\sigma \# i)$-state such that $\Sigma(r, n) \approx_i s$, then there exists a point (r', n') such that $(r, n) \sim_i (r', n')$ and $\Sigma(r', n') = s$.*

Intuitively, in an enriched (resp., enriched$^+$) system, the points where Σ is defined are the points that are "relevant" to the truth of certain formulas at certain points.

Given an enriched (resp., enriched$^+$) system $(\mathcal{R}, \Sigma)$, we obtain an interpreted system $\mathcal{I} = (\mathcal{R}, \pi)$ by defining the valuation π on basic propositions p by $\pi(r, n)(p) =$ **true** just when $\Sigma(r, n)$ is defined and $\Sigma(r, n) \Vdash p$.[5] The following theorem gives a sufficient condition for a formula in the basic closure to hold at a point in this standard system. If σ is the index $i_1 \ldots i_k$, let $K_\sigma\varphi$ be an abbreviation for $K_{i_1} \ldots K_{i_k}\varphi$. (If $\sigma = \epsilon$, then we take $K_\sigma\varphi$ to be φ.)

THEOREM 4.10.

(a) *If $(\mathcal{R}, \Sigma)$ is an enriched system for ψ, $\mathcal{I}$ is the associated interpreted system, φ is in the basic closure $cl_0(\psi)$, and $\Sigma(r, n)$ is defined, then $(\mathcal{I}, r, n) \vDash \varphi$ iff $\Sigma(r, n) \Vdash \varphi$.*

(b) *If $(\mathcal{R}, \Sigma)$ is an enriched$^+$ system for $\psi \in KL_m$, $\mathcal{I}$ is the associated standard system, φ is in the basic closure $cl_0(\psi)$, $\Sigma(r, n)$ is a σ-state, and $ad(K_\sigma\varphi) \leq d$, then $(\mathcal{I}, r, n) \vDash \varphi$ iff $\Sigma(r, n) \Vdash \varphi$.*

Proof. We first prove part (a). We proceed by induction on the complexity of φ. If φ is a propositional constant, then the result is immediate from the definition of $\mathcal{I}$. The cases where φ is of the form $\neg\varphi_1$ or $\varphi_1 \wedge \varphi_2$ are similarly trivial. This leaves five cases.

Case 1. Suppose that φ is of the form $\bigcirc\varphi_1$. Then $(\mathcal{I}, r, n) \vDash \varphi$ iff $(\mathcal{I}, r, n+1) \vDash \varphi_1$. Note that $\Sigma(r, n+1)$ must be defined by condition 1 of Definition 4.9. Since φ_1 is a subformula of φ it is in $cl_0(\psi)$, so it follows by the induction hypothesis that $(\mathcal{I}, r, n+1) \vDash \varphi_1$ holds precisely when $\Sigma(r, n+1) \Vdash \varphi_1$. By condition 1, $\Sigma(r, n) \rightarrow \Sigma(r, n+1)$, so we obtain from Lemma 4.6(a) that $\Sigma(r, n+1) \Vdash \varphi_1$ iff $\Sigma(r, n) \Vdash \bigcirc\varphi_1$. Putting the pieces together, we get $(\mathcal{I}, r, n) \vDash \varphi$ iff $\Sigma(r, n) \Vdash \varphi$.

Case 2. Suppose that φ is of the form $\varphi_1 \, U \, \varphi_2$. Then the subformulas φ_1 and φ_2 are also in $cl_0(\psi)$. Note also that by condition 1 of Definition 4.9, $\Sigma(r, n')$ is defined for all $n' \geq n$, and $\Sigma(r, n), \Sigma(r, n+1), \ldots$ is an acceptable $\rightarrow$-sequence. Thus, if $\Sigma(r, n) \Vdash \varphi_1 U \varphi_2$, then, by the definition of acceptability, there exists some $n' \geq n$ such

[5] This definition makes p false at points where Σ is undefined. We could just as well have made p true at such points, without changing our results.

that $\Sigma(r,n') \Vdash \varphi_2$ and $\Sigma(r,k) \Vdash \varphi_1$ for $n \le k < n'$. By the induction hypothesis, this implies that $(\mathcal{I},r,n') \models \varphi_2$ and $(\mathcal{I},r,k) \models \varphi_1$ for $n \le k < n'$. In other words, we have $(\mathcal{I},r,n) \models \varphi_1 \, U \, \varphi_2$. Conversely, if $(\mathcal{I},r,n) \models \varphi_1 \, U \, \varphi_2$, then by the induction hypothesis and the semantics of U we have that there exists some $n' \ge n$ such that $\Sigma(r,n') \Vdash \varphi_2$ and $\Sigma(r,k) \Vdash \varphi_1$ for $n \le k < n'$. Since $\Sigma(r,n) \to \Sigma(r,n+1) \to \cdots \to \Sigma(r,n')$, it follows using Lemma 4.6(c) that $\Sigma(r,n) \Vdash \varphi_1 \, U \, \varphi_2$.

Case 3. Suppose that φ is of the form $K_i\varphi_1$. We first show that $\Sigma(r,n) \Vdash K_i\varphi_1$ implies $(\mathcal{I},r,n) \models K_i\varphi_1$. Assume $\Sigma(r,n) \Vdash K_i\varphi_1$ and suppose that $(r,n) \sim_i (r',n')$. Then by condition 2 of Definition 4.9, we have that $\Sigma(r',n')$ is defined and $\Sigma(r,n) \approx_i \Sigma(r',n')$. Since $K_i\varphi \in cl_0(\psi)$ we obtain $\Sigma(r,n') \Vdash K_i\varphi_1$. By K3 this implies $\Sigma(r,n') \Vdash \varphi_1$. Since $\varphi \in cl_0(\psi)$, by the induction hypothesis, we obtain that $(\mathcal{I},r',n') \models \varphi_1$. This shows that $(\mathcal{I},r',n') \models \varphi_1$ for all points $(r',n') \sim_i (r,n)$. That is, we have $(\mathcal{I},r,n) \models K_i\varphi_1$.

For the converse, suppose that $\Sigma(r,n) \Vdash \neg K_i\varphi_1$ and that $\Sigma(r,n)$ is a σ-state. By Lemma 4.6(b), there exists a σ-state t such that $\Sigma(r,n) \approx_i t$ and $t \Vdash \neg\varphi_1$. By condition 3 of Definition 4.9, there exists a point (r',n') such that $(r,n) \sim_i (r',n')$ and $\Sigma(r',n') = t$. Using the induction hypothesis we obtain that $(\mathcal{I},r',n') \models \neg\varphi_1$. It follows that $(\mathcal{I},r,n) \models \neg K_i\varphi_1$.

Case 4. If φ is of the form $E\varphi_1$, the result follows easily from the induction hypothesis, using axiom C1.

Case 5. Suppose that φ is of the form $C\varphi_1$. By condition 2 of Definition 4.9 we have that $\Sigma(r',n')$ is defined for all (r',n') reachable from (r,n). An easy induction on the length of the path from (r,n) to (r',n'), using the fact that $K_iC\varphi_1$ is in the basic closure and axioms C1, C2, and K3, can be used to show that $\Sigma(r',n') \Vdash C\varphi_1$ for each point (r',n') reachable from (r',n). Using C1, C2, and K3, it is easy to see that $\Sigma(r',n') \Vdash \varphi_1$. By the induction hypothesis, this implies that $(\mathcal{I},r',n') \models \varphi_1$. Thus, $(\mathcal{I},r,n) \models C\varphi_1$.

For the converse, suppose that $\Sigma(r,n) \Vdash \neg C\varphi_1$. Then by condition 4 of Definition 4.9, we have $\Sigma(r',n') \Vdash \neg\varphi_1$ for some point (r',n') reachable from (r,n). By the induction hypothesis, we have that $(\mathcal{I},r',n') \models \neg\varphi_1$, and hence $(\mathcal{I},r,n) \models \neg C\varphi_1$.

For part (b), since $\psi \in KL_m$, we only need to check the analogues of Cases 1, 2, and 3 above. The proofs in Cases 1 and 2 are identical to those above. The proof of Case 3 is also quite similar, but we must be a little careful in applying the inductive hypothesis. So suppose that φ is of the form $K_i\varphi_1$, $\Sigma(r,n)$ is a σ-state, and $ad(K_\sigma\varphi) \le d$. The implication from left to right, showing that if $\Sigma(r,n) \Vdash K_i\varphi$, then $(\mathcal{I},r,n) \models K_i\varphi$, is identical to that above. We just need the observation that if $(r,n) \sim_i (r',n')$, then $\Sigma(r',n')$ is a τ-state, where $\tau\#i = \sigma\#i$. It follows that $ad(K_\tau\varphi) \le ad(K_{\sigma\#i}\varphi) \le ad(K_\sigma K_i\varphi) \le d$, so we can apply the inductive hypothesis to conclude that $(\mathcal{I},r',n') \models \varphi_1$. For the converse, the proof is again similar. Note that if $ad(K_\sigma K_i\varphi) \le d$, then $|\sigma\#i| \le d$, so by Lemma 4.6(b), there exists a $(\sigma\#i)$-state t such that $\Sigma(r,n) \approx_i t$ and $t \Vdash \neg\varphi_1$. By condition 3′ of Definition 4.9, there exists a point (r',n') such that $(r,n) \sim_i (r',n')$ and $\Sigma(r',n') = t$. Since $ad(K_{\sigma\#i}\varphi) = ad(K_\sigma K_i\varphi) \le d$, using the induction hypothesis we obtain that $(\mathcal{I},r',n') \models \neg\varphi_1$. It follows that $(\mathcal{I},r,n) \models \neg K_i\varphi_1$. □

COROLLARY 4.11. *If $(\mathcal{R},\Sigma)$ is an enriched (resp., enriched$^+$) system for ψ, $\mathcal{I}$ is the associated interpreted system, and (r,n) is a point of $\mathcal{I}$ such that $\Sigma(r,n)$ is an ϵ-state and $\Sigma(r,n) \Vdash \psi$, then $(\mathcal{I},r,n) \models \psi$.*

We apply this corollary in all our completeness proofs, constructing an appropriate enriched or enriched$^+$ system in all cases.

5. Proofs of soundness and completeness. We are now in a position to prove the completeness results claimed in section 3. Sections 5.1–5.3 will deal with the cases involving only perfect recall, synchrony, and unique initial states. The cases involving no learning are a little more complex and are dealt with in sections 5.4–5.7.

5.1. Dealing with $\mathcal{C}_m$, $\mathcal{C}_m^{sync}$, $\mathcal{C}_m^{uis}$, and $\mathcal{C}_m^{sync,uis}$ (Theorems 3.1 and 3.2). The fact that $\mathrm{S5C}_m^U$ is sound for $\mathcal{C}_m$, the class of all systems, is straightforward and left to the reader (see also [1]). To prove completeness of $\mathrm{S5}_m^U$ for the language KL_m and of $\mathrm{S5C}_m^U$ for the language CKL_m with respect to $\mathcal{C}_m$, $\mathcal{C}_m^{sync}$, $\mathcal{C}_m^{uis}$, and $\mathcal{C}_m^{sync,uis}$, we construct an enriched system and use Corollary 4.11. The proof proceeds in the same way whether or not common knowledge is in the language. We assume here that the language includes common knowledge and that we are dealing with the axiom system $\mathrm{S5C}_m^U$ when constructing the states in the enriched structure. Recall that in this case we work with ϵ-states only.

The following result suffices for the generation of the acceptable sequences required for the construction of an enriched system in the cases not involving no learning; a more complex construction will be required in the presence of no learning.

LEMMA 5.1. *Every finite $\rightarrow$-sequence of states can be extended to an infinite acceptable sequence.*

Proof. First note that for every σ-state s there exists a state t with $s \rightarrow t$, for otherwise, $s \Vdash \neg\bigcirc\varphi_t$ for all σ-states t, which contradicts $\vdash \bigcirc \bigvee_{t \text{ a } \sigma\text{-state}} \varphi_t$. (Note that $\vdash \bigcirc \bigvee_{t \text{ a } \sigma\text{-state}} \varphi_t$ follows from Lemma 4.1(c) and RT1.) Thus every finite sequence of states can be extended to an infinite sequence, and it remains to show that the obligations arising from the until formulas can be satisfied.

Suppose that the finite $\rightarrow$-sequence is $s_0 \rightarrow \cdots \rightarrow s_n$, where $s_k = (\sigma, X_k)$ for $k = 1, \ldots, n$. Now, for any formula $\varphi_1 \, U \, \varphi_2 \in X_0$, it follows using T3 and the fact that the s_i directly decide each of the formulas φ_1, φ_2, and $\varphi_1 \, U \, \varphi_2$ that either the obligation imposed by $\varphi_1 \, U \, \varphi_2$ at s_0 is already satisfied in the sequence $(s_0, \ldots, s_n)$, or else $s_n \Vdash \varphi_1 \, U \, \varphi_2$ and $s_k \Vdash \varphi_1$ for $0 \leq k \leq n$. In the latter case, by Lemma 4.6(c), there exists a sequence $s_n \rightarrow s_{n+1} \rightarrow \cdots \rightarrow s_{n'}$ such that $s_{n'} \Vdash \varphi_2$ and $s_k \Vdash \varphi_1$ for $n \leq k < n'$. This gives a finite extension of the original sequence that satisfies the obligation imposed by $\varphi_1 \, U \, \varphi_2$ at s_0. Applying this argument to the remaining obligations at s_0, we eventually obtain a finite sequence that satisfies all the obligations at s_0. We may then move on to s_1 and apply the same procedure. It is clear that in the limit we obtain an acceptable sequence extending the original sequence. □

For each agent i, let O_i be the function that maps the state (σ, U) to the pair $(\sigma \# i, U/K_i)$. O_i is also used later in our other constructions. Given a state s, we call $O_i(s)$ agent i's *current information* at s. Let x be a new object not equal to any state. We say that a sequence $S = (x, x, \ldots, x, s_N, s_{N+1}, \ldots)$ is an *acceptable sequence from N* if it starts with N copies of x and the suffix $(s_N, s_{N+1}, \ldots)$ is an acceptable $\rightarrow$-sequence of states for ψ. Given a sequence S acceptable from N, we define a run r as follows. For each agent i, take $r_i(n) = (n, S)$ when $n < N$, and take $r_i(n) = (n, O_i(s_n))$ otherwise. For the environment component e, take $r_e(n) = S_n$ (so that $r_e(n) = x$ if $n < N$ and $r_e(n) = s_n$ for $n \geq N$).

Let $\mathcal{R}^{sync}$ be the set of all runs so obtained, and define the partial function Σ on points in $\mathcal{R}^{sync} \times \mathbb{N}$ so that $\Sigma(r, n) = s_n$ when r is derived from a sequence $(x, x, \ldots, x, s_N, s_{N+1}, \ldots)$ acceptable from N and $n \geq N$, and $\Sigma(r, n)$ is undefined otherwise.

LEMMA 5.2. *The pair $(\mathcal{R}^{sync}, \Sigma)$ is an enriched system.*

Proof. It is immediate from the construction that $(\mathcal{R}^{sync}, \Sigma)$ satisfies conditions

1 and 2 of Definition 4.9. To see that it satisfies condition 3, suppose that (r, n) is a point such that $\Sigma(r, n)$ is defined and $\Sigma(r, n) \approx_i s$. By Lemma 5.1 there exists an acceptable sequence $(s_n, s_{n+1}, \ldots)$ with $s = s_n$. Let r' be the run obtained from the sequence $(x, \ldots, x, s_n, s_{n+1}, \ldots)$. Then it is immediate that $(r, n) \sim_i (r', n')$ and $\Sigma(r', n') = s$. Finally, to see that it satisfies condition 4, suppose that $C\varphi \in cl_0(\psi)$ and $\Sigma(r, n) \Vdash \neg C\varphi$. By Lemma 4.8, there is a state t reachable from $\Sigma(r, n)$ through the relations $\approx_i$ such that $t \Vdash \neg\varphi$. An easy inductive argument on the length of the path from $\Sigma(r, n)$ to t, using condition 3, shows that there is a point (r', n') reachable from (r, n) through the relations $\sim_i$ such that $\Sigma(r', n') = t$. Thus, the enriched system satisfies condition 4. □

Clearly the system $\mathcal{R}^{sync}$ is synchronous, so the interpreted system $\mathcal{I}$ derived from $(\mathcal{R}^{sync}, \Sigma)$ is also synchronous. Let s be an ϵ-state such that $s \Vdash \psi$. Such a state must exist because ψ was assumed consistent. By Lemma 5.1 there exists an acceptable sequence $(s_0, s_1, \ldots)$ with $s = s_0$. Let r be the corresponding run in $\mathcal{R}^{sync}$. Corollary 4.11 implies that $(\mathcal{I}, r, 0) \models \psi$. This establishes the completeness of the axiomatization $\mathrm{S5C}_m^U$ for the language CKL_m (resp., of $\mathrm{S5}_m^U$ for the language KL_m) with respect to the classes of systems $\mathcal{C}_m$ and $\mathcal{C}_m^{sync}$. To establish completeness of these axiomatizations for the corresponding languages with respect to the classes of systems $\mathcal{C}_m^{uis}$ and $\mathcal{C}_m^{sync,uis}$, we make use of the following result, which shows that sound and complete axiomatizations for the class of systems satisfying some subset of the properties of perfect recall and synchrony are also sound and complete axiomatizations for the class of systems with the same subset of these properties, but with unique initial states in addition. This completes the proofs of Theorems 3.1 and 3.2.

LEMMA 5.3. *Suppose x is a subset of $\{pr, sync\}$. If $\varphi \in CKL_m$ is satisfiable with respect to $\mathcal{C}_m^x$, then it is also satisfiable with respect to $\mathcal{C}_m^{x,uis}$.*

Proof. Suppose $\mathcal{I} = (\mathcal{R}, \pi) \in \mathcal{C}_m^x$. We define a system $\mathcal{I}'$ by adding a new initial state to each run in $\mathcal{R}$. Formally, we define the system $\mathcal{I}' = (\mathcal{R}', \pi')$ as follows. Let l be some local state that does not occur in $\mathcal{I}$ and let s_e be any state of the environment. For each run $r \in \mathcal{R}$, let r^+ be the run such that $r^+(0) = (s_e, l, \ldots, l)$ and $r^+(n+1) = r(n)$. Let $\mathcal{R}' = \{r^+ : r \in \mathcal{R}\}$. The valuation π' is given by $\pi'(r, 0)(p) = \mathbf{false}$ and $\pi'(r, n+1)(p) = \pi(r, n)(p)$ for $n \geq 0$ and propositions p. It is clear that $\mathcal{I}'$ is a system with unique initial states. Moreover, if $\mathcal{I}$ is synchronous, then so is $\mathcal{I}'$, and if $\mathcal{I}$ is a system with perfect recall, then so is $\mathcal{I}'$. A straightforward induction on the construction of the formula $\varphi \in CKL_m$ now shows that, for all points (r, n) in $\mathcal{I}$, we have $(\mathcal{I}, r, n) \models \varphi$ iff $(\mathcal{I}', r^+, n+1) \models \varphi$. □

5.2. Dealing with $\mathcal{C}_m^{pr}$ and $\mathcal{C}_m^{pr,uis}$ (Theorem 3.5). We want to show that $\mathrm{S5}_m^U + \mathrm{KT3}$ is sound and complete with respect to $\mathcal{C}_m^{pr}$. We first consider soundness. As we observed above, all axioms and rules of inference other than KT3 are known to be sound in *all* systems, so their soundness in systems $\mathcal{C}_m^{pr}$ is immediate. The next result establishes soundness of KT3.

LEMMA 5.4. *All instances of* KT3 *are valid in $\mathcal{C}_m^{pr}$.*

Proof. To show that KT3 is sound, we assume that $(\mathcal{I}, r, n) \models K_i\varphi_1 \wedge \bigcirc(K_i\varphi_2 \wedge \neg K_i\varphi_3)$. We show that $(\mathcal{I}, r, n) \models L_i((K_i\varphi_1)\, U\, [(K_i\varphi_2)\, U\, \neg\varphi_3])$. Now it follows from the assumption that $(\mathcal{I}, r, n+1) \models \neg K_i\varphi_3$, so there exists a point (r', n') such that $(r, n+1) \sim_i (r', n')$ and $(\mathcal{I}, r', n') \models \neg\varphi_3$. Since $\mathcal{I} \in \mathcal{C}_m^{pr}$, by Lemma 2.2(d), either (i) $(r, n) \sim_i (r', n')$ or (ii) there exists a number $l < n'$ such that $(r, n) \sim_i (r', l)$ and $(r, n+1) \sim_i (r', k)$ for all k with $l < k \leq n'$. We claim that in either case $(\mathcal{I}, r, n) \models L_i((K_i\varphi_1)\, U\, [(K_i\varphi_2)\, U\, \neg\varphi_3])$. In case (i), since $(\mathcal{I}, r', n') \models \neg\varphi_3$, we have $(\mathcal{I}, r', n') \models (K_i\varphi_1)\, U\, [(K_i\varphi_2)\, U\, \neg\varphi_3]$. The desired conclusion is then immediate from

the fact that $(r,n) \sim_i (r',n')$. In case (ii), since $(\mathcal{I},r,n) \models K_i\varphi_1$, and $(r,n) \sim_i (r',l)$, we have that $(\mathcal{I},r',l) \models K_i\varphi_1$. Similarly, because $(\mathcal{I},r,n+1) \models K_i\varphi_2$, we obtain that $(\mathcal{I},r',k) \models K_i\varphi_2$ for all k with $l < k \leq n'$. Together with $(\mathcal{I},r',n') \models \neg\varphi_3$, this implies that $(\mathcal{I},r',l) \models (K_i\varphi_1)\, U\, [(K_i\varphi_2)\, U\, \neg\varphi_3]$. Again, since $(r,n) \sim_i (r',l)$, we obtain that $(\mathcal{I},r,n) \models L_i((K_i\varphi_1)\, U\, [(K_i\varphi_2)\, U\, \neg\varphi_3])$. □

We now establish a lemma characterizing the interaction of knowledge and time in the premodel. This result will enable us to satisfy the perfect-recall requirement in using the premodel to construct an interpreted system. It is convenient to introduce the notation $[s]_i$, where s is a state, for the set of $(\sigma\#i)$-states t such that $s \approx_i t$. The reader is encouraged to compare the following result with Lemma 2.2(c).

LEMMA 5.5. *Suppose that the axiomatization includes* KT3. *Then for all σ-states s,t and for all $(\sigma\#i)$-states t', if $s \to t$ and $t \approx_i t'$, then either* (a) $s \approx_i t'$ *or* (b) *there exists a $(\sigma\#i)$-state s' such that $s \approx_i s'$ and there exists a sequence of $(\sigma\#i)$-states $u_0 \to u_1 \to \cdots \to u_n = t'$, where $n \geq 0$, such that $s' \to u_0$ and $u_l \approx_i u_{l+1}$ for all $l = 0,\ldots,n-1$.*

Proof. We derive a contradiction from the assumption that $s \to t$ and $t \approx_i t'$, but $s \not\approx_i t'$ and for all $(\sigma\#i)$-states s' such that $s \approx_i s'$ and all sequences of $(\sigma\#i)$-states $u_0 \to u_1 \to \cdots \to u_n$ such that $s' \to u_0$ and $u_i \approx_i u_{i+1}$ for $i = 0,\ldots,n-1$, we have $u_n \neq t'$. Let T be the smallest set of $(\sigma\#i)$-states such that

1. if $v \in [s]_i$, $v \to v'$, and $v' \in [t]_i$, then $v' \in T$; and
2. if $v \in T$, $v \to v'$, and $v' \in [t]_i$, then $v' \in T$.

Because $s \not\approx_i t'$, it follows from the fact that $\approx_i$ is an equivalence relation that the intersection $[s]_i \cap [t]_i$ is empty. Additionally, t' is not in T, for otherwise we could find a sequence of the sort presumed not to exist. Thus, for all $v \in T$, we have $\vdash \varphi_v \Rightarrow \neg\varphi_{t'}$. This implies that $\vdash \varphi_T \Rightarrow \neg\varphi_{t'}$. Let T' be the set of $(\sigma\#i)$-states v' such that $v \to v'$ for some $v \in T$. We want to show that

$$v' \Vdash \varphi_T \vee (\neg K_i\Phi^+_{t,i} \wedge \neg\varphi_{t'}) \tag{5.1}$$

for all $v' \in T'$. If $v' \in T$, then clearly we have $v' \Vdash \varphi_T$, so (5.1) holds. If $v' \notin T$, then the second condition in the definition of T implies that v' is not in $[t]_i$. It follows using Lemma 4.3(d) that $v' \Vdash \neg K_i\Phi^+_{t,i}$. Further, $t \not\approx_i v'$ implies that $v' \neq t'$, so $v' \Vdash \neg\varphi_{t'}$. Thus, again we have (5.1). Since (5.1) holds for all $v' \in T$, it follows that $\vdash \varphi_{T'} \Rightarrow (\varphi_T \vee (\neg K_i\Phi^+_{t,i} \wedge \neg\varphi_{t'}))$. Now by Lemma 4.4, we have $\vdash \varphi_T \Rightarrow \bigcirc\varphi_{T'}$, so using T1 and RT1 we obtain that $\vdash \varphi_T \Rightarrow \bigcirc(\varphi_T \vee (\neg K_i\Phi^+_{t,i} \wedge \neg\varphi_{t'}))$. Combining this with $\vdash \varphi_T \Rightarrow \neg\varphi_{t'}$ and using Lemma 4.5, we get that $\vdash \varphi_T \Rightarrow \neg(K_i\Phi^+_{t,i}\, U\, \varphi_{t'})$. In particular, we obtain $v \Vdash \neg(K_i\Phi^+_{t,i}\, U\, \varphi_{t'})$ for all states v in T.

We now repeat this argument to obtain a similar conclusion for the elements of $[s]_i$. Since t' is not in $[s]_i$ we have that $v \in [s]_i$ implies $v \Vdash \neg\varphi_{t'}$. Further, since $[s]_i \cap [t]_i$ is empty we also have by Lemma 4.3(d) that $v \in [s]_i$ implies $v \Vdash \neg K_i\Phi^+_{t,i}$. Using T3 this yields that $\vdash \Phi^+_{s,i} \Rightarrow \neg(K_i\Phi^+_{t,i}\, U\, \varphi_{t'})$.

Let P be the set of $(\sigma\#i)$-states v' such that $v \to v'$ for some $v \in [s]_i$. Let $v' \in P$. We want to show that

$$v' \Vdash \Phi^+_{s,i} \vee (\neg K_i\Phi^+_{s,i} \wedge \neg(K_i\Phi^+_{t,i}\, U\, \varphi_{t'})). \tag{5.2}$$

If $v' \in [s]_i$, then clearly $v' \Vdash \Phi^+_{s,i}$, so (5.2) holds. If $v' \notin [s]_i$, then, by Lemma 4.3(d), we have that $v' \Vdash \neg K_i\Phi^+_{s,i}$. We now consider two subcases: (a) $v' \in T$ and (b) $v' \notin T$. If $v' \in T$, then, as we showed earlier, we have $v' \Vdash \neg(K_i\Phi^+_{t,i} U \varphi_{t'})$. If $v' \notin T$, then by the definition of T it follows that $t \not\approx_i v'$. By Lemma 4.3(d), this implies that $v' \Vdash \neg K_i\Phi^+_{t,i}$.

Further, since $t \approx_i t'$, we also obtain that $v' \neq t'$, so $v' \Vdash \neg\varphi_{t'}$. Using T3, this yields $v' \Vdash \neg(K_i\Phi^+_{t,i}\, U\, \varphi_{t'})$, and again we have (5.2). Using Lemma 4.4, we obtain that $\vdash \Phi^+_{s,i} \Rightarrow \bigcirc[\Phi^+_{s,i} \vee (\neg K_i\Phi^+_{s,i} \wedge \neg(K_i\Phi^+_{t,i}\, U\, \varphi_{t'}))]$. Applying Lemma 4.5 to this and the result of the preceding paragraph establishes that $\vdash \Phi^+_{s,i} \Rightarrow \neg(K_i\Phi^+_{s,i} U\, (K_i\Phi^+_{t,i} U\, \varphi_{t'}))$.

It follows using Lemma 4.3(b), R2, and K2 that $s \Vdash K_i\neg(K_i\Phi^+_{s,i} U\, (K_i\Phi^+_{t,i} U\, \varphi_{t'}))$. By KT3, we obtain $s \Vdash \neg(K_i\Phi^+_{s,i} \wedge \bigcirc(K_i\Phi^+_{t,i} \wedge L_i\varphi_{t'}))$. Since, by Lemma 4.3(b), $s \Vdash K_i\Phi^+_{s,i}$, we obtain using T2 that $s \Vdash \bigcirc\neg(K_i\Phi^+_{t,i} \wedge L_i\varphi_{t'})$. Because $s \to t$, we have that $\varphi_s \wedge \bigcirc\varphi_t$ is consistent, so it follows that $\varphi_t \wedge \neg(K_i\Phi^+_{t,i} \wedge L_i\varphi_{t'})$ is consistent. However, by Lemma 4.3, $t \Vdash K_i\Phi^+_{t,i} \wedge L_i\varphi_{t'}$, so this is a contradiction. □

We are now ready to define, for each consistent ψ, an enriched$^+$ system for ψ that establishes completeness of $\mathrm{S5}^U_m + \mathrm{KT3}$ with respect to $\mathcal{C}^{pr}_m$. The runs of this system are those derived from the acceptable sequences $(s_0, s_1, \ldots)$ (of states for ψ) by putting $r_e(n) = s_n$ and $r_i(n) = O_i(s_0)\# \cdots \# O_i(s_n)$, for each agent i and $n \geq 0$. Thus, $r_i(n)$ is the sequence of current information that agent i has had up to time n. Let $\mathcal{R}^{pr}$ be the set of runs defined in this way. The function Σ is given by $\Sigma(r, n) = s_n$ for each $n \geq 0$.

LEMMA 5.6. *Suppose that the axiomatization includes* KT3. *Then* $(\mathcal{R}^{pr}, \Sigma)$ *is an enriched*$^+$ *system.*

Proof. It is clear that $(\mathcal{R}^{pr}, \Sigma)$ satisfies conditions 1 and 2 of Definition 4.9. It remains to show that condition 3′ holds. So suppose that $\Sigma(r, n)$ is a σ-state and $\Sigma(r, n) \approx_i s$ for some $(\sigma\#i)$-state s. We must find a point (r', n') such that $\Sigma(r', n') = s$.

The proof proceeds by induction on n. The result for $n = 0$ is immediate, since we can take r' to be an acceptable sequence starting from s (such a sequence exists by Lemma 5.1), so $\Sigma(r', 0) = s$ and clearly $(r, 0) \sim_i (r', 0)$.

Now suppose that $n > 0$ and the result holds for $n - 1$. Because $\Sigma(r, n-1) \to \Sigma(r, n)$ and $\Sigma(r, n) \approx_i s$, it follows by Lemma 5.5 that either (a) $\Sigma(r, n-1) \approx_i s$ or (b) there exists a $(\sigma\#i)$-state s' such that $\Sigma(r, n-1) \approx_i s'$ and there exists a sequence of $(\sigma\#i)$-states $u_0 \to u_1 \to \cdots \to u_k$ such that $s' \to u_0$, $u_l \approx_i u_{l+1}$ for $l = 0, \ldots, k-1$, and $u_k = s$. By the induction hypothesis, there exists for every $(\sigma\#i)$-state t with $\Sigma(r, n-1) \approx_i t$ a point (r', n') such that $(r, n-1) \sim_i (r', n')$ and $\Sigma(r', n') = t$. In case (a), we take $t = s$, and we then have that $\Sigma(r, n-1) \approx_i \Sigma(r, n)$ and $\Sigma(r', n') = s$. It follows that $(r, n) \sim_i (r', n-1)$, and by the transitivity of $\sim_i$, we also have $(r, n) \sim_i (r', n')$. Hence we are done. In case (b), we take $t = s'$. Suppose that r' is derived from the sequence $(v_0, v_1, \ldots)$. Let r'' be any run derived from an acceptable sequence with initial segment $(v_0, \ldots, v_{n'}, u_0, \ldots, u_k)$. Again, such a run exists by Lemma 5.1. By construction, $\Sigma(r'', n' + k + 1) = u_k = s$. Moreover, since $r''_i(n') = r'_i(n') = r_i(n-1)$ and $O_i(u_l) = O_i(s)$ for all $l = 0, \ldots, k$, we have $r''_i(n' + k + 1) = r''_i(n')\#O_i(u_0)\# \cdots \#O_i(u_k) = r_i(n-1)\#O_i(s) = r_i(n)$, and hence $(r, n) \sim_i (r'', n' + k + 1)$. □

Now take any ϵ-state s such that $s \Vdash \psi$, and let r be a run derived from an acceptable sequence starting with s. By construction, the system $\mathcal{I}$ obtained from the enriched$^+$ system is in $\mathcal{C}^{pr}_m$, and by Corollary 4.11, we have $(\mathcal{I}, r, 0) \vDash \psi$. Thus, ψ is satisfiable in $\mathcal{C}^{pr}_m$. By Lemma 5.3, ψ is also satisfiable in systems in $\mathcal{C}^{pr,uis}_m$. Since this argument applies to an arbitrary formula ψ consistent with respect to $\mathrm{S5}^U_m + \mathrm{KT3}$, this completes the proof of Theorem 3.5.

5.3. Dealing with $\mathcal{C}^{pr,sync}_m$ and $\mathcal{C}^{pr,sync,uis}_m$ (Theorem 3.6). We now show that $\mathrm{S5}^U_m + \mathrm{KT2}$ is sound and complete with respect to KL_m for the classes of systems

$\mathcal{C}_m^{pr,sync}$ and $\mathcal{C}_m^{pr,sync,uis}$. For soundness, the following result suffices.

LEMMA 5.7. *All instances of* KT2 *are valid in* $\mathcal{C}_m^{pr,sync}$.

Proof. Let $\mathcal{I}$ be a system in $\mathcal{C}_m^{pr,sync}$ and let r be a run of $\mathcal{I}$. Suppose that $(\mathcal{I}, r, n) \vDash K_i \bigcirc \varphi$. If $(r, n+1) \sim_i (r', n')$, then by synchrony we must have $n' = n+1$. Thus, by perfect recall and synchrony, we have $(r, n) \sim_i (r', n'-1)$. It follows that $(\mathcal{I}, r', n'-1) \vDash \bigcirc\varphi$, which implies that $(\mathcal{I}, r', n') \vDash \varphi$. This shows that $(\mathcal{I}, r', n') \vDash \varphi$ for all $(r', n') \sim_i (r, n+1)$. Thus, we have $(\mathcal{I}, r, n+1) \vDash K_i\varphi$, and hence $(\mathcal{I}, r, n) \vDash \bigcirc K_i\varphi$. □

Before constructing an enriched$^+$ system for the completeness proof, we first note a property of the premodel, analogous to that given in Lemma 5.5.

LEMMA 5.8. *Suppose that the axiomatization includes* KT2. *Then for all* σ*-states* s, t *with* $s \to t$, *we have that for all* $(\sigma\#i)$*-states* t' *with* $t \approx_i t'$ *there exists a* $(\sigma\#i)$*-state* s' *such that* $s \approx_i s'$ *and* $s' \to t'$.

Proof. By way of contradiction, suppose that s, t are σ-states with $s \to t$, that t' is a $(\sigma\#i)$-state such that $t \approx_i t'$, but that for all $(\sigma\#i)$-states s' such that $s \approx_i s'$, we have that $s' \Vdash \neg\bigcirc\varphi_{t'}$. By T2, we have that $s' \Vdash \bigcirc\neg\varphi_{t'}$ for all $(\sigma\#i)$-states s' such that $s \approx_i s'$. By Lemma 4.3(b), it follows that $s \Vdash K_i\bigcirc\neg\varphi_{t'}$. By KT2, we have that $s \Vdash \bigcirc K_i\neg\varphi_{t'}$. Since $s \to t$, it follows that $\varphi_t \wedge K_i\neg\varphi_{t'}$ is consistent. However, since $t \approx_i t'$, by Lemma 4.3(c), we have $t \Vdash L_i\varphi_{t'}$. This is a contradiction. □

To construct the enriched$^+$ system, we now take $\mathcal{R}^{pr,sync}$ to be the set of runs r derived from acceptable sequences $(s_0, s_1, \ldots)$ of states for the formula ψ by putting $r_e(n) = s_n$ and $r_i(n) = O_i(s_0)\ldots O_i(s_n)$, for each agent i and $n \geq 0$. The notation $O_i(s_0)\ldots O_i(s_n)$ is meant to denote the sequence formed by concatenating $O_i(s_0), O_i(s_1), \ldots, O_i(s_n)$. Thus, the length of the sequence is $n+1$, which enforces synchrony. Again, the function Σ is given by $\Sigma(r, n) = s_n$ for each $n \geq 0$.

LEMMA 5.9. *Suppose that the axiomatization includes* KT2. *Then* $(\mathcal{R}^{pr,sync}, \Sigma)$ *is an enriched*$^+$ *system.*

Proof. Conditions 1 and 2 of the definition of an enriched$^+$ system are immediate. To show that condition 3′ holds, suppose that $\Sigma(r, n)$ is a σ-state and that t is a $(\sigma\#i)$-state such that $\Sigma(r, n) \approx_i t$. Suppose that r is derived from the acceptable sequence $(s_0, s_1, \ldots)$, so $\Sigma(r, n) = s_n$. It follows from Lemma 5.8 that there exists a $\to$-sequence $t_0 \to \cdots \to t_n$ such that $t_n = t$ and $s_j \approx_i t_j$ for $j = 1, \ldots, n$. By Lemma 5.1, this sequence may be extended to an infinite acceptable sequence. Taking r' to be the run derived from this sequence, we see that $(r, n) \sim_i (r', n)$ and $\Sigma(r', n) = t$. □

Take $\mathcal{I}^{pr,sync}$ to be the system obtained from $(\mathcal{R}^{pr,sync}, \Sigma)$. By construction, this system is in $\mathcal{C}^{pr,sync}$. Now take any ϵ-state s such that $s \Vdash \psi$, and let r be a run derived from an acceptable sequence starting with s. By construction, the system $\mathcal{I}$ obtained from the enriched$^+$ system is in $\mathcal{C}_m^{pr,sync}$, and by Corollary 4.11, we have $(\mathcal{I}, r, 0) \vDash \psi$. Thus, ψ is satisfiable in $\mathcal{C}_m^{pr,sync}$. By Lemma 5.3, ψ is also satisfiable in systems in $\mathcal{C}_m^{pr,sync,uis}$. Since this argument applies to any formula ψ consistent with respect to $\mathrm{S5}_m^U + \mathrm{KT2}$, this completes the proof of Theorem 3.6.

5.4. Dealing with $\mathcal{C}_m^{nl}$ (Theorem 3.7). We want to show that $\mathrm{S5}_m^U + \mathrm{KT4}$ is sound and complete for KL_m with respect to $\mathcal{C}_m^{nl}$. For soundness, it suffices to show that KT4 is valid in $\mathcal{C}_m^{nl}$. This is straightforward.

LEMMA 5.10. *All instances of* KT4 *are valid in* $\mathcal{C}_m^{nl}$.

Proof. Suppose that $\mathcal{I} \in \mathcal{C}_m^{nl}$ and $(\mathcal{I}, r, n) \vDash K_i\varphi\, U\, K_i\psi$. We want to show that $(\mathcal{I}, r, n) \vDash K_i(K_i\varphi\, U\, K_i\psi)$. Thus, if $(r', n') \sim_i (r, n)$, we must show that $(\mathcal{I}, r', n') \vDash K_i\varphi\, U\, K_i\psi$. Since $(\mathcal{I}, r, n) \vDash K_i\varphi\, U\, K_i\psi$, there exists $l \geq n$ such that $(\mathcal{I}, r, l) \vDash K_i\psi$ and $(\mathcal{I}, r, k) \vDash K_i\varphi \wedge \neg K_i\psi$ for all k with $n \leq k < l$. Note that this means that if

$n \leq k < l$, then $r_i(k) \neq r_i(l)$. Since $\mathcal{I} \in \mathcal{C}_m^{nl}$ and $(r,n) \sim_i (r',n')$, there must be some $l' \geq n'$ such that $((r,n),\ldots,(r,l))$ is $\sim_i$-concordant with $((r,n'),\ldots,(r,l'))$. Thus, there exists some h, a partition $S_1,\ldots,S_h$ of the sequence $((r,n),\ldots,(r,l))$, and a partition $T_1,\ldots,T_h$ of the sequence $((r',n'),\ldots,(r,l'))$ such that for all $j = 1,\ldots,h$, we have $(r,k) \sim_i (r',k')$ for all points $(r,k) \in S_j$ and $(r',k') \in T_j$. It easily follows that $(\mathcal{I},r',n') \models K_i\varphi\, U\, K_i\psi$, as desired. □

For completeness, we define an appropriate enriched$^+$ system. As we shall see, the demands of no learning make this a little more subtle than in the case of no forgetting.

For the remainder of this section, consistency and provability are with respect to a logic that includes $\mathrm{S5}_m^U + \mathrm{KT4}$. Fix a consistent formula ψ such that $ad(\psi) = d$.

Our first step is to prove an analogue of Lemma 5.5.

LEMMA 5.11. *Suppose that the axiomatization includes* KT4. *If s is a σ-state, t is a $(\sigma\#i)$-state, $s \approx_i t$, and $s \to s'$, then there exists a sequence $t_0,\ldots,t_k$ such that* (a) $t = t_0$, (b) $t_j \approx_i s$ *for* $j < k$, (c) $t_j \to t_{j+1}$ *for* $j < k$, *and* (d) $s' \approx_i t_k$.

Proof. If $s' \approx_i t$, then we can take the sequence to consist only of t, and we are done. Otherwise, since $\varphi_s \wedge \bigcirc\varphi_{s'}$ is consistent, it follows from Lemma 4.3(b) that $\varphi_s \wedge K_i\Phi_{s,i}^+\, U\, K_i\Phi_{s',i}^+$ is consistent. Moreover, by Lemma 4.3(c), we have that $\varphi_s \Vdash L_i\varphi_t$. Thus, $\varphi_s \wedge L_i\varphi_t \wedge K_i\Phi_{s,i}^+\, U\, K_i\Phi_{s',i}^+$ is consistent. Using KT4, it follows that $\varphi_t \wedge K_i\Phi_{s,i}^+ U\, K_i\Phi_{s',i}^+$ is consistent. The result now follows from Lemma 4.7. □

Unfortunately, Lemma 5.11 does not suffice to construct an enriched$^+$ system. Roughly speaking, the problem is the following. In the case of perfect recall, we used Lemma 5.5 to show that, given a $\to$-sequence $S = (s_0,\ldots,s_n)$ of σ-states and a $(\sigma\#i)$-state t such that $s_n \approx_i t$, we can construct a $\to$-sequence T of $(\sigma\#i)$-states ending with t such that S is $\approx_i$-concordant with T. There is no problem then extending T to an acceptable sequence. Moreover, we can extend S and T independently to acceptable sequences; all that matters is that the finite prefixes of these sequences—namely, S and T—are $\approx_i$-concordant. With no learning, on the other hand, it is the infinite suffixes that must be $\approx_i$-concordant. Given a $\to$-sequence $S = (s_0,\ldots)$ of σ-states and a $(\sigma\#i)$-state t such that $s_0 \approx_i t$, using Lemma 5.11, we can find a $\to$-sequence T starting with t that is $\approx_i$-concordant with S. This suggests that it is possible to find the appropriate sequences for the construction of runs satisfying the no learning condition. Unfortunately, it does not follow from the acceptability of S that T is also acceptable. This makes it necessary to work with a smaller set of sequences than the set of all acceptable sequences, and to build up the sequences S and T simultaneously. To ensure that the appropriate obligations are satisfied at all points in the set of runs constructed, we need to work not just with single states, but with trees of states.

A *k-tree for ψ* (with $k \leq d$) is a set S of states with index σ such that $|\sigma| \leq k$, containing a unique ϵ state such that if $s \in S$ is a σ-state, then

- if t is a $(\sigma\#i)$-state such that $s \approx_i t$ and $|\sigma\#i| \leq k$, then $t \in S$;
- if $\sigma = \tau\#i$, then there is a τ-state t in S such that $s \approx_i t$.

We extend the $\to$ relation to k-trees as follows. If S_1 and S_2 are k-trees for ψ, then $S_1 \to_f S_2$ if f is a function associating with each σ-state $s \in S_1$ a finite sequence of σ-states in $S_1 \cup S_2$ such that

- if $f(s) = (s_0,\ldots,s_k)$, then
  - $s = s_0$,
  - $s_0 \to \cdots \to s_k$,
  - $s_0,\ldots,s_{k-1} \in S_1$ and $s_k \in S_2$;
- if $s \approx_i s'$, then $f(s)$ and $f(s')$ are $\approx_i$-concordant;

- for at least one $s \in S_1$, the sequence $f(s)$ has length at least 2.

Given two sequences of σ-states $\alpha = (s_0, \ldots, s_k)$ and $\beta = (t_0, \ldots)$, where α is finite, the *fusion* of α and β, denoted $\alpha \cdot \beta$, is defined only if $s_k = t_0$; in this case, it is the sequence $(s_0, s_{k-1}, t_0, \ldots)$. Given an infinite sequence $\mathcal{S} = S_0 \rightarrow_{f_0} S_1 \rightarrow_{f_1} S_2 \rightarrow_{f_2} \cdots$ of k-trees, we say a sequence α of σ-states is *compatible with* $\mathcal{S}$ if there exists some h, and σ-states $s_h, s_{h+1}, \ldots$ with $s_j \in S_j$ for $j \geq h$, such that $\alpha = f_h(s_h) \cdot f_{h+1}(s_{h+1}) \cdot \ldots$. (Implicit in this notation is the assumption that this fusion product is defined, so that the last state in $f_j(s_j)$ is the same as the first state in $f_{j+1}(s_{j+1})$ for $j \geq h$.) $\mathcal{S}$ is *acceptable* if every $\rightarrow$-sequence compatible with $\mathcal{S}$ is infinite and acceptable. Our goal is to construct an acceptable sequence of d-trees; we then use this to define the enriched$^+$ system.

Note that by Lemma 4.3, the formula φ_s essentially describes the subtree below s of any k-tree containing s. Given a k-tree S and a σ-state s in S, we inductively define a formula $tree_{S,s}$ that describes all of S from the point of view of s. If s is an ϵ-state, then $tree_{S,s} = \varphi_s$. Otherwise, if s is a $(\tau \# i)$-state, where $\tau \neq \tau \# i$, then

$$tree_{S,s} = \varphi_s \wedge \bigwedge_{\{\tau\text{-states } t\colon\ s \approx_i t\}} L_i tree_{S,t}.$$

If S and T are k-trees, $s \in S$, and $t \in T$, then we write $(S, s) \rightarrow^+ (T, t)$ if there exists a sequence of k-trees $S_0, \ldots, S_l$ and functions $f_0, \ldots, f_{l-1}$ such that $S_0 \rightarrow_{f_0} \cdots \rightarrow_{f_{l-1}} S_l$, $S_0 = S$, $S_l = T$, $f_j(s) = (s)$ for $j \leq l-2$, and $f_{l-1}(s) = (s, t)$.

LEMMA 5.12. *Suppose that the axiomatization includes* KT4*, S is a k-tree, and s is a σ-state in S, where $|\sigma| = k$.*

(a) *If t is a σ-state and $tree_{S,s} \wedge \bigcirc(\varphi_t \wedge \xi)$ is consistent, then there exists a k-tree T such that $t \in T$, $(S, s) \rightarrow^+ (T, t)$, and $tree_{T,t} \wedge \xi$ is consistent.*

(b) *$tree_{S,s} \Rightarrow \bigcirc \bigvee_{\{(T,t)\colon\ (S,s) \rightarrow^+ (T,t)\}} tree_{T,t}$ is provable.*

(c) *If $tree_{S,s} \wedge \varphi\ U\ \varphi'$ is consistent, then for some $l \geq 0$ there is a sequence $S_0, \ldots, S_l$ of k-trees and states $s_0, \ldots, s_l$ such that* (i) *$s_j \in S_j$,* (ii) *$(S, s) = (S_0, s_0)$,* (iii) *$(S_j, s_j) \rightarrow^+ (S_{j+1}, s_{j+1})$ for $j = 0, \ldots, l-1$,* (iv) *$tree_{S_j,s_j} \wedge \varphi$ is consistent for $j = 0, \ldots, l-1$, and* (v) *$tree_{S_l,s_l} \wedge \varphi'$ is consistent.*

Proof. We proceed by induction on k. The case that $k = 0$ is immediate using standard arguments, since then $tree_{S,s}$ is just φ_s.

So suppose $k > 0$ and $\sigma = \tau \# i$, with $\sigma \neq \tau$. We first prove part (a) in the case that ξ is of the form $K_i \xi'$, then part (b), the general case of part (a), and part (c). First consider (a) in the case that ξ is of the form $K_i \xi'$. Note that $tree_{S,s} \wedge \bigcirc(\varphi_t \wedge K_i \xi')$ implies $tree_{S,s} \wedge K_i \Phi_{s,i}\ U\ K_i(\xi' \wedge \Phi_{t,i})$. From the definition of k-tree, it follows that there is a τ-state s' in S such that $s \approx_i s'$. Let S' be the $(k-1)$-tree consisting of all σ'-states in S with $|\sigma'| \leq k-1$. From KT4, it follows that

$$tree_{S',s'} \wedge K_i \Phi_{s,i}\ U\ K_i(\xi' \wedge \Phi_{t,i})$$

is consistent. Applying part (c) of the inductive hypothesis, we get a sequence $S_0, \ldots, S_l$ of $(k-1)$-trees and states $s_0, \ldots, s_l$ such that (i) $s_j \in S_j$, (ii) $(S', s') = (S_0, s_0)$, (iii) $(S_j, s_j) \rightarrow^+ (S_{j+1}, s_{j+1})$ for $j = 0, \ldots, l-1$, (iv) $tree_{S_j,s_j} \wedge K_i \Phi_{s,i}$ is consistent for $j = 0, \ldots, l-1$, and (v) $tree_{S_l,s_l} \wedge K_i(\xi' \wedge \Phi_{t,i})$ is consistent. It follows by definition that there is a sequence $T_0, \ldots, T_m$ of $(k-1)$-trees and functions $f_0, \ldots, f_{m-1}$ such that $T_0 \rightarrow_{f_0} \rightarrow \cdots \rightarrow_{f_{m-1}} T_m$, $T_0 = S_0$, and $T_m = S_l$. Moreover, there are elements $t_0, \ldots, t_m$ such that $t_0 = s'$, $t_m = s_l$, if $j < m$, then $t_j = s_{j'}$ for some $j' \leq j$, and if $t_j = t_{j+1}$, then $f_j(t_j) = (t_j)$, while if $t_j \neq t_{j+1}$, then $f_j(t_j) = (t_j, t_{j+1})$ for $j = 0, \ldots, m-1$.

Let T'_j be the unique k-tree extending T_j for $j = 0, \ldots, m$. Since $\varphi_{t_j} \wedge K_i \Phi_{s,i}$ is consistent for $j < m$, we have that $t_j \approx_i s$, and so $s \in T'_j$ for $j < m$. Similarly, we have that $t \in T'_m$. We now show how to construct f'_j for $j < m$. For each state $u' \in T'_j - T_j$, there must exist a state $u \in T_j$ and an agent j' such that $u \approx_{j'} u'$. (There may be more than one such state u, of course. In this case, in the construction below, we can pick u arbitrarily.) It easily follows from Lemma 5.11 that there exists a sequence $\alpha_{u'}$ starting with u' that is $\approx_{j'}$-concordant with $f_j(u)$. Moreover, we can take $\alpha_{t_j} = (s)$ for $j < m-1$, and take $\alpha_{t_{m-1}} = (s,t)$. We define f'_j so that it agrees with f_j on T_j, and for each $u' \in T'_j - T_j$, we have $f'_j(u') = \alpha_{u'}$.

Notice that $T'_0 = S$. If $m > 0$, it follows immediately from the definition that $(S,s) \rightarrow^+ (T_m, t)$ and that $tree_{T_m,t} \wedge K_i \xi'$ is consistent. If $m = 0$, it is easy to check that we must have $t \in S$, for we have $s' \approx_i t$. Since we also have $s' \approx_i s$, it follows that $s \approx_i t$. Define f so that $f(u) = (u)$ for $u \neq s$ and $f(s) = (s,t)$. Then $(S,s) \rightarrow_f (S,t)$. Since $s \rightarrow t$, we have $(S,s) \rightarrow^+ (S,t)$. This completes the proof of part (a).

To prove part (b), suppose not. Then $tree_{S,s} \wedge \bigcirc \bigwedge_{\{(T,t):\ (S,s) \rightarrow^+ (T,t)\}} \neg tree_{T,t}$ is consistent. Straightforward temporal reasoning shows that there must be some u such that

$$tree_{S,s} \wedge \bigcirc \left(\varphi_u \wedge \bigwedge_{\{(T,t):\ (S,s) \rightarrow^+ (T,t)\}} \neg tree_{T,t} \right) \tag{5.3}$$

is consistent. Now $\neg tree_{T,t}$ is equivalent to $\neg \varphi_t \vee \bigvee_{\{\tau\text{-states } t':\ t' \approx_i t\}} K_i \neg tree_{T,t'}$. Thus, it follows that the consistency of (5.3) implies that for each tree T such that $(S,s) \rightarrow^+ (T,u)$, there is a τ-state $t_T \approx_i u$ such that

$$tree_{S,s} \wedge \bigcirc \left(\varphi_u \wedge K_i \left(\bigwedge_{\{T:\ (S,s) \rightarrow^+ (T,u)\}} \neg tree_{T,t_T} \right) \right) \tag{5.4}$$

is consistent. By part (a), there exists a k-tree T' and $t' \in T'$ such that $(S,s) \rightarrow^+ (T',t')$ and $tree_{T',t'} \wedge \varphi_u \wedge K_i(\bigwedge_{\{T:\ (S,s) \rightarrow^+ (T,u)\}} \neg tree_{T,t_T})$ is consistent. But this means that $t' = u$. Thus, we have a contradiction, since $tree_{T',u} \wedge K_i \neg tree_{T',t_{T'}}$ is inconsistent.

The general case of part (a) follows easily from part (b). Part (c) also follows from part (b), using arguments much like those of Lemma 4.7; we omit details here. □

LEMMA 5.13. *Suppose that the axiomatization includes* KT4 *and ψ is consistent. Then there is an acceptable sequence of d-trees such that ψ is true at the root of the first tree.*

Proof. The key part of the proof is to show that given a finite sequence $S_0 \rightarrow_{f_0} \cdots \rightarrow_{f_{l-1}} S_l$ of d-trees and a σ-state s in S_l such that $s \Vdash \bigcirc \varphi$ (resp., $s \Vdash \varphi_1 \, U \, \varphi_2$), we can extend the sequence of trees in such a way as to satisfy this obligation. This follows easily from Lemmas 5.11 and 5.12. In more detail, suppose $s \Vdash \varphi_1 U \varphi_2$. Let S' consist of all τ-states in S_l, with $|\tau| \leq k = |\sigma|$. By Lemma 5.12, we can find a sequence of k-trees starting with S' that satisfies this obligation. Using Lemma 5.11, we can extend this to a sequence of d-trees starting with S_l that satisfies the obligation. The argument in the case that $s_k \Vdash \bigcirc \varphi$ is similar. We can then take care of the obligations one by one, and construct an acceptable sequence, in the obvious way.

Since ψ is consistent, there must be some tree S with root s_0 such that $s_0 \Vdash \psi$. We just extend S as above to complete the proof. □

Once we have an acceptable sequence $\mathcal{S}$ of d-trees as in Lemma 5.13, we can easily construct the enriched$^+$ system much as we did in the case of perfect recall.

Given a $\rightarrow$-sequence $s_0 \rightarrow s_1 \rightarrow \cdots$ the *nl-run* r derived from it is defined so that $r_e(n) = s_n$ and $r_i(n) = O_i(s_n)\#O_i(s_{n+1})\#\cdots$ for each agent i and $n \geq 0$. Thus, while for perfect recall we take $r_i(n)$ to consist of the agent's current information up to time n, for no learning we take $r_i(n)$ to consist of the current information from time n on. The construction stresses the duality between perfect recall and no learning. Let $\mathcal{R}^{nl}$ consist of all the *nl*-runs derived from $\rightarrow$-sequences that are compatible with $\mathcal{S}$. Again, the function Σ is given by $\Sigma(r, n) = s_n$ for each $n \geq 0$.

LEMMA 5.14. *Suppose that the axiomatization includes* KT4. *Then* $(\mathcal{R}^{nl}, \Sigma)$ *is an enriched*$^+$ *system.*

Proof. Again, conditions 1 and 2 in the definition of enriched$^+$ system follow immediately from the construction. For condition 3′, suppose that (r, n) is a point in the system, $\Sigma(r, n)$ is a σ-state, and s is a $(\sigma\#i)$-state with $s \approx_i \Sigma(r, n)$. Suppose that $\mathcal{S} = S_0 \rightarrow_{f_0} S_1 \rightarrow_{f_1} S_2 \rightarrow_{f_2} \cdots$. By definition, the *nl*-run r is derived from some sequence $(s_0, s_1, s_2, \ldots)$ of σ-states compatible with $\mathcal{S}$. Suppose that $\Sigma(r, n)$ is in the interval of this sequence from S_k. Then s must also be in S_k. Let $(t_0, t_1, \ldots)$ be the (unique) sequence compatible with $\mathcal{S}$ that starts at s in S_k. Let r' be the run derived from this sequence. Then, by definition, we have $\Sigma(r', 0) = s$ and $(r, n) \sim_i (r', 0)$. □

Take $\mathcal{I}^{nl}$ to be the system obtained from $(\mathcal{R}^{nl}, \Sigma)$. By construction, this system is in $\mathcal{C}^{nl}$. Now take any ϵ-state s such that $s \Vdash \psi$, and let r be a run derived from a sequence compatible with $\mathcal{S}$ starting with s. It follows that $(\mathcal{I}, r, 0) \vDash \psi$. Thus, ψ is satisfiable in $\mathcal{C}^{nl}_m$. This completes the proof of Theorem 3.7.

5.5. Dealing with $\mathcal{C}^{nl,pr}_m$ and $\mathcal{C}^{nl,pr,uis}_1$ (Theorem 3.8). We now want to show that $\mathrm{S5}^U_m + \mathrm{KT3} + \mathrm{KT4}$ is sound and complete for KL_m with respect to $\mathcal{C}^{nl,pr}_m$. Soundness is immediate from Lemmas 5.4 and 5.10.

For completeness, we construct an enriched$^+$ system much as in the proof of Theorem 3.7, using k-trees. By Lemma 5.13, there is an acceptable sequence $\mathcal{S}$ of d-trees such that ψ is true at the root of the first tree. Given a $\rightarrow$-sequence $(s_0, s_1, \ldots)$, the *nl–pr-run* r derived from it is defined so that $r_e(n) = s_n$ and $r_i(n) = (O_i(s_0)\#O_i(s_1)\#\cdots\#O_i(s_n), O_i(s_n)\#O_i(s_{n+1})\#\cdots)$ for each agent i and $n \geq 0$. Thus, the agents' local states enforce both perfect recall (by keeping track of all the information up to time n) and no learning (by keeping track of the current information from time n on). Let $\mathcal{R}^{nl,pr}$ consist of all *nl–pr*-runs that are derived from $\rightarrow$-sequences that have a suffix that is compatible with $\mathcal{S}$. Note that now we consider $\rightarrow$-sequences whose *suffixes* are compatible with $\mathcal{S}$. The reason we have allowed the greater generality of suffixes will become clear shortly. Since $\mathcal{S}$ is acceptable, it is easy to see that every such $\rightarrow$-sequence must be infinite and acceptable. Again, the function Σ is given by $\Sigma(r, n) = s_n$ for each $n \geq 0$.

LEMMA 5.15. *Suppose that the axiomatization includes* KT3 *and* KT4. *Then* $(\mathcal{R}^{nl,pr}, \Sigma)$ *is an enriched*$^+$ *system.*

Proof. As usual, conditions 1 and 2 in the definition of enriched$^+$ system follow immediately from the construction. For condition 3′, suppose that (r, n) is a point in the system, $\Sigma(r, n)$ is a σ-state, and s is a $(\sigma\#i)$-state. Suppose that $\mathcal{S} = S_0 \rightarrow_{f_0} S_1 \rightarrow_{f_1} S_2 \rightarrow_{f_2} \cdots$. By definition, the *nl–pr*-run r is derived from a $\rightarrow$-sequence $(s_0, s_1, \ldots)$ that has a suffix $(s_N, s_{N+1}, \ldots)$ that is compatible with $\mathcal{S}$, and $\Sigma(r, n) = s_n$. There are now two cases to consider. If $n \geq N$, then there exists some k such that s_n is in S_k. Then s must also be in S_k. Let $(u_0, u_1, \ldots)$ be the unique sequence compatible with $\mathcal{S}$ that starts with s in S_k. By Lemma 5.5, there exist a sequence $v_0 \rightarrow \cdots \rightarrow v_h$ of $\sigma\#i$-states such that $v_h = s$ and $(v_0, \ldots, v_h)$ is $\approx_i$-compatible

with $(s_0, \ldots, s_n)$. Consider the $\rightarrow$-sequence formed from the fusion of $(v_0, \ldots, v_h)$ and $(u_0, u_1, \ldots)$. By construction, the *nl–pr*-run r' derived from this $\rightarrow$-sequence is in $\mathcal{R}^{nl,pr}$, $\Sigma(r', h) = s$, and $(r, n) \sim_i (r', h)$.

Now suppose $n < N$. By Lemma 5.5, there exist $(\sigma\#i)$-states $v_0 \rightarrow \cdots \rightarrow v_h$ such that $v_h = s$ and $(v_0, \ldots, v_h)$ is $\approx_i$-concordant with $(s_0, \ldots, s_n)$. Moreover, by Lemma 5.11, this sequence can be extended to a sequence $(v_0, \ldots, v_k)$ that is $\approx_i$-concordant with $(s_0, \ldots, s_N)$. Since $s_N \in S_M$ for some M, we must have $v_k \in S_M$. Let $(u_0, u_1, \ldots)$ be the unique sequence compatible with $\mathcal{S}$ that starts at v_k in S_M. Consider the $\rightarrow$-sequence formed from the fusion of $(v_0, \ldots, v_k)$ and $(u_0, u_1, \ldots)$. By construction, the *nl–pr*-run r' derived from this $\rightarrow$-sequence is in $\mathcal{R}^{nl,pr}$, $\Sigma(r', h) = s$, and $(r, n) \sim_i (r', h)$. □

Again, we complete the proof by taking $\mathcal{I}^{nl,pr}$ to be the system obtained from $(\mathcal{R}^{nl,pr}, \Sigma)$. By construction, this system is in $\mathcal{C}^{nl,pr}$ and satisfies ψ. This shows that $\mathrm{S5}_m^U + \mathrm{KT3} + \mathrm{KT4}$ is a sound and complete axiomatization for the language KL_m with respect to $\mathcal{C}_m^{nl,pr}$.

The fact that it is also a sound and complete axiomatization for the language KL_1 with respect to $\mathcal{C}_1^{nl,pr,uis}$ follows immediately from the following lemma.

LEMMA 5.16. *The formula $\psi \in KL_1$ is satisfiable with respect to $\mathcal{C}_1^{nl,pr}$ (resp., $\mathcal{C}_1^{nl,pr,sync}$) iff it is satisfiable with respect to $\mathcal{C}_1^{nl,pr,uis}$ (resp., $\mathcal{C}_1^{nl,pr,sync,uis}$).*

Proof. Clearly if ψ is satisfiable with respect to $\mathcal{C}_1^{nl,pr,uis}$ (resp., $\mathcal{C}_1^{nl,pr,sync,uis}$) it is satisfiable with respect to $\mathcal{C}_1^{nl,pr}$ (resp., $\mathcal{C}_1^{nl,pr,sync}$). For the converse, suppose that $(\mathcal{I}, r^*, n^*) \models \psi$, where $\mathcal{I} = (\mathcal{R}, \pi) \in \mathcal{C}_1^{nl,pr}$. For each run $r \in \mathcal{R}$, define the run r^+ just as in Lemma 5.3, to be the result of adding a new initial state to r. Let $\mathcal{R}' = \{r^+ : (r, 0) \sim_1 (r^*, 0)\}$. Define π' as on $\mathcal{R}'$ as in Lemma 5.3, so that $\pi'(r^+, 0)(p) = \mathbf{false}$ for all primitive propositions p, and $\pi'(r^+, n+1) = \pi(r, n)$. Let $\mathcal{I}' = (\mathcal{R}', \pi')$. Clearly $\mathcal{I}' \in \mathcal{C}_1^{nl,pr,uis}$, and if $\mathcal{I}$ is synchronous, then so is $\mathcal{I}'$. We claim that $(\mathcal{I}', r^+, n+1) \models \varphi$ iff $(\mathcal{I}, r, n) \models \varphi$ for all formulas $\varphi \in KL_1$ and all $r^+ \in \mathcal{R}'$. We prove this by induction on the structure of φ. The only nontrivial case is if φ is of the form $K_1\varphi'$. But this case is immediate from the observation that if $r^+ \in \mathcal{R}'$, $r' \in \mathcal{R}$, and $(r, n) \sim_1 (r', n')$, then since $\mathcal{I}$ is a system of perfect recall, we must have $(r, 0) \sim_1 (r', 0)$, and hence $(r')^+ \in \mathcal{R}'$. We leave details of the proof of the claim to the reader. From the claim, it follows that ψ is satisfiable in $\mathcal{C}_1^{nl,pr,uis}$, and that if ψ is satisfiable in $\mathcal{C}_1^{nl,pr,sync}$, then it is also satisfiable in $\mathcal{C}_1^{nl,pr,sync,uis}$. □

5.6. Dealing with $\mathcal{C}_m^{nl,sync}$ (Theorem 3.9). We now want to show that $\mathrm{S5}_m^U + \mathrm{KT5}$ is sound and complete for KL_m with respect to $\mathcal{C}_m^{nl,sync}$. Soundness follows from the following lemma.

LEMMA 5.17. *All instances of* KT5 *are valid in $\mathcal{C}_m^{nl,sync}$.*

Proof. Suppose that $\mathcal{I} \in \mathcal{C}_m^{nl,sync}$ and $(\mathcal{I}, r, n) \models \bigcirc K_i\varphi$. We want to show that $(\mathcal{I}, r, n) \models K_i\bigcirc\varphi$. Thus, suppose that $(r', n') \sim_i (r, n)$. We must show that $(\mathcal{I}, r', n') \models \bigcirc\varphi$. By synchrony, we must have $n' = n$. Moreover, by no learning and synchrony, we have that $(r, n+1) \sim_i (r', n+1)$. Since $(\mathcal{I}, r, n+1) \models K_i\varphi$, it follows that $(\mathcal{I}, r', n+1) \models \varphi$, and hence that $(\mathcal{I}, r', n) \models \bigcirc\varphi$, as desired. □

For completeness, we construct an enriched$^+$ system much as in the proof of Theorem 3.7, using k-trees, with an appropriate strengthening of the $\rightarrow$ relation.

We start by proving the following analogue of Lemma 5.11.

LEMMA 5.18. *Suppose that the axiomatization includes* KT5. *If s is a σ-state, t is a $(\sigma\#i)$-state, $s \approx_i t$, and $s \rightarrow s'$, then there exists a $(\sigma\#i)$-state t' such that $t \rightarrow t'$ and $s' \approx_i t'$.*

Proof. Since $\varphi_s \wedge \bigcirc\varphi_{s'}$ is consistent, it follows from Lemma 4.3(b) that $\varphi_{s_0} \wedge \bigcirc K_i\Phi^+_{s',i}$ is consistent. Moreover, by Lemma 4.3(c), we have that $\varphi_s \Vdash L_i\varphi_t$. Thus, $\varphi_s \wedge L_i\varphi_t \wedge \bigcirc K_i\Phi^+_{s',i}$ is consistent. Using KT5, it follows that $\varphi_s \wedge L_i\varphi_t \wedge K_i\bigcirc\Phi^+_{s',i}$ is consistent. It follows that $\varphi_t \wedge \bigcirc\Phi^+_{s',i}$ is consistent. Hence, there is some $(\sigma\#i)$-state t' such that $s' \approx_i t'$ and $\varphi_t \wedge \bigcirc\varphi_{t'}$ is consistent. Thus, we have $s' \approx_i t'$ and $t \to t'$. □

If S and T are k-trees, $s \in S$, and $t \in T$, we define $(S,s) \rightarrow^{sync,+} (T,t)$ if $S \rightarrow_f T$ for some f such that $f(s) = (s,t)$ and $f(s')$ has length 2 for all $s' \in S$. We now get the following simplification of Lemma 5.12.

LEMMA 5.19. *Suppose that the axiomatization includes* KT5*, S is a k-tree, and s is a σ-state in S, where $|\sigma| = k$.*

(a) *If $tree_{S,s} \wedge \bigcirc(\varphi_t \wedge \xi)$ is consistent, then there exists a k-tree T and $t \in T$ such that $(S,s) \rightarrow^{sync,+} (T,t)$ and $tree_{T,t} \wedge \xi$ is consistent.*

(b) *$tree_{S,s} \Rightarrow \bigcirc \bigvee_{\{(T,t):\ (S,s) \rightarrow^{sync,+} (T,t)\}} tree_{T,t}$ is provable.*

(c) *If $tree_{S,s} \wedge \varphi\ U\ \varphi'$ is consistent, then there is a sequence $S_0, \ldots, S_l$ of k-trees and states $s_0, \ldots, s_l$ such that* (i) *$s_j \in S_j$,* (ii) *$(S,s) = (S_0,s_0)$,* (iii) *$(S_j,s_j) \rightarrow^{sync,+} (S_{j+1},s_{j+1})$ for $j = 0, \ldots, l-1$,* (iv) *$tree_{S_j,s_j} \wedge \varphi$ is consistent for $j = 0, \ldots, l-1$, and* (v) *$tree_{S_l,s_l} \wedge \varphi'$ is consistent.*

Proof. The proof is like that of Lemma 5.12, using Lemma 5.18 instead of Lemma 5.11. We leave details to the reader. □

We can then define a *sync*-acceptable sequence of trees by replacing $\rightarrow^+$ by $\rightarrow^{sync,+}$ in the definition of acceptable sequence of trees. Using Lemma 5.19, we can show that if the axiom system contains KT5, then we can construct an infinite *sync*-acceptable sequence $\mathcal{S} = S_0 \rightarrow^{sync,+} S_1 \rightarrow^{sync,+} S_2 \rightarrow^{sync,+} \cdots$ of d-trees. As in section 5.1, we use an object x not equal to any state. Given a $\rightarrow$-sequence $s_N \rightarrow s_{N+1} \rightarrow \cdots$ starting at $s_N \in S_N$ the *nl–sync-run* r derived from it is defined so that $r_e(n) = s_n$ for $n \geq N$, else $r_e(n) = x$, and for each agent i, if $n \geq N$, then $r_i(n) = (n, O_i(s_n)O_i(s_{n+1})\ldots)$, else $r_i(n) = (n, x^{N-n}O_i(s_n)O_i(s_{n+1})\ldots)$. Thus, the local state of the agent enforces synchrony (by encoding the time) and enforces no learning. Let $\mathcal{R}^{nl,sync}$ consist of all *nl–sync*-runs derived from $\rightarrow$-sequences compatible with $\mathcal{S}$, and define Σ by taking $\Sigma(r,n) = s_n$ for $n \geq N$ and $\Sigma(r,n)$ undefined for $n < N$.

LEMMA 5.20. *Suppose that the axiomatization includes* KT5*. Then $(\mathcal{R}^{nl,sync}, \Sigma)$ is an enriched$^+$ system.*

Proof. The proof is essentially the same as that of Lemma 5.14. We leave details to the reader. □

We complete the proof of Theorem 3.9 just as we did all the previous proofs.

5.7. Dealing with $\mathcal{C}^{nl,pr,sync}_m$ (Theorem 3.10). We now want to show that $S5^U_m$+KT2+KT5 is sound and complete for KL_m with respect to $\mathcal{C}^{nl,pr,sync}_m$. Soundness follows from Lemmas 5.7 and 5.17.

For completeness, we construct an enriched$^+$ system by combining the ideas of the proofs of Theorems 3.8 and 3.9. Using Lemma 5.19, we can show that if the axiom system contains KT5, then we can construct an infinite *sync*-acceptable sequence $\mathcal{S}$ of d-trees. Given a $\rightarrow$-sequence $s_0 \rightarrow s_1 \rightarrow \cdots$, the *nl–pr–sync-run* r derived from it is defined so that $r_e(n) = s_n$ and $r_i(n) = (O_i(s_1)\ldots O_i(s_n), O_i(s_n)O_i(s_{n+1})\ldots)$. Thus, the local state of the agent enforces both perfect recall and no learning. It also enforces synchrony, since the agent can determine n from the length of the first of the two sequences in its local state. Let $\mathcal{R}^{nl,pr,sync}$ consist of all *nl–pr–sync*-runs derived from $\rightarrow$-sequences with suffixes that are compatible with $\mathcal{S}$; again, we define Σ by

taking $\Sigma(r,n) = s_n$.

Using ideas similar to those in earlier proofs, we can now prove the following result.

LEMMA 5.21. *Suppose that the axiomatization includes* KT2 *and* KT5. *Then* $(\mathcal{R}^{nl,pr,sync}, \Sigma)$ *is an enriched*$^+$ *system.*

We complete the proof of Theorem 3.10 just as we did the earlier proofs.

5.8. Dealing with $\mathcal{C}_m^{nl,sync,uis}$ and $\mathcal{C}_m^{nl,pr,sync,uis}$ (Theorem 3.11). Finally, we want to show that $\mathrm{S5}_m^U + \mathrm{KT2} + \mathrm{KT5} + \{K_i\varphi \Leftrightarrow K_1\varphi\}$ is sound and complete for KL_m with respect to $\mathcal{C}_m^{nl,sync,uis}$ and $\mathcal{C}_m^{nl,pr,sync,uis}$. Soundness follows easily using the following result, which is Proposition 3.9 in [8] (restated using our notation).

PROPOSITION 5.22.

(a) $\mathcal{C}_m^{nl,sync,uis} = \mathcal{C}_m^{nl,pr,sync,uis}$.

(b) *Any formula* φ *in* KL_m *is equivalent in* $\mathcal{C}_m^{nl,sync,uis}$ *to the formula* φ' *that results by replacing all occurrences of* K_i, $i \geq 2$, *by* K_1.

It follows from part (a) of Proposition 5.22 that the same axioms characterize $\mathcal{C}_m^{nl,sync,uis}$ and $\mathcal{C}_m^{nl,pr,sync,uis}$. Now using Lemmas 5.7 and 5.17, the soundness of KT2 and KT5 follows. The soundness of $K_i\varphi \equiv K_1\varphi$ follows from part (b).

For completeness, using the axiom $K_i\varphi \equiv K_1\varphi$, it suffices to show the completeness of $\mathrm{S5}_1^U + \mathrm{KT2} + \mathrm{KT5}$ with respect to $\mathcal{C}_1^{nl,pr,sync,uis}$. By Theorem 3.10, this axiomatization is complete with respect to $\mathcal{C}_1^{nl,pr,sync}$. The result now follows using Lemma 5.16.

6. Remarks on no learning. We noted in section 2 that the definition of no learning adopted in this paper differs from that used in [5, 8]. We now comment on the reason for this change and the relationship between these alternative definitions of no learning.

First, recall from part (d) of Lemma 2.2 that agent i has perfect recall in system $\mathcal{R}$ iff

($*$) for all points $(r,n) \sim_i (r',n')$ in $\mathcal{R}$, if $k \leq n$, then there exists $k' \leq n'$ such that $(r,k) \sim_i (r',k')$.

Intuitively, no learning is the dual of perfect recall, so it seems reasonable to define no learning by replacing references to the past in a definition of perfect recall by references to the future. This was done in [5, 8], where the definition given for no learning was the following future time variant of condition ($*$), which we call no learning$'$, to distinguish it from our current definition: Agent i does not learn$'$ in system $\mathcal{R}$ iff

($**$) for all points $(r,n) \sim_i (r',n')$ in $\mathcal{R}$, if $k \geq n$, then there exists $k' \geq n'$ such that $(r,k) \sim_i (r',k')$.

The following lemma states a number of relations holding between condition ($**$) and the other properties we have considered in this paper.

LEMMA 6.1.

(a) *If agent* i *does not learn in system* $\mathcal{R}$, *then agent* i *does not learn*$'$ *in system* $\mathcal{R}$.

(b) *If system* $\mathcal{R}$ *is synchronous or if agent* i *has perfect recall in* $\mathcal{R}$, *then agent* i *does not learn in* $\mathcal{R}$ *iff agent* i *does not learn*$'$ *in* $\mathcal{R}$.

Proof. We first prove part (a). Suppose that agent i does not learn in $\mathcal{R}$. Assume that $(r,n) \sim_i (r',n')$ and let $k \geq n$. Since i does not learn, the future local state sequences at (r,n) and (r',n') are equal. It follows that there exists $k' \geq n'$ such that $(r,k) \sim_i (r',k')$. Thus, agent i does not learn$'$.

For part (b), it follows from part (a) that it suffices to show the implication from no learning′ to no learning. We consider the cases of synchrony and perfect recall independently. In each case, we show that if $(r,n) \sim_i (r',n')$, then there exists $k \geq n'$ such that the sequences $((r,n),(r,n+1))$ and $((r',n'),\ldots,(r',k))$ are $\sim_i$-concordant. It then follows by Lemma 2.3 that agent i does not learn.

Assume first that $\mathcal{R}$ is a synchronous system and that $(r,n) \sim_i (r',n')$. By synchrony, we must have $n = n'$. By no learning′, there exists $k \geq n$ such that $(r,n+1) \sim_i (r',k)$. By synchrony, k must equal $n+1$. It is immediate that $((r,n),(r,n+1))$ and $((r',n'),(r',n'+1))$ are $\sim_i$-concordant.

Next, assume that agent i has perfect recall in $\mathcal{R}$ and that $(r,n) \sim_i (r',n')$. By no learning′, there exists $k \geq n'$ such that $(r,n+1) \sim_i (r',k)$. By perfect recall, agent i's local state sequences $(r,n+1)$ and (r',k) are identical, as are the local state sequences at (r,n) and (r',n'). It follows that the sequences $((r,n),(r,n+1))$ and $((r',n'),\ldots,(r',k))$ are $\sim_i$-concordant. □

Thus, in the context of either synchrony or perfect recall, no learning and no learning′ are equivalent. However, in systems without synchrony or perfect recall, no learning′ is strictly weaker than no learning, as the following example shows. Consider the system $\mathcal{R} = \{r^1, r^2\}$ for a single agent, where the runs are defined by

$$r^1(n) = \begin{cases} (s_e, a) & \text{if } n = 0, \\ (s_e, b) & \text{if } n > 0 \text{ is odd}, \\ (s_e, c) & \text{if } n > 0 \text{ is even}, \end{cases}$$

where s_e is some state of the environment, and a, b, c are local states of agent 1, and similarly

$$r^2(n) = \begin{cases} (s_e, a) & \text{if } n = 0, \\ (s_e, c) & \text{if } n > 0 \text{ is odd}, \\ (s_e, b) & \text{if } n > 0 \text{ is even}. \end{cases}$$

This system clearly satisfies *uis* and condition $(**)$, so we have no learning′ (for both agents). However, agent 1's future local-state sequences from the points $(r^1, 0) \sim_1 (r^2, 0)$ are not $\sim_1$-concordant, so we do not have no learning. Thus, no learning and no learning′ are distinct in general.

This raises the question of which variant to take as the definition of no learning for the cases $\mathcal{C}^{nl}$ and $\mathcal{C}^{uis,nl}$. The origin of this notion in the literature lies in Ladner and Reif's paper [11], where it is motivated as arising in the context of blindfold games. Their logic LLP assumes perfect recall, so is not decisive on the distinction. However, it seems that the behavior in the above example is somewhat unnatural for this application, and the definition we have adopted in this paper better fits the intuition of a player in a blindfold game following a fixed linear strategy, but with some uncertainty about timing. It is such examples that in fact led us to use the current definition of no learning.

It is worth noting that the example above also shows that the axiom KT4 is not sound with respect to the class of systems satisfying $(**)$. Define the interpretation π of the propositions p and q on runs $r \in \mathcal{R}$ by $\pi(r,n)(p) = \mathbf{true}$ iff $r_1(n) = a$ and $\pi(r,n)(q) = \mathbf{true}$ iff $r_1(n) = b$. Let $\mathcal{I} = (\mathcal{R}, \pi)$. It is then readily seen that $(\mathcal{I}, r^1, 0) \models K_1 p U K_1 q$ but not $(\mathcal{I}, r^1, 0) \models K_1(K_1 p U K_1 q)$. Hence KT4 fails in this system. (This example is a future time version of an example used in [14] to show that the axiom KT1 is incomplete for systems with perfect recall.) We have not investigated the issue of axiomatization using no learning′ rather than no learning in the two cases where there

is a difference—$\mathcal{C}_m^{nl}$ and $\mathcal{C}_1^{nl,uis}$. We conjecture that, while there will be a relatively clean complete axiomatization in these cases, it will not be as elegant as the one proposed here. That is, the axiom that captures no learning will be somewhat more complicated than KT4. This conjecture is in line with our feeling that no learning is the "right" definition, not no learning$'$.

We remark that the complexity results of [5, 8, 7] are proved in the context of no learning$'$, but it is relatively straightforward to show that the same results hold if we use the definition of no learning instead.

7. Discussion. While we have looked in this paper at the effect on axiomatization of some combinations of classes of systems and language (48 in all!), there are certainly other cases of interest. One issue we have already mentioned is that of branching time versus linear time. Basing the temporal fragment of the language on branching time yields another 48 logics, whose complexity is studied in [5]. We would conjecture that the obvious translations of the axioms we have presented here deal with branching time, with similar proofs of completeness, but this remains to be verified.

It is worth remarking that our results are very sensitive to the language studied. As we have seen, the language considered in this paper is too coarse to reflect some properties of systems. In the absence of the other properties, synchrony and unique initial states do not require additional axioms. This may no longer be true for richer languages. For example, if we allow past-time operators [13], we need not only the additional axioms capturing the properties of these, but also new axioms describing the interaction of knowledge and time. Suppose that we add an operator $\ominus$ such that $(\mathcal{I}, r, n) \models \ominus\varphi$ if $n \geq 1$ and $(\mathcal{I}, r, n-1) \models \varphi$. Notice that $\neg\ominus \mathit{true}$ expresses the property "the time is 0" and $\ominus\neg\ominus \mathit{true}$ expresses the property "the time is 1." Similarly, we can inductively define formulas that express the property "the time is m" for each $m \geq 0$. If $\mathit{time} = m$ is an abbreviation for this formula, then $\mathit{time} = m \Rightarrow K_i(\mathit{time} = m)$ is valid in $\mathcal{C}^{sync}$ for each time m.

On the other hand, by adding past-time operators we can simplify the axiom for perfect recall. Introducing the operator S for "since," we may show that the formula

$$(K_i\varphi)S(K_i\psi) \Rightarrow K_i((K_i\varphi)S(K_i\psi))$$

is valid in $\mathcal{C}^{pr}$. This axiom very neatly expresses the meaning of perfect recall, and a comparison with KT4 shows clearly the sense in which perfect recall is a dual of no learning. Techniques similar to those developed in this paper may be used to prove that this axiom, together with the usual axioms for past time [13] and for knowledge, yields a complete axiomatization for $\mathcal{C}^{pr}$.

Besides changes to the language, there are also additional properties of systems worth considering. One case of interest is the class of *asynchronous message passing systems* of [1]. That extra axioms are required in such systems is known (see [1, Exercise 8.8]), but the question of complete axiomatization is still open.

HARDNESS OF APPROXIMATION FOR VERTEX-CONNECTIVITY NETWORK DESIGN PROBLEMS*

GUY KORTSARZ†, ROBERT KRAUTHGAMER‡, AND JAMES R. LEE§

Abstract. In the survivable network design problem (SNDP), the goal is to find a minimum-cost spanning subgraph satisfying certain connectivity requirements. We study the vertex-connectivity variant of SNDP in which the input specifies, for each pair of vertices, a required number of vertex-disjoint paths connecting them.

We give the first strong lower bound on the approximability of SNDP, showing that the problem admits no efficient $2^{\log^{1-\epsilon} n}$ ratio approximation for any fixed $\epsilon > 0$, unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{\mathrm{polylog}(n)})$. We show hardness of approximation results for some important special cases of SNDP, and we exhibit the first lower bound on the approximability of the related classical NP-hard problem of augmenting the connectivity of a graph using edges from a given set.

1. Introduction.

A basic problem in network design is to find, in an input graph $G = (V, E)$ with nonnegative edge costs, a spanning subgraph of minimum cost that satisfies certain connectivity requirements; see, for example, the surveys [15, 24]. A fundamental problem in this area is the vertex-connectivity variant of the *survivable network design problem* (SNDP). Here, the input also specifies a *connectivity requirement* $k_{u,v}$ for every pair of vertices $\{u, v\}$, and the goal is to find a minimum-cost spanning subgraph with the property that, between every pair of vertices $\{u, v\}$, there are at least $k_{u,v}$ *vertex-disjoint* paths.

Many network design problems (including SNDP) are NP-hard, and a significant amount of research is concerned with *approximation algorithms* for these problems, i.e., polynomial-time algorithms that find a solution whose value is guaranteed to be within some factor (called the *approximation ratio*) of the optimum. A notable success is the 2-approximation of Jain [20] for the edge-connectivity version of SNDP, in which the paths are required only to be *edge-disjoint*. (See also [21, 14] for an extension to a more general version of SNDP.) However, for the vertex-connectivity variant of SNDP, no algorithm that achieves a sublinear (in $|V|$) approximation ratio has been found, despite a considerable amount of study.

This disparity between the known approximations for different variants of SNDP might suggest a lack in our understanding of vertex-connectivity network design or, perhaps, that vertex-connectivity problems are inherently more difficult to approxi-

mate. Resolving this question (see, e.g., [34, section 30.2]) is one of the important open problems in the field of approximation algorithms. We provide an answer by showing that there is a striking difference between the approximability of the edge- and vertex-connectivity variants of SNDP. Specifically, we show that it is hard to approximate the vertex-connectivity variant of SNDP within a factor of $2^{\log^{1-\epsilon}|V|}$ for any fixed $\epsilon > 0$.

In general, we address the *hardness of approximation* of vertex-connectivity problems by presenting relatively simple variants of SNDP that are nevertheless hard to approximate. Therefore, unless stated otherwise, *connectivity* means vertex-connectivity, *disjoint paths* means vertex-disjoint paths, and all graphs are assumed to be undirected. (For a more in-depth account of approximation algorithms for edge-connectivity problems, see [15, 24].)

Two special cases of SNDP for which we show hardness of approximation are the *subset connectivity problem* and the *outconnectivity to a subset problem* (OSP). In the first problem, the input contains a subset S of the vertices and a number k, and the goal is to find a minimum-cost subgraph that contains at least k vertex-disjoint paths between every pair of vertices in S. This is SNDP with $k_{u,v} = k$ for all $u, v \in S$ and $k_{u,v} = 0$ otherwise. In the second problem, the input contains a special vertex r (called the *root*), a subset S of the vertices, and a number k, and the goal is to find a minimum-cost subgraph that contains at least k vertex-disjoint paths between r and any vertex in S. In other words, this is SNDP with $k_{r,v} = k$ for all $v \in S$ and $k_{u,v} = 0$ otherwise.

A related problem is the *vertex-connectivity augmentation problem* ($\mathrm{VCAP}_{\ell,k}$), where the goal is to find a minimum-cost set of edges that augments an ℓ-connected graph into a k-connected graph. We exhibit the first hardness of approximation results for this problem.

1.1. Previous work. Throughout, let $n = |V|$ denote the number of vertices in the input graph G.

A classical and well-studied special case of SNDP is the problem of finding a minimum-cost k-vertex connected spanning subgraph, i.e., the special case where $k_{u,v} = k$ for all vertex pairs $\{u, v\}$. This is called the *k-vertex connected spanning subgraph problem* (k-VCSS). k-VCSS is NP-hard even for $k = 2$ and *uniform costs* (i.e., when all edges have the same cost), as this problem already generalizes the Hamiltonian cycle problem (note that a 2-connected subgraph of G has n edges if and only if it is a Hamiltonian cycle). By a similar argument, the outconnectivity to a subset problem is also NP-hard, even for $k = 2$ and $S = V \setminus \{r\}$ [3]. It immediately follows that SNDP (which is a more general problem) is also NP-hard. $\mathrm{VCAP}_{0,2}$ is NP-hard by a similar argument [11], and $\mathrm{VCAP}_{1,2}$ is proved to be NP-hard in [17].

Most previous work on approximating vertex-connectivity problems concentrated on upper bounds, i.e., on designing approximation algorithms. An approximation ratio of $2k$ for k-VCSS was obtained in [3] by a straightforward application of [16], and the approximation ratio was later improved to k in [28]. Recently, Cheriyan, Vempala, and Vetta [5] devised improved approximation algorithms for the problem. For the case where $k \leq \sqrt{n/6}$, they achieve approximation ratio $6H(k) = O(\log k)$, where $H(k)$ is the kth harmonic number. For the case where $k \leq (1-\epsilon)n$, they achieve approximation ratio $\sqrt{n/\epsilon}$, which was very recently improved to $O(\frac{1}{\epsilon}\log^2 k)$ by Kortsarz and Nutov [29]. (An approximation ratio of $O(\log k)$ claimed in [31] was found to be erroneous; see [32].)

Better approximation ratios are known for several special cases of k-VCSS. For

$k \leq 7$ an approximation ratio of $\lceil (k+1)/2 \rceil$ is known (see [25] for $k = 2$, [2] for $k = 2, 3$, [9] for $k = 4, 5$, and [28] for $k = 6, 7$). For *metric costs* (i.e., when the costs satisfy the triangle inequality) an approximation ratio $2 + \frac{(k-1)}{n}$ is given in [28] (building on a ratio $2 + \frac{2(k-1)}{n}$ previously shown in [25]). For uniform costs, an approximation ratio of $1 + 1/k$ is obtained in [4]. For k-VCSS in a complete Euclidean graph in $\mathbb{R}^{O(1)}$, a polynomial time approximation scheme (i.e., factor $1+\epsilon$ for any fixed $\epsilon > 0$) is devised in [7]. For 2-VCSS in dense graphs and graphs with maximum degree 3, improved approximations are given in [6].

The connectivity augmentation problem also has attracted a lot of attention. A 2-approximation for $\mathrm{VCAP}_{1,2}$ is shown in [17, 26]. In the case where every pair of vertices in the graph forms an augmenting edge of unit cost, $\mathrm{VCAP}_{k,k+1}$ is not known to be in P nor to be NP-hard. For the latter problem, a $k-2$ additive approximation is presented in [22], and optimal algorithms for small values of k are shown in [11, 35, 19, 18].

The special case of OSP with $S = V \setminus \{r\}$ (called the k-outconnectivity problem), can be approximated within ratio 2; see, for example, [25]. Approximation algorithms for related problems are given in [3].

In contrast, there are few lower bounds for approximating vertex-connectivity problems. It is shown in [7] that 2-VCSS is APX-hard (i.e., there exists some fixed $\epsilon > 0$ such that approximation within ratio $1+\epsilon$ is NP-hard) even for bounded-degree graphs with uniform costs and for complete Euclidean graphs in $\mathbb{R}^{\log n}$. In [6], APX-hardness is shown for instances of 2-VCSS on dense graphs and graphs of degree at most 3. No stronger lower bound is known for the more general SNDP.

1.2. Our results. We show hardness of approximation for several of these vertex-connectivity network design problems. In section 2, we show that SNDP cannot be approximated within a ratio of $2^{\log^{1-\epsilon} n}$ for any fixed $\epsilon > 0$, unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{\mathrm{polylog}(n)})$. This hardness of approximation result also extends to the subset k-connectivity problem which is a special case of SNDP. The lower bound holds for $k = n^{\rho}$, where $0 < \rho < 1$ is any fixed constant. It follows that when k/n is bounded away from 1, SNDP is provably harder to approximate than k-VCSS, unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{\mathrm{polylog}(n)})$.

In section 3, we show that the OSP cannot be approximated within a ratio of $(\frac{1}{2} - \epsilon) \ln n$ for any fixed $\epsilon > 0$, unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\log \log n)})$. This hardness contrasts with other simple cases of SNDP. First, OSP with a general subset S is much harder to approximate than the special case $S = V \setminus \{r\}$ (which can be approximated within ratio 2). Second, this special case of SNDP is already much harder to approximate than the edge-connectivity variant of (general) SNDP (which can be approximated within ratio 2). Both claims assume, of course, that $\mathsf{NP} \not\subseteq \mathsf{DTIME}(n^{O(\log \log n)})$.

In section 4, we exhibit APX-hardness for $\mathrm{VCAP}_{1,2}$, even in the case where every pair of vertices in the graph forms an augmenting edge of cost 1 or 2. From this, it follows that $\mathrm{VCAP}_{k,k+1}$ with uniform costs is APX-hard for every $k \geq 2$. For fixed k, this hardness result matches, up to constant factors, the approximation algorithms mentioned in section 1.1.

Remark. SNDP with integer costs bounded by a polynomial in n can be reduced to SNDP with uniform costs. Indeed, one can replace every edge of cost $c > 0$ with a path consisting of c unit-cost edges, letting the new vertices have no connectivity requirement; i.e., $k_{u,v} = 0$ if $\{u, v\}$ contains a new vertex. Edges of cost 0 can be handled by changing their cost to, say, $1/n^3$, and then the reduction above is applicable (with a suitable scaling). It is straightforward that the argument above

regarding SNDP also holds for OSP and for the subset k-connectivity problem; thus our hardness of approximation results for these three problems hold even in the case of uniform costs.

1.3. Preliminaries. For an arbitrary graph G, let $V(G)$ denote the vertex set of G and let $E(G)$ denote the edge set of G. For a nonnegative cost function c on the edges of G and a subgraph $G' = (V', E')$ of G we use the notation $\text{cost}(G') = \text{cost}(E') = \sum_{e \in E'} c(e)$. We denote the set of *neighbors* of a vertex v in $W \subset V$ (namely, the vertices $w \in W$ such that $(v, w) \in E$) by $N(v, W, G)$. When $W = V(G)$ we omit W and write $N(v, G)$, and when G is clear from the context, we use simply $N(v)$.

A set W of k vertices in a graph $G = (V, E)$ is called a *k–vertex-cut* (or just a *vertex-cut*) if the subgraph of G induced on $V \setminus W$ is not connected. A vertex $w \in V$ is called a *cut-vertex* if $W = \{w\}$ is a vertex-cut. A graph is *k–vertex-connected* if there are k vertex-disjoint paths between every pair of vertices. We will use the following classical result.

THEOREM 1.1 (Menger's theorem; see, e.g., [8]).

(a) *A graph G contains at least k vertex-disjoint paths between two nonadjacent vertices u, v if and only if every vertex-cut that separates u from v must be of size at least k.*

(b) *A graph G is k–vertex-connected if and only if it has no $(k-1)$–vertex-cut.*

2. Survivable network design and subset connectivity. In this section, we exhibit a hardness result for approximating the subset connectivity problem, and thus also for SNDP, within a ratio of $2^{\log^{1-\epsilon} n}$ for any fixed $\epsilon > 0$. The lower bound is proved by a reduction from a graph-theoretic problem called MINREP, which is defined in [27]. This problem is closely related to the LABELCOVER$_{\max}$ problem of [1] and to the parallel repetition theorem of [33]. We first describe the MINREP problem and the hardness results known for it in section 2.1. We then give a reduction from MINREP to SNDP in section 2.2. Finally, we adapt this reduction to the subset connectivity problem in section 2.3.

2.1. The MINREP problem. Arora and Lund [1] introduced a problem called LABELCOVER$_{\max}$ as a graph-theoretic description of one-round two-prover proof systems for which the parallel repetition theorem of Raz [33] applies. The MINREP problem described below is closely related to LABELCOVER$_{\max}$ and was defined in [27] for the same purpose.

The input to the MINREP problem consists of a bipartite graph $G(A, B, E)$, with an explicit partitioning of each of A and B into equal-sized subsets, namely, $A = \bigcup_{i=1}^{q_A} A_i$ and $B = \bigcup_{j=1}^{q_B} B_j$, where all the sets A_i have the same size $m_A = |A|/q_A$ and all the sets B_j have the same size $m_B = |B|/q_B$. The bipartite graph G induces a *super-graph* H as follows. The *super-vertices* (i.e., the vertices of H) are the $q_A + q_B$ sets A_i and B_j. A *super-edge* (an edge in H) connects two super-vertices A_i and B_j if there exist some $a \in A_i$ and $b \in B_j$ which are adjacent in G.

A pair (a, b) *covers* a super-edge (A_i, B_j) if $a \in A_i$ and $b \in B_j$ are adjacent in G. Let $S \subseteq A_i \cup B_j$. (The vertices of S can be thought of as *representatives* from A_i and from B_j.) We say that S *covers* the super-edge (A_i, B_j) if there exist two vertices $a, b \in S$ such that the pair (a, b) covers the super-edge (A_i, B_j).

The goal in the MINREP problem is to select representatives from each set A_i and each set B_j such that all the super-edges are covered and the total number of representatives selected is minimal. That is, we wish to find subsets $A' \subseteq A$ and

$B' \subseteq B$ with minimal total size $|A'| + |B'|$, such that for every super-edge (A_i, B_j) there exist representatives $a \in A' \cap A_i$ and $b \in B' \cap B_j$ that are adjacent in G.

For our purposes, it is convenient (and possible) to restrict the MinRep problem so that for every super-edge (A_i, B_j), each vertex in B_j is adjacent to at most one vertex in A_i. We call this additional property of G the *star property* because it is equivalent to saying that for every super-edge (A_i, B_j) the subgraph of G induced on $A_i \cup B_j$ is a collection of vertex-disjoint stars whose centers are in A_i.[1] See Figure 1 for an illustration.

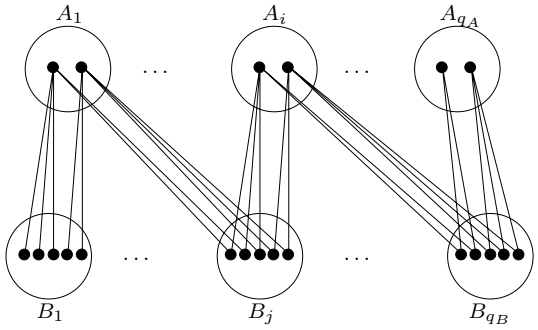

FIG. 1. *An instance of* MinRep *with the star property.*

The next theorem follows by a straightforward application of the parallel repetition theorem of Raz [33], since the MinRep problem is a graph-theoretic description of two-prover one-round proof systems. The additional star property is achieved by using a specific proof system. A description can be found in [12, section 2.2].

THEOREM 2.1. *Let $L \in \mathsf{NP}$ and fix $\epsilon > 0$. Then there exists an algorithm (a reduction), whose running time is quasi-polynomial, namely, $n^{\mathrm{polylog}(n)}$, and that given an instance x of L, produces an instance $G(A, B, E)$ of the* MinRep *problem with the star property, such that the following holds.*

- *If $x \in L$, then the* MinRep *instance G has a solution of value $q_A + q_B$ (namely, with one representative from each A_i and one from each B_j).*
- *If $x \notin L$, then the value of any solution of the* MinRep *instance G is at least $(q_A + q_B) \cdot 2^{\log^{1-\epsilon}|V(G)|}$.*

Hence, MinRep *cannot be approximated within ratio $2^{\log^{1-\epsilon} n}$, for any fixed $\epsilon > 0$, unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{\mathrm{polylog}(n)})$.*

2.2. Hardness of survivable network design.

THEOREM 2.2. SNDP *cannot be approximated within ratio $2^{\log^{1-\epsilon} n}$, for any fixed $\epsilon > 0$, unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{\mathrm{polylog}(n)})$.*

The reduction. The proof of Theorem 2.2 is by a reduction whose starting point is Theorem 2.1. Specifically, given the instance $G(A, B, E)$ of the MinRep problem as described in section 2.1, create an instance $\bar{G}(\bar{V}, \bar{E})$ of SNDP as follows. (See Figure 2 for an illustration.)

1. Take G and let all its edges have cost 0.
2. For each $i = 1, \ldots, q_A$ create a new vertex u_i that is connected to every vertex in A_i by an edge of cost 1. Similarly, for each $j = 1, \ldots, q_B$ create a

[1] A *star* is a graph all of whose vertices have degree 1, except for one vertex that may have degree larger than 1. This vertex is called the *center* of the star, and the other vertices are called *leaves* of the star.

new vertex w_j that is connected to every vertex in B_j by an edge of cost 1. (Informally, these edges correspond to choosing representatives from A_i and B_j.) Let $U = \{u_1, \ldots, u_{q_A}\}$ and $W = \{w_1, \ldots, w_{q_B}\}$.

3. For every super-edge (A_i, B_j) create two new vertices x_i^j and y_j^i. For every i, let $X_i = \{x_i^j : (A_i, B_j) \text{ is a super-edge}\}$ and connect every vertex of X_i to u_i by edges of cost 0. Similarly, for every j, let $Y_j = \{y_j{}^i : (A_i, B_j) \text{ is a super-edge}\}$ and connect every vertex in Y_j to w_j by an edge of cost 0. (Informally, the connectivity requirement between x_i^j and y_j^i "guarantees" that the super-edge (A_i, B_j) is covered.)
4. For every super-edge (A_i, B_j) connect every vertex in $\{x_i^j, y_j^i\}$ to every vertex in $(A \setminus A_i) \cup (B \setminus B_j)$ by an edge of cost 0.
5. Let $X = \cup_{i=1}^{q_A} X_i$ and $Y = \cup_{j=1}^{q_B} Y_j$. Connect every two vertices in $X \cup Y$ by an edge of cost 0.
6. Finally, require $k = |X| + |Y| + (q_A - 1)m_A + (q_B - 1)m_B$ vertex-disjoint paths from x_i^j to y_j^i for every super-edge (A_i, B_j).

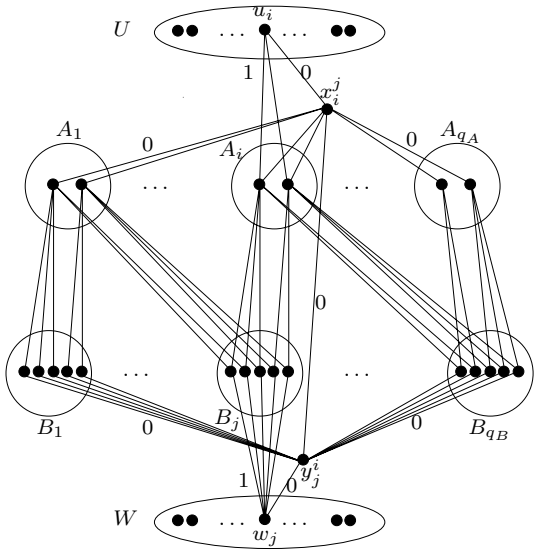

FIG. 2. *The vertices x_i^j, y_j^i in the* SNDP *instance $\bar{G}$.*

The analysis. Suppose $x \in L$ and then by Theorem 2.1 there exists a choice of $q_A + q_B$ representatives (one representative from each A_i and one from each B_j) that cover all the super-edges. Let G' be the subgraph of $\bar{G}$ that contains an edge between each u_i and the representative chosen in A_i, an edge between each w_j and the representative chosen in B_j, and all the edges of cost 0 in $\bar{G}$. Clearly, $\text{cost}(G') = q_A + q_B$. Let us now show that G' is a solution to the instance $\bar{G}$ of the SNDP. Consider a pair of vertices x_i^j, y_j^i such that (A_i, B_j) is a super-edge in G. Each vertex in $\mathcal{F}_{i,j} = (X \setminus \{x_i^j\}) \cup (Y \setminus \{y_j^i\}) \cup (A \setminus A_i) \cup (B \setminus B_j)$ defines a path of length 2 in G' between x_i^j and y_j^i, and the edge (x_i^j, y_j^i) defines a path of length 1, so we get a total of $|X| - 1 + |Y| - 1 + (q_A - 1)m_A + (q_B - 1)m_B + 1 = k - 1$ vertex-disjoint paths between x_i^j and y_j^i. There is an additional path that goes through $V \setminus \mathcal{F}_{i,j} = U \cup W \cup A_i \cup B_j \cup \{x_i^j, y_j^i\}$, namely, $x_i^j - u_i - a_i - b_j - w_j - y_j^i$, where

a_i and b_j are the representatives chosen from A_i and B_j, respectively. This path is clearly vertex-disjoint from the other $k-1$ paths, yielding a total of k vertex-disjoint paths between x_i^j and y_j^i.

The next lemma will be used to complete the proof of Theorem 2.2. Let G' be a feasible solution to the instance $\bar{G}$ of SNDP, i.e., a subgraph of $\bar{G}$ in which for every super-edge (A_i, B_j) there are k vertex-disjoint paths between x_i^j and y_j^i.

LEMMA 2.3. *For every super-edge (A_i, B_j), the subgraph G' contains an edge connecting u_i to some $a_i \in A_i$, and an edge connecting w_j to some $b_j \in B_j$, such that $(a_i, b_j) \in E$ (i.e., the pair (a_i, b_j) covers the super-edge).*

Proof. Since G' is a feasible solution, it contains k vertex-disjoint paths between x_i^j and y_j^i. Let $\mathcal{F}_{i,j} = (X \setminus \{x_i^j\}) \cup (Y \setminus \{y_j^i\}) \cup (A \setminus A_i) \cup (B \setminus B_j)$. At most $|\mathcal{F}_{i,j}| = |X|-1+|Y|-1+(q_A-1)m_A+(q_B-1)m_B = k-2$ of these k paths can visit vertices of $\mathcal{F}_{i,j}$, and at most one of these paths can use the edge (x_i^j, y_j^i). Hence, G' contains a path between x_i^j and y_j^i that visits only vertices of $\bar{V} \setminus \mathcal{F}_{i,j} = U \cup W \cup A_i \cup B_j \cup \{x_i^j, y_j^i\}$ and whose length is at least 2.

Observe that in the subgraph of G' induced on $\bar{V} \setminus \mathcal{F}_{i,j}$ the following holds. (Assume without loss of generality that G' contains all the edges of cost 0 in $\bar{G}$.) The only neighbor of x_i^j is u_i, so the vertices at distance 2 from x_i^j (i.e., the neighbors of u_i except for x_i^j) form a subset A_i' of A_i. Thus, the vertices at distance 3 from x_i^j (i.e., all the neighbors of A_i' except for u_i) are all from B_j. Similarly, the only neighbor of y_j^i is w_j, so vertices at distance 2 from y_j^i form a subset B_j' of B_j, and all vertices at distance 3 from y_j^i are from A_i. Note that the subgraph of $\bar{G}$ induced on $A_i \cup B_j$ is a collection of vertex-disjoint stars, whose centers are in A_i and whose leaves are in B_j. The aforementioned path in G' between x_i^j and y_j^i (that visits only vertices of $\bar{V} \setminus \mathcal{F}_{i,j}$) must then be of the form $x_i^j - u_i - a_i - b_j - w_j - y_j^i$ with $a_i \in A_i'$ and $b_j \in B_j'$ (note that the other vertices of $U \cup W$ are unreachable from x_i^j and y_j^i), and Lemma 2.3 follows. ∎

We now complete the proof of Theorem 2.2. Suppose that $x \notin L$ and let G' be a feasible solution to the instance $\bar{G}$ of the SNDP. Let A_i' be the set of neighbors of u_i among A_i (in G'), and let B_j' be the set of neighbors of w_j among B_j (in G'). By Lemma 2.3 the representatives $A' = \cup_i A_i'$ and $B' = \cup_j B_j'$ cover all the super-edges (A_i, B_j), thus forming a feasible solution to the MINREP instance G. By Theorem 2.1 the value of this MINREP solution, which is $|A'| + |B'|$, is at least $(q_A + q_B) \cdot 2^{\log^{1-\epsilon} n}$, where n denotes the number of vertices in G. Observe that $\text{cost}(G') = |A'| + |B'|$. Since $|V(\bar{G})| = |V(G)|^{O(1)}$, we get that $\text{cost}(G') \geq (q_A + q_B) \cdot 2^{\log^{1-\epsilon} |V(\bar{G})|}$, proving Theorem 2.2.

2.3. Hardness of subset *k*-connectivity. We can adapt the reduction of Theorem 2.2 to the subset k-connectivity problem as follows. We require that the subset $S = X \cup Y$ is k–vertex-connected. For this S to be k–vertex-connected in the case $x \in L$, we add, for every $z, z' \in S$ that are not a pair x_i^j, y_j^i, a set $Q_{z,z'}$ of k new vertices that are all connected to z and to z' by edges of cost 0. It can be seen that the analysis of the case $x \notin L$ (including the proof of Lemma 2.3) remains valid, and the number of vertices in the graph is still $|V(G)|^{O(1)}$. We thus obtain the following hardness of approximation result for the subset k-connectivity problem.

THEOREM 2.4. *The subset k-connectivity problem cannot be approximated within ratio $2^{\log^{1-\epsilon} n}$, for any fixed $\epsilon > 0$, unless* $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{\text{polylog}(n)})$.

Note that in the reduction in Theorem 2.2 $|X| = |Y|$ is the number of super-edges in G, and thus $k = \Theta(|A \cup B| + |X|)$ while the number of vertices is $\Theta(|A \cup B| + k|X|^2)$.

Therefore, our hardness result for the subset k-connectivity applies for $k \geq \Omega(n^{1/3})$, where n denotes the number of vertices in the input graph. In this problem, it is straightforward to achieve $k = n^{\alpha}$ for any fixed $0 < \alpha < 1$ by adding sufficiently many vertices that are either isolated or connected to all other vertices by edges of cost 0. It follows that the min-cost subset k-connectivity problem is provably harder to approximate than the min-cost k-connectivity problem (for values of k as above). Indeed, it is shown in [5] that the latter problem can be approximated within ratio $O(\log k)$ for $k \leq \sqrt{n/6}$.

3. Outconnectivity to a subset. In this section we show a lower bound of $\Omega(\log n)$ for approximating the outconnectivity from a root to a subset problem (OSP).

THEOREM 3.1. *The OSP cannot be approximated within a ratio of* $(\frac{1}{2} - \epsilon) \ln n$ *for any fixed* $\epsilon > 0$, *unless* $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\log \log n)})$.

For ease of exposition, we present the reduction to the OSP in stages by going through an intermediate problem which is easier to deal with. The 3-OSP is defined as OSP with the additional restriction that the k vertex-disjoint paths between r and each $s \in S$ are required to have length at most 3. Note that 3-OSP is not a special case of the SNDP. We give a hardness of approximation result for the 3-OSP in section 3.2 and for the OSP in section 3.3. The starting point for these reductions is a gap shown in [13] for the problem of packing set-covers, as described in section 3.1.

3.1. The set-cover packing problem. Let $G(V_1, V_2, E)$ be a bipartite graph. We say that a vertex $v_1 \in V_1$ *covers* a vertex $v_2 \in V_2$ if the two vertices are adjacent, i.e., $(v_1, v_2) \in E$. A *set-cover* (of V_2) in $G(V_1, V_2, E)$ is a subset $S \subseteq V_1$ such that every vertex of V_2 is covered by some vertex from S. Throughout, we assume that the intended bipartition (V_1, V_2) is given explicitly as part of the input, and that every vertex in V_2 can be covered (i.e., has at least one neighbor in V_1).

A *set-cover packing* in the bipartite graph G is a collection of pairwise-disjoint set-covers of V_2. The *set-cover packing problem* is to find in an input bipartite graph G (as above), a maximum number of pairwise-disjoint set-covers of V_2. We denote by $\mathrm{sc}^*(G)$ the minimum size of a set-cover of V_2 in G, and by $\mathrm{scp}^*(G)$ the maximum size of a set-cover packing of G. Note that $\mathrm{scp}^*(G) \leq |V_1|/\mathrm{sc}^*(G)$. Feige, Halldórsson, Kortsarz, and Srinivasan [13] give a hardness of approximation result for the set-cover packing problem by proving the following theorem.

THEOREM 3.2 (see [13]). *Let* $L \in \mathsf{NP}$ *and fix* $\epsilon > 0$. *Then there exists an algorithm (a reduction), whose running time is nearly polynomial, namely* $n^{O(\log \log n)}$, *and that given an instance* x *(for* L*), produces an instance* $G(V_1, V_2, E)$ *of the set-cover packing problem (and a number* $d \leq |V_1|$*) such that* $|V_1| \leq |V_2|^{\epsilon}$ *and the following holds.*

- *If* $x \in L$, *then* V_1 *can be partitioned into* d *equal-sized set-covers of* V_2. *(Therefore,* $\mathrm{scp}^*(G) \geq d$.*)*
- *If* $x \notin L$, *then the size of any set-cover of* V_2 *is at least* $(|V_1|/d) \cdot (1-\epsilon) \ln |V_1 \cup V_2|$. *(Therefore,* $\mathrm{scp}^*(G) \leq d/[(1-\epsilon) \ln |V_1 \cup V_2|]$.*)*

It is straightforward from this reduction that for any fixed $\epsilon > 0$, the set-cover packing problem cannot be approximated within ratio $(1 - \epsilon) \ln n$ (where n is the number of vertices in the graph), unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\log \log n)})$.

3.2. Hardness of outconnectivity to a subset with path length 3. We prove the following theorem as an intermediate step towards proving hardness of approximation for the OSP.

THEOREM 3.3. 3-OSP *cannot be approximated within ratio* $(1-\epsilon)\ln n$*, for any fixed* $\epsilon > 0$*, unless* $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\log\log n)})$.

The reduction. The proof of Theorem 3.3 is by a reduction whose starting point is Theorem 3.2. Specifically, given the set-cover packing instance $G(V_1, V_2, E)$ we construct from G a new graph $\bar{G}$ as follows. (See Figure 3 for illustration.) Add to G a set A of d new vertices (where d is the number from the reduction), and form a complete bipartite graph between A and V_1. Let all the edges of G have cost 0, and all the edges between A and V_1 have cost 1. Now add a new vertex r that will be the root, and connect it to each vertex of A by an edge of cost 0. Finally, set $S = V_2$ and $k = d$. That is, a feasible solution is a subgraph of $\bar{G}$ that contains at least d vertex-disjoint paths of length at most 3 between r and each $s \in S$.

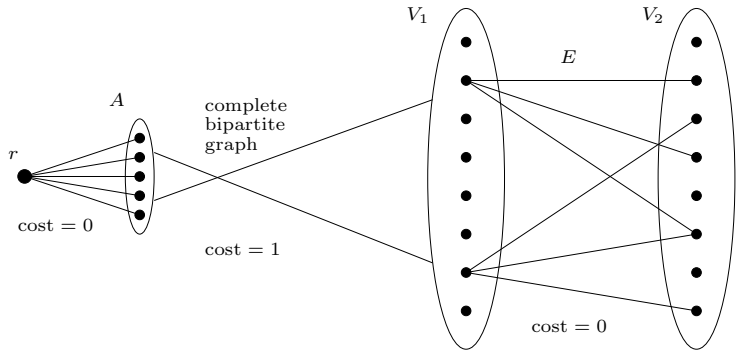

FIG. 3. *The graph* $\bar{G}$ *of the reduction from set-cover packing to* 3-OSP.

The analysis. Suppose $x \in L$ and then by Theorem 3.2 the set-cover packing graph $G(V_1, V_2, E)$ has a set-cover packing of size d. Let G' be a subgraph of $\bar{G}$ that contains all the edges of cost 0, and that connects each $a \in A$ to (all the vertices of) a set-cover N_a of V_2, such that the set-covers $\{N_a\}_{a\in A}$ are pairwise-disjoint. Such a subgraph G' exists since $|A| = d \le \mathrm{scp}^*(G)$. Since the edges of cost 1 in G' are incident at distinct vertices of V_1, we get that $\mathrm{cost}(G') \le |V_1|$.

To prove that G' is a feasible solution to 3-OSP we show d vertex-disjoint paths between r and any $v_2 \in V_2$. For every $a \in A$ we have that $N_a = N(a, V_1, G')$ is a set-cover of V_2 and thus contains a neighbor of v_2. Therefore, a defines a path of length 3 in G' between r and v_2. The $|A| = d$ paths that we obtain are vertex-disjoint because each vertex $a \in A$ is contained in exactly one of these paths, and because each vertex of V_1 belongs to at most one set-cover N_a.

The next lemma will be used to complete the proof of Theorem 3.3. Let G' be a feasible solution to the above described instance $\bar{G}$ of the 3-OSP problem.

LEMMA 3.4. *For every* $a \in A$*, the set* $N_a = N(a, V_1, G')$ *is a set-cover (in* G*) of* V_2 *(i.e., every* $a \in A$ *is at distance* 2 *in* G' *from every* $v_2 \in V_2$*).*

Proof. Let $a \in A$ and $v_2 \in V_2$; we will show that N_a covers v_2. Since $N(r, \bar{G}) = A$ and the distance in $\bar{G}$ between r and v_2 is 3, any path of length at most 3 between r and v_2 in G' must contain at least one vertex of A. Since G' is a feasible solution, it contains $d = |A|$ vertex-disjoint paths; these paths are vertex-disjoint and hence exactly one of these d paths must contain the vertex $a \in A$. In this path a is at distance 2 from v_2, implying that N_a covers v_2. □

We now complete the proof of Theorem 3.3. Suppose $x \notin L$. Let G' be a feasible solution to $\bar{G}$ and let $N_a = N(a, V_1, G')$, as in the above analysis of Theorem 3.3.

Clearly, $\text{cost}(G') = \sum_{a \in A} |N_a|$. By Lemma 3.4, each set N_a forms a set-cover (in G) of V_2. By Theorem 3.2 (and since $|A| = d$) we get that $\text{cost}(G') \geq |A| \cdot \text{sc}^*(G) \geq (1-\epsilon)|V_1| \cdot \ln |V_1 \cup V_2|$. Note that $|V(\bar{G})| = |V_1 \cup V_2| + d + 1 \leq 2|V_1 \cup V_2|$ and thus the gap between the case $x \in L$ and the case $x \notin L$ is at least $(1-\epsilon) \ln |V_1 \cup V_2| \geq (1-2\epsilon) \ln |V(\bar{G})|$, proving Theorem 3.3.

3.3. Hardness of outconnectivity to a subset. We now prove Theorem 3.1, i.e., that OSP cannot be approximated within ratio $(\frac{1}{2} - \epsilon) \ln n$, for any fixed $\epsilon > 0$, unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\log \log n)})$. Observe that the reduction to 3-OSP (in section 3.2) might not work for OSP because in the case $x \notin L$, a feasible solution G' might connect r and $v_2 \in V_2$ by d long paths (namely, of length more than 3), where each path contains one (distinct) vertex of A. However, each of these paths must contain at least one vertex of $V_2 \setminus \{v_2\}$, so at most $|V_2|$ such paths are vertex-disjoint. Here we use the special properties of the set-cover packing problem; by duplicating V_1 sufficiently many times, we increase $\text{scp}^*(G)$ and, accordingly, the connectivity requirement k, so that they are both much larger than $|V_2|$, ensuring that paths of length more than 3 have only a negligible effect in any feasible solution.

The reduction. Define a *copy* of a vertex v in a graph as a new vertex v' that is connected by edges to the same vertices as v, and with the same edge costs. In the reduction below, we replace certain vertices by many copies of them. Let us denote by $\tilde{v}$ the set of all *copies* of v. Note that no two vertices in $\tilde{v}$ are connected by an edge. For a set of vertices $W = \{w_1, w_2, \ldots\}$, let $\tilde{W} = \bigcup_i \tilde{w}_i$ be the set of all copies of all vertices in W.

The proof of Theorem 3.3 is by a reduction whose starting point is Theorem 3.2. Specifically, given the set-cover packing instance $G(V_1, V_2, E)$ construct a new graph $\tilde{G}$ as follows. First, add to G a set $A = \{a_1, \ldots, a_d\}$ of d new vertices that are connected by a complete bipartite graph to V_1, letting all the edges of G have cost 0 and all the edges between A and V_1 have cost 1. Next, add a new vertex r that will be the root, and connect it to each vertex of A by an edge of cost 0. (So far, this graph is $\bar{G}$ from section 3.2.) Now, replace each vertex of $A \cup V_1$ by $|V_2|^2$ copies of it. Thus, $\tilde{A} = \bigcup_{i=1}^{d} \tilde{a}_i$, where $\tilde{a}_i$ is the set of $|V_2|^2$ copies of a_i, and $\tilde{V}_1 = \bigcup_{v \in V_1} \tilde{v}$, where $\tilde{v}$ is the set of $|V_2|^2$ copies of v. Finally, set $S = V_2$, $k = |V_2|^2 d$. That is, a feasible solution is a subgraph of $\tilde{G}$ that contains at least k vertex-disjoint paths between r and each $s \in S$.

The analysis. Throughout the proof, let *set-cover in* $\tilde{G}$ refer to a set-cover of V_2 by vertices of $\tilde{V}_1$ in the bipartite graph that $\tilde{G}$ induces on $\tilde{V}_1 \cup V_2$. Observe that the minimum size of a set-cover of V_2 in $\tilde{G}$ is the same as in G; i.e., $\text{sc}^*(\tilde{G}) = \text{sc}^*(G)$. Also, $\text{scp}^*(\tilde{G}) \geq |V_2|^2 \cdot \text{scp}^*(G)$ since a set-cover packing of G has $|V_2|^2$ pairwise-disjoint copies in $\tilde{G}$.

Suppose $x \in L$ and then by Theorem 3.2 the set-cover packing graph $G(V_1, V_2, E)$ has a set-cover packing of size d. It follows that $\text{scp}^*(\tilde{G}) \geq |V_2|^2 d$. Now an argument identical to the one in section 3.2 shows a subgraph G' that is a feasible solution to OSP and with $\text{cost}(G') \leq |\tilde{V}_1| = |V_2|^2 |V_1|$.

Lemmas 3.5 and 3.6 will be used to complete the proof of Theorem 3.1. They are essentially analogous to Lemma 3.4. Let G' be a feasible solution to the instance $\tilde{G}$ of the OSP.

LEMMA 3.5. *For every $v_2 \in V_2$, less than $|V_2|$ vertices of $\tilde{A}$ are not at distance* 2 *in G' from v_2.*

Proof. Since G' is a feasible solution to the OSP instance $\tilde{G}$, it must contain at least k vertex-disjoint paths between v_2 and r. The $k = |\tilde{A}|$ paths are disjoint but

they all have to go through $\tilde{A}$, and thus each vertex of $\tilde{A}$ must belong to exactly one of these paths. Now, if a vertex of $\tilde{A}$ is not at distance 2 from v_2, then the path containing it must visit at least one additional vertex of V_2. But since the paths are disjoint, this event happens less than $|V_2|$ times. □

LEMMA 3.6. *There exists a feasible solution* G'_+ *with* $\text{cost}(G'_+) \leq \text{cost}(G') + |V_2|^2$, *such that for every* $a \in \tilde{A}$ *the set* $N(a, \tilde{V}_1, G'_+)$ *is a set-cover (in* $\tilde{G}$*) of* V_2.

Proof. Augment the feasible solution G' to a graph G'_+ as follows. For every $v_2 \in V_2$ and every $a \in \tilde{A}$, if a is not at distance 2 in G' from v_2, then add to G' an edge between a and an arbitrary vertex in $N(v_2, \tilde{G})$. By Lemma 3.5, every $v_2 \in V_2$ causes the addition of at most $|V_2|$ edges. Since each added edge has cost 1, the resulting G'_+ is a feasible solution with $\text{cost}(G'_+) \leq \text{cost}(G') + |V_2|^2$. Furthermore, every $a \in \tilde{A}$ is at distance 2 in G'_+ from every vertex $v_2 \in V_2$; i.e., the set $N(a, \tilde{V}_1, G'_+)$ is a set-cover (in G) of V_2. □

We now complete the proof of Theorem 3.1. Suppose $x \notin L$ and let G' be a feasible solution to $\tilde{G}$, as above. By Theorem 3.2 we have $\text{sc}^*(\tilde{G}) = \text{sc}^*(G) \geq (|V_1|/d) \cdot (1-\epsilon) \ln |V_1 \cup V_2|$. Let G'_+ be the augmented solution that follows from Lemma 3.6. Then for every $a \in \tilde{A}$, the set $N(a, \tilde{V}_1, G'_+)$ is a set-cover (in $\tilde{G}$) of V_2. Therefore, $\text{cost}(G'_+) = \sum_{a \in \tilde{A}} |N(a, \tilde{V}_1, G'_+)| \geq |\tilde{A}| \cdot \text{sc}^*(\tilde{G}) \geq |V_2|^2 |V_1| \cdot (1-\epsilon) \ln |V_1 \cup V_2|$. It follows that $\text{cost}(G') \geq \text{cost}(G'_+) - |V_2|^2 \geq |V_2|^2 |V_1| \cdot (1-2\epsilon) \ln |V_1 \cup V_2|$.

Since $d \leq |V_1| \leq |V_2|^\epsilon$, we have that $|V(\tilde{G})| = |V_2| + (|V_1| + d) \cdot |V_2|^2 \leq 3|V_1| \cdot |V_2|^2 \leq |V_2|^{2+2\epsilon}$. Thus, the gap between the case $x \in L$ and the case $x \notin L$ is at least $(1-2\epsilon) \ln |V_1 \cup V_2| \geq \frac{1-2\epsilon}{2+2\epsilon} \ln |V(\tilde{G})| \geq (\frac{1}{2} - 2\epsilon) \ln |V(\tilde{G})|$, proving Theorem 3.1.

4. Vertex-connectivity augmentation. In this section we show APX-hardness for the following vertex-connectivity augmentation problem ($\text{VCAP}_{\ell,k}$): Given a k-connected graph $G_0 = (V, E_0)$ and a cost function $c : V \times V \to \mathbb{N}$, find a set $E_1 \subseteq V \times V$ of minimum cost so that $G_1 = (V, E_0 \cup E_1)$ is ℓ-connected. Since all graphs considered here are simple, we will not allow G_1 to contain self-loops. $\text{VCAP}_{k,\ell}(a, b)$ will represent a version of the problem where edges have only cost a or b (so that $c : V \times V \to \{a, b\}$). The main result of this section is that for some fixed $\epsilon > 0$ and for every $k \geq 1$, it is NP-hard to approximate $\text{VCAP}_{k,k+1}(1, 2)$ within a factor of $1 + \epsilon$; this holds even in the case of uniform costs, i.e., $\text{VCAP}_{k,k+1}(1, \infty)$.

It is possible to convert any instance of $\text{VCAP}_{k_0,k_0+\alpha}$ to an "equivalent" instance of $\text{VCAP}_{k_0+1,k_0+1+\alpha}$ by adding to G_0 a new vertex that is connected to every old vertex. In addition, it will be immediate that our proof extends to edge costs from the set $\{1, \infty\}$. It thus suffices to prove the following.

THEOREM 4.1. *For any* $k \geq 1$ *and some fixed* $\epsilon > 0$ *(independent of* k*), it is* NP*-hard to approximate* $\text{VCAP}_{1,2}(1, 2)$ *within a factor of* $1 + \epsilon$.

The proof of Theorem 4.1 employs a reduction from 3-dimensional matching (3DM) that was used in [17] to prove that solving $\text{VCAP}_{1,2}(1, 2)$ (optimally) is NP-hard. We obtain a stronger result (hardness of approximation) by a more involved analysis of the reduction and by relying on the hardness of approximating a bounded version of the 3DM problem shown in [30].

3-*dimensional matching* (3DM) is the following problem. Given three (disjoint) sets W, X, Y, with $|W| = |Y| = |Z|$, and a set of hyperedges $M \subseteq W \times Y \times Z$, find the largest subset $M' \subseteq M$ which is a *matching*; i.e., if $(w, x, y), (w', x', y') \in M'$, then $w \neq w'$, $x \neq x'$, and $y \neq y'$. For any $z \in W \cup X \cup Y$, let $\deg(z)$ be the number of hyperedges in M that contain z. We define the *maximum degree* of an instance to be $\Delta = \max_{z \in W \cup X \cup Y} \deg(z)$. For an instance $\mathcal{I}$ of 3DM, let $\text{3DM}(\mathcal{I})$ be the size of an

optimal matching. For an instance $\mathcal{J}$ of $\text{VCAP}_{1,2}(1,2)$, let $\text{VCAP}(\mathcal{J})$ be the cost of an optimal augmentation.

The reduction. Let $\mathcal{I} = (M, W, X, Y)$ be an instance of 3DM with $|M| = p$ and $|W| = |X| = |Y| = q$. We create an instance $\mathcal{J}$ of $\text{VCAP}_{1,2}$ as follows. (See Figure 4 for illustration.) Let $G_0 = (V, E_0)$ with

$$V = \{r, \bar{r}\} \cup \{w_i, \bar{w}_i, x_i, y_i : i = 1, 2, \ldots, q\} \cup \{a_{ijk}, \bar{a}_{ijk} : (w_i, x_j, y_k) \in M\},$$

$$E_0 = \{(r, \bar{r})\} \cup \{(w_i, \bar{w}_i), (w_i, r), (x_i, \bar{r}), (y_i, r) : i = 1 \ldots, q\}$$
$$\cup \{(a_{ijk}, w_i), (\bar{w}_i, \bar{a}_{ijk}) : (w_i, x_j, y_k) \in M\}.$$

We will define $\text{cost}(\bar{a}_{ijk}, a_{ijk}) = \text{cost}(x_j, \bar{a}_{ijk}) = \text{cost}(y_k, a_{ijk}) = 1$ if $(w_i, x_j, y_k) \in M$ and $\text{cost}(u, v) = 2$ for all other $(u, v) \in V \times V$.

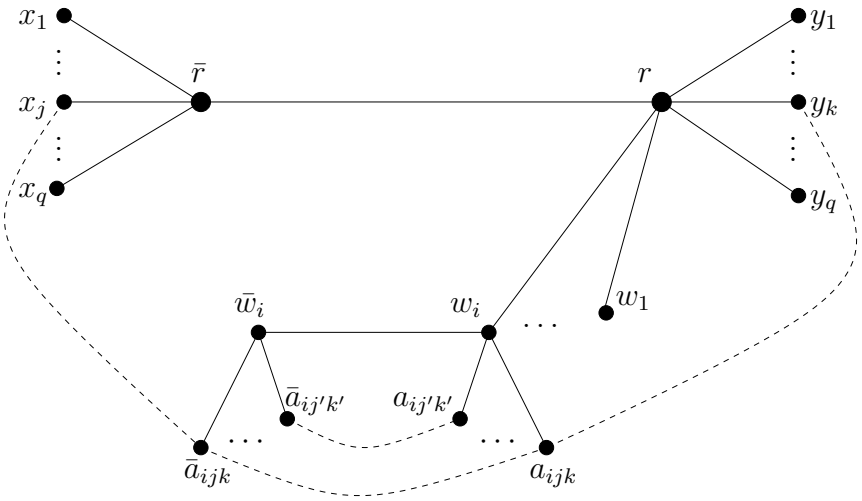

FIG. 4. *An instance of* VCAP *produced by the reduction. The solid lines represent edges of* G_0. *Some cost* 1 *edges are represented by dashed lines.*

LEMMA 4.2. *If* $\text{3DM}(\mathcal{I}) = q$, *then* $\text{VCAP}(\mathcal{J}) = p + q$.

Proof. Letting $M' \subseteq M$ be a matching of size q, we will construct an augmenting set E_1 consisting of $p + q$ edges of cost 1. These edges will be $(x_j, \bar{a}_{ijk})$ and (y_k, a_{ijk}) for every $(w_i, x_j, y_k) \in M'$ and $(a_{ijk}, \bar{a}_{ijk})$ for $(w_i, x_j, y_k) \in M - M'$. We must show that $G_1 = (V, E_0 \cup E_1)$ is 2-connected. By Menger's theorem (see section 1.3) it suffices to show that G_1 contains no cut-vertex.

Notice that G_0 is a tree with the $2(p+q)$ leaves $X \cup Y \cup \{a_{ijk}, \bar{a}_{ijk} : (w_i, x_j, y_k) \in M\}$. Neither of these leaves is a cut-vertex in G_0, and hence the same is true in G_1. So it remains to verify that each of r, $\bar{r}$, w_i, and $\bar{w}_i$ also is not a cut-vertex in G_1. It is easy to see that this indeed holds; for instance, if we remove some $\bar{w}_i$ from the graph, we may risk cutting off the vertices $\{\bar{a}_{ijk}\}$, but there is always some edge, either to a_{ijk} or to x_j (depending on whether $(w_i, x_j, y_k) \in M'$ or not), which leads back to the rest of the graph. Similar arguments hold for $r, \bar{r}$, and w_i. It follows that G_1 is 2-connected.

Hence E_1 is an augmenting set of cost $p+q$. To see that this is the cheapest such set, notice that for G_1 to be 2-connected, each leaf of G_0 must be incident to at least

one edge from E_1. Since there are $2(p+q)$ leaves and a single edge is incident to at most two of them, it follows that at least $p+q$ edges are necessary. ∎

LEMMA 4.3. *If* $\mathrm{VCAP}(\mathcal{J}) \le (p+q)(1+\epsilon)$, *then* $3\mathrm{DM}(\mathcal{I}) \ge q-(2+10\Delta)(p+q)\epsilon$.

Proof. Let $E_1 \subseteq E$ be a set of augmenting edges of cost at most $(p+q)(1+\epsilon)$ such that $G_1 = (V, E_0 \cup E_1)$ is 2-connected. As in Lemma 4.2, G_0 is a tree with the $2(p+q)$ leaves $X \cup Y \cup \{a_{ijk}, \bar{a}_{ijk} : (w_i, x_j, y_k) \in M\}$. Each leaf of G_0 must be adjacent to at least one edge of E_1 for G_1 to be 2-connected. Call a leaf *permissible* if it is adjacent to exactly one edge of E_1 and that edge has cost 1. Call a leaf *impermissible* otherwise (i.e., it is incident upon at least one edge of E_1 of cost 2 or upon more than one edge of E_1).

We first claim that at most $2(p+q)\epsilon$ leaves are impermissible. Indeed, for every impermissible leaf, the total cost of edges of E_1 that are incident at this leaf is at least 2. Similarly, for every permissible leaf this cost is exactly 1. The sum of these costs over all leaves is at most $2 \cdot \mathrm{cost}(E_1)$, since the cost of every edge of E_1 is counted at most twice (once from every end). Thus,

$$\#\{\text{permissible leaves}\} + 2 \cdot \#\{\text{impermissible leaves}\} \le 2 \cdot \mathrm{cost}(E_1) \le 2(p+q)(1+\epsilon).$$

Observing that the left-hand side is just $2(p+q)+\#\{\text{impermissible leaves}\}$, the claim follows immediately.

We now construct a set M' which is almost a matching. Initially, let $M' = \emptyset$. Then iteratively for $j = 1, 2, \ldots, q$ we try to find a hyperedge (in M) that contains x_j and add it to M', as follows. If x_j is permissible, then it is adjacent to a cost 1 edge of E_1; hence it is adjacent to some leaf $\bar{a}_{ijk}$. If both $\bar{a}_{ijk}$ and a_{ijk} are permissible, then the latter is adjacent (via a cost 1 edge) to some leaf y_k. If this leaf y_k is permissible, then add the hyperedge (w_i, x_j, y_k) to M'. Notice that $M' \subseteq M$ since the above process relies on cost 1 edges.

We next claim that $|M'| \ge q - 2\Delta(p+q)\epsilon$. Indeed, an impermissible x_j, a_{ijk}, or $\bar{a}_{ijk}$ can cause only one iteration (namely, the one with the corresponding value of j) to fail. An impermissible y_k can cause at most Δ iterations to fail, since it can be connected by edges of cost 1 to at most Δ leaves a_{ijk}. Denoting the number of impermissible y_k by n_y, we have that the number of iterations that fail is at most $2(p+q)\epsilon - n_y + n_y\Delta$. Since our claim shows that $n_y \le 2(p+q)\epsilon$, this is at most $2\Delta(p+q)\epsilon$.

By our construction, M' is almost a matching; its hyperedges have distinct elements from X and from Y, but its elements from W might be repeated, i.e., not distinct. For every element w_i that belongs to more than one hyperedge in M', let us remove from M' all but one of the hyperedges that contain w_i. The resulting set of hyperedges, denoted M'', is thus a matching. Let $\mu = q - |M''|$ be the number of vertices w_i that do not appear in any hyperedge of M' (or equivalently, of M''). Notice that $|M'| - |M''| \le q - |M''| = \mu$, so an upper bound on μ yields a lower bound on the size of the matching M''.

We now show that $\mu \le (2+8\Delta)(p+q)\epsilon$. Let E_1' be the edges of E_1 that correspond to hyperedges in M', namely, those edges $\{(x_j, \bar{a}_{ijk}) \text{ and } (y_k, a_{ijk})\}$ for $(w_i, x_j, y_k) \in M'$. We have that $\mathrm{cost}(E_1') \ge 2|M'| \ge 2q - 4\Delta(p+q)\epsilon$; hence

$$\mathrm{cost}(E_1 \setminus E_1') \le (p+q)(1+\epsilon) - 2q + 4\Delta(p+q)\epsilon = p - q + (1+4\Delta)(p+q)\epsilon. \quad (4.1)$$

Recall that each leaf (of G_0) a_{ijk} or $\bar{a}_{ijk}$ must be incident to an edge of E_1. The edges of E_1' are incident, by their definition, to at most $2|M'| \le 2q$ distinct such leaves; thus, the edges of $E_1 \setminus E_1'$ must be incident to the (at least) $2p - 2q$ remaining leaves

a_{ijk} and $\bar{a}_{ijk}$. If we split the cost of every edge in $E_1 \setminus E_1'$ (evenly) between its two endpoints, then we get that at least $2p - 2q$ leaves are each charged a cost of at least $1/2$. It follows that

$$\text{cost}(E_1 \setminus E_1') \geq (2p - 2q) \cdot (1/2). \tag{4.2}$$

We shall now improve over the lower bound (4.2) by considering the μ vertices w_i which do not make an appearance in M'. Each such w_i is a cut-vertex of $(V, E_0 \cup E_1')$ (by definition of E_1'), since its removal disconnects $W_i = \{\bar{w}_i\} \cup \{a_{ijk}, \bar{a}_{ijk} : (w_i, x_j, y_k) \in M\}$ from the rest of the graph. But w_i cannot be a cut-vertex of G_1, and thus $E_1 \setminus E_1'$ must contain an edge that connects W_i to the rest of the graph. We have three cases for this edge: (i) if it is incident (in W_i) to $\bar{w}_i$, then the edge's cost is at least 2 and $\bar{w}_i$ is charged at least 1; (ii) if the edge is incident (in W_i) to some a_{ijk} or $\bar{a}_{ijk}$ and (in the rest of the graph) to some $a_{i'j'k'}$ or $\bar{a}_{i'j'k'}$ (with $i \neq i'$), then the edge's cost is 2, and the endpoint in W_i is actually charged $1/2$ more than in the lower bound (4.2); or (iii) if this edge is incident (in W_i) to some a_{ijk} or $\bar{a}_{ijk}$ and (in the rest of the graph) to a vertex that is not $a_{i'j'k'}$ or $\bar{a}_{i'j'k'}$, then the edge's cost is at least 1, so the endpoint not in W_i is charged at least $1/2$. In all three cases, the fact that w_i is a cut-vertex in $(V, E_0 \cup E_1')$ implies that the lower bound (4.2) can be increased by $1/2$. It is easy to see that the increases corresponding to different w_i's are distinct, and thus,

$$\text{cost}(E_1 \setminus E_1') \geq (2p - 2q) \cdot (1/2) + \mu \cdot (1/2). \tag{4.3}$$

Combining equations (4.1) and (4.3) we indeed get that $\mu \leq (2 + 8\Delta)(p + q)\epsilon$. We conclude that $\mathcal{I}$ contains a matching M'' of size

$$|M''| \geq |M'| - \mu \geq q - 2\Delta(p + q)\epsilon - (2 + 8\Delta)(p + q)\epsilon = q - (2 + 10\Delta)(p + q)\epsilon,$$

which completes the proof of Lemma 4.3. □

3DM-5 is a bounded version of the 3DM problem in which every element of $W \cup Y \cup Z$ can appear at most five times in a triple of M, i.e., one in which $\Delta = 5$. It is shown in [30] that this variant is Max SNP-hard. In particular, the following theorem is proved.

THEOREM 4.4 (Petrank [30]). *For some fixed $\epsilon_0 > 0$, it is* NP*-hard to distinguish whether an instance of* 3DM-5 *with $|W| = |X| = |Y| = q$ has a perfect matching (of size q) or every matching has size at most $(1 - \epsilon_0)q$.*

If $|M| = p$ and $|W| = |X| = |Y| = q$, then in any instance of 3DM-5, we must have $p \leq 5q$. This observation, together with Lemmas 4.2 and 4.3 and Theorem 4.4, yield a proof of Theorem 4.1.

Proof of Theorem 4.1. We will show that our reduction above (see Theorem 4.1) is gap-preserving. Specifically, we will show that if $\mathcal{I}$ is an instance of 3DM-5 and $\mathcal{J}$ is the corresponding instance of $\text{VCAP}_{1,2}(1, 2)$, then

$$\begin{aligned} \text{3DM}(\mathcal{I}) = q &\Longrightarrow \text{VCAP}(\mathcal{J}) = p + q, \\ \text{3DM}(\mathcal{I}) < q(1 - \epsilon_0) &\Longrightarrow \text{VCAP}(\mathcal{J}) > (p + q)\,(1 + \epsilon_0/312)\,. \end{aligned}$$

The first implication follows directly from Lemma 4.2. The second one is the contrapositive of Lemma 4.3 with $\epsilon = \frac{\epsilon_0}{312}$, and then $\text{3DM}(\mathcal{I}) \geq q - (2 + 10\Delta)(5q + q)\epsilon = q(1 - 312\epsilon) = q(1 - \epsilon_0)$. □

Remark. A similar analysis can be applied to the NP-hardness reduction of [17] for the edge-connectivity augmentation problem (ECAP). This would prove that for

any $k \geq 1$ and some fixed $\epsilon > 0$ (independent of k), it is NP-hard to approximate $\mathrm{ECAP}_{k,k+1}(1,2)$ within a factor of $1+\epsilon$. The same holds for a model with uniform edge costs.

5. Discussion. We have shown that, in terms of approximation, the vertex-connectivity variant of SNDP differs significantly from the edge-connectivity variant, and that this holds even in relatively simple special cases. But there are a few important special cases which remain open. Most notably, for k-VCSS there is still a large gap between the known upper and lower bounds. It is particularly interesting that no result is known to exclude a 2-approximation; such a result would separate this problem from its edge-connectivity counterpart. The techniques that we relied on in section 3 were successfully applied to various problems to achieve (roughly) logarithmic hardness of approximation. It was our hope that these powerful techniques might also be applied to k-VCSS, but we were not able to do so.

An important observation to keep in mind is that the approximation ratios of SNDP and of k-VCSS are nondecreasing with the maximum requirement $k_{\max} := \max\{k_{u,v} : u, v \in V\}$. Indeed, given an instance graph with n vertices and maximum requirement $k_{\max}$, one can add a new vertex that is connected to all the existing vertices with zero-cost edges and increase all the existing requirements by 1. It is easy to see that any feasible solution to the original instance corresponds to a feasible solution with the same cost in the new instance, while $k_{\max}$ is increased by 1. It follows that any approximation ratio $f(k)$ (that is independent of n) must be nondecreasing with k. This argument also extends to the uniform cost case of SNDP by the remark at the end of section 1.2.

This observation may underlie two perplexing aspects of k-VCSS: (i) The known approximation ratio significantly degrades (approaches $\sqrt{n}$) as k gets closer to n, and one may suspect that this is not a coincidence. (ii) An interesting open question is whether the asymptotic approximation ratio of uniform cost k-VCSS is $1 + \Theta(1/k)$. Such an approximability threshold is known to exist for the Max k-Cut problem [23]. Nevertheless, general cost k-VCSS has completely different asymptotics; the result of [7] in conjunction with the observation in the previous paragraph shows that there is a fixed $\epsilon > 0$, such that for all $k \geq 2$, it is NP-hard to $1+\epsilon$ approximate k-VCSS with edge costs 0 and 1.

Finally, we stress that our reduction in section 2.2 relies on what we call the star property (in our graph-theoretic description) and which some literature refers to as the projection test. The hardness result of [10] improves over Theorem 2.1 by achieving a slightly larger inapproximability factor and by assuming the weaker complexity assumption $\mathsf{P} \neq \mathsf{NP}$. However, it lacks the star property that we require, and thus cannot be used to strengthen our result for SNDP.

Acknowledgments. We thank Joseph Cheriyan for raising the question of SNDP with uniform costs, which led to the remark at the end of section 1.2. We are also grateful to David Williamson and to the anonymous referees for comments that improved the presentation and for pointing out some of the issues mentioned in section 5.

THE GLAUBER DYNAMICS ON COLORINGS OF A GRAPH WITH HIGH GIRTH AND MAXIMUM DEGREE*

MICHAEL MOLLOY†

Abstract. We prove that the Glauber dynamics on the C-colorings of a graph G on n vertices with girth g and maximum degree Δ mixes rapidly if (i) $C = q\Delta$ and $q > q^*$, where $q^* = 1.4890\ldots$ is the root of $(1 - \mathrm{e}^{-1/q})^2 + q\mathrm{e}^{-1/q} = 1$; and (ii) $\Delta \geq D \log n$ and $g \geq D \log \Delta$ for some constant $D = D(q)$. This improves the bound of roughly 1.763Δ obtained by Dyer and Frieze [*Proceedings of the 32nd Annual Symposium on Foundations of Computer Science*, 2001] for the same class of graphs. Our bound on this class of graphs is lower than the bound of $11\Delta/6 \approx 1.833\Delta$ obtained by Vigoda [*J. Math. Phys.*, 41 (2000), pp. 1555–1569] for general graphs.

Key words. rapidly mixing Markov chains, Glauber dynamics, colorings

Introduction. For a given graph G and integer C which is at least the chromatic number of G, we define the Glauber dynamics on the C-colorings of G to be the Markov chain described as follows. We start with an arbitrary C-coloring, and at each step we choose a uniformly random vertex v, and a uniformly random color c from $L(v)$, the list of colors which do not appear on any neighbors of v. Then we change the color of v to c. (If $L(v)$ is empty, then we do not choose a color; note that $L(v)$ is never empty if $C > \Delta$.)

Unless specified otherwise, we consider all colorings to be proper, i.e., no two adjacent vertices can have the same color. In section 3, it will be important to note that we can apply this step even to a nonproper coloring of G. But note that if a coloring is proper, then applying a step of the chain cannot produce an improper coloring.

The main question in this area is: For what values of C does this Markov chain mix in polytime? Usually this is studied in terms of Δ, the maximum degree of G. It is well known that for some graphs, the chain does not mix for $C \leq \Delta + 1$. (In fact, there are some graphs and $(\Delta + 1)$-colorings for which no color changes are possible, and so the chain is not even ergodic.) Jerrum [7] showed that for all graphs, the chain mixes in polytime for $C \geq 2\Delta$ and in optimal time, i.e., $O(n \log n)$ time, for $C \geq 2\Delta + 1$. Salas and Sokal [11] independently obtained the latter result. Vigoda [13] showed that for all graphs, a different chain mixes in optimal time for $C \geq \frac{11}{6}\Delta$ and this implies that for the same values of C, the Glauber dynamics mixes in polytime. Dyer, Greenhill, and Molloy [5] showed that the Glauber dynamics mixes in optimal time for $C \geq (2 - \epsilon)\Delta$, where ϵ is a small positive constant (see also [9]). Some work has been done on special classes of graphs. Dyer et al. [3] showed that the Glauber dynamics mixes in optimal time on triangle-free graphs when $C \geq (2 - x)\Delta$ for a different small positive constant x. More recently, Dyer and Frieze [2] showed that if the maximum degree, Δ, of G is at least $D \log n$ and the girth is at least $D \log \Delta$ for

†Department of Computer Science, University of Toronto, Toronto, ON, M4E 3G1 Canada (molloy@cs.toronto.edu).

some sufficiently large constant D, then the chain mixes in optimal time for $C \geq q\Delta$ for any constant $q > \beta$, where $\beta = 1.763\ldots < 11/6$ is the root of $\beta e^{-1/\beta} = 1$. Here we improve on this latter result. We define $q^* = 1.4890\ldots$ to be the root of $(1 - e^{-1/q})^2 + qe^{-1/q} = 1$.

THEOREM 1. *For any $q > q^*$ and integer ω, there exists D for which: Suppose G has n vertices, maximum degree $\Delta \geq D \log n$, and no vertex lies in more than ω cycles of length less than $D \log \Delta$. Then the Glauber dynamics mixes in time $O(n \log n)$ for $C = q\Delta$.*

Of course, this covers all graphs with girth at least $D \log \Delta$. It also covers natural models of random graphs such as $G_{n,p=c/n}$ for $c \approx D \log n$ and random Δ-regular graphs for $\Delta = D \log n$. Dyer and Frieze [2] showed that their theorem also extends to such graphs.

Throughout the paper, we assume that n is large enough for various asymptotic bounds to hold. We can also assume that q is sufficiently close to q^*. We use $N(v)$ to denote the neighborhood of v, i.e., the set of vertices which are adjacent to v. We define $d(v) = |N(v)|$ to be the degree of v. A *short cycle* is a cycle of length less than $D \log \Delta$.

1. Some intuition. The proofs of the results mentioned above, except for that of Vigoda [13], all come from the following idea.[1] Consider two colorings X, W which differ only at one vertex v. We will carry out one step of the process on each coloring, where we couple these two random steps maximally. Specifically, we first choose a uniform vertex u for both colorings. If $L_X(u)$ and $L_W(u)$ are the sets of allowable colors for u in X, W, respectively, then we take two mappings $f_X : [0,1] \to L_X(u), f_W : [0,1] \to L_W(u)$, such that

- for each $c \in L_X(u)$, $|f_X^{-1}(c)| = 1/|L_X(u)|$ and similarly for W, and
- $\{x : f_X(x) \neq f_W(x)\}$ is as small as possible.

Then we take a uniform random real $x \in [0,1]$ and choose $u, f_X(x)$ for X and $u, f_W(x)$ for W. Note that since $L_X(u), L_W(u)$ differ in at most one color per list, we will have $|\{x : f_X(x) \neq f_W(x)\}| \leq \min\{|L_X(u)|^{-1}, |L_W(u)|^{-1}\}$. Note further that $L_X(u) = L_W(u)$ unless u is a neighbor of v.

Using the path-coupling technique of Bubley and Dyer [1], it suffices to show that the probability of X, W converging after one step is greater than the probability of their differing in a second vertex after one step (we elaborate on this in section 3). They converge iff we choose $u = v$, which occurs with probability $1/n$. They differ on a second vertex iff we choose some $u \in N(v)$ and we choose $x \in \{x : f_X(x) \neq f_W(x)\}$. Since no list can ever be smaller than $C - \Delta$, this occurs with probability at most $\frac{\Delta}{n} \times \frac{1}{C-\Delta}$ which is less than $\frac{1}{n}$ so long as $C > 2\Delta$.

The bound was improved slightly in [3] by showing that for triangle-free graphs, after a relatively short period, most vertices will tend to have many repeated colors in their neighborhoods. Thus, their lists of available colors will tend to be somewhat greater than $C - \Delta$, and this leads to a gain in the above calculations. The same idea played a key role in [5].

In [2], Dyer and Frieze showed that for graphs with large girth and maximum degree, after $O(n \log n)$ steps, with high probability every vertex will have a list of size at least roughly $qe^{-1/q}\Delta$. If X, W are such that all vertices have lists of this size, then this yields that the probability of X, W differing on a second color is at most $\frac{\Delta}{n} \times \frac{1}{qe^{-1/q}\Delta}$. Since q is chosen so that $qe^{-1/q} > 1$, this probability is less than $\frac{1}{n}$.

[1] Jerrum's original proof in [7] predated this idea, but the idea yields a simpler proof.

The key new idea used in this paper is to show that, after $O(n \log n)$ steps, many neighbors u of v will satisfy $L_X(u) = L_W(u)$. If, for the sake of this intuitive introduction, we make the simplifying assumption that the graph is Δ-regular, then with high probability there will be roughly $(1 - \mathrm{e}^{-1/q})^2\Delta$ such neighbors. This improves our bound on the probability of X, W differing on a second color to $\frac{(1-(1-\mathrm{e}^{-1/q})^2)\Delta}{n} \times \frac{1}{q\mathrm{e}^{-1/q}\Delta}$, which is less than $\frac{1}{n}$ for $q > q^*$.

1.1. Uniform-like color sets. Suppose that G is Δ-regular and that every vertex in $N(v)$ is assigned an independent uniform color from $\{1, \ldots, C\}$. Then the probability that some color c does not appear on any neighbor of v is $(1 - 1/C)^\Delta = \mathrm{e}^{-1/q} + o(1)$. Thus we would expect that each list would have size roughly $C \times \mathrm{e}^{-1/q} = q\mathrm{e}^{-1/q}\Delta$. This explains, at least intuitively, the lower bound that Dyer and Frieze obtain.

Now suppose that every vertex of distance 2 from v is also assigned an independent uniform color from $\{1, \ldots, C\}$. Suppose further that we change the color of v in our coloring X to obtain another coloring W. For each $u \in N(v)$, $L_X(u) = L_W(u)$ iff the colors $X(v)$ and $W(v)$ both appear on $N(u) - v$. The probability that this occurs is $(1 - \mathrm{e}^{-1/q})^2 + o(1)$, and so this explains the result in this paper.

Of course, the colors appearing on the neighbors of v are far from independent. But intuitively, since there are few short cycles near v, after $O(n \log n)$ steps the colors on vertices close to v are "close enough" to being independent. Much of the work in this paper can be viewed as proving this statement.

1.2. A recursive analysis. Our situation is somewhat more complicated than that in [2]. To illustrate this, suppose that $N(v) = w_1, \ldots, w_\Delta$ and consider any assignment of colors to the vertices in $N(w_1), \ldots, N(w_\Delta)$. Now, assign to each w_i a uniform color from among those not appearing on $N(w_i)$, independently of the choice for any other w_j. It turns out, that for any assignment of colors to $N(w_1), \ldots, N(w_\Delta)$, the expected number of colors not appearing on $N(v)$ is at least $q\mathrm{e}^{-1/q}\Delta - o(\Delta)$. Thus, Dyer and Frieze did not have to ensure that the random colors appearing on $N(w_1), \ldots, N(w_\Delta)$ are close to uniform. Unfortunately, when analyzing our other parameter, we do not have this advantage and we need to prove rather tight results on the distributions of the colors appearing at distance 2 and 3 from v.

To do this, we require a complicated iterative analysis. We'll introduce that analysis now, in an oversimplified setting, before formalizing it in the next section. First, it will be much simpler to assume that G is regular and so every vertex has degree Δ. We will also pretend that the time steps are partitioned into a series of epochs, $\Psi_0, \Psi_1, \Psi_2, \ldots$ and that every vertex is recolored at least once during each epoch.

We will be interested in two parameters. The first is the number of colors available to each vertex. We will create a sequence $L_0 > L_1 > L_2 > \cdots$ such that during epoch Ψ_i, the set $L(v)$ of colors available to vertex v satisfies

$$|L(v)| \leq L_i$$

for every v. Furthermore, the same analysis as in [2] will yield that for $i \geq 1$, at any time during epoch Ψ_i we have

$$|L(v)| \geq (\mathrm{e}^{-1/q} - o(1))C = q\mathrm{e}^{-1/q}\Delta - o(\Delta).$$

The second parameter has to do with the probability that a particular color c is in L_v. For any color c and vertex v, we define

$$T(v,c) = \sum_{w \in N(v), c \in L(w)} \frac{1}{|L(w)|}.$$

Thus, if we were to choose a random color for each neighbor of v in turn, then $T(v,c)$ would be the expected number of neighbors which are assigned c. Furthermore, if we assume as in subsection 1.1 that these choices are independent, then the probability that no neighbors are assigned c, i.e., that at the end of these choices we have $c \in L(v)$, is roughly $\mathrm{e}^{-T(v,c)}$.

Of course, we need to be a bit careful here, because the sets $L(w)$ vary with time and we are actually interested in their values at different time steps. But we will overlook such details now as we are just providing an intuitive overview.

We will introduce sequences $A_0 < A_1 < A_2 < \cdots$ and $B_0 > B_1 > B_2 > \cdots$ such that during epoch Ψ_i, we have for every pair v, c

$$A_i \le T(v,c) \le B_i.$$

We start with our recursive equation for A_i. Suppose that we are in epoch Ψ_{i+1} and for each neighbor w of v, let's pretend that the neighbors of w were most recently colored during epoch Ψ_i. At that time we had $T(w,c) \le B_i$ and so the probability that c is now in $L(w)$ is at least roughly e^{-B_i}. We also have $|L(w)| \le L_i$. This inspires us to define

$$A_{i+1} = \Delta \times \mathrm{e}^{-B_i}/L_i.$$

Similarly, we obtain

$$B_{i+1} = \Delta \times \mathrm{e}^{-A_i}/(\mathrm{e}^{-1/q}C).$$

Finally, we consider L_{i+1}. $\mathbf{Exp}(|L(v)|)$ is roughly $\sum_{c=1}^{C} \mathrm{e}^{-T(v,c)}$. Also, note that

$$\sum_{c=1}^{C} T(v,c) = \sum_{w \in N(v)} \sum_{c \in L(w)} \frac{1}{|L(w)|} = \Delta.$$

Thus, our expression for $\mathbf{Exp}(|L(v)|)$ is minimized when each $T(v,c)$ is equal to Δ/C, which yields a nonrecursive lower bound of $C \times \mathrm{e}^{-\Delta/C} = C \times \mathrm{e}^{-1/q}$, as obtained in [2]. Furthermore, the expression is maximized when the values of $T(v,c)$ are as disparate as possible. Since each $T(v,c)$ is between A_i and B_i, we get a recursive upper bound by assuming that every $T(v,c)$ is either A_i or B_i. Since they sum to Δ, we must have $(\Delta - CB_i)/(A_i - B_i)$ of them equal to A_i and $(\Delta - CA_i)/(B_i - A_i)$ of them equal to B_i. That gives an upper bound of

$$L_{i+1} = \frac{\Delta - CB_i}{A_i - B_i} \times \mathrm{e}^{-A_i} + \frac{\Delta - CA_i}{B_i - A_i} \times \mathrm{e}^{-B_i}.$$

After choosing appropriate initial values, it is straightforward to show that these recursive equations have a limit of $A_i = B_i = 1/q$ and $L_i = C \times \mathrm{e}^{-1/q}$. Therefore, by running our Markov chain for enough epochs, we can guarantee that for every v, c we have $L(v)$ arbitrarily close to $\mathrm{e}^{-1/q}$ and $T(v,c)$ arbitrarily close to Δ/C. This

goes a long way towards allowing us to show that the intuitive analysis outlined in subsection 1.1 holds.

To transform this intuition into a proof, we need to be much more precise. For one thing, we have to be careful about specifying the time steps at which we are measuring $L(v)$ in some of these quantities. We also can't assume that every vertex is selected exactly once per epoch; it turns out that at least once per epoch will do, and we can achieve that by taking each epoch to be of length $O(n \log n)$. Also, these recursive equations were obtained by (implicitly) assuming that in each epoch, every quantity will be equal to its expected value. In order to allow for the possibility that some quantities differ slightly from their expected values, we decrease each A_i and increase each B_i, L_i by a small amount; we also apply a concentration inequality to show that they don't differ more than slightly from their expected values. Finally, we can't assume that every vertex has degree exactly Δ, and so we have to allow our bounds on $|L(v)|$ to be functions of the degree of v.

All of the adjustments outlined in the preceding paragraph are straightforward, but tedious if we assume, as in subsection 1.1, that the random colors assigned to the neighbors of a vertex are independent. Of course, this assumption is not valid and so we need to prove that they are, in some sense, close to being independent. We do this by focusing on "long paths of disagreement," which will be described further in later sections.

2. The main lemmas. As described in the opening part of section 1, our goal is essentially to show that after $O(n \log n)$ steps, many neighbors u of v will satisfy $L_X(u) = L_W(u)$. We must complicate this condition somewhat. First, for technical reasons, we wish to make this hold independently of our choice of the colors v has in X, W and so we make a statement that holds for every pair of colors c_1, c_2. Also, we have to adjust our goal somewhat to deal with the case where v has neighbors of degree less than Δ. In fact, neighbors of very small degree, less than $\rho\Delta$ for some small positive constant ρ, are particularly problematic and so have to be dealt with separately. Our main lemma is as follows.

LEMMA 2. *For every $\epsilon, \rho > 0$, there exist constants D, τ such that with probability at least $1 - O(n^{-6})$, for every vertex v, colors c_1, c_2, and time $\tau n \log n \le t \le n^2$, we have the following: Define $\theta = \theta_{c_1,c_2}(v)$ to be the set of neighbors w of v with $d(w) \ge \rho\Delta$ and with at least one of c_1, c_2 not appearing in $N(w) - v$, and define*

$$R_{c_1,c_2}(v) = \sum_{w \in \theta} \frac{1}{|L(w)|}.$$

Then

$$R_{c_1,c_2}(v) \le \frac{1 - (1 - \mathrm{e}^{-1/q})^2}{q\mathrm{e}^{-1/q}} \times \frac{d(v)}{\Delta} + \epsilon.$$

Note that, under the notation of section 1, if v has c_1 in X and c_2 in W, and if $d(w) > \rho\Delta$ and $L_X(w) \ne L_W(w)$, then $w \in \theta_{c_1,c_2}(v)$. Thus if the graph is Δ-regular, then this lemma implies what we said our goal was in the opening part of section 1.

In section 3, we will strengthen this lemma and then show how it implies Theorem 1. For ease of presentation, we first prove Lemma 2 and then show how to adapt the proof to yield the stronger lemma.

We begin with a recursive definition. This is along the same lines as that described in subsection 1.2, but modified somewhat to facilitate a formal proof. For

each $0 \le d \le \Delta$,

- $\alpha_1 = 0, \beta_1 = 1/(q-1), \lambda_1^{(d)} = q$;
- $\alpha_{k+1} = \mathrm{e}^{-\beta_k}/\lambda_k^{(\Delta)}$;
- $\beta_{k+1} = \mathrm{e}^{-\alpha_k}/(q\mathrm{e}^{-1/q})$;
- $\lambda_{k+1}^{(d)} = \frac{q\beta_k - 1}{\beta_k - \alpha_k}\mathrm{e}^{-\alpha_k d/\Delta} + \frac{1-q\alpha_k}{\beta_k-\alpha_k}\mathrm{e}^{-\beta_k d/\Delta}$.

LEMMA 3. $\lim_{k\to\infty}\alpha_k = \lim_{k\to\infty}\beta_k = 1/q, \lim_{k\to\infty}\lambda_k^{(d)} = q\mathrm{e}^{-d/q\Delta}$.

We postpone the proof of Lemma 3 until later. But for now, we require the following simple observation.

LEMMA 4. *For all $k \ge 1$ and $0 \le d \le \Delta$,*

(a) $\alpha_k < 1/q < \beta_k$, *and*

(b) $q\mathrm{e}^{-\beta_k d/\Delta} \le \lambda_{k+1}^{(d)} \le q\mathrm{e}^{-\alpha_k d/\Delta}$.

Proof. (b) follows since $\lambda_{k+1}^{(d)}$ is a linear combination of $q\mathrm{e}^{-\beta_k d/\Delta}$ and $q\mathrm{e}^{-\alpha_k d/\Delta}$. (a) follows from a simple induction. □

In subsection 1.2 we said that we have to adjust our sequences by a small amount, in order to allow for the possibility that some terms differ slightly from their expected values. We do so now.

Fix some small δ to be named later, and choose k^* such that $\alpha_{k^*} > \frac{1}{q} - \delta/2$, $\beta_{k^*} < \frac{1}{q} + \delta/2$, and $\lambda_{k^*} < q\mathrm{e}^{-1/q} + \delta/2$ (such a k^* exists by Lemma 3). Choose a sufficiently small constant ζ and constants $a_1, \dots, a_{k^*}, b_1, \dots, b_{k^*}, \ell_1^{(0)}, \dots, \ell_{k^*}^{(\Delta)}$ such that

(i) $a_1 = \alpha_1, b_1 = \beta_1, \ell_1^{(d)} = \lambda_1^{(d)}$;

(ii)
- $a_{k+1} < \mathrm{e}^{-b_k}/\ell_k^{(\Delta)} - \zeta$;
- $b_{k+1} > \mathrm{e}^{-a_k}/(q\mathrm{e}^{-(1+\zeta)/q}) + \zeta$;
- $\ell_{k+1}^{(d)} = \frac{qb_k - 1}{b_k - a_k}\mathrm{e}^{-(1-\zeta)a_k d/\Delta} + \frac{1-qa_k}{b_k-a_k}\mathrm{e}^{-(1-\zeta)b_k d/\Delta}$

(iii) $a_{k^*} > \frac{1}{q} - \delta, b_{k^*} < \frac{1}{q} + \delta$.

The existence of such constants follows easily from the continuity of the relevant functions over the region $a \ne b$.

Note that we can assume that ρ is as small as we wish, as if Lemma 2 holds with $\rho = \rho_1$ then it clearly holds with $\rho = \rho_2$ for any $\rho_2 > \rho_1$. In particular, we will assume that

- $1/(q-\rho) < \mathrm{e}^{(1+\zeta-a_{k^*})/q}/q$; and
- $\mathrm{e}^{-\rho/(q-1)} > \mathrm{e}^{1/q - b_{k^*}}$.

We define $L_t(v)$ to be the set of colors available for v at time t; we sometimes omit the subscript t when it is not necessary. For any vertex u and time t, we define $\bar{t}(u,t)$ to be the last time before t that u is selected. To be precise, we define $\bar{t}(u,t)$ to be zero in the event that u is not selected before time t. This notation allows us to define a more careful refinement of the vague quantity $T(v,c)$ from subsection 1.2:

$$T_t(v,c) = \sum_{w\in N(v), c\in L_{\bar{t}(w,t)}(w)} \frac{1}{|L_{\bar{t}(w,t)}(w)|}.$$

Note that

$$\sum_{c=1}^{C} T_t(v,c) = \sum_{w\in N(v)} \sum_{c\in L_{\bar{t}(w,t)}(w)} \frac{1}{|L_{\bar{t}(w,t)}(w)|} = d(v).$$

We will prove the following lemma inductively.

LEMMA 5. *For each $1 \le k \le k^*$, with probability at least $1 - n^{-6}$, for every v with $d(v) > \rho\Delta$, color c and $30kn \log n \le t \le n^2$, we have*

(a) $q e^{-(1+\zeta)d(v)/C}\Delta \le |L_t(v)| \le \ell_k^{(d(v))}\Delta$;

(b) $a_k d(v)/\Delta \le T_t(v,c) \le b_k d(v)/\Delta$.

The lower bound in part (a) is essentially Lemma 4.1 and (7) of Dyer and Frieze [2], and our proof is similar to theirs.

Proof. The proof is by induction on k. The base case $k = 1$ holds trivially. So assume that it holds for some k and consider $k+1$.

Let the neighbors of v be $w_1, \dots, w_{d(v)}$ and for each i let $t_i = \bar{t}(w_i, t)$ be the last time before t that w_i is selected. For each i, let $N_{w_i} - v = \{w_{i,1}, \dots, w_{i,d(w_i)-1}\}$ and let $t_{i,j} = \bar{t}(w_{i,j}, t_i)$ be the last time before t_i that $w_{i,j}$ is selected. Similarly, for each i, j let $N_{w_{i,j}} - w_i = \{w_{i,j,1}, \dots, w_{i,j,d(w_{i,j})-1}\}$ and let $t_{i,j,r} = \bar{t}(w_{i,j,r}, t_{i,j})$ be the last time before $t_{i,j}$ that $w_{i,j,r}$ is selected. (If v lies in some cycles of length at most 6, then some vertices will receive more than one label, but this does not create a problem.)

The idea of focusing on the colors assigned at these times was used by Dyer and Frieze [2].

With high probability, each $t_i \ge t - 10n\log n$. Indeed, the probability that this is not true is at most $\Delta(1 - \frac{1}{n})^{10n\log n} < n^{-9}$. The same calculations give the same bound on the probability that some $t_{i,j}$ is less than $t - 20n\log n$ or that some $t_{i,j,r}$ is less than $t - 30n\log n$.

We start by proving part (a). Expose the values of $t_1, \dots, t_{d(v)}, t_{1,1}, \dots, t_{d(v),d(w_{d(v)})-1}$.

It would be nice if we could say that the colors assigned to $w_1, \dots, w_{d(v)}$ were independent, as that would greatly simplify our calculations. However, this is clearly not the case, since the color assigned to w_i has an effect on the next color assigned to a neighbor of w_i, and this effect can propagate along a path which eventually leads to some w_j. This can be a very short path if it goes through v; we will deal with such paths later. Otherwise, unless w_i is one of the at most $O(1)$ vertices lying on a short cycle through v, the path must have length at least $D\log\Delta - 2$. Our first concern will be such long paths.

Consider the following procedure, which we denote GLAUB(i). It follows the usual Glauber dynamics, but after step t_i all neighbors of w_i ignore w_i. More specifically, for each $u \in N(w_i)$, $L(u)$ is the set of colors which do not appear on $N(u) - w_i$, and whenever u is selected, u is assigned a uniformly random color from $L(u)$. Thus, for example, w_i might have the same color as some of its neighbors.

We use GLAUB to denote the usual Glauber dynamics, and we consider the two procedures to be coupled in that each has the same initial state and chooses the same vertex at each step. The color choice at each step is coupled maximally.

A *long path of disagreement* from w_i is a path P of length at least $\ell = (D/3)\log\Delta$ beginning at w_i and not going through v, such that the color of each vertex in the path differs between GLAUB and GLAUB(i). (Such paths were used in a slightly different way by Dyer and Frieze [2] and earlier, in a different setting, by van den Berg and Steif [12].) We say that w_i is *influential* if there is a long path of disagreement from w_i or if by changing the color assigned to w_i at time t_i, and not changing any future color/vertex choices in GLAUB(i), it is possible to create a long path of disagreement from w_i.

We define B to be the set of neighbors w_i such that either w_i lies in a cycle through v of length less than $D\log\Delta$ or w_i is influential.

LEMMA 6. *With probability at least* $1 - n^{-10}$, $|B| < \Delta/\log\Delta$.

Proof. The set of neighbors which lie on a short cycle through v is at most 2ω. Therefore, we only have to count the influential vertices which do not lie on any short cycle through v. Consider such a vertex w_i; we will bound the probability that it is influential.

We will bound this probability by the probability that either w_i is influential, or $t_i < t - 20n\log\Delta$. The probability of the latter is $(1-1/n)^{20n\log\Delta} < \frac{1}{2}\Delta^{-11}$.

If w_i is influential and $t_i \geq t - 20n\log\Delta$, then there is a path $P : w_j = p_0, p_1, \ldots, p_\ell$, a color c to assign to w_i at time t_i, and time steps $t - 20n\log\Delta < s_1 < \cdots < s_\ell \leq t$ such that at step s_r, p_r is selected and assigned different colors in the two procedures.

Suppose that P is the lexicographically first such path formed. Thus, at each step s_r, if the colors of some neighbor u of p_r disagree in the two procedures, then there is a path of disagreement from u to w_j which does not go through p_r. Since that path has length less than ℓ, then p_r and u lie in a cycle of length less than $D\log\Delta$. Since p_r lies in at most ω such cycles, there can be at most 2ω such neighbors. Thus, since $|L(p_r)|$ is always at least $C - \Delta = (q-1)\Delta$, the probability that p_r chooses a different color for each procedure, under the maximal coupling, is less than $2\omega/((q-1)\Delta)$. Therefore, the probability that such a path is formed is at most

$$\Delta \times (\Delta-1)^\ell \times \binom{20n\log\Delta}{\ell} \times \left(\frac{2\omega}{(q-1)\Delta}\right)^\ell < \Delta \times \left(\frac{100\mathrm{e}\omega}{D}\right)^\ell < \frac{1}{2}\Delta^{-11}$$

for D sufficiently large and q near q^*. Thus, after adding the probability that $t_i < t - 20n\log\Delta$, the probability that w_i is influential is at most Δ^{-11}.

Now consider any collection $w_{i_1}, \ldots, w_{i_m}$ of $m = \Delta/\log\Delta - 2\omega$ neighbors which don't lie in short cycles through v. Using the fact that long paths of disagreement from any two such neighbors must be disjoint, similar calculations yield that the probability of all m neighbors being influential is at most $(\Delta^{-11})^m$. Therefore, the probability that at least m such neighbors of v are influential is at most

$$\binom{\Delta}{m} \times \Delta^{-11m} < \Delta^{-10m} < n^{-10}$$

for $D > 1$. ∎

Now, for each i, j, we expose the color assigned to $u_{i,j}$ at time $t_{i,j}$. We also expose the set B. We denote this set of information, along with the values of $t_1, \ldots t_{d(v)}, t_{1,1}, \ldots t_{d(v),d(w_{d(v)})-1}$, by $\mathcal{H}$. We say that $\mathcal{H}$ is *good* if every $t_i, t_{i,j} \geq t - 30n\log n$, if the sets of color assignments satisfy the conditions of Lemma 5 for k, and if $|B| \leq \Delta/\log\Delta$. We will show by induction that the probability of $\mathcal{H}$ not being good is at most $O(n^{-9})$.

LEMMA 7. *For any good* $\mathcal{H}$*, the conditional probability that, at a particular time* $t \geq 30(k+1)n\log n$ *during MOD-GLAUB,* $|L(v)| \leq q\mathrm{e}^{-(1+\zeta/2)d(v)/C}\Delta$ *or* $|L(v)| \geq \ell_{k+1}^{(d(v))}\Delta - \zeta/2$ *is at most* n^{-9}.

Proof. Rather than analyzing $|L(v)|$ directly, we will focus on $|L^*(v)|$, the set of colors which do not appear on any $w_i \in N(v) - B$. Note that $|L^*(v)| \geq |L(v)| \geq |L^*(v)| - |B| = |L^*(v)| - o(\Delta)$.

Rather than dealing with GLAUB directly, we consider the procedure MOD-GLAUB, whereby after time $t - 30n\log n$, neighbors of v ignore the color on v.

The advantage of focusing on $|L^*(v)|$ and MOD-GLAUB is that the color assignments to the vertices in $N(v) - B$ are independent. This is because no combination of assignments to these vertices can produce a long path of disagreement from one such vertex to another, and, since the vertices ignore the color on v and no two lie on a short cycle through v, there are no short paths of disagreement between these vertices.

Furthermore, exposing the fact that $w_i \notin B$ only exposes that w_i is not influential. Since the definition of "influential" does not depend on the particular color assigned to w_i, this does not expose anything about that choice of color.

So each w_i receives a uniformly random color from among those colors which $\mathcal{H}$ dictates to not appear on $N(w_i) - v$ at time t_i, and the choices for $w_1, \dots, w_\Delta$ are independent. Thus, for any color c the conditional probability that c belongs to $L^*(v)$ at time t is

$$\prod_{w \in N(v)-B, c \in L(w)} 1 - \frac{1}{L(w)} = \exp(-T(v,c)) + o(1),$$

since every $L(w)$ has size at least $C - \Delta = (q-1)\Delta$, and since $|B| = o(\Delta)$. Therefore, the expected size of $L^*(v)$ at time t is equal to $\sum_c \exp(-T(v,c)) + o(\Delta)$.

Recall that $\sum_c T(v,c) = d(v)$. Furthermore, since $\mathcal{H}$ is good, each $T(v,c)$ lies between $a_k d(v)/\Delta$ and $b_k d(v)/\Delta$. Subject to these constraints, $\sum_c \exp(-T(v,c))$ is easily seen to be minimized when every $T(v,c) = d(v)/C$, and maximized when every $T(v,c)$ is either $a_k d(v)/\Delta$ or $b_k d(v)/\Delta$. In the latter case, the fact that there are $C = q\Delta$ different $T(v,c)$ terms and they sum to $d(v)$ implies that $\Delta(qb_k - 1)/(b_k - a_k)$ of them are equal to $a_k d(v)/\Delta$ and the remaining $\Delta(1 - qa_k)/(b_k - a_k)$ of them are equal to $b_k d(v)/\Delta$. This yields

$$q\mathrm{e}^{-d(v)/C}\Delta \le \mathbf{Exp}(|L^*(v)|) \le \Delta \times \left(\frac{qb_k - 1}{b_k - a_k} \mathrm{e}^{-a_k d(v)/\Delta} + \frac{1 - qa_k}{b_k - a_k} \mathrm{e}^{-b_k d(v)/\Delta} \right).$$

Note that these calculations can be used to show that for all d, k,

$$\ell_k^{(d)} > q\mathrm{e}^{-d/q}. \tag{1}$$

Since the color choice for w_i can affect $|L^*(v)|$ by at most 1, Azuma's inequality implies that $|L^*(v)|$ is highly concentrated and, in particular, that the probability of it differing from its expected value by $\Theta(\Delta)$ is $\mathrm{e}^{-\Theta(\Delta)}$. Since $d(v) > \rho\Delta$, this proves our bound on $|L^*(v)|$ in MOD-GLAUB.

Now we extend this bound to GLAUB. If the color of w_i differs in the two procedures, then at some step after $t - 30n \log n$, w_i is assigned a color that appears on v and on no other neighbor of w_i. Since $|L(w_i)|$ is always greater than $C - \Delta = (q-1)\Delta$, this occurs with probability at most $((q-1)n\Delta)^{-1}$ at any one time step, so the probability that it occurs at least once is at most $30n \log n/((q-1)n\Delta) < 100/D$.

So the expected number of vertices in $N(v)$ which are affected in this way is at most $100\Delta/D = O(\log n)$. A simple application of the Chernoff bounds shows that this number is highly concentrated, and so the probability that it is higher than $\Theta(\Delta)$ is at most $\mathrm{e}^{-\Theta(\Delta)} < n^{-10}$ for $\Delta \ge D \log n$, where D is sufficiently large in terms of ν. This proves the lemma. □

Adding the probability of $n^{-10} + O(n^{-9})$ that $\mathcal{H}$ is not good and multiplying by the $n \times n^2$ choices for v, t establish part (a) of Lemma 5.

Part (b) follows in the same manner. We define B^* in a similar way to B, with the exception that a neighbor w_i is in B^* if (i) $w_i \in B$, (ii) it is possible, by changing the color assigned to a neighbor u of w_i, to form a long path of disagreement from u not passing through w_i, or (iii) some neighbor u of w_i lies in a short cycle through w_i. The same analysis shows that $\mathbf{Pr}(|B^*| > \Delta/\log\Delta) < n^{-11}$. (An extra factor of Δ appears in the expected number calculation, and this is not enough to raise that expected number significantly.) We then restrict our attention to

$$T_t^*(v,c) = \sum_{w \in N(v) - B*, c \in L_{\bar{t}(w,t)}(w)} \frac{1}{|L_{\bar{t}(w,t)}(w)|}.$$

$\mathcal{H}$ exposes B^*, all times $t_i, t_{i,j}, t_{i,j,r}$, and the colors assigned to each $u_{i,j,r}$ at time $t_{i,j,r}$. Then we modify our procedure as follows: All vertices ignore the colors on $v, w_1, \ldots, w_\Delta$, and after time $t_{i,j}$, the neighbors of $w_{i,j}$ ignore the color of $w_{i,j}$. If some $w_{i,j}$ is adjacent to $w_{i',j'}$, then they ignore each other's colors. We refer to this modified procedure as MOD-GLAUB2.

Consider any $w_i \notin B^*$ and let $I(w_i, c)$ be the indicator variable that $c \in L(w_i)$ at time t_i. Suppose that $d(w_i) > \rho\Delta$. As in the proof of part (a), $\mathbf{Pr}(I(w_i,c) = 1) = \exp(-T_{t_i}(w_i,c)) + o(1)$. Therefore, using the bounds on $T_{t_i}(w_i,c)$ and the list sizes from the fact that $\mathcal{H}$ is good, the expected value of $I(w_i,c)/|L_{t_i}(w_i)|$ is at most

$$(\mathrm{e}^{-a_k d(w_i)/\Delta} + o(1)) \times \frac{1}{q\mathrm{e}^{-(1+\zeta)d(w_i)/C}\Delta} \le \frac{1}{\Delta} \times \mathrm{e}^{-a_k/q}/(q\mathrm{e}^{-(1+\zeta)/q}) + o(1),$$

since the fact that $a_k < 1/q$ implies that the left-hand side is maximized at $d(w_i) = \Delta$.

We must take more care in proving our lower bound. We use L to denote $|L(w_i)|$ at time t_i, we let R be the event that $L \le \ell_{k+1}^{(d(v))}\Delta$, and we let I_R be the indicator variable for R. In part (a), we proved that $\mathbf{Pr}(I_R = 0) = O(n^{-9})$. Therefore,

$$\begin{aligned}
\mathbf{Exp}\left(\frac{I(w_i,c)}{L}\right) &\ge \mathbf{Exp}\left(\frac{I(w_i,c)}{L} \times I_R\right) \\
&\ge \frac{\mathbf{Pr}(I(w_i,c)=1) - \mathbf{Pr}(I_r = 0)}{\ell_{k+1}^{(d(v))}\Delta} \\
&= \frac{\mathbf{Pr}(I(w_i,c))}{\ell_{k+1}^{(d(v))}\Delta} + o(1/\Delta).
\end{aligned}$$

Furthermore, we have

$$\begin{aligned}
\ell_{k+1}^d &= \frac{1}{b_k - a_k}\left((qb_k - 1)\mathrm{e}^{-(1-\zeta)a_k d/\Delta} + (1 - qa_k)\mathrm{e}^{-(1-\zeta)b_k d/\Delta}\right) \\
&< \frac{1}{b_k - a_k}\left((qb_k - 1)\mathrm{e}^{-(1-\zeta)a_k} + (1 - qa_k)\mathrm{e}^{-(1-\zeta)b_k}\right) \times \mathrm{e}^{(1-\zeta)b_k(1-d/D)} \\
&= \ell_{k+1}^{(\Delta)} \times \mathrm{e}^{(1-\zeta)b_k(1-d/D)}.
\end{aligned}$$

Thus, the expected value of $I(w_i, c)/|L(w_i)|$ at time t is at least

$$\begin{aligned}(\mathrm{e}^{-b_k d(w_i)/\Delta} + o(1)) \times \frac{1}{\ell_{k+1}^{(d(w))}\Delta} &\geq \frac{1}{\Delta} \times \frac{\mathrm{e}^{-b_k}}{\ell_{k+1}^{(\Delta)}} \times \mathrm{e}^{(b_k-(1-\zeta)b_k)(1-d(w_i)/\Delta)} + o(1)\\ &\geq \frac{1}{\Delta} \times \frac{\mathrm{e}^{-b_k}}{\ell_{k+1}^{(\Delta)}} + o(1)\\ &\geq \frac{1}{\Delta} \times \frac{\mathrm{e}^{-b_k}}{\ell_{k}^{(\Delta)}} + o(1).\end{aligned}$$

If $d(w_i) \leq \rho\Delta$, then $|L(w_i)|$ is never less than $C - \rho\Delta = (q-\rho)\Delta$. Therefore, by our assumptions on how small ρ is, the expected value of $I(w_i, c)/|L(w_i)|$ is at most

$$\frac{1}{(q-\rho)\Delta} < \frac{1}{\Delta} \times \mathrm{e}^{-a_k/q}/(q\mathrm{e}^{-(1+\zeta)/q}).$$

Furthermore, since no list is ever smaller than $(q-1)\Delta$, $\mathbf{Pr}(I(w_i, c)) \geq (1 - \frac{1}{(q-1)\Delta})^{\rho\Delta}$ which, by (1) and our assumptions on the size of ρ, is greater than $\frac{C}{\Delta} \times \mathrm{e}^{-b_k}/\ell_k^{(\Delta)}$. Therefore, the expected value of $I(w_i, c)/|L(w_i)|$ is again at least $\frac{1}{\Delta} \times \mathrm{e}^{-b_k}/\ell_k^{(\Delta)}$.

This implies that the expected value of $T_t^*(v, c)$ is at most $(a_{k+1} - \zeta)d(v)/\Delta$ and at least $(b_{k+1} - \zeta)d(v)/\Delta$. By viewing the color assignments to $w_{i,1}, \ldots, w_{i,\Delta-1}$ as one single random choice, we have Δ choices, each of which can affect $T_t^*(v, c)$ by at most $1/((q-1)\Delta)$, since no $L(u)$ can have size less than $(q-1)\Delta$. Therefore by Azuma's inequality, the probability that, under the procedure MOD-GLAUB2, $T_{v,c}$ differs from its expected value by more than $(\zeta/2)d(v)/\Delta$ is at most $\mathrm{e}^{-\Theta(\Delta)} < n^{-10}$ for D sufficiently large in terms of ζ. (Again, we use the fact that $d(v) \geq \rho\Delta$.)

Virtually the same argument as that used for part (a) proves that with sufficiently high probability, $T_t^*(v, c)$ in GLAUB is within $(\zeta/4)d(v)/C$ of its value in MOD-GLAUB2. Furthermore, if $\mathcal{H}$ is good then $|T_t^*(v, c) - T_t(v, c)| < (\Delta/\log\Delta) \times (1/(q-1)\Delta) = o(1)$. This proves part (b).

Finally, we need to note that, since with probability at least $1 - n^{-9}$ we have each $t_i, t_{i,j} \geq t - 30n\log n \geq 30kn\log n$, then we have by induction that the probability $\mathcal{H}$ is not good is at most $2n^{-9}$. □

We now show that Lemma 2 follows from Lemma 5 if we take δ sufficiently small when specifying k^* and thus obtain $a_k, b_k, \ell_{k^*}^d$ sufficiently close to $1/q, 1/q, q\mathrm{e}^{-d/C}$.

Proof of Lemma 2. We prove Lemma 2 in the same way as the inductive step for Lemma 5(b). We consider the procedure MOD-GLAUB2. We expose $\mathcal{H}$ and, by taking $\tau \geq 30k^*$, we can assume it is (with probability at least $1 - O(n^{-6})$) such that for each w_i with $d(w_i) > \rho\Delta$,

$$\left(\frac{1}{q} - \delta\right) d(w_i)/\Delta < T(w_i, c_1), T(w_i, c_2) < \left(\frac{1}{q} + \delta\right) d(w_i)/\Delta,$$

and

$$|L(w_i)| \geq q\mathrm{e}^{-(1+\zeta)d(v)/C}\Delta$$

and that $|B^*| < \Delta/\log\Delta$. This last assumption, along with the fact that $|L(u)| \geq C - q$ for every vertex u, implies that $\sum_{w_i \in B^*} |L(w_i)|^{-1} = o(1)$. Thus we can restrict our attention to $N(v) - B^*$.

Now consider any $w_i \in N(v) - B^*$ with $d(w_i) > \rho\Delta$. Let E_1 (resp., E_2) be the event that c_1 (resp., c_2) appears on $N(w_i) - v$. Thus $E_1 \cap E_2$ is the event that $w_i \notin \theta$. We will estimate $\mathbf{Pr}(E_1 \cap E_2) = 1 - \mathbf{Pr}(\overline{E_1}) - \mathbf{Pr}(\overline{E_2}) + \mathbf{Pr}(\overline{E_1} \cap \overline{E_2})$. By our assumption on $\mathcal{H}$, each $\mathbf{Pr}(\overline{E_r})$ is at most

$$\exp(-T(w_i, c_r)) \leq \exp\left(-\left(\frac{1}{q} - \delta\right) d(w_i)/\Delta\right).$$

Also, $\mathbf{Pr}(\overline{E_1} \cap \overline{E_2})$ is at least

$$\begin{aligned}
&\prod_{u \in N(w_i); c_1 \in L(u); c_2 \notin L(u)} \left(1 - \frac{1}{|L(u)|}\right) \times \prod_{u \in N(w_i); c_2 \in L(u); c_2 \notin L(u)} \left(1 - \frac{1}{|L(u)|}\right) \\
&\quad \times \prod_{u \in N(w_i); c_1, c_2 \in L(u)} \left(1 - \frac{2}{|L(u)|}\right) \\
&= \exp(-T(w_i, c_1) - T(w_i, c_2)) + o(1) \\
&\geq \exp\left(-2\left(\frac{1}{q} + \delta\right) d(w_i)/\Delta\right) + o(1).
\end{aligned}$$

For δ sufficiently small in terms of ϵ, this yields $\mathbf{Pr}(E_1 \cap E_2) > (1 - \mathrm{e}^{-d(w_i)/q\Delta})^2 - \epsilon/2$. Setting $y = \mathrm{e}^{-d(w_i)/q\Delta}$, note that $(1 - (1-y)^2)/(yq\Delta) = (2-y)/(q\Delta)$ increases as y decreases and so is maximized at $d(w_i) = \Delta$. Therefore, for ζ sufficiently small in terms of ϵ, we have

$$\begin{aligned}
\mathbf{Exp}(R_{c_1,c_2}(v)) &\leq o(1) + \sum_{w \in N(v)} \frac{(1 - (1 - \mathrm{e}^{-d(w_i)/q\Delta})^2) + \epsilon/2}{q\mathrm{e}^{-(1+\zeta)d(w_i)/C}\Delta} \\
&\leq \epsilon/2 + \sum_{w \in N(v)} \frac{(1 - (1 - \mathrm{e}^{-d(w_i)/q\Delta})^2)}{q\mathrm{e}^{-d(w_i)/C}\Delta} \\
&\leq \epsilon/2 + \frac{(1 - (1 - \mathrm{e}^{-1/q})^2)}{q\mathrm{e}^{-1/q}} \times \frac{d(v)}{\Delta}.
\end{aligned}$$

It follows as in the proof of Lemma 5(b) that this sum is highly concentrated and so the probability that it differs from its expected value by more than $\epsilon/4$ is at most n^{-10} for D sufficiently large.

It follows again as in the proof of Lemma 5(b) that the probability of it differing by more than $\epsilon/4$ from GLAUB to MOD-GLAUB is at most n^{-10} for D sufficiently large. This proves Lemma 2.

We close this section with the proof of Lemma 3, thus completing the proof of Lemma 2.

Proof of Lemma 3. Recall that we can assume that $q > q^*$ is sufficiently small, and so we will take $q < 1.49$.

It is straightforward to show that α_k is strictly increasing and β_k is strictly decreasing, and so by Lemma 2, $\alpha = \lim_{k\to\infty} \alpha_k, \beta = \lim_{k\to\infty} \beta_k, \lambda = \lim_{k\to\infty} \lambda_k^{(\Delta)}$ exist. They must satisfy

$$\begin{aligned}
\alpha &= \mathrm{e}^{-\beta}/\lambda, \\
\beta &= \mathrm{e}^{-\alpha}/(q\mathrm{e}^{-1/q}), \\
\lambda &= \frac{q\beta - 1}{\beta - \alpha}\mathrm{e}^{-\alpha} + \frac{1 - q\alpha}{\beta - \alpha}\mathrm{e}^{-b}.
\end{aligned}$$

We will prove that this system has no roots for $0 \le \alpha < 1/q$. This, along with Lemma 4, implies Lemma 3.

Rearranging the first equation of our system, we get $f(\alpha) = \alpha\lambda - \mathrm{e}^{-\beta} = 0$. We will bound the derivative of f with respect to α. We start by bounding

$$g(\alpha) = 1 - \beta q + \beta - \alpha\beta q.$$

Clearly $g(\alpha) \to 0$ as $\alpha \to 1/q$. Also, noting that the derivative of β with respect to α is $-\beta$, we have $g'(\alpha) = q\beta - \beta - q\beta + q\alpha\beta = q\alpha\beta - \beta < 0$ for $\alpha < 1/q$. Therefore, $g(\alpha) > 0$ for $\alpha < 1/q$.

Now, using the fact that by (1) $q\mathrm{e}^{-1/q} \le \lambda \le q\mathrm{e}^{-\alpha}$, we have

$$\begin{aligned}
f'(\alpha) &= \lambda - \beta\mathrm{e}^{-\beta} + \frac{\alpha}{\beta-\alpha}((1-2\beta q)\mathrm{e}^{-\alpha} + (\beta - q - \alpha\beta q)\mathrm{e}^{-\beta} + (\beta+1)\lambda) \\
&\ge \lambda - \beta\mathrm{e}^{-\beta} + \frac{\alpha\mathrm{e}^{-\beta}}{\beta-\alpha}(1 - 2\beta q + \beta - q - \alpha\beta q + q\beta + q) \\
&\qquad + \frac{\mathrm{e}^{-\alpha} - \mathrm{e}^{-\beta}}{\beta-\alpha}(\alpha - 2\alpha\beta q) \\
&\ge \lambda - \beta\mathrm{e}^{-\beta} + \frac{\mathrm{e}^{-\alpha} - \mathrm{e}^{-\beta}}{\beta-\alpha}(\alpha - 2\beta) \\
&\ge q\mathrm{e}^{-1/q} - \beta\mathrm{e}^{-\beta} - (\mathrm{e}^{-\alpha} - \mathrm{e}^{-\beta}) - \beta\frac{\mathrm{e}^{-\alpha} - \mathrm{e}^{-\beta}}{\beta-\alpha} \\
&\ge q\mathrm{e}^{-\beta} - \beta\mathrm{e}^{-\beta} - (\mathrm{e}^{-\alpha} - \mathrm{e}^{-\beta}) - \beta\mathrm{e}^{-\beta}\frac{\mathrm{e}^{-(\alpha-\beta)} - 1}{\beta-\alpha} \\
&\ge q\mathrm{e}^{-\beta} - \beta\mathrm{e}^{-\beta} - (\mathrm{e}^{-\alpha} - \mathrm{e}^{-\beta}) - \beta\mathrm{e}^{-\beta}(1 + \frac{1}{2}(\beta-\alpha)) \\
&= (q - 2\beta)\mathrm{e}^{-\beta} - (\mathrm{e}^{-\alpha} - \mathrm{e}^{-\beta}) - (\beta-\alpha)\beta\mathrm{e}^{-\beta}.
\end{aligned}$$

As $\alpha \to 1/q$, we get $\alpha \to \beta$ and so the latter two terms tend to 0. So this allows us to bound $f'(\alpha)$ away from 0 when α is close to the discontinuity at $\alpha = 1/q$. In particular, for $1.489 < q < 1.49$ we have $f'(\alpha) > .01$ when $.64 \le a < 1/q$ and so $f(\alpha)$ has no roots in that range. Having dealt with this discontinuity, it is straightforward to check that for the same range of q, $f(\alpha)$ has no roots in $0 \le \alpha \le .58$, thus proving the lemma.

3. Path coupling and the proof of Theorem 1. Here, we prove Theorem 1. We consider a fixed small ϵ, ρ to be named later. We begin with a burn-in period of $\tau n \log n$ steps, where $\tau > 30$ is as in Lemma 2. All of our analysis will assume that $\tau n \log n < t < n^2$. For now, we assume that for every vertex v and pair of colors c_1, c_2, we have (i) $|L(v)| \ge C\mathrm{e}^{-d(v)/C} - \epsilon\Delta$ and (ii) v has fewer than $\gamma d(v) - \epsilon\Delta$ neighbors w with $d(w) \ge \rho\Delta$ and $c_1, c_2 \notin L(w)$. Later we will account for the $O(n^{-5})$ probability that this is not the case.

We use the path coupling technique of Bubley and Dyer [1]. To do so, we couple two chains $X_0, X_1, \ldots$ and $W_0, W_1, \ldots$ with arbitrary initial colorings X_0, W_0 and show that, with high probability, they coincide within $O(n \log n)$ steps. To prove this fact using path coupling, at any time t, we consider a "path" of possibly improper colorings $X_t = Z_0, Z_1, \ldots, Z_h = W_t$. We define this path as follows. Consider an arbitrary ordering of the vertices $v_1, \ldots, v_n$. To form Z_1 from Z_0, we change the color of the first vertex on which X_t and W_t differ from its color in X_t to its color in W_t.

To form Z_2 from Z_1, we change the color of the second vertex on which X_t, W_t differ, and so on. Thus, h is the Hamming distance between X_t, W_t, i.e., the number of vertices on which they differ. (If $X_t = W_t$ then $h = 0$ and $X_t = Z_0 = W_t$.)

We couple the chains as follows: We carry out a step of $Z_0 = X_t$, thus obtaining $Z_0^{'} = X_{t+1}$. Then we maximally couple a random choice for Z_1 to the choice for Z_0, thus obtaining $Z_1^{'}$. (Recall that, even though Z_r may not be a proper coloring, we can apply a step of our process to it.) Repeatedly, we maximally couple Z_i to Z_{i-1} obtaining $Z_i^{'}$, finally yielding $W_{t+1} = Z_h^{'}$.

Recall that in our key Lemma 2, vertices of degree less than $\rho\Delta$ are not included in the sum $R_{c_1,c_2}(v)$. Because of this, we need to modify the notion of Hamming distance as follows.

Suppose that we are given a particular $\rho > 0$. For any two (not necessarily proper) colorings X, W, we define their *weighted Hamming distance* $H^{'}(X, W)$ to be the number of vertices v with $d(v) > \rho\Delta$ and $X(v) \neq W(v)$ plus 3ρ times the number of vertices v with $d(v) \leq \rho\Delta$ and $X(v) \neq W(v)$. Note that $H^{'}(X_t, W_t) = \sum_{i=0}^{h-1} H^{'}(Z_i, Z_{i+1})$. Note further that $H^{'}(X_{t+1}, W_{t+1}) \leq \sum_{i=0}^{h-1} H^{'}(Z_i^{'}, Z_{i+1}^{'})$, since if $X_{t+1}(v) \neq W_{t+1}(v)$ then $Z_i^{'}(v) \neq Z_{i+1}^{'}(v)$ for at least one i.

We will prove that, after an $O(n \log n)$ burn-in period, the expected value of the change of the weighted Hamming distance between any pair Z_r, Z_{r+1} is at most $-\psi/n$ for some constant $\psi > 0$. Thus, the expected value of the change of the weighted Hamming distance between X, W is at most $-h \times \psi/n < -\psi/n$.

To prove this, we need to know that, with high probability, the bound in Lemma 2 applies to each Z_r. So for each $0 \leq s \leq n$ and step t, we define M_t^s to be the (possibly improper) coloring in which vertices $v_1, \ldots, v_s$ have their color from W_t and $v_{s+1}, \ldots, v_n$ have their colors from X_t. Note that at time t, each Z_r is equal to M_t^s for at least one value of s. At time t, for each vertex v and for each $0 \leq s \leq n$, we define $L^s(v)$ to be the set of colors which do not appear in M_t^s on the neighborhood of v. $L^X(v) = L^0(v)$ is the set of colors which do not appear in X on $N(v)$, and $L^W(v) = L^n(v)$ is the set of colors which do not appear in W on $N(v)$.

LEMMA 8. *For every $\epsilon, \rho > 0$, there exist constants D, τ such that with probability at least $1 - n^{-5}$, for every vertex v, colors c_1, c_2, $0 \leq s \leq n$ and time $\tau n \log n \leq t \leq n^2$, we have the following: Define $\theta = \theta_{c_1,c_2}^s(v)$ to be the set of neighbors w of v with $d(w) \geq \rho\Delta$ and with at least one of c_1, c_2 not appearing in M_t^s on $N(w) - v$, and define*

$$R_{c_1,c_2}^s(v) = \sum_{w \in \theta} \frac{1}{|L(w)|}.$$

Then

$$R_{c_1,c_2}^s(v) \leq \frac{1 - (1 - \mathrm{e}^{-1/q})^2}{q\mathrm{e}^{-1/q}} \times \frac{d(v)}{\Delta} + \epsilon.$$

To prove Lemma 8, we define

$$T_t^s(v, c) = \sum_{v_j \in N(v); j \leq s; c \in L^W_{\tilde{t}(v_j,t)}(v_j)} \frac{1}{|L^W_{\tilde{t}(v_j,t)}(v_j)|} + \sum_{v_j \in N(v); j > s; c \in L^X_{\tilde{t}(v_j,t)}(v_j)} \frac{1}{|L^X_{\tilde{t}(v_j,t)}(v_j)|},$$

and we modify Lemma 5 to the following.

LEMMA 9. *For each $1 \le k \le k^*$, with probability at least $1 - n^{-5}$, for every v with $d(v) > \rho\Delta$, color c, $0 \le s \le n$ and $30kn \log n \le t \le n^2$, we have at time t*

(a) $q\mathrm{e}^{-(1+\zeta)d(v)/C}\Delta \le |L^X(v)|, |L^W(v)| \le \ell_k^{(d(v))}\Delta$;

(b) $a_k d(v)/\Delta \le T_t^s(v,c) \le b_k d(v)/\Delta$.

The proof of part (a) is essentially the same as in Lemma 5. To prove part (b), for each $w_i = v_j$, $\mathcal{H}$ exposes the colors that $w_{i,1,1}, \dots, w_{i,\Delta-1,\Delta-1}$ receive in the chain W if $j \le s$, and exposes the colors they receive in X otherwise. The rest of the proof is the same. The exponent of n in the probability bound changes from -6 to -5 because of the extra n choices for s.

Then we prove Lemma 8 from Lemma 9 by defining $\mathcal{H}$ in the same way.

For now we assume that for every vertex v, $0 \le s \le n$ and pair of colors c_1, c_2, we have

$$R^s_{c_1,c_2}(v) \le \frac{1-(1-\mathrm{e}^{-1/q})^2}{q\mathrm{e}^{-1/q}}\frac{d(v)}{\Delta} + \epsilon.$$

Later we will account for the $O(n^{-5})$ probability that this is not the case.

Now, consider any Z_r and Z_{r+1}. They differ on exactly one vertex, say v which has color c_1 in Z_r and c_2 in Z_{r+1}. We apply one step of our process to Z_r and to Z_{r+1}, coupled as described in the introduction.

Case 1. $d(v) > \rho\Delta$.

The weighted Hamming distance between Z_r and Z_{r+1} decreases by 1 iff we select v. This has probability $1/n$ of occurring. The weighted Hamming distance increases iff we choose a neighbor u of v and assign it color c_1 in Z_r and/or assign it color c_2 in Z_{r+1}. If $d(u) > \rho\Delta$, then it increases by 1; otherwise it increases by 3ρ. Thus, to increase by 1, we must choose a neighbor $u \in \theta$ and so the probability that it increases by 1 is $R_{c_1,c_2}(v)/n$. The probability that it increases by 3ρ is at most $d(v)/(n(C-\Delta))$. Therefore, the expected change in the Hamming distance is at most

$$\frac{1}{n} \times \left(-1 + \frac{1-(1-\mathrm{e}^{-1/q})^2}{q\mathrm{e}^{-1/q} - \epsilon} + \epsilon + \frac{3\rho}{q-1} \right),$$

which is negative if we choose ϵ and ρ to be sufficiently small in terms of q, since we chose q such that $(1-\mathrm{e}^{-1/q})^2 + q\mathrm{e}^{-1/q} > 1$.

Case 2. $d(v) \le \rho\Delta$.

The weighted Hamming distance decreases by 3ρ with probability $\frac{1}{n}$ and it increases with probability at most $\rho\Delta/(n(C-\Delta))$. Since it never increases by more than 1, the expected change in the Hamming distance is at most

$$\frac{1}{n} \times \left(-3\rho + \frac{\rho}{q-1} \right),$$

which is negative for ϵ sufficiently small since $q - 1 > 1/3$ for $q > q^*$.

Thus, in either case, the expected change in the weighted Hamming distance is less than $-\psi/n$ for some $\psi = \psi(q) > 0$. This implies that with sufficiently high probability, the weighted Hamming distance drops to 0 within $O(n \log n)$ steps.

Now we still have to account for the $O(n^{-5})$ chance that for some v, t, s, c_1, c_2, $R^s_{c_1,c_2}(v)$ is too large. Let t^* be the first time at which this occurs. Consider the random variable $H^*(t)$ defined as follows. Until time t^*, $H^*(t) = H'(X_t, W_t)$. After time t^*, if $H^*(t-1) > 0$ then $H^*(t) = H^*(t-1) - 1$ with probability $\frac{1}{n}$ and $H^*(t) = H^*(t-1) + 1$ with probability $\frac{1-\psi}{n}$; if $H^*(t-1) = 0$ then $H^*(t) = 0$. $H^*(t)$ is a simple

random walk with negative drift after time $t = \tau n \log n$, and it is straightforward to verify that with high probability, $H^*(t) = 0$ when $t = O(n \log n)$. Furthermore, with probability $1 - O(n^{-4})$, $H'(X_t, W_t) = H^*(t)$ for each $1 \leq t \leq n^2$. Therefore, with high probability, $H'(X_t, W_t) = 0$ when $t = O(n \log n)$. This is enough to prove Theorem 1. See, for example, [4] for the standard argument.

4. Some final comments. In this section, we note that this coupling argument cannot be used for the case $C = q\Delta$ for any $q < q^*$. To see this, consider any polynomial n^x and any Δ-regular graph G with $\Delta \geq D \log n$ and girth at least $D \log \Delta$ for some sufficiently large D in terms of x.

Note that Lemmas 2 through 9 hold for all $q > 1.489$ (and in fact, if needed, we could show that they hold for even smaller q). The only place where we required $q > q^*$ was in the proof of Theorem 1 in section 3. Furthermore, the upper bound $t \leq n^2$ in their statements can be easily increased to n^x. Therefore, if the Glauber dynamics mixes rapidly, then a "typical" coloring will satisfy that for all v, c, $|L_v|$ is arbitrarily close to $Ce^{-1/q}$ and $T(v, c)$ is arbitrarily close to $1/q$. Thus, such a coloring must exist; call it Ψ.

Suppose that we choose Ψ as our initial coloring. Then for the first n^x steps, with high probability, for all v, c, $|L_v|$ is arbitrarily close to $Ce^{-1/q}$ and $T(v, c)$ is arbitrarily close to $1/q$. This implies that with high probability, for any v, c_1, c_2, the number of neighbors of v which have either c_1 or c_2 in their list is arbitrarily close to $(1-(1-e^{-1/q})^2)\Delta$. So if we couple the coloring arising at any time less than n^x with another coloring which differs in exactly one vertex, then since $q < q^*$, the expected change in their Hamming distance will be positive.

Furthermore, since the graph has large girth, we cannot apply the technique from [5] and [9], where by analyzing the expected total change over a few steps, we were able to get some gain from edges in $N(v)$.

So in an extended abstract of this paper [10], the author raised the following question: *Is there any $q < q^*$ and $D > 0$ such that the Glauber dynamics for $q\Delta$-colorings mixes in polytime on graphs with girth at least D and maximum degree Δ at least $D \log n$?*

He noted that a positive answer would require a substantial new idea. Very recently, Hayes and Vigoda [6] provided such an answer, proving that any $q > 1$ will do even when the girth is as small as 9. Their substantial new idea was to use a "non-Markovian coupling." We refer the reader to their paper for further description.

Acknowledgments. The author is grateful to Martin Dyer and Alan Frieze for some helpful discussions, for providing him with an early copy of their paper [2], and for pointing out an error in an early version. He is also grateful to two anonymous referees for suggestions that greatly improved the presentation.

QUANTUM COMPUTATION AND LATTICE PROBLEMS*

ODED REGEV†

Abstract. We present the first explicit connection between quantum computation and lattice problems. Namely, our main result is a solution to the unique shortest vector problem (SVP) under the assumption that there exists an algorithm that solves the hidden subgroup problem on the dihedral group by coset sampling. Additionally, we present an approach to solving the hidden subgroup problem on the dihedral group by using an average case subset sum routine.

Key words. lattices, quantum computation, shortest vector problem, hidden subgroup problem

1. Introduction.

Quantum computation is a computation model based on quantum physics. Assuming that the laws of nature as we know them are true, this might allow us to build computers that are able to perform tasks that classical computers cannot perform in any reasonable time. One task which quantum algorithms are known to perform much better than classical algorithms is that of factoring large integers. The importance of this problem stems from its ubiquitous use in cryptographic applications. While there are no known polynomial time classical algorithms for this problem, a groundbreaking result of Shor [25] showed a polynomial time quantum algorithm for factoring integers. In the same paper, Shor showed an algorithm for finding the discrete log. However, despite enormous effort, we have only a few other problems for which quantum algorithms provide an exponential speedup (e.g., [12, 5]). Other notable quantum algorithms such as Deutsch and Jozsa's algorithm [6] and Simon's algorithm [26] operate in the black box model. Grover's algorithm [11] provides a square root speedup over classical algorithms.

The current search for new quantum algorithms concentrates on problems which are not known to be NP-hard. These include the graph isomorphism problem and lattice problems. In this paper we are interested in lattice problems or specifically, the unique shortest vector problem (SVP). A lattice is a set of all integral linear combinations of a set of n linearly independent vectors in $\mathbb{R}^n$. This set of n vectors is known as a basis of the lattice. In the SVP we are interested in finding the shortest nonzero vector in a lattice. In the $f(n)$-unique-SVP we are given the additional promise that the shortest vector is shorter by a factor of at least $f(n)$ than all other nonparallel vectors. This problem has also important applications in cryptography. Namely, Ajtai and Dwork's cryptosystem [2] and the recent cryptosystem by Regev [23] are based on the hardness of this lattice problem.

A central problem in quantum computation is the hidden subgroup problem (HSP). Here, we are given a black box that computes a function on elements of a group G. The function is known to be constant and distinct on left cosets of a subgroup $H \leqslant G$, and our goal is to find H. Interestingly, almost all known quantum

algorithms which run superpolynomially faster than classical algorithms solve special cases of the HSP on Abelian groups. Also, it is known that solving the HSP on the symmetric group leads to a solution to graph isomorphism [15]. This motivated research into possible extensions of the HSP to noncommutative groups (see, e.g., [9, 13, 24, 8]). However, prior to this paper the HSP on groups other than the symmetric group and Abelian groups had no known applications.

In this paper we will be interested in the HSP on the dihedral group. The dihedral group of order $2N$, denoted D_N, is the group of symmetries of an N-sided regular polygon. It is isomorphic to the abstract group generated by the element ρ of order n and the element τ of order 2 subject to the relation $\rho\tau = \tau\rho^{-1}$. Although the dihedral group has a much simpler structure than the symmetric group, no efficient solution to the HSP on the dihedral group is known. Ettinger and Høyer [7] showed that one can obtain sufficient statistical *information* about the hidden subgroup with only a polynomial number of queries. However, there is no efficient algorithm that solves the HSP using this information. Currently, the best known algorithm is due to Kuperberg [18] and runs in subexponential time $2^{O(\sqrt{\log N})}$.

The following is the main theorem of this paper. The dihedral coset problem is described in the following paragraph.

THEOREM 1.1. *If there exists a solution to the dihedral coset problem with failure parameter* f*, then there exists a quantum algorithm that solves the* $\Theta(n^{\frac{1}{2}+2\mathsf{f}})$*-unique-SVP.*

The input to the dihedral coset problem (DCP) is a tensor product of a polynomial number of registers. Each register is in the state

$$|0, x\rangle + |1, (x + d) \bmod N\rangle$$

for some arbitrary $x \in \{0, \ldots, N-1\}$, and d is the same for all registers. These can also be thought of as cosets of the subgroup $\{(0,0),(1,d)\}$ in D_N. Our goal is to find the value d. In addition, we say that the DCP has a failure parameter f if each of the registers with probability at most $\frac{1}{(\log N)^{\mathsf{f}}}$ is in the state $|b, x\rangle$ for arbitrary b, x instead of a coset state. We note that any algorithm that solves the dihedral HSP by sampling cosets also solves the DCP for some failure parameter f. The reason is that since the algorithm samples only a polynomial number of cosets, we can take f to be large enough such that with high probability all the registers are coset states. This is summarized in the following corollary.

COROLLARY 1.2. *If there exists a solution to the dihedral HSP that samples cosets (e.g., any solution using the "standard method"), then there exists a quantum algorithm that solves poly*(n)*-unique-SVP.*

The following is the second result of this paper. While still not an efficient solution, it shows a new way to approach the dihedral HSP. In the subset sum problem we are given two integers t, N and a set of numbers. We are asked to find a subset of the numbers that sums to t modulo N. A legal input is an input for which such a subset exists (a formal definition appears in section 4) and we are interested in algorithms that solve a nonnegligible fraction of the inputs.

THEOREM 1.3. *If there exists an algorithm* S *that solves* $\frac{1}{poly(\log N)}$ *of the legal subset sum inputs with parameter* N*, then there exists a solution to the DCP with failure parameter* $\mathsf{f} = 1$*.*

As shown in [7], the dihedral HSP can be reduced to the case where the subgroup is of the form $\{(0,0),(1,d)\}$. Then, by sampling cosets, we obtain states of the form $|0, x\rangle + |1, (x + d) \bmod N\rangle$ with no error. Hence, we have the following.

COROLLARY 1.4. *If there exists an algorithm S that solves $\frac{1}{poly(\log N)}$ of the legal subset sum inputs with parameter N, then there exists a solution to the dihedral HSP.*

Finally, as a curiosity, let us comment that by combining the two previous theorems one can obtain the following corollary.

COROLLARY 1.5. *If there exists an algorithm that solves $\frac{1}{poly(\log N)}$ of the legal subset sum inputs with parameter N, then there exists a quantum algorithm for the $\Theta(n^{2.5})$-unique-SVP.*

This result can be described as a worst-case to average-case quantum reduction. Such reductions are already known in the classical case [1, 3, 4, 20, 23]. The exponent 2.5 in our reduction is better than the one in [1, 3, 4, 20]. However, the reduction in [23], which appeared after the original publication of the current paper, further improves the exponent to 1.5 and hence subsumes our reduction. In addition, unlike the classical reductions, our subset sum problems have a density of one; i.e., the size of the input set is very close to $\log N$. Therefore, some cryptographic applications such as the one by Impagliazzo and Naor [14] cannot be used.

Intuitive overview. Before proceeding to the main part of the paper, we describe our methods in a somewhat intuitive way. First, let us describe the methods used in solving the unique-SVP. Recall that our solution is based on a solution to the DCP. We begin by showing how such a solution can be used to solve a slightly different problem, which we call the two-point problem. Instead of a superposition of two numbers with a fixed difference, our input consists of registers in a superposition of two n-dimensional vectors with a fixed difference. Then the idea is to create an input to the two-point problem in the following way. Start by creating a superposition of many lattice points and collapse the state to just two lattice points whose difference is the shortest vector. Repeating this procedure creates an input to the two-point problem, whose solution is the shortest vector.

Collapsing the state is performed by partitioning the space into cubes. Assume the partition has the property that in each cube there are exactly two lattice points whose difference is the shortest vector. Then we compute the cube in which each point is located and measure the result. The state collapses to a superposition of just the two points inside the cube we measured. The important thing is to make sure that exactly two points are located in each cube. First, in order to make sure that the cubes are not aligned with the lattice, we randomly translate them. The length of the cubes is proportional to the length of the shortest vector. Although the exact length of the shortest vector is unknown, we can try several estimates until we find the right value. Since the lattice has a unique shortest vector, all other nonparallel vectors are considerably longer and do not fit inside a cube. Therefore we know that the difference between any two points inside the same cube is a multiple of the shortest vector. Still, this is not good enough since instead of two points inside each box we are likely to have more points aligned along the shortest vector. Hence, we space out the lattice: instead of creating a superposition of all the lattice points we create a superposition of a subset of the points. The set of points created by this technique has the property that along the direction of the shortest vector there are pairs of points whose difference is the shortest vector and the distance between two such pairs is much larger than the shortest vector. As before, this can be done without knowing the shortest vector by trying several possibilities.

The second part of the paper describes a solution to the DCP with failure parameter 1 which uses a solution to the average-case subset sum problem. Recall that we

are given registers of the form

$$|0, x\rangle + |1, (x + d) \bmod N\rangle,$$

where $x \in \{0, \ldots, N-1\}$ is arbitrary, and we wish to find $d \in \{0, \ldots, N-1\}$. Consider one such register. We begin by applying the Fourier transform to the second part of the register (the one holding x and $x + d$) and then measuring it. If a is the value we measured, the state collapses to a combination of the basis states $|0\rangle$ and $|1\rangle$ such that their phase difference is $2\pi\frac{ad}{N}$. If we were lucky enough to measure $a = 1$, then the phase difference is $2\pi\frac{d}{N}$ and by measuring this phase difference we can obtain an estimation on d. This, however, happens with exponentially small probability. Since the phase is modulo 2π, extracting the value d is much harder when a is larger. Instead, we perform the same process on r registers and let $a_1, \ldots, a_r$ be the values we measure. The resulting tensor state includes a combination of all 2^r different $0, 1$ sequences. The phase of each sequence can be described as follows. By ignoring a fixed phase, we can assume that the phase of the sequence $00\ldots0$ is 0. Then the phase of the sequence $100\ldots0$ is $2\pi\frac{a_1 d}{N}$ and, in general, the phase of the sequence $\alpha_1\alpha_2\ldots\alpha_r$ is $2\pi\frac{d}{N}$ multiplied by the sum of the values a_i for which $\alpha_i = 1$. This indicates that we should try to measure the phase difference of two sequences whose sums differ by 1. However, although we can estimate the phase difference of one qubit, estimating the phase difference of two arbitrary sequences is not possible.

We proceed by choosing r to be very close to $\log N$. This creates a situation in which for almost every $t \in \{0, \ldots, N-1\}$ there is a subset whose sum modulo N is t and, in addition, there are not too many subsets that sum to the same t modulo N. Assume for simplicity that every t has exactly one subset that sums to t modulo N. We calculate for each sequence the value $\lfloor\frac{t}{2}\rfloor$, where t is its sum. After measuring the result, say s, we know that the state is a superposition of two sequences: one that sums to $2s$ and one that sums to $2s + 1$. Notice that since $a_1, \ldots, a_r$ are uniformly chosen between $\{0, \ldots, N-1\}$ we can use them as an input to the subset sum algorithm. The key observation here is that the subset sum algorithm provides the reverse mapping, i.e., from a value t to a subset that sums to t. So, from s we can find the sequence α_1 that sums to $2s$ and the sequence α_2 that sums to $2s + 1$. Since we know that the state is a superposition of $|\alpha_1\rangle$ and $|\alpha_2\rangle$ we can use a unitary transformation that transforms $|\alpha_1\rangle$ to $|0\rangle$ and $|\alpha_2\rangle$ to $|1\rangle$. Now, since the two states differ in one qubit, we can easily measure the phase difference and obtain an estimate on d. This almost completes the description of the DCP algorithm. The estimate on d is only polynomially accurate but in order to find d we need exponential accuracy. Hence, we repeat the same process with pairs whose difference is higher. So, instead of choosing pairs of difference 1 we choose pairs of difference 2 to get an estimate on $2d$, then 4 to get an estimate on $4d$ and so on.[1]

Outline. The next section contains some notation that is used in this paper. The two main sections of this paper are independent. In section 3 we prove Theorem 1.1, and section 4 contains the proof of Theorem 1.3.

2. Preliminaries. We denote the imaginary unit by $\imath$ and use the notation $e(x) = e^{2\pi\imath x}$. Occasionally, we omit the normalization of quantum states. We use the

[1] This description is very similar to the method of exponentially accurate phase estimation used in Kitaev's algorithm [17]. Actually, our case is slightly more difficult because we cannot measure all the multiples 2^i. Nevertheless, we can measure enough multiples of the phase to guarantee exponential accuracy.

term *n-ball* to refer to the n-dimensional solid body and the term *sphere* to refer to its surface. We denote the set $\{1,\ldots,n\}$ by $[n]$. All logarithms are of base 2. We use δ_{ij} to denote the Kronecker delta, i.e., 1 if $i=j$ and 0 otherwise. A sequence $\bar{\alpha}\in\{0,1\}^r$ is identified with the set $\{i \mid \alpha_i = 1\}$. Several constants appear in our proofs. To make it easier to follow, we denote constants with a subscript that is somewhat related to their meaning. Specifically, in section 3, c_{cub} is related to the cubes that partition the space, c_{bal} is related to the radius of the balls, and c_{unq} appears in the guarantee of the unique shortest vector. Also, in section 4 we use c_{r} in the definition of the parameter r, c_{s} in our assumptions on the subset sum subroutine and c_{m} when we prove the existence of matchings.

The following is the formal definition of the DCP.

DEFINITION 2.1. *The input to the DCP with failure parameter* f *consists of* $poly(\log N)$ *registers. Each register is with probability at least* $1-\frac{1}{(\log N)^{\mathsf{f}}}$ *in the state*

$$\frac{1}{\sqrt{2}}(|0,x\rangle + |1,(x+d) \bmod N\rangle)$$

on $1+\lceil\log N\rceil$ *qubits, where* $x\in\{0,\ldots,N-1\}$ *is arbitrary and* d *is fixed. Otherwise, with probability at most* $\frac{1}{(\log N)^{\mathsf{f}}}$*, its state is* $|b,x\rangle$*, where* $b\in\{0,1\}$ *and* $x\in\{0,\ldots,N-1\}$ *are arbitrary. We call such a register a "bad" register. We say that an algorithm solves the DCP if it outputs* d *with probability* $poly(\frac{1}{\log N})$ *in time* $poly(\log N)$*.*

3. A quantum algorithm for unique-SVP. In this section we prove Theorem 1.1. We begin by showing a simple reduction from the two-point problem to the DCP in section 3.1. We then prove a weaker version of Theorem 1.1 with $\Theta(n^{1+2\mathsf{f}})$ instead of $\Theta(n^{\frac{1}{2}+2\mathsf{f}})$ in section 3.2. We complete the proof of Theorem 1.1 in section 3.3. Throughout this section, we use a failure parameter $\mathsf{f}>0$ in order to make our results more general. The reader might find it easier to take $\mathsf{f}=1$.

3.1. The two-point problem.

DEFINITION 3.1. *The input to the two-point problem with failure parameter* f *consists of* $poly(n\log M)$ *registers. Each register is with probability at least* $1-\frac{1}{(n\log(2M))^{\mathsf{f}}}$ *in the state*

$$\frac{1}{\sqrt{2}}(|0,\bar{a}\rangle + |1,\bar{a}'\rangle)$$

on $1+n\lceil\log M\rceil$ *qubits, where* $\bar{a},\bar{a}'\in\{0,\ldots,M-1\}^n$ *are arbitrary such that* $\bar{a}'-\bar{a}$ *is fixed. Otherwise, with probability at most* $\frac{1}{(n\log(2M))^{\mathsf{f}}}$*, its state is* $|b,\bar{a}\rangle$*, where* $b\in\{0,1\}$ *and* $\bar{a}\in\{0,\ldots,M-1\}^n$ *are arbitrary. We say that an algorithm solves the two-point problem if it outputs* $\bar{a}'-\bar{a}$ *with probability* $poly(\frac{1}{n\log M})$ *in time* $poly(n\log M)$*.*

LEMMA 3.2. *If there exists an algorithm that solves the DCP with failure parameter* f*, then there is an algorithm that solves the two-point problem with failure parameter* f*.*

Proof. Consider the following mapping from $\{0,\ldots,M-1\}^n$ to $\{0,\ldots,(2M)^n-1\}$:

$$f(a_1,\ldots,a_n) = a_1 + a_2\cdot 2M + \cdots + a_n(2M)^{n-1}.$$

Given an input to the two-point problem, we create an input to the DCP by using the above mapping on the last $n\lceil\log M\rceil$ qubits of each register. Hence, each register

is with probability at least $1 - \frac{1}{(n(\log 2M))^{\mathrm{f}}}$ in the state

$$\frac{1}{\sqrt{2}}(|0, f(\bar{a})\rangle + |1, f(\bar{a}')\rangle).$$

The difference $f(\bar{a}') - f(\bar{a})$ is

$$(a_1' - a_1) + (a_2' - a_2) \cdot 2M + \cdots + (a_n' - a_n)(2M)^{n-1}$$

and is therefore fixed. Otherwise, with probability at most $\frac{1}{(n(\log 2M))^{\mathrm{f}}}$ the register is in the state $|b, f(\bar{a})\rangle$ for arbitrary $b, \bar{a}$. This is a valid input to the DCP with $N = (2M)^n$ since the probability of a bad register is at most $\frac{1}{(n \log(2M))^{\mathrm{f}}} = \frac{1}{(\log N)^{\mathrm{f}}}$.

Using the DCP algorithm with the above input, we obtain the difference

$$b_1 + b_2 \cdot 2M + \cdots + b_n(2M)^{n-1},$$

where $b_i = a_i' - a_i$. In order to extract the b_i's, we add

$$M + M \cdot 2M + M(2M)^2 + \cdots + M(2M)^{n-1}.$$

Extracting b_i from

$$(b_1 + M) + (b_2 + M) \cdot 2M + \cdots + (b_n + M)(2M)^{n-1}$$

is possible since each $b_i + M$ is an integer in the range 1 to $2M - 1$. The solution to the two-point problem is the vector $(b_1, \ldots, b_n)$. □

3.2. A weaker algorithm. We recall several facts about an LLL-reduced basis. Such a basis can be found for any lattice by using a polynomial time algorithm [19]. Given a basis $\langle \bar{b}_1, \ldots, \bar{b}_n \rangle$, let $\langle \bar{b}_1^*, \ldots, \bar{b}_n^* \rangle$ be its Gram–Schmidt orthogonalization. That is, $\bar{b}_i^*$ is the component of $\bar{b}_i$ orthogonal to the subspace spanned by $\bar{b}_1, \ldots, \bar{b}_{i-1}$. An LLL-reduced basis $\langle \bar{b}_1, \ldots, \bar{b}_n \rangle$ satisfies that

$$\|\bar{b}_i^*\| \leq \sqrt{2}\|\bar{b}_{i+1}^*\|$$

and that for $i > j$,

$$|\langle \bar{b}_i, \bar{b}_j^* \rangle| \leq \frac{1}{2}\|\bar{b}_j^*\|^2.$$

In addition, recall that $\min_i \|\bar{b}_i^*\|$ is a lower bound on the length of the shortest vector. Since $\bar{b}_1^* = \bar{b}_1$ and $\|\bar{b}_1^*\| \leq 2^{(i-1)/2}\|\bar{b}_i^*\|$ we get that the vector $\bar{b}_1$ is at most $2^{(n-1)/2}$ times longer than the shortest vector. Consider the representation of the LLL basis in the orthonormal basis

$$\left\langle \frac{\bar{b}_1^*}{\|\bar{b}_1^*\|}, \ldots, \frac{\bar{b}_n^*}{\|\bar{b}_n^*\|} \right\rangle.$$

The vector $\bar{b}_i$ can be written as $(b_{i1}, b_{i2}, \ldots, b_{ii}, 0, \ldots, 0)$. Notice that $b_{ii} = \|\bar{b}_i^*\|$ and that $|b_{ij}| \leq \frac{1}{2}\|\bar{b}_j^*\|$ for every $i > j$. In the following, $\bar{u}$ denotes the shortest vector.

LEMMA 3.3. *Consider the representation of the shortest vector $\bar{u}$ in the LLL-reduced lattice basis $\bar{u} = \sum_{i=1}^n u_i \bar{b}_i$. Then $|u_i| \leq 2^{2n}$ for $i \in [n]$.*

Proof. Changing to the orthonormal basis,

$$\bar{u} = \sum_{i=1}^{n} u_i \bar{b}_i = \sum_{i=1}^{n} \left(\sum_{j=i}^{n} u_j b_{j,i} \right) \frac{\bar{b}_i^*}{\|\bar{b}_i^*\|}.$$

In addition, we know that $\|\bar{b}_i^*\| \geq 2^{-(i-1)/2} \|\bar{b}_1^*\| \geq 2^{-n} \|\bar{u}\|$. Hence,

$$\left| \sum_{j=i}^{n} u_j b_{j,i} \right| \leq 2^n \|\bar{b}_i^*\|$$

for every $i \in [n]$. By taking $i = n$ we get that $|u_n|$ is at most 2^n. We continue inductively and show that $|u_k| \leq 2^{2n-k}$. Assume that the claim holds for $u_{k+1}, \ldots, u_n$. Then

$$\left| \sum_{j=k+1}^{n} u_j b_{j,k} \right| \leq \frac{1}{2} \left| \sum_{j=k+1}^{n} u_j \right| \|\bar{b}_k^*\| \leq \frac{1}{2} \left(\sum_{j=k+1}^{n} 2^{2n-j} \right) \|\bar{b}_k^*\| \leq \frac{1}{2} \cdot 2^{2n-k} \|\bar{b}_k^*\|.$$

By the triangle inequality,

$$|u_k b_{k,k}| \leq \left| \sum_{j=k+1}^{n} u_j b_{j,k} \right| + \left| \sum_{j=k}^{n} u_j b_{j,k} \right| \leq \left(\frac{1}{2} 2^{2n-k} + 2^n \right) \|\bar{b}_k^*\| \leq 2^{2n-k} \|\bar{b}_k^*\|$$

and the proof is completed. ∎

Let $p > n^{2+2\mathsf{f}}$ be any fixed prime. The following is the main lemma of this section.

LEMMA 3.4. *For any $\mathsf{f} > 0$, if there exists a solution to the two-point problem with failure parameter f, then the following holds. There exists a quantum algorithm that, given a $(c_{\mathsf{unq}} n^{1+2\mathsf{f}})$-unique lattice for some large enough constant $c_{\mathsf{unq}} > 0$ whose shortest vector is $\bar{u} = \sum_{i=1}^{n} u_i \bar{b}_i$, two integers m, i_0 and a number l returns*

$$\left(u_1, \ldots, u_{i_0 - 1}, \frac{u_{i_0} - m}{p}, u_{i_0 + 1}, \ldots, u_n \right),$$

with probability $1/poly(n)$ if the following conditions hold: $\|\bar{u}\| \leq l \leq 2\|\bar{u}\|$, $u_{i_0} \equiv m \pmod{p}$, and $1 \leq m \leq p - 1$.

We first show how this lemma implies Theorem 1.1 with $\Theta(n^{1+2\mathsf{f}})$ by describing the SVP algorithm. According to Lemma 3.2 and the assumption of the theorem, there exists a solution to the two-point problem with failure parameter f. Hence, Lemma 3.4 implies that there exists an algorithm that, given the right values of l, m, i_0, outputs

$$\left(u_1, \ldots, u_{i_0 - 1}, \frac{u_{i_0} - m}{p}, u_{i_0 + 1}, \ldots, u_n \right).$$

The value l is an estimate of the length of the shortest vector $\bar{u}$. Because the LLL algorithm gives a $2^{(n-1)/2}$-approximation to the length of the shortest vector, one of $(n-1)/2$ different values of l is as required. In addition, since $\bar{u}$ is the shortest vector, $\bar{u}/p$ cannot be a lattice vector, and therefore there exists an i_0 such that $u_{i_0} \not\equiv 0 \pmod{p}$. Hence, there are only $O(pn^2)$ possible values for l, m, and i_0. With each of these values the SVP algorithm calls the algorithm of Lemma 3.4 a polynomial

number of times. With high probability in one of these calls the algorithm returns the vector

$$\left(u_1, \ldots, u_{i_0-1}, \frac{u_{i_0} - m}{p}, u_{i_0+1}, \ldots, u_n\right),$$

from which $\bar{u}$ can be extracted. The results of the other calls can be easily discarded because they are either longer lattice vectors or nonlattice vectors.

Proof of Lemma 3.4. We start by applying the LLL algorithm to the unique lattice in order to create a reduced basis. Denote the resulting basis by $\langle \bar{b}_1, \ldots, \bar{b}_n \rangle$. Let $\langle \bar{e}_1, \ldots, \bar{e}_n \rangle$ be the standard orthonormal basis of $\mathbb{R}^n$.

Let $w_1, \ldots, w_n$ be n real values in $[0, 1)$ and let $M = 2^{4n}$. Assume without loss of generality that $i_0 = 1$. The function f is defined as

$$f(t, \bar{a}) = (a_1 p + tm)\bar{b}_1 + \sum_{i=2}^{n} a_i \bar{b}_i,$$

where $t \in \{0, 1\}$ and $\bar{a} = (a_1, \ldots, a_n) \in \mathcal{A} = \{0, \ldots, M - 1\}^n$. It maps the elements of $\{0, 1\} \times \mathcal{A}$ to lattice points. In addition, consider a lattice vector $\bar{v}$ represented in the orthonormal basis $\bar{v} = \sum_{i=1}^{n} v_i \bar{e}_i$. The function g maps $\bar{v}$ to the vector

$$\left(\lfloor v_1/(c_{\mathsf{cub}} n^{\frac{1}{2}+2\mathsf{f}} \cdot l) - w_1 \rfloor, \ldots, \lfloor v_n/(c_{\mathsf{cub}} n^{\frac{1}{2}+2\mathsf{f}} \cdot l) - w_n \rfloor\right)$$

in $\mathbb{Z}^n$, where the constant $c_{\mathsf{cub}} > 0$ will be specified later.

In the following, we describe a routine that creates one register in the input to the two-point problem that hides the difference

$$\left(u_1, \ldots, u_{i_0-1}, \frac{u_{i_0} - m}{p}, u_{i_0+1}, \ldots, u_n\right).$$

We call the routine $poly(n \log M) = poly(n)$ times in order to create a complete input to the two-point problem. We then call the two-point algorithm and output its result. This completes the proof of the lemma since with probability $1/poly(n \log M) = 1/poly(n)$ our output is correct.

The routine starts by choosing $w_1, \ldots, w_n$ uniformly from $[0, 1)$. We create the state

$$\frac{1}{\sqrt{2M^n}} \sum_{t \in \{0,1\}, \bar{a} \in \mathcal{A}} |t, \bar{a}\rangle.$$

Then we compute the function $F = g \circ f$ and measure the result, say $r_1, \ldots, r_n$. The state collapses to (normalization omitted)

$$\sum_{\substack{t \in \{0,1\} \quad \bar{a} \in \mathcal{A} \\ F(t, \bar{a}) = (r_1, \ldots, r_n)}} |t, \bar{a}\rangle |r_1, \ldots, r_n\rangle.$$

This completes the description of the routine. Its correctness is shown in the next two claims.

Claim 3.5. *For every $\bar{r} \in \mathbb{Z}^n$, there is at most one element of the form $(0, \bar{a})$ and at most one element of the form $(1, \bar{a}')$ that get mapped to $\bar{r}$ by F. Moreover, if both $(0, \bar{a})$ and $(1, \bar{a}')$ get mapped to $\bar{r}$, then $\bar{a}' - \bar{a}$ is the vector*

$$\left(\frac{u_1 - m}{p}, u_2, \ldots, u_m\right).$$

Proof. Consider two different lattice points in the image of f, $\bar{v} = f(t, \bar{a})$ and $\bar{v}' = f(t', \bar{a}')$, that get mapped to $\bar{r}$ by g. Let $\bar{v} = \sum_{i=1}^n v_i \bar{e}_i$ and $\bar{v}' = \sum_{i=1}^n v_i' \bar{e}_i$ be their representation in the orthonormal basis. If $\bar{v}' - \bar{v}$ is not a multiple of the shortest vector, then

$$\|\bar{v}' - \bar{v}\| > c_{\mathsf{unq}} n^{1+2\mathsf{f}} \|\bar{u}\| \geq \frac{1}{2} c_{\mathsf{unq}} n^{1+2\mathsf{f}} \cdot l.$$

Therefore, there exists a coordinate $i \in [n]$ such that $|v_i' - v_i| \geq \frac{1}{2} c_{\mathsf{unq}} n^{\frac{1}{2}+2\mathsf{f}} \cdot l$, and for $c_{\mathsf{unq}} > 2c_{\mathsf{cub}}$ this implies $g(\bar{v}) \neq g(\bar{v}')$ no matter how $w_1, \ldots, w_n$ are chosen. Hence, $\bar{v}' - \bar{v} = k \cdot \bar{u}$ for some integer $k \neq 0$. By considering the first coordinate of $\bar{v}' - \bar{v}$ in the lattice basis, we get that

$$(a_1' p + t' m) - (a_1 p + t m) \equiv k \cdot m \pmod{p}.$$

This implies that $k \equiv t' - t \pmod{p}$. If $t = t'$, then $k \equiv 0 \pmod{p}$, which implies that $|k| \geq p$. Thus,

$$\|\bar{v}' - \bar{v}\| \geq p \|\bar{u}\| > c_{\mathsf{cub}} n^{1+2\mathsf{f}} \cdot l$$

and, again, $g(\bar{v}) \neq g(\bar{v}')$. This proves the first part of the claim. For the second part, let $t = 0$ and $t' = 1$. Then $k \equiv 1 \pmod{p}$. As before, this can happen only when $k = 1$, and hence the second part of the claim holds. □

Hence, it is enough to show that the probability that this register is bad is low enough. The probability of measuring $|r_1, \ldots, r_n\rangle$ equals

$$\frac{1}{2M^n} \cdot \left| \{(t, \bar{a}) \mid F(t, \bar{a}) = (r_1, \ldots, r_n)\} \right|.$$

Notice that this probability is the same as the probability that $F(t, \bar{a}) = (r_1, \ldots, r_n)$ for randomly chosen t and $\bar{a}$. Hence, we consider a randomly chosen t and $\bar{a}$. If $t = 0$, let

$$\bar{a}' = \left(a_1 + \frac{u_1 - m}{p}, a_2 + u_2, \ldots, a_n + u_n \right),$$

and if $t = 1$ let

$$\bar{a}' = \left(a_1 - \frac{u_1 - m}{p}, a_2 - u_2, \ldots, a_n - u_n \right).$$

Claim 3.6. *With probability at least* $1 - \frac{1}{(n \log(2M))^{\mathsf{f}}}$, *for randomly chosen* t *and* $\bar{a}$, $\bar{a}'$ *is in* $\mathcal{A}$ *and* $F(1 - t, \bar{a}') = F(t, \bar{a})$.

Proof. We assume that $t = 0$, and the proof for $t = 1$ is similar. According to Lemma 3.3, $|u_i| < 2^{2n}$. Hence, unless there exists an i for which $a_i < 2^{2n}$ or $a_i > M - 2^{2n}$, $\bar{a}'$ is guaranteed to be in $\mathcal{A}$. This happens with probability at most $n 2^{2n+1}/M$ because $\bar{a}$ is a random element of $\mathcal{A}$.

Notice that $f(1, \bar{a}') - f(0, \bar{a}) = \bar{u}$. Since $w_1, \ldots, w_n$ are randomly chosen, the probability that $F(1 - t, \bar{a}')$ and $F(t, \bar{a})$ differ on the ith coordinate is at most

$$\frac{|\langle \bar{u}, \bar{e}_i \rangle|}{c_{\mathsf{cub}} n^{\frac{1}{2}+2\mathsf{f}} \cdot l} \leq \frac{|\langle \bar{u}, \bar{e}_i \rangle|}{c_{\mathsf{cub}} n^{\frac{1}{2}+2\mathsf{f}} \cdot \|\bar{u}\|}.$$

By the union bound, the probability that $F(1-t,\bar{a}') \neq F(t,\bar{a})$ is at most

$$\frac{\sum_i |\langle \bar{u}, \bar{e}_i \rangle|}{c_{\mathsf{cub}} n^{\frac{1}{2}+2\mathsf{f}} \cdot \|\bar{u}\|} \leq \frac{1}{c_{\mathsf{cub}} n^{2\mathsf{f}}},$$

where we used the fact that the l_1 norm of a vector is at most $\sqrt{n}$ times its l_2 norm.

The sum of the two error probabilities $n\frac{2^{2n+1}}{M} + \frac{1}{c_{\mathsf{cub}} n^{2\mathsf{f}}}$ is at most $\frac{1}{(n\log(2M))^{\mathsf{f}}}$ for c_{cub} large enough. □

This concludes the proof of Lemma 3.4. □

3.3. An improved algorithm. In this section we complete the proof of Theorem 1.1. The algorithm we describe has many similarities with the one in the previous section. The main difference is that it is based on n-dimensional balls instead of cubes. The idea is to construct a ball of the right radius around lattice points and to show that if two lattice points are close, then the two balls have a large intersection, while for any two far lattice points the balls do not intersect. For technical reasons, we will assume in this section that the lattice is a subset of $\mathbb{Z}^n$. Any lattice with rational points can be scaled so that it is a subset of $\mathbb{Z}^n$. We begin with some technical claims.

CLAIM 3.7. *For any $R > 0$, let B_n be the ball of radius R centered around the origin in $\mathbb{R}^n$ and let $B'_n = B_n + \bar{d}$ for some vector $\bar{d}$ be a shifted ball. Then the relative n-dimensional volume of their intersection is at least $1 - O(\sqrt{n}\|\bar{d}\|/R)$, i.e.,*

$$\frac{\mathrm{vol}(B_n \cap B'_n)}{\mathrm{vol}(B_n)} \geq 1 - O(\sqrt{n}\|\bar{d}\|/R).$$

Proof. Consider a point $\bar{x} \in \mathbb{R}^n$ such that $\langle \bar{x}, \bar{d} \rangle / \|\bar{d}\| \geq \|\bar{d}\|/2$, i.e., a point which is closer to the center of B'_n than to the center of B_n. Notice that $\bar{x} \in B_n$ implies $\bar{x} \in B'_n$. In other words, the cap C_n of B_n given by all such points $\bar{x}$ is contained in $B_n \cap B'_n$. By using a symmetric argument for points $\bar{x} \in \mathbb{R}^n$ such that $\langle \bar{x}, \bar{d} \rangle / \|\bar{d}\| < \|\bar{d}\|/2$, we get

$$\mathrm{vol}(B_n \cap B'_n) = 2 \cdot \mathrm{vol}(C_n).$$

We can lower bound the volume of C_n by half the volume of B_n minus the volume of an n-dimensional cylinder of radius R and height $\|\bar{d}\|/2$:

$$\mathrm{vol}(C_n) \geq \frac{1}{2}\mathrm{vol}(B_n) - \frac{\|\bar{d}\|}{2}\mathrm{vol}(B_{n-1}),$$

where B_{n-1} is the $n-1$-ball of radius R. We complete the proof by using the estimate $\mathrm{vol}(B_{n-1})/\mathrm{vol}(B_n) = O(\sqrt{n}/R)$,

$$\mathrm{vol}(C_n)/\mathrm{vol}(B_n) \geq \frac{1}{2} - O(\sqrt{n}\|\bar{d}\|/R). \qquad \square$$

In the algorithm we will actually represent the balls using points of a fine grid. Therefore, we would like to say that the above claim still holds if we consider the number of grid points inside B_n, B'_n, and $B_n \cap B'_n$ instead of their volumes. The following claim is more than enough for our needs.

CLAIM 3.8 (special case of Proposition 8.7 in [21]). *Let L be an integer and consider the scaled integer grid $\frac{1}{L}\mathbb{Z}^n$. Then, for any convex body Q that contains a ball of radius $r \geq \frac{1}{L}n^{1.5}$,*

$$\left| \frac{|\frac{1}{L}\mathbb{Z}^n \cap Q|}{L^n \mathrm{vol}(Q)} - 1 \right| < \frac{2n^{1.5}}{rL}.$$

COROLLARY 3.9. *Let $L = 2^n$ and consider the scaled integer grid $\frac{1}{L}\mathbb{Z}^n$. For any $R \geq 1$, let B_n be the ball of radius R centered around the origin in $\mathbb{R}^n$ and let $B'_n = B_n + \bar{d}$ for some vector $\bar{d}$ such that $R/poly(n) \leq \|\bar{d}\| \leq R$. Then the relative number of grid points in their intersection is at least $1 - O(\sqrt{n}\|\bar{d}\|/R)$, i.e.,*

$$\frac{|\frac{1}{L}\mathbb{Z}^n \cap B_n \cap B'_n|}{|\frac{1}{L}\mathbb{Z}^n \cap B_n|} \geq 1 - O(\sqrt{n}\|\bar{d}\|/R).$$

Proof. We first note that B_n, B'_n, and $B_n \cap B'_n$ all contain the ball of radius $R/2 \geq 1/2$ centered around $\bar{d}/2$. Using Claim 3.8 we obtain that the number of grid points in these bodies approximates their volume up to a multiplicative error of $\frac{2n^{1.5}}{L/2} = 2^{-\Omega(n)}$. We complete the proof by using Claim 3.7. ∎

Let $D(\cdot,\cdot)$ denote the trace distance between two quantum states [22], i.e.,

$$D(\sigma_1, \sigma_2) = \frac{1}{2}\mathrm{tr}\sqrt{(\sigma_1 - \sigma_2)^\dagger(\sigma_1 - \sigma_2)}.$$

It is known that the trace distance represents the maximum probability of distinguishing between the two states using quantum measurements. We need the following simple bound on the trace distance.

CLAIM 3.10. *For all $k > 0$ and density matrices $\sigma_1, \ldots, \sigma_k, \sigma'_1, \ldots, \sigma'_k$,*

$$D(\sigma_1 \otimes \cdots \otimes \sigma_k, \sigma'_1 \otimes \cdots \otimes \sigma'_k) \leq \sum_{i=1}^{k} D(\sigma_i, \sigma'_i).$$

Proof. Using the triangle inequality,

$$\begin{aligned} D(\sigma_1 \otimes \cdots \otimes \sigma_k,\ & \sigma'_1 \otimes \cdots \otimes \sigma'_k) \\ &\leq D(\sigma_1 \otimes \cdots \otimes \sigma_k,\ \sigma'_1 \otimes \sigma_2 \otimes \cdots \otimes \sigma_k) \\ &\quad + D(\sigma'_1 \otimes \sigma_2 \otimes \cdots \otimes \sigma_k,\ \sigma'_1 \otimes \sigma'_2 \otimes \sigma_3 \otimes \cdots \otimes \sigma_k) + \cdots \\ &\quad + D(\sigma'_1 \otimes \cdots \otimes \sigma'_{k-1} \otimes \sigma_k,\ \sigma'_1 \otimes \cdots \otimes \sigma'_k) \\ &= D(\sigma_1,\ \sigma'_1) + D(\sigma_2,\ \sigma'_2) + \cdots + D(\sigma_k,\ \sigma'_k). \end{aligned}$$ ∎

In addition, we will need the following lemma.

LEMMA 3.11. *For any $1 \leq R \leq 2^{poly(n)}$, let*

$$|\eta\rangle = \frac{1}{\sqrt{|\frac{1}{L}\mathbb{Z}^n \cap B_n|}} \sum_{\bar{x} \in \frac{1}{L}\mathbb{Z}^n \cap B_n} |\bar{x}\rangle$$

be the uniform superposition on grid points inside a ball of radius R around the origin where $L = 2^n$. Then, for any $c > 0$, a state $|\tilde{\eta}\rangle$ whose trace distance from $|\eta\rangle$ is at most $1/n^c$ can be efficiently computed.

Proof. In order to bound the trace distance, we will use the fact that for any two pure states $|\psi_1\rangle, |\psi_2\rangle$,

$$D(|\psi_1\rangle, |\psi_2\rangle) = \sqrt{1 - |\langle\psi_1|\psi_2\rangle|^2} \leq \||\psi_1\rangle - |\psi_2\rangle\|_2. \tag{3.1}$$

The first equality appears in [22], and the inequality follows by a simple calculation.

Consider the (continuous) uniform probability distribution q over B_n. Then one can define its discretization q' to the grid $\frac{1}{L}\mathbb{Z}^n$ as

$$q'(\bar{x}) = \int_{\bar{x}+[0,1/L]^n} q(\bar{y})d\bar{y}$$

for $\bar{x} \in \frac{1}{L}\mathbb{Z}^n$. In other words, $q'(\bar{x})$ is proportional to the volume of the intersection of B_n with the cube $\bar{x} + [0, 1/L]^n$. Notice that for points $\bar{x}$ such that $\bar{x} + [0, 1/L]^n$ is completely contained in B_n, $q'(\bar{x}) = 1/(L^n \mathrm{vol}(B_n))$. We claim that the state

$$|\eta'\rangle = \sum_{\bar{x} \in \frac{1}{L}\mathbb{Z}^n} \sqrt{q'(\bar{x})}|\bar{x}\rangle$$

is exponentially close to $|\eta\rangle$. Intuitively, this holds since the two differ only on points which are very close to the boundary of the ball, namely, of distance $\sqrt{n}/L$ from the boundary. The number of such points is negligible compared to the number of points in the interior of the ball. More formally, define

$$|\eta''\rangle = \sqrt{\frac{L^n \mathrm{vol}(B_n)}{|\frac{1}{L}\mathbb{Z}^n \cap B_n|}}|\eta'\rangle.$$

Using (3.1),

$$D(|\eta\rangle, |\eta'\rangle) \leq \||\eta'\rangle - |\eta\rangle\|_2 \leq \||\eta'\rangle - |\eta''\rangle\|_2 + \||\eta''\rangle - |\eta\rangle\|_2.$$

The first term is at most $2^{-\Omega(n)}$ according to Claim 3.8. For the second term, notice that the amplitudes of $|\eta''\rangle$ and $|\eta\rangle$ are the same except possibly on points $\bar{x}$ of distance $\sqrt{n}/L$ from the boundary. Using Claim 3.8 again we get that the fraction of such points is closely approximated by one minus the ratio of volumes of the ball of radius $R - \sqrt{n}/L$ and the ball of radius R. This ratio of volumes is

$$(1 - \sqrt{n}/(RL))^n \geq (1 - \sqrt{n}/L)^n \geq 1 - n^{1.5}/L = 1 - 2^{-\Omega(n)}.$$

In the following we show how to approximate the state $|\eta'\rangle$. This idea is essentially due to Grover and Rudolph [10]. Let $m \in \mathbb{Z}$ be large enough so that B_n is contained in the cube $[-2^m, 2^m]^n$. Using our assumption on R, $m < n^{c_1}$ for some $c_1 \geq 1$. We represent $\bar{x}$ using $K = n(m + 1 + \log L) < 2n^{1+c_1}$ qubits, i.e., a block of $m + 1 + \log L$ qubits for each dimension. Hence, we can write $|\eta'\rangle$ as

$$|\eta'\rangle = \sum_{x_1,\ldots,x_K \in \{0,1\}} \sqrt{q'(x_1, \ldots, x_K)}|x_1, \ldots, x_K\rangle.$$

We now show an equivalent way of writing $|\eta'\rangle$. Let us extend the definition of q' in the following way: for any $k \leq K$ and any $x_1, \ldots, x_k \in \{0, 1\}$ define $q'(x_1, \ldots, x_k)$ as the sum of $q'(x_1, \ldots, x_k, x_{k+1}, \ldots, x_K)$ over all sequences $x_{k+1}, \ldots, x_K \in \{0, 1\}$. Notice that $q'(x_1, \ldots, x_k)$ corresponds to the volume of the intersection of B_n with a certain cuboid (also known as a rectangular parallelepiped). For example, $q'(0) = q'(1) = \frac{1}{2}$ since they represent the intersection of B_n with two halves of the cube $[-2^m, 2^m]^n$. Using the definition $s(x_1) = q'(x_1)$ and for $k > 1$, $s(x_1, \ldots, x_k) = q'(x_1, \ldots, x_k)/q'(x_1, \ldots, x_{k-1})$, we see that

$$|\eta'\rangle = \sum_{x_1 \in \{0,1\}} \sqrt{s(x_1)} \sum_{x_2 \in \{0,1\}} \sqrt{s(x_1, x_2)} \ldots \sum_{x_K \in \{0,1\}} \sqrt{s(x_1, \ldots, x_K)}|x_1, \ldots, x_K\rangle.$$

The algorithm starts with all K qubits in the state $|0\rangle$ and sets one qubit at a time. The first qubit is rotated to the state $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$. Assume we are now in the kth step after setting the state of qubits $1, \ldots, k-1$. We use the fact that there

exists a classical algorithm for approximating the volume of a convex body up to any $1/poly(n)$ error (see [16] and the references therein). The body should be provided by a "well-guaranteed weak membership oracle," i.e., a sphere containing the body, a sphere contained in the body, both of nonzero radius, and an oracle that, given a point, decides whether it is inside the body or not. It is easy to construct such two spheres and an oracle for a body given by the intersection of a ball with a cuboid. Hence, we can compute two values $\tilde{s}(x_1,\ldots,x_{k-1},0)$ and $\tilde{s}(x_1,\ldots,x_{k-1},1)$ such that

$$\tilde{s}(x_1,\ldots,x_{k-1},0)+\tilde{s}(x_1,\ldots,x_{k-1},1)=1$$

and

$$\left|\frac{\tilde{s}(x_1,\ldots,x_{k-1},i)}{s(x_1,\ldots,x_{k-1},i)}-1\right|<n^{-c_2}$$

for $i=0,1$ and some constant c_2 which will be chosen later. Then we rotate the ith qubit to the state

$$\sqrt{\tilde{s}(x_1,\ldots,x_{k-1},0)}|0\rangle+\sqrt{\tilde{s}(x_1,\ldots,x_{k-1},1)}|1\rangle.$$

This completes the description of the procedure.

Notice that the amplitude of each basis state $|x_1,\ldots,x_K\rangle$ in the resulting state $|\tilde{\eta}\rangle$ is given by

$$\prod_{k=1}^{K}\sqrt{\tilde{s}(x_1,\ldots,x_k)}\geq(1-n^{-c_2})^K\prod_{k=1}^{K}\sqrt{s(x_1,\ldots,x_k)}.$$

Hence the inner product $\langle\tilde{\eta}|\eta'\rangle$ is at least

$$\begin{aligned}(1-n^{-c_2})^K&\sum_{x_1,\ldots,x_K\in\{0,1\}}\prod_{k=1}^{K}s(x_1,\ldots,x_k)\\&=(1-n^{-c_2})^K\sum_{x_1,\ldots,x_K\in\{0,1\}}q'(x_1,\ldots,x_K)\\&=(1-n^{-c_2})^K\geq 1-K\cdot n^{-c_2}\geq 1-2n^{1+c_1-c_2}.\end{aligned}$$

Using (3.1),

$$D(|\eta'\rangle,|\tilde{\eta}\rangle)=\sqrt{1-|\langle\tilde{\eta}|\eta'\rangle|^2}<n^{-c}$$

for a large enough c_2. □

Let $p>n^{2+2\mathsf{f}}$ be any fixed prime. The following is the main lemma of this section. It essentially replaces Lemma 3.4 and hence implies Theorem 1.1.

LEMMA 3.12. *For any $\mathsf{f}>0$, if there exists a solution to the two-point problem with failure parameter f, then the following holds. There exists a quantum algorithm that, given a $(c_{\mathsf{unq}}n^{\frac{1}{2}+2\mathsf{f}})$-unique lattice for some large enough constant $c_{\mathsf{unq}}>0$ whose shortest vector is $\bar{u}=\sum_{i=1}^{n}u_i\bar{b}_i$, two integers m,i_0 and a number l returns*

$$\left(u_1,\ldots,u_{i_0-1},\frac{u_{i_0}-m}{p},u_{i_0+1},\ldots,u_n\right)$$

with probability $1/poly(n)$ if the following conditions hold: $\|\bar{u}\|\leq l\leq 2\|\bar{u}\|$, $u_{i_0}\equiv m \pmod p$, and $1\leq m\leq p-1$.

Proof. As before, let $\langle \bar{b}_1, \ldots, \bar{b}_n \rangle$ be an LLL-reduced basis, let $M = 2^{4n}$, and assume that $i_0 = 1$. We also define $f(t, \bar{a})$ as before. Assume that the number of registers needed by the two-point algorithm is at most n^{c_1} for some constant $c_1 > 0$.

The algorithm starts by calling the routine of Lemma 3.11 n^{c_1} times with accuracy parameter n^{-c_2} and $R = c_{\mathsf{bal}} n^{\frac{1}{2}+2\mathsf{f}} \cdot l$ for some constants $c_2, c_{\mathsf{bal}} > 0$. The state we obtain is

$$|\tilde{\eta}_1\rangle \otimes \cdots \otimes |\tilde{\eta}_{n^{c_1}}\rangle, \tag{3.2}$$

where each $|\tilde{\eta}_i\rangle$ has a trace distance of at most n^{-c_2} from $|\eta\rangle$. According to Claim 3.10, the above tensor product has a trace distance of at most $n^{c_1-c_2}$ from $|\eta\rangle^{\otimes n^{c_1}}$. In the following we show that the algorithm succeeds with probability at least n^{-c_3} for some $c_3 > 0$ given the state $|\eta\rangle^{\otimes n^{c_1}}$. This would complete the proof since, given the state in (3.2), the algorithm succeeds with probability at least $n^{-c_3} - n^{c_1-c_2} > \frac{1}{2} n^{-c_3}$ for large enough c_2.

We describe a routine that given the state $|\eta\rangle$ creates one register in the input to the two-point problem. In order to produce a complete input to the two-point problem, the algorithm calls this routine n^{c_1} times, each time with a new $|\eta\rangle$ register. It then calls the two-point algorithm and outputs the result. As required, the success probability is $1/poly(n \log M) = n^{-c_3}$ for some $c_3 > 0$.

Given $|\eta\rangle$, the routine creates the state

$$\frac{1}{\sqrt{2M^n}} \sum_{t \in \{0,1\}, \bar{a} \in \mathcal{A}} |t, \bar{a}\rangle \otimes |\eta\rangle$$

or, equivalently,

$$\sum_{t \in \{0,1\}, \bar{a} \in \mathcal{A}, \bar{x} \in \frac{1}{L}\mathbb{Z}^n \cap B_n} |t, \bar{a}, \bar{x}\rangle,$$

where B_n is the ball of radius R around the origin and $L = 2^n$. We add the value $f(t, \bar{a})$ to the last register,

$$\sum_{t \in \{0,1\}, \bar{a} \in \mathcal{A}, \bar{x} \in \frac{1}{L}\mathbb{Z}^n \cap B_n} |t, \bar{a}, f(t, \bar{a}) + \bar{x}\rangle.$$

Finally, we measure the last register, and if $\bar{x}'$ denotes the result, the state collapses to

$$\sum_{t \in \{0,1\}, \bar{a} \in \mathcal{A} | \bar{x}' \in f(t,\bar{a}) + \frac{1}{L}\mathbb{Z}^n \cap B_n} |t, \bar{a}, \bar{x}'\rangle.$$

CLAIM 3.13. *For every $\bar{x}'$, there is at most one element of the form $(0, \bar{a})$ and at most one element of the form $(1, \bar{a}')$ such that $\bar{x}' \in f(t, \bar{a}) + \frac{1}{L}\mathbb{Z}^n \cap B_n$. Moreover, if there are two such elements $(0, \bar{a})$ and $(1, \bar{a}')$, then $\bar{a}' - \bar{a}$ is the vector*

$$\left(\frac{u_1 - m}{p}, u_2, \ldots, u_m \right).$$

Proof. Consider two different lattice points in the image of f, $\bar{v} = f(t, \bar{a})$ and $\bar{v}' = f(t', \bar{a}')$, such that $\bar{x}'$ is in both $\bar{v} + \frac{1}{L}\mathbb{Z}^n \cap B_n$ and $\bar{v}' + \frac{1}{L}\mathbb{Z}^n \cap B_n$. This implies that

$$\|\bar{v} - \bar{v}'\| \leq c_{\mathsf{bal}} n^{\frac{1}{2}+2\mathsf{f}} \cdot l \leq 2 c_{\mathsf{bal}} n^{\frac{1}{2}+2\mathsf{f}} \cdot \|\bar{u}\|.$$

For $c_{\mathsf{unq}} > 2c_{\mathsf{bal}}$ this means that $\bar{v}' - \bar{v} = k \cdot \bar{u}$ for some integer $k \neq 0$. As before, by considering the first coordinate of $\bar{v}' - \bar{v}$ in the lattice basis, we get that

$$(a_1' p + t' m) - (a_1 p + t m) \equiv k \cdot m \pmod{p}.$$

Hence, $k \equiv t' - t \pmod{p}$. If $t = t'$, then $k \equiv 0 \pmod{p}$ and therefore $|k| \geq p$, which contradicts the above upper bound on the distance between $\bar{v}$ and $\bar{v}'$. This proves the first part of the claim. For the second part, let $t = 0$ and $t' = 1$. Then $k \equiv 1 \pmod{p}$. As before, this can happen only when $k = 1$, and hence the second part of the claim holds. □

Notice that the probability of measuring $\bar{x}'$ is the same as that obtained by first choosing random t and $\bar{a}$ and then choosing a random point in $f(t, \bar{a}) + \frac{1}{L}\mathbb{Z}^n \cap B_n$. Let us define for any t and $\bar{a}$ the vector $\bar{a}'$ as before.

Claim 3.14. *With probability at least* $1 - \frac{1}{(n \log(2M))^{\mathsf{f}}}$, *for randomly chosen* t *and* $\bar{a}$ *and a random point* $\bar{x}'$ *in* $f(t, \bar{a}) + \frac{1}{L}\mathbb{Z}^n \cap B_n$, $\bar{a}'$ *is in* $\mathcal{A}$ *and* $\bar{x}'$ *is also in* $f(1 - t, \bar{a}') + \frac{1}{L}\mathbb{Z}^n \cap B_n$.

Proof. According to Lemma 3.3, $|u_i| < 2^{2n}$. Hence, unless there exists an i for which $a_i < 2^{2n}$ or $a_i > M - 2^{2n}$, $\bar{a}'$ is guaranteed to be in $\mathcal{A}$. This happens with probability at most $n2^{2n+1}/M$ because $\bar{a}$ is a random element of $\mathcal{A}$.

Fix $\bar{a}, \bar{a}' \in \mathcal{A}$. We would like to show that if $\bar{x}'$ is chosen uniformly from $f(t, \bar{a}) + \frac{1}{L}\mathbb{Z}^n \cap B_n$, then with high probability it is also in

$$f(1 - t, \bar{a}') + \frac{1}{L}\mathbb{Z}^n \cap B_n.$$

By translating both sets by $-f(t, \bar{a})$, we get the equivalent statement that if $\bar{x}'$ is chosen uniformly from $\frac{1}{L}\mathbb{Z}^n \cap B_n$, then with high probability it is also in $(f(1 - t, \bar{a}') - f(t, \bar{a})) + \frac{1}{L}\mathbb{Z}^n \cap B_n$. Since we assumed that our lattice is a subset of $\mathbb{Z}^n$, $f(1 - t, \bar{a}') - f(t, \bar{a}) \in \mathbb{Z}^n$ and the latter set equals $\frac{1}{L}\mathbb{Z}^n \cap (f(1 - t, \bar{a}') - f(t, \bar{a}) + B_n)$. Using Corollary 3.9 and the fact that $\|f(1 - t, \bar{a}') - f(t, \bar{a})\| = \|\bar{u}\| \leq l$, we get that the required probability is at least

$$1 - O(\sqrt{n} l / R) = 1 - O(\sqrt{n} l / (c_{\mathsf{bal}} n^{\frac{1}{2} + 2\mathsf{f}} \cdot l)) = 1 - O(1/(c_{\mathsf{bal}} n^{2\mathsf{f}})).$$

The sum of the two error probabilities $n2^{2n+1}/M + O(1/(c_{\mathsf{bal}} n^{2\mathsf{f}}))$ is at most $\frac{1}{(n \log(2M))^{\mathsf{f}}}$ for c_{bal} large enough. □

This concludes the proof of Lemma 3.12. □

4. The dihedral coset problem. We begin this section with a description of the average-case subset sum problem. We describe our assumptions on the subroutine that solves it and prove some properties of such a subroutine. In the second subsection we present an algorithm that solves the DCP with calls to an average-case subset sum subroutine.

4.1. Subset sum. The subset sum problem is defined as follows. An input is a sequence of numbers $A = (a_1, \ldots, a_r)$ and two numbers t, N. The output is a subset $B \subseteq [r]$ such that $\sum_{i \in B} a_i \equiv t \pmod{N}$. Let a legal input be an input for which there exists a subset B with $\sum_{i \in B} a_i \equiv t \pmod{N}$. For a constant $c_{\mathsf{r}} > 0$, we fix r to be $\log N + c_{\mathsf{r}}$ since we will only be interested in such instances. First we show that there are many legal inputs.

Lemma 4.1. *Let* c_{r} *be a large enough constant. Then, for randomly chosen* $a_1, \ldots, a_r, t$ *in* $\{0, \ldots, N - 1\}$, *the probability that there is no* $B \subseteq [r]$ *such that* $\sum_{i \in B} a_i \equiv t \pmod{N}$ *is at most* $\frac{1}{2}$.

Proof. Fix a value of t. For each $\bar{b} \in \{0,1\}^r, \bar{b} \neq 0^r$, define a random variable $X_{\bar{b}}$ as $\sum_i b_i a_i \bmod N$. It is easy to check that for any $\bar{b} \neq 0^r$, $X_{\bar{b}}$ is uniformly distributed on $\{0,\ldots,N-1\}$ and that the random variables $X_{\bar{b}}$ are pairwise independent. For every $\bar{b} \in \{0,1\}^r, \bar{b} \neq 0^r$, define a random variable $Y_{\bar{b}}$ as 1 if $X_{\bar{b}} = t$ and 0 otherwise. Then the expectation of $Y_{\bar{b}}$ is $\frac{1}{N}$ and its variance is $\frac{1}{N} - \frac{1}{N^2} < \frac{1}{N}$. Hence,

$$E\left[\sum_{\bar{b}} Y_{\bar{b}}\right] = \sum_{\bar{b}} E[Y_{\bar{b}}] = \frac{2^r - 1}{N}.$$

The $Y_{\bar{b}}$'s are defined as a function of the $X_{\bar{b}}$'s and are therefore also pairwise independent. Therefore, by the Chebyshev bound,

$$\Pr\left[\sum_{\bar{b}} Y_{\bar{b}} < \frac{1}{2} \cdot \frac{2^r - 1}{N}\right] \leq 4 \cdot \frac{N}{2^r - 1} \leq \frac{8}{2^{c_r}}.$$

In particular, the probability of $\sum_{\bar{b}} Y_{\bar{b}} = 0$, that is, the probability that there is no B such that $\sum_{i \in B} a_i \equiv t \pmod N$, is at most $\frac{8}{2^{c_r}} = \frac{1}{2}$ for $c_r = 4$. □

We assume that we are given a deterministic subroutine S that answers a $\frac{1}{\log^{c_s} N}$ fraction of the legal subset sum inputs with parameter N, where $c_s > 0$ is any constant.[2] The previous lemma implies that S answers a nonnegligible fraction of all inputs (and not just the legal inputs). We denote by $S(A,t)$ the result of the subroutine S on the input $A = (a_1,\ldots,a_r), t$ and we omit N. This result can be either a set or an error. We assume that whenever $S(A,t)$ is not an error, it is correct; i.e., it represents a subset of A that sums to t modulo N. This can be assumed without loss of generality since we can easily check the correctness of any output of S. Let $S(A)$ denote the set of t's for which the subroutine returns a set and not an error, i.e., $S(A) = \{t \mid S(A,t) \neq error\}$.

LEMMA 4.2. *For randomly chosen $a_1,\ldots,a_r$ in $\{0,\ldots,N-1\}$,*

$$\Pr_A\left[|S(A)| \geq \frac{N}{4\log^{c_s} N}\right] = \Omega\left(\frac{1}{\log^{c_s} N}\right),$$

where $A = (a_1,\ldots,a_r)$.

Proof. Since $S(A,t) \neq error$ only when (A,t) is a legal input,

$$\begin{aligned}
&\Pr_{A,t}[S(A,t) \neq error] \\
&= \Pr_{A,t}[\ S(A,t) \neq error \ \wedge\ (A,t) \text{ is legal }] \\
&= \Pr_{A,t}[\ S(A,t) \neq error \mid (A,t) \text{ is legal }] \cdot \Pr_{A,t}[\ (A,t) \text{ is legal }] \geq \frac{1}{2\log^{c_s} N}.
\end{aligned}$$

In addition,

$$\begin{aligned}
&\Pr_{A,t}[S(A,t) \neq error] = E_A\left[\ \frac{|S(A)|}{N}\ \right] \\
&\leq \Pr_A\left[\ |S(A)| \geq \frac{N}{4\log^{c_s} N}\ \right] + \Pr_A\left[\ |S(A)| < \frac{N}{4\log^{c_s} N}\ \right] \cdot \frac{1}{4\log^{c_s} N} \\
&\leq \Pr_A\left[\ |S(A)| \geq \frac{N}{4\log^{c_s} N}\ \right] + \frac{1}{4\log^{c_s} N}.
\end{aligned}$$

[2] We could also consider randomized routines S, but this makes essentially no difference: there is always a way to fix the random coins of a randomized routine such that the resulting deterministic routine answers an equally large fraction of the inputs.

We complete the proof by combining the two inequalities. ∎

LEMMA 4.3. *Let $T \subseteq \{0,\ldots,N-1\}$ be a set such that $|T| > \frac{N}{s}$ for a certain s. Then, for any $q < \frac{N}{8s}$ there exists $q' \in \{q, 2q, \ldots, sq\}$ such that the number of pairs $t, t+q'$ that are both in T is $\Omega(\frac{N}{s^3})$.*

Proof. Define the partition of T into sets $T_0,\ldots,T_{q-1}$ as

$$T_k = \{i \mid i \in T, i \equiv k \pmod q\}.$$

At least $\frac{q}{2s}$ of the sets are of size at least $\frac{N}{2sq}$ since their union is T and $\frac{q}{2s}\cdot\frac{N}{q}+\frac{N}{2s} < |T|$. Let T_i be such a set and for $t \in T_i$ consider the values

$$t+q, t+2q, \ldots, t+4sq.$$

Therefore, the number of $t \in T_i$ such that none of these values is in T_i is less than $\frac{N}{4sq}$ because

$$|\{i \mid 0 \le i < N, i \equiv k \pmod q\}| = \frac{N}{q}.$$

Therefore, more than $|T_i| - \frac{N}{4sq} \ge \frac{N}{4sq}$ of the elements $t \in T_i$ are such that one of

$$t+q, t+2q, \ldots, t+4sq$$

is also in T_i. Summing over all sets T_i such that $|T_i| \ge \frac{N}{2sq}$, there are at least $\frac{N}{4sq}\cdot\frac{q}{2s} = \frac{N}{8s^2}$ elements $t \in T$ for which one of $t+q, t+2q, \ldots, t+4sq$ is also in T. Thus, there exists a $q' \in \{q, 2q, \ldots, 4sq\}$ such that the number of $t \in T$ for which $t+q' \in T$ is at least $\frac{N}{32s^3}$. ∎

DEFINITION 4.4. *A partial function $f : \{0,\ldots,N-1\} \to \{0,\ldots,N-1\}$ is called a matching if for all i such that $f(i)$ is defined, $f(i) \ne i$ and $f(f(i)) = i$. A matching is a q-matching if for all i such that $f(i)$ is defined, $|f(i)-i| = q$. We define an equal partition of the domain of a matching f by $A_1(f) = \{i \mid f(i)$ defined $\wedge\ f(i) > i\}$ and $A_2(f) = \{i \mid f(i)$ defined $\wedge\ f(i) < i\}$. The intersection of a matching f and a set $T \subseteq \{0,\ldots,N-1\}$ is the set $\{i \mid i \in T \wedge f(i) \in T\}$.*

For any q we define the following q-matchings:

$$f_q^1(t) = \begin{cases} t+q & t \bmod 2q < q,\ t+q < N, \\ t-q & t \bmod 2q \ge q,\ t-q \ge 0, \\ \textit{undefined} & \text{otherwise.} \end{cases}$$

$$f_q^2(t) = \begin{cases} t-q & t \bmod 2q < q,\ t-q \ge 0, \\ t+q & t \bmod 2q \ge q,\ t+q < N, \\ \textit{undefined} & \text{otherwise.} \end{cases}$$

LEMMA 4.5. *There exists a constant c_{m} such that for any integer $q < \frac{N}{\log^{c_{\mathsf{m}}} N}$ there exists a matching f among the $2\log^{c_{\mathsf{m}}} N$ matchings*

$$f_q^1, f_{2q}^1, \ldots, f_{\log^{c_{\mathsf{m}}} Nq}^1, f_q^2, f_{2q}^2, \ldots, f_{\log^{c_{\mathsf{m}}} Nq}^2$$

such that with probability at least $\frac{1}{\log^{c_{\mathsf{m}}} N}$ on the choice of A, the intersection of f and $S(A)$ is $\frac{N}{\log^{c_{\mathsf{m}}} N}$. We call such an f a good *matching.*

Proof. According to Lemma 4.2, $\frac{1}{4\log^{c_{\mathsf{s}}} N}$ of the possible values of A satisfy $|S(A)| > \frac{N}{4\log^{c_{\mathsf{s}}} N}$. For such A, Lemma 4.3 with $s = 4\log^{c_{\mathsf{s}}} N$ implies that there exists a value

$$q' \in \{q, 2q, \ldots, 4\log^{c_{\mathsf{s}}} N \cdot q\}$$

such that the number of pairs $t, t+q'$ that are both in $S(A)$ is $\Omega(\frac{N}{\log^{3c_s} N})$. Therefore, for such A and q', the size of the intersection of one of the matchings $f^1_{q'}, f^2_{q'}$ and $S(A)$ is $\Omega(\frac{N}{\log^{3c_s} N})$. This implies that one of the $8\log^{c_s} N$ matchings considered must have an intersection of size $\Omega(\frac{N}{\log^{3c_s} N})$ with at least $\frac{1}{32\log^{2c_s} N}$ of the possible values of A. We conclude the proof by choosing $c_m > 3c_s$. □

4.2. The quantum algorithm. We begin with the following simple claim.

CLAIM 4.6. *For any two basis states $|a\rangle$ and $|b\rangle$, $a \neq b$, there exists a routine such that, given the state $|a\rangle + e(\phi)|b\rangle$, outputs the state $|0\rangle + e(\phi)|1\rangle$.*

Proof. Consider the function f defined as $f(a) = 0, f(0) = a, f(b) = 1, f(1) = b$, and $f(i) = i$ otherwise. It is reversible and can therefore be implemented as a quantum routine. □

We now describe the main routine in the DCP algorithm.

LEMMA 4.7. *There exist routines R_1, R_2 such that given a q-matching f and an input for the DCP with failure parameter 1, either they output a bit or they fail. Conditioned on nonfailure, the probability of the bit being 1 is $\frac{1}{2} - \frac{1}{2}\cos(2\pi q\frac{d}{N})$ for R_1 and $\frac{1}{2} + \frac{1}{2}\sin(2\pi q\frac{d}{N})$ for R_2. Moreover, if f is a good matching, the success probability is $\Omega(\frac{1}{\log^{c_m} N})$.*

Proof. The routines begin by performing a Fourier transform on the last $\log N$ qubits of each input register. Consider one register. Assuming it is a good register, the resulting state is

$$\frac{1}{\sqrt{2N}}\sum_{i=0}^{N-1} e(ix/N)|0,i\rangle + \frac{1}{\sqrt{2N}}\sum_{i=0}^{N-1} e(i(x+d)/N)|1,i\rangle$$
$$= \frac{1}{\sqrt{2N}}\sum_{i=0}^{N-1} e(ix/N)(|0\rangle + e(id/N)|1\rangle)|i\rangle.$$

We measure the last $\log N$ qubits and let $a \in \{0,\ldots,N-1\}$ be the result. The state collapses to

$$\frac{1}{\sqrt{2}} e(ax/N)(|0\rangle + e(ad/N)|1\rangle)|a\rangle.$$

If it is a bad register, it is in the state $|b,x\rangle$, where both b and x are arbitrary. After the Fourier transform the state is

$$\frac{1}{\sqrt{N}}\sum_{i=0}^{N-1} e(ix/N)|b,i\rangle,$$

and after measuring a in the last $\log N$ qubits, the state is $e(ax/N)|b,a\rangle$. Notice that in both cases any value a in $\{0,\ldots,N-1\}$ has an equal probability of being measured.

We choose the number of input registers to be r. Let $A = (a_1,\ldots,a_r)$ be the sequence of values measured in the above process. Notice that this sequence is uniform and hence can be used as an input to the average-case subset sum algorithm. In the following, we assume that s of the r registers are bad. Later we will claim that with good probability, none of the registers is bad. Yet, we have to show that even if one of the registers is bad, the routine does not return erroneous results. Without loss of generality, assume that the first s registers are bad. The resulting state is

$$\bigotimes_{i=1}^{s}[e(a_i x_i/N)|b_i,a_i\rangle] \bigotimes_{i=s+1}^{r}\left[\frac{1}{\sqrt{2}} e(a_i x_i/N)(|0\rangle + e(a_i d/N)|1\rangle)|a_i\rangle\right],$$

or, by omitting the multiplication by the fixed phase and the $r \cdot \lceil \log N \rceil$ fixed qubits,

$$\bigotimes_{i=1}^{s}[|b_i\rangle] \bigotimes_{i=s+1}^{r}\left[\frac{1}{\sqrt{2}}(|0\rangle + e(a_i d/N)|1\rangle)\right].$$

Denote these r qubits by $\bar{\alpha} = (\alpha_1, \ldots, \alpha_r)$.

We add $r+1$ new qubits, $\bar{\beta} = (\beta_1, \ldots, \beta_r)$ and γ. Let $t_{\bar{\alpha}}$ denote the sum $\sum_{i=1}^{r} \alpha_i a_i$. Next, we perform the following operations:

if $S(A, t_{\bar{\alpha}}) \neq \bar{\alpha} \ \vee \ S(A, f(t_{\bar{\alpha}})) = error$
  then *exit*
if $t_{\bar{\alpha}} \in A_1(f)$
  then $\begin{cases} \bar{\beta} \leftarrow \bar{\alpha} \\ \gamma \leftarrow 1 \end{cases}$
  else if $t_{\bar{\alpha}} \in A_2(f)$
  then $\begin{cases} \bar{\beta} \leftarrow S(A, f(t_{\bar{\alpha}})) \\ \gamma \leftarrow 1 \end{cases}$
  else *exit*

In order to describe the state after the above procedure, we define the following subsets of $\{0,1\}^r$:

$$\begin{aligned} M &= \{\bar{\alpha} \in \{0,1\}^r \mid \alpha_1 = b_1, \ldots, \alpha_s = b_s\}, \\ L &= \{\bar{\alpha} \in M \mid t_{\bar{\alpha}} \in A_1(f) \ \wedge \ S(A, t_{\bar{\alpha}}) = \bar{\alpha} \ \wedge S(A, f(t_{\bar{\alpha}})) \neq error\}, \\ R &= \{\bar{\alpha} \in M \mid t_{\bar{\alpha}} \in A_2(f) \ \wedge \ S(A, t_{\bar{\alpha}}) = \bar{\alpha} \ \wedge S(A, f(t_{\bar{\alpha}})) \neq error\}. \end{aligned}$$

Using the order $|\bar{\alpha}, \bar{\beta}, \gamma\rangle$, the resulting state is

$$\begin{aligned} &\frac{1}{\sqrt{2^{r-s}}}\left(\sum_{\bar{\alpha}\in M-L-R} e\left(\langle\bar{\alpha},\bar{a}\rangle\frac{d}{N}\right)|\bar{\alpha},\bar{0},0\rangle\right. \\ &\qquad\left. + \sum_{\bar{\alpha}\in L} e\left(\langle\bar{\alpha},\bar{a}\rangle\frac{d}{N}\right)|\bar{\alpha},\bar{\alpha},1\rangle + \sum_{\bar{\alpha}\in R} e\left(\langle\bar{\alpha},\bar{a}\rangle\frac{d}{N}\right)|\bar{\alpha},S(A,f(t_{\bar{\alpha}})),1\rangle\right) \\ &= \frac{1}{\sqrt{2^{r-s}}}\left(\sum_{\bar{\alpha}\in M-L-R} e\left(\langle\bar{\alpha},\bar{a}\rangle\frac{d}{N}\right)|\bar{\alpha},\bar{0},0\rangle\right. \\ &\qquad\left. + \sum_{\bar{\alpha}\in L}\left(e\left(\langle\bar{\alpha},\bar{a}\rangle\frac{d}{N}\right)|\bar{\alpha},\bar{\alpha},1\rangle + e\left(\langle S(A,f(t_{\bar{\alpha}})),\bar{a}\rangle\frac{d}{N}\right)|S(A,f(t_{\bar{\alpha}})),\bar{\alpha},1\rangle\right)\right) \\ &= \frac{1}{\sqrt{2^{r-s}}}\left(\sum_{\bar{\alpha}\in M-L-R} e\left(\langle\bar{\alpha},\bar{a}\rangle\frac{d}{N}\right)|\bar{\alpha},\bar{0},0\rangle\right. \\ &\qquad\left. + \sum_{\bar{\alpha}\in L} e\left(\langle\bar{\alpha},\bar{a}\rangle\frac{d}{N}\right)(|\bar{\alpha}\rangle + e(q\cdot\frac{d}{N})|S(A,f(t_{\bar{\alpha}}))\rangle)|\bar{\alpha},1\rangle\right). \end{aligned}$$

Now we measure $\bar{\beta}$ and γ. If $\gamma = 0$, the routine failed. Otherwise, the state of $\bar{\alpha}$ is (omitting the fixed $\bar{\beta}$ and γ)

$$\frac{1}{\sqrt{2}}\left(|\bar{\beta}\rangle + e\left(q\cdot\frac{d}{N}\right)|S(A,f(t_{\bar{\beta}}))\rangle\right).$$

Notice that since $\bar{\beta}$ is known and $S(A, f(t_{\bar{\beta}}))$ can be easily found by calling S, we can transform this state to the state

$$\frac{1}{\sqrt{2}}\left(|0\rangle + e\left(q \cdot \frac{d}{N}\right)|1\rangle\right)$$

by using Claim 4.6. By omitting some qubits, we can assume that this is a state on one qubit. By using the Hadamard transform the state becomes

$$\frac{1}{2}\left(\left(1 + e\left(q \cdot \frac{d}{N}\right)\right)|0\rangle + \left(1 - e\left(q \cdot \frac{d}{N}\right)\right)|1\rangle\right).$$

We measure the qubit, and the probability of measuring 1 is

$$\frac{1}{4}\left|1 - e\left(q \cdot \frac{d}{N}\right)\right|^2 = \frac{1}{4}\left(2 - 2\cos\left(2\pi q \cdot \frac{d}{N}\right)\right) = \frac{1}{2} - \frac{1}{2}\cos\left(2\pi q \cdot \frac{d}{N}\right).$$

This completes the description of R_1. The routine R_2 applies the transform

$$\begin{pmatrix} 1 & 0 \\ 0 & \imath \end{pmatrix}$$

before the Hadamard transform and thus the state becomes

$$\frac{1}{2}\left(\left(1 + e\left(1/4 + q \cdot \frac{d}{N}\right)\right)|0\rangle + \left(1 - e\left(1/4 + q \cdot \frac{d}{N}\right)\right)|1\rangle\right),$$

and the probability of measuring 1 becomes

$$\frac{1}{2} - \frac{1}{2}\cos\left(\pi/2 + 2\pi q \cdot \frac{d}{N}\right) = \frac{1}{2} + \frac{1}{2}\sin\left(2\pi q \cdot \frac{d}{N}\right).$$

From the previous description, it is clear that the probability of measuring 1 conditioned on a nonfailure is correct. Thus, it remains to prove that when f is a good matching the failure probability is low. The success probability equals the probability of measuring $\gamma = 1$, which is $|L \cup R|/2^{r-s}$. Assume that none of the r registers is bad. Then $|L \cup R|/2^{r-s} = |L \cup R|/2^r$ and $L \cup R$ becomes

$$\{\bar{\alpha} \in \{0,1\}^r \mid t_{\bar{\alpha}} \in A_1(f) \cup A_2(f) \ \wedge \ S(A, t_{\bar{\alpha}}) = \bar{\alpha} \ \wedge \ S(A, f(t_{\bar{\alpha}})) \neq error\}.$$

Notice that the size of this set equals

$$|\{t \mid t \in S(A) \ \wedge \ f(t) \in S(A)\}|,$$

which, according to the definition of a good matching, is at least $\frac{N}{\log^{c_m} N}$. Therefore the probability of success conditioned on all of the registers being good is

$$|L \cup R|/2^r = \frac{1}{2^{c_r}\log^{c_m} N} = \Omega\left(\frac{1}{\log^{c_m} N}\right).$$

This concludes the proof since with probability at least

$$\left(1 - \frac{1}{\log N}\right)^r = \left(1 - \frac{1}{\log N}\right)^{\log N + c_r} = \Omega(1)$$

none of the registers is bad. ∎

CLAIM 4.8. *Given an approximation x of $\sin\phi$ and an approximation y of $\cos\phi$ with additive error ϵ, we can find $\phi \bmod 2\pi$ up to an additive error of $O(\epsilon)$.*

Proof. Assume $y \geq 0$ and let $z = \frac{x}{1+y}$. A simple calculation shows that z is an estimate of $\frac{\sin\phi}{1+\cos\phi}$ up to an additive error of at most 4ϵ. The estimate on ϕ is $2\arctan z$. Since the absolute value of the differential of arctan is at most 1, this is an estimate of $2\arctan(\frac{\sin\phi}{1+\cos\phi}) = \phi$ with an additive error of at most 8ϵ. When $y < 0$ we compute an estimate of $2\operatorname{arccot}(\frac{\sin\phi}{1-\cos\phi}) = \phi$. ∎

LEMMA 4.9. *There exists a routine R_3 such that with probability exponentially close to 1, given any $q < \frac{N}{\log^{c_{\mathsf{m}}} N}$, finds a value $q' \in \{q, \ldots, \log^{c_{\mathsf{m}}} N \cdot q\}$ and an estimate x such that*

$$x \in \left[q'd - \frac{N}{\log^{c_{\mathsf{m}}+1} N}, q'd + \frac{N}{\log^{c_{\mathsf{m}}+1} N}\right] \pmod N.$$

Proof. Assume we are given a q'-matching f. We call routines R_1 and R_2 $\log^{3c_{\mathsf{m}}+4} N$ times. If the number of successful calls to one of the routines is less than $\log^{2c_{\mathsf{m}}+3} N$, we fail. Otherwise, let $x \in [0,1]$ be the average of the successful calls to R_1 and let $y \in [0,1]$ be the average of the successful calls to R_2. According to the Chernoff bound,

$$\Pr\left[\left|x - \left(\frac{1}{2} - \frac{1}{2}\cos\left(2\pi q' \cdot \frac{d}{N}\right)\right)\right| > \frac{1}{c_{\mathsf{e}} \log^{c_{\mathsf{m}}+1} N}\right] < 2e^{-2\log^{2c_{\mathsf{m}}+3} N/(c_{\mathsf{e}}{}^2 \log^{2c_{\mathsf{m}}+2} N)},$$

which is exponentially low in $\log N$ for any constant $c_{\mathsf{e}} > 0$. A similar bound holds for y. Hence, we can assume that $x' = 1 - 2x$ and $y' = 2y - 1$ are approximations of $\cos(2\pi q' \cdot \frac{d}{N})$ and of $\sin(2\pi q' \cdot \frac{d}{N})$, respectively, up to an additive error of $\frac{2}{c_{\mathsf{e}} \log^{c_{\mathsf{m}}+1} N}$. According to Claim 4.8, this translates to an estimate of $q' \cdot \frac{d}{N} \bmod 1$ with an additive error of $\frac{1}{\log^{c_{\mathsf{m}}+1} N}$ for c_{e} large enough.

By repeating the above procedure with all the matchings that appear in Lemma 4.5, we are guaranteed to find a good matching. According to Lemma 4.7, a call to routine R_1 or to routine R_2 with a good matching succeeds with probability at least $c_{\mathsf{g}} \frac{1}{\log^{c_{\mathsf{m}}} N}$ for a certain $c_{\mathsf{g}} > 0$. The probability that none of $\log^{c_{\mathsf{m}}+1} N$ calls to the subroutine succeeds is

$$\left(1 - c_{\mathsf{g}} \frac{1}{\log^{c_{\mathsf{m}}} N}\right)^{\log^{c_{\mathsf{m}}+1} N},$$

which is exponentially small. Thus, for one of the matchings, with probability exponentially close to 1, we have $\log^{2c_{\mathsf{m}}+3} N$ successful calls to routines R_1 and R_2 and routine R_3 is successful. ∎

We conclude the proof of Theorem 1.3 with a description of the algorithm for finding d. We begin by using routine R_3 with the value 1 to obtain an estimate x_1 and a value $\hat{q} \leq \log^{c_{\mathsf{m}}} N$ such that

$$x_1 \in \left[d' - \frac{N}{\log^{c_{\mathsf{m}}+1} N}, d' + \frac{N}{\log^{c_{\mathsf{m}}+1} N}\right] \pmod N,$$

where d' denotes $(d\hat{q} \bmod N)$. In the following we find d' exactly by calling R_3 with multiples of $\hat{q}$. The algorithm works in stages. In stage i we have an estimate x_i and

a value q_i. The invariant we maintain is

$$x_i \in \left[q_i d' - \frac{N}{\log^{c_m+1} N},\ q_i d' + \frac{N}{\log^{c_m+1} N} \right] \pmod{q_i N}.$$

We begin with x_1 as above and $q_1 = 1$. Assume that the invariant holds in stage i. We use routine R_3 with the value $2q_i\hat{q}$ to obtain an estimate x with a value

$$q' \in \{2q_i\hat{q}, 4q_i\hat{q}, \ldots, 2\log^{c_m} N \cdot q_i\hat{q}\}$$

such that

$$x \in \left[q_{i+1} d' - \frac{N}{\log^{c_m+1} N},\ q_{i+1} d' + \frac{N}{\log^{c_m+1} N} \right] \pmod{N},$$

where $q_{i+1} = q'/\hat{q}$. Notice that our previous estimate x_i satisfies

$$\frac{q_{i+1}}{q_i} x_i \in \left[q_{i+1} d' - \frac{2N}{\log N}, q_{i+1} d' + \frac{2N}{\log N} \right] \pmod{q_{i+1} N}.$$

Since this range is much smaller than N, we can combine the estimate x on $(q_{i+1}d' \bmod N)$ and the estimate $\frac{q_{i+1}}{q_i} x_i$ on $(q_{i+1}d' \bmod q_{i+1}N)$ to obtain x_{i+1} such that

$$x_{i+1} \in \left[q_{i+1} d' - \frac{N}{\log^{c_m+1} N},\ q_{i+1} d' + \frac{N}{\log^{c_m+1} N} \right] \pmod{q_{i+1} N}.$$

The last stage is when $q_i \geq \frac{4N}{\log^{c_m+1} N}$. Then d' can be found by rounding $\frac{x_i}{q_i}$ to the nearest integer. Given d' there are at most $\hat{q} \leq \log^{c_m} N$ possible values for q. Since this is only a polynomial number of options, we can output one randomly.

Acknowledgments. COMPACTION, RETRACTION, AND CONSTRAINT SATISFACTION*

NARAYAN VIKAS†

Abstract. In this paper, we show a very close relationship among the compaction, retraction, and constraint satisfaction problems in the context of reflexive and bipartite graphs. The compaction and retraction problems are special graph coloring problems, and the constraint satisfaction problem is well known to have an important role in artificial intelligence. The relationships we present provide evidence that, similar to the retraction problem, it is likely to be difficult to determine whether for every fixed reflexive or bipartite graph, the compaction problem is polynomial time solvable or NP-complete. In particular, the relationships that we present relate to a long-standing open problem concerning the equivalence of the compaction and retraction problems.

1. Introduction.

We first introduce the following definitions and problems, and then describe the motivation and results.

1.1. Definitions.

The pair of vertices forming an edge in a graph are called the *endpoints* of the edge. An edge is said to be *incident* with a vertex v in a graph if v is an endpoint of the edge. An edge of a graph with the same endpoints is called a *loop*. We say that a vertex v of a graph has a loop if vv is an edge of the graph. A *reflexive graph* is a graph in which every vertex has a loop. An *irreflexive graph* is a graph in which no vertex has a loop. Any graph, in general, is a *partially reflexive graph*, meaning that its individual vertices may or may not have loops. Thus reflexive and irreflexive graphs are special partially reflexive graphs. A *bipartite graph* G is a graph whose vertex set can be partitioned into two distinct subsets G_A and G_B, such that each edge of G has one endpoint in G_A and the other endpoint in G_B; we say that (G_A, G_B) is a bipartition of G. Thus a bipartite graph is irreflexive by definition. When we do not mention the terms reflexive, irreflexive, or bipartite, the corresponding graph may be assumed to be a partially reflexive graph. We denote the vertex set and the edge set of a graph G by $V(G)$ and $E(G)$ respectively. A vertex u is said to be *adjacent* to a vertex v in a graph if uv is an edge of the graph; if u is adjacent to v then v is also adjacent to u. If a vertex u is adjacent to a vertex v then u is said to be a *neighbor* of v, and v is said to be a neighbor of u. A graph in which each pair of distinct vertices are adjacent is called a *complete graph*. We denote an irreflexive complete graph with k vertices by K_k. A bipartite graph, with bipartition (G_A, G_B), in which every vertex in G_A is adjacent to every vertex in G_B is called a *complete bipartite graph*. A *path* of length $k-1$ is a graph containing k distinct vertices, say $v_0, v_1, v_2, \ldots, v_{k-1}$, such that $v_0v_1, v_1v_2, \ldots, v_{k-2}v_{k-1}$ are all the nonloop edges of the graph, $k \geq 1$; we may write such a path as $v_0v_1v_2 \ldots v_{k-1}$. A *cycle* of length k, called a *k-cycle*, is a graph containing k distinct vertices, say $v_0, v_1, v_2, \ldots, v_{k-1}$, such that

$v_0v_1, v_1v_2, \ldots, v_{k-2}v_{k-1}, v_{k-1}v_0$ are all the nonloop edges of the graph, $k \geq 3$; we may write such a cycle as $v_0v_1v_2 \ldots v_{k-1}v_0$.

Let G be a graph. A vertex v of G is said to be an *isolated vertex* of G if v is not adjacent to any other vertex v' of G, $v \neq v'$ (note that an isolated vertex may have a loop). When a set S is an argument of a mapping f, we define $f(S) = \{f(s)|s \in S\}$. We use $|S|$ to denote the cardinality of a set S. The *distance* between a pair of vertices u and v in G, denoted by $d_G(u, v)$ or $d_G(v, u)$, is the length of a shortest path from u to v in G if u and v are connected in G; we define $d_G(u, v)$ (and $d_G(v, u)$) to be infinite if u and v are disconnected in G. The *diameter* of G is the maximum distance between any two vertices in G, i.e., $\max \{d_G(u, v)|u, v \in V(G)\}$, where $\max A$ gives the maximum element in a set A. The distance between two sets X and Y of vertices in G, denoted by $d_G(X, Y)$ or $d_G(Y, X)$, is the minimum distance between any vertex of X and any vertex of Y in G, i.e., $d_G(X, Y) = \min \{d_G(x, y)|x \in X, y \in Y\}$, where $\min A$ gives the minimum element in a set A. If a set has only one vertex, we may just write the vertex instead of the set. A graph H is a *subgraph* of G if $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. If H is a subgraph of G such that H contains all the edges of G that have both endpoints in $V(H)$ then H is called the subgraph of G *induced by* $V(H)$, and we say that H is an *induced subgraph* of G. Given an induced subgraph H of G, we denote by $G - H$, the subgraph obtained by deleting from G the vertices of H together with the edges incident with them; thus $G - H$ is a subgraph of G induced by $V(G) - V(H)$. A *chordal graph* is a graph which does not contain any induced cycle of length greater than three. A *chordal bipartite graph* is a bipartite graph which does not contain any induced cycle of length greater than four. In the following, let G and H be graphs.

A *homomorphism* $f : G \to H$, of G to H, is a mapping f of the vertices of G to the vertices of H, such that $f(g)$ and $f(g')$ are adjacent vertices of H whenever g and g' are adjacent vertices of G. If there exists a homomorphism of G to H then G is said to be *homomorphic* to H. Note that for any homomorphism $f : G \to H$, if a vertex v of G has a loop then the vertex $f(v)$ of H necessarily also has a loop. If G is irreflexive then clearly G is k-colorable if and only if G is homomorphic to K_k. Thus the concept of a homomorphism generalizes the concept of a k-colorability.

A *compaction* $c : G \to H$, of G to H, is a homomorphism of G to H, such that for every vertex x of H, there exists a vertex v of G with $c(v) = x$, and for every edge hh' of H, $h \neq h'$, there exists an edge gg' of G with $c(g) = h$ and $c(g') = h'$. Notice that the first part of the definition for compaction (the requirement for every vertex x of H) is relevant only if H has isolated vertices. If there exists a compaction of G to H then G is said to *compact* to H. Given a compaction $c : G \to H$, if for a vertex v of G, we have $c(v) = x$, where x is a vertex of H, then we say that the vertex v of G *covers the vertex* x of H under c; and if for an edge gg' of G, we have $c(\{g, g'\}) = \{h, h'\}$, where hh' is an edge of H, then we say that the edge gg' of G *covers the edge* hh' of H under c (note that in the definition of compaction, it is not necessary that a loop of H be covered by any edge of G under c).

We note that the notion of a *homomorphic image* used in [Harary, 1969] (also cf. [Hell and Miller, 1979]) coincides with the notion of a compaction in the case of irreflexive graphs (i.e., when G and H are irreflexive in the above definition for compaction).

A *retraction* $r : G \to H$, of G to H, with H as an induced subgraph of G, is a homomorphism of G to H, such that $r(h) = h$, for every vertex h of H. If there exists a retraction of G to H then G is said to *retract* to H. Note that every retraction $r : G \to H$ is necessarily also a compaction but not vice versa.

For each vertex v of G, let $L(v)$ be a list of vertices of H. We denote by L the entire set of lists $L(v)$ for the vertices v of G. A *list homomorphism* $l : G \to H$, of G to H, with respect to L is a homomorphism of G to H, such that $l(v) \in L(v)$, for every vertex v of G. If $l : G \to H$ is a list homomorphism with respect to L then we say that $l : G \to H$ is a list-L-homomorphism.

Let L be the set of lists as defined above. The *consistency test* for G with respect to H and L produces a set L^* of lists $L^*(v) \subseteq L(v)$, for all $v \in V(G)$, such that for every edge ab of G, if a vertex $h \in L^*(a)$ then there exists a vertex $h' \in L^*(b)$ such that hh' is an edge of H, and if a vertex $z \in L^*(b)$ then there exists a vertex $z' \in L^*(a)$ such that zz' is an edge of H; the set L^* is obtained in such a way that minimum number of vertices are removed from $L(v)$, for all $v \in V(G)$. Thus for an edge ab of G, if a vertex h in $L(a)$ has no neighbor h' in $L(b)$, with $hh' \in E(H)$, then the consistency test will delete h from $L(a)$, and similarly if a vertex z in $L(b)$ has no neighbor z' in $L(a)$, with $zz' \in E(H)$, then the consistency test will delete z from $L(b)$. Due to such deletions, the consistency test can propagate further such deletions from other lists with respect to other edges of G even if those edges have been considered before. The process of the consistency test stops after no further such deletions are possible, at which point we obtain L^*, which is the final modified set L of lists after all the deletions. Note that there exists a list-L-homomorphism of G to H if and only if there exists a list-L^*-homomorphism of G to H. The consistency test we have described is in essence the *arc consistency test* used in artificial intelligence [Mackworth, 1977]. It follows from the result of [Mackworth and Freuder, 1985] that if H is fixed then L^* can be obtained in time linear in the size of G. We say that the consistency test for G with respect to H and L *succeeds* if $L^*(v) \neq \phi$, for all $v \in V(G)$; otherwise we say that it does not succeed. We shall be using the consistency test in our proofs. The consistency test has been an important tool in artificial intelligence where it has been widely used for a long time, including in earlier studies on constraint satisfaction problems [Montanari, 1974]. The consistency test has been increasingly used in graph homomorphism problems over the last years including [Gutjahr, Welzl, and Woeginger, 1992], [Hell, Nesetril, and Zhu, 1996], [Vikas, 2002].

An *identification* of two distinct vertices u and v of G is an execution of the following steps (1), (2), and (3), resulting in a new graph: (1) For every nonloop edge uu' of G, if vu' is not an edge of G then we add the edge vu' to G (note that if uv is an edge of G then $u' = v$ and we will have the loop vv). (2) If u has a loop then v is also made to have a loop if it does not already have one. (3) Delete the vertex u together with the edges incident with u from G.

An *isomorphism* $f : G \to H$, of G to H, is a mapping f of the vertices of G to the vertices of H, such that f is one-to-one and onto, and $f(g)$ and $f(g')$ are adjacent vertices of H if and only if g and g' are adjacent vertices of G (we are not assuming more than one edge between endpoints in any graph). If there exists an isomorphism of G to H then G is said to be *isomorphic* to H. An *automorphism* of G is an isomorphism of G to itself.

We may call a polynomial transformation under Turing reduction, just a polynomial transformation, and a polynomial equivalence under Turing reduction, just a polynomial equivalence, but the context will be clear in the proofs where we explicitly mention Turing reduction if Turing reduction is used.

1.2. Homomorphism, compaction, retraction, and constraint satisfaction problems. The problem of deciding the existence of a homomorphism to a fixed graph H, called the *homomorphism problem for* H, also known as the *H-coloring*

problem, and denoted as *H-COL*, asks whether or not an input graph G is homomorphic to H. If a vertex h of a graph H has a loop then every graph G is trivially homomorphic to H, as we will have a homomorphism $f : G \to H$, with $f(v) = h$, for all $v \in V(G)$. Thus the problem *H-COL* is interesting only if H is irreflexive. Further, among irreflexive graphs H, if H is bipartite then the problem *H-COL* is again trivial, as explained below. Note that only a bipartite graph may be homomorphic to another bipartite graph. If H is a bipartite graph containing an edge, say hh', then clearly every bipartite graph G is homomorphic to H, as we will have a homomorphism $f : G \to H$, with $f(a) = h$ and $f(b) = h'$, for all $a \in G_A$, $b \in G_B$, where (G_A, G_B) is a bipartition of G. If H is a graph containing no edge then clearly only graphs with no edge will be homomorphic to H. Thus a graph G is homomorphic to a bipartite graph H if and only if G is also bipartite, and H has an edge if G has an edge. Thus the problem *H-COL* is interesting only if H is an irreflexive nonbipartite graph. It has been shown in [Hell and Nesetril, 1990] that *H-COL* is NP-complete for any fixed irreflexive nonbipartite graph H, thus providing a complete complexity classification of *H-COL*. Note that the classic k-colorability problem is a special case of the problem *H-COL* when H is K_k and the input graph G is irreflexive.

The problem of deciding the existence of a compaction to a fixed graph H, called the *compaction problem for H*, and denoted as *COMP-H*, asks whether or not an input graph G compacts to H.

When both G and H are input graphs (i.e., H is not fixed), and H is reflexive, the problem of deciding whether or not G compacts to H has been studied in [Karabeg and Karabeg, 1991, 1993]. Note that unlike the problem *H-COL*, the problem *COMP-H* is still interesting if H has a loop or H is bipartite.

The problem of deciding the existence of a retraction to a fixed graph H, called the *retraction problem for H*, and denoted as *RET-H*, asks whether or not an input graph G, containing H as an induced subgraph, retracts to H. Note that H is a particular copy in G. It is possible that G contains another induced subgraph H' that is isomorphic to H but distinct from H, and it may be the case that G retracts to H but not to H', and vice versa.

Retraction problems have been of continuing interest in graph theory for a long time and have been studied in various literature including [Hell, 1972, 1974], [Nowakowski and Rival, 1979], [Pesch and Poguntke, 1985], [Bandelt, Dahlmann, and Schutte, 1987], [Hell and Rival, 1987], [Pesch, 1988], [Feder and Winkler, 1988], [Bandelt, Farber, and Hell, 1993], [Feder and Hell, 1998], [Feder, Hell, and Huang, 1999].

Note that the graph H for the problems *H-COL*, *COMP-H*, and *RET-H* is assumed to be fixed by default even if not explicitly mentioned.

We now define the constraint satisfaction problem after introducing the following terms. The *domain* of a variable is a set of permissible values that the variable can assume. A *relation* R on k variables $x_1, x_2, \ldots, x_k$, denoted by $R(x_1, x_2, \ldots, x_k)$, imposes constraints on the values that the variables $x_1, x_2, \ldots, x_k$ can assume from their domains; R is a *relation name* of *arity* k, where we assume that k is fixed, $R(x_1, x_2, \ldots, x_k)$ is a *tuple* of R, and R can be defined on several tuples. A tuple $R(a_1, a_2, \ldots, a_k)$ is said to be fixed if a_i is fixed, for all $i = 1, 2, \ldots, k$. A relation R is said to be a *fixed relation* if all of its tuples are fixed.

Let T be a set of fixed relations, and suppose that the cardinality of T is fixed. We call T a *fixed template*. Let S be a finite set of relations such that every relation name in S is also in T with the same arity. Let V_S be the set of all variables in any tuple of S. For each variable x in V_S, let $D(x)$ be the domain of x. The domains of

the variables in V_S will be assumed to be associated with the set S, and we shall not mention it explicitly. The set S is said to be *satisfied* with respect to the template T if there exists a mapping f from S to T such that for every tuple $R(x_1, x_2, \ldots, x_{k_R})$ of every relation R, if $R(x_1, x_2, \ldots, x_{k_R})$ is in S then $f(R(x_1, x_2, \ldots, x_{k_R}))$ defined to be $R(f(x_1), f(x_2), \ldots, f(x_{k_R}))$ is in T, where k_R denotes the arity of R, $f(x_i) \in D(x_i)$ if x_i is a variable, and $f(x_i) = x_i$ if x_i is fixed, for all $i = 1, 2, \ldots, k_R$. The *constraint satisfaction problem with respect to* T, denoted as *CSP-T*, takes S as an instance and asks the question whether or not S is satisfied with respect to T.

The constraint satisfaction problem is known to be of great interest in artificial intelligence. Many problems can be viewed as constraint satisfaction problems. We give an example here to demonstrate how the H-coloring problem can be viewed as the constraint satisfaction problem. Let H be a fixed graph with vertices $h_1, h_2, \ldots, h_p$. Let a graph G with vertices $v_1, v_2, \ldots, v_n$ be an instance of *H-COL*. Define T to be a fixed template containing a single relation E such that $E(h_i, h_j)$ is a tuple in T if and only if $h_i h_j$ is an edge of H, for all $i, j = 1, 2, \ldots, p$. Define S to contain the relation E such that $E(v_i, v_j)$ is a tuple in S if and only if $v_i v_j$ is an edge of G, for all $i, j = 1, 2, \ldots, n$. Define the domain of v_i to be $V(H)$, i.e., $\{h_1, h_2, \ldots, h_p\}$, for all $i = 1, 2, \ldots, n$. Thus S is an instance of *CSP-T*. Clearly, there exists a homomorphism of G to H if and only if S is satisfied with respect to T.

The template T for the problem *CSP-T* is assumed to be fixed by default even if not explicitly mentioned. Clearly, for a given template T, the problem *CSP-T* is in NP. As mentioned earlier, the problem *H-COL* is known to be NP-complete for all irreflexive nonbipartite graphs H [Hell and Nesetril, 1990]. We gave above a polynomial transformation from *H-COL* to *CSP-T*, implying that *CSP-T* is NP-complete for certain T. It is easy to see that there are also templates T for which *CSP-T* is polynomial time solvable. It is thought to be likely difficult to determine whether for every template T, the problem *CSP-T* is polynomial time solvable or NP-complete. Issues related to the constraint satisfaction problem have also been considered in [Feder and Vardi, 1993, 1998]. A very close relationship between the constraint satisfaction problem and the retraction problem for bipartite graphs has also been shown in [Feder and Vardi, 1998]. We shall describe this result later.

1.3. Motivation and results. It is not difficult to show that for every fixed graph H, if *RET-H* is solvable in polynomial time then *COMP-H* is also solvable in polynomial time. Is the converse true? This was also asked, in the context of reflexive graphs, by Peter Winkler in 1988 (personal communication, cf. [Feder and Winkler, 1988]). Thus the question is whether *RET-H* and *COMP-H* are polynomially equivalent for every fixed graph H. The answer to this is not known even when H is reflexive or bipartite. In this paper, we show that for every fixed reflexive (bipartite) graph H, there exists a fixed reflexive (bipartite) graph H' such that *RET-H* and *COMP-H'* are polynomially equivalent.

Using our above result and results of [Feder and Hell, 1998] and [Feder and Vardi, 1998], we establish that for every fixed template T of a set of relations, there exists a fixed reflexive (bipartite) graph H such that the constraint satisfaction problem *CSP-T* and the compaction problem *COMP-H* are polynomially equivalent. Since it is thought to be likely difficult to determine whether for every fixed template T, the problem *CSP-T* is polynomial time solvable or NP-complete, we thus provide evidence that it is likely to be difficult to determine whether for every fixed reflexive (bipartite) graph H, the problem *COMP-H* is polynomial time solvable or NP-complete. Similar evidence has been shown for *RET-H* in [Feder and Hell, 1998] in the case of fixed

reflexive graphs H, and in [Feder and Vardi, 1998] in the case of fixed bipartite graphs H.

We however have results giving a complete complexity classification of *COMP-H* and *RET-H* when H has four or fewer vertices, i.e., for every graph H with at most four vertices (including when H is partially reflexive), we determine whether *COMP-H* is polynomial time solvable or NP-complete, and whether *RET-H* is polynomial time solvable or NP-complete. The complexity classification of *COMP-H* and *RET-H* do not differ for such graphs H.

We have more results showing that for several graphs H, the problems *RET-H* and *COMP-H* are polynomially equivalent. We mention below a few classes of such graphs. We do not know of any graph H for which the complexity classification of *RET-H* and *COMP-H* differ.

It is known that *RET-H* is NP-complete when H is a reflexive k-cycle, for all $k \geq 4$, cf. [Feder and Hell, 1998], G. MacGillivray, 1988 (personal communication), and for $k = 4$, also [Feder and Winkler, 1988]. It is shown in [Vikas, 1999, 2003] that *COMP-H* is NP-complete when H is a reflexive k-cycle, for all $k \geq 4$. In particular, for $k = 4$, this result in [Vikas, 1999, 2003] solves a widely publicized open problem posed by Peter Winkler in 1988. It is easy to see that when H is a reflexive 3-cycle, *RET-H*, and hence *COMP-H*, are both polynomial time solvable. In fact, when H is a reflexive chordal graph (which includes a reflexive 3-cycle), the problem *RET-H* is polynomial time solvable [Feder and Hell, 1998], and hence *COMP-H* is also polynomial time solvable.

It is also known that *RET-H* is NP-complete when H is an irreflexive even k-cycle, for all even $k \geq 6$, cf. [Feder, Hell, and Huang, 1999], G. MacGillivray, 1988 (personal communication). It is shown in [Vikas, 1999, 2004] that *COMP-H* is NP-complete when H is an irreflexive even k-cycle, for all even $k \geq 6$. This result in [Vikas, 1999, 2004] also solves a long-standing problem that has been of interest to various people including Pavol Hell and Jaroslav Nesetril (personal communications). It is easily seen that when H is an irreflexive 4-cycle, *RET-H*, and hence *COMP-H*, are both polynomial time solvable. In fact, when H is a chordal bipartite graph (which includes an irreflexive 4-cycle), the problem *RET-H* is polynomial time solvable [Bandelt, Dahlmann, and Schutte, 1987], and hence *COMP-H* is also polynomial time solvable.

The case of irreflexive odd cycles is a special case of a more general result whereby *RET-H* and *COMP-H* are polynomially equivalent for every nonbipartite irreflexive graph H. Note that a graph G is homomorphic to a graph H if and only if the disjoint union $G \cup H$ retracts/compacts to H. Thus we have a polynomial transformation from *H-COL* to *RET-H* and *COMP-H*. The problem *H-COL* is NP-complete for any nonbipartite irreflexive graph H [Hell and Nesetril, 1990]. It follows that *RET-H* and *COMP-H* are also NP-complete for any nonbipartite irreflexive graph H; in particular, if H is an irreflexive odd k-cycle then *RET-H* and *COMP-H* are NP-complete, for all odd $k \geq 3$. Thus we conclude that *RET-H* and *COMP-H* both are NP-complete when H is an irreflexive k-cycle, for all $k \geq 3$, $k \neq 4$.

In section 2, we give a polynomial transformation from *COMP-H* to *RET-H* under Turing reduction. We shall need to refer to this transformation later in our proofs. In section 3, we study the relationship between compaction and retraction problems for reflexive graphs, and then study its consequences in relation to the constraint satisfaction problem. In section 4, we study the relationship between compaction and retraction problems for bipartite graphs, and its consequences in relation to the constraint satisfaction problem.

2. A polynomial transformation from compaction to retraction. We prove the following theorem in this section.

THEOREM 2.1. *For every fixed graph H, the problem COMP-H is polynomially transformable to the problem RET-H under Turing reduction.*

Proof. Let H be a fixed graph, and let a graph G be an instance of *COMP-H*. For a graph Z, let $E^*(Z)$ denote the set of all nonloop edges of Z, and let $I(Z)$ denote the set of all isolated vertices in Z. We note from the definition of compaction that if $c : G \to H$ is a compaction then part of the requirement for c is that for all $x \in I(H)$, there exists $v \in V(G)$ with $c(v) = x$, and for all $hh' \in E^*(H)$, there exists $gg' \in E^*(G)$ with $c(g) = h$ and $c(g') = h'$. Thus, there exists a set of $|E^*(H)|$ nonloop edges of G which cover all the nonloop edges of H under c, and there exists a set of $|I(H)|$ vertices in G which cover all the isolated vertices in H under c. In other words, there exists a subgraph Q of G induced by $V(Q')$, where Q' is a subgraph (not necessarily an induced subgraph) of G with $|E^*(Q')| = |E^*(H)|$ and $|I(Q')| = |I(H)|$, such that $c : Q \to H$ is a compaction.

In general, there may exist several such above described induced subgraphs Q of G such that Q compacts to H, regardless of whether or not G compacts to H. Further, if Q compacts to H then there may exist several compactions f of Q to H. The pair (Q, f) will be used to denote such a subgraph Q of G with a compaction $f : Q \to H$. Note that for each such subgraph Q of G, there may be more than one but a fixed number of such pairs (since H is fixed). Also, note that for such a subgraph Q of G, we have $|V(Q)| \leq 2 * |E^*(H)| + |I(H)|$. Thus, since H is fixed, all such subgraphs Q of G, and all compactions f of Q to H, i.e., all the pairs (Q, f), can be found in time polynomial in the size of G.

Let β denote the number of different possible pairs (Q, f). Clearly, β is a polynomial in the size of G. Consider the ith pair (Q, f) (under an arbitrary ordering of the pairs), $1 \leq i \leq \beta$. We define $L_i(q) = \{f(q)\}$ (i.e., $L_i(q)$ is a singleton containing the vertex $f(q)$ of H), for all $q \in V(Q)$, and $L_i(u) = V(H)$, for all $u \in V(G) - V(Q)$. Thus we obtain the lists $L_i(v) \subseteq V(H)$, for all $v \in V(G)$, $i = 1, 2, \ldots, \beta$ in polynomial time. Clearly, G compacts to H if and only if there exists an i such that there is a list-L_i-homomorphism of G to H, $1 \leq i \leq \beta$.

We construct a graph G_i from G and L_i, for all $i = 1, 2, \ldots, \beta$, as follows. We identify every pair of distinct vertices u and w in G if $L_i(u)$ and $L_i(w)$ are singletons with $L_i(u) = L_i(w)$, and we call the resultant graph after identifications, the graph G_i, for all $i = 1, 2, \ldots, \beta$. Note that, as a result of the identifications, G_i has a copy of H as an induced subgraph, except that possibly some of the loops, that may be present on some of the vertices of H, may not be present in the copy of H in G_i, in which case we add the missing loops to obtain an exact copy of H in G_i, for all $i = 1, 2, \ldots, \beta$. Since β is a polynomial, we have only polynomially many graphs $G_1, G_2, \ldots, G_\beta$. Thus we obtain the graphs $G_1, G_2, \ldots, G_\beta$ in polynomial time. Clearly, G compacts to H if and only if there exists an i such that G_i retracts to H, $1 \leq i \leq \beta$. Thus we have a polynomial transformation from *COMP-H* to *RET-H* under Turing reduction. □

It follows from Theorem 2.1 that for a fixed graph H, if *RET-H* is solvable in polynomial time then *COMP-H* is also solvable in polynomial time. We shall also refer later the transformation from *COMP-H* to *RET-H* given in the proof of Theorem 2.1.

3. Relationship between compaction and retraction problems for reflexive graphs. In this section, we prove the following theorem showing a very close relationship between compaction and retraction problems for reflexive graphs, and

then study its consequences in relation to the constraint satisfaction problem.

THEOREM 3.1. *For every reflexive graph H, there exists a reflexive graph H' such that RET-H is polynomially equivalent to COMP-H'.*

Proof. Let H be a reflexive graph. We construct in a fixed time, a reflexive graph H' from H such that the following two statements (a) and (b) hold:

(a) *RET-H* polynomially transforms to *COMP-H'*.

(b) *COMP-H'* polynomially transforms to *RET-H*.

The theorem then follows from (a) and (b).

We assume that H is connected. Later, we will make remarks for the case when H may be disconnected.

Suppose first that the diameter of H is ≤ 1. Clearly then H is a complete graph. Let G be any graph containing H as an induced subgraph, i.e., let G be an instance of *RET-H*. Clearly, G always retracts and hence compacts to H. Let H' also be the graph H. Trivially, G retracts to H if and only if G compacts to H. Hence statement (a) is trivially true. We know from Theorem 2.1 in section 2 that *COMP-H* polynomially transforms to *RET-H* under Turing reduction. Hence statement (b) is true. Thus the theorem holds for reflexive graphs H of diameter ≤ 1.

Now suppose that the diameter of H is > 1. The construction of H' is as follows. Let x be any vertex of H such that there exists a vertex at distance > 1 from x in H. There exists such a vertex x in H, as the diameter of H is > 1. Let the maximum distance from x to a vertex of H be s (thus $s > 1$). Let $d_H(x, h) = s_h$, for all $h \in V(H)$. For each vertex h of H, we add to H a path $P_h = p_1^h p_2^h \dots p_{s-s_h+1}^h$ containing $s - s_h + 1$ new vertices with p_1^h adjacent to h. We also add the reflexive edge $p_i^h p_i^h$, for all $i = 1, 2, \dots, s - s_h + 1$, with $h \in V(H)$. The resultant graph is our H', which is reflexive. Clearly, H' is constructed in a fixed time, as H is fixed. We shall denote the vertex $p_{s-s_h+1}^h$ by t_h and call it the *tip* of the path P_h, with $h \in V(H)$. Note that, among the paths added to H, P_x is the longest path (of length s) added to H, and P_y is a shortest path (of length 0 containing only one vertex) added to H, where $y \in V(H)$ is a furthest vertex from x in H, i.e., $d_H(x, y) = s$. See Figure 3.1, where we show the path P_h for an arbitrary vertex h of H. Also shown in the figure are paths P_x and P_y, where y is a vertex of H with $d_H(x, y) = s$. The graph H is denoted as an ellipse in the figure. The loops

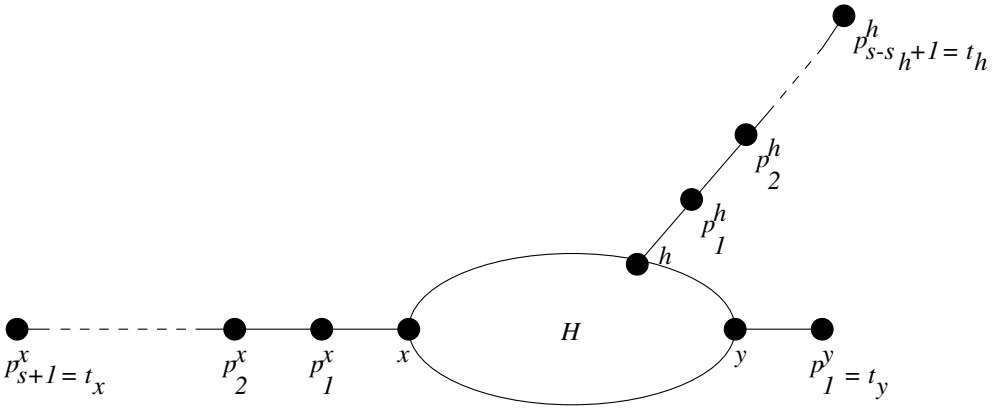

FIG. 3.1. *Construction of H'.*

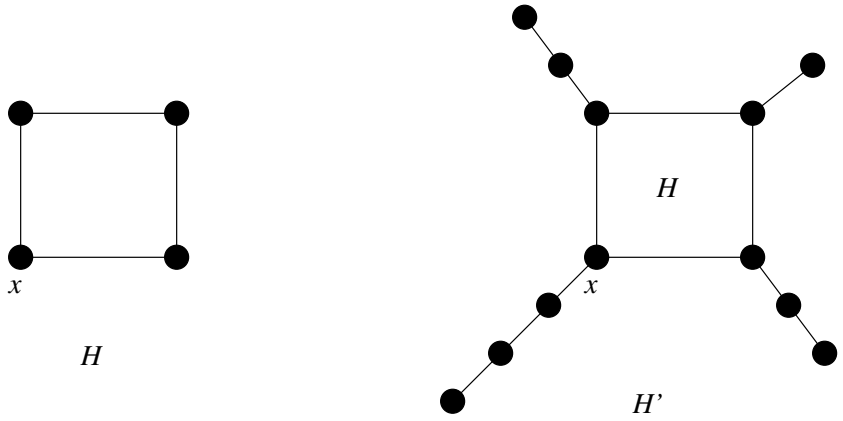

FIG. 3.2. *An example of H and H'.*

are not depicted in the figure but are assumed to be present on every vertex of H'. Clearly, H' retracts to H. See Figure 3.2 for an example of H and H'. Note that $d_{H'}(x,t_h) = d_{H'}(x,p^h_{s-s_h+1}) = d_{H'}(x,h)+d_{H'}(h,p^h_{s-s_h+1}) = s_h+(s-s_h+1) = s+1$, with $h \in V(H)$, and all other vertices are at distances less than $s+1$ from x in H'. Thus $d_{H'}(x,h) \leq s+1$, for all $h \in V(H')$, and the only vertices at distance $s+1$ from x in H' are the tip vertices t_h, for all $h \in V(H)$.

We prove the statements (a) and (b) in Theorem 3.1.1 and Theorem 3.1.2 respectively for the case when the diameter of H is > 1.

THEOREM 3.1.1. *RET-H polynomially transforms to COMP-H'.*

Proof. When the diameter of H is ≤ 1, we have already shown that the theorem is trivially proved. We assume here that the diameter of H is > 1. Let a graph G containing H as an induced subgraph be an instance of *RET-H*. We construct in time polynomial in the size of G, a graph G' (containing G and H' as induced subgraphs) such that the following statements (i) and (ii) are equivalent:

(i) G retracts to H.

(ii) G' compacts to H'.

This would imply that *RET-H* polynomially transforms to *COMP-H'*.

The construction of G' is as follows. We add to the subgraph H of G, the vertices of $V(H') - V(H)$ and the edges of $E(H') - E(H)$ such that H is expanded to the graph H' (the vertices of $H' - H$ are not adjacent to any vertex of $G - H$). For each vertex v of $G - H$, we add to G a path $U_v = u^v_1 u^v_2 \dots u^v_{s-1}$ containing $s-1$ new vertices, and we add the edges xu^v_1 and vu^v_{s-1}. This completes the construction of G'.

Note that $d_{G'}(x,v) \leq d_{G'}(x,u^v_1)+d_{G'}(u^v_1,u^v_{s-1})+d_{G'}(u^v_{s-1},v) = 1+(s-2)+1 = s$, for all $v \in V(G-H)$. Clearly then $d_{G'}(x,w) \leq s$, for all $v \in V(G') - V(H')$. Earlier we noted that $d_{H'}(x,h) \leq s+1$, for all $h \in V(H')$, and the only vertices at distance $s+1$ (calculated in H') from x in H' are the tip vertices t_h, for all $h \in V(H)$. Thus $d_{G'}(x,u) \leq s+1$, for all $u \in V(G')$, and the only vertices that are possibly at distance $s+1$ (calculated in G') from x in G' are the tip vertices t_h, for all $h \in V(H)$. We are saying $s+1$ to be an upper bound for $d_{G'}(x,t_h)$ also, as the presence of an edge from a vertex of $G-H$ to a vertex of H may result in a path of length shorter than $s+1$ from x to a tip vertex t_h in G', with $h \in V(H)$.

We now prove the equivalence of statements (i) and (ii), from which Theorem 3.1.1 follows.

First suppose that $r : G \to H$ is a retraction. We define below a retraction $r' : G' \to H'$, which by definition is also a compaction.

We define

$r'(v) = r(v)$, for all $v \in V(G)$,

$r'(h') = h'$, for all $h' \in V(H') - V(H)$.

We now fix a vertex $v \in V(G - H)$ for defining r' for the vertices of U_v. Let $P_{xv} = h_0 h_1 \dots h_j$ be a shortest path from $r(x)$ to $r(v)$ in H, with $r(x) = h_0$ and $r(v) = h_j$, $h_i \in V(H)$, for all $i = 0, 1, 2, \dots, j$. Clearly, the length of the path P_{xv} is $\leq s$, as $d_H(x, h) \leq s$, for all $h \in V(H)$. Thus $j \leq s$.

For the vertices of U_v, we define

$r'(u_i^v) = h_i$, for all $i = 1, 2, \dots, j-1$,

$r'(u_i^v) = h_{j-1}$, for all $i = j, j+1, \dots, s-1$.

It is easily verified that $r' : G' \to H'$ is a retraction, and hence a compaction.

Now suppose that $c : G' \to H'$ is a compaction. We shall prove that $c(h) \neq c(h')$, for all $h, h' \in V(H')$, $h \neq h'$. In order to prove this, we shall be proving a number of other claims. Note that this would imply that $c : H' \to H'$ is an automorphism. As we will see, we can easily define a retraction of G' to H' from this fact, and finally conclude that G retracts to H, proving the theorem.

We first show that $c(x) = x$. If $c(x) \neq x$ then either $c(x) \in V(P_x)$ or $c(x) \in V(H') - \{V(P_x) \cup \{x\}\}$. Since $s > 0$, there exists a vertex $h \in V(H)$, $h \neq x$. For every $p \in V(P_x)$, we have $d_{H'}(p, t_h) = d_{H'}(p, x) + d_{H'}(x, t_h) > d_{H'}(x, t_h) = s+1$. Since there is no vertex at distance greater than $s+1$ from x in G', this implies that $c(x) \neq p$, for all $p \in V(P_x)$, as otherwise no vertex of G' will map to t_h under c, contradicting that $c : G' \to H'$ is a compaction. Since $d_{H'}(z, t_x) = d_{H'}(z, x) + d_{H'}(x, t_x) > d_{H'}(x, t_x) = s + 1$, similarly we argue that $c(x) \neq z$, for all $z \in V(H') - \{V(P_x) \cup \{x\}\}$. Thus we have shown that $c(x) \notin V(P_x)$ and $c(x) \notin V(H') - \{V(P_x) \cup \{x\}\}$. Hence $c(x) = x$.

We next show that for each vertex t_h, with $h \in V(H)$, there exists an unique vertex t_{z_h}, with $z_h \in V(H)$, such that $c(t_{z_h}) = t_h$. That is, we show that the tips are mapped to tips under c, and exactly one tip maps to a tip under c. We have $d_{H'}(c(x) = x, t_h) = s+1$, for all $h \in V(H)$. Also, $d_{G'}(x, u) \leq s+1$, for all $u \in V(G')$, and the only vertices that can possibly be at distance $s+1$ from x in G' are t_h, for all $h \in V(H)$. This implies that for each vertex t_h, with $h \in V(H)$, there exists a unique vertex t_{z_h}, with $z_h \in V(H)$, such that $c(t_{z_h}) = t_h$. Thus every tip is mapped to a tip under c, and exactly one tip maps to a tip under c.

Now we show that $d_{H'}(x, h') = d_{H'}(c(x), c(h'))$, for all $h' \in V(H')$, and $d_{H'}(h, t_h) = d_{H'}(c(h), c(t_h))$, for all $h \in V(H)$. It follows from the above result that $d_{H'}(c(x), c(t_h)) = s+1$, for all $h \in V(H)$. It must be that $d_{H'}(c(h), c(h')) \leq d_{H'}(h, h')$, for all $h, h' \in V(H')$, as $c : G' \to H'$ is a homomorphism. Clearly, $d_{H'}(c(x), c(t_h)) \leq d_{H'}(c(x), c(h')) + d_{H'}(c(h'), c(t_h)) \leq d_{H'}(x, h') + d_{H'}(h', t_h) = d_{H'}(x, t_h) = s + 1$, for all $h' \in \{h\} \cup V(P_h)$, $h \in V(H)$. Thus if $d_{H'}(c(x), c(h')) < d_{H'}(x, h')$ or if $d_{H'}(c(h'), c(t_h)) < d_{H'}(h', t_h)$ then we will have that $d_{H'}(c(x), c(t_h)) < s + 1$, which would be a contradiction, with $h' \in \{h\} \cup V(P_h)$, $h \in V(H)$. Thus $d_{H'}(c(x), c(h')) = d_{H'}(x, h')$, and $d_{H'}(c(h'), c(t_h)) = d_{H'}(h', t_h)$, for all $h' \in \{h\} \cup V(P_h)$, $h \in V(H)$. This implies that $d_{H'}(x, h') = d_{H'}(c(x), c(h'))$, for all $h' \in V(H')$, and $d_{H'}(h, t_h) = d_{H'}(c(h), c(t_h))$, for all $h \in V(H)$.

We now prove a few claims below, concluding that we can choose the compaction $c : G' \to H'$ in such a way that $c(h) \in V(H)$, for all $h \in V(H)$.

We show that for each path P_h, with $h \in V(H)$, there exists at most one vertex $z \in V(H)$ such that $c(z) \in V(P_h)$, and if $c(z) \in V(P_h)$ then $c(t_z) = t_h$. Suppose that

there exist two distinct vertices $z, z' \in V(H)$ such that $c(z), c(z') \in V(P_h)$, for some $h \in V(H)$. We have $d_{H'}(c(x), p) + d_{H'}(p, t_y) = d_{H'}(c(x), h) + d_{H'}(h, p) + d_{H'}(p, h) + d_{H'}(h, t_y) > d_{H'}(c(x), h) + d_{H'}(h, t_y) \geq d_{H'}(c(x), t_y) = s + 1$, for all $p \in V(P_h)$, $y \in V(H)$, $y \neq h$. We have $d_{H'}(x, t_z) = d_{H'}(x, z) + d_{H'}(z, t_z) = s + 1$. Under the assumption that $c(z) \in V(P_h)$, this implies that $d_{H'}(x, z) + d_{H'}(z, t_z) < d_{H'}(c(x), c(z)) + d_{H'}(c(z), t_y)$, for all $y \in V(H)$, $y \neq h$. Since $d_{H'}(x, z) = d_{H'}(c(x), c(z))$ (as proved earlier), we have that $d_{H'}(z, t_z) < d_{H'}(c(z), t_y)$, implying that $c(t_z) \neq t_y$, for all $y \in V(H)$, $y \neq h$. Similarly, $c(t'_z) \neq t_y$, for all $y \in V(H)$, $y \neq h$. Since tips map only to tips under c, this would imply that $c(t_z) = c(t_{z'}) = t_h$, which is a contradiction, as we showed earlier that exactly one tip maps to a tip under c. Thus there cannot exist more than one vertex of H with image in $V(P_h)$ under c, and if there exists such a vertex z of H with $c(z) \in V(P_h)$ then $c(t_z) = t_h$.

We also show that $c(z) \notin V(P_h) - \{p_1^h\}$, for all $z, h \in V(H)$. Suppose that $c(z) \in V(P_h) - \{p_1^h\}$, for some $z, h \in V(H)$. Clearly, x is not adjacent to z in H, as $c(x) \in V(H)$ and $c(z)$ is not adjacent to $V(H)$ as $c(z) \neq p_1^h$. Since H is connected and x is not adjacent to z, there exists a path from x to z of length ≥ 2 in H, and hence there exists a neighbor z' of z in H, $z' \neq z$. Since z' is adjacent to z in H, and $c(z) \in V(P_h) - \{p_1^h\}$, this implies that $c(z') \in V(P_h)$. Thus we have two distinct vertices z and z' of H which have images in $V(P_h)$ under c. This is impossible, as shown above.

Further, we show that $c(z) \notin V(P_h)$ if z has a neighbor z' in H, $z \neq z'$, such that $d_{H'}(x, z') \geq d_{H'}(x, z)$, for all $z, h \in V(H)$. Suppose that $c(z) \in V(P_h)$, for some $z, h \in V(H)$, and z has such a neighbor z' in H. We proved earlier that $d_{H'}(x, h') = d_{H'}(c(x), c(h'))$, for all $h' \in V(H')$. Hence we have $d_{H'}(x, z) = d_{H'}(c(x), c(z))$ and $d_{H'}(x, z') = d_{H'}(c(x), c(z'))$. Since $d_{H'}(x, z') \geq d_{H'}(x, z)$, this implies that $d_{H'}(c(x), c(z')) \geq d_{H'}(c(x), c(z))$. Since z' is adjacent to z, either $c(z') = h$ or $c(z') \in V(P_h)$. We shall prove that $c(z') \neq h$. Suppose that $c(z') = h$. We have $d_{H'}(c(x), c(z')) = d_{H'}(x, h)$ and $d_{H'}(c(x), c(z)) = d_{H'}(x, c(z)) = d_{H'}(x, h) + d_{H'}(h, c(z))$. Thus $d_{H'}(c(x), c(z')) < d_{H'}(c(x), c(z))$, which is a contradiction. Thus $c(z') \neq h$, and hence $c(z') \in V(P_h)$. We then have two distinct vertices z and z' of H which have images in $V(P_h)$ under c. This is impossible, as shown earlier.

Thus if a vertex z of H has an image in a path P_h under c, with $h \in V(H)$, then $c(z) = p_1^h$ and $d_{H'}(x, z') < d_{H'}(x, z)$, for any neighbor z' of z in H. Suppose that $c(z) = p_1^h$, for some $z, h \in V(H)$. Let z' be any neighbor of z in H, $z' \neq z$ (since H is connected and clearly $z \neq x$, there exists such a neighbor). We proved earlier that there cannot exist more than one vertex of H with image in $V(P_h)$ under c. Since $c(z) = p_1^h \in V(P_h)$ and z' is a neighbor of z in H, this implies that $c(z') = h$. As proved earlier, since $c(z) \in V(P_h)$, we have $c(t_z) = t_h$. Also, as proved earlier, we have $d_{H'}(z, t_z) = d_{H'}(c(z) = p_1^h, c(t_z) = t_h)$, and hence $c(p_i^z) = p_{i+1}^h$, for all $i = 1, 2, \ldots, s - s_z + 1 = s - s_h$ (recall that $p_{s-s_z+1}^z = t_z$ and $p_{s-s_h+1}^h = t_h$). Further, since exactly one tip maps to a tip under c, this implies that $c(t_{z'}) = t_y$, for some $y \in V(H)$, $y \neq h$. Note, it must be that the length of the path P_y is smaller than the length of the path P_h (length of P_h = length of $P_{z'}$, as $d_{H'}(x, z') = d_{H'}(c(x) = x, c(z') = h)$), i.e., $d_{H'}(x, y) > d_{H'}(x, h) (= d_{H'}(x, z'))$, in order that $c(t_{z'}) = t_y$ (as some of the vertices of $P_{z'}$ are now mapped to H under c, as $d_{H'}(z', t_{z'}) = d_{H'}(c(z') = h, c(t_{z'}) = t_y)$; clearly at least $c(p_1^{z'}) \in V(H)$). We know that $d_{H'}(x, z') < d_{H'}(x, z)$, and hence $d_{H'}(x, z') = d_{H'}(x, z) - 1$. Thus the length of the path P_z is 1 less than the length of the path $P_{z'}$. Let $S = \{v | v \in V(G') - V(H') \text{ and } c(v) \in V(P_h)\}$. Note that apart from the vertices of $\{z\} \cup P_z$, only vertices in S may map to a vertex of P_h under c.

We can define a compaction $c' : G' \to H'$ such that $c'(z) \in V(H)$ by interchanging $c(t_z)$ and $c(t_{z'})$ as follows:

$c'(v) = c(v)$, for all $v \in V(G') - \{V(P_z) \cup V(P_{z'}) \cup \{z\} \cup S\}$,
$c'(v) = h$, for all $v \in S$,
$c'(p_i^{z'}) = p_i^h$, for all $i = 1, 2, \ldots, s - s_{z'} + 1 = s - s_h + 1$
(thus $c'(t_{z'}) = t_h = c(t_z)$ and $c(p_1^{z'}) = p_1^h = c(z)$),
$c'(z) = c(p_1^{z'})$ and $c'(p_i^z) = c(p_{i+1}^{z'})$, for all $i = 1, 2, \ldots, s - s_z + 1 = s - s_{z'}$
(thus $c'(z) \in V(H)$, as $c(p_1^{z'}) \in V(H)$, and $c'(t_z) = c(t_{z'})$).

It can be easily verified that $c' : G' \to H'$ is a compaction. We have $c'(z) \in V(H)$. We apply similar arguments for any path $P_{h'}$ of H', with $h' \in V(H)$, to which a vertex of H may map under c. This implies that there exists a compaction of G' to H' such that all the vertices of H have images in H under this compaction. We choose $c : G' \to H'$ to be such a compaction.

We now show that for any vertex z of H, if $c(z) = h$, for some vertex h of H (we assume $h \in V(H)$, as we proved that we choose c such that the vertices of H map to H under c), then $c(t_z) = t_h$.

Let $c(z_0) = h_0$, for some $z_0, h_0 \in V(H)$. Suppose that $c(t_{z_0}) \neq t_{h_0}$. Since tips map to tips under c, this implies that $c(t_{z_0}) = t_{h_1}$, for some vertex $h_1 \in V(H)$, $h_1 \neq h_0$. Note that the length of the path P_{h_1} is necessarily smaller than the length of the path P_{z_0}, as some of the vertices of P_{z_0} now map to H under c; clearly at least $c(p_1^{z_0}) \in V(H)$. From the construction of H', this implies that $d_{H'}(x, h_1) > d_{H'}(x, z_0)$. Since $d_{H'}(x, h) = d_{H'}(c(x), c(h))$, for all $h \in V(H')$, we have $d_{H'}(x, z_0) = d_{H'}(c(x) = x, c(z_0) = h_0)$. Thus $d_{H'}(x, h_1) > d_{H'}(x, h_0)$.

We show that there exists a vertex $z_1 \in Z = \{z | z \in V(H)$ and $d_{H'}(x, z) = d_{H'}(x, h_1)\}$ such that $c(t_{z_1}) \neq t_z$, for all $z \in Z$. Since $d_{H'}(x, h) = d_{H'}(c(x) = x, c(h))$ and $c(h) \in V(H)$, for all $h \in V(H)$, this implies that $c(z) \in Z$, for all $z \in Z$. First suppose that $c(y) = h_1$, for some vertex $y \in Z$ (trivially, $h_1 \in Z$). Then $c(t_y) \neq t_{h_1}$, as $c(t_{z_0}) = t_{h_1}$ and exactly one tip maps to a tip under c. Note that for any pair of vertices a and b in Z, the length of the path P_a is the same as the length of the path P_b. Hence $d_{H'}(y, t_y) = d_{H'}(z, t_z) < d_{H'}(h_1, z) + d_{H'}(z, t_z) = d_{H'}(c(y) = h_1, t_z)$, for all $z \in Z$, $z \neq h_1$. This implies that $c(t_y) \neq t_z$, for all $z \in Z$, $z \neq h_1$. Since $c(t_y) \neq t_{h_1}$, we have $c(t_y) \neq t_z$, for all $z \in Z$.

Now suppose that $c(z) \neq h_1$, for all $z \in Z$. Then clearly there exists a pair of distinct vertices y and y' in Z such that $c(y) = c(y') = u$, for some $u \in Z$. Since exactly one tip maps to a tip under c, we have $c(t_y) \neq t_u$ or $c(t_{y'}) \neq t_u$ (both may hold). Without loss of generality, suppose that $c(t_y) \neq t_u$. We have $d_{H'}(y, t_y) = d_{H'}(z, t_z) < d_{H'}(u, z) + d_{H'}(z, t_z) = d_{H'}(c(y) = u, t_z)$, for all $z \in Z$, $z \neq u$. This implies that $c(t_y) \neq t_z$, for all $z \in Z$, $z \neq u$. Since $c(t_y) \neq t_u$, we have $c(t_y) \neq t_z$, for all $z \in Z$. Earlier we showed above that if $c(y) = h_1$, for any vertex $y \in Z$, then $c(t_y) \neq t_z$, for all $z \in Z$. Thus we have proved that there exists a vertex $z_1 \in Z$ such that $c(t_{z_1}) \neq t_z$, for all $z \in Z$. Since tips map to tips under c, this implies that $c(t_{z_1}) = t_{h_2}$, for some vertex $h_2 \in V(H)$, $h_2 \notin Z$, such that the length of the path P_{h_2} is smaller than the length of the path P_{z_1} (as some of the vertices of P_{z_1} now map to H under c; clearly at least $c(p_1^{z_1}) \in V(H)$), i.e., $d_{H'}(x, h_2) > d_{H'}(x, z_1) = d_{H'}(x, h_1)$. For convenience, we call Z the set Z_1, and we define $Z_0 = \{z | z \in V(H)$ and $d_{H'}(x, z) = d_{H'}(x, h_0)\}$. Thus $z_0 \in Z_0$ and $z_1 \in Z_1$.

Earlier we showed that $c(t_{z_0}) = t_{h_1}$ and $d_{H'}(x, h_1) > d_{H'}(x, h_0)$, and now we have shown that $c(t_{z_1}) = t_{h_2}$ and $d_{H'}(x, h_2) > d_{H'}(x, h_1)$. We can continue this argument and show that there exists a vertex $h_{i+1} \in V(H)$ and a vertex $z_i \in Z_i = \{z | z \in V(H)$

and $d_{H'}(x,z) = d_{H'}(x,h_i)\}$ such that $c(t_{z_i}) = t_{h_{i+1}}$ and $d_{H'}(x,h_{i+1}) > d_{H'}(x,h_i)$, for all $i = 0,1,2,\ldots,p$, where $d_{H'}(x,h_{p+1}) > s$. This is a contradiction, as no vertex of H is at distance larger than s from x in H'. Thus our assumption that $c(t_{z_0}) \neq t_{h_0}$ is wrong. Thus for any vertex z of H, if $c(z) = h$, for some vertex h of H, then $c(t_z) = t_h$.

Now suppose that $c(y) = c(z) = h$, for some $y,z,h \in V(H)$, $y \neq z$. From the above result, this implies that $c(t_y) = c(t_z) = t_h$. This is a contradiction, as exactly one tip maps to a tip under c. Hence $c(y) \neq c(z)$, for all $y,z \in V(H)$, $y \neq z$. Let $c(z) = h$, for some $z,h \in V(H)$. Since $d_{H'}(x,z) = d_{H'}(c(x) = x, c(z) = h)$, it follows from our construction that the length of the path P_z is same as the length of the path P_h. Since, as shown above, $c(t_z) = t_h$, we have $c(p_i^z) = p_i^h$, for all $i = 1,2,\ldots,s - s_z + 1 = s - s_h + 1$ (recall that $p_{s-s_z+1}^z = t_z$ and $p_{s-s_h+1}^h = t_h$). This completes the proof that $c(h) \neq c(h')$, for all $h,h' \in V(H')$, $h \neq h'$.

Since $c(h) \neq c(h')$, for all $h,h' \in V(H')$, $h \neq h'$, this implies that $c : H' \to H'$ is an automorphism. Let $f : H' \to H'$ be the automorphism $c : H' \to H'$. We define a retraction $r : G' \to H'$ as follows:

$$r(a) = f^{-1}(c(a)), \text{ for all } a \in V(G').$$

Thus G' retracts to H'. Since H' retracts to H, it follows that G' retracts to H. Hence G retracts to H, as G is a subgraph of G'. We have thus proved that (i) is equivalent to (ii), and the theorem follows. □

THEOREM 3.1.2. *COMP-H′ polynomially transforms to RET-H.*

Proof. We have already shown that the theorem holds when the diameter of H is ≤ 1. We assume here that the diameter of H is > 1. Let a graph G be an instance of *COMP-H′*. We construct in time polynomial in the size of G, polynomial (in the size of G) number of graphs $G_1, G_2, \ldots, G_\beta$, each containing a copy of H' as an induced subgraph, and for each G_i, we construct in time polynomial (in the size of G_i and hence in the size of G), a graph G_i' also containing a copy of H' as an induced subgraph, $1 \leq i \leq \beta$, such that the following statements (i), (ii), (iii), and (iv) are equivalent for some value of i, $1 \leq i \leq \beta$:

(i) G compacts to H'.
(ii) G_i retracts to H'.
(iii) G_i' retracts to H'.
(iv) G_i' retracts to H.

We prove that (i) is equivalent to (ii), (ii) is equivalent to (iii), and (iii) is equivalent to (iv). Thus, in effect, we prove that (i) is equivalent to (iv), which shows that *COMP-H′* polynomially transforms to *RET-H* under Turing reduction.

The graphs $G_1, G_2, \ldots, G_\beta$ are constructed as in the proof of Theorem 2.1 in section 2 (where we replace H by H'). As discussed there, β is a polynomial in the size of G, and the graphs $G_1, G_2, \ldots, G_\beta$ are constructed in time polynomial in the size of G. The equivalence of (i) and (ii) follows from the proof of Theorem 2.1.

For constructing G_i', we go through a number of steps that follow. We define $LST_i(h) = \{h\}$, for all $h \in V(H')$, and $LST_i(v) = V(H')$, for all $v \in V(G_i) - V(H')$, where H' is the copy in G_i, for all $i = 1,2,\ldots,\beta$. We perform the consistency test for G_i with respect to H' and LST_i, and obtain $L_i(v) \subseteq LST_i(v) \subseteq V(H')$, for all $v \in V(G_i)$, after completing the consistency test (recall that the consistency test will run in time linear in the size of G_i), for all $i = 1,2,\ldots,\beta$. It is clear that every possible retraction $r_i : G_i \to H'$ is a list-L_i-homomorphism, and every possible list-L_i-homomorphism $l_i : G_i \to H'$ is a retraction, for all $i = 1,2,\ldots,\beta$. Thus G_i retracts to H' if and only if there exists a list-L_i-homomorphism of G_i to H', for all $i = 1,2,\ldots,\beta$.

Suppose that G_i retracts to H', i.e., there exists a list-L_i-homomorphism of G_i to H', for some value of i, $1 \leq i \leq \beta$ (hence $L_i(v) \neq \phi$, for all $v \in V(G_i)$, i.e., the consistency test we performed for G_i has succeeded). Let $r : G_i \rightarrow H'$ be a retraction (thus $r : G_i \rightarrow H'$ is a list-L_i-homomorphism). We define another retraction $r' : G_i \rightarrow H'$ below. First we partition the vertex set of G_i into two sets V_1 and V_2 as follows:

$V_1 = \{v \in V(G_i) | L_i(v) \subseteq \{h_v\} \cup V(P_{h_v}),$ for some vertex $h_v \in V(H)\}$,
$V_2 = V(G_i) - V_1$.

For $v \in V_1$, we let

$r'(v) = h,$ where h is the vertex in $L_i(v)$ closest to h_v, that is, $d_{H'}(h, h_v) < d_{H'}(h', h_v),$ for all $h' \in L_i(v), h' \neq h$.

For $v \in V_2$, we let

$r'(v) = h,$ if $r(v) \in \{h\} \cup V(P_h),$ with $h \in V(H)$.

This completes the definition of r'.

Since $L_i(h) = \{h\}$, for all $h \in V(H')$, we have $V(H') \subseteq V_1$ and it is clear from the definition of r' that $r'(h) = h$, for all $h \in V(H')$. We now verify that $r' : G_i \rightarrow H'$ is indeed a homomorphism (and hence a retraction). We shall do this by considering all the edges ab of G_i and proving that $r'(a)r'(b)$ is an edge of H'.

Consider first an edge ab of G_i, with $a, b \in V_1$. From the definition of V_1, $L_i(a) \subseteq \{h_a\} \cup V(P_{h_a})$ and $L_i(b) \subseteq \{h_b\} \cup V(P_{h_b})$ (h_a may be the same as h_b), for some $h_a, h_b \in V(H)$. Let the vertex in $L_i(a)$ closest to h_a be h'_a, and the vertex in $L_i(b)$ closest to h_b be h'_b, i.e., $r'(a) = h'_a$ and $r'(b) = h'_b$. If $h_a \neq h_b$ then clearly $L_i(a) = \{h_a\}$ and $L_i(b) = \{h_b\}$, and h_a is adjacent to h_b in H, as L_i is nonempty and these are the only vertices the consistency test will keep. Thus if $h_a \neq h_b$ then $r'(a)r'(b) = h'_a h'_b = h_a h_b$ is an edge of H'. Now suppose that $h_a = h_b$. If $d_{H'}(h'_a, h_a) = d_{H'}(h'_b, h_a)$ then clearly $h'_a = h'_b$ and $r'(a)r'(b) = h'_a h'_b = h'_a h'_a$ is an edge of H'. Now assume that $d_{H'}(h'_a, h_a) < d_{H'}(h'_b, h_a)$. If h'_a is not adjacent to h'_b in H' then this implies that h'_b is not the closest vertex to h_a in $L_i(b)$, as otherwise the consistency test would have deleted h'_a from $L_i(a)$. Thus h'_a is adjacent to h'_b in H'. Similarly, we argue that if $d_{H'}(h'_a, h_a) > d_{H'}(h'_b, h_a)$ and h'_a is not adjacent to h'_b in H' then h'_a is not the closest vertex to h_a in $L_i(a)$, and hence h'_a is adjacent to h'_b in H'. Thus $r'(a)r'(b) = h'_a h'_b$ is always an edge of H'.

Next consider an edge ab of G_i, with $a, b \in V_2$. Let $r(a) \in \{h\} \cup V(P_h)$, for some $h \in V(H)$. Since $r(a)r(b)$ is an edge of H', this implies that $r(b) \in \{h\} \cup V(P_h)$ or $r(b) = h'$, for some h' adjacent to h, $h' \in V(H)$, $h' \neq h$. Hence, from the definition of r', we have $r'(a)r'(b) = hh$ or hh'. Thus $r'(a)r'(b)$ is always an edge of H' (and of H).

Now consider an edge ab of G_i, with $a \in V_1$ and $b \in V_2$. From the definition of V_2, $L_i(b) \not\subseteq \{h\} \cup V(P_h)$, for all $h \in V(H)$. Hence there exist two vertices h_1 and h_2 in $L_i(b)$, with $h_1 \in \{h\} \cup V(P_h)$ and $h_2 \in \{h'\} \cup V(P_{h'})$, for some $h, h' \in V(H)$, $h \neq h'$ (thus $h_1 \neq h_2$). From the definition of V_1, $L_i(a) \subseteq \{h_a\} \cup V(P_{h_a})$, for some vertex $h_a \in V(H)$. Since the consistency test we performed for G_i has succeeded, if $h_j \notin \{h_a\} \cup V(P_{h_a})$ then $h_j \in V(H) - \{h_a\}$ and is adjacent to h_a, and $h_a \in L_i(a)$, $j = 1, 2$. We know that at least one of $h_1, h_2 \notin \{h_a\} \cup V(P_{h_a})$, as at least one of h, h' is different from h_a. It follows that $h_a \in L_i(a)$, and from the definition of r', we have $r'(a) = h_a$. Now first suppose that $r(b) \notin \{h_a\} \cup V(P_{h_a})$. This implies that $r(a) = h_a$ and $r(b) = h_b$, for some vertex $h_b \in V(H)$ adjacent to h_a in H', $h_b \neq h_a$ (since $r(a) \in L_i(a) \subseteq \{h_a\} \cup V(P_{h_a})$ and $r : G_i \rightarrow H'$ is a homomorphism). Thus, from the definition of r', we have $r'(b) = h_b$. Hence $r'(a)r'(b) = h_a h_b$ is an edge of

H'. Now suppose that $r(b) \in \{h_a\} \cup V(P_{h_a})$. Then from the definition of r', we have $r'(b) = h_a$, and hence $r'(a)r'(b) = h_a h_a$ is an edge of H'.

Thus we have proved that $r' : G_i \to H'$ is a homomorphism, and hence a retraction. We now define a new set of lists L'_i as follows:

$L'_i(v) = \{r'(v)\}$, for all $v \in V_1$,

$L'_i(v) = L_i(v)$, for all $v \in V_2$.

Thus $L'_i(v) \subseteq L_i(v)$, for all $v \in V(G_i)$. Since every retraction of G_i to H' is a list-L_i-homomorphism of G_i to H', it follows that $r' : G_i \to H'$ is a list-L_i-homomorphism and a list-L'_i-homomorphism. Thus for every retraction $r : G_i \to H'$, there exists a list-L'_i-homomorphism $r' : G_i \to H'$. Clearly, every list-L'_i-homomorphism $l'_i : G_i \to H'$ is a retraction. Hence G_i retracts to H' if and only if there exists a list-L'_i-homomorphism of G_i to H'.

We now identify every pair of vertices v and v' in G_i for which $L'_i(v) = L'_i(v')$, $v, v' \in V_1$ (we know that $L'_i(a)$ is a singleton, for all $a \in V_1$), and call the resultant graph G'_i. Recall that for every vertex $h \in V(H')$, we have $L_i(h) = \{h\}$, and hence $h \in V_1$, and thus $L'_i(h) = \{r'(h) = h\}$. Clearly, G'_i retracts to H' if and only if there exists a list-L'_i-homomorphism of G_i to H'. Hence G_i retracts to H' if and only if G'_i retracts to H'. Thus we have proved that (ii) is equivalent to (iii). Note that we could have very well chosen $L'_i(v) = L_i(v) \cap V(H)$, for all $v \in V_2$, and all the above discussions would still hold, as $r'(v) \in V(H)$, for all $v \in V_2$.

We look at the structure of G'_i. Only vertices in V_1 have been identified with vertices in H'. For corresponding vertices of G_i and G'_i, we call them the same name. Thus $V(G'_i) = V(H') \cup V_2$. Note that no vertex v of $V(G'_i) - V(H') = V_2$ is adjacent to any vertex of P_h in G'_i, for all $h \in V(H)$. To see this, we recall our earlier explanation that if a vertex v of V_2 is adjacent to a vertex v' of V_1 in G_i then $h_{v'} \in L_i(v') \subseteq \{h_{v'}\} \cup V(P_{h_{v'}})$, with $h_{v'} \in V(H)$ (due to success of the consistency test). Hence $L'_i(v') = \{r'(v')\} = \{h_{v'}\}$, and in constructing G'_i, v' is identified with $h_{v'}$ which belongs to $V(H)$. Hence no vertex v of $V(G'_i) - V(H') = V_2$ can possibly be adjacent to any vertex of P_h in G'_i, for all $h \in V(H)$. Since G'_i contains H' as an induced subgraph and no vertex of $V(G'_i) - V(H')$ is adjacent to any vertex of P_h, for all $h \in V(H)$, it follows that G'_i retracts to H' if and only if G'_i retracts to H. Thus we have proved that (iii) is equivalent to (iv).

Thus we have shown that G compacts to H' if and only if G'_i retracts to H for some value of i, $1 \leq i \leq \beta$, which shows that *COMP-H'* polynomially transforms to *RET-H* under Turing reduction. □

We have thus proved Theorem 3.1 when H is connected. Now suppose that H may be disconnected. Let $H_1, H_2, \ldots, H_p$ be the components of H, $p \geq 1$. For each component H_i, we construct a graph H'_i analogous to the construction described earlier for the connected case depending on whether the diameter of H_i is ≤ 1 or > 1, $1 \leq i \leq p$. For a graph H_i with diameter > 1, we may assume x_i and s_i to play the role of x and s respectively described earlier for the connected case, $1 \leq i \leq p$. For a graph H_i with diameter ≤ 1, we let x_i be any vertex of H_i, and s_i (≤ 1) is defined similarly, $1 \leq i \leq p$. Our graph H' is the set of components $H'_1, H'_2, \ldots, H'_p$. We have to prove statements (a) and (b) mentioned at the beginning of the proof of Theorem 3.1.

For proving statement (a), we need to consider the construction of the graph G' in the proof of Theorem 3.1.1. Let $G_1, G_2, \ldots, G_t$ be the components of a graph G, with H_i as an induced subgraph of G_i, for all $i = 1, 2, \ldots, p$. Thus G is an instance of *RET-H*. If the diameter of H_i is > 1, the construction of G'_i is analogous to the

construction described in the proof of Theorem 3.1.1, $1 \leq i \leq p$. If the diameter of H_i is ≤ 1 then G'_i is obtained simply by adding an edge $x_i v$ in G_i, for each vertex v of $G_i - H_i$; thus the diameter of G'_i is ≤ 2, $1 \leq i \leq p$. When constructing G'_1, we also add an edge $x_1 v$ in G_1, for each vertex v of $G_{p+1}, G_{p+2}, \ldots, G_t$. Note that the diameter of G'_1 is still ≤ 2 if the diameter of H_1 is ≤ 1. Our graph G' is the set of components $G'_1, G'_2, \ldots, G'_p$.

If G retracts to H then it can be seen that G' retracts to H', and hence G' compacts to H'. Now suppose that G' compacts to H', and let $c : G' \to H'$ be a compaction. No two components of G' compact to the same component of H' under c, as the number of components in G' and H' is the same. Without loss of generality, suppose that the diameter of H_i is > 1, for all $i = 1, 2, \ldots, j$, and is ≤ 1, for all $i = j+1, j+2, \ldots, p$, $0 \leq j \leq p$. Since the diameter of H'_i is ≥ 3, for all $i = 1, 2, \ldots, j$, and the diameter of G'_k is ≤ 2, for all $k = j+1, j+2, \ldots, p$, no component among $G'_{j+1}, G'_{j+2}, \ldots, G'_p$ compacts to any component among $H'_1, H'_2, \ldots, H'_j$. Thus only the components among $G'_1, G'_2, \ldots, G'_j$ compact to the components among $H'_1, H'_2, \ldots, H'_j$. We know that H'_i is an induced subgraph of G'_i, for all $i = 1, 2, \ldots, j$. We note from our constructions that if G'_i compacts to H'_m under c then H'_m must be isomorphic to H'_i, as otherwise we will have a tip of some component H'_n not covered under c, $1 \leq i \leq j$, $1 \leq m \leq j$, $1 \leq n \leq j$. Thus we conclude that G'_i compacts to H'_i, for all $i = 1, 2, \ldots, j$. Since H_i is connected, we prove as in the proof of Theorem 3.1.1 that G_i retracts to H_i, for all $i = 1, 2, \ldots, j$. Clearly, G'_k and G_k retract and hence compact to H'_k, as H'_k, which is the same graph as H_k, is a complete graph, for all $k = j+1, j+2, \ldots, p$. Also, $G_{p+1}, G_{p+2}, \ldots, G_t$ is homomorphic to H, as H is reflexive. Thus we have that G retracts to H. Hence statement (a) follows.

For proving statement (b), we just need to assume in the proof of Theorem 3.1.2 that if the diameter of H_i is ≤ 1 then $V(P_h) = \phi$, for all $h \in V(H_i)$, $1 \leq i \leq p$. □

3.1. Compaction to reflexive graphs in relation to constraint satisfaction. It is shown in [Feder and Vardi, 1998] that for every fixed template T of a set of relations, there exists a bipartite graph H such that the constraint satisfaction problem *CSP-T* is polynomially equivalent to the retraction problem *RET-H*. Since it is thought to be likely difficult to determine whether for every template T, the problem *CSP-T* is polynomial time solvable or NP-complete, it follows that it is equally difficult to determine whether for every bipartite graph H, the problem *RET-H* is polynomial time solvable or NP-complete.

It has been shown in [Feder and Hell, 1998] that for every bipartite graph H, there exists a reflexive graph H' such that *RET-H* is polynomially equivalent to *RET-H'*. It follows from this result of [Feder and Hell, 1998] and the above result of [Feder and Vardi, 1998] that for every template T of a set of relations, there exists a reflexive graph H such that the constraint satisfaction problem *CSP-T* is polynomially equivalent to the retraction problem *RET-H*. This is taken as evidence in [Feder and Hell, 1998] that determining whether for every reflexive graph H, the problem *RET-H* is polynomial time solvable or NP-complete is likely to be difficult also.

We have shown in Theorem 3.1 that for every reflexive graph H, there exists a reflexive graph H' such that *RET-H* is polynomially equivalent to *COMP-H'*. Thus we have the following theorem which follows from Theorem 3.1 and the above mentioned results of [Feder and Vardi, 1998] and [Feder and Hell, 1998].

THEOREM 3.2. *For every fixed template T of a set of relations, there exists a fixed reflexive graph H such that the constraint satisfaction problem CSP-T is polynomially equivalent to the compaction problem COMP-H.* □

Thus we have evidence, due to Theorem 3.2, that it is likely to be difficult to determine whether for every reflexive graph H, the problem *COMP-H* is polynomial time solvable or NP-complete.

4. Relationship between compaction and retraction problems for bipartite graphs. In this section, we prove the following theorem showing a very close relationship between compaction and retraction problems for bipartite graphs, and then study its consequences in relation to the constraint satisfaction problem.

THEOREM 4.1. *For every bipartite graph H, there exists a bipartite graph H' such that RET-H is polynomially equivalent to COMP-H′.*

Proof. The proof is very similar to the proof of Theorem 3.1 for reflexive graphs. Here we will only highlight the differences in the proofs.

Let H be a bipartite graph. We construct in a fixed time, a bipartite graph H' from H such that the following two statements (a) and (b) hold:

(a) *RET-H* polynomially transforms to *COMP-H′*.

(b) *COMP-H′* polynomially transforms to *RET-H*.

The theorem then follows from (a) and (b).

We assume that H is connected. Later, we will make remarks for the case when H may be disconnected.

We had shown how Theorem 3.1 for reflexive H was trivially proved when the diameter of H was ≤ 1, in which case H was a complete graph. Note that for bipartite H, if the diameter of H is ≤ 2 then H is a complete bipartite graph. Also recall that for bipartite H, a graph G is homomorphic to H if and only if G is also bipartite, and H has an edge if G has an edge (if the diameter of H is 0 then H has no edge and contains a single isolated vertex). Similar to the proof for Theorem 3.1, together with the above observation, we see that this theorem holds if the diameter of H is ≤ 2.

Now suppose that the diameter of H is > 2. Let x be any vertex of H such that there exists a vertex at distance > 2 from x in H. There exists such a vertex x in H, as the diameter of H is > 2. The construction of H' is exactly like in the proof of Theorem 3.1 except that now we choose the vertex x as defined above, and there is no loop present in H'. Thus H' is bipartite. Recall that in the construction of H', we are assuming that the maximum distance from x to a vertex of H is s. Thus $s > 2$ here.

In analogy to the reflexive case, we prove the statements (a) and (b) in Theorem 4.1.1 and Theorem 4.1.2 respectively for the case when the diameter of H is > 2.

THEOREM 4.1.1. *RET-H polynomially transforms to COMP-H′.*

Proof. As shown earlier, the theorem is trivially proved when the diameter of H is ≤ 2. We assume here that the diameter of H is > 2. Let a graph G containing H as an induced subgraph be an instance of *RET-H*. Since H is bipartite, only bipartite graphs may be homomorphic to H. Thus for nonbipartite instances of *RET-H*, the theorem is trivially true. Suppose that G is bipartite. We construct in time polynomial in the size of G, a graph G' (containing G and H' as induced subgraphs) such that the following statements (i) and (ii) are equivalent:

(i) G retracts to H.

(ii) G' compacts to H'.

This would imply that *RET-H* polynomially transforms to *COMP-H′*.

Let (G_A, G_B) be a bipartition of G, and (H_A, H_B) be a bipartition of H, with $H_A \subseteq G_A$ and $H_B \subseteq G_B$. Without loss of generality, suppose that $x \in H_A$. The construction of G' is as follows. We add to the subgraph H of G, the vertices of $V(H') - V(H)$ and the edges of $E(H') - E(H)$ such that H is expanded to the graph

H' (the vertices of $H' - H$ are not adjacent to any vertex of $G - H$). Depending on whether s is odd or even, we add paths and edges as described below.

We first assume that s is odd. For each $a \in G_A - H_A$, we add to G a path $U_a = u_1^a u_2^a \dots u_{s-2}^a$ containing $s-2$ new vertices, and we add the edges xu_1^a and au_{s-2}^a (thus we have the path $xU_a a$ of even length $s-1$, and hence $d_{G'}(x,a) \leq s-1$). For each $b \in G_B - H_B$, we add to G a path $U_b = u_1^b u_2^b \dots u_{s-1}^b$ containing $s-1$ new vertices, and we add the edges xu_1^b and bu_{s-1}^b (thus we have the path $xU_b b$ of odd length s, and hence $d_{G'}(x,b) \leq s$).

Now, we assume that s is even. For each $a \in G_A - H_A$, we add to G a path $U_a = u_1^a u_2^a \dots u_{s-1}^a$ containing $s-1$ new vertices, and we add the edges xu_1^a and au_{s-1}^a (thus we have the path $xU_a a$ of even length s, and hence $d_{G'}(x,a) \leq s$). For each $b \in G_B - H_B$, we add to G a path $U_b = u_1^b u_2^b \dots u_{s-2}^b$ containing $s-2$ new vertices, and we add the edges xu_1^b and bu_{s-2}^b (thus we have the path $xU_b b$ of odd length $s-1$, and hence $d_{G'}(x,b) \leq s-1$).

This completes the construction of G'. We thus have $d_{G'}(x,v) \leq s$, for all $v \in V(G-H)$. Now we return to our claim for the equivalence of statements (i) and (ii).

First suppose that $r : G \to H$ is a retraction. We define below a retraction $r' : G' \to H'$, which by definition is also a compaction.

We define

$r'(v) = r(v)$, for all $v \in V(G)$,

$r'(h') = h'$, for all $h' \in V(H') - V(H)$.

We now fix a vertex $v \in V(G-H)$ for defining r' for the vertices of U_v. Let $P_{xv} = h_0 h_1 \dots h_j$ be a shortest path from $r(x)$ to $r(v)$ in H, with $r(x) = h_0$ and $r(v) = h_j$, $h_i \in V(H)$, for all $i = 0, 1, 2, \dots, j$. Note that if $v \in G_A - H_A$ then j is even, as $x, v \in G_A$, and further, $j \leq s-1$ when s is odd, and $j \leq s$ when s is even, as $d_{G'}(x,a) \leq s-1$ when s is odd, and $d_{G'}(x,a) \leq s$ when s is even, for all $a \in G_A - H_A$, and we define $p = s-2$ when s is odd, and $p = s-1$ when s is even. If $v \in G_B - H_B$ then j is odd, as $x \in G_A$, $v \in G_B$, and further, $j \leq s$ when s is odd, and $j \leq s-1$ when s is even, as $d_{G'}(x,b) \leq s$ when s is odd, and $d_{G'}(x,b) \leq s-1$ when s is even, for all $b \in G_B - H_B$, and we define $p = s-1$ when s is odd, and $p = s-2$ when s is even.

For the vertices of U_v, we define

$r'(u_i^v) = h_i$, for all $i = 1, 2, \dots, j-1$,

$r'(u_i^v) = h_j$, and $r'(u_{i+1}^v) = h_{j-1}$, for all $i = j, j+1, \dots, p-1$.

It is easily verified that $r' : G' \to H'$ is a retraction, and hence a compaction.

Conversely, if G' compacts to H' then the proof that G retracts to H is exactly as in the proof of Theorem 3.1.1 for the reflexive case, except when we define c' for the vertices in S, which we now define as follows:

$c'(v) = h$, if $d_{G'}(z,v)$ is odd, $v \in S$,

$c'(v) = h'$, $h' \in V(H')$ is any neighbor of h, if $d_{G'}(z,v)$ is even, $v \in S$. □

THEOREM 4.1.2. *COMP-H′ polynomially transforms to RET-H.*

Proof. As shown earlier, the theorem holds when the diameter of H is ≤ 2. We assume here that the diameter of H is > 2. Let a graph G be an instance of *COMP-H′*. Since H' is bipartite, only bipartite graphs may be homomorphic to H'. Thus for nonbipartite instances of *COMP-H′*, the theorem is trivially true. Suppose that G is bipartite. We construct in time polynomial in the size of G, polynomial (in the size of G) number of graphs $G_1, G_2, \dots, G_\beta$, each containing a copy of H' as an induced subgraph, and for each G_i, we construct in time polynomial (in the size of G_i and hence in the size of G), a graph G_i' also containing a copy of H' as an induced

subgraph, $1 \leq i \leq \beta$, such that the following statements (i), (ii), (iii), and (iv) are equivalent for some value of i, $1 \leq i \leq \beta$:

(i) G compacts to H'.
(ii) G_i retracts to H'.
(iii) G'_i retracts to H'.
(iv) G'_i retracts to H.

We prove that (i) is equivalent to (ii), (ii) is equivalent to (iii), and (iii) is equivalent to (iv). Thus, in effect, we prove that (i) is equivalent to (iv), which shows that *COMP-H′* polynomially transforms to *RET-H* under Turing reduction.

The graphs G_i and G'_i, for all $i = 1, 2, \ldots, \beta$, are constructed exactly the same way as in the proof of Theorem 3.1.2 for the reflexive case. The proof for the equivalence of the statements (i), (ii), (iii), and (iv) is exactly as in the proof of Theorem 3.1.2, except as noted below for defining the retraction $r' : G_i \rightarrow H'$ and corresponding changes for verifying that it is indeed a retraction.

The lists $L_i(v) \subseteq V(H')$, for all $v \in V(G_i)$, are obtained as in the proof of Theorem 3.1.2, as a result of performing the consistency test for G_i with respect to H' and the lists $LST_i(h) = \{h\}$, for all $h \in V(H')$, and $LST_i(v) = V(H')$, for all $v \in V(G_i) - V(H')$, where H' is the copy in G_i, for all $i = 1, 2, \ldots, \beta$.

Suppose that G_i retracts to H', for some value of i, $1 \leq i \leq \beta$. This implies that the consistency test we performed for G_i has succeeded, i.e., $L_i(v) \neq \phi$, for all $v \in V(G_i)$. Let $r : G_i \rightarrow H'$ be a retraction (clearly, $r : G_i \rightarrow H'$ is a list-L_i-homomorphism). We now define another retraction $r' : G_i \rightarrow H'$ as follows. We partition the vertex set of G_i into two sets V_1 and V_2 just as for the reflexive case. Recall that

$V_1 = \{v \in V(G_i) | L_i(v) \subseteq \{h_v\} \cup V(P_{h_v})$, for some vertex $h_v \in V(H)\}$,
$V_2 = V(G_i) - V_1$.

For $v \in V_1$, we let

$r'(v) = h$, where h is the vertex in $L_i(v)$ closest to h_v, that is, $d_{H'}(h, h_v) < d_{H'}(h', h_v)$, for all $h' \in L_i(v), h' \neq h$.

For $v \in V_2$, we let

$r'(v) = h$, if $r(v) \in \{h\} \cup V(P_h)$, and $d_{H'}(r(v), h)$ is even, with $h \in V(H)$,
$r'(v) = h'$, if $r(v) \in \{h\} \cup V(P_h)$, and $d_{H'}(r(v), h)$ is odd, with $h \in V(H)$, and $h' \in V(H)$ is any neighbor of h in H (every vertex in H has a neighbor, as H does not have an isolated vertex).

This completes the definition of r'.

Now we see the changes for verifying that $r' : G_i \rightarrow H'$ is a retraction. We only highlight the differences for the verification as compared to the reflexive case in the proof of Theorem 3.1.2.

While considering the edge ab of G_i, with $a, b \in V_1$, we do not need to consider the case that $d_{H'}(h'_a, h_a) = d_{H'}(h'_b, h_a)$, as this will not happen for bipartite H'. All other arguments for the edge hold as for the reflexive case.

While considering the edge ab of G_i, with $a, b \in V_2$, if $r(a) \in \{h\} \cup V(P_h)$, with $h \in V(H)$, then from the definition of r', we will have $r'(a) = h$ and $r'(b) = h'$, or we will have $r'(a) = h'$ and $r'(b) = h$, where $h' \in V(H)$ is any neighbor of h in H, implying that $r'(a)r'(b)$ is always an edge of H'. All other arguments for the edge hold as for the reflexive case.

While considering the edge ab of G_i, with $a \in V_1$ and $b \in V_2$, if $r(b) \in \{h_a\} \cup V(P_{h_a})$, with $h_a \in V(H)$, then $d_{H'}(r(b), h_a)$ must be odd, as otherwise $h_a \notin L_i(a)$ (due to success of the consistency test), and hence from the definition of r', we will have that $r'(a)r'(b) = h_a h'_a$ is an edge of H', where $h'_a \in V(H)$ is any neighbor of h_a

in H. All other arguments for the edge hold as for the reflexive case. □

We have now proved Theorem 4.1 when H is connected. Suppose now that H may be disconnected. Let $H_1, H_2, \ldots, H_p$, $p \geq 1$, be the components of H. For each component H_i, we construct a graph H_i' analogous to the construction described earlier for the connected case depending on whether the diameter of H_i is ≤ 2 or > 2, $1 \leq i \leq p$. For a graph H_i with diameter > 2, we may assume x_i and s_i to play the role of x and s respectively described earlier for the connected case, $1 \leq i \leq p$. For a graph H_i with diameter ≤ 2, we let x_i be any vertex of H_i, and s_i (≤ 2) is defined similarly, $1 \leq i \leq p$. Our graph H' is the set of components $H_1', H_2', \ldots, H_p'$. We have to prove statements (a) and (b) mentioned at the beginning of the proof of Theorem 4.1.

For proving statement (a), we need to consider the construction of the graph G' in the proof of Theorem 4.1.1. Let $G_1, G_2, \ldots, G_t$ be the components of a graph G, with H_i as an induced subgraph of G_i, for all $i = 1, 2, \ldots, p$. Thus G is an instance of *RET-H*. Since H is bipartite, only bipartite graphs may be homomorphic to H. Thus for nonbipartite instances of *RET-H*, statement (a) is trivially true. Suppose that G is bipartite. Let $(G_{i,A}, G_{i,B})$ be a bipartition of G_i, for all $i = 1, 2, \ldots, t$. Let $(H_{i,A}, H_{i,B})$ be a bipartition of H_i, with $H_{i,A} \subseteq G_{i,A}$, $H_{i,B} \subseteq G_{i,B}$, for all $i = 1, 2, \ldots, p$. Without loss of generality, let $x_i \in H_{i,A}$, for all $i = 1, 2, \ldots, p$.

Suppose first that H has no edge. Then H_i has only one vertex and the diameter of H_i is 0, and hence from our construction, H_i' is the graph H_i, for all $i = 1, 2, \ldots, p$. For G to be homomorphic to H, it must be that G also has no edge, in which case G_i would be the graph H_i, for all $i = 1, 2, \ldots, p$. Clearly, G retracts to H if and only if G compacts to H', and hence statement (a) is true.

Now suppose that H has an edge. Without loss of generality, let H_1 have an edge. If the diameter of H_i is > 2, the construction of G_i' is analogous to the construction described in the proof of Theorem 4.1.1, $1 \leq i \leq p$. If the diameter of H_i is ≤ 2 then G_i' is obtained by adding a path $x_i z_i a$ in G_i, where z_i is a single new vertex added in G_i, for all $a \in G_{i,A} - H_{i,A}$, and by adding an edge $x_i b$ in G_i, for all $b \in G_{i,B} - H_{i,B}$; thus the diameter of G_i' is ≤ 3, $1 \leq i \leq p$. When constructing G_1', we also add a path $x_1 z_1 a$ and an edge $x_1 b$ in G_1, for all $a \in G_{p+1,A}, G_{p+2,A}, \ldots, G_{t,A}$, $b \in G_{p+1,B}, G_{p+2,B}, \ldots, G_{t,B}$, where the vertex z_1 already exists if the diameter of H_1 is ≤ 2, or is a new vertex if the diameter of H_1 is > 2. Notice that the diameter of G_1' is still ≤ 3 if the diameter of H_1 is ≤ 2. Our graph G' is the set of components $G_1', G_2', \ldots, G_p'$. Also note that the diameter of H_i' is ≥ 4 if the diameter of H_i is > 2, and recall that the graph H_i' is the graph H_i if the diameter of H_i is ≤ 2, $1 \leq i \leq p$. We now argue analogous to the arguments in the proof of Theorem 3.1 for the disconnected case for proving statement (a). We however make some remarks as noted below.

Note that if $t > p$ then G_1' has edges as a result of its construction due to the graphs $G_{p+1}, G_{p+2}, \ldots, G_t$. If G retracts to H then in the case when $t > p$, the fact that H_1 has an edge establishes that G_1' is homomorphic to H_1', which is a requirement for G_1' to compact to H_1'.

If G' compacts to H' then in the case when the diameter of H_k is 0, i.e., when H_k has no edge, we point out the reasoning as to why G_k retracts to H_k, $1 \leq i \leq p$. Suppose that the diameter of H_k is 0 for some k, $1 \leq k \leq p$. From our construction, the graph H_k' is the graph H_k. If a component G_i' of G' compacts to H_k' then the graph H_i' must be of diameter 0, as G_i', which contains H_i' as an induced subgraph, must have no edge, $1 \leq i \leq p$. We have that G_k' contains H_k' of diameter 0 as an induced subgraph. Thus if G_k' has an edge then there exists some component H_m' of

diameter 0 to which no component of G' compacts, $1 \leq m \leq p$. Hence if G' compacts to H' then the graph G'_k (and G_k) is the graph H'_k, i.e., H_k, implying that G'_k trivially compacts to H'_k, and G_k trivially retracts to H_k.

For proving statement (b), we just need to assume in the proof of Theorem 4.1.2 that if the diameter of H_i is ≤ 2 then $V(P_h) = \phi$, for all $h \in V(H_i)$, $1 \leq i \leq p$. □

4.1. Compaction to bipartite graphs in relation to constraint satisfaction. As we mentioned in section 3.1, it is shown in [Feder and Vardi, 1998] that for every fixed template T of a set of relations, there exists a fixed bipartite graph H such that the constraint satisfaction problem *CSP-T* and the retraction problem *RET-H* are polynomially equivalent. Since it is thought to be likely difficult to determine whether for every template T, the problem *CSP-T* is polynomial time solvable or NP-complete, this is taken as evidence that to determine whether for every bipartite graph H, the problem *RET-H* is polynomial time solvable or NP-complete is likely to be difficult also.

We have shown in Theorem 4.1 that for every bipartite graph H, there exists a bipartite graph H' such that *RET-H* is polynomially equivalent to *COMP-H'*. Thus from Theorem 4.1 and the above mentioned result of [Feder and Vardi, 1998], we have the following theorem.

THEOREM 4.2. *For every fixed template T of a set of relations, there exists a fixed bipartite graph H such that the constraint satisfaction problem CSP-T and the compaction problem COMP-H are polynomially equivalent.* □

Thus we have evidence, due to Theorem 4.2, that to determine whether for every bipartite graph H, the problem *COMP-H* is polynomial time solvable or NP-complete is likely to be difficult.

STRICT POLYNOMIAL-TIME IN SIMULATION AND EXTRACTION*

BOAZ BARAK† AND YEHUDA LINDELL‡

Abstract. The notion of efficient computation is usually identified in cryptography and complexity with (strict) probabilistic polynomial-time. However, until recently, in order to obtain *constant-round* zero-knowledge proofs and proofs of knowledge, one had to allow simulators and knowledge extractors to run in time that is only polynomial *on the average* (i.e., *expected* polynomial-time). Recently Barak gave the first constant-round zero-knowledge argument with a *strict* (in contrast to expected) polynomial-time simulator. The simulator in his protocol is a *nonblack-box* simulator (i.e., it makes inherent use of the description of the *code* of the verifier).

In this paper, we further address the question of strict polynomial-time in constant-round zero-knowledge proofs and arguments of knowledge. First, we show that there exists a constant-round zero-knowledge *argument of knowledge* with a *strict* polynomial-time *knowledge extractor*. As in the simulator of Barak's zero-knowledge protocol, the extractor for our argument of knowledge is not black-box and makes inherent use of the code of the prover. On the negative side, we show that nonblack-box techniques are *essential* for both strict polynomial-time simulation and extraction. That is, we show that no (nontrivial) constant-round zero-knowledge proof or argument can have a strict polynomial-time *black-box* simulator. Similarly, we show that no (nontrivial) constant-round zero-knowledge proof or argument of knowledge can have a strict polynomial-time *black-box* knowledge extractor.

Key words. zero-knowledge proof systems, proofs of knowledge, expected vs. strict polynomial-time, black-box vs. nonblack-box algorithms

1. Introduction.

This paper deals with the issue of *expected* versus *strict* polynomial-time with respect to simulators and extractors for zero-knowledge proofs and arguments and zero-knowledge proofs and arguments of knowledge.[1]

1.1. Expected polynomial-time in zero knowledge.

The principle behind the definition of (computational) zero-knowledge proofs, as introduced by Goldwasser, Micali, and Rackoff [29], is the following:

> *Anything that an* efficient *verifier can learn as a result of interacting with the prover, can be learned* without interaction *by applying an* efficient *procedure (i.e., simulator) to the public input.*

Note that there are two occurrences of the word "efficient" in this sentence. When providing a formal definition of zero knowledge, the issue of what is actually meant by "efficient computation" must be addressed. The standard interpretation in cryptography and complexity is that of probabilistic polynomial-time. However, in the context

[1] In a *proof* system, soundness holds unconditionally and with respect to all-powerful cheating provers. In contrast, in an *argument* system, soundness is only guaranteed to hold with respect to polynomial-time bounded provers. We note that lower bounds for proofs do not necessarily hold for arguments, because in arguments the soundness condition is only computational. Likewise, lower bounds for arguments do not necessarily hold for proofs, because proofs are allowed to have super-polynomial honest prover strategies, whereas arguments are not. See section 2.1.

of zero knowledge, efficiency has also been taken to mean *polynomial on the average* (also known as *expected polynomial-time*). That is, if we fix the input, and look at the running time of the machine in question as a random variable (depending on the machine's coins), then we require only that the *expectation* of this random variable is polynomial. Three versions of the formal definition of zero knowledge appear in the literature, differing in their interpretations of efficient computation:

1. Definition 1—STRICT/STRICT: According to this definition both the verifier and simulator run in strict polynomial-time. This is the definition adopted by Goldreich [22, section 4.3] and is natural in the sense that only the standard interpretation of efficiency is used.
2. Definition 2—STRICT/EXPECTED: This more popular (and liberal) definition requires the verifier to run in strict polynomial-time while allowing the simulator to run in expected polynomial-time. This was actually the definition proposed in the original paper on zero knowledge [29].
3. Definition 3—EXPECTED/EXPECTED: In this definition, *both* the verifier and simulator are allowed to run in expected polynomial-time. This definition is far less standard than the above two, but is nevertheless a natural one to consider. As we describe below, this definition was considered by Feige [17], who showed that (at least for one definition of expected polynomial-time) it is problematic.

As we have mentioned, the standard interpretation of efficient computation is that of (strict) polynomial-time. In light of this, Definition 1 (STRICT/STRICT) seems to be the most natural. Despite this, expected polynomial-time was introduced in the context of zero knowledge because a number of known protocols that could be proven zero knowledge according to the more liberal STRICT/EXPECTED definition were not known to satisfy the more severe STRICT/STRICT definition. In particular, until very recently no *constant-round* zero knowledge argument (or proof) for $\mathcal{NP}$ was known to satisfy Definition 1 (STRICT/STRICT).[2] It was therefore necessary to relax the definition and allow expected polynomial-time simulation (as in Definition 2).

Proofs of knowledge. An analogous situation arises in proofs *of knowledge* [29, 33, 18, 6]. There, the underlying principle is the following:

> *If an* efficient *prover can convince the honest verifier with some probability that $x \in L$, then this prover can apply an* efficient *procedure (i.e., extractor) to x and its private inputs and obtain a witness for x with essentially the same probability.*

Again, the word "efficient" occurs twice, and again three possible definitions can be used. In particular, the prover and extractor can be instantiated by strict polynomial-time machines, expected polynomial-time machines, or a combination of both.

The different definitions—discussion. As has been observed before (e.g., see [17, section 3.2], [22, section 4.12.3]), the definitions that allow for expected polynomial-time computation are not fully satisfactory for several reasons:

- *Philosophical considerations*: Equating "efficient computation" with *expected polynomial-time* is more controversial than equating efficient computation with (strict) probabilistic polynomial-time. For example, Levin [30] (see also [20], [22, section 4.3.1.6]) has shown that when expected polynomial-time is defined as above, the definition is too machine dependent and is not closed under reductions. He proposed a different definition for expected polynomial-time that is closed under reductions and is less machine dependent. However,

[2] We note that throughout this paper we always refer to protocols with negligible soundness error.

it is still unclear whether expected polynomial-time, even under Levin's definition, should be considered as efficient computation.

- *Technical considerations*: Expected polynomial-time is less understood than the more standard strict polynomial-time. This means that rigorous proofs of security of protocols that use zero-knowledge arguments with expected polynomial-time simulators (or arguments of knowledge with expected polynomial-time extractors) as components are typically more complicated (see [31] for an example). Another technical problem that arises is that expected polynomial-time simulation is not closed under composition. Consider, for example, a protocol that uses zero-knowledge as a subprotocol. Furthermore, assume that the security of the larger protocol is proved in two stages. First, the zero-knowledge subprotocol is simulated for the adversary (using an expected polynomial-time simulator). This results in an expected polynomial-time adversary that runs the protocol with the zero-knowledge executions removed. Then, in the next stage, the rest of the protocol is simulated for this adversary. A problem arises because the simulation of the second stage must now be carried out for an expected polynomial-time adversary. However, simulation for an expected polynomial-time adversary can be highly problematic (as the protocol of [24] demonstrates; see [31, Appendix A] for details).
- *Practical considerations*: A proof of security that uses expected polynomial-time simulation does not always achieve the "expected" level of security. For example, assume that a protocol's security relies on a hard problem that would take 100 years to solve, using the best known algorithm. Then, we would like to prove that the probability that an adversary can successfully break the protocol is negligible, unless it runs for 100 years. However, when expected polynomial-time simulation is used, we cannot rule out an adversary that runs for one year and succeeds with probability 1/100. This is a weaker level of security and may not be acceptable. See section 1.4 for a more detailed discussion of this issue.

The liberal STRICT/EXPECTED definition also suffers from a conceptual drawback regarding the notion of zero knowledge itself. Specifically, the idea behind the definition of zero knowledge is that anything that a verifier can learn as a result of the interaction, it can learn by just looking at its input. Therefore, it seems that the simulator should *not* be of a higher complexity class than the verifier. Rather, both the verifier and simulator should be restricted to the same complexity class (i.e., either strict or expected polynomial-time). The EXPECTED/EXPECTED definition has the advantage of not having any discrepancy between the computational power of the verifier and simulator. However, it still suffers from the above described drawbacks with any use of expected polynomial-time. In addition, as Feige [17, section 3.3] pointed out, in order to prove that known protocols remain zero knowledge for expected polynomial-time verifiers, one needs to restrict the verifiers to run in expected polynomial-time not only when interacting with the honest prover but also when interacting with all other interactive machines. This restriction is somewhat controversial because any efficient adversarial strategy should be allowed. In particular, there seems to be no reason to disqualify an adversarial strategy that takes expected polynomial-time when attacking the honest prover, but runs longer otherwise (notice that the adversary is only interested in attacking the honest prover, and so its attack is efficient).

In contrast, the STRICT/STRICT definition suffers from none of the above conceptual difficulties. For this reason, it is arguably a preferred definition. However, as

we have mentioned, it was not known whether this definition can be satisfied by a protocol with a *constant* number of rounds. Thus a natural open question (posed by [17, section 3.4] and [22, section 4.12.3]) was the following:

> *Are expected polynomial-time simulation and extraction necessary in order to obtain constant-round zero-knowledge proofs and proofs of knowledge?*

A first step in answering the above question was recently taken by Barak in [3]. Specifically, [3] presented a zero-knowledge argument system that is both *constant-round* and has a *strict* polynomial-time simulator. Interestingly, the protocol of [3] is not black-box zero knowledge. That is, the simulator utilizes the description of the code of the verifier. (This is in contrast to black-box zero knowledge where the simulator is only given oracle access to the verifier.) Given the existence of non-black-box zero-knowledge arguments with a constant number of rounds and strict polynomial-time simulation, it is natural to ask the following questions:

1. Is it possible to obtain constant-round zero-knowledge *arguments of knowledge* with strict polynomial-time extraction?
2. Is the fact that the protocol of [3] is not black-box zero knowledge coincidental, or is this an inherent property of any constant-round zero-knowledge protocol with strict polynomial-time simulation?

1.2. Our results. In this paper we resolve both the above questions. First, we show that it is possible to obtain *strict* polynomial-time knowledge extraction in a *constant-round* protocol. In fact, we show that it is possible to obtain strict polynomial-time simulation and extraction simultaneously in a zero-knowledge protocol. That is, we prove the following theorem.

THEOREM 1.1. *Assume the existence of collision-resistant hash functions and collections of trapdoor permutations such that the domain of each permutation is the set of all strings of a certain length.*[3] *Then, there exists a* constant-round *zero-knowledge argument of knowledge for $\mathcal{NP}$ with a* strict *polynomial-time knowledge extractor and a* strict *polynomial-time simulator.*

The definition of arguments of knowledge that we refer to in Theorem 1.1 differs from the standard definition of [6] in an important way. In the definition of [6], the knowledge extractor is given only black-box access to the prover. In contrast, in our definition, the knowledge extractor is given the actual description of the prover (i.e., it has nonblack-box access). As we will see below, this modification is actually necessary for obtaining *constant-round* arguments of knowledge with *strict* polynomial-time extraction.

In addition to the above positive result, we show that it is impossible to obtain a (nontrivial) constant-round zero-knowledge protocol that has a strict polynomial-time *black-box* simulator. Likewise, a strict polynomial-time extractor for a constant-round zero-knowledge argument of knowledge cannot be black-box. That is, we prove the following two theorems.

THEOREM 1.2. *There do not exist* constant-round *zero-knowledge proofs or arguments with* strict polynomial-time black-box *simulators for any language $L \notin \mathcal{BPP}$.*

THEOREM 1.3. *There do not exist* constant-round *zero-knowledge proofs or arguments of knowledge with* strict polynomial-time black-box *knowledge extractors for*

[3] By this we mean that there exists a trapdoor permutation family $\{f_s\}_{s\in\{0,1\}^*}$ such that $f_s : \{0,1\}^{|s|} \to \{0,1\}^{|s|}$. It actually suffices to assume the existence of a family of enhanced trapdoor permutations [23, Appendix C.1]. Such a family can be constructed under the RSA and factoring assumptions; see [2, section 6.2] and [23, Appendix C.1].

any language $L \notin \mathcal{BPP}$.

We therefore conclude that the liberal definitions that allow the simulator (resp., extractor) to run in expected polynomial-time are necessary for achieving constant-round *black-box* zero knowledge (resp., arguments of knowledge). Furthermore, our use of nonblack-box techniques is essential in order to obtain Theorem 1.1.

We note that Theorems 1.2 and 1.3 are tight in the sense that if any super-constant number of rounds is allowed, then zero-knowledge proofs of knowledge with strict polynomial-time black-box extraction and simulation *can* be obtained. This was shown by Goldreich in [22, section 4.7.6]. (Actually, [22] shows that a *super-logarithmic* number of sequential executions of the 3-round zero-knowledge proof for Hamiltonicity [9] suffices. However, using the same ideas, it can be shown that by running $\log n$ parallel executions of the proof of Hamiltonicity, any super-constant number of sequential repetitions is actually enough.)

Zero knowledge versus ε-knowledge. Our impossibility result regarding constant-round black-box zero knowledge with strict polynomial-time simulation has an additional ramification to the question of the relation between black-box ε-knowledge [15] and black-box zero knowledge. Loosely speaking, an interactive proof is called ε-knowledge if for every ε, there exists a simulator that runs in time polynomial in the input and in $1/\varepsilon$, and outputs a distribution that can be distinguished from a real proof transcript with probability at most ε. Despite the fact that this definition seems to be a significant relaxation of zero knowledge, no separation between ε-knowledge and zero knowledge was previously known. Our lower bound indicates a separation for the black-box versions; that is, *black-box* ε-knowledge is strictly weaker than *black-box* zero knowledge. Specifically, on one hand, constant-round black-box ε-knowledge protocols with strict polynomial-time simulators do exist.[4] On the other hand, as we show, analogous protocols for black-box *zero* knowledge do not exist.

Witness-extended emulation. Zero-knowledge proofs of knowledge are often used as subprotocols within larger protocols. Typically, in this context the mere existence of a knowledge extractor does not suffice for proving the security of the larger protocol. Loosely speaking, what is required is the existence of a machine that not only outputs a witness with the required probability (as is required from a knowledge extractor), but also outputs a corresponding simulated transcript of the interaction between the prover and the verifier. Furthermore, whenever the transcript of the interaction is such that the verifier accepts, then the witness that is obtained is valid. To explain this further, consider a case in which the prover convinces the verifier in a real interaction with probability p. Then, with probability negligibly close to p, the aforementioned machine should output an accepting transcript and a valid witness. Furthermore, with probability negligibly close to $1-p$, the machine should output a rejecting transcript (and we don't care about the witness).

This issue was addressed in [31] by Lindell, who called such a machine a "witness-extended emulator." It was proved there that there exists such a witness-extended emulator for any proof of knowledge. However, the extended emulator that is obtained runs in *expected* polynomial-time, even if the original knowledge extractor runs in *strict* polynomial-time. Unfortunately, we do not know how to prove an analogous result that, given any strict polynomial-time knowledge extractor, would provide a

[4] Such a protocol can be constructed by taking any constant-round protocol with an expected polynomial-time simulator and truncating the simulator's run (outputting $\perp$), if it runs for more than $1/\varepsilon$ times its expected running time. By Markov's inequality, the probability of this bad event happening is at most ε.

strict polynomial-time emulator. Instead, we directly construct a strict polynomial-time witness-extended emulator for our zero-knowledge proof of knowledge (under a slightly different definition than [31]).

1.3. On the effect of truncating expected polynomial-time executions. A naive approach to solving the problem of expected polynomial-time in simulation and extraction is to simply truncate the execution of the simulator or extractor after it exceeds its expected running time by "too much." However, this does not necessarily work. The case of knowledge extractors is a good example. Let us fix a proof (or argument) of knowledge for some NP-language L. Let $x \in \{0,1\}^*$, and let P^* be a polynomial-time prover that, for some ϵ, aborts with probability $1-\epsilon$ and convinces the honest verifier that $x \in L$ with probability ϵ. For all previously known constant-round proofs of knowledge, the expected polynomial-time knowledge extractor works in roughly the following way: it first verifies the proof from P^*, and if P^* is not convincing (which occurs in this case with probability $1-\epsilon$), then it aborts. On the other hand, if P^* is convincing (which happens in this case with probability ϵ), then it does expected $p(n) \cdot \frac{1}{\epsilon}$ work (where $p(\cdot)$ is some fixed polynomial) and outputs a witness for x. Clearly, the expected running time of the extractor is polynomial (in particular, it is $p(n)$ plus the time taken to honestly verify a proof). However, if we halt this extractor before it completes $\frac{1}{\epsilon}$ steps, then, with high probability, the extractor will *not* output a witness. Note that $\frac{1}{\epsilon}$ may be much larger than $p(n)$, and therefore the extractor may far exceed its expected running time and yet still not output anything.

In contrast to the above, the knowledge extractor of the argument of knowledge presented in this paper (in section 4) runs in strict polynomial-time which is *independent* of the acceptance probability (i.e., ϵ). For example, if there exists a cheating prover P^* that runs in time n^2, but convinces the verifier that $x \in L$ with probability $\epsilon = n^{-10}$, then our extractor will always run in time, say, n^4 and output a witness with probability at least (negligibly less than) n^{-10}. On the other hand, the extractors for previous protocols would work as follows: with probability $1-n^{-10}$ they would do almost nothing, and with probability n^{-10} they would run for, say, n^{12} steps and output a witness.

1.4. Trading success probability for running time. The observation in section 1.3 about how expected polynomial-time extractors typically work raises serious security issues with respect to the application of proofs of knowledge that have such extractors. For example, suppose that we use a proof of knowledge for an identification protocol based on factoring. Suppose, furthermore, that we use numbers for which the fastest known algorithms will take 100 years to factor. We claim that in this case, if we use a proof of knowledge with an *expected* polynomial-time extractor, then we cannot rule out the possible existence of an adversary that will take one year of computation time and succeed in an impersonation attack with probability 1/100.

In order to see this, notice that the proof of security of the identification protocol works by constructing a factoring algorithm from any impersonator, using the extractor for the proof of knowledge. Thus, for typical protocols, what will actually be proven is that given an algorithm that runs for T steps and successfully impersonates with probability ϵ, we can construct an algorithm that solves the factoring problem with probability ϵ and *expected* running time T. In particular, this factoring algorithm may (and actually will) work in the following way: with probability $1-\epsilon$ it will do nothing and with probability ϵ it will run in T/ϵ steps and factor its input. Thus, the existence of an impersonator that runs for one year and succeeds with probabil-

ity 1/100 only implies the existence of a factoring algorithm that runs for 100 years. Therefore, we cannot rule out such an impersonator. We conclude that the standard proofs of knowledge potentially allow adversaries to trade their success probability for running time. In the concrete example above, the impersonator lowered its running time from 100 years to one year, at the expense of succeeding with probability 1/100 instead of 1. We stress that the fastest known algorithms for factoring *do not* allow such a trade-off. That is, if the parameters are chosen so that 100 years are required to factor, then the probability of successfully factoring after one year is extremely small, and not close to 1/100.

We stress that not only is it the case that the *definition* of expected polynomial-time extraction does not allow us to rule out such an adversary, but also that such adversaries cannot be ruled out by the current proofs of security for known constant-round protocols (thus, the problem also lies with the protocols and not just with the definition). In contrast, such a trade-off is not possible if the extractor runs in *strict* polynomial-time. Rather, an impersonator that runs in time T and succeeds with probability ϵ yields a factoring algorithm that runs in time (polynomially related) to T and succeeds with probability ϵ. Thus, in the above concrete example, an analogous impersonator for a protocol with a strict polynomial-time extractor would yield a factoring algorithm that runs for one year and succeeds with probability 1/100. However, such an algorithm is conjectured not to exist, and therefore such an impersonator also does not exist (unless the conjecture is wrong).

1.5. Further discussion of prior work. Zero-knowledge proofs were introduced by Goldwasser, Micali, and Rackoff [29], and were then shown to exist for all $\mathcal{NP}$ by Goldreich, Micali, and Wigderson [26]. Constant-round zero-knowledge arguments and proofs were constructed by Feige and Shamir [19], Brassard, Crépeau, and Yung [11], and Goldreich and Kahan [24]. All these constant-round protocols utilize expected polynomial-time simulators. Regarding zero-knowledge proofs *of knowledge*, following a discussion in [29], the first formal definitions were provided by Feige, Fiat, and Shamir [18], and by Tompa and Woll [33]. These definitions were later modified by Bellare and Goldreich [6].

The issue of expected polynomial-time is treated in Feige's thesis [17] and Goldreich's book [22]. Goldreich [22, section 4.7.6] also presents a construction for a proof of knowledge with *strict* polynomial-time extraction (and simulation) that uses any super-logarithmic number of rounds (as discussed above, a variant of this construction can be obtained that uses any super-constant number of rounds).

As we have mentioned, until a short time ago, all known constant-round zero-knowledge protocols had expected polynomial-time simulators. However, recently this barrier was broken by Barak [3], who provided the first constant-round zero-knowledge argument for $\mathcal{NP}$ with a *strict* polynomial-time simulator, assuming the existence of collision-resistant hash functions with super-polynomial hardness. Barak and Goldreich [4] later showed how to obtain the same result under the weaker assumption of the existence of standard collision-resistant hash functions (with polynomial-time hardness). The construction of [3] was also the first zero-knowledge argument to utilize a nonblack-box simulator. In a similar fashion, the constant-round argument of knowledge presented in this paper utilizes a nonblack-box *knowledge extractor*. We note that [5] also utilized a nonblack-box knowledge extractor. However, their extractor ran in *expected* polynomial-time, and the nonblack-box access was used there for a completely different reason (specifically, to achieve a *resettable* zero-knowledge argument of knowledge).

1.6. Organization. In section 2 we describe the basic notation and definitions that we use. Then, in section 3 we define and construct a commit-with-extract commitment scheme, which is the main technical tool used to construct our zero-knowledge argument of knowledge. The proof of Theorem 1.1 can be found in section 4 where we present the construction of a zero-knowledge argument of knowledge with strict polynomial-time extraction. Finally, in section 5 we prove Theorems 1.2 and 1.3. That is, we prove that it is impossible to construct strict polynomial-time black-box simulators and extractors for (nontrivial) constant-round protocols.

2. Definitions.

Notation. For a binary relation R, we denote by $R(x)$ the set of all "witnesses" for x. That is, $R(x) \stackrel{\text{def}}{=} \{y \mid (x,y) \in R\}$. Furthermore, we denote by L_R the language induced by the relation R. That is, $L_R \stackrel{\text{def}}{=} \{x \mid R(x) \neq \emptyset\}$.

For a finite set $S \subseteq \{0,1\}^*$, we write $x \in_R S$ to say that x is distributed uniformly over the set S. We denote by U_n the uniform distribution over the set $\{0,1\}^n$.

A function $\mu(\cdot)$ is negligible if for every positive polynomial $p(\cdot)$ and all sufficiently large n's, it holds that $\mu(n) < 1/p(n)$. We let $\mu(\cdot)$ denote an arbitrary negligible function. That is, when we say that $f(n) < \mu(n)$ for some function $f(\cdot)$, we mean that *there exists* a negligible function $\mu(\cdot)$ such that for every n, $f(n) < \mu(n)$. A function $f(\cdot)$ is noticeable if there exists a positive polynomial $p(\cdot)$ such that for all sufficiently large n's, it holds that $f(n) > 1/p(n)$. We note that "noticeable" is not the complement of "negligible."

For two probability ensembles (sequences of random variables) $X = \{X_s\}_{s\in S}$ and $Y = \{Y_s\}_{s\in S}$ (where $S \subseteq \{0,1\}^*$ is a set of strings), we say that X is computationally indistinguishable from Y, denoted $X \stackrel{\text{c}}{\equiv} Y$, if for every polynomial-sized circuit family $\{D_n\}_{n\in\mathsf{N}}$ and every $s \in S$, it holds that $|\Pr[D_{|s|}(X_s) = 1] - \Pr[D_{|s|}(Y_s) = 1]| < \mu(|s|)$. We will sometime drop the subscripts s when they can be inferred from the context. In all our protocols, we will denote the security parameter by n.

Let A be a probabilistic polynomial-time machine. We denote by $A(x,y,r)$ the output of the machine A on input x, auxiliary input y and random tape r. We stress that the running time of A is polynomial in $|x|$.[5] If M is a Turing machine, then we denote by $\mathsf{desc}_n(M)$ the description of a *circuit* that computes M on inputs of size n. Note that a polynomial-time machine that receives $\mathsf{desc}_n(M)$ for input runs in time that is polynomial in the running time of M. Let A and B be interactive machines. We denote by $\mathsf{view}_A(A(x,y,r), B(x,z,r'))$ the view of party A in an interactive execution with machine B, on public input x, where A has auxiliary input y and random tape r, and B has auxiliary input z and random tape r'. The view of party B is denoted similarly. Recall that a party's view of an execution includes the contents of its input, auxiliary input, and random tape plus the transcript of messages that it receives during the execution. We sometimes drop r or r' from this notation, which means that the random tape is not fixed but rather chosen at random. For example, we denote by $\mathsf{view}_A(A(x,y), B(x,z))$ the random variable $\mathsf{view}_A(A(x,y,U_m), B(x,z,U'_{m'}))$, where m (resp., m') is the number of random bits that A (resp., B) uses on input of size $|x|$.

2.1. Zero knowledge. Loosely speaking, an interactive proof system for a language L involves a prover P and a verifier V, where upon common input x, the prover P attempts to convince V that $x \in L$. We note that the prover is often given

[5] We assume that y and r are on different tapes. Therefore, even if y is very long (e.g., $|y| > \text{poly}(|x|)$), it is still possible for A to read r.

some private auxiliary input that "helps" it to prove the statement in question to V. Such a proof system has the following two properties:

1. *Completeness*: this states that when honest P and V interact on common input $x \in L$, then V is convinced of the correctness of the statement that $x \in L$ (except with at most negligible probability).
2. *Soundness*: this states that when V interacts with any (cheating) prover P^* on common input $x \notin L$, then V will be convinced *with at most negligible probability*. (Thus V cannot be tricked into accepting a false statement.)

There are two flavors of soundness: *unconditional* (or statistical) soundness that must hold even for an all-powerful cheating prover, and *computational soundness* that needs hold only for (nonuniform) polynomial-time cheating provers. In *proof* systems [29], unconditional soundness is guaranteed, whereas in *argument* systems [10] only computational soundness must hold. We remark that a proof system is not necessarily an argument system, because the honest prover strategy in a proof system is not required to be polynomial-time (in contrast to arguments where the honest prover as well as the cheating provers must be nonuniform polynomial-time). Unless explicitly stated, when we mention "protocols" in discussion, we mean both proofs and arguments.

Throughout this paper, we will always assume that the soundness error is at most negligible. However, we will not always require this of completeness. Specifically, our lower bounds in section 5 hold even if the completeness error is $1 - 1/p(n)$ for some polynomial $p(\cdot)$; in this case, we will call $p(n)$ the completeness bound.

We now recall the definition of zero knowledge [29]. Actually, we present (a slightly strengthened form of) the definition of *auxiliary-input* zero knowledge [22, section 4.3.3].[6] The main difference between our definition below and the standard definition is that we require the simulator to run in *strict*, rather than *expected*, polynomial-time. We note that in this paper, when we say zero knowledge, our intention is always auxiliary-input zero knowledge.

DEFINITION 2.1 (auxiliary-input zero knowledge). *Let (P, V) be an interactive proof (or argument) system for a language L. Denote by $P_L(x)$ the set of strings y satisfying the completeness condition with respect to $x \in L$ (i.e., when the completeness bound is $p(\cdot)$, then $P_L(x)$ is the set of strings y for which the probability that $\mathsf{view}_V(P(x,y), V(x))$ is accepting is at least $p(|x|)$). We say that (P, V) is* auxiliary-input zero knowledge *if there exists a strict probabilistic polynomial-time algorithm S such that for every strict probabilistic polynomial-time machine V^* it holds that*

$$\left\{\mathsf{view}_{V^*}(P(x,y), V^*(x,z))\right\}_{x\in L, y\in P_L(x), z\in\{0,1\}^*} \stackrel{c}{\equiv} \left\{S(\mathsf{desc}_{|x|}(V^*), x, z)\right\}_{x\in L, y\in P_L(x), z\in\{0,1\}^*}$$ [7]

Black-box zero knowledge. A zero-knowledge proof system is called black-box zero knowledge [27] if the simulator S only uses its input $\mathsf{desc}(V^*)$ as a black-box

[6] We deviate from the definition of auxiliary-input zero knowledge of [22, section 4.3.3] by making the slightly stronger requirement that there exists a single universal simulator for all verifiers, rather than a different simulator for each verifier as in [22, section 4.3.3]. Note however, that the definition of [22, section 4.3.3] already implies that for any $c > 0$ there exists a universal simulator for all $\mathbf{Time}(n^c)$ verifiers.

[7] Recall that $\mathsf{desc}_n(M)$ is the description of a circuit that computes M on inputs of size n. An equivalent formulation provides the simulator S with the description of the actual Turing machine M. However, in this case, it is also necessary to provide S with 1^t, where t is a bound on the running time of V^* on inputs of length $|x|$. This additional input is provided in order to allow S to run in time which is (some fixed) polynomial in the running time of V^*.

subroutine. That is, S is an oracle algorithm such that

$$\left\{\mathsf{view}_{V^*}(P(x,y),V^*(x,z))\right\}_{x\in L,y\in P_L(x),z\in\{0,1\}^*} \stackrel{c}{\equiv} \left\{S^{V^*(x,z,\cdot,\cdot)}(x)\right\}_{x\in L,y\in P_L(x),z\in\{0,1\}^*},$$

where $V^*(x,z,\cdot,\cdot)$ denotes the *next-message function* of the interactive machine V^* when the common input x and auxiliary input z are fixed (i.e., the next-message function of V^* receives a random tape r and a message history h and outputs $V^*(x,z,r,h)$).

2.2. Zero-knowledge arguments of knowledge. Our definition of proofs and arguments of knowledge below differs from the standard definition of [6] in two ways:

Strict polynomial-time extraction. We require that the knowledge extractor run in *strict* polynomial-time (rather than in expected polynomial-time).

Nonblack-box extraction. The knowledge extractor is given access to the *description* of the prover. This is a relaxation of the standard definition of proofs of knowledge (cf. [6, 22]) in which the knowledge extractor is given *only* oracle (or black-box) access to the prover strategy. The relaxed definition appeared originally in Feige and Shamir [19] (which differs from the definition in [18]; see discussion in [6]), and suffices for all practical applications of arguments of knowledge.

Until recently, all known proofs of knowledge (including [19]) were coupled with an extractor that used the prover algorithm only as a black-box. The extra power of nonblack-box extraction (where the knowledge extractor is given the actual description of the prover) was first used in an essential way by [5] in order to obtain resettable zero-knowledge arguments of knowledge for $\mathcal{NP}$.[8] We show in section 5 that our use of nonblack-box extraction is also essential, as there do not exist constant-round proofs of knowledge with *black-box* strict polynomial-time extractors.

We are now ready to present the following definition.

DEFINITION 2.2 (system of proofs/arguments of knowledge). *Let R be a binary relation. We say that a probabilistic, polynomial-time interactive machine V is a* knowledge verifier for the relation R *with* negligible knowledge error *if the following two conditions hold:*

- Nontriviality: *There exists a probabilistic polynomial-time*[9] *interactive machine P such that for every $(x,y)\in R$, all possible interactions of V with P on common input x, where P has auxiliary input y, are accepting.*
- Validity (or knowledge soundness) with negligible error: *There exists a* strict *probabilistic polynomial-time machine K such that for every strict probabilistic polynomial-time machine P^* and every $x,y,r\in\{0,1\}^*$, machine K satisfies the following condition:*

  Denote by $p(x,y,r)$ the probability (over the random tape of V) that V accepts upon input x, when interacting with the prover P^* that has input x, auxiliary input y, and random tape r. Then, machine K, upon input $(\mathsf{desc}_{|x|}(P^*),x,y,r)$, outputs a solution $s\in R(x)$ with probability at least $p(x,y,r)-\mu(|x|)$.

[8] The use there is critical as it can be shown that if the knowledge extractor is restricted to only black-box access to the prover, then resettable zero-knowledge arguments of knowledge are possible for languages in $\mathcal{BPP}$ only; see [12].

[9] The requirement that P be polynomial-time is inherent for arguments, but not for proofs. A proof system with such a prover is called an efficient-prover proof.

An interactive pair (P, V) such that V is a knowledge verifier for a relation R and P is a machine satisfying the nontriviality condition (with respect to V and R) is called an argument of knowledge *for the relation R. If the validity condition holds with respect to any (not necessarily polynomial-time) machine P^*, then (P, V) is called a* proof of knowledge *for R.*

If an argument (resp., proof) of knowledge (P, V) is zero knowledge for the language L_R induced by R, then we say that (P, V) constitutes a system of zero-knowledge arguments (resp., proofs) of knowledge for R.

2.3. Witness-extended emulation. In this section, we present an extension of the notion of proofs of knowledge, called witness-extended emulation. This extension is of importance when zero-knowledge proofs or arguments of knowledge are used as subprotocols within larger protocols, as is often the case. Typically in this context, the extractor for the proof of knowledge supplies the simulator for the larger protocol with some secret information. This information is then used in the proof of security of the rest of the larger protocol.

The final output of the simulator for the larger protocol is usually a transcript of the entire simulated protocol execution (where this transcript is indistinguishable from a real execution). Thus, the extractor needs to not only extract a witness from the proof of knowledge, but must also obtain a matching transcript of the execution of the proof of knowledge itself. However, by definition, the extractor only outputs a witness and does not provide the simulator with such a transcript. This issue was addressed in [31] where, loosely speaking, it was shown that for any zero-knowledge proof of knowledge, there exists a machine that outputs both the witness (with the appropriate probability) *and* a matching transcript of messages sent in the execution. Such a machine was termed a "witness-extended emulator" because its role is to emulate a protocol execution while also providing a witness (see [31] for a more detailed discussion). We proceed by presenting a slightly different definition of witness-extended emulation and then discuss its relevance to our work. We begin with some notation and terminology:

- Recall that $\mathsf{view}_{P^*}(P^*(x, y, r), V(x))$ denotes a random variable describing the view of P^* in a protocol execution with the honest verifier V, where P^* has input x, auxiliary input y, and random tape r, and the honest verifier V has input x. (This random variable depends only on the coins of V.)
- We say that a zero-knowledge protocol (P, V) is *publicly verifiable* if given the transcript of messages between any P^* and V, it is possible to efficiently determine whether or not V accepted the proof. (For example, any protocol can be made publicly verifiable by having the verifier send the contents of its random tape at the end of the protocol execution. Note, however, that this can affect other properties of the protocol. Indeed, our proof of knowledge, Protocol 4.1, *cannot* be made publicly verifiable in this way while still preserving the witness-extended emulation property.)

  When a protocol is publicly verifiable, then V's accept/reject bit can be deduced efficiently (and deterministically) from the prover's view. We denote by $\mathsf{accept}_V(\cdot)$ the deterministic function that takes a specific view of the prover in a protocol execution, and outputs whether or not V accepts in this execution.

We are now ready to present the following definition.

DEFINITION 2.3 (witness-extended emulator). *Let R be a binary relation, and let (P, V) be an interactive proof system that is* publicly verifiable. *Consider a probabilis-*

tic machine E that is given the description of a probabilistic polynomial-time prover $\mathsf{desc}_{|x|}(P^*)$, and the contents of P^*'s input, auxiliary input, and random tapes, x, y and r, respectively. We denote by $E_1(\mathsf{desc}_{|x|}(P^*), x, y, r)$ and $E_2(\mathsf{desc}_{|x|}(P^*), x, y, r)$ the random variables representing the first and second elements of the output of E, respectively. We say that E is a witness-extended emulator for (P, V) and R *if it runs in* strict *polynomial-time and if for every probabilistic polynomial-time interactive machine P^*, every $y, r \in \{0,1\}^*$, and all sufficiently large x's, the following hold:*

1. *E_1's output distribution is indistinguishable from the distribution of the view of P^* in a real execution with the honest verifier V. That is,*

$$\left\{E_1(\mathsf{desc}_{|x|}(P^*), x, y, r)\right\}_{x,y,r} \stackrel{\mathrm{c}}{\equiv} \left\{\mathsf{view}_{P^*}(P^*(x, y, r), V(x))\right\}_{x,y,r}.$$

2. *The probability that V accepts in the view of P^* that is output by E_1, and yet E_2 does not output a correct witness, is negligible. That is,*

$$\begin{aligned}\Pr\big[&\mathsf{accept}_V(E_1(\mathsf{desc}_{|x|}(P^*), x, y, r)) \\ &= 1 \ \&\ E_2(\mathsf{desc}_{|x|}(P^*), x, y, r) \notin R_L(x)\big] < \mu(|x|).\end{aligned}$$

Definition 2.3 differs from the definition of [31] in a number of ways. Most notably, we provide the witness-extended emulator with the description of P^* (rather than just black-box access) and also require it to run in strict polynomial-time (rather than expected polynomial-time). The other differences are technical and are mainly due to the need to achieve strict polynomial-time emulation. Despite the differences, the definitions are the same in spirit and both achieve the desired goal of enabling a proof of knowledge to be used as a subprotocol in some other, larger protocol.

Recall that [31] proved the existence of a witness-extended emulator for any proof of knowledge. However, the emulator that is obtained runs in expected polynomial-time and thus does not achieve our goal of strict polynomial-time emulation. We will therefore directly prove the existence of a witness-extended emulator for our zero-knowledge argument of knowledge.

3. Commitment with extraction. In order to construct a constant-round zero-knowledge argument of knowledge with strict polynomial-time extraction, we first construct a new primitive that we call commit-with-extract. Loosely speaking, a commit-with-extract scheme is a commitment scheme with the additional property that the committed value can be extracted from the sender. More precisely, there exists a (strict polynomial-time) commitment extractor that is given the description of the sender (along with the contents of its input, auxiliary input, and random tape) and extracts the value being committed to during the commit stage of the protocol. This notion of "extractable commitments" is not completely new. It has been used in the context of secure multiparty computation (e.g., [21, Construction 2.3.8]) and has been called both commit-with-knowledge [14] and nonoblivious commitment [22, Definition 4.9.3]. One main technical difference between our primitive and previous ones is the requirement that the extractor run in *strict* polynomial-time. At the end of this section we discuss another significant difference that is related to the question of "knowledge" versus "extraction."

We remark that in a standard commitment scheme, the committer may not "know" the value that it committed to. This is the case, for example, in the case that the range of the commitment scheme is $\{0,1\}^*$, and so any value is a valid

commitment. Clearly, such a commitment scheme does *not* have the property that the committed value can be extracted from the committer.

3.1. Definition. We begin by informally defining perfectly binding commitment schemes.

Commitment schemes. A commitment scheme is a two-party protocol that enables a party, known as the *sender*, to commit itself to a value while keeping it secret from the *receiver*. A commitment scheme must be both *hiding* and *binding*. The hiding property of a commitment scheme says that the receiver's view in the case that the sender commits to 0 is computationally indistinguishable from its view in the case that the sender commits to 1. (Thus, the committed value is unknown to the receiver.) The binding property of a commitment scheme states that in a later stage when the commitment is opened, the "opening" can yield only a single value that was determined in the committing phase. (Thus, the sender cannot modify its committed value.) In a *perfectly binding* commitment scheme, the binding property states that transcripts resulting from a commitment to 0 and a commitment to 1 must be *disjoint*. Thus, for any given transcript, there is at most one commitment value that can yield that transcript. See [22, section 4.4.1] for a formal definition of commitment schemes.

Commit-with-extract. As we have mentioned, a commit-with-extract scheme is a commitment scheme with the following additional property: there exists a (strict polynomial-time) commitment extractor that is given the description of the sender and extracts the value being committed to during the commit stage of the protocol. In addition to outputting the committed value, we also require the extractor to output the sender's view of an execution (this is similar in spirit to witness-extended emulation and is needed when the commit-with-extract is used as a subprotocol).[10] Of course, the committed value and sender's view output by the extractor must be compatible. In order to enforce this compatibility, we denote by $\mathsf{commit\text{-}value}(\cdot)$ a function that takes a sender's view and outputs the *unique* committed value implicit in this view, or $\perp$ if no such value exists. (This function is well defined for perfectly binding commitments because in such a case every transcript can define at most one value.) Then, compatibility between the view and committed value is obtained by requiring that $x = \mathsf{commit\text{-}value}(v)$, where x and v are the committed value and sender's view, respectively, as output by the extractor. We now present the formal definition.

DEFINITION 3.1 (commit-with-extract). *A* perfectly binding *commitment scheme C (with sender A and receiver B) is a* commit-with-extract *commitment scheme if the following holds: there exists a strict probabilistic polynomial-time commitment extractor CK such that for every probabilistic polynomial-time committing party A^* and for every $x, y, r \in \{0,1\}^*$, upon input $(\mathsf{desc}_{|x|}(A^*), x, y, r)$, machine CK outputs a pair, denoted $(CK_1(\mathsf{desc}_{|x|}(A^*), x, y, r), CK_2(\mathsf{desc}_{|x|}(A^*), x, y, r))$, satisfying the following conditions:*

1. $\{CK_1(\mathsf{desc}_{|x|}(A^*), x, y, r)\}_{x,y,r\in\{0,1\}^*} \stackrel{\mathrm{c}}{\equiv} \{\mathsf{view}_{A^*}(A^*(x, y, r), B)\}_{x,y,r\in\{0,1\}^*}$.
2. $\Pr[CK_2(\mathsf{desc}_{|x|}(A^*), x, y, r) = \mathsf{commit\text{-}value}(CK_1(\mathsf{desc}_{|x|}(A^*), x, y, r))] > 1 - \mu(|x|)$.

We note that the requirements on the extractor CK can be relaxed such that in the case that there is no committed value (i.e., where the view v is such that $\mathsf{commit\text{-}value}(v) = \perp$), then CK can output any arbitrary value, and not just $\perp$. This relaxation suffices for our applications.

[10] The extractor outputs the view of the *sender* (and not the receiver) because the extraction procedure is used in the simulation of a corrupted sender (not receiver).

Commit-with-extract using proofs of knowledge. We note that it is possible to achieve a commit-with-extract scheme in the following straightforward way. First, the sender sends a standard perfectly binding commitment to the receiver. Then, the sender proves knowledge of the committed value using a zero-knowledge proof or argument of knowledge. A commitment extractor can easily be constructed for this scheme by having it run the knowledge extractor from the proof of knowledge and obtain the committed value. However, as mentioned above, known constructions of proofs of knowledge with strict polynomial-time extraction have a nonconstant number of rounds. In contrast, our aim is to construct a commit-with-extract scheme that has a *constant* number of rounds.

Public decommitment. We say that a commitment scheme satisfies public decommitment if the validity of a decommitment can be ascertained by any party that holds the transcript of the messages between the sender and receiver from the commitment stage. In particular, this party need not know the random coins used by the receiver during the commitment. More formally, the specification of a commitment scheme consists of two sender protocols and two receiver protocols: one protocol for the commit phase and one for the reveal phase. In general, the input of a protocol in the reveal phase may be the *entire view* of the corresponding party from the protocol of the commit phase. We say that a commitment scheme satisfies public decommitment if the input of the *receiver* protocol in the reveal phase may consist merely of the *transcript of messages* sent by the parties in the commit phase, and nothing else. That is, see the following definition.

DEFINITION 3.2 (commitment schemes with public decommitment). *A commitment scheme satisfies* public decommitment *if the receiver's decision in the reveal phase depends only on the transcript of messages sent between the parties.*

This notion is analogous to that of "publicly verifiable" protocols, as described in section 2.3. (Again, as described in section 2.3, any perfectly binding commitment scheme can be modified into one that provides public decommitment by having the receiver send its random coins at the conclusion of the commitment phase. However, this may affect other properties of the commitment scheme. Indeed, the extractor for our commit-with-extract scheme would fail to generate a view that is indistinguishable from the sender's view, as required in Definition 3.1, if the receiver were required to send all of its random coins when the commitment phase concludes.) We use the additional feature of public decommitment for constructing a zero-knowledge argument of knowledge from a commit-with-extract scheme.

3.2. Constant-round commit-with-extract. In this section we show how to construct a constant-round commit-with-extract commitment scheme. That is, we prove the following theorem.

THEOREM 3.3. *Assume the existence of collision-resistant hash functions and collections of trapdoor permutations such that the domain of each permutation is the set of all strings of a certain length.*[11] *Then, there exist constant-round commit-with-extract string commitment schemes satisfying public decommitment.*

Before presenting our scheme, we note that it suffices to present a scheme that is perfectly binding, *except with negligible probability* (where the probability is taken over the coins of the receiver). A perfectly binding scheme (with no error) can then be obtained by augmenting the commitment phase with an additional perfectly binding commitment. Specifically, the sender will commit to the same value twice, once using

[11] See footnote 3.

a perfectly binding scheme (that does not enable extraction but is perfectly binding with no error), and once using a commit-with-extract scheme (that enables extraction but has a negligible error with respect to binding). The decommitment phase is then also modified so that both commitments must be opened. The result is a commit-with-extract scheme that is perfectly binding with no error. (We note that perfect binding with negligible error usually suffices, and so no such augmentation is really necessary.)

We now present our construction. In order to simplify the presentation, we start by showing a commit-with-extract *bit* commitment scheme and then show how to generalize our construction to a *string* commitment scheme. Our protocol is based on the following well-known noninteractive commitment scheme that uses one-way permutations [8]: Let f be a one-way permutation over $\{0,1\}^n$ and let b be a hard-core predicate of f. Then, in order to commit to a bit σ, the sender chooses $r \in_R \{0,1\}^n$, lets $y = f(r)$, and sends $\langle y, b(r) \oplus \sigma \rangle$ to the receiver. Loosely speaking, our commitment scheme is similar except that the value y is chosen *jointly* by the sender and the receiver using a coin-tossing protocol (which is based on the coin-tossing protocol of [31]). Since y is uniformly distributed, the hiding property remains as in the original scheme. Likewise, because f is a permutation, y defines a unique value $b(f^{-1}(y))$ and thus the scheme remains perfectly binding. The novelty of our scheme is that for every sender, there exists an extractor that can bias the coin-tossing protocol such that it concludes with a value y for which the extractor knows the preimage $r = f^{-1}(y)$. In this case, the extractor can easily obtain the commitment value σ, as desired.

In order to allow the sender to be implementable by an efficient algorithm, we choose f to be a *trapdoor* one-way permutation. Thus, the sender is able to efficiently compute $r = f^{-1}(y)$, where y is the output of the coin-tossing protocol (this is similar to the noninteractive zero-knowledge protocol constructed in [16]). Formally, the protocol is parameterized by a family of trapdoor permutations over $\{0,1\}^n$, with a function sampling algorithm I. We denote a permutation from the family by f and its associated trapdoor by t. Furthermore, we denote by b a hard-core of f.

One of the components of the protocol is a constant-round zero-knowledge argument with a *strict* polynomial-time simulator. We note that such an argument exists if collision-resistant hash functions exist [3, 4]. As we have mentioned above, another component of our commit-with-extract protocol is a coin-tossing subprotocol that is based on the protocol of [31]. We do not plug in the exact protocol of [31] (while replacing the zero-knowledge proofs with those that run in strict polynomial-time), because its proof of security uses *extraction* from a proof of knowledge, and no proof of knowledge with strict polynomial-time extraction was previously known (indeed, providing such a proof is the aim of our construction).

PROTOCOL 3.4 (commit-with-extract bit commitment scheme).

- **Input:** *The sender has a bit σ to be committed to.*
- **Commit phase:**
  1. A chooses a trapdoor permutation:
     (a) *The sender A chooses a trapdoor permutation f along with its trapdoor t (by running the sampling algorithm I on a uniformly chosen string $s_I \in_R \{0,1\}^n$), and sends f to the receiver B.*
     (b) *A proves to B that f is a permutation, using any constant-round zero-knowledge proof or argument (even one with an expected polynomial-time simulator). For example, if I is such that it outputs a permutation with probability 1, then A may prove that there exists*

a string s_I such that f is the permutation output from $I(s_I)$.[12] *If B does not accept the proof, then it aborts.*

2. A and B run a coin-tossing protocol:
   (a) *B chooses a random string $r_1 \in_R \{0,1\}^n$ and sends $c = \mathsf{Commit}(r_1; s)$ to A (where $\mathsf{Commit}(\cdot)$ denotes any perfectly binding commitment scheme, and $\mathsf{Commit}(r_1; s)$ denotes a commitment to value r_1 using random coins s).*
   (b) *A chooses a random string $r_2 \in_R \{0,1\}^n$ and sends r_2 to B.*
   (c) *B sends r_1 to A (without decommitting).*
   (d) *B proves that the string r_1 sent in Step 2(c) is indeed the value that it committed to in Step 2(a), using a constant-round zero-knowledge argument with a* strict *polynomial-time simulator. Formally, B proves that there exists a string s such that $c = \mathsf{Commit}(r_1; s)$.*
   (e) *The output of the coin-tossing phase is $r_1 \oplus r_2$.*
3. A sends the actual commitment:
   A computes $r = f^{-1}(r_1 \oplus r_2)$ and sends B the value $v = b(r) \oplus \sigma$.

- **Reveal phase:**
  1. *A sends B the string r.*
  2. *B checks that $f(r) = r_1 \oplus r_2$. If this is the case, then B computes $b(r) \oplus v$ obtaining σ. Otherwise, B outputs $\perp$.*

(By convention, if the commit phase of the protocol is not completed, then the committed value is defined to equal 0.) We now prove that Protocol 3.4 is a secure commit-with-extract commitment scheme. We first show that it is a secure *commitment scheme*. This involves demonstrating both the binding and hiding properties. Intuitively, these properties hold because the only difference between the above protocol and the basic commitment scheme defined by $C_n(\sigma; r) \stackrel{\text{def}}{=} \langle f(r), b(r) \oplus \sigma \rangle$ for $r \in_R \{0,1\}^n$ is that the random string r is chosen via a coin-tossing protocol (rather than being determined by the sender).

PROPOSITION 3.5. *Protocol* 3.4 *is a secure bit commitment scheme with public decommitment.*

Proof. We first claim that Protocol 3.4 satisfies public decommitment (see Definition 3.2). This is due to the fact that the only information needed by B to verify A's decommitment is the pair of strings r_1 and r_2 that appear in the transcript between A and B from the commit phase.

Next, we prove the (almost) perfect binding property. That is, we show that except with negligible probability, for any transcript of messages trans generated by an execution between an arbitrary probabilistic polynomial-time sender A^* and the honest receiver B, there exists a *unique* value $\sigma \in \{0,1\}$ such that $\mathsf{commit\text{-}value}(\mathsf{trans}) = \sigma$. Intuitively, the perfect binding property holds as long as the function f sent by A^* is a permutation. This is the case because when f is a permutation, the values r_1 and r_2 in the transcript define a unique value $r = f^{-1}(r_1 \oplus r_2)$, which in turn uniquely defines the value $\sigma = v \oplus b(r)$. The formal argument follows.

First, note that if B does not accept the proof provided by A^* in Step 1(b), then B will abort and then, by convention, σ equals 0. Likewise, if A^* does not complete

[12] We note that by using the primality testers of [28] or [1], for example, the sampling algorithms for both the RSA and Rabin families of trapdoor permutations can be made to output a permutation with probability 1. In the case that the sampling algorithm does not output a permutation with probability 1, a different method of proving that f is a permutation is needed. General methods for achieving this can be found in [7].

the entire commit phase, σ also equals 0. Therefore, the binding property trivially holds in these cases. We continue to show that it holds when B does not abort and the commit phase is completed.

Now, assume that the function f sent by A^* is a permutation. In this case, any pair of strings r_1 and r_2 appearing in the transcript define a single preimage $r = f^{-1}(r_1 \oplus r_2)$. Therefore, any bit v sent by A^* in Step 3 defines a single value $\sigma = v \oplus b(r)$. That is, the values r_1, r_2, and v in the transcript define a single committed value σ, as required. This, however, holds only as long as f is a permutation (otherwise, there may be more than one possible preimage to $r_1 \oplus r_2$). By the soundness of the proof (or argument) of Step 1(b), we have that the probability that f is not a permutation is at most negligible. We therefore conclude that, except with negligible probability, the transcript defines a single committed value.

We now turn to the computational hiding property. Intuitively, the hiding property follows from the hiding property of the noninteractive commitment scheme of [8] and the security of the coin-tossing protocol. In particular, if $r_1 \oplus r_2$ is uniform (or pseudorandom), then distinguishing between a commitment to 0 and a commitment to 1 is essentially equivalent to distinguishing between $\{f(U_n), b(U_n)\}$ and $\{f(U_n), b(U_n) \oplus 1\}$. Since b is a hard-core of f, it is infeasible to distinguish between these distributions in polynomial time. The hiding property therefore follows from the security of the coin-tossing protocol that ensures that $r_1 \oplus r_2$ is pseudorandom.

In the above intuition, the security of the coin-tossing protocol is reduced to a single instance of a commitment. However, in the actual proof, we reduce the indistinguishability of our commitment scheme to the indistinguishability of *multiple samples* of the basic commitment scheme relative to a single permutation f. That is, we show that distinguishing between a commitment to 0 and a commitment to 1 is equivalent to distinguishing between the random variables X_0^m and X_1^m, where $X_\sigma^m = \langle f, f(U_n^{(1)}), b(U_n^{(1)}) \oplus \sigma, \ldots, f(U_n^{(m)}), b(U_n^{(m)}) \oplus \sigma \rangle$, where f is a trapdoor one-way permutation, b is a hard-core bit for f, and $m = \text{poly}(n)$. One can use a standard hybrid argument to show that X_0^m and X_1^m are computationally indistinguishable.

Formally, for any polynomial-size receiver B^*, denote by $v_n^{B^*}(\sigma)$ the distribution over B^*'s view, when the honest sender A commits to the value σ (the distribution is over the uniform choice of random coins for A). Then, the hiding property is stated as follows: for any polynomial-size receiver B^*, it holds that

$$\left\{v_n^{B^*}(0)\right\}_{n\in\mathsf{N}} \stackrel{\text{c}}{\equiv} \left\{v_n^{B^*}(1)\right\}_{n\in\mathsf{N}}.$$

Assume by contradiction that there exists a polynomial-size receiver B^*, a polynomial-time distinguisher D, and a polynomial $p(\cdot)$ such that for infinitely many n's

$$\mathsf{adv}_n^D \stackrel{\text{def}}{=} \left|\Pr[D(v_n^{B^*}(0)) = 1] - \Pr[D(v_n^{B^*}(1)) = 1]\right| \geq \frac{1}{p(n)}. \tag{3.1}$$

We will use D and B^* to construct a distinguisher D' that will distinguish between the random variables X_0^m and X_1^m mentioned above, for $m = 5p(n)$. To get an intuition for the operation of D', consider the case in which B^* doesn't behave in an ostensibly faulty way (i.e., B^* does not "abort" the computation). If this is the case, we can actually construct a distinguisher D' for the basic commitment scheme (i.e., a distinguisher between X_0^1 and X_1^1). The distinguisher D' receives a commitment $C_n(\sigma) = \langle f(r), b(r) \oplus \sigma \rangle$ for input (where $r \in_R \{0,1\}^n$) and works by invoking B^* and running an execution of Protocol 3.4 with B^*, until B^* sends a commitment

$c = \mathsf{Commit}(r_1; s)$ as part of the coin-tossing protocol. At this point, D' learns r_1 by running the continuation of the coin-tossing protocol with B^*. After learning r_1, algorithm D' rewinds B^* back to the point after B^* sent the commitment to r_1, and then D' feeds B^* with the message $r_2 = f(r) \oplus r_1$, where $f(r)$ is the first part of its input commitment $C_n(\sigma) = \langle f(r), b(r) \oplus \sigma \rangle$. The result of the coin-tossing protocol is thus $r_1 \oplus r_2 = f(r)$, which means that as the final message D' can send B^* its input $b(r) \oplus \sigma$. We see that if D distinguishes between the result of this experiment when $\sigma = 0$ and when $\sigma = 1$, then D' breaks the basic commitment scheme C_n and distinguishes between X_0^1 and X_1^1. Unfortunately, the fact that B^* may ostensibly misbehave makes the formal proof somewhat more complicated than this description. We are now ready for the formal description of the distinguisher D'.

Distinguisher D' receives for input a trapdoor one-way permutation f and a sequence

$$\langle f, f(r^{(1)}), b(r^{(1)}) \oplus \sigma, \ldots, f(r^{(m)}), b(r^{(m)}) \oplus \sigma \rangle,$$

where $r^{(1)}, \ldots, r^{(m)}$ are independently and randomly distributed in $\{0,1\}^n$. Algorithm D' then simulates an execution of A with B^* as follows:

1. *Simulation of A choosing a trapdoor permutation*:
   (a) D' passes B^* the permutation f that it was given as part of its input.
   (b) D' runs the zero-knowledge simulator (for the proof that f is a permutation) using the residual B^* as the verifier.[13]
2. *Sample an execution of the coin-tossing protocol*:
   (a) D' receives a commitment c from B^* (c is supposed to equal $\mathsf{Commit}(r_1)$ for some r_1).
   (b) D' chooses a random string $r_2 \in_R \{0,1\}^n$ and passes it to B^*.
   (c) D' obtains some string r_1 from B^*.
   (d) D' verifies the zero knowledge argument given by B^*. If D' accepts the argument from B^*, then it continues. Otherwise, D' sets Z to be the partial transcript until the point that the execution aborted and jumps to Step 5.
3. *Iterate until successful simulation*: D' does the following for $i = 1, 2, \ldots, m$:
   (a) D' rewinds B^* to the point after B^* sent the commitment c (i.e., Step 2(a)) and sends B^* the string $r_2 = f(r^{(i)}) \oplus r_1$, where r_1 is the value obtained in Step 2(c), and $f(r^{(i)})$ comes from D''s input sequence.
   (b) D' obtains some string r_1' from B^* and verifies the zero knowledge argument given by B^*. There are three possibilities at this point:
      i. If D' does not accept the argument from B^*, then it lets $i \leftarrow i + 1$ and continues on to the next iteration (i.e., it returns to Step 3(a)). If the maximum number of attempts have elapsed (i.e., if $i = m$), then D' halts and outputs fail.
      ii. If D' does accept the argument from B^* but $r_1' \neq r_1$, then D' halts and outputs fail.
      iii. If D' accepts the argument from B^* and $r_1' = r_1$, then D' proceeds to Step 4 below.

[13] Note that *any* constant-round zero-knowledge proof or argument may be used for this step in the protocol. Therefore, the simulation of this argument by D' may require expected (rather than strict) polynomial-time. We therefore obtain a distinguisher that runs in expected polynomial-time. This suffices here because in the context of distinguishing commitments (or solving a hard problem), it is possible to truncate D''s execution without lowering its success below what is needed for deriving a contradiction.

4. *Simulation of the actual commitment*: D' passes the bit $v^i = b(U_n^{(i)}) \oplus \sigma$ (from its input sequence) to B^*. Algorithm D' lets Z denote the transcript of the simulated execution and proceeds to Step 5.
5. *Output*: D' passes the transcript Z of the simulated execution to D and outputs whatever D does.
   (We stress that this transcript (as passed by D' to D) may not be complete, as in the case that D' does not accept the argument from B^* in Step 2(d).)

To prove that D' distinguishes between X_0^m and X_1^m with nonnegligible probability, it suffices to prove the following claim:

CLAIM 3.5.1. *Let Z_σ be the random variable that denotes the simulated transcript that D' feeds to D in Step* 5*, when D gets X_σ^m as input. Let Y_σ be the random variable that denotes the view of B^* in an interaction with the sender A when the sender commits to σ. Then Z_σ and Y_σ are $\frac{2}{m}$-computationally indistinguishable. That is, for every polynomial-sized circuit C,*

$$\Big|\Pr[C(Z_\sigma) = 1] - \Pr[C(Y_\sigma) = 1]\Big| < \frac{2}{m}.$$

Claim 3.5.1 is sufficient to show that D' distinguishes between X_0^m and X_1^m because our contradiction hypothesis is that (for infinitely many n's) the distinguisher D distinguishes between Y_0 and Y_1 with gap $\frac{1}{p(n)} = \frac{5}{m}$. Thus, Claim 3.5.1 implies that D will also distinguish between Z_0 and Z_1 with gap at least $\frac{1}{m}$, and hence D' will distinguish between X_0^m and X_1^m with this gap (in contradiction to their computational indistinguishability). We now prove the claim.

To prove Claim 3.5.1, we will use a hybrid argument with two intermediate random variables $\tilde{Z}_\sigma$ and $\hat{Z}_\sigma$ that are computationally indistinguishable from Z_σ and Y_σ, respectively. We then show that $\tilde{Z}_\sigma$ and $\hat{Z}_\sigma$ are $1/m$-indistinguishable.

The random variable $\tilde{Z}_\sigma$. The random variable $\tilde{Z}_\sigma$ is defined to be the result of the following process: Let $\tilde{D}$ be an algorithm that behaves exactly like D' except for the following two differences. First, instead of using a *simulated* zero-knowledge proof in Step 1(b), it uses the honest prover algorithm (we assume that $\tilde{D}$ is given the trapdoor information for the one-way permutation). Second, if $\tilde{D}$ accepts the argument from B^* but $r_1' \neq r_1$, as in Step 3(b)ii, then it does *not* output fail. Rather, it proceeds to Step 4 and uses its knowledge of the trapdoor in order to complete the commitment like an honest committer (note that $\tilde{D}$ can derive the value of σ from its input sequence because it knows the trapdoor). We define $\tilde{Z}_\sigma$ to be the corresponding value computed by $\tilde{D}$ on input X_σ^m in Step 5.

Assuming that $\tilde{D}$ does not accept the argument from B^* when $r_1' \neq r_1$ (i.e., the case in Step 3(b)ii does not happen), the random variable $\tilde{Z}_\sigma$ is computationally indistinguishable from Z_σ because the only difference is whether the zero-knowledge protocol of Step 1(b) is simulated or real. It therefore suffices to show that the probability that $\tilde{D}$ accepts an argument from B^* when $r_1' \neq r_1$ is at most negligible (i.e., the case in Step 3(b)ii happens with at most negligible probability). In order to see this, notice that the case in Step 3(b)ii happens if $r_1 \neq r_1'$ and, in addition, $\tilde{D}$ accepted an argument from B^* that $c = \mathsf{Commit}(r_1)$ (in Step 2(d)) and also an argument from B^* that $c = \mathsf{Commit}(r_1')$ (in Step 3(b)). However, the commitment c that $\tilde{D}$ receives from B^* in Step 2(a) is perfectly binding. Therefore, c defines a single decommitment value; in particular, it cannot be a commitment to both r_1 and r_1'. This means that one of the statements $c = \mathsf{Commit}(r_1)$ and $c = \mathsf{Commit}(r_1')$ is *false*. Therefore, by the soundness of the zero-knowledge argument, $\tilde{D}$ will accept both

arguments from B^* (in Steps 2(d) and 3(b)) with at most negligible probability. We conclude that for large enough n, no polynomial-sized circuit can distinguish between $\tilde{Z}_\sigma$ and Z_σ with nonnegligible probability.

The random variable $\hat{Z}_\sigma$. The random variable $\hat{Z}_\sigma$ is defined by considering the output of the algorithm $\hat{D}$. This algorithm behaves like $\tilde{D}$ except that it does not halt after m iterations. Rather, it continues until it accepts the argument from B^* in Step 3(b) (irrespective of whether or not $r_1 = r_1'$). According to the above description, in the ith iteration, algorithm $\tilde{D}$ sends $r_2 = f(r^{(i)}) \oplus r_1$ to B^*. Thus, for the first $i \leq m$ iterations $\hat{D}$ works in the same way as $\tilde{D}$ and also sends $r_2 = f(r^{(i)}) \oplus r_1$ to B^*. However, if $\hat{D}$ exceeds m iterations, it cannot compute r_2 in this way (because its input includes only m commitments of the form $\langle f(r^{(i)}), b(r^{(i)}) \oplus \sigma \rangle$). Rather, it chooses r_2 uniformly at random (like the honest committer) and sends it to B^*. Then, if it accepts the argument from B^*, algorithm $\hat{D}$ proceeds to Step 4, computes $f^{-1}(r_1 \oplus r_2)$, and commits to σ like the honest committer. (Recall that, like $\tilde{D}$, machine $\hat{D}$ knows the trapdoor and so it can compute f^{-1} and can also obtain the value σ from its input sequence of commitments.) We stress that $\hat{D}$ uses fresh random choices for r_2 in every iteration $i > m$.

We claim that the statistical distance between $\hat{Z}_\sigma$ and $\tilde{Z}_\sigma$ is at most $\frac{1}{m}$. Indeed, one can see that the expected number of iterations that algorithm $\hat{D}$ runs is at most 1: let π be the partial execution of the protocol obtained by $\hat{D}$ until the point that B^* sends the commitment to r_1, and let p_π be the probability that B^* successfully proves the argument to $\hat{D}$, when continuing from the partial execution π. Then, the probability that $\hat{D}$ enters Step 3 equals p_π (because if B^* does not convince $\hat{D}$ in Step 2(d), then $\hat{D}$ does not enter Step 3). Now, within the iterations of Step 3, the probability that B^* convinces $\hat{D}$ is exactly p_π. Therefore, given that $\hat{D}$ enters Step 3, the expected number of iterations is $\frac{1}{p_\pi}$. We conclude that the overall expected number of iterations made by $\hat{D}$ in Step 3 conditioned on the initial partial execution being π equals $p_\pi \cdot \frac{1}{p_\pi} = 1$. Averaging over all partial executions we obtain that the overall expected number of repetitions is also 1, and thus by Markov's inequality, we have that the probability that $\hat{D}$ will require more than m iterations is less than $\frac{1}{m}$. Notice finally that if $\hat{D}$ does not require more than m iterations, then it generates exactly the same distribution as $\tilde{D}$. Therefore, the statistical difference between $\tilde{Z}_\sigma$ and $\hat{Z}_\sigma$ is at most $\frac{1}{m}$.

Comparing $\hat{Z}_\sigma$ with Y_σ. Finally, we claim that the random variable $\hat{Z}_\sigma$ is identical to the variable Y_σ, which denotes the transcript of a real execution. In order to see this, observe that $\hat{D}$ essentially does the following. It first samples a partial execution until the point that B^* sends its commitment to r_1 (this sample is identical to a real execution). Next, it samples the remainder of the execution. If B^* does not convince $\hat{D}$ in the argument that it provides in this sample, then $\hat{D}$ outputs the transcripts and halts. In contrast, if B^* does convince $\hat{D}$ in this sample, then $\hat{D}$ continues until it obtains another sample in which B^* is convincing (all of this sampling is identical to a real execution). Assuming that $\hat{D}$ eventually halts, we have that the result is identical to Y_σ. The fact that $\hat{D}$ eventually halts follows from the fact that it enters Step 3 only if there is a nonzero probability of B^* convincing $\hat{D}$.

Combining the above, we have that the random variables Z_σ and Y_σ can be distinguished with advantage at most $\frac{1}{m} + \mu(n) < \frac{2}{m}$. With this the proof of Claim 3.5.1, and hence the proof of the computational hiding property, is completed. □

Having proven that Protocol 3.4 is a secure commitment scheme, we proceed to show that it is also a *commit-with-extract* scheme, by demonstrating the existence of

a *strict* polynomial-time extractor.

PROPOSITION 3.6. *Protocol* 3.4 *constitutes a commit-with-extract commitment scheme.*

Proof. Intuitively, the extractor CK works by biasing the outcome $r_1 \oplus r_2$ of the coin-tossing protocol such that it knows the preimage under f. More specifically, CK chooses a random string r, computes $f(r)$, and then makes the output $r_1 \oplus r_2$ equal $f(r)$. This is clearly not possible for a real receiver (as the coin-tossing protocol ensures that $f(r)$ is pseudorandom). However, recall that CK has the description of the sender A^*, and therefore has more power than a real receiver. In particular, this gives CK the capability of running the simulator for the proof that B provides in Step 2(d) of the protocol. As we will see, this is enough.

Recall that CK should output a view indistinguishable from the one seen by A^* in a real interaction, as well as the unique commitment value defined by this view. Extractor CK receives the description of an arbitrary polynomial-time sender A^* and a triple (x, y, r), and works as follows:

1. *A^* chooses a trapdoor permutation*:
   (a) CK invokes $A^*(x, y, r)$ and receives the description of a permutation f from A^*.
   (b) Next, CK verifies the zero-knowledge proof from A^* attesting to the fact that f is a permutation. If the verification fails, then CK outputs A^*'s view until this point along with the value 0, and halts. (CK outputs 0 because, by our convention, in an aborted execution this is the default committed value.)
2. *CK biases the outcome of the coin-tossing protocol*:
   (a) CK passes $c = \mathsf{Commit}(0^n)$ to A^* (this is a commitment to "garbage").
   (b) CK obtains a string r_2 from A^*.
   (c) CK chooses $r \in_R \{0,1\}^n$, computes $f(r)$, and passes A^* the string $r_1 = f(r) \oplus r_2$. (Notice that r_1 is distributed uniformly and independently of the initial commitment c, and that $f^{-1}(r_1 \oplus r_2) = r$.)
   (d) CK invokes the zero-knowledge simulator, with the residual A^* as the verifier, for the appropriate (false) statement that there exists a string s such that $c = \mathsf{Commit}(r_1; s)$.
3. *A^* sends the actual commitment*:
   CK receives a bit v from A^*.
4. *Output*: CK outputs A^*'s view of the above execution along with $\sigma = b(r) \oplus v$.

We first claim that CK extracts the bit committed to in the execution (we focus on the case that A^* does not abort; otherwise the claim trivially holds). This is immediate because CK knows the preimage under f of $f(r_1 \oplus r_2) = f(r)$. Therefore, $b(r) \oplus v$ is exactly the unique value committed to by A^*. (The above assumes that f is indeed a permutation. However, by the soundness of the zero-knowledge argument of Step 1(b), it can only occur that f is not a permutation with negligible probability.)

Next, we show that the view output by CK is computationally indistinguishable from A^*'s view in a real execution. These two distributions differ in two aspects: first, the commitment received by A^* in Step 2(a) is to 0^n rather than to r_1. Second, the zero-knowledge argument verified by A^* in Step 2(d) is simulated rather than real. Using a standard hybrid argument, computational indistinguishability can be shown. Specifically, define a hybrid experiment whereby A^* receives a commitment to r_1 (instead of to 0^n), and yet the zero-knowledge proof that it verifies is simulated. Then, by the hiding property of commitment schemes, A^*'s view in the hybrid experiment is indistinguishable from its view output by CK. On the other hand, by the

indistinguishability of zero-knowledge simulation, A^*'s view in the hybrid experiment is indistinguishable from its view in a real execution. We conclude that CK outputs a view that is indistinguishable from A^*'s view in a real execution.

It remains to show that CK runs in strict polynomial-time. However, this immediately follows from the above description and from the fact that the zero-knowledge simulator used by CK runs in strict polynomial-time. This completes the proof. □

We note that any constant-round zero-knowledge argument system with a strict polynomial-time simulator suffices for Step 2(d) of Protocol 3.4. However, the only known such argument system is that of [3] (or its modified version in [4]) and this system utilizes a *nonblack-box* simulator. Since the extractor must run this simulator, it follows that it is also nonblack-box. As we will see in section 5, this is in fact necessary for obtaining a constant-round protocol with strict polynomial-time extraction. (Recall that any constant-round zero-knowledge protocol suffices for Step 1(b), even one with expected polynomial-time simulation.)

Extending Protocol 3.4 *to strings.* To prove Theorem 3.3 we need to generalize Protocol 3.4 to allow commitments to strings of length m (where m is polynomial in the security parameter n), instead of just allowing commitments to single bits. This extension can be obtained in two ways. First, one can simply run Protocol 3.4 in parallel m times (taking care that the zero-knowledge arguments used are closed under the parallel composition of m executions, as is the case with the bounded-concurrent zero-knowledge protocol of [3, 4]). Alternatively, one can directly modify Protocol 3.4 and have A and B run m copies of the coin-tossing protocol in parallel, and then use only a single zero-knowledge argument to prove a compound statement relating to all copies.

Discussion—knowledge versus extraction. As we have mentioned, the notion of a commitment scheme with the additional property that the committed value can be extracted from the sender is not new. However, all previous constructions worked by first committing to a value and then proving knowledge of this committed value. In contrast, Protocol 3.4 works in a completely different way: it does not consist of two distinct "commit" and "knowledge/extract" phases; rather the commitment and extraction are intertwined. Interestingly, this results in a subtle, yet important difference.

In order to exemplify this, consider the following sender A^*. Sender A^* obtains a one-way permutation and erases the corresponding trapdoor. Then, in Step 3 of Protocol 3.4, A^* sends a *random* bit $b \in \{0,1\}$ to B. Otherwise, A^* follows the instructions for A (and successfully concludes the commit stage). The important observation here is that since $r_1 \oplus r_2$ is uniformly distributed, A^* cannot guess the value of the bit that it itself committed to with probability nonnegligibly greater than 1/2. This is very strange, especially considering the fact that extraction is supposed to imply "knowledge."

Such a phenomenon cannot occur in an extractable commitment scheme that uses separate commit and extract phases. This is because the committed value is determined *before* the extraction begins. Therefore, the sender can apply the extractor to itself and thereby obtain the committed value. Thus, it makes sense to say that the sender "knows" the committed value. However, in our protocol, the committed value is determined only at the *conclusion* of the protocol. Furthermore, the value that is committed to may also depend on the random coins of the receiver B (as is indeed the case for the above-described sender A^*). Therefore, it is not possible for the sender to later "apply the extractor to itself in order to obtain the committed value."

Thus, on one hand, it seems that the intuition that the sender "knows" the

committed value cannot be justified here. On the other hand, it seems that for applications that use such schemes, it suffices to extract the actual committed value, irrespective of whether or not the value is predetermined.

Open problem. Our construction of a commit-with-extract scheme requires trapdoor permutations (for finding the preimage to $r_1 \oplus r_2$), and collision-resistant hash functions (for the constant-round zero-knowledge argument with strict polynomial-time simulation [3, 4]). In contrast, when the commitment extractor may run in *expected* polynomial-time or when a *nonconstant* number of rounds may be tolerated, such a scheme can be constructed based on one-way functions only. This raises an interesting question as to whether a constant-round commit-with-extract scheme can be constructed from one-way functions only.

4. A zero-knowledge argument of knowledge. Given a constant-round commit-with-extract commitment scheme, it is not hard to construct a constant-round zero-knowledge argument of knowledge with strict polynomial-time extraction, thereby proving Theorem 1.1. The basic idea is that the prover commits to a witness using the commit-with-extract scheme, and then proves that it has committed to a valid witness using a zero-knowledge proof of membership. Intuitively, soundness follows from the soundness of the zero-knowledge proof of membership and from the fact that the commit-with-extract scheme is perfectly binding. Zero knowledge follows from the hiding property of the commit-with-extract scheme and from the zero-knowledge property of the proof of membership. Lastly, a knowledge extractor is immediately obtained from the extractor of the commit-with-extract scheme. Details follow.

Let R be an NP-relation. Without loss of generality, we assume that all witnesses for R are of the same length. We construct a zero-knowledge argument of knowledge for R as follows.

PROTOCOL 4.1 (zero-knowledge argument of knowledge for R).

- Common input: x.
- Auxiliary input to prover: *w such that $(x, w) \in R$.*
- Phase 1: *P and V run a commit-with-extract protocol (with public decommitment) in which P commits to the witness w.*
- Phase 2: *P proves to V, using a* constant-round *zero-knowledge proof (or argument) of membership (with a strict polynomial-time simulator) that it has committed to a valid witness w in the previous step.*
  Formally, let trans *be the transcript of the commit-with-extract execution of Phase* 1*, and let d be the decommitment message that P would send to V in the decommit phase of the commit-with-extract scheme. Then, P proves the NP-statement that there exists a value d such that* (trans, d) *defines a value w, such that $(x, w) \in R$.*[14]

In Phase 2, we use a zero-knowledge argument system with a strict polynomial-time simulator so that the resulting protocol will be a zero-knowledge argument of knowledge with both a strict polynomial-time extractor and a strict polynomial-time simulator. If the system used in Phase 2 has an *expected* polynomial-time simulator, then the resulting protocol will have a strict polynomial-time knowledge extractor but an *expected* polynomial-time simulator.

Theorem 1.1 is obtained by combining the following proposition with Theorem 3.3 (i.e., the existence of commit-with-extract schemes).

[14]Here we use the assumption that the commit-with-extract scheme satisfies public decommitment as in Definition 3.2. Otherwise, the statement that P needs to prove is not guaranteed to be in $\mathcal{NP}$.

PROPOSITION 4.2. *Assume that the commitment scheme of Phase* 1 *is a* constant-round *commit-with-extract string commitment scheme. Then, Protocol* 4.1 *is a* constant-round *zero-knowledge argument of knowledge for* R*, as defined in Definitions* 2.1 *and* 2.2 *(i.e., it has a strict polynomial-time simulator and a strict polynomial-time knowledge extractor). Furthermore, there exists a witness-extended emulator for Protocol* 4.1*, as defined in Definition* 2.3.

Proof. In order to prove that Protocol 4.1 is a zero-knowledge argument of knowledge, we prove three properties: completeness, knowledge soundness (which implies computational soundness), and zero knowledge. The proof of completeness is immediate. We proceed to prove zero knowledge and knowledge soundness.

Zero knowledge. The simulator S that we build to demonstrate the zero-knowledge property works as follows. In Phase 1 of the protocol, S follows the honest sender strategy of the commit-with-extract scheme, but instead of committing to a real witness w (which it does not have), it commits to garbage (e.g., to all zeros). Next, in Phase 2, simulator S cannot prove that it committed to a correct witness (because it indeed did not). Rather, S runs the simulator for the zero-knowledge proof of Phase 2. The hiding property of the commit-with-extract scheme implies that the commitment to garbage is indistinguishable from a commitment to a real witness. In addition, the zero-knowledge property of the proof of membership implies that the simulation is indistinguishable from a real proof of membership. Combining these together (and using a standard hybrid argument), we obtain that the overall simulation by S is indistinguishable from a real execution of Protocol 4.1. Formally, let V^* be a verifier algorithm for Protocol 4.1. Then the simulator S works as follows.

ALGORITHM 4.3 (simulator S).

- Input: $x \in L$, $z \in \{0,1\}^*$.

1. *S plays the honest sender for the commit-with-extract scheme with $V^*(x,z)$ as the receiver, and commits to $0^{p(|x|)}$ (where $p(n)$ is the length of all witnesses for statements of length n).*
2. *Let* trans *be the series of messages sent to V^* in the previous step, and denote by $V^*(x,z,\mathsf{trans})$ the residual machine that verifies the proof in Phase* 2.[15] *Then, S runs the simulator for the zero-knowledge proof of Phase* 2*, with $V^*(x,z,\mathsf{trans})$ as the verifier.*
3. *Output whatever V^* outputs (without loss of generality, we assume that V^* always outputs its view).*

We need to prove that

$$\{S(x,z)\}_{x\in L, z\in\{0,1\}^*} \stackrel{\mathrm{c}}{\equiv} \{\mathsf{view}_{V^*}(P(x,y),V^*(x,z))\}_{x\in L, y\in R_L(x), z\in\{0,1\}^*},$$

where P is the honest prover algorithm. This is proven using a standard hybrid argument. We define an intermediate distribution $H_{x,y,z}$ in the following way: $H_{x,y,z}$ is produced by an algorithm S' that follows the honest prover's strategy in the first phase and the simulator's strategy in the second phase (in order to enable it to run the honest prover's strategy in the first phase, it is explicitly given a valid witness y). That is, on input (x,y,z), where $(x,y) \in R$, algorithm S' runs the commit-with-extract algorithm and commits to the value y as the honest prover does (instead of to $0^{p(|x|)}$ as the simulator S would). However, in Phase 2, algorithm S' runs the zero-

[15] The residual machine $V^*(x,z,\mathsf{trans})$ is formally defined as the machine that upon receiving a sequence of messages $(\alpha_1,\ldots,\alpha_i)$ replies with the message that $V^*(x,z)$ would send upon receiving the sequence of messages $(\mathsf{trans},\alpha_1,\ldots,\alpha_i)$.

knowledge simulator on $V^*(x, z, \mathsf{trans})$ exactly as S does (instead of really proving the statement as the honest prover would).

The fact that $\{S(x,z)\} \stackrel{c}{\equiv} \{H_{x,y,z}\}$ follows directly from the hiding (secrecy) property of the commit-with-extract scheme. The fact that $\{H_{x,y,z}\} \stackrel{c}{\equiv} \{\mathsf{view}_{V^*}(P(x,y), V^*(x,z))\}$ follows directly from the (auxiliary-input) zero-knowledge property of the proof of membership used in Phase 2. These two facts together imply that $\{S(x,z)\} \stackrel{c}{\equiv} \{\mathsf{view}_{V^*}(P(x,y), V^*(x,z))\}$, as required.

We note that the simulator S inherits the properties of the underlying simulator for the proof of Phase 2. Thus, if the underlying simulator is strict polynomial-time and nonblack-box, then so too is S. On the other hand, if the underlying simulator is black-box or runs in expected polynomial-time, then the same is true for S.

Knowledge soundness. Let P^* be a (possibly cheating) prover that convinces the honest verifier that $x \in L$ with probability ϵ. The extractor for the zero-knowledge argument simply uses the extractor CK of the commit-with-extract scheme in order to obtain P^*'s view of the first phase, along with a string w that is the unique value that is committed to in this phase. Intuitively, w must be a valid witness with probability at least $\epsilon - \mu(|x|)$, for some negligible function $\mu(\cdot)$. This holds because in Phase 2 of the protocol, P^* proves the validity of the committed witness. It then follows from the soundness of the proof of membership that if w is not a valid witness, the verifier rejects (except with negligible probability). In the formal proof of this, we also use the fact that P^* "behaves" in a similar way in its interaction with CK and in a real interaction with the honest verifier. (If this was not the case, then P^* may always convince V, but never commit to a valid witness with CK. The extractor CK would then never extract a valid witness from P^*.) We note that this fact regarding the similarity of P^*'s behavior with CK and V follows from the fact that CK also outputs a view that is computationally indistinguishable to P^*'s view in a real interaction with V. We now formally describe the knowledge extractor algorithm K.

ALGORITHM 4.4 (knowledge extractor K).

- Input: $(\mathsf{desc}_{|x|}(P^*), x, y, r)$.

1. *Let CK be the extractor for the commit-with-extract scheme. Then, invoke CK on input $(\mathsf{desc}_{|x|}(P^*), x, y, r)$, and obtain the view of P^* in Phase 1, denoted v, along with a string w that is the committed value corresponding to that view (i.e., $w = \mathsf{commit\text{-}value}(v)$).*
2. *Output w.*

Let $p(x,y,r)$ be the probability that $P^*(x,y,r)$ convinces the honest verifier on input x in a real execution. We claim that the probability that the witness output by K is valid is at least $p(x,y,r) - \mu(|x|)$, for some negligible function $\mu(\cdot)$. In order to show this, consider a modified extractor $\tilde{K}$ that has the same Step 1 as K, but in Step 2 it first verifies the proof of membership provided by P^* (in Phase 2 of the protocol) and then outputs w if and only if it accepts this proof. Formally, in Step 1, $\tilde{K}$ runs the extractor CK and obtains a pair (v, w), as described for K. Then, in Step 2, $\tilde{K}$ verifies the proof of membership given in Phase 2 by the residual prover P^* that is defined by the view v (i.e., the residual prover is the original P^*, but with its current view set to v). Extractor $\tilde{K}$ then outputs w if and only if it accepts this proof.

Now, since $\tilde{K}$ only contains additional checks, it follows that K outputs w whenever $\tilde{K}$ outputs w. Therefore, it suffices to show that $\tilde{K}$ outputs a correct witness w with probability at least $p(x,y,r) - \mu(|x|)$. In order to demonstrate that $\tilde{K}$ succeeds with this probability, first recall that by the definition of a commit-with-extract

scheme, it holds that

$$\left\{\mathsf{view}_{P^*}^{CK}(x,y,r)\right\} \stackrel{c}{\equiv} \left\{\mathsf{view}_{P^*}(P^*(x,y,r),V)\right\},$$

where $\mathsf{view}_{P^*}^{CK}(x,y,r)$ is the random variable describing the view of P^* as output by CK, and $\mathsf{view}_{P^*}(P^*(x,y,r),V)$ is the random variable describing the view of P^* in a real execution with V. Therefore, the probability that $\tilde{K}$ accepts the proof of membership from the residual P^* is negligibly close to the probability that the honest verifier V accepts this proof of membership. (Otherwise, it is possible to distinguish between P^*'s real view and the view output by CK by emulating an execution of the proof between the residual prover P^* and the verifier $\tilde{K}$, and then outputting 1 if and only if $\tilde{K}$ accepts. This emulation is carried out by running the residual prover that is defined by the view v and seeing if the honest verifier accepts. Note that this emulation can be carried out because P^* is polynomial-time and, in addition, the description of P^* and the view v fully define the residual prover. Therefore, the residual prover can be obtained and run in polynomial-time.) Thus, $\tilde{K}$ accepts the proof of membership with probability at least $p(x,y,r) - \mu(|x|)$. By the soundness of this proof of membership, it must be that w is a valid witness with probability at least $p(x,y,r) - \mu'(|x|)$, for some negligible function μ' (otherwise, the residual prover is able to prove a false statement with nonnegligible probability). This completes the proof of knowledge soundness.

Witness-extended emulation. We conclude by providing a proof of the existence of a witness-extended emulator E for Protocol 4.1. Recall that, upon input $(\mathsf{desc}_{|x|}(P^*), x, y, r)$, E must output a view that is indistinguishable from $P^*(x,y,r)$'s view in a real execution. Furthermore, if this view contains a transcript in which the honest verifier V accepts the proof, then E must also output a valid witness (except with negligible probability). This is easily accomplished as follows:

Emulator E extracts a witness in the same way as the extractor K described above. However, E must also output P^*'s complete view of an execution. In order to do this, after CK concludes, E proceeds to verify the proof of membership of Phase 2 (like the aforementioned $\tilde{K}$). This suffices to obtain P^*'s entire view: the commit-with-extract extractor CK provides P^*'s view from Phase 1, and the remainder of P^*'s view is derived from the verification of the proof of membership of Phase 2.

More formally, the witness-extended emulator E invokes the commit-with-extract extractor CK with input $(\mathsf{desc}_{|x|}(P^*), x, y, r)$ and obtains the output. This output contains a view v that is indistinguishable from P^*'s view in a real execution of commit-with-extract. Furthermore, if this view defines a committed value, then CK also outputs this value (with overwhelming probability). Next, E verifies the proof of membership from the residual prover P^* that is defined by the view v (as described above for $\tilde{K}$). In this proof, E obtains the residual P^*'s view of Phase 2. Then, E concatenates the view output by CK in Phase 1 with P^*'s view in Phase 2, and outputs them both as P^*'s view of the entire execution. Furthermore, if E accepted the proof of Phase 2, then it outputs the witness obtained from CK in Phase 1.

It is easy to see that the view output by E is indistinguishable from P^*'s view in a real execution (P^*'s view from Phase 1 is indistinguishable from its view in a real execution, and the view from Phase 2 is identical). Furthermore, if E accepts the proof of Phase 2, then with overwhelming probability the transcript of Phase 1 defines a valid witness. As we have mentioned above, by the properties of CK, it follows that with overwhelming probability it also outputs this witness. This concludes the proof. □

5. Black-box lower bounds. In this section, we show that there does not exist a constant-round zero-knowledge argument (resp., argument of knowledge), with a black-box simulator (resp., extractor) that runs in strict polynomial-time. That is, we prove Theorems 1.2 and 1.3.

Before presenting the proofs, we provide intuition as to why it is not possible to obtain a strict polynomial-time black-box extractor for constant-round zero-knowledge protocols. First, consider a very simple (cheating) prover P^* that at every step either aborts or sends the honest prover message. Furthermore, the probability that it does not abort at any given step is $\epsilon = \epsilon(n)$. Then, black-box extractors for constant-round zero-knowledge protocols typically extract a witness using the following strategy: Invoke an execution with P^* and if P^* aborts, then also abort. However, if P^* does not abort (and thus sends a prover message in some crucial round), then continually rewind P^* until another prover message is obtained for this round. It is essential that the extractor obtains at least two different prover messages, because this is what gives it additional power over an honest verifier. (Additional power is essential because an honest verifier should not learn anything from the prover, whereas the extractor must obtain the actual witness.) Now, for P^* described above, the extractor enters the "rewinding stage" with probability only ϵ. However, once it enters this stage, the expected number of rewinding attempts by the extractor until a second nonabort reply is obtained equals $1/\epsilon$ (because P^*'s nonabort probability at every step is only ϵ). We therefore have that the overall expected amount of work is bounded. However, we cannot provide *any* strict polynomial upper bound on the running time of the simulator, because for every given polynomial, it is possible to choose ϵ so that $1/\epsilon$ is greater than this polynomial.

This idea underlies our lower bounds. Specifically, we show that by carefully choosing the abort probabilities, it is possible to achieve the following effect: A strict polynomial-time black-box extractor will not have "time" to obtain two nonabort responses from the prover P^* in any given round. (By "not having time," we mean that with noticeable probability, the extractor will have to wait longer than the bound on its running time in order to see a second nonabort response.) Essentially, this means that the extractor cannot "rewind" the prover. However, as we have mentioned above, an extractor must have additional power over a real verifier, and the only additional power awarded a *black-box* extractor is essentially the ability to rewind the prover. We therefore conclude that strict polynomial-time black-box extractors cannot exist for constant-round zero-knowledge protocols. The same argument also holds for strict polynomial-time simulation of constant-round zero-knowledge protocols. We now proceed to the proofs.

THEOREM 5.1 (Theorem 1.2—restated). *There do not exist* constant-round *zero-knowledge proofs or arguments with* strict polynomial-time black-box *simulators for any language* $L \notin \mathcal{BPP}$.

THEOREM 5.2 (Theorem 1.3—restated). *There do not exist* constant-round *zero-knowledge proofs or arguments of knowledge with* strict polynomial-time black-box *knowledge extractors for any relation* R *such that the language* $L_R \notin \mathcal{BPP}$.

Our proofs of the above lower bounds closely follow the methodology and techniques used in previous black-box lower bounds [25, 13].

5.1. Outline of the proofs. As we have mentioned above, the underlying idea behind the proofs of both Theorems 5.2 and 5.1 is the same. We will explain the intuition behind this idea in the context of knowledge extraction (i.e., in the context of the proof of Theorem 5.2) and then describe how this intuition generalizes also to

the context of simulation (for the proof of Theorem 5.1).

Theorem 5.2 is proven by showing that if a language L has a constant-round zero-knowledge protocol (P, V) with a black-box strict polynomial-time knowledge extractor, then there exists a cheating verifier strategy V^*, such that for every $x \in L$, if V^* interacts with the honest prover P, then with noticeable probability, V^* will obtain a witness w for x from the interaction with P. Of course, the ability to do this contradicts the zero-knowledge property of the protocol, unless the verifier V^* could obtain a witness by itself anyway. Since V^* runs in probabilistic polynomial-time, it must therefore be the case that $L \in \mathcal{BPP}$ (because then, indeed, V^* could obtain a witness by itself).

We construct this verifier V^* from the black-box knowledge extractor of the system (P, V). Loosely speaking, this is done in the following way:

1. We let $x \in L$ and consider a cheating prover strategy P^* that is of the following form: P^* behaves exactly as the honest prover P behaves on input x, except that in each round of the proof, it may choose to abort the execution with some probability. We will choose these probabilities so that P^* will still have a noticeable probability to convince the honest verifier to accept x.
   The actual strategy that we use for P^* is one that causes it to abort with quite high probabilities (but still noticeably bounded away from 1). In particular, P^* will abort in each round with probability greater than $1/2$ (and even greater than $1 - 1/n$). Note, however, that since the number of rounds in the protocol is constant, this does not preclude P^* from causing the honest verifier to accept with noticeable probability.
2. Consider an execution of the knowledge extractor when it is given black-box access to P^*. Every query that the extractor makes to the black-box is a list of messages $(\alpha_1, \ldots, \alpha_i)$, and the reply received by the extractor is what P^* would send in a real execution when the first i verifier messages were $\alpha_1, \ldots, \alpha_i$. Thus, if P^* would abort on this series of messages in a real execution, then the extractor receives back an abort reply, denoted by $\perp$. Note that at the end of the execution the knowledge extractor should output a witness for x with some noticeable probability.
   We show that it is possible to choose P^*'s abort probabilities in such a way, that if we run the knowledge extractor with black-box access to P^*, then with very high probability, the extractor will get at most c nonabort replies, where c is the number of verifier messages in the protocol. Furthermore, these replies will correspond to i queries (where $i \leq c$) of the form $(\alpha_1), (\alpha_1, \alpha_2), \ldots, (\alpha_1, \ldots, \alpha_i)$, where $\alpha_1, \ldots, \alpha_i$ are some strings. That is, all these queries are prefixes of a single sequence $(\alpha_1, \ldots, \alpha_i)$. Notice that when this occurs, the extractor's view is like a real interaction with the honest prover P (in particular, it does not gain anything by "rewinding" P^*).
3. We then implement a verifier strategy V^* that sends these messages $\alpha_1, \ldots, \alpha_i$ when it interacts with the prescribed prover P. Basically, the verifier works by internally running the knowledge extractor. When the extractor makes a query, the verifier either answers it with $\perp$ or forwards the query to the prover, and then returns the prover's reply to the knowledge extractor. We show that the verifier has a noticeable probability of perfectly simulating P^* to the knowledge extractor. Therefore, with noticeable probability, the knowledge extractor (in conjunction with the verifier) is able to extract a witness x during this interaction with the prover P. We conclude that with noticeable probability, V^* obtains a witness w for x from the interaction with P, and so

the proof system cannot be zero knowledge (unless $L \in \mathcal{BPP}$).

As mentioned above, in the simulation case (i.e., when proving Theorem 5.1) we use a similar technique. Basically, we prove Theorem 5.1 by showing that if L has a constant-round zero-knowledge proof or argument system (P, V) with a black-box strict polynomial-time simulator, then there exists a cheating prover strategy P^* that does not have any auxiliary input (like a witness), and yet for every $x \in L$ causes the honest verifier V to accept x with noticeable probability. We stress that, unlike the honest prover, this cheating strategy P^* does *not* get a witness for x as auxiliary input. It is not hard to show that the existence of such a strategy P^* implies that $L \in \mathcal{BPP}$.

In summary, both impossibility results are due to the following two facts:

1. Intuitively, in order to successfully extract or simulate, the extractor (resp., simulator) must see at least two different continuations of the same transcript. That is, it must get meaningful replies to queries of the form $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i)$ and $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i')$, where $\alpha_i' \neq \alpha_i$. Otherwise the extractor (resp., simulator) does not have any advantage over the interactive verifier (resp., prover). (Informally speaking, "rewinding" is essential for black-box simulation and extraction.)
2. For any strict polynomial-time extractor or simulator, there exist provers (resp., verifiers) for which the time required to obtain nonabort responses to two queries $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i)$ and $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i')$, where $\alpha_i' \neq \alpha_i$, is greater than the running time of the extractor (resp., simulator).

Comparison with the black-box zero-knowledge lower bounds of [25, 13]. As we have mentioned above, we use the methodology and techniques of [25, 13] in proving our lower bounds. The lower bounds of [25, 13] and this paper all work by using a black-box simulator to construct a cheating prover P^* that convinces an honest verifier that $x \in L$, without having a witness. The prover P^* works by internally invoking the simulator and forwarding some of the messages between the simulator and the external honest verifier (the other messages are dealt with internally). The main issue to be resolved is how to carry out this execution of the simulator; the difficulty being due to the fact that the simulator is allowed to rewind the verifier during simulation, whereas the cheating prover *cannot* rewind the external honest verifier. Regarding this issue, each of the three lower bounds differs. The lower bound of [25] for constant-round public-coin proofs follows from the fact that in public-coin proofs, all verifier messages are independent of each other. Therefore, it is possible to "guess" messages that should be forwarded to the verifier, and all other messages can be internally generated by the cheating prover (independence of the verifier messages is necessary so that the internal messages generated by the cheating prover do not look inconsistent with messages that the external honest verifier generates). The lower bound of [13] for the concurrent setting is proven by showing that a polynomial-time simulator is unable to rewind the verifier in every execution (because this would require super-polynomial time). Therefore, the messages of the execution in which there is no rewinding can be forwarded to the external real verifier. Finally, in our lower bound, we show that a strict polynomial-time simulator must succeed without effectively rewinding the verifier because rewinding attempts will yield $\perp$ replies with high probability. Therefore, the messages of the simulator that do not yield $\perp$ replies can be sent to the external verifier and no rewinding will be necessary.

5.2. Proof of Theorems 5.2 and 5.1. We now proceed to the actual proofs.

Notation and conventions. We identify an interactive program A with its *next*

message function (or process, if it is randomized). That is, we consider A as a *noninteractive* algorithm that gets as input the history of the interaction (i.e., the sequence of messages that A received until this point), and outputs the next message that A would send in a protocol execution in which it sees this history.

We say that an algorithm B has *oracle access* to an interactive algorithm A, if B has oracle access to A's next message function (after fixing its random tape to some value). That is, B can query its oracle with any sequence of messages of the form $(\alpha_1, \ldots, \alpha_i)$ and it will receive back the next message that A would send in an interaction in which it received this sequence of messages.

We say that an interactive program *aborts* an execution if it sends the message $\perp$. We assume that once a party sends the message $\perp$, then (since it aborted the execution) all its future messages are also $\perp$. In the notation of the next message function, this means that if $A(\alpha_1, \ldots, \alpha_i) = \perp$ for some strings $\alpha_1, \ldots, \alpha_i$, then $A(\alpha_1, \ldots, \alpha_i, \alpha_{i+1}, \ldots, \alpha_j) = \perp$ for every choice of $\alpha_{i+1}, \ldots, \alpha_j$.

The following two lemmas (whose proofs are very similar) lie at the heart of the proofs of Theorems 5.2 and 5.1, respectively.

LEMMA 5.3. *Let (P, V) be a constant-round system of proofs or arguments of knowledge for a relation R with a black-box strict polynomial-time knowledge extractor K. Then, there exists a probabilistic polynomial-time cheating verifier algorithm V^* and a polynomial $p(\cdot)$ such that for every $x \in L_R$, the probability that V^* outputs a witness for x after interacting with the honest prover P on input x is at least $1/p(|x|)$.*

We later show that if the proof system (P, V) is zero knowledge, then the existence of such a cheating verifier V^* implies that $L \in \mathcal{BPP}$. Likewise, we prove the following.

LEMMA 5.4. *Let (P, V) be a constant-round zero-knowledge proof or argument system for a language L, with a black-box strict polynomial-time simulator S. Then, there exists a probabilistic polynomial-time cheating prover algorithm P^* and a polynomial $p(\cdot)$ such that for every $x \in L$, the honest verifier V accepts after interacting with $P^*(x)$ with probability at least $1/p(|x|)$.*

We stress that P^*'s only input is x and, in particular, it does *not* receive a witness for x as auxiliary input. Later we will show that the existence of such a prover P^* implies that $L \in \mathcal{BPP}$ (as shown in previous black-box lower bounds for zero knowledge; e.g., see [25, 13]).

5.2.1. Proof of Lemma 5.3. Let R be a relation and let (P, V) be a system of proofs or arguments of knowledge for R, where the number of messages sent by the verifier equals some constant c. Furthermore, let K be a black-box knowledge extractor for (P, V) that when extracting a witness for x runs for at most $t(n)$ steps, where $n = |x|$ and $t(\cdot)$ is some polynomial. Thus, the number of oracle queries made by K is strictly upper-bounded by a polynomial $t(n)$.[16] We assume without loss of generality that all verifier messages in the proof system are of length $m = m(n)$, where $m(\cdot)$ is some polynomial. We also assume without loss of generality that the first message in the system is from the verifier to the prover.

[16] Note that the running time of the extractor is independent of the running time of the prover. That is, the extractor is restricted to $t(n)$-time (and thus oracle queries) even if the cheating prover runs in time that is larger than $t(n)$. This may seems like an "unfair" restriction, even for a black-box extractor. However, we can extend our lower bound to hold even if the running time of the extractor is allowed to be a fixed polynomial in the running time of the cheating prover. This extension holds under the assumption that one-way functions exist and applies to any proof system that has an efficient prover algorithm. This can be shown by considering a prover strategy P^* that uses a pseudorandom function instead of a t-wise independent hash function, as we use here.

Conventions regarding the extractor K. Recall that a black-box extractor has oracle access to the prover from whom it extracts. Thus it can query this oracle on sequences of messages of the form $(\alpha_1, \ldots, \alpha_i)$. For the sake of simplicity, we can assume without loss of generality that the extractor K always behaves in the following way:

1. It never asks the same query twice.
2. If K queries the oracle with q, then prior to this query, it has queried the oracle with all the proper prefixes of q. (If $q = (\alpha_1, \ldots, \alpha_i)$ is a sequence of messages, then the *prefixes* of q are all the sequences of the form $(\alpha_1, \ldots, \alpha_j)$ for $j \leq i$.)
3. For some polynomial $t' = t'(n)$, the extractor makes exactly $t'(n)$ queries to its black-box in every execution.

We can assume all of the above because any extractor can be easily modified such that it behaves in the above way, without affecting its output distribution. Furthermore, if the upper bound on the number of queries made by the original extractor is $t(n)$, then the number of queries t' made by the modified extractor is at most $c \cdot t(n)$ (the multiplicative factor of c is used for asking all of the prefixes of a query before the query itself). From now on, we will denote the number of queries made by K by $t = t(n)$, rather than by $t'(n)$.

Our proof will follow the outline mentioned at the beginning of section 5. That is, we will construct a prover strategy P^* that aborts with certain probability p^*, but when it does not abort, uses the same strategy as the honest prover. On one hand, the knowledge extractor K will have to output a witness with probability close to p^* when given access to P^*. On the other hand, we will show a cheating verifier V^* that can successfully simulate the behavior of K^{P^*} with noticeable probability, even though it only gets access to one interaction with the honest prover P (and does not get black-box access to P^*).

The prover strategy P^*. We are now ready to describe the prover strategy P^*. Let $\epsilon = \epsilon(n)$ be some value that will be determined later (it will be of the form $1/q(n)$ for some polynomial $q(\cdot)$). Let $\mathcal{H} = \{H_n\}_{n \in \mathsf{N}}$ be a family of $t(n)$-wise independent hash functions,[17] such that every $h \in H_n$ is a function from $\{0,1\}^{\leq c \cdot m}$ to $\{0,1\}^n$, where $\{0,1\}^{\leq c \cdot m}$ denotes the set of all strings of length at most $c \cdot m$. (Recall that $t = t(n)$ denotes the number of queries the knowledge extractor K makes to its black-box.)

Our prover strategy P^* behaves as follows: in the ith round of the protocol, with probability $\epsilon^{2^{c-i}}$, it behaves exactly as the honest prover, and otherwise (with probability $1-\epsilon^{2^{c-i}}$) it aborts. The random coins the prover P^* uses to decide whether to abort or continue will be chosen by applying a fixed hash function $h \in H_n$ (that was initially chosen at random) to the current message history. Before proceeding to a more formal description of P^*, we explain why we choose its abort probabilities in this way. As we have described above, the main idea is to prevent an extractor from obtaining two nonabort responses from P^* for the same round. More exactly, we wish to fix the abort probabilities so that the probability that an extractor sees two nonabort responses for the same round is *significantly less* than the probability that P^* provides a full proof without aborting at all, in which case it convinces V. (Since the extractor must obtain a witness with the probability that P^* convinces V, this means

[17] Recall that a hash family is t-wise independent if for every t distinct values $x_1, \ldots, x_t$ the random variables $h(x_1), \ldots, h(x_t)$ (where h is chosen at random from H_n) are independently and uniformly distributed in the range of h. We will never make more than t queries to the function, and so one can think of it as a truly random function.

that there is a significant probability that the extractor will *not* see two nonabort messages for any given round, but must still succeed in obtaining a witness.) Now, by choosing the abort probabilities so that they degrade exponentially, we achieve our aim. Specifically, for any i, the product $\epsilon^{2^{c-1}} \cdot \ldots \cdot \epsilon^{2^{c-i+1}} \cdot (\epsilon^{2^{c-i}})^2$ (which is the probability that two nonabort responses are obtained for the ith round) is *significantly less* than the product $\epsilon^{2^{c-1}} \cdot \ldots \cdot \epsilon^{2^0}$ (which is the probability that P^* never aborts).

We now describe the strategy for P^*'s operation (note that we define P^* in the form of its next-message function) in the following algorithm:

ALGORITHM 5.5 (prover P^*).

- Common input: x—*the statement to be proven;*
- Auxiliary input: $y \in R(x)$—*a witness for* x*;*
- Random tape: (h, r)—h *defines a function in* H_n*, and* r *is of the length of the random tape required by the honest prover strategy;*
- Input: *series of verifier messages* $q = (\alpha_1, \ldots, \alpha_i)$*.*

1. Step 1—decide whether or not to abort:
   (a) *Compute* $h(q')$ *for every prefix* q' *of* q*. That is, for every* j $(1 \leq j \leq i)$*, compute* $h(\alpha_1, \ldots, \alpha_j)$*.*
   (b) *Abort (outputting a special symbol* $\perp$*), unless for every* j*, the first* $2^{c-j} \log(1/\epsilon)$ *bits of* $h(\alpha_1, \ldots, \alpha_j)$ *are equal to* 0*.*

   (Notice that since the definition of P^* *is by its next message function, we have to ensure that it replies to* q *only if it would not have aborted on messages sent prior to* q *in an interactive setting. This is carried out by checking that it would not have aborted on all prefixes of* q*.)*
2. Step 2—if the decision is to not abort, then follow the honest prover strategy:
   (a) *Run the honest prover* P*, with initial input* (x, y) *and random tape* r*, on input messages* $(\alpha_1, \ldots, \alpha_i)$*, and obtain its response* β*.*
   (b) *Return* β*.*

Note that if the honest prover P is computationally efficient, then so is the cheating prover P^*. (This is important because for the case of arguments, all provers must be efficient.) Our first step is to show that P^* convinces V with noticeable probability. Suppose that the system (P, V) has completeness bound p (i.e., the honest prover causes the honest verifier to accept with probability at least p; recall that p is assumed to be noticeable). Then, define $p^* = \epsilon^{2^c-1} p$. We claim that the probability (over P^*'s random tape) that P^* convinces the honest verifier to accept is at least p^*. Indeed, conditioned on P^* not aborting, its behavior is identical to the behavior of the honest prover P, in which case it convinces V with probability p. Now, since P^*'s probability of not aborting is equal to $\epsilon^{2^{c-1}} \cdot \ldots \cdot \epsilon^{2^0} = \epsilon^{2^c-1}$, the claim follows. As we have mentioned above, we will choose ϵ so that $\epsilon > 1/q(n)$ for some polynomial $q(\cdot)$. Then, since c is a constant, it follows that the probability p^* that P^* convinces the honest V is noticeable, as desired.

We have shown that P^* convinces V with probability at least $p^* = \epsilon^{2^c-1} p$. By the validity (or knowledge soundness) condition on the system (P, V), this means that when the knowledge extractor K is given oracle access to P^*, then it outputs a witness for the statement x with probability at least $p^* - \mu(|x|)$ (where the probability is over the random tapes of both P^* and K).[18] In particular, K outputs a witness

[18] Strictly speaking, the knowledge soundness property is defined for *deterministic* prover strategies. That is, denote by $P^*_{h,r}$ the prover strategy of P^* with its random tape set to (h, r), and denote by $p_{h,r}$ the probability (now over V's random tape only) that $P^*_{h,r}$ convinces V that $x \in L$. Then, the knowledge soundness property states that K must extract a witness from $P^*_{h,r}$ with probability

with probability at least $p^*/2$.

We now claim that if ϵ is chosen appropriately, then with probability at least $p^*/4$, the extractor K will receive at most c non-$\perp$ answers from P^*, and all of these answers are prefixes of a single sequence $(\alpha_1, \ldots, \alpha_i)$ for some $i \leq c$. Informally speaking, this means that with probability at least $p^*/4$, the extractor K is unable to obtain any meaningful information by rewinding P^* (all attempts at rewinding P^* result in abort responses).

CLAIM 5.6. *Let $\tilde{p}$ be the probability (over all choices of P^*'s random tape) that K obtains non-$\perp$ replies for two queries of the form $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i)$ and $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i')$, where $\alpha_i \neq \alpha_i'$. Then, there is a choice of ϵ such that for every fixed random tape for K, it holds that $\tilde{p} < p^*/4$. Furthermore, $\epsilon = \frac{1}{q(n)}$ for some polynomial $q(\cdot)$.*

Proof. Let $\epsilon(n) = \frac{p}{4 \cdot t^2 c}$ (recall that p is the completeness bound of the honest prover and that t is the number of oracle queries made by K). First, note that for this choice of ϵ, there exists a polynomial $q(\cdot)$ such that $\epsilon = \frac{1}{q(n)}$. Next, for every $i \leq c$ and every $j, k \in [t]$, we let $p^i_{j,k}$ denote the probability that the jth query of K is of the form $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i)$, the kth query of K is of the form $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i')$, and K receives a non-$\perp$ response for both of these queries. (Recall that by convention K never asks the same query twice, so this means that $\alpha_i \neq \alpha_i'$.) We now bound the probability $p^i_{j,k}$. Recall that P^* decides whether or not to abort by applying a t-wise independent hash function to the query. By the t-wise independence of the function, P^*'s abort decision is independent for each query. Therefore, if K makes two queries of this form, it will obtain a reply with probability that is $\epsilon^{2^{c-1}+\cdots+2^{c-i+1}} \cdot (\epsilon^{2^{c-i}})^2$, which is the probability that P^* does not abort in the first $i-1$ rounds on history $(\alpha_1, \ldots, \alpha_{i-1})$ multiplied by the probability that P^* does not abort in the ith round both when given the message α_i and when given the message α_i'. Since $2^{c-1}+\cdots+2^{c-i+1}+2 \cdot 2^{c-i} = 2^c$, we have

$$p^i_{j,k} = \epsilon^{2^{c-1}+\cdots+2^{c-i+1}+2 \cdot 2^{c-i}} = \epsilon^{2^c}.$$

By applying the union bound over all $i \in [c]$ and $j, k \in [t]$, we have that $\tilde{p} \leq t^2 c \cdot \epsilon^{2^c}$, where $\tilde{p}$ is defined in the claim statement. Plugging in $p^* = \epsilon^{2^c - 1} p$, we have that $\tilde{p} \leq t^2 c \cdot \epsilon p^*/p$. Finally, since $\epsilon = \frac{p}{4 \cdot t^2 c}$, we have that $\tilde{p} \leq p^*/4$, as required. □

Summing up, we have shown the following. On one hand, when the extractor K is given oracle access to P^*, it must obtain a witness with probability at least $p^*/2$ (where the probability is over the random tapes of both P^*'s and K). On the other hand, the probability that K views two nonabort responses from P^* of the form discussed in Claim 5.6 is at most $p^*/4$. This means that with probability $p^*/2 - p^*/4 = p^*/4$, the extractor K obtains a witness without obtaining non-$\perp$ replies for two queries of the form $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i)$ and $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i')$, where $\alpha_i \neq \alpha_i'$.

We are now ready to construct the verifier V^*. Loosely speaking, the verifier V^* will manage to output a witness after interacting with the honest prover by internally running the knowledge extractor K, and referring some of its queries to the real prover. The important point is that with noticeable probability, K will work in exactly the same way as when it is given oracle access to P^*. The description of V^* is as follows.

ALGORITHM 5.7 (verifier V^*).

- Input: *x (statement to be proven).*

at least $\tilde{p}_{h,r} = p_{h,r} - \mu(|x|)$. Now, as we have shown, the expectation of $p_{h,r}$ taken over all of P^*'s random tapes is p^* (this is the probability over both P^* and V's random tapes that P^* convinces V that $x \in L$). Therefore, the expectation of $\tilde{p}_{h,r}$ (which is the probability over both P^* and K's random tapes that K extracts a witness for x) is at least $p^* - \mu(|x|)$, as required.

1. *Choose a random $h \in H_n$.*
2. *The verifier will store the history of messages that it has sent to the prover so far in the execution. Initially, this list is empty.*
3. *Run the knowledge extractor K on input x.*
4. *When the extractor K makes a query $(\alpha_1, \ldots, \alpha_k)$ do the following:*
   (a) *Follow the same procedure as P^* in order to decide whether or not to answer the query with $\perp$ (i.e., answer the query with $\perp$ unless for every $j \in [k]$ the first $2^{c-j} log(1/\epsilon)$ bits of $h(\alpha_1, \ldots, \alpha_j)$ are equal to 0).*
   (b) *If the above decision was to not answer the query with $\perp$, then check whether the history of messages sent so far to the prover consists exactly of $(\alpha_1, \ldots, \alpha_{k-1})$. If this is the case, then send α_k to the prover and forward the prover's response β to the knowledge extractor K. If this is not the case, and so there was a previous query that was not answered with $\perp$ and is not a prefix of this query, then abort. (In this case we say that the verifier* fail*.)*
5. *At the end of the execution, if the extractor outputted a witness for x, then output this witness.*

Intuitively, when V^* does not output fail, it perfectly emulates an execution of K with oracle access to P^*. Therefore, V^* outputs a valid witness whenever K would output a witness without obtaining non-$\perp$ replies for two queries of the form $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i)$ and $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i')$, where $\alpha_i \neq \alpha_i'$. This means that V^* outputs a valid witness with probability at least $p^*/4$.

More formally, let good be the event that K outputs a witness without obtaining non-$\perp$ replies for two queries of the form $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i)$ and $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i')$, where $\alpha_i \neq \alpha_i'$. Then, as we have shown, the probability that the good event occurs is at least $p^*/4$. Now, the probability space over which we computed the probability that good occurs is (h, r, r_K), where (h, r) is the random tape of P^* and r_K is the random tape of the extractor K. Recall that h was used by P^* for deciding whether or not to abort and r was used by P^* for running the honest prover strategy. Now, observe that the probability space over which we need to compute V^*'s success in outputting a valid witness is also (h, r, r_K). The only difference is that here h and r_K are randomly chosen by V^*, and r is the random tape of the honest prover with which V^* interacts. Therefore the probability space is the same and we have that the probability that V^* outputs a witness is also at least $p^*/4$, which is noticeable. This completes the proof. □

5.2.2. Concluding the proof of Theorem 5.2. To prove Theorem 5.2 we need to show that if (P, V) is a constant-round zero-knowledge proof of knowledge for some relation R with a strict polynomial-time knowledge extractor, then $L_R \in \mathcal{BPP}$. Indeed, if (P, V) is such a system, then by Lemma 5.3, there exists a verifier V^* that, for every $x \in L$, outputs a witness for x with noticeable probability after interacting with the honest prover. Now, since (P, V) is zero knowledge, there exists a simulator S^* for V^* whose output is computationally indistinguishable from the output of V^*. Thus, for every $x \in L_R$, it holds that simulator $S^*(x)$ outputs a witness for x with noticeable probability. On the other hand, if $x \notin L_R$, then S^* will certainly not output a witness for x. Therefore, S^* can be used to obtain a probabilistic polynomial-time procedure for deciding membership in L_R. In other words, $L_R \in \mathcal{BPP}$.

5.2.3. Proof of Lemma 5.4 and Theorem 5.1. The proof of Lemma 5.4 largely follows the proof of Lemma 5.3. Given a c-round zero-knowledge protocol

(P, V) with a black-box strict polynomial-time simulator S, one first constructs a verifier V^* that behaves identically to the honest verifier V, except that it may choose to abort in any round. This verifier V^* corresponds to the cheating prover constructed in Algorithm 5.5 within the proof of Lemma 5.3, and uses the same procedure to decide whether or not to abort. Specifically, the probability that it does not abort in the ith round of the protocol is $\epsilon^{2^{c-i}}$, in which case it follows the instructions of the honest verifier. Now, let $p^* = \epsilon^{2^c-1} \cdot p$, where p is the completeness bound of the zero-knowledge protocol. Then, as above, it follows that an interaction between the honest prover and V^* yields an accepting transcript with probability exactly p^*. Therefore, any simulator given oracle access to V^* must output an accepting transcript with probability at least $p^* - \mu(n) > p^*/2$. Next, a claim analogous to Claim 5.6 is proved. That is, we show that it is possible to choose ϵ so that the probability that the (strict polynomial-time) simulator obtains non-$\perp$ replies from V^* for two queries of the form $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i)$ and $(\alpha_1, \ldots, \alpha_{i-1}, \alpha_i')$, where $\alpha_i \neq \alpha_i'$, is at most $p^*/4$. Furthermore, ϵ is noticeable (implying that p^* is also noticeable). Putting this together, we have that when given black-box access to V^*, the simulator S has a noticeable probability of outputting an accepting transcript, even after viewing at most c non-$\perp$ responses from its oracle, where all these responses are prefixes of the same sequence $(\alpha_1, \ldots, \alpha_i)$. Thus, S can be used to convince the honest verifier with noticeable probability that $x \in L$. That is, in a way similar to the proof of Lemma 5.3, we use this observation about the simulator S in order to construct a cheating prover algorithm P^* (the construction of P^* corresponds to the cheating verifier algorithm described in Algorithm 5.7). This prover P^* does *not* get a witness as auxiliary input, but still for every $x \in L$, it manages to convince the honest verifier to accept with noticeable probability. We omit the full details of the proof of Lemma 5.4.

To prove Theorem 5.1, we need to show that if (P, V) is a constant-round zero-knowledge protocol for L with a black-box strict polynomial-time simulator, then $L \in \mathcal{BPP}$. Now, let (P, V) be such a protocol. By Lemma 5.4, there exists a prover algorithm P^* such that on every input $x \in L$, the prover P^* with input x only (and no witness) manages to convince the honest verifier to accept x with noticeable probability. By the soundness of the system, we know that if $x \notin L$, then the honest verifier will accept x with negligible probability. Therefore, one can test whether or not $x \in L$ in probabilistic polynomial-time, by emulating an interaction between P^* and V on input x, and outputting 1 if and only if the verifier accepts in this execution. Thus, $L \in \mathcal{BPP}$.

Acknowledgments. We wish to thank Oded Goldreich for many helpful discussions and comments. We would also like to thank Moni Naor for pointing out the connection between our lower bound and the separation of black-box ε-knowledge from black-box zero knowledge. Finally, we thank Jonathan Katz for pointing out an error in an earlier version of this work.

THE COMPLEXITY OF THREE-WAY STATISTICAL TABLES*

JESUS DE LOERA† AND SHMUEL ONN‡

Dedicated to Bernd Sturmfels on the occasion of his 40th birthday

Abstract. Multiway tables with specified marginals arise in a variety of applications in statistics and operations research. We provide a comprehensive complexity classification of three fundamental computational problems on tables: existence, counting, and entry-security.

One outcome of our work is that each of the following problems is intractable already for "slim" 3-tables, with constant number 3 of rows: (1) deciding existence of 3-tables with specified 2-marginals; (2) counting all 3-tables with specified 2-marginals; (3) deciding whether a specified value is attained in a specified entry by at least one of the 3-tables having the same 2-marginals as a given table. This implies that a characterization of feasible marginals for such slim tables, sought by much recent research, is unlikely to exist.

Another consequence of our study is a systematic efficient way of embedding the set of 3-tables satisfying any given 1-marginals and entry upper bounds in a set of slim 3-tables satisfying suitable 2-marginals with no entry bounds. This provides a valuable tool for studying multi-index transportation problems and multi-index transportation polytopes. Remarkably, it enables us to automatically recover a famous example due to Vlach of a "real-feasible integer-infeasible" collection of 2-marginals for 3-tables of smallest possible size $(3, 4, 6)$.

1. Introduction.

A *d-table of size* $(n_1, \ldots, n_d)$ is an array of nonnegative integers $v = (v_{i_1,\ldots,i_d})$, $1 \le i_j \le n_j$. For $0 \le m < d$, an *m-marginal* of v is any of the $\binom{d}{m}$ possible m-tables obtained by summing the entries over all but m indices. For instance, if $(v_{i,j,k})$ is a 3-table, then its 0-marginal is $v_{+,+,+} = \sum_{i=1}^{n_1} \sum_{j=1}^{n_2} \sum_{k=1}^{n_3} v_{i,j,k}$, its 1-marginals are $(v_{i,+,+}) = (\sum_{j=1}^{n_2} \sum_{k=1}^{n_3} v_{i,j,k})$, and likewise, $(v_{+,j,+})$, $(v_{+,+,k})$. Its 2-marginals are $(v_{i,j,+}) = (\sum_{k=1}^{n_3} v_{i,j,k})$, and similarly, $(v_{i,+,k})$, $(v_{+,j,k})$.

Such tables appear naturally in statistics and operations research under various names such as *multiway contingency tables*, *transportation matrices*, or *tabular data*. In all these applications, the tables of interest are those satisfying various constraints such as specified marginals or specified upper and lower bounds on the various table entries. Tables are central products of statistical agencies (for example, see the website [2] of the U.S. Bureau of Census).

In this article we study three essential computational problems of constrained tables, primarily motivated by applications in statistical analysis and statistical data security (see, e.g., [10, 12, 14] and the references therein): the *table existence* or *feasibility problem*, the *table counting problem*, and the *table entry-security problem*. We

provide comprehensive computational complexity classifications of these problems, which are discussed, respectively in subsections 1.1–1.3 below, where we make the precise definition, include a briefing on the motivating statistical background, and describe our results for each problem. On the way we also show that the set of 3-tables satisfying any given 1-marginals and upper bounds on entries can be embedded in a set of "slim" 3-tables satisfying suitable 2-marginals with no entry bounds; this is discussed further, with the implications for the class of so-called *multi-index transportation polytopes* (cf. [28, 29]), in subsection 1.4 below.

We demonstrate that even *slim* 3-tables, of size $(3, c, h)$, having a fixed number of rows, 3, can have an arbitrarily complex behavior. This improves on earlier results of Irving and Jerrum [20]. For statisticians and agencies manipulating tabular data, our results have practical repercussions: polynomial time algorithms for solving any one of the problems (feasibility, counting, or entry-security) are unlikely to exist. Thus, in taming 2-marginals arising in practice it will be necessary to exploit particular features of the real data in each specific application.

Our results on the intractability of slim 3-tables stand in contrast with the efficient methods available for 2-way contingency tables (see [16, 17]) and for the so-called decomposable-log-linear models [11, 14, 18]. Thus, we settle a problem that has been the focus of much recent research (see [7, 12, 26] and further references therein), that of trying to find efficient methods for slim 3-tables, and demonstrate that already the 3-tables of smallest possible size $(3, c, h)$ which are not decomposable-graph-log-linear models can have an arbitrarily complex behavior.

Finally, we point out that our results on the intractability of 2-marginals in 3-tables obviously extend to higher dimensions as 2-marginals in 3-tables can be embedded in higher dimensions.

1.1. Table existence or feasibility. First, we consider the *table existence problem*, also called the *feasibility problem* (cf. [5, 28]): *Given a prescribed collection of marginals that seem to describe a d-table of size* $(n_1, \ldots, n_d)$*, does there really exist a table with these marginals?* This problem is relevant for statistical analysis; for instance, disclosed or transmitted marginals may become perturbed or distorted in such a way that a feasible table may no longer exist, in which case not only will the data lose utility to the users, but also algorithms such as the iterative proportional fitting can fail to converge. This can be a problem because several statistical procedures are insensitive to existence, e.g., Fréchet-type bounds presented in [14]. See [5, 6] for a discussion of the importance of table existence in statistics applications. An obvious necessary condition for the existence of a table with a specified collection of marginals is that the collection is *consistent*; that is, any two given marginals must agree on any of their common lower-dimensional marginals. For instance, for the existence of a 3-table with specified 2-marginals $(v_{i,j,+})$ and $(v_{i,+,k})$, these marginals must agree on their common 1-marginal $(v_{i,+,+})$, so the 1-table equation $(\sum_{j=1}^{n} v_{i,j,+}) = (\sum_{k=1}^{n} v_{i,+,k})$ must hold. In general, however, these consistency equations do not even guarantee the existence of an array with nonnegative *real* entries (cf. [28, 29]).

The existence problem is easy to solve for 2-tables [16, 17] or 1-marginals (which are so-called decomposable-log-linear models) [11, 14, 18]. Therefore, the first really interesting case is that of 3-tables with all 2-marginals specified. The following theorem provides an almost complete classification of the complexity of this problem. We assume without loss of generality that the size (r, c, h) of the tables satisfies $3 \leq r \leq c \leq h$. For $r \leq 2$ the problem reduces to the well-studied case of two-dimensional tables (with upper bounds on entries) and is polynomial time solvable using linear

programming over the corresponding *transportation polytope*. See further discussion of these polytopes and their *multi-index* generalizations in subsection 1.4 below.

THEOREM 1.1. *The computational complexity of the existence problem for* 3*-tables of size* (r, c, h) *with* $3 \le r \le c \le h$ *and all* 2*-marginals specified is provided by the following table:*

	r, c, h *fixed*	r, c *fixed,* h *variable*	r *fixed,* c, h *variable*	r, c, h *variable*
unary 2*-marginals*	P	P	NPC	NPC
binary 2*-marginals*	P	?	NPC	NPC

Each entry (i, j) of this table ($i = 1, 2$, $j = 1, 2, 3, 4$) represents a refined version of the existence problem; any problem $(2, j)$ is at least as hard as the problem $(1, j)$ above it, and for $j \ge 2$, any problem (i, j) is at least as hard as the problem $(i, j-1)$ to its left. Here NPC stands for *NP-complete*, and hence presumably intractable and practically unsolvable for large inputs (cf. [15]), whereas P stands for *polynomial time*, and hence efficiently solvable. Binary versus unary are the two standard ways of encoding numbers: for *binary* marginals, the size of each marginal is taken to be the number of digits in its binary (or decimal) expansion, and hence is proportional to its logarithm, whereas for *unary* marginals, the size of each marginal is the marginal itself.

Thus, some of the entries follow at once from others but are included for complete classification. Entry $(1, 1)$ easily follows from an exhaustive search. However, already entry $(2, 1)$ requires the sophisticated algorithm of Lenstra for integer programming in fixed dimension [21]: it would be interesting to devise a special faster polynomial time algorithm for this entry. In section 3 we shall prove entry $(1, 2)$, that is, the polynomial time solvability of existence for unary marginals with r, c fixed ("small") and h variable ("large"). In section 2 we shall establish entries $(1, 3)$ and $(2, 3)$, that is, the NP-completeness of existence for marginals with $r = 3$ fixed and c, h variable. This implies at once entries $(1, 4)$ and $(2, 4)$ in the right column, established previously by Irving and Jerrum [20], strengthening their results. Entry $(2, 2)$ remains unsettled and challenging.

1.2. Table counting. Next, we consider the *table counting problem*: *Given a prescribed collection of marginals, how many d-tables are there that share these marginals?* Table counting has several applications in statistical analysis, in particular independence testing, and has been the focus of much research (see [9, 10, 22] and the extensive list of references therein). The counting problem can be formulated as that of counting the number of integer points in the associated multi-index transportation polytope (see further discussion in subsection 1.4 below). The following analogue of Theorem 1.1 provides a complete classification of the complexity of this problem.

THEOREM 1.2. *The computational complexity of the counting problem for* 3*-tables of size* (r, c, h) *with* $2 \le r \le c \le h$ *and all* 2*-marginals specified is provided by the following table:*

	r, c, h *fixed*	r, c *fixed,* h *variable*	r *fixed,* c, h *variable*	r, c, h *variable*
unary 2*-marginals*	P	P	$\#PC$	$\#PC$
binary 2*-marginals*	P	$\#PC$	$\#PC$	$\#PC$

Here $\#PC$ stands for *#P-complete*, and hence presumably intractable; see Valiant's seminal paper [27], which introduces the complexity theory of counting, or consult [15].

Entry $(1, 1)$ is easy, but already entry $(2, 1)$ requires the sophisticated algorithm of Barvinok for counting integer points in polytopes in fixed dimension [4]. In section 3 we prove entry $(1, 2)$, that is, counting in polynomial time for unary marginals with

r, c fixed and h variable. Entry $(2,2)$ follows from the $\#P$-completeness of counting 2-tables of size $(2,n)$ with binary marginals [13]. In section 3 we also prove entry $(1,3)$, that is, the $\#P$-completeness of counting for unary marginals with $r=2$ fixed and c, h variable, implying entries $(2,3)$, $(1,4)$, and $(2,4)$ as well.

1.3. Table entry-security. The third problem we consider arises in the context of secure and confidential disclosure of public statistical data (see [7, 12, 14] and the references therein). The goal in this context is the release of some marginals of a table in the database but not the table's entries themselves. If the range of possible values that an entry can attain in any table satisfying the released collection of marginals is too narrow, or even worse, consists of the unique value of that entry in the actual table in the database, then this entry may be exposed. This shows the importance of determining tight integer lower and upper bounds on each entry. We consider the following versions of this problem, the *lower* (respectively, *upper*) *table entry-security problem*: *Given a d-table y, a specified collection of marginals of this table, an index tuple $(i_1, \ldots, i_d)$, and a nonnegative integer L (respectively, U), is there a d-table x having the same specified collection of marginals as y, whose entry $x_{i_1,\ldots,i_d}$ is greater than or equal to L (respectively, less than or equal to U)?*

There is an extensive work on the entry-security problem (see, e.g., [6, 11, 14, 25, 26]), where properties are sought that may help address the problem. The state-of-the-art on research and practical techniques is surveyed in [12]. The following analogue of Theorems 1.1 and 1.2 provides an almost complete classification of the complexity of the entry-security problem as well.

THEOREM 1.3. *The complexity of the lower (upper) entry-security problem for 3-tables of size (r,c,h) with $3 \le r \le c \le h$ ($4 \le r \le c \le h$) and all 2-marginals specified is provided by the following table:*

	r,c,h fixed	*r,c fixed, h variable*	*r fixed, c,h variable*	*r,c,h variable*
unary 2-marginals	*P*	*P*	*NPC*	*NPC*
binary 2-marginals	*P*	*?*	*NPC*	*NPC*

Once again, entry $(1,1)$ is easy and entry $(2,1)$ follows from [21]. In section 4 we prove the polynomial time solvability for the case of unary marginals with r, c fixed and h variable (entry $(1,2)$), and the intractability for r fixed and c, h variable (entries $(1,3)$ and $(2,3)$), strengthening earlier hardness results of Irving and Jerrum [20] reflected in entries $(1,4)$ and $(2,4)$. Again, entry $(2,2)$ remains unsettled.

1.4. Multi-index transportation polytopes and the power of 2-marginals. Given a specified collection of marginals for d-tables of size $(n_1, \ldots, n_d)$, possibly together with specified lower and upper bounds on some of the table entries, the associated *multi-index transportation polytope* is the set of all nonnegative *real-valued* arrays satisfying these marginals and entry bounds (cf. [29]) and is a (typically bounded) convex polyhedron in $\mathbf{R}^{n_1 \cdots n_d}$. For instance, for 2-tables of size (n,n) with all 1-marginals equal to 1 and no entry bounds, this is the Birkhoff polytope of n by n bistochastic matrices. The d-tables satisfying the given marginals and entry bounds are precisely the *integer points* in the associated multi-index transportation polytope.

In section 5 we show how a system of 1-marginal and entry upper bound constraints on 3-tables can be embedded into a system of 2-marginal constraints (with no entry bounds) on "slim" 3-tables, demonstrating the expressive power of 2-marginals and reducing the existence, counting, and entry-security problems for 1-marginals with upper bounds to that for 2-marginals with no upper bounds in slim tables. We prove the following somewhat technical statement.

THEOREM 1.4. *Given* 1*-marginals* $(u_{i,+,+})$, $(u_{+,j,+})$, $(u_{+,+,k})$ *and entry upper bounds* $(p_{i,j,k})$ *for* 3*-tables of size* (r,c,h)*, there exist polynomial time constructible* 2*-marginals* $(v_{i,j,+})$, $(v_{i,+,k})$, $(v_{+,j,k})$ *for* 3*-tables of size* $(3, rc, r+c+h)$ *such that the set of nonnegative real* (r,c,h)*-arrays with the given upper bounds and* 1*-marginals is in integer preserving affine bijection with the set of nonnegative real* $(3, rc, r+c+h)$*-arrays with the constructed* 2*-marginals.*

A particularly appealing outcome of our constructions is the systematic and illuminating derivation of "real-feasible integer-infeasible" collections of 2-marginals, admitting nonnegative real 3-arrays but no (integer) 3-tables. Remarkably, applying our construction to very simple $\{0,1\}$-valued 1-marginals and entry upper bounds for 3-tables of size $(2,2,2)$, we "automatically" recover a famous example due to Vlach of a real-feasible integer-infeasible collection of $\{0,1\}$-valued 2-marginals for 3-tables of smallest possible size $(3,4,6)$; see our Example 2.2.

We conclude this introduction with some final discussion. First, we refer to the open problems left in the $(2,2)$ entries of Theorems 1.1 and 1.3. Consider the set of 3-tables v of size (r,c,h) with r,c fixed satisfying specified marginals $(v_{i,+,k})$ and $(v_{+,j,k})$ but *without* restriction on the marginal $(v_{i,j,+})$. The projection $\mathbf{R}^{r\cdot c\cdot h} \longrightarrow \mathbf{R}^{r\cdot c} : v \mapsto (v_{i,j,+}) = \sum_{k=1}^{h} v_{i,j,k}$ sends the associated multi-index transportation polytope onto a subpolytope P of the transportation polytope of all 2-tables of size (r,c) with 1-marginals $(u_{i,+}) := (v_{i,+,+})$ and $(u_{+,j}) := (v_{+,j,+})$. The techniques of [1, 3, 19, 23, 24] allow us to produce the vertices of P in polynomial time and check if any given "vertical" marginal $(v_{i,j,+})$ lies in P, which is necessary for the existence of a 3-table with $(v_{i,+,k})$, $(v_{+,j,k})$, *and* $(v_{i,j,+})$. Further development of the methods of [1, 3, 19, 23, 24] combined with integer programming in fixed dimension might help in addressing these remaining problems.

Although our results stress the complexity of handling even small and slim 3-way tables for statistical applications, recent results using special structure in specific systems may make such table systems amenable to geometric algorithms for practical computations. For example, in [11, 14, 18] the specified marginals satisfy a hierarchical structure of certain graphical models in statistics. Other approaches include the new generation of algebraic and randomized algorithms [8, 13], which will allow, in practice, faster computations for increasingly larger problems.

2. The table existence problem. In this section we provide the proof of Theorem 1.1 discussed in subsection 1.1 and demonstrate our constructions with some examples. In particular, as explained in the introduction, using our construction we recover the smallest possible real-feasible integer-infeasible collection of 2-marginals of 3-tables of size $(3,4,6)$.

Proof of Theorem 1.1. As explained in subsection 1.1, entry $(1,1)$ of the complexity table claimed by Theorem 1.1 is easy and entry $(2,1)$ follows from [21]. Entry $(1,2)$ follows from entry $(1,2)$ in the table of Theorem 1.2, which will be proved in the next section: indeed, we shall show in section 3 how to compute in polynomial time the number of 3-tables of size (r,c,h) with r,c fixed satisfying given 2-marginals in unary, and hence in particular how to decide if this number is zero or not, providing a solution of the existence problem as well.

We need then prove entry $(1,3)$ of the table, which implies at once entries $(2,3),(1,4),(2,4)$ as well. It is easy to see that the well-known three-dimensional matching problem (cf. [15]) is equivalent to the following problem: Given a $\{0,1\}$-valued 3-table $p = (p_{i,j,k})$ of size (n,n,n), is there a 3-table $x = (x_{i,j,k})$ with all 1-marginals equal to 1 which is *dominated* by p, i.e., satisfies the upper bounds

$x_{i,j,k} \le p_{i,j,k}$ for all i,j,k? We reduce this problem to ours, which is clearly in NP. Then let $p = (p_{i,j,k})$ be a given $\{0,1\}$-valued 3-table of size (n,n,n). We define efficiently constructible 2-marginals for $(3, n^2, 3n)$-tables such that nonnegative real arrays y with these marginals are in integer preserving affine bijection with nonnegative real (n,n,n)-arrays x with all 1-marginals equal to 1 dominated by p. For clarity, the table will be indexed by triplets of special form, which we now explain. The first index will be an integer $1 \le t \le 3$. The second index will be an ordered pair ij with $1 \le i,j \le n$. The third index will belong into one of three groups—the "domination" group, the "row" group, and the "column" group—and will consist of one of three three-letter abbreviations $_{\text{gro}} \in \{_{\text{dom}}, _{\text{row}}, _{\text{col}}\}$ according to the group it belongs to, along with a numerical index $1 \le k \le n$. The 2-marginals are provided by the following:

$(v_{+,ij,\text{gro}\,k}) =$

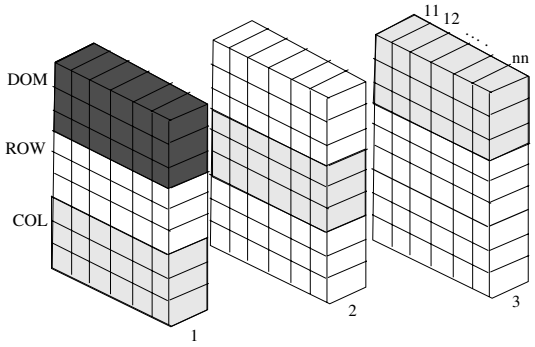

FIG. 1. *Block partition of* $(3, n^2, 3n)$*-arrays.*

First consider any nonnegative real (n, n, n)-array x dominated by p with all 1-marginals equal to 1. We show that it uniquely extends to a nonnegative real $(3, n^2, 3n)$-array with 2-marginals as above. It will be convenient to keep in mind a partition of $(3, n^2, 3n)$-arrays into blocks, as shown in Figure 1. Given then such an array x, embed it in the *black block* $(1, \text{dom})$ of a $(3, n^2, 3n)$-array y by

$$y_{1,ij,\text{dom}\,k} := x_{i,j,k}\,, \qquad 1 \le i, j, k \le n\ .$$

We now show that the block x can be uniquely extended to a whole nonnegative real $(3, n^2, 3n)$-array y with the above 2-marginals. First consider the entries in the *grey blocks* $(1, \text{col})$*,* $(2, \text{row})$*, and* $(3, \text{dom})$ in Figure 1: since $v_{1,+,\text{col}\,k} = v_{2,+,\text{row}\,k} = v_{3,+,\text{dom}\,k} = 0$ for all k, it follows that all the entries $y_{1,ij,\text{col}\,k}$, $y_{2,ij,\text{row}\,k}$, and $y_{3,ij,\text{dom}\,k}$ constituting these blocks are zero. Next, consider the entries in the *white block* $(1, \text{row})$: using the fact just established that all entries in the block $(1, \text{col})$ below it are zero, and examining the 2-marginals $v_{+,ij,\text{row}\,k}$ and $v_{1,ij,+} = 1$, we find that $y_{1,ij,\text{row}\,i} = 1 - \sum_{k=1}^{n} y_{1,ij,\text{dom}\,k} = 1 - x_{i,j,+} \ge 0$, whereas for $k \ne i$ we have $y_{1,ij,\text{row}\,k} = 0$. This also yields the entries in the *white block* $(3, \text{row})$: we have $y_{3,ij,\text{row}\,i} = 1 - y_{1,ij,\text{row}\,i} = x_{i,j,+} \ge 0$, whereas for $k \ne i$ we have $y_{3,ij,\text{row}\,k} = 0$. Next, consider the entries in the *white block* $(2, \text{dom})$: using the fact that all entries in the block $(3, \text{dom})$ to its right are zero, and examining the 2-marginals $v_{+,ij,\text{dom}\,k} = p_{i,j,k}$, we find that $y_{2,ij,\text{dom}\,k} = p_{i,j,k} - x_{i,j,k} \ge 0$ for all i, j, k. Next consider the entries in the *white block* $(2, \text{col})$: using the fact that all entries in the block $(2, \text{row})$ above it are zero, and examining the 2-marginals $v_{+,ij,\text{col}\,k}$ and $v_{2,ij,+} = p_{i,j,+}$, we find that $y_{2,ij,\text{col}\,j} = p_{i,j,+} - \sum_{k=1}^{n} y_{2,ij,\text{dom}\,k} = x_{i,j,+} \ge 0$, whereas for $k \ne j$ we have $y_{2,ij,\text{col}\,k} = 0$. This also yields the entries in the *white block* $(3, \text{col})$: we have $y_{3,ij,\text{col}\,j} = 1 - y_{2,ij,\text{col}\,j} = 1 - x_{i,j,+} \ge 0$, whereas for $k \ne j$ we have $y_{3,ij,\text{col}\,k} = 0$.

Next consider any nonnegative real $(3, n^2, 3n)$-array y with the above 2-marginals, and let x be its (n, n, n)-subarray given by the black block $(1, \text{dom})$ of y, defined by $x_{i,j,k} := y_{1,ij,\text{dom}\,k}$ for all i, j, k. We show that x is nonnegative, dominated by p, and has all 1-marginals equal to 1. It is nonnegative since so is y. It is dominated by p since, for all i, j, k, we have $p_{i,j,k} - x_{i,j,k} = y_{2,ij,\text{dom}\,k} \ge 0$. Finally, all the 1-marginals of x are equal to 1 since

$$x_{+,+,k} \;=\; \sum_{i,j} y_{1,ij,\text{dom}\,k} \;=\; v_{1,+,\text{dom}\,k} \;=\; 1\,, \qquad 1 \le k \le n\ ;$$

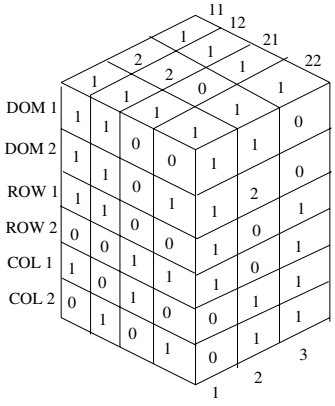

FIG. 2. *The* 2*-marginals* $v_{+,ij,\mathrm{gro}\,k}$, $v_{t,+,\mathrm{gro}\,k}$, $v_{t,ij,+}$ *constructed in Example* 2.1.

$$x_{i,+,+} \;=\; \sum_j y_{3,ij,\mathrm{row}\,i} \;=\; v_{3,+,\mathrm{row}\,i} \;=\; 1\,, \qquad 1 \le i \le n\;;$$

$$x_{+,j,+} \;=\; \sum_i y_{2,ij,\mathrm{col}\,j} \;=\; v_{2,+,\mathrm{col}\,j} \;=\; 1\,, \qquad 1 \le j \le n\;.$$

Thus, the set of nonnegative real (n,n,n)-arrays x dominated by p and with all 1-marginals 1 is in integer preserving affine bijection with the set of nonnegative real $(3,n^2,3n)$-arrays y with the constructed 2-marginals. In particular, the corresponding sets of tables are in bijection, and therefore the former is nonempty if and only if the latter is. This completes the reduction of three-dimensional matching to our problem, the proof of entry $(1,3)$, and the proof of Theorem 1.1.

The following two examples illustrate our construction.

Example 2.1. Let $n = 2$ and let p be the $\{0,1\}$-valued 3-table of size $(2,2,2)$ given by

$$p_{1,1,1}=1,\; p_{1,2,1}=1,\; p_{2,1,1}=0,\; p_{2,2,1}=0,\; p_{1,1,2}=1,\; p_{1,2,2}=1,\; p_{2,1,2}=0,\; p_{2,2,2}=1\,.$$

Our construction yields the 2-marginals for 3-tables of size $(3,4,6)$ presented in Figure 2. The unique 3-table x with all 1-marginals equal to 1 which is dominated by p is given by

$$x_{1,1,1}=1,\; x_{1,2,1}=0,\; x_{2,1,1}=0,\; x_{2,2,1}=0,\; x_{1,1,2}=0,\; x_{1,2,2}=0,\; x_{2,1,2}=0,\; x_{2,2,2}=1\,,$$

and the corresponding 3-table y with the above 2-marginals is given by the following blocks:

$y_{1,ij,\mathrm{gro}\,k}$

	11	12	21	22
dom 1	1	0	0	0
dom 2	0	0	0	1

col 2	0	1	0	0

.

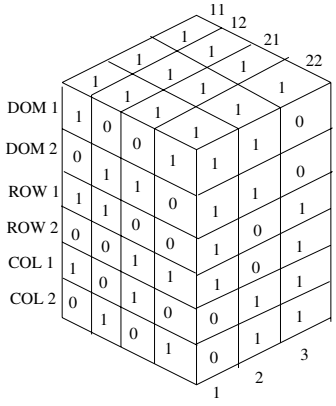

FIG. 3. *Derivation of Vlach's example from our construction.*

As pointed out in the introduction, our construction can be used to systematically obtain "real-nonempty integer-empty" multi-index transportation polytopes, namely, collections of 2-marginals admitting nonnegative real 3-arrays but no (integer) 3-tables. In particular, we next recover the smallest such example, first discovered by Vlach [28], as follows.

Example 2.2. Again, let $n = 2$ and let p be the $\{0,1\}$-valued 3-table of size $(2,2,2)$ given by

$$p_{1,1,1} = 1,\ p_{1,2,1} = 0,\ p_{2,1,1} = 0,\ p_{2,2,1} = 1,\ p_{1,1,2} = 0,\ p_{1,2,2} = 1,\ p_{2,1,2} = 1,\ p_{2,2,2} = 0\,.$$

Our construction yields the 2-marginals for 3-tables of size $(3,4,6)$ presented in Figure 3. It can be verified that there is a single nonnegative real array of size $(2,2,2)$ with all 1-marginals equal to 1 which is dominated by the upper-bound table p. All entries of this array are $\{0,\frac{1}{2}\}$-valued, and there is no (integer) table with the prescribed constraints. Our construction lifts this situation to 2-marginals with no upper bounds: all entries of the unique corresponding nonnegative real array of size $(3,4,6)$ with the 2-marginals in Figure 3 are $\{0,\frac{1}{2}\}$-valued, and there is no (integer) table with these constructed 2-marginals.

3. The table counting problem. In this section we provide the proof of Theorem 1.2 discussed in subsection 1.2.

Proof of Theorem 1.2. As explained in subsection 1.2, entry $(1,1)$ of the complexity table claimed by Theorem 1.2 is easy, entry $(2,1)$ follows from [4], and entry $(2,2)$ follows from [13].

First, we prove entry $(1,3)$ of the table, which implies at once entries $(2,3),(1,4)$, $(2,4)$ as well. We describe a direct reduction from Valiant's canonical $\#P$-complete problem of computing the *permanent* of a $\{0,1\}$-valued matrix [27] (recall that the *permanent* of an n by n matrix A is $\mathrm{perm}(A) := \sum_\sigma \prod_{i=1}^n A_{i,\sigma(i)}$, the sum extending over all permutations σ of $\{1,\ldots,n\}$; for instance, the permanent of the adjacency matrix of a subgraph of the complete bipartite graph $K_{n,n}$ is the number of perfect matchings in that subgraph).

Then let A be a $\{0,1\}$-valued n by n matrix, the permanent of which is to be

computed. Define 2-marginals for 3-tables of size $(2,n,n)$ by

$$v_{i,j,+} := A_{i,j}\,, \quad v_{i,+,1} := v_{+,j,1} := 1\,, \quad v_{i,+,2} := A_{i,+} - 1\,, \quad v_{+,j,2} := A_{+,j} - 1, \qquad 1 \le i,j \le n.$$

Any 3-table x with these marginals is determined by its 2-subtable $(x_{i,j,1})$ since for all i,j we have $x_{i,j,2} = A_{i,j} - x_{i,j,1}$. Now, it is not hard to see that a nonnegative integer n by n matrix Σ can arise as the subtable $(x_{i,j,1})$ of a 3-table x with the constructed 2-marginals if and only if it is the standard representing matrix of a permutation σ satisfying $\prod_{i=1}^{n} A_{i,\sigma(i)} = 1$. Therefore, the permanent of A, which is the number of such permutations σ, is precisely the number of 3-tables with the constructed 2-marginals, completing the reduction and the proof of entry $(1,3)$.

Next we prove entry $(1,2)$ of the table of Theorem 1.2. Note that, as explained in the proof of Theorem 1.1, this implies the corresponding entry $(1,2)$ in the table of Theorem 1.1 as well.

So, r,c are fixed, and we are given unary presented 2-marginals $v_{i,j,+}$, $v_{i,+,k}$, and $v_{+,j,k}$ for 3-tables of size (r,c,h). Let S be the set of all 2-tables s of size (r,c) satisfying the upper bounds $s_{i,j} \le v_{i,j,+}$ for all i,j, that is, dominated by the given "vertical" marginals. For $k = 1,\ldots,h$ define a matrix A_k whose rows and columns are indexed by the elements of S, with entries

$$(A_k)_{s,t} := \begin{cases} 1 & \text{if } (t-s)_{i,+} = v_{i,+,k} \text{ for all } i \text{ and } (t-s)_{+,j} = v_{+,j,k} \text{ for all } j, \\ 0 & \text{otherwise,} \end{cases} \qquad s,t \in S. \tag{3.1}$$

For $p = 1,\ldots,h$ let $A^p := A_1 \cdot A_2 \cdot \ldots \cdot A_p$ be the product of the matrices A_k, $k = 1,\ldots,p$. Further, let l,u denote, respectively, the tables in S with entries $l_{i,j} := 0$ and $u_{i,j} := v_{i,j,+}$ for all i,j.

We claim that for any $1 \le p \le h$ and for any $s,t \in S$, the number of 3-tables x of size (r,c,p) with $x_{i,+,k} = v_{i,+,k}$, $x_{+,j,k} = v_{+,j,k}$, and $x_{i,j,+} = (t-s)_{i,j}$ for $1 \le i \le r$, $1 \le j \le c$, and $1 \le k \le p$ is precisely equal to the entry $A^p_{s,t}$ of A^p. In particular, the number of (r,c,h)-tables with the given 2-marginals is given by $A^h_{l,u}$. Since r,c are fixed and the 2-marginals are presented in unary, the number $\prod_{i=1}^{r}\prod_{j=1}^{c}(v_{i,j,+}+1)$ of tables in S is polynomial in the size of the input, and therefore the matrix A^h and its sought entry $A^h_{l,u}$ can be computed in polynomial time.

We prove the claim by induction on p. First, consider the case $p = 1$ and let s,t be any pair of tables of S. There is a unique $(r,c,1)$-array x satisfying $x_{i,j,1} = x_{i,j,+} = (t-s)_{i,j}$ for all i,j, and x is a table satisfying $x_{i,+,1} = v_{i,+,1}$ and $x_{+,j,1} = v_{+,j,1}$ if and only if $(t-s)_{i,+} = v_{i,+,1}$ and $(t-s)_{+,j} = v_{+,j,1}$ for all i,j, which by (3.1) holds if and only if $A^1_{s,t} = (A_1)_{s,t} = 1$.

Next, consider any $2 \le p \le h$ and suppose the statement is true for all values less than p. Let s,t be any pair of tables of S. Then any (r,c,p)-table x with $x_{i,+,k} = v_{i,+,k}$, $x_{+,j,k} = v_{+,j,k}$, and $x_{i,j,+} = (t-s)_{i,j}$ for all i,j,k is obtained, for some $w \in S$, by augmenting any of the $A^{p-1}_{s,w}$ tables y of size $(r,c,p-1)$ with $y_{i,+,k} = v_{i,+,k}$, $y_{+,j,k} = v_{+,j,k}$, and $y_{i,j,+} = (w-s)_{i,j}$ for all i,j,k by any of the $(A_p)_{w,t}$ tables z of size $(r,c,1)$ with $z_{i,+,1} = v_{i,+,p}$, $z_{+,j,1} = v_{+,j,p}$, and $z_{i,j,+} = (t-w)_{i,j}$ for all i,j. Thus, the number of such tables is $\sum_{w\in S} A^{p-1}_{s,w}(A_p)_{w,t}$, which is precisely $A^p_{s,t}$, proving the induction step and the claim, and thus completing the proof of entry $(1,2)$ and of Theorem 1.2. □

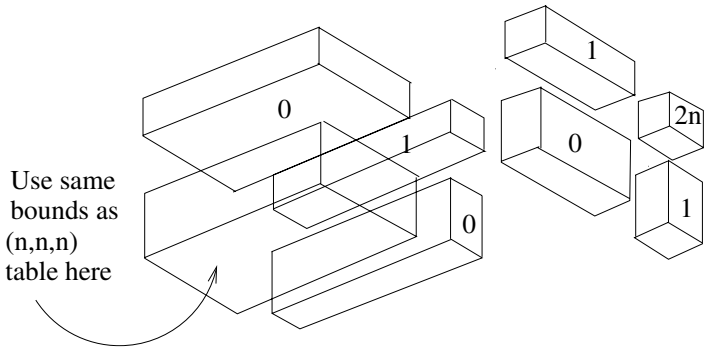

FIG. 4. *The entry bounds for* 3*-tables of size* $(n+1, n+1, n+1)$.

4. The table entry-security problem. In this section we provide the proof of Theorem 1.3 discussed in subsection 1.3.

Proof of Theorem 1.3. Once again, as explained in subsection 1.3, entry $(1,1)$ of the complexity table claimed by Theorem 1.3 is easy and entry $(2,1)$ follows from [21]. We need to prove entry $(1,3)$, which implies at once entries $(2,3), (1,4), (2,4)$ as well, and entry $(1,2)$.

We begin with the proof of entry $(1,3)$: we prove that both the lower and upper entry-security problems are hard. In fact, we prove stronger results by showing that each of the following special cases is already hard: (a) we reduce three-dimensional matching to the problem of deciding whether, given a feasible collection of 2-marginals, there is a 3-table with a specified entry equal to the maximal possible value given by the Fréchet upper bound (minimal value of the three 2-marginals involving this entry). Thus, even the special case of the lower entry-security problem with L the Fréchet upper bound is hard. (b) We reduce the table existence problem to the problem of deciding whether, given a feasible collection of 2-marginals, there is a 3-table with a specified entry equal to the minimal possible value zero; thus, even the special case of the upper entry-security problem with $U = 0$ is hard.

We begin with part (a). We reduce the three-dimensional matching problem to the problem of deciding whether, given feasible 2-marginals, there is a slim 3-table with a specified entry attaining the Fréchet upper bound. As mentioned in section 2, the three-dimensional matching problem is equivalent to the following problem: Given a $\{0,1\}$-valued 3-table $p = (p_{i,j,k})$ of size (n,n,n), is there a 3-table $x = (x_{i,j,k})$ with all 1-marginals $u_{i,+,+}$, $u_{+,j,+}$, $u_{+,+,k}$ equal to 1 which is *dominated* by p, i.e., satisfies the upper bounds $x_{i,j,k} \le p_{i,j,k}$ for all i,j,k? Given such data, we expand it to data for upper bounds and 1-marginals for 3-tables of enlarged size $(n+1, n+1, n+1)$ as follows: we maintain the given upper bounds $p_{i,j,k}$ and the 1-marginals $u_{i,+,+}$, $u_{+,j,+}$, $u_{+,+,k}$ equal to 1 for $1 \le i,j,k \le n$; we introduce the new upper bounds $p_{n+1,n+1,n+1} := 2n$, $p_{i,j,n+1} := p_{i,n+1,k} := p_{n+1,j,k} := 0$ for $1 \le i,j,k \le n$, and $p_{i,n+1,n+1} := p_{n+1,n+1,k} := p_{n+1,j,n+1} := 1$ for $1 \le i,j,k \le n$. Finally, the three new 1-marginals are introduced by $u_{n+1,+,+} := 2n$, $u_{+,n+1,+} := 2n$, and $u_{+,+,n+1} := 2n$. The extended bounds are shown in Figure 4 on the union of the input (n,n,n)-table and seven other blocks. We claim that the extended 1-marginals and upper bounds are feasible: indeed, the $(n+1, n+1, n+1)$-table x defined by setting $x_{i,n+1,n+1} := x_{n+1,n+1,k} := x_{n+1,j,n+1} := 1$ for all $1 \le i,j,k \le n$ and zero in all other entries has the specified marginals.

Now consider any feasible extended table x: then it is not hard to see that its (n,n,n)-subtable $(x_{i,j,k})_{1,1,1}^{n,n,n}$ is feasible for the original data (coming from the input to the three-dimensional matching) if and only if the entry $x_{n+1,n+1,n+1}$ equals the maximal possible value $2n$.

Now, we "lift" the situation to the problem with 2-marginals and no upper bounds in slim tables as follows: To the extended upper bound and 1-marginal data for $(n+1,n+1,n+1)$-tables, apply the transformation described in Theorem 1.4 (to be proved in the next section). This gives feasible 2-marginals for 3-tables of size $(3,(n+1)^2,3(n+1))$. By Theorem 1.4, there is a feasible $(n+1,n+1,n+1)$-table x whose entry $x_{n+1,n+1,n+1}$ attains the maximal possible value $2n$ if and only if there is a feasible $(3,(n+1)^2,3(n+1))$-table y whose entry $y_{1,(n+1)(n+1),\mathrm{dom}\,(n+1)}$ attains the maximal possible value $2n$. This completes the proof of part (a).

Next we prove part (b). Suppose then that we are given all the 2-marginals $v_{i,j,+}$, $v_{+,j,k}$, $v_{i,+,k}$ for 3-tables of size (r,c,h), and we need to decide whether there exists a 3-table with these 2-marginals. For simplicity we denote the given 2-marginals by $A_{i,j} := v_{i,j,+}, B_{j,k} := v_{+,j,k}$, and $C_{i,k} := v_{i,+,k}$. Without loss of generality we may assume that the given 2-marginals are consistent. Recall that consistency means that any pair of adjacent 2-marginals agree on their common 1-marginals and 0-marginals. This is a necessary condition for the problem to be feasible at all. Otherwise there is no table with these marginals. In our situation, consistency means that $A_{i,j}, B_{j,k}$, and $C_{i,k}$ have the same 0-marginal $T := \sum_i^r \sum_k^h C_{i,k} = \sum_i^r \sum_j^c A_{i,j} = \sum_j^c \sum_k^h B_{j,k}$. This is the total entry sum of any 3-table with 2-marginals A, B, C. In addition, any pair of adjacent 2-marginals must agree on their common 1-marginals, i.e., $C_{i,+} = A_{i,+}$, $A_{+,j} = B_{j,+}$, and $C_{+,k} = B_{+,k}$. These consistency equalities will be useful later on.

We will now construct a *feasible* set of 2-marginals for a family of 3-tables $R_{s,t,u}$ of size $(r+1,c+1,h+1)$. The entry-value of a certain entry $R_{s,t,u}$ can be used to decide whether the original set of 2-marginals A,B,C is feasible. We present the 2-marginals in Figure 5 as numbers on the surface of a 3-table. The three 2-marginals $R_{+,t,u}$, $R_{s,+,u}$, $R_{s,t,+}$ are indicated by the coordinate directions in Figure 5.

The reader can verify (see Figure 5) that the assignment is done as follows: for 2-marginal $R_{s,+,u}$ we set $R_{1,+,1} = T$, $R_{1,+,2} = C_{+,h}, R_{1,+,3} = C_{+,h-1}, \ldots, R_{1,+,t} = C_{+,h-t+2}, \ldots, R_{1,+,h+1} = C_{+,1}$. Similarly $R_{2,+,1} = C_{1,+}, \ldots, R_{s,+,1} = C_{s-1,+}, \ldots, R_{r+1,+,1} = C_{r,+}$. Finally, we have the assignment $R_{s,+,u} = C_{s-1,u-1}$ for $s = 2,\ldots,r+1$ and $u = 2,\ldots,h+1$. Next for 2-marginal $R_{s,t,+}$ we have $R_{1,1,+} = T$, $R_{1,2,+} = B_{1,+}, \ldots, R_{1,t,+} = B_{t-1,+}, \ldots, R_{1,c+1,+} = B_{c,+}$; we also have $R_{2,1,+} = C_{1,+}, \ldots, R_{s,1,+} = C_{s-1,+}, \ldots, R_{r+1,1,+} = C_{r,+}$, and $R_{s,t,+} = A_{s-1,t-1}$ for $s = 2,\ldots,r+1$ and $t = 2,\ldots,c+1$. Finally for 2-marginal $R_{+,t,u}$ we have that $R_{+,1,1} = T$ and we set $R_{+,2,1} = A_{+,1}, \ldots, R_{+,t,1} = A_{+,t-1}, \ldots, R_{+,c+1,1} = A_{+,c}$. Also from the picture we see that $R_{+,1,2} = C_{+,h}, \ldots, R_{+,1,u} = C_{+,h-u+2}, \ldots, R_{+,1,h+1} = C_{+,1}$ and $R_{+,t,u} = B_{t-1,u-1}$ for $t = 2,\ldots,c+1$ and $u = 2,\ldots,h+1$.

Note that any such 3-table R with the given 2-marginals breaks up naturally into eight smaller 3-tables. We show these "blocks" $b(1),\ldots,b(8)$ in Figure 6 marking their dimensions. We will use these eight blocks to explain how to fill in the entries of the 3-table and thus to prove that our construction indeed gives (1) *a feasible set of* 2*-marginals and* (2) *the entry* $R_{1,1,1}$ *can be filled in with zero for some* 3*-table satisfying all* 2*-marginals if and only if the original set of* 2*-marginals* A,B,C *is feasible.* The notation we use in subsequent figures to depict a way of filling the entries of a block is by either writing a single number (e.g., zero), which is used to fill *all* the block's entries, or listing a table (e.g., $C_{i,k}$) which indicates that the entries of that table are

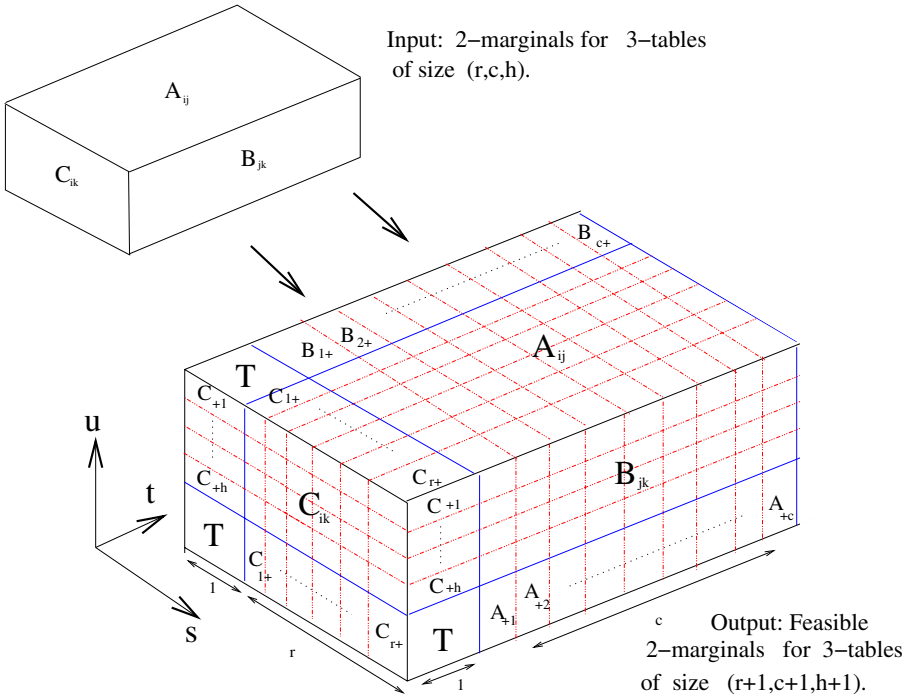

FIG. 5. *The construction of feasible* 2*-marginals from input* 2*-marginals.*

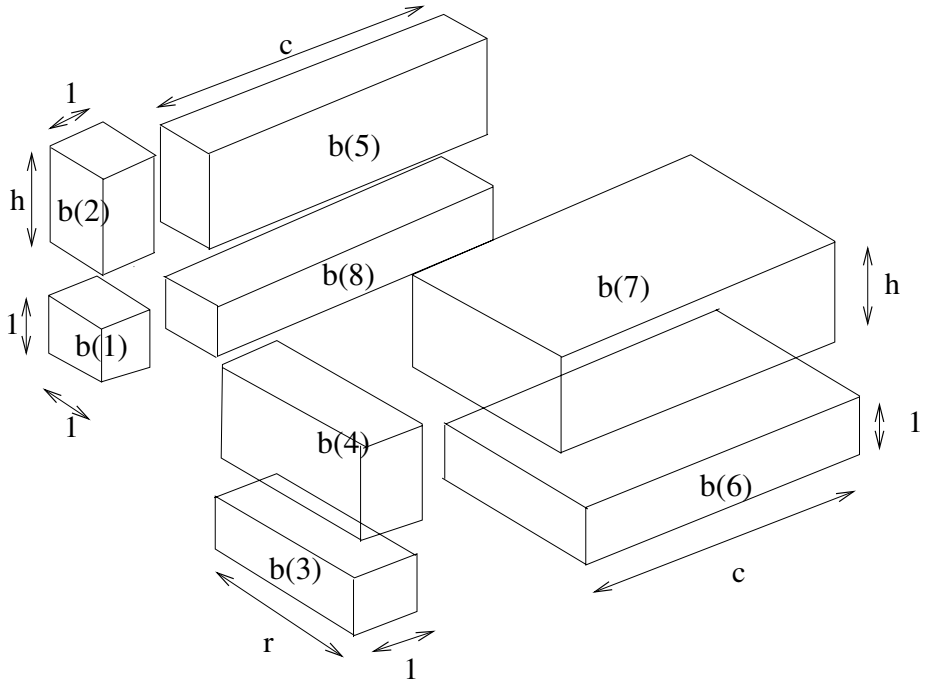

FIG. 6. *Blocks determined by the proposed* 2*-marginals.*

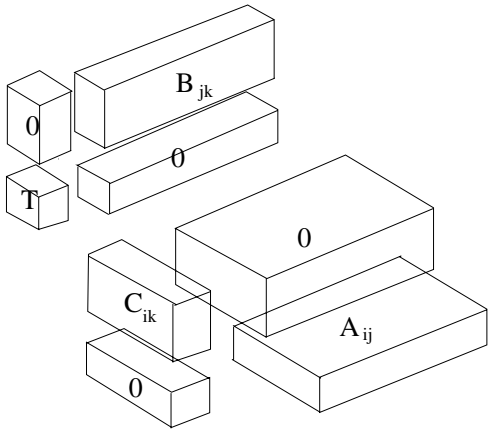

FIG. 7. *A 3-table with the proposed 2-marginals.*

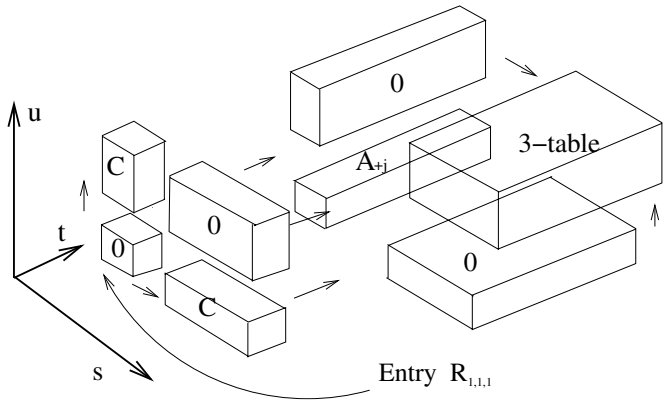

FIG. 8. *A 3-table with the proposed 2-marginals when* $R_{1,1,1} = 0$.

copied down verbatim to be the entries of the block.

Figure 7 shows a concrete 3-table which indeed satisfies the 2-marginals given in the construction. More explicitly, fill the entries as follows: *Block* $b(1)$, a single entry $R_{1,1,1} = T$. *Block* $b(2)$ has entries $R_{1,1,u}$ for $u = 2, \ldots, h+1$. We fill them by $R_{1,1,u} = 0$. *Block* $b(3)$ has entries $R_{s,1,1}$ for $s = 2, \ldots, r+1$. We fill them by $R_{s,1,1} = 0$. *Block* $b(4)$ has entries $R_{s,1,u}$ for $s = 2, \ldots, r+1$ and $u = 2, \ldots, h+1$. We fill them by $R_{s,1,u} = C_{s-1,u-1}$. *Block* $b(5)$ has entries $R_{1,t,u}$ for $t = 2, \ldots, c+1$ and $u = 2, \ldots, h+1$. We fill them by $R_{1,t,u} = B_{t-1,u-1}$. *Block* $b(6)$ has entries $R_{s,t,1}$ for $s = 2, \ldots, c+1$ and $t = 2, \ldots, r+1$. We fill them by $R_{s,t,1} = A_{s-1,t-1}$. The entries of $b(7)$ and $b(8)$ are all zero. It is simple to verify that all the line sums agree with the totals stated in Figure 5, because in the construction we used the 1-marginals of the 2-tables A, B, C as part of the 2-marginals, and the data is consistent. This proves the first claim.

Now we claim that the entry $R_{1,1,1}$ takes on the value zero for some 3-table $R_{s,t,u}$ of size $(r+1, c+1, h+1)$ if and only if the 2-marginals A, B, C have a feasible solution. Let us assume that there is a 3-table $R_{s,t,u}$ of size $(r+1, c+1, h+1)$ and $R_{1,1,1} = 0$. We divide the argument into two steps illustrated on the left-hand side of Figure 8.

If the entry $R_{1,1,1}$ is zero, we must have filled $R_{2,1,1} = C_{1,+}$, $R_{3,1,1} = C_{2,+}, \ldots,$ $R_{(r+1),1,1} = C_{c,+}$ and $R_{1,1,2} = C_{+,1}, \ldots, R_{1,1,2} = C_{+,2}, \ldots, R_{1,1,(h+1)} = C_{+,h}$. The reason is that the 2-marginals $R_{+,1,1}$ and $R_{1,1,+}$ are equal to the total sum T, and $T = \sum C_{i,+} = \sum C_{+,j}$. This completes the filling of blocks $b(2)$ and $b(3)$. Now, the marginals $R_{s,t,+}$ and $R_{+,t,u}$ attached to $b(4)$ imply that $b(4)$ is simply full of zeros; otherwise we surpass the 2-marginals. This completes the first step of the argument.

For the second step we refer to the right-hand side of Figure 8. The marginal table $R_{s,+,u}$ and the assignments so far for blocks $b(2)$ and $b(3)$ imply that only zero values can be put in the entries of blocks $b(5)$ and $b(6)$; otherwise we surpass $R_{s,+,u}$. Now blocks $b(7), b(8)$ are left to be determined. The 2-marginals corresponding to $b(8)$ indicate the entries of $b(8)$ are $R_{1,2,1} = A_{+,1} = B_{1,+}, \ldots, R_{1,j,1} = A_{+,j} = B_{j,+}, \ldots, R_{1,(c+1),1} = A_{+,c} = B_{c,+}$. Note that these are in fact the 1-marginals that follow from the input 2-marginals A, B, C. Finally, block $b(7)$ is the only block unfilled so far. Looking at the zeros that fill blocks $b(4), b(5)$, and $b(6)$, we see block $b(7)$ is indeed a 3-table with 2-marginals A, B, C, and this ends the proof of the claim. Now conversely, and essentially following a reverse order, if there is a 3-table with 2-marginals A, B, C, we can put a copy of it as block $b(7)$. Then by the corresponding 2-marginals we see $b(4), b(5), b(6)$ are filled with zeros. This forces $R_{2,1,1} = C_{1,+}, R_{3,1,1} = C_{2,+}, \ldots, R_{(r+1),1,1} = C_{c,+}$ and $R_{1,1,2} = C_{+,1}, \ldots, R_{1,1,2} = C_{+,2}, \ldots, R_{1,1,(h+1)} = C_{+,h}$. This is because the 2-marginals $R_{+,1,1}$ and $R_{1,1,+}$ equal the total sum T and the 2-marginals $R_{s,+,u}$. Finally, the entry $R_{1,1,1}$ is forced to be zero. This completes the proof of part (b) and the proof of entry $(1,3)$, and hence also of entries $(2,3), (1,4), (2,4)$ in the table of Theorem 1.3.

Finally, we establish entry $(1,2)$ in the statement of Theorem 1.3: we present a polynomial time algorithm for deciding whether there is a 3-table x with specified 2-marginals whose entry $x_{1,1,1}$ is in the range $L \le x_{1,1,1} \le U$. The lower (respectively, upper) entry-security problem is the special case of this entry-range problem obtained by taking U to be the Fréchet upper bound $U := \min\{v_{1,1,+}, v_{1,+,1}, v_{+,+,1}\}$ (respectively, taking $L := 0$). We use a simple modification of the algorithm for enumeration presented in the proof of Theorem 1.2 in the previous section; using the notation in that proof, we simply need to modify the definition of the first matrix A_1, where for $s, t \in S$, its (s,t)th entry is now redefined to be

$$(A_1)_{s,t} := \begin{cases} 1 & \text{if } (t-s)_{i,+} = v_{i,+,k} \text{ for all } i,\ (t-s)_{+,j} = v_{+,j,k} \text{ for all } j, \\ & \text{and } L \le (t-s)_{1,1} \le U, \\ 0 & \text{otherwise.} \end{cases}$$

The other matrices A_k remain as before. The entry $A^h_{l,u}$ of the product matrix now yields the number of tables with $L \le x_{1,1,1} \le U$ and hence is nonzero if and only if such a table exists. □

5. Multi-index transportation polytopes and the power of 2-marginals. We conclude with the proof of Theorem 1.4 discussed in subsection 1.4.

Proof of Theorem 1.4. The proof is based on an extension of the construction used in the proof of Theorem 1.1. We provide the construction and an abridged form of the argumentation.

Given 1-marginals $(u_{i,+,+})$, $(u_{+,j,+})$, $(u_{+,+,k})$ and entry upper bounds $(p_{i,j,k})$ for 3-tables of size (r, c, h), we define efficiently constructible 2-marginals $(v_{i,j,+})$, $(v_{i,+,k})$, $(v_{+,j,k})$ for 3-tables of size $(3, rc, r + c + h)$ such that nonnegative real arrays y with

these marginals are in integer preserving affine bijection with nonnegative real 3-arrays x of size (r,c,h) satisfying the given 1-marginals and upper bounds, thus providing an isomorphism of the corresponding multi-index transportation polytopes and sets of tables of the two systems.

As in the proof of Theorem 1.1, $(3, rc, r+c+h)$-tables will be indexed by triplets, with the first index an integer $1 \le t \le 3$, the second index an ordered pair ij with $1 \le i \le r$ and $1 \le j \le c$, and the third index a three-letter abbreviation $_{\text{gro}} \in \{_{\text{dom}}, _{\text{row}}, _{\text{col}}\}$ along with a numerical index $1 \le k \le h$. Let U denote the minimal of the two values $\max\{u_{i,+,+} : 1 \le i \le r\}$ and $\max\{u_{+,j,+} : 1 \le j \le c\}$. The 2-marginals are provided by the following three matrices:

We make use again of a partition of $(3, rc, r+c+h)$-arrays into blocks similar to Figure 1. First consider any nonnegative real (r, c, h)-array x satisfying the given 1-marginals and upper bounds. We show that it uniquely extends to a nonnegative real $(3, rc, r+c+h)$-array with 2-marginals as above. Given such an array x, embed it in the *black block* $(1, \text{dom})$ of a $(3, rc, r+c+h)$-array y by $y_{1,ij,\text{dom}\,k} := x_{i,j,k}$ for all i, j, k. We now show that the block x can be uniquely extended to a whole nonnegative real $(3, rc, r+c+h)$-array y with the above 2-marginals. First, the entries in the *grey blocks* $(1, \text{col})$, $(2, \text{row})$, *and* $(3, \text{dom})$ in Figure 1 are all zero since so are the 2-marginals $v_{1,+,\text{col}\,k} = v_{2,+,\text{row}\,k} = v_{3,+,\text{dom}\,k} = 0$ for all k. Next, consider the entries in the *white block* $(1, \text{row})$: using the fact that all entries in the block $(1, \text{col})$ below it are zero, and examining the 2-marginals $v_{+,ij,\text{row}\,k}$ and $v_{1,ij,+} = U$, we find that $y_{1,ij,\text{row}\,i} = U - \sum_{k=1}^{h} y_{1,ij,\text{dom}\,k} = U - x_{i,j,+} \geq 0$, whereas for $k \neq i$ we have $y_{1,ij,\text{row}\,k} = 0$. This also yields the entries in the *white block* $(3, \text{row})$: we have $y_{3,ij,\text{row}\,i} = U - y_{1,ij,\text{row}\,i} = x_{i,j,+} \geq 0$, whereas for $k \neq i$ we have $y_{3,ij,\text{row}\,k} = 0$. Next, consider the entries in the *white block* $(2, \text{dom})$: using the fact that all entries in the block $(3, \text{dom})$ to its right are zero, and examining the 2-marginals $v_{+,ij,\text{dom}\,k} = p_{i,j,k}$, we find that $y_{2,ij,\text{dom}\,k} = p_{i,j,k} - x_{i,j,k} \geq 0$ for all i, j, k. Next consider the entries in the *white block* $(2, \text{col})$: using the fact that all entries in the block $(2, \text{row})$ above it are zero, and examining the 2-marginals $v_{+,ij,\text{col}\,k}$ and $v_{2,ij,+} = p_{i,j,+}$, we find that $y_{2,ij,\text{col}\,j} = p_{i,j,+} - \sum_{k=1}^{h} y_{2,ij,\text{dom}\,k} = x_{i,j,+} \geq 0$, whereas for $k \neq j$ we have $y_{2,ij,\text{col}\,k} = 0$. This also yields the entries in the *white block* $(3, \text{col})$: we have $y_{3,ij,\text{col}\,j} = U - y_{2,ij,\text{col}\,j} = U - x_{i,j,+} \geq 0$, whereas for $k \neq j$ we have $y_{3,ij,\text{col}\,k} = 0$.

Next consider any nonnegative real $(3, rc, r+c+h)$-array y with the above 2-marginals, and let x be its (r, c, h)-subarray given by the black block $(1, \text{dom})$ of y, defined by $x_{i,j,k} := y_{1,ij,\text{dom}\,k}$ for all i, j, k. We show that x is nonnegative and satisfies the given upper bounds and 1-marginals. It is nonnegative since so is y. It is dominated by p since, for all i, j, k, we have $p_{i,j,k} - x_{i,j,k} = y_{2,ij,\text{dom}\,k} \geq 0$. Finally, it obeys the 1-marginals $u_{i,+,+}$, $u_{+,j,+}$, and $u_{+,+,k}$ since

$$x_{+,+,k} = \sum_{i,j} y_{1,ij,\text{dom}\,k} = v_{1,+,\text{dom}\,k} = u_{+,+,k}\,, \qquad 1 \leq k \leq h\,;$$

$$x_{i,+,+} = \sum_{j} y_{3,ij,\text{row}\,i} = v_{3,+,\text{row}\,i} = u_{i,+,+}\,, \qquad 1 \leq i \leq r\,;$$

$$x_{+,j,+} = \sum_{i} y_{2,ij,\text{col}\,j} = v_{2,+,\text{col}\,j} = u_{+,j,+}\,, \qquad 1 \leq j \leq c\,.$$

Thus, the set of nonnegative real (r, c, h)-arrays x satisfying the given upper bounds and 1-marginals is in integer preserving affine bijection with the set of nonnegative real $(3, rc, r+c+h)$-arrays y with the constructed 2-marginals. In particular, the corresponding multi-index transportation polytopes and sets of tables of the two systems are isomorphic, completing the proof. □

ON MULTIDIMENSIONAL PACKING PROBLEMS*

CHANDRA CHEKURI† AND SANJEEV KHANNA‡

Abstract. We study the approximability of multidimensional generalizations of three classical packing problems: multiprocessor scheduling, bin packing, and the knapsack problem. Specifically, we study the *vector scheduling* problem, its dual problem, namely, the *vector bin packing* problem, and a class of *packing integer programs*. The vector scheduling problem is to schedule n d-dimensional tasks on m machines such that the maximum load over all dimensions and all machines is minimized. The vector bin packing problem, on the other hand, seeks to minimize the number of bins needed to schedule all n tasks such that the maximum load on any dimension across all bins is bounded by a fixed quantity, say, 1. Such problems naturally arise when scheduling tasks that have multiple resource requirements. Finally, packing integer programs capture a core problem that directly relates to both vector scheduling and vector bin packing, namely, the problem of packing a maximum number of vectors in a single bin of unit height. We obtain a variety of new algorithmic as well as inapproximability results for these three problems.

Key words. multidimensional packing, vector scheduling, vector bin packing, packing integer programs, multiprocessor scheduling, bin packing, knapsack, approximation algorithms, hardness of approximation, combinatorial optimization

1. Introduction.

Multiprocessor scheduling, bin packing, and the knapsack problem are very well studied problems in combinatorial optimization. Their study has had a large impact on the design and analysis of approximation algorithms. All of these problems involve packing items of different sizes into bins of finite capacities. In this work we study *multidimensional* generalizations of these problems where the items to be packed are d-dimensional vectors and bins are d-dimensional objects as well. We obtain a variety of approximability and inapproximability results in the process, significantly improving upon earlier known results for these problems. Some of our results include a polynomial time approximation scheme (PTAS) for the vector scheduling problem when the dimension is fixed, and an approximation algorithm for the vector bin-packing problem that improves a two-decade-old bound. Though our primary motivation is vector scheduling and vector bin packing, an underlying problem that arises is the problem of maximizing the numbers of vectors that can be packed into a bin of fixed size. This is a special case of the multidimensional knapsack problem that is equivalent to packing integer programs (PIPs) [27, 29]. PIPs are an important class of integer programs that capture several NP-hard combinatorial optimization problems including the maximum independent set problem, the disjoint

paths problem, and hypergraph matchings. The only general technique known for approximating PIPs is to use randomized rounding on the natural LP relaxation [27, 29]. We show here that the approximation guarantee for PIPs, as obtained via randomized rounding, is essentially the best possible unless NP = ZPP.

In addition to their theoretical importance, these problems have several applications such as load balancing, cutting stock, and resource allocation, to name a few. One of our motivations for studying these problems comes from recent interest [12, 13, 14] in multidimensional resource scheduling problems in parallel query optimization. A favored architecture for parallel databases is the so-called shared-nothing environment [4] where the parallel system consists of a set of independent processing units each of which has a set of time-sharable resources such as CPU, one or more disks, network controllers, etc. A task executing on one of these units has requirements from each of these resources and is best described as a multidimensional load vector. However in most work on scheduling, both in theory and practice, it is assumed that the load of a task is described by a single aggregate work measure. This simplification is done typically to reduce the complexity of the scheduling problem. However, for large task systems that are typically encountered in database applications, ignoring the multidimensionality could lead to bad performance. The work in [11, 12, 13, 14] demonstrates the practical effectiveness of the multidimensional approach. One of the basic resource scheduling problems that is considered in the above papers is the problem of scheduling d-dimensional vectors (tasks) on d-dimensional bins (machines) to minimize the maximum load on any dimension (the load on the most loaded resource). Surprisingly, despite the large body of work on approximation algorithms for multiprocessor scheduling and its several variants [15, 23], the authors in [11] had to settle for a naive $(d+1)$-approximation for the d-dimensional vector scheduling problem. Our work here provides a PTAS when d is fixed and an $O(\ln^2 d)$-approximation when d is arbitrary. A similar situation existed for the vector bin packing problem where the best known approximation ratio prior to our work was $(d+\epsilon)$. In this paper, we improve this to obtain a $(1+\epsilon \cdot d + O(\ln \epsilon^{-1}))$-approximation for any fixed $\epsilon > 0$. In what follows, we formally define the problems that we study and provide a detailed description of our results.

1.1. Problem definitions. We start by defining the vector scheduling problem. For a vector x, the quantity $\|x\|_\infty$ denotes the standard ℓ_∞ norm.

DEFINITION 1.1 (vector scheduling (VS)). *We are given a set J of n rational d-dimensional vectors $p_1, \ldots, p_n$ from $[0,\infty)^d$ and a number m. A valid solution is a partition of J into m sets $A_1, \ldots, A_m$. The objective is to minimize* $\max_{1 \le i \le m} \|\bar{A}_i\|_\infty$, *where $\bar{A}_i = \sum_{j \in A_i} p_j$ is the sum of the vectors in A_i.*

DEFINITION 1.2 (vector bin packing (VBP)). *Given a set of n rational vectors $p_1, \ldots, p_n$ from $[0,1]^d$, find a partition of the set into sets $A_1, \ldots, A_m$ such that $\|\bar{A}_i\|_\infty \le 1$ for $1 \le j \le m$. The objective is to minimize m, the size of the partition.*

The following definition of PIPs is from [29]. In the literature this problem is also referred to as the d-dimensional 0-1 knapsack problem [7].

DEFINITION 1.3 (packing integer program (PIP)). *Given $A \in [0,1]^{d \times n}$, $b \in [1,\infty)^d$, and $c \in [0,1]^n$ with $\max_j c_j = 1$, a PIP seeks to maximize $c^T x$ subject to $x \in \{0,1\}^n$ and $Ax \le b$. Furthermore if $A \in \{0,1\}^{d \times n}$, b is assumed to be integral. Finally, B is defined to be* $\min_i b_i$.

The restrictions on A, b, and c in the above definition are without loss of generality: an arbitrary packing problem can be reduced to the above form (see [29]). We are interested in PIPs where $b_i = B$ for $1 \le i \le d$. When $A \in \{0,1\}^{d \times n}$ this

problem is known as the *simple B-matching in hypergraphs* [24]: given a hypergraph with nonnegative edge weights, find a maximum weight collection of edges such that no vertex occurs in more than B of them. When $B = 1$ this is the usual hypergraph matching problem. We note that the maximum *independent set* problem in graphs is a special case of the hypergraph matching problem.

1.2. Related work and our results. All the problems we consider are NP-complete for $d = 1$ (multiprocessor scheduling, bin packing, and the knapsack problem). The dimension of the vectors, d, plays an important role in determining the complexity. We concentrate on two cases, when d is a fixed constant, and when d is part of the input and can be arbitrary. Below is an outline of the various positive and negative results that we obtain for these problems.

Vector scheduling. For the VS problem the best approximation algorithm [13] prior to our work had a ratio of $(d+1)$. When d is a fixed constant (a case of practical interest) we obtain a PTAS, generalizing the result of Hochbaum and Shmoys [19] for multiprocessor scheduling. In addition we obtain a simpler $O(\ln d)$-approximation algorithm that is better than $(d+1)$ for all $d \geq 2$. When d is large we give an $O(\ln^2 d)$-approximation that uses known approximation algorithms for PIPs as a subroutine. We also give a very simple $O(\ln dm / \ln \ln dm)$-approximation. Finally, we show that it is hard to approximate the VS problem to within *any* constant factor when d is arbitrary.

Vector bin packing. The previous best known approximation algorithms for this problem gave a ratio of $(d + \epsilon)$ for any fixed $\epsilon > 0$ [6] and $(d + 7/10)$ [9]; the latter result holds even in an online setting. All the ratios mentioned are asymptotic; that is, there is an additive term depending on d and on ϵ. Karp, Luby, and Marchetti-Spaccamela [22] do a probabilistic analysis and show bounds on the average wastage in the bins. We design an approximation algorithm that for any fixed $\epsilon > 0$, achieves a $(1 + \epsilon \cdot d + O(\ln \epsilon^{-1}))$-approximation in polynomial time, thus improving upon the previous guarantees. One useful corollary of this result is that when d is a fixed constant we can approximate the problem to within a ratio of $O(\ln d)$. When d is arbitrary a simple reduction from the graph coloring problem gives a $d^{\frac{1}{2}-\epsilon}$ hardness for any fixed $\epsilon > 0$ even when vectors are drawn from the set $[0, 1]^d$. Moreover, even when $d = 2$ the problem is APX-hard [31]; this is an interesting departure from the classical bin packing problem ($d = 1$) which exhibits an asymptotic FPTAS.

Packing integer programs. For fixed d there is a PTAS for PIPs [7]. For large d the randomized rounding technique of Raghavan and Thompson [27] yields integral solutions of value $t_1 = \Omega(\text{OPT}/d^{1/B})$ if $A \in [0, 1]^{d \times n}$, and $t_2 = \Omega(\text{OPT}/d^{1/(B+1)})$ if $A \in \{0, 1\}^{d \times n}$. Srinivasan [29] improved these results to obtain solutions of value $\Omega(t_1^{B/(B-1)})$ and $\Omega(t_2^{(B+1)/B})$, respectively (see discussion at the end of section 4.1 concerning when these values are better). Thus the parameter B plays an important role in the approximation ratio achieved, with better ratios obtained as B gets larger (recall that entries in A are upper bounded by 1). It is natural to question if the dependence of the approximation ratio on B could be any better. We show that PIPs are hard to approximate to within a factor of $\Omega(d^{\frac{1}{B+1}-\epsilon})$ for every fixed B, thus establishing that randomized rounding essentially gives the best possible approximation guarantees. Hardness was known only for the case $B = 1$ via a reduction from the maximum independent set problem. We show how this can be amplified to work for larger values of B and then use Haståd's result [18] on the inapproximability of the maximum independent set problem. An interesting aspect of our reduction is that the hardness result holds even when the optimal is restricted to choosing a solution

that satisfies $Ax \leq 1^d$ while the approximation algorithm is required to satisfy only the relaxed constraint of $Ax \leq B^d$.

Table 1.1 summarizes our results. For conciseness, in the table below when we indicate that a problem is c-hard we mean that, unless NP = ZPP, no polynomial time algorithm can approximate it to within a factor of c.

TABLE 1.1
Approximation bounds and inapproximability results for each problem.

Problem	$d = 1$	Constant $d \geq 2$	Arbitrary d
Vector Scheduling	PTAS [19]	$(d+1)$ (folklore) PTAS (this paper)	$(d+1)$ (folklore) $O(\ln^2 d)$ (this paper)
	NP-hard	NP-hard	NP-hard c-hard $\forall\ c > 1$ (this paper)
Vector Bin Packing	AFPTAS[1] [6, 21]	$(d+\epsilon)$ [6] $O(\ln d)$ (this paper)	$(d+\epsilon)$ [6] $1 + \epsilon d + O(\ln \frac{1}{\epsilon})$ (this paper)
	NP-hard	APX-hard [31]	APX-hard [31] $d^{\frac{1}{2}-\epsilon}$-hard (this paper)
Packing Integer Programs	FPTAS [20]	PTAS [7]	$O(d^{\frac{1}{(B+1)}})$ [26, 27, 29]
	NP-hard	NP-hard	$d^{\frac{1}{2}-\epsilon}$-hard for $B = 1$ $d^{\frac{1}{(B+1)}-\epsilon}$-hard $\forall\ B \geq 1$ (this paper)

1.3. Organization. The rest of the paper is organized as follows. Sections 2 and 3 present our approximation algorithms for the vector scheduling problem and the vector bin packing problem, respectively. In section 4 we present our inapproximability results for the three problems.

2. Algorithms for vector scheduling. For any set of vectors (jobs) A, we define $\bar{A}$ to be the vector sum $\sum_{j \in A} p_j$. The quantity $\bar{A}^i$ denotes component i of the vector $\bar{A}$. Throughout this section, we assume without loss of generality that the vectors have been scaled such that the optimal schedule value is 1.

2.1. A PTAS for fixed *d*. Hochbaum and Shmoys [19] gave a PTAS for the multiprocessor scheduling problem (VS problem with $d = 1$) using dual approximation schemes. We now show that a nontrivial generalization of their ideas yields a PTAS for arbitrary but fixed d.

The basic idea used in [19] is a primal-dual approach whereby the scheduling problem is viewed as a bin packing problem. If an optimal solution can pack all jobs with load not exceeding some height h (assume $h = 1$ from here on), then the scheduling problem is to pack all the jobs into m bins (machines) of height 1. The authors then give an algorithm to solve this bin packing problem with bin height relaxed to $(1 + \epsilon)$, where $\epsilon > 0$ is a fixed constant. In order to do so, they classify a job as large or small depending on whether its size is greater than ϵ or not. Only a fixed number (at most $1/\epsilon$) of large jobs can be packed into any bin. The sizes of the large jobs are then rounded up to be one of $O(\ln 1/\epsilon)$ distinct values. Dynamic programming is used to pack the rounded up large jobs into the m bins such that no

[1] AFPTAS denotes an *asymptotic* FPTAS. A problem has an AFPTAS if for any $\epsilon > 0$, there exists a positive integer N_ϵ such that there is a $(1 + \epsilon)$-approximation algorithm that runs in time polynomial in the input size and $1/\epsilon$ for all instances of the problem with optimum value at least N_ϵ.

bin exceeds a height of $(1+\epsilon)$. The small jobs are then greedily packed on top of the large jobs.

We take a similar approach to the problem. Our dual problem is VBP. The primary difficulty in generalizing the above ideas to the case of jobs or vectors of $d \geq 2$ dimensions is the lack of a total order on the "size" of the jobs. It is still possible to classify a vector as large or small depending on its ℓ_∞ norm. However, the scheme of [19], whereby the small jobs are greedily packed on top of the large jobs, does not apply. We need to take into account the interaction between the packing of large and small vectors. In addition, the packing of small vectors is nontrivial. In fact we use a linear programming relaxation and a careful rounding to pack the small jobs. We describe our ideas in detail below. Following the above discussion we will think of machines as d-dimensional bins and the schedule length as bin capacity (height). Given an $\epsilon > 0$ and a guess for the optimal value (that we assume is normalized to 1), we describe an ϵ-relaxed decision procedure A_ϵ that either returns a schedule of height $(1+\epsilon)$ or proves that the guess is incorrect. We can use A_ϵ to do a binary search for the optimal value. Let δ be ϵ/d.

Preprocessing step. Our first idea is to reduce to zero all coordinates of the vectors that are too small relative to the largest coordinate. This allows us to bound the ratio of the largest coordinate to the smallest nonzero coordinate.

LEMMA 2.1. *Let I be an instance of the VS problem. Let I' be a modified instance where we replace each p_j in I with a vector q_j as follows. For each $1 \leq i \leq d$, $q_j^i = p_j^i$ if $p_j^i > \delta \|p_j\|_\infty$ and $q_j^i = 0$ otherwise. Then, replacing the vector q_j by the vector p_j in any valid solution to I' results in a valid solution to I of height at most a factor of $(1+\epsilon)$ that of I'.*

Proof. Let A be a set of vectors in I, and let B be the corresponding set of vectors in I'. Then it follows from the transformation described above that

$$\begin{aligned}
\bar{A}^i &\leq \bar{B}^i + \delta \sum_{j \in B} \|q_j\|_\infty \\
&\leq \bar{B}^i + \delta \sum_{j \in B} \|q_j\|_1 \\
&\leq \bar{B}^i + \delta \|B\|_1 \\
&\leq \bar{B}^i + \delta d \|B\|_\infty \\
&\leq \bar{B}^i + \epsilon \|B\|_\infty.
\end{aligned}$$

Therefore $\|A\|_\infty \leq (1+\epsilon)\|B\|_\infty$. It follows that replacing vectors in I' by those in I' increases the height of the machines by only a $(1+\epsilon)$ factor. □

Large versus small vectors. Assume from here on that we have transformed our instance as described in the above lemma. The second step in the algorithm is to partition the vectors into two sets L and S corresponding to *large* and *small*. L consists of all vectors whose ℓ_∞ norm is greater than δ, and S is the rest of the vectors. The algorithm A_ϵ will have two stages; the first stage packs all the large jobs, and the second stage packs the small jobs. Unlike the case of $d = 1$, the interaction between the two stages has to be taken into account for $d \geq 2$. We show that the interaction can be captured in a compact way as follows. Let $(a_1, a_2, \ldots, a_d)$ be a d-tuple of integers such that $0 \leq a_i \leq \lceil 1/\epsilon \rceil$. We will call each such distinct tuple a *capacity configuration*. There are at most $t = (1 + \lceil 1/\epsilon \rceil)^d$ such configurations. Assume that the t capacity configurations (tuples) are ordered in some way and let a_i^k be the value of coordinate i in tuple k. A capacity configuration approximately describes how a

bin is filled. However, we have m bins. A t-tuple $(m_1, \ldots, m_t)$, where $0 \leq m_i \leq m$ and $\sum_i m_i = m$, is called a *bin configuration* that describes the number of bins of each capacity configuration. The number of possible bin configurations is clearly $O(m^t)$. Since there are only a polynomial number of such configurations for fixed d and ϵ we can "guess" the configuration used by a feasible packing. A packing of vectors in a bin is said to *respect* a capacity configuration $(a_1, \ldots, a_d)$ if the height of the packing in each dimension i is less than ϵa_i. Given a capacity configuration we can define the corresponding *empty capacity configuration* as the tuple obtained by subtracting each entry from $(\lceil 1/\epsilon \rceil + 1)$. For a bin configuration M we denote by $\bar{M}$ the corresponding bin configuration as the one obtained by taking the empty capacity configurations for each of the bins in M.

Overview of the algorithm. The algorithm performs the following steps for each bin configuration M:

(a) decide if vectors in L can be packed respecting M,

(b) decide if vectors in S can be packed respecting $\bar{M}$.

If both steps above succeed for some M, we have a packing of height at most $(1+\epsilon)$. Otherwise we will prove that the assumption that the optimal packing has a height of 1 is false.

Packing the large vectors. The first stage consists of packing the vectors in L. Observe that the smallest nonzero coordinate of the vectors in L is at least δ^2. We partition the interval $[\delta^2, 1]$ into $q = \lceil \frac{2}{\epsilon} \ln \delta^{-1} \rceil$ intervals of the form $(x_0, (1+\epsilon)x_0]$, $(x_1, (1+\epsilon)x_1], \ldots, (x_{q-1}, 1]$, where $x_0 = \delta^2$ and $x_{i+1} = (1+\epsilon)x_i$. We discretize every nonzero coordinate of the vectors in L by rounding the coordinate down to the left end point of the interval in which it falls. Let L' be the resulting set of vectors.

LEMMA 2.2. *Let I' be an instance obtained from the original instance I by rounding vectors in L as described above. Then, replacing each vector in L' by the corresponding vector in L in any solution for I' results in a solution for I of height at most $(1+\epsilon)$ times that of I'.*

Proof. Each coordinate of a vector in L' is at least $(1+\epsilon)^{-1}$ times the coordinate of the corresponding vector in L. The lemma follows trivially. □

Vectors in L' can be classified into one of $s = (1 + \lceil \frac{2}{\epsilon} \ln \delta^{-1} \rceil)^d$ distinct classes. Any packing of the vectors into one bin can be described as a tuple $(k_1, k_2, \ldots, k_s)$, where k_i indicates the number of vectors of the ith class. Note that at most d/δ vectors from L' can be packed in any bin. Therefore $\sum k_i \leq d/\delta$. Thus there are at most $(d/\delta)^s$ *configurations.* A configuration is *feasible* for a capacity configuration if the vectors described by the configuration can be packed without violating the height constraints described by the capacity configuration. Let C_k denote the set of all configurations of the jobs in L' that are feasible for the kth capacity configuration. From our discussion $|C_k| \leq (d/\delta)^s$.

LEMMA 2.3. *Let $M = (m_1, m_2, \ldots, m_t)$ be a bin configuration. There exists an algorithm with running time $O((d/\delta)^s mn^s)$ to decide if there is a packing of the jobs in L' that respects M.*

Proof. We use a simple dynamic programming-based algorithm. Observe that the number of vector classes in L' is at most s. Thus any subset of vectors from L' can be specified by a tuple of size s, and there are $O(n^s)$ distinct tuples. The algorithm orders bins in some arbitrary way and assigns to each bin a capacity configuration from M. For $1 \leq i \leq m$, the algorithm computes all possible subsets of vectors from L' (tuples) that can be packed validly in the first i bins. For each i this information can be maintained in $O(n^s)$ space. Given the tuples for bin i, the tuples for bin $(i+1)$ can be computed in $O(d/\delta)^s$ time per tuple since that is an upper bound on the

number of feasible configurations for any capacity configuration. Thus for each bin i, in $O((d/\delta)^s n^s)$ time, we can compute the tuples that can be packed into the first i bins given the information for bin $(i-1)$. The number of bins is m so we get the required time bound. □

Packing the small vectors. We now describe the second stage, that of packing the vectors in S. For the second stage we write an integer programming formulation and round the resulting LP relaxation to find an approximate feasible solution. Without loss of generality assume that the vectors in S are numbered 1 to $|S|$. The IP formulation has 0-1 variables x_{ij} for $1 \le i \le |S|$ and $1 \le j \le m$. Variable x_{ij} is 1 if p_i is assigned to machine j. Every vector has to be assigned to some machine. This results in the following equation.

$$\sum_j x_{ij} = 1, \qquad 1 \le i \le |S|. \tag{2.1}$$

Given a bin configuration M, we can define for each machine j and dimension k a height bound b_j^k that an assignment should satisfy. Thus we obtain

$$\sum_i p_i^k \cdot x_{ij} \le b_j^k, \qquad 1 \le j \le m,\ 1 \le k \le d. \tag{2.2}$$

In addition we have the integrality constraints, namely, $x_{ij} \in \{0,1\}$. We obtain a linear program by replacing these constraints by

$$x_{ij} \ge 0. \tag{2.3}$$

PROPOSITION 2.4. *Any* basic feasible solution *to the LP defined by* (2.1), (2.2), *and* (2.3) *has at most* $d \cdot m$ *vectors that are assigned fractionally to more than one machine.*

Proof. The number of variables in our LP is $n \cdot m$. The number of nontrivial constraints (those that are other than $x_{ij} \ge 0$) is $(n + d \cdot m)$. From standard polyhedral theory [28] any basic (vertex) solution to our LP has $n \cdot m$ tight constraints. Therefore by a simple counting argument, at most $(n + d \cdot m)$ variables can be strictly positive. Since each vector is assigned to at least one machine, the number of vectors that are fractionally assigned to more than one machine is at most $d \cdot m$. □

We can solve the above linear program in polynomial time and obtain a basic feasible solution. Let S' be the set of vectors that are not assigned integrally to any machine. By the above lemma, $|S'| \le d \cdot m$. We partition the set S' into m sets of at most d vectors each in an *arbitrary* manner and assign the ith set to the ith machine. Since $\|p_j\|_\infty \le \delta = \epsilon/d$ for every $j \in S'$, the above step does not violate the height by more than ϵ in any dimension.

Putting together all the ingredients we obtain our main theorem below.

THEOREM 2.5. *Given any fixed* $\epsilon > 0$, *there is a* $(1+\epsilon)$*-approximation algorithm for the VS problem that runs in* $(nd/\epsilon)^{O(s)}$ *time, where* $s = O((\frac{\ln(d/\epsilon)}{\epsilon})^d)$.

Proof. Given a correct guess for the optimal schedule height it is clear from the description that we obtain a $(1+O(\epsilon))$-approximation. Following the overview of the algorithm we find a packing of vectors in L and S for each choice of bin configuration M. The running time is dominated by the time to pack L. Since there are at most $m^t = O(n^{O(\epsilon^{-d})})$ bin configurations, the running time follows from Lemma 2.3. We can guess the optimal value to within a $(1+\epsilon)$ precision using the estimate provided by a simple $(d+1)$-approximation algorithm described in section 2.2. □

2.2. The general case. We now consider the case when d is arbitrary and present two approximation algorithms for this case. The first algorithm is deterministic and has an approximation ratio that is a function of only d ($O(\ln^2 d)$), while the second algorithm is randomized and achieves an approximation ratio that is a function of both d and m ($O(\ln dm/\ln\ln dm)$). Given a set of positive vectors A we denote by $\mathcal{V}(A)$ the *volume* of A which is the sum of all coordinates of all vectors in A, in other words, the ℓ_1 norm of $\sum_{j\in A} p_j$. We once again assume that the optimal schedule height is 1.

2.2.1. An $O(\ln^2 d)$-approximation. We start by analyzing a simple algorithm which will serve as a base case for our $O(\ln^2 d)$-approximation algorithm. Recall that J is the set of vectors in the input instance. The infinity norm of each of the job vectors is clearly a lower bound on the optimal value. Hence

$$\max_{j\in J} \|p_j\|_\infty \le 1. \tag{2.4}$$

The second lower bound is obtained by using the average volume per dimension:

$$\frac{\mathcal{V}(J)}{m\cdot d} \le 1. \tag{2.5}$$

We can strengthen the above bound by splitting the sum dimension-wise:

$$\max_{i=1}^{d} \frac{\bar{J}^i}{m} \le 1. \tag{2.6}$$

A naive algorithm for our problem is to ignore the multidimensional aspect of the jobs and treat them as one-dimensional vectors of size equal to the sum of their components. The dimensionality of the bins is also ignored. Then one can apply the standard list scheduling algorithm of Graham [16] for multiprocessor scheduling to obtain the following theorem that uses the simple lower bounds developed above.

LEMMA 2.6. *Applying list scheduling on the volumes of the vectors results in a schedule of height at most* $\frac{\mathcal{V}(J)}{m} + \max_{j\in J}\|p_j\|_\infty$. *This yields a* $(d+1)$*-approximation.*

Proof. The upper bound follows from standard analysis of list scheduling. The approximation guarantee follows from the lower bounds in (2.4) and (2.5). ∎

The $O(\ln^2 d)$-approximation algorithm. Before we state the algorithm formally we need a couple of definitions. The following problem is a special case of a general PIP.

DEFINITION 2.7. *Given a set J of n vectors in $[0,1]^d$, the* largest volume packing problem *is the problem of finding a subset S such that $\|\bar{S}\|_\infty \le 1$ and $\mathcal{V}(S)$ is maximized. Let $\mathcal{V}_{\max}$ denote the value of the optimal solution.*

DEFINITION 2.8. *An (α,β)-approximation to the largest volume packing problem is a subset S that satisfies the conditions $\|\bar{S}\|_\infty \le \alpha$ and $\mathcal{V}(S) \ge \beta\mathcal{V}_{\max}$.*

We will typically use the above definition with $\alpha \ge 1$ and $\beta \le 1$.

Algorithm Volume Pack:

1. **repeat** for t stages
   (a) **for** $k = 1$ to m **do**
      i. Find an (α,β)-approximation to the largest volume packing problem with the current set of job vectors.
      ii. Allocate jobs in packing to machine k and remove them.
2. Find a separate schedule for the remaining jobs using naive volume based list scheduling.
3. Combine the two schedules machine by machine in the obvious way.

We now prove several simple lemmas to analyze the performance of the above algorithm.

LEMMA 2.9. *Let $J(i)$ be the set of jobs remaining at the beginning of the ith stage with $J(1) = J$. Let $J_k(i)$ be the set of jobs remaining after machine k has been packed in stage i. Then*

$$\mathcal{V}(J_k(i)) \leq \mathcal{V}(J(i)) \cdot (1 - \beta/m)^k.$$

Proof. We prove the lemma by induction on k. The claim is trivially true for $k = 0$. Suppose the claim is true up to machine k. We show that the claim is true for machine $(k + 1)$. Since all jobs in J can be scheduled on m machines with height 1, it follows that all jobs in $J_k(i)$ can be likewise scheduled. By a simple averaging argument we can infer that there exists a set of jobs in $J_k(i)$ with volume at least $\mathcal{V}(J_k(i))/m$ that can be packed in a machine with height at most 1. Since we obtain a β-approximation to largest volume packing, we pack jobs with a volume of at least $\beta \cdot \mathcal{V}(J_k(i))/m$. Therefore $\mathcal{V}(J_{(k+1)}(i)) \leq \mathcal{V}(J_k(i)) \cdot (1 - \beta/m)$. By our induction hypothesis $\mathcal{V}(J_k(i)) \leq \mathcal{V}(J(i)) \cdot (1 - \beta/m)^k$. The lemma follows. □

COROLLARY 2.10. $\mathcal{V}(J(i)) \leq \mathcal{V}(J)/e^{(i-1)\beta}$.

Proof. From Lemma 2.9, $\mathcal{V}(J(i)) \leq \mathcal{V}(J(i-1)) \cdot (1-\beta/m)^m$. Since $(1-\beta/m)^m \leq e^{-\beta}$, we get the required bound. □

LEMMA 2.11. *Algorithm* Volume Pack *yields a schedule of height at most* $(t \cdot \alpha + \frac{d}{e^{t\beta}} + 1)$.

Proof. Consider the machine that achieves the maximum height in the schedule produced by Volume Pack. Let J_1 and J_2 be the set of jobs allocated to that machine in the packing stage and the list scheduling stage, respectively. From the packing property it is easy to see that the height of machine due to jobs in J_1 is at most $t\alpha$. Let J' be the set of jobs remaining after the t stages of packing. These are scheduled using list scheduling. From Corollary 2.10 we have that

$$\mathcal{V}(J') \leq \mathcal{V}(J)/e^{t\beta}.$$

From Lemma 2.6, the height increase of the machine due to jobs in J_2 is at most

$$\mathcal{V}(J')/m + \max_j \|p_j\|_\infty \leq \frac{d}{e^{t\beta}} \cdot \mathcal{V}(J)/(dm) + 1 \leq \frac{d}{e^{t\beta}} + 1.$$

In the above inequality we are using the fact that the two lower bounds are less than 1, the optimal value. Combining the two equations gives us the desired bound. □

The parameter t in the algorithm can be chosen as a function of α and β to obtain the best ratio. Note that the largest volume packing problem is a special case of a PIP, where c_i is simply the volume of vector i. PIPs have an $(O(\ln d), 1/2)$-approximation via randomized rounding [27, 29] that can be derandomized by techniques from [26]. When d is fixed there is a $(1, 1 - \epsilon)$ approximation [7] that runs in time polynomial in $n^{d/\epsilon}$. These observations imply the following.

THEOREM 2.12. *There is an $O(\ln^2 d)$-approximation algorithm for the VS problem.*

THEOREM 2.13. *There is an $O(\ln d)$-approximation algorithm for the VS problem that runs in time polynomial in n^d.*

2.2.2. An $O(\ln dm/\ln\ln dm)$-approximation. The approximation result of Theorem 2.12 is good when d is small compared to m. However, when d is large we can obtain an $O(\ln dm/\ln\ln dm)$-approximation by a simple randomized algorithm

that assigns each vector independently to a machine chosen uniformly at random from the set of m machines. Theorem 2.15 bounds the performance of this algorithm, referred to as *Random*. We need a version of the standard Chernoff bound on sums of independent random variables.

PROPOSITION 2.14. *Let $X_1, \ldots, X_n$ be independent binary random variables and let $X = \sum_{i=1}^{n} t_i X_i$. Let $T = \max_i t_i$ and $\mu = \mathbf{E}[X]$. Then, for any sufficiently large h, $\mathbf{Pr}\left[X > (1 + c\frac{\ln h}{\ln \ln h})(\mu + T)\right] \leq h^{-c/2}$.*

Proof. Let Y_i be a random variable such that $Y_i = \frac{t_i}{T} X_i$. Note that Y_i takes on values in $[0, 1]$. Let $Y = \sum_i Y_i$. It follows that $Y = X/T$ and that $\mathbf{E}[Y] = \mu/T$. Therefore, for any $\delta > 0$, $\mathbf{Pr}[X > (1+\delta)(\mu+T)] = \mathbf{Pr}[Y > (1+\delta)(\mu/T + 1)]$. Applying the standard Chernoff–Hoeffding bounds [25] on sums of independent random variables that assume values in $[0, 1]$ to Y, we get the desired result. ∎

THEOREM 2.15. *Random gives an $O(\ln dm / \ln \ln dm)$-approximation with high probability.*

Proof. Consider the first machine. Let X_j be the indicator random variable that is 1 if vector j is assigned to the first machine. The X_j's are independent. By uniformity $\mathbf{Pr}[X_j = 1] = 1/m$. Let $P = \sum_j p_j X_j$. Note that P is a vector since each p_j is a vector: let P^i denote the ith coordinate of P. By linearity of expectations, $\mathbf{E}[P^i] = \sum_j p_j^i / m \leq 1$ (using (2.5)). Also observe that $\max_j p_j^i \leq 1$ (using (2.4)). Now we estimate the probability that P^i deviates significantly from its expected value. From Proposition 2.14, $\mathbf{Pr}\left[P^i > (\mathbf{E}[P^i] + \max_j p_j^i)(1 + c \ln dm / \ln \ln dm)\right] \leq (dm)^{-c/2}$. Thus with high probability P^i is $O(\ln dm / \ln \ln dm)$. In general, if A_k^i is the event that the ith dimension of machine k is greater than $2(1+c) \ln dm / \ln \ln dm$, then from above we know that $\mathbf{Pr}\left[A_k^i\right] \leq (dm)^{-c/2}$. Thus $\mathbf{Pr}\left[(A = \cup_{i=1}^{d} \cup_{k=1}^{m} A_k^i)\right] \leq dm(dm)^{-c/2}$. By choosing c sufficiently large we can ensure that $\mathbf{Pr}[A]$ is less than an inverse polynomial factor. But the complement of A is the event that the schedule length is $O(\ln dm / \ln \ln dm)$. Thus with high probability we get an $O(\ln dm / \ln \ln dm)$-approximation. ∎

3. Algorithms for vector bin packing. We now examine the problem of packing a given set of vectors into the smallest possible number of bins. Our main result here is as follows.

THEOREM 3.1. *For any fixed $\epsilon > 0$, we can obtain in polynomial time a $(1 + \epsilon \cdot d + O(\ln(1/\epsilon)))$-approximate solution for vector bin packing.*

This improves upon the long-standing $(d+\epsilon)$-approximation algorithm of [6]. Our approach is based on solving a linear programming relaxation for this problem. As in section 2.1, we use a variable x_{ij} to indicate if vector p_i is assigned to bin j. We guess the least number of bins m (easily located via binary search) for which the following LP relaxation is feasible; clearly $m \leq \text{OPT}$.

$$\begin{aligned} \sum_j x_{ij} &= 1, && 1 \leq i \leq n, \\ \sum_i p_i^k \cdot x_{ij} &\leq 1, && 1 \leq j \leq m,\ 1 \leq k \leq d, \\ x_{ij} &\geq 0, && 1 \leq i \leq n,\ 1 \leq j \leq m. \end{aligned}$$

Once again, we use the fact that a basic feasible solution would make fractional bin assignments for at most $d \cdot m$ vectors. Thus at this point, all but a set S of at most $d \cdot m$ vectors have integral assignments in m bins. To find a bin assignment for S, we repeatedly find a set $S' \subseteq S$ of up to $k = \lceil 1/\epsilon \rceil$ vectors that can all be packed together

and assign them to a new bin. This step is performed greedily; i.e., we seek to find a largest possible such set in each iteration. We can perform this step by trying out all possible sets of vectors of cardinality less than $(k+1)$. We now claim that this procedure must terminate in $\epsilon \cdot d \cdot m + O(\ln \epsilon^{-1}) \cdot \text{OPT}$ steps. To see this, consider the first time that we pack less than k vectors in a bin. The number of bins used thus far is bounded by $(d \cdot m)/k$. Moreover, the total number of vectors that remain at this point is at most $(k-1)\text{OPT}$; let S' denote this remaining set of vectors. Since the optimal algorithm cannot pack more than $(k-1)$ vectors of S' in one bin, our greedy bin assignment procedure is identical to a greedy set cover algorithm, where each set has size at most $(k-1)$. Following the analysis of the greedy algorithm in [17], the total number of bins used in packing vectors in S' is bounded by $H_{k-1} \cdot \text{OPT}$ (H_i is the ith harmonic number). Putting things together, we obtain that the number of bins used by our algorithm, A, is bounded as follows:

$$A \leq m + (d \cdot m)/k + H_{k-1} \cdot \text{OPT} \leq (1 + \epsilon \cdot d + O(\ln \epsilon^{-1})) \cdot \text{OPT}.$$

This completes the proof of Theorem 3.1. Substituting $\epsilon = 1/d$, we obtain the following simple corollary.

COROLLARY 3.2. *For fixed d, VBP can be approximated to within $O(\ln d)$ in polynomial time.*

4. Inapproximability results. In this section we show hardness of approximation results for the three problems we consider, vector scheduling, vector bin packing, and packing integer programs. We start with PIPs.

4.1. Packing integer programs. Randomized rounding techniques of Raghavan and Thompson [27] yield integral solutions of value $t_1 = \Omega(\text{OPT}/d^{1/B})$ if $A \in [0,1]^{d \times n}$, and $t_2 = \Omega(\text{OPT}/d^{1/(B+1)})$ if $A \in \{0,1\}^{d \times n}$. Srinivasan [29] improved these results to obtain solutions of value $\Omega(t_1^{B/(B-1)})$ and $\Omega(t_2^{(B+1)/B})$, respectively. We show that PIPs are hard to approximate to within a factor of $\Omega(d^{\frac{1}{B+1}-\epsilon})$ for every fixed integer B. We start with the case $A \in \{0,1\}^{d \times n}$ and then indicate how our result extends to $A \in [0,1]^{d \times n}$. Our reduction uses the result of Haståd [18] that shows that unless $NP = ZPP$ the maximum independent set problem is hard to approximate within a factor of $n^{1-\epsilon}$ for any fixed $\epsilon > 0$. Since the upper bounds are in terms of d, from here on, we will express the inapproximability factor only as a function of d.

Given a graph $G = (V, E)$ with $|V| = n$ and a positive integer B, we construct an instance of a PIP, I_G, as follows. Let A be a $d \times n$ 0-1 matrix with $d = n^{(B+1)}$ such that each row corresponds to an element from $V^{(B+1)}$. Let $r_i = (v_{i_1}, \ldots, v_{i_{(B+1)}})$ denote the tuple associated with the ith row of A. We set $a_{ij} = 1$ if and only if the following conditions hold, otherwise we set it to 0: (a) the vertex v_j occurs in r_i, and (b) the vertices in r_i induce a *clique* in G.

We set $c = \{1\}^n$ and $b = \{B\}^d$. For any fixed integer B, the reduction can be done in polynomial time. Note that a feasible solution to I_G can be described as a set of indices $S \subseteq \{1, \ldots, n\}$.

LEMMA 4.1. *Let $X \subseteq V$ be an independent set of G. Then $S = \{i \mid v_i \in X\}$ is a feasible solution to I_G of value $|S| = |X|$. Furthermore, S can be packed with a height bound of 1.*

Proof. Suppose that in some dimension the height induced by S is greater than 1. Let r be the tuple associated with this dimension. Then there exist $i, j \in S$ such that $v_i, v_j \in r$ and $(v_i, v_j) \in E$. This contradicts the assumption that X is an independent set. ∎

LEMMA 4.2. *Let S be any feasible solution to I_G and let G_S be the subgraph of G induced by the set of vertices v_i such that $i \in S$. Then $\omega(G_S) \leq B$, where $\omega(G_S)$ is the clique number of G_S.*

Proof. Suppose there is a clique of size $(B+1)$ in G_S; without loss of generality assume that $v_1, \ldots, v_{(B+1)}$ are the vertices of that clique. Consider the tuple $(v_1, v_2, \ldots, v_{(B+1)})$ and let i be the row of A corresponding to the above tuple. Then by our construction, $a_{ij} = 1$ for $1 \leq j \leq (B+1)$. There are $(B+1)$ vectors in S with a 1 in the same dimension i, violating the ith row constraint. This contradicts the feasibility of S. □

The following is a standard Ramsey type result.

LEMMA 4.3. *Let G be a graph on n vertices with $\omega(G) \leq k$. Then $\alpha(G) \geq n^{1/k}$.*

Lemmas 4.2 and 4.3 give us the following corollary.

COROLLARY 4.4. *Let S be any valid solution to I_G of value $t = |S|$. Then $\alpha(G) \geq t^{1/B}$.*

THEOREM 4.5. *Unless $NP = ZPP$, for every fixed integer B and fixed $\epsilon_0 > 0$, PIPs with bound $b = \{B\}^d$ and $A \in \{0,1\}^{d \times n}$ are hard to approximate to within a factor of $d^{\frac{1}{B+1} - \epsilon_0}$. PIPs with $A \in [0,1]^{d \times n}$ and B rational are hard to approximate to within a factor of $d^{\frac{1}{\lfloor B \rfloor + 1} - \epsilon_0}$.*

Proof. We first look at the case of PIPs with $A \in \{0,1\}^{d \times n}$. Notice that our reduction produces only such instances. Suppose there is a polynomial time approximation algorithm $\mathcal{A}$ for PIPs with bound B that has an approximation ratio $d^{\frac{1}{B+1} - \epsilon_0}$ for some fixed $\epsilon_0 > 0$. This can be reinterpreted as a $d^{\frac{1-\epsilon}{B+1}}$-approximation, where $\epsilon = \epsilon_0(B+1)$ is another constant. We will obtain an approximation algorithm $\mathcal{G}$ for the maximum independent set problem with a ratio $n^{1-\delta}$ for $\delta = \epsilon/B$. The hardness of maximum independent [18] will then imply the desired result. Given a graph G, the algorithm $\mathcal{G}$ constructs an instance I_G of a PIP as described above and gives it as input to $\mathcal{A}$. $\mathcal{G}$ returns $\max(1, t^{1/B})$ as the independent set size of G, where t is the value returned by $\mathcal{A}$ on I_G. Note that by Corollary 4.4, $\alpha(G) \geq t^{1/B}$, which proves the correctness of the algorithm. Now we prove the approximation guarantee. We are interested only in the case when $\alpha(G) \geq n^{1-\delta}$, for otherwise a trivial independent set of size 1 gives the required approximation ratio. From Lemma 4.1 it follows that the optimal value for I_G is at least $\alpha(G)$. Since $\mathcal{A}$ provides a $d^{\frac{1-\epsilon}{B+1}}$-approximation, $t \geq \alpha(G)/d^{\frac{1-\epsilon}{(B+1)}}$. In the construction of I_G, $d = n^{(B+1)}$. Therefore $t \geq \alpha(G)/n^{(1-\epsilon)}$. Simple algebra verifies that $t^{1/B} \geq \alpha(G)/n^{1-\delta}$ when $\alpha(G) \geq n^{1-\delta}$.

Now we consider the case of PIPs with $A \in [0,1]^{d \times n}$. Let B be some real number. For a given B we can create an instance of a PIP as before with $B' = \lfloor B \rfloor$. The only difference is that we set $b = B^d$. Since all entries of A are integral, effectively the bound is B'. Therefore it is hard to approximate to within a factor of $d^{(1-\epsilon)/(B'+1)} = d^{(1-\epsilon)/(\lfloor B \rfloor + 1)}$. Since $(\lfloor B + 1/d \rfloor + 1) = B + 1$, $d^{(1-\epsilon)/(\lfloor B \rfloor + 1)} = \Theta(d^{(1-\epsilon)/B})$. □

Discussion. An interesting aspect of our reduction above is that the hardness results hold even when the optimal algorithm is restricted to a height bound of 1 while allowing a height bound of B for the approximation algorithm. Let an (α, β)-bicriteria approximation be one that satisfies the relaxed constraint matrix $Ax \leq \alpha b$ and gets a solution of value at least OPT/β; here OPT satisfies $Ax \leq b$. Then we have the following corollary.

COROLLARY 4.6. *Unless $NP = ZPP$, for every fixed integer B and fixed $\epsilon > 0$, it is hard to obtain a $(B, d^{\frac{1}{B+1} - \epsilon})$ bicriteria approximation for PIPs.*

For a given B, we use $d = n^{B+1}$, and a hardness of $d^{\frac{1}{B+1} - \epsilon}$ is essentially the

hardness of $n^{1-\epsilon}$ for the independent set problem. This raises two related questions. First, should d be larger than n to obtain the inapproximability results? Second, should the approximability (and inapproximability) results be parameterized in terms of n instead of d? These questions are important to understand the complexity of PIPs as d varies from $O(1)$ to poly(n). We observe that the hardness result holds as long as d is $\Omega(n^{\epsilon})$ for some fixed $\epsilon > 0$. To see this, observe that in our reduction, we can always add poly(n) dummy columns (vectors) that are either useless (their c_j value is 0) or cannot be packed (add a dummy dimension where only B of the dummy vectors can be packed). Thus we can ensure that $n \geq$ poly(d) without changing the essence of the reduction. We have a PTAS when $d = O(1)$ and a hardness result of $d^{1/(B+1)}$ when $d =$ poly(n). An interesting question is to resolve the complexity of the problem when $d =$ polylog(n).

As remarked earlier, Srinivasan [29] improves the results obtained using randomized rounding to obtain solutions of value $\Omega(t_2^{(B+1)/B})$, where $t_2 = \Omega(y^*/d^{1/(B+1)})$ for $A \in \{0,1\}^{d \times n}$. In the above y^* is the optimal fractional solution to the PIP. It might appear that this contradicts our hardness result but observe that for the instances we create in our reduction $y^*/d^{1/(B+1)} \leq 1$. For such instances Srinivasan's bounds do not yield an improvement over randomized rounding.

4.2. Vector scheduling. We now extend the ideas used in the hardness result for PIPs to show the following hardness result for the VS problem.

THEOREM 4.7. *Unless NP = ZPP, for every constant $\gamma > 1$, there is no polynomial time algorithm that approximates the schedule height in the VS problem to within a factor of γ.*

Our result here uses the hardness of graph coloring; Feige and Kilian [5] building on the work of Hastad [18] show that graph coloring is $n^{1-\epsilon}$-hard unless NP = ZPP. Our reduction is motivated by the fact that graph coloring corresponds to covering a graph by independent sets. We start with the following simple lemma that is easily derived from Lemma 4.3.

LEMMA 4.8. *Let G be a graph on n vertices with $\omega(G) \leq k$. Then $\chi(G) \leq O(n^{1-1/k} \ln n)$.*

Let $B = \lceil \gamma \rceil$; we will show that it is hard to obtain a B-approximation using a reduction from chromatic number. Given graph G we construct an instance I of the VS problem as follows. We construct n vectors of n^{B+1} dimensions as in the proof of Theorem 4.5. We set m, the number of machines, to be $n^{\frac{1}{2B}}$.

LEMMA 4.9. *If $\chi(G) \leq m$, then the optimal schedule height for I is 1.*

Proof. Let $V_1, \ldots, V_{\chi(G)}$ be the color classes. Each color class is an independent set, and by Lemma 4.1 the corresponding vectors can be packed on one machine with height at most 1. Since $\chi(G) \leq m$, the vectors corresponding to each color class can be packed in a separate machine. ∎

LEMMA 4.10. *If the schedule height for I is bounded by B, then $\chi(G) \leq \beta n^{1-1/2B} \ln n$ for some fixed constant β.*

Proof. Let $V_1, V_2, \ldots, V_m$ be the partition of vertices of G induced by the assignment of the vectors to the machines. Let G_i be the subgraph of G induced by the vertex set V_i. From Lemma 4.2 we have $\omega(G_i) \leq B$. Using Lemma 4.8 we obtain that $\chi(G_i) \leq \beta n^{1-1/B} \ln n$ for $1 \leq i \leq m$. Therefore it follows that $\chi(G) \leq \sum_i \chi(G_i) \leq m \cdot \beta n^{1-1/B} \ln n \leq \beta n^{1-1/2B} \ln n$. ∎

Proof of Theorem 4.7. Feige and Kilian [5] showed that unless $ZPP = NP$ for every $\epsilon > 0$ there is no polynomial time algorithm to approximate the chromatic number to within a factor of $n^{1-\epsilon}$. Suppose there is a B-approximation for the

VS problem. Lemmas 4.9 and 4.10 establish that if $\chi(G) \leq n^{1/2B}$, then we can infer by running the B-approximation algorithm for the VS problem that $\chi(G) \leq \beta n^{1-1/2B} \ln n$. This implies a $\beta n^{1-1/2B} \ln n$-approximation to the chromatic number. From the result of [5] it follows that this is not possible unless $NP = ZPP$. □

4.3. Vector bin packing. As mentioned before, VBP is APX-hard even for $d = 2$. We show a simple $d^{\frac{1}{2}-\epsilon}$ hardness for VBP when d is arbitrary. The reduction is similar to that in the previous subsection and uses hardness of graph coloring. Given a graph G with n vertices and m edges we create an instance I_G of VBP with n vectors, each of m dimensions. For a vector v_i corresponding to a vertex i of G, the jth coordinate is 1 if i is incident on the jth edge, otherwise it is 0. If the vectors are required to be packed into bins of height 1, it is easily seen that the number of bins required corresponds exactly to a coloring of G. Thus the hardness of chromatic number applies directly to VBP.

THEOREM 4.11. *Unless $NP = ZPP$, VBP is hard to approximate to within a $d^{\frac{1}{2}-\epsilon}$ factor for every fixed $\epsilon > 0$.*

5. Conclusions. We studied multidimensional generalizations of multiprocessor scheduling, bin packing, and the knapsack problem and obtained a variety of new algorithmic as well as inapproximability results for them. While our work gives new insights into the approximability of these problems, several questions remain open. In particular, large gaps remain between the upper and lower bounds for both VS and VBP when the number of dimensions is arbitrary. For packing integer programs, our hardness result is essentially tight, but it applies only to fixed values of B. The quality of approximation improves dramatically when B is allowed to grow as a logarithmic function of d; in particular a constant factor approximation is achievable when $B = \Omega(\log d / \log \log d)$. It will be interesting to see if our techniques can be extended to obtain a hardness result when B is allowed to be a function of d.

Acknowledgments. We are grateful to Aravind Srinivasan for guiding us through the literature on packing integer programs and his encouragement at the early stages of this research. We thank Cliff Stein for his comments on this work in its form as a chapter in the dissertation of the first author. We also thank the anonymous referees for many useful comments on an earlier version of the paper.

COUNTING COMPLEXITY OF SOLVABLE BLACK-BOX GROUP PROBLEMS*

N. V. VINODCHANDRAN†

Abstract. We place many computational problems over solvable black-box groups in the counting complexity classes SPP or LWPP. The classes SPP and LWPP are considered classes of low counting complexity. In particular, SPP is *low* (powerless when used as oracles) for all gap-definable counting classes (PP, C$_=$P, Mod$_k$P, etc.) and LWPP is low for PP and C$_=$P. The results improve the upper bounds for these problems proved in [Arvind and Vinodchandran, *Theoret. Comput. Sci.*, 180 (1997), pp. 17–45], where the authors place these problems in randomized versions of SPP and LWPP. Because of the randomization, upper bounds in that paper implied lowness only for the class PP. The results in this paper favor the belief that these problems are unlikely to be complete for NP.

Key words. computational complexity theory, complexity classes, computational group theory

1. Introduction.

Computational problems in group theory have recently been of considerable interest in computational complexity theory. One of the main reasons for this is that the exact complexity of many of the computational problems that arise from group theory are not exactly characterized. For example, consider the basic problem of testing membership in matrix groups over finite fields represented by a set of generators. No efficient algorithm is known for this problem even for the simplest case when the group involved in the problem instance is cyclic. While no polynomial time algorithm exists for many problems over matrix groups, it is not known whether it is hard for NP. The associated group-theoretic structure makes reductions to these problems difficult. Do these problems have complexity intermediate between P and NP? The results of this paper supports this belief. It is interesting to note that, while most of the natural problems that are not known to be in P are proved to be NP-complete, candidates for natural problems that are of intermediate complexity are very few. The well-known graph isomorphism problem, the problem of testing whether two labeled graphs are isomorphic, is one such candidate.

In order to study the complexity of computational group-theoretic problems in a generalized framework, Babai and Szemerédi [6] introduced the theory of *black-box* groups. Intuitively speaking, in this framework we have an infinite family of abstract groups. The elements of each group in the family are uniquely encoded as strings of uniform length. The group operations (product, inverse, etc.) are assumed to be provided by a group oracle and hence are easily computable. Black-box groups are subgroups of groups from such a family and are presented by generator sets. For example, matrix groups over finite fields and permutation groups presented by generator sets can be seen as examples of black-box groups. It is shown in [6] that

many computational problems over black-box groups, including membership testing, are in NP.

A central problem considered in the papers of Babai and Szemerédi [6] and Babai [4] is order verification: given a black-box group G presented by a generator set and a positive integer n, verify that $|G| = n$. This problem is important because it turns out that several other problems reduce to order verification. In [4], using randomization to compute approximate lower bounds and sophisticated group-theoretic tools, it is shown that order verification for general black-box groups is in AM. As a consequence, it turns out that several problems for black-box groups are in NP $\cap$ co-AM. It follows that these problems cannot be NP-complete unless the polynomial hierarchy collapses to Σ_2^p [9, 19]. These results strongly indicate that these group-theoretic problems may be of intermediate complexity between P and NP.

In order to better understand the complexity status of these problems, researchers have taken alternative approaches. Investigating the *counting complexity* of these problems is one such approach. In these investigations, the classes of interest are counting complexity classes SPP and LWPP, defined and studied by Fenner, Fortnow, and Kurtz [12]. These classes can be seen as structural generalizations of the class UP. It holds that P $\subseteq$ UP $\subseteq$ SPP $\subseteq$ LWPP. The classes SPP and LWPP are of low counting complexity in the sense they do not add power to other counting classes such as PP and $C_=P$ when used as oracles. Membership of a problem in the class SPP or LWPP can be seen as evidence that the problem is unlikely to be hard for the class NP. First, intuitively we can say that problems that are in SPP or LWPP are of low counting complexity, and hence it is unlikely that these problems are NP-hard. Second, the classes SPP and LWPP are defined by imposing strong restrictions on the computation tree of nondeterministic Turing machines accepting languages in them. It would be surprising if all problems in NP can be accepted by Turing machines with such restrictions.

Köbler, Schöning, and Torán [16] studied the counting complexity of graph isomorphism and certain group-theoretic problems, such as group intersection, group factorization, etc., over permutation groups. They showed that these problems are in the counting class LWPP. Very recently, this upper bound has been improved to SPP by Arvind and Kurur [2].

The study of the counting complexity of black-box group problems was initiated by Arvind and Vinodchandran in [3]. There the authors study the counting complexity of a number of problems over a large subclass of groups called *solvable* black-box groups. Since solvable groups are a generalization of abelian groups, the authors first consider problems over *abelian* groups. Using a constructive version of a fundamental theorem on the structure of finite abelian groups, they show that, over abelian groups, the problems membership testing, order verification, group isomorphism, and group intersection are in the class SPP. They also show lowness of the problems group factorization, coset intersection, and double-coset membership over abelian groups for PP and $C_=P$.

In the case of solvable groups, using a randomized algorithm for computing the commutator series of a solvable black-box group from [5] and a constructive version of the fundamental theorem for abelian *factor* groups, in order to construct a special set of generators called the *canonical generator set*, the authors of [3] show that all the above-mentioned problems are in *randomized versions* of SPP or LWPP. While these randomized versions of SPP and LWPP are low for the class PP, the lowness properties of these problems for classes such as $C_=P$, $\mathrm{Mod}_k P$, and other gap-definable

counting classes were not clear from [3].

The present paper overcomes this randomization bottleneck. We show an upper bound of SPP (and in some cases LWPP) for a whole host of problems over solvable black-box groups. The main technical contribution of this paper is the design of a *deterministic* oracle Turing machine for converting a set of generators of a solvable group to a canonical generator set. This oracle algorithm can then be combined with the constructions in [3] to obtain the upper bounds for various problems. In particular, we show that, over solvable black-box groups, the problems solvability testing, membership testing, subgroup testing, normality testing, order verification, nilpotence testing, group isomorphism, and group intersection are in the class SPP. We also show that the problems group intersection, group factorization, coset intersection, and double-coset membership over solvable groups are in the class LWPP. Thus, at least with respect to their counting complexity, problems over solvable groups may not be harder than their counterparts over abelian groups.

The rest of the paper is organized as follows. In section 2, we give complexity-theoretic and group-theoretic notation and definitions which are necessary for the paper. The definition of a canonical generator set for solvable groups and results relating to it are also given. Section 3 is devoted to the design of a deterministic oracle algorithm, CanonicalGenerator, for computing a canonical generator set for a solvable group from an arbitrary generator set. In section 4, we give definitions of the computational problems that we are interested in, and we improve the upper bounds on the counting complexity of these problems using the algorithm given in section 3. Finally, in section 5, we conclude the paper with some open problems.

2. Preliminaries. In this section, we give relevant definitions from complexity theory and group theory. We also present complexity-theoretic as well as group-theoretic techniques that we use in this paper.

2.1. Complexity theory. We refer the reader to [7, 8] for standard complexity-theoretic definitions. Here we give only the minimal notation and definitions. We fix the finite alphabet $\Sigma = \{0, 1\}$. Let $A, B \subseteq \Sigma^*$ be two languages. The language $0A \cup 1B$ is denoted by $A \oplus B$. In [12], a uniform method for defining a number of counting classes using GapP, the class of gap-definable functions, is given. The classes that can be defined in this manner are called *gap-definable* classes. Refer to [12] for details. We give explicit definitions of only two classes, SPP and LWPP. Let GapP [12] denote the class of gap-definable functions. A language L is in LWPP if there are functions $f \in \text{GapP}$ and $h \in \text{FP}$ (h is positive) such that $x \in L$ implies that $f(x) = h(|x|)$, and $x \notin L$ implies that $f(x) = 0$. A language L is in SPP if there is an $f \in \text{GapP}$ such that $x \in L$ implies that $f(x) = 1$, and $x \notin L$ implies that $f(x) = 0$. It follows that $\text{SPP} \subseteq \text{LWPP}$.

The concept of lowness is a well-studied notion in structural complexity theory. Intuitively, we say that the class $\mathcal{L}$ is low for class $\mathcal{C}$ if $\mathcal{L}$ is powerless as an oracle to a machine accepting languages in $\mathcal{C}$. Next we give the formal definition of lowness.

Definition 2.1. *Let $\mathcal{C}$ be any complexity class which allows natural relativization. Then the class $\mathcal{L}$ is said to be* low *for $\mathcal{C}$ if for all $L \in \mathcal{L}$, $\mathcal{C}^L = \mathcal{C}$, where $\mathcal{C}^L$ denotes the complexity class that is obtained by relativizing $\mathcal{C}$ with respect to the language L.*

The main interest in these classes is because of the following theorem proved in [12] regarding their complexity. This result indicates that SPP and LWPP are counting classes of low complexity. It is believed that those problems in SPP or LWPP cannot be complete for NP.

THEOREM 2.2 (see [12]). *The class* SPP *is low for all gap-definable counting classes. The class* LWPP *is low for* PP *and* $C_=P$.

Let M be an oracle NP machine, let $A \in$ NP be accepted by an NP machine N, and let $f \in$ FP. We say that M makes $f(n)$-*guarded* queries to A if, on length n inputs, M asks only queries y for which $N(y)$ has either 0 or $f(n)$ accepting paths for each n. In this terminology, we state a weaker version of a theorem from [16] which gives a method for proving membership of languages in the classes SPP and LWPP.

THEOREM 2.3 (see [16]). *Let M be a deterministic polynomial time oracle machine and let f be a polynomial time computable function. If $A \in$ NP such that M makes $f(n)$-guarded queries to A, then there is a polynomial q such that the function h, where $h(x) = f(|x|)^{q(|x|)}$ if M on input x accepts and $h(x) = 0$ if M on input x rejects, is in* GapP.

For proving our upper bounds we use the following corollary of the above theorem.

COROLLARY 2.4. *Let L be a language accepted by a deterministic polynomial time oracle machine M with queries to a language A in* NP. *Let f be a polynomial time computable function.*

1. *If M makes* 1*-guarded queries to A, then $L \in$* SPP.
2. *If M makes $f(n)$-guarded queries to A, then $L \in$* LWPP.

2.2. Group theory. Here we give some notation and basic definitions from group theory. We also state some basic results. For further results and their proofs, please refer to standard textbooks [10, 13].

Let G be a group. A subset H of G is called a *subgroup* of G (denoted $H < G$ or $G > H$) if H is a group under the group operation of G. For a subset S of G, the smallest subgroup of G containing S is called the group *generated by* S and is denoted by $\langle S \rangle$. This group is the same as the set of all finite products of elements from S. A subset S of G is a generator set for G if G is identical to $\langle S \rangle$. A group G is *finite* if the cardinality of the set G is finite. In this paper, we are only interested in finite groups. Henceforth by a group we mean a finite group. The *order* of G is defined as the cardinality of the set G and is denoted by $|G|$. A group is said to be cyclic if it is generated by a single element. For an element $g \in G$, the *order* of g (denoted as $o(g)$) is the order of the cyclic subgroup generated by g. This is the same as the smallest positive integer k such that $g^k = e$ (g^k denotes the product of g, k times), where e is the identity of G. Two groups G and H are said to be isomorphic if there is a bijection (set-theoretic) ϕ from G to H such that for any $x, y \in G$, $\phi(xy) = \phi(x)\phi(y)$. Isomorphism preserves all structural properties of groups.

A fundamental theorem in finite group theory, due to Lagrange, states that if $H < G$, then $|H|$ divides $|G|$. This theorem has a large number of algorithmic applications. For example, it follows from Lagrange's theorem that any finite group G is generated by a set of group elements of cardinality bounded by $\log |G|$.

Let H be a subgroup of a group G. For $g \in G$ the set $\{hg \mid h \in H\}$, denoted by Hg, is called a *right coset* of H in G. Similarly, the set $gH = \{gh \mid h \in H\}$ is called a *left coset* of H in G. H is a *normal* subgroup of G if for all $g \in G$ it holds that $Hg = gH$. A fundamental result in the theory of groups is that if H is a normal subgroup of G, then the set of right cosets of H in G forms a group (called the *factor group* or a *quotient group* induced by H and denoted by G/H) under the binary operation $\cdot$ defined as $Hx \cdot Hy = Hxy$. The identity element of this group is the coset $He = H$. For a set $X \subseteq G$, the *normal closure* of X is the smallest normal subgroup containing X.

Solvable groups. Here we give the definition of a *solvable* group and state some properties of them. Intuitively solvable groups can be thought of as a generalization of *abelian groups*. A group G is *abelian* if for all $x, y \in G$, $xy = yx$; that is, $xyx^{-1}y^{-1} = e$. In general, the element $xyx^{-1}y^{-1}$ is called the *commutator* of elements x and y in G. The subgroup of G generated by the set $\{xyx^{-1}y^{-1} \mid x, y \in G\}$ is called the *commutator subgroup* of G. We denote this subgroup by G'. Observe that if G is abelian, G' is the trivial group containing only the identity element. The commutator subgroup G' is actually a normal subgroup of G and the factor group G/G' is abelian. For a group G, the sequence $G = G_0 > G_1 > \cdots$ is called the commutator sequence, where each group G_i is the commutator subgroup of G_{i-1}. G is solvable if the commutator sequence terminates in the trivial subgroup $\langle e \rangle$ in finitely many steps. This intuitively means that any solvable group can be decomposed into a series of abelian factor groups. Therefore understanding the structure of a solvable group boils down to understanding the structure of the abelian factor groups involved. Next we state a structure theorem for abelian groups which essentially states that any abelian group can be uniquely decomposed into a set of cyclic groups. We need some more definitions to state the theorem.

Let p be a prime. A p-group is a finite group whose order is a power of p. Let G be finite group such that $|G| = p_1^{e_1} p_2^{e_2} \dots p_r^{e_r}$. The existence of subgroups in G which are p-groups is given by Sylow's theorem. That is, for each i there is a subgroup of G of order $p_i^{e_i}$. A subgroup of G of order $p_i^{e_i}$ is referred to as a *p_i-Sylow subgroup* of G.

THEOREM 2.5 (see [10]). *Let G be a finite abelian group such that $|G| = p_1^{e_1} p_2^{e_2} \dots p_r^{e_r}$, where the p_i's are distinct primes. The group G can be expressed as the direct product of its Sylow subgroups $S(p_1), S(p_2), \dots, S(p_r)$, where $|S(p_i)| = p_i^{e_i}$ for $1 \le i \le r$. Furthermore, for $1 \le i \le r$, each Sylow subgroup $S(p_i)$ can be uniquely expressed as the direct product of cyclic groups of orders $p_i^{e_{i1}}, p_i^{e_{i2}}, \dots, p_i^{e_{is_i}}$ such that $e_{i1} \ge e_{i2} \ge \cdots \ge e_{is_i}$ and $\Sigma_{j=1}^{s_i} e_{ij} = e_i$. This decomposition of G is unique up to isomorphism.*

Solvable groups form a large subclass of all finite groups. In fact, a celebrated result due to Fiet and Thompson says that any finite group of odd order is solvable. Subgroups of solvable groups are solvable. It follows from Lagrange's theorem that, if G is solvable, then the length of the commutator sequence is bounded by $\log |G|$. From a computational viewpoint this fact is very useful. It also holds that two solvable groups G and H are isomorphic if and only if the factor group H_{i-1}/H_i is isomorphic to G_{i-1}/G_i for all i where H_i (G_i) is the ith element in the commutator series of H (respectively, G).

We will also consider nilpotent groups. Let H_1, H_2 be two subgroups of G. The *mutual commutator subgroup* of H_1 and H_2 is the group generated by the set $\{xyx^{-1}y^{-1} \mid x \in H_1,\ y \in H_2\}$ and is denoted by $[H_1, H_2]$. Note that using this notation the commutator subgroup G' of G is $[G, G]$. The chain of subgroups $G = L^0(G) > L^1(G) > \cdots$, where $L^i(G) = [G, L^{i-1}(G)]$, is called the *lower central series* of G. G is called *nilpotent* if the series terminates in the trivial subgroup $\{e\}$. A nilpotent group is also solvable.

Computational problems over black-box groups. Now we define the notion of black-box groups.

DEFINITION 2.6. *A* group family *is a countable sequence $\mathcal{B} = \{B_m\}_{m \ge 1}$ of finite groups B_m, such that there are polynomials p and q satisfying the following conditions. For each $m \ge 1$, elements of B_m are uniquely encoded as strings in $\Sigma^{p(m)}$. The group operations (inverse, product, and testing for identity) of B_m can be performed in time*

bounded by $q(m)$ for every $m \geq 1$. The order of B_m is computable in time bounded by $q(m)$ for each m. We refer to the groups B_m of a group family and their subgroups (presented by generators sets) as black-box *groups. A class $\mathcal{C}$ of finite groups is said to be a* subclass *of $\mathcal{B}$ if every $G \in \mathcal{C}$ is a subgroup of some $B_m \in \mathcal{B}$.*

Remark. The black-box groups we consider are a somewhat restricted version of the black-box groups introduced in [6]. The main difference is that, while we require identity testing to be in polynomial time, they require only that it be in *nondeterministic* polynomial time. This naturally places factor groups within the framework of black-box groups. Since in [6] the authors focus on proving many group-theoretic problems in NP, this generality does not cause additional complications. Since we are interested on certain "uniqueness" properties, we need this restriction.

Let S_n denote the permutation group on n elements. Then $\{S_n\}_{n\geq 1}$ is a group family of all permutation groups S_n. As another example let $GL_n(q)$ denote the group of all $n \times n$ invertible matrices over the finite field F_q of size q. The collection $\mathrm{GL(q)} = \{GL_n(q)\}_{n\geq 1}$ is a group family. The class of all solvable subgroups, $\{G \mid G < GL_n(q)$ for some n and G is solvable$\}$ is a subclass of GL(q).

The following decision problems which we consider in this paper are well studied in computational group theory [4, 6, 11, 16]. Let $\mathcal{B} = \{B_m\}_{m>0}$ be a group family.

Solvability testing $\stackrel{\triangle}{=} \{(0^m, S) \mid \langle S\rangle < B_m$ and $\langle S\rangle$ is solvable$\}$.
Membership testing $\stackrel{\triangle}{=} \{(0^m, S, g) \mid \langle S\rangle < B_m$ and $g \in \langle S\rangle\}$.
Subgroup testing $\stackrel{\triangle}{=} \{(0^m, S_1, S_2) \mid \langle S_1\rangle, \langle S_2\rangle < B_m$ and $\langle S_1\rangle$ is a subgroup of $\langle S_2\rangle\}$.
Normality testing $\stackrel{\triangle}{=} \{(0^m, S_1, S_2) \mid \langle S_1\rangle, \langle S_2\rangle < B_m$ and $\langle S_1\rangle$ is a normal subgroup of $\langle S_2\rangle\}$.
Nilpotence testing $\stackrel{\triangle}{=} \{(0^m, S) \mid \langle S\rangle < B_m$ and $\langle S\rangle$ is nilpotent$\}$.
Order verification $\stackrel{\triangle}{=} \{(0^m, S, n) \mid \langle S\rangle < B_m$ and $|\langle S\rangle| = n\}$.
Group isomorphism $\stackrel{\triangle}{=} \{(0^m, S_1, S_2) \mid \langle S_1\rangle, \langle S_2\rangle < B_m$ and are isomorphic$\}$.
Group intersection $\stackrel{\triangle}{=} \{(0^m, S_1, S_2) \mid \langle S_1\rangle, \langle S_2\rangle < B_m$ and $\langle S_1\rangle \cap \langle S_2\rangle \neq (e)\}$.
Group factorization $\stackrel{\triangle}{=} \{(0^m, S_1, S_2, g) \mid \langle S_1\rangle, \langle S_2\rangle < B_m$ and $g \in \langle S_1\rangle\langle S_2\rangle\}$.
Coset intersection $\stackrel{\triangle}{=} \{(0^m, S_1, S_2, g) \mid \langle S_1\rangle, \langle S_2\rangle < B_m$ and $\langle S_1\rangle g \cap \langle S_2\rangle \neq \emptyset\}$.
Double coset memb $\stackrel{\triangle}{=} \{(0^m, S_1, S_2, g, h) \mid \langle S_1\rangle, \langle S_2\rangle < B_m$ and $g \in \langle S_1\rangle h\langle S_2\rangle\}$.

The problems group factorization, coset intersection, and double coset memb are very closely related. In particular, over permutation groups these problems are Turing equivalent to each other [15, 18]. Also the graph isomorphism problem is a special case of double coset memb over permutation groups [14].

Group-theoretic techniques. We are interested in the counting complexity of the problems when the groups involved are solvable. Since solvable groups are a generalization of abelian groups, some remarks about the complexity of these problems over abelian black-box groups are in order. For proving tight upper bounds on the counting complexity of the above-mentioned problems over abelian groups in [3], the authors employ a constructive version of the structure theorem (Theorem 2.5). One of the immediate consequences of this theorem is the existence of a special generator set, called the *independent generator set*, for any abelian group. To be precise, let G be a finite abelian group. An element $g \in G$ is said to be *independent* of a set $X \subseteq G$

if $\langle g\rangle \cap \langle X\rangle = \{e\}$. A generator set S of G is an *independent generator set* for G if all $g \in S$ is independent of $S - \{g\}$. A set of generators of the cyclic groups involved forms an independent generator set for any abelian group. One of the very useful properties of independent generator sets is the following. Let S be an independent generator set for an abelian group G. Then for any $g \in G$, there exist *unique* indices l_h for $h \in S$; $l_h < o(h)$ such that $g = \prod_{h\in S} h^{l_h}$. Hence membership testing in G can be done in a 1-guarded manner if G is presented by an independent generator set. In [3], an algorithm for converting a given generator set to an independent generator set is given, which is used in proving the upper bounds on the counting complexity for problems over abelian black-box groups.

For proving the upper bounds for problems over solvable black-box groups in [3], the authors introduce a generalization of the notion of independent generator set, called the *canonical generator set* for any class of finite groups. We now give the definition of a canonical generator set. The existence of canonical generators for the class of solvable groups is shown in [3].

DEFINITION 2.7. *Let $\mathcal{B} = \{B_m\}_{m>0}$ be any group family. Let $\mathcal{C}$ be a subclass of $\mathcal{B}$. The class of groups $\mathcal{C}$ has* canonical generator sets *if for every $G \in \mathcal{C}$, if $G < B_m$, there is an* ordered *set $S = \{g_1, g_2, \ldots, g_s\} \subseteq G$ such that each $g \in G$ can be* uniquely *expressed as $g = g_1^{l_1} g_2^{l_2} \ldots g_s^{l_s}$, where $0 \le l_i < o(g_i)$, $1 \le i \le s$. Furthermore, $s \le q(m)$ for a polynomial q. S is called a* canonical generator set *for G.*

Notice that the above definition is a generalization of the definition of an independent generator set in the sense that the uniqueness property of the indices is preserved. Define a language L as follows:

$$L = \left\{ (0^m, S, g) | S \subseteq B_m, g \in B_m; \forall h \in S\ \exists l_h; 0 \le l_h < o(h) \text{ and } g = \prod_{h\in S} h^{l_h} \right\}.$$

The following proposition brings out the fact that the language L can act as a "pseudo membership testing" in the sense that if S is a canonical generator set, then $(0^m, S, g) \in L$ if and only if $g \in \langle S\rangle$. More importantly in this case, the NP machine M_u (given in the proposition) will have a *unique* accepting path for those instances inside L.

PROPOSITION 2.8. *Let $\mathcal{B} = \{B_m\}_{m>0}$ be any group family. Then there exists an* NP *machine M_u witnessing $L \in$ NP with the following property. Let $\mathcal{C}$ be a subclass of $\mathcal{B}$ which has a canonical generator set, and suppose the input to M_u satisfies the promise that S is a canonical generator set for $\langle S\rangle \in \mathcal{C}$. Then M_u on input $(0^m, S, g)$ will have a unique accepting path if $g \in \langle S\rangle$, and M_u will have no accepting path if $g \notin \langle S\rangle$. The behavior of M_u is unspecified if the input does not satisfy the promise.*

Proof. We know that checking whether a number is prime or not is in P [1]. Using this, one can easily design an unambiguous nondeterministic polynomial time transducer which computes the prime factorization of any number. Let M' be such a machine. Now, it is easy to see that the order of any $g \in B_m$ can be computed if the prime factorization of $|B_m|$ is given. So, M_u first computes $|B_m|$ in polynomial time. Then by simulating M', it computes the prime factorization of $|B_m|$ and computes the order $o(h)$ for all $h \in S$. Now, M_u guesses indices l_h such that $1 \le l_h < o(h)$ and accepts if $g = \prod_{h\in S} h^{l_h}$ and rejects otherwise. From the definition of canonical generator sets, it follows that M_u has the behavior as described in the proposition. ∎

The next lemma shows the existence of canonical generator sets for any solvable group.

LEMMA 2.9 (see [3, Lemma 3.4]). *Let $\mathcal{B} = \{B_m\}_{m>0}$ be a group family such that $|B_m| \leq 2^{q(m)}$ for a polynomial q. Let $G < B_m$ be a finite solvable group and let $G = G_0 > G_1 > \cdots > G_{k-1} > G_k = e$ be the commutator series of G. Let $T_i = \{h_{i1}, h_{i2}, \ldots, h_{is_i}\}$ be a set of distinct coset representatives corresponding to an independent set of generators for the abelian group $H_i = G_{i-1}/G_i$. Then for any i, $1 \leq i \leq k$, the ordered set*[1] *$S_i = \bigcup_{j=i}^{k} T_j$ forms a canonical generator set for the group G_i and $|S_i| \leq q(m)$. Thus the class of solvable groups from $\mathcal{B}$ has canonical generator sets.*

The basic steps implicitly involved in the upper bound proofs given in [3], for problems over solvable black-box groups, are the following:

1. A deterministic oracle algorithm (let us call it CANONIZE) is developed which takes an arbitrary set of generators for the commutator series of a solvable black-box group as input and converts it into a canonical generator set by making 1-guarded queries to a language in NP.
2. By carefully combining the algorithm CANONIZE with a randomized algorithm from [5] for computing generator sets of the commutator series for any solvable black-box group, a randomized oracle algorithm (let us call it RANDCANONICALGENERATOR) for converting a generator set for any solvable group to a canonical generator set (which makes 1-guarded queries to an NP language) is given.
3. RANDCANONICALGENERATOR is then easily modified to give membership of many computational problems over solvable groups in randomized counting classes which are low for PP.

In this paper, we avoid the randomization involved in step 2. More precisely, by using the algorithm CANONIZE as a subroutine, we give a *deterministic* oracle algorithm CANONICALGENERATOR (which makes 1-guarded queries to an NP language) for converting an arbitrary generator set to a canonical generator set for any solvable black-box group G. This will immediately give improved upper bounds on the counting complexity of many problems over solvable groups. In the next section we present the algorithm CANONICALGENERATOR for converting an arbitrary generator set to a canonical generator set for any solvable group.

Since we will be using the algorithm CANONIZE as a subroutine in CANONICALGENERATOR, we describe the behavior of CANONIZE as a theorem. First we state a result (Corollary 4.9 from [3]) regarding abelian factor groups which is the building-block for CANONIZE.

LEMMA 2.10 (see [3, Corollary 4.9]). *Let $\mathcal{B} = \{B_m\}_{m>0}$ be a group family. There is a deterministic oracle machine M_f that takes as input tuples $(0^m, X, Y)$, where $X, Y \subseteq B_m$ are finite sets, and a language $L_f \in$ NP as oracle. Let $G = \langle X \rangle$ and $H = \langle Y \rangle$ and suppose the input $(0^m, X, Y)$ satisfies the following properties:*

1. *Y is a canonical generator set for H.*
2. *H is a normal subgroup of G and the factor group G/H is abelian.*

Then the machine outputs a list of coset representatives corresponding to an independent generator set for G/H and also outputs $|G/H|$. Furthermore, it runs in time polynomial in input length, and it makes 1-guarded queries to the NP *oracle L_f. The behavior of the machine is not specified if the input does not satisfy the properties.*

The following theorem describes the behavior CANONIZE. The proof essentially follows from an iterative application of the above lemma. We omit the details.

[1] The elements of the set $\bigcup_{j=i}^{k} T_j$ are ordered on increasing values of the index j, and lexicographically within each set T_j.

THEOREM 2.11. *Let $\mathcal{B} = \{B_m\}_{m\geq 0}$ be a group family. Then there is a deterministic oracle machine* CANONIZE *and a language $L' \in$ NP such that* CANONIZE *takes $\langle 0^m, S_0, \ldots, S_k\rangle$, $S_i \subseteq B_m$ as input and L' as oracle. Suppose the input satisfies the promise that $\langle S_0\rangle$ is solvable and for $0 \leq i \leq k$, S_i generates the ith commutator subgroup of $\langle S_0\rangle$. Then* CANONIZE *outputs canonical generator sets for $\langle S_i\rangle$ for $0 \leq i \leq k$. Moreover,* CANONIZE *runs in time polynomial in the length of the input and makes only 1-guarded queries to L'. The behavior of* CANONIZE *is unspecified if the input does not satisfy the promise.*

3. Computing a canonical generator set. This section is devoted to the proof of the following theorem.

THEOREM 3.1. *Let $\mathcal{B} = \{B_m\}_{m\geq 0}$ be a group family. Then there is a language $L_{ca} \in$ NP and a deterministic oracle machine* CANONICALGENERATOR *that takes $(0^m, S)$ as input and L_{ca} as oracle, and outputs canonical generator set for all the groups in the commutator series of $\langle S\rangle$ if $\langle S\rangle$ is solvable and outputs* NOT SOLVABLE *otherwise. Moreover,* CANONICALGENERATOR *runs in time polynomial in the length of the input and makes only 1-guarded queries to L_{ca}.*

Before going into the formal proof of the theorem, we give basic ideas behind the proof. Let S be a set of generators for a solvable group. Let $\langle S\rangle = G_0 > \cdots > G_i > \cdots > G_k = \{e\}$ be the commutator series of $\langle S\rangle$. We are interested in computing generator sets for all G_i. The following theorem based on normal closure provides a method for computing a generator set for the commutator subgroup of any group. Recall that the normal closure of $X \subseteq G$ is the smallest normal subgroup of G which contains X.

THEOREM 3.2. *Let G be a finite group generated by the set S. Then the commutator subgroup of G is the normal closure of the set $\{ghg^{-1}h^{-1} \mid g, h \in S\}$ in G.*

Proof. The proof uses standard group-theoretic argument. Let N be the normal closure of the set $X = \{ghg^{-1}h^{-1} \mid g, h \in S\}$ in G and let G' be the commutator subgroup of G. Recall that $G' = \langle\{ghg^{-1}h^{-1} \mid g, h \in G\}\rangle$. It is a well-known group-theoretic fact that G' is normal in G and G/G' is abelian. Moreover if H is a normal subgroup of G such that G/H is abelian, then $G' < H$. Now, from the definition of N and G' and the fact that G' is normal in G, it follows that $N < G'$. Hence to show that $N = G'$, it is enough to show that G/N is abelian. First, observe that G/N is generated by $\{gN \mid g \in S\}$. But for all $g, h \in S$, $(gN)(hN)(gN)^{-1}(hN)^{-1} = N$. Hence the theorem. □

The above theorem gives us the following easy polynomial time oracle algorithm COMMUTATORSUBGROUP, which takes $(0^m, S)$ as input and membership testing as oracle and computes a generator set for the commutator group of $\langle S\rangle$.

COMMUTATORSUBGROUP$(0^m, S)$
1 $X \leftarrow \{ghg^{-1}h^{-1} \mid g, h \in S\}$
2 **while** $\exists g \in S$; $x \in X$ such that $(0^m, X, gxg^{-1}) \notin$ membership testing
3 **do** $X \leftarrow X \cup gxg^{-1}$
4 **end-while**
5 **Output** X

CLAIM 3.2.1. *On input $(0^m, S)$,* COMMUTATORSUBGROUP *runs in polynomial time and outputs a generator set for the commutator subgroup of $\langle S\rangle$.*

Proof. We can argue that COMMUTATORSUBGROUP outputs a generator set for the commutator subgroup of $\langle S\rangle$ as follows. From Theorem 3.2, it follows that we need a generator set for the smallest normal subgroup of $\langle S\rangle$ containing X. Moreover

it easily follows from the definition that, in order to check whether $H = \langle X \rangle$ is normal in $G = \langle S \rangle$, it is enough to check for all pairs $g \in S$ and $x \in X$ whether $gxg^{-1} \in H$. The algorithm adds new elements of the form gxg^{-1} to X until this condition is satisfied. Therefore the output of this algorithm generates a normal subgroup of $\langle S \rangle$ containing X. Since all the elements added should be contained in any normal subgroup of $\langle S \rangle$ containing X, the output generates the smallest such normal subgroup. To argue that CommutatorSubgroup runs in polynomial time, let X_i be the set X at the beginning of the ith iteration of the **while**-loop. If, after the ith iteration, no new element is added to X_i, then X_i is output. Otherwise, if $X_{i+1} = X_i \cup \{g\}$, it follows from Lagrange's theorem that $|\langle X_{i+1} \rangle| \geq 2|\langle X_i \rangle|$. Hence the number of iterations of the **while**-loop is bounded by the polynomial $p(m)$. □

Since in the above algorithm, the queries to the membership testing oracle may not be 1-guarded, a straightforward adaptation of the algorithm for computing a generator set for all elements in the commutator series seems difficult. Suppose we can make sure that whenever a query $y = \langle 0^m, X, g \rangle$ to membership testing is made, X is a canonical generator set for the solvable group $\langle X \rangle$. Then from Proposition 2.8 it follows that we can replace the membership testing oracle with the NP language L and the query y will be 1-guarded. We ensure this promise by constructing the commutator series in stages.

Let S_l^j denote the partial generator set for the lth element in the commutator series of G_0 constructed at the beginning of *stage* j. At *stage* 1 we have $S_0^1 = S$ and $S_i^1 = \{e\}$ for $1 \leq l \leq p(m)$, where p is the polynomial bounding the length of any element in the group family. Input to *Stage* j is the tuple $\langle i, S_i^j, \ldots, S_{p(m)}^j \rangle$ such that for $k > i$, S_k^j is a canonical generator set for the solvable group $\langle S_k^j \rangle$. At this stage, the only oracle queries made are with generator sets S_k^j for $k > i$ and, in particular, will not involve S_i^j. This allows us to make only queries that are 1-guarded. At the end of the stage, we update each S_l^j to S_l^{j+1} such that S_l^{j+1} is still a subgroup of G_l, the lth commutator subgroup of G_0. To keep the running time within polynomial bound, we make sure that after $p(m)$ stages, there exists k, such that the kth partial commutator subgroup doubles in size. Then from Lagrange's theorem, it will follow that the commutator series will be generated after $p^3(m)$ stages. We now formally prove the theorem.

Proof of Theorem 3.1. We will first give the formal description of the algorithm CanonicalGenerator and then prove the correctness.

CanonicalGenerator uses oracle algorithms CheckCommutator and Canonize as subroutines. CheckCommutator takes as input $(0^m, X, Y)$ such that $X, Y \subseteq B_m$ and checks whether $\langle Y \rangle$ contains the commutator subgroup of $\langle X \rangle$. This is done by first checking whether the commutators of all the elements in X are in $\langle Y \rangle$. If this is not the case, the algorithm returns a commutator not in $\langle Y \rangle$. Otherwise, it further checks whether $\langle Y \rangle$ is normal in $\langle X \rangle$. Notice that to do this it is enough to verify that for all $x \in X$ and $y \in Y$, $xyx^{-1} \in \langle Y \rangle$. If this condition is false, the algorithm returns an element $xyx^{-1} \notin \langle Y \rangle$. If both the conditions are true, it follows from Theorem 3.2 that $\langle Y \rangle$ contains the commutator subgroup of $\langle X \rangle$.

CheckCommutator makes oracle queries to the language L (defined in the previous section) for testing membership in $\langle Y \rangle$. It should be noted that, for CheckCommutator to work as intended, Y should be a canonical generator set for the group $\langle Y \rangle$. Also the definition of normality requires $\langle Y \rangle < \langle X \rangle$. We will make sure that CanonicalGenerator makes calls to CheckCommutator with $(0^m, X, Y)$ as input only when Y is a canonical generator set for the solvable group $\langle Y \rangle$ and

$\langle Y \rangle < \langle X \rangle$. A formal description of the subroutine CheckCommutator is given below.

CheckCommutator$(0^m, X, Y)$
if $\exists x_1, x_2 \in X$, such that $(0^m, Y, x_1 x_2 x_1^{-1} x_2^{-1}) \notin L$
  then $g \leftarrow x_1 x_2 x_1^{-1} x_2^{-1}$
    Return g
  else **if** $\exists x \in X, y \in Y$ such that $(0^m, Y, xyx^{-1}) \notin L$
    then $g \leftarrow xyx^{-1}$
      Return g
    else $g \leftarrow$ YES
      Return g
    end-if
end-if

The subroutine Canonize is the algorithm promised by Theorem 2.11 for computing a canonical generator set for a solvable black-box group G, given an arbitrary generator set for the commutator series of G. Canonize makes 1-guarded queries to the NP language L' if the input satisfies the promise given in Theorem 2.11. For $0 \leq k \leq l \leq p(m)$, let $[Canonize(S_k^j, \ldots, S_{p(m)}^j)]_l$ denote the generator set produced by Canonize for the group $\langle S_l^j \rangle$.

The following is the description of the algorithm CanonicalGenerator. Define the language L_{ca} as $L_{ca} = L' \oplus L$. Notice that the oracle access to L_{ca} is implicit in the description. That is, CanonicalGenerator queries L' through the subroutine Canonize and L through CheckCommutator.

CanonicalGenerator$(0^m, S)$
$S_0^1 \leftarrow S$; $S_i^1 \leftarrow \{e\}$ for $1 \leq i \leq p(m)$
$i \leftarrow 0$
$j \leftarrow 1$
Stage j (Input to this stage is $\langle i, S_i^j, \ldots, S_{p(m)}^j \rangle$)
$k \leftarrow i$
$g \leftarrow CheckCommutator(0^m, S_k^j, S_{k+1}^j)$
while $g \neq$ YES
  do $S_{k+1}^j \leftarrow S_{k+1}^j \cup \{g\}$
    $k \leftarrow k + 1$
    if $k = p(m)$
      then Output NOT SOLVABLE
    end-if
    $g \leftarrow CheckCommutator(0^m, S_k^j, S_{k+1}^j)$
end-while
if $k = 0$
  then Output $[Canonize(S_0^j, S_1^j, \ldots, S_{p(m)}^j)]_l$ for all $0 \leq l \leq p(m)$
  else $S_l^{j+1} \leftarrow S_l^j$ for $1 \leq l \leq (k-1)$
    $S_l^{j+1} \leftarrow [Canonize(S_k^j, S_{k+1}^j, \ldots, S_{p(m)}^j)]_l$ for $k \leq l \leq p(m)$
    $i \leftarrow (k-1)$
    goto **Stage** $j+1$
end-if

Now we are ready to prove the correctness of CanonicalGenerator. We first prove a series of claims, from which the correctness will follow easily.

CLAIM 3.2.2. *In the algorithm* CANONICALGENERATOR*, at any stage j, it holds that for all i, $1 \leq i < p(m)$, $\langle S_{i+1}^j \rangle < \langle S_i^j \rangle'$.*

Proof. We prove this by induction on the stages. For the base case, when $j = 0$, it is clear that the claim holds. Assume that it is true for the $(j-1)$th stage. Now consider S_{i+1}^j and S_i^j. Depending on how the sets S_{i+1}^j and S_i^j are updated in lines 17 and 18 of CANONICALGENERATOR, we have the following cases.

Case 1. $S_i^j = S_i^{j-1}$; $S_{i+1}^j = S_{i+1}^{j-1}$. In this case, from the induction hypothesis, it is clear that $\langle S_{i+1}^j \rangle < \langle S_i^j \rangle'$.

Case 2. $S_i^j = S_i^{j-1} \cup \{g_i\}$; $S_{i+1}^j = S_{i+1}^{j-1}$. From the induction hypothesis, it follows that $\langle S_{i+1}^j \rangle = \langle S_{i+1}^{j-1} \rangle < \langle S_i^{j-1} \rangle' < \langle S_i^j \rangle'$.

Case 3. $S_i^j = S_i^{j-1}$; $S_{i+1}^j = S_{i+1}^{j-1} \cup \{g_{i+1}\}$. The element g_{i+1} is added to the set S_{i+1}^{j-1} at line 8 of the algorithm, where g_{i+1} is the element returned by the subroutine CHECKCOMMUTATOR. Suppose g_{i+1} is a commutator of the set $S_i^j = S_i^{j-1}$. Then $g_{i+1} = xyx^{-1}y^{-1}$ for some elements $x, y \in S_i^j$. From induction hypothesis we have that $\langle S_{i+1}^{j-1} \rangle < \langle S_i^{j-1} \rangle' = \langle S_i^j \rangle'$. Also $g_{i+1} \in \langle S_i^j \rangle'$ since g_{i+1} is a commutator of S_i^j. Therefore $\langle S_{i+1}^j \rangle = \langle S_{i+1}^{j-1} \cup \{g_{i+1}\} \rangle < \langle S_i^j \rangle'$. On the other hand, suppose g_{i+1} is of the form xyx^{-1} for some $x \in S_i^j = S_i^{j-1}$ and $y \in S_{i+1}^{j-1}$. We have $\langle S_{i+1}^{j-1} \rangle < \langle S_i^{j-1} \rangle' = \langle S_i^j \rangle'$. But we know that $\langle S_i^j \rangle'$ is normal in $\langle S_i^j \rangle$. So, in particular $g_{i+1} \in \langle S_i^j \rangle'$. Therefore in this case also $\langle S_{i+1}^j \rangle = \langle S_{i+1}^{j-1} \cup \{g_{i+1}\} \rangle < \langle S_i^j \rangle'$.

Case 4. $S_i^j = S_i^{j-1} \cup \{g_i\}$; $S_{i+1}^j = S_{i+1}^{j-1} \cup \{g_{i+1}\}$. From induction hypothesis, we have $\langle S_{i+1}^{j-1} \rangle < \langle S_i^{j-1} \rangle'$. It follows that $\langle S_{i+1}^{j-1} \rangle < \langle S_i^{j-1} \cup \{g_i\} \rangle' = \langle S_i^j \rangle'$. Now we are in the same situation as in Case 3, and using an argument identical to that of Case 3 we have $\langle S_{i+1}^j \rangle < \langle S_i^j \rangle'$.

Hence the claim. □

CLAIM 3.2.3. *In* CANONICALGENERATOR*, the input $\langle i, S_i^j, S_{i+1}^j, \ldots, S_{p(m)}^j \rangle$ to any stage j is such that for all $i < t \leq p(m)$, S_t^j is a canonical generator for the solvable group $\langle S_t^j \rangle$.*

Proof. We prove this by induction. For $j = 1$, it is easily verified that the claim is true. Let us assume that the claim is true for the jth stage. Let $\langle i, S_i^j, \ldots, S_{p(m)}^j \rangle$ be the input to the jth stage. Suppose the **while**-loop is exited through line 14 after l iterations with the value of g = YES. (If the loop is exited through line 11, then there are no more stages to be considered.) Then the value of $k = i + l$, and for $t > k$, S_t^j is not updated inside the loop, and hence by induction hypothesis it remains a canonical generator set for the solvable group $\langle S_t^j \rangle$. Since the value of $g = CheckCommutator(0^m, S_k^j, S_{k+1}^j)$ is YES we have that $\langle S_k^j \rangle' < \langle S_{k+1}^j \rangle$. From Claim 3.2.2 we have $\langle S_{k+1}^j \rangle < \langle S_k^j \rangle'$. Hence $\langle S_{k+1}^j \rangle = \langle S_k^j \rangle'$. It follows that $\langle S_k^j \rangle$ is solvable and S_t^j for $k \leq t \leq p(m)$ are generator sets for the commutator series of $\langle S_k^j \rangle$. Hence at line 18, CANONIZE will output a canonical generator set for each of the elements in the commutator series of $\langle S_k^j \rangle$. At line 19, i is updated to $k-1$, and the input to the $j+1$th stage is $\langle k-1, S_{k-1}^{j+1}, S_k^{j+1}, \ldots, S_{p(m)}^{j+1} \rangle$, where S_t^{j+1} is a canonical generator set for the solvable group $\langle S_t^{j+1} \rangle$ for $k \leq t \leq p(m)$. Hence the claim.[2] □

CLAIM 3.2.4. *In the algorithm* CANONICALGENERATOR*, for any stage j, it holds that $\exists i$ such that $|\langle S_i^{j+p(m)} \rangle| \geq 2|\langle S_i^j \rangle|$ if stage $j + p(m)$ exists.*

[2]Technically, one should establish Claims 3.2.2 and 3.2.3 together. We separated them for clarity of presentation.

Proof. Notice that if the algorithm at stage j enters the **while**-loop, then $\exists i$ such that $S_i^{j+1} = S_i^j \cup g$ for a $g \notin \langle S_i^j \rangle$, and the claim follows from Lagrange's theorem. So, it is enough to show that the **while**-loop is entered at least once after every $p(m)$ stages, if such a stage exists. Suppose the stage j is entered with the value of $i = i'$. Note that in a stage where the algorithm does not enter the **while**-loop, the variable k remains at i. So if the algorithm never enters the **while**-loop in the next $p(m)$ stages, at stage $(j + p(m) + 1)$, the value of $k = i = i' - (p(m) + 1) < 0$ for all $i' \leq p(m)$. But when $k = 0$ (line 15) the algorithm stops. Therefore it is not possible that $k < 0$. Hence the claim. □

To complete the proof of the theorem, first we shall see that the algorithm CanonicalGenerator runs in time polynomial in the length of the input. Observe that it is enough to show that the number of stages executed by the algorithm is bounded by a polynomial, since the number of iterations of the **while**-loop in lines 7–14 is bounded by $p(m)$. Now, the claim is that the number of stages executed by the algorithm is bounded by $2p^3(m)$. First, notice that for any $H < B_m$, $|H| \leq 2^{p(m)}$. Hence for any j, $\prod_{i=1}^{p(m)} |\langle S_i^j \rangle| \leq 2^{p^2(m)}$. Suppose the claim is false. Now from Claim 3.2.4 it follows that $\prod_{i=1}^{p(m)} |\langle S_i^{j+p(m)} \rangle| \geq 2 \prod_{i=1}^{p(m)} |\langle S_i^j \rangle|$. Hence $\prod_{i=1}^{p(m)} |\langle S_i^{2p^3(m)} \rangle| > 2^{p^2(m)}$, a contradiction.

Now we shall see that CanonicalGenerator makes only 1-guarded queries to L_{ca}, where $L_{ca} = L' \oplus L$. Let us first see that the queries to L through CheckCommutator are 1-guarded. It is enough to show that whenever CanonicalGenerator calls CheckCommutator with argument $(0^m, S_k^j, S_{k+1}^j)$ in *stage* j, S_{k+1}^j is a canonical generator set. But from Claim 3.2.3, the input $\langle i, S_i^j, S_{i+1}^j, \ldots, S_{p(m)}^j \rangle$ to any stage j is such that for all $i < t \leq p(m)$, S_t^j is a canonical generator for the solvable group $\langle S_t^j \rangle$. In this stage CanonicalGenerator calls CheckCommutator only with argument $(0^m, S_k^j, S_{k+1}^j)$ for $k \geq i$. Since S_{k+1}^j for $k \geq i$ is a canonical generator set, the queries made to L will be 1-guarded.

To see that the queries to L' through Canonize are 1-guarded, notice that calls to Canonize are made outside the **while**-loop. This means that CheckCommutator with input $(0^m, S_k^j, S_{k+1}^j)$ returns YES. That is, $\langle S_k^j \rangle' < \langle S_{k+1}^j \rangle$. Hence $\langle S_k^j \rangle' = \langle S_{k+1}^j \rangle$ from Claim 3.2.2. So it follows that calls to Canonize with argument $(S_i^j, S_{i+1}^j, \ldots, S_{p(m)}^j)$ will be such that S_l^j for $i \leq l \leq p(m)$ will generate the commutator series of S_i^j for all i. It follows from Theorem 2.11 that queries to L' will be 1-guarded.

Finally, we show that the above algorithm on input $(0^m, S)$ outputs a canonical generator set for the group $G = \langle S \rangle$ if G is solvable and outputs NOT SOLVABLE otherwise. Now, observe that if $H_1 < H_2$ are two finite groups, $H_1' < H_2'$. Hence it follows from Claim 3.2.2 that $\langle S_i^j \rangle < G_i$ for any i at any stage j, where G_i is the ith element in the commutator series of G. We know that after the execution of $2p^3(m)$ stages, the algorithm outputs either a set $X \subseteq B_m$ or NOT SOLVABLE. Suppose it outputs NOT SOLVABLE in stage j. This happens after the value of the variable inside the **while**-loop is assigned $p(m)$. From line 8 of the algorithm it follows that $S_{p(m)}^j \neq \{e\}$. But if G where solvable, then we know that $G_{p(m)} = \{e\}$, and since $\langle S_{p(m)}^j \rangle < G_{p(m)}$ from Claim 3.2.2, we have a contradiction.

Suppose the algorithm outputs a set $X \subseteq B_m$ at line 16 in stage j. Thus the value of the variable k is 0. Notice that inside the **while**-loop, the value of k is only incremented. This implies that at stage j the **while**-loop is not entered (the value of i could not have become 0 at a previous stage). So input to stage j is

$\langle 0, S_0^j, \ldots, S_{p(m)}^j \rangle$. From Claim 3.2.3, it follows that for all $1 \leq t \leq p(m)$, $\langle S_t^j \rangle$ is solvable and S_t^j is a canonical generator set for the group $\langle S_t^j \rangle$. From the value of g = YES and Claim 3.2.2, it follows that $\langle S_1^j \rangle' = \langle S_2^j \rangle$. Also, since $S_0^j = S$ for any stage j, it follows that S_i^j generates the ith element in the commutator series of $\langle S \rangle = G$. Hence, from Theorem 2.11, it follows that $[Canonize(S_1^j, \ldots, S_{p(m)}^j)]_l$ is a canonical generator set for G_l. Hence the theorem. □

4. Applications to computational problems. In this section we will use the algorithm CanonicalGenerator to prove upper bounds on the complexity of computational problems over solvable black-box groups that we defined in section 2.

Theorem 4.1. *Over any group family,* solvability testing *is in* SPP *and hence low for all gap-definable counting classes.*

Proof. We can easily modify CanonicalGenerator to get an oracle machine which makes only 1-guarded queries to an NP oracle to test whether the input group is solvable or not. Now applying Corollary 2.4 we get that solvability testing is in SPP. □

Remark. In [5], a co-RP algorithm is given for solvability testing. While this upper bound gives lowness for PP [17], it does not show lowness for other gap-definable counting classes.

In view of the above theorem and the fact that $\mathrm{P}^{\mathrm{SPP}} = \mathrm{SPP}$, for all the problems that we consider here, we assume without loss of generality that the groups encoded in the problem instances are solvable.

Theorem 4.2. *Over any group family,* membership testing *for the subclass of solvable groups is in* SPP *and hence low for all gap-definable counting classes.*

Proof. A direct application of Theorem 3.1, Proposition 2.8, and Corollary 2.4 shows that membership testing over solvable groups is in SPP. □

Theorem 4.3. *Over any group family,* subgroup testing *for the subclass of solvable groups is in* SPP *and hence low for all gap-definable counting classes.*

Proof. Let S_1 and S_2 be generator sets for groups G_1 and G_2. Then G_1 is a subgroup of G_2 if and only if for all $g \in S_1$, $g \in \langle S_2 \rangle$. This testing can be done in $\mathrm{P}^{\mathrm{SPP}}$ since membership testing is in SPP. Since $\mathrm{P}^{\mathrm{SPP}} = \mathrm{SPP}$, it follows that subgroup testing is in SPP. □

Theorem 4.4. *Over any group family,* normality testing *for the subclass of solvable groups is in* SPP *and hence low for all gap-definable counting classes.*

Proof. Let S_1 and S_2 be generator sets for groups G_1 and G_2. In order to check whether G_2 is normal in G_1 it is enough to check for pairs $g_1 \in S_1$ and $g_2 \in S_2$ whether $g_1 g_2 g_1^{-1} \in G_2$. This can be done in $\mathrm{P}^{\mathrm{SPP}}$ since membership testing is in SPP. Since $\mathrm{P}^{\mathrm{SPP}} = \mathrm{SPP}$, it follows that normality testing is in SPP. □

We have seen that checking whether a group is solvable or not is in SPP. Using this result we can design an SPP algorithm for testing whether a group is nilpotent or not. We need the following generalization of Theorem 3.2. We omit the proof of this group-theoretic result.

Theorem 4.5. *Let G be a group and let H_1 and H_2 be normal subgroups of G generated by S_1 and S_2. Then the mutual commutator subgroup $[H_1, H_2]$ is the normal closure of the set $\{g_1 g_2 g_1^{-1} g_2^{-1} \mid g_1 \in S_1, g_2 \in S_2\}$.*

Using this result we can design an oracle algorithm for computing a generator set for the mutual commutator subgroup for a given pair of groups. The following is the subroutine for computing a generator set for the mutual commutator subgroup. We will be interested in the case when the groups involved are solvable. This subroutine

will use membership testing, normality testing, and solvability testing as oracles.

MutualCommutator$(0^m, S, S_1, S_2)$
1 **if** $\langle S\rangle$ or $\langle S_1\rangle$ or $\langle S_2\rangle$ not Solvable
2 **then Output** NA
3 **if** $\langle S_1\rangle$ is not Normal in $\langle S\rangle$ or $\langle S_2\rangle$ is not Normal in $\langle S\rangle$
4 **then Output** NA
5 $X \leftarrow \{ghg^{-1}h^{-1} \mid g \in S_1, h \in S_2\}$
6 **while** $\exists g \in S$; $x \in X$ such that $(0^m, X, gxg^{-1}) \notin$ membership testing
7 **do** $X \leftarrow X \cup gxg^{-1}$
8 **end-while**
9 **Output** X

Theorem 4.6. *Over any group family,* nilpotence testing *is in* SPP *and hence low for all gap-definable counting classes.*

Proof. We can use the subroutine MutualCommutator for designing the following $\mathrm{P}^{\mathrm{SPP}}$ algorithm for nilpotence testing.

NilpotenceTester$(0^m, S)$
1 **if** $\langle S\rangle$ is not Solvable
2 **then Output** NOT NILPOTENT
3 $L^0 \leftarrow S$
4 **for** $i = 1$ to $p(m)$
5 **do** $L^i \leftarrow MutualCommutator(0^m, S, S, L^{i-1})$
6 **if** $\langle L^i\rangle = \langle L^{i-1}\rangle \neq \{e\}$
7 **then Output** NOT NILPOTENT
8 **end-for**
9 **Output** NILPOTENT

The above algorithm first tests whether the group is solvable. Since any nilpotent groups is also solvable, in the remaining computation we need only worry about groups which are solvable. Hence we can use any of the problems that we have already shown to be in SPP as oracles. The algorithm essentially computes the lower central series of the group. If the lower central series is not terminating, then for some i between 1 and $p(m)$ (where p is the polynomial bounding the size of B_m in the definition of the group family) the mutual commutator subgroups L^i and L^{i-1} must be equal and nontrivial for some i. This is tested in line 6. Note that testing whether two solvable groups are equal can be done with two queries to the subgroup testing oracle which we have shown to be in SPP. Hence the overall algorithm is a $\mathrm{P}^{\mathrm{SPP}}$ algorithm which can be converted into an SPP algorithm. □

Theorem 4.7. *Over any group family,* order verification *for the subclass of solvable groups is in* SPP *and hence low for all gap-definable counting classes.*

Proof. Let S be the generator for a solvable group G. Let the sequence $G = G_0 > G_1 > \cdots > G_k = \{e\}$ be the commutator sequence of G. Then we have $|G| = \prod_{i=1}^{k} |\frac{G_{i-1}}{G_i}|$. Consider an oracle machine M_o which uses oracle L_o as follows. M_o first simulated CanonicalGenerator to construct a canonical generator set for G. Then it simulates the oracle algorithm M_f provided in Lemma 2.10 to compute $|\frac{G_{i-1}}{G_i}|$ for each i using the canonical generator for G_{i-1} and G_i. Finally, it computes $\prod_{i=1}^{k} |\frac{G_{i-1}}{G_i}|$. The oracle L_o is the disjoint union of the NP oracles used by CanonicalGenerator and M_f. CanonicalGenerator makes only 1-guarded queries. Also since inputs

to M_f are canonical generator sets, M_f makes only 1-guarded queries. Therefore M_o makes only 1-guarded queries to L_o. Hence by Corollary 2.4, order verification for the subclass of solvable groups is in SPP. □

THEOREM 4.8. *Over any group family,* group isomorphism *for the subclass of solvable groups is in* SPP *and hence low for all gap-definable counting classes.*

Proof. We know that two solvable groups G and H are isomorphic if and only if the factor group H_{i-1}/H_i is isomorphic to G_{i-1}/G_i for all i where H_i (G_i) is the ith element in the commutator series of H (respectively, G). Isomorphism among abelian groups can be tested by computing the orders of the elements in the independent generators. Two abelian groups are isomorphic if the orders of the elements in their independent generators (arranged in some fixed order, say ascending) are the same. This suggests the following oracle algorithm M_{is} for testing isomorphism. M_{is} uses a language $L_{is} \in$ NP as oracle.

Let S_1 and S_2 be the generator sets for solvable groups G and H. M_{is} first computes canonical generator sets for both G and H using CANONICALGENERATOR. Then it simulates the oracle algorithm M_f provided in Lemma 2.10 to compute independent generators sets for the abelian factor groups H_{i-1}/H_i and G_{i-1}/G_i for all i. For each of these groups it computes the orders of all the elements in the independent generator set, say by using M_f. Then it compares whether the orders of the elements of the independent generator of H_{i-1}/H_i is the same as orders of the elements of the independent generator of G_{i-1}/G_i for all i to decide whether G and H are isomorphic. The oracle L_{is} is the disjoint union of the NP oracles used by CANONICALGENERATOR and M_f. CANONICALGENERATOR makes only 1-guarded queries. Also since inputs to M_f are canonical generator sets, M_f makes only 1-guarded queries. Therefore M_{is} makes only 1-guarded queries to L_{is}. Hence by Corollary 2.4, group isomorphism for the subclass of solvable groups are in SPP. □

For proving upper bound for group intersection, we need a result from [3], which we state next as a lemma.

LEMMA 4.9 (see [3, Lemma 5.7]). *Let $\mathcal{B} = \{B_m\}_{m>0}$ be a group family. There is a deterministic polynomial time oracle machine M that takes $(0^m, X, Y, Z, K)$ as input. Let $G = \langle X \rangle$ and $H = \langle Y \rangle$. Suppose the input has the following properties:*

1. *G and H are solvable groups.*
2. *X and Y are canonical generator sets for G and H, respectively.*
3. *Z is a canonical generator set for G' the commutator subgroup for G.*
4. *The number K is $|G' \cap H|$.*

Then the machine M outputs $|G \cap H|$. Furthermore, M makes $|B_m|$-guarded queries to an NP *language A and* 1*-guarded queries to another* NP *language B. The behavior of machine M is not specified for inputs that does not satisfy the above properties.*

THEOREM 4.10. *Over any group family,* group intersection *for the subclass of solvable groups is in* LWPP *and hence low for the classes* PP *and* $C_=P$.

Proof. Let S_1 and S_2 be the generator sets for solvable groups G and H. We will design an oracle algorithm M_{int} which first computes canonical generator sets for all the groups in the commutator series of both G and H, and then uses the machine M from the above result inductively to compute $G \cap H$ as follows. Let $G = G_0 > G_1 > \cdots > G_{k-1} > G_k = \langle e \rangle$ be the commutator series for G. To begin with, G_{k-1} is abelian, and we have an independent generator set for it. Applying the algorithm M of Lemma 4.9 to the groups G_{k-1} and H, with $Z = \{e\}$ and $K = 1$, M_{int} can compute $|G_{k-1} \cap H|$. Now, M can be used inductively to compute $|G_{i-1} \cap H|$

given canonical generator sets for G_i and H as well as the number $|G_i \cap H|$ for each i. Since all the generator sets that input to M are canonical generator sets, it is clear that M_{int} makes only $|B_m|$-guarded and 1-guarded queries. Also by standard techniques, 1-guarded queries can be made $|B_m|$-guarded. Now applying Corollary 2.4 we get that group intersection is in LWPP. □

Finally we show that group factorization, coset intersection, and double coset memb for solvable groups are also in LWPP.

THEOREM 4.11. *Over any group family, the problems* group factorization, coset intersection, *and* double coset memb *for the subclass of solvable groups are in* LWPP *and hence low for the classes* PP *and* $C_=P$.

Proof. We give proof for group factorization. Proofs for the other two problems are very similar and are omitted. Let $\mathcal{B} = \{B_m\}_{m \geq 1}$ be a group family with elements of B_m uniquely encoded as strings in $\Sigma^{p(m)}$ for a polynomial p. Consider the following NP machine R, which takes $\langle 0^m, S_1, S_2, g, K \rangle$ as input, where S_1 and S_2 are the generator sets for two groups, g is an element of B_m, and K divides $|B_m|$.

R$(0^m, S_1, S_2, g, K)$
1 Verify that K divides $|B_m|$;
2 Guess $w \in \Sigma^{p(m)}$;
3 Verify that $w \in \langle S_1 \rangle$ and $w^{-1}g \in \langle S_2 \rangle$;
4 Branch into $|B_m|/K$ paths and **accept** on each of them.

We are interested in the behavior of this machine only when the following conditions are satisfied: S_1 and S_2 are canonical generator sets for two solvable groups G and H, and $K = |G \cap H|$. Line 3 of this algorithm can be implemented by simulating M_u in Proposition 2.8.

Machine R accepts the input if and only if $(0^m, S_1, S_2, g)$ is a positive instance of group factorization. This is because $g \in GH$ if and only if there exists a w such that $w \in G$ and $w^{-1}g \in H$. Moreover, in this case R will have $\frac{|B_m|}{K} * |G \cap H|$ accepting paths since there will be exactly $|G \cap H|$ elements w satisfying $w \in G$ and $w^{-1}g \in H$. Now consider an oracle machine M_{gf} which on input $(0^m, S_1, S_2, g)$ as input, first computes canonical generator sets for G and H using CANONICALGENERATOR, then computes $|G \cap H|$ using the machine M_{int}, and then queries the language accepted by R the string $(0^m, S_1, S_2, g, |G \cap H|)$. It is clear that M_{gf} only makes $|B_m|$-guarded and 1-guarded queries. 1-guarded queries can be made $|B_m|$-guarded using standard techniques. Therefore, applying Corollary 2.4, we have that group factorization is in LWPP. □

5. Conclusion and open problems. In this paper we investigated the complexity of many computational group-theoretic problems over solvable black-box groups. All the problems considered are computationally difficult: there is no known polynomial time algorithm for any of them. But it is also not known whether they are hard for NP. We showed that these problems over solvable black-box groups are in the counting class SPP or LWPP. The SPP upper bound implies that they will not provide additional power as oracles to counting classes such as PP, $C_=P$, and Mod_kP. The upper bound of LWPP implies that problems will not provide additional power as oracles to counting classes such as PP and $C_=P$. These upper bounds support the belief that the problems considered are unlikely to be hard for NP. Another important aspect of the results is that they provide more examples of natural problems in SPP and LWPP which are not known to be in P.

There is one major open question that arises from this investigation: extend the above upper bound to problems defined over a general black-box group. We believe that the problems we considered here are in SPP even over general black-box groups. The methods we used for solvable groups will not extend for the general case. We feel that new methods based on classification theorems about finite simple groups may be required for the proof of this. A more general question is to show membership of other natural problems in the counting complexity classes like SPP or LWPP.

Acknowledgments. I thank V. Arvind for discussions we had about the results in this paper and his comments. I would like to thank the referees for carefully reading the first version of this paper and giving very detailed comments and pointing out crucial omissions. Their input has helped me to greatly improve the presentation of the paper.

TIME OF DETERMINISTIC BROADCASTING IN RADIO NETWORKS WITH LOCAL KNOWLEDGE*

DARIUSZ R. KOWALSKI† AND ANDRZEJ PELC‡

Abstract. We consider broadcasting in radio networks, modeled as undirected graphs, whose nodes know only their own label and labels of their neighbors. In every step every node acts either as a *transmitter* or as a *receiver*. A node acting as a transmitter sends a message which can potentially reach all of its neighbors. A node acting as a receiver in a given step gets a message if and only if exactly one of its neighbors transmits in this step.

Bar-Yehuda, Goldreich, and Itai [*J. Comput. System Sci.*, 45 (1992), pp. 104–126] considered broadcasting in this model. They claimed a linear lower bound on the time of deterministic broadcasting in such radio networks of diameter 3. This claim turns out to be incorrect in this model (although it is valid in a more pessimistic model [R. Bar-Yehuda, O. Goldreich, and A. Itai, *Errata Regarding "On the time complexity of broadcast in radio networks: An exponential gap between determinism and randomization,"* http://www.wisdom.weizmann.ac.il/mathusers/oded/p_bgi.html, 2002]). We construct an algorithm that broadcasts in logarithmic time on all graphs from the Bar-Yehuda, Goldreich, and Itai paper (BGI). Moreover, we show how to broadcast in sublinear time on all n-node graphs of diameter $o(\log\log n)$. On the other hand, we construct a class of graphs of diameter 4, such that every broadcasting algorithm requires time $\Omega(\sqrt[4]{n})$ on these graphs. In view of the randomized algorithm from BGI, running in expected time $\mathcal{O}(D\log n+\log^2 n)$ on all n-node graphs of diameter D (cf. also a recent $\mathcal{O}(D\log(n/D)+\log^2 n)$-time algorithm from [D. Kowalski and A. Pelc, *Proceedings of the 22nd Annual ACM Symposium on Principles of Distributed Computing*, Boston, 2003, pp. 73–82; A. Czumaj and W. Rytter, *Proceedings of the 44th Annual IEEE Symposium on Foundations of Computer Science*, Cambridge, MA, 2003, pp. 492–501]), our lower bound gives the first correct proof of an exponential gap between determinism and randomization in the time of radio broadcasting, under the considered model of radio communication.

1. Introduction.

A radio network is modeled as an undirected connected graph whose nodes are transmitter-receiver devices. An edge e between two nodes means that the transmitter of one end of e can reach the other end. Nodes send messages in synchronous *steps* (time slots), measured by a global clock which indicates the current step number. In every step every node acts either as a *transmitter* or as a *receiver*. A node acting as a transmitter sends a message which can potentially reach all of its neighbors. A node acting as a receiver in a given step gets a message if and only if exactly one of its neighbors transmits in this step. The message received in this case is the one that was transmitted. If at least two neighbors of u transmit simultaneously

in a given step, none of the messages is received by u in this step. In this case we say that a *collision* occurred at u. It is assumed that the effect at node u of more than one of its neighbors transmitting is the same as that of no neighbor transmitting (i.e., a node cannot distinguish a collision from silence). We assume that nodes know only their own label and the labels of their neighbors. Apart from that, the only a priori information on the network available to nodes is a polynomial upper bound on the number of nodes.

One of the fundamental tasks in network communication is *broadcasting*. Its goal is to transmit a message from one node of the network, called the *source*, to all other nodes. Remote nodes get the source message via intermediate nodes, along paths in the network. In this paper we concentrate on one of the most important and widely studied performance parameters of a broadcasting scheme, which is the total time—that is, the number of steps it uses to inform all the nodes of the network. We measure complexity in terms of the number of nodes in the network.

1.1. Our results. In a seminal paper [3], Bar-Yehuda, Goldreich, and Itai considered broadcasting in radio networks in the model described above. They claimed a linear lower bound on the time of deterministic broadcasting in such radio networks of diameter 3. This claim turns out to be incorrect, although it is valid in a more pessimistic model [4]. In fact, as pointed out in [4], the error is due to a gap between two models handling collisions in radio broadcasting: that from [3] and a more pessimistic but equally reasonable one. (See more comments on this point in subsection 1.2.) As discussed below, a lot of work on radio broadcasting has been done following [3], most of it modeling collisions as in [3].

Using the same model as in [3], we construct an algorithm that broadcasts in logarithmic time on all graphs from [3]. Moreover, we show how to broadcast in sublinear time on all n-node graphs of diameter $o(\log \log n)$. On the other hand, we construct a class of graphs of diameter 4, such that every broadcasting algorithm requires time $\Omega(\sqrt[4]{n})$ on one of these graphs. In view of the randomized algorithm from [3] running in expected time $\mathcal{O}(D \log n + \log^2 n)$ on all n-node graphs of diameter D (cf. also a recent $\mathcal{O}(D \log(n/D) + \log^2 n)$-time algorithm from [23, 15]), our lower bound gives the first correct proof of an exponential gap between determinism and randomization in the time of radio broadcasting, in the model from [3].

1.2. Related work. Most of the results concerning broadcasting in radio networks can be divided into two parts: those which assume complete knowledge of the topology of the network at all nodes, or equivalently, dealing with centralized broadcasting for a given network, and those assuming only limited knowledge of the network at all nodes and dealing with distributed broadcasting in arbitrary networks.

Deterministic centralized broadcasting assuming complete knowledge of the network was first considered in [10], where a $\mathcal{O}(D \log^2 n)$-time broadcasting algorithm was given for all n-node networks of diameter D. In [18], $\mathcal{O}(D + \log^5 n)$-time broadcasting was proposed. On the other hand, in [1] the authors proved the existence of a family of n-node networks of radius 2, for which any broadcast requires time $\Omega(\log^2 n)$.

The study of deterministic distributed broadcasting in radio networks whose nodes have only limited knowledge of the topology was initiated in [3]. The authors assumed that nodes know only their own label and the labels of their neighbors (and that collision at a node has the same effect as silence). Under this scenario, a simple $\mathcal{O}(n)$-time broadcasting algorithm based on depth-first search (DFS) follows from [2]. In [3] the authors constructed a class of n-node graphs of diameter 3, and claimed

that every broadcasting algorithm requires time $\Omega(n)$ on one of these graphs. In [19] this claim was further strengthened to a lower bound of $n-1$ on broadcasting time required on one of these graphs. It follows from the present paper that both these claims (concerning lower bounds) are incorrect.

As pointed out in [4], the linear lower bound from [3] is valid in a more pessimistic model than that of [3]. Namely, one could assume that in the case of a collision at u the effect can be either the same as if no neighbor of u transmitted or the same as if *any single* neighbor of u transmitted, the choice of the effect being left to the adversary. That is, either noise caused by many transmitting neighbors may be undistinguishable from background noise or else one of the competing neighbors may prevail, and it is impossible to predict which situation occurs for a given collision. For this model, which seems equally reasonable to that from [3], the argument and the linear lower bound of [3] are valid (cf. [4]). In fact, as explained in [4], the error in [3] is due to the gap between these two models.

Many authors [5, 7, 8, 9, 11, 12, 13, 14, 16, 26] studied deterministic distributed broadcasting in radio networks under the even weaker assumption that nodes know only their own label (but do not know the labels of their neighbors). In all these papers the collision issue was modeled as in [3]. In [11] the authors gave a broadcasting algorithm working in time $\mathcal{O}(n)$ for arbitrary n-node networks, assuming that nodes can transmit spontaneously before getting the source message. It was shown in [24] that if nodes know only their own label, the argument from [3] can be modified to prove a lower bound $\Omega(n)$ on broadcasting time for networks of radius 2. Thus the algorithm from [11] is optimal.

In [11, 12, 13, 14, 16, 26] the model of directed graphs was used. Increasingly faster broadcasting algorithms working on arbitrary n-node (directed) radio networks were constructed, culminating with the $\mathcal{O}(n\log^2 n)$-time algorithm from [13]. Recently, a $\mathcal{O}(n\log n\log D)$-time broadcasting algorithm was shown in [22] for n-node networks of radius D. This was further improved to $\mathcal{O}(n\log^2 D)$ in [15]. In [14] the authors showed a lower bound $\Omega(n\log D)$ on broadcasting time for n-node networks of radius D. On the other hand, in [5, 7, 8, 9, 12, 14] the problem was to find efficient broadcasting algorithms on radio networks of maximum in-degree Δ.

Finally, randomized broadcasting algorithms in radio networks were studied, e.g., in [3, 15, 25, 23]. For these algorithms no topological knowledge of the network was assumed. In [3] the authors showed a randomized broadcasting algorithm running in expected time $\mathcal{O}(D\log n+\log^2 n)$. A faster algorithm, running in expected time $\mathcal{O}(D\log(n/D)+\log^2 n)$ was presented in [23] (see also [15]). In [25] it was shown that for any randomized broadcasting algorithm (and parameters $D\le n$), there exists an n-node network of diameter D requiring expected time $\Omega(D\log(n/D))$. It should be noted that the lower bound $\Omega(\log^2 n)$ from [1], for some networks of radius 2, holds for randomized algorithms as well. This shows that the algorithm from [23] is optimal.

1.3. Organization of the paper. In section 2 we summarize the communication model (taken from [3]) and the terminology used in this paper. Section 3 is devoted to showing a logarithmic broadcasting algorithm for the class of networks for which a linear lower bound was claimed in [3]. In this section we first describe the novel Procedure Echo, which is later used for more complicated algorithms. In section 4 we describe and analyze a broadcasting algorithm working in sublinear time on all shallow networks. This indicates that if a linear lower bound on broadcasting time can at all be proved (for networks of sublinear diameter), then it requires the construction of quite complicated networks. Section 5 is devoted to the proof of the

lower bound $\Omega(\sqrt[4]{n})$ on broadcasting time in networks of bounded diameter. Finally, section 6 contains concluding remarks and open problems.

2. Model and terminology. We consider undirected graphs whose nodes have distinct labels belonging to the set $\{0, 1, \ldots, r\}$, where r is polynomial in the number n of nodes. The parameter r is known to all nodes. In the lower bounds we assume that n itself is known to all nodes. A distinguished node with label 0 is called the *source*. We denote by D the *radius* of the graph, i.e., the distance from the source to the farthest node. (For undirected graphs, the diameter is of the order of the radius.) The jth *layer* of a graph is the set of nodes at distance j from the source. We adopt the communication model used by Bar-Yehuda, Goldreich, and Itai [3]. It is summarized in the following definition.

DEFINITION 2.1 (see [3]). *A* broadcast protocol *for radio networks is a multiprocessor (multinode) protocol, the execution of which proceeds in steps (time-slots) (numbered* $0, 1, \ldots$*) as follows:*

1. *In the initial step* 0*, only the source transmits a message called the* source message*.*
2. *In each step each node acts either as a transmitter or as a receiver (or is inactive).*
3. *A node receives a message in a specific step if and only if it acts as a receiver in this step and exactly one of its neighbors acts as a transmitter in that step. The message received in this case is the message transmitted by that neighbor.*
4. *The action of a node in a specific step is determined as a function of its initial input (which consists of its own label and the labels of its neighbors) and the (sequence of) messages that it has received in previous steps. All nodes have identical copies of the same program.*
5. *A node may act as a transmitter in a step* > 0 *only if it has received a message in a previous time-slot (there are no "spontaneous" transmissions of nodes other than the source in step* 0*).*
6. *The broadcast is completed at step* t *if all nodes have received the source message at one of the steps* $0, 1, \ldots, t$*.*

As in [3], we assume that a node cannot distinguish whether more than one neighbor or no neighbor transmitted in a given step; i.e., we work in the model without collision detection.

3. Logarithmic broadcasting in *BGI* networks. In [3] the following class of $(n+2)$-node networks was defined. Let S be a nonempty subset of $\{1, \ldots, n\}$. The network G_S is a graph (of radius 2) whose nodes are labeled $0, 1, \ldots, n+1$. The set of edges of G_S is $E = \{(0, i) : 1 \leq i \leq n\} \cup \{(i, n+1) : i \in S\}$. Node 0 is the source, and node $n+1$ (the only node in layer 2) is called the *sink*. We refer to all networks G_S as *BGI-n* networks (see Figure 3.1).

It was claimed in [3] that for any broadcast protocol there is a *BGI-n* network on which this protocol works in time $\Omega(n)$. However, assuming the model from [3], which is the same as that from the present paper, the proof in [3] contains the following flaw. *Predetermined* sets of nodes transmitting in consecutive steps are fixed, and then a network is constructed in which some node is not informed during any of these steps. However, during the broadcasting process, the source may potentially acquire some information, which it may pass to other nodes, thus modifying the sets of nodes transmitting in subsequent steps. So, in fact, under the considered model, the proof from [3] works only for oblivious algorithms, in which sets of nodes transmitting in a given step must be fixed in advance.

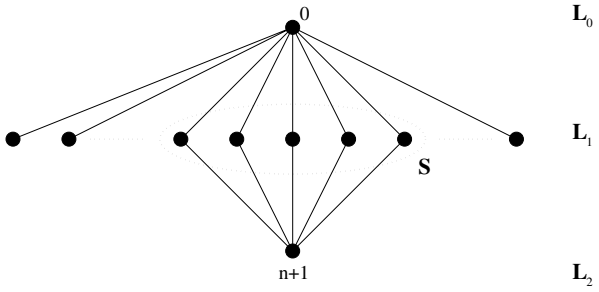

FIG. 3.1. *BGI-n network* G_S.

It turns out that not only is the argument from [3] erroneous under the considered model but, in fact, the above result itself is incorrect. (As mentioned in the introduction, the argument and the proof remain correct in a more pessimistic communication model.) Below we give an algorithm that broadcasts in all *BGI-n* networks in time $\mathcal{O}(\log n)$. The technique of selecting one out of many simultaneously transmitting neighbors, which is the main ingredient of this algorithm, will be further used in the construction of a much more involved algorithm which guarantees fast broadcasting in arbitrary networks of small radius.

The main idea of our algorithm is to simulate the collision detection capability in some nodes of the network. (Recall that collision detection is not available a priori in our model.) In order to get logarithmic broadcasting for *BGI-n* networks, it is enough to simulate collision detection at the source. To get sublinear broadcasting in all networks of radius $o(\log \log n)$, we will need to simulate this capability in many nodes from different levels.

Let A be a set of neighbors of the source (possibly unknown to it), and let $i \notin A$ be another neighbor of the source. Suppose that nodes in A want to transmit. Our goal is to let the source distinguish whether A has 0, 1, or more than 1 element. This can be done using the following 2-step procedure.

PROCEDURE ECHO (i, A).

Step 1. Every node in A transmits its label.

Step 2. Every node in $A \cup \{i\}$ transmits its label.

There are 3 possible effects of Procedure Echo (i, A) at the source.

Case 1. A message is received in Step 1 and no message in Step 2. In this case the source knows that A has 1 node and knows the label of this unique node.

Case 2. No message is received in Step 1 and a message (from i) is received in Step 2. In this case the source knows that A is empty.

Case 3. No message is received in either step. In this case the source knows that A has at least 2 nodes.

Procedure Echo is used to select one node in the set S of nodes connected to the sink, in a *BGI-n* network G_S. Once such a unique node is selected and transmits, the sink receives the source message, and broadcast is completed. This is done using the following algorithm. (In the original definition of *BGI-n* networks, nodes are labeled by consecutive numbers $0, 1, \ldots, n+1$, but we formulate our algorithm in the more general case, when labels are chosen arbitrarily from a set $\{0, 1, \ldots, r\}$, where r is polynomial in the number of nodes. Without loss of generality, assume that r is a power of 2.)

ALGORITHM BINARY-SELECTION-BROADCAST. In step 0, the source transmits the source message and the lowest label i of its neighbor (in the original definition of

BGI-n networks, $i = 1$). In step 1, node with label i transmits the source message and its degree. If this degree is 2 ($i \in S$), the sink receives the message and broadcast stops. Assume that the degree of i is 1.

All remaining steps $2, 3, \ldots$ are divided into segments of length 3. In the first step of each segment, the source transmits a range R of labels and orders the execution of Procedure Echo $(i, R \cap S)$ during the last two steps of the segment. (Notice that all nodes from layer 1 know if they are in $R \cap S$.) In the first segment, $R := \{1, \ldots, r/2\}$. If a range $R = \{x, \ldots, y\}$ is transmitted in a given segment, the range to transmit in the next segment is chosen according to the three possible effects of Procedure Echo $(i, R \cap S)$, described above. In Case 1, the sink is informed and broadcast stops. In Case 2, $R := \{y+1, \ldots, y+(y-x+1)/2\}$. In Case 3, $R := \{x, \ldots, (y+x-1)/2\}$. □

THEOREM 3.1. *Algorithm Binary-Selection-Broadcast completes broadcasting in any BGI-n network in time* $\mathcal{O}(\log n)$.

Proof. Since the size of R transmitted in the ith segment is $r/2^i$, after at most $\log r \in \mathcal{O}(\log n)$ steps, the set $R \cap S$ contains exactly one node, and hence broadcast is completed in time $\mathcal{O}(\log n)$. □

4. Sublinear time broadcasting in networks of radius $o(\log \log n)$. In this section we construct a broadcasting algorithm working in time $o(n)$ on all n-node networks of radius $o(\log \log n)$. We will use the following results from the literature. The following two theorems assume that nodes know parameters r and d but do not assume any knowledge of the network topology.

THEOREM 4.1 (see [14]). *Consider a radio network modeled by an arbitrary graph* (V, E), *where* V *is a subset of* $\{1, \ldots, r\}$. *Let* A *and* B *be a partition of* V *such that all nodes in* A *have the same message* m. *Then there exists a protocol working in time* $\mathcal{O}(\min(r, d \log(r/d)))$, *which makes message* m *known to all nodes* $v \in B$ *having at least one and at most* d *neighbors in* A.

THEOREM 4.2 (see [17, 14]). *Given a radio network modeled by an arbitrary graph* (V, E), *where* V *is a subset of* $\{1, \ldots, r\}$ *and in which every node has a (possibly different) message, there exists a protocol working in time* $\mathcal{O}(\min(r, d^2 \log r))$, *upon the completion of which, every node of degree at most* d *learns the messages of all its neighbors.*

It should be mentioned that, while the protocols in the above theorems were obtained in a nonconstructive way, constructive counterparts of both these results (involving polynomial time local computations) are known and yield only slightly slower protocols. A constructive counterpart of Theorem 4.1 yielding a $\mathcal{O}(\min(r, d \cdot \text{polylog}\, r))$-time protocol follows from [20, 27], and a constructive counterpart of Theorem 4.2 yielding a $\mathcal{O}(\min(r, d^2 \log^2 r))$-time protocol follows from [21]. In our algorithm we use protocols from Theorems 4.1 and 4.2, but these constructive counterparts could be used as well, and our resulting broadcasting algorithm would still work in sublinear time.

The next result refers to radio networks of known topology.

THEOREM 4.3 (see [10]). *Consider a radio network modeled by an arbitrary graph* (V, E), *where* V *is a subset of* $\{1, \ldots, r\}$, *and assume that all nodes know the topology of the graph. Let* A *and* B *be a partition of* V *such that all nodes in* A *have the same message* m. *Then there exists a protocol working in time* $\mathcal{O}(\log^2 r)$, *which makes message* m *known to all nodes* $v \in B$ *having a neighbor in* A.

4.1. Broadcasting in networks of radius 2. We first describe a sublinear time broadcasting algorithm working for all networks of radius 2. More generally, in every network G, this algorithm informs all nodes in levels 1 and 2 in sublinear time.

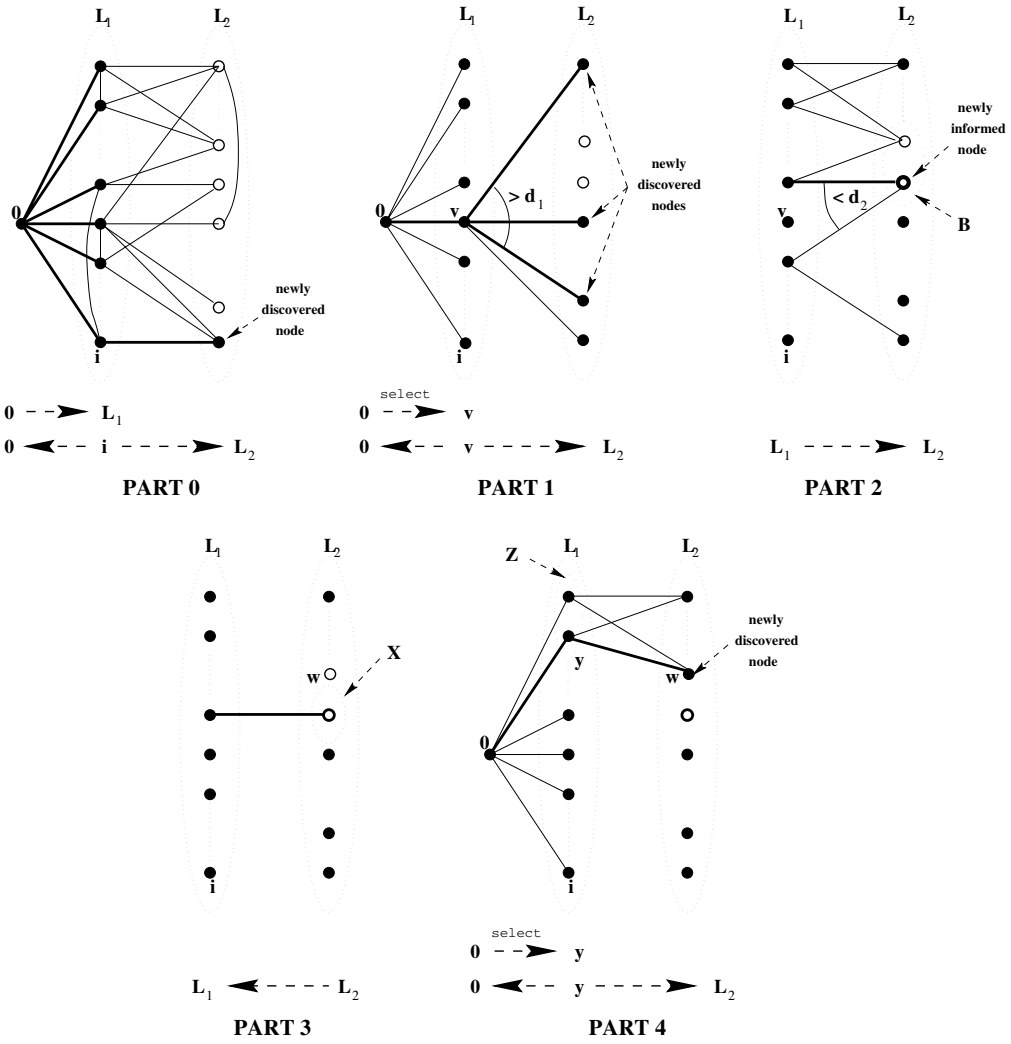

FIG. 4.1. *Algorithm* $\mathcal{A}_2$.

At each step of the execution, the source maintains a set DIS of *discovered* nodes: those about which it knows that they received the source message. The algorithm uses the polynomial upper bound r on the number of nodes, and two parameters d_1 and d_2, whose values will be specified later.

ALGORITHM $\mathcal{A}_2$ (see Figure 4.1).

Part 0. In step 0, the source transmits the source message, the set L_1, and the lowest label $i \in L_1$. In step 1, node with label i transmits the source message and the set C of its neighbors in L_2. The source sets the set DIS of discovered nodes to $\{0\} \cup L_1 \cup C$ and transmits it in step 2.

Part 1. Using a similar mechanism as in Algorithm Binary-Selection-Broadcast, the source selects a node in L_1 for which the number of undiscovered neighbors in L_2 is maximum. (Every node in L_1 can distinguish its neighbors in L_1 and in L_2.) In the next step the selected node transmits the source message and the set of its neighbors in L_2. The source adds them to discovered nodes and transmits the updated set DIS.

This process is repeated until there are no nodes in L_1 with more than d_1 undiscovered neighbors in L_2.

Part 2. Apply the protocol from Theorem 4.1 (with $d = d_2$) to the subgraph of G induced by $L_1 \cup B$ and to the partition (L_1, B), where B is the set of undiscovered nodes in L_2. This protocol makes the source message known to all undiscovered nodes from L_2 which have at most d_2 neighbors in L_1.

Part 3. Let X be the set of all nodes from L_2 which received the source message during Part 2 and have at most d_2 neighbors in L_1. Apply the protocol from Theorem 4.2 (for $d = d_1$) to the subgraph of G induced by $X \cup L_1$. The message transmitted by each node contains its label and the source message.

Part 4. All nodes from L_1 check if all their neighbors in L_2 got the source message. Nodes selected in Part 1 know that all their neighbors in L_2 were informed and discovered. Let Z be the set of nodes in L_1 which did not get a message in Part 3 from some of their undiscovered neighbors in L_2. Using a similar mechanism as in Algorithm Binary-Selection-Broadcast, the source selects one node in Z; then this node transmits (alone) the source message and the set of all its neighbors in L_2, and the source adds these neighbors to the set DIS of discovered nodes. After each selection, at least one currently undiscovered node gets the source message. This process continues until all nodes in L_1 know that all their neighbors in L_2 received the source message. □

THEOREM 4.4. *Algorithm $\mathcal{A}_2$ completes broadcasting in any n-node network of radius 2 in $\mathcal{O}(n^{2/3} \log n)$ time.*

Proof. Correctness is straightforward. The complexity of the algorithm is estimated as follows. Part 0 takes 3 steps. Each selection in Part 1 takes $\mathcal{O}(\log r)$ steps and there are at most n/d_1 selections; hence the entire Part 1 takes $\mathcal{O}((n/d_1) \cdot \log r)$ steps. In view of Theorem 4.1, Part 2 takes $\mathcal{O}(d_2 \cdot \log r)$ steps. In view of Theorem 4.2, Part 3 takes $\mathcal{O}(d_1^2 \log r)$ steps. Each selection in Part 4 takes $\mathcal{O}(\log r)$ steps and there are at most nd_1/d_2 selections; hence the entire Part 4 takes $\mathcal{O}((nd_1/d_2) \cdot \log r)$ steps. Taking $d_1 = \sqrt[3]{n}$ and $d_2 = \sqrt[3]{n^2}$, this adds up to $\mathcal{O}(n^{2/3} \log r) = \mathcal{O}(n^{2/3} \log n)$ steps. □

4.2. Extension to arbitrary networks of radius $o(\log \log n)$. We now describe an algorithm which broadcasts in sublinear time in arbitrary networks of radius $o(\log \log n)$. The algorithm uses the polynomial upper bound r on the number of nodes, and parameters d_j, d'_j, for $j = 2, 3, \ldots$, whose values will be specified later. The algorithm is constructed inductively. The construction is local, in the sense that every node constructs its part of the algorithm, using some coordination guaranteed by the properties and remarks listed below. After the kth phase of the algorithm, where k is an integer larger than 1, the following properties will be satisfied for some positive constant α.

Property 1. All nodes from layers L_j, $j = 1, \ldots, k$, know the source message and know to which layer they belong.

Property 2. For all $j = 1, \ldots, k$, a Procedure SEND(j), coordinated by the source, can be constructed, which has the following effect: if all nodes in L_{j-1} have the same message m and start at the same time, then all nodes in L_j learn message m. (SEND(1) consists of one step in which the source transmits.) Procedure SEND(j) lasts at most $\alpha \cdot (d_j + \log r) \log r$ time.

Remarks.

1. Let $j = 1, \ldots, k-1$, and $A \subseteq L_{j+1}$ be a set of nodes that want to transmit. It follows from Property 2 that a Procedure DETECT(j, A), coordinated by

the source, can be constructed, which enables every node in L_j to distinguish whether it has 0, 1, or more than 1 neighbor in A. Procedure DETECT(j, A) works as follows. Starting at a given time step t_0, all nodes in A repeat transmission in $1+\alpha\cdot(d_j+\log r)\log r$ consecutive time steps. Simultaneously, nodes in L_{j-1} perform Procedure SEND(j).
Each node $v \in L_j$ detects the number of its neighbors in A similarly as in Procedure Echo. By Property 2, v would get message m, during $\alpha\cdot(d_j+\log r)\log r$ steps after t_0, if nodes from A did not transmit. Hence v decides as follows. If it receives a message from a neighbor not in L_{j-1} during Procedure DETECT(j, A), it knows that it has exactly one neighbor in A and knows its label. Otherwise, two cases are possible. (1) If v receives only messages from L_{j-1} during Procedure DETECT(j, A), then it knows that none of its neighbors is in A. (2) If v receives no messages during Procedure DETECT(j, A), then it knows that at least two of its neighbors are in A.

2. Let $j = 0, \ldots, k-1$, $i \in L_j$, and let $A \subseteq L_{j+1}$ be a subset of neighbors of i that want to transmit. A Procedure SELECT(j, i, A), coordinated by node i, can be constructed, in which node i selects one element in A. This can be done in $\alpha \cdot \log r$ steps, similarly as in Algorithm Binary-Selection-Broadcast, where node i plays the role of the source.

ALGORITHM SUBLINEAR-BROADCAST. In phase 1 do nothing. In phase 2 perform algorithm $\mathcal{A}_2$. Let $k > 1$. Suppose that Properties 1 and 2 are satisfied after phase k. We describe phase $k+1$. The source maintains a set DIS of *discovered* nodes: these are nodes from $L_{k-1} \cup L_k \cup L_{k+1}$ whose labels the source learned in phase $k+1$. At the beginning of phase $k+1$ this set is empty. Each node from L_k appends the number k of its layer to all its messages.
Description of phase $k+1$:

Part 0. The aim of this part is the verification of whether layer L_k is empty or not. If $L_k = \emptyset$, then the radius of the network is $D = k-1$ and broadcasting was completed at the end of phase $k-1$, by Property 1 for k. In this case the source sends a stop message. Otherwise, the source sends a message requesting the start of Part 1. Here is a detailed description of Part 0.

- The source initiates broadcast of the message "start verification in step t," by consecutive use of Procedures SEND(j), for $j = 1, \ldots, k$, according to Property 2 for k. Step t is calculated to guarantee reception of this message by all nodes in L_j, for $j = 1, \ldots, k$, i.e., to guarantee completion of all Procedures SEND(j).
- Verification of whether layer L_k is empty starts in step t.
  - Using Procedure DETECT$(k-1, L_k)$, nodes from L_{k-1} detect if they have neighbors in L_k.
  - Let A_{k-1} be the set of nodes from L_{k-1} which detected neighbors in L_k. Using Procedure DETECT$(k-2, A_{k-1})$, nodes from L_{k-2} detect if they have neighbors in A_{k-1}. This process continues with sets $A_i \subseteq L_i$, until the source detects if it has neighbors in A_1.
- If the source does not have neighbors in A_1 (i.e., A_1 is empty, which means that L_k is empty as well), then it initiates broadcast of the message "stop in step t_1" (for an appropriately calculated t_1), by consecutive use of Procedures SEND(j), for $j = 1, \ldots, k-1$, according to Property 2 for k. Otherwise, a message requesting the start of Part 1 in an appropriately calculated step is sent similarly as above (to all layers L_j for $j = 1, \ldots, k$).

Part 1. The aim of this part is selection of consecutive nodes from L_k which

have at least d'_{k+1} undiscovered neighbors. This is done as follows, using a similar cascade of Procedures DETECT, as in Part 0.

- Let B_k be the set of nodes from L_k which have at least d'_{k+1} undiscovered neighbors. Using Procedure DETECT$(k-1, B_k)$, nodes from L_{k-1} detect if they have neighbors in B_k.
- Let B_{k-1} be the set of nodes from L_{k-1} which detected neighbors in B_k. Using Procedure DETECT$(k-2, B_{k-1})$, nodes from L_{k-2} detect if they have neighbors in B_{k-1}. This process continues with sets $B_i \subseteq L_i$, until the source detects if it has neighbors in B_1.
- If the source does not have neighbors in B_1 (i.e., B_1 is empty), then it initiates broadcast of the message "go to Part 2 in step t_2" (for an appropriately calculated t_2), by consecutive use of Procedures SEND(j) for $j = 1, \ldots, k$, according to Property 2 for k. Otherwise the source selects one node from B_1, using Procedure SELECT$(0, 0, B_1)$.
- The selected node v performs SELECT$(1, v, B_2)$ to select one of its neighbors in B_2. This is continued until one node w in B_k is selected.
- Node w broadcasts a message (containing the source message, the label w, and labels of neighbors of w). All these neighbors get the source message. Moreover, broadcast is propagated along the path containing selected nodes from consecutive sets B_i. The source discovers neighbors of w and possibly w itself, updates the set DIS, and propagates this information to all nodes in layers $L_1, \ldots, L_k$, using SEND procedures.

This selection process continues until all nodes in L_k have less than d'_{k+1} undiscovered neighbors.

Part 2. Let X be the set of all undiscovered nodes in L_k, and Y the set of all undiscovered nodes in $L_{k-1} \cup L_k \cup L_{k+1}$ which have at most d_{k+1} neighbors in X. A node can tell if it is in X, since in view of Property 1 it knows if it is in L_k, and after Part 1 of phase $k+1$ it knows whether it is in set DIS.

Apply the protocol from Theorem 4.2 (for $d = d_{k+1}$ and for the source message) to the subgraph of G induced by $X \cup Y$. At the end of Part 2, all nodes from Y got the source message.

Part 3. Consider the subgraph G of the radio network induced by the set of nodes V consisting of all undiscovered nodes in $L_{k-1} \cup L_k$, and of all undiscovered nodes in L_{k+1} which got the source message in Part 2. Each node knows if it is in V, in view of Part 2, of the knowledge of DIS gotten at the end of Part 1, and of Property 1.

Apply the protocol from Theorem 4.2 to the graph G (for $d = d'_{k+1}$). The message transmitted by each node contains its label and the source message. At the end of Part 3, all undiscovered nodes in L_k, which have at most d'_{k+1} neighbors in G, know which of their neighbors in G got the source message.

Part 4. All undiscovered nodes from L_k check if all their undiscovered neighbors got the source message. Consider the set Z of undiscovered nodes from L_k which did not get a message in Part 3 from some of their undiscovered neighbors. As in Part 1, we do the following:

- Procedures DETECT and SELECT are used to select one node in Z,
- this node transmits (alone) the source message and the set of all its neighbors in L_{k+1},
- this message is propagated to the source,
- the source updates the set DIS of discovered nodes (now DIS includes the selected node from Z and all of its neighbors) and propagates DIS to layer L_k.

After each selection, at least one currently undiscovered node in L_{k+1} gets the source message. This process continues until all nodes in L_k know that all their neighbors received the source message. □

THEOREM 4.5. *Algorithm Sublinear-Broadcast completes broadcasting in arbitrary radio networks.*

Proof. It is enough to prove that Properties 1 and 2 are satisfied after each phase $k > 1$. First we prove them for $k = 2$, i.e., upon completion of Algorithm $\mathcal{A}_2$.

Property 1. By correctness of Algorithm $\mathcal{A}_2$, all nodes in L_1 and L_2 get the source message. All nodes in L_1 know that they are in L_1 because they got the message directly from the source. All nodes from L_2 got the message from some neighbor in L_1, by the description of Algorithm $\mathcal{A}_2$. On the other hand, they know that they are not in L_1, so they deduce that they are in L_2.

Property 2. Upon completion of Algorithm $\mathcal{A}_2$, all nodes in L_2 either are discovered or have at most d_2 neighbors in L_2. Procedure SEND(2) can be executed as follows. Broadcasting assuming knowledge of topology is executed in the graph containing all nodes from L_1 and all discovered nodes from L_2. This is done according to the protocol from Theorem 4.3 in time $\alpha_1 \cdot \log^2 r$. Broadcasting to the remaining nodes is done using the protocol from Theorem 4.1 in time $\alpha_2 \cdot (d_2 \log r)$. The property follows for $\alpha = \max(\alpha_1, \alpha_2)$.

Now assume that Properties 1 and 2 hold after phase k of Algorithm Sublinear-Broadcast. We have to prove that they hold after phase $k + 1$.

Property 1. Every node v in L_{k+1} gets a message from a neighbor w in L_k in phase $k + 1$. This is proved as follows. If v did not get a message until the end of Part 3, then all neighbors of v in L_k know that v did not get a message. Then at least one neighbor of v from L_k is selected in Part 4 and v gets a message from it. Node v learns that neighbor w is in L_k because w knows this by Property 1 after phase k and attaches this information to its message. Node v also knows that itself is not in L_i for $i \leq k$, so it deduces that it is in L_{k+1}.

Property 2. Procedure SEND$(k + 1)$ is executed similarly as SEND(2) (described above), by replacing L_1 by L_k, L_2 by L_{k+1}, and d_2 by d_{k+1}. □

Our next result estimates time complexity of Algorithm Sublinear-Broadcast for networks of small radius.

THEOREM 4.6. *Algorithm Sublinear-Broadcast completes broadcasting in time $o(n)$, for all n-node radio networks of radius $o(\log \log n)$.*

Proof. Fix a phase $k > 2$ of the algorithm. We estimate time complexity of each of its five parts separately.

Part 0. All Procedures SEND take a total of at most $2\alpha \cdot (\sum_{j<k}(d_j + \log r) \log r)$ steps. All Procedures DETECT take a total of at most $k - 1 + \alpha \cdot (\sum_{j<k-1}(d_j + \log r) \log r)$ steps. Hence the number of steps in the entire Part 0 is at most $\mathcal{O}(\sum_{j<k}(d_j + \log r) \log r) = \mathcal{O}(\sum_{j<k}(d_j + \log n) \log n)$.

Part 1. There can be at most (n/d'_k) selected nodes. We estimate the number of steps needed for each selection. All Procedures DETECT take a total of at most $k - 1 + \alpha \cdot (\sum_{j<k-1}(d_j + \log r) \log r)$ steps. All Procedures SELECT take a total of at most $\alpha(k - 1) \cdot \log r$ steps. Sending back a message to the source along a fixed path of selected nodes takes $k - 1$ steps. All Procedures SEND take a total of at most $\alpha \cdot (\sum_{j<k}(d_j + \log r) \log r)$ steps. Defining $\gamma = \alpha \cdot (\log r / \log n)^2$, we get the estimate

$$2\alpha \cdot \left(\sum_{j<k} (d_j + \log r) \log r \right) + \alpha(k-1) \cdot \log r + 2(k-1) \leq 4\gamma \cdot \left(\sum_{j<k} (d_j + \log n) \log n \right)$$

on the number of steps for each selection. Hence the number of steps in the entire Part 1 is at most $4\gamma \cdot ((n/d'_k) \cdot \sum_{j<k}(d_j + \log n)\log n) \in \mathcal{O}((n/d'_k) \cdot \sum_{j<k}(d_j + \log n)\log n)$.

Part 2. By Theorem 4.2, this part takes $\mathcal{O}(d_k^2 \log r) = \mathcal{O}(d_k^2 \log n)$ steps.

Part 3. By Theorem 4.2, this part takes $\mathcal{O}((d'_k)^2 \log r) = \mathcal{O}((d'_k)^2 \log n)$ steps.

Part 4. Every node in set Z has at most d'_k undiscovered neighbors (otherwise it would be selected in Part 1). Every undiscovered neighbor w of a node $v \in Z$, from which v did not get a message in Part 3, is not in the graph G (defined in Part 3), hence it does not have the source message yet. By the description of Part 2, node w has more than d_k neighbors in L_{k-1}. Hence at most nd'_k/d_k selections of nodes in Z will be performed. The number of steps for each node is $\mathcal{O}(\sum_{j<k}(d_j + \log n)\log n)$, similarly as in Part 1. This gives a total of $\mathcal{O}((nd'_k/d_k)\sum_{j<k}(d_j + \log n)\log n)$.

We now choose the following parameters: $d_1 = \lfloor \log r \rfloor$, $d'_{i+1} = d_i^2$, and $d_{i+1} = (d'_{i+1})^2$. This gives the following estimates of the numbers of steps in different parts of phase k:

Part 0: $\mathcal{O}(d_{k-1} \log n) \subseteq \mathcal{O}(d_k^2 \log n)$.

Part 1: $\mathcal{O}((n/d'_k) \cdot d_{k-1} \log n) \subseteq \mathcal{O}((n \log n)/d_{k-1})$.

Part 2: $\mathcal{O}(d_k^2 \log n)$.

Part 3: $\mathcal{O}((d'_k)^2 \log n) \subseteq \mathcal{O}(d_k^2 \log n)$.

Part 4: $\mathcal{O}((nd'_k/d_k) \cdot d_{k-1} \log n) \subseteq \mathcal{O}((n \log n)/d_{k-1})$.

Thus the entire phase k lasts $\mathcal{O}((n/d_{k-1}) \cdot \log n + d_k^2 \log n)$ steps.

The last phase of the algorithm run on a radio network of radius D is $D+2$ (in fact only Part 0 of phase $D+2$ is executed). The total time of phases $k = 3, \ldots, D+2$ is at most $\mathcal{O}(d_{D+2}^2 \log n + (n \log n)/d_2) \subseteq \mathcal{O}(\min(n, (\log n)^{4^{D+3}+1} + n/\log^2 n))$. Since $D \in o(\log \log n)$, we get that this time is $o(n)$. By Theorem 4.4 the time of the first two phases (occupied by execution of Algorithm $\mathcal{A}_2$) is $\mathcal{O}(n^{2/3} \log n)$, which is $o(n)$ as well. Hence the entire Algorithm Sublinear-Broadcast completes broadcasting in time $o(n)$. □

5. Lower bound. In this section we show that for every deterministic broadcasting algorithm $\mathcal{A}$, there exists a network $G_{\mathcal{A}}$ of radius 2, with at most $2n$ nodes, on which $\mathcal{A}$ requires $\Omega(\sqrt[4]{n})$ steps to complete broadcast. This network is chosen from the family $\mathcal{C}_n$ of networks defined as follows. Every graph $G \in \mathcal{C}_n$ (see Figure 5.1) consists of the source 0 and two layers $L_1 = \{1, \ldots, n\}$ and $L_2 = \{n+1, \ldots, n+q\}$, where q is the largest odd integer smaller than $\sqrt[4]{n}$. The source is adjacent to all nodes in L_1, and every node in L_1 is adjacent to exactly one node in L_2. These are the only edges in G. If G is fixed, we denote by V the set $\{0\} \cup L_1 \cup L_2$ of all nodes of G. For every node v, we denote by N_v the set of its neighbors.

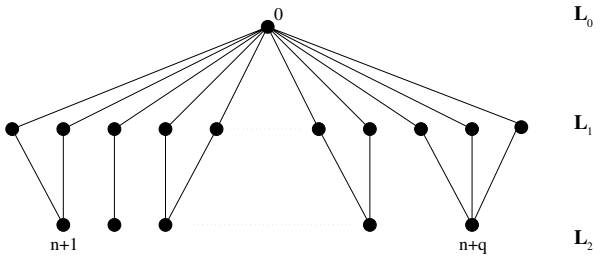

FIG. 5.1. *Network* $G \in \mathcal{C}_n$.

The idea of the proof is the following. We construct the network step by step, using consecutive steps of the fixed broadcasting algorithm $\mathcal{A}$, and *assuming* that particular nodes got particular messages in given steps. In order to express this, we use the notion of *abstract history* of a node, formally defined below. Intuitively, an abstract history of a node v at a given step k consists of a neighborhood of node v and of a sequence of messages received by this node until step k. Since the network is not yet constructed, neighborhoods of some nodes are not determined by step k, and consequently it is not yet known which abstract history will become the real one—the one given by algorithm $\mathcal{A}$ running on the final network. We can ensure that, if a given node had some abstract history up to a certain step, then it would behave in a given way (this is captured by the notion of abstract action function, defined below). Based on that we do the next step of the construction of the network (by determining neighborhoods of two nodes in layer L_2) and simultaneously define abstract histories of nodes in this step. These abstract histories are defined so as to prevent some nodes in layer L_2 of the network from getting any message for a long time. In particular, nodes of L_2 whose neighborhood is not yet determined have not gotten the source message so far.

When the construction is finished, we prove that if the algorithm $\mathcal{A}$ runs on the resulting network, then the real histories of all nodes are identical to the abstract (assumed) ones, and consequently some nodes of layer L_2 will indeed fail to receive the source message for $\Omega(\sqrt[4]{n})$ steps.

5.1. Construction. Fix a deterministic broadcasting algorithm $\mathcal{A}$. For this algorithm, running on any network, we define the following objects.

Histories and message format. H_k denotes the history of computation of algorithm $\mathcal{A}$ until the end of step k. This is the set $\{H_k(v) : v \in V\}$, where $H_k(v)$ is the history of computation at node v, until the end of step k. For any v and k, $H_k(v)$ is a sequence of (received) *messages* $(M_0(v), M_1(v), \ldots, M_k(v))$. Messages are defined inductively, as follows. $M_0(v)$ is either the triple $(\emptyset, \emptyset, \emptyset)$, called the *empty message*, or the triple $(0, N_0, \mathit{source\_message})$. $M_l(v)$ (for $l = 1, \ldots, k$) is the empty message if node v did not get any message in step l. Otherwise, it is a triple consisting of

- the label of node w from which node v received a message in step l,
- the set N_w,
- history $H_{l-1}(w)$.

Notice that we restrict attention to messages conveying the entire history of the transmitter. If a particular protocol requires transmitting specific information, the receiver can deduce this information from the received history, since programs of all nodes are the same. History $H_k(v)$ containing only empty messages is called the *empty history*.

Action function and sets of transmitters. Given algorithm $\mathcal{A}$, we denote by $\pi(v, N_v, H_{k-1}(v))$ the action of node v in step k, if its set of neighbors is N_v and its history until the end of step $k-1$ is $H_{k-1}(v)$. The values of the function π can be 1 or 0: if the value is 1, node v is sending the message $(v, N_v, H_{k-1}(v))$ in step k, otherwise it is receiving in step k. Under a fixed history H_{k-1}, we define the set of neighbors of v transmitting in step k as follows: $T_k(v) = \{w \in N_v : \pi(w, N_w, H_{k-1}(w)) = 1\}$.

We construct a network $G_{\mathcal{A}} \in \mathcal{C}_n$ on which $\mathcal{A}$ will work inefficiently. We first present the general overview of the construction and abstracts objects used in it. The construction is by induction on steps of the algorithm $\mathcal{A}$. The set of nodes $\{0\} \cup L_1 \cup L_2$, where $L_1 = \{1, \ldots, n\}$ and $L_2 = \{n+1, \ldots, n+q\}$, as well as all edges $\{(0, i) : i = 1, \ldots, n\}$ are given in the beginning. At each step of the induction some

edges between nodes from L_1 and L_2 are added. Since at each stage of the construction only a part of the network $G_{\mathcal{A}}$ is specified, the new edges are constructed using algorithm $\mathcal{A}$ and some *abstract history* $\hat{H}_k$ until this step. Abstract histories at each node are parametrized with a nonempty set A representing a possible neighborhood of v to be constructed in a later step.

Abstract objects. Abstract objects (messages, histories, action function, transmitters) are abstract versions of real objects, used in the construction because real ones do not exist until the network is completely defined. Let $v \in V$ and $A \subseteq V$. An abstract history $\hat{H}_k(v, A)$ of node v, assuming that its neighborhood is A, is defined as a sequence $(\hat{M}_0(v, A), \hat{M}_1(v, A), \ldots, \hat{M}_k(v, A))$ of *abstract messages*. $\hat{M}_0(v, A) = M_0(v)$, and $\hat{M}_l(v, A)$, for $l > 0$, either is the empty message or is of the format $(w, B, \hat{H}_{l-1}(w, B))$, for some $w \in V$ and $B \subseteq V$. We will construct the abstract history step by step, in parallel with the construction of network $G_{\mathcal{A}}$. Notice that, in general, abstract histories and abstract messages are not necessarily linked to any particular protocol.

We also define the *abstract action function* $\hat{\pi}(v, A, \hat{H}_{k-1}(v, A))$ as an extension of the action function π described above. For every v and A, if $\pi(v, A, \hat{H}_{k-1}(v, A))$ is defined, then $\hat{\pi}(v, A, \hat{H}_{k-1}(v, A)) = \pi(v, A, \hat{H}_{k-1}(v, A))$. Otherwise, $\hat{\pi}(v, A, \hat{H}_{k-1}(v, A)) = 0$.

We now define sets of *abstract transmitters*. First consider a node v with neighborhood N_v fixed at the end of step k of the construction, and assume that neighborhoods N_w of all nodes $w \in N_v$ are also fixed. Under a fixed abstract history $\hat{H}_{k-1}$, we define the set of abstract transmitters $\hat{T}_k(v, N_v) = \{w \in N_v : \hat{\pi}(w, N_w, \hat{H}_{k-1}(w, N_w)) = 1\}$.

Now define sets of abstract transmitters for nodes whose neighborhood is not yet fixed. Suppose that S_k is the set of all nodes j in L_2 for which the neighborhood N_j is not fixed until the end of step k of the construction. Suppose that R_k is the set of nodes in L_1 that do not belong to any fixed neighborhood at the end of step k, i.e., $R_k = L_1 \setminus \bigcup_{j \in L_2 \setminus S_k} N_j$. (Additionally, let $S_0 = L_2$ and $R_0 = L_1$.) For nodes of R_k and S_k, we define the sets of abstract transmitters in step k as follows:

- if $v \in R_k$, then for any $j \in S_k$, $\hat{T}_k(v, \{0, j\}) = \{0\}$ if $\hat{\pi}(0, L_1, \hat{H}_{k-1}(0, L_1)) = 1$, and $\hat{T}_k(v, \{0, j\}) = \emptyset$ otherwise;
- if $v \in S_k$ and $R \subseteq L_1$, then $\hat{T}_k(v, R) = \{i \in R : \hat{\pi}(i, \{0, v\}, \hat{H}_{k-1}(i, \{0, v\})) = 1\}$.

Sets R_k and S_k will be defined dynamically in a formal way, during step k of the construction. We will prove that these formal definitions correspond to the meaning intended above for R_k and S_k, by proving Property 1 of the invariant after step k.

We now describe the inductive construction of the graph $G_{\mathcal{A}}$. We begin by defining the abstract history $\hat{H}_0$. $\hat{H}_0(v, A) = (\hat{M}_0(v, A))$, for all nodes v and sets A, where $\hat{M}_0(v, A)$ is the empty message for all $v \notin L_1$, and $\hat{M}_0(v, A) = (0, L_1, source\_message)$, for all $v \in L_1$.

We now begin step 1 of the construction, on the basis of step 1 of the algorithm and of the abstract history $\hat{H}_0$ already defined. To this end we will need the function First-Step-Selection, formally described below. We want to choose an element j of the set S (corresponding to L_2), to which the largest number of elements of the set R (corresponding to L_1) would transmit, if they were neighbors of j. Then we determine neighbors of j in L_1. When the function determines j, it also determines its neighborhood, and it deletes j from S. Hence, if S was the set of nodes with undetermined neighborhood before applying the function, it will preserve this property after applying it. When the neighborhood of j is determined, then (since neighbors of j are in L_1 and nodes in L_1 have exactly one neighbor in L_2) we automatically

determine neighborhoods of neighbors of j. These neighbors are deleted from R, and hence R preserves the property of containing nodes with undetermined neighborhood, similar to S.

FUNCTION FIRST-STEP-SELECTION(R, S).

- Choose some node $j \in S$ such that the size of $X = \hat{T}_1(j, R)$ is maximal, and put two nodes from X to N_j (or one if X has one element, or nothing if X is empty); then remove these nodes from R. Remove j from S.
- Modify N_j as follows:
  if $N_j = \emptyset$, **then** put an arbitrary $i \in R$ to N_j and remove i from R;
  while there exists a node $i \in R$ such that $\hat{T}_1(v, R) = \{i\}$, for some $v \in S$
  do put i into N_j and remove i from R.
- Return (R, S, j, N_j).

Step 1 of the construction. The goal of step 1 of the construction is choosing two nodes j_1' and j_1 in L_2, together with their neighborhoods, in such a way that if some node from R_1 transmits in the first step of algorithm $\mathcal{A}$, then at least one other node from R_1 transmits as well. This is essential to guarantee the following property of abstract history $\hat{H}_1(0, L_1)$: no node from L_1 with yet undetermined neighborhood is heard by the source.

0. Initialize $R := L_1$ and $S := L_2$.
1. $(R, S, j_1', N_{j_1'}) :=$ FIRST-STEP-SELECTION(R, S);
   $R_1' := R$;
   $(R, S, j_1, N_{j_1}) :=$ FIRST-STEP-SELECTION(R, S);
   $R_1 := R$ and $S_1 := S$.
2. We construct the abstract history $\hat{H}_1$. Its definition corresponds to the definition of the "real" history, if neighborhoods are determined. Otherwise, the definition depends on the conditions on nodes and neighborhoods, the crucial case being the last item of the description below. History $\hat{H}_0$ is fixed; hence it is enough to define $\hat{M}_1(v, A)$, for all v, A. If $\hat{\pi}(v, A, \hat{H}_0(v, A)) = 1$, then $\hat{M}_1(v, A)$ is the empty message (transmitting nodes should not receive messages). Otherwise, $\hat{M}_1(v, A)$ is defined as follows:
   - Since nodes in $(L_1 \setminus R_1) \cup (L_2 \setminus S_1)$ have fixed neighborhoods, and also their neighbors have fixed neighborhoods, for each $v \in (L_1 \setminus R_1) \cup (L_2 \setminus S_1)$ we define $\hat{M}_1(v, N_v) = (w, N_w, \hat{H}_0(w, N_w))$, if $\hat{T}_1(v, N_v) = \{w\}$, and we define $\hat{M}_1(v, A)$ as the empty message in all other cases.
   - We define $\hat{M}_1(v, A)$ as the empty message, for all nodes $v \in S_1$ and all sets A.
   - We define $\hat{M}_1(0, L_1)$ as follows:
     – if $|\hat{T}_1(j_1', N_{j_1'}) \cup \hat{T}_1(j_1, N_{j_1})| \neq 1$, then $\hat{M}_1(0, L_1)$ is empty;
     – if $\hat{T}_1(j_1', N_{j_1'}) \cup \hat{T}_1(j_1, N_{j_1}) = \{i\}$, then $\hat{M}_1(0, L_1) = (i, N_i, \hat{H}_0(i, N_i))$. (Note that N_i is already defined at this point.)

     $\hat{M}_1(0, A)$ is defined as the empty message, for all $A \neq L_1$.
   - For every $v \in R_1$ and $j \in S_1$, if $\hat{T}_1(v, \{0, j\}) = \{0\}$, then $\hat{M}_1(v, \{0, j\}) = (0, L_1, \hat{H}_0(0, L_1))$, and $\hat{M}_1(v, A)$ is the empty message in all other cases.

This concludes the first step of the construction.

For any $k \geq 1$, the following invariant will be preserved after step k of the construction.

INVARIANT AFTER STEP k. The following objects are defined:
sets $S_l \subseteq L_2$ for $l = 0, 1, \ldots, k$;
sets $R_l \subseteq L_1$ for $l = 0, 1, \ldots, k$;

sets $R'_l \subseteq L_1$ for $l = 1, \ldots, k$;
nodes j'_l, j_l such that $S_{l-1} \setminus S_l = \{j'_l, j_l\}$ and $R_{l-1} \setminus R_l = N_{j'_l} \cup N_{j_l}$ for $l = 1, \ldots, k$.
The following properties hold:

1. Neighborhoods of nodes in $\{0\} \cup (L_1 \setminus R_k) \cup (L_2 \setminus S_k)$ are defined.
2. Histories $\hat{H}_k(v, A)$ are defined, for all nodes v and all sets A.
3. For all sets A, histories $\hat{H}_k(j, A)$ are empty for all $j \in S_k$, and histories $\hat{H}_{k-1}(j, A)$ are empty for all $j \in S_{k-1} \setminus S_k$.
4. For all nodes $j \in S_k \cup \{j_k\}$ and steps $l \leq k$, we have $|\hat{T}_l(j, R'_k)| \neq 1$.
5. For all nodes $j \in S_k$ and steps $l \leq k$, we have $|\hat{T}_l(j, R_k)| \neq 1$.
6. For all nodes $j \in S_{k-1} \setminus S_k$ and steps $l < k$, we have $|\hat{T}_l(j, N_j)| \neq 1$.

We now begin step $k+1$ of the construction, on the basis of step $k+1$ of the algorithm and of the invariant after step k. We will need a function similar to Function First-Step-Selection. Its aim is to choose $j \in S$ with the property as before (see the comment preceding the description of Function First-Step-Selection). This is done in the first item of the formal description given below. We also need to modify the neighborhood of j, so that choices (and elimination) of such nodes in previous steps of the construction do not yield a single transmitter to nodes with yet undetermined neighborhood. This is required in order to preserve Properties 4, 5, and 6 of the invariant. Modification of the neighborhood is done in the second item of the following formal description.

Function $(k+1)$st-Step-Selection(R, S).

- Choose some node $j \in S$ such that the size of $X = \hat{T}_{k+1}(j, R)$ is maximal and put two nodes from X to N_j (or one if X has one element, or nothing if X is empty), then remove these nodes from R. Remove j from S.
- Modify N_j as follows:
  if $N_j = \emptyset$, **then** put an arbitrary $i \in R$ to N_j and remove i from R;
  - **set** `stop` $:= 0$,
  - **while** `stop` $= 0$ **do**
    - **set** `stop` $:= 1$,
    - **while** there exists a node $i \in R$ such that $\hat{T}_l(j', R) = \{i\}$, for some $l \leq k+1$, $j' \in S$
      do put i into N_j and remove i from R,
    - **while** there exists a node $i \in N_j$ such that $\hat{T}_l(j, N_j) = \{i\}$, for some $l \leq k$
      do find another node $i' \in \hat{T}_l(j, R)$ (if it exists), put i' into N_j, and remove i' from R, **set** `stop` $:= 0$;
- Return (R, S, j, N_j).

Step $(k+1)$ of the construction (see Figure 5.2). The goal of step $(k+1)$ of the construction is choosing two nodes, $j'_{k+1}, j_{k+1} \in S_k$ (in L_2), together with their neighborhoods (included in R_k), and defining abstract history $\hat{H}_{k+1}$, so as to satisfy the invariant after step $(k+1)$ of the construction. Note that we do not initialize variables R and S because their values have been fixed after step k of the construction; indeed, at the beginning of step $k+1$, we have $R = R_k$ and $S = S_k$.

1. $(R, S, j'_{k+1}, N_{j'_{k+1}}) := (k+1)$st-Step-Selection$(R, S)$;
   $R'_{k+1} := R$;
   $(R, S, j_{k+1}, N_{j_{k+1}}) := (k+1)$st-Step-Selection$(R, S)$;
   $R_{k+1} := R$ and $S_{k+1} := S$.
2. We construct the abstract history $\hat{H}_{k+1}$. Its definition corresponds to the definition of the "real" history, if neighborhoods are determined. Otherwise,

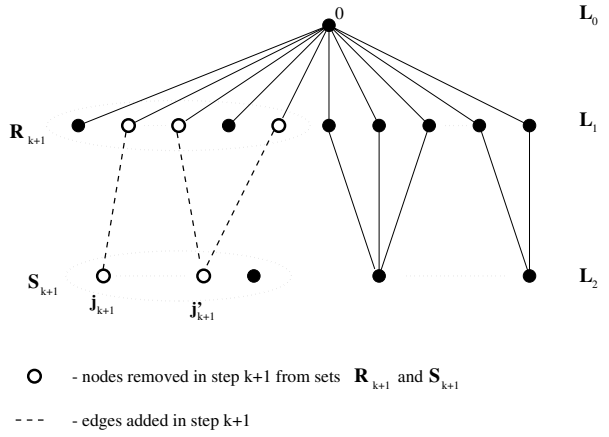

FIG. 5.2. *Step $k+1$ of the construction of $G_{\mathcal{A}} \in \mathcal{C}_n$.*

the definition depends on the conditions on nodes and neighborhoods, the crucial case being the last item of the description below. History $\hat{H}_k$ is fixed; hence it is enough to define $\hat{M}_{k+1}(v, A)$, for all v, A. If $\hat{\pi}(v, A, \hat{H}_k(v, A)) = 1$, then $\hat{M}_{k+1}(v, A)$ is the empty message (transmitting nodes should not receive messages). Otherwise, $\hat{M}_{k+1}(v, A)$ is defined as follows:

- Since nodes in $(L_1 \setminus R_{k+1}) \cup (L_2 \setminus S_{k+1})$ have fixed neighborhoods, and also their neighbors have fixed neighborhoods, for each $v \in (L_1 \setminus R_{k+1}) \cup (L_2 \setminus S_{k+1})$ we define $\hat{M}_{k+1}(v, N_v) = (w, N_w, \hat{H}_k(w, N_w))$, if $\hat{T}_{k+1}(v, N_v) = \{w\}$, and we define $\hat{M}_{k+1}(v, A)$ as the empty message in all other cases.
- We define $\hat{M}_{k+1}(v, A)$ as the empty message, for all nodes $v \in S_{k+1}$ and all sets A.
- We define $\hat{M}_{k+1}(0, L_1)$ as follows:
  - if $|\bigcup_{j \in L_2 \setminus S_{k+1}} \hat{T}_{k+1}(j, N_j)| \neq 1$, then $\hat{M}_{k+1}(0, L_1)$ is empty;
  - if $\bigcup_{j \in L_2 \setminus S_{k+1}} \hat{T}_{k+1}(j, N_j) = \{i\}$, then $\hat{M}_{k+1}(0, L_1) = (i, N_i, \hat{H}_k(i, N_i))$. (Note that N_i is already defined at this point.)

  $\hat{M}_{k+1}(0, A)$ is defined as the empty message, for all $A \neq L_1$.
- For every $v \in R_{k+1}$ and $j \in S_{k+1}$, if $\hat{T}_{k+1}(v, \{0, j\}) = \{0\}$, then $\hat{M}_{k+1}(v, \{0, j\}) = (0, L_1, \hat{H}_k(0, L_1))$, and $\hat{M}_{k+1}(v, A)$ is the empty message in all other cases.

5.2. Analysis. We first show that the invariant after step k of the construction holds if sets R_k, S_k are nonempty. This guarantees the correctness of the construction until one of these sets becomes empty, i.e., until all nodes either of L_1 or of L_2 have determined neighborhoods. Next we show that sets R_k, S_k are nonempty for $k \leq \frac{q-1}{2}$, where q is the largest odd integer smaller than $\sqrt[4]{n}$. This implies that the construction is correct until step $k = \frac{q-1}{2}$. Then we show how to finish the construction of network $G_{\mathcal{A}}$. Finally, we prove that histories determined by algorithm $\mathcal{A}$ running on network $G_{\mathcal{A}}$ are identical to the previously constructed abstract histories. In view of the invariant after step $k = \frac{q-1}{2} \in \Omega(\sqrt[4]{n})$ of the construction, this implies the desired lower bound on broadcasting time.

LEMMA 5.1. *The invariant after step k is preserved, for all $k \geq 1$ such that S_k and R_k are nonempty.*

Proof. The validity of the invariant after step 1 follows from the exit conditions in the first and second executions of function FIRST-STEP-SELECTION(R, S), in Part 1 of step 1 of the construction.

Assume that the invariant holds after step k and that S_{k+1} and R_{k+1} are nonempty. We prove that it holds after step $k+1$.

All required objects are defined by the construction in step $k+1$, using nonemptiness of S_{k+1} and R_{k+1}. It remains to prove the six properties.

1. This follows from Property 1 of the invariant after step k and from the construction of j'_{k+1}, j_{k+1}, and of their neighborhoods during Part 1 of the construction in step $k+1$.
2. $\hat{H}_{k+1}$ was defined in Part 2 of step $(k+1)$ of the construction.
3. The fact that $\hat{H}_{k+1}(v, A)$ is empty for all nodes $v \in S_{k+1}$ and all sets A follows from the assumption in Part 2 of step $(k+1)$ of the construction. The fact that $\hat{H}_k(j'_{k+1}, A)$ and $\hat{H}_k(j_{k+1}, A)$ are empty (j'_{k+1}, j_{k+1} are the only elements of $S_k \setminus S_{k+1}$) follows from Property 3 of the invariant after step k.
4. We prove that, for all nodes $j \in S_k \cup \{j_k\}$ and steps $l \leq k+1$, we have $|\hat{T}_l(j, R'_{k+1})| \neq 1$. This follows from the exit conditions of the external and of the first internal loop in function $(k+1)$ST-STEP-SELECTION(R, S) (more precisely, in the first execution of this function in Part 1 of step $(k+1)$ of the construction). The execution of the external loop ends if and only if the value of `stop` becomes 1, which means that the condition in the second internal loop is always false in the last turn of the external loop. Hence the condition of the first internal loop must be false at the end of the last turn of the external loop. This implies $|\hat{T}_l(j, R'_{k+1})| \neq 1$, for all nodes $j \in S_{k+1}$ and steps $l \leq k+1$.
5. We prove that for all nodes $j \in S_{k+1}$ and steps $l \leq k+1$ we have $|\hat{T}_l(j, R_{k+1})| \neq 1$. This follows by an argument similar as above, applied to function $(k+1)$ST-STEP-SELECTION(R, S) (now we refer to the second execution of this function in Part 1 of step $(k+1)$ of the construction).
6. The property $|\hat{T}_l(j, N_j)| \neq 1$, for all nodes $j \in S_k \setminus S_{k+1}$ and steps $l < k+1$, follows from the exit condition of the second internal loop in the first and second executions of function $(k+1)$ST-STEP-SELECTION(R, S), in Part 1 of step $(k+1)$ of the construction. Observe that the existence of i' in the second internal loop follows from Property 5 of the invariant after step k and from (the just proved) Property 4 of the invariant after step $k+1$. ∎

LEMMA 5.2. *The inductive construction of the network can be carried out for at least* $\frac{q-1}{2}$ *steps, where* q *is the largest odd integer smaller than* $\sqrt[4]{n}$.

Proof. Let $k \leq (q-1)/2$. Sets S_k are decreased by two nodes during one step; hence $S_k \neq \emptyset$, since $|S_0| = q$.

Claim. Sets R_k are decreased by at most $2q^3$ nodes during one step, at most q^3 for each of the chosen nodes j'_k, j_k.

This can be computed by analyzing loops in both executions of function kTH-STEP-SELECTION(R, S) in Part 1 of step k of the construction. Every turn of each of the internal loops increases the neighborhood $N_{j'_k}$ (resp., N_{j_k}) by at most one element and consequently decreases R by at most one element.

Consider the first execution. During the first internal loop, at most $kq \leq q^2/2$ nodes can be added to $N_{j'_k}$, since each action makes one set $\hat{T}_l(j, R)$ empty, where $l \leq k$, and $n+1 \leq j \leq n+q$. (Since we analyze subsequent executions of the loop in the function, symbol R in the expressions containing R corresponds to the current value of this variable, which changes dynamically. Hence values of these expressions

may also change dynamically.)

During the second internal loop, at most $k-1 \leq q/2$ nodes can be added to $N_{j'_k}$, since each action makes one set $\hat{T}_l(j'_k, N_{j'_k})$ of size at least 2, where $l \leq k-1$. There may be at most $k-1 \leq q/2$ executions of the external loop, since every execution of the external loop increases the size $|\hat{T}_l(j'_k, N_{j'_k})|$ to at least 2 for some $l \leq k-1$ while performing the second internal loop. When $|\hat{T}_l(j'_k, N_{j'_k})| \neq 1$, for all $l \leq k-1$, the execution of the external loop stops. Hence $N_{j'_k}$ is bounded by $(q^2/2+q/2)\cdot(q/2) \leq q^3$, and consequently R is decreased at the rate of at most q^3 nodes per step. The same is true for the second execution. Hence R_k is smaller than R_{k-1} by at most $2q^3$ nodes, which concludes the proof of the claim.

Since $q < \sqrt[4]{n}$, we have $R_k \neq \emptyset$ for all $k \leq (q-1)/2$. It follows that the construction can be carried out for $(q-1)/2$ steps. □

Using Lemma 5.2, the construction of the network $G_{\mathcal{A}}$ can be now concluded as follows. All nodes in $R_{(q-1)/2}$ are made adjacent to the only node in $S_{(q-1)/2}$. It follows from the construction that $G_{\mathcal{A}}$ belongs to the class $\mathcal{C}_n$ defined in the beginning of this section.

The histories $\hat{H}_k$ in consecutive steps of the construction were abstract histories defined in order to continue the construction in subsequent steps. The next lemma shows that the actual histories $H_k(v)$ of all nodes v of network $G_{\mathcal{A}}$ obtained by running algorithm $\mathcal{A}$ on this network, are identical to abstract histories $\hat{H}_k(v, N_v)$.

LEMMA 5.3. *Let $k \leq (q-1)/2$ be a step of the execution of algorithm $\mathcal{A}$ on network $G_{\mathcal{A}}$. Then $H_k(v) = \hat{H}_k(v, N_v)$, for all nodes v of network $G_{\mathcal{A}}$.*

Proof. In the first step of the algorithm execution, the source transmits and all nodes in L_1 receive the message. Nodes in L_2 receive nothing. Hence $H_0(v) = \hat{H}_0(v, N_v)$ by definition of $\hat{H}_0$.

Note that the definition of abstract history in step 1 of the construction is the same as that in step $k+1$, taken for $k=0$. Hence it is not necessary to separately analyze step 1, and we can proceed with the argument by induction, for an arbitrary k.

Assume by induction that $H_k(v) = \hat{H}_k(v, N_v)$, where $k < (q-1)/2$. We prove $H_{k+1}(v) = \hat{H}_{k+1}(v, N_v)$ by showing $M_{k+1}(v) = \hat{M}_{k+1}(v, N_v)$. (Since $k+1 \leq (q-1)/2$, the abstract history $\hat{H}_{k+1}$ is well defined, in view of Lemma 5.2.) Observe that, since $\hat{\pi}$ is an extension of π and $H_k(v) = \hat{H}_k(v, N_v)$, we have $\hat{\pi}(v, N_v, \hat{H}_k(v, N_v)) = \pi(v, N_v, H_k(v))$. Hence, if $\hat{\pi}(v, N_v, \hat{H}_k(v, N_v)) = 1$, then v acts as a transmitter in step $k+1$, and hence both $M_{k+1}(v)$ and $\hat{M}_{k+1}(v, N_v)$ are empty messages. Thus we assume in the following that $\hat{\pi}(v, N_v, \hat{H}_k(v, N_v)) = 0$, i.e., that v acts as a receiver.

Case 1. $v \in (L_1 \setminus R_{k+1}) \cup (L_2 \setminus S_{k+1})$.

By Property 1 of the invariant after step $k+1$ of the construction, v has a fixed neighborhood and all of its neighbors w have fixed neighborhoods. Since $\hat{H}_k(w, N_w) = H_k(w)$, we get $M_{k+1}(v) = \hat{M}_{k+1}(v, N_v)$.

Case 2. $v \in S_{k+1}$.

$\hat{M}_{k+1}(v, N_v)$ is the empty message by Property 3 of the construction invariant after step $k+1$. Let k' be the step in which the neighborhood N_v was constructed. Since $v \in S_{k+1}$, we have $k' > k+1$. By Property 6 of the invariant after step k' of the construction, $|\hat{T}_l(v, N_v)| \neq 1$, for all steps $l < k'$. In particular, $|\hat{T}_{k+1}(v, N_v)| \neq 1$. Since $\hat{H}_k(w, N_w) = H_k(w)$ for all $w \in N_v$, we have $T_{k+1}(v) = \hat{T}_{k+1}(v, N_v)$, and hence $T_{k+1}(v)$ is not a singleton. It follows that $M_{k+1}(v)$ is the empty message.

Case 3. $v = 0$.

If $j \in L_2 \setminus S_{k+1}$, then $\hat{T}_{k+1}(j, N_j) = T_{k+1}(j)$, since $\hat{H}_k(w, N_w) = H_k(w)$, for all $w \in N_j$. Hence $\bigcup_{j \in L_2 \setminus S_{k+1}} \hat{T}_{k+1}(j, N_j) = \bigcup_{j \in L_2 \setminus S_{k+1}} T_{k+1}(j)$. We consider three cases.

If $|\bigcup_{j \in L_2 \setminus S_{k+1}} \hat{T}_{k+1}(j, N_j)| > 1$, then $\hat{M}_{k+1}(0, L_1)$ is empty. In this case, $|T_{k+1}(0)| = |\bigcup_{j \in L_2} T_{k+1}(j)| > 1$ and hence $M_{k+1}(0)$ is the empty message.

If $\bigcup_{j \in L_2 \setminus S_{k+1}} \hat{T}_{k+1}(j, N_j) = \{i\}$, then $\hat{M}_{k+1}(0, L_1) = (i, N_i, \hat{H}_k(i, N_i))$. In this case, $\bigcup_{j \in L_2 \setminus S_{k+1}} T_{k+1}(j) = \{i\}$. By construction of j_{k+1}, we have $\hat{T}_{k+1}(j_{k+1}, R_{k+1}) = \emptyset$, and hence $\hat{T}_{k+1}(j, R_{k+1}) = \emptyset$, for all $j \in S_{k+1}$. Consequently, $T_{k+1}(j) = \hat{T}_{k+1}(j, N_j) \subseteq \hat{T}_{k+1}(j, R_{k+1}) = \emptyset$. It follows that $M_{k+1}(0) = (i, N_i, H_k(i))$. In view of $H_k(i) = \hat{H}_k(i, N_i)$, we get $M_{k+1}(0) = \hat{M}_{k+1}(0, L_1)$.

If $\bigcup_{j \in L_2 \setminus S_{k+1}} \hat{T}_{k+1}(j, N_j) = \emptyset$, then $\hat{M}_{k+1}(0, L_1)$ is the empty message. In this case, $\bigcup_{j \in L_2 \setminus S_{k+1}} T_{k+1}(j) = \emptyset$. The same reasoning as above gives $\hat{T}_{k+1}(j, R_{k+1}) = \emptyset$ for all $j \in S_{k+1}$. Consequently, $M_{k+1}(0)$ is the empty message.

Case 4. $v \in R_{k+1}$.

Since for all $j \in S_{k+1}$, $\hat{H}_{k+1}(j, N_j) = H_{k+1}(j)$ is the empty history, it follows that each node $v \in R_{k+1}$ can receive a message in step $k+1$ of $\mathcal{A}$ only from node 0, if this node transmits. If node 0 transmits in step $k+1$ of $\mathcal{A}$, then v receives the message $M_{k+1}(v) = (0, L_1, H_k(0))$. Since $H_k(0) = \hat{H}_k(0, L_1)$, by definition we have $\hat{T}_{k+1}(v, N_v) = \{0\}$. By construction of message $\hat{M}_{k+1}(v, N_v)$ we get $\hat{M}_{k+1}(v, N_v) = (0, L_1, \hat{H}_k(0, L_1))$. Since $H_k(0) = \hat{H}_k(0, L_1)$, we have $\hat{M}_{k+1}(v, N_v) = M_{k+1}(v)$. If node 0 does not transmit in step $k+1$ of $\mathcal{A}$, then $M_{k+1}(v)$ is empty. Since $H_k(0) = \hat{H}_k(0, L_1)$, by definition we have $\hat{T}_{k+1}(v, N_v) = \emptyset$. By construction, $\hat{M}_{k+1}(v, N_v)$ is the empty message. □

THEOREM 5.4. *For any deterministic broadcasting algorithm $\mathcal{A}$, there exists a network $G_{\mathcal{A}}$ of radius 2, with at most $2n$ nodes, for which this algorithm requires time $\Omega(\sqrt[4]{n})$.*

Proof. Network $G_{\mathcal{A}}$ constructed above has $n + 1 + q \leq 2n$ nodes, since q is the largest odd integer smaller than $\sqrt[4]{n}$. It has radius 2 by construction. Let $k = (q-1)/2$. By Lemma 5.2, S_k is nonempty. By Lemma 5.1 and Property 3 of the invariant after step k, histories $\hat{H}_k(j, N_j)$ are empty for all $j \in S_k$. By Lemma 5.3, histories $H_k(j)$ are empty for all $j \in S_k$. Hence no node in S_k receives the source message by step k of algorithm $\mathcal{A}$. It follows that algorithm $\mathcal{A}$ requires time $\Omega(\sqrt[4]{n})$ to broadcast on network $G_{\mathcal{A}}$. □

Using the above technique we can prove the following more general result.

COROLLARY 5.5. *For any deterministic broadcasting algorithm $\mathcal{A}$ and any parameters $D \leq n$, there exists an n-node network of radius D, for which this algorithm requires time $\Omega(\sqrt[4]{nD^3})$.*

6. Conclusion. In this paper we studied deterministic broadcasting time in radio networks whose nodes know only their immediate neighborhood. We presented an algorithm for broadcasting in sublinear time in all networks of radius $o(\log \log n)$ and we proved a lower bound $\Omega(\sqrt[4]{n})$ on broadcasting time even in networks of radius 2. In view of the randomized algorithm from [3] running in expected time $\mathcal{O}(D \log n + \log^2 n)$ on all n-node graphs of diameter D, our lower bound proves an exponential gap between time of deterministic and randomized broadcasting in radio networks.

The main problem that remains open is the following. Is there a deterministic broadcasting algorithm running in sublinear time on all networks with sublinear radius, if nodes know only their immediate neighborhood? If complete knowledge of the network is available, the positive answer follows from [18].

THE PARAMETERIZED COMPLEXITY OF COUNTING PROBLEMS*

JÖRG FLUM† AND MARTIN GROHE‡

Abstract. We develop a parameterized complexity theory for counting problems. As the basis of this theory, we introduce a hierarchy of parameterized counting complexity classes #W[t], for $t \geq 1$, that corresponds to Downey and Fellows's W-hierarchy [R. G. Downey and M. R. Fellows, *Parameterized Complexity*, Springer-Verlag, New York, 1999] and we show that a few central W-completeness results for decision problems translate to #W-completeness results for the corresponding counting problems.

Counting complexity gets interesting with problems whose decision version is tractable, but whose counting version is hard. Our main result states that counting cycles and paths of length k in both directed and undirected graphs, parameterized by k, is #W[1]-complete. This makes it highly unlikely that these problems are fixed-parameter tractable, even though their decision versions are fixed-parameter tractable. More explicitly, our result shows that most likely there is no $f(k) \cdot n^c$-algorithm for counting cycles or paths of length k in a graph of size n for any computable function $f : \mathbb{N} \to \mathbb{N}$ and constant c, even though there is a $2^{O(k)} \cdot n^{2.376}$ algorithm for finding a cycle or path of length k [N. Alon, R. Yuster, and U. Zwick, *J. ACM*, 42 (1995), pp. 844–856].

1. Introduction.

Counting problems have been the source for some of the deepest and most fascinating results in computational complexity theory, ranging from Valiant's fundamental result [29] that counting perfect matchings of bipartite graphs is #P-complete over Toda's theorem [28] that the class $\mathrm{P}^{\#\mathrm{P}}$ contains the polynomial hierarchy to Jerrum, Sinclair, and Vigoda's [20] fully polynomial randomized approximation scheme for computing the number of perfect matchings of a bipartite graph. In this paper, we develop a basic parameterized complexity theory for counting problems.

Parameterized complexity theory provides a framework for a fine-grain complexity analysis of algorithmic problems that are intractable in general. In recent years, ideas from parameterized complexity theory have found their way into various areas of computer science, such as database theory [19, 24], artificial intelligence [18], and computational biology [6, 27]. Central to the theory is the notion of *fixed-parameter tractability*, which relaxes the classical notion of tractability, i.e., polynomial time computability, by admitting algorithms whose running time is exponential, but only in terms of some *parameter* of the problem instance that can be expected to be small in the typical applications. A good example is the evaluation of database queries: Usually, the size k of the query to be evaluated is very small compared to the size n of the database. An algorithm evaluating the query in time $O(2^k \cdot n)$ may therefore be acceptable, even quite good. On the other hand, an $\Omega(n^k)$ evaluation algorithm

usually cannot be considered feasible. Fixed-parameter tractability is based on this distinction: A parameterized problem is *fixed-parameter tractable* if there is a computable function f and a constant c such that the problem can be solved in time $f(k) \cdot n^c$, where n is the input size and k is the parameter value.

A standard example of a fixed-parameter tractable problem is the vertex cover problem parameterized by the size k of the vertex cover. It is quite easy to see that a vertex cover of size k of a graph of size n can be computed in time $O(2^k \cdot n)$ by a simple search tree algorithm based on the fact that at least one of the two endpoints of each edge must be contained in a vertex cover. (As a matter of fact, such an algorithm computes all minimum vertex covers of size at most k.) A standard example of a problem that does not seem to be fixed-parameter tractable is the clique problem, parameterized by the size of the clique. Indeed, all known algorithms for deciding whether a graph of size n has a clique of size k have a running time of $n^{\Omega(k)}$.

To give evidence that parameterized problems such as the clique problem are not fixed-parameter tractable, a theory of *parameterized intractability* has been developed (see [11, 12, 13]). It resulted in a rather unwieldy variety of parameterized complexity classes. The most important of these classes are the classes W[t], for $t \geq 1$, forming the so-called *W-hierarchy*. It is believed that W[1] strictly contains the class FPT of all fixed-parameter tractable problems and that the W-hierarchy is strict. Many natural parameterized problems fall into one of the classes of the W-hierarchy. For example, the parameterized clique problem is complete for the class W[1], and the parameterized dominating set problem is complete for the class W[2] (under suitable parameterized reductions).

So far, the parameterized complexity of counting problems has not been studied very systematically. A few tractability results are known: First, some fixed-parameter tractable decision problems have algorithms that can easily be adapted to the corresponding counting problems. An example is the vertex cover problem; since all minimum vertex covers of size at most k of a graph of size n can be computed in time $O(2^k \cdot n)$, a simple application of the inclusion-exclusion principle yields a fixed-parameter tractable counting algorithm for the vertex covers of size k. Similar counting algorithms are possible for other problems that have a fixed-parameter tractable algorithm based on the *method of bounded search tree* (see [13]). More interesting are results of Arnborg, Lagergren, and Seese [4], Courcelle, Makowsky, and Rotics [10], and Makowsky [22] stating that counting problems definable in monadic second-order logic (in various ways) are fixed-parameter tractable when parameterized by the tree-width of the input graph. For example, Arnborg, Lagergren, and Seese's result implies that counting the Hamiltonian cycles of a graph is fixed-parameter tractable when parameterized by the tree-width of the graph, and Makowsky's result implies that evaluating the Tutte polynomial is fixed-parameter tractable when parameterized by the tree-width of the graph. Courcelle, Makowsky, and Rotics [10] also proved similar results for graphs of bounded clique-width. Frick [16] showed that counting problems definable in first-order logic are fixed-parameter tractable on locally tree-decomposable graphs. For example, this implies that counting dominating sets of a planar graph is fixed-parameter tractable when parameterized by the size of the dominating sets.

We focus on the *intractability* of parameterized counting problems. We define classes #W[t], for $t \geq 1$, of parameterized counting problems that correspond to the classes of the W-hierarchy. Our first results show that a few central completeness results for the classes W[1] and W[2] translate to corresponding completeness results for the first two levels #W[1] and #W[2] of the #W-hierarchy. For example, we show

that counting cliques of size k is #W[1]-complete and counting dominating sets of size k is #W[2]-complete (both under *parsimonious parameterized reductions*). We then characterize the class #W[1] as the class of all counting problems that can be described in terms of numbers of accepting computations of certain nondeterministic programs. To give further evidence that the class #W[1] strictly contains the class of fixed-parameter tractable counting problems, we show that if this were not the case there would be a $2^{o(n)}$-algorithm counting the satisfying assignments of a 3-CNF-formula with n variables. This is the counting version of a result due to Abrahamson, Downey, and Fellows [1]. While these results are necessary to lay a solid foundation for the theory and not always easy to prove, by and large they do not give us remarkable new insights. The theory gets interesting with those counting problems that are harder than their decision versions.

Our main result states that *counting cycles and paths of length k in both directed and undirected graphs, parameterized by k, is* #W[1]*-complete under parameterized Turing reductions.* It is an immediate consequence of a theorem of Plehn and Voigt [26] that the decision versions of these problems are fixed-parameter tractable (but of course not in polynomial time, because if they were, the Hamiltonian path/cycle problem would be also). Alon, Yuster, and Zwick's [2] *color coding* technique provides algorithms for finding a path of length k in time $O(k! \cdot m)$ in a graph with m edges and for finding a cycle of length k in time $O(2^{O(k)} \cdot n^\omega)$ in a graph with n vertices, where $\omega < 2.376$ is the exponent of matrix multiplication. The hardness of the cycle counting problem in undirected graphs may be surprising in view of another algorithm due to Alon, Yuster, and Zwick [3] showing that cycles *up to length* 7 in an undirected graph can be counted in time $O(n^\omega)$. Our result implies that it is very unlikely that there is such an algorithm for counting cycles of arbitrary fixed length k.

The paper is organized as follows. After giving the necessary preliminaries in section 2, in section 3 we discuss fixed-parameter tractable counting problems. This section has the character of a short survey; apart from a few observations it contains no new results. In section 4, we introduce the #W-hierarchy and establish the basic completeness results. The hardness of counting cycles and paths is established in section 5. Definitions of all parameterized problems considered in this paper can be found in Appendix A.

We would like to point out that some of the results in section 4 have independently been obtained by others in two recent papers: McCartin [23] proves the #W[1]-completeness of clique and the #W[2]-completeness of dominating set. (Our proofs of these results are quite different from hers.) Furthermore, she shows that a number of further completeness results for parameterized decision problems translate to the corresponding counting problems. Arvind and Raman [5] also obtain the #W[1]-completeness of clique. Their main result is that the number of cycles or paths of length k can be approximated by a randomized fixed-parameter tractable algorithm. Indeed, they prove this not only for cycles and paths, but for arbitrary graphs of bounded tree-width. These results nicely complement our main result that exactly counting paths and cycles is hard.

2. Preliminaries.

2.1. Parameterized complexity theory. A *parameterized problem* is a set $P \subseteq \Sigma^* \times \mathbb{N}$, where Σ is a finite alphabet. If $(x, k) \in \Sigma^* \times \mathbb{N}$ is an instance of a parameterized problem, we refer to x as the *input* and to k as the *parameter*.

Definition 2.1. *A parameterized problem $P \subseteq \Sigma^* \times \mathbb{N}$ is* fixed-parameter tractable *if there is a computable function $f : \mathbb{N} \to \mathbb{N}$, a constant $c \in \mathbb{N}$, and an algorithm*

that, given a pair $(x, k) \in \Sigma^* \times \mathbb{N}$*, decides if* $(x, k) \in P$ *in at most* $f(k) \cdot |x|^c$ *steps.*

We usually use k to denote the parameter and $n = |x|$ to denote the size of the input.

To illustrate our notation, let us give one example of a parameterized problem, the *parameterized vertex cover problem*, which is well known to be fixed-parameter tractable:

p-VC	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if $\mathcal{G}$ has a vertex cover of size k.

From now on, we will give only brief definitions of the parameterized problems we consider in the main text; for exact definitions we refer the reader to Appendix A.

To define the classes of the W-hierarchy, we need a few notions from propositional logic. Formulas of propositional logic are built up from *propositional variables* $X_1, X_2, \ldots$ by taking conjunctions, disjunctions, and negations. The negation of a formula θ is denoted by $\neg\theta$. We distinguish between *small conjunctions*, denoted by $\wedge$, which are just conjunctions of two formulas, and *big conjunctions*, denoted by $\bigwedge$, which are conjunctions of arbitrary finite sets of formulas. Analogously, we distinguish between *small disjunctions*, denoted by $\vee$, and *big disjunctions*, denoted by $\bigvee$.

A formula is *small* if it contains only small conjunctions and small disjunctions. We define $\Gamma_0 = \Delta_0$ to be the class of all small formulas. For $t \geq 1$, we define Γ_t to be the class of all big conjunctions of formulas in Δ_{t-1} and we define Δ_t to be the class of all big disjunctions of formulas in Γ_{t-1}.

The *depth* of a propositional formula θ is the maximum number of nested conjunctions or disjunctions in θ. Note that the definitions of Γ_t and Δ_t are purely syntactical; every formula in Γ_t or Δ_t is equivalent to a formula in Γ_0. But the translation from a formula in Γ_t to an equivalent formula in Γ_0 usually increases the depth of a formula. For all $t, d \geq 0$ we let $\Gamma_{t,d}$ denote the class of all formulas in Γ_t whose small subformulas have depth at most d (equivalently, we may say that the whole formula has depth at most $d + t$). We define $\Delta_{t,d}$ analogously.

Let CNF denote the class of all propositional formulas in conjunctive normal form, that is, conjunctions of disjunctions of literals; if we ignore arbitrarily nested negations, then CNF is just $\Gamma_{2,0}$. A formula is in *d conjunctive normal form* if it is a conjunction of disjunctions of at most d literals; the class of all such formulas is denoted by d-CNF.

The *weight* of a truth value assignment to the variables of a propositional formula is the number of variables set to TRUE by the assignment. For any class Θ of propositional formulas, the *weighted satisfiability problem for* Θ, denoted by $\mathrm{WSAT}(\Theta)$, is the problem of deciding whether a formula in Θ has a satisfying assignment of weight k, parameterized by k. We are now ready to define the W-hierarchy as follows.

DEFINITION 2.2. *For* $t \geq 1$, $\mathrm{W}[t]$ *is the class of all parameterized problems that can be reduced to* $\mathrm{WSAT}(\Gamma_{t,d})$ *for some* $d \geq 0$ *by a parameterized many-one reduction.*

We omit the definition of parameterized many-one reductions here and refer the reader to [13] for this definition and further background on parameterized complexity theory.

2.2. Relational structures. A *vocabulary* is a finite set of relation symbols. Associated with every relation symbol is a natural number, its *arity*. The arity of a

vocabulary is the maximum of the arities of the relation symbols it contains. In the following, τ always denotes a vocabulary.

A *τ-structure* $\mathcal{A}$ consists of a nonempty set A, called the *universe* of $\mathcal{A}$, and a relation $R^{\mathcal{A}} \subseteq A^r$ for each r-ary relation symbol $R \in \tau$. For example, we view a *directed graph* as a structure $\mathcal{G} = (G, E^{\mathcal{G}})$ whose vocabulary consists of one binary relation symbol E. $\mathcal{G} = (G, E^{\mathcal{G}})$ is an *(undirected) graph* if $E^{\mathcal{G}}$ is symmetric. For graphs, we often write $\{a, b\} \in E^{\mathcal{G}}$ instead of $(a, b) \in E^{\mathcal{G}}$. In this paper, we consider only structures whose universe is finite. We distinguish between the size of the universe A of a τ-structure $\mathcal{A}$, which we denote by $|A|$, and the *size* of $\mathcal{A}$, which is defined to be

$$\|\mathcal{A}\| = |\tau| + |A| + \sum_{R \in \tau} |R^{\mathcal{A}}| \cdot \text{arity}(R).$$

An *expansion* of a τ-structure $\mathcal{A}$ to a vocabulary $\tau' \supseteq \tau$ is a τ'-structure $\mathcal{A}'$ with $A' = A$ and $R^{\mathcal{A}'} = R^{\mathcal{A}}$ for all $R \in \tau$.

A *substructure* of $\mathcal{A}$ is a structure $\mathcal{B}$ with $B \subseteq A$ and $R^{\mathcal{B}} \subseteq R^{\mathcal{A}}$ for all $R \in \tau$.[1] A *homomorphism* from a τ-structure $\mathcal{A}$ to a τ-structure $\mathcal{B}$ is a mapping $h : A \to B$, where for all $R \in \tau$, say, of arity r, and all tuples $(a_1, \ldots, a_r) \in R^{\mathcal{A}}$ we have $\big(h(a_1), \ldots, h(a_r)\big) \in R^{\mathcal{B}}$. An *embedding* is a homomorphism that is one-to-one.

The *homomorphism problem* asks whether there is a homomorphism from a given structure $\mathcal{A}$ to a given structure $\mathcal{B}$. We parameterize this problem by the size of $\mathcal{A}$ and denote the resulting *parameterized homomorphism problem* by p-Hom. We will also consider the *parameterized embedding problem*, denoted by p-Emb, and the *parameterized substructure problem* (Does structure $\mathcal{B}$ have a substructure isomorphic to $\mathcal{A}$?), denoted by p-Sub. Of course when considered as decision problems, p-Emb and p-Sub are equivalent, but as counting problems they are slightly different. All three decision problems are complete for the class W[1] under parameterized many-one reductions [13].

2.3. Logic and descriptive complexity. Let us remark that the following notions are not needed for understanding our results on the hardness of counting cycles and paths or their proofs.

The formulas of *first-order logic* are built up from *atomic formulas* using the usual Boolean connectives and existential and universal quantification over the elements of the universe of a structure. Remember that an *atomic formula*, or *atom*, is a formula of the form $x = y$ or $Rx_1 \ldots x_r$, where R is an r-ary relation symbol and $x, y, x_1, \ldots, x_r$ are variables. A *literal* is either an atom or a negated atom. The *vocabulary* of a formula φ is the set of all relation symbols occurring in φ. A *free variable* of a formula φ is a variable that is not bound by any existential or universal quantifier of φ.

If $\mathcal{A}$ is a τ-structure, $a_1, \ldots, a_n$ are elements of the universe A of $\mathcal{A}$, and $\varphi(x_1, \ldots, x_n)$ is a formula whose vocabulary is a subset of τ and whose free variables are $x_1, \ldots, x_n$, then we write $\mathcal{A} \models \varphi(a_1, \ldots, a_n)$ to denote that $\mathcal{A}$ satisfies φ if the variables $x_1, \ldots, x_n$ are interpreted by $a_1, \ldots, a_n$, respectively. We let

$$\varphi(\mathcal{A}) := \big\{(a_1, \ldots, a_n) \in A^n \;\big|\; \mathcal{A} \models \varphi(a_1, \ldots, a_n)\big\}.$$

[1] Note that in logic, substructures are usually required to satisfy the stronger condition $R^{\mathcal{B}} = R^{\mathcal{A}} \cap A^r$, where r is the arity of R. Our notion of substructure is the direct generalization of the standard graph theoretic notion of subgraph. Since we are dealing mainly with graphs, this seems appropriate. A similar remark applies to our notion of embedding.

To get a uniform notation, we let A^0 be a one-point space and identify $\emptyset$ with FALSE and A^0 with TRUE. Then for a sentence φ (i.e., a formula without free variables), we have $\mathcal{A} \models \varphi \iff \varphi(\mathcal{A}) = \text{TRUE}$. Furthermore, if the vocabulary of the formula φ is not contained in the vocabulary of $\mathcal{A}$, then we let $\varphi(\mathcal{A}) = \emptyset$.

For every class Φ of formulas, we let $\Phi[\tau]$ be the class of all $\varphi \in \Phi$ whose vocabulary is contained in τ. We let both Σ_0 and Π_0 be the class of all quantifier-free first-order formulas (although we usually use Π_0 to denote this class). For $t \geq 1$, we let Σ_t be the class of all first-order formulas of the form $\exists x_1 \dots \exists x_k\ \psi$, where $k \in \mathbb{N}$ and $\psi \in \Pi_{t-1}$. Analogously, we let Π_t be the class of all first-order formulas of the form $\forall x_1 \dots \forall x_k\ \psi$, where $k \in \mathbb{N}$ and $\psi \in \Sigma_{t-1}$.

We have to define two additional hierarchies $(\Sigma_{t,u})_{t\geq 1}$ and $(\Pi_{t,u})_{t\geq 1}$ for every fixed $u \geq 1$. Again we let $\Sigma_{0,u} = \Pi_{0,u} = \Pi_0$. We let $\Pi_{1,u}$ be the class of all first-order formulas of the form $\forall x_1 \dots \forall x_k\ \psi$, where $k \leq u$ and $\psi \in \Pi_0$. For $t \geq 2$, we let $\Pi_{t,u}$ be the class of all first-order formulas of the form $\forall x_1 \dots \forall x_{k_1}\ \exists y_1 \dots \exists y_{k_2}\ \psi$, where $k_1, k_2 \leq u$ and $\psi \in \Pi_{t-2,u}$. For $t \geq 1$, we let $\Sigma_{t,u}$ be the class of all first-order formulas of the form $\exists x_1 \dots \exists x_k\ \psi$, where $k \in \mathbb{N}$ and $\psi \in \Pi_{t-1,u}$. Note the asymmetry in the definitions of $\Pi_{t,u}$ and $\Sigma_{t,u}$—the length of the first quantifier block in a $\Sigma_{t,u}$-formula is not restricted.

Definability of parameterized problems I: *Model-checking problems.* We can use logic to define certain generic families of parameterized problems. For a class Φ of formulas, the *model-checking problem* for Φ is the problem of deciding whether for a given structure $\mathcal{A}$ and a given formula $\varphi \in \Phi$ we have $\varphi(\mathcal{A}) \neq \emptyset$. We parameterize this problem by the length of the formula φ and obtain the *parameterized model-checking problem* p-MC(Φ).

Many parameterized problems can be naturally translated into model-checking problems. For example, the parameterized clique problem is essentially the same as the parameterized model-checking problem for the class

$$\Phi_{\text{CLIQUE}} = \left\{ \bigwedge_{1\leq i<j\leq k} (Ex_ix_j \wedge x_i \neq x_j) \;\middle|\; k \geq 1 \right\}.$$

Model-checking problems provide another basis for the W-hierarchy: For every $t \geq 1$, W[t] is the class of all problems that are reducible to p-MC($\Sigma_{t,1}[\tau]$) for some vocabulary τ by a parameterized many-one reduction [14, 15]. Observe, furthermore, that for all $t \geq 1$ the problems p-MC($\Sigma_{t,1}$) and p-MC($\Pi_{t-1,1}$) are easily reducible to each other, because for every formula

$$\varphi(x_1, \dots, x_k) = \exists y_1 \dots \exists y_l\ \psi(x_1, \dots, x_k, y_1, \dots, y_l)$$

and every structure $\mathcal{A}$ we have $\varphi(\mathcal{A}) \neq \emptyset$ if and only if $\psi(\mathcal{A}) \neq \emptyset$. This explains why the hierarchies $(\Sigma_{t,u})_{t\geq 1}$ and $(\Pi_{t,u})_{t\geq 1}$ are defined asymmetrically.

Definability of parameterized problems II: *Fagin-definability.* There is a second way of defining parameterized problems that has been dubbed *Fagin-definability* in [15]. Let φ be a sentence of vocabulary $\tau \cup \{X\}$, where X is a relation symbol not contained in τ. We view X as a *relation variable*; to illustrate this we usually write $\varphi(X)$ instead of just φ. Let r be the arity of X. For a τ-structure $\mathcal{A}$ we let

$$\varphi(\mathcal{A}) = \big\{ R \subseteq A^r \;\big|\; (\mathcal{A}, R) \models \varphi \big\},$$

where $(\mathcal{A}, R)$ denotes the $\tau \cup \{X\}$-expansion of $\mathcal{A}$ with $X^{(\mathcal{A},R)} = R$. For example, let X be unary and

$$\varphi_{\text{VC}}(X) = \forall y \forall z \big(Eyz \to (Xy \vee Xz) \big).$$

```
1  Initialize S ⊆ Pow(G) by S := {∅}
2  for all {a, b} ∈ E^G do
3      for all S ∈ S do
4          if S ∩ {a, b} = ∅ then
5              S := S \ {S}
6              if |S| < k then S := S ∪ {S ∪ {a}, S ∪ {b}}.
7  output S.
```

ALGORITHM 1

Then for a graph $\mathcal{G}$, $\varphi_{\mathrm{VC}}(\mathcal{G})$ is the set of all vertex covers of $\mathcal{G}$.

With each formula $\varphi(X)$ we associate a parameterized problem p-FD($\varphi(X)$) which asks whether for a given structure $\mathcal{A}$, the set $\varphi(\mathcal{A})$ contains a relation with k elements (where k is the parameter). We call p-FD($\varphi(X)$) the problem *Fagin-defined* by $\varphi(X)$.

For example, p-FD($\varphi_{\mathrm{VC}}(X)$) is precisely the parameterized vertex cover problem.

3. Tractable parameterized counting problems. A *parameterized counting problem* is simply a function $F : \Sigma^* \times \mathbb{N} \to \mathbb{N}$, for some alphabet Σ. Arguably, this definition includes problems that we would not intuitively call counting problems, but there is no harm in including them.

DEFINITION 3.1. *A parameterized counting problem $F : \Sigma^* \times \mathbb{N} \to \mathbb{N}$ is* fixed-parameter tractable*, or $F \in \mathrm{FPT}$, if there is an algorithm computing $F(x, k)$ in time $f(k) \cdot |x|^c$ for some computable function $f : \mathbb{N} \to \mathbb{N}$ and some constant $c \in \mathbb{N}$.*

The standard example of a fixed-parameter tractable decision problem is the parameterized version of the vertex cover problem. As a first example, we observe that the corresponding counting problem is also fixed-parameter tractable, as shown in the following example.

Example 3.2. The parameterized vertex cover counting problem

p-#VC	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the number of vertex covers of $\mathcal{G}$ of size k.

is fixed-parameter tractable.

Proof. Essentially, Algorithm 1 is the standard procedure showing that the parameterized vertex cover problem is fixed-parameter tractable. It yields, given a graph $\mathcal{G} = (G, E^{\mathcal{G}})$ as input and $k \in \mathbb{N}$ as parameter, a set $\mathcal{S}$ of subsets of cardinality $\leq k$ of G in time $O(2^k \cdot \|\mathcal{G}\|)$ such that for the set $\mathrm{VC}_k(\mathcal{G})$ of vertex covers of $\mathcal{G}$ of cardinality k we have

$$\mathrm{VC}_k(\mathcal{G}) = \{X \subseteq G \mid |X| = k \text{ and } S \subseteq X \text{ for some } S \in \mathcal{S}\}.$$

Now, we can compute $|\mathrm{VC}_k(\mathcal{G})|$ by applying the inclusion-exclusion principle to the sets

$$\{X \subseteq G \mid |X| = k \text{ and } S \subseteq X\}$$

for $S \in \mathcal{S}$. ∎

We could now go through a list of known fixed-parameter tractable problems and check if the corresponding counting problems are also fixed-parameter tractable. Fortunately, this boring task can largely be avoided, because there are a few general principles underlying most fixed-parameter tractability results. They are formulated in the terminology of descriptive complexity theory.

(1) *Problems definable in monadic second-order logic are fixed-parameter tractable when parameterized by tree-width of the structure* (Courcelle [9]). This accounts for the fixed-parameter tractability of NP-complete problems such as 3-Colorability or Hamiltonicity when parameterized by the tree-width of the input graph.

(2) *Parameterized problems that can be described as model-checking problems for first-order logic are fixed-parameter tractable on classes of structures of bounded local tree-width and classes of graphs with excluded minors* (Frick and Grohe [17], Flum and Grohe [15]). This implies that parameterized versions of problems such as dominating set, independent set, or subgraph isomorphism are fixed-parameter tractable on planar graphs or on graphs of bounded degree.

(3) *Parameterized problems that are Fagin-definable by a first-order formula $\varphi(X)$, where X does not occur in the scope of a negation symbol or existential quantifier, are fixed-parameter tractable* (Cai and Chen [7], Flum and Grohe [15]). This accounts for the fixed-parameter tractability of the standard parameterization of minimization problems in the classes MIN $\mathrm{F}^{+}\Pi_1$ [21], for example, minimum vertex cover.

(4) *Parameterized problems that can be described as parameterized model-checking problems for Σ_1-formulas of bounded tree-width are fixed-parameter tractable* (Flum and Grohe [15]). This implies, and is actually equivalent to, the results that the parameterized homomorphism problem and the parameterized embedding problem for relational structures of bounded tree-width are fixed-parameter tractable.

Let us consider the counting versions of these general "meta-theorems." It has already been proved by Arnborg, Lagergren, and Seese [4] that the counting version of (1) holds. Variants and extensions of this result have been proved by Courcelle, Makowsky, and Rotics [10] and Makowsky [22]. Frick proved that (most of) (2) also extends to counting problems [16]. We shall see below that (3) also extends to counting problems. (4) is more problematic. While the counting version of the parameterized homomorphism problem for structures of bounded tree-width is fixed-parameter tractable (actually in polynomial time), the general equivalence between homomorphism, embedding, and model-checking for Σ_1 breaks down for counting problems. This is the point where counting shows some genuinely new aspects, and in some sense, most of this paper is devoted to this phenomenon.

Let us turn to (3), the Fagin-definable problems. For a formula $\varphi(X)$, we let p-#FD($\varphi(X)$) denote the natural counting version of the problem p-FD($\varphi(X)$) Fagin-defined by $\varphi(X)$. Recalling the formula $\varphi_{\mathrm{VC}}(X)$ that Fagin-defines the parameterized vertex cover problem, we see that the following proposition generalizes Example 3.2.

Proposition 3.3. *Let $\varphi(X)$ be a first-order formula in which X does not occur in the scope of an existential quantifier or negation symbol. Then p-#FD($\varphi(X)$) $\in$ FPT.*

Proof. Let X be of arity r. As for the vertex cover problem one obtains an FPT-algorithm (cf. [15]) that, given a structure $\mathcal{A}$ and $k \in \mathbb{N}$, yields a set $\mathcal{S}$ of subsets of cardinality $\leq k$ of A^r such that

$\{X \subseteq A^r \mid |X| = k \text{ and } \mathcal{A} \models \varphi(X)\} = \{X \subseteq A^r \mid |X| = k \text{ and } S \subseteq X \text{ for some } S \in \mathcal{S}\}.$

Again, an application of the inclusion-exclusion principle allows us to compute the cardinality of the set on the right-hand side. □

This implies that the counting versions of the standard parameterizations of all minimization problems in the class MIN $\mathrm{F}^+\Pi_1$ are fixed-parameter tractable.

As we have mentioned, the situation with item (4) in the list above is more complicated. The core problem for which counting remains tractable is the homomorphism problem for graphs of bounded tree-width. Again, the algorithm showing tractability can best be illustrated by an example.

Example 3.4. The number of homomorphisms from a given colored tree $\mathcal{T}$ to a given colored graph $\mathcal{G}$ can be computed in polynomial time.

This can be done by a simple dynamic programming algorithm. Starting from the leaves, for every vertex t of the tree we compute a table that stores, for all vertices v of the graph, the number $H(t, v)$ of homomorphisms h from $\mathcal{T}_t$, the induced colored subtree rooted at t, to $\mathcal{G}$ with $h(t) = v$. Then the total number of homomorphisms from $\mathcal{T}$ to $\mathcal{G}$ is $\sum_{v \in G} H(r, v)$, where r is the root of $\mathcal{T}$.

If t is a leaf, then $H(t, v) = 1$ if t and v have the same color and $H(t, v) = 0$ otherwise. If t has children $t_1, \dots, t_l$, then if t and v have the same color we have

$$H(t, v) = \prod_{i=1}^{l} \sum_{\substack{w \in G \\ w \text{ adjacent to } v}} H(t_i, w).$$

If t and v have distinct colors, we have $H(t, v) = 0$.

The previous example can easily be generalized to structures of bounded tree-width. We just state the result, omit a definition of tree-width, and omit the proof, which is a straightforward generalization of the example.

PROPOSITION 3.5. *Let $w \geq 1$. Then the following restriction of the homomorphism problem is in polynomial time:*

Input:	Structure $\mathcal{A}$ of tree-width at most w, structure $\mathcal{B}$.
Problem:	Count the homomorphisms from $\mathcal{A}$ to $\mathcal{B}$.

For a class Φ of formulas, we let $p\text{-}\#(\Phi)$ denote the counting version of the model-checking problem $p\text{-MC}(\Phi)$ ("given $\mathcal{A}$ and $\varphi \in \Phi$, compute $|\varphi(\mathcal{A})|$, parameterized by $|\varphi|$").

With every first-order formula φ we associate a graph $\mathcal{G}_\varphi$ as follows: The vertices of $\mathcal{G}_\varphi$ are the variables of φ, and there is an edge between two vertices if they occur together in an atomic subformula of φ. The *tree-width* of a formula φ is the tree-width of $\mathcal{G}_\varphi$. For a class Φ of formulas and $w \geq 1$, we let $\Phi[\mathrm{tw}\, w]$ denote the class of all formulas in Φ of tree-width at most w. Recall that Π_0 denotes the class of all quantifier-free formulas.

PROPOSITION 3.6. *For every $w \geq 1$ we have $p\text{-}\#(\Pi_0[\mathrm{tw}\, w]) \in \mathrm{FPT}$.*

Proof. We can effectively transform every $\varphi(\bar{x}) \in \Pi_0[\mathrm{tw}\, w]$ into an equivalent $\psi(\bar{x}) \in \Pi_0[\mathrm{tw}\, w]$ in disjunctive normal form, $\psi(\bar{x}) = \psi_1(\bar{x}) \vee \cdots \vee \psi_r(\bar{x})$, where each $\psi_i(\bar{x})$ is a conjunction of literals and where $\psi_i(\bar{x}) \wedge \psi_j(\bar{x})$ is unsatisfiable for all i, j with $i \neq j$. Note that this transformation does not change the tree-width of the formula because the set of atomic subformulas remains unchanged. Then for every structure $\mathcal{A}$ we have

$$|\psi(\mathcal{A})| = |\psi_1(\mathcal{A})| + \cdots + |\psi_r(\mathcal{A})|.$$

Thus we can restrict our attention to formulas in $\Pi_0[\operatorname{tw} w]$ that are conjunctions of literals. Since every literal of a formula whose underlying graph has tree-width at most w contains at most $w+1$ variables, by standard techniques (cf. the proof of Theorem 4.4) the counting problem for such formulas can be reduced to the counting version of the homomorphism problem for structures of tree-width at most w, which is in polynomial time by Proposition 3.5. □

Remark 3.7. Note that although its core is a reduction to Proposition 3.5, the proof of the previous proposition does *not* yield a polynomial time algorithm. The reason is that the transformation of a formula to an equivalent formula in disjunctive normal form is not polynomial.

Indeed, it is easy to see that the unparameterized counting problem for quantifier-free formulas of tree-width 0 is #P-complete.

Clearly, if p-MC(Φ) is fixed-parameter tractable, then so is p-MC(Φ^*), where Φ^* is the closure of Φ under existential quantification. Thus in particular, for $w \geq 1$ the problem p-MC($\Sigma_1[\operatorname{tw} w]$) is fixed-parameter tractable. The situation is different for the counting problems: The formula

$$\varphi(x_1, \ldots, x_k) := \exists y \bigwedge_{i=1}^{k} (\neg E y x_i \wedge \neg y = x_i)$$

is a Σ_1-formula of tree-width 1. For all graphs $\mathcal{G}$, the set $\varphi(\mathcal{G})$ is the set of all tuples $(a_1, \ldots, a_k)$ of vertices of $\mathcal{G}$ such that $\{a_1, \ldots, a_k\}$ is *not* a dominating set. Thus $\mathcal{G}$ has a dominating set of size at most k if and only if $|\varphi(\mathcal{G})| < n^k$, where n is the number of vertices of $\mathcal{G}$. Since the parameterized dominating set problem is complete for the class W[2], this implies the following:

PROPOSITION 3.8. *If* W[2] $\neq$ FPT*, then* p-#($\Sigma_1[\operatorname{tw} w]$) $\notin$ FPT.

4. Classes of intractable problems.

Example 4.1. Valiant's [29] fundamental theorem states that counting the number of perfect matchings of a bipartite graph is #P-complete (whereas deciding whether a perfect matching exists is in P). We consider a *trivial parameterization* of the matching problem, which is obtained by adding a "dummy" parameter as follows:

Input:	Bipartite Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if $\mathcal{G}$ has a perfect matching.

Clearly, this problem is in polynomial time and thus fixed-parameter tractable. On the other hand, its counting version ("Count the perfect matchings of $\mathcal{G}$") cannot be fixed-parameter tractable unless P = #P. The reason for this is that the problem is already #P-complete for the fixed parameter value $k = 1$, but if it were fixed-parameter tractable it would be in polynomial time for any fixed parameter value.

Of course this example is quite artificial. We are more interested in the question of whether natural parameterized counting problems are fixed-parameter tractable. As examples of such natural problems we mention p-#CLIQUE ("Count cliques of size k in a graph, where k is the parameter"), p-#DOMINATING SET ("Count dominating sets of size k"), p-#CYCLE ("Count cycles of size k"), or, as a more natural parameterization of the matching problem, p-#MATCHING ("Count the matchings of size k in a bipartite graph"). An argument such as the one in Example 4.1 cannot be used to show that any of these problems is not fixed-parameter tractable, because for any fixed parameter value k the problems are in polynomial time.

Recall that the decision problems p-Clique and p-Dominating Set are complete for the classes W[1] and W[2], respectively, so the counting problems cannot be fixed-parameter tractable unless W[1] = FPT (W[2] = FPT, respectively). We will define classes #W[t] of counting problems and show for a few central W[1]-complete and W[2]-complete problems that their counting versions are #W[1]-complete (#W[2]-complete, respectively). More interestingly, in the next section we shall prove that p-#Cycle and a number of similar problems whose decision versions are fixed-parameter tractable are complete for #W[1].

Definition 4.2. *Let $F : \Sigma^* \times \mathbb{N} \to \mathbb{N}$ and $G : \Pi^* \times \mathbb{N} \to \mathbb{N}$ be parameterized counting problems.*

(1) *A* parameterized parsimonious reduction *from F to G is an algorithm that computes for every instance (x, k) of F an instance (y, ℓ) of G in time $f(k) \cdot |x|^c$ such that $\ell \leq g(k)$ and*

$$F(x, k) = G(y, \ell)$$

(for computable functions $f, g : \mathbb{N} \to \mathbb{N}$ and a constant $c \in \mathbb{N}$).
We write $F \leq^{\mathrm{fp}}_{\mathrm{pars}} G$ to denote that there is a parameterized parsimonious reduction from F to G.

(2) *A* parameterized T-reduction *from F to G is an algorithm with an oracle for G that solves any instance (x, k) of F in time $f(k) \cdot |x|^c$ in such a way that for all oracle queries the instances (y, ℓ) satisfy $\ell \leq g(k)$ (for computable functions $f, g : \mathbb{N} \to \mathbb{N}$ and a constant $c \in \mathbb{N}$).*
We write $F \leq^{\mathrm{fp}}_{\mathrm{T}} G$ to denote that there is a parameterized T-reduction from F to G.

Obviously, if $F \leq^{\mathrm{fp}}_{\mathrm{pars}} G$, then $F \leq^{\mathrm{fp}}_{\mathrm{T}} G$. An easy computation shows that if $G \in \mathrm{FPT}$ and $F \leq^{\mathrm{fp}}_{\mathrm{T}} G$, then $F \in \mathrm{FPT}$.

For a class Θ of propositional formulas, we let #WSat(Θ) be the counting version of the weighted satisfiability problem for Θ ("Count the weight k satisfying assignments for a formula $\theta \in \Theta$"). We define the counting analogue of the W-hierarchy in the following straightforward way:

Definition 4.3. *For $t \geq 1$, #W[t] is the class of all parameterized counting problems that are fixed-parameter parsimonious reducible to #WSat($\Gamma_{t,d}$), for some $d \geq 0$.*

The notation #W[t] may be slightly misleading when compared with the notation #P of classical complexity theory (which is not #NP), but since there is no obvious #FPT, we think that it is appropriate. Note that we write FPT to denote both the class of fixed-parameter tractable decision problems and the class of fixed-parameter tractable counting problems; the intended meaning will always be clear from the context.

4.1. #W[1]-complete problems.

Theorem 4.4. *The following problems are complete for #W[1] under parameterized parsimonious reductions:*

(1) *#WSat(2-CNF),*
(2) *p-#Clique, p-#Sub, p-#Hom, p-#Emb,*
(3) *p-#($\Pi_0[\tau]$) for every vocabulary τ that is not monadic,*
(4) *p-#Halt ("Count the k-step accepting computation paths of a nondeterministic Turing machine").*

Proof. Basically, the proof of these results amounts to checking that the many-one reductions proving the W[1]-completeness of the corresponding decision problems are

parsimonious (or can be made parsimonious by simple modifications). Some of these reductions are quite simple, and we can sketch them here. For those that are more complicated, we just give appropriate references.

A *conjunctive query* is a first-order formula of the form $\exists x_1 \dots \exists x_k(\alpha_1 \wedge \dots \wedge \alpha_\ell)$, where $\alpha_1, \dots, \alpha_\ell$ are atoms. In particular, a *quantifier-free* conjunctive query is just a conjunction of atoms. We denote the class of all conjunctive queries by CQ and the class of all quantifier-free conjunctive queries by Π_0-CQ. If Φ is a class of formulas, then Φ[binary] is the class of all formulas $\varphi \in \Phi$ whose vocabulary is at most binary.

We will first establish the following chain of reductions:

$$p\text{-}\#(\Pi_0\text{-CQ}) \leq^{\text{fp}}_{\text{pars}} p\text{-}\#\textsc{Hom} \leq^{\text{fp}}_{\text{pars}} p\text{-}\#\textsc{Emb} \leq^{\text{fp}}_{\text{pars}} p\text{-}\#(\Pi_0\text{-CQ}). \tag{4.1}$$

p-$\#(\Pi_0$-CQ$) \leq^{\text{fp}}_{\text{pars}} p$-$\#$Hom: With every formula $\varphi(x_1, \dots, x_k) \in \Pi_0$-CQ of vocabulary τ we associate a $\tau \cup \{\text{EQ}\}$-structure $\mathcal{A}_\varphi$, where EQ is a binary relation symbol not contained in τ. The universe of $\mathcal{A}_\varphi$ is $\{x_1, \dots, x_k\}$, the set of variables of φ. For $R \in \tau$, say, r-ary, $R^{\mathcal{A}_\varphi}$ is the set of all tuples $(x_{i_1}, \dots, x_{i_r})$ such that $Rx_{i_1} \dots x_{i_r}$ is an atom of φ. Moreover, $\text{EQ}^{\mathcal{A}_\varphi}$ is the set of all pairs (x_{i_1}, x_{i_2}) such that $x_{i_1} = x_{i_2}$ is an atom of φ. Note that $\|\mathcal{A}_\varphi\| \in O(|\varphi|)$.

For a τ-structure $\mathcal{B}$ we let $\mathcal{B}_{\text{EQ}}$ be the $\tau \cup \{\text{EQ}\}$-expansion of $\mathcal{B}$ in which EQ is interpreted by the equality relation on B. Then it is easy to see that for all $(b_1, \dots, b_k) \in B^k$ we have $(b_1, \dots, b_k) \in \varphi(\mathcal{B})$ if and only if the mapping $x_i \mapsto b_i$, for $1 \leq i \leq k$, is a homomorphism from $\mathcal{A}_\varphi$ to $\mathcal{B}$. This yields a parsimonious reduction from p-$\#(\Pi_0$-CQ$)$ to p-$\#$Hom.

p-$\#$Hom $\leq^{\text{fp}}_{\text{pars}} p$-$\#$Emb: Suppose we have structures $\mathcal{A}$ and $\mathcal{B}$ and want to count the homomorphisms from $\mathcal{A}$ to $\mathcal{B}$. Let τ be the vocabulary of $\mathcal{A}$ and $\mathcal{B}$ and $\tau^* = \tau \cup \{P_a \mid a \in A\}$, where for every $a \in A$, P_a is a new unary relation symbol that is not contained in τ. Let $\mathcal{A}^*$ be the τ^*-expansion of $\mathcal{A}$ with $P_a = \{a\}$ for $a \in A$. We can view $\mathcal{A}^*$ as the expansion of $\mathcal{A}$ where each element gets its individual color. We let $\mathcal{B}^*$ be the following τ^*-structure: The universe of $\mathcal{B}^*$ is $A \times B$. For r-ary $R \in \tau$ and $(a_1, b_1), \dots, (a_r, b_r) \in A \times B$ we let $\big((a_1, b_1), \dots, (a_r, b_r)\big) \in R^{\mathcal{B}^*}$ if and only if $(b_1, \dots, b_r) \in R^{\mathcal{B}}$. For $a \in A$ let $P_a^{\mathcal{B}^*} = \{a\} \times B$. For a homomorphism $h : \mathcal{A} \to \mathcal{B}$ we let $h^* : A^* \to B^*$ be the mapping defined by $h^*(a) = (a, h(a))$. It is easy to see that the mapping $h \mapsto h^*$ is a bijection between the homomorphisms from $\mathcal{A}$ to $\mathcal{B}$ and the embeddings from $\mathcal{A}^*$ to $\mathcal{B}^*$.

p-$\#$Emb $\leq^{\text{fp}}_{\text{pars}} p$-$\#(\Pi_0$-CQ$)$: For every τ-structure $\mathcal{A}$ we define a formula $\varphi_{\mathcal{A}} \in \Pi_0$-CQ of vocabulary $\tau \cup \{\text{NEQ}\}$, where NEQ is a new binary relation symbol. Suppose that $\mathcal{A} = \{a_1, \dots, a_k\}$. The formula $\varphi_{\mathcal{A}}$ has variables $x_1, \dots, x_k$. For every r-ary $R \in \tau$ and every tuple $(a_{i_1}, \dots, a_{i_r}) \in R^{\mathcal{A}}$, $\varphi_{\mathcal{A}}$ contains the atom $Rx_{i_1} \dots x_{i_r}$. In addition, $\varphi_{\mathcal{A}}$ contains the atoms $\text{NEQ}x_i x_j$ for $1 \leq i < j \leq k$.

For a τ-structure $\mathcal{B}$ we let $\mathcal{B}_{\text{NEQ}}$ be the $\tau \cup \{\text{NEQ}\}$-expansion of $\mathcal{B}$ in which NEQ is interpreted by the inequality relation on B. Then it is easy to see that for all mappings $h : A \to B$ we have that h is an embedding of $\mathcal{A}$ into $\mathcal{B}$ if and only if $\big(h(a_1), \dots, h(a_k)\big) \in \varphi_{\mathcal{A}}(\mathcal{B})$.

Next, we establish the following chain of reductions (for every $d \geq 1$):

$$\begin{aligned} \#\text{WSat}(\Gamma_{1,d}) &\leq^{\text{fp}}_{\text{pars}} p\text{-}\#(\Pi_0\text{-CQ}) \leq^{\text{fp}}_{\text{pars}} p\text{-}\#(\Pi_0\text{-CQ[binary]}) \\ &\leq^{\text{fp}}_{\text{pars}} p\text{-}\#\textsc{Clique} \leq^{\text{fp}}_{\text{pars}} \#\text{WSat(2-CNF)} \leq^{\text{fp}}_{\text{pars}} \#\text{WSat}(\Gamma_{1,1}). \end{aligned} \tag{4.2}$$

Together with (4.1), this proves the #W[1]-completeness of all problems listed in (1) and (2) except p-$\#$Sub.

$\#\mathrm{WSAT}(\Gamma_{1,d}) \leq^{\mathrm{fp}}_{\mathrm{pars}} p\text{-}\#(\Pi_0\text{-CQ})$: The proof of Lemma 21 in [19] showing that $\mathrm{WSAT}(\Gamma_{1,d})$ is fixed-parameter many-one reducible to p-MC(CQ) yields a parsimonious reduction from $\#\mathrm{WSAT}(\Gamma_{1,d})$ to $p\text{-}\#(\Pi_0\text{-CQ})$.

$p\text{-}\#(\Pi_0\text{-CQ}) \leq^{\mathrm{fp}}_{\mathrm{pars}} p\text{-}\#(\Pi_0\text{-CQ[binary]})$: The proof of Lemma 17 in [19] showing that p-MC(CQ) is fixed-parameter many-one reducible to p-MC(CQ[binary]) yields the claimed parsimonious reduction. Here and in later proofs we use (variants of) the following observation: Let $\varphi(\bar{x})$ and $\psi(\bar{x},\bar{y})$ be formulas and $\mathcal{A}$ a structure. If for all tuples $\bar{a} \in A$ we have

$$\mathcal{A} \models \varphi(\bar{a}) \iff \mathcal{A} \models \exists \bar{y} \psi(\bar{a},\bar{y}),$$

and for all tuples $\bar{a} \in A$ there exists at most one tuple $\bar{b} \in A$ such that $\mathcal{A} \models \psi(\bar{a},\bar{b})$, then $|\varphi(\mathcal{A})| = |\psi(\mathcal{A})|$.

$p\text{-}\#(\Pi_0\text{-CQ[binary]}) \leq^{\mathrm{fp}}_{\mathrm{pars}} p\text{-}\#\mathrm{CLIQUE}$: The reduction in Proposition 22 of [19] is parsimonious.

$p\text{-}\#\mathrm{CLIQUE} \leq^{\mathrm{fp}}_{\mathrm{pars}} \#\mathrm{WSAT}(\text{2-CNF})$: Let $\mathcal{G}$ be a graph. For every $a \in G$ let X_a be a propositional variable. Set

$$\alpha_{\mathcal{G}} = \bigwedge_{a,b \in G,\, a \neq b,\, (a,b) \notin E^{\mathcal{G}}} (\neg X_a \vee \neg X_b) \;\wedge\; \bigwedge_{a \in G} (X_a \vee \neg X_a).$$

Then $\alpha_{\mathcal{G}}$ is (equivalent to) a formula in 2-CNF. The second part of the formula ensures that every variable X_a with $a \in G$ occurs in $\alpha_{\mathcal{G}}$. The number of cliques of size k is just the number of assignments of weight k satisfying $\alpha_{\mathcal{G}}$.

$\#\mathrm{WSAT}(\text{2-CNF}) \leq^{\mathrm{fp}}_{\mathrm{pars}} \#\mathrm{WSAT}(\Gamma_{1,1})$: 2-CNF is a subset of $\Gamma_{1,1}$, so the reduction is trivial.

This completes the proof of (4.2). We next show (3). Let τ be a vocabulary that is not monadic. We leave it to the reader to show that $p\text{-}\#\mathrm{CLIQUE} \leq^{\mathrm{fp}}_{\mathrm{pars}} p\text{-}\#(\Pi_0[\tau])$.

$p\text{-}\#(\Pi_0[\tau]) \leq^{\mathrm{fp}}_{\mathrm{pars}} p\text{-}\#(\Pi_0\text{-CQ})$: Let $\mathcal{A}$ be a τ-structure and $\varphi \in \Pi_0[\tau]$. We can assume that $\varphi = \varphi_1 \vee \cdots \vee \varphi_m$, where each φ_i is a conjunction of literals and $\varphi_i \wedge \varphi_j$ is unsatisfiable for all $i \neq j$. Let $\tau' := \tau \cup \{\bar{R} \mid R \in \tau\} \cup \{\mathrm{EQ}, \mathrm{NEQ}\}$, where for all $R \in \tau$ the symbol $\bar{R}$ is a new relation symbol of the same arity as R and $\mathrm{EQ}, \mathrm{NEQ}$ are new binary relation symbols. Let $\mathcal{A}'$ be the τ'-expansion of $\mathcal{A}$ in which $\bar{R}$ is interpreted as the complement of $R^{\mathcal{A}}$ and EQ and NEQ are interpreted as equality and inequality, respectively. Since the vocabulary is fixed, $\mathcal{A}'$ can be computed from $\mathcal{A}$ in polynomial time. If n is the size of the universe of $\mathcal{A}$, then computing the relations $\mathrm{EQ}^{\mathcal{A}'}$ and $\mathrm{NEQ}^{\mathcal{A}'}$ requires quadratic time, and for an r-ary $R \in \tau$, computing $\bar{R}^{\mathcal{A}'} = A^r \setminus R^{\mathcal{A}}$ requires time $O(n^r)$.

Let φ' be the formula obtained by replacing positive literals of the form $x = y$ by $\mathrm{EQ}xy$ and by replacing negative literals by positive ones in the obvious way using the new relation symbols $\bar{R}$ and NEQ. Then $\varphi' = \varphi'_1 \vee \cdots \vee \varphi'_m$, where each φ'_i is a conjunction of atoms (i.e., positive literals). Note that $\varphi(\mathcal{A}) = \varphi'(\mathcal{A}')$ and

(4.3) for $\bar{a} \in \mathcal{A}'$ there is at most one i with $\mathcal{A}' \models \varphi'_i(\bar{a})$.

Finally we want to get rid of the disjunctions in φ'. For this purpose we introduce a structure $\mathcal{A}''$ essentially consisting of m copies of $\mathcal{A}'$, the ith one taking care of φ'_i. More precisely, let $\tau'' := \{\hat{R} \mid R \in \tau'\} \cup \{<, T\}$, where $\mathrm{arity}(\hat{R}) = \mathrm{arity}(R) + 1$ and where $<$ and T are binary. Define the τ''-structure $\mathcal{A}''$ by

$$
\begin{aligned}
A'' &:= \{1,\dots,m\} \cup (\{1,\dots,m\} \times A),\\
<^{\mathcal{A}''} &:= \text{the natural ordering on } \{1,\dots,m\},\\
T^{\mathcal{A}''} &:= \{((i,a),(i,b)) \mid 1 \le i \le m,\ a,b \in A\},\\
\hat{R}^{\mathcal{A}''} &:= \{(i,(i,a_1),\dots,(i,a_{\mathrm{arity}(R)})) \mid 1 \le i \le m,\ R^{\mathcal{A}'}a_1\dots a_{\mathrm{arity}(R)}\}\\
&\quad \cup \{(i,(j,a_1),\dots,(j,a_{\mathrm{arity}(R)})) \mid 1 \le i,j \le m,\ i \ne j,\ a_1,\dots,a_{\mathrm{arity}(R)} \in A\}.
\end{aligned}
$$

Moreover, set

$$
\varphi''(x_1,\dots,x_k,y_1,\dots,y_m) := y_1 < \dots < y_m \wedge \bigwedge_{1\le \ell \le \ell' \le k} Tx_\ell x_{\ell'} \wedge \bigwedge_{i=1}^{m} \varphi_i'^{\frac{\hat{R}y_i\bar{z}}{R\bar{z}}},
$$

where $\varphi_i'^{\frac{\hat{R}y_i\bar{z}}{R\bar{z}}}$ is obtained from φ_i' by replacing, for all $R \in \tau'$, atomic subformulas of the form $R\bar{z}$ by $\hat{R}y_i\bar{z}$. Clearly, $\varphi(\bar{x},\bar{y}) \in \Pi_0$-CQ. By (4.3), we have $|\varphi(\mathcal{A})| = |\varphi''(\mathcal{A}'')|$.

Next, we prove the #W[1]-completeness of p-#Sub. We observe that the number of substructures of a structure $\mathcal{B}$ that are isomorphic to a structure $\mathcal{A}$ equals the number of embeddings of $\mathcal{A}$ into $\mathcal{B}$ divided by the number of automorphisms of $\mathcal{A}$. Unfortunately, this does not immediately yield a parsimonious reduction from p-#Sub to p-#Emb or vice versa. However, p-#Clique is a restriction of p-#Sub; thus we have p-#Clique $\le^{\mathrm{fp}}_{\mathrm{pars}}$ p-#Sub.

To prove that p-#Sub is in #W[1], we reduce p-#Sub to p-#Emb. Let $\mathcal{A},\mathcal{B}$ be τ-structures and let $<$ be a binary relation symbol not contained in τ. Let us call a $\tau \cup \{<\}$-structure $\mathcal{C}$, in which $<^{\mathcal{C}}$ is a linear order of the universe, an *ordered* $\tau \cup \{<\}$-*structure*. Let $\mathcal{A}_1,\dots,\mathcal{A}_m$ be a list of expansions of $\mathcal{A}$ to ordered $\tau \cup \{<\}$-structures such that

(i) for $1 \le i < j \le m$, the structures $\mathcal{A}_i$ and $\mathcal{A}_j$ are not isomorphic,
(ii) every expansion $\mathcal{A}'$ of $\mathcal{A}$ to an ordered $\tau \cup \{<\}$-structure is isomorphic to an $\mathcal{A}_i$ for some i, $1 \le i \le m$.

Thus $\mathcal{A}_1,\dots,\mathcal{A}_m$ is a list of all ordered expansions of $\mathcal{A}$, where each isomorphism type is listed only once.

Let $\mathcal{B}_<$ be an arbitrary expansion of $\mathcal{B}$ to an ordered $\tau \cup \{<\}$-structure. Then

$$
\Big|\{\mathcal{A}' \subseteq \mathcal{B} \mid \mathcal{A}' \cong \mathcal{A}\}\Big| = \sum_{i=1}^{m} \Big|\{\mathcal{A}' \subseteq \mathcal{B}_< \mid \mathcal{A}' \cong \mathcal{A}_i\}\Big|.
$$

Moreover, for each i the number of substructures of $\mathcal{B}_<$ isomorphic to $\mathcal{A}_i$ is equal to the number of embeddings of $\mathcal{A}_i$ into $\mathcal{B}_<$.

Let $\prec$ be another binary relation symbol not contained in $\tau \cup \{<\}$ and let $\tau^* = \tau \cup \{<,\prec\}$. Let $\mathcal{A}^*$ be the τ^*-structure obtained by taking the disjoint union of $\mathcal{A}_1,\dots,\mathcal{A}_m$ and defining $\prec^{\mathcal{A}}$ such that for all $a_i \in A_i$, $a_j \in A_j$ we have $a_i \prec^{\mathcal{A}^*} a_j$ if and only if $i < j$. For $1 \le i \le m$, let $\mathcal{B}_i^*$ be the τ^*-structure obtained by replacing the copy of $\mathcal{A}_i$ in $\mathcal{A}^*$ by a copy of $\mathcal{B}_<$. Then the number of embeddings of $\mathcal{A}^*$ into $\mathcal{B}_i^*$ is equal to the number of embeddings of $\mathcal{A}_i$ into $\mathcal{B}_<$. Finally let $\mathcal{B}^*$ be the disjoint union of $\mathcal{B}_1^*,\dots,\mathcal{B}_m^*$. Then the number of embeddings of $\mathcal{A}^*$ into $\mathcal{B}^*$ is equal to the sum of the numbers of embeddings of $\mathcal{A}^*$ into $\mathcal{B}_i^*$ for $1 \le i \le m$. Putting everything together, the number of substructures of $\mathcal{B}$ isomorphic to $\mathcal{A}$ is equal to the number of embeddings of $\mathcal{A}^*$ into $\mathcal{B}^*$.

It remains to prove #W[1]-completeness of p-#Halt. The proof of Theorem 8.3 in [15] implicitly contains parsimonious reductions from p-#(Π_0-CQ[binary]) to p-#Halt and from p-#Halt to p-#(Π_0-CQ). □

The decision versions of all problems mentioned in Theorem 4.4 are W[1]-complete under parameterized many-one reductions. The following theorem is interesting because it is not known whether the decision problem p-MC(Π_0) is contained in the closure of W[1] under parameterized T-reductions.

THEOREM 4.5. *p-#(Π_0) is contained in the closure of #W[1] under parameterized T-reductions.*

Proof. We shall prove that p-#(Π_0) $\leq_{\mathrm{T}}^{\mathrm{fp}}$ p-#(Π_0-CQ).

Note that the reduction from p-#($\Pi_0[\tau]$) to p-#(Π_0-CQ) we gave in the proof of Theorem 4.4 does not yield a parameterized parsimonious reduction from p-#(Π_0) to p-#(Π_0-CQ), because if the vocabulary is not fixed in advance the structure $\mathcal{A}'$ can get much larger than $\mathcal{A}$.

At least, the same argument as given in the proof of Theorem 4.4 shows that we can restrict our attention to conjunctions of literals (instead of arbitrary quantifier-free formulas). Consider a formula

$$\varphi = \alpha_1 \wedge \cdots \wedge \alpha_\ell \wedge \neg\beta_1 \wedge \cdots \wedge \neg\beta_m,$$

where $\alpha_1, \ldots, \alpha_\ell, \beta_1, \ldots, \beta_m$ are atoms. The crucial observation is that for any structure $\mathcal{A}$ we have

$$\begin{aligned} |\varphi(\mathcal{A})| = {} & \big|(\alpha_1 \wedge \cdots \wedge \alpha_\ell \wedge \neg\beta_1 \wedge \cdots \wedge \neg\beta_{m-1})(\mathcal{A})\big| \\ & - \big|(\alpha_1 \wedge \cdots \wedge \alpha_\ell \wedge \neg\beta_1 \wedge \cdots \wedge \neg\beta_{m-1} \wedge \beta_m)(\mathcal{A})\big|. \end{aligned}$$

Note that the two formulas on the left-hand side of the equality have fewer negated atoms than φ. We can now recursively reduce the number of negated atoms in these two formulas using the same trick until we end up with a family of quantifier-free conjunctive queries. This gives us a parameterized Turing reduction from p-#(Π_0) to p-#(Π_0-CQ). □

4.2. A machine characterization of #W[1]. As it is also the case for many other parameterized complexity classes, the definition of the classes #W[t] is a bit unsatisfactory because all the classes are defined only as the closure of a certain problem under a certain type of reduction. In particular, one may ask why we chose parsimonious reductions and not, say, Turing reductions. Indeed, McCartin [23] defined her version of the classes #W[t] using a different form of reductions, and that makes the theory seem a bit arbitrary. Compare this with the situation for the class #P, which has a natural machine characterization: A classical counting problem $F : \Sigma^* \to \mathbb{N}$ is in #P if and only if there is a polynomial time nondeterministic Turing machine N such that for every instance x of the problem, $F(x)$ is the number of accepting paths of N on input x.

Recently, a machine characterization of the class W[1] was given [8]. In this subsection, we adapt this characterization to give a characterization of #W[1] along the lines of the above mentioned characterization of #P.

The machine model we use, which has been introduced in [8], is based on the standard random access machines (RAMs) described in [25]. The arithmetic operations are addition, subtraction, and division by 2 (rounded off), and we use a uniform cost measure. The model is nonstandard when it comes to nondeterminism. A *nondeterministic RAM* is a RAM with an additional instruction "GUESS i j" whose semantics is "guess a natural number less than or equal to the number stored in register i and store it in register j." Acceptance of an input by a nondeterministic RAM program is defined as usually for nondeterministic machines. Steps of a computation of a

nondeterministic RAM that execute a GUESS instruction are called *nondeterministic steps*.

Following [8], we call a nondeterministic RAM program $\mathbb{P}$ a W-*program*, if there is a computable function f and a polynomial p such that for every input (x,k) with $|x| = n$ the program $\mathbb{P}$ on every run

(1) performs at most $f(k) \cdot p(n)$ steps;
(2) performs at most $f(k)$ nondeterministic steps;
(3) uses at most the first $f(k) \cdot p(n)$ registers;
(4) contains numbers $\leq f(k) \cdot p(n)$ in all registers at any time.

We call a W-program $\mathbb{P}$ a W[1]-*program* if there is a computable function h such that for every input (x,k), for every run of $\mathbb{P}$

(5) all nondeterministic steps are among the last $h(k)$ steps.

THEOREM 4.6 (Chen, Flum, and Grohe [8]). *Let $Q \subseteq \Sigma^* \times \mathbb{N}$ be a parameterized decision problem. Then $Q \in$ W[1] if and only if there is a* W[1]*-program deciding Q.*

The main result of this section is a counting version of Theorem 4.6.

THEOREM 4.7. *Let $F : \Sigma^* \times \mathbb{N} \to \mathbb{N}$ be a parameterized counting problem. Then $F \in \#$W[1] if and only if there is a* W[1]*-program $\mathbb{P}$ such that, for all $(x,k) \in \Sigma^* \times \mathbb{N}$, $F(x,k)$ is the number of accepting paths of $\mathbb{P}$ on input (x,k).*

Proof. First assume that $F \in \#$W[1]. Then, by Theorem 4.4, there is a parsimonious reduction from F to p-#HALT. Hence, there are computable functions f, g, a polynomial p, and an algorithm assigning to every instance (x,k) of F, in time $\leq f(k) \cdot p(n)$, a nondeterministic Turing machine $M = M_{x,k}$ and a natural number $k' = k'(x,k) \leq g(k)$ such that $F(x,k)$ is the number of accepting paths of M of length k'.

We can assume that the states and the symbols of the alphabet of M are natural numbers $\leq f(k) \cdot p(n)$. We define a W-program $\mathbb{P}$ that on input $(x,k) \in \Sigma^* \times \mathbb{N}$ proceeds as follows:

1. It computes M and k';
2. It guesses a sequence of k' configurations of M;
3. It verifies that the sequence of guessed configurations forms an accepting computation of M.

We can do this, in particular line 1, with a W-program using our parameterized parsimonious reduction from F to p-#HALT. Moreover, the number of steps needed by lines 2 and 3 is bounded by $h(k)$ for a suitable computable function h. Finally, the number of accepting paths of $\mathbb{P}$ is exactly the number of accepting paths of M.

Assume now that we have a W[1]-program $\mathbb{P}$ such that for all $(x,k) \in \Sigma^* \times \mathbb{N}$, $F(x,k)$ is the number of accepting paths of $\mathbb{P}$ on input (x,k). Let f, p, h witness that $\mathbb{P}$ is a W[1]-program. For every instance $(x,k) \in \Sigma^* \times \mathbb{N}$ of F we shall define a nondeterministic Turing machine $M = M_{x,k}$ and an integer k' such that $F(x,k)$ is the number of accepting paths of M of length at most k'. Of course we have to do this in such a way that the mapping $(x,k) \mapsto (M,k')$ is a parameterized reduction.

So let $(x,k) \in \Sigma^* \times \mathbb{N}$ and $n = |x|$. The alphabet of $M = M_{x,k}$ contains $0, 1, \ldots, f(k) \cdot p(n)$. Thus alphabet symbols can be used to represent register content and register addresses of all runs of $\mathbb{P}$ on input (x,k). In addition, the alphabet contains a few control symbols. The transition function of M will be defined in such a way that M simulates the computation of $\mathbb{P}$ on input (x,k) *from the first nondeterministic step onwards*. The content of all the registers before the first nondeterministic step is hardwired into M. The changes of the register contents during the at most $h(k)$ nondeterministic steps are written on the worktape, so eventually the worktape contains pairs $(i_1, a_1), \ldots, (i_\ell, a_\ell)$ in any order, where (i_j, a_j) indicates

that the current content of register i_j is a_j, and $\ell \leq h(k)$. For more details on the definition of M we refer the reader to [8]. □

4.3. #W[1] and counting satisfying assignments of a 3-CNF-formula. The following theorem gives further evidence that #W[1] ≠ FPT, because it seems unlikely that counting the satisfying assignments of a 3-CNF-formula with n variables is possible in time $2^{o(n)}$. A decision version of this theorem has been proved by Abrahamson, Downey, and Fellows [1].

THEOREM 4.8. *If* #W[1] = FPT*, then there is an algorithm counting the satisfying assignments of a* 3-CNF*-formula with n variables in time $2^{o(n)}$.*

Proof. Suppose that #W[1] = FPT. Then #WSAT(3-CNF) is in FPT. Thus there is an algorithm solving #WSAT(3-CNF) in time $f(k) \cdot n^c$ for some computable function $f : \mathbb{N} \to \mathbb{N}$ and constant c. Then there exists a function $g : \mathbb{N} \to \mathbb{N}$ such that

(i) $f(g(n)) \leq 2^{o(n)}$,
(ii) $\lim_{n\to\infty} g(n) = \infty$,
(iii) $g(n)$ can be computed in time $2^{o(n)}$.

Let $\gamma = \bigwedge_{i=1}^{m} \delta_i$, where each clause δ_i is a disjunction of at most three literals, be a formula in 3-CNF, and let $\mathcal{X} = \{X_1, \ldots, X_n\}$ be the set of variables of γ. We assume that no clause appears twice; thus we have $m \leq (2n)^3$. We want to compute the number of satisfying assignments of γ in time $2^{o(n)}$.

Let $k = g(n)$. Note that (ii) implies $n/k \leq o(n)$; we will use this repeatedly in the following argument. For $1 \leq j \leq k$, let

$$\mathcal{X}_j = \Big\{ X_i \;\Big|\; (j-1) \cdot \frac{n}{k} < i \leq j \cdot \frac{n}{k} \Big\}.$$

For every $S \subseteq \mathcal{X}_j$, let Y_j^S be a new variable. Let $\mathcal{Y}_j$ be the set of all Y_j^S and $\mathcal{Y} = \bigcup_{j=1}^{k} \mathcal{Y}_j$. Then

$$|\mathcal{Y}| \leq k \cdot 2^{\lceil n/k \rceil} \leq 2^{o(n)}.$$

Call a truth value assignment to the variables in $\mathcal{Y}$ *good* if for $1 \leq j \leq k$ exactly one variable in $\mathcal{Y}_j$ is set to TRUE. There is a bijection I between the truth value assignments to the variables in $\mathcal{X}$ and the good truth value assignments to the variables in $\mathcal{Y}$ defined by

$$I(A)(Y_j^S) = \text{TRUE} \iff \forall X \in \mathcal{X}_j : \big(A(X) = \text{TRUE} \iff X \in S\big),$$

for all $A : \mathcal{X} \to \{\text{TRUE}, \text{FALSE}\}$, $1 \leq j \leq k$, and $S \subseteq \mathcal{X}_j$. Let

$$\beta = \bigwedge_{\substack{1 \leq j \leq k \\ S,T \subseteq \mathcal{X}_j,\, S \neq T}} (\neg Y_j^S \vee \neg Y_j^T)$$

and note that $|\beta| \leq k \cdot \big(2^{\lceil n/k \rceil}\big)^2 \leq 2^{o(n)}$. Observe that the weight k assignments to the variables in $\mathcal{Y}$ satisfying β are precisely the good assignments. Thus there is a bijection between the weight k satisfying assignments for β and the assignments to the variables in $\mathcal{X}$.

For $1 \leq j \leq k$ and every variable $X \in \mathcal{X}_j$, let

$$\alpha_X = \bigwedge_{S \subseteq \mathcal{X}_j,\, X \notin S} \neg Y_j^S,$$

$$\alpha_{\neg X} = \bigwedge_{S \subseteq \mathcal{X}_j,\, X \in S} \neg Y_j^S$$

and observe that for every assignment $A : \mathcal{X} \to \{\text{TRUE}, \text{FALSE}\}$ we have

$$\begin{aligned} A(X) = \text{TRUE} &\iff I(A) \text{ satisfies } \alpha_X \\ &\iff I(A) \text{ does not satisfy } \alpha_{\neg X}. \end{aligned}$$

Let γ' be the formula obtained from γ by replacing each literal X by the formula α_X and each literal $\neg X$ by $\alpha_{\neg X}$. Then for every assignment $A : \mathcal{X} \to \{\text{TRUE}, \text{FALSE}\}$ we have

$$A \text{ satisfies } \gamma \iff I(A) \text{ satisfies } \gamma'.$$

By applying de Morgan's rule to each clause δ_j of γ (or rather to the disjunction of conjunctions δ_j has become in γ') we can turn γ' into an equivalent conjunction of at most

$$m \cdot \left(2^{\lceil n/k \rceil}\right)^3$$

disjunctions of at most three literals each. Let γ'' be this 3-CNF-formula and let $\gamma^* = \beta \wedge \gamma''$. Then I is a bijection between the satisfying assignments of γ and the weight k satisfying assignments of γ^*.

By our initial assumption, we can compute the number of weight k satisfying assignments of γ^* in time $f(k) \cdot (n^*)^c$, where $n^* = |\mathcal{Y}| \leq 2^{o(n)}$ is the number of variables of γ^*. Since $f(k) = f(g(n)) \leq 2^{o(n)}$, this shows that we can compute the number of satisfying assignments of γ in time $2^{o(n)}$. □

4.4. #W[2]-complete problems.

THEOREM 4.9. *The following problems are complete for* #W[2] *under parameterized parsimonious reductions:*

(1) #WSAT(CNF),

(2) *p*-#DOMINATING SET,

(3) *p*-#($\Pi_{1,1}[\tau]$) *for every vocabulary* τ *that is not monadic.*

The equivalence between (1) and (3) in Theorem 4.9 can be lifted to the other classes of the #W-hierarchy, but we deal only with #W[2] here.

Proof of Theorem 4.9. Let $\Pi_{1,1}[s]$ denote the class of all formulas in $\Pi_{1,1}$ whose vocabulary is at most s-ary. We will establish the following chain of reductions for every $d \geq 0$ and $s \geq 2$:

$$\#\text{WSAT}(\Gamma_{2,d}) \leq^{\text{fp}}_{\text{pars}} p\text{-}\#(\Pi_{1,1}[s]) \leq^{\text{fp}}_{\text{pars}} p\text{-}\#\text{DOMINATING SET} \leq^{\text{fp}}_{\text{pars}} \#\text{WSAT(CNF)}.$$

Recalling that CNF $\subseteq \Gamma_{2,0}$ and observing that p-#DOMINATING SET $\leq^{\text{fp}}_{\text{pars}}$ p-#($\Pi_{1,1}[\tau]$) for every vocabulary τ that is not monadic, we see that this proves the theorem.

#WSAT($\Gamma_{2,d}$) $\leq^{\text{fp}}_{\text{pars}}$ p-#($\Pi_{1,1}[2]$): By standard means one can show that there is a d' depending only on d such that every formula in $\Gamma_{2,d}$ is equivalent to a formula of the form

$$\alpha = \bigwedge_{i \in I} \delta_i,$$

where for some $d_\alpha \leq d'$ every δ_i is a disjunction of conjunctions of exactly d_α literals,

$$\delta_i = \bigvee_{j \in J^i} \beta_{ij}$$

with

$$\beta_{ij} = \lambda_{ij1} \wedge \cdots \wedge \lambda_{ijd_\alpha}. \tag{4.4}$$

So let such an α, say, with variables $X_1, \dots, X_n$, and a $k \in \mathbb{N}$ be given. If we have an assignment of weight k setting $X_{i_1}, \dots, X_{i_k}$ with $i_1 < \cdots < i_k$ TRUE and satisfying β_{ij} as in (4.4), then the positive literals in β_{ij} must be among $X_{i_1}, \dots, X_{i_k}$. Thus for every negative literal $\neg X_r$ in β_{ij} we must have $r < i_1$ or $i_k < r$ or $i_s < r < i_{s+1}$ for some s. We use this fact in our reduction appropriately.

For $m \in \mathbb{N}$ set $[m] := \{1, \dots, m\}$ and

$$[m]_2 := \{(i,j) \mid 0 \le i < j \le m+1\}.$$

For a set M and $m \in \mathbb{N}$ denote by $\mathrm{Pow}_{\le m}(M) := \{Y \subseteq M \mid |Y| \le m\}$ the set of subsets of M of cardinality $\le m$.

We let $\tau = \{<, \prec, E, \mathrm{FIRST}, \mathrm{LAST}, F, \mathrm{DISJ}, \mathrm{SAT}\}$ with binary $<, \prec, E, F, \mathrm{SAT}$ and unary FIRST, LAST, DISJ. Let $\mathcal{A}_\alpha$ be the following τ-structure: The universe is

$$A_\alpha := [n] \cup [n]_2 \cup \mathrm{Pow}_{\le d_\alpha}([n] \cup [n]_2) \cup \{\delta_i \mid i \in I\}.$$

Recall that I is the index set of the conjunction in the formula α. The selection of $i \in [n]$ means that the variable X_i gets the value TRUE and the selection of $(i,j) \in [n]_2$ means that all variables X_ℓ with $i < \ell < j$ get the truth value FALSE.

The relations of $\mathcal{A}_\alpha$ are specified by

$$\begin{aligned}
<^{\mathcal{A}_\alpha} &:= \text{the natural ordering on } [n];\\
\prec^{\mathcal{A}_\alpha} &:= \text{a total (“lexicographic”) ordering on } \mathrm{Pow}_{\le d_\alpha}([n] \cup [n]_2);\\
E^{\mathcal{A}_\alpha} &:= \{(j,(i,j)) \mid 0 \le i < j \le n+1\} \cup \{(i,(i,j)) \mid 0 \le i < j \le n+1\};\\
\mathrm{FIRST}^{\mathcal{A}_\alpha} &:= \{(0,j) \mid 0 \le j \le n+1\};\\
\mathrm{LAST}^{\mathcal{A}_\alpha} &:= \{(i,n+1) \mid 0 \le i \le n+1\};\\
F^{\mathcal{A}_\alpha} &:= \{(i,M) \mid i \in [n],\ M \in \mathrm{Pow}_{\le d_\alpha}([n] \cup [n]_2),\ i \in M\}\\
&\quad \cup \{((i,j),M) \mid (i,j) \in [n]_2,\ M \in \mathrm{Pow}_{\le d_\alpha}([n] \cup [n]_2),\ (i,j) \in M\};\\
\mathrm{DISJ}^{\mathcal{A}_\alpha} &:= \{\delta_i \mid i \in I\};\\
\mathrm{SAT}^{\mathcal{A}_\alpha} &:= \{(M,\delta_i) \mid M \in \mathrm{Pow}_{\le d_\alpha}([n] \cup [n]_2),\ i \in I,\\
&\qquad \text{there is a } j \in J^i \text{ such that for } s = 1, \dots, n,\\
&\qquad\quad \text{if } X_s \text{ is a literal of } \beta_{ij}, \text{ then } s \in M \text{ and}\\
&\qquad\quad \text{if } \neg X_s \text{ is a literal of } \beta_{ij}, \text{ then there is } (\ell,m) \in M \text{ with } \ell < s < m\}.
\end{aligned}$$

Let $r := |\mathrm{Pow}_{\le d_\alpha}([2 \cdot k+1])|$. Note that $\|\mathcal{A}_\alpha\| \le \|\mathcal{A}\|^c$, where $c = c(d)$, and $r \le g(d,k)$ for some computable function g.

The number of satisfying assignments of α of weight k is $|\varphi_{\alpha,k}(\mathcal{A}_\alpha)|$, where $\varphi_{\alpha,k}(x_1, \dots, x_k, z_1, \dots, z_{k+1}, u_1, \dots, u_r)$ is the $\Pi_{1,1}$-formula

$$\begin{aligned}
\varphi_{\alpha,k} = \forall y \Big(& x_1 < \cdots < x_k \wedge \textstyle\bigwedge_{i=1}^k (Ex_iz_i \wedge Ex_iz_{i+1}) \wedge \mathrm{FIRST}\, z_1 \wedge \mathrm{LAST}\, z_{k+1}\\
& \wedge u_1 \prec \cdots \prec u_r \wedge \textstyle\bigwedge_{i=1}^r \Big(Fyu_i \to \big(\bigvee_{j=1}^k y = x_j \vee \bigvee_{j=1}^{k+1} y = z_j \big) \Big)\\
& \wedge \big(\mathrm{DISJ}\, y \to \textstyle\bigvee_{j=1}^r \mathrm{SAT}\, u_j y \big) \Big).
\end{aligned}$$

$p\text{-}\#(\Pi_{1,1}[s]) \leq^{\text{fp}}_{\text{pars}} p\text{-}\#\text{DOMINATING SET}$: For notational simplicity, we assume $s = 2$. Let τ be a vocabulary that contains only unary and binary relation symbols. Assume we are given a τ-structure $\mathcal{A}$ with universe A and a $\Pi_{1,1}[\tau]$-formula

$$\varphi(x_1, \ldots, x_\ell) = \forall y \psi(x_1, \ldots, x_\ell, y).$$

Let $\mathcal{G} = (G, E^{\mathcal{G}})$ be the graph defined as follows: The vertex set is

$$\begin{aligned} G := {} & (\{1, \ldots, \ell\} \times A) \,\dot\cup\, A^\ell \,\dot\cup\, (A \times \{0\}) \\ & \dot\cup\, \{b_i^j \mid 1 \leq i \leq \ell,\ 1 \leq j \leq \ell + 2\} \\ & \dot\cup\, \{b^j \mid 1 \leq j \leq \ell + 2\} \end{aligned}$$

($\dot\cup$ denotes disjoint union), where b_i^j and b^j are new elements. The edge relation $E^{\mathcal{G}}$ is defined in such a way that

(i) every $(a_1, \ldots, a_\ell) \in A^\ell$ is connected to all elements of $\{i\} \times (A \setminus \{a_i\})$ for $1 \leq i \leq \ell$;
(ii) for $\bar{a} \in A^\ell$ and $(b, 0) \in A \times \{0\}$: $\{\bar{a}, (b, 0)\} \in E^{\mathcal{G}} \iff \mathcal{A} \models \psi(\bar{a}, b)$;
(iii) b_i^j is connected to (i, a) for $1 \leq i \leq \ell$, $1 \leq j \leq \ell + 2$, $a \in A$;
(iv) b^j is connected to all $\bar{a} \in A^\ell$ for $1 \leq j \leq \ell + 2$.

We claim that

- Every dominating set of $\mathcal{G}$ of cardinality $\ell + 1$ contains exactly one element of each $\{i\} \times A$, and if we label these elements, say, (i, a_i) for $1 \leq i \leq \ell$, then the $(\ell + 1)$st element in the dominating set is $(a_1, \ldots, a_\ell) \in A^\ell$.
- For all $a_1, \ldots, a_\ell \in A$,

$$\big\{(i, a_i) \;\big|\; 1 \leq i \leq \ell\big\} \cup \{\bar{a}\} \text{ is a dominating set of } \mathcal{G} \iff \mathcal{A} \models \varphi(\bar{a}).$$

To see this, suppose that D is a dominating set of $\mathcal{G}$ of size $\ell + 1$. Then D must contain at least one vertex of $\{i\} \times A$ for $1 \leq i \leq \ell$ and one vertex of A^ℓ, because this is the only way the vertices b_i^j and b^j, for $1 \leq j \leq \ell + 2$, can be dominated with $\ell + 1$ vertices. Suppose that D contains the vertices $(1, a_1), \ldots, (\ell, a_\ell)$. Let d be the remaining element of D. If $d = (d_1, \ldots, d_\ell) \neq (a_1, \ldots, a_\ell)$, say, $d_1 \neq a_1$, then $(1, d_1)$ is not dominated by $a_1, \ldots, a_\ell, d$. Therefore, d must be $(a_1, \ldots, a_\ell)$. However, d must also dominate $A \times \{0\}$, and this is possible only if $\mathcal{A} \models \psi(a_1, \ldots, a_\ell, b)$ for all $b \in A$.

Thus $|\varphi(\mathcal{A})|$ is the number of dominating sets of $\mathcal{G}$ of cardinality $\ell + 1$. But note that $\mathcal{G}$ is too big for a parameterized reduction, since G contains the set A^ℓ, where the exponent depends on the parameter φ. So we need a more refined reduction. We can assume that $\psi(\bar{x}, y) = \psi_1 \wedge \cdots \wedge \psi_m$ where each ψ_i is a disjunction of literals. Each literal contains at most two variables. Therefore, we do not need A^ℓ but a copy A_{ij} of A^2 for $1 \leq i < j \leq \ell$. We replace A^ℓ above by all these copies and $A \times \{0\}$ by $A \times \{1, \ldots, m\}$. We replace (i) by

(i′) every (a_i, a_j) in the copy A_{ij} of A^2 is connected to all elements of $\{i\} \times (A \setminus \{a_i\})$ and all elements of $\{j\} \times (A \setminus \{a_j\})$.

Furthermore, we replace (ii) by

(ii′) for $1 \leq i < j \leq \ell$, (a_i, a_j) in the copy A_{ij} of A^2, and for $(b, k) \in A \times \{1, \ldots, m\}$,

$$\{(a_i, a_j), (b, k)\} \in E^{\mathcal{G}} \iff \begin{array}{l}\text{there is a literal } \lambda(x_i, x_j, y) \text{ in } \psi_k \text{ whose (at most} \\ \text{two) free variables are among } x_i, x_j, y \text{ such that} \\ \mathcal{A} \models \lambda(a_i, a_j, b).\end{array}$$

Moreover, instead of the b_i^j and the b^j we add for every $i = 1, \dots, \ell$ and for every copy of A^2 a set of $\ell + \binom{\ell}{2} + 1$ new elements that ensure that every dominating set of cardinality $\ell + \binom{\ell}{2}$ contains exactly one element of every $\{i\} \times A$ and of every copy of A^2.

Then dominating sets of cardinality $\ell + \binom{\ell}{2}$ and tuples in $\mathcal{A}$ satisfying φ are related in a one-to-one fashion.

p-#DOMINATING SET $\leq^{\text{fp}}_{\text{pars}}$ #WSAT(CNF): Let $\mathcal{G} = (G, E^{\mathcal{G}})$ be a graph. For $a \in G$ let X_a be a propositional variable. Let $\alpha_{\mathcal{G}}$ be the propositional formula

$$\alpha_{\mathcal{G}} := \bigwedge_{a \in G} \left(X_a \vee \bigvee_{(a,b) \in E} X_b \right).$$

Then, $\alpha_{\mathcal{G}}$ is (equivalent to) a formula in $\Gamma_{2,0}$. Clearly the number of satisfying assignments of $\alpha_{\mathcal{G}}$ of weight k equals the number of dominating sets of $\mathcal{G}$ of size k. □

Remark 4.10. As opposed to the proof of Theorem 4.4, the reductions given in the proof of Theorem 4.9 are not just variants of the standard reductions showing the W[2]-completeness of the respective problems under many-one reductions. As a matter of fact, our proof yields a new proof of the complicated result that p-DOMINATING SET is W[2]-complete under parameterized many-one reductions.

5. Counting cycles and paths.

THEOREM 5.1. *The following problems are* #W[1]*-complete under parameterized Turing reductions:*

(1) p-#CYCLE *and* p-#DIRCYCLE
("Count the cycles of length k in a (directed) graph").
(2) p-#PATH *and* p-#DIRPATH
("Count the paths of length k in a (directed) graph").

To be precise, let us define a *path of length* k in a directed graph $(G, E^{\mathcal{G}})$ to be a substructure of G isomorphic to $\big(\{1, \dots, k\}, \{(i, i+1) \mid 1 \leq i < k\}\big)$. A *cycle of length* k is a substructure isomorphic to $\big(\{1, \dots, k\}, \{(i, i+1) \mid 1 \leq i < k\} \cup \{(k, 1)\}\big)$. Paths and cycles in undirected graphs are defined similarly.

Thus all problems in Theorem 5.1 are restrictions of the substructure problem p-#SUB and thus in #W[1] by Theorem 4.4. The decision versions of the problems are fixed-parameter tractable. This is an immediate consequence of Plehn and Voigt's [26] theorem that the parameterized embedding problem restricted to graphs of bounded tree-width is fixed-parameter tractable and the fact that paths have tree-width 1 and cycles have tree-width 2.

LEMMA 5.2.

$$p\text{-\#DIRCYCLE} \leq^{\text{fp}}_{\text{pars}} p\text{-\#CYCLE} \leq^{\text{fp}}_{\text{T}} p\text{-\#PATH} \leq^{\text{fp}}_{\text{T}} p\text{-\#DIRPATH}.$$

Proof. p-#DIRCYCLE $\leq^{\text{fp}}_{\text{pars}}$ p-#CYCLE: For a directed graph $\mathcal{G}$, let $\mathcal{G}^u_{p,q}$ be the undirected graph obtained from $\mathcal{G}$ by the following two steps:

(1) Replace each vertex a of $\mathcal{G}$ by an undirected path of length p such that the (directed) edges with head a in $\mathcal{G}$ get the first vertex of this path as their new head and the edges with tail a in $\mathcal{G}$ get the last vertex of this path as their new tail.
(2) Replace each directed edge in this graph (corresponding to an edge of $\mathcal{G}$) by an undirected path of length q.

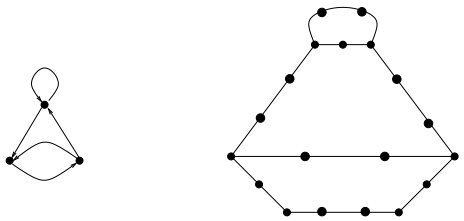

FIG. 5.1. *A directed graph $\mathcal{G}$ and the corresponding $\mathcal{G}^u_{2,3}$.*

Figure 5.1 gives an example.

Observe that each cycle in $\mathcal{G}^u_{p,q}$ has length $\ell \cdot p + m \cdot q$ for some integers $\ell, m \geq 0$ with $\ell \leq m$. Further observe that each directed cycle of length k in $\mathcal{G}$ lifts to a cycle of length $k(p+q)$ in $\mathcal{G}^u_{p,q}$. Given k, we want to choose p and q in such a way that each cycle of length $k(p+q)$ in $\mathcal{G}^u_{p,q}$ is the lifting of a directed cycle of length k in $\mathcal{G}$. To achieve this, we have to choose p and q in such a way that

$$k(p+q) \neq \ell \cdot p + m \cdot q \tag{5.1}$$

for all $\ell, m \geq 0$ with $\ell < m$. If we choose $p \leq q$, then (5.1) holds for $m > 2k$. So we have to fulfill (5.1) for $0 \leq \ell < m \leq 2k$. Hence, we have to avoid $\binom{2k+1}{2}$ linear equalities. Clearly we can find natural numbers $p \leq q$ satisfying none of these equalities.

For such p and q, the number of directed cycles of length k in $\mathcal{G}$ equals the number of undirected cycles of length $k(p+q)$ in $\mathcal{G}^u_{p,q}$.

p-#CYCLE $\leq^{\text{fp}}_{\text{T}}$ p-#PATH: Let $\mathcal{G}$ be an undirected graph and $k \geq 1$. Without loss of generality we can assume that $k \geq 3$ because counting loops in a graph is easy.

For each $e = \{v, w\} \in E^{\mathcal{G}}$ and all $\ell, m \geq 0$, we let $\mathcal{G}_e(\ell, m)$ be the graph obtained from $\mathcal{G}$ by adding vertices as $v_1, \ldots, v_\ell, w_1, \ldots, w_m$ and adding edges between v_i and w for $1 \leq i \leq \ell$ and between w_j and v for $1 \leq j \leq m$.

We observe that the number x_e of paths of length $k+1$ from v_1 to w_1 in $\mathcal{G}_e(\ell, m)$ is exactly the number of cycles of length k in $\mathcal{G}$ containing the edge e. We now show how to compute x_e from the numbers of paths of length $k+1$ in the graphs $\mathcal{G}_e(\ell, m)$ for $0 \leq \ell, m \leq 1$. This yields a parameterized Turing reduction from p-#CYCLE to p-#PATH.

We observe that the v_i and w_j can only be endpoints of paths in $\mathcal{G}_e(\ell, m)$, and that each path can have at most one endpoint among $v_1, \ldots, v_\ell$ and at most one endpoint among $w_1, \ldots, w_m$ (because each path ending in v_i must go through w and each path ending in w_j must go through v).

We let

- $x = x_e$ be the number of paths of length $(k+1)$ from v_1 to w_1 in $\mathcal{G}_e(1,1)$,
- y be the number of paths of length $(k+1)$ in $\mathcal{G}_e(1,1)$ that contain v_1 but not w_1,
- z be the number of paths of length $(k+1)$ in $\mathcal{G}_e(1,1)$ that contain w_1 but not v_1,
- w be the number of paths of length $(k+1)$ in $\mathcal{G}_e(1,1)$ that contain neither v_1 nor w_1.

Let $p_{\ell m}$ be the number of paths of length $(k+1)$ in $\mathcal{G}_e(\ell, m)$. Then we have

$$p_{\ell m} = w + \ell \cdot m \cdot x + \ell \cdot y + m \cdot z.$$

For $0 \leq \ell, m \leq 1$ we obtain a system of four linear equations in the variables w, x, y, z whose matrix is nonsingular. Thus it has a unique solution which, in particular, gives us the desired value x.

p-#Path $\leq_{\mathrm{T}}^{\mathrm{fp}}$ p-#DirPath: This is trivial; just replace each edge of an undirected graph that is not a loop by two directed edges. Then each path (of length at least 2) in the undirected graph corresponds to exactly two paths of the same length in the directed graph. □

Next, we will prove that p-#Clique $\leq_{\mathrm{T}}^{\mathrm{fp}}$ p-#DirCycle. This requires a sequence of lemmas. Let $h : \mathcal{H} \to \mathcal{G}$ be a homomorphism and, for $i \geq 1$, let k_i be the number of vertices $b \in G$ such that $|h^{-1}(b)| \geq i$. Then $\sum_{i \geq 1} k_i = |H|$. The *type* of h is the polynomial

$$t_h(X) = \prod_{i \geq 1} (X - i + 1)^{k_i} = \prod_{b \in G} (X)_{|h^{-1}(b)|},$$

where the notation $(X)_i$ is used for the "falling factorial"; that is, $(X)_0 = 1$ and $(X)_{i+1} = (X)_i(X - i)$ for all $i \geq 0$. In particular, an embedding from $\mathcal{H}$ into $\mathcal{G}$ is a homomorphism of type $X^{|H|}$.

Let $\mathcal{D}_k$ denote the directed cycle of length k whose vertices are $1, \ldots, k$ in cyclic order. We consider the following generalization of p-#DirCycle:

p-#TDC	
Input:	Directed graph $\mathcal{G}$, polynomial $t(X)$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the homomorphisms $h : \mathcal{D}_k \to \mathcal{G}$ of type $t(X)$.

Lemma 5.3.

$$p\text{-}\#\mathrm{TDC} \leq_{\mathrm{T}}^{\mathrm{fp}} p\text{-}\#\mathrm{DirCycle}.$$

Proof. For a directed graph $\mathcal{G}$ and natural numbers $\ell, m \geq 1$, let $\mathcal{G}_{\ell,m}$ be the graph obtained from $\mathcal{G}$ as follows:

- The universe of $\mathcal{G}_{\ell,m}$ is
$$G_{\ell,m} = G \times \{1, \ldots, \ell\} \times \{1, \ldots, m\}.$$
- There is an edge from (a, i, j) to (a', i', j') in $\mathcal{G}_{\ell,m}$ either if $i = \ell$ and $i' = 1$ and there is an edge from a to a' in $\mathcal{G}$, or if $a = a'$ and $i' = i + 1$.

Figure 5.2 gives an example.

Recall that the vertices of the cycle $\mathcal{D}_k$ are $1, \ldots, k$. The *projection* of an embedding $e : \mathcal{D}_{k \cdot \ell} \to \mathcal{G}_{\ell,m}$ is the homomorphism $\pi(e) : \mathcal{D}_k \to \mathcal{G}$ which maps vertex $a \in D_k$ to the first component of $e((a - 1) \cdot \ell + 1)$; that is, we let $\pi(e)(a) = b$ if $e((a - 1) \cdot \ell + 1) = (b, i, j)$ for some $i \in \{1, \ldots, \ell\}, j \in \{1, \ldots, m\}$.

Observe that for every homomorphism $h : \mathcal{D}_k \to \mathcal{G}$ there are

$$\ell \cdot t_h(m)^\ell$$

embeddings $e : \mathcal{D}_{k \cdot \ell} \to \mathcal{G}_{\ell,m}$ with projection $\pi(e) = h$. Let T be the set of all types of homomorphisms from $\mathcal{D}_k$ into some graph. For every type $t \in T$, let x_t be the number of homomorphisms $h : \mathcal{D}_k \to \mathcal{G}$ with $t_h = t$. Then

$$b_\ell = \sum_{t \in T} x_t \cdot \ell \cdot t(m)^\ell$$

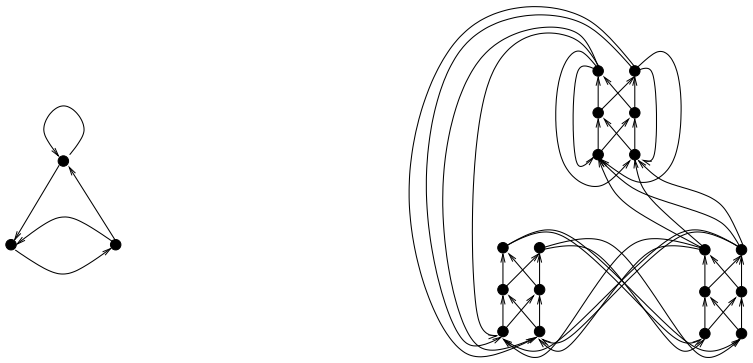

FIG. 5.2. *A directed graph $\mathcal{G}$ and the corresponding $\mathcal{G}_{3,2}$.*

is the number of embeddings $e : \mathcal{D}_{k\cdot\ell} \to \mathcal{G}_{\ell,m}$.

The types in T are polynomials of degree at most k. Thus for distinct $t(X), t'(X) \in T$ there are at most k distinct $x \in \mathbb{N}$ such that $t(x) = t'(x)$. Therefore, there is an $m \leq k \cdot |T|^2$ such that for all distinct $t(X), t'(X) \in T$ we have $t(m) \neq t'(m)$. We fix such an m.

We let $\vec{b} = (b_1, \ldots, b_{|T|})$, $\vec{x} = (x_t)_{t\in T}$, and $A = (a_{\ell t})_{\substack{1\leq \ell \leq |T| \\ t\in T}}$, where $a_{\ell t} = \ell \cdot t(m)^\ell$. Then

$$A \cdot \vec{x} = \vec{b}.$$

Since the matrix $(\frac{1}{\ell} a_{\ell t})_{\substack{1\leq \ell \leq |T| \\ t\in T}}$ is a Vandermonde matrix and thus nonsingular, the matrix A is also nonsingular, and thus

$$\vec{x} = A^{-1}\vec{b}.$$

Now our Turing reduction from p-#TDC to p-#DIRCYCLE works as follows:

1. Compute the set T and a suitable m.
2. For $1 \leq \ell \leq |T|$, compute the graph $\mathcal{G}_{\ell,m}$.
3. For $1 \leq \ell \leq |T|$, compute the number b_ℓ of embeddings $e : \mathcal{D}_{k\cdot\ell} \to \mathcal{G}_{\ell\cdot m}$ (using the oracle to p-#DIRCYCLE and noting that b_ℓ is $k \cdot \ell$ times the number of cycles of length $k \cdot \ell$ in $\mathcal{G}_{\ell\cdot m}$).
4. Compute the matrix A and solve the system $A \cdot \vec{x} = \vec{b}$.
5. Return x_t, where $t(X)$ is the input polynomial. (If $t \notin T$, then return 0.)

Since the set T, the number m, and the matrix A depend only on the parameter k, this is a parameterized Turing reduction. □

For $k, \ell \geq 1$, let $\Omega(k, \ell)$ denote the space of all mappings $f : \{1, \ldots, k \cdot \ell\} \to \{1, \ldots, k\}$ such that $|f^{-1}(i)| = \ell$ for $1 \leq i \leq k$.

LEMMA 5.4. *Let $k \geq 1$, and let $\mathcal{H} = (H, E^{\mathcal{H}})$ be a directed graph with universe $H = \{1, \ldots, k\}$ and $E^{\mathcal{H}} \neq H^2$. Then*

$$\lim_{\ell\to\infty} \Pr_{f\in\Omega(k,\ell)} \big(f \text{ is a homomorphism from } \mathcal{D}_{k\cdot\ell} \text{ to } \mathcal{H}\big) = 0$$

(where f is chosen uniformly at random).

Proof. Let $(x,y) \in H^2 \setminus E^{\mathcal{H}}$ and $m \leq k \cdot \ell$. We call a tuple $(i_1,\dots,i_m) \in H^m$ *good* if $(i_j, i_{j+1}) \neq (x,y)$ for $1 \leq j \leq m-1$ and *bad* otherwise. For $(i_1,\dots,i_m) \in H^m$ chosen uniformly at random we have

$$\begin{aligned}\Pr\big((i_1,\dots,i_m) \text{ good}\big) &\leq \Pr\big(\forall j,\, 1 \leq j \leq m/2 : (i_{2j-1}, i_{2j}) \neq (x,y)\big)\\ &= \left(1 - \frac{1}{k^2}\right)^{\lfloor m/2 \rfloor}.\end{aligned}$$

Furthermore, for all $i_1,\dots,i_m \in H$ we have

$$\Pr_{f \in \Omega(k,\ell)}\big(\forall j,\, 1 \leq j \leq m :\ f(j) = i_j\big) \leq \left(\frac{\ell}{k \cdot \ell - m}\right)^m.$$

To see this inequality, note that choosing a random function $f \in \Omega(k,\ell)$ can be modeled by randomly picking $k \cdot \ell$ balls without repetitions out of a bin that initially contains ℓ balls of each color $1,\dots,k$. The probability that the ith ball is of color j is at most

$$\frac{\ell}{k \cdot \ell - (i-1)},$$

because at most ℓ balls of the remaining $k \cdot \ell - (i-1)$ are of color j. Now the inequality follows straightforwardly.

Thus

$$\begin{aligned}&\Pr_{f \in \Omega(k,\ell)}(f \text{ is a homomorphism from } \mathcal{D}_{k\cdot\ell} \text{ to } \mathcal{H})\\ &\leq \sum_{(i_1,\dots,i_m) \in H^m \text{ good}} \Pr_{f \in \Omega(k,\ell)}(f(j) = i_j \text{ for } 1 \leq j \leq m)\\ &\leq \sum_{(i_1,\dots,i_m) \in H^m \text{ good}} \left(\frac{\ell}{k \cdot \ell - m}\right)^m\\ &= \left(\frac{\ell}{k \cdot \ell - m}\right)^m \cdot k^m \cdot \Pr_{(i_1,\dots,i_m) \in H^m}\big((i_1,\dots,i_m) \text{ good}\big)\\ &\leq \left(\frac{k \cdot \ell}{k \cdot \ell - m}\right)^m \cdot \left(1 - \frac{1}{k^2}\right)^{\lfloor m/2 \rfloor}.\end{aligned}$$

Let $\varepsilon > 0$. Then there exists an $m(\varepsilon,k)$ such that for $m \geq m(\varepsilon,k)$ we have

$$\left(1 - \frac{1}{k^2}\right)^{\lfloor m/2 \rfloor} \leq \frac{\varepsilon}{2}.$$

Moreover, for every m there exists an $\ell(m)$ such that for $\ell \geq \ell(m)$ we have

$$\left(\frac{k \cdot \ell}{k \cdot \ell - m}\right)^m = \left(\frac{1}{1 - \frac{m}{k\cdot\ell}}\right)^m \leq \frac{1}{\big(1 - \frac{m}{\ell}\big)^m} \leq 2.$$

Thus for all $\ell \geq \ell(m(\varepsilon,k))$ we have

$$\Pr_{f \in \Omega(k,\ell)}(f \text{ is a homomorphism from } \mathcal{D}_{k\cdot\ell} \text{ to } \mathcal{H}) \leq \varepsilon. \qquad \square$$

LEMMA 5.5.

$$p\text{-}\#\textsc{Clique} \leq_{\mathrm{T}}^{\mathrm{fp}} p\text{-}\#\mathrm{TDC}.$$

Proof. Let $k \geq 1$. For a graph $\mathcal{H}$, let $\overleftrightarrow{\mathcal{H}}$ denote the directed graph with the same vertex set and edge set

$$\big\{(a,a) \bigm| a \in H\big\} \cup \big\{(a,b) \bigm| \{a,b\} \in E^{\mathcal{H}}\big\}.$$

For every graph $\mathcal{H}$ with k vertices and every $\ell \geq 1$, let $a_{\mathcal{H}\ell}$ be the number of homomorphisms of type $(X)_\ell^k$ from $\mathcal{D}_{k\cdot\ell}$ into $\overleftrightarrow{\mathcal{H}}$ (that is, homomorphisms for which each point in the image has exactly ℓ preimages). Let $\overset{\mathbb{N}}{a}_{\mathcal{H}} = (a_{\mathcal{H}1}, a_{\mathcal{H}2}, \dots)$ and, for every $\ell \geq 1$, $\overset{\ell}{a}_{\mathcal{H}} = (a_{\mathcal{H}1}, a_{\mathcal{H}2}, \dots, a_{\mathcal{H}\ell})$. We consider $\overset{\mathbb{N}}{a}_{\mathcal{H}}$ and $\overset{\ell}{a}_{\mathcal{H}}$ as vectors in the vector spaces $\mathbb{Q}^{\mathbb{N}}$ and $\mathbb{Q}^\ell$, respectively.

Let $k \geq 1$, and let $\mathcal{K}$ be the complete graph with vertices $\{1,\dots,k\}$. Let $\mathbb{H}$ be the set of all graphs with vertex set $\{1,\dots,k\}$, where up to isomorphism each graph occurs only once in $\mathbb{H}$, and let $\mathbb{H}^- = \mathbb{H} \setminus \{\mathcal{K}\}$.

For a set S of vectors in $\mathbb{Q}^{\mathbb{N}}$ or $\mathbb{Q}^\ell$, we let $\langle S\rangle$ denote the linear span of S.

Claim 1.

$$\overset{\mathbb{N}}{a}_{\mathcal{K}} \notin \left\langle \left\{ \overset{\mathbb{N}}{a}_{\mathcal{H}} \bigm| \mathcal{H} \in \mathbb{H}^- \right\} \right\rangle.$$

Proof. Recall that $\Omega(k,\ell)$ denotes the set of all mappings $h : \{1,\dots,k\cdot\ell\} \to \{1,\dots,k\}$ with the property that $|h^{-1}(i)| = \ell$ for $1 \leq i \leq k$.

We first observe that for all $\ell \geq 1$,

$$a_{\mathcal{K}\ell} = |\Omega(k,\ell)|.$$

On the other hand, by Lemma 5.4 for all graphs $\mathcal{H} \in \mathbb{H}^-$ we have

$$\lim_{\ell\to\infty} \frac{a_{\mathcal{H}\ell}}{|\Omega(k,\ell)|} = 0.$$

Suppose for contradiction that

$$\overset{\mathbb{N}}{a}_{\mathcal{K}} = \sum_{i=1}^{n} \lambda_i \overset{\mathbb{N}}{a}_{\mathcal{H}_i}$$

for graphs $\mathcal{H}_1,\dots,\mathcal{H}_n \in \mathbb{H}^-$. Choose ℓ sufficiently large such that for $1 \leq i \leq n$

$$\frac{a_{\mathcal{H}_i\ell}}{a_{\mathcal{K}\ell}} = \frac{a_{\mathcal{H}_i\ell}}{|\Omega(k,\ell)|} < \frac{1}{\sum_{i=1}^n |\lambda_i|}.$$

Then

$$a_{\mathcal{K}\ell} = \sum_{i=1}^{n} \lambda_i a_{\mathcal{H}_i\ell} \leq a_{\mathcal{K}\ell} \sum_{i=1}^{n} |\lambda_i| \frac{a_{\mathcal{H}_i\ell}}{a_{\mathcal{K}\ell}} < a_{\mathcal{K}\ell} \sum_{i=1}^{n} |\lambda_i| \frac{1}{\sum_{j=1}^n |\lambda_j|} = a_{\mathcal{K}\ell},$$

which is a contradiction. This proves Claim 1.

Claim 2. There is an $\ell = \ell(k) \in \mathbb{N}$ such that

$$\overset{\ell}{a}_{\mathcal{K}} \notin \left\langle \left\{ \overset{\ell}{a}_{\mathcal{H}} \bigm| \mathcal{H} \in \mathbb{H}^- \right\} \right\rangle.$$

Furthermore, the mapping $k \mapsto \ell(k)$ is computable.

Proof. For $\iota \in \mathbb{N} \cup \{\mathbb{N}\}$, let

$$V_\iota = \left\langle \left\{ \overset{\iota}{a}_{\mathcal{H}} \;\middle|\; \mathcal{H} \in \mathbb{H}^- \right\} \right\rangle.$$

Identifying $(a_1, \dots, a_i) \in \mathbb{Q}^i$ with $(a_1, \dots, a_i, 0, 0, \dots) \in \mathbb{Q}^{\mathbb{N}}$, for all $i \geq 1$ we can view V_i as a subspace of V_j for all $j \geq i$ and of $V_{\mathbb{N}}$. Thus we can find an increasing sequence

$$\mathbb{B}_1 \subseteq \mathbb{B}_2 \subseteq \mathbb{B}_3 \subseteq \cdots \subseteq \mathbb{H}^-$$

such that for all $i \geq 1$

$$\left\{ \overset{i}{a}_{\mathcal{H}} \;\middle|\; \mathcal{H} \in \mathbb{B}_i \right\}$$

is a basis of V_i. Since $V_{\mathbb{N}}$ is a finite dimensional vector space, there is an $n \in \mathbb{N}$ such that $\mathbb{B}_i = \mathbb{B}_n$ for all $i \geq n$.

Now if $\overset{i}{a}_{\mathcal{K}}$ was in V_i for all $i \geq 1$, then for all $i \geq 1$, the vector $\overset{i}{a}_{\mathcal{K}}$ could be written as a unique linear combination of the vectors in $\left\{ \overset{i}{a}_{\mathcal{H}} \;\middle|\; \mathcal{H} \in \mathbb{B}_i \right\}$. For all $i \geq n$, these linear combinations would be identical; thus $\overset{\mathbb{N}}{a}_{\mathcal{K}}$ would be in $V_{\mathbb{N}}$. This contradicts Claim 1 and thus proves that for some $\ell \in \mathbb{N}$,

$$\overset{\ell}{a}_{\mathcal{K}} \notin V_\ell.$$

Clearly such an ℓ is computable from k, since we can compute all vectors $\overset{i}{a}_{\mathcal{H}}$ for $\mathcal{H} \in \mathbb{H}$ and $i \in \mathbb{N}$. This completes the proof of Claim 2.

Now we are ready to prove the lemma. Let $k \geq 1$ and define $\mathcal{K}$, $\mathbb{H}$, $\mathbb{H}^-$, and the vectors $\overset{\iota}{a}_{\mathcal{H}}$ as above. Choose $\ell = \ell(k)$ according to Claim 2.

Let $\mathcal{G}$ be a graph. For every graph $\mathcal{H} \in \mathbb{H}$, let $x_{\mathcal{H}}$ be the number of subsets $A \subseteq G$ such that the subgraph induced by $\mathcal{G}$ on A is isomorphic to $\mathcal{H}$. We want to determine the number $x_{\mathcal{K}}$. For $1 \leq i \leq \ell$, let b_i be the number of homomorphisms from $\mathcal{D}_{k \cdot i}$ into $\overset{\leftrightarrow}{\mathcal{G}}$ of type $(X)_i^k$, and let $\overset{\ell}{b} = (b_1, \dots, b_\ell)$. The numbers b_i can be computed by an oracle to p-#TDC.

Observe that for $1 \leq i \leq \ell$ we have

$$b_i = \sum_{\mathcal{H} \in \mathbb{H}} x_{\mathcal{H}} a_{\mathcal{H}i}$$

and thus

$$\overset{\ell}{b} = \sum_{\mathcal{H} \in \mathbb{H}} x_{\mathcal{H}} \overset{\ell}{a}_{\mathcal{H}}.$$

Since $\overset{\ell}{a}_{\mathcal{K}}$ is linearly independent from $\left\{ \overset{\ell}{a}_{\mathcal{H}} \;\middle|\; \mathcal{H} \in \mathbb{H}^- \right\}$, the coefficient $x_{\mathcal{K}}$ can be computed by solving this system of linear equations. □

Proof of Theorem 5.1. The theorem follows immediately from Lemmas 5.2, 5.3, and 5.5 and Theorem 4.4. □

6. Conclusions. We have set up a framework for a parameterized complexity theory of counting problems and proved a number of completeness results. In particular, we proved the fixed-parameter intractability of natural counting problems whose decision version is fixed-parameter tractable.

A lot of interesting problems remain open; let us just mention two of them.

- In view of Valiant's #P-completeness result for counting perfect matchings, it would be quite nice to show that the parameterized matching problem p-#Matching is #W[1]-complete. We conjecture that this is the case.
- Another interesting question is related to Toda's theorem: Does #W[1] contain the whole W-hierarchy, or maybe even the A-hierarchy (introduced in [15])?

Appendix A: A list of problems appearing in this paper.

Vertex cover and related problems. A *vertex cover* of a graph $\mathcal{G} = (G, E^{\mathcal{G}})$ is a subset $X \subseteq G$ such that for all edges $(v, w) \in E^{\mathcal{G}}$ either $v \in X$ or $w \in X$.

p-Vertex Cover	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if $\mathcal{G}$ has a vertex cover of size k.

p-#Vertex Cover	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the vertex covers of $\mathcal{G}$ of size k.

A *dominating set* of a graph $\mathcal{G} = (G, E^{\mathcal{G}})$ is a subset $X \subseteq G$ such that for all vertices $w \in G$ either $w \in X$ or $(v, w) \in E^{\mathcal{G}}$ for some $v \in X$.

p-Dominating Set	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if $\mathcal{G}$ has a dominating set of size k.

p-#Dominating Set	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the dominating sets of $\mathcal{G}$ of size k.

In general, the *standard parameterization* of an optimization problem is the parameterized decision problem asking whether there exists a solution of size k, where k is the quantity to be optimized and the parameter. The counting version can be defined accordingly.

Homomorphisms, embeddings, and substructures.

p-Hom	
Input:	Structures $\mathcal{A}$ and $\mathcal{B}$.
Parameter:	$\|\mathcal{A}\|$.
Problem:	Decide if there exists a homomorphism from $\mathcal{A}$ to $\mathcal{B}$.

p-#Hom	
Input:	Structures $\mathcal{A}$ and $\mathcal{B}$.
Parameter:	$\|\mathcal{A}\|$.
Problem:	Count the homomorphisms from $\mathcal{A}$ to $\mathcal{B}$.

p-Emb	
Input:	Structures $\mathcal{A}$ and $\mathcal{B}$.
Parameter:	$\|\mathcal{A}\|$.
Problem:	Decide if there exists an embedding of $\mathcal{A}$ into $\mathcal{B}$.

p-#Emb	
Input:	Structures $\mathcal{A}$ and $\mathcal{B}$.
Parameter:	$\|\mathcal{A}\|$.
Problem:	Count the embeddings of $\mathcal{A}$ into $\mathcal{B}$.

p-Sub	
Input:	Structures $\mathcal{A}$ and $\mathcal{B}$.
Parameter:	$\|\mathcal{A}\|$.
Problem:	Decide if $\mathcal{B}$ has a substructure isomorphic to $\mathcal{A}$.

p-#Sub	
Input:	Structures $\mathcal{A}$ and $\mathcal{B}$.
Parameter:	$\|\mathcal{A}\|$.
Problem:	Count the substructures of $\mathcal{B}$ isomorphic to $\mathcal{A}$.

A *clique* in a graph $\mathcal{G}$ is a subset X of G such that for all distinct $v, w \in X$, $(v, w) \in E^{\mathcal{G}}$.

p-Clique	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if $\mathcal{G}$ has a clique of size k.

p-#Clique	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the cliques of $\mathcal{G}$ of size k.

p-Path	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if $\mathcal{G}$ contains a path of length k.

p-#Path	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the paths of length k in $\mathcal{G}$.

p-DirPath	
Input:	Directed graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if $\mathcal{G}$ contains a directed path of length k.

p-#DirPath	
Input:	Directed graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the directed paths of length k in $\mathcal{G}$.

p-Cycle	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if $\mathcal{G}$ contains a cycle of length k.

p-#Cycle	
Input:	Graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the cycles of length k in $\mathcal{G}$.

p-DirCycle	
Input:	Directed graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if $\mathcal{G}$ contains a directed cycle of length k.

p-#DirCycle	
Input:	Directed graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the directed cycles of length k in $\mathcal{G}$.

A *matching* of a graph is a set of edges that pairwise have no endpoint in common.

p-Matching	
Input:	Bipartite graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if $\mathcal{G}$ contains a matching of size k.

p-#Matching	
Input:	Bipartite graph $\mathcal{G}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the matchings of size k in $\mathcal{G}$.

Logically defined problems. The *weight* of an assignment S for the variables of a propositional formula is the number of variables set to TRUE by S. Let Θ be a class of propositional formulas

WSAT(Θ)	
Input:	$\theta \in \Theta$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if θ has a satisfying assignment of weight k.

#WSAT(Θ)	
Input:	$\theta \in \Theta$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the satisfying assignments of θ of weight k.

$|\varphi|$ denotes the length of a formula φ. Let Φ be a class of first-order formulas.

p-MC(Φ)	
Input:	Structure $\mathcal{A}$, formula $\varphi \in \Phi$.
Parameter:	$\lvert\varphi\rvert$.
Problem:	Decide if $\varphi(\mathcal{A}) \neq \emptyset$.

p-#(Φ)	
Input:	Structure $\mathcal{A}$, formula $\varphi \in \Phi$.
Parameter:	$\lvert\varphi\rvert$.
Problem:	Compute $\lvert\varphi(\mathcal{A})\rvert$.

Let $\varphi(X)$ be a formula of vocabulary $\tau \cup \{X\}$.

p-FD($\varphi(X)$)	
Input:	τ-structure $\mathcal{A}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if $\varphi(\mathcal{A})$ contains a relation of size k.

p-#FD($\varphi(X)$)	
Input:	Structure $\mathcal{A}$.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the number of relations of size k in $\varphi(\mathcal{A})$.

The parameterized halting problem.

p-HALT	
Input:	Nondeterministic Turing machine M.
Parameter:	$k \in \mathbb{N}$.
Problem:	Decide if M accepts the empty word in at most k steps.

p-#HALT	
Input:	Nondeterministic Turing machine M.
Parameter:	$k \in \mathbb{N}$.
Problem:	Count the accepting computation paths of M of length at most k for the empty word.

ON WORST-CASE ROBIN HOOD HASHING*

LUC DEVROYE†, PAT MORIN†, AND ALFREDO VIOLA‡

Abstract. We consider open addressing hashing and implement it by using the Robin Hood strategy; that is, in case of collision, the element that has traveled the farthest can stay in the slot. We hash $\sim \alpha n$ elements into a table of size n where each probe is independent and uniformly distributed over the table, and $\alpha < 1$ is a constant. Let M_n be the maximum search time for any of the elements in the table. We show that with probability tending to one, $M_n \in [\log_2 \log n + \sigma, \log_2 \log n + \tau]$ for some constants σ, τ depending upon α only. This is an exponential improvement over the maximum search time in case of the standard FCFS (first come first served) collision strategy and virtually matches the performance of multiple-choice hash methods.

Key words. open addressing, hashing, Robin Hood, worst-case search time, collision resolution, probabilistic analysis of algorithms

1. Introduction.

In hashing with chaining with a table of size n holding $m = \lceil \alpha n \rceil$ elements, where $\alpha > 0$ is a constant, the worst-case search time is equal to the length of the longest chain. If the hash values are independent and uniformly distributed over the table, then the maximum chain length is asymptotic to $\log n / \log \log n$ in probability (Gonnet (1981); Devroye (1985)) for any fixed value of α.

In this paper we consider open addressing hashing with random probing. A table of size n is given, into which we place $m = \lceil \alpha n \rceil$ elements, where $\alpha \in (0, 1)$ is a fixed constant. Each element has associated with it an infinite probe sequence consisting of independently and identically distributed (i.i.d.) integers uniformly distributed over $\{1, \ldots, n\}$, representing the consecutive places of probes for that element. It is assumed that when searching for an element, its infinite probe sequence is available to the searcher. The probe sequence for the ith element is denoted by $X_{i,0}, X_{i,1}, X_{i,2}, \ldots$. Elements are inserted sequentially into the table. If the ith element is placed in position $X_{i,j}$, then we say that the ith element has age j, as it requires j hops to reach the element in case of a search. When the ith element of age j and the i'th element of age j' compete for the same slot ($X_{i,j} = X_{i',j'}$), a collision resolution strategy is needed. Several collision resolution strategies have dominated the literature.

The standard open addressing method resolves the collision by giving the place to the first key to arrive there according to a first come first served (FCFS) policy, so the test is based on $\min(i, i')$. Amble and Knuth (1974) suggested the idea that *any* of the colliding elements could get the position in the hope of speeding up unsuccessful searches. Note that for random probing, for any strategy that does not look ahead, the sum of the ages of all elements in a hash table has a distribution that is independent

of the collision resolution strategy. There are differences, though, when one considers the maximal age among all elements in a table. Two of the strategies that do not look ahead before deciding which element should get the position are the LCFS (last come first served) heuristic (Poblete and Munro (1989)), in which the position is given to the last element that arrives (thus, using $\max(i, i')$), and the Robin Hood strategy (Celis (1986); Celis, Larson, and Munro (1985); Viola and Poblete (1998)), in which the position is given to the element that is farthest away from its home location (the element corresponding to $\max(j, j')$). The Robin Hood strategy tends to equalize the ages of all inserted elements (hence the name Robin Hood), thus reducing the maximum successful search time. Both FCFS and Robin Hood decrease the variance of the search time. As pointed out earlier, for random probing, the expected search time for a single random element is identical for all collision resolution strategies that do not look ahead. An interesting property of Robin Hood is that every permutation of the insertion sequence produces the same final hash table, provided that a consistent tiebreaker is used (for example, $\min(i, i')$).

In open addressing hashing, most of the proposed schemes to improve the search cost of a random element in a hash table (like Brent's method, binary tree, optimal and min-max hashing) have very high cost for table creation. Other methods like multiple-choice hashing are more inefficient in the use of space. As presented in Celis (1986), Robin Hood is an open addressing hashing scheme that is as simple to program as the standard algorithm, takes only $\Theta(n \log n)$ on the average to load a full table, requires no additional memory for insertions, and has very small variance. This last fact is a key observation in Celis (1986), to speed up the searching cost of a random element. The main idea is not to probe the first position in the probe sequence but rather the most probable place and then move away from it in both directions.

For uniform probing (that is, a probe sequence without repetition) the expected value of the longest probe sequence for the standard FCFS algorithm for α-full tables ($\alpha < 1$) is $\log_{1/\alpha} n - \log_{1/\alpha}(\log_{1/\alpha} n) + O(1)$ and for full tables is $0.631587\ldots \times n + O(1)$ (Gonnet (1981)).

Poblete and Munro (1989) prove that for random probing (that is, a probe sequence with repetition) the expected value of the longest probe sequence for the LCFS heuristic is bounded by

$$1 + \Gamma^{-1}(\alpha n)\left(1 + \frac{\log\log(1/(1-\alpha))}{\log \Gamma^{-1}(\alpha n)} + O\left(\frac{1}{\log^2 \Gamma^{-1}(\alpha n)}\right)\right),$$

where Γ is the Gamma function, and

$$\Gamma^{-1}(\alpha n) = \frac{\log n}{\log\log n}\left(1 + \frac{\log\log\log n}{\log\log n} + O\left(\frac{1}{\log\log n}\right)\right).$$

Although this is not a tight bound, this was the first open addressing method for which a sublogarithmic bound in n was proven.

Celis (1986) proves that the expected value of the longest probe sequence for random probing and a full Robin Hood hash table ($\alpha = 1$) is $\Theta(\log n)$. Moreover, when $\alpha < 1$ he proved that for random probing, the expected value of the longest probe sequence for the Robin Hood heuristic is bounded by $3(H_n - H_{n-m})/\alpha + \lceil \log(n-2) \rceil$, where $H_n = \sum_{1 \le i \le n} 1/i$. This bound is improved in this paper to $\log_2 \log n$. For further discussions and results, see Knuth (1998), Vitter and Flajolet (1990), Gonnet and Baeza-Yates (1991), or Flajolet, Poblete, and Viola (1998). It is perhaps worth

TABLE 1.1

reproducing Table 5.9 from Celis's dissertation, in which empirical estimates were computed for the longest successful probe length with the Robin Hood strategy, which suggests a $\Theta(\log\log n)$ complexity for the problem when $\alpha < 1$ (see Table 1.1).

It is perhaps worth mentioning that there are several other ways of obtaining dynamic hash tables with $O(\log\log n)$ expected maximum successful search times. Consider hashing with chaining, and let the elements have a choice of two randomly picked positions. An element is placed into the slot with the least number of elements (at the time of insertion). This simple double choice shows that the maximum slot occupancy is in probability asymptotic to $\log_2\log_2 n$ (Azar et al. (1999); Broder and Karlin (1990); Czumaj and Stemann (1997); Mitzenmacher (1997)).

There has been interest in obtaining $O(1)$ expected worst-case performance, or even $O(1)$ deterministic worst-case performance, for search in hash tables. For static hash tables, Fredman, Komlós, and Szemerédi (1984) proposed a solution. Czumaj and Stemann (1997) showed that if each element has two randomly chosen hash positions, then with high probability, a static (off-line) chaining hash table can be constructed that has worst chain length 2, provided that the table size is at least αn for some threshold constant α. For dynamic hash tables, the early research was in the direction of dynamic perfect hash functions (Dietzfelbinger and Meyer auf der Heide (1990); Dietzfelbinger et al. (1992); Dietzfelbinger et al. (1994); Brodnik and Munro (1999)). Cuckoo hashing (Pagh and Rodler (2001)) is also an attempt in this direction. It stands out though through its simplicity and the promising experimental results reported by Pagh and Rodler: each of m data points has two hash functions, one to be used in each of two tables of size $n \geq (1+\epsilon)m$. The element must be placed in one of the tables at one of the two locations. Upon insertion of a new element, old elements get kicked out and move around, kicking out other elements if necessary, until either a loop is detected or the insertion process halts. In case of a loop, the entire table is rehashed. The expected time for an insertion is still $O(1)$, and the worst-case successful search time is bounded by 2. However, one needs a powerful collection of hash functions, as each rehash operation requires an entirely new and independent set of hash values.

Let us denote by M_n the maximal successful search time, that is, the maximal age among any of the m elements in the hash table, and by T_n the maximum insertion cost of an element. In an FCFS strategy, we note that $M_n = T_n - 1$, but this is no longer true for other strategies. In fact, in this paper we show the following.

THEOREM 1.1. *In open addressing with Robin Hood collision resolution, there exists a constant C depending upon α only such that*

$$\lim_{n\to\infty} \mathbf{P}\{M_n \geq \log_2\log n + C\} = 0 \ .$$

We will see that $C \to \infty$ when $\alpha \to 1$, so this result is meaningful only when

$\alpha < 1$. The result above implies an exponential improvement over the FCFS strategy. Furthermore, this bound is optimal modulo a finite constant, as follows.

THEOREM 1.2. *In open addressing with Robin Hood collision resolution (and any method of breaking ties),*

$$\mathbf{P}\{M_n \le \log_2 \log n - \log_2(6\log(8/\alpha))\} = O(1/\sqrt{n}) \ .$$

The implications of this should not be underestimated, as open addressing tables are the oldest and simplest hashing structures. The multiple-choice hashing methods in their original form are intrinsically chaining methods, and thus slightly more inefficient spacewise.

The $\log_2 \log n$ behavior follows, roughly speaking, from the following observation. If we place all m elements in their first choice bins, then all but one element from each bin must move to another bin. The number of these excess elements is about m^2/n times a constant. Just looking at these displaced elements, we repeat the argument k times, obtaining increasingly smallest sets to be displaced. After k steps, the number of elements left is of the order of $n(m/n)^{2^k}$, or $n\alpha^{2^k}$. This is of constant order when k is about $\log_2 \log n$.

1.1. Balls in urns. Throw m balls uniformly at random into n urns. Let urn i receive N_i balls, and define

$$A = \sum_{i=1}^{n} (N_i - 1)_+$$

as the number of balls left after removing one ball from each occupied urn. We say that A has the (m, n) urn distribution.

The (m, n) urn distribution. Let A have the (m, n) urn distribution. Then

$$\mathbf{E}\{A\} = \sum_{j=1}^{m} \left(1 - (1 - 1/n)^{j-1}\right) \ .$$

Note that $(1 - 1/n)^m \ge 1 - m/n$ and $(1 - 1/n)^m \le 1 - m/n + m(m-1)/2n^2$, so that

$$\begin{aligned}
\frac{m^2}{2n} &\ge \frac{m(m-1)}{2n} \\
&= \sum_{j=1}^{m-1} \frac{j}{n} \\
&\ge \mathbf{E}\{A\} \\
&\ge \sum_{j=1}^{m-1} \frac{j}{n} - \sum_{j=1}^{m-1} \frac{j(j-1)}{2n^2} \qquad (1) \\
&= \frac{m(m-1)}{2n} - \frac{m(m-1)(m-2)}{6n^2} \\
&\ge \frac{m(m-1)}{3n} \\
&\ge \frac{m^2}{4n} \quad \text{(the last step is true only if } m \ge 4) \ .
\end{aligned}$$

We also need some concentration inequalities for A. To present these inequalities, let $(X_1, \ldots, X_n)$ be a vector of independent random variables (on an arbitrary measurable space S), let $f : S \to \mathbf{R}$ be a measurable function, and set

$$Z = f(X_1, \ldots, X_m) \ .$$

Let $X_1', \ldots, X_m'$ be independent copies of $X_1, \ldots, X_m$, and write

$$Z^{(i)} = f(X_1, \ldots, X_{i-1}, X_i', X_{i+1}, \ldots, X_m) \ .$$

The Efron–Stein inequality (Efron and Stein (1981); Steele (1986)) states that

$$\mathbf{V}\{Z\} \le \frac{1}{2}\mathbf{E}\left\{\sum_{i=1}^{m}(Z - Z^{(i)})^2\right\} \ .$$

If $Z \equiv A$, and $X_1, \ldots, X_m$ are the urns chosen by elements 1 through m, and X_i' is independent of the X_j's and distributed as X_i, then $|Z^{(i)} - Z| \le 1$. Thus, $\mathbf{V}\{Z\} \le m/2$. With the inequalities for $\mathbf{E}\{A\}$ taken into account, we have, by Chebyshev's inequality, for all $t > 0$,

$$\mathbf{P}\left\{|A - \mathbf{E}\{A\}| \ge t\right\} \le \frac{\mathbf{V}\{A\}}{t^2} \le \frac{m}{2t^2} \ .$$

1.2. The head-and-belly view. The construction of the hash table may be looked at in a global manner for Robin Hood strategies, since every permutation of the input sequence produces the same hash table. We start by placing all elements at their first choices $X_{i,0}$, $1 \le i \le m$. Some bins in the table may have many elements, but that is acceptable. We call this the first stage. At the kth stage in our construction, picture a hash table ("the head") containing elements of age k, possibly many per cell, and a second hash table ("the belly") containing at most one element per cell, and that element is of age less than k. Furthermore—and this is crucial—if cell i in the head is occupied, then cell i is empty in the belly. This head-and-belly view allows us to proceed, by letting k grow until finally the head is empty, and all elements are in the belly.

The belly is initially empty, and all elements are in the head, in stage one. Given the $(k-1)$st stage situation, we construct the kth stage as follows (see Figure 1.1).

A. All elements in the $(k-1)$-stage head that are in positions two and above in their bins move to a randomly selected bin in the k-head.

B. The remaining elements of the $(k-1)$-head (at most one per cell) are added to the $(k-1)$-belly (in the corresponding position). Note that this may create some conflicts with the k-head just created.

C. While there is a head-belly conflict, take a conflicting element in the belly (that is, an element in cell i, such that the k-head also has an element in cell i), and let it start hopping uniformly and randomly (and aging by one with each hop), according to the rules of Robin Hood hashing, until it, or the element it causes to move, finds a position in a cell by itself in the belly, without conflict with the k-head, or a position in the k-head (an element that reaches age k must move to the k-head). In the latter case, a new conflict may be triggered. At the end of this, there is no further conflict, and the resulting tables are called the k-head and the k-belly.

LEMMA 1.3. *Let N be the number of elements added to the k-head in step C, given that the k-head has at most K elements to start with after steps A and B,*

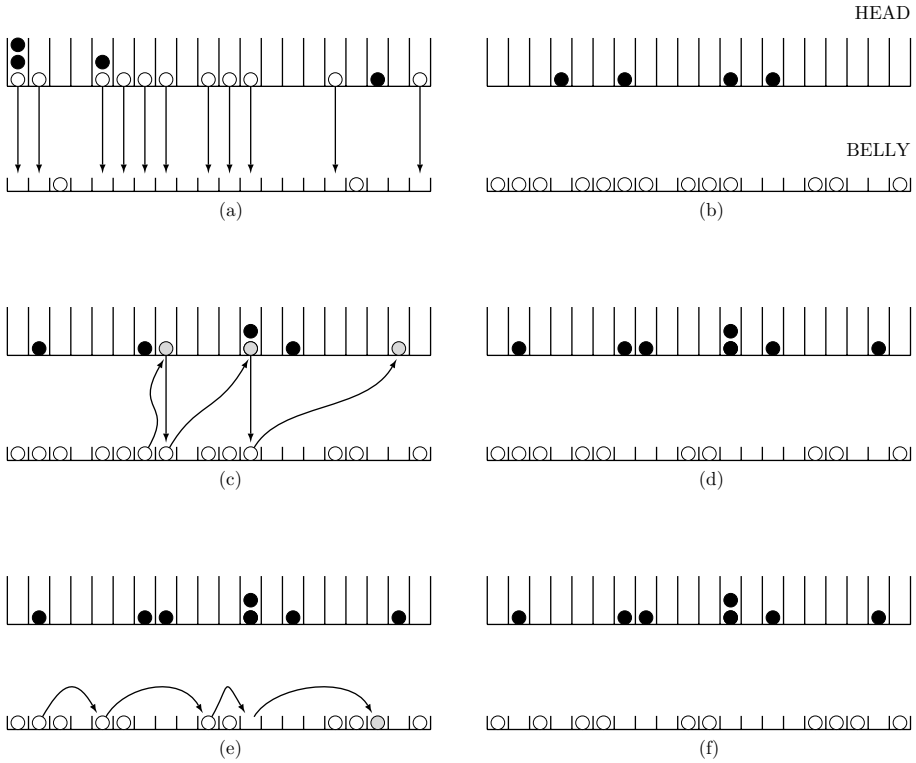

FIG. 1.1. *In* (a)*, we show a* $(k-1)$*-head that is not empty. The elements in position one in their bins (in white) move to the belly (step B). The other elements (in black) move to a random position in the* k*-head, shown in figure* (b)*. This is step A. Clearly, there are some conflicts between head and belly in* (b)*. In step C, these are resolved. For each conflict, an element in the belly is taken and is moved to a random position in the belly. For example, in* (c)*, we show the moves of an element, as it first ages to age* k *(so that its randomly picked position lands it in the head), which triggers a new conflict in the belly, which is immediately taken care of by letting that element move to a random position, which again happens to be in the head (gray element), and finally, the last conflict generated leads to yet another element in the head, causing no further conflicts. The resulting configuration is* (d)*. In* (e)*, the last remaining conflict is taken care of by random hops, resulting in the final configuration* (f) *of the* k*-belly and* k*-head. In example* (e)*, all hops remain in the belly, and result finally in a cell in the belly being filled with a new element.*

and given any distribution of elements in belly and head at that point. Then, with $\lambda = 1/\log(1/\alpha)$*,* N *is stochastically smaller than* $\lambda G_K + K$*, where* G_K *is a gamma* (K) *random variable. In particular,* $\mathbf{E}\{N\} \le (\lambda+1)K$*, and*

$$\mathbf{P}\{N \ge (2\lambda+1)K\} \le \left(\frac{2}{e}\right)^K .$$

Proof. There are initially at most K elements in the belly that can cause a conflict with the head. When these elements move, at each step we have a probability at least $1-\alpha$ of finding an empty slot (empty for both head and belly). When such a slot is found, the chain of moves ends. In each step, at most one element moves to the k-head. The number of additions to the k-head to just eliminate one belly conflict is thus stochastically smaller than one plus a geometric (α) random variable Y:

$$\mathbf{P}\{Y \ge i\} \le \alpha^i, \quad i \ge 0 .$$

If E is unit exponential, then we see that

$$\mathbf{P}\{\lambda E \geq i\} = \exp\left(-\frac{i}{\lambda}\right) = \alpha^i \ ,$$

provided that $\alpha = \exp(-1/\lambda)$ or $\lambda = 1/\log(1/\alpha)$. Therefore, $Y \prec E/\log(1/\alpha)$. Since we have to eliminate K possible conflict elements in the belly, the total number of elements added to the head is stochastically smaller than $K + Y_1 + \cdots + Y_K$, where the Y_i's are independent and are all stochastically dominated by λE. Thus, if $E_1, \ldots, E_K$ are independent exponential random variables, and G_K is a gamma (K) random variable, we see that the number N of additions to the head in part C is stochastically smaller than $K + \lambda(E_1 + \cdots + E_K) \stackrel{\mathcal{L}}{=} K + \lambda G_K$. In other words,

$$\begin{aligned}
\mathbf{P}\{N \geq (2\lambda+1)K\} &\leq \mathbf{P}\{\lambda G_K \geq 2\lambda K\} \\
&= \mathbf{P}\{G_K \geq 2K\} \\
&\leq \mathbf{E}\left\{e^{tG_K} e^{-2tK}\right\} \quad (\text{any } t > 0) \\
&= \left(\frac{e^{-2t}}{1-t}\right)^K \\
&= \left(\frac{2}{e}\right)^K \quad (\text{take } t = 1/2) \ .
\end{aligned}$$

This concludes the proof of Lemma 1.3. □

It is important to note that if $\alpha \to 1$, then $\lambda \to \infty$, so the results below are meaningful only when $\alpha < 1$.

LEMMA 1.4. *Define $b = (2\lambda+2)\alpha$ and assume that $b < 1$. Let D be the integer*

$$D = \left\lfloor \log_2\left(\frac{2}{3\log(1/b)}\right) - 0.1 \right\rfloor \ .$$

Let Z be the number of elements in the r-head, with $r = \lfloor \log_2 \log n \rfloor + D$. Then

$$\lim_{n\to\infty} \mathbf{P}\left\{Z \geq \frac{nb^{2^r}}{2\lambda+2}\right\} = 0 \ .$$

In particular,

$$\lim_{n\to\infty} \mathbf{P}\left\{Z \geq n^{1-1/(6\times 2^{0.1})}\right\} = 0 \ .$$

Proof. Given that the $(k-1)$-head has K elements or less, then if A denotes the number of elements in the k-head after step A (not including steps B and C), we have

$$\mathbf{E}\{A\} \leq \frac{K^2}{2n}$$

and

$$\mathbf{P}\{|A - \mathbf{E}\{A\}| \geq t\} \leq \frac{K}{2t^2} \ .$$

In particular, we note that

$$\mathbf{P}\left\{A \geq \frac{K^2}{n}\right\} \leq \frac{2n^2}{K^3} \ .$$

After steps B and C, N more elements are added to the k-head. We have

$$\mathbf{P}\left\{A+N \geq \frac{(2\lambda+2)K^2}{n}\right\} \leq \mathbf{P}\left\{A \geq \frac{K^2}{n}\right\} + \mathbf{P}\left\{N \geq \frac{(2\lambda+1)K^2}{n} \Big| A \leq \frac{K^2}{n}\right\}$$
$$\leq \frac{2n^2}{K^3} + \left(\frac{2}{e}\right)^{\frac{K^2}{n}} .$$

Now define the sequence a_k by $a_0 = m$,

$$a_{k+1} = \frac{(2\lambda+2)a_k^2}{n} .$$

Then it is easy to see that for $k > 0$,

$$a_k = \frac{n}{2\lambda+2}\left(\frac{(2\lambda+2)a_0}{n}\right)^{2^k} = \frac{n}{2\lambda+2}\left((2\lambda+2)\alpha\right)^{2^k} .$$

Let A_k, N_k denote the k-head cardinalities as defined above. Then

$$\begin{aligned}\mathbf{P}\{A_r + N_r \geq a_r\} \leq\ & \mathbf{P}\left\{A_r + N_r \geq a_r \mid A_{r-1} + N_{r-1} \leq a_{r-1}\right\} \\ & + \mathbf{P}\{A_{r-1} + N_{r-1} \geq a_{r-1} \mid A_{r-2} + N_{r-2} \leq a_{r-2}\} \\ & + \cdots + \mathbf{P}\{A_1 + N_1 \geq a_1 \mid A_0 + N_0 \leq a_0\} ,\end{aligned}$$

since $A_0 + N_0 = m = a_0$. By the definition of the a_k sequence, we note that the general term

$$\mathbf{P}\{A_k + N_k \geq a_k \mid A_{k-1} + N_{k-1} \leq a_{k-1}\}$$

is bounded by

$$\frac{2n^2}{a_{k-1}^3} + \left(\frac{2}{e}\right)^{\frac{a_{k-1}^2}{n}} .$$

Thus, defining $b = (2\lambda+2)\alpha$, and assuming that $b < 1$, we have

$$\begin{aligned}\mathbf{P}\{A_r + N_r \geq a_r\} &\leq \sum_{k=0}^{r-1}\left(\frac{2n^2}{a_k^3} + \left(\frac{2}{e}\right)^{\frac{a_k^2}{n}}\right) \\ &= \sum_{k=0}^{r-1}\left(\frac{2(2\lambda+2)^3}{n\left((2\lambda+2)\alpha\right)^{3\times 2^k}} + \left(\frac{2}{e}\right)^{\frac{\left((2\lambda+2)\alpha\right)^{2^{k+1}} n}{(2\lambda+2)^2}}\right) \\ &\leq C\left(\frac{1}{nb^{3\times 2^{r-1}}} + \left(\frac{2}{e}\right)^{\frac{nb^{2^r}}{(2\lambda+2)^2}}\right) \\ &\qquad \text{(for some constant } C) .\end{aligned}$$

Let $r = \lfloor \log_2 \log n \rfloor + D$ for some integer D. Then $2^{D-1}\log n \leq 2^r \leq 2^D \log n$, and $nb^{2^r} \geq nb^{3\times 2^{r-1}} \geq nb^{(3/2)2^D \log n} = n^{1+(3/2)2^D \log b}$. Thus, if $2^D \log(1/b) < 2/3$, then

$$\lim_{n\to\infty} \mathbf{P}\{A_r + N_r \geq a_r\} = 0 .$$

The last statement follows from the fact that

$$\begin{aligned} nb^{2^r} &\le nb^{2^{D-1}\log n} \\ &= n^{1-2^{D-1}\log(1/b)} \\ &\le n^{1-2^{\log_2\left(\frac{2}{3\log(1/b)}\right)-2.1}\log(1/b)} \\ &= n^{1-1/(6\times 2^{0.1})} \ . \end{aligned}$$

This concludes the proof of Lemma 1.4. □

Remark. The condition $b = (2\lambda+2)\alpha < 1$ reduces to $(2 + 2/\log(1/\alpha))\alpha < 1$. This is satisfied if $\alpha \le 0.306891\ldots$.

LEMMA 1.5. *Let r be as in Lemma 1.4. Then the probability that the $(r+3)$-head has at least one element is $o(1)$. Thus, with probability tending to one, the maximum successful search time is bounded by $r+2$.*

Proof. Let r be as in Lemma 1.4, and let Z be the number of elements in the r-head. Then it is of interest to study Z_j, the number of elements in the $(r+j)$-head, for $j > 0$. Recall that $a_r \le n^{1-1/(6\times 2^{0.1})}$. Given Z, we have $\mathbf{E}\{Z_1 \mid Z\} \le (2+\lambda)Z^2/2n$, where we used (1) and Lemma 1.3. On $Z \le a_r$, we have $\mathbf{E}\{Z_1 \mid Z\} \le (2+\lambda)a_r^2/2n \le (2+\lambda)n^{1-2^{0.9}/6}$. Thus, $\mathbf{P}\{Z_1 > (2+\lambda)\log n \times n^{1-2^{0.9}/6} \mid Z\} \le 1/\log n$ by Markov's inequality, on $Z \le a_r$. Next, on $Z_1 \le (2+\lambda)\log n \times n^{1-2^{0.9}/6}$,

$$\mathbf{E}\{Z_2 \mid Z_1\} \le (2+\lambda)\left((2+\lambda)\log n \times n^{1-2^{0.9}/6}\right)^2/2n < (2+\lambda)^3\log^2 n \times n^{1-2^{1.9}/6} \ .$$

Thus,

$$\mathbf{P}\left\{Z_2 > (2+\lambda)^3\log^3 n \times n^{1-2^{1.9}/6} \mid Z_1\right\} \le \frac{1}{\log n} \ .$$

Finally, on $Z_2 \le (2+\lambda)^3\log^3 n \times n^{1-2^{1.9}/6}$,

$$\mathbf{E}\{Z_3 \mid Z_2\} \le (2+\lambda)\left((2+\lambda)^3\log^3 n \times n^{1-2^{1.9}/6}\right)^2/2n < (2+\lambda)^7\log^6 n \times n^{1-2^{2.9}/6} = o(1) \ .$$

Thus,

$$\mathbf{P}\{Z_3 \ge 1 \mid Z_2\} \le \mathbf{E}\{Z_3 \mid Z_2\} = o(1) \ .$$

Thus,

$$\begin{aligned} \mathbf{P}\{Z_3 > 0\} \le\ & \mathbf{P}\left\{Z \ge n^{1-1/(6\times 2^{0.1})}\right\} \\ & + \mathbf{P}\left\{Z_1 \ge (2+\lambda)\log n \times n^{1-2^{0.9}/6} \mid Z \le n^{1-1/6\times 2^{0.1}}\right\} \\ & + \mathbf{P}\left\{Z_2 \ge (2+\lambda)^3\log^3 n \times n^{1-2^{1.9}/6} \mid Z_1 \le (2+\lambda)\log n \times n^{1-2^{0.9}/6}\right\} \\ & + \mathbf{P}\left\{Z_3 \ge 1 \mid Z_2 \le (2+\lambda)^3\log^3 n \times n^{1-2^{1.9}/6}\right\} \\ =\ & o(1). \qquad \square \end{aligned}$$

Thus far, we have shown that if $\alpha \le 0..306891\ldots$, the probability that the maximal displacement of any element is more than $\log_2\log n + C$ for a constant C depending upon α only tends to zero. This matches the lower bound that we will present later on. We will now fill the gap and show this result for all α.

Proof of Theorem 1.1. In the proof, we let $m = \lfloor \alpha n \rfloor$ without loss of generality. We define the level of an element as the number of probes required to locate it. The level is one if the element is stored at its original location. (Thus, the level is one more than the age of an element.) We define the level of a cell in the table as the level of the element occupying the cell if the cell is occupied, and zero otherwise. At time t, when the table holds t elements, we define

$$N_t(i) = \#\text{ elements of level} \geq i \ .$$

Note that $N_t(i)$ is monotone in t for fixed i. When inserting the tth element, let K_t be the number of cells probed. Clearly, K_t is geometric:

$$\mathbf{P}\{K_t = k\} = \left(1 - \frac{t-1}{n}\right)\left(\frac{t-1}{n}\right)^{k-1}, \quad k \geq 1 \ .$$

We begin with a rough tail bound for $N_t(i)$.

LEMMA 1.6. *Define*

$$\beta = \frac{2(1+\alpha)}{(1-\alpha)\log((1+\alpha)/2\alpha)} \ .$$

Then for all $t \leq m$, $i \geq 1$,

$$\mathbf{P}\left\{N_t(i) \geq \beta m \alpha^{i-1}\right\} \leq \mathbf{P}\left\{N_m(i) \geq \beta m \alpha^{i-1}\right\} \leq \exp\left(-\frac{1+\alpha}{1-\alpha} m \alpha^{i-1}\right) \ .$$

Proof. When we insert the tth element, we can increase the number of elements of level $\geq i$ by at most $(K_t - i)_+$. Therefore,

$$N_t(i) \leq \sum_{j=1}^{t} (K_j - i)_+ \ ,$$

where $K_1, K_2, \ldots, K_t$ are independent. As $K_1 \prec K_2 \prec \cdots \prec K_t$ (where $\prec$ denotes stochastic ordering), we see that

$$N_t(i) \prec \sum_{j=1}^{t} (K_{t,j} - i)_+ \ ,$$

where $K_{t,1}, \ldots, K_{t,t}$ are i.i.d. and distributed as K_t. We will use Chernoff bounding (Chernoff (1952); Hoeffding (1963); Azuma (1967); McDiarmid (1989, 1998)). Let $\lambda, u > 0$. Then

$$\begin{aligned}
\mathbf{P}\{N_t(i) \geq u\} &\leq \mathbf{P}\{N_m(i) \geq u\} \\
&\leq e^{-\lambda u}\left(\mathbf{E}\left\{e^{\lambda(K_m - i)_+}\right\}\right)^m \\
&\leq e^{-\lambda u}\left(\mathbf{P}\{K_m \leq i\} + \sum_{j=1}^{\infty} e^{\lambda j}\mathbf{P}\left\{K_m = i + j\right\}\right)^m \\
&\leq e^{-\lambda u}\left(1 + \sum_{j=1}^{\infty} e^{\lambda j}\left(1 - \frac{m-1}{n}\right)\left(\frac{m-1}{n}\right)^{i+j-1}\right)^m
\end{aligned}$$

$$
\begin{aligned}
&\le e^{-\lambda u}\left(1+\sum_{j=1}^{\infty} e^{\lambda j}\,(\alpha)^{i+j-1}\right)^m \\
&\le e^{-\lambda u}\left(1+\alpha^{i-1}\frac{e^{\lambda}\alpha}{1-e^{\lambda}\alpha}\right)^m \\
&= e^{-\lambda u}\left(1+\frac{1+\alpha}{1-\alpha}\alpha^{i-1}\right)^m \\
&\quad (\text{set } e^{\lambda}\alpha=(1+\alpha)/2) \\
&\le \exp\left(-u\log((1+\alpha)/2\alpha)+\frac{1+\alpha}{1-\alpha}\alpha^{i-1}m\right) \\
&= \exp\left(-\frac{1+\alpha}{1-\alpha}\alpha^{i-1}m\right) \\
&\quad \left(\text{set } u=\tfrac{2(1+\alpha)\alpha^{i-1}m}{(1-\alpha)\log((1+\alpha)/2\alpha)}\right) .
\end{aligned}
$$

This concludes the proof. □

Note that, for any given R, the cardinality of the R-head in the previous section is not more than $N_m(R)$. Assume that we were to start with an R-head of size $m' \le \alpha' n$, where R and α' are defined in Lemma 1.7. Then, by mimicking the argument of the previous section, we have the following.

LEMMA 1.7. *Define* $b=(2\lambda+2)\alpha'$ *and assume that* $b<1$. *Define*

$$D=\left\lfloor \log_2\left(\frac{2}{3\log(1/b)}\right)-0.1\right\rfloor$$

and

$$R=\lceil \lambda\log\left(\beta(2\lambda+3)\right)\rceil \ .$$

Let Z *be the number of elements in the* $(R+r)$*-head, with* $r=\lfloor \log_2\log n\rfloor + D$. *Then*

$$\lim_{n\to\infty}\mathbf{P}\left\{Z\ge\frac{nb^{2^r}}{2\lambda+2}\right\}=0 \ .$$

In particular,

$$\lim_{n\to\infty}\mathbf{P}\left\{Z\ge n^{1-1/(6\times 2^{0.1})}\right\}=0 \ .$$

Note in particular that the only difference between Lemma 1.4 and Lemma 1.7 is in the replacement of α in the definition of b by α'. The definition of λ is unaltered. Lemma 1.5 would then imply that with probability tending to one, $M_n \le R+r+2$, with r as in Lemma 1.7. Since the number of elements in the R-head is random, we use the following argument, based on Lemma 1.6. Define

$$\beta=\frac{2(1+\alpha)}{(1-\alpha)\log((1+\alpha)/2\alpha)} \ .$$

Then

$$
\begin{aligned}
&\mathbf{P}\ \{M_n > R+r+2\} \\
&\quad \le \mathbf{P}\left\{N_m(R)\ge\beta m\alpha^{R-1}\right\}+\mathbf{P}\{M_n>R+r+2\mid N_m(R)\le\beta m\alpha^{R-1}\} \\
&\quad \le \exp\left(-\frac{1+\alpha}{1-\alpha}m\alpha^{R-1}\right)+o(1) \ ,
\end{aligned}
$$

provided that $\beta m\alpha^{R-1} \le \alpha' n$, where $\alpha' = 1/(2\lambda+3)$ (to make b in Lemma 1.7 less than one). But $\beta m\alpha^{R-1} \le \beta n\alpha^R$, and thus it suffices to set

$$R = \left\lceil \frac{\log\left(\beta(2\lambda+3)\right)}{\log(1/\alpha)} \right\rceil = \lceil \lambda \log\left(\beta(2\lambda+3)\right) \rceil \ .$$

With this choice of R, and the choice of r given in Lemma 1.7, we thus conclude that

$$\lim_{n\to\infty} \mathbf{P}\{M_n > R + r + 2\} = 0 \ .$$

This concludes the proof of Theorem 1.1. □

Proof of Theorem 1.2. We prove the theorem by construction. This is done by identifying a subset of elements that must be of age at least 1, a further subset of age 2, and so forth. We show that this process can be carried out at least k times with high probability until we run out of elements, where k is of the order of $\log\log n$. We consider all values $X_{i,0}$, $1 \le i \le m$, first. Consider that ball i is dropped in urn $X_{i,0}$. If an urn receives j elements, then at least $j-1$ of them must move on, and will have an age at least equal to 1. Who moves on depends upon the tiebreaking strategy, but in our analysis, it only matters to know how many move on. We introduce A_r, the number of elements that are marked in the rth step. A_1 is the number of elements of age at least 1 in the process above. We formally set $A_0 = m$. Given A_{r-1}, we take the A_{r-1} elements of age at least $r-1$ (note: these are not the only ones of age at least $r-1$) and look at their $X_{i,r}$ values, with the number of i's clearly being A_{r-1}. We consider the subset that has to move on, so only urns with at least two elements can be of any use. Note that in view of the tiebreaking policy, an earlier element may move on. But in any case, if an urn receives j elements from the A_{r-1}, at least $j-1$ of them must move on and increase their age by one. These $j-1$ elements are collected and form a further subset of size A_r, consisting entirely of elements of age at least r.

We return now to our process A_r. We observe that A_r has the (A_{r-1}, n) urn distribution. The inequalities (1) suggest natural bounds for A_r. We define an integer sequence a_r such that with high probability, $a_r \le A_r$. We have $a_0 = m = \lceil \alpha n \rceil$. Then set

$$a_{r+1} = a_r^2/8n \ .$$

Note that

$$a_r = 8n(a_0/8n)^{2^r} \ge 8n(\alpha/8)^{2^r} \ .$$

Define the events

$$E_r = \cap_{j\le r}[a_j \le A_j]$$

and let $(.)^c$ denote the complement of an event. Observe the following:

$$\mathbf{P}\{E_r^c\} \le \mathbf{P}\{E_1^c\} + \sum_{j=2}^{r} \mathbf{P}\{E_j^c \mid E_0, \ldots, E_{j-1}\} = \sum_{j=2}^{r} \mathbf{P}\{E_j^c \mid E_{j-1}\} \ .$$

Also, if r is so small that at all times $a_{r-1} \ge 4$ (a condition that is needed so that we may apply the inequalities derived in section 1.1), we have

$$\begin{aligned}\mathbf{P}\{E_r^c \mid E_{r-1}\} &\le \mathbf{P}\left\{[A_r < a_r] \mid a_{r-1} \le A_{r-1}\right\} \\ &\le \mathbf{P}\left\{A_r < \frac{1}{2}\mathbf{E}\{A_r \mid a_{r-1} \le A_{r-1}\} \mid a_{r-1} \le A_{r-1}\right\} \ ,\end{aligned}$$

provided that $a_r \le (1/2)\mathbf{E}\{A_r \mid a_{r-1} \le A_{r-1}\}$. But this follows from $a_r = a_{r-1}^2/8n = (1/2)a_{r-1}^2/4n \le \mathbf{E}\{A_r \mid a_{r-1} \le A_{r-1}\}$. We let A have the $(\lceil a_{r-1} \rceil, n)$ urn distribution. Thus,

$$\begin{aligned}
\mathbf{P}\{E_r^c \mid E_{r-1}\} &\le \mathbf{P}\left\{A < \frac{1}{2}\mathbf{E}\{A\}\right\} \\
&\le \frac{\lceil a_{r-1} \rceil}{2(\mathbf{E}\{A\}/2)^2} \\
&\le \frac{2\lceil a_{r-1} \rceil}{((\lceil a_{r-1} \rceil)^2/4n)^2} \\
&\le \frac{32n^2}{a_{r-1}^3} \\
&\le \frac{(8/\alpha)^{3\times 2^{r-1}}}{16n} \ .
\end{aligned}$$

Therefore,

$$\mathbf{P}\{E_r^c\} \le \sum_{j=0}^{r-1} \frac{(8/\alpha)^{3\times 2^j}}{16n} = \frac{1}{16n}\sum_{j=0}^{r-1}(8/\alpha)^{3\times 2^j} \le \frac{(8/\alpha)^{3\times 2^{r-1}}}{16n(1-(\alpha/8)^3)} \ .$$

Set $r = \lceil \log_2(c \log n) \rceil$ for $c > 0$, and note that the upper bound is not more than

$$\frac{n^{3c\log(8/\alpha)-1}}{16(1-\alpha/8)} \ ;$$

this tends to zero if $c < 1/3\log(8/\alpha)$. With that choice of r, we note that

$$a_r \ge \frac{8n}{(8/\alpha)^{3\times 2^r}} \ge \frac{8n}{n^{6c\log(8/\alpha)}} \ge 8 \ ,$$

provided we take $c = 1/6\log(8/\alpha)$. With such a choice, we then have

$$\mathbf{P}\{A_r = 0\} \le \mathbf{P}\{A_r < a_r\} \le \mathbf{P}\{E_r^c\} \le \frac{1}{16(1-(\alpha/8)^3)\sqrt{n}} \ . \qquad \square$$

ONLINE ROUTING IN TRIANGULATIONS*

PROSENJIT BOSE† AND PAT MORIN†

Abstract. We consider online routing algorithms for routing between the vertices of embedded planar straight line graphs. Our results include (1) two deterministic memoryless routing algorithms, one that works for all Delaunay triangulations and the other that works for all regular triangulations; (2) a randomized memoryless algorithm that works for all triangulations; (3) an $O(1)$ memory algorithm that works for all convex subdivisions; (4) an $O(1)$ memory algorithm that approximates the shortest path in Delaunay triangulations; and (5) theoretical and experimental results on the competitiveness of these algorithms.

Key words. routing, online algorithms, Delaunay triangulations, shortest path, spanning path

1. Introduction.

Path finding, or routing, is central to a number of fields, including geographic information systems, urban planning, robotics, and communication networks. In many cases, knowledge about the environment in which routing takes place is not available beforehand, and the vehicle/robot/packet must learn this information through exploration. Algorithms for routing in these types of environments are referred to as *online* [3] routing algorithms.

In this paper we consider online routing in the following abstract setting: The environment is a planar straight line graph [17], T, with n vertices, whose edges are weighted by the Euclidean distance between their endpoints, the source v_{src} and destination v_{dst} are vertices of T, and a packet can only move on edges of T. Initially, a packet only knows v_{src}, v_{dst}, and $N(v_{\text{src}})$, where $N(v)$ denotes the set of vertices adjacent to v.

We classify online routing algorithms based on their use of memory and/or randomization. Define v_{cur} as the vertex at which the packet is currently stored. A routing algorithm is called *memoryless* if the next step taken by a packet depends only on v_{cur}, v_{dst}, and $N(v_{\text{cur}})$. An algorithm is *randomized* if the next step taken by a packet is chosen randomly from $N(v_{\text{cur}})$. A randomized algorithm is memoryless if the distribution used to choose from $N(v_{\text{cur}})$ is a function only of v_{cur}, v_{dst}, and $N(v_{\text{cur}})$.

The justification for studying the memory requirements of routing algorithms comes from communication networks, in which memory used by an algorithm results in header information that travels with a packet. Since this information is used only for routing purposes and is of no use to the sender or receiver, it effectively produces a decrease in communication bandwidth.

For an algorithm $\mathcal{A}$ we say that a graph *defeats* $\mathcal{A}$ if there is a source/destination pair such that a packet never reaches the destination when beginning at the source. If $\mathcal{A}$ finds a path P from v_{src} to v_{dst}, we call P the $\mathcal{A}$ path from v_{src} to v_{dst}. Here

*Received by the editors March 15, 2000; accepted for publication (in revised form) January 28, 2004; published electronically May 25, 2004. This research was supported by the Natural Sciences and Engineering Research Council of Canada.

we use the term *path* in an intuitive sense rather than a strict graph theoretic sense, since P may visit the same vertex more than once.

In this paper we also consider, as a special case, a class of "well-behaved" triangulations. The *Voronoi diagram* [16] of S is a partitioning of space into cells such that all points within a Voronoi cell are closer to the same element $p \in S$ than any other point in S. The *Delaunay triangulation* is the straight line face dual of the Voronoi diagram; i.e., two points in S have an edge between them in the Delaunay triangulation if their Voronoi cells have an edge in common.

In this paper we consider several different routing algorithms and compare their performance empirically. In particular, we describe

1. a memoryless algorithm that is not defeated by any Delaunay triangulation;
2. a memoryless algorithm that is not defeated by any regular triangulation;
3. a memoryless randomized algorithm that uses 1 random bit per step and is not defeated by any triangulation;
4. an algorithm that only remembers a constant number of vertex locations that is not defeated by any convex subdivision (we say that such an algorithm *uses* $O(1)$ *memory*);
5. an algorithm for Delaunay triangulations that uses $O(1)$ memory in which a packet never travels more than a constant times the Euclidean distance between v_{src} and v_{dst}; and
6. a theoretical and empirical study of the quality (length) of the paths found by these algorithms.

The first four routing algorithms are described in section 2. Section 3 presents theoretical and empirical results on the length of the paths found by these algorithms and describes our algorithm for Delaunay triangulations. A discussion of related work is provided in section 4. Finally, section 5 summarizes our results and describes directions for future research.

2. Four simple algorithms. In this section we describe four online routing algorithms and prove theorems about which types of graphs never defeat them. We begin with the simplest (memoryless) algorithms and proceed to the more complex algorithms.

However, before beginning we should note that deterministic memoryless algorithms have some inherent limitations. Consider what happens when such an algorithm tries to route from one of the vertices of the outer face to v_{dst} in the graphs shown in Figure 2.1. In each of these graphs, the neighborhoods of the corner vertices look the same. Therefore, any deterministic memoryless algorithm must make the same decisions at the corners in each of the graphs. There are then four cases to consider.

1. At all three corners, the algorithm chooses to use an edge of the convex hull. In this case, the algorithm will fail on the graph in Figure 2.1.a since it will never enter the interior of the convex hull and will therefore never reach v_{dst}.
2. At two of the corners, the algorithm chooses to use an edge of the convex hull and at the third corner it does not. We can assume, without loss of generality that the third corner is the bottom right corner. In this case, the algorithm will fail on the graph shown in Figure 2.1.b since the only way to reach v_{dst} from the convex hull is via one of the two paths in the other two corners.
3. At one of the corners, the algorithm chooses to use an edge of the convex hull and at the other two corners it does not. We may assume without loss of generality that the corner that uses the interior edge is the top corner. In

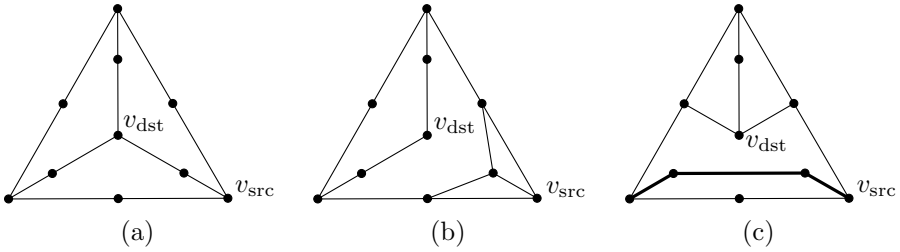

FIG. 2.1. *No deterministic memoryless routing algorithm can work for all* 2*-connected graphs.*

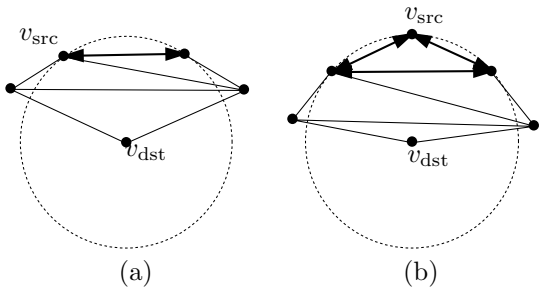

FIG. 2.2. *Triangulations that defeat the greedy routing algorithm.*

this case, the algorithm will fail on the graph in Figure 2.1.c since it will get trapped cycling among the edges shown in bold.

4. At all of the corners, the algorithm chooses not to use an edge of the convex hull. In this case the algorithm will also fail on the graph in Figure 2.1.c for the same reasons as in case 3.

Since the graphs in Figure 2.1 are all 2-connected we have the following negative result.

LEMMA 2.1. *No deterministic memoryless algorithm works for all* 2*-connected planar graphs.*

2.1. Greedy routing. The *greedy routing* algorithm always moves the packet to the neighbor $gdy(v_{\text{cur}})$ of v_{cur} that minimizes $dist(gdy(v_{\text{cur}}), v_{\text{dst}})$, where $dist(p, q)$ denotes the Euclidean distance between p and q. In the case of ties, one of the vertices is chosen arbitrarily. The greedy routing algorithm can be defeated by a triangulation T in two ways (the first way is an important special case of the second): (1) the packet can get trapped moving back and forth on an edge of the triangulation (Figure 2.2.a), or (2) the packet can get trapped on a cycle of three or more vertices (Figure 2.2.b). However, as the following theorem shows, neither of these situations can occur if T is a Delaunay triangulation.

THEOREM 2.2. *There is no point set whose Delaunay triangulation defeats the greedy routing algorithm.*

Proof. We proceed by showing that every vertex v of T has a neighbor that is strictly closer to v_{dst} than v is. Thus, at each routing step, the packet gets closer to v_{dst} and therefore, after at most n steps, reaches v_{dst}. Refer to Figure 2.3.

Consider the Voronoi diagram [16] $VD(T)$ of the vertices of T and let e be the first edge of $VD(T)$ intersected by the directed line segment (v, v_{dst}). Note that e is on the boundary of two Voronoi cells, one for v and one for some other vertex u, and the

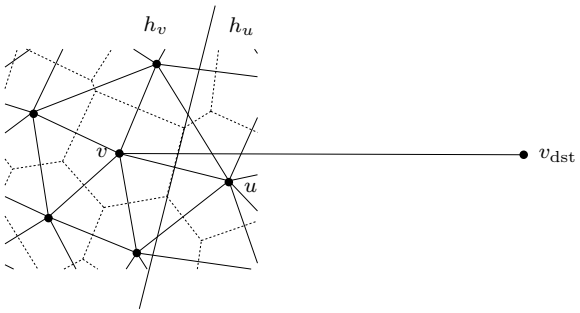

FIG. 2.3. *The proof of Theorem* 2.2.

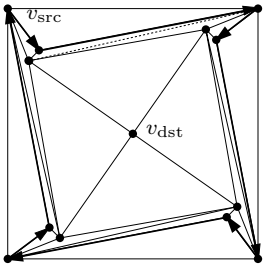

FIG. 2.4. *A triangulation that defeats the compass routing algorithm.*

supporting line of e partitions the plane into two open half planes $h_v = \{p : dist(p, v) < dist(p, u)\}$ and $h_u = \{p : dist(p, u) < dist(p, v)\}$. Since the Voronoi diagram is the straight line face dual of the Delaunay triangulation, the edge $(u, v) \in T$. Also, by the choice of e, $v_{\text{dst}} \in h_u$, i.e., $dist(u, v_{\text{dst}}) < dist(v, v_{\text{dst}})$. □

2.2. Compass routing. The *compass routing* algorithm always moves the packet to the vertex $cmp(v_{\text{cur}})$ that minimizes the angle $\angle v_{\text{dst}}, v_{\text{cur}}, cmp(v_{\text{cur}})$ over all vertices adjacent to v_{cur}. Here the angle is taken to be the smaller of the two angles as measured in the clockwise and counterclockwise directions. In the case of ties, one of the (at most 2) vertices is chosen using some arbitrary deterministic rule.

One might initially believe (as we did) that compass routing can always be used to find a path between any two vertices in a triangulation. However, the triangulation in Figure 2.4 defeats compass routing. When starting from one of the vertices on the outer face of T, and routing to v_{dst}, the compass routing algorithm gets trapped on the cycle shown in bold. The following lemma shows that any triangulation that defeats compass routing causes the packet to get trapped in a cycle.

LEMMA 2.3. *Let T be a triangulation that defeats compass routing, and let v_{dst} be a vertex such that compass routing fails to route a packet to v_{dst} when given some other vertex as the source. Then there exists a cycle $C = v_0, \ldots, v_{k-1}$ ($k \geq 3$) in T such that $cmp(v_i) = v_{i+1}$ for all $0 \leq i < k$.*[1]

Proof. Since T defeats compass routing, and the compass routing algorithm makes the same decision each time it visits a vertex, either there is an edge (u, v) such that $cmp(u) = v$ and $cmp(v) = u$, or there is the situation described in the lemma. We prove that there can be no such edge (u, v). Suppose such an edge (u, v) does exist.

[1]Here and henceforth, all subscripts are assumed to be taken mod$k$.

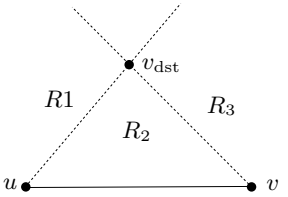

FIG. 2.5. *The proof of Lemma* 2.3.

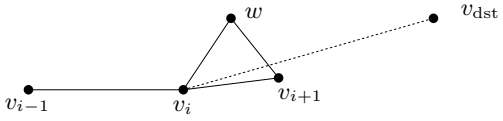

FIG. 2.6. *The proof of Lemma* 2.4.

Then there is a triangle (u, v, w) in T such that w is in the same half plane bounded by the line through u and v as v_{dst}. Referring to Figure 2.5, the vertex w must be in one of the regions 1, 2, or 3. But this is a contradiction, since if w is in region 1, then $cmp(v) = w$; if w is in region 2, then $cmp(u) = w$ (and $cmp(v) = w$); and if w is in region 3, then $cmp(u) = w$. □

We call such a cycle, C, a *trapping cycle* in T for v_{dst}. Next we characterize trapping cycles in terms of a visibility property of triangulations. Let t_1 and t_2 be two triangles in T. Then we say that t_1 *obscures* t_2 with respect to viewpoint v_{dst} if there exists a ray originating at v_{dst} that strikes t_1 first and then t_2. Let u and v be any two vertices of T such that $cmp(u) = v$. Then define $\triangle uv$ as the triangle of T that is contained in the closed half plane bounded by the line through uv, that contains the edge uv, and that contains v_{dst}. We obtain the following useful characterization of trapping cycles.

LEMMA 2.4. *Let T be a triangulation that defeats compass routing and let $C = v_0, \ldots, v_{k-1}$ be a trapping cycle in T for vertex v_{dst}. Then $\triangle v_i v_{i+1}$ is either identical to or obscures $\triangle v_{i-1} v_i$ for all $0 \leq i < k$.*

Proof. Refer to Figure 2.6. Assume that $\triangle v_i v_{i+1}$ and $\triangle v_{i-1} v_i$ are not identical; otherwise the lemma is trivially true. Let w be the third vertex of $\triangle v_i v_{i+1}$. Then w cannot lie in the cone defined by v_{dst}, v_i, and v_{i+1}; otherwise we would have $cmp(v_i) = w$. But then the line segment joining w and v_{i+1} obscures v_i and hence $\triangle v_i v_{i+1}$ obscures $\triangle v_{i-1} v_i$. □

A *regular triangulation* [18] is a triangulation obtained by orthogonal projection of the faces of the lower hull of a three-dimensional polytope onto the plane. Note that the Delaunay triangulation is a special case of a regular triangulation in which the vertices of the polytope all lie on a paraboloid. Edelsbrunner [8] showed that if T is a regular triangulation, then T has no set of triangles that obscure each other cyclically from *any* viewpoint. This result, combined with Lemma 2.4, yields our main result on compass routing.

THEOREM 2.5. *There is no regular triangulation that defeats the compass routing algorithm.*

2.3. Randomized compass routing. In this section, we consider a randomized routing algorithm that is not defeated by any triangulation. Let $cw(v)$ be the vertex in

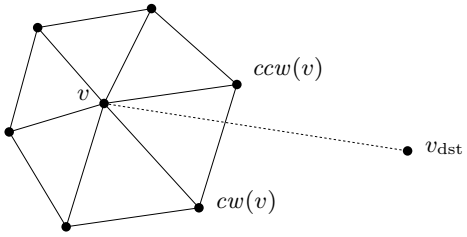

FIG. 2.7. *Definition of $cw(v)$ and $ccw(v)$.*

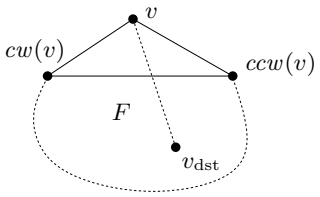

FIG. 2.8. *The proof of Theorem* 2.6.

$N(v)$ that minimizes the clockwise angle $\angle v_{\text{dst}}, v, cw(v)$ and let $ccw(v)$ be the vertex in $N(v)$ that minimizes the counterclockwise angle $\angle v_{\text{dst}}, v, ccw(v)$ (see Figure 2.7). Then the *randomized compass routing* (RCR) algorithm moves the packet to one of $\{cw(v_{\text{cur}}), ccw(v_{\text{cur}})\}$ with equal probability.

Before we can make statements about which triangulations defeat randomized compass routing, we must define what it means for a triangulation to defeat a randomized algorithm. We say that a triangulation T defeats a (randomized) routing algorithm if there exists a pair of vertices v_{src} and v_{dst} of T such that a packet originating at v_{src} with destination v_{dst} has probability 0 of reaching v_{dst} in any finite number of steps. Note that proving that a triangulation T does not defeat a memoryless routing algorithm implies that a packet reaches its destination with probability 1.

It is well known that a random walk will eventually visit every vertex of a connected graph. Thus, a random walk is a randomized routing algorithm that is not defeated by any connected graph. However, this result is not satisfactory for two reasons: (1) Because a random walk does not take the destination into account, the path it takes is by no means direct, and (2) the number of random bits required at each step of a random walk is $\log d_{\text{cur}}$, where d_{cur} is the degree of the current vertex. In contrast, randomized compass routing requires only 1 bit at each step and is more likely to take a direct path to the destination vertex.

The following theorem shows the versatility of randomized compass routing.

THEOREM 2.6. *There is no triangulation that defeats the randomized compass routing algorithm.*

Proof. Assume, by way of contradiction that a triangulation T exists that defeats the randomized compass routing algorithm. Then there is a vertex v_{dst} of T and a minimal set S of vertices such that (1) $v_{\text{dst}} \notin S$, (2) the subgraph H of T induced by S is connected, and (3) for every $v \in S$, $cw(v) \in S$ and $ccw(v) \in S$.

Refer to Figure 2.8 for what follows. The vertex v_{dst} lies in some face F of H. Let v be a vertex on the boundary of F such that the line segment (v, v_{dst}) is contained in F. Such a vertex is guaranteed to exist [5]. The two neighbors of v on the boundary of

F must be $cw(v)$ and $ccw(v)$, and these cannot be the same vertex (since F contains (v, v_{dst}) in its interior). Note that, by the definitions of $cw(v)$ and $ccw(v)$, and by the fact that T is a triangulation, the triangle $(cw(v), v, ccw(v))$ is in T. But this is a contradiction, since then v is not on the boundary of F. □

2.4. Right-hand routing. The folklore "right-hand rule" for exploring a maze states that if a player in a maze walks around never lifting her right-hand from the wall, then she will eventually visit every wall in the maze. More specifically, if the maze is the face of a connected planar straight line graph, the player will visit every edge and vertex of the face [2].

Let T be any convex subdivision. Consider the planar subdivision T' obtained by deleting from T all edges that properly intersect the line segment joining v_{src} and v_{dst}. Because of convexity, T' is connected, and v_{src} and v_{dst} are on the boundary of the same face F of T'. The *right-hand routing* algorithm uses the right-hand rule on the face F to route from v_{src} to v_{dst}. Right-hand routing is easily implemented using only $O(1)$ additional memory by remembering v_{src}, v_{dst}, and the last vertex visited.

THEOREM 2.7. *There is no convex subdivision that defeats the right-hand routing algorithm.*

3. Competitiveness of paths. Thus far we have considered only the question of whether routing algorithms can find *a* path between any two vertices in T. An obvious direction for research is to consider the length of the path found by a routing algorithm. We say that a routing algorithm $\mathcal{A}$ is c-competitive for T if for any pair $(v_{\text{src}}, v_{\text{dst}})$ in T, the length (sum of the edge lengths) of the path between v_{src} and v_{dst} found by $\mathcal{A}$ is at most c times the length of the shortest path between v_{src} and v_{dst} in T. In the case of randomized algorithms, we use the expected length of the path. We say that $\mathcal{A}$ has a competitive ratio of c if it is c-competitive.

This section addresses questions about the competitive ratio of the algorithms described so far, as well as a new algorithm specifically targeted for Delaunay triangulations. We present theoretical as well as experimental results.

3.1. Negative results. It is not difficult to contrive triangulations for which none of our algorithms is c-competitive for any constant c. Thus it is natural to restrict our attention to a well-behaved class of triangulations. Unfortunately, even for Delaunay triangulations none of the algorithms described so far is c-competitive.

THEOREM 3.1. *There exist Delaunay triangulations for which none of the greedy, compass, randomized compass, or right-hand routing algorithms is c-competitive for any constant c.*

Proof. We begin with greedy routing. Consider the set of points that are placed on a circle and then triangulated to obtain the zig-zag triangulation T shown in Figure 3.1.a. Since the points are cocircular, this is a valid Delaunay triangulation. The points are placed so that each vertex v has a neighbor on the opposite side of the line through v_{src} and v_{dst} that is closer to v_{dst} than v's two neighbors on the same side of the line.

Note that there exists a path between v_{src} and v_{dst} of length approximately $(\pi/2) \cdot dist(v_{\text{src}}, v_{\text{dst}})$, and this is therefore an upper bound on the length of the shortest path between v_{src} and v_{dst}. The length of the "zig-zag" path that uses the diagonals of T between v_{src} and v_{dst} is $\Theta(n) \cdot dist(v_{\text{src}}, v_{\text{dst}})$, and this is the path taken by the greedy routing algorithm. Thus, greedy routing is not c-competitive for this triangulation.

To show that compass routing is not c-competitive, we again consider a set of cocircular points and make a zig-zag triangulation. Let v_{cur} be any point on the

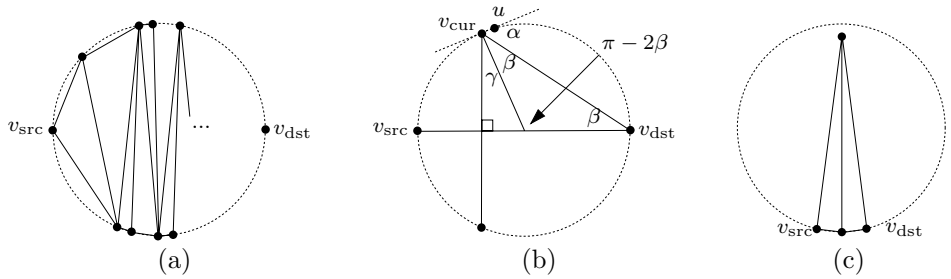

FIG. 3.1. *The proof of Theorem* 3.1.

circle with diameter $v_{\text{src}}, v_{\text{dst}}$. Consider the angle α between the tangent line passing through v_{cur} and the line through v_{src} and v_{dst}. Compare this with the angle between the line perpendicular to v_{src} and v_{dst} that passes through v_{cur} and the line through v_{src} and v_{dst}. Referring to Figure 3.1.b, we have

$$\alpha = \pi/2 - \beta, \tag{3.1}$$

$$\gamma = \pi/2 - 2\beta, \tag{3.2}$$

and therefore $\gamma + \beta = \pi/2 - \beta = \alpha$, i.e., the two angles are equal. Thus if compass routing were to choose between the tangent line and the line crossing the circle, it would be a tie. Now, by placing a point u on the circle close to v_{cur} we can make $\angle u, v_{\text{cur}}, v_{\text{dst}} = \alpha - \epsilon$ for arbitrarily small $\epsilon > 0$. Similarly, by placing a point v_{nxt} on the opposite side of the circle we can make $\angle v_{\text{nxt}}, v_{\text{cur}}, v_{\text{dst}} = \alpha - \epsilon - \delta$ for arbitrarily small $\delta > 0$, so that $cmp(v_{\text{cur}}) = v_{\text{nxt}}$. Since ϵ and δ can be arbitrarily small, we can repeat this construction as often as we like, thereby making the compass routing path arbitrarily long.

To see that randomized compass routing and right-hand routing are not c-competitive, consider a configuration of points like that in Figure 3.1.c. By making v_{src} and v_{dst} almost collinear with a third point, it is possible to produce arbitrarily long thin triangles that make the length of the path found by right-hand routing arbitrarily long. Furthermore, in this configuration the probability that the randomized compass routing path is the same as the right-hand path is 1/2, and thus the expected length of the randomized compass path can be arbitrarily large. □

3.2. A *c*-competitive algorithm for Delaunay triangulations. Since none of the algorithms described in section 2 is competitive, even for Delaunay triangulations, an obvious question is whether there exists any algorithm that is competitive for Delaunay triangulations. In this section we answer this question in the affirmative. In fact, we prove an even stronger result by giving an algorithm that finds a path whose cost is at most a constant times $dist(v_{\text{src}}, v_{\text{dst}})$.

Our algorithm is based on the remarkable proof of Dobkin, Friedman, and Supowit [7] that the Delaunay triangulation approximates the complete Euclidean graph to within a constant factor in terms of shortest path length. In the following we will use the notation $\text{x}(p)$ (resp., $\text{y}(p)$) to denote the x-coordinate (resp., y-coordinate) of the point p and the notation $|X|$ to denote the Euclidean length of the path X.

Consider the directed line segment from v_{src} to v_{dst}. This segment intersects regions of the Voronoi diagram in some order, say $R_0, \ldots, R_{m-1}$, where R_0 is the Voronoi region of v_{src} and R_{m-1} is the Voronoi region of v_{dst}. The *Voronoi routing* algorithm for Delaunay triangulations moves the packet from v_{src} to v_{dst} along the

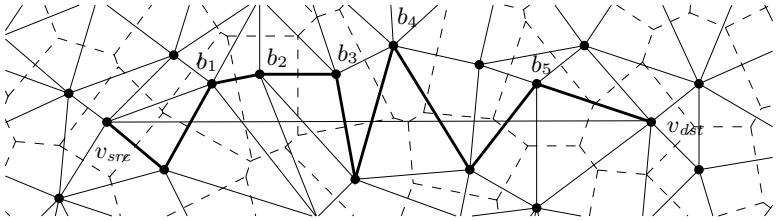

FIG. 3.2. *A path obtained by the Voronoi routing algorithm.*

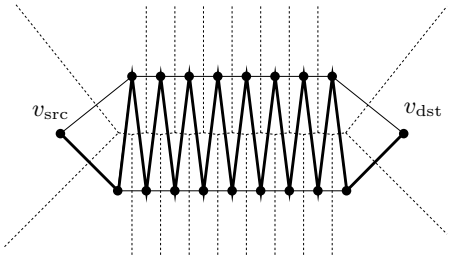

FIG. 3.3. *The Voronoi routing algorithm is not c-competitive for all Delaunay triangulations.*

path $v_0, \ldots, v_{m-1}$, where v_i is the site defining R_i. An example of a path obtained by the Voronoi routing algorithm is shown in Figure 3.2. Since the Voronoi region of a vertex v can be computed given only the neighbors of v in the Delaunay triangulation, it follows that the Voronoi routing algorithm is an $O(1)$ memory routing algorithm.

The Voronoi routing algorithm on its own is not c-competitive for all Delaunay triangulations, as can be seen from Figure 3.3.

However, it does have some properties that allow us to derive a c-competitive algorithm. As with right-hand routing, let T' be the graph obtained from T by removing all edges of T that properly intersect the segment $(v_{\text{src}}, v_{\text{dst}})$, and let F be the face of T' that contains both v_{src} and v_{dst}. Assume without loss of generality that v_{src} and v_{dst} both lie on the x-axis and that $\text{x}(v_{\text{src}}) < \text{x}(v_{\text{dst}})$. The following two lemmas follow from the work of Dobkin, Friedman, and Supowit [7].

LEMMA 3.2. *The Voronoi path is x-monotone, i.e.,* $\text{x}(v_i) < \text{x}(v_j)$ *for all* $i < j$.

LEMMA 3.3. *Let* P' *be the collection of maximal subpaths of* $v_0, \ldots, v_{m-1}$ *that remain above the x-axis, i.e.,* $P' = \{v_i, \ldots, v_j : \text{y}(v_{i-1}) < 0$ *and* $\text{y}(v_{j+1}) < 0$ *and* $\text{y}(v_k) \geq 0$ *for all* $i \leq k \leq j\}$. *Then* $\sum_{X \in P'} |X| \leq (\pi/2) \cdot dist(v_{\text{src}}, v_{\text{dst}})$.

Let $b_0, \ldots, b_{l-1}$ be the subsequence of vertices of $v_0, \ldots, v_{m-1}$ that are above or on the segment $(v_{\text{src}}, v_{\text{dst}})$. (Refer to Figure 3.2.) Consider two vertices $b_i = v_j$ and $b_{i+1} = v_k$, where $k \neq j+1$; i.e., the Voronoi path between b_i and b_{i+1} is not a direct edge. Let $P_V = (b_i = p_0, \ldots, p_x = b_{i+1})$ be the portion of the Voronoi path between b_i and b_{i+1} and let $P_F = (b_i = q_0, \ldots, q_y = b_{i+1})$ be the upper boundary of F between b_i and b_{i+1} (see Figure 3.4). Then the following holds.

LEMMA 3.4. *Let* $c_{\text{dfs}} = (1 + \sqrt{5})\frac{\pi}{2}$.[2] *Then* $|P_V| \leq c_{\text{dfs}} \cdot (\text{x}(b_i) - \text{x}(b_i))$ *or* $|P_F| \leq c_{\text{dfs}} \cdot (\text{x}(b_i) - \text{x}(b_i))$.

Proof. Let $c_0, \ldots, c_z$ be the lower convex hull of P_F, and let P_j be the Voronoi

[2]We call c_{dfs} the Dobkin–Friedman–Supowit constant [7].

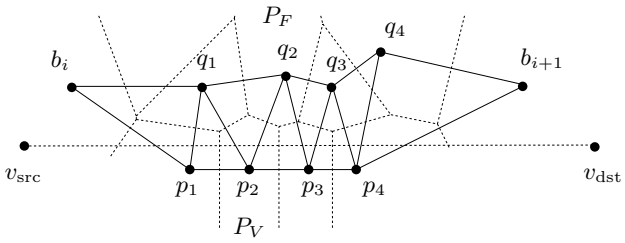

FIG. 3.4. *Definitions of P_V and P_F.*

path from c_j to c_{j+1}. Dobkin et al. prove that

$$|P_V| \leq c_{\text{dfs}} \cdot (\text{x}(b_{i+1} - \text{x}(b_i)) \quad \text{or} \quad \sum_{j=0}^{z-1} |P_j| \leq c_{\text{dfs}} \cdot (\text{x}(b_{i+1} - \text{x}(b_i)). \tag{3.3}$$

We claim that this implies Lemma 3.4 and prove this by showing that P_j visits all vertices of P_F between c_j and c_{j+1}. Thus, by the triangle inequality,

$$|P_F| \leq \sum_{j=0}^{z-1} |P_j|. \tag{3.4}$$

Refer to Figure 3.5 for what follows. Assume for the sake of contradiction that there is a vertex q in P_F between c_j and c_{j+1} that is not in P_j. As part of their proof, Dobkin et al. show that P_j remains entirely above the segment (c_j, c_{j+1}). Therefore, let Q be the polygon bounded by P_j and the segment (c_j, c_{j+1}). Since q is on P_F between c_j and c_{j+1}, it must be that q is contained in Q.

Since Q is monotone in the direction from c_j to c_{j+1}, it can be partioned into trapezoids whose top sides are edges of P_j, whose bottom sides are on the line segment (c_j, c_{j+1}), and whose left and right sides are perpendicular to (c_j, c_{j+1}). Refer to Figure 3.5.

Let a and b be the two vertices of P_j that define the trapezoid containing q. We claim that a and b cannot be consecutive on P_j because their Voronoi regions do not share an edge that intersects (c_j, c_{j+1}). We will prove this by showing that in the Voronoi diagram of q, a, and b the bisector of a and b does not intersect the segment (c_j, c_{j+1}). This is sufficient, since this bisector contains the bisector of a and b in the entire Voronoi diagram.

Let C be the circle with center on (c_j, c_{j+1}) and with a and b on its boundary. If the bisector of a and b in the Voronoi diagram of q, a, and b intersects the segment (c_j, c_{j+1}), then C must not contain q. However, C does contain the top, left, right, and bottom sides of the trapezoid containing q. But this can't be, since then C contains the entire trapezoid and contains q. We conclude that there is no point q on the boundary of F between c_j and c_{j+1} that is not on P_j. □

Our c-competitive routing algorithm will visit all the vertices $b_0, \ldots, b_{l-1}$ in order. If b_i and b_{i+1} are consecutive on the Voronoi path (i.e., $b_i = v_j$ and $b_{i+1} = v_{j+1}$ for some j), then our algorithm will use the Voronoi path (i.e., the direct edge) from b_i to b_{i+1}. On the other hand, if b_i and b_{i+1} are not consecutive on the Voronoi path, then by Lemma 3.4, there exists a path from b_i to b_{i+1} of length at most $c_{\text{dfs}} \cdot (\text{x}(b_{i+1}) - \text{x}(b_i))$.

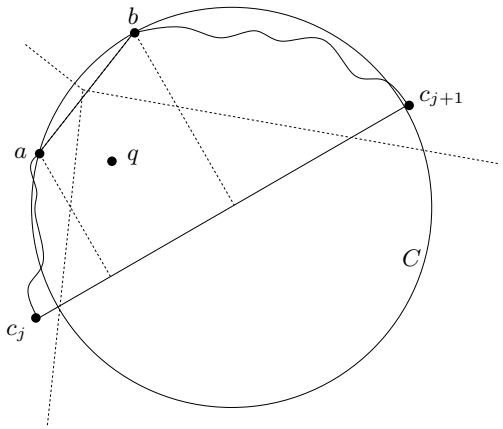

FIG. 3.5. *The proof of Lemma* 3.4.

The difficulty occurs because the algorithm does not know beforehand which path to take. The solution is to simulate exploring both paths "in parallel" and stopping when the first one reaches b_{i+1}.[3]

More formally, let P_V and P_F be defined as in Lemma 3.4. The algorithm for finding a path from b_i to b_{i+1} is described by the following pseudocode.

1: $j \leftarrow 0$, $l_0 \leftarrow \min\{dist(p_0, p_1), dist(q_0, q_1)\}$.
2: **repeat**
3: Explore P_F until reaching b_{i+1} or until reaching a vertex q_x such that $|q_0, \ldots, q_{x+1}| > 2l_j$. If b_{i+1} is reached, then quit; otherwise return to b_i.
4: $j \leftarrow j + 1$, $l_j \leftarrow |q_0, \ldots, q_{y+1}|$.
5: Explore P_V until reaching b_{i+1} or until reaching a vertex p_y such that $|p_0, \ldots, p_{y+1}| > 2l_j$. If b_{i+1} is reached, then quit; otherwise return to b_i.
6: $j \leftarrow j + 1$, $l_j \leftarrow |p_0, \ldots, p_{y+1}|$.
7: **until** b_{i+1} is reached

LEMMA 3.5. *Using the parallel search algorithm described above, a packet reaches* b_{i+1} *after traveling a distance of at most* $9 \cdot c_{\mathrm{dfs}} \cdot (\mathrm{x}(b_{i+1}) - \mathrm{x}(b_i)) \sim 45.75 \cdot (\mathrm{x}(b_{i+1}) - \mathrm{x}(b_i))$.

Proof. Clearly the algorithm reaches b_{i+1} in a finite number of steps, since lines 4 and 6 ensure that both paths advance by at least one edge at each iteration. Let k be the maximum value of j, and let d_j be the distance traveled during the jth exploration step of the algorithm. Thus, the total distance d traveled by the packet is given by $d = \sum_{j=0}^{k} d_j$.

Since the algorithm did not terminate with $j = k - 1$, by Lemma 3.4 we have

$$d_k < 2 \cdot c_{\mathrm{dfs}} \cdot (\mathrm{x}(b_{i+1}) - \mathrm{x}(b_i)). \tag{3.5}$$

Similarly, since the algorithm did not terminate with $j = k - 1$ or $j = k - 2$, we have

$$l_{k-1} < 2 \cdot c_{\mathrm{dfs}} \cdot (\mathrm{x}(b_{i+1}) - \mathrm{x}(b_i)). \tag{3.6}$$

[3] A similar algorithm for finding an unknown target point on a line is given by Baeza-Yates, Culberson, and Rawlins [1]. See also Klein [12].

Since $l_j \geq 2l_{j-1}$ for each $j > 0$, we have

$$d \leq \sum_{j=0}^{k-1} 2l_j + d_k \tag{3.7}$$

$$\leq \sum_{j=0}^{k-1} 2l_{k-1}/2^j + d_k, \tag{3.8}$$

which immediately yields a bound of $10 \cdot c_{\mathrm{dfs}} \cdot (\mathrm{x}(b_{i+1}) - \mathrm{x}(b_i))$. To obtain a tighter bound, we note that $d_k > c_{\mathrm{dfs}} \cdot (\mathrm{x}(b_{i+1}) - \mathrm{x}(b_i))$ implies $l_{k-1} < c_{\mathrm{dfs}} \cdot (\mathrm{x}(b_{i+1}) - \mathrm{x}(b_i))$. Subject to this constraint, (3.8) is maximized when $l_{k-1} = 2 \cdot c_{\mathrm{dfs}} \cdot (\mathrm{x}(b_{i+1}) - \mathrm{x}(b_i))$, yielding

$$d \leq \sum_{j=0}^{k-1} 4 \cdot c_{\mathrm{dfs}} \cdot (\mathrm{x}(b_{i+1}) - \mathrm{x}(b_i))/2^j + c_{\mathrm{dfs}} \cdot (\mathrm{x}(b_{i+1}) - \mathrm{x}(b_i)) \tag{3.9}$$

$$< 9 \cdot c_{\mathrm{dfs}} \cdot (\mathrm{x}(b_{i+1}) - \mathrm{x}(b_i)). \qquad \square \tag{3.10}$$

Given the positions of v_{dst} and v_{src} the parallel search algorithm described above is easily implemented as part of an $O(1)$ memory routing algorithm. We refer to the combination of the Voronoi routing algorithm with this parallel search algorithm as the *parallel Voronoi routing* algorithm.

THEOREM 3.6. *The parallel Voronoi routing algorithm produces a path whose length is at most* $(9 \cdot c_{\mathrm{dfs}} + \pi/2) \cdot dist(v_{\mathrm{src}}, v_{\mathrm{dst}})$.

Proof. The algorithm incurs two costs: (1) the cost of traveling on subpaths of the Voronoi path that remain above the y-axis, and (2) the cost of applications of the parallel search algorithm. By Lemma 3.3, the first cost is at most $(\pi/2) \cdot dist(v_{\mathrm{src}}, v_{\mathrm{dst}})$. By Lemma 3.5 and the fact that $b_0, \ldots, b_{l-1}$ is x-monotone (Lemma 3.2), the cost of the second is at most $9 \cdot c_{\mathrm{dfs}} \cdot dist(v_{\mathrm{src}}, v_{\mathrm{dst}})$. $\square$

3.3. Empirical results. While it is sometimes possible to come up with pathological examples of triangulations for which an algorithm is not competitive, it is often more reasonable to use the competitive ratio of an algorithm on average or random inputs as an indicator of how it will perform in practice. In this section we describe some experimental results about the competitiveness of our algorithms. All experiments were performed on sets of random points uniformly distributed in the unit square, and each data point is the maximum of 50 independent trials.

The first set of experiments, shown in Figure 3.6, involved measuring the performance of all six routing algorithms on Delaunay triangulations. Compass routing, greedy routing, and Voronoi routing consistently achieve better competitive ratios, with greedy routing slightly worse than the other two. Randomized compass routing, right-hand routing, and parallel Voronoi routing had significantly higher competitive ratios. The results for randomized compass routing and right-hand routing show a significant amount of jitter. This is due to the fact that relatively simple configurations (see Figure 3.1.b) that can easily occur in random point sets result in high competitive ratios for these algorithms. On the other hand, parallel Voronoi routing seems much more stable, and achieves better competitive ratios in practice than its worst-case analysis would indicate.

The most important conclusion drawn from these experiments is that there are no simple configurations (i.e., that occur often in random point sets) that result in

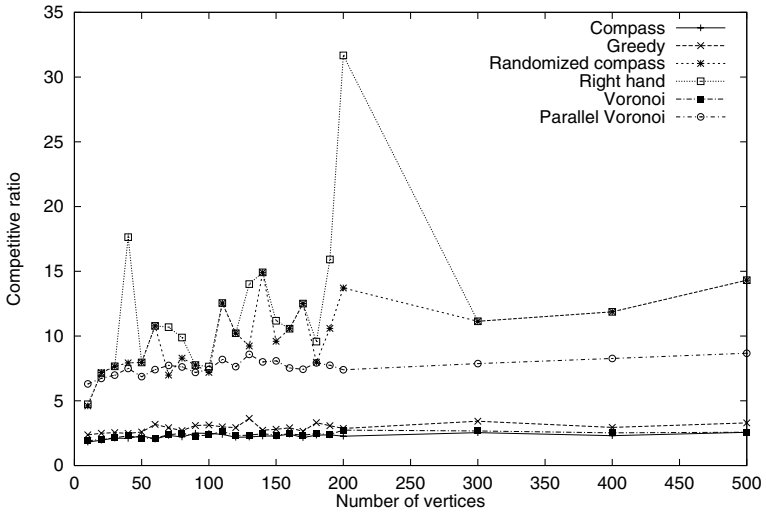

FIG. 3.6. *Empirical competitive ratios for Delaunay triangulations.*

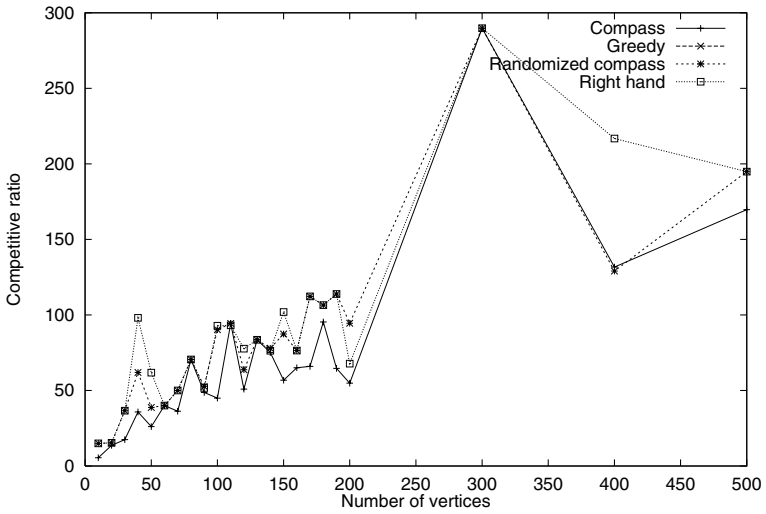

FIG. 3.7. *Empirical competitive ratios for Graham triangulations.*

extremely high competitive ratios for greedy, compass, Voronoi, or parallel Voronoi routing in Delaunay triangulations. This suggests that any of these algorithms would work well in practice.

The four simple routing algorithms of section 2 were also tested on Graham triangulations. These are obtained by first sorting the points by x-coordinate and then triangulating the resulting monotone chain using a linear time algorithm for computing the convex hull of a monotone polygonal chain [17]. The results are shown in Figure 3.7. In these tests it was always the case that at least one of the 50 independent triangulations defeated greedy routing. Thus, there are no results shown for greedy routing. The relative performance of the compass, randomized compass, and

right-hand routing algorithms was the same as for Delaunay triangulations. However, unlike the results for Delaunay triangulations, the competitive ratio appears to be increasing linearly with the number of vertices.

4. Comparison with related work. In this section we survey related work in the area of geometric online routing and compare our results with this work. We restrict our attention to work directly related to routing between the vertices of geometric graphs in which the source and destination are inputs, and we do not consider routing in other geometric settings such as polygons (cf. [9, 10, 12]).

Keil and Gutwin [11] give an algorithm for the construction of a geometric graph called the θ-graph for which a memoryless routing algorithm similar to compass routing always results in a path whose length is at most a constant (dependent only on θ) times the Euclidean distance between v_{src} and v_{dst}.

Kranakis, Singh, and Urrutia [13] study compass routing and provide a proof that no Delaunay triangulation defeats compass routing. The current paper makes use of a very different proof technique to show that compass routing works for a larger class of triangulations. They also describe an $O(1)$ memory routing algorithm that is not defeated by any connected planar graph, thus proving a stronger result than Theorem 2.7.

Lin and Stojmenović [15] and Bose et al. [4] consider online routing in the context of ad hoc wireless networks modeled by unit disk graphs. They provide simulation results for a variety of algorithms that measure success rates (how often a packet never reaches its destination) as well as hop-counts of these algorithms on unit graphs of random point sets.

Lawson's oriented walk [14] is a simple algorithm for point location in Delaunay triangulations without preprocessing. The algorithm can be converted to an $O(1)$ memory routing algorithm that is not defeated by any Delaunay triangulation. The results of the current paper improve on this algorithm by providing two *memoryless* routing algorithms that are not defeated by any Delaunay triangulation.

De Berg et al. [6] describe an algorithm for enumerating all the vertices of a connected planar subdivision using only $O(1)$ additional memory. This algorithm can also be viewed as an $O(1)$ memory routing algorithm. Similarly, in any connected graph with a finite number of vertices, a random walk will eventually visit every vertex. Thus, random walking can be viewed as a randomized memoryless routing algorithm that is not defeated by any graph. Unfortunately paths found by these techniques will usually be much longer than the shortest path, since they are general traversal techniques. In contrast, the right-hand routing and randomized compass routing algorithms make use of information about the source and destination to find more direct paths.

To the best of our knowledge, no literature currently exists on the competitiveness of geometric routing algorithms in our abstract setting, and our parallel Voronoi routing algorithm is the first theoretical result in this area.

5. Conclusions. We have studied the problem of online routing in geometric graphs. Our theoretical results show which types of graphs our algorithms are guaranteed to work on, while our simulation results rank the performance of the algorithms on two types of random triangulations. These results are summarized in Table 5.1.

We conclude with an open problem. In section 2 we showed that no deterministic memoryless routing algorithm works for every 2-connected embedded planar graph. Can a similar argument be made for triangulations, thus proving that randomization or memory is necessary for an algorithm that is not defeated by any triangulation?

DISTRIBUTIONAL RESULTS FOR COSTS OF PARTIAL MATCH QUERIES IN ASYMMETRIC K-DIMENSIONAL TRIES*

WERNER SCHACHINGER†

Abstract. In this paper we study the costs C_N of partial match retrievals in K-dimensional tries (K-d tries), constructed from N records. The probabilistic model that we assume is the asymmetric Bernoulli model: keys are sequences of independently and identically distributed random variables, which assume the values 0 and 1 with probability $p \neq \frac{1}{2}$ and $1-p$, and are pairwise independent. We determine the extremal asymptotic orders that the sequence of expectations $(\mathbb{E}\, C_N)_{N\geq 0}$ may have for different fixed queries, as well as the narrow region that contains $(\mathbb{E}\, C_N)_{N\geq 0}$ for almost every query. Furthermore we show that $(\mathbb{E}\, C_N)_{N\geq 0}$ and $(\operatorname{Var} C_N)_{N\geq 0}$ have the same asymptotics up to a logarithmic factor and, employing a central limit theorem for martingale difference arrays, we prove asymptotic normality of $\frac{C_N - \mathbb{E}\, C_N}{\sqrt{\operatorname{Var} C_N}}$. For random queries, assumed to be independent of the keys and having their specified components distributed according to the same Bernoulli model, no limiting distribution for C_N exists, but we can prove asymptotic normality of $\ln C_N$, when appropriately normalized, and determine $\operatorname{Var} C_N$ up to a logarithmic factor, where now $(\mathbb{E}\, C_N)^2 = o(\operatorname{Var} C_N)$.

Key words. K-d trie, multidimensional data, partial match retrieval, martingale, asymptotic normality

1. Introduction.

Data structures supporting retrieval of multidimensional data are indispensable for the design of database systems and find further applications in the management of geographical data and the realm of computational geometry. Among the data structures, which have been developed for retrieval of multidimensional data, are Bentley's K-dimensional (K-d) search trees [1], which are comparison based, and Rivest's digital K-d trees [24]. Of the latter type are also the K-d tries (cf. [2, 10, 19]), which will be studied in this paper. Given a set of N records, a particular problem consists in finding all records whose keys match a given query. This means that some fixed components of the K-tuple-keys must coincide with the corresponding components of the query, while the others are not specified and can take arbitrary values. The cost C_N of such a *partial match retrieval* is defined to be the number of the K-d trie's internal nodes visited during the search for all matches.

Partial match retrieval in K-d tries has been studied from the average-case point of view under the Bernoulli and Poisson models of randomness. Flajolet and Puech [10] computed asymptotics (as $N \to \infty$) of $\mathbb{E}\, C_N$ under the symmetric Bernoulli and Poisson models. Kirschenhofer and Prodinger [16] extended these results to K-d digital search trees and Patricia tries. Kirschenhofer, Prodinger, and Szpankowski [17] computed $\mathbb{E}\, C_N$ under the asymmetric Bernoulli model, both for the case of a random query and the case of a fixed periodic query. (No distinction between fixed and random queries has to be made in the symmetric Bernoulli model.) The first result concerning $\operatorname{Var} C_N$ in the symmetric Bernoulli model (the case $K = 2$) can also be found in [17], and, using different methods, the author [25] could settle the case $K \geq 3$. Recently, *relaxed* variants of K-d trees have attracted interest; see [8] and [20]

for results concerning expectation and variance of cost. Results regarding limiting distributions have so far only been obtained for the symmetric Bernoulli model [26], where $\frac{C_N - \mathbb{E}\, C_N}{\sqrt{\operatorname{Var} C_N}}$ is shown to converge in distribution and with all its moments to a standard normal random variable. The present paper has its focus on variance and limiting distribution of C_N under the asymmetric Bernoulli model, both for the case of a random query and the case of a fixed query.

For results on partial match retrievals in K-d search trees and quadtrees, ranging from expectations to limiting distributions, we refer to [3, 4, 7, 8, 10, 19, 20, 22, 23].

We start with a description of K-d tries, partial match retrieval, and the probabilistic model under consideration.

1.1. Tries and K-d tries. The trie (cf. [11, 18, 19]) is designed to store data, whose keys are given as sequences over a finite alphabet Σ. Here we confine ourselves to the case $\Sigma = \{0, 1\}$. Now let a set $\mathcal{S} = \{k_i \in \Sigma^{\mathbb{N}} : 1 \le i \le N\}$ of keys be given. The trie built from these keys is a binary tree, whose internal nodes serve as branching nodes. Each leaf (external node) either stores one key or is empty. If we label in this tree each edge to the left (resp., right) 0 (resp., 1), we obtain an encoding of the leaves by taking the 0-1-sequence along the path starting from the root. A key k_i is stored in the leaf encoded by k_i's minimal unique prefix among the N keys in $\mathcal{S}$.

K-d tries (cf. [24, 10]) are built the same way, but some preprocessing of the keys, which are now K-tuples of "simple" keys, has to be done. Given a key $k_i = (k_{i1}, \dots, k_{iK})$, where $k_{i\ell} = (k_{i\ell}^1, k_{i\ell}^2, \dots) \in \Sigma^{\mathbb{N}}$, we construct a key $\tilde{k}_i \in \Sigma^{\mathbb{N}}$ by "shuffling":

$$\tilde{k}_i = (k_{i1}^1, k_{i2}^1, \dots, k_{iK}^1, k_{i1}^2, k_{i2}^2, \dots, k_{iK}^2, \dots).$$

The trie constructed from the keys $\tilde{k}_i$, $1 \le i \le N$, is called a K-d trie. The set of all K-d tries $\mathtt{t}$ built from N keys is denoted by T_N, and $|\mathtt{t}| = N$ is said to be the size of $\mathtt{t}$.

1.2. Partial match retrieval. A *partial match query* is a K-tuple

$$q = (q_1, \dots, q_K) \in \{\Sigma^{\mathbb{N}}, *\}^K.$$

We say that the component q_i is unspecified if $q_i = *$, and is otherwise specified. The task of performing a *partial match retrieval* asks for all keys k_i that match the query q, which means $k_{ij} = q_j$ whenever q_j is specified, and $k_{ij} \in \Sigma^{\mathbb{N}}$ is arbitrary whenever $q_j = *$. The *cost* $C(\mathtt{t}, \tilde{q})$ of the partial match retrieval in a K-d trie $\mathtt{t}$ is defined to be the number of internal nodes of $\mathtt{t}$ visited during the search for the shuffled query $\tilde{q}$ (before shuffling, each component $*$ of q is replaced by the constant sequence $(*, *, *, \dots)$). For any sequence $k = (k^1, k^2, \dots)$ we denote by $k' = (k^2, k^3, \dots)$ the shift to the left by one position of k, and more generally by $k^{(m)}$ the shift to the left by m positions. We can now compute $C(\mathtt{t}, \tilde{q})$ inductively by

$$C(\mathtt{t}, \tilde{q}) = \begin{cases} 0, & |\mathtt{t}| \le 1, \\ 1 + C(\mathtt{t}_\ell, \tilde{q}'), & \tilde{q} = 0\tilde{q}', \\ 1 + C(\mathtt{t}_r, \tilde{q}'), & \tilde{q} = 1\tilde{q}', \\ 1 + C(\mathtt{t}_\ell, \tilde{q}') + C(\mathtt{t}_r, \tilde{q}'), & \tilde{q} = *\tilde{q}', \end{cases} \tag{1}$$

where $\mathtt{t}_\ell$, respectively, $\mathtt{t}_r$, denote the left, respectively, right, subtree of $\mathtt{t}$ when $|\mathtt{t}| \ge 2$.

The *specification pattern* ω of $\tilde{q} = (\tilde{q}_1, \tilde{q}_2, \dots)$ is some element of $\{S, *\}^K$, such that periodic repetition of ω indicates specified and unspecified positions of $\tilde{q}$. The

number of symbols $*$ in a specification pattern $\omega \in \{S, *\}^K$ is denoted by u, and we assume throughout the paper that $0 < u < K$. The set of all $\tilde{q}$ with given specification pattern ω is denoted by K_ω.

1.3. The probabilistic model. We are going to analyze for fixed or random $\boldsymbol{\kappa} \in K_\omega$ and $N \in \mathbb{N}$ the quantity $C(\mathsf{t}, \boldsymbol{\kappa})$, where $\mathsf{t} \in \mathsf{T}_N$ is random and independent of $\boldsymbol{\kappa}$. The probabilistic model we use for T_N assumes that the shuffled keys $\tilde{k}_i$ are independently and identically distributed (i.i.d.) sequences of elements from Σ, where 0 and 1 occur with probability $p \in]0,1[$ and $q := 1 - p$, respectively, and that keys $\tilde{k}_i, \tilde{k}_j$ are independent for $1 \le i < j \le N$. If $p = \frac{1}{2}$, this is called the symmetric, otherwise the asymmetric, Bernoulli model. These models give rise to a sequence of discrete probability spaces $(\mathsf{T}_N, \mathcal{T}_N, P_N)$, with $\mathcal{T}_N$ simply the set of subsets of T_N. (Regarding discreteness, there are indeed only finitely many binary trees of fixed height, and the minimal prefixes needed for the construction of the trie are almost surely finite. On the other hand, T_N is infinite for $N \ge 2$, due to the fact that leaves can be empty.) The computation of probabilities $P_{|\mathsf{t}|}(\mathsf{t})$ is facilitated using the binomial splitting probabilities

$$p_{N,k} := \mathbb{P}\left(|\mathsf{t}_\ell| = k \big| |\mathsf{t}| = N\right) = \binom{N}{k} p^k q^{N-k}.$$

Both T_0 and T_1 are singletons; therefore $P_0(\mathsf{t}) = P_1(\mathsf{t}) = 1$ for t taken from T_0, respectively, T_1. For $|\mathsf{t}| \ge 2$, $\mathsf{t} = \overset{\mathrm{O}}{/\ \backslash}_{\mathsf{t}_l\ \mathsf{t}_r}$, we have $P_{|\mathsf{t}|}(\mathsf{t}) = p_{|\mathsf{t}|,|\mathsf{t}_\ell|} P_{|\mathsf{t}_\ell|}(\mathsf{t}_\ell) P_{|\mathsf{t}_r|}(\mathsf{t}_r)$.

We further introduce the probability space $(K_\omega, \mathcal{B}(K_\omega), Q)$, where, according to Q, the specified elements of $\boldsymbol{\kappa} \in K_\omega$ constitute an i.i.d. sequence of elements from Σ, where 0 and 1 occur with the probabilities p and q, just as for the keys.

The main objects of our study are the random variables $C_N := C(\mathsf{t}, \boldsymbol{\kappa})$ defined on $\mathsf{T}_N \times K_\omega$, and $F_{\boldsymbol{\kappa},N} = F_{\boldsymbol{\kappa},N}(\mathsf{t}) := C(\mathsf{t}, \boldsymbol{\kappa})$ defined on T_N, as well as $F^i_{\boldsymbol{\kappa},N} = F^i_{\boldsymbol{\kappa},N}(\mathsf{t}) := C(\mathsf{t}, \boldsymbol{\kappa}^{(i)})$ for $i \ge 0$, defined on T_N, where $F^0_{\boldsymbol{\kappa},N} = F_{\boldsymbol{\kappa},N}$. For some statements we need the sequences of random variables $(C_N)_{N\ge0}$, respectively, $(F^i_{\boldsymbol{\kappa},N})_{N\ge0}$, live on the same probability space, which we choose to be $(\Sigma^{\mathbb{N}\times\mathbb{N}} \times K_\omega, \mathcal{B}(\Sigma^{\mathbb{N}\times\mathbb{N}} \times K_\omega), P \times Q)$, respectively, $(\Sigma^{\mathbb{N}\times\mathbb{N}}, \mathcal{B}(\Sigma^{\mathbb{N}\times\mathbb{N}}), P)$, with $\boldsymbol{\tau} = (k_i)_{i\in\mathbb{N}} \in \Sigma^{\mathbb{N}\times\mathbb{N}}$ representing an infinite sequence of keys, where, according to P, all the symbols of all the keys form an i.i.d. sequence of elements from Σ, where 0 and 1 occur with probability p and q, respectively. We denote by $\boldsymbol{\tau}_N = (k_i)_{i=1}^N$ the set of the first N keys and by $\mathsf{t}(\boldsymbol{\tau}_N)$ the trie built from that set. Costs for random and fixed queries are then defined by $C_N = C_N(\boldsymbol{\tau}, \boldsymbol{\kappa}) = C(\mathsf{t}(\boldsymbol{\tau}_N), \boldsymbol{\kappa})$ and $F^i_{\boldsymbol{\kappa},N} = F^i_{\boldsymbol{\kappa},N}(\boldsymbol{\tau}) = C(\mathsf{t}(\boldsymbol{\tau}_N), \boldsymbol{\kappa}^{(i)})$. By definition, the random sequence $(F^i_{\boldsymbol{\kappa},N})_{N\ge0}$ is increasing. We let $f^i_{\boldsymbol{\kappa},N} := \mathbb{E}\, F^i_{\boldsymbol{\kappa},N}$ and $v^i_{\boldsymbol{\kappa},N} := \operatorname{Var} F^i_{\boldsymbol{\kappa},N}$ for $i \ge 0$ and use the shorthand notation $f_{\boldsymbol{\kappa},N} = f^0_{\boldsymbol{\kappa},N}$, $v_{\boldsymbol{\kappa},N} = v^0_{\boldsymbol{\kappa},N}$. The subscript $\boldsymbol{\kappa}$ will frequently be suppressed.

Throughout the paper we denote convergence (resp., equality) in distribution by $\xrightarrow{\mathcal{D}}$ (resp., $\overset{\mathcal{D}}{=}$). We write $X \sim F$ if the random variable X has distribution F, and $\mathcal{N}(0,1)$ denotes a standard normal random variable. We put $a \vee b = \max(a,b)$ and $a \wedge b = \min(a,b)$ for any real numbers a and b. The indicator function of a set A is denoted by $\mathbb{1}_A$, and for a Boolean expression B we let $\mathbb{1}_{\{B\}}$ be 1 if B is true and 0 otherwise. The difference operator, Δ, is defined by $\Delta x_k = x_{k+1} - x_k$. Bold lowercase letters, such as $\boldsymbol{\kappa}$ or $\mathbf{f}^i$, always denote sequences, and bold uppercase letters are used for matrices. We will use the standard asymptotic notation $\mathcal{O}$, o, Ω, and Θ.

We use the symbol $\sim$ also to denote asymptotic equivalence, and write occasionally $a_n \asymp b_n$ if $a_n = \Theta(b_n)$.

2. Main results. Our first result, Theorem 1, and its Corollary 1, demonstrate that in the asymmetric Bernoulli model the expectations $f_{\boldsymbol{\kappa},N}$ may enjoy a growth between $\Omega(N^{\gamma_2})$ and $\mathcal{O}(N^{\gamma_1})$ and will almost surely be "close" to N^{β} for certain constants $\gamma_2 < \beta < \gamma_1$. Note that things are different in the symmetric Bernoulli model, where $F_{\boldsymbol{\kappa},N} \stackrel{\mathcal{D}}{=} C_N$, and hence $f_{\boldsymbol{\kappa},N} = \mathbb{E}\, C_N$ holds regardless of the value of the query $\boldsymbol{\kappa}$, and where $\mathbb{E}\, C_N = \Theta(N^{u/K})$ was shown to hold in [10], with a positive periodic function of $\ln N$ hidden in the Θ symbol.

THEOREM 1. *Let $p \in [\frac{1}{2}, 1[$, $q := 1-p$, $0 < u < K$ and define $\beta = \beta(p)$, $\gamma_1 = \gamma_1(p)$, and $\gamma_2 = \gamma_2(p)$ to be the unique real solutions of the equations*

$$(p^p q^q)^{(K-u)\beta}(p^\beta + q^\beta)^u = 1, \quad p^{(K-u)\gamma_1}(p^{\gamma_1} + q^{\gamma_1})^u = 1, \quad q^{(K-u)\gamma_2}(p^{\gamma_2} + q^{\gamma_2})^u = 1.$$

Moreover denote $P_x := \frac{p^x}{p^x + q^x}$ and $Q_x := 1 - P_x$ for $x \in \mathbb{R}$. Then

$$\begin{aligned} \sup_{\boldsymbol{\kappa} \in K_\omega} f_{\boldsymbol{\kappa},N} &= \Theta(N^{\gamma_1}), \\ \inf_{\boldsymbol{\kappa} \in K_\omega} f_{\boldsymbol{\kappa},N} &= \Theta(N^{\gamma_2}). \end{aligned} \tag{2}$$

Furthermore, for Q-almost every $\boldsymbol{\kappa} \in K_\omega$ we have

$$\lim_{N\to\infty} \frac{|\ln f_{\boldsymbol{\kappa},N} - \beta \ln N - \beta S_{\boldsymbol{\kappa},\lfloor c_\beta \ln N \rfloor}|}{\ln^{\frac{1}{3}} N \ln\ln N} = 0, \tag{3}$$

where

$$S_{\boldsymbol{\kappa},n} := \sum_{j=1}^{Kn} \big(\mathbb{1}_{\{\kappa_j = 0\}} \ln p + \mathbb{1}_{\{\kappa_j = 1\}} \ln q \big) - n(K-u) \ln p^p q^q$$

and

$$c_\beta := \frac{\beta}{u \ln\Big(P_\beta^{-P_\beta} Q_\beta^{-Q_\beta} \Big)}.$$

It is important to note that with

$$X_{\boldsymbol{\kappa},j} := \sum_{i=jK-K+1}^{jK} \big(\mathbb{1}_{\{\kappa_i = 0\}} \ln p + \mathbb{1}_{\{\kappa_i = 1\}} \ln q \big) - (K-u) \ln p^p q^q$$

we have $S_{\boldsymbol{\kappa},n} = \sum_{j=1}^{n} X_{\boldsymbol{\kappa},j}$. Note further that with respect to Q, the random variables $(X_{\boldsymbol{\kappa},j})_{j\geq 1}$ are i.i.d. with $\mathbb{E}\, X_{\boldsymbol{\kappa},1} = 0$ and $\operatorname{Var} X_{\boldsymbol{\kappa},1} = (K-u)pq \ln^2 \frac{p}{q}$. In fact, $X_{\boldsymbol{\kappa},1}$ has the distribution of $\ln \frac{p}{q}$ times a centered binomially $B(K-u,p)$ distributed random variable. Thus the following corollary is a simple consequence of the law of the iterated logarithm and of the central limit theorem for sums of i.i.d. random variables with finite variance.

COROLLARY 1. *For Q-almost every $\boldsymbol{\kappa} \in K_\omega$ we have*

$$\begin{aligned} \limsup_{N\to\infty} \frac{\ln f_{\boldsymbol{\kappa},N} - \beta \ln N}{\sqrt{2\beta \ln N \ln\ln\ln N}} &= \sigma, \\ \liminf_{N\to\infty} \frac{\ln f_{\boldsymbol{\kappa},N} - \beta \ln N}{\sqrt{2\beta \ln N \ln\ln\ln N}} &= -\sigma, \end{aligned} \tag{4}$$

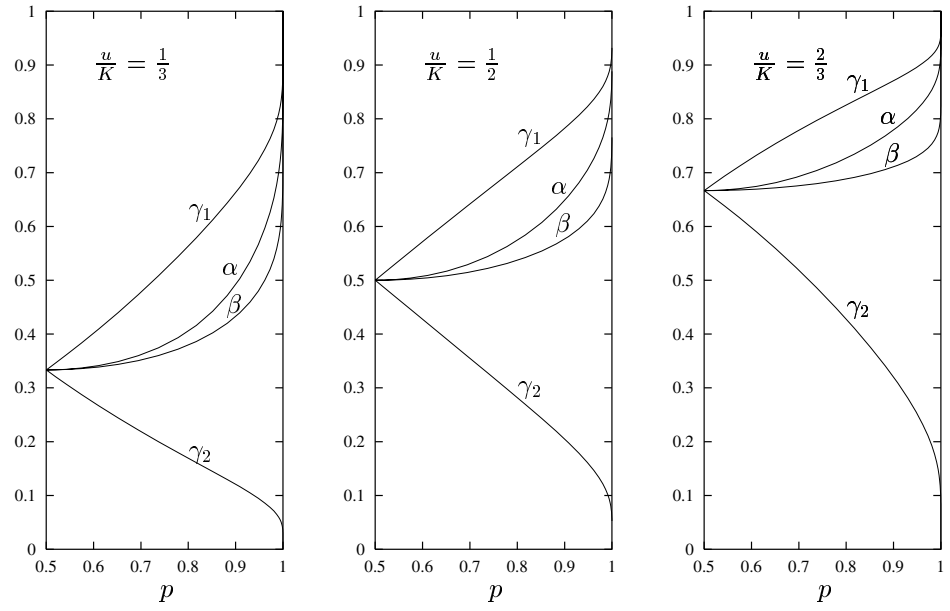

FIG. 1. *The exponents γ_1, γ_2, and β from Theorem* 1 *and α from Remark* 2 *for various values of $\frac{u}{K}$; cf. also the table in* [17].

where $\sigma = \sigma(p) = \beta \ln \frac{p}{q} \sqrt{\left(\frac{K}{u} - 1\right) pq / \ln\left(P_\beta^{-P_\beta} Q_\beta^{-Q_\beta}\right)}$. *Moreover*

$$\frac{\ln f_{\boldsymbol{\kappa},N} - \beta \ln N}{\sqrt{\beta \ln N}} \xrightarrow{\mathcal{D}} \mathcal{N}(0, \sigma^2). \tag{5}$$

Remark 1. Note that $0 < \gamma_2 < \beta < \gamma_1 < 1$, unless $p = \frac{1}{2}$, in which case $\gamma_2 = \beta = \gamma_1 = \frac{u}{K}$; cf. Figure 1. For an illustration of (3), see Figure 2.

Remark 2. It follows from [17, Theorem 1.1] that we have $N^{-\alpha} \mathbb{E}\, f_{\boldsymbol{\kappa},N} = \Theta(1)$, where the expectation is with respect to Q, and where $\alpha = \alpha(p)$ is the unique real solution of the equation

$$(p^{1+\alpha} + q^{1+\alpha})^{K-u} (p^\alpha + q^\alpha)^u = 1.$$

We have $\beta(p) \le \alpha(p)$ with equality only for $p \in \{\frac{1}{2}, 1\}$: $\beta(\frac{1}{2}) = \alpha(\frac{1}{2}) = \frac{u}{K}$ and $\lim_{p\to 1} \beta(p) = \lim_{p\to 1} \alpha(p) = 1$.

Remark 3. Theorem 1 also holds true for $u = K$, in which case $K_\omega = \{(*, *, \dots)\}$ is a singleton, and we have $\gamma_1 = \beta = \gamma_2 = 1$ and $\sigma = 0$. In the case $p = \frac{1}{2}$ the random variable $f_{\boldsymbol{\kappa},N}$ is constant on K_ω, and again $\sigma = 0$. For $0 < u < K$ fixed, $\sigma(p)$ appears to be strictly increasing with p (we have not proved that), and a tedious calculation shows that $\lim_{p\to 1} \sigma(p) = 1$.

The next two theorems deal with variances. It is known from [17, 25] that in the symmetric Bernoulli model $\operatorname{Var} C_N = \Theta(N^{u/K})$ holds, again with a positive periodic function of $\ln N$ hidden in the Θ symbol, which implies $\operatorname{Var} C_N = \mathcal{O}(\mathbb{E}\, C_N)$. As it will turn out in Theorem 2, that property is shared, up to a logarithmic factor, by the asymmetric fixed query model. On the other hand, Theorem 3 implies $(\mathbb{E}\, C_N)^2 = o(\operatorname{Var} C_N)$ for the asymmetric random query model. Finally, Theorem 4 shows that also the central limit theorem known for the symmetric Bernoulli model (see [26]) persists in the asymmetric fixed query model.

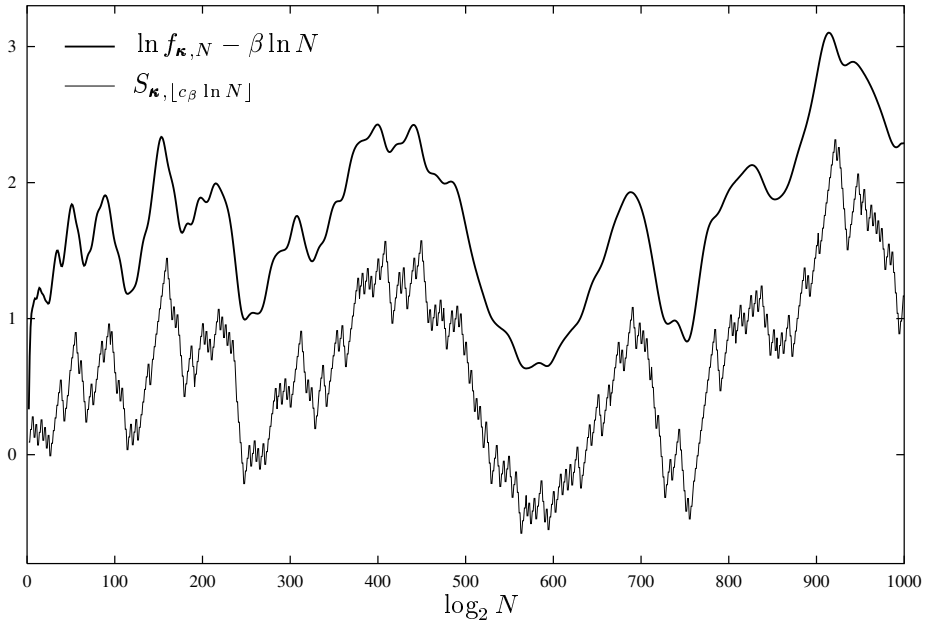

FIG. 2. *An illustration of* (3) *for a particular* $\kappa \in K_\omega$, *with* $\omega = (*, S)$, $p = \frac{1}{2}(\sqrt{5}-1)$, *and* $N \le 2^{1000}$. *The difference between the two curves seems to be bounded, as* $N \to \infty$, *but actually it is not; cf. Remark* 7.

THEOREM 2. *Uniformly in* $\boldsymbol{\kappa} \in K_\omega$, *the variance* $v_{\boldsymbol{\kappa},N}$ *satisfies*

$$v_{\boldsymbol{\kappa},N} = \begin{cases} \mathcal{O}(f_{\boldsymbol{\kappa},N} \ln N), \\ \Omega(f_{\boldsymbol{\kappa},N}). \end{cases}$$

Remark 4. The stronger upper estimate $v_{\boldsymbol{\kappa},N} = \mathcal{O}(f_{\boldsymbol{\kappa},N})$ follows from results obtained in [27] by means of poissonization techniques.

COROLLARY 2. *If in Corollary* 1 *we replace* $f_{\boldsymbol{\kappa},N}$ *by* C_N, *then* (4) *holds* $P \times Q$-*almost surely, and also* (5) *remains valid.*

Moreover all the limit laws that we can obtain for $\frac{C_N - b_N}{a_N}$ *by choosing appropriate normalizing sequences* $(a_N)_{N\ge 0}, (b_N)_{N\ge 0}$ *are degenerate.*

THEOREM 3. *Let* $\frac{1}{2} < p < 1$, *and let* $\xi = \xi(p)$ *be defined as the unique real solution of the equation*

$$(p^{1+2\xi} + q^{1+2\xi})^{(K-u)/2}(p^\xi + q^\xi)^u = 1.$$

Then $\alpha < \xi < \gamma_1$ *and, for large* N,

$$\operatorname{Var} C_N = N^{2\xi} e^{\mathcal{O}(\ln \ln N)}.$$

THEOREM 4. *We have for every fixed* $\boldsymbol{\kappa} \in K_\omega$

$$\frac{F_{\boldsymbol{\kappa},N} - f_{\boldsymbol{\kappa},N}}{\sqrt{v_{\boldsymbol{\kappa},N}}} \xrightarrow{\mathcal{D}} \mathcal{N}(0,1).$$

The paper is organized as follows. Section 3 starts with some preliminaries and continues with the proof of Theorem 1. Several lemmas will be needed. In particular, the close coupling between $f_{\boldsymbol{\kappa},N}$ and a certain sequence of partial sums derived

from $\boldsymbol{\kappa}$, which is expressed in (3), will become a corollary of Lemma 4, which allows for extensions of Theorem 1 and Corollary 1 to models, where the query is still independent of the keys but need not follow the same Bernoulli model as the keys. In section 4 we give proofs of the results concerning variances. Two lemmas used for establishing the Ω estimate in Theorem 2 might be of independent interest. In the proof of Theorem 3 inverse Mellin integrals of functions with dominant algebraic singularities have to be calculated. Finally in section 5 we prove Theorem 4 by invoking a central limit theorem for martingale difference arrays, and section 6 concludes the paper.

3. The expectation.

3.1. Some preliminaries and notation. For $i \in \mathbb{N}$ we denote by $\nu(i)$ the string obtained by stripping off the leading 1 in i's binary representation, i.e., $\nu(i) := s'$, when $i = (s)_2$. For any binary tree t we denote by t^i the subtree of t which has its root in the node v_i, which we define to be the node to which we are guided by the string $\nu(i)$. (If v_i is not in the vertex set of t, then t^i is empty.) For example, v_1 is the root of t (thus $\mathsf{t}^1 = \mathsf{t}$, $\mathsf{t}^2 = \mathsf{t}_\ell$, and $\mathsf{t}^3 = \mathsf{t}_r$), and we are guided to v_5 by the string $\nu(5) = 01$, since $5 = (101)_2$.

It readily follows from (1) and properties of the Bernoulli model that for fixed $\boldsymbol{\kappa} \in K_\omega$ the random variables $F^i_{\boldsymbol{\kappa},N}$ satisfy, for $i, N \geq 0$,

$$F^i_{\boldsymbol{\kappa},N} \stackrel{\mathcal{D}}{=} \mathbb{1}_{\{N\geq 2\}} \left(1 + a_{0,i+1} F^{i+1}_{\boldsymbol{\kappa},k} + a_{1,i+1} \bar{F}^{i+1}_{\boldsymbol{\kappa},N-k}\right), \tag{6}$$

where k follows a binomial distribution $B(N,p)$, the sequence $(\bar{F}^{i+1}_{\boldsymbol{\kappa},\ell})_{\ell\geq 0}$ is an independent copy of $(F^{i+1}_{\boldsymbol{\kappa},\ell})_{\ell\geq 0}$, and finally

$$a_{0,i} = \mathbb{1}_{\{\kappa_i \in \{0,*\}\}} \quad \text{and} \quad a_{1,i} = \mathbb{1}_{\{\kappa_i \in \{1,*\}\}}.$$

Indeed, $(F^i_{\boldsymbol{\kappa},N})_{i,N\geq 0}$ can be defined by (6), i.e., $(X^i_N)_{i,N\geq 0} = (F^i_{\boldsymbol{\kappa},N})_{i,N\geq 0}$ is the only finite solution, up to equality in distribution, to

$$X^i_N \stackrel{\mathcal{D}}{=} \mathbb{1}_{\{N\geq 2\}} \left(1 + a_{0,i+1} X^{i+1}_k + a_{1,i+1} \bar{X}^{i+1}_{N-k}\right)$$

with the same assumptions on distributions and independence as in (6). To see that, we iterate the latter equation $M-1$ times, thus representing X^0_N as

$$X^0_N \stackrel{\mathcal{D}}{=} \sum_{m=1}^{2^M-1} \varepsilon^0_m \mathbb{1}_{\{|\mathsf{t}^m|\geq 2\}} + \sum_{m=2^M}^{2^{M+1}-1} \varepsilon^0_m \mathbb{1}_{\{|\mathsf{t}^m|\geq 2\}} X^{M,m}_{|\mathsf{t}^m|}, \tag{7}$$

where

$$\varepsilon^i_m = \mathbb{1}_{\{\nu(m) \text{ matches } \boldsymbol{\kappa}^{(i)}\}}. \tag{8}$$

(We say that a finite string s matches a query $\boldsymbol{\kappa}$ if s is a prefix of some infinite string $\bar{s}$ that matches $\boldsymbol{\kappa}$.) Moreover $X^{M,m}_k \stackrel{\mathcal{D}}{=} X^M_k$ for $2^M \leq m < 2^{M+1}$, and $(X^{M,m}_k)_{k\geq 0}$ and $(X^{M,m'}_k)_{k\geq 0}$ are independent for $2^M \leq m < m' < 2^{M+1}$. Now, the probability that the second sum of (7) equals 0 is not smaller than $\mathbb{P}(\mathsf{height}(\mathsf{t}) \leq M)$, which approaches 1 as $M \to \infty$; cf. [19, p. 257] for the limiting distribution of the height of a binary asymmetric trie. This proves that the system of equations (6) indeed

uniquely determines $(F^i_{\boldsymbol{\kappa},N})_{i,N\ge 0}$. As a byproduct we have derived the almost surely convergent representation

$$F^i_{\boldsymbol{\kappa},N} = \sum_{m\ge 1} \varepsilon^i_m \mathbb{1}_{\{|\mathtt{t}^m|\ge 2\}}, \tag{9}$$

where ε^i_m depends only on $\boldsymbol{\kappa}$, and $\mathbb{1}_{\{|\mathtt{t}^m|\ge 2\}}$ depends only on $\mathtt{t}$. Note that the random variables summed in (9) are not independent. Equation (6) could be used to prove that moments of all orders of $F_{\boldsymbol{\kappa},N}$ exist. This, however, follows more easily from the fact that $F_{\boldsymbol{\kappa},N}$ is not larger than I_N, the number of internal nodes of the corresponding trie, which has itself moments of all orders (cf. [15]).

Proof of Theorem 1. We will actually show that the sup (and likewise the inf) in (2) is attained for each N, and it is attained at the same $\boldsymbol{\kappa}$ for all N. Denoting $\mathbf{f}^i_{\boldsymbol{\kappa}} = (f^i_{\boldsymbol{\kappa},N})_{N\ge 0}$, we derive from (6)

$$\mathbf{f}^i_{\boldsymbol{\kappa}} = \mathbf{e} + a_{0,i+1}\mathbf{M}_p\mathbf{f}^{i+1}_{\boldsymbol{\kappa}} + a_{1,i+1}\mathbf{M}_q\mathbf{f}^{i+1}_{\boldsymbol{\kappa}} = \mathbf{e} + \mathbf{B}_{i+1}\mathbf{f}^{i+1}_{\boldsymbol{\kappa}}, \tag{10}$$

where $\mathbf{e} := (0,0,1,1,1,\dots)$, $f^i_{\boldsymbol{\kappa},0} = f^i_{\boldsymbol{\kappa},1} = 0$ for $i \ge 0$, the matrix $\mathbf{M}_r$ is defined by $(\mathbf{M}_r)_{N,k} := \binom{N}{k} r^k(1-r)^{N-k}$ (with $0^0 := 1$) and has the property $\mathbf{M}_r\mathbf{M}_{r'} = \mathbf{M}_{rr'} = \mathbf{M}_{r'}\mathbf{M}_r$, and

$$\mathbf{B}_i := a_{0,i}\mathbf{M}_p + a_{1,i}\mathbf{M}_q = \begin{cases} \mathbf{M}_p, & \kappa_i = 0,\\ \mathbf{M}_q, & \kappa_i = 1,\\ \mathbf{M}_p + \mathbf{M}_q, & \kappa_i = *. \end{cases}$$

Iterating (10), we obtain

$$\begin{aligned} \mathbf{f}_{\boldsymbol{\kappa}} = (\mathbf{I} + \mathbf{B}_1 + \mathbf{B}_1\mathbf{B}_2 + \mathbf{B}_1\mathbf{B}_2\mathbf{B}_3 + \cdots)\mathbf{e} &= \sum_{n\ge 0}\prod_{i=1}^{n}\mathbf{B}_i\mathbf{e},\\ &= \sum_{n\ge 0}(\mathbf{M}_p + \mathbf{M}_q)^{\mu_n}\mathbf{M}_{\rho_n}\mathbf{e}, \end{aligned} \tag{11}$$

where $\prod_{i=1}^{0}\mathbf{B}_i = \mathbf{I}$ is the infinite identity matrix, and

$$\mu_n = \mu_n(\boldsymbol{\kappa}) = \sum_{i=1}^{n}\mathbb{1}_{\{\kappa_i = *\}} = \sum_{i=1}^{n} a_{0,i}a_{1,i}, \tag{12}$$

$$\rho_n = \rho_n(\boldsymbol{\kappa}) = \prod_{i=1}^{n}\left(p\mathbb{1}_{\{\kappa_i\in\{0,*\}\}} + q\mathbb{1}_{\{\kappa_i\in\{1,*\}\}}\right) = \prod_{i=1}^{n}(pa_{0,i} + qa_{1,i}). \tag{13}$$

Several lemmas are needed in the further investigation of (11). In the following we write $\mathbf{x}\nearrow$ if the sequence $\mathbf{x}$ is increasing, and we define a partial order $\preceq$ on sequences by

$$\mathbf{x}\preceq\mathbf{y} \;:\Leftrightarrow\; x_N \le y_N \quad \text{for all } N.$$

First we cite a lemma from [27], listing some properties of the matrices $\mathbf{M}_r$.

LEMMA 1. *For $0 \le r \le 1$ and any sequence $\mathbf{x}$ we have the following:*

1. $\mathbf{x} \succeq 0 \;\Rightarrow\; \mathbf{M}_r\mathbf{x} \succeq 0$.
2. $\Delta\mathbf{M}_r\mathbf{x} = r\mathbf{M}_r\Delta\mathbf{x}$.
3. $\mathbf{x} \nearrow \Rightarrow\; \mathbf{x} \succeq \mathbf{M}_r\mathbf{x}$ *and* $\mathbf{M}_r\mathbf{x} \nearrow$.
4. *If* $\mathbf{x} \succeq 0$ *and* $|\Delta^m x_N| \le c\frac{x_{N+m}}{(N+m)^{\underline{m}}}$ *for some* $c > 0$, *some integer* $m \ge 1$, *and all* $N \ge 0$, *then* $|\Delta^m(\mathbf{M}_r\mathbf{x})_N| \le c\frac{(\mathbf{M}_r\mathbf{x})_{N+m}}{(N+m)^{\underline{m}}}$ *for all* $N \ge 0$, *where* $n^{\underline{m}} = n(n-1)\cdot\ldots\cdot(n-m+1)$ *denotes falling factorial powers.*

A few simple facts concerning the sequences $\mathbf{f}^i$ are listed in the next lemma.

LEMMA 2. *For $i \ge 0$ and any fixed $\boldsymbol{\kappa} \in K_\omega$ (which we suppress) we have the following:*

1. $f_N^i \ge f_M^i \ge \frac{M(M-1)}{N(N-1)} f_N^i$ *for* $2 \le M \le N$, *in particular* $\mathbf{f}^i \nearrow$.
2. $f_N^i = \Theta\left(f_N^{i+1}\right)$, *as* $N \to \infty$.

Proof. Since we can represent $\mathbf{f}^i$ as

$$\mathbf{f}^i = \sum_{n\ge 0}\prod_{k=1}^{n}\mathbf{B}_{i+k}\mathbf{e} = \sum_{k\ge 0} b_k\mathbf{M}_{p_k}\mathbf{e}, \tag{14}$$

with $0 < p_k \le 1$ and $b_k > 0$ for $k \ge 0$, and since $\mathbf{e} \nearrow$, the left inequality of the first fact follows from property 3 of Lemma 1. Denoting for $0 < x \le 1$

(15)

$$E_N(x) := (\mathbf{M}_x\mathbf{e})_N = 1 - (1-x)^N - Nx(1-x)^{N-1} = N(N-1)\int_0^x \xi(1-\xi)^{N-2}d\xi,$$

we deduce $E_M(x) \ge \frac{M(M-1)}{N(N-1)}E_N(x)$, which proves the right inequality of the first fact. Furthermore, from (10) and $\mathbf{f}^{i+1} \succeq \mathbf{e}$ we deduce $f_N^i \le 1 + 2f_N^{i+1} \le 3f_N^{i+1}$, and, since $\mathbf{f}^{i+1} \nearrow$ and $(\mathbf{M}_p + \mathbf{M}_q)\mathbf{f}^{i+1} \succeq \mathbf{M}_p\mathbf{f}^{i+1} \succeq \mathbf{M}_q\mathbf{f}^{i+1} = \mathbf{M}_{q/p}\mathbf{M}_p\mathbf{f}^{i+1}$ by property 3 of Lemma 1,

$$f_N^i \ge 1 + \sum_{k=0}^{N}\binom{N}{k}q^k p^{N-k} f_k^{i+1} \ge \sum_{k=0}^{N}\binom{N}{k}q^k p^{N-k}\frac{k(k-1)}{N(N-1)}f_N^{i+1} = q^2 f_N^{i+1},$$

which completes the proof. ∎

A key step in the proof of (2) is the following result.

LEMMA 3. *With $\rho_n(\boldsymbol{\kappa})$ defined in* (13), *we let $\boldsymbol{\rho}(\boldsymbol{\kappa}) = (\rho_n(\boldsymbol{\kappa}))_{n\ge 0}$. If $\boldsymbol{\kappa}, \bar{\boldsymbol{\kappa}} \in K_\omega$ satisfy*

$$\boldsymbol{\rho}(\boldsymbol{\kappa}) \succeq \boldsymbol{\rho}(\bar{\boldsymbol{\kappa}}),$$

then

$$\mathbf{f}_{\boldsymbol{\kappa}} \succeq \mathbf{f}_{\bar{\boldsymbol{\kappa}}}.$$

Proof. Since μ_n depends only on the specification pattern ω, we have $\mu_n(\boldsymbol{\kappa}) = \mu_n(\bar{\boldsymbol{\kappa}})$ for $n \ge 0$. Using (11), we derive

$$\begin{aligned}\mathbf{f}_{\boldsymbol{\kappa}} - \mathbf{f}_{\bar{\boldsymbol{\kappa}}} &= \sum_{n\ge 0}(\mathbf{M}_p + \mathbf{M}_q)^{\mu_n}\mathbf{M}_{\rho_n(\boldsymbol{\kappa})}\mathbf{e} - \sum_{n\ge 0}(\mathbf{M}_p + \mathbf{M}_q)^{\mu_n}\mathbf{M}_{\rho_n(\bar{\boldsymbol{\kappa}})}\mathbf{e}\\ &= \sum_{n\ge 0}\left(\mathbf{I} - \mathbf{M}_{\rho_n(\bar{\boldsymbol{\kappa}})/\rho_n(\boldsymbol{\kappa})}\right)\mathbf{M}_{\rho_n(\boldsymbol{\kappa})}(\mathbf{M}_p + \mathbf{M}_q)^{\mu_n}\mathbf{e} \succeq 0,\end{aligned}$$

where in the latter sum each term is $\succeq 0$ by property 3 of Lemma 1. ∎

Next we note that there are unique sequences $\boldsymbol{\kappa}^{\sup} \in K_\omega \cap \{0,*\}^{\mathbb{N}}$ and $\boldsymbol{\kappa}^{\inf} \in K_\omega \cap \{1,*\}^{\mathbb{N}}$, such that $\boldsymbol{\rho}(\boldsymbol{\kappa}^{\sup}) \succeq \boldsymbol{\rho}(\boldsymbol{\kappa}) \succeq \boldsymbol{\rho}(\boldsymbol{\kappa}^{\inf})$ holds for $\boldsymbol{\kappa} \in K_\omega$, to which Lemma 3 applies, yielding

$$\sup_{\boldsymbol{\kappa}\in K_\omega} \mathbf{f}_{\boldsymbol{\kappa}} = \mathbf{f}_{\boldsymbol{\kappa}^{\sup}} = \sum_{n\geq 0} (\mathbf{M}_p + \mathbf{M}_q)^{\mu_n} \mathbf{M}_{p^{n-\mu_n}} \mathbf{e} =: \mathbf{f}^{\sup},$$

and similarly

$$\inf_{\boldsymbol{\kappa}\in K_\omega} \mathbf{f}_{\boldsymbol{\kappa}} = \mathbf{f}_{\boldsymbol{\kappa}^{\inf}} = \sum_{n\geq 0} (\mathbf{M}_p + \mathbf{M}_q)^{\mu_n} \mathbf{M}_{q^{n-\mu_n}} \mathbf{e} =: \mathbf{f}^{\inf}.$$

To complete the proof of (2) we have to derive Θ-estimates of the sequences $\mathbf{f}^{\sup}$ and $\mathbf{f}^{\inf}$. Here we can resort to Kirschenhofer, Prodinger, and Szpankowski [17, Theorem 1.2], where exact asymptotics of costs of partial match retrievals for fixed *periodic* queries are obtained. The method used there is a Mellin transform approach (cf. [9] for details) that, in our case, would make use of the representation

$$f_N^{\sup} = -\frac{1}{2\pi i} \int_{-1-i\infty}^{-1+i\infty} \frac{P(p^{-s}, q^{-s})(s+1)\Gamma(s)}{1 - p^{-s(K-u)}(p^{-s}+q^{-s})^u} N^{-s} ds \left(1 + \mathcal{O}\left(N^{-1}\right)\right),$$

where $P(\cdot,\cdot)$ is a polynomial of two variables of degree $K-1$, and which allows us, by invoking residue calculus, to derive

$$f_N^{\sup} = N^{\gamma_1} \xi(\ln N) + o\left(N^{\gamma_1}\right),$$

where ξ is a continuous positive periodic function which is constant if $\frac{\ln p}{\ln q}$ is irrational. For more details see also [26, Theorem 1, Lemma 4]. This proves the first part of (2), and the proof of the second part follows along the same lines, establishing $f_N^{\inf} = \Theta(N^{\gamma_2})$.

It remains to prove (3), which will be an immediate consequence of the following result.

LEMMA 4. *Assume that $(\rho_n)_{n\geq 1}$, as defined in* (13)*, is nicely approximated by a geometric sequence in the following sense. There is $r \in [q,p]$, an increasing sequence $(a_n)_{n\geq 1}$ of positive real numbers, and an increasing differentiable concave function g, defined on $[0,\infty[$, with $g(0)=0$, $a_n \leq g(n)$, and $g'(x) = o(1)$, as $x \to \infty$, such that*

$$|\ln(\rho_{Kn} r^{-(K-u)n}) - \ln(\rho_{Km} r^{-(K-u)m})| < a_n \vee g(|n-m|) \tag{16}$$

holds for $m,n \in \mathbb{N}$ with n sufficiently large. Then, denoting $\bar{S}_{\boldsymbol{\kappa},n} := \ln(\rho_{Kn} r^{-(K-u)n})$, we have

$$\ln f_{\boldsymbol{\kappa},N} = b \ln N + b\bar{S}_{\boldsymbol{\kappa},n_b} + \mathcal{O}\left(a_{n_b} + G(n_b) + \sqrt{\tfrac{g^3(n_b)}{n_b}} + \ln\ln N\right), \tag{17}$$

where b satisfies $(p^b+q^b)^u r^{(K-u)b} = 1$. The constant $c_b = b\big(u \ln(P_b^{-P_b} Q_b^{-Q_b})\big)^{-1}$ is as defined in Theorem 1, and $n_b = \lfloor c_b \ln N \rfloor$. Moreover $G(n) := \max_{x\geq 0}\big(bg(x) - d_b \frac{x^2}{2n}\big)$, with $d_b := \big(uc_b^2 P_b Q_b \ln^2 \frac{p}{q}\big)^{-1}$.

We are now ready to complete the proof of Theorem 1. First we claim the following: Equation (16) of Lemma 4 is satisfied for Q-almost every $\boldsymbol{\kappa} \in K_\omega$ if we choose $r = p^p q^q$, $g(x) = (\ln \frac{p}{q})\sqrt{2x\ln(x+1)}$, and $a_n = g(\sqrt{n})$.

Note that $\bar{S}_{\boldsymbol{\kappa},n}$ and $S_{\boldsymbol{\kappa},n}$, as defined in Theorem 1, coincide for $r = p^p q^p$, and that also $b = \beta$. We define the events

$$E_{n,m} := \{\boldsymbol{\kappa} \in K_\omega : |S_{\boldsymbol{\kappa},n} - S_{\boldsymbol{\kappa},m}| \geq a_n \vee g(|n-m|)\}.$$

Since $S_{\cdot,n} \overset{\mathcal{D}}{=} \ln \frac{p}{q} \sum_{i=1}^{n(K-u)} (Y_i - p)$, with $(Y_i)_{i\geq 1}$ i.i.d. and $\mathbb{P}(Y_1 = 1) = p = 1 - \mathbb{P}(Y_1 = 0)$, we obtain, applying Chernoff's bound (cf. [21]),

$$Q(E_{n,m}) \leq 2\exp\left(-2\frac{\sqrt{n}\ln n}{|n-m|}\right) \wedge 2\exp\left(-4\ln|n-m|\right).$$

Next we find $\sum_{m\geq 1} Q(E_{n,m}) = \mathcal{O}(n^{-3/2})$, and thus $\sum_{n,m\geq 1} Q(E_{n,m}) < \infty$. Now, by the Borel–Cantelli lemma, $Q(E_{n,m} \text{ i.o.}) = 0$, which proves the claim.

Next we are going to determine $G(n)$. We have to solve $bg'(x) = d_\beta \frac{x}{n}$ for x, which yields

$$x = x_n = \left(\frac{\beta^2 \ln^2 \frac{p}{q}}{12 d_\beta^2}\right)^{1/3} n^{2/3} (\ln n)^{1/3} \left(1 + \mathcal{O}\left(\frac{\ln\ln n}{\ln n}\right)\right).$$

So we obtain

$$G(n) = \beta g(x_n) - d_\beta \frac{x_n^2}{n} = \left(\frac{3\beta^4 \ln^4 \frac{p}{q}}{16 d_\beta}\right)^{1/3} n^{1/3} (\ln n)^{2/3} \left(1 + \mathcal{O}\left(\frac{\ln\ln n}{\ln n}\right)\right).$$

Thus, for n large enough, $a_n \vee G(n) \vee \sqrt{\frac{g^3(n)}{n}} = G(n) = \mathcal{O}(n^{1/3}(\ln n)^{2/3})$, which, via (17), proves (3), and thus completes the proof of Theorem 1. ∎

Remark 5. As a simple modification of the preceding proof shows, Lemma 4 allows us to generalize (3) and Corollary 1 to queries distributed according to a Bernoulli model that differs from the key model. Still we assume that the query is independent of the keys, but now a specified element of the query equals 0 with probability $\bar{p}$, and 1 with probability $\bar{q}$, which satisfy $r = p^{\bar{p}} q^{\bar{q}}$. Then (3) and Corollary 1 remain true if we replace $(S, \beta, c_\beta, \sigma)$ by $(\bar{S}, b, c_b, \bar{\sigma})$, with $\bar{\sigma} = b \ln \frac{p}{q} \sqrt{\left(\frac{K}{u} - 1\right)\bar{p}\bar{q} \big/ \ln\left(P_b^{-P_b} Q_b^{-Q_b}\right)}$.

Proof of Lemma 4. We only have to consider logarithms of $f_{\boldsymbol{\kappa},N}$, and thus the following crude estimate becomes useful:

$$f_{\boldsymbol{\kappa},N} = \Theta\left(\sum_{n\geq 0} \left[(\mathbf{M}_p + \mathbf{M}_q)^{un} \mathbf{M}_{\rho_{Kn}} \mathbf{e}\right]_N\right), \tag{18}$$

where the constants implied only depend on the dimension K. This follows from (11), from which we deduce, with the help of property 3 of Lemma 1,

$$\sum_{n\geq 0} \prod_{k=1}^{Kn} \mathbf{B}_k \mathbf{e} \preceq \mathbf{f}_{\boldsymbol{\kappa}} \preceq K \sum_{n\geq 0} \prod_{k=1}^{Kn} \mathbf{B}_k \mathbf{e}. \tag{19}$$

Recall that we put $P_a := \frac{p^a}{p^a + q^a}$ and $Q_a := 1 - P_a$ for $a \in \mathbb{R}$. We extend this definition by putting $P_{-\infty} := 0$ and $P_\infty := 1$, and we continue defining

$$k_n = k_n(N, \boldsymbol{\kappa}) := \log_{\frac{p}{q}}(N \rho_{Kn} p^{un}) \tag{20}$$

and

(21)
$$n_a = n_a(N, \boldsymbol{\kappa}) := \max(n \geq 0 : N\rho_{_{Kn}} p^{P_a un} q^{Q_a un} \geq 1) = \max(n \geq 0 : k_n \geq Q_a un).$$

By our assumption $p > q$, both P_a and n_a are increasing as a increases, and k_n is decreasing as n increases. Moreover $n_a = \Theta(\ln N)$ holds uniformly in $\boldsymbol{\kappa} \in K_\omega$ and $a \in [-\infty, \infty]$, since from $q^{(K-u)n} \leq \rho_{_{Kn}} \leq p^{(K-u)n}$ we can deduce $\lfloor \frac{1}{K} \log_{\frac{1}{q}} N \rfloor \leq n_a \leq \lfloor \frac{1}{K} \log_{\frac{1}{p}} N \rfloor$.

The first step towards (17) is the following result.

LEMMA 5. *Let $H : \mathbb{R}^2 \to \mathbb{R}$ be defined by*

$$H(n,k) := k \ln \frac{un}{k} + (un - k) \ln \frac{un}{un - k}. \tag{22}$$

Then, uniformly in $\boldsymbol{\kappa} \in K_\omega$,

$$\ln f_{\boldsymbol{\kappa},N} = \max_{n_0 \leq n \leq n_2} H(n, k_n) + \mathcal{O}(\ln \ln N). \tag{23}$$

Proof. We observe that $E_N(x) = \Theta(1 \wedge N^2 x^2)$, with $E_N(x)$ defined in (15); thus by (18)

$$f_{\boldsymbol{\kappa},N} \asymp \sum_{n \geq 0} \sum_{k=0}^{un} \binom{un}{k} E_N\left(\rho_{_{Kn}} p^{un-k} q^k\right) \asymp \sum_{n \geq 0} \underbrace{\sum_{k=0}^{un} \binom{un}{k} \left(1 \wedge \left(N\rho_{_{Kn}} p^{un-k} q^k\right)^2\right)}_{\Sigma_{N,n}}.$$

Note that $\Sigma_{N,n}$ grows (resp., decays) like a geometric sequence for $n \leq n_0$ (resp., $n > n_2$); more precisely, we have

$$\Sigma_{N,n} \leq 2^{un} \wedge N^2 \rho_{_{Kn}}^2 (p^2 + q^2)^{un}$$

for any $n \geq 0$, and moreover $\Sigma_{N,n} \geq \sum_{k \leq Q_0 un} \binom{un}{k} \geq 2^{un-1}$ for $n \leq n_0$, and

$$\begin{aligned} \Sigma_{N,n} &\geq \sum_{k \geq Q_2 un} \binom{un}{k} \left(N\rho_{_{Kn}} p^{un-k} q^k\right)^2 = N^2 \rho_{_{Kn}}^2 (p^2 + q^2)^{un} \sum_{k \geq Q_2 un} \binom{un}{k} P_2^{un-k} Q_2^k \\ &\geq c N^2 \rho_{_{Kn}}^2 (p^2 + q^2)^{un}, \end{aligned}$$

for $n > n_2$ and some $c > 0$. (It follows from results in [13] that we can choose $c = \frac{1}{4} \wedge Q_2$.) Thus $\sum_{n=0}^{n_0} \Sigma_{N,n} = \mathcal{O}(\Sigma_{N,n_0})$ and $\sum_{n \geq n_2} \Sigma_{N,n} = \mathcal{O}(\Sigma_{N,n_2})$. For $n_0 \leq n \leq n_2$ we have for any $a \in [0, 2]$

$$\Sigma_{N,n} \leq \sum_{k=0}^{un} \binom{un}{k} \left(N\rho_{_{Kn}} p^{un-k} q^k\right)^a = (N\rho_{_{Kn}})^a (p^a + q^a)^{un}, \tag{24}$$

and a_n, which minimizes the right-hand side of (24), obeys

$$\ln(N\rho_{_{Kn}}) + un(P_{a_n} \ln p + Q_{a_n} \ln q) = 0.$$

Note that $n_{a_m} = m$; cf. (21). This results in

$$\Sigma_{N,n} \leq \left(P_{a_n}^{-P_{a_n}} Q_{a_n}^{-Q_{a_n}}\right)^{un} = e^{H(n,k_n)},$$

where we used $Q_{a_n} un = \log_{\frac{p}{q}}(N\rho_{K_n} p^{un}) = k_n$. Furthermore, $Q_2 un_0 \le k_n \le Q_0 un_2$ implies $k_n = \Theta(\ln N)$, uniformly in $\boldsymbol{\kappa} \in K_\omega$ and $n_0 \le n \le n_2$. This is used, together with Stirling's formula, in the following lower estimate:

$$\Sigma_{N,n} \ge \binom{un}{\lfloor k_n \rfloor} = \Omega\left(\frac{e^{H(n,k_n)}}{\sqrt{\ln N}}\right).$$

Thus, $(\max_{n_0\le n\le n_2} e^{H(n,k_n)})^{-1} \sum_{n=n_0}^{n_2} \Sigma_{N,n}$ is upper bounded by $n_2 - n_0 + 1$ and lower bounded by $\Omega(\ln^{-\frac{1}{2}} N)$, so we finally obtain

$$\ln f_{\boldsymbol{\kappa},N} = \ln\left(\sum_{n=n_0}^{n_2} \Sigma_{N,n}\right) + \mathcal{O}(1) = \max_{n_0\le n\le n_2} H(n,k_n) + \mathcal{O}(\ln\ln N), \tag{25}$$

which completes the proof of the lemma. □

Some properties of the function H are explored in the following three lemmas.

LEMMA 6. *If either $n_0 \le m \le n \le n_{\gamma_2}$ or $n_2 \ge m \ge n \ge n_{\gamma_1}$, then*

$$H(n,k_n) \ge H(m,k_m). \tag{26}$$

Proof. First observe that $-\log_{\frac{p}{q}} p^{K-u}p^u \le k_m - k_{m+1} \le -\log_{\frac{p}{q}} q^{K-u}p^u$. We let

$$h(t) := H(m+t, k_m + (k_{m+1}-k_m)t)$$

and assume $n_0 \le m < n_{\gamma_2}$, which implies $a_{m+1} \le \gamma_2$. Next we apply the mean value theorem. For some $0 < \tau < 1$ and $a_m < \bar a < a_{m+1}$ we have

$$\begin{aligned}
H(m+1,k_{m+1}) - H(m,k_m) &= h(1) - h(0) = h'(\tau)\\
&= u\ln\frac{u(m+\tau)}{u(m+\tau) - k_m - (k_{m+1}-k_m)\tau}\\
&\quad + (k_{m+1}-k_m)\ln\frac{u(m+\tau) - k_m - (k_{m+1}-k_m)\tau}{k_m + (k_{m+1}-k_m)\tau}\\
&= u\ln\frac{1}{P_{\bar a}} + (k_{m+1}-k_m)\ln\frac{P_{\bar a}}{Q_{\bar a}}\\
&\ge u\ln\frac{1}{P_{\bar a}} + \log_{\frac{p}{q}}(q^{K-u}p^u)\ln\frac{P_{\bar a}}{Q_{\bar a}} = u\ln\frac{1}{P_{\bar a}} + \bar a\ln q^{K-u}p^u\\
&= \ln\left((p^{\bar a}+q^{\bar a})^u q^{(K-u)\bar a}\right) \ge \ln\left((p^{\gamma_2}+q^{\gamma_2})^u q^{(K-u)\gamma_2}\right) = 0.
\end{aligned}$$

This proves (26) in the case $n_0 \le m \le n \le n_{\gamma_2}$. The proof in the case $n_2 \ge m \ge n \ge n_{\gamma_1}$ follows similar lines. □

LEMMA 7. *For $0 \le b \le 1$ and $Q_1 un \le k, k' \le Q_0 un$ we have*

$$\left|H(n,k) - H(n,k') - (k-k')b\ln\frac{p}{q}\right| \le \frac{2|k-k'|}{qun}\left(|k - Q_b un| \vee |k' - Q_b un|\right). \tag{27}$$

Proof. Assume without loss of generality (w.l.o.g.) that $k \ge k'$. The left-hand side of (27) equals $\left|\int_{k'}^{k} \ln\frac{P_b x}{Q_b(un-x)}dx\right|$ and is less than $(k-k')\max_{k'\le x\le k}\left|\ln\frac{P_b x}{Q_b(un-x)}\right|$. The latter absolute value can be estimated as follows:

$$\left|\ln\frac{P_b x}{Q_b(un-x)}\right| = \left|\int_{Q_b(un-x)}^{P_b x}\frac{d\xi}{\xi}\right| \le \frac{|Q_b un - x|}{un}\left(\frac{1}{P_bQ_1} \vee \frac{1}{Q_bP_0}\right).$$

Furthermore $P_bQ_1 \wedge Q_bP_0 \geq Q_1P_0 = \frac{q}{2}$. □

LEMMA 8. *Let $r \in [q,p]$ and $b \in \mathbb{R}$ be such that $r^{(K-u)b}(p^b+q^b)^u = 1$. Moreover let k_n and n_a be defined by (20) and (21), with $\rho_{Kn} = r^{(K-u)n}$, and for $a \in [-\infty,\infty]$ let ν_a be such that $N\left(r^{K-u}p^{uP_a}q^{uQ_a}\right)^{\nu_a} = 1$.*

Then $\phi_N(n) := H(n,k_n)$ is a concave function, defined for real $n \in]\nu_{-\infty},\nu_\infty[$, which satisfies

$$\phi_N(n) = b\ln N - d_b\frac{(n-n_b)^2}{2n_b} + \mathcal{O}\left(\frac{1+|n-n_b|}{n_b} + \frac{|n-n_b|^3}{n_b^2}\right), \tag{28}$$

and for some $C > 0$

$$\phi_N(n) - b\ln N \leq -C\frac{(n-\nu_b)^2}{2\nu_b}. \tag{29}$$

Proof. First note that $n_a = \lfloor \nu_a \rfloor$ for $-\infty \leq a \leq \infty$, and that

$$\nu_b = \frac{\ln N}{\ln r^{-(K-u)}p^{-P_b}q^{-Q_b}} = c_b\ln N,$$
$$\nu_{-\infty} = \frac{\ln N}{\ln r^{-(K-u)}q^{-u}}, \quad \nu_\infty = \frac{\ln N}{\ln r^{-(K-u)}p^{-u}}.$$

We observe that $\frac{k_n}{un}$ decreases from 1 to 0, as n increases from $\nu_{-\infty}$ to ν_∞; more precisely

$$\frac{k_n}{un} = \frac{1}{un}\log_{\frac{p}{q}} N + \frac{1}{u}\log_{\frac{p}{q}} r^{(K-u)}p^u = \frac{\nu_{-\infty}}{\nu_{-\infty}-\nu_\infty}\left(1-\frac{\nu_\infty}{n}\right),$$

and thus ϕ_N is well defined on $]\nu_{-\infty},\nu_\infty[$. We are seeking the Taylor expansion of ϕ_N at its maximum, and we derive, along lines similar to the proof of Lemma 6,

$$\begin{aligned}\phi_N'(\nu_a) &= u\ln\frac{u\nu_a}{u\nu_a - k_{\nu_a}} + \ln\frac{u\nu_a - k_{\nu_a}}{k_{\nu_a}}\left.\frac{dk_n}{dn}\right|_{n=\nu_a} \\ &= u\ln\frac{1}{P_a} + \log_{\frac{p}{q}}(r^{K-u}p^u)\ln\frac{P_a}{Q_a} = \ln\left((p^a+q^a)^u r^{(K-u)a}\right),\end{aligned}$$

which equals 0 iff $a = b$. Next

$$\phi_N(\nu_b) = u\nu_b\left(P_b\ln\frac{1}{P_b} + Q_b\ln\frac{1}{Q_b}\right) = \frac{b}{c_b}\nu_b = b\ln N.$$

Furthermore

$$\phi_N''(n) = \frac{u}{n} - \frac{u\nu_\infty}{\nu_\infty-\nu_{-\infty}}\frac{1}{n-\nu_{-\infty}} - \frac{u\nu_{-\infty}}{\nu_\infty-\nu_{-\infty}}\frac{1}{\nu_\infty-n} = -\frac{u\nu_{-\infty}\nu_\infty}{n(n-\nu_{-\infty})(\nu_\infty-n)}$$

is easily seen to be strictly negative for $n \in]\nu_{-\infty},\nu_\infty[$, which proves that ϕ_N is

concave on that interval. Now we compute

$$\begin{aligned}
\phi_N''(\nu_b) &= -\frac{u}{\nu_b}\left(\frac{\nu_b}{\nu_{-\infty}}-1\right)^{-1}\left(1-\frac{\nu_b}{\nu_\infty}\right)^{-1}\\
&= -\frac{u}{c_b^2\nu_b}\left(\ln r^{-(K-u)}q^{-u}-\frac{1}{c_b}\right)^{-1}\left(\frac{1}{c_b}-\ln r^{-(K-u)}p^{-u}\right)^{-1}\\
&= -\frac{b^2}{uc_b^2\nu_b}\left(\ln\frac{1}{Q_b}-\ln P_b^{-P_b}Q_b^{-Q_b}\right)^{-1}\left(\ln P_b^{-P_b}Q_b^{-Q_b}-\ln\frac{1}{P_b}\right)^{-1}\\
&= -\frac{1}{uc_b^2\nu_b}\left(P_bQ_b\ln^2\frac{p}{q}\right)^{-1}\\
&= -\frac{d_b}{\nu_b};
\end{aligned}$$

moreover, $\int_0^{n-\nu_b}\frac{x^2}{2!}\phi_N'''(n-x)dx$, the remainder in the order two Taylor expansion of ϕ_N at ν_b, can be shown to be $\mathcal{O}\big(\frac{|n-\nu_b|^3}{\nu_b^2}\big)$ as $N\to\infty$ and uniformly for $\nu_{-\infty}<n<\nu_\infty$, using $\nu_\infty-\nu_b=\Theta(\nu_b)$ and $\nu_b-\nu_{-\infty}=\Theta(\nu_b)$. We thus derive

$$\phi_N(n)=b\ln N-d_b\frac{(n-\nu_b)^2}{2\nu_b}+\mathcal{O}\left(\frac{|n-\nu_b|^3}{\nu_b^2}\right).$$

Now, replacing ν_b by n_b yields (28), with the slightly changed error term. The following upper estimate for ϕ_N'' on the interval $]\nu_{-\infty},\nu_\infty[$ yields the definition of the constant C, needed for the proof of (29):

$$\phi_N''(n)\le-\frac{u\nu_{-\infty}}{(n-\nu_{-\infty})(\nu_\infty-n)}\le-\frac{4u\nu_{-\infty}}{(\nu_\infty-\nu_{-\infty})^2}=:-\frac{C}{\nu_b}.\qquad\square$$

We proceed in the proof of Lemma 4. Our aim is to approximate in (23) the terms $H(n,k_n)$ corresponding to $\rho_{_{Kn}}$ by terms $H(n,k_n')$ corresponding to the approximating sequence $r^{(K-u)n}$. Note that k_n is defined in (20), and we let

$$k_n':=\log_{\frac{p}{q}}Nr^{(K-u)n}p^{un}.$$

Putting $m=0$ in (16) yields

$$|\ln(\rho_{_{Kn}}r^{-(K-u)n})|=|k_n-k_n'|\ln\frac{p}{q}=o(n).$$

Thus $k_n\in[Q_{\gamma_1}un,Q_{\gamma_2}un]$ implies $k_n'\in[Q_1un,Q_0un]$ for large enough n, and we can deduce

$$|H(n,k_n)-H(n,k_n')|=\mathcal{O}(|k_n-k_n'|)=\mathcal{O}\left(g(\nu_b)+g(|n-\nu_b|)\right),\tag{30}$$

where the left equality follows easily from Lemma 7, and the right equality is implied by

$$\begin{aligned}
|k_n-k_n'|\ln\frac{p}{q}&\le|k_{n_b}-k_{n_b}'|\ln\frac{p}{q}+|k_n-k_n'-(k_{n_b}-k_{n_b}')|\ln\frac{p}{q}\\
&=|\ln(\rho_{_{Kn_b}}r^{-(K-u)n_b})|+|\ln(\rho_{_{Kn}}r^{-(K-u)n})-\ln(\rho_{_{Kn_b}}r^{-(K-u)n_b})|\\
&=\mathcal{O}\left(g(\nu_b)+g(|n-\nu_b|)\right),
\end{aligned}$$

which holds by the assumptions made in (16).

Lemma 6 and (29) and (30) will be used in the following, where we show that the max in (23) is attained on a small subset of $[n_0, n_2]$:

$$\begin{aligned}\max_{n_0\le n\le n_2} H(n,k_n) &= \max_{n_{\gamma_2}\le n\le n_{\gamma_1}} H(n,k_n)\\ &= \max_{n_{\gamma_2}\le n\le n_{\gamma_1}} (H(n,k_n) - H(n,k'_n) + H(n,k'_n))\\ &\le b\ln N + \mathcal{O}(g(\nu_b)) + \max_{n_{\gamma_2}\le n\le n_{\gamma_1}} \left(\mathcal{O}(g(|n-\nu_b|)) - C\frac{(n-\nu_b)^2}{2\nu_b}\right).\end{aligned}$$

Defining $\operatorname{argmax}\{F(x), x\ge 0\} := \sup\left\{x\ge 0 : F(x) = \sup_{y\ge 0} F(y)\right\}$ for a real function F, we obtain

$$\begin{aligned}x^* :&= \operatorname{argmax}\left\{\mathcal{O}(g(x)) - C\frac{x^2}{2\nu_b}, x\ge 0\right\}\\ &\le \sup\left\{x\ge 0 : \mathcal{O}(g(x)) - C\frac{x^2}{2\nu_b}\ge 0\right\}\\ &\le \sup\left\{x\ge 0 : \mathcal{O}(g(\nu_b)) - C\frac{x^2}{2\nu_b}\ge 0\right\}\\ &= \mathcal{O}\left(\sqrt{\nu_b g(\nu_b)}\right),\end{aligned}$$

where the first sup yields the estimate $x^* = \mathcal{O}(\nu_b)$, which, together with $g(\mathcal{O}(n)) = \mathcal{O}(g(n))$, is then used to obtain the second inequality. Of course, the constants implied by $\mathcal{O}$ can vary from line to line, but as they are derived from Lemma 7, they are independent of $\boldsymbol{\kappa}$. The maximizing n has to belong to the set

$$\mathcal{N}_b := \left\{n\in\mathbb{N} : |n-\nu_b| = \mathcal{O}\left(\sqrt{\nu_b g(\nu_b)}\right)\right\}.$$

We continue observing that

$$|k_n - Q_b u n| \vee |k'_n - Q_b u n| = \mathcal{O}\left(g(\nu_b) + |n-\nu_b|\right),$$

which allows us to rewrite the error term of Lemma 7:

$$\begin{aligned}&\frac{2|k_n-k'_n|}{qun_b}\left(|k_n - Q_b u n| \vee |k'_n - Q_b u n|\right)\\ &\qquad = \mathcal{O}\left(\frac{g^2(\nu_b)}{n_b} + \frac{g(\nu_b)|n-\nu_b|}{n_b} + \frac{g(|n-\nu_b|)|n-\nu_b|}{n_b}\right).\end{aligned}$$

Now we can be more precise, again employing Lemmas 7 and 8:

(31)
$$\begin{aligned}&\max_{n_0\le n\le n_2} H(n,k_n) = \max_{n\in\mathcal{N}_b}\left(H(n,k_n) - H(n,k'_n) + H(n,k'_n)\right)\\ &\quad= \max_{n\in\mathcal{N}_b}\left[(k_n-k'_n)b\ln\frac{p}{q} + \mathcal{O}\left(\frac{|k_n-k'_n|}{n_b}\left(|k_n - Q_b u n| \vee |k'_n - Q_b u n|\right)\right)\right.\\ &\qquad\qquad \left. + b\ln N - d_b\frac{(n-n_b)^2}{2n_b} + \mathcal{O}\left(\frac{1+|n-n_b|}{n_b} + \frac{|n-n_b|^3}{n_b^2}\right)\right]\\ &\quad= b\ln N + b\bar{S}_{\boldsymbol{\kappa},n_b} + \mathcal{O}\left(\sqrt{\tfrac{g^3(n_b)}{n_b}}\right) + \max_{n\in\mathcal{N}_b}\left[-d_b\frac{(n-n_b)^2}{2n_b} + b(\bar{S}_{\boldsymbol{\kappa},n} - \bar{S}_{\boldsymbol{\kappa},n_b})\right].\end{aligned}$$

By the definition of G we have

$$
\begin{aligned}
0 &\le \max_{n\in\mathcal{N}_b}\left[-d_b\frac{(n-n_b)^2}{2n_b}+b(\bar{S}_{\boldsymbol{\kappa},n}-\bar{S}_{\boldsymbol{\kappa},n_b})\right]\\
&\le \max_{n\in\mathcal{N}_b}\left[-d_b\frac{(n-n_b)^2}{2n_b}+b\big(a_{n_b}\vee g(|n-n_b|)\big)\right]\\
&\le a_{n_b}\vee G(n_b).
\end{aligned}
\tag{32}
$$

Now, fitting Lemma 5 and equations (31) and (32) together finishes the proof of Lemma 4. □

Remark 6. It is clear that we need not be that precise about the constant d_b in Lemma 4. Since the function G satisfies $G(n)\ge G(cn)\ge cG(n)$ for $0<c\le 1$, i.e., $G(cn)=\Theta(G(n))$ for fixed $c>0$ (actually G can be shown to be increasing, concave, and satisfying $\lim_{x\searrow 0}G(x)=0$), it is only $d_b>0$ which matters. There are, however, two instances where we could wish to have the precise value. To these we devote the following remarks.

Remark 7. Suppose we want to get hold of what is hidden behind the error terms in (17), when $\boldsymbol{\kappa}$ is distributed according to Q, in which case we have $b=\beta$. Reworking the preceding proof with $g(x)=(\ln\frac{p}{q})\sqrt{2x\ln(x+1)}$, we find that the terms estimated by $\mathcal{O}\big(\sqrt{g^3(n_\beta)/n_\beta}\,\big)$ are indeed of order $\mathcal{O}(n_\beta^{1/6}\ln^{5/6}n_\beta)$. Furthermore, $a_{n_\beta}+G(n_\beta)$ is an upper bound for the quantity

$$
Y_{n_\beta}:=\max_{n\ge 0}\left(\beta(S_n-S_{n_\beta})-d_\beta\frac{(n-n_\beta)^2}{2n_\beta}\right).
$$

Donsker's invariance principle (and scaling properties of Brownian motion) can be used to show that $D_\beta^{-1}(c_\beta/\beta)^{1/3}n_\beta^{-1/3}Y_{n_\beta}$ converges in distribution to the random variable

$$
Y:=\sup_{t\in\mathbb{R}}(W_t-t^2),
$$

where W is a two-sided Brownian motion, and

$$
D_\beta:=\frac{\beta^2\ln^2\frac{p}{q}}{\ln\left(P_\beta^{-P_\beta}Q_\beta^{-Q_\beta}\right)}\left(2p^2q^2\left(\frac{K}{u}-1\right)^2P_\beta Q_\beta\right)^{1/3}.
$$

Komlós–Major–Tusnády-type strong approximation results (cf. [6]) then even allow us to deduce

$$
\mathbb{E}\,\ln f_{\boldsymbol{\kappa},N}=\beta\ln N+D_\beta\mathbb{E}\,Y(\beta\ln N)^{1/3}+\mathcal{O}\left(\ln^{1/6}N\,\ln^{5/6}\ln N\right).
$$

Moreover, since $Q\big(\beta(S_{\boldsymbol{\kappa},n^3+n^2}-S_{\boldsymbol{\kappa},n^3})\ge\big(\frac{d_\beta}{2}+2D_\beta\big(\frac{\beta}{c_\beta}\big)^{1/3}\mathbb{E}\,Y\big)n,\ \text{i.o.}\big)=1$, by the second Borel–Cantelli lemma, we easily deduce

$$
Q\left(\ln f_{\boldsymbol{\kappa},N}-\beta\ln N-\beta S_{\boldsymbol{\kappa},\lfloor c_\beta\ln N\rfloor}\ge D_\beta\mathbb{E}\,Y(\beta\ln N)^{1/3},\ \text{i.o.}\right)=1.
$$

Since in the example depicted in Figure 2 the constant $D_\beta\mathbb{E}\,Y\approx 0.02$ is very small, we do not observe the gaps of size $\Theta(\ln^{1/3}N)$ between the two curves in the plotted range.

The distribution of Y surfaces in a paper of Chernoff [5] and was studied analytically by Groeneboom [12]. There also seems to be a close connection to results obtained by Steinsaltz in his thesis [29], where he develops general methods to investigate for a certain class of processes the difference of expected maximum and maximum expectation, which in many cases turns out to be approximately distributed like a third root term times the random variable Y.

Remark 8. It is of course essential to know the dependence on p of the error terms in (17) when we want to investigate the phase change from standard normal to Dirac at 0 of $\frac{C_N - \mathbb{E}\, C_N}{\sqrt{\operatorname{Var} C_N}}$ at the transition from the symmetric to the asymmetric Bernoulli models. One would have to vary p with N, and $p = p_N = \frac{1}{2} + \lambda/\sqrt{\ln N}$ with $\lambda \geq 0$ seems to be the right choice.

Remark 9. A heuristic derivation of the values of b and n_b appearing in Lemma 4 could be along the following lines. Suppose that $\boldsymbol{\kappa}$ satisfies $\ln(\rho_{Kn} r^{-(K-u)n}) = \mathcal{O}(1)$, which is a stronger regularity assumption than (16). With μ_n defined in (12), we let K_n denote the set of the 2^{μ_n} prefixes of length n that match $\boldsymbol{\kappa}$. Given N keys, the number of those keys having the prefix $\pi \in K_n$ is denoted N_π, and it is binomially distributed. Suppose now that for some $c > 0$ we have $f^i_{\boldsymbol{\kappa},N} = \Theta(N^c)$, uniformly in i. Then (10) is iterated $n-1$ times, and computing expectations, we obtain $f_{\boldsymbol{\kappa},N} = \mathcal{O}(2^{\mu_n}) + \mathbb{E} \sum_{\pi \in K_n} f^n_{\boldsymbol{\kappa},N_\pi}$, and thus $\Theta(N^c) = \mathcal{O}(2^{\mu_n}) + \Theta\left(\sum \binom{\mu_n}{k} (N \rho_n p^k q^{\mu_n - k})^c\right)$. Since the latter has to hold for $N, n \to \infty$ in such a way that $n = o(\ln N)$, we must have $c = b$. Suppose further that $F^i_{\boldsymbol{\kappa},N} / f^i_{\boldsymbol{\kappa},N} \to 1$ in probability as $N \to \infty$, uniformly in i. Then, for large N, keys with prefix π (whose $*$-positions contain k zeros and $\mu_n - k$ ones) will contribute a proportion of

$$\mathbb{E}\, F^n_{\boldsymbol{\kappa},N_\pi} / f_{\boldsymbol{\kappa},N} = \Theta\left((\rho_n p^k q^{\mu_n - k})^b\right) = \Theta(P_b^k Q_b^{\mu_n - k})$$

to the total cost with high probability. This suggests that we should consider a different probabilistic model, where keys are distributed according to the Bernoulli(P_b) model, but conditioned to match $\boldsymbol{\kappa}$. Denoting by $\tilde{F}_{\boldsymbol{\kappa},N}$ (resp., $\tilde{I}_N$) the cost of a partial match query for $\boldsymbol{\kappa}$ (resp., the number of internal nodes) in the new model, we have $\tilde{F}_{\boldsymbol{\kappa},N} = \Theta(\tilde{I}_N)$ and $\mathbb{E}\, \tilde{I}_N = \Theta(N)$, and therefore also

$$\mathbb{E}\, \tilde{F}^n_{\boldsymbol{\kappa},N_\pi} / \tilde{f}_{\boldsymbol{\kappa},N} = \Theta(P_b^k Q_b^{\mu_n - k}),$$

as $N \to \infty$, with high probability, where $\tilde{f}_{\boldsymbol{\kappa},N} := \mathbb{E}\, \tilde{F}_{\boldsymbol{\kappa},N}$. This might convince us that there is an asymptotic equivalence between the levels with highest expected contribution to $f_{\boldsymbol{\kappa},N}$ and $\tilde{f}_{\boldsymbol{\kappa},\lfloor N^b \rfloor}$. Now any level ν, which contributes most to $\mathbb{E}\, \tilde{I}_N$, satisfies $\nu \sim \frac{\ln N}{h}$, where $h = -P_b \ln P_b - Q_b \ln Q_b$ denotes the entropy of the Bernoulli(P_b) distribution. This follows from the $u = K$ case of Lemma 8, but one could also argue that only with that choice of ν do typical prefixes of length ν have probabilities of order $N^{-1+o(1)}$, or one could use the fact that the depth D_N of a full external node chosen uniformly at random in a trie built from N keys according to the Bernoulli(P_b) model is concentrated around its expected value $\mathbb{E}\, D_N \sim \frac{\ln N}{h}$. See Szpankowski's book [30] for the *asymptotic equipartition property* and other entropy related issues, as well as for references and results on depth in digital data structures. From $\mu_n \sim Kn/u$ we deduce that the main contribution to $\tilde{f}_{\boldsymbol{\kappa},\lfloor N^b \rfloor}$ comes from levels $\sim \frac{Kb \ln N}{uh}$, and the value of n_b becomes clear, observing that Lemma 4 is stated in terms of Kn rather than n. Finally one has to argue that n_b is insensitive to small irregularities of the query, as allowed by (16), but that due to those irregularities, the expected contributions to $f_{\boldsymbol{\kappa},N}$ from levels $n \sim n_b$ change by a factor of $(\rho_{Kn} r^{-(K-u)n})^b = e^{b \bar{S}_{\boldsymbol{\kappa},n}}$.

4. The variance. Note that $\boldsymbol{\kappa}$ is fixed throughout this section, and dependencies on $\boldsymbol{\kappa}$ will mostly be suppressed.

Proof of Theorem 2. Subtracting (10) from (6), squaring, and taking expectations, we obtain

$$\mathbf{v}^i = \mathbf{s}^i + \mathbf{B}_{i+1}\mathbf{v}^{i+1}, \quad i \geq 0, \tag{33}$$

where

$$s_N^i = \sum_{k=0}^{N} \binom{N}{k} p^k q^{N-k} \left(a_{0,i+1}(f_k^{i+1} - (\mathbf{M}_p \mathbf{f}^{i+1})_N) + a_{1,i+1}(f_{N-k}^{i+1} - (\mathbf{M}_q \mathbf{f}^{i+1})_N)\right)^2. \tag{34}$$

Iterating, we find

$$\mathbf{v} = \mathbf{I}\mathbf{s}^0 + \mathbf{B}_1\mathbf{s}^1 + \mathbf{B}_1\mathbf{B}_2\mathbf{s}^2 + \cdots = \sum_{n\geq 0}\prod_{k=1}^{n} \mathbf{B}_k \mathbf{s}^n. \tag{35}$$

The $\mathcal{O}$ result will follow from the following more general result, which holds for fixed nonnegative integers m, uniformly in $\boldsymbol{\kappa} \in K_\omega$:

$$\Delta^m v_N = \mathcal{O}\left(\frac{f_N}{N^m} \ln N\right). \tag{36}$$

For its proof we need more information about the sequences $\mathbf{s}^i$ and thus about the sequences $\Delta^m \mathbf{f}^i$ for $m \geq 0$.

LEMMA 9. *For any fixed integer $m \geq 0$ we have*

$$\Delta^m f_N^i = \mathcal{O}\left(\frac{f_N^i}{N^m}\right), \qquad \Delta^m s_N^i = \mathcal{O}\left(\frac{(f_N^i)^2}{N^{m+1}}\right), \tag{37}$$

as $N \to \infty$, where the constants implied by the $\mathcal{O}$ symbols depend on neither i nor $\boldsymbol{\kappa} \in K_\omega$.

Proof. Throughout the proof i is fixed. Since $|\Delta^m \mathbf{e}_N| \leq (m+1)! \frac{e_{N+m}}{(N+1)\cdots(N+m)}$, we can apply property 4 of Lemma 1 to the representation (14). Furthermore we use $f_{N+m}^i = \mathcal{O}(f_N^i)$, which we deduce from item 1 of Lemma 2. This proves the first statement regarding differences of $\mathbf{f}^i$, which is now used, together with item 1 of Lemma 2, to estimate the remainder term in the following Newton-type expansion of f_k^i around $k = \lfloor pN \rfloor$:

$$f_k^i = \sum_{\mu=0}^{M} \Delta^\mu f_{\lfloor pN \rfloor}^i \frac{(k - \lfloor pN \rfloor)^{\underline{\mu}}}{\mu!} + \mathcal{O}\left(\frac{f_N^i}{N^{M+1}} |k - pN|^{M+1}\right). \tag{38}$$

We fix N and obtain a similar expansion of $f_{N'-k}^i$ around $k = \lfloor pN \rfloor + \nu$, where $N' = N + \nu$ and $\nu = \mathcal{O}(1)$,

$$f_{N'-k}^i = \sum_{\mu=0}^{M} \Delta^\mu f_{\lceil qN \rceil}^i \frac{(\lfloor pN \rfloor - k + \nu)^{\underline{\mu}}}{\mu!} + \mathcal{O}\left(\frac{f_N^i}{N^{M+1}} (|k - pN|^{M+1} + 1)\right),$$

and, expanding $(k - \lfloor pN \rfloor)^{\underline{\mu}}$ and $(\lfloor pN \rfloor - k + \nu)^{\underline{\mu}}$ in powers of $k - pN'$, we obtain

$$a_{0,i} f_k^i + a_{1,i} f_{N'-k}^i = f_N^i \sum_{\mu=0}^{M} N^{-\mu} P_\mu(k - pN', \nu) + \mathcal{O}\left(\frac{f_N^i}{N^{M+1}} (|k - pN|^{M+1} + 1)\right),$$

where P_μ is a polynomial of two variables of degree μ, which depends on i and N. More precisely, the coefficients of P_μ involve the quantities $\{pN\} := pN - \lfloor pN \rfloor$, $\frac{N^\mu}{f_N^i}\Delta^\mu f^i_{\lfloor pN \rfloor}$, and $\frac{N^\mu}{f_N^i}\Delta^\mu f^i_{\lceil qN \rceil}$ but are uniformly bounded in i and N. Notice that in particular $P_0 = a_{0,i} f^i_{\lfloor pN \rfloor}/f^i_N + a_{1,i} f^i_{\lceil qN \rceil}/f^i_N$ and

$$P_1 = a_{0,i}\frac{N}{f_N^i}\Delta f^i_{\lfloor pN \rfloor}(k - pN' + \nu p + \{pN\}) + a_{1,i}\frac{N}{f_N^i}\Delta f^i_{\lceil qN \rceil}(pN' - k + \nu q - \{pN\}).$$

For k following a binomial distribution $B(N', p)$, we now have

$$\begin{aligned} s^{i-1}_{N'} &= \operatorname{Var}\left(a_{0,i} f^i_k + a_{1,i} f^i_{N'-k}\right) \\ &= (f^i_N)^2 \sum_{\mu,\mu'=1}^{M} N^{-\mu-\mu'} \operatorname{Cov}\left(P_\mu\left(k - pN', \nu\right), P_{\mu'}\left(k - pN', \nu\right)\right) \\ &\quad + \mathcal{O}\left((f^i_N)^2 N^{-\frac{M}{2}-1}\right). \end{aligned} \tag{39}$$

Note that we can start the summation with $\mu, \mu' = 1$, since $\operatorname{Cov}(P_\mu, P_{\mu'}) = 0$ if $\mu \wedge \mu' = 0$. For $\mu \wedge \mu' \geq 1$ we find

$$\operatorname{Cov}(P_\mu, P_{\mu'}) = \sum_{j=1}^{\lfloor \frac{\mu+\mu'}{2} \rfloor} \bar{P}_j(N') p_{\mu+\mu'-2j}(\nu),$$

where $\bar{P}_j$ and p_j are polynomials of degree j, with coefficients uniformly bounded in i and N; thus, computing differences with respect to ν, we obtain

$$\begin{aligned} \Delta^m \operatorname{Cov}(P_\mu, P_{\mu'}) &= \Delta^m \sum_{j=1}^{\lfloor \frac{\mu+\mu'}{2} \rfloor} \bar{P}_j(N+\nu) p_{\mu+\mu'-2j}(\nu) \\ &= \begin{cases} \mathcal{O}\left(N^{\lfloor \frac{\mu+\mu'-m}{2} \rfloor}\right) & \text{for } m < \mu + \mu', \\ 0 & \text{for } m \geq \mu + \mu'; \end{cases} \end{aligned}$$

thus the second statement of the lemma follows with $M = 2m$ from computing the mth differences in (39) and from item 2 of Lemma 2. The special case $m = 1$ of (39) reads

$$s^i_N = Npq\left(a_{0,i+1}\Delta f^{i+1}_{\lfloor pN \rfloor} - a_{1,i+1}\Delta f^{i+1}_{\lceil qN \rceil}\right)^2 + \mathcal{O}\left(\frac{(f^i_N)^2}{N^2}\right). \qquad \square$$

LEMMA 10. *The sequences $\mathbf{x}^i$ and $\mathbf{y}^i$, defined for $i \geq 0$ and some integer $m \geq 0$ by $x^i_N = N^{\underline{m}}\Delta^m s^i_{N-m}$ and $y^i_N = N^{\underline{m}}\Delta^m v^i_{N-m}$, satisfy the system of equations*

$$\mathbf{y}^i = \mathbf{x}^i + \mathbf{B}_{i+1}\mathbf{y}^{i+1}, \quad i \geq 0. \tag{40}$$

If in (40) the sequences $\mathbf{x}^i$ satisfy $|x^i_N| \leq c \cdot f^i_N$ for some $c > 0$ and $i, N \geq 0$, then $\mathbf{y}^0$ satisfies $y^0_N = \mathcal{O}(f_N \ln N)$, and the $\mathcal{O}$-constant is uniform in $\boldsymbol{\kappa} \in K_\omega$.

Proof. We multiply both sides of (33) with the matrix $\mathbf{D}_m$, which is defined by

$$(\mathbf{D}_m)_{N,k} = N^{\underline{m}}\binom{m}{N-k}(-1)^{N-k},$$

and obtain (40), since $\mathbf{x}^i = \mathbf{D}_m \mathbf{s}^i$, $\mathbf{y}^i = \mathbf{D}_m \mathbf{v}^i$, and $\mathbf{D}_m$ commutes with $\mathbf{M}_x$ for $m \in \mathbb{N}$ and $0 < x \le 1$. The latter is clear from the representations $\mathbf{D}_m = \mathbf{P}\mathbf{F}_m\mathbf{P}^{-1}$ and $\mathbf{M}_x = \mathbf{P}\mathbf{G}_x\mathbf{P}^{-1}$, with $\mathbf{P}_{N,k} = \binom{N}{k}$ and diagonal matrices $\mathbf{F}_m, \mathbf{G}_x$ defined by $(\mathbf{F}_m)_{N,k} = N^{\underline{m}}\delta_{N,k}$ and $(\mathbf{G}_x)_{N,k} = x^N\delta_{N,k}$. For the proof of the second assertion we note that in

$$-c\sum_{n\ge 0}\prod_{k=1}^{n}\mathbf{B}_k\mathbf{f}^n \preceq \mathbf{y}^0 = \sum_{n\ge 0}\prod_{k=1}^{n}\mathbf{B}_k\mathbf{x}^n \preceq c\sum_{n\ge 0}\prod_{k=1}^{n}\mathbf{B}_k\mathbf{f}^n$$

we can estimate the first $\bar{n} := \lfloor \frac{K}{K-u}\log_{1/p} N \rfloor$ terms of the right-hand side by

$$\prod_{k=1}^{n}\mathbf{B}_k\mathbf{f}^n = \mathbf{f} - \sum_{j=0}^{n-1}\prod_{k=1}^{j}\mathbf{B}_k\mathbf{e} \preceq \mathbf{f}.$$

For the remaining terms (for $n \ge \bar{n}$) we use $f_N^i = \mathcal{O}(N)$, which follows from (2), and property 2 of Lemma 1:

$$\sum_{n\ge\bar{n}}\prod_{k=1}^{n}\mathbf{B}_k\mathbf{f}^n \preceq c'\sum_{n\ge\bar{n}}\prod_{k=1}^{n}\mathbf{B}_k\mathbf{id} = c'\,\mathbf{id}\sum_{n\ge\bar{n}}\prod_{k=1}^{n}(a_{0,k}p + a_{1,k}q) \preceq \tfrac{c''}{N}\mathbf{id},$$

with $c', c'' > 0$ and $\mathbf{id}$ denoting the sequence $(N)_{N\ge 0}$. We conclude by obtaining $|y_N^0| \le c(\bar{n}f_N + c'') = \mathcal{O}(f_N \ln N)$. □

By Lemma 9, item 1 of Lemma 2, and (2) we have for $m \ge 0$

$$N^{\underline{m}}\Delta^m s_{N-m}^i = \mathcal{O}\left(\frac{(f_{N-m}^i)^2}{N}\right) = \mathcal{O}\left(\frac{(f_N^i)^2}{N}\right) = \mathcal{O}\left(f_N^i\right),$$

and hence Lemma 10 yields (36). The proof of the $\mathcal{O}$-part of Theorem 2 is thus complete.

In order to obtain the Ω result, we define the sequence $\underline{\mathbf{s}}$ via $\underline{s}_N := \inf_{i\ge 0} s_N^i$ and derive from (35)

$$\mathbf{v} \succeq (\mathbf{I} + \mathbf{B}_1 + \mathbf{B}_1\mathbf{B}_2 + \cdots)\underline{\mathbf{s}}.$$

Since $\underline{s}_N \ge 0$ for all $N \ge 0$ and $\underline{s}_2 > 0$, the latter because of $f_2^{i+1} \ge 1$ and

$$\begin{aligned} s_2^i &= \sum_{k=0}^{2}\binom{2}{k}p^k q^{2-k}\left(a_{0,i+1}(f_k^{i+1} - p^2 f_2^{i+1}) + a_{1,i+1}(f_{2-k}^{i+1} - q^2 f_2^{i+1})\right)^2 \\ &= (f_2^{i+1})^2 \times \begin{cases} p^2(1-p^2), & (a_{0,i+1}, a_{1,i+1}) = (1,0), \\ q^2(1-q^2), & (a_{0,i+1}, a_{1,i+1}) = (0,1), \\ (p^2+q^2)(1-p^2-q^2), & (a_{0,i+1}, a_{1,i+1}) = (1,1), \end{cases} \end{aligned}$$

we can prove $v_N = \Omega(f_N)$ by applying the following two lemmas.

LEMMA 11. *Let sequences* $\mathbf{p}$ *and* $\mathbf{b}$ *be given, with* $p_0 = b_0 = 1$ *and* $0 < p_i < 1$, $b_i > 0$ *for* $i \ge 1$, *and let* $\boldsymbol{\ell} := \sum_{i\ge 0} b_i \mathbf{M}_{p_i}\mathbf{e}$. *If there exists* $\varepsilon > 0$ *such that for all* $0 < x < 1$ *we have*

$$\sum_{i\ge 0} b_i \mathbb{1}_{]\varepsilon x, x]}(p_i) \ge \varepsilon \sum_{i\ge 0} b_i \mathbb{1}_{]x,\infty[}(p_i) \tag{41}$$

and

$$\sum_{i\ge 0} b_i p_i^2 \mathbb{1}_{]\varepsilon x, x]}(p_i) \ge \varepsilon \sum_{i\ge 0} b_i p_i^2 \mathbb{1}_{]0,\varepsilon x]}(p_i), \tag{42}$$

then for any sequence $\mathbf{x}$ *of nonnegative terms having at least one positive term and satisfying* $x_0 = x_1 = 0$, *the sequence* $\mathbf{y} := \sum_{i\geq 0} b_i \mathbf{M}_{p_i}\mathbf{x}$ *satisfies*

$$y_N = \Omega(\ell_N).$$

Proof. Let $k_0 \geq 2$ be the smallest k such that $x_k > 0$. With the help of (15) it is easily checked that

$$(\mathbf{M}_p \mathbf{e})_N \leq 1 \wedge N^2 p^2.$$

Thus for $N \geq k_0$ we have

$$\begin{aligned}
&\inf_{\varepsilon N^{-1} < p \leq N^{-1}} \binom{N}{k_0} p^{k_0}(1-p)^{N-k_0} \\
&\qquad = \binom{N}{k_0}\left[\left(\frac{\varepsilon}{N}\right)^{k_0}\left(1-\frac{\varepsilon}{N}\right)^{N-k_0} \wedge \left(\frac{1}{N}\right)^{k_0}\left(1-\frac{1}{N}\right)^{N-k_0}\right] \\
&\qquad \geq \binom{N}{k_0}\left[\left(\frac{\varepsilon}{N}\right)^{k_0} e^{-\varepsilon} \wedge \left(\frac{1}{N}\right)^{k_0} e^{-1}\right] \geq k_0^{-k_0}\left(\varepsilon^{k_0} e^{-\varepsilon} \wedge e^{-1}\right).
\end{aligned}$$

We define $C_{k_0,\varepsilon} := k_0^{k_0}\left(\varepsilon^{-k_0} e^{\varepsilon} \vee e\right)$. Using properties (41) and (42) with $x = \frac{1}{N}$, we obtain for $N \geq k_0$

$$\begin{aligned}
\ell_N &\leq \sum_{p_i \leq \frac{1}{N}} b_i (Np_i)^2 + \sum_{p_i > \frac{1}{N}} b_i \leq \left(\frac{1}{\varepsilon}+1\right) \sum_{\frac{\varepsilon}{N} < p_i \leq \frac{1}{N}} b_i (Np_i)^2 + \frac{1}{\varepsilon} \sum_{\frac{\varepsilon}{N} < p_i \leq \frac{1}{N}} b_i \\
&\leq \left(1+\frac{2}{\varepsilon}\right) \sum_{\frac{\varepsilon}{N} < p_i \leq \frac{1}{N}} b_i \leq \left(1+\frac{2}{\varepsilon}\right) C_{k_0,\varepsilon} \sum_{i\geq 0} \binom{N}{k_0} b_i p_i^{k_0} (1-p_i)^{N-k_0} \\
&\leq \left(1+\frac{2}{\varepsilon}\right) C_{k_0,\varepsilon} \frac{1}{x_{k_0}} \sum_{i\geq 0} b_i \mathbf{M}_{p_i} \mathbf{x}_N.
\end{aligned}$$

This completes the proof. □

Remark 10. For any $N \geq 2$ we have $\ell_N < \infty$ iff $\sum_{i\geq 0} b_i p_i^2 < \infty$, since $\frac{1}{4}(1 \wedge N^2 p^2) \leq (\mathbf{M}_p \mathbf{e})_N \leq 1 \wedge N^2 p^2$ for $N \geq 2$. Moreover, for $N \geq k_0$ we have $y_N < \infty$ iff $\ell_N < \infty$ by Lemma 11 and because of $y_N \leq \ell_N \max_{k\leq N} x_k$. If the sequence $\mathbf{p}$ has only one limit point, it follows from (41) that this limit point must be 0, and then from (42) that $\sum_{i\geq 0} b_i p_i^2 < \infty$ holds.

LEMMA 12. *Let* $\mathbf{p}$ *and* $\mathbf{b}$ *be as in Lemma* 11. *Then the conditions* (41) *and* (42) *of Lemma* 11 *are satisfied, and, moreover,* $\sum_{i\geq 0} b_i p_i^2 < \infty$ *holds, if the function* G, *defined by* $G(x) := -\sum_{i\geq 0} b_i \mathbb{1}_{]-\infty, p_i[}(x)$, *with values in* $[-\infty, 0]$, *has a representation*

$$G(x) = \sum_{n\geq 0} g_n(x),$$

with $g_0(x) = -\mathbb{1}_{]-\infty,1[}(x)$ *and* $g_n(x) = \sum_{i\geq 0} b_i^{(n)} g_{n-1}\left(\frac{x}{p_i^{(n)}}\right)$ *for* $n \geq 1$, *where the* $b_i^{(n)}$ *are nonnegative, the* $p_i^{(n)}$ *are positive and less than or equal to* 1, *and*

$$\inf_{n\geq 1} \sum_{i\geq 0} b_i^{(n)} > 1, \quad \sup_{n\geq 1} \sum_{i\geq 0} b_i^{(n)} \left(p_i^{(n)}\right)^2 < 1, \quad \text{and} \quad \inf_{n,i:\, b_i^{(n)} > 0} p_i^{(n)} > 0$$

hold.

Proof. We redefine, only for purposes of this proof, the symbol Δ: We let $\Delta f(x) = f(x) - f(x-)$ denote the jump of the right continuous function f at x. As we will shortly show,

$$\sum_{i\geq 0} b_i p_i^2 =: C < \infty \tag{43}$$

holds, so we derive for $x > 0$

$$G(x) = -\sum_{p_i > x} b_i \geq -\frac{1}{x^2} \sum_{p_i > x} b_i p_i^2 \geq -\frac{C}{x^2}.$$

Hence G is an increasing and right continuous step function on $]0,\infty[$, with values in $]-\infty, 0]$, and thus serves as a generalized distribution function (cf. [28, p. 158]) of a discrete measure μ on $]0,\infty[$ given by

$$\mu(]a,b]) := G(b) - G(a) = \sum_{a<t\leq b} \Delta G(t).$$

Defining another measure ν, absolutely continuous with respect to μ, by

$$\nu(]a,b]) := \sum_{a<t\leq b} t^2 \Delta G(t),$$

we have to prove the inequalities

$$\mu(]\varepsilon x, x]) \geq \varepsilon \mu(]x,\infty[), \qquad \nu(]\varepsilon x, x]) \geq \varepsilon \nu(]0, \varepsilon x]),$$

which are obtained by rephrasing (41) and (42) in terms of μ and ν. Moreover, (43) will be proved by showing $\nu(]0,\infty[) < \infty$. Therefore we denote

$$\alpha = \inf_{n\geq 1} \sum_{i\geq 0} b_i^{(n)}, \ \beta = \sup_{n\geq 1} \sum_{i\geq 0} b_i^{(n)} \left(p_i^{(n)}\right)^2, \ \text{ and } \ \eta = \inf_{n,i:\, b_i^{(n)}>0} p_i^{(n)} \tag{44}$$

and define measures μ_n, ν_n for $n \geq 0$ by

$$\mu_n(]a,b]) := g_n(b) - g_n(a), \quad \nu_n(]a,b]) := \sum_{a<t\leq b} t^2 \Delta g_n(t).$$

Now we observe that for $x > 0$

$$\mu_n(]x,\infty[) = -g_n(x) = -\sum_{i\geq 0} b_i^{(n)} g_{n-1}\left(\frac{x}{p_i^{(n)}}\right) \geq -\alpha g_{n-1}\left(\frac{x}{\eta}\right) = \alpha \mu_{n-1}(]x/\eta,\infty[),$$

which results in

$$\alpha\mu(]x,\infty[) = \alpha \sum_{n\geq 0} \mu_n(]x,\infty[) \leq \sum_{n\geq 1} \mu_n(]x\eta,\infty[) \leq \mu(]x\eta,\infty[)$$

and thus, since both sides are finite,

$$\mu(]x\eta, x]) \geq (\alpha - 1)\mu(]x,\infty[). \tag{45}$$

Similarly, we obtain

$$\begin{aligned}\nu_n(]0,x]) &= \sum_{0<t\le x} t^2\Delta g_n(t) = \sum_{i\ge0} b_i^{(n)} \sum_{0<t\le x} t^2\Delta g_{n-1}\left(\frac{t}{p_i^{(n)}}\right)\\ &= \sum_{i\ge0} b_i^{(n)} \left(p_i^{(n)}\right)^2 \sum_{0<t\le x/p_i^{(n)}} t^2\Delta g_{n-1}(t)\\ &\le \beta \sum_{0<t\le x/\eta} t^2\Delta g_{n-1}(t) = \beta\nu_{n-1}(]0,x/\eta]).\end{aligned}$$

Starting with $\nu_0(]0,\infty[) = 1$, induction yields $\nu_k(]0,\infty[) \le \beta^k$ and therefore

$$\sum_{i\ge0} b_i p_i^2 = \nu(]0,\infty[) = \sum_{n\ge0} \nu_n(]0,\infty[) \le \frac{1}{1-\beta} < \infty,$$

which proves (43), and, moreover,

$$\nu(]0,x\eta]) = \sum_{n\ge0} \nu_n(]0,x\eta]) \le \nu_0(]0,x\eta]) + \beta \sum_{n\ge0} \nu_n(]0,x]) = \nu_0(]0,x\eta]) + \beta\nu(]0,x]).$$

If $x < 1$, then also $x\eta < 1$ and thus $\nu_0(]0,x\eta]) = 0$, so we end up with

$$\nu(]x\eta,x]) \ge \frac{1-\beta}{\beta}\nu(]0,x\eta]). \tag{46}$$

The inequalities (45) and (46) remain true if we replace η, $\alpha-1$, and $\frac{1-\beta}{\beta}$ by $\varepsilon := \min\bigl(\eta, \alpha-1, \frac{1-\beta}{\beta}\bigr)$; thus the hypotheses (41) and (42) are valid. □

We cannot apply Lemma 12 directly since the sequences $\mathbf{b}^{(n)}, \mathbf{p}^{(n)}$ that would have to be chosen, namely, $b_i^{(n)} = a_{i,n}\mathbb{1}_{\{0,1\}}(i)$, $p_0^{(n)} = p$, $p_1^{(n)} = q$, do not satisfy the hypotheses. In the notation of (44) we have $\alpha = 1$, $\beta = p^2+q^2$, and $\gamma = q$, and thus the condition $\alpha > 1$ is violated. We thus recall (19) and apply Lemma 12 to the sequences $\mathbf{b}$ and $\mathbf{p}$ given by $\sum_{n\ge0}\prod_{k=1}^{Kn}\mathbf{B}_k = \sum_{i\ge0} b_i\mathbf{M}_{p_i}$. The pairs of sequences $\mathbf{b}^{(n)}, \mathbf{p}^{(n)}$ that we have to provide directly correspond to the products

$$\prod_{k=Kn-K+1}^{Kn} \mathbf{B}_k = (\mathbf{M}_p+\mathbf{M}_q)^u(\mathbf{M}_p)^{s_0}(\mathbf{M}_q)^{s_1},$$

where $0 \le s_0 \le K-u$ and $s_0+s_1 = K-u$, in which case $\mathbf{b}^{(n)}$ (resp., $\mathbf{p}^{(n)}$) is defined by $b_i^{(n)} = \binom{u}{i}$ (resp., $p_i^{(n)} = p^{i+s_0}q^{u-i+s_1}$) for $0 \le i \le u$, and these are easily seen to satisfy the conditions listed in Lemma 12. The estimate $v_N = \Omega(f_N)$ thus follows from

$$\sum_{n\ge0}\prod_{k=1}^{Kn} \mathbf{B}_k\underline{\mathbf{s}} \preceq \sum_{n\ge0}\prod_{k=1}^{Kn} \mathbf{B}_k\mathbf{s}^{Kn} \preceq \mathbf{v},$$

and the proof of Theorem 2 is complete. □

Proof of Corollary 2. It suffices to show that for each $\boldsymbol{\kappa} \in K_\omega$ we have P-almost surely $\frac{F_{\boldsymbol{\kappa},N}}{f_{\boldsymbol{\kappa},N}} \to 1$, as $N\to\infty$, since then also $P\times Q$-almost surely, as $N\to\infty$,

$$\ln C_N - \beta\ln N = \ln f_{\boldsymbol{\kappa},N} - \beta\ln N + o(1). \tag{47}$$

We will derive a stronger result: For fixed $\boldsymbol{\kappa} \in K_\omega$ and $\varepsilon > 0$ we have, P-almost surely, as $N \to \infty$,

$$\frac{F_{\boldsymbol{\kappa},N} - f_{\boldsymbol{\kappa},N}}{(f_{\boldsymbol{\kappa},N})^{2/3+\varepsilon}} \to 0. \tag{48}$$

We suppress $\boldsymbol{\kappa}$ and indeed obtain, by Theorem 2 and Chebyshev's inequality,

$$\mathbb{P}\left(|F_N - f_N| \geq (f_N)^{2/3+\varepsilon/2}\right) = \mathcal{O}\left((f_N)^{-1/3-\varepsilon} \ln N\right),$$

so that (48) is P-almost surely fulfilled for

$$N = N_k := \min(N \in \mathbb{N} : (f_N)^{1/3+\varepsilon} \geq k^{1+3\varepsilon})$$

and $k \to \infty$ by the Borel–Cantelli lemma. We readily derive

$$f_{N_{k+1}} - f_{N_k} \sim (k+1)^3 - k^3 \sim 3k^2 \leq 3(f_{N_{k+1}})^{2/3},$$

and $\sup_{k\geq 1} f_{N_{k+1}}/f_{N_k} < \infty$. Thus, if $|F_N - f_N| < (f_N)^{2/3+\varepsilon/2}$ holds for each $N \in \{N_k, N_{k+1}\}$, then for $N_k < n < N_{k+1}$ we obtain

$$|F_n - f_n| \leq |F_{N_k} - f_{N_{k+1}}| \vee |F_{N_{k+1}} - f_{N_k}| = \mathcal{O}\left((f_{N_{k+1}})^{\frac{2}{3}+\frac{\varepsilon}{2}}\right) = \mathcal{O}\left((f_n)^{\frac{2}{3}+\frac{\varepsilon}{2}}\right),$$

using the fact that the sequence $(f_k)_{k\geq 0}$ and the random sequence $(F_k)_{k\geq 0}$ are both increasing. This proves (48).

Next we show that there is no limiting distribution for C_N, no matter how we normalize it. We will rather consider $C_N N^{-\beta}$, which for $N \to \infty$-almost surely equals $\exp(\beta S_{\cdot,n} + \mathcal{O}(n^{0.4})) =: X_n$ with $n = \lfloor c_\beta \ln N \rfloor$; cf. (3) and (47). In order to obtain a nondegenerate limiting distribution for $\frac{X_n - b_n}{a_n}$, we should choose a_n at least of the order of the distance of the 0.25 and the 0.75 quantile of X_n, which is $e^{c\sqrt{n}+\mathcal{O}(n^{0.4})}$ with some $c > 0$. The median of X_n, which would be a good candidate for b_n, is of order $e^{\mathcal{O}(n^{0.4})} = o(a_n)$, therefore we can w.l.o.g. choose $b_n = 0$ for $n \geq 0$. Assume now that $Y_n := a_n^{-1} X_n \xrightarrow{\mathcal{D}} Y$ for some positive random variable Y which is not almost surely constant. By appropriate choice of $(a_n)_{n\geq 0}$ we can w.l.o.g. achieve that $\delta := \mathbb{P}(Y \in]0,1])$ satisfies $0 < \delta < 1$. Then

$$\mathbb{P}(Y_n \in]0,1]) = \mathbb{P}(\ln X_n \in]-\infty, \ln a_n]) =: \delta_n \to \delta,$$

but also

$$\begin{aligned}\mathbb{P}(Y_n \in]0,n]) &= \delta_n + \mathbb{P}(\ln X_n \in]\ln a_n, \ln a_n + \ln n]) \\ &= \delta_n + \mathbb{P}(\beta S_{\cdot,n} \in]\ln a_n - \mathcal{O}(n^{0.4}), \ln a_n + \mathcal{O}(n^{0.4})]) \\ &= \delta_n + \mathcal{O}(n^{-0.1}) \to \delta.\end{aligned}$$

Thus for any $x \geq 1$ we deduce $\mathbb{P}(Y \in]0,x]) = \delta$, which implies $\delta = 1$ and so contradicts our assumption on δ. □

Proof of Theorem 3. For the proof of the inequality $\alpha < \xi < \gamma_1$ we compare the corresponding defining equations, where we have to show

$$p^s > \left(p^{1+2s} + q^{1+2s}\right)^{\frac{1}{2}} > (p^{1+s} + q^{1+s}).$$

Now, the left inequality is a simple consequence of $q < p$, and the right inequality follows from the arithmetic-quadratic mean inequality.

For the result concerning $\operatorname{Var} C_N$ we first observe

$$\begin{aligned}\operatorname{Var} C_N &= \operatorname{Var} f_{\boldsymbol{\kappa},N} + \mathbb{E}\, v_{\boldsymbol{\kappa},N}\\ &= \mathbb{E}\,(f_{\boldsymbol{\kappa},N})^2 - (\mathbb{E}\, f_{\boldsymbol{\kappa},N})^2 + \mathcal{O}(N^{\alpha}\ln N)\\ &= \mathbb{E}\,(f_{\boldsymbol{\kappa},N})^2 + \mathcal{O}(N^{2\alpha}),\end{aligned}$$

where all the expectations and variances on the right-hand side are with respect to Q. From Lemma 5 we know that

$$f_{\boldsymbol{\kappa},N} \asymp \sum_{n\ge 0}\sum_{k=0}^{un}\binom{un}{k}\left(1\wedge\left(N\rho_{_{Kn}}p^{un-k}q^{k}\right)^2\right) = e^{\mathcal{O}(\ln\ln N)}\max_{n_0\le n\le n_2}\binom{un}{\lfloor k_n\rfloor},$$

from which we deduce

$$(f_{\boldsymbol{\kappa},N})^2 = e^{\mathcal{O}(\ln\ln N)}\sum_{n\ge 0}\sum_{k=0}^{un}\binom{un}{k}^2\left(1\wedge\left(N\rho_{_{Kn}}p^{un-k}q^{k}\right)^4\right),$$

and furthermore $\mathbb{E}\,(f_{\boldsymbol{\kappa},N})^2 = e^{\mathcal{O}(\ln\ln N)}\Psi(N)$, where

$$\Psi(N) = \sum_{n\ge 0}\sum_{j=0}^{(K-u)n}\binom{(K-u)n}{j}p^{(K-u)n-j}q^{j}\sum_{k=0}^{un}\binom{un}{k}^2\left(1\wedge\left(Np^{Kn-k-j}q^{k+j}\right)^4\right).$$

The asymptotics of $\Psi(N)$ will now be determined by invoking its Mellin transform $\Psi^*(s)$, which will be seen to exist for $-4 < \Re s < -2\xi$.

$$\Psi^*(s) := \int_0^\infty N^{s-1}\Psi(N)dN = \int_0^\infty N^{s-1}(1\wedge N^4)dN\cdot\Lambda(s) = -\frac{4}{s(s+4)}\Lambda(s),$$

where, with the abbreviation $a_s = (p^{1-s}+q^{1-s})^{K/u-1}$,

$$\begin{aligned}\Lambda(s) &= \sum_{n\ge 0}\sum_{j=0}^{(K-u)n}\binom{(K-u)n}{j}(p^{(K-u)n-j}q^{j})^{1-s}\sum_{k=0}^{un}\binom{un}{k}^2(p^{un-k}q^{k})^{-s}\\ &= \sum_{n\ge 0}a_s^{un}[z^{un}](1+p^{-s}z)^{un}(1+q^{-s}z)^{un}\\ &= \frac{1}{2\pi i}\oint_{|z|=(pq)^{\Re s/2}}\frac{dz/z}{1-a_s^u(1+p^{-s}z)^u(1+q^{-s}z)^u z^{-u}}\\ &= \frac{1}{u}\sum_{k=1}^{u}\frac{1}{2\pi i}\oint_{|z|=(pq)^{\Re s/2}}\frac{dz}{z-\varepsilon_k a_s(1+p^{-s}z)(1+q^{-s}z)}\\ &= \frac{1}{u}\sum_{k=1}^{u}\frac{1}{\sqrt{\left(1-\varepsilon_k a_s(p^{-s}+q^{-s})\right)^2-4\varepsilon_k^2a_s^2(pq)^{-s}}}\\ &= \frac{1}{u}\sum_{k=1}^{u}\frac{1}{\sqrt{(1-\varepsilon_k a_s(p^{-s/2}+q^{-s/2})^2)(1-\varepsilon_k a_s(p^{-s/2}-q^{-s/2})^2)}}.\end{aligned}$$

Here $(\varepsilon_k)_{k=1}^u$ denotes the set of the uth roots of unity. Next, for $\Re s < -2\xi$ we have $|\varepsilon_k a_s(p^{-s/2}\pm q^{-s/2})^2| < a_{-2\xi}(p^{\xi}+q^{\xi})^2 = 1$ by the definition of ξ. Thus $\Psi^*(s)$ is

analytic for $\Re s < -2\xi$, with the exception of a simple pole at $s = -4$. Moreover it can be shown that for some $\delta > 0$ all the zeros of the functions $1-\varepsilon_k a_s(p^{-s/2}\pm q^{-s/2})^2$ belonging to the strip $-2\xi \le \Re s \le -2\xi + \delta$ are simple and uniformly discrete in the sense that distances between distinct zeros are lower bounded by a positive constant; cf. [26, Lemma 4]. The function $\Lambda(s)$ is analytic in a domain which is cut along rays that start at the singularities and have the direction of the positive real axis. We can therefore recover the asymptotics of $\Psi(N)$ by applying the Cauchy integral theorem to the inverse Mellin integral

$$\Psi(N) = \frac{1}{2\pi i}\int_{-2-i\infty}^{-2+i\infty} \Psi^*(s) N^{-s} ds,$$

moving the line of integration to the right, thereby obtaining a curve which is composed of vertical pieces and Hankel-type pieces encircling the singularities of $\Lambda(s)$ in the strip $-2\xi \le \Re s \le -2\xi + \delta$. One of the main terms (and in the case $\frac{\ln p}{\ln q} \notin \mathbb{Q}$ the only main term; cf. [26, Lemma 4]) of the asymptotics of $\Psi(N)$ is contributed by the singularity at $s = -2\xi$. There we have the expansion

$$\Psi^*(s) = \frac{d_{-1}}{\sqrt{-s-2\xi}} + d_0 + \mathcal{O}\left(\sqrt{-s-2\xi}\right),$$

with positive d_{-1}. Now, for $r > 0$ and $r + \delta' \le \delta$, let the clockwise-oriented curve $\mathcal{C}$ consist of the piece $\{te^{2\pi i} : r \le t + 2\xi \le r + \delta'\}$ "below" the cut, the circle $\{-2\xi + re^{i\phi} : 0 \le \phi \le 2\pi\}$ and the piece $\{t : r \le t + 2\xi \le r + \delta'\}$ "above" the cut. Making use of Hankel's integral representation of $1/\Gamma(s)$, we obtain

$$\frac{1}{2\pi i}\int_{\mathcal{C}} \Psi^*(s) N^{-s} ds = \frac{N^{2\xi}}{\sqrt{\pi \ln N}}\left(d_{-1} + \mathcal{O}\left(\frac{1}{\ln N}\right)\right).$$

In the case $\frac{\ln p}{\ln q} \in \mathbb{Q}$ there will be infinitely many singularities with real part -2ξ and imaginary parts that are integer multiples of some positive constant, whose total contribution is $\frac{N^{2\xi}}{\sqrt{\pi \ln N}}\tau(\ln N) + \mathcal{O}(N^{2\xi}\ln^{-3/2} N)$, where τ is a continuous periodic function of mean d_{-1}. The other singularities in the strip $-2\xi \le \Re s \le -2\xi + \delta$ and the vertical pieces of the contour contribute $o(N^{2\xi}\ln^{-1/2} N)$. Since $\Psi(N)$ is increasing, the periodic function τ has to be strictly positive, so we indeed obtain $\Psi(N) = N^{2\xi}e^{\mathcal{O}(\ln\ln N)}$, which completes the proof. □

5. The limiting distribution for fixed queries.

Proof of Theorem 4. Throughout this proof, dependencies on $\boldsymbol{\kappa}$, which is fixed, will be suppressed. A central limit theorem for martingale difference arrays will be employed. To show that the two hypotheses of that theorem are satisfied, we will make heavy use of Lemmas 9 and 10 from the preceding section. Some notation of the first paragraph of section 3 will be used, and in particular we note that

$$\{\nu(m) : m \ge 2\} = \{0.\nu(m) : m \ge 1\} \cup \{1.\nu(m) : m \ge 1\},$$

with the dot denoting concatenation. For instance, $\nu(10) = 010 = 0.\nu(6)$ implies $\mathsf{t}^{10} = \mathsf{t}_\ell^6$.

Our first goal is to represent each $(F_N^i - f_N^i)/\sqrt{v_N^i}$ as the terminal value of some martingale. We observe that $X_{N,m} := |\mathsf{t}^{2m}|$ is a random variable on T_N for $m \ge 1$. Moreover we let $X_{N,0} \equiv N$ and define for $m \ge 0$ sigma algebras

$$\mathcal{F}_{N,m} = \sigma(X_{N,j},\, 0 \le j \le m),$$

in particular $\mathcal{F}_{N,0} = \{\emptyset, \mathsf{T}_N\}$. This gives rise to a filtration $\mathbb{F}_N := (\mathcal{F}_{N,m})_{m\geq 0}$. For $m \geq 1$ a wordy description of $\mathcal{F}_{N,m}$ would be that it accumulates knowledge of the sizes of the $2m$ subtrees of a trie t built from N keys that are rooted in the two sons of any of the nodes v_j for $1 \leq j \leq m$.

For $i \geq 0$ and $m \geq 1$ we define functions on $\bigcup_{N\geq 0} \mathsf{T}_N$ by

$$\lambda_m^i(\mathsf{t}) := \varepsilon_m^i \left(1 + a_{0,i+1+\ell(m)} f_{|\mathsf{t}^{2m}|}^{i+1+\ell(m)} + a_{1,i+1+\ell(m)} f_{|\mathsf{t}^{2m+1}|}^{i+1+\ell(m)} - f_{|\mathsf{t}^m|}^{i+\ell(m)}\right) \mathbb{1}_{\{|\mathsf{t}^m|\geq 2\}}$$

and immediately note that

$$\lambda_m^i(\mathsf{t}) = \varepsilon_m^i \lambda_1^{i+\ell(m)}(\mathsf{t}^m),$$

where $\ell(m) := \lfloor \log_2 m \rfloor$ denotes the level of node v_m, and ε_m^i is defined in (8). We let $\lambda_{N,m}^i$ be the restriction of λ_m^i to T_N and claim

(i) $f_N^i + \sum_{m\geq 1} \lambda_{N,m}^i = F_N^i$,
(ii) $\lambda_{N,m}^i$ is $\mathcal{F}_{N,m}$-measurable,
(iii) $\mathbb{E}\left[\lambda_{N,m}^i \middle| \mathcal{F}_{N,m-1}\right] = 0$.

For the proof of (i) we observe, using $\varepsilon_{2m}^i = \varepsilon_m^i a_{0,i+1+\ell(m)}$ and $\varepsilon_{2m+1}^i = \varepsilon_m^i a_{1,i+1+\ell(m)}$, that the terms involving f form a telescoping series, and what remains is exactly the series given in (9). Since $|\mathsf{t}^m|$, $|\mathsf{t}^{2m}|$, and $|\mathsf{t}^{2m+1}| = |\mathsf{t}^m| - |\mathsf{t}^{2m}|$ are all $\mathcal{F}_{N,m}$-measurable, so is $\lambda_{N,m}^i$, which proves (ii). Finally we turn to (iii), which is true, since for any fixed $n \geq 2$ and for $k \sim B(n,p)$ we have

$$\begin{aligned}&\mathbb{E}\left[\lambda_{N,m}^i \middle| |\mathsf{t}^m| = n\right] \\ &\quad = \varepsilon_m^i \mathbb{E}\left[1 + a_{0,i+1+\ell(m)} f_k^{i+1+\ell(m)} + a_{1,i+1+\ell(m)} f_{n-k}^{i+1+\ell(m)} - f_n^{i+\ell(m)}\right] = 0\end{aligned}$$

by (10). We continue defining

$$\xi_{N,m}^i := \frac{\lambda_{N,m}^i}{\sqrt{v_N^i}}$$

and observe that the sequence $\left(\sum_{m=1}^M \xi_{N,m}^i\right)_{M\geq 1}$ is a martingale with respect to the filtration $\mathbb{F}_N$, which converges P_N-almost surely and in $L^2(\mathsf{T}_N, \mathcal{T}_N, P_N)$ to the terminal value

$$\frac{F_N^i - f_N^i}{\sqrt{v_N^i}} = \sum_{m=1}^{\infty} \xi_{N,m}^i.$$

By a well-known central limit theorem for martingale difference arrays [14, 28] we have, as $N \to \infty$,

$$\sum_{m=1}^{\infty} \xi_{N,m}^i \xrightarrow{\mathcal{D}} \mathcal{N}(0,1)$$

if both the "conditional normalizing condition"

$$\text{(No)} \qquad \sum_{m=1}^{\infty} \mathbb{E}\left[(\xi_{N,m}^i)^2 | \mathcal{F}_{N,m-1}\right] \xrightarrow{P} 1 \text{ as } N \to \infty$$

and the "conditional Lindeberg condition"

$$\text{(Li)} \qquad \sum_{m=1}^{\infty} \mathbb{E}\left[(\xi^i_{N,m})^2 \mathbb{1}_{\{|\xi^i_{N,m}|>\varepsilon\}} \middle| \mathcal{F}_{N,m-1}\right] \xrightarrow{P} 0 \text{ as } N \to \infty \quad \text{ for all } \varepsilon > 0$$

are satisfied.

It is easy to derive sufficient conditions for (No) and (Li): Let

$$V^i_N := \sum_{m=1}^{\infty} \mathbb{E}\left[(\lambda^i_{N,m})^2 | \mathcal{F}_{N,m-1}\right]$$

be the terminal value of the predictable quadratic variation process of the martingale $\left(\sum_{m=1}^{M} \lambda^i_{N,m}\right)_{M\geq 0}$. As we will shortly show, V^i_N satisfies the following equation, which is reminiscent of (6):

$$V^i_N \overset{\mathcal{D}}{=} \mathbb{1}_{\{N\geq 2\}} \left(s^i_N + a_{0,i+1} V^{i+1}_k + a_{1,i+1} \bar{V}^{i+1}_{N-k}\right),$$

where $k \sim B(N,p)$, $V^i_k \overset{\mathcal{D}}{=} \bar{V}^i_k$, and $V^i_k, \bar{V}^i_{N-k}$ are independent, conditional on k, and where

$$s^i_N = \mathbb{E}\left[(\lambda^i_{N,1})^2 | \mathcal{F}_{N,0}\right] = \operatorname{Var}\left(a_{0,i+1} f^{i+1}_k + a_{1,i+1} f^{i+1}_{N-k}\right)$$

was introduced in (34). We first derive

$$\mathbb{E}\left[(\lambda^i_{N,m})^2 | \mathcal{F}_{N,m-1}\right] = \mathbb{E}\left[(\varepsilon^i_m \lambda^{i+\ell(m)}_{|\mathsf{t}^m|,1})^2 | \mathcal{F}_{|\mathsf{t}^m|,0}\right] = \varepsilon^i_m \mathbb{E}\left(\lambda^{i+\ell(m)}_{|\mathsf{t}^m|,1}\right)^2 = \varepsilon^i_m s^{i+\ell(m)}_{|\mathsf{t}^m|}.$$

Now, for $m \geq 2$, let the numbers $\alpha \in \{0,1\}$ and $\mu \in \mathbb{N}$ be uniquely defined by $\nu(m) = \alpha.\nu(\mu)$. Then $\varepsilon^i_m s^{i+\ell(m)}_{|\mathsf{t}^m|} = a_{\alpha,i+1} \varepsilon^{i+1}_\mu s^{i+1+\ell(\mu)}_{|(\mathsf{t}^{2+\alpha})^\mu|}$ holds, which implies

$$\begin{aligned} V^i(\mathsf{t}) :&= \sum_{m\geq 1} \varepsilon^i_m s^{i+\ell(m)}_{|\mathsf{t}^m|} = s^i_{|\mathsf{t}|} + a_{0,i+1} \sum_{m\geq 1} \varepsilon^{i+1}_m s^{i+1+\ell(m)}_{|\mathsf{t}_\ell{}^m|} + a_{1,i+1} \sum_{m\geq 1} \varepsilon^{i+1}_m s^{i+1+\ell(m)}_{|\mathsf{t}_r{}^m|} \\ &= s^i_{|\mathsf{t}|} + a_{0,i+1} V^{i+1}(\mathsf{t}_\ell) + a_{1,i+1} V^{i+1}(\mathsf{t}_r); \end{aligned} \tag{49}$$

hence, with V^i_N of course the restriction of V^i to T_N, the above distributional equation for V^i_N readily follows.

Condition (No) demands $\frac{V^i_N}{v^i_N} \xrightarrow{P} 1$, which is implied by

$$\text{(No}_2\text{)} \qquad \operatorname{Var} V^i_N = o\left((v^i_N)^2\right).$$

Note that by (49) we have

$$\operatorname{Var} F^i_N = v^i_N = \mathbb{E}\, V^i_N = \mathbb{E} \sum_{m\geq 1} \varepsilon^i_m s^{\ell(m)+i}_{|\mathsf{t}^m|},$$

and thus similarly (i.e., by constructing a martingale with respect to $\mathbb{F}_N$ converging to V^i_N, and considering its predictable quadratic variation process) we obtain

$$\operatorname{Var} V^i_N = \mathbb{E} \sum_{m\geq 1} \varepsilon^i_m \sigma^{\ell(m)+i}_{|\mathsf{t}^m|},$$

where

$$\sigma_N^i = \operatorname{Var}\left(a_{0,i+1}v_k^{i+1} + a_{1,i+1}v_{N-k}^{i+1}\right).$$

In (Li) we fix $a > 1$ and use $x^2 \mathbb{1}_{\{|x|>\varepsilon\}} \le \frac{x^{2a}}{\varepsilon^{2(a-1)}}$ to construct another sequence of random variables

$$\Lambda_N^i \overset{\mathcal{D}}{=} \mathbb{1}_{\{N\ge 2\}}\left(\tilde{s}_N^i + a_{0,i+1}\Lambda_k^{i+1} + a_{1,i+1}\bar{\Lambda}_{N-k}^{i+1}\right),$$

where $k \sim B(N,p)$, $\Lambda_k^i \overset{\mathcal{D}}{=} \bar{\Lambda}_k^i$, and Λ_k^i, $\bar{\Lambda}_{N-k}^i$ are independent, conditional on k, and where

$$\tilde{s}_N^i = \mathbb{E}\left[(\lambda_{N,1}^i)^{2a}|\mathcal{F}_{N,0}\right].$$

Condition (Li) is thus implied by

$$\mathbb{E}\,\Lambda_N^i = o\left((v_N^i)^a\right). \tag{Li$_a$}$$

We obtain equations of the same type as (11) and (35) for $w_N := \operatorname{Var} V_N^0$ and $y_N := \mathbb{E}\,\Lambda_N^0$, namely,

$$\mathbf{w} = \sum_{n\ge 0}\prod_{i=1}^n \mathbf{B}_i\boldsymbol{\sigma}^n, \qquad \mathbf{y} = \sum_{n\ge 0}\prod_{i=1}^n \mathbf{B}_i\tilde{\mathbf{s}}^n,$$

and will show $w_N = o((v_N)^2)$ and $y_N = o((v_N)^a)$. Using the expansion (38) of f_k^i around $k = pN$ (we can choose $M = 0$), we obtain $\tilde{s}_N^i = \mathcal{O}\big(\frac{(f_N^i)^{2a}}{N^a}\big)$, which will be $\mathcal{O}(f_N^i)$ if $a > 1$ is only small enough. With the help of Lemma 9 we obtain $\Delta^m s_N^i = \mathcal{O}\big(\frac{f_N^i}{N^m}\big)$, and thus upon application of Lemma 10 also $\Delta^m v_N^i = \mathcal{O}\big(\frac{v_N^i}{N^m}\ln N\big)$. Now an expansion of v_k^i around $k = pN$ yields $\sigma_N^i = \mathcal{O}\big(\frac{(v_N^i)^2}{N}\big) = \mathcal{O}\big(\frac{(f_N^i)^2\ln^2 N}{N}\big) = \mathcal{O}\big(f_N^i\big)$. We have thus proven $\sigma_N^i = \mathcal{O}(f_N^i)$ and $\tilde{s}_N^i = \mathcal{O}(f_N^i)$, and it follows from Lemma 10 that both w_N and y_N are of order $\mathcal{O}(f_N \ln N)$. On the other hand, $(v_N)^a = \Omega((f_N)^a)$ for $a \ge 0$. Since $\ln N = o\left((f_N)^{a-1}\right)$ for any $a > 1$ by (2), we see that (No$_2$) and (Li$_a$) indeed hold. □

6. Conclusion. While costs C_N of partial match retrievals in K-d tries constructed from N records have been investigated in depth under the symmetric Bernoulli model (sBm), no results going beyond asymptotics of expected costs seem to be available under the asymmetric Bernoulli model (aBm). It has been the aim of the present paper to fill this gap. For aBm a distinction between fixed and random queries has to be made which is not necessary for sBm. In the random query model it turns out that for aBm we have $(\mathbb{E}\,C_N)^2 = o(\mathbb{E}\,C_N^2)$, in contrast to sBm, where $(\mathbb{E}\,C_N)^2 \sim \mathbb{E}\,C_N^2$, and due to cancellations, $\operatorname{Var} C_N = \Theta(\mathbb{E}\,C_N)$ emerges. Furthermore for sBm the normalized cost $\frac{C_N - \mathbb{E}\,C_N}{\sqrt{\operatorname{Var} C_N}}$ converges in distribution to a standard normal random variable. This does not hold for aBm, where there is no nondegenerate limiting distribution at all. However, in this case $\ln C_N$, properly normalized, follows a central limit law. Differences between sBm and aBm are not so drastic for the fixed query model. Here $\operatorname{Var} C_N = \Theta(\mathbb{E}\,C_N)$ and $\frac{C_N - \mathbb{E}\,C_N}{\sqrt{\operatorname{Var} C_N}} \overset{\mathcal{D}}{\to} \mathcal{N}(0,1)$ are true also for aBm, but, depending on the query, $\mathbb{E}\,C_N$ may now enjoy a growth between $\Omega(N^{\gamma_2})$ and $\mathcal{O}(N^{\gamma_1})$ and will almost surely be "close" to N^β, for certain constants

$\gamma_2 < \beta < \gamma_1$, where closeness is expressed in terms of a law of the iterated logarithm. In particular, expected growth and almost sure growth are not the same for aBm.

The paper considers only alphabets of size 2, but we are quite sure that our results can without much pain be generalized to analogous statements holding for larger alphabets.

Acknowledgment. I wish to thank the referees for their detailed reading and constructive comments on the first version of this paper.

ON PROVING CIRCUIT LOWER BOUNDS AGAINST THE POLYNOMIAL-TIME HIERARCHY*

JIN-YI CAI† AND OSAMU WATANABE‡

Abstract. We consider the problem of proving circuit lower bounds against the polynomial-time hierarchy. We give both positive and negative results. For the positive side, for any fixed integer $k > 0$, we give an explicit Σ_2^{p} language, acceptable by a Σ_2^{p} machine with running time $O(n^{k^2+k})$, that requires circuit size $> n^k$. This provides a constructive version of an existence theorem of R. Kannan [*Inform. and Control*, 55 (1982), pp. 40–56]. Our main theorem is on the negative side. We give evidence that it is infeasible to give relativizable proofs that any single language in the polynomial-time hierarchy requires superpolynomial circuit size. Our proof techniques are based on the decision tree version of the Switching Lemma for constant depth circuits and the Nisan–Wigderson pseudorandom generator. We also take this opportunity to publish some previously unpublished older results of the first author on constant depth circuits, both straight lower bounds and inapproximability results based on decision tree–type Switching Lemmas.

Key words. stringent relativization, circuit complexity, computational complexity, Switching Lemma, Nisan–Wigderson generator

1. Introduction.

It is a most basic open problem in theoretical computer science to give circuit lower bounds for various complexity classes. The class P has polynomial-size circuits. It is also widely believed that NP does not share this property, i.e., that some specific set such as SAT in NP requires superpolynomial circuit size. While this remains the most concrete approach to the NP vs. P problem, we can't even prove, for any fixed $k > 1$, that any set $L \in \mathrm{NP}$ requires circuit size $> n^k$.

If we relax the restriction from NP to the second level of the Polynomial-time Hierarchy[1] Σ_2^{p}, R. Kannan [Kan82] did prove that for any fixed polynomial n^k, there is some set L in Σ_2^{p} which requires circuit size $> n^k$. Kannan in fact proved the existence theorem for some set in $\Sigma_2^{\mathrm{p}} \cap \Pi_2^{\mathrm{p}}$. This result has been improved by Köbler and Watanabe [KW98], who showed, based on the technique developed in [BCGKT], that such a set exists in $\mathrm{ZPP}^{\mathrm{NP}}$. More recently, the work in [Cai01] implies that a yet lower class $\mathrm{S}_2^{\mathrm{p}}$ contains such a set. (See [BFT98, MVW99] for related topics.)

However, Kannan's proof for Σ_2^{p}, and all the subsequent improvements mentioned above, are not "constructive" in the sense that it does not identify a single Σ_2^{p} machine whose language requires circuit size $> n^k$. In this paper we first remark on this point and give some constructive proofs for Σ_2^{p}.

[1]We will use standard notions and notation of complexity theory; see textbooks, e.g., [DK00], for definitions.

At the top level, all these proofs for the above-mentioned results are of the same type. Let us review Kannan's proof for Σ_2^{p}: *Either* SAT does not have n^k size circuits, and then we are done, *or* SAT has n^k size circuits, and then we can define some other set, which by the existence of the hypothetical circuit for SAT can be shown in Σ_2^{p}, and it requires circuit size $> n^k$. Thus, in each case, we have some set L_0 in Σ_2^{p} that has no n^k size circuits; but this does not give any single Σ_2^{p} machine whose language requires circuit size $> n^k$. Constructively, Kannan gave a set in $\Sigma_4^{\mathrm{p}} \cap \Pi_4^{\mathrm{p}}$. In [MVW99] a set in Δ_3^{p} was constructively given. We improve this to Σ_2^{p}.

THEOREM 1. *For any integer $k > 0$, we can construct a Σ_2^{p} machine with $O(n^{k^2} \log^{k+1} n)$ running time that accepts a set with no n^k size circuits.*

Notice that Σ_2^{p} has complete languages. Thus, by using any standard complete language C for Σ_2^{p}, it is easy to obtain a result like the above. We can argue as follows: Estimate the time complexity of a reduction from L_0 to C, which is possible even from the above "nonconstructive" proof of the existence of L_0. Then define a padded version C' of C so that L_0 is reducible to C in linear time. This C' is a language that requires circuit size $> n^k$; clearly, we can give explicitly a Σ_2^{p} machine recognizing C' and its time bound. Our contribution here is to show a way to construct such a machine directly, which we hope to be of any help when discussing a similar constructive proof that is open for the stronger statements, i.e., the existence of a set with n^k circuit size lower bound in $\Sigma_2^{\mathrm{p}} \cap \Pi_2^{\mathrm{p}}$ (resp., $\mathrm{ZPP}^{\mathrm{NP}}$ and $\mathrm{S}_2^{\mathrm{p}}$).

Our main result in this paper deals with the difficulty in proving superpolynomial circuit size lower bound for any set in the Polynomial-time Hierarchy, PH. While it is possible to prove, for any fixed $k > 0$, that Σ_2^{p} has a set with circuit size $> n^k$, the real challenge is to prove a superpolynomial circuit size lower bound for a single language. Not only have we not been able to do this for any set in NP, but also no superpolynomial lower bound is known for any set in PH. In this paper we prove that it is infeasible to give relativizable superpolynomial lower bound for any set in the Polynomial-time Hierarchy.

For our relativized argument, we propose a new computation model that gives us more "stringent" relativized results. Relativization results can be generally classified as either separation or collapsing/containment results. The implication of a relativized separation result is that the corresponding collapse is difficult to prove. Similarly a relativized collapsing result implies that the corresponding separation is difficult to prove. Notice that it is still possible (and, in fact, such examples have been shown) to have a separation or collapsing result against the corresponding relativized result; relativized results just suggest some "difficulty" and not "impossibility." Also we should note that the degree of "difficulty" may depend on a relativization type. Here we deal with relativized collapsing results, and we introduce a new relativization notion—stringent relativization—for demonstrating the difficulty of proving circuit lower bounds for PH.

By surveying existing relativized collapsing results, we came to realize that an asymmetry is often present. In almost all of these relativized collapsing results the proof is achieved by allowing stronger access to oracles by the simulating computation than the simulated computation. For example, in the usual proof of $\mathrm{P}^A = \mathrm{NP}^A$ or $\mathrm{P}^A = \mathrm{PSPACE}^A$, we encode QBF in the oracle. In terms of the simulation by the $\mathrm{P}^{\mathrm{QBF}}$ machine $\mathcal{M}$ simulating an $\mathrm{NP}^{\mathrm{QBF}}$ or $\mathrm{PSPACE}^{\mathrm{QBF}}$ computation $\mathcal{M}'$ on an input x, $\mathcal{M}$ will access an oracle location polynomially longer than the corresponding access that $\mathcal{M}'$ makes. That is, P^A machines are given more powerful oracle access. One can argue that this asymmetry is within a polynomial factor, but it nonetheless denies

access to certain segments of the oracle to the simulated machine while affording such access to the simulating machine. In our present study of specific polynomial bounds such as n^k of either circuit size or running time, this arbitrary polynomial stretch in oracle access is not acceptable.

We study in this paper some specific circuit size lower bound with respect to some specific, say n^k, time bound. Then, as the above observation suggests, we must adopt the following more "stringent" oracle computation model. In this more "stringent" oracle access model, we require that, for any input, the simulating machine or circuit does not access the oracle of length longer than the simulated machine or circuit can access on this input. We consider circuits consisting of standard AND, OR, and NOT gates and oracle query gates. An oracle query gate takes m input bits $z = b_1 b_2 \dots b_m$ and has output $\chi_{[z \in X]}$, i.e., it outputs 1 or 0 depending on whether $z \in X$ or otherwise. Now the proviso of "stringent access to an oracle" is stated as follows: To show that, at length n, a circuit C_n recognizes the language of machine $\mathcal{M}$ with running time n^k, we allow the circuit access only to those strings of length $\leq n^k$. For any machine $\mathcal{M}$, we say that a family of circuits $\{C_n\}_{n \geq 0}$ *simulates* $\mathcal{M}^X$ under a *stringent access* to the oracle X if at every length n, C_n recognizes $L(\mathcal{M}^X)^{=n}$ by stringent access to the oracle X.

Though we defined our stringency notion as above for the comparison between machines and circuits with polynomial-time and polynomial-size resource bounds, we believe that the notion of "stringent oracle access" is meaningful in a more general setting. (For more general situations, it might be better to consider a more robust notion of "stringent relativization." We leave this issue and more general investigations of "stringent relativization" for our future work; see, e.g., [CW04].)

From a more general perspective, the main utility of relativization is to show the inadequacy of certain proof techniques. Certainly the more "stringent" a requirement we place on the type of relativization, the stronger the result will be, and perhaps it says more about the infeasibility of certain techniques. Imagine there are three possible claims of proving a certain lower bound, such as Σ_2^{p} requires superpolynomial circuit size:

1. A proof totally specific to a specific set in Σ_2^{p} that uses specific properties of the circuit combinatorics.
2. A proof for a general Σ_2^{p} machine that uses properties of the circuit, but which can be carried through if the machine and circuit were allowed to access any but the same segment of any oracle, i.e., they could ask queries within the same length bound. (In our case, the length bound is defined as the time bound of the simulated Σ_2^{p} machine.)
3. A proof more general, for a general Σ_2^{p} machine and circuit, and which can go through even if we allowed the machine and circuit to access different segments of the oracle.

Any relativization to the contrary says nothing about the first possibility. A relativization to the contrary with stringent access model rules out possibilities 2 and 3. If we did not have the "stringent access requirement," then we can only rule out 3, but not 2.

In this paper we focus on specific time/size bounds. In the stringent oracle access model, we prove that for any alternating oracle TM $\mathcal{M}$ with running time $O(n^k)$, there is an oracle X and a polynomial-size circuit family accepting it. Therefore we rule out possibilities 2 and 3 above.

THEOREM 2 (main theorem). *For any integer $d > 0$ and any real $k > 1$, let $\mathcal{M}$*

be an oracle Σ_d^{p} machine with running time $O(n^k)$. Then we have an oracle X and a family of Boolean circuits $\{C_n\}_{n\geq 0}$ that recognizes $L(\mathcal{M}^X)$ under a stringent access *to the oracle X. For all sufficiently large n, the size of C_n is bounded by n^{cdk} for some universal constant $c > 0$.*

From this, we can conclude that, relative to the oracle X given above, every set in PH has some polynomial-size circuits, i.e., $\mathrm{PH}^X \subseteq \mathrm{P}^X/\mathrm{poly}$. Recall that Heller [He84] showed an oracle Y such that $\mathrm{EXP}^Y \subseteq \mathrm{P}^Y/\mathrm{poly}$, which immediately implies that $\mathrm{PH}^Y \subseteq \mathrm{P}^Y/\mathrm{poly}$. But this oracle Y is not used in a stringent way; that is, a circuit simulating a given Σ_d^{p} machine $\mathcal{M}$ on inputs of length n makes queries to Y that are longer than the time bound of $\mathcal{M}$ on length n inputs. (Notice that our stringency condition is for polynomial-time bounds. It would be possible to extend it to exponential-time bounds, and we may claim that the oracle Y is used in a stringent way in the relation $\mathrm{EXP}^Y \subseteq \mathrm{P}^Y/\mathrm{poly}$, because any polynomial bound for circuit size is less than exponential-time bounds of simulated EXP machines. In this sense, our stringency notion is not robust, and we need a more robust notion for general investigations; see, e.g., [CW04].)

Our proof technique for the main theorem is based on the decision tree version of the Switching Lemma for constant depth circuits and the Nisan–Wigderson pseudorandom generator.

As these results crucially depend on lower bounds for constant depth circuits, we take this opportunity to publish some unpublished older results of the first author on constant depth circuits, as it would fit the theme. These include both straight lower bounds and inapproximability results based on decision tree–type Switching Lemmas. We give some better constants in the exponents than previously published lower bounds.

2. Proof of Theorem 1. R. Kannan [Kan82] proved that for any fixed polynomial n^k, there is some set L in $\Sigma_2^{\mathrm{p}} \cap \Pi_2^{\mathrm{p}}$ with circuit size $> n^k$. However, in terms of explicit construction, he only gave a set in $\Sigma_4^{\mathrm{p}} \cap \Pi_4^{\mathrm{p}}$. An improvement to Δ_3^{p} was stated in [MVW99].

In this section we give a constructive proof of Kannan's theorem for Σ_2^{p}.

For any $n \geq 0$, a binary sequence χ of length $\ell \leq 2^n$ is called a *partial characteristic sequence*, which will specify lexicographically the membership of the first ℓ strings of $\{0,1\}^n$. We denote this subset of $\{0,1\}^n$ by $L(\chi)$. We say that χ is consistent with a circuit C with n input gates iff $\forall i$, $1 \leq i \leq \ell$, $C(x_i)$ outputs the ith bit of χ, where x_i is the ith string of $\{0,1\}^n$.

We can encode every circuit C of size $\leq s$ as a string u of length $\mathrm{len}(s)$, where $\mathrm{len}(s)$ is defined as $\mathrm{len}(s) = c_{\mathrm{circ}} \lfloor s \log s \rfloor$ with some constant c_{circ}. We may consider every u with $|u| = \mathrm{len}(s)$ encodes some circuit of size $\leq s$; if a string u is not a proper code or the encoded circuit has size $> s$, we assume that this u encodes the constant 0 circuit. The following lemma is immediate by counting.

LEMMA 3. *For any $s > 1$, there exists a partial characteristic sequence of length $\ell = \mathrm{len}(s) + 1$ that is not consistent with any circuit of size $\leq s$.*

Our goal is to define a set L that has no n^k size circuit but that is recognized by some explicitly defined Σ_2^{p} machine. Our construction follows essentially the same outline as the one given in [MVW99], which in turn uses ideas given in Kannan's original proof. The further improvement is mainly an even more efficient use of alternation.

For a given n, let $\ell = \mathrm{len}(n^k) + 1$. We try to construct a partial characteristic sequence χ_{non} of length ℓ that is consistent with *no* circuit of size $\leq n^k$. We will

introduce an auxiliary set PreCIRC that is in NP. With this PreCIRC, some Σ_2^{p} machine can *uniquely* determine the desired characteristic sequence χ_{non} (on its accepting path). We would like to define our set L (partially) consistent with this sequence χ_{non}. But Σ_2^{p} computation using some auxiliary NP set cannot be implemented, in general, by any Σ_2^{p} machine. Suppose here that PreCIRC has n^k size circuits; then some Σ_2^{p} machine can guess such circuits, verify them, and use them for computing χ_{non} and recognizing strings according to χ_{non}. What if there are no such circuits for PreCIRC? We will define L so that one part of L is consistent with PreCIRC (while the other part is consistent with χ_{non} if PreCIRC is computable by some n^k size circuits). If PreCIRC has no n^k size circuit, then the part of L that is consistent with PreCIRC can guarantee the desired hardness of L.

Now we describe our construction in detail. We fix any sufficiently large n and let $\ell = \mathrm{len}(n^k) + 1$. By "$v \succ u$" we mean that u is a prefix of v. To compute the "hard" characteristic sequence χ_{non}, we want to determine, for a given pair of a partial characteristic sequence χ and a string u, whether u can be extended to some description v of a circuit that is consistent with χ. The set PreCIRC is defined for this task. More precisely, for any $n > 0$, and for any strings χ of length ℓ and u of length $\leq \mathrm{len}(n^k)$, we define PreCIRC as follows.

$$1^n 0 \chi u 0 1^{\mathrm{len}(n^k)-|u|} \in \mathrm{PreCIRC}$$
$$\Leftrightarrow\ (\exists v \succ u)\ [\ |v| = \mathrm{len}(n^k), \text{ and the circuit encoded by } v \text{ is consistent with } \chi\ ].$$

Strings of any other form are not contained in PreCIRC. For simplifying our notation, we will simply write (χ, u) for $1^n 0 \chi u 0 1^{\mathrm{len}(n^k)-|u|}$. Since n determines ℓ, and the length of χ is ℓ, χ and u are uniquely determined from $0^n 1 \chi u 1 0^{\mathrm{len}(n^k)-|u|}$. The length of (χ, u) is $\widetilde{n} = n + 2\ell + 1$. Note that $\widetilde{n}$ is $O(n^k \log n)$.

We now define our machine $\mathcal{M}$. Informally we want $\mathcal{M}$ to accept an input x iff either $x \in 1\{0,1\}^{n-1}$ and $x \in \mathrm{PreCIRC}$, or $x \in 0\{0,1\}^{n-1}$ and $x \in L$, where $L^{=n}$ is a set with no n^k size circuits, for all sufficiently large n, *if* $\mathrm{PreCIRC}^{=n}$ has n^k size circuits for all sufficiently large n. Specifically, $\mathcal{M}$ is designed so that $L^{=n}$ would be $L(\chi_{\mathrm{non}})$, where χ_{non} is lexicographically the first χ of length ℓ with no n^k size circuit, *provided* $\mathrm{PreCIRC}^{=\widetilde{n}}$ has an $\widetilde{n}^k$ size circuit for length $\widetilde{n}$. Note that $L(\chi_{\mathrm{non}}) \subseteq 0\{0,1\}^{n-1}$ since $|\chi_{\mathrm{non}}| = \mathrm{len}(n^k) + 1 < 2^{n-1}$.

More formally, for any given input x of length n, if x starts with 1, then $\mathcal{M}$ accepts it iff $x \in \mathrm{PreCIRC}$. Suppose otherwise; that is, x starts with 0. Then first $\mathcal{M}$ existentially guesses a partial characteristic sequence χ_{non} of length ℓ *and* a circuit C_{pre} of size $\widetilde{n}^k$, more precisely, a string v_{pre} of length $\mathrm{len}(\widetilde{n}^k)$ encoding a circuit for $\mathrm{PreCIRC}^{=\widetilde{n}}$ of size $\leq \widetilde{n}^k$. (Below we use C_{pre} to denote the circuit that is encoded by the guessed v_{pre}.) After that, $\mathcal{M}$ enters the universal stage, where it checks the following items.

(1) C_{pre} makes no mistake whenever it says "yes": $\forall \chi$, $|\chi| = \ell$, and $\forall u$, $|u| \leq \mathrm{len}(n^k)$, verify that C_{pre} is "locally consistent" on (χ, u) if $C_{\mathrm{pre}}(\chi, u) = 1$; that is, check as follows:

$$C_{\mathrm{pre}}(\chi, u) = 1 \ \&\ |u| = \mathrm{len}(n^k) \implies \text{the circuit that } u \text{ encodes is consistent with } \chi,$$
$$C_{\mathrm{pre}}(\chi, u) = 1 \ \&\ |u| < \mathrm{len}(n^k) \implies \text{either } C_{\mathrm{pre}}(\chi, u0) = 1 \text{ or } C_{\mathrm{pre}}(\chi, u1) = 1.$$

(2) C_{pre} says "yes" for all positive instances: $\forall u$, $|u| = \mathrm{len}(n^k)$, compute the χ_u of length ℓ defined by (the circuit encoded by) u, and verify that $C_{\mathrm{pre}}(\chi_u, u') = 1$ for every prefix u' of u.

(3) The guessed χ_{non} is lexicographically the first string of length ℓ such that no circuit of size s is consistent with it, *according to* C_{pre}: Check $C_{\text{pre}}(\chi_{\text{non}}, \epsilon) = 0$, and $\forall \chi$ such that $|\chi| = \ell$ and χ is lexicographically smaller than χ_{non}, check that $C_{\text{pre}}(\chi, \epsilon) = 1$ holds. (Here ϵ denotes the empty string.)

Finally on each universal branch, if $\mathcal{M}$ passes the particular test of this branch, then $\mathcal{M}$ accepts the input $x \in 0\{0,1\}^{n-1}$ iff χ_{non} has bit 1 for the string x.

For all (χ, u), such that $|\chi| = \ell$ and $|u| \leq \text{len}(n^k)$, if C_{pre} passes item (1), then

$$C_{\text{pre}}(\chi, u) = 1 \implies (\chi, u) \in \text{PreCIRC},$$

and if C_{pre} passes item (2), then

$$(\chi, u) \in \text{PreCIRC} \implies C_{\text{pre}}(\chi, u) = 1.$$

Of course there is no guarantee that there exists a circuit C_{pre} (more precisely, v_{pre}) that will pass the tests in items (1) and (2). But if there is such a C_{pre}, then some existential path leads to such a C_{pre} together with the right χ_{non}. This χ_{non} is the lexicographically first string of length ℓ such that no circuit of size n^k is consistent with it, which exists by Lemma 3. In particular it is independent of the particular C_{pre} guessed. Hence, if there is a circuit for $\text{PreCIRC}^{=\widetilde{n}}$ of size $\widetilde{n}^k$, then $\mathcal{M}$ accepts $x \in 0\{0,1\}^{n-1}$ iff x is in $L(\chi_{\text{non}})$, where χ_{non} is the unique lexicographically first string of length ℓ with no consistent circuit of size $\leq n^k$.

On the other hand, if no circuit of size $\widetilde{n}^k$ can accept $\text{PreCIRC}^{=\widetilde{n}}$ correctly, then no circuit passes the tests in items (1) and (2), and hence $\mathcal{M}$ simply rejects all $x \in 0\{0,1\}^{n-1}$. But since $\text{PreCIRC}^{=\widetilde{n}}$ has no $\widetilde{n}^k$ size circuit, the hardness is guaranteed by the PreCIRC part of $L(\mathcal{M})$. More formally, if $\text{PreCIRC}^{=n}$ has no circuit of size n^k *infinitely often*, then we are done. Otherwise, for all sufficiently large n, and hence for all sufficiently large $\widetilde{n}$, a circuit C_{pre} exists for $\text{PreCIRC}^{=\widetilde{n}}$ of size $\widetilde{n}^k$; then the part $L(\mathcal{M}) \cap 0\{0,1\}^{n-1}$ is defined so that no n^k size circuit can accept it correctly, and hence again we are done. Therefore, we can conclude that $L(\mathcal{M})$ has no n^k size circuit (which by definition means that for infinitely many n this is so). This Σ_2^{p} language proves Theorem 1. It can be easily checked that the machine $\mathcal{M}$ runs in $O(n^{k^2} \log^{k+1} n)$ steps.

3. Proof of Theorem 2. We first give an outline of the proof.

3.1. Proof outline. Consider any Σ_d^{p} polynomial-time bounded oracle alternating Turing machine $\mathcal{M}$, with time bound n^k. We want to design an oracle X so that some family of small size circuits can simulate $\mathcal{M}^X$ with stringent oracle access. More specifically, for any fixed sufficiently large n, we want a circuit $C_{\mathcal{M}}$ that simulates $\mathcal{M}^X$ on inputs of length n, where, since $\mathcal{M}$ can query strings only of length at most n^k, we require that $C_{\mathcal{M}}$ can also only ask queries of length at most n^k.

It is well known from [FSS81] that a Σ_d^{p} machine $\mathcal{M}$ bounded in time n^k with oracle X, when given an input x of length n, gives rise to a bounded depth Boolean circuit C_x of the following type: The inputs are Boolean variables, and their negations, representing membership of a string $z \in \{0,1\}^{\leq n^k}$ in the oracle X. The Boolean circuit C_x starts with an OR gate at the top and alternates with AND's and OR's with depth $d+1$, where the bottom level gates have bounded fan-in at most n^k, and all other AND and OR gates are unbounded fan-in, except by the overall circuit size, which is bounded by $n^k 2^{n^k}$. Without loss of generality we may assume the Boolean circuit

is tree-like, except for the input level, where each Boolean variable corresponding to $\chi_{[z \in X]}$ is represented by a pair of complemented variables, which we will denote by z and $\overline{z}$.

Our first idea is to use random restrictions to "kill" the circuit. By this we mean that for any circuit C over Boolean variables $x_1, \ldots, x_n$, a *random restriction* ρ (for some specified parameter p) is a random function that assigns each x_i either 0, 1, or $*$, with probability $\Pr[\rho(x_i) = *] = p$ and $\Pr[\rho(x_i) = 0] = \Pr[\rho(x_i) = 1] = (1-p)/2$ for each i independently. Assigning $*$ means to leave it as a variable. Let $C\mid_\rho$ denote a circuit obtained by this random restriction. It is known that after a random restriction ρ (for a suitably chosen parameter p), the circuit $C\mid_\rho$ is sufficiently weakened so as to have either small min-terms or small max-terms. Results of this type are generally known as Switching Lemmas, and the strongest form known is due to Håstad [Hås86a]. (See also [Ajt83, FSS81, Yao85, Cai86, Hås86b].) However it turns out that we need a different form, namely, a decision tree–type Switching Lemma [Cai86]. We want to assign a suitably chosen random restriction ρ, after which the circuit admits a small depth decision tree. We in fact will have to consider an aggregate of 2^n such Boolean circuits C_x simultaneously, one each for an input x of size n. We want to assign ρ, after which all these circuits have small depth decision trees. We then will proceed to set those variables to ensure that all these circuits are "killed"; i.e., they all have a definite value now, either 0 or 1. We need to assign those variables consistently over all 2^n small depth decision trees. For decision trees, it is easy to achieve this by always setting "the next variable" asked by the decision tree to 0, say; it is not clear how to maintain this consistency in terms of min-terms and max-terms. If each decision tree has depth bounded by t, then we will have assigned at most $2^n t$ many variables corresponding to those strings of length n^k where ρ initially assigned an $*$ (i.e., they are left unassigned by ρ). We will argue that there are still plenty of unassigned variables left, where we may try to encode the now-determined computational values of these 2^n circuits. We will argue that t is sufficiently small, and yet with high probability all 2^n circuits admit decision trees of depth at most t.

The problem with this idea is that after we have coded the values of all the 2^n circuits in X, there does not seem to be any easy way to recover this information. Since X had already been "ravaged" by the random restriction ρ, it is not clear how to distinguish those "code bits" from those "random bits." Further complicating the matter are those bits assigned during the decision tree settlement. All of this must be sorted out, supposedly, by a polynomial-size oracle circuit which is to accept $L(\mathcal{M}^X)^{=n}$. Note that, after a random restriction ρ, it is probabilistically almost impossible to have an easily identifiable segment of the set X all assigned $*$ by ρ (e.g., all strings in $\{0,1\}^{=n^k}$ with a certain leading bit pattern), not to mention the subsequent all 0 assignment to fix the decision trees. On the other hand, we have 2^n computations to code. It is infeasible for the final polynomial-size oracle circuit to "remember" more than a polynomial number of bits as the address of the coding region. So it appears that we must have an easily identifiable region to code, identified with at most a polynomial number of bits for its address, and, to accommodate 2^n computations, this region must be large.

To overcome this difficulty, our idea is to use not true random restrictions, but rather pseudorandom restrictions via the Nisan–Wigderson generator [Nis91a, Nis91b, NW88]. Nisan and Wigderson designed a pseudorandom generator (which we will call an *NW generator*) provably indistinguishable from true random bits by polynomial-size constant depth circuits. While our circuits are not of polynomial size, this can

be scaled up easily. Our idea is then to use the output of some NW generator to perform the "random" restriction, and to argue that all 2^n circuits are "killed" with high probability, just as before with true random restrictions. The basic argument is that no constant depth circuits of an appropriate size can tell the difference under either a true random assignment or a pseudorandom assignment coming from the NW generator. However, for our purpose in this paper, we wish to say that a certain behavior of these 2^n constant depth circuits—namely, they are likely to possess small depth decision trees after a "random" restriction with 0's, 1's, and $*$'s—is preserved when "pseudorandom restrictions" are substituted for "random restrictions." It is vitally important that whatever property we wish to claim was maintained by the substitution of random bits by pseudorandom bits, the property must be expressible as a constant depth circuit with an appropriate size upper bound. It is not clear whether the property of "having a small depth decision tree" can be expressed in this way.

We overcome this difficulty by using a weaker property which is a consequence of "having a small depth decision tree," which nonetheless is sufficient for our purpose. Namely, we take directly the property that, after a restriction with 0's, 1's, and $*$'s, every one of the 2^n circuits can be determined by assigning additionally 0's to a small number of variables, which had been assigned $*$'s. This property is expressible in a constant depth way. Then we will mimic the probability distribution of the 0's, 1's, and $*$'s under the random restrictions by uniform random bits 0's and 1's, so that we can come up with a constant depth circuit D with the following property: It takes only Boolean inputs Ω of 0's and 1's, and D evaluates to 1 iff when a restriction ρ_Ω with 0's, 1's, and $*$'s defined by Ω is applied to all 2^n circuits C_x, every C_x can be set to either 0 or 1 after a small number of additional variables are set to 0. We will design D in such a way that under a uniform bit sequence Ω, D will almost certainly evaluate to 1.

In fact we need more than that. We also need to have the property that a certain segment of the oracle is untouched by the additional setting of 0's in all 2^n decision tree settlements. We will argue by the pigeonhole principle that our bounds guarantee a suitable region unspoiled by all these decision tree settlement variables. It is not reasonable to expect that any such region is entirely assigned with $*$'s, but at least there should be many $*$'s.

Assume now we have designed such a D satisfying all these requirements. For this D we apply the NW generator, substituting pseudorandom bits for true random bits Ω given to D as inputs. We conclude that D still evaluates to 1 with high probability. In particular, there must be some setting of the source bits ω for the generator, such that D is evaluated to 1. This implies that we can assign the oracle set X first according to the pseudorandom restriction described by the pseudorandom bits, then according to the 2^n small depth decision trees, which are guaranteed by the evaluation of D, and set these additional variables all to 0. This settles all the decision trees, and thus the values of all 2^n circuits C_x are determined. Furthermore, there is a significant segment T_{y_0} of X free from any variables used in any decision tree settlement, where we will code these 2^n results of C_x.

Even though this segment T_{y_0} is free from any variables used in any decision tree settlement, in order to code the computation results of C_x, there must be plenty of $*$'s left, and they must be recoverable by polynomial-size circuits. We will show that with high probability over a uniformly chosen random seed ω, the pseudorandom restriction defined by ω will leave plenty of $*$'s in each segment such as T_{y_0}. We then in fact choose a sequence of bits ω that satisfies both the requirement $D = 1$ and this additional requirement.

Finally, we will show that with a suitable choice of parameters in the *combinatorial design* used in the NW generator, we will be able to recover in polynomial time the location where we assigned $*$'s in X, in particular from within the coding segment of X given the address of this segment. Now our polynomial-size circuit $C_{\mathcal{M}}$ is designed as follows: It remembers (is hardwired with) y_0, i.e., the address of T_{y_0}, and remembers the seed ω for the NW generator, which is of polynomial length. Then on any input x, it performs the polynomial-time computation over a finite field to extract the coded result of C_x from the appropriate location in X.

3.2. Proof detail. Now we specify the parameters and state our proof precisely.

Fix any Σ_d^{p} polynomial-time bounded oracle alternating Turing machine $\mathcal{M}$, with time bound n^k. For notational convenience we will assume $k > 2$ and $d \geq 7$. We assume that n is sufficiently large. On input of length n, $\mathcal{M}$ can query strings only of length at most n^k. We will use m to denote n^k and M to denote 2^m throughout this proof.

Assume that membership in the oracle set has already been decided for all strings of length less than m. Our task is to fix the membership for "$z \in X$?" of length exactly m in X, so that for each input x of length n, membership "$x \in L(\mathcal{M}^X)$?" can be decided by a polynomial-size circuit $C_{\mathcal{M}}$ with oracle gates that can access $X^{=m}$. Since $X^{<m}$ has already been fixed, membership "$x \in L(\mathcal{M}^X)$?" is determined by the set $X^{=m}$. Here we specifically require that the circuit $C_{\mathcal{M}}$ can access only those strings that can be possibly accessed by the simulated machine $\mathcal{M}$ on input of length n.

There are 2^n inputs x of length n, and each computation of $\mathcal{M}$ on x gives rise to a depth $d+1$ Boolean circuit C_x with bottom fan-in at most m. The inputs to each circuit C_x are the $2M$ literals z and $\overline{z}$, where $z \in \{0,1\}^m$ corresponds to the truth value of $\chi_{[z \in X]}$. (To simplify our notation, we will denote by z both a string in $\{0,1\}^m$ as well as the Boolean variable corresponding to $\chi_{[z \in X]}$.) As stated earlier, we assume that each circuit C_x is a tree, starting with an OR gate at the top, and alternating with AND's and OR's until inputs z's and $\overline{z}$'s, where these inputs are duplicated to keep the tree structure. That is, each circuit C_x is a depth $d+1$ tree with size at most mM and bottom fan-in at most m.

A Switching Lemma shows that such a constant depth circuit is sufficiently weakened, after a suitably chosen random restriction ρ, so as to have either small min-terms or small max-terms. The strongest form known is due to Håstad [Hås86a]. For our purpose in this paper, however, we will require something more.

The decision tree complexity of a Boolean function f, denoted by $\mathrm{DC}(f)$, is the smallest depth of a Boolean decision tree computing the function. It can be shown easily that if $\mathrm{DC}(f) \leq t$, then f can be expressed both as an AND of OR's as well as an OR of AND's, with bottom fan-in at most t. Moreover, clearly, there is a subset of no more than t variables, such that if one assigns all of them to 0, the function f will be determined. This is an important advantage as we will have to assign many nondisjoint subsets of variables for multiple Boolean functions, and all these assignments need to be consistent.

A decision tree version of the Switching Lemma was first proved in [Cai86], where a different terminology, i.e., Master-Player Game and t-monochromaticity, was introduced. Adapting Håstad's proof to the decision tree model, one can prove the following lemma. In section 4, we will discuss these lemmas more thoroughly. See Remark 4 at the end of the paper for more background discussions.

LEMMA 4. *For any depth $d+1$ Boolean circuit C on M inputs $z_1, z_2, \ldots, z_M$, of*

size at most s and bottom fan-in at most t, we have

$$\Pr_\rho[\mathrm{DC}(C\mid_\rho) \geq t] \;\leq\; \frac{s}{2^t},$$

where the random restriction ρ is defined for $p = \frac{1}{(10t)^d}$.

To reduce all circuits C_x, $x \in \{0,1\}^n$, to small depth decision trees, we apply a random restriction with $p = 1/(20m)^d$ to these circuits. Then by the union bound we have the following.

Claim 1.

$$\Pr_\rho\left[\bigvee_{x\in\{0,1\}^n} [\mathrm{DC}(C_x\mid_\rho) \geq 2m]\right] \;\leq\; 2^n \cdot \frac{mM}{2^{2m}} \;=\; \frac{m}{2^{m-n}}.$$

That is, with probability close to 1, a random restriction reduces *every* circuit C_x to a decision tree of depth $< 2m$.

Below we will carry out a sequence of transformations on the circuits C_x, $x \in \{0,1\}^n$, with the ultimate goal of constructing the circuit D, which, in some sense, is a test for the success of a "random restriction."

Step 1 (C^1_x). C^1_x takes $2M$ Boolean inputs (a_z, b_z) for $z \in \{0,1\}^m$. The pair (a_z, b_z) will represent the status of the Boolean variable z to C_x as follows: $a_z = 1$ iff the value of z is set (to either 0 or 1, i.e., not set to $*$), and $a_z = 0$ otherwise. If $a_z = 1$, then the 0-1 value of z is represented by b_z. If the pair (a_z, b_z) represents the value of z, then the pair $(a_z, \overline{b_z})$ represents that of $\overline{z_i}$. Clearly, if z is set 0 (resp., 1), then $\overline{z}$ must be set 1 (resp., 0).

C^1_x is constructed from C_x as follows. Each gate g in C_x will be represented by a pair of gates (g_s, g_v). $g_s = 1$ iff g is set to either 0 or 1, i.e., it is determined; $g_s = 0$ otherwise. If $g_s = 1$, then $g = g_v$. Thus, $(g_s, g_v) = (0,0)$ or $(0,1)$ represent the situation where g has not been determined, and $(g_s, g_v) = (1,0)$ or $(1,1)$, respectively, represent the case where g is set to 0 or 1, respectively.

Suppose g is an OR gate, $g = \bigvee_{i=1}^s g^{(i)}$, where $g^{(i)}$ is an input literal or an internal gate. Suppose $g^{(i)}$ is represented by the pair $(g^{(i)}_s, g^{(i)}_v)$. This representation is already defined inductively. Then we let

$$g_s \;=\; \bigvee_{i=1}^s \left((g^{(i)}_s \wedge g^{(i)}_v)\right) \vee \left(\bigwedge_{i=1}^s (g^{(i)}_s \wedge \overline{g^{(i)}_v})\right).$$

That is, g is set iff either some g_i is set to 1 or else all g_i are set to 0. Note that the formula given for g_s is a depth 2 circuit of size $O(s)$. Also let

$$g_v \;=\; \bigvee_{i=1}^s g^{(i)}_v.$$

Note that g_v is a "valid" value for g only when $g_s = 1$. Also g_v is depth 1 and has size s.

The case $g = \bigwedge_{i=1}^s g^{(i)}$ is dual. In this case, g is set iff either some g_i is set to 0 or else all g_i are set to 1. Thus

$$g_s \;=\; \bigvee_{i=1}^s \left((g^{(i)}_s \wedge \overline{g^{(i)}_v})\right) \vee \left(\bigwedge_{i=1}^s (g^{(i)}_s \wedge g^{(i)}_v)\right) \quad \text{and} \quad g_v \;=\; \bigwedge_{i=1}^s g^{(i)}_v.$$

Again they are depth 2, size $O(s)$, and depth 1, size s, respectively.

In order to maintain alternating forms of AND's and OR's in the circuit C_x^1, with all negations pushed to the input level, we can represent each gate g by both g and its negated value $\overline{g}$. This can introduce at most a factor of 2 in the size. (In fact we will define only three gates g_s, g_v, and $\overline{g_v}$ in our construction; we do not need $(\overline{g})_s$. But we will omit the detailed analysis of constant factors.) C_x^1 has two output gates g_s and g_v for the output gate g of C_x. It follows that

$$\text{size}(C_x^1) = O(\text{size}(C_x)) \text{ and } \text{depth}(C_x^1) = 2\ \text{depth}(C_x).$$

We can take the constant in $O(\text{size}(C_x))$ to be 10, say.

Step 2 (C_x^2). Let $p = \frac{1}{(2m)^d}$. Let $L = \lceil \log_2 \frac{1}{p} \rceil \approx dk \log_2(20n)$. C_x^2 takes Boolean inputs $(a_{z,1}, \ldots, a_{z,L}, b_z)$ for $z \in \{0,1\}^m$. The circuit C_x^2 is identical to C_x^1, except instead of taking inputs a_z, it has $a_z = \bigvee_{j=1}^{L} a_{z,j}$.

Note that a random restriction ρ with parameter $\Pr[\rho(z) = *] = 1/2^L$ on C_x is simulated by uniformly and independently assigning all the bits $(a_{z,1}, \ldots, a_{z,L}, b_z)$ to 0 or 1, in C_x^2, for $z \in \{0,1\}^m$. The behavior of C_x is represented in C_x^2 exactly. Here we have

$$\text{size}(C_x^2) = \text{size}(C_x^1) + O(ML) \text{ and } \text{depth}(C_x^2) = \text{depth}(C_x^1) + 1.$$

Note also that $2^{-L} \leq p$. The same upper bound in Lemma 4 and Claim 1 still applies when ρ has parameter 2^{-L}.

Step 3 (C_x^3). In C_x^3 we will check for the existence of a subset $S \subset [M]$ of cardinality $|S| = 2m$ such that, first, they are assigned $*$ by the ρ, and, second, if we further set them all to 0, it would determine the circuit C_x. We know from Claim 1 that this is almost certainly true for our random restriction.

Thus, we let

$$C_x^3 \ = \ \bigvee_S \left[\ \bigwedge_{z \in S} \overline{a_z} \wedge [(C_x^2)_s]_S \ \right],$$

where $\bigvee_S$ ranges over all subsets $S \subset [M]$ of cardinality $|S| = 2m$, and $(C_x^2)_s$ is the "set bit output" for C_x^2, and $[(C_x^2)_s]_S$ is obtained from $(C_x^2)_s$ by setting all $b_z = 0$ for $z \in S$. Recall that $a_z = \bigvee_{j=1}^{L} a_{z,j}$. Then we have

$$\text{size}(C_x^3) \leq \binom{M}{2m} (\text{size}(C_x^2) + O(m)) \text{ and } \text{depth}(C_x^3) = \text{depth}(C_x^2) + 2.$$

Step 4 (D). Finally, define D by

$$D \ = \ \bigwedge_{x \in \{0,1\}^n} C_x^3.$$

Then we have

$$\text{size}(D) = 2^n (\text{size}(C_x^3)) \text{ and } \text{depth}(D) = \text{depth}(C_x^3) + 1.$$

This completes the construction of D, with

$$\text{size}(D) < 2^{3m^2} \text{ and } \text{depth}(D) \leq 2d + 6 \leq 3d - 1.$$

Below we will denote $3d-1$ by $\widehat{d}$.

From our construction, it follows that (i) the uniform independent distribution on the input bits of D simulates the random restriction ρ with $p = 2^{-L} \approx 1/(20m)^d$, and that (ii) D becomes true if every $C_x|\rho$ has decision tree depth at most $2m$. Hence, the following claim follows from Claim 1.

CLAIM 2.

$$\Pr[D=1] \;\geq\; 1 - \frac{m}{2^{m-n}},$$

where the probability is over uniform input bits of D.

Now we apply an NW generator to this circuit D. First we recall some basic notions on NW generators from [NW94].

Let U, M, m, and q be positive integers. Let $[U]$ be some set of cardinality U, e.g., $\{1,2,\ldots,U\}$. A collection of subsets $\mathcal{S} = \{S_1,\ldots,S_M\}$ of some domain $[U]$ is called an (m,q)-*design* if it satisfies the following conditions.

(1) $\forall i,\ 1 \leq i \leq M,\ [\ |S_i| = q\ ]$, and

(2) $\forall i, \forall j,\ 1 \leq i \neq j \leq M,\ [\ |S_i \cap S_j| \leq m\ ]$.

Based on a given (m,q)-design $\mathcal{S} = \{S_1,\ldots,S_M\}$ with domain $[U]$, we define the following function $g_{\mathcal{S}}$: $\{0,1\}^U \to \{0,1\}^M$, which we call a (parity-based) *NW generator*:

$$\begin{aligned} &g_{\mathcal{S}}(x_1 \cdots x_U) \;=\; y_1 \cdots y_M, \\ &\quad \text{where each } y_i,\ 1 \leq i \leq M, \text{ is defined} \\ &\quad \text{by } y_i \;=\; x_{s_1} \oplus \cdots \oplus x_{s_q} \text{ (where } S_i = \{s_1,\ldots,s_q\} \subseteq [U]). \end{aligned}$$

For the pseudorandomness of this generator, we have the following lemma [NW94].

LEMMA 5. *For any positive integers U, M, m, q, s, and e, and positive real ϵ, let $g_{\mathcal{S}}$ be the NW generator defined using an (m,q)-design $\{S_1,\ldots,S_M\}$ with domain $[U]$, and suppose for any depth $e+1$ circuit C on q input bits and of size at most $s + c_{\mathrm{nw}} 2^m M$ (where c_{nw} is some constant), the q-bit parity function has the following bias:*

$$\left| \Pr_{(u_1,\ldots,u_q)\in\{0,1\}^q}[C(u_1,\ldots,u_q) = u_1 \oplus \cdots \oplus u_q] - \frac{1}{2} \right| \;\leq\; \frac{\epsilon}{M}.$$

Then $g_{\mathcal{S}}$ has the following pseudorandomness against any depth e circuit E on M input bits and of size at most s.

$$\left| \Pr_{\boldsymbol{y}\in\{0,1\}^M}[E(\boldsymbol{y}) = 1] - \Pr_{\boldsymbol{x}\in\{0,1\}^U}[E(g_{\mathcal{S}}(\boldsymbol{x})) = 1] \right| \;\leq\; \epsilon.$$

To apply the NW generator to our depth $\widehat{d}$ circuit D constructed above, we set our parameters and define our (m,q)-design, as follows. For the parameters m and M, we will use the same ones that have been used so far, namely, $m = n^k$ and $M = 2^m$. We will take a finite field $\mathbf{F}$ and set $q = |\mathbf{F}|$ and $U = q^2$. We will take a specific finite field $\mathbf{F} = \mathbf{Z}_2[X]/(X^{2\cdot 3^u} + X^{3^u} + 1)$ [vL91], where each element $\alpha \in \mathbf{F}$ takes $K = 2 \cdot 3^u$ bits, and $q = |\mathbf{F}| = 2^K$. We choose u so that $q \geq (3m^2+1)^{\widehat{d}+2}$. Then $q^{1/(\widehat{d}+2)} \geq \log_2(2^{3m^2} + c_{\mathrm{nw}} 2^m M)$, where c_{nw} is the constant in the above lemma. Clearly $q \leq n^{ckd}$ will do, for some universal constant c, for example, $c = 7$. Then $K = O(dk \log n)$. Thus, this field has polynomial size and each element is represented by $O(\log n)$ bits. All arithmetic operations in this field $\mathbf{F}$ are easy.

We will consider precisely $M = 2^m$ polynomials $f_z(\xi) \in \mathbf{F}[\xi]$, each of degree at most m, where each f_z is indexed by its coefficients, concatenated as a bit sequence

of length exactly m. The precise manner in which this is done is not very important, but for definiteness, we can take the following. We take polynomials of degree $\delta = \lfloor m/K \rfloor = \Omega(n^k/(dk \log n)) \gg n^2$, with exactly $\delta + 1$ coefficients,

$$f_z(\xi) \;=\; c_\delta \xi^\delta + \cdots + c_1 \xi + c_0,$$

where all c_j varies over $\mathbf{F}$, except that c_δ is restricted to exactly $2^{m-K\cdot\delta}$ many values. Note that $0 \le m - K \cdot \delta < K$. The concatenation $z = \langle c_\delta \cdots c_0 \rangle$ has exactly m bits. Each f_z defines a subset of $\mathbf{F} \times \mathbf{F}$ of cardinality q, $\{(\alpha, f_z(\alpha)) \mid \alpha \in \mathbf{F}\}$, which we denote by S_z. An (m, q)-design that we will use is defined as $\mathcal{S} = \{S_1, \ldots, S_M\}$, indexed by $z \in \{0,1\}^m$, which we identify with the index set $\{1, \ldots, M\}$. Note that $\mathbf{F} \times \mathbf{F}$ is a domain $[U]$ with $U = q^2$. The first condition of an (m, q)-design is immediate, and the second condition, i.e., $|S_z \cap S_{z'}| \le m \;\forall z \ne z'$, is also easy to see by noting that $\deg(f_z) < m$ and $\deg(f_{z'}) < m$. Note that our NW generator $g_{\mathcal{S}}$ generates a pseudorandom sequence of length $M = 2^m$ from a seed of length $U = q^2$.

For showing the pseudorandomness of $g_{\mathcal{S}}$, we use the following lemma, which follows from the decision tree version of the Switching Lemma.

LEMMA 6. *For any depth e, and for all sufficiently large q, any circuit C on q inputs and of size at most $2^{q^{1/(e+1)}}$ satisfies*

$$\left| \Pr_{(u_1,\ldots,u_q)\in\{0,1\}^q}[C(u_1, \ldots, u_q) = u_1 \oplus \cdots \oplus u_q] - \frac{1}{2} \right| \;\le\; 2^{-q^{1/(e+1)}}.$$

Then the following claim is immediate from Lemmas 5 and 6.

CLAIM 3. *Our NW generator $g_{\mathcal{S}}$ has the following pseudorandomness against any circuit E of size at most 2^{3m^2} and depth $\widehat{d}$:*

$$\left| \Pr_{\boldsymbol{y}\in\{0,1\}^M}[E(\boldsymbol{y}) = 1] - \Pr_{\boldsymbol{x}\in\{0,1\}^U}[E(g_{\mathcal{S}}(\boldsymbol{x})) = 1] \right| \;\le\; 2^{m-3m^2}.$$

Recall that the circuit D takes $(L+1)M$ Boolean inputs, i.e., $(a_{z,1}, \ldots, a_{z,L}, b_z)$ for $z \in \{0,1\}^m$, where $M = 2^m$ and $L = \lceil \log_2 \frac{1}{p} \rceil$. We provide these input values by our NW generator that produces an M-bit pseudorandom string from a q^2-bit random seed. Hence, for the seed to the generator, a random string of length $(L+1)q^2$ is needed, and we use a sequence of independently and uniformly distributed bits $\{u^{(0)}_{\alpha,\beta}, u^{(1)}_{\alpha,\beta}, \ldots, u^{(L)}_{\alpha,\beta}\}$ for each $\alpha, \beta \in \mathbf{F}$. That is, for each $j = 1, \ldots, L$, we use q^2 bits $\{u^{(j)}_{\alpha,\beta} \mid \alpha, \beta \in \mathbf{F}\}$ to generate the M Boolean values of $a_{z,j}$ for $z \in \{0,1\}^m$. Similarly, the set $\{u^{(0)}_{\alpha,\beta} \mid \alpha, \beta \in \mathbf{F}\}$ of q^2 bits is used to generate the M Boolean values of b_z for $z \in \{0,1\}^m$. More specifically, for each $z \in \{0,1\}^m$ and $j = 1, \ldots, L$, we define $a_{z,j}$ and b_z as follows:

$$a_{z,j} \;=\; \bigoplus_{\alpha\in\mathbf{F}} u^{(j)}_{\alpha,f_z(\alpha)} \;\text{ and }\; b_z \;=\; \bigoplus_{\alpha\in\mathbf{F}} u^{(0)}_{\alpha,f_z(\alpha)}.$$

Then we have the following claim.

CLAIM 4. *Let $\boldsymbol{g}^{(i)}_{\mathcal{S}}$ denote the pseudorandom output sequence of $g_{\mathcal{S}}$ on random seed bits $\{u^{(i)}_{\alpha,\beta} \mid \alpha, \beta \in \mathbf{F}\}$ for $0 \le i \le L$. Then*

$$\Pr[D(\boldsymbol{g}^{(1)}_{\mathcal{S}}, \ldots, \boldsymbol{g}^{(L)}_{\mathcal{S}}, \boldsymbol{g}^{(0)}_{\mathcal{S}}) = 1] \;\ge\; 1 - o(1),$$

where the probability is over independently and uniformly distributed bits $\{u^{(0)}_{\alpha,\beta}, u^{(1)}_{\alpha,\beta}, \ldots, u^{(L)}_{\alpha,\beta}\}$ for $\alpha, \beta \in \mathbf{F}$.

Proof. Let us denote by $\boldsymbol{a}_i$ and $\boldsymbol{b}$, respectively, a sequence of M true random bits assigned to D's input variables $a_{z,i}$ and b_z for $z \in \{0,1\}^m$. Then our goal is to show that $\Pr[D(\boldsymbol{g}_{\mathcal{S}}^{(1)}, \ldots, \boldsymbol{g}_{\mathcal{S}}^{(L)}, \boldsymbol{g}_{\mathcal{S}}^{(0)}) = 1]$ is close to 1. We claim $\Pr[D(\boldsymbol{g}_{\mathcal{S}}^{(1)}, \ldots, \boldsymbol{g}_{\mathcal{S}}^{(L)}, \boldsymbol{g}_{\mathcal{S}}^{(0)}) \neq 1] \leq 1/2^{n-1}$. For a contradiction suppose it is $> 1/2^{n-1}$.

Recall that from Claim 2 $\Pr[D(\boldsymbol{a}_1, \ldots, \boldsymbol{a}_L, \boldsymbol{b}) \neq 1] \leq m/2^{m-n}$.

Then we have

$$\left|\Pr[D(\boldsymbol{a}_1, \ldots, \boldsymbol{a}_L, \boldsymbol{b}) \neq 1] - \Pr[D(\boldsymbol{g}_{\mathcal{S}}^{(1)}, \ldots, \boldsymbol{g}_{\mathcal{S}}^{(L)}, \boldsymbol{g}_{\mathcal{S}}^{(0)}) \neq 1]\right| \;>\; \frac{1}{2^{n-1}} - \frac{m}{2^{m-n}} \;>\; \frac{1}{2^n}.$$

This implies, by the telescoping argument

$$\begin{aligned}
\frac{1}{2^n} &< \left|\Pr[D(\boldsymbol{a}_1, \ldots, \boldsymbol{a}_L, \boldsymbol{b}) \neq 1] - \Pr[D(\boldsymbol{g}_{\mathcal{S}}^{(1)}, \ldots, \boldsymbol{g}_{\mathcal{S}}^{(L)}, \boldsymbol{g}_{\mathcal{S}}^{(0)}) \neq 1]\right| \\
&\leq \left|\Pr[D(\boldsymbol{a}_1, \ldots, \boldsymbol{a}_L, \boldsymbol{b}) \neq 1] - \Pr[D(\boldsymbol{g}_{\mathcal{S}}^{(1)}, \boldsymbol{a}_2, \ldots, \boldsymbol{a}_L, \boldsymbol{b}) \neq 1]\right| \\
&\quad + \left|\Pr[D(\boldsymbol{g}_{\mathcal{S}}^{(1)}, \boldsymbol{a}_2, \ldots, \boldsymbol{a}_L, \boldsymbol{b}) \neq 1] - \Pr[D(\boldsymbol{g}_{\mathcal{S}}^{(1)}, \boldsymbol{g}_{\mathcal{S}}^{(2)}, \boldsymbol{a}_3, \ldots, \boldsymbol{a}_L, \boldsymbol{b}) \neq 1]\right| \\
&\quad \cdots \\
&\quad + \left|\Pr[D(\boldsymbol{g}_{\mathcal{S}}^{(1)}, \ldots, \boldsymbol{g}_{\mathcal{S}}^{(L)}, \boldsymbol{b}) \neq 1] - \Pr[D(\boldsymbol{g}_{\mathcal{S}}^{(1)}, \ldots, \boldsymbol{g}_{\mathcal{S}}^{(L)}, \boldsymbol{g}_{\mathcal{S}}^{(0)}) \neq 1]\right|,
\end{aligned}$$

that there exists some i such that

$$\begin{aligned}
&\Big| \Pr\left[D(\boldsymbol{g}_{\mathcal{S}}^{(1)}, \ldots, \boldsymbol{g}_{\mathcal{S}}^{(i-1)}, \boldsymbol{a}_i, \ldots, \boldsymbol{a}_L, \boldsymbol{b}) \neq 1\right] \\
&\quad - \Pr[D(\boldsymbol{g}_{\mathcal{S}}^{(1)}, \ldots, \boldsymbol{g}_{\mathcal{S}}^{(i-1)}, \boldsymbol{g}_{\mathcal{S}}^{(i)}, \boldsymbol{a}_{i+1}, \ldots, \boldsymbol{a}_L, \boldsymbol{b}) \neq 1]\Big| > \frac{1}{L2^n}.
\end{aligned}$$

By an averaging argument, this bound still holds by appropriately fixing random bits other than $\boldsymbol{a}_i$ and the source bits for $\boldsymbol{g}_{\mathcal{S}}^{(i)}$. In other words, for some circuit D' with M input variables of size at most $\text{size}(D) = 2^{3m^2}$ and depth $\text{depth}(D) = \widehat{d}$, we have

$$\left|\Pr[D'(\boldsymbol{a}_i) = 1] - \Pr[D'(\boldsymbol{g}_{\mathcal{S}}^{(i)}) = 1]\right| \;>\; \frac{1}{L2^n}.$$

This is a contradiction of Claim 3, the pseudorandomness of the generator $g_{\mathcal{S}}$, since $L = O(d \log m)$. □

This claim states that with high probability, a pseudorandom sequence satisfies D, meaning that the random restriction induced from the pseudorandom sequence reduces *every* C_x to a simple function (e.g., a small decision tree) whose value can be fixed by fixing $t = 2m$ additional variables (for each C_x) to 0. Next we will argue that for such a pseudorandom restriction, one can find some space to encode the determined value of each C_x.

Consider a restriction induced by a pseudorandom sequence satisfying D. Apply this restriction to all variables z of circuits C_x, and fix further the value of some set Y of variables to 0 in order to determine the value of circuits C_x $\forall x \in \{0,1\}^n$. We may assume that the size of Y is at most $2m2^n$, which is guaranteed by the fact that $D = 1$ with our pseudorandom sequence. Then there exists y_0 of length $n^2/2$ such that a segment $T_{y_0} = \{z \in \{0,1\}^m \mid y_0 \text{ is a prefix of } z\}$ has no intersection with Y; that is, all variables in T_{y_0} are free from any variables used to fix the value of circuits C_x . This is simply because $2m2^n \ll 2^{n^2/2}$. Our plan is to code the results of C_x by a Boolean variable z of the form $z = y_0 x w$ for some w. The key requirements are that

(i) the variable z is assigned $*$ by the pseudorandom restriction, and (ii) it is easy to find such z (i.e., w) from a given x. (We may assume that the string y_0 and the seed for the chosen pseudorandom sequence are remembered by being encoded in the target polynomial-size circuit $C_{\mathcal{M}}$.)

Let $\boldsymbol{u}_{\alpha,\beta}$ be a column vector of 0-1 uniform bits $(u^{(1)}_{\alpha,\beta}, u^{(2)}_{\alpha,\beta}, \ldots, u^{(L)}_{\alpha,\beta})^{\mathrm{T}}$. Recall that in D's simulation of circuits C_x, a Boolean variable z (of C_x) is assigned $*$ iff $a_{z,j} = 0\ \forall j = 1, \ldots, L$. Hence, z is assigned $*$ by a pseudorandom restriction iff $\sum_{\alpha\in\mathbf{F}} \boldsymbol{u}_{\alpha,f_z(\alpha)} = \mathbf{0}$ in $\mathbf{Z}_2^L$. y_0 is determined by the pigeonhole principle and depends on the source bits $\boldsymbol{u}_{\alpha,\beta}$. We also need to have plenty of $*$'s in the segment T_{y_0}. Since we cannot predetermine y_0, we demand all segments T_y have plenty of $*$'s. So, we want our source bits $\boldsymbol{u}_{\alpha,\beta}$ to satisfy the following condition:

$$(1)\quad \forall y \in \{0,1\}^{n^2/2},\ \forall x \in \{0,1\}^n,\ \exists z = yxw \in \{0,1\}^m\ \left[\ \sum_{\alpha\in\mathbf{F}} \boldsymbol{u}_{\alpha,f_z(\alpha)} = \mathbf{0}\ \right].$$

Furthermore, such a w should be easy to compute from the source bits $\boldsymbol{u}_{\alpha,\beta}$, and the given y, and x.

Recall that for any $z \in \{0,1\}^m$, f_z is defined by the sequence of the coefficients $\langle c_\delta \cdots c_0\rangle$, which concatenates to z. Let γ be the largest index such that the binary concatenation $\langle c_\delta \cdots c_\gamma\rangle$ becomes longer than $n^2/2+n$ bits, so $n^2/2+n < |\langle c_\delta \cdots c_\gamma\rangle| \le n^2/2+n+K$. Then for any $y \in \{0,1\}^{n^2/2}$ and $x \in \{0,1\}^n$, we have some subsequence of coefficients $c_\delta, \ldots, c_\gamma$ such that $yx0^v = \langle c_\delta \cdots c_\gamma\rangle$, with some v for padding. Note that $\gamma > 0$, since $m = n^k$ and $k > 2$. We will show (see Claim 5 below) that with high probability a sequence of random source bits $\boldsymbol{u}_{\alpha,\beta}$ satisfies the following:

$$(2)\qquad \forall c_\delta \in \mathbf{F},\ \ldots,\ \forall c_\gamma \in \mathbf{F},\ \exists c_0 \in \mathbf{F}\ \left[\ \sum_{\alpha\in\mathbf{F}} \boldsymbol{u}_{\alpha,f_{z^*}(\alpha)} = \mathbf{0}\ \right],$$

where z^* is a string in $\{0,1\}^m$ that is the concatenation $\langle c_\delta \cdots c_\gamma 0 \cdots 0 c_0\rangle$. Observe that condition (2) is sufficient for our requirement (1). Consider any $y \in \{0,1\}^{n^2/2}$ and $x \in \{0,1\}^n$, and let $c_\delta, \ldots, c_\gamma$ be the coefficients corresponding to $yx0^v$. Then from (2), there exists some c_0 by which we can define $z^* = \langle c_\delta \cdots c_\gamma 0 \cdots 0 c_0\rangle$ satisfying the condition of (1). Furthermore, we will show that we can easily find such c_0 (thus z^*) given $\boldsymbol{u}_{\alpha,\beta}$, and $c_\delta, \ldots, c_\gamma$, by checking all q elements of $\mathbf{F}$.

We now summarize our oracle construction. Choose any setting of the random bits $\omega = \boldsymbol{u}_{\alpha,\beta}$, such that it generates $(L+1)M$ pseudorandom bits Ω satisfying both $D = 1$ and (2); let ρ_Ω be the restriction induced by this pseudorandom sequence. We construct the segment $X^{=m}$ of our oracle by ρ_Ω as follows. Below z denotes a string in $\{0,1\}^m$ whose membership to X has not been determined yet in the construction. Let X_{fixed} (resp., $\overline{X}_{\mathrm{fixed}}$) be the set of strings in $\{0,1\}^m$ whose membership to X (resp., $\overline{X}$) has been determined. Initially, both X_{fixed} and $\overline{X}_{\mathrm{fixed}}$ are empty. First fix the membership according to ρ_Ω; that is, z is put into X_{fixed} (resp., $\overline{X}_{\mathrm{fixed}}$) iff ρ_Ω sets 1 (resp., 0) to the corresponding variable. Secondly, choose a set $Y \subseteq \{0,1\}^m - (X_{\mathrm{fixed}} \cup \overline{X}_{\mathrm{fixed}})$ of at most $2m2^n$ strings such that adding Y to $\overline{X}_{\mathrm{fixed}}$ determines the value of circuits $C_x\ \forall x \in \{0,1\}^n$. This set Y is guaranteed by $D = 1$. Add Y to $\overline{X}_{\mathrm{fixed}}$. Fix one y_0 such that $T_{y_0} \cap Y = \emptyset$. This y_0 exists by the pigeonhole principle. Then for any $x \in \{0,1\}^n$, put any z of the form y_0xw for some w into X_{fixed} (resp., $\overline{X}_{\mathrm{fixed}}$) iff the (already determined) value of C_x is 1 (resp., 0). Then put all remaining z into $\overline{X}_{\mathrm{fixed}}$.

Now we explain how to design a polynomial-size circuit $C_{\mathcal{M}}$ simulating $\mathcal{M}^X$. We may assume that the information on the seed ω (of length $(L+1)q^2 = n^{O(kd)}$) and y_0 are hardwired into the circuit, and they can be used in the computation. For a given input x, the circuit exhaustively searches for $c_0 \in \mathbf{F}$ satisfying the condition of (2) for the coefficients $c_\delta, \ldots, c_\gamma$ corresponding to $y_0 x 0^v$. Since the seed is given, for any $z^* = \langle c_\delta \cdots c_\gamma 0 \cdots 0 c_0 \rangle$, one can compute $\sum_{\alpha \in \mathbf{F}} \boldsymbol{u}_{\alpha, f_{z^*}(\alpha)}$ within polynomial time in n. Also the size of $\mathbf{F}$ is $q = n^{O(kd)}$. Thus, the desired c_0 (and hence z^*) is computable in polynomial time. When z^* is obtained, the circuit queries the oracle whether "$z^* \in X$?" and accepts the input iff $z^* \in X$. It is easy to check whether the whole computation can be implemented by some circuit of size n^{ckd} for some constant $c > 0$.

We complete the proof by proving the following claim.

CLAIM 5. *Over $q^2 L$ independent and uniform random bits $\{u^{(1)}_{\alpha,\beta}, \ldots, u^{(L)}_{\alpha,\beta} \mid \alpha, \beta \in \mathbf{F}\}$, condition (2) holds with probability $1 - o(1)$.*

Proof. For any fixed $c_\delta, \ldots, c_\gamma$, let $z^*(c)$ denote $\langle c_\delta \cdots c_\gamma 0 \cdots 0 c \rangle$. Then $f_{z^*(c)}(\xi)$ is expressed as $f_{z^*(c)}(\xi) = g(\xi) + c$, where the polynomial $g(\xi) = c_\delta \xi^\delta + \cdots + c_\gamma \xi^\gamma$ is independent of c.

Define $\boldsymbol{u}^*_{\alpha,c} = \boldsymbol{u}_{\alpha, g(\alpha)+c}$. Then since $\boldsymbol{u}^*_{\alpha,c} = \boldsymbol{u}_{\alpha, f_{z^*(c)}(\alpha)}$, condition (2) can be stated as

$$\forall c_\delta,\ \ldots,\ \forall c_\gamma,\ \exists c_0 \left[\sum_{\alpha \in \mathbf{F}} \boldsymbol{u}^*_{\alpha,c_0} = \mathbf{0} \right].$$

Notice that for any fixed $c_\delta, \ldots, c_\gamma$, for any α, α', c, and c', the vectors $\boldsymbol{u}^*_{\alpha,c}$ and $\boldsymbol{u}^*_{\alpha',c'}$ consist of disjoint sets of bits, unless $\alpha = \alpha'$ and $c = c'$. Hence, if $c \neq c'$, they are (probabilistically) independent, from which the following bound follows: $\forall c_\delta, \ldots, c_\gamma$,

$$\Pr\left[\forall c_0 \left[\sum_{\alpha \in \mathbf{F}} \boldsymbol{u}^*_{\alpha,c_0} \neq \mathbf{0} \right] \right] = \prod_{c \in \mathbf{F}} \Pr\left[\sum_{\alpha \in \mathbf{F}} \boldsymbol{u}^*_{\alpha,c} \neq \mathbf{0} \right] = \left(1 - \frac{1}{2^L}\right)^q < e^{-\Omega(q/(20m)^d)},$$

where the probability is taken uniformly over all the bits $u^{(1)}_{\alpha,\beta}, \ldots, u^{(L)}_{\alpha,\beta}$ $\forall \alpha, \beta \in \mathbf{F}$. Then the claim is proved as follows:

$$\begin{aligned} &\Pr \left[\forall c_\delta,\ \ldots,\ \forall c_\gamma,\ \exists c_0 \left[\sum_{\alpha \in \mathbf{F}} \boldsymbol{u}^*_{\alpha,c_0}(\alpha) = \mathbf{0} \right] \right] \\ &\quad \geq 1 - 2^{n^2/2+n+K} e^{-\Omega(q/(20m)^d)} = 1 - o(1). \qquad \square \end{aligned}$$

Remark 1. For convenience we assumed in the proof that $k > 2$ and $d \geq 7$. This is only to simplify notation. Clearly $d \geq 7$ is unnecessary. We only need to forgo the estimate of $2d + 6 \leq 3d - 1$ and use $2d + 6$. Also any machine $\mathcal{M}$ in Σ^{p}_d for $d < 7$ can always be considered in a higher level. Similarly, $k > 2$ is not necessary. If one traces through the proof, with slight modification, any real number $k > 1$ is sufficient.

Remark 2. The final computation by the polynomial-size circuit can be done in NC^1. We only need to evaluate some arithmetic operations in the finite field $\mathbf{F}$. It turns out that since elements in $\mathbf{F}$ are represented by $O(\log n)$ bits, the only step that really requires NC^1 is the parity sum of $n^{O(1)}$ terms, when we evaluate the polynomial f_z.

Remark 3. Though the proof is stated for simulating one machine $\mathcal{M}$, it is also possible to construct a single oracle X such that for every d and k, and every Σ^{p}_d

machine $\mathcal{M}$ running in time $O(n^k)$, the language $L(\mathcal{M}^X)$ can be recognized by some polynomial-size circuit family with stringent access to oracle X.

4. Some results on constant depth circuits. As lower bound results on constant depth circuits play a crucial role in this work, we take this opportunity to present some previously unpublished older results of the first author on these circuits. In particular we emphasize the decision tree viewpoint and give some better constants in the exponents than previously published lower bounds. We give a historical account at the end of the section.

The decision tree perspective was first proposed in [Cai86], where a weaker version of the following lemma was proved. The following proof essentially adapts the techniques from [Hås86a].

We say a Boolean function G on variables $\{x_1, \ldots, x_n\}$ is a *t-AND-OR* if $G = G_1 \wedge G_2 \wedge \cdots \wedge G_w$, where each G_i is the OR of at most t literals (a literal is a variable or its complement). Similarly, we say G is a *t-OR-AND* if $G = G_1 \vee G_2 \vee \cdots \vee G_w$, where each G_i is the AND of at most t literals.

As a base step for analyzing general circuits, we first prove the following lemma.

LEMMA 7. *Let G be a t-AND-OR formula $G_1 \wedge G_2 \wedge \cdots \wedge G_w$. Let ρ be a random p-restriction. Then, $\forall \Delta \geq 0$,*

$$\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta\ ] \ \leq\ (5pt)^\Delta. \tag{3}$$

Proof. The lemma is proved by an induction on w. Concerning G_1, immediately there are 2 cases, either $G_1|_\rho \equiv 1$ or $G_1|_\rho \not\equiv 1$. By renaming literals, we may assume $G_1 = \bigvee_{i \in T} x_i$. Then $G_1|_\rho \equiv 1$ is equivalent to $\rho(i) = 1$ for some $i \in T$. If $G_1|_\rho \equiv 1$, we want to prove that the conditional probability that the rest of G has $\mathrm{DC}(G|_\rho) \geq \Delta$ is no larger. If, however, $G_1|_\rho \not\equiv 1$, we want to carefully analyze what happens to the variables in T. All of this will accumulate as some prior condition on ρ. It will be seen that the inductive step will carry a condition that refers to some collection of subsets of variables on each of which ρ has assigned some variable of it in some definite way. In the earlier proof of Yao [Yao85], as well as in the proof of Cai [Cai86], these conditions were explicitly carried along in the proof. The following device used in Håstad's proof [Hås86a] is more elegant.

One makes the stronger claim that for *any* Boolean function F, we have

$$\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta \mid F|_\rho \equiv 1\ ] \ \leq\ \alpha^\Delta, \tag{4}$$

where α will be set to $5pt$, and we agree that the conditional probability is 0 if the condition is not satisfied. The lemma follows from (4) by taking F to be the constant function 1.

The statement (4) is trivially true for $\Delta = 0$, since the right-hand side becomes 1 in this case. Similarly, if $\alpha \geq 1$, then the statement is true. Thus, we may assume $\Delta > 0$ and $\alpha < 1$.

We prove (4) by induction on w. If $w = 0$, then $G \equiv 1$ by definition and the statement holds since the left-hand side is 0. Let $w > 0$. Put $G = G_1 \wedge G'$, where $G' = G_2 \wedge \cdots \wedge G_w$. Now, either $G_1|_\rho \equiv 1$ or $G_1|_\rho \not\equiv 1$. If $G_1|_\rho \equiv 1$, then we have, by induction,

$$\begin{aligned} &\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta \mid F|_\rho \equiv 1, G_1|_\rho \equiv 1\ ] \\ &\quad =\ \Pr[\ \mathrm{DC}(G'|_\rho) \geq \Delta \mid (F \wedge G_1)|_\rho \equiv 1\ ] \ \leq\ \alpha^\Delta. \end{aligned}$$

Now consider the case $G_1|_\rho \not\equiv 1$. We want to prove

$$\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta \mid F|_\rho \equiv 1, G_1|_\rho \not\equiv 1\ ] \ \leq\ \alpha^\Delta \tag{5}$$

as well. We have renamed the variables so that $G_1 = \bigvee_{i\in T} x_i$. Then $G_1|_\rho \not\equiv 1$ means that for each $i \in T$, $\rho(i) = 0$ or $*$. Moreover, since $\Delta > 0$, it cannot be that $\rho(i) = 0\ \forall i \in T$, or else $G_1|_\rho \equiv 0$, and $\mathrm{DC}(G|_\rho) = 0$. Thus, the set of restrictions ρ such that $F|_\rho \equiv 1, G_1|_\rho \not\equiv 1$, and $\mathrm{DC}(G|_\rho) \geq \Delta$ is contained in

$$\bigcup_{\emptyset\neq Y\subseteq T} \{\rho\ :\ \rho(Y) = *, \rho(T-Y) = 0, F|_\rho \equiv 1, \mathrm{DC}(G|_\rho) \geq \Delta\,\}.$$

Suppose $\rho(Y) = *$ and $\rho(T - Y) = 0$ for some $\emptyset \neq Y \subseteq T$.

First we assume $|Y| < \Delta$. Then there must be some assignment $\sigma_Y : Y \to \{0,1\}$, and $\sigma_Y \neq 0^Y$, where we denote by 0^Y the all-0 assignment on Y, such that $\mathrm{DC}(G|_\rho|_{\sigma_Y}) \geq \Delta - |Y|$. For otherwise, one could obtain *some* decision tree of depth $< \Delta$ for $G|_\rho$ by first asking all the variables in Y. Note that such a $\sigma_Y \neq 0^Y$ because the all-0 assignment leads to $G_1|_\rho|_{0^Y} \equiv 0$.

For $\sigma_Y \neq 0^Y$, $G_1|_\rho|_{\sigma_Y} \equiv 1$, so that $G|_\rho|_{\sigma_Y} \equiv G'|_\rho|_{\sigma_Y}$. Then

$$\begin{aligned}&\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta \mid F|_\rho \equiv 1 \wedge \rho(Y) = * \wedge \rho(T-Y) = 0\ ]\\ &\leq \sum_{\substack{\sigma_Y : Y\to\{0,1\}\\ \sigma_Y\neq 0^Y}} \Pr[\ \mathrm{DC}(G'|_\rho|_{\sigma_Y}) \geq \Delta - |Y| \mid F|_\rho \equiv 1 \wedge \rho(Y) = * \wedge \rho(T-Y) = 0)\ ].\end{aligned} \tag{6}$$

Set

$$\begin{aligned} 0^{T-Y} &= \text{the all-0 assignment on } T - Y,\\ \widetilde{F} &= \textstyle\bigwedge_{\tau_Y : Y\to\{0,1\}} F|_{0^{T-Y}}|_{\tau_Y},\ \text{ and}\\ \widetilde{\rho} &= \rho \text{ restricted to the complement of } T;\end{aligned}$$

then under the condition $\rho(Y) = * \wedge \rho(T - Y) = 0$ we have

$$F|_\rho \equiv 1 \iff \widetilde{F}|_{\widetilde{\rho}} \equiv 1.$$

Hence, the sum in (6) has the upper bound

$$\sum_{\substack{\sigma_Y : Y\to\{0,1\}\\ \sigma_Y\neq 0^Y}} \Pr[\ \mathrm{DC}(G'|_{0^{T-Y}}|_{\sigma_Y}|_{\widetilde{\rho}}) \geq \Delta - |Y| \mid \widetilde{F}|_{\widetilde{\rho}} \equiv 1\ ] \ \leq\ (2^{|Y|} - 1)\alpha^{\Delta-|Y|}, \tag{7}$$

by induction.

The upper bound (7) holds for

$$\Pr[\ \mathrm{DC}(G|\rho) \geq \Delta \mid F|\rho \equiv 1 \wedge \rho(Y) = * \wedge \rho(T-Y) = 0\ ] \tag{8}$$

$\forall Y \neq \emptyset$ with $|Y| < \Delta$. However, for $|Y| \geq \Delta$, the bound in (7) holds trivially for a probability (8), since in this case the bound in (7) is ≥ 1, as $|Y| \geq \Delta > 0$ and $\alpha < 1$. Hence in fact it holds $\forall Y \neq \emptyset$.

Let

$$\begin{aligned} a_Y &= \Pr[\ \rho(Y) = * \wedge \rho(T-Y) = 0 \mid F|_\rho \equiv 1 \wedge G_1|_\rho \not\equiv 1\ ],\\ b_Y &= \Pr[\ \rho(Y) = * \mid F|_\rho \equiv 1 \wedge G_1|_\rho \not\equiv 1\ ].\end{aligned}$$

Then

$$b_Y \;=\; \sum_{Y\subseteq Z\subseteq T} a_Z,$$

and by the Möbius inversion formula,

$$a_Y \;=\; \sum_{Y\subseteq Z\subseteq T} (-1)^{|Z-Y|} b_Z.$$

It follows that

$$\begin{aligned}
&\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta \mid F|_\rho \equiv 1, G_1|_\rho \not\equiv 1\ ] \\
&\leq \sum_{\emptyset\neq Y\subseteq T} a_Y \cdot (2^{|Y|}-1)\alpha^{\Delta-|Y|} \\
&= \sum_{Y\subseteq T} a_Y \cdot (2^{|Y|}-1)\alpha^{\Delta-|Y|}.
\end{aligned}$$

Substituting b_Z for a_Y, we have

$$\begin{aligned}
&\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta \mid F|_\rho \equiv 1, G_1|_\rho \not\equiv 1\ ] \\
&\leq \sum_{Y\subseteq T} \sum_{Y\subseteq Z\subseteq T} (-1)^{|Z-Y|} b_Z \cdot (2^{|Y|}-1)\alpha^{\Delta-|Y|} \\
&= \sum_{Z\subseteq T} b_Z \sum_{Y\subseteq Z} (-1)^{|Z-Y|}(2^{|Y|}-1)\alpha^{\Delta-|Y|} \\
&= \sum_{Z\subseteq T} b_Z (-1)^{|Z|}\alpha^\Delta \sum_{Y\subseteq Z} \left[\left(\frac{-2}{\alpha}\right)^{|Y|} - \left(\frac{-1}{\alpha}\right)^{|Y|}\right] \\
&= \alpha^\Delta \sum_{Z\subseteq T} b_Z (-1)^{|Z|} \left[\left(1-\frac{2}{\alpha}\right)^{|Z|} - \left(1-\frac{1}{\alpha}\right)^{|Z|}\right] \\
&= \alpha^\Delta \sum_{Z\subseteq T} b_Z \left[\left(\frac{2}{\alpha}-1\right)^{|Z|} - \left(\frac{1}{\alpha}-1\right)^{|Z|}\right].
\end{aligned}$$

Concerning b_Z, intuitively, under the condition that $F|_\rho \equiv 1 \wedge G_1|_\rho \not\equiv 1$, the probability of $\rho(Z) = *$ is at most $q^{|Z|}$, where $q = p/(p + \frac{1-p}{2}) \approx 2p$, i.e., $b_Z \leq q^{|Z|}$. We already saw that $G_1|_\rho \not\equiv 1$ means that each variable in Z is assigned either 0 or $*$. The additional condition that $F|_\rho \equiv 1$ can only decrease the probability that some variable is assigned an $*$. We will argue this point more carefully. For the moment, we accept the upper bound $b_Z \leq q^{|Z|}$.

Then, since the coefficients of b_Z are nonnegative, we have

$$\begin{aligned}
&\alpha^\Delta \sum_{Z\subseteq T} b_Z \left[\left(\frac{2}{\alpha}-1\right)^{|Z|} - \left(\frac{1}{\alpha}-1\right)^{|Z|}\right] \\
&\leq \alpha^\Delta \sum_{Z\subseteq T} q^{|Z|} \left[\left(\frac{2}{\alpha}-1\right)^{|Z|} - \left(\frac{1}{\alpha}-1\right)^{|Z|}\right] \\
&= \alpha^\Delta \left\{\left[1+q\left(\frac{2}{\alpha}-1\right)\right]^{|T|} - \left[1+q\left(\frac{1}{\alpha}-1\right)\right]^{|T|}\right\}
\end{aligned}$$

$$\leq \alpha^{\Delta} \left\{ \left[1 - q + \frac{2q}{\alpha}\right]^t - \left[1 - q + \frac{q}{\alpha}\right]^t \right\}. \tag{9}$$

At this point, we can recover the bound $(5pt)^{\Delta}$ as follows [Hås86a]. Observe that

$$\left[1 - q + \frac{2q}{\alpha}\right]^t - \left[1 - q + \frac{q}{\alpha}\right]^t \;\leq\; \left(1 + \frac{2q}{\alpha}\right)^t - \left(1 + \frac{q}{\alpha}\right)^t. \tag{10}$$

If we set $c = 1/\log\phi \approx 2.078$, where $\phi = \frac{1+\sqrt{5}}{2} \approx 1.618$ is the golden ratio, then we have $e^{2/c} - e^{1/c} = 1$. Then, setting $\alpha = cqt < 5pt$, we get

$$\left(1 + \frac{2q}{\alpha}\right)^t - \left(1 + \frac{q}{\alpha}\right)^t \;=\; \left(1 + \frac{2}{ct}\right)^t - \left(1 + \frac{1}{ct}\right)^t \;<\; e^{2/c} - e^{1/c} \;=\; 1.$$

Then

$$\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta \mid F|_\rho \equiv 1, G_1|_\rho \not\equiv 1\ ] \;<\; \alpha^{\Delta}.$$

This completes the proof of

$$\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta \mid F|_\rho \equiv 1\ ] \;<\; (5pt)^{\Delta}. \qquad \square$$

Finally, we show that $b_Z \leq q^{|Z|}$. Note that for $Z \subseteq T$, we have

$$\Pr[\ \rho(Z) = * \mid G_1|_\rho \not\equiv 1\ ] \;=\; q^{|Z|}.$$

This is because $G_1|_\rho \not\equiv 1$ is the same as ρ assigns only $*$ or 0 on T.

We show that $F|_\rho \equiv 1$ cannot increase the probability of $\rho(Z) = *$. This is trivial if $Z = \emptyset$. Suppose $Z \neq \emptyset$. Consider any fixed restriction ρ' on the complement of Z, $\rho' : Z^c \to \{0, 1, *\}$. Then there is a unique extension of ρ' over Z—call it ρ^*—that satisfies $\rho^*(Z) = *$.

We claim that

$$\Pr[\ \rho(Z) = * \mid F|_\rho \equiv 1, G_1|_\rho \not\equiv 1, \rho|_{Z^c} = \rho'\ ] \;\leq\; q^{|Z|}.$$

The event $\rho(Z) = *$ refers to the unique ρ^*, under the condition $\rho|_{Z^c} = \rho'$. If $F|_{\rho^*} \not\equiv 1$, then the above conditional probability is 0 and the claim trivially holds. Otherwise, $F|_\rho \equiv 1$ for all extensions ρ of ρ' to Z. Hence $F|_\rho \equiv 1, G_1|_\rho \not\equiv 1, \rho|_{Z^c} = \rho'$ refers to exactly $2^{|Z|}$ assignments ρ, such that $\rho(i) \in \{0, *\}\ \forall i \in Z$. The claim follows. Lemma 7 is proved. $\square$

If we take $p = \frac{1}{10t}$, then we get the following bound: For any G as in Lemma 7, and $\forall \Delta \geq 0$,

$$\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta\ ] \;\leq\; 2^{-\Delta}. \tag{11}$$

Using this bound as the base case, we can inductively prove Lemma 4.

On the other hand, it is possible to obtain a slightly stronger bound from (9). In fact the use of the inclusion-exclusion formula has been ignored in (10). In the following, we will show this slightly stronger bound.

We will set $q = \beta/t$ for some constant $\beta > 0$, to be determined later. Set

$$\alpha \;=\; \beta \Big/ \ln\left[\frac{1 + \sqrt{1 + 4e^{\beta}}}{2}\right].$$

Then

$$e^{2\beta/\alpha} - e^{\beta/\alpha} \;=\; e^{\beta}.$$

It follows that

$$\begin{aligned}
&\left[1 - q + \frac{2q}{\alpha}\right]^t - \left[1 - q + \frac{q}{\alpha}\right] \\
&= \left[1 + \left(\frac{2\beta}{\alpha} - \beta\right)\frac{1}{t}\right]^t - \left[1 + \left(\frac{\beta}{\alpha} - \beta\right)\frac{1}{t}\right]^t \\
&< e^{\frac{2\beta}{\alpha} - \beta} - e^{\frac{\beta}{\alpha} - \beta} \;=\; 1.
\end{aligned}$$

Replacing the analysis after (9) in the above proof, we obtain the following lemma.

LEMMA 8. *Let G be a t-AND-OR formula $G_1 \wedge G_2 \wedge \cdots \wedge G_w$. For any β, $0 < \beta < t$, let ρ be a random p-restriction, where $p = \frac{\beta}{t-\beta}$, and let $\alpha = \beta / \ln\left[\frac{1+\sqrt{1+4e^{\beta}}}{2}\right]$. Then $\forall \Delta \geq 0$, we have*

$$\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta\ ] \;\leq\; \alpha^{\Delta}.$$

Minimizing α we find at $\beta_0 = 0.227537$, $\alpha_0 = \alpha(\beta_0) \approx 2^{-1.2638031} \approx 0.4164447$. Let $\gamma_0 = \beta_0/2 \approx 0.1137685$. Then we have the following bound. This is a strengthening of (11).

LEMMA 9. *Let G be a t-AND-OR formula $G_1 \wedge G_2 \wedge \cdots \wedge G_w$, and let ρ be a random γ_0/t-restriction. Then $\forall \Delta \geq 0$, we have*

$$\Pr[\ \mathrm{DC}(G|_\rho) \geq \Delta\ ] \;\leq\; \alpha_0^{\Delta}.$$

Proof. Let $q = \beta_0/t$ and $p = \frac{q}{2-q}$. Then $q = \frac{2p}{1+p}$ is the probability of getting a 0 or an $*$ in a random p-restriction.

We have shown that

$$\Pr[\ \mathrm{DC}(G|_{\rho'}) \geq \Delta\ ] \;\leq\; \alpha_0^{\Delta},$$

where ρ' is a random p-restriction.

Since $p > q/2 = \gamma_0/t$, a random γ_0/t-restriction ρ can be realized by first applying a random p-restriction ρ', followed by a $\gamma_0/(pt)$-restriction. Note that if $\mathrm{DC}(G|_{\rho'}) < \Delta$, then $\mathrm{DC}(G|_\rho) < \Delta$. The lemma follows. □

Now consider general constant depth circuits. Denote by $C^d(s,t)$ the class of depth d circuits with bfi[2] $\leq t$, and the number of gates above the first level $\leq s$. Denote by $C^d(s)$ the class of depth d circuits without a bfi condition but with total size $\leq s$. By extending one level with fan-in 1, clearly $C^d(s) = C^{d+1}(s,1)$. (Here in this notation we suppress the number n of variables and the depth d, where s and t are understood to be functions of one or both of them.)

LEMMA 10. *For all $C \in C^d(s, \gamma_0 n^{1/d})$, we have*

$$\Pr[\ \mathrm{DC}(G|_\rho) \geq \gamma_0 n^{1/d}\ ] \;\leq\; s \cdot \alpha_0^{\gamma_0 n^{1/d}} \;\approx\; s \cdot 2^{-0.143781 \cdot n^{1/d}},$$

where ρ is a random $1/n^{\frac{d-1}{d}}$-restriction.

[2] *bfi* is the abbreviation of bottom fan-in, the maximum fan-in of the bottom level gates. By a "bfi condition" we mean a bound of the form bfi $\leq t$ that is given in each context.

Proof. Apply Lemma 9 repeatedly $d-1$ times, each time with a random $1/n^{\frac{1}{d}}$-restriction. Note that any function with decision tree depth $\leq \Delta$ can be expressed both as a Δ-AND-OR as well as a Δ-OR-AND. After switching bottom level AND-OR formulas to OR-AND's, or vice versa, one can merge two successive levels of gates and reduce the depth by 1. Then the lemma follows. □

Let $C \in C^d(s)$ with no bfi requirement. By considering $C \in C^{d+1}(s,1)$ we may first apply Lemma 9 to each of the bottom depth 2 subcircuits with bfi 1, with a random γ_0-restriction. But we can actually do slightly better by looking at it directly.

Fix any 1-OR-AND formula S. (The case with any 1-AND-OR is dual.) S is just a simple OR; by renaming variables, we may assume $S = \bigvee_{i=1}^m x_i$. Fix any $\Delta > 0$. If we apply a random p-restriction ρ, and if ρ assigns any $x_i = 1$, or if ρ assigns all x_i to 0 or $*$ but fewer than Δ of them are assigned $*$, then $\mathrm{DC}(S|_\rho) < \Delta$. Thus

$$\begin{aligned}\Pr[\ \mathrm{DC}(S|_\rho) \geq \Delta\ ] &\leq \sum_{\substack{J\subseteq\{1,\ldots,m\}\\ |J|\geq\Delta}} \Pr[\ \rho(J) = *, \rho(J^c) = 0\ ] \\ &= \left(\frac{1+p}{2}\right)^m \sum_{j=\Delta}^{m} \binom{m}{j} q^j (1-q)^{m-j},\end{aligned}$$

where $\Pr[\ \rho(i) \neq 1\ ] = p + \frac{1-p}{2} = \frac{1+p}{2}$, and $q = \Pr[\ \rho(i) = * \,|\, \rho(i) \neq 1\ ] = \frac{2p}{1+p}$. Hence

$$\Pr[\ \mathrm{DC}(S|_\rho) \geq \Delta\ ] \ \leq\ q^\Delta \left(\frac{1+p}{2}\right)^m \sum_{i=0}^{m} \binom{m}{i} (1-q)^{m-i} \ =\ q^\Delta \ <\ (2p)^\Delta.$$

So if we first apply a random restriction with $p = \frac{\alpha_0}{2} \approx 0.2082223$, with probability $> 1 - s_1 \alpha_0^{\gamma_0 n^{1/d}}$, all bottom level 1-OR-AND subcircuits are switched to $\gamma_0 n^{1/d}$-AND-OR (or all 1-AND-OR switched to $\gamma_0 n^{1/d}$-OR-AND), where s_1 is the total number of level 1 gates in the depth d circuit C, which are the depth 2 gates in the depth $d+1$ circuit with bfi 1. After the switching we get a circuit of depth $d+1$ with bfi $\leq \gamma_0 n^{1/d}$, but with the same type of gates on the 2 levels just above the bottom level gates. After merging these two levels, we get a circuit in $C^d(s', \gamma_0 n^{1/d})$, where $s' = s - s_1$. Now we apply Lemma 10. This gives the following bound.

LEMMA 11. *For all $C \in C^d(s)$, we have*

$$\Pr[\ \mathrm{DC}(G|_\rho) \geq \gamma_0 n^{1/d}\ ] \ <\ s \cdot \alpha_0^{\gamma_0 n^{1/d}} \ \approx\ s \cdot 2^{-0.143781 \cdot n^{1/d}},$$

where ρ is a random $\alpha_0/(2n^{\frac{d-1}{d}})$-restriction.

These results can be used to prove circuit lower bounds for such circuits. Consider any circuit C in $C^d(s, \gamma_0 n^{1/(d-1)})$. Applying $d-2$ rounds of random $1/n^{1/(d-1)}$-restrictions, with probability greater than $1 - s \cdot 2^{-0.143781 \cdot n^{1/(d-1)}}$, we get a circuit in $C^2(1, \gamma_0 n^{1/(d-1)})$ after switching and merging. The number of variables N left has expectation $\mathrm{Exp}[N] = n^{1/(d-1)}$. By Chernoff bound, we have

$$\Pr[\ N \leq \gamma_0 n^{\frac{1}{d-1}}\ ] \ =\ \Pr[\ N - n^{\frac{1}{d-1}} \leq -(1-\gamma_0) n^{\frac{1}{d-1}}\ ] \ <\ e^{-\frac{(1-\gamma_0)^2}{2} \cdot n^{\frac{1}{d-1}}} \ <\ e^{-0.3927 n^{\frac{1}{d-1}}}.$$

Hence, if $s < 2^{0.143781 \cdot n^{1/(d-1)}}$, the probability is approaching 1 that both C is reduced to a circuit in $C^2(1, \gamma_0 n^{1/(d-1)})$ and $N > \gamma_0 n^{1/(d-1)}$. Therefore C does not compute the parity.

LEMMA 12. *For all $C \in C^d(s, \gamma_0 n^{1/(d-1)})$, if C computes the parity function, then its size s must satisfy*

$$s \;\geq\; 2^{0.143781 \cdot n^{1/(d-1)}}.$$

Let $C \in C^d(s)$ with no bfi requirements. As in the proof of Lemma 11 we will separate the bottom level gates from the rest. Thus we first apply a random $\alpha_0/2$-restriction followed by $d-2$ rounds of random $(n^{1/(d-1)})^{-1}$-restrictions. Thus altogether we applied a random $\alpha_0 \cdot (2n^{\frac{d-2}{d-1}})^{-1}$-restriction, and with probability greater than $1 - (s-1) \cdot 2^{-0.143781 \cdot n^{1/(d-1)}}$ we end up with a circuit in $C^2(1, \gamma_0 n^{1/(d-1)})$. By Chernoff bound again, if N is the number of variables left, then $\mathrm{Exp}[N] = \alpha_0 n^{1/(d-1)}/2$, and therefore

$$\Pr[\, N \leq \gamma_0 n^{\frac{1}{d-1}} \,] \;=\; \Pr\left[\, N - \frac{\alpha_0 n^{1/(d-1)}}{2} \leq -\left(\frac{\alpha_0}{2} - \gamma_0\right) n^{\frac{1}{d-1}} \,\right] \;<\; e^{-0.021423 n^{\frac{1}{d-1}}}.$$

Hence, if $s < 2^{0.143781 \cdot n^{1/(d-1)}}$, C does not compute the parity.

THEOREM 13. *For all $C \in C^d(s)$, if C computes the parity function, then its size s must satisfy*

$$s \;\geq\; 2^{0.143781 \cdot n^{1/(d-1)}}.$$

Now we consider the inapproximability-type lower bound. The decision tree depth lower bound is ideally suited for deriving the inapproximability-type lower bound, and the decision tree perspective was introduced precisely for this reason.

Denote for the rest of this section $m = n^{1/d}$. Let C be a depth d circuit. Note that after some restriction ρ, if C is reduced to a decision tree of depth smaller than the number of variables left, then for exactly half of the 0-1 extensions of ρ, C agrees with parity. This is because at every leaf of the decision tree, the circuit C is completely determined. (This property was called *monochromaticity* in [Cai86].)

Consider $\Pr[\, C(x_1, \ldots, x_n) = \oplus(x_1, \ldots, x_n) \,]$, where $\oplus(x_1, \ldots, x_n)$ denotes the parity function, and the probability is over all 2^n assignments. This can be evaluated by first assigning any random restriction, followed by an unbiased 0-1 assignment for all the remaining variables. Let $E = E_1 \wedge E_2$, where E_1 denotes the event that after the random restriction, we end up with a decision tree of depth t, and E_2 denotes the event that the number of variables N assigned to $*$ is more than t, where t will be specified later as $O(m)$. Let $[\, C = \oplus \,]$ denote $[\, C(x_1, \ldots, x_n) = \oplus(x_1, \ldots, x_n) \,]$ for short.

Note first

$$\begin{aligned}\Pr[\, C = \oplus \,] \;&=\; \Pr[E] \cdot \Pr[\, C = \oplus \,|\, E \,] + \Pr[\neg E] \cdot \Pr[\, C = \oplus \,|\, \neg E \,] \\ &=\; \Pr[\, C = \oplus \,|\, E \,] + \Pr[\neg E]\big(\, \Pr[\, C = \oplus \,|\, \neg E \,] - \Pr[\, C = \oplus \,|\, E \,] \,\big).\end{aligned}$$

As we noted $\Pr[\, C = \oplus \,|\, E \,] = \frac{1}{2}$. Then

$$\left| \Pr[\, C = \oplus \,] - \frac{1}{2} \right| \;\leq\; \frac{1}{2} \Pr[\neg E].$$

Also since $\Pr[\, C = \oplus \,] - \Pr[\, C \neq \oplus \,] = 2(\Pr[\, C = \oplus \,] - \frac{1}{2})$, we have

$$|\Pr[\, C = \oplus \,] - \Pr[\, C \neq \oplus \,]| \;\leq\; \Pr[\neg E].$$

Now we specify the parameter of the random restrictions.

First consider any $C \in C^d(s, \gamma_0 m)$. Then let $t = \gamma_0 m$, and we apply Lemma 10. With a random $(n^{\frac{d-1}{d}})^{-1}$-restriction, we have

$$\Pr[\neg E_1] \;\le\; s\alpha_0^t \;\approx\; s \cdot 2^{-0.143781 \cdot m}.$$

Then again by using the Chernoff bound, we estimate $\Pr[\neg E_2] = \Pr[\, N \le \gamma_0 m \,]$ as follows:

$$\Pr[\neg E_2] \;\le\; e^{-\frac{(1-\gamma_0)^2}{2} m} \;<\; e^{-0.3927m}.$$

Thus $\Pr[\neg E_2]$ is dominated by $\Pr[\neg E_1]$. This analysis gives the following bound.

LEMMA 14. *For all $C \in C^d(2^{0.07189 n^{1/d}}, \gamma_0 n^{1/d})$, we have*

$$|\Pr[\, C = \oplus \,] - \Pr[\, C \neq \oplus \,]| \;\le\; 2^{-0.07189 n^{1/d}}.$$

Finally we consider $C \in C^d(s)$ with no bfi condition. This time we have to work harder to optimize the exponents. Our strategy is as follows. We will first assign a $\frac{\alpha_0}{2}$-restriction, and this will give us a depth d circuit *with* bfi $\le \gamma_0 m$. Then we assign $d-2$ rounds of $1/m$-restrictions, each time using Lemma 9 with the same parameters $p = 1/m$ and $t = \Delta = \gamma_0 m$. This will give us a depth 2 circuit *with* bfi $\le \gamma_0 m$. So far the failure probability is $(s-1)\alpha_0^{\gamma_0 m}$. Finally we assign another $1/m$-restriction, but this time using the parameters $t = \gamma_0 m$ and $\Delta = x\gamma_0 m$, where $0 < x < 1$ is to be determined later. The overall failure probability is $< s\alpha_0^{\gamma_0 m} + \alpha_0^{\Delta} + \Pr[\, N \le \Delta \,]$, where N is the number of variables left.

It turns out that if we used the same values for t and Δ for the estimate in the last round, the bound for $\Pr[\, N \le \Delta \,]$ would be too weak. We will use a more exacting form of the Chernoff bound, and then optimize the overall bound by balancing the last two terms with a judicious choice of x.

We use the following version of the Chernoff bound. (See, for example, p. 70 of [MR95].)

$$\Pr[\, N < (1-\delta)\mathrm{Exp}[N] \,] \;<\; \exp\left[-\mathrm{Exp}[N] \cdot (\delta + (1-\delta) \cdot \ln(1-\delta))\right].$$

Here we have

$$\mathrm{Exp}[N] \;=\; \frac{\alpha_0}{2} m \;\text{ and }\; \delta \;=\; 1 - \frac{2\gamma_0 x}{\alpha_0}.$$

We balance the two bounds by setting x such that

$$x\gamma_0 \ln \frac{1}{\alpha_0} \;=\; \frac{\alpha_0}{2} \left[\, \delta + (1-\delta) \cdot \ln(1-\delta) \,\right].$$

This leads to choosing $x = 0.617945$, and we get both

$$\alpha_0^{\Delta} \;<\; 2^{-0.0888488 \cdot m} \;\text{ and }\; \Pr[\, N \le \Delta \,] \;<\; 2^{-0.0888488 \cdot m}.$$

Then by setting $s = 2^{0.07189 \cdot m}$ we get a balanced discrepancy lower bound.

THEOREM 15. *For all $C \in C^d(2^{0.07189 n^{1/d}})$, we have*

$$|\Pr[\, C = \oplus \,] - \Pr[\, C \neq \oplus \,]| \;\le\; 2^{-0.07189 n^{1/d}}.$$

Note that the bound in Theorem 15 is the same as that of Lemma 14 with the bfi condition. Lemma 6 follows from Theorem 15 for large input size.

Remark 4. The original motivation for Furst–Saxe–Sipser [FSS81], where superpolynomial lower bounds were proved for parity against constant depth circuits, was to provide an oracle separation of PH and PSPACE. This was achieved in a breakthrough result by Yao [Yao85], who proved a lower bound of the form $2^{n^{\Omega(1/d)}}$ for parity on n bits for depth d circuits. Yao's bound was further improved by Håstad [Hås86a] from $2^{-n^{\Omega(1/d)}}$ to $2^{-\frac{1}{10}n^{\frac{1}{d-1}}}$, and his proof has become the standard proof. Independently, Yao's work was improved upon in another direction. Cai investigated in [Cai86] whether constant depth circuits of size $2^{n^{\Omega(1/d)}}$ must err on an asymptotically 50% of inputs against parity. This was motivated by another long-standing open problem, that of random oracle separation of PH and PSPACE (see also [Bab87]). To attack this problem, the decision tree point of view was first adopted in [Cai86], although a different but completely synonymous terminology (Master-Player Game and t-monochromaticity) was used. It was proved in [Cai86] that after a suitable random restriction ρ, with high probability, the constant depth circuit $C\mid_\rho$ has decision tree depth smaller than the number of unassigned Boolean variables. In such cases, $\Pr[C = \oplus]$ is exactly $\frac{1}{2}$. Thus the discrepancy

$$|\Pr[C = \oplus] - \Pr[C \neq \oplus]| \tag{12}$$

was shown to be $o(1)$ for circuits of depth d and size $2^{n^{\Omega(1/d)}}$. Implicitly a bound of the form $2^{-n^{\Omega(1/d)}}$ for the discrepancy (12) was proved there as well [Cai86]. The $o(1)$ upper bound for the discrepancy was sufficient for the random oracle separation result, which was the purpose of [Cai86], but one needs Håstad's technique to improve the bound from $2^{-n^{\Omega(1/d)}}$ to $2^{-cn^{\frac{1}{d}}}$ as in Theorem 15. However, the weaker bound $2^{-n^{\Omega(1/d)}}$ would have sufficed for our Theorem 2. Ko [Ko89a] also used circuit lower bounds to establish the following: For any k, one can construct an oracle with which the polynomial hierarchy collapses to exactly k levels.

It was a marvelous application by Nisan and Wigderson [Nis91a, Nis91b, NW88] that turned the inapproximability type of lower bounds based on decision trees on its head and produced an explicit construction—usually considered an upper bound—of a pseudorandom generator provably indistinguishable from true random bits by polynomial-size constant depth circuits. A central ingredient in [Nis91a, Nis91b, NW88] is a suitable combinatorial design. Seen in this way, our proof of Theorem 2 can be viewed as using a *lower bound* (Switching Lemma) to get an *upper bound* (the NW pseudorandom generator) to prove a *lower bound* (to kill all 2^n circuits C_x simultaneously with the pseudorandom assignments) to finally prove an *upper bound* (to be able to code all the computations). And all this is to show that it is impossible to prove a superpolynomial circuit *lower bound* for any fixed language in the Polynomial-time Hierarchy, with a relativizable proof with stringent access to an oracle.

Acknowledgment. We would like to thank the anonymous referees for their detailed comments, which helped us improve the presentation of the paper.

EFFICIENT ALGORITHMS FOR OPTIMAL STREAM MERGING FOR MEDIA-ON-DEMAND*

AMOTZ BAR-NOY† AND RICHARD E. LADNER‡

Abstract. We address the problem of designing optimal off-line algorithms that minimize the required bandwidth for media-on-demand systems that use stream merging. We concentrate on the case where clients can receive two media streams simultaneously and can buffer up to half of a full stream. We construct an $O(nm)$ optimal algorithm for n arbitrary time arrivals of clients, where m is the average number of arrivals in an interval of a stream length. We then show how to adopt our algorithm to be optimal even if clients have a limited size buffer. The complexity remains the same.

We also prove that using stream merging may reduce the required bandwidth by a factor of order $\rho L/\log(\rho L)$ compared to the simple batching solution where L is the length of a stream and $\rho \leq 1$ is the density in time of all the n arrivals. On the other hand, we show that the bandwidth required when clients can receive an unbounded number of streams simultaneously is always at least $1/2$ the bandwidth required when clients are limited to receiving at most two streams.

Key words. media-on-demand, stream merging, dynamic programming, monotonicity property

1. Introduction.

Media-on-demand is the demand by clients to play back, view, listen to, or read various types of media such as video, audio, and large files with as small as possible startup delays and with no interruptions. The solution of dedicating a private channel to each client for the required media is implausible even with the ever growing available network bandwidth. Thus, multicasting popular media to groups of clients seems to be the ultimate solution to the ever growing demand for media. The first, and most natural, way to exploit the advantage of multicasting is to *batch* clients together. This implies a trade-off between the overall server bandwidth and the guaranteed startup delay. The main advantage of the batching solutions lies in their simplicity. The main disadvantage is that the guaranteed startup delay may be too large.

The pyramid broadcasting paradigm, pioneered by Viswanathan and Imielinski [43, 44], was the first solution that dramatically reduced the bandwidth requirements for servers by using larger receiving bandwidth for clients and by adding buffers to clients. Many papers have followed this line of research; all of them have demonstrated the huge improvement over the traditional batching solutions. We adopt the *stream merging* technique, introduced by Eager, Vernon, and Zahorjan [18, 19]. Stream merging seems to incorporate all the advantages of the pyramid broadcasting paradigm and is very useful in designing and implementing efficient off-line and on-line solutions.

A system with stream merging capabilities is illustrated in Figure 1. The server multicasts the popular media in a staggered way via several channels. Clients may

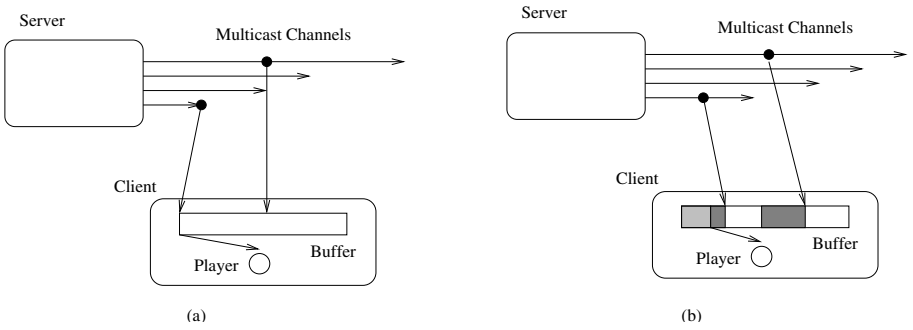

FIG. 1. *The mechanism of receiving data from two streams simultaneously.*

receive data from two streams simultaneously while playing data they have accumulated in their buffers. The playback rate is identical to each of the channels, so that the receiving bandwidth is twice the playback bandwidth. The initial position is illustrated in (a) where the client is about to receive data from a new stream and a stream that was initiated earlier. After some time the system may look as illustrated in (b). The client still receives data from both streams. The top of its buffer, which represents the beginning of the stream, has been viewed by the player. This technique is called stream merging because eventually, as the client receives both the earlier and later streams, it no longer needs the later stream because it already has the data from buffering the earlier one. At this point, if no other client needs the later stream, it can terminate. In a sense the later stream merges with the earlier one, forming just one stream. The termination of the later stream is where bandwidth is saved.

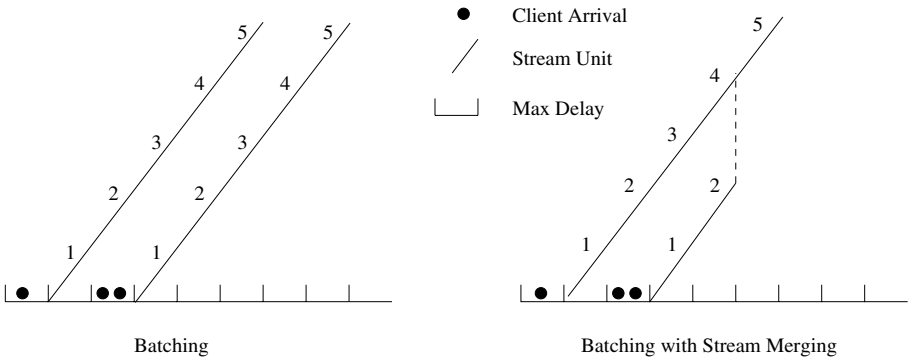

FIG. 2. *The figure on the left shows batching, while the figure on the right shows batching with stream merging.*

It is interesting to contrast stream merging with *batching*, the most common technique for reducing server bandwidth in the presence of multicast. In batching time is divided into intervals. A client that arrives in an interval is satisfied by a full stream at the end of the interval. Bandwidth is saved at the expense of longer guaranteed startup delay for the clients. Stream merging and batching can be combined so that there is a bandwidth saving from both stream merging and batching. Figure 2 shows the difference between pure batching and stream merging with batching. In this figure full streams are of length 5. The three clients require 2 full streams (10 units) with batching alone, but require only 1.4 streams (7 units) with stream merging. The

second and the third clients receive parts 3 and 4 of the first stream at the same time they receive parts 1 and 2 from the second stream; then they receive part 5 from the first stream.

Given a sequence of arrivals, there can be a number of different stream merging solutions to accommodate this sequence. Typically, a stream merging solution has a number of full streams each associated with a number of other truncated streams that eventually merge to this full stream. We measure the bandwidth required by a solution as the sum of the lengths of all the individual (full or truncated) streams in the solutions. We call this sum the *full cost* of the solution. This cost represents the total bandwidth required by the solution and by dividing it by the time span of arrivals it represents the average bandwidth to serve the clients during that time span. In our example of Figure 2, the full cost of the batching solution is 10 units (or 2 streams) and the full cost of the stream merging with the batching solution is 7 units (or 1.4 streams).

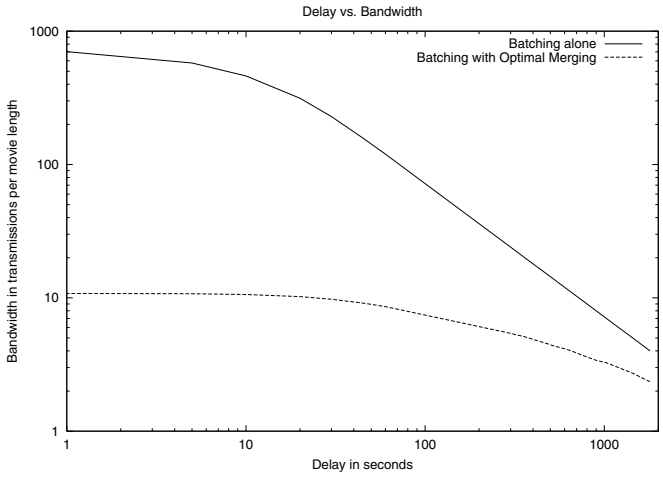

FIG. 3. *Comparison of bandwidth required for batching and batching with optimal stream merging. The figure plots the bandwidth requirement vs. delay for a* 2*-hour movie, with Poisson arrivals averaging every* 10 *seconds.*

Figure 3 shows the bandwidth requirement vs. delay for a popular 2-hour movie, with Poisson arrivals averaging every 10 seconds. The guaranteed startup delay ranges from 1 second to 30 minutes. For stream merging with batching we used an optimal stream merging algorithm. At 1 second delay the difference in bandwidth is dramatic. For batching the bandwidth required is almost the same as it would be if each client had its own stream. On the other hand, at 1 second delay, stream merging with batching uses 1/60 the bandwidth of batching.

1.1. Contributions. The main goal of this paper is to find efficient ways to compute the optimal stream merging solutions, those that minimize the full cost. To determine an optimal solution, we have to decide when to start full streams and how to merge the rest of the streams into the full streams. We assume that the arrival times of clients are known ahead of time and we call this the *off-line* problem, as opposed to the *on-line* problem where client arrivals are not known ahead of time. Computing the optimal off-line solution quickly is a major focus of this paper. The off-line scenario happens when clients make reservations for when their streams will

begin. However, good on-line solutions are required for media-on-demand systems that run in real time. The optimal off-line solution is the gold standard against which on-line solutions should be compared. Fast algorithms for computing an optimal off-line solution allow us to evaluate the quality of on-line solutions on large numbers of media requests.

In our main model a client is capable of receiving two streams simultaneously. We call this the *receive-two* model. It is instructive to consider the *receive-all* model in which a client is capable of receiving any number of streams simultaneously. There are several reasons to consider this case. First, we will see that there is very little gain in going from the receive-two model to the receive-all model. Most of the benefit of stream merging comes from just the ability to receive two streams simultaneously. Second, we will see that many of the results from the receive-two model carry over in a simpler form to the receive-all model.

Our first contribution is a novel model for the stream merging technique. A key concept in our model is that of a *merge tree*, which is an abstraction of the diagram in Figure 2. See Figure 4 for an example. A sequence of merge trees is called a *merge forest*. The root of a merge tree represents a full stream; its structure represents the merging pattern of the remaining streams that are associated with its descendent. A sequence of merge trees is called a *merge forest*. We show that the knowledge of the arrival times and the structure of the merge trees is sufficient to compute the lengths of all the streams and to compute the full cost (total bandwidth) required by the merge forest. A key component of our approach is the concept of *merge cost*. For a given merge tree, the merge cost is the sum of the lengths of all the streams except the root stream. The full cost counts everything, merge cost and the length of the roots for all the merge trees in the forest. This separation into merge cost and full cost helps in designing the optimal algorithms and in having a cleaner analysis. Later in the paper, we first show how to construct an optimal merge tree for a sequence that forms a single tree and then show how to construct the optimal merge forest for a given sequence.

We show several properties that optimal merge trees must have. For example, there is no gain in having streams that do not start at an arrival time of some clients. Other properties will be defined in section 2. These properties were assumed implicitly by all the on-line algorithms that use the stream merging technique [18, 19, 5, 14, 11, 12]. Thus our model, in a way, builds the foundations for designing "good" on-line algorithms.

Our main focus is in designing efficient optimal algorithms in the receive-two model, that is, algorithms that, for a given a sequence of arrivals, either find a merge tree that minimizes merge cost or find a merge forest that minimizes full cost. We have the following results depending on n, the number of arrivals. For the merge cost, we present an efficient $O(n^2)$ time algorithm improving the known $O(n^3)$ time algorithm (see [2, 19]). The latter algorithm is based on a straightforward dynamic programming implementation. Our algorithm implements the dynamic programming utilizing the monotonicity property ([34]) of the recursive definition for the merge cost. For the full cost we use the optimal solution of the merge cost as a subroutine. We describe an $O(nm)$ time algorithm where m is the average number of arrivals in an interval that begins with an arrival and whose length is a full stream length. We also have efficient algorithms for a model in which clients have a limited buffer size. We maintain the $O(nm)$ complexity where this time m is the average number of arrivals in an interval that begins or ends with an arrival and whose length is the minimum

between the stream length and the maximum buffer size.

Additional results establish the performance of the optimal stream merging solutions. Let L be the length of a full stream in slots, where a *slot* is the worst-case waiting time for any arrival before it receives the first segment of the media. For a fixed length media, as the parameter L grows the waiting time tends to zero. Define $\rho \leq 1$ to be the ratio of slots that have at least one arrival to all the slots in a given period of time. We show that an optimal stream merging solution reduces the required full cost by a factor of order $\rho L/\log(\rho L)$ for the full cost compared to the simple batching solution. Note that the improvement is huge for large L because simple batching solutions must dedicate a full stream for each arrival. However, L cannot grow forever because then ρ would approach zero.

Finally, we present optimal algorithms for the receive-all model that have the same time complexity bounds as the receive-two model. We show that the full cost required in an optimal solution in the receive-all model is always at least half the optimal full cost required in the receive-two model.

1.2. Related research. Several papers (e.g., [15, 13, 3]) proposed various batching solutions demonstrating the trade-off between the guaranteed startup delay and the required server bandwidth. The solutions are simple but may cause large startup delays. The seminal pyramid broadcasting solution [43, 44] was the first paper to explore the trade-off with two other resources: the receiving bandwidth of clients and the buffer size of clients. Many researchers were concerned about reducing the buffer size (see e.g., [1]). However, all of them demonstrated the huge improvement over the traditional batching solutions.

The skyscraper broadcasting paper [27] showed that the receive-two model already exploits the dramatic improvement. Researchers also demonstrated the trade-off between the server bandwidth and the receiving bandwidth [26, 20, 37, 38] in this framework. All of these papers assumed a static allocation of bandwidth per transmission. The need for dynamic allocation (or on-line algorithms) motivated the papers [17, 16] that still used the skyscraper broadcasting model. The patching solution [25, 21, 8], the tapping solution [9, 10], the piggybacking solution [2, 23, 24, 35], and the stream merging solution [18, 19] assumed the attractive dynamic allocation of bandwidth to transmissions. The early papers regarding patching assumed that clients may merge only to full streams. Later papers regarding patching assumed a model that is essentially the stream merging model. New research regarding patching [40] assumed that streams may be fragmented into many segments.

The original stream merging algorithms [18, 19] were on-line and event-driven, where telling clients which streams to listen to was done at the time of an event. The specific events were the arrival of a client, the merge time of two streams, and the termination of a stream. The papers reported good practical results compared to the optimal algorithm on Poisson arrivals. These event-driven algorithms are quite different in character from the series of on-line algorithms that appeared subsequently [5, 14, 11, 12]. Unlike in the event-driven algorithms, in the newer algorithms, a client learns all the streams it will be receiving from at the time it arrives. The dynamic Fibonacci tree algorithm of [5] used merge trees and had a competitive analysis. Next, the dyadic algorithm [14] was proposed and analyzed for its average performance on Poisson arrivals. Next, an algorithm based on a new version of merge trees called rectilinear trees was shown to be 5-competitive (full cost no more than 5 times that of the optimal) [11]. Later these same authors proved that the dyadic algorithm is 3-competitive [12]. A comparison of the performance of on-line stream merging

algorithms can be found in [4].

Finally, the following is a partial list of additional papers that address trade-offs among the four parameters: server bandwidth, delay guaranteed, receiving bandwidth, and buffer size: [28, 29, 30, 31, 32, 36, 39, 7, 22, 41, 42].

1.3. Paper organization. In section 2 we define our stream merging model and prove properties of optimal solutions. Section 3 presents our algorithm in the receive-two model with unbounded buffers. In section 4, we consider the limited buffer size case. In section 5, we describe our results for the receive-all model. Finally, we discuss our results and some related problems in section 6.

2. The stream merging model.

Basic definitions. Assume that time starts at 0 and is slotted into unit sized intervals. For example, a 2-hour movie could be slotted into time intervals of 15 minutes. Thus, the movie is 8 units long. For a positive integer t, call the slot that starts at time $t-1$ slot t. The length of a full stream is L units. There are n arrival times for clients denoted by integers $0 \le t_1 < t_2 < \cdots < t_n$. Clients that arrive at the same time slot are considered as one client. At each arrival time a stream must be scheduled, although for a given arrival the stream may not run until conclusion because only an initial segment of the stream is needed by the clients. A client may receive and buffer data from two streams at the same time while viewing the data it accumulated in its buffer. The objective of each client is to receive all the L parts of the stream and to view them without any interruption starting at the time of its arrival.

At this point we would like to note the following:

- We will show later that there is no gain in scheduling streams except at arrival times. Hence, it is very useful to use the client arrival time t as both a name for the client that arrives at time t and for the stream that is initiated at time t. Moreover, for ease of presentation, in the rest of this section we assume that only such streams exist.
- Our results hold for the nondiscrete time model as well by letting the time slots be as small as desired and therefore the value of L as large as needed. We adopt the discrete time model for ease of presentation.

Merge forests and merge trees. A *solution* to an arrival sequence is a *merge forest* which is a sequence of *merge trees*. A merge tree is an ordered labeled tree, where each node is labeled with an arrival time and the stream initiated at that time. The root is labeled t_1 and if a nonroot node is labeled t_i, then its parent is labeled t_j, where $j < i$. This requirement means that a stream can merge only to an earlier stream. Additionally, if t_j is a right sibling of t_i then $j > i$. This requirement means that the children of a node are ordered by their arrival times. Clearly, in a merge forest all the arrival times in one tree must precede the arrival times in the successive tree. We say that an ordered labeled tree has the *preorder traversal property* if a preorder traversal of the tree yields the arrival times in order. Any ordered labeled tree with the preorder traversal property is a merge tree, but not necessarily vice versa. We will see later in Lemma 2.2 that every optimal merge tree satisfies the preorder traversal property.

Figure 4 illustrates a merge tree and a concrete diagram showing how merging would proceed for the given merge tree. In the concrete diagram each arrival is shown on the time axis and for each arrival a new stream is initiated. The vertical axis shows the particular unit of the stream that is transmitted. The root stream, t_1, is of full length, while all the other streams are truncated. A stream is truncated because all

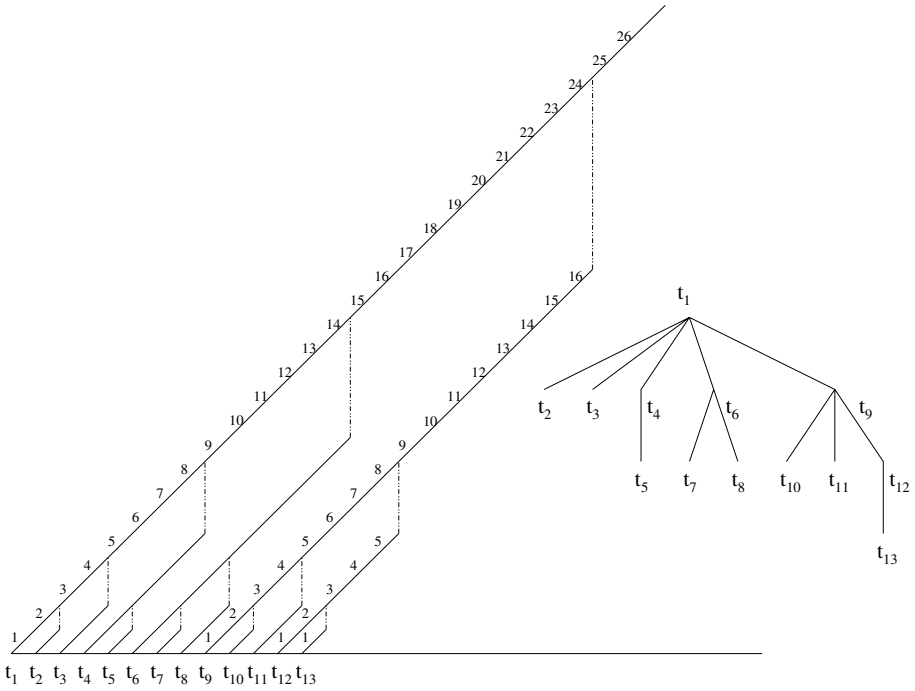

FIG. 4. *On the left is a concrete diagram showing the length of each stream with its merging pattern. On the right is its corresponding merge tree. In this example there are* 13 *arrivals at times* $0, \ldots, 12$.

the clients that were receiving the stream no longer need any data from it, having already received the data from some other stream(s). Note that although the merge tree does not show the stream lengths, it implicitly contains all the information in the concrete diagram, as will be shown in Lemma 2.1.

For the moment, we postpone the explanation of how we calculate the lengths of the truncated streams because we need more explanations of how merging works. Nonetheless, we can now explain that the problem we are addressing is how to find a solution that minimizes the sum of the lengths of all the streams in the solution. This is equivalent to minimizing the total number of units (total bandwidth) needed to serve all the clients. Minimizing the total bandwidth is essentially the same as minimizing the average bandwidth needed to satisfy the requests. The average bandwidth required to satisfy the requests by the forest F is the sum of the total bandwidth required by F divided by $(t_n - t_1)$ which is the time span of the n arrivals. The equivalence follows since the quantity $t_n - t_1$ is independent of the solution.

Receiving procedures. Clients receive and buffer data from various streams according to their location in the forest. At any one time a client can receive data from at most two streams. Informally, a client arriving at time x receives data from all the nodes on the path from x to the *root* of the tree. At the same time it receives data from a node y and its parent until it does not need any more data from the node. At that point the client moves closer to the root by receiving data from the parent of y and its parent. We call this transition a merge operation. In the following we formally define the actions of a client in the merge tree.

Let $x_0 < x_1 < \ldots < x_k$ be the path from the root x_0 to node x_k that is the

arrival time of a specific client. We call this sequence of length $k+1$ the *receiving procedure* of the client. Denote by $x_0, x_1, \ldots, x_k$ the streams that are scheduled at the corresponding arrival times. The client obeys the following *stream merging rules*.

Stage i, $0 \le i \le k-1$: For $x_{k-i} - x_{k-i-1}$ time slots from time $2x_k - x_{k-i}$ to time $2x_k - x_{k-i-1}$ the client receives parts $2x_k - 2x_{k-i} + 1, \ldots, 2x_k - x_{k-i} - x_{k-i-1}$ from stream x_{k-i} and parts $2x_k - x_{k-i} - x_{k-i-1} + 1, \ldots, 2x_k - 2x_{k-i-1}$ from stream x_{k-i-1}.

Stage k: For $L - 2(x_k - x_0)$ time slots from time $2x_k - x_0$ to time $x_0 + L$ the client receives parts $2(x_k - x_0) + 1, \ldots, L$ from stream x_0.

This describes how the client arriving at x_k receives the entire transmission of the stream. In particular, part j of the stream is received in stage $i = k$ if $2(x_k - x_0) < j$ and in stage $i < k$ if $2(x_k - x_{k-i}) < j \le 2(x_k - x_{k-i-1})$. Notice that if $x_k - x_0 \le \lfloor L/2 \rfloor$, then the client is busy receiving data for $L - (x_k - x_0)$ time slots since in $x_k - x_0$ slots it receives data from two streams, and if $x_k - x_0 > \lfloor L/2 \rfloor$, then the client is busy receiving data for $x_k - x_0$ time slots since in $L - (x_k - x_0)$ slots it receives data from two streams.

Consider the example depicted in Figure 4. Assume a full stream of length 26 and the following stream merging rules for the client that arrives at time $t_{13} = 12$. In this case, we have $k = 3$ with $x_0 = 0, x_1 = 8, x_2 = 11, x_3 = 12$. From time 12 to time 13 the client receives part 1 from stream x_3 and part 2 from stream x_2. From time 13 to time 16 the client receives parts $3, \ldots, 5$ from stream x_2 and parts $6, \ldots, 8$ from stream x_1. From time 16 to time 24 the client receives parts $9, \ldots, 16$ from stream x_1 and parts $17, \ldots, 24$ from stream x_0. Finally, from time 24 to time 26 the client receives parts $25, 26$ from stream x_0.

Length of streams. Given the stream merging rules, we must still determine the minimum length of each stream so that all the clients requiring the stream receive their data. In a merge tree T the root is denoted by $r(T)$. If x is a node in the merge tree, then we define $\ell_T(x)$ to be its *length* in T. That is, $\ell_T(x)$ is the minimum length needed to guarantee that all the clients can receive their data from stream x using the stream merging rules. For a nonroot node x define $p_T(x)$ to be its parent and $z_T(x)$ to be the latest arrival time of a stream in the subtree rooted at x. If x is a leaf, then $z_T(x) = x$. We drop the subscript T when there is no ambiguity.

We can see from our definition of the stages that the length L of the root stream must satisfy $z - r(T) \le L - 1$, where z is the last arrival in the merge tree T. Otherwise, the clients arriving at z do not receive data from the stream initiated at $r(T)$. The next lemma shows how to compute the lengths of all the nonroot streams.

LEMMA 2.1. *Let $x \ne r(T)$ be a nonroot node in a tree T. Then*

$$\ell(x) = 2z(x) - x - p(x). \tag{1}$$

In particular, if x is a leaf, then $\ell(x) = x - p(x)$ since $z(x) = x$.

Proof. First observe that if clients $y' < y$ both receive data from x, then client y receives later parts of the stream x. This implies that the length of the stream x is dictated by the needs of the client that arrives at time $z(x)$. Let $x_0, x_1, \ldots, x_k$ be the path from the root of the tree T that contains both x and $z(x)$. That is, $x = x_i$ and $p(x) = x_{i-1}$ for some $i > 0$ and $z(x) = x_k$. By the stream merging rule of stage $k - i$, the client $z(x)$ receives data from the stream $x = x_i$ until time $2x_k - x_{i-1} = 2z(x) - p(x)$. Since $z(x)$ is the last client requiring stream x, then no more transmission of stream x is required. Since the stream x begins at time x and ends at time $2z(x) - p(x)$, its length is $2z(x) - x - p(x)$. ∎

In this paper, we will use for $\ell(x)$ either expression (1) or the following two alternative expressions:

$$\ell(x) = (x - p(x)) + 2(z(x) - x) \tag{2}$$

$$= (z(x) - x) + (z(x) - p(x)). \tag{3}$$

Expression (3) could be viewed as follows. The length of the stream x is composed of two components. The first component is the time needed for clients arriving at time x to receive data from stream x before they can merge with stream $p(x)$. The second component is the time stream x must spend until the clients arriving at time $z(x)$ merge to $p(x)$.

2.1. The merge cost. Let T be a merge tree. The *merge cost* of T is defined as

$$\text{Mcost}(T) = \sum_{x \neq r(T) \in T} \ell(x).$$

That is, the merge cost of a tree is the sum of all lengths in the tree except the length of the root of the tree. For an arrival sequence $t_1, \ldots, t_n$, define the *optimal merge cost* for the sequence to be the minimum cost of any merge tree for the sequence. An *optimal merge tree* is one that has optimal merge cost. The following technical lemma justifies restricting our attention to merge trees with the preorder traversal property.

LEMMA 2.2. *Every optimal merge tree satisfies the preorder traversal property.*

Proof. The proof is by induction on the number of arrivals. The lemma is clearly true for one arrival. Assume we have $n > 1$ arrivals and the lemma holds for any number of arrivals less than n. Let T be an optimal merge tree for the arrivals and let x be the last arrival to merge to the root r of T. Define T_R to be the subtree of T rooted at x and let T_L be the subtree of T obtained by removing T_R. By the induction hypothesis we can assume that T_R and T_L both have the preorder traversal property. Let w be the last arrival in the subtree T_L and let z be the last arrival in the subtree T_R. If $w < x$, then the entire tree T must already have the preorder property, and we are done. We need consider only the case where $w > x$. In this case we will construct another merge tree T' for the same arrivals whose merge cost is less than T's, contradicting the optimality of T.

Define a *high tree* to be a subtree of T_L whose root is greater than x and whose parent of the root is less than x. Let T' be the tree T where all the high trees are removed from T_L and are inserted as children of x. Naturally, the high trees must be inserted so that all the children of x in T' are in arrival order. For all nodes u in T such that $u \neq x$ or u is not an ancestor of a root of a high tree, we have $\ell_T(u) = \ell_{T'}(u)$. For an ancestor u of a root of a high tree we have $\ell_T(u) > \ell_{T'}(u)$, and for x we have $\ell_T(x) < \ell_{T'}(x)$. Let p be the parent of the root of the high tree containing w. We must have $p \neq r$ for otherwise x would not be the last arrival to merge to the root because the root of the high tree containing w is greater than x. We can just examine the change in length of the nodes p and x. We have

$$\text{Mcost}(T) - \text{Mcost}(T') \geq \ell_T(p) - \ell_{T'}(p) + \ell_T(x) - \ell_{T'}(x).$$

Let w' be the largest arrival in the tree rooted at p in T'. We must have $w' < x$; otherwise, w' is in some high tree that was removed from T_L and made a child of x in T'. Since w is the largest arrival in the tree rooted at p in T, we have $\ell_T(p) - \ell_{T'}(p) =$

$2(w - w')$ by Lemma 2.1. There are two cases to consider depending on whether $w < z$ or $w > z$. If $w < z$, then $\ell_T(x) = \ell_{T'}(x)$ because z is the largest arrival in the subtree rooted at x in both T and T'. By definition $w > w'$; hence,

$$\text{Mcost}(T) - \text{Mcost}(T') \geq 2(w - w') > 0.$$

If $w > z$, then $\ell_T(x) - \ell_{T'}(x) = 2(z - w)$ by Lemma 2.1. Hence,

$$\text{Mcost}(T) - \text{Mcost}(T') \geq 2(w - w') + 2(z - w) = 2(z - w') > 0$$

because $w' < x \leq z$. □

Lemma 2.2 allows us to consider only merge trees with the preorder traversal property. As a consequence, henceforth, *we assume that all merge trees have the preorder traversal property.* Hence, a key property of merge trees is that for any node t_i, the subtree rooted at t_i contains the interval of arrivals $t_i, t_{i+1}, \ldots, t_j$, where $z(t_i) = t_j$. Furthermore, t_j is the rightmost descendant of t_i. As a result, we can recursively decompose any merge tree into two in a natural way as shown in the following lemma and seen in Figure 5.

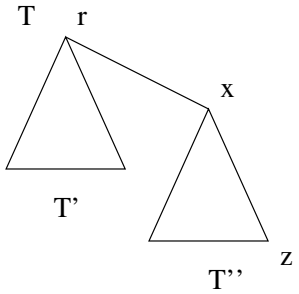

FIG. 5. *The recursive structure of a merge tree T with root r. The last arrival to merge directly with r is x. All the arrivals before x are in T' and all the arrivals after x are in T'' and z is the last arrival.*

LEMMA 2.3. *Let T be a merge tree with root r and last stream z and let x be the last stream to merge to the root of T.*

$$\text{Mcost}(T) = \text{Mcost}(T') + \text{Mcost}(T'') + 2z - x - r, \tag{4}$$

where T' is the subtree of all arrivals before x including r and T'' is the subtree of all arrivals after and including x.

Proof. The length of any node in T' and T'' is the same as its length in T. Since the root of T' is the root of T, it follows that x is the only node in $\text{Mcost}(T)$ whose length is not included in $\text{Mcost}(T')$ or $\text{Mcost}(T'')$. The lemma follows, since by Lemma 2.1 the length of x is $2z(x) - x - p(x) = 2z - x - r$. □

We now prove that there is no gain in broadcasting a prefix of the full stream if there is no arrival for it. That is, an optimal merge tree does not contain a node that represents a prefix of the stream if this prefix does not start at t_i for some $1 \leq i \leq n$. We first prove a lemma that shows that adding nodes to a merge tree always increases the merge cost.

LEMMA 2.4. *Let T be a merge tree and let $x \in T$ be one of its nodes. Then there exists a merge tree T' on the nodes $T - \{x\}$ such that* $\text{Mcost}(T') < \text{Mcost}(T)$.

Proof. Assume first that x is a leaf. Then let T' be T without x. We get that $\text{Mcost}(T) \geq \text{Mcost}(T') + \ell_T(x)$ and therefore $\text{Mcost}(T') < \text{Mcost}(T)$. Let x be a nonleaf node of T and let w be its leftmost child in T. The first modification is for node w. If x is not the root of T, then let the parent of x in T be the parent of w in T'. Otherwise, make w the root of T'. The second modification is for the rest of the children of x in T. Make all of them children of w in T' and add them after w's own children, preserving their original order in T. The rest of the nodes maintain in T' their parent-child relationship from T. By (1),

$$\ell_T(v) = \ell_{T'}(v) \quad \text{for } p_T(v) \neq x. \tag{5}$$

That is, the length of any node v that is not a child of x in T remains the same in T' because there is no change in $p(v)$ and $z(v)$. If $v \neq w$ is a child of x, then (1) implies that

$$\ell_T(v) - \ell_{T'}(v) = w - x > 0 \quad \text{for } v \neq w \text{ and } p_T(v) = x, \tag{6}$$

since w is a later arrival than x. As for w, there are two cases to consider depending on whether w is the root of T' or not. If w is the root of T', then x is the root of T. Hence, $\ell_T(x)$ is not counted in $\text{Mcost}(T)$ and $\ell_{T'}(w)$ is not counted in $\text{Mcost}(T')$. Hence, we have by inequalities (5) and (6)

$$\text{Mcost}(T) - \text{Mcost}(T') = \ell_T(w) + \sum_{(v \neq w) \wedge (p_T(v) = x)} (\ell_T(v) - \ell_{T'}(v)) > 0.$$

If w is not the root of T', then we might have $\ell_{T'}(w) > \ell_T(w)$. However, this is more than compensated for by the inequality

$$\ell_T(x) > \ell_{T'}(w). \tag{7}$$

To see inequality (7), note that $z_T(x) = z_{T'}(w)$ and that $p_T(x) = p_{T'}(w)$; hence by (1), $\ell_T(x) - \ell_{T'}(w) = w - x > 0$. By combining inequalities (5), (6), and (7) we obtain the following:

$$\text{Mcost}(T) - \text{Mcost}(T') = \ell_T(x) + \ell_T(w) - \ell_{T'}(w) + \sum_{(v \neq w) \wedge (p_T(v) = x)} (\ell_T(v) - \ell_{T'}(v)) > 0,$$

which is our desired result. ∎

LEMMA 2.5. *For arrivals $t_1, t_2, \ldots, t_n$ every node (stream) x in an optimal merge tree starts at time t_i for some $1 \leq i \leq n$.*

Proof. Assume to the contrary that there exists a stream x that starts at time t that is not one of the n arrival times $t_1, \ldots, t_n$. By definition, no client needs stream x. Hence, by Lemma 2.4, we could omit node x from T to get a tree T' without x, whose merge cost is smaller than the merge cost of T and is a contradiction to the optimality of T. ∎

Remark. Optimal merge trees also give a lower bound on the bandwidth for the more dynamic event-driven algorithms [18, 19]. A client's receiving procedure, which streams it listens to and when, is determined, in part, by future arrivals. Nonetheless, in the end, the final receiving pattern of a client forms a path in a merge tree. At any point in time only a set of subtrees of the final merge tree is known. Each root of a subtree represents an active stream at that time. When a merge event occurs, the root of some subtree becomes the child of some root in another subtree.

2.2. The full cost. Let F be composed of s merge trees $T_1, \ldots, T_s$. The *full cost* of F is defined as

$$\text{Fcost}(F) = s \cdot L + \sum_{1 \le i \le s} \text{Mcost}(T_i).$$

The above definition is a bit problematic since in the way we define the merge cost it could be the case that a length of a stream is L or larger. Consider the following example. Suppose that the root arrives at time 0 and there are two additional arrivals at times $L-2$ and $L-1$. In one optimal merge tree the third arrival first merges with the second arrival and then both merge with the root; that is, $p(L-1) = L-2$ and $p(L-2) = 0$. The cost of this tree is L for the root, L for the second arrival, and 1 for the third arrival for a total cost of $2L+1$. It is clear that this single merge tree can be considered as a merge forest of two merge trees, the first with one arrival, 0, and the second with two, $L-2$ and $L-1$. A more serious problem is exposed by the following example where the arrival times are 0, $L-3$, and $L-1$. In this case the definition of a merge tree would allow $p(L-1) = L-3$ and $p(L-3) = 0$. In this case the full cost of the merge tree is $2L+3$. Length L for the root 0, length $L+1$ for $L-3$, and length 2 for $L-1$. We have $\ell(L-3)$ greater than L. However, this merge tree is not an optimal merge forest for these three arrivals. The optimal merge forest has two trees, one with root 0 and one with root $L-3$ for a full cost of $2L+2$.

Naturally, we cannot allow the length of any stream to be greater than L. To remedy this problem we define an *L-tree* to be a merge tree in which the length of each stream has length less than or equal to L and the length of the root is L. The first example above is an L-tree, but the second is not. It should be clear that an L-tree with a nonroot x of length L can be split into two L-trees of the same cost by simply making x a new root. An *L-forest* is a merge forest that is composed of L-trees only. For an arrival sequence $t_1, \ldots, t_n$ and stream length L define the *optimal full cost* for the sequence to be the minimum full cost of any L-forest for the sequence. An *optimal L-forest* is one that has optimal full cost.

Our strategy for searching for the optimal L-forest is to consider all possible merge forests as candidates for the optimal. The following lemma shows that this extended search always yields an L-forest as the optimal.

LEMMA 2.6. *Any merge forest F that minimizes* $\text{Fcost}(F)$ *is an L-forest.*

Proof. Define the following split operation on trees. Let T be a merge tree on the arrivals $t_1, \ldots, t_n$. Let $x = t_i$ be a node in the tree. Then the x-split of T creates two trees: T' and T''. T' is rooted at t_1 and contains the arrivals $t_1, \ldots, t_{i-1}$ with the same parent-child relation as in T. T'' is rooted at x and contains the arrivals $t_i, \ldots, t_n$. The parent relation in T'' is defined as follows: Let $y = t_j$ for $i < j \le n$ and let $w = p(y)$ be the parent of y in T. If $w > x$, then $w = p(y)$ in T'' as well. Otherwise, $x = p(y)$ in T''.

Let T be a non-L-tree and let $x \in T$ be a node whose length is $\ell(x) > L$. We claim that

$$\text{Fcost}(T') + \text{Fcost}(T'') < \text{Fcost}(T). \tag{8}$$

We prove this claim by showing that the length of each node, other than x, in T' or T'' is no more than its length in T. Since the length of x is greater than L in T and equal to L in T'', we are done. There are two cases to consider: (i) The length of all the nodes that have the same parent in T' or T'' as they had in T remains the same;

(ii) By Lemma 2.1, the length of all nodes y such that $w = p(y)$ in T but $x = p(y)$ in T'' is reduced since $w < x$.

To prove the lemma, let F be a merge forest that minimizes $\mathrm{Fcost}(F)$. If F is not an L-forest, then there is some merge tree T in F which is not an L-tree. Apply the above split procedure to this tree to obtain a new merge forest with less cost than F. Thus, F must be an L-forest. □

3. The optimal algorithm. In this section we give efficient algorithms for finding a merge tree that minimizes the merge cost and for finding a merge forest that minimizes the full cost. For the merge cost case we assume that the root has length infinity and that all the arrivals can merge to it. In the full cost case we assume that the length of a full stream is L. We then search for the best assignment of roots among the n arrivals. Although some of the assignments may lead to non-L-trees (trees in which some of the nodes have length greater than L), by Lemma 2.6 we know that an optimal merge forest is an L-forest.

For the merge cost we present an efficient $O(n^2)$ time algorithm improving the known $O(n^3)$ time algorithm (see [2, 19]). The latter algorithm is based on a straightforward dynamic programming implementation. Our algorithm implements the dynamic programming utilizing the monotonicity property of the recursive definition for the merge cost. For the full cost we use the optimal solution of the merge cost as a subroutine. We describe an $O(nm)$ time algorithm where m is the average number of arrivals in an interval of length $L - 1$ that begins with an arrival.

3.1. Optimal merge cost. Let $t_1, t_2, \ldots, t_n$ be a sequence of arrivals. Define $M(i, j)$ to be the optimal merge cost for the input sequence $t_i, \ldots, t_j$. In a dynamic programming fashion we show how to compute $M(i, j)$. The optimal cost for the entire sequence is $M(1, n)$. By Lemma 2.3 we can recursively define

$$M(i,j) = \min_{i<k\le j} \{M(i,k-1) + M(k,j) + (2t_j - t_k - t_i)\} \tag{9}$$

with the initialization $M(i, i) = 0$. Using the notation of Lemma 2.3, t_i is the root r, t_j is the last arrival z, and we are looking for the optimal last arrival t_k, which is x, that merges to the root. This recursive formulation naturally leads to an $O(n^3)$ time algorithm using dynamic programming. The following theorem shows that this can be significantly improved.

THEOREM 3.1. *An optimal merge tree can be computed in time $O(n^2)$.*

Proof. To reduce the time to compute the optimal merge cost to $O(n^2)$ we employ monotonicity, a classic technique pioneered by Knuth [33, 34]. Define $r(i, i) = i$ and for $i < j$

$$r(i,j) = \max\{k : M(i,j) = M(i,k-1) + M(k,j) + 2t_j - t_k - t_i\}.$$

That is, $r(i, j)$ is the last arrival that can merge to the root in some optimal merge tree for $t_i, \ldots, t_j$. *Monotonicity* is the property that for $1 \le i < n$ and $1 < j \le n$

$$r(i,j-1) \le r(i,j) \le r(i+1,j). \tag{10}$$

We should note that there is nothing special about using the max in the definition of $r(i, j)$; the min would yield the same inequality (10). Once monotonicity is demonstrated then the search for the k in (9) can be reduced to $r(i + 1, j) - r(i, j - 1) + 1$ possibilities from $j - i$ possibilities. Hence, the sum of the lengths of all the search

intervals is reduced to $\sum_{1\le i<n}\sum_{i<j\le n}(r(i+1,j)-r(i,j-1)+1)=O(n^2)$ from $\sum_{1\le i<j\le n}(j-i)=O(n^3)$. This yields an $O(n^2)$ algorithm.

Fortunately, for our problem we can apply the very elegant method of quadrangle inequalities, pioneered by Yao [45] and extended by Borchers and Gupta [6], that leads to a proof of monotonicity. Define $h(i,k,j)=2t_j-t_k-t_i$ which is the third term in (9). Borchers and Gupta show that if h satisfies the following two properties, then monotonicity holds. For $i\le j<t\le k\le l$ and $i<s\le l$,

1. if $t\le s$, then $h(i,t,k)-h(j,t,k)+h(j,s,l)-h(i,s,l)\le 0$ and $h(j,s,l)-h(i,s,l)\le 0$;
2. if $s\le t$, then $h(j,t,l)-h(j,t,k)+h(i,s,k)-h(i,s,l)\le 0$ and $h(i,s,k)-h(i,s,l)\le 0$.

In our case, both four-term sums are identically zero, while $h(j,s,l)-h(i,s,l)=t_i-t_j\le 0$ and $h(i,s,k)-h(i,s,l)=2(t_k-t_l)\le 0$.

As a byproduct of the computation of $r(i,j)$ we can recursively compute the optimal merge tree using the recursive characterization of Lemma 2.3. We define a recursive procedure for computing an optimal merge tree for the input $t_i,\ldots,t_j$ as follows. If $i=j$, then return the tree with one node labeled t_i. Otherwise, recursively compute optimal merge trees T' for the input $t_i,\ldots,t_{r(i,j)-1}$ and T'' for $t_{r(i,j)},\ldots,t_j$, then attach the root of T'' as an additional last child of the root of T' and return the resulting tree. This procedure is then called for the input $t_1,\ldots,t_n$ to get the final result. With an elementary data structure, and with $r(i,j)$ already computed for $1\le i\le j\le n$, the construction of the optimal merge tree can be done in linear time. □

We conclude this subsection with an upper bound on the merge cost of an arrival sequence $t_1,t_2,\ldots,t_n$. Denote by $N=t_n-t_i$ the span of the arrivals. We are looking for an upper bound that depends only on N and n and not on the sequence itself. In the following theorem we establish an $O(N\log n)$ upper bound based on a full binary merge tree.

THEOREM 3.2. *The optimal merge cost is $O(N\log n)$.*

Proof. Using the notation of this subsection, we prove that

$$M(i,j)\le c(t_j-t_i)\log_2(j-i+1)$$

by induction on $h=j-i$, for some constant $c\ge 4$. For the rest of the proof we omit the base 2 from the log function. The theorem follows by choosing $i=1$ and $j=n$. The claim trivially holds for $h=0$. For $h=1$ the claim holds for $c=1$ since $M(i,i+1)=t_{i+1}-t_i$. Assume $h\ge 2$ and that the claim holds for $1,\ldots,h-1$. We distinguish between the cases of an odd h and an even h. In both cases assume that $j-i=h$ for some $1\le i<j\le n$.

An odd h.

$$\begin{aligned}
M(i,j) &\le M\left(i,(i+j-1)/2\right)+M\left((i+j+1)/2,j\right)+2t_j-t_{(i+j+1)/2}-t_i\\
&\le c(t_{(i+j-1)/2}-t_i)\log\left((h+1)/2\right)+c(t_j-t_{(i+j+1)/2})\log\left((h+1)/2\right)+2(t_j-t_i)\\
&\le c(t_j-t_i)\log\left((h+1)/2\right)+2(t_j-t_i)\\
&\le c(t_j-t_i)\log(h+1)-(c-2)(t_j-t_i)\\
&\le c(t_j-t_i)\log(h+1).
\end{aligned}$$

The first inequality is based on (9). The second inequality is by the induction hypothesis and by the fact that $t_{(i+j+1)/2}>t_i$. The third inequality is valid since $t_j-t_i\ge(t_{(i+j-1)/2})-(t_i+t_j-t_{(i+j+1)/2})$. The fourth inequality is implied since $\log((h+1)/2)=\log(h+1)-1$. Finally, the last inequality holds for $c\ge 2$.

An even h.

$$\begin{aligned}
M(i,j) &\le M\left(i,(i+j-2)/2\right) + M\left((i+j)/2,j\right) + 2t_j - t_{(i+j)/2} - t_i \\
&\le c(t_{(i+j-2)/2} - t_i)\log\left(h/2\right) + c(t_j - t_{(i+j)/2})\log\left((h+2)/2\right) + 2(t_j - t_i) \\
&\le c(t_j - t_i)\log\left((h+2)/2\right) + 2(t_j - t_i) \\
&\le c(t_j - t_i)\log(h+2) - (c-2)(t_j - t_i) \\
&\le c(t_j - t_i)\log(h+1) + 0.5c(t_j - t_i) - (c-2)(t - j - t_i) \\
&\le c(t_j - t_i)\log(h+1) - (0.5c-2)(t - j - t_i) \\
&\le c(t_j - t_i)\log(h+1).
\end{aligned}$$

The first inequality is based on (9). The second inequality is by the induction hypothesis and by the fact that $t_{(i+j)/2} > t_i$. The third inequality is valid since $t_j - t_i \ge (t_{(i+j-1)/2} - t_i) + (t_j - t_{(i+j+1)/2})$ and $\log((h+2)/2) \ge \log(h/2)$. The fourth inequality is implied since $\log((h+2)/2) = \log(h+2) - 1$. The fifth inequality is due to the fact that $\log_2(h+2) \le \log_2(h+1) + 0.5$ for $h \ge 2$. Rearranging terms implies the sixth inequality. Finally, the last inequality holds for $c \ge 4$. ∎

3.2. Optimal full cost. The optimal algorithm for full cost uses the optimal algorithm for merge cost as a subroutine. Let $t_1, t_2, \ldots, t_n$ be a sequence of arrivals and let L be the length of a full stream. We know that a full stream must begin at t_1; then there are two possible cases in an optimal solution. Either all the remaining streams merge to this first stream or there is a next full stream t_k for some $k \le n$. In the former case, the optimal full cost is simply $L + M(1,n)$. In the latter case, the optimal full cost is $L + M(1,k-1)$ plus the optimal full cost of the remaining arrivals $t_k, \ldots, t_n$. In both cases, the last arrival to merge to the first stream must be within $L-1$ of the first stream. That is, in the former case $t_n - t_1 \le L-1$ and in the latter case $t_{k-1} - t_1 \le L-1$.

For $1 \le i \le n$, define $G(i)$ to be the optimal full cost for the last $n-i+1$ arrivals $t_i, \ldots, t_n$. By the analysis above, we can define $G(n+1) = 0$ and for $1 \le i \le n$

$$G(i) = L + \min\left\{M(i,k-1) + G(k) : i < k \le n+1 \text{ and } t_{k-1} - t_i \le L-1\right\}. \tag{11}$$

The order of computation is $G(n+1), G(n), \ldots, G(1)$. The optimal full cost is $G(1)$. This analysis leads us to the following theorem.

THEOREM 3.3. *An optimal L-forest can be computed in time $O(nm)$ where m is the average number of arrivals in an interval of length $L-1$ that begins with an arrival.*

Proof. We begin by giving an algorithm for computing the optimal full cost and then show how it yields an algorithm to construct an optimal merge forest. By Lemma 2.6 this optimal merge forest is an L-forest. The optimal full cost algorithm proceeds in two phases. In the first phase we compute the optimal merge cost $M(i,j)$ for all i and j such that $0 \le t_j - t_i \le L-1$, so that these values can be used to compute $G(i)$. In the second phase we compute $G(i)$ from $i = n$ down to 1 using (11). Define m_i to be the cardinality of the set $\{j : 0 \le t_j - t_i \le L-1\}$ and define m to be the average of the m_i's, that is, $m = \sum_{i=1}^{n} m_i/n$. The quantity m can be thought of as the average number of arrivals in an interval of length $L-1$ that begins with an arrival.

We argue that each of the two phases can be computed in $O(nm) = O\left(\sum_{i=1}^{n} m_i\right)$ time. This is mostly a data structure issue because the number of additions and subtractions in the two phases is bounded by a constant times $\sum_{i=1}^{n} m_i$. To facilitate

the computations we define an array $A[1..n]$ of arrays. The array $A[i]$ is indexed from 0 to $m_i - 1$. Ultimately, the array entry $A[i][d]$ will contain $M(i, i+d)$ for $1 \le i \le n$ and $0 \le d < m_i$. Initially, $A[i][0] = 0$ and $A[i][d] = \infty$ for $1 \le d < m_i$. In phase one, a dynamic program based on (9) can be used to compute the ultimate value of $A[i][d] = M(i, i+d)$. Here, a specific order is required for the computation of all the nm entries in the array $A[1..n]$. Using the monotonicity property, it can be done in time $O(nm)$. In phase two, we use the array A to access the value $M(i, k-1)$ when it is needed. Since the minimization in (11) ranges over at most m_i values, the time of phase two is bounded by a constant times $\sum_{i=1}^{n} m_i$. Hence both phases together run in time $O(nm)$.

We have already seen how to construct an optimal merge tree, so all that is left is to identify the full streams. This is done inductively using the values $G(i)$ for $1 \le i \le n$ that we have already computed. We know that t_1 is a full stream. Suppose that we know the first $j \ge 1$ full streams that are indexed $f_1, f_2, \ldots, f_j$. We want to determine if f_j is the last full stream, or that the next full stream is indexed f_{j+1}. Find the smallest k such that

$$G(f_j) = L + M(f_j, k-1) + G(k),$$

where $f_j < k \le n+1$ and $t_{k-1} - t_{f_j} \le L - 1$. If $k = n+1$, then f_j is the last full stream. If $k < n+1$, then the next full stream is indexed $f_{j+1} = k$. When we are done, suppose there are s full streams which start at the arrivals indexed $f_1, f_2, \ldots, f_s$. We then compute s merge trees where the ith merge tree is for inputs $t_{f_i}, \ldots, t_{f_{i+1}-1}$ if $i < s$ and for inputs $t_{f_s}, \ldots, t_n$ if $i = s$. Given that $G(i)$ for $1 \le i \le n+1$ and $M(i,j)$ and $r(i,j)$ for $t_j - t_i \le L-1$ are already computed, then the time to compute the sequence $f_1, f_2, \ldots, f_s$ and to compute the merge trees rooted at these arrivals is $O(\sum_{i=s}^{n} m_{f_i})$ which is $O(n)$. □

We now compute an upper bound on the full cost of an arrival sequence $t_1, t_2, \ldots, t_n$, where $n \ge 2$. This time we are looking for an upper bound that depends only on $N = t_n - t_1$, n, and L and not on the sequence itself. Define $\rho = n/N$ to be the density of the n arrivals. We have $0 < \rho \le 1$. If ρ is near zero, then there are very few arrivals over the span N, so we would expect the optimal full cost to be $O(nL)$. On the other hand, if ρ is large, we would expect a lot of merging to occur, reducing the full cost considerably. This intuition is quantified in the following theorem.

THEOREM 3.4. *The optimal full cost is $O(nL)$ for any values of n and N. The optimal full cost is $O(N \log(\rho L))$ for $\rho \ge \alpha/L$ for some positive constant α.*

Proof. The first statement of the theorem is true for any solution since in the worst case each arrival gets a full stream for a total cost of nL. This is optimal if any two arrivals are more than L apart.

To prove the second statement of the theorem, assume that the optimal full cost is obtained by the L-forest F that contains s L-trees. Let the cardinalities of these trees be $m_1, m_2, \ldots, m_s$, where $m_i \ge 1$ for $1 \le i \le s$ and $\sum_{i=1}^{s} m_i = n$. It follows that

$$\text{Fcost}(F) = sL + \sum_{i=1}^{s} \text{Mcost}(m_i).$$

By Theorem 3.2 there is a constant c ($c = 4 \log_2 e$ is sufficient) such that

$$\text{Fcost}(F) \le sL + cL \sum_{i=1}^{s} \log_e m_i.$$

The convexity of the function $\log_e$ implies that

$$\text{Fcost}(F) \le sL + cL\sum_{i=1}^{s}\log_e(n/s) = sL + csL\log_e(n/s) = sL(c\log_e(n/s)+1). \tag{12}$$

The expression $sL(c\log_e(n/s)+1)$ as a function of s is concave and, by calculus, achieves a global maximum of $ce^{-1+1/c}nL$ at $s = e^{-1+1/c}n$.

We now show a natural upper bound on s:

$$s \le \frac{4N}{L}. \tag{13}$$

To see this we argue that there cannot be three full streams in an interval of length $L/2$. In such a case, the last arrival of the second tree is less than $L/2$ slots far from the root of the first tree. One could save cost by merging the root of the second tree to the root of the first tree. The worst case happens when every $L/4+1$ slots there is a new stream.

We conclude the proof of the second statement by letting $\alpha = 4e^{1-1/c}$ and assuming that $\rho \ge \alpha/L$. It follows that $e^{-1+1/c}n \ge 4N/L$. The concavity of the Fcost as a function of s implies that $\text{Fcost}(F)$ is bounded above when $s = 4N/L$ which is the maximum value for s by (13). By plugging this value for s into (12) we get

$$\begin{aligned}\text{Fcost}(F) &\le \frac{4N}{L}L\left(c\log_e\frac{n}{4N/L}+1\right)\\ &= O(N\log(\rho L)).\end{aligned}$$ □

The statement of Theorem 3.4 seems to be different from the statement of Theorem 3.2. Here the performance depends on L as well. Nevertheless, when ρ is large, the term ρL, which is close to the average number of arrivals in an interval of length L, is analogous to n.

We conclude this section by comparing analytically the performance of the traditional batching with the performance of the optimal full cost using the upper bound of Theorem 3.4.

THEOREM 3.5. *There is a positive constant α such that if $\rho \ge \alpha/L$, then batching with stream merging is $\Omega(\rho L/\log(\rho L))$ better than batching alone.*

Proof. Choose α by Theorem 3.4. The cost of batching the n full streams is nL. Therefore, by Theorem 3.4, the ratio between the performance of batching alone and batching with stream merging is

$$\Omega\left(\frac{nL}{N\log(\rho L)}\right) = \Omega\left(\frac{\rho L}{\log(\rho L)}\right).$$ □

If $\rho < \alpha/L$, then the gain is at most a constant factor in using batching with stream merging over batching alone.

4. Limited buffer size. In this section we show how to adapt our solution to the case in which each client has a limited buffer size for storing later parts of streams. Let B be the maximum buffer size. Clients start viewing the stream immediately while being able to receive data from at most two streams. Therefore, if a client has b parts in its buffer it must have viewed the first b parts of the stream. Hence, clients never need a buffer of size more than $\lfloor L/2\rfloor$. In this section, we assume that $B < \lfloor L/2\rfloor$ and we modify the algorithms accordingly.

Suppose that arrival x belongs to the merge tree T that is rooted at $r < x$. Assume further that T is an L-tree (the length of all nonroot nodes in the tree is less than or equal to L). Our goal is to calculate $b(x)$, the buffer size required by clients that arrive at time x. These clients base their receiving procedure only on earlier arrivals; therefore in calculating $b(x)$, it is enough to consider the merge tree T without all the arrivals after x. Define $T(x)$ to be this tree; in particular, x is the last arrival in $T(x)$.

LEMMA 4.1. *The buffer size required by clients arriving at x in the merge L-tree T rooted at r is*

$$b(x) = \min\{x - r, L - (x - r)\}.$$

Proof. We distinguish between the following two cases.

Case 1. Assume $0 < x - r \leq \lfloor L/2 \rfloor$. Let y be the ancestor of x in $T(x)$ (could be x itself) that is the child of the root r. It follows that x merges to r at time $y + \ell(y)$ that is the end time of the stream that was initiated at y. Now, $\ell(y) = (x-y)+(x-r)$ by (3) which implies that x merges to r at time $2x-r$. At this time x spent $(2x-r)-x = x-r$ slots receiving data from two streams and from this time on x receives data from only one stream. Hence, $b(x) = x - r$.

Case 2. Assume $\lfloor L/2 \rfloor < x - r \leq L - 1$. By the assumption T is an L-tree and hence the length of all the ancestors of x is strictly less than L. It follows that x receives the Lth part of the stream from the root and stops buffering after time $r + L$ which is the end time of the stream initiated at the root. This implies that x buffers exactly $L + r - x$ parts of the stream.

The lemma follows since if $x - r \leq \lfloor L/2 \rfloor$, then $x - r < L - (x - r)$ and if $\lfloor L/2 \rfloor < x \leq L - 1$, then $L - (x - r) < x - r$. ∎

We are now ready to describe the optimal algorithm for the full cost assuming $B < \lfloor L/2 \rfloor$. Let $t_1, t_2, \ldots, t_n$ be the sequence of arrivals. The only change is in the definition of $G(i)$ in (11). In this equation the search for the minimum value was for $i < k \leq n + 1$ such that $t_{k-1} - t_i \leq L - 1$. In what follows we modify this condition.

LEMMA 4.2. *For $1 \leq i \leq i' \leq n$, let $t_{i'}$ be the last arrival that can merge to t_i assuming t_i is a root. Then either* (i) $t_{i'} - t_i \leq B$, *or* (ii) $L - (t_{i'} - t_i) \leq B$ *and there are no arrivals t_j such that $t_i + B < t_j < t_i + L - B$.*

Proof. Assume first that there exists an arrival t_j such that $t_i + B < t_j < t_i + L - B$. By Lemma 4.1 it follows that if t_j belongs to a tree rooted at t_i then its buffer size must be greater than B. This means that t_j must belong to a tree rooted at a later arrival than t_i. Thus, in this case $t_{i'} - t_i \leq B$. Assume now that there are no arrivals t_j such that $t_i + B < t_j < t_i + L - B$. The same lemma implies that arrivals in the range $[t_i + L - B, t_i + L - 1]$ need buffer size less than or equal to B if they merge to a tree rooted at t_i. Hence, if there exists an arrival t_j such that $t_i + L - B \leq t_j \leq t_i + L - 1$, then $L - (t_{i'} - t_i) \leq B$. Otherwise, $t_{i'} - t_i \leq B$ since arrivals after $t_i + L - 1$ cannot merge to a tree rooted at t_i. ∎

Let $t_{i'}$ be the last arrival that can belong to a merge L-tree rooted at t_i as implied by Lemma 4.2. Define $G_B(i)$ to be the optimal full cost for the last $n - i + 1$ arrivals $t_i, \ldots, t_n$. We can define $G_B(n + 1) = 0$ and for $1 \leq i \leq n$

$$G_B(i) = L + \min\{M(i, k-1) + G_B(k) : i < k \leq n + 1 \text{ and } t_{k-1} \leq t_{i'}\}. \tag{14}$$

The order of computation is $G_B(n + 1), G_B(n), \ldots, G_B(1)$. The optimal full cost is $G(1)$. The following theorem is a modification of Theorem 3.3.

THEOREM 4.3. *An optimal merge forest can be computed in time $O(nm)$ where m is the average number of arrivals in an interval of length B that begins or ends with an arrival.*

Proof. The proof is almost identical to the proof of Theorem 3.3. The only change is the definition of m. The $O(nm)$ is true since by Lemma 4.2 the search for the minimum in computing $G_B(i)$ is conducted in at most in two intervals each of size B. □

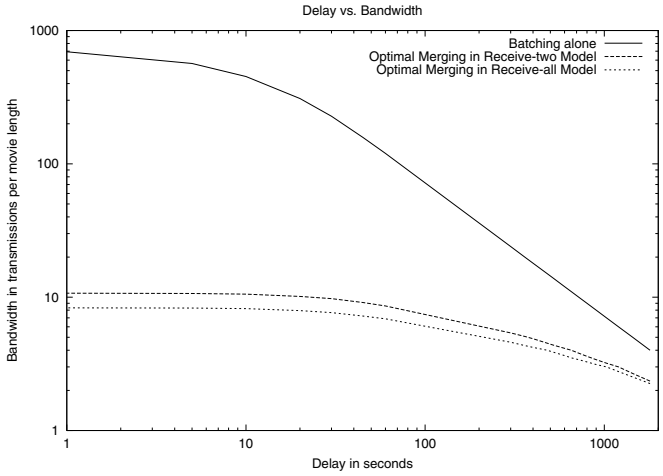

FIG. 6. *Comparison of bandwidth required for batching, batching in the receive-two model, and batching in the receive-all model. The figure plots the bandwidth requirement vs. delay for a* 2*-hour movie, with Poisson arrivals averaging every* 10 *seconds.*

5. The receive-all model. In this section we consider the receive-all model. In this model a client is capable of receiving data from all the existing streams. Surprisingly, the gain is very little compared to the receive-two model. Experimentally these two models are compared with the traditional batching (receive-one) in Figure 6. We added batching in the receive-all model to the plot of Figure 3. The figure speaks for itself. The rest of the section is devoted to demonstrating analytical comparisons of the full cost. In particular, we show a gain of at most 2. Recall that the gain from the traditional batching to the receive-two model is $\Omega(\rho L/\log(\rho L))$ (for $\rho \geq \alpha/L$ for some α).

We omit some of the details in the proofs of our claims in this section since the proofs are very similar to those in the receive-two model. We first prove some preliminary results as we did in the receive-two model.

In the receive-all model we define merge trees in exactly the same way as the receive-two model. Without going into detail, if $x_0, x_1, \ldots, x_k$ is the path from the root x_0 to node x_k that is the arrival time of a specific client, then the client x_k can receive data from all the streams $x_0, \ldots, x_k$. As in the receive-two model each stream starts at the beginning and runs continuously until it terminates, perhaps early.

Given a merge tree T and a node x, define $\ell_\omega(x)$ to be the minimum length needed to guarantee that all the clients can receive the stream using the receive-all stream merging rules.

LEMMA 5.1. *Let $x \neq r(T)$ be a nonroot node in a tree T. Then*

$$\ell_\omega(x) = z(x) - p(x). \tag{15}$$

In particular, if x is a leaf, then $\ell(x) = x - p(x)$ since $z(x) = x$.

Proof. Let a path from the root r to a leaf y be $r = x_0, x_1, \ldots, x_k = y$. At time x_k the clients arriving at y receive the following parts of the stream: part 1 from x_k, part $1 + (x_k - x_{k-1})$ from x_{k-1}, part $1 + (x_k - x_{k-2})$ from x_{k-2}, and in general part $1 + (x_k - x_i)$ from x_i. In particular they receive part $1 + (x_k - x_0)$ from the root. This means that the stream at x_k must last for at least $x_k - x_{k-1}$ slots in order for the clients arriving at y to receive parts $[1, (x_k - x_{k-1})]$. Since the only stream that can provide parts $[1 + (x_k - x_{k-1}), (x_k - x_{k-2})]$ to these clients is the one at x_{k-1}, this stream must last for at least $x_k - x_{k-2}$ slots. In general, since the stream at x_i provides parts $[1 + (x_k - x_i), (x_k - x_{i-1})]$ to these clients, this stream must last for at least $x_k - x_i$ slots.

Now let x be a node in the tree, let $p(x)$ be its parent, and let $z(x)$ be the node representing the last arrival in the subtree rooted at x. The above arguments imply that the stream at x provides parts $[1 + (z(x) - x), (z(x) - p(x))]$ to the clients arriving at $z(x)$. Since a stream is always a prefix of the full transmission, the length of the stream at x must be at least $z(x) - p(x)$. The proof is completed, since by the definition of $z(x)$, no other clients require later parts from the stream at x. ∎

Define $\text{Mcost}_\omega(T)$ to be the sum of $\ell_\omega(x)$ for all x in T except the root. For a merge forest F consisting of merge trees $T_1, \ldots, T_s$, define $\text{Fcost}_\omega(F) = s \cdot L + \sum_{i=1}^{s} \text{Mcost}_\omega(T_i)$, where L is the length of a full stream. Again we have an elegant recursive formula for the merge cost.

LEMMA 5.2. *Let T be a merge tree with root r and last stream z and let x be the last stream to merge to the root of T. Then we have*

$$\text{Mcost}_\omega(T) = \text{Mcost}_\omega(T') + \text{Mcost}_\omega(T'') + (z - r), \tag{16}$$

where T' is the subtree of all arrivals before the last stream to merge to the root of T and T'' is the subtree rooted at the last stream to merge to the root.

Proof. The length of any node in T' and T'' is the same as its length in T. Since the root of T' is the root of T, it follows that x is the only node in $\text{Mcost}(T)$ whose length is not included in $\text{Mcost}(T')$ or $\text{Mcost}(T'')$. The lemma follows, since by Lemma 5.1 the length of x is $z(x) - p(x) = z - r$. ∎

We are now ready to compute the merge cost and then the full cost. Let $t_1, \ldots, t_n$ be a sequence of arrivals. Define $M_\omega(i, j)$ to be the minimum cost of a merge tree in the receive-all model for the input sequence $t_i, \ldots, t_j$. Similar to the way we computed $M(i, j)$ we can compute $M_\omega(i, j)$ using the recursive formulation based on (16):

$$M_\omega(i, j) = \min_{i<k\leq j} \{M_\omega(i, k-1) + M_\omega(k, j)\} + (t_j - t_i) \tag{17}$$

with the initialization $M_\omega(i, i) = 0$ for $1 \leq i \leq n$. The optimal cost for the entire sequence is $M_\omega(1, n)$. Because t_k does not appear as a parameter in (17), we can use the simpler approach of Yao [45] to show monotonicity. As a result we have an $O(n^2)$ time algorithm for computing an optimal merge tree in the receive-all model.

Equations (9) and (17) allow us to give bounds on the gain in optimal merge cost that can be achieved by moving to the receive-all model.

THEOREM 5.3. *For any arrival sequence $t_1, \ldots, t_n$ and $1 \leq i \leq j \leq n$*

$$M_\omega(i, j) \leq M(i, j) \leq 2M_\omega(i, j).$$

Proof. The proof is by induction on $j-i$. If $j-i=0$, then $M(i,j)=M_\omega(i,j)=0$. If $j-i>0$, then let k and h be such that

$$M(i,j) = M(i,k-1) + M(k,j) + 2t_j - t_k - t_i, \tag{18}$$

$$M_\omega(i,j) = M_\omega(i,h-1) + M_\omega(h,j) + t_j - t_i. \tag{19}$$

The following proves the lower bound claim of the theorem.

$$\begin{aligned} M_\omega(i,j) &\le M_\omega(i,k-1) + M_\omega(k,j) + t_j - t_i \\ &\le M(i,k-1) + M(k,j) + t_j - t_i \\ &\le M(i,k-1) + M(k,j) + 2t_j - t_k - t_i \\ &\le M(i,j). \end{aligned}$$

The first inequality follows since $M_\omega(i,j)$ is a minimization. By the induction hypothesis, we get the second inequality. The third inequality is implied since $t_j \ge t_k$. Finally, (18) yields the last inequality.

The following proves the upper bound claim of the theorem:

$$\begin{aligned} M(i,j) &\le M(i,h-1) + M(h,j) + 2t_j - t_h - t_i \\ &\le 2M_\omega(i,h-1) + 2M_\omega(h,j) + 2t_j - t_h - t_i \\ &\le 2M_\omega(i,h-1) + 2M_\omega(h,j) + 2(t_j - t_i) \\ &\le 2M_\omega(i,j). \end{aligned}$$

The first inequality follows since $M(i,j)$ is a minimization. By the induction hypothesis, we get the second inequality. The third inequality is implied since $t_h \ge t_i$. Finally, (19) yields the last inequality. □ In the same way as we did for the receive-two model, define $G_\omega(i)$ to be the optimal full cost in the receive-all model for the sequence $t_i, \ldots t_n$, the last $n-i+1$ arrivals. We have $G(n+1)=0$ and for $1 \le i \le n$

$$G_\omega(i) = L + \min\{M_\omega(i,k-1) + G_\omega(k) : i < k \le n+1 \text{ and } t_{k-1} - t_i \le L-1\}. \tag{20}$$

The order of computation is $G_\omega(n+1), G_\omega(n), \ldots, G_\omega(1)$. The optimal full cost is $G_\omega(1)$. Using exactly the same technique as we did for the receive-two model, we achieve an $O(nm)$ algorithm for computing an optimal merge forest in the receive-all model, where m is the average number of arrivals in a interval of length $L-1$ that begins with an arrival.

We now apply Theorem 5.3 to show the same factor of 2 bound on the optimal full cost.

THEOREM 5.4. *For any arrival sequence $t_1, \ldots, t_n$ and $1 \le i \le n+1$,*

$$G_\omega(i) \le G(i) \le 2G_\omega(i).$$

Proof. The proof is by a reverse induction from $n+1$ to 1. For $n+1$ we have $G_\omega(n+1) = G(n+1) = 0$. If $i < n+1$, then we proceed in a way similar to the proof of theorem 5.3, by letting $k > i$ and $h > i$ be such that $t_{k-1} - t_i \le L-1$, $t_{h-1} - t_i \le L-1$, and

$$G(i) = L + M(i,k-1) + G(k), \tag{21}$$

$$G_\omega(i) = L + M_\omega(i,h-1) + G_\omega(h). \tag{22}$$

The following proves the lower bound claim of the theorem:

$$\begin{aligned} G_\omega(i) &\le L + M_\omega(i, k-1) + G_\omega(k) \\ &\le L + M(i, k-1) + G(k) \\ &\le G(i). \end{aligned}$$

The first inequality follows since $G_\omega(i)$ is a minimization. The induction hypothesis and Theorem 5.3 imply the second inequality. The last inequality is by (21).

The following proves the upper bound claim of the theorem:

$$\begin{aligned} G(i) &\le L + M(i, h-1) + G(h) \\ &\le 2L + 2M_\omega(i, h-1) + 2G_\omega(h) \\ &\le 2G_\omega(i). \end{aligned}$$

The first inequality follows since $G(i)$ is a minimization. The induction hypothesis, Theorem 5.3, and the fact that L is positive imply the second inequality. The last inequality is by (22). □

The factor of 2 is not at all tight for optimal full cost. For example, if $L = 2$, then it can be shown that the optimal full cost in the receive-two model is identical to the optimal full cost in the receive-all model.

6. Conclusions. In this paper, we addressed the problem of designing efficient off-line algorithms to compute the optimal stream merging in media-on-demand systems. In a stream merging system, clients are assigned to receive data from streams that transmit a popular media where they are capable of receiving data from two streams simultaneously. When clients arrive, they get a receiving program that instructs them from which streams to receive data and when. Their program is independent of later arrivals and is simple. Streams are broadcast by the server each time clients request to view the transmission. However, very few of the streams are full streams, thus allowing the savings in the total utilized bandwidth per one popular media. The main advantage of stream merging is its flexibility. With stream merging, it is easier to allocate channels dynamically to various media based on the current demand.

The main objective of this paper was to construct an efficient optimal algorithm. Recall that n is the number of arrivals, L is the length of the full stream, and m is the average number of arrivals in an interval of length $L - 1$ that starts with an arrival. With these parameters, we have an $O(nm)$ optimal algorithm. We also showed how to modify our algorithm to be optimal even if the buffer of clients is limited in its size while maintaining the same running time complexity. To obtain these results, we introduced a new abstract model for the stream merging paradigm. Our merge forest model captures all the information regarding the system. We first analyze a single merge tree and then the merge forest itself.

Finally, we considered a stronger model in which clients may receive data from all the existing streams simultaneously. We showed how our techniques extend to this model with less effort. We used these results to show that analytically the gain from the receive-two model to the receive-all model is at most 2, whereas the gain from the traditional batching to the receive-two model is of order $\rho L / \log(\rho L)$, where $\rho \le 1$ is the density of the n arrivals in the time interval between the first and the last arrival and ρ is large enough. This phenomenon was known experimentally and we support it with analytical results.

BETTER ONLINE ALGORITHMS FOR SCHEDULING WITH MACHINE COST*

GYÖRGY DÓSA† AND YONG HE‡

Abstract. For most scheduling problems the set of machines is fixed initially and remains unchanged for the duration of the problem. Recently Imreh and Noga proposed adding the concept of machine cost to scheduling problems and considered the so-called *list model* problem. For this problem, we are given a sequence of independent jobs with positive sizes, which must be processed nonpreemptively on a machine. No machines are initially provided, and when a job is revealed the algorithm has the option to purchase new machines. The objective is to minimize the sum of the makespan and cost of machines. In this paper, we first present an online algorithm with a competitive ratio at most 1.5798, which improves the known upper bound 1.618. Then for a special case where every job size is no greater than the machine cost, we present an optimal online algorithm with a competitive ratio 4/3. Last, we present an algorithm with a competitive ratio at most 3/2 for the semionline problem with known largest size, which improves the known upper bound 1.5309.

Key words. parallel machine scheduling, machine cost, online algorithm, competitive analysis

1. Introduction.

In the classical parallel identical machine scheduling problem $P|online|C_{\max}$, we are given a sequence $\mathcal{J}$ of independent jobs with positive processing times (sizes) $p_1, p_2, \ldots, p_n$, which must be nonpreemptively scheduled on m parallel and identical machines with the objective to minimize the *makespan* $C_{\max}$ (i.e., the maximum machine load, where machine load means the total size of jobs assigned to this machine). Jobs come one by one (online over list), and it requires one to schedule jobs irrevocably to a machine as soon as they are given, without any knowledge about jobs that follow later on. There has been a great deal of work on this problem [1, 2, 3, 5, 6, 7, 8, 12, 14], but the optimal online algorithm is still unknown for $m > 3$. In [11], Imreh and Noga proposed a variant of the above problem. The differences are that (1) no machines are initially provided, (2) when a job is revealed the algorithm has the option to purchase new machines, and (3) the objective is to minimize the sum of the makespan and cost of machines. We refer to this problem as the *list model*.

This problem is quite different from the classical scheduling problems, where we typically have a fixed number m of machines, the algorithm (scheduler) makes no decision regarding the machine number nor is it allowed to change the machine number later, and the provided machines can be utilized without cost. Imreh and Noga [11] proposed adding the concept of machine cost to the scheduling problem due to the following main motivation: First, real machines have cost. Second, the performance of an algorithm on a given input can be highly dependent on the number of machines. This seems particularly true when considering worst-case measures (such as competitive analysis). Last, by considering such a variant we may find other

interesting problems and/or gain insight into the original.

Following [11], He and Cai [9, 4] considered a variant of the list model problem. They studied the problem in a *semionline* environment. Here semionline means that we have partial knowledge of jobs before constructing a schedule, and we still cannot rearrange any job which has been assigned to machines. If the problem is *semionline with known largest size*, then we know the size of the largest job as a priori. If the problem is *semionline with known total size*, then we know the sum of sizes of all jobs in advance. If the problem is *semionline with decreasing sizes*, then we know that jobs come in an order of nonincreasing sizes. Note that the semionline problem with known largest size can be viewed as a relaxation of the problem with decreasing sizes. These semionline versions were first proposed by different authors when the problem $P||C_{\max}$ was studied [10, 13, 8, 16].

The quality of an online or semionline algorithm A is measured by its *competitive ratio*. For any sequence I of jobs, let $A(I)$ denote the corresponding objective value of a schedule produced by A, and let $OPT(I)$ denote the optimal objective value. Then the competitive ratio of A is defined as the smallest number c such that $A(I) \leq cOPT(I)$ for all sequences. An algorithm with a competitive ratio c is called a *c-competitive algorithm*. An online (semionline) scheduling problem has a *lower bound* ρ if no online (semionline) algorithm has a competitive ratio smaller than ρ. An online (semionline) algorithm is called *optimal* if its competitive ratio matches the lower bound of the problem.

For the list model problem, Imreh and Noga [11] presented an online $(1+\sqrt{5})/2 \approx 1.618$-competitive algorithm A_ρ while the lower bound was 4/3. If randomization is allowed, Seiden [15] provided a lower bound 1.06532. For the semionline problem with known largest size, He and Cai [9] presented an algorithm with a competitive ratio at most 1.5309 while the lower bound was 4/3. For the semionline problem with known total size, He and Cai [9] presented an algorithm with a competitive ratio at most 1.414 while the lower bound was 1.161. For the semionline problem with decreasing sizes, Cai and He [4] presented an algorithm with a competitive ratio 3/2 while the lower bound was still 4/3. These semionline algorithms are essentially modified from A_ρ.

In this paper, we continue to consider the list model problem and its semionline problem with known largest size. We first present a new online algorithm with a competitive ratio at most $(2\sqrt{6}+3)/5 \approx 1.5798$, which improves the known upper bound 1.618. Then for a special case where every job has a size no greater than the machine cost (called *small job*), we present an optimal online algorithm with a competitive ratio 4/3. Last, we present a new two-phase algorithm with a competitive ratio at most 3/2 for the semionline problem with known largest size, which also improves the known result. Compared with A_ρ, our algorithms apply new strategies to decide when to purchase machines. In fact, the decision regarding when to purchase new machines depends on the current makespan, and the current objective value with respect to the lower bounds of the current optimal value, while A_ρ simply depends on the total size of all arrived jobs.

The paper is organized as follows. Section 2 presents several preliminary results. Section 3 considers the general case and small job case of the list model problem. Section 4 deals with the semionline problem with known largest size. Finally section 5 contains some remarks.

2. Preliminaries. Throughout the remainder of the paper, we will use the following notation. Denote by $L = \max_{1,2,\ldots,n}\{p_i\}$ the largest size of all jobs, by $P = \sum_{i=1}^{n} p_i$ the total size of all jobs, and by $P_k = \sum_{j=1}^{k} p_j$ the total size of the first

k jobs. By normalizing, we assume that the cost of purchasing a machine is 1. If m' is the number of machines used by an online or semionline algorithm A after all jobs are assigned, and $C_{\max}$ is its makespan, then the objective value produced by A is $A(I) = C_{\max} + m'$.

LEMMA 2.1 (see [11]). *The optimal objective value is at least* $2\sqrt{P}$. *Further, if* $L \geq \sqrt{P}$, *then the optimal objective value is at least* $L + P/L$; *or, equivalently, if there is a job* p_k *such that* $p_k \geq \sqrt{P}$, *then the optimal objective value is at least* $p_k + P/p_k$.

The following online algorithm A_ρ was presented by Imreh and Noga [11] to solve the list model problem.

ALGORITHM A_ρ. Set $\rho = \{\rho_1, \rho_2, \rho_3, \dots, \rho_i, \dots\} = \{0, 4, 9, 16, \dots, i^2, \dots\}$. When job p_i is revealed A_ρ purchases machines (if necessary) so that the current number of machines j satisfies $\rho_j \leq P_i < \rho_{j+1}$. A_ρ then assigns job p_i to the machine with the minimum current load.

In [11], Imreh and Noga have shown that A_ρ is $(1+\sqrt{5})/2$-competitive. Lemma 2.2 shows that the ratio can be tightened for a special case.

LEMMA 2.2 (see [9]). *If* $L \leq 3$, *then* A_ρ *has a competitive ratio* $3/2$.

LEMMA 2.3 (see [11, 9]). *Any online algorithm for the problem with small jobs and any semionline algorithm for the problem with known largest size have a competitive ratio at least* $4/3$.

Proof. We show the result by adversary method. Let the largest size be $L = 1/N$, where N is a sufficiently large positive integer. Consider a long sequence of jobs, each with size L. If an algorithm A never purchases a second machine, then $8N$ jobs come. It follows that $\frac{A(I)}{OPT(I)} \geq \frac{8N/N+1}{8N/(2N)+2} = \frac{3}{2}$. So we assume that A purchases a second machine when job p_i arrives. Then no new job comes. If $P_i \leq 2$, then in the optimal schedule all jobs are processed on one machine and $\frac{A(I)}{OPT(I)} \geq \frac{P_i - 1/N+2}{P_i+1} \geq \frac{4-1/N}{3}$. If $P_i > 2$, then in the optimal schedule all jobs can be split nearly evenly between two machines and $\frac{A(I)}{OPT(I)} \geq \frac{P_i - 1/N+2}{P_i/2+2} \geq \frac{4-1/N}{3+1/N}$. Since we choose N to be arbitrarily large, we obtain the result. □

Before going to the main content, we further define some notation. When analyzing an online or semionline algorithm in the later sections, we use the following:

m = the current number of machines purchased;

$m_0 = \lceil L \rceil$;

p_{i_j} = the first job which is processed on the jth machine, $j = 1, \dots, m$.

Right after the algorithm scheduling job p_k, $k = 1, 2, \dots, n$, we define

$s_{j,k}$ = the current load of the jth machine, $j = 1, 2, \dots, m$;

s_k = the minimum current machine load, i.e., $s_k = \min\{s_{j,k} | j = 1, \dots, m\}$;

C_k = the current makespan;

z_k = the current objective value, i.e., $z_k = C_k + m$;

$C_{1,k} = 2\sqrt{P_k}$, a lower bound of the current optimal objective value;

$C_{2,k} = L + \frac{P_k}{L}$, another lower bound of the current optimal objective value, where $L \geq \sqrt{P_k}$.

3. Online algorithms.

3.1. Better online algorithm for general case. This subsection considers the original list model problem. We present an algorithm $H1$ with a competitive ratio at most $\frac{2\sqrt{6}+3}{5} \approx 1.5798$. Compared with A_ρ, $H1$ uses a different strategy to decide when a new machine is purchased. It always assigns an incoming job to the machine with minimum current load as long as its new load would be no greater than $2m$,

where m is the current machine number. Otherwise, a new machine is purchased to process the incoming job. Formally, it can be described as follows.

ALGORITHM $H1$.

1. Assign p_1 to the first machine. Let $k = 2$, $m = 1$.
2. Assign p_k to the machine with minimum current load if the new load will be no more than $2m$, and go to 4. Else go to 3.
3. Assign p_k to a new machine, $m = m + 1$, go to 4.
4. Let $k = k + 1$, if $k > n$, stop. Otherwise, return 2.

LEMMA 3.1. *Let $m \geq 2$ be the number of machines currently purchased by $H1$. If the current minimum machine load satisfies $s_k \leq m - 1$, then the sum of the current machine loads is*

$$\sum_{j=1}^{m} s_{j,k} \geq s_k^2 - (m-1)s_k + (m-1)m.$$

Proof. Obviously for any $1 \leq j < l \leq m$, we have that

$$s_{j,k} + s_{l,k} \geq s_k + p_{i_l} > 2\,(l-1)$$

by the algorithm rule. Consider the following parametric nonlinear program with parameter $s_k \in [0, m-1]$:

$$\begin{array}{ll} \min & u(s_k) = \sum_{j=1}^{m} s_{j,k} \\ \text{s.t.} & s_{j,k} + s_{l,k} \geq 2\,(l-1)\,, \quad 1 \leq j < l \leq m, \\ & \min\{s_{j,k} : 1 \leq j \leq m\} = s_k. \end{array}$$

Assume that $i \leq s_k < i + 1 \leq m - 1$ for some integer $i \geq 0$. Then it is easy to see that its optimal solution is

$$s_{j,k} = \begin{cases} s_k & \text{if} \quad 1 \leq j \leq i+1, \\ 2(j-1) - s_k & \text{if} \quad i+1 < j \leq m, \end{cases}$$

and its minimum value is

$$u^*(s_k) = \begin{cases} s_k^2 - (m-1)s_k + (m-1)m & \text{if} \quad s_k = i, \\ (m+i)(m-i-1) - ms_k + 2(i+1)s_k & \text{if} \quad i < s_k < i+1. \end{cases}$$

We define the functions $f_1(s_k) = s_k^2 - (m-1)s_k + (m-1)m$ on the interval $[0, m-1]$, and $f_2(s_k) = (m+i)(m-i-1) - ms_k + 2(i+1)s_k$ on $[i, i+1]$ for each $i = 0, 1, \ldots, m-2$. Since the function $f_2(s_k)$ is linear on the interval $[i, i+1]$, and $f_2(s_k) = f_1(s_k)$ at $s_k = 0, 1, \ldots, m-1$, hence the function $u^*(s_k)$ is continuous and piecewise linear on $[0, m-1]$. Further, the function $f_1(s_k)$ is convex on $[0, m-1]$, and we conclude that $u^*(s_k) \geq f_1(s_k)$ for any $0 \leq s_k \leq m-1$. Therefore we know that $u(s_k) \geq u^*(s_k) \geq f_1(s_k) = s_k^2 - (m-1)s_k + (m-1)m$ for any $0 \leq s_k \leq m-1$. ∎

COROLLARY 3.2. *Under the same conditions as those of Lemma 3.1, we have $\sum_{j=1}^{m} s_{j,k} \geq \frac{3}{4}(m-1)^2 + (m-1) > \frac{3}{4}m(m-1)$.*

Proof. The function $s_k^2 - (m-1)s_k + (m-1)m$ attains its minimum value when $s_k = \frac{m-1}{2}$. ∎

Remark 3.1. Let $m \geq 2$ be the number of machines currently purchased by $H1$. If the minimum current machine load satisfies $s_k \geq m - 1$, then trivially $\sum_{j=1}^{m} s_{j,k} \geq (m-1)m$.

To prove the competitive ratio of $H1$, we introduce more notation. For any $l \geq 1$, denote $u_l = \max\{p_i | 1 \leq i \leq l\}$, and define

$$C'_l = \begin{cases} C_{1,l} & \text{if} \quad u_l \leq \sqrt{P_l}, \\ C_{2,l} & \text{if} \quad u_l > \sqrt{P_l}. \end{cases}$$

It is clear that $C'_l \geq C_{1,l}$ for any $l \geq 1$.

LEMMA 3.3. *C'_l is increasing with regard to l, i.e., $C'_1 \leq C'_2 \leq \cdots \leq C'_n$.*

Proof. If $C'_{l-1} = C_{1,l-1}$, then trivially $C'_l \geq C_{1,l} > C_{1,l-1} = C'_{l-1}$. Hence suppose that $C'_{l-1} = C_{2,l-1}$. If further $C'_l = C_{2,l}$, then from $u_{l-1} \geq \sqrt{P_{l-1}}$, we have $C'_l = C_{2,l} = \frac{P_l}{u_l} + u_l > \frac{P_{l-1}}{u_l} + u_l \geq \frac{P_{l-1}}{u_{l-1}} + u_{l-1} = C_{2,l-1} = C'_{l-1}$. Otherwise $C'_l = C_{1,l}$, and we know that $u_{l-1}^2 > P_{l-1}$ and $u_l^2 \leq P_l$. It follows that $C'_l = C_{1,l} = 2\sqrt{P_l} \geq 2u_l \geq u_{l-1} + u_{l-1} > u_{l-1} + \frac{P_{l-1}}{u_{l-1}} = C_{2,l-1} = C'_{l-1}$. We are done. ∎

THEOREM 3.4. *The competitive ratio of $H1$ is at most $\alpha \doteq \frac{2\sqrt{6}+3}{5} \approx 1.5798$.*

Proof. We show by induction that for every $l = 1, 2, \ldots, n$, $z_l \leq \alpha C'_l$ holds. It follows that the competitive ratio of $H1$ is at most α.

It is clear that the result is true for $l = 1$. Assuming that the result is true for $l = k - 1$, two cases are considered according to the assignment of p_k.

Case 1. p_k is assigned to one of m machines by step 2. If the makespan is unchanged (i.e., $C_k = C_{k-1}$), then $z_k = z_{k-1}$ and thus the result trivially holds for $l = k$ by the induction assumption and Lemma 3.3. Hence we assume that the makespan is increased and equal to $C_k = s_{k-1} + p_k$, and

$$z_k = C_k + m = s_{k-1} + p_k + m. \tag{3.1}$$

We distinguish three subcases according to the value of m.

Subcase 1.1. $m = 1$ or $m = 2$. From $\alpha C'_k \geq \alpha C_{1,k} \geq 3\sqrt{P_k}$ and (3.1), it suffices to show

$$s_{k-1} + p_k + m \leq 3\sqrt{P_k}. \tag{3.2}$$

If $m = 1$, then by the algorithm rule we have $s_{k-1} + p_k \leq 2m = 2$. If $s_{k-1} + p_k < 1$, then $z_k < 2$, from which it follows that in the optimal schedule there is also only one machine and thus the schedule yielded by $H1$ is optimal. If $1 \leq s_{k-1} + p_k \leq 2$, then trivially $s_{k-1} + p_k + 1 \leq 3\sqrt{s_{k-1} + p_k}$ holds, and we thus get (3.2).

If $m = 2$, then by the algorithm rule we have $s_{k-1} + p_k \leq 4$. On the other hand, right after p_{i_2} is assigned to the second machine, the sum of all job sizes is more than 2; thus the makespan $s_{k-1} + p_k$ must be greater than 1. $1 < s_{k-1} + p_k \leq 4$ implies $s_{k-1} + p_k + 2 \leq 3\sqrt{s_{k-1} + p_k}$, and thus $s_{k-1} + p_k + 2 \leq 3\sqrt{s_{k-1} + p_k} \leq 3\sqrt{P_k}$.

Subcase 1.2. $2 < m \leq s_{k-1} + 1$. If further $m \leq s_{k-1}$, then trivially $P_k \geq s_{k-1}m + p_k \geq m^2$, and thus $z_k = s_{k-1} + p_k + m \leq 2m + m \leq 3\sqrt{P_k} = \frac{3}{2}C_{1,k}$. The desired competitive ratio is obtained; hence we assume that $m - 1 \leq s_{k-1} < m$. If $p_k > s_{k-1} + 1$, then $P_k \geq s_{k-1}m + p_k \geq (m-1)\,m + m = m^2$, and again $z_k \leq \frac{3}{2}C_{1,k}$. If $p_k \leq s_{k-1}$, then by (3.1) and $\frac{1}{4} \leq \frac{s_{k-1}}{m} \leq 1$, we have that $z_k \leq 2s_{k-1} + m \leq 3\sqrt{s_{k-1}m} \leq 3\sqrt{P_k} = \frac{3}{2}C_{1,k}$. Last, if $s_{k-1} < p_k \leq s_{k-1} + 1$, then similarly $z_k \leq 2s_{k-1} + 1 + m \leq 3\sqrt{s_{k-1}m + s_{k-1}} \leq 3\sqrt{P_k} = \frac{3}{2}C_{1,k}$ since $\frac{1}{4} \leq \frac{s_{k-1}}{m+1} \leq 1$.

Subcase 1.3. $m > s_{k-1} + 1$. If $p_k \leq m - s_{k-1}$, then $z_k \leq 2m$ by (3.1). By Corollary 3.2, we have $P_k \geq \frac{3}{4}m\,(m-1)$. $m > 2$ implies $2m \leq 3\sqrt{\frac{3}{4}m\,(m-1)}$, and we thus get $z_k \leq \frac{3}{2}C_{1,k}$. Hence we assume that

$$p_k > m - s_{k-1}. \tag{3.3}$$

Combining (3.3) with Lemma 3.1, we have

$$P_k = \sum_{j=1}^{m} s_{j,k} + p_k \geq s_{k-1}^2 - (m-1)\, s_{k-1} + (m-1)\, m + p_k \tag{3.4}$$
$$> s_{k-1}^2 - m s_{k-1} + m^2.$$

If $p_k \leq \sqrt{P_k}$, then by (3.1) and (3.4), we have

$$z_k \leq \sqrt{P_k} + s_{k-1} + m \leq \sqrt{P_k} + 2\sqrt{s_{k-1}^2 - m s_{k-1} + m^2} < 3\sqrt{P_k} = \frac{3}{2} C_{1,k}.$$

Hence we assume that $p_k \geq \sqrt{P_k}$. It follows from Lemma 2.1 that $p_k + \frac{P_k}{p_k}$ $(\leq C'_k)$ is a valid lower bound of the current optimal objective value. In order to get the desired competitive ratio, from (3.1) and (3.4), it suffices to prove

$$s_{k-1} + p_k + m - \alpha \left(p_k + \frac{s_{k-1}^2 - m s_{k-1} + m^2}{p_k} \right) \leq 0. \tag{3.5}$$

To see it, we first consider the case of $\frac{s_{k-1}}{m} > \frac{3}{5}$. Since $\alpha \leq \frac{8}{5}$, $s_{k-1} + p_k \leq 2m$, and ${p_k}^2 \geq P_k > s_{k-1}^2 - m s_{k-1} + m^2$, the derivative of the left side of (3.5) with respect to p_k is

$$1 - \alpha \left(1 - \frac{s_{k-1}^2 - m s_{k-1} + m^2}{{p_k}^2} \right) > 1 - \frac{8}{5} \left(1 - \frac{s_{k-1}^2 - m s_{k-1} + m^2}{(2m - s_{k-1})^2} \right) > 0,$$

where the last inequality is equivalent to $5(\frac{s_{k-1}}{m})^2 + 4\frac{s_{k-1}}{m} - 4 > 0$, which is trivially true due to $\frac{s_{k-1}}{m} > \frac{3}{5}$. Hence we only need to show (3.5) is valid when $p_k = 2m - s_{k-1}$. Substituting $p_k = 2m - s_{k-1}$ into (3.5), we have $3m \leq \alpha\big(2m - s_{k-1} + \frac{s_{k-1}^2 - m s_{k-1} + m^2}{2m - s_{k-1}}\big)$, i.e.,

$$3 \leq \alpha \left(2 - \frac{s_{k-1}}{m} + \frac{(\frac{s_{k-1}}{m})^2 - \frac{s_{k-1}}{m} + 1}{2 - \frac{s_{k-1}}{m}} \right). \tag{3.6}$$

Note that the minimum value of the function

$$f_3\left(\frac{s_{k-1}}{m}\right) \doteq 2 - \frac{s_{k-1}}{m} + \frac{(\frac{s_{k-1}}{m})^2 - \frac{s_{k-1}}{m} + 1}{2 - \frac{s_{k-1}}{m}}$$

is achieved at $\frac{s_{k-1}}{m} = 2 - \sqrt{3/2}$, and $f_3(2 - \sqrt{3/2}) = 4\sqrt{3/2} - 3$. Since $\alpha \cdot (4\sqrt{3/2} - 3) = 3$, we are done.

Now we assume that $\frac{s_{k-1}}{m} \leq \frac{3}{5}$. The derivative of the left side of (3.5) with respect to s_{k-1} is $1 - \alpha\frac{2s_{k-1} - m}{p_k}$. If $1 - \alpha\frac{2s_{k-1} - m}{p_k} \leq 0$, then from $\frac{s_{k-1}}{m} \leq \frac{3}{5}$, we have $s_{k-1} + p_k \leq s_{k-1} + \alpha\,(2s_{k-1} - m) < \frac{3}{5}m + \frac{8}{5} \cdot \frac{1}{5}m < m$, which contradicts (3.3). In the opposite case this derivative is positive, thus we only need to show that (3.5) is valid when $s_{k-1} = \frac{3}{5}m$. That is to say,

$$p_k + \frac{3}{5}m + m \leq \alpha \left(p_k + \frac{\left(\frac{9}{25} - \frac{3}{5} + 1\right) m^2}{p_k} \right). \tag{3.7}$$

In fact, the right side of (3.7) equals $p_k + (\alpha - 1)p_k + \frac{19\alpha m^2}{25 p_k} \geq p_k + 2\sqrt{\frac{19(\alpha-1)\alpha}{25}}m > p_k + \frac{8}{5}m$, and thus the proof of Case 1 is finished.

Case 2. p_k is the first job assigned to the mth machine (i.e., p_k is assigned by step 3). Hence we have $m \geq 2$ and $s_{j,k-1} + p_k > 2(m-1)$ for all $1 \leq j \leq m-1$. From the algorithm rule, we know that $s_{j,k-1} \leq \max\{u_k, 2(m-1)\}$ for all $1 \leq j \leq m-1$. We obtain the following basic propositions which are useful in obtaining the desired competitive ratio for Case 2.

We first show that $u_k \leq 2(m-1)$. Otherwise, we suppose that $u_k > 2(m-1)$. Note that the makespan is no greater than u_k right before assigning p_k; we have $P_k = \sum_{j=1}^{m-1} s_{j,k-1} + p_k \leq (m-1)u_k + u_k = u_k m \leq u_k \cdot 2(m-1) < u_k^2$. It follows that $C'_k = C_{2,k}$. Furthermore, we get that $z_k \leq \max\{p_k, 2(m-1)\} + m \leq u_k + m < \frac{3}{2}(u_k + 1) \leq \frac{3}{2}\big(u_k + \frac{P_k}{u_k}\big)$, and we are done. Hence we have $u_k \leq 2(m-1)$. It follows that

$$C_{k-1} = \max\{s_{j,k-1} \mid 1 \leq j \leq m-1\} \leq 2(m-1). \tag{3.8}$$

Next we show that $P_k < (m - \frac{2}{3})^2$ and $p_k > m - \frac{2}{3}$. If $P_k \geq (m - \frac{2}{3})^2$, then we have $z_k \leq \max\{u_k, 2(m-1)\} + m \leq 3m - 2 \leq 3\sqrt{P_k} = \frac{3}{2}C_{1,k}$, and the desired competitive ratio is proved. Hence we assume that $P_k < (m - \frac{2}{3})^2$ in the following. If $p_k \leq m - \frac{2}{3}$, considering that $s_{j,k-1} > 2(m-1) - p_k$ for all $1 \leq j \leq m-1$, we have $P_k > (m-1)\,(2(m-1) - p_k) + p_k \geq 2(m-1)^2 - (m-2)\,\big(m - \frac{2}{3}\big) > (m - \frac{2}{3})^2$. Hence we can assume that $p_k > m - \frac{2}{3}$.

$P_k < (m - \frac{2}{3})^2$ and $p_k > m - \frac{2}{3}$, implying that $p_k \geq \sqrt{P_k}$; hence we have $C'_k = C_{2,k}$. Now we show the result by considering three subcases according to the values of C_{k-1} and p_k.

Subcase 2.1. $C_{k-1} \leq p_k$. In this subcase p_k is the largest job, and $z_k = p_k + m$. By Corollary 3.2 and Remark 3.1, we know that $P_k > \frac{3}{4}(m-1)m$; hence it suffices to prove $p_k + m \leq \frac{3}{2}\big(p_k + \frac{\frac{3}{4}(m-1)m}{p_k}\big)$, i.e.,

$$m \leq \frac{p_k}{2} + \frac{9(m-1)m}{8p_k}. \tag{3.9}$$

In fact, the right-hand side of (3.9) is at least $2\sqrt{\frac{9}{16}(m-1)m} = \frac{3}{2}\sqrt{(m-1)m} \geq m$; we thus finish Subcase 2.1.

Subcase 2.2. $C_{k-1} > p_k$ and $u_k \geq \frac{3}{2}(m-1)$. Similarly we have $P_k > \frac{3}{4}(m-1)^2 + m - 1$ by Corollary 3.2 and Remark 3.1. Combining it with (3.8), we only need to show that

$$z_k = C_{k-1} + m \leq 2(m-1) + m \leq \frac{3}{2}\left(u_k + \frac{\frac{3}{4}(m-1)^2 + m - 1}{u_k}\right). \tag{3.10}$$

Inequality (3.10) is equivalent to $0 \leq 12{u_k}^2 - 8(3m-2)u_k + 9m^2 - 6m - 3$, i.e.,

$$\left(u_k - \frac{3(m-1)}{2}\right)\left(u_k - \frac{3m+1}{6}\right) \geq 0. \tag{3.11}$$

Since $u_k \geq \frac{3}{2}(m-1)$, (3.11) is obviously true.

Subcase 2.3. $C_{k-1} > p_k$ and $u_k < \frac{3}{2}(m-1)$. For this subcase, we need to apply the induction assumption.

If $z_{k-1} \leq \alpha C_{1,k-1}$, i.e., $C_{k-1} + m - 1 \leq 2\alpha\sqrt{P_{k-1}}$, we show that $z_k \leq \alpha C_{1,k}$ also holds, i.e., $C_{k-1} + m \leq 2\alpha\sqrt{P_k} = 2\alpha\sqrt{P_{k-1} + p_k}$. It suffices to show that $2\alpha\sqrt{P_{k-1} + p_k} \geq 2\alpha\sqrt{P_{k-1}} + 1$, i.e.,

$$p_k \geq \frac{1}{\alpha}\sqrt{P_{k-1}} + \frac{1}{4\alpha^2}. \tag{3.12}$$

In fact, by applying $p_k > m - \frac{2}{3}$ and $P_k < (m - \frac{2}{3})^2$, we have $p_k > m - \frac{2}{3} = \frac{1}{\alpha}\left(m - \frac{2}{3}\right) + (1 - \frac{1}{\alpha})(m - \frac{2}{3}) > \frac{1}{\alpha}\sqrt{P_k} + \frac{1}{4\alpha^2} > \frac{1}{\alpha}\sqrt{P_{k-1}} + \frac{1}{4\alpha^2}$.

If $z_{k-1} \le \alpha C_{2,k-1}$, i.e., $C_{k-1} + m - 1 \le \alpha\big(u_{k-1} + \frac{P_{k-1}}{u_{k-1}}\big)$, then we have $u_{k-1} \ge \sqrt{P_{k-1}}$ by the induction assumption. It follows that $\alpha\big(u_{k-1} + \frac{P_{k-1}}{u_{k-1}}\big) \le \alpha\big(u_k + \frac{P_{k-1}}{u_k}\big)$. Hence we only need to show

$$\alpha\frac{P_{k-1} + p_k}{u_k} \ge \alpha\frac{P_{k-1}}{u_k} + 1 \tag{3.13}$$

to get $z_k = C_{k-1} + m \le \alpha\big(u_k + \frac{P_{k-1}+p_k}{u_k}\big) = \alpha C_{2,k}$. Inequality (3.13) is equivalent to $p_k \ge \frac{1}{\alpha}u_k$, which immediately follows from $p_k > m - \frac{2}{3}$ and $u_k < \frac{3}{2}(m-1)$.

In summary, we have shown that the result is true for $l = k$. We thus get Theorem 3.4. □

3.2. Optimal online algorithm for small job case. In this subsection we assume that all jobs have sizes no greater than 1, i.e., $L \le 1$. We present an online algorithm which is optimal with a competitive ratio 4/3. Note that by considering the job sequence $p_1 = \cdots = p_{4N} = 1/N$, where N is a sufficiently large positive integer, we get $A_\rho(I)/OPT(I) = (6-1/N)/4 \longrightarrow 3/2$. It concludes that the competitive ratio of A_ρ cannot be smaller than 3/2 for small job case.

ALGORITHM $H2$. The algorithm works in the same way as $H1$ except that step 2 is defined as follows:

2. Assign p_k to the machine with minimum current load if the new load will be no more than $m+1$, and go to 4. Else go to 3.

LEMMA 3.5. *Let $m \ge 2$ be an integer, and let b satisfy $m < b \le m+1$.*

(1) *Define the function $f_4(i) = \frac{(m-1)^2+1}{i} + i$ for any integer $i \ge 1$. Then the minimum value of $f_4(i)$ is $2(m-1) + \frac{1}{m-1}$.*

(2) *Define the function $f_5(i) = \frac{m(b-1)}{i} + i$ for any integer $i \ge 1$. Then the minimum value of $f_5(i)$ is $b + m - 1$.*

Proof. (1) Define $g(x) = \frac{(m-1)^2+1}{x} + x$ for any real number $x \ge 1$. Then

$$g'(x) = \frac{1}{x^2}\left(x^2 - \left((m-1)^2+1\right)\right) = \frac{x + \sqrt{(m-1)^2+1}}{x^2}\left(x - \sqrt{(m-1)^2+1}\right),$$

$$g''(x) = \frac{2((m-1)^2+1)}{x^3} > 0.$$

Therefore the function $g(x)$ achieves its minimum value at $x = \sqrt{(m-1)^2+1}$, and the function $f_4(i)$ achieves its minimum at $i = \left\lfloor\sqrt{(m-1)^2+1}\right\rfloor = m-1$ or $i = \left\lceil\sqrt{(m-1)^2+1}\right\rceil = m$. On the other hand, it is easy to see that $f_4(m-1) = \frac{(m-1)^2+1}{m-1} + m - 1 \le f_4(m) = \frac{(m-1)^2+1}{m} + m$ for any given $m \ge 2$. We thus get (1).

(2) It can be proved similarly that the minimum value is achieved at $i = m$. □

THEOREM 3.6. *The competitive ratio of $H2$ is 4/3 if every job has size no greater than 1, and thus it is optimal.*

Proof. Analogous to the proof of Theorem 3.4, we show the result by distinguishing the value of m', the number of machines purchased by $H2$ right after scheduling all jobs, and the assignment of the last job p_n.

Case 1. $m' = 1$. Then by the algorithm rule, we have $C_{\max} = P = \sum_{i=1}^{n} p_i \le 2$, and $H2(I) = C_{\max} + m' \le 3$. It follows that there are at most two machines in the

optimal schedule. If there is one machine in the optimal schedule, then obviously $H2$ yields the optimal schedule. Otherwise, $OPT(I) \geq \frac{P}{2} + 2$ by averaging argument. It is straightforward to see that $H2(I) = P + 1 \leq \frac{4}{3}\left(\frac{P}{2} + 2\right) \leq \frac{4}{3}OPT(I)$.

Case 2. $m' \geq 2$ and p_n is the first job assigned to the m'th machine (i.e., p_n is assigned by step 3). Then right before scheduling p_n, there are exactly $m'-1$ machines. By the algorithm rule, we have $s_{j,n-1} + p_n > m'$ for every $j = 1, \ldots, m'-1$. Thus we get

$$\sum_{j=1}^{m'-1} (s_{j,n-1} + p_n) = \sum_{j=1}^{m'-1} s_{j,n-1} + (m'-1)p_n > m'(m'-1).$$

Combining it with $p_n \leq 1$, we obtain

$$\begin{aligned} P &= \sum_{j=1}^{m'-1} s_{j,n-1} + p_n > m'(m'-1) - (m'-2)\, p_n \\ &\geq m'(m'-1) - (m'-2) = (m'-1)^2 + 1. \end{aligned}$$

By averaging argument, we have $OPT(I) \geq \min_{i \geq 1}\left\{\frac{(m'-1)^2+1}{i} + i\right\}$, where i is the possible machine number in the optimal schedule. By Lemma 3.5(1), we get that $OPT(I) \geq 2(m'-1) + \frac{1}{m'-1}$. On the other hand, it is clear that $C_{\max} \leq m'$ from the algorithm rule; thus $H2(I) = C_{\max} + m' \leq 2m'$. For every $m' \geq 2$, $\frac{2m'-3}{2m'^2-4m'+3} \leq \frac{4}{3}$ holds trivially. Therefore we have

$$\frac{H2(I)}{OPT(I)} \leq \frac{2m'}{2(m'-1) + \frac{1}{m'-1}} = \frac{2\,(m'-1)\,m'}{2(m'-1)^2+1} = 1 + \frac{2m'-3}{2m'^2-4m'+3} \leq \frac{4}{3}.$$

Case 3. $m' \geq 2$ and p_n is assigned to one of m' machines by step 2. It is clear that the final makespan $C_{\max} \leq m'+1$ and $H2(I) = C_{\max} + m'$. If further $C_{\max} \leq m'$, we have $H2(I) \leq 2m'$. Assume that the m'th machine is purchased when assigning job p_k. By the same argument as that in Case 2, we get $P_n \geq P_k \geq (m'-1)^2 + 1$, and thus $H2(I)/OPT(I) \leq 4/3$.

Hence we can assume that $m' < C_{\max} \leq m'+1$. Since p_n is assigned to the machine with minimum current load, the load of every machine is at least $C_{\max} - p_n \geq C_{\max} - 1$; thus the sum of all sizes $P \geq (m'-1)\,(C_{\max}-1) + C_{\max} > m'\,(C_{\max}-1)$. It follows that $OPT(I) \geq \min_{i \geq 1}\left\{\frac{m'(C_{\max}-1)}{i} + i\right\}$. By Lemma 3.5(2), we get $OPT(I) \geq C_{\max} + m' - 1$. Hence we get that

$$\frac{H2(I)}{OPT(I)} \leq \frac{C_{\max} + m'}{C_{\max} + m' - 1} = 1 + \frac{1}{C_{\max} + m' - 1} \leq \frac{4}{3},$$

where the last inequality follows from $m' \geq 2$ and $C_{\max} > m' \geq 2$.

Therefore we have shown that $H2$ is 4/3-competitive, and the optimality is obtained directly from Lemma 2.3. □

Remark 3.2. $H2$ also works for the case $1 < L \leq 3$ by simple modification as follows: The algorithm is the same as $H2$ except that in step 2, $m+1$ is replaced by $m + L$. It can be shown similarly that the competitive ratio of modified $H2$ is no greater than 3/2 for the problem where L is known in advance and $1 < L \leq 3$.

4. Semionline algorithm for the problem with known largest size. In this section, we assume that jobs arrive one by one and the largest size L of all jobs is known in advance. As we have seen in previous sections, if $L \le 1$, $H2$ is 4/3-competitive, and if $1 < L \le 3$, both A_ρ and modified $H2$ have a competitive ratio at most 3/2; therefore we assume that $L > 3$ in the remainder of the section. We present a two-phase algorithm with a competitive ratio at most 3/2, which uses new strategies to purchase machines in two phases.

ALGORITHM $H3$.

PHASE 1.

1.1 Let $k = 1$, $m = 1$.

1.2 Assign p_k to the machine with minimum current load if the new load will be no more than $\frac{3}{2}L$, and go to 1.4. Else go to 1.3.

1.3 Assign p_k to a new machine, and let $m = m + 1$. If $m = m_0$, then go to 2.6 in Phase 2, else go to 1.4.

1.4 Let $k = k + 1$, if $k > n$, stop. Otherwise, go to 1.2.

PHASE 2.

2.1 Compute the current value $C_{1,k} = 2\sqrt{P_k}$, and the minimum current machine load s_{k-1}.

2.2 If $s_{k-1} + p_k$ is not greater than the current makespan, then assign p_k to the machine with minimum current load, go to 2.6.

2.3 If $P_k > m^2$, then assign p_k to a new machine, let $m = m + 1$, go to 2.6.

2.4 If $s_{k-1} + p_k + m > \frac{3}{2}C_{1,k}$, then assign p_k to a new machine, let $m = m + 1$, go to 2.6.

2.5 Else assign p_k to the machine with minimum current load, go to 2.6.

2.6 Let $k = k + 1$. If $k > n$, stop. Else return 2.1.

THEOREM 4.1. *The competitive ratio of $H3$ is at most 3/2.*

We prove Theorem 4.1 step by step by showing a series of technical lemmas in the following. We first consider Phase 1.

LEMMA 4.2. *For every $m \le m_0$, we have $P_{i_m} > \frac{3}{4}mL$.*

Proof. It is clear that $P_{i_m} = \sum_{l=1}^{m} s_{l,i_m}$. By the rule of Phase 1, we know that $s_{l,i_m} + s_{j,i_m} \ge s_{i_m} + p_{i_j} > \frac{3}{2}L$ for all $1 \le l < j \le m$. Summing up these inequalities, we get $P_{i_m} > \frac{3}{4}mL$. □

LEMMA 4.3. *If $H3$ stops at Phase 1, then the competitive ratio is no greater than 3/2.*

Proof. Suppose a total of $m' \le m_0$ machines are purchased by $H3$. Then by Lemma 4.2, we know $P \ge P_{i_{m'}} > \frac{3}{4}m'L$. If $P \le L^2$, then by Lemma 2.1 we get

$$\begin{aligned} \frac{3}{2}OPT(I) \ge \frac{3}{2}C_{2,n} &= \frac{3}{2}\left(L + \frac{P}{L}\right) > \frac{3}{2}\left(L + \frac{3}{4}m'\right) \\ &= \frac{3}{2}L + \frac{9}{8}m' > C_{\max} + m' = H3(I). \end{aligned} \tag{4.1}$$

If $P > L^2$, then again by Lemma 2.1 we have

$$\frac{3}{2}OPT(I) \ge \frac{3}{2}C_{1,n} \ge 3\sqrt{L^2} = \frac{3}{2}L + \frac{3}{2}L \ge C_{\max} + m' = H3(I), \tag{4.2}$$

where the last inequality follows from $m' \le m_0 = \lceil L \rceil$ and $L > 3$. □

In the remainder of this section, we focus on analyzing Phase 2. We are going to prove $z_k \le \frac{3}{2}C_{1,k}$ for every $k = i_{m_0}, \ldots, n$, from which it follows that the competitive ratio of $H3$ is at most 3/2. Note that at the beginning of Phase 2 we have purchased

exactly m_0 machines, there is only one job $p_{i_{m_0}}$ assigned to the m_0th machine, the total size of all arrived jobs Q_{m_0} is between $\frac{3}{4}m_0L$ and $\frac{3}{2}m_0L$, and the current makespan is no greater than $\frac{3}{2}L$.

LEMMA 4.4. $z_{i_{m_0}} \le \frac{3}{2}C_{1,i_{m_0}}$.

Proof. By Lemma 4.2, we get $P_{i_{m_0}} \ge \frac{3}{4}m_0L$. As $z_{i_{m_0}} \le m_0 + \frac{3}{2}L$ and $C_{1,i_{m_0}} = 2\sqrt{P_{i_{m_0}}}$, it suffices to show $3\sqrt{\frac{3}{4}m_0L} \ge \frac{3}{2}L + m_0$, i.e., $9\left(\frac{L}{m_0}\right)^2 - 15\left(\frac{L}{m_0}\right) + 4 \le 0$. Since $L > 3$, it is obvious that $\frac{1}{3} \le \frac{L}{m_0} \le \frac{4}{3}$, from which it follows that the desired inequality is true. ∎

Notice that in Phase 2, the competitive ratio may become worse than 3/2 only when a new machine is purchased by steps 2.3 and 2.4 and the incoming job is assigned to this machine. Thus if $z_{k-1} \le \frac{3}{2}C_{1,k-1}$ holds and job p_k is assigned by step 2.2 or by step 2.5, then we have $z_k \le \frac{3}{2}C_{1,k}$. In the following, we mainly focus on analyzing steps 2.3 and 2.4, that is, considering the assignment of p_{i_m} and estimating z_{i_m}, $m \ge m_0 + 1$.

LEMMA 4.5. *At Phase 2, if $z_k \le \frac{3}{2}C_{1,k}$ holds, then we know that the current makespan $C_k \le 2m$, where m is the number of currently purchased machines.*

Proof. It is clear that no job can have a size greater than $2m$ at Phase 2. Hence the makespan may be increased to more than $2m$ only at step 2.5. But in this case we have $P_k \le m^2$, and thus $z_k = C_k + m \le \frac{3}{2}C_{1,k} \le 3m$. It follows that $C_k \le 2m$. ∎

LEMMA 4.6. *If the mth machine is purchased by step 2.3, where $m \ge m_0 + 1$, and if $z_{i_m-1} \le \frac{3}{2}C_{1,i_m-1}$ holds, then we have $z_{i_m} \le \frac{3}{2}C_{1,i_m}$.*

Proof. Since the mth machine is purchased by step 2.3 (i.e., p_{i_m} is not assigned by step 2.2), there exists some $\beta > 1$ such that $P_{i_m} = \beta(m-1)^2$, and

$$C_{i_m-1} < s_{i_m-1} + p_{i_m} \le s_{i_m-1} + L \le s_{i_m-1} + m - 1. \tag{4.3}$$

By Lemma 4.5, we get that

$$P_{i_m} \le (m-1)C_{i_m-1} + p_{i_m} \le 2(m-1)^2 + (m-1) \le 3(m-1)^2, \tag{4.4}$$

and thus $\beta \le 3$. We estimate the value of C_{i_m-1} as follows. If $C_{i_m-1} > 3\sqrt{\beta}(m-1) - m$, then we know from (4.3) that $s_{i_m-1} > 3\sqrt{\beta}(m-1) - m - (m-1)$. Therefore

$$\begin{aligned} P_{i_m} &= \sum_{j=1}^{m-1} s_{j,i_m-1} + p_{i_m} \ge (m-2)\, s_{i_m-1} + C_{i_m-1} \\ &> (m-1)\left(3\sqrt{\beta}(m-1) - m\right) - (m-2)\,(m-1) \\ &= (m-1)^2(3\sqrt{\beta} - 2) > \beta(m-1)^2 = P_{i_m}, \end{aligned} \tag{4.5}$$

where the last inequality follows from $1 < \beta \le 3$—a contradiction. Hence we have $C_{i_m-1} \le 3\sqrt{\beta}(m-1) - m$. With this estimation, we obtain

$$z_{i_m} = C_{i_m-1} + m \le 3\sqrt{\beta}(m-1) = 3\sqrt{P_{i_m}} = \frac{3}{2}C_{1,i_m},$$

or

$$z_{i_m} = p_{i_m} + m \le 2m - 1 < 3(m-1) < 3\sqrt{\beta}(m-1) = \frac{3}{2}C_{1,i_m}. \quad ∎$$

LEMMA 4.7. *If the $(m-1)$th machine is purchased by step 2.3, where $m > m_0+1$, then so is the mth machine. It follows that $H3$ will not enter step 2.4 since then, i.e., all remaining new machines (if necessary) are purchased by step 2.3.*

Proof. If $P_{i_m} > (m-1)^2$, i.e., all the arrived jobs have total size greater than $(m-1)^2$ before purchasing the mth machine, then the algorithm enters step 2.3 by the rule, and the statement is clearly true. Hence we assume that $P_{i_m-1} \le P_{i_m} \le (m-1)^2$. Since the $(m-1)$th machine is purchased by step 2.3, we get $P_{i_m-1} \ge P_{i_{m-1}} > (m-2)^2$ by the algorithm rule.

To prove that the mth machine must be purchased by step 2.3, we verify that $s_{i_m-1} + p_{i_m} + m - 1 \le \frac{3}{2} C_{1,i_m}$. To see it, since $s_{i_m-1} \le \frac{P_{i_m-1}}{m-1}$ by averaging argument and $C_{1,i_m} = 2\sqrt{P_{i_m-1} + p_{i_m}}$, it suffices to verify that

$$\frac{P_{i_m-1}}{m-1} + p_{i_m} + m - 1 - 3\sqrt{P_{i_m-1} + p_{i_m}} \le 0. \tag{4.6}$$

The derivative of the left side of (4.6) with respect to P_{i_m-1} is $\frac{1}{m-1} - \frac{3}{2\sqrt{P_{i_m-1}+p_{i_m}}}$. From $P_{i_m-1} \le (m-1)^2$ and $p_{i_m} \le L \le m-2$, we know that the derivative is negative. Thus from $P_{i_m-1} > (m-2)^2$, it suffices to show that

$$\frac{(m-2)^2}{m-1} + p_{i_m} + m - 1 - 3\sqrt{(m-2)^2 + p_{i_m}} \le 0, \tag{4.7}$$

i.e.,

$$2m - 4 + \frac{1}{m-1} + p_{i_m} - 3\sqrt{(m-2)^2 + p_{i_m}} \le 0. \tag{4.8}$$

The derivative of the left side of (4.8) with respect to p_{i_m} is $1 - \frac{3}{2\sqrt{(m-2)^2+p_{i_m}}} > 0$ because $m > m_0 + 1 \ge 5$. Since $p_{i_m} \le m-2$, $\frac{1}{m-1} < 1$, and $3m - 5 - 3\sqrt{(m-2)^2 + m - 2} \le 0$, we can conclude that (4.8) is true. The lemma is thus proved. □

Remark 4.1. From Lemmas 4.6 and 4.7, we can conclude that once a new machine is purchased by step 2.3—and at this time the competitive ratio of $H3$ is no greater than 3/2—then the competitive ratio cannot become worse than 3/2 after that. For example, if the (m_0+1)th machine is purchased by step 2.3, then from Lemma 4.4, we conclude that the competitive ratio of $H3$ must be no greater than 3/2 after assigning all jobs. Take another example: if there exists some $m \ge m_0 + 1$ such that $P_{i_m} > (m-1)^2$, and the competitive ratio is not greater than 3/2 before purchasing the mth machine, then we can also conclude that the competitive ratio of $H3$ must be no greater than 3/2 after assigning all jobs. Hence we assume that $P_{i_m} \le (m-1)^2$ for every $m \ge m_0 + 1$.

LEMMA 4.8. $s_{i_{m_0+1}-1} > \frac{m_0}{2}$.

Proof. Otherwise $s_{i_{m_0+1}-1} + p_{i_{m_0+1}} + m_0 \le \frac{3}{2} m_0 + L$. Analogous to the proof of Lemma 4.4, we get that $\frac{3}{2} m_0 + L \le 3\sqrt{\frac{3}{4} L m_0} \le \frac{3}{2} C_{1,s_{i_{m_0+1}}}$. Then it follows that the (m_0+1)th machine is purchased by step 2.3, and by Remark 4.1 the proof is complete. □

LEMMA 4.9. *If $m_0 \le 11$ and $P_{i_{m_0+1}} \le m_0^2$, then $s_{i_{m_0+1}-1} + p_{i_{m_0+1}} + m_0 \le \frac{3}{2} C_{1,i_{m_0+1}}$. It follows that the (m_0+1)th machine is purchased by step* 2.3.

Proof. Otherwise, we have

$$s_{i_{m_0+1}-1} + p_{i_{m_0+1}} + m_0 > \frac{3}{2} C_{1,i_{m_0+1}} = 3\sqrt{P_{i_{m_0+1}}}, \tag{4.9}$$

and the (m_0+1)th machine would be purchased by step 2.4. We distinguish two cases according to the value of $s_{i_{m_0+1}-1}$ to get a contradiction.

Case 1. $s_{i_{m_0+1}-1} \geq \frac{3}{4}L$. Because $P_{i_{m_0+1}} \geq s_{i_{m_0+1}-1}m_0 + p_{i_{m_0+1}}$, (4.9) implies that

$$s_{i_{m_0+1}-1} + p_{i_{m_0+1}} + m_0 - 3\sqrt{s_{i_{m_0+1}-1}m_0 + p_{i_{m_0+1}}} > 0. \tag{4.10}$$

The derivative of the left side of (4.10) with respect to $p_{i_{m_0+1}}$ is

$$1 - \frac{3}{2\sqrt{s_{i_{m_0+1}-1}m_0 + p_{i_{m_0+1}}}} > 0$$

because $m_0 \geq L > 3$ and $s_{i_{m_0+1}-1} \geq \frac{3}{4}L$. Thus it follows from $p_{i_{m_0+1}} \leq L$ that

$$s_{i_{m_0+1}-1} + L + m_0 - 3\sqrt{s_{i_{m_0+1}-1}m_0 + L} > 0. \tag{4.11}$$

Again, the derivative of the left side of (4.11) with respect to $s_{i_{m_0+1}-1}$ is

$$1 - \frac{3m_0}{2\sqrt{s_{i_{m_0+1}-1}m_0 + L}}.$$

$P_{i_{m_0+1}} \leq m_0^2$ implies $s_{i_{m_0+1}-1} \leq m_0$. Combining it with $s_{i_{m_0+1}-1}m_0 + L \leq m_0^2 + m_0 < \frac{9}{4}m_0^2$, we know that the derivative is negative. Because $s_{i_{m_0+1}-1} \geq \frac{3}{4}L$, it follows from (4.11) that

$$\frac{3}{4}L + L + m_0 > 3\sqrt{\frac{3}{4}Lm_0 + L}, \tag{4.12}$$

i.e., $(\frac{7}{4}L + m_0)^2 > (3\sqrt{\frac{3}{4}Lm_0 + L})^2$. Therefore we have

$$f_6(L) \doteq 49L^2 - (52m_0 + 144)\,L + 16m_0^2 > 0 \tag{4.13}$$

for any $L > 3$ and $m_0 = \lceil L \rceil \geq 4$.

On the other hand, it is clear that the function $f_6(L)$ achieves the maximum value at $L = m_0$ if $m_0 > 4$, and at $L = m_0 - 1$ if $m_0 = 4$. Therefore the maximum value is $f_6(3) = 49 \cdot 3^2 - (52 \cdot 4 + 144)\,3 + 16 \cdot 4^2 = -359 < 0$ if $m_0 = 4$, or $f_6(m_0) = 49m_0^2 - (52m_0 + 144)\,m_0 + 16m_0^2 < 0$ if $4 < m_0 \leq 11$, which contradicts (4.13).

Case 2. $s_{i_{m_0+1}-1} < \frac{3}{4}L$. Then from (4.9) and Lemma 4.2, we get

$$s_{i_{m_0+1}-1} + p_{i_{m_0+1}} + m_0 - 3\sqrt{\frac{3}{4}Lm_0 + p_{i_{m_0+1}}} > 0. \tag{4.14}$$

Again, the derivative of the left side with respect to $p_{i_{m_0}+1}$ is positive; thus it follows from $p_{i_{m_0}+1} \leq L$ that

$$s_{i_{m_0+1}-1} + L + m_0 - 3\sqrt{\frac{3}{4}Lm_0 + L} > 0. \tag{4.15}$$

Substituting $s_{i_{m_0+1}-1} < \frac{3}{4}L$ into (4.15), we get (4.11) again. Then the same argument can yield a contradiction. □

By Lemma 4.9, we know that $H3$ may enter step 2.4 only if $m_0 \geq 12$ (and $P_{i_m} \leq (m-1)^2$ for every $m \geq m_0+1$, as declared before). Hence we further assume in the following that $m_0 \geq 12$. Suppose that $H3$ is worse than 3/2-competitive. Then there must exist an m with $m_0+1 \leq m$ such that the mth machine is purchased by step 2.4, and right after assigning p_{i_m} to this machine, $H3$ becomes worse than 3/2-competitive. In the following lemmas we will see that there is no such m. Next Lemmas 4.10–4.12 consider the case $m_0 \leq m \leq 2m_0$, and Lemmas 4.13 and 4.14 consider the case $m > 2m_0$.

LEMMA 4.10. *For every $m_0 \leq m \leq 2m_0$, we have $p_{i_{m+1}} > s_{i_{m+1}-1}$.*

Proof. First we show that the result is true for $m = m_0$. Suppose in contrast that $p_{i_{m_0+1}} \leq s_{i_{m_0+1}-1}$. We show that $s_{i_{m_0+1}-1} + p_{i_{m_0+1}} + m_0 \leq 3\sqrt{P_{i_{m_0+1}}}$, which implies that the (m_0+1)th machine is purchased by step 2.3. It is clear that $P_{i_{m_0+1}} \geq m_0 s_{i_{m_0+1}-1}$. Thus it suffices to prove that $2s_{i_{m_0+1}-1} + m_0 \leq 3\sqrt{m_0 s_{i_{m_0+1}-1}}$. This is equivalent to $\frac{1}{4} \leq \frac{s_{i_{m_0+1}-1}}{m_0} \leq 1$, which is obviously true since $s_{i_{m_0+1}-1} > \frac{m_0}{2}$ by Lemma 4.8 and $s_{i_{m_0+1}-1} \leq \frac{P_{i_{m_0+1}-1}}{m_0} \leq m_0$. Hence we get $p_{i_{m_0+1}} > s_{i_{m_0+1}-1}$.

Since the minimum current machine load is not decreased before or right when a new machine is purchased, hence we know that $s_{i_{m_0+2}-1} \geq \min\{p_{i_{m_0+1}}, s_{i_{m_0+1}-1}\} > \frac{m_0}{2}$. On the other hand, $s_{i_{m_0+2}-1} \leq \frac{P_{i_{m_0+2}-1}}{m_0+1} \leq m_0+1$, and hence we have $\frac{1}{4} \leq \frac{s_{i_{m_0+2}-1}}{m_0+1} \leq 1$. Then by the same argument as above we can show that $p_{i_{m_0+2}} > s_{i_{m_0+2}-1}$. The result for other $m = m_0+2, \ldots, 2m_0$ can be obtained similarly. ∎

Remark 4.2. By Lemma 4.10, we know that through $m_0 \leq m \leq 2m_0$, the minimum current machine load is not decreased. That is, $s_{i_{m+1}-1} \geq s_{i_{m_0+1}-1}$ for any $m_0+1 \leq m \leq 2m_0$. Furthermore if $s_{i_{m_0+1}-1} \geq \frac{3}{4}L$, then $p_{i_{m+1}} \geq s_{i_{m_0+1}-1} \geq \frac{3}{4}L$ for all $m_0 \leq m \leq 2m_0$, and thus from Lemma 4.2, we get $P_{i_m} \geq P_{i_{m_0}} + p_{i_{m_0+1}} + \cdots + p_{i_m} \geq \frac{3}{4}Lm_0 + \frac{3}{4}L\,(m-m_0) = \frac{3}{4}Lm$ for every $m_0 \leq m \leq 2m_0$.

LEMMA 4.11. *For every $m_0 \leq m \leq 2m_0$, we have $p_{i_{m+1}} \geq \frac{3}{4}L$, and thus $P_{i_m} \geq \frac{3}{4}Lm$.*

Proof. Suppose $p_{i_{m_0+1}} < \frac{3}{4}L$. By Remark 4.2, we only need to consider the case $s_{i_{m_0+1}-1} < \frac{3}{4}L$. It suffices to show that $s_{i_{m_0+1}-1} + p_{i_{m_0+1}} + m_0 \leq 3\sqrt{P_{i_{m_0+1}}}$, which implies that the (m_0+1)th machine is purchased by step 2.3, and we are done by Remark 4.1. Because of $s_{i_{m_0+1}-1} < \frac{3}{4}L$, we only need to show that $\frac{3}{2}L + m_0 \leq 3\sqrt{\frac{3}{4}Lm_0}$. This is equivalent to $\frac{1}{3} \leq \frac{L}{m_0} \leq \frac{4}{3}$, which is obviously true. Hence we have $p_{i_{m_0+1}} \geq \frac{3}{4}L$ and thus $P_{i_{m_0+1}} \geq \frac{3}{4}L(m_0+1)$ by an argument similar to that in Remark 4.2. The result for $m = m_0+1, \ldots, 2m_0$ can be obtained similarly one by one. ∎

LEMMA 4.12. *If for some $m_0 \leq m \leq 2m_0$, the $(m+1)$th machine is purchased by step 2.4, and $z_{i_{m+1}-1} \leq \frac{3}{2}C_{1,i_{m+1}-1}$ holds, then we have $z_{i_{m+1}} \leq \frac{3}{2}C_{1,i_{m+1}}$.*

Proof. If $p_{i_{m+1}} \geq \max\{s_{j,i_{m+1}-1} |\ j = 1, \ldots, m\}$, then it is easy to see that $z_{i_{m+1}} = p_{i_{m+1}} + m + 1 \leq L + m + 1 \leq 3\sqrt{\frac{3}{4}Lm} \leq \frac{3}{2}C_{1,i_{m+1}}$, where the last inequality follows from Lemma 4.11. In the opposite case the objective value is increased by 1, because the makespan remains unchanged. Since $z_{i_{m+1}-1} \leq \frac{3}{2}C_{1,i_{m+1}-1}$ holds, to get the desired result, it suffices to show that $3\sqrt{P_{i_{m+1}-1} + p_{i_{m+1}}} \geq 3\sqrt{P_{i_{m+1}-1}} + 1$, i.e.,

$$p_{i_{m+1}} \geq \frac{2}{3}\sqrt{P_{i_{m+1}-1}} + \frac{1}{9}. \tag{4.16}$$

Let $P_{i_{m+1}-1} = \beta m^2$ with some $\beta \le 1$. From $\frac{L}{m} > \frac{m_0-1}{2m_0} \ge \frac{1}{2} - \frac{1}{24} > \frac{4}{9}$ and Lemma 4.11, we get $P_{i_{m+1}-1} \ge P_{i_m} \ge \frac{3}{4}Lm > \frac{1}{3}m^2$. Thus $\frac{1}{3} < \beta \le 1$. Since the $(m+1)$th machine is purchased by step 2.4, we have

$$s_{i_{m+1}-1} + p_{i_{m+1}} + m > 3\sqrt{P_{i_{m+1}-1}} = 3\sqrt{\beta}m. \tag{4.17}$$

By applying $s_{i_{m+1}-1} \le \frac{P_{i_{m+1}-1}}{m} = \beta m$, we get $p_{i_{m+1}} > \left(3\sqrt{\beta} - \beta - 1\right) m$. Thus (4.16) holds if we can show that

$$\left(3\sqrt{\beta} - \beta - 1\right) m > \frac{2}{3}\sqrt{\beta}m + \frac{1}{9}, \tag{4.18}$$

i.e., $\left(\frac{7}{3}\sqrt{\beta} - \beta - 1\right) m > \frac{1}{9}$. This inequality holds obviously since $\frac{1}{3} < \beta \le 1$ and $m \ge 12$. □

By Lemmas 4.10–4.12, we conclude that the competitive ratio of Algorithm $H3$ must be no greater than 3/2 before the $(2m_0+1)$th machine is purchased.

LEMMA 4.13. *Let m satisfy $m_0 \le m \le 2m_0$. Then we know $p_{i_{m+1}} > y$, where*

$$y = 3\sqrt{\frac{3}{4}Lm_0} - m_0 - \frac{3}{4}L.$$

Proof. By the algorithm rule it is clear that for any $m_0 \le m \le 2m_0$, we have $s_{i_{m+1}-1} + p_{i_{m+1}} + m > \frac{3}{2}C_{1,i_{m+1}} \ge 3\sqrt{s_{i_{m+1}-1}m}$, since otherwise the mth machine is purchased by step 2.3. Hence we obtain

$$p_{i_{m+1}} > 3\sqrt{s_{i_{m+1}-1}m} - s_{i_{m+1}-1} - m. \tag{4.19}$$

Define the function $f(s_t, m) = 3\sqrt{s_t m} - s_t - m$. It is clear that this function is symmetric, and increasing in both variables, since now $s_t < m$ holds. Recall that for any $m_0 \le m_1 < m_2 \le 2m_0$, we have that $s_{i_{m_1}} \le s_{i_{m_2}}$ by Remark 4.2.

If $s_{i_{m+1}-1} \ge \frac{3}{4}L$, we then have

$$\begin{aligned} p_{i_{m+1}} &> 3\sqrt{s_{i_{m+1}-1}m} - s_{i_{m+1}-1} - m \\ &\ge 3\sqrt{s_{i_{m+1}-1}m_0} - s_{i_{m+1}-1} - m_0 \\ &\ge 3\sqrt{s_{i_{m_0+1}-1}m_0} - s_{i_{m_0+1}-1} - m_0 \\ &\ge 3\sqrt{\frac{3}{4}Lm_0} - \frac{3}{4}L - m_0 = y. \end{aligned} \tag{4.20}$$

If $s_{i_{m+1}-1} < \frac{3}{4}L$, then by Lemma 4.11 and the algorithm rule, we have $p_{i_{m+1}} + s_{i_{m+1}-1} + m > \frac{3}{2}C_{1,i_{m+1}} \ge 3\sqrt{\frac{3}{4}Lm}$. Thus we get similarly that

$$\begin{aligned} p_{i_{m+1}} &> 3\sqrt{\frac{3}{4}Lm} - s_{i_{m+1}-1} - m \\ &> 3\sqrt{\frac{3}{4}Lm} - \frac{3}{4}L - m \\ &\ge 3\sqrt{\frac{3}{4}Lm_0} - \frac{3}{4}L - m_0 = y. \end{aligned} \tag{4.21}$$

□

LEMMA 4.14. *The* $(2m_0+1)$*th machine is not purchased by step* 2.4.

Proof. First we consider the case $s_{i_{2m_0+1}-1} \geq \frac{3}{4}L$. By Lemma 4.13, we get that

$$\begin{aligned} P_{i_{2m_0+1}} &\geq m_0 s_{i_{2m_0+1}-1} + p_{i_{m_0+1}} + \cdots + p_{i_{2m_0}} \\ &> m_0 s_{i_{2m_0+1}-1} + m_0 y \\ &= m_0 \left(s_{i_{2m_0+1}-1} + y \right), \end{aligned}$$

where $y = 3\sqrt{\frac{3}{4}Lm_0} - \frac{3}{4}L - m_0$. To get the result, due to $p_{i_{2m_0+1}} \leq L$, we only need to show that

$$L + s_{i_{2m_0+1}-1} + 2m_0 < 3\sqrt{m_0 \left(s_{i_{2m_0+1}-1} + y \right)}. \tag{4.22}$$

By an argument similar to what we have used before, it suffices to prove

$$\frac{7}{4}L + 2m_0 < 3\sqrt{3m_0\sqrt{\frac{3}{4}Lm_0} - m_0^2}, \tag{4.23}$$

which can be verified easily since $L \leq m_0$ and $m_0 \geq 12$.

For the case $s_{i_{2m_0+1}-1} < \frac{3}{4}L$, we have $P_{i_{2m_0+1}} \geq P_{i_{2m_0}} \geq \frac{3}{4}Lm_0 + m_0 y = 3m_0\sqrt{\frac{3}{4}Lm_0} - m_0^2$. Hence we need to show that

$$L + s_{i_{2m_0+1}-1} + 2m_0 < 3\sqrt{3m_0\sqrt{\frac{3}{4}Lm_0} - m_0^2}. \tag{4.24}$$

Since $s_{i_{2m_0+1}-1} < \frac{3}{4}L$, it suffices to prove the stronger inequality (4.23), which can be done by the same argument. □

Combining Lemmas 4.14 and 4.12 and Remark 4.1, we have shown in all cases that Algorithm $H3$ has a competitive ratio no greater than 3/2. We thus finish the proof of Theorem 4.1.

5. Conclusions. Even for the basic online scheduling problem $Pm|online|C_{\max}$, where the machine number m is fixed, we do not know its optimal online algorithm for any $m > 3$; therefore it may not be easy to get the optimal online algorithm for the list model problem, too. In this paper, we first devised an online algorithm with a competitive ratio at most $(2\sqrt{6}+3)/5 \approx 1.5798$. It improves upon the known algorithm, which has a competitive ratio $(1+\sqrt{5})/2 \approx 1.618$. As another attempt to make problem easier to solve, in this paper we considered a special case with small jobs. We presented its optimal online algorithm with a competitive ratio 4/3. We further considered the semionline problem with known largest processing time. A new algorithm with a competitive ratio no greater than 3/2 was presented which improves the known upper bound 1.5309.

To tighten the upper bounds, our algorithms applied new strategies for deciding when to purchase machines. Their decision regarding when to purchase machines depends on the current makespan, and upon the current objective value with respect to the lower bounds of the current optimal value, which is quite different from A_ρ, whose decision simply depends on the total size of arrived jobs. We conjecture that it is valuable to get a tighter lower bound of the optimal value for improving online and semionline algorithms (with competitive analysis). On the other hand, all known algorithms assign jobs to machines in greedy ways (by the classical LS rule). It is well

known that LS is not an optimal algorithm for the problem $Pm|online|C_{\max}$ when $m > 3$. Hence it is interesting whether we can obtain better algorithms by combining the new purchasing strategies and improved algorithms for $Pm|online|C_{\max}$.

Although we have a randomized lower bound $6e/(6e-1) > 1.06532$ for the online list model problem [15], which is clearly also valid for the semionline problem with known largest size, to the best of the authors' knowledge, randomized algorithm is still unknown. Hence it is promising to devise randomized online and semionline algorithms for the discussed problems. It will also be interesting to devise improved algorithms for other semionline problems of the list model.

SOLVING EQUATIONS IN THE RELATIONAL ALGEBRA*

JOACHIM BISKUP†, JAN PAREDAENS‡,
THOMAS SCHWENTICK§, AND JAN VAN DEN BUSSCHE¶

Abstract. Enumerating all solutions of a relational algebra equation is a natural and powerful operation which, when added as a query language primitive to the nested relational algebra, yields a query language for nested relational databases, equivalent to the well-known powerset algebra. We study *sparse* equations, which are equations with at most polynomially many solutions. We look at their complexity and compare their expressive power with that of similar notions in the powerset algebra.

Key words. relational algebra, equation, nested relation, Fagin's theorem, sparse expression, parity

1. Introduction.

Suppose we are allowed to see only a view on a database B, computed by a relational algebra expression e. If we still want to find out what B is, we might try to "invert" e (assuming we know this expression), which will only work when we also know the finite domain D of B. Specifically, we can enumerate all databases X over D, and test for each X whether it satisfies the equation $e(X) = e(B)$. One of these solutions will be B, of course, so if the set of all solutions is not too big, it might provide us with useful information for starting our detective work.

The above simple scenario from database security led us to wonder what can be said in general about the solution of equations in the relational algebra. Generally, if e_1 and e_2 are two algebra expressions over some database schema augmented with some relation variables $X_1, \ldots, X_p$, we can consider the equation $e_1 = e_2$. A *solution* of this equation, given a database B with finite domain D, is a tuple $(X_1, \ldots, X_p)$ of relations over D such that e_1 and e_2 evaluate to the same relation on the augmented database $(B, X_1, \ldots, X_p)$.

Asking whether there exists a solution of a relational algebra equation on a database is almost exactly the same thing as asking whether an existential second-order logic sentence is true on that database. Hence, by Fagin's theorem [Fag74, EF95], the problems that can be formulated as finding a solution of some relational algebra equation are nothing but the problems in NP.

However, in the present paper, we start from the observation that the set of all solutions of an equation, being a set of tuples of relations, is a *nested* relation. One can therefore consider the enumeration of all solutions of an equation as a query language primitive, which can be added to the nested relational algebra. We introduce and study this extension of the nested relational algebra, which we call the *equation*

algebra. The equation algebra is extremely powerful: it is equivalent to the well-known powerset algebra for nested relations. Our particular interest, however, is in what can be expressed in the equation algebra by using only equations that have a solution set of polynomial size on each database. We call such equations *sparse*.

Our interest in sparse equations does not stem from time efficiency considerations. Indeed, it is not obvious how knowing that an equation is sparse would help in actually finding even one solution more quickly. Neither is it obvious, however, that it would *not* help. For example, consider the problem of checking on a given database whether some fixed sparse relational algebra equation has a solution. Using an extension of Fagin's theorem to nested relational databases, we show that this problem can be NP-hard only if every problem in NP can already be decided by a polynomial-time nondeterministic Turing machine that has only polynomially many accepting computations on each input. The latter is one of the many unresolved questions in computational complexity theory [All86].

Nevertheless, sparse equations are still interesting from a space efficiency standpoint. Indeed, for the natural evaluation strategy for equation algebra expressions to run in polynomial space, it is necessary that all equations occurring in the expression be sparse. Interest in fragments of powerful query languages for which the natural evaluation strategy is polynomial-space is not new to database theory research. For example, Abiteboul and Vianu [AV91] showed that the parity query is not expressible in the polynomial-space fragment of various computationally complete query languages.

Closer to our topic is the work of Suciu and Paredaens [SP97], who showed that queries such as transitive closure and parity are not expressible in the polynomial-space fragment of the powerset algebra for nested relations. This fragment consists of all powerset algebra expressions where all intermediate results are of polynomial size, on each database. Note that this fragment does make sense, as there are expressions that always produce a result of logarithmic size; applying the (exponential) powerset operator to such expressions produces a result of polynomial size.

We also mention Grumbach and Vianu [GV95], who also studied a sparsity notion in connection with queries over nested relational databases, although they considered sparsity as a property of databases rather than of query language expressions.

Suciu and Paredaens conjectured in general that the polynomial-space fragment of the powerset algebra has no more power than the nested relational algebra without powerset. (This conjecture has been confirmed for monadic database schemas [VdB].) At first sight, the operator that we add to the nested relational algebra, to enumerate all solutions of an equation, does not seem to be that different from the powerset operator. After all, both operators perform some kind of potentially exponential enumeration.

Yet, as we will point out, the analogue of the Suciu–Paredaens conjecture does not hold for the sparse fragment of the equation algebra. Specifically, using sparse equations only, we can express transitive closure; in fact, we can express any fixpoint query. This complements a result by Abiteboul and Hillebrand [AH95], who showed that transitive closure becomes expressible in the powerset algebra in polynomial space, provided we use a more clever "pipelined" evaluation strategy. Actually, every fixpoint query is already expressible using equations that are not just sparse, but even unambiguous: they have a unique solution on each database. Unambiguous equations in the relational algebra are known as *implicit definitions* in first-order logic, and were studied in the context of finite model theory by Kolaitis [Kol90]. Kolaitis already showed that every fixpoint query can be implicitly defined. We offer

a straightforward, direct proof.

Another example of the differences between the sparse fragment of the equation algebra and that of the powerset algebra is given by the well-known nesting operator of the nested relational algebra. This operator becomes redundant once we extend the algebra with the solution operator or with the powerset operator. However, the original nesting operator never blows up exponentially. We show that, without using the nesting operator itself, nesting is expressible in the equation algebra using sparse equations only, but that the same is not possible with a polynomial-space powerset algebra expression.

However, there are also similarities between the two fragments. Specifically, we prove an analogue to the Suciu–Paredaens result, to the effect that the parity query is not expressible in the sparse fragment of the equation algebra either. This is our main technical contribution; the proof is in the style of an elegant argument of Liebeck [Lie83], invoking Bochert's theorem on the order of primitive permutation groups. Coming back to connection with implicit definitions in first-order logic, our result generalizes the known and easy fact that the parity query cannot be defined implicitly [Kol90], in two directions: from unambiguous to sparse, and from a single equation to an arbitrarily complex expression involving several, possibly nested, equations.

This paper is organized as follows. Section 2 recalls the nested relational data model. Section 3 introduces relational algebra equations. Section 4 introduces the equation algebra. Section 5 introduces sparse equations, as well as the natural evaluation strategy for equation algebra expressions. Section 6 studies the time complexity of sparse equations. Finally, section 7 presents the comparison with the polynomial-space powerset algebra.

2. Preliminaries. We quickly recall the nested relational data model and algebra [TF86, AHV95].

Relation types are defined as follows. The symbol 0 is a type, and, if $\tau_1, \ldots, \tau_k$ are types, then so is $(\tau_1, \ldots, \tau_k)$. For a type τ and some set D of atomic values, the *relations of type τ on D* are inductively defined as follows. A relation of type 0 on D is just an element of D (this serves merely as the base case for the induction). A relation of type $(\tau_1, \ldots, \tau_k)$ on D is a set of k-tuples $(x_1, \ldots, x_k)$ such that x_i is a relation of type τ_i on D for $i = 1, \ldots, k$.

A *database schema* is a finite set $\mathcal{S}$ of relation names, where each relation name has an associated type different from 0. A *database* B over $\mathcal{S}$ consists of a nonempty finite domain D of atomic values, together with, for each relation name R in $\mathcal{S}$, a relation R^B of type τ on D, where τ is the type of R.

The operators of the nested relational algebra are those of the standard relational algebra (union $\cup$ and difference $-$ of relations of the same type; Cartesian product $\times$; projection π; selection σ for equality, which can now be set-equality of nested relations), plus the operators *nesting* ν and *unnesting* μ, defined as follows.

Let R be a relation of type $(\tau_1, \ldots, \tau_k)$, and let $i_1, \ldots, i_p \in \{1, \ldots, k\}$. Then the nesting $\nu_{i_1,\ldots,i_p}(R)$ equals the relation

$$\Big\{\Big(x_1, \ldots, x_k, \big\{(y_{i_1}, \ldots, y_{i_p}) \mid (y_1, \ldots, y_k) \in R \text{ and } x_j = y_j \text{ for each } j \in \{1, \ldots, k\} - \{i_1, \ldots, i_p\}\big\}\Big) \;\Big|\; (x_1, \ldots, x_k) \in R\Big\}$$

of type $(\tau_1, \ldots, \tau_k, (\tau_{i_1}, \ldots, \tau_{i_p}))$.

Let R be as in the previous paragraph, and let $i \in \{1, \ldots, k\}$ such that $\tau_i \neq 0$; thus τ_i is of the form $(\omega_1, \ldots, \omega_\ell)$. Then the unnesting $\mu_i(R)$ equals the relation

$$\{(x_1, \ldots, x_k, y_1, \ldots, y_\ell) \mid (x_1, \ldots, x_k) \in R \text{ and } (y_1, \ldots, y_\ell) \in x_i\}$$

of type $(\tau_1, \ldots, \tau_k, \omega_1, \ldots, \omega_\ell)$.

The expressions of the *nested relational algebra* over a schema $\mathcal{S}$ are now built up using the above operators from the relation names in $\mathcal{S}$ and the symbol D, which stands for the finite domain of the input database. The relation to which an expression e evaluates on a database B is denoted by $e(B)$.

One can extend the nested relational algebra to the *powerset algebra* by adding the powerset operator, defined as follows. Let R be a relation of type $(\tau_1, \ldots, \tau_k)$. Then the powerset $\Pi(R)$ equals the relation $\{S \mid S \subseteq R\}$ of type $((\tau_1, \ldots, \tau_k))$.

3. Equations. Let $\mathcal{S}$ and $\mathcal{X}$ be disjoint database schemas; $\mathcal{S}$ is the actual database schema, while $\mathcal{X}$ is thought of as a set of additional relation variables. Let e_1 and e_2 be two expressions over the expanded schema $\mathcal{S} \cup \mathcal{X}$.

DEFINITION 3.1. *Given a database B over $\mathcal{S}$, a* solution to the equation $e_1 = e_2$ *is a database A over $\mathcal{X}$ with the same finite domain as B, such that $e_1(B, A) = e_2(B, A)$.*

Here, (B, A) denotes the expansion of B with A, i.e., the database over $\mathcal{S} \cup \mathcal{X}$ that has the same finite domain as B, that equals B on $\mathcal{S}$, and that equals A on $\mathcal{X}$.

Example 3.2. For a very simple example, let $R \in \mathcal{S}$ and let $\mathcal{X} = \{X\}$, where X has the same type as R. Then $X \cup R = R$ is an equation. Given a database B over $\mathcal{S}$, a database A over $\{X\}$ is a solution if and only if $X^A \subseteq R^B$.

For another example, let X be a relation variable of type $(0, 0)$. One can write a relational algebra expression e such that on any database A over $\{X\}$ with finite domain D, $e(A)$ is empty if and only if X^A is one-to-one, the projections $\pi_1(X^A)$ and $\pi_2(X^A)$ are disjoint, and their union equals D. An example of an e that works is

$$\begin{aligned}\pi_1\sigma_{2\neq 4}\sigma_{1=3}(X \times X) \cup \pi_2\sigma_{2=4}\sigma_{1\neq 3}(X \times X) \\ \cup \big(\pi_1(X) - (\pi_1(X) - \pi_2(X))\big) \\ \cup \big(D - (\pi_1(X) \cup \pi_2(X))\big) \cup \big((\pi_1(X) \cup \pi_2(X)) - D\big).\end{aligned}$$

Then the equation $e = \varnothing$ has a solution on a database B with finite domain D if and only if the cardinality of D is even. (Technically, $e = \varnothing$ is not an equation because the symbol $\varnothing$ is not an expression, but we can easily take $\varnothing$ here to stand for the expression $D - D$, which always evaluates to the empty relation.) □

Remark 3.3. In the above example, we used an equation of the special form $e = \varnothing$. Actually, this form is not so special at all, because any equation $e_1 = e_2$ can be brought in this form as $e_1 \,\Delta\, e_2 = \varnothing$, where $e_1 \,\Delta\, e_2$ stands for $(e_1 - e_2) \cup (e_2 - e_1)$ (symmetric difference).

Alternatively, one might wonder about the use of *dis*equations, of the form $e \neq \varnothing$. These are nothing but equations in disguise, because they can also be written as $\pi_1(D \times e) = D$. Conversely, any equation $e_1 = e_2$ can also be written as the disequation $D - \pi_1(D \times (e_1 \,\Delta\, e_2)) \neq \varnothing$. □

4. The equation algebra. We are now ready to extend the nested relational algebra with a solution operator for equations. We refer to the resulting algebra as the *equation algebra*.

To allow for an elegant definition, we do not fix a schema $\mathcal{S}$ in advance. Rather, we assume a sufficiently large supply of relation names of all possible types. Any relation name can now occur in an expression. Like in logic formulas, some will occur *free* and others will occur *bound*. Bound relation names are bound by the solution of an equation, and serve as the variables of the equation. Within the equation, however, they are still free. We denote the set of relation names that occur free in an equation algebra expression e by $\mathit{free}(e)$.

For the constructs of the nested relational algebra, this is all straightforward: for a relation name R, we have $\mathit{free}(R) := \{R\}$; for expressions e of the form $(e_1 \cup e_2)$, $(e_1 - e_2)$, or $(e_1 \times e_2)$, we have $\mathit{free}(e) := \mathit{free}(e_1) \cup \mathit{free}(e_2)$; for expressions e of the form $\sigma(e')$, $\pi(e')$, $\nu(e')$, or $\mu(e')$, we have $\mathit{free}(e) := \mathit{free}(e')$. For the expression D, we have $\mathit{free}(D) := \varnothing$.

The definition of the new solution operator is now the following.

DEFINITION 4.1. *Let e_1 and e_2 be expressions, and let $X_1, \ldots, X_p$ be a sequence of distinct relation names. Then*

$$\{(X_1, \ldots, X_p) \mid e_1 = e_2\}$$

is also an expression (called a solution expression). We define its free *set as* $(\mathit{free}(e_1) \cup \mathit{free}(e_2)) - \{X_1, \ldots, X_p\}$. *We say that the X_i* become bound.

Note that this is a recursive definition, in the sense that e_1 and e_2 can contain solution operators in turn. To avoid clutter, we disallow equation algebra expressions in which a free relation name at the same time becomes bound in some subexpression, as in $X \times \{(X) \mid X \cup R = R\}$.

An expression e in the equation algebra can be evaluated on databases B over any schema that contains $\mathit{free}(e)$. We already know how this evaluation is defined for the constructs of the nested relational algebra. So we only have to give the following definition.

DEFINITION 4.2. *For a solution expression, e, of the form $\{(X_1, \ldots, X_p) \mid e_1 = e_2\}$, and a database B, the evaluation $e(B)$ equals the relation*

$$\{(X_1^A, \ldots, X_p^A) \mid A \text{ is a database over } \{X_1, \ldots, X_p\} \text{ that is a solution of } e_1 = e_2, \text{ given } B\}.$$

This relation is of type $(\tau_1, \ldots, \tau_p)$, where τ_i is the type of X_i for $i = 1, \ldots, p$.

Example 4.3. Recall the simple example equation $X \cup R = R$ from Example 3.2. We can turn this equation into the following equation algebra expression e: $\{(X) \mid X \cup R = R\}$, or, more readibly, $\{(X) \mid X \subseteq R\}$. Note that $\mathit{free}(e) = \{R\}$. On any database B over $\{R\}$, the relation $e(B)$ equals $\Pi(R^B)$ (recall the powerset operator Π from section 2). In other words, the equation algebra expression e is equivalent to the powerset algebra expression $\Pi(R)$.

The equation algebra allows equations to be used inside equations. For example, if we want to compute the powerset of the powerset of R, we can write:

$$\big\{(Y) \mid Y \subseteq \{(X) \mid X \subseteq R\}\big\}.$$

As a third example, let R and T be relation names of the same binary type (τ, τ) for some τ. One can write a relational algebra expression e_{tc} such that on any database C over $\{R, T\}$, e_{tc} is empty if and only if $R^C \subseteq T^C$ and T^C is transitively closed. One can also write a nested relational algebra expression $e_{\min}$ that selects, out

of a set of binary relations, the minimal ones w.r.t. set inclusion. Explicit forms for e_{tc} and $e_{\min}$ have been given by Gyssens and Van Gucht [GVG]. Then the following equation algebra expression computes the transitive closure of relation R:

$$\pi_{2,3}\mu_1 e_{\min}\big(\{(T) \mid e_{\mathrm{tc}} = \varnothing\}\big).$$

Indeed, the subexpression $\{(T) \mid e_{\mathrm{tc}} = \varnothing\}$ returns the collection of all transitively closed relations on the same domain as R and containing R; applying $e_{\min}$ to that collection results in the singleton consisting of the minimal element, i.e., the transitive closure of R (by definition of transitive closure); applying unnesting μ_1 produces the actual tuples in the transitive closure, keeping the nested relation (cf. our definition of the effect of μ in section 2); and applying $\pi_{2,3}$ finally removes the nested relation. □

In the above example we saw that the powerset operator is expressible in the equation algebra. Conversely, the solution operator is easily expressed in the powerset algebra. Hence, we obtain the following.

PROPOSITION 4.4. *The equation algebra is equivalent to the powerset algebra.*

Proof. To see that $\{(X_1, \ldots, X_p) \mid e_1 = e_2\}$ can be expressed in the powerset algebra, we begin by noting that for any relation type τ one can write a powerset algebra expression Π^τ yielding the collection of all relations of type τ on D. For example, $\Pi^{(0,0)}$ is $\Pi(D \times D)$, and $\Pi^{(0,(0))}$ is $\Pi(D \times \Pi(D))$. Hence, if the type of X_i is τ_i for $i = 1, \ldots, p$, then $\Pi^{\tau_1} \times \cdots \times \Pi^{\tau_p}$ yields the collection of all potential solutions. Now it suffices to observe that one can write nested relational algebra expressions that apply e_1 or e_2 to each database in this collection separately. Explicit forms of such expressions have been given by Gyssens and Van Gucht [GVG]. After that, the actual solutions can be selected by an equality selection. □

5. Sparse equations. So far, the equation algebra is merely another syntax for the powerset algebra, or, if you want, higher-order logic. However, when we consider a natural evaluation strategy for equation algebra expressions, we start to notice some differences.

By the natural strategy to evaluate a solution expression of the form $\{(X_1, \ldots, X_p) \mid e_1 = e_2\}$, we mean the following. Enumerate all databases A over $\{X_1, \ldots, X_p\}$, on the finite domain of the given input database, *one by one, reusing the same space.* For each A we test whether it is a solution (by recursively evaluating e_1 and e_2), and if so, we include it in the result.

For the constructs of the nested relational algebra, the natural evaluation strategy is clear: if we have to evaluate an expression of the form $e_1 \,\Theta\, e_2$, with $\Theta \in \{\cup, -, \times\}$, we create two intermediate results by recursively evaluating e_1 and e_2, and then apply Θ to these two intermediate results. Similarly, if we have to evaluate an expression of the form $\theta(e)$, with $\theta \in \{\pi, \sigma, \nu, \mu\}$ (and parameters added in subscript), we create an intermediate result by recursively evaluating e, and then apply θ to this intermediate result.

In view of this natural evaluation strategy, we now propose the following.

DEFINITION 5.1. *An equation is called* sparse *if all its relation variables are of* flat *type, i.e., of the form* $(0, \ldots, 0)$*, and the number of solutions on any given database is at most polynomial in the size of that database.*

Example 5.2. The two equations from Example 3.2 are not sparse. Probably the simplest example of a nontrivial sparse equation is the following. Let X be a relation name of type (0). One can write a relational algebra expression e over $\{X\}$ such that on any database A over $\{X\}$, $e(A)$ is empty if and only if X^A is a singleton. Then the equation $e = \varnothing$, where X is taken as the relation variable to be solved for, is sparse.

Indeed, given any database B with finite domain D, the solutions are precisely all singleton subsets of D. There clearly are only a linear (and thus at most polynomial) number of possible solutions. □

Remark 5.3. A natural alternative definition of sparsity would be the one where, in Definition 5.1, we would look only at databases over the schema consisting of the relation names that actually occur free in the equation. One easily sees, however, that this alternative definition yields the same notion of sparsity. □

Sparse equations are connected to the natural evaluation strategy in the following way.

PROPOSITION 5.4. *The natural strategy for evaluating an equation algebra expression e runs in polynomial space if and only if all equations occurring in e are sparse.*

Here, we count not only the space occupied by the intermediate results stored during evaluation, but also the size of the final result.

Proof. The if direction is clear. For the only-if direction, we work by induction on the nesting depth of equations. The base case—expressions that do not contain any equations at all—is trivial.

For the inductive step, consider a top-level equation $\{(X_1, \ldots, X_p) \mid e_1 = e_2\}$ occurring in e. The natural strategy for evaluating this equation runs in polynomial space, so in particular, for each expansion of each database B over $\mathit{free}(e)$ with a candidate solution A over $\{X_1, \ldots, X_p\}$, the natural evaluation of e_1 and e_2 on (B, A) runs in polynomial space. In this way we consider every possible database C over $\mathit{free}(e) \cup \{X_1, \ldots, X_p\}$, because the restriction of C to $\mathit{free}(e)$ is a possible B, and C itself then is a possible expansion of B. Hence, the natural evaluation strategies of e_1 and e_2 in general run in polynomial space.

Formally, we must note here that e_1 and e_2 might not actually mention certain relation names in $\mathit{free}(e)$ or $\{X_1, \ldots, X_p\}$, and that there is still the formal possibility that their natural evaluation might not run in polynomial space on databases over schemas not containing these names. However, using Remark 5.3, it can be seen that this is impossible.

By induction, we can therefore conclude that all equations occurring nested inside a top-level equation are sparse.

The top-level equation itself must also be sparse. In proof, if one of the X_i would be of nonflat type, even one candidate solution can already be of exponential size. Indeed, even in the simplest case where X_i would be of type $((0))$, on a domain with n elements, a possible candidate value for X_i is the collection of all subsets of that domain, which is of size 2^n. Thus, every X_i is of flat type. Furthermore, since we store the solution set as an intermediate result, it must be of at most polynomial size on all databases over $\mathit{free}(e)$. Since the individual solutions are flat databases and thus of polynomial size, the cardinality of the solution set must therefore be at most polynomial. □

6. Time complexity of equation nonemptiness. The *time* complexity of solving sparse equations is closely linked to an open question from computational complexity theory. Unlike the previous section, in this section we are not talking about the natural evaluation strategy, whose time complexity is clearly at least exponential as soon as there are equations to be solved. Instead, we will be looking at the time complexity of the *nonemptiness problem* of equations.

The nonemptiness problem of an equation over a schema $\mathcal{S}$ with relation variables $\mathcal{X}$ is the problem of deciding, given a database over $\mathcal{S}$, whether the equation has a

solution on that database. *In the present section we will consider only equations that do not contain equations inside.*

Let us begin by considering equations that are not necessarily sparse but that still have only flat variables. The nonemptiness problem of such a flat-variable equation is clearly in NP. Now suppose, moreover, that the database schema $\mathcal{S}$ is also flat; then $\mathcal{S} \cup \mathcal{X}$ (the expansion of $\mathcal{S}$ with the relation variables of the equation) is an entirely flat schema. Of course, the equation $e_1 = e_2$ is still in general in the *nested* relational algebra; i.e., e_1 and e_2 can contain ν and μ operators. A result by Paredaens and Van Gucht [PVG92], however, implies that the nested relational algebra condition $e_1 = e_2$ can also be expressed in the form $e \neq \varnothing$, with e a *flat* relational algebra expression. The nonemptiness problem of the equation thus amounts to asking whether $\{(X_1, \ldots, X_p) \mid e \neq \varnothing\}$ is nonempty on a given database B over $\mathcal{S}$. Equivalently, we ask whether the existential second-order logic ($\exists$SO) sentence $\exists X_1 \ldots \exists X_p \, \varphi_e$ is true on B, where φ_e is a first-order logic sentence expressing that $e \neq \varnothing$. Moreover, by the equivalence of relational algebra and first-order logic, *any* $\exists$SO property can be obtained in this way. Now, Fagin's theorem [Fag74, EF95] states that $\exists$SO captures exactly the NP properties of flat relational databases. Hence, *the class of nonemptiness problems of flat-variable equations over flat database schemas is exactly the class of NP properties of flat relational databases.*

What if $\mathcal{S}$ is not necessarily flat? We next show that we still get exactly NP. In essence, this is an extension of Fagin's theorem to nested relational databases.

PROPOSITION 6.1. *Every property of nested relational databases over some fixed schema $\mathcal{S}$ that is in NP and closed under isomorphism corresponds to the nonemptiness problem of some flat-variable equation over $\mathcal{S}$.*

Proof. The crux is a representation of nested relational databases by "pseudoflat" ones, also used by Gyssens, Suciu, and Van Gucht [GSVG01]. Given a nested relational database B, we define its *extended domain*, denoted by $\mathrm{edom}(B)$, as the union of its finite domain of atomic values with the set of all relations occurring (possibly deeply nested) in B. We regard the relations in the extended domain as if they were atomic values. Now for any nested relational database schema $\mathcal{S}$ we can construct a flat one $\bar{\mathcal{S}}$, together with a mapping *rep* from the set of databases over $\bar{\mathcal{S}}$ *onto* the set of databases over $\mathcal{S}$, expressible in the nested relational algebra. The details of this mapping need not concern us here. Important is that we can furthermore construct a converse mapping *flat* from the set of databases over $\mathcal{S}$ to the set of databases over $\bar{\mathcal{S}}$, also expressible in the nested relational algebra, with the following properties for each database B over $\mathcal{S}$: (1) the finite domain of $\mathit{flat}(B)$ equals $\mathrm{edom}(B)$; and (2) $\mathit{rep}(\mathit{flat}(B)) = B$. Note that while *flat* is expressed in the nested relational algebra, the result $\mathit{flat}(B)$ is not really a flat database, because of the nested relations in the extended domain. However, it is "pseudoflat," in the sense that we regard these relations as if they were atomic values. For any relation name R of $\bar{\mathcal{S}}$, we denote the nested relational algebra expression defining the R-component of the mapping *flat* by flat_R. Likewise, we denote the expression defining the D-component by flat_D.

Given this representation, the proof is straightforward. Let L be an NP property of databases over $\mathcal{S}$, closed under isomorphism. Define the property $\bar{L}$ of databases over $\bar{\mathcal{S}}$ as follows: F satisfies $\bar{L}$ if $\mathit{rep}(F)$ satisfies L. Then $\bar{L}$ is in NP and is also closed under isomorphism. Hence, Fagin's theorem gives us an $\exists$SO sentence $\exists X_1 \ldots \exists X_p \, \varphi$ over $\bar{\mathcal{S}}$ expressing $\bar{L}$. By the equivalence of relational algebra and first-order logic, there is a flat relational algebra expression e over $\bar{\mathcal{S}} \cup \{X_1, \ldots, X_p\}$ such that the first-order logic sentence φ is equivalent to $e \neq \varnothing$. Now modify e as follows: for every relation name R of $\bar{\mathcal{S}}$, replace every occurrence of R in e by flat_R. Likewise, replace

every occurrence of D in e by flat_D. Denote the resulting nested relational algebra expression by e'.

We now have, for any database B over $\mathcal{S}$, that B satisfies L if and only if $\exists X_1 \dots X_p\, e' \neq \varnothing$ is true on B. The condition $e' \neq \varnothing$ can easily be written as an equation (cf. Remark 3.3). □

We are now ready to turn to sparse equations. Their nonemptiness problem is not just in NP, but actually in the complexity class *FewP* [All86], consisting of all problems that can be decided by a polynomial-time nondeterministic Turing machine that has at most polynomially many accepting computations on each input. Clearly, $\mathrm{P} \subseteq \mathrm{FewP} \subseteq \mathrm{NP}$, but the strictness of these inclusions remains open.

The obvious question to ask is whether Proposition 6.1 remains true if we focus on sparse equations, and replace "NP" by "FewP." The answer is an easy "yes," but then we must restrict our attention to *ordered* databases: databases that include a total order on their finite domain as one of their relations.

PROPOSITION 6.2. *Every property of ordered nested relational databases over some fixed schema $\mathcal{S}$ that is in FewP and closed under isomorphism corresponds to the nonemptiness problem of some sparse equation over $\mathcal{S}$, when restricted to ordered databases only.*

Proof. The usual proof of Fagin's theorem immediately yields the case where $\mathcal{S}$ is flat. Indeed, in that proof, to express an NP property decided by some polynomial-time bounded nondeterministic Turing machine M, one writes an $\exists$SO sentence $\exists X_1 \exists X_2 \dots \exists X_p\, \varphi$, where X_1 stands for an order on the domain, $X_2, \dots, X_p$ encode (using the order in X_1) a computation of M, and φ checks whether the computation is accepting. As we are dealing with a FewP property, M has only polynomially many accepting computations. Hence, the equation $\{(X_1, \dots, X_p) \mid \varphi\}$ would be sparse, were it not for X_1, as there are exponentially many possible orders on a finite domain. On ordered databases, however, there is no need for X_1, and we obtain a genuinely sparse equation.

This is for flat databases; for general nested relational databases we use the same representation technique as in the proof of Proposition 6.1. □

As a corollary we get the following.

COROLLARY 6.3. *There exists a sparse equation whose nonemptiness problem is NP-complete, if and only if* $\mathrm{FewP} = \mathrm{NP}$.

7. Sparse equations versus sparse powerset expressions. Naturally, we call an equation algebra expression sparse if all equations occurring in it are sparse. Inspired by Proposition 5.4, we can also define a sparsity condition on powerset algebra expressions: call a powerset algebra expression *sparse* if its natural evaluation strategy (defined in the obvious way) runs in polynomial space.

Remark 7.1. Using standard techniques, one can show that sparsity is undecidable for equation algebra expressions as well as powerset algebra expressions. An interesting question, raised by an anonymous referee, is whether one can give useful syntactic restrictions that guarantee sparsity. Ideally every sparse expression would be equivalent to one satisfying the syntactic restrictions. □

Suciu and Paredaens [SP97] showed that transitive closure of a flat binary relation is not expressible by a sparse powerset expression. In Example 4.3, we gave an obvious equation algebra expression for transitive closure, but that expression was not sparse. We can do better, as in the following.

PROPOSITION 7.2. *Transitive closure of a flat relation is expressible by a sparse equation algebra expression.*

Proof. Given a binary relation R and a natural number $n \geqslant 1$, we define the relation R^n as $R \circ \cdots \circ R$ (n times R), where $\circ$ is the classical composition operator of binary relations: $S \circ T = \pi_{1,4}\sigma_{2=3}(S \times T)$. Further, define $R^{\leqslant n}$ as $\bigcup_{i=1}^{n} R^i$, and define $R^{=n}$ as $R^n - R^{\leqslant n-1}$. Note that $R^{\leqslant |R|}$ equals the transitive closure of R, and that for $n > |R|$, $R^{\leqslant n} = R^{\leqslant |R|}$.

Now consider the following 6-ary relation *Run*:

$$Run := \bigcup_{i=1}^{|R|} R^{\leqslant i} \times R^{\leqslant i+1} \times R^{=i+1}.$$

We show next that there is an equation whose *only* solution, given R, is *Run*. This proves the proposition, because all we then have to do is unnest the solution set and project on the middle two columns to get the transitive closure. (The only exception is when *Run* is empty, in which case the transitive closure of R is R itself, but this can also easily be tested in the nested relational algebra.)

The desired equation expresses the conjunction of the following conditions on relation variable X:

1. For any pair $(x_5, x_6) \in \pi_{5,6}(X)$, we denote the relation

$$\{(x_1, x_2, x_3, x_4) \mid (x_1, \ldots, x_6) \in X\}$$

by $\tilde{X}(x_5, x_6)$, and denote further

$$\hat{X}(x_5, x_6) := \pi_{1,2}(\tilde{X}(x_5, x_6)) \quad \text{and}$$
$$\check{X}(x_5, x_6) := \pi_{3,4}(\tilde{X}(x_5, x_6)).$$

Then for every $(x, y) \in \pi_{5,6}(X)$ we must have
   (a) $\tilde{X}(x, y) = \hat{X}(x, y) \times \check{X}(x, y)$;
   (b) $\hat{X}(x, y) \supseteq R$;
   (c) $\check{X}(x, y) = \hat{X}(x, y) \cup \hat{X}(x, y) \circ R$; and
   (d) $(x, y) \in \check{X}(x, y) - \hat{X}(x, y)$.
   (e) Furthermore, *every* pair (x', y') in difference (d) above belongs to $\pi_{5,6}(X)$, with $\hat{X}(x', y') = \hat{X}(x, y)$ (and thus also $\check{X}(x', y') = \check{X}(x, y)$).
2. $R^{=2} \subseteq \pi_{5,6}(X)$, and for every $(x, y) \in R^{=2}$ we have $\hat{X}(x, y) = R$.
3. For every $(x, y) \in \pi_{5,6}(X)$ such that $\check{X}(x, y) \circ R - \check{X}(x, y) \neq \varnothing$, there exists a pair $(x', y') \in \pi_{5,6}(X)$ with $\hat{X}(x', y') = \check{X}(x, y)$.
4. For every $(x, y) \in \pi_{5,6}(X)$ such that $\hat{X}(x, y) \neq R$, there exists a pair $(x', y') \in \pi_{5,6}(X)$ with $\check{X}(x', y') = \hat{X}(x, y)$.

The conjunction of the above conditions expresses that X equals *Run*. Indeed, by (2), (1c), and (1a) we know that $R^{\leqslant 1} \times R^{\leqslant 2} \times R^{=2} \subseteq X$. By induction and by (3), (1c), (1e), and (1a) we know that $R^{\leqslant i} \times R^{\leqslant i+1} \times R^{=i+1} \subseteq X$ and hence $Run \subseteq X$. Moreover, for every $(x, y) \in R^{=i+1}$ we have $\{(x_1, y_1, x_2, y_2) \mid (x_1, y_1, x_2, y_2, x, y) \in X\} = R^{\leqslant i} \times R^{\leqslant i+1}$. On the other hand, if $(x, y) \in \pi_{5,6}(X)$, then $\hat{X}(x, y) = R$, in which case $(x, y) \in R^{=2}$ by (1c) and (1d), or $\hat{X}(x, y) \neq R$, in which case we know by induction and by (4) and (1b) that $(x, y) \in R^{=i+1}$ for some i. This proves $X = Run$. □

Remark 7.3. The equation constructed in the above proof is not only sparse, it is *unambiguous*: it has a unique solution on each input database. Moreover, the same proof works more generally for any *fixpoint query* [AHV95] on flat databases.

The only difficulty is that fixpoint queries start from the empty relation, while in our proof of Proposition 7.2 we start from R, but that is easily dealt with. As already explained in the Introduction, we thus basically rediscovered an earlier result by Kolaitis to the effect that every fixpoint query is implicitly definable in first-order logic [Kol90]. But note the directness of our proof, straightforwardly specifying the run of the fixpoint computation in an unambiguous way. The original proof (also presented by Ebbinghaus and Flum [EF95]) is a bit more roundabout, specifying the "stage comparison" relation instead. □

Another, perhaps a bit frivolous, example of a query that is expressible using sparse equations but not using sparse powerset expressions is the nesting operator ν. It is easy to express ν in the powerset algebra using the powerset operator and the other operators, but not ν itself; so ν is not primitive in the powerset algebra. As a consequence (Proposition 4.4), ν is not primitive in the equation algebra either. We next observe that when we restrict our analysis to sparse expressions, nesting remains imprimitive in the equation algebra, but becomes primitive again in the powerset algebra.

PROPOSITION 7.4. *Nesting is not expressible by a sparse powerset expression without using the ν operator itself.*

Proof. Suppose we want to express nesting of a flat binary relation R. The first application of the powerset operator is to the result of a flat relational algebra expression e applied to R. Let us focus on the case where R is the identity relation on a finite domain of n elements. A straightforward argument by structural induction shows that, on identity relations, every relational algebra expression is equivalent to a finite disjunction of *equality types*. Here, an equality type is a maximally consistent conjunction of equalities $x_i = x_j$ and nonequalities $x_i \neq x_j$ over the variables $x_1, \ldots, x_k$, where k is the output arity of e. We thus see that either $e(R)$ is empty on all such R (this is when the disjunction is empty), or $e(R)$ is of size at least n when n is at least k. In the empty case, the powerset operator is useless, and we continue to the next application of powerset. Otherwise, the powerset operator explodes, and the overall expression is not sparse. □

PROPOSITION 7.5. *Nesting is expressible by a sparse equation algebra expression without using the ν operator itself.*

Proof. Let R be a relation name of type $(0,0)$, and let X and Y be relation variables of type (0). We can write a relational algebra expression e such that on any database C over $\{R, X, Y\}$, $e(C)$ is empty if and only if X is a singleton $\{x\}$ with $x \in \pi_1(R)$, and $Y = \{y \mid (x, y) \in R\}$. An example of an e that works is (Δ stands for symmetric difference)

$$\pi_1\sigma_{1\neq 2}(X \times X) \cup (X - \pi_1(R)) \cup (Y \,\Delta\, \pi_3\sigma_{1=2}(X \times R)).$$

Hence, the expression

$$\mu_1\big(\{(X, Y) \mid e = \varnothing\}\big)$$

is a sparse equation algebra expression equivalent to $\nu_2(R)$.

The construction for general nesting operations is analogous. □

Our final, and main technical, contribution concerns the parity query. Suciu and Paredaens showed that the parity of the cardinality of a finite set is not expressible by a sparse powerset expression. We show the analogue for the equation algebra as follows.

PROPOSITION 7.6. *The parity query is not expressible by a sparse equation algebra expression.*

Proof. Suppose, to the contrary, that we have a sparse equation algebra expression to express the parity of the cardinality of a finite domain D. We may assume that the input schema is empty; i.e., an input database consists of D and nothing else. Consider an innermost equation E_0 occurring in our expression. It may be nested inside other equations $E_1, \ldots, E_k$, enumerated from the inside to the outside. By Remark 3.3, for each $j \in \{0, \ldots, k\}$, E_j can be written in the form $\{(X_1^j, \ldots, X_{i_j}^j) \mid e_j \neq \varnothing\}$, for some i_j, where e_j is a flat relational algebra expression over the flat schema $\{X_1^j, \ldots, X_{i_j}^j\}$ possibly expanded with certain free variables X_m^l, where $l > j$ and $m \leq i_l$.

By our assumption, there are at most polynomially many solutions to equation E_k. For each solution A_k of E_k there are at most polynomially many solutions A_{k-1} of e_{k-1} and so on. A sequence $\bar{A} = (A_k, \ldots, A_0)$ of databases is a *solution vector for* E_0 if A_k is a solution for E_k, and each A_j, $j < k$, is a solution for E_j, given $A_k, \ldots, A_{j+1}$.

Now let $\bar{A} = (A_k, \ldots, A_0)$ be a solution vector for E_0, given an input D of size n. Then for every permutation f of D, $f(\bar{A}) = (f(A_k), \ldots, f(A_0))$ is also a solution vector for E_0. The number of different such $f(\bar{A})$ is precisely $n!/|\mathrm{Aut}(\bar{A})|$, where $\mathrm{Aut}(\bar{A})$ is the group of automorphisms of $\bar{A}$. Since all equations are supposed to be sparse, this number is at most n^ℓ for some fixed ℓ, or, equivalently, $|\mathrm{Aut}(\bar{A})| \geqslant n!/n^\ell$. Setting $k = \ell + 1$, this implies $|\mathrm{Aut}(\bar{A})| \geqslant (n-k)!$ for sufficiently large n.

We thus need to know more about large permutation groups. The following crucial lemma will give us the information we need. The group of permutations of a finite set D is denoted by $\mathrm{Sym}(D)$, and its alternating subgroup of even permutations by $\mathrm{Alt}(D)$. If G is a subgroup of $\mathrm{Sym}(D)$, a *fixed set* for G is a subset $\Delta \subseteq D$ such that every $g \in G$ maps Δ to Δ. The action of G on a fixed set Δ (as a subgroup of $\mathrm{Sym}(\Delta)$) is denoted by G^Δ.

LEMMA 7.7. *Let k be a fixed natural number. Let G be a subgroup of* $\mathrm{Sym}(D)$*, $|D| = n$, n sufficiently large. Then $|G| \geqslant (n-k)!$ implies the existence of a fixed set Δ with $|\Delta| \geqslant n-k$, such that G^Δ contains* $\mathrm{Alt}(\Delta)$.

Proof of Lemma 7.7. For background on finite permutation groups, we refer to Wielandt's book [Wie64], but here are a few preliminaries. An *orbit* of a permutation group G on a set D is a set of the form $\{g(x) \mid g \in G\}$, for some $x \in D$. We call G *transitive* if D is one single orbit of G. Further, G is called *primitive* if it is transitive and has no nontrivial blocks. Here, a *block* of G is a subset $\Delta \subseteq D$ such that for all $g \in G$ the set $g(\Delta)$ is either equal to Δ or disjoint from it. *Trivial* blocks are $\varnothing$, D, and the singletons. If G is not primitive but transitive, there is always a *complete block system* which partitions D into equal-sized nontrivial blocks. We recall the following.

BOCHERT'S THEOREM (1889). *Let G be primitive on D, not containing* $\mathrm{Alt}(D)$*. Let $|D| = n$. Then $|G| \leqslant n!/\lceil n/2 \rceil !$.*

For the proof of the lemma, first assume that G is transitive. There are two possibilities:

1. G is imprimitive with, say, b blocks of size a ($a > 1$, $b > 1$, $ab = n$). Then $|G| \leqslant b!\,(a!)^b$, which in turn is at most $2(\lfloor n/2 \rfloor !)^2$ for n sufficiently large. Thus, by what is given about $|G|$,

   $$(n-k)! \leqslant 2(\lfloor n/2 \rfloor !)^2. \tag{7.1}$$

   However, this is impossible for n sufficiently large.
2. G is primitive. Then, unless G contains $\mathrm{Alt}(D)$ (in which case the lemma is

proved), by Bochert's theorem,

$$(n-k)! \leqslant \frac{n!}{\lceil n/2 \rceil !}. \tag{7.2}$$

Again, this is impossible for n sufficiently large.

Now assume G is intransitive. Let Δ be an orbit of G of maximal size; let $\ell \geqslant 1$ be such that the size of Δ equals $n-\ell$. We have $|G| \leqslant (n-\ell)!\,\ell!$. Suppose $\ell > k$. Then $(n-\ell)!\,\ell!$ reaches its maximum at $\ell = k+1$. Hence, $(n-k)! \leqslant |G| \leqslant (n-k-1)!\,(k+1)!$, and thus $n-k \leqslant (k+1)!$, which is impossible for large enough n.

Thus, $\ell \leqslant k$, or in other words, the size of Δ is at least $n-k$. We have $|G| \leqslant \ell!\,|G^{\Delta}| \leqslant k!\,|G^{\Delta}|$, and so $|G^{\Delta}| \geqslant (n-k)!/k!$. By definition, G^{Δ} is transitive on Δ. We can now apply the same arguments as in the case "G is transitive" above, for G^{Δ} instead of G, and get that G^{Δ} must contain $\mathrm{Alt}(\Delta)$. Indeed, in the right-hand sides of inequalities (7.1) and (7.2), n now becomes $n-\ell$, which has for effect that the upper bounds become smaller. Hence, as these inequalities already were impossible, they now become even more impossible. The extra factor of $1/k!$ in the left-hand sides does not have a significant influence. □

Invoking this lemma for $G = \mathrm{Aut}(\bar{A})$, we get a fixed set Δ of size at least $n-k$ such that any even permutation of Δ can be extended to an automorphism of $\bar{A}$.

Now let X be one of the relation variables of an equation E_j, of arity, say, r, and consider any r-tuple t whose components either are the symbol $*$ or are in $D-\Delta$. Let r' be the number of components that are the symbol $*$. Further, let ξ be an equality type of r'-tuples. Denote by $\mathit{Neighbors}_X^{\bar{A}}(t,\xi)$ the set of r'-tuples over Δ of equality type ξ such that, if we replace the $*$-components of t by the components of the r'-tuple (from left to right), we get a tuple in $X^{\bar{A}}$.

Claim 7.8. *$\mathit{Neighbors}_X^{\bar{A}}(t,\xi)$ either is empty or consists of* all *r'-tuples over Δ of equality type ξ.*

Proof of Claim 7.8. Suppose to the contrary that $N := \mathit{Neighbors}_X^{\bar{A}}(t,\xi)$ is neither empty nor full. Take h_1 in N, and take h_2 (of arity r' and of type ξ) not in N. Take two arbitrary elements from Δ that appear neither in h_1 nor in h_2, and remove them from Δ, resulting in Δ'. Take a third tuple h_3 (of the right arity and type) over Δ', and disjoint from h_1 and h_2. If h_3 is in N, initialize the set I to $\{h_2, h_3\}$; otherwise, set $I := \{h_1, h_3\}$. Now complete I to a maximal set of pairwise disjoint r'-tuples over Δ' of equality type ξ. There are at least $(n-k-2)/r'$ tuples in I.

Assume that at least half of I is outside N; denote the set of these by I'. (The case where at least half of I is *in* N is symmetric.) Fix an $h \in I \cap N$. For each tuple s in I', we consider the permutation ϖ_s that transposes s and h and leaves everything else fixed. If ϖ_s happens to be odd, we make it even by adding the transposition of the two dummy elements we took out of Δ (when we defined Δ'). Then each set $\varpi_s(N)$ contains s but does not contain any other tuples from I'. Thus, we produce in this way at least $f(n) := (n-k-2)/2r'$ different sets of r'-tuples over Δ. Since they are even, each ϖ_s can be extended to an automorphism. Hence, each of the $f(n)$ sets must be the $\mathit{Neighbors}_X^{\bar{A}}(t',\xi)$ of some t'. However, there are less than $(k+1)^r$ different possibilities for t', while $f(n)$ is larger than $(k+1)^r$ for n sufficiently large. Thus we get to the desired contradiction. □

We call (t,ξ) an *r-ary pattern*. If $\mathit{Neighbors}_X^{\bar{A}}(t,\xi)$ is nonempty (and thus full), we say that the pattern is *instantiated in* $X^{\bar{A}}$. Note also that the extreme cases, where t consists exclusively of stars or where t has no star at all, are also allowed and make sense.

By the above, we thus see that any solution vector $\bar{A}$ can be generated by the following nondeterministic procedure:

1. Initialize all relations of $\bar{A}$ to empty.
2. Choose at most k different elements from D, playing the role of the elements outside Δ.
3. For every relation variable X (of arity r, say), run through all r-ary patterns, and for each of them, choose nondeterministically to instantiate it in $X^{\bar{A}}$ or not.

Since k and the number of relation variables are fixed, the number of possible patterns is also fixed. Hence, we can write an expression in the nested relational algebra that, given D, constructs the set of all possible vectors $\bar{A}$ of the above nondeterministic procedure. This set is a superset of the actual set of solution vectors for E_0. Equation E_0 can now be replaced by a nested relational algebra expression which (1) constructs the set of solution candidates $\bar{A}$, (2) projects out the relations for $X_1^0, \ldots, X_{i_0}^0$, and (3) selects those relations which fulfil E_0. The latter is an easy task for the nested relational algebra [GVG].

Hence, we can get rid of E_0. Repeating this process, we can get rid of all equations, so that in the end we are left with a standard nested relational algebra expression for the parity query. But this is well known to be impossible [AHV95, PVG92]. □

Remark 7.9. Note that we have actually shown that over the empty schema, where databases consist of a finite domain and nothing else, the sparse equation algebra is no more powerful than the standard relational algebra. As a matter of fact, the proof can easily be generalized to apply also to schemas having only relation names of type (0). □

Acknowledgment. We are indebted to László Babai, who pointed us to Liebeck's paper.

EQUIVALENCES AND SEPARATIONS BETWEEN QUANTUM AND CLASSICAL LEARNABILITY*

ROCCO A. SERVEDIO† AND STEVEN J. GORTLER‡

Abstract. We consider quantum versions of two well-studied models of learning Boolean functions: Angluin's model of exact learning from membership queries and Valiant's probably approximately correct (PAC) model of learning from random examples. For each of these two learning models we establish a polynomial relationship between the number of quantum or classical queries required for learning. These results contrast known results that show that testing black-box functions for various properties, as opposed to learning, can require exponentially more classical queries than quantum queries. We also show that, under a widely held computational hardness assumption (the intractability of factoring Blum integers), there is a class of Boolean functions which is polynomial-time learnable in the quantum version but not the classical version of each learning model. For the model of exact learning from membership queries, we establish a stronger separation by showing that if any one-way function exists, then there is a class of functions which is polynomial-time learnable in the quantum setting but not in the classical setting. Thus, while quantum and classical learning are equally powerful from an information theory perspective, the models are different when viewed from a computational complexity perspective.

Key words. computational learning theory, quantum computation, PAC learning, query complexity

DOI. 10.1137/S0097539704412910

1. Introduction.

1.1. Motivation. In recent years many researchers have investigated the power of quantum computers which can query a black-box oracle for an unknown function [1, 5, 6, 9, 14, 10, 11, 15, 17, 20, 21, 24, 40, 46]. The broad goal of research in this area is to understand the relationship between the number of quantum or classical oracle queries which are required to answer various questions about the function computed by the oracle. For example, a well-known result due to Deutsch and Jozsa [17] shows that exponentially fewer queries are required in the quantum model in order to determine with certainty whether a black-box oracle computes a constant Boolean function or a function which is balanced between outputs 0 and 1. More recently, several researchers have studied the number of quantum oracle queries which are required to determine whether the function computed by a black-box oracle is identically zero [5, 6, 9, 15, 24, 46].

A natural question which arises in this framework is the following: what is the relationship between the number of quantum and classical oracle queries which are

required in order to *exactly identify* the function computed by a black-box oracle? Here the goal is not to determine whether a black-box function satisfies some particular property, such as ever taking a nonzero value, but rather to precisely identify an unknown black-box function from some restricted class of possible functions. The classical version of this problem has been well studied in the computational learning theory literature [2, 12, 22, 26, 27] and is known as the problem of *exact learning from membership queries*. The question stated above can thus be rephrased as follows: what is the relationship between the number of quantum or classical membership queries which are required for exact learning? We answer this question in this paper.

In addition to the model of exact learning from membership queries, we also consider a quantum version of Valiant's widely studied PAC (probably approximately correct) learning model, which was introduced by Bshouty and Jackson [13]. While a learning algorithm in the classical PAC model has access to labeled examples drawn from some fixed probability distribution, a learning algorithm in the quantum PAC model has access to some fixed quantum superposition of labeled examples. Bshouty and Jackson gave a polynomial-time algorithm for a particular learning problem in the quantum PAC model, but did not address the general relationship between the number of quantum versus classical examples which are required for PAC learning. We answer this question as well.

1.2. Our results. We show that in an information-theoretic sense, quantum and classical learning are equivalent up to polynomial factors: for both the model of exact learning from membership queries and the PAC model, there is no learning problem which can be solved using significantly fewer quantum queries than classical queries. More precisely, our first main theorem is the following.

THEOREM 1. *Let $\mathcal{C}$ be any class of Boolean functions over $\{0,1\}^n$, and let D and Q be such that $\mathcal{C}$ is exact learnable from D classical membership queries or from Q quantum membership queries. Then $D = O(nQ^3)$.*

Our second main theorem is an analogous result for quantum versus classical PAC learnability.

THEOREM 2. *Let $\mathcal{C}$ be any class of Boolean functions over $\{0,1\}^n$, and let D and Q be such that $\mathcal{C}$ is PAC learnable from D classical examples or from Q quantum examples. Then $D = O(nQ)$.*

These results draw on lower bound techniques from both quantum computation and computational learning theory [2, 5, 6, 8, 12, 26]. A detailed description of the relationship between our results and previous work on quantum versus classical black-box query complexity is given in section 3.4.

Theorems 1 and 2 are information-theoretic rather than computational in nature; they show that for any learning problem, if there is a quantum learning algorithm which uses polynomially many examples, then there must also exist a classical learning algorithm which uses polynomially many examples. However, Theorems 1 and 2 do not imply that every *polynomial-time* quantum learning algorithm must have a polynomial-time classical analogue. In fact, we show that a separation exists between efficient quantum learnability and efficient classical learnability. Under a widely held computational hardness assumption for classical computation (the hardness of factoring Blum integers), we observe that for each of the two learning models considered in this paper there is a concept class which is polynomial-time learnable in the quantum version but not in the classical version of the model.

For the model of exact learning from membership queries we give an even stronger separation between efficient quantum and classical learnability. Our third main theorem is the following.

THEOREM 3. *If any one-way function exists, then there is a concept class C which is polynomial-time exact learnable from quantum membership queries but is not polynomial-time exact learnable from classical membership queries.*

This result establishes a robust separation between efficient quantum and classical learnability. Even if a polynomial-time classical factoring algorithm were to be discovered, the separation would hold as long as *any* one-way function existed (a universally held belief in public-key cryptography). As discussed in section 9, our results prove the existence of a quantum oracle algorithm which defeats a general cryptographic construction secure in the classical setting. More precisely, given any one-way function, we construct a family of pseudorandom functions which are classically secure but can be distinguished from truly random functions (and in fact exactly identified) by an algorithm that can make quantum oracle queries. To our knowledge, this is the first break of a generic cryptographic construction (not based on a specific assumption such as factoring) in a quantum setting.

The main cryptographic tool underlying Theorem 3 is a new construction of pseudorandom functions which are invariant under an XOR mask (see section 7). As described in section 8.1, each concept $c \in C$ combines these new pseudorandom functions with pseudorandom permutations in a particular way. Roughly speaking, the XOR mask invariance of the new pseudorandom functions ensures that a quantum algorithm due to Simon [40] can be used to extract some information about the structure of the target concept and thus make progress towards learning. On the other hand, the pseudorandomness ensures that no probabilistic polynomial-time learning algorithm can extract any useful information, and thus no such algorithm can learn successfully.

1.3. Organization. We set notation, define the exact learning model and the PAC learning model, and describe the quantum computation framework in section 2. We prove the relationship between quantum and classical exact learning from membership queries (Theorem 1) in section 3, and we prove the relationship between quantum and classical PAC learning (Theorem 2) in section 4. In section 5 we observe that if factoring Blum integers is classically hard, then in each of these two learning models there is a concept class which is quantum learnable in polynomial time but not classically learnable in polynomial time. We prove Theorem 3 in sections 6 through 8.

2. Preliminaries. For $\alpha, \beta \in \{0,1\}$ we write $\alpha \oplus \beta$ to denote the exclusive-or $\alpha + \beta \pmod 2$. Similarly for $x, y \in \{0,1\}^n$ we write $x \oplus y$ to denote the n-bit string that is the bitwise XOR of x and y. We write $x \cdot y$ to denote the inner product $x_1 y_1 + \cdots + x_n y_n \pmod 2$, and we write $|x|$ to denote the length of string x.

We use script capital letters to denote probability distributions over sets of functions; in particular, $\mathcal{F}_n$ denotes the uniform distribution over all 2^{n2^n} functions from $\{0,1\}^n$ to $\{0,1\}^n$. If S is a finite set, we write $\Pr_{s \in S}$ to denote a uniform choice of s from S.

We write $M(s)$ to indicate that algorithm M is given string s as input, and M^g to indicate that M has access to an oracle for the function g. If M is a probabilistic polynomial-time (henceforth abbreviated p.p.t.) algorithm which has access to an oracle $g : \{0,1\}^{\ell_1} \to \{0,1\}^{\ell_2}$, then the running time of M^g is bounded by $p(\ell_1 + \ell_2)$ for some polynomial p.

A *concept* c over $\{0,1\}^n$ is a Boolean function over the domain $\{0,1\}^n$, or equivalently a concept can be viewed as a subset $\{x \in \{0,1\}^n : c(x) = 1\}$ of $\{0,1\}^n$. A *concept class* $\mathcal{C} = \cup_{n \geq 1} C_n$ is a collection of concepts, where $C_n = \{c \in \mathcal{C} : \ c \text{ is a}$

concept over $\{0,1\}^n\}$. For example, C_n might be the family of all Boolean formulae over n variables which are of size at most n^2. We say that a pair $\langle x, c(x)\rangle$ is a *labeled example* of the concept c.

While many different learning models have been proposed, most models follow the same basic paradigm: a learning algorithm for a concept class $\mathcal{C}$ typically has access to some kind of oracle which provides examples that are labeled according to a fixed but unknown target concept $c \in \mathcal{C}$, and the goal of the learning algorithm is to infer (in some sense) the target concept c. The two learning models which we discuss in this paper, the model of exact learning from membership queries and the PAC model, make this rough notion precise in different ways.

2.1. Classical exact learning from membership queries. The model of *exact learning from membership queries* was introduced by Angluin [2] and has since been widely studied [2, 12, 22, 26, 27]. In this model the learning algorithm has access to a *membership oracle* MQ_c, where $c \in C_n$ is the unknown target concept. When given an input string $x \in \{0,1\}^n$, in one time step the oracle MQ_c returns the bit $c(x)$; such an invocation is known as a *membership query* since the oracle's answer tells whether or not $x \in c$ (viewing c as a subset of $\{0,1\}^n$). The goal of the learning algorithm is to construct a hypothesis $h : \{0,1\}^n \to \{0,1\}$ that is logically equivalent to c, i.e., $h(x) = c(x)$ for all $x \in \{0,1\}^n$. Formally, we say that an algorithm A is an *exact learning algorithm for $\mathcal{C}$ using membership queries* if for all $n \geq 1$, for all $c \in C_n$, if A is given n and access to MQ_c, then with probability at least $2/3$ (over the internal randomness of A) algorithm A outputs a Boolean circuit h such that $h(x) = c(x)$ for all $x \in \{0,1\}^n$. The *sample complexity* $T(n)$ of a learning algorithm A for $\mathcal{C}$ is the maximum number of calls to MQ_c which A ever makes for any $c \in C_n$.

2.2. Classical PAC learning. The PAC model of concept learning was introduced by Valiant in [41] and has since been extensively studied [4, 29]. In this model the learning algorithm has access to an *example oracle* $EX(c, \mathcal{D})$, where $c \in C_n$ is the unknown target concept and $\mathcal{D}$ is an unknown distribution over $\{0,1\}^n$. The oracle $EX(c, \mathcal{D})$ takes no inputs; when invoked, in one time step it returns a labeled example $\langle x, c(x)\rangle$, where $x \in \{0,1\}^n$ is randomly selected according to the distribution $\mathcal{D}$. The goal of the learning algorithm is to generate a hypothesis $h : \{0,1\}^n \to \{0,1\}$ that is an *ϵ-approximator for c under $\mathcal{D}$*, i.e., a hypothesis h such that $\Pr_{x\in\mathcal{D}}[h(x) \neq c(x)] \leq \epsilon$. An algorithm A is a *PAC learning algorithm for $\mathcal{C}$* if the following condition holds: for all $n \geq 1$ and $0 < \epsilon, \delta < 1$, for all $c \in C_n$, for all distributions $\mathcal{D}$ over $\{0,1\}^n$, if A is given n, ϵ, δ and access to $EX(c, \mathcal{D})$, then with probability at least $1 - \delta$ algorithm A outputs a circuit h which is an ϵ-approximator for c under $\mathcal{D}$. The *sample complexity* $T(n, \epsilon, \delta)$ of a learning algorithm A for $\mathcal{C}$ is the maximum number of calls to $EX(c, \mathcal{D})$ that A ever makes for any concept $c \in C_n$ and any distribution $\mathcal{D}$ over $\{0,1\}^n$.

2.3. Quantum computation. Detailed descriptions of the quantum computation model can be found in [7, 16, 31, 45]; here we outline only the basics using the terminology of *quantum networks* as presented in [5]. A quantum network $\mathcal{N}$ is a quantum circuit (over some standard basis augmented with one oracle gate) that acts on an m-bit quantum register; the computational basis states of this register are the 2^m binary strings of length m. A quantum network can be viewed as a sequence of unitary transformations

$$U_0, O_1, U_1, O_2, \ldots, U_{T-1}, O_T, U_T,$$

where each U_i is an arbitrary unitary transformation on m qubits and each O_i is a unitary transformation which corresponds to an oracle call.[1] Such a network is said to have *query complexity* T. At every stage in the execution of the network, the current state of the register can be represented as a superposition $\sum_{z\in\{0,1\}^m} \alpha_z|z\rangle$, where the α_z are complex numbers that satisfy $\sum_{z\in\{0,1\}^m} \|\alpha_z\|^2 = 1$. If this state is measured, then with probability $\|\alpha_z\|^2$ the string $z \in \{0,1\}^m$ is observed and the state collapses down to $|z\rangle$. After the final transformation U_T takes place, a measurement is performed on some subset of the bits in the register, and the observed value (a classical bit string) is the output of the computation.

Several points deserve mention here. First, since the information which our quantum network uses for its computation comes from the oracle calls, we may stipulate that the initial state of the quantum register is $|0^m\rangle$. Second, as described above, each U_i can be an arbitrarily complicated unitary transformation (as long as it does not contain any oracle calls) which may require a large quantum circuit to implement. This is of small concern since we are chiefly interested in query complexity and not circuit size. Third, as defined above, our quantum networks can make only one measurement at the very end of the computation; this is an inessential restriction since any algorithm which uses intermediate measurements can be modified to an algorithm which makes only one final measurement. Finally, we have not specified just how the oracle calls O_i work; we address this point separately in sections 3.1 and 4.1 for each type of oracle.

If $|\phi\rangle = \sum_z \alpha_z|z\rangle$ and $|\psi\rangle = \sum_z \beta_z|z\rangle$ are two superpositions of basis states, then the *Euclidean distance* between $|\phi\rangle$ and $|\psi\rangle$ is $||\phi\rangle - |\psi\rangle| = (\sum_z |\alpha_z - \beta_z|^2)^{1/2}$. The *total variation distance* between two distributions $\mathcal{D}_1$ and $\mathcal{D}_2$ is defined to be $\sum_x |\mathcal{D}_1(x) - \mathcal{D}_2(x)|$. The following fact (Lemma 3.2.6 of [7]), which relates the Euclidean distance between two superpositions and the total variation distance between the distributions induced by measuring the two superpositions, will be useful.

FACT 1. *Let $|\phi\rangle$ and $|\psi\rangle$ be two unit-length superpositions which represent possible states of a quantum register. If the Euclidean distance $||\phi\rangle - |\psi\rangle|$ is at most ϵ, then performing the same observation on $|\phi\rangle$ and $|\psi\rangle$ induces distributions $\mathcal{D}_\phi$ and $\mathcal{D}_\psi$, which have total variation distance at most 4ϵ.*

3. Exact learning from quantum membership queries.

3.1. Quantum membership queries. A *quantum membership oracle* QMQ_c is the natural quantum generalization of a classical membership oracle MQ_c: on input of a superposition of query strings, the oracle QMQ_c generates the corresponding superposition of example labels. More formally, a QMQ_c gate maps the basis state $|x, b\rangle$ (where $x \in \{0,1\}^n$ and $b \in \{0,1\}$) to the state $|x, b\oplus c(x)\rangle$. If $\mathcal{N}$ is a quantum network which has QMQ_c gates as its oracle gates, then each O_i is the unitary transformation which maps $|x, b, y\rangle$ (where $x \in \{0,1\}^n$, $b \in \{0,1\}$ and $y \in \{0,1\}^{m-n-1}$) to $|x, b\oplus c(x), y\rangle$.[2] Our QMQ_c oracle is identical to the well-studied notion of a quantum black-box oracle for c [5, 6, 7, 9, 10, 11, 15, 17, 24, 46].

A *quantum exact learning algorithm for* $\mathcal{C}$ is a family $\mathcal{N}_1, \mathcal{N}_2, \ldots$ of quantum networks, where each network $\mathcal{N}_n$ has a fixed architecture independent of the choice of $c \in C_n$, with the following property: for all $n \geq 1$, for all $c \in C_n$, if the oracle gates of $\mathcal{N}_n$ are instantiated as QMQ_c gates, then with probability at least $2/3$ the network

[1] Since there is only one kind of oracle gate, each O_i is the same transformation.

[2] Note that each O_i affects only the first $n+1$ bits of a basis state. This is without loss of generality since the transformations U_j can "permute bits" of the network.

$\mathcal{N}_n$ outputs a representation of a (classical) Boolean circuit $h : \{0,1\}^n \to \{0,1\}$ such that $h(x) = c(x)$ for all $x \in \{0,1\}^n$. The *quantum sample complexity* of a quantum exact learning algorithm for $\mathcal{C}$ is $T(n)$, where $T(n)$ is the query complexity of $\mathcal{N}_n$.

3.2. Lower bounds on classical and quantum exact learning. Two different lower bounds are known for the number of classical membership queries which are required to exact learn any concept class. In this section we prove two analogous lower bounds on the number of quantum membership queries required to exactly learn any concept class. Throughout this section for ease of notation we omit the subscript n and write C for C_n.

A lower bound based on similarity of concepts. Consider a set of concepts which are all "similar" in the sense that for every input almost all concepts in the set agree. Known results in learning theory state that such a concept class must require a large number of membership queries for exact learning. More formally, let $C' \subseteq C$ be any subset of C. For $a \in \{0,1\}^n$ and $b \in \{0,1\}$ let $C'_{\langle a,b \rangle}$ denote the set of those concepts in C' which assign the label b to example a, i.e., $C'_{\langle a,b \rangle} = \{c \in C' : c(a) = b\}$. Let $\gamma^{C'}_{\langle a,b \rangle} = |C'_{\langle a,b \rangle}|/|C'|$ be the fraction of such concepts in C', and let $\gamma^{C'}_a = \min\{\gamma^{C'}_{\langle a,0 \rangle}, \gamma^{C'}_{\langle a,1 \rangle}\}$; thus $\gamma^{C'}_a$ is the minimum fraction of concepts in C' which can be eliminated by querying MQ_c on the string a. Let $\gamma^{C'} = \max\{\gamma^{C'}_a : a \in \{0,1\}^n\}$. Finally, let $\hat{\gamma}^C$ be the minimum of $\gamma^{C'}$ across all $C' \subseteq C$ such that $|C'| \geq 2$. Thus

$$\hat{\gamma}^C = \min_{C' \subseteq C, |C'| \geq 2} \max_{a \in \{0,1\}^n} \min_{b \in \{0,1\}} \frac{|C'_{\langle a,b \rangle}|}{|C'|}.$$

Intuitively, the inner min corresponds to the fact that the oracle may provide a worst-case response to any query; the max corresponds to the fact that the learning algorithm gets to choose the "best" query point a; and the outer min corresponds to the fact that the learner must succeed, no matter what subset C' of C the target concept is drawn from. Thus $\hat{\gamma}^C$ is small if there is a large set C' of concepts which are all very similar in that any query eliminates only a few concepts from C'. If this is the case, then many membership queries should be required to learn C; formally, we have the following lemma, which is a variant of Fact 2 from [12].

LEMMA 4. *Any (classical) exact learning algorithm for C must have sample complexity $\Omega(1/\hat{\gamma^C})$.*

Proof. Let $C' \subseteq C$, $|C'| \geq 2$, be such that $\gamma^{C'} = \hat{\gamma}^C$. Consider the following adversarial strategy for answering queries: given the query string a, answer the bit b which maximizes $\gamma^{C'}_{\langle a,b \rangle}$. This strategy ensures that each response eliminates at most a $\gamma^{C'}_a \leq \gamma^{C'} = \hat{\gamma}^C$ fraction of the concepts in C'. After $\frac{1}{2\hat{\gamma}^C} - 1$ membership queries, fewer than half of the concepts in C' have been eliminated, so at least two concepts have not yet been eliminated. Consequently, it is impossible for A to output a hypothesis which is equivalent to the correct concept with probability greater than $1/2$. ∎

We now develop some tools which will enable us to prove a quantum version of Lemma 4. Let $C' \subseteq C, |C'| \geq 2$, be such that $\gamma^{C'} = \hat{\gamma}^C$, and let $c_1, \ldots, c_{|C'|}$ be a listing of the concepts in C'. Let the *typical concept for C'* be the function $\hat{c} : \{0,1\}^n \to \{0,1\}$ defined as follows: for all $a \in \{0,1\}^n$, $\hat{c}(a)$ is the bit b such that $|C'_{\langle a,b \rangle}| \geq |C'|/2$. (Ties are broken arbitrarily; note that a tie occurs only if $\hat{\gamma}^C = 1/2$.) The typical concept $\hat{c}$ need not belong to C' or even to C. The *difference matrix* D is the $|C'| \times 2^n$ zero/one matrix where rows are indexed by concepts in C', columns are indexed by strings in $\{0,1\}^n$, and $D_{i,x} = 1$ iff $c_i(x) \neq \hat{c}(x)$. By our choice of C' and

the definition of $\hat{\gamma}^C$, each column of D has at most $|C'| \cdot \hat{\gamma}^C$ ones, so the L_1 matrix norm of D is $\|D\|_1 \leq |C'| \cdot \hat{\gamma}^C$.

Our quantum lower bound proof uses ideas which were first introduced by Bennett et al. [6]. Let $\mathcal{N}$ be a fixed quantum network architecture and let $U_0, O_1, \ldots, U_{T-1}$, O_T, U_T be the corresponding sequence of transformations. For $1 \leq t \leq T$ let $|\phi_t^c\rangle$ be the state of the quantum register after the transformations up through U_{t-1} have been performed (we refer to this stage of the computation as time t) if the oracle gate is QMQ_c. As in [6], for $x \in \{0,1\}^n$ let $q_x(|\phi_t^c\rangle)$, the *query magnitude of string x at time t with respect to c,* be the sum of the squared magnitudes in $|\phi_t^c\rangle$ of the basis states which are querying QMQ_c on string x at time t; thus if $|\phi_t^c\rangle = \sum_{z \in \{0,1\}^m} \alpha_z |z\rangle$, then

$$q_x(|\phi_t^c\rangle) = \sum_{w \in \{0,1\}^{m-n}} \|\alpha_{xw}\|^2.$$

The quantity $q_x(|\phi_t^c\rangle)$ can be viewed as the amount of amplitude which the network $\mathcal{N}$ invests in the query string x to QMQ_c at time t. Intuitively, the final outcome of $\mathcal{N}$'s computation cannot depend very much on the oracle's responses to queries which have little amplitude invested in them. Bennett et al. formalized this intuition in the following theorem [6, Theorem 3.3].

THEOREM 5. *Let $|\phi_t^c\rangle$ be defined as above. Let $F \subseteq \{0, \ldots, T-1\} \times \{0,1\}^n$ be a set of time-string pairs such that $\sum_{(t,x) \in F} q_x(|\phi_t^c\rangle) \leq \frac{\epsilon^2}{T}$. Now suppose that the answer to each query instance $(t,x) \in F$ is modified to some arbitrary fixed bit $a_{t,x}$ (these answers need not be consistent with any oracle). Let $|\tilde{\phi}_t^c\rangle$ be the state of the quantum register at time t if the oracle responses are modified as stated above. Then $||\phi_T^c\rangle - |\tilde{\phi}_T^c\rangle| \leq \epsilon$.*

The following lemma, which is an extension of Corollary 3.4 from [6], shows that no quantum learning algorithm that makes few QMQ queries can effectively distinguish many concepts in C' from the typical concept $\hat{c}$.

LEMMA 6. *Fix any quantum network architecture $\mathcal{N}$ which has query complexity T. For all $\epsilon > 0$ there is a set $S \subseteq C'$ of cardinality at most $T^2|C'|\hat{\gamma}^C/\epsilon^2$ such that for all $c \in C' \setminus S$ we have $||\phi_T^{\hat{c}}\rangle - |\phi_T^c\rangle| \leq \epsilon$.*

Proof. Since $||\phi_t^{\hat{c}}\rangle| = 1$ for $t = 0, 1, \ldots, T-1$, we have $\sum_{t=0}^{T-1} \sum_{x \in \{0,1\}^n} q_x(|\phi_t^{\hat{c}}\rangle) = T$. Let $q(|\phi_t^{\hat{c}}\rangle) \in \Re^{2^n}$ be the 2^n-dimensional vector which has entries indexed by strings $x \in \{0,1\}^n$ and which has $q_x(|\phi_t^{\hat{c}}\rangle)$ as its xth entry. Note that the L_1 norm $\|q(|\phi_t^{\hat{c}}\rangle)\|_1$ is 1 for all $t = 0, \ldots, T-1$. For any $c_i \in C'$ let $q_{c_i}(|\phi_t^{\hat{c}}\rangle)$ be defined as $\sum_{x : c_i(x) \neq \hat{c}(x)} q_x(|\phi_t^{\hat{c}}\rangle)$. The quantity $q_{c_i}(|\phi_t^{\hat{c}}\rangle)$ can be viewed as the total query magnitude with respect to $\hat{c}$ at time t of those strings which distinguish c_i from $\hat{c}$. Note that $Dq(|\phi_t^{\hat{c}}\rangle) \in \Re^{|C'|}$ is a $|C'|$-dimensional vector whose ith element is precisely $\sum_{x : c_i(x) \neq \hat{c}(x)} q_x(|\phi_t^{\hat{c}}\rangle) = q_{c_i}(|\phi_t^{\hat{c}}\rangle)$. Since $\|D\|_1 \leq |C'| \cdot \hat{\gamma}^C$ and $\|q(|\phi_t^{\hat{c}}\rangle)\|_1 = 1$, by the basic property of matrix norms we have that $\|Dq(|\phi_t^{\hat{c}}\rangle)\|_1 \leq |C'| \cdot \hat{\gamma}^C$, i.e., $\sum_{c_i \in C'} q_{c_i}(|\phi_t^{\hat{c}}\rangle) \leq |C'| \cdot \hat{\gamma}^C$. Hence

$$\sum_{t=0}^{T-1} \sum_{c_i \in C'} q_{c_i}(|\phi_t^{\hat{c}}\rangle) \leq T|C'| \cdot \hat{\gamma}^C.$$

If we let $S = \{c_i \in C' : \sum_{t=0}^{T-1} q_{c_i}(|\phi_t^{\hat{c}}\rangle) \geq \frac{\epsilon^2}{T}\}$, by Markov's inequality we have $|S| \leq T^2|C'|\hat{\gamma}^C/\epsilon^2$. Finally, if $c \notin S$, then $\sum_{t=0}^{T-1} q_c(|\phi_t^{\hat{c}}\rangle) \leq \frac{\epsilon^2}{T}$. Theorem 5 then implies that $||\phi_T^{\hat{c}}\rangle - |\phi_T^c\rangle| \leq \epsilon$. ∎

Now we can prove our quantum version of Lemma 4.

THEOREM 7. *Any quantum exact learning algorithm for C must have sample complexity* $\Omega\Big(\big(1/\hat{\gamma}^C\big)^{1/2}\Big)$.

Proof. Suppose that $\mathcal{N}$ is a quantum exact learning algorithm for $\mathcal{C}$ which makes at most $T = \frac{1}{64} \cdot (\frac{1}{\hat{\gamma}^C})^{1/2}$ quantum membership queries. If we take $\epsilon = \frac{1}{32}$, then Lemma 6 implies that there is a set $S \subset C'$ of cardinality at most $\frac{|C'|}{4}$ such that for all $c \in C' \setminus S$ we have $||\phi_T^c\rangle - |\phi_T^{\hat{c}}\rangle| \leq \frac{1}{32}$. Let c_1, c_2 be any two concepts in $C' \setminus S$. By Fact 1, the probability that $\mathcal{N}$ outputs a circuit equivalent to c_1 can differ by at most $\frac{1}{8}$ if $\mathcal{N}$'s oracle gates are $QMQ_{\hat{c}}$ as opposed to QMQ_{c_1}, and likewise for $QMQ_{\hat{c}}$ versus QMQ_{c_2}. It follows that the probability that $\mathcal{N}$ outputs a circuit equivalent to c_1 can differ by at most one fourth if $\mathcal{N}$'s oracle gates are QMQ_{c_1} as opposed to QMQ_{c_2}, but this contradicts the assumption that $\mathcal{N}$ is a quantum exact learning algorithm for C. □

Well-known results [9, 24] show that $O(\sqrt{N})$ queries are sufficient to search a quantum database of N unordered items for a desired item. These upper bounds can easily be used to show that Theorem 7 is tight up to constant factors.

A lower bound based on concept class size. A second reason why a concept class can require many membership queries is its size. Angluin [2] has given the following simple bound, incomparable to the bound of Lemma 4, on the number of classical membership queries required for exact learning.

LEMMA 8. *Any classical exact learning algorithm for C must have sample complexity* $\Omega(\log |C|)$.

Proof. Consider the following adversarial strategy for answering queries: if $C' \subseteq C$ is the set of concepts which have not yet been eliminated by previous responses to queries, then given the query string a, answer the bit b such that $\gamma^{C'}_{\langle a,b\rangle} \geq \frac{1}{2}$. Under this strategy, after $\log |C| - 1$ membership queries, at least two possible target concepts will remain. □

In this section we prove a variant of this lemma for the quantum model. Our proof uses ideas from [5], so we introduce some of their notation. Let $N = 2^n$. For each concept $c \in C$, let $X^c = (X^c_0, \ldots, X^c_{N-1}) \in \{0,1\}^N$ be a vector which represents c as an N-tuple, i.e., $X^c_i = c(x^i)$, where $x^i \in \{0,1\}^n$ is the binary representation of i. From this perspective we may identify C with a subset of $\{0,1\}^N$, and we may view a QMQ_c gate as a black-box oracle for X^c which maps basis state $|x^i, b, y\rangle$ to $|x^i, b \oplus X^c_i, y\rangle$.

Using ideas from [20, 21], Beals et al. have proved the following useful lemma, which relates the query complexity of a quantum network to the degree of a certain polynomial [5, Lemma 4.2].

LEMMA 9. *Let $\mathcal{N}$ be a quantum network that makes T queries to a black-box X, and let $B \subseteq \{0,1\}^m$ be a set of basis states. Then there exists a real-valued multilinear polynomial $P_B(X)$ of degree at most $2T$ which equals the probability that observing the final state of the network with black-box X yields a state from B.*

We use Lemma 9 to prove the following quantum lower bound based on concept class size. (de Wolf has observed [18] that this lower bound can also be obtained from the results of [19].)

THEOREM 10. *Any exact quantum learning algorithm for C must have sample complexity* $\Omega\big(\frac{\log |C|}{n}\big)$.

Proof. Let $\mathcal{N}$ be a quantum network which learns C and has query complexity T. For all $c \in C$ we have the following: if $\mathcal{N}$'s oracle gates are QMQ_c gates, then

with probability at least 2/3 the output of $\mathcal{N}$ is a representation of a Boolean circuit h which computes c. Let $c_1, \ldots, c_{|C|}$ be all of the concepts in C, and let $X^1, \ldots, X^{|C|}$ be the corresponding vectors in $\{0,1\}^N$. For all $i = 1, \ldots, |C|$ let $B_i \subseteq \{0,1\}^m$ be the collection of those basis states which are such that if the final observation performed by $\mathcal{N}$ yields a state from B_i, then the output of $\mathcal{N}$ is a representation of a Boolean circuit which computes c_i. Clearly for $i \neq j$ the sets B_i and B_j are disjoint. By Lemma 9, for each $i = 1, \ldots, |C|$ there is a real-valued multilinear polynomial P_i of degree at most $2T$ such that for all $j = 1, \ldots, |C|$ the value of $P_i(X^j)$ is precisely the probability that the final observation on $\mathcal{N}$ yields a representation of a circuit which computes c_i, provided that the oracle gates are QMQ_{c_j} gates. The polynomials P_i thus have the following properties:

1. $P_i(X^i) \geq 2/3$ for all $i = 1, \ldots, |C|$;
2. for any $j = 1, \ldots, |C|$, we have $\sum_{i \neq j} P_i(X^j) \leq 1/3$ (since the total probability across all possible observations is 1).

Let $N_0 = \sum_{i=0}^{2T} \binom{N}{i}$. For any $X = (X_0, \ldots, X_{N-1}) \in \{0,1\}^N$ let $\tilde{X} \in \{0,1\}^{N_0}$ be the column vector which has a coordinate for each monic multilinear monomial over $X_0, \ldots, X_{N-1}$ of degree at most $2T$. Thus, for example, if $N = 4$ and $2T = 2$, we have $X = (X_0, X_1, X_2, X_3)$ and

$$\tilde{X}^t = (1, X_0, X_1, X_2, X_3, X_0X_1, X_0X_2, X_0X_3, X_1X_2, X_1X_3, X_2X_3).$$

If V is a column vector in $\Re^{N_0}$, then $V^t\tilde{X}$ corresponds to the degree-$2T$ polynomial whose coefficients are given by the entries of V. For $i = 1, \ldots, |C|$ let $V_i \in \Re^{N_0}$ be the column vector which corresponds to the coefficients of the polynomial P_i. Let M be the $|C| \times N_0$ matrix whose ith row is V_i^t; note that multiplication by M defines a linear transformation from $\Re^{N_0}$ to $\Re^{|C|}$. Since $V_i^t\tilde{X}^j$ is precisely $P_i(X^j)$, the product $M\tilde{X}^j$ is a column vector in $\Re^{|C|}$ which has $P_i(X^j)$ as its ith coordinate.

Now let L be the $|C| \times |C|$ matrix whose jth column is the vector $M\tilde{X}^j$. A square matrix A is said to be *diagonally dominant* if $|a_{ii}| > \sum_{j \neq i} |a_{ij}|$ for all i. Properties 1 and 2 above imply that the transpose of L is diagonally dominant. It is well known that any diagonally dominant matrix must be of full rank (see, e.g., [32]). Since L is of full rank and each column of L is in the image of M, it follows that the image under M of $\Re^{N_0}$ is all of $\Re^{|C|}$, and hence $N_0 \geq |C|$. Finally, since $N_0 = \sum_{i=0}^{2T} \binom{N}{i} \leq N^{2T}$, we have $T \geq \frac{\log |C|}{2 \log N} = \frac{\log |C|}{2n}$, which proves the theorem. □

The lower bound of Theorem 10 is nearly tight, as witnessed by the following example: let C be the collection of all 2^n parity functions over $\{0,1\}^n$, so that each function in C is defined by a string $a \in \{0,1\}^n$ and $c_a(x) = a \cdot x$. The quantum algorithm which solves the well-known Deutsch–Jozsa problem [17] can be used to exactly identify a and thus learn the target concept with probability 1 from a single query. It follows that the factor of n in the denominator of Theorem 10 cannot be replaced by any function $g(n) = o(n)$.

3.3. Quantum and classical exact learning are equivalent. We have seen two different reasons why exact learning of a concept class can require a large number of classical membership queries: the class may contain many similar concepts (i.e., $\hat{\gamma}^C$ is small) or the class may contain very many concepts (i.e., $\log |C|$ is large). The following lemma, which is a variant of Theorem 3.1 from [26], shows that these are the only reasons why many membership queries may be required.

LEMMA 11. *There is an exact learning algorithm for C which has sample complexity $O((\log |C|)/\hat{\gamma}^C)$.*

Proof. Consider the following learning algorithm A: at each stage in its execution, if C' is the set of concepts in C which have not yet been eliminated by previous responses to queries, algorithm A's next query string is the string $a \in \{0,1\}^n$, which maximizes $\gamma_a^{C'}$. By following this strategy, each query response received from the oracle must eliminate at least a $\gamma^{C'}$ fraction of the set C', so with each query the size of the set of possible target concepts is multiplied by a factor which is at most $1 - \gamma^{C'} \leq 1 - \hat{\gamma}^C$. Consequently, after $O((\log |C|)/\hat{\gamma}^C)$ queries, only a single concept will not have been eliminated; this concept must be the target concept, so that A can output a hypothesis h which is equivalent to c. ∎

Combining Theorem 7, Theorem 10, and Lemma 11, we obtain the following relationship between the quantum and classical sample complexity of exact learning.

THEOREM 12. *Let $\mathcal{C}$ be any concept class over $\{0,1\}^n$, and let D and Q be such that $\mathcal{C}$ is exact learnable from D classical membership queries or from Q quantum membership queries. Then $D = O(nQ^3)$.*

We note that a QMQ_c oracle can clearly be used to simulate an MQ_c oracle, and thus $Q \leq D$ as well.

3.4. Discussion. Theorem 12 provides an interesting contrast to several known results for black-box quantum computation. Let F denote the set of all 2^{2^n} functions from $\{0,1\}^n$ to $\{0,1\}$. Beals et al. [5] have shown that if $f : F \to \{0,1\}$ is any total function (i.e., $f(c)$ is defined for every possible concept c over $\{0,1\}^n$), then the query complexity of any quantum network that computes f is polynomially related to the number of classical black-box queries required to compute f. Their result is interesting because it is well known [7, 11, 17, 40] that, for certain concept classes $C \subset F$ and partial functions $f : C \to \{0,1\}$, the quantum black-box query complexity of f can be exponentially smaller than the classical black-box query complexity.

Our Theorem 12 provides a sort of dual to the results of Beals et al.: their bound on query complexity holds only for the fixed concept class F but for any function $f : F \to \{0,1\}$, while our bound holds for any concept class $C \subseteq F$ but only for the fixed problem of exact learning. In general, the problem of computing a function $f : C \to \{0,1\}$ from black-box queries can be viewed as an easier version of the corresponding exact learning problem: instead of having to figure out only one bit of information about the unknown concept c (the value of f), for the learning problem the algorithm must identify c exactly. Theorem 1 shows that for this more demanding problem, unlike the results in [7, 11, 17, 40], there is no way of restricting the concept class C so that learning becomes substantially easier in the quantum setting than in the classical setting.

4. PAC learning from a quantum example oracle.

4.1. The quantum example oracle. Bshouty and Jackson [13] have introduced a natural quantum generalization of the standard PAC-model example oracle. While a standard PAC example oracle $EX(c, \mathcal{D})$ generates each example $\langle x, c(x)\rangle$ with probability $\mathcal{D}(x)$, where $\mathcal{D}$ is a distribution over $\{0,1\}^n$, a *quantum PAC example oracle* $QEX(c, \mathcal{D})$ generates a superposition of all labeled examples, where each labeled example $\langle x, c(x)\rangle$ appears in the superposition with amplitude proportional to the square root of $\mathcal{D}(x)$. More formally, a $QEX(c, \mathcal{D})$ gate maps the initial basis state $|0^n, 0\rangle$ to the state $\sum_{x \in \{0,1\}^n} \sqrt{\mathcal{D}(x)}|x, c(x)\rangle$. (We leave the action of a $QEX(c, \mathcal{D})$ gate undefined on other basis states, and stipulate that any quantum network which includes T $QEX(c, \mathcal{D})$ gates must have all T gates at the "bottom of the circuit," i.e., no gate may occur on any wire between the inputs and any $QEX(c, \mathcal{D})$ gate.) A

quantum network with T $QEX(c, \mathcal{D})$ gates is said to be a QEX network with *query complexity* T.

A *quantum PAC learning algorithm for* $\mathcal{C}$ is a family $\{\mathcal{N}_{(n,\epsilon,\delta)} : n \geq 1,\ 0 < \epsilon, \delta < 1\}$ of QEX networks with the following property: for all $n \geq 1$ and $0 < \epsilon, \delta < 1$, for all $c \in C_n$, for all distributions $\mathcal{D}$ over $\{0,1\}^n$, if the network $\mathcal{N}_{(n,\epsilon,\delta)}$ has all its oracle gates instantiated as $QEX(c, \mathcal{D})$ gates, then with probability at least $1 - \delta$ the network $\mathcal{N}_{(n,\epsilon,\delta)}$ outputs a representation of a circuit h, which is an ϵ-approximator to c under $\mathcal{D}$. The *quantum sample complexity* $T(n, \epsilon, \delta)$ of a quantum PAC algorithm is the query complexity of $\mathcal{N}_{(n,\epsilon,\delta)}$.

4.2. Lower bounds on classical and quantum PAC learning. Throughout this section for ease of notation we omit the subscript n and write C for C_n. We view each concept $c \in C$ as a subset of $\{0,1\}^n$. For $S \subseteq \{0,1\}^n$, we write $\Pi_C(S)$ to denote $\{c \cap S : c \in C\}$, so $|\Pi_C(S)|$ is the number of different "dichotomies" which the concepts in C induce on the points in S. A subset $S \subseteq \{0,1\}^n$ is said to be *shattered* by C if $|\Pi_C(S)| = 2^{|S|}$, i.e., if C induces every possible dichotomy on the points in S. The *Vapnik–Chervonenkis dimension of* C, VC-DIM(C), is the size of the largest subset $S \subseteq \{0,1\}^n$ which is shattered by C (see [43]).

Well-known results in computational learning theory show that the Vapnik–Chervonenkis dimension of a concept class C characterizes the number of calls to $EX(c, \mathcal{D})$, which are information-theoretically necessary and sufficient to PAC learn C. For the lower bound, the following theorem is a slight simplification of a result due to Blumer et al. [8, Theorem 2.1.ii.b].

THEOREM 13. *Let C be any concept class and $d =$ VC-DIM(C). Then any (classical) PAC learning algorithm for $\mathcal{C}$ must have sample complexity $\Omega(d)$.*

Proof sketch. The idea behind Theorem 13 is to consider the distribution $\mathcal{D}$ which is uniform over some shattered set S of size d and assigns zero weight to points outside of S. Any learning algorithm which makes only $d/2$ calls to $EX(c, \mathcal{D})$ will have no information about the value of c on at least $d/2$ points in S; moreover, since the set S is shattered by C, any labeling is possible for these unseen points. Since the error of any hypothesis h under $\mathcal{D}$ is the fraction of points in S at which h and the target concept disagree, a simple analysis shows that no learning algorithm which performs only $d/2$ calls to $EX(c, \mathcal{D})$ can have a high probability (e.g., $1 - \delta = 2/3$) of generating a low-error hypothesis (e.g., $\epsilon = 1/10$). □

We now give a quantum analogue of the classical lower bound given by Theorem 13.

THEOREM 14. *Let $\mathcal{C}$ be any concept class and $d =$ VC-DIM(C). Then any quantum PAC learning algorithm for $\mathcal{C}$ must have quantum sample complexity $\Omega(\frac{d}{n})$.*

Proof. Let $S = \{x^1, \ldots, x^d\}$ be a set which is shattered by C, and let $\mathcal{D}$ be the distribution which is uniform on S and assigns zero weight to points outside S. If $h : \{0,1\}^n \to \{0,1\}$ is a Boolean function on $\{0,1\}^n$, we say that the *relative distance of h and c on S* is the fraction of points in S at which h and c disagree. We will prove the following result, which is stronger than Theorem 14: let $\mathcal{N}$ be a quantum network with QMQ gates such that for all $c \in C$, if $\mathcal{N}$'s oracle gates are QMQ_c gates, then with probability at least $2/3$ the output of $\mathcal{N}$ is a hypothesis h such that the relative distance of h and c on S is at most $1/10$. We will show that such a network $\mathcal{N}$ must have query complexity at least $d/12n$. Since any QEX network with query complexity T can be simulated by a QMQ network with query complexity T, taking $\epsilon = 1/10$ and $\delta = 1/3$ will prove Theorem 14.

The argument is a modification of the proof of Theorem 10 using ideas from

error correcting codes. Let $\mathcal{N}$ be a quantum network with query complexity T which satisfies the following condition: for all $c \in C$, if $\mathcal{N}$'s oracle gates are QMQ_c gates, then with probability at least $2/3$ the output of $\mathcal{N}$ is a representation of a Boolean circuit h such that the relative distance of h and c on S is at most $1/10$. By the well-known Gilbert–Varshamov bound from coding theory (see, e.g., Theorem 5.1.7 of [42]), there exists a set $s^1, \ldots, s^A$ of d-bit strings such that for all $i \neq j$ the strings s^i and s^j differ in at least $d/4$ bit positions, where

$$A \geq \frac{2^d}{\sum_{i=0}^{d/4-1} \binom{d}{i}} \geq \frac{2^d}{\sum_{i=0}^{d/4} \binom{d}{i}} \geq 2^{d(1-H(1/4))} > 2^{d/6}.$$

(Here $H(p) = -p \log p - (1-p)\log(1-p)$ is the binary entropy function.) For each $i = 1, \ldots, A$ let $c_i \in C$ be a concept such that the d-bit string $c_i(x^1) \cdots c_i(x^d)$ is s^i (such a concept c_i must exist since the set S is shattered by C).

For $i = 1, \ldots, A$ let $B_i \subseteq \{0,1\}^m$ be the collection of those basis states which are such that if the final observation performed by $\mathcal{N}$ yields a state from B_i, then the output of $\mathcal{N}$ is a hypothesis h such that h and c_i have relative distance at most $1/10$ on S. Since each pair of concepts c_i, c_j has relative distance at least $1/4$ on S, the sets B_i and B_j are disjoint for all $i \neq j$.

As in section 3.2, let $N = 2^n$ and let $X^j = (X^j_0, \ldots, X^j_{N-1}) \in \{0,1\}^n$, where X^j is the N-tuple representation of the concept c_j. By Lemma 9, for each $i = 1, \ldots, A$ there is a real-valued multilinear polynomial P_i of degree at most $2T$ such that for all $j = 1, \ldots, A$ the value of $P_i(X^j)$ is precisely the probability that the final observation on $\mathcal{N}$ yields a state from B_i, provided that the oracle gates are QMQ_{c_j} gates. Since, by assumption, if c_i is the target concept, then with probability at least $2/3$, $\mathcal{N}$ generates a hypothesis that has relative distance at most $1/10$ from c_i on S, the polynomials P_i have the following properties:

1. $P_i(X^i) \geq 2/3$ for all $i = 1, \ldots, A$;
2. for any $j = 1, \ldots, A$ we have that $\sum_{i \neq j} P_i(X^j) \leq 1/3$ (since the B_i's are disjoint and the total probability across all observations is 1).

Let N_0 and $\tilde{X}$ be defined as in the proof of Theorem 10. For $i = 1, \ldots, A$ let $V_i \in \Re^{N_0}$ be the column vector which corresponds to the coefficients of the polynomial P_i, so that $V_i^t \tilde{X} = P_i(X)$. Let M be the $A \times N_0$ matrix whose ith row is the vector V_i^t, so that multiplication by M is a linear transformation from $\Re^{N_0}$ to $\Re^A$. The product $M\tilde{X}^j$ is a column vector in $\Re^A$ which has $P_i(X)$ as its ith coordinate.

Now let L be the $A \times A$ matrix whose jth column is the vector $M\tilde{X}^j$. As in Theorem 10, we have that the transpose of L is diagonally dominant, and thus L is of full rank and hence $N_0 \geq A$. Since $A \geq 2^{d/6}$, we thus have that $T \geq \frac{d/6}{2 \log_2 N} = \frac{d}{12n}$, and the theorem is proved. □

Since the class of parity functions over $\{0,1\}^n$ has VC-dimension n, as in Theorem 10 the n in the denominator of Theorem 14 cannot be replaced by any function $g(n) = o(n)$.

4.3. Quantum and classical PAC learning are equivalent. A well-known theorem due to Blumer et al. (Theorem 3.2.1.ii.a of [8]) shows that VC-DIM(C) also upper-bounds the number of $EX(c, \mathcal{D})$ calls required for (classical) PAC learning.

THEOREM 15. *Let C be any concept class and $d =$ VC-DIM(C). There is a classical PAC learning algorithm for C which has sample complexity $O(\frac{1}{\epsilon} \log \frac{1}{\delta} + \frac{d}{\epsilon} \log \frac{1}{\epsilon})$.*

The proof of Theorem 15 is quite complex, and thus we do not attempt to sketch it. As in section 3.3, this upper bound along with our lower bound from Theorem 14

together yield the following.

THEOREM 16. *Let $\mathcal{C}$ be any concept class over $\{0,1\}^n$, and let D and Q be such that $\mathcal{C}$ is PAC learnable from D classical examples or from Q quantum examples. Then $D = O(nQ)$.*

We note that a $QEX(c, \mathcal{D})$ oracle can be used to simulate the corresponding $EX(c, \mathcal{D})$ oracle by immediately performing an observation on the QEX gate's outputs[3] (such an observation yields each example $\langle x, c(x)\rangle$ with probability $\mathcal{D}(x)$), and thus $Q \leq D$.

5. Quantum versus classical efficient learnability. We have shown that, from an information-theoretic perspective, up to polynomial factors quantum learning is no more powerful than classical learning. However, we now observe that the apparent *computational* advantages of the quantum model yield efficient quantum learning algorithms which seem to have no efficient classical counterparts.

A *Blum integer* is an integer $N = pq$, where $p \neq q$ are ℓ-bit primes each congruent to 3 modulo 4. It is widely believed that there is no polynomial-time classical algorithm which can successfully factor a randomly selected Blum integer with nonnegligible success probability.

Kearns and Valiant [28] have constructed a concept class $\mathcal{C}$ whose PAC learnability is closely related to the problem of factoring Blum integers. In their construction each concept $c \in \mathcal{C}$ is uniquely defined by some Blum integer N. Furthermore, c has the property that if $c(x) = 1$, then the prefix of x is the binary representation of N. Kearns and Valiant prove that if there is a polynomial-time PAC learning algorithm for $\mathcal{C}$, then there is a polynomial-time algorithm which factors Blum integers. Thus, assuming that factoring Blum integers is a computationally hard problem for classical computation, the Kearns–Valiant concept class $\mathcal{C}$ is not efficiently PAC learnable.

On the other hand, in a celebrated result, Shor [39] has exhibited a poly(n) size quantum network that can factor any n-bit integer with high success probability. Since each positive example of a concept $c \in \mathcal{C}$ reveals the Blum integer N which defines c, using Shor's algorithm it is easy to obtain an efficient quantum PAC learning algorithm for the Kearns–Valiant concept class. We thus have the following.

OBSERVATION 2. *If there is no polynomial-time classical algorithm for factoring Blum integers, then there is a concept class $\mathcal{C}$ that is efficiently quantum PAC learnable but not efficiently classically PAC learnable.*

The hardness results of Kearns and Valiant were later extended by Angluin and Kharitonov [3]. Using a public-key encryption system which is secure against chosen-cyphertext attack (based on the assumption that factoring Blum integers is computationally hard for polynomial-time algorithms), they constructed a concept class $\mathcal{C}$ which cannot be learned by any polynomial-time learning algorithm that makes membership queries. As with the Kearns–Valiant concept class, though, using Shor's quantum factoring algorithm it is possible to construct an efficient quantum exact learning algorithm for this concept class. Thus, for the exact learning model as well, we have the following.

OBSERVATION 3. *If there is no polynomial-time classical algorithm for factoring Blum integers, then there is a concept class $\mathcal{C}$ which is efficiently quantum exact learnable from membership queries but not efficiently classically exact learnable from membership queries.*

[3] As noted in section 2.3, intermediate observations during a computation can always be simulated by a single observation at the end of the computation.

In the next sections we prove Theorem 3, which establishes a stronger computational separation between the quantum and classical models of exact learning from membership queries than is implied by Observation 3. The proof involves Simon's quantum oracle algorithm, which we briefly describe in the next section.

6. Simon's algorithm. Let $f : \{0,1\}^n \to \{0,1\}^n$ be a function, and let $0^n \neq s \in \{0,1\}^n$. We say that f is *two-to-one with XOR mask* s if for all $y \neq x$, $f(x) = f(y) \iff y = x \oplus s$. More generally, f is *invariant under XOR mask with* s if $f(x) = f(x \oplus s)$ for all $x \in \{0,1\}^n$ (note that such a function need not be two-to-one).

Simon [40] has given a simple quantum algorithm which takes oracle access to a function $f : \{0,1\}^n \to \{0,1\}^n$, runs in poly$(n)$ time, and behaves as follows:

1. If f is a permutation on $\{0,1\}^n$, the algorithm outputs an n-bit string y which is uniformly distributed over $\{0,1\}^n$.
2. If f is two-to-one with XOR mask s, the algorithm outputs an n-bit string y which is uniformly distributed over the 2^{n-1} strings such that $y \cdot s = 0$.
3. If f is invariant under XOR mask with s, the algorithm outputs some n-bit string y which satisfies $y \cdot s = 0$.

Simon showed that by running this procedure $O(n)$ times, a quantum algorithm can distinguish between case 1 (f is a permutation) and case 3 (f is invariant under some XOR mask) with high probability. In case 1, after $O(n)$ repetitions the strings obtained will with probability $1 - 2^{-O(n)}$ contain a basis for the vector space $(Z_2)^n$ (here we are viewing n-bit strings as vectors over Z_2), while in case 3 the strings obtained cannot contain such a basis since each string must lie in the subspace $\{y : y \cdot s = 0\}$. Simon also observed that in case 2 (f is two-to-one with XOR mask s) the algorithm can be used to efficiently identify s with high probability. This is because after $O(n)$ repetitions, with high probability s will be the unique nonzero vector whose dot product with each y is 0; this vector can be found by solving the linear system defined by the y's.

Simon also analyzed the success probability of classical oracle algorithms for this problem. His analysis establishes the following theorem.

THEOREM 17. *Let $0^n \neq s \in \{0,1\}^n$ be chosen uniformly and let $f : \{0,1\}^n \to \{0,1\}^n$ be an oracle chosen uniformly from the set of all functions which are two-to-one with XOR mask s. Then* (i) *there is a polynomial-time quantum oracle algorithm which identifies s with high probability;* (ii) *any p.p.t. classical oracle algorithm identifies s with probability $1/2^{\Omega(n)}$.*

This surprising ability of quantum oracle algorithms to efficiently find s is highly suggestive in the context of our search for a learning problem which separates efficient classical and quantum computation. Indeed, Simon's algorithm will play a crucial role in establishing that the concept class which we construct in section 8 is learnable in poly(n) time by a quantum algorithm. Recall that in our learning scenario, though, the goal is to *exactly identify* the unknown target function, not just to identify the string s. Since $2^{\Omega(n)}$ bits are required to specify a randomly chosen function f which is two-to-one with XOR mask s, no algorithm (classical or quantum) can output a description of f in poly(n) time, much less learn f in poly(n) time. Thus it will not do to use truly random functions for our learning problem; instead we use *pseudorandom* functions as described in the next section.

7. Pseudorandomness. A *pseudorandom function family* [23] is a collection of functions $\{f_s : \{0,1\}^{|s|} \to \{0,1\}^{|s|}\}_{s \in \{0,1\}^*}$ with the following two properties:

- *(efficient evaluation)* there is a deterministic algorithm which, given an n-bit seed s and an n-bit input x, runs in time poly(n) and outputs $f_s(x)$;

- *(pseudorandomness)* for all polynomials Q, all p.p.t. oracle algorithms M, and all sufficiently large n, we have that

$$\left| \Pr_{F \in \mathcal{F}_n} [M^F \text{ outputs } 1] - \Pr_{s \in \{0,1\}^n} [M^{f_s} \text{ outputs } 1] \right| < \frac{1}{Q(n)}.$$

Intuitively, the pseudorandomess property ensures that in any p.p.t. computation that uses a truly random function, a randomly chosen pseudorandom function may be used instead without affecting the outcome in a noticeable way. Well-known results [23, 25] imply that pseudorandom function families exist iff any one-way function exists.

A *pseudorandom permutation family* is a pseudorandom function family with the added property that each function $f_s : \{0,1\}^{|s|} \to \{0,1\}^{|s|}$ is a permutation. Luby and Rackoff [30] gave the first construction of a pseudorandom permutation family from any pseudorandom function family. In their construction each permutation $f_s : \{0,1\}^n \to \{0,1\}^n$ has a seed s of length $|s| = 3n/2$ rather than n as in our definition above. Subsequent constructions [33, 34, 35] of pseudorandom permutation families $\{f_s : \{0,1\}^n \to \{0,1\}^n\}$ use n-bit seeds and hence match our definition exactly. (Our definition of pseudorandomness could easily be extended to allow seed lengths other than n. For our construction in section 8 it will be convenient to have n-bit seeds.)

7.1. Pseudorandom functions invariant under XOR mask. Our main cryptographic result, stated below, is proved in the appendix.

THEOREM 18. *If any one-way function exists, then there is a pseudorandom function family* $\{g_s : \{0,1\}^{|s|} \to \{0,1\}^{|s|}\}$ *such that* $g_s(x) = g_s(x \oplus s)$ *for all* $|x| = |s|$.

A first approach to constructing such a family is as follows: given any pseudorandom function family $\{f_s\}$, let $\{g_s\}$ be defined by

$$g_s(x) \stackrel{\text{def}}{=} f_s(x) \oplus f_s(x \oplus s). \tag{1}$$

This simple construction ensures that each function g_s is invariant under XOR mask with s, but the family $\{g_s\}$ need not be pseudorandom just because $\{f_s\}$ is pseudorandom. Indeed, if $\{h_s\}$ is similarly defined by $h_s(x) \stackrel{\text{def}}{=} g_s(x) \oplus g_s(x \oplus s)$, then $\{h_s\}$ is not pseudorandom since

$$h_s(x) \;=\; (f_s(x) \oplus f_s(x \oplus s)) \oplus (f_s(x \oplus s) \oplus f_s(x \oplus s \oplus s)) \;=\; 0^n.$$

While this example shows that (1) does not always preserve pseudorandomness, it leaves open the possibility that (1) may preserve pseudorandomness for certain function families $\{f_s\}$. In the appendix we show that if $\{f_s\}$ is a pseudorandom function family which is constructed from any one-way function in a particular way, then the family $\{g_s\}$ defined by (1) is indeed pseudorandom.

It may at first appear that the pseudorandom function family $\{g_s\}$ given by Theorem 18 immediately yields a concept class which separates efficient quantum learning from efficient classical learning. The pseudorandomness of $\{g_s\}$ ensures that no p.p.t. algorithm can learn successfully; on the other hand, if Simon's quantum algorithm is given oracle access to a function which is two-to-one with XOR mask s, then it can efficiently find s with high probability. Hence it may seem that, given access to g_s, Simon's quantum algorithm can efficiently identify the seed s and thus learn the target concept.

The flaw in this argument is that each function g_s from Theorem 18, while invariant under XOR mask with s, need not be two-to-one. Indeed g_s could conceivably be invariant under XOR mask with, say, $\sqrt{n}$ linearly independent strings $s = s^1, s^2, \ldots, s^{\sqrt{n}}$. Such a set of strings spans a $2^{\sqrt{n}}$-element subspace of $\{0,1\}^n$; even if Simon's algorithm could identify this subspace, it would not indicate which element of the subspace is the true seed s. Hence a more sophisticated construction is required.

8. Proof of Theorem 3.

8.1. The concept class C. We describe concepts over $\{0,1\}^m$, where $m = n + 2\log n + 1$. Each concept in C_m is defined by an $(n+1)$-tuple $(y, s^1, \ldots, s^n)$, where $y = y_1 \cdots y_n \in \{0,1\}^n$ and each $s^i \in \{0,1\}^n \setminus \{0^n\}$, so C_m contains $2^n(2^n-1)^n$ distinct concepts. For brevity we write $\tilde{s}$ to stand for $s^1, \ldots, s^n$ below.

Roughly speaking, each concept in C_m comprises n pseudorandom functions; as explained below, the string y acts as a "password" and the strings $s^1, \ldots, s^n$ are the seeds to the pseudorandom functions. Each concept $c \in C_m$ takes m-bit strings as inputs; we view such an m-bit input as a 4-tuple (b, x, i, j), where $b \in \{0,1\}$, $x \in \{0,1\}^n$, and $i, j \in \{0,1\}^{\log n}$ each represent a number in the range $\{1, 2, \ldots, n\}$.

Let $\{h_s^0 : \{0,1\}^{|s|} \to \{0,1\}^{|s|}\}_{s \in \{0,1\}^*}$ be a pseudorandom permutation family and let $\{h_s^1 : \{0,1\}^{|s|} \to \{0,1\}^{|s|}\}_{s \in \{0,1\}^*}$ be the pseudorandom function family from Theorem 18, so that $h_s^1(x) = h_s^1(x \oplus s)$. The concept $c_{y,\tilde{s}}$ is defined as follows on input (b, x, i, j) :

- **If $b = 0$**: A query $(0, x, i, j)$ is called a *function query.* The value of $c_{y,\tilde{s}}(0, x, i, j)$ is $h_{s^i}^{y_i}(x)_j$, i.e., the jth bit of the n-bit string $h_{s^i}^{y_i}(x)$. Thus the bit y_i determines whether the ith pseudorandom function used is a permutation or is invariant under XOR mask with s^i.
- **If $b = 1$**: A query $(1, x, i, j)$ is called a *seed query.* The value of $c_{y,\tilde{s}}(1, x, i, j)$ is 0 if $x \neq y$ and is s_j^i (the jth bit of the ith seed s^i) if $x = y$.

The intuition behind our construction is simple: in order to learn the target concept successfully a learning algorithm must identify each seed string $s^1, \ldots, s^n$. These strings can be identified by making seed queries $(1, y, i, j)$, but in order to make the correct seed queries the learning algorithm must know y. Since each bit y_i corresponds to whether an oracle is a permutation or is XOR-mask invariant, a quantum algorithm can determine each y_i and thus can learn successfully. However, no p.p.t. algorithm can distinguish between these two types of oracles (since in either case the oracle is pseudorandom and hence is indistinguishable from a truly random function), and thus no p.p.t. algorithm can learn y.

8.2. A quantum algorithm which learns C in polynomial time. The main result of this section is the following.

THEOREM 19. *The concept class C described above is polynomial-time learnable from quantum membership queries.*

Proof. Let $c_{y,\tilde{s}} \in C_m$ be the target concept. Each function $h_{s^i}^{y_i}$ is a permutation iff $y_i = 0$, and is XOR-mask invariant iff $y_i = 1$. (This is why we do not allow $s^i = 0^n$ in the definition of the concept class.) Using quantum membership queries, a poly(n)-time quantum algorithm can run Simon's procedure n times, once for each function $h_{s^i}^{y_i}$, and thus determine each bit y_i with high probability. (One detail which arises here is that Simon's algorithm uses an oracle $\{0,1\}^n \to \{0,1\}^n$, whereas in our learning setting the oracle outputs one bit at a time. This is not a problem since it is possible to simulate any call to Simon's oracle by making n sequential calls,

bit by bit, to our oracle.) Given the string $y = y_1 \cdots y_n$, the algorithm can then make n^2 queries on inputs $(1, y, i, j)$ for $1 \leq i, j \leq n$ to learn each of the n strings $s^1, \ldots, s^n$. Once y and $s^1, \ldots, s^n$ are known, it is straightforward to output a circuit for $c_{y,\tilde{s}}$. □

8.3. No classical algorithm learns C in polynomial time. The main result of this section is the following.

THEOREM 20. *C is not polynomial-time learnable from classical membership queries.*

Let $C'_m \supset C_m$, $|C'_m| = 2^{n^2+n}$, be the concept class $C'_m = \{c_{y,\tilde{s}} : y, s^1, \ldots, s^n \in \{0,1\}^n\}$; thus C'_m includes concepts in which s^i may be 0^n. The following lemma states that it is hard to learn a target concept chosen uniformly from C'_m.

LEMMA 21. *For all polynomials Q, all p.p.t. learning algorithms A, and all sufficiently large n,*

$$\Pr_{c_{y,\tilde{s}} \in C'_m}[A^{c_{y,\tilde{s}}} \text{ outputs a hypothesis } h \equiv c_{y,\tilde{s}}] < \frac{1}{Q(n)}.$$

To see that Lemma 21 implies Theorem 20, we note that the uniform distribution over C'_m and the uniform distribution over C_m are nearly identical (the two distributions have total variation distance $O(n/2^n)$). Lemma 21 thus has the following analogue for C_m, which clearly implies Theorem 20.

LEMMA 22. *For all polynomials Q, all p.p.t. learning algorithms A, and all sufficiently large n,*

$$\Pr_{c_{y,\tilde{s}} \in C_m}[A^{c_{y,\tilde{s}}} \text{ outputs a hypothesis } h \equiv c_{y,\tilde{s}}] < \frac{1}{Q(n)}.$$

The proof of Lemma 21 proceeds as follows: we say that a learning algorithm A *hits* y if at some point during its execution A makes a seed query $(1, y, i, j)$, and we say that A *misses* y if A does not hit y. We have that

$$\begin{aligned}\Pr_{c_{y,\tilde{s}} \in C'_m}[A^{c_{y,\tilde{s}}} \text{ outputs } h \equiv c_{y,\tilde{s}}] &= \Pr[A^{c_{y,\tilde{s}}} \text{ outputs } h \equiv c_{y,\tilde{s}} \ \ \& \ \ A^{c_{y,\tilde{s}}} \text{ hits } y] \\ &\quad + \Pr[A^{c_{y,\tilde{s}}} \text{ outputs } h \equiv c_{y,\tilde{s}} \ \ \& \ \ A^{c_{y,\tilde{s}}} \text{ misses } y] \\ &\leq \Pr[A^{c_{y,\tilde{s}}} \text{ hits } y] \\ &\quad + \Pr[A^{c_{y,\tilde{s}}} \text{ outputs } h \equiv c_{y,\tilde{s}} \ \mid \ A^{c_{y,\tilde{s}}} \text{ misses } y].\end{aligned}$$

Lemma 21 thus follows from the following two lemmas.

LEMMA 23. *For all polynomials Q, all p.p.t. learning algorithms A, and all sufficiently large n,*

$$\Pr_{c_{y,\tilde{s}} \in C'_m}[A^{c_{y,\tilde{s}}} \text{ hits } y] < \frac{1}{Q(n)}.$$

LEMMA 24. *For all polynomials Q, all p.p.t. learning algorithms A, and all sufficiently large n,*

$$\Pr_{c_{y,\tilde{s}} \in C'_m}[A^{c_{y,\tilde{s}}} \text{ outputs } h \equiv c_{y,\tilde{s}} \ \mid \ A^{c_{y,\tilde{s}}} \text{ misses } y] < \frac{1}{Q(n)}.$$

8.3.1. Proof of Lemma 23. The idea of the proof is as follows: before hitting y for the first time, algorithm A gets 0 as the answer to each seed query, so A might as well be querying a modified oracle which answers 0 to *every* seed query. We show that no p.p.t. algorithm which has access to such an oracle can output y with inverse polynomial success probability (intuitively this is because such an oracle consists entirely of pseudorandom functions and hence can provide no information to any p.p.t. algorithm), and thus A's probability of hitting y must be less than $1/\mathrm{poly}(n)$ as well.

More formally, let A be any p.p.t. learning algorithm. Without loss of generality we may suppose that A always makes exactly $q(n)$ seed queries during its execution for some polynomial q. Let $X^1, \ldots, X^{q(n)}$ be the sequence of strings in $\{0,1\}^n$ on which $A^{c_{y,\tilde{s}}}$ makes its seed queries; i.e., $A^{c_{y,\tilde{s}}}$ uses $(1, X^t, i_t, j_t)$ as its tth seed query. Each X^t is a random variable over the probability space defined by the uniform choice of $c_{y,\tilde{s}} \in C'_m$ and any internal randomness of algorithm A.

For each $c_{y,\tilde{s}} \in C'_m$ let $\tilde{c}_{y,\tilde{s}} : \{0,1\}^m \to \{0,1\}$ be a modified version of $c_{y,\tilde{s}}$ which answers 0 to all seed queries; i.e., $\tilde{c}_{y,\tilde{s}}(b,x,i,j)$ is $c_{y,\tilde{s}}(b,x,i,j)$ if $b = 0$ and is 0 if $b = 1$. Consider the following algorithm B which takes access to an oracle for $\tilde{c}_{y,\tilde{s}}$ and outputs an n-bit string. B executes algorithm $A^{\tilde{c}_{y,\tilde{s}}}$ (note that the oracle used is $\tilde{c}_{y,\tilde{s}}$ rather than $c_{y,\tilde{s}}$), then chooses a uniform random value $1 \le t \le q(n)$, and outputs $\tilde{X}^t$, the string on which $A^{\tilde{c}_{y,\tilde{s}}}$ made its tth seed query. Like the X^t's, each $\tilde{X}^t$ is a random variable over the probability space defined by a uniform choice of $c_{y,\tilde{s}} \in C'_m$ and any internal randomness of A.

The following two lemmas together imply Lemma 23.

LEMMA 25. $2q(n)^2 \cdot \Pr_{c_{y,\tilde{s}} \in C'_m}[B^{\tilde{c}_{y,\tilde{s}}} \textit{ outputs } y] \ge \Pr_{c_{y,\tilde{s}} \in C'_m}[A^{c_{y,\tilde{s}}} \textit{ hits } y]$.

LEMMA 26. *For all polynomials Q and all sufficiently large n, we have*

$$\left| \Pr_{c_{y,\tilde{s}} \in C'_m}[B^{\tilde{c}_{y,\tilde{s}}} \textit{ outputs } y] - \frac{1}{2^n} \right| < \frac{1}{Q(n)}.$$

Proof of Lemma 25. We have that

$$\sum_{t=1}^{q(n)} \Pr[X^t = y \text{ and } X^\tau \neq y \text{ for } \tau < t] \le \sum_{t=1}^{q(n)} \Pr[X^t = y \mid X^\tau \neq y \text{ for } \tau < t].$$

Since the left-hand side of this inequality is exactly $\Pr_{c_{y,\tilde{s}} \in C'_m}[A^{c_{y,\tilde{s}}} \text{ hits } y]$, for some value $1 \le t_0 \le q(n)$ we have

$$\Pr[X^{t_0} = y \mid X^\tau \neq y \text{ for } \tau < t_0] \ge \Pr[A^{c_{y,\tilde{s}}} \text{ hits } y]/q(n). \tag{2}$$

Since the distribution of responses to function queries that A makes prior to its first seed query is the same regardless of whether the oracle is $c_{y,\tilde{s}}$ or $\tilde{c}_{y,\tilde{s}}$, it is clear that the random variables X^1 and $\tilde{X}^1$ are identically distributed. An inductive argument shows that for all $t \ge 1$, the conditional random variables $X^t \mid (X^\tau \neq y \text{ for } \tau < t)$ and $\tilde{X}^t \mid (\tilde{X}^\tau \neq y \text{ for } \tau < t)$ are identically distributed. (In each case the conditioning ensures that the distribution of responses to seed queries that A makes prior to its tth seed query is the same, i.e., all 0.)

We consider two possible cases. If $\Pr_{c_{y,\bar{s}} \in C'_m}[\tilde{X}^\tau \neq y \text{ for } \tau < t_0] > 1/2$, then

$$\begin{aligned}
\Pr_{c_{y,\bar{s}} \in C'_m}[B^{\tilde{c}_{y,\bar{s}}} \text{ outputs } y] &\geq \Pr[B^{\tilde{c}_{y,\bar{s}}} \text{ chooses } t_0] \cdot \Pr[\tilde{X}^{t_0} = y \ \&\ \tilde{X}^\tau \neq y \text{ for } \tau < t_0] \\
&= \frac{\Pr[\tilde{X}^{t_0} = y \mid \tilde{X}^\tau \neq y \text{ for } \tau < t_0] \cdot \Pr[\tilde{X}^\tau \neq y \text{ for } \tau < t_0]}{q(n)} \\
&> \frac{\Pr[\tilde{X}^{t_0} = y \mid \tilde{X}^\tau \neq y \text{ for } \tau < t_0]}{2q(n)} \\
&= \frac{\Pr[X^{t_0} = y \mid X^\tau \neq y \text{ for } \tau < t_0]}{2q(n)} \\
&\geq \frac{\Pr[A^{c_{y,\bar{s}}} \text{ hits } y]}{2q(n)^2}. \qquad \text{(by (2))}
\end{aligned}$$

Otherwise if $\Pr_{c_{y,\bar{s}} \in C'_m}[\tilde{X}^\tau \neq y \text{ for } \ \tau < t_0] \leq 1/2$, then $\sum_{t=1}^{t_0-1} \Pr[\tilde{X}^t = y] \geq 1/2$ and hence $\Pr_{c_{y,\bar{s}} \in C'_m}[B^{\tilde{c}_{y,\bar{s}}} \text{ outputs } y]$ is at least

$$\sum_{t=1}^{t_0-1} \Pr[B^{\tilde{c}_{y,\bar{s}}} \text{ chooses } t] \cdot \Pr[\tilde{X}^t = y] \geq \frac{1}{2q(n)} \geq \frac{\Pr[A^{c_{y,\bar{s}}} \text{ hits } y]}{2q(n)^2}. \qquad \square$$

Proof of Lemma 26. For $z, \zeta \in \{0,1\}^n$ let

$$p_\zeta^z = \Pr_{c_{y,\bar{s}} \in C'_m}[B^{\tilde{c}_{y,\bar{s}}} \text{ outputs } z \ \mid \ y = \zeta].$$

For $\ell \in \{1, \ldots, n\}$ let $\zeta || \ell$ denote ζ with the ℓth bit flipped. Similarly, for $S \subseteq \{1, \ldots, n\}$ let $\zeta || S$ denote ζ with bits flipped in all positions corresponding to S.

Fix $z, \zeta \in \{0,1\}^n$ and $\ell \in \{1, \ldots, n\}$ and consider the following algorithm $D_{z,\zeta,\ell}$, which takes access to an oracle $f : \{0,1\}^n \to \{0,1\}^n$ and outputs a single bit. For all $i \neq \ell$, algorithm $D_{z,\zeta,\ell}$ first chooses a random n-bit string s^i. $D_{z,\zeta,\ell}$ then runs algorithm B, simulating the oracle for B as follows:

- queries $(0, x, \ell, j)$ are answered with the bit $f(x)_j$,
- for $i \neq \ell$ queries $(0, x, i, j)$ are answered with the bit $h_{s^i}^{\zeta_i}(x)_j$,
- all queries $(1, x, i, j)$ are answered with the bit 0.

Finally algorithm $D_{z,\zeta,\ell}$ outputs 1 if B's output is z and outputs 0 otherwise.

It is easy to verify that for all z, ζ, ℓ we have

$$p_\zeta^z = \Pr_{s \in \{0,1\}^n}[D_{z,\zeta,\ell}^{h_s^{\zeta_\ell}} \text{ outputs } 1]$$

and

$$p_{\zeta||\ell}^z = \Pr_{s \in \{0,1\}^n}[D_{z,\zeta,\ell}^{h_s^{1-\zeta_\ell}} \text{ outputs } 1].$$

From the definition of pseudorandomness and the triangle inequality it follows that $|p_\zeta^z - p_{\zeta||\ell}^z| < \frac{1}{nQ(n)}$. Making $|S| \leq n$ applications of this inequality and using the triangle inequality, we find that

$$|p_\zeta^z - p_{\zeta||S}^z| < \frac{1}{Q(n)}.$$

We thus have that $|p_\zeta^z - p_z^z| < \frac{1}{Q(n)}$ for all $z, \zeta \in \{0,1\}^n$. Since $\sum_{z\in\{0,1\}^n} p_\zeta^z = 1$, we have that

$$\begin{aligned}\left|\Pr_{c_{y,\tilde{s}}\in C'_m}[B^{\tilde{c}_{y,\tilde{s}}} \text{ outputs } y] - \frac{1}{2^n}\right| &= \left|\frac{1}{2^n}\left(\sum_{z\in\{0,1\}^n} p_z^z\right) - \frac{1}{2^n}\right| \\ &= \frac{1}{2^n}\left|\sum_{z\in\{0,1\}^n}(p_z^z - p_\zeta^z)\right| \\ &< \frac{1}{Q(n)}. \qquad \square\end{aligned}$$

8.3.2. Proof of Lemma 24. The idea here is that conditioning on the event that A misses y ensures that the only information which A has about y and $\tilde{s}$ comes from querying oracles for the pseudorandom functions $h_{s^i}^{y_i}$. Since these pseudorandom functions are indistinguishable from truly random functions, no p.p.t. algorithm can learn successfully.

Formally, let A be any p.p.t. learning algorithm. Consider the following algorithm B which takes access to an oracle $h_{s^n}^{y_n} : \{0,1\}^n \to \{0,1\}^n$ and outputs a representation of a function $g : \{0,1\}^n \to \{0,1\}^n$. Algorithm B first chooses $\hat{y} = y_1 \cdots y_{n-1}$ uniformly from $\{0,1\}^{n-1}$ and chooses $n-1$ strings $s^1, \ldots, s^{n-1}$ each uniformly from $\{0,1\}^n$. B then runs algorithm $A^{\tilde{c}_{y,\tilde{s}}}$ (observe that B can simulate the oracle $\tilde{c}_{y,\tilde{s}}$ since it has access to an oracle for $h_{s^n}^{y_n}$ and knows y_i, s^i for $i \neq n$), which generates some hypothesis h. Finally B outputs the function $g : \{0,1\}^n \to \{0,1\}^n$ defined by $g(x) \stackrel{\text{def}}{=} h(0,x,n,1)h(0,x,n,2)\cdots h(0,x,n,n)$.

The following two lemmas together imply Lemma 24.

LEMMA 27. *For all sufficiently large n,*

$$\begin{aligned}&\Pr_{y_n\in\{0,1\}, s^n\in\{0,1\}^n}[B^{h_{s^n}^{y_n}} \textit{ outputs } g \equiv h_{s^n}^{y_n}] \\ &\qquad > \frac{\Pr_{c_{y,\tilde{s}}\in C'_m}[A^{c_{y,\tilde{s}}} \textit{ outputs } h \equiv c_{y,\tilde{s}} \mid A^{c_{y,\tilde{s}}} \textit{ misses } y]}{2}.\end{aligned}$$

LEMMA 28. *For all polynomials Q and all sufficiently large n, we have*

$$\Pr_{y_n\in\{0,1\}, s^n\in\{0,1\}^n}[B^{h_{s^n}^{y_n}} \textit{ outputs } g \equiv h_{s^n}^{y_n}] < \frac{1}{Q(n)}.$$

Proof of Lemma 27. It is easy to see that if $A^{\tilde{c}_{y,\tilde{s}}}$ outputs a hypothesis which is equivalent to $c_{y,\tilde{s}}$, then g will be equivalent to $h_{s^n}^{y_n}$. For sufficiently large n we thus have that $\Pr_{y_n\in\{0,1\}, s^n\in\{0,1\}^n}[B^{h_{s^n}^{y_n}} \text{ outputs } g \equiv h_{s^n}^{y_n}]$ is at least

$$\begin{aligned}\Pr_{c_{y,\tilde{s}}\in C'_m}[A^{\tilde{c}_{y,\tilde{s}}} \text{ outputs } h \equiv c_{y,\tilde{s}}] &\geq \Pr[A^{\tilde{c}_{y,\tilde{s}}} \text{ outputs } h \equiv c_{y,\tilde{s}} \text{ and } A^{\tilde{c}_{y,\tilde{s}}} \text{ misses } y] \\ &= \Pr[A^{\tilde{c}_{y,\tilde{s}}} \text{ outputs } h \equiv c_{y,\tilde{s}} \mid A^{\tilde{c}_{y,\tilde{s}}} \text{ misses } y] \\ &\quad \cdot \Pr[A^{\tilde{c}_{y,\tilde{s}}} \text{ misses } y] \\ &> \frac{\Pr[A^{\tilde{c}_{y,\tilde{s}}} \text{ outputs } h \equiv c_{y,\tilde{s}} \mid A^{\tilde{c}_{y,\tilde{s}}} \text{ misses } y]}{2},\end{aligned}$$

where the last inequality follows from Lemma 23.

Let $TRANS(A^{c_{y,\tilde{s}}})$ ($TRANS(A^{\tilde{c}_{y,\tilde{s}}})$, respectively) denote a complete transcript of algorithm A's execution on oracle $c_{y,\tilde{s}}$ ($\tilde{c}_{y,\tilde{s}}$, respectively). $TRANS(A^{c_{y,\tilde{s}}})$ and $TRANS(A^{\tilde{c}_{y,\tilde{s}}})$ are each random variables over the probability space defined by a uniform choice of $c_{y,\tilde{s}} \in C'_m$ and any internal randomness of algorithm A. An easy induction shows that the two conditional random variables $TRANS(A^{\tilde{c}_{y,\tilde{s}}}) \mid (A^{\tilde{c}_{y,\tilde{s}}}$ misses $y)$ and $TRANS(A^{c_{y,\tilde{s}}}) \mid (A^{c_{y,\tilde{s}}}$ misses $y)$ are identically distributed. This implies that

$$\Pr_{c_{y,\tilde{s}} \in C'_m}[A^{\tilde{c}_{y,\tilde{s}}} \text{ outputs } h \equiv c_{y,\tilde{s}} | A^{\tilde{c}_{y,\tilde{s}}} \text{ misses } y] = \Pr_{c_{y,\tilde{s}} \in C'_m}[A^{c_{y,\tilde{s}}} \text{ outputs } h \equiv c_{y,\tilde{s}} | A^{c_{y,\tilde{s}}} \text{ misses } y],$$

which combined with the inequality above proves the lemma. □

Proof of Lemma 28. The following fact, which follows easily from the pseudorandomness of $\{h^0\}$ and $\{h^1\}$, states that $\{h^b_s\}_{b \in \{0,1\}, s \in \{0,1\}^n}$ is a pseudorandom function family.

FACT 4. *For all polynomials Q, p.p.t. oracle algorithms A, and sufficiently large n, we have*

$$\left| \Pr_{b \in \{0,1\}, s \in \{0,1\}^n}[A^{h^b_s} \textit{ outputs } 1] - \Pr_{F \in \mathcal{F}_n}[A^F \textit{ outputs } 1] \right| < \frac{1}{Q(n)}.$$

Intuitively the pseudorandomness of $\{h^b_s\}$ should make it hard for $B^{h^{y_n}_{s^n}}$ to output $h^{y_n}_{s^n}$ since clearly no p.p.t. algorithm, given oracle access to a truly random function F, could output a function equivalent to F. Formally, we consider an algorithm D which takes oracle access to a function $f : \{0,1\}^n \to \{0,1\}^n$ and outputs a single bit. D runs B^f to obtain a function g and then selects a string $z \in \{0,1\}^n$ which was not used as an oracle query in the computation of B^f. D calls the oracle to obtain $f(z)$, evaluates g to obtain $g(z)$, and outputs 1 if the two values are equal and 0 otherwise.

Clearly $\Pr[D^f \text{ outputs } 1] \geq \Pr[B^f \text{ outputs } g \equiv f]$. Since $\Pr_{F \in \mathcal{F}_n}[D^F \text{ outputs } 1] = 1/2^n$, using Fact 4, we find that

$$\left| \Pr_{y_n \in \{0,1\}, s^n \in \{0,1\}^n}[D^{h^{y_n}_{s^n}} \text{ outputs } 1] - \frac{1}{2^n} \right| < \frac{1}{2Q(n)}$$

and hence

$$\Pr_{y_n \in \{0,1\}, s^n \in \{0,1\}^n}[B^{h^{y_n}_{s^n}} \text{ outputs } g \equiv h^{y_n}_{s^n}] < \frac{1}{Q(n)}. \quad \square$$

9. Breaking classical cryptography in a quantum setting. Our constructions highlight some interesting issues concerning the relation between quantum oracle computation and classical cryptography. It is clear that a quantum algorithm, given access to a quantum black-box oracle for an unknown function, can efficiently distinguish between truly random functions and pseudorandom functions drawn from the family $\{g_s\}$ of Theorem 18. Our construction of $\{g_s\}$ thus shows that cryptographic constructions which are provably secure in the classical model can fail in a quantum setting. We emphasize that this failure does *not* depend on the ability of polynomial-time quantum algorithms to invert particular one-way functions such as factoring; even if no quantum algorithm can efficiently invert the one-way function used to construct $\{g_s\}$, our results show that a polynomial-time quantum algorithm can be a successful distinguisher. It would be interesting to obtain stronger constructions of pseudorandom functions which are provably secure in the quantum oracle framework.

10. Conclusion and future directions. While we have shown that quantum and classical learning are information-theoretically equivalent up to polynomial factors, we have not attempted to obtain the tightest possible bounds relating the two query complexities. In another direction, while we have shown the existence of concept classes which separate efficient quantum and classical learning, many questions remain about the relationship between efficient quantum and classical learnability for natural concept classes studied in learning theory. It would be interesting to develop efficient quantum learning algorithms for natural concept classes, such as the polynomial-time quantum algorithm of Bshouty and Jackson [13] for learning DNF formulae from uniform quantum examples.

Appendix: Proof of Theorem 18. We say that a polynomial-time deterministic algorithm $G : \{0,1\}^n \to \{0,1\}^{2n}$ is a *pseudorandom generator* if for all polynomials Q, all p.p.t. algorithms A, and all sufficiently large n,

$$\left| \Pr_{z \in \{0,1\}^n} [A(G(z)) \text{ outputs } 1] - \Pr_{z \in \{0,1\}^{2n}} [A(z) \text{ outputs } 1] \right| < \frac{1}{Q(n)}.$$

Thus a pseudorandom generator is an efficient algorithm which converts an n-bit random string into a $2n$-bit string which "looks random" to any polynomial-time algorithm. Håstad et al. [25] have shown that pseudorandom generators exist if any one-way function exists.

For G a pseudorandom generator and $s \in \{0,1\}^n$ we write $G_0(s)$ to denote the first n bits of $G(s)$, and $G_1(s)$ to denote the last n bits of $G(s)$. For $x, s \in \{0,1\}^n$ let $f_s : \{0,1\}^n \to \{0,1\}^n$ be defined as

$$f_s(x) \stackrel{\text{def}}{=} G_{x_n}(G_{x_{n-1}}(\cdots(G_{x_2}(G_{x_1}(s)))\cdots)).$$

In [23] it is shown that $\{f_s\}$ is a pseudorandom function family. We now show that the family $\{g_s\}$ defined by $g_s(x) \stackrel{\text{def}}{=} f_s(x) \oplus f_s(x \oplus s)$ is pseudorandom.

Let $\mathcal{F}'_n$ be the following probability distribution over functions from $\{0,1\}^n$ to $\{0,1\}^n$: a function F' is drawn from $\mathcal{F}'_n$ by drawing a random function F from $\mathcal{F}_n$, drawing a random string $s \in \{0,1\}^n$, and letting F' be the function defined as $F'(x) = F(x) \oplus F(x \oplus s)$. Theorem 18 follows from the following two lemmas.

LEMMA 29. *For all polynomials Q, all p.p.t. oracle algorithms M, and all sufficiently large n,*

$$\left| \Pr_{F \in \mathcal{F}_n} [M^F \text{ outputs } 1] - \Pr_{F' \in \mathcal{F}'_n} [M^{F'} \text{ outputs } 1] \right| < \frac{1}{Q(n)}.$$

Proof. Consider an execution of M with an oracle $F' \in \mathcal{F}'_n$ defined by $F'(x) = F(x) \oplus F(x \oplus s)$. Let $S = \{x^1, \ldots, x^t\} \subset \{0,1\}^n$ be the set of strings which M uses as queries to F'. We say that M *finds* s if $x^i = x^j \oplus s$ for some $x^i, x^j \in S$. If M does not find s, then the distribution of answers which M receives from F' is identical to the distribution which M would receive if it were querying a random function $F \in \mathcal{F}_n$, since in both cases each distinct query is answered with a uniformly distributed n-bit string. Thus the left side of the inequality above is at most $\Pr[M \text{ finds } s]$. A simple inductive argument given in the proof of Theorem 3.3 of [40] shows that this probability is at most $\sum_{k=1}^{t} (k/(2^n - (k-2)(k-1)/2))$. Since M is polynomial-time, t is at most $\text{poly}(n)$, and the lemma follows. ∎

LEMMA 30. *For all polynomials Q, all p.p.t. oracle algorithms A, and all sufficiently large n,*

$$\left| \Pr_{F' \in \mathcal{F}'_n}[M^{F'} \text{ outputs } 1] - \Pr_{s \in \{0,1\}^n}[M^{g_s} \text{ outputs } 1] \right| < \frac{1}{Q(n)}.$$

Proof. We require the following fact which is due to Yao [44].

FACT 5. *Let G be a pseudorandom generator, let $q(n)$ and $Q(n)$ be polynomials, and let M_* be a p.p.t. algorithm which takes as input $q(n)$ strings each of length $2n$ bits. Then for all sufficiently large n we have*

$$|p_n^G - p_n^U| < \frac{1}{Q(n)},$$

where p_n^U is the probability that M_* outputs 1 on input $q(n)$ random strings in $\{0,1\}^{2n}$ and p_n^G is the probability that M_* outputs 1 on input $q(n)$ strings each of which is obtained by applying G to a random string from $\{0,1\}^n$.

We prove Lemma 30 by contradiction; suppose that there exists a p.p.t. oracle algorithm M and a polynomial Q such that for infinitely many values of n,

$$\left| \Pr_{F' \in \mathcal{F}'_n}[M^{F'} \text{ outputs } 1] - \Pr_{s \in \{0,1\}^n}[M^{g_s} \text{ outputs } 1] \right| \geq \frac{1}{Q(n)}. \tag{3}$$

We will show that there is a p.p.t. algorithm M_* which contradicts Fact 5.

As in the proof in [23] that $\{f_s\}$ is a pseudorandom function family, we use a so-called "hybrid" argument. Consider the following algorithms A_i ($i = 0, 1, \ldots, n$), each of which defines a mapping from $\{0,1\}^n$ to $\{0,1\}^n$ and hence could conceivably be used as an oracle to answer M's queries. Conceptually, each algorithm A_i contains a full binary tree of depth n in which the root (at depth 0) is labeled with a random n-bit string s; if $i > 0$, then each node at depth i is also labeled with an independently chosen random n-bit string. Each node at depth $j > i$ also has an n-bit label determined as follows: if node v has label z, then the left child of v has label $G_0(z)$, and the right child of v has label $G_1(z)$. Each node in the tree has an *address* which is a binary string: the root's address is the empty string, and if a node has address $\alpha \in \{0,1\}^*$, then its left child has address $\alpha 0$ and its right child has address $\alpha 1$ (so each leaf has a different n-bit string as its address). Let $L(x)$ denote the label of the node whose address is x. Algorithm A_i answers a query $x \in \{0,1\}^n$ with the n-bit string $L(x) \oplus L(x \oplus s)$.

(Note that algorithm A_i need not precompute any leaf labels. Instead, A_i can run in poly(n) time at each invocation by randomly choosing s once-and-for-all the first time it is invoked and labeling the necessary portion of the tree "on the fly" at each invocation by choosing random strings for the depth-i nodes as required and computing descendants' labels as described above. A_i must store the random strings which it uses to label depth-i nodes so as to maintain consistency over successive invocations.)

For $i = 0, 1, \ldots, n$ let p_n^i denote $\Pr[M^{A_i} \text{ outputs } 1]$, i.e., the probability that M outputs 1 if its oracle queries are answered by algorithm A_i. Let p_n^g denote $\Pr_{s \in \{0,1\}^n}[M^{g_s} \text{ outputs } 1]$ and $p_n^{F'}$ denote $\Pr_{F' \in \mathcal{F}'_n}[M^{F'} \text{ outputs } 1]$. We have that $p_n^0 = p_n^g$ since algorithm A_0 behaves exactly like an oracle for g_s, where s is a random n-bit string. We also have that $p_n^n = p_n^{F'}$ since algorithm A_n behaves exactly like an oracle for $F' \in \mathcal{F}'_n$. Inequality (3) thus implies that $|p_n^0 - p_n^n| \geq 1/Q(n)$ for infinitely many values of n.

Now we describe the algorithm M_*, which distinguishes between sets of strings. Let $q(n)$ be a polynomial which bounds the running time of M on inputs of length n (so M makes at most $q(n)$ oracle queries, given access to an oracle from $\{0,1\}^n$ to $\{0,1\}^n$). The algorithm M_* takes as input a set U_n of $2q(n)$ strings of length $2n$. M_* works by first selecting a uniform random value $0 \le i \le n-1$ and a uniform random string $s \in \{0,1\}^n$. M_* then runs algorithm M, answering M's oracle queries as follows. There are two cases, depending on whether or not the prefix $s_1 \dots s_i$ is 0^i:

- *Case* 1. $s_1 \dots s_i \neq 0^i$. Let $x = x_1 \dots x_n$ be the query string. If no earlier query string had prefix $x_1 \dots x_i$ or $(x_1 \oplus s_1) \dots (x_i \oplus s_i)$, then M_* takes the next two $2n$-bit strings from U_n; call these strings $u^1 = u^1_0 u^1_1$ and $u^2 = u^2_0 u^2_1$, where $|u^i_j| = n$. Now M_* stores the four pairs

$$(x_1 \dots x_i 0, u^1_0),\ (x_1 \dots x_i 1, u^1_1),\ ((x_1 \oplus s_1) \dots (x_i \oplus s_i)0, u^2_0),\ \text{and}$$
$$((x_1 \oplus s_1) \dots (x_i \oplus s_i)1, u^2_1)$$

  and answers with the string

$$(*) \qquad G_{x_n}(G_{x_{n-1}}(\dots G_{x_{i+2}}(u^1_{x_{i+1}}) \dots)) \oplus G_{x_n \oplus s_n}(G_{x_{n-1} \oplus s_{n-1}}(\dots G_{x_{i+2} \oplus s_{i+2}}(u^2_{x_{i+1} \oplus s_{i+1}}) \dots)).$$

  Otherwise, if an earlier query string had prefix $x_1 \dots x_i$ or $(x_1 \oplus s_1) \dots (x_i \oplus s_i)$, then instead M_* retrieves the two previously stored pairs

$$(x_1 \dots x_i x_{i+1}, u^1_{x_{i+1}}) \quad \text{and} \quad ((x_1 \oplus s_1) \dots (x_i \oplus s_i)(x_{i+1} \oplus s_{i+1}), u^2_{x_{i+1} \oplus s_{i+1}})$$

  and answers with $(*)$ as above.
- *Case* 2. $s_1 \dots s_i = 0^i$. Let $x = x_1 \dots x_n$ be the query string. If no earlier query string had prefix $x_1 \dots x_i$, then M_* takes the next $2n$-bit string from U_n; call this string $u = u_0 u_1$, where $|u_0| = |u_1| = n$. Now M_* stores the two pairs

$$(x_1 \dots x_i 0, u_0),\ (x_1 \dots x_i 1, u_1)$$

  and answers with

$$(**) \qquad G_{x_n}(G_{x_{n-1}}(\dots G_{x_{i+2}}(u_{x_{i+1}}) \dots)) \oplus G_{x_n \oplus s_n}(G_{x_{n-1} \oplus s_{n-1}}(\dots G_{x_{i+2} \oplus s_{i+2}}(u_{x_{i+1} \oplus s_{i+1}}) \dots)).$$

  Otherwise, if an earlier query string had prefix $x_1 \dots x_i$, then M_* retrieves the two pairs

$$(x_1 \dots x_i x_{i+1}, u_{x_{i+1}}) \qquad \text{and} \qquad (x_1 \dots x_i (x_{i+1} \oplus s_{i+1}), u_{x_{i+1} \oplus s_{i+1}})$$

  (these two pairs are the same if $s_{i+1} = 0$) and answers with $(**)$ as above.

The crucial properties of algorithm M_*, which are straightforwardly verified, are the following: if each string in U_n is generated by applying G to a random n-bit string (scenario 1), then M_* simulates a computation of M with oracle A_i. On the other hand, if each string in U_n is chosen uniformly from $\{0,1\}^{2n}$ (scenario 2), then M_* simulates a computation of M with oracle A_{i+1}.

It is easy to see now that in scenario 1 we have $\Pr[M_* \text{ outputs } 1] = \sum_{i=0}^{n-1} p^i_n / n$, while in scenario 2 we have $\Pr[M_* \text{ outputs } 1] = \sum_{i=1}^{n} p^{i+1}_n / n$. These two probabilities differ by $(1/n) \cdot |p^0_n - p^n_n|$, which is at least $1/nQ(n)$ for infinitely many values of n. Now by Fact 5, the existence of M_* contradicts the fact that G is a pseudorandom generator, and the lemma is proved. ∎

Acknowledgments. We thank R. de Wolf for helpful comments and suggestions, and A. Klivans for stimulating discussions.

ON THE HARDNESS OF GRAPH ISOMORPHISM*

JACOBO TORÁN†

Abstract. We show that the graph isomorphism problem is hard under DLOGTIME uniform AC^0 many-one reductions for the complexity classes NL, PL (probabilistic logarithmic space) for every logarithmic space modular class Mod_kL and for the class DET of problems NC^1 reducible to the determinant. These are the strongest known hardness results for the graph isomorphism problem and imply a randomized logarithmic space reduction from the perfect matching problem to graph isomorphism. We also investigate hardness results for the graph automorphism problem.

Key words. graph isomorphism, complexity, reducibility

1. Introduction.

The graph isomorphism problem (GI) consists in determining whether two given graphs are isomorphic—in other words, whether there is a bijection between the nodes of the graphs preserving the edges. This problem has been intensively studied, in part because of its many applications, and in part because it is one of the few problems in NP that has resisted all attempts to be classified as NP-complete, or within P. The best existing upper bound for the problem given by Luks and Zemlyachenko is $\exp\sqrt{cn\log n}$ (cf. [7]), but there is no evidence of this bound being optimal, and for many restricted graph classes, polynomial time algorithms are known. This is, for example, the case for planar graphs [19], graphs of bounded degree [29], or graphs with bounded eigenvalue multiplicity [6]. In some cases, like trees [28, 11] or graphs with colored vertices and bounded color classes [30], even NC algorithms for isomorphism are known.

Concerning the hardness of GI, there is evidence indicating that the problem is not NP-complete. On the one hand, the counting version of GI is known to be reducible to its decisional version [31], while for all known NP-complete problems the counting version seems to be much harder. On the other hand it has been shown that if GI were NP-complete, then the polynomial time hierarchy would collapse to its second level [9, 36]. Because of these facts, there is a common belief that GI does not contain enough structure or redundancy to be hard for NP. The question of whether GI is P-hard is also open, and, moreover, the known lower bounds in terms of hardness results for GI are surprisingly weak. It is only known that isomorphism for trees is hard for NC^1 and for L (logarithmic space) depending on the encoding of the input [23].

In this paper we improve the existing hardness results by showing that GI is hard for all complexity classes defined in terms of the number of accepting computations of a nondeterministic logarithmic space Turing machine.

The key ingredient in the proof of our results is a graph gadget showing that GI has enough structure to encode a modular addition gate. Using this fact, we are able to give for any $k \in \mathbb{N}$ an AC^0 many-one reduction from the circuit value problem for

addition mod k gates, which is complete for $\mathrm{Mod}_k\mathrm{L}$, to GI. $\mathrm{Mod}_k\mathrm{L}$ is the complexity class corresponding to sets recognized by nondeterministic logarithmic space machines in which the number of accepting computations satisfies a congruence modulo k [10], and it lies within NC^2. We show that a circuit with modular gates can be directly transformed into a graph in which any automorphism of a certain kind maps a special vertex encoding the output gate to a vertex encoding the output of the circuit. The graphs used in the reduction have degree 3 and its vertices can be partitioned into color classes of size k^2. Luks [30] has given an NC upper bound for the complexity of the isomorphism problem restricted to graphs with bounded color classes. For isomorphism in this class of graphs, the gap between our hardness results and the upper bound given by Luks is therefore small. In fact, in [27] we have recently shown that for graphs of bounded color classes of sizes 2 and 3, GI is complete for symmetric logarithmic space.

By a simple use of the Chinese remainder theorem, the hardness results for the modular classes can be transformed into hardness results for NL. It is interesting to observe that the graphs obtained in this reduction have automorphism groups in which the sizes of the orbits of some of the nodes depend on the input size, and therefore these graphs do not have classes of colored vertices of constant size, as in the modular case.

Using the recent result that division can be performed in TC^0 [15, 17, 18], and the fact that an NC^1 circuit can be encoded in an isomorphism problem [23], we can, moreover, prove that any logarithmic space counting function can be reduced to GI. In particular this implies that GI is many-one hard for $\mathrm{C}_=\mathrm{L}$ and for probabilistic logarithmic space, PL. The hardness results culminate in Theorem 4.9, where it is shown that GI is hard for DET, defined by Cook [13] as the class of problems NC^1 Turing reducible to the determinant.

The perfect matching problem is (as GI) another problem of the short list that has resisted classification in terms of completeness. It was shown in [5] that perfect matching is randomly (or nonuniformly) reducible to $\mathrm{Mod}_k\mathrm{L}$ for every k. From our results this implies a (random or nonuniform) reduction from matching to GI, which provides the first reduction between the two well-studied problems. Moreover, as a consequence of derandomization results from [21, 3, 25], under the natural hypothesis that there is a set in $\mathrm{DSPACE}(n)$ with circuits of size $2^{\Omega(n)}$, our reduction implies a many-one AC^0 (deterministic) reduction from perfect matching to GI.

The graph automorphism problem (GA), determining whether a given graph has a nontrivial automorphism, is known to be many-one reducible to GI and seems to be a slightly easier problem. We show in section 5 that the hardness results for GI hold also for GA.

2. Preliminaries. We assume familiarity with basic notions of complexity theory such as can be found in standard textbooks in the area. We will prove hardness results for several logarithmic space complexity classes: NL is the class of languages accepted by nondeterministic Turing machines using logarithmic space. The graph accessibility problem (GAP; given a directed graph with two designated nodes s and t, determine whether there is a path from s to t) is known to be complete for NL, even in the case of acyclic graphs with in-degree at most 2.

#L, defined in [4] analogously to Valiant's class #P, is the class of functions $f : \Sigma^* \to \mathbb{N}$ that count the number of accepting paths of a nondeterministic Turing machine M on input x. The computation of a #L function on an input x can be reduced to the problem computing the number paths from node s to node t in a

directed graph G_x. The complexity classes PL (probabilistic logarithmic space), $\mathrm{C_{=}L}$ (exact threshold in logarithmic space), and $\mathrm{Mod}_k\mathrm{L}$ (modular counting in logarithmic space, $k \geq 2$) can be defined in terms of #L functions:

$$\mathrm{PL} = \{A : \exists p \in \text{ Poly}, f \in \#\mathrm{L}, \ x \in A \Leftrightarrow f(x) \geq 2^{p(|x|)}\} \text{ [16, 35]}.$$

$$\mathrm{C_{=}L} = \{A : \exists p \in \text{ Poly}, f \in \#\mathrm{L}, \ x \in A \Leftrightarrow f(x) = 2^{p(|x|)}\} \text{ [2]}.$$

$$\mathrm{Mod}_k\mathrm{L} = \{A : \exists f \in \#\mathrm{L}, \ x \in A \Leftrightarrow f(x) = 1 \bmod k\} \text{ [10]}.$$

Mod_k circuits ($k \geq 2$) are circuits where the input variables (and the wires) can take values in $\mathbb{Z}_k$, and the gates compute addition in $\mathbb{Z}_k$. The evaluation problem for such circuits (given fixed values for the inputs, determine if the output value is, for example, 1) is complete for $\mathrm{Mod}_k\mathrm{L}$ under AC^0 many-one reductions. This is because a directed acyclic graph with in-degree at most 2, and two designated nodes, s, t, can be easily transformed into a mod_k circuit computing the residue of the number of paths from s to t in G, modulo k.

In some of the proofs we will make use of NC^1 circuits. These are families of logarithmic depth, polynomial size Boolean circuits of bounded fan-in over the basis $\{\wedge, \vee, \neg\}$. DET [13] is the class of problems NC^1 Turing reducible to the determinant, or, in other words, the class of problems that can be solved by NC^1 circuits with additional oracle gates that can compute the determinant of integer matrices.

The known relationships among the considered classes are as follows:

$$\mathrm{Mod}_k\mathrm{L} \subseteq \mathrm{DET},$$

$$\mathrm{NL} \subseteq \mathrm{C_{=}L} \subseteq \mathrm{PL} \subseteq \mathrm{DET}.$$

Looking at the known inclusions, the hardness of GI for DET implies hardness with respect to the other classes. We prove, however, the result for all the classes separately, showing how the graphs produced by the reductions increase in complexity.

2.1. Reducibilities. We prove our hardness results for the DLOGTIME uniform AC^0 many-one reducibility (in short AC^0 reducibility). A set A is AC^0 reducible to another set B if there is family of circuits $\{C_n \mid n \in \mathbb{N}\}$ where each circuit C_n contains only AND, OR, and NOT gates, has size $n^{O(1)}$ and depth $O(1)$, and for each x of length n, $x \in A \Leftrightarrow C_n(x) \in B$. Moreover, the uniformity condition requires that there be a DLOGTIME Turing machine with direct access to its input defining the circuit in the sense that the machine can recognize the direct connection language of C_n [34, 8]. This language consists of the set of tuples $\langle t, a, b, y\rangle$, where a and b are numbers of nodes in C_n, t is the type of a, b is a child of a, and y is a string of length n.

2.2. Graph isomorphism, automorphism, and promise isomorphism. An automorphism in an undirected graph $G = (V, E)$ is a permutation φ of the nodes that preserves adjacency. That is, for every $u, v \in V, (u, v) \in E \Leftrightarrow (\varphi(u), \varphi(v)) \in E$. An isomorphism between two graphs G, H is a bijection between their sets of vertices which preserves the edges. $G \simeq H$ denotes that G and H are isomorphic. GI is the problem

$$\mathrm{GI} = \{(G, H) \mid G \text{ and } H \text{ are isomorphic graphs}\},$$

and GA is defined as

$$\text{GA} = \{G |\ G \text{ has an automorphism different from the identity}\}.$$

A graph G in $\overline{\text{GA}}$ is called rigid. For technical reasons we will consider the set of graph pairs $((G,H),(I,J))$ with exactly one of the pairs consisting of isomorphic graphs:

$$\text{PGI} = \{((G,H),(I,J)) |\ G \simeq H \text{ if and only if } I \not\simeq J\}.$$

For a tuple in PGI we are given the promise of G being isomorphic to H or I being isomorphic to J, and the problem is to determine which one is the isomorphic pair.

Sometimes we will deal with graphs with colored vertices. A coloring with k colors is a function $f : V \to \{1,\ldots,k\}$. In an isomorphism between colored graphs, the colors have to be preserved. The isomorphism problem for colored graphs can be easily reduced (by AC^0 reductions) to graph isomorphism without colors (see, e.g., [26]).

In some cases we will consider the following restricted automorphism problem: Given a graph $G = (V,E)$ and two lists of nodes $(x_1,\ldots,x_k),(y_1,\ldots,y_k)$, is there an automorphism in G mapping x_i to y_i for $1 \le i \le k$? This problem is also easily reducible to GI. In order to check whether there is an automorphism with the desired properties one can make two copies of G, G' and G''. In G' each of the nodes x_i has color i and in G'' node y_i receives this color. All the other nodes are colored with a new color 0, for example. G' and G'' are isomorphic if and only if G has an automorphism with the mentioned properties.

3. Hardness for the modular counting classes. We show now that GI is hard for all the logarithmic space modular counting classes Mod_kL ($k \ge 2$). The idea for this proof is to simulate a modular gate with a graph gadget and then combine the gadgets for the different gates into a graph, whose automorphisms simulate the behavior of the modular circuit.

The gadgets are defined by the following graphs (shown in Figure 3.1 for the case $k = 2$).

DEFINITION 3.1. *Let $k \ge 2$, and denote by $\oplus$ the addition in $\mathbb{Z}_k$. We define the undirected graph $G^k = (V,E)$, given by the set of $k^2 + 3k$ nodes*

$$\begin{aligned} V = &\{x_a, y_a, z_a \mid a \in \{0,\ldots,k-1\} \\ &\cup \{u_{a,b} \mid a,b \in \{0,\ldots,k-1,\}\} \end{aligned}$$

and edges

$$\begin{aligned} E = &\{(x_a, u_{a,b}) \mid a,b \in \{0,\ldots,k-1\}\} \\ &\cup \{(y_b, u_{a,b}) \mid a,b \in \{0,\ldots,k-1\}\} \\ &\cup \{(u_{a,b}, z_{a\oplus b}) \mid a,b \in \{0,\ldots,k-1\}\}. \end{aligned}$$

The graph gadget for a modular gate has nodes encoding the inputs and outputs of the gate. Any automorphism in the graph mapping the input nodes in a certain way must map the output nodes according to the value of the modular gate being simulated.

LEMMA 3.2. *Fix $k \ge 2$; for any $a,b \in \{0,\ldots,k-1\}$,*

(1) *there is a unique automorphism φ in G^k mapping x_i to $x_{a\oplus i}$ and y_i to $y_{b\oplus i}$ for $i = 0,\ldots,k-1$; and*
(2) *this automorphism maps z_i to $z_{a\oplus b\oplus i}$.*

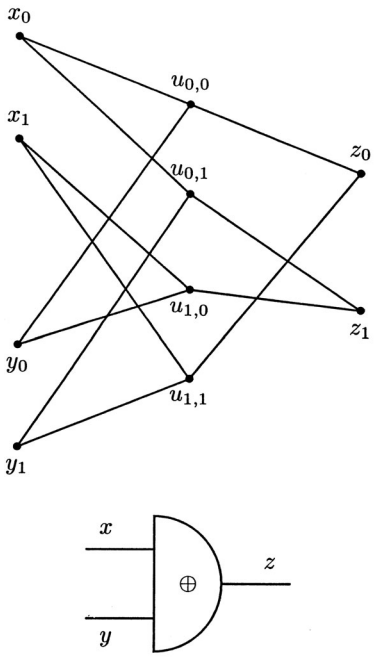

FIG. 3.1. *The graph G^2 simulating a parity gate.*

Proof. Let $a, b \in \{0, \ldots, k-1\}$, and denote by $\oplus$ the addition in $\mathbb{Z}_k$. We consider the following function $\varphi : V \to V$ defined as

$$\begin{aligned}
\varphi(x_i) &= x_{a\oplus i} \text{ for } i \in 0, \ldots, k-1, \\
\varphi(y_i) &= y_{b\oplus i} \text{ for } i \in 0, \ldots, k-1, \\
\varphi(u_{i,j}) &= u_{a\oplus i, b\oplus j} \text{ for } i, j \in 0, \ldots, k-1, \\
\varphi(z_i) &= z_{a\oplus b\oplus i} \text{ for } i \in 0, \ldots, k-1.
\end{aligned}$$

We prove first that φ is an automorphism. For this we have to show that for every pair of nodes v, w, $(v, w) \in E$ if and only if $(\varphi(v), \varphi(w)) \in E$. The nodes in graph G^k can be partitioned in three layers, the x and y nodes (input layer), the u nodes, and the z nodes (output layer). Edges exist only between nodes from the first and second layers, or between nodes from the second and third layers. We consider first an edge between the first two layers. Let $v = x_i$ and $w = u_{l,m}$ with $i, l, m \in \{0, \ldots, k-1\}$. Then $\varphi(v) = x_{a\oplus i}$ and $\varphi(w) = u_{a\oplus l, b\oplus m}$. By the definition of G^k,

$$\begin{aligned}
(x_i, u_{l,m}) \in E &\Leftrightarrow i = l \\
&\Leftrightarrow a \oplus i = a \oplus l \\
&\Leftrightarrow (x_{a\oplus i}, u_{a\oplus l, b\oplus m}) \in E \\
&\Leftrightarrow (\varphi(x_i), \varphi(u_{l,m})) \in E.
\end{aligned}$$

In the case $v = y_j$ the proof is analogous. For an edge (v, w) between the second and third layers, let $(v, w) = (u_{i,j}, z_l)$ with $i, j, l \in \{0, \ldots, k-1\}$. Then $\varphi(v) = u_{a\oplus i, b\oplus j}$

and $\varphi(w) = z_{a\oplus b\oplus l}$. By the definition of G^k,

$$\begin{aligned}(u_{i,j}, z_l) \in E &\Leftrightarrow i \oplus j = l \\ &\Leftrightarrow a \oplus b \oplus i \oplus j = a \oplus b \oplus l \\ &\Leftrightarrow a \oplus i \oplus b \oplus j = a \oplus b \oplus l \\ &\Leftrightarrow (u_{a\oplus i, b\oplus j}, z_{a\oplus b\oplus l}) \in E \\ &\Leftrightarrow (\varphi(u_{i,j}), \varphi(z_l)) \in E.\end{aligned}$$

In any automorphism ϕ with the restrictions $\phi(x_i) = x_{a\oplus i}$ and $\phi(y_i) = y_{b\oplus i}$, the node $\phi(u_{i,j})$ must have edges to $x_{a\oplus i}$ and $y_{b\oplus j}$, but the only node with such connections is $u_{a\oplus i, b\oplus j} = \varphi(u_{i,j})$.

Analogously $\phi(z_i)$ must be connected to $\phi(u_{0,i}) = u_{a,b\oplus i}$, and this implies $\phi(z_i) = z_{a\oplus b\oplus i} = \varphi(z_i)$. This means that φ is the unique automorphism in G^k mapping x_i to $x_{a\oplus i}$ and y_i to $y_{b\oplus i}$. □

We observe that the gadget in Lemma 3.2 for the case $k = 2$ has already been used for a different application in [12]. It is not hard to see that a gadget like the one defined in Lemma 3.2 for $(\mathbb{Z}_k, \oplus)$ can be constructed for any finite Abelian group $G = (A, \circ)$. We mean by this that for any such group a graph whose automorphism group simulates the group operation $\circ$ in the sense of the lemma can be defined.

THEOREM 3.3. *For any $k \geq 2$, GI is hard for $Mod_k L$ under AC^0 many-one reductions.*

Proof. Let $k \geq 2$. We reduce the mod_k circuit value problem to GI. We transform an instance C of the circuit value problem for mod_k circuits into a graph G_C by constructing for every modular gate g_j of C a subgraph like the one described in Lemma 3.2. Moreover, we color the x, y, u, and z nodes of the jth gadget, respectively, with one of the colors $(x, j), (y, j), (u, j)$, and (z, j). Connections between gates are translated in the following way: If the output z of a gate in the circuit is connected to one of the inputs x of another gate, the reduction puts k additional edges connecting (for $i \in \{0, \ldots, k-1\}$) node z_i from the first gate to node x_i from the second gate. For an input variable v^j, k nodes $v_0^j, \ldots, v_{k-1}^j$ are considered in the reduction. The coloring implies that in any automorphism the nodes corresponding to a gate are mapped to nodes from the same gate. Suppose the input variables of the circuit, $v^1, \ldots, v^n$, take values $a_1, \ldots, a_n$. It follows from Lemma 3.2, by induction on the circuit depth, that the output gate z takes value $b \in \{0, \ldots, k-1\}$ if and only if there is an automorphism in G_C mapping v_i^j to $v_{i\oplus a_i}^j$ for all $i = 0, \ldots, k-1$ and $j = 1, \ldots, n$, and mapping z_i to $z_{i\oplus b}$.

All the steps in the reduction can be done locally by an AC^0 circuit. The question of whether the output of the circuit equals $b \in \{0, \ldots, k-1\}$ can be easily reduced to whether two graphs G_b, G_b' are isomorphic, as explained in the preliminaries. In fact this question can be reduced to two graphs pairs $((G, H), (I, J)) \in \mathrm{PGI}$, with G being isomorphic to H if the value of the circuit is b, and I being isomorphic to J otherwise. For this it suffices to define G as G_b, H as G_b', and I and J as the standard OR-function for GI of $\bigcup_{i\neq b}(G_i, G_i')$. □

Observe that the graphs obtained in the reduction have at most k^2 nodes with the same color (the nodes $u_{i,j}$ in any of the gate gadgets). The maximum degree can be reduced to 3. In the above description this does not necessarily hold because of the connection between gates. However, the reduction can be easily modified to achieve degree 3 by adding some extra nodes and arranging the fan-out connections of the gates in a tree-like fashion.

4. Hardness for other complexity classes. In this section we show the hardness of GI for nondeterministic logarithmic space, for $C_=L$, for probabilistic logarithmic space, and for the class DET of problems NC^1 reducible to the determinant. The proofs follow by the modular results, using the Chinese remainder theorem (CRT).

A Chinese remainder representation base is a set $m_1, \ldots, m_n$ of pairwise coprime integers. Let $M = \prod_{i=1}^{n} m_n$. By the CRT, every integer $0 \leq x < M$ is uniquely represented by its Chinese remainder representation $(x_1, \ldots, x_n)$, where $0 \leq x_i < m_i$ and $x_i = x \bmod m_i$. We will consider the base B_n formed by the first n prime numbers.

THEOREM 4.1. *GI is hard for NL under AC^0 many-one reductions.*

Proof. The graph accessibility problem for directed acyclic graphs with fan-in at most 2 is complete for the class NL. We reduce the complement of this set (nonreachability) to GI. The result follows by the closure of NL under complementation [20, 37]. Let $G = (V, E)$ be such a graph, with $|V| = n$ and with two designated nodes s and t. Let P denote the number of paths from s to t in G. Clearly $P \leq 2^n$ and $P = 0$ if and only if for every i between 1 and n it holds that $P \bmod i = 0$.

In the reduction, on input G, an AC^0 circuit, for each i between 1 and n, transforms G into a circuit C_i with addition modulo i gates. The circuits have the property that their outputs coincide with $P \bmod i$ (see the preliminaries). In a second step the reduction transforms the sequence of C_i circuits into a sequence of graphs G_{C_i} (as in the proof of Theorem 3.3) in which there is an automorphism mapping the input nodes according to the inputs of C_i and mapping z_0^i (the node corresponding to the output gate of G_{C_i}) to z_j^i if and only if $P = j \bmod i$. The number of paths from s to t in G is then 0 if and only if for all $i \leq n$ there is an automorphism in G_{C_i} mapping the input nodes G_{C_i} according to the inputs of C_i and mapping z_0^i to itself. This can be easily reduced to GI, as explained in the preliminaries. □

Observe that in the graphs obtained in this reduction, the sizes of the classes of the nodes with the same color are not bounded by a constant, as before, but by n^2.

In fact, we can reduce any logarithmic space counting function to GI. We understand by this that for any function $f \in \#L$ the set

$$A_f = \{\langle x, 0^i \rangle \mid \text{ the } i\text{th bit of } f(x) \text{ is } 1\}$$

is many-one reducible to GI.

For proving this reduction, we need two known results. On the one hand we need the surprising fact that division can be computed by uniform TC^0 circuits[1] [17, 18]. More precisely we need the following part of the mentioned result.

THEOREM 4.2 (see [17, 18]). *There is a DLOGTIME uniform family of TC^0 circuits that, on inputting the Chinese remainder representation $(x_1, \ldots, x_n)$ in base B_n of a number x, outputs the binary representation of x.*

We also need the fact that the result of an NC^1 circuit with fixed values in the input nodes can be encoded as a graph isomorphism question. This follows from an adaptation of the proof of Theorem 3.1 in [22], stating that GI is hard for NC^1 under DLOGTIME uniform AC^0 many-one reductions. For completeness we give a sketch of the proof. The reader is referred to [22] for the details. For technical reasons needed in the proof of Theorem 4.9, we encode the values of the circuit as tuples of graphs $((G, H), (I, J))$ in PGI, with $G \simeq H$ and $I \not\simeq J$ for the encoding of a 1 and with

[1] In fact for our purposes the weaker result—stating that division is in alternating time $O(\log n)$, which was proved in [14]—suffices.

$G \not\simeq H$ and $I \simeq J$ for the encoding of a 0. Recall that PGI was the set of graph tuples $((G,H),(I,J))$ with exactly one of the graphs pairs being isomorphic.

THEOREM 4.3. *Given a uniform family of circuits C_n with logarithmic depth and polynomial size and given n tuples of graphs $((G_i,H_i),(I_i,J_i)) \in PGI$, there is an AC^0 reduction constructing a tuple $((G,H),(I,J)) \in PGI$ with the property that $G \simeq H$ if and only if C_n outputs 1 and $I \simeq J$ if and only if C_n outputs 0, where the ith input to C_n consists of the bit of the Boolean value of the statement $G_i \simeq H_i$.*

Proof. (Sketch.) An NC^1 circuit can be simulated by a balanced DLOGTIME uniform family of circuits with fan-out 1, logarithmic depth, polynomial size, and alternating layers of ANDs and ORs [8]. We show how to transform these expressions to graph tuples. The idea is to construct graph gadgets to simulate the AND and OR connectives in the circuit. Given two tuples $((G_1,H_1),(I_1,J_1))$ and $((G_2,H_2),(I_2,J_2))$ in PGI, consider the graphs $G_\wedge, H_\wedge, I_\wedge$, and $J_\wedge$ in Figure 4.1, where an edge between two graphs represents that each node of the first graph is connected to each node of the second graph. These graphs have the property that $G_\wedge \simeq H_\wedge$ if and only if $G_1 \simeq H_1$ and $G_2 \simeq H_2$. Also $I_\wedge \simeq J_\wedge$ if and only if $G_1 \not\simeq H_1$ or $G_2 \not\simeq H_2$ (in this case $I_1 \simeq J_1$ or $I_2 \simeq J_2$).

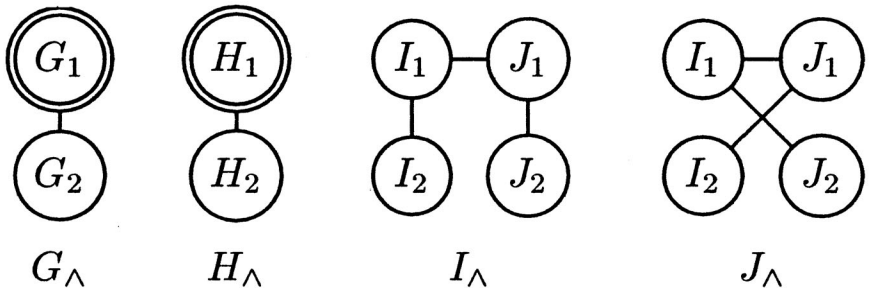

FIG. 4.1. *Tuple $(G_\wedge, H_\wedge, I_\wedge, J_\wedge)$ simulating AND.*

Similarly, the graphs $G_\vee, H_\vee, I_\vee$, and $J_\vee$ from Figure 4.2 have the property that $G_\vee \simeq H_\vee$ if and only if $G_1 \simeq H_1$ or $G_2 \simeq H_2$, and $I_\vee \simeq J_\vee$ if and only if $G_1 \not\simeq H_1$ and $G_2 \not\simeq H_2$. Observe that $((G_\wedge,H_\wedge),(I_\wedge,J_\wedge))$ and $((G_\vee,H_\vee),(I_\vee,J_\vee))$ belong to PGI.

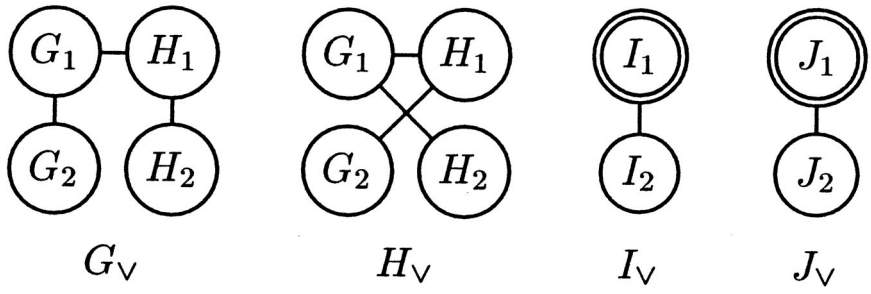

FIG. 4.2. *Tuple $((G_\vee, H_\vee),(I_\vee, J_\vee))$ simulating OR.*

The constructions double the number of nodes of the initial tuples. Notice also that it is easy to simulate a NOT by transforming $((G,H),(I,J))$ to $((I,J),(G,H))$.

A 1 in the circuit is represented by a tuple $((G,H),(I,J))$ with $G \simeq H$, and a 0 by a tuple with $I \simeq J$. Starting from the input nodes the reduction transforms the

nodes of the circuit into graph tuples encoding the values of the circuit gates. Since the circuit has logarithmic depth, the tuples corresponding to the output gate have a polynomial number of nodes. □

We can now show the hardness of GI with respect to #L.

THEOREM 4.4. *Every #L function*[2] *is AC^0 many-one reducible to GI.*

Proof. Let $f \in \#\mathrm{L}$. For some polynomial q, it is possible to construct in AC^0 for $x \in \Sigma^*$ a graph G_x with at most $q(|x|)$ nodes so that $f(x)$ is the number of $s-t$ paths in G_x. Let i be the bit of $f(x)$ we want to reduce to GI, and let $m = q(|x|)$. By Theorem 4.2, in order to compute $f(x)$, it suffices to compute its Chinese remainder representation $(f(x)_1, \ldots, f(x)_m)$ in B_m. Once this is done, $f(x)$ can be computed by an NC^1 circuit.

The Chinese remainder representation can be obtained by computing prime number p_i for every $1 \leq i \leq m$ (this can be done by an NC^1 circuit) and reducing G_x to a circuit with addition gates in $\mathbb{Z}_{p_i}$, as in the proof of Theorem 4.1. The circuits are transformed into p_i graph tuples $((G_j, H_j), (I_j, J_j))$ with the property that in the jth tuple the first two graphs are isomorphic if and only if $f(x) = j - 1 \bmod p_i$. These form a list of $\sum_{i=1}^{m} p_i$ graph tuples and can be considered as an encoding of the Chinese reminder representation of $f(x)$ $(f(x)_1, \ldots, f(x)_m)$ of the form $(w_1, \ldots, w_m)$, where each $w_i \in \{0,1\}^{p_i}$ is formed by 0's with a 1 in position $f(x)_i + 1$. The 0's and 1's in the w_i's are encoded by tuples in PGI.

By Theorem 4.2 it is possible to construct in DLOGTIME a TC^0 (and therefore also an NC^1) circuit that, having as inputs the Chinese reminder representation of $f(x)$, outputs the ith bit of $f(x)$. We can consider the list of graph tuples as the inputs of this circuit.

So far we have shown that there is a uniform AC^0 reduction that on input x computes an NC^1 circuit that outputs the ith bit of $f(x)$ and has its input values encoded as graph tuples in PGI. As done in the proof of Theorem 4.3, an AC^0 reduction can also transform the whole circuit into a single tuple of graphs $((G, H), (I, J))$. G is isomorphic to H or I is isomorphic to J depending on the output of the NC^1 circuit, which coincides with the ith bit of $f(x)$. □

Basically the same proof as the one for the hardness for NL holds for proving hardness for the class $\mathrm{C_{=}L}$. Here instead of checking that the number of paths from s to t is 0, we have to check that this number coincides with some exact threshold $f(G) \leq 2^n$. For this the reduction machine has to compute for each small prime p_i the residue $r_i = f(G) \bmod p_i$ (this can be done in NC^1 [32] and in fact in TC^0 by the mentioned result on division in [18]), and then check whether there is an automorphism that for all i maps z_0^i to $z_{r_i}^i$.

COROLLARY 4.5. *GI is hard for $C_{=}L$ under AC^0 many-one reductions.*

As mentioned in the preliminaries, for a set $L \in \mathrm{PL}$, there is a function $f \in \#\mathrm{L}$ and a polynomial p such that for any input x, $x \in L$ if and only if $f(x) \geq 2^{p(|x|)}$. The next result follows then directly from Theorem 4.4 since an input x belongs to L if and only if at least one of the bits corresponding to positions $\geq p(|x|)$ (starting from the right) in the binary representation of $f(x)$ is a 1.

COROLLARY 4.6. *GI is hard for the class PL under AC^0 many-one reductions.*

The class DET of problems NC^1 Turing reducible to the determinant coincides with $\mathrm{NC}^1(\#\mathrm{L})$ (see, e.g., [2]). Combining Theorems 4.3 and 4.4, we can prove the hardness of GI for DET, which is the strongest known hardness result for GI.

[2] In fact this result also holds for the more powerful class of GapL functions defined in [2].

The proof of this result is based on a simulation of the NC^1 circuit as done in Theorem 4.3, replacing each of the oracle queries to f by a small circuit as in the proof of Theorem 4.4. The main problem here is that while in Theorem 4.4 the input for the #L function to be computed is a binary string x, in the simulation of the NC^1 circuit the input to the oracle calls is not given as a sequence of bits but as a sequence of graph tuples encoding these bits. To deal with this problem we need the following lemma, stating that Theorem 4.4 is also true when the input is encoded as a sequence of tuples.

LEMMA 4.7. *For each function $f \in \#L$ there is a DLOGTIME uniform family $\{C_n\}$ of AC^0 circuits such that, on inputting a sequence of graph tuples $((G_i, H_i), (I_i, J_i))$ in PGI, $1 \leq i \leq n$, of size polynomial in n encoding a binary string $x \in \Sigma^n$, C_n constructs a sequence of tuples $((G'_i, H'_i), (I'_i, J'_i))$ in PGI, $1 \leq i \leq q(n)$, encoding the bits of $f(x)$.*

Proof. Let $f \in \#L$ and $n, k, m \in \mathbb{N}$. From the description of the nondeterministic logarithmic space machine M computing f, the reduction constructs first in AC^0 a graph G_f^n of polynomial size in n related to the configuration graph of M. We can consider that M has a read-only tape for the input and a work tape of logarithmic size. The set of nodes of G_f^n consists of the set of tuples (s, c, p_1, p_2, b), where s is a state of M, c is a possible content of the work tape, p_1 and p_2 are the positions of the tape heads on the input and work tape, respectively, and b is one bit that will be used to encode the content at position p_1 on the input tape. For a concrete input some of these descriptions are not consistent with the input information since b might not be the correct bit at position p_1. Nevertheless we consider the set of all such possible descriptions at this point. This set has polynomial size in n. The set of edges in G_f^n is given by the transition function of M. If the machine can reach from a description $d = (s, c, p_1, p_2, b)$ the configuration (s', c', p'_1, p'_2) in one step, then there is a directed edge in G_f^n from d to $(s', c', p'_1, p'_2, 0)$ and another one from d to $(s', c', p'_1, p'_2, 1)$.

Let x be the input for f encoded by a sequence of graph triplets in PGI. In order to compute whether $f(x) \bmod k$ is congruent with m we will consider that the nodes of G_f^n are addition gates in $\mathbb{Z}_k$ in a polynomial size circuit C. If all the nodes of C would correspond to descriptions consistent with the input, then the output of this circuit would be $f(x) \bmod k$. However, half of the gates in C correspond to inconsistent descriptions and corrupt the final sum. To avoid this problem we use a method that guarantees that the wires coming out of the inconsistent gates always have value 0 and therefore do not contribute to the final sum. This will be done with a new graph gadget. Using first the graph gadgets in section 2.1, circuit C can be transformed into a graph G_C, where each of the mod k gates corresponding to a machine description $d = (s, c, p, p', b)$ is transformed into a subgraph with input nodes $x_0, \ldots, x_{k-1}$ and $y_0, \ldots, y_{k-1}$ and output nodes $z_0, \ldots, z_{k-1}$ in such a way that if there is an automorphism mapping x_l to $x_{l \oplus i}$ and y_l to $y_{l \oplus j}$ in this subgraph, then the automorphism maps z_l to $z_{l \oplus i \oplus j}$ for $i, j, l \in \{0, \ldots, k-1\}$ (Lemma 3.2). The output nodes z_l are then connected with an edge to the input nodes of other gates, nodes $w_0, \ldots, w_{k-1}$ (the nodes of z are connected to as many nodes as the fan-out of the corresponding gate; for simplicity we consider it is just one). Let us suppose that the bit b in description d is 1 (the 0 case is completely analogous) and let $((G_p, H_p), (I_p, J_p))$ be the input tuple in PGI encoding the correct value for the position p in the input x. The gate corresponding to d is a consistent gate if and only if b equals the Boolean value of $G_p \simeq H_p$. To force the inconsistent gates always to propagate a 0 (an automorphism mapping z_0 to itself) the reduction includes between

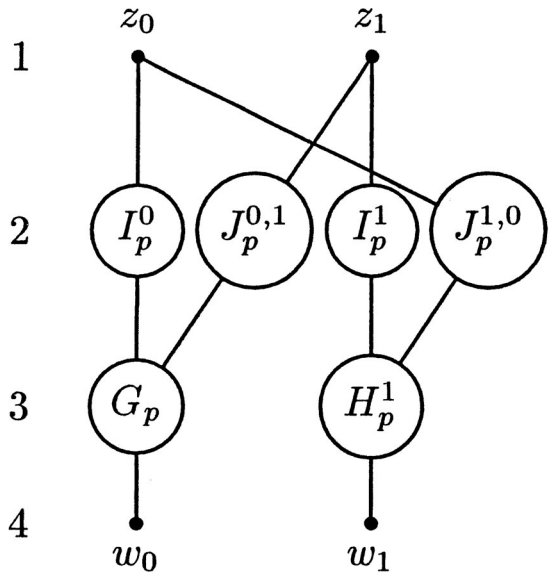

FIG. 4.3. *The graph Gad_2.*

the z and w nodes the following gadget Gad_k, which can be seen in Figure 4.3 for the case $k = 2$. Connections between a node v and a graph in the figure and in the following description of Gad_k mean that there is an edge between v and each of the nodes in the graph.

Subgraph Gad_k can be represented in four levels. Levels 1 and 4 contain the nodes z_i, and w_i, respectively, for $i \in \{0, \ldots, k-1\}$. Level 2 contains for each i a copy I_p^i of I_p and $k-1$ copies of J_p, $J_p^{i,j}$, $j \in \{0, \ldots, k-1\}$, $j \neq i$. Level 3 contains a copy of G_p and for each i in $\{1, \ldots, k-1\}$ a copy H_p^i of H_p. The edges are defined as follows:

- Each node z_i is connected to the graphs I_p^i and to the $k-1$ graphs $J_p^{l,i}$ for $l \neq i$ in the second level.
- Graph G_p in the third level is connected to I_p^0 and to each of the graphs $J_p^{0,j}$ $j \neq 0$, all of them in the second level.
- The graphs H_p^i, $i \neq 0$, in the third level are connected to I_p^i and to $J_p^{i,j}$, $j \neq i$.
- Finally, in the fourth level, node w_0 is connected to G_p and each w_i for $i \neq 0$ is connected to H_p^i.

Gad_k has very nice properties, as can be seen in the next lemma.

LEMMA 4.8. *Subgraph Gad_k has the following properties:*

(1) *If the gate is consistent with the input, that is, if $G_p \simeq H_p$, then for any $c \in \{0, \ldots, k-1\}$ there is an automorphism in Gad_k mapping z_i to $z_{i \oplus c}$ for each i. Such automorphism also maps w_i to $w_{i \oplus c}$.*

(2) *If the gate is inconsistent with the input, that is, if $I_p \simeq J_p$, then for any $c \in \{0, \ldots, k-1\}$ there is an automorphism in Gad_k mapping z_i to $z_{i \oplus c}$ for each i. Such automorphism also maps w_i to w_i.*

Proof. In order to see item 1 of Lemma 4.8, observe that if the automorphism maps z_i to $z_{i \oplus c}$, then the graph I_p^i connected to z_i has to be mapped to one of the graphs connected to $z_{i \oplus c}$, $J_p^{j, i \oplus c}$, or $I_p^{i \oplus c}$. But I_p cannot be mapped to J_p since these graphs are not isomorphic. This implies that in any automorphism all the graphs

I_p in the second level have to be mapped to graphs of type I_p. In particular I_p^i has to be mapped to $I_p^{i\oplus c}$. This means that the graph G_p at the third level has to be mapped to the H_p graph over w_c (this can happen since $G_p \simeq H_p$), and this implies that for all i, w_i has to be mapped to $w_{i\oplus c}$. An automorphism satisfying all these conditions can be defined by mapping for all i, j with $i \neq j$ $J_p^{i,j}$ to $J_p^{i\oplus c, j\oplus c}$ at the second level. Observe that in the case that G_p, H_p, I_p, and J_p are rigid graphs, the described automorphism is the only one mapping z_i to $z_{i\oplus c}$ for each i.

For the proof of item 2 above, observe that in the case that the gate is inconsistent with the input, then the graph G_p at the third level has to be mapped to itself, and therefore the w nodes also have to be mapped to themselves. We have to prove that there is an automorphism with these properties mapping z_i to $z_{i\oplus c}$ for each i. This is clear for $c = 0$. For $c \neq 0$ this automorphism maps in the second level graph I_p^i to $J_p^{i,i\oplus c}$ (this is possible since $I_p \simeq J_p$) and maps $G_p^{i,j}$ to $G_p^{i,j\oplus c}$ if $i \neq j \oplus c$ or to I_p^i in the case that $i = j \oplus c$. The automorphism fixes the third and fourth levels, and again, in the case that G, H, I, and J are rigid graphs, it is the only one mapping z_i to $z_{i\oplus c}$ for each i. □

We continue with the proof of Lemma 4.7. Let G'_C be the graph corresponding to circuit C with the new gadgets on the edges coming out of the gates in C. The above lemma guarantees that inconsistent gates always produce value 0, and therefore the circuit produces the correct value for $f(x)$ mod k. Let $z_0, \ldots, z_{k-1}$ be the output nodes in G'_C corresponding to the output gate of the circuit. By the results in section 2.1, there is an automorphism in G'_C mapping for each i z_i to $z_{i\oplus m}$ if and only if $f(x) \equiv m$ mod k. This property can be encoded by the reduction, using standard methods, into a graph tuple in PGI $((G, H), (I, J))$ satisfying that $G \simeq H$ if $f(x) \equiv m$ mod k, and $G \simeq I$ otherwise. Observe that if the graphs in the tuples have size at most s, then the sizes of the output graphs are at most $p(n)s$ for a polynomial p depending on the machine M. The rest of the proof is exactly as in Theorem 4.4. □

We can now prove the hardness of GI for DET. This result answers positively a question posed by Allender in [1]. Recall that DET can be characterized as $\mathrm{NC}^1(\#\mathrm{L})$, the class of problems computed by an AC^0 uniform family of polynomial size and logarithmic depth circuits with oracle gates to a function f in #L. By convention, an oracle gate querying a string x contributes with $\log(|x| + |f(x)|)$ to the total circuit depth.

THEOREM 4.9. *GI is hard for the class DET under AC^0 many-one reductions.*

Proof. Let L be a set in $\mathrm{NC}^1(\#\mathrm{L})$ and let $\{C_n\}$ be the family of NC^1 circuits computing L with functional oracle queries to a function f in #L.

We want to compute $C_n(x)$ for a string x of length n. The reduction can first transform each oracle gate g into a circuit D_g, as done in Theorem 4.4. Observe that the structure of the circuit computing gate g does not depend on the input bits of g, but just on the number of such bits. D_g computes the query using modular gates as well as AND and OR gates. D_g has polynomial size (in the size of its input) and its depth is not necessarily logarithmic, but the number of levels with AND or OR gates in this circuit is logarithmic in the input size of g. If we count only the depth of the AND and OR gates (the maximum number of such gates in a path from an input to the output gate), C_n with the expanded oracles gates still has logarithmic depth in n since we are dealing with an NC^1 reduction.

Each gate in the circuit C_n with expanded oracle queries can be transformed by the AC^0 reduction into a tuple of four graphs $((G, H), (I, J))$ encoding the value of the

gate as explained before. Using Theorems 4.3 and 4.9, the reduction can construct these tuples for all the levels of the circuit. The graph tuple corresponding to the output gate encodes the result of the circuit computation.

It is only left to show that the size of the graph tuples corresponding to the circuit gates remain of polynomial size in n. The gadgets corresponding to the AND and OR gates increase the size of the graph tuples at most by a factor of 2 in each level, and the number of circuit levels with AND or OR gates is logarithmic in n. The gadgets attached to the modular computations in the query gates increase the sizes of the tuples by a factor of $p(m)$, where m is the size of the query and p is a polynomial. Because C_n computes an NC^1 reduction, in a circuit path with oracle queries with sizes $m_1, \ldots, m_l$, it must hold that the sum of the logarithms of all the query sizes is at most $c \log(n)$ for some constant c. From this it follows that the product of the increasing factors $p(m_i)$ corresponding to all the oracle queries in the path is bounded by a polynomial in n. These facts imply that the sizes of the graph tuples corresponding to every gate in C_n are polynomial in n. □

4.1. Matching is reducible to GI. We mention an interesting connection between the perfect matching problem and GI. The perfect matching problem consists in determining whether a given undirected graph has a perfect matching, that is, a set of edges that contain all the vertices, and such that no two of these edges share a vertex. This problem has been intensively studied, but like GI, it has resisted all classification attempts in terms of completeness in a class. The problem has polynomial time algorithms, and it is known to be in random NC [24, 33]. In [5] it has been proved that for any $k \geq 2$, the perfect matching problem is randomly reducible to a set in $\mathrm{Mod}_k\mathrm{L}$. Together with Theorem 3.3 this implies the following corollary.

COROLLARY 4.10. *The perfect matching problem is reducible to GI under randomized reductions.*

Since the reduction works correctly with probability exponentially close to 1, for each input size n there is a sequence of random choices that can be taken as correct advice in the reduction of all instances of size n. This implies a nonuniform reduction from the perfect matching problem to GI. Moreover, as noted in [3], under a natural hardness hypothesis, the reduction from the perfect matching problem to $\mathrm{Mod}_k\mathrm{L}$ can be derandomized using techniques from [21, 25]. This yields the following corollary.

COROLLARY 4.11. *If there is a set A in $DSPACE(n)$ and $\delta > 0$ with the property that, for all large n, no circuit of size less than $2^{\delta n}$ accepts exactly the strings of length n in A, then perfect matching is included in Mod_kL for any $k \geq 2$, and thus the problem is reducible to GI under AC^0 many-one reductions.*

5. Hardness results for graph automorphism. The graph automorphism problem (GA)—determining whether a given graph has a nontrivial automorphism—is many-one reducible to GI, and it seems to be a slightly easier problem. In this section we show that the proven hardness results for GI hold also for GA. We show first that the hardness for the modular classes can be easily translated to GA.

THEOREM 5.1. *For any $k \geq 2$, GA is hard for Mod_kL under AC^0 many-one reductions.*

Proof. In Theorem 3.3 we transformed a circuit with addition gates in $\mathbb{Z}_k$ and values for the input gates into a graph G having a unique automorphism with certain restrictions (some nodes encoding the input and output values of the circuits had to be mapped in a certain way) if and only if the output value of the circuit is 1. The question of whether G has an automorphism with the desired properties can in turn be transformed into a GI problem by making two copies of G, G_1 and G_2. These

graphs have to include some coloring in the nodes representing the input and output values of the circuit in order to encode the restrictions in the automorphism. Observe that there is at most one isomorphism between G_1 and G_2. From this follows that there is a nontrivial automorphism in $G_1 \cup G_2$ if and only if the output of the original circuit is 1. □

Based on this theorem the proof of Theorem 4.1 can be modified to show hardness of GA for NL.

COROLLARY 5.2. *GA is hard for NL under AC^0 many-one reductions.*

The additional ingredient that is needed to prove the stronger hardness results is the fact that an NC^1 computation can be encoded as a GA question, that is, a version of Theorem 4.3 for GA. A direct translation of this result does not work since GA is not known to have AND-functions. An AND-function for GA is a function that is easy to compute and transforms pairs of graphs into single graphs in such a way that both of the original graphs have nontrivial automorphisms if and only if the final graph has such an automorphism. Dieter van Melkebeek has found a way to avoid this problem.

THEOREM 5.3 (van Melkebeek). *Given a uniform family of circuits C_n with logarithmic depth and polynomial size and given n tuples of rigid graphs $((G,H),(I,J)) \in$ PGI, there is an AC^0 reduction constructing a tuple of rigid graphs $((G,H),(I,J)) \in$ PGI with the property that $G \simeq H$ if and only if C_n outputs 1, and $I \simeq J$ if and only if C_n outputs 0, where the ith input to C_n consists of the bit of the Boolean value of the statement $G_i \simeq H_i$.*

Proof. The proof is like that for Theorem 4.3 simulating the alternating layers of ANDs and ORs of an NC^1 circuit by graph gadgets for the tuples. The main difficulty is preserving the rigidity of the tuple components.

In order to simulate the AND, given two tuples of rigid graphs $((G_1,H_1),(I_1,J_1))$ and $((G_2,H_2),(I_2,J_2))$ in PGI consider the graphs $G_\wedge, H_\wedge, I_\wedge$, and $J_\wedge$ in Figure 5.1. $G_\wedge$ and $H_\wedge$ are defined as the standard AND-function for GI of the G and H graphs, while $I_\wedge$ and $J_\wedge$ are constructed as the OR of (I_1,J_1) and (I_2 AND G_1, J_2 AND H_1).

These graphs have the property that $G_\wedge \simeq H_\wedge$ if and only if $G_1 \simeq H_1$ and $G_2 \simeq H_2$. Also $I_\wedge \simeq J_\wedge$ if and only if $I_1 \simeq J_1$ (and therefore $G_1 \not\simeq H_1$) or $I_2 \simeq J_2$ (in this case $G_2 \not\simeq H_2$ and either $G_1 \simeq H_1$ or $I_1 \simeq J_1$). Observe that if all the graphs in the input tuples are rigid, then $G_\wedge, H_\wedge, I_\wedge$, and $J_\wedge$ are also rigid.

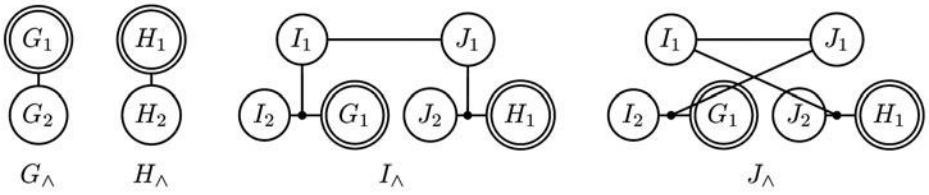

FIG. 5.1. *Tuple $(G_\wedge, H_\wedge, I_\wedge, J_\wedge)$ simulating AND.*

Similarly, the graphs $G_\vee, H_\vee, I_\vee$, and $J_\vee$ from Figure 5.2 have the property that $G_\vee \simeq H_\vee$ if and only if $G_1 \simeq H_1$ or $G_2 \simeq H_2$ and $I_\vee \simeq J_\vee$ if and only if $G_1 \not\simeq H_1$ and $G_2 \not\simeq H_2$. These gadgets simulate, therefore, an OR gate. Moreover, if the all the graphs G_i, H_i, I_i, and J_i are rigid for $i \in \{1,2\}$, then the constructed graphs $G_\vee$, $H_\vee$, $I_\vee$, and $J_\vee$ are also rigid.

Observe that the size of the constructed gadgets is at most $3n$, n being the sum of

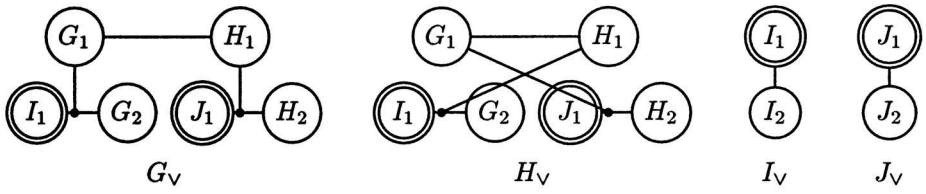

FIG. 5.2. *Tuple* $(G_\vee, H_\vee, I_\vee, J_\vee)$ *simulating OR.*

all the nodes in the input tuples. Because of this fact, for a logarithmic depth circuit C with alternating layers of AND and OR fan-out 1 gates, a tuple of polynomial size rigid graphs $((G,H)(I,J))$ can be constructed such that C has value 1 if and only if $G \simeq H$. Since G and H are rigid, this is equivalent to $G \cup H \in \mathrm{GA}$. □

An immediate consequence of this result is that GA is hard for NC^1. Using this fact and Theorem 5.1, it is now possible to prove the hardness of GA for the class DET. The proof of this result follows exactly the same lines as that for Theorem 4.9, taking into consideration that the graph pairs produced in the reduction from Theorem 3.3 are rigid, and that the gadgets in the proof of Theorem 4.9 also preserve rigidity.

COROLLARY 5.4. *GA is hard for the class DET under* AC^0 *many-one reductions.*

One final observation is that from Theorem 5.1 it follows also that the perfect matching problem is randomly reducible to GA.

Acknowledgments. I would like to thank D. van Melkebeek for providing the proof for Theorem 5.3. He and an anonymous referee suggested also many improvements to the original version of the results. I had several interesting discussions with V. Arvind and J. Köbler that clarified the results of the paper. E. Allender pointed out to me the connection to the determinant. I also would like to thank D. Therien for organizing the McGill Invitational Workshop, where this research started.

A LAMBDA CALCULUS FOR QUANTUM COMPUTATION*

ANDRÉ VAN TONDER†

Abstract. The classical lambda calculus may be regarded both as a programming language and as a formal algebraic system for reasoning about computation. It provides a computational model equivalent to the Turing machine and continues to be of enormous benefit in the classical theory of computation. We propose that quantum computation, like its classical counterpart, may benefit from a version of the lambda calculus suitable for expressing and reasoning about quantum algorithms. In this paper we develop a quantum lambda calculus as an alternative model of quantum computation, which combines some of the benefits of both the quantum Turing machine and the quantum circuit models. The calculus turns out to be closely related to the linear lambda calculi used in the study of linear logic. We set up a computational model and an equational proof system for this calculus, and we argue that it is equivalent to the quantum Turing machine.

Key words. quantum computation, lambda calculus, linear logic, models of computation

1. Introduction.

There are two main approaches to the theory of quantum computation: the quantum Turing machine, introduced by Benioff [1] and Deutsch [2], and the quantum circuit model, introduced by Deutsch [3]. These two approaches were shown to be essentially equivalent by Yao [4].

The quantum Turing machine provides a fundamental model of quantum computation that may be regarded as a baseline for defining universality. However, reasoning about Turing machines can be a cumbersome process, requiring word-at-a-time thinking while keeping track of complicated machine and tape states. Turing machine programs do not satisfy a simple algebra.

For this reason, the quantum circuit model is more popular in the practical investigation of quantum algorithms. Quantum circuits are visual and compositional and may be manipulated algebraically. However, no single finite quantum circuit is universal. Indeed, Yao's proof of Turing equivalence relies on the concept of uniform circuit families generated by classical computation [4, 5]. To define what we mean by such a circuit family, we need to rely on a separate model of classical computation not described by any finite quantum circuit.

In classical computation, the lambda calculus provides an alternative computational model, equivalent to the Turing machine, which continues to be of enormous utility in the theory of computation, in mathematical logic, and in the study of computer languages and their semantics [6, 7, 8, 9, 10]. Due to its simplicity and expressive power, the lambda calculus has been used as the basis of several powerful computer languages, including Lisp, Scheme, ML, and Haskell [11, 12, 13, 14].

In this article, we propose that quantum computing, like its classical counterpart, may benefit from an alternative computational model based on a version of the lambda calculus suitable for expressing and reasoning about quantum algorithms. We develop such a calculus, which turns out to be closely related to the linear lambda calculi used

in the study of linear logic. We set up its computational model and equational proof system and argue that the computational model is equivalent to the quantum Turing machine.

The quantum lambda calculus combines some of the benefits of both quantum circuits and the quantum Turing machine. The quantum lambda calculus describes functions that may be composed and manipulated algebraically, like quantum circuits. Programs can be algebraically transformed into equivalent programs, and one can solve equations whose unknowns are programs, in much the same way as one solves equations in high school algebra [15]. Unlike quantum circuits, the quantum lambda calculus provides a unified framework that is universal for quantum computation without the need to rely on a separate model of classical computation.

In a practical vein, we show how various known quantum algorithms may be expressed as simple programs in the lambda calculus. Indeed, the calculi described in this paper may be used as a programming language for prototyping quantum algorithms. In fact, the algorithms exhibited in this article were transcribed into Scheme for testing. The simulator, which was also written in Scheme, is available on request from the author.

Since the first version of this paper was written, some progress has been made by the author in devising a typed version, with accompanying denotational semantics, of a fragment of the quantum calculus described here [16].

2. The classical lambda calculus. We begin by providing a reasonably self-contained introduction to concepts and constructions in the classical lambda calculus that will be used in the rest of the paper. The intended audience for this section includes physicists and general computer scientists. The expert may skip this section and refer back as needed.

The classical lambda calculus may be regarded both as a programming language and as a formal algebraic system for reasoning about computation. It was originally introduced by Church in the study of the foundations of mathematics [17, 18]. Church postulated that it provides a universal model of computation, which was later shown by Turing to be equivalent to the Turing machine [19].

As a formal system, the lambda calculus has axioms and rules of inference, and it lends itself to analysis using the language and tools of mathematical logic. Computation may be regarded as guided deduction in this formal system. This provides a directed form of equational reasoning that corresponds to symbolic evaluation of programs via a sequence of algebraic simplifications called reductions [6, 7, 8, 9, 10].

The syntax of the classical untyped lambda calculus λ is as follows. Expressions (also called terms) are constructed recursively from variables x, y, z, ... , parentheses, spaces, the period, and the symbol λ, according to the grammar of Figure 1.

A term of the form $(\lambda x.\, t)$ is called a *functional abstraction*. It represents the

function $x \mapsto t$. For example, the identity function $x \mapsto x$ is written as

$$(\lambda x.\, x)$$

The dummy variable x here is called a bound variable and conforms to the usual rules governing bound variables in mathematical formulas. For example, we identify expressions that differ only in the renaming of bound variables.

A term of the form $(t\ t)$ represents a *function application*. The sole means of computation in the lambda calculus is the operation of applying a function to its argument consistent with the following axiom:

$$((\lambda x.\, t)\ v) = t\,[v/x] \qquad (\beta)$$

Here v denotes a *value*, to be defined shortly. Reading this axiom from left to right defines an algebraic rewrite rule for transforming terms, substituting the argument v in place of the variable x into the function body. This transformation is called beta reduction. We will use the arrow $\longrightarrow$ to indicate one (and sometimes more than one) beta reduction step. A reducible term is called a *redex*.

Unabridged lambda terms can be painful to read. For this reason, we will often introduce abbreviations using the symbol $\equiv$. In addition, we will often omit parentheses according to the convention that nested lambda abstractions associate to the right and applications associate to the left.

Consider the simple program $((\lambda x.\, x)\ \mathsf{apple})$, where apple stands for some term in our language. With the abbreviation $\mathsf{id} \equiv (\lambda x.\, x)$, this may be written more legibly as $(\mathsf{id}\ \mathsf{apple})$, which should evaluate to apple. Indeed, beta reduction gives

$$((\lambda x.\, x)\ \mathsf{apple}) \longrightarrow \mathsf{apple}$$

in a single step.

In general, a computation consists of a sequence of beta reductions executed according to some deterministic strategy until the resulting term cannot be reduced any further, at which point the computation terminates.

A slightly more complicated example, which serves to show how multiple-argument functions can be represented in terms of nested single-argument functions (a technique known as currying), is given by

$$\begin{aligned} \mathsf{apply} &\equiv \lambda f.\, \lambda x.\, (f\ x) \\ &\equiv \lambda f.\, (\lambda x.\, (f\ x)), \end{aligned}$$

which represents a function that applies its first argument f, which should be a function, to its second argument x. Applying the identity function to banana should give banana. To see this, the program $(\mathsf{apply}\ \mathsf{id}\ \mathsf{banana})$, which is shorthand for $((\mathsf{apply}\ \mathsf{id})\ \mathsf{banana})$, is now executed by the following sequence of beta reductions (underlining redexes):

$$\begin{aligned} ((\mathsf{apply}\ \mathsf{id})\ \mathsf{banana}) &\equiv (\underline{((\lambda f.\, (\lambda x.\, (f\ x)))\ \mathsf{id})}\ \mathsf{banana}) \\ &\longrightarrow (\underline{(\lambda x.\, (\mathsf{id}\ x))}\ \mathsf{banana}) \\ &\longrightarrow \underline{(\mathsf{id}\ \mathsf{banana})} \\ &\longrightarrow \mathsf{banana}. \end{aligned}$$

$v ::=$	*values:*
x	*variable*
$(\lambda x.\, t)$	*abstraction value*

FIG. 2. *Values in the call-by-value calculus* λ_v.

$$\frac{t_1 \longrightarrow t_1'}{(t_1\ t_2) \longrightarrow (t_1'\ t_2)} \qquad (app_1)$$

$$\frac{t_2 \longrightarrow t_2'}{(v_1\ t_2) \longrightarrow (v_1\ t_2')} \qquad (app_2)$$

$$(\lambda x.\, t)\ v \longrightarrow t\,[v/x] \qquad (\beta)$$

FIG. 3. *Reduction rules for the call-by-value calculus* λ_v.

Often there is more than one reducible subterm at any given step and a strategy is required to make the process unambiguous. For definiteness, we will use a *call by value* strategy. This works as follows. Abstractions (terms of the form $(\lambda x.\, t)$) are considered *values* and may not be reduced any further. A function application $(t\ t)$ may be reduced only if both the operator and the operand are values. Otherwise the operator and operand must be reduced first. We will call the resulting calculus the call-by-value lambda calculus λ_v. Formally, we state the syntax for values [20, 21] in Figure 2. The reduction rules are listed in Figure 3.

We will denote by $\langle\!\langle t \rangle\!\rangle$ the term, when it exists, obtained by fully reducing t to a value.

We will often use a less cumbersome informal notation when defining functions. For example, the apply function above satisfies the property

$$\mathsf{apply}\ f\ x \longrightarrow (f\ x)$$

under beta reduction. Given this specification, the translation into a lambda term is straightforward.

How do we represent data in the lambda calculus? Since all we have at our disposal are lambda terms, we need a way of encoding data as lambda abstractions with specified properties. There is a technique that can be used for any kind of data structure, which we will illustrate with two examples: natural numbers and lists.

Let us first consider how the natural numbers may be represented. As with any kind of data, we need a way to construct natural numbers and a way to deconstruct them, extracting their constituents.

One possible encoding is as the sequence

$$\underline{0}, \quad \underline{1} \equiv \langle\!\langle \mathsf{succ}\ \underline{0} \rangle\!\rangle, \quad \underline{2} \equiv \langle\!\langle \mathsf{succ}\ \underline{1} \rangle\!\rangle, \quad \ldots,$$

where

$$\underline{0} \equiv \lambda x.\, \lambda y.\, (x\ \mathsf{id}),$$
$$\mathsf{succ} \equiv \lambda n.\, \lambda x.\, \lambda y.\, (y\ n)$$

are the constructors.[1] The above definitions were motivated by the need to be able to define a **case** expression (deconstructor),

$$\textbf{case } t_1 \textbf{ of } (\underline{0} \to t_2,\ \mathsf{succ}\ m \to t_3),$$

which may now be taken as an abbreviation for

$$t_1\ (\lambda z.\, t_2)\ (\lambda m.\, t_3).$$

Here z denotes a variable that does not appear free in t_2. This expression allows us to deconstruct a natural number, extracting the ingredients that went into its construction, i.e., either 0 or its predecessor m. Indeed, it is not difficult to verify the following behavior under beta reduction:

$$\begin{aligned}\textbf{case } \underline{0} \textbf{ of } (\underline{0} \to t_2,\ \mathsf{succ}\ m \to t_3) &\longrightarrow t_2,\\ \textbf{case } \langle\!\langle \mathsf{succ}\ t_0 \rangle\!\rangle \textbf{ of } (\underline{0} \to t_2,\ \mathsf{succ}\ m \to t_3) &\longrightarrow t_3\,[\langle\!\langle t_0 \rangle\!\rangle / m].\end{aligned}$$

As an example, it is now trivial to define the predecessor function (with the convention that $\mathsf{pred}\ \underline{0} = \underline{0}$),

$$\mathsf{pred} \equiv \lambda n.\, \textbf{case } n \textbf{ of } \begin{cases} \underline{0} \to \underline{0} \\ \mathsf{succ}\ m \to m. \end{cases}$$

To program arbitrary computations, we need to verify that the lambda calculus is sufficiently powerful to represent *recursive* functions. Indeed, recursion can be used to represent any kind of iterative or looping computation.

For example, to define addition, we need an expression add which behaves as follows under beta reduction:

$$\mathsf{add}\ m\ n \longrightarrow \textbf{case } m \textbf{ of } \begin{cases} \underline{0} \to n \\ \mathsf{succ}\ k \to \mathsf{add}\ k\ (\mathsf{succ}\ n), \end{cases}$$

where the subterm denoted by add on the left has copied itself into the body of the term on the right-hand side. One of the simplest ways to achieve this is to define [22]

$$\mathsf{add} \equiv (t\ t), \tag{1}$$

where

$$t \equiv \lambda f.\left(\lambda m.\, \lambda n.\, \textbf{case } m \textbf{ of } \begin{cases} \underline{0} \to n \\ \mathsf{succ}\ k \to (f\ f)\ k\ (\mathsf{succ}\ n) \end{cases}\right). \tag{2}$$

In other words, t is an abstraction consisting of the body of the addition function with the combination $(f\ f)$ in the position where add should insert itself after reduction.

[1] Explicitly,

$$\begin{aligned} 0 &\equiv \lambda x.\, \lambda y.\, (x\ (\lambda w.\, w)),\\ 1 &\equiv \lambda x.\, \lambda y.\, (y\ \lambda x.\, \lambda y.\, (x\ (\lambda w.\, w))),\\ 2 &\equiv \lambda x.\, \lambda y.\, (y\ \lambda x.\, \lambda y.\, (y\ \lambda x.\, \lambda y.\, (x\ (\lambda w.\, w))))\\ &\vdots \end{aligned}$$

It is a simple exercise to show that add indeed has the specified behavior under beta reduction. This method can be applied to any recursive function.

The computation of the program ($\mathsf{add}\ \underline{2}\ \underline{2}$) then proceeds via the following sequence of beta reductions:

$$\begin{aligned}
\mathsf{add}\ \underline{2}\ \underline{2} &\equiv \mathsf{add}\ \langle\!\langle \mathsf{succ}\ \underline{1} \rangle\!\rangle\ \underline{2} \\
&\longrightarrow \mathbf{case}\ \langle\!\langle \mathsf{succ}\ \underline{1} \rangle\!\rangle\ \mathbf{of}\ (\underline{0} \to \underline{2},\ \mathsf{succ}\ k \to \mathsf{add}\ k\ (\mathsf{succ}\ \underline{2})) \\
&\longrightarrow \mathsf{add}\ \underline{1}\ \langle\!\langle \mathsf{succ}\ \underline{2} \rangle\!\rangle \equiv \mathsf{add}\ \langle\!\langle \mathsf{succ}\ \underline{0} \rangle\!\rangle\ \underline{3} \\
&\longrightarrow \mathbf{case}\ \langle\!\langle \mathsf{succ}\ \underline{0} \rangle\!\rangle\ \mathbf{of}\ (\underline{0} \to \underline{3},\ \mathsf{succ}\ k \to \mathsf{add}\ k\ (\mathsf{succ}\ \underline{3})) \\
&\longrightarrow \mathsf{add}\ \underline{0}\ \langle\!\langle \mathsf{succ}\ \underline{3} \rangle\!\rangle \equiv \mathsf{add}\ \underline{0}\ \underline{4} \\
&\longrightarrow \mathbf{case}\ \underline{0}\ \mathbf{of}\ (\underline{0} \to \underline{4}, \mathsf{succ}\ k \to \mathsf{add}\ k\ (\mathsf{succ}\ \underline{4})) \\
&\longrightarrow \underline{4}.
\end{aligned}$$

The above technique can be generalized to arbitrary data structures. For example, lists can be represented by the following constructors, which are entirely analogous to those of the natural numbers:

$$\begin{aligned}
() &\equiv \lambda x.\, \lambda y.\, (x\ \mathsf{id}), \\
\mathsf{cons} &\equiv \lambda h.\, \lambda t.\, \lambda x.\, \lambda y.\, ((y\ h)\ t),
\end{aligned}$$

where $()$ denotes the empty list and cons constructs a list consisting of a first (head) element h followed by a list t (the tail) containing the rest of the elements. Again, the above definitions were motivated by the need to be able to define a deconstructor

$$\mathbf{case}\ t_1\ \mathbf{of}\ (() \to t_2,\ \mathsf{cons}\ h\ t \to t_3),$$

which may now be taken as an abbreviation for

$$t_1\ (\lambda z.\, t_2)\ (\lambda h.\, \lambda t.\, t_3).$$

We will often abbreviate $h : t \equiv (\mathsf{cons}\ h\ t)$. We can define tuples in terms of lists as $(x_1, \ldots, x_n) \equiv x_1 : x_2 : \cdots : x_n : ()$. Under beta reduction, we have the behavior

$$\begin{aligned}
\mathbf{case}\ ()\ \mathbf{of}\ (() \to t_2,\ h : t \to t_3) &\longrightarrow t_2, \\
\mathbf{case}\ \langle\!\langle t_0 : t_1 \rangle\!\rangle\ \mathbf{of}\ (() \to t_2,\ h : t \to t_3) &\longrightarrow t_3\,[\langle\!\langle t_0 \rangle\!\rangle / h,\ \langle\!\langle t_1 \rangle\!\rangle / t],
\end{aligned}$$

showing how the case expression may be used to deconstruct the list, extracting its head and tail. To see how these abstractions are used, consider the recursive function

$$\mathsf{map}\ f\ \mathit{list} \longrightarrow \mathbf{case}\ \mathit{list}\ \mathbf{of}\ \begin{cases} () \to () \\ h : t \to (f\ h) : (\mathsf{map}\ f\ t), \end{cases}$$

which takes as input a function and a list and applies the function to each element of the list. The reader may verify that, for example,

$$\mathsf{map}\ \mathsf{double}\ (\underline{4}, \underline{7}, \underline{2}) \longrightarrow (\underline{8}, \underline{14}, \underline{4}), \qquad \mathsf{double} \equiv \lambda x.\, (\mathsf{add}\ x\ x).$$

Finally, we introduce some convenient notation. Since we can represent tuples as lists, we can define functions on tuples using notation such as

$$\lambda(x, y).\, t \equiv \lambda u.\, \mathbf{case}\ u\ \mathbf{of}\ \begin{cases} () \to () \\ \\ x : t' \to \mathbf{case}\ t'\ \mathbf{of}\ \begin{cases} () \to () \\ \\ y : t'' \to t. \end{cases} \end{cases}$$

For example, $(\lambda(x, y).\,(\mathsf{add}\ x\ y))\ (\underline{7}, \underline{7})$ evaluates to $\underline{14}$. It is also useful to have a notation for representing intermediate results. The **let** notation

$$\begin{aligned}\textbf{let}\ (x_1, \ldots, x_n) = (t_1, \ldots, t_n)\ \textbf{in}\ t \\ \equiv (\lambda(x_1, \ldots, x_n).\,t)\ (t_1, \ldots, t_n)\end{aligned}$$

allows us to write terms such as

$$\begin{aligned}&\textbf{let}\ x = \underline{1}\ \textbf{in} \\ &\textbf{let}\ (y, z) = (\underline{2}, \underline{3})\ \textbf{in} \\ &\ \mathsf{add}\ x\ (\mathsf{add}\ y\ z)\end{aligned}$$

which evaluates to $\underline{6}$.

3. A quantum computational model. In this section we will construct a computational model, based on the lambda calculus, suitable for describing quantum computations. The language used will be an adaptation of the classical lambda calculus, extended with a set of quantum primitives. We will denote it by λ_i, where the subscript stands for intermediate. For reasons to be discussed in the next section, this language is not suitable as a formal system. In particular, reduction in λ_i does not correspond to a simple system for equational reasoning. In section 5 we will correct these deficiencies to obtain the full quantum lambda calculus λ_q.

In the classical lambda calculus, beta reduction consumes the program to give the result. At each step, information is discarded, which makes the process irreversible. For quantum computing, we need reduction rules that take computational states to superpositions of states in a way that is unitary and reversible.

Bennett [23] showed that any classical computation can be transformed into a reversible computation. The construction, adapted to our situation, is as follows. Let x denote the term being computed, and let $\beta : x \mapsto \beta(x)$ denote a single beta reduction step. Instead of the noninvertible function β, one considers the function $x \mapsto (x, \beta(x))$, which is invertible on its range. In its simplest version, the computation proceeds as

$$x \mapsto (x, \beta(x)) \mapsto (x, \beta(x), \beta^2(x)) \mapsto (x, \beta(x), \beta^2(x), \beta^3(x)) \mapsto \cdots.$$

More complicated schemes exist that reversibly erase the intermediate steps, saving space at the expense of running time. Although this process does not end by itself, we may observe it and regard the computation as having terminated when $\beta^{n+1}(x) = \beta^n(x)$, at which time we may stop the machine by external intervention.

Although this scheme can be used to reversibly implement computations in the classical lambda calculus, we will soon see that it does not work unmodified in the quantum case.

To represent computations involving qubits, we will add a few constant symbols as additional primitives to our language, as in Figure 4.

The symbols 0 and 1 here are *primitives* and should not be confused with the abbreviations $\underline{0}$ and $\underline{1}$ of the previous section. Additional constants H, S, ..., will denote elementary gate operations on qubits. These should include symbols for a universal set of elementary quantum gates [3, 24, 25]. For example, the set consisting of the Hadamard gate H, the phase gate S, the $\pi/8$ gate R_3, and the controlled-not gate *cnot* is universal [25, 5]. Additional primitives, such as the Pauli gates X, Y, and Z, may be added for convenience.

$t ::=$	*terms:*
x	*variable*

$c ::=$	*constants:*
$0 \mid 1 \mid H \mid S \mid R_3 \mid \mathit{cnot} \mid X \mid Y \mid Z \mid \ldots$	

FIG. 4. *Syntax of the intermediate language* λ_i.

We now allow the state of a computation to be a quantum superposition of terms in this language. As a model, one may imagine lambda terms encoded as strings of symbols on the tape of a quantum Turing machine.

As a first example, consider an initial state written in ket notation as

$$|(H\ 0)\rangle\,.$$

We would like to choose the transition rules of the quantum computer in such a way that this string will evaluate to the Hadamard operator applied to $|0\rangle$, which should give the superposition $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$ of the states $|0\rangle$ and $|1\rangle$ containing unit-length strings. The candidate reduction rule

$$\begin{aligned} |(H\ 0)\rangle &\longrightarrow \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)\,, \\ |(H\ 1)\rangle &\longrightarrow \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle) \end{aligned}$$

is not reversible. To make it reversible, we first try the same trick as in the classical case,

$$\begin{aligned} |(H\ 0)\rangle &\longrightarrow \frac{1}{\sqrt{2}}(|(H\ 0);\, 0\rangle + |(H\ 0);\, 1\rangle) \\ &= |(H\ 0)\rangle \otimes \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)\,, \end{aligned}$$

where we have factored out the common substring. The semicolon denotes string concatenation. In this simple example, the answer indeed factors out on the right. However, notice what happens if we apply this method to the term

$$\begin{aligned} |(H\ (H\ 0))\rangle &\longrightarrow \frac{1}{\sqrt{2}}(|(H\ (H\ 0));\, (H\ 0)\rangle + |(H\ (H\ 0));\, (H\ 1)\rangle) \\ &\longrightarrow \frac{1}{2}\,|(H\ (H\ 0))\rangle \otimes \\ &\qquad \otimes \Big(|(H\ 0);\, 0\rangle + |(H\ 0);\, 1\rangle + |(H\ 1);\, 0\rangle - |(H\ 1);\, 1\rangle\Big). \end{aligned}$$

Here the answer does not factor out. The fully reduced rightmost term is entangled with the intermediate term in the history.

$v ::=$	*values:*
x	*variable*
c	*constant*
$(\lambda x.\, t)$	*abstraction value*

FIG. 5. *Values in the intermediate language* λ_i.

Note, however, that this scheme keeps more information than necessary. For reversibility, it is sufficient to record at each step only which subterm has been reduced and the operation that has been applied to it. We may encode this in our example as follows (to be formalized below):

$$\begin{aligned}|(H\ (H\ 0))\rangle &\longrightarrow \frac{1}{\sqrt{2}}\left(|(\_\ (H\ \_));\ (H\ 0)\rangle + |(\_\ (H\ \_));\ (H\ 1)\rangle\right)\\ &\longrightarrow \frac{1}{2}\,|(\_\ (H\ \_))\rangle \otimes\\ &\qquad \otimes \Big(|(H\ \_);\ 0\rangle + |(H\ \_);\ 1\rangle + |(H\ \_);\ 0\rangle - |(H\ \_);\ 1\rangle\Big)\\ &= |(\_\ (H\ \_));\ (H\ \_)\rangle \otimes |0\rangle\,.\end{aligned}$$

Here, at each step we have replaced subterms that do not need to be recorded by the constant placeholder symbol _. Now the answer does indeed factor out on the right as required, consistent with $H^2\,|0\rangle = |0\rangle$. It is also clear that at each step we have kept enough information to reconstruct the previous step, thus ensuring reversibility.

The computational model may now be formalized with the following rules: First, we extend our definition of values to include constants as in Figure 5. The computational state is taken to be a quantum superposition of sequences of the form

$$h_1;\ \ldots\ ;\ h_n;\ t,$$

where $h_1;\ \ldots\ ;\ h_n$ will be called the history track and t will be called the computational register. The classical subset of the transition rules is shown in Figure 6.

In these rules $\mathcal{H}$ denotes the (possibly empty) history track, and $\overline{t}_x$ is obtained from t by recursively replacing all subterms that do not contain x with the placeholder symbol and keeping x. More formally,

$$\begin{aligned}\overline{t}_x &\equiv \_ \qquad \text{if } x \text{ not free in } t,\\ \overline{(\lambda y.\, t)}_x &\equiv (\_.\,\overline{t}_x),\\ \overline{(t\ t')}_x &\equiv (\overline{t}_x\ \overline{t'}_x),\\ \overline{x}_x &\equiv x.\end{aligned} \tag{3}$$

These rules are sufficient to make classical computations reversible, provided that lambda terms that differ only by renaming of bound variables have been identified. In this regard, we note here that in a quantum Turing machine model, it is possible to represent terms on the tape of the quantum Turing machine in an unambiguous way (e.g., using De Bruijn indices instead of bound variables) [7, 8].

$$\frac{t_1 \longrightarrow h_1;\, t_1'}{\mathcal{H};\, (t_1\ t_2) \longrightarrow \mathcal{H};\, (h_1\ \_);\, (t_1'\ t_2)} \qquad (app_1)$$

$$\frac{t_2 \longrightarrow h_2;\, t_2'}{\mathcal{H};\, (v_1\ t_2) \longrightarrow \mathcal{H};\, (\_\ h_2);\, (v_1\ t_2')} \qquad (app_2)$$

$$\mathcal{H};\, ((\lambda x.\, t)\ v) \longrightarrow \mathcal{H};\, ((\lambda x.\, \overline{t}_x)\ \_);\, t\,[v/x] \qquad (\beta_1) \text{ if } x \text{ appears free in } t$$

$$\mathcal{H};\, ((\lambda x.\, t)\ v) \longrightarrow \mathcal{H};\, ((\lambda x.\, \_)\ v);\, t \qquad (\beta_2) \text{ if } x \text{ not free in } t$$

$$\mathcal{H};\, t \longrightarrow \mathcal{H};\, \_;\, t \qquad (Id) \text{ otherwise}$$

FIG. 6. *Operational model for the classical subset of* λ_i.

$$|\mathcal{H};\, (H\ 0)\rangle \longrightarrow |\mathcal{H};\, (H\ \_)\rangle \otimes \frac{1}{\sqrt{2}}\,(|0\rangle + |1\rangle)$$

$$|\mathcal{H};\, (H\ 1)\rangle \longrightarrow |\mathcal{H};\, (H\ \_)\rangle \otimes \frac{1}{\sqrt{2}}\,(|0\rangle - |1\rangle)$$

FIG. 7. *Operational model for* H.

Here is an example computation:

$$\begin{aligned}
|((\mathsf{apply}\ \mathsf{id})\ \mathsf{banana})\rangle &\equiv (((\lambda f.\,(\lambda x.\,(f\ x)))\ (\lambda z.\, z))\ \mathsf{banana}) \\
&\longrightarrow |(((\lambda f.\,(_.\,(f\ _)))\ _)\ _);\, ((\lambda x.\,((\lambda z.\, z)\ x))\ \mathsf{banana})\rangle \\
&\longrightarrow |(((\lambda f.\,(_.\,(f\ _)))\ _)\ _);\, ((\lambda x.\,(_\ x))\ _);\, ((\lambda z.\, z)\ \mathsf{banana})\rangle \\
&\longrightarrow |(((\lambda f.\,(_.\,(f\ _)))\ _)\ _);\, ((\lambda x.\,(_\ x))\ _);\, ((\lambda z.\, z)\ _);\, \mathsf{banana}\rangle \\
&\longrightarrow |(((\lambda f.\,(_.\,(f\ _)))\ _)\ _);\, ((\lambda x.\,(_\ x))\ _);\, ((\lambda z.\, z)\ _);\, _;\, \mathsf{banana}\rangle \\
&\longrightarrow |(((\lambda f.\,(_.\,(f\ _)))\ _)\ _);\, ((\lambda x.\,(_\ x))\ _);\, ((\lambda z.\, z)\ _);\, _;\, _;\, \mathsf{banana}\rangle \\
&\longrightarrow \cdots .
\end{aligned}$$

At each step, just enough information is kept to reconstruct the previous step. Although in this particular example termination can be tested by observing and comparing the last expression in the history with _, in general we do not have a well-defined criterion for termination in the calculus λ_i, because the state may involve a superposition of several computational histories, some of which have terminated and others not. Thus, to observe termination would potentially disturb the state. This problem will be solved in the quantum calculus λ_q of section 5.

In addition, we have some extra reduction rules involving the quantum gate symbols such as those provided in Figure 7.

The rules for quantum primitives are summarized in Figure 8.

Here c_U denotes any one of the quantum primitive symbols and U the corresponding unitary transformation, while ϕ stands for 0 or 1 in the case of single-bit operators, or one of $(0,0)$, $(0,1)$, $(1,0)$ or $(1,1)$ in the case of two-bit operators. For example,

$$|(cnot\ (1,0))\rangle \longrightarrow |(cnot\ \_);\, (1,1)\rangle\,.$$

$$|\mathcal{H};\ (c_U\ \phi)\rangle \longrightarrow |\mathcal{H};\ (c_U\ \_)\rangle \otimes U\,|\phi\rangle \qquad (U)$$

FIG. 8. *Operational model for the quantum primitives of* λ_i.

4. Toward an equational theory. While the language λ_i constructed in the previous section can be used to describe quantum computations, reduction in λ_i does not correspond to a simple system for equational reasoning. This makes λ_i unsuitable as a formal proof system for quantum computation. We will discuss the problem in this section and resolve it in the next with the introduction of the quantum lambda calculus λ_q.

In the classical lambda calculus, program evaluation through beta reduction can be regarded as a directed form of equational reasoning consistent with the axiom

$$(\lambda x.\,t)\ v = t\,[v/x] \qquad (\beta).$$

Indeed, the classical lambda calculus provides both a model of computation and a formal system for reasoning about functions, a property we would like to keep in the quantum case.

To understand the difficulty, notice what happens when a function application discards its argument (in other words, the argument does not appear in the function body). For example,

$$|((\lambda x.\,\mathsf{apple})\ \mathsf{banana})\rangle \longrightarrow |((\lambda x.\,\_)\ \mathsf{banana});\ \mathsf{apple}\rangle\,.$$

We see that to maintain reversibility, a record of the argument banana is kept in the history. Restricting our attention to the computational register, we see that its evolution is consistent with replacing the original expression with an equal expression according to the axiom (β). In other words, in this example reduction is consistent with equational reasoning.

However, we run into problems when the discarded subterm is in a quantum superposition with respect to the computational basis. For example, consider the reduction of

$$\begin{aligned}|(\lambda x.\,0)\ (H\ 0)\rangle &\longrightarrow |(\_\ (H\ \_)\rangle \otimes \frac{1}{\sqrt{2}}\Big(|(\lambda x.\,0)\ 0\rangle + |(\lambda x.\,0)\ 1\rangle\Big)\\ &\longrightarrow |(\_\ (H\ \_)\rangle \otimes \frac{1}{\sqrt{2}}\Big(|(\lambda x.\,\_)\ 0\rangle + |(\lambda x.\,\_)\ 1\rangle\Big) \otimes |0\rangle\,.\end{aligned}$$

In the second step, a discarded subterm in a superposition is saved in the history and the computational register becomes $|0\rangle$. However, if we were to apply the axiom (β) to the contents of the computational register, we would get the equation

$$\frac{1}{\sqrt{2}}\Big(|(\lambda x.\,0)\ 0\rangle + |(\lambda x.\,0)\ 1\rangle\Big) = \sqrt{2}\ |0\rangle\,,$$

which is invalid since the right-hand side is not a legal normalized state.

As a second example, consider the following computation, where the inner func-

tion discards its argument x:

$$
\begin{aligned}
&|((\lambda y.\,((\lambda x.\,y)\ y))\ (H\ 0))\rangle \\
&\quad\longrightarrow \frac{1}{\sqrt{2}}\,|(\_\ (H\ \_))\rangle \otimes \Big(|((\lambda y.\,((\lambda x.\,y)\ y))\ 0)\rangle + |((\lambda y.\,((\lambda x.\,y)\ y))\ 1)\rangle\Big) \\
&\quad\longrightarrow \frac{1}{\sqrt{2}}\,|(\_\ (H\ \_));\ ((\lambda y.\,((\_.\,y)\ y))\ \_)\rangle \otimes \\
&\qquad\qquad \otimes \Big(|((\lambda x.\,0)\ 0)\rangle + |((\lambda x.\,1)\ 1)\rangle\Big) \\
&\quad\longrightarrow \frac{1}{\sqrt{2}}\,|(\_\ (H\ \_));\ ((\lambda y.\,((\_.\,y)\ y))\ \_)\rangle \otimes \\
&\qquad\qquad \otimes \Big(|((\lambda x.\,\_)\ 0);\ 0\rangle + |((\lambda x.\,\_)\ 1);\ 1\rangle\Big).
\end{aligned}
$$

Now the computational register is entangled with the last expression in the history. Ignoring the history, the computational register would be in a mixed state with density matrix

$$\begin{pmatrix} \frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{pmatrix}.$$

However, an attempt to apply the equational axiom (β) to the contents of the computational register would give

$$\frac{1}{\sqrt{2}}\Big(|((\lambda x.\,0)\ 0)\rangle + |((\lambda x.\,1)\ 1)\rangle\Big) = \frac{1}{\sqrt{2}}\,(|0\rangle + |1\rangle)\,,$$

which is clearly inconsistent.

5. A quantum lambda calculus. We will resolve the shortcomings of the language λ_i by developing a quantum lambda calculus λ_q which has a consistent equational theory. This section will be somewhat heavier on the formalities, and the reader who wishes to see some concrete examples may skip ahead to section 7 after reading the introductory paragraphs.

The previous discussion suggests that the problems with equational reasoning in the presence of quantum operations can be avoided by preventing functions from discarding arguments that may be in a superposition with respect to the computational basis.

Let us call a subexpression definite with respect to the computational basis if it is textually the same in all branches of the superposition. For example, in the state

$$\frac{1}{\sqrt{2}}\Big(|(\lambda x.\,0)\ 0\rangle + |(\lambda x.\,0)\ 1\rangle\Big),$$

the subexpression $(\lambda x.\,0)$ is definite, whereas the argument $\frac{1}{2}\,(|0\rangle + |1\rangle)$ is nondefinite. Definite subexpressions may be thought of as a classical resource. They can be observed without affecting the state of the computation. On the other hand, nondefinite subexpressions represent purely quantum resources.

To avoid the problems pointed out in the previous section, we seek a calculus that will keep track of whether an argument is definite or nondefinite and that will make it impossible to write a function that discards a nondefinite resource. Calculi that are

FIG. 9. *Syntax of the quantum calculus* λ_q.

resource sensitive, known as linear lambda calculi, have been studied intensively in recent years [26, 27, 28, 29]. So-called typed linear lambda calculi are very closely related to the field of linear logic [30, 31]. Linear logic is a resource-sensitive logic where, for example, certain assumptions may be used only once in the course of a derivation.

For our purposes it will be sufficient to study a simple untyped linear calculus. The syntax is a fragment of the one introduced in [27], extended with quantum operations as in Figure 9.

Here terms of the form $!t$ are called nonlinear. Nonlinear terms will be guaranteed to be definite with respect to the computational basis and may be thought of physically as classical strings of symbols that may be discarded and duplicated at will. On the other hand, linear terms may be nondefinite, possibly containing embedded qubits in superpositions with respect to the computational basis. Abstractions of the form $(\lambda !x.\, t)$ denote functions of nonlinear arguments. In an abstraction of the form $(\lambda x.\, t)$, the argument is called linear.

A functional abstraction may use a nonlinear argument any number of times in its body, or not at all. On the other hand, a linear argument must appear exactly once in the function body (hence the name linear).

To enforce these rules, we require terms to be well formed. This corresponds to the constraint that linear arguments appear linearly in a function body and that all free variables appearing in a term $!t$ refer to nonlinear variables [28]. In the following examples, the terms in the left column are well formed while those in the right column are ill formed:[2]

$(\lambda !x.\, 0)$	$(\lambda x.\, 0)$
$(\lambda x.\, x)$	$(\lambda x.\, !x)$
$(\lambda !x.\, (x\ x))$	$(\lambda x.\, (x\ x))$
$(\lambda y.\, (\lambda !x.\, y))$	$(\lambda y.\, (\lambda x.\, y))$
$(\lambda !y.\, !(\lambda !x.\, y))(\lambda y.\, !(\lambda !x.\, y))$.	

[2]Notice that while well-formedness guarantees that linear resources will be used appropriately, it does not guarantee that terms are meaningful. For example, the term $(\lambda y.\, (\lambda\, !z.0)\ y)$ is well formed, but it may or may not get stuck at run time, according to the operational model of Figure 12, when applied to a linear or nonlinear argument, respectively. A typed calculus would be needed to specify which terms can be legally substituted for y. For recent progress in this direction, see [16].

$$\frac{}{\vdash c} \quad \textit{Const}$$

$$\frac{}{x \vdash x} \quad \textit{Id}$$

$$\frac{!x_1, \ldots, !x_n \vdash t}{!x_1, \ldots, !x_n \vdash !t} \quad \textit{Pomotion}$$

$$\frac{\Gamma, x \vdash t}{\Gamma, !x \vdash t} \quad \textit{Dereliction}$$

$$\frac{\Gamma, !x, !y \vdash t}{\Gamma, !z \vdash t\,[z/x, z/y]} \quad \textit{Contraction}$$

$$\frac{\Gamma, x \vdash t}{\Gamma \vdash (\lambda x.\, t)} \quad \multimap\textit{-I}$$

$$\frac{\Gamma, !x \vdash t}{\Gamma \vdash (\lambda !x.\, t)} \quad \to\textit{-I}$$

$$\frac{\Gamma \vdash t_1 \quad \Delta \vdash t_2}{\Gamma, \Delta \vdash (t_1\ t_2)} \quad \multimap\textit{-E}$$

FIG. 10. *Rules for well-formed terms in the quantum calculus* λ_q.

Well-formedness is a property that can be checked syntactically. For completeness, we formally state the rules for well-formedness [28], which the reader satisfied with the above informal characterization may skip, in Figure 10.

These rules may be related to the typed linear calculi described in [28, 27] by erasing the type annotations from the typing rules of the latter. Here Γ and Δ denote *contexts*, which are sets containing linearity assumptions of the form x and $!x$, where each variable x is distinct. If Γ and Δ are contexts with no variables in common, then Γ, Δ denotes their union. For example, the rule $\multimap$-E implicitly assumes that $\Gamma \cap \Delta = \emptyset$. Rules may be read as follows. For example, the promotion rule says that if t is a well-formed term under the assumption that x_1 to x_n are nonlinear, then $!t$ is a well-formed term under the same assumption. The condition $\Gamma \cap \Delta = \emptyset$ in ($\multimap$-E) ensures that a linear variable can appear only once in the body of a formula. The weakening and ($\to$-I) rules allow a function to discard a nonlinear argument, whereas the contraction and ($\multimap$-E) rules allow us to duplicate a nonlinear argument any number of times in the body of a function.

The well-formedness constraint prevents us from writing a function that discards a linear argument. However, this is not sufficient to prevent unsafe computations without further specification of the substitution order. To see this, consider the expression $((\lambda !x.\, 0)\ !(H\ 0))$, which is well formed. The problem is that we are allowed to use ! to promote the expression $(H\ 0)$ to a nonlinear value, which can then be discarded. If we were allowed to reduce the subterm $(H\ 0)$ first, equational reasoning

FIG. 12. *Operational model for the quantum lambda calculus* λ_q.

would give

$$\begin{aligned} |((\lambda !x.\, 0)\ !(H\ 0))\rangle &= \frac{1}{\sqrt{2}}\Big(|((\lambda !x.\, 0)\ !0)\rangle + |((\lambda !x.\, 0)\ !1)\rangle\Big) \\ &= \sqrt{2}\,|0\rangle\,, \end{aligned}$$

which is an invalid equation since the last line is not a valid normalized state. On the other hand, if we consider $!(H\ 0)$ as an irreducible value, we may use beta reduction immediately to obtain

$$|((\lambda !x.\, 0)\ !(H\ 0))\rangle = |0\rangle\,,$$

which is a valid result, since we are discarding the unevaluated expression $!(H\ 0)$, which is definite.

To prevent terms of the form $!t$ from being evaluated, we follow Abramsky [26] and extend our definition of values as in Figure 11.

The computational model is described in Figure 12,[3] where $\overline{t}$ is defined as in (3).

According to these rules, quantum superpositions can be created only by evaluating terms containing quantum primitives. The result of applying a quantum gate is a

[3]See [26, 32, 33] for related operational interpretations of linear lambda calculi. Our evaluation model recomputes !-closures (see [32]).

linear value, not preceded by a !. As we prove below, there is no way to include such a linear value in a nonlinear subterm. It follows that subterms that may be quantum nondefinite will never be discarded since, by $(!\beta_1)$ and $(!\beta_2)$, nonlinear functions can be applied only to nonlinear terms.

Note that when a nonlinear function encounters a linear argument, it simply gets stuck. More precisely, the rule (Id) applies.

The above reduction rules may create superpositions. However, such superpositions are not arbitrary. Indeed, terms in a superposition will differ only in positions containing the constants 0 and 1. Otherwise they will have the same shape. We may formalize this by defining two terms to be *congruent* if they coincide symbol by symbol except possibly in positions containing 0 or 1. Lemma 5.1 then follows.

LEMMA 5.1. *All terms in a superposition obtained via a reduction sequence from a definite initial term are congruent.*

Proof. The proof is by a simple induction on the length of the reduction sequence, analyzing the reduction rules case by case. □

Another case-by-case induction argument may be used to prove that reduction preserves well-formedness.

LEMMA 5.2. *If t is well formed and $|\mathcal{H}; t\rangle \longrightarrow \sum_i c_i\, |\mathcal{H}'_i; t'_i\rangle$, then all terms t'_i appearing in the resulting superposition are well formed.*[4]

Because terms appearing in a superposition have the same shape, it makes sense to talk about specific subterms of the expression in the computational register. We can therefore formulate the following lemma.

LEMMA 5.3. *Starting from a definite initial term, any* !*-suspension subterm occurring during reduction is definite with respect to the computational basis.*

Proof. This follows by induction on the length of the reduction sequence. The initial term is definite by assumption. Assume that the lemma holds after n steps. We have argued that all terms in a superposition obtained from a definite initial term are congruent. They therefore have the same structure of subterms, and the same reduction rule applies to them all. Since we have argued that these terms are well formed, there are then three ways in which we may obtain a !-suspension subterm after $n+1$ steps. First, the suspension may not be part of the redex, in which case it is included unmodified in the resulting expression. Second, it may be the result of beta reduction of an application of the form

$$(\lambda x.\,(\cdots x\cdots))\ (\cdots !t\cdots),$$

where $!t$ is definite by the induction assumption. The result is $(\cdots(\cdots !t\cdots)\cdots)$, where $!t$ has been copied without modification. Third, it may be the result of beta reduction of an application of the form

$$(\lambda !x.\ \cdots !(\cdots x\cdots)\cdots)\ !t,$$

where $!t$ and $!(\cdots x\cdots)$ are definite by the induction assumption. This creates a suspension $!(\cdots t\cdots)$, which is definite because all its subterms are definite. This completes the proof. □

It is worth pointing out that we cannot create possibly nondefinite suspensions by reducing terms like

$$(\lambda x.\ \cdots !(\cdots x\cdots)\cdots)\ (H\ 0)$$

because x is linear, which implies that $!(\cdots x\cdots)$ is not a well-formed subterm.

[4]Thanks to one of the referees for suggesting improvements in the exposition of this section.

$$\frac{t_1 \longrightarrow t_1'}{(t_1\ t_2) \longrightarrow (t_1'\ t_2)} \qquad (app_1)$$

$$\frac{t_2 \longrightarrow t_2'}{(v_1\ t_2) \longrightarrow (v_1\ t_2')} \qquad (app_2)$$

$$(\lambda x.\, t)\ v \longrightarrow t\,[v/x] \qquad (\beta)$$

$$(\lambda !x.\, t)\ !t' \longrightarrow t\,[t'/x] \qquad (!\beta)$$

$$|c_U\ \phi\rangle \longrightarrow U\,|\phi\rangle \qquad (U)$$

FIG. 13. *Reduction rules for the quantum calculus* λ_q.

LEMMA 5.4. *Given a definite initial term, the contents of the history track remains definite throughout reduction.*

Proof. We have argued that all terms in a superposition obtained from a definite initial term are congruent. They therefore have the same structure of subterms, and the same reduction rule applies to them all. Since our reduction rules allow only !-suspensions to be discarded (which saves a copy in the history), and since !-suspensions are always definite by the previous lemma, the result follows by induction on the length of the reduction sequence. □

Since both the history and the shape of the term in the computational register remain definite throughout reduction, we can state the following conclusion.

COROLLARY 5.5. *Termination can be tested without disturbing the computation by observing the last term in the history. When this term becomes equal to the placeholder _, the result can be read off from the computational register.*

Not only is termination a "classical" property, but so is the entire shape of the term itself, i.e., term shapes can be implemented in classical memory, and only their data slots need to point to qubits on a quantum device.[5]

The fact that the history remains definite in λ_q eliminates the specific impediments to setting up an equational theory that were pointed out in the previous section. Indeed, since the state of the computation is now always guaranteed to be a direct product $|\mathcal{H}\rangle \otimes |c\rangle$ of the history $|\mathcal{H}\rangle$ and the computational register $|c\rangle$, reduction can never lead to a computational register $|c\rangle$ that is in a mixed state. In addition, since $|\mathcal{H}\rangle$ remains definite, the restriction of the reduction rules to the computational register will preserve the normalization. We are therefore led to the following theorem.

THEOREM 5.6. *In the quantum calculus* λ_q*, the evolution of the computational register is governed by the reduction rules of Figure* 13.

Proof. This easily follows from a case-by-case analysis of the computational rules of Figure 12.

For example, consider the rule $(!\beta_2)$ applied to a state of the form $|\mathcal{H}\rangle \otimes |c\rangle$, where $|c\rangle$ is a normalized superposition of the form

$$\sum_i c_i\ |(\cdots_i\ ((\lambda !x.\, t_i)\ !t')\ \cdots_i)\rangle\,,$$

in which, by Lemma 5.1, all terms have the same structure and, by Lemma 5.3, the

[5] I would like to thank one of the referees for suggesting this improved formulation.

subterm $!t'$ does not depend on i. This then reduces to

$$|\mathcal{H}\rangle \otimes \sum_i c_i \, |(\_\_\_((\lambda!x.\,\_)\;!t')\_\_\_);\, (\cdots_i\; t_i\,[t'/x]\;\cdots_i)\rangle$$
$$= |\mathcal{H};\, (\_\_\_((\lambda!x.\,\_)\;!t')\_\_\_)\rangle \otimes \sum_i c_i \, |(\cdots_i\; t_i\,[t'/x]\;\cdots_i)\rangle\,,$$

where the computational register is in the normalized state $\sum_i c_i \, |(\cdots_i\; t_i\,[t'/x]\;\cdots_i)\rangle$, consistent with applying the reduction rule $(\lambda!x.\,t_i)\;!t' \longrightarrow t_i\,[t'/x]$ to its contents. □

The big win is that we now have a simple set of reduction rules that can be used to reason about the computation without having to keep track of the history.

To define an equational theory for this calculus, we will simply define a notion of equality that is compatible with the reduction rules of Figure 13. Intuitively, reduction should be understood as a simple algebraic operation of replacing subterms with equal subterms. However, we need to take into account that reduction may not take place inside !-suspensions.

We therefore need to introduce algebraic rules governing just when we can replace subterms in an expression with equal subterms [20, 21]. One way to do that is to introduce the notion of a *term context*, which are expressions with a hole $[\,]$ in place of a subexpression,

$$C,\, C_i ::= [\,] \mid (t\;C) \mid (C\;t) \mid (\lambda x.\,C) \mid (\lambda!x.\,C) \mid \sum_i c_i\, C_i,$$

where the last term denotes a superposition of shape-congruent contexts. It is important to note that there are no contexts of the form $!(\cdots[\,]\cdots)$. As a result, subterms preceded by ! will be opaque in the sense that we will not be able to perform substitutions under the ! sign.

DEFINITION 5.7. *The equational theory of λ_q is the least equivalence relation $=$ containing the reduction relation ($\longrightarrow$) of Figure* 13 *and which is closed under substitution in term contexts* [20, 21]. *In other words,*

$$\frac{t_1 = t_2}{C[t_1] = C[t_2]} \qquad (\textit{subst}),$$

where C is an arbitrary term context and $C[t]$ denotes the textual replacement of the hole in C by the term t, extended by linearity to superpositions of congruent terms and congruent contexts, i.e., for $t = \sum_i c_i\, t_i$, we define $C[t] = \sum_i c_i\, C[t_i]$ and for $C = \sum_i c_i\, C_i$, we define $C[t] = \sum_i c_i\, C_i[t]$.

An alternative way to present the equational theory is by listing a set of axioms and rules of inference as in Figure 14.

These rules should again be understood as extending via linearity to congruent superpositions of terms. In this formulation, the rules (*app*), (λ_1), and (λ_2) are together equivalent to the term context substitution rule (*subst*) above. Again, there is no rule that permits substitutions inside !-suspensions.

THEOREM 5.8. *In the quantum lambda calculus, the evolution of the computational register proceeds by replacing terms by equal terms according to the equational theory of Definition* 5.7.

Proof. This is true by construction. □

$$t = t \qquad (\mathit{refl})$$

$$\frac{t_1 = t_2}{t_2 = t_1} \qquad (\mathit{sym})$$

$$\frac{t_1 = t_2 \quad t_2 = t_3}{t_1 = t_3} \qquad (\mathit{trans})$$

$$\frac{t_1 = t_2 \quad t_3 = t_4}{(t_1\ t_3) = (t_2\ t_4)} \qquad (\mathit{app})$$

$$\frac{t_1 = t_2}{\lambda x.\, t_1 = \lambda x.\, t_2} \qquad (\lambda_1)$$

$$\frac{t_1 = t_2}{\lambda !x.\, t_1 = \lambda !x.\, t_2} \qquad (\lambda_2)$$

$$(\lambda x.\, t)\ v = t\,[v/x] \qquad (\beta)$$

$$(\lambda !x.\, t)\ !t' = t\,[t'/x] \qquad (!\beta)$$

$$|(c_U\ \phi)\rangle = U\,|\phi\rangle \qquad (U)$$

FIG. 14. *Equational proof system for the quantum calculus* λ_q.

6. Recursion and a fixed-point operator. Recursive functions may be defined in the calculus λ_q in a way analogous to that described in section 2. We simply replace $(t\ t)$ in (1) with $(t\ !t)$, where now $t \equiv \lambda !f.\,(\cdots\,(f\ !f)\cdots)$.

Here we describe a related approach based on so-called fixed-point combinators. A fixed-point operator suitable for the linear lambda calculus is given by the following adaptation of the classical Turing combinator:

$$\begin{aligned}\mathsf{fix} \equiv (\ &(\lambda !u.\, \lambda !f.\, (f\ !((u\ !u)\ !f))) \\ &!(\lambda !u.\, \lambda !f.\, (f\ !((u\ !u)\ !f)))).\end{aligned}$$

It is easy to check that under reduction

$$\mathsf{fix}\ !t \longrightarrow t\ !(\mathsf{fix}\ !t),$$

where the !-suspension prevents further reduction of the term in brackets. Recursive functions can be defined as follows. If

$$t \equiv \lambda !f.\, u,$$

then it easily follows that

$$\mathsf{fix}\ !t \longrightarrow u\,[(\mathsf{fix}\ !t)/f].$$

In other words, $\mathsf{fix}\ !t$ copies itself into the body u of t under reduction, as required for recursion.

7. Examples of algorithms. We are now ready to formulate some algorithms in the quantum lambda calculus. First, we reproduce some classical constructions, now decorated with the proper nonlinearity annotations.

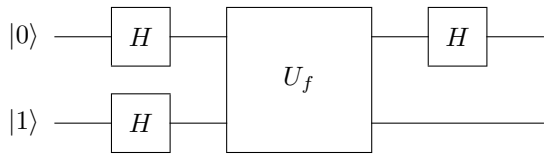

FIG. 15. *Deutsch's algorithm.*

First, we introduce list constructors that will enable us to build lists of linear values (qubits or structures containing qubits),

$$\begin{aligned} () &\equiv \lambda!x.\, \lambda!y.\, (x\ \mathsf{id}),\\ \mathsf{cons} &\equiv \lambda h.\, \lambda t.\, \lambda!x.\, \lambda!y.\, ((y\ h)\ t), \end{aligned}$$

with abbreviations $h : t \equiv (\mathsf{cons}\ h\ t)$ and $(x_1, \ldots, x_n) \equiv x_1 : x_2 : \cdots : x_n : ()$ as before. Since the arguments $!x$ and $!y$ above are nonlinear, we need to redefine our **case** abbreviation as follows:

$$\mathbf{case}\ t_1\ \mathbf{of}\ (() \to t_2,\ h : t \to t_3)$$

now stands for

$$t_1\ !(\lambda!z.\, t_2)\ !(\lambda h.\, \lambda t.\, t_3).$$

Deutsch's algorithm [1, 5] can be very simply expressed as follows:

$$\begin{aligned} \mathsf{deutsch}\ U_f \longrightarrow\ & \mathbf{let}\ (x, y) = U_f\ ((H\ 0), (H\ 1))\ \mathbf{in}\\ & ((H\ x), y) \end{aligned}$$

(see Figure 15). Here the argument U_f is assumed to be a function that takes (x, y) to $(x, y \oplus f(x))$, where f is some (unknown) function of one bit. For example, if f is the identity function, then we should take U_f to be *cnot*. Indeed, the reader may check that

$$|\mathsf{deutsch}\ \mathit{cnot}\rangle \longrightarrow |1\rangle \otimes \frac{1}{2}\Big(|0\rangle - |1\rangle\Big),$$

where the first bit $1 = f(0) \oplus f(1)$ indicates that the function is balanced, as required.

Let us write a simple expression that creates an EPR pair:

$$\mathsf{epr} \equiv \mathit{cnot}\ ((H\ 0), 0).$$

The quantum teleportation gate array with deferred measurement (see Figure 16) [34, 5] can easily be translated into the following code. We create an EPR pair and pass the first EPR qubit, along with the unknown qubit x to be teleported, to Alice. The outcome (x', y') of Alice's computation then gets sent to Bob, who has access to the second EPR qubit e_2,

$$\begin{aligned} \mathsf{teleport}\ x \longrightarrow\ & \mathbf{let}\ (e_1, e_2) = \mathsf{epr}\ \mathbf{in}\\ & \mathbf{let}\ (x', y') = \mathsf{alice}\ (x, e_1)\ \mathbf{in}\\ & \quad \mathsf{bob}\ (x', y', e_2). \end{aligned}$$

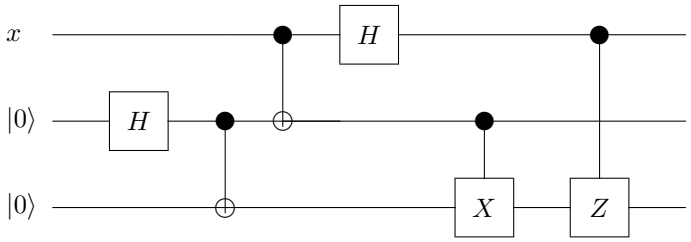

FIG. 16. *Quantum teleportation.*

Here

$$\mathsf{alice}\ (x, e_1) \longrightarrow\ \mathbf{let}\ (x', y') = \mathit{cnot}\ (x, e_1)\ \mathbf{in}\ ((H\ x'), y')$$

and

$$\begin{aligned}\mathsf{bob}\ (x', y', e_2) \longrightarrow\ & \mathbf{let}\ (y'', e_2') = cX\ (y', e_2)\ \mathbf{in} \\ & \mathbf{let}\ (x'', e_2'') = cZ\ (x', e_2')\ \mathbf{in} \\ & (x'', y'', e_2'').\end{aligned}$$

The outcome of the computation consists of the list of three qubits (x'', y'', e_2''). The teleported qubit is e_2'', but notice how linearity requires us to keep the other two qubits in the answer. The reader may check that throughout the computation, linear arguments are used exactly once. Implementing the conditional operations cX and cZ in terms of the primitive constants is left as an easy exercise.

Given recursion and lists, the map function, which applies a given function f to each element of a list, may be defined as

$$\mathsf{map}\ !f\ \mathit{list} \longrightarrow \mathbf{case}\ \mathit{list}\ \mathbf{of}\ \begin{cases} () \to () \\ h : t \to (f\ h) : (\mathsf{map}\ !f\ t) \end{cases}.$$

The arguments *list*, h, and t may refer to qubits or data structures containing qubits and are therefore chosen linear. The expression is well formed because *list*, h, and t are each used exactly once.

It is now trivial to define a program that computes a uniform superposition of a list of qubits by applying the Hadamard gate to each qubit in the list:

$$H^{\otimes n}\ \mathit{list} \longrightarrow \mathsf{map}\ !H\ \mathit{list}.$$

For example, we may evaluate

$$\big|H^{\otimes n}\ (0,0)\big\rangle \longrightarrow \frac{1}{2}\big(\,|(0,0)\rangle + |(0,1)\rangle + |(1,0)\rangle + |(1,1)\rangle\,\big).$$

Note that the well-formedness conditions may be somewhat subtle, as the following example illustrates. A naive attempt at defining an append function that concatenates two linear lists,

$$\mathsf{append}\ x\ y \longrightarrow \mathbf{case}\ x\ \mathbf{of}\ \begin{cases} () \to y \\ h : t \to h : (\mathsf{append}\ t\ y), \end{cases}$$

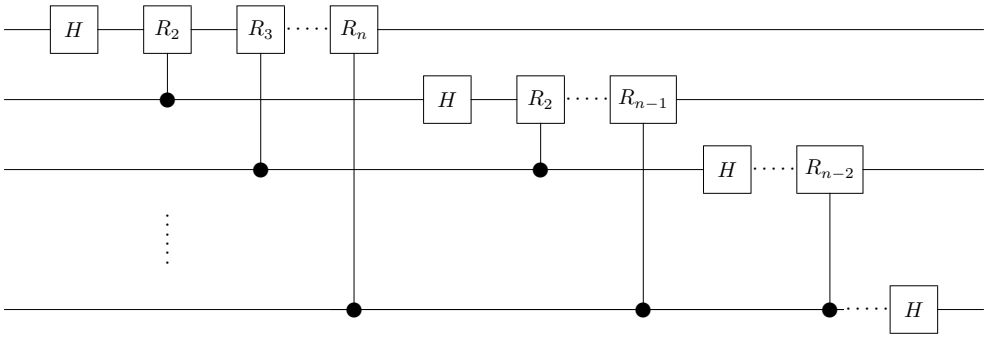

FIG. 17. *The quantum Fourier transform (without reversal).*

fails to be well formed. The problem can be seen by expanding the **case** abbreviation

$$x\ !(\lambda z.\, y)\ !(\lambda h.\, \lambda t.\, (h : (\mathsf{append}\ t\ y))).$$

Since y is a linear variable, we may not promote the λ subterms to nonlinear values with the prepended !. An alternative definition that does work is

$$\mathsf{append}\ x\ y \longrightarrow \left(\mathbf{case}\ x\ \mathbf{of}\ \begin{cases} () \to (\lambda u.\, u) \\ h : t \to \lambda u.\, (h : (\mathsf{append}\ t\ u)) \end{cases}\right)\ y.$$

Next we define a reverse function

$$\mathsf{reverse}\ \mathit{list} \longrightarrow \mathbf{case}\ \mathit{list}\ \mathbf{of}\ \begin{cases} () \to () \\ h : t \to \mathsf{append}\ (\mathsf{reverse}\ t)\ (h). \end{cases}$$

The quantum Fourier transform [35, 36, 37, 38] can now be defined as a direct translation of the corresponding quantum circuit [5] as follows:

$$\mathsf{fourier}\ \mathit{list} \longrightarrow \mathsf{reverse}\ \mathsf{fourier}'\ \mathit{list},$$

where

$$\mathsf{fourier}'\ \mathit{list} \longrightarrow \mathbf{case}\ \mathit{list}\ \mathbf{of}\ \begin{cases} () \to () \\ h : t \to\ \ \mathbf{let}\ h' : t' = \mathsf{phases}\ (H\ h)\ t\ !\underline{2}\ \mathbf{in} \\ \qquad\qquad\qquad h' : (\mathsf{fourier}'\ t') \end{cases}$$

recursively applies the appropriate conditional phase operations to the first qubit in the list, using the helper function

$$\begin{aligned} &\mathsf{phases}\ \mathit{target}\ \mathit{controls}\ !n \\ &\longrightarrow \mathbf{case}\ \mathit{controls}\ \mathbf{of}\ \begin{cases} () \to (\mathit{target}) \\ \mathit{control} : t \to\ \ \mathbf{let}\ (\mathit{control}', \mathit{target}') \\ \qquad\qquad\qquad\quad = (cR\ !n)\ (\mathit{control}, \mathit{target})\ \mathbf{in} \\ \qquad\qquad\qquad \mathbf{let}\ \mathit{target}'' : t' \\ \qquad\qquad\qquad\quad = \mathsf{phases}\ \mathit{target}'\ t\ !(\mathsf{succ}\ n)\ \mathbf{in} \\ \qquad\qquad\qquad\ \ \mathit{target}'' : \mathit{control}' : t'. \end{cases} \end{aligned}$$

Here $(cR\ !n)$ composes an appropriate combination of elementary gates to implement a conditional phase operation with phase $2\pi i/2^n$. Since this is essentially a classical computation and depends on the particular set of primitive constants chosen, we will not write it out here.

Note that we have assumed that the classical construction of the natural numbers may be adapted to the quantum lambda calculus. That this is possible for all classical constructions follows from the fact that there is an embedding of the classical lambda calculus into the linear lambda calculus, as shown in formula (4).

8. Relating λ_q to quantum Turing machines. In this section we will sketch a proof of the following theorem, leaving a more rigorous analysis to future work.

THEOREM 8.1. *The computational model provided by the quantum lambda calculus λ_q is equivalent to the quantum Turing machine.*

Proof. First, we argue that the quantum lambda calculus λ_q may be efficiently simulated on a quantum Turing machine.

In λ_q the current state of the computation consists of a superposition of term sequences of the form $\mathcal{H}; t$, which may be encoded as strings of symbols on the tape of the quantum Turing machine. By Lemma 5.1, term sequences in different branches of the superposition are congruent, and the same reduction rule will apply for all branches at each time step. The subset of λ_q not involving quantum operations consists of a set of reversible classical rewritings, which can be unitarily and efficiently implemented on a quantum Turing machine by [2, 39, 40]. The fragment involving quantum operators again involves simple classical rewritings followed by a unitary transformation involving one or two symbols on the tape. Once again, the methods of [2, 39, 40] may be used to construct a quantum Turing machine that can execute these transformations. This completes the proof of the first half of the equivalence.

Next we argue that a quantum Turing machine can be efficiently simulated by the calculus λ_q.

Yao shows in [4] that for any quantum Turing machine T, there is quantum circuit $C_{n,t}$ that efficiently simulates T on inputs of size n after t steps. The circuit family $C_{n,t}$ may be efficiently constructed via a classical computation. But λ_q is universal for classical computation. This follows from the fact that the classical call-by-value lambda calculus may be embedded in λ_q via the following translation, adapted from [28]:

$$\begin{aligned}(t_1\ t_2)^* &= ((\lambda!z.\, z)\ t_1^*)\ t_2^*,\\ x^* &= !x,\\ (\lambda x.\, t)^* &= !(\lambda!x.\, t^*).\end{aligned} \tag{4}$$

So, given the specification of a quantum Turing machine and an input of length n, a classical computation in λ_q first constructs a representation of the appropriate quantum circuit family $C_{n,t}$. It then follows the circuit diagram and applies the appropriate quantum operations one by one to the input. Since λ_q has primitive quantum operations available corresponding to a universal set of quantum gates, this proves the second half of the equivalence. □

9. Related work. In a series of papers, H. Baker [41, 42, 43] develops an untyped linear language based on Lisp. His language is similar to the classical fragment of the lambda calculus developed in the current article. It served as the initial inspiration for the linear approach followed here.

Ideas stemming from linear logic have been used previously by Abramsky in the study of classical reversible computation [44].

One of the earlier attempts at formulating a language for quantum computation was G. Baker's Qgol [45]. Its implementation (which remained incomplete) used so-called uniqueness types (similar but not identical to our linear variables) for quantum objects [46]. The language is not universal for quantum computation.

The language QCL, developed by Ömer, is described in [47, 48]. QCL is an imperative language with classical control structures combined with special operations on quantum registers. It provides facilities for inverting quantum functions and for scratch space management. No formal program calculus is provided. A simulator is publicly available.

Another imperative language, based on C++, is the Q language developed by Bettelli, Calarco, and Serafini [49]. As in the case of QCL, no formal calculus is provided. A simulator is also available.

A more theoretical approach is taken by Selinger in his description of the functional language QPL [50]. This language has both a graphical and a textual representation. A formal semantics is provided.

The imperative language qGCL, developed by Sanders and Zuliani [51], is based on Dijkstra's guarded command language. It has a formal semantics and proof system.

A previous attempt to construct a lambda calculus for quantum computation is described by Maymin in [52]. However, his calculus appears to be strictly stronger than the quantum Turing machine [53]. It seems to go beyond quantum mechanics in that it does not appear to have a unitary and reversible operational model, instead relying on a more general class of transformations. It is an open question whether the calculus is physically realizable.

A seminar by Wehr [54] suggests that linear logic may be useful in constructing a calculus for quantum computation within the mathematical framework of Chu spaces. However, the author stops short of developing such a calculus.

Abramsky and Coecke describe a realization of a model of multiplicative linear logic via the quantum processes of entangling and deentangling by means of typed projectors. They briefly discuss how these processes can be represented as terms of an affine lambda calculus [55].

10. Conclusion. In this article we developed a lambda calculus λ_q suitable for expressing and reasoning about quantum algorithms. We discussed both its computational model and its equational proof system. We argued that the resulting calculus provides a computational model equivalent to the quantum Turing machine and is therefore universal for quantum computation.

There are many possible directions for future work. The proof of Turing equivalence should be fleshed out. Formal issues relating to consistency and semantics need to be addressed further. While our computational model provides an operational semantics, the problem of providing a denotational semantics is open. The formalism of [56] may be useful in this regard.

In this article, the introduction of a linear calculus was motivated by requiring consistency of its operational model with equational reasoning. The fact that linear arguments, denoting quantum resources, may not be duplicated suggests a separate motivation for linearity, not addressed here, based on the no-cloning theorem [57, 58].

While our calculus is untyped, it would be interesting to investigate typed linear calculi with quantum primitives and, via the Curry–Howard correspondence, the corresponding generalizations of linear logic [59, 60]. We might mention that there have been prior attempts to relate linear logic to quantum mechanics, starting with a suggestion by Girard [30, 61, 62].

On the practical side, the calculi described in this paper may be used as a programming language for prototyping quantum algorithms. Indeed, the algorithms exhibited in this article were transcribed into Scheme for testing. The simulator, which was also written in Scheme, is available on request from the author.

It is our hope that the field of quantum computation, like its classical counterpart, may benefit from the insights provided by the alternative computational model provided by the quantum lambda calculus.

Note. Since the first version of this paper was written, some progress has been made by the author in devising a typed version, with accompanying denotational semantics, of a fragment of the quantum calculus described here [16].

Acknowledgments. I would like to thank Prof. Antal Jevicki and the Brown University physics department for their support. I would also like to thank the two anonymous referees for their brilliant, detailed, and thoughtful comments leading to various corrections and improvements in the exposition.

CIRCUMFERENCE OF GRAPHS WITH BOUNDED DEGREE*

GUANTAO CHEN†, JUN XU‡, AND XINGXING YU§

Abstract. Karger, Motwani, and Ramkumar [*Algorithmica*, 18 (1997), pp. 82–98] have shown that there is no constant approximation algorithm to find a longest cycle in a Hamiltonian graph, and they conjectured that this is the case even for graphs with bounded degree. On the other hand, Feder, Motwani, and Subi [*SIAM J. Comput.*, 31 (2002), pp. 1596–1607] have shown that there is a polynomial time algorithm for finding a cycle of length $n^{\log_3 2}$ in a 3-connected cubic n-vertex graph. In this paper, we show that if G is a 3-connected n-vertex graph with maximum degree at most d, then one can find, in $O(n^3)$ time, a cycle in G of length at least $\Omega(n^{\log_b 2})$, where $b = 2(d-1)^2 + 1$.

Key words. bounded degree, 3-connected components, long cycles and paths, circumference

1. Introduction and notation. The *circumference* of a graph is the length of a longest cycle in that graph. The problem of approximating the circumference of a graph is NP-hard [15]. For many canonical NP-hard problems, either good approximation algorithms have been devised, or strong negative results have been established, leading to better understanding of the approximability of these problems. However, not much is known for finding longest paths and cycles, positive or negative. For example, there is no known algorithm which guarantees an approximation ratio better than $n/\text{polylog}(n)$, where n denotes the number of vertices. This is true even for graphs which are Hamiltonian or have bounded degree. Karger, Motwani, and Ramkumar [15] showed that unless $\mathcal{P} = \mathcal{NP}$, it is impossible to find, in polynomial time, a path of length $n - n^\epsilon$ in an n-vertex Hamiltonian graph for any $\epsilon < 1$. They conjectured that it is just as hard for graphs with bounded degree.

On the positive side, if a graph has a path of length L, then one can find a path of length $\Omega((\log L/\log\log L)^2)$ [1] (also see [20]). Feder, Motwani, and Subi [6] showed that there is a polynomial time algorithm for finding a cycle of length at least $n^{\log_3 2}$ in a 3-connected cubic n-vertex graph. They also showed that if a graph has maximum degree at most three and has a path or cycle of length L, then one can find a path or cycle of length at least $L^{(\log_3^2)/2}$. Therefore, an intermediate problem is to find long paths or cycles in graphs of bounded degree that have a Hamilton cycle. Specifically, Feder, Motwani, and Subi (see [6], p. 1605) asked (1) whether there exists some constant $0 < c < 1$ such that if G is a 3-connected planar n-vertex graph, then the circumference of G is at least $\Omega(n^c)$, and (2) whether there exists some constant $0 < c < 1$ such that if G is a 3-connected n-vertex graph with bounded degree, then

the circumference of G is at least $\Omega(n^c)$. There are known results showing that such a constant c exists in both cases ([3], [14]); however, none addresses the algorithmic issue. The main goal of this paper is to establish a cubic algorithm that produces a long cycle in a 3-connected graph with bounded degree.

The work on circumferences of planar graphs dates back to 1931, when Whitney [21] proved that every 4-connected planar triangulation contains a Hamilton cycle (and, hence, its faces are 4-colorable). This result is generalized to all 4-connected planar graphs in [18]. A linear time algorithm is given in [4] for finding a Hamilton cycle in a 4-connected planar graph. There are many 3-connected planar graphs which do not contain Hamilton cycles (see [9]). On the other hand, the following conjecture of Barnette (see [16]) remains open: every bipartite, cubic, 3-connected, planar graph contains a Hamilton cycle. When studying paths in polytopes, Moon and Moser [17] implicitly conjectured that if G is a 3-connected planar n-vertex graph then G contains a cycle of length at least $\Omega(n^{\log_3 2})$. (Grünbaum and Walther [8] made the same conjecture for a class of 3-connected cubic planar graphs.) Jackson and Wormald [13] gave the first polynomial lower bound $\Omega(n^c)$, where c is approximately 0.2, which was improved to $\Omega(n^{0.4})$ by Gao and Yu [7]. Chung [5] further improved this lower bound to $\Omega(n^{0.5})$. Recently, Chen and Yu [3] fully established the Moon–Moser conjecture; their proof implies a quadratic algorithm for finding a cycle of length at least $\Omega(n^{\log_3 2})$ in a 3-connected planar n-vertex graph. We conjecture that such a cycle may be found in linear time.

The work on circumferences of 3-connected graphs with bounded degree dates back to 1980, when Bondy and Simonovits [2] conjectured that there exists a constant $0 < c < 1$ such that the circumference of any 3-connected cubic n-vertex graph is at least $\Omega(n^c)$. This conjecture was verified by Jackson [12]. In 1993, Jackson and Wormald [14] proved that if G is a 3-connected n-vertex graph with maximum degree at most d, then the circumference of G is at least $\frac{1}{2}n^{\log_b 2} + 1$, where $b = 6d^2$. The argument in [14] is technical, and Jackson and Wormald did not address the algorithmic issue.

In this paper, we improve the lower bound of Jackson and Wormald, for both the exponent and the constant coefficient. Our argument makes efficient use of two results: a convexity result of a function and a decomposition result of 2-connected graphs. Our proof gives rise to a cubic algorithm for finding a long cycle in 3-connected graphs with bounded degree. More precisely, we prove the following result.

THEOREM 1.1. *Let $n \geq 4$ and $d \geq 3$ be integers. Let G be a 3-connected graph on n vertices such that the maximum degree of G is at most d. Then G contains a cycle of length at least $n^{\log_b 2} + 2$, where $b = 2(d-1)^2 + 1$. Moreover, such a cycle can be found in $O(n^3)$ time.*

It is conjectured in [14] that, for $d \geq 4$, the lower bound in Theorem 1.1 may be replaced by $\Omega(n^{\log_{d-1} 2})$. We are hopeful that our approach will eventually lead to a resolution of this conjecture.

To prove Theorem 1.1, we will need to deal with graphs which result from a 3-connected graph by deleting one vertex. Such graphs are 2-connected but not necessarily 3-connected. Our technique is to decompose such a graph into "3-connected components." This can be done in linear time by a result of Hopcroft and Tarjan [10]. (A similar idea is used in [14], but our decomposition is done once for each graph in a single iteration of the algorithm, and we make more efficient use of such a decomposition.) In most situations, we will not use all 3-connected components of a graph. Instead, we will pick some large 3-connected components and find long cycles in such components. We will then use a convexity property of the function $f(x) = x^{\log_b 2}$ to

account for the unused components. These two ideas will be made more precise in the next two sections.

This paper is organized as follows. In section 2, we will state a technical result, consisting of three statements about (a) the existence of a long cycle through a given edge and avoiding a given vertex, (b) the existence of a long cycle through two given edges, and (c) the existence of a long cycle through a given edge. (We will see that (c) implies Theorem 1.1.) We will also describe the decomposition of a 2-connected graph into 3-connected components. In section 3, we will prove useful properties of the convex function $f(x) = x^{\log_b 2}$, for $b = 3$ and $b \geq 4$. We will also prove several lemmas to be used in the proof of our main result. In sections 4–6, we will show that each of (a), (b), and (c) can be reduced in linear time to (a), (b), and/or (c) for smaller graphs. In section 7, we will complete the proof of our main result and give a cubic algorithm that finds a long cycle in a 3-connected graph with bounded degree.

We end this section with notation and terminology to be used throughout this paper. Let G be a graph. We use $V(G)$ and $E(G)$ to denote the vertex set and edge set of G, respectively, and we write $G = (V(G), E(G))$. For convenience, we write $|G|$ instead of $|V(G)|$. If $e \in E(G)$ and x, y are the vertices of G incident with e, then we write $e = xy$. For any $S \subseteq V(G) \cup E(G)$, $G - S$ denotes the graph obtained from G by deleting S and all edges of G with an incident vertex in S. If $S = \{x\}$, then we simply write $G - x$ instead of $G - S$.

Let G and H be two graphs. By $H \subseteq G$ we mean that H is a subgraph of G. We use $G \cup H$ and $G \cap H$ to denote the union and intersection, respectively, of G and H. For any $S \subseteq V(G) \cup E(G)$ and for any $H \subseteq G$, we use $H + S$ to denote the graph with vertex set $V(H) \cup (S \cap V(G))$ and edge set $E(H) \cup \{uv \in S : \{u, v\} \subseteq V(H) \cup (S \cap V(G))\}$.

We say that a graph G is k-connected if $|G| \geq k + 1$ and, for any $S \subseteq V(G)$ with $|S| \leq k - 1$, $G - S$ is connected. Let G be a graph. If $S \subseteq V(G)$ for which $G - S$ is not connected, then S is a *cut* of G, and if, in addition, $|S| = k$, then S is a *k-cut*. If $x \in V(G)$ for which $G - x$ is not connected, then x is called a *cut vertex* of G. If $e \in E(G)$ for which $G - e$ is not connected, then e is called a *cut edge* of G.

2. 3-connected components. We begin this section by stating a technical result which implies Theorem 1.1. To motivate that statement, let G be a 3-connected graph. In order to find a long cycle in G, we will try to find a cycle through a specific edge $e = xy$ (for induction purposes). To reduce the problem to smaller graphs, we consider $G - y$. Clearly $G - y$ is 2-connected but not necessarily 3-connected. In the case when $G - y$ is not 3-connected, y is contained in a 3-cut T of G. Let $T := \{y, a, b\}$, and let G_1, G_2 be subgraphs of G such that $E(G_1) \cap E(G_2) = \emptyset$, $V(G_1) \cap V(G_2) = T$, and $G_1 \cup G_2 = G$. See Figure 1 for an illustration. Assume $x \in V(G_1) - T$. We could find a long cycle C_1 through both e and ab in $G_1 + ab$ and a long cycle C_2 through ab in $(G_2 + ab) - y$, and then $C := (C_1 - ab) \cup (C_2 - ab)$ would give a long cycle in G. Note that C_1 is a cycle through two given edges, C_2 is a cycle through one given edge and avoiding a given vertex, and C is a cycle through one given edge. This suggests that we prove three statements simultaneously. Indeed, we will prove the following.

THEOREM 2.1. *Let $n \geq 5$ and $d \geq 3$ be integers, let $r = \log_{2(d-1)^2+1} 2$, and let G be a 3-connected graph on n vertices. Then the following statements hold:*

(a) *Let $xy \in E(G)$ and $z \in V(G) - \{x, y\}$, and let t denote the number of neighbors of z distinct from x and y. Assume that the maximum degree of G is at most $d + 1$, and every vertex of degree $d + 1$ (if any) is incident with the edge zx or zy. Then there is a cycle C through xy in $G - z$ such that $|C| \geq (\frac{n}{2t})^r + 2$.*

(b) *Suppose the maximum degree of G is at most d. Then, for any distinct $e, f \in E(G)$, there is a cycle C through e and f in G such that $|C| \geq (\frac{n}{2(d-1)})^r + 3$.*

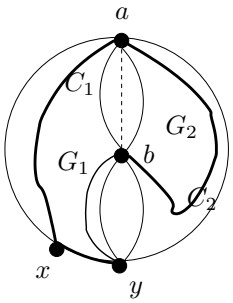

FIG. 1. *An illustration.*

(c) *Suppose that the maximum degree of G is at most d. Then, for any $e \in E(G)$, there is a cycle C through e in G such that $|C| \geq n^r + 3$.*

Clearly, Theorem 2.1(c) implies Theorem 1.1 when $n \geq 5$, and Theorem 1.1 is obvious when $n = 4$. Note the condition in (a) about the maximum degree; it is due to the addition of edges in order to maintain 3-connectivity.

To prove Theorem 2.1, we need to decompose a 2-connected graph (such as $G - z$ in (a) above) into 3-connected components. This is similar to the decomposition of a connected graph into 2-connected components. Let G be a connected graph. A *block* of G is a subgraph of G which is either a maximal 2-connected subgraph of G or a subgraph of G induced by a cut edge of G. A block of G is also called a 2-*connected component of* G. It is easy to see that the intersection of any two blocks of G either is empty or consists of only one vertex (which is a cut vertex). Also any noncut vertex of G occurs in exactly one block of G. This implies that the blocks and cut vertices of G form a tree structure.

Now let G be a 2-connected graph. We describe the 3-connected components of G, following Hopcroft and Tarjan [10]. For this purpose, we allow multiple edges (and hence $E(G)$ is a multiset). We say that $\{a, b\} \subseteq V(G)$ is a *separation pair* in G if there are subgraphs G_1, G_2 of G such that $G_1 \cup G_2 = G$, $V(G_1) \cap V(G_2) = \{a, b\}$, $E(G_1) \cap E(G_2) = \emptyset$, and $|E(G_i)| \geq 2$ for $i = 1, 2$. Let $G'_i := (V(G_i), E(G_i) \cup \{ab\})$ for $i = 1, 2$. See Figure 2 for an example. Then G'_1 and G'_2 are called *split graphs* of G with respect to the separation pair $\{a, b\}$, and the new edge ab added to G_i is called a *virtual* edge. Virtual edges are illustrated with dashed edges in Figures 2–4. It is easy to see that since G is 2-connected, G'_i is 2-connected or G'_i consists of two vertices and at least three multiple edges between them.

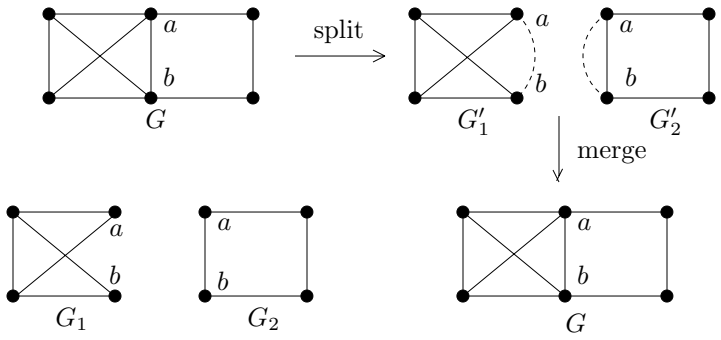

FIG. 2. *Split and merge.*

Suppose that a multigraph is split, and the split graphs are split, and so on, until no more splits are possible. Then each remaining graph is called a *split component*. See Figure 3 for a graph G and its split components. No split component contains a separation pair, and therefore each split component must be one of the following: a triangle, a *triple bond* (two vertices with three multiple edges between), or a 3-connected graph.

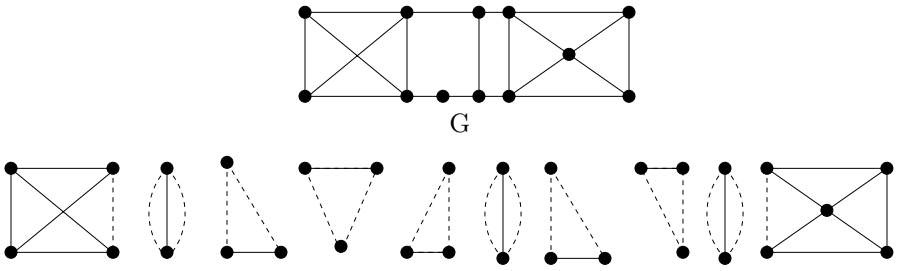

FIG. 3. *Split components of G.*

It is not hard to see that if a split component of a 2-connected graph is 3-connected, then it is unique. It is also easy to see that, for any two split components G_1, G_2 of a 2-connected graph, we have $|V(G_1) \cap V(G_2)| = 0$ or 2, and if $|V(G_1) \cap V(G_2)| = 2$, then either G_1 and G_2 share a virtual edge between vertices in $V(G_1) \cap V(G_2)$ or there is a sequence of triple bonds such that the first shares a virtual edge with G_1, any two consecutive triple bonds in the sequence share a virtual edge, and the last triple bond shares a virtual edge with G_2.

In order to get unique 3-connected components, we need to merge some triple bonds and to merge some triangles. Let $G_i' = (V_i', E_i')$, $i = 1, 2$, be two split components, both containing a virtual edge ab. Let $G' = (V_1' \cup V_2', (E_1' - \{ab\}) \cup (E_2' - \{ab\}))$. Then the graph G' is called the *merge graph* of G_1 and G_2. See Figure 2 for an example of a merge graph. Clearly, a merge of triple bonds gives a graph consisting of two vertices and multiple edges, which is called a *bond*. Also a merge of triangles gives a cycle, and a merge of cycles also gives a cycle.

Let $\mathcal{D}$ denote the set of 3-connected split components of a 2-connected graph G. We merge the other split components of G as follows: the triple bonds are merged as much as possible to give a set of bonds $\mathcal{B}$, and the triangles are merged as much as possible to give a set of cycles $\mathcal{C}$. Then $\mathcal{B} \cup \mathcal{C} \cup \mathcal{D}$ is the set of the 3-*connected components* of G. Figure 4 gives the 3-connected components of the graph in Figure 3. Note that any two 3-connected components either are edge disjoint or share exactly one virtual edge.

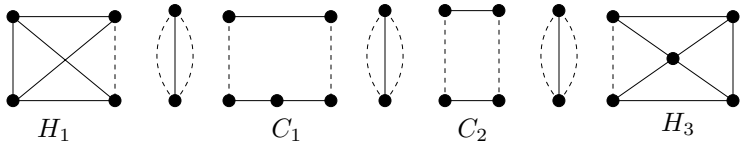

FIG. 4. 3-*connected components of the graph G in Figure* 3.

Tutte [19] proved that the above decomposition of a 2-connected graph into 3-connected components is unique. Hopcroft and Tarjan [10] gave a linear time algorithm for finding the 3-connected components of a graph.

THEOREM 2.2. *For any 2-connected graph, the 3-connected components are unique and can be found in $O(|E|)$ time. Moreover, the total number of edges in the 3-connected components is at most $3|E| - 6$.*

We define a graph whose vertices are the 3-connected components of G, and two vertices are adjacent if the corresponding 3-connected components share a virtual edge. Then it is easy to see that such a graph is a tree, and we call it the *block-bond tree* of G.

For convenience, 3-connected components that are not bonds are called 3-*blocks*. An *extreme* 3-block is a 3-block that contains at most one virtual edge. That is, either it is the only 3-connected component, or it corresponds to a degree one vertex in the block-bond tree.

We will make use of cycle chains. Intuitively, a cycle chain in a 2-connected graph G is a sequence $C_1C_2 \dots C_k$ of 3-blocks of G for which each C_i is a cycle and there exist bonds B_1, B_2, …, B_{k-1} of G such that $C_1B_1C_2B_2 \dots B_{k-1}C_k$ is a path in the block-bond tree of G. More precisely, we have the following.

DEFINITION 2.3. *Let G be a 2-connected graph. By a cycle chain in G we mean a sequence $C_1 \dots C_k$ with the following properties:*

(i) *for each $1 \le i \le k$, C_i is a 3-block of G and C_i is a cycle;*
(ii) *$|V(C_i) \cap V(C_{i+1})| = 2$, and C_i and C_{i+1} each contain a virtual edge between the vertices in $V(C_i) \cap V(C_{i+1})$; and*
(iii) *$|V(C_i) \cap V(C_j)| \le 1$ when $j \ge i + 2$, and if $i < j$ and $|V(C_i) \cap V(C_j)| = 1$, then, for all $i \le t \le j$, $V(C_i) \cap V(C_j) \subseteq V(C_t) \cap V(C_j)$.*

For convenience, we sometimes write $H := C_1 \dots C_k$ and view H as the graph $\bigcup_{i=1}^{k} C_i$. Hence $V(H) := \bigcup_{i=1}^{k} V(C_i)$. Note that H is a multigraph, with two virtual edges between the vertices in $V(C_i) \cap V(C_{i+1})$, $1 \le i \le k-1$.

As an example, take the graph G in Figure 3 and its 3-connected components in Figure 4; we see that C_1C_2 is a cycle chain.

Remark. We choose not to include bonds in our definition of cycle chains because those bonds do not contribute to the vertex count in our arguments.

It is easy to see that if $C_1 \dots C_k$ is a cycle chain, then deleting all virtual edges with both ends in $V(C_i) \cap V(C_{i+1})$, $1 \le i \le k-1$, results in a cycle. We state it as follows.

PROPOSITION 2.4. *Let G be a 2-connected graph, let $C_1 \dots C_k$ be a cycle chain in G, let $uv \in E(C_1)$ with $\{u, v\} \ne V(C_1) \cap V(C_2)$ when $k \ne 1$, and let $xy \in E(C_k)$ with $\{x, y\} \ne V(C_{k-1}) \cap V(C_k)$ when $k \ne 1$. Then $\bigcup_{i=1}^{k} C_i$ contains a Hamilton cycle through uv and xy. Moreover, such a cycle can be found in $O(|\bigcup_{i=1}^{k} V(C_i)|)$ time.*

For later applications, we need several facts about paths in cycle chains. We say that a path P in a graph G is from a vertex $x \in V(G)$ to a set $S \subseteq V(G) - \{x\}$ if one end of P is x, the other end of P is in S, and P is otherwise disjoint from S.

PROPOSITION 2.5. *Let G be a 2-connected graph, let $C_1 \dots C_k$ be a cycle chain in G, let $uv \in E(C_1)$ with $\{u, v\} \ne V(C_1) \cap V(C_2)$ when $k \ne 1$, and let $xy \in E(C_k)$ with $\{x, y\} \ne V(C_{k-1}) \cap V(C_k)$ when $k \ne 1$. Then there is a path in $(\bigcup_{i=1}^{k} C_i) - \{uv, xy\}$ which is from u to $\{x, y\}$ and contains $(\bigcup_{i=1}^{k-1}(V(C_i) \cap V(C_{i+1}))) - (\{x, y\} \cup \{u, v\})$. Moreover, such a path can be found in $O(|\bigcup_{i=1}^{k} V(C_i)|)$ time.*

Proof. If $k = 1$, this is obvious. So assume that $k \ge 2$. Let $x'y'$ denote the virtual edge in C_{k-1} such that $\{x', y'\} = V(C_{k-1}) \cap V(C_k)$. By induction, $(\bigcup_{i=1}^{k-1} C_i) - \{uv, x'y'\}$ contains a path P' that is from u to $\{x', y'\}$ and contains $(\bigcup_{i=1}^{k-2}(V(C_i) \cap V(C_{i+1}))) - (\{x', y'\} \cup \{u, v\})$. By symmetry, we may assume that P' ends at x'.

If $y' \in V(P')$, then let Q' denote the path in $C_k - \{xy, y'\}$ from x' to $\{x, y\}$. If $y' \notin V(P')$, then let Q' denote the path in $C_k - xy$ that is from x' to $\{x, y\}$ and through the virtual edge $x'y'$. Clearly, $P := P' \cup Q'$ gives the desired path.

It is easy to see that such a path can be found in $O(|\bigcup_{i=1}^{k} V(C_i)|)$ time. □

By a similar argument, we can prove the following.

PROPOSITION 2.6. *Let G be a 2-connected graph, let $C_1 \dots C_k$ be a cycle chain in G, let $uv \in E(C_1)$ with $\{u, v\} \neq V(C_1) \cap V(C_2)$ when $k \neq 1$, and let $x \in V(C_k)$ with $x \notin V(C_{k-1})$ when $k \neq 1$. Then there is a path in $(\bigcup_{i=1}^{k} C_i) - uv$ which is from u to x and contains $(\bigcup_{i=1}^{k-1}(V(C_i) \cap V(C_{i+1}))) - \{u, v, x\}$. Moreover, such a path can be found in $O(|\bigcup_{i=1}^{k} V(C_i)|)$ time.*

The next two facts about cycle chains are slightly more complicated. We only prove the first; the other can be proved similarly.

PROPOSITION 2.7. *Let G be a 2-connected graph, let $C_1 \dots C_k$ be a cycle chain in G, let $uv \in E(C_1)$ with $\{u, v\} \neq V(C_1) \cap V(C_2)$ when $k \neq 1$, $ab \in E(C_k)$ with $\{a, b\} \neq V(C_{k-1}) \cap V(C_k)$ when $k \neq 1$, and $cd \in E(\bigcup_{i=1}^{k} C_i) - \{ab\}$. Suppose $ab \neq uv$ when $k = 1$. Then there is a path P in $(\bigcup_{i=1}^{k} C_i) - ab$ from $\{a, b\}$ to $\{c, d\}$ such that $uv \in E(P)$, $cd \notin E(P)$ unless $cd = uv$, and $(\bigcup_{i=1}^{k-1}(V(C_i) \cap V(C_{i+1}))) \subseteq V(P)$. Moreover, such a path can be found in $O(|\bigcup_{i=1}^{k} V(C_i)|)$ time.*

Proof. We apply induction on k. If $k = 1$, then since $ab \neq uv$, the result is obvious. So assume that $k \geq 2$.

First, assume that $cd \in E(C_k)$ and $\{c, d\} \neq V(C_{k-1}) \cap V(C_k)$. Let $a'b'$ denote the virtual edge in C_k with $\{a', b'\} = V(C_{k-1}) \cap V(C_k)$. In $C_k - \{ab, cd\}$, we find a path P' from $\{a, b\}$ to $\{c, d\}$ through $a'b'$. In $\bigcup_{i=1}^{k-1} C_i$, we apply Proposition 2.4 to find a Hamilton cycle C through uv and $a'b'$. Now $P := (P' - a'b') \cup (C - a'b')$ gives the desired path.

Thus we may assume that there is some $1 \leq t < k$ such that $cd \in E(C_t)$. We may choose t so that $\{c, d\} \neq V(C_{t-1}) \cap V(C_t)$ when $t \neq 1$.

Suppose $\{c, d\} = V(C_t) \cap V(C_{t+1})$. By applying Proposition 2.4, we find a Hamilton cycle C in $\bigcup_{i=1}^{t} C_i$ such that $uv, cd \in E(C)$. Now $P' := C - cd$ is a path in $\bigcup_{i=1}^{t} C_i$ from c to d through uv. By Proposition 2.5, we find a path P'' in $(\bigcup_{i=t+1}^{k} C_i) - \{ab, cd\}$ that is from d to $\{a, b\}$ and contains $(\bigcup_{i=t+1}^{k-1}(V(C_i) \cap V(C_{i+1}))) - (\{a, b\} \cup \{c, d\})$. Now $P := P' \cup P''$ gives the desired path.

So assume that $\{c, d\} \neq V(C_t) \cap V(C_{t+1})$. By applying induction, there is a path P' from $V(C_t) \cap V(C_{t+1})$ to $\{c, d\}$ in $\bigcup_{i=1}^{t} C_i$ such that $uv \in E(P')$, $cd \notin E(P')$ unless $cd = uv$, and $(\bigcup_{i=1}^{t-1}(V(C_i) \cap V(C_{i+1}))) \subseteq V(P')$. Let e' denote the virtual edge of C_{t+1} between the vertices in $V(C_t) \cap V(C_{t+1})$, and let $u \in V(C_t) \cap V(C_{t+1})$ be an end of P'. Now apply Proposition 2.5 to $C_{t+1} \dots C_k$, we find a path P'' from u to $\{a, b\}$ in $(\bigcup_{i=t+1}^{k} C_i) - \{e', ab\}$ such that $(\bigcup_{i=t}^{k-1}(V(C_i) \cap V(C_{i+1}))) - (V(C_t) \cap V(C_{t+1})) \subseteq V(P'')$. Clearly, $P := P' \cup P''$ gives the desired path.

Since finding P' and P'' takes $O(|\bigcup_{i=1}^{k} V(C_i)|)$ time, P can also be found in $O(|\bigcup_{i=1}^{k} V(C_i)|)$ time. □

By a similar argument, we can prove the following.

PROPOSITION 2.8. *Let G be a 2-connected graph, let $C_1 \dots C_k$ be a cycle chain in G, let $uv \in E(C_1)$ with $\{u, v\} \neq V(C_1) \cap V(C_2)$ when $k \neq 1$, $x \in V(C_k)$ with $x \notin V(C_{k-1})$ when $k \neq 1$, and $cd \in E(\bigcup_{i=1}^{k} C_i)$. Then there is a path P in $(\bigcup_{i=1}^{k} C_i) - uv$ from x to $\{c, d\}$ such that $uv \in E(P)$, $cd \notin E(P)$ unless $cd = uv$, and $(\bigcup_{i=1}^{k-1}(V(C_i) \cap V(C_{i+1}))) \subseteq V(P)$. Moreover, such a path can be found in $O(|\bigcup_{i=1}^{k} V(C_i)|)$ time.*

We conclude this section by generalizing the concept of a cycle chain to a block chain. Intuitively, a *block chain* in a 2-connected graph G is a sequence $H_1 \dots H_k$ for which (1) each H_i is either a 3-connected 3-block of G or a cycle chain in G and (2) there exist bonds $B_1, \dots, B_{h-1}$ of G such that $H_1 B_1 H_2 B_2 \dots B_{h-1} H_h$ form a path in the block-bond tree of G (by also patching the tree paths corresponding to H_i when H_i is a cycle chain). More precisely, we have the following.

DEFINITION 2.9. *Let G be a 2-connected graph. By a block chain in G we mean a sequence $H_1 \dots H_h$ with the following properties:*

(i) *For each $1 \le i \le h$, either H_i is a 3-connected component of G or H_i is a cycle chain in G, and for $1 \le i \le h-1$, H_i and H_{i+1} cannot both be cycle chains.*

(ii) *For each $1 \le i \le h-1$, $|V(H_i) \cap V(H_{i+1})| = 2$ and both H_i and H_{i+1} contain a virtual edge between the vertices in $V(H_i) \cap V(H_{i+1})$.*

(iii) *$|V(H_i) \cap V(H_j)| \le 1$ if $3 \le i+2 \le j \le h$, and if $1 \le i < j \le h$ and $|V(H_i) \cap V(H_j)| = 1$, then, for all $i \le t \le j$, $V(H_i) \cap V(H_j) \subseteq V(H_t) \cap V(H_j)$.*
